have been obtained by procedures analogous to that reported for cobalt(IV) ammine complexes with 5-nitrosalicylato ligands.

In the previous work,[1] cobalt(IV) ammine complexes with 5-nitrosalicylato ligands were isolated from the reaction product of salicylatotetraamminecobalt(III) chloride monohydrate and 14 N nitric acid.

In the present report the preparation and some

*1 Presented at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, 1967.

1) Y. Yamamoto, the Late K. Ito, H. Yoneda and M. Mori, This Bulletin, **40**, 2580 (1967).

fundamental properties of analogous compounds containing ethylenediamine and those containing 3-methyl or 4-methylsalicylato ligands will be described.

Experimental

Preparation. *Salicylatotetraamminecobalt(III) Chloride Monohydrate, Salicylatobis(ethylenediamine)cobalt(III) Chloride Dihydrate, 3-Methylsalicylatotetraaminecobalt(III) Chloride Monohydrate and 4-Methylsalicylatotetraamminecobalt(III) Chloride Monohydrate.* These were prepared by Morgan and Smith's method[2] and recrystallized from water. In the preparation of the latter two compounds, equimolar amounts of the 3-methyl and 4-methylsalicylic acid were used as ligands instead of salicylic acid.

Found in 3-methylsalicylato cobalt(III) ammine complex: C, 29.22; H, 6.23; N, 16.55; Cl, 10.80%. Found in 4-methylsalicylatocobalt(III) ammine complex: C, 28.99; H, 5.81; N, 16.49; Cl, 10.97; NH_3 20.22%. Calcd for $[CoC_8H_{18}N_4O_3]Cl\cdot H_2O$: C, 29.06; H, 6.10; N, 16.94; Cl, 10.72; NH_3, 20.60%.

5-Nitro-3-methylsalicylatotetraamminecobalt(IV) Chloride Nitrate (Abbreviated as A), 5-Nitro-4-methylsalicylatotetraamminecobalt(IV) Chloride Nitrate (Abbreviated as C) and 5-Nitrosalicylatobis(ethylenediamine)cobalt(IV) Chloride Nitrate (Abbreviated as E). The following procedure is an improvement of that reported in paper I for the preparation of 5-nitrosalicylatotetraamminecobalt(IV) salts, and is applicable to the preparation of the original compound as well.

Five milliliters of 14 N nitric acid was added to 5 g of 3-methylsalicylatotetraamminecobalt(III) chloride monohydrate, 4-methylsalicylatotetraamminecobalt(III) chloride monohydrate or salicylatobis(ethylenediamine)cobalt(III) chloride dihydrate. Heat was evolved and the color of the solution changed from russet to green. To the cooled solution was added 10 ml of 14 N nitric acid. The solution was filtered with a glass filter (G4), and the green filtrate was added to acetone. The green substance separated out was filtered with a glass filter (G3), washed with acetone, and dried in a vacuum desiccator. Two grams of this green substance was dissolved in 4 ml of 14 N nitric acid, and the green solution was added into acetone. The precipitated green substance was filtered, washed with acetone and dried. It was reprecipitated twice more by dissolution in 14 N nitric acid and addition of acetone. Yield, 2 g in each case. When dried in a silicagel desiccator, trihydrates were obtained, whereas drying in a desiccator over phosphorus pentoxide yielded monohydrates.

Found in Monohydrate (A): C, 21.99; H, 4.35; N, 19.22; Cl, 7.96; Co, 13.78; NH_3, 15.79%. Found in Monohydrate (C): C, 22.23; H, 4.31; N, 19.10; Cl, 7.98; Co, 13.10; NH_3, 15.60%. Calcd for $[CoC_8H_{17}N_5O_5]\cdot Cl\cdot NO_3\cdot H_2O$: C, 21.955; H, 4.375; N, 19.20; Cl, 8.10; Co, 13.47; NH_3, 15.55%.

Found in Trihydrate (A): C, 20.29; H, 4.41; N, 17.73%. Found in Trihydrate (C): C, 20.10; H, 4.10; N, 17.64%. Calcd for $[CoC_8H_{17}N_5O_5]\cdot Cl\cdot NO_3\cdot 3H_2O$: C, 20.28; H, 4.89; N, 17.74%.

Found in Monohydrate (E): C, 28.17; H, 4.42; N, 18.06; Cl, 7.35%. Calcd for $[CoC_{11}H_{19}N_5O_5]Cl\cdot NO_3\cdot H_2O$: C, 27.77; H, 4.45; N, 17.67; Cl, 7.45%.

5-Nitro-3-methylsalicylatotetraamminecobalt(IV) Dichloride (Abbreviated as B), 5-Nitro-4-methylsalicylatotetraamminecobalt(IV) Dichloride (Abbreviated as D) and 5-Nitrosalicylatobis(ethylenediamine)cobalt(IV) Dichloride (Abbreviated as F). Two grams of substance A, C or E was dissolved in 2 ml of 12 N hydrochloric acid, and the solution was filtered with a glass filter (G4). Acetone was added to the green solution, and the substance separated out was filtered with a glass filter (G3), washed with acetone and dried in a vacuum desiccator. It was reprecipitated from hydrochloric acid solution by addition of acetone. Yield 1.6 g.

When the product was dried in a desiccator over phosphorus pentoxide, dihydrates were formed. In the case of (B) and (D) drying in a silicagel desiccator produced trihydrates.

Found in Dihydrate (B): C, 22.71; H, 4.85; N, 16.37; Cl, 15.58; Co, 14.59%. Found in Dihydrate (D): C, 22.65; H, 4.42; N, 16.21; Cl, 15.67%. Calcd for $[CoC_8H_{17}N_5O_5]Cl_2\cdot 2H_2O$: C, 22.39; H, 4.93; N, 16.32; Cl, 16.52; Co, 13.75%.

Found in Trihydrate (B): C, 21.14; H, 5.06; N, 15.94%. Found in Trihydrate (D): C, 20.66; H, 5.29; N, 15.53%. Calcd for $[CoC_8H_{17}N_5O_5]Cl_2\cdot 3H_2O$: C, 21.49; H, 5.18; N, 15.66%.

Found in Dihydrate (F): C, 28.20; H, 4.97; N, 15.01; Cl, 15.20%. Calcd for $[CoC_{11}H_{19}N_5O_5]Cl_2\cdot 2H_2O$: C, 28.28; H, 4.96; N, 14.99; Cl, 15.18%.

Determination of Organic Ligands. In order to identify the organic ligand, 3 g of A or C was heated in 3 N potassium hydroxide at 60°C for 3 hr. The mixture was filtered and acidified with hydrochloric acid. The ligand acid thus isolated was extracted with ethylether, with subsequent evaporation, to yield the free acid; the acid from A was identified as 3-methyl-5-nitrosalicylic acid and that from C as 4-methyl-5-nitrosalicylic acid by melting point measurements.

Chromatography. In order to examine the purity of the substances, the samples dissolved in mixture solvents of water and acetone (1 : 3 by volume, pH=3 with hydrochloric acid) were chromatographed on acid alumina (Merck, Germany) or silica gel (Wako Pure Chemical Ind., Japan). Each sample was found to contain substantially a single species.

Physicochemical Measurements. The magnetic susceptibilities of the complexes were measured by the Gouy method with a magnetic balance (Shimadzu Seisaku Sho) in the temperature range between 80°K and room temperature.

The visible and ultraviolet absorption spectra were recorded with a recording spectrophotometer, Hitachi EPS-2.

The NMR spectra were recorded at 25+2°C with a Varian A-60-type instrument, and were quoted for a trifluoroacetic acid or deuterium oxide solution using tetramethylsilane as an external standard.

The electric conductivities of the aqueous solutions of the salts were determined by the use of a conductometer, CM-1DB, Toa Denpa Kogyo.

Result and Discussion

The Constitution of the Compounds. The constitution of each compound was inferred as in the previous study,[1] on the basis of elemental analyses, isolation of the ligand acid (*cf.* Experimental), iodometry, magnetic susceptibility, and the electric conductivity and the absorption spectrum of the aqueous solution. Some of these data are given in Table 1 and Fig. 1.

Recently, Garbett and Gillard[3] studied the reaction of salicylatobis(ethylenediamine)cobalt(III) complex with nitric acid. From the reaction mixture, they obtained a dark green weakly paramagnetic material which, however, they considered impure; they tentatively formulated it as [Co en_2(5-NO-salH)$(NO_3)_2 \cdot 4H_2O$, *i. e.* as a complex containing nitrososalicylate ligand. In its absorption spectrum they found strong absorption maxima at 375 mμ (ε=8700) and 682 mμ (ε=2640). Although the method of preparation of this green material is more or less analogous to the procedure of preparing green complex (E) of the present paper, the spectrum of E (Fig. 1, Table 1) was quite different from their spectra; it showed an absorption peak of much higher intensity (ε=10000) at 682 mμ and also a peak at 450 mμ (ε=3200), but only a very weak peak or a shoulder at 365—375 mμ which was barely perceptible under the strong absorption background (ε=3200) present in this range. It seems possible that the complex of Garbett and Gillard is different from that obtained in the present research. If, instead, their sample were to contain the same green complex as that obtained in the present research, their sample would contain less than 30% of the true green complex as judged from the absorptivity of the peak at 682 mμ. In this latter possibility the very high intensity of the peak at 375 mμ observed by these investigators might be explained as caused by contamination by [Co en_2-(5-NO_2-salH)]$(NO_3)_2 \cdot H_2O$ which ha san absorption peak of very high intensity at this wavelength (374 mμ, ε=21400).

Chromatography of the green complex obtained by the present authors has shown that the material is substantially pure and single. The success in obtaining comparatively pure materials may be due to the fact that all the compounds contained at least one outer chloride ion; complete removal of the chloride ion *e. g.* by use of silver nitrate has been

found to make the complex very unstable.

In the present paper we shall continue to formulate the compounds as nitro compounds because the only experimental fact so far obtained about this problem was isolation of nitrosalicylic acid or nitrocresotic acid. Of course we can not deny the possibility that the ligand was initially nitroso compound which was oxidized during the treatment with alkalis; the final decision should await further experimental proofs.

There seems to be no ambiguity as to the fact that the formal oxidation state of cobalt is four, this, of course including the possibility that the complex ion as a whole is a free radical carrying one electron vacancy. This can be verified by the effective Bohr magneton number, the charge of +2 and the high oxidizing ability of the complex. Our sample tested neutral in freshly prepared aqueous solution, so that the formulation as the protonated ion is not acceptable.

The magnetic susceptibilities of the compounds obeyed the Curie-Weiss law down to liquid nitrogen temperatures. The effective magnetic moment μ_{eff} in Bohr magnetons (Table 1) was obtained using the formula, $\mu_{eff}=2.84\sqrt{\chi^{cor}_{mol}(T-\theta)}$ where χ^{cor}_{mol} was obtained by correcting the observed molar magnetic susceptibility χ_{mol} for the diamagnetic contribution of the molecule. A more detailed study on the magnetic susceptibilities will be reported elsewhere.

Solubilities. The cobalt(IV) ammine complexes obtained in the present study are soluble in water, dimethylsulfoxide, methanol, nitric acid, hydrochloric acid, trifluoroacetic acid and several acidic solvents, but insoluble in acetone, chloroform, benzene, acetonitrile and other organic solvents of similar nature.

On the other hand, the salts of tetraphenylboric acid, picric acid, 3,5-dinitrosalicylic acid or chloranilic acid are soluble in acetone, chloroform, benzene and similar organic solvents, but are almost insoluble in water.

Stability. The solution of 5-nitrosalicylato-(bisethylenediamine)cobalt(IV) complexes did not undergo any color change after 12 hr, but the solution of 5-nitrosalicylatotetraamminecobalt(IV) complex and its methyl derivatives changed from green to yellowish brown after several hours. The greater stability of the ethylenediamine complexes as compared with the corresponding ammine complexes as shown in this example could be explained in terms of the entropy effect.[4] Another such example is offered by a series of μ-peroxodicobaltammine and μ-peroxodicobalt ethylenediamine complexes, the latter being much more stable toward decomposition.

NMR Spectra. The NMR spectra of 5-nitrosalicylatobis(ethylenediamine)cobalt(IV) chloride

Table 2. The proton magnetic resonance of CH_2 or NH_2 in salicylatoammine cobalt(IV) complex (E)

	Methylene protons		Ammine protons

nitrate were measured in trifluoroacetic acid or deuterium oxide. The spectra had signals at 106.5, 148.0, 236.6 and 284.0 cps for trifluoroacetic acid solution and at 121.4 and 157. 4 cps in the case of deuterium oxide solution (Table 2).

The authors wish to express their gratitude to Mr. Takuzo Fujino, Mr. Junichi Goda and Mr. Tsuneyo Shishido for the elemental analyses, and to Miss Yoshiko Kawashima for the NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 988—994 (1969)

Circular Dichroism of Chromium(III) Complexes. I. L-Tartrato Complexes. Their Stereospecific Formation and Spin-forbidden Absorption Bands

Sumio KAIZAKI, Jinsai HIDAKA and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received August 5, 1968)

Two novel mixed chromium(III) complexes containing L-tartrates and 2,2'-dipyridyl or 1,10-phenanthroline have been prepared, and their electronic absorption and circular dichroism spectra and the rotatory dispersion have been measured in the region of near-infrared to ultraviolet. From the construction of molecular models and from the comparison of the CD bands of the present complexes with those of the resolved oxalato complexes, $(-)_{546}$-$K[Cr(ox)_2(dip)]\cdot 3H_2O$ and $(-)_{546}$-$K[Cr(ox)_2(phen)]\cdot 4H_2O$, it has been concluded that the present complexes have a binuclear structure in which two Cr(III) ions are bridged by two tetradentate L-tartrato ligands and that the absolute configuration of the binuclear complexes is $\Lambda(C_2)$-$\Lambda(C_2)$. Their formation is completely stereospecific and their formulae are represented by $Ba[Cr_2(L\text{-}tart_2H)(dip)_2]_2\cdot 9H_2O$ and $NH_4[Cr_2(L\text{-}tart_2H)(phen)_2]\cdot 6.5H_2O$. The absolute configurations of several complexes which commonly belong to a general type, *cis*-$[Cr(O)_4(N)_2]$ have been determined on the basis of circular dichroism studies of the present binuclear complexes. The circular dichroism in the spin-forbidden absorption band region have also been measured and discussed.

Much evidence has been obtained for the fact that an octahedral metal complex with two or three optically active bidentate ligands has been often stereospecifically formed or isolated; namely, only a limited number of its configurationally optically active isomers has been preferentially formed or isolated.[1] Naturally occuring L-tartrate is one of such bidentate ligands. A definite but not so marked stereospecific formation has been reported in a complex containing one L-tartrate($C_4H_4O_6^{2-}$) and two ethylenediamine ligands.[2] Moreover it is well known that L-tartrate forms various kinds of transition metal complexes which show the so-called anomalous rotatory dispersion in the visible region; most famous and historically important of these is believed to be the tris(L-tartrato)chromium(III) complex,[3] on which the so-called Cotton effect was first observed in 1896 by Cotton.[4] Recently, McCaffery and Mason[5] have shown from their studies using circular dichroism (CD) and rotatory dispersion (RD) techniques that one of the two possible configurationally optically active isomers has been produced in a solution of chromium(III) in 4M potassium L-tartrate at pH 12. That is, the stereospecificity is complete in this tris(L-tartrato) case. In the complexes mentioned above, the L-tartrate ligand is thought to be coordinated as a bidentate ligand, being free from the coordination of two of its four donor groups. Of course, no mononuclear complex which contains a tartrate ion as a tetradentate ligand seems to exist owing to its steric requirement. It has been shown by some X-ray analyses, however, that the tetradentate tartrato ligands exist in some binuclear complexes.[6,7] These binuclear complexes have a

structure in which two five-coordinate metal ions, *i.e.*, antimony(III) or vanadium(IV), are bridged by two tetranegative tartrate anions.

In the persent paper, two new examples of such binuclear complexes will be reported, in which the two central metal ions have octahedral coordination. These are chromium(III) complexes of L-tartrate ($C_4H_2O_6^{4-}$ = tart) and 2,2'-dipyridyl (=dip) or 1,10-phenanthroline (=phen), namely, $Ba[Cr_2(L\text{-}tart_2H)(dip)_2]_2\cdot 9H_2O$ and $NH_4[Cr_2(L\text{-}tart_2H)(phen)_2]\cdot 6.5H_2O$. A preliminary short communication[8] has already been reported for the stereospecific formation of these complexes. The electronic absorption, and CD spectra and RD of these binuclear complexes will be discussed in comparison with those of the corresponding mononuclear complexes, $(-)_{546}$-$K[Cr(ox)_2(dip)]\cdot 3H_2O$ and $(-)_{546}$-$K[Cr(ox)_2(phen)]\cdot 4H_2O$.

Experimental

Preparation. 1) $Ba[Cr_2(L\text{-}tart_2H)(dip)_2]_2\cdot 9H_2O$: To a solution containing 2.3 g of sodium L-tartrate dihydrate ($L\text{-}Na_2H_2tart\cdot 2H_2O$) in 30 m*l* of a boiling dmf water*1 mixture (1 : 1), 3.88 g of $[CrCl_3(dmf)(dip)]$ was added. The reaction mixture was heated at about 120°C for a few minutes in an oil bath. After the color of the solution changed to dark red, the resulting solution was filtered and 1.2 g of $BaCl_2\cdot 2H_2O$ was added to the filtrate. When the solution was cooled in an ice bath, the desired dark crystals began to separate. The crude product was recrystallized from hot water. The pure crystals were filtered off and washed with a little ice water, ethanol and then with ether.

Found: C, 43.51; H, 3.03; N, 7.33; Ba, 9.98%*2. Calcd for $C_{56}H_{42}N_8O_{24}BaCr_4 = Ba[Cr_2(L\text{-}tart_2H)(dip)_2]_2$: C, 43.21; H, 2.73; N, 7.20; Ba, 8.83%. Found: H_2O, 9.24%. Calcd for $Ba[Cr_2(L\text{-}tart_2H)(dip)_2]_2\cdot 9H_2O$: 9.44%.

2) $NH_4[Cr_2(L\text{-}tart_2H)(phen)_2]\cdot 6.5H_2O$: A solution containing 7.7 g of $[CrCl_3(dmf)(phen)]$ and 3.45 g of ammonium L-tartrate ($L\text{-}(NH_4)_2H_2tart$) in 50 m*l* of a dmf-water mixture (1 : 1) was heated at about 120°C in an oil bath for a few minutes, while the color of the solution changed to dark red and the brown complex began to precipitate. It was allowed to stand at room temperature. The product was filtered off, and recrystallized from a hot dmf-water mixture (1 : 1). The pure crystals obtained were washed with a dmf-water mixture, ethanol and then with ether. This complex is sparingly soluble in water, but soluble in a dmf-water mixture (1 : 1).

Found: C, 49.26; H, 3.41; N, 8.46%. Calcd for $C_{32}H_{25}N_5O_{12}Cr_2$: C, 49.55; H, 3.26; N, 9.03%. Found: H_2O, 13.38%. Calcd for the 6.5 hydrate: H_2O, 13.09%.

3) $[CrCl_3(dmf)(dip)]$: This starting complex was prepared by Dwyer's method.[9] The hygroscopic anhydrous chromium(III) chloride, which was used instead of sublimated chromium(III) chloride, was completely dissolved in dry dmf without a trace of zinc dust.[10] To a hot solution of 5 g of chromium(III) chloride in 50 m*l* of dry dmf was added 5 g of 2,2'-dipyridyl. After refluxing the resulting solution for a few minutes, the greenish material began to separate. The reaction mixture was allowed to cool to room temperature. The product was filtered off and washed with cold dmf and then with ether.

4) $[CrCl_3(dmf)(phen)]$: This complex was obtained by the same method as that used for the 2,2'-dipyridyl complex, using 1,10-phenanthroline instead of 2,2'-dipyridyl.

5) $K[Cr(ox)_2(dip)]\cdot 3H_2O$ and $K[Cr(ox)_2(phen)]\cdot 4H_2O$: The preparation and optical resolution of these complexes were carried out by Broomhead's method.[11] The electronic absorption and rotatory dispersion of these complexes obtained coincided with those reported by Bürer.[12]

6) $K[Cr(ox)_2(en)]\cdot 2H_2O$: This was prepared by Werner's method,[13] and resolved by the method of Bushra and Johnson.[14]

Measurements. The electronic absorption spectra Were measured by a Beckman DU spectrophotometer. The CD spectra were recorded with a Roussel-Jouan dichrographe, while the RD curves were obtained with a Yanagimoto Recording spectropolarimeter model-185. The solvent employed for $(-)_{546}$-$K[Cr(ox)_2(dip)]\cdot 3H_2O$, $Ba[Cr_2(L\text{-}tart_2H)(dip)_2]_2\cdot 9H_2O$ and $(+)_{546}$-$K[Cr(ox)_2(en)]\cdot 2H_2O$ was water, and for $(-)_{546}$-$K[Cr(ox)_2(phen)]\cdot 4H_2O$ and $NH_4[Cr_2(L\text{-}tart_2H)(phen)_2]\cdot 6.5H_2O$ a dmf-water mixture (1 : 1). Because the oxalato complexes racemize at moderate rates in aqueous solutions,[11] the measurement for these complexes were made as rapidly as possible using solutions freshly prepared in turn.

Results and Discussion

Spectra of the Visible and Ultraviolet Region. The absorption and CD spectra, and RD of the complexes studied are shown in Figs. 1, 2, 4 and 5, and their characteristics are summarized in Table 1. The data of $(-)_{546}$-$K[Cr(ox)_2(phen)]\cdot 4H_2O$ and of $NH_4[Cr_2(L\text{-}tart_2H)(phen)_2]\cdot 6.5H_2O$ were obtained in a dmf-water mixture (1 : 1), since the L-tartrato complex is sparingly soluble in water. From a comparison of the absorption and CD spectra of $(-)_{546}$-$K[Cr(ox)_2(phen)]\cdot 4H_2O$ in water and in a dmf-water mixture (1 : 1), it was confirmed that the solvent dependence of the spectra of the 1,10-phenanthroline complex is negligibly small.

* The intensities are given per one complex ion, *i.e.*, per two chromium(III) ions.

The absorption curves of the L-tartrato and oxalato complexes resemble each other on the whole. It is possible to point out that the new L-tartrato complexes have a geometrical structure similar to that of $[Cr(ox)_2(dip)]^-$ and $[Cr(ox)_2(phen)]^-$. As may be seen in Fig. 1 and Table 1, the 2, 2'-dipyridyl complexes show three narrow inflections in the second spin-allowed absorption band region. In the corresponding region, a few small inversive dispersions are also observed.

The CD spectra and RD of the oxalato and L-tartrato complexes are also similar to each other (Figs. 1 and 2). That is, both the complexes show two CD bands, one positive at about 600 mμ and the other negative at about 520 mμ, in the first spin-allowed d→d absorption band region, and a weak positive CD band (at about 400 mμ) in the second spin-allowed d→d absorption band region. The CD band of the L-tartrato complexes are shifted to longer wavelengths than those of the oxalato complexes in the first spin-allowed absorption band region. Furthermore, the negative CD bands of these complexes are much higher in intensity than the positive one. These facts resemble those of the optically active tris(oxalato) and tris(L-tartrato) chromium(III) complexes in the corresponding region.[5] Assuming that the complexes employed here belong to pseudo D_3 symmetry, the negative CD bands are assigned to the $^4A_2 \rightarrow {}^4E_a$ transition and the positive ones to the $^4A_2 \rightarrow {}^4A_1$ transition as in $(-)_{546}$-[Cr-

$(ox)_3]^{3-}$.[5,15]

From a comparison with the data for the other complexes containing 2,2′-dipyridyl or 1,10-phenanthroline,[16,17] the intense absorption bands at about 300 mμ are assigned to the $\pi \rightarrow \pi^*$ transition originating from the coordinated 2,2′-dipyridyl or 1,10-phenanthroline ligand (Figs. 1 and 2).

Stereospecificity of the L-Tartrato Complexes. The L-tartrato complexes obtained by the reaction of $[CrCl_3(dmf)(dip)]$ or $[CrCl_3(dmf)(phen)]$ with L-tartrate have rather complicated formulae, but the similarity between these complexes and the oxalato complexes are evident. An L-tartrate ion can not span four coordination sites around one metal ion, and the elemental analysis data exclude any possibilities of mononuclear structures for these L-tartrato complexes. It is clear that the optical activity of the L-tartrato complexes is due to a kind of configurational dissymmetry rather

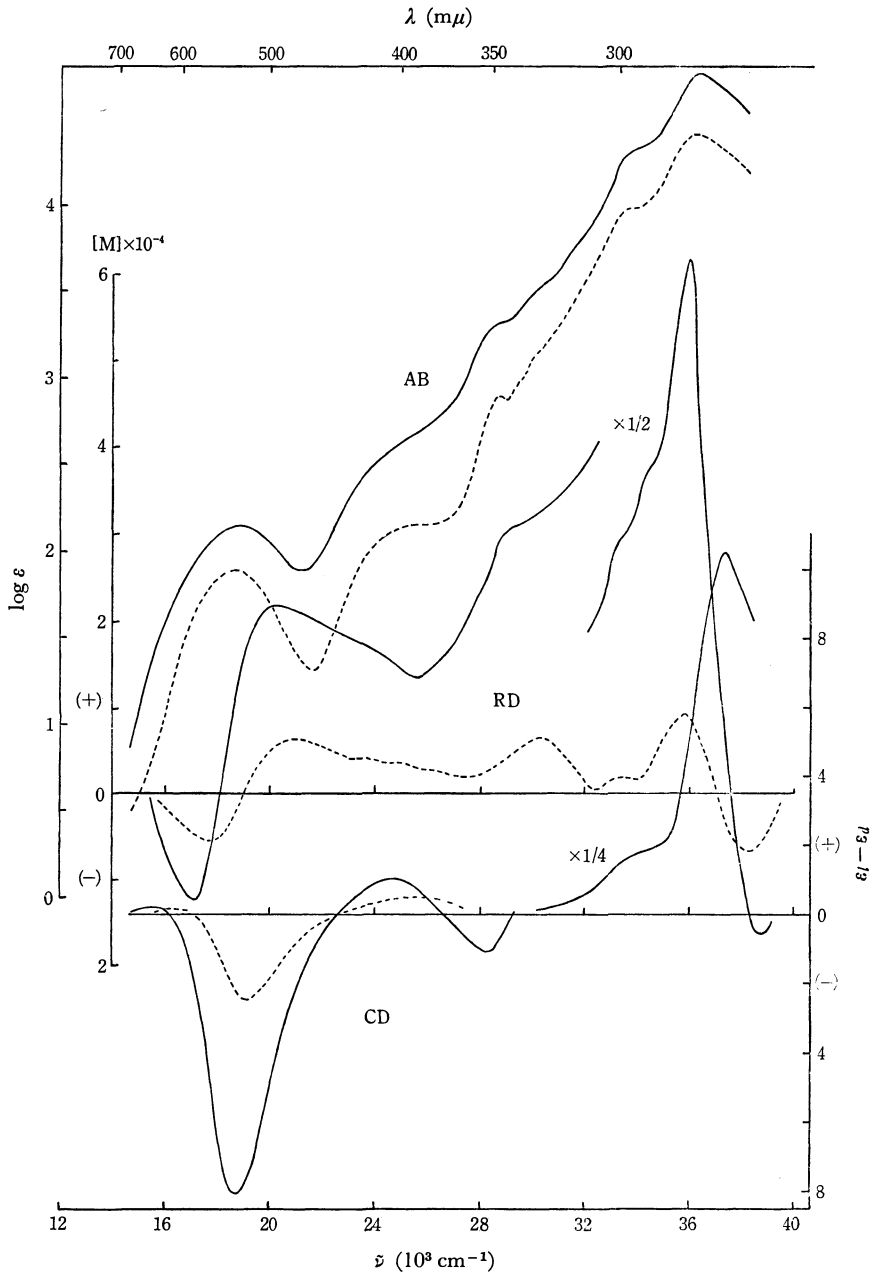

Fig. 2. Absorption (AB), CD and RD curves of, —— $[Cr_2(L\text{-}tart_2H)(phen)_2]^-$, and ---- $(-)_{546}$-$[Cr(ox)_2(phen)]^-$. (AB curve of the mononuclear complex was measured for the racemic one.)

than vicinal contribution of the coordinated L-tartrate ions from following reasons. Firstly, the absorption spectrum, CD and RD of the L-tartrato complexes in the visible region, if calculated per Cr(III) ion, have just the same or stronger intensities than those of the corresponding oxalato complexes. It has been known that the oxalato complexes easily racemize in aqueous solutions with half-lives of about 50 min.[11] On the other hand, the L-tartrato complexes do not racemize at all. Secondly, according to the construction of molecular models, the most probable structure for the experimental formula obtained is a binuclear one in which two chromium (III) ions are bridged by two tetradentate L-tartrate ions, as may be seen in Fig. 3. In this structure, the stereospecificity due to the two dissymmetric ligands is perfect; namely, as far as the L-tartrate is used, the binuclear complex which has an absolute configuration $\Lambda(C_2)$-$\Lambda(C_2)$ about the two tris-chelate type octahedra is the only one possible to be con-

structed. A similar structure has been revealed for the vanadyl tartrato complexes by the X-ray analyses.[6] In the vanadyl tartrato complexes, the tartrates are tetranegative and tetradentate ligands. On the contrary, it seems likely that in the present chromium(III) complexes, one proton remains undissociated per two tetranegative L-tartrates. Nevertheless, all the L-tartrates seems to be acting as tetradentate ligands. A question remains to be answered about the exact position of this proton or

its role in the binuclear structure.

On the basis that the L-tartrato complexes have the absolute configuration $\Lambda(C_2)$-$\Lambda(C_2)$, it is possible to determine the absolute configurations of the mononuclear complexes which belong to a general type, *cis*-$[Cr(O)_4(N)_2]$, because the similarity of the CD or RD curves between the L-tartrato and the oxalato complexes is quite good. Namely, it can be concluded that $(-)_{546}$-$K[Cr(ox)_2(dip)]\cdot 3H_2O$ and $(+)_{546}$-$K[Cr(ox)_2(phen)]\cdot 4H_2O$, both of which were obtained from the less soluble diastereomers with $(-)_{546}$-$[Co(ox)(en)_2]^+$, have the $\Lambda(C_2)$ and $\Delta(C_2)$ configurations respectively, and that the ethylenediamine complex, $(+)_{546}$-$K[Cr(ox)_2(en)]\cdot 2H_2O$, forming the less soluble diastereomer with brucinium ion, has the $\Delta(C_2)$ configuration.

The $\Lambda(C_2)$ isomers of both the 2,2'-dipyridyl and 1,10-phenanthroline complexes, including the present binuclear complexes show a positive CD band in their ligand $\pi\rightarrow\pi^*$ absorption band region (280—300 mμ). This is also true for another mono-phen-Co(III) complex, $(-)_{546}$-$[Co(en)_2(phen)]I_3$, which shows an intense positive CD band at about 280 mμ and a negative CD band in its first d→d absorption band region.[17]

Spin-forbidden Bands. A few reports have been made on the CD or RD in the region of the spin-forbidden absorption bands of chromium(III) complexes. Kling and Woldbye[18] measured the RD of $(+)_{546}$-$[Cr(en)_3](ClO_4)_3$ and $(+)_{546}$-$[Cr(tn)_3]Cl_3$ in their spin-forbidden bands, and found many sharp inversive dispersions superimposed with each other. McCaffery and Mason[5] measured the CD of tris(L-tartrato)chromium(III) ion in the corresponding region and found a CD band of weak intensity. As may be seen in Figs. 4 and 5, all of the oxalato complexes, $(+)_{546}$-$K[Cr(ox)_2(dip)]\cdot 3H_2O$, $(+)_{546}$-$K[Cr(ox)_2(phen)]\cdot 4H_2O$, and $(+)_{546}$-$K[Cr(ox)_2(en)]\cdot 2H_2O$, show a group of weak CD bands in the spin-forbidden absorption bands. The L-tartrato complexes, $Ba[Cr_2(L\text{-}tart_2H)(dip)_2]_2\cdot 9H_2O$ and $NH_4[Cr_2(L\text{-}tart_2H)(phen)_2]\cdot 6.5H_2O$, also show an apparently positive weak CD band (at about 690 mμ) superposed on the positive CD component (at about 640 mμ) of the first spin-allowed absorption band. Each of the oxalato complexes with the $\Delta(C_2)$ configuration shows three sharp CD peaks, (+), (−), (+) listing from the side of the long wavelengths, though the negative CD peak (at about 690 mμ) of $(+)_{546}$-$K[Cr(ox)_2(dip)]$ splits into two components. The CD intensities of the spin-forbidden bands are one over a few hundred as weak as those of the spin-allowed ones.

The spin-forbidden d→d transition bands which appear in the longer wavelength region than the spin-allowed transition bands should be assigned to the $^4A_{2g}\rightarrow{}^2E_g$ and $^4A_{2g}\rightarrow{}^2T_{1g}$ in a complex of octahedral symmetry. But it seems that the exact assignments of these bands of various chromium(III) complexes are still difficult.[19] The CD band which appears at longest wavelengths for the present complexes may be assigned to the $^4A_{2g}\rightarrow{}^2E_g$ transition under O_h symmetry. In D_3 symmetry, the T_{1g} state breaks down into the E and A_2 states and the E_g state remains as the E state. Since these spin-forbidden transitions acquire their rotational strengths only by borrowing the electric and magnetic moments from the upper quartet state of the same symmetry,[20] the spin-forbidden transitions must have the same sign of the CD bands with that of the spin-allowed transition to the state with the same symmetry. Now, assuming that the present complexes belong to pseudo D_3 symmetry, two positive CD bands of their $(+)_{546}$-isomers may be assigned to the ^2E state and the negative one to the $^2A_2$ state, because the ^4E_a components of the first spin-allowed bands of these complexes have the positive CD sign. However, from the fact that the negative orbitally nondegenerate $^2A_2$ state of $(+)_{546}$-$K[Cr(ox)_2(dip)]$ splits into two CD components, it seems likely that the spin-orbit coupling or vibrational structures must be taken into consideration.

The Synergistic Effect in Solvent Extraction. The Effect of the Chelating Ligands on the Stability Constant of Lutetium β-Diketonate Adducts with TOPO

Takaharu HONJYO

Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received August 7, 1968)

The steric effect and the inductive effect of the functional groups of β-diketones on the adduct formation between lutetium chelates and TOPO in benzene was studied by using various β-diketones with aliphatic groups (acetylacetone, dipropionylmethane, pivaroylacetone, diisobutyrylmethane and dipivaroylmethane), aromatic groups (benzoylacetone, naphthoylacetone and dibenzoylmethane) and fluoromethyl groups (trifluoroacetylacetone, furoyltrifluoroacetone, thenoyltrifluoroacetone, benzoyltrifluoroacetone and hexafluoroacetylacetone). The effect of the temperature on the adduct formation was then estimated. These results may be summarized as follows: (1) The stability of the adduct increases, and the larger synergism appears, as aliphatic groups, aromatic groups, and fluoromethyl groups are successively substituted for the functional groups of β-diketones. This effect may be due to the electron-withdrawing effect of the fluoromethyl group and the conjugation effect (with a metal chelate ring) of the phenyl group. (2) The adducts contain one molecule of TOPO per metal chelate except for the HFA adduct, which contains two molecules of TOPO. The steric hindrance of the terminal groups is hardly recognizable. (3) The extraction constant of the chelates increases, while the stability of the adducts decreases, with a rise in the temperature. The apparent enthalpy change ($-\Delta H$ kcal/mol) upon the adduct formation increases in the order: DPM (5.5)<BzA(5.9)<BFA(8.6) chelates.

During the course of the solvent extraction of metal chelates, an extremely enhanced extraction is often observed in the presence of some neutral Lewis bases. This phenomenon is generally called the synergistic effect and explained by the adduct formation between the metal chelates and the Lewis bases.

The synergism in the extraction of rare earth β-diketonate has been widely investigated;[1-4] solid adducts have been prepared and their properties studied.[5,6] However, the mechanism of the adduct formation and the nature of the metal chelate adducts are not yet completely understood.

Shigematsu and his co-workers have carried out a systematic study of the synergistic extraction of rare earth metals,[7,8] and the following results have been obtained.

(1) In rare earth-benzoyltrifluoroacetone(BFA)-TOPO, TBP and *n*-hexanol systems, the extraction constant of the chelates increases, while the stability of the adducts decreases, with a decrease in the ionic size of the metal. The tendency has also been reported for lanthanum, europium, lutetium-TTA-dimethylsulfoxide, TBP, and hexone systems.[9]

(2) Oxygen-containing Lewis bases, having a stronger donating power of lone-pair electrons, form more stable adducts and therefore show a larger synergism; esters and ketones<alcohols<TBP<TOPO. Organic phosphate and phosphine oxide especially give rise to a large synergism.

(3) Nitrogen-containing Lewis bases, such as amines and heterocyclic compounds, also produce the synergism. The synergistic enhancement of the extraction is of almost the same magnitude as that of oxygen-containing Lewis bases: The effect of the amines is similar to that of alcohols. However, the solid adducts of the former are thermally more stable than the adducts of the latter.

(4) The maximum number of base molecules bound to one molecule of the metal chelate is 2 except in the case of lutetium β-diketonates-TOPO in benzene, where only one molecule of TOPO binds one molecule of the chelates.

In order to obtain more detailed information on this interesting phenomenon, the present research studied the steric effect and the inductive effect of the functional groups of various β-diketones on the adduct formation between lutetium chelates and TOPO.

Experimental

Materials. The radioisotope of lutetium-177 was produced by irradiating pure lutetium oxide in a thermal neutron flux of about 5×10^{12} n/cm²sec in the Research Reactor of Kyoto University. After the irradiated sample had been dissolved in hot hydrochloric acid, the lutetium was extracted at pH 5 with 0.05 M BFA in benzene and stripped into 0.1 M perchloric acid. The resulting solution was evaporated to fumes, and then the residue was dissolved in an appropriate amount of perchloric acid to make a stock solution. The specific activity of the tracer was sufficiently high for this investigation. The sodium perchlorate was prepared from perchloric acid and sodium carbonate and purified by recrystallization from water.

Some substituted β-diketones were synthesized by the acylation of methylketone with aromatic- or aliphatic ethylester in the presence of sodium amide as the base catalyzer.[10] The boiling points and the melting point of these β-diketones were as follows:

Prepared β-diketones

β-Diketones	Bp(°C/mmHg)	Mp(°C)
DPM (dipropionylmethane)	77 — 78/30	—
DIBM (diisobutyrylmethane)	80.5— 81.5/17	—
PvA (pivaroylacetone)	66 — 67/17	—
NtA (naphthoylacetone)	—	79

The other β-diketones, AA (acetylacetone), BzA (benzoylacetone), DBM (dibenzoylmethane), TAA (trifluoroacetylacetone), BFA (benzoyltrifluoroacetone), TTA (thenoyltrifluoroacetone), FTA (furoyltrifluoroacetone), HFA (hexafluoroacetylacetone), DPvM (dipivaroylmethane), and TOPO (tri-*n*-octylphosphine oxide), were obtained from the Dojindo Co. and the Tokyo Kasei Kogyo Co.

Procedure. The experimental procedure was almost the same as has previously been described.[7] To 5 m*l* of an aqueous solution containing lutetium (a few ppm), sodium perchlorate (0.1 M) and acetic acid (0.01 M) and having a desirable pH, 5 m*l* of benzene containing β-diketone (0.05 M or 0.1 M) and various amounts of TOPO were added. Both phases were placed in a 30 m*l* glass-stoppered centrifuge tube and agitated by a mechanical shaker for from one to three hours at a constant temperature in an electric thermostat (−5—30±0.05°C). After centrifugation, 2 m*l* of each phase were pipetted into test tubes (14 mm in diameter), and the γ-radioactivities were measured with a NaI(Tl) well-type scintillation counter. The pH value of the aqueous layers was checked after the extraction.

The extraction constants of the metal chelates, K, and the stability constants of the metal chelate adducts, β_n, can be calculated by the following equations*1:

$$K = [MR_3]_o[H^+]^3/[M^{3+}][HR]_o^3 \quad (1)$$

$$\log K = \log D - 3\log[HR]_o - 3pH \quad (2)$$

$$\beta_n = [MR_3L_n]_o/[MR_3]_o[L]_o^n \quad (3)$$

$$\log D^*/D = \log(1+\sum_{n=1}^{n}\beta_n[L]_o^n) \quad (4)$$

where D and D^* are the distribution ratio in the absence and in the presence of TOPO; M stand for metal, HR for β-diketone, and L for TOPO, and [ ] and [ ]$_o$ designate the concentration of the chemical species in the aqueous and organic phases respectively.

Results and Discussion

Lutetium-β-diketone System. Figure 1 shows the log$D$ *vs.* pH plots in the extraction of lutetium ions with various β-diketones in benzene. With β-diketones with a fluoromethyl group, lutetium can be extracted in the lower pH region. This fact is caused by the inductive effect of the fluoromethyl group, which raises the acidity of the enol form.[11,12] The high extractability can be

attained with β-diketones possessing bulky groups, such as benzoyl-, thenoyl- and pivaroyl groups (*e. g.*, BFA, TTA, and DPvM); this may be due to the hydrophobic structure of the molecule, which prevents the formation of water-soluble complexes[13] and minimizes the solubility of the metal chelates into water. In the extraction with β-diketones which are comparatively soluble in water (*e.g.*, AA, TAA and HFA), the slopes of the log$D$ *vs.* pH plots deviate from 3, the theoretical value, because of the formation of water-soluble complexes.

Figure 1 confirms the general concept that the $pH_{1/2}$ value for the extraction of metal β-diketonates is directly correlative with the pK_D value of the β-diketone.

Lutetium-β-diketone-TOPO System. Figure 2 indicates the log$D$* *vs.* pH plots in the synergistic extraction of lutetium ions with 10^{-3}M TOPO and various β-diketones in benzene. In the presence of TOPO, the extraction of lutetium is very much enhanced by the adduct formation. As may be seen in the figure, the plots of DBM, NtA and BzA curve concavely in the low-distribution region. This curious behavior, however, can not be explained in the present time and was not studied in detail, because it seems not to be very important in this research.

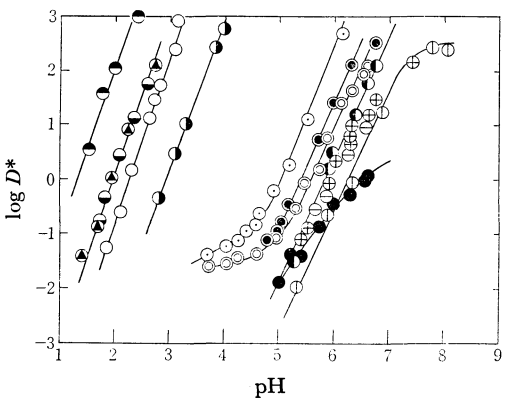

Fig. 2. The distribution ratio of lutetium with various β-diketones in the presence of 0.001 M TOPO as a function of pH. The symbols in the figure are the same as in Fig. 1.

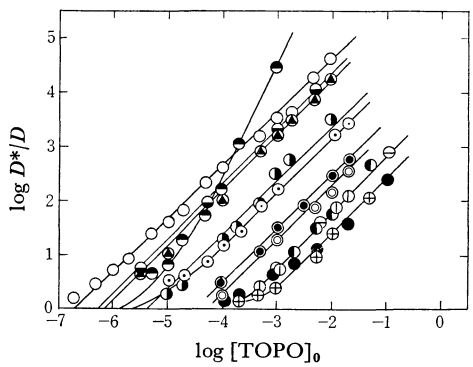

Fig. 3. The distribution ratio of lutetium with β-diketones having various functional groups as a function of TOPO concentration. The symbols in the figure are the same as in Fig. 1.

The effects of the functional groups of various β-diketones on the adduct formation are shown in Fig. 3 as log$D$*/D *vs.* log $[TOPO]_0$ plots. The straight lines with a slope of 1 indicate that one molecule of TOPO binds one molecule of the metal chelate. The HFA chelate adduct contains two molecules of TOPO.

The extraction constants of lutetium β-diketonates, log K, and the stability constants of their TOPO adducts, logβ_n, are summarized in Table 1. The stability of the TOPO adduct with various lutetium β-diketonates increases in the follwing order: aliphatic groups (AA and DPM<PvA, DIBM and DPvM)<aromatic groups (BzA<NtA≪DBM)< fluoromethyl groups (TFA≪FTA<TTA<BFA≪ HFA). In general, the log β_n increases with an increase in the log K value, as is indicated in Fig. 4, and no steric hindrance by terminal aliphatic or aromatic groups upon the adduct formation is observed.

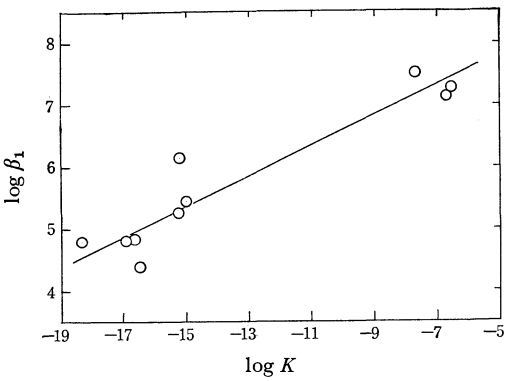

Fig. 4. The stability constant of lutetium β-diketonate TOPO adduct, log β_n as a function of the extraction constant of metal chelate, log K.

As has been described above, the chelates with a fluoromethyl group in the ligand form stable adducts. This may be due to the fact that the electron-withdrawing fluoromethyl group decreases the electron density around the metal ion.[14,15] The fluoromethyl group does not hinder the resonance of the metal chelate ring.[16] The chelates containing the

aromatic group in the ligand also form more stable adducts than those with the aliphatic group do (*e.g.*, TFA<BFA; AA<BvA<DBM). The contribution of the phenyl substitution to the adduct formation may result from the conjugation effect of the groups with the metal chelate rings. Such a conjugation effect may weaken the binding power between the central metals and the coordinated ligand,[17] thereby enhancing the adduct formation. The conjugation effect was also observed in the NMR measurements of metal TTA chelates.[18] As a result of the electron-withdrawing effect of the fluoromethyl group and by the conjugation effect of the phenyl-, thenoyl-, and furoyl-groups, BFA, TTA, and FTA form more stable adducts with TOPO than do other β-diketones. A similar ten-

dency has also been found in the adduct formation between uranyl β-diketonates and TBP.[19]

Figure 5 shows the effect of the temperature on the adduct formation of DPM, BzA, and BFA chelates with TOPO, while Table 2 presents the extraction constants of these chelates and the stability constants of their adducts. The extraction constants of the chelates increase, while the stability of the TOPO adducts decreases, with a rise in the temperature. This phenomenon supports the empirical fact that the more stable a chelate, the less stable the adduct is, because the extraction constant can be taken as a measure of the stability of the metal chelate in the extraction with the same chelating reagent. As may be expected from this fact, the logD^* *vs.* pH plots in the synergistic extraction are little affected by the temperature (in the range from 10°C to 30°C), as is presented in Fig. 6. The apparent enthalpy changes in the adduct formation have been estimated and are presented in Table 2. The value increases in the sequence of DPM, BzA, and BFA.

Cobalt(IV) Ammine Complexes with 5-Nitrosalicylato or Similar Ligands. III. Electric Resistivity, Magnetic Susceptibility, and ESR*[1]

Yoshihisa YAMAMOTO

Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received August 15, 1968)

The electric and magnetic properties of a series of 5-nitrosalicyclato ammine cobalt(IV) complexes (paramagnetic), the salicylato ammine cobalt(III) complex (diamagnetic), μ-superoxo-dicobalt ammine complexes (paramagnetic), and the μ-peroxodicobalt ammine complex were studied. The resistivity(ρ) at room temperature and the energy gap(ε) for paramagnetic complexes were in the range of, $\rho=7.6\times10^{10}$—1.5×10^{11} Ω cm and $\varepsilon=0.7$—1.1 eV, whereas those for diamagnetic complexes were in the range of $\rho=10^{12}$—10^{14} Ω cm and $\varepsilon=0.75$—1.2 eV. The magnetic susceptibilities of the paramagnetic complexes obeyed the Curie-Weiss law, with comparatively large Curie-Weiss constants (-18—26°K). The g-values and line widths (ΔH_{msl}) in the ESR signals at room temperature were determined for powdered samples of 5-nitrosalicylatotetraamminecobalt(IV) complexes and their derivatives. The ESR parameters obtained were in the range of $g=2.0030$—2.0070 and $\Delta H_{msl}=22.0$—30.6 Oe for powders.

Previous papers have reported on the preparation of cobalt(IV) ammine complexes with 5-nitrosalicylato[1] or similar ligands[2]. Inasmuch as these compounds contain cobalt in the unusual valence state (IV, d^5 in the low spin state), various anomalies are expected in their physical properties. The present paper deals with the results of measurements of the solid electric conductivities, magnetic susceptibilities, and ESR of these compounds.

Experimental

Preparation. *5-Nitrosalicylatotetraamminecobalt(IV) Complexes, 5-Nitrosalicylatobis(ethylenediamine)cobalt(IV) Complexes, 3-Methyl-5-Nitrosalicylatotetraamminecobalt(IV) Complexes, and 4-Methyl-5-Nitrosalicylatotetraamminecobalt-(IV) Complexes.* These complexes were prepared by the methods reported in Papers I[1] and II[2].

The salicylatotetraamminecobalt(III) Complex and its Derivatives and the Salicylatobis(ethylenediamine)-cobalt(III) Complex. These complexes were prepared by Morgan's method.[3]

The μ-Amido-μ-superoxo-bis(tetraamminecobalt)(4+) Complex. This complex was prepared according to the method of Mori, Weil and Ishiguro.[4]

The μ-Superoxo-bis(pentaamminecobalt)(5+) Complex. This complex was prepared according to the method of Gleu and Rehm.[5]

The μ-Peroxo-bis(pentaamminecobalt)(4+) Complex. This complex was prepared by Werner's method.[6]

Measurements of Electrical Conductivities. The measurements were made with a Toa Denpa Kogyo Microvolt Ammeter, Model PM-18 (for the range 10^{-4}—10^{-12} A), and a Takeda Riken Vibrating Reed Electrometer, Model TR-81 (10^{-7}—10^{-15} A). A fine powder of each complex was compressed into a disk (12 mm in diameter and 1—2 mm thick) under a pressure of about 3×10^2 kg/cm^2. Silver-paste was used as the electrode. The D.C. conductivity was measured in the temperature range from −50 to +120°C. The conductivity vessel, as shown in Fig. 1[7], was evacuated down to 10^{-2} mmHg.

Measurements of Magnetic Susceptibilities. The measurements were made by the Gouy method with a magnetic balance (Shimadzu Seisaku Sho) in the temperature range between 80°K and room temperature. The magnetic susceptibility of 5-nitro-4-methylsalicylatotetraamminecobalt(IV) chloride nitrate was also measured by the AC method, using a Hartshorn bridge in the temperature range between 4.22°K and 1.21°K. The accuracy was ±0.1%.

Electron Spin Resonance. The spectra were recorded at room temperature with a TMF-20305 Tokyo Denki Seiki. Quartz sample tubes 1.5 mm in diameter were used; they were filled with solutions in several kinds of solvent to about 4 cm from the bottom.

Results and Discussion

Electrical Resistivities. An almost linear relationship was observed between the current and the applied voltage up to 15V in the temperature range from −50—+120°C. In most cases the tempera-

	5.2×10^{11}	0.95
	1.5×10^{11}	0.75

ture dependence of the resistivity obeyed the $\rho = \exp(\varepsilon/2\boldsymbol{k}T)$ equation (Fig. 2). The resistivity at 25°C (ρ_{25}) and the apparent energy gap (ε) as calculated from the above equation are tabulated in Table 1.

It should be noted that most of these complexes have the water of crystalliaztion; the influence of this water must be considered in analysing the results of these electric measurements. For the μ-amido-μ-superoxo-bis(tetraamminecobalt) complex, measurement was made in the −40—+80°C range. An almost linear relationship between ρ and $1/T$ was observed between −40 and −10°C, and also between −10°C and +50°C, but the linear relation was not observed above +55°C (Fig. 3). This change in the conductivity behavior is thought to be due to such water molecules. On the other hand, the resistivity of cobalt(IV) complexes showed an almost linear relationship with $1/T$ up to 120°C (*cf.* Fig. 2). This seems to indicate that, in this compound, the water is bound tightly to the carbonyl group of the salicylato ligand. This idea of tightly-bound water was presented by Morgan and Smith[3] for their salicylatotetraamminecobalt(III) salts and was proved by the X-ray analysis of the chloride monohydrate by Hosoo, Kushi, and Kuroya.[8]

Next, let us consider the effect of the number of d-electrons in the cetral metal ion on the electric resistivities of the complexes. Balto and Weiss[9]

reported the preparation and the resistivity measurements of the iron(III) complex (d^5, 4.7×10^5 Ωcm) and the iron(II) complex (d^6, 3.8×10^4 Ωcm), both with a pentacyclic ligand which had been prepared from chloranil and o-phenylenediamine. Inoue, Hayashi, Takiuchi and Imoto[10] reported on the organic polymer-tin(IV) complex (d^{10}, 3.8×10^{10} Ωcm) and the organic polymer-tin(II) complex ($d^{10}s^2$, 1.76×10^9 Ωcm). Thus, both these groups of investigations found that the number of d or s-electrons in the central metal ion does not have much effect on the electric resistivity, provided that the relevant orbital is sufficiently localized on the central metal ion.

Consequently, if our cobalt compounds contained true tetravalent cobalt atoms, *i.e.*, if the hole produced as the result of oxidation were localized on the cobalt atom, the resistivity should not be much different from that of the normal cobalt(III) ammine complex. Actually, the resistivities of our paramagnetic cobalt(IV) ammine complexes with 5-nitrosalicylato or similar ligands are lower than those of cobalt(III) complexes with similar ligands by factors of 10^2—10^4. Such large differences in the electrical resistivities seem to suggest that the distribution of the electron hole is spread over the entire molecule, or that our green compounds might preferably be regarded as containing free radial complex ions. We might, for comparison, refer to the electrical resistivity of violanthrone-B (a free radical, $\rho_{15}=6.9\times10^6$ Ωcm[11]) and that of violanthrone (with no unpaired spin, $\rho_{15}=1.1\times10^{11}$ Ω·cm[11] or 2.3×10^{10} Ωcm[12]). These results indicate that the radical formation has much effect on the electrical resistivity.

A similar relationship holds between the electrical resistivities of diamagnetic peroxo dicobalt complexes and those of paramagnetic superoxo dicobalt (formerly called peroxo cobalt(III) cobalt(IV)) complexes. The electrical resistivities of paramagnetic μ-superoxo compounds are lower than those of diamagnetic peroxo complexes by factors of 10^2—10^4 (Table 1).

Fielding[13] had reported the resistivity of μ-superoxobis(pentaamminecobalt)(5+) hydrogen trisulfate trihydrate to be $\rho=2\times10^7$ Ωcm at 20°C, which is almost in complete agreement with the measurements made by the present author (Table 1).

Electron Spin Resonance. In the case of superoxo dicobalt complexes, Ebsworth and Weil[14] observed a hyperfine structure with 15 equally-spaced components in the paramagnetic resonance spectra of aqueous solutions: this structure clearly indicated that the unpaired electron spends equal fractions of time on the two cobalt nuclei. Recently, Weil and Kinnaird[15] reported that the ESR spectra of O^{17}-labeled $[(NH_3)_4Co\langle{}^{OO}_{NH_2}\rangle Co(NH_3)_4]^{4+}$ dissolved in very dilute nitric acid showed a hyperfine structure of oxygen-17 in addition to 15 hyperfine lines of cobalt. These ESR spectra show that the unpaired electron is located on the molecular orbital extending over cobalt-oxygen-cobalt.

The present research has revealed that ESR signals are also observable in the green 5-nitrosalicylato cobalt ammine complexes at room temperature. This proves that the complex is actually in a high oxidation state, because coblt(II) compounds known to have too short a relaxation time to allow any ESR signal to appear at room temperature.

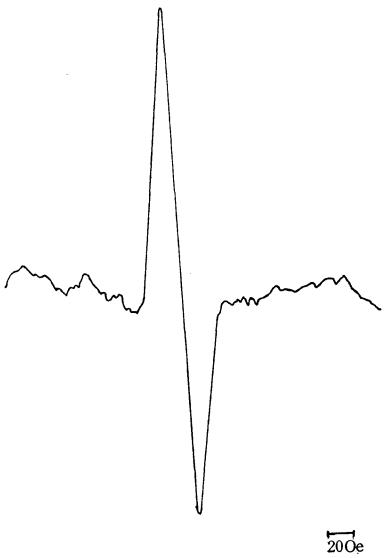

Fig. 5. ESR spectrum of $\left[(en)_2Co\langle^{O}_{OOC}\!\!-\!\!\bigcirc\!\!\bigcirc\!\!-NO_2\right]Cl\cdot NO_3\cdot H_2O$ in aqueous solution at 22°C (about 10^{-1} mol/*l*).

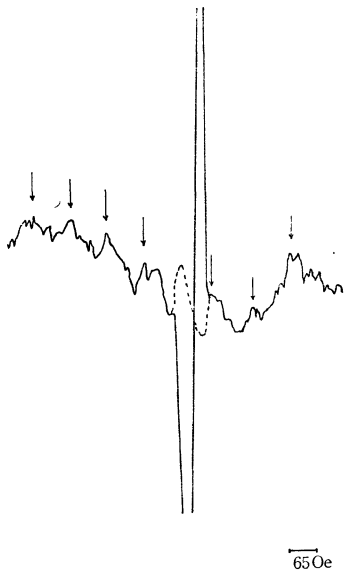

Fig. 6. ESR spectrum of $\left[(en)_2Co\langle^{O}_{OOC}\!\!-\!\!\bigcirc\!\!\bigcirc\!\!-NO_2\right]Cl\cdot NO_3\cdot H_2O$ in aqueous solution at 22°C (about 10^{-2} mol/*l*).

The powder ESR of 5-nitrosalicylatotetraamminecobalt(IV) salts, 3-methyl or 4-methyl-5-nitrosalicylatotetraamminecobalt(IV) salts (Fig. 4), and 5 - nitrosalicylatobis (ethylenediammine) cobalt (IV) salts gave symmetrical spectra; the obtained values of *g*-factor and line width (between points of maximum slope)are given in Table 1.

As has been stated in Paper II,[2] the 5-nitrosalicylatobis(ethylenediamine)cobalt(IV) complex is more stable than the 5-nitrosalicylatotetraamminecobalt-(IV) complex and its methyl derivatives, hence, it is more suitable for the ESR study of solutions.

The solution of 5-nitrosalicylatotetraamminecobalt(IV) salts in water gave spectra without any hyperfine structure and were slightly asymmetric, the high field side being slightly broader. The spectra could be observed for only about an hour

after the dissolution of the samples. Solutions in 35% hydrochloric acid, 20—60% phosphoric acid, and 100% methanol gave no observable spectra.

A solution of 5-nitrosalicylatobis(ethylenediamine)cobalt(IV) complexes in mthanol or 35% hydrochloric acid gave spectra without any hyperfine structure, and the line slope was asymmetric, the high-field side being broader. The aqueous ESR spectra of 5-nitrosalicylatobis(ethylenediamine)-cobalt(IV) salts showed no hyperfine structure, except in a limited range of concentration of about 10^{-1}—10^{-3} mol/l (Fig. 5). At the sample concentration of about 10^{-2}—10^{-3} mol/l, a hyperfine structure of eight lines developed on both field sides of one strong line (Fig. 6). At present, however, it is difficult to assign these hyperfine structures.

One thing that can be said about the obtained spectra described above is that the g-value is always close to the free electron value (Table 2), This seems to be in line with the afore-mentioned assumption of the free-radical nature of the green paramagnetic 5-nitrosalicylatc ammine cobalt complexes.

Magnetic Susceptibilities. The susceptibilities of the compounds were found to be independent of the temperature. χ_{mol}^{cor} was obtained by correcting the observed molar magnetic susceptibility, χ_{mol}, for the diamagnetic contribution of the molecule, which was taken to be 0.000200—0.000220 c.g.s.e. m.u. The effective magnetic moment of the molecule in Bohr magnetons, μ_{eff}, was obtained using the formula:

$$\mu_{eff} = 2.84\sqrt{\chi_{mol}^{cor}(T-\theta)}$$

The Curie-Weiss plots and some related parameters are given in Fig. 7 and Table 2 respectively. The comparatively large Curie-Weiss constants again seem to conform with the free radical nature of the substance as assumed in the foregoing discussion of the electric resistivities. These values might be compared with the Curie-Weiss constants of such free radical as diphenylpicrylhydrazyl (−10°K[16]), diphenylpicrylhydrazyl (in CS_2, −22°K[17]), and violanthron-B (−45°K[11]).

In the case of 5-nitro-4-methylsalicylatotetraamminecobalt(IV) chloride nitrate, the susceptibility measurements were also made at the temperatures of liquid helium; these measurements gave the Curie-Weiss constant of 0°K(Fig. 8) and the

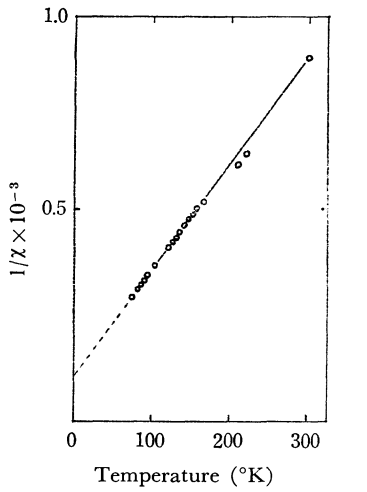

Fig. 7. $1/\chi$ *vs.* temperature diagram.

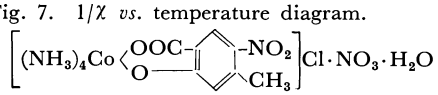

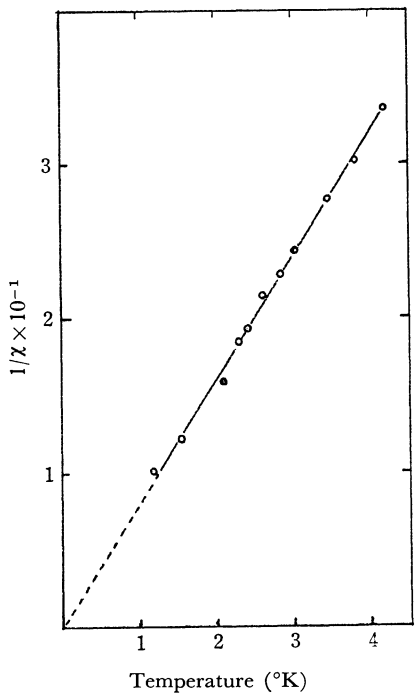

Fig. 8. $1/\chi$ *vs.* Temperature diagram.

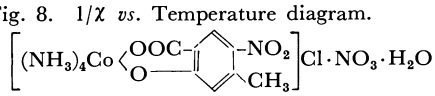

effective Bohr magneton number of 1.05±0.05, in contrast to the values above the temperature of liquid nitrogen, (−18°K, 1.7 B.M., Table 2). This discrepancy between results in different temperature ranges is doubtless due to the bending of the Curie-Weiss plot in the region of very low temperatures.

The author is grateful to Professor Hiroshi Mikawa of Osaka University for his kind offer of conductivity equipment, to Professor Ikuji Tsujikawa and Dr. Hanako Kobayashi of Kyoto University for their kind guidance in the susceptibility measurements, and to Dr. Setsuo Takamuku of Oasaka University for his whole-hearted cooperation in the ESR spectroscopy.

and Tadashi Iwachido

College of Liberal Arts and Sciences, Okayama University, Tsushima, Okayama

(Received August 17, 1968)

The Hexyl(2,4,6,2′,4′,6′-hexanitrodiphenylamine) anion forms ion-pairs with alkali metal cations to some extent in an aqueous solution. The association constants of these ion-pairs were determined both in nitrobenzene by conductivity measurements and in water by the solvent extraction method. The association constants in nitrobenzene (K_o^{MR}) decrease in the following order: Li>Na>K>Rb>Cs. The plot of log K_o^{MR} against the ionic potential of the alkali metal ions was found to be linear. In nitrobenzene saturated with water, however, the constants vary from 2 to 4. In water the asscoiation constants (K_a^{MR}) vary from about 10 to 400, and the value increases as follows: Li<Na<K<Rb (<Cs). A plot of log K_a^{MR} against the reciprocal of the effective diameter of the hydrated alkali metal ions was found to be linear.

The extraction of alkali metal ions with the Hexyl anion into nitrobenzene has been reported by several authors.[1,2] The mechanism of the extraction is very attractive to us, because many alkali metal salts are well known to be very soluble in water but not in ordinary organic solvents immiscible with water. Generally alkali metal salts, such as chlorides and nitrates, are completely dissociated in an aqueous solution. However, potassium, rubidium, or cesium ions with larger radii than those of other cations, form a precipitate with such a large and symmetric anion as the perchlorate, tetraphenylborate, or Hexyl anion, and this precipitate is occasionally extracted into an organic solvent immiscible with water. This fact implies that the alkali metal ions associate to some extent with a large anion in an aqueous solution to form ion-pairs which can be extracted into nitrobenzene, and that such salts as alkali metal tetraphenylborate or Hexylate would be dissociated in nitrobenzene. In the present paper, the dissociation constants of the Hexyl salts in nitrobenzene were measured by electric conductance measurements. The constants in water were determined by the solvent extraction method.

Experimental

Reagents. Hexyl salt with an alkali metal ion was prepared by dissolving Hexyl into an aqueous solution of an equivalent amount of each alkali metal hydroxide or carbonate. The resulting precipitates were filtered and recrystallized two or three times from ethanol or acetone. The salts were dried at 50°C for 3—5 hr under a pressure of less than 10 mmHg.

The nitrobenzene for the conductivity measurements was prepared by distilling special-grade nitrobenzene which had been dried over anhydrous sodium sulfate. The fraction was collected at 75°C under a pressure of 5 mmHg and was stored in an ampoule to protect it from moisture. The nitrobenzene thus obtained had a specific conductance of $3—5\times10^{-9}$. This value is, however, satisfactory enough for the present purposes.

Potassium chloride for calibrating the conductance cell was purified by recrystallizing it from distilled water and was dried at 45°C in an electric furnace for three hours.

All the other chemicals used were of an analytical reagent grade and were used without further purification.

Electric Conductance Measurements. The electric conductivity of the nitrobenzene solution was determined by the use of a conductometer, CM-1DB, from Toa Electronics Ltd. Measurements were made in a jacketted vessel equipped with platinized platinum electrodes, a thermometer, and a microburet. The jacketted vessel was maintained at 25°C by circulating water from a constant-temperature bath. To a known amount of pure nitrobenzene in the vessel, small quantities of a concentrated nitrobenzene solution of these salts were introduced successively from the microburet.

Extraction Procedure. Twenty milliliters of an aqueous solution of the alkali metal ion (the pH being adjusted to about 11 with each alkali metal hydroxide or carbonate) was shaken moderately with 20 ml of a nitrobenzene solution containing each Hexyl salt for about thirty minutes. After this mixture had been allowed to stand for one or two hours, the organic and the aqueous layers were separated and the Hexyl salt in each phase was determined spectrophotometrically by using a Hitachi-Perkin Elmer Spectrophotometer, Model 139. The final pH of the aqueous phase was 10—11.

All the procedures were made in a constant-temperature room (25±1°C).

Calculations

Association Constants of Hexyl Salt in Nitrobenzene. In non-aqueous systems, where the dielectric constant of the solvent is about 40 or less, to evaluate the limiting conductance, Λ_∞, and the dissociation constant, K_S, from the conductance data, Shedlovsky[3] proposed this equation:

$$\frac{1}{\Lambda S} = \frac{1}{\Lambda_\infty} + \frac{C\Lambda S f^2}{K_S \Lambda_\infty^2} \tag{1}$$

where C is the analytical concentration of 1-1 electrolytes, f is the activity coefficient, $S \equiv \left(\frac{z}{2} + \sqrt{1 + \left(\frac{z}{2}\right)^2}\right)^2$, and z is defined as:

$$z = \alpha\sqrt{C\Lambda}/\Lambda_\infty^{3/2} \tag{2}$$

where α is the Onsager coefficient.

From Eq. (1), $1/\Lambda S$ is found to be linear against $C\Lambda S f^2$ at low concentrations, and Λ_∞ and K_S are obtained from the intercept and the slope.

Hexyl salts are associated in nitrobenzene as follows:

$$M^+ + R^- \overset{K_o^{MR}}{\rightleftharpoons} MR$$

The association constant in nitrobenzene, K_o^{MR}, is written as:

$$K_o^{MR} = \frac{[MR]_o}{[M^+]_o[R^-]_o f_o^2} \left(= \frac{1}{K_S}\right) \tag{3}$$

where the subscript O refers to the organic phase where $[M^+]$, $[R^-]$, and $[MR]$ are the concentrations of the alkali metal ions, the Hexyl anion, and the ion-pairs respectively.

Association Constants of Hexyl Salts in Water. The data of the solvent extraction of Hexyl salts were treated in the following way. Consider the association reaction:

$$M^+ + R^- \overset{K_a^{MR}}{\rightleftharpoons} MR$$

where M^+ represents an alkali metal ion, R^-, a Hexyl anion, and MR, an ion-pair. The association constant of the above equilibrium is:

$$K_a^{MR} = \frac{[MR]_a}{[M^+]_a[R^-]_a f_a^2} \tag{4}$$

Where [ ] indicates the concentration of the substance indicated, where the subscript a refers to the aqueous phase, and where f_a is the activity coefficient.

Besides, at a distribution equilibrium of the two phases, the partition coefficient of the ion-pair MR, D_{MR}, is:

$$D_{MR} = \frac{[MR]_o}{[MR]_a} \tag{5}$$

The distribution ratio of the Hexyl salt, q_R, is written as:

$$q_R \equiv \frac{C_o^R}{C_a^R} = \frac{[MR]_o + [R^-]_o}{[MR]_a + [R^-]_a} \tag{6}$$

where C_o^R and C_a^R represent the total concentrations of the Hexyl salt in the organic and the aqueous phases respectively.

The combination of Eqs. (3), (4), (5) and (6) leads to Eq. (7):

$$\frac{Y}{q_R} = \frac{1}{D_{MR}} + \frac{1}{D_{MR} \cdot K_a^{MR} \cdot f_a^2 [M^+]_a} \tag{7}$$

where:

$$Y \equiv \{0.5 + (0.25 + C_o^R K_o^{MR} f_o^2)^{1/2}\}/C_o^R K_o^{MR} f_o^2 + 1$$

From Eq. (7), a plot of Y/q_R against $(f_a^2[M^+]_a)^{-1}$ should give a straight line and from the intercept and the slope D_{MR} and K_a^{MR} are obtained.

Results and Discussion

Association Constants of Hexyl Salts in Nitrobenzene. The association constants, K_o^{MR}, were calculated from Eq. (1). The starting value of Λ_∞ was determined by the extrapolation of a plot of Λ against $C^{1/2}$. The Λ_∞ was then inserted into Eq. (2), and S and f were calculated. From a plot of $1/\Lambda S$ *vs.* $C\Lambda S f^2$, Λ_∞ and K_S were obtained. The above-mentioned process was repeated (usually three or four times) until a plot of $1/\Lambda S$ against $C\Lambda S f^2$ showed linearity. In Figs. 1 and 2, the equivalent conductances are plotted against the square root of C. In these figures the Λ values at $C^{1/2}=0$ are the calculated Λ_∞ values. From the Λ-$C^{1/2}$ curves, it is obvious that in nitrobenzene, Hexyl salts except Hexyl-Li are very strong electrolytes and that in nitrobenzene almost saturated with water (0.14M) even Hexyl-Li behaves like a very strong electrolyte. Figures 3 and 4 show the

plots of $1/\Lambda S$ *vs.* $C\Lambda Sf^2$. The linearity of each plot is very good, and the constants, Λ_∞ and K_0^{MR}, were obtained algebraically by the method of least squares. $\Lambda_{\infty(H_2O)}$ and $K^{MR}_{0(H_2O)}$ refer to Λ_∞ and K_0^{MR} in nitrobenzene almost saturated with water (0.14M) and have been calculated on the assumption that nitrobenzene containing water has the same values of the dielectric constants and viscosity as those of pure nitrobenzene. The constants thus obtained, Λ_∞, $\Lambda_{\infty(H_2O)}$, K_0^{MR} and $K^{MR}_{0(H_2O)}$, are listed in Table 1. In Fig. 5 shows a plot of log K_0^{MR} against the ionic potential of alkali metal (the ratio of the charge to the radius[4] z/r).

In nitrobenzene, the ionic mobilities[5] of hydrogen, sodium, and potassium ions are 23, 17.2, and 19.2 ($cm^2\ sec^{-1}\ V^{-1}$) respectively; that is, the difference between the limiting conductances of Hexyl-Na and Hexyl-K in Table 1 is smaller than expected (~0.5). This result may be ascribed to the residual water in nitrobenzene (~10^{-3}M), because the water saturated in nitrobenzene shows a tendency to increase the limiting conductance and, furthermore, the effect of the water is striking in going from Cs^+ to Na^+, as is shown in Table 1.

It is clear that the larger the radius of the alkali metal ion, the smaller the association constant, K_0^{MR}. However, the association constants, $K^{MR}_{0(H_2O)}$, are

nearly the same. It seems that these facts are attributable to the solvation of the alkali metal ions with water. In nitrobenzene containing little water, the ion-pairs are formed between non-solvated metal ions and the Hexyl anion. The association constants, K_o^{MR}, have, therefore, a very close relation with the crystal ionic radius of the cation, as is shown in Fig. 5. However, in nitrobenzene containing much water, as the free cation is strongly solvated with water, the ion-pairs will be formed between hydrated metal cations and the Hexyl anion. Therefore, the formation of the ion-pairs will be more difficult than in nitrobenzene containing little water.

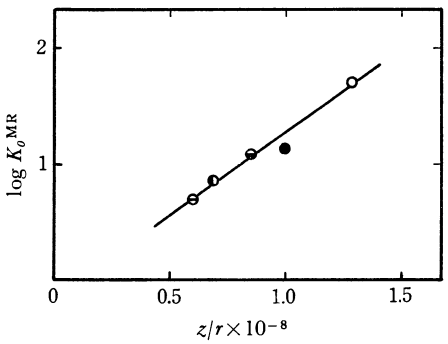

Fig. 5. The plot of $\log K_o^{MR}$ *vs.* z/r.
The symbols used are the same as those in Fig. 1.

These concepts are supported by the following two facts. One is that water is coextracted in nitrobenzene with Hexyl salts, the amount of the coextracted water, as determined by the Karl-Fisher method, decreases in the folowing order: Hexyl-Li (5.5 H_2O mol/Hexyl salts mol)>-Na (3.5)>-K (1.3)>-Rb (0.7), -Cs (0.7), showing that lithium and sodium are solvated very strongly with water. The other fact is that a plot of $\log K_o^{MR}$ *vs.* z/r shows a linearity; that is, the association affinities of Hexyl salts are found to be electrostatic and to be determined chiefly by the ionic radius of the alkali metal.

Kyrš[6] obtained the dissociation constants (K') of Hexyl salts by solvent extraction. His values ($1/K'$) are different from the values ($K^{MR}_{o(H_2O)}$) obtained by the present authors and are closer to the constants, K_o^{MR}, rather than to $K^{MR}_{o(H_2O)}$.

Distribution Ratio of Hexyl Salts. q_R was calculated from C_o^R and C_a^R which had been determined spectrophotometrically. In nitrobenzene, the calibration curves of Hexyl salts follow Beer's law under the conditions of $C_o^R=1—10\times10^{-5}$M at 470 mμ ($\varepsilon=19500$) and $C_o^R=1—10\times10^{-4}$M at 545 mμ ($\varepsilon=885$) and in water follow Beer's law under the conditions of $C_a^R=1—10\times10^{-6}$M at 430 mμ ($\varepsilon=$26200), $C_a^R=1—10\times10^{-5}$M at 505 mμ ($\varepsilon=8920$), and $C_a^R=1—10\times10^{-4}$M at 525 mμ ($\varepsilon=4580$).

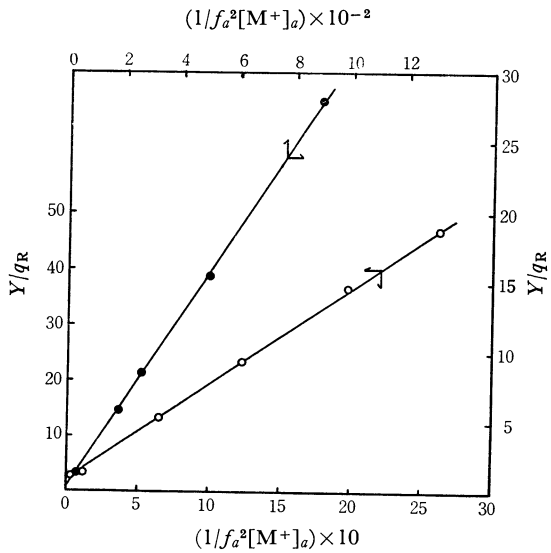

Fig. 6. The plot of Y/q_R *vs.* $1/f_a^2[M^+]_a$.
The symbols used are the same as those in Fig. 1.

In a nitrobenzene solution, the molar extinction coefficients of Hexyl-alkali metal salts are identical; this is also true in water. Besides, no difference between the molar extinction coefficients of the ion-pair and the Hexyl anion was noticed.

Association Constants of Hexyl Salts in an Aqueous Solution. The values of K_a^{MR} can be estimated from Eq. (7). The extractions were carried out by shaking the nitrobenzene solution of Hexyl salts with an aqueous solution containing a known amount of the same kind of alkali metal.

Figures 6 and 7 show the plot of Y/q_R against $1/f_a^2[M^+]_a$. All the straight lines were drawn by means of the method of least squares. In the case of Hexyl-Cs, the association constants could not be obtained, because the distribution ratio is very large, so q_R becomes very uncertain.

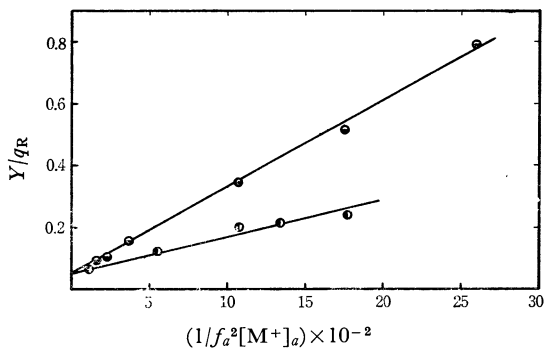

Fig. 7. The plot of Y/q_R *vs.* $1/f_a^2[M^+]_a$.
The symbols used are the same as those in Fig. 1.

6) M. Kyrš and S. Podešva, *Collection Czech. Chem. Commun.*, **27**, 289 (1962).

In Table 2, the constants thus obtained, K_a^{MR} and D_{MR}, are shown; the extraction constants, E_{MR} ($= [MR]_o/[M^+]_a[R^-]_a = D_{MR} \cdot K_a^{MR}$), are also shown in order to compare them with the results obtained by a different method.[6] Though the extraction constant of Hexyl-Cs could not be obtained accurately, $\log E_{CsR}$ was estimated to be more than 5. The values of the extraction constants in the present studies have the same tendency as the results obtained by a different method.

Figure 8 shows a plot of $\log K_a^{MR}$ against z/r_{hyd}, where r_{hyd} is the effective diameter[5] of the hydrated

Table 2. The constants of K_a^{MR}, D_{MR} and $\log E_{MR}$ for hexyl salts

MR	K_a^{MR}	D_{MR}	$\log E_{MR}$	
Hexyl-Li	8.9	0.5	0.76	
Hexyl-Na	9.4	3.4	1.51	2.4[6]
Hexyl-K	174	20.4	3.55	
Hexyl-Rb	365	22.2	3.91	
Hexyl-Cs			(>5)	5.4[6]

alkali metal ions in an aqueous solution. From this plot it is found that, in an aqueous solution, the association affinities depend chiefly upon the hydrated radius of the alkali metal ion, and that ion-pairs will be formed between the Hexyl anion and the hydrated alkali metal cation.

From the association constants of Hexyl alkali metal salts in an aqueous solution, it is found that the larger the constant, K_a^{MR}, the smaller the solubility of the Hexyl salts. When the extraction of the alkali metal is discussed, K_a^{MR}, D_{MR} and K_o^{MR}

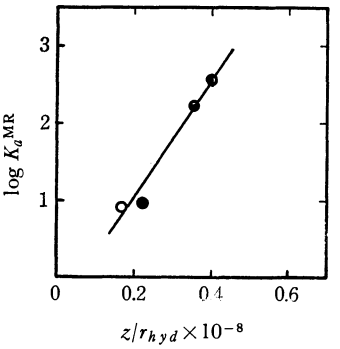

Fig. 8. The plot of $\log K_a^{MR}$ *vs.* z/r_{hyd}.
The symbols used are the same as those in Fig. 1.

are very important. The relation of the distribution ratio, q_M, to these values is shown by Eq. (8):

$$q_M = \frac{C_o^M}{C_a^M} = D_{MR}\left(1 + \frac{1}{K_o^{MR}[R^-]_o f_o^2}\right) \times \left(1 + \frac{1}{K_a^{MR}[R^-]_a f_a^2}\right)^{-1} \quad (8)$$

where C_o^M and C_a^M represent the total concentrations of alkali metal in the organic and aqueous phases respectively. From Eq. (8), it is clear that the extractability of the alkali metal increases with an increase in the values of K_a^{MR} and D_{MR} and with a decrease in the K_o^{MR} value.

The authors are very grateful to Dr. Syozo Sato (Mitsubishi Kasei Co., Ltd.) for his generous gifts of "Hexyl Natrium."

The Spectrophotometric Determination of Palladium with Chromazurol S*[1]

Ryoei ISHIDA

Department of Chemistry, Hakodate Branch, Hokkaido University of Education, Hachiman-cho, Hakodate, Hokkaido

(Received August 21, 1968)

A simple spectrophotometric method for the determination of palladium was studied, using chromazurol S as a reagent. Palladium(II), in a slightly acidic or a nearly neutral solution, reacts with chromazurol S to form blue or red complexes, each consisting of one molecule of the reagent and one atom of palladium. The maximum absorption wavelengths of blue and red complexes are respectively 596 mμ and 500 mμ, against the reagent blanks. The color development of the blue complex formed in a slightly acidic medium is more sensitive, therefore, it was applied to the spectrophotometric determination of palladium. Several conditions for the color development were investigated; a calibration curve was made under the optimum conditions; and the influences of coexisting ions were also investigated. The blue complex gives a maximum absorbance at 596 mμ in the pH range from 4.3 to 5.3. About a 2-fold excess of the reagent over the palladium concentration is necessary in order to obtain the maximum color intensity. The color development is almost instantaneous, and the absorbance remains constant for at least 4 hr. The order of the addition of reagents has no effect upon the absorbance. The color system obeys Beer's law over the concentration range up to 70 μg of palladium per 10 ml. The molar extinction coefficient at 596 mμ is 18600, which corresponds to a sensitivity index of 0.0058 μg/cm^2 for an absorbance of 0.001. Sulfate, chloride, fluoride, phosphate and acetate ions do not interfere with the color reaction. Thiosulfate ion and polycarboxylate ions such as oxalate, citrate and EDTA *etc.* bleach the color of the complex. Cations such as Sc(III), Y(III), Th(IV), U(VI), Be(II), Al(III) and Cu(II) ions cause an over-estimation of palladium; the interference by these cations except copper, however, could be eliminated by the addition of appropriate amounts of either sodium fluoride or sodium phosphate as masking agent.

Chromazurol S reacts with palladous ion in a weakly acidic or a nearly neutral medium to form blue or red complexes according to the pH value of the solution.

In the present paper are described conditions which permit the spectrophotometric determination of palladium at microgram levels.

Dey *et al.*[1,2] and Horiuchi *et al.*[3] have previously proposed methods for determining palladium, using the colored complex with chromazurol S. Their results differ, however, appreciably from the present results and their procedures for the determination are more complicated.

Several conditions for the color development and the composition of the colored complex were investigated. A calibration curve was made under the optimum condition. The influences of coexisting ions were investigated.

Experimental

Apparatus. Spectrophotometric measurements were made with a Shimadzu model QR-50 spectrophotometer, using 1 cm glass transmission cells. All absorbance measurements were carried out at about 20°C. The pH measurements of the solutions were made with a Hitachi-Horiba model M-4 glass electrode pH meter.

Reagents. *Stock Solution of Palladium.* A palladium stock solution was prepared by dissolving palladous chloride powder of analytical reagent grade in a small amount of 1 N perchloric acid, with heating, and then by diluting with distilled water. The resultant solution was standardized by EDTA titration. A standard working solution was prepared by taking an aliquot of the stock solution and diluting it to the desired concentration.

Chromazurol S Solution. About 1.0×10^{-3} M of a chromazurol S solution was prepared by dissolving Dotite Chromazurol S reagent (Dojindo & Co., Kumamoto) in distilled water and then by filtering off the floating residue.

Buffer Solution. Buffer solutions of various pH values were prepared by mixing 1.0 M hexamethylenetetramine and 1.0 N perchloric acid solutions in different ratios.

Other Reagents. All other reagents were of reagent grade.

*1 Presented at the Hokkaido Branch Meeting of the Chemical Society of Japan, Kitami, July, 1967. This paper is a part of the author's doctorate dissertation submitted to Hokkaido University, 1967.

1) S. P. Sangal and A. K. Dey, *Mikrochim. Ichnoanal. Acta*, **1963**, 993.

2) S. P. Sangal and A. K. Dey, *J. Indian Chem. Soc.*, **40**, 464 (1963).

3) Y. Horiuchi and H. Nishida, *Bunseki Kagaku (Japan Analyst)*, **16**, 1018 (1967).

Standard Procedure. Transfer a sample aliquot, containing 10 to 50 μg of palladium, to a 10 m*l* volumetric flask, and then add 0.3 m*l* of a pH 5.0 buffer solution and 1.0 to 1.5 m*l* of a 1.0×10^{-3} M solution of chromazurol S. The solution is diluted to the mark with distilled water, mixed, and allowed to stand for about 1 hr. The absorbance of the solution is measured at 596 mμ by using the reagent blank.

Results and Discussion

Absorption Spectra. The absorption spectrum of the palladium - chromazurol S complex is greatly affected in its shape by pH value of the medium. As described in the following section, however, a spectrum with an absorption maximum at 596 mμ in the pH range between 4.3 and 5.3 was obtained. Figure 1 shows the absorption spectra of chromazurol S and its palladium complex at a pH of 5.0. Chromazurol S is abbreviated as ChS in all figures.

In order to observe the spectral changes cause by varying pH values, a series of solutions containing 32 μg of palladium and 1.0 m*l* of a 1.0×10^{-3} M solution of chromazurol S were prepared at different pH values. The absorption spectrum of each solution was measured against the reagent blank. The results are shown in Fig. 2. In the pH range between 4.3 and 5.3, the maximum absorption wavelength is found at 596 mμ, and the absorption spectra indicate similar shapes. At pH below 4, each peak of the spectrum is shifted toward a longer wavelength; and at pH below 2, a part of the formed complex precipitates. In the pH range between 5.3 and 7.0, the intensity of the absorbance at 596 mμ decreases gradually, in accordance with the increasing pH value of the solution, while an absorption newly appears with a maximum at 500 mμ (curves 7, 6, 5 and 4 in Fig. 2); moreover, these spectra show an isosbestic point at about 545 mμ. It seems that two absorbing species which are in equilibrium with each other have absorption maxima at respectively 596 and 500 mμ. At pH 7.5 or higher, the disappearance of the absorption at 596 mμ is observed, only giving small shoulders. Any absorbance of the complex almost disappears at a pH value of about 8.5.

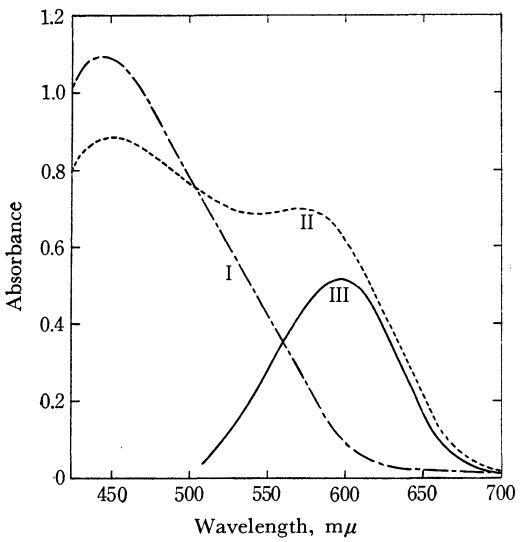

Fig. 1. Absorption spectra of chromazurol S and its palladium complex.
Pd: 3.0×10^{-5} M, ChS: 1.0×10^{-4} M, pH: 5.0

III: Pd-ChS *vs.* ChS

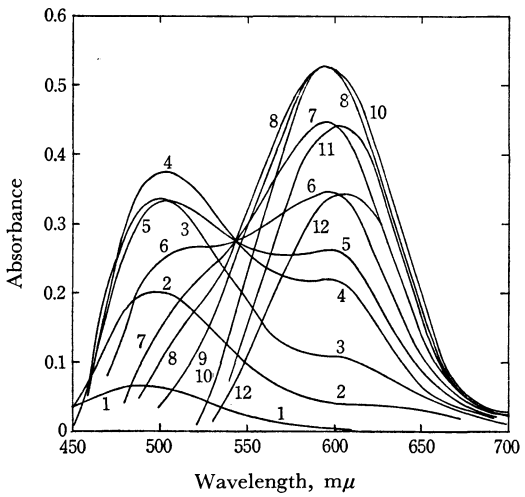

Fig. 2. Absorption spectra of Pd-ChS complex at various pH values.
Pd: 32 μg, ChS: 1.0×10^{-4} M
1: pH 8.2, 2: pH 7.8, 3: pH 7.5, 4: pH 7.1
5: pH 6.9, 6: pH 6.4, 7: pH 5.9, 8: pH 5.3
9: pH 5.0, 10: pH 4.3, 11: pH 3.7, 12: pH 2.7

In the practical spectrophotometric determination of palladium, the complex with absorption maximum at 596 mμ in the pH range between 4.3 and 5.3 was used.

Though the figure is not given, the absorption spectra of solutions containing 0.5 μmol of chromazurol S and palladium added in various amounts up to 5.0×10^{-5} M, show an isosbestic point at about 505 mμ against the water blank at pH 5.0. The occurrence of an isosbestic point indicates that there is only one kind of complex under these conditions.

Effect of pH Value and That of the Amount of the Buffer Solution. The effect of pH on the color development of the palladium complex was studied with solutions varying in pH value from 4 to 8. Figure 3 shows that the maximum and nearly constant absorbance is obtained over the pH range from 4.3 to 5.3.

At a constant pH, the absorbance of the colored solution was measured by varying the amount of the buffer solution. In consequence, the color intensity decreased gradually, by increasing amounts

Pd: 0.3 μmol (32 μg), pH: 5.0
Wavelength: 596 mμ

of the buffer solution. In this series of experiments, therefore, 0.3 ml of a 1.0 M buffer solution per 10 ml was always used.

Effect of the Addition of Chromazurol S. In order to study the effect of the concentration of chromazurol S, a series of absorbances was measured under various concentrations of chromazurol S, reagent blanks of same concentration being used as the reference. The results are shown in Fig. 4. The maximum absorbance is obtained by adding more than 0.6 ml of a 1.0×10^{-3} M chromazurol S solution for 0.3 μmol of palladium. Namely, more than a 2-fold excess of the reagent over the palladium concentration is necessary in order to obtain the maximum color intensity.

Effect of Temperature. The absorbance of colored solution was measured at various temperatures. The absorbance gradually decreases with the rise of temperature, and over 30°C the color intensity decreased remarkably. In this series of experiments, therefore, all absorbance measurements were carried out at about 20°C.

Effect of the Order of Adding Reagents. The varying orders in which the reagents were added had no significant effects on the absorbances.

Color Stability. As is shown in Fig. 5, the absorbance of the resultant solution decreased slowly for the first 30 min. After this period, however, it remained practically constant for at least 4 hr.

Calibration Curve. A calibration curve was made under the optimum conditions of those in the sections above-mentioned. The results are

4) A. Ringbom, *Z. Anal. Chem.*, **115**, 332 (1939).
5) E. B. Sandell, "Colorimetric Determination of Traces of Metals," 3rd Ed., Interscience Publishers Inc., New York (1959), p. 80.

shown in Fig. 6. A linear relationship exists between the absorbance and the palladium concentration over the range investigated. The optimum concentration range was then determined by Ringbom's procedure[4] and was found to lie between 10 and 50 μg palladium per 10 ml. Under the conditions of the spectrophotometric determination, the apparent molar extinction coefficient was found to be 18600. The sensitivity of the reaction as expressed by Sandell's notation[5] is 0.0058 μg of palladium per cm^2. This value is about 7-folds more sensitive than that of the data of Dey *et al.*[1]

For the spectrophotometric determination of palladium, several reagents have been used, such as *p*-nitrosodiphenylamine,[6] *p*-nitrosodimethylaniline,[7] mercaptoacetic acid,[8] potassium iodide,[9] ethylenediaminetetraacetic acid,[10] 2-nitroso-1-naphthol,[11] α-furildioxime,[12] xylenol orange,[13] 2-hydroxy-5-methylpropiophenone oxime,[14] and *p*-(mercaptoacetamido)benzenesulfonic acid.[15] The methods using the above reagents, however, in many cases, required the extraction of the complexes into an organic solvent.

The present reagent, chromazurol S, like xylenol orange,[13] has an advantages as a colorimetric reagent for palladium; that is, no extraction of the complex is required, since a palladium-chromazurol S complex is water soluble. This method is comparable in sensitivity with the 2-nitroso-1-naphthol[11] and α-furildioxime[12] methods.

Complex Formation. The combining ratio of palladium and chromazurol S in the complex was studied by the continuous variation method[16] and by the mole ratio method.[17] The results are shown in Figs. 7 and 8. Curves A and B in Figs. 7 and 8 show respectively the plots for the complex having a maximum at 596 mμ, which is formed in a weakly acidic medium, and those for the complex having a maximum at 500 mμ, which is formed in a nearly neutral medium. As is shown in these figures, it may be concluded that palladium forms either of two 1 : 1 complexes, one a red complex with its absorption maximum at 500 mμ and the other a blue complex with its absorption maximum at 596 mμ. From the results of these spectrophotometric studies and the appearance of an isosbestic point, which has already been shown in Fig. 2, it is assumed that the two complex ions are charged differently. It is impossible to obtain definite information on the structures of these palladium-chromazurol S complexes on the basis

of the experimental results described in the present paper.

Horiuchi *et al.*[3] have indicated that the optimum pH value range for color development is 5.8 to 6.7 and that complexes of 1 to 1 or 1 to 2 are formed, according to the concentration of the reagent used. It seems that the difference between their results and those obtained here may be attributed to the difference between the experimental conditions used.

Effect of Diverse Ions. In order to test the effect of diverse ions upon the palladium determination, absorbance measurements were made for the solutions containing 32.0 μg of palladium and various amounts of particular ion. The results are summarized in Table 1.

Sulfate, chloride, fluoride, phosphate and acetate ions do not interfere, even when present in considerably large amounts. Such anions as carbonate, cyanide and pyroborate ions do not interfere when their amounts are equivalent with palladium; however, these ions give negative errors at higher concentrations. Thiosulfate, oxalate, citrate and EDTA ions inhibit the color formation of the complex, even when added in very small amounts.

Of the 30 cations tested, Fe(II, III), In(III), Y(III), Th(IV), Cu(II), Be(II), Sc(III), U(VI), Al(III), W(VI), Hg(I, II), Sn(II), Nd(III), Ce(III) and Bi(III) interfere with the palladium determination. Among the above cations, Hg(I), Sn(II), Nd(III) and Fe(III) give negative error,

Table 2. Effect of masking agents on palladium determination

Palladium taken: 32.0 μg
Cation added: each 0.3 μmol

Cation	Palladium found, μg Masking agents added:		
	None	Na_3PO_4 3.0 μmol	NaF 6.0 μmol
In(III)	36.8	32.6	33.9
Y(III)	39.6	31.6	32.3
Th(IV)	47.5	31.3	32.3
Sc(III)	70.2	31.1	30.6
Be(II)	59.1	51.0	31.5
Al(III)	73.1	54.0	31.3
U(VI)	75.9	31.9	39.6
Cu(II)	47.1	42.7	45.5

and 0.6 μmol of Ce(III) and Bi(III) precipitate and interfere under these conditions. However, fluoride and phosphate ions, which probably form more stable complexes with many other metal ions to decompose the corresponding chromazurol S complexes, have almost no influence on the complex formation with palladium and chromazurol S unless large amounts are added. Sodium fluoride and sodium phosphate can, therefore, serve as excellent masking agents to prevent the interference of other metals. The results when used fluoride and phosphate ions as masking agent are shown in Table 2.

As is shown in Table 2, among the coexisting ions which introduce positive error with the determination of palladium, metal cations except copper can be effectively masked by either phosphate or fluoride. Accordingly, it is possible to improve selectivity of chromazurol S reagent for palladium.

The author wishes to express his thanks to Miss Kimiko Imai for her assistance in the measurements. Support by the Scientific Research Fund of the Ministry of Education is gratefully acknowledged.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1016—1020 (1969)

The Crystal Structure of $(-)_D$-Tris(trimethylenediamine)cobalt(III) Bromide Monohydrate*1

Teruo NOMURA,*2 Fumiyuki MARUMO and Yoshihiko SAITO

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received August 22, 1968)

The structure of $(-)_D$-$[Co(tn)_3]Br_3 \cdot H_2O$ (tn: $H_2N-CH_2-CH_2-CH_2-NH_2$) has been solved by the heavy atom method and refined to $R=0.11$ by least-squares analysis based on 1845 three-dimensional data. The substance crystallizes in the monoclinic space group $P2_1$ with unit cell dimensions: $a=16.274$, $b=9.863$, $c=9.489$ Å, $\beta=126.4°$ and $Z=2$. The complex ion in the structure has approximately a three-fold axis of rotation. The three six-membered Co-tn rings are nearly identical and take chair form. The chelate ring is rather flattened out, owing to the strong H-H repulsion. The absolute configuration of $(-)_D$-$[Co(tn)_3]^{3+}$ has been found to be the same as that of $(+)_D$-$[Co(en)_3]^{3+}$.

The absolute configuration of the complex ions, $(+)_D$-$[Co(en)_3]^{3+}$ and $(-)_D$-$[Co(l\text{-}pn)_3]^{3+}$ have been determined by means of X-rays.[1-3] They have five-membered chelate rings. No investigation has, however, been made on the absolute configurations of the complex ions with six-membered chelate rings. One of the simplest of those is tris(trimethylenediamine)cobalt(III) ion, $[Co(tn)_3]^{3+}$. The ORD and CD of $[Co(tn)_3]^{3+}$ have been measured by Woldbye.[4,5] The present investigation of the crystal structure of $(-)_D$-tris(trimethylenediamine)cobalt(III) bromide

monohydrate was undertaken with the purpose of contributing a better knowledge about the relation of the absolute configuration and optical properties of transition metal complexes.

Experimental

$(-)_D$-Tris(trimethylenediamine)cobalt(III) bromide monohydrate was kindly supplied by Professor Woldbye, Technical University of Denmark. Single crystals suitable for X-ray work were grown by slow evaporation of aqueous solution at room temperature. The specimens used for the collection of the intensity data were polished into cylinders of diameter 0.07 cm, the axes being parallel to the *b*- and *c*-axis, respectively. Using Cu$K\alpha$ radiation, equi-inclination Weissenberg photographs were taken of the zero to sixth levels for the crystal rotating about the *b*-axis and the zero to ninth level of the *c*-axis rotation. The intensities were measured visually using standard calibrated scales and were converted to structure amplitude values in the usual way. Correction was also made for absorption by assuming the crystal to be a perfect cylinder. It was soon found that the intensity data obtained with the *c*-axis rotation are not very accurate owing to the ill-formed shape of the specimen, so that they were eliminated from the final set of data used for the refinement. A total of 1845 independent pieces of intensity data were collected.

The crystal data are as follows: $[Co(H_2N\text{-}CH_2\text{-}CH_2\text{-}CH_2\text{-}NH_2)_3]Br_3 \cdot H_2O$, F.W.=538.6, Monoclinic, space group $P2_1$ (No. 4*[3]), a=16.275(10), b=7.863(15), c=9.489(5) Å, β=126.4(1)°, U=970 Å^3, (Cu$K\alpha$ radiation, λ=1.5418 Å), D_m=1.80 g·cm^{-3}, Z=2, D_x=1.79 g·cm^{-3}. Linear absorption coefficient for Cu$K\alpha$ radiation μ=154.0 cm^{-1}.

Determination of the Structure

A three-dimensional Patterson synthesis was calculated, in order to seek the heavy atom-heavy atom vectors. This normal Patterson synthesis was, however, found to be inadequate for this purpose since rather serious overlappings of peaks were observed. To reduce the overlappings a Patterson synthesis was calculated with only the reflections, of which $\sin\theta/\lambda \geq 0.45$. These reflections were supposed to consist mainly of the contributions of the heavy atoms. The peaks were sharpened to a good extent. The interpretation of the Patterson synthesis was not so straightforward because there exist as many as eight heavy atoms in the unit cell (6 Br and 2 Co). After several trials positions of the heavy atoms could be assigned. The coordinates of these atoms were refined by a block-diagonal least-squares method. The discrepancy factor, $R=\sum||F_o|-|F_c||/\sum|F_o|$, decreased to 0.27. A three-dimensional Fourier synthesis with phases determined by the heavy atoms allowed the six nitrogen atoms to be located around the cobalt atom. After further refinements a Fourier synthesis of electron density and a difference synthesis revealed the positions of the rest of all the lighter atoms except those of hydrogen atoms and also indicated that anisotropic temperature factors were required for all the atoms. After several cycles of least-squares refinement with anisotropic thermal parameters, the discrepancy factor was 0.11. The absolute configuration of the complex ion was automatically determined when dispersion corrections were taken into account during the course of the refinement. Part of observed and calculated relations between hkl and $h\bar{k}l$ are compared in Table 1. A final difference Fourier synthesis gave no significant indications of the positions of hydrogen atoms. Atomic scattering factors were taken from International Tables for X-ray Crystallography.[6] Dispersion corrections were also taken from the International Tables. The Fourier synthesis program used is ANSFR-1 written by Dr. H. Iwasaki, in which the anomalous scattering is taken into consideration. The least-squares program is HBLS-III written by Dr. T. Ashida. The weights were assumed as 1 for all

*4 A complete list of the observed and calculated structure factors has been submitted to and is kept as Document No. 6902 at the office of the Bulletin of the Chemical Society of Japan, 1—5 Kanda-Surugadai, Chiyoda-ku, Tokyo. A copy may be secured by citing the Doument number and by remitting, in advance, ¥ 1,600 for photo prints. Pay by check or money order, payable to: Chemical Society of Japan.

e.s.d.'s are listed in Table 4, and pertinent intermolecular contacts (*i. e.*, those less than 4.5 Å) are given in Table 5.

The complex cation, $[Co(tn)_3]^{3+}$, has approximately a three-fold symmetry. A projection of the complex ion along its approximate three-fold axis is shown in Fig. 3. The three chelate rings are nearly but not exactly identical and take chair forms, in contrast to a puckered form of the five-membered chelate rings formed by ethylenediamine. The six-membered ring seems to be more flexible than the five-membered ring. Its conformation may be easily affected by the specific intermolecular forces in the crystal. The chelate ring is rather flattened out due to non-bonded hydrogen interactions. Bond angles Co–N–C are larger than the normal tetrahedral angle, the mean value being 117.4°. This value does not differ significantly from those found in the six-membered ring in *trans*-dichloro(1,4,8,11-tetraazacyclotetradecane)nickel(II).[7] But the mean value of N–C–C and C–C–C angles is 112.8°, which is closer to the normal tetrahedral angle. The N–Co–N angle is larger than 90°, the mean value being 94.5°. The interatomic distances are normal as shown in Table 4. The displacement of the nitrogen atoms from the regular octahedral position is recognized in Fig. 3. The displacements are quite irregular. Distortions of the chelate rings described above and of octahedral coordination appear to make the complex less stable than that with five-membered chelate rings.[8] It is to be noted here that the chair conformation of the metal-trimethylenediamine ring is maintained in various complexes with multidentate chelating agents that contain these amines as their fragments.

A complex cation is surrounded by six bromide anions. Eight closest Br–N approaches occur at distances ranging from 3.24 Å to 3.44 Å. The

closest O–N contact occurs at a distance of 3.04 Å between O and N(2), whereas the van der Waals radii are 1.92 Å for Br, 1.50 Å for N and 1.40 Å for O. The molecule of water of crystallization has contact to Br(2) with a distance of 3.27 Å.

The absolute configuration of the complex ion, $(-)_D$-$[Co(tn)_3]^{3+}$, is represented in Fig. 3, which has the same absolute configuration as that of $(+)_D$-$[Co(en)_3]^{3+}$ and may be denoted by Λ.[9] The optical rotatory dispersion and circular dichroism spectra of the complex ion has been measured by Woldbye. Its absolute configuration is enantiomeric to that assigned on the basis of the sign of the prominent Cotton effect.[10,11] Woldbye has assigned correctly its absolute configuration by examining the behavior of CD spectra in the presence of phosphate ions.[12] The complex ions, $(-)_D$-$[Co(tn)_3]^{3+}$ and $(+)_D$-$[Co(en)_3]^{3+}$ have similar circular dichroism spectra and consequently the sign of the Cotton effect of a particular transition does not depend on the N–Co–N ring angle, as some workers suppose.[13]

A simple empirical rule relating the sign of the longer wavelength CD band and the absolute configuration of the chelate ring about the metal atom seems to hold in this case, too.[14]

The rotatory strength of $[Co(tn)_3]^{3+}$ was found to be smaller than that of $[Co(en)_3]^{3+}$ by a factor of ten. This ring size effect seems natural in view of Moffit's model[15] for the tris(bidentate) complexes, in which he ascribed the optical activity to the crowding of the carbon chains of the ligands in space, the crowding becoming greater the shorter the chain. The difference in rotatory strength may also be attributable to the difference in the conformation of the chelate ring. In the cobalt-ethylenediamine ring the two carbon atoms are arranged symmetrically above and below the plane formed by the central metal atom and the two nitrogen atoms, while in the cobalt-trimethylenediamine ring the three methylene groups are located on one side of the plane of the cobalt and the two nitrogen atoms and each chelate ring has approximately a mirror symmetry.

The authors wish to thank Professor Flemming Woldbye for providing the crystals of $(-)_D$-$[Co(tn)_3]Br_3 \cdot H_2O$. This research was partly aided by funds from the Scientific Research Fund of the Ministry of Education to which the authors' thanks are due.

Polarographic Behavior of Tris(2,2′-bipyridine)chromium(III) and Tris(ethylenediamine)chromium(III) in Acetonitrile Solutions

Yuichi SATO and Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received September 10, 1968)

Polarographic behavior of tris(2,2′-bipyridine)chromium(III) perchlorate and tris(ethylenediamine)chromium(III) perchlorate in acetonitrile solutions has been investigated by the measurement of d.c., a.c. and Kalousek polarograms. The bipyridine complex gives a six-step reduction wave when tetraethylammonium perchlorate is used as supporting electrolyte. The limiting currents of the first four steps are all diffusion-controlled, and each of them is of a one-electron reduction process. It has been proposed that at the fourth step univalent tris(2,2′-bipyridine)-chromate anions, $[Cr(bipy)_3]^-$, are formed at the electrode surface in acetonitrile. The limiting current of the one-electron reduction wave of tris(ethylenediamine)chromium(III) is increased upon the addition of 2,2′-bipyridine. It was explained as a reduction of an electroactive species, Cr(II)-bipyridine complex, which was formed by the reaction between Cr(II) produced by the reduction of tris(ethylenediamine)chromium(III) complex and 2,2′-bipyridine at the electrode surface.

As acetonitrile is an aprotic solvent and has less oxidizing power than water, the electrode process in acetonitrile is sometimes quite different in water. Tris(2,2′-bipyridine) complexes of manganese(II),[1] iron(II),[2] cobalt(II)[3] and nickel(II)[4] are reduced to the univalent anions at the dropping mercury electrode(DME). Such a low valent state is expected also in bipyridine complex of chromium.

In the present paper, the electrode processes of tris(2,2′-bipyridine)chromium(III) and tris-(ethylenediamine)chromium(III) are studied and the effect of 2,2′-bipyridine on the reduction wave of the latter complex is discussed. The support on the formation of tris(2,2′-bipyridine)chromate anion, $[Cr(bipy)_3]^-$, at the DME in acetonitrile solutions and an example of electrode process followed by chemical reaction involving electroactive species are presented.

Experimental

Tris(2,2′-bipyridine)chromium(III) perchlorate[5] and tris(ethylenediamine)chromium(III) perchlorate[6] were prepared and identified by elementary analysis. Other reagents were the same as described in a previous paper.[2]

The dropping mercury electrode used had an m value of 0.63_1 mg/sec and a drop time t_d of 4.83 sec when measured in an air-free acetonitrile solutions containing 0.05 M of tetraethylammonium perchlorate, $(C_2H_5)_4NClO_4$ at 25°C and at −0.5 V *vs.* SCE at 50 cm of the height of mercury reservoir. An aqueous saturated calomel electrode(SCE) served as reference electrode. The electrolysis cell and other apparatus are previously reported.[2]

Results

Tris(2,2′-bipyridine)chromium(III) complex gave a six-step reduction wave when tetraethylammonium perchlorate was used as supporting electrolyte. The limiting currents of the first four reduction steps were each found to be proportional to the square root of the mercury pressure between 45 cm and 60 cm on the DME and also to the concentration of the complex. Six reduction steps were also observed at 2.8°C and the ratio of the wave heights was nearly equal to the value at 25°C. The temperature coefficient of the limiting current at 25°C is about 0.8%/deg for each step. No anodic wave was observed at the potentials less positive than about +0.65 V, where the dissolution of mercury started. Upon the addition of free 2,2′-bipyridine to the solution containing 0.5 mM of the complex, the first four steps of the reduction wave were not affected in wave height and reduction potentials, but the wave heights of the fifth and the sixth step were increased. Free 2,2′-bipyridine gave a two-step reduction wave[2] at potentials corresponding nearly to the fifth and the sixth step of the polarogram of the complex. The results of log-plot analysis of the first three

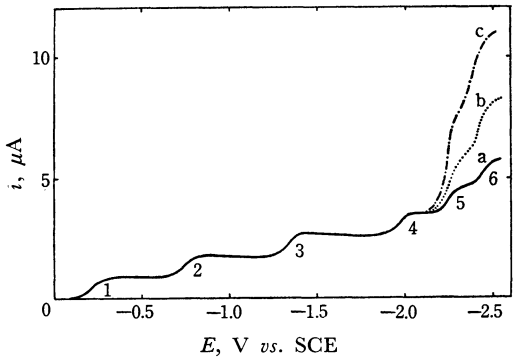

Fig. 2. D.c. polarograms of 0.5 mM $[Cr(bipy)_3](ClO_4)_3$ (a) in the absence and in the presence of (b) 0.028 M, (c) 0.139 M of water. Supporting electrolyte is 0.05 M $(C_2H_5)_4NClO_4$.

steps are given in Table 1. Upon the addition of a small concentration of water, the limiting currents of the fifth and the sixth step were increased, although no influence was found for the first four steps of the polarogram of the complex (see Fig. 2). The reduction wave of free 2,2'-bipyridine is also affected by the addition of a small concentration of water.[2] A. c. polarograms were recorded with solutions containing 0.5 mM of the complex. Six peaks were observed and their peak potentials were found to coincide with the half-wave potentials of the corresponding steps of the d. c. polarogram. The addition of 10 mM of free 2,2'-bipyridine increased the fifth and the sixth peak current, but gave almost no influence on the first four steps.

Table 1. Log-plot analysis for the first three steps of the reduction wave of the chromium(III)-bipyridine complex at 25°C

	$E_{1/2}$, V *vs.* SCE	Slope, mV
1st step	−0.221	61
2nd step	−1.741	58
3rd step	−1.327	51

Electrolytic solutions contain 0.5 mM $[Cr(bipy)_3](ClO_4)_3$, 10.0 mM 2,2'-bipyridine and 0.05 M $(C_2H_5)_4NClO_4$.

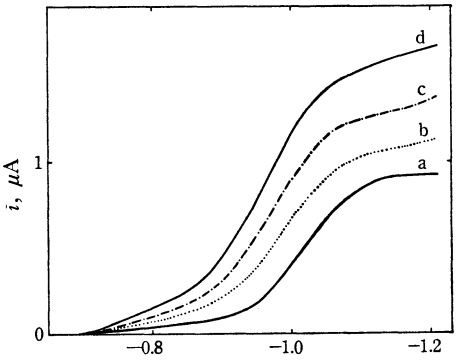

Fig. 3. The effect of 2,2'-bipyridine upon the reduction wave of 0.5 mM $[Cr(en)_3](ClO_4)_3$ containing 0.05 M $(C_2H_5)_4NClO_4$ as supporting electrolyte. 2,2'-bipyridine concentrations are (a) 0, (b) 0.5 mM, (c) 1.0 mM and (d) 3.0 mM.

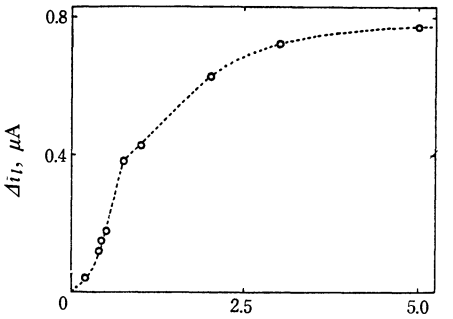

Fig. 4. Relation between the limiting current and the concentration of added 2,2'-bipyridine. Electrolytic solutions contain 0.5 mM $[Cr(en)_3](ClO_4)_3$, 0.05 M $(C_2H_5)_4NClO_4$ and 2,2'-bipyridine. Δi_l is the difference of the limiting current at −1.20 V in the presence and the absence of 2,2'-bipyridine.

The reversibilities of the first four steps were confirmed by the measurement of Kalousek polarograms, when the electrode potentials of the DME were set up at −0.5 V, −1.0 V, −1.6 V and −2.1 V, which are the potentials on the limiting currents of the first, the second, the third and the fourth

52.86	1.85	0.99	0.86	7.27	0.118
57.86	1.94	1.03	0.91	7.61	0.119

Electrolytic solutions contain 0.5 mM $[Cr(en)_3](ClO_4)_3$, 0.05 M $(C_2H_5)_4NClO_4$ and 2,2'-bipyridine. $\bar{i}_l°$ is the limiting current of the complex in the absence of 2,2'-bipyridine at −1.20 V. $\Delta\bar{i}_l=\bar{i}_l-\bar{i}_l°$

step, respectively. A four-step oxidation wave was obtained, when the electrode potential was set up at −2.1 V (Fig. 1).

Tris(ethylenediamine)chromium(III) perchlorate gave a two-step reduction wave at −1.018 V and −1.650 V when tetraethylammonium perchlorate was used as supporting electrolyte. The ratio in wave height was 1 : 2 and the limiting current of each step was diffusion-controlled. Diffusion current constant, $I_d(=\bar{i}_d/m^{2/3}t_d^{1/6}C)$, for the first step was 1.86, which showed one-electron[1-4] reduction from chromium(III) to chromium(II). Log-plot analysis for the first step was not linear. As 2,2'-bipyridine was added to the solution containing $[Cr(en)_3](ClO_4)_3$ and $(C_2H_5)_4NClO_4$, the limiting current of the first step was increased as shown in Fig. 3. Although the limiting current of the first step was increased with increasing concentration of bipyridine at constant concentration of the complex, $\Delta\bar{i}_l$ (the difference of the limiting current at −1.2 V in the presence and the absence of free bipyridine) was not proportional to the concentration of bipyridine, but approached to the definite value (Fig. 4). The total limiting current of the first step never exceeded twice of the limiting current of the complex. The limiting current ($\Delta\bar{i}_l$) was proportional to the square root of the mercury pressure in the presence of excess bipyridine, whereas it was independent of the mercury pressure when the concentration of bipyridine was smaller than that of the complex (See Table 2). The addition of free anhydrous ethylenediamine to the solution containing the complex and 2,2'-bipyridine depressed the limiting current to the original wave height of the complex only. Kalousek polarograms of 0.5 mM tris(ethylenediamine)chromium(III) which were obtained in the presence and the absence of 2,2'-bipyridine are given in Fig. 5.

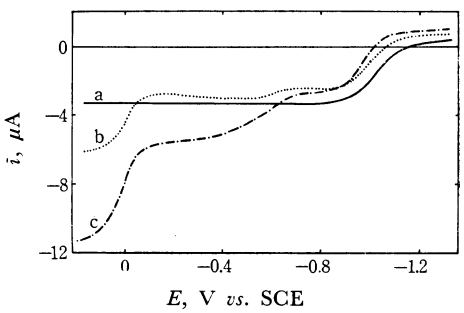

Fig. 5. Kalousek polarograms of 0.5 mM $[Cr(en)_3](ClO_4)_3$ (a) in the absence and in the presence of (b) 0.4 mM, (c) 5.0 mM 2,2'-bipyridine. Supporting electrolyte is 0.05 M $(C_2H_5)_4NClO_4$ and E_2 potentials are set up at −1.20 V.

When the electrode potential was set up at −1.2 V (the potential of the limiting current of the first step of the reduction wave), a one-step oxidation wave was observed in the absence of free bipyridine (curve a in Fig. 5), but two new steps appeared at about 0 V and −0.6 V in the presence of free bipyridine (curves b and c in Fig. 5). The limiting currents of two new oxidation waves were increased with increasing concentrations of bipyridine at the constant concentration of the complex.

Discussion

The limiting current of the first four steps of tris(2,2'-bipyridine)chromium(III) is concluded to be diffusion-controlled from the linear dependence of the wave height on the square root of the mercury pressure and on the complex concentrations and from the temperature coefficient of the limiting currents.[2] The diffusion current constant, $I_d(=\bar{i}_d/m^{2/3}t_d^{1/6}C)$, for the limiting current of the first step is 1.86, which is nearly equal to the value

for the one-electron reduction of various 2,2'-bipyridine complexes in acetonitrile.[1-4] The ratio of the wave heights of the first five steps is $1.00 : 1.1_0 : 1.1_0 : 1.0_7 : 1.8_7$. The fact that the wave heights of the first four steps of the complex are not influenced but those of the last two steps are by the addition of free 2,2'-bipyridine and a small concentration of water shows that the electrode processes of the first four steps and the latter two steps are different in nature. The log-plot analysis and Kalousek polarograms indicate that the electrode processes of the first four steps are reversible. From the same consideration as in the case with the reduction of the iron(II) complex[2] in addition to the fact that the reduction potential of free 2,2'-bipyridine is equal to the potential of the fifth and the sixth step of the reduction wave of the complex, the first four steps are concluded to be each due to the one-electron reduction of the chromium(III) complex itself and the latter two steps, the reduction of free bipyridine liberated from the complex. The first four steps are:

$$[Cr(bipy)_3]^{3+} \underset{-e}{\overset{e}{\rightleftarrows}} [Cr(bipy)_3]^{2+} \underset{-e}{\overset{e}{\rightleftarrows}} [Cr(bipy)_3]^{+} \underset{-e}{\overset{e}{\rightleftarrows}} [Cr(bipy)_3] \underset{-e}{\overset{e}{\rightleftarrows}} [Cr(bipy)_3]^{-} \quad (1)$$

A four-step oxidation wave obtained by Kalousek circuit (Fig. 1) clearly showed the formation of tris(2,2'-bipyridine)chromate anion, $[Cr(bipy)_3]^-$, at the electrode surface in the potential region of the fourth step of the reduction wave. Recently Herzog, Grimm and Waicenbauer[7] prepared $Li[Cr(bipy)_3]\cdot 4THF$ (THF: tetrahydrofuran). The preparations of $Na_2[Cr(bipy)_3]\cdot 7THF$, $Na_3[Cr(bipy)_3]\cdot 7THF$ and $Ca_3[Cr(bipy)_3]\cdot 7NH_3$ were also reported in their paper.[7] In acetonitrile solutions the wave height of the fifth step of the reduction wave is influenced by the addition of water and is larger than that of the first four steps, and the reduction potential of the fifth step coincides nearly to the reduction potential of free bipyridine. Therefore, the formation of stable bivalent or higher valent anions of tris(bipyridine)chromate at the electrode surface seems unlikely. In aqueous solutions some confusing results on the reduction of $[Cr(bipy)_3]^{3+}$ at the DME are obtained.[5,8,9] The result obtained in acetonitrile solution is similar to that obtained by Vlček, but in aqueous solutions only three reduction steps were observed and $[Cr(bipy)_3]$ is the lowest oxidation state.

The increase in wave height of the reduction of tris(ethylenediamine)chromium(III) to chromium(II) by the addition of 2,2'-bipyridine is explained as follows. The limiting current at -1.2 V is considered to be kinetic in nature in the presence of a small concentration of bipyridine from the result that the wave height ($\Delta\bar{i}_l$) is independent of the mercury pressure (Table 2). The fact that the reduction product of $[Cr(en)_3]^{3+}$ is substitution-labile suggests the occurrence of the following substitution reaction at the electrode surface (Eq. (3)).

$$[Cr(en)_3]^{3+} + e \rightarrow [Cr(en)_3]^{2+} \quad (2)$$

$$[Cr(en)_3]^{2+} + p\,bipy \rightleftarrows [Cr(en)_{3-p}(bipy)_p]^{2+} + p\,en \quad (3)$$

$$[Cr(en)_{3-p}(bipy)_p]^{2+} + e \rightarrow [Cr(en)_{3-p}(bipy)_p]^{+} \quad (4)$$

The increase in wave height is owing to the reduction of $[Cr(en)_{3-p}(bipy)_p]^{2+}$ (Eq. (4)), because the half-wave potentials of $[Cr(en)_{3-p}(bipy)_p]^{2+}$ is considered to be nearly equal to that of $[Cr(bipy)_3]^{2+}$ ($E_{1/2}=-0.741$ V as cited in Table 1) and is less negative than that of the first step of $[Cr(en)_3]^{3+}$ ($E_{1/2}=-1.018$ V). The appearance of the new oxidation steps on the Kalousek polarogram (curves b and c in Fig. 5) shows the oxidation of $[Cr(en)_{3-p}(bipy)_p]^{+}$ to higher oxidation states, which is the reduction product of $[Cr(en)_{3-p}(bipy)_p]^{2+}$ formed at -1.20 V. Half-wave potentials of two new steps of the oxidation wave are somewhat less negative than those of the corresponding steps in the case of $[Cr(bipy)_3]^{3+}$ as shown in Fig. 1,

$$[Cr(bipy)_3]^{+} \rightarrow [Cr(bipy)_3]^{2+} + e \quad (5)$$

$$[Cr(bipy)_3]^{2+} \rightarrow [Cr(bipy)_3]^{3+} + e \quad (6)$$

When the concentration of 2,2'-bipyridine added (C_{bipy}) was less than that of the complex, the plot of $\log\Delta\bar{i}_l$ *vs.* $\log C_{bipy}$ was linear and its slope was about 2. This seems to suggest that two bipyridine molecules are coordinated to the electroactive Cr(II) species (namely $p=2$ in Eq. (3)), though electroactive species is not $[Cr(en)(bipy)_2]^{2+}$ but $[Cr(bipy)_2(CH_3CN)_q]^{2+}$. In the case with the reduction of *trans*-$[Cr(NCS)_2(en)_2](SCN)$ in acetonitrile ($E_{1/2}$ is about -1.17 V), a similar phenomenon is also observed in the presence of 2,2'-bipyridine. The depression of wave height ($\Delta\bar{i}_l$) by the addition of free ethylenediamine shows that the rate of the backward reaction of reaction (3) is accelerated. If the above discussion is correct, this is another example of the electrode process followed by chemical reaction involving an electroactive species.[10-12]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1025—1029 (1969)

On the Viscosity of Liquid Selenium

Shuichi HAMADA, Naosato YOSHIDA and Toshiaki SHIRAI

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received September, 14, 1968)

The viscosities of liquid selenium and partially-chlorinated liquid selenium were measured in the temperature range from 235°C to 305°C using an Ubbelohde-type tilting viscometer. The "intrinsic" viscosities, η_0, were estimated by extrapolating the values of the viscosities, η_θ, of various rates of shear to a zero rate of shear. The "intrinsic" viscosities of the liquid selenium were estimated to be 20.18, 13.46, 9.11, 6.32, 3.67 and 2.30 poise at 235, 245, 255, 265, 285, and 305°C respectively. The viscosities of the chlorinated liquid selenium decreased with an increase in the chlorine content, but they varied discontinuously at a chlorine content of 0.0125% and then decreased linearly. The apparent activation energy for the viscous flow of the liquid selenium was estimated to be 17.9 kcal/mol. The apparent activation energies for the viscous flow of the chlorinated selenium varied discontinuously at a chlorine content of about 0.0125%, as in the case of the viscosity. The average-chain length of the selenium molecules was considered not to be changed, but the radicals at both ends of the linear chain vanish in forming the bonds with chlorine atoms with an increase in the chlorination below a chlorine content of 0.0125%. Therefore, it is concluded that the presence of radicals at the molecular ends would have an influence upon the viscosity and the apparent activation energy for the viscous flow of selenium. The notable large value of the apparent activation energy of such a non-branched polymer as selenium was attributed to the large amount of energy needed to transport the segments into the holes.

Liquid selenium is considered to be a mixture of Se_8 ring molecules and long chains.[1] The properties of the liquid selenium should be governed by those of the long-chain molecules, since the liquid selenium contains few ring molecules. The number of selenium atoms in a chain of average length was calculated to be 7200 at 230°C by the thermodynamic theory developed by Eisenberg and Tobolsky.[1] The linear chains are considered to be diradical molecules with an unpaired electron at each end of the chain. The presence of radicals in the amorphous selenium was confirmed by Abdullaev *et al.*[2] and Sampath *et al.*[3] on the basis of their ESR studies. Sampath[4] reported that the results obtained by Eisenberg and Tobolsky were supported by the value of the spin concentration in the amorphous selenium. In this study, the effect of radicals on the viscous flow of the liquid selenium was studied.

Experimental

Materials. The selenium and the partially-chlorinated selenium samples were prepared in the manner described in a previous paper.[5]

Procedure. An Ubbelohde-type tilting viscometer[6] was used for the measurements of the viscosities of the liquid samples. The viscosity, η_θ, at the tilting angle, θ, of the viscometer was calculated by the following equation:

$$\eta_\theta = A_\theta \rho t$$

where A_θ, ρ, and t are the parameter of the viscometer, the density of the liquid sample, and the efflux time respectively. The tilting angle, θ, is the angle of the capillary of the viscometer to the vertical line. The parameter, A_θ, of the viscometer was estimated by means of the measurement of the efflux time of glycerol of a known viscosity at 25°C and at various tilting angles, θ. The viscosities, η_θ, of the liquid samples were measured at several tilting angles. The "intrinsic" viscosity, η_0, was estimated graphically by extrapolating the values of the viscosities, η_θ, to a ninety-degree tilting angle, *i.e.*, to a zero rate of shear. The viscosities and the densities of the liquid samples were measured at specified temperatures within an accuracy of ±0.1°C in an electric furnace.

The densimeter is shown in Fig. 1. The volume between the fixed lines, and the diameters of both the capillaries were measured using mercury at 30°C. The height of the liquid selenium column in the capillary was measured with a measuring microscope to an accuracy of 1/100 mm. The linear expansion coefficient of the densimeter is 7.95×10^{-7}°C^{-1} over the temperature

range from 20°C to 50°C, and those of the liquid selenium and of the chlorinated liquid selenium are calculated to be from 1.06×10^{-4} to $1.22\times10^{-4}°C^{-1}$ over the temperature range from 230°C to 305°C. Therefore, the expansion of the densimeter is negligible compared with those of the liquid samples.

Results

The Stability of the Chlorinated Liquid Selenium. Figure 2 shows the relationship between the chlorine content of the chlorinated selenium and the heating time at 265°C. The chlorine content decreased linearly with an increase in the heating time until about 3 hr, but the chlorinated selenium was stabilized after 3 hr. Because the escape of chlorine from the chlorinated selenium is considered to be negligible after 3 hrs' heating at 265°C, the viscosities and the densities were measured after 4 hrs' heating at 265°C.

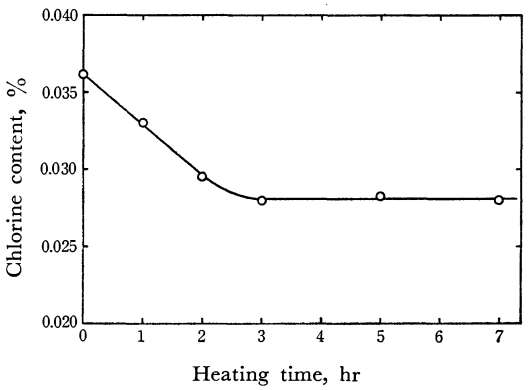

Fig. 2. Variation of chlorine content by heating at 265°C in chlorinated selenium.

The Densities of the Liquid Selenium and of the Chlorinated Liquid Selenium. The density of the liquid selenium was estimated to be 3.9850 g/cm³ at 235°C, and the linear expansion coefficient was calculated to be $1.09\times10^{-4}°C^{-1}$ in the temperature range from 230°C to 305°C, from the temperature dependence of the density. The densities of the chlorinated selenium were estimated to be from 3.9835 to 3.9770 g/cm³ at 235°C in the chlorine-content range from 0.0033 to 0.0257%, and their linear expansion coefficients were calculated to be from 1.08×10^{-4} to $1.19\times10^{-4}°C^{-1}$ in the temperature range from 230°C to 305°C.

The Viscosities of the Liquid Selenium and of the Chlorinated Liquid Selenium. The viscosities, η_θ, of the liquid samples at several tilting angles were measured at temperatures from 230°C to 305°C. Figure 3 shows the dependence of the viscosities, η_θ, of the liquid selenium on the tilting angle, θ, of the viscometer. The viscosity of the liquid selenium decreased with a decrease in the tilting angle of the viscometer, *i. e.*, with an increase in the rate of shear. The viscosities of the chlorinated liquid selenium showed the same appearance as that of the liquid selenium. Both

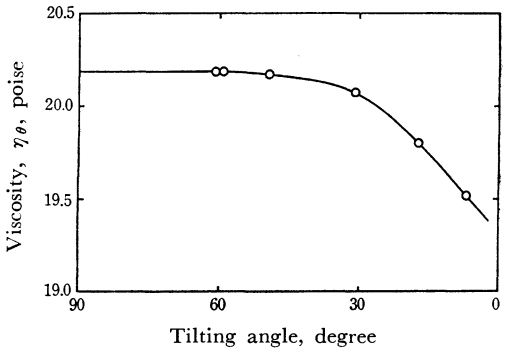

Fig. 3. Dependence of viscosity of liquid selenium on tilting angle.

the liquid selenium and the chlorinated liquid selenium are considered to behave as non-Newtonian liquids. Therefore, the "intrinsic" viscosities, η_0, of the liquid samples were estimated by extrapolating the viscosity values, η_θ, to a zero rate of shear in order to discuss the behavior of their viscous flow.

The "intrinsic" viscosities, η_0, of the liquid samples are given in Table 1.

The dependence of the logarithm of the viscosity, $\log \eta_0$, on the chlorine content at 235°C is shown in Fig. 4. The $\log \eta_0$ values decreased continuously to a chlorine content of 0.0125%, and then more rapidly and linearly with an increase in the chlorine content.

The chlorine content of 0.0125% corresponds to the state when all the radicals at both ends of the linear-chain molecules of selenium vanish in forming bonds with chlorine atoms.[5] The radicals vanish more and more with an increase in the chlorination until 0.0125%, and the average chain length of the chlorinated selenium molecules

Table 1. Viscosities of liquid selenium and of chlorinated liquid selenium

Chlorine Content, %	Viscosities, η_0, poise					
	235°C	245°C	255°C	265°C	285°C	305°C
0	20.18	13.46	9.11	6.32	3.67	2.30
0.0033	17.22	12.40	8.93	6.61	3.76	2.35
0.0053	16.31	11.76	8.48	6.40	3.68	2.20
0.0092	15.95	11.43	8.45	6.25	3.64	2.26
0.0113	15.41	11.11	8.18	6.04	3.54	2.13
0.0126	15.31	10.94	8.06	5.97	3.52	2.10
0.0134	14.83	10.51	7.73	5.82	3.45	2.12
0.0146	14.61	10.19	7.66	5.88	3.39	2.07

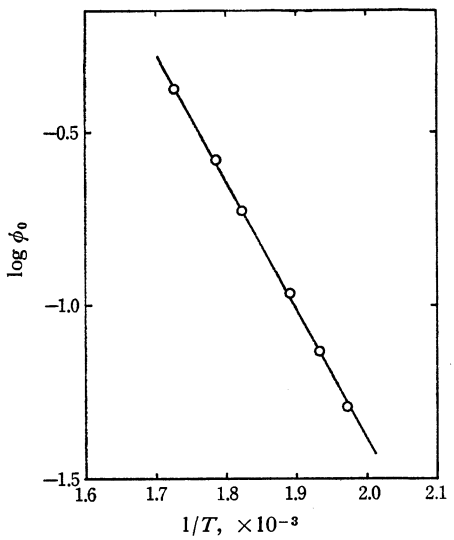

Fig. 5. Temperature dependence of fluidity of liquid selenium.

will not be changed. Therefore, the discontinuous variation in the viscosity at the chlorine content of 0.0125% suggests the influence of the fulfilment of the radicals of the chain ends.

The decreases in the viscosity of the chlorinated selenium above 0.0125% are considered to be due to a cut-off of the chain molecules by chlorine.

The Apparent Activation Energies for the Viscous Flow of the Liquid Selenium and of the Chlorinated Liquid Selenium. Figure 5 shows the relationship between the fluidity, ϕ_0, *i. e.*, $1/\eta_0$, of the liquid selenium and the temperature, T. The log ϕ_0 varied linearly with $1/T$. The temperature dependences of the log ϕ_0 of the chlorinated selenium were similar to that of the liquid selenium. Since the dependences of the log ϕ_0 on the temperature showed an Arrhenius-type variation, the apparent activation energies for the viscous flow, E_{vis}, were estimated from the following equation:

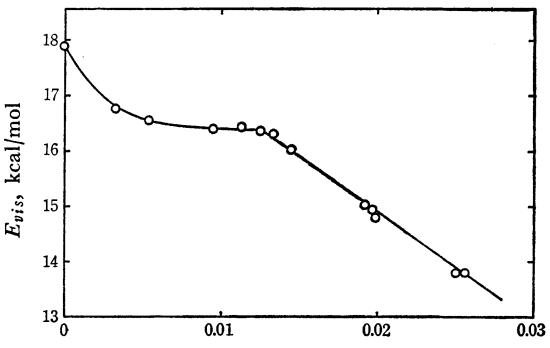

Fig. 6. Dependence of E_{vis} on chlorine content.

$$E_{vis} = -R\mathrm{d}(\ln \phi_0)/\mathrm{d}T$$

The apparent activation energy for the viscous flow of the liquid selenium was estimated to be 17.9 kcal/mol. The dependence of the E_{vis} of

the chlorinated selenium on the chlorine content is shown in Fig. 6. The E_{vis} decreased abruptly with an increase in the chlorine content. The E_{vis} varied discontinuously near the chlorine content of 0.0125%, and then decreased linearly above 0.0125%.

Discussion

The liquid organic-chain polymers, in general, show comparatively small values of E_{vis}, though they increase with an increase in the bulk of the side chains. The E_{vis} values for some organic chain polymers are shown in Table 2.[7] The value of E_{vis} is considerably larger for selenium, though it has no branched chain.

TABLE 2. E_{vis} FOR SOME ORGANIC CHAIN POLYMERS AT A ZERO RATE OF SHEAR

	Ethylene	Propylene	Isobutylene	Styrene
E_{vis} kcal/mol	6.5—7.0	9.0—9.6	12.0—16.2	22.6

The apparent activation energy for the viscous flow consists of two parts. One of them is the energy necessary to produce holes. The other is the energy, ΔE_f which is necessary to drive the segments into the holes. If ϕ_1 and ϕ_2 are the fluidities at a constant volume, that is, the iso-state of a free volume, at temperatures of T_1 and T_2 respectively, ΔE_f can be expressed by the following equation:[8]

$$-\Delta E_f(1/T_1-1/T_2) = \boldsymbol{R}\ln(\phi_1/\phi_2) + \ln(T_1/T_2)/2$$

The relationship between the specific volume of the liquid selenium and the temperature at the specified pressures can be calculated using the values of the thermal expansion coefficient of liquid selenium, $\alpha=3.27\times10^{-4}$, and of the compressibility of liquid selenium,[9] $\beta=1.53\times10^{-5}$ bar^{-1}. From this relationship, certain conditions, *i. e.*, the temperature and the pressure, under which the compressed liquid selenium possesses an iso-volume state can be estimated graphically. Harrison[9] reported the viscosity of liquid selenium over the temperature range from 260°C to 350°C under a compressed system in the range from 1 bar to 1500 bar. The viscosities of the compressed liquid selenium in an iso-volume state at the corresponding temperatures and pressures can be deduced from Harrison's results.

Table 3 shows the viscosities in the case of the iso-volume state of 0.2533 cm^3/g, as an example. The ΔE_f value was calculated to be 11.5 kcal/mol from the data in Table 3. The ΔE_f value for ordinary liquids is, in general, assessed to be within the range from one-tenth to one-fifth of the total apparent activation energy for the viscous flow. A larger amount of energy, however, is necessary to drive the segments into the holes for the viscous flow of the liquid selenium than those of ordinary liquids; this must cause the larger E_{vis} value for the liquid selenium. Moreover, the apparent activation energy for the viscous flow of the liquid selenium shows the character of a "structure activation energy," as in the case of water.

TABLE 3. VISCOSITIES AT ISO-VOLUME STATE $v=0.2533$ cm^3/g

Press., bar	1	500	1000	1500
Temp., °K	533	556	581	605
η, poise	5.69	3.74	2.39	1.61

Bondi[10] expressed the viscosity of the liquid in connection with the v_f and the ΔE_f as follows:

$$\eta = (v_f^{1/3}/v_L)(2\pi m\boldsymbol{k}T)^{1/2}\exp(\Delta E_f/\boldsymbol{R}T)$$

where v_f is the free volume; v_L, the molecular volume in the liquid; m, the mass per molecule, and $\boldsymbol{k}$, the Boltzmann constant. The fraction of v_f at T_g, f_g, defined by Williams, Landel and Ferry,[11] is well known to be 2.5×10^{-2} in usual organic and inorganic polymers. The abnormality of the f_g of the amorphous selenium has been shown by the volume relaxation phenomenon.[5] The f_g value of the amorphous selenium is 6.33×10^{-2}; it is larger than those of the usual polymers, but it decreases with an increase in the chlorination, reaching the normal value, 2.5×10^{-2}, at a chlorine content of more than 0.0125%. Therefore, the free volume of the liquid selenium would be larger than that of the chlorinated liquid selenium. However, the contribution of the free volume term, $(v_f^{1/3}/v_L)$, on the viscosity is not very large. The ΔE_f of the chlorinated selenium could not be established, for the dependence of the viscosity of the chlorinated selenium on the pressure was obscure. However, a decrease in ΔE_f upon the chlorination was suggested by the dependence of the E_{vis}, of the chlorinated selenium on the chlorine content below 0.0125%, as is shown in Fig. 6 (assuming that the chain length of selenium molecules does not change at chlorine contents below 0.0125%). The abrupt decrease in the viscosity of the chlorinated liquid selenium at chlorine contents below 0.0125% is due to the decrease in ΔE_f, in spite of the decrease in the f_g upon chlorination.

The decreases in the viscosity and E_{vis} value of the chlorinated selenium at chlorine contents above 0.0125% are probably due to the shortening of the chain molecules with an increase in the chlorination.

Bipolar Ion-Exchange Membranes Prepared from Blends of Graft Copolymers

Hiroshi KAWABE and Masaya YANAGITA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received April 12, 1968)

Bipolar ion-exchange membranes were prepared from graft copolymers of polyethylene (PE). Powders of styrene-grafted PE (I) and 4-vinylpyridine-grafted PE (II), or powders of ethyl acrylate-grafted PE (III) and II were blended in various proportions and melt-pressed to films. Ion-exchange groups were then introduced by the sulfonation (100%), alkaline hydrolysis (100%), or *N*-methylation (80—90%) of the blend polymer films. Although, in the titration curves of bipolar membranes, pH regions which apparently resemble the isoelectric point of polyampholytes appeared, no behavior based on the interaction between acidic and basic groups was indicated in the survey of their physico-chemical properties. The dependency of the concentration potential of the membranes (E_m), containing one kind of ionized group, on the mole fraction of the group (F_i) is not remarkable. On the other hand, the E_m of the membranes containing both positively- and negatively-charged groups is strongly dependent on F_i, because of the additive contribution of the oppositely-charged groups to the potential. The bi-ionic potential of the membrane, E_{K-Li}, was found to be a function of $E_m/|E_0|$ ($|E_0|$ is the absolute value of the concentration potential for ideal permselective membranes) in the cases of both I-II and II-III.

The behavior of polyampholites, which characterize many natural substances of biological importance, has long been an object of interest. Recently, some amphoteric ion-exchange membranes have been reported,[1-4] and interaction between acidic and basic groups in the membranes was observed in such phenomena as the membrane potential and the electric conductance.[3]

The gamma-ray-induced vapor-phase grafting of the ionogenic monomer onto polyethylene (PE) affords a convenient way for preparing homogeneous ion-exchange membranes.[4] In the present study, the preparation of bipolar membranes by blending monofunctional graft copolymers, and their physico-chemical properties as a function of the membrane composition, were investigated.

Experimental

Materials. Commercial high-pressure PE powder of 200 mesh (mol wt of 23000) was used. The monomers used were styrene (St), 4-vinylpyridine (VP), and ethyl acrylate (EA), all of commercial grade. Deionized water was used throughout.

TABLE 1. GRAFT COPOLYMERS USED FOR THE PREPARATION OF BLEND FILMS

Code	Monomer	Dose 10^5 R	g %	C_g mmol/g	PMT °C
Ia(A)	ST	1.3	45.6	3.01	195
IIa(G)	VP	14.5	103	4.83	180
IIIa(H)	EA	2.2	58.5	3.69	185
IIb(N)	VP	3.1	43.5	2.89	181
IIIb	EA	2.2	65.0	3.94	185
IIc	VP	2.6	33.6	2.40	181

Preparation of Membranes. The procedures used in the preparation of membranes are shown in Scheme 1. The grafting onto PE powder was carried out by the irradiation of gamma rays in monomer vapor, as has been described in previous papers.[5,6]

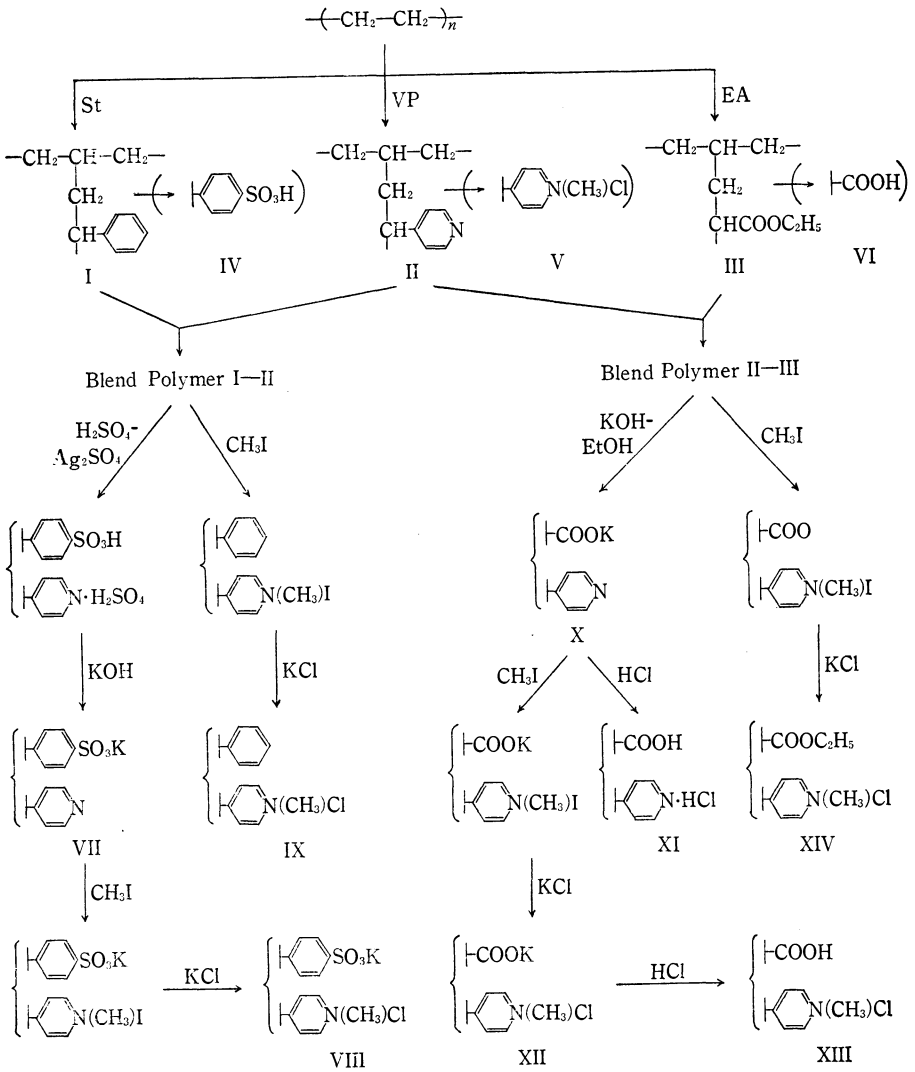

Scheme 1. Preparation of Membranes.

TABLE 2. COMPOSITION OF BLEND POLYMER FILMS[a)]

Code		A	B	C	D	E	F	G
I-II	Ia	3.01	2.54	2.20	1.74	1.22	0.77	0
	IIa	0	0.75	1.29	2.05	2.86	3.59	4.83
Code		H	I	J	K	L	M	N
II-III	IIIa	3.60		2.23	1.61	1.04		0
	IIb	0		1.11	1.61	2.06		2.89
	IIIb		2.79				0.52	
	IIc		0.77				2.08	

a) The composition is expressed in the term of C_g (mmol/g) of both functional groups in the blends.

Three kinds of graft copolymers have been prepared: St-grafted PE (I), VP-grafted PE (II), and EA-grafted PE (III). The degree of grafting (g) (defined by the increase in the weight as $100\times[(W-W_0)/W_0]$), the content of the functional group in the graft copolymer (C_g in mmol/g), and the polymer-melt temperature (PMT) are shown in Table 1. Two kinds of copolymers, I and II or II and III, were well mixed in various ratios, and the blend powders were melt-pressed to film 0.15 mm thick under a pressure of 200 kg/cm^2 at 180°C for ten minutes. The compositions of the copolymers in the blend films are shown in Table 2.

Various kinds of membranes were prepared by the chemical treatments of the blend-polymer films shown in Scheme 1. The sulfonation of the phenyl group, the quaternization of the pyridine group, and the saponification of the ester group in the blend polymers were carried out according to previously-described procedures.[5,6]

Determination of Ion-exchange Capacity. Each group in the bipolar membranes was determined by a combination of the precipitation titration of the halogen ion with acid-base titration, as will be described below.

a) A membrane containing both a carboxylic acid group (a meq) and a pyridine group (b meq) was treated with a potassium hydroxide solution, washed thoroughly with water, and left immersed in 0.1 N HCl (x ml). After the membrane had then been removed, the solution was titrated with 0.1 N NaOH (y ml), and then with 0.1 N $AgNO_3$ (z ml) in the presence of nitric acid. The contents of the groups in membrane are:

$$a = 0.1 \times (z-y);\ b = 0.1 \times (x-y)$$

b) A membrane containing both a sulfonic acid group (a meq) and a pyridine group (b meq) was treated with a hydrochloric acid solution, washed with water, and left immersed in 0.1 N NaOH (x ml). The solution was titrated with 0.1 N HCl (y ml at the equivalent point, and with y' ml added), and then with 0.1 N $AgNO_3$ (z ml).

$$a = 0.1 \times [(x-y) - (z-y')];\ b = 0.1 \times (z-y')$$

c) A membrane containing both a carboxylic or sulfonic acid group (a meq) and a quaternary pyridinium group (b meq) was treated with a hydrochloric acid solution, washed with water, and left immersed in 0.1 N NaOH containing sodium nitrate in a 1 N concentration (x ml). The solution was titrated with 0.1 N HCl (y ml at the equivalent point, and with y' ml added), and then with 0.1 N $AgNO_3$ (z ml).

$$a = 0.1 \times (x-y);\ b = 0.1 \times (z-y')$$

The ion-exchange capacity was calculated for acidic and quaternary pyridinium groups on the basis of the dry weight of the membrane in the salt-form (C_d^K or C_d^{Cl} in meq/g), and also for both the groups on the basis of the wet weight (C_w in meq/g).

Titration Curves of Membranes. The titration curves of monopolar membranes in the presence of sodium chloride were determined in the usual ways reported previously.[7,8] In the case of bipolar membranes, each sample was titrated with a 1 N HCl solution, washed thoroughly, and left immersed in 40 ml of the solution, containing various amounts of sodium hydroxide or hydrogen chloride but no salt, for seven days. The pH of the solution was then measured, and the portions were titrated with 0.1 N HCl or 0.1 N NaOH and with 0.1 N $AgNO_3$. The initial content of chloride ions in the membrane sample was determined separately. The amounts of both sodium and chloride ions in membrane and in solution at each equilibrium were calculated in a way similar to that described in the previous section.

Other Properties of Membranes. The thickness, water content (w in wt%), molality of the ionized group ($\bar{m}$), concentration potential (E_m in mV), and electric conductivity ($\bar{k}$ in $\Omega^{-1}cm^{-1}$) of membranes were measured in the ways described in a previous paper.[6] The bi-ionic potential was measured, in a way similar to the E_m measurement, by using the cell: |0.1 N KCl| membrane|0.1 N LiCl|. The density of the wet membrane (d) was determined by the use of a pycnmeter.

Results and Discussion

Preparation of the Membranes. The blend polymer films, I-II (B–F), containing both phenyl and pyridine groups, were quantitatively sulfonated in a concentrated sulfuric acid containing 1% silver sulfate. The sulfonation of the sample, D, was followed by the capacity measurement and found to be almost completed within an hour at 50°C. The monofunctional film I (A), containing a phenyl group, was sulfonated under the same conditions and found to reach a constant capacity value in five hours. The higher reaction rate of the sulfonation of I-II than of I may be attributed to the swelling effect of ionized pyridine groups in sulfuric acid. The film II (G), containing only pyridine groups, was not sulfonated under the above conditions. The II-III (I-M) films, containing both ester and pyridine groups, were treated with a 1 N KOH - 80% ethanol solution at 75°C for three hours and found to be hydrolysed almost quantitatively. After sulfonation or saponification, the films were treated with methyl iodide - acetone (1 : 1 volume ratio) at 30°C for 5—24 hr; the degree of the quaternization of pyridine groups were found to be 80—90%.

Titration Curves of the Membranes. The titration curves of monopolar membranes were

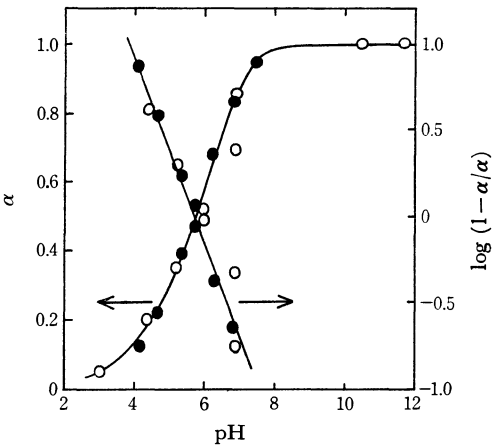

Fig. 1. Titration curves of membrane VI (○) and saponified EA-DVB resin (●) in the presence of 0.1 N NaCl.

7) H. Kawabe, S. Sugimoto and M. Yanagita, *Reports Sci. Res. Inst.* (in Japanese), **30**, 257 (1954).

8) H. Kawabe and M. Yanagita, *J. Sci. Res. Inst.*, **50**, 199 (1959).

first examined. The titration curve of IV (A), containing only sulfonic acid groups, in the presence of 0.1 N NaCl was shown to be typical for strong acid at pH's lower than 7, where the ion-exchange capacity of a dry membrane in the H-form was 2.10 meq/g. The elementary analysis of the membrane showed 7.03% S, which agrees with the value calculated from the capacity at pH 7.

The titration curve of VI (H), containing only carboxylic acid groups, in the presence of 0.1 N NaCl, and that of the saponified EA-divinylbenzene (DVB) copolymer[9,10] containing 5% DVB, are shown in Fig. 1, where α is the degree of ionization. The plots for both the exchangers are, coincidentally, on the same curve. In the figure, the Henderson-Hasselbach-Kathchalsky relation,[11] $pH=pK_a-n'\log[(1-\alpha)/\alpha]$, is also shown, where pK_a and n' are 5.8 and 1.9 respectively. Gregor and Frederic[12] reported that the values of pK_a and n' for the titration of polyacrylic acid with sodium hydroxide were 5.29 and 1.95 in the presence of 0.1 N NaCl, and 6.79 and 2.13 in the absence of any added salt.

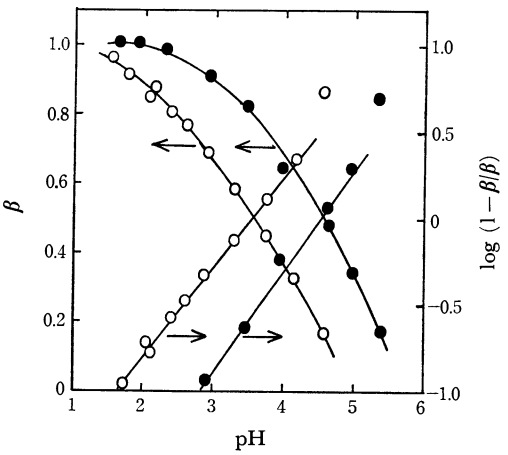

Fig. 2. Titration curves of VP grafted PE film (II) in the presence of 0.1 N NaCl (○) and 1 N NaCl (●).

The titration curves of II, containing only pyridine groups, are shown in Fig. 2, where β is the degree of ionization. From the plots for the $pH=pK_a+n'\log[(1-\beta)/\beta]$ relation, also shown in the figure, the values of pK_a and n' are 3.5 and 1.9 in 0.1 N NaCl, and 4.5 and 1.7 in 1 N NaCl. As may be seen in Fig. 2, the increase in the concentration of added salt (C_s) by $\Delta\log C_s=1$ results in the increase of pK_a by about unity. A similar effect of added salt has been observed in the titration curve of the cross-linked polyacrylic acid resin, though the value of pK_a decreases upon the addition of salt.[10] Since the internal pH of an ion-exchange membrane or resin is different from that of an external solution, it is noticeable that the Henderson-Hasselbach-Katchalsky relation is established for these exchangers. This titration behavior of weak electrolyte-type exchangers may be understood when it is considered that the concentration of salt in the exchangers is quite low as a result of Donnan exclusion and that α or β is directly dependent on the internal pH ($\overline{pH}$), which is a simple function of the external pH, as may be estimated by $(pH+\log a_{Na})$ in the case of cation exchangers and by $(pH-\log a_{Cl})$ in the case of anion exchangers, where a is the activity of the ion in solution.*1

When Figs. 1 and 2 are compared, it may be seen that if both II and VI exist in 0.1 N NaCl, both the groups will ionize at the pH region of 3—5.

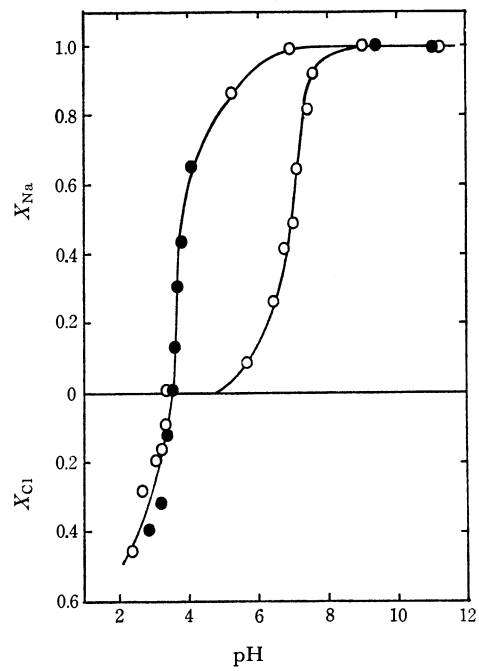

Fig. 3. Titration curves of membranes VII(●) and X (○) in the absence of added salt.

*1 The relation between the internal pH value and the external pH value of ion-exchange resins has been discussed by Kawabe and Yanagita[8] and by Nagasawa, Ishitani and Kagawa,[13] and quantitatively expressed by Eq. (15) and Eq. (5) of the respective papers.

13) M. Nagasawa, H. Ishitani and I. Kagawa, *Kogyo Kagaku Zassi (J. Chem. Soc. Japan, Ind. Chem. Sect.)*, **61**, 806 (1958).

Such a region will become narrow as the concentration of salt in the solution decreases, because the titration curves of II and VI transfer to lower and higher pH values respectively. It can, then, be predicted that if there is no interaction between acidic and basic groups in the bipolar membrane X (or XI), each group will be separately determined in the titration curve of the membrane at lower salt concentrations, probably lower than 0.01 N. Under such conditions, a pH region which apparently resembles the isoelectric point of polyampholytes may be observed in the titration curve of X, though neither group is ionized in the region in this case. Figure 3 shows the titration curve of X in the absence of any added salt;*2 here the above-mentioned region is observed at pH 3.5—5, where neither group is ionized. The titration curve of the membrane VII, containing both sulfonic acid and pyridine groups, is also shown in Fig. 3. The fact that each titration curve separated by the line, $\overline{X}=0$, is quite similar to that of the corresponding monopolar membrane seems to justify the assumption that there is no interaction between acidic and basic groups in VII and X.

Table 3. General properties of membranes

*2 In Fig. 3, $\overline{X}_{Na}$ and $\overline{X}_{Cl}$ are the mole fractions of exchanged sodium and chloride ions in the bipolar membranes, respectively as defined by $\overline{X}_{Na}=\bar{n}_{RNa}/(\bar{n}_{RH}+\bar{n}_{RNa})$ and $\overline{X}_{Cl}=\bar{n}_{RNHCl}/(\bar{n}_{RN}+\bar{n}_{RNHCl})$, where $\bar{n}_i$ is the number of moles of the species i in the membrane and where RH and RN represent free acidic and basic groups respectively.

General Properties of the Membranes. The properties of the membranes are summarized in Table 3. In the membranes containing oppositely-charged groups (VIII and XII) the properties appear to be attributable to the additive contribution of the two groups and no abnormal behavior based on the interaction between the two groups is indicated.

Electrochemical Properties of the membranes. The relation between the conductivity of a membrane ($\bar{k}$ in $\Omega^{-1}\,cm^{-1}$) in a 1-1-type electrolyte solution and the concentration of the ion ($\overline{C}_i$ in eq/l) in the membrane may be expressed by:

$$\bar{k} = 10^{-3}\sum \bar{\lambda}_i \overline{C}_i \qquad (1)$$

where $\bar{\lambda}_i$ is the equivalent conductivity of the ionic species i. When a membrane is in a dilute solution of electrolytes, since the concentration of sorbed salt in the membrane will be negligible compared with that of exchanged ions, $\bar{\lambda}_i$ may be related to the limiting equivalent conductivity of the species, λ_i^0, by the equation:[14]

$$\bar{\lambda}_i = \lambda_i^0 \phi h A_i F_i' F_i \qquad (2)$$

where ϕ is the pore volume fraction; h, the tortuosity factor, and F_i' and F_i, Ferry and Faxen's drag factors, and where A_i is related to the activation energy for diffusion. Thus, $\bar{k}$ will be strongly dependent on the structural factors of the membrane and on the interactions between the mobile species and its surroundings.

The linear relation between $\bar{k}$ and $\overline{C}$ has been reported for an anion-exchange membrane prepared from ethyleneimine and epichlorohydrin.[15] As is shown in Figs. 4 and 5, in the case of graft copolymer membranes containing one kind of ionized group, the plots of $\bar{k}$ against $\overline{C}$ can be substancially expressed by:

$$\log \bar{k} = a + b\,\overline{C} \qquad (3)$$

where a and b are the experimental constants. This means, in turn, that $\bar{\lambda}_i$ decreases greatly as

the capacity of the membrane decreases. The exceptionally higher values of $\bar{k}$ of XIII at lower $\bar{C}$ values may be ascribed to the contribution of a carboxylic acid group. In graft copolymer membranes, polar groups are not homogeneously distributed but are concentrated on graft chain; here the exchange-diffusion of ions may take place mainly through the internal polyelectrolyte region, which is composed of ionized groups. Therefore, the lower $\bar{\lambda}$ values at lower $\bar{C}$(or C_w) values, shown in Table 4, are probably attributable mainly to the lower pore-volume fraction and partly to the lower tortuosity factor. In fact, the calculated

	M	1.29	4.7	27

values of $100\times(\bar{\lambda}/w)$ listed in the table seem to be almost independent of $\bar{C}$. In the case of membranes containing oppositely-charged groups (VIII and XII), large values of $\bar{k}$ (around $2\times10^{-2}\Omega^{-1}\cdot$ cm^{-1}) are observed almost independently of the membrane composition.

The concentration potential of a membrane is given by:

$$E_m = -\frac{RT}{F}\left[\bar{t}_K \ln\frac{a_{K''}}{a_{K'}} - \bar{t}_{Cl}\ln\frac{a_{Cl''}}{a_{Cl'}}\right] \qquad (4)$$

where a_i is the activity of the species i in solution ($a'>a''$) and where $\bar{t}_i$ is the transference number of ions in the membrane. The concentration potentials of various membranes placed between 0.1 N KCl and 0.05 N KCl are shown in Fig. 6, in which F_K and F_{Cl} are the mole fractions of ionized acidic and basic groups*3 respectively, and in which $|E_0|$ is the absolute value of the ideal concentration potential as given by the Nernst equation. The absolute values of the concentration potential of VII and XIII increase, and those of IX, X, and XIV, decrease with an in-

*3 The mole fractions F_K and F_{Cl} are defined as follows: $F_K=\bar{n}_{RK}/(\bar{n}_{RK}+\bar{n}_{RN})$ for VII and X; $F_K=\bar{n}_{RK}/(\bar{n}_{RK}+\bar{n}_{RNCl})$ for VIII and XII; $F_{Cl}=\bar{n}_{RNCl}/(\bar{n}_{RK}+\bar{n}_{RNCl})$ for VIII and XII; $F_{Cl}=\bar{n}_{RNCl}/(\bar{n}_{RH}+\bar{n}_{RNCl})$ for IX and XIV, and $F_{Cl}=\bar{n}_{RNCl}/(\bar{n}_{RH}+\bar{n}_{RNCl})$ for XIII, where $\bar{n}_R$ represents the number of moles of an inactive group, such as phenyl and the ester, and where $\bar{n}_{RNCl}$ is that of the quaternary pyridinium group.

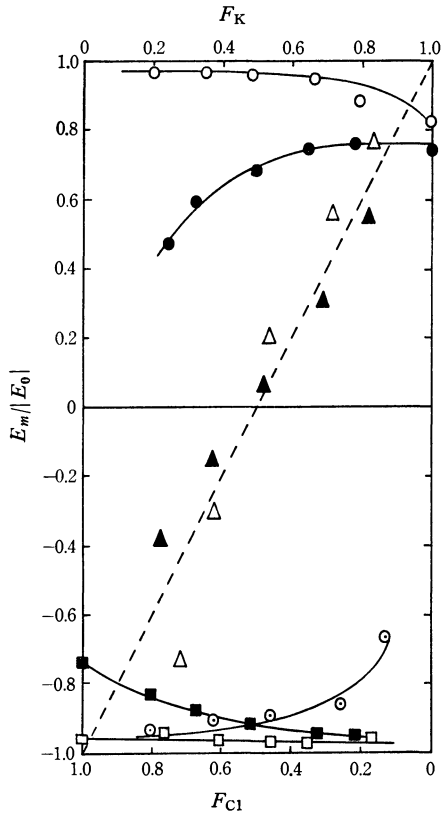

Fig. 6. Dependence of permselectivity of membranes VII (●), VIII (▲), IX (■), X (○), XII (△), XIII (⊙) and XIV (□) on mole fraction of membrane components.

crease in the mole fraction of each ionized group. This is in accordance with the behavior of each membrane except X with respect to the molality of the ionized group described in the previous section. As the Donnan exclusion of salt becomes less effective upon the decrease in $\bar{m}$, the salt content in membrane will increase and the potential will decrease. The sign of the E_m of the membrane XI, containing a carboxylic acid group and a partially-ionized pyridine group, is negative under acidic conditions, but it becomes positive upon repeated washings of the membrane, probably because of the very weak basicity of the pyridine group and the high mobility of the hydrogen ions. Thus, the behavior of X and XI is similar to that of an amphoteric membrane, in which the potential varies from negative to positive depending upon the pH of the solution.[3)]

The plots for VIII and XII, which contain oppositely-charged groups, are on the broken line in Fig. 6. Since E_m is expressed by Eq. (4) and since $\bar{t}_i$ is given by $(\bar{\lambda}_i\bar{C}_i)/(\sum\bar{\lambda}_i\bar{C}_i)$, the potential of VIII and XII will be a linear function of $F_i(=\bar{C}_i/\sum\bar{C}_i)$ provided that there is no interaction between the two groups and provided the mobilities

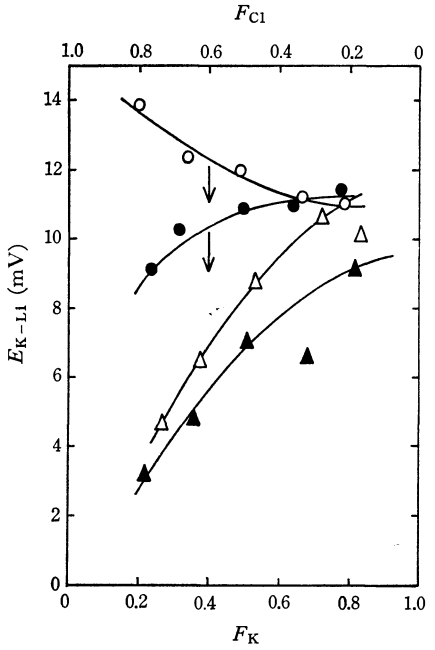

Fig. 7. Dependence of bi-ionic potential of membranes VII (●), VIII (▲), X (○), and XII (△) on mole fraction of membrane components.

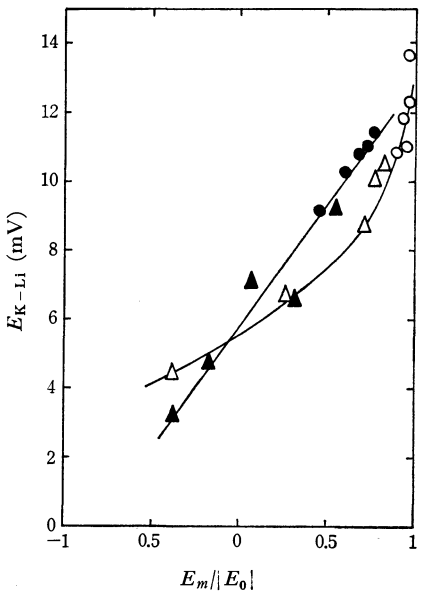

Fig. 8. Dependence of bi-ionic potential of membranes VII (●), VIII (▲), X (○) and XII (△) on permselectivity of the membranes.

of K and Cl ions are equal in a membrane.

The bi-ionic potential of the bipolar membranes for 0.1 N KCl - 0.1 N LiCl, E_{K-Li}, is shown as a function of F_i in Fig. 7. When E_{K-Li} is plotted against $E_m/|E_0|$, a simple relationship is indicated, as is shown in Fig. 8. The fact that E_{K-Li} decreases simply with the decrease in $E_m/|E_0|$

may be understood by considering that chloride ions in a membrane tend to transfer in a direction so as to reduce the bi-ionic potential, which is given for ideal permselective membranes[16] by:

$$E_{K-Li} = \frac{RT}{F} \ln \frac{\bar{D}_K a K' \bar{f}_{Li}}{\bar{D}_{Li} a_{Li}'' \bar{f}_K} \quad (5)$$

where $\bar{D}$ represents the diffusion coefficient of the ions in a membrane; a, the activity of ions in solution, and $\bar{f}$, the activity coefficient of the ions in a membrane. The fact that the E_{K-Li} of the membrane is positive may be qualitatively explained by Eq. (5). Provided that the ion-exchange selectivity coefficient, K_{Li}^K, is expressed by the activity coefficient ratio, $\bar{f}_{Li}/\bar{f}_K$, and that the diffusion coefficient is related to the conductivity through the Nernst-Einstein equation, $D=RT\lambda/F^2$, the following equation is established:

$$E_{K-Li} = \frac{RT}{F} \ln \left[\frac{\bar{k}_K}{\bar{k}_{Li}} K_{Li}^K \right] \quad (6)$$

In the membranes containing a sulfonic acid group (VII and VIII), the selectivity coefficient term seems to be more important, because $\bar{k}_K/\bar{k}_{Li}$ for the membrane VII is less than unity in some regions in Fig. 9. It is known that K_{Li}^K is greater than unity for sulfonic acid-type resins. On the other hand, since the K_{Li}^K of a carboxylic acid-type resin is known to be less than unity, it may be predicted from Eq. (6) that $\bar{k}_K$ will be much higher than $\bar{k}_{Li}$ for the membranes containing a carboxylic-acid group (X and XII). It may be seen in Fig. 9 that $\bar{k}_K/\bar{k}_{Li}$ is greater than 3 for the membrane X.*4

*4 A large difference between sulfonic acid - type membranes and carboxylic acid - type membranes in regard to the conductance of alkali-metal ions was previously observed for monofunctional graft copolymer membranes.[5]

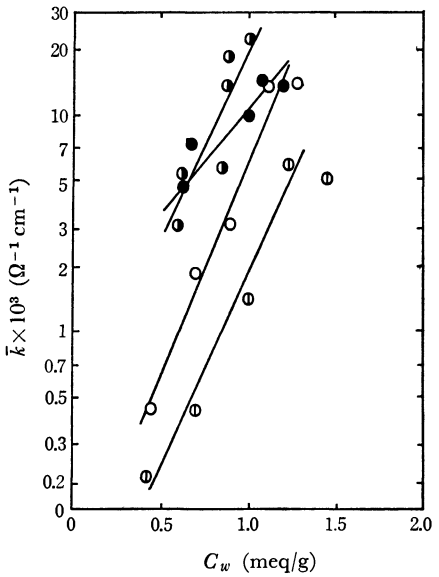

Fig. 9. Conductivities of membrane VII and X.
●: VII in K-form ◑: VII in Li-form
○: X in K-form ⦶: X in Li-form

In reviewing the properties of the membranes prepared from blends of monofunctional graft copolymers, no interaction between acidic and basic groups is indicated, and the concentration potentials of the membranes containing oppositely-charged groups are shown to be additive contributions of the two terms in Eq. (4) in relation to both the groups. This suggests that most of the functional groups of both copolymers in a blend are not brought into contact by the melt-pressed procedure.

The authors wish to express their thanks to Dr. T. Takamatsu for his kind advice in the radiation grafting and to Mr. T. Takeuchi and Mrs. K. Hayashi for their helpful assistance in preparing the samples and carrying out the measurements.

Solvent Effects on ρ Values of the Hammett Equation

Yasuhiko KONDO, Takeki MATSUI and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received April 15, 1968)

The effects of selvents on ρ values have been systematically treated as a two-variable problem within a linear free-energy relationship framework. It is assumed that the standard activation free energy is a continuous function of σ, a substituent variable, and ξ, a solvent variable. The applicability of the resultant equations is proved by a test of the dissociation constants (obtained from the literature) of benzoic acids in various solvents. As a result, it is proposed that these effects on ρ values can be explained in terms of the interaction or cross-term of σ and ξ. The application to the reaction rates of a typical Menschutkin reaction, obtained by experiments in ten non-aqueous solvents, suggests that the solvent dependence in these reactivities is much more complicated.

Systematic studies of the substituent effects of the dissociation constants of organic acids in solution have been carried out comprehensively by many authors since the proposal of Hammett's equation.[1] The relationships between the ρ values and the environmental changes have also been the subject of some studies.[2,3]

Concerning the effects of solvent on the ρ values, Wynne-Jones[4] discussed the relative acid strengths of some acids in such hydroxylic solvents as water, methanol, and ethanol; he suggested the inverse proportionality of these values to the dielectric constants of the solvents used. Furthermore, Kilpatrick and his co-workers[5] confirmed Wynne-Jones's results on the dissociations of acids in aqueous dioxane; however, they indicated that this relationship was limited to solvents with dielectric constants larger than $\sim$25. In low dielectric solvents (lower than $\sim$25) it did not hold; here the dipole-dipole interaction may dominate. Recently, Grunwald[6] proposed a linearity between the ρ values and his Y_0 values for the dissociation of anilinium ions.

On the other hand, the existence of a linear dependence of ρ values on the reciprocals of the absolute temperatures has also been reported.[2,3] Separating the external contributions to the thermodynamic quantities from the internal ones, Hepler[7] established the dissociation of phenols in an aqueous solution and supported the concept of the existence of a linear relation.

The interest in the effects of solvents on the ρ values, one of the Hammett reaction parameters, has prompted the present authors to initiate this project in the hope of establishing a more systematic treatment of the solvent effects on the Hammett constants. It seems that these problems may be treated as a two-variable problem by considering that both the standard activation free energy for the reaction and the standard free-energy changes in the equilibrium are continuous functions of x and y; x and y standing for the characteristics of the substituent, *i.e.*, σ, and the characteristics of such environmental factors as the solvent properties and the temperatures respectively.

Taylor's expansion theorem is used to treat this problem. Equation (1) represents this theorem for the standard free-energy change, ΔF°, which is a continuous function of foth x and y:[8]

$$\Delta F^\circ(x,y) = \Delta F^\circ(0,0) + \left(\frac{\partial \Delta F^\circ}{\partial x}\right)_{0,0} x + \left(\frac{\partial \Delta F^\circ}{\partial y}\right)_{0,0} y + \left(\frac{\partial^2 \Delta F^\circ}{\partial x \partial y}\right)_{0,0} x \cdot y + \frac{1}{2}\left(\frac{\partial^2 \Delta F^\circ}{\partial x^2}\right)_{0,0} x^2 + \frac{1}{2}\left(\frac{\partial^2 \Delta F^\circ}{\partial y^2}\right)_{0,0} y^2 + 0(x^3, y^3) \quad (1)$$

Here the subscripts indicate the arbitrarily-destinated conditions.

If a linear free-energy relationship is assumed with regard to x and y, the terms of the second and higher powers of x and y, except for the fourth on the right hand side of Eq. (1), can be omitted. Therefore, Eq. (2) can be written as:

1) L. P. Hammett, *J. Am. Chem. Soc.*, **59**, 96 (1937).
2) P. R. Wells, *Chem. Revs.*, **63**, 171 (1963).
3) H. H. Jaffe, *ibid.*, **53**, 191 (1953).
4) W. F. K. Wynne-Jones, *Proc. Roy. Soc. (London)*, **A140**, 440 (1933).
5) J. H. Elliott and M. Kilpatrick, *J. Phys. Chem.*, **45**, 454 (1941).
6) E. Grunwald and B. Gutbezahl, *J. Am. Chem. Soc.*, **75**, 559 (1953).
7) L. G. Hepler, *ibid.*, **85**, 3089 (1963).
8) W. Kaplan, "Advanced Calculus," Addison-Wesley Publishing Co., Massachusetts, U. S. A. (1952), p. 369.

$$\Delta F^\circ(x,y) = \Delta F^\circ(0,0) + \left(\frac{\partial \Delta F^\circ}{\partial x}\right)_{0,0} x + \left(\frac{\partial \Delta F^\circ}{\partial y}\right)_{0,0} y + \left(\frac{\partial^2 \Delta F^\circ}{\partial x \partial y}\right)_{0,0} x \cdot y \quad (2)$$

Then, using Eq. (4), Eq. (2) can be rewritten as follows:

$$\Delta F^\circ(x,y) = \Delta F^\circ(0,0) + A_0 x + B_0 y + \left(\frac{\partial A}{\partial y}\right)_0 x \cdot y \quad (3)$$

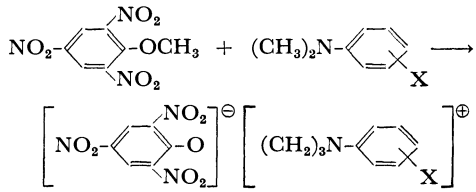
$$\left(\frac{\partial A}{\partial y}\right)_0 = \left(\frac{\partial B}{\partial x}\right)_0 \quad (4)$$

Eq. (4) is based on the mathematical theory that the order of differentiation is immaterial because ΔF° is the "property" of the reaction system[9] and because it has been assumed that all the derivatives concerned are continuous in the domain considered.

This equation (3) is essentially the same as that of Miller[10] provided that $\partial A/\partial y$ or $\partial B/\partial x$ is constant. Especially if $\partial A/\partial y$ or $\partial B/\partial x$ is zero, this situation shows that x and y contribute to ΔF° independently; the resultant equation (5) has been useful for the separation of the factors in the substituent effects, *i. e.*, polar, steric, resonance, and so on.[11]

$$\Delta F^\circ(x,y) = \Delta F^\circ(0,0) + A_0 x + B_0 y \quad (5)$$

In order to examine the usefulness of such a treatment of the solvent effects, the dissociation constants of substituted benzoic acids in various aqueous solvents were compared with many literature values, and then the rates of a Menschutkin-type reaction series (I) were followed in various non-aqueous solvents which had not hitherto been studied. This reaction was chosen for the present research because it was expected that the ρ values might be liable to variation in proportion to the solvent changes, since in acetone this value was significantly large.[3,12]



(I)

Results and Discussion

The Application of Eqs. (3) and (4) to the Solvent Effect. Usually, as has been seen in may results, if the Hammett rule holds good in one solvent, it is valid also in other solvents so far as the non-charged substituents are concerned.[3,13] Moreover, if the linear free-energy relationship is assumed also for solvent variation, x and y in Eq. (3) may be replaced by σ and ξ, the characteristic features of a solvent. We can also replace ΔF° with the equilibrium constant, K. Thus Eqs. (3) and (4) yield:

$$\log\left(\frac{K_\sigma^\xi}{K_0^0}\right) = \rho_0 \sigma + \zeta_0 \xi + \left(\frac{\partial \rho}{\partial \xi}\right)_0 \sigma \cdot \xi \quad (6)$$

$$\left(\frac{\partial \rho}{\partial \xi}\right)_0 = \left(\frac{\partial \xi}{\partial \sigma}\right)_0 \quad (7)$$

Now it does not appear that ξ can be uniquely determined by such a special characteristic of a solvent as $1/D$ or $(D-1)/(2D+1)$. Therefore, ξ will be here defined as the logarithmic ratio of the equilibrium constant in a standard solvent to that in others when the unsubstituted reactant is used; that is to say, log $(K_0^{\text{other solv}}/K_0^{\text{reference}})$ (the subscript indicates the substituent and the superscript indicates the solvent). ζ is a measure of the susceptibility of a given reaction series to the ξ defined above.

Equation (6) contains the interaction or the cross term of σ and ξ. This term may be used to explain the solvent effects on ρ and the substituent effects on ζ if these effects are two sides of one thing; that is to say, Eq. (7) is valid. Equations such as Eq. (7) have been frequently used in the form of $pK(H_2O)$ *vs.* pK(other solvent).[14] The arising of this cross-term suggests how the contribution of σ to ΔF° affects the contribution of ξ to ΔF°.

To begin with, the above treatment should be applicable to the thermodynamic equilibrium constants, K_{th}, of benzoic acids in various solvents, for σ may depend on the solvent although it is defined as the logarithmic ratio of the thermodynamic ionization constants of substituted benzoic acid to that of unsubstituted acid in an aqueous solution. Moreover, the thermodynamic values should be used for theoretical treatment.[15] Fortunately, the true acid strengths of benzoic acid and its derivatives have been studied by many workers.

Table 1 shows the ξ values for several solvents, which have been calculated by using the average values of these data taken from the references, together with the dielectric constants (ξ is defined as $\log(K_0^{\text{other solvent}}/K_0^{H_2O})$). Figure 1 represents the plots of $\log(K_\sigma^{\text{other solvent}}/K_\sigma^{H_2O})$ *vs.* ξ. The

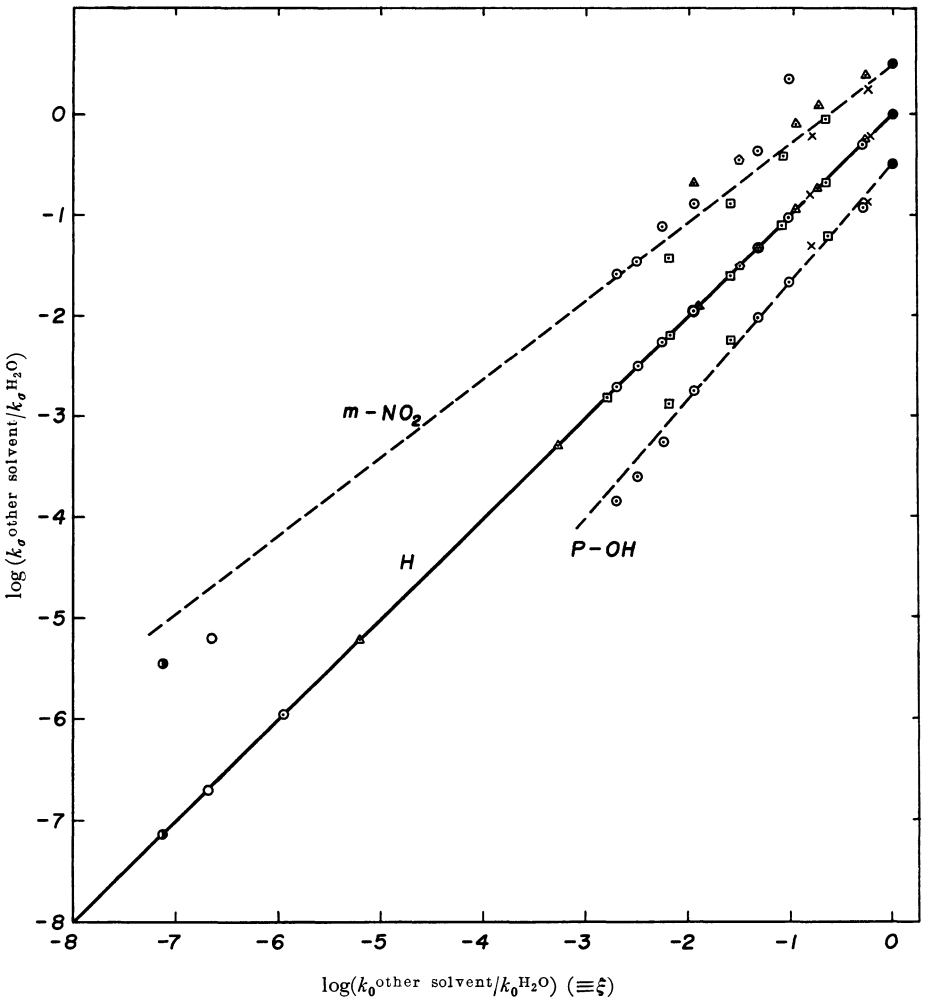

Fig. 1. The representation of linear free energy relationship with regard to solvent variations for the equilibrium constants of benzoic acid and its derivatives at 25°C. The $\log(k_\sigma^{\text{other solvent}}/k_\sigma^{H_2O})$ scale is displaced 0.5 to the upward or downward for m-NO_2 or p-OH derivatives for avoiding confusion. ●, Water; ×, water-acetone mixture; △, water-methanol mixture; ⊙, water-ethanol mixture; ⊡, water-dioxane; ○, isopropanol; ◑, hexanol; ⬠, anisole. See references in Table 1.

slope of this figure results in ζ (ζ_0 is equal to 1.00 according to the definition of ξ). The existence of a relation of the type of Eq. (7) is clearly shown in Figs. 2 and 3; this proves that the variation in the ρ values with the properties of the solvents arises from the cross-interaction of σ and ξ. Figure 2 shows that ρ decreases linearly with an increase in ξ; that is to say, the more polar the solvents are, the smaller this value becomes.

In order to discuss further details of the solvent effect on the ρ value, the relationship between ξ and the dielectric property of the solvent should be examined. As is shown in Fig. 4, an approximately linear relationship exists between ξ and $1/D$, the reciprocal of the dielectric constant, but in aqueous dioxane it is not observed. This is very similar to the situation which Hyne explained as the effect of specific solvation.[16] Judging from this point of view, in this case it may also be considered that dioxane - water mixed solvents have a larger dielectric character than expected and that they affect this equilibrium. The reason why the interaction term has some value is explained if only σ contains some component varying with the solvent.

On the other hand, the effects of the field in which the solute are located are taken as among the most important factors which contribute to the cross - interaction between σ and ξ. Dewar

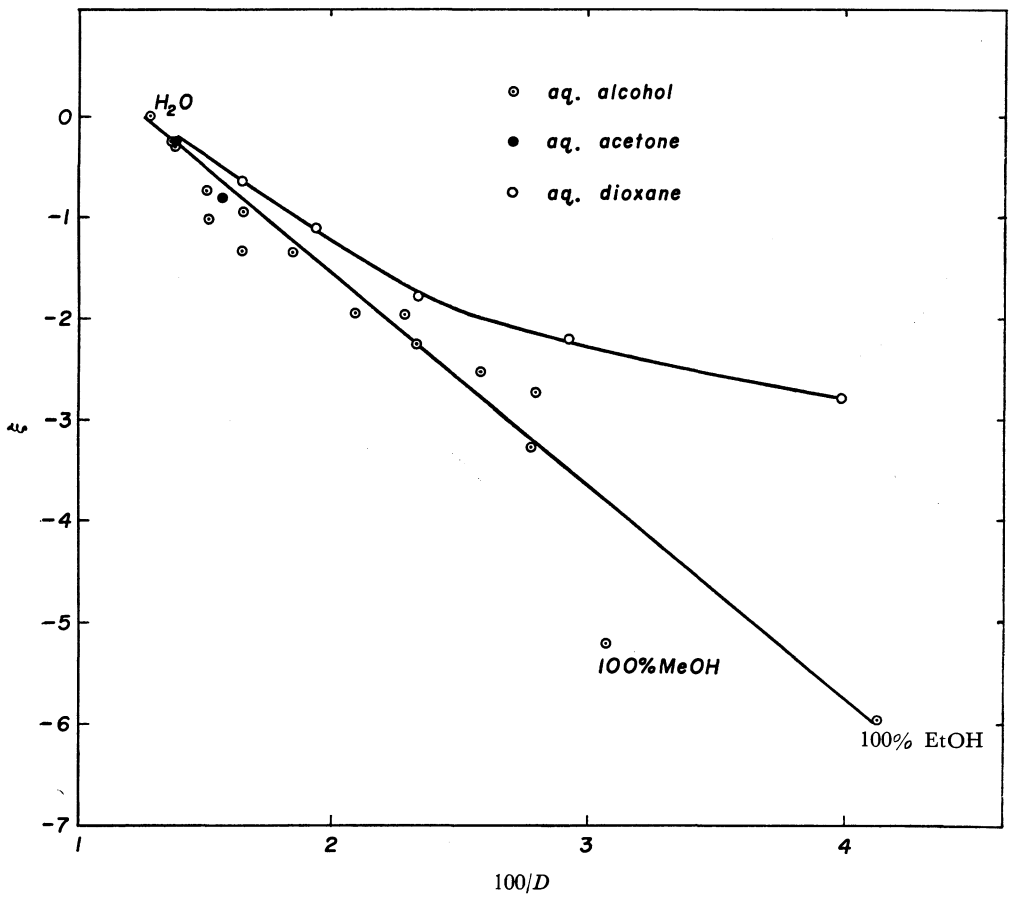

Fig. 4. The relationship between ξ, defined for the dissociation constants of benzoic acid, and $1/D$ for various aqueous solvents.

et al.[17] have emphasized the importance of this factor in a substituent effect. Thus, it seems reasonable that the field effect of each substituent results in the variation in ρ with ξ, as Willi has also suggested.[18]

17) M. J. S. Dewar and P. J. Grisdale, *ibid.*, **84**, 3539 (1962).

18) A. V. Willi, *Helv. Chem. Acta*, **40**, 2032 (1957).

Usually this effect results from both the electrostatic contribution described as $1/D$ and the non-electrostatic (*i. e.*, specific) solvent effect. However, in the equilibrium under consideration, it seems that only the former acts on this effect (Fig. 4). The slope of such a linear plot (Fig. 2) may give a relative measure of the field effect which depends on the type of reaction.

The same treatment is applicable to the other dissociation equilibrium, those of anilinium ions or bicyclo[2.2.2]octane-1-carboxylic acid.[13] Equation (7) holds good for these series. The results of Grunwald showed that the ξ of the former equilibrium is linearly dependent on his Y_0[6] values and then he used the similar equation as Eq. (7) for the prediction of ρ values in several solvents.

On the other hand, the sign of the interaction constant[19] is negative, which seems to be generally true for the equilibrium with a positive ρ value. Over the range of negative ξ values, *i. e.*, in solvents less polar than water, the electron-withdrawing ability of a substituent in this situation increases the force driving for an equilibrium more than that in the additive relation which comes into existence when the interaction term is equal to zero. This can be explained if it is considered that the electron-withdrawing substituent operates to stabilize the carboxylate anion directly through space. The less polar the solvent is, the larger the degree of this effect becomes.

The Non-Aqueous Solvent Effects on ρ Value. It should be noted that the above treatment is also applicable to the variation in the velocity coefficient, k, with both substituents and solvents, using the concept of the theory of the absolute reaction rate;[20] *i. e.*, the standard activation free energy of a reaction is the thermodynamic property. Equation (8) is derived as:

$$\log\left(\frac{k_\sigma{}^\xi}{k_0{}^0}\right) = \rho_0\sigma + \zeta_0\xi + \left(\frac{\partial\rho}{\partial\xi}\right)_0\sigma\cdot\xi \qquad (8)$$

Few systematic studies have been carried out on the non-aqueous solvent effects on the ρ value. Regarding this problem, the present authors have, however, obtained some results of the Menschutkin-type reaction I (Table 2).

Figure 5 shows a Hammett plot based upon some of these data. The correlation coefficient of this plot from Table 2 is good in every solvent except in methanol.[21] This means that the substituent effects on the rates of these reactions can be expressed sufficiently in terms of a simple Hammett substituent constant, and that the reaction mechanisms are not influenced by the change in substituents. Also, it must be emphasized that for even this reaction of the highly hindered system (2,4,6-trinitro substituted reactant), the Hammett relationship holds good. This observation, as has been suggested by Taft,[22] seems to be attributable to the fact that the steric requirement of the reaction is not influenced by the variation in the substituent at the *m*- or *p*-position.

The non-aqueous solvent effects on the ρ value are extremely complex in the reaction under examination, as is shown in Table 2. However, a clear tendency is observed; the ρ values in aromatic solvents are all larger in absolute value than those in other solvents. The above-mentioned treatment has been applied to this reaction. We chose benzene as the standard solvent, and ξ was defined as $\log(k_0{}^{\text{other solvent}}/k_0{}^{C_6H_6})$. The plot of $\log(k_\sigma{}^{\text{other solvent}}/k_\sigma{}^{C_6H_6})$ against ξ (not shown) gives two distinctly different lines, which is equivalent to the fact that the two Hammett plots intersect with each other. The substituents also influence the mode of the variation in the logarithm of the rate constant with the solvent. The solvent constant can not be determined *a priori*. In this respect, the solid and dashed lines in Fig. 6 were drawn in to show that the solvents fall naturally into two groups: group a, along the dashed line in Fig. 6, consists of benzene, *p*-xylene, bromobenzene, and chloroform, while group b, along the solid line in Fig. 6, consists of tetrahydrofuran, methyl ethyl ketone, methanol, and acetonitrile. It goes without saying that Eq. (7) holds for each group. Nitrobenzene shows, however, a deviation from these two lines. The absolute value of ρ decreases with an increase in the solvent polarity in the members of group b, but in the members of group a this tendency is just reversed. In other words, $\partial\rho/\partial\xi$, the measure of the sensitivity to the field effects, is positive in group b and negative in group a since the reaction under consideration has a negative value of ρ.

It is now necessary to review the non-aqueous solvent effects on the kinetics of this type of reaction. A linear dependence of ξ on the $(D-1)/(2D+1)$ function can be expected from the first approximation of Kirkwood's theory[23] for dipole-dipole reactions, but no such simple relationship is observed in group a. Recently Reinheimer *et al.*[24] correlated the abnormally-high reactivity of the

19) The terms $\partial\rho/\partial\xi$ and $\partial\zeta/\partial\sigma$ mean the interaction constants of σ and ξ when it is constant, as is shown in Figs. 2 and 3, judging from the similarity to the estimation of energy levels for polyatomic molecules. See, for example, Ref. 11, p. 503.

20) S. Glasstone, K. J. Laidler and H. Eyring, "Theory of Rate Processes," McGraw-Hill Book Co., New York (1940).

21) As the concurrent methanolysis of the reactant occurs, the pseudo second-order rate constants in methanol must be calculated after a consideration of this solvolysis. For this reason, in methanol the correlation is worse than in other solvents.

Menschutkin reaction in aromatic solvents with the non-electrostatic properties of these solvents. On examination of the data described in the literature[24] and the data at hand, it can be said that the electron density in the aromatic nucleus seems to play a role in determining the kinetics of this type of reaction in aromatic solvents. There seems to be a specific solvation of a leaving anion in a transition state by aromatic solvents. This effect is clearly in the sequence: nitrobenzene>bromobenzene>benzene>toluene>*p*-xylene. For example, in such aromatic solvents as toluene or *p*-xylene, containing electron-releasing substituents, the rate of this type of reaction is slower than in other solvents.

On the other hand, it has also been noticed that a transition state assumed to be close enough to picrate, the reaction product, may be considerably sensitive to the non-electrostatic or diffusion factor of solvent effects.[25]

These factors may cause a difference in the mode of the variation in ρ with the solvent between the members of group a and those of group b. However, the explanation of this difference must be reserved until it is confirmed that this behavior is not unusual for the Menschutkin type of reaction in non-aqueous solvents; we shall continue our examination on this problem.

Experimental

Kinetic Procedure. It was conductmetrically verified by Hertel and Dressel[12] that the reaction (I) strictly follows the bimolecular rate law and that it is practically completed through the scheme. However, the formation of picrates enabled us to follow the kinetic runs by the convenient spectroscopic technique. The stock solution was introduced into a reaction vessel with a capacity of 50 m*l*, equipped with a slender and long-necked flask, and placed in a thermostat held at 50±0.1°C; then the stock solution of dimethylaniline or its derivatives was added. The sampling solution from this vessel was extracted three times with a constant volume of a water-benzene mixture so that the picrate produced might be obtained as an aqueous solution. This solution was diluted to a concentration favorable for measuring the optical density of the solution. In the experiments using nitrobenzene as the solvent, the water layer was further washed with benzene in order to prevent the contamination by this solvent from markedly affecting the optical densities of the water layer. The optical density of the samples was obtained over the range of 360—400 mμ at intervals of 10 mμ on a Hitachi spectrophotometer EPU-2A, using quartz cells 1.0 cm thick.

These salts appear to be completely dissociated in water. To check this point, the molecular extinction coefficients, ε, of *N,N,N*-trimethylanilinium and *p*-tolyl-*N,N,N*-trimethylanilinium picrate were measured. The calibration curves which were obtained in the range of 360—400 mμ at intervals of 10 mμ obeyed Beer's law excellently in each case. The results are given in Table 3. The table shows that these coefficients are essentially identical with each other, so the data of the *N,N,N*-trimethylanilinium salt were taken for the calculation of the rate constants.

A typical run, the reaction of *m*-methyl-dimethylaniline with 2,4-6-trinitroanisole in tetrahydrofuran at 50°C, is shown in Fig. 7, where D and D_∞ are the

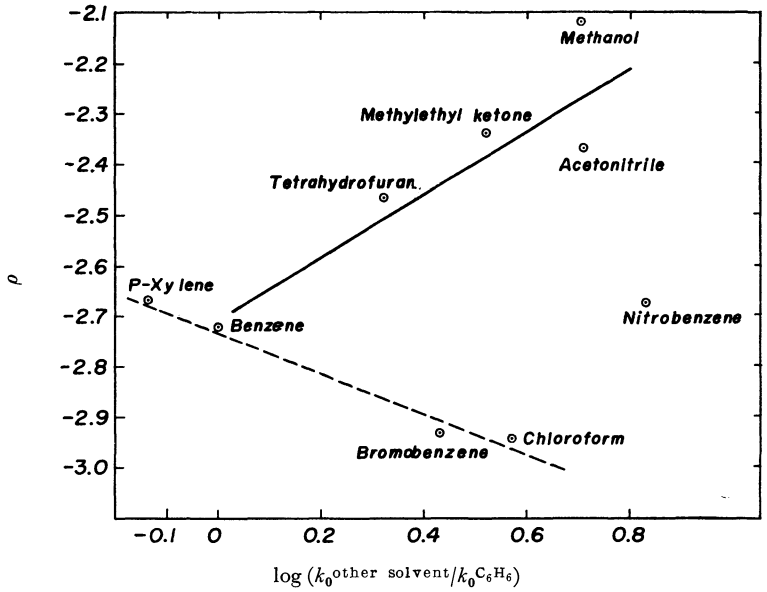

Fig. 6. The relationship between ρ and log ($k_0$other solvent/$k_0C_6H_6$) as the solvent parameter for the reaction (I).

TABLE 3. MOLECULAR EXTINCTION COEFFICIENTS OF SOME PICRATES IN WATER

Picrates, λ, mμ	360	370	380	390	400
Sodium	14080	13090	11730	10780	9870
N,N,N-Trimethylanilinium	13990	12890	12890	11670	9796
p-Methylphenyltrimethyl-ammonium	13960	13050	11850	10860	10010

optical densities of the samples in water at finite and infinite times respectively. Since the optical density is proportional to the concentration of the picrate produced, the second-order rate constant can be obtained by multiplying the slope of such a figure by εl (l indicates the cell length; 10 mm). In the case of slower reactions the method of initial rates was carried out in order to estimate the rate constants by the equation: $dD/dt = (k/\varepsilon l)D^a_\infty \cdot D^b_\infty$. The rate constants obtained by the two procedures agree with each other within 10%, as is shown in the case of bromobenzene in Table 2. The concentrations used in the calculation of the velocity constants were the concentrations at the temperature of the experiment by correcting for solvent expansion. The densities of THF at several temperatures were calculated by the usual manner using one experimental value, d_{20}.[26]

At least one duplicate experiment was always performed with a different initial concentration. As a result, it was observed that the rate coefficient is independent of the concentration. In methanol, however, it was observed that the rate of the methanolysis of trinitroanisole is comparable to the rate of the reaction of *m*-nitro-dimethylaniline with trinitroanisole. The estimation of the rates of the methanolysis of trinitroanisole in methanol was carried out by the initial rate method. The plot of D against t gives a straight line through the zero point. The slope of this plot was $(5.38 \pm 0.21) \times 10^{-3}$ hr^{-1} for the pseudo first-order methanolysis rate (the average value of three independent runs). Using this value, the rate coefficients of the reaction between *m*-methyl- or *p*-methoxy-*N,N*-dimethylaniline and trinitroanisole in methanol were given in the following form:

$$k = \frac{1}{a \cdot b}\left(\frac{dx}{dt}\right)_0 = \frac{k_{\text{methanolysis}}}{b}$$

where $(dx/dt)_0$ was obtained by means of Newton's numerical differential equations.[27]

The rate of the reaction between *m*-nitro-dimethylaniline and trinitroanisole in methanol was obtained by the method of Andrews and Young[28] using the following equation:

$$\frac{(dx/dt)_0}{[\text{TNA}]_0} = k[\text{DMA}]_0 + k_{\text{methanolysis}}$$

A plot of $(dx/dt)_0/[\text{TNA}]_0$ *vs.* $[\text{DMA}]_0$ was a straight line the slope of which gave k.

Table 2 gives the results for the reaction rates in various solvents obtained as has been described above.

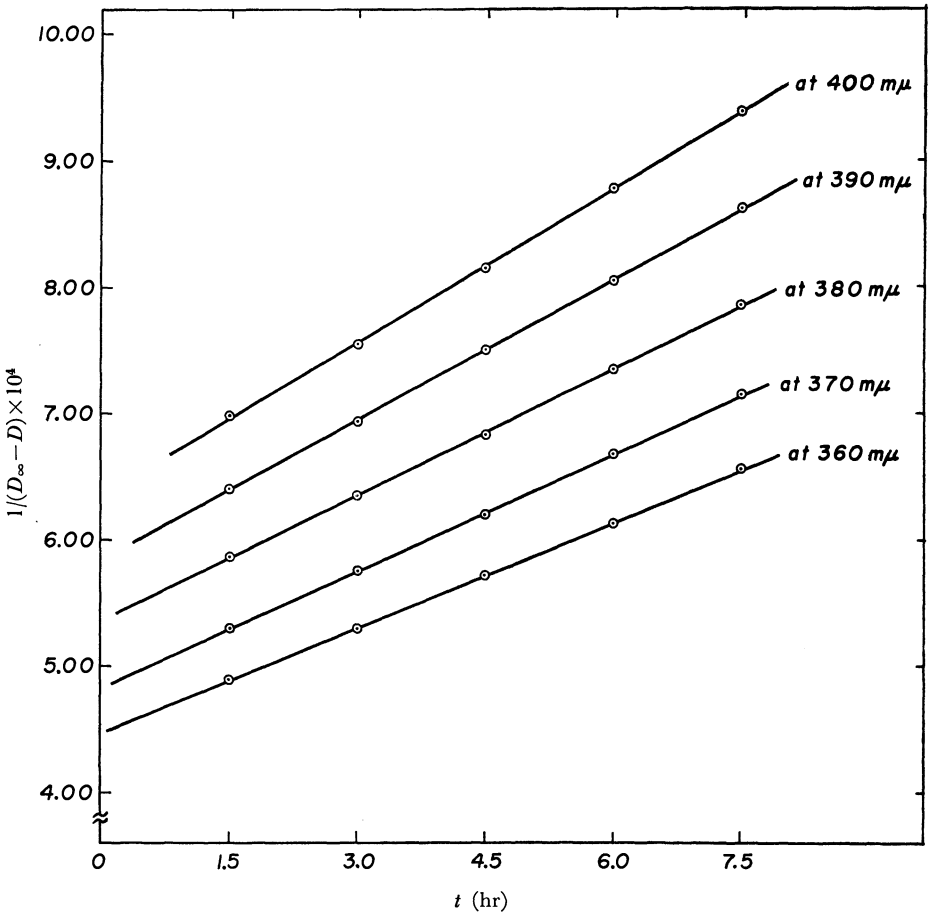

Fig. 7. A typical run for the reaction between *m*-methyl-dimethylaniline and trinitroanisole in tetrahydrofuran at 50°C.

Materials. The *N,N*-dimethylaniline, from Wako Pure Chemicals, was purified according to the procedure described by Fieser[29] and stored in an atmosphere of dry nitrogen until use.

The *p*-methoxy-, *p*-methyl-, *m*-chloro-, and *m*-methyl-*N,N*-dimethylanilines were prepared according to the directions of Fukui *et al.*[30] from commercial *p*-methoxy-, *p*-methyl-, *m*-chloro-, and *m*-methylanilines respectively. The purification of these materials was similar to that of *N,N*-dimethylaniline. The purity of these samples was assured to be sufficient by elemental analysis, infrared spectroscopy, and gas chromatography, in which only a single peak was observed in every case, using two solid supports, P. E. G. 6000 and Silicone D. C. 550.

The *m*-nitro-*N,N*-dimethylaniline was prepared by the usual method of nitration[31] and recrystallized from 95% ethanol at least four times; mp 57—58°C, lit. 57—58°C.[32]

The 2,4,6-trinitroanisole (TNA) was prepared by the reaction[33] of dissolved sodium hydroxide in methanol at 0—5°C with picryl chloride (which was taken from picric acid and phosphorus pentachloride), recrystallized from methanol several times, and dried over silica gel in a desiccator; mp 67—68°C, lit. 67—68°C.[32] Found: C, 34.71; H, 2.35; N, 17.05%. Calcd for $C_7H_5N_3O_7$: C, 34.58; H, 2.0; N, 17.28%.

The *N,N,N*-trimethylanilinium- and *p*-methylphenyltrimethylammonium picrates were prepared from equimolar quantities of amines and anisole at 50°C in THF and were recrystallized from water until a constant melting point was obtained; mp 120—120.5°C and 195—196°C[33] respectively. The sodium salt was prepared from picric acid and sodium hydroxide in boiling water and recrystallized. These salts were dried in an Abderhalden flask for several hours at the boiling point of acetone and then used to obtain the molecular extinction coefficients in water. Benzene, *p*-xylene, and bromobenzene were shaken with concentrated sulfuric

acid several times until no further discoloration was observed; they were then washed with water, about 10% aqueous potassium hydroxide, and again with water, dried over calcium chloride, and distilled. The center fraction was further distilled twice from phosphorus pentoxide.

The nitrobenzene and methyl ethyl ketone were commercial reagents used without further purification. After drying with calcium chloride and then phosphorus pentoxide, they were distilled three times. The center fraction was collected for use.

The tetrahydrofuran was refluxed with potassium hydroxide and distilled. After drying and refluxing with sodium wire, the center fraction was redistilled. It was stored over sodium wire and then further distilled before use.

The acetonitrile was dired over phosphorus pentoxide, distilled, and treated as before. The center franction was stored over phosphorus pentoxide and distilled before use.

The methanol,[34] chloroform,[35] and carbon disulfide[36] were purified as has been described in the literature.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1047—1051 (1969)

The Anodic Reaction of Acetic Acid in the Presence of Enanthaldehyde, Enanthaldehyde Diethyl Acetal, and 2-Octanone

Akira TAKEDA and Satosi WADA

Department of Synthetics Chemistry

and Sigeru TORII and Yuji MATSUI[1]

Department of Industrial Chemistry, Okayama University, Okayama

(Received June 21, 1968)

The anodic methylation of enanthaldehyde, enanthaldehyde diethyl acetal, and 2-octanone was attempted by electrolyzing a mixture of acetic acid, ethanol (or tetrahydrofuran and/or acetone), water, and potassium hydroxide. The major products from the electrolysis of enanthaldehyde consisted of 2-octanone, 1-heptanol, 3-methyl-2-octanone, and enanthaldehyde diethyl acetal. Similar products were isolated from the reaction mixture of enanthaldehyde diethyl acetal. The anodic methylation of 2-octanone gave 3-methyl-2-octanone as a major product. Possible mechanisms of the formation of these ketones were discussed.

Several workers[2-4] have reported the anodic methylation of aromatic rings, *i. e.*, trinitrotoluene and pyridine, and of double bond of 1,1-diphenylethylene. In the anodic methylation of benzaldehyde in aqueous acetic acid-potassium hydroxide solution,[5] we found the replacement of the hydrogen atom of the formyl group of benzaldehyde by a methyl group to give acetophenone. Such anodic methylation has been found to occur, recently, in the course of the electrolysis of the acetic acid solution containing cinnamic[6] and β-phenylglycidic acids.[7] As an extension of the above

$$\mathrm{Ph{-}\overset{\overset{\mathrm{O}}{\|}}{C}{-}H} \xrightarrow[CH_3COOH]{\text{Anodic Reaction}} \mathrm{Ph{-}\overset{\overset{\mathrm{O}}{\|}}{C}{-}CH_3}$$

method, the anodic methylation of enanthaldehyde and its related compounds were investigated for the preparation of aliphatic methyl ketone.

Results and Discussion

Two platinum foil electrodes were used in the

present experiments. Some typical reaction procedures are shown in Table 1. The products of the anodic reaction of enanthaldehyde and its related compounds were separated by chemical procedure into two groups as illustrated in Scheme 1. Both the ketone and aldehyde and the non-ketone and non-aldehyde components were characterized by vapor-phase gas chromatography (vpc). The principal products are summarized in Tables 2 and 3. 2-Octanone and its derivatives, which are expected to be produced from the anodic methylation of enanthaldehyde, were detected. By using the Girard P reagent, the ketone and aldehyde component was separated in about 50% yield. About 64% of the ketone and aldehyde component consisted of 2-octanone. The change of organic solvent had little effect on the constituent of the

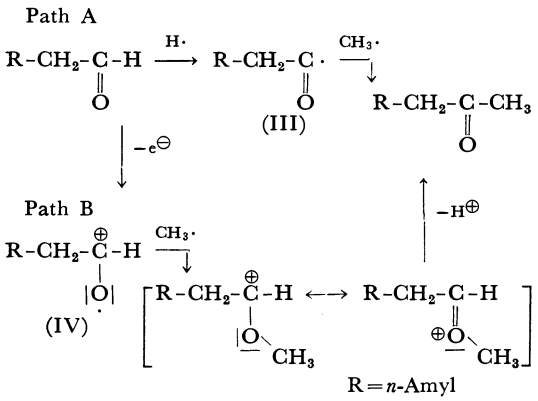
products.

When anodic methylation was carried out in the presence of enanthaldehyde diethyl acetal as a substrate, the constituent of the major products was similar to that described in Table 2. The anodic methylation of 2-octanone afforded 3-methyl-2-octanone as a major product. The results of each reaction which was carried out for 210 hr are illustrated in Figs. 1, 2, and 3. The

results of the formation of 2-octanone in different solvents are shown in Fig. 4.

The results given in Fig. 1 show that the methylation and the reduction of enanthaldehyde proceed principally to afford 2-octanone and 1-heptanol. In the course of this reaction, some enanthaldehyde may be converted into its hemiacetal and diethyl acetal. By electrolyzing 2-octanone in the same media, 3-methyl-2-octanone was produced (Fig. 3). The maximum yield of 2-octanone, in Fig. 1, was estimated when electrolysis was continued for about 140 hr. The line attributed to enanthaldehyde hemiacetal in Fig. 2 shows that the conversion of enanthaldehyde diethyl acetal into the hemiacetal may be performed for a relatively short period. In Fig. 4, it seems that the organic solvent used in the present reaction affected only the rate of the formation of 2-octanone.

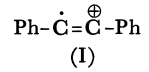


Scheme 2. Formation of 2-octanone.

Path A: The abstraction of a hydrogen atom directly from the formyl group by anodically generated radicals.

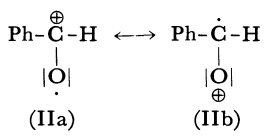
Path B: The formation of radical ion (IV) by discharge of the substrate on the anode and the addition of a methyl radical followed by carbonium ion rearrangement.

Recently, Koehl hypothesized[8] that a cation-radical intermediate (I) may be produced, when the triple bond of diphenylacetylene was subjected to discharge at the anode surface. In a previous paper,[5] we also assumed a possibility in which



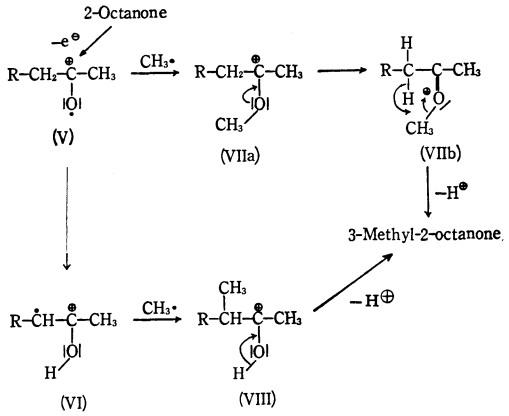
(I)

discharge of the carbonyl group of benzaldehyde at the anode may give cation radical intermediate (IIa and IIb), since no appreciable amount of



(IIa) (IIb)

8) W. J. Koehl, *J. Org. Chem.*, **32**, 614 (1967).



Scheme 3. Formation of 3-methyl-2-octanone.

benzil was detected on the gas chromatogram. Similarly, in the case of enanthaldehyde, absence of dimer of heptanoyl radical (III) was confirmed by vpc. A possible pathway of the formation of 2-octanone may be considered as follows (Scheme 2):

However, considering the mode of attack of a methyl radical to 2-octanone, the assumption of the cation-radical intermediate (IV) seems to be more reasonable. A mechanism of the formation of 3-methyl-2-octanone *via* radical-cation intermediates is outlined in Scheme 3. Considering the facility of the formation of 3-methyl-2-octanone rather than 3-nonanone, it seems that the anodically generated methyl radical[9] may attack radical-cation intermediates (V and VI) to form (VII and VIII), which may further undergo carbonium ion rearrangement giving 3-methyl-2-octanone.

Experimental

All boiling points are uncorrected. The products were analyzed by vapor-phase chromatography (Hitachi F6-D gas chromatograph) using Golay column (Z-45) coated with silicone oil (SE-30).

Apparatus. The electrochemical cell consisted of a cylindrical glass vessel, 7 cm long in diameter and 14 cm high, fitted with a gas lead pipe, a thermometer, and a magnetic stirrer. The vessel was immersed in a water bath, cooled with circulating cold water. The electrodes were two platinum foils (1.5×2.0 cm^2) spaced about 2 mm apart and the current direction was changed every 30 sec by means of a commutator.

Materials. Analytical grade enanthaldehyde, 2-octanone, acetic acid, ethanol, tetrahydrofuran, acetone, and inorganic chemicals were used. The following reference compounds were prepared: enanthaldehyde diethyl acetal,[10] bp 99—102°C/25 mmHg, α-methyl-

10) E. W. Adams and H. Adkins, *J. Am. Chem. Soc.*, **47**, 1365 (1925).

enanthaldehyde,[11] bp 50—52°C/10 mmHg, 3-methyl-2-octanone,[12] bp 64°C/18 mmHg, 3-nonanone,[13] bp 85—88°C/20 mmHg, 1-heptanol,[14] bp 71—72°C/12 mmHg, 1-heptyl acetate,[15] bp 192°C.

General Procedure. A typical reaction procedure is shown in Table 1. A mixed solution of the substrate, acetic acid, water, the organic solvent, and potassium hydroxide was electrolyzed at Pt electrodes for about 210 hr at 25—35°C, with terminal voltage 14—16 V at a current of 1.2—2.4 A, magnetically stirring, and changing the current direction every 30 sec by means of a commutator. The resulting reaction mixture was diluted with 300 m*l* of water and extracted with ether. The extracts were washed with a saturated aqueous sodium chloride solution and concentrated *in vacuo*. The separation of the products was carried out in the manner shown in Scheme 1. The results of gas chromatography of each experiment are indicated in Tables 2 and 3. The isolation of enanthaldehyde ethyl hemiacetal from the non-ketone and non-aldehyde components through distillation failed. However, we succeeded in detecting the hemiacetal in the high-boiling fraction of the non-ketone and non-aldehyde components both spectroscopically and gas chromatographically: IR (cm^{-1}) 3500—3200 (OH) and 1120—1040 (hemiacetal); vpc with a 1 m, 10% silicone oil (SE-30) coated Chromosorb W (NAW) column operating at 140°C and 0.4 kg/cm^2 (N_2): Retention time 18 min.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1052—1059 (1969)

The Rotatory Dispersion and Stereochemistry of Organic Compounds. XV.[1] Nitrophenyl Glycosides

Yojiro Tsuzuki, Motoo Koyama, Kazuyuki Aoki, Tatsuo Kato and Koko Tanabe

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received September 17, 1968)

It has been reported that some ortho-nitrophenyl glycosides exhibit anomalous optical rotation (Montgomery *et al.*, *J. Am. Chem. Soc.*, **64**, 690 (1942)). To investigate this anomalous effect of the ortho-nitro group the authors have observed the RD spectra on twenty-five derivatives of *o*-nitrophenyl, *p*-nitrophenyl and phenyl glycosides. Every *o*-nitrophenyl derivative (I, IV, VII, XI, XIV, XVII and XX) exhibited a positive Cotton effect near 340 mμ. Furthermore, in order to inquire into this anomaly the authors have observed the CD and UV spectra of these compounds. It follows that the *o*-nitro group is twisted from the benzene ring plane, and that the *o*-nitrophenyl group itself becomes an optical active chromophore, so that the Cotton effects near 340 mμ are caused by the $n\rightarrow\pi^*$ transition of the nitro group. Therefore, the anomaly of *o*-nitrophenyl glycosides in the $[\alpha]_D$ values is concluded to be affected by the strong Cotton effect near 340 mμ.

In the previous paper[1] the rotatory contribution of the nitrophenyl group was reported with diethyl nitrobenzylidene-*d*-tartrates, where the compound with a nitro group in the ortho-position of the phenyl group shows an anomalous rotation in contrast with the corresponding meta and para nitro compounds, whose rotations are normal, and it was really found that the rotatory dispersion (RD) of the *o*-nitro-derivative exhibited such a strong positive Cotton effect near 340 mμ, so that it showed an anomalous rotation affected by the Cotton effect.

The anomaly of the optical rotation due to an *o*-nitro group can be seen in another group of compounds. While the specific rotation $[\alpha]_D$ has been observed with a large number of aryl glycosides,[2-5] only *o*-nitrophenyl glycosides show anomalous rotations, and are exceptions which do not obey the isorotation rule of Hudson.[2,6]

This paper will deal with the studies made with a view of inquiring into the anomalous rotation of *o*-nitrophenyl glycosides by comparing them with those of the tartrates. For that purpose the following twenty-five aryl glycosides have been investigated by means of RD, CD (circular dichroism), as well as UV (ultraviolet absorption) methods and in some cases with the help of NMR method.

Tetraacetyl *o*-nitrophenyl β-D-glucoside (Compound I),
Tetraacetyl *p*-nitrophenyl β-D-glucoside (Compound II),
Tetraacetyl phenyl β-D-glucoside (Compound III),
Tetraacetyl *o*-nitrophenyl β-D-galactoside (Compound IV),
Tetraacetyl *p*-nitrophenyl β-D-galactoside (Compound V),
Tetraacetyl phenyl β-D-galactoside (Compound VI),
Triacetyl *o*-nitrophenyl β-D-xyloside (Compound VII),
Triacetyl *p*-nitrophenyl β-D-xyloside (Compound VIII),
Tetraacetyl *p*-nitrophenyl α-D-glucoside (Compound IX),
Tetraacetyl phenyl α-D-glucoside (Compound X),
Tetraacetyl *o*-nitrophenyl α-D-galactoside (Compound XI),
Tetraacetyl *p*-nitrophenyl α-D-galactoside (Compound XII),
Tetraacetyl phenyl α-D-galactoside (Compound XIII),
o-Nitrophenyl β-D-glucoside (Compound XIV),
p-Nitrophenyl β-D-glucoside (Compound XV),
Phenyl β-D-glucoside (Compound XVI),

o-Nitrophenyl β-D-galactoside (Compound XVII), *p*-Nitrophenyl β-D-galactoside (Compound XVIII), Phenyl β-D-galactoside (Compound XIX), *o*-Nitrophenyl β-D-xyloside (Compound XX), *p*-Nitrophenyl β-D-xyloside (Compound XXI), *p*-Nitrophenyl α-D-glucoside (Compound XXII), Phenyl α-D-glucoside (Compound XXIII), Phenyl α-D-galactoside (Compound XXIV), and Tetraacetyl 4-nitro-3-methylphenyl β-D-glucoside (Compound XXV).

Results and Discussion

I. Acetylated Glycosides. *Acetylated o-Nitrophenyl β-Glycosides.* In Figs. 1—3 are shown the RD, CD and UV curves of acetyl *o*-nitrophenyl β-D-glucoside (I), -galactoside (IV) and -xyloside (VII). The RD curves of these compounds exhibit complex Cotton effects, the signs of which can be determined by the positive CD_{max} near 325 mμ. The peaks of the positive Cotton effects appear at 370—376 mμ. The two troughs observed at 300—305 mμ and 266—270 mμ can be regarded, in view of the CD curves, to be due to the two negative Cotton effects. As may be seen from Figs. 1 and 2 the UV absorption maxima appear near 255 mμ and 305 mμ.

Acetylated p-Nitrophenyl β-Glycosides. In Figs. 4 and 5 are exhibited the RD, CD and UV curves of tetraacetyl *p*-nitrophenyl derivatives, also showing complex Cotton effects, which are, however, opposite in sign to those of the *o*-nitrophenyl derivatives.

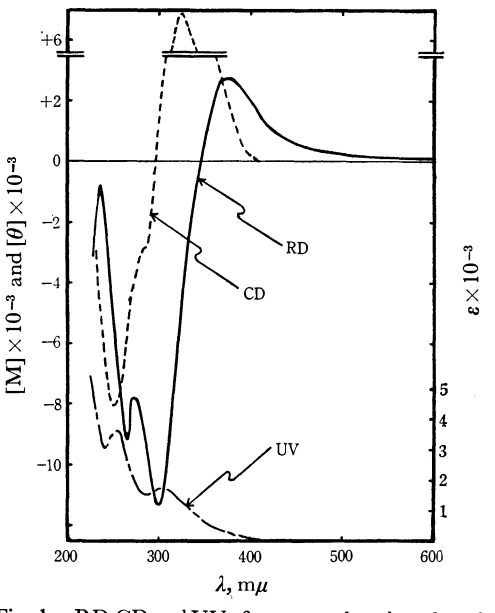

Fig. 1. RD,CD and UV of tetraacetyl *o*-nitrophenyl β-D-glucoside (I).

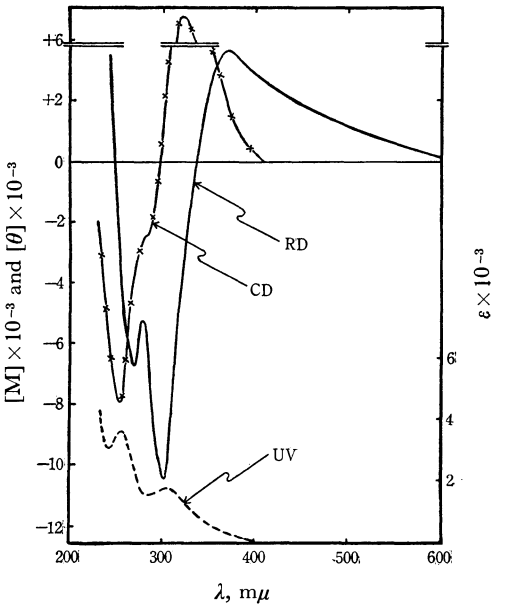

Fig. 2. RD, CD and UV of tetraacetyl *o*-nitrophenyl β-D-galactoside (IV).

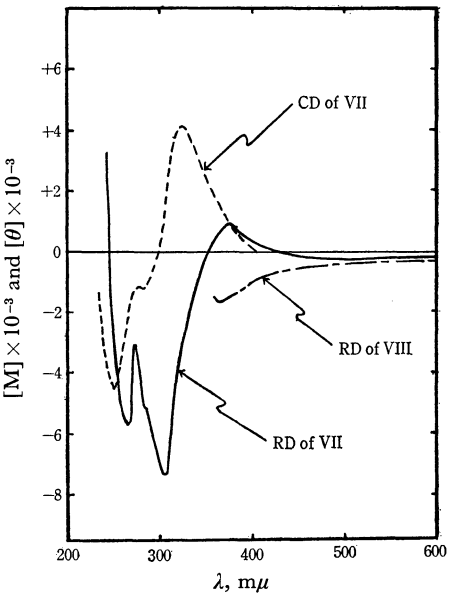

Fig. 3. RD and CD of triacetyl *o*-and *p*-nitrophenyl β-D-xylosides (VII and VIII).

The broad troughs of the RD curves of the compounds II and V may be due to their negative Cotton effects. The same interpretation is also valid for *p*-nitrophenyl xyloside (VIII, Fig. 3). The RD curves of the compounds II and V are, in the longer wavelength region, similar to those of their background compounds with no nitro group III and VI, which, however, exhibit below

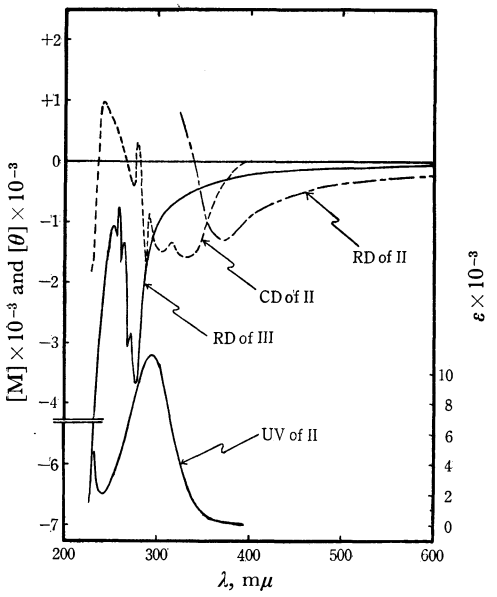

Fig. 4. RD, CD and UV of tetraacetyl aryl β-D-glucosides (II and III).

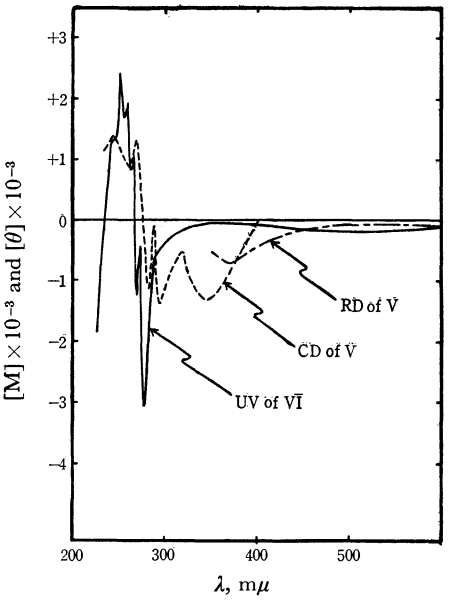

Fig. 5. RD and CD of tetraacetyl aryl β-D-galactoside (V and VI).

270 mμ negative Cotton effects due to the B-band of the phenyl group.

Acetylated o-Nitrophenyl α-Glycoside. Figure 6 represents the RD, CD and UV curves of tetraacetyl o-nitrophenyl α-D-galactoside (XI), where the RD curve shows a positive Cotton effect with a peak around 370 mμ, the shape of which is similar to that of the β-anomer (IV, Fig. 2).

The above stated facts indicate that the RD of

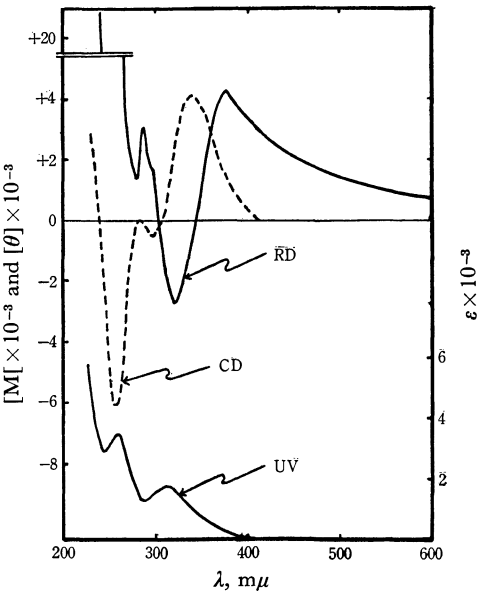

Fig. 6. RD, CD and UV of tetraacetyl o-nitrophenyl α-D-galactoside (XI).

acetylated o-nitrophenyl glycosides are not influenced by the C_1-configuration.

Acetylated p-Nitrophenyl α-Glycosides. The RD curves of tetraacetyl p-nitrophenyl α-D-glucoside (IX) and -galactoside (XII) are given respectively in Figs. 7 and 8. They run in the positive side, quite contrary to those of the β-anomers II and V (Figs. 4 and 5), and rather resemble those of the background RD curves X and XIII (Figs. 7 and 8), but, unlike II and V, show no distinct

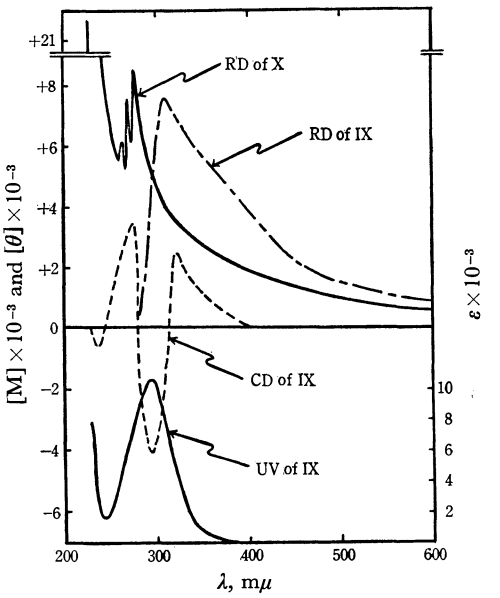

Fig. 7. RD, CD and UV of tetraacetyl aryl α-D-glucosides (IX and X).

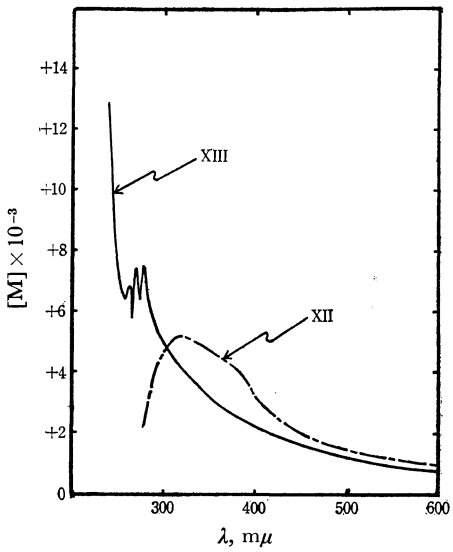

Fig. 8. RD of tetraacetyl aryl α-D-galactosides (XII and XIII).

peaks near 370 mμ, with only a slight shoulder around 370 mμ. This phenomenon can be interpreted as follows, namely, the weak Cotton effect has disappeared under the powerful influence of the strong, positive rotation of the background or of its strong Cotton effect in the shorter wavelength region.

As may be seen from Figs. 7 and 8, the background compounds X and XIII bearing no nitro group really exhibit positive RD curves with positive Cotton effects below 270 mμ attributed to the B-band. The curves contrast finely with the

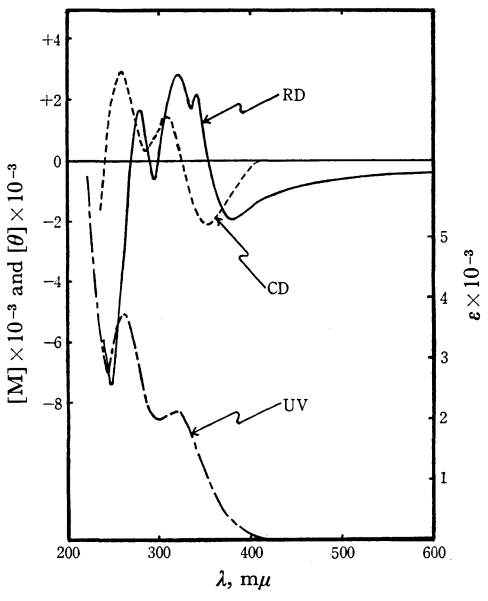

Fig. 9. RD, CD and UV of o-nitrophenyl β-D-glucoside (XIV).

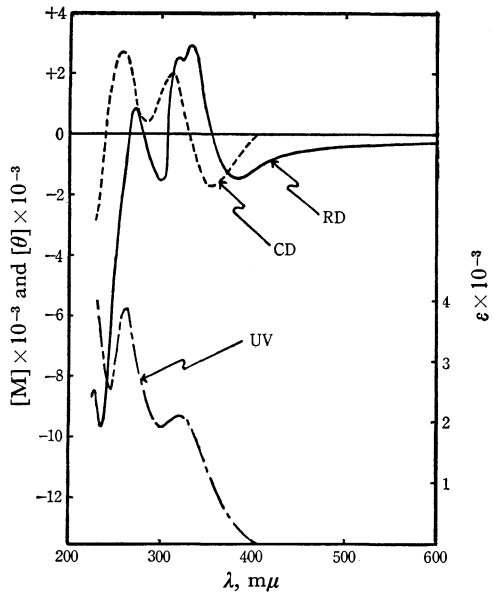

Fig. 10. RD, CD and UV of o-nitrophenyl β-D-galactoside (XVII).

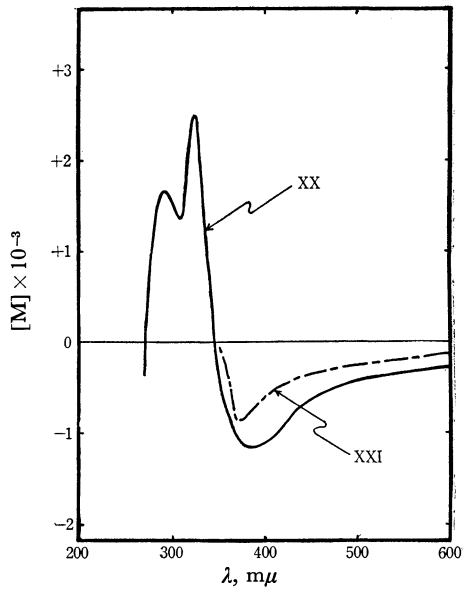

Fig. 11. RD of nitrophenyl β-D-xylosides (XX and XXI).

negative RD curves of the β-anomers III and VI (Figs. 4 and 5). The signs of the Cotton effects agreeing in all cases with the C_1-configurations.

II. Deacetylated Glycosides. *o-Nitrophenyl β-Glycosides.* In Figs. 9—11 are given the RD, CD and UV curves of o-nitrophenyl β-D-glucoside (XIV), -galactoside (XVII) and -xyloside (XX). Each RD curve shows a negative Cotton effect with a trough at 380 mμ. The strengths are estimated from the CD_{max} to be nearly 1/3 of those

of the acetylated derivatives (I and IV), so that these *o*-nitrophenyl β-glycosides show no anomaly in the values $[\alpha]_D$.

And further, these deacetylated *o*-nitrophenyl β-D-glycosides (XIV, XVII and XX) have two positive Cotton effects, as evidenced by the CD_{max} around 310 mμ and 260 mμ, the signs of the Cotton effects are all opposite to those of the corresponding acetylated derivatives (I and IV and VII) and their RD curves are diametrically opposite in each case.

p-Nitrophenyl β-Glycosides. The RD curves of *p*-nitrophenyl β-D-xyloside (XXI), -glucoside (XV) and -galactoside (XVIII) are shown respectively in Figs. 11, 12 and 13, the shapes of which are almost the same with the corresponding acetylated derivatives (VIII in Fig. 3, II in Fig. 4 and V in Fig. 5).

p-Nitrophenyl α-Glycoside. Figure 14 shows the RD, CD and UV curves of *p*-nitrophenyl α-D-glucoside (XXII). While the CD curve (XXII) is similar to that of the acetylated derivative (IX in Fig. 7), the RD curve has a peak around 370 mμ, which corresponds to the slight shoulders observed around 370 mμ in IX as well as in acetylated α-galactoside (XII in Fig. 8). It is to be noted that the RD curve of XII is diametrically symmetrical and opposite to that of the β-anomer (XV). It follows, therefore, that the α-anomer exhibits a positive Cotton effect and the β-anomer a negative one in acetylated as well as in deacetylated derivatives, although the acetyl group enhances the rotation to a certain extent.

Phenyl Glycosides. The CD curves of phenyl β-D-glucoside (XVI), -galactoside (XIX), and of their anomers XXIII znd XXIV are given in Figs. 12, 13 and 14. They all exhibit around 270 mμ Cotton effects due to the B-band, quite likewise the corresponding acetylated derivatives (III, VI, X and XIII), the signs of which are positive in the α-anomers and negative in the β-anomers in accordance with their C_1-configuration.

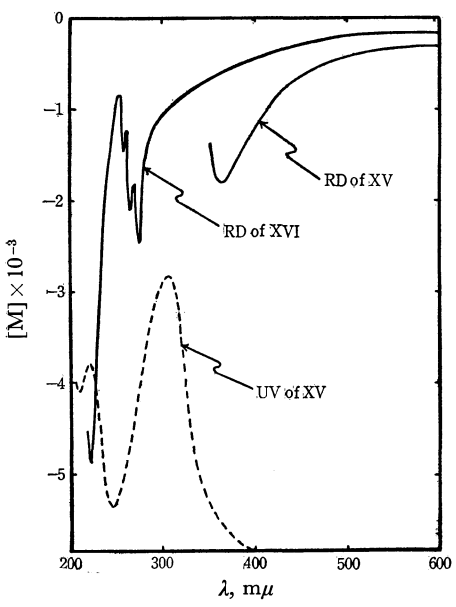

Fig. 12. RD and UV of aryl β-D-glucosides (XV and XVI).

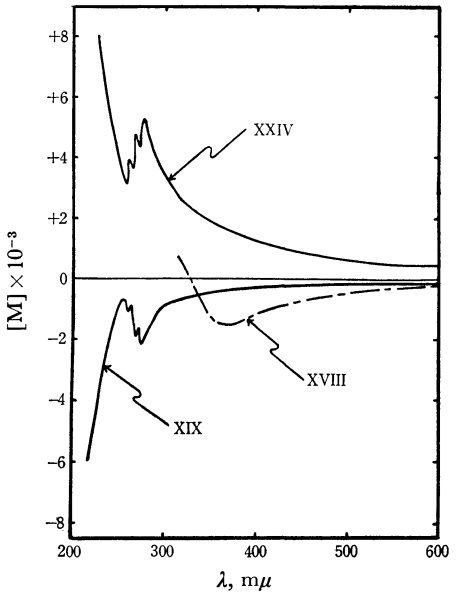

Fig. 13. RD of aryl α- and β-D-galactosides (XVIII, XIX and XXIV).

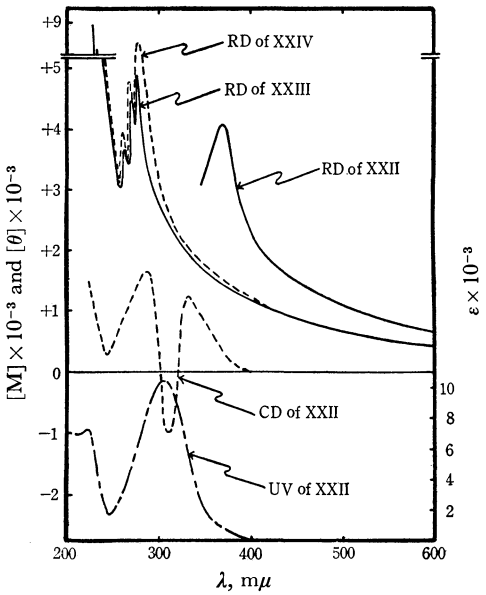

Fig. 14. RD, CD and UV of aryl α-D-glycosides (XXII, XXIII and XXIV).

General Considerations

In the first place the effect of *p*-nitrophenyl

group will be considered. In general the RD curves of *p*-nitrophenyl glycosides exhibit in the region 370—380 mμ more or less distinct Cotton effects or less slight shoulders. A most typical Cotton effect in this region can be seen in a *p*-nitrophenyl β-D-glucoside with an adjacent methyl group (XXV in Fig. 15).

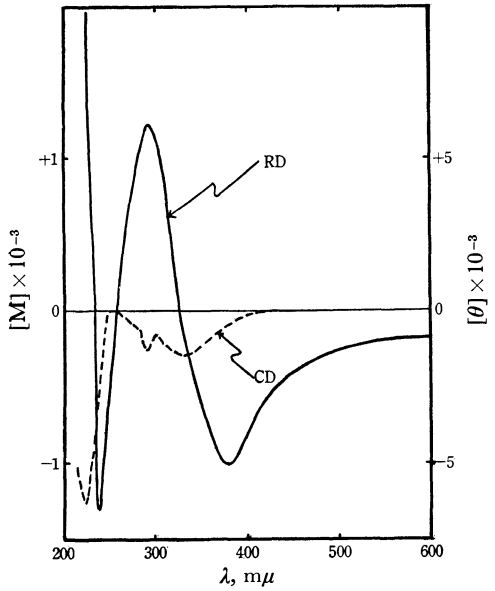

Fig. 15. RD and CD of tetraacetyl 4-nitro-3-methylphenyl glucoside (XXV).

Now, the effect of *o*-nitrophenyl derivatives will be taken into consideration.

The *o*-NO_2 group is regarded to be more twisted from the benzene ring than the *p*-NO_2 group, since the intensity of absorption due to the electronic transition in the molecule is decreased in the former than in the latter. This is evidenced in their UV curves. And since the sugar moiety possesses asymmetry, the nitrophenoxy group is expected to be an asymmetric chromophore in view of the difference in the degrees of twisting toward the right and the left sides.

In the next place, discussions will be made about the following notable facts that acetylated *o*-nitrophenyl glycosides exhibit positive Cotton effects around 340 mμ irrespective of the C_1 configuration, whereas the corresponding deacetylated compounds show negative Cotton effects.

In view of the possibility that the conformation of C_1 may be distorted by the presence of a large group such as *o*-nitrophenoxy group, the conformation of the anomer proton (H_1) has been investigated by means of NMR method.

As the authors' previous reports on the NMR spectra of aryl glycopyranosides,[7] similar results were obtained with tetraacetyl *o*-nitrophenyl galactosides (measured in $CDCl_3$), namely, the H_1 signal of α-galactoside (XI) appears at $\delta=5.89$ ppm, separated from the other signals and the coupling constant is 3.5 Hz, which shows that H_1 is equatorial.

On the other hand, the H_1 signal of β-galactoside (IV) is overlapped with those of H_2, H_3 and H_4, so that the coupling constant can not be obtained. However, since the H_1 signal appears in the magnetic field at least 0.4 ppm higher than in the α-type (XI), the H_1 of the β-glycoside can be concluded to be axial. By these NMR data it has become clear that the C_1-conformation is not distorted and that the anomaly of the *o*-nitro derivatives has another cause.

Hereupon the authors have investigated solvent effects on the optical rotation. In Table 1 are shown the data of studies on tetraacetyl nitrophenyl galactosides.

Table 1. The specific rotation of tetraacetyl nitrophenyl galactosides $\left([\alpha]_{400}^{23}\times\frac{3}{n^2+2}\right)$

Tetraacetyl nitrophenyl galactoside		in CH_3CN (1)	in *s*-$C_2H_4Cl_2$ (2)	(1)−(2)
o-NO_2	α-anomer	664°	544°	120°
	β-anomer	152°	264°	−112°
p-NO_2	α-anomer	507°	504°	3°
	β-anomer	− 83°	− 61°	− 22°

As may be seen in Table 1, the solvent effect is far greater with both the α- and β-anomers in *o*-NO_2 than in *p*-NO_2 derivative. This fact means that a certain interaction between the NO_2 group and the adjacent substituent exerts a significant influence on the optical activity. Furthermore, it is observed that the rotation of the α-anomer is raised with the greater polarity of the solvent, but with the β-anomer the relation is reversed. This indicates that the electrostatic action on the nitro group is in the opposite direction between the α- and β-anomers with respect to the rotation, and that the environment of the nitro group is quite different in the α- and β-anomers. Nevertheless, a series of Cotton effects at 260, 300 and 340 mμ are often nearly equal with the α- and β-anomers (for example, see IV in Fig. 2 and XI in Fig. 6), which suggests, however, that the direct factor making the *o*-nitrophenyl group to be anisotropic really lies in the chromophore. It is then conceivable that the direction of twisting of the nitro group due to a certain stabilized rotamer, one of the possible rotational isomers brought about by the rotation of the *o*-nitrophenoxy group determines the sign of the Cotton effect near 340 mμ, whose high peak affects the value of $[\alpha]_D$.

As to the attribution of the Cotton effects at 260, 300 and 340 mμ the reports of Burawoy *et al.*[8]

7) Y. Tsuzuki and K. Tanaka, This Bulletin, **40**, 1208 (1967).

may be taken into consideration, who observed the UV spectra of nitrophenols. In view of their wavelengths and intensities in absorption, the Cotton effect centered at 260 mμ may be attributed to the K-band of phenyl group, the one at 300—320 mμ to the B-band. And the Cotton effect in the longer wavelength region at 320—355 mμ can be attributed to the $n\rightarrow\pi^*$ transition of the nitro group, as reported in the previous paper.[1]

Finally, mention should be made that each of the derivatives lacking a nitro group (III, VI, X, XIII, XVI, XIX, XXIII and XXIV) exhibits a Cotton effect with a fine structure around 270 mμ irrespective of the presence of acetyl groups. The sign is invariably positive in the α-anomer, and negagive in the β-anomer. The Cotton effect is doubtlessly due to the benzenoid band, as may be evidenced in Fig. 16.

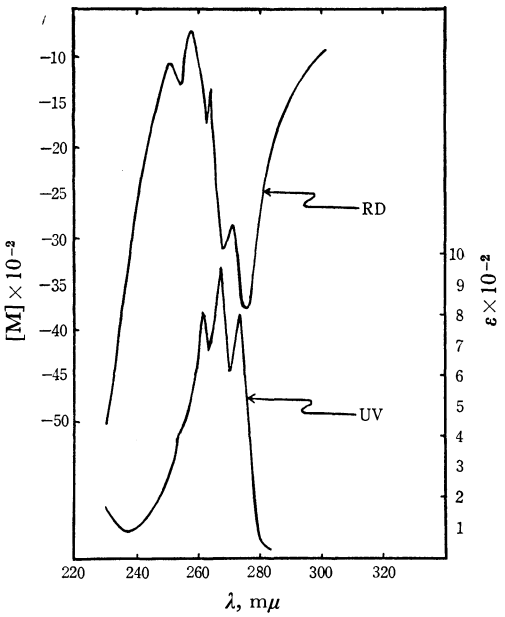

Fig. 16. RD and UV of tetraacetyl phenyl β-D-glucoside (III).

Experimental

The samples were prepared according to the methods described in the literature. The others were also synthesized in a similar way. The rotatory dispersion and the circular dichroism were measured in 1,2-dichloroethane and water at the temperature about 25°C in the wavelength region from 210 to 600 mμ with a JASCO optical rotatory dispersion recorder of the ORD/UV-5 type. The ultraviolet absorption was measured in 1,2-dichloroethane and water with a self-recording spectrophotometer of Hitachi EPU-II type. The NMR spectra were measured with a Varian A-60 spectrometer.

Tetraacetyl *o*-nitrophenyl β-D-glucoside (Compound I).[3] Yellowish needles; mp 159—160°C. The RD was measured at 25°C in 1,2-dichloroethane (*c* 1.152). $[\alpha]_{600}$ +10.0°, $[\alpha]_{589}$ +11.6°, $[\alpha]_{500}$ +44.3°, $[\alpha]_{400}$ +348°, $[\alpha]_{372}$ +591° (peak), $[\alpha]_{300}$ −2420° (trough), $[\alpha]_{274}$ −1660°, $[\alpha]_{266}$ −1950° (trough), $[\alpha]_{236}$ −145°, $[\alpha]_{228}$ −563°. The CD was measured at 25°C in 1,2-dichloroethane (*c* 0.550). $[\theta]_{410}$ +57°, $[\theta]_{324}$ +6920° (peak), $[\theta]_{288}$ −2650°, $[\theta]_{286}$ −2870°, $[\theta]_{284}$ −2870°, $[\theta]_{250}$ −8130° (trough), $[\theta]_{232}$ −2820°. The UV spectrum was measured at 25°C in 1,2-dichloroethane. ε_{max} 1700 at 305 mμ and ε_{max} 3600 at 256 mμ.

Tetraacetyl *p*-nitrophenyl β-D-glucoside (Compound II).[3] Yellowish needles; mp 174°C. The RD was measured at 25°C in 1,2-dichloroethane (*c* 0.906). $[\alpha]_{600}$ −46.3°, $[\alpha]_{589}$ −48.6°, $[\alpha]_{500}$ −75.1°, $[\alpha]_{400}$ −192°, $[\alpha]_{370}$ −285° (trough), $[\alpha]_{320}$ +179°. The CD was measured at 25°C in 1,2-dichloroethane (*c* 0.252). The UV spectrum was measured at 25°C in the same solvent. ε_{max} 11000 at 295 mμ.

Tetraacetyl phenyl β-D-glucoside (Compound III).[3] Colorless needles; mp 122—123°C. The RD was measured at 25°C (*c* 0.509). $[\alpha]_{600}$ −19.1°, $[\alpha]_{589}$ −19.8°, $[\alpha]_{500}$ −34.7°, $[\alpha]_{300}$ −219°, $[\alpha]_{276}$ −873° (trough), $[\alpha]_{271}$ −668°, $[\alpha]_{268}$ −739°, $[\alpha]_{264}$ −311°, $[\alpha]_{263}$ −408°, $[\alpha]_{258}$ −165° (peak), $[\alpha]_{250}$ −266°, $[\alpha]_{226}$ −1590°.

Tetraacetyl *o*-nitrophenyl β-D-galactoside (Compound IV).[9] Yellowish prisms; mp 171—172°C. The RD was measured at 25°C (*c* 1.072). $[\alpha]_{600}$ +37.4°, $[\alpha]_{589}$ +56.7°, $[\alpha]_{500}$ +224°, $[\alpha]_{400}$ +597°, $[\alpha]_{370}$ +785° (peak), $[\alpha]_{350}$ +463°, $[\alpha]_{302}$ −2240° (trough), $[\alpha]_{280}$ −1120°, $[\alpha]_{270}$ −1440° (trough), $[\alpha]_{240}$ +1180°. The CD was measured at 25°C (*c* 0.254). $[\theta]_{400}$ +73.1°, $[\theta]_{322}$ +6760° (peak), $[\theta]_{286}$ −2250°, $[\theta]_{284}$ −2440°, $[\theta]_{282}$ −2500°, $[\theta]_{252}$ −7920° (trough), $[\theta]_{230}$ −1950°. The UV maxima were ε_{max} 1700 at 306 mμ and 3500 at 255 mμ.

Tetraacetyl *p*-nitrophenyl β-D-galctoside (Compound V).[9] Yellowish needles; mp 144°C. The RD was measured at 25°C (*c* 1.024). $[\alpha]_{600}$ −4.89°, $[\alpha]_{589}$ −4.28°, $[\alpha]_{500}$ −9.18°, $[\alpha]_{400}$ −89.9°, $[\alpha]_{370}$ −149° (trough), $[\alpha]_{356}$ −140°. The CD was measured at 25°C (*c* 0.280), $[\theta]_{400}$ −11.1°, $[\theta]_{340}$ −1320° (trough), $[\theta]_{294}$ −1440° (trough), $[\theta]_{288}$ 0°, $[\theta]_{282}$ −1770° (trough), $[\theta]_{268}$ +1330°, $[\theta]_{232}$ +1110°.

Tetraacetyl phenyl β-D-galactoside (Compound VI).[10] Colorless needles; mp 122—123°C. The RD was measured at 25°C (*c* 0.540). $[\alpha]_{600}$ +8.23°, $[\alpha]_{589}$ +7.43°, $[\alpha]_{500}$ +4.53°, $[\alpha]_{400}$ +12.5°, $[\alpha]_{300}$ −43.4°, $[\alpha]_{278}$ −709° (trough), $[\alpha]_{272}$ −60.8°, $[\alpha]_{270}$ −281° (trough), $[\alpha]_{266}$ +315°, $[\alpha]_{263}$ −211° (trough), $[\alpha]_{258}$ +497°, $[\alpha]_{256}$ +432° (trough), $[\alpha]_{252}$ +613°, $[\alpha]_{226}$ −411°.

Triacetyl *o*-nitrophenyl β-D-xyloside (Compound VII).[3] Yellowish prisms; mp 111—112°C. The RD was measured at 25°C (*c* 1.420). $[\alpha]_{600}$ −49.4°, $[\alpha]_{589}$ −50.6°, $[\alpha]_{500}$ −53.5°, $[\alpha]_{400}$ +92.8°, $[\alpha]_{376}$ +228° (peak), $[\alpha]_{306}$ −1850° (trough), $[\alpha]_{274}$ −760° (peak), $[\alpha]_{266}$ −1440° (trough), $[\alpha]_{244}$ +836°. The CD was measured at 25°C (*c* 0.259). $[\theta]_{400}$ +50.6°, $[\theta]_{324}$ +413° (peak), $[\theta]_{300}$ +506°, $[\theta]_{284}$ −1210° (trough),

$[\theta]_{280}$ −1110°, $[\theta]_{254}$ −4500° (trough), $[\theta]_{236}$ −1370°.

Triacetyl *p*-nitrophenyl β-D-xyloside (Compound VIII). Yellowish prisms; 137—138°C. The RD was measured at 25°C (*c* 1.051). $[\alpha]_{600}$ −70.3°, $[\alpha]_{589}$ −71.3°, $[\alpha]_{500}$ −107°, $[\alpha]_{400}$ −249°, $[\alpha]_{366}$ −431°, $[\alpha]_{360}$ −375°.

Tetraacetyl *p*-nitrophenyl α-D-glucoside (Compound IX).[2] Colorless needles; mp 109—110°C. The RD was measured at 25°C (*c* 0.985). $[\alpha]_{600}$ +198°, $[\alpha]_{589}$ +209°, $[\alpha]_{500}$ +329°, $[\alpha]_{400}$ +816°, $[\alpha]_{370}$ +1050°, $[\alpha]_{360}$ +1140°, $[\alpha]_{350}$ +1210°, $[\alpha]_{308}$ +1640° (peak), $[\alpha]_{260}$ −264°, $[\alpha]_{230}$ +1190°. The CD was measured at 25°C (*c* 0.270). $[\theta]_{400}$ +57.3°, $[\theta]_{323}$ +2470°, $[\theta]_{293}$ −4180°, $[\theta]_{276}$ +3140°, $[\theta]_{250}$ +803°, $[\theta]_{230}$ −493°, $[\theta]_{220}$ 0°. The UV maximum ε_{max} was 11000 at 294 mμ.

Tetraacetyl phenyl α-D-glucoside (Compound X).[2] Colorless needles; mp 114°C. The RD was measured at 25°C (*c* 0.517). $[\alpha]_{600}$ +143°, $[\alpha]_{589}$ +151°, $[\alpha]_{500}$ +233°, $[\alpha]_{276}$ +1990° (peak), $[\alpha]_{273}$ +1430°, $[\alpha]_{270}$ +1780°, $[\alpha]_{266}$ +1230° (trough), $[\alpha]_{262}$ +1430°, $[\alpha]_{260}$ +1300°, $[\alpha]_{256}$ +1430°, $[\alpha]_{254}$ +1430°, $[\alpha]_{226}$ +5130°.

Tetraacetyl *o*-nitrophenyl α-D-galactoside (Compound XI). Yellowish prisms; mp 170.5—171°C. The RD was measured at 25°C (*c* 0.985). $[\alpha]_{600}$ +147°, $[\alpha]_{589}$ +157°, $[\alpha]_{500}$ +280°, $[\alpha]_{400}$ +700°, $[\alpha]_{376}$ +910° (peak), $[\alpha]_{320}$ −593° (trough), $[\alpha]_{290}$ +661° (peak), $[\alpha]_{280}$ +284° (trough), $[\alpha]_{240}$ +4420°. The CD was measured at 25°C (*c* 0.247). $[\theta]_{400}$ +313°, $[\theta]_{338}$ +4140° (peak), $[\theta]_{298}$ −576° (trough), $[\theta]_{284}$ 0°, $[\theta]_{282}$ 0°, $[\theta]_{280}$ −75.2°, $[\theta]_{256}$ −6140° (trough), $[\theta]_{230}$ +2760°. The UV maxima ε_{max} were 1800 at 314 mμ and 3500 at 258 mμ.

Tetraacetyl *p*-nitrophenyl α-D-galactoside (Compound XII). Colorless needles; mp 131—132°C. The RD measured at 25°C (*c* 0.955). $[\alpha]_{600}$ +209°, $[\alpha]_{589}$ +218°, $[\alpha]_{500}$ +308°, $[\alpha]_{400}$ +612°, $[\alpha]_{380}$ +815°, $[\alpha]_{350}$ +747°.

Tetraacetyl phenyl α-D-galactoside (Compound XIII). Colorless needles; mp 128—129°C. The RD was measured at 25°C (*c* 0.553). $[\alpha]_{600}$ +170°, $[\alpha]_{589}$ +177°, $[\alpha]_{500}$ +264°, $[\alpha]_{400}$ +496°, $[\alpha]_{300}$ +1160°, $[\alpha]_{278}$ +1770° (peak), $[\alpha]_{274}$ +1570°, $[\alpha]_{238}$ +3020°.

o-Nitrophenyl β-D-glucoside (Compound XIV). Yellowish crystals; mp 198°C. The RD was measured at at 25°C in water (*c* 0.676). $[\alpha]_{600}$ −108°, $[\alpha]_{589}$ −114°, $[\alpha]_{500}$ −179°, $[\alpha]_{400}$ −489°, $[\alpha]_{379}$ −640° (trough), $[\alpha]_{350}$ +228°, $[\alpha]_{320}$ +979° (peak), $[\alpha]_{296}$ −211° (trough), $[\alpha]_{278}$ +560° (peak), $[\alpha]_{248}$ −2460°, $[\alpha]_{240}$ −1830°. The CD was measured at 25°C in water (*c* 0.253). $[\theta]_{400}$ −157°, $[\theta]_{354}$ −2070° (trough), $[\theta]_{350}$ −2040°, $[\theta]_{306}$ +1492° (peak), $[\theta]_{284}$ +314°, $[\theta]_{260}$ +2980° (peak), $[\theta]_{234}$ −1570°. The UV was measured at 22°C in water; ε_{max} was 2100 at 320 mμ and 3800 at 260.4 mμ.

p-Nitrophenyl β-D-glucoside (Compound XV). Colorless needles; mp 163°C. The RD was measured at 25°C in water (*c* 1.150). $[\alpha]_{600}$ −96.3°, $[\alpha]_{589}$ −103°, $[\alpha]_{500}$ −154°, $[\alpha]_{370}$ −609° (trough), $[\alpha]_{314}$ +1140°, $[\alpha]_{300}$ +1060°. The UV spectrum was measured at 22°C in water. The maxima ε_{max} were 8900 at 304 mμ and 6100 at 222 mμ.

Phenyl β-D-glucoside (Compound XVI).[11] White needles; mp 171—172°C. The RD was measured at 25°C in water (*c* 0.600). $[\alpha]_{600}$ −73.4°, $[\alpha]_{589}$ −74.8°, $[\alpha]_{500}$ −110°, $[\alpha]_{300}$ −470°, $[\alpha]_{275}$ −1130° (trough), $[\alpha]_{270}$ −810°, $[\alpha]_{267}$ −930°, $[\alpha]_{263}$ −530°, $[\alpha]_{261}$ −650°, $[\alpha]_{254}$ −370° (peak), $[\alpha]_{222}$ −2170°, $[\alpha]_{220}$ −1990°.

o-Nitrophenyl β-D-galactoside (Compound XVII).[9] Yellowish needles; mp 191—192°C. The RD was measured at 25°C (*c* 0.995). $[\alpha]_{600}$ −65.9°, $[\alpha]_{589}$ −66.7°, $[\alpha]_{500}$ −115°, $[\alpha]_{400}$ −392°, $[\alpha]_{382}$ −499° (trough), $[\alpha]_{334}$ +984° (peak), $[\alpha]_{324}$ +791°, $[\alpha]_{322}$ +841°, $[\alpha]_{300}$ −505° (trough), $[\alpha]_{274}$ +286° (peak), $[\alpha]_{234}$ −3170°, $[\alpha]_{230}$ −2810°, $[\alpha]_{228}$ −2910°. The CD was measured at 25°C (*c* 0.252). $[\theta]_{400}$ −78.8°, $[\theta]_{356}$ −1660° (trough), $[\theta]_{308}$ +1970° (peak), $[\theta]_{280}$ +552°, $[\theta]_{260}$ +2760°, $[\theta]_{240}$ 0°, $[\theta]_{234}$ −2050°, $[\theta]_{228}$ −2520°.

p-Nitrophenyl β-D-galactoside (Compound XVIII). yellowish needles; mp 162—163°C. The RD was measured at 25°C (*c* 0.727). $[\alpha]_{600}$ −77.7°, $[\alpha]_{589}$ −105°, $[\alpha]_{500}$ −164°, $[\alpha]_{400}$ −378°, $[\alpha]_{366}$ −551° (trough), $[\alpha]_{320}$ −105°, $[\alpha]_{270}$ −522°, $[\alpha]_{230}$ −1710°.

Phenyl β-D-galactoside (Compound XIX).[10] Colorless crystals; mp 144°C. The RD was measured at 25°C (*c* 0.484). $[\alpha]_{600}$ −41.1°, $[\alpha]_{589}$ −42.3°, $[\alpha]_{450}$ −82.8°, $[\alpha]_{300}$ −343°, $[\alpha]_{275}$ −965°, $[\alpha]_{274}$ −912°, $[\alpha]_{272}$ −1110° (trough), $[\alpha]_{271}$ −591°, $[\alpha]_{270}$ −815°, $[\alpha]_{266}$ −788°, $[\alpha]_{263}$ −314° (peak), $[\alpha]_{260}$ −443°, $[\alpha]_{256}$ −244°, $[\alpha]_{220}$ −255°.

o-Nitrophenyl β-D-xyloside (Compound XX). Yellowish needles; mp 166—167°C. The RD was measured at 22°C (*c* 0.150). $[\alpha]_{700}$ −66.0°, $[\alpha]_{589}$ −98.7°, $[\alpha]_{500}$ −144°, $[\alpha]_{410}$ −275°, $[\alpha]_{380}$ −418° (trough), $[\alpha]_{325}$ +868° (peak), $[\alpha]_{310}$ +468°, $[\alpha]_{280}$ +1230°, $[\alpha]_{270}$ −92.0°.

p-Nitrophenyl β-D-xyloside (Compound XXI). Yellowish needles; mp 156—157°C. The RD was measured at 22°C (*c* 0.249). $[\alpha]_{600}$ −38.6°, $[\alpha]_{589}$ −55.4°, $[\alpha]_{500}$ −83.5°, $[\alpha]_{380}$ −266°, $[\alpha]_{370}$ −284°.

p-Nitrophenyl α-D-glucoside (Compound XXII). Yellowish needles; mp 216—217°C. The RD was measured at 25°C (*c* 0.249). $[\alpha]_{600}$ +223°, $[\alpha]_{589}$ +232°, $[\alpha]_{500}$ +346°, $[\alpha]_{400}$ +721°, $[\alpha]_{370}$ +1350°, $[\alpha]_{350}$ +1030°, $[\alpha]_{330}$ +2540°, $[\alpha]_{320}$ +1410°. The CD was measured at 25°C (*c* 0.302). $[\theta]_{400}$ +65.8°, $[\theta]_{326}$ +888°, $[\theta]_{310}$ −1010°, $[\theta]_{268}$ +1610°, $[\theta]_{242}$ +296°, $[\theta]_{224}$ +1380°. The UV maxima ε_{max} were 10000 at 306 mμ and 6100 at 222 mμ.

Phenyl α-D-glucoside (Compound XXIII). Colorless needles; mp 153—154°C. The RD was measured at 25°C (*c* 0.522). $[\alpha]_{600}$ +180°, $[\alpha]_{589}$ +190°, $[\alpha]_{500}$ +284°, $[\alpha]_{400}$ +507°, $[\alpha]_{300}$ +1170°, $[\alpha]_{276}$ +2180° (peak), $[\alpha]_{272}$ +1760°, $[\alpha]_{270}$ +1990°, $[\alpha]_{266}$ +1490°, $[\alpha]_{263}$ +1650°, $[\alpha]_{259}$ +1350° (trough), $[\alpha]_{250}$ +1630°, $[\alpha]_{228}$ +3930°.

Phenyl α-D-galactoside (Compound XXIV). Colorless needles; mp 96—97°C. The RD was measured at 25°C in water (*c* 0.543). $[\alpha]_{600}$ +188°, $[\alpha]_{589}$ +195°, $[\alpha]_{500}$ +298°, $[\alpha]_{300}$ +1280°, $[\alpha]_{276}$ +2390° (peak), $[\alpha]_{272}$ +1850°, $[\alpha]_{270}$ +2120°, $[\alpha]_{266}$ +1590°, $[\alpha]_{262}$ +1770°, $[\alpha]_{259}$ +1360° (trough), $[\alpha]_{256}$ +3500°, $[\alpha]_{230}$ +3580°.

Tetraacetyl 4-nitro-3-methylphenyl β-D-glucoside Compound XXV). Colorless needles; mp 138°C. The RD and CD were measured at 25°C in 1,2-dichloroethane (*c* 0.486). $[\alpha]_{600}$ −31°, $[\alpha]_{500}$ −54°, $[\alpha]_{400}$ −168°, $[\alpha]_{380}$ −205° (trough), $[\alpha]_{290}$ +248° (peak), $[\alpha]_{240}$ −269° (trough), $[\alpha]_{220}$ +1490°. $[\theta]_{420}$ 0°, $[\theta]_{330-320}$ −1478°, $[\theta]_{300}$ −800°, $[\theta]_{290}$ −1313°, $[\theta]_{260-250}$ 0°, $[\theta]_{220}$ −5580°.

The Insertion Reaction of Propylene into Metal-Ethyl Bonds in the Ziegler-Natta Catalyst

Yoshinobu TAKEGAMI, Toshimitsu SUZUKI and Takuya OKAZAKI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received June 30, 1968)

The insertion reaction of propylene into metal-ethyl bonds in $TiCl_4$-$AlEt_3$, $TiCl_3$-$AlEt_3$, $TiCl_3$-$AlEt_2Cl$, and $TiCl_3$-$ZnEt_2$ catalyst systems was studied. The insertion products were converted to the corresponding hydrocarbons by methanolysis, and then analysed by gas-liquid chromatography. From these hydrocarbons, the following three metal alkyls were considered to be formed in the reaction system;

M–C–C–Et (I), M–C–C–Et (II), and M–C–C–C–C–Et (III).
C C C C

These metal alkyls were formed in the solid phase of the catalyst at first and were then transferred to the liquid phase of the catalyst. The amount of the metal alkyls formed in the reaction system was dependent on the catalytic system used. The active polymerization system $TiCl_3$-$AlEt_3$ gave a very small amount of metal alkyls, but the less active $TiCl_3$-$ZnEt_2$ and -$AlEt_2Cl$ systems gave a much greater quantity of the metal alkyls, (I) and (III). In the case of the $TiCl_4$-$AlEt_3$ system, metal alkyl formation was much affected by the Al/Ti molar ratio and the reaction time. Finally, it was concluded that the metal alkyls formed in the system were connected to the polymerization of propylene.

The initiation reaction of the Ziegler-Natta polymerization of α-olefins is considered to be the insertion reaction of the olefin into a metal-alkyl bond in the catalyst.[1] Only a few workers have however, studied the insertion reaction of olefins into metal-alkyl bonds in Ziegler-type catalysts. Vries studied the reaction of isobutene with methyltitanium trichloride. Isobutene was not polymerised by this catalyst, but the formation of neopentane was observed after the hydrolysis of the reaction mixture. In the case of ethylene, no insertion products were obtained and only high-molecular-weight polyethylene was obtained.[2] Azuma and his co-workers found that propylene was formed by the reaction of ethylene with bis(cyclopentadienyl)dimethyltitanium.[3] Shilov studied the reaction of heptene-1 with a soluble Ziegler catalyst ($(C_5H_5)_2TiCl_2$-$AlMe_3$) to give 2-methylheptene-1.[4]

These results apparently indicate that the insertion reaction of olefins into alkyl-titanium bonds occurs.

The present study deals with the insertion reaction of propylene in the presence of active polymerization catalysts, and discusses the course of metal-alkyl formation.

Experimental

Material. The titanium trichloride (HA grade; hydrogen-reduced $TiCl_4$ and activated by grinding) was obtained from the Stauffer Chemical Co. The titanium tetrachloride was distilled in the presence of a small amount of copper powder under an argon atmosphere.

The alkylaluminum compounds were obtained from the Ethyl Corporation and were used without further purification. The decalin was twice distilled under reduced pressure (bp 70—75°C/25 mmHg).

Reaction Procedure. A three-necked flask was equipped with a magnetic stirrer, a gas inlet, a self-sealing rubber cap, and a gas outlet connected to a mercury manometer and a vacuum system. The gas inlet was connected with a line for propylene, argon, or hydrogen.

To the reaction flask flushed with argon, titanium trichloride, a solvent, and an alkylaluminum compound were added in this order. The catalyst mixture was aged for ten minutes at a certain temperature, the

remaining argon was pumped off, and propylene was introduced to start the reaction. After a certain reaction time, the residual propylene was pumped off and the reaction mixture was cooled to −70°C to prevent any unexpected side reactions (isomerization or a transfer reaction). The reaction mixture was then transferred to the precipitation tube, which had previously been purged by argon, under an argon atmosphere, and separated into solids (titanium trichloride and an insoluble polymer) and liquids (the solvent and alkylaluminum compounds) by means of a centrifuge.

The two phases thus obtained were treated with cold methanolic hydrochloric acid. By this treatment the metal-alkyl bonds formed in the system were converted to the corresponding hydrocarbons. The polymers were filtered off, and the filtrate was subjected to gas-chromatographic analysis.

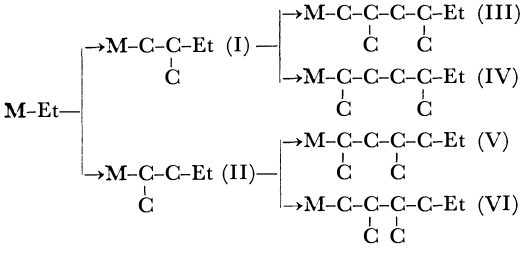
A Hitachi model F6D gas-liquid chromatograph equipped with a hydrogen flame ionization detector was employed for the quantitative and qualitative analyses of the reaction products. The operating conditions are presented below:

Column	Golay Z45 (SE30)	Golay R45 (PEG)
Size	0.5 mmϕ × 45 m	0.25 mmϕ × 45 m
Temperature	40°C	60°C
N_2 flow rate	1.5 ml/min	0.6 ml/min
Split ratio	1/80	1/150
Sample size	2μl	5μl

Results and Discussion

It is well known that the titanium on the solid surface of the Ziegler-Natta catalyst is ethylated and complexed with alkylaluminum compounds.[5] This metal-ethyl bond is considered to be very reactive, and olefins are easily inserted.

The insertion processes of propylene into metal-ethyl bonds may be formulated as follows:



From the end-group analysis of a polymer chain, using ^{14}C-labeled triethylaluminum with titanium trichloride catalyst, it has been said that one end of the polymer chain is an ethyl group,[6] while the other end is a vinylidene double bond as a result of chain transfer to the monomer.[7] These findings lead to the conclusion that the polymerization may proceed *via* primary metal alkyls, (I), (III), and so on.

Identification of the Products. The metal alkyls (I)—(VI) in the catalyst system were converted to the corresponding saturated hydrocarbons by the methanolysis of the reaction mixture. These hydrocarbons were analysed by gas chromatography.

First of all, as a blank test, the catalyst mixture itself ($TiCl_3$-$AlEt_3$ or $TiCl_4$-$AlEt_3$) was decomposed by methanol and then gas-chromatographed. Besides ethane (from ethylaluminum), several small peaks were observed; these were considered to be ethylene oligomers. Three small peaks, which have retention times of 4—5 min were also observed; these have the same retention times as those of isopentane, *n*-pentane, and isopropyl chloride respectively. However, the concentrations of these products were too low for them to be identified more precisely. After the reaction with propylene, three rather remarkable peaks and complex peaks (CP) with retention times of 25—27 min were observed. These peaks were absent in the propylene-free system. Mixing with authentic samples confirmed the formation of isopentane, *n*-pentane, and 2,4-dimethyl-hexane. These hydrocarbons correspond to the methanolysis products of the metal alkyls (I), (II), and (III) respectively. The possibilities of the formation of the metal alkyls (IV), (V), and (VI) were carefully examined in the region of (CP). However, these hydrocarbons were not detected by the gas chromatography.

In the presence of aluminum trichloride, propylene gave many C_6-C_8 hydrocarbons, some of which were also observed in the case of titanium-containing catalyst systems. (CP) seemed to be the products from propylene in the presence of a cationic catalyst. This is also supported by the fact that the more acidic $TiCl_4$-containing system gave much (CP).

$TiCl_4$-$AlEt_3$ System. In this catalyst system the polymerization activity of propylene is remarkably affected by the molar ratio of Al/Ti.[8] The amount of the metal alkyls formed in the initial stage (3 or 15 min) is plotted against the molar ratio of Al/Ti in Fig. 1. At 3 min, the quantity of metal alkyls reached a maximum at the Al/Ti molar ratio of 2.0. At 15 min, however, we could not observe the maximum of the metal-alkyl formation at the Al/Ti molar ratio of 2.0. The amounts of the metal alkyls (I) and (III) are almost parallel at any Al/Ti molar ratio at each reaction time.

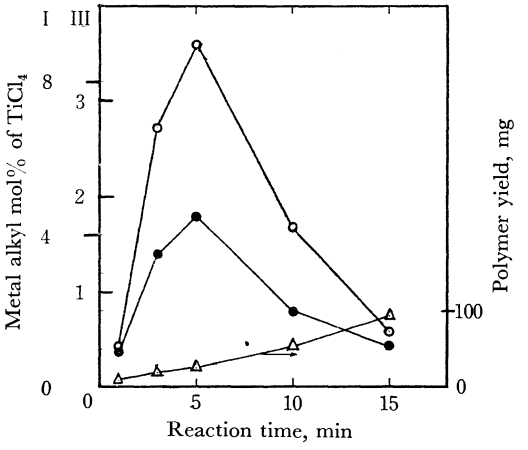

Fig. 2. Metal alkyls *vs.* reaction time.
○ metal alkyl (I) ● metal alkyl (III)

The influence of the reaction time on the course of metal-alkyl formation at the Al/Ti molar ratio of 2.0 is shown in Fig. 2. The amount of the metal alkyls in the solid phase reaches a maximum after about 5 min and then gradually decreases, while the yield of the isotactic polymer increases. In this system transfer reactions of metal alkyls in the solid phase to the liquid phase were also observed (see the next section).

In this catalyst system, the formation of the primary metal alkyls (I) and (III) was observed, while the formation of secondary metal alkyls or cross-inserted metal alkyls was not observed. On the other hand, the insertion reactions of such internal olefins as cyclohexene[9] or pentene-2[10] into metal-ethyl bonds in the Ziegler-Natta catalyst occur under severe conditions. Therefore, we can not rule out the possibility of the formation of secondary metal alkyls in the course of the propylene polymerization; actually, a small amount of the secondary metal alkyl (II) was indeed found in the propylene-polymerization system. Therefore, it becomes an important problem which of these metal alkyls is connected with the isotactic polymerization of propylene.

The behavior of the primary metal alkyls, (I) and (III), in Fig. 2 quite resembles that of the intermediate of a successive reaction. The decrease in metal alkyls with an increase in the reaction time may show that propylene is inserted into these metal alkyls and that the regeneration of these metal alkyl slows or the quantity of metal-ethyl bonds decreases. The same phenomenon was observed in the insertion reaction of isoprene into the metal-ethyl bonds in the $TiCl_4$-$AlEt_3$ catalyst system.[11]

The results obtained from the variation in the Al/Ti molar ratio can be explained by the fact that, at the Al/Ti molar ratio of 1.0, the rate of the insertion reaction of propylene into the metal-ethyl bond and into the metal alkyl (I) is slower than that at the Al/Ti molar ratio of 2.0. The maximum amount of these metal alkyls is about 10 mol% of the titanium used; if all of these metal alkyls are intermediates of the polymerization, this value is too large. As will be discussed below, some of them must be deactivated by being transferred to alkyl-aluminum compounds in the liquid phase and contaminated with an insoluble polymer in the solid phase.

The isotacticity of the polymer obtained in this catalyst system is 50 to 60%. However, no formation of corss-inserted metal alkyls (IV or VI) was detected. This shows the good selectivity of an olefin orientation to a metal-alkyl bond. In the present study we have paid close attention to the structure of the metal alkyls; as Natta has pointed out,[12] the stereospecificity are not a structural problem but a configurational problems in the metal alkyls. Therefore, our findings are not inconsistent with the fact that even in the case of a low-stereospecific catalyst, no cross-inserted metal alkyls were found.

$TiCl_3$-$AlEt_3$ System. In our experiments the

rate of the polymerization is almost constant throughout the reaction, and no deactivation of the catalyst is observed.[13] The concentration of the metal alkyls is higher in the solid phase than in the liquid phase. The metal aklyls in the liquid phase are considered to be as a result of the chain-transfer reaction of the metal alkyls formed in the solid phase to alkylaluminum compounds in the liquid phase. This consideration is supported by the fact that after the catalyst mixture had been separated by a centrifuge, and after to the liquid phase thus obtained, propylene had been added and the mixture had then been treated with methanol and submitted to analysis, no metal alkyl formation was observed. The role of metal-ethyl bonds in the solid phase was examined. The solid phase of the catalyst was washed with decalin and centrifuged three times to remove alkylaluminum compounds and then to this solid phase decalin and propylene was added. After the methanolysis small amounts of polypropylene and the metal alkyl (I) were observed in the solid phase of the reaction mixture, but the metal alkyl (III) was not found. These findings indicate that the amount of the metal alkyl (I) in the solid phase is connected with the polymerization.

In Tables 1 and 2 the effect of the Al/Ti molar ratio and the reaction time on the amounts of the metal alkyls is shown. The Al/Ti molar ratio has little effect on the formation of metal alkyls. The metal alkyls do, however, increase slightly with an increase in the reaction time. Usually a few more metal alkyls are found in this system than in the $TiCl_4$-$AlEt_3$ system. This may be attributed to the low concenentration of the metal-ethyl bond and to the higher propagation rate. The $TiCl_3$-$AlEt_3$ system gives a polymer with a molecular weight of 400000 in a 1-min reaction, while the $TiCl_4$-$AlEt_3$ system gives only a 50000-molecular-weight polymer under the same conditions.

$TiCl_3$-$AlEt_3$-H_2 System. The addition of hydrogen to the Natta catalyst caused a remarkable reduction in the molecular weight of the polymer, suggesting that a chain termination by the hydrogenolysis of metal-polymer bonds occurred. The amount of metal alkyls in the solid phase increased slightly upon the addition of hydrogen, as is shown in Table 3. In this case much isopentane and much 2,4-dimethylhexane were observed in the liquid phase, suggesting that the metal alkyls formed are decomposed by hydrogen before methanolysis.

The increase in the amount of the metal alkyls in the solid phase compared to that in the hydrogen-free system may be attributed to the decrease in the propagation rate and to the contamination of the liberated hydrocarbons in the solid phase.

$TiCl_3$-$AlEt_2Cl$ System. In this catalyst system, the so-called settling time[14] was observed. During the settling period the amount of the metal alkyls in the system (in both the liquid and the solid phase) increased with an increase in the polymerization rate (Fig. 3).

The effect of the reaction temperatures on the formation of the metal alkyls is shown in Table 4;

with a remarkable increase in the polymer yield, the amount of metal alkyls increases.

The electron paramagnetic resonance study of this catalyst[15] has established that the liquid phase of this catalyst contains Ti^{3+} species. The catalyst mixture was separated into liquid and solid phases in the manner described above. To the liquid phase propylene was then added, and after methanolysis, the products were analysed. In this case, contrary to the case of the $TiCl_3$-$AlEt_3$ system,

the metal alkyls (I) and (III) were found in the reaction mixture.

The titanium contents in the liquid phase were determined by colorimetry. The amount of metal alkyls in the liquid phase corresponds to the amount of titanium in the liquid phase.*1

These findings indicate that, in this catalyst system, the active site for the polymerization is connected with some complex in the liquid phase.

$TiCl_3$-$ZnEt_2$ System. This catalyst system has a very low activity with regard to the polymerization of propylene, while the amount of the metal alkyls formed in the solid phase is rather large. The large amount of the metal alkyls found also in the liquid phase of the reaction mixture indicates that the diethylzinc has a high ability to make chain transfers.[16]

The last two catalytic systems have low activity in the polymerization of propylene at the initial stage of the reaction, but with an increase in the polymerization activity, the metal alkyls increase. The $AlEt_2Cl$ system is usually considered to be a transfer-free polymerization system,[5] however, and it is difficult to confirm our finding. In our opinion this transfer reaction is connected with the activation of the catalyst.

*1 When 13 mmol of $TiCl_3$ and 6.5 mmol of $AlEt_2Cl$ in 20 m*l* of a solvent are used at 30°C, the reaction mixture gives a liquid phase containing 0.06 mmol of titanium. After a 60-min reaction with propylene, this liquid phase gives 0 05 mmol of the metal alkyls (I)+(III).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1065—1071 (1969)

The Ionic Telomerization of Diene Compounds. IV. The Cationic Telomerization of Butadiene with Its Hydrobromides

Teruzo ASAHARA and Hideo KISE

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received July 24, 1968)

The cationic telomerization of butadiene with its hydrobromides (1-bromo-2-butene and 3-bromo-1-butene) in the presence of metal halide was investigated. It was found that the molecular weights of the telomers depend on the conversion of the telomerization, initial bromide/butadiene ratio and the solvent used. When halogenated hydrocarbons were used as solvents, telomers with high molecular weights and low unsaturations were obtained. On the other hand, the telomerizations in ether solvents gave telomers with low molecular weights, which contained appreciable amounts of the simple adducts of butadiene and bromobutene. The infrared spectra of the telomers suggested that the addition of butadiene occurred mainly at 1,4-position. On the basis of the analyses of the telomers, the reactivities of the carbonium ion to the basic species which were present in the reaction system were estimated.

The cationic telomerization of butadiene and isoprene with alkyl and alkenyl halides have been investigated by some workers.[1-5] The main subject of the investigations were the development of the method of controlling the molecular weight of the telomers and the clarification of the structures of the telomers.

It was found that the cationic telomerization of butadiene and its hydrochlorides gave their simple adducts and higher telomers (telomers with more than three butadiene units), and the addition occurred both at 1,4 and 1,2 positions of butadiene molecule.[1,2] The structures of higher telomers were very complex because of the multiple reactivities of the carbonium ions. Thus, the telomers had lower degrees of unsaturation and higher chlorine contents as compared with telomers with the ideal formula; $H(C_4H_6)_nCl$.

The amount of the simple adducts of butadiene with chlorobutenes and the average molecular weight of higher telomers depended mainly on the conversion of the reaction and the solvent used.

The present paper refers to the telomerization of butadiene with its hydrobromides in the presence of metal halides. When bromobutene is used as a telogen instead of chlorobutene, there will be some variations in the rate of initiation process; the formation of carbonium ion through the interaction between halogenated butenes and the catalyst. The carbonium ion formed may be surrounded by basic species present in the reaction system, namely, counter-anion, solvent, *etc.*, and the structure of the counter-anion may probably affect the reactivity of the carbonium ion.

Experimental

Materials. Bromobutenes, which were used as telogens, were prepared by the method described in a patent.[6] The reaction of butadiene with hydrobromic acid in the presence of sulfuric acid at 60°C gave two isomeric bromobutenes; 1-bromo-2-butene (crotyl bromide, bp 50—51°C/128 mmHg) and 3-bromo-1-butene (bp 42—43°C/128 mmHg). The total yield of bromobutenes was about 70%, and the content of crotyl bromide in the products was about 80%. As will be described later, the two isomers give telomers with the same structure, though 1-bromo-2-butene enters into the reaction faster than 3-bromo-1-butene. Therefore, the mixture of the isomers was used as telogen except when the difference in the reactivity was estimated. In this paper the mixture of two isomeric bromobutenes is named crotyl bromide (CB).

Butadiene (BD, purity was above 99.3%) was passed before use through columns packed with calcium chloride and sodium hydroxide.

Ethyl bromide was washed several times with a chilled concentrated sulfuric acid and water, dried on

calcium chloride, and distilled. Dichloromethane was washed with a dilute aqueous sodium carbonate solution and water, dried on calcium chloride, and distilled. Ethers were dried on sodium and distilled.

Telomerization. Into a 300 ml round-bottomed glass flask, equipped with a sealed stirrer, a thermometer, a condenser and an inlet for gas, definite amounts of the telogen, butadiene and the solvent were placed. Then the catalyst, dissolved in part of the solvent, was slowly added under a stream of nitrogen. The reaction was exothermic, and the rate of the addition of the catalyst solution was adjusted to keep the rise in temperature within 15°C. After the reaction, a small amount of pyridine was added, and the precipitated pyridine/catalyst complex was separated. Then the solution was washed with a 5% sodium carbonate solution, a 5% hydrochloric acid solution, and then water, and dried on anhydrous sodium sulfate. The solvent and the unreacted bromobutene and butadiene were distilled off under a reduced pressure, and the residue was subjected to vacuum distillation to separate the simple adducts of butadiene with bromobutene from the other products.

Analysis. The molecular weights of the telomers were measured with a Mechrolab vapor-pressure osmometer, model 301A, in a benzene solution at 37°C. DDT was used as a standard material.

The infrared spectra of the telomers were taken with a Hitachi-Perkin-Elmer double beam grating spectrophotometer, model 125. The evaluation of the absorption intensity was made by the ordinary base-line method.

The adducts with a 1 : 1 ratio of butadiene with crotyl bromide were analyzed by a gas chromatograph with a flame ionization detector. The separation column was a stainless steel tube packed with Diasolid L; the liquid phase was tricresyl phosphate (10%).

The adducts were isolated by distillation and liquid chromatography through a column packed with activated alumina. The elution was made by carbon tetrachloride or ethyl acetate.

The amounts of unsaturation of the telomers were determined by the Wijs method in the acetic acid solution.

The Alcoholysis of the Telomers. The telomers of butadiene with bromobutene were treated by the 0.5N potassium hydroxide-benzyl alcohol solution at 90°C. Initial ratio of bromine to potassium hydroxide was 0.5. The amounts of the bromine which entered into the reaction were calculated from the titration of the residual alkali with a 0.5N hydrochloric acid solution.

Results and Discussion

1) **Catalyst and Solvent.** The telomerization was carried out in several sorts of solvent in the presence of metal halides (Table 1). The reaction products are yellow or brownish viscous liquid or semisolid. In halogenated hydrocarbons, the reaction is too fast to be controlled. In ethereal solvent, the reaction is mild and reproducible. When ferric chloride is used as a catalyst, the yield of the telomer decreases as follows:

i-Propyl ether>*n*-Butyl ether>Ethyl ether>Dioxane>Ethyl alcohol

A dilute dichloromethane solution of the complex of ferric chloride with ethyl ether had an absorption at 365 mμ. It is known that ethereal compounds form charge transfer complexes with ferric chloride. The result mentioned above may be explained by the differences in the basicity of the solvents. Namely, the catalytic activity of the complexes for the telomerization decreases with the increasing stabilities of the complexes. Elementary analyses and the infrared spectra of the telomers obtained in ethers confirm that any fragment of the solvent molecule is not contained in the reaction products. Accordingly, the dissociation constant, K_2, may be small, and the initiation through the formation

of carbonium ion from the solvent would be neglected.

$$FeCl_3+ROR \underset{K_1}{\rightleftarrows} FeCl_3\cdot OR_2 \underset{K_2}{\rightleftarrows} [FeCl_3\cdot OR]^-+R^+ \quad (1)$$

When aluminum chloride and stannic chloride in halogenated hydrocarbons were used as catalysts, the telomers have high molecular weights and low degrees of unsaturation. As will be discussed later, it is presumed that some side reactions occur concurrently with the main reactions; *e. g.*, the addition of carbonium ion to the double bonds in the telomer or telogen.

The catalytic ability of metal halides in ethers decreases in the order, $FeCl_3>SnCl_4>AlCl_3$. The result is a little different from those of Friedel-Crafts reaction and the telomerizations in halogenated hydrocarbons. The apparent rate of telomerization which is designated by total yield of the telomers would primarily depend on the rate of initiation; the formation of carbonium ion through the interaction of catalyst and crotyl bromide. The strength of the association of metal halide with the solvents may reflect on the catalytic activity of the catalyst solutions.

Table 2. Telomerization of butadiene with two bromobutene isomers

Telogen	Yield (%)	Simple adduct (%)	Av. mol wt of higher telomers
1-Bromo-2-butene	34.8	41.5	285
3-Bromo-1-butene	25.9	51.2	308

Catalyst: $FeCl_3$; Solvent: Et_2O
Reaction time: 150 min
Reaction temperature: 5—15°C

Each of the two isomeric bromobutenes, which were obtained by the hydrobromination of butadiene, was used as telogens (Table 2). It was found that the primary bromide gave a larger amount of telomer than the secondary bromide under the same reaction condition. However, from the infrared spectra of the telomers and the gas chromatogram of the simple adducts, no significant difference in the structures of the telomers from respective bromides was observed. This was also confirmed in the case when chlorobutenes were used as telogens.[2] The fact suggestes that the two isomeric halobutenes form the same carbonium ion with the resonance structures A and B.

$$CH_3\text{-}CH\text{=}CH\text{-}CH_2^+ \text{ (A)} \leftrightarrow CH_3\text{-}\overset{+}{C}H\text{-}CH\text{=}CH_2 \text{ (B)}$$

2) The Effect of Initial CB/BD Ratio. The effects of CB/BD ratio on the yield and the molecular weight of the telomer were investigated. When aluminum chloride in ethyl bromide solution is used, average molecular weight of the telomer mixture decreases monotonously with the increase in the ratio (Fig. 1). However, the yields of the simple adducts of butadiene with crotyl bromide were very low under the conditions. In the region of CB/BD<1, appreciable amounts of insoluble product are obtained, which causes the decrease in the soluble telomers.

adducts of butadiene with bromobutene are obtained; the maximum yield of the adduct is obtained at CB/BD=1 (Fig. 2). In the region where the ratio is larger than unity, no significant change in the yield ratio of the adduct to the total product is observed. In addition, the average molecular weights of the higher telomers vary little with the variation of the initial CB/BD ratio. It appears that the excess crotyl bromide exists only as a diluent, and does not act as a chain transfer reagent.

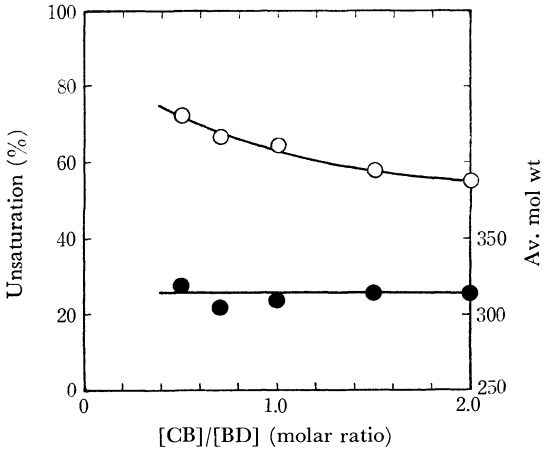

Fig. 3. Effect of the ratio of crotyl bromide to butadiene.
○, Unsaturation of higher telomer; ●, average molecular weight of higher telomer.
Reaction condition is the same as in Fig. 2.

As Fig. 3 shows, however, the increase in the CB/BD ratio causes a decrease in the degree of unsaturation of the higher telomers. It was concluded that the excess crotyl bromide increases the proportion of side reactions (see Section 5). This may be the reason why the simple adduct of butadiene with bromobutene decreases in the region CB/BD>1.

3) The Effect of Catalyst Concentration. As Fig. 5 shows, the average molecular weight of the telomer increases with the increase in the catalyst concentration. This effect may be attributed to the increase in the conversion of the reaction (Fig. 4), because it should be presumed in general that the increase in the catalyst results in the lowering of the molecular weight of the telomer. The relation between the conversion of reaction and the amount of the simple adducts of telogen and taxogen was examined and discussed in the case of telomerizations of butadiene with crotyl chloride[2] and isoprene with prenyl chloride.[3]

4) The Structure of Telomers. The fraction with bp 35—45°C/1 mmHg (I) was separated from the telomer mixture. It was found that the fraction consists of three components from its gas chromatogram. The elementary analysis and the

determination of iodine value indicate that the fraction consists of the simple adducts of butadiene with crotyl bromide.

Found: C, 51.68; H, 7.18; Br, 41.14%. Iodine value, 262.2. Calcd for $H(C_4H_6)_2Br$: C, 50.80; H, 6.94; Br, 42.26%. Iodine value, 268.40.

The fraction I was redistilled into two fractions; bp 35—40°C/1 mmHg (II) and 40—42°C/1 mmHg (III). From the infrared spectra (Figs. 6-2 and 6-3) and NMR spectrum (Fig. 7-2), it was concluded that the fraction II is a mixture of adducts D and E, and the fraction III is adduct C (Fig. 7). The infrared spectrum of II exhibits

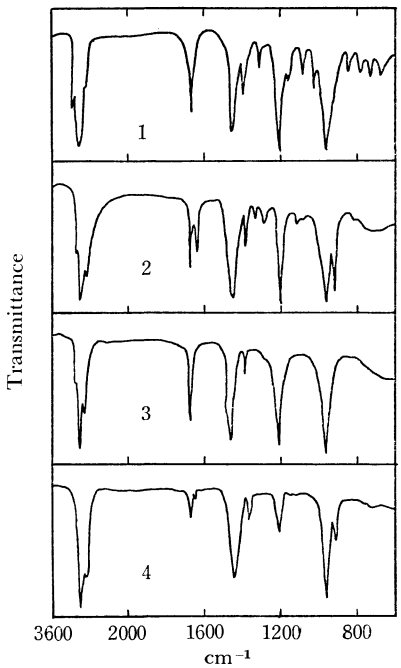

Fig. 6. Infrared spectra of crotyl bromide and telomers.
1, Crotyl bromide; 2, fraction II; 3, fraction III; 4, higher telomer.

the characteristic stretching (1665 cm^{-1}) and deformation (965 cm^{-1}) bands of the internal double bond, as well as the bands of vinyl grouping (1645 and 910 cm^{-1}), while the spectrum of III has only the bands of internal double bond. Adducts D and E, which were contaminated a little by each other, were separated from the fraction II by liquid chromatography. The proportion of C, D and E in the fraction I can be determined from its NMR spectrum (Fig. 7-3) by using the relative intensities of the bands, 8.35/9.00 and 4.55/4.22 (in τ). Thus, the proportions of C, D and E were estimated to be 80%, 10% and 10% respectively. There were found small differences in the value for the adducts obtained under various reaction conditions.

The infrared spectrum of the mixture of telomers other than the simple adducts represents the bands characteristic of internal olefin and vinyl grouping (Fig. 6-4). From the absorption intensities, the ratio of the 1,4 linkage of butadiene unit was calculated to be about 90%.[7]

5) Mechanism of Telomerization. The cationic telomerization of butadiene with crotyl bromide is assumed to proceed as follows:

Initiation:

$$FeCl_3\cdot(Et_2O)_x + CH_3\text{-}CH{=}CH\text{-}CH_2Br \longrightarrow CH_3\text{-}\overset{+}{C}H\text{-}CH{=}CH_2 \leftrightarrow CH_3\text{-}CH{=}CH\text{-}\overset{+}{C}H_2 + [FeCl_3Br]^- + xEt_2O \quad (2)$$

Fig. 7. NMR spectra of crotyl bromide and telomers.
1, Crotyl bromide; 2, fraction III; 3, fraction I.
Assignments:

$$\overset{a}{CH_3}\text{-}\overset{b}{CH}{=}\overset{c}{CH}\text{-}\overset{d}{CH_2}\text{-}\overset{e}{CH_2}\text{-}\overset{f}{CH}{=}\overset{g}{CH}\text{-}\overset{h}{CH_2}Br \quad (C)$$

$$CH_3\text{-}CH{=}CH\text{-}CH_2\text{-}CH_2\text{-}\overset{i}{CH}Br\text{-}\overset{j}{CH}{=}\overset{k}{CH_2} \quad (D)$$

$$CH_2{=}\overset{l}{CH}\text{-}\overset{m}{CH}(CH_3)\text{-}CH_2\text{-}CH{=}CH\text{-}CH_2Br \quad (E)$$

a, 8.35; b and c, 4.55; d and e, 7.87; f and g, 4.22; h, 6.08; i, 5.7; j and k, 4.90; l, 8.15; m, 9.00.

Propagation:

$$CH_3\text{-}CH{=}CH\text{-}CH_2^+ + (n-1)CH_2{=}CH\text{-}CH{=}CH_2 \longrightarrow H(C_4H_6)_{n-1}CH_2\text{-}CH{=}CH\text{-}CH_2^+ \quad (3)$$

Transfer reaction:

$$H(C_4H_6)_{n-1}CH_2\text{-}CH{=}CH\text{-}CH_2^+ + CH_3\text{-}CH{=}CH\text{-}CH_2Br \longrightarrow H(C_4H_6)_nBr + CH_3\text{-}CH{=}CH\text{-}CH_2^+ \quad (4)$$

Termination:

$$H(C_4H_6)_{n-1}CH_2\text{-}CH{=}CH\text{-}CH_2^+ + [FeCl_3Br]^- \longrightarrow H(C_4H_6)_nBr + FeCl_3 \quad (5)$$

It is known that ferric chloride forms a complex with ether in about 1 : 1 ratio.[2] If the solvent used has a smaller basicity than crotyl bromide, ferric chloride may form an adduct with crotyl bromide and subsequently form a carbonium ion, which initiates telomerization. It is deduced that a growing carbonium ion reacts with butadiene or crotyl bromide preferentially in the form with a positive charge on the chain end. Namely, 1,4 addition occurs more predominantly in the present system than the case of butadiene with crotyl chloride.

7) W. S. Richardson, *J. Polymer Sci.*, **13**, 229 (1954).

In the termination reaction (5), the telomer with chlorine atom may be possibly formed. However, analysis by gas chromatograph shows that a very small amount of chlorine cantaining telomer is obtained.

As mentioned above, the increase in the conversion of reaction is followed by the decrease in the proportion of the simple adducts and the increase in the average molecular weight of the higher telomers. The fact may be attributed to the consumption of the simple adducts by retelomerization and/or by side reactions. The τ-values of NMR spectra of 1-position hydrogens in 1-bromo-2-butene and 1-bromoocta-2,6-diene are nearly the same (6.07 and 6.08, Figs. 7-1 and 7-2). This suggests that 1-bromoocta-2,6-diene forms its carbonium ion through the interaction with catalyst as well as crotyl bromide. Thus, the simple adducts and higher telomers once formed may again enter into reactions, which results in the increase in molecular weight of the telomer mixture with the conversion of reaction.

If the telomerization proceeds according to Eqs. (2)—(5), the telomers formed can be represented by $H(C_4H_6)_nBr$. However, it turned out that the telomer mixtures have always higher bromine contents and lower degrees of unsaturation than those expected from the formula shown above. Thus, we represent telomers by $[H(C_4H_6)_\alpha Br]_\beta$; the deviation from $\beta=1$ may be attributed to the side reactions shown below.

Branching:

$$-CH_2-CH=CH-CH_2- + -CH_2^+ \longrightarrow -CH_2-\overset{+}{C}H-\underset{CH_2-}{\overset{|}{C}}H-CH_2- \qquad (6)$$

Cyclization:

$$-CH=CH-\underset{CH_2-CH}{\overset{CH_2-CH_2}{\overset{+}{C}H}} \longrightarrow -\overset{+}{C}H-CH\underset{CH_2-CH}{\overset{CH_2-CH_2}{CH}} \qquad (7)$$

The proton transfer and hydride ion transfer reactions are also plausible,but these reactions have no effect on the average bromine content and the degree of unsaturation. It was found that crotyl bromide itself forms polymers under the action

Table 3. Polymerization of crotyl bromide

Catalyst (C)	[C]/[CB] $\times 10^2$	Solvent	Temp. (°C)	Time (min)	Yield (%)	Av. mol wt
$FeCl_3$	2.43	Et_2O	5—12	150	2.5	327
$AlCl_3$	1.00	EtBr	−49—−41	240	4.6	462

of aluminum chloride or ferric chlorie (Table 3). Therefore, in the telomerization of butadiene and crotyl bromide, a part of crotyl bromide may probably be consumed by the polymerization. The polymerization of crotyl bromide may be included in reaction (6). Reaction (6) increases average bromine content, and reactions (6) and (7) decrease average degree of unsaturation in the telomer mixture. The proportions of the reactions of carbonium ions with basic species were calculated from the analysis of telomers obtained under various reaction conditions[2] (Table 4). It is obvious that the increase in the initial ratio of crotyl bromide to butadiene causes the increase in the probability of branching, while the proportion of cyclization is little affected by the variation of the ratio. In ethereal solvents, the proportion of cyclization varies with the solvent, but the differences are so small that no definite trend can be discerned.

Table 4. Reactivity of carbonium ion

Catalyst	Solvent	[CB]/[BD] (molar ratio)	Yield (%)	Av. mol wt[a]	Proportion of reactions (%)[b]		
					a	*b*	*c*

used as a catalyst, a marked increase in the proportion of side reactions was found. Namely, the telomers obtained by aluminum chloride in ethyl bromide have structures more branched and cyclized than those obtained by ferric chloride in ethers. The difference may be attributed to the difference in the basicity of the solvent, which interacts with the growing carbonium ions. In other words, reactivities of carbonium ions toward butadiene, crotyl bromide and telomers are influenced by the species of medium in which the carbonium ions exist.

6) Reaction of Telomers with Potassium Hydroxide in Benzyl Alcohol. In order to estimate the reactivities of bromine atoms in the telomers, the telomers were treated with potassium hydroxide in a benzyl alcohol solution. This alcoholysis affords unsaturated ethers with benzene nucleus. As Fig. 8 shows, higher telomers enter into reaction more slowly than 1:1 adducts, which may be ascribed to the steric factor of the telomers. It was also found that the telomers with bromine are more reactive than the telomers with chlorine. That is, the ionic cleavage of carbon–bromine bond is easier than that of carbon–chlorine bond. However, no significant differences were found between the reactivities of crotyl chloride and crotyl bromide in the telomerization. The fact may be explained by the stability of the counter-anions formed through the interaction of crotyl halides and the catalyst. Namely, $[FeCl_3Br]^-$ may be more unstable than $[FeCl_4]^-$, and easily recombines with carbonium ions, which results in the formation of the telomers with lower molecular weights.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1071—1077 (1969)

Catalysis in Peptide Synthesis with Active Esters. I. Bifunctional Catalysis in the Aminolysis of Benzyloxycarbonyl-L-phenylalanine *p*-Nitrophenyl Ester in Dioxane

Nobuhiro NAKAMIZO*1

Peptide Center, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received July 31, 1968)

The aminolysis reaction of benzyloxycarbonyl-L-phenylalanine *p*-nitrophenyl ester (I) with glycine *t*-butyl ester (II) was kinetically investigated in anhydrous dioxane. The spontaneous reaction was confirmed to follow the equation:

$$d[p\text{-nitrophenol}]/dt = k_{obs}[I] = (k_0 + k_{amine}[II])[I][II]$$

The catalytic actions of various additives were studied at a 2×10^{-3}M concentration of I and II, where the amine-catalyzed term could be neglected. Of the many additives, only carboxylic acids and α-pyridone were effective as catalysts. The catalytic effect apparently decreased in the sequence: trimethylacetic acid>acetic acid>α-pyridone>monochloroacetic acid. For these catalyses, a bifunctional, concerted mechanism was proposed which involves an 8-membered transition state.

In recent years, active ester procedures have been widely used in peptide synthesis.[1,2] It is also well-known that some carboxylic acids accelerate the aminolysis reactions of active esters.[3–5] On

the other hand, Beyerman *et al.*[6] proposed the use of bifunctional catalysts, such as α-pyridone, 1,2,4-triazole, and succinimide, for the syntheses of peptides *via* some active esters. Little information has, however, been available as to whether carboxylic acids act as simple acid catalysts or as bifunctional catalysts. The present author, therefore, undertook kinetic studies of the catalytic effects of various additives, including some carboxylic acids, on the aminolysis of benzyloxycarbonyl-L-phenylalanine *p*-nitrophenyl ester (I) with glycine *t*-butyl ester (II) in anhydrous dioxane. These studies may also provide an important clue to the general mechanism[7] of the aminolysis of esters.

Experimental

Materials. Dioxane was purified by an ordinary method.[8] Reagent-grade acetic acid was distilled and was fractionally crystallized to a constant mp 16.5°C. Monochloroacetic acid and *p*-nitrophenol were recrystallized from toluene; 1,2,4-triazole, from ether; α-pyridone, from benzene, and tropolone,*2 from cyclohexane. Pentachlorophenol was recrystallized from a mixture of methanol and water after treatment with active carbon; mp 185—188°C. 2,4-Dinitrophenol was recrystallized several times from water, and finally from carbon tetrachloride. Triethylamine was treated with benzyloxycarbonyl-L-phenylalanine *p*-nitrophenyl ester 2 days at room temperature to remove any primary and secondary amines, and then fractionally distilled; bp 89°C. (lit., 89.5°C). Trimethylacetic acid (an extra-pure reagent) and succinimide (a guaranteed reagent) were used without further purification.

Benzyloxycarbonyl-L-phenylalanine *p*-nitrophenyl ester was prepared from benzyloxycarbonyl-L-phenylalanine and *p*-nitrophenol by the dicyclohexylcarbodiimide method; mp 126—127°C (lit. 126—126.5°C)[9]; $[\alpha]_D^{23}$ −24.9 (*c* 2, DMF) (lit., −24.7, *c* 2, DMF).[9] Glycine *t*-butyl ester obtained by the hydrogenolysis of benzyloxycarbonylglycine *t*-butyl ester was fractionally distilled through a 35-cm Vigreaux column under reduced pressure; bp 51—54°C/15 mmHg (lit., 30°C/2 mmHg).[10] The purity of the ester was checked by an amino-group titration with standard hydrochloric acid (100.1% theoretical).

Kinetic Procedure. The reactions were carried out in 50-m*l* graduated flasks immersed in a constant-temperature bath which was controlled to 0.05°C. The reaction mixture was prepared in the following way. Known weights of I and an additive, if any, were placed in the reaction flask, and dioxane was added nearly to the mark. After a thermal equilibrium had been obtained, the mixture was made up with the solvent to exactly 50 m*l*. The reaction was initiated by adding an appropriate volume of a stock solution of II in dioxane. The quantities of both the reactants and the additive were predetermined in order to obtain the desired concentrations when the solution of II was added. Aliquots (0.1 m*l* or 0.2 m*l*) were withdrawn at suitable intervals, diluted to 5 m*l* with dioxane containing an excess anhydrous hydrogen chloride, and analyzed spectrophotometrically. The reactions were followed by the rate of the formation of *p*-nitrophenol. The molar extinction coefficients of I and *p*-nitrophenol were measured at 267 and 304 mμ in anhydrous dioxane; the following data were obtained:

	I	*p*-Nitrophenol
267 mμ	10600 (max)	3430
304 mμ	2250	12150 (max)

The concentrations of *p*-nitrophenol were determined by measuring the absorbance at the two wavelengths and by solving the simultaneous equations. The analysis of the known mixtures of I and *p*-nitrophenol by this method gave an agreement within ±1%. The absorptions of the benzyloxycarbonyl-L-phenylalanylglycine *t*-butyl ester and of the hydrochloride of II can be neglected at these wavelengths. The reference solution was dioxane containing amounts of the additive and hydrogen chloride equal to those in the sample solution. The reaction was generally followed to 60—90% completion with at least 10 readings.

The average deviation from the mean value of the rate constant in duplicate or triplicate experiments was ±3% or less.

Reaction Products and Stoichiometry. The kinetic experiments in dioxane suggested that the reaction of I with II is virtually quantitative. This was checked by the isolation of the benzyloxycarbonyl-L-phenylalanylglycine *t*-butyl ester from a reaction mixture after kinetic measurements. The protected dipeptide ester was recrystallized from ethyl acetate-petroleum ether in a yield of about 90%; mp 88.5—89.5°C. Found: C, 66.99; H, 6.87; N, 6.75%. Calcd for $C_{23}H_{28}O_5N_2$: C, 66.97; H, 6.84: N, 6.79%.

Results

Kinetic studies of the aminolysis reactions of I with II were carried out in anhydrous dioxane in the absence and in the presence of various additives.

In the presence of a large excess of II, good pseudo-first-order canstants, k^{I}_{obs}, were obtained. In all the kinetic experiments under these conditions the concentration of I was 1.0×10^{-3}M. The second-order rate constants, k^{II}_{obs}, derived from k^{I}_{obs} were variable functions of the concentrations of II, as represented by the following equation:

$$\frac{k^{I}_{obs}}{[II]} = k^{II}_{obs} = k_0 + k_{amine}[II] \qquad (1)$$

where k_0 and k_{amine} are the rate constants for the second- (uncatalyzed) and third-order (amine-catalyzed) processes respectively, and where the superscript I or II denotes the reaction order. This relationship is illustrated in Fig. 1, where

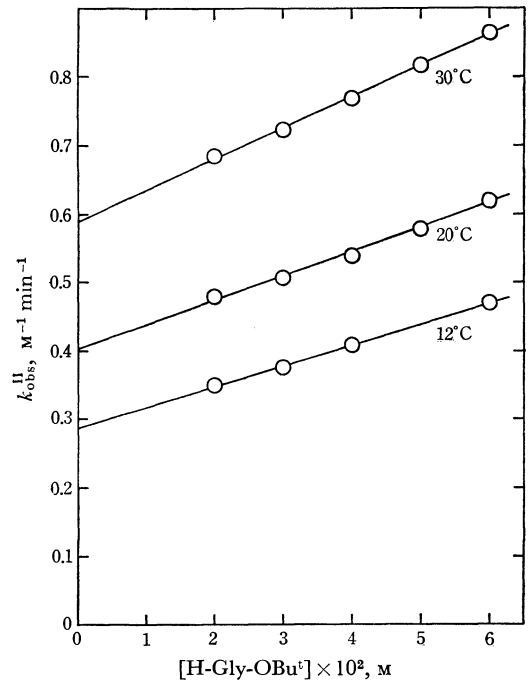

Fig. 1. Effects of the concentration of the amine component on the observed second-order rate constants at different temperatures.

plots of k^{II}_{obs} against the concentration to II give a straight line at each temperature. The values of k_0 and k_{amine} which were calculated from, respectively, the intercepts and slopes of these straight lines by the method of least squares are summarized in Table 1. It follows from these values that the contribution of the amine-catalyzed term to the overall reaction rate is not more than

Table 1. Uncatalyzed and amine-catalyzed rate constants at various temperatures

Temperature, °C	k_0, M^{-1} min^{-1}	k_{amine}, M^{-2} min^{-1}
30	0.59	4.6
20	0.40	3.6
12	0.29	3.1

1% at the concentration of the amine component lower than 10^{-3}M. Thus, in order to simplify the kinetic analysis, all the kinetic runs with additives were carried out at low concentrations where the contribution of the amine-catalyzed term was negligible. Spectrophotometric studies showed that, in anhydrous dioxane, the *p*-nitrophenol formed did not detectably ionize even in the presence of a large excess of II or triethylamine,*3 indicating that the amine component remained in its free form. Accordingly, the formation of *p*-nitrophenol does not disturb the second-order kinetics.

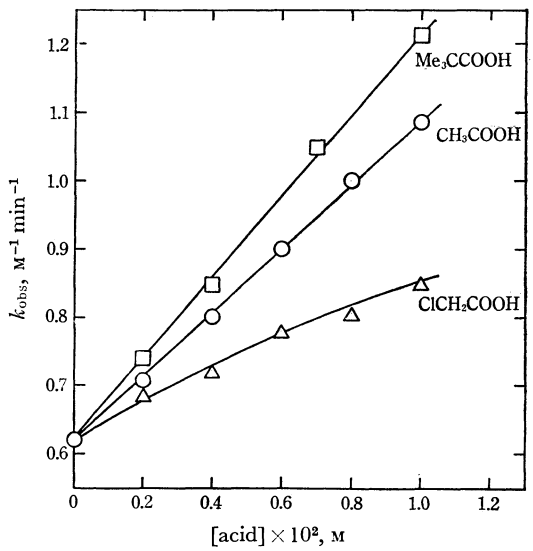

Fig. 2. Effects of the concentration of three carboxylic acids on the observed rate constants at 30°C.

As is shown in Fig. 2, carboxylic acids with a relatively weak acidity, such as trimethylacetic acid and acetic acid, powerfully catalyze the aminolysis of the active ester in dioxane. When

*3 Although it has often been assumed, without any experimental support, that in anhydrous dioxane *p*-nitrophenol ionizes to give the *p*-nitrophenolate anion in the presence of tertiary amine,[11] this is incorrect.

[I] = [II] = 2×10^{-3} M

a) The observed rate constants when the concentrations of additives are 2×10^{-3} M.

the acid concentrations were lower than 10^{-2} M, the following relationship was found to hold:

$$k_{obs} = k_0 + k'_{cat}\,[catalyst] \qquad (2)$$

where k'_{cat} was the (apparent)*4 catalyzed constant (Fig. 2). The values of k'_{cat} for each catalyst can be calculated from the slopes of the lines shown in Fig. 2.

Monochloroacetic acid, a slightly stronger acid, also showed a catalytic effect, but a negative deviation*5 from Eq. (2) was observed (Fig. 2).

Such phenols as p-nitro-, pentachloro-, and 2,4-dinitro-phenol did not accelerate, but, rather, came to retard the reaction as their acid strengths increased (*cf.* the 5th column in Table 2).

The trichloroacetate of triethylamine, an acidic salt, also retarded the reaction (Table 2).

α-Pyridone, a classical example of a bifunctional catalyst,[6,12] was almost as effective as acetic acid. Water, triethylamine, succinimide, and tropolone showed little or no catalytic activity. Dimethylacetamide (not as a solvent*6 but as a catalyst) and 1,2,4-triazole showed only a small accelerating effect. Although Bayerman *et al.*[6] found that the catalytic effects of succinimide and 1,2,4-triazole were as large as that of α-pyridone for the syntheses of peptides *via* active esters in acetonitrile or others, the catalytic activities of the former compounds were much smaller than that of the latter under the present conditions. The results mentioned above are summarized in Table 2.

The second-order rate constants observed for the acetic acid-catalyzed reaction at three different temperatures are shown in Table 3.

Table 4 shows the Arrhenius parameters for the uncatalyzed, amine-catalyzed, and acetic acid-catalyzed reactions.

TABLE 3. OBSERVED SECOND-ORDER RATE CONSTANTS FOR THE ACETIC ACID-CATALYZED REACTION AT THE THREE DIFFERENT TEMPERATURES

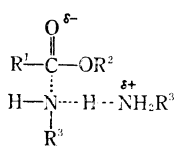
*6 The results of the study on the effect of dimethylacetamide as a solvent will be published in a separate communication.

Discussion

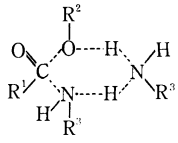
The general acid-base catalysis for the aminolysis of esters is a well-established phenomenon.[7] In the aminolysis (and related reactions) of esters[7] or thiolesters[7] in protic solvents, the kinetic orders of amines in rate expressions are often not unity, because amine components themselves can act as base catalysts. Recently some evidence has been presented for the catalytic actions of the amine components in the acylation of amines with ketenes or esters in aprotic solvents.[13-17] A similar catalysis was found for the present system also.

At a relatively higher concentration of reactants (10^{-2}M), the integrated second-order rate constant decreased with the progress of reaction, indicating the presence of a higher-order process. As has been described in the preceding section, when II was present in at least a twenty-fold excess over I, pseudo-first-order constants, k^{I}_{obs}, were obtained. The second-order rate constants, k^{II}_{obs}, were variable functions of the concentrations of II, as are represented by Eq. (1) and Fig. 1. This finding implies that the reaction consists of two independent processes involving one and two amine molecules. In the latter process the second amine molecule apparently acts as a catalyst.

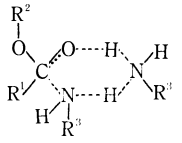
It is possible to write three transition states, III, IV, and V, for the catalytic process:



III



IV



V

In III, the second amine molecule makes the attacking amine more nucleophilic by accepting a proton partly. This process involves a charge creation. The transition state IV, first proposed by Bruice and Mayahi[18] in the ammonolysis of substituted phenyl acetates, is a cyclic, concerted process which involves no charge formation in the transition state. In this cyclic transition state, the catalytic molecule removes a proton from the one undergoing acylation, while there is a simultaneous proton transfer to the leaving group. The transition state V also represents a cyclic mechanism, but it differs from IV in that the carbonyl oxygen atom accepts the proton of the catalyst.

If the first mechanism is correct, a tertiary amine can be expected to exhibit a catalytic effect, because it too can remove a proton from the nucleophile. If a cyclic concerted mechanism, IV or V, is correct, then the tertiary amine should have little effect on the rate, because it cannot participate in the concerted process because of the absence of a labile proton. The author found that triethylamine has little or no catalytic activity in spite of its strong basicity. This fact favors the concerted mechanism. Similar arguments have recently been proposed for the aminolysis of *p*-nitrophenyl acetate in chlorobenzene[15] and for the the acylation of aniline derivatives by ketenes in ether.[13b,c]

It must be remembered, however, that the effectivenesss of a given amine as a general-base catalyst depends not only on its basicity but also on the steric factor. It has been pointed out that the aminolysis by sterically-hindered amines, especially secondary amines, is less susceptible to the general-base catalysis in spite of the availability of a proton.[14,19,20] Therefore, at present, care must be taken in drawing conclusions about the amine-catalyzed mechanism. The cyclic, concerted mechanism is nevertheless very attractive in that, in a nonpolar solvent such as dioxane, the charge creation (ionization) which is required for the mechanism III is not favored.

Even in an aqueous solution much experimental evidence suggestive of cyclic mechanism has been presented in analogous reactions, such as the hydrolysis[7] and ammonolysis[18] of esters.

The validity of this cyclic, concerted mechanism has been more unambiguously demonstrated in the case of carboxylic acid catalysis. As is shown in Table 2, with the single exception of α-pyridone, only carboxylic acids among the many acidic additives examined were more effective as catalysts. Phenols or acidic salts such as triethylammonium trichloroacetate exhibited no effect or a negative effect on the reaction rate, depending on the concentration and strength of the acid. If the reaction proceeds through the simple general-acid catalysis, these acids should possess a catalytic activity similar to that of carboxylic acids. This

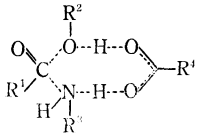
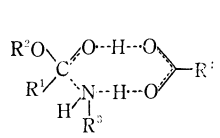
is, however, not the case. The possibility that the effect of carboxylic acids may be due to a nonspecific "medium effect" was also eliminated by the finding that water and dimethylacetamide, which have much larger dielectric constants, were far less effective in the acceleration of the reaction.

These facts suggest a specific mechanism, that is, one with a cyclic transition state, as is shown by VI or VII:*7



VI

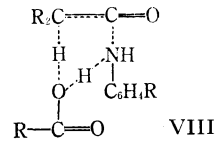


VII

A similar proposal has been made regarding the carboxylic acid-catalysis of the methoxyaminolysis of *p*-nitrophenyl acetate in an aqueous solution on the ground that the catalytic constants for the carboxylic acids are, within the limits of error of the experimental measurements, independent of the acid strength of the catalyst.[20] That Litvinenko and his co-workers established an analogous mechanism of the carboxylic acid catalysis in the acylation of aniline derivatives by carboxylic acid anhydrides or chlorides in a benzene or nitrobenzene solution is particularly noteworthy in this connection.[21-27]

Although the form of this transition state is an eight-membered ring, it should be noted that it perhaps has an atomic configuration analgous to that of the carboxylic acid cyclic dimer. The fact that carboxylic acid and α-pyridone are most effective as catalysts indicates that their atomic configurations are most suitable to the formation of the cyclic transition state. That the geometry of a catalyst (its ability to fit into the eight-membered ring involving two hydrogen atoms) could be an important factor is also supported by the fact that 1,2,4-triazole[6] and tropolone, which would form 7- and 9-membered rings respectively, exhibit little or no catalytic activity (Table 2). Tropolone will prefer forming an intramolecular hydrogen bond of a five-membered ring to acting as a bifunctional catalyst.

Lillford and Satchell,[13b] who recently established the carboxylic acid catalysis for the acylation of aniline derivatives by dimethylketene or isobutyric anhydride in an ether solution, proposed a cyclic transition state such as VIII for the catalysis.



VIII

However, such a formulation cannot explain our finding that phenols do not catalyze the aminolysis of the ester.

Now, there remains a qeutsion which states are correct, IV or V and VI or VIII. In order to answer this question it is necessary to understand the characteristics of the reactions of this type. There is a distinct difference in the characteristics of the reaction between the nucleophilic displacement on the carbonyl carbon and the bimolecular substitution on saturated carbon. In the former the negative charge brought into the reacting site by the attacking nucleophile is once "absorbed" into the carbonyl oxygen, whereas in the latter the charge is directly transmitted to the leaving group. In the former, consequenlty, the factors which assist the "absorption" of the negative charge by the carbonyl oxygen, such as the presence of acid species protonating the oxygen atom (acid catalysis), or the addition of protic solvent which forms a hydrogen bond with the oxygen atom,[28] will promote the formation of an intermediate. The charge "stored" in the carbonyl oxygen atom becomes a driving force to accelerate the decomposition of the intermediate in both forward and backward directions. In this way one cannot speak of the nucleophilic displacement reaction on the carbonyl carbon without considering the role of the carbonyl oxygen. If the formation of the intermediate is the rate-determining step in the presence of the catalyst, as is expected to be indeed

*7 In the aminolysis of the 1-hydroxypiperidine ester and the related compounds, Young *et al.*[5] attributed the accelerating effect of acetic acid to a specific acid catalysis, in which the nitrogen atom of the leaving group is protonated. The acid may, however, act as a bifunctional catalyst, as in the present case.

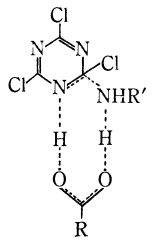
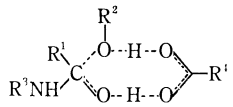
the case,*8 the catalyst must give its proton, not to ether oxygen, but to the carbonyl oxygen atom of the substrate in the transition state. In brief, it follows that the mechanisms which include the transition states V and VII are probably correct. This conclusion is also in accord with the prediction by the "Anthropomorphic rule."[29]

This situation is very similar to that found in the carboxylic acid catalysis for some aromatic nucleophilic substitution reactions; that is, while carboxylic acids catalyzed the aminolysis of cyanuric chloride by aromatic amines,[30] they failed to catalyze the analogous substitution reactions on 2,4,6-trinitrochlorobenzene by amines.[24,30a,31] This fact has been explained as follows. In the former reaction the catalyst accelerates the reaction by protonating the nitrogen atom on the triazine ring, as is shown in IX, but in the latter the catalyst does not accelerate because of the absence of a nitrogen atom.[30a] If the proton of the carboxylic group is directly transferred to the leaving atom (Cl^-), the reaction of 2,4,6-trinitrochlorobenzene will be promoted by carboxylic acids in the same manner as the reaction of cyanuric chloride.



IX

Since the formation of the intermediate is probably a rate-determining step, the collapse rate of the intermediate will be of no importance in the kinetics. However, the carboxylic acid may participate in the collapse process also, as is formulated in X:



X

The assistance to the nucleophilic attack by catalysts should bring about a lowering of the potential energy barrier. On the other hand, since the catalytic processes represent the higher-order reactions, it may be anticipated that they will have low frequency factors compared with the uncatalyzed process. The Arrhenius parameters for the uncatalyzed, amine-catalyzed, and acetic acid-catalyzed reactions shown in Table 4 reveal that this is indeed the case.

The author would like to express his gratitude to Assistant Professor S. Sakakibara, Osaka University, for his guidance and valuable advice and to Assistant Professor S. Nishida, Osaka University, for his helpful discussions. The author wishes also to thank the Kyowa Hakko Kogyo, Co., Ltd., for the opportunity to conduct this work and publish his resutls.

*8 Since the $-OC_6H_4NO_2$ group is a much better leaving group than the $-NHCH_2COOBu^t$ group, it is probable that the collapse rate of the intermediate to the product is larger than to the starting material, —that, in other words, the second step is of no importance in the kinetics.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1078—1082 (1969)

Catalysis in Peptide Synthesis with Active Esters. II. Effects of Concentrated Carboxylic Acids on the Aminolysis of Benzyloxycarbonyl-L-phenylalanine *p*-Nitrophenyl Ester in Dioxane

Nobuhiro NAKAMIZO*1

Peptide Center, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received July 31, 1968)

The kinetics of the aminolysis reaction of benzyloxycarbonyl-L-phenylalanine *p*-nitrophenyl ester with glycine *t*-butyl ester in dioxane were studied in the presence of high concentrations of several carboxylic acids. Bell-shaped curves were obtained when the rate constants observed for the trimethylacetic acid-, acetic acid-, and monochloroacetic acid-catalyzed reactions were plotted against the logarithms of the reciprocals of the acid concentrations. Cyanoacetic acid and trichloroacetic acid did not accelerate, but, rather, retarded the reaction. In the mathematical derivation the catalyst apparently exhibits no accelerating effect, if $k_0K > k_{cat}$, where k_0 and k_{cat} are the uncatalyzed and the true catalyzed rate constants respectively, and where K is the acid-base equilibrium constant between the nucleophile and the catalyst in a given solvent. The true catalyzed rate constants, k_{cat}, from which the effect of the protonation of the nucleophile had been eliminated were estimated for the trimethylacetic acid- and acetic acid-catalyzed reactions. The fact that the k_{cat} value ($63\text{M}^{-2}\,\text{min}^{-1}$) for trimethylacetic acid, the weaker acid, was greater than that ($53\text{M}^{-2}\,\text{min}^{-1}$) for acetic acid strongly supports the bifunctional, concerted mechanism presented in the preceding paper.

In the preceding paper,[1] evidence was presented that some carboxylic acids act as bifunctional catalysts in the aminolysis of an active ester, benzyloxycarbonyl-L-phenylalanine *p*-nitrophenyl ester (I), in anhydrous dioxane. The catalytic effect apparently decreased in the sequence: trimethylacetic acid>acetic acid>monochloroacetic acid. The apparent effects of these carboxylic acids must, however, be the sum of the accelerating effects due to the catalysis and the retarding effects due to the protonation of the amine component. In order to confirm this supposition, further investigations were undertaken in which the concentrations of the carboxylic acids were varied over wide ranges and the stronger carboxylic acids were used. If the supposition is correct, it is desirable to ascertain the "true" catalytic abilities of these acidic catalysts by substracting the effects due to the protonation of the nucleophile from the apparent effects. The present author has succeeded in estimating the "true" catalyzed constants for some carboxylic acids from the rate data. The present results support strongly the bifunctional, concerted mechanism which was presented in the preceding paper.[1]

Experimental

The cyanoacetic acid and trichloroacetic acid were recrystallized from ether and toluene respectively. The other materials and kinetic procedure were the same as have been described in the preceding paper. All the reactions were conducted at 30°C.

Results

Table 1 summarizes the observed second-order rate canstants in the aminolysis of I with glycine *t*-butyl ester (II) at 30°C in anhydrous dioxane in the presence of trimethylacetic, acetic, monochloroacetic, cyanoacetic, and trichloroacetic acid. The latter two acids did not accelerate, but, rather, retarded the reaction. The constants for trimethylacetic, acetic, and monochloroacetic acid are plotted against the logarithms of the reciprocals of the acid concentrations (p[acid]) in Fig. 1.

The possibilities of the mixed anhydride formation and the acyl exchange reaction between I and carboxylic acid can be ruled out, because benzyloxycarbonyl-L-phenylalanine and acylglycine *t*-butyl esters, which would be formed if these reactions took place, could not be detected by

thin-layer chromatography even at a high concentration of carboxylic acid.

Discussion

As has been shown in the preceding paper,[1] the observed second-order rate constants for the aminolysis reaction of I with II in the presence of trimethylacetic or acetic acid at concentrations lower than 10^{-2}M in dioxane were linearly proportional to the acid concentration. On the other hand, for the monochloroacetic acid - catalyzed reaction, plots of the rate constants against the catalyst concentration showed a negative deviation from the linear relationship. These facts appear to reflect the increase in the protonation of the amine component accompanying the increase in the acid strength and the concentration of the acidic catalyst. If this presumption is correct, similar negative deviations will also appear for the trimethylacetic acid- and acetic acid-catalyzed reactions in higher concentrations of the catalysts. Moreover, for

stronger acids, the apparent catalytic effect may disappear.

The data in Table 1 and Fig. 1 show that this is indeed the case. For example the observed constants for trimethylacetic acid deviated from the calculated curve (dotted line) for which a linear relationship between the rate and the acid concentration was assumed. Furthermore, the values observed at concentrations of more than 0.1M of the acid exhibited a negative deviation even from the calculated curve (broken line) which was based on the assumption that the acidic catalyst partly protonates the amine component to convert it to inactive species, thus resulting in the characteristic bell-shaped curve. For the acetic acid- and monochloroacetic acid-catalyzed reactions also, similar phenomena were observed. The stronger the strength of the acid, the smaller becomes the maximum value of the curve, and the position of the maximum shifts toward a lower acid concentration.*2

In the case of cyanoacetic acid, no maximum was any longer detectable, and the values of k_{obs} for this acid decreased monotonically with an increase in the acid concentration (Table 1). Furthermore, trichloroacetic acid, which is the strongest acid among the catalysts used in the present investigation, inhibited the reaction almost completely when more than one equivalent was added to the amine component (Table 1).

If the apparent effects of the carboxylic acids are the sum of the accelerating effects by the catalysis and the retarding effects by the protonation of the nucleophile, it is necessary to obtain "true" rate constants which do not involve the effects of the protonation.

The acid-base equilibria between carboxylic acids and the amine in a given solvent were assumed to conform to the general equation:

$$RCOOH + H_2N\text{-}R' \overset{K}{\rightleftharpoons} RCOO^- \cdot H_3{}^+N^-R' \quad (1)$$

To simplify, the difference between the free carboxylic acid monomer and the monomer-solvent complex[5] is neglected. With relatively low concentrations (below 0.1M), the presence of the acid dimer in dioxane can be neglected.[6] Then, the ionization constant, K, is written:

$$K = \frac{\alpha}{(c-\alpha b)(1-\alpha)} \quad (2)$$

where b and c are the total concentrations of II and carboxylic acid respectively, and where α is the degree of the ionization of II. When $c \gg \alpha b$, we may write:

$$\alpha = cK/(1+cK) \quad (3)$$

If only free amine is a reactive species, the observed second-order rate constants are represented by:

$$k_{obs} = k_0(1-\alpha) + k_{cat}(1-\alpha)c \quad (4)$$

where k_0 and k_{cat} are the uncatalyzed and the "true" catalyzed rate constant respectively. The substitution of $(1-\alpha)$ from Eq. (3) into Eq. (4) gives:

$$k_{obs} = \frac{k_0 + c \cdot k_{cat}}{1 + cK} \quad (5)$$

Differentiating this with respect to the concentration of the catalyst, we obtain:

$$\frac{dk_{obs}}{dc} = \frac{k_{cat} - k_0K}{(1+cK)^2} \quad (6)$$

Equation (6) reveals that when $k_{cat} > k_0K$, dk_{obs}/dc is positive; that is, the catalyst exhibits a positive effect on the aminolysis reaction in a given solvent. On the other hand, when $k_{cat} < k_0K$, the catalyst apparently shows a negative effect. The right limb of each profile shown in Fig. 1 corresponds to the former case, while the left side of each maximum, and the effects of cyanoacetic and trichloroacetic acid, correspond to the latter.

In order to determine the "true" rate constant, k_{cat}, it is necessary to know the value of K. This information is, however, not available at present. Therefore, the author tried conversely to derive the ionization constants, K, from the rate data obtained here.

Rearranging Eq. (5), we obtain:

$$k_{obs} = \frac{k_{cat}}{K} - \frac{k_{obs} - k_0}{cK} \quad (7)$$

Equation (7) requires that a plot of k_{obs} against $(k_{obs}-k_0)/c$ be a straight line with a slope equal to $-(1/K)$ and an intercept at k_{cat}/K. The resulting plots (Fig. 2) for data below 0.1M of trimethylacetic and acetic acids were satisfactorily linear, with deviations only at the lower catalyst concentrations, where the proximity in the values of k_{obs} and k_0 brings about large uncertainties in the remainder $(k_{obs}-k_0)$. These good linearities may substantiate the validity of the assumptions on which Eq. (7) is based.

*2 Litvinenko *et al.* found that for the acetylation of *p*-nitroaniline with acetic anhydride in mixture of benzene and acetic acid, the maximum of the rate constants appears at about 50%(v/v) of the acid,[2] while for the acylation of *m*-chloroaniline[3,4] or aniline[4] in mixtures of benzene and trichloroacetic acid, the rate constants have maxima at much lower concentrations (~0.01M) of the acid.

TABLE 2. THE "TRUE" CATALYZED-RATE CONSTANTS AND THE IONIZATION CONSTANTS FOR TRIMETHYLACETIC ACID AND ACETIC ACID

	k_{cat}, M^{-2} min^{-1}	K, M^{-1}
Trimethylacetic acid	63±2	5.3±0.2
Acetic acid	53±2	6.0±0.2

From the least-squares calculations for the plots, k_{cat} and K values for these two acids were obtained (Table 2).

The theoretical curves calculated from these rate and equilibrium constants are shown as broken lines in Fig. 1.

Similar mathematical treatments were not applicable to other acids because of the larger uncertainties in the values of the remainder $k_{obs}-k_0$.

If the treatments mentioned above are correct, it follows that the weaker trimethylacetic acid (pk_a in H_2O 5.03) has truly, not apparently, a greater catalytic activity than the stronger acetic acid (pk_a 4.76), despite its larger steric requirement. This result, which it is impossible to interpret by a simple general acid catalysis, strongly supports the cyclic, concerted mechanism which was proposed in the preceding paper.[1] When carboxylic acids act bifunctionally, substituents in carboxylic acids will affect the proton-donating powers of the hydroxyl function and the proton-accepting powers of the carbonyl oxygen atom in opposite fashions. As a result, for example, the monomer-dimer equilibrium constants of carboxylic acids in the gas phase are almost independent of their acid strengths.[7]

When they act as bifunctional catalysts, whether the catalytic activities are directly proportional to the acid strengths or whether the reverse is true, will depend on the proportion of the contribution of both the acidic and basic functions to the lowering of the activation free energy. For the mutarotation of tetramethylglucose in a benzene solution, the order of the magnitude of the catalytic ability is as follows: $CCl_3COOH > C_6H_5COOH > \alpha$-pyridone $>$2-aminopyridine.[8] Similarly, for the acylation of aniline derivatives with acetic and benzoic anhydride or benzoyl chloride in benzene, the catalytic effect decreases in the order: $CCl_3COOH > CH_2ClCOOH > C_6H_5COOH > CH_3COOH$.[3,4] In these instances, although carboxylic acids act again as bifunctional catalysts, it seems that their role as acid catalysts rather than as base catalysts is of predominant importance. Bitter and Zollinger[9] found, on the contrary, that for the nucleophilic substitution reaction on cyanuric chloride by aniline in a benzene solution, the catalytic effect increases in the sequence: $CCl_3COOH < CH_2ClCOOH < CH_3COOH < \alpha$-pyridone. On the basis of this finding they considered that the proton-accepting property of a bifunctional catalyst is essential for the catalytic action.

In the present investigation, it may be premature to draw a definitive conclusion, for we still lack the "true" catalytic constants for any catalysts other than trimethylacetic acid and acetic acid. However, the data for the latter two acids seem to show that the proton-accepting ability of the catalyst in the transition complex plays a more important role in the catalysis. It should be noted that, in the transition complex, the proton of the catalyst is transferred to the substrate to a different extent depending on the kind of catalyst; therefore, the basicity of the proton-accepting site on the catalyst is not necessarily parallel to that of the initial catalyst molecule.

As for the bell-shaped, p[acid] - rate profiles illustrated in Fig. 1, a further comment is required. In many organic and enzymatic reactions bell-shaped profiles have been obtained.[10] The reason why such characteristic curves were obtained here, however, appears to be distinct from that for many of the hitherto-known instances in aqueous solutions. No change in the reaction mechanism in both sides of the maximum of the profile, such as those observed in imine formation,[11] nitrone formation,[12]

and the aminolysis of imido esters,[13] could be proved in the present case. Of course, the interpretation[10] proposed for the enzymatic reactions with bell-shaped pH-rate profiles are not applicable here either. The author prefers to explain this phenomenon by a change in the nature of the medium. As the concentration of carboxylic acid increases, the ionization "constant" will come not to be constant because of the change from pure dioxane to a mixed solvent of dioxane and carboxylic acid. At such a high acid concentration, the amine component is presumably protonated much more than would be expected from the ionization constant, K, determined above, and consequently the reaction rate decreases. In such a case the extent of the protonation of the amine component will have to be estimated, not by the concentration of the acid, but by the acidity function of the solution.*3 Unfortunately, the acidity function for the dioxane-carboxylic acid system does not seem to have been established. Furthermore, the change in the medium effect on the aminolysis reaction itself, which accompanies the change in the solvent composition, can not be neglected. Therefore, it is difficult to predict theoretically the rate data on the left side of the maximum at the present time.

The author wishes to express his gratitude to Assistant Professor S. Sakakibara of Osaka University for his valuable advice and to Assistant Professor S. Nishida of Osaka University for his helpful discussions.

(Received August 8, 1968)

Allyl chloride has been pyrolyzed in a flow system over a wide range of conditions (temperature, 800—1200°C; contact time, 0.665×10^{-3}—78.9×10^{-3} sec; concentration, 4.0—13.5 mol%; pressure, atmospheric pressure) to find suitable conditions for producing methylacetylene and allene. In addition, a study on the mechanism of pyrolysis of allyl chloride at high temperatures (800—1200°C) has been made. A total yield of allene and methylacetylene of 14 mol per 100 mol of allyl chloride pyrolyzed was obtained under suitable conditions. By means of the zero conversion method, hydrogen, propylene, allene, diallyl, 1,3-cyclohexadiene, and benzene have been found to be the main reaction products in the early stage of the pyrolysis, while methane, acetylene, ethylene, methylacetylene, butene-1, and butadiene have been found to be the side reaction products. The over-all activation energy of decomposition was 39.4 kcal/mol for an A factor of $10^{8.7}$ sec^{-1}. On the basis of the observed results, a free-radical mechanism has been proposed for the main reactions and the principal side reactions. It was further concluded that the pyrolysis was a radical decomposition initiated by the reaction $C_3H_5Cl\rightarrow C_3H_5\cdot+Cl$ and that the over-all mechanism in the early stage of the pyrolysis was represented essentially by the reaction $2C_3H_5Cl\rightarrow C_3H_5\cdot+\dot{C}_3H_4Cl+HCl$.

In previous papers,[1,2] the authors reported the synthesis of methylacetylene and allene by the pyrolysis of propylene at high temperatures. High temperatures, low conversions, and low pressures

were found to be required for the good production of allene and methylacetylene. Since the C–Cl bond dissociation energy of allyl chloride[3] (58 kcal/mol) is considerably lower than that of α-(C–H) of propylene[4] (85 kcal/mol), the pyrolysis of allyl chloride would be expected to bring about better results under moderate conditions and to give available information about the behavior of allyl radical at high temperatures. In this report, the pyrolysis of allyl chloride under low pressure and high temperature was investigated with the aim of the production of allene and methylacetylene. Although several papers[5–8] have been published on the pyrolysis of allyl chloride, the investigations are mainly carried out below 800°C. Up to the present, it is known that only small amounts of allene and methylacetylene are obtained and that certain products seem to be produced through allene. The reaction products reported by previous investigators are summarized in Table 1.

Table 1. Summary of previous investigations

Reference	Temperature range (°C)	Products
5) Goodall and Howlett	370 to 475	Allene, allene polymers, acetylene, *etc.*
6) Shilov*	594 to 709	Allene, propylene, diallyl, dibenzyl, 4-phenyl-1-butene, *etc.*
7) Porter and Rust	550	Propylene, benzene, C_3H_4, 1,3-cyclohexadiene, hydrogen, methane, ethylene, diallyl, *etc.*
8) Hughes and Yates	540 to 765	Propylene, diallyl, 1,3-cyclohexadiene, benzene, *etc.*

* toluene-carrier technique

Goodall and Howlett first studied the pyrolysis of allyl chloride and concluded that the reaction was a complex homogeneous, heterogeneous process to yield, initially, allene and hydrogen chloride. They found the over-all activation energy of 42.5 kcal/mol for an A factor of $10^{9.10}$ sec^{-1}. They obtained large amounts of allene polymers, but only small amounts of allene were identified, presumably because of the rapid polymerization reaction under the reaction conditions. Shilov, on the other hand, found an activation energy of 59.3 kcal/mol at 623°C for the primary decomposition of allyl chloride in a stream of toluene and proposed that the first step in the pyrolysis was the splitting of the C–Cl bond leading to the formation of Cl atoms and allyl radicals. He obtained allene as the minor reaction product, and the amount of allene was less than 3% of hydrogen chloride.[6b] On the basis of the identification of the products, Porter and Rust, and Hughes and Yates also proposed a mechanism which involved the formation of Cl atoms and allyl radicals in the primary step of the reaction. Both of these authors indicated that allene and methylacetylene were only trace amounts of the pyrolysis products. Moreover, Hughes and Yates obtained 34.7 kcal/mol as the over-all activation energy of the pyrolysis.

The purpose of the present investigation is to determine suitable conditions for the production of methylacetylene and allene by the pyrolysis of allyl chloride and to obtain data on the distribution of the pyrolysis products. Based on the observed experimental results, an effort was made to clarify the reaction mechanism for the pyrolysis at higher temperatures (800—1200°C).

Experimental

Materials. Allyl chloride was prepared from allyl alcohol.[9] Bp 44—45°C; n_D^{22} 1.4135. Cylinder nitrogen of 99.9 mol% purity was used as a diluent.

Apparatus and Procedure. The apparatus is shown in Fig. 1. Dry nitrogen was passed through a rotameter to an allyl chloride mixing bottle which was immersed in a constant temperature oil bath set at about 120°C. Allyl chloride was added to the

bottle at a constant rate using an automatic injector. The resulting mixture, containing 4.0—13.5 mol% of allyl chloride, was passed through a short preheater maintained at *ca.* 100°C and then pyrolyzed in a silica reaction tube under the specified conditions at atmospheric pressure. The reactor was heated to the desired temperature while a stream of dry nitrogen was passed through. The electric furnace was made of "Siliconit," and is the same as the one used in a previous investigation.[1a] After the temperature had become stationary the reactant mixture was passed through the reaction tube. The liquid products were collected in a water-trap and then in two dry ice-acetone traps containing 150 ml of ether as an absorbent. After that the gaseous products were collected in a 500 ml sampling flask to which the effluent was bypassed. The water trap was washed twice with 25 ml ether, and then a portion of the ether washed was taken up according to the collection time of the liquid products and was combined with the ether of two dry ice-acetone traps. The pyrolysis was performed under conditions varying over the following wide range; temperature, 800—1200°C; contact time, 0.665×10^{-3}—78.9×10^{-3} sec; concentration of allyl chloride, 4.0—13.5 mol%.

Analysis. Reaction products, consisting of hydrogen and hydrocarbons (mainly from methane up to C_6's), were analyzed by gas chromatography (g.l.c) using six different columns. The columns and their operating conditions are shown in the above table.

Product identification followed careful comparison of the retention behavior of standard hydrocarbons with the unknown products, employing two or more columns with different polarity.

Results

A part of the experimental results is shown in Tables 2 and 3. The yield of each product was given by moles per 100 mol of allyl chloride pyrolyzed. Since methylacetylene and allene are equilibrated rapidly over the isomerization catalysts,[10] their total yield was shown to evaluate conditions for the synthesis of methylacetylene. In order to examine the hydrogen and carbon balance, the percentage of hydrogen and carbon accounted for in the reaction products (H_2 and C_1–C_6 hydrocarbons) was calculated from their yields. Though we tried to identify C_5 components (for example, cyclopentadiene, *etc.*), they were not produced in our experimental conditions.

The Effect of Temperature on Product Yields. For the gaseous products, the results obtained in the conversion range from 18 to 26% are shown in Table 2 and Fig. 2. The yields of

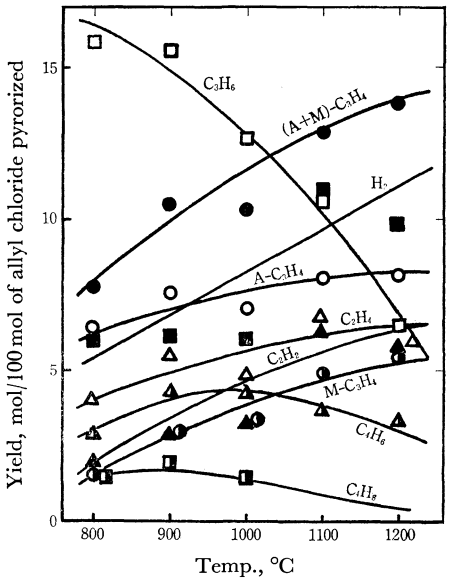

Fig. 2. Effect of temperature on gaseous product yields. Conversion, 18—26%

both methylacetylene and allene increased with the increase of temperature from 800 to 1200°C; the total yield of methylacetylene and allene ranged from 8 mol at 800°C up to 14 mol at 1200°C. Although the total yield increased rapidly at the lower temperatures, the increase was much slower at higher temperatures, ranging from 1100 to 1200°C. Propylene, on the other hand, decreased with an increase in the temperature from 16 mol to 7 mol. At 1000°C, the yield of propylene was much the same as the total yield of allene and methylacetylene. The other main products through C_4 hydrocarbons were hydrogen, methane, acetylene, ethylene, butene-1, and butadiene. The yields of hydrogen, acetylene, and ethylene increased

gradually with an increase in the temperature, reaching 10 mol, 6 mol, and 6 mol, respectively, while the yield of butadiene showed a maximum near 1000°C, and then decreased to 3 mol at 1200°C. The yield of butene-1 decreased gradually from 2 mol at 800°C to the trace amount at 1200°C.

For the liquid products (C_6 components), the results obtained in the conversion range from 18 to 26% are shown in Table 2 and Fig. 3. The yield of benzene decreased with the increase of temperature from 20 mol at 800°C to 10 mol at 1200°C. The yield of 1,3-cyclohexadiene decreased fairly rapidly until 1000°C, and then decreased gradually, ranging from 7 mol at 800°C to 2 mol at 1100°C, while the yield of diallyl was almost constant at about 2 mol all through the temperature examined. Consequently the total yields of C_6 components fell gradually from 28 mol at 800°C to 12 mol at 1200°C.

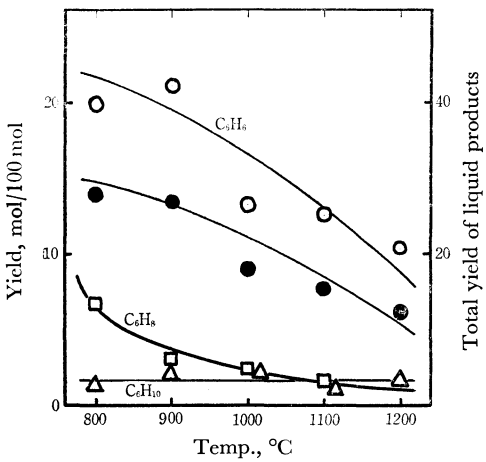

Fig. 3. Effect of temperature on liquid product yields. Conversion, 18—26%
●: total yield of liquid products

On the whole, the polymerization products, C_6 compounds, decreased with the increase in temperature, as is generally known for the decomposition of hydrocarbons (Fig. 3). The carbon and hydrogen balance, however, became remarkably worse at higher temperatures, owing to the increase of tarry and carbonaceous products (Table 2).

The Effect of Conversion on Yields. For the gaseous products, the results of the pyrolysis at 1000°C are shown in Table 3 and Fig. 4. The total yield of methylacetylene and allene decreased with the increasing conversion, ranging from 15 mol at 10% conversion to 4 mol at 90% conversion. In this connection, as the conversion was increased, the yield of allene fell at a considerable rate from 11 mol at 10% conversion to 2 mol at 90% con-

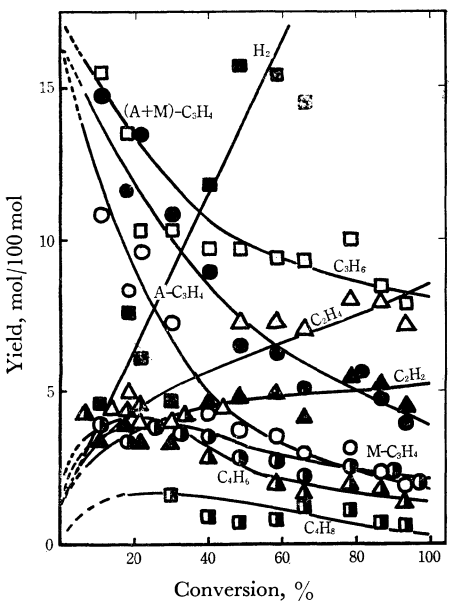

Fig. 4. Effect of conversion on gaseous product yields. Temp., 1000°C

version, while that of methylacetylene was fairly constant at 4 mol in a 10—30% conversion range, and beyond this conversion range, it decreased gradually from 4 mol to 2 mol at 90% conversion. Thus, taking account of an equilibrium relation between methylacetylene and allene, it seems probable that methylacetylene is not a primary product, but a secondary one produced by the isomerization of allene.[1b] The yield of propylene decreased from 15 mol at 10% conversion to 8 mol at 90% conversion. Hydrogen increased from 4 mol at 10% conversion to 20 mol at 90% conversion. The yields of acetylene and ethylene increased gradually from 3 mol and 4 mol at 10% conversion to 5 mol and 8 mol at 90% conversion, respectively. The yield of butadiene decreased gradually from 4 mol at 10% conversion to 2 mol at 90% conversion.

The results for the liquid products at the same temperature are shown in Table 3 and Fig. 5. As the conversion increased, the yield of benzene increased gradually from 14 mol at 10% conversion to 18 mol at 80% conversion, while those of 1,3-cyclohexadiene and diallyl fell rapidly in the lower part of the conversion range from 6 mol at 10% conversion to trace amounts at 60% conversion. As a result, the total yields of C_6 components decreased gradually with the increasing conversion from 26 mol at 10% conversion to 18 mol at 80% conversion.

The amounts of tarry and carbonaceous products

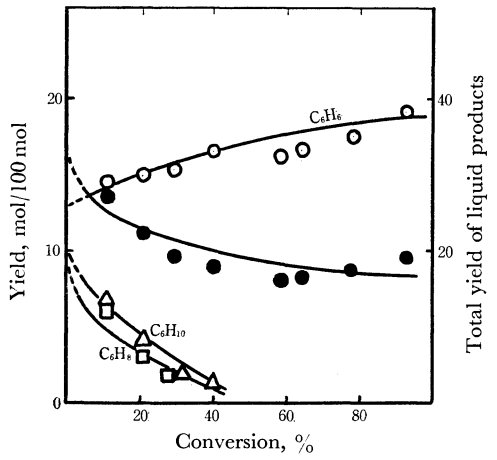

Fig. 5. Effect of conversion on liquid product yields. Temp., 1000°C

●: total yield of liquid products

increased with the increasing conversion to make the material balance remarkably worse, as described in Table 3. Furthermore, it was determined by the zero conversion method that the main products in the early stage of the pyrolysis were propylene, allene, hydrogen, benzene, 1,3-cyclohexadiene, and diallyl, as shown in Figs. 4 and 5.

The Effect of Concentration on Yields. The yields of products obtained in a concentration range of 4 to 12 mol% at 1000°C are shown in Fig. 6 (also in Table 3). When the concentration increased, the yield of propylene was almost constant, being about 11 mol, while the yields of allene and methylacetylene were influenced remarkably and fell from 8 mol to 6 mol and 4 mol to 3 mol, respectively. As a result, the total yield of allene and methylacetylene decreased at a considerable rate with the increasing concentration, ranging from 12 mol at 4 mol% to 9 mol at 12 mol%. The yield of benzene increased from 13 mol to 16 mol with an increase in the concentration. It was further observed that the change of the concentration had no remarkable influence on the yield of any other products, that is, hydrogen, methane, acetylene, ethylene, butene-1, butadiene, diallyl, and 1,3-cyclohexadiene.

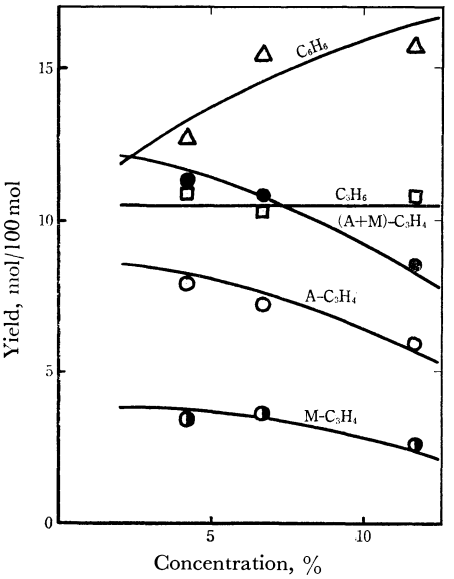

Fig. 6. Effect of concentration on product yields. Temp., 1000°C. Conversion, 29—33%

Kinetics. A rough estimate of the activation energy for the over-all process was made using our data at 800—1200°C. The pyrolysis was found to be first order at a given temperature range. An Arrhenius plot (Fig. 7) of first order

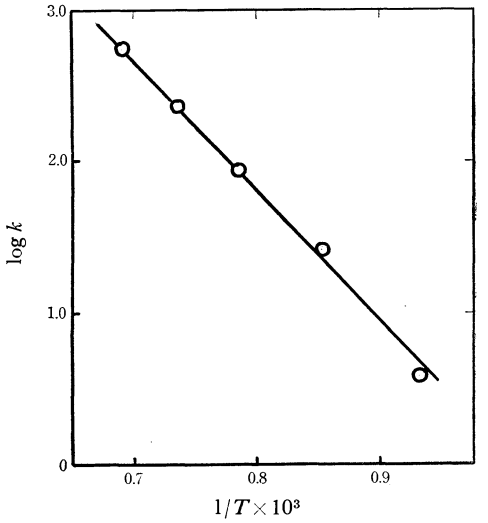

Fig. 7. Plot log k against $1/T$ for allyl chloride.

rate constants based on gas chromatographic analysis for allyl chloride consumed gave a value of 39.4 kcal/mol for the over-all activation energy. This value is much lower than the dissociation energy of allyl chloride, $E_{C_3H_5\text{-}Cl}=58$ kcal/mol.[3] The corresponding A factor was $10^{8.7}$ sec^{-1}. The values of the activation energy and A factor obtained were in good agreement with the values of 42.5 kcal/mol and $10^{9.10}$ sec^{-1} found by Goodall and Howlett. In addition, the activation energy we found was intermediate between those reported by Goodall and Howlett, and Hughes and Yates who reported 34.7 kcal/mol as the over-all activation energy of the pyrolysis.

Discussion

Mechanism. In the present investigation, the reaction products were essentially identical with

those of Porter and Rust, and Hughes and Yates, except that allene and methylacetylene were found as the major products. Thus, the mechanism proposed by both of these authors may be convenient for explaining the experimental results, taking into further consideration the formation steps of allene and methylacetylene. According to the zero conversion method (Figs. 4 and 5), it was concluded that propylene, allene, hydrogen, diallyl, 1,3-cyclohexadiene, and benzene were the main products in the early stage of the pyrolysis. Consequently, a following mechanism may be proposed for the pyrolysis of allyl chloride.

Main Reactions

$$CH_2{=}CH{-}CH_2Cl \rightarrow CH_2{=}CH{-}CH_2\cdot + Cl \quad (1)$$

$$CH_2{=}CH{-}CH_2\cdot + CH_2{=}CH{-}CH_2Cl \rightarrow CH_2{=}CH{-}CH_3 + CH_2{=}CH{-}\dot{C}HCl \quad (2)$$

$$Cl + CH_2{=}CH{-}CH_2Cl \rightarrow HCl + CH_2{=}CH{-}\dot{C}HCl \quad (3)$$

$$CH_2{=}CH{-}CH_2\cdot \rightarrow CH_2{=}C{=}CH_2 + H \quad (4)$$

$$H + CH_2{=}CH{-}CH_2Cl \rightarrow H_2 + CH_2{=}CH{-}\dot{C}HCl \quad (5)$$

$$CH_2{=}CH{-}CH_2\cdot + H \rightarrow CH_2{=}CH{-}CH_3 \quad (6)$$

$$2CH_2{=}CH{-}CH_2\cdot \rightarrow C_6H_{10} \quad (7)$$

$$CH_2{=}CH{-}CH_2\cdot + CH_2{=}CH{-}\dot{C}HCl \rightarrow C_6H_8 + HCl \quad (8)$$

$$2CH_2{=}CH{-}\dot{C}HCl \rightarrow C_6H_6 + 2HCl \quad (9)$$

Side Reactions

Methane

$$CH_3\cdot + RH \rightarrow CH_4 + R\cdot \quad (10)$$

Acetylene

$$CH_3{-}C{\equiv}CH + H \rightarrow HC{\equiv}CH + CH_3\cdot \quad (11)$$

$$\cdot CH{=}CH_2 \rightarrow CH{\equiv}CH + H \quad (12)$$

Ethylene

$$CH_3{-}CH{=}CH_2 + H \rightarrow CH_3\cdot + CH_2{=}CH_2 \quad (13)$$

$$CH_2{=}CH{-}CH_2{-}CH_2{-}CH{=}CH_2 + H \rightarrow CH_2{=}CH_2 + \cdot CH_2{-}CH_2{-}CH{=}CH_2 \quad (14)$$

$$\cdot CH_2{-}CH_2{-}CH{=}CH_2 \rightarrow CH_2{=}CH_2 + \cdot CH{=}CH_2 \quad (15)$$

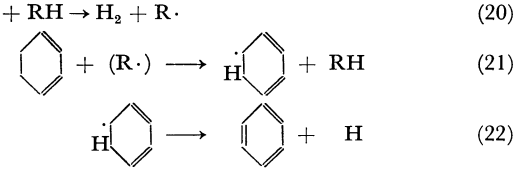
Hydrogen

$$H + RH \rightarrow H_2 + R\cdot \quad (20)$$



Reactions (1) to (9) are the main reactions in the early stage of the pyrolysis. Reactions (10) to (22) are the principal side reactions, which would be predominant in the higher conversions. The compatibility of the proposed mechanism with the observed experimental data can now be explained.

Main Reactions. Reaction (1) is the initial step which indicates the dissociation of allyl chloride into an allyl radical and a chlorine atom. All the main products, propylene, allene, hydrogen, diallyl, 1,3-cyclohexadiene, and benzene are formed by subsequent Reactions (2) and (6), (4), (5), (7), (8), and (9), respectively. Reaction (4), being the step of the formation of allene from allyl radical,[11,12,1b] appears to be an important course under the conditions studied. Reactions (2), (4), (6), (7), and (8) involving allyl radical proceed competitively with each other. Of these reactions, Reaction (4) appears to become predominant at higher temperature and lower concentration, as supported by the experimental results that allene and methylacetylene increase with an increase in the temperature, and propylene and all C_6 compounds decrease reversely (Figs. 2 and 3). This may be plausible judging from the theoretical foundation that Reaction (4) only is a unimolecular reaction which requires a high activation energy of about 62 kcal/mol.[12a,13] Reactions (8) and (9) are complicated reactions which include combination of allyl and chloroallyl radicals followed by cyclization.[7]

Keeping our mind on Reactions (1) and (3), the over-all reaction in the early stage of the pyrolysis will be represented by the reaction $2C_3H_5Cl \rightarrow C_3H_5 + C_3H_4Cl + HCl$. Consequently, when 100 mol of allyl chloride is decomposed, 50 mol of allyl radical and 50 mol of chloroallyl radical are formed, respectively. Among the reaction products, propylene, allene, methylacetylene, and diallyl are derived certainly from allyl radicals, similarly benzene from chloroallyl radicals, and 1,3-cyclohexadiene from both radicals. As a result, in the early stage of the pyrolysis, the amount of allyl radical should be approximately equal to the sum of the amounts of propylene, allene, methylacetylene, 1,3-cyclohexadiene, and twice of the amounts of diallyl, while the amount of chloroallyl radical should be equal to the sum of the amounts of 1,3-cyclohexadiene and twice of the amounts of benzene. The fact that this relationship is approximately correct can be confirmed from the following results taken from Run 11 at 800°C and Run 12 at 1000°C (Table 3). These observed values 50.4, 46.8, and

11) M. Szwarc, *J. Chem. Phys.*, **17**, 284 (1949).

12) a) A. Amano and M. Uchiyama, *J. Phys. Chem.*, **68**, 1133 (1964); b) K. J. Laidler and B. W. Wojciechowski, *Proc. Roy. Soc.*, **A259**, 257 (1960).

13) K. W. Egger, D. M. Golden and S. W. Benson, *J. Am. Chem. Soc.*, **86**, 5420 (1964); R. J. Ellis and H. M. Frey, *J. Chem. Soc.*, **1964**, 5578; D. M. Golden, A. S. Rodgers and S. W. Benson, *J. Am. Chem. Soc.*, **88**, 3196 (1966).

49.5 are approximate to theoretical value 50.0.

Run 11

$$C_3H_5\cdot \rightarrow C_3H_6 + C_3H_4 + 2C_6H_{10} + C_6H_8$$
$$50.0 \fallingdotseq 17.9 + 8.1 + 2 \times 6.7 + 11.0 = 50.4$$
$$\dot{C}_3H_4Cl \rightarrow C_6H_8 + 2C_6H_6$$
$$50.0 \fallingdotseq 11.0 + 2 \times 17.9 = 46.8$$

Run 12

$$C_3H_5\cdot = 49.5, \quad \dot{C}_3H_4Cl = 35.1$$

The discrepancy between the value of Run 11 and that of Run 12 lies in the difference of temperature. The lower value of chloroallyl radical for Run 12 may be caused by the decomposition of chloroallyl radical to chloroallene and/or $CH_2{=}CH{-}\dot{C}H$ that appears to be probable at higher temperature, though it is not shown in the reaction mechanism. Furthermore, the decrease of carbon and hydrogen balance with the increasing temperature (Table 2) may be discussed in connection with this. Namely, it seems reasonable to presume that the decompositions, followed by association, of allyl and chloroallyl radicals leading to tarry and carbonaceous products may increase remarkably at higher temperature, judging from the fact that benzene is fairly stable under our experimental conditions. From the results mentioned above, it is concluded that the decomposition products in the early stage of the pyrolysis are well accounted for by considering the mechanism comprised mainly reactions of allyl and chloroallyl radicals formed in the pyrolysis.

Side Reactions. Besides the main products, several side reaction products were obtained: methane, acetylene, ethylene, methylacetylene, butene-1, butadiene. The formations of these side reaction products are assumed to proceed largely by Reactions (10)—(15) and (17)—(19). In the experimental results, C_2 compounds, ethylene and acetylene, and C_4 compounds, butene and butadiene, were formed in considerable amounts (Table 2). This fact suggests that diallyl decomposed to give C_2 and C_4 compounds, as shown in Reaction (14). In fact, it was confirmed by our reference experiment that almost the same amounts of C_2 compounds, ethylene and acetylene, and C_4 compounds, butene and butadiene were formed in the pyrolysis of diallyl. Concerning thermal isomerization of allene to methylacetylene, it is reported also by the present authors that allene isomerizes to methylacetylene in fairly good yield at high temperatures.[1] Propylene, hydrogen, and benzene would probably be formed also by Reactions (16), (20), (21), and (22) in addition to the main Reactions (2) and (6), (5), and (9).

As the conversion increases, the pyrolysis reaction would become complex since the participation of hydrogen abstraction by chlorine atom in secondary reactions increases remarkably . Thus, it is difficult to account for the experimental results at high conversions. The rapid decrease in the yields of propylene and allene - methylacetylene with the increasing conversion (Fig. 4) may be responsible for the loss owing to various secondary decomposition and polymerization reactions; the extremely rapid decrease in allene appears to be plausible from the fact that allene is unstable, compared with propylene, and is apt to undergo various secondary reactions including the isomerization Reaction (17). On the other hand, the yield of benzene increases little by little with the increasing conversion (Fig. 5). This may be due mainly to the conversion of 1,3-cyclohexadiene into benzene by Reactions (21) and (22), and to large stability of benzene under our experimental conditions.

As the concentration of allyl chloride increases, bimolecular reactions become more advantageous than unimolecular reactions. The increase in the yield of benzene and the decrease in the yield of allene and methylacetylene with the increasing concentration correspond with this (Fig. 6).

Oxygen Exchange Reaction of Sulfoxides in Dinitrogen Tetroxide[1]

Norio KUNIEDA, Kazuo SAKAI and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received August 17, 1968)

Sulfoxides are known to undergo concurrent oxygen exchange and racemization reactions with various reagents (*Bull. Chem. Soc. Japan*, **41**, 1025 (1968)). Especially well studied are the oxygen exchange reactions in acid media. We have found a similar concurrent oxygen exchange and racemization reaction of sulfoxides with liquid dinitrogen tetroxide. The pseudo first order reaction rates of both oxygen exchange and racemization reactions have been determined using both optically active and ^{18}O-labeled sulfoxides. The k_{ex}/k_{rac} value was found to be unity, and the polar effect of substituents on the rates of oxygen exchange of substituted diphenyl sulfoxides was found to be considerably large, and correlated with σ^+ values with $\rho = -1.30$. From these results a plausible mechanism for this reaction has been discussed.

Sulfoxides are of stable pyramidal structure and isoelectronic to carbanions, amines, phosphines, sulfonium ions, *etc.*[2] Therefore, the optical isomerism can exist in sulfoxides, and the stereochemical stability of sulfoxides are known to be far exceeding those of similar sulfonium compounds. Furthermore, unlike those in sulfone group, the S-O linkage of sulfoxides is weak and readily cleaves. These are quite advantageoues for nucleophilic substitutions to occur on the sulfur atom. In fact, there are number of reactions which involve the facile cleavage of the S-O linkage.[3] The concurrent oxygen exchange and racemization reactions of sulfoxides are interesting reactions in these connections, and have attracted considerable attentions in recent years. These oxygen exchange reactions are very convenient for studying the nature of nucleophilic substitution on the trivalent sulfur atom, since one can readily prepare both ^{18}O-labeled and optically active sulfoxides[4] and follow both the loss of ^{18}O-content and the change of optical rotation simultaneously.

There are three types of mechanistic pathways in the nucleophilic substitution on the trivalent sulfur atom. The first type (Type-1) is like an S_N1-type reaction on sp^3 carbon atom, where, the cleavage of the S-O bond takes place in the initial slow step followed by fast recombination with solvent, resulting in the racemization. Among many examples of this type, there are concurrent oxygen exchange and racemization reactions of sulfoxides in concentrated sulfuric acid,[5] in phosphoric acid[6] and in chloroacetic acids.[7] The second type (Type-2) is the mechanism involving an S_N2-like nucleophilic replacement at the sulfur atom forming a new S-O bond while cleaving the old S-O bond at the rate-determining step, resulting in the inversion of configuration of the original sulfoxide. However, unlike the S_N2 reaction on saturated carbon atom there are two possible steric arrangements of both entering and outgoing groups in the nucleophilic substitution involving steric inversion on the sulfur atom, since the intermediate or the incipient complex at the transition state is expected to assume a typical bipyramidal structure. Namely, in addition to the usual S_N2 type arrangement in which both entering and leaving groups assume axial positions, there is another arrangement in which both groups assume radical positions. Both steric arrangements will lead to the net inversion of configuration. Among the former examples are the oxygen exchange reactions of sulfoxides in acetic anhydride[8] and in less concentrated sulfuric acid.[9] The latter example may be found among the reactions of sulfoxides with cyclic oxy-compounds which is now under investigation. There is another type, *i. e.*, (Type-3); when leaving

Dibenzothiophene oxide	0.43	0.24	88	10	CCl_4-$CHCl_3$
Phenoxathiin 5-oxide	0.86	0.26	93	10	CCl_4-$CHCl_3$

and entering groups assume axial and radial positions, the oxygen exchange will lead to the retention of configuration. The first example of this type may be the reaction of sulfoxides with DMSO.[10]

Dinitrogen tetroxide is known to be a unique reagent which can oxidize sulfides specifically to the corresponding sulfoxides.[11] Recently we have found that the oxygen exchange reaction of diphenyl sulfoxide readily takes place in liquid dinitrogen tetroxide[12] in similar conditions used for the oxidation of sulfides. Meanwhile Johnson and McCants have also reported that (+)- benzyl *p*-tolyl sulfoxide is rapidly racemized in this reagent.[13] Since dinitrogen tetroxide is a somewhat different oxygen exchange reagent from those used previously, one might expect an entirely different mechanistic route for the oxygen exchange reaction. However, a more careful kinetic study has been desired in order to elucidate a plausible mechanism for this reaction. We now have compiled substantial amounts of kinetic data on this reaction with several sulfoxides in liquid dinitrogen tetroxide and found that this reaction is one of a typical example of Type-1 proceeding through an S_N1-like S–O bond cleavage at the rate-determining step. This paper describes a detailed account of the kinetic study.

Results and Discussion

When a sulfoxide is dissolved in an excess of dinitrogen tetroxide at 0°C, the sulfoxide can be recovered almost quantitatively after an hour without undergoing further oxidation to the sulfone or any other side reaction with dinitrogen tetroxide, and its mp and IR spectrum are completely identical to those of the starting sulfoxide. A few representative results are shown in Table 1. The heteroaromatic sulfoxides, *i. e.*, dibenzothiophene oxide and phenoxathiin 5-oxide, also undergo the oxygen exchange with this reagent.

Earlier Johnson and McCants reported that (+)-benzyl *p*-tolyl sulfoxide is rapidly racemized by liquid dinitrogen tetroxide.[13] We have examined the oxygen exchange reaction of ^{18}O-labeled, optically active ethyl *p*-tolyl sulfoxide in this reagent,[12] and found, as shown in Table 2, that

b) Ratio of oxygen exhcange=91%.

the racemization is not an independent reaction but accompanies concurrent oxygen exchange reaction in a fashion similar to that in acid media of our previous works.[14]

In the oxidations of sulfides or disulfides with dinitrogen tetroxide, the reaction mixture usually develops a green or blue color, due to the formation of dinitrogen trioxide, and nitric oxide (NO) is evolved.[11]

$$R_2S + N_2O_4 \longrightarrow R_2S{\rightarrow}O + N_2O_3$$
$$N_2O_3 \rightleftarrows NO + NO_2$$

However, when a sulfoxide is dissolved in dinitrogen tetroxide there is no color change or evolution of nitric oxide. Apparently the concurrent oxygen exchange and racemization reactions of sulfoxides proceed without consuming dinitrogen tetroxide. Actually, when 0.997 g of ^{18}O-labeled diphenyl sulfoxide (0.66 atom%-^{18}O) was dissolved in 2.386 g of dinitrogen tetroxide in a vessel connected to

a vacuum line and the solution was kept for 30 min at 0°C, almost quantitative amount of dinitrogen tetroxide (2.379 g) (colorless crystals at the temperature of dry ice-acetone bath) was recovered together with 0.997 g of the oxygen-exchanged sulfoxide (0.25 atom%-^{18}O).

$$\begin{matrix} R \\ R' \end{matrix}\!\!\diagdown\!\!\diagup S^{*}\!\rightarrow {}^{18}O + N_2O_4 \rightleftharpoons O\leftarrow S^{*}\!\!\begin{matrix} \diagup R \\ \diagdown R' \end{matrix} + N_2{}^{18}O_4$$

Since the oxygen exchange reaction accompanies the racemization of sulfoxides, the mechanism of Type-3 is excluded, leaving two other possible mechanistic routes. If the cleavage of S–O bond takes place in the initial slow step followed by fast recombination with solvent according to the Type-1, each oxygen exchange will cause racemization, and then the rate of oxygen exchange becomes identical to that of racemization; $k_{ex}/k_{rac}=1$. The other is the Type-2 mechanism which involves an S_N2-like simultaneous bond forming and cleavage of S–O bond at the rate-determining step, and each oxygen exchange of sulfoxides will result in the inversion of configuration at the central sulfur atom and hence the ratio k_{ex}/k_{rac} becomes 0.5.

The rates of both oxygen exchange and racemization of ^{18}O-labeled and optically active *p*-tolyl phenyl sulfoxide in dinitrogen tetroxide - carbon tetrachloride solution were carefully measured. The results, shown in Table 3, clearly reveal that the rate of the oxygen exchange is identical to that of the racemization, suggesting that the reaction proceeds through the Type-1 mechanism. Furthermore, the rate of this reaction was found to be of first order dependence on the concentration of dinitrogen tetroxide as shown in Fig. 1. The rate constants obtained are of pseudo first order even under the condition when the mole ratio of sulfoxide to dinitrogen tetroxide is atmost 1 : 2—3.

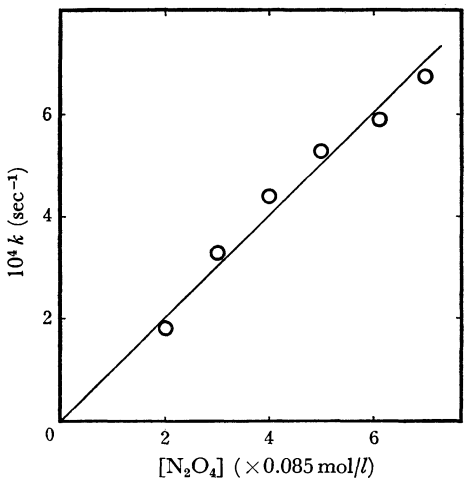

Fig. 1. Rate constants of racemization reaction of (+)- *p*-tolyl phenyl sulfoxide (0.1 mol/l) plotted against mole concentration of dignitrogen tetroxide in carbon tetrachloride at 0°C.
Slope = 1.01 (r=0.993)

It is known that alkyl sulfoxides form molecular addition compounds with dinitrogen tetroxide[15] and the formation of such addition compounds may inhibit further oxidation of sulfoxides to sulfones. The compound formation is considered to be resulted by the interation between electron-rich sulfoxide oxygen and the electron-deficient dinitrogen tetroxide molecule.

TABLE 3. RATE CONSTANTS OF ^{18}O-EXCHANGE AND RACEMIZATION OF *p*-TOLYL PHENYL SULFOXIDE[a] IN DINITROGEN TETROXIDE AT 0°C

Mole concentration of N_2O_4 (mol/l)	10^4k(sec^{-1}) k_{ex}	k_{rac}	k_{ex}/k_{rac}
0.530[b]	6.23±0.12	6.35±0.30	0.983±0.027
0.462[c]	10.4 ±0.1	10.4 ±0.6	1.00 ±0.05
0.281[c]	4.64±0.13	4.80±0.28	0.970±0.030

a) Sulfoxide=0.1 mol/l. b) and c) are media of different batch.

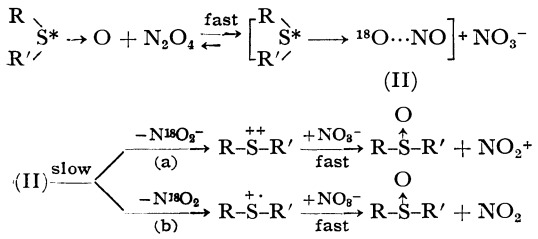
There are two possible structures, *i. e.*, molecular (I) and ionic complex (II), for the addition compounds of sulfoxides.

$$[R_2SO\cdot N_2O_4] \quad [R_2SO\cdots NO]^+ NO_3^-$$
$$\text{(I)} \qquad\qquad \text{(II)}$$

Addison and Sheldon have shown that the molecular complex (I) is favorable in solid state.[15] But in liquid state the ionic structure (II) would be more favorable, since its equilibrium $N_2O_4 \rightleftarrows NO^+NO_3^-$ is also established in the liquid state and the NO^+ ion is also electron deficient, and, morevoer, the sulfoxides are considered to be the donors of medium strength.[16] Therefore, the sulfoxides would form the ionic complex (I) in liquid dinitrogen tetroxide at the initial step of the oxygen exchange and racemization reaction. On the basis of these informations, the following reaction scheme may be constructed, in which the second step of the cleavage of S–O bond is the slow rate-determining step. Path (a) is the heterolysis of the S–O bond to form the doubly positively charged "sulfidonium ion" intermediate. Path (b) is the homolysis to form the cation radical intermediate. If the reaction follows the path (a), the

15) C. C. Addison and J. C. Sheldon, *J. Chem. Soc.*, **1956**, 2705.

16) The classification of structure of dinitrogen tetroxide addition compounds has been offered by Addison and Sheldon [Ref. 15, and H. H. Sisler, *J. Chem. Educ.*, **34**, 555 (1957)], which said a medium strength donors, *e. g.*, carbonyl compounds and sulfoxides, *etc.*, form together ionic and molecular complexes in liquid dinitrogen tetroxide.



rate would be substantially more effected by polar substituents like in the case of the S_N1-type reaction of carbon compounds than in the case of path (b). Recently, we have found that the most reasonable mechanism for the concurrent oxygen exchange and racemization reactions of diaryl sulfoxides in concentrated sulfuric acid is through the path involving the homolysis of the S–O bond forming the radical cation intermediate. In this case, the polar effects of substituents on the phenyl group are very small and *p*-methyl group accelerates the rate only less than twofold while the electron-withdrawing *p*-chloro group also give a small acceleration.[5b] The rates of the oxygen exchange of several *p*-substituted diphenyl sulfoxides were measured in dinitrogen tetroxide - carbon tetrachloride solution. One finds in Table 4 that the polar effects of *p*-substituents on the rates are considerably large, and the rates are nicely correlated with Brown-Okamoto's σ^+ values and give a considerably large negative ρ value (for σ; $\rho=-1.58$, Correlation coefficient $r=0.948$) (for σ^+; $\rho=-1.30$, $r=0.990$).

Table 5. Oxygen exchange of ^{18}O-labeled diphenyl sulfone[a] in dinitrogen tetroxide at 0°C for 1 hr

	^{18}O-Concentration (atom%)	
	Starting sulfone	Recovered sulfone
Run 1	1.64	1.60
Run 2	1.76	1.71

a) Mole ratio of sulfone to N_2O_4 was 1 : 10.

These rather large polar effect seems to favor the heterolytic cleavage, *i. e.*, path (a) for the reaction.

Diphenyl sulfone was found not to undergo the oxygen exchange in this reagent even without the solvent, as shown in Table 5. This is undoubtedly due to the much strong nature of the S–O bond of sulfones for cleavage in comparison with that of sulfoxides.

Experimental

Materials. *^{18}O-Labeled sulfoxides* were prepared by the oxidation of corresponding sulfides with bromine complex of pyridine and ^{18}O-enriched water in acetic acid by the same procedure as described in our previous paper.[17] Diphenyl sulfoxide; mp 70—71°C (71°C),[18] 0.86_3atom%-^{18}O. Phenyl *p*-tolyl sulfoxide; mp 71—72°C (71—72°C),[18] 1.0_7atom%-^{18}O. Phenyl *p*-chlorophenyl sulfoxide; mp 45—46°C (45—46°C),[18] 1.1_8atom-^{18}O. Phenyl *p*-methoxyphenyl sulfoxide; mp 60°C (55—57°C),[18] 0.57_0atom%-^{18}O. Benzyl phenyl sulfoxide; mp 121—122°C (123°C),[19] 1.0_5atom%-^{18}O. Dibenzyl sulfoxide; mp 136—137°C (133°C),[19] 1.6_8-atom%-^{18}O. Dibenzothiophene oxide; mp 62—67°C, 0.43atom%-^{18}O. Phenoxathiin 5-oxide; mp 151°C (153—154°C),[20] 0.86atom%-^{18}O.

Optically active p-tolyl phenyl sulfoxide was prepared from (−)-menthyl (−)-*p*-toluenesulfinate and phenyl magnesium bromide according to the method developed by Andersen.[4a] Mp 91.5—92°C, $[\alpha]_D=+31.8°$ in CCl_4 ($l=0.5$, $c=1.68$), $[\alpha]_D=+27.8°$ in 96% EtOH ($l=0.5$, $c=1.63$) (lit.[21]); mp 92—93°C, $[\alpha]_D=+27°$ in 95% EtOH).

^{18}O-Labeled optically active ethyl p-tolyl sulfoxide was prepared by Andersen's method[4a] using ^{18}O-labeled (−)-menthyl (−)-*p*-toluenesulfinate which was prepared from ^{18}O-labeled sulfinic acid.[4b] Bp 95—97°C/0.5 mmHg, $[\alpha]_D=+183°$ in acetone ($l=1$, $c=2.1$) (lit[4a]; bp 123—126°C/1.5 mmHg, $[\alpha]_D^{25}=+186°$ in acetone).

^{18}O-Labeled diphenyl sulfone was prepared by the oxidation of diphenyl sulfide with *t*-butyl hypochlorite in the presence of ^{18}O-enriched water by the same procedure as described in our previous paper.[22] Mp 125—126°C (lit.[23]; 124°C), yield 98%.

Dinitrogen tetroxide was prepared by the pyrolysis of dinitrogen pentoxide.[24] The crude oxide was twice distilled over phosphorus pentoxide under faint stream

of dry oxygen, and then dissolved in pure carbon tetrachloride. The solution was stored in glass vessel with a secured stopper. Concentrations of dinitrogen tetroxide in carbon tetrachloride were determined by titration with a standard alkali solution.

Kinetic Procedure of the Oxygen Exchange and Racemization Reactions of Sulfoxides. An ^{18}O-labeled or an optically active sulfoxide was dissolved in the dinitrogen tetroxide - carbon tetrachloride solution of a predetermined concentration, in such a way as to maintain the concentration of the sulfoxide just about 0.1 mol/*l*, at a preset temperature (0°C). An aliquot portion (7.0 m*l*) of the solution was taken up from time to time for 6—7 times and was quenched witha cold alkaline solution (10% aqueous solution of K_2CO_3). The recovered sulfoxide was extracted with carbon tetrachloride, and the solution was washed with water, and dried over anhydrous sodium sulfate. Finally, carbon tetrachloride was distilled *in vacuo* and then the sulfoxide recovered was subjected to the ^{18}O-analysis or the measurement of optical activity according to the same procedures described in our previous paper[5] using Yanagimoto OR-10 Type polarimater and Hitachi RMU-6E Type mass-spectrometer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1094—1098 (1969)

A Study of the Solvent Effect on the Polymerization of *N*-Phenylethyleneimine

Tsutomu KAGIYA, Tomizo KONDO, Kozo NAKAO and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received August 21, 1968)

The effect of solvents on the cationic polymerization of *N*-phenylethyleneimine with formic acid catalyst has been studied quantitatively. The polymerization rates in the various solvents used increase in the following order: diethyl ether≃tetrahydrofuran<toluene≃carbon tetrachloride<anisole<methyl acetate<ethylene dichloride<*N*,*N*-dimethylacetamide<dimethyl sulfoxide<epichlorohydrin<acetonitrile. In polar solvents with high dielectric constants, the rates are much larger than those in nonpolar solvents with low dielectric constants. However, in the solvents with similar dielectric constants, such as acetonitrile and *N*,*N*-dimethylacetamide, ethylene dichloride, methyl acetate and tetrahydrofuran, and anisole and diethyl ether, the rates decreased with an increase in the nucleophilicity of the solvents, and the dependence of the polymerization rate on the nucleophilicity of the solvents is much larger in polar solvents than in nonpolar solvents. The propagation rate was markedly influenced by the nature of the solvent, whereas the initiation rate was only a little influenced.

A number of instances have been reported in which the polymerization rate was markedly influenced by the solvents used. No quantitative study of the solvent effect on the polymerization has yet been reported, however. It has been pointed out by many authors that the difference in the rate can not be explained only by the magnitude of the dielectric constant of the solvent, and that the characteristic features of the solvation also affect the reaction rate. As a part of the investigation of the electric nature of the molecule in the liquid phase, we have previously made a quantitative study of the nucleophilic solvation to a deuterium atom of the methanol-d molecule by using the infrared spectroscopic method, and have determined the equilibrium constant, K_D, of various solvents.[1]

1) T. Kagiya, Y. Sumida and T. Inoue, This Bulletin, **41**, 767 (1968).

The purpose of this paper is to investigate quantitatively the effect of the solvent on the polymerization of *N*-phenylethyleneimine by using the equilibrium constants thus obtained.

Experimental

The methods used in the preparation and purification of *N*-phenylethyleneimine have been described in a previous paper.[2] Formic acid and dimethyl sulfoxide of a guaranteed grade were used without further purification. The acetonitrile, epichlorohydrin, anisole, diethyl ether, methyl acetate, *N*,*N*-dimethylacetamide, carbon tetrachloride, toluene and ethylene dichloride were purified by the conventional method.[3] The tetrahydrofuran was distilled in the presence of sodium

naphthalene after drying over potassium hydroxide and calcium hydride. The methods of the polymerization and molecular-weight determination of the polymer were described in the previous paper. The polymerization was carried out under the following conditions: monomer, 0.005 mol; solvent, 1 ml; catalyst, 2 mol% on monomer; temperature, 0°C.

Results and Discussion

The polymerization of *N*-phenylethyleneimine was carried out in various solvents using formic acid as the catalyst. The plots of the polymer yield against the reaction period are shown in Fig. 1 and Fig. 2. These figures show that the polymerization rate varies markedly with the kind of solvent used. As is shown in Fig. 3 and Fig. 4, the rate of the monomer consumption is expressed by a first-order rate equation with respect to the monomer concentration in the early stages of the polymerization. Considering the fact that the steady-state method is applicable in the polymerization with formic acid in acetonitrile, as has been described in the previous paper, Figs. 3 and 4 may indicate that the concentrations of the propagating species, [P*], are almost constant in the early stages of the polymerization. Moreover, from the fact that the plot of the number-average degree of polymerization is almost proportional to

Experimental conditions are the same as in Fig. 1 and Fig. 2. (1) Acetonitrile, (2) Epichlorohydrin, (3) Dimethyl sulfoxide, (4) *N,N*-Dimethylacetamide, (5) Ethylene dichloride, (6) Methyl acetate, (7) Anisole, (8) Carbon tetrachloride, (9) Toluene, (10) Tetrahydrofuran, (11) Diethyl ether.

the polymer yield in the solvent used (Fig. 5), the concentration of the propagating species may be constant independently of the kind of solvent. The difference in the slopes of the line in Fig. 3 and Fig. 4 may, then, be due to the differences in the propagation rate between solvents.

From the slopes of the straight line in Fig. 3 and Fig. 4, the products of the rate constant of the propagation reaction, k_p, and the concentrations of the propagating species were obtained. The values of k_p[P*] are summarized in Table 1, along with the physical properties of the solvents. Figure 6 shows the result of plotting the logk_p[P*] value against the dielectric constant of the solvent. Although the polymerization rate tends to increase with an increase in the dielectric constant of the solvent, there was a great difference in the rates, even in solvents with similar dielectric constants, *e. g.*, acetonitrile and *N,N*-dimethylacetamide.

TABLE 1. THE POLYMERIZATION RATES AND THE PHYSICAL PROPERTIES OF THE SOLVENTS

No.	Solvent	k_p[P*] l/min	Dielectric constant ε	K_D
1	Acetonitrile	1720×10^{-5}	37.5	0.352
2	Epichlorohydrin	450	22.6	0.307
3	Dimethyl sulfoxide	210	48.9	2.79
4	*N,N*-Dimethyl acetamide	153	36.7	1.61
5	Ethylene dichloride	43.3	10.4	0.035
6	Methyl acetate	16.7	6.68	0.213
7	Anisole	14.2	4.33	0.136
8	Carbon tetrachloride	11.7	2.24	0.0051
9	Toluene	11.0	2.38	0.0348
10	Tetrahydrofuran	6.25	7.4	1.153
11	Diethyl ether	6.25	4.34	0.854

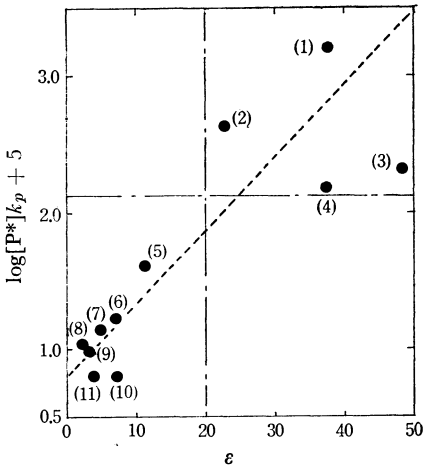

Fig. 6. Relation between log k_p[P*] and dielectric constant of solvents. The numbers of the solvent are the same as in Table 1.

In order to investigate the effect of the electric nature of the solvent on this polymerization, logk_p[P*] was plotted against K_D,[1] where K_D is the nucleophilic equilibrium constant of the solvent in the nucleophilic solvation to a deuterium atom of a methanol-d molecule (Fig. 7). Figure 7 shows

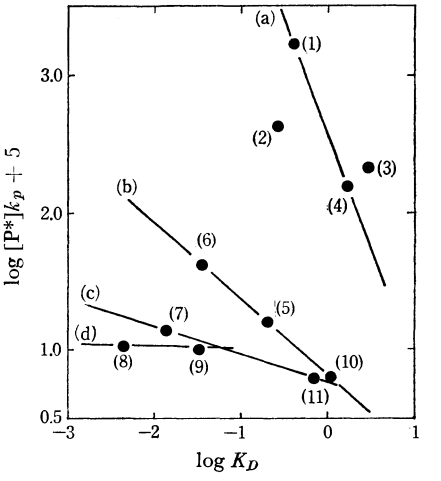

Fig. 7. Relation between log k_p[P*] and logK_D.
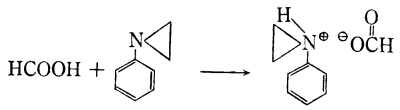
Solvents: (a) Acetonitrile and *N,N*-Dimethylacetamide, (ε; 36.6—37.5), (b) Ethylene dichloride, Methyl acetate and Tetrahydrofuran, (ε; 6.68—10.4), (c) Anisole and Diethyl ether, (ε; 4.33—4.34), (d) Carbon tetrachloride and Toluene, (ε; 2.24—2.38). The numbers of the solvent are the same as in Table 1.

that in solvents with similar dielectric constants ((a), (b), (c) and (d)), $k_p[P^*]$ decreased with an increase in the nuculeophilicity of the solvent. This fact indicates that the solvents coordinate competitively to the cationic end group of the polymer and that they depress the propagation rate. Moreover, from the fact that the slope of the straight line increases with an increase in the dielectric constant of the solvent, it is found that the dependency of $k_p[P^*]$ on the nucleophilicity of the solvent is larger in a solvent with high dielectric constant than in one with a low dielectric constant. As has been mentioned in the previous paper, the propagating species are considered to be the dissociated immonium ion and the undissociated immonium ion, which are in equilibrium in a solvent, and the polar solvent is considered to have a larger dissociation constant than the nonpolar solvent. Therefore, the higher dependency of the rate on the electron donability of the polar solvent than on that of the nonpolar solvent may indicate that the solvation of the solvent to the dissociated immonium ion is much larger than that to the undissociated immonium ion.

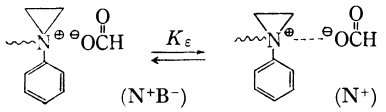
Mechanism of the Polymerization. From these experimental facts, the mechanism of the polymerization was postulated, with due consideration taken of the solvent effect.

Initiation:



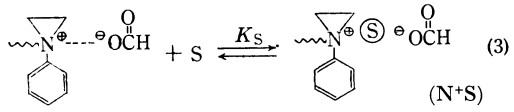
(1)

Propagation:



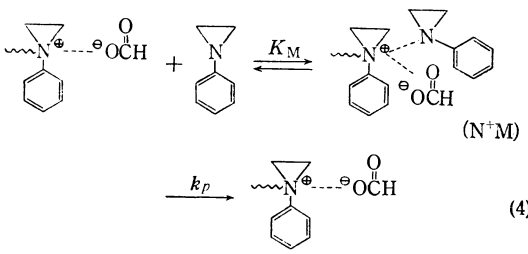
(2)

Propagation by the dissociated immonium ion:



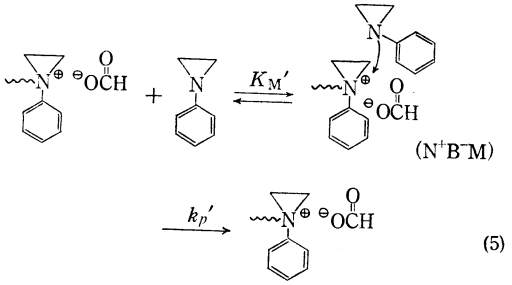
(3)

S: Solvent



(4)

Propagation by the undissociated immonium ion:



(5)

The initiation reaction is considered to be the reaction of formic acid with *N*-phenylethyleneimine to produce the compound (I). This compound dissociates partially to the immonium ion, and the reaction is in equilibrium. The equilibrium constant is considered to increase with an increase in the dielectric constant of the solvent. Equation (3) shows the solvation of the solvents to the dissociated immonium ion. Since the coordinations of solvents to both propagating species and methanol-d are nucleophilic reactions, the equilibrium constant (K_s) is considered to increase with an increase in K_D. From the facts that, in polar solvents, the propagation rates decrease with an increase in the electron donability of the solvent, propagation is considered to occur by means of a non-solvated immonium ion (Eq. (4)). On the other hand, since in nonpolar solvents, the propagation rate was constant independently of the kind of solvent, it is considered that the coordination of the solvent to the undissociated immonium ion is little, and that propagation occurs as is shown in Eq. (5).

Kinetics. On the basis of the mechanism postulated, the effect of the solvent on the rate of the polymerization (R_p) was quantitatively investigated. When the concentration of compound (I) is expressed by $\alpha[C]_0$, where $[C]_0$ is the initial concentration of the catalyst and whose α is the constant ($0<\alpha<1$), $\alpha[C]_0$ is expressed by Eq. (6):

$$\alpha[C]_0 = [N^+] + [N^+B^-] + [N^+S] + [N^+M] + [N^+B^-M] \quad (6)$$

On the other hand, from Eqs. (2), (3), (4) and (5), Eqs. (7), (8), (9) and (10) were obtained:

$$[N^+]/[N^+B^-] = K_\varepsilon \quad (7)$$

$$[N^+S]/([N^+][S]) = K_S \quad (8)$$

$$[N^+M]/([N^+][M]) = K_M \quad (9)$$

$$[N^+B^-M]/([N^+B^-][M]) = K'_M \quad (10)$$

By combining Eqs. (6), (7), (8), (9) and (10), the concentrations of (N^+B^-M) and (N^+M) are expressed in Eqs. (11) and (12) respectively:

$$[N^+B^-M] = \frac{\alpha[C]_0 K'_M[M]}{1 + K'_M[M] + K_\varepsilon(1+K_M[M] + K_S[S])} \quad (11)$$

$$[N^+M] = \frac{\alpha[C]_0 K_\varepsilon K_M[M]}{1 + K'_M[M] + K_\varepsilon(1+K_M[M] + K_S[S])} \quad (12)$$

The rate of the propagation is expressed in Eq. (13):

$$R_p = -\,\mathrm{d[M]}/\mathrm{d}t = k_p[\mathrm{N^+M}] + k'_p[\mathrm{N^+B^-M}] \quad (13)$$

By substituting Eqs. (11) and (12) into Eq. (13), Eq. (14) is derived:

$$R_p = \frac{(K\varepsilon K_\mathrm{M} k_p + K'_\mathrm{M} k'_p)\alpha[\mathrm{C}]_0}{1 + K'_\mathrm{M}[\mathrm{M}] + K\varepsilon(1+K_\mathrm{M}[\mathrm{M}] + K_\mathrm{S}[\mathrm{S}])}[\mathrm{M}] \quad (14)$$

Considering that K_M and K'_M are much smaller than unity, Eq. (14) may be expressed by Eq. (15):

$$-\mathrm{d[M]}/\mathrm{d}t \fallingdotseq \frac{(K\varepsilon K_\mathrm{M} k_p + K'_\mathrm{M} k'_p)\alpha[\mathrm{C}]_0}{1 + K\varepsilon(1+K_\mathrm{S}[\mathrm{S}])}[\mathrm{M}] \quad (15)$$

Equation (15) shows that the rate of the monomer consumption is expressed by a first-order rate equation with respect to the monomer concentration.

Since, in polar solvents, it is considered that propagation occurs mainly by the dissociated immonium ion, and that k_p is much larger than k_p', Eq. (14) may be expressed approximately by Eq. (16):

$$R_p \fallingdotseq \frac{K\varepsilon K_\mathrm{M} K_p \alpha[\mathrm{C}]_0}{1 + K'_\mathrm{M}[\mathrm{M}] + K\varepsilon(1+K_\mathrm{M}[\mathrm{M}] + K_\mathrm{S}[\mathrm{S}])} \quad (16)$$

By assuming $0 < K\varepsilon < 1$, Equation (16) explains the experimental facts that, in polar solvents, the polymerization rate increases with an increase in the $K\varepsilon$ value (that is, the dielectric constant of the solvent), and that, in a solvent with a similar dielectric constant, the rate decreases with an increase in the K_D (the nucleophilicity of the solvents). Moreover, it can be interpreted by Eq. (16) that the dependency of the rate on the electron donability of the solvent increases as the dielectric constant of the solvent increases. In nonpolar solvents, it is reasonable to consider that the terms of $K\varepsilon K_\mathrm{M} K_p$ and $K\varepsilon(1+K_\mathrm{M}[\mathrm{M}]+K_\mathrm{S}[\mathrm{S}])$ are negligible. Therefore, the rate equation with the use of the nonpolar solvents may be approximately expressed by Eq. (17):

$$R_p \fallingdotseq K'_\mathrm{M}\, k'_p\, \alpha[\mathrm{C}]_0[\mathrm{M}]/(1+K'_\mathrm{M}[\mathrm{M}]) \quad (17)$$

According to Eq. (17), we can explain the experimental finding that, in a nonpolar solvent, the nucleophilicity of the solvent has no effect on the polymerization rate.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1098—1100 (1969)

Photochemistry of β-Acylacrylic Acids and Their Esters

Noboru SUGIYAMA, Hiroshi KATAOKA, Choji KASHIMA and Kazutoshi YAMADA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received August 23, 1968)

The irradiation of methyl *trans*-β-acetylacrylate (I-A) in methanol or acetone or without any solvent gave the *cis*-isomer (I-B). On the contrary, the irradiation of the free acid of I-A, *trans*-β-acetylacrylic acid (II-A), in methanol or without any solvent gave the angelica lactone, 5-methyl-5-hydroxy-2-oxo-2,5-dihydrofuran (II-C). The irradiation of *trans*-β-pivaloylacrylic acid (III-A) in methanol also afforded the angelica lactone, 5-*t*-butyl-5-hydroxy-2-oxo-2,5-dihydrofuran (III-C). The reaction route from a *cis*-isomer to an angelica lactone was explained in terms of the inductive effect.

In a previous report of this series[1] three isomeric forms of β-acylacrylic acid, the *trans* form, the *cis* form, and the angelica lactone form, were described. We also found that, on irradiation in ether, *trans*-β-benzoylacrylic acid was isomerized to the *cis* form, while in methanol the methanol addition product, β-benzoyl-α-methoxypropionic acid, was obtained.[2-4] Similarly, β-(*p*-toluoyl)-, β-(*p*-anisoyl)- and β-(*p*-bromobenzoyl)-acrylic acids were found to give the methanol adduct.[5] On the other hand, an angelica lactone was obtained as a by-product of the irradiation of β-(*p*-toluoyl)-acrylic acid. Therefore, three reactions are possible in the irradiation of β-aroylacrylic acids: *cis-trans* isomerization, methanol addition, and lactonization.

4) D. V. Rao, V. Lamberti and H. M. Gardner, *Tetrahedron Letters*, **1968**, 1613.

5) Unpublished data.

It seemed of interest to examine the irradiation of methyl *trans*-β-acetylacrylate (I-A), *trans*-β-acetylacrylic acid (II-A), and *trans*-β-pivaloylacrylic acid (III-A).

Methyl *trans*-β-acetylacrylate (I-A) was irradiated in methanol by a high-pressure mercury lamp for 17 hr at room temperature. The structure of the product was determined to be methyl *cis*-β-acetylacrylate (I-B) as follows. New NMR signals observed as an AB quartet at τ 3.84 (J=12.0 c/s) can be assigned to the *cis* olefinic protons, while the two singlet signals at τ 6.27 and 7.72 represent ester methyl and acetyl methyl protons respectively. The yield of the *cis* isomer was 80%. In the reaction mixture, α-methoxylevulinate[6] was not detected.

Methyl *trans*-β-acetylacrylate (I-A) was also irradiated in a solid state and in an acetone solution under the same conditions as have been described above. In a solid state, I-A gradually turned to a liquid. The product in either a solid state or acetone was identified with its *cis*-isomer by means of the NMR spectra as well as by thin-layer chromatography. The yields were 64% in a solid state and 78% in acetone. When the solid state irradiation was continued for a week, no reaction proceeded except the formation of the *cis*-isomer in a yield of 90%.

The methanol solution of *trans*-β-acetylacrylic acid (II-A) was irradiated for 45 hr at room temperature. The photoproduct shows the carbonyl bands at 1760 and 1740 cm^{-1} in the IR spectrum. The NMR spectrum shows the singlet of methyl protons at τ 8.24 and two doublet signals of olefinic protons at τ 2.74 and 3.92 with a coupling constant of 6.0 c/s. These data suggest that the photoproduct is the angelica lactone of II-A, 5-methyl-5-hydroxy-2-oxo-2,5-dihydrofuran (II-C), which is also obtained from II-A by the treatment of thionyl chloride, followed by alkaline hydrolysis.[7]

The most conspicuous feature of NMR data is that the signals of the olefinic protons of methyl *cis*-β-acetylacrylate (I-B) appear in an AB quartet at τ 3.87 with a coupling constant 12.0 c/s, while that of methyl α-methoxylevulinate appears at τ 5.55 with a coupling constant of 6.0 c/s, while no signals of *cis*-isomer or of the methanol adduct are observed in this region. The yield of II-C was calculated for 60% based on the signal intensities of II-A and II-C at τ 3.40 and 3.92 respectively.

When the irradiation of II-A was continued for 115 hr, the yield of II-C reached 85%, while no other products were detected except II-A. This yield is reasonable because II-C is unstable, as has been reported by Scheffold,[7] and so about 15% of II-C might return to II-A.

When II-A was irradiated in a solid state, only II-C was obtained. The yield was 32%.

All the β-acylacrylic acids generally exist in the *trans* form at room temperature except for maleinaldehydic acid, which favors the angelica lactone form.[8] Considering the fact that methyl *trans*-β-acetylacrylate (I-A) is isomerized to the *cis* form I-B by the irradiation, the *trans* form of II-A is expected to isomerized first into *cis*-β-acetylacrylic acid (II-B). The *cis* acid II-B is expected to cyclize easily to the angelica lactone II-C, for the acid carbonyl is close to the acetyl carbonyl and the dissociated proton can attack acetyl carbonyl as is shown in Scheme 1.

If the acetyl group of II-A is replaced by the bulky pivaloyl group, the keto carbonyl group will be inaccessible to the carboxyl group because of the steric hindrance of the pivaloyl group. Thus, the irradiation of *trans*-β-pivaloylacrylic acid (III-A) was examined. A methanol solution of *trans*-β-pivaloylacrylic acid (III-A)[9] was irradiated for

6) L. Birkofer and R. Dutz, *Ann.*, **608**, 7 (1957).

7) R. Scheffold and P. Dubs, *Helv. chim. Acta*, **50**, 798 (1967).

8) N. Hellström and S. Gronowitz, *Kgl. Lantbruks-Högskol. Ann.*, **25**, 363 (1959). *Cf. Chem. Abstr.*, **54**, 9751f (1960).

9) N. Hellström, *Nature*, **187**, 146 (1960).

55 hr at room temperature. The photoproduct shows the singals characteristic of the angelica lactone, but no signals characteristic of the *cis* form, the methanol adduct, or the starting material, III-A. The angelica lactone III-C was obtained almost quantitatively. The structure of the angelica lactone, 5-*t*-butyl-5-hydroxy-2-oxo-2,5-dihydrofuran (III-C), was confirmed as follows. The IR spectrum shows the lactone carbonyl bands at 1765 and 1740 cm^{-1}, and the olefinic band at 1610 cm^{-1}. The UV spectrum shows the absorption maximum at 204 nm. In the NMR spectrum, the singlet signal of the *t*-butyl group appears at τ 8.96, and the singlet signal of the hydroxyl proton appears at τ 5.15. The two doublet signals at τ 2.62 and 3.84, which were assigned to olefinic protons (J= 6.0 c/s).

These results make it clear that the steric hindrance does not influence the cyclization step, and that the +I effect is more important. This conclusion is also consistent with the fact that β-adamantoylacrylic acid is cyclized to lactone by the irradiation.[10]

Experimental

Instrumentation. The IR and UV spectra were measured on a Hitachi EPI-2-type infrared spectrometer and a Hitachi EPS-3T-type recording spectrometer respectively.

The NMR spectra were recorded in deuterochloroform, with TMS as the internal standard with a Hitachi H-60-type high-resolution nuclear spectrometer.

A Taika 500 W high-pressure mercury lamp was used as the irradiation source, and a Pyrex tube was used as a filter and also as a reaction vessel.

Materials. *trans-β-Acetylacrylic acid* (*II-A*) was prepared by the method previously reported;[11] mp 125—126°C (lit. 126°C).[11]

Methyl trans-β-acetylacrylate (*I-A*) was prepared by the method of Pauly;[12] mp 58.5—60°C (lit. 60°C).[12]

trans-β-Pivaloylacrylic acid (*III-A*) was prepared by the method of Hellström;[9] mp 68—86°C (lit. 70—92°C).[9]

Irradiation of Methyl *trans*-β-Acetylacrylate (I-A). *A) In Methanol.* One hundred milligrams of methyl *trans*-β-acetylacrylate (I-A) were dissolved in 2 m*l* of methanol, after which the mixture was irradiated for 48 hr at room temperature. After the solvent had been removed methyl *cis*-β-acetylacrylate (I-B) was isolated by silica-gel column chromatography and eluted as a yellow oil with benzene. Yield, 80%.

IR (cm^{-1}, liq. film): 1730 (νC=O, ester), 1695 (νC=O, Ac), 1640 (νC=C), 1380, 900, 800 (δCH).

UV (λ_{max}, in EtOH): end absorption.

Found: C, 60.50; H, 7.70%. Calcd for $C_8H_{12}O_3$: C, 61.52; H, 7.75%.

The formation of the methanol adduct, methyl α-methoxylevulinate, was checked by comparing it with an authentic sample which had been synthesized from II-A by treatment with methanol in the presence of sulfuric acid.[6] Neither a study of the NMR spectra nor thin-layer chromatography could detect the adduct.

B) In Acetone. Fifty milligrams of I-A were dissolved in 1 m*l* of acetone, and the mixture was irradiated for 17 hr. Immediately after the solvent had been removed, the NMR spectrum was measured; the yield of I-B was 78%.

C) Without the Solvents. Fifty milligrams of I-A were dissolved in methanol; the solvent was then removed under reduced pressure, and I-A was fixed on the wall of the Pyrex tube. This solid-state I-A was irradiated for 17 hr at room temperature. The reaction mixture was dissolved in deuterochloroform and was measured on a NMR spectrum. I-B was produced in a 64% yield. When the irradiation continued for 1 week, the yield of I-B was raised to 90%.

Irradiation of *trans*-β-Acetylacrylic Acid (II-A). A methanol solution of *trans*-β-acetylacrylic acid (II-A) (500 mg/10 m*l*) was irradiated for 45 hr at room temperature. 5-Methyl-5-hydroxy-2-oxo-2,5-dihydrofuran (II-C) was then obtained as colorless needles from benzene - methanol (10 : 1). Mp 121—124°C (lit. 126°C);[7] yield, 60%. II-C was identified with an authentic sample.[7]

IR (cm^{-1}, KBr): 3500 (νOH), 1770, 1740 (νC=O, angelica lactone), 1650 (νC=C).

UV (λ_{max} nm(ε), in EtOH): 206 (28900).

NMR (τ, in $CDCl_3$): 2.74 (d, J=6.0 c/s, β-olefinic proton), 3.92 (d, J=6.0 c/s, α-olefinic proton), 4.42 (s, hydroxy proton), 8.24 (s, methyl).

When the irradiation was continued for 1 week, the yield of II-C was 85%, while when II-A was irradiated in the solid state for 112 hr, the yield of II-C was only 32%.

Irradiation of *trans*-β-Pivaloylacrylic Acid (III-A). Sixty milligrams of *trans*-β-pivaloylacrylic acid (III-A) were dissolved in 1 m*l* of methanol, after which the mixture was irradiated for 55 hr at room temperature. After removing the solvent, the residue was recrystallized from ether-benzene. 5-*t*-Butyl-5-hydroxy-2-oxo-2,5-dihydrofuran (III-C) was obtained almost quantitatively, as colorless needles; mp 72—74°C.

IR (cm^{-1}, KBr): 3380 (νOH), 1765, 1740 (νC=O, angelica lactone), 1610 (νC=C).

UV (λ_{max} nm(ε), in EtOH): 204 (18600)..

NMR (τ, in $CDCl_3$): 2.62 (d, J=6.0 c/s, β-olefinic proton), 3.84 (d, J=6.0 c/s, α-olefinic proton), 5.15 (broad s, OH), 8.96 (s, *t*-butyl).

Found: C, 60.52; H, 7.70%. Calcd for $C_8H_{12}O_3$: C, 61.52; H, 7.75%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1101—1104 (1969)

Syntheses and Reactions of Functional Polymers. XLV. Synthesis and Properties of Poly(*N*-glycidyl-2-oxazolidone)

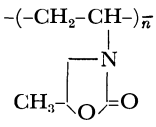
Takeshi ENDO, Ryozo NUMAZAWA and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received August 24, 1968)

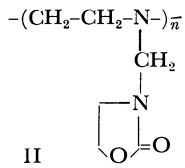
N-Glycidyl-2-oxazolidone was synthesized by the reaction of *N*-sodium-2-oxazolidone with epichlorohydrin. *N*-Glycidyl-2-oxazolidone was polymerized with such Lewis acids as boron trifluoride etherate and aluminum chloride to give a white powder. These polymers adsorbed phenol and methyl bromide effectively. In addition, the copolymerization of *N*-glycidyl-2-oxazolidone with styrene was carried out, and the amount of the adsorption of methyl bromide on the copolymers was measured. The amount of the adsorption of methyl bromide increased in the copolymers as the content of 2-oxazolidone moiety increased. A 1 : 1 molar complex of stannic chloride with *N*-glycidyl-2-oxazolidone was isolated; when the complex was heated, poly(*N*-glycidyl-2-oxazolidone) was obtained quantitatively.

It has been previously reported that poly(*N*-vinyl-5-methyl-2-oxazolidone) **I** formed complexes with phenol, halogen alkyls, and halogens.[1]

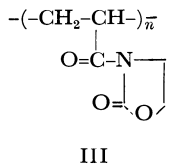


I

Further, we have reported that polyethyleneimine **II**[2] containing 2-oxazolidone moiety in the side chain and poly(*N*-acrylyl-2-oxazolidone)[3] **III** formed complexes with phenols and methyl bromide.

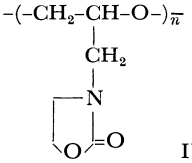


II



III

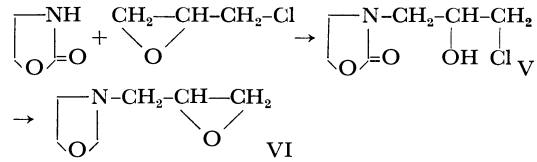
In the present investigation, we attempted to prepare a new type of polymer, poly (*N*-glycidyl-2-oxazolidone) **IV**, and to investigate its ability to form complexes with phenol and methyl bromide.



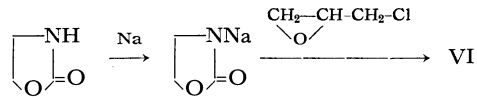
IV

Results and Discussion

Preparation of *N*-Glycidyl-2-oxazolidone (VI). The reactions of active hydrogen compounds with epichlorohydrin using a base[4] or an acid[5] as a catalyst have been reported. Here we tried to synthesize V by the reaction of 2-oxazolidone with epichlorohydrin in the presence of triethylamine, trimethylbenzylammonium chloride, or boron trifluoride etherate, and to prepare VI by treating V with a base. Neither V nor VI could be obtained by these procedures.



On the other hand, by the reaction of *N*-sodium-2-oxazolidone with epichlorohydrin, VI was obtained in a 41% yield. In this reaction, much residue was obtained, probably due to the polymerization during distillation.



The residue was purified by the reprecipitation (adding benzene to a dimethylformamide (DMF) solution) and identified as poly(*N*-glycidyl-2-oxazolidone) by means of its IR spectrum. The

conversion of 2-oxazolidone to VI amounted to 90%, when the polymer produced during distillation was added. VI was identified by an elementary analysis and by means of its IR spectrum. The IR spectrum of VI is shown in Fig. 1. The absorptions of the carbonyl group of cyclic urethane (1745 cm^{-1}) and epoxy ring (910, 850 cm^{-1}) were observed. The results of elementary analysis were in good agreement with the theoretical values.

Polymerization of *N*-Glycidyl-2-oxazolidone (VI). As indicated in Table 1, *N*-glycidyl-2-oxazolidone VI was polymerized at 70°C by such Lewis acids as boron trifluoride etherate and aluminum chloride to give a white powder. At low temperatures, however, VI formed stable complexes with Lewis acids and the polymerization did not proceed appreciably. Anionic catalysts, such as triethylamine and sodium methoxide, were also useless in polymerizing VI. The IR spectrum of IV showed the characteristic C=O absorption band at 1745 cm^{-1} and the absorption attributable to ether linkage (1070 cm^{-1}), as is shown in Fig. 1. On the other hand, the epoxy bands at 910 and 850 cm^{-1} in VI disappeared in the IV polymer. Furthermore, the results of the elementary analysis of IV were in good agreement with the theoretical values. IV was soluble in DMF, dimethyl sulfoxide (DMSO), and formic acid, but it was insoluble in common organic solvents, such as alcohols, ketones, and hydrocarbons. However, the IV polymer of a low molecular weight which was polymerized during distillation was soluble in alcohols and water.

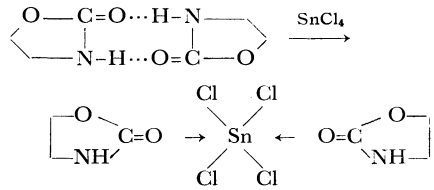
Preparation of the Complexes of 2-Oxazolidone-$SnCl_4$ and *N*-Glycidyl-2-oxazolidone (VI)-$SnCl_4$. When stannic chloride was added, drop by drop to a chloroform or methylene chloride solution of 2-oxazolidone at 0°C, a white precipitate was isolated. The structure of the precipitate was determined by means of a study of the IR spectrum and elementary analysis. The carbonyl absorption (1740 cm^{-1}) of 2-oxazolidone shifted to a lower energy region (1710 cm^{-1}). On the contrary, the absorption band due to the N–H linkage (3275 cm^{-1}) of 2-oxazolidone shifted to a high wave number (3420 cm^{-1}). These observations can be interpreted by assuming that the associated 2-oxazolidone changes to the monomeric structure as a result of the formation of a complex with stannic chloride:



In a similar way, the VI-stannic chloride complex was isolated. The results of the elementary analysis and the IR spectral data of the complex of VI with stannic chloride are summarized in Table 2. The absorption bands due to both C=O and the epoxy ring shifted to lower wave numbers in the complex. From these data, it was concluded that a 1 : 1 molar complex VII of stannic chloride and VI in which two oxygen atoms of VI are coordinated to stannic chloride might be formed as is shown

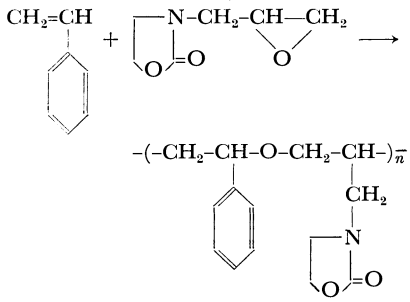
consisted of a white powder. The copolymer composition was determined from the nitrogen content. In the IR spectrum of copolymer, the absorptions of the carbonyl group of the 2-oxazolidone moiety (1745 cm^{-1}), the ether linkage (1070 cm^{-1}) and the phenyl group (1600 and 1490 cm^{-1}) were observed.



The copolymerization of cyclic ethers with vinyl compounds has been reported.[6]

Complex Formation of Poly(*N*-glydicyl-2-oxazolidone) IV with Phenol and Methyl Bromide. When an aqueous solution of IV with a low viscosity ($[\eta]=0.25$) was added to a phenolic aqueous solution, the complex of IV with phenol was precipitated as a white viscous form; it was then dried under reduced pressure. The amount of phenol in the complex, as determined by the bromide-bromate method, was 19.6 mol%. In the case of IV of a high viscosity ($[\eta]=0.44$,) which was insoluble in water, the polymer was suspended in a phenolic aqueous solution; the solution was then stirred at room temperature for 3 hr. The amount of phenol in the complex, as determined from the amount of decreased phenol in the solution, was 74 mol%. The carbonyl absorption (1745 cm^{-1}) of IV shifted to a lower wave number (1735 cm^{-1}) as a result of the formation of the complex with phenol. Therefore, the bonding force in the IV-phenol complex might be attributable to the hydrogen bonding between the C=O group of the 2-oxazolidone moiety and the hydrogen atom of phenol, as has been discussed before.[3]

In a previous paper,[3] it has been reported that the amount of the adsorption of methyl bromide on the copolymers of *N*-acrylyl-2-oxazolidone and styrene was measured, and that the amount of the adsorption of methyl bromide in the copolymers increased as the content of the 2-oxazolidone group increased. Further, it was suggested the bonding force of the complex formation of the polymers containing a 2-oxazolidone moiety with methyl bromide was the dipole-dipole interaction.

In the present paper, the amount of the adsorption of methyl bromide on the copolymers of *N*-glycidyl-2-oxazolidone VI and styrene was measured at room temperature and 1 atm. The amount of the adsorption of methyl bromide increased as the content of the 2-oxazolidone moiety in the copolymer increased, as is shown in Table 4. Therefore, it was apparent that 2-oxazolidone ring played an important role in the adsorption of methyl bromide on the copolymer.

(content 40%; medium, toluene) was a commercial product (Kawaken Fine Chemicals Co.). The epichlorohydrin was dried on calcium hydride and distilled; bp 116—117°C. BF_3OEt_2, $SnCl_4$ and $AlCl_3$ of a reagent grade were used.

Measurements. The IR spectra and refractive indices were measured on Hitachi infrared EPI-S2 and Erma Abbe-refractometers, respectively.

Synthesis of *N*-Glycidyl-2-oxazolidone (VI). The sodium dispersion (20 g, 0.3 g atom) was stirred drop by drop, into a solution containing 22 g (0.25 mol) of 2-oxazolidone in 50 m*l* of benzene at room temperature. After the stirring had been continued for 5 hr at 40°C, epichlorohydrin (46.3 g 0.5 mol) in 50 m*l* of tetrahydrofuran was stirred drop by drop into this solution at 3—5°C. After the stirring had been continued for 5 hr at 60°C the solvents and the unreacted epichlorohydrin were evaporated and the residue was distilled under reduced pressure to obtain 14.6 g (41%) of VI. The VI was redistilled and analyzed bp 107—108°C/0.1 mmHg n_D^{21} 1.4478. Found: C, 49.82; H, 6.38; N, 9.72%. Calcd. for $C_6H_9O_3N$: C, 50.34; H, 6.34; N, 9.72%. The sizable residue obtained on distillation was dissolved in DMF and poured into benzene. The intrinsic viscosity of the polymer thus obtained was 0.25 in water at 30°C.

Polymerization of *N*-Glycidyl-2-oxazolidone (VI). The polymerization was carried out in sealed tubes at 80°C, using BF_3OEt_2 as the catalyst. After polymerization, the polymer was isolated by pouring the reaction mixture into an agitated acetone-water mixture (20 : 1) and the polymer thus precipitated was dried under reduced pressure.

Found: C, 49.70; H, 6.50; N, 9.70%. Calcd for $C_6H_9O_3N$: C, 50.34; H, 6.34; N, 9.79%. The intrinsic viscosity was measured at 30°C in DMF.

Copolymerization of *N*-Glycidyl-2-oxazolidone (VI) with Styrene. The copolymerization of *N*-glycidyl-2-oxazolidone with styrene was carried out in sealed tubes at 70°C, using BF_3OEt_2 as the catalyst. The copolymer was isolated by pouring the reaction mixture into a methanol-acetone mixture (4 : 1) containing a small amount of water. The white polymer thus precipitated was filtered and dried under reduced pressure. The copolymer compositions were determined by nitrogen analysis.

Preparation of 2-Oxazolidone-Stannic Chloride and *N*-Glycidyl-2-oxazolidone (VI)-Stannic Chloride Complexes. Stannic chloride (13 g, 0.05 mol) in 50 m*l* of chloroform was stirred, drop by drop, into a solution containing 3.5 g (0.04 mol) of 2-oxazolidone in 30 m*l* of chloroform at 0°C. The stirring was then continued for 30 min at 0°C. A white crystalline precipitate was isolated from the solution. After having been washed with chloroform five times, the precipitate was dried under reduced pressure to produce 13 g (93%) of the complex of 2-oxazolidone-stannic chloride, mp 145—146°C.

Found: C, 16.49; H, 2.35; N, 6.42; Cl, 31.53%. Calcd for $C_6H_{10}O_4N_2\ SnCl_4$: C, 16.75; H, 2.30; N, 6.44; Cl, 32.68%.

The VI-stannic chloride complex was prepared in a similar way. Stannic chloride (23.3 g, 0.84 mol) in 50 m*l* of chloroform was stirred drop by drop, into a solution containing 2 g (0.014 mol) of VI in 50 m*l* of chloroform at 0°C. The stirring had been continued for 30 min at 0°C, a white crystalline complex was isolated from the solution. After having been washed with chloroform five times, the complex was dried under reduced pressure to obtaine 5.1 g (90%) of VI-stannic chloride. The complex was heated for 2 hr at 65°C and then extracted with chloroform. After the chloroform had been evaporated, IV was obtained quantitatively. The polymer was dried *in vacuo*. The intrinsic viscosity of the polymer was 0.27 at 30°C in water.

Complex Formation of Poly(*N*-glycidyl-2-oxazolidone) (IV) with Phenol and Methyl Bromide. A solution containing 0.874 g of phenol in 20 m*l* of water was added, drop by drop, to a solution containing 0.05 g of IV ($[\eta]=0.25$) in 10 m*l* of water. A viscous precipitate was then isolated from the solution and dried under reduced pressure. The amount of phenol in the complex was determined by the bromide-bromate method. For a heterogeneous system, 0.1 g of IV ($[\eta]=0.44$) was suspended in a solution containing 0.437 g of phenol in 10 m*l* of water. The solution was then stirred for 3 hr at room temperature.

The amount of phenol in the complex was determined from the decrease in the amount of phenol in the solution.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1105—1109 (1969)

The Reaction between Hydrocarbon and Hydrogen Cyanide in Silent Electrical Discharge. III.[1] The Reaction of Ethylene or Propylene with Hydrogen Cyanide*1

Kazuaki KAWAMOTO and Yoshiharu NISHIMURA*2

Institute of Commodities, Faculty of Economics, Kagawa University, Takamatsu

(Received August 31, 1968)

The present investigation was undertaken to find out whether or not the relative amounts of acrylonitrile obtained by the reaction between ethylene and hydrogen cyanide in a silent discharge are affected by the substances ($Hg(CN)_2$, Cu, CuCN, Al, Zn and Fe) placed in a glass filter of the special discharge tube, and to examine the possibility of the direct introduction of a cyano radical into propylene by means of the silent discharge. The yield of acrylonitrile depended upon the packing materials in the glass filter. When the discharge wall of the glass filter was filled with $Hg(CN)_2$, the yield of acrylonitrile was at its maximum. When a mixture of propylene and hydrogen cyanide was discharged in an ozonizer in the absence of air, the main liquid products were crotononitrile, methacrylonitrile, and *n*-propyl cyanide. Besides these compounds, the reaction products were confirmed to consist of isopropyl cyanide, acetonitrile, acrylonitrile, 4-methyl-1-pentene, 2,3-dimethylbutane, 1,5-hexadiene, 2-methylpentane, 1-hexene, *n*-hexane, and gaseous products. Judging from the relative concentration of each compound in the reaction products, it may be said that 2-methylvinyl, isopropenyl, propyl, allyl, isopropyl, and cyano radicals are the main intermediates in this reaction system.

In a preceding study,[1] it was found that when a mixture of ethylene and hydrogen cyanide was discharged in an ozonizer, acrylonitrile was obtained in one step. It has been reported by Suzuki[2] and Naito[3] that the formation of ozone is affected by the nature of substances forming the wall of discharge tube; in the case of the commercial processes, one side of the discharge tube is replaced with a wall of stainless steel or aluminum. Further, it has been found by Morinaga and Suzuki[4] that the ozone formation rate is affected by the materials (Soda glass, $2MgO/TiO_2$, TiO_2, $BaTiO_3$ and 95 $BaTiO_3/5SnO_2$) placed in a special-type discharge tube. However, when Sahasrabudhey and Deshpande[5] investigated the influence of wall catalysts on the production of formaldehyde by the interaction of carbon monoxide and hydrogen under the silent discharge, the reaction giving rise to formaldehyde was not affected by the surface catalysts employed.

The reaction of propylene and oxygen under a silent discharge has been investigated by Tsutsumi *et al.*[6] However, no detailed study of the interaction of propylene and hydrogen cyanide in the silent discharge has yet been reported.

The present study has been undertaken to discover how the type of discharge tube influences the reaction between ethylene and hydrogen cyanide; to establish, if possible, the most suitable conditions for the preparation of acrylonitrile, and furthermore, to find out whether or not the direct formation of such cyano-compounds as crotononitrile and methacrylonitrile results from the reaction of propylene and hydrogen cyanide in a silent discharge.

In the case of the reaction between ethylene and hydrogen cyanide, the experiments were carried out in discharge tubes filled with mercuric cyanide, copper, cuprous cyanide, aluminum, zinc, and reduced iron powders using a voltage of 15 kilovolts and a frequency of 60 cycles per second. Propylene and hydrogen cyanide were discharged in a Siemen ozonizer for 9 hr, using a voltage of

13.5 kilovolts.

Experimental

Materials. The ethylene and propylene used in this experiment showed no impurity in gas-chromatographic analysis. (Columns of activated charcoal, acetonylacetone, and dimethylsulfolane were used.) The hydrogen cyanide was prepared according to the procedure of Brauer.[7]

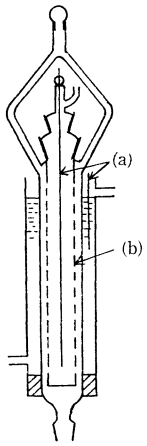

Fig. 1. Discharge tube used in the case of ethylene and hydrogen cyanide.
(a) Electrode (b) Glass filter

Discharge Tube. The discharge tube used for the formation of acrylonitrile is shown in Fig. 1. In this case, two kinds of discharge tubes were used. One was a Pyrex tube (A) with a glass filter (b) 30 cm in length and 2 cm in diameter, and with a space gap of 0.25 cm. The other was a Pyrex tube (B) with a glass filter (b) 10 cm in length and 2 cm in diameter, and with a space gap of 0.25 cm. In the case of propylene and hydrogen cyanide, the discharge tube employed was a Pyrex tube 45 cm in effective length, 4 cm in outside diameter, and with a space gap of 0.25 cm.

Packing. The materials placed in the glass filter in Fig. 1 were mercuric cyanide, copper, cuprous cyanide, aluminum, zinc, and reduced iron; they were used in the powder state.

Apparatus and Procedure. The apparatus employed in the reaction of ethylene and hydrogen cyanide was similar to that used in the passing method in a previous investigation,[8] except that the special tubes described above were used. The glass filter part of the discharge tube was filled with the powder of the packing materials. In the case of propylene, the apparatus was similar to that used in the passing method. These discharge tubes were then maintained at the operating temperature. A mixture of ethylene or propylene and hydrogen cyanide was passed through these discharge tubes at a constant velocity for the period of the reaction. Two moles of hydrogen cyanide were used in each experiment. A current of 60 cycles was sent through a voltage regulator, and the voltage was stepped up by a transformer (Capacity: 15 kV) to give the required value. The reaction products coming out of the discharge tubes were condensed by passing them through A condenser cooled with ice water, and then they were collected by being passed through two ice-cooled traps. The liquid products thus obtained were analyzed by the method described below, while the non-condensable gas was analyzed by gas chromatography at intervals of 30 min.

Identification and Analysis of the Reaction Products. The reaction products obtained by the reaction between ethylene and hydrogen cyanide were identified by the same method as was used in a previous paper.[1] In this case, the gaseous products were found to be hydrogen, ethane, acetylene, *n*-butane, 1-butene, 1,3-butadiene, methane, propane, and propylene.

The liquid products obtained by the reaction between propylene and hydrogen cyanide were identified by comparing their retention times on a gas chromatogram with those of authentic samples.*3 (Tricresyl phosphate, PEG-6000 and silicone DC 550 columns were used for the cyano compounds listed in Table 4, while squalane, β,β'-oxydipropionitrile, tricresyl phosphate and dimethylsulfolane columns were used for the liquid hydrocarbon products.) In addition, the reaction products were fractionally distilled in the presence of a small amount of hydroquinone; the constituents of the fraction were identified by observing the formation of the derivative described below and the infrared absorption.

The fraction boiling at 86—91°C was confirmed to consist mainly of methacrylonitrile by transforming it into the *N-t*-butylmethacrylamide,*4 mp 57—58°C. A mixed-melting-point determination with an authentic sample showed no depression. The infrared spectrum of this fraction agreed with that of the authentic methacrylonitrile.

The crotononitrile and *n*-propyl cyanide were obtained in a fraction boiling at 115—120°C. Upon gas-chromatographic analysis, this fraction showed the same retention time as that of authentic crotononitrile and that of authentic *n*-propyl cyanide.

No allyl cyanide was detected in the reaction products of any experiments. The gas chromatogram (columns: PEG-6000 and tricresyl phosphate) of the liquid products presented three peaks behind the peak of crotononitrile.

8) K. Kawamoto, N. Sonoda and S. Tsutsumi, This Bulletin, **41**, 1376 (1968).

*3 The authentic samples were prepared as follows. The crotononitrile (bp 118—119°C, n_D^{20} 1.4221) was prepared by the reaction of crotonamide (mp 158—159°C) and phosphorus pentoxide. The methacrylonitrile (bp 90—91°C, n_D^{25} 1.3979) was prepared from methacrylamide by means of the procedure of Mowry and Morner (D. T. Mowry and R. R. Morner, *J. Am. Chem. Soc.*, **69**, 1831 (1947)). Further, the following commercial chemicals were used for identification; *n*-propyl cyanide, isopropyl cyanide, acetonitrile, acrylonitrile, 4-methyl-1-pentene, 2,3-dimethylbutane, 1,5-hexadiene, 2-methylpentane, 1-hexene, and *n*-hexane.

*4 *N-t*-Butylmethacrylamide was prepared by the method of Plaut and Ritter (H. Plaut and J. J. Ritter, *J. Am. Chem. Soc.*, **73**, 4076 (1951).

From their retention times, hexyl cyanides seem to be present in the unidentified products*5 listed in Table 4. The quantitative analysis of the liquid products in this experiment was performed by gas chromatography.

The gaseous products, when analyzed by gas chromatography, were found to consist of hydrogen, propane, methylacetylene, allene, ethane, ethylene, acetylene, and methane. (Columns of activated charcoal, tricresyl phosphate, dimethylsulfolane, and acetonylacetone were used.) The gaseous products could not be determined quantitatively.

Results and Discussion

The results obtained by the reaction of ethylene and hydrogen cyanide under the conditions described in Table 1 are summarized in Table 2. Further, the results obtained by running propylene with hydrogen cyanide only once in an ozonizer under the conditions listed in Table 3 are summarized in Table 4. The compositions of the reaction products given in these tables are re-

producible within 1 per cet. In both ethylene and propylene, the presence of even a small quantity of air formed a solid brown deposit on the discharge wall. Therefore, the air was completely removed from the reaction system.

Influence of the Discharge Tube on the Reaction between Ethylene and Hydrogen Cyanide. The special discharge tube shown in Fig. 1 was used for the purpose of investigating the effects of the discharge wall on the formation of acrylonitrile.

It was reported by Galvin and Pritchard[9] that, when a stream of nitrogen containing a hydrocarbon RH was passed over solid mercuric cyanide heated at 350°C, hydrogen cyanide, cyanogen, and the corresponding nitrile RCN were obtained, and that when unsaturated hydrocarbons were used the addition products were found (*i. e.*, ethylene gave ethyl cyanide and succinonitrile). Further, they also found that silver cyanide and cupric cyanide behaved analogously. Thus, in this experiment mercuric cyanide and cuprous cyanide were placed in the glass filter of the discharge tube.

As may be seen from Table 2, there are differences between the special tube and the Siemen tube. It has been found that when the Siemen tube is used the yield of the liquid product increases, and that when one side of discharge tube is replaced by a wall of the glass filter filled with mercuric cyanide, copper, cuprous cyanide, aluminum, zinc and reduced iron, the yield of the liquid products decreases, while the proportion of acrylonitrile in the liquid products increases. In the case of the special tube filled with mercuric cyanide, the yield of liquid product was at its maximum. Thus, it may be said that the use of mercuric cyanide as packing material favors the formation of acrylonitrile.

As may be seen from Experiment Nos. 1, 2, and 3 in Table 2, the yield of the reaction product depends upon the quantity of packing material used (namely, the effective length of the discharge tube); it has been found that increasing the packing material increases the yields of the liquid products and the gaseous products, while it decreases the proportion of acrylonitrile in the liquid products.

When ethylene alone was discharged in the special tube filled with mercuric cyanide, the component of the gaseous products was similar to that of the gaseous products obtained by the reaction between ethylene and hydrogen cyanide. Further, in the case of ethylene alone, a solid brown deposit was formed on the glass wall, while no liquid product was formed.

The Reaction between Propylene and Hydrogen Cyanide. When a mixture of propylene and hydrogen cyanide was allowed to react in the silent discharge, a large number of compounds (summarized in Table 4) were obtained. However, the formation of allyl cyanide, dicyano-compounds, and isocyano-compounds could not be observed by gas-chromatographic analysis.

As may be seen from Experiment Nos. 1 and 3 in Table 4, the conversion efficiency (grams of reaction product/grams of propylene used $\times$ 100) depends upon the temperature at which the discharge is carried out; it has been found that the yields of the liquid products and the gaseous products increase with a rise in the discharge temperature, and that in the case of a high-temperature discharge, the proportion of unsaturated nitriles, such as crotononitrile and methacrylonitrile, in the liquid products decreases, while the yield of the high-boiling-point compounds (the unidentified products listed in Table 4) increases. Accordingly, it may be said that a low temperature favors the formation of the directly-introduced

9) J. P. Galvin and H. O. Pritchard, *J. Phys. Chem.*, **68**, 1035 (1964).

cyano compounds.

Addition products, such as *n*-propyl cyanide and isopropyl cyanide, were also formed. In this case, the yield of *n*-propyl cyanide was higher than that of isopropyl cyanide. Therefore, the addition followed a non-Markownikoff rule. This rule was observed in both the radiation-induced addition of hydrogen sulfide to propylene[10] and the photochemical addition of hydrogen sulfide or hydrogen bromide to propylene.[11,12] The nature of the discharge-induced addition appears to be similar to that of these additions.

The Mechanism of the Formation of the Main Products Obtained by the Reaction of Propylene and Hydrogen Cyanide. The formation of the main products obtained by the reaction of propylene with hydrogen cyanide in a silent discharge may be represented as follows: The first step is the excitation of the propylene molecule and the hydrogen cyanide molecule by electron impact,*6 while the second step consists of both (1) the reaction of the excited propylene molecule with a normal propylene molecule to give 2-methylvinyl, isopropenyl, allyl, propyl, and isopropyl radicals*7 (two molecular processes*8), and (2) the decomposition of the excited propylene or hydrogen cyanide to give 2-methylvinyl, isopropenyl, allyl, and cyano radicals and the hydrogen atom.*9

The cyano compounds, such as crotononitrile, methacrylonitrile, and *n*-propyl cyanide, may be formed by the combination*10 of these radicals and the cyano radical thus obtained. Crotononitrile and methacrylonitrile were obtained in yields comparable with that of *n*-propyl cyanide. This observation indicates that 2-methylvinyl and isopropenyl radicals are fairly much involved in this reaction system. Since the yield of *n*-propyl cyanide is higher than that of isopropyl cyanide, an alternative mechanism for the formation of *n*-propyl cyanide may be the addition of a cyano radical to the terminal carbon atom of propylene, followed by the addition of a hydrogen atom to the CH_3-$\dot{C}HCH_2CN$ radical so formed.*11 The formation of allyl cyanide was not observed, presumably because of the isomerization of allyl cyanide to crotononitrile.

The dimeric products, such as 4-methyl-1-pentene, 2,3-dimethylbutane, 2-methylpentane, 1,5-hexadiene, 1-hexene, and *n*-hexane, may be formed by coupling reactions between propyl, isopropyl, and allyl radicals. For instance, the occurrence of 2,3-dimethylbutane can be explained by a combination of two isopropyl radicals.

The formation of acetonitrile and acrylonitrile may be represented as follows. The methyl radical and the vinyl radical may be formed through the bond fission of the excited propylene molecule, and acetonitrile and acrylonitrile may be obtained by combination between these radicals and the cyano radical.

The authors wish to thank Professor S. Tsutsumi of Osaka University for his kind advice.

*6 Although ion-molecular process are possible in some electron impact reactions, in the present case this process does not seem to be a main path, judging from the results reported by Devins *et al.*, Egloff *et al.*, and Inoue. The present reaction is presumed to be mostly a radical reaction (J. C. Devins and M. Burton, *J. Am. Chem. Soc.*, **76**, 2618 (1954); C. L. Thomas, G. Egloff and J. C. Morell, *Chem. Revs.*, **28**, 1 (1941); E. Inoue, *Bull. Tokyo Inst. Technol., Series A*, **1957**, No. 2, p. 1.).

*7 $CH_2{=}CH{-}CH_3 + e^* \longrightarrow C_3H_6^* + e$

$C_3H_6^* + CH_2{=}CH{-}CH_3 \longrightarrow$

$\left\{\begin{array}{l}\dot{C}H{=}CH{-}CH_3\\ CH_2{=}\dot{C}{-}CH_3\\ CH_2{=}CH{-}CH_2\bullet\end{array}\right. + \left\{\begin{array}{l}CH_3{-}CH_2{-}CH_2\bullet\\ CH_3{-}\dot{C}H{-}CH_3\end{array}\right.$

*8 Tsutsumi reported that when ethylene was discharged, the vinyl radical and the ethyl radical were produced by two molecular processes (S. Tsutsumi, *Chem. Ind.* (*Kagaku Kogyo*), **16**, 623 (1965).).

*9 $HCN + e^* \longrightarrow HCN^* + e \longrightarrow \bullet H + \bullet CN$

$C_3H_6^* \longrightarrow \left\{\begin{array}{l}\dot{C}H{=}CH{-}CH_3\\ CH_2{=}\dot{C}{-}CH_3 + \bullet H\\ CH_2{=}CH{-}CH_2\bullet\end{array}\right.$

*10 For instance, crotononitrile and methacrylonitrile were formed as follows:

$\dot{C}H{=}CH{-}CH_3 + \bullet CN \longrightarrow CH_3CH{=}CHCN$

$CH_2{=}\dot{C}{-}CH_3 + \bullet CN \longrightarrow CH_3C(CN){=}CH_2$

*11 It was reported by Moore that when the mercury-photosensitized hydrogenation of propylene was carried out over a range of temperatures from 30 to 200°C, a hydrogen atom added preferentially to the terminal carbon atom of propylene to form the isopropyl radical (W. J. Moore, *J. Chem. Phys.*, **16**, 916 (1948).). Therefore, if a hydrogen atom is first added to propylene, the radical thus produced will yield a large quantity of isopropyl cyanide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1110—1112 (1969)

The α Effect. Aminolysis on a Saturated Carbon Atom*1

Shigeru OAE, Yoshihito KADOMA and Yumihiko YANO

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received August 31, 1968)

The rates of aminolyses of methyl, isopropyl, allyl and benzyl iodides have been determined in acetonitrile. Bases used were hydrazine, morpholine, imidazole and piperidine. The rates of all the aminolysis reactions can be correlated nicely with the basicities. Hydrazine also did not show any positive deviation from the Brønsted plots. This fact suggests that the α-effect is not operative in these displacement reactions on the saturated carbon atom.

In a number of bimolecular nucleophilic reactions, various nucleophiles having unshared electron pairs adjacent to the nucleophilic center-atom show much higher reactivities than those anticipated from their basicities. These high reactivities are generally estimated from large positive deviations from the Brønsted plots and are ascribed to so called α-effect.[1] As Bruice *et al.* pointed out,[2] several possible explanations concerning the α-effect have been proposed. However, no satisfactory one has been presented; nor do we have sufficient data to draw any conclusion as to the origin of the α-effect.

One of the attractive approach to this problem is to focus the attention on the relation between the α-effect and the nature of the hybridization of the carbon atom of the reaction center, *i. e.*, sp, sp^2 and sp^3. Concerning the sp and sp^2 hybridized carbon atoms, relatively large amounts of works have been carried out and large α-effects have been observed with both nonionic[3] and ionic[1b,4] nucleophiles. But in the S_N2 reactions on the sp^3 hybridized carbon atom only two data are available, the one is the reaction of benzyl bromide with hydroperoxide anion and hydroxide anion[5] (ionic nucleophiles) and the other is the aminolysis of methyl iodide in water[3a] (nonionic nucleophiles). In either reaction, α-effects were rather small or negligible. From these investigations,[1b,3a,3c,4,5] it appears that the magnitude of the α-effect seems to depend generally on the character of the reacting site of substrate, and falls in the following order.

$$sp > sp^2 > sp^3 \text{ carbon.}$$

In general, rates of nucleophilic reaction on the sp and sp^2 carbon atoms such as nitrile[4] and carbonyl are mainly controlled by basicity rather than polarizability of the nucleophile used, while, in the case of the sp^3 carbon atom, polarizability is the more important factor than basicity. Apparently the higher the demand for stronger basicity, the larger α-effect is observed in the case with the sp and sp^2 carbon atoms whereas in the substitution reaction on the sp^3 carbon atom, the reaction requiring higher polarizable nucleophile would display a larger α-effect. Incidentally, α-effect, though small, was reported in the reaction of benzyl bromide with hydroperoxide anion in 50% acetone-water,[5] while, no α-effect was observed in the aminolysis reaction of methyl iodide in water.[3a] The former case is different from the latter one in that in the former reaction the nucleophile is ionic while π electrons of phenyl ring can delocalize to the reaction center in the transition state and hence the whole system is quite susceptible to polarizability.

The present work was initiated in order to examine the effect of the structural change of the substrates, in the aminolyses of methyl, isopropyl, allyl and benzyl iodides in acetonitrile.

Results and Discussion

The substrates examined were unfortunately very sparingly soluble in water, however, pK_a's of these

amines in acetonitrile[6] are available. Therefore we chose anhydrous acetonitrile as the solvent. The results are shown in Table 1. In all the cases fairly good correlations of logarithms of the rate constants on the pK_a's of the nucleophiles were observed, and no positive deviations from the Brϕnsted plots were observed, (Fig. 1). From the slopes, α values, the Brϕnsted parameter, were obtained and are listed in Table 2.

The α values obtained in the aminolysis reactions varied from 0.36 to 0.60. This means that the transition states of these reactions cover a certain range of spectrum from near S_N1 to S_N2.[7] The α value

Table 2. α-Values of the aminolysis reactions in acetonitrile

Substrates	α-Value	°C
Allyl iodide	0.60	40
Benzyl iodide	0.55	30
Methyl iodide	0.50	40
Isopropyl iodide	0.36	40
p-Nitrophenyl acetate[a]	0.54	30

a) See Ref. 3a.

of 0.60 in the aminolysis reaction of allyl iodide suggests that the bond forming step is the rate limiting, while α value of 0.36 of isopropyl iodide suggests the importance of bond breaking step.

It is commonly believed that the α-effect is associated with displacement reactions which are highly dependent on the basicity of the nucleophile. It would suggests then that α-effect would appear in the aminolysis reaction of allyl iodide. However, it was not the case. The aminolyses of isopropyl, methyl and benzyl iodides also showed no positive deviations from the Brϕnsted plots. As can be seen in Table 2, α values of p-nitrophenyl acetate and benzyl iodide are almost comparable and yet a large α-effect is observed in the reaction with the former compound and not with the latter.

Both benzyl and allyl iodides are considered to develop a substantial sp^2 character at the reacting center in the transition states. The lack of α-effect for these compounds may be due to the high electron delocalizations with π electrons at the transition state to kill the partial sp^2 character of the reaction center.

Experimental

Preparation of Materials. All the amines were purified according to Coetzee and Padmanabhan's

6) J. F. Coetzee and G. R. Padmanabhan, *J. Am. Chem. Soc.*, **87**, 5005 (1965).
7) R. F. Hudson and R. J. Withey, *J. Chem. Soc.*, **1964**, 3513.

method.[6] Methyl iodide was purified by fractional distillation from the commercial product, bp 42.4°C. Benzyl iodide (mp 24.1°C) and allyl iodide (bp 102.5°C) were prepared from the corresponding chlorides by halogen exchange reaction in acetone.[8] Isopropyl iodide was prepared according to Stone and Shechter's method,[9] bp 89.3°C. Commercial acetonitrile was dried over calcium chloride, and then refluxed three times over phosphorus pentoxide, then distilled into freshly fused potassium carbonate, after drying, it was finally fractionally distilled,[10] and the center-cut fraction was used, bp 81.6°C.

Kinetic Measurement. The reactions were followed by the UV spectrophotometry using the absorption of iodide ion at 246 mμ ($\varepsilon=1.38\times10^4$), except for benzyl iodide, of which the absorption band of 275 mμ was followed (no iodide ion absorption at 275 mμ). A desired amount of an organic iodide was weighed accurately in a 50 m*l* volumetric flask. After equilibration at a reaction temperature, it was made up to 50 m*l* with a desired amount of an amine solution and with the solvent at the same temperature. The flask was shaken vigorously and kept in a thermostat. Initial concentration was determined after two minutes. From time to time, 5 m*l* of the solution was pipetted out and diluted to a suitable concentration with acetonitrile. A typical run is shown below.

Table 3. Reaction of allyl iodide with piperidine in CH_3CN

Sec	O.D.[a] Observed	O.D. Corrected[b]	k_2 $l\,mol^{-1}\,sec^{-1}$	Percentage of reaction (%)

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1113—1118 (1969)

Spectrophotometric Studies of the Copolymer of L-Tryptophan and L-Glutamic Acid in an Aqueous Solution[1]

Akio OHNISHI, Katsuya HAYASHI*[1] and Junzo NOGUCHI

Department of Polymer Science, Faculty of Science, Hokkaido University, Nishi-8-chome, Kita-10-jo, Sapporo

(Received August 31, 1968)

The synthetic copolymer of L-tryptophan and L-glutamic acid exhibited two specific bands, around 292 mμ and 234 mμ, in the difference spectrum at pH 4.68 *vs.* pH 7.60 in a 0.1 M phosphate buffer. The former, that at 292 mμ, might be caused by the red shift of the ordinary absorption band around 280 mμ, and the latter, that at 234 mμ, by the red shift of the far-ultraviolet absorption band, around 220 mμ, of the tryptophanyl residue in the copolymer. This specific peak at 234 mμ in the difference spectrum of the tryptophan copolymer may be distinguished from that at 222 mμ, which is due to the hyperchromisity ($n\rightarrow\pi^*$ transition) of the amide group in the peptide bond reported with poly-L-glutamic acid. The peak at 230—235 mμ appearing in the difference spectrum between native and denaturated proteins may be due to the same red shift ($\pi\rightarrow\pi^*$ transition) of the far-ultraviolet absorption band of the tryptophanyl residue as that shown by the tryptophan copolymer. The difference in absorption at 234 mμ was five times larger than that at 292 mμ, and both of them increase proportionally with a lowering of the pH. The relation between the difference absorption and the pH was quite similar to that between the helical content and the pH. The relative fluorescence intensity of the tryptophanyl residue was also depressed with a lowering of the pH, and the profile of the pH-dependence curve on the fluorescence intensity was almost identical with the titration curve of the copolymer. Therefore, it may be said that the appearance of the difference spectrum at 234 mμ corresponds to the formation of the α-helix in polypeptide and that the protonation of the glutamyl residue induces the quenching of the fluorescence of the tryptophanyl residue.

The characteristic absorption spectrum of the tryptophanyl residue in protein has been widely used to study the structure and the biological activity of protein; *e.g.*, the enzyme-substrate complex was demonstrated spectrophotometrically by means of the concomitant change of the absorption spectrum of the tryptophanyl residue in the lysozyme molecule.[2] To elucidate the role and behavior of the tryptophanyl residue in protein, it may be instructive to ascertain spectrophotometrically basic information on the tryptophanyl residue using some simple tryptophan copolymers.

Tryptophan has two specific absorption bands in the near visible region (250—300 mμ) and the far-ultraviolet region (200—240 mμ);[3] the same absorption bands were observed in the tryptophan copolymer in these experiments. Recently, Fasman *et al.*[4] showed that the fluorescence of the tryptophanyl residue in copoly(Glu,Trp) and copoly(Lys,Trp) was strongly quenched by the unionized carboxyl group of glutamyl or the unionized amino group of the lysyl residue in these copolymers, but the fluorescence was almost independent of the conformation of α-helix in the copolymers. They suggested also that the hyperchromisity on the absorption spectrum of the tryptophanyl residue might be affected by the dissociation of the carboxyl group of the glutamyl residue from the difference spectrum between pH 4.6 and pH 7.3 in the range of 250—320 mμ, using copoly(Glu,Trp 99 : 1). However, the difference spectrum seems to be somewhat ambiguous as a basis for a further, detailed discussion of the behavior of the tryptophanyl residue, because the copolymers contained so many amide bonds in relation to the tryptophanyl residue (99 : 1 molar ratio) that the absorption band of the tryptophanyl residue in the far-ultraviolet region overlapped with that of the amide bond with a high optical density. It is interest to study the behavior of a copolymer with a higher

content of tryptophan, since the absorption spectrum of the tryptophanyl residue seems to be a good indicator of the molecular conformation of the tryptophan copolymer. The present work is concerned with a spectrophotometric study of copoly-(Glu,Trp 9 : 1) in an aqueous solution in relation to a study of NPA*2 hydrolysis[5] by means of the interaction between glutamyl and tryptophanyl residues.

Further, the difference spectra between the native and denaturated states of proteins containing tryptophanyl residues presented by Glazer and Smith[6,7] are discussed in comparison with the results presented in this paper.

Experimental

Preparation of the Copolymer. The copolymer of L-tryptophan and L-glutamic acid was prepared from the *N*-carboxyanhydride (NCA) of each amino acid in a molar ratio of 9 : 1 as follows; 1.34 g (0.0058 mol) of L-tryptophan NCA,[8] after having been purified in a two-layer column (charcoal-silver oxide/activated charcoal),[9] and 13.8 g (0.053 mol) of γ-benzyl-L-glutamate NCA[10,11] were dissolved in 150 m*l* of dioxane; then 0.55 g (0.0049 mol) of triethylenediamine[9] was added to the mixture as an initiator. The solution was allowed to stand for 5 days at 40°C under stirring, and then the viscous solution was poured into a large amount of water in order to precipitate the copolymer. The precipitate was washed with water and ethanol, and dried *in vacuo*. To remove the benzyl group of the glutamyl residue, the copolymer was dissolved in 90 m*l* of dioxane, and then 0.2N aqueous alcoholic sodium hydroxide (0.9 g of sodium hydroxide, 22.5 m*l* of water, and 90.0 m*l* of ethanol)[12] was added. The mixture was allowed to stand for 10 hr at 15°C to complete the debenzylation of the glutamyl residues. The debenzylation of the copolymer was confirmed by the disappearance of the 1740 cm^{-1} absorption band of the ester. The sodium salt of the copolymer was precipitated with ethanol and washed several times with ethanol. It was colorless and easily soluble in water. Yield 7.5 g (85%). The tryptophanyl residue in the copolymer was estimated from the optical density at 280 mμ,[13] while the glutamyl residue was analysed with ninhydrin[14] by paper chromatography after acid hydrolysis. The molar ratio of glutamyl and tryptophanyl residues in this copolymer was 89.7 : 10.3. The intrinsic viscosity of the copolymer was 1.84 in 0.2M sodium chloride at pH 7.6 and 25°C. The molecular weight of the copolymer was calculated to be 85000 by applying the relation between the intrinsic viscosity and the molecular weight of poly-L-glutamic acid.[15]

Poly-L-glutamic Acid. Poly-L-glutamic acid was obtained by the saponification[12] of poly-γ-benzyl-L-glutamate prepared from γ-benzyl-L-glutamate NCA.[10,11] The intrinsic viscosity was 2.13 in 0.2M sodium chloride at pH 7.6 and 25°C; the molecular weight was calculated to be 97000 by the method described above.

Fractionation of Copolymer. The copolymer was fractionated by gel filtration through a column of Sephadex G-50, using a 0.1M phosphate buffer at pH 7.0 as an eluant.

Titration. Samples were titrated with 0.1N sodium hydroxide, using a Radiometer TTT-1 titrator with a SBR2-C titrigraph. Before titration, the solution of polyamino acid was treated by passing it through a mix-bed column of Amberite IR-120 and IRA-410 to remove the sodium ions; it was then adjusted to a 0.1M so ium chloride solution by the addition of 1.0M sodium chloride.[16]

Optical Rotatory Dispersion. The optical rotatory dispersion of the copolymer in a 0.1M phosphate buffer at various pH values was measured in the 300—600 mμ range with a Yanagimoto ORD-3 spectropolarimeter using a 50-mm quartz cell at 25°C (c=0.5), and the parameter, b_0, was calculated from the Moffitt-Yang equation.[17] The helical content from b_0 was corrected by applying the results of Fasman *et al.*[18]

Absorption Spectrum and Difference Spectrum. The ultraviolet absorption spectrum and the difference spectrum were studied with a Hitachi 124 spectrophotometer, using 10-mm quartz cells at 25°C. In the measurement of the difference spectrum, a copolymer solution at pH 7.60 was used as the reference.

Fluorescence Spectrum. The fluorescence spectra of the copolymer and tryptophan in 0.1M phosphate buffer were measured with a Hitachi MPF-2 spectrofluorophotometer, using a 10-mm quartz cell at 25°C.

Results

Fractionation. The results by gel filtration on a column of Sephadex G-50 are shown in Fig. 1.

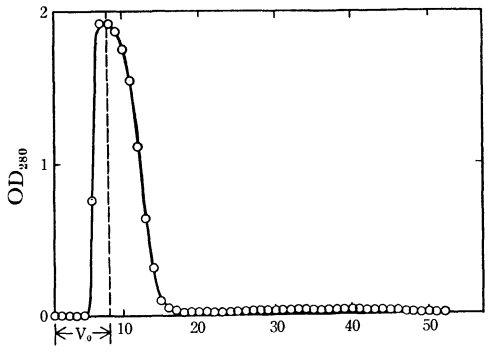

Fig. 1. Elution diagram of copoly(L-Glu, L-Trp 9 : 1) on Sephadex G-50, Fine.
Eluant: 0.1 M phosphate buffer at pH 7.0.
Bed dimensions: 2 cm×28 cm
Sample: 2 ml containing 10 mg of substance
Flow rate: 0.6 ml/min
V_0: void volume of the column which was determined with Blue Dextran 2000.

Since only one peak of the copolymer appears at the position of the void volume of the column, and since there is no other peak, the copolymer does not contain the fraction with a molecular weight less than 30000, because the effective fractionation with Sephadex G-50 for peptides is in the 1500—30000 range;*3 the molecular weight of 85000 obtained from the viscosity seems to support the above statement. It was shown also that no oxidation of the tryptophanyl residue occurred during the preparation of the copolymer, for normal absorption spectra of the tryptophanyl residue (250—300 mμ) were observed in each fraction and no absorption spectra of the oxidized tryptophanyl residue[19,20] were detected in any of the fractions.

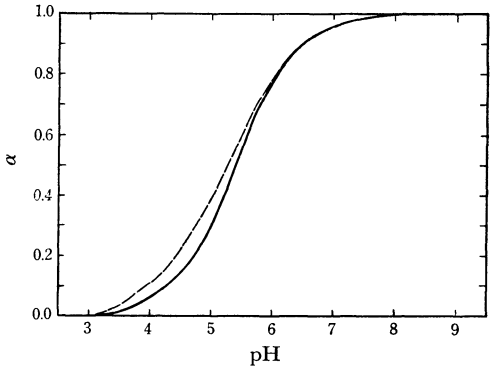

Fig. 2. Titration curve of copoly(L-Glu, L-Trp 9 : 1) (——) and poly-L-glutamic acid (------) at 20°C.
Sample: 10 ml of 0.1M NaCl aqueous solution containing 20 mg of substance
Titor: 0.1N NaOH aqueous solution

*3 The data is shown in the catalogue of Pharmacia Fine Chemicals, Uppsala, Sweden.

Titration. The titration curves of the tryptophan copolymer and poly-L-glutamic acid are shown in Fig. 2. The apparent pK values of both polymers were 5.34 and 5.26 respectively in 0.1M sodium chloride.

Optical Rotatory Dispersion. Figure 3 shows

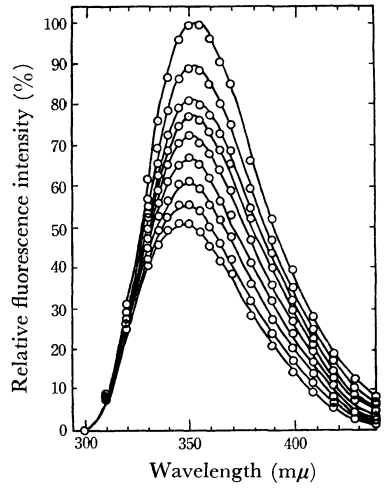

Fig. 7. Fluorescence emission spectra of copoly(L-Glu, L-Trp 9 : 1) in 0.1M phosphate buffer at various pH, pH 4.95—pH 7.40, at 25°C.
Exciting wavelength is 280 mμ.
Optical density at 280 mμ is 1.5 at pH 7.40.

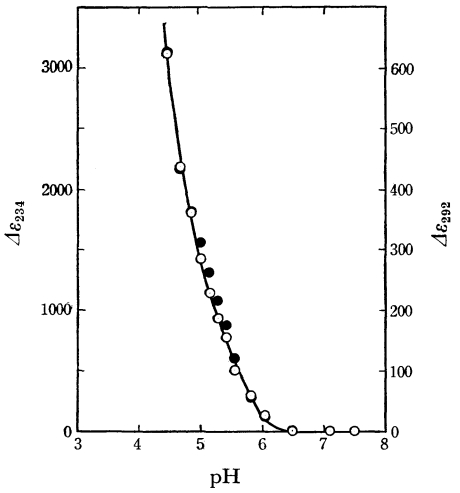

Fig. 6. Relationship between pH and difference absorption at 234 mμ (○) and 292 mμ (●) of copoly-(L-Glu, L-Trp 9 : 1).

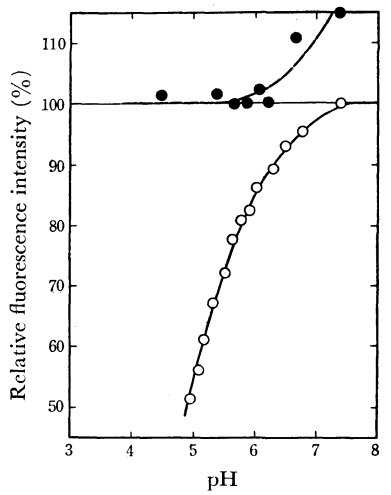

Fig. 8. Relationship between pH and the relative fluorescence intensity of copoly(L-Glu, L-Trp 9 : 1) (—○—) and L-tryptophan (--●--).

the relation between the pH and the helical content of the copolymer. The inflection point of the curve was at pH 5.2, and a helical content of 0% was shown above pH 5.5, where the copolymer was in the random state.

Difference Spectrum and Absorption Spectrum. The difference spectrum of the tryptophan copolymer and that of tryptophan itself are shown in Fig. 4. The difference spectrum of the tryptophan copolymer at pH 4.68 *vs.* pH 7.60 (shown by the solid line in Fig. 4) shows two specific bands, though that of tryptophan itself under the same conditions (shown by the dashed line) has no detectable absorption. The absorption spectrum of the tryptophan copolymer and that of tryptophan itself are shown in Fig. 5. The absorption shoulder at 220 mμ of the copolymer seems to correspond with the absorption peak at 218 mμ (ε=35000) of tryptophan.

The relationships between the pH and the difference absorption at 234 and 292 mμ respectively are shown in Fig. 6.

Fluorescence Spectrum. The fluorescence spectra of copolymers excited with a 280 mμ wavelength at various pH values are shown in Fig. 7. The fluorescence intensities of the copolymer and tryptophan at various pH values are shown in Fig. 8, in which the intensity at pH 7.40 is put as 100%. The pH-dependence of the

relative fluorescence intensity of the copolymer is quite different from that of tryptophan itself.

Discussion

The peaks at 273, 283, and 292 mμ of the difference spectrum at pH 4.68 *vs.* pH 7.60 in Fig. 4 seem to be due to the red shift ($\pi \rightarrow \pi^*$ transition) of the ordinary absorption band in the 250—300 mμ region on the tryptophanyl residue. Donovan *et al.*[21] reported that, in the difference spectrum of tryptophan at pH 1.7, 2.6, 6.4, and 8.7 *vs.* pH 1.2 at a high concentration ($OD_{280}=6$), the peak at 293 mμ decreased with a lowering of the pH; this suggested a blue shift of the absorption band around 280 mμ with a lowering of the pH. On the contrary, in the difference spectrum of the tryptophan copolymer at the low concentration of $OD_{280}=1.5$, the peak at 292 mμ increased with a lowering of the pH and showed a red shift of the absorption band around 280 mμ based on the tryptophanyl residue.

As is shown by the dashed line in Fig. 4, such a specific difference spectrum of tryptophan itself as was shown by Donovan *et al.*[21] was not observed in a dilute solution, in which tryptophan was dissolved at the same concentration as the tryptophanyl residue in the copolymer ($OD_{280}=1.5$). The difference spectrum of tryptophan itself[21] and that of the tryptophan copolymer were reversed in sign; also, the absolute value of the latter was much larger than that of the former. This might show that the behavior of the tryptophanyl residue in the copolymer is quite different from that of tryptophan itself upon a change in the pH in a solution.

The absorption peak of tryptophan itself at 218 mμ seems to correspond to the characteristic absorption shoulder in the 220 mμ region of the tryptophanyl residue in the copolymer, as is shown in Fig. 5; the red shift of the latter seems to give a peak at 234 mμ in the difference spectrum of the copolymer in Fig. 4. Therefore, from these results, it may be concluded that the sharp and large peak at 234 mμ in the difference spectrum of the copolymer was caused by the red shift ($\pi \rightarrow \pi^*$ transition) of the ultraviolet absorption band in the 220 mμ region of the tryptophanyl residue in the copolymer.

On the other hand, it has been explained that a large peak at 230—235 mμ in the difference spectrum between native and denaturated proteins, such as bovine albumin (234 mμ),[6] papain (235 mμ),[7] ovalbumin (232 mμ),[7] and lysozyme (231 mμ),[7] would be due to the hyperchromisity ($n \rightarrow \pi^*$ transition) of the amide group in the peptide bond, for in the case of poly-L-glutamic acid the hyperchromisity of the amide group was observed at 222 mμ in the difference spectrum between the α-helix and the random coil.[22] However, the difference spectrum at 230—235 mμ in proteins seems to be different from that of poly-L-glutamic acid at 222 mμ, since it is too big a shift to have the identical source ($n \rightarrow \pi^*$ transition). The hyperchromisity at 222 mμ due to the $n \rightarrow \pi^*$ transition of the amide group, as reported with poly-L-glutamic acid, was undetectable with the tryptophan copolymer (Fig. 4), for the intensity of transmitted light below 225 mμ was extremely weakened because of the high optical density of the tryptophanyl residue. The difference spectra of proteins are quite similar to that of the tryptophan copolymer (Fig. 4). Therefore, the difference absorptions at 234 mμ observed with the tryptophan copolymer and at 230—235 mμ with proteins must be due to the red shift ($\pi \rightarrow \pi^*$ transition) of the far-ultraviolet absorption band of the tryptophanyl residue, and not to the $n \rightarrow \pi^*$ transition of the amide group in peptide bond.

When we compare Fig. 6 with Fig. 3, it is obvious that the peaks of the difference absorption at both 234 mμ and 292 mμ vary proportionally to the helical content of the copolymer and that these difference absorptions are closely related to the secondary structure of polypeptides. Also, the difference absorption at 234 mμ in the tryptophan copolymer was completely proportional to that at 292 mμ; the former was five times of the latter. Therefore, it would be more accurate to confirm the conformation of a tryptophan copolymer or a tryptophan-containing protein by the difference absorption at 324 mμ instead of that at 292 mμ.

The fluorescence emission spectra of the tryptophan copolymer at various pH values (Fig. 7) are similar to that of the tyrosine copolymer, copoly-(Glu,Tyr 95 : 5), reported by Pesce and Fasman.[23]

In view of the titration curve of the tryptophan copolymer (Fig. 2), the relative intensity of fluorescence of the tryptophanyl residue at 350 mμ against the pH (Fig. 8) is in good agreement with the extent of the protonation of the carboxyl group in the copolymer against the pH. The unionized carboxyl group seems to act as a quencher of the fluorescence of the tryptophanyl residue. These results support Fasman's suggestion[4] that the fluorescence intensity of the tryptophanyl residue depends on the degree of ionization of the carboxyl group in copoly(Glu,Trp 99 : 1).

The spectrophotometric behavior of the tryptophanyl residue in polypeptide is quite different from that of tryptophan itself. The appearance of

23) A. Pesce and G. D. Fasman, *J. Am. Chem. Soc.*, **86**, 5669 (1964).

the difference spectrum seems to correspond closely to the formation of the α-helix in the polypeptide molecule, and the protonation of carboxyl groups in polypeptide seems to induce the quenching of the fluorescence of the tryptophanyl residue. It is not yet clear whether the spectrophotometrical results are related to the catalytic activity[5] of the tryptophan copolymer.

The authors wish to thank Professor Motozo Kaneko of this Department for his help in the measurements of the fluorescence spectra; Professor Shintaro Sugai of this Department for his advice in the measurements of the optical rotatory dispersion, and Professor Masaru Funatsu of Kyushu Univeristy for his kind support of this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1118—1123 (1969)

Alkoxysilanes. II. Preparation of Tributoxysiloxychlorosilanes, Silanols, and Their Polymeric Substances

Yoshimoto ABE*1 and Ichiro KIJIMA*1

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received September 2, 1968)

Tributoxysiloxychlorosilanes $[(BuO)_3SiO]_xSiCl_{4-x}$ (Bu=*t*: $x=1, 2$; Bu=*s*: $x=1, 2, 3$ or 4) were prepared by the reaction of silicon tetrachloride with tributoxysilanol in the presence of pyridine. The hydrolysis of these compounds led to the formation of tributoxysiloxysilanols $[(BuO)_3SiO]_xSi(OH)_{4-x}$ (Bu=*t*: $x=2$; Bu=*s*: $x=2$ or 3). Tri-*t*-butoxysiloxysilanetriol was obtained from the corresponding trichlorosilane under mild hydrolytic conditions by using aniline as an hydrogen-chloride acceptor. On the other hand, the hydrolysis of the trichlorosilane with excess water in the presence of pyridine gave a resinous product. The fractional precipitation of this product gave a white powder soluble in such organic solvents as benzene, *n*-hexane, ether, and carbon tetrachloride; the powder had a molecular weight between 2500 and 4300. This resin turned into glassy solids upon being heated at 200 or 300°C under reduced pressure; these solids had molecular weights between 5500 and 12500. The possible structures for these polymeric substances were discussed on the basis of the results of the elemental analysis, the IR spectra, and the gas chromatography of volatile substances produced in the course of polymerization.

Although alkoxysilanes with functional groups have been prepared, the isolation of alkoxysilanes $(RO)_xSiX_{4-x}$ (R=Me, Et, Pr, Bu; X=OH, NH_2; $x=1, 2$ or 3) containing hydroxy or amino[1] groups as functional groups is very difficult because of the easy condensation. Tiralkoxysilanols with *s*-[2] or *t*-[3]alkoxy groups, however, are obtained, and in the latter case di-*t*-butoxysilanediol[4] is also isolated. The above facts show that the steric hindrance of alkyl groups protects the functional group from condensation. Therefore, we tried to prepare tributoxysiloxychlorosilanes in which the alkoxy group on an alkoxysilane is replaced by the tributoxysiloxy group and tried to isolate the stable silanediol and silanetriol by the hydrolysis of the corresponding chlorosilanes:

$$SiCl_4 + x(BuO)_3SiOH + xC_5H_5N = [(BuO)_3SiO]_xSiCl_{4-x} + xC_5H_5NHCl$$

$$[(BuO)_3]_xSiCl_{4-x} + xH_2O = [(BuO)_3SiO]_xSi(OH)_{4-x} + xHCl$$

In the course of our investigation into the hydrolysis of alkoxysiloxychlorosilane, our attention was called to polymeric substances produced because the structures of the polyalkyl(aryl)silsesquioxanes formed by the hydrolysis of alkyl(aryl)trichloro-

silane[5] or alkyltrialkoxysilanes[6,7] were discussed, but the structures of substances formed by the hydrolysis of alkoxysiloxytrichlorosilane were not. Therefore, it seemed necessary that the structures of the polymers were considered since it was thought that the polymeric substances formed by the hydrolysis of tri-*t*-butoxysiloxytrichlorosilane do not have such a simple structure constructed of silsesquioxane units as have the hydrolysis products of alkyltrichlorosilanes.

Experimental

The boilling points and melting points are uncorrected. The experiments were carried out under a dry atmosphere.

Materials. The amines and the solvents were dehydrated, and the silicon tetrachloride was purified by distillation. Tri-*s*-butoxysilanol was obtained by the method of Wright[2]; bp 89.5°C/1 mmHg, n_D^{20} 1.4135.

Tri-*t*-butoxysilanol was first prepared by Backer and Klasens[8] by the hydrolysis of sodium tri-*t*-butoxysilanolate. Wright *et al.* had described how silanol was obtained by the hydrolysis of tri-*t*-butoxychlorosilane in boilling water, but its details had not been documented. In the present work, the silanol was prepared in good yields by a modification of the procedure of Wright.

To a solution of 72.7 g of pyridine and 280 g of water, 200 g of tri-*t*-butoxychlorosilane[9] were added. Then the mixture was stirred at 70—80°C for 1 hr and left standing overnight. After the white solid thus formed was filtered and washed with water, the solid was dissolved in petroleum ether and dehydrated with anhydrous sodium sulfate. The solvent was removed, and the residue gave 130 g (70%) of a white crystalline solid, mp 65—66°C (lit. 65.5°C). Found: C, 54.67; H, 11.64; Si, 10.60%; mol wt, 268. Calcd for $C_{12}H_{28}O_4Si$: C, 54.51; H, 10.67; Si, 10.60%; mol wt, 264.

Preparation of Tri-*s*- and -*t*-butoxysiloxychlorosilanes. Into a solution of tri-*t*-butoxysilanol and pyridine in *n*-hexane, silicon tetrachloride in *n*-hexane was stirred, drop by drop, at 0——5°C. (In the preparation of *s*-derivatives the addition of the silanol was reversed, and for tris or tetrakis derivatives toluene was used as the solvent.) The mixture was refluxed for one (trichloro-derivatives) or two (the other derivatives) hours. After the filtration of pyridine hydrochloride and the removal of the solvent, the filtrate gave products by fractional distillation *in vacuo* with a 20 cm Widmer column. The results are shown in Table 1.

Preparation of Tri-*s*- and -*t*-butoxysiloxysilanols. Into a mixture of pyridine, water, and petroleum ether, tributoxysiloxychlorosilane in dry petroleum ether was vigorously stirred, drop by drop, at 0——5°C. Then the oil layer was separated and dried over anhydrous sodium sulfate. The evaporation of the solvent gave silanols by fractional distillation *in vacuo*. The results are given in Table 2.

Preparation of Tri-*t*-butoxysiloxysilanetriol. A mixture of 2.5 g of water, 13.2 g of aniline, and 300 m*l* of ether was made homogeneous by the addition of 30 m*l* of acetone.[10] To the solution, 18.7 g of tri-*t*-butoxysiloxytrichlorosilane in 200 m*l* of ether were then stirred in, drop by drop, at −10——20°C for 2 hr. Then the mixture was allowed to come to room temperature, and the aniline hydrochloride was filtered out. The white solid formed by evporation of the ether *in vacuo* was dissolved in 60 m*l* of benzene without heating. The needle crystals which formed when the solution stood for several hours were filtered out, washed with benzene, and dried *in vacuo*; yield 3 g (18.8%); mp 114—117°C. The results of the elemental analysis are given in Table 2.

Hydrolytic Polycondensation of Tri-*t*-butoxysiloxytrichlorosilane. Into a mixture of 29.8 g of pyridine, 198 g of water, and 50 m*l* of petroleum ether, a 50 g portion of the trichlorosilane in 50 m*l* of petroleum ether was stirred at 0°C. The oil layer was then separated, washed fully with water, and dried over anhydrous sodium sulfate. The evaporation of the solvent *in vacuo* gave a colorless residue (39 g). The purification of this product was carried out by fractional precipitation. Into 50 m*l* of vigorously stirred methanol there were added, drop by drop, 6 g of the product dissolved in 10 m*l* of benzene. A white precipitate was formed and separated by decantation. The precipitate was again submitted to the same treatment, giving 1.0 g (No. 1-a) of a white solid when dried *in vacuo*. The solvent was evaporated from the mother liquor under reduced pressure, and the residue was treated with 5 m*l* or 3 m*l* of benzene through the same method to give 1.2 g (No. 1-b) and 1.3 g (No. 1-c) respectively of a white solid. The results of the elemental analysis are given in Table 4.

Heat Polymerization of the Hydrolysis Product. The unpurified hydrolysis product (9.5 g) obtained in the above experiment was heated at 200 or 300°C for 2 hr under reduced pressure (1—2 mmHg). The volatile and sublimable products formed in the procedure were trapped into a vessel cooled with dry ice and acetone. The total weight loss was 1.9 g at 200°C and 4.1 g at 300°C, including 1.7 and 1.9 g, respectively, of tri-*t*-butoxysilanol as the sublimate. The colorless glassy solid (4.5 g) at 200°C was treated by the same procedure to give 1.3 g (No. 2-a; 10 m*l* of benzene), 0.6 g (No. 2-b; 5 m*l*), and 0.4 g (No. 2-c; 3 m*l*) of a white powder. The residue (1.5 g) at 300°C was extracted with 100 m*l* of benzene for 3 hr to give 1.2 g of a soluble solid and 0.3 g (20 wt%) of an insoluble one. The former (2 g) was further treated with benzene to give 1.4 g (No. 3-a; 10 m*l* of benzene) and 0.5 g (No. 3-b; 5 m*l*) of a white powder.

It was confirmed by means of gas chromatography that the volatile substance obtained in the course of

the heat polymerization, which was dissolved in benzene, contained water and *t*-butyl alcohol. The results are given in Table 4.

Heat Polymerization of Tri-*t*-butoxysiloxysilanetriol. The silanetriol (2.6 g) was heated at 145—155°C for 30 min under reduced pressure (2 mmHg). The same treatment of the product with 5, 3, and 1 m*l* of benzene gave 0.3 g (No. 4-a), 0.7 g (No. 4-b), and 0.8 g (No. 4-c) of a white powder. The results are given in Table 4.

Instruments. The IR spectra were measured in a KBr disk or a liquid film with a Hitadhi EPI-S2 spectrometer. The NMR spectra were measured with a Varian A-60 spectrometer in a carbon tetrachloride solution or in dueterated chloroform, with tetramethylsilane as the internal standard. The molecular weight was determined by the cryoscopic method or the vapor-pressure method in benzene. The gas chromatography was measured under these conditions: carbowax 6000, 1-m, 136°C, 46 m*l*/min. The thermal property of the products was determined by thermogravimetric analysis and by differential thermal analysis.

Results and Discussion

Monomers. The chlorosilanes and the silanols obtained are shown in Tables 1 and 2. As is shown in Table 1, the number of the replaced chlorine atoms indicates that the tri-*t*-butoxysiloxy group has a greater steric hindrance than the tri-*s*-butoxysiloxy one. Under these experimental conditions, further substituion did not occur even when excess tri-*t*-butoxysilanol was used. The difference in this steric hindrance between the two groups greatly contributes to the stabilization of the functional group. Table 2 shows that bis(tri-*s*-

butoxysiloxy)silanediol polymerizes partially during prolonged distillation at a high temperature (yield 28%), whereas bis(tri-*t*-butoxysiloxy)silanediol can be distilled quantitatively (yield 80%) without condensation. On the other hand, tri-*t*-butoxysiloxysilanetriol is unstable and easily polymerizes, like other silanetriols.

The silanetriol is slightly soluble in benzene and chloroform. The other products obtained as solids are very soluble in organic solvents and have low melting points.

The silanols were confirmed by the IR and NMR spectra given in Table 3. The IR spectra are essentially identical and exhibited characteristic peaks at 3425—3460 (OH), 1365 and 1387 (branching of the alkyl groups), and 1060—1070 (Si–O–Si) cm^{-1}. A little shift toward the lower wave numbers for the hydroxy group of going from *t*- to *s*-derivatives was observed, probably because of an increace in the hydrogen bond with a decrease in the steric effect. The relative ratio of the protons of the hydroxy to those of the alkyl group is in good accordance with each of the structures. The NMR spectra of tri-*t*-butoxysiloxysilanetriol were measured in deuterated chloroform, but an exact ratio was not given because of its low solubility. The proton signal for the hydroxy group of bis(tri-*s*-butoxysiloxy)silanediol was not detected as a singlet. Since proton signals of the *t*-derivatives have a tendency toward an up-field shift as the number of substituent increases, in this case the signal seems to overlap with that of the methine proton. The ratio of the sum of methine and hydroxy protons to that of methyl and methylene protons is in good agreement with the structure.

The signal for the hydroxy proton of the silanols has a tendency to shift up-field with a larger steric hindrance; this is parallel to that tendency observed in the IR spectra.

Polymers. The results of the hydrolytic polycondensation and the heat polymerization are given in Table 4. Although No. 3-c was insoluble and infusible, the polymers were white powders, soluble in such organic sovents as benzene, *n*-hexane, ether, and carbon tetrachloride, and insoluble in methanol and ethanol.

The structures of these polymers are thought to be similar to those of polyalkyl(aryl)silsesquioxanes.

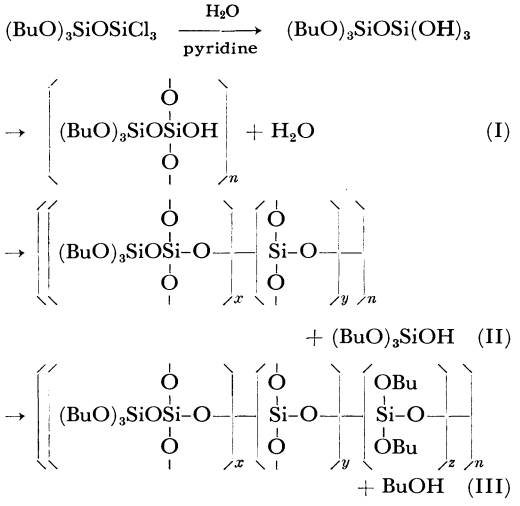
It has been known that alkyl(aryl)silsesquioxanes are obtained from the corresponding trichlorosilanes or silanetriols and are composed of a ladder-type linear chain[11] or a cage-like[7,12] structure repeating a cyclosiloxane ring. In the present work, however, it is evident from the results of the elemental analysis (Table 5) that none of the polymers are constructred of a simple silsesquioxane, a so-called "T" unit. The unit structures of these polymers are the Q (tetrafunctional silicon atom: SiO_2) and the D (difunctional silicon atom $(Bu^tO)_2SiO_{0.5}$), along with the T (trifunctional silicon atom $(Bu^tO)_3SiOSiO_{1.5}$). This is confirmed from the following facts: 1. Tri-*t*-butoxysilanol was obtained as a component of the fractional precipitation and as a sublimate in the course of the heat polymerization *in vacuo*. 2. *t*-Butyl alcohol was detected as a volatile substance at from 200 to 300°C. Additional pieces of evidence are the remarkable weight loss at the temperature shown by thermogravimetric analysis curve (Fig. 1) and the three exothermic peaks at 65, 125, and 175°C observed in the differential thermal analysis of tri-*t*-butoxysiloxysilanetriol (Fig. 2). The two peaks at 90 and 295°C were also found for the No. 2-a polymer. These facts result from three different condensations in the course of the polymerization:



11) J. F. Brown, *J. Polymer Sci.*, **No. 1**, P-c, 83 (1963).
12) K. A. Andrianov and B. A. Izmaylov, *J. Organometal. Chem.*, **8**, 435 (1967).

The empirical formulas cited in Table 5 have been deduced by comparison with the atom ratio calculated from the experimental data (Table 4) and that obtained from the structural units, *x*, *y*, and *z*, in (II) and (III); the calculated values are also shown. The results of the elemental analysis (Tables 4 and 5) show that the polymers of No. 1 and No. 4 have no significant difference in structure except for the molecular weight and are in agreement with a (II) structure; on the other hand, the polymers of No. 2 and No. 3 are constructured of (III).

The probable structures of these polymers are shown in Fig. 3. In view of the fact that each of the polymers except for No. 3-c is very soluble in organic solvents, there appears to be no significant cross-linking. The polymers of No. 1 and No. 4 seem to have a linear sheet-like structure formed by the condensation of the three molecules of the silanetriol. As to the polymers of No. 2 and No. 3, however, it seems reasonable to assume three-dimensional polymers like a prism or cube (Fig. 4) rather than sheet-like ladder types. In this case the structural units might be eight, ten or twelve member-rings, since two or three functional silane monomers containing larger steric groups are apt to give cyclic or cage-like structures and since the stretching vibration of Si–O–Si in the cyclosiloxanes with more than eight member-rings is in the region of wave number higher than 1045 cm^{-1} (in these cases, at 1060—1070 cm^{-1}).[12,13] Besides the fact that the polymers of No. 3 contain an insoluble gel (20%) indirectly shows a three-dimensional structure in No. 2 and No. 3. The polymer of No. 3-c seems to be a network polymer.

The IR spectra of all polymers are essentially identical and show absorption peaks at 3400—3450, 2960, 1389, 1364, 1240, 1190, and 1060—1070 cm^{-1}.

The X-ray powdery diffraction pattern of No. 2-a indicates no crystallinity.

The authors wish to thank Mr. Isao Orita for his assistance in the experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1124—1129 (1969)

Synthesis of Carboxylic Acid from Aryl Halide and Carbon Monoxide Catalyzed by Nickel Carbonyl

Mikitake NAKAYAMA and Tsutomu MIZOROKI

Government Chemical Industrial Research Institute, Tokyo, Meguro-ku, Tokyo

(Received September 2, 1968)

In the reacion of aryl bromide with carbon monoxide in the presence of water and a catalytic amount of nickel carbonyl, it has been found that aromatic carboxylic acids (benzoic acid, polymethylbenzoic acid, α-naphthoic acid, *etc.*) are formed in very high yields when such salts of carboxylic acids as potassium acetate or sodium benzoate are added to the starting materials. The carbonylation reaction of aryl bromide is strongly inhibited by the hydrobromic acid formed, and the addition of the salt of carboxylic acid effectively decreases its concentration in the course of the reaction. When the amount of potassium acetate is larger than that of aryl bromide, the rate of the carbonylation reaction of bromobenzene to form benzoic acid is proportional to the amounts of bromobenzene, nickel tetracarbonyl, and water and to the reciprocal of the carbon monoxide pressure. From these kinetic data, the effect of the salts of carboxylic acids and the course of the reaction are discussed.

Many attempts to obtain aromatic carboxylic acids or their esters from the reactions of aryl halides with carbon monoxide using transition metal compounds as catalysts have been made. Nickel complexes have been demonstrated to be the most effective catalysts since the synthesis of benzoic acid from halobenzene with $Ni(CO)_2(Ph_3P)_2$[1] or a nickel(II) iodide catalyst[2] and that of phthalic anhydride from bromobenzene in the presence of sodium carbonate with a nickel tetracarbonyl catalyst[3] were published. The yields of aromatic carboxylic acids have, however, depended to a cansiderable degree on the nickel catalysts, the solvents, and the additives. On the other hand, it has been shown that the treatment of aryl iodide with a stoichiometric amount of nickel tetracarbonyl under milder reaction conditions results in forming an aryl carbonyl compound (carboxylic ester or diketone) in a high yield.[4] We expected that the low yields of aromatic carboxylic acids by the catalytic reactions of aryl halides with carbon monoxide would be caused by the inhibition of the hydrogen halides formed and have found that their yields really become very high when salts of carboxylic acids are added to the starting materials to decrease effectively the concentration of hydrogen halide during the reaction.[5]

This work has been undertaken to obtain substituted benzoic acids from the reactions of aryl bromides with carbon monoxide in the presence of potassium acetate and water using nickel tetracarbonyl, and to investigate their reaction rates.

Experimental

Apparatus. The same apparatus as has been described in a previous paper was used.[6] All the reactions were carried out in titanium-molybdenum alloy autoclaves (225 m*l* and 300 m*l* in volume). A titanium or a titanium-manganese alloy autoclave could not be used in these corrosive reactions. Aryl bromide, water, salt of carboxylic acid, and nickel(II) acetate were placed in the autoclave, and it was heated by a shaking-type electric furnance. The temperature of the autoclave was kept constant for about one hour before carbon monoxide was introduced from a pressure-accumulator vessel. Carbon monoxide was supplied to keep the reaction pressure constant during the reaction. After the reaction had been carried out for 90 min, both the heating and the supply of carbon monoxide were stopped and the autoclave was allowed to cool to room temperature.

Materials. 4-Bromo-*o*-xylene, 4-bromo-*m*-xylene, and 2-bromo-*p*-xylene were formed selectively from *o*-, *m*-, and *p*-xylenes respectively by the bromination of xylenes, using iodine as the catalyst according to

Wisansky method;[7] they were purified by distillation. 5-Bromo-pseudocumene was obtained by the bromination of pseudocumene[8] and recrystallized from ethanol (mp 73°C). 2-Bromo-mesitylene was prepared from mesitylene[9] and purified by distillation. The other aryl halides and salts of carboxylic acids were commercial product; their purities were checked by gas chromatography before use. Commercially-available nickel(II) acetate and nickel tetracarbonyl (made by Alfa Inorganic, Inc.) were used without further purification. The carbon monoxide was obtained from the decomposition of formic acid; its purity was more than 98%.

Analyses. The organic products were extracted by diethyl ether, and the aqueous phase was separated from the ether phase. Carboxylic acids present in the ethereal layer were extracted with an aqueous potassium hydroxide or sodium carbonate solution (2N) from the other organic compounds. The carboxylic acids were precipitated from a given amount of the aqueous solution with an aqueous hydrochloric acid solution. Before the white precipitates were filtrated and washed well with cold water, they had been cooled well in a freezer. The amounts of carboxylic acids were determined by titration with an aqueous potassium hydroxide solution. They were identified by gas chromatographies of their methyl esters or by means of their IR absorption spectra or melting points. The amounts of Br^- and Ni^{2+} present in the aqueous phase were determined by the Volhard method and by EDTA titration respectively, and those of carbon monoxide and carbon dioxide, by absorption methods.

Results

Reaction Conditions. The reaction rates of aryl halides with carbon monoxide catalyzed by nickel tetracarbonyl depend greatly on the temperature, the pressure of carbon monoxide, and the amounts of water and of a salt of carboxylic acid to be discussed later. The effect of the temperature, for example, is shown in Fig. 1. Most of the reactions with aryl bromides were carried out under 200 kg/cm² at 250°C for 90 min. Carbon monoxide was absorbed within 40—60 min under the reaction conditions. Preliminary experiments showed that no aryl bromide was hydrolyzed under the reaction conditions, although most of the alkyl halides were hydrolyzed into alcohols and potassium halides by adding potassium acetate,

without absorbing any carbon monoxide.

Syntheses of Substituted Benzoic Acids. The yields of polymethylbenzoic acids from the reactions with bromopolymethylbenzenes are described in Table 1. Carbon monoxide was absorbed almost quantitatively in the reactions of bromotoluenes (*o*-, *m*- and *p*-) or bromoxylenes (4-bromo-*o*-xylene, 4-bromo-*m*-xylene, and 2-bromo-*p*-xylene), and the corresponding benzoic acids were formed in very high yields. The amounts of Br^- described in Table 1 also show that bromotoluene and bromoxylene react quantitatively. In the reaction with bromobenzene, small amounts of benzene, phenol, and biphenyl were formed as by-products.*1 The corresponding hydrocarbons and phenols were also detected in the products obtained from the reactions with bromopolymethylbenzene. This is the reason why the amounts of benzoic acids formed are smaller than those of Br^-. 2,4,5-Trimethylbenzoic acid was also formed quantitatively from the reaction with 5-bromopseudocumene, while 2,4,6-trimethylbenzoic acid could not be obtained in a high yield from the reaction with bromomesitylene, probably because of the steric hindrance of two ortho methyls.

Carbonylations of *p*-bromoanisole, *p*-bromoacetophenone, and *p*-bromobenzoic acid were tested under the same conditions. *p*-Bromoanisole was very reactive, but *p*-methoxybenzoic acid was not formed selectively and a lot of by-product (*p*-methoxyphenol and anisole) were found in the product. On the other hand, *p*-bromobenzoic acid was not so reactive. Either the reaction temperature or the amount of water had to be increased in order to obtain terephthalic acid in a high yield. The reactivity of aryl bromide in the carbonylation reaction seemed to increase when methyls (electron-releasing substituents) were introduced into the benzene ring, but it was difficult to know the effects of other substituents on this reaction because of the side reactions.

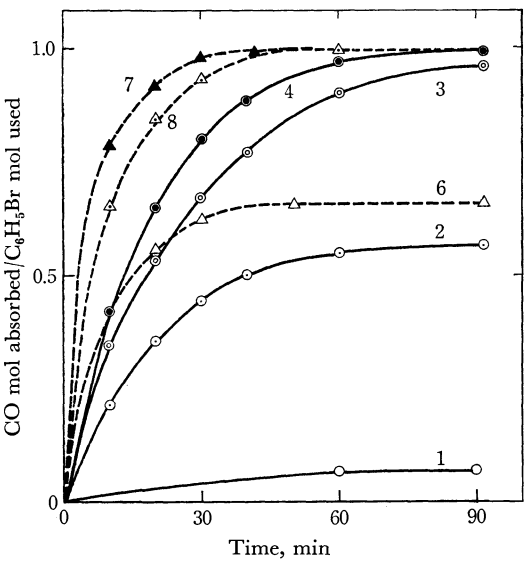

Fig. 2. Effect of potassium acetate on absorption rate of carbon monoxide.

a) Bromobenzene used was 0.50 mol.
b) Bromobenzene used was 0.30 mol.

Effect of Salt of Carboxylic Acid. The effect of potassium acetate on the reaction of bromobenzene in the presence of either water or methanol is represented in Table 2 and Fig. 2. Figure 2 shows how effectively the addition of potassium acetate increases the absorption rate of carbon monoxide. Practically no carbonylation reaction took place when no potassium acetate was added. When the amount of potassium acetate was half of the amount of bromobenzene, that of the carbon monoxide absorbed was also nearly a half of the amount calculated from bromobenzene. Carbon monoxide was not absorbed quantitatively unless the amount of potassium acetate reached that of bromobenzene. The absorption rate of carbon monoxide was larger in methanol than in water.

Most of the nickel(II) acetate used as a catalyst was present as Ni^{2+} in the product when the amount of potassium acetate was smaller than bromobenzene. Only a small amount of Ni^{2+} was, however, detected and most of the nickel was present as nickel tetracarbonyl when enough potassium acetate was added, as is shown in Table 2. This means that the addition of potassium acetate is favorable for the formation of nickel tetracarbonyl during the reaction as well as for the carbonylation of bromobenzene. Its effect on the formation of nickel tetracarbonyl from nickel(II) bromide ($NiBr_2+5CO+H_2O\rightarrow Ni(CO)_4+CO_2+2HBr$) was,

*1 Carbon monoxide was partly consumed to form formic acid, but the amount so consumed was only 5—10% of the amount of carbon monoxide absorbed.

therefore, examined separately. Without potassium acetate, no absorption of carbon monoxide to form nickel tetracarbonyl was observed under the same conditions as for the carbonylation reaction of bromobenzene, but rapid absorption took place when twice as much potassium acetate was added as the amount of nickel(II) bromide, and most of the nickel(II) bromide (more than 95%) was reduced into either nickel tetracarbonyl or metallic nickel. Amines, such as pyridine, triethylamine, and aniline,*2 had nearly the same effect as salts of carboxylic acids, while the latter were more effective.

Kinetic Study. The rate of the carbonylation reaction of bromobenzene in the presence of enough potassium acetate ($AcOK/C_6H_5Br = 1.1$ mol ratio) was investigated on the basis of the absorption rate of carbon monoxide. $-\log(1-C_t)$ are plotted against the reaction time (min) in Fig. 3, where

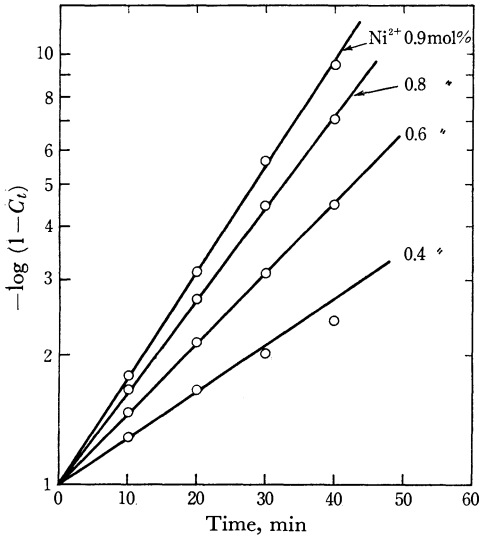

Fig. 3. Reaction rate of carbonylation of bromobenzene.
Reaction conditions: C_6H_5Br 0.50 mol, H_2O 3.00 mol, AcOK 0.55 mol, Temperature 250°C, Pressure 200 kg/cm²

C_t is the conversion of bromobenzene into benzoic acid calculated from the amount of carbon monoxide absorbed in t min. The rate was proportional to the amount of bromobenzene, and its rate constants could be obtained from the gradients of these linear plots. As is shown in Fig. 4, the rate was proportional to the amount (mol % based on bromobenzene) of nickel(II) acetate; in this figure the rate constants obtained in the case of introducing nickel tetracarbonyl*3 are also plotted. No difference between nickel(II) acetate and nickel tetra-

carbonyl was observed in their catalytic activities. The effect of water is shown in Fig. 5. The rate was also proportional to the amount of water over the range of 2—8 times as much as bromobenzene. When the amount of water added was more than 8 times, the absorption rate of carbon monoxide became too large to take its rate constant. The pressure of carbon monoxide had a strong effect, as is shown in Fig. 6 and Table 3. The maximum reaction rate was observed at 150 kg/cm² under the reaction conditions described in the figure. Under pressures of carbon monoxide higher than 150 kg/cm², the rate was nearly proportional to the reciprocal of the pressure. Somewhat different kinetic behavior was observed in the absorption

*2 Besides benzoic acid, a lot of *N*-benzoylaniline was formed.

*3 $Ni(CO)_4$ was introduced into the autoclave by carbon monoxide pressure when the temperature of the autoclave became 250°C.

rates under lower pressures. However, it was difficult to obtain reliable data here, partly because the reaction was accompanied by side reactions (the formation of phenol and biphenyl) and benzoic acid was not selectively formed, as is shown in Table 3 (the difference between the amounts of benzoic acid and Br^- becomes large), and partly because the carbon monoxide pressure could not be assumed to be constant during the reaction as a result of the accumulations of carbon dioxide and hydrogen formed by a water-gas reaction in the autoclave.

Discussion

On the Effect of Salts of Carboxylic Acids. Figure 2 and Table 2 show that a strong protonic acid, HBr, strongly inhibits the carbonylation of bromobenzene, and that the inhibition can easily be removed by adding potassium acetate. From the facts that the equilibrium of the reaction of $RCOOK + HBr \rightleftarrows RCOOH + KBr$ ($R=CH_3-$, C_6H_5-, *etc.*) inclines much toward the right and that its reaction rate is very fast, it can be postulated that the hydrobromic acid formed from the carbonylation of bromobenzene is converted quantitatively into potassium bromide. The inhibition by hydrobromic acid can be explained as follows:

$$NiBr_2 + 5CO + H_2O \xrightarrow{r_1} Ni(CO)_4 + 2HBr + CO_2 \quad (1)$$

$$C_6H_5Br + Ni(CO)_4 \xrightarrow{r_2} (C_6H_5Br)Ni(CO)_n + (4-n)CO \quad (2)$$

$$(C_6H_5Br)Ni(CO)_n + H_2O \xrightarrow{r_2'} C_6H_5COOH + (HBr)Ni(CO)_{n-1} \quad (2')$$

$$HBr + Ni(CO)_4 \xrightarrow{r_3} (HBr)Ni(CO)_n + (4-n)CO \quad (3)$$

$$HBr + (HBr)Ni(CO)_n \xrightarrow{r_4} NiBr_2 + H_2 + nCO \quad (4)$$

The reaction rate (r_3) of $Ni(CO)_4$ with HBr would be much larger than that (r_2) of $Ni(CO)_4$ with C_6H_5Br, and the reaction rate (r_4) represented by Eq. (4) would also be very fast. Nickel tetracarbonyl is, consequently, difficult to be reformed so as to keep its concentration high, while the effective decrease in the concentration of hydrobromic acid by adding potassium acetate results in controlling the reaction of (3) and (4), and the $(HBr)Ni(CO)_{n-1}$ formed from the reaction of (2′) can be reconverted into nickel tetracarbonyl without any accompanying water-gas reaction, as is represented by Eq. (5):

$$(HBr)Ni(CO)_{n-1} \xrightarrow[-RCOOH,\ -Br^-]{+RCOO^-} Ni(CO)_{n-1} \xrightarrow{+CO} Ni(CO)_4 \quad (5)$$

The catalytic carbonylation of bromobenzene, therefore, takes place smoothly.

On the Kinetic Study. The kinetic behavior of the reaction with aryl bromide catalyzed by $Ni(CO)_4$ is similar to an oxo reaction catalyzed by $Co_2(CO)_8$. The rate of the latter is proportional to the amounts of an olefin and dicobalt octa-

carbonyl, the partial pressure of hydrogen, and the reciprocal of the partial pressure of carbon monoxide.[10] The former in the presence of enough potassium acetate is proportional also to the amounts of bromobenzene, nickel tetracarbonyl, and water, and to the reciprocal of carbon monoxide pressure, as is shown in Figs. 3, 4, 5, and 6, when the pressure is more than 150 kg/cm^2. Consequently, a reaction scheme similar to that derived from the kinetic study of the oxo reaction can be given to the carbonylation of bromobenzene catalyzed by nickel tetracarbonyl.

$$C_6H_5Br + Ni(CO)_4 \overset{K}{\rightleftarrows} (C_6H_5Br)Ni(CO)_3 + CO \quad (a)$$

$$(C_6H_5Br)Ni(CO)_3 + H_2O \xrightarrow{k} C_6H_5COOH + (HBr)Ni(CO)_2 \quad (b)$$

$$(HBr)Ni(CO)_2 + 2CO + AcOK \xrightarrow{fast} Ni(CO)_4 + AcOH + KBr \quad (c)$$

Assuming that nickel tetracarbonyl is reproduced sufficiently fast during the reaction and that the equilibrium of Eq. (a) is very small, the reaction rate, r, can be given by Eq. (d):

$$r = K \cdot k \frac{[Ni(CO)_4][C_6H_5Br][H_2O]}{p_{CO}}$$
$$k_0 = k \cdot K \frac{[Ni(CO)_4][H_2O]}{p_{CO}} \quad (d)$$

The $(k_0 \times p_{CO})$ values obtained from the k_0 of the reactions under pressures higher than 150 kg/cm^2, shown in Figs. 3, 4, 5, and 6, are plotted against $[Ni(CO)_4] \times [H_2O]$ in Fig. 7. The linear plot is in reasonable agreement with the rate Eq. (d). From these kinetic data alone, however, it was difficult to determine whether benzoic acid is formed by the attack of a water molecule or by a hydroxide ion in Eq. (b).

In the oxo reaction, hydrocobalt carbonyl was regenerated so rapidly that its concentration could be assumed to be constant during the reaction; otherwise, it is difficult to explain its kinetic behavior.[11] On the other hand, in the carbonylation of bromobenzene catalyzed by nickel tetracarbonyl, a σ-aryl nickel carbonyl could be formed by the oxidative addition of bromobenzene to nickel tetracarbonyl, as in a Grignard's reaction[12] or as in the carbonylation of aryl halide by the Rh-$(Ph_3P)_2(CO)Cl$ catalyst.[13] This σ-aryl carbonyl would also be rapidly rearranged with carbon monoxide coordinated to nickel into an acyl nickel carbonyl, which would, then, be attacked by a water molecule or a hydroxide ion to form benzoic acid; it is essential that nickel tetracarbonyl itself be regenerated rapidly for a smooth catalytic recycling. Its kinetic behavior, nevertheless, is very similar to the oxo reaction as long as enough potassium acetate is added to regenerate the nickel tetracarbonyl sufficiently fast. This means that acyl metal carbonyls are relatively stable in the catalytic carbonylation of aryl bromides as well as in oxo reactions.

Amino-quinoid Polymeric System. The Preparation of a Polyester Containing 2,5-Diamino-*p*-benzoquinone Nuclei and Its Crosslinking

Ju KUMANOTANI, Kazuyuki SUGITA,*1 Seiji KAZAMA*2 and Toshio YOSHIKAWA*3

The Engineering Research Institute, Faculty of Engineering, The University of Tokyo, Yayoi, Bunkyo-ku, Tokyo

(Received February 20, 1968)

A polyester containing 2,5-diamino-*p*-benzoquinone nuclei was prepared by the polycondensation of 2,5-bis(ω-carboxyl-pentylamino)-*p*-benzoquinone with polyethylene glycol 400 at 160°C, 170°C and 180°C. At 160°C the esterification was brought about easily without gelation, giving an amino-quinoid polyester (prepolymer), but above 170°C an unexpected gelation was observed. The amino-quinone nuclei incorporated in the polyester thus prepared were confirmed by NMR spectroscopy. To make clear the influence of the amino-quinone nuclei upon the gelation, the thermal reactions of the model compounds, the above amino-quinoid dibasic acid, and its ethyl ester were investigated by means of IR spectroscopy and chemical analysis. It was concluded that the hydrogen atoms in the amino-groups of the quinone move to the oxygen atoms and that the resulting hydroxy groups combine with each other to form an ether bond as a result of dehydration. When the prepolymer prepared at 160°C was heated at 170°C for 4 hr with *p*-toluenesulfonic acid (5% by weight) or at 180°C for 8 hr without the acid catalyst, there was obtained an infusible and insoluble film which made crosslinkage as shown in the above mechanism.

While studying a new type of crosslinking polyamides, the present authors found that there is a possibility that the 2,5-diamino-*p*-benzoquinone nuclei introduced in the linear polymer chains will become new functional groups to undergo a crosslinking reaction upon the application of heat. Therefore, in order to elucidate the contribution of the amino-quinone nuclei linked in the polymer backbone to the crosslinking reaction, the present paper will deal with the system of a polyester prepared from 2,5-bis(ω-carboxyl-pentylamino)-*p*-benzoquinone (designated as Q-ACA) and a polyethyleneglycol. In comparison with the polyamide system, a clear interpretation can be obtained IR-spectroscopically for the change in the amino-quinone nucleus without any overlapping of its characteristic absorption bands (see Table 1) with those of the polyamides.

Thus, by using Q-ACA and a commercially-available polyethyleneglycol, PEG 400, we attempted to prepare a linear amino-quinoid polyester without gelation. The progress of the esterification was interpreted in terms of the results of the chemical and IR-spectral analyses. We also tried to reveal the mode of the crosslinking of the amino-quinone nucleus introduced into the polyester by investigating the spectral change in the amino-quinone nucleus, using model compounds of Q-ACA and its ethyl ester. The variation in the linkage of the resulting polyester was also accommodated by the mechanism shown in the scheme. (Eqs. (1), (2), and (3))

Experimental

Materials. PEG 400 of a chemically-pure grade was obtained commercially.

2,5-Bis(ω-carboxyl-pentylamino)-*p*-benzoquinone (Q-ACA) was prepared by the reaction of *p*-benzoquinone with ω-aminocaproic acid according to the method used for the preparation of 2,5-dialkylamino-*p*-benzoquinone derivatives,[1] except that methanol was used as the solvent instead of ethanol. Methanol gave a product with a higher purity than did ethanol. The blowing of air into the reacting solution, with or without cuprous acetate,[2] had no effect upon the yield. An example of the preparation of Q-ACA is the following: a solution of amino-caproic acid (12.9 g, 0.10mol) in 550 m*l* of methanol was mixed with a solution of *p*-benzoquinone (16.2 g, 0.15mol) in 200 m*l* of methanol in a one-liter, round-bottomed flask equipped with a refluxing condenser, and then the mixture was refluxed in a boiling

water bath for 15 min; the resulting solution was cooled to room temperature with ice. The brownish precipitates thus formed were filtered off, washed with benzene, dried *in vacuo*, and found to weigh 12.9 g (theor. 71.3%); decomposing melting point, *ca.* 204°C (measured by the capillary method).

Found: C, 58.75; H, 7.06; N, 7.49%. Calcd for $C_{18}H_{26}O_6N_2$: C, 59.00; H, 7.16; N, 7.65%.

The infrared spectrum of this compound was consistent with that of Q-ACA (see Table 1).

2,5-Bis(ω-ethoxycarbonyl-pentylamino)-*p*-benzoquinone (designated as Q-ACEt hereafter) was prepared by the reaction of *p*-benzoquinone with the ω-aminocaproic acid ethyl ester much as in the case of Q-ACA; a solution of the ω-aminocaproic acid ethyl ester (12.7 g, 0.08mol) in 50 m*l* of methanol was reacted with a solution of *p*-benzoquinone (13.0 g, 0.12mol) in 200 m*l* of methanol, and the resulting yellowish red precipitates were recrystallized from chloroform, dried *in vacuo*, and found to weigh 5.0 g (theor. 29.6%); mp 103—104°C.

Found: C, 62.40; H, 8.25; N, 6.77%. Calcd for $C_{22}H_{34}O_6N_2$: C, 62.54; H, 8.11; N, 6.63%.

The infrared spectrum of this compound was consistent with that of Q-ACEt (compare Fig. 5).

Polyesterification of Q-ACA with PEG 400. In a 50-m*l* flask equipped with an air-tight stirrer, a nitrogen inlet tube reaching to the bottom of the flask, a thermometer, and a short air-condenser for collecting water formed during the reaction, there was placed an equimolar mixture of Q-ACA (3.66 g, 0.01mol) and PEG 400 (4.00 g, 0.01mol). The mixture was heated while being stirred at 160°C, 170°C, or 180°C by means of an oil bath, while a slow stream of deoxygenated nitrogen was passed through it. In order to measure the degree of polyesterification, a sample (0.1—0.5 g) was taken out from the reacting mixture every two or three hours. This sample was dissolved in 50 m*l* of a mixed solvent (acetone-methanol-water, 10 : 5 : 1 by volume) and titrated with a 0.1N KOH ethanol solution on a Potentiograph, E336 (Methrohm Co., Ltd.). The change in the acid value *vs.* the reaction time is shown in Fig. 1.

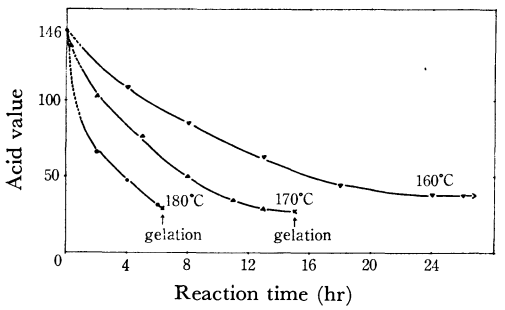

Fig. 1. Relation of the acid-value *vs.* reaction time in the polyesterification of Q-ACA with PEG 400.

Measurement of Curability of the Prepolymer. An acetone-methanol (2 : 1 by volume) solution of the prepolymer was evaporated on a glass plate (1 × 10 × 30 mm) at room temperature with or without the addition of 5% of *p*-toluenesulfonic acid as a catalyst. The thin film thus formed on the glass plate was placed into a heating apparatus *in vacuo*. In order to estimate the extent of the crosslinking of the film, the specimen on the glass plate was dipped in a mixed solvent of acetone-methanol (2 : 1 by volume) at room temperature for ten days or more to determine its solubility; the glass transition temperature was measured by the swinging-beam method.[3]

Results and Discussion

Polyesterification of Q-ACA with PEG 400. *Gelation.* On the basis of the relation between the acid value and the reaction time (see Fig. 1), the esterification of Q-ACA with PEG 400 was found to progress at 160°C, 170°C, and 180°C. In the polyesterification carried out above 170°C, gelation was found unexpectedly; it may be due to the amino-quinone nuclei, since such gelation cannot be seen in the usual polyesterification of a diol with a dibasic acid. The observed gelation time

(the interval between the beginning of the heating of the reaction mixture and the gleation) was 15 hr at 170°C and 6.3 hr at 180°C. Accordingly, any polyesterification without such gelation should be carried out at 160°C or below.

Infrared Spectral Change. Upon an examination of the spectral change observed during the course of the polyesterification of Q-ACA with PEG 400, the characteristic absorption bands of Q-ACA could be assigned as is shown in Table 1.[4)]

As may be seen from the spectral change *vs.* the reaction time (see Fig. 2), as the polyesterification progresses, an increase in the absorption at 1730 cm^{-1} (characteristic of the carbonyl group of the ester) and a decrease in the absorption at 1705 cm^{-1} (characteristic of the carbonyl group of the carboxylic acid) may be seen.

Furthermore, remarkable spectral changes were observed for the characteristic absorption bands of the amino-quinone nucleus during the polyesterification. For example, in the polyesterification at 160°C, shown in Fig. 2, characteristic bands of the amino-quinone nucleus at 3270, 1500, and 1460 cm^{-1} decrease and the absorption band at 1550 cm^{-1} shifts to 1580 cm^{-1} as the esterification progresses. These spectral changes, nevertheless, cannot be interpreted in terms of the chemical change of the amino-quinone nucleus.

An infrared spectrum of the solution of an amino-quinoid compound differs markedly from that of a solute (*e. g.*, in a KBr disk) as a result of the strong molecular interaction of solid solute;[4)] the same is true of 2,5-bis(*n*-butylamino)-*p*-benzoquinone, as is shown in Fig. 3. This spectral difference observed for the amino-quinoid compound was used for the interpretation of the spectral change already observed in the above polyesterification. At the initial stage of the reaction, the reacting mixture, because the solubility of Q-ACA in PEG 400 was small, showed absorption bands characteristic of the solid amino-quinone, but as the esterification progressed and as the homogeneity of the reacting mixture increased, the absorptions characteristic of the amino-quinone dissolved in a solvent appeared. Moreover, the fact that the absorption shifts from 1550 cm^{-1} to 1580 cm^{-1} is in harmony with the above spectral results.

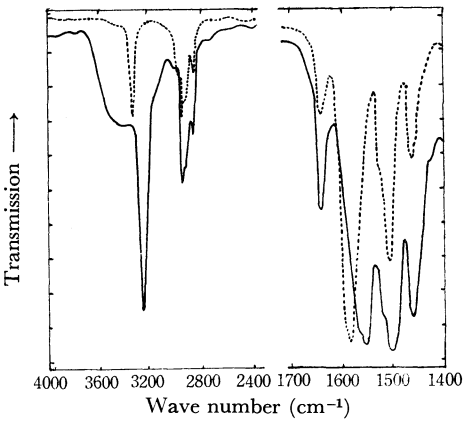

Fig. 3. IR-spectra of 2,5-bis(*n*-butylamino)-*p*-benzoquinone (—, KBr disk; ---, $CHCl_3$ solution).

NMR Spectra. A further chemical evidence for the stability of the amino-quinone nucleus was given by the NMR spectrum, measured for the polyester prepared at 160°C for 26 hr; the peak ratio between the proton (τ, 2.29) attached to nitrogen and the proton (τ, 4.81) attached to the quinone nucleus was approximately 1 : 1. Their peak intensities were comparable to the expected

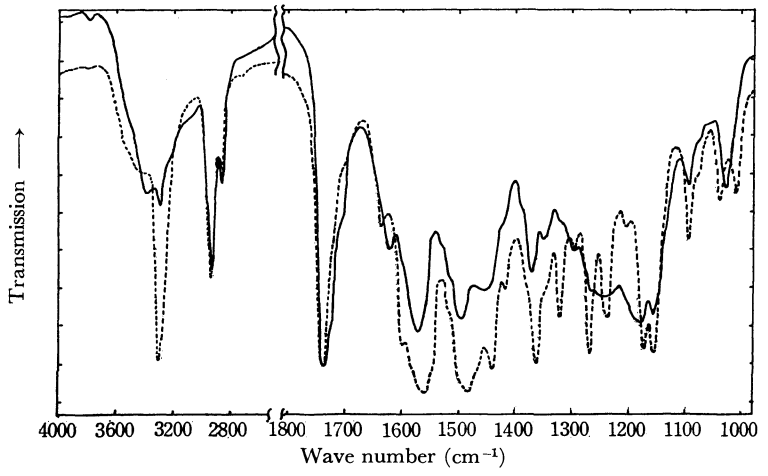

Fig. 4. IR-spectral change of Q-ACEt (---), kept at 200°C for 8 hr (—), (KBr disk).

4) Unpublished data: the spectral data of the amino-quinoid compounds will be shortly submitted for publication.

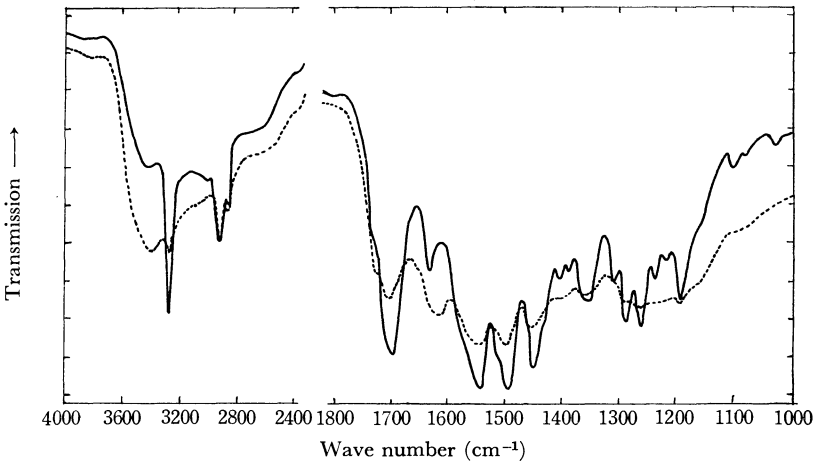

Fig. 5. IR-spectral change for Q-ACA kept at 170°C for 4 hr (—) and at 170°C for 8 hr (---), (KBr disk).

amount of the amino-quinone nuclei involved in the polyester. The assignment of the signals of protons attached to both nitrogen and the quinone nucleus was made using Q-ACEt as a standard material.

On the basis of the above results, it can readily be concluded that the polyester prepared by the reaction of Q-ACA with PEG 400 at 160°C has the expected amino-quinone nuclei.

Crosslinking Character of the 2,5-Diamino-quinone Nucleus. To avoid the trouble of interpreting the infrared spectra recorded during the course of the polyesterification, model compounds, *i. e.*, Q-ACEt and Q-ACA, were used to interpret the mode of the crosslinking of the polyesters containing amino-quinone nuclei in terms of their infrared spectra; a sample (50 mg), placed in an evacuated ampoule, was kept between 150°C and 210°C (±1°C) in an oil bath, and the spectral changes were observed in a KBr disk.

Q-ACEt. When the amino-quinone was kept at 190°C for 8 hr, the change (2—3%) of the amino-quinone was found IR-spectroscopically in a chloroform solution by measuring the intensity of the band at 3270 cm^{-1} (νN-H). As may be seen in Fig. 4, an abrupt decrease in the absorption was observed in the amino-quinone kept at 200°C for 8 hr. With this spectral change, the following absorption bands appeared: the broadened band at 3000—3600 cm^{-1}, attributable to the hydroxy groups formed according to Eq. (1); the band at 1625 cm^{-1}, attributable to the C=C group of the quinonediimine formed (Eq. (1)); the bands near 1250 cm^{-1} and 1027 cm^{-1}, attributable to the ether group of the compound formed due to Eq. (2), and understandable considering that vinyl ether homologues show the characteristic absorption bands of the ether group at 1270—1210 cm^{-1} and 1075—1020 cm^{-1} [5] and that the compound under consideration has structual units similar to those of vinyl ether compounds.

From the above spectral observations, it may be seen that hydrogen atoms in the amino-groups of the amino-quinone move to the oxygen atoms and that the resulting hydroxy groups combine with each other as a result of dehydration to form ether bonds (Eqs. (1), (2) and (3)).

Q-ACA. The amino-quinone kept at 170°C for 4 hr showed no apparent spectral change, but that kept for 8 hr showed a clear change in its nucleus. As is shown in Fig. 5:

(1) The absorption bands characteristic of the amino-quinone nucleus show a minor decrease in its intensity.

(2) The increased, broadened band at 3000—

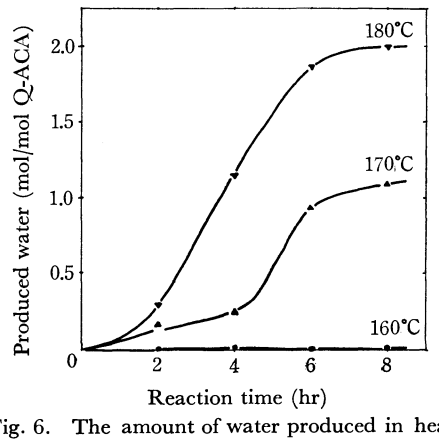

Fig. 6. The amount of water produced in heating Q-ACA at various temperatures.

5) see, *e. g.*, M. Ōki, "Sekigai Kyushu Supekutoru," (The Infrared Spectra), The Tokyo University Press, Tokyo (1968), p. 193.

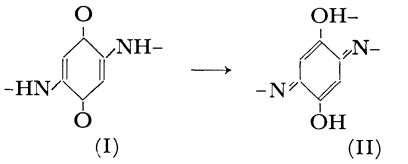
3600 cm^{-1} is attributable to the hydroxy groups formed according to Eq. (1).

(3) The band attributable to the carbonyl group of the ester group occurs at 1730 cm^{-1} as a shoulder, while the absorption band of the carbonyl group at 1705 cm^{-1} decreases. This may be due to the ester group formed by the reaction between the carboxylic group present in the starting dibasic acid and the hydroxy group formed as has already been demonstrated (Eqs. (2) and (3)).

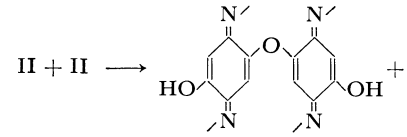
(4) In the region from 1100 cm^{-1} to 1300 cm^{-1}, near 1230 cm^{-1} and 1155 cm^{-1} there appear broadened absorption bands which may be ascribed to the ether (Eq. (2)) and ester (Eq. (3)) groups respectively. This assignment is reasonable in view of the spectral results shown already for the thermal reaction of Q-ACEt.

Further evidence supporting Eqs. (1), (2) and (3) was obtained by measuring the amount of the water formed in the thermal reaction of Q-ACA by the Karl-Fisher method: Samples (100 mg) were placed in evacuated ampoules. Several ampoules thus prepared were kept at 160°C, 170°C, or 180°C in an oil bath, and then each ampoule was taken out from the bath at intervals and cooled. The reacting mixture was taken out from the opened ampoule with 10 m*l* of methanol and submitted to titration. In order to calibrate the amount of the water formed, a blank test was carried out with the same volume of methanol as was used in the determination. The relation between the amount of the water formed and the time is plotted in Fig. 6. Figure 6 demonstrates that at 160°C and 8 hr heating, no formation of water was observed, and the amount of water per mole of Q-ACA was approximately 1 and 2 mol at 170°C-8 hr and 180°C-8 hr heating respectively, indicating that the amino-quinone nucleus was changed thermally above 170°C and that the esterification reaction (Eq. (3)) between the carboxyl groups of Q-ACA and the hydroxyl groups formed contributes predominantly to the formation of the water at 180°C.

On the basis of the results of the IR-spectral observation of the thermal reaction of Q-ACA and Q-ACEt, together with those of the above dehydration reaction of Q-ACA, the following scheme can be proposed for the thermal reaction of the 2,5-diamino-quinone nucleus; this scheme involves the isomerization of the amino-quinone nucleus and subsequent reactions:

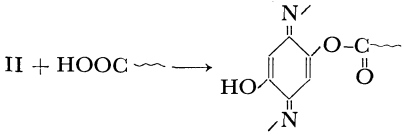


(I) (II) (1)



(2)

In addition, in the case of Q-ACA:



(3)

Crosslinking Character of the Quinoid Prepolymer. The mode of the crosslinkage of the prepolymer prepared by the reaction of Q-ACA with PEG 400 at 160°C for 26 hr was examined for a film baked at 180°C for 8 hr, and for that made by the addition of *p*-toluenesulfonic acid (5% by weight) to it, followed by baking at 170°C for 4 hr. For this purpose, the glass transition temperature on the cured film was measured by the swinging-beam method or the solubility of the film in a mixed

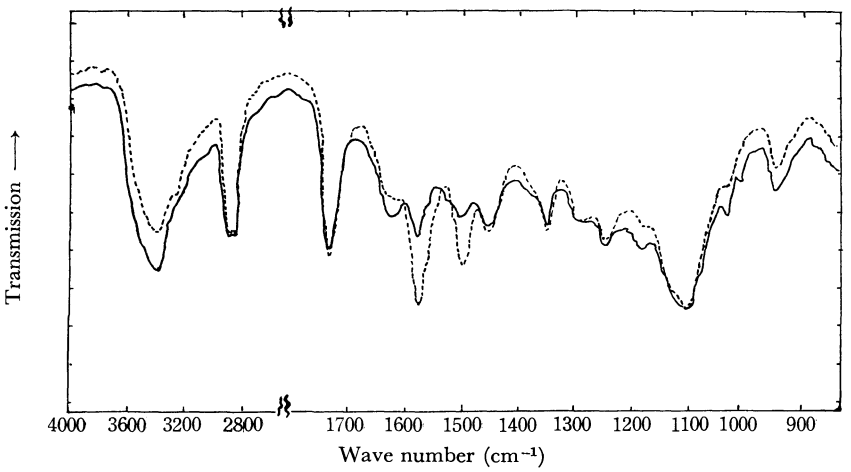


Fig. 7. IR spectra of an amino-quinoid polyester (---) and its cured film (—) at 170°C-4 hr heating with *p*-toluenesulfonic acid (5% by weight).

solvent of acetone-methanol (2 : 1 by volume) was determined. The reaction that occurred during the curing was inferred by means of an IR-spectral analysis of the cured film (see Fig. 7).

The glass-transition temperature was below 20°C for the film baked at 180°C-8 hr and 30°C for that baked at 170°C-4 hr. These facts show that the acid-catalyzed effect is predominant in giving an insoluble and infusible film, and that the glass-transition temperatures found on the cured films were not as high as had been expected from the rigid structure of the amino-quinone nucleus. This may be ascribed to the existence of flexible polyethylene ether chains introduced into the polymer chain by the PEG 400.

As may be seen in Fig. 7, a decrease in the absorption band characteristic of the amino-quinone nucleus and the appearance of the bands at 1250 cm^{-1} and 1030 cm^{-1} characteristic of the ether bond were more obvious in the film baked in the presence of *p*-toluenesulfonic acid than in that of the original polyester (prepolymer).

The thermal and acid-catalyzed baking procedures which bring about the crosslinkages to form an insoluble and infusible film are almost quite the same, since the spectra observed on the baked films formed by these two different methods are almost the same.

These results obviously indicate the contribution of the amino-quinone nuclei incorporated in the polyester to the crosslinking reaction through the steps of Eqs. (1), (2) and (3).

The authors are greatly indebted to Professor Tsutomu Kuwata, for his encouragement, help, and advice.

Electroless Nickel Plating from Acid-acetate Baths Containing Hypophosphite as a Reducing Agent

Kin'ya OGAWA

Hitachi Research Laboratory, Hitachi, Ltd., Kuji-machi, Hitachi, Ibaraki

(Received August 28, 1968)

The properties of acid-acetate baths containing hypophosphite as a reducing agent were studied in an attempt to obtain an electroless nickel deposit; further, the protective property of such deposits with phosphorus contents of 4 to 13% was investigated. The hypophosphite utilization efficiency for the deposition of electroless nickel was found to be 0.33; the deposition rate indicates a first-order dependence on hypophosphite, but it is independent of nickel concentration, within the limits specified in the range of suitable conditions. The phosphorus content of the deposits increases with a decrease in the pH value of the bath and with an increase in the initial concentration of hypophosphite, but it is independent of that of nickel. An electoless nickel with a high phosphorus content affords more protection against metallic bases.

Since the deposition of nickel containing a low percentage of phosphorus on a catalytic surface from an aqueous solution by means of the reduction of nickel salts with hypophospite was first described by Brenner and Riddell[1] in 1946, the deposit has been called electroless nickel to distinguish it from electroplated nickel. Although much research has been done on the subject, most of the work has been concerned with practical applications of the process[2-5] or with the structure[6-8] and the mechanical properties[7,9] of the deposit. It has also been

established that the electroless nickel affords far more protection to metallic bases than does the electroplated nickel.[3,5,10] However, little attention has been paid to the phosphorus content as an important variable with regard to the protective properties of electroless nickel, except for two reports of Ishibashi, Takano and Shimizu,[11,12] and they only intimated that it should not be ignored.

The present paper will be concerned with our fundamental studies of the electroless nickel plating from an acid-acetate bath; the reaction balance, the deposition rate, and the phosphorus content of the deposit will be described, and the life of the bath will be considered. In addition, the protective properties of the deposit will be discussed as a function of its phosphorus content.

Experimental

Reagents. All the chemicals used were of the reagent grade. Sodium hypophosphite monohydrate, nickel chloride hexahydrate and sodium acetate trihydrate were used to prepare the plating baths. The pH of the bath was adjusted to the desired value by adding hydrochloric acid using a Horiba M-3 pH Meter with a glass electrode.

Plating Procedure. The equipment used in the plating tests was simple. A plating solution buffered with 0.3M acetate was placed in a covered cylindrical glass vessel; the bath temperature was kept constant within ± 0.3°C of the desired temperature by means of a water thermostat, the bath being left unagitated. A specimen, a brass or mild steel plate, which had previously been cleaned with trichloroethylene or electrocleaned, was immersed in the bath for the desired time. The deposition rate was obtained by weighing the dry specimens before and after the plating test. At each run, the nickel concentration was determined by the EDTA-titration method[13] and the phosphite and hypophosphite concentrations were determined by cerimetric procedures.[14,15]

The Determination of Phosphorus in the Deposits. The deposit on a bakelite coupon previousely sensitized with a palladium chloride solution[2] served to determine its phosphorus content. At the completion of a plating run, a calculated amount of the deposit was stripped from the base and dissolved in a small volume of hot nitric acid. The amount of phosphorus in the resulting solution was determined by spectrophotometric measurements[16] of the phosphomolybdic acid extracted with a mixed solvent composed of two parts of isobutyl alcohol and three parts of chloroform.

Estimation of the Protective Value of the Deposits. *Polarization Measurement.* Polarization curves in 1N sulfuric acid and 0.5N hydrochloric acid solutions were obtained by the galvanostatic method. Electroless nickel about 15 μ thick deposited on a brass plate, with a working area of 1 cm^2, was used as the working electrode. The potentials were measured by the direct method with a Luggin capillary using a saturated calomel electrode (SCE) as the reference electrode. A carbon plate was employed as the auxiliary electrode. All the measurements were made in 500-m*l* portions of the dilute acid solutions saturated with air, while the temperature was maintained at 30 ± 0.1°C by means of a water thermostat.

Porosity and Salt-spray Resistance. Electroless nickel for both the porosity measurements and the salt-spray test was deposited on a mild steel plate. The porosity of the deposits up to 20 μ thick was evaluated by means of a ferroxyl test. A filter paper saturated with a solution containing 10 g of potassium ferricyanide, 10 g of potassium ferrocyanide, 60 g of sodium chloride, and 5 m*l* of 28% ammonia water in 1*l* was pressed to the surface of the deposit for 5 min, and the blue spots which appeared on the filter paper were counted. The salt-spray test was performed in an Itabashi Salt-spray Chamber with a 5% sodium chloride solution at room temperature (25—30°C). Cycles of spraying for 8 hr and stopping for 16 hr were periodically repeated for five days, and then the rust spots on the surface were counted. The results of these tests are given as the average for the five samples.

Results and Discussion

Reaction Balance. According to Brenner,[1] the significant overall reaction for the deposition of electroless nickel can be writen as:

$$H_2PO_2^- + Ni^{2+} + H_2O \longrightarrow H_2PO_3^- + Ni + 2H^+ \quad (1)$$

Concurrently, more hypophosphite anions are oxidized to phosphite anions with the evolution of gaseous hydrogen according to the reaction:

$$H_2PO_2^- + H_2O \longrightarrow H_2PO_3^- + H_2 \quad (2)$$

Moreover, some of the hypophosphite anions supply the elemental phosphorus which alloys with the metallic nickel.

Table 1 lists the reaction balances for the deposition of electroless nickel from an acetate bath of pH 4.0. Attention is invited to Table 1, wherein the hypophosphite utilization efficiency, expressed as the molar ratio of the nickel deposited to the hypophosphite utilized, is always close to 0.33. Therefore, in order to examine whether this efficiency is independent of the plating conditions, a few tests were performed; the results are shown in Figs. 1 and 2. The discordance of the efficiencies in Figs. 1 and 2 must be considered as an inevitable consequence of the precision of the analytical method employed. It seems, therefore, as has been described by Gutzeit,[4] that the hypophosphite utili-

120	9.0	1.88	30.6	28.6	10.00	0.32

* In each run, electroless nickel was deposited on a 25 cm^2 bakelite coupon from about a 350 m*l* bath containing 44.2 mmol of nickel, 49.3 mmol of hypophosphite and 12 mmol of acetate. All the initial pH values were 4.0 and the temperatures, 90°C.

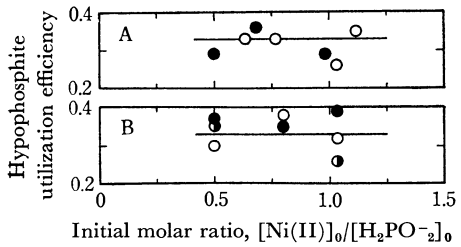

Fig. 1. Hypophosphite utilization efficiency for 30 min in electroless nickel deposition on a 25 cm^2 brass plate from a 400 m*l* bath at 90°C. The initial concentrations of baths are: (A) $[Ni(II)]_0=0.10$ M but $[H_2PO_2^-]_0$=variable, and (B) $[H_2PO_2^-]_0=0.10$ M but $[Ni(II)]_0$=variable.

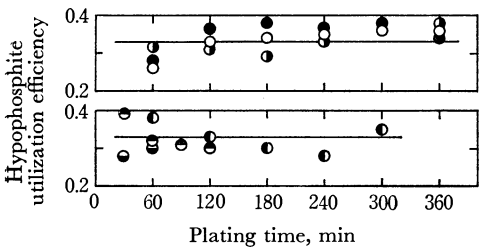

Fig. 2. Hypophosphite utilization efficiency in electroless nickel deposition on a 22.5 cm^2 mild steel plate from a 500 m*l* bath. The initial concentrations of baths are: $[Ni(II)]_0=0.10$ M, and $[H_2PO_2^-]_0=0.10$ M for pH 4.0, or 0.15 M for pH 4.5.
○ 80°C, ● 85°C, ◑ 90°C, ◐ 95°C at pH 4.0;
◒ 90°C at pH 4.5; ◓ 90°C at pH 5.0

zation efficiency is 0.33 independently of the plating conditions, within the range examined at least. This suggests that three moles of hypophosphite are consumed in order to deposit every mole of nickel, and that thus two moles of hydrogen are generated when one mole of nickel is deposited. However, we do not yet have an good explanation of why such a phenomenon occurs.

Deposition Rate. The deposition rates of electroless nickel from the baths of pH 4.0 and 4.5 are shown as the fucntions of nickel and of hypophosphite concentrations in Fig. 3. The deposition rate seems to be proportional to the hypophosphite concentration up to 0.1M at pH 4.0 or up to 0.15M at pH 4.5, but indepenent of the nickel concentration in the range of 0.05—0.2M in the pH range of 4—4.5.

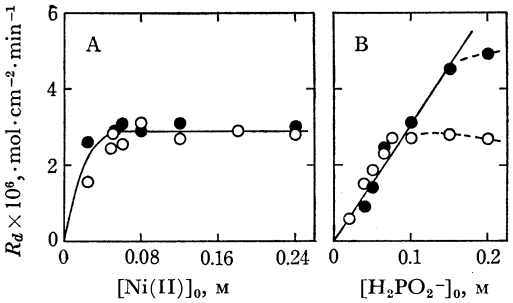

Fig. 3. The deposition rate of electroless nickel on a 25 cm^2 brass plate from a 400 m*l* bath at 90°C as the functions of nickel and of hypophosphite concentrations. The initial concentrations are:
(A) $[H_2PO_2^-]_0=0.10$ M but $[Ni(II)]_0$=variable, and
(B) $[Ni(II)]_0=0.12$ M but $[H_2PO_2^-]_0$=variable.
○ pH 4.0; ● pH 4.5

This can be verified by making the assumption, as has been described by Gutzeit[4] or by Ishibashi,[17] that the reaction undergoes an intermediate step as follows: the hypophosphite anion is converted into an active intermediate species, A^*, which is then adsorbed or loosely bonded to the catalytic surface:[18]

16) M. Ura, *Bunseki Kagaku* (*Japan Analyst*), **7**, 420 (1958).

17) S. Ishibashi *Kinzoku Hyomen Gijutsu* (*J. Metal Finishing Soc. Japan*), **12** 447 (1961).

18) Gutzeit[4] postulated that an active intermediate species is atomic hydrogen produced by the catalytic dehydrogenation of hypophosphite anion to metaphosphite anion: $H_2PO_2^- \rightarrow PO_2^- + 2H$; $PO_2^- + H_2O \rightarrow HPO_3^{2-} + H^+$. On the other hand, Ishibashi[17] departed from Gutzeit's concept and instead proposed that the hypophosphite anion converts from "normal type" into "active type" (probably adsorbed on the catalytic surface). A choice between the above explanations was not made.

$$H_2PO_2^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} A^* \qquad (3)$$

thus taking part in the following simultaneous reactions:[19]

$$A^* + Ni(II) \xrightarrow{k_2} Ni \qquad (4)$$

$$A^* \xrightarrow{k_3} H_2 \qquad (5)$$

where Ni(II) represents bivalent nickel whether or not it forms complexes with acetate, and where the k's denote the rate constants of the reactions. Reaction (5) can be considered, on the basis of the aforementioned reaction balance, to take place twice as fast as Reaction (4). Therefore, by making a steady-state treatment, the deposition rate can be derived as:

$$R_d = \frac{k_1^0 k_2 [H_2PO_2^-][Ni(II)]}{k_{-1} + 3k_2[Ni(II)]} \qquad (6)$$

where R_d represents the deposition rate in mol·min^{-1}·cm^{-2}, where k_1^0 is k_1 V/A, where V is the bath volume in l, and where A is the deposited area in cm^2. By transposing Eq. (6), the following equation is derived:

$$\frac{[H_2PO_2^-]}{R_d} = \frac{3}{k_1^0} + \frac{k_{-1}}{k_1^0 k_2} \frac{1}{[Ni(II)]} \qquad (7)$$

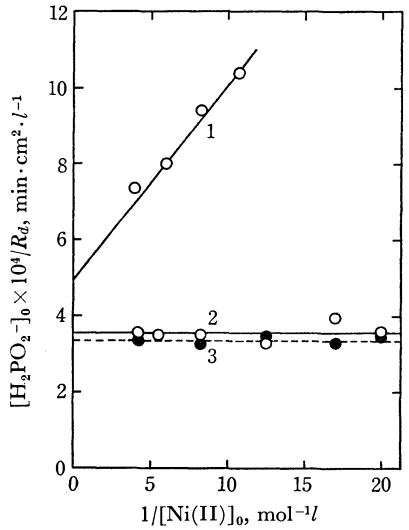

Fig. 4. Plots of $[H_2PO_2^-]_0/R_d$ *vs.* $1/[Ni(II)]_0$. The pH values of baths are: (1) 3.5, (2) 4.0, and (3) 4.5. Other plating conditions are the same as in Fig. 3(A).

19) According to West, both Reactions (4) and (5) may occur by electrochemical means: Ni(II)+2e→Ni and $2H^+ + 2e \rightarrow H_2$ for cathode reaction, $H \rightarrow H^+ + e$ for anode reaction: J. M. West, "Denseki to Fushoku (Electrodeposition and Corrosion Processes) (Translated from English by T. Ishikawa and T. Shibata)," Sangyo Tosho Publ. Co., Ltd. (1968) p. 63. A similar local cell type model for electroless nickel deposition was also suggested by Ishibashi.[17] The present author will also support West's concept.

The experimental data plotted according to Eq. (7) are shown in Fig. 4. Although the expected linearity is apparent, there are some discrepancies between the results at different pH values. A plot of pH 3.5 produces a slopig line, for instance, but the values of $[H_2PO_2^-]/R_d$ at pH 4.0 and 4.5 are almost independent of 1/[Ni(II)] in the concentration range examined. This suggests that the assumed active intermediate species, A^*, may react with Ni(II) at a much faster rate than it returns to hypophosphite anion in the pH range of 4—4.5. If this suggestion can be accepted as true, Eq. (6) takes a simpler form:

$$R_d = \frac{1}{3} k_1^0 [H_2PO_2^-] \qquad (8)$$

demonstrating that the deposition rate of electroless nickel is proportional only to the hypophosphite concentration.

The Change in the Hypophosphite Concentration of a Bath. From the aforementioned reaction balance, the hypophosphite concentration of a bath after t min can be expressed as:

$$[H_2PO_2^-]_t = [H_2PO_2^-]_0 - 3A\, x_{Ni}/V \qquad (9)$$

where x_{Ni} is the molar amounts of nickel deposited on the unit area and where the subscripts 0 and t indicate the concentrations at the initiation of the reaction and after t min respectively. By substituting Eq. (9) into Eq. (8) and by integrating, the following equation can be derived:

$$\log [H_2PO_2^-]_t = \log [H_2PO_2^-]_0 - \frac{k_1^0}{2.3} \frac{A}{V} \qquad (10)$$

The examples of plots according to Eq. (10) shown in Fig. 5 demonstrate their consistency with the

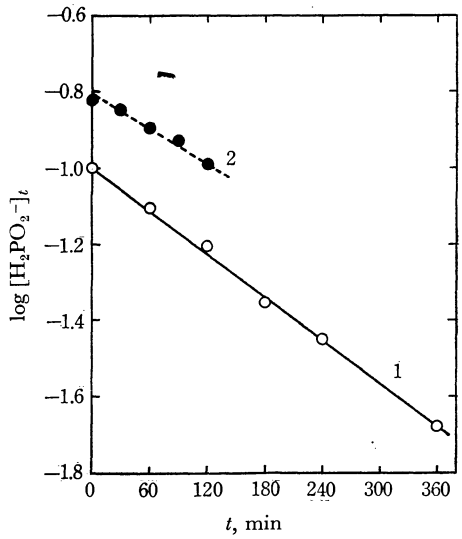

Fig. 5. Plots of $\log [H_2PO_2^-]_t$ *vs.* t at 90°C. The pH values of baths are: (1) 4.0 and (2) 4.5. Other plating conditions are the same as in Fig. 2.

Table 2. Rate constants at 90°C

90	9.6×10^{-5}
95	12.2×10^{-5}

first-order mechanism. The values of k_1^0 calculated from Fig. 5 are tabulated in Table 2, together with those obtained from Fig. 4. The two values are in reasonable agreement. Table 3 gives the values of k_1^0 obtained at different temperatures from plots according to Eq. (10). A liner relation was found between the logarithmic values of k_1^0 and the reciprocal of the absolute temperature, in which the apparent activation energy was estimated to be 15 kcal/mol.

The Life of the Bath. The only stable anion produced during the reaction is phosphite, which forms a greenish nickel phosphite precipitate.[4,10,20] This precipitate is undesirable, because it initiates the nucleation of nickel and causes the spontaneous decomposition of the bath and the eventual roughness of the deposit.

As has been indicated in connection with the reaction balance, the phosphite concentration accumulated in the bath is nearly equal to the decrease in the hypophosphite concentration, while the latter is approximately three times the decrease in the nickel concentration. Therefore, no precipitation occurs under the following conditions:

$$3x_{Ni}\frac{A}{V}\left([Ni(II)]_0 - x_{Ni}\frac{A}{V}\right) < L\left(1+\frac{[H^+]}{K_2}+\frac{[H^+]^2}{K_1K_2}\right) = L_{app} \quad (11)$$

where L and L_{app} are the absolute and the apparent solubility products of nickel phosphite, and K_1 and K_2, the first and the second acid dissociation constants of phosphorous acid; these values, determined at 90°C, are given in Table 4. The value of the left-hand of Eq. (11) cannot be above

20) S. Ishibashi, S. Orii and N. Tezuka, *Kinzoku Hyomen Gijutsu* (*J. Metal Finishing Soc. Japan*), **12**, 94 (1961).

Table 4. The acid dissociation constants of phosphorous acid and the solubility product of nickel phosphite at 90°C

H_3PO_3 *1 pK_1	H_3PO_3 *1 pK_2	$NiHPO_3$ *2 L $mol^2\cdot l^{-2}$
2.21	6.77	2.3×10^{-5}

*1 The values of pK_1 and pK_2 were determined by the pH titration method.

*2 The precipitation of $NiHPO_3$ was investigated in solutions containing 0.1 M of hypophosphite, 0.1 M of nickel and 0.3 M of acetate for various pH's and phosphite concentrations. The value of L was determined by observing whether a turbidity developed for 60 min at 90°C.

$3[Ni(II)]_0/4$. Therefore, if a set of conditions is selected where $[Ni(II)]_0 < 4L_{app}/3$, no precipitation is expected through the plating as long as no hypophosphite or nikcel salt is supplied. Calculations indicate that this limit is: $[Ni(II)]_0 < 0.13$M for pH 4.0, < 0.06M for pH 4.5, and < 0.03M for pH 5.0.

On the other hand, when the bath compositions exceed the above limit, the life can be estimated by the following equations derived from Eqs. (10) and (11):

$$life = \frac{V}{A}\frac{2.3}{k_1^0}\log\frac{[H_2PO_2^-]_0}{[H_2PO_2^-]_0 - 3\frac{A}{V}x_{Ni}} \quad 12)$$

$$\frac{A}{V}x_{Ni} = \frac{3[Ni(II)]_0 - \sqrt{9[Ni(II)]_0^2 - 12L_{app}}}{6}$$

Some examples of the estimated life are shown in Fig. 6.

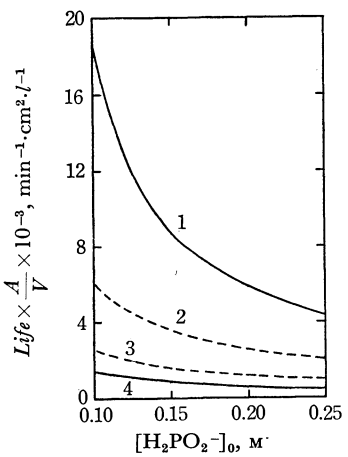

Fig. 6. The life of electroless nickel plating baths buffered with 0.3 M acetate at 90°C. (1) pH 4.0, $[Ni(II)]_0=0.2$M; (2) pH 4.5, $[Ni(II)]_0=0.1$ M; (3) pH 4.5, $[Ni(II)]_0=0.2$ M; (4) pH 5.0, $[Ni(II)]_0=0.1$ M.

The Phosphorus Content of the Deposit.

As a result of the change in the bath compositions through the plating, it is expected that a phosphorus gradient exists across a deposit. However, as may be seen in Table 1, the phosphorus content of the deposit is almost constant, independent of the plating time, up to 120 min, in spite of the fact that the bath compositions change. Therefore, a phosphorus gradient across a deposit may be not very steep.

The phosphorus content for the deposits obtained at a constant plating time of 60 min was also investigated as a function of the bath compositions. The results in Figs. 7 and 8 reveal that the phosphorus content of a deposit increases as the pH rises and with an increase in the initial concentration of hypophosphite, but that it is independent of the concentration of nickel.

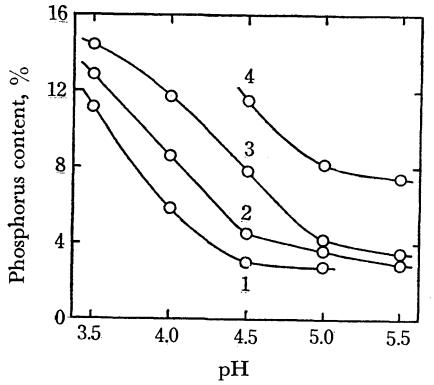

Fig. 7. The phosphorus content of electroless nickel deposit as a function of the initial pH value of bath. The initial concentrations of baths are: $[Ni(II)]_0$ =0.09 M, and $[H_2PO_2^-]_0$=(1) 0.05 M, (2) 0.10 M, (3) 0.15 M, and (4) 0.20 M.

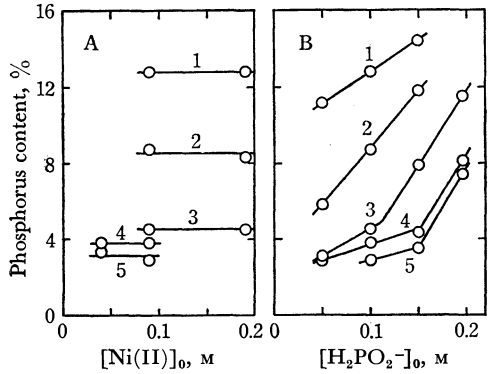

Fig. 8. The phosphorus content of electroless nickel deposit as the functions of bath compositions. The initial concentrations of baths are: (A) $[H_2PO_2^-]_0$ =0.10 M but $[Ni(II)]_0$=variable, and (B) $[Ni(II)]_0$ =0.09 M but $[H_2PO_2^-]_0$=variable. The initial pH values are: (1) 3.5, (2) 4.0, (3) 4.5, (4) 5.0, (5) 5.5.

The Protective Value of the Deposit. Examples of the polarization curves of the deposits in a 1N sulfuric acid solution are shown in Fig. 9. Similar results were obtained in a 0.5N hydrochloric acid solution. In all cases, both anodic and cathodic polarization curves exhibited Tafel-type behavior, and an increase in the phosphorus content moves the corrosion potential to a more positve value and reduces the corrosion currents. The corrosion rates calculated from the corrosion currents are given in Fig. 10, together with the minimum thickness free of pores and the salt-spray

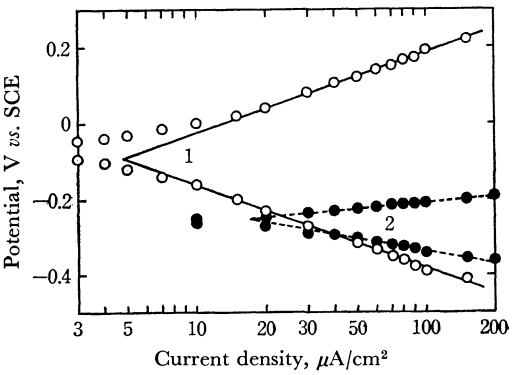

Fig. 9. The polarization curves of electroless nickel deposits in a 1 N sulfuric acid solution. The deposits contain (1) 8.7 and (2) 3.6% phosphorus.

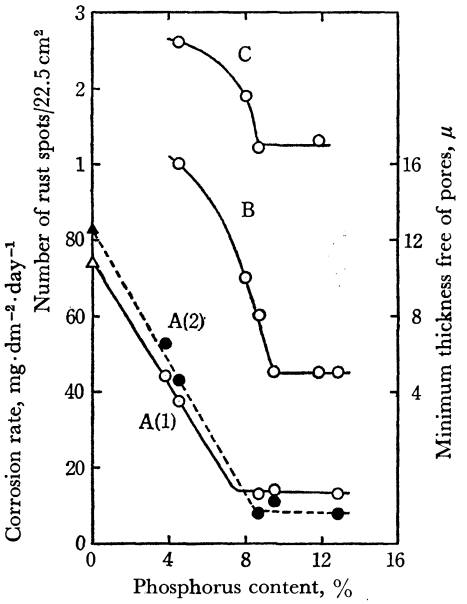

Fig. 10. The protective values of electroless nickel as the function of its phosphorus content.

resistance as functions of the phosphorus content. Generally, an electroless nickel with a high phosphorus content affords low porosity; it also exhibits a high resistance to dilute acid media and to salt-spray. These results are in qualitative agreement with some observations of deMinjer and Brenner,[10] who reported a rise in the resistance of similar electroplated alloys to salt-spray and outdoor exprosure with an increase in the phosphorus content. In Fig. 10 it is also shown that all of the curves change in the vicinity of 9% phosphorus; the corrosion rate by dilute acid solutions, the minimum thickness free of pores, and the number of rust spots caused by salt-spray, all decrease with a rise in the phosphorus content up to about 9%, while they remain practically as constant as the phosphorus content when it increases above 9%. This behavior seems to be connected with the fact that the as-deposited electroless nickel deviates gradually from a face-centered cubic lattice condition with an increase in the phosphorus content and is converted into an amorphous state above 7.4% of phosphorus.[8]

The author wishes to express his deep gratitude to Dr. Natsuki Kawashima of the Hitachi Research Laboratory, Hitachi, Ltd., and to Dr. Takeshi Nakatogawa of the Hitachi Kasei Co., Ltd., for their guidance and encouragement throughout this work.

NOTES

Studies on Photo-polarography. II. Photo-polarographic Behavior of Dissolved Oxygen under Ultraviolet Irradiation

Hideo IMAI and Kazuo YAMASHITA

Department of Chemistry, Faculty of General Education, Hiroshima University, Hiroshima

(Received June 24, 1968)

In the past five years the photocurrents produced by the ultraviolet irradiation of the mercury electrode have been investigated and developed by several workers.[1-6]

Heyrovsky[1] has found a rapid current increase in a magnitude of about 1 microA at the irradiated dropping mercury electrode (DME) in solutions of sulfuric acid. He interpreted the experimental finding in terms of the photosensitized decomposition of water molecules adsorbed on the electrode surface. On the other hand, Barker and his co-workers[2] and Delahay and Srinivasan[3] have explained the same phenomenon by assuming a simplified model in which all the hydrated electrons*1 are deposited on a plane at a distance, δ, away from the electrode surface.

According to the radiolysis study, it is assumed that, in oxygenated aqueous solutions, the hydrated electron reacts immediately with dissolved oxygen to form the hydroperoxy radical;

$$e^-_{aq} + H^+ \rightarrow H \quad (1)^{*2}$$

$$H + O_2 \rightarrow HO_2 \quad (2)$$

$$e^-_{aq} + O_2 \rightarrow O_2^- \quad (3)^{*2}$$

The relative importance of these relevant reactions depends upon the pH and the oxygen concentration. The kinetics of the hydroperoxy radical there formed have been investigated by fast reaction techniques.[8-11]

Our present investigation is primarily concerned with anomalies of the second reduction wave of dissolved oxygen under polychromatic ultraviolet irradiation on the DME. Observations were carried out on the field dependence of the photocurrents and on the effects of surface-active substances, hydrated electron scavengers, and radical scavengers on the photocurrent. A possible reaction mechanism is proposed for the reaction of dissolved oxygen under ultraviolet irradiation.

Experimental

Reagent-grade methanol, ethanol, and acetone were redistilled. Special-grade sodium sulfate from Wako Pure Chemicals Ind., Ltd., was used without further purification. The water used was distilled twice. All the other chemicals and the apparatus used were the same as those reported in a previous paper.[12] The solutions contained 0.5 M Na_2SO_4 as the supporting electrolyte. The solutions were equilibrated with atmospheric oxygen at room temperature.

Results and Discussion

Polarograms of Dissolved Oxygen under Ultraviolet Irradiation. Oxygen develops two polarographic reduction waves in neutral aqueous salt solutions, the first wave corresponding to the two-electron reduction of oxygen to hydrogen peroxide, and the second, to the two-electron reduction of hydrogen peroxide to hydroxyl ions.

(2) The positive photocurrent of the dissolved oxygen observed at −1.3 V in solutions of 0.5M Na_2SO_4.
(The photocurrent represents the difference between the currents measured with and without irradiation.)

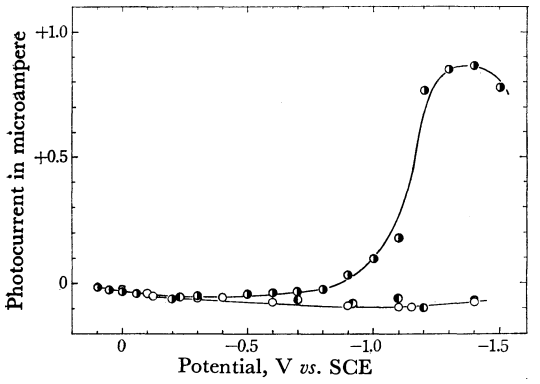

Fig. 2. Dependence of photocurrents on the electrode potentials in aqueous solutions of 0.5 M Na_2SO_4.
○ deaerated 0.5M Na_2SO_2 solutions
◑ 0.5M Na_2SO_4 solutions containing 0.25 mM oxygen
◐ 0.5M Na_2SO_4 solutions containing 0.25 mM oxygen and 0.005% gelatine

In a deaerated 0.5 M Na_2SO_4 solution, a small negative photocurrent was observed under the continuous ultraviolet irradiation of the DME. This residual photocurrent is shown in Figs. 1 and 2. The surface tension and the differential capacity of the DME and the effect of the carbon dioxide dissolved in the solution on the anodic residual photocurrent were measured with and without ultraviolet irradiation. The results, however, showed no appreciable irradiation effect. The mechanism of this negative residual photocurrent may be attributed to the presence of impurities in the solution, but the details are still unknown.

In the presence of oxygen the polarographic reduction under ultraviolet irradiation showed a different pattern from the normal wave; *i. e.*, the first wave did not show any appreciable change, while the height of the second wave was markedly increased. Figure 1 shows the positive photocurrent measured at −1.3 V *vs.* SCE. Figure 2 shows the dependence of the photocurrent on the electrode potential. The marked positive photocurrent begins to appear from the potentials at about −0.9 V when hydrogen peroxide is reduced. In this connection Silvestroni and Carelli[13] have observed anomalies in the oscillograph polarographic wave of oxygen at an irradiated mercury drop; they explain the anomalies as the effect of streaming caused by the heat absorption at the electrode-solution interface. It is noteworthy that, in our experiment, the positive photocurrent are observed at potentials more negative than −0.9 V, while the effect of irradiation was scarcely observed at potentials less negative than −0.9 V. Moreover, it was confirmed that the surface tension and differential capacity of the DME were little influenced by irradiation. Thus, the variation on the reduction wave upon exposure to light can not be interpreted in terms of a mere physical effect such as streaming. The apparent quadratic field dependence of the photocurrent (charge) has been pointed out for the scavenging of e_{aq}^- with H^+ by Delahay and Srinivasan.[3] They have cited Fowler's theory[14] on photoemission by a metal under a vacuum and monochromatic irradiation. No interpretation has, however, been worked out for their particular case, *i. e.*, emission in an aqueous electrolyte and polychromatic irradiation. In our experiment the square root of the photocurrent *versus* the potential plot was far from a linear relationship. The concave curvilinear plot seems to suggest the regeneration of H_2O_2 by a subsequent homogeneous chemical reaction, probably the bimolecular decay of O_2^- to yield H_2O_2.

Effect of Surface-active Substances on Photocurrent. The positive photocurrent was conspicuously affected by very small amounts of such surface-active substances as gelatin (*cf.* Fig. 2) and methylcellulose, and it completely disappeared in the presence of about 2×10^{-4}% gelatin or 4×10^{-4}% methylcellulose. The negative photocurrent was more pronounced with any increase in the methyl-

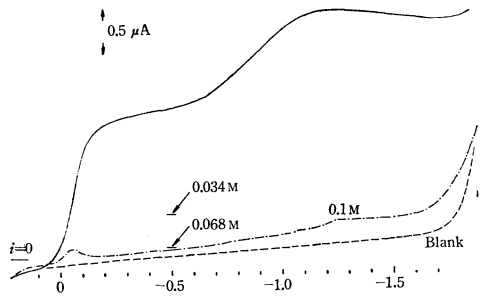

Fig. 3. Effect of acetone on the polarograms of the dissolved oxygen with the continuous irradiation in solutions of 0.5M Na_2SO_4.

cellulose concentration higher than 4×10^{-4}%. Anodic photocurrents similar to those in the case of methylcellulose have been observed in solutions of glyoxal, diacetyl, sodium oxalate, *etc.* by Heyrovsky,[15] who explained these findings by assuming that the light-absorbing species responsible for the anodic photocurrents are the complexes between the adsorbed organic molecules and the mercury electrode. In view of the photoemission of electrons and the formation of hydrated electrons, it seems that the effect of surface-active substances on the photocurrents can be interpreted on the basis of the variation in the work function due to the adsorbed molecules or/and to the scavenging of hydrated electrons by the adsorbed molecules.

Effect of Hydrated Electron Scavenger and OH Radical Scavenger on Photocurrent. The effect of acetone as a scavenger for hydrated electrons on the photocurrents was investigated. When the concentration of acetone was increased, the height of the reduction wave of the dissolved oxygen under ultraviolet irradiation was markedly decreased, and it completely disappeared upon the addition of 0.2 M acetone, as is shown in Fig. 3. This indicates that the amount of dissolved oxygen is reduced by the reduced form of acetone.*3 Reaction (3) may be followed by a slow reaction;

$$O_2^- + H_2O_2 \rightarrow O_2 + OH + OH^- \qquad (4)$$

The OH radical thus formed will pertain to the electrode process through several reaction paths such as the dimerization of OH to form H_2O_2, and the reaction of OH with H_2O_2 to form O_2^- and H^+. Methanol and ethanol are known to be effective OH radical scavengers. It was confirmed that these scavengers slightly affected the photocurrent. It

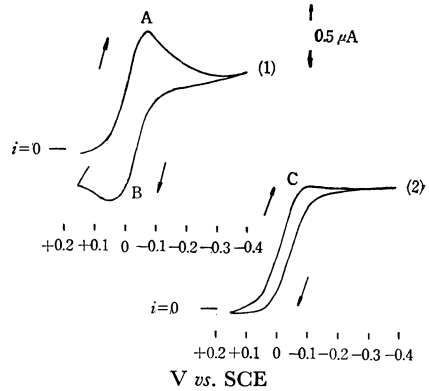

Fig. 4. Cyclic voltammetric curves of the first reduction of oxygen in aqueous solutions of 0.5 M Na_2SO_4 and 0.30 mM oxygen.
(1) without irradiation
(2) with irradiation

may be concluded that contribution of reaction (4) to the photocurrent is negligibly small.

Reaction Mechanism and Cyclic Voltammetry. From the above-mentioned results, we assumed the following reaction scheme;

$$(e^-)_{metal} + h\nu \rightarrow (e^-)^*_{metal} \qquad (5)$$

$$(e^-)^*_{metal} \xrightarrow{\text{(transfer reaction)}} e^- \qquad (6)$$

$$e^- + H_2O \rightarrow e^-_{aq} \qquad (7)$$

$$e^-_{aq} + O_2 \rightarrow O_2^- \qquad (8)$$

$$O_2^- + O_2^- + H_2O \rightarrow O_2 + H_2O_2 + 2OH^- \qquad (9)^{*4}$$

The concentration of hydrogen peroxide in the vicinity of the irradiated DME is increased through reaction (9). It is noteworthy that the cyclic regeneration of O_2 through reactions (8) and (9) results in the formation of H_2O_2. This assumption agrees well with the positive photocurrents observed in relation to the second reduction wave of dissolved oxygen.

The *i-E* curves recorded in the cyclic voltammetry of the first reduction of oxygen are shown in Fig. 4. Under continuous irradiation the anodic wave disappeared, as is shown in Fig. 4, curve (2). It seems that this results also supports the assumption of the coupled chemical reaction (possibly by reactions (8) and (9)) through which the irreversible behavior of the $O_2-H_2O_2$ redox couple is favored.

The authors wish to express their hearty gratitude to Professor Niro Matsuura of the University of Tokyo for his kind suggestions regarding this investigation.

15) M. Heyrovsky, *Nature*, **209**, 708 (1966).

*3 The reduction of methylene blue by ultraviolet irradiation was more pronounced in the presence of acetone. This inherently suggests that the reduced form of acetone was formed in the bulk of the solution.

*4 The validity of reaction (9) was confirmed by radiation chemistry reaction.

Surface Potential Study of Stearic Acid Monolayer on Mercury

Takuya YAMASHITA, Tadashi NAGAI*1 and Kozo HIROTA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received July 4, 1968)

Numerous investigations of insoluble monolayers on aqueous surfaces have been reported. Such studies, however, are limited to materials which spread on and are insoluble in water.

Mercury is an ideal substrate to examine surface films because of the high surface tension and the insolubility of organic materials in it. The force-area properties of organic monolayers on mercury have been reported by Fahir[1] and Ellison.[2] In the present work, the surface potential of stearic acid monolayer spread on mercury surface was investigated as a function of the film area.

Experimental

Stearic acid (Merck) was of analytical grade, and used without further purification. Benzene was used as the spreading solvent. C. p. benzene was shaken with sulfuric acid until free from thiophene and then washed with alkali and water. After drying over sodium, it was distilled and kept over sodium. The solute concentration in a spreading solution was 0.04%.

Mercury was purified by the method of Nicholas *et al.*[3]; mercury was washed with a series of solutions (3N NaOH, 3N HNO_3, and 0.001N HNO_3) by bubbling air. The purified mercury was distilled *in vacuo* and stored under nitrogen.

The surface potential, ΔV, was measured by the vibrating electrode method. The potential was reproducible within ± 10 mV. Surface moment of the film, μ, was calculated by utilizing the Helmholtz formula, $\mu = \Delta V A / 4\pi$, where A is the area per molecule.

The trough measured $300 \times 100 \times 4$ mm, and was made of glass. Prior to use, the trough was washed with running water and then with distilled water. It was dried by flushing dry nitrogen.

All the experiments were carried out at room temperature under the flow of dry nitrogen.

The trough was filled with mercury. The equilibrium value of the potential was attained 20 min after formation of the surface and no appreciable change was detected after 20 hr. The potential was increased by 300 mV by replacing nitrogen with moist air (relative humidity, 80%; 22°C).

The spreading solution was applied to the mercury surface of 300 cm^2 by means of a micrometer syringe. The film area was changed by the successive injection method. The interval between injections was 10 min. When 0.01 m*l* benzene was spread on the mercury surface with 10 min interval up to the amount of 0.13 m*l*, no appreciable surface potentials were produced. Ellison[2] reported that no detectable surface pressures were developed by spreading benzene on the mercury surface in the atmosphere of nitrogen.

Results and Discussion

Figures 1 and 2 show the surface potential-area and surface moment-area curves for stearic acid on mercury, respectively. In Fig. 1, the maximal value of surface potential is 35 mV at the area of 30 $Å^2$ per molecule. Figure 2 indicates that the

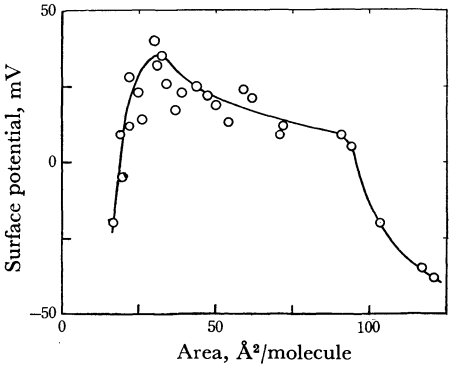

Fig. 1. Surface potential-area curve for stearic acid monolayer on mercury (23±1°C).

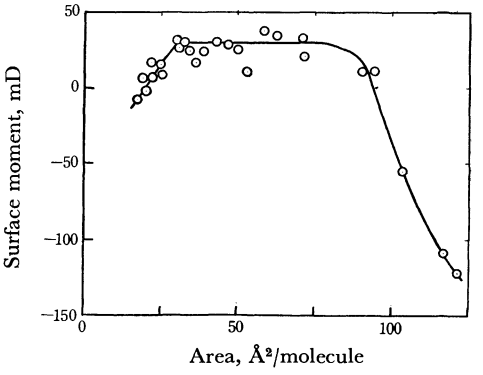

Fig. 2. Surface moment-area curve for stearic acid monolayer on mercury (23±1°C).

surface moment is independent of the film area from 30 to 80 Å^2 per molecule with a value of 30 mD.

The results shown in Figs. 1 and 2 suggest that the monolayer of stearic acid on mercury collapses at the area of about 30 Å^2 per molecule. This area agrees well with that obtained from the surface pressure measurements.[2)]

It is to be noted that the values of surface potential and moment on mercury surface are considerably smaller than those found on acidic aqueous subphases (400 mV and 210 mD at maximum),[4)] and are comparable to the values reported on metals. Timmons and Zisman[5)] found that the values of surface potential for stearic acid monolayer ranged from a maximum of 365 mV on tungsten to −95 mV on lead. They concluded that the perpendicular component of dipole moment of the adsorbed acid molecule (surface moment) varied as a result of the specific interaction of metal substrate and the acid carboxyl group. However, they could not evaluate the values of surface moment because the surface concentration of the acid adsorbed on metals remained unknown. In the present work, the value of surface moment was found to be 30 mD for the stearic acid monolayer on mercury. The considerably small value of the moment seems to indicate a strong interaction of acid carboxyl group with liquid mercury at the interface.

Throughout the present work, no direct evidence is available regarding the chemical purity of the mercury surface. However, it should be noted that the potential value on a mercury surface without film was increased remarkably by replacing nitrogen with moist air. This fact would be caused by either oxidation of the mercury surface or adsorption of water to the surface, or by both.

Two-stage Polymerization of (1,3-Dioxolan-4-yl)methyl Acrylate

Hiroshi MINATO*1 and Namiko MURAMATSU

Department of Chemistry, International Christian University, Mitaka, Tokyo

(Received July 13, 1968)

A monomer containing two different polymerizable functional groups is of interest from the viewpoint of the two-stage polymerization. Monomers containing a vinyl group and an epoxy group such as glycidyl methacrylate,[1,2] and monomers containing a vinyl group and a tetrahydrofuran ring such as tetrahydrofurfuryl methacrylate[3,4] have been investigated in detail. (1,3-Dioxolan-4-yl)methyl acrylate containing a vinyl group and a dioxolane ring appears to be a very interesting monomer, but it has been mentioned only briefly in two patents.[5]

The preparation, the structure and the two-stage polymerization of this monomer have been investigated in detail, and the findings will be described in this paper.

Experimental

1,2-Methyleneglycerol. This was prepared as a mixture with 1,3-methyleneglycerol according to the method of Hibbert and Carter.[6] From 175 g of paraformaldehyde and 525 g of glycerol, 309 g of a mixture of methyleneglycols was obtained (52%).

(1,3-Dioxolan-4-yl)methyl Acrylate (DA). Into a 1-liter three-necked flask equipped with a mechanical stirrer, a condenser and a thermometer, 300 g of methylene glycerol, 122 g of acrylic acid and 258 g of benzene were added. After 1 ml of concentrated sulfuric acid and 8.6 g of copper powder were added, the mixture was placed in an oil bath at 110°C. The solution was refluxed at about 88°C, and became yellow after 12 hr of heating and stirring. The unreacted 1,3-methyleneglycerol was removed by washing with saturated sodium chloride solution. Four washings with 50 g portions of

the salt solution removed 275 g of 1,3-methyleneglycerol. Then benzene was distilled off at 20 mmHg in a water bath at 30°C, and finally 82 g of a colorless liquid was collected by distillation at 55—57.5°C/0.2—0.3 mmHg. Its infrared spectrum shows absorptions at 1705 and 1723 cm^{-1}, which indicate that this liquid is a mixture of acrylic acid and an acrylic acid ester. The liquid was dissolved in carbon tetrachloirde, and acrylic acid was extracted with a 5% sodium hydrogen carbonate solution. Ten washings removed all the acrylic acid in the mixture. The carbon tetrachloride solution was dried by use of anhydrous sodium carbonate. The solvent was removed under reduced pressure, and 34.5 g (19%) of DA was obtained by distillation at 60—64°C/0.8 mmHg. Found: C, 53.10; 53.14; H, 6.41; 6.43%. Calcd for $C_7H_{10}O_4$: C, 53.14; H, 6.37%.

Determination of Formaldehyde from DA. About 0.1 g of DA was accurately weighed, and was added to a 20% sulfuric acid solution. The solution was refluxed for one hour, and then was steam-distilled. About 300 m*l* of a distillate was collected, which was refluxed for one hour with 20 m*l* of a 7% hydroxylamine hydrochloride solution. After cooled to room temperature, the hydrochloric acid liberated was titrated with 0.1 N sodium hydroxide solution by use of a pH meter. Because of the very dilute concentration, the titration curve was not so sharp. Eighty-three percent of formaldehyde was detected. When authentic 1,3-dioxolane was subjected to this analysis, 0.88 mol of formaldehyde per mole of dioxolane was detected.

Free Radical Polymerization of DA. *In Toluene.* One gram of DA, 0.0197 g of azoisobutyronitrile, and 3 g of toluene were heated at 80°C under nitrogen atmosphere. After 5 min of heating, viscous materials precipitated as a lower layer. After two hours of heating, the precipitated polymer was separated by decantation. The polymer was dissolved in acetone and reprecipitated by addition of petroleum ether. This purification was repeated twice. White solids obtained were soluble in acetone or chloroform, and were hygroscopic. The surface became smooth upon absorption of moisture in air.

In Benzene. DA, 0.9458 g, was refluxed in 3 g of benzene with 0.0197 g of azoisobutyronitrile for 3 hr. Though the hot solution was transparent, a transparent polymer precipitated when the solution was cooled to room temperature. The polymer was separated by decantation, and was dissolved in acetone, but a fraction of the polymer was insoluble in acetone which corresponded to 17% of the monomer used. The acetone-soluble polymer was reprecipitated by addition of petroleum ether. The dissolution-reprecipitation was repeated twice. The polymer dried under reduced pressure weighed 0.689 g (73%), and resembled to the polymer obtained in toluene.

The viscosity of the polymer was determined in acetone at 30°C, and it was found that $[\eta]$ was 0.137. The application of the equations established for poly (methyl acrylate) ($[\eta]=1.49\times10^{-3}\times P^{0.52}$, acetone, 30°C)[7] and poly (ethyl acrylate) ($[\eta]=4.19\times10^{-4}\times P^{0.66}$, acetone, 30°C)[8] gave the molecular weights of 5.14×10^5 and 3.39×10^5, respectively. Therefore, it is likely that the molecular weight of the polymer obtained is about 10^5.

Second-stage Cationic Polymerization of Poly-(1,3-dioxolan-4-yl)methyl Acrylate. The polymer obtained by azoisobutyronitrile was subjected to a ring-opening polymerization.

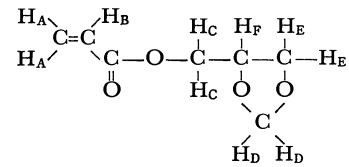
When the polymer was heated at 140°C with about 10 weight percent of *p*-toluenesulfonic acid, some reaction took place and the polymer became insoluble in acetone. Apparently some crosslinking occurred through opening of the dioxolane ring. The polymer was not hard solids at high temperatures, but a gummy material. Probably the crosslinking was not so extensive.

When the polymer was mixed in acetone with about 45 weight percent of boron trifluoride etherate and the mixture was evaporated under reduced pressure, the polymer became light brown in 1 hr at room temperature, and became reddish brown in 3 hr. The brown polymer was insoluble in acetone, and when heated up to 160°C it became black hard solids.

Cationic Polymerization of DA. When a mixture of 1 g of DA and 0.15 m*l* of boron trifluoride etherate was allowed to stand in a test tube protected by a calcium chloride tube at room temperature for 67 hr, a hard brown solid polymer was obtained. The polymer was not soluble in acetone, and when heated up to 180°C it was hard black solids.

Results and Discussion

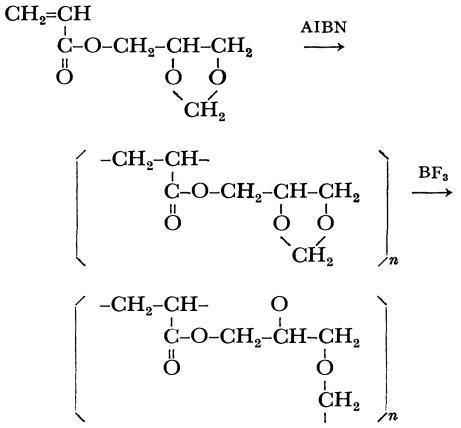
(1,3-Dioxolan-4-yl)methyl acrylate (DA) was prepared from acrylic acid and a mixture of 1,2- and 1,3-methyleneglycerol. The assignment of the structure was supported by correct elemental analyses, formaldehyde determinations, infrared and NMR spectra. The NMR spectrum showed chemical shifts at 6.45 ppm(2H; H_A), 6.1 ppm (1H; H_B), 5.0 ppm (2H; H_C), 4.29 ppm (2H; H_D), 4.0 ppm (2H; H_E) and 3.8 ppm (1H; H_F).



When DA was polymerized in toluene or benzene by azoisobutyronitrile at 80°C, white solid polymer was obtained. The polymer was soluble in acetone or chloroform, and its NMR spectrum showed that vinyl hydrogens (6.45 ppm and 6.1 ppm) were completely converted into aliphatic hydrogens. The evidence suggests that this polymer was formed through the polymerization of carbon-carbon double bonds without participation of dioxolane rings. When the poly DA was heated with *p*-toluenesulfonic acid or was allowed to stand at room temperature with boron trifluoride etherate, some crosslinking occurred and the polymer became insoluble in acetone.

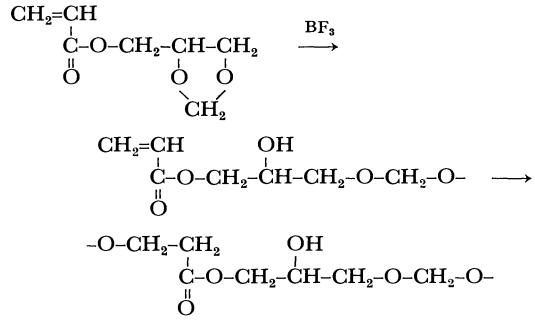
7) H. Ito, S. Shimizu and S. Suzuki, *Kogyo Kagaku Zasshi(J. Chem. Soc. Japan, Ind. Chem. Sect.)*, **59**, 930 (1956).

8) H. Sumitomo and Y. Hachihama, *Kobunshikagaku*, **10**, 544 (1953).



When the poly DA was heated alone to 270°C and then cooled, the polymer was insoluble in acetone. Apparently some crosslinking occurred, but much less extensively than the case with boron trifluoride, since the acetone-insoluble polymer was soft at high temperatures.

When the DA monomer was treated with boron trifluoride etherate at room temperature, a reddish brown solid polymer was obtained. It was insoluble in acetone. Its infrared spectrum resembled to that of the polymer prepared by the second-stage cationic polymerization of the poly DA obtained by azoisobutyronitrile. Therefore, it appears that the treatment of DA with boron trifluoride polymerizes not only the dioxolane rings but also vinyl bonds.



BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1148—1150 (1969)

Alkoxysilanes. I. Preparation of Alkoxysiloxy Derivatives of Antimony

Yoshimoto ABE*1 and Ichiro KIJIMA*1

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received July 15, 1968)

Much work has been done concerning the preparation of alkyl or arylsiloxy derivatives of metals $(R_3SiO)_nM$ (M=Si,[1] Al,[2] Sn,[3] Ti,[4] Zr,[4]). Although the preparation of tris(triethylsilyl) antimonite by Andrianov[5] and the preparation of (trimethylsiloxy)(alkyl)antimony derivatives of the $(Me_3SiO)_nSbR_{m-n}$ ($m=3$ or 5, $n=1$ or 2, R=Me or Ph) type by Schmidbaur[6] have been reported, no other derivatives of antimony are known. Moreover, none of the alkoxysiloxyderivative of metals have been investigated.

We, therefore, attempted to prepare antimony derivatives containing a relatively stable trialkoxysiloxy group and tris(trimethyl or triphenylsilyl) antimonite.[7] The results of measurements of the relative hydrolytic stability and the infrared absorption spectra of these new compounds will also be indicated.

The preparation of tris(triorganosilyl) antimonite was carried out according to two procedures. One was a reaction between antimony trialkoxide and silanols; the other was a reaction of antimony trichloride with silanols in the presence of amine. Tris(tri-*t*-butoxysilyl) antimonite was distilled out as a white crystalline solid; it was very soluble in common organic solvents. Tris(triphenylsilyl)

antimonite was obtained from recrystallization; it was also distilled at about 180—182°C/2 mmHg. It was soluble in THF, chloroform and hot benzene, but insoluble in ether and *n*-hexane.

The IR spectra of stibiosiloxane have been reported by Schmidbaur,[6,8] who assigned the absorption at 940—980 cm^{-1} to ν_{as}Si–O–Sb. He also observed that the absorption peaks of the Si–O–X (X=Si, Ge, Sn, Pb) bond in the structural unit of the heterosiloxanes shift systematically to lower wave numbers in the sequence; Si, Ge, Sn, Pb (1055, 990, 980, 959 cm^{-1}). Therefore, it is reasonable to assume the absorption related to ν_{as}Si–O–Sb is in the region between Ge and Sn. The absorption peaks of phenyl and methyl derivatives were observed in this region (at 990 and 995 cm^{-1} respectively), but in tris(tri-*t*-butoxysilyl) antimonite the characteristic absorption band in the vicinity of 990 cm^{-1} was not observed. It seems that the band shifts to a higher wave number (1025 cm^{-1}).

The relative hydrolytic stability of these compounds was determined by measuring the antimonous ion, Sb^{3+}, formed by hydrolysis in an acidic medium. The results are shown in Fig. 1. The results indicate that the relative stability decreases in the order; tris(triphenylsilyl) antimonite, tris(tri-*t*-butoxysilyl) antimonite, tris(trimethylsilyl) antimonite (Sb% × 10). On the other hand, when the hydrolysis was carried out using a basic solvent (THF) at 50°C, the stability decreased as follows; tris(triphenylsilyl) antimonite, tris(trimethylsilyl) antimonite, tris(tri-*t*-butoxysilyl) antimonite. The first was remarkably stable.

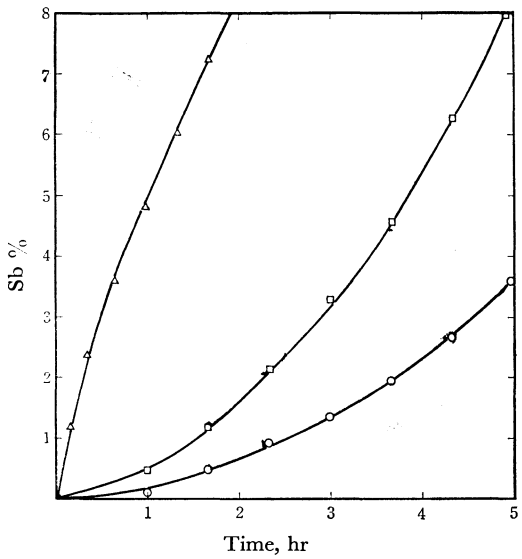

Fig. 1. The relative hydrolytic stability.
○: tris(triphenylsilyl) antimonite
□: tris(tri-*t*-butoxysilyl) antimonite
△: tris(trimethylsilyl) antimonite (Sb % × 10)

Experimental[9]

Materials. Antimony tri-*i*-propoxide was prepared by the reaction of antimony trichloride with *i*-propyl alcohol in the presence of ammonia,[10] bp 62—63°C/1 mmHg. Trimethylsilanol was prepared by Sauer's method,[11] 99—100°C. Triphenylsilanol was prepared by the hydrolysis of triphenylchlorosilane in the presence of triethylamine, mp 149—150°C. Tri-*s*-butoxysilanol was obtained by Wright's method,[12] bp 89.5°C/1 mmHg, n_D^{20} 1.4135. Tri-*t*-butoxysilanol was first prepared by Backer and Klasens through the hydrolysis of sodium tri-*t*-butoxysilanolate.[13] Wright *et al.*[12] described how the silanol was obtained by the hydrolysis of tri-*t*-butoxychlorosilane in boilling water, but its details have not been documented. In the present work, the silanol was prepared by a modification of the procedure of Wright; tri-*t*-butoxychlorosilane[14] was hydrolyzed in the presence of pyridine, yield 69.5% mp 65—66°C (Found: Si, 10.60%; mol wt, 268).

Preparation of Tris(tri-*t*-butoxysilyl)Antimonite. *Method A.* A solution of 9.8 g (0.033 mol) of antimony tri-*i*-propoxide in 50 m*l* of *n*-hexane was added to a solution of 26.0 g (0.099 mol) of tri-*t*-butoxysilanol in 50 m*l* of *n*-hexane. Then the combined solution was refluxed for 1.5 hr, and the alcohol formed was distilled with the solvent. The residue was distilled under reduced pressure to give 22.3 g (74.5%) of a white crystalline solid, bp 200.5—201.0°C/1 mmHg, mp 102—104°C. Found: C, 47.35; H, 9.79; Si, 9.22; Sb, 13.20 %; mol wt, 900. Calcd for $C_{36}H_{81}O_{12}Si_3Sb$: C, 47.41; H, 8.94; Si, 9.24; Sb, 13.35%; mol wt, 912.

Method B. Into a solution of 26.0 g (0.099 mol) of tri-*t*-butoxysilanol, 10.0 g (0.099 mol) of triethylamine in 130 m*l* of benzene was stirred, drop by drop, at 0—5°C. At the end of the addition, the mixture was refluxed for 2.5 hr. The triethylamine hydrochloride was filtered out, and the benzene was removed. The residue was distilled under reduced pressure to give 20.0 g (66.7%) of a pale yellow solid, bp 197.0—198°C/0.5 mmHg. IR: 2975 (m), 1474(w), 1390(m), 1365(m), 1240(m), 1215(shoulder), 1190(m), 1060(s), 1025(m), 915(s), 830(m), 850(w), 705(m) cm^{-1}.

Preparation of Tris(tri-*s*-butoxysilyl) Antimonite. *Method A.* The reaction of 9.8 g of antimony tri-*i*-propoxide with 26.0 g of tri-*s*-butoxysilanol in *n*-hexane gave 10.3 g (34.4%) of a colorless liquid, bp 204—207°C/1 mmHg. Found: C, 46.80; H, 9.82; Si, 9.21; Sb, 13.79%; mol wt, 889. Calcd for $C_{36}H_{81}O_{12}$-

9) All experiments were carried out in dry atmosphere or nitrogen purge. Melting points and boilling points were uncorrected.

Si_3Sb: C, 47.41; H, 8.94; Si, 9.24, Sb, 13.35%; mol wt, 912.

Method B. The reaction with the same molar ratio of reactants as the case of the tri-*t*-butoxysiloxy derivative gave 5.6 g (18.7%) of a pale yellow liquid, bp 202—204°C/0.5 mmHg.

Preparation of Tris(trimethylsilyl) Antimonite. *Method A.* The reaction of 33.3 g (0.111 mol) of antimony tri-*i*-propoxide with 34.6 g (0.388 mol) of trimethylsilanol in *n*-hexane gave 28.0 g (65.0%) of a colorless liquid, bp 108—108.2°C/21.5 mmHg, n_D^{20} 1.4368. Found: Si, 21.52; Sb, 31.24%; mol wt, 382. Calcd for $C_9H_{27}O_3Si_3Sb$: Si, 21.66 Sb, 31.28%; mol wt, 389.

Method B. The reaction of 9.0 g (0.0393 mol) of antimony trichloride with 14.0 g (0.157 mol) of trimethylsilanol in the presence of 15.9 g (0.157 mol) of triethylamine gave 8.4 g (55.0%) of a colorless liquid, bp 118—119°C/33.5 mmHg, n_D^{20} 1.4363. IR: 2900(s), 1247(s), 995(m), 900(s), 840(s), 752(m) cm^{-1}.

Preparation of Tris(triphenylsilyl) Antimonite. A solution of 6.5 g (0.0221 mol) of antimony tri-*i*-propoxide in 50 m*l* of benzene was added to a dispersed solution of 19.0 g (0.0687 mol) of triphenylsilanol in 50 m*l* of benzene. Then the clear solution was refluxed for 1.5 hr. When the solvent was removed along with the alcohol formed, a pale yellow solid appeared. After the solvent had been removed completely, the solid was recrystallized from a mixed solvent of benzene and ether(2 : 1), giving 9.7 g (94.0%) of a white, crystalline matter, mp 202—205°C. Found: C, 69.62; H, 4.75; Si, 8.41; Sb, 12.58%; mol wt, 920. Calcd for $C_{64}H_{45}O_3Si_3Sb$: C, 68.42; H, 4.78; Si, 8.98; Sb, 12.84%; mol wt, 948. IR: 3050(m), 2990(shoulder), 1585(w), 1564 (shoulder), 1480(w), 1425(m), 1380(vs), 1330(vw), 1256(vw), 1183(vw), 1155(vw), 1114(s), 1103(shoulder), 1060(vw), 1025(vw), 990(m), 905(s), 740(m), 710 and 700(s), 680(m) cm^{-1}.

Measurement of Relative Hydrolytic Stability. Weighed samples (0.5—0.8 g) of tris(triorganosilyl) antimonite were vigorously stirred at 23°C, into a mixture of 100 m*l* of a 5% aqueous hydrochloric acid solution, 30 m*l* of acetone, and 1 g of sodium potassium tartrate. After twenty minutes, 5 m*l* of the solution was neutralized with a saturated sodium bicarbonate solution and then titrated with an iodine solution, using a starch indicator. The results are shown in Fig. 1. On the other hand, samples (0.4—0.2 g) in 10 m*l* of THF were added to a solution of 1 g of sodium potassium tartrate in 20 m*l* of a 5% aqueous hydrochloric acid solution, they were titrated after having been stirred at 50°C. The results were as follows; tris(triphenylsilyl) antimonite; Sb, 72.5% (after 5 minutes), 77.0(10), 99.0(20): tris(trimethylsilyl) antimonite; 90.2(5), 100 (10): tris(tri-*t*-butoxysilyl) antimonite; 100(5).

Analysis. The antimony was determined by iodometry after a weighed sample had been hydrolyzed with a 20% alcohol solution, a few drops of concentrated hydrochloric acid, and 1 g of sodium potassium tartrate. The silicon was determined as silicon dioxide after a sample had been decomposed by concentrated sulfuric acid and a mixture of ammonium nitrate and sulfate.

Preparation of Pentacyanotriphenylphosphine- and Tetracyano-bis(triphenylphosphine)cobaltate(III)*1

Kiyokatsu WATANABE,*2 Hiroaki NISHIKAWA and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received July 27, 1968)

As far as octahedral cobalt(III) complexes containing the ligand triphenylphosphine are concerned, a few types are known. They are $[Co(DH)_2P(C_6H_5)_3X]$ (DH=dimethylglyoxime monoanion, X=halogen, alkyl and phenyl[1]; X=CN[2]), $[Co(TSB)P(C_6H_5)_3Br]$[3] (TSB=tetradendate Schiff base dianion) and $[Co(CN)_2(acac)(P(C_6H_5)_3)_2]$[4] (acac=acetylacetone anion).

We have attempted to prepare some triphenylphosphine complexes by using the so-called Werner-type complexes as the starting materials; we have now succeeded in obtaining two complexes of the cyanotriphenylphosphine series.

Experimental

Potassium Pentacyanotriphenylphosphinecobaltate(III) Trihydrate, $K_2[Co(CN)_5P(C_6H_5)_3]\cdot 3H_2O$. Potassium bromopentacyanocobaltate(III)[5] (3.8 g, 0.01

mol) was dissolved in a minimum amount of water (2 ml). On the other hand, triphenylphosphine (5.2 g, 0.02 mol) was dissolved in glacial acetic acid (70 ml). The former solution was added to the latter solution, and the mixture was stirred at 75°C for 6 hr. The resulting yellow solution was filtered and the filtrate was evaporated to dryness under reduced pressure. The residue was treated with a large amount of water (100 ml). After the filtration of the aqueous solution, the filtrate was again evaporated to dryness under reduced pressure. The residue was treated with methanol (100 ml) and the methanolic solution was concentrated to a small volume (30—40 ml). This concentrated solution was added to a cellulose column which had previously been washed with methanol. When methanol was passed through the column, a yellow band of the desired complex was eluted. This eluted solution was concentrated to a small volume under reduced pressure. When this solution was cooled a pale-yellow material separated out, this was dried over calcium chloride. Yield, 1 g. The complex was soluble in water and methanol, but not soluble in benzene.

Found: C, 47.45; H, 3.27; N, 12.65%. Calcd for $K_2[Co(CN)_5P(C_6H_5)_3]\cdot 3H_2O$: C, 47.30; H, 3.59; N, 12.00%.

The use of iodopentacyano- or chloropentacyanocobaltate(III) in place of the bromo complex gave the same product, but the yield was extremely poor in the case of the iodo complex.

Potassium Tetracyanobis(triphenylphosphine) cobaltate(III) Dihydrate, $K[Co(CN)_4(P(C_6H_5)_3)_2]\cdot 2H_2O$. To a triphenylphosphine solution in glacial acetic acid (5.2 g in 70 ml), was added an aqueous solution (a few ml) of potassium iodopentacyanocobaltate (III)[5] (4.3 g, 0.01 mol), after which the mixture was stirred at 75°C for 6 hr. The resulting yellow solution was filtered, and a large quantity of water (500 ml) was added to the filtrate; then the whole was kept in a refrigerator until a yellow solid began to appear on the surface of the solution. The solid was collected by filtration and suspended in benzene (200 ml) in oder to remove any unreacted triphenylphosphine. Finally, the remaining solid was dried over calcium chloride. Yield, 2.5 g. This complex was soluble in methanol to some extent, but it was insoluble in water and benzene.

Found: C, 63.05; H, 4.76; N, 7.48%. Calcd for $K[Co(CN)_4(P(C_6H_5)_3)_2]\cdot 2H_2O$: C, 62.99; H, 4.46; N, 7.34%.

The use of the other halogenopentacyano complexes for the preparation was also possible, but their reaction times were considerably different; the use of the chloro complex took the longest time, while the use of the iodo complex was the best.

Results and Discussion

The two complexes thus obtained were characterized by their electronic absorption spectra (Fig. 1). Each spectrum shows an absorption band as a shoulder in the longer wavelength region. Although its intensity was quite high, this band may be due to a ligand-field transition.

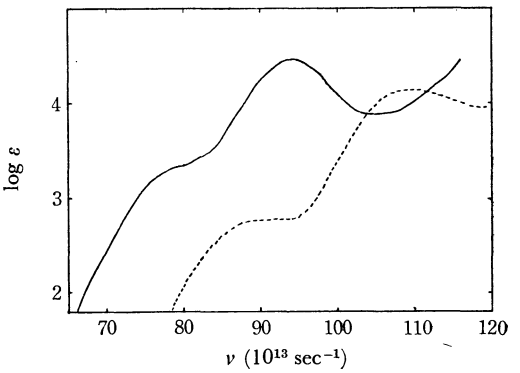

Fig. 1. Absorption spectra in methanol solution.
----- $K_2[Co(CN)_5P(C_6H_5)_3]\cdot 3H_2O$
—— $K[Co(CN)_4(P(C_6H_5)_3)_2]\cdot 2H_2O$

The existence of water of crystallization in the present complexes was established by the thermal analyses and the IR spectra. The presence of complexed CN^- was ascertained from the IR absorption peak in the neighborhood of 2100 cm^{-1} ($\nu_{C\equiv N}$); the pentacyano complex showed a well-split band (2118, 2140 cm^{-1}), and the tetracyano one, a sharp peak with a shoulder (2110, 2150_{sh} cm^{-1}). Concerning the existence of triphenylphosphine, a large number of the characteristic bands were observed for both complexes (1435, 1190, 1090, 1020, 1000 and 750 cm^{-1}). It is not certain which structure, *trans* or *cis*, is to be assigned to the present tetracyano complex.

The Reaction of 3-Chloro-benzo[*d*]isothiazole with Thiophenols

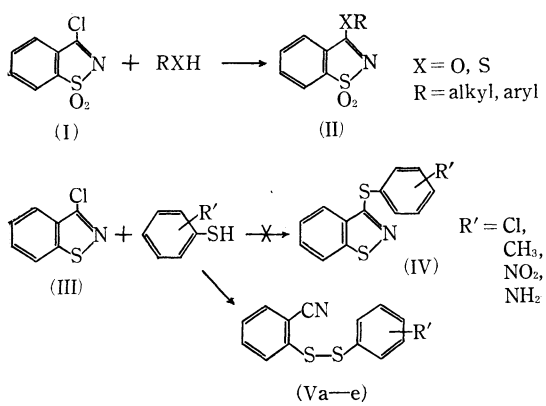
Suzuo WATANABE

Central Research Laboratories, Meiji Seika Kaisha, Ltd., Morooka-cho, Kohoku-ku, Yokohama

(Received August 5, 1968)

The condensation of 3-chloro-benzo[*d*]isothiazole 1,1-dioxide (saccharin chloride) (I) with alcohols, phenols, or mercaptans was reported to give a series of saccharin derivatives (II),[1] which have distinct melting points, so they have been used for the identification of alcohols, phenols, or mercaptans.

The present report deals with the reaction of thiophenols with 3-chloro-benzo[*d*]isothiazole (III).[2]



When III was treated with substituted thiophenols at 40°C, a vigorous evolution of hydrogen chloride gas occured. By adding ethanol to the reaction mixture, the crystalline product was obtained in yield of 87—28%.

This product was not the expected compound, 3-arylthio-benzo[*d*]isothiazoles (IV), but aryl *o*-cyanophenyl disulfides (V), which are listed in Table 1.

The structure of the compounds Va—e was determined by their elemental analyses and infrared spectra, which showed a characteristic band at 2210 cm^{-1} due to -CN group. To confirm the structure, Vc was reduced with lithium aluminum hydride to *p*-methylthiophenol, which was identified by its melting point and by the reaction with 2,4-dinitrochlorobenzene to *p*-tolyl 2,4-dinitrophenyl sulfide.

It was reported[3] that 2-substituted-benzo[*d*]isothiazole-3(2)-ones were reacted with aniline to afford *o*-(*N*-substituted carbamoyl)-benzenesulfenanilides. When III was treated with alcohols or aniline, no reaction occurred and starting materials were recovered.

Table 1. Disulfides by the reaction of 3-chloro-benzo[*d*]isothiazole with thiophenols

	R	Yield (%)	Mp (°C)	Anal. %	Found	Calcd
					N	S

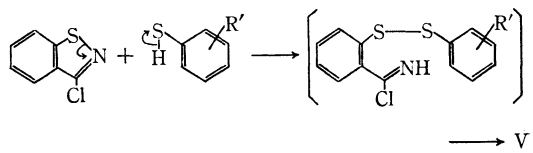
Ve	*o*-NH_2	33.5	83.0—86.0	10.98	24.82	
				10.82	24.78	

The reaction mechanism of III with thiophenols was thought to be as follows.



The compounds Va-e showed moderate antibacterial and antifungal activities. The minimum inhibition concentrations (MIC) are listed in Table 2.

Experimental

Two typical examples for the reaction of III with thiophenols were described below.

***p*-Chlorophenyl *o*-Cyanophenyl Disulfide (Va).** *p*-Chlorothiophenol (8.7 g) was added to 3-chloro-benzo[*d*]isothiazole (III) (10.2 g) with shaking in small portions at 40°C. The reaction mixture was thoroughly shaken until the vigorous evolution of hydrogen chloride gas stopped, and then allowed to stand in an ice box overnight. Ethanol (20 *ml*) was added to the reaction mixture, and the resulting suspension was thoroughly

stirred over a period of 15 min, then crystals were collected, washed with ethanol and dried. Recrystallization from ethanol gave 14.5 g (87.0%) of *p*-chlorophenyl *o*-cyanophenyl disulfide, mp 47.0—49.0°C. Found: C, 56.55; H, 3.39; N, 5.23%. Calcd for $C_{13}H_8ClNS_2$: C, 56.21; H, 2.90; N, 5.04%.

o-Aminophenyl o-Cyanophenyl Disulfide (Ve). 3-Chlorobenzo[*d*]isothiazole (10.2 g) was added to *o*-aminothiophenol (14.8 g) with shaking in small portions. The reaction mixture was thoroughly shaken for an additional 15 min, and then allowed to stand in an ice box overnight. Crystalline precipitate was filtered and washed with ethanol (25 m*l*). The filtrate and the washings were combined, concentrated *in vacuo* to a half volume, and cooled, then crystals which separated were collected. Further concentration of the mother liquor to 7 m*l* yielded more crystals. The entire crystals were recrystallized from ethanol, the yield of *o*-aminophenyl *o*-cyanophenyl disulfide was 5.2 g (33.5%), mp 83.0—86.0°C. Found: C, 60.81; H, 4.37; N, 10.98; S, 24.82%. Calcd for $C_{13}H_{10}N_2S_2$: C, 60.40; H, 3.89; N, 10.82; S, 24.78%.

Photoreaction of Pseudoionone

Noboru SUGIYAMA, Yoshiaki SATO, Michikazu YOSHIOKA, Kazutoshi YAMADA and Hiroshi KATAOKA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received August 20, 1968)

The great majority of works on the photoreaction of conjugated dienone has been dealt extensively with cyclic compounds.[1-4] Only a few examples involving acyclic dienone have been known, *e. g.*, the photodimerization of cinnamylidene acetone[5,6] and the photoisomerization of crotonylidene acetone.[3] Büchi and Yang[3] obtained a polymeric material by the photoreaction of pseudoionone (I), an acyclic dienone. This is the only report on the photoreaction of I. As part of photochemical studies on enone systems the photoreaction of I has been studied.

First, it was confirmed that I had a structure of conjugated dienone (all trans type in diene[7]) with

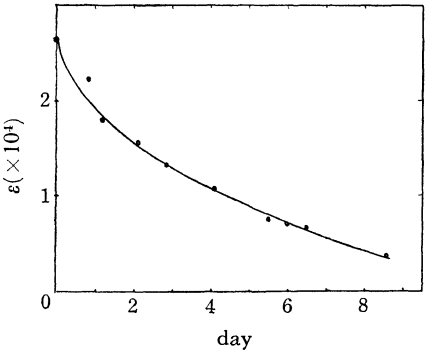

Fig. 1. The change of ε at 293 mn of pseudoionone with irradiation time.

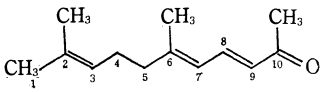
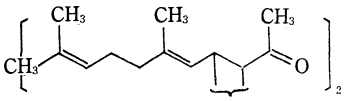
one isolated double bond by UV, IR and NMR spectra as shown in experimental part. When the solution of I in *n*-hexane was irradiated with a high pressure mercury lamp, UV absorption at 293 nm gradually decreased indicating the disappearance of the conjugated double bond. (Fig. 1) The reaction mixture showed four spots of R_f values of 0.45, 0.43, 0.40 and 0.0 on a silica gel thin layer chromatogram with benzene - ethyl acetate (9 : 1). The substance of R_f 0.45 was identified with I. The substances which show the R_f values of 0.43, 0.40 and 0.0 were designated as II, III and IV, respectively. Both II and III were isolated by a silica gel chromatography. When left at room temperature, I readily, and II or III gradually polymerized. So the viscous IV would be a mixture of polymers from I, II and III.



I



II and III

The ozonolysis of II and III, followed by decomposition with hydrogen peroxide and then by esterification with diazomethane, gave methyl levulinate as a main product. However, II and III were presumed to be cyclobutane derivatives from the following spectra and other reactions.

The UV spectra indicate that no conjugated system is contained in II and III. It is also supported by the shift of IR band at 1665 cm^{-1} of I to 1705 cm^{-1}. The NMR spectra of II and III show signals at τ 8.35 due to isopropylidene methyls. This shows that 2,3-double bond remains. The signals at τ 4.9 of II and III are assigned to 3- and 7-protons. The molecular peaks of mass spectra of (V) and (VI) (*m/e* 394 and 392 respectively), which were obtained by the catalytic reduction of II and III respectively, are consistent with the experimental facts that II absorbed five moles of hydrogen over platinum oxide and III absorbed four moles over palladium black. The above facts and A_2B_2 like multiplets at τ 7.6—6.9 of II and τ 7.1—6.3 of III also support the cyclobutane structure. The chemical shifts of 6-methyl protons and acetyl methyl protons of II and III move to a higher magnetic field, compared with I. Especially acetyl methyl protons of III show two singlets, indicating that the surrounding of two acetyl groups are slightly different. The IR spectrum of V shows strong absorption at 3450 cm^{-1} (OH) and 1700 cm^{-1} (CO). A doublet at τ 8.84 in NMR of V is due to methyl of CH_3-CH-OH and a singlet at τ 7.86 comes from acetyl methyl group. This indicates that four C=C bonds and one C=O bond were reduced in V. On the other hand, the IR spectrum of VI shows a strong absorption at 1710 cm^{-1} (CO) and no hydroxy absorption, indicating that only C=C bond were reduced in VI. Consequently it can be concluded that II and III are dimers of I, which contain cyclobutane ring at 8,9-positions.

Experimental

Pseudoionone was purified by fractional distillation *in vacuo* and column chromatography. UV: λ_{max}^{EtOH} 293 nm (ε 26000); IR: $\nu_{max}^{liq.\ film}$ cm^{-1}, 1665 (CO), 1630, 1590, 973 (diene), 825(C=C); NMR: (τ, in CCl_4), 8.36 (d, J=4.5 cps, isopropylidene methyls), 8.09 (s, 6-methyl), 7.80 (m, 4- and 5-methylenes), 7.80 (s, acetyl), 4.90 (m, 3-proton), 3.98 (d, J=12.5 cps, 7-proton), 3.93 (d, J= 15.5 cps, 9-proton) and 2.58 (q, J=12.5 and 15.5 cps, 8-proton). A Taika H-type 125W high pressure mercury lamp was used as light source. IR, UV, NMR and Mass spectra were measured by Hitachi ESI-S2 type spectrometer, Hitachi EPS-3T type spectrophotometer, Hitachi H-60 type spectrometer and Hitachi Mass spectrometer, respectively. Hitachi KGL-2A type gas chromatography apparatus (polydiethylene glycol succinate) was used for analysis.

Irradiation of Pseudoionone (I). A *n*-hexane solution of I (7.5 g/70 m*l*) was irradiated with a high pressure mercury lamp for 8 days at room temperature. The reaction was followed by UV spectra of aliquots (Fig. 1). From the reaction mixture the solvent was evaporated under reduced pressure and the residual pale yellow liquid was fractionated by column chromatography using silica gel eluted with benzene - ethyl acetate. Unreacted I (0.75 g) was recovered from the benzene elute. From the benzene - ethyl acetate (9 : 1) elute, the mixture of II and III (1.8—1.9 g), was obtained. Ratio of II by III was found to be 1 : 1 by measuring the intensity of methine proton signals in NMR spectra. Pure II and III were separated by repeating column chromatography. Photodimer II, a pale yellow liquid, Found: C, 81.49; H, 10.31%. Calcd for $C_{26}H_{40}O_2$: C, 81.20; H, 10.48%.

UV: λ_{max}^{EtOH} nm(ε), 283 (sh, 190).

IR: (cm^{-1}, liq. film) 1705, 1675, 1445, 1358, 832.

NMR: (τ, in CCl_4) 8.35 (d, J=4.5 cps, 12H), 8.34 (d, J=1.0 cps, 6H), 8.00 (s, 6H), 7.6—6.9 (m, 4H), 4.9 (m, 4H).

Photodimer III, a pale yellow liquid. Found: C, 81.79; H, 9.99%. Calcd for $C_{26}H_{40}O_2$: C, 81.20; H, 10.48%.

UV: λ_{max}^{EtOH} nm (ε), 283 (sh, 200).

IR: (cm^{-1}, liq. film) 1705, 1670, 1440, 1355, 820.

NMR: (τ, in CCl_4) 8.35 (d, J=4.5 cps, 12H), 8.36 (d, J=1.0 cps, 6H), 7.96 (s, 3H), 7.93 (s, 3H), 7.1—6.3 (m, 4H), 4.9 (m, 4H).

Catalytic Reduction of Photodimer II. In the presence of 28 mg of platinum oxide as catalyst, 205 mg of II was hydrogenated in ethanol (7.5 m*l*). The sample absorbed 59 m*l* of hydrogen. After the solvent was evaporated, 210 mg of a colorless liquid (V) was obtained.

Found: C, 79.89; H, 12.50%. Calcd for $C_{26}H_{50}O_2$: C, 79.12; H, 12.77%.

UV: λ_{max}^{EtOH} nm (ε), 282 (48).

IR: (cm^{-1}, liq. film), 3450, 1700, 1460, 1360, 1070.

NMR: (τ, in CCl_4), 9.11 (d, J=6.0 cps, 18H), 8.80 (m, 20H), 8.84 (d, J=8.0 cps, 3H), 7.86 (s, 3H), 7.8—7.3 (m, 4H), 6.4 (m, 1H), 4.7 (broad s, 1H).

Mass: (*m/e*) 394 (mol. peak), 376, 198, 197, 196, 195, 127, 113, 111, 109 (base peak), 97, 96, 85, 83, 71, 57, 43.

Catalytic Reduction of Photodimer III. In the presence of palladium black (51 mg) as catalyst, 54 mg of III was hydrogenated in ethanol (10 m*l*). The sample absorbed 12 m*l* of hydrogen. Removal of the solvent gave 55 mg of a colorless liquid (VI).

Found: C, 79.67; H, 11.86%. Calcd for $C_{26}H_{48}O_2$: C, 79.53; H, 12.32%.

UV: λ_{max}^{EtOH} nm (ε), 283 (sh, 78).

IR: (cm^{-1}, liq. film), 1710, 1460, 1360.

NMR: (τ, in CCl_4), 9.10 (d, J=6.0 cps, 18H), 8.77 (m, 20H), 7.98 (s, 3H), 7.92 (s, 3H), 7.7—6.6 (m, 4H).

Mass: (*m/e*), 392 (mol. peak), 196, 195, 127, 113, 109 (base peak), 97, 95, 85, 83, 71, 57, 43.

Ozone Oxidation of II. Ozonolysis and decomposition with hydrogen peroxide of 980 mg of II gave neutral material (260 mg) and acidic material (280 mg). Esterification of acidic material by diazomethane gave 62 mg of methyl levulinate as main product, identified with the authentic sample by NMR and gas chromatography.

Ozone Oxidation of III. By a similar procedure as described above, 800 mg of III gave 200 mg of neutral material, 220 mg of acidic material and 55 mg of methyl levulinate.

The Addition Reactions of Fluoroalkyl Ethyl Ethers to Perfluoropropene

Hiroshige MURAMATSU, Hiroshi KIMOTO and Kan INUKAI

Government Industrial Research Institute, Nagoya, Kita-ku, Nagoya

(Received September 13, 1968)

The free-radical reactions of aliphatic or alicyclic ethers to fluoroolefins under γ-irradiation[1-3] or in the presence of peroxide[4] have been reported to give the 1 : 1 adduct, the ethers with fluoroalkyl or fluorocycloalkyl group on the α-carbon, in good yields. In the addition of diethyl ether,[1-3] the 1 : 2 adduct with symmetrical structure has been produced along with the 1 : 1 adduct.

In order to investigate the scope and limitation of these addition reactions for the syntheses of fluorine-containing ethers, the reaction of various fluoroalkyl ethyl ethers and perfluoropropene was undertaken. The effects of the substitution of fluorine for hydrogen in the ethers on their reactivity in the addition reaction were also investigated by a competitive reaction.

The two types of fluoroakyl ethyl ethers with general formulas of $RCH_2OCH_2CH_3$ ($R=CH_2F$, CHF_2, CF_3, CH_2Cl, CHF_2CF_2) and $R'CF_2OCH_2CH_3$ ($R'=CHF_2$, CHFCl, $CHCl_2$) were prepared and used as addends. A mixture of perfluoropropene and an ether in an autoclave was irradiated by γ-ray ($5—20\times10^7$ R). The products were separated by distillation or by preparative gas chromatography. Their structures were established by elemental analyses, and by IR and NMR (proton and fluorine) spectra.

While the addition of ethers of the type $R'CF_2OCH_2CH_3$ gave only the 1 : 1 adduct IV, the addition of ethers of the type $RCH_2OCH_2CH_3$ resulted in a mixture of products composed of the 1 : 1 adducts, I and II, and the 1 : 2 adduct III.

$$RCH_2OCH_2CH_3 + CF_3CF{=}CF_2 \longrightarrow$$

$$\underset{\displaystyle CF_2CHFCF_3}{\underset{|}{RCH_2OCHCH_3}} + \underset{\displaystyle CF_2CHFCF_3}{\underset{|}{RCHOCH_2CH_3}} +$$

I II

$$\underset{\displaystyle CF_2CHFCF_3}{\underset{|}{RCH}}\!\!-\!\!O\!\!-\!\!\underset{\displaystyle CF_2CHFCF_3}{\underset{|}{CHCH_3}}$$

III

$$R'CF_2OCH_2CH_3 + CF_3CF{=}CF_2 \longrightarrow$$

$$\underset{\displaystyle CF_2CHFCF_3}{\underset{|}{R'CF_2OCHCH_3}}$$

IV

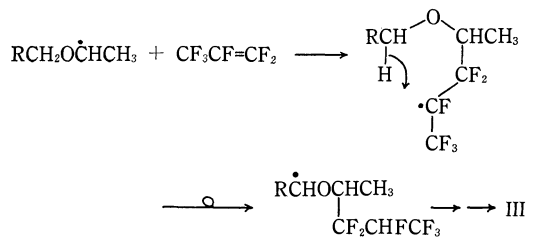
4) W. E. Hanford, U. S. Pat. 2433844 (1948).

The reaction conditions and yields of the adducts are shown in Table 1. It is apparent that, in the case of the type $RCH_2OCH_2CH_3$, the ratio of III/I decreases with the number of fluorine on the β-carbon and that perfluoropropene adds preferentially on the α-methylene with a less electronegative group. The addition of ethers of the type $RCF_2OCH_2CH_3$ was much more difficult than that of ethers of the type $RCH_2OCH_2CH_3$.

Table 1. Reaction conditions and yields of adducts

Ether R	Molar ratio of propene/ether	Total dose MR	Yield, % I	II	III	IV
		$RCH_2OCH_2CH_3$				
CF_3	2.2	113	67	0.3	5.3	
CHF_2	2.7	60	64	1.3	19.3	
CH_2F	2.2	60	37	7.1	39	
CH_3[3]	0.3	11	43.5		56.5	
CH_2Cl	2.3	63	7.6			
CHF_2CF_2	0.9	46	35			
		$RCF_2OCH_2CH_3$				
CHF_2	0.7	143				8
CHFCl	0.8	145				10
$CHCl_2$	0.7	218				22

The 1 : 2 adduct III could be formed by two pathways. One pathway is a successive addition of two perfluoropropenes and another is an addition involving an intramolecular rearrangement.



To clarify this point, we studied the addition reaction of diethyl ether to perfluoropropene under various reaction conditions. As shown in Table 2, the ratio of III/I in products was almost constant if the ratio of olefin/ether was kept constant, showing no dependence on irradiation time. Besides, the ratio of III/I increased with increasing the ratio of olefin/ether (Table 3).

The fact that the reaction of I with perfluoropropene produced only a small amount of III and that the addition reaction of a cyclic ether such as tetrahydrofuran to perfluoropropene did not give any 1 : 2 adduct,[3] also support the latter pathway involving the radical rearrangement. The rigid structure of tetrahydrofuran would prohibit the formation of six-membered cyclic structure of the intermediate radical.

Table 2. Relations between irradiation time and ratio of III to I

Propene/diethyl ether	Irradiation time, hr	Yield, % I	III	Ratio of III/I
1.0	22.9	8.0	12.2	1.52
1.0	45.6	10.8	14.7	1.36
1.0	68.6	13.2	19.1	1.44
1.0	112.0	15.3	23.2	1.52
2.0	45.6	10.9	22.8	2.08
2.0	112.0	16.2	33.6	2.08

Table 3. Relations between ratio of perfluoropropene to diethyl ether and ratio of III to I

Propene/diethyl ether	Concentration of ether, mol %	Yield, % I	III	Ratio of III/I
0.25	0.80	6.47	5.67	0.88
0.50	0.67	7.03	7.13	1.01
1.00	0.50	7.00	10.1	1.44
2.00	0.33	8.40	17.6	2.10

The relative reactivities of fluoroalkyl ethyl ethers in the addition reaction to perfluoropropene were determined by a competitive reaction. A one-to-one mixture of two substrates was irradiated with olefin in a glass ampoule. The amount of each adduct was determined by gas chromatography. The relative reactivities of the ethers are listed in Table 4, taking the reactivity of diethyl ether as 1000.

$CHF_2CHOCHCH_3$	168	1.3218	1.595	51.3	51.5	29.1	29.3	1.68	1.97
$CH_2FCHOCHCH_3$	176	1.3270	1.560	50.9	51.1	30.6	30.6	1.95	2.31

In the ethers of the type $RCH_2OCH_2CH_3$ (R= CH_3, CH_2F, CHF_2, CF_3), the logarithm of reactivity was found to be inversely proportional to the number of substituted fluorines in the β-methyl group, indicating that the Hammett relationship holds in the radiation-induced addition reaction. As expected, it was also observed that τ values of chemical shift of hydrogen in α-methylene of the fluoroalkyl ethyl ethers have a linear relation with the logarithms of their reactivity as shown in Fig. 1. All these facts indicate that the substituted fluorines exerted their electron-withdrawing effect remarkably through oxygen upon the α-methylene group and that the hydrogen abstraction on the α-methylene was a rate-determining step in the radiation-induced addition reaction of ethers to fluoroolefins.

The physical properties of the 1 : 1 adduct and 1 : 2 adduct are shown in Table 5. In the adducts of the type $RCH_2OCH_2CH_3$, the substitution of fluorine for hydrogen of β-methyl group of diethyl ether decreases the boiling point and refractive index of both the 1 : 1 adduct and 1 : 2 adduct, but increases their density. Similar trends were known[5] for $RCOCH_3$, $RCH_2OC_2H_5$, $RCOOC_2H_5$, and RCOCl where R is CH_2F, CHF_2 or CF_3.

Experimental[6]

Preparation of Ethers of the Type $RCH_2OCH_2CH_3$. *(1) β-Fluoroethyl Ethyl Ether.* Ethylene chlorohydrin was fluorinated with potassium fluoride in ethylene glycol-diethylenel gycol solvent at 150°C to give β-fluoroethanol (60% yield). Upon heating at 130°C with ethanol in the presence of sulfuric acid, β-fluoroethanol gave β-fluoroethyl etheyl ether (30% yield). bp 75—76°C(lit.[7] 74.5—75.5°C).

(2) β,β-Difluoroethyl Ethyl Ether. $\alpha,\alpha,\beta,\beta$,-Tetrafluoroethyl ethyl ether prepared from tetrafluoroethylene and ethanol was hydrolyzed in the presence of sulfuric acid at 0°C to produce ethyl difluoroacetate (45% yield). The difluoroacetate was converted into difluoroethanol by reduction with lithium aluminum hydride in ether (65% yield). A mixture of the difluoroethanol and ethanol was heated at 130°C with sulfuric acid to give β,β-difluoroethyl ethyl ether (55% yeild). bp 66—67°C (lit.[8] 66.3—66.7°C).

(3) β,β,β-Trifluoroethyl Ethyl Ether. Reduction of trifluoroacetic acid with lithium aluminum hydride

6) All temperature readings are uncorrected. NMR spectra were taken on a JNM-C-60 NMR high resolution spectrometer with tetramethylsilane as an internal standard for ^1H and with trifluoroacetic acid as an external standard for ^{19}F.

8) F. Swarts, *Bull. Acad. Roy. Belg.*, **1901**, 383.

was carried out in ether at 35°C to yield β,β,β-trifluoroethanol (50% yield). The trifluoroethanol was refluxed with ethanol in the presence of sulfuric acid to give trifluoroethyl ethyl ether (18% yield). bp 50—51°C (lit.[9] 49.9°C).

(4) β-Chloroethyl Ethyl Ether. β-Chloroethyl ethyl ether was prepared from ethylene chlorohydrin and ethanol as mentioned above (65% yield). bp 107—108°C (lit.[10] 108—109°C).

(5) β,β,γ,γ-Tetrafluoropropyl Ethyl Ether. A mixture of sodium β,β,γ,γ-tetrafluoropropoxide, ethyl bromide, and dioxane in a stainless steel autoclave was heated at about 190°C for 54 hr to give β,β,γ,γ-tetrafluoropropyl ethyl ether (34% yield). bp 86—88°C, n_D^{20} 1.3252, d_4^{20} 1.184.

Found: F, 47.2%; MR_D 27.2 Calcd for $C_5H_8OF_4$: F, 47.5%; MR_D 27.3.

Preparation of Ethers of the Type $RCF_2OCH_2CH_3$. α,α,β,β-Tetrafluoroethyl-, α,α,β-trifluoro-β-chloroethyl- and α,α-difluoro-β,β-dichloroethyl ethyl ether were prepared by the nucleophilic addition reaction[11] of ethanol to tetrafluoroethylene, trifluorochloroethylene, and 1,1-dichloro-2,2-difluoroethylene, respectively.

Addition Reaction of Ethers to Perfluoropropene. A mixture of 37 g (0.34 mol) of β,β-difluoroethyl ethyl ether and 137 g (0.91 mol) of perfluoropropene was placed in an autoclave (capacity, 200 m*l*) and received γ-irradiation at room temperature to a total dose 60 MR for a period of 1030 hr. After recovery of unchanged perfluoropropene (72.5 g), the content in the autoclave was distilled to give dimers of perfluoropropene (0.8 g), a mixture of 1 : 1 adducts (58.3 g), a 1 : 2 adduct (27 g, 0.066 mol, 19.3% yield) and viscous residues (8 g). From its gas chromatogram and NMR spectrum, the mixture of 1 : 1 adducts was found to consist of β,β-difluoroethyl α-methyl-β,β,γ,δ,δ,δ-hexafluorobutyl ether (57 g, 0.22 mol, 64% yield) and ethyl α-fluoromethyl-β,β,γ,δ,δ,δ-hexafluorobutyl ether (1.3 g, 0.0051 mol, 1.5% yield).

Addition reactions of other ethers were carried out under similar conditions, which are summarized in Table 1 together with the yields. Though products were mainly separated by distillation, some products were isolated by a preparative gas chromatograph. Physical properties of the 1 : 1 adducts and 1 : 2 adducts are shown in Table 5.

The authors wish to express their thanks to the Daikin Kogyo Co. for supplying perfluopropene.

Dipole Moments of 1,2-Dihalogeno- and 1,1,2,2-Tetrahalogenoethanes in Aromatic and Non-Aromatic Solvents

Osamu KIYOHARA and Ken-iti HIGASI[*1]

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received September 18, 1968)

A weak interaction between 1,2-dichloroethane and aromatic solvents has been detected by studies of the dielectric relaxation times and dipole moments.[1] In the present study measurements were made of the dipole moments of 1,2-dihalogeno- and 1,1,2,2-tetrahalogenoethanes in various solvents (Table 1). The observed moment of 1,2-diiodoethane in benzene, 0.5_3D, is considerably lower than the literature value, 1.3 D,[2] which was obtained in the very early stage of dipole moment studies.

The interaction between 1,2-dichloroethane and an aromatic solvent has been believed to occur through hydrogen-bonding; the hydrogen atoms of dichloroethane have been assumed to interact with π-electrons of an aromatic solvent.[3] However, this hydrogen-bonding mechanism can not explain the "benzene effect" of 2,3-dihalogeno-2,3-dimethylbutane[4] and that of chloroacetone,[5] because this effect appears when hydrogen atoms are replaced by methyl groups.

As an alternative mechanism, the chlorine atoms of 1,2-dichloroethane have been considered to play an important role in the complex formation between the solute and the aromatic solvent.[1,6] If this mechanism were true, one might expect to find some regular changes upon the replacement of Cl by Br or by I, which have smaller electronegativities than that of the chlorine atom. The results collected in Table 1 do not offer any definitive evidence for this, however.

It was pointed out by Sutton[7] to one of the present authors that the benzene effect might be due to the hyperpolarizability[8] of the aromatic solvent in the very strong field of the solute dipole. This hyperpolarizability effect is not necessarily restricted to an aromatic solvent. It is interesting to find that the dipole moments of dihalogeno- and tetrahalogenoethanes are higher in cyclohexene than those in cyclohexane and other non-aromatic solvents. However, those in amylene are not much different from the moments in cyclohexane. The effect of hyperpolarizability seems to need further study.

(Received January 13, 1969)

Coordinated ligands in metal complexes are under the influence of the electron-withdrawing effect of the central metal ion, and, in some complexes, some of their protons are dissociated in solution. Thus, if such complexes are dissolved in deuterium oxide, hydrogen deuterium exchange is to be observed. We noticed this kind of exchange from the finding[1] that the NMR signal of the methylene protons in malonato chelates dissolved in deuterium oxide decreased in intensity with time. We have been looking for such exchange reactions by means of the NMR technique. As a result, several other exchanges were found, *i. e.* in the methylenes in trisglycinatocobalt(III)[2] and in the palladium complex[3] of glycine and pyruvic acid and in the methyl in diammine-acetylacetone-ethylenediiminecobalt(III) complex.[4]

Here we wish to report an example of the exchange active ethylene group, *viz.* the ethylene group in the ethylenediaminetetraacetatocobaltate(III) complex.

Figure 1 shows the NMR spectra of the complex. Curve (a) represents the spectrum of the complex dissolved in neutral deuterium oxide. The spectrum shows a complicated pattern because the proton signals due to the ethylene and two kinds of methylenes (out-of-plane and in-plane) appear almost in the same region. Addition of a small amount of potassium carbonate to the solution caused a decrease in the intensity of the NMR signal as shown in curve (b) and (c). This is not surprising because Reilley[5] already reported the hydrogen-deuterium exchange in the acetato methylenes of this complex dissolved in acidified deuterium oxide solution at elevated temperature (85—105°C). However, when the solution was kept at 90°C for 20 min, all signals due to the ethylene as well as the methylene protons completely disappeared as shown in curve (d). This means that the ethylene protons are also exchanged by deuterium at elevated temperatures.

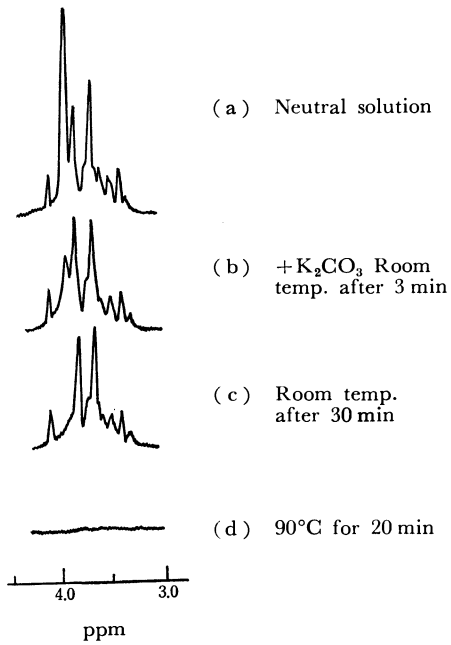

Fig. 1. The NMR spectra of Na[CoEDTA] in deuterium oxide. Sodium trimethylsilyl-propane-sulfonate was used as an internal standard.

We are now investigating the NMR spectra of other metal EDTA complexes and the results will be reported in the near future.

The Adsorbed State of Oxygen on Vanadium Pentoxide Catalyst

Kimio TARAMA, Satohiro YOSHIDA, Shingo ISHIDA and Yasuo DOI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received December 5, 1968)

ESR studies on the adsorbed state of oxygen on metal oxides have been reported, the most extensive works being performed with the adsorbed oxygen on zinc oxide and titanium oxide.[1)]

We[2)] observed three kinds of ESR signals (α, β and γ) for oxygen adsorbed on vanadium oxide supported on silica. One of these signals, β-signal, is similar to that which was recently reported by Kasansky.[3)] The present communication is concerned with the ESR spectra of the adsorbed oxygen and their stability.

Vanadium oxide catalyst was prepared as follows. Synthetic silica which was prepared by hydrolysis of ethyl ortho silicate was impregnated with aqueous solution of ammonium meta vanadate, followed by drying at 100°C and calcination in air at 500°C. The content of vanadium oxide was 5 wt%.

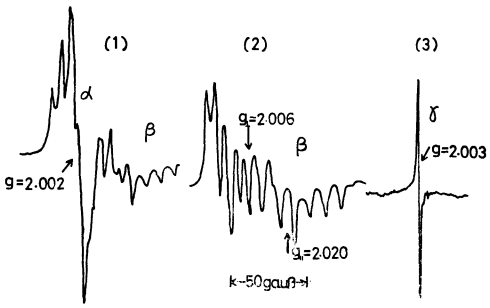

Fig. 1. ESR spectra of the oxygen adsorbed on $V_2O_{5-\delta}$-SiO_2.
(1) measured at −80°C. (P_{O_2} ; 20 Torr)
(2) measured at room temperature. (P_{O_2} ; 20 Torr)
(3) measured at room temperature. $V_2O_{5-\delta}$-SiO_2 was treated by O_2 at 200°C for 30 min and followed by evacuation at the same temperature.

Prior to the adsorption of oxygen, the catalyst was treated with hydrogen at 350°C in a glass reactor which had a quartz tube for ESR measurement as a side arm. This treated catalyst can be expressed as $V_2O_{5-\delta}$-SiO_2 ($\delta \simeq 0.1$).

ESR measurements were carried out at various temperatures by a 3BSX type spectrometer manufactured by Japan Electron Optics Co.

Some observed ESR spectra are shown in Fig. 1. Spectrum (1) is composed of two kinds of absorption signals. One (β-signal) is essentially the same as spectrum (2) which has h.f.s. due to interaction with ^{51}V ($I=7/2$),[3)] and the other (α-signal) is a singlet signal. At temperatures higher than −60°C, this α-singal is very unstable and disappears to leave β-signal. Spectrum (3) is a narrow singlet signal (γ-signal) observed for the catalyst treated with oxygen at 200°C. In Table 1, the temperature range in which each signal can be observed in spectra is shown together with characteristic parameters of signals.

By comparing these signals with those of the adsorbed oxygen on zinc oxide and titanium oxide, we tentatively assigned α-, β- and γ-signal as adsorbed $O_2^-(\alpha)$, $O_2^-(\beta)$ and O^- respectively. Preliminary studies on the reactivity of these adsorbed species reveal that $O_2^-(\beta)$ reacts with ethylene at room temperature and O^- reacts with sulfur dioxide at 200°C.

TABLE 1. CHARACTERISTICS OF SIGNALS

Signal	Observed temperature	g	A or ΔH_{msl} (gauss)
α	from −120°C to −60°C	2.002	$\Delta H=8.0$
β	from −120°C to 150°C	$g_{\parallel}=2.020$	$A_{\parallel}=9.4$
		$g_{\perp}=2.006$	$A_{\perp}=5.8$
γ	from 20°C to 350°C	2.003	$\Delta H=0.96$

The Reactions of Aroyl Peroxides with Grignard Reagents. I. On the Formation of a Stable Complex Containing Peroxide

Masao ŌKUBO,* Kazuhiro MARUYAMA** and Jirō ŌSUGI**

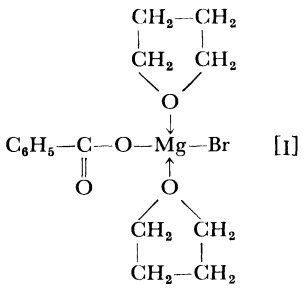
* *Government Industrial Research Institute, Nagoya*

** *Department of Chemistry, Faculty of Science, Kyoto University*

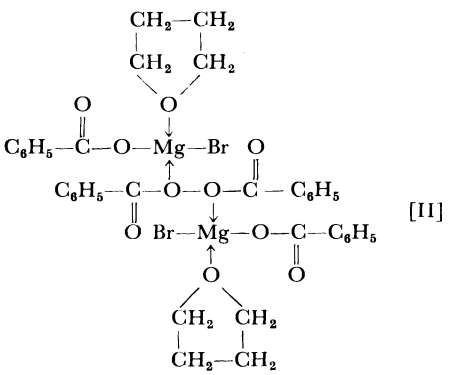
(Received January 30, 1969)

When a THF solution of BPO was mixed with the equimolar PhMgBr solution at 0°C under nitrogen stream and stirred for 2 hrs, 18—20% of BPO was found to remain in the solution. After the mixture was stood for 24 hr and/or even if it was heated at 50°C for 1 hr, the content of peroxide still remained unchanged. By adding ethyl ether to the concentrated reaction mixture, orange-yellow crystals were precipitated. The precipitate (ppt. 1) was filtered and dried in a vacuum-desiccator.*1 The ppt. 1 is fairly stable in air, but dissolves in water releasing bromine, finally to leave $(PhCOO)_2Mg$ and THF. The yellow color of the THF solution of ppt. 1 disappeared suddenly by the addition of a suitable amount*2 of PhMgBr solution, and the resulting mixture contained no peroxide.

On the other hand, when 50% molar excess of Grignard reagent to the peroxide was used and worked up similarly, no color change was observed during the course of the reaction, and white precipitate (ppt. 2), containing no peroxide was finally obtained. For the analysis of ppt. 2, the precipitate was dissolved in water, acidified and extracted with ether. Contents of Mg^{2+} and Br^- in the aqueous layer were analyzed by oxinechelate method[1] and $AgNO_3$-titration method, respectively. Content of THF in the ether layer was determined by v.p.c. technique. Analytical results are as follows: Mg^{2+} 7.8 (6.6)%; Br^- 21.7 (21.6)%; $PhCOO^{\ominus}$ 31.9(32.8)%; and THF 37.5(39.1)%. The values given in parentheses are calculated by assuming the formula[I] to ppt. 2. The yield of ppt. 2 based on the BPO used was quantitative. If a suitable amount of BPO was added to a THF solution of ppt. 2, an orange-yellow color appeared after a few minutes. When this solution was concentrated, orange-yellow precipitate was obtained, having the same composition as the ppt. 1. The peroxide content of ppt. 1 was determined by iodometry. A portion



[I]



[II]

of ppt. 1 was treated with $Fe(II)SO_4$ solution, and the amounts of Br^-, PhCOOH and THF were determined. From $[PhCOO]_{total}$ and $[PhCOO]_{BPO}$, one can estimate $[PhCOO^{\ominus}]$ in ppt. 1. Another portion of ppt. 1 was submitted to the analysis of Mg^{2+} content. Analytical results are as follows: Br^- 18.0(19.1)%; Mg^{2+} 5.5(5.8)%; $PhCOO^{\ominus}$ 35.0(29.0)%; BPO 18.4(29.0)%; and THF 15.7(17.2)%. The values given in parentheses are calculated by assuming the formula[II] to ppt. 1. Moreover, the same orange-yellow colored solution was obtained, if one added BPO to the completely carbonated PhMgBr solution. Taking account of the chemical behaviors of ppt. 1 and the said reaction, formula[II] seems to be reasonable. The fact that the ppt. 1 dissolves in water releasing bromine can be nicely explained by considering the electron-transfer from the Mg–Br linkage to the peroxidic linkage through the coordination bond. The lower content of BPO and the higher content of $PhCOO^{\ominus}$, compared with the calculated values, may be due to the gradual decomposition of the ppt. 1 by moisture.

---

*1 From the filtrate, PhCOOPh was obtained.

*2 When BPO was treated with 4/3 molar equivalent of PhMgBr, the peroxide was found to be consumed completely after 2 hrs at room temperature.

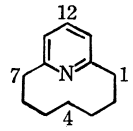
[7](2,6)Pyridinophane and [7](2,6)Pyrylophanium Perchlorate

Hitosi NOZAKI, Shinsaku FUJITA and Takasi MORI

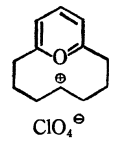
Department of Industrial Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received February 5, 1969)

Although preparation of [10](2,6)pyridinophane and 15-methyl[10](2,6)pyrylophanium perchlorate has been reported,[1] homologs with shorter methylene bridge still remain to be synthesized. In continuing the work on heterocyclophanes,[2] we were interested in the title compounds.



(I)



(III)

[7](2,6)Pyridinophane (I) (bp 70—73°C/3 mm Hg. Anal. Found: C, 82.5; H, 9.9; N, 7.7%) was obtained in a 44% yield by treatment of cyclododecane-1,5-dione (II) with 2.5 mol equivalents of hydroxylamine hydrochloride in an autoclave at 150—175°C. The dione II (mp 66.5—67.5°C, lit.[3] 64—65°C) was conveniently prepared by the Jones oxidation of cyclododecane-1,5-diol and/or by oxidation of *B*-acetoxy-13-borabicyclo[7.3.1]-tridecane[4] with aqueous sodium dichromate in ether.

Compound I exhibited aromatic absorptions (neat) at 3060, 1588 and 1575 cm^{-1} and a UV maximum (EtOH) at 272 nm (log ε 3.50). The bathochromic shift in the UV absorption as compared with [10](2,6)pyridinophane[5] may be ascribed to the nonplanar pyridine ring bridged by the heptamethylene group. The aromatic NMR signal (3 protons) (Fig. 1) showed a typical AB_2 pattern (ν_A δ 7.40, ν_B δ 6.87, J_{AB} 7 Hz) which resembled the splitting pattern of 2,6-lutidine very closely. The absorptions due to the heptamethylene protons were composed of three groups of multiplets. Protons of one methylene (a quintet at δ 0.16) were unexpectedly shielded in comparison with usual paraffinic methylenes. Tentatively, we assign the absorption to C_4 protons[6] locating close to the pyridine ring on inspection of the Dreiding model. Since the multiplet (centered at δ 2.84) due to C_1 and C_7 protons can be regarded as a triplet approximately, the heptamethylene chain should be flexible at room temperature.[2] Heating of I with a mixture of 30% hydrogen peroxide and acetic acid failed to give the *N*-oxide, whereas similar treatment of [10](2,6)-pyridinophane afforded the corresponding *N*-oxide.[1a] This is another point of difference introduced by the shorter polymethylene chain.

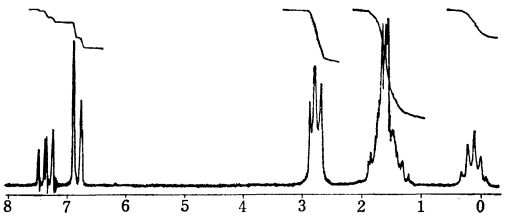


Fig. 1. NMR spectrum of I (in $CDCl_3$ at 24°, 60 MHz).

Reaction of II with trityl perchlorate in glacial acetic acid at 110—120°C afforded [7](2,6)-pyrylophanium perchlorate (III) (mp 150°C (dec.). Found: C, 52.6; H, 6.0; Cl, 12.6%) in a 65% yield. The IR spectrum (Nujol) exhibited aromatic bands at 3060, 1627 and 1498 cm^{-1} and a broad band due to the perchlorate anion at 1088 cm^{-1}. The NMR spectrum of III (in trifluoroacetic acid) consisted of an AB_2-type signal (3 aromatic protons, ν_A δ 8.85, ν_B δ 7.98, J_{AB} 8 Hz), a triplet at δ 3.42 (4 methylene protons on C_1 and C_7), a multiplet at δ 2.4—1.5 (8 methylene protons on C_2, C_3, C_5 and C_6) and a quintet at δ 0.82 (2 methylene protons on C_4). Treatment of the pyrylium salt III with ammonium acetate in glacial acetic acid yielded the pyridinophane I (66%) which was identical with the sample prepared directly from II.[7] Details of the experiments and further discussions will be presented in a paper to be published later.

Radical Formation in the Radiolysis of Solid Isobutane as Studied by ESR Spectroscopy

Terunobu WAKAYAMA, Tetsuo MIYAZAKI, Kenji FUEKI and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received February 10, 1969)

Extensive studies have been made of the mechanism of radical formation in the radiolysis of hydrocarbons in condensed phases. Generally speaking, primary radicals can be produced from the neutralization reaction between positive ions and electrons, the ion-molecule reaction, and the decomposition of directly excited molecules or ions. It is of essential importance for understanding elementary processes in radiation chemistry to elucidate the mechanism of radical formation in irradiated systems. Most of the previous studies were based on the analysis of final products and not on the direct observation of radicals.

In the present work, we have made an ESR study of radicals produced in γ-irradiated isobutane with and without additives at 77°K. Figure 1(a) shows the ESR spectrum of pure isobutane, which is assigned to the isobutyl radical.[1] Figure 1(b) shows the ESR spectrum of isobutane containing 1 mol% carbon tetrachloride.
It is seen from a comparison of Fig. 1(a) and (b) that there is a drastic change in the spectrum. The absorption line (A) in Fig. 1(b) is attributed to the CCl_3 radical.[2] Figure 2 shows the relative yields of isobutyl radical and CCl_3 radical against the concentration of carbon tetrachloride. The yield of isobutyl radical decreases and that of CCl_3 radical increases with increaseing concentration of carbon tetrachloride.

We have also investigated the radical formation in γ-irradiated isobutane containing ethyl iodide. The ESR spectrum of ethyl radical was observed in this system, while the yield of isobutyl radical did not change significantly with increasing concentration of ethyl iodide. It can be said that the ethyl radical is produced by dissociative electron attachment to ethyl iodide. The addition of electron scavengers such as nitrous oxide and sulfur hexafluoride also did not cause a change in the yield of isobutyl radical.

These results indicate that in the radiolysis of solid isobutane the isobutyl radical is not produced from the neutralization reaction, but mainly from the decomposition of directly excited isobutane molecules or ions, and that energy transfer from isobutane to carbon tetrachloride plays a role in suppressing the decomposition of isobutane.

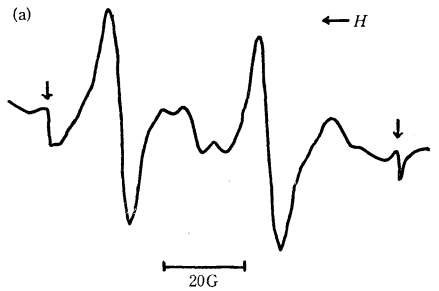

Fig. 1 (a)

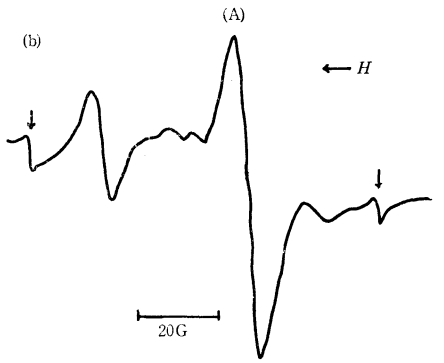

Fig. 1 (b)

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1165—1170 (1969)

The Surface Structure of Silica Gel Studied by Dielectric Dispersion*1

Seiichi KONDO

Osaka University of Education, Tennoji-ku, Osaka

and Masa-aki MUROYA

Osaka Electro-Communication University, Hatsu-machi, Neyagawa

(Received June 11, 1968)

The effect of water adsorption and heat treatment at various temperatures between 200 and 1100°C on the dielectric dispersions of silica gel was measured in the frequency range from 50 to 3×10^6 Hz and 9.81 GHz and in the temperature range from −196°C to 180°C. Two anomalous dispersions (Dispersion I and II) and one anomaly (Anomaly III) were found. The mechanisms of those anomalies were discussed in relation to some physical properties and silica crystal structures. Dispersion I, having activation energy ΔE equal to 11 to 14 kcal/mol, can be ascribed to the monomolecular layer of adsorbed water. Dispersion II, with activation energy of about 5 to 7 kcal/mol, can be attributed to proton diffusion through hydrogen-bond chain of surface silanol groups. Anomaly III, having activation energy of about 3 kcal/mol, may be assigned to dipolar rotation of free silanol.

Recent studies of the surface structure of silica gel by means of dielectric measurements,[1-3] infrared spectroscopy[4] and so forth have revealed many interesting aspects in detail. However, there are still some ambiguities on the nature of surface silanols and their interaction with adsorbed molecule. In this report, dielectric dispersions of silica gel were studied in respect to the effect of heat treatment and water adsorption and some interpretations of these results in combination with other physical properties are given in view of the surface structure of silica gel.

Experiment

Dielectric Measurement. The dielectric constant of silica gel in the frequency range from 50 to 3×10^6 Hz was measured with an Ando Electric Model TR-1 transformer-bridge. A dielectric cell A in Fig. 1 is composed of two coaxial cylindrical electrodes in a glass container with electric capacity of about 10 pF. The temperature of the cell can be changed from −196 to 180°C with the constancy of less than ± 1°. The dielectric constant at 9.81 GHz was measured by a transmission-line method. In this case, the sample holder was constructed so that the atmosphere and temperature of the holder could be controlled easily from −60 to 100°C within ± 1°.

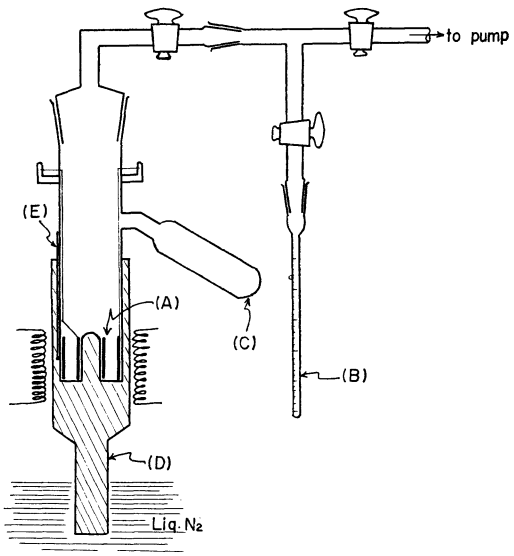

Fig. 1. Low frequency dielectric cell (A), with water burette (B), borosilicate or quartz glass tube for heat treatment (C), copper block (D), and Cu-Constantan thermocouple (E).

In order to obtain the real part of the dielectric constant ε', from the apparent value E, measured with powder sample, Pearce's equation[5] was used.

$$\frac{E-1}{\varepsilon'-1} = \frac{(1-v)P}{1-vP} \quad (1)$$

Here, v is the parameter which is determined empirically and P is the volume filling factor, being equal to the ratio of bulk density of packed powder and particle density listed in Table 1. Values of the dielectric constant of powder materials of known dielectric constant obtained by this method are in good agreement with those of literature in the range under investigation.

TABLE 1. CHEMICAL COMPOSITION AND PHYSICAL PROPERTY OF SILICA GEL

Na_2O	0.01%
Fe	0.005%
Al	0.03%
Specific surface area	700 m^2/g
Pore volume (V_p)	0.35 cc/g
Particle density (d)	1.24 g/cc

Material. Silica gel was synthesized from sodium silicate and sulferic acid of analytical grade and washed carefully with dilute hydrochloric acid and distilled water. The material dried was powdered to less than 80 mesh. Some of the physical and chemical properties of the sampe thus obtained are shown in Table 1, where specific surface area, S m^2/g, was determined by BET method using nitrogen and pore volume, V_p cc/g, by liquid immersion method using ethyl alcohol. Particle density, d g/cc, of silica gel granule, which is the aggregate of primary particles having the density of 2.2 g/cc, was calculated by the following formula.

$$d = \frac{1}{V_p + 1/2.2} \quad (2)$$

The amount of water adsorbed on silica gel was obtained by drying a known amount of sample in cell A in Fig. 1 at 170°C for two hours under vacuum of 10^{-4} mmHg and then introducing to cell A a necessary amount of water in burette B which was degassed beforehand. Silica gel was heat-treated in vacuum of 10^{-4} mmHg in the quartz container C at various temperatures from 200 to 1100°C for about 2 hr and then transferred to A. There is no exposure of silica gel to the atmospheric air in the procedure.

Experimental Results

Effect of Adsorbed Water (Dispersion I). Figure 2(a) shows the curves of tan δ *versus* frequency of silica gel at 23°C having various amount of adsorbed water. The heights of tan δ maxima of these curves are roughly proportional to water content of silica gel from 0 to 10% as seen in Fig. 3. Those heights become approximately constant beyond 10% water but the accompanying increase of tan δ background level makes the measurement less accurate. Since the monomolecular layer of water is completed statistically at about 10% water, this anomaly may be interpreted as related to this statistical monomolecular layer. Tan δ maxima change with temperature as seen in Fig. 2(b), in a similar manner to tan δ *versus* frequency curves in Fig. 2(a). In this figure, we find another one at lower temperature side being discussed in

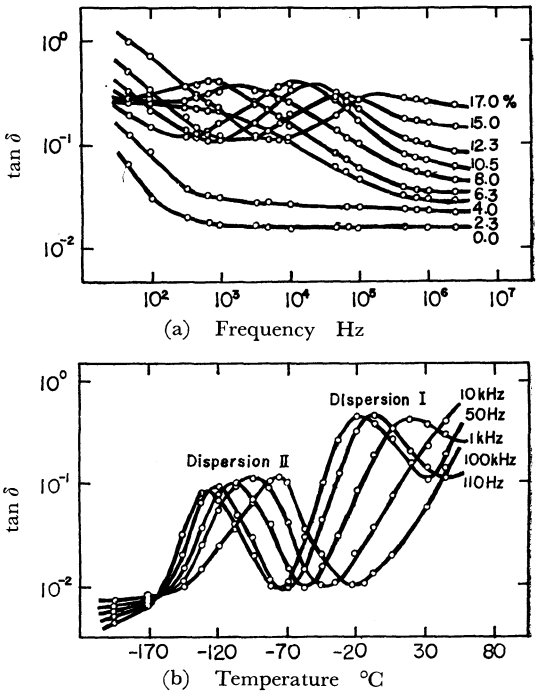

Fig. 2. Dielectric loss of silica gel with various water content.
(a) shows the frequency *versus* tan δ curves at 23°C.
(b) shows the temperature *versus* tan δ curves at 5.3% water adsorption.

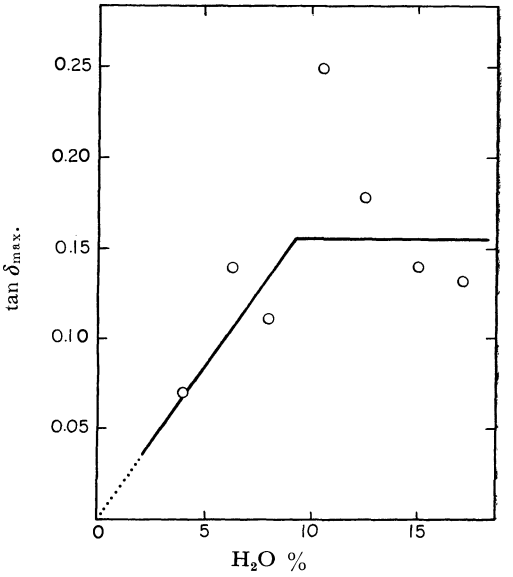

Fig. 3. Relation between the peak heights of tan δ maxima and water content of silica gel of Dispersion I at 23°C.

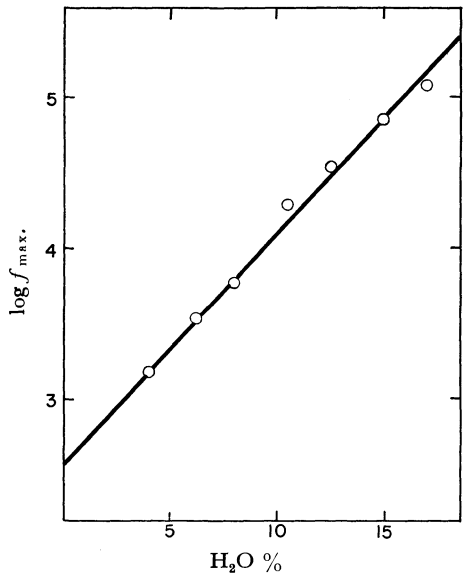

Fig. 4. Log frequency of tan δ maximum of Dispersion I *versus* water content of silica gel at 23°C.

the next section. In Fig. 4, water content is proportional to the shift of frequency of tanδ maximum at 23°C. At constant frequency, water content is proportional to the temperature of tan δ maximum.

Figure 5 shows the curves of complex dielectric constant *versus* frequency at 5.3% water adsorption

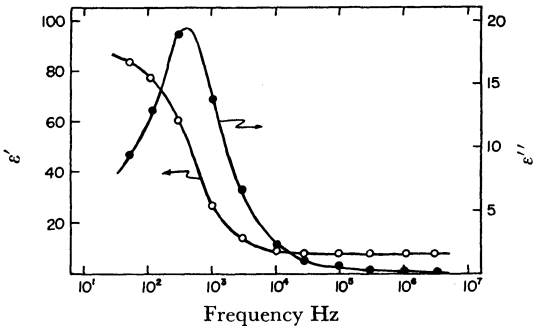

Fig. 5. Frequency *versus* complex dielectric constants, ε' and ε'', curves of Dispersion I of silica gel of 5.3% H_2O and at 23°C.

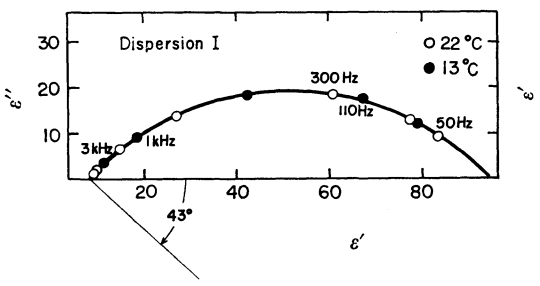

Fig. 6. Cole-Cole arc plots of Dispersion I of silica gel of 5.3% H_2O at 13 and 22°C.

and 23°C. These curves are characteristic of dielectric dispersion, so this anomaly will be called Dispersion I hereafter in this report. Cole-Cole arc plots of Dispersion I at 5.3% shown in Fig. 6 deviate largely from semi-circle law and indicate a large distribution of relaxation times. However, it is difficult to tell whether Dispersion I is the Debye or Maxwell-Wagner type from data available in this study. Figure 7 shows the curves of log relaxation time, τ, *versus* reciprocal temperature obtained from Cole-Cole arc plots, mentioned above, at various temperatures, together with the values at 11.5% water adsorption measured by Kamiyoshi.[2] Table 2 shows activation energies ΔE and constant τ_0 of Dispersion I and those by Kamiyoshi[2] and of ice measured by Auty and Cole.[6] These values of Dispersion I are close to those of ice and differ from that of water. This similarity suggests the existence of some kind of ordered configuration of

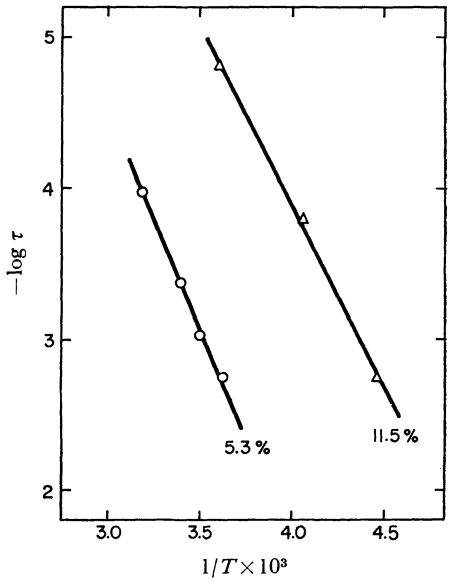

Fig. 7. Log relaxation times τ *versus* reciprocal temperature of Dispersion I by the present investigation and by Kamiyoshi[2] shown by circular and triangle plots respectively.

TABLE 2. ACTIVATION ENERGY ΔE AND RELAXATION TIME τ_0 OF DISPERSION I OF SILICA GEL CONTAINING ADSORBED WATER AND OF ICE[6]

H_2O %	ΔE (kcal/mol)	τ_0 (sec)
5.3	14.2	2.5×10^{-16}
11.5*	11.3	5.9×10^{-15}
ice	13.2	5.3×10^{-16}

* These were obtained by Kamiyoshi.[2]

adsorbed water molecule on silica gel surface, which will be discussed in section IV.

Silica Gel Without Adsorbed Water (Dispersion II). Figure 8(a) and (b) show the curves

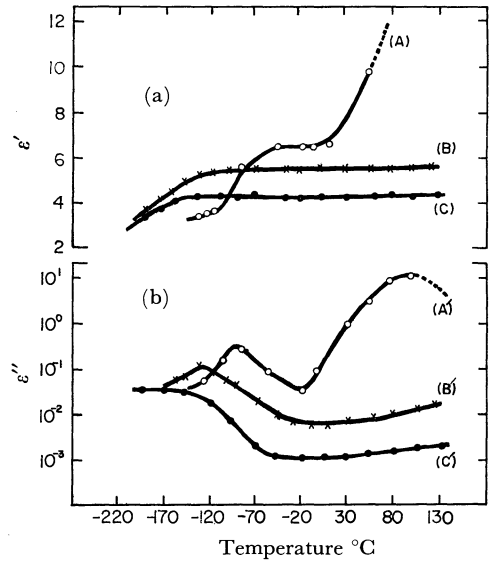

Fig. 8. Real and imaginary parts of complex dielectric constants *versus* temperature curves are shown in figures (a) and (b) respectively. Curves (A), (B) and (C) show those values at 1% H_2O, and 200 and 300°C of heat-treatment of silica gel, respectively. Note Dispersion I appearing at higher temperature.

of ε' and ε'' at 1 kHz against temperature of silica gel thermally treated at 200 and 300°C (curves B, C, B′ and C′) and those of 1% water adsorption (curves A and A′). The anomaly at 1% water adsorption of curves A and A′ is Dispersion I as described in section 1. The anomaly at −100°C can be observed not only in curves A and A′ but

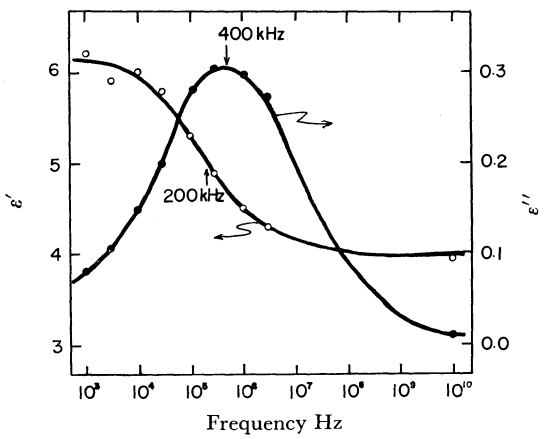

Fig. 9. Frequency *versus* complex dielectric constant curves of Dispersion II of silica gel at −58°C and 1% H_2O.

also in curves B, B′, C and C′ in which silica gels are treated at higher temperature. The curves of ε' and ε'' *versus* frequency of this anomaly at −58°C and 1% water adsorption for example, as seen in Fig. 9, suggest this anomaly to be a dielectric dispersion (Dispersion II). In this figure, the frequency of inflection point of ε' curve, about 200 kHz, differs from that of ε'' maximum, about 400 kHz, and this discrepancy suggests Dispersion II being the Maxwell-Wagner type. Cole-Cole arc plots of Dispersion II, shown in Fig. 10, indicate

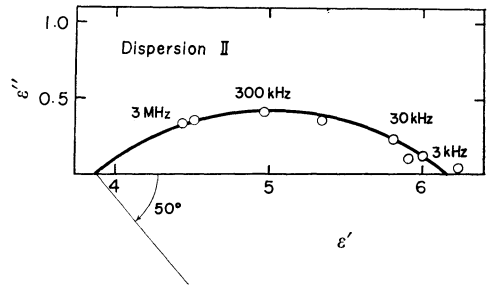

Fig. 10. Cole-Cole arc plots of Dispersion II of silica gel at −58°C and 1% H_2O.

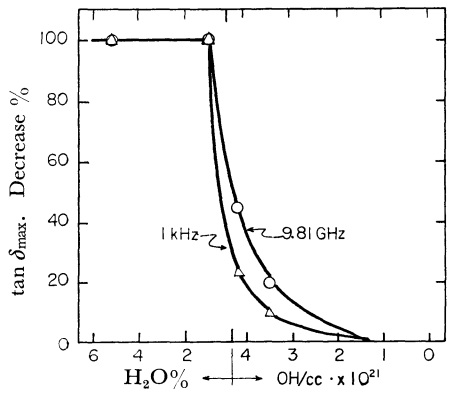

Fig. 11. Relation of decrease of the height of tan δ maxima shown by per cent of Dispersion II to water content and OH concentration per unit volume of silica gel.

the existence of large distribution of relaxation times as often seen in colloid system.[7] Figure 11 shows the height of tanδ maxima of Dispersion II at 1 kHz and 9.81 GHz against water adsorption and the concentration of silanol groups per unit volume which is equal to the weight loss by heating in the form of water divided by particle density at the temperature of heat treatment. ε'' maxima are not affected by the amount of water adsorption, become smaller by the decrease of hydroxyl concentration (or the increase of temperature) and are unobservable at about 500°C. The

7) S. Oka, "Theory of Solid Dielectrics," Iwanami Press, Tokyo (1964), p. 161.

values of ε' decrease also by elevating temperature and become almost constant and equal to that of vitrous silica above 500°C. This shows the decrease of contribution of polar silanol groups to the dielectric constant. From those results, it seems reasonable to assume Dispersion II to be caused by the diffusion of ion such as proton through hydrogen-bond chain of surface silanol groups.

The relation of log frequency of ε'' maxima of this dispersion to the reciprocal temperature is shown in Fig. 12 on silica gel treated at four different conditions; 5.3 and 1% water adsorption and 200 and 300°C of heat treatment. ε'' maxima at 2.89 GHz obtained by Le Bot and Le Montagner[1] and at low frequency by Kamiyoshi and Ripoche[3] on silica gel both dried at 110°C (about 1% water adsorption) are well on the line of 1% water of the present investigation. Table 3 shows the activation energies obtained from Fig. 12. The activation energies at 5.3% and 1% water are much larger than those without water. This may suggest the higher potential barrier for ionic diffusion by the presence of bound water. It should be added that Dispersions I and II have been found with deuterium-exchanged silica gel showing similar behavior to the ordinary silica gel.[8]

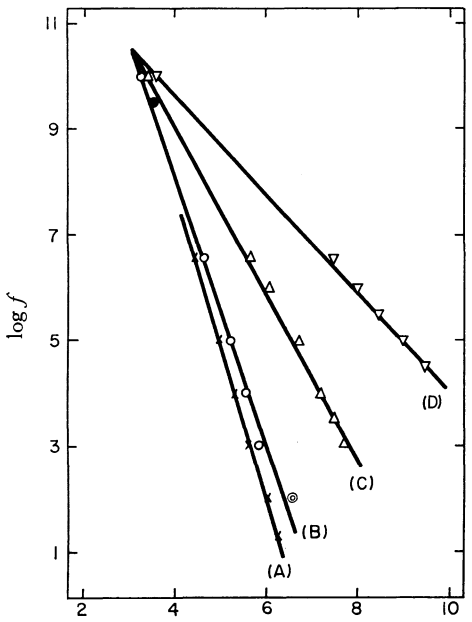

Fig. 12. Log frequency *versus* reciprocal temperature curves of Dispersion II of silica gel, in which (A), (B), (C) and (D) show those of 5.3% H_2O, 1% H_2O, and 200 and 300°C of heat treatment respectively and black and double circles show the values measured by Le Bot[1] and Kamiyoshi[2] respectively.

Table 3. Activation energy ΔE and relaxation time τ_0 of Dispersion II of silica gel containing adsorbed water and treated thermally

	ΔE (kcal/mol)	τ_0 (sec)
5.3 H_2O %	14.0	4.0×10^{-21}
1.0 H_2O %	11.4	1.9×10^{-18}
200°C	6.8	8.3×10^{-16}
300°C	5.0	1.6×10^{-14}

High Temperature Heat Treatment (Anomaly III). A very small maximum of ε'' can be observed at −178°C and at 1 kHz on silica gel treated at 500°C as seen in Fig. 13. This maximum becomes smaller by elevating the temperature of heat treatment and becomes unobservable at 1000°C. Therefore, this anomaly may be related to silanol groups existing above 500°C. Owing to the smallness of this anomaly, it is difficult to obtain the values of dielectric constant accurately and sufficiently enough to tell whether this is a dielectric relaxation. However, an approximate activation energy was obtained from the dependency of ε'' maximum frequency on temperature. ΔE and τ_0 are equal to about 3 kcal/mol and 1×10^{-10} sec respectively. The smallness of the activation energy suggests that this anomaly might be caused by the rotation of free silanol dipoles surviving after heat treatment.

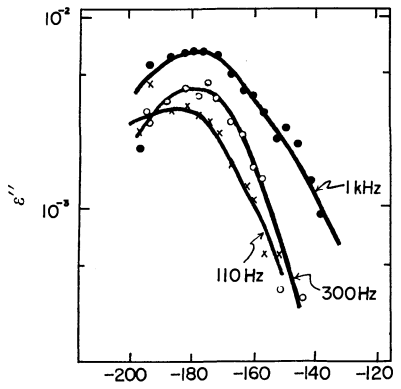

Fig. 13. Curves of imaginary part of the complex dielectric constant *versus* temperature of silica gel heat-treated at 500°C.

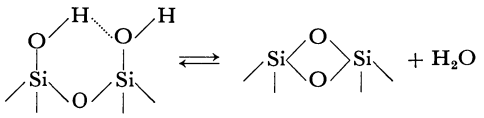
Discussion

The weight loss of silica gel by heating is usually considered to be caused by desorption of adsorbed water and condensational dehydration of surface

8) S. Kondo and M. Muroya, presented at the 21st Annual Meeting of The Chemical Society of Japan, 1968.

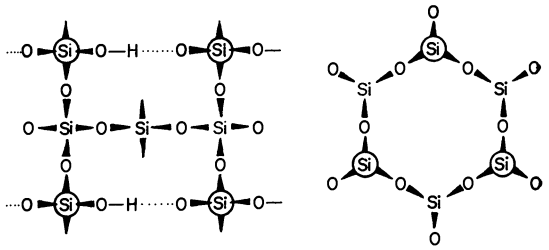
silanol groups. However, it is difficult to distinguish between each other by such means as thermogravimetric analysis and infrared spectroscopy. In the latter case, a broad and strong band at about 3500 cm^{-1} and at room temperature becomes gradually weaker by heating and almost disappears at about 600°C. On the other hand, a sharp band at 3750 cm^{-1} which is very obscure at low temperature becomes clear by heating. This latter band starts to decrease from about 600°C and disappears at 1000°C. The 3500 cm^{-1} band can be assigned to the hydrogen-bonded O–H stretching vibration of either adsorbed water or surface silanol. Since adsorbed water desorbs almost completely at 200°C as studied by the thermal behavior of Dispersion I, this band above 200°C may be assigned to the hydrogen-bonded silanol groups, in which the Dispersion II of this report originates.

Models to illustrate the structure of this type of hydrogen-bonded surface silanol have been proposed by several authors[4,9] as shown below.



With such a model, however, it seems rather difficult to construct a reasonable siloxane skeletal structure in three dimensions and to satisfiy such physical properties of the surface as silanol surface density of about 8/100 Å^2. Moreover, the dehydration reaction according to this model requires a considerable distortion of valence angle of surface siloxane or deformation of succesive skeletal siloxane, which would cause changes of physical properties such as the decrease of surface area. This is not likely because the surface area decreases markedly only above about 500°C and drastic change of the structure starts above 700°C depending upon the nature of impurities.[10]

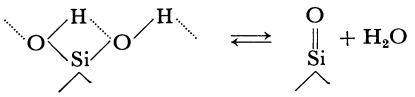
In this report, the model as shown in Fig. 14 (a) and (b) is taken into consideration under the assumption that primary particle of silica gel has a very short range order of siloxane structure similar to some of the silica crystals such as cristobalite, tridymite and quartz. In these crystals the silicium atom exposed on the crystal plane surface can possess one or two hydroxyl groups depending upon the index of the plane. Figure 14 (a) and (b) show the (100) and (111) planes of cristobalite as example, since the density of silica gel, 2.2 g/cc, is almost equal to that of cristobalite and silica gel changes to cristobalite most easily by heating. In Fig. 14 (a), each silicium atom on the (100) plane



(a) (b)

Fig. 14. (a) and (b) are (100) and (111) crystal planes of cristobalite respectively. Rounded Si atoms are on the top surface.

can have two hydroxyl groups which would form hydrogen-bond chain with each other with the distance of about 2.7 Å and whose surface density is 7.85/100 Å^2. Dispersion II may be attributed to the proton diffusion through those one-dimensional chains of hydrogen-bond. Without adsorbed water, the activation energy for this diffusion may not be as large as that with the presence of adsorbed water as seen in Table 3. The dehydration reaction with this model would be as follows;



although we have no evidence for the existence of Si=O.

In such a model, the first layer, at least, of adsorbed water might have some kind of very short range order which may be three dimensional by including substrate structure, and the activation energy for the proton diffusion would be larger than that of water and close to that of ice as shown in Table 2. Considering the statistical nature of this quasi-crystalline model, the distribution of relaxation times may be large, as shown in this report.

The Anomaly III and the 3750 cm^{-1} band can both be assigned to free silanol groups. It might be interesting to see that silicium atoms on the (111) plane of cristobalite, as shown in Fig. 14 (b) for example, can have one hydroxyl group whose distance to each other is about 5 Å and is too far to form a hydrogen-bond and which has low surface silanol density of 4/100 Å^2. The dehydration reaction of such type of silanol requires some rearrangement of skeletal structure at high temperature and leads to the decrease of specific surface area and crystal growth.[10]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1171—1178 (1969)

Mechanism of Emulsification with Special Reference to Solid Stabilized Emulsions

S. P. JAIN and S. N. SRIVASTAVA

Chemical Laboratories, Agra College, Agra, India

(Received March 9, 1968)

Mechanism of emulsification with special reference to ferric hydroxide as emulsifier has been studied. The sol of ferric hydroxide having maximum possible stability has been prepared. Its particle size as determined by electron microscope is of 63 Å radius. The stability of the sol in presence of different amounts of electrolytes of different valencies has been studied by measuring its zeta potentials in terms of interaction energy curves. By using these different stages of partially flocculated ferric hydroxide sol as emulsifier the emulsions of toluene in water were prepared and their relative stabilities assessed by adding various electrolytes. Then the stability of the emulsions formed has been studied by the measurement of zeta potentials micro-electrophoretically in the light of the D.V.O. theory. The size of the emulsion globules as determined microphotographically is 1.1μ radius. The pH and interfacial tension measurements have also been carried out. From interfacial tensions between the disperse phase and the dispersion medium at different amounts of electrolytes, the surface charge of the emulsions has been deduced which is found to be in good agreement with the electrophoretic results. Finally a correlation has been sought between the stability of the emulsions and the corresponding partially flocculated sols used in emulsification.

A few workers[1-4] have used insoluble inorganic precipitates such as calcium and barium carbonates, basic sulphates, oxychlorides, hydrous oxide and hydroxides of various metals as emulsifiers. Pickering[5] was first to use such substances as emulsifiers for oil in water type of emulsions and was able to conclude that the size of the oil globules depends on the size of the powder. An analogous behaviour was also observed by Bechhold, Dede and Reiner[6] who concluded that smaller the grains the better is the emulsion until an optimum is reached after which smaller grains have less effect. Briggs[7] found that oil in water type emulsions could not be stabilized with colloidal ferric hydroxide or arsenious sulphide but can be obtained by the addition of some weak flocculating agents. However, emulsification was not possible by the completely flocculated sol. A similar effect was also noticed by Van der Waarden[8] for emulsions of water in mineral oil which could only be stabilized by asphaltenes if the asphaltenes were near or above the point of incipient flocculation.

In the literature the theories of stabilization of the emulsions by the solid particles generally deal with the effect of wetting and with the contact angle. Therefore, in the present work it is proposed to explain the mechanism of emulsification and subsequent stabilization on the basis of energy considerations.

Materials and Preparations

The ferric chloride and ammonium carbonate for the preparation of sol were of Analar Grade obtained from B.D.H. For the preparation of emulsion the oil phase toluene was of B.D.H. Analar Grade, which was weighted by bromoform obtained from Rhome-Poulene, France and was distilled and the fraction of 148—149°C were collected. All the other chemicals used were of B.D.H. or E. Merck (Analar Grade) and used as such. The glass apparatus used was all pyrex and the water was twice distilled.

The ferric hydroxide sol was prepared by adding concentrated ammonium carbonate solution to a solution of ferric chloride with constant stirring until the precipitate just ceased to dissolve. The precipitated ferric hydroxide was then dissolved by adding just the sufficient quantity of concentrated ferric chloride solution. The sol was then dialysed in a parchment paper bag against running distilled water, until maximum stability obtained.

The concentration of the sol was 0.002 g/m*l* of ferric hydroxide. To this sol were then added different

amounts of electrolytes so as to bring about partial flocculation. Then 5 m*l* of toluene were dispersed per 100 m*l* of the partially flocculated sol, the dispersion medium. The emulsions were first well hand shaken and then homogenized well in a hand operated stainless steel homogenizer (C.W. Logenman Co., U.S.A.). The sampling was done under identical conditions.

Experimental and Theoretical

The Sol. The size of the sol particles was determined by taking the photographs (Fig. 1)

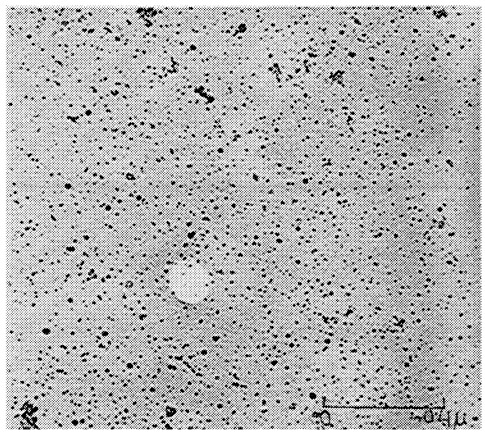

Fig. 1. Electron micrograph of $Fe(OH)_3$ sol × 77600.

by the electron microscope using 19400 x times magnification. The size of 400 particles was then measured with the help of a Cathetometer and a size frequency curve was plotted as shown in Fig. 2. The average radius was found to be 63 Å.

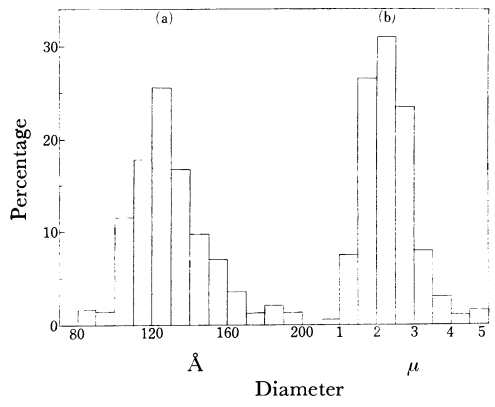

Fig. 2. Size-distribution curves.
Percentage of particles *vs.* diameter
(a) For $Fe(OH)_3$ sol (b) For Emulsion

The electrophoretic mobility of sol particles was measured by a modified form of the Burton tube method. The equiconducting solution of lithium chloride in the outer electrode vessel was used to prepare a sharp boundary, a constant current was supplied to the electrodes and the voltage across the two ends of the U tube was read off by the potentiovacuum tube voltmeter. The movement of the sol boundary per second under the applied potential gradient was measured by the Cathetometer and the electrokinetic potential ζ was calculated by the Hückel[9] equation. The correction for relaxation and the Henry effect were made using following equations given by Overbeek.[10]
For symmetrical electrolytes.

$$U = \frac{\varepsilon\zeta E}{6\pi\eta}\left[f_1(\kappa a) - Z^2\left(\frac{e\zeta}{kT}\right)^2 f_3(\kappa a) - \frac{\rho_+ + \rho_-}{2e}\frac{\varepsilon kT}{6\pi\eta e}\left(\frac{e\zeta}{kT}\right)^2 f_4(\kappa a)\right] \quad (1)$$

and for unsymmetrical electrolytes.

$$U = \frac{\varepsilon\zeta E}{6\pi\eta}\left[f_1(\kappa a) - (Z_+ - Z_-)\frac{e\zeta}{kT} f_2(\kappa a) - \frac{Z_+\rho_+ + Z_-\rho_-}{(Z_+ + Z_-)e}\frac{\varepsilon kT}{6\pi\eta e}\left(\frac{e\zeta}{kT}\right)^2 f_4(\kappa a)\right] \quad (2)$$

where U is the mobility per second per unit potential gradient, ε the dielectric constant (taken to be equal to the bulk phase *i. e.* for water at 25°C), η the viscosity of the medium, Z_+ and Z_- are the valencies, and ρ_+ and ρ_- the frictional constants of the cations and anions respectively, and f_1 is identical with the Henry function, f_2, f_3 and f_4 are the functions dependent on the values of κa which were noted from the tables.[11]

The interactions between the colloidal particles of lyophobic systems have been quantitatively treated by Derjaguin,[12] Verwey and Overbeek[13] (D.V.O. theory). On the basis of the free energy of the double layer and the London - Van der Waals' dispersion forces. According to their theory the net force on mutual approach of the particles is a resultant (V) of an attraction V_A and a repulsion V_R which increases differently as the distance apart decreases. The double layer repulsion V_R for the present system has been calculated from an approximate equation given by

$$V_R = \frac{\varepsilon a \Psi_0^2}{(U+2)} e^{-\tau U} \text{ (for small values of } \tau) \quad (3)$$

where ψ_0 is the surface potential (assumed to be eual to the electrokinetic potential for the present system), $U = H_0/a$ and $\tau = \kappa a$ and a the particle

radius, H the interparticle distance and κ is the Debye-Hückel parameter. The attraction energy is calculated from the following equation.[14]

$$V_A = -\frac{Aa}{12H} \tag{4}$$

Therefore, the total interaction energies of the lyophobic systems showing the nature of flocculation and the stability can be determined by the following equation.

$$V = \frac{\varepsilon a \Psi_0^2}{(U+2)} e^{-\tau U} - \frac{Aa}{12H} \tag{5}$$

The Emulsion. The size-frequency curve of emulsion was drawn by taking the photograph (Fig. 3) microphotographically with a Olympus

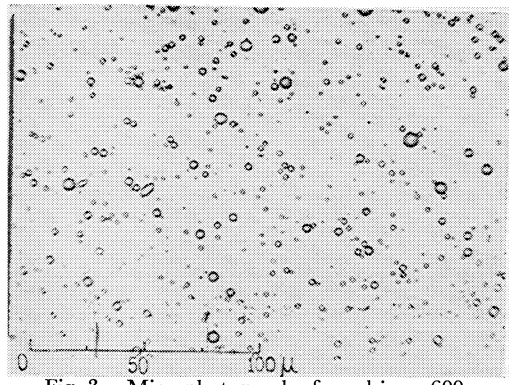

Fig. 3. Microphotograph of emulsion × 600.

Camera attached with a Olympus microscope. The radius of about 400 particles was measured by the Cathetometer and the average radius for all the emulsions was found to be 1.12μ (Fig. 2).

The electrophoretic mobility of the emulsions was determined by microelectrophoresis apparatus. The micro-electrophoresis cell used in the apparatus was of Northrup and Kunitz type, fitted in a special design apparatus and was set in a air conditioned room. The diluted emulsion was filled in the cell and the electrode vessels were filled with equiconducting potassium chloride solution to avoid diffusion. A constant d. c. voltage was applied between the two electrodes (Ag-AgCl) and the current was measured by the microammeter. From the velocity of the particles measured under the applied voltage the mobility U was calculated by the relation.

$$U = \frac{dSA}{it} \tag{6}$$

where d is the distance travelled by the particle in a time t under the influence of current i, S the specific conductance of the emulsion and A is the area of the cell.

From a knowledge of the mobility electrokinetic potential ζ can be calculated by the following equation due to Helmholtz and Smoluchowski, which is applicable to the case for spherical particles and $\kappa a \gg 1$.

$$\zeta = \frac{4\pi\eta}{\varepsilon} U \tag{7}$$

The total interaction energy between the two diffuse double layers of the emulsion globules is the summation of repulsive and attractive energies, where the repulsion energy can be calculated by the approximate equation given by Derjaguin and Kussakov.[15]

$$V_R = \frac{\varepsilon a \Psi_0^2}{2} \ln(1+e^{-\kappa H_0}) \tag{8}$$

and the attraction energy has been calculated from the following approximate equation.[16]

$$V_A = -\frac{Aa}{12H}\left\{\frac{\lambda}{\lambda+3.54H\pi}\right\} \quad \text{for } H<150\,\text{Å} \tag{9a}$$

$$V_A = -\frac{Aa}{\pi}\left\{\frac{2.45}{120H^2}\cdot\lambda - \frac{\lambda^2}{1045H^3} + \frac{\lambda^3}{5.62\times10^4\cdot H^4}\right\} \quad \text{for } H>150\,\text{Å} \tag{9b}$$

where λ is the wavelength of the London frequency (approximately equal to 10^{-5} cm) and A is the Van der Waals constant of the droplet.

Calculation of Surface Charge from Interfacial Tension. The Gibbs adsorption isotherm is

$$-d\gamma = \Gamma_S RT d\ln C_S \tag{10}$$

This permits the determination of the surface excess Γ_S of the adsorbed ions from a knowledge of change in interfacial tension γ with the concentration of the adsorbed ions C_S. The surface charge of the particle is given by the following equation.

$$\sigma = eV\Gamma_S \tag{11}$$

If no excess of electrolytes is present, Γ_S will not correspond exactly with ρ/ve, because there is a deficiency of same charge ions in the diffuse part of the double layer, though this deficiency is only a few percent of ρ.

The fraction of the counter ions present in the Stern layer can be represented by the following equation by the application of the Langmuir-Stern equation.[17]

$$\frac{\sigma_1}{eV} = \frac{N_1}{1+\frac{N}{n}e^{(ve\psi_0/kT)}} \tag{12}$$

where N_1 is the number of available positions in 1 cm^2 of the Stern layer (here assumed to be equal to 1×10^{15}), N is the number of positions available

14) H. C. Hamaker, *Physica*, **4**, 1058 (1937).

15) B. Derjaguin and M. Kussakov, *Acta Phys. Chim.*, **10**, 25, 155 (1939).

16) J. N. Schenkel and J. A. Kitchener, *Trans. Faraday Soc.*, **56**, 161 (1960).

17) H. R. Kruyt, "Colloid Science," Vol. I, N. Y. Elsevier, Amsterdam (1952), pp. 130, 133.

to the counter ions in 1 cm^3 of the homogeneous solution (which is to be equal to $6.02\times10^{23}/18$), n is the number of counter ions of valency V in 1 cm^3 of the homogeneous solution, e is the elementary charge and ψ_0 is the potential in the Stern layer with respect to a point in the aqueous phase far from the interface.

The diffuse part of the double layer has a charge σ_2 which is related to the potential at the boundary between the Stern and the Gouy Layers ψ_0 by the equation

$$\sigma_2 = \left(\sqrt{\frac{\varepsilon kT}{\pi}\sum nv^2}\right) \sinh\left(\frac{ve\psi_0}{2kT}\right) \qquad (13)$$

From the condition of electrical neutrality the total charge σ is

$$\sigma = \sigma_1 + \sigma_2 \qquad (14)$$

Thus the surface potential ψ_0 can be calculated as a function of n and σ with the help of the above equations.

The interfacial tensions between the disperse phase and the dispersion medium containing various amounts of sol and electrolytes were measured by the drop weight method. The apparatus used was as designed by Cook and Kitchener,[18] in which the drops of disperse phase were made at the edge of the capillary tube by the displacement of the mercury. A number of drops was allowed to fall into the dispersion medium, the average volume being noted from the reading of microburette. The interfacial tension was calculated by the formula

$$\gamma = \frac{v(d_2-d_1)}{rg} f \qquad (15)$$

where d_1 and d_2 are the densities of the disperse phase and the dispersion medium respectively, which were determined by the pycknometer taking water as standard, r the radius of the edge of the capillary, v the volume of the one drop of oil and f is the factor depending upon the value of v/r^3 being taken from the standard tables.[19]

Results

(a) Influence of Electrolytes on Zeta Potentials of the Sol. The ferric hydroxide sol was prepared in the excess of ferric chloride and was positively charged on account of excess of ferric ions, adsorbed to the surface of the ferric hydroxide sol particles. The flocculation was, therefore, brought about by different valent anions. The electrokinetic mobilities at different concentrations of electrolytes were measured and zeta potentials calculated by Eqs. (1) and (2). The

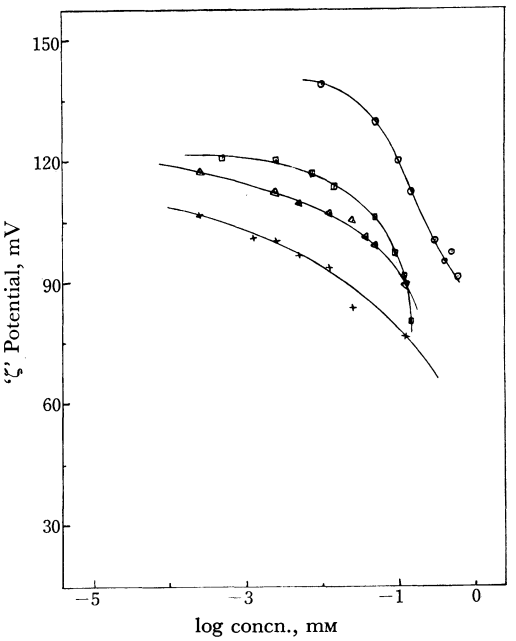

Fig. 4. Curves showing the variation in zeta potentials at various concentrations of electrolytes.

× Pot. ferrocyanide

observed value of the zeta potential of the initial sol is 154.5 mV at 25°C.

The curves for the zeta potentials of ferric hydroxide sol particles as a function of log molar concentration of different electrolytes, *viz* KBr, $K_2(C_2O_4)$, $K_3Fe(CN)_6$, $K_3(C_6H_5O_7)$ and $K_4Fe(CN)_6$ are represented in (Fig. 4). In general, the zeta potential decreases as the concentration of electrolytes increases. In case of potassium bromide and potassium oxalate the fall of zeta potential is

almost linear throughout, but in case of ferricyanide, citrate and ferrocyanide it is comparatively slow at the initial stages and then becomes sharp.

(b) Interaction Energy Curves. For the complete assessment of the stability of the sol in presence of different amounts of electrolytes the potential energies of interaction for the sol particles were calculated. Only representative energy profiles are shown in Figs. 5 and 6.

The curve I of Fig. 5 shows that the net potential energy of interaction of the ferric hydroxide sol corresponding to zeta potential 154.5 mV has the maximum energy $V_m=94.3\,kT$ which is indicative of the complete stability of the sol. In these calculations the value of the Van der Waals constant A is taken to be equal to 3.13×10^{-12} erg, the calculated value by the physico optical data which is in the range suggested by Overbeek (*loc. cit.*) for solid particles suspended in water.

In general by the addition of electrolytes the maximum energy V_m and hence the sol stability decreases with the increase in concentration of the electrolytes (Table 1).

(c) Studies of Zeta Potentials of the Emulsions. The initial emulsion with pure ferric hydroxide sol without any electrolyte had zeta potential equal to 63.5 mV (*cf.* this with the value 154.5 mV of the emulsifying sol). The corresponding emulsions were prepared by the partially flocculated sol and the zeta potentials are plotted in Fig. 7 against the log molar concentration of the electrolytes used for partial flocculation.

(d) Interaction Energy Curves and the Flocculation in the Secondary Minima. The potential energy V of the interacting emulsion droplets was calculated by Eqs. (8) and (9) and the energy curves were plotted, only a few typical curves being shown in Figs. 8 and 9 in case of potassium oxalate and potassium ferrocyanide.

From these curves it is seen that in all the emulsions globules possess a high potential energy barrier at intermediate distances, the extent of which depends upon the values of the zeta potential which invariably varies with the electrolyte concentrations. At small and larger separating distances between the particles there is net attraction which shows that at higher distances the particles are flocculated but still separated by a larger distance, called secondary minimum flocculation. The secondary minima have also been represented separately in a more elaborate form on the same graphs and are found to be 3 to 6 kT deep at 500—800Å distances (*cf.* Schenkel and Kitchener[16]). In these energy calculations the value of Van der

Waals constant for the disperse globules in the dispersion medium is taken to be 1×10^{-12} erg which was obtained by physico optical data for toluene globules coated by ferric hydroxide sol and disperse in water. In case of all the electrolytes the potential energy first increases with the addition of electrolytes and after a certain maximum value it begins to decrease and the system becomes unstable.

The results obtained for ferric hydroxide sol and the corresponding emulsions for the various electrolytes are summarised in Table 1.

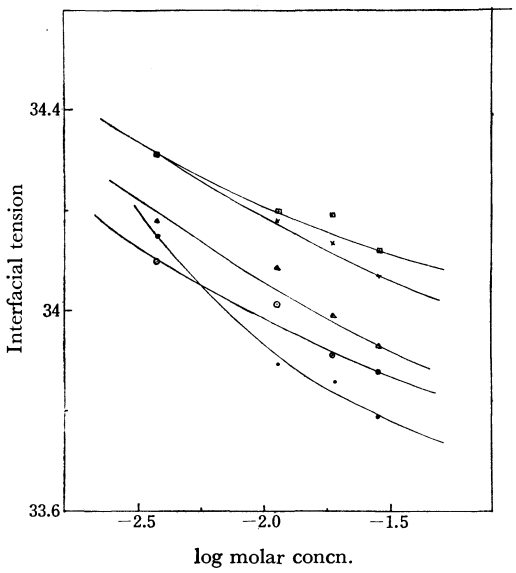

Fig. 10. Curves showing the change in interfacial tension with the concentration of $Fe(OH)_3$ sol in presence of Pot. bromide.

(e) Surface Charge by the Interfacial Tension. The change in interfacial tension with the concentration of ferric hydroxide sol in presence of different amounts of electrolytes has been also measured and a few representative curves have been shown in (Fig. 10). From these curves the surface excess of the sol particles at the particular concentration of the sol has been calculated which ultimately gives the total charge on the oil globules for that definite concentration of the sol.

The distribution of the charge between the Stern layer and diffuse double layer of the emulsion globule for the particular concentration of the sol at the same concentration of the electrolyte in the dispersion medium has been calculated from Eqs. (12), (13) and (14). A few typical curves showing the distribution of charge for the different values of $e\Psi_0/kT$ are given in (Fig. 11). From these curves the value of $e\Psi_0/kT$ has been calculated

corresponding to the experimentally obtained value of the total surface charge σ. The graphs in Fig. 12 have been plotted between the log molar concentrations and the value of $e\Psi_0/kT$ obtained from the interfacial tension data and the results are also given in Table 2. The results, in general, agree with those obtained electrophoretically.

(f) Effect of pH on the Stability of the Emulsion. This is depicted in Fig. 13 where it is found that pH of the emulsion continuously increases with the addition of the electrolyte. But zeta potentials first increase with pH, reach a maximum and then decrease regularly. The increase in pH may be due to desorption of OH^- ions from the flocculated particles which are obtained by the addition of respective anions.

Similar curves were obtained when pH is adjusted after emulsification.[20]

Discussion

The zeta potential of the emulsion prepared by the most stable ferric hydroxide sol (having zeta= 154.5 mV and energy barrier 94.3 kT) was 63.5 mV but by the addition of small amounts of different electrolytes the zeta potential of the emulsion first increases with the increase of electrolyte and after a certain maximum value it decreases by the further addition of electrolyte thereby indicating instability. It can be seen from Fig. 7 that the decrease is much more sharp in case of mono and bivalent anions than with tri and tetra valent.

However, when the sol is partially flocculated by the additon of electrolytes and the zeta potential is lowered to about 110 ± 10 mV and the corresponding energy barrier is reduced to nearly 40 ± 5 kT, more stable emulsions are obtained, which have zeta potentials in the range 115 ± 10 mV and the energy barrier above 7500 kT.

It is obvious that for the efficient stabilisation of an emulsion by solid particles some prevalent attraction between the sol particles is necessary. The emulsification is governed by the flocculation of the sol particles in the continuous liquid phase and the stabilizing power of solid particles as a function of their degree of flocculation thus first increases, then reaches a maximum and at still higher degrees of flocculation again decreases. Thus by the pure sol a stable emulsion cannot result on account of high potential energy barrier whereas in the case of flocculated sol by the addition of electrolytes stable emulsions can be formed when the potential energy barrier between the stabilising particles is reduced.

The authors wish to thank to Dr. S. K. Sharma, Scientist, National Physical Laboratories, N. Delhi for taking the electron microphotograph of the sol particles. They are also extremely grateful to the Ministry of Education, Government of India for the award of a research training scholarship to one of them (S.P.J.).

Studies in Nuclear Magnetic Resonance Spectroscopy. Long-range Shielding by Triple Bonds

J. M. JACKMAN and George Y. SARKIS

Department of Chemistry, University of Pennsylvania, Philladelphia, Pa., U.S.A.
Department of Chemistry, University of Baghdad, College of Science, Baghdad, Iraq.

(Received March 9, 1968)

The magnetic shielding of nuclei due to distant chemical groups may be calculated from the knowledge of the magnetic anisotropy of the bonds in these groups. The reverse procedure, namely, the calculation of the magnetic anisotropy of bonds from NMR relative chemical shifts has been employed here to estimate the magnetic anisotropy of $-C\equiv C$, $-C\equiv N$, and $-N\equiv C$ triple bonds. The paramagnetic contribution to the shielding of the acetylenic proton was estimated from the calculated value of $\Delta\chi^{C\equiv C}$, and from the known geometry of the molecule. The value thus obtained is compared with that calculated by quantum mechanical methods.

One of the persistent problems encountered in interpreting chemical shifts in NMR spectroscopy is of adequately taking account of effects produced by the magnetic anisotropy of neighboring atoms or groups. Unless this is done, it is difficult to decide what portion of an observed shift is indeed chemical. In certain cases, *e. g.*, acetylene and hydrogen cyanide, the occurrence of serious discrepancies between experimental shift and expectations have served to call attention to the existence of important anisotropic contributions. Unfortunately, no reliable and generally applicable methods for independently estimating such contributions have yet appeared.

The magnetic shielding ζ of a proton in a molecule can be calculated theoretically using the second-order perturbation theory of Ramsey,[1] or the variational methods.[2,3] Application of the second-order perturbation theory to this problem is possible only if the excited-state wave functions in addition to the ground-state wave functions are available for the molecule in question. Hence, very few direct theoretical calculations of ζ have been made.

McConnell,[4] have derived a quantum mechanical expression for calculating the chemical shifts due to long-range bonds or groups. For an axially symmetric bond, the expression appears in the form:

$$\zeta = \Delta\chi(1-3\cos^2\theta_z)/3L_0R^3 \qquad (1)$$

Where, R, is the radius vector for the proton, θ_z, is the angle between R and the symmetry axis of the bond (usually the bond axis itself). The scalar $\Delta\chi=\chi_L-\chi_T$, where the scalars χ_L and χ_T are the average of the susceptibility components parallel and perpendicular to the symmetry axis.

The theory has been extended by Narasimhan and Rogers,[5] to the three dimensional case, where all the three principal magnetic susceptibilities are different. These authors have also derived expressions for the case of rotating methyl groups, in which the shielding is averaged over all possible orientations.

The theory of McConnell for long-range shielding appears capable of fairly general applicability, although it is not very well suited to quantitative calculations of aromatic proton shieldings, since it has been developed only to the extent that the shielding fields are approximated by dipolar fields. Quantitative application of the shielding equation due to the magnetic anisotropy of a long-range bond in a molecule suffer from two very important difficulties. The first difficulty is that the shielding of a proton is a function of the anisotropy in the magnetic susceptibility of the distant group, and only very few data for the magnetic anisotropies of bonds are known. The second difficulty is that R, appears in the equation as R^{-3}, so that with decreasing R, the shielding becomes larger and more important, and the dipolar approximation becomes less and less accurate.[4,6,7]

For distances less than 5 Å, we have followed Pople's suggestion[7] of describing the anisotropy of the acetylenic bond in terms of the atomic

anisotropy of the acetylenic carbons, and the shielding expression becomes,

$$\xi = \Delta\chi[\tfrac{1}{3}R_1^3(1-3\cos^2\theta_1) + \tfrac{1}{3}R_2^3(1-3\cos^2\theta_2)] \quad (2)$$

Where, R_1, R_2, θ_1, and θ_2 are shown in Fig. 1.

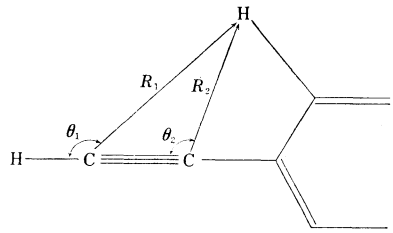

Fig. 1. Dipole approximation for the magnetic anisotropies of the acetylenic carbons in phenylacetylene.

The present work represent an attempt to investigate the role of the neighbor-anisotropy effect and to calculate the electrostatic effects due to electric fields at a particular nucleus arising from polar groups in other parts of the molecule. From the relative chemical shifts and the known molecular geometries, we determine the anisotropy in the magnetic susceptibilities of the C≡C, C≡N, and N≡C triple bonds. In doing so, we have shown experimentally that long-range shielding does exist and that it is correctly explained to lower order of accuracy by the McConnell's expression. We have also shown that the electrostatic effects in the case of –C≡N, and –N≡C triple bonds are very important in determining the chemical shift of a particular proton.

Experimental

The NMR Spectrometer. The measurements were made on a Varian Associates high-resolution spectrometer, operating at a fixed frequency of 56.45 Mc/s. The measurements of the NMR spectra of the bicyclo-compounds were made at 60 Mc/s. The frequency separation between lines were measured using the usual audiomodulation side-band technique. The chemical shifts were measured for several concentrations in carbon tetrachloride solutions containing 1% TMS, used as an internal standard, extrapolated to infinite dilution, and are quoted as τ-values. All τ-values which were employed in the calculations are the average of four determinations and are accurate to ± 0.01 ppm.

Results and Calculations

a. Diamagnetic Anisotropy. In order to simplify the problem of calculating magnetic anisotropy of a long-range bond, we have followed the general method adopted by Narasimhan and Rogers.[5] For a given proton the net shielding ζ, can be written as the sum of two quantities, namely, ζ_l and ζ_d, where ζ_l, denotes the shielding

TABLE 1. THE CHEMICAL SHIFTS OF ALL PROTONS IN I—IX

due to the immediately surrounding electron cloud (primary shielding), and it corresponds to Pople's local diamagnetic term. The second term, ζ_d, arises from distant electron distributions within the molecule itself (secondary shielding), and corresponds to Pople's neighbor-anisotropy effect. ζ_l can be calculated by using the wave functions of the bond attached to the proton of interest.[3] ζ_d can be evaluated from a knowledge of the magnetic anisotropy $\Delta\chi$ of the various charge distributions in the molecule.[3–5] Thus we may write:

$$\zeta = \zeta_l + \zeta_d$$

A difference in the net shielding, or the internal chemical shift $\Delta\zeta$, between two protons A and B in a molecule may originate from differences in ζ_l and/or ζ_d ($\Delta\zeta_l$ and $\Delta\zeta_d$ respectively). Thus we have;

* Complete analysis of the NMR spectrum of acrylonitrile and α-D-acrylonitrile are carried out by Goldstein and co-workers.[11] Several other workers have analysed the spectrum of acrylonitrile.[11-14] The results of Banwell and Sheppard[12] are different from that of Goldstein and co-workers,[11] and Bruegel,[13] in that the two protons at the β-position have been interchanged. There are some variations in the values of the chemical shifts of the three protons. The most reliable analysis is that of Castellano and Waugh.[14] In this work, the values of the chemical shifts obtained by the later authors are employed in the calculation of the magnetic anisotropy of the $-C{\equiv}N$ group.

TABLE 3. THE CHEMICAL SHIFT OF ALL PROTONS IN I—V

 IV	3.02	5.93			7.63
 V		7.03 6.86			

$$\Delta\zeta = (\zeta^A-\zeta^B) = (\zeta_l^A-\zeta_l^B) + (\zeta_d^A-\zeta_d^B)$$
$$= \Delta\zeta_l + \Delta\zeta_d$$

Since the magnitude of the shielding contribution from distant groups depend on their diamagnetic anisotropy and on molecular geometry, we have calculated the diamagnetic anisotropy of the $-C{\equiv}C-$, $-C{\equiv}N$, and $-N{\equiv}C$ groups, using the internal chemical shift between two protons located on the same carbon atom or on two different atoms with the same electron distribution around. Hence, $\Delta\zeta_l$, for such protons will be zero, and the difference in the chemical shift $\Delta\zeta_T$, will arise from the magnetic anisotropy of the distant groups alone.

To calculate ζ_d, for cases where θ and/or R changes with internal molecular motions, one must use appropriately averaged values. The component,

$$T_z = (1-3\cos^2\theta_z)/R^3 \qquad (3)$$

was calculated numerically in the following manner:

Let us consider the case of a nucleus H, which is free to move in a circular path around the axis of the bond AC*, this axis being taken to be in

the Z–Y plane, with point dipole placed at "0" as shown in Fig. 2.

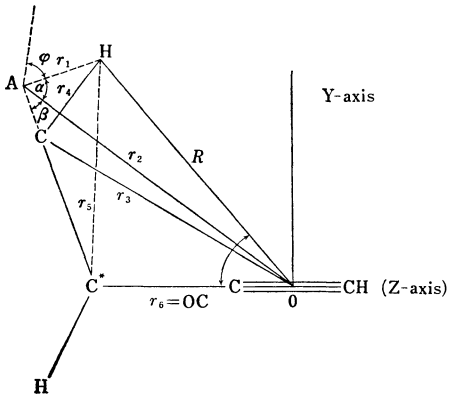

Fig. 2. Evaluation of T_z value.
The dipole is located at "0", and nucleus H free to rotate around the axis AC*.

Since r_1 and AC* are chosen to be at right angles to each other, we can express α in terms of β and φ (φ is the angle of rotation of r_1, in its plane). Thus it can be shown that,

$$\cos\alpha = \sin\beta\cdot\cos\varphi \tag{4}$$

and hence we can express R as,

$$R = (r_1^2+r_2^2-2r_1r_2\sin\beta\cdot\cos\varphi)^{1/2} \tag{5}$$

now we also have,

$$\cos\theta_z = (R^2+r_6^2-r_5^2)/2R\,r_6, \tag{6}$$

and hence we can write,

$$\begin{aligned} T_z &= (1-3\cos^2\theta_z)/R^3 \\ &= \{R^{-3}[1-3(R^2+r_6^2-r_5^2)^2/(2R\,r_6)^2]\}_{av}. \end{aligned} \tag{7}$$

Since φ varies from 0 to 2π, we can find the average value by integrating the left-hand side of Eq. (7), after substituting of Eq. (5) for R, and dividing finally by 2π. Thus after rearranging we obtain:

$$\begin{aligned} T_z = \tfrac{1}{2}H\{&J_B-\tfrac{3}{4}r_6^2[(r_6^2-r_5^2)J_C \\ &+2(r_6^2-r_5^2)J_B+J_A]\}_{av}. \end{aligned} \tag{8}$$

where,

$$J_A = \int_0^{2\pi}(a+b\cos\varphi)^{-1/2}\,d\varphi$$

$$J_B = \int_0^{2\pi}(a+b\cos\varphi)^{-3/2}\,d\varphi$$

$$J_C = \int_0^{2\pi}(a+b\cos\varphi)^{-5/2}\,d\varphi$$

with, $a = r_1^2 + r_2^2$, and
$b = -2r_1r_2\sin\beta$

The evaluation of the integrals in Eq. (8), is necessary for the calculation of T_z, for the methyl groups. These integrals are of the elleptical type and cannot be evaluated in a closed form. These were calculated numerically using the Gauss quadrature method.

b. Electrostatic Effects. In dealing with bonds which are more highly polar than the –C≡C– triple bond, account must be taken of direct electrostatic contributions to ζ_e. This problem arises in the case of the –C≡N and –N≡C triple bonds. A treatment of this problem has been given by Buckingham.[15] Buckingham has shown that molecules containing polar bonds produce an electric field at a particular nucleus, and this leads to chemical shifts proportional to the first powder of the field strength.

The electric field at any point due to a dipole can be evaluated in the usual manner.[16] In our calculations, an improved approximation for the electrostatic effect is made by replacing the point dipole by partial positive and negative charges placed at the two atoms forming the polar bond. These partial charges are derived from the dipole moment and the length of the bond.

According to Coulomb's law, the force exerted by the positive charge ($+e$) on the unit charge placed at the nucleus H in Fig. 3, is

$$E_1 = e/R_1^2$$

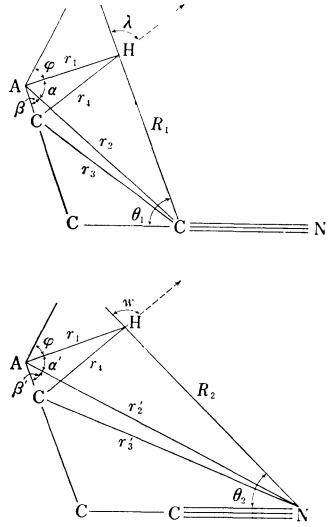

Fig. 3. Calculation of a electrical shielding for rotating methyl groups, based on the point charge approximation.

The component of this force along the C→H bond is given by,

$$E_1^{C\to H} = e/E_1^2\cdot\cos\lambda$$

Similarly,

$$E_2 = -e/R_2^2, \text{ and } E_2^{C\to H} = -e/R_2^2\cdot\cos w$$

The electrical field at the nucleus H is completely defined by the total force exerted by the two charges ($+e$) and ($-e$), and is given by:

15) A. D. Buckingham, *Can. J. Chem.*, **38**, 300 (1960).
16) V. C. A. Ferraro, "Electromagnetic Theory," The Athlone Press, London (1954), p. 70.

$$E_T = e/R_1^2 \cdot \cos\lambda - e/R_2^2 \cdot \cos w \qquad (9)$$

From the geometry of the figure, we can show,

$$\cos\lambda = (R_1^2+r_4^2-r_3^2)/2R_1r_4,$$
$$\text{and} \quad \cos w = (R_2^2+r_4^2-r_3'^2)/2R_2r_4$$

Therefore,

$$\langle E\rangle = e/R_1^2[(R_1^2+r_4^2-r_3^2)/2R_1\,r_4] - e/R_2^2[R_2^2+r_4^2-r_3'^2)/2R_2\,r_4] \qquad (10)$$

Since, $\mu=el$, therefore

$$\langle E\rangle = \mu/2lr_4[(R_1^{-1}+R_1^{-3}(r_4^2-r_3^2) - R_2^{-1} - R_2^{-3}(r_4^2-r_3'^2)]_{av}.$$

Since φ varies from 0 to 2π, we can find the average value by integrating the left-hand side of this equation after substituting the values of R_1 and R_2 given by:

$$R_1 = (r_1^2+r_2^2-2r_1r_2\sin\beta\cdot\cos\varphi)^{1/2}$$
$$R_2 = (r_1^2+r_2^2-2r_1r_2'\sin\beta'\cdot\cos\varphi)^{1/2}$$

Thus after rearranging, we obtain,

$$E = \mu/4l\pi r_4[J_{A_1}+J_{B_1}(r_4^2-r_3^2) - J_{A_2}-J_{B_2}(r_4^2-r_3'^2)]_{av}. \qquad (11)$$

Where, J_{A_1}, J_{A_2}, J_{B_1}, and J_{B_2} are the elleptical integrals referred to before.

c. Electronegativity Effects. Following the original investigation of Meyer, Saika, and Gutowsky,[17] it was found empirically by Daily and Shoolery,[18] that for a series of ethyl derivatives, a linear relation exists between the internal chemical shift of the ethyl group protons and the electronegativity of the substituent. Cavanaugh and Daily[10] have re-examined this relationship, in which they replaced the solvent (benzene) by carbon tetrachloride. These results were reviewed and measurements were made on dilute solutions of these compounds in carbon tetrachloride and extrapolated to infinite dilution. The internal chemical shifts of the ethyl derivatives as measured in carbon tetrachloride differ slightly from those measured in benzene. A revised Daily and Shoolery equation was set up using the new data.

$$\text{Electronegativity} = 0.0114\,\delta\ (\text{internal}) + 1.78$$

Where, δ is in c/s at 60 Mc/s.

Since the electronegativity of the substituent determines the electron distribution around the protons; this equation may be taken as an empirical expression for estimating $\Delta\zeta_l$, between the methyl and methylene protons in ethyl and isopropyl acetylenes, nitriles and isonitriles. The estimation of $\Delta\zeta_l$, in this manner compares favourably with the theoretical values calculated from electron density distribution.[19,20]

Discussion

We wish now to demonstrate experimentally the presence of long-range contributions to the shielding of a proton in a molecule. The molecules are assumed to be in the liquid state and summations in the shielding expression is over all long-range triple bonds, which are assumed to be axially symmetric with magnetic anisotropies $\Delta\chi^{X\equiv Y}$. Therefore,

$$\Delta\zeta_d^{A-B} = \Delta\chi^{X\equiv Y}\sum(T_z^A - T_z^B)/3L_0$$

Thus, from the calculated value of $\sum(T_z^A - T_z^B)/3L_0$, and the experimentally observed value of $\Delta\zeta_d^{A-B}$, we determine $\Delta\chi^{X\equiv Y}$, where, X≡Y, represents a triple bond. In Tables 4, 5, and 6, are listed the values of $\sum(T_z^A - T_z^B)/3L_0$ for specific nuclei, also are listed in the tables the appropriate experimental NMR relative chemical shifts for these nuclei, in a series of molecules containing the three different triple bonds. The values from Tables 4, 5 and 6, are plotted with $\Delta\zeta_d^{A-B}$ as abscissa and $\sum(T_z^A - T_z^B)/3L_0$ as the ordinate. A marked linear dependence of these points is found, enabling us to conclude that such long-range bonds do contribute to the shielding. Drawing the line of best fit through these points, we obtain from its slope the values of:

$$\Delta\chi^{C\equiv C} = \chi_L^{C\equiv C} - \chi_T^{C\equiv C} = -35.27\pm0.23\times10^{-6}\text{cm}^3\cdot\text{mol}^{-1} = -5.859\pm0.039\times10^{-29}\text{cm}^3\cdot\text{molecule}^{-1}$$

$$\Delta\chi^{C\equiv N} = \chi_L^{C\equiv N} - \chi_T^{C\equiv N} = -39.75\pm0.33\times10^{-6}\text{cm}^3\cdot\text{mol}^{-1} = -6.60\pm0.055\times10^{-29}\text{cm}^3\cdot\text{molecule}^{-1}$$

$$\Delta\chi^{N\equiv C} = \chi_L^{C\equiv N} - \chi_T^{N\equiv C} = -39.05\pm0.19\times10^{-6}\text{cm}^3\cdot\text{mol}^{-1} = -6.48\pm0.032\times10^{-29}\text{cm}^3\cdot\text{molecule}^{-1}$$

The fact that these points do not lie on a straight line, indicates that the assumptions we have made are not frequently valid. We feel, however, that our conclusions are justified and give every indication that other contributing effects are of high order.

The value of $\Delta\chi$ for –C≡N and –N≡C bonds depend strongly on various parameters, such as the location of the –C≡N and –N≡C dipoles. For mathematical simplification, we have idealised the dipoles by point dipoles, and such idealization is valid only when we consider the field due to these dipoles at very large distances. For actual calculations, it is customary to locate this dipole somewhere along the bond by making certain assumptions; one such assumption is to locate the dipole at the electrical centre of gravity of the electron distribution constituting the bond.

The negative sign of $\Delta\chi$ indicates that the diamagnetic susceptibility perpendicular to the axis of symmetry $|\chi_T^D|$, must be considerably smaller in magnitude than $|\chi_L^D|$. This is so because in an axially symmetric system, $\chi_L^P=0$, and only χ_T^P

$(>)\neq 0$, therefore, $\Delta\chi^{X\equiv Y}=\chi_L-\chi_T=\chi_L^D-\chi_T^D-\chi_T^P<0$, therefore $|\chi_L^D|$, must be large and negative.

The measurement of $\Delta\chi$ for a triple bond by this method accomplishes what would be very difficult to do by any other method. The ideal experiment for measuring susceptibility of a triple bond in both the transverse and longitudinal directions would be to freeze acetylene, as an example, in a crystal in which all the acetylenic bonds are parallel and then performing the magnetic susceptibility measurements. By using the experimental value of $\Delta\chi$ and the quantum mechanical expression of $\Delta\chi$, the validity of different possible wave functions for the triple bond can be determined.

The present semi-quantitative treatment indicates that, in the case of ethylacetylene, ethyl cyanide, and ethyl isocyanide, the major contribution to the observed chemical shift comes from $\Delta\zeta_l$, and that the observed chemical shift cannot be satisfactorilly explained on the basis of bond magnetic anisotropy alone. It seems probable from the present work, that both bond magnetic anisotropies and electronegativity differences contribute to the chemical shift between the methyl and methylene protons in these three molecules and that both effects are of the same order of magnitude. The local shielding differences perhaps being somewhat the more important.

A review of the literature on the values of the magnetic anisotropy of the acetylenic group, calculated either from theoretical quantum mechanical treatments or from experimental data have been made by Bothner-By and Pople.[20] The theoretical values range[20,21] from -1.61 to 1.94×10^{-6} $cm^3\cdot mol^{-1}$. The experimental ones from[22] -16.5 to[23–25] -34.0×10^{-6} $cm^3\cdot mol^{-1}$. In view of the widely scattered range of values reported in the literature, our datum must be considered in good agreement with the values given by Heel and Zwil,[9,24] and that obtained by Englert and Saupe[26] in a study of some acetylenic compounds oriented

in a nematic phase.

In another attempt, Goldstein and Reddy,[27] have devised an empirical method of the estimation of diamagnetic anisotropy effects in NMR spectroscopy based upon correlations between proton chemical shift and C^{13}–H coupling constants. The anisotropy shift for the acetylenic hydrogen as obtained by this method is +4.12 ppm. This anisotropy effect for acetylene is considerably smaller than Pople's theoretical estimate of about +10 ppm. Although this result is qualitatively in the expected order with respect to ethylene and methane, the difference is considerably less than might have been anticipated.

The value of $\Delta\zeta_d^{\equiv CH}$ cantribution to the shielding of the proton in acetylene and methylacetylene could be estimated from the calculated value of $\Delta\chi^{C\equiv C}$ and the known geometry of these molecules.[28] The corresponding paramagnetic contribution to ζ is +9.03 ppm. It is interesting to compare this value with that obtained by Pople[29] in a quantum mechanical study of the proton chemical shift in acetylene. Pople found that the paramagnetic contribution to the shielding of the acetylenic proton is +10 ppm. Pople has emphasised that this value is only an order of magnitude for the effect, and is clearly large enough to account for the anomalous position of the acetylenic proton. Again, we may notice, that, both bond magnetic anisotropy and electronegativity effects of the –C≡CH group contribute to the chemical shift of the acetylenic proton.

Studies on steroids, which are available in great number, appear most promising the geometry of the steroid nucleus is well established and the effects of substituents have been shown to be nearly additive. Zürcher[30] has obtained and analysed data on a large number of steroids. He gives additive contributions for substituents and discusses the contribution of groups from equivalent positions.

Corss and Harrison[31] have studied a series of steroids with and without nitrile substituents in the 5α- or 5β-positions. In each case they observed a deshielding of the C-19 methyl protons, on substitution with –C≡N, although the dipolar formula predicts a shielding, whether the substituent is introduced α or β. The value of $\Delta\chi^{C\equiv N}$ employed in their calculations is that of Goldstein and collaborators.[11] These authors have neglected the electrostatic effect of the –C≡N group. Our calculations on these steroids, using Eqs. (2) and (11) for estimating anisotropic and electrostatic effects, shows that the C-19 methyl protons in 5α-cyano-steroids should be shifted upfields by 11.8 c/s, relative to the 5α-H-steroid, contrary to the observed shift. The explanation given by Cross and Harrison that ring A in the 5α-cyano-steroids is distorted from the chair form due to dipole-dipole interaction between substituents at the 3- and 5-positions may explain part of the observed downfield shift.

When considering 5β-cyano-steroids, our results show that the electrostatic effect of the –C≡N group is very important in determining the C-19 methyl protons shift, and explain the deshielding of these protons, relative to the parent steroid. Table 7 shows the calculated and observed shifts of these protons. The agreement between calculated and observed shifts in the 5β-cyano-steroids, where the stereochemistry of ring A is normal and repulsion between the C=O and C≡N groups is minimum, gives an indication that our value for the diamagnetic anisotropy of the –C≡N group is correct. To obtain better agreement between observed and calculated shifts in these molecules, one may take into account the electronegativity effects of the –C≡N group, as both magnetic anisotropy and electronegativity effects contribute to the proton chemical shift.

Molecular Orbital Treatment of Nitric Oxide Radicals. II. ESR Spectra of Aliphatic Nitric Oxide Radicals

Osamu KIKUCHI

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received July 25, 1968)

Quantitative discussions of the ESR spectra of aliphatic nitric oxide radicals have been undertaken on the basis of the molecular orbitals of all-valence-electrons, which were evaluated by the approximate SCF method with the CNDO/2 approximation. The spin density on the methyl proton in the dimethyl nitric oxide radical is proportional to $\cos^2\theta$, where θ is the angle between the nitrogen $2p_z$ orbital and the plane containing the C–N and the C–H bonds; the small hyperfine splitting constants of β-protons appearing in some substituted nitric oxide radicals are understood as resulting from the sterically-restricted conformations of substituted groups. The deviation of the g factor of aliphatic nitric oxide from the free spin comes from the large spin densities localized on the nitrogen and the oxygen atoms, and the small excitation energy, from the non-bonding orbital of the oxygen to the odd π-orbital. The electronic structures and g factors of some other radicals are compared to those of aliphatic nitric oxide radicals.

Theoretical treatments have been made by several investigators of the β-proton coupling in free radicals.[1–4] These have mainly been carried out by the perturbation method based on the hyperconjugation model. McLachlan[2] and Lykos[3] have applied the valence bond theory to some alkyl radicals and shown that hyperconjugation takes place between methyl groups and the α-carbon atom. Symons[4] has pointed out that the theory of hyperconjugation affords the best explanation of the large hyperfine coupling of β-protons in alkyl radicals. The hyperconjugation model corresponds to the delocalization of an odd electron onto the β-protons in the molecular orbital theory. The recently-developed molecular orbital theory, in which all valence electrons are explicitly considered, will make clear the mechanism of the β-proton coupling.

Stone[5] has presented a theory which can be used to calculate the g factors of aromatic molecules and has shown that the results for hydrocarbon and semiquinone ions calculated according to the theory agree well with the experimental results. This theory has since been used for a study of the solvent effect on the g factor of the diphenyl nitric oxide radical.[6] However, there have been few theoretical investigations of the correlation between the g factor and the molecular electronic structure, perhaps because it is difficult to calculate the electronic structures for all the valence electrons of large molecules.

In the present study, the approximate self-consistent molecular orbital method of Longuet-Higgins and Pople[7] is applied to the all-valence-electron system of several nitric oxide radicals, and the hyperfine splitting constants of β-protons and the g factors for aliphatic nitric oxide radicals are discussed.

Methods

The ground configuration of the free radical is a doublet, and its antisymmetrized wave function can be described by:

$$\Psi_g = |\phi_1\bar{\phi}_1 \cdots \phi_{m-1}\bar{\phi}_{m-1}\phi_m| \quad (1)$$

where $2m-1$ is the number of the valence electrons considered. The molecular orbital, ϕ_i, is obtained using the LCAO MO approximation:

$$\phi_i = \sum_r C_{ri}\chi_r \quad (2)$$

where χ_r is the valence atomic orbital: 1s for hydrogen and 2s, $2p_x$, $2p_y$, and $2p_z$, for carbon, nitrogen, and oxygen atoms. The LCAO coefficients and the orbital energy, ε_i, are calculated by the approximate SCF method, which has been applied to the discussion of the electronic structure

and spectra of the H_2NO radical in a previous paper.[8]

The spin density on the valence atomic orbital, r, can be simply computed by:

$$\rho_r = C_{rm}^2 \tag{3}$$

The diagonal components of the g factor are obtained by;[5]

$$g_{aa} = 2.00232 + \Delta g_{aa} \tag{4}$$

$$\Delta g_{aa} = 2\sum_{i=1}^{m-1} \frac{\langle\phi_m|\sum_t l_a^t|\phi_i\rangle\langle\phi_i|\sum_t \zeta_t l_a^t|\phi_m\rangle}{E_{i\to m}-E_0} - 2\sum_{j=m+1}^{2m-1} \frac{\langle\phi_m|\sum_t l_a^t|\phi_j\rangle\langle\phi_j|\sum_t \zeta_t l_a^t|\phi_m\rangle}{E_{m\to j}-E_0} \tag{5}$$

where l^t is the angular momentum about the tth nucleus and where ζ_t is the spin-orbit coupling constant for the tth atom; the values of 29 cm^{-1}, 76 cm^{-1}, and 151 cm^{-1} were used for carbon, nitrogen, and oxygen atoms respectively.[9] $E_{i\to m}$ and $E_{m\to j}$ are the energies of the following antisymmetrized wave functions:

$$\Psi_{i\to m} = |\phi_1\bar{\phi}_1 \cdots \phi_i\bar{\phi}_m \cdots \phi_{m-1}\bar{\phi}_{m-1}\phi_m| \tag{6}$$

$$\Psi_{m\to j} = |\phi_1\bar{\phi}_1 \cdots \phi_i\bar{\phi}_i \cdots \phi_{m-1}\bar{\phi}_{m-1}\phi_j| \tag{7}$$

then the energy differences in Eq. (5) are computed by the following equations:

$$\left.\begin{aligned} \Delta E_{i\to m} &\equiv E_{i\to m} - E_0 = \varepsilon_m - \varepsilon_i - (mm|ii) \\ &\quad + \frac{1}{2}(mm|mm) + \frac{1}{2}(mi|im) \\ \Delta E_{m\to j} &\equiv E_{m\to j} - E_0 = \varepsilon_j - \varepsilon_m - (mm|jj) \\ &\quad + \frac{1}{2}(mm|mm) + \frac{1}{2}(mj|jm) \end{aligned}\right\} \tag{8}$$

The two-electron integrals were evaluated by the method described by Pople *et al.*[10] The g factor of the free radical in solution was estimated by:

$$g_{av} = \frac{1}{3}(g_{xx} + g_{yy} + g_{zz}) \tag{9}$$

Results and Discussion

β-Proton Coupling Constants. A simple nitric oxide radical, $(CH_3)_2NO$, was adopted for discussing the β-proton coupling; the calculations were performed using the following assumptions for bond lengths and bond angles: 1.23, 1.41, and 1.10 Å[11] for N–O, N–C, and C–H bonds respectively, and 120° for the CNO and CNC bond angles. The spin distributions have been obtained for a number of conformations of two methyl groups in the $(CH_3)_2NO$ radical. The results for a particular conformation of methyl groups (θ=90°, ϕ=90°) are presented in Table 1. In this table,

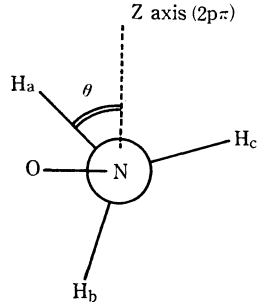

Fig. 1. CH_3–NO group in dimethyl nitric oxide radical.
The angle ϕ is defined as θ between the 2pπ orbital and the other methyl group.

indicated. The unrestricted SCF method shows that there are actually negative spin densities on some atomic orbitals. In the present calculation of the spin distribution on the valence atomic orbitals, the angular dependence of the spin distribution on the methyl protons is discussed on the basis of the results obtained by the I method.

The methyl groups will rotate freely in solution, and the isotropic hyperfine splitting observed will be an average one. When the methyl group is not rotating freely, the proton splitting depends on the angle, θ, between the nitrogen $2p_z$ orbital and the plane containing the C–N and C–H bonds. In the molecular orbital treatment, this angular dependence of the hyperfine splitting constants can be resolved by the direct calculation of the spin densities on the 1s orbitals of the methyl protons, which are fixed at any angle. The $(CH_3)_2NO$ radical has two methyl groups; the splitting constant (spin density) for the proton in one methyl group (CH_3(I)) depends not only on the θ angle, but also on the conformation of the other methyl group (CH_3(II)). The variation in the spin density on the methyl protons with the conformation of the other methyl group was about 0.002 (5%); this corresponds to 1 gauss of the proton hyperfine splitting constant. The spin distribution on the methyl protons fixed at the θ angle was obtained on the assumption of free rotation for the other methyl group. The results are listed in Table 2.

According to Symons,[4] if the hyperfine coupling occurs purely by hyperconjugation, it varies between zero when the β-C–H bond lies in the nodal plane of the unpaired electron and a maximum when it lies on a plane at right angles to this, while the splitting constants for intermediate positions vary according to the $\cos^2\theta$ law:

$$a_{\beta-H} = B\cos^2\theta \qquad (10)$$

The present finding regarding the angular dependence of the β-proton coupling coincides with that obtained by the hyperconjugation model, and the $\rho_{\beta-H} \propto \cos^2\theta$ relation holds strictly (Fig. 2). The spin density on the proton in the CH_3 group rotating freely can be estimated from Table 2 or Fig. 2, taking $\cos^2\theta=0.5$. The obtained value, ρ (average)$=0.019$, corresponds to the 9.5 gauss[12] β-proton splitting constant, while the experimental value of the $(CH_3)_2NO$ radical in solution is 13.4 gauss.[13]

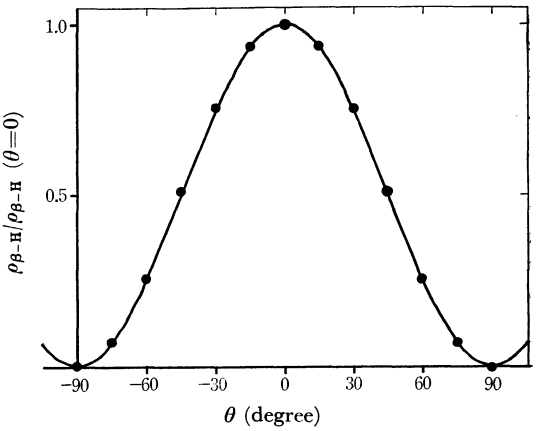

Fig. 2. Angular dependence of spin density on methyl-protons.
solid line: $\cos^2\theta$.
closed circle: calculated spin density.

From Fig. 2 or Table 2, the value of B in Eq. (10) can be estimated. The value of B is equal to $a_{\beta-H}$ at $\theta=0$. The calculated hyperfine splitting constant at $\theta=0$ was about 19 gauss; this is slightly smaller than the value of 27 gauss which was obtained from the experimental splitting constant, 13.4 gauss,[13] of the $(CH_3)_2NO$ radical in solution. From the calculated spin densities on the β-proton and on the nitrogen $2p_z$ orbital, the magnitude of McConnell's parameter, Q_{N-CH_3}, was estimated to be about 30 gauss.

The present results for the delocalization of the spin density on the β-methyl protons explain some interesting ESR experimental results for nitric oxide radicals. Some nitric oxide radicals reveal small hyperfine splitting constants of the β-protons.[13,14] For example, for di-isopropyl nitric oxide it is about 4 gauss, one third of that of β-protons in a freely-rotating methyl groups. Our results, shown in Fig. 3, indicate that the rotation of the isopropyl groups of this radical is restricted

12) Hyperfine splitting constants of hydrogen atoms are computed by $a_H=\rho$ (1s) $\times 502$ gauss.

by the bulky substituents to a structure in which the β-proton oscillates through a small region ($-45°<\theta+90<45°$) close to the N–O molecular plane.

For cyclic nitric oxide radicals, the axial and equatorial β-protons show equal hyperfine splitting constants. This is due to their rapid chair-to-chair conformational interconversion, and a time-averaged splitting constant, $\frac{1}{2}(a_{ax}+a_{eq})$, was observed. For the piperidine nitric oxide radical, it is 11.3 gauss;[13] from this value and the present calculations it can be understood that the equatorial proton in cyclic nitric oxide radicals lies in the region of $\theta=90°$.

g Factors of Aliphatic Nitric Oxide Radicals. The simplest nitric oxide radical, the H_2NO radical, was used in our attempt to understand the relation between the g factor and the molecular structure for the nitric oxide radical. The electronic structure of this radical has been discussed in the previous paper,[8] while the molecular orbital scheme obtained is shown in Fig. 3. In this figure, the

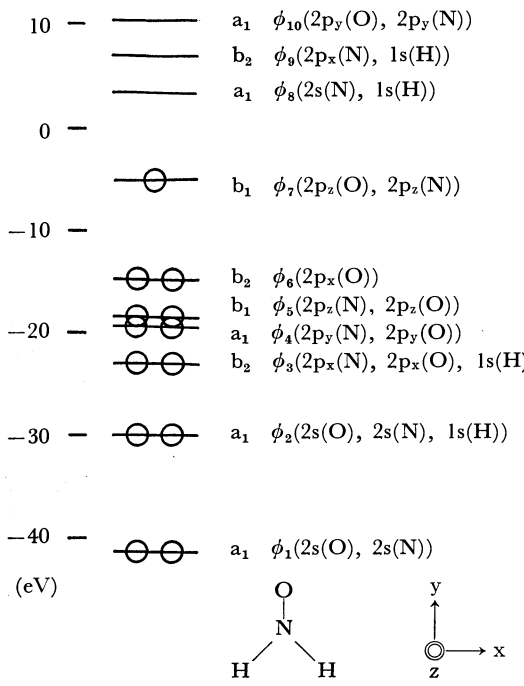

Fig. 3. Molecular orbital scheme for the H_2NO radical.

atomic orbitals contributing to each molecular orbital are also presented. The odd electron resides in the π-orbital, and since the planarity of the H_2NO radical is assumed, $\Delta g_{zz}=0$ (see Eq. (5)) and the z component of the g factor is the value for the free spin, 2.0023. The deviations, Δg_{xx} and Δg_{yy}, from the free spin can be calculated by Eq. (5). In this equation, the first term shows the contribution of the Ψ_{i-m} excited states, while the second term is the contribution of the Ψ_{m-j} excited states. The excitation energies were calculated from Eq. (8). The excitation energies and Δg_{xx} and Δg_{yy} are tabulated in Table 3. The

*2 $\Delta g_{zz}=0$

most important excitation for the g_{xx} is the excitation from the N–O σ-bonding orbital (ϕ_4) to the odd orbital, while for g_{yy}, it is the excitation from the lone-pair orbital of the oxygen atom (ϕ_6) to the odd π-orbital. The small contribution of the N–O anti-bonding orbital (ϕ_{10}) is due to the LCAO coefficients of the ϕ_7 and ϕ_{10} molecular orbitals; when the electrons in these orbitals are shared equally by nitrogen and oxygen atoms, the contribution of this orbital is zero. The experimental values of g_{xx}, g_{yy}, and g_{zz} for the di-*t*-butyl nitric oxide radical have been reported as 2.0061, 2.0089, and 2.0027 respectively.[15] The present results show that the large deviations of g_{xx} and g_{yy} for this nitric oxide from the free spin are due to, respectively, the N–O bonding orbital and the lone pair of the oxygen atom. The average g factor of the H_2NO radical was 2.0062; this agrees well with the g factors (2.0055—2.0061[16]) of many aliphatic nitric oxide radicals in solution.

Similar results were obtained for the dimethyl nitric oxide radical. In this radical the lone-pair orbital of the oxygen atom and the N–O σ-bonding orbital mainly contribute to Δg_{yy} and Δg_{xx} respectively, while the contribution of the N–O anti-bonding orbital was again small. $\Delta g_{xx}=167\times 10^{-5}$ and $\Delta g_{yy}=627\times 10^{-5}$. These values are smaller than those of the H_2NO radical, mainly because of the smaller electron density of the non-bonding orbital and the smaller spin density on the oxygen atom in the dimethyl nitric oxide radical.

It is important to investigate the g factors for the other radicals in order to make clear the rela-

tion between the g factor and the electronic structure of the free radical. In aromatic nitric oxide radicals such as diphenyl nitric oxide, π-electrons delocalize upon the large conjugate system. Nevertheless, some experimental results have shown that aromatic nitric oxide radicals have g factors similar to those of aliphatic nitric oxide radicals.[6,17] It would be difficult to calculate the electronic structure of the all-valence-electron system for aromatic radicals; simple method for estimating the g factor of aromatic radicals is desirable. The relation between the g factor of aromatic nitric oxide and the spin densities on the nitrogen and oxygen atoms has been obtained employing some assumptions based on the electronic structure of aliphatic nitric oxide radicals. The g factor of the diphenyl nitric oxide radical in solution has been calculated by this method to be 2.0051. The details will be reported subsequently.

Another interesting kind of radical is the amino-radical. Unlike nitric oxide radicals, only a few investigations of these radicals by the ESR technique have been presented, perhaps because of their instability. Some of the amino-radicals investigated by the ESR method have been the NH_2 radical,[18] the substituted anilino radical,[19] and substituted diphenyl aminoradicals.[20] In the present investigation, the g factor of the NH_2 radical has been calculated and compared with that for the H_2NO radical. In the NH_2 radical an odd electron occupies the $2p_z$ orbital of the nitrogen atom, and effective lone-pair electrons are on the y axis on the side away from the rest of the molecule.[21] As a result, the deviation of g_{xx} from the free spin is expected to be large; the calculated results show that $\Delta g_{xx}=347\times10^{-5}$ and that the contribution of the NH σ-bond is small. The average value was 2.0037[22]; this agrees with the experimental value.[17] The main reason for the difference between the g factor of the H_2NO radical and that of the NH_2 radical is the different spin-orbit coupling constants for oxygen and nitrogen atoms.

The author wishes to express his thanks to Professor Keizo Suzuki, Tokyo Kyoiku University, and Dr. Kazuo Someno, Government Chemical Industrial Research Institute Tokyo, for their helpful suggestions and encouragement during the course of this work.

Decomposition of Formic Acid on Silver Catalyst —Adsorption Measurement during Surface Catalysis—

Kenzo FUKUDA, Takaharu ONISHI and Kenzi TAMARU

Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received July 27, 1968)

The mechanism of the decomposition of formic acid over reduced silver catalyst has been studied by means of the adsorption measurement during surface catalysis. It was found that the decomposition of formic acid on the silver catalyst at 100°C was first order at lower pressures of formic acid, while at medium pressures it was zero order, the reaction rate being independent of the pressures of ambient formic acid; in the first region the amount of adsorbed formic acid was proportional to the pressure of formic acid, and in the second region it was constant, independent of the pressure of formic acid in the ambient gas. The second region corresponds to "saturation" in an ordinary sense. At pressures of formic acid higher than that in the "saturation" region the amount of adsorbed formic acid increases again linearly with the pressure of formic acid. The linear relation between the reaction rate and the amount of formic acid adsorbed during the reaction was observed over the whole range of the pressure of formic acid studied. It is accordingly concluded that a surface unimolecular reaction in terms of the adsorbed formic acid is the rate-determining step. The exchange reaction of surface formic acid with those in the ambient gas was studied and it was demonstrated all the formic acid in the adsorbed layer accordingly participated in the exchange reaction. The numbers of surface silver atoms occupied by one molecule of adsorbed formic acid at the saturation points at various temperatures are estimated from the number of surface silver atoms and the amount of formic acid adsorbed at the zero-order kinetics. The number of surface silver atoms occupied by one molecule of adsorbed formic acid increases linearly with temperature.

The rate of chemical reaction is generally determined by the reactivities of the reacting species of the rate-determining step. In the case of heterogeneous catalysis, the concentration of some of the reaction intermediates, as well as those of reacting species in the ambient gas, may be determined by the techniques to measure adsorption during the course of the reaction.[1] The dependence of the reaction rate upon the concentration of each of the species on the catalyst surface and those in the ambient gas would reveal the reactants of the rate-determining step or the mechanism of the overall reaction. By means of this approach, the decomposition of formic acid has been previously studied by the authors over such metal oxides as alumina and zinc oxide which are typical dehydration and dehydrogenation catalysts respectively.[2]

The decomposition of formic acid over metal catalysts has been studied extensively by many investigators. Fahrenfort, van Reijen and Sachtler[3] studied the kinetic behaviour of the formate ion on a nickel surface and concluded that the decomposition of formic acid over a nickel catalyst proceeded *via* formate ion as a key intermediate. They correlated accordingly the activities of various metals for the decomposition of formic acid with the heat of formation of their formates which gave a "volcano-shaped" curve.

On the other hand, the examination of the kinetic behaviour of surface formate layers in more detail during the decomposition of formic acid over nickel catalyst has revealed that the reaction proceeds through two different mechanisms: a part of the overall reaction proceeds between formic acid molecule and the surface not covered by the formate ion, and that *via* the surface formate ion.[4] Consequently, it is of great interest to elucidate the reaction mechanism of the dehydrogenation reaction of formic acid over a silver catalyst which is a typical metal on the left-hand side of the "volcano-shaped" curve.

The mechanism of the decomposition of formic acid over reduced silver catalyst has been previously studied by means of the adsorption measurement

during surface catalysis.[5] It has been accordingly suggested to be most probable that the decomposition rate of formic acid over the silver catalyst is proportional to the amount of formic acid adsorbed. In this study, the kinetic behavior of the adsorbed species on a silver catalyst was examined in more detail by using a silver catalyst having greater specific surface area, and the dependence of the rate of the overall reaction upon the concentration of chemisorbed species was determined.

Experimental

The apparatus employed was an ordinary closed circulating system similar to that previously described.[2] The amount of adsorbed species on the catalyst surface can be calculated from the amount of the reactant introduced into the system and the pressure and composition of the circulating gas. The adsorption of formic acid by apparatus was measured spearately and was taken into consideration in estimating the adsorption on the catalyst surface during the reaction. The circulating gas was analyzed by gas chromatography, where dioctyl sebacate and molecular sieve 13X were used in the separation columns: the former for formic acid, water and carbon dioxide, and the latter for carbon monoxide and hydrogen. The silver catalyst was prepared from silver nitrate according to the method adopted by Benton and Drake.[6] The catalyst was reduced for about 160 hr at 100—120°C with circulating hydrogen gas.

The surface area of the catalyst was 7×10^5 cm^2 (61 g), which was determined by the BET method by means of nitrogen adsorption at liquid nitrogen temperature.

Results

A typical result at 100°C is given in Fig. 1, where the amount of carbon dioxide evolved, the amount of adsorbed formic acid on the silver catalyst and the partial pressure of formic acid in the gas phase are plotted against the reaction time. The composition of the adsorbed species was the same as that of formic acid as is given in Fig. 2. (It does not always follow, however, that the adsorbed species is in the form of formic acid.) The decomposition of formic acid on the silver catalyst at 100°C was first order at lower pressures of formic acid, while at medium pressures it was zero order, the reaction rate being independent of the pressures of ambient formic acid; in the first region the amount of adsorbed formic acid was proportional to the pressure of formic acid and in the second region it was constant, independent of the pressure of formic acid in the ambient gas. The second region corresponds to "saturation" in an ordinary sense.

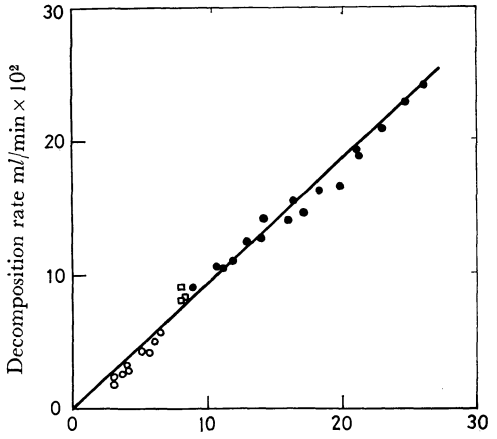

Fig. 4. Dependence of the reaction rate upon the amount of adsorbed formic acid at 100°C.

The dependence of the amount of formic acid adsorbed during the reaction upon the partial pressure of formic acid is given in Fig. 3, which shows that at lower temperatures the adsorption of formic acid reaches a "saturation" value at lower pressures, and increases again at higher pressures.

The dependence of the reaction rate upon the amount of adsorbed formic acid at 100°C is given in Fig. 4, which is obtained from three runs at 100°C. It is shown from Fig. 4 that the reaction rate is proportional to the amount of formic acid adsorbed. It should be noted here that the linear relation between the reaction rate and the amount of formic acid adsorbed during the reaction was observed over the whole range of the pressure of formic acid studied. Thus the reaction rate (r), $d(CO_2)/dt$, is expressed by the following equation;

$$r = kX_{ads.} \quad (1)$$

or

$$r = k\theta_{HCOOH} \quad (1')$$

where $X_{ads.}$ is the amount of adsorbed formic acid.

The zero order reaction rate at 80—122°C was divided by the corresponding saturation amounts of adsorbed formic acid to obtain the specific rate for the equal amount of adsorption at full coverages. The dependence of the calculated rates upon the reaction temperature gave an activation energy of 29.8 kcal/mol as shown in Fig. 5. The apparent frequency factor was 3.86×10^{15} min^{-1}. Thus the reaction rate was expressed by the following equation;

$$r = X_{ads.}(3.86 \times 10^{-15}) \exp(-29.8 \times 10^3/RT) \text{ ml/min}, \quad (2)$$

where $X_{ads.}$ is the amounts of adsorbed formic acid at zero-order kinetics at each temperature.

The exchange reaction of formic acid on the surface with that in the ambient gas was studied in the

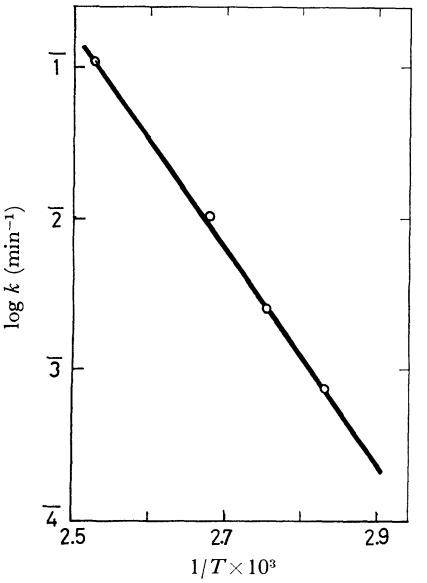

Fig. 5. Temperature dependence of the decomposition rate.

circulation system. In this experiment HCOOH was first introduced in the system and was decomposed at 100°C for a short time, then the gas phase was evacuated rapidly, the reaction vessel being cooled to about 10°C to prevent further decomposition and desorption of the formic acid remaining on the surface. Then DCOOD was introduced in the system and the change in D-content in the ambient formic acid molecule at 60°C was followed with time to study the exchange reaction. The procedure itself involved some ambiguity in its initial stage, but the exchange rate could be followed in such a manner. The ratio of HCOO/DCOO in the formic acid vapour was estimated by the infrared technique from the intensity of CH and CD stretching bands of adsorbed isotopic mixture of formic acid over fresh alumina.[2]

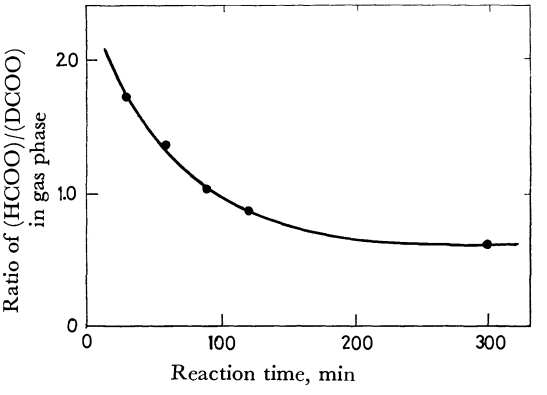

Fig. 6. Exchange reaction of surface formic acid on Ag with DCOOD at 60°C.

The exchange reaction proceeded at a comparatively slow rate as shown in Fig. 6. In this case the total amount of adsorbed formic acid was 14 m*l* (stp) at 60°C and the exchangeable formic acid on the surface was approximately estimated to be 13 m*l* (stp), which substantially corresponded to all the surface formic acid. All the formic acid in the adsorbed layer accordingly participated in the exchange reaction.

Discussion

The mechanism of the decomposition of formic acid over silver catalysts has been studied by many investigators. Otaki studied kinetic isotope effect in the decomposition of formic acid over a reduced silver catalyst.[7] He found the decomposition rate of various deuterium-substituted formic acid to be in the following decreasing order HCOOH$>$HCOOD$>$DCOOH. Schwab and Watson recently found the isotope effect in the decomposition of formic acid over a silver foil catalyst, where the order of the decomposition rate was HCOOH$>$HCOOD$>$DCOOH$>$DCOOD.[8]

Hirota, Kuwata and Asai studied the adsorption of formic acid on various metals by the infrared technique and reported that formate ion was detected on a silver surface.[9] From these observations they presumed that the primary step of the decomposition of formic acid over silver catalyst was the formation of surface formate which is subsequently followed by the processes as follows;

(1) $HCOO^-(ads.) + H^+(ads.) \rightarrow H_2 + CO_2$

(2) $2HCOO^-(ads.) \rightarrow H_2 + 2CO_2 + e$

(3) $HCOO^-(ads.) + HCOOH(ads.) \rightarrow H_2 + CO_2 + HCOO^-(ads.)$

(4) $HCOOH(ads.) \rightarrow H_2 + CO_2$

(5) $2H^+(ads.) + 2e \rightarrow H_2$

where each of these reactions was slow as compared with the formation of surface formate. Hirota and his coworkers suggested a possibility of participation of neutral formic acid molecule adsorbed on the catalyst surface.[10]

It was shown in Fig. 4 that the overall reaction rate is proportional to the total amount of adsorbed formic acid. It is accordingly concluded that a surface unimolecular reaction in terms of the adsorbed formic acid is the rate-determining step.

Block and Kral previously proposed a unimolecular mechanism for the decomposition of formic acid on a silver wire catalyst from their study on the kinetic isotope effects for various deutero-formic acids.[11] They assumed that the C–H and O–H bond in formic acid molecule cleaved at the same time in the rate-determining step, showing that the calculated kinetic isotope effects agreed with the experimental values fairly well. Eley and Leutic also proposed a unimolecular mechanism for the decomposition of formic acid on metal catalysts.[12,13] In those cases, however, any direct experimental basis for a unimolecular mechanism does not seem to be presented.

The results given in Fig. 4 and those of the exchange reaction, demonstrate that the formic acids adsorbed on the catalyst surface during the decomposition reaction behaves uniformly and the coverage of the silver surface by formic acid, which was directly measured during the decomposition, agrees with that of the active region in the surface which was estimated from the reaction kinetics, assuming that the reaction rate is proportional to the coverage of the active region. The characteristic dependences of both coverages upon pressure were quite similar as shown in Figs. 3 and 4, which strongly suggest that the coverage over the active region during the reaction agrees with that of the whole surface.

This conclusion is in marked contrast to that in the case of reduced copper catalyst obtained previously by one of the authors,[14] where the reaction rates were independent of the masured adsorption during the reaction, suggesting the heterogeneity of the adsorbed formic acid. Accordingly the adsorption measurements during surface catalysis may demonstrate the heterogeneity and/or homogeneity of the catalyst surface.

It is generally admitted that the following equation can be applied for the zero order reaction.[15]

$$\text{rate} = c_a(kT/h)\exp(-E/RT), \qquad (3)$$

where c_a is the number of adsorbed molecules on a unit surface area. Using this equation and the activation energy (E) of 29.8 kcal/mol which was obtained in this study, c_a becomes 1.8×10^{15} molecules per square centimetre at 100°C, while

the saturation value of the adsorbed formic acid at 100°C is 3.1×10^{14} molecules per square centimetre. It suggests consequently that all of the adsorbed formic acid participates in the decomposition reaction, which is well compatiable with the results obtained from the kinetic studies.

It is of great interest that at pressures of formic acid higher than that in the "saturation" region the amount of adsorbed formic acid increases again linearly with the pressure of formic acid as shown in Fig. 3. In this region of adsorption the reaction rate was proportional to the total amount of adsorbed formic acid. This result also indicates that the adsorbed formic acids uniformly participate in the reaction over the whole range of the pressure of formic acid.

The numbers of surface silver atoms occupied by one molecule of adsorbed formic acid at the saturation points at various temperatures are estimated from the number of surface silver atoms [1.30×10^{15} for (110) and (111) planes in average], and the amount of formic acid adsorbed at the zero-order kinetics, and are given in Table 1, where the values at 134, 142 and 160°C were obtained previously by one of the authors.[5]

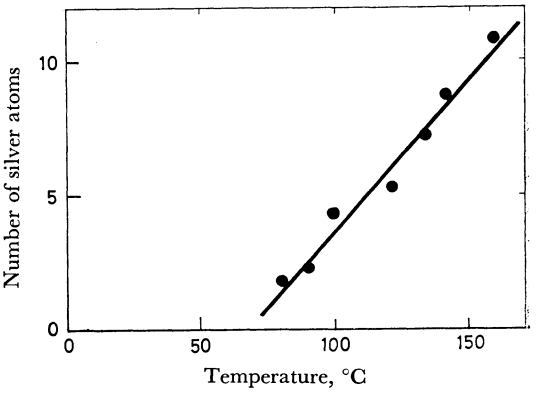

Fig. 7. Dependence of the number of silver atoms occupied by one molecule of absorbed formic acid upon temperature.

It is very interesting to note that the results in these experiments agrees reasonably well with those in the previous paper and the number of surface silver atoms occupied by one molecule of adsorbed formic acid increases linearly with temperature as shown in Fig. 7.

The area occupied by a surface formic acid at full coverage is seemingly determined by the range the surface molecule moves around at saturation, which expands with temperature.

Spectroscopic Studies on Radicals Produced from Acridine and Acridan in γ-Irradiated Rigid Solutions at −196°C

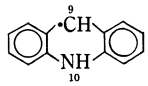
Tadamasa SHIDA and Akira KIRA

The Institute of Physical and Chemical Research, Yamatomachi, Kitaadachi-gun, Saitama

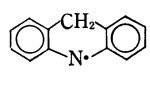
(Received August 9, 1968)

Dilute solutions of acridine in ethers and amines were frozen at −196°C to a glassy solid and were γ-irradiated. Electrons ejected by ionization are effectively scavenged by acridine to produce acridine anions which are the sole species having an electronic absorption band in the visible region. In alcohol and ester matrices the anion abstracts a proton from the matrix molecule even at −196°C and yields a semiquinone radical equivalent to the species formed by H-atom abstraction at the 9-position of acridan (dihydroacridine). Acridan in γ-irradiated butyl chloride matrix forms acridan cation which has a characteristic absorption band at 500—750 mμ. Detachment of a proton from the acridan cation produces another semiquinone radical identifiable with the species formed by H-atom abstraction at the 10-position of acridan. Both radicals have a similar yet clearly distinguishable absorption band in the visible region.

Flash photolytic studies on acridine and acridan systems have revealed that H-addition to acridine produces a C-radical (I) and that H-abstraction from acridan forms an N-radical (II).[1]



(I)



(II)

Since the spectral assignment of the N-radical in the previous work[1] was achieved by a process of elimination, it is desirable to get positive confirmation of the assignment by an independent method. Photolysis of rigid solutions at low temperatures often proves to be informative to the identification of reactive intermediates. Zanker *et al.* have shown that UV-illumination of alkylated acridans in alcoholic matrices at low temperatures yield radicals homologous to the N-radical shown above.[2]

Despite a seemingly prevailing preoccupation that γ-irradiation of organic systems leads to a chaotic mess, we have shown in a series of work[3] that γ-irradiation of rigid solutions at the liquid nitrogen temperature very frequently gives only a single species having absorption bands in the near UV through near infrared (IR) region. Applying the same radiation chemical technique we have studied acridine and acridan systems and obtained acridine anion and cation, acridan cation, the C- and N-radicals, each of which is produced exclusively from the others in a proper matrix.

Experimental

Preparations of acridine and acridan have been described in the previous paper.[1] The solvents, methyltetrahydrofuran (MTHF), diisopropyl ether, triethylamine (TEA), and *s*-butylamine were purified by vacuum distillation immediately after passing through an activated alumina column. Reagent grade *s*-butyl chloride (BuCl) and ethanol were used without further purification. Ethyl *n*-butyrate was distilled using a Vigreux column. All samples were degassed by freeze-thaw-reflux cycles, and sealed in a 1.5 mm Suprasil quartz cell which was irradiated with Co-60 γ-rays at −196°C.

A Cary 14R spectrometer and a quartz Dewar vessel with quartz windows were used for the optical measurement. Absorption spectra were obtained by plotting the difference of the absorption at the low temperature before and after irradiation.

Results

Pure MTHF forms a clear glass at −196°C which, upon γ-irradiation, yields a broad, intense absorption band with the $\lambda_{max} \cong 1.2\ \mu$. The band has been associated with the electron trapped by the matrix.[4] When 50 mM of acridine was present in the MTHF matrix, the band due to the solvent-trapped electron was replaced by a new absorption band in the visible region (Fig. 1). The spectrum

4) P. J. Dyne and O. A. Miller, *Can. J. Chem.*, **43**, 2696 (1965).

agrees well with the reported spectrum of acridine anion which had been produced by the treatment of acridine with alkali metals.[5] Besides MTHF, glassy matrices of *s*-butylamine and diisopropyl ether, when doped with acridine, also gave a spectrum almost identical with that shown in Fig. 1.

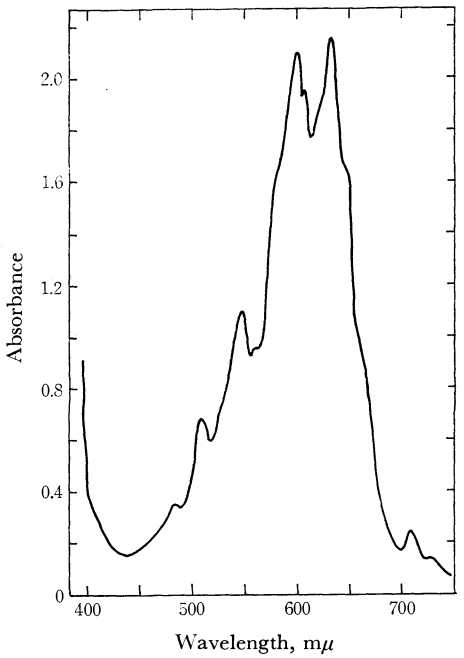

Fig. 1. Absorption spectrum of acridine anion. Acridine (50 mM) in MTHF glass γ-irradiated to the dose of 3.8×10^{19} eV/m*l*.

In contrast with ethers and amines, matrices of alcohols or esters did not yield the band of acridine anion or the band of solvent-trapped electrons; instead, a new spectrum similar to that of the C-radical in our previous paper[1] was obtained (Fig. 2). In Fig. 2 the result of acridine-ethanol system is shown. Acridine in glassy ethyl-*n*-butyrate also gave a similar spectrum.

Unlike acridine, acridan in MTHF did not affect appreciably the IR band due to the trapped electron nor did any new absorption band appear in the accessible spectral region. Apparently acridan does not scavenge electrons to form the anion. On the other hand, both acridine and acridan in BuCl matrix produced a new absorption band characteristic of the solutes (Fig. 3 and curve 1 of Fig. 4). When the irradiated acridan-BuCl solid was slightly warmed (*ca.* -170°C), the color of the sample changed from blue to purplish pink. Curve 2 of Fig. 4 demonstrates the spectrum of the pink solid measured at -196°C.

5) S. Niizuma, M. Okuda and M. Koizumi, This Bulletin, **41**, 795 (1968).

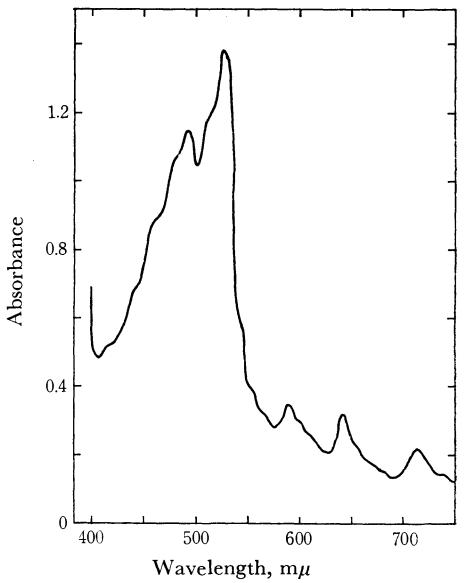

Fig. 2. Absorption spectrum of the C-radical. Acridine (50 mM) in ethanol galss γ-irradiated to the dose of 3.8×10^{19} eV/m*l*.

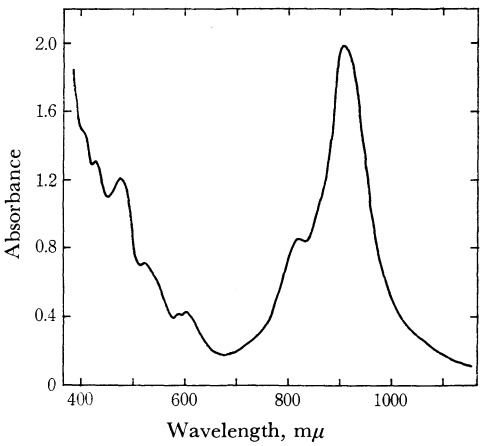

Fig. 3. Absorption spectrum of acridine cation. Acridine (50 mM) in *s*-BuCl glass γ-irradiated to the dose of 9.3×10^{19} eV/m*l*.

The spectrum of irradiated acridan in TEA matrix resembles that of the sample in curve 2 of Fig. 4. The intensity of the spectrum was markedly enhanced by the addition of a small amount of alkyl chloride, the band shape being unaltered. Curve 1 of Fig. 5 shows the spectrum in the presence of 0.1M BuCl. The curve changed to curve 4 when the sample was cautiously warmed to about -170°C. The latter spectrum is practically the same as the spectrum shown in Fig. 2. Curves 2 and 3 of Fig. 5 which are the components of curve 1 will be explained later in the discussion.

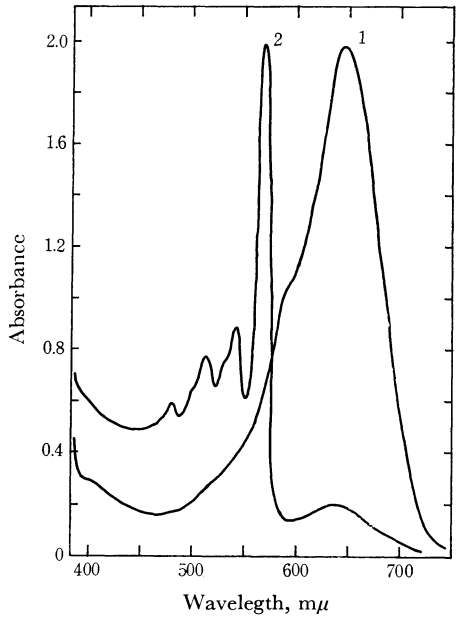

Fig. 4. Absorption spectra of acridan cation (curve 1) and the N-radical (curve 2).
Curve 1: acridan (25 mM) in *s*-BuCl glass γ-irradiated to the dose of 2.9×10^{19} eV/m*l*.
Curve 2: preceding sample after warming to *ca.* −170°C (the spectrum was recorded at −196°C).

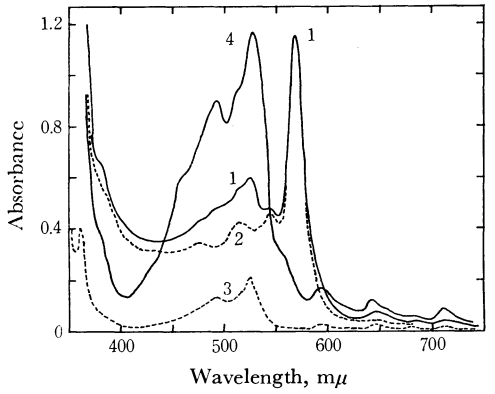

Fig. 5. Absorption spectra of the C- and N-radicals. Curve 1; acridan (50 mM) plus *s*-BuCl (100 mM) in TEA glass γ-irradiated to the dose of 9.3×10^{19} eV/m*l*. Curve 1 is divisible into two components, curves 2 and 3 where curve 2 matches with the spectrum of the N-radical shown in Fig. 4 and curve 3 is comparable with the spectrum of the C-radical in Fig. 2. Curve 4; preceding sample giving curve 1 after warming to *ca.* −170°C (the spectrum was recorded at −196°C).

Discussion

Electronic Absorption Spectra. In the low temperature rigid solution, events ensuing from ionization of the matrix molecule which is the major component of the system are "frozen" so that observation can be made at leisure. Electrons and positive holes are stabilized as intermediate products of reactions with solutes or matrix molecules. The metastable species thus formed often have strong absorption in the UV through near IR region. A proper choice of matrix enables us to produce a single species which is solely responsible for the absorption in the visible and near IR regions. Criteria for the choice have been expounded in previous papers.[3,6] A brief summary would be conducive to the following discussion; mass spectroscopic studies indicate that the parent ion of ethers, amines, alcohols and esters performs an efficient proton transfer reaction,

$$RH^+ + RH \rightarrow R\cdot + RH_2^+ \qquad (1)$$

Therefore when these substances are used as an isolating matrix for a small amount of solutes, ionization induced in the matrix molecule should result in reaction (1) while the detached electron migrates in the matrix to produce a solute anion. A typical example of this type of matrix is MTHF. Since the products of reaction (1) for MTHF do not absorb in the visible region, any absorption in the spectral region should be attributed to products of the reaction of electron with solute. Appearance of a new band in the acridine-MTHF system identifiable with acridine anion (Fig. 1) is thus accounted for in terms of electron attachment to the solute acridine.

Solute anions produced in alcoholic matrices often undergo further change by a proton addition,[7]

$$S^- + ROH \rightarrow \cdot SH + RO^- \qquad (2)$$

Acridine as the solute would yield a semiquinone radical by reaction (2). Since the band appearing in acridine-ethanol system (Fig. 2) resembles closely that of the C-radical proposed in a previous paper,[1] we regard that reaction (2) holds good for this system also. Since the electron in the acridine anion would most plausibly be populated at the nitrogen atom,[8] the alcoholic proton must have been bridged to the nitrogen of the anion before it is incorporated into the acridine ring. Thus the C-radical and not the N-radical should be favorably formed. Besides alcohols, glass-forming esters, when used as a matrix for acridine, gave the C-radical. For this system reaction (3) will take over reaction (2) to give the same radical,

$$S^- + RCH_2COOR \rightarrow \cdot SH + RCHCOOR^- \qquad (3)$$

6) T. Shida and W. H. Hamill, *J. Chem. Phys.*, **44**, 4372 (1966).
7) T. Shida and W. H. Hamill, *J. Am. Chem. Soc.*, **88**, 3689 (1966).
8) A quantitative study on the electronic state of acridine anion is currently being carried out by us.

The formation of the carbanion is assumed in numerous organic reactions.

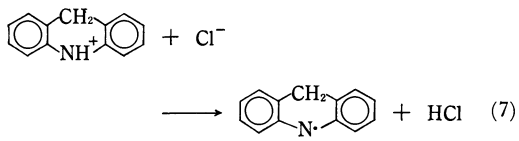
In contrast with the matrices so far discussed, the matrix of alkyl halides provides cationic species of solute molecules.[3] This is because the electron ejected from matrix molecules is scavenged by another matrix molecule and cannot reach a solute molecule in the distance. Meanwhile the positive hole in the matrix is found to migrate quickly to the solute molecule.[3] Processes in the butyl chloride matrix will be summarized as follows,

$$BuCl \xrightarrow{\gamma} (BuCl^+)_{mobile} + e^- \quad (4)$$

$$e^- + BuCl \rightarrow Bu\cdot + Cl^- \quad (5)$$

$$(BuCl^+)_{mobile} + S \rightarrow BuCl + S^+ \quad (6)$$

Decisive evidence for reaction (5) has been obtained by ESR studies.[9] In the absence of solute S migrating holes are eventually trapped by the matrix itself giving rise to the band of the trapped hole at about 400—600 mμ.[6] The band was eliminated when acridine or acridan was present in the chloride matrix and the new bands shown in Figs. 3 and 4 appeared which is accomodated to the above scheme with the assignment of the newly appearing bands to the respective solute cations. It is noted that the spectrum of acridan cation is very much like the spectrum of diphenylamine cation,[10] and is also comparable with the spectrum of alkylated acridan cations studied by Zanker *et al.*[2] Spectral change from curve 1 to 2 in Fig. 4 is explained as follows; upon softening the sample the chloride ion produced by reaction (5) will diffuse to the acridan cation in which the positive charge would be mainly localized at the nitrogen atom. Abstraction of the proton attached to the nitrogen by chloride ion will produce the N-radical,



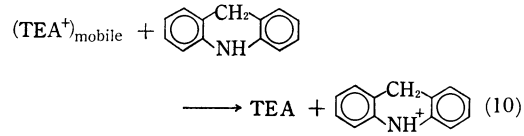
(7)

Similarity of curve 2 with both the spectra of N-radicals of alkylated acridans[2] and the spectrum of N-radical in our previous paper[1] gives credence to the previous assignment.

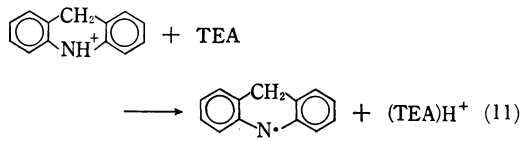
The formation of the N-radical was also noticed in another system. As mentioned before alkyl amines (primary and secondary) are subject to reaction (1) and are therefore used as a matrix to obtain solute anions. In tertiary amines such as TEA, however, it was found that the positive hole can migrate to some extent apparently because of the lack of protonation reaction (1).[11] Since acridan is expected to have a lower ionization potential than that of TEA,[12,13] acridan in TEA might produce acridan cation by accepting the migrating positive hole. Contrary to expectation, the spectrum obtained is very similar to that of the N-radical (curve 1 of Fig. 5). The enhancement of the signal by the addition of electron scavenger (100 mM of BuCl) suggests that the precursor of the N-radical is cationic. For the result the following scheme is proposed,

$$TEA \xrightarrow{\gamma} (TEA^+)_{mobile} + e^- \quad (8)$$

$$e^- + BuCl \longrightarrow Bu\cdot + Cl^- \quad (9)$$

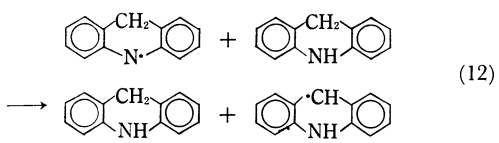


(10)



(11)

That is, although the acridan cation is once formed by reactions (8) and (10), the proton of the cation will be transferred to TEA on account of the high basicity of the amine. The spectral change from curve 1 to 4 in Fig. 5 indicates the transformation of the N-radical to the C-radical in the soft medium. In such a relaxed matrix the N-radical will be able to diffuse. On encountering an acridan molecule the radical may induce the following substitution reaction,



(12)

Careful comparison of curve 1 of Fig. 5 with the spectrum of the N-radical (curve 2 of Fig. 4) and of the C-radical (Fig. 2) shows that the curve in Fig. 5 comprises a small contribution of the C-

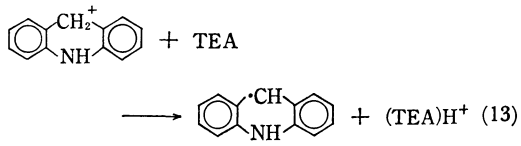
radical. The broken curves in Fig. 5 illustrate that curve 1 is divisible into the two components. At present it is not known whether the concomitant C-radical is formed by reaction (13) which competes with reaction (11),



or it is subsequently formed from the N-radical by reaction (12) as a result of possible local softening of the matrix upon the formation of N-radical. The notation for acridan cation in reaction (13) implies that a fraction of positive charge may reside in the carbon atom at the 9-position.

Although conformational data are not available for the acridan molecule, most probably it has a bent form. The extraordinarily sharp peaks and well-structured spectrum of the N-radical suggest that the radical is planar or near-planar[14] and the equilibrium nuclear distances of the radical do not appreciably change upon the electronic excitation corresponding to the visible band.[14,15]

The authors wish to thank Professor Masao Koizumi for his pertinent comment on the mechanism of radical transformation (*cf.* reaction (12) in the text) and for reading the manuscript.

The Micellar Properties of Disodium Monoalkyl Phosphates in Aqueous Solutions

Takashi TAHARA, Iwao SATAKE and Ryohei MATUURA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received August 15, 1968)

The disodium monoalkyl phosphate with *n*-dodecyl, *n*-tetradecyl and *n*-hexadecyl radical was synthesized, and pNa and light scattering studies were performed on the micellar properties of these surfactants in aqueous solutions. The critical micelle concentrations (CMC) of these salt solutions were confirmed to be considerably higher than those of ordinary 1–1 type ionic surfactants with the same alkyl chain length. The degree of dissociation of the micelle was, however, found to be not so different from that of corresponding sodium alkyl sulfate. The fact that these salts have comparatively large aggregation number reflects one of the characteristic features of alkyl phosphate anion which has two dissociable groups.

The detailed surface chemical studies of various ionic surfactant solutions have led to the realization that the micellar properties, such as critical micelle concentration, aggregation number and the degree of dissociation of the micelle, depend on the structure of constituent detergent molecule, *e. g.*, on the valency of counter ion and on the number of ionic groups at the end of the hydrocarbon chain.

The studies with the ionic surfactants which have two dissociable groups were performed by Shinoda,[1] who determined the CMC's of potassium alkyl malonates, $RCH(COOK)_2$, and confirmed that they are much higher than those of corresponding fatty acid soaps.

The elevation of the CMC is also anticipated to be the case with the monoalkyl phosphate detergents. However, in spite of their wide industrial applications, the available informations on the basic surface chemical properties of purified alkyl phosphate detergents are extremely scanty, since the purification procedures of the reaction mixture are rather complicated. So far as we know, the only available data were presented by Cooper,[2] who synthesized the mono- and disodium alkyl phosphates with various chain length and determined the CMC's of their aqueous solutions on the basis of surface tension measurements.

1) K. Shinoda, *J. Phys. Chem.*, **59**, 432 (1955).

2) R. S. Cooper, *J. Am. Oil Chemists' Soc.*, **40**, 642 (1963).

It is, thus, desirable to investigate the micellar properties of alkyl phosphate detergents in order to make clear their characteristics which will in turn contribute to the general understanding of common features of ionic surfactants.

The present work concerns the preparation and the determination of CMC and other related micellar properties of disodium monoalkyl phosphates with alkyl chain length from n-C_{12} to n-C_{16}.

Experimental

Materials. The monoalkyl phosphoric acids {RH_2PO_4; here, R=dodecyl, tetradecyl and hexadecyl radical} were synthesized from the purified alkyl alcohols and pyrophosphoric acid by violent stirring in absolute benzene for 100 hr at 25°C.[3]

$$\begin{aligned} R\text{–}OH + H_4P_2O_7 &\rightarrow RH_2PO_4 + H_3PO_4 \\ &\rightarrow RH_3P_2O_7 + H_2O, \\ R\text{–}OH + RH_3P_2O_7 &\rightarrow R_2HPO_4 + H_3PO_4 \\ &\rightarrow R_2H_2P_2O_7 + H_2O, \ etc. \end{aligned}$$

The reaction mixture was dissolved in ether and washed twice with water to remove residual inorganic acids. The crude monoalkyl phosphoric acid in oil phase was then treated with an aqueous solution of sodium hydroxide (pH=12) to extract the water soluble disodium monoalkyl phosphate into aqueous phase. By the addition of hydrochloric acid to the aqueous phase obtained above until the pH of the solution was lowered to about 0.5, alkyl phosphoric acids were precipitated. Then the monoalkyl phosphoric acid was selectively extracted into ether at pH 0.5, since the solubility of alkyl phosphoric acids in ether is known to be in the decreasing order of mono-, di- and trialkyl substitute.[4] The purity of the monoalkyl phosphoric acid was improved by repeating above processes until a thin layer chromatographical test gave 1 spot of monoalkyl phosphoric acid.

The test plate used in the thin layer chromatography was made of silica gel mixed with 0.5N oxalic acid solution in the ratio of 7 to 10. For the purpose of activation, the plate was first heated for 1 hr at 80°C. The subsequent development was carried out by using the mixed solvent which contains five parts of benzene and one part of methanol. We used 5% ethanol solution of molybdatophosphoric acid for the detection. The value of R_f was found to be in the order of mono-$>$di-$>$ trialkyl substitute.

The evaporation of the ether solution *in vacuo* yielded white waxy solid of monoalkyl phosphoric acid. It was then recrystallized several times from hot n-hexane until the white crystalline monoalkyl ester could be obtained. The purity of the product was confirmed by elementary analysis, mp measurement and pH titration with sodium hydroxide.

The disodium monoalkyl phosphate was easily obtained by the neutralization to pH 12 with NaOH solution and the subsequent dehydration process by the successive extraction with acetone. In order to remove surface active impurities, the sodium salts were extracted with ether for 50 hr, and then dried *in vacuo* over phosphorus pentoxide. The final products are white crystalline compounds which have hygroscopicity. It was, however, confirmed by means of thermogravimetric and elementary analysis that these salts have no water of crystallization.

Apparatus and Method. The method used in the present experiment for measuring the counter ion activity in the solution was exactly the same as the technique previously used to study the solutions of sodium alkyl sulfates.[5] That is, we used a Horiba pNa meter model N-5 with the sodium sensitive glass electrode, making a cell as follows:

Na glass electrode | Detergent solution | N NH_4NO_3 | 3.33N KCl agar bridge | Calomel electrode

We used the mean activity of sodium chloride presented by Janz and Gordon[6] for calibrating the apparatus. The experimental reproducibility of the sodium ion activity was found to be within ± 0.005 pNa unit. The measurements were conducted at 35 and 45°C for C_{12} and C_{14} salts, and at 45°C for C_{16} salt, in order to prevent the formation of the precipitation of ammonium alkyl phosphate at the liquid junction.

The conductivity measurements were performed by using Yanagimoto conductivity outfit model MY-7 at the same temperature as above.

A Shimadzu photoelectric light scattering photometer model PG-21 was used for estimating the micellar molecular weights of the detergents in solution. The measurements were carried out at 436 mμ with a semi-octagonal cell. The concentration dependence of the refractive indices was estimated by a Shimadzu differential refractometer at the same wavelength. The temperature of the cell was controlled at about 48°C.

Results and Discussion

Figure 1 shows the typical plots of the logarithm of sodium ion activity *vs.* the logarithm of the molar concentration of disodium dodecyl phosphate at 35 and 45°C, and of hexadecyl phosphate at 45°C, respectively. As is clearly shown in this figure, a sharp break occurs at the CMC of each detergent. The values of CMC determined from the break points in Fig. 1 are given in Table 1, together with those obtained from the specific conductivity (κ) *vs.* concentration plots. The differences between them are found to be within an experimental error. The observed values of CMC for disodium monoalkyl phosphates are considerably higher than those of 1–1 type ionic surfactants with the same alkyl

chain length, suggesting the significant contribution of increased electrical repulsion between bivalent head groups to the micelle formation. The value of CMC obtained for C_{16} salt is in good agreement with that reported by Cooper.[2] A comparison of the values for C_{12} and C_{14} salts is, however, rather difficult since no exact values for these salts are given in his paper. As would be expected, the CMC's of disodium monoalkyl phosphates are nearly identical with those of potassium alkyl malonates.[1]

As is the case with ordinary 1-1 type ionic surfactants, there is a linear relationship between log CMC and the number of carbon atoms (m) in the alkyl chain. Figure 2 shows the relation between log CMC and m in the disodium monoalkyl phosphates. The slope of the straight line is determined as −0.21 at 45°C, which is considerably large compared with the value of −0.29—−0.30 observed for various types of 1-1 type surfactants.[7]

According to the theory of micelle formation of ionic surfactants,[7] the slope of the log CMC *vs.* m plot may be given as

$$\mathrm{d}\log \mathrm{CMC}/\mathrm{d}m = -\omega/2.303kT(1+iK). \quad (1)$$

Here, i is the number of ionic groups in the alkyl chain, ω the cohesive energy change transferring one methylene group from a hydrocarbon environment to an aqueous medium and K the experimental canstant for the particular surface active agent which has a meaning similar to the degree of dissociation of the micelle (α). It is thus anticipated from Eq. (1), that the values of K (or α) for the present detergents are not so different from those of 1-1 type surfactants, *e. g.*, of sodium alkyl sulfates.

The degree of dissociation of the micelle may be evaluated from the concentration dependence of the counter ion activity by using the convenient method derived by Botré *et al.*[8] and applied for various systems by subsequent authors.[9]

If we assume that the concentration of singly dispersed detergent anion is constant (C_0) over the concentration range above CMC, the sodium ion activity can be written as

$$a_+ = 2\gamma_{\pm\mathrm{app}}C = 2\gamma_+\{C_0+\alpha(C-C_0)\} \quad (2)$$

or

$$\gamma_{\mathrm{app}} = \alpha\gamma_+ + \gamma_+(1-\alpha)C_0/C, \quad (3)$$

where, C is the total analytical concentration of the detergent in mol/l, γ_{app} the apparent ionic

activity coefficient of sodium ion defined by $a_+/2C$, γ_+ the ionic activity coefficient of the sodium ion and α the degree of the dissociation of the micelle. A theoretical consideration on Eq. (3) based on lamellar micelle model was given in our previous work.[5] Equation (3) suggests that γ_{app} will vary linearly with C_0/C throughout the concentration range in which both γ_+ and α are assumed to be constant. This is the case for present experimental results. As is shown in Figs. 3 and 4, γ_{app} *vs.* C_0/C plots give straight lines over whole concentration range studied. The values of α and γ_+ estimated from the intercept and slope of γ_{app} *vs.* C_0/C plots are summarized in Table 1. In the previous pNa study with the sodium alkyl sulfates,[5] the degree of dissociation of the micelle was determined to be 0.28 for sodium dodecyl sulfate and 0.24 for sodium tetradecyl sulfate, both at 35°C. Although the values of α obtained for disodium monoalkyl phosphates are slightly larger than those of sodium alkyl sulfates it, seems reasonable to consider that the degree of dissociation of the micelle is almost unaffected by the number of ionizable groups so far as the other structural constitutions are the same.

In a crude picture of micellar solution, the activity coefficient of sodium ion may be expected to be characterized by the ionic strength of the solution. It is, therefore interesting to note that the constant

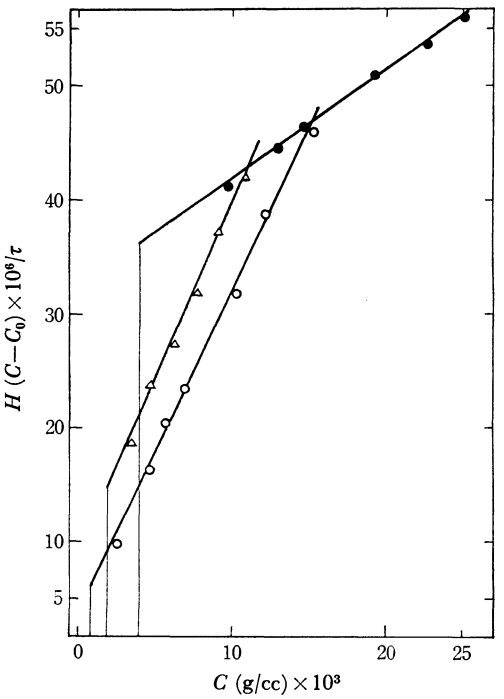

Fig. 5. $H(C-C_0)/\tau$ *vs.* C curves for disodium monoalkyl phosphates in NaCl solution at 48°C.

value of γ_+ obtained for C_{14} salt at 35°C is considerably small as compared with the value of 0.83 for sodium dodecyl sulfate having the similar CMC at the same temperature. Since no difference is found between the values of α, this depression must be ascribed to the existence of more highly charged polyions in disodium tetradecyl phosphate solution than in sodium dodecyl sulfate solution. This means that the micellar aggregation number of the tetradecyl phosphate micelle is much larger than that of sodium dodecyl sulfate.

In Fig. 5 are given the scattering data for disodium monoalkyl phosphates in sodium chloride solution. The values of CMC in salt solutions were determined from turbidity curves. The micellar molecular weights estimated from the intercept at CMC are summarized in Table 2.

Table 2. The micellar molecular weights of disodium monoalkyl phosphates determined from light scattering experiment

Detergent	Solvent	CMC (mol/l)	MMW	AN
C_{12}	0.5N NaCl	1.25×10^{-2}	27800	90
C_{14}	0.2N NaCl	4.2×10^{-3}	70400	207
C_{16}	0.08N NaCl	1.73×10^{-3}	156200	426

MMW: Micellar molecular weight
AN: Aggregation number

In accordance with the consideration on the sodium ion activity coefficients above CMC, the aggregation number of 207 obtained for C_{14} salt is about twice as large as that of 101 for sodium dodecyl sulfate,[10] both in 0.2N NaCl solution. This result indicates an interesting feature of disodium monoalkyl phosphates that their micellar aggregation number is considerably large compared with that of 1-1 type surfactant which has the comparable order of CMC. It is, however, rather difficult to compare the obtained aggregation number for the present detergents with that of 1-1 type surfactants which have the same chain length, since they are found to increase with increasing concentration of added salt.[10,11]

In view of the acidic character of the phosphate radical, these detergents may be considered to be hydrolyzed in water, giving rise to the minimum in surface tension *vs.* concentration curve. It was, in fact, observed in the present experiment that the surface tension *vs.* concentration curves for these salt solutions showed a pronounced minimum. However, the fact that the minimum could be reduced with the addition of sodium chloride, explains well the hydrolyzing nature of these salts in solutions. From the pH measurements on these salt solutions, the degree of hydrolysis was estimated to be 0.12% in 0.1 mol/l, 0.14% in 5×10^{-2} mol/l and 0.55% in 1.1×10^{-2} mol/l for C_{12} salt, and 0.37% in 0.1 mol/l and 0.60% in 1.5×10^{-2} mol/l for C_{16} salt, both at 45°C, respectively. Since the values of the degree of hydrolysis of the alkyl phosphate anion are negligibly small, the effect of hydrolysis products on the bulk properties is not taken into account in this paper.

(Received August 17, 1968)

The solubilities and critical micelle concentrations (CMC) of potassium dodecyl sulfate (KDS) and hexadecyl sulfate (KHS) were measured in methanol-, ethanol-, 1-propanol-, ethylene glycol-, 1,2-propanediol-, and glycerol-water mixed solvents over the temperature range from 0 to 40°C. It was found that the higher the hydroxy group density in the solvent, the less the effects on both the solubility and the CMC, and that the presence of an alkyl group in the solvent causes a greater temperature-dependence in the solubility. The solvent effects on the CMC and on the single-ion dispersion were discussed separately. An effect of a net-work structure formed between the hydroxy compound and water on the solubility is suggested. Solvent effects on the alkyl group and the ionic group of a surfactant molecule were separated by considering the difference between the standard free-energy change for the solution process of KHS and that of KDS. The effects on the Krafft point were also discussed in term of the above suggestions.

There are many factors that govern the monomer-micelle equilibrium in the surfactant solution. The solvent effects on the CMC have been studied by many investigators; some additives raise the CMC,[1,5] while others lower it.[2,5] However, no definite conclusion has ever been drawn. These phenomena are considered to be closely related to the structure of water.[3–5] In order to make clear how the addition of an organic substance affects the solution behavior of the micelle and the single ion, which are equilibriated with each other in micellar solution, it was necessary to measure the CMC and the single-ion solubility (not equilibriated with the micelle) of the surfactant in various organic solvent–water mixtures over a wide range of temperature. The potassium alkyl sulfates used in the present work are suitable for determining the solubility and CMC separately, near room temperature, as their Krafft points are about 20°C higher than those of the sodium salt analogs, typical anionic surfactants, the micellar properties of which have been well studied.

In the present paper, we will describe the effects of added hydroxy compounds on the solution properties of the surfactant.

Experimental

Materials. The potassium alkyl sulfates were synthesized by the sulfation of the corresponding long-chain alcohols with concentrated sulfuric acid, followed by neutralization with potassium hydroxide. The crude alkyl sulfates were extracted by butanol, recrystallized from butanol and from water three times each and finally washed with ether in Soxhlet's extractor. The methanol was simply distilled. The ethanol and 1-propanol were refluxed over dried calcium oxide for hours and then distilled. The glycols were distilled under reduced pressure. Glycerol of a G.R. grade was used without further purification.

Measurements of Solubility and CMC. By using an electric conductivity meter outfit, Model CM-1 DB, of the Towa Dempa Kogyo Co., Ltd., solubility and CMC measurements were made with KDS. As the solubilities of KHS were too low to be determined by the electric conductivity method, colorimetry was employed: The supernatant of the saturated solution (a long time was necessary to reach an equilibrium, so the surfactant solution in the presence of the solid phase was shaken mechanically for more than 50 hr and then left to stand for 12 hr in a thermostat) was pipetted through a 4G sintered-glass filter and then extracted as a methylene blue-alkyl sulfate complex into a chloroform phase.[6] The optical density of the blue-colored

chloroform was measured at the wavelength of 650 mμ using a spectrophotometer, Model 139, of the Hitachi Mfg. Co., Ltd. The calibration curve is shown in Fig. 1, where it may be seen that the methylene blue-alkyl sulfate complex shows the same absorbance whatever the length of the alkyl chain.

Results and Discussion

The solubilities and CMC's of KDS are shown as a function of the temperature in Figs. 2—6. A general trend for the solubility to increase slightly in the lower temperature range and to increase markedly in the higher temperature range is apparent. The abrupt change in solubility may be understood as a change in the solution behavior of the surfactant, that is, the micelle formation.

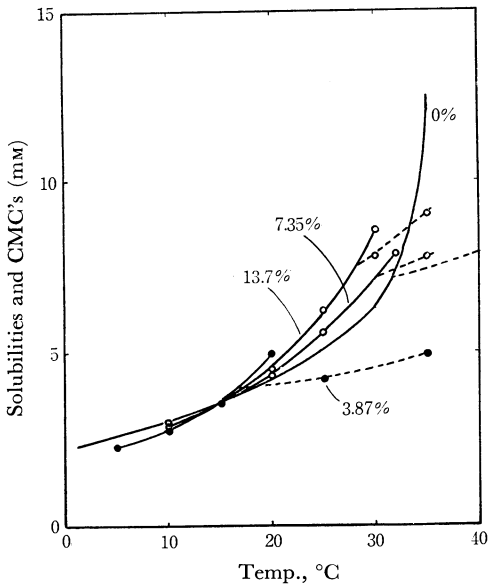

Fig. 2. Solubilities and CMC's of KDS in propanol-water mixtures ●, and in methanol-water mixtures ○.

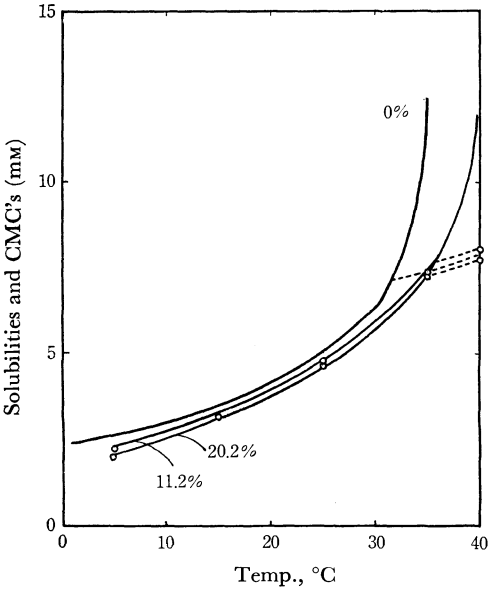

Fig. 6. Solubilities and CMC's of KDS in glycerol-water mixtures.

Thus, a temperature at which the solubility curve intersects the CMC curve is defined as the Krafft point. Therefore, it will be convenient to discuss the solvent effects on micelle formation and on single-ion dispersion separately.

Solvent Effects on Micelle Formation. The CMC's at 35°C are shown in Fig. 7, where the abscissa indicates the weight percentages of the organic

CMC's in ethanol-water mixtures ar extrapolated from lower temperatures to 35°C in Fig. 3.

additives. As for the effect of alcohols on the CMC, it has been known that there are both CMC-increasing and CMC-decreasing effects, depending on the chain lengths of the alcohols added.[1,3,5] The same is observed here: methanol shows a CMC-increasing effect, ethanol both, and propanol may have a CMC-decreasing effect, but the addition of much more propanol will have a CMC-increasing effect, too.[2]

In contrast, glycols have a CMC-increasing effect only. Glycerol brings about a very slight minimum in the CMC curve, but it is not clear whether or not this minimum is related to the action of sucrose, which lowers the CMC of sodium dodecyl sulfate. This is attributable to the dehydration of surfactant ions, caused by the strong hydrophile of the sucrose added.[7]

The CMC-decreasing effect found in alcohol solutions may be due to the solubilization of alcohol molecules into micelles, resulting in a decease in the free energy caused by both the entropy of mixing and the reduction of the charge density on the micelle surface.[8,9] Glycols and glycerol do not penetrate the micelle because they have fewer lipophile. Thus, solvent effects other than solubilization have to be sought in connection with

these compounds.

As the CMC is the characteristic parameter of the micelle-single ion equilibrium, a solvent effect on single ions as well as on the micelle should be taken into account. For this purpose, the solubilities of the surfactants in the lower temperature range, where only single-ion dispersion is supposed, was examined.

Solvent Effects on Single Ions. It is evident from Figs. 2—6 that the addition of alcohols causes a comparatively small solubility change, but an observable increase in the temperature coefficient of the solubility. For example, the solubility of KDS in the 9.3 wt% methanol solution intersects at 16°C with that for pure water. Thus, the solubility of KDS in a methanolic solution is larger at 20°C, but becomes smaller at 10°C, than in pure water. These properties become exaggerated with increases of alcohol concentration and the chain length of alcohols.

On the other hand, in glycerol mixtures KDS is less soluble than in pure water at all temperatures lower than the Krafft point. Glycols are intermediate between glycerol and mono-alcohols, in that their solubility curves intersect at higher temperatures. In order to observe these effects more quantitatively, a standard free-energy change for the solution process, ΔF°, will now be introduced:

$$\Delta E^\circ = -2RT\ln X_s \qquad (1)$$

where X_s is a solubility in the mole fraction scale which should be replaced by an activity, but the experimental concentrations are so low (less than 5 mM) that the mole fraction can be used with a minimum loss of accuracy. The other notations have the usual meanings. The temperature coefficient of the solubility and thermodynamics also give:

$$\Delta H^\circ = -R\frac{\partial \ln X_s}{\partial\left(\frac{1}{T}\right)} \qquad (2)$$

and:

$$\Delta S^\circ = \frac{\Delta H^\circ - F\Delta^\circ}{T} \qquad (3)$$

where ΔH° and ΔS° are the standard enthalpy and entropy changes for the solution process respectively. In Fig. 8, ΔH°'s and $T\Delta S^\circ$'s are shown as functions of the weight percentages of the organic additives. It is evident that the longer the alkyl group in an alcohol molecule, the more temperature-dependent the solubility becomes, while the hydroxy group in additives surpresses the temperature dependence of the solubility. The higher hydroxy density in ethylene glycol and glycerol solutions supports the idea of a net-work structure formation which resists the thermal breaking of the structure much more than in alcohol solutions. The net-work structure also refuses to share space with dissolved solutes, *i. e.*, with surfactant molecules. This might be closely related to the smaller solvent effect seen in glycols and, above all, in glycerol solutions. On the other hand, the alkyl group in alcohol solutions interferes with the net-work formation and favors the thermal agitation. Thus, at higher temperatures, the alkyl group in a mixed solvent loosens the structure and affords space for surfactant molecules. At lower temperatures, the structure in the solvent becomes more rigid due both to hydrogen bonding and to iceberg formation about the alkyl group in the sense of Némethy-Scheraga.[10] In connection with the structure formation between the hydroxy compound and water, it may be noted that the micelle formation was found in a 34.5% ethanol solution at a lower temperature than 10°C, as may be seen in Fig. 3. As a micelle is an aggregation of "refugees" of surfactant molecules from a highly cohesive solvent, *i. e.*, water, a concentrated ethanol solution which is free from micelle formation at higher temperatures would cohesive enough to be disliked by the surfactant molecules at sufficiently low temperatures. It is also clear from Fig. 8

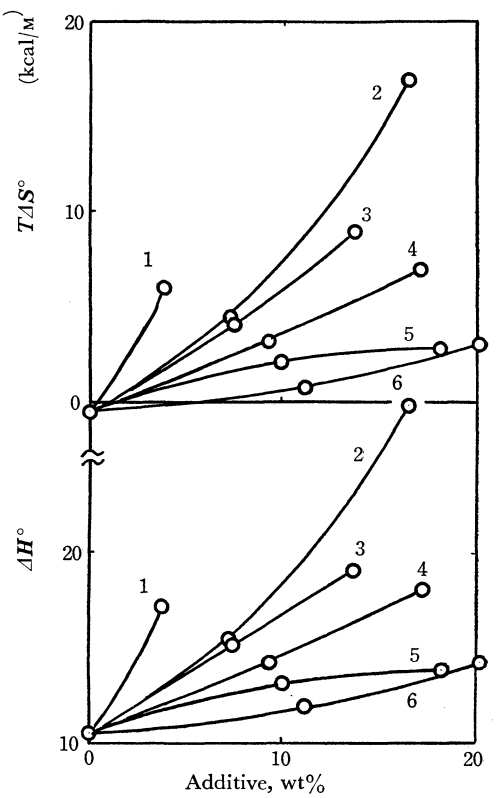

Fig. 8. ΔH°'s and $T\Delta S^\circ$'s of KDS in mixed solvents.
1: 1-propanol, 2: ethanol, 3: methanol, 4: propylene glycol, 5: ethylene glycol, and 6: glycerol.

that propylene glycol lies between glycerol and alcohols in that it has both glycol and methyl groups in a molecule. The iceberg around the hydrocarbon entity of a surfactant molecule might be attacked by the additives, because $T\Delta S°$ increases from negative value to a positive one with the additive concentration, as may be seen in Fig. 8.

Separation of Solvent Effects. The solvent effects can be divided into two groups: the solvent effect on a nonpolar group and that on an ionic group of a surfactant molecule. On the assumption that these two effects are additive, the separation can be experimentally made by measuring the solubility of, for example, KHS in each solvent and by applying the following equation:

$$\Delta\Delta F° = \Delta F°_{KHS} - \Delta F°_{KDS} = -2RT \ln \frac{C_{KHS}}{C_{KDS}} \quad (4)$$

where $\Delta\Delta F°$ means the solvent effect on the nonpolar group (exactly on the tetramethylene group) and where the subscripts KHS and KDS refer to the surfactants used. The C's are the solubilities of the surfactants. The solubilities of KHS are shown in Figs. 9—10 except for those in propylene glycol-, and glycerol-water mixed solvents, for which measurements were made at 15°C only; the results are shown in Table 1. In Fig. 11, the $\Delta\Delta F°$'s are plotted against the weight percentages of the additives at 15°. Although the points are scattered, it is observed that all alcohols show the same inclination and that glycols and glycerol show a smaller solvent effect, as was also noted in the

enthalpy change for the solution process. For comparison, a hypothetical solvent effect, defined below, may be tentatively introduced:

$$\Delta\Delta F°_{hypo} = \phi_W \Delta F°_W + \phi_H \Delta F°_H \quad (5)$$

where ϕ_W and ϕ_H are, respectively, the volume fractions of water and some hypothetical solvent such as "hexane" in a hypothetical mixed solvent where the two components are supposed to be

freely miscible without any overall change in the water structure, and where ΔF°_W and ΔF°_H are the standard free-energy changes for the nonpolar group when it is dissolved into water and into "hexane" respectively. Furthermore, $\Delta F^\circ_W > \Delta F^\circ_H \fallingdotseq 0$, because, when, for example, butane is dissolved into hexane, its free-energy change is negligibly small; therefore, Eq. (5) reduces to:

$$\Delta\Delta F^\circ_{hypo} = \Delta F^\circ_w (1-\phi_H) \qquad (6)$$

Equation (6) proves that a strongly cohesive solvent, such as water, becomes energetically void and liable to accept a hydrocarbon entity when mixed with "hexane." A formula similar to Eq. (6) can be derived from the Flory-Huggins' equation for three component system on the assumptions that: (1) the molar volumes are all alike, (2) the solution is very dilute with respect to solute, and (3) all the interaction energies except that between solute and water molecules are zero.[11] The hypothetical solvent effect is shown as a solid line in Fig. 11. A positive deviation from the hypothetical line would be due to the structure formation in alcohols-, in glycols-, and, above all, in glycerol-water mixed solvents.

The solvent effect on the ionic group can be calculated by the following equation:

$$\Delta F^\circ_{ion} = \Delta F^\circ_{KDS} - \Delta\Delta F^\circ \times 3 \qquad (7)$$

Since $\Delta\Delta F^\circ$ is a contribution from a tetramethylene group, the factor of three is introduced to obtain the contribution from a dodecyl group. The values of ΔF°_{ion}'s are plotted against the reciprocal of the dielectric constant*1 of the mixed solvents in Fig. 12. The straight line was drawn by the least-square method; the slope gives a "Born radius" of 0.3 Å. This value is smaller than the probable one (around 5 Å) deduced by the electric conductivity method for sodium dodecyl sulfate.[12] However, it may not be unacceptable taking into account the facts that the solvation energy cannot be explained by the Born mechanism alone and that, in addition, the experimental points are scattered. As a first approximation, the solvent effect on the ionic group is explained by the electrostatic theory; further mechanisms, such as selective solvation and the effect of a large hydrocarbon

group adjacent to the charged center, would be important and more precise experiments and theory would be required before they could be established.

Solvent Effect on the Krafft Point. In order to clarify the solvent effects on the Krafft point, detailed knowledge of the CMC and the single-ion dispersion, and of their temperature dependence is necessary. However, for the sake of simplicity, we consider in Fig. 13 two extreme cases in which: (a) the solubility curve is unchanged, but the CMC curve is increased or decreased, and (b) the CMC curve is unchanged, but the solubility curve is altered by the addition of organic compounds. The Krafft points are shown in Fig. 14 as functions of the weight percentages of the additives. If, from (a), CMC decreases, the Krafft point also decreases. This corresponds to the effect of propanol, which lowers the CMC, as has been pointed out above. An extreme example of this type of effect has been reported by Shinoda and Nakayama, who studied the very sensitive Krafft point-decreasing power of some higher alcohols (C_6–C_8).[13] As for the (b) case, the effect of glycerol may be pointed out. The solubility-decreasing effect and the small effect on the CMC of glycerol cause an increase in the Krafft point; such an increase is rare except as an effect of added electrolytes.[14] The medium decrease in the Krafft point affected by methanol can be understood on the assumption that the mechanism (b) slightly exceeds the (a), as there is also a CMC-increasing effect, which would otherwise raise the Krafft point. The effect of ethanol is indicative of the mechanism (a), which results from the large temperature dependence of CMC. For glycols, the two mechanisms compensate each other; hence, relatively small changes in the Krafft point are observed. Propylene glycol's greater inclination to decrease may well represent the effect of the methyl group, which ethylene glycol lacks.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1212—1216 (1969)

Paramagnetic Susceptibilities of Some DPPH Derivatives

Noriko OHIGASHI and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received August 22, 1968)

The static magnetic susceptibilities of polycrystalline samples of 1,1-bis(*p*-chlorophenyl)-2-picrylhydrazyl (Cl-DPPH), 1,1-bis(*p*-bromophenyl)-2-picrylhydrazyl (Br-DPPH), and 1,1-bis (*p*-methoxyphenyl)-2-picrylhydrazyl (CH_3O-DPPH) were measured in the temperature range from 10°K to 300°K. These three substances showed strong paramagnetism comparable to that of DPPH, having relatively weak interaction energies between their unpaired electrons. Of these, the paramagnetic susceptibility of CH_3O-DPPH was analysed on the basis of the singlet-triplet model with the energy separation of $2J/k=33.8$°K.

The typical neutral organic free radical, 1,1-diphenyl-2-picrylhydrazyl (DPPH), is known to have a sharp, exchange-narrowed ESR absorption line. A number of investigations have been carried out to find a transition to the magnetic ordered state on DPPH at a low temperature.[1-4] All of these measurements (except for the work of Gerritsen *et al.*[2]) agree with each other concerning the following points that the paramagnetic susceptibility of this compound obeys the Curie-Weiss law, having a Weiss constant of about −25°K between 60°K and room temperature, that it deviates at lower temperatures, and that no antiferromagnetic transition has been found, at least above liquid helium temperature.

The magnetic susceptibility of another neutral free radical, *N*-picrylaminocarbazyl (PAC), the molecular structure of which is very similar to that

of DPPH, behaves quite differently.[5] The magnetic susceptibility *versus* the temperature curve has a broad maximum at about 70°K. The difference in behaviour between these two compounds can mainly be attributed to the different crystal structures. However, there is another remarkable difference between them, *i. e.*, the difference in the distribution of the unpaired electron over the molecule. The electron spin resonance spectra of these compounds differ considerably from each other.[6] The spectra of DPPH and PAC apparently consist of five lines and four lines respectively; these ESR spectra can be explained in terms of almost equal hyperfine coupling constants of the two central nitrogens in the former, whereas in the latter one nitrogen should have twice as large a coupling constant as the other. This remarkable difference in the distribution of the unpaired electron is probably one of the factors distinguishing the magnetic behaviour of these compounds. The ratio of the hyperfine coupling constants of the two hydrazyl nitrogens in DPPH changes when the substituents are introduced into the para-positions of the two phenyl groups.[7] We intended to investigate the change in the magnetic properties when the distribution of the unpaired electron varied in the molecule.

In this paper we will present the results of our measurements of the temperature dependence of the static magnetic susceptibilities of several DPPH derivatives, *i. e.*, 1,1-bis(*p*-chlorophenyl)-2-picrylhydrazyl (abbreviated as Cl-DPPH), 1,1-bis(*p*-bromophenyl)-2-picrylhydrazyl (Br-DPPH), and 1,1-bis(*p*-methoxyphenyl)-2-picrylhydrazyl (CH_3O-DPPH) (Fig. 1). Among these, the paramagnetic

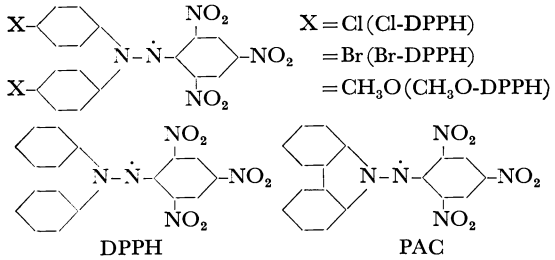

Fig. 1. Molecular structures of DPPH, derivatives of DPPH, and PAC.

susceptibility of CH_3O-DPPH is analysed on the basis of the singlet-triplet model, whereas the other two obey Curie law in the high-temperature range in spite of the appearance of the maximum in the susceptibility-*vs.*-temperature curve in Br-DPPH at 15°K.

Experimental

The susceptibility measurements were made by the Faraday method. Figure 2 shows the apparatus schematically. A quartz bucket containing a powder

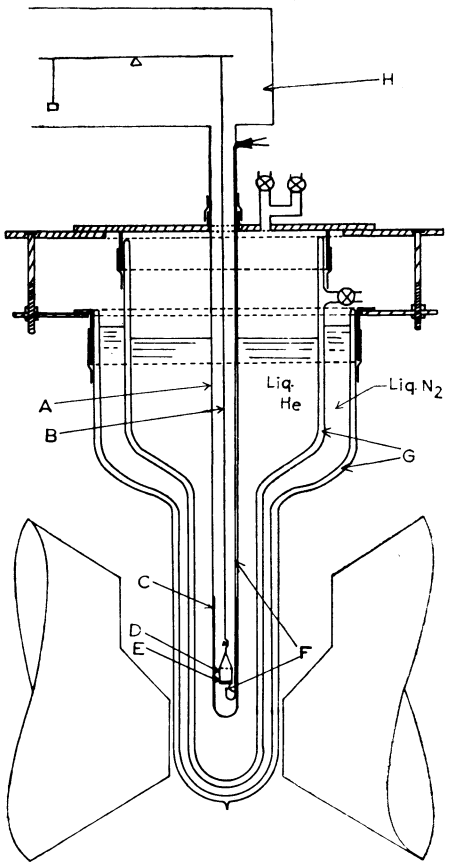

Fig. 2. Apparatus for susceptibility measurements.
A: Pyrex tube, B: Quartz string, C: Copper foil, D: Quartz bucket, E: Sample, F: Thermocouple, G: Glass Dewar, H: Vacuum balance.

sample of a few mg or more was suspended by a quartz string from the arm of a vacuum balance, a Sartorius Electrono microbalance. Helium gas (30 mmHg) which had been purified by passing it through an active charcoal at 77°K was admitted around the sample to facilitate the heat exchange. Each measurement was carried out continuously from 10°K to 300°K, the output of the microbalance being recorded on a X-Y recorder as a function of the e.m.f. of an Au : CO-Cu thermocouple. As the thermocouple was placed below the sample bucket (Fig. 2), the temperature in the sample was calibrated by measuring several times the susceptibilities of the paramagnetic salts whose susceptibilities are known, *i.e.*, Mohr's salt ($Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$) and Tutton's salt ($Mn(NH_4)_2(SO_4)_2 \cdot 6H_2O$), under the same conditions as for the usual measurements. The rate of raise of the temperature was set similarly for each run by controlling the pressure in the wall of the inner Dewar vessel. The Dewar vessel was placed between

the Sucksmith-type pole pieces with a pole gap of 5 cm, as is illustrated in Fig. 2. The sample bucket was adjusted so as to locate it at the plateau of $H\cdot\partial H/\partial x$ (usually 6.31×10^6 gauss^2/cm). At 10°K and also at room temperature while the susceptibility measurements were made the field strength was changed in order to check the field dependence. The field strength was calibrated by measuring the susceptibility of sucrose, the mass susceptibility of which was taken to be -0.566×10^{-6} emu/g.

The solvents for the recrystallization of the measured samples, Cl-DPPH, Br-DPPH, and CH_3O-DPPH, were benzene, benzene, and carbon tetrachloride respectively. All these samples were provided by R. I. Walter. Their molecular structures are illustrated in Fig. 1, along with those of DPPH and PAC.

Results and Discussion

The paramagnetic susceptibilities of all these compounds were comparable to that of DPPH; they all increased with a decrease in the temperature, as was mentioned in the previous communication.[8] In Br-DPPH and CH_3O-DPPH, however, the susceptibility reached its maximum value at 15°K and 21°K respectively, and then it decreased with the decrease in the temperature.

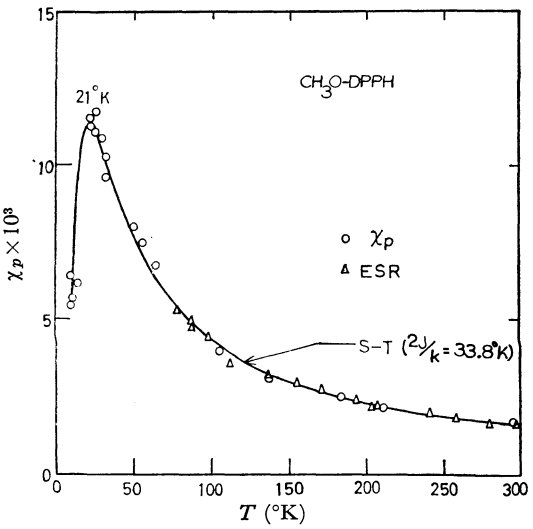

Fig. 3. Paramagnetic molar susceptibility of CH_3O-DPPH. Data are corrected for diamagnetism and an assumed impurity. The solid line is the theoretical fit based on singlet-triplet model with $2J/k$=33.8° K. The ESR data (arbitrarily normalized at 300° K) are also plotted.

The data were analysed by the formula;

$$\chi(T)=f(T)+\frac{C}{T}+D \qquad (1)$$

where $\chi(T)$ is the observed susceptibility at temperature, T; where the term C/T denotes the contribution from the assumed isolated paramagnetic "impurities"; where D is a diamagnetic term, and where $f(T)$ is a function of the temperature, which is assumed to have one of the following four forms:

1) $f(T)=Ng^2\beta^2/4kT$ (Curie law), (1-a)

2) $f(T)=Ng^2\beta^2/4k(T-\theta)$ (Curie-Weiss law), (1-b)

3) $f(T)=Ng^2\beta^2/kT\cdot(3+\exp(2J/kT))^{-1}$ (singlet-triplet model), (1-c)

4) $f(T)=Ng^2\beta^2/4kT\cdot\exp(-J/kT)$ (linear Ising model). (1-d)

In Eqs. (1-c), (1-d), we assumed the following spin exchange Hamiltonian:

$$\mathcal{H}=\sum_i^{N/2}(2JS_{2i-1}S_{2i}+2J'S_{2i}S_{2i+1}), \qquad (2)$$

and took $J\neq J'=0$ and $J=J'\neq0$, $S_iS_j=S_i^zS_j^z$, respectively.

In Eq. (1), the first term and the parameters C and D were chosen to give the best fits to the observed values. The results are shown in Figs. 3—5. Equation (1) reproduces fairly well the paramagnetic susceptibility data of CH_3O-DPPH if we take $f(T)$ as Eq. (1-c) with $2J/k$=33.8°K (the singlet-triplet energy separation) and if we assume the concentration of the impurity of spin 1/2 to be 8.7%, as is shown in Fig. 3. The maximum of χ_p was found at 21°K. The ESR measurement was

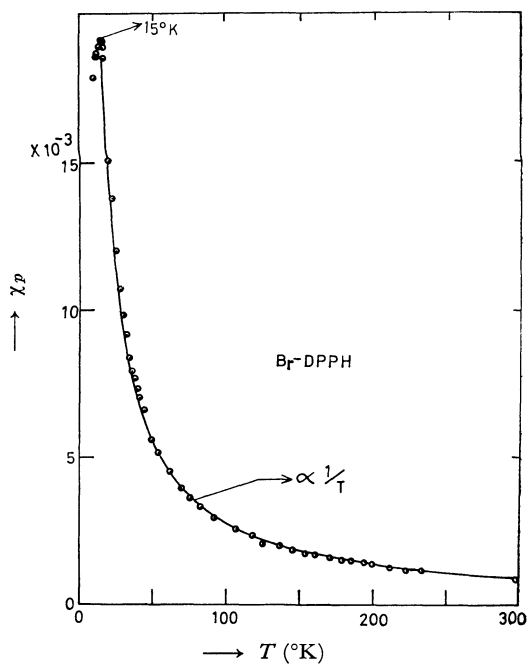

Fig. 4. Paramagnetic susceptibility of Br-DPPH.

8) N. Ohigashi and H. Inokuchi, This Bulletin, **41**, 269 (1968).

made on this powder sample between 77°K and room temperature. The absorption spectrum was very sharp, ΔH_{msl} being smaller than 1 gauss. As the absorption shape did not change with the temperature, the peak heights of the first derivative curves were thought to be proportional to the absorption intensity. These values are in good agreement with the static susceptibility data (Fig. 3), confirming that the observed strongly exchange-narrowed ESR absorption line at $g=2$ has the same origin as that giving rise to the static paramagnetic susceptibility.

The susceptibility, χ_p, of Br-DPPH had its maximum at 15°K and at higher temperatures followed a Curie law (Fig. 4), whereas that of Cl-DPPH obeyed a Curie law over the entire temperature range (Fig. 5). There is some evidence

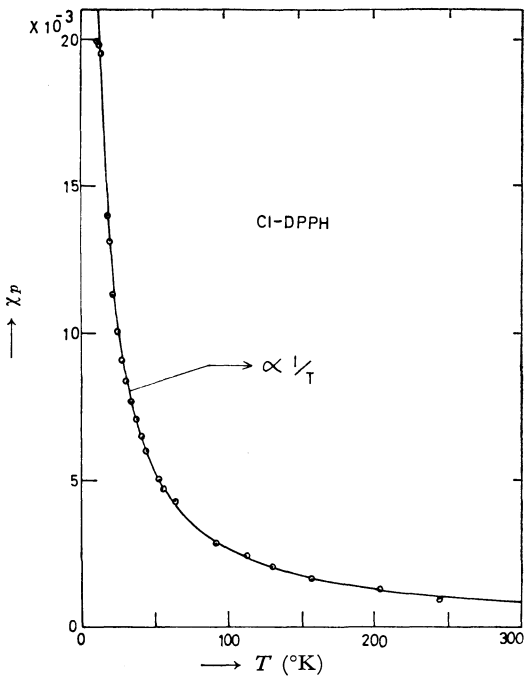

Fig. 5. Paramagnetic susceptibility of Cl-DPPH.

that the χ_p of Cl-DPPH has its maximum near 10°K, but our present apparatus can not give detailed information in this temperature region. The line widths at room temperature of the ESR absorption lines of these two compounds were about four times broader than that of CH_3O-DPPH. Further, in contrast to CH_3O-DPPH, they became narrow (about 2/3) when the temperature was lowered to 77°K. This fact probably suggests that in these two compounds, the crystal lattice spacings change with the temperature more rapidly than that of CH_3O-DPPH, and that the sudden decreases in the magnetic susceptibilities at 15°K and 10°K may be explained by the phase transitions. On the other hand, the χ_p of CH_3O-DPPH is represented by a single equation based on the singlet-triplet model from 10°K to 300°K, indicating that no phase transition occurs in this temperature range; this is consistent with the fact that no change in the line shape or width of the ESR absorption line is found from 77°K to room temperature.

As has been seen above, Cl- and Br-DPPH behave differently from CH_3O-DPPH. The crystal structures of these compounds have not yet been analysed. However, several crystal modifications of DPPH are known according to the solvents from which the crystals are grown. Our samples were crystallized from different solvents, benzene and carbon tetrachloride, but it has been inferred that their magnetic susceptibilities depend little on the solvents used for recrystallization. This is because the susceptibilities of the DPPH crystal measured by several authors seem to show small influences of solvents, whether or not the crystal contains molecules of solvation.[1-3] This suggests that the relative arrangement of the nearest neighbouring molecules is but little altered when the crystal structure changes. Similarly, in the DPPH derivatives used in this work, the arrangement of the neighbouring molecules may be determined mainly from the interaction between DPPH derivative molecules, but not from the interaction between the free radical molecule and a solvent molecule. Considering the size of the substituent, CH_3O-DPPH may fairly differ in the arrangement of molecules in the crystal from the other two radicals, Br- and Cl-DPPH.

The crystal structure of DPPH crystallized from benzene was recently determined by Williams.[9] His results show that the hydrazyl nitrogens of DPPH are surrounded sterically by the other atoms of the same molecule, indicating that the unpaired electron of DPPH is stabilized not only by conjugation with phenyl rings but also by the steric hindrance. In such circumstances, interaction among unpaired electrons in the crystal is generally small, but it may increase if the delocalization of an unpaired electron over a molecule advances upon the introduction of substituents. Of the three compounds studied, CH_3O-DPPH has the smallest hyperfine coupling constants for nitrogen nuclei,[7] suggesting that the unpaired electron in this compound delocalizes over the phenyl rings most extensively. The larger intermolecular interaction observed in CH_3O-DPPH may be attributed partly to this delocalization of the unpaired electron.

The magnetic interactions observed in DPPH-derivative crystals are smaller than those of many ion radical salts such as TCNQ anion radical salts, which crystallize with their molecular planes parallel

to each other.[10] The stabilization of unpaired electrons by the steric hindrance may explain this fact.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1216—1219 (1969)

Electrophoretic Behavior of Micelles of a Polyether-sulfate Type Surfactant

Fumikatsu Tokiwa and Kenji Ohki

Research Laboratories, Kao Soap Company, Minato-Yakushubata, Wakayama-shi

(Received August 30, 1968)

The electrophoretic properties of the micelle of sodium dodecyltrioxyethylene sulfate have been studied in the presence of various types of inorganic z_+-z_- electrolytes and in the presence of organic electrolytes (RNH_3Cl and $RCOONa$) of various sizes. The effect of the type of electrolytes on the zeta potential of the micelle, ζ, is similar in tendency to the effect to be expected on the basis of the Gouy-Chapman equation for spherical colloid particles. The valence of counter-ions has a considerable effect on ζ, but that of the co-ions has only a slight effect. With respect to the size of ions, counter-ions (RNH^+) appreciably influence the potential of the micelle, whereas co-ions ($RCOO^-$) influence the potential almost not at all. The value of ζ slightly increases, and then steeply decreases, with an increase in the size of the cations through a maximum value.

In a previous work[1] studies have been made of the effects of small electrolyte ions and long-chain alkyl ions on the surface potential of the micelle, ψ_0, of dimethyldodecylamine oxide by means of potentiometric titrations. The results have shown that the effect of small ions on ψ_0 is in accord with the effect predicted on the basis of the Gouy-Chapman equation for spherical colloid particles, while the effect of long-chain alkyl ions is directly related to their charge properties.

In the present work the zeta potential of the micelle, ζ, of sodium dodecyltrioxyethylene sulfate (SDPS-3), $C_{12}H_{25}O(CH_2CH_2O)_3SO_3Na$, has been studied by electrophoretic measurements in the presence of various electrolytes in order to learn the effect of the type of electrolytes on ζ. The reason for the choice of SDPS-3 was that the surfactant is dissolved in water in the presence of any types of electrolytes used and is, therefore, fit for the purposes of the present experiment. Further, the effect of the size of cationic and anionic ions on ζ has also been examined using a series of alkylamine hydrochlorides or sodium alkanoates.

Experimental

Materials. Sodium dodecyltrioxyethylene sulfate (SDPS-3) was synthesized by the sulfation of dodecyl trioxyethylene ether by the procedure described in a previous paper.[2] The dodecyl trioxyethylene ether, $C_{12}H_{25}O(CH_2CH_2O)_3H$, was prepared from dodecyl alcohol of a high purity by the addition of ethylene oxide and was pruified by fractional distillation to remove polyethylene glycol and higher and lower homologues. The number of oxyethylene units per molecule for the distilled ether was found, from its hydroxyl value, to be 3.05. The sample of SDPS-3 was purified by the ion-exchange method of Ginn and Church.[3] All of the inorganic electrolytes used in this experiment were of a guaranteed reagent grade. The short-chain alkylamine hydrochlorides and sodium alkanoates, which had been obtained from the Tokyo Kasei Kogyo Co., were also of a guaranteed reagent grade.

Electrophoresis. The electrophoretic measurements were carried out at 25°C with a Tiselius-type apparatus, Hitachi Model HTB-2A. The concentrations of SDPS-3 in both the upper and lower layers of the cell were taken to be higher than the critical micelle concentration in order to avoid the dissociation of the micelle into the monomers at the moving boundary;[4,5] the concentrations were taken to be 0.2 g/100 m*l* in the upper layer and 1.0 g/100 m*l* in the lower layer. An electrolyte was then added to give the solution an ionic strength of 0.10. The electrophoretic mobility of the micelle, U_M, was calculated from the velocities of the

ascending and descending boundaries, V_a and V_d, by the equation[4,6]:

$$U_M = V_d\tau^\beta - \frac{V_a\tau^\alpha - V_d\tau^\beta}{(T_M{}^\beta/T_M{}^\alpha) - 1} \quad (1)$$

where T_M is the transference number of the micelle, τ is the specific conductance of the solution, and where α and β superscripts refer to the upper and lower layers respectively.

Results and Discussion

The Effect of the Type of Electrolytes. Table 1 summarizes the electrophoretic mobilities, U_M, of SDPS-3 micelles in the presence of various types of inorganic electrolytes at an ionic strength of 0.10. The zeta potential of the micelle, ζ, can be evaluated from U_M by the numerical computation developed by Wiersema *et al.*[7] on the assumptions that, for example, the interaction between micellar particles is negligible, that the micelle may be treated as a rigid sphere, and that the charge of the micelle is uniformly distributed on the surface. This numerical computation is rather elaborate. However, the relation between ζ and U_M becomes linear when the value of U_M is small; the Henry equation[8] may then be used to evaluate the zeta potential:

$$\zeta = \frac{6\pi\eta}{D \cdot f(\kappa r_0)} U_M \quad (2)$$

where $f(\kappa r_0)$ is Henry's function; κ, the Debye-Hückel parameter; r_0, the radius of the micelle, and η and D, the viscosity and dielectric constant of the medium respectively. The values of ζ obtained from U_M in terms of Eq. (2), assuming that the radius of the micelle is 25 Å in the present case, are also given in Table 1. In the solutions of $MgCl_2$, $MgSO_4$, $AlCl_3$, and $Al_2(SO_4)_3$, the ζ values obtained by Eq. (2) are reliable since the values of U_M are small. In the solutions of NaCl, Na_2SO_4, and Na_3PO_4, on the other hand, the values of U_M are relatively high. In these cases, the use of Eq. (2) will introduce errors into the calculated ζ values. For example, the errors in ζ compared with the numerical calculation are about 9%, 3%, and 1% for the values in the solutions of NaCl, Na_2SO_4, and Na_3PO_4 respectively, when $\zeta = 51$ mV and when $\kappa r_0 = 2.5$ (at a radius of 25 Å and an ionic strength of 0.10).*1 Henry's approximation (Eq. (2)) is better for 1-2 and 1-3 electrolytes than it is for the 1-1 type; it also happens to be more accurate than Overbeek's approximation.[7,9]

It may be seen in Table 1 that the difference in U_M or ζ among chlorides, sulfates, and phosphates is relatively small (*e.g.*, compare NaCl with Na_2SO_4 and Na_3PO_4), while the difference among sodium, magnesium, and aluminium salts is considerable (*e.g.*, compare NaCl with $MgCl_2$ and $AlCl_3$). Namely, the valence of anions (co-ions) has only a slight influence on U_M or ζ, but the valence of cations (counter-ions) has a considerable influence. These results are similar to those obtained in the previous work studying the effect of electrolyte ions on the surface potential of the micelle, ψ_0, of dimethyldodecylamine oxide.[1]

The surface charge density of the micelle at the plane of shear, σ_s, is given by the equation[10]:

10) A. E. Loeb, P. H. Wiersema and J. Th. G. Overbeek, "The Electrical Double Layer Around a Spherical Colloid Particle," M. I. T. Press, Cambridge, Massachusetts (1961).

$$\sigma_s = -\frac{D}{4\pi}\left(\frac{d\phi}{dr}\right)_{r=r_s} \quad (3)$$

where ϕ is the electrical potential at a certain distance, r, from the center of the particle and where the subscript s denotes values at the plane of shear. To obtain the quantity of $(d\phi/dr)_{r=r_s}$ in Eq. (3), we must solve the Poisson-Boltzmann equation for negatively-charged, spherical particles. Loeb *et al.* have solved the equation exactly under different conditions; the results are tabulated in Ref. 10. The results are given as functions of the "reduced distance" ($q_0 \equiv \kappa r_s/\lambda$, where $\lambda^2=(z_+ + z_-)/2z_+$), the "reduced potential" ($y_0 \equiv e\zeta/kT$), and the valence of positive and negative ions (z_+ and z_-). With the aid of the $I(q_0, y_0, z_+, z_-)$ tables of Loeb *et al.*, Eq. (3) may be rewritten:

$$\sigma_s = \frac{D}{4\pi} \cdot \frac{kT\kappa}{e\lambda} I(q_0, y_0, z_+, z_-) \quad (4)$$

If the values of q_0 and of z_+ and z_- are given, we can obtain the relation between σ_s and y_0, or that between σ_s and ζ, from Eq. (4). Figure 1 shows

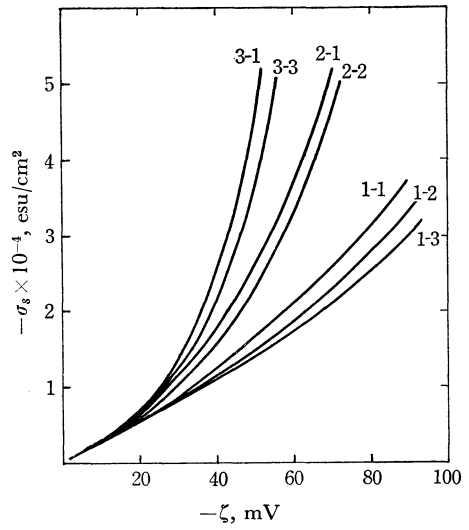

Fig. 1. The σ_s *vs.* ζ curves for a negatively charged, spherical particle with r_s of 25 Å in aqueous solutions of various z_+-z_- electrolytes at an ionic strength of 0.10.

the relation between σ_s and ζ for negatively-charged, spherical particles with r_s of 25 Å in aqueous solutions of various types of electrolytes at an ionic strength of 0.10.

As may be seen in Fig. 1, the relation of σ_s to ζ depends on the type of added electrolytes, especially on the valence of the cationic ions, which may be related to the results given in Table 1. We can now obtain the values of σ_s from ζ for the micelle of SDPS-3 using the curves shown in Fig. 1. The values of σ_s thus obtained are given in Table 1. It may be seen that the values of σ_s are also considerably influenced by the valence of the cations rather than by that of the anions. This implies that the valence of the counter-ions primarily governs the effective charge of the micelle, which must then be reflected to σ_s.

The Effect of the Size of Electrolytes. In Fig. 2 the values of U_M for SDPS-3 in the presence

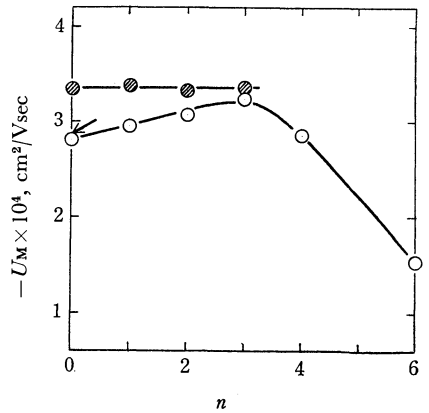

Fig. 2. The values of U_M for SDPS-3 in the presence of $C_nH_{2n+1}NH_3Cl$ (○) or $C_nH_{2n+1}COONa$ (●) at an ionic strength of 0.10 plotted against n. The arrow indicates the value in 0.10M NaCl.

of alkylamine hydrochlorides ($C_nH_{2n+1}NH_3Cl$) or sodium alkanoates ($C_nH_{2n+1}COONa$) are plotted against the alkyl chain length, n. The value of U_M is dependent on the size of the cations and is almost independent of the size of the anions. With the cations, the maximum value appears around $n=3$. It is of interest to note that the value of U_M in the presence of HCOONa is somewhat higher than the value observed in the presence of NaCl or NH_4Cl, even though the same value is to be expected for these three 1-1 electrolytes according to the Gouy-Chapman equation. The reason for this is not clear at present. However, it could be explained by the difference in steric effect between $HCOO^-$ and Cl^- anions or by the effect of the hydration of the anions.

In the general treatment of the distribution of ions in an electrical double layer based on the Boltzmann equation, electrolyte ions are assumed to be point charges instead of ions of a finite volume. A number of authors have attempted to introduce the ionic volume correction into the double-layer theory by rewriting the Boltzmann equation with some form of space restriction factor.[11] Thus, Haydon and Taylor[12] have derived relationships

11) D. A. Haydon, "Recent Progress in Surface Science," ed. by J. F. Danielli *et al.*, Academic Press, New York (1964), p. 97.

12) D. A. Haydon and F. H. Taylor, *Phil. Trans.*, **A253**, 255 (1960).

corresponding to the Gouy-Chapman equation for symmetrical electrolytes, corrected for the finite ionic volumes. According to their results, the surface potential increases with an increase in the size of the counter-ion when the surface charge density, the radius of the co-ion, and the concentration of the electrolyte are kept constant. With alkylamine hydrochlorides, the initial increase in U_M with an increase in n may be explained by the above result, although the effect is not as large as that to be expected from the calculation of Haydon and Taylor. The steep decrease in U_M after passing through a maximum value may be attributed to a direct influence of added alkylamine hydrochloride with a relatively large alkyl group. Probably, the SDPS-3 surfactant forms a complex with the alkylamine hydrochloride by the partial neutralization of the micellar charge. The fact that SDPS-3 is precipitated in the presence of octylamine hydrochloride supports this complex formation. With sodium alkanoates, the finding that the value of U_M is almost independent of n may be accounted for by the slight effect of anions on the potential of the micelle, as has been described above.

The authors wish to express their thanks to Dr. H. Kita, Director of the Research Laboratories, for his encouragement and for the permission to publish this paper.

Exo-electron Emission from Sandblasted Steel

Yasukatsu TAMAI and Yoshihiro MOMOSE

The Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai

(Received September 5, 1968)

The exo-electron glow curves up to about 250°C were measured for the sandblasted steel specimens, which had been kept in air for 2 min 30 sec, 2 hr 30 min or 13 hr after the sandblast. It was found that the plots of the integrated total counts against the keeping time in double-logarithmic scales gave a straight line with negative slope and that the emission peak moved to higher temperatures and at the same time the emission intensity decreased with the keeping time. It was also found that at the higher heating rate the peak intensity became larger and the peak temperature became higher than at the lower heating rate and that the remaining counts above a given temperature in the glow curve was linearly related with the temperature in semi-logarithmic scales, regardless of the heating rate. Comparing the behavior of exo-electron emission with that of the thermoluminescence of phosphors, it is supposed that electron traps are distributed on or in the deformed solid surface.

The phenomena of exo-electrons have been studied by many workers, which are emitted from solid surfaces stimulated by various treatments such as mechanical deformation and irradiation by X-rays. Some workers[1,2] have analyzed the exo-electron phenomena by means of the glow curve, which shows the characteristics of emission intensity observed at a constant rate of temperature rise, and estimated the electron trap depth. But they have not referred to the dependence of the glow curve on the time elapsed after the stimulation of the solid surface.

The reproducibility of the emission seems to be dependent on the method of surface treatment. In a previous paper[3] it was found that exo-electron glow curves were well reproducible if experimental conditions of surface treatment were properly regulated and the solid surface was uniformly deformed by suitable means such as sandblasting.

The purpose of the present work was to examine the dependence of the glow curves for sandblasted steel on the time for which the specimens, after sandblasted, were left in various atmospheres at room temperature, and to investigate the exo-electron decay mechanism.

Experimental

The details of the experimental apparatus have been

1) J. F. Young and D. J. Williams, *J. Appl. Phys.*, **34**, 3157 (1963).

2) H. Birgfellner and H. Hüller, *Acta Phys. Austriaca*, **14**, 56 (1961).

3) Y. Tamai and Y. Momose, *J. Appl. Phys.*, **39**, 5329 (1968).

described elsewhere.[4] A disk of commercial mild steel, 20 mm in diameter and 2 mm in thickness, was used. Prior to the experiments the mild steel specimens were annealed in air for 2 hr at about 400°C. Commercial standard sand (60 mesh through, the components: SiO_2 92%, Al_2O_3 4%) was used as blasting material.

A given amount (280 g) of sand was blown against the specimen by compressed air or nitrogen gas, at the gauge pressure of 1 atm, through a glass-made nozzle (2 mm, dia.) for 30 sec. The distance between the specimen and the blasting nozzle tip was 86 mm.

The counting device of the emission was a kind of open windowless Geiger-Müller counter. The working anode voltage was 1320 V and the accelerating voltage of 96 V was applied between the specimen holder and the grid (brass gauze) located at 10 mm above the holder. The counter gas was a mixture of ethanol (20 mmHg) and argon (83 mmHg). The measurements were conducted in the following way: The specimen was kept in air, argon or oxygen for a given time after sandblasting (this time is called "keeping time" hereafter) and then mounted on the specimen holder. It took about 3.5 min to evacuate the counter chamber, fill the counter gas in it for washing then repeat the same process again before the start of the counting. After one-minute counting at room temperature for steady operation of the ratemeter, the specimen was heated to about 250°C at the rate of 16°C/min or 27°C/min. Both the total counts and the count rate were recorded by a scaler and a ratemeter. The natural counting rate was approximately 0.8 counts/sec.

Results

Change of Glow Curves for Blasted Specimens Kept in Different Atmospheres. The black oxide film on the annealed specimen was removed under the present blasting conditions, and the freshly deformed metal surface was gray. Figure 1 shows the glow curves at a heating rate of 27°C/min for various keeping times in air (20°C, 50% relative humidity) after the sandblast by compressed nitrogen gas. In the glow curves, the intensity of the emission first rises, with rise of temperature, to a maximum at a definite temperature then slowly falls down to nearly the natural count rate. As seen in Fig. 1, as the keeping time becomes longer, the glow curves show a broader peak, the peak intensity and the total counts are smaller and the peak temperature is higher, but the emission intensity is almost the same in the higher temperature region in all cases.

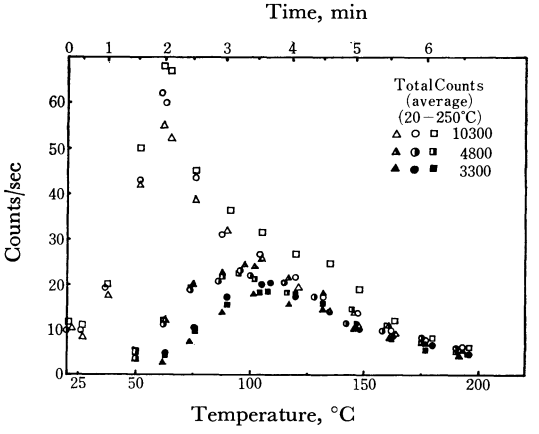

Fig. 1. Exo-electron glow curves for various keeping time in air after sandblasting.
△ ○ □: 2 min 30 sec
▲ ◑ ◨: 2 hr 30 min
▲ ● ■: 13 hr

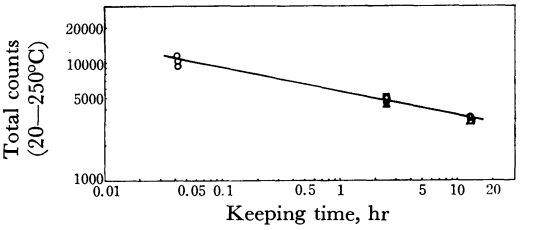

Fig. 2. Total counts of exo-electron glow curve (20—250°C) *vs.* keeping time.
○: Keeping in air (20°C, 50% relative humidity)
□: Keeping in oxygen (20°C, 1 atm)
△: Keeping in argon (20°C, 1 atm)

The plots of the total counts, N, against the keeping time, t, in double-logarithmic scales are shown in Fig. 2, which give a straight line with a negative slope. The empirical equation of the decay in air (20°C, 50% relative humidity) therefore was represented by

$$N(t) = C \cdot t^{-a}, \tag{1}$$

where a and C are constants, with $a=2.0\times10^{-1}$ and $C=2.9\times10^{4}$ (t: sec). Differentiation of Eq. (1) gives a decay of exo-electron emission in air;

$$\frac{dN}{dt} = -a \cdot C \cdot t^{-(a+1)}. \tag{2}$$

The decay equation in this form has been reported by many workers.[5,6] Lohff and Raether obtained the values of $a \cdot C$ and $(a+1)$ for various metals abraded by steel brush and for example the values of $a \cdot C$ and $(a+1)$ for aluminum were 8×10^{3} and 1.1, respectively.

On the other hand, in this experiment these values were 5.8×10^{3} and 1.2; namely the emission intensity of the sandblasted steel under the present blasting conditions had the same order as that of the abraded aluminum in their study. According

4) Y. Tamai and Y. Momose, *Kogyo Kagaku Zasshi* (*J. Chem. Soc. Japan, Ind. Chem. Sect.*), **71**, 1423 (1968).

5) J. Kramer, *Z. Physik*, **128**, 538 (1950).

6) J. Lohff and H. Raether, *ibid.*, **142**, 310 (1955).

to Eq. (2), the emission intensity at 2 hr 30 min sandblast becomes to 0.1 counts/sec. This value is the same order as the emission intensity at room temperature in the glow curve of 2 hr 30 min-keeping time in Fig. 1.

Next, the effect of keeping the blasted specimen in other atmospheres than air was examined.[3] The gases employed were oxygen and argon. It was found that the general characteristics of the peak temperature, the peak intensity and the total counts were almost the same as that obtained for the specimen kept in air after the blast. In addition, according to Eq. (1), the decay line is also applicable to the cases of argon and oxygen, as shown in Fig. 2.

Dependence of Glow Curve on Heating Rate. The effect of heating rate on the emission intensity in the glow curve was examined. The glow curves of three different specimens were obtained, which were all kept in air (25°C, 62% relative humidity) for 2.5 min after the sandblast by compressed air and were heated at a constant rate, *viz.*, 16°C/min or 27°C/min. Table 1 shows the average

Table 1. Dependence of glow curve on heating rate

Heating rate (°C/min)	Average values Peak temp. (°C)	Peak intensity (counts/sec)	Total counts (25—250°C)
16	54	32	8.1×10^3
27	62	50	8.7×10^3

values of the characteristics of three glow curves in each case. At the higher heating rate the peak intensity became larger and the peak temperature shifted to a higher potential than at the lower heating rate. The dependence of the peak temperature on the heating rate has been reported by former researchers,[2] but the increase of peak intensity at higher heating rates has not been referred to, probably because of poor reproducibility in the former studies. The total counts were nearly equal in six measurements and independent of heating rates. Concerning this problem, Haxel, Houtermans and Seeger[7] have reported the similar results that the total number of exo-electrons from abraded metals was independent of the degree of temperature rise.

The remaining counts, n, above a given temperature in the glow curve, were plotted against the temperature. The representative plots of the data of the glow curves in Table 1 are shown in semi-logarithmic scales in Fig. 3, which give almost the same straight lines independent of the heating rate in the present conditions except the initial lower temperature region. The empirical equation is represented by

$$n = S\cdot e^{-\beta T}, \tag{3}$$

where S and β are constants and T absolute temperature. The values of S and β are 4.4×10^6 and $2.0\times10^{-2}\,\mathrm{deg}^{-1}$, respectively. The value of β in the glow curve of 2 min 30 sec-keeping time in Fig. 1 is also equal to the above value.

Discussion and Conclusion

As for the source of the emission, it was found that electrons mostly originated in the deformed sand (*i. e.* SiO_2 and Al_2O_3) embedded in the metal surface by sandblasting.[3] The emission was observed from mild steel surface abraded by steel brush or by iron powder-blasting, although the intensity was rather weak. But in this experiment the emission was so strong as it was probably brought about by deformed sand.

The relation of the remaining counts *vs.* the temperature is given by Eq. (3) regardless of the heating rate. This fact suggests that the emission during temperature rise may be essentially dependent on temperature rather than time. Also, the linearity in an examined temperature range, shown in Fig. 3, suggests that the emission may

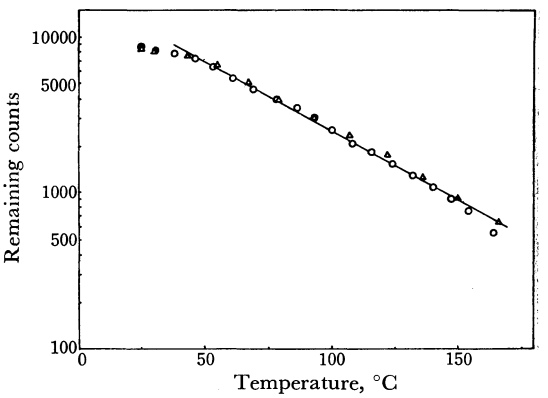

Fig. 3. Remaining counts in glow curve *vs.* temperature.
○: at the rate of 16°C/min
△: at the rate of 27°C/min

be due to the emission centers distributed in different levels of energy; this means that under the assumption that electrons are emitted by thermal energy corresponding to the depth of the electron traps in the deformed blast sand, the emission centers have the different thermal activation energies. If the emission peak in the glow curve corresponds to a single trap depth, the peak would decay as a whole and its maximum would remain at a definite temperature. However, as seen in Fig. 1, the

7) O. Haxel, F. G. Houtermans and K. Seeger, *Z. Physik*, **130**, 109 (1951).

maximum shifts to higher temperatures as the keeping time in air becomes longer; this means that a distribution of trap depth is presented and that the electrons to be emitted at lower temperatures decay more rapidly than those at higher temperatures.

Lepper[8] suggested that the behavior of exoelectron emission was very analogous to that of thermoluminescence and it has been reported by Randall and Wilkins[9] and Garlick and Gibson[10] that in the thermoluminescence glow curve of phosphors, such as KCl-Tl and ZnS-Cu, its peak shifted to higher temperatures as the phosphorescence decay proceeded.

According to Randall and Wilkins,[11] under the assumption that the distribution of the traps is exponential in form, if N_E is the number of traps between trap depth E and $E+dE$, then

$$N_E = A \cdot e^{-\alpha E} dE \tag{4}$$

and the emission intensity, I, at a given temperature is represented by

$$I \simeq f(s\boldsymbol{k}T) \cdot B \cdot t^{-(\alpha \boldsymbol{k} T+1)}, \tag{5}$$

where A, s, B and α are constants and $\boldsymbol{k}$ Boltzman constant. Also, it was shown by Randall and Wilkins[11] that if there is an equal number of electrons in all traps: the trap distribution is uniform, the emission intensity is proportional to $1/t$.

On the other hand, in the present experiments the relation of the emission intensity *vs.* time at 20°C is given by Eq. (2). The negative slope with respect to time is 1.20 and therefore it is probable that the trap distribution is exponential in form. Comparing this value with that of Eq. (5), that is $(\alpha kT+1)$, the value of α becomes 7.9 eV^{-1}.

The authors wish to thank Mr. Y. Nishiyama and Mr. T. Matsunaga for their helpful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1223—1230 (1969)

Determination of the S*–T Transition Probabilities of Some Xanthene and Thiazine Dyes on the Basis of the T-Energy Transfer. I. Experiment in Ethanol Solutions

Masae NEMOTO, Hiroshi KOKUBUN and Masao KOIZUMI

Department of Chemistry, Faclty of Science, Tohoku Univercity, Katahira-cho, Sendai

(Received September 6, 1968)

Intersystem crossing probability, φ_{ST}^{A} for fluorescein, eosine, erythrosine, methylene blue and thionine in ethanol (only for fluorescein, 30 vol% alkaline aqueous ethanol solution), has been determined by comparing the quantum yield of the direct (Φ) and sensitized photoreduction (Φ^{s}), on the basis of the following relations,

$$\Phi=\varphi_{ST}^{A}\beta \qquad \Phi^{s}=\varphi_{ST}^{D}\gamma\beta$$

where β is the fraction of triplet dye molecules that are reduced eventually, φ_{ST}^{A} and φ_{ST}^{D} are respectively for acceptor (dye) and donor (sensitizer) and γ is the energy transfer efficiency, which was assumed as 1. ATU was used as a reducing agent. 1,2,5,6-dibenzanthracene, triphenylene, anthracene and β-acetonaphthone were used as sensitizers. It has been confirmed that the above relations and assumption hold generally. Different sensitizers usually gave nearly the same φ_{ST}^{A} values (with the exception of thionine-anthracene. β-Acetonaphthone gave in general somewhat smaller values). The most probable φ_{ST}^{A} values obtained are; fluorescein (0.007), eosine 0.43 ± 0.04, erythrosine 1.1 ± 0.06, methylene blue 0.52 ± 0.03, thionine 0.62 ± 0.03. The values for xanthene dyes agree moderately well with the ones reported by Porter *et al.* for the aqueous solution of pH=9, fluorescein 0.05, eosine 0.71, erythrosine 1.07. Using the above φ_{ST}^{A} values, the ratio of the deactivation and genuine reaction between triplet dye and ATU has been evaluated. The ratio increases in the order, fluorescein$<$eosine$<$erythrosine, thionine$<$methylene blue.

One of the present authors (M. K.) with many collaborators, has long been engaged in the elucidation of the primary processes in the photochemical oxidation and reduction of some typical dyes. By means of the steady light and the flash photolytic investigations, detailed informations about many elementary processes have been obtained. But an important problem of determining the probability of S*→T transition *i. e.*, φ_{ST} still remains to be solved.

A few years ago, our group attacked this problem by Oster's method,[1] but a series of our work has revealed that the method is in general not applicable.[2-4]

Oster's method is based upon the general principle that if all the triplet dye molecules produced react with a certain substance giving a definite product, then the quantum yield of the reaction under such a condition can be taken as the value of φ_{ST}. Although the method appears simple and elegant, it often gives different φ_{ST} values depending upon the reaction adopted. For example, in the case of photoreduction, EDTA and ATU (allylthiourea) have been found to give quite different φ_{ST} values for eosine,[2] fluorescein[3] and methylene blue.[4] This fact strongly suggests that the mere deactivation of the triplet dye by the reducing agent is also occurring and that its magnitude largely depends upon the nature of the latter.

Since then our attention has been focused on the utilization of the triplet energy transfer. The principle of the method which is somewhat similar to that of Hammond,[5] is to compare the quantum yield of the direct (Φ) and sensitized photoreduction (Φ^{S}) under otherwise similar conditions. Denoting φ_{ST} for a sensitizer (donor) and a dye (acceptor) respectively as φ_{ST}^{D} and φ_{ST}^{A}, Φ and Φ^{S} will be given under favorable conditions, by

$$\Phi=\varphi_{ST}^{A}\beta^{A} \tag{1}$$

$$\Phi^{S}=\varphi_{ST}^{D}\gamma\beta^{A} \tag{2}$$

where β^A is a fraction of the triplet dye that yields the product and γ is the efficiency of the triplet energy transfer. If φ_{ST}^{D} is known and if γ is unity, then the measurement of Φ^S and Φ enables us to evaluate the value of φ_{ST}^{A} from Eqs. (1) and (2). Of course some conditions must be fulfilled for the method to be applicable. In particular, it must be ascertained that β^A is really the same in value for the two reactions, and also that the only interaction between donor and acceptor is the triplet energy transfer.

For the aqueous solution, the selection of a suitable sensitizer is quite a big problem because very few work has yet been performed on the triplet energy transfer in the aqueous solution. Aromatic hydrocarbons of which the nature and the behavior of the triplet states have been investigated by many workers, cannot be used for the aqueous solution because of their very small solubility. There is of course no such obstacle for the ethanol solution; hence we have taken up the problem as a start, to decide φ_{ST} values of fluorescein, eosine, erythrosine (xanthene dyes), methylene blue and thionine (thiazine dyes) in ethanol by comparing the quantum yields of the direct and sensitized photoreduction. ATU was used as a reducing agent.

In the course of our work, some reliable data were published by Porter *et al.* on the φ_{ST} values of some xanthene dyes in aqueous solution.[6] The present results are somewhat similar to theirs in spite of a great difference in the method, supporting the reliability of their data as well as ours. In addition, our results give some interesting informations on the interaction between triplet dye and the reducing agent.

Experimental

Materials. Fluorescein and eosine of Gluber, G. R. grade, were recrystallized three times from ethanol. Erythrosine of Wako Junyaku, G. R. grade, was recrystallized three times from an ethanol-benzene mixture. Methylene blue and thionine of Merck, G. R. grade, were recrystallized three times respectively from *n*-butanol and ethanol.

1,2,5,6-Dibenzanthracene of Wako Junyaku, G. R. grade, was recrystallized from acetic acid and then from ethanol two times. Triphenylene of Tokyo Kasei, G. R. grade, was recrystallized three times from ethanol. β-Acetonaphthone of Tokyo Kasei, G. R. grade, was recrystallized three times from ligroin. Anthracene of high purity was kindly supplied by Professor Shimpachiro Kato of the Univeristy of Tokyo. Purity of these donors was checked by measuring the fluorescence and phosphorescence spectra.

Allylthiourea of Tokyo Kasei, G. R. grade, was recrystallized three times from water.

Ethanol of Wako Junyaku, G. R. grade, was fractionally distilled.

Degassing of the samples was performed by three times distillation to a trap immersed in liquid nitrogen under evacuation.

F_2	cut-off filter	R·	recorder
M	monochromator	W	incandescent lamp

Apparatus and Procedures. Figure 1 shows a schematic diagram of the apparatus for the sensitized reaction. As a light source, an Ushio UX-L 150D Xe-lamp was used; a Toshiba UV-D2 filter was used to excite the donor selectively.

Photobleaching of dyes was measured by a monochromatic light of the wavelength at the absorption maximum which was passed through the solution in the direction perpendicular to the exciting beam. A suitable cut-off filter was inserted to remove donor's fluorescence and scattered light. To reduce the fluctuation of light intensity, special care was taken; a storage battery employed as a power supply for monitoring light (6V-5A incandescent lamp), was kept charged during the measurement.

The measurement of the light absorption was performed as follows, using a potassium ferri-oxalate actinometer. Actinometry is made at first in cell 1 and next in cell 2 with cell 1 filled with the sample solution; the difference of the two measurements then gives the quantity of light absorbed by the sample solution.

Cells for spectrophotometry, $1\times1\times4$ cm, were used as the reaction cells. The concentration of each substance was chosen as follows; dyes 1×10^{-5}M, ATU 1×10^{-2}—5×10^{-4}M, 1,2,5,6-dibenzanthracene 5×10^{-4}M, triphenylene 1×10^{-4}M, anthracene 1.1×10^{-4}M, β-aceto naphthone 5×10^{-4}M. The reaction temperature was always 30 ± 0.5°C.

The apparatus and procedures for the direct photoreduction were similar to those described in a previous paper.[7] The quantity of light absorbed by dyes, was measured by a calibrated Kipp and Zonen thermopile having a sensitivity of 1.02×10^{-5} V/m² watt and a Shimadzu K-2 potentiometer.*1

7) M. Nemoto, Y. Usui and M. Koizumi, This Bulletin, **40**, 1035 (1967).

*1 Some discrepancy was observed in the quantum yield of photoreduction of eosine in ethanol, as compared with the previous results.[7] This is due to the difference in the method of determining the magnitude of light absorption. In the previous paper, a relative method was employed using Imamura's Φ value on the oxydative photobleaching of eosine in the aqueous solution.[8] Reinvestigation of Φ of this reaction using the thermopile, gave about one third of the previous value.

Results

Dependence of the Quantum Yield of the Direct Photoreduction of Dye upon the Concentration of ATU. Quantum yields for five dyes in the ethanol solutions (except fluorescein) containing different concentrations of ATU are summarized in Table 1.

Some remarks will be added below on each dye.

As for eosine, the reaction has been investigated intensively in a previous paper.[7] Hence only the experiments using 1.0×10^{-5}M of dye were supplemented.

A detailed report on the photoreduction of erythrosine in ethanol will be published elsewhere. The feature of the reaction is essentially similar to eosine. Here only the results for 1×10^{-5}M of dye are listed in Table 1.

As for fluorescein, it is well-known that its ethanol solution has no distinct absorption in the visible region perhaps because of the isomerization into lactonic form.[9] 30 vol% aqueous alkaline (0.02N KOH) alcoholic solution was successful for the present purpose. Figure 2 shows the $\ln(e^{E}-1)$ *vs.* t plots for the two experiments (E is the optical density).

The photoreduction of thiazine dyes by ATU in ethanol have not yet been investigated in detail. But the general feature of the reaction is believed to be similar to that of xanthene dyes. $\ln(e^{E}-1)$ *vs.* t plots for thionine and methylene blue are given in Figs. 3 and 4. They are satisfactorily linear, and it may be said that the reaction proceeds *via* D-R mechanism. No shift of the absorption maximum has been observed during the reaction, and upon introduction of air into the bleached solution, 100% recovery of the dye occurred.

Sensitized Photoreduction of Dye. In Table 2 some characteristics of the triplet states of the sensitizers and the dyes used in the present investigation, are tabulated.

The sensitizers were chosen from the following viewpoints; 1) high triplet levels compared with those of the dyes, 2) the φ_{ST} value is known and is close to unity, 3) rather small decay constant. In addition, it is desirable that a sensitizers' absorption band is located in the region where there is no appreciable absorption by dyes. For the sensitizers used in the present investigation, there was scarcely any fear of the appreciable superposition of the direct photochemical reaction over the sensitized one. From the values of τ listed in Table 2, 10^{-5}M of dye is expected to be sufficient for the energy transfer to occur as a diffusion controlled process. This was really proved in most cases by the zero order rate law as described below. It was checked by the flash experiments that the decays of the triplet sensitizers are not affected by the addition of 1×10^{-2}M of ATU. Some examples are shown in Fig. 5. The plots of optical density against

time are always satisfactorily linear for 10^{-5}M of dye. Some examples are shown in Fig. 6.

Since the rate is expressed by the following formula,

$$-\frac{dA}{dt} = I_{ab}\varphi_{ST}^{D}\gamma\beta^{A} \qquad (3)$$

the results in Fig. 6 ensures that all the factors on the right hand side are kept constant during the reaction. On the contrary, when the concentration of dye was smaller, the rate gradually decreased which undoubtedly is due to the decrease of the energy transfer efficiency, γ. Some examples for such a case are shown in Fig. 7. In all cases there was no sign that the sensitized reaction proceeds rather in a different way than in the direct reaction.

Table 3 gives the quantum yields of the sensitized photoreduction of xanthene dyes at various ATU

concentrations.

In the case of fluorescein, only 1,2,5,6-dibenzanthracene and β-acetonaphthone could be used for the reason of solubility. Moreover, in the case of the former sensitizer, its absorption declined when the solution containing 1×10^{-2}M of ATU was illuminated. The reason is unknown. Such a phenomenon was not observed when the solvent was a pure ethanol.

Table 4 summarizes the similar data for thiazine dyes.

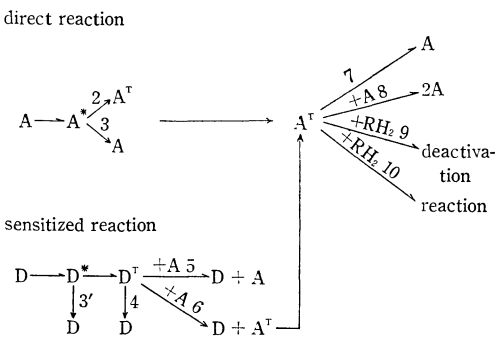
Table 5 gives the φ_{ST}^{A} values for five kinds of dye evaluated by applying Eqs. (1) and (2) respectively to Φ's and Φ^{S}'s obtained under otherwise similar conditions.

φ_{ST}^{A} values of each dye obtained by using different sensitizers, agree fairly well except the ones for fluorescein and for the thionine-anthracene system. The reason for the very low φ_{ST}^{A} value for the latter system is unknown. The value for fluorescein is somewhat doubtful on account of the scanty data. A survey of the data in Table 5 may indicate that the φ_{ST}^{A} values in the case of β-acetonaphthone are laways somewhat smaller. The value of φ_{ST}^{D} of this compound might not be correct. Apart from these points, the results are very satisfactory. It is judged that the conditions for the method to be applicable, are amply satisfied.

Discussion

In view of the results obtained, the method seems to be generally applicable. But in order to make it more confident, two further confirmations will be added below.

Firstly, according to the following reaction schemes,[2-4]



γ and β^{A} are written in general as,

$$\gamma=\frac{k_6[A]}{k_4+(k_5+k_6)[A]} \tag{4}$$

$$\beta^{A}=\frac{k_{10}[RH_2]}{k_7+k_8[A]+k_9[RH_2]+k_{10}[RH_2]} \tag{5}$$

Hence the plots $1/\Phi^{S}$ *vs.* $1/[RH_2]$ as well as $1/\Phi$ *vs.* $1/[RH_2]$ for the same dye concentration, should give, irrespective of a sensitizer, the same value of intercept/slope, which corresponds to $(k_9+k_{10})/(k_7+k_8[A])$. The comparison is made in Table 6, which shows that the above requirement is well satisfied. This assures that the steps succeeding the formation of triplet dye are quite the same in all the systems.

Secondly, the rate constant of the triplet energy transfer was estimated as follows. Under the condition $k_7>k_8$ [A], the inverse Φ^{S} is written as follows,

$$\frac{1}{\Phi^{S}}=\frac{1}{\varphi_{ST}^{D}}\left(\frac{k_9+k_{10}}{k_{10}}+\frac{k_7}{k_{10}[RH_2]}\right)\times\left(\frac{k_5+k_6}{k_6}+\frac{k_4}{k_6[A]}\right)$$

Table 6

Donor	$(k_9+k_{10})/(k_7+k_8[A])$ Fluorescein	Eosine	Erythrosine	Methylene blue	Thionine
None	~200	45—95	42	~500	1050
1,2,5,6-Dibenzanthracene	100	82	45	~750	~1000
Triphenylene		73	33		
β-Acetonaphtone	100	80	35	~750	~1000
Anthracene				~750	~1000

Table 7. Ratio of the deactivation and true reaction between triplet dye and ATU (k_9/k_{10})

Donor/Acceptor	Fluorescein	Eosine	Erythrosine	Methylene blue	Thionine
1,2,5,6-Dibenzanthracene	9	28	97	30	9
Triphenylene	—	24	81	—	—
β-Acetonaphthone	14	19	72	—	—
Anthracene	—	—	—	23	7
None	2	7	51	23	8

Thus the plot $1/\Phi^S$ *vs.* $1/[A]$ gives $k_4/(k_5+k_6)$ as the ratio, intercept/slope. The plots were drawn by using such data as given in Fig. 7. The method is of course very rough, but the values of k_5+k_6 obtained by using the k_4 values in Table 2 were 10^9—10^{10} M^{-1} sec^{-1}. This assures that the energy transfer occurs as diffusion controlled.

As seen in Table 5, the φ_{ST}^A values obtained in the present research are much larger than the tentative values already published,[2-4] and of course, the ones of Oster. They are compared with the values of Porter and Bowers[6] (in the aqueous solution of pH 9), for fluorescein (0.05), eosine (0.71), erythrosine (1.07) and Schenck's values for fluorescein (0.03), eosine (0.3) and erythrosine[10] (0.6) (in methanol at 20°C). Somewhat smaller values of Schenck may be due to the method being similar as the Oster's one. Thus it can now be concluded that the values evaluated by Oster's method are in general smaller than the real ones due to the participation of the deactivation reaction between D^T and ATU.

The φ_{ST}^A values of xanthene dyes increase in the order, fluorescein<eosine<erythrosine. This is interpreted in terms of the internal heavy atom effect.

The magnitude of the mere deactivation of triplet dye by the attack of ATU which largely influences the quantum yield can simply be evaluated as follows. Thus the values of β_{max}^A, as obtained from the intercepts of the $1/\Phi^S$ (or $1/\Phi$) *vs.* $1/[RH_2]$ plots, using the φ_{ST}^D (or φ_{ST}^A) values and assuming $\gamma=1$, give $(k_9+k_{10})/k_9$. Table 7 lists the values of k_9/k_{10}, *i. e.*, the ratio of the mere deactivation and the genuine reaction between triplet dye and ATU. It is seen that for each dye, the values are about the same for different sensitizers and also for the direct reaction. This verifies again the assumption, $\gamma=1$.

Table 7 shows that the mere deactivation of triplet dye by ATU increases in the order, fluorescein <eosine<erythrosine. Thus it has been established unequivocally that the magnitude of the photoreduction quantum yield largely depends on such a deactivation process and that the internal conversion does not matter as once Oster proposed.[1] All the values of $\Phi_F+\Phi_T$ for fluorescein (0.9_3), eosine (0.9_5) and erythrosine (~ 1.0) are close to unity.

Finally, correction will be made on the previously reported rate constants of some elementary reactions involved in the photoreduction of eosine in ethanol,*2 using the present value of φ_{ST} (0.40).*2

TABLE 8. RATE CONSTANTS OF SOME ELEMENTARY REACTIONS INVOLVED IN THE PHOTOREDUCTION OF EOSINE IN ETHANOL

From the reactions in pure ethanol

$k_7'/k_7=3.8\times10^{-3}$ (3×10^{-2})

$k_7(\approx k_7'')=2.3\times10^3$ sec^{-1}

$k_7'=\sim10$ sec^{-1} $(70$ $sec^{-1})$

$k_8'/k_8=\sim2\times10^{-3}$ $(\sim4\times10^{-3})$

$k_8=\sim2\times10^8$ M^{-1} sec^{-1}

$k_8'=\sim9\times10^4$ M^{-1} sec^{-1}

From the reactions with ATU in ethanol

$k_8'/k_8=1$—3×10^{-3} $k_8=1.3$—3.7×10^8 M^{-1} sec^{-1}

$k_8'=1$—5.5×10^5 M^{-1} sec^{-1}

$k_9'/k_9=0.7$—5×10^{-1} $k_9=1.1$—4×10^5 M^{-1} sec^{-1}

$k_9'=2.6$—5.5×10^4 M^{-1} sec^{-1}

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1231—1239 (1969)

Reactions of Singlet Oxygen and Half-reduced Oxygen which are Produced Simultaneously by the Interaction of Triplet Dye and Oxygen

Yoshiharu Usui, Chieko Iwanaga and Masao Koizumi

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received September 11, 1968)

Under experimental conditions in which the interaction between triplet dye and oxygen is an initiating process (D–O mechanism), the photosensitized oxidation of leucofluorescein in the aqueous solution (reaction (1)) has been found to decrease in rate with the increasing oxygen concentration and that the magnitude of the retarding effect of oxygen is almost the same independent of sensitizing dye. This is in sharp contrast to the kinetic feature of the oxidative photobleaching of dye (reaction (2)), where the rate becomes constant beyond a certain small oxygen concentration. On the basis of these findings, it has been proposed that in reaction (1), $^1O_2$ plays a dominant role and it is deactivated by process $^1O_2+{}^3O_2\rightarrow 2{}^3O_2$. As to reaction (2), strong evidence has been presented for the view that the interaction of triplet dye and oxygen in the aqueous solution produces a rather stable $D^+\cdots O_2^-$ of which only a small portion decomposes irreversibly. The principal evidence is as follows; 1) the free half-oxidized dye (produced by the reaction between triplet dye and $[Co(Ox)_3]^{3-}$ was found to oxidize FH_2 with a high rate and its decay was found to be accelerated by the addition of FH_2; 2) the decay of the half-oxidized species (first order decay!) produced in the aerated aqueous solution, on the other hand, was not affected by FH_2 under otherwise similar conditions as in (1).

It is well known that the following three mechanisms have long been proposed for the photosensitized oxidation, initiated by the interaction between triplet dye and oxygen.[1)]

a) Formation of singlet oxygen (Kautsky, Gaffron)
b) Electron transfer (Weiss, Franck)
c) Formation of molecular complex between dye and oxygen (Schenck).

At present, it seems that special interest is being focused on the first mechanism. Since the appearance of Foote and Wexler's work,[2)] a number of papers have been published in favor of the singlet oxygen theory. In spite of such a trend, the authors believe that the other two mechanisms must also be taken into account. In fact, the existence of half-oxidized and half-reduced dye found by Lindqvist,[3,4)] Grossweiner[5)] and by us[6,7)] has naturally led to the possible occurrence of photooxidation by virtue of the half-oxidized dye, *i. e.*, by the second mechanism; Lindqvist[8a)] for instance, has found such an example in the eosine-EDTA-Fe^{3+} system. Other examples have also been reported by us[19)] and by Kasche.[8b)]

The third mechanism which Schenck has long been advocating, was modified recently as a charge transfer type complex,[9)] and this mechanism is now thought to be closely related with the second one.

The first object of the present paper is to report a new kind of reaction which proceeds *via* singlet oxygen; it is the photosensitized oxidation of leucofluorescein (FH_2) initiated by D–O mechanism, some thiazine and xanthene dyes being used as sensitizer. The second object is to make it clear that the photooxidative bleaching of such dyes does not occur by singlet oxygen but *via* electron transfer reaction or alternatively *via* radical ion pair. This has been substantiated partly, by the

finding of a quite different dependence of the two types of reaction on the oxygen concentration. Thirdly we would like to compare the oxidative behavior of all the conceivable transient species, $D^+\cdots O_2^-$, O_2^-, $D^+\cdots D^-$ and D^+ *1 in addition to singlet oxygen $^1O_2$, choosing FH_2 as an oxidizable substance. A remarkable finding is that $D^+\cdots O_2^-$ is less reactive than singlet oxygen, whereas the free D^+ is more reactive. This may be the first chemical evidence for the formation of a rather stable complex, $D^+\cdots O_2^-$.

Experimental

Purification of materials and most of the experimental procedures are similar to those in previous papers. All the experiments were performed at 30°C. pH of the solution was fixed at 6.2 by using the buffer of acetic acid-acetate, except otherwise mentioned.

Results and Discussion

Photosensitized Oxidation of Leucofluorescein. This reaction was studied by one of the present authors (M. K.) in collaboration with Uchida and Kato.[10-12] It was found in this series of work that the oxidation of FH_2 by acridine in the presence of such a large quantity of oxygen as to make the attack of oxygen on the triplet acridine predominant (D–O mechanism), decreases in rate with the increase of the oxygen concentration. Any attempt to clarify the cause of this phenomenon, however, was not made at that time. A few years later, a similar phenomenon was found in the photooxidation of acridan by acridine in the benzene solution containing oxygen.[13] In these papers, the phenomenon was tentatively interpreted by the scheme

$$A^T + {}^3O_2 \rightarrow A + {}^1O_2$$
$$^1O_2 + AH_2 \rightarrow AH + HO_2$$
$$^1O_2 + {}^3O_2 \rightarrow 2{}^3O_2,$$

in which A^T, $^1O_2$ and AH_2 are respectively triplet acridine, singlet oxygen and acridan. If a similar scheme holds for the photooxidation of FH_2, then the ratio of the rate constants for reaction, $^1O_2+FH_2\rightarrow HO_2+FH$ and $^1O_2+{}^3O_2=2{}^3O_2$ should be constant irrespective of the sensitizing dye. To support the above scheme, it is necessary to make experiments using various sensitizers. Therefore, in the present paper, the reaction was investigated quantitatively in a somewhat modified way, using methylene blue (MB), eosine (Es), and thionine (Th), as sensitizers. Before this, some experiments were performed using MB in order to reconfirm the previous result and to find a more suitable condition for the quantitative investigation ((A) and (B)).

A) Reaction in the Degassed Solution. The photochemical oxidation of FH_2 sensitized by MB, in the degassed aqueous solution (pH, 6.2) was reconfirmed. As reported in the previous paper, MB is partially photobleached accompanied with the oxidation of FH_2. To simplify the kinetic treatment, it is desirable to keep the concentration of MB as constant; the addition of a certain quantity of H_2O_2 was attempted to reconvert the reduced MB back to the original dye. It was found that 8.8×10^{-3}M of H_2O_2 restores MB very efficiently without affecting any essential feature of the reaction.*2 In fact, the reaction was found to occur approximately as first order in FH_2 (when $[FH_2]$ is small), as expected from the following rate formula which can be derived directly from reaction scheme I.

$$\Phi_{D-F} = \varphi_{ST}\frac{k^r_L[FH_2]}{k_d^S + k_L^S[FH_2]} \qquad (I)$$

Scheme I

$$MB \xrightarrow{I_{ab}\varphi_{ST}} MB^T \xrightarrow{MB} 2MB \text{ or } MB^+ + MB^- \quad k_D^s \quad (1)$$

$$k_d \swarrow \quad \downarrow MB \qquad \downarrow FH_2 \rightarrow \begin{cases} MB + FH_2 & k_L^d \quad (2) \\ MB^- + FH_2^+ & k_L^r \quad (3) \end{cases} \Big\} k_L^s$$

$$MB \qquad k_d^s = k_d + k_D^s\,[MB]$$

φ_{ST}, k^r_L, k^S_L and k_d are respectively the probability for intersystem crossing, rate constant for the genuine reaction, the total rate constant including deactivation and the rate constant for (spontaneous) deactivation of triplet MB.

Keeping the concentration of MB as 7.8×10^{-6}M,

Table 1. Dependence of the quantum yield on the concentration of FH_2 in degassed solution

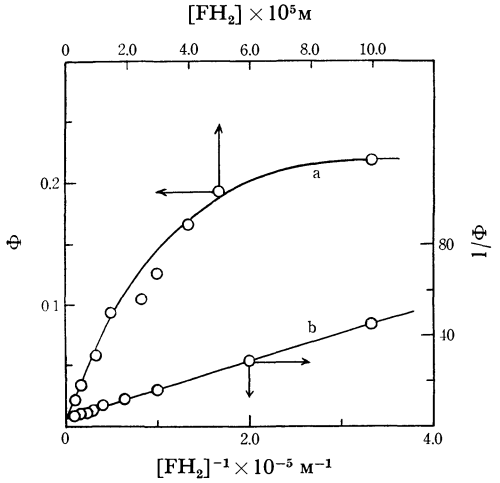

Fig. 1. Dependence of the quantum yield on the concn. of FH_2 ([MB]$=7.8\times10^{-6}$M) in degassed soln.

a ---- Φ *vs.* $[FH_2]$ plot
b ---- Φ^{-1} *vs.* $[FH_2]^{-1}$ plot

the dependence of the quantum yield on the FH_2 concentration was examined. The results are given in Table 1 and in Fig. 1.

Figure 1 shows that a linear relationship holds between $1/\Phi$ and $1/[FH_2]$, as is expected from Eq. (I). From the intercept and the slope, the values of φ_{ST} k^r_L/k^S_L and k^S_L/k^S_d were evaluated respectively as 0.30 and $2.9\times10^4M^{-1}$. The value of k^S_d reported by us is $1.5—3\times10^4$ sec^{-1}.[6] The recent value of Danziger *et al.*[14] is 2.5×10^4 sec^{-1}. Using the latter value we get k^S_L as $7.2\times10^8M^{-1}\cdot sec^{-1}$. Thus reaction $MB^T+FH_2\rightarrow MBH+FH\cdot$ occurs with a rate constant which is a little smaller than the diffusion-controlled one. The above value is more than ten times larger than the one for reaction $MB^T+EDTA\rightarrow MB^-+EDTA^+$.[14]

B) Reaction in the Aerated Solution and in the Solution Equilibrated with one Atmosphere of Oxygen (hereafter abbreviated oxygenated solution). It

Table 2. Quantum yield of FH_2 oxidation in the aerated and in the oxygenated solution

$[FH_2]\times10^5$M	Φ (air saturated)	Φ (1 atm. of oxygen)
0.3	0.011	—

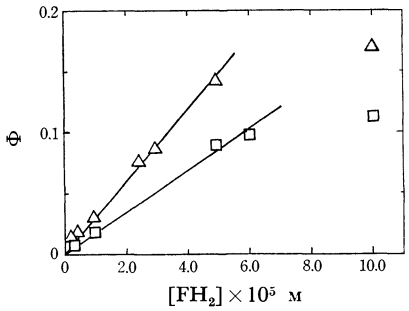

Fig. 2. Dependence of the quantum yield on the concn. of FH_2 in the aerated (△) and in the oxygenated (○) acetate buffer solution. ([MB]$=7.7\times10^{-6}$ M)

was established that the photosensitized oxidation of FH_2 by MB, occurs in the aerated solution as well as in the oxygenated solution. The results are given in Table 2 and in Fig. 2.

Figure 2 shows that the rate is proportional to $[FH_2]$ below 6×10^{-5}M of FH_2. The quantum yield in the aerated solution is about one half that of the degassed solution under otherwise similar conditions, when the FH_2 concentration is less than 1×10^{-5}M. In the oxygenated solution the rate is much smaller than in the aerated solution.

Now triplet MB is attacked by oxygen with a rate constant of $3\times10^9M^{-1}$ sec^{-1}. This value was evaluated by combining the value of $k^S_d/k^S_{O2}=7.75\times10^{-6}$ (k^S_{O2}, rate constant for the entire reaction including the mere deactivation between MB^T and O_2 reported already[15]) with the k^S_d value mentioned above. Comparison of this value with that of k^S_L ($7.2\times10^8M^{-1}$ sec^{-1}) leads to the expectation that in the aerated solution, triplet MB is mainly attacked by oxygen instead of by FH_2 as long as the latter concentration is less than 6×10^{-5}M. Accordingly there is no doubt that the above reaction is due to a certain oxidative species that is produced by the reaction between MB^T and oxygen. Moreover, the smaller Φ in the oxygenated solution suggests that this species is deactivated by the ground state oxygen. Such a possibility was investigated more quantitatively by changing the concentration of dissolved oxygen in a wider range.

C) Dependence of the Quantum Yield on the Concentration of Oxygen. Fixing the concentration of FH_2 and MB respectively at 1.0×10^{-5} and 8.0×10^{-6}M, the dependence of the quantum yield of the reaction on the oxygen concentration was examined from $[O_2]=0$ to 1.2×10^{-3}M. The results are given in Table 3 and in Fig. 3.

As Fig. 3 shows, the $1/\Phi$ *vs.* $[O_2]$ plot consists of two linear portions, which can be explained as

follows. In the low concentration region of oxygen, Φ decreases with the increase of oxygen concentration due to the competition of the reaction between MB^T and FH_2 and that between MB^T and oxygen. In the higher concentration region of oxygen where D–O mechanism prevails, the quantum yield still maintains the value of $\sim10^{-2}$ but it gradually decreases with the oxygen concentration. Thus a quite similar interpretation as in the oxidation of acridan with acridine in benzene[13] has been found to hold in the case of MB. If one assumes that Scheme II (D–O mechanism) holds for the high oxygen concentration region, one can easily derive Eq. (II).

Scheme II

$$MB \xrightarrow{I_a b\varphi_{ST}} MB^T \xrightarrow[k^s_{O_2}]{O_2} \begin{cases} {}^1O_2 + MB & k^r_{O_2} \quad (4) \\ {}^3O_2 + MB & k^d_{O_2} \quad (5) \end{cases}$$

$$^1O_2 \xrightarrow{\text{(Solvent)}} {}^3O_2 \qquad k_d' \quad (6)$$

$$^1O_2 + {}^3O_2 \rightarrow 2{}^3O_2 \qquad k'_{d,O_2} \quad (7)$$

$$^1O_2 + FH_2 \rightarrow HO_2 + FH \quad k_L' \quad (8)$$

$$\Phi_{D-O} = \varphi_{ST}\frac{k^r_{O_2}}{k^s_{O_2}}\frac{k_L'[FH_2]}{k_d'+k'_{d,O_2}[O_2]+k_L'[FH_2]} \approx \varphi_{ST}\frac{k^r_{O_2}}{k^s_{O_2}}\frac{k_L'[FH_2]}{k_d'+k'_{d,O_2}[O_2]} \qquad (II)$$

Applying Eq. (II) to the linear portion in the higher concentration region of oxygen, one can estimate the value of $k'_{d,O_2}/k'_d$ as $1.1—1.2\times10^3M^{-1}$. The linear part in the lower oxygen concentration region consists of the contribution from Φ_{D-F} and Φ_{D-O} and cannot be analysed in a simple way.

D) Comparison of the Values of $k'_{d,O_2}/k'_d$ for Several Sensitizers. If Scheme II really holds, the value of $k'_{d,O_2}/k'_d$ should be independent of a sensitizer used. To examine this, oxygen concentration effect on Φ_{D-O} in the higher concentration region of oxygen was examined using thionine

and eosine as a sensitizer. The results are given in Tables 4, 5 and in Fig. 4. In Table 5 are added the values for acridine calculated from the old data.[12,13]

E) Assignment of the Oxidative Species in the Above Reaction. From the above result, one can say that in the photosensitized oxidation of FH_2 *via* D–O mechanism, the rate decreases with the increase of oxygen concentration in a quite similar way irrespective of a sensitizer used. This implies that the oxidative species reacting with FH_2 is the same one species for all the dyes. Further, one can conclude that this species does not participate in the oxidative bleaching of dye, because in contrast to the retarding effect of excess oxygen in the above reaction, the rate of oxidative bleaching of dye increases with the oxygen concentration and becomes constant when the concentration is high enough,[15,16] as shown in Fig. 5. The limiting

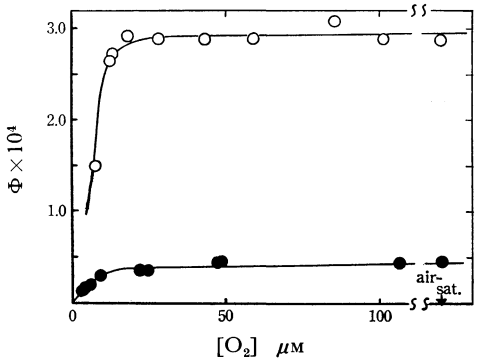

Fig. 5. Effect of the dissolved oxygen concn. on the quantum yield of photobleaching of eosine (○) and methylene blue (●).

quantum yields reported by our group are given in Table 6.

Table 6 shows that Φ for the oxidative photobleaching of dye is about two orders of magnitude less than that of the sensitized oxidation of FH_2.

The conceivable oxidative species produced *via* D–O mechanism are $^1O_2$, O_2^-, D^+ and $D^+\cdots O_2^-$ which are produced by the following processes.

$$D^T + {}^3O_2 \rightarrow D + {}^1O_2 \quad (9)$$

$$D^T + {}^3O_2 \rightarrow D^+\cdots O_2^- \quad (10)$$

$$\rightarrow D^+ + O_2^- \quad (11)$$

The production of half-oxidized dye has been fully established by Lindqvist,[3,17] Grossweiner[5] and by us.[6,7] To interpret the result that $k'_{d,O_2}/k'_d$ is independent of sensitizing dyes, only $^1O_2$ or O_2^- should be a reactive species. But the latter can be ruled out because D^+ which is produced accompanied by O_2^- (reaction (11)) is very reactive toward FH_2, as will be shown below. Furthermore half-oxidized dye is thought to be rather insensitive to oxygen.[6,7] Thus the most plausible interpretation is that the oxidation of FH_2 occurs *via* $^1O_2$ and the oxidative bleaching of sensitizing dyes occurs *via* electron transfer between D^T and oxygen. That acridine sensitized photooxidation of acridan, in which there is no evidence of the formation of half-oxidized form, occurs with about equal $k'_{d,O_2}/k'_d$ is also consistent with this view.

Further evidence for the electron transfer mechanism of the oxidative bleaching is supplied by our previous result that in the high concentration of dye the D–D mechanism occurs and in this case oxidative bleaching of dye as well as the rate of oxygen consumption becomes very much larger than in the D–O mechanism[18]; thus in the D–D mechanism, the reaction proceeds as follows. $D^T + D \rightarrow D^+ + D^-$ or $D^+\cdots D^-$, $D^- + O_2 \rightarrow D + O_2^-$, $D^+ \rightarrow$ destruction. If a reactive species were $^1O_2$ for the photobleaching, the larger Φ in the D–D mechanism cannot be explained.

The present results in conjunction with the results so far obtained previously lead to the conclusion that the oxidation of FH_2 and the oxidative

17) V. Kasche and L. Lindqvist, *Photochem. Photobiol.*, **4**, 923 (1965).

18) Y. Usui, K. Itoh and M. Koizumi, This Bulletin, **38**, 1015 (1965).

bleaching of sensitizing dyes occur as two different processes and that it is most likely that the former proceeds *via* $^1O_2$ while the latter *via* electron transfer.

This view will be further supported when the experimental condition is controlled in such a way that a particular species such as $D^+\cdots O_2^-$, O_2^-, $D^+\cdots D^-$ or D^+ is predominantly produced, and we compare the reactivity of these species toward FH_2. Such a comparison will, furthermore, allow us to make a more distinct discrimination of the reactive species in the oxidative bleaching of dye.

Experiments for Comparing the Reactivity of Various Transient Species to FH_2. A) $D^+\cdots O_2^-$. Strong support for the existence of such a complex has been presented already in the case of eosine.[19] Thus this dye gives the transient spectrum due to the half-oxidized dye in the aerated solution, which decays in the first order ($k=10^3$ sec^{-1}) independent of the oxygen concentration (phosphate buffer). For MB there is still no clear-cut evidence for the existence of such a complex, although this is plausible.[6,14] Hence, choosing eosine, the effect of the addition of FH_2 on the decay of $D^+\cdots O_2^-$ was examined at 458 nm (the absorption peak of the half-oxidized dye) at which the absorption due to half-reduced fluorescein is not appreciable.[3] The results are given in Table 7.

Table 7. The effect of the addition of FH_2 on the decay of $D^+\cdots O_2^-$

[Eos] $=1.0\times10^{-5}$M; aerated solution of pH=6.2 (0.1M Ac-buffer)

Concn. of FH_2 M	Decay const.* of $D^+\cdots O_2^-$ (sec^{-1}) $\times10^{-4}$
0	7
1.0×10^{-5}	5.3
4.0×10^{-5}	6.1
8.0×10^{-5}	4.9
20.0×10^{-5}	3.9—5.0

* The values have unexpectedly, been found to be more than the ones for the phosphate buffer solution. The decay constants in the 0.01M AcOH-AcONa buffer solution are nearly equal to the latter. The phenomenon is worthy of further investigation.

From Table 7, it appears that the addition of FH_2 causes a slight decrease of the decay, but this may perhaps be due to the overlap of the absorption due to F which is produced by the simultaneous oxidation of FH_2 by $^1O_2$. Thus the above experiment definitely indicates that $D^+...O_2^-$ is indifferent to FH_2, when the latter concentration is 10^{-5}—10^{-4}M.

19) Y. Usui and M. Koizumi, This Bulletin, **40**, 440 (1967).

B) O_2^-. According to Usui and Koizumi,[19] the following reaction occurs when a suitable quantity of EDTA is added to the aerated solution of eosine (phosphate buffer).

$$D^+\cdots O_2^- + EDTA \xrightarrow{k_R} D + EDTA^+ + O_2^- \quad (12)$$

Flash experiments were made in order to know the exact rate constant of the above reaction. Figure 6 gives the plot of the first order decay constant at 460 nm against the EDTA concentration. From this plot k_R was evaluated as $k_R=7.0\times10^5M^{-1}\,sec^{-1}$. This value is consistent with the results previously reported.[19] If the free O_2^- were to react with FH_2. Then the addition of a suitable quantity of EDTA is expected to increase the rate of oxidation of FH_2. The result, as shown in Table 8, is contrary to this expectation.

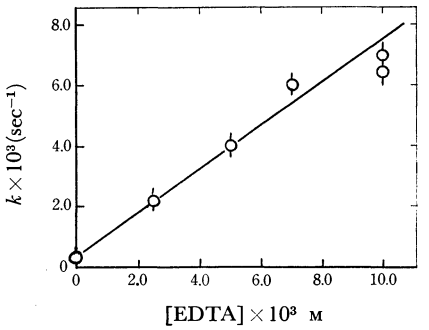

Fig. 6. Plot of the first order decay constant of $D^+\cdots O_2^-$ against [EDTA)]. (phos. buffer, pH=6.8)

[EDTA]M	Φ_{D-0}
0	0.0046
4×10^{-3}	0.0042
4×10^{-2}	0.0026

There is no sign of increase in Φ_{D-0} values.*3

A moderate decrease in the case of 4×10^{-2}M of EDTA may be due to the accompanied photobleaching of eosine due to reaction, $D^T+EDTA\rightarrow D^-+EDTA^+$.

C) $D^+\cdots D^-$. The formation of $D^+\cdots D^-$ has not been fully established. In the case of eosine in the aqueous solution, the formation of the free D^+ and D^- seems rather predominant, since the half-oxidized and half-reduced species decay in the

*3 We feel that the concentrations of EDTA were too low for reaction (12) to compete with the spontaneous deactivation of $D^+\cdots O_2^-$ in the present buffer solution. Further increase of EDTA may, however, change the initial process from $D^T+O_2\rightarrow D^+\cdots O_2^-$ ($k=2.5$—$3.1\times10^8M^{-1}\,sec^{-1}$ [19]) to $D^T+EDTA\rightarrow D^-+EDTA$ ($k=5\times10^5M^{-1}\,sec^{-1}$ [7]).

second order with approximately the same rate constant.[7),*4] On the other hand, according to Danziger *et al.*[14] the existence of $D^+\cdots D^-$ is likely to occur in the case of MB. Hence choosing MB, the dependence of the oxidation reaction of FH_2 on the concentration of MB was examined in the aerated solution. If the switch-over from D-O to D-D mechanism occurs with the increase in [D], it is expected that $D^+\cdots D^-$ will probably be attacked first by oxygen when $[FH_2]$ is not so large, as in the oxidative photobleaching and also as in the oxygen absorption experiment,[18] leaving D^+ as free. The free D^+ may then react with FH_2. Hence it is possible that the rate of the oxidation of FH_2 increases with the concentration of dye. Since an appreciable quantity of dimer exists in the high concentrated solution of dye, chiefly monomer was excited using a suitable cut-off filter.*5 The concentration of monomer was calculated by using the dissociation constant $K=2.8\times10^{-4}$ [21] (at 26.7°C). The results are shown in Table 9 and in Fig. 7.

As Fig. 7 shows, the quantum yield really increases with [MB] and reaches about a constant value above 2×10^{-5}M of MB. Thus the switch-over from D-O to D-D mechanism seems to occur around 2×10^{-5}M. This value is about one order smaller than the oxygen concentration, and it is suggested that the rate constant for $D^T+D\rightarrow$ is appreciably larger

than that for $D^T+O_2\rightarrow$. There is, however, some possibility that the contribution of the ground state dimer still remains. In addition, it is to be noted that in the experiment described in A), D-D mechanism participates to some extent in the low concentration region of oxygen. But, for the plots drawn in Figs. 3 and 4 in the range $[O_2]>2.4\times10^{-4}$M, the contribution of D-D mechanism may be neglected. The above result indicates that a species $D^+\cdots D^-$ in the presence of oxygen is more effective than $^1O_2$.

The investigation of the influence of the oxygen concentration on the rate in the high [MB] region where D-D mechanism prevails, is thought to be interesting, because it may provide information on the reactivity of $D^+\cdots D^-$ and the free D^+ toward FH_2; the latter species may perhaps be produced by reaction $D^+\cdots D^-+O_2\rightarrow D^++D+O_2^-$. Fixing $[MB]=8.0\times10^{-5}$M ($[MB_m]=5.2\times10^{-5}$M) and $[FH_2]=1.0\times10^{-5}$M, the concentration of oxygen was changed from zero to 12.0×10^{-4}M. The results are shown in Fig. 8. It is seen that in the high concentration region of oxygen, the plot essentially coincides with that given in Fig. 3. This is natural because the D-O mechanism prevails in this region. But in the low concentration region of oxygen, the increase of Φ with the decrease in oxygen concentration is not so large as in the case of 8.0×10^{-6}M of MB. The value of $\Phi=0.041$ in the absence of oxygen is undoubtedly due to the reaction between $D^+\cdots D^-$ and FH_2, because under present experimental conditions the reaction of D^T with D prevails over that with FH_2. In the presence of a small amount of oxygen, reactions, $D^T+O_2\rightarrow D+{}^1O_2$, $D^T+O_2\rightarrow D^+\cdots O_2^-$ will compete with reaction $D^T+D\rightarrow D^+\cdots D^-$ on the one hand, and reaction $D^+\cdots D^-+FH_2\rightarrow$ and $D^+\cdots D^-+O_2\rightarrow D^++D+O_2^-$ will compete on the other hand. The last reaction may possibly increase the overall rate of FH_2-oxidation. The plot shown in Fig. 8 is consistent with this view although not conclusive, because of the scantiness of the data. At any rate,

*4 In the alcoholic solution, however, some evidence exists for the formation[20] of $D^+\cdots D^-$.

20) A. Kira and S. Kato, *Sci. Rep. of Tohoku Univ., Ser. I*, **48**, 1964 (1965).

*5 Danziger *et al.*[14] claimed that $D^+\cdots D^-$ is mainly produced by the excitation of the ground state dimer. However, we believe their result does not eliminate the possibility of $D^T+D\rightarrow D^+\cdots D^-$. The first order decay of D^T never excludes reaction $D_T+D\rightarrow2D$, as has already been domonstrated in the case of eosine.[7] Moreover, the present result cannot be explained unless reaction $D^T+D\rightarrow D^+...D^-$ occurs.

21) E. Rabinowitch and L. F. Epstein, *Ind. Eng. Chem.*, **63**, 69 (1941).

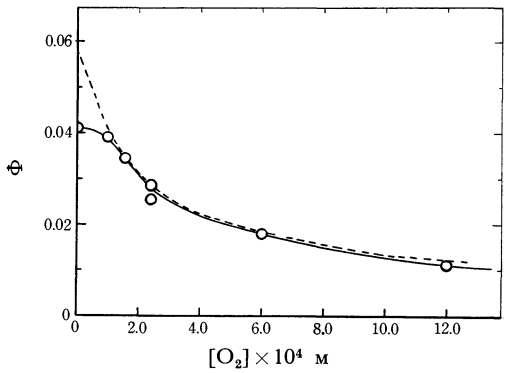

Fig. 8. Effect of oxygen concn. on the quantum yield of fluorescein formation in high MB concn. (8.0×10^{-5}M). *cf.* ---- [MB]$=8.0\times10^{-6}$M (Dotted line)

there is scarcely any doubt that in the case of MB, D–R mechanism is the most effective for the photo-oxidation of FH_2, D–D mechanism next and D–O mechanism the least effective.

D) Free D^+. In the case of the deaerated aqueous eosine solution, half-oxidized and half-reduced dye seem to exist mainly as free species.[7] But this is not yet completely conclusive. According to our result, not yet published, electron transfer reaction between triplet dye and $[Co(Ox)_3]^{3-}$ occurs very efficiently, yielding D^+ and $[Co(Ox)_3]^{4-}$. Hence the reactivity of free D^+ toward FH_2 was examined by using the system consisting eosine $\sim1\times10^{-5}$M, $K_3[Co(Ox)_3]$, 6.0×10^{-4}M and FH_2, 6.0×10^{-5}M (pH=6.2). Preliminary experiments by means of the steady light illumination has shown that the oxidation of FH_2 occurs very efficiently with $\Phi=ca.$ 0.15. This value is about the same as the quantum yield of the decomposition of eosine by $K_3[Co(Ox)_3]$ under similar conditions. It was ascertained that the bleaching of eosine never occurs in the early stage of the reaction. Thus one can conclude that the free D^+ produced by the reaction between D^T and $[Co(Ox)_3]^{3-}$ oxidizes FH_2 very quickly.

To confirm this further, the decay rate of the free D^+ was compared in the two systems, a) [Es]$=5.0\times10^{-6}$M, $K_3[Co(Ox)_3]=5.0\times10^{-4}$M, b) [Es]$=5.0\times10^{-6}$M, $K_3[Co(Ox)_3]=5.0\times10^{-4}$M, $[FH_2]=1.0\times10^{-5}$M, both in the deaerated solution. The preliminary experiment has shown that the decay for system (a) obeys rather the second order rate formula, but the apparent first order rate constant evaluated from the initial slope was $2-9\times10^2$ sec^{-1}. On the other hand, the first order rate constant for system (b) was $0.9-1.0\times10^4$ sec^{-1}, which implies that the rate constant for $D^+ + FH_2 \rightarrow D + FH + H^+$, is of the magnitude of 10^9M^{-1}·sec^{-1}.*6 Thus one can conclude that the free D^+ reacts with FH_2 very quickly.

Summary and Conclusion

In the present investigation, it has been proposed that FH_2 in the aerated solution, is oxidized by the singlet oxygen originating from the interaction of D^T with O_2 (D–O mechanism). This view was supported by the finding that the retarding effect of the excess oxygen is independent of a sensitizer. On the other hand, the oxidative photobleaching of dye occurs most (probably) *via* the electron transfer reaction. Hence the quantum yield of the two types of reaction depends on the occurrence of the following two processes.

$$D^T + {}^3O_2 \rightarrow D^+\cdots O_2^-, \quad (10)$$

$$D^T + {}^3O_2 \rightarrow D + {}^1O_2. \quad (9)$$

** Deaerated solution (for MB $\Phi_{0,max}=\varphi_{ST}k^r_L/k^s_L=0.3$).
*** Quantum yield for the oxidative photobleaching by oxygen.

*6 According to Ref. 7 the first order decay constant of D^+ (maybe partly exists as $D^+\cdots D^-$) is *ca.* 9×10^2 sec^{-1}. The addition of 1.0×10^{-5}M of FH_2 does not change it so much in the absence of $K_3[Co(Ox)_3]$, the observed value being 1.6×10^3 sec^{-1}. This is consistent with the view that some part of half-oxidized dye exists as $D^+\cdots D^-$.

That thiazine dyes have larger quantum yields for the oxidation of FH_2 than xanthene dyes and smaller quantum yields for the oxydative bleaching, may be attributed partly to the more favorable occurrence of (9) than (10). This seems to be well correlated with the oxidation-reduction potential of the two types of dye. In the case of acridine, the only reaction is perhaps (9), since there is no evidence of the occurrence of reaction (10).

As to the reactivity of various oxidative species toward FH_2, O_2^- and $D^+\cdots O_2^-$ have been found to be ineffective, although the evidence for the former is rather weak. Both the free D^+ and $D^+\cdots D^-$ are effective. The free D^+ is perhaps more effective than $D^+\cdots D^-$ but the quantitative comparison is a future problem and such studies will be helpful for the discrimination of the two species.

The low reactivity of $D^+\cdots O_2^-$, in sharp contrast to the free D^+, may be considered to be an unambiguous proof of the formation of such a complex by reaction $D^T+O_2\rightarrow D^+\cdots O_2^-$. This we, believe, is the first chemical evidence for the formation of transient molecular compound between dye and oxygen having the nature of ion-pair. It has now become almost certain that the half-oxidized dye produced by triplet eosine and oxygen, does not exist as free radical ion but exists as a rather stable ion pair $D^+\cdots O_2^-$. That the oxidative bleaching starts from the electron transfer process is further supported by a larger value of Φ for D–D mechanism than for D–O mechanism. In the D–O mechanism, it is most likely that most of $D^+\cdots O_2^-$ goes back to D and O_2 with only a very small portion resulting in destruction of dye. In the D–D mechanism on the other hand, oxygen will attack $D^+\cdots D^-$ or D^-, producing D and O_2^- and the remaining D^+ will give colourless product(s).

The quantitative data, some of which are still preliminary are summarized in Table 10.

The authors would like to thank Professor H. Kokubun for helpful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1239—1247 (1969)

The Crystal and Molecular Structure of *N*-(*p*-Bromophenyl)-α-D-ribopyranosylamine 2,4-Phenylboronate

Hirotaka SHIMANOUCHI, Norio SAITO*1 and Yoshio SASADA

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 9, 1968)

Crystals of *N*-(*p*-bromophenyl)-α-D-ribopyranosylamine 2,4-phenylboronate, $C_{17}H_{17}O_4NBBr$, are monoclinic, with two molecules in a unit cell of the dimensions, $a=12.98$, $b=10.80$, $c=6.34$Å, and $\beta=99.4°$, and with the space group of $P2_1$. The intensity data were collected by a photographic method and the structure was solved by the heavy atom method. The final R factor is 0.100. The absolute configuration was also determined.

1,2-Diols (I) have been well known to enhance the conductivity of boric acid, suggesting that they form the borate complex of the type (II) in solution.[1] T. Sato obtained a crystalline borate complex, *N*-arylribosylamine borate, by the reaction of *N*-arylribosylamine and boric acid.[2] *N*-Arylribosylamine also forms a complex with phenylboronic acid. However, the organic chemical and spectral studies failed to reveal whether the ribose is α or β, whether it is a five- or six-membered ring, and to which oxygen atoms the boron is attached.

The present X-ray diffraction study establishes the conformation of the molecule in the crystalline state, and furthermore gives the bond lengths and angles about the boron atom.

A heavy atom derivative for the X-ray work, prepared by the reaction of D-ribose, phenylboronic acid and *p*-bromoaniline, was supplied by Y. Sato.[3]

Experimental

Colorless scale-like crystals were obtained from a methanol solution, (100) plane being well developed. The unit cell dimensions were determined from zero-layer Weissenberg photographs about the b and the c axes, calibrated with superimposed aluminum powder lines.

Multiple-film equi-inclination Weissenberg photographs were taken at room temperature for the layer lines from 0 to 7 about the b axis and from 0 to 4 about c, using CuKα radiation. The crystals used were square in cross-section with rectangular dimensions of 0.03×0.10 cm and 0.06×0.03 cm for the b and c axis rotation, respectively. By visual comparison with a standard scale prepared with the same crystal, intensities were estimated, which ranged from 1 to 11900. Out of 1873 reflections recorded, about 290 were too weak to be measured. The corrections for the Lorentz and polarization factors were made in the usual way and those for spot-size variation in high layer photographs by the method of Phillips.[4] The correction for absorption was neglected.

Crystal Data

The crystallographic and physical data obtained are: N-(p-Bromophenyl)-α-D-ribopyranosylamine 2,4-phenylboronate $C_{17}H_{17}O_4NBBr$, mp 150—150.5°C. Monoclinic, $a=12.98$, $b=10.80$, $c=6.34$ Å, $\beta=99.4°$. Absent spectra, $(0k0)$ when k is odd. Space group, $P2_1$. Two molecules per unit cell. Volume of the unit cell, 876.3 Å^3. Density (by flotation), 1.461 g·cm^{-3}. Density (calculated), 1.478 g·cm^{-3}. Linear absorption coefficient for CuKα radiation, $\mu=36.9$ cm^{-1}. Total number of electrons per unit cell, $F(000)=396$.

Structure Determination

Three-dimensional sharpened Patterson function was synthesized with factors $\exp(2B\sin^2\theta/\lambda^2)$ where $B=5.0$ Å^2, and the bromine atom was located almost on the screw axis. The first three-dimensional Fourier synthesis was made with phases based on the bromine atom. In the resulting electron density distribution, a false mirror plane at $y=1/4$, in addition to that at $y=0$, appeared as a result of the special values of the bromine coordinates. In spite of a disturbance caused by additional mirrors, it was possible to pick out the atoms in the p-bromoanilino group. Minimum function, based on the Br–Br vector, also supported this interpretation.

Phases for the second Fourier synthesis were based on the eight atoms in the p-bromoanilino group. Although the false mirrors were not yet completely excluded, all the light atoms were picked out from the electron density distribution, so that a reasonable molecular model was constructed. Two successive three-dimensional Fourier syntheses with revised phases confirmed the positions of all the light atoms and considerably reduced the false details which had appeared in the earlier stages. The coordinates of all the atoms obtained from the fourth map gave a discrepancy factor, $R=\sum||F_o|-|F_c||/\sum|F_o|$, of 0.42.

Further refinement of the parameters was made by the block-diagonal matrix least-squares method. Anisotropic temperature factors in the form of $\exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)\}$ were applied for the bromine atom, while the light atoms were treated as undergoing isotropic thermal motions. After nine cycles of refinement, the R factor was reduced to 0.100 for the observed reflections. The atomic scattering factors used in the calculations were taken from the International Tables for X-ray Crystallography (1962). The final atomic coordinates and temperature factors are given in Table 1, and their standard deviations in Table 2. The observed and calculated structure factors are listed in Table 3. The final three-dimensional electron density distribution calculated with phases based on these parameters is shown in Fig. 1.

The computations were done on a HITAC 5020E computer in the University of Tokyo with programs written by Dr. T. Ashida.

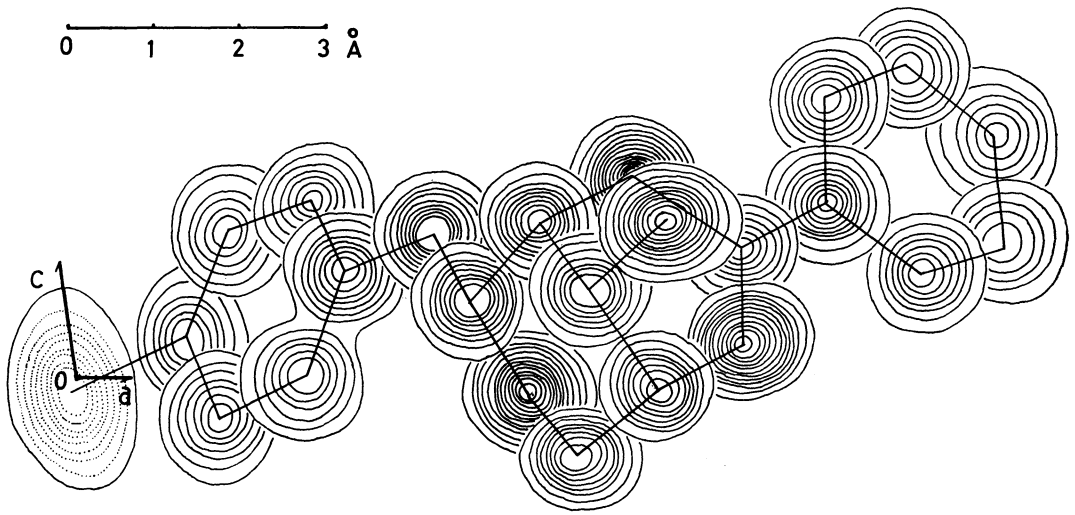

Fig. 1. Composite electron density diagram of sections parallel to (010). The contours of light atoms are at intervals of 1.0e.Å^{-3} starting with 1.0e.Å^{-3}, and those of the bromine atom are at intervals of 5.0e.Å^{-3} from 5.0e.Å^{-3} shown by dotted lines, the lowest being at 1.0e.Å^{-3}.

TABLE 3. OBSERVED AND CALCULATED STRUCTURE FACTORS

Determination of Absolute Configuration

After the errors due to neglecting the correction for absorption were taken into account, it was observed that for seven sets of Bijvoet pair in the upper layer photographs around the c axis, intensities in each pair were significantly different. For the Bijvoet pairs, $|F(hkl)|$ and $|F(h\bar{k}\bar{l})|$ were calculated using $\Delta f'$ and $\Delta f''$ for the bromine atom on the basis of the model in a right-handed coordinate system. As shown in Table 4, inequality relation observed in each pair is opposite to that of the calculated values, so that the model used in the calculations is the mirror image of the actual molecule. Therefore, the absolute configuration of ribose has been established as indicated in Fig. 2.

TABLE 4. THE DETERMINATION OF THE ABSOLUTE CONFIGURATION

$h\ k\ l$	Calculated		Observed	
	$\|F(hkl)\|$	$\|F(h\bar{k}\bar{l})\|$	$\|I(hkl)\|$	$\|I(h\bar{k}\bar{l})\|$

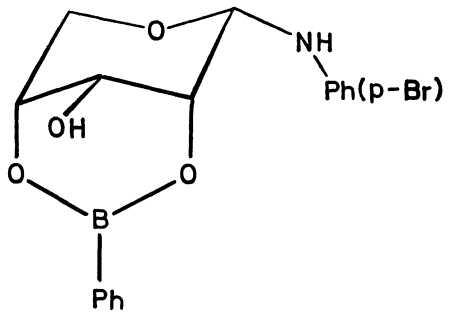

Fig. 2. Absolute configuration and conformation.

Results and Discussion

Conformation. As shown in Fig. 2 three surprising features are found in the molecular conformation. The first is that the sugar residue is pyranoid; the ribose residue so far reported is in the furanose form in crystal.[5-7] The second is that it is the α-D anomer; the free sugar customarily crystallizes as a β-D anomer. The third is that it is in a chair 1C conformation ($1e2a3e4a$); in free ribopyranose this is a very unstable form owing to strong 1,3-diaxial O(2)···O(4) interaction. These features are interrelated to each other as will be discussed below.

The conformations about the six single bonds in the pyranose ring are shown in Fig. 3[8] and the

conformation angles range from 56.0 to 62.5°, as compared with 55.8—61.7° for an ideal pyranose ring,[9] 51.3—62.2° for glucose,[10] 54.8—56.0° for sucrose[11] and 56.2—60.5° for β-methyl maltoside.[12] The range in the present molecule is very close to that in an ideal pyranose ring indicating no evidence of strain in the ring. This suggests that the pyranose 1C conformation is most favorable to form a borate complex with ribose. In this ring conformation the present equatorial α-D anomer is more stable than the axial β-D one. It follows that the energy of the present three-dimensional structure is undoubtedly lower than any other isomer and only one isomer is predominantly formed and crystallizes as a pure form. Thus, it is reasonably interpreted that the formation of a stable borate complex is characteristic of D-ribose.[13]

Molecular Geometry. The intramolecular bond lengths and angles are shown in Figs. 4 and

5, respectively. The mean estimated standard deviations in bond lengths of C–Br, C–O, C–N C–C, O–B and C–B, are 0.018, 0.015, 0.016, 0.021, 0.016 and 0.019 Å, respectively, and that in bond angle is about 1.2°. The C–C single bond lengths range from 1.528 to 1.568 Å and none of them differ significantly from the mean value of 1.549 Å. The C–O bond lengths range from 1.407 to 1.478 Å with the mean value of 1.444 Å. The distance of C(1)–N(1) is 1.417 Å, which is significantly shorter than the normal C(sp^3)–N< length, *i. e.* 1.463 Å in *N,N'*-dinitroethylenediamine.[14] There is no significant inequality of the ring C(1)–O(5) and C(5)–O(5) bonds. Similar shortening of the equatorial C(1)–O(1) bond, which corresponds to the present C(1)–N(1), and equality of the ring C–O bonds have been observed in pyranose sugars.[15] These phenomena have been connected with a property of the equatorial C(1)–O(1) bond,[12,15] and by the present observation this interpretation may be extended to the equatorial C(1)–X bond where X is an atom with lone pair.

The valence angles on O(2) and O(4) atoms are somewhat larger than the usual. This tendency is consistent in that the C(2)–O(2) and C(4)–O(4) distances are shorter than C(1)–O(5) and C(5)–O(5).

The two B–O bond lengths are essentially equal to the mean value of 1.396 Å. The π-bond order of these B–O bonds was found to be about 0.35 using B–O π-bond order *versus* bond length curve given by Coulson.[16] Armstrong and Perkins have predicted that in some substituted phenylboronic acids a migration of charge from the oxygen to the boron atom results in a π-bond order in the range 0.3 to 0.5.[17] The present π-bond order agrees well with their prediction. The three bond angles around the boron atom are very close to 120°. The equation for the least-squares plane of the four atoms, O(2), O(4), B and C(12) is:

$$-0.438x' - 0.751y' - 0.494z' + 7.841 = 0$$

where $x' = x + z\cos\beta$, $y' = y$ and $z' = z\sin\beta$. The deviations from this plane are shown in Fig. 6. It is apparent that the boron atom is trigonally hybridized and the C(2) and C(4) atoms also lie nearly within the plane. This seems to satisfy the most favorable condition for forming B–O π-bond. The dihedral angle between this plane and the benzene ring, C(12)–C(17), plane is only

TABLE 5. HYDROGEN-BOND DISTANCES AND ANGLES

Bonds		Acceptor at
O(3)···O(5)	2.710 Å	$1-x$, $\frac{1}{2}+y$, $\bar{z}$
N(1)···O(3)	3.325 Å	$1-x$, $\frac{1}{2}+y$, $1-z$

Angles	
C(3)—O(3)···O(5)	104.3°
C(9)—N(1)···O(3)	101.1°
C(1)—N(1)···O(3)	136.2°

6.8°, suggesting some π interaction between the phenyl group and the boron atom. The C(12)–B distance is 1.506 Å.

Crystal Structure. The packing arrangements of the crystal viewed along the *b* and *c* axes are shown in Figs. 7 and 8, respectively. The presumed hydrogen bonds are indicated by dashed lines. As shown in Table 5, a strong hydrogen-bond clearly exists between O(3) and O(5) atoms forming a helical chain along the b axis. Although the N(1)···O(3) distance is rather long, the angles lie within possible range to form a hydrogen-bond. There may be weak interaction between them along the *c* axis. These are compatible with the predominant shape of the crystal. There is no unusual short approach in the crystal.

The authors are indebted to Professor Tetsuo Sato for suggesting the problem and continued interest and Mr. Yoshikuni Sato for a gift of the sample.

A Theoretical Interpretation of Substituent Effects on the H-H and ^{13}C-H Spin Coupling Constants for CH_3X, $(CH_2)_2X$, and CH_2=CHX Derivatives[1]

Teijiro YONEZAWA, Isao MORISHIMA, Mutsuo FUJII and Hiroshi KATO

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto

(Received September 27, 1968)

An attempt has been made to explain the experimental trend of H–H and ^{13}C–H nuclear spin coupling constants for CH_3X, $(CH_2)_2X$, and CH_2=CHX systems on the basis of the Pople and Santry expression for the contact term. The calculated magnitudes of the coupling constants are parallel with the observed values, but are uniformly lower by a factor of between 1.5 and 2. The variation in the calculated coupling constants with the electronegativity (E_x) of the substituent, X, follows the well-acknowledged observed tendency for directly-bonded ^{13}C–H, geminal H–H, and vicinal *cis* and *trans* H–H coupling constants. Theoretical calculations also predict the E_x dependency of the directly-bonded ^{13}C–H coupling constants for two geminal C–H bonds in the $^{13}CH_2$=CHX fragment. The difference between two geminal ^{13}C–C–H coupling constants in the CH_2=^{13}CHX system is also obtained by calculation. Discussions of the factors which dominate the couplings are also presented.

The theory of nuclear spin-coupling based on delocalized molecular orbitals presented by Pople and Santry[3] has been used, with a good deal of success, to estimate numerical values for a large number of couplings. Pople and Santry themselves applied[4] the theory to H–H, ^{13}C–H, and ^{13}C–^{13}C couplings in ethane, ethylene, and acetylene; Murrell *et al.*[5] also carried out similar calculations. Fahey *et al.*[6] calculated the H–H and ^{13}C–H coupling constants for various hydrocarbons using the extended Hückel theory. The present authors[2] also calculated the H–H couplings for saturated and unsaturated simple hydrocarbons, aldehydes, and small strained ring compounds by using a modified Hückel MO theory. In addition to these calculations of coupling constants, the couplings involving other nuclei, ^{19}F, ^{31}P, and ^{29}Si, have been investigated theoretically with fair success.[7,8]

There have, however, been only a few investigations of theoretical interpretations of the substituent effects on the signs and magnitudes of the nuclear spin coupling constants. As is well known,[9] the signs and magnitudes of geminal and vicinal H–H couplings, particularly of the geminal coupling, $J^{gem}_{H\text{-}H}$, depend sensitively on the nature of the substituent, X, for CH_3X, $(CH_2)_2X$, and CH_2=CHX systems. Pople and Bothner-By[10] gave a satisfactory interpretation of the substituent effects of geminal H–H coupling with the aid of simple MO formalism, distinguishing the electronic effects into inductive and hyperconjugative electron transfer.

However, the substituent effects on the ^{13}C–H and vicinal H–H couplings are still open to further investigation. The substituent effect on the directly-bonded ^{13}C–H couplings has been attributed to the change in the hybridization[11] of the carbon atom in the C–H bond, in the C–H bond distances,[12] or in the $1s$(H)–$2s$(C) partial bond order.[13] However, there have been no systematic studies of the substituent effect on the directly bonded ^{13}C–H and

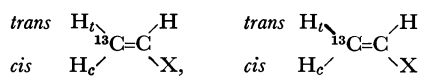
^{13}C–C–H couplings through the geminal two bonds, such as J_{C-H_t} and J_{C-H_c}, and vicinal J_{C-C-H_t} and J_{C-C-H_c}, specified as follows:



In the present study, we attempt to gain a comprehensive theoretical understanding of the substituent effect on the signs and magnitudes of directly-bonded ^{13}C–H, geminal H–H, and ^{13}C–H, and of vicinal H–H coupling constants for CH_3X, $(CH_2)_2X$, and CH_2=CHX systems.

Method of Calculation

For most of the couplings studied to date, particularly those involving only carbon and hydrogen atoms, it has been found that the Fermi contact term is most dominant.[3] All of our calculations are carried out, therefore, by neglecting the other two terms, the orbital and dipolar terms. In the LCAO approximation, the molecular orbital expression for the contact contribution to the spin-spin coupling constant between the A and B nuclei is given by:[3]

$$J_{AB} = -h\gamma_A\gamma_B\left(\frac{8\beta}{3}\right)^2 \sum_{i}^{occ}\sum_{j}^{unocc}({}^3\Delta E_{i\to j})^{-1} \times \sum_{\lambda\mu\gamma\sigma} C_{i\lambda}C_{j\mu}C_{j\gamma}C_{i\sigma}(\phi_\lambda|\delta(\gamma_A)|\phi_\mu) \times (\phi_\gamma|\delta(r_B)|\phi_\sigma) \quad (1)$$

The notations in Eq. (1) are the same as in Ref. 3. In the approximation which retains only one-center integrals involving valence s orbitals on the atoms A and B and in the one-electron independent MO approximation, Eq. (1) becomes:[3]

$$J_{AB} = \frac{16}{9}\beta^2\gamma_A\gamma_B h(S_A|\delta(r_A)|S_A)(S_B|\delta(r_B)|S_B)\pi_{S_A,S_B} = \frac{16}{9}\beta^2 h\gamma_A\gamma_B S_A^2(0)S_B^2(0)\pi_{S_A,S_B} \quad (2)$$

$S_A^2(0)$ and $S_B^2(0)$ denote the spin densities at the A and B nuclei of the valence s orbitals, and $\pi_{S_AS_B}$ is the mutual polarizability of the s valence orbital belonging to the atoms A and B. It is written as:

$$\pi_{S_A,S_B} = 4\sum_{i}^{occ}\sum_{j}^{unocc}(\varepsilon_i-\varepsilon_j)^{-1}C_{iS_A}C_{jS_A}C_{jS_B}C_{iS_A} \quad (3)$$

The values of $S_A^2(0)$ for the $1s$ and $2s$ valence orbitals for the H and C atoms were obtained using the Slater AO with an orbital exponent of 1.2 for H and using the SCF AO for the carbon atom.[14] With the appropriate constants, the H–H and ^{13}C–H spin coupling constants are given by the equations:

$$J_{H-H} = 6.235\times10^3\pi_{H-H}(\text{Hz}) \quad (4)$$

$$J_{C-H} = 7.885\times10^3\pi_{C-H}(\text{Hz}) \quad (5)$$

when π_{H-H} are π_{C-H} are given in units of $(\text{eV})^{-1}$.

In the present calculation, three types of molecular orbitals are employed for most of the molecules.

One-electron MO functions and energies were obtained by the extended Hückel method[15] (method A) and by two modified methods with a zero overlap approximation (methods B and C). The secular equations and parameters adopted in these three methods are summarized in Table 1. To construct a molecular orbital, Slater atomic orbitals were used as the basis set. The atomic coordinates for the evaluation of an overlap matrix, $S_{\mu\nu}$, were calculated from the pertienent bond distances and bond angles.[16] The valence-state ionization potentials (I_μ) used for the diagonal element of the H matrix are given in Table 2, together with the calculated values of $-0.5(I_\mu+A_\mu)$, where A_μ denotes an electron affinity. In method A, all the overlaps are included. In methods B and C, however, all the overlap integrals, $S_{\mu\nu}$, in the secular equations are replaced by $\delta_{\mu\nu}$ (=1 for $\mu=\nu$ and=0 for $\mu=\nu$). The method B was adopted in one of our previous paper,[2] where it was shown to have an advantage over method A. In the method C, the evaluation of $H_{\mu\mu}$ is slightly modified, as may be seen in Table 1. Pople and Segal[17] used this type of $H_{\mu\mu}$ parametrization for the starting

Table 1. Summary of the methods of the one-electron MO calculation

	Method A (EHMO)	Method B	Method C
$H_{\mu\nu}$	$0.5S_{\mu\nu}(H_{\mu\mu}+H_{\nu\nu})K$	$0.5S_{\mu\nu}(H_{\mu\mu}+H_{\nu\nu})K$	$0.5S_{\mu\nu}(H_{\mu\mu}+H_{\nu\nu})K$
Secular Eq.	$\lvert H_{\mu\nu}-\varepsilon S_{\mu\nu}\rvert=0$	$\lvert H_{\mu\nu}-\varepsilon\delta_{\mu\nu}\rvert=0$	$\lvert H_{\mu\nu}-\varepsilon\delta_{\mu\nu}\rvert=0$

a) The values of the ionization popotential and the electron affinity were taken from Pritchard and Skinner, *Chem. Revs.*, **55**, 745 (1955).

MO functions in their semi-empirical SCF MO-(CNDO) theory. Compared with method B, method C gives slightly smaller ionization potentials and coupling constants which are in better agreement with the experimental results.

Results

The calculated and observed coupling constants are compared in Tables 3 to 7. In Figs. 1 to 4, the variation in the observed and calculated H–H and ^{13}C–H coupling constants is plotted against the electronegativity, E_x, of the substituent, X. The values of E_x are tentatively taken from those of Cavanaugh and Daily,[18)] which were derived empirically from the internal chemical shifts, as is summarized in Table 8. The empirical linear correlation between the observed nuclear spin-coupling constants and their E_x values has been established by many workers.[9)] For the saturated CH_3X system, the calculation by the method A gives somewhat unfavorable*1 values of the geminal

*1 The calculated coupling constants obtained by three methods differ to some extent each other. The major concern in this work is the theoretical interpretation of the observed trend of E_x dependency and the sign of the coupling constants, with rather crude approximation. Therefore we reserve the quantitative discussion on the absolute value of the coupling constants.

H–H coupling; they are too negative, particularly for molecules with electronegative substituents such as X=O, N, F. The method B also gives improper results, as is depicted in Fig. 1; the substituent effect of the calculated values is opposite to that of the observed values. The results calculated by method C are the most acceptable, though the magnitudes are uniformly lower than those of the experiments by a factor of 1.5 (Fig. 1).

The linear dependence of the directly-bonded J_{CH} on E_x is also satisfactorily provided for by the method C than by the method B (Fig. 3). Thus, for the following discussion, the results obtained by method C are adopted for CH_3X systems.

For three-membered ring systems, $(CH_2)_2X$, none of the methods of calculation predict the observed trend of the H–H and C–H couplings. The most striking discrepancy between the cal-

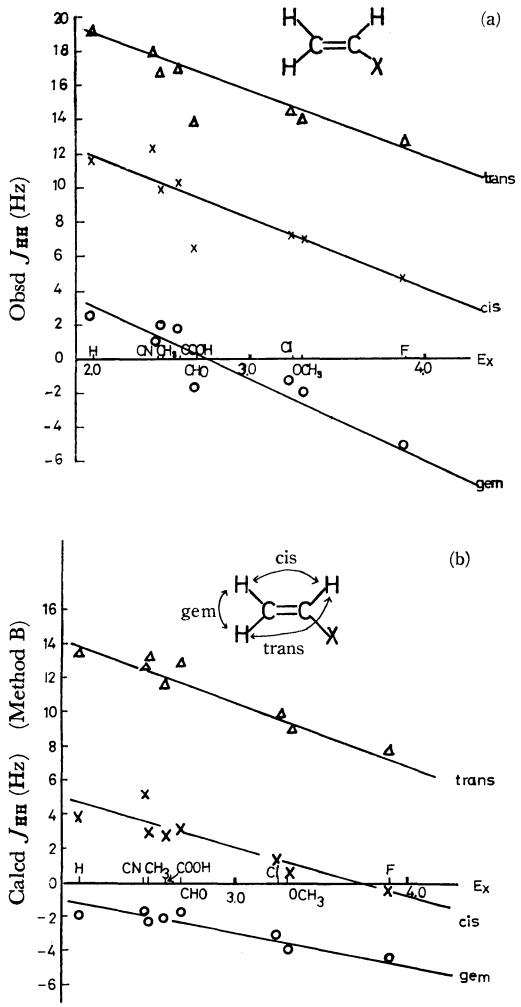

Fig. 2. The geminal, vicinal *cis*, and vicinal *trans* coupling constants in mono-substituted vinyl compounds are plotted *versus* the electronegativity of the substituent, X (E_x); (a): calculated values, (b) experimental values.

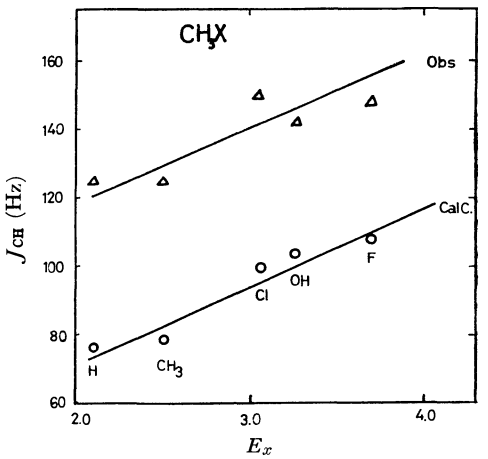

Fig. 3. The calculated and experimental ^{13}C–H coupling constants, J_{CH}, in CH_3X systems are plotted *versus* the electronegativity of the substituent, X (E_x).

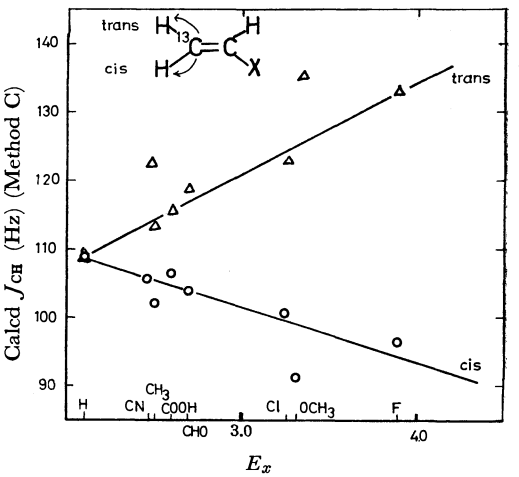

Fig. 4. The calculated ^{13}C–H coupling constants for directly bonded ^{13}C–H (*cis*) and ^{13}C–H (*trans*) in $^{13}CH_2$=CHX systems are plotted *versus* the electronegativity of the substituent, X (E_x).

culated and experimental coupling constants is in the vicinal H–H coupling constants. The greater value of the vicinal *cis* H–H coupling than that of the *trans* coupling is not reproduced by calculations.

For vinyl derivatives the geminal and vicinal *cis* and *trans* H–H coupling constants calculated by method B decrease linearly as E_x increases and are in agreement with the observed results (Fig. 2), but their magnitudes are lower than those of the experiments by a factor of about 1.5. Method C gives a poorer agreement with the experimental results in the present case because: (i) the *trans* H–H couplings are too positive, (ii) the *cis* coupling is more negative than the geminal coupling, behavior which contradicts the observed tendency, and (iii) the linear dependency of J_{H-H} on E_x disagrees with the observed feature.*2 Table 7 gives the ^{13}C–H couplings through one bond, J_{C-H}, and through two bonds, J_{C-C-H}. Because of the lack of experimental data, no comparison between calculated and observed values is yet possible. The calculated values of directly bonded ^{13}C–H coupling constants are somewhat different for ^{13}C–H_t and ^{13}C–H_c bonds, which are located respectively *cis* and *trans*, with respect to the substituent, X.

The variation in the calculated J_{C-H} values is

*2 The method C is adopted to improve the overestimated polarization due to heteroatoms in method B. However, this may cause improper sequence of σ and π orbitals in the vinyl compounds. So this may lead to a poor agreement with experiments.

plotted against E_x in Fig. 4. The J_{C-H_t} value increases as E_x increases, while the J_{C-H_c} value decreases. As may easily be seen from Table 7 and Fig. 4, the J_{C-H_c} value is generally greater than J_{C-H_t}. This definite trend of the J_{C-H} dependency on E_x has not been found experimentally. This prediction has, however, been partly confirmed experimentally by the present authors;[19] our results will be published elsewhere. However, the trend of J_{C-H_c} is also supported here by limited examples of the observed data (Table 7). Table 7 and Fig. 5 also reveal that the calculated values of

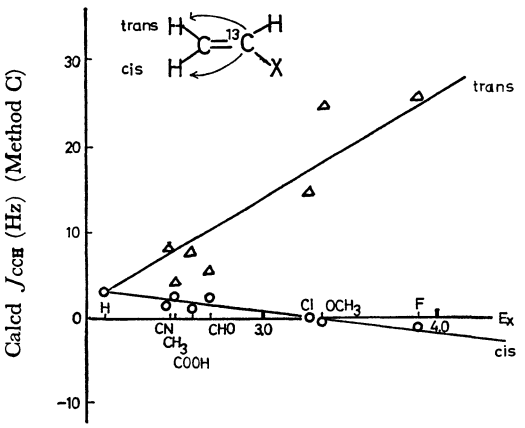

Fig. 5. The calculated ^{13}C–C–H coupling constants for *cis* and *trans* protons in CH_2=^{13}CHX systems are plotted *versus* the electronegativity of the substituent, X (E_x).

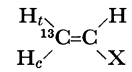
J_{C-C-H_t} are more positive than J_{C-C-H_c}. Figure 5 also reveals the opposite trend of J_{C-C-H_t} and J_{C-C-H_c}, a trend which is similar to the case with the directly-bonded ^{13}C–H coupling constants, J_{C-H_t} and J_{C-H_c}. The observed ^{13}C–C–H coupling constant for 1,2-dichloroethylene may serve as the only example of a compound with different *cis*- and *trans*-type ^{13}C–C–H coupling constants. Calculations by methods B and C reproduce the trend of the experimental value.

Discussion

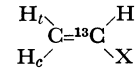
Before entering into our discussion, it should be pointed out that the present calculations do not include the contributions of the π-electrons to the coupling. The neglect of σ-π-interaction in the present study fails to account for π-electron contribution. Semiempirical methods for estimating π-electron coupling have been developed by McConnell[20] and Karplus.[21] They have shown that, for ethylene, the π-contribution is 1.8 Hz for the vicinal H–H coupling. This correction, however, is insufficient to cover the difference between the calculated coupling constants and the observed values. Since a major concern of this study is to give a theoretical interpretation of the experimental trend of the nuclear spin coupling constants, apart from the magnitude and sign of the calculated coupling constants, the substituent effect on the J value will be discussed without taking any account of the π-electron contirubition.

In general, the magnitudes of the coupling constants, as calculated on the basis of the contact term, reproduce the trend of the experimental values, but they are lower by a factor of between 1.5 to 2 (Figs. 1—3). Of the three types of calculations employed here, methods B and C are generally more satisfactory for the molecules containing heteroatoms. For hydrocarbons, the extended Hückel method (method A) is promising[6,8] except for the calculation of the J_{H-H} value for geminal protons. The most unfavorable aspect of method A is the too negative values for the geminal H–H coupling constants of most compounds, particularly for a geminal coupling in the CH_2 group adjacent to the heteroatom. This shortcoming is imporved by methods B and C, as has been discussed in a previous paper.[2] For example, the geminal H–H and directly-bonded ^{13}C–H coupling constants for formaldehyde are calculated to be -39.8 Hz and $+105.6$ Hz by method A, $+2.1$ Hz and $+99.1$ Hz by method B, and $+23.7$ Hz and $+161.7$ Hz by method C. The last set is comparable with the observed values of $+40.2$ and $+172$ Hz.

Let us now discuss our theoretical predictions of a general trend of the J_{C-H} and J_{C-C-H} values in vinyl derivatives. The directly-bonded ^{13}C–H coupling constants, J_{C-H_t} and J_{C-H_c}, increase and decrease respectively, with the increase in the electronegativity, E_x, in the vinyl compound (Fig. 4):



The same situation is also obtained for the geminal ^{13}C–C–H coupling constants, J_{C-C-H_t} and J_{C-C-H_c}, in:



(Figs. 4 and 5). It is well accepted that a linear relationship exists between the *s* character in the bonding carbon orbital and the directly-bonded J_{C-H}. The positive trend of the geminal H–H coupling constants, J_{H-H}, with an increase in the *s* character of the C–H bond has also been observed for geminal ^{13}C–C–H coupling constants, J_{C-C-H}, in ethane (-4.5 Hz), ethylene (-2.4 Hz), and

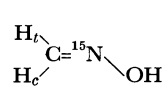
acetylene (+49.2 Hz).[22] Hence, an increase or decrease in the coupling constants can be expected in both cases as the *s* character of the carbon atom in the C–H bond increases or decreases. Therefore, it seems a reasonable prediction by calculation that the general trend of J_{C-H} is similar to that of J_{C-C-H}. It can also be said that the positive or negative trend of J_{C-C-H_t} and J_{C-C-H_c} depends mainly on the increase or decrease in the *s* character of the carbon atom in the C–H_t and C–H_c bonds.

In their theory of nuclear spin-coupling between geminal hydrogens, Pople and Bothner-By[10] have given elegant explanations of the general trend of J_{H-H} in terms of inductive and hyperconjugative electron withdrawal or donation of an adjacent substituent. Their theory can be qualitatively extended to the case of the ^{13}C–C–H geminal coupling in the ^{13}C–CX–H system, as has been done by McLauchlan and Shaefer.[23] However, the general features of J_{C-C-H} in H–C–^{13}C–X system can not be explained by the theory of Pople and Bothner-By.

The experimental values of J_{C-H} and J_{C-C-H} are completely lacking. The only instance of an experimental J_{C-C-H} value has been obtained for vinyl bromide,[24] $J_{C-C-H_t}=+7.5$ Hz, while $J_{C-C-H_c}=-8.5$ Hz, the calculation for which is not performed in the present study. A similar situation may hold for other substituted compounds. In fact, the values of $J_{C-C-H}=0$ in *trans*-dichloroethylene and $J_{C-C-H}=+15.7$ Hz (assumed positive) in *cis*-dichloroethylene are consistent with this assumption. Although calculation yields too positive values for J_{C-C-H_t} and J_{C-C-H_c}, the relative magnitudes of these two couplings may be reliable. The validity of the above predictions that $J_{C-H_t}>J_{C-H_c}$ and $J_{C-C-H_t}>J_{C-C-H_c}$ in the $H_2{}^{13}C{=}CHX$ and $H_2C{-}{}^{13}CHX$ systems respectively should be examined by further experiments. A similar relation, $J_{^{15}N-H_t}>J_{^{15}N-H_c}$, also holds for:



Lehn *et al.*[25] have obtained values of $J_{^{15}N-C-H_t}=-13.88$Hz and $J_{^{15}N-C-H_c}=+2.68$ Hz. Since the gyromagnetic ratio of the ^{15}N nucleus has the minus sign, the large minus coupling constant for $J_{^{15}N-C-H_t}$ is related to the large positive coupling for $J_{^{13}C-C-H_t}$ in the $H_2{}^{13}C{=}CHX$ system. Also, in this case the present calculation gives the values of −11.53 Hz and −3.09 Hz (method B) for $J_{^{15}N-C-H_t}$ and $J_{^{15}N-C-H_c}$ respectively. The large difference between these two geminal coupling constants is again reproduced by the calculation. Similar behavior is also seen in directly-bonded ^{13}C–H coupling constants of propionaldoxime:[26]

Observed:[26] $J_{C-H_c}=161$Hz $J_{C-H_t}=171$Hz

Calculated:[27] $J_{C-H_c}=131$Hz $J_{C-H_t}=141$Hz
(method C)

The ^{13}C–H coupling constant for the *trans* C–H bond with respect to the substituent OH is much larger than the *cis* one; this trend is also reproduced by the present calculation. This is also the case for formaldoxime ($J_{C-H_t}=141$ Hz and $J_{C-H_t}=129$ Hz). However, these differences in the coupling constants may possibly be considered to be due to the effect of lone-pair orientation.[26-28]

Because of the delocalized nature of the MO wave functions, and of the many different terms involved in Eq. (1), it does not seem to be easy to isolate the factors which dominate the coupling. In a previous work[2] we found a definite rule for finding the dominant contribution of the excitations which are specified by the orbital symmetry. Below we will discuss briefly the substituent effects on the coupling constant by considering how the dominant excitations vary with the substituent, X.

As we demonstrated previously,[2] a dominant contribution to the geminal H–H′ coupling constant for the CH_3X system is the excitation from the highest occupied (HO) MO, *a* (antisymmetric with respect to the two 1*s* atomic orbitals, *h* and *h*′), to the lowest or second lowest vacant (LV) MO, *a**. As the substituent, X, becomes more electronegative, the antisymmetric orbital energy is lowered, but the LV *a** orbital energy remains almost unchanged, resulting in an increase in the excitation energy ($\varepsilon_j-\varepsilon_i$). The effect of the substituent, X, on the numerator of Eq. (3) is somewhat difficult to analyse. Let us now tentatively consider the value of $2C_{i\mathrm{H}}C_{i\mathrm{H}}$, for an occupied *a* orbital which contributes dominantly to $J_{H-H'}$. This value is now designated as the "partial bond order" between *h* and *h*′ 1*s* orbitals. The partial bond order for the HO *a* orbital increases in its absolute value with an increase in the electronegativity, E_x. This enhancement of the antibonding character between H and H′ decreases the absolute value of the geminal H–H′ coupling constant. These two effects, the lowering of the HO *a* orbital energy and the increas-

Fig. 6. HO and LV molecular orbital energies (eV) and signs of the orbital coefficients for monosubstituted vinyl compounds.

ing of the atomic orbital coefficient in the HO *a* orbital, contribute dominantly to the increase in the geminal H–H′ couplings in CH_3X systems.

It is well-known that the replacement of X by hyperconjugative groups, such as –C≡CH, –C≡N, and CH_3, increases the negative geminal coupling constant.[29,30] These experimental results are well reproduced by the present calculations, as may be seen in Table 3. The dominant contribution to the geminal and vicinal H–H coupling for vinyl derivatives is made by the excitation from the highest occupied to the lowest unoccupied orbitals, whose orbital symmetry are shown in Fig. 6. These electronic excitations lead to negative and positive H–H coupling constants for geminal and vicinal couplings respectively. The energy difference between these orbitals increases as the electronegative group is replaced. This is illustrated in Fig. 6. Although, of course, the atomic orbital coefficients change, the increases in the excitation energy may play a dominant role in the decrease of the geminal and vicinal coupling constants.

Further progress in the calculation of the signs and magnitudes of nuclear spin coupling constants will come from improvements in the MO energies and LCAO coefficients. Some promise in this regard is shown by the approach using a semi-empirical SCF-MO calculation developed in our laboratory.[31] We got a value of +12.3 Hz for the geminal proton-proton coupling constant of formaldehyde, for instance, by this method. The ^{13}C–H coupling constant is even more improved. The details[32] will be given in the near future.

(Received September 27, 1968)

The change in the electronic state in the course of the E2 reaction of ethyl chloride was followed by means of the extended Hückel calculation. A model is adopted in which the nucleophilic reagent approaches the *trans*-β-hydrogen atom. The valence-inactive population of the *trans*-β-hydrogen atom in the lowest unoccupied (LU) molecular orbital (MO) was employed as a theoretical reactivity index. The theoretical conclusion derived was consistent with the experimental results.

The mechanism of the base-promoted, bimolecular elimination (E2) reactions has been experimentally studied in detail.[1] In this type of reaction, the attack of bases on the β-hydrogen atom and the departure of the nucleophile, X, from the α-carbon atom are thought to occur in concert with the double-bond formation between the C_α–C_β bond, and it is accepted that the hydrogen atom *trans* coplanar with respect to the leaving group is

1) See, *e.g.*, C. K. Ingold, "Structure and Mechanism in Organic Chemistry," Cornell University Press, Ithaca, New York (1953), p. 419.

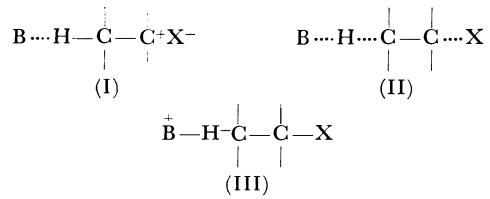
attacked dominantly.

In one of our previous papers[2] we, using MO calculations, have shown that the base should attack the *trans*-β-hydrogen atom most easily. Also, a quantitative method to interpret the reactivity in E2 reactions has been proposed.[3]

In the present paper, the change in the electronic state in the course of the E2 reaction of ethyl chloride will be discussed by the use of the extended Hückel method proposed by Hoffmann.[4] It is well established that this MO method is suitable for treating the electronic structure of sizable molecules which include unstable intermediates. Indeed, the mechanisms of various kinds of organic reactions have already been elucidated by means of this method.[2,3,5–10]

Setting-up of the Reaction Model

The β-eliminations are said to proceed by means of the following three processes[1]: one is the usual E2 mechanism (II), and the others are the two-step mechanisms, E1 (I) and E1cB (III).



Various examples of E1 reactions are known, while the carbanion mechanism (E1cB) is observed only in the extreme case where the β-carbon atom bears strongly-electron-attracting substituents.[11] It is considered that a bimolecular E2 reaction proceeds through a transition state like the II type, with varying contributions of I and III, depending on the structure and the reaction conditions.[12–14]

An alternative E2 mechanism in which S_N2 and E2 are "merged"[15,16] has been proposed, but it applies only to very special cases.[17]

In view of this, it is appropriate to adopt the model for the bimolecular elimination in the staggered ethyl chloride molecule as occurring in normal E2 fashion, with a concerted and a nearly complete synchronous mechanism.

For the convenience of calculation, we employ a chloride anion as the attacking base. The coordinates of this reacting system are presented in Fig. 1, where Cl_8, C_α, C_β, H_5, and Cl_9 atoms lie in the X-Z plane, the line of C_α–C_β being taken as the X-axis. The origin of the coordinates is at the middle point between C_α and C_β. The angles, H_5–C_β–H_4, H_5–C_β–H_3, H_5–C_β–C_α, Cl_8–C_α–H_6, Cl_8–C_α–H_7, and Cl_8–C_α–C_β, are all assumed to be equal to ϑ, and r_1, r_2, and r_3 refer to the distances of C_β–H_5, H_5–Cl_9, and C_α–Cl_8 respectively.

Here, we set up various combinations of r_1, r_2, r_3, and ϑ, as shown in Table 1. In these models, all the C_α–C_β and C–H bond distances, except for C_β–H_5, are fixed at 1.54 Å and 1.09 Å respectively. Of course, the C_α–C_β distance will vary with the reaction path. Therefore, in order to cover this ambiguity, we have changed the C_α–C_β ($=r_4$) distance in the models from V-1 to V-4 and in the models VI′ and VII′, as is shown in Table 1.

Method of Calculation

The numerical values used in the extended Hückel calculation are the same as those in the preceding paper.[3] For the sake of simplicity, the Coulomb integral of the attacking chloride anion is assumed to be constant throughout, equal to that of the neutral atom. The various populations calculated are defined as indicated in Table 2,[18]

Table 2. Definition of various populations

The AO population of AO r;

$$N(r) = 2\sum_{j}^{occ}\sum_{s} C_r^j C_s^j S_{rs}$$

The valence-inactive AO population of AO r;

$$p(r) = 2\sum_{j}^{occ}(C_r^j)^2$$

The valence-active AO population of AO r;

$$v(r) = 2\sum_{j}^{occ}\sum_{s\neq r} C_r^j C_s^j S_{rs}$$

The atom population of atom A;

$$M(\mathrm{A}) = \sum_{r}^{A} N(r)$$

The AO bond population between AO's r and s;

$$N(r\text{–}s) = 4\sum_{j}^{occ} C_r^j C_s^j S_{rs}$$

The atom bond population between atoms A and B;

$$M(\mathrm{A\text{–}B}) = \sum_{r}^{A}\sum_{s}^{B} N(r\text{–}s)$$

where r and s denote the rth and sth atomic orbitals respectively; C_r^j is the coefficient of the rth atomic orbital in the jth molecular orbital; $\sum_{j}^{occ}$ refers to the summation over all the occupied orbitals; $\sum_{r}^{A}$ signifies the sum over all the atomic orbitals belonging to the atom, A, and S_{rs} is the overlap integral between the rth and sth atomic orbitals as calculated by Mulliken's formula with Slater-type AO's.[19]

The geometry of an isolated ethyl chloride molecule is determined by the following interatomic distances and bond angles:[20]

C–Cl 1.77Å, C–C 1.54Å, C–H 1.09Å, ∠ClCC 110°

Also, the shape of ethylene molecule is taken as follows:

C–C 1.34Å, C–H 1.09Å, all angles 120°

Results and Discussions

1. The Electronic Structure of Ethyl Chloride. The highest occupied (HO) MO and the lowest unoccupied (LU) MO of ethyl chloride and their energies are shown in Table 3. The obtained HO energy, −12.5864 eV, is somewhat lower than is to be expected from the ionization potential value, 10.97 eV, or from the value, 11.2

Table 3. The AO coefficients and energy of HO and LU MO's of ethyl chloride

eV reported by Irsa[21] and Watanabe.[22] The energy of LU MO, 1.3394 eV, is considerably lower than the value, 3.2120 eV, of ethane,[23] reflecting the reactivity toward the nucleophilic attack. The HO level shows a π-type character, with the direction of extension parallel to the Y-axis; the occupying electrons are largely localized on the Cl 3py and C_α 2py orbitals, thus contributing to the C–H bonding. The LU orbital is of a pσ-type, with a strong antibonding character on the C_α–Cl and C_α–C_β, especially on the former. These trends correspond to the fact that the C_α–Cl bond is weakened by the electron transfer from the approaching nucleophilic reagent. In this MO the coefficient of the β-hydrogen atom (H_5) situated *trans* to the chlorine atom is the largest among those of the hydrogen orbitals, as has already been pointed out.[2]

2. The Change in the Electronic Structure of Ethyl Chloride along the Reaction Path. *2-1. The Change in AO Populations.* It is, of course, not confirmed that the models adopted, indicated in Table 1, correspond to the points on the reaction path on the potential energy surface. However, they at least provide us with some qualitative information concerning the electronic process of the reaction.

The calculated values of the total energy in models I—VII are given in Table 4. The results show that the total energy increases as the reaction proceeds reaching a maximum in model VI.

The atom population, M(A), in each atom is also shown in Table 4. The $M(C_\beta)$ increases from 4.387 at the initial state (ethyl chloride) to 4.705 in model VI, and then it decreases. On the contrary, $M(C_\alpha)$ decreases from 3.958 to 3.862 in model VI and then increases to 4.234 at the final product (ethylene) through the model VII, 4.079. From these data, C_α and C_β seem to form, respectively, the cationic and anionic centers in the transition state; afterwards, however, they approach electronically the same state. The β-hydrogen atom (H_5) is attacked by the base, which possesses monotonously decreasing values of $M(H_5)$, while the atom population of the leaving nucleophilic chlorine atom, $M(Cl_8)$, increases from 7.260 to 7.926. Hence, we find that the H_5 and Cl_8 atoms are likely to depart from the molecule as a cation and an anion respectively; this is consistent with the experimental results. It should be noted that the M(H) values of the hydrogen atoms which have less direct concern with the reaction, *i.e.*, $H_3(=H_4)$ and $H_6(=H_7)$, are almost unchanged.

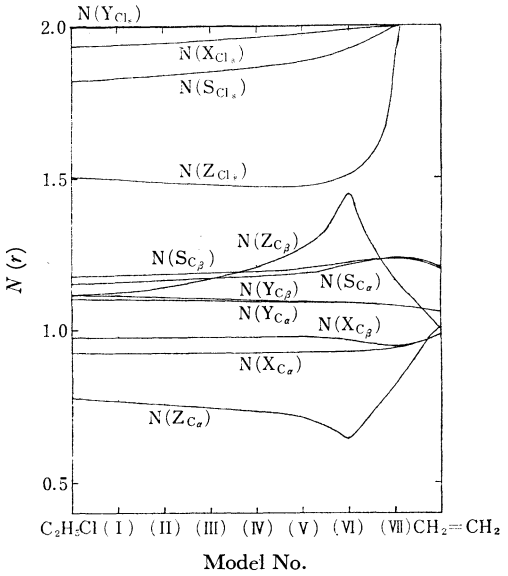

Fig. 2. The change of AO populations, $N(r)$, of the C_α, C_β and Cl_8 atoms in the reaction processes.

In order to obtain further knowledge, the AO populations of various atoms are collected in Fig. 2. The $N(Zc_\beta)$ increases remarkably from 1.114 at

the ethyl chloride to 1.446 at model VI and is responsible for making C_β an anionic center, while the $N(Zc_\alpha)$ decreases prominently from 0.776 to 0.649, thus mainly contributing to the cationic character of the C_α atom in model VI. We can also see that the electrons gradually migrate from the β-carbon 2px orbital to the α-carbon 2s orbital, and from the 2py orbitals of both carbon atoms to the H_3, H_4, H_6, and H_7 atoms. The AO populations of the 2s orbitals of both carbon atoms, $N(Sc_\alpha)$ and $N(Sc_\beta)$, increase monotonously. This may correspond to the carbon hybridization change from sp^3 to sp^2, in which the valence electrons in the C_α–Cl_8 and C_β–H_5 bonds become localized at the 2s orbitals as the Cl_8 and H_5 atoms start to leave both the carbon atoms.

The changes in the AO populations of Cl_8 were found to decrease in the order of $N(Z_{Cl_8})>N(S_{Cl_8})>N(X_{Cl_8})$. The $N(Y_{Cl_8})$ is almost constant, *ca.* 2.000. Therefore, the 2py orbital of the Cl_8 atom is assigned to a lone-pair orbital.

2-2. The Change in Bond Populations. The atom bond population, $M(C_\alpha$–$C_\beta)$, increases from 0.700 (ethyl chloride) to 1.024 (Model VII), as is shown in Fig. 3.

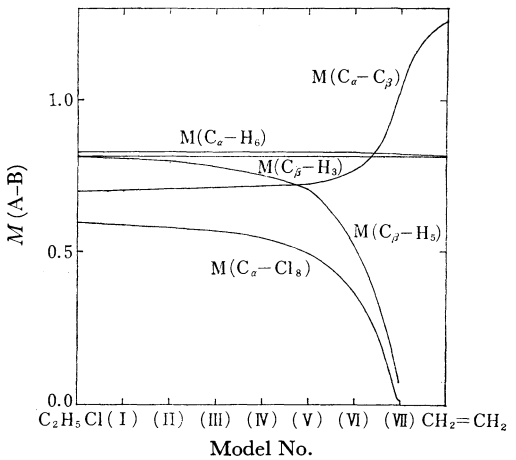

Fig. 3. The change of the atom bond populations, M (A–B), in the various models.

The values of $M(C_\alpha$–$Cl_8)$ and $M(C_\beta$–$H_5)$ decrease as their bond distances increase. The $M(C_\beta$–$H_3)$ and $M(C_\alpha$–$H_6)$ remain almost unchanged.

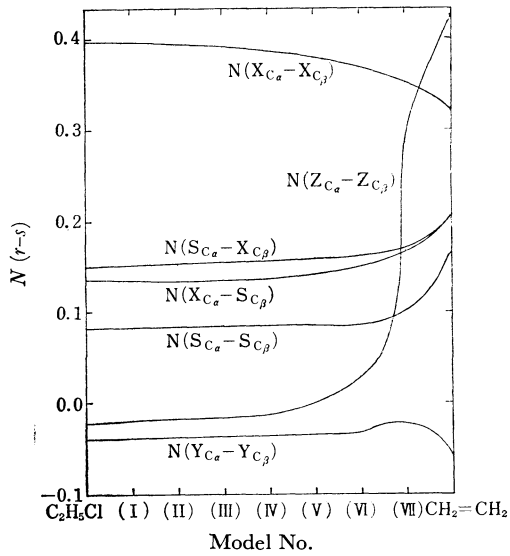

Fig. 4. The change of AO bond populations between α- and β-carbons.

For a further discussion of the C–C bond, the AO bond populations are listed in Fig. 4. The $N(Zc_\alpha$–$Zc_\beta)$ increases most remarkably from -0.022 to 0.285 (Model VII), contributing dominantly to the increase in $M(C_\alpha$–$C_\beta)$. Obviously, this reflects the progress of the double-bond formation. In models I—V, $N(Zc_\alpha$–$Zc_\beta)$ exhibits an antibonding nature, whereas models VI and VII indicate a bonding between the two 2pz orbitals. The $N(Xc_\alpha$–$Xc_\beta)$ and $N(Yc_\alpha$–$Yc_\beta)$ are larger than ethylene throughout the models from I to VII.

2-3. Influence of the Change in C–C Bond Distance upon the Electronic Structure. In the discussion above, the C–C bond distance was tentatively fixed as equal to 1.54Å. Now let us investigate the influence of the change in C–C bond distance.

Let us vary the C_α–C_β bond distance in model V as is shown in Table 1. The mode of the change in the electronic structure is given in Table 5 and in Figs. 5—7. These transient models seem to fit the states before the transition state, since the total energies are lower than the tentatively-assumed model VI. With the change from V to V-4, $M(C_\alpha)$ and $M(C_\beta)$ are reduced, showing an electron shift from the α-carbon to Cl_8, H_6, and H_7 and from the β-carbon to H_3 and H_4, while $M(H_5)$ and

Table 5. The calculated values of the total energy (eV), E, and atom population M(A) in models V-1—V-4

V-4	−474.1588	4.533	3.883	7.349	7.886	0.809	0.878	0.893

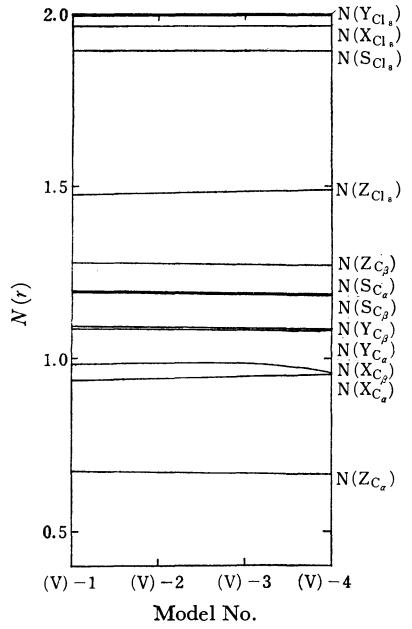

Fig. 5. The change of AO populations, $N(r)$, in the models V-1—V-4.

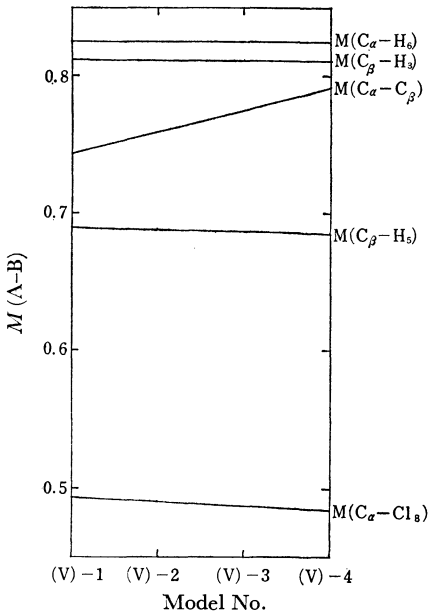

Fig. 6. The change of atom bond populations in the models V-1—V-4.

$M(Cl_9)$ remain almost unchanged. The changes in AO populations are listed in Fig. 5. The data indicate that $N(Sc_\alpha)$ and $N(Sc_\beta)$ decrease, while $N(Xc_\alpha)$ and $N(Xc_\beta)$ increase.

Figure 6 shows that $M(C_\beta-H_3)$ and $M(C_\alpha-H_6)$ remain constant. The $M(C_\beta-C_3)$ increases with a decrease in the $C_\alpha-C_\beta$ bond distance, while $M(C_\alpha-Cl_8)$ and $M(C_\beta-H_5)$ change in the reverse

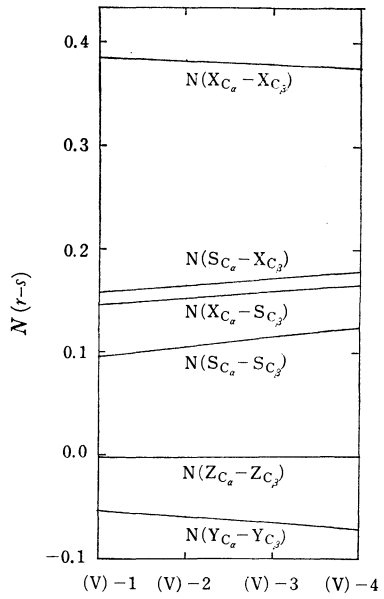

Fig. 7. The change of AO bond populations between α- and β-carbons in the models V-1—V-4.

fashion. The AO bond populations, $N(Sc_\alpha-Xc_\beta)$ and $N(Xc_\alpha-Sc_\beta)$ increase from 0.157 to 0.179 and from 0.142 to 0.166 respectively, as may be seen in Fig. 7. In this step of the reaction, the double-bond formation is not yet appreciable, as may be understood from the negative values of $N(Zc_\alpha-Zc_\beta)$.

Next, let us investigate the effect of the $C_\alpha-C_\beta$ bond distance near and after the transition state. Among the models listed in Table 1, models VI and VII seem to correspond to such states. If we change the bond distance from 1.54Å to 1.51Å, $M(C_\beta)$ decreases from 4.416 to 4.397, while $M(C_\alpha)$ increases from 4.079 to 4.090, in model VII, as may be observed from Tables 4 and 6. In this electron migration, the 2pz orbitals play a dominant role. The increase in $N(Zc_\alpha-Zc_\beta)$ expresses the double-bond formation. All the other populations, $N(r)$, $M(A)$, $N(r-s)$, and $M(A-B)$, in models VI′ and VII′, except for $M(C_\alpha)$ and $N(Zc_\alpha)$ in model VI′, come close to the corresponding ones of the ethylene molecule.

2-4. The Change in the Electronic Structure of the Leaving Chlorine Atom. In Section 2-1, it has been noted that the Cl_8 2py AO exhibits a lone-pair-like behavior. In this connection let us now attempt to discuss this point in more detail by the use of the concept of the valence atomic orbital (VAO) proposed by Ruedenberg.[24] The VAO is the orbital which makes the diagonal elements of the intra-atomic local bond order matrix reach a maximum

24) K. Ruedenberg, *Rev. Mod. Phys.*, **34**, 356 (1962).

or a minimum. The four VAO's belonging to the leaving chlorine atom attached to the α-carbon atom are designated as X, X_2, X_3, and X_4, among which X_4 is taken to be associated with the 3py orbital. These VAO's are obtained by using the bond-order matrix obtained by the extended Hückel calculation. The results are shown along with the hybrid states and the valence-inactive populations, in Fig. 8. The VAO X_1 is supposed to be associated with the Cl_8–C_α bond. The calculated valence angles of X_1 are well in agreement with the assumed angle, $\angle Cl_8C_\alpha C_\beta$, in models I—VI. (In Fig. 8, the discrepancy from the Cl_8–C_α bond is shown.) The hybrid of X_1 changes from $sp^{3.34}$ at the model I to $sp^{87.5}$ at the model VII. This indicates that X_1 becomes a 3p lone-pair orbital as the reaction proceeds. The X_2 and X_3 orbitals are lone-pair orbitals mainly composed of 3p and 3s AO respectively. As the reaction proceeds, the discrepancy of the obtained bond angle from the assumed angle becomes greater; *e.g.*, it is 13°14′ in model VII. This seems to be due to the decrease in the valence-active population between C_α and Cl_8 atoms.

The calculations were carried out on the HITAC 5020 computer at the computation center of the University of Tokyo.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1263—1265 (1969)

Microwave Spectrum of Cyclohexene*1

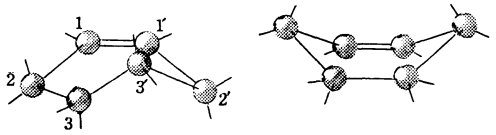
Teruhiko OGATA and Kunio KOZIMA

Laboratory of Molecular Spectroscopy, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 30, 1968)

The microwave spectrum of cyclohexene has been investigated in the frequency region from 7.3 to 27 Gc/sec with a conventional Stark modulation spectrometer, and the spectrum in the ground vibrational state has been assigned. The dipole moment lies entirely along the *b*-principal axis; its value, as obtained from the Stark displacements, is 0.332 ± 0.012D. From the rotational constants and the orientation of the dipole moment, it can be concluded that the equilibrium conformation is a "half-chair" form. Its most probable structure has been determined.

As there are many natural compounds which have a cyclohexene ring, such as terpenes and steroids, it may be considered important to investigate the structure of cyclohexene. Cyclohexene can exist in two conformations without making very great deformations in the normal values of the bond angles, *i.e.*, in a "half-chair" form with C_2 symmetry or in a "half-boat" form with C_s symmetry,[1] as Fig. 1 shows. Beckett, Freeman,



"half-chair" form "half-boat" form

Fig. 1

and Pitzer[2] concluded, by calculating its entropy and gaseous heat capacity, that the "half-chair" form was more stable than the "half-boat" form by about 2.7 kcal/mol. Sakashita[3] reported that no essential difference was observed among the infrared spectra of cyclohexene in the vapor, liquid, and solid states; that the spectrum could be assigned by assuming a single configuration, and that the value of the energy difference estimated by Beckett *et al.*, was reasonable.

X-Ray investigations of pentachlorocyclohexene[4] and naphthalenetetrachloride[5] showed that the molecules have the "half-chair" conformation. However, no detailed structural information is available on cyclohexene.

Experimental

The sample was prepared by dehydrating cyclohexanol.[6] The product was dried over calcium chloride

and purified by fractional distillation. The infrared spectrum of the sample thus obtained showed no evidence of impurities.

The microwave spectrum was investigated in the frequency region from 7.3 to 27 Gc/sec by using a conventional Stark modulation spectrometer with 110 kc/sec sine- and squar-ewave modulation. All measurements were made at the temperature of dry ice. The frequency measurements were performed with a frequency standard monitored against the standard signals from Station JJY.

Results and Discussion

Microwave Spectrum. The spectrum was found to be quite rich; about 400 sharp and weak lines were observed because of its small dipole moment. No investigation of the electron or X-ray diffraction has yet been made on this molecule. Therefore, the preliminary rotational constants, which were tentatively calculated by assuming the usual values for the bond lengths and the bond angles, were not very useful for the assignments. In order to assign the spectrum, it was necessary to investigate the Stark behavior of many absorption lines.

When the Stark voltage for all the absorption lines in the frequency ranges, which differed by several hundreds Mc/sec from the tentatively-calculated frequencies for the $J=1\rightarrow2$ transitions, were changed, careful examination revealed the lines which were split in two by the Stark effect. By using the three $J=1\rightarrow2$ frequencies thus determined, the rigid-rotor rotational constants were calculated. The assignments of the other transitions, as is shown in Table 2, could be made by the use of these rotational constants. The rotational constants listed in Table 1 were determined so as to get the best fit between these observed and calculated frequencies by assuming a rigid-rotor approximation. In Table 2 the observed frequencies which are marked with * were ascertained by means of their Stark effects. Relative intensity measurements confirmed that these spectrum are due to the vibrational ground state.

The absorption line of the $0_{00}\rightarrow1_{11}$ transtion could not be observed by the spectrometer mentioned above. Therefore, the measurable frequency of the spectrometer was lowered by using 8V69 klystron of the Nippon Elec. Co. and a 6-m J-band absorption cell. As is shown in Table 2, the observed frequency of the $0_{00}\rightarrow1_{11}$ transition is in good agreement with that calculated by the rotational constants.

Dipole Moment. The dipole moment for the ground vibrational state was determined from the Stark displacements of the $1_{10}\rightarrow2_{21}$ and $1_{01}\rightarrow2_{12}$ transitions. The observed and calculated Stark coefficients are given in Table 3. The absorption cell was calibrated using the $J=1\rightarrow2$ transition of OCS, taking the dipole moment of OCS as 0.7124.[7]

Table 3. Stark coefficients and dipole moment

7) S. A. Marshall and I. Weber, *Phys. Rev.*, **105**, 1502 (1957).

The value of the dipole moment of 0.332 D obtained by us is considerably lower than those of 0.75D[8] (in a hexane solution), 0.63 D[8] (in a CCl_4 solution), and 0.61 D[9] (in vapor) obtained by Debye's method. Our value supports Smyth's suggestion[10] that the value of 0.61 D is too high. Kumler *et al.*[11] obtained the value of 0.21 D (in a heptane solution) for this molecule by Debye's method. This value is a little lower than ours. However, their value of the atomic polarization, as estimated from those of analogous compounds, seems to be nearly correct.

A possible upper limit for the μ_c component of the dipole moment could be estimated from the Stark effect of the $1_{01}\rightarrow 2_{12}$ transition, since the effect of μ_c on the observed Stark effect would be to alter the Stark effect of the μ_b component. By assuming the error in the frequency measurement to be ± 0.1 Mc/sec, it could be estimated that the possible upper limit of the value of μ_c is 5.84×10^{-3}D. Therefore, it is very probable that the value of μ_c is zero within the limits of exprimental error.

Molecular Structure. The possibility of the "half-boat" form can be excluded in view of the fact that the value of μ_c is zero or nearly zero. As a possible structure, a planar cyclohexene ring might be considered, because the μ_c value of the molecule with this ring should be zero. In this case, as the molecule has C_{2v} symmetry, the quantity of $(I_c-I_a-I_b)/2$ is given approximately by $8mr^2\sin^2(\theta/2)$, where θ is the valency angle of $\angle$ H–C_i–H and where r is the bond length of the C_i–H bond ($i=2$, 2′, 3, and 3′; see Fig. 1). By assuming that θ is 109°28′ and that r is 1.10Å, we can obtain $(I_c-I_a-I_b)/2=-6.687$ amu·Å^2. Since this value is quite different from the observed value of -10.3098 amu·Å^2, the possibilities of a planar ring and of a nearly planar ring can be eliminated. Therefore, as a remaining possibility we have to check whether or not the molecule has the "half-chair" form.

As the molecule of the "half-chair" form should have C_2 symmetry, the value of μ_c is zero, in agreement with the experimental fact. Next we have to obtain a reasonable set of structural parameters so as to get the best fit between the observed and the calculated principal moments of inertia. However, as there are many structural parameters to be determined, a number of assumptions or approximations are necessary. It is reasonable to consider that the ethylene group of $\begin{matrix}H\\C\end{matrix}\!\!>\!C=C\!<\!\!\begin{matrix}H\\C\end{matrix}$ has a planar structure. Furthermore, the following assumptions may be safely made:

(1) the C–H bond of the ethylene group is located along the angle bisector of $\angle$C=C–C;

(2) the angle bisector of $\angle$H–C_i–H is that of $\angle$C–C_i–C ($i=2$, 2′, 3, and 3′);

(3) the angles of $\angle$H–C_i–H are tetrahedral;

(4) the internuclear distance, r_{2-3}, between C_2 and C_3 is equal to that, $r_{3-3'}$ between C_3 and $C_{3'}$ and

(5) all aliphatic C–H bonds are of equal length.

When taking into account the relation that only two of three $\angle$CCC bond angles are independent, there are still seven structural parameters to be determined.

By calculating the value of $\partial I_i/\partial X_j$, where I_j is the jth moment of inertia and X_i is the ith structural parameter, we can see that the angles of $\angle$C=C–C and $\angle$C–C–C and the bond length of C=C and C–C are highly sensitive to the values of the moment of inertia. By assuming the values of the aliphatic and the olefinic C–H bond lengths, r_{C-H} and $r_{=C-H}$; the double bond length, $r_{1-1'}$, and either r_{1-2} or r_{2-3}, the values of the two $\angle$CCC bond angles and either r_{1-2} or r_{2-3} were determined so as to get a good fit for the observed moments of inertia. For each set of structural parameters the value of $r_{1-1'}$ was assumed to be that of propylene.[12] For the set I, all the assumed values are those of propylene. For the set II, the assumed values of r_{2-3} and r_{C-H} are those of ethane,[13] while $r_{=C-H}$ is that of ethylene.[14] For the set III, the values of r_{2-3}, r_{C-H}, and $r_{=C-H}$ are those of propane,[15] ethane, and ethylene respectively.

The calculated values of the set III do not seem reasonable, because the r_{1-2} value is almost the same to that of r_{2-3}. The values of the sets I and II are not so different from each other. The values of both sets are very probable for the structural parameters of this molecule.

TABLE 4. STRUCTURAL PARAMETERS OF CYCLOHEXENE

	Set I	Set II	Set III
$r_{1-1'}$	1.336*	1.336*	1.336Å*
r_{1-2}	1.501*	1.495	1.523Å
$r_{2-3}=r_{3-3'}$	1.541	1.543*	1.526Å*
$r_{=C-H}$	1.090*	1.086*	1.086Å*

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1266—1271 (1969)

On the Order of Isotopic Exchange Reactions

Tetsuo TAKAISHI

The Institute for Atomic Energy of Rikkyo (St. Paul's) University, Yokosuka

(Received October 5, 1968)

The conditions for the applicability of the McKay law were studied. It was concluded that the first order kinetics no longer holds when the concentrations of intermediates cannot be disregarded when compared with those of reactants and products and when the rate determining step cannot be specified. Some reactions were illustrated in which McKay's law cannot be applied.

In 1938, studying the kinetics of isotopic exchange reaction, McKay[1] arrived at the following conclusion. The exchange reaction is expressed by as,

$$AX^* + BX = AX + BX^*, \tag{1}$$

where X* represents a tagged X atom, and the reaction (1) is in equilibrium apart from the isotopic distribution. Let the concentration be denoted by

$$\begin{aligned} [AX] + [AX^*] &= a, & [AX^*] &= x, \\ [BX] + [BX^*] &= b, & [BX^*] &= y, \end{aligned} \tag{2}$$

and the rate of total exchange reaction by R. Then, whatever the reaction mechanism might be, the relation,

$$\frac{dx}{dt} = -\frac{dy}{dt} = R\frac{a-x}{a}\frac{y}{b} - R\frac{x}{a}\frac{b-y}{b} = -\frac{x}{a}R + \frac{y}{b}R \tag{3}$$

holds and we have

$$-\ln\left(\frac{x_\infty - x}{x_\infty}\right) = R\left(\frac{a+b}{ab}\right)t \tag{4}$$

under the condition $x+y=$const., where x_∞ designates the value for x in equilibrium. Equation (4) may be referred to as McKay's law hereafter.

Since then, many workers[2-8] have discussed the validity of McKay's law. Though some modifications must be introduced in such a case where two or more atoms in a molecule are tagged,[7,8] the main features of the law are accepted to be true. Recently, Kawaguchi[9] raised some questions as to its validity. The present author[10] briefly commented on his note, mentioning limitations to the validity of McKay's law. In the present paper, the problem is discussed in more detail and practical problems in kinetic analysis are considered, since kinetic studies today frequently involve special conditions that could not be considered in earlier days.

Conditions for the Applicability of McKay's Law

Elementary Reaction. We adopt, in what follows, the fundamental simplifying assumption that the isotopic mass effects can be ignored not only in rate processes but also in equilibrium properties. This may be appropriate to the study of the fundamental nature of McKay's law. Moreover, we assume that only an atom in a specified position in the molecule is tagged. The case where two or more atoms in some positions in the molecule with different reactivities are tagged[7,8] can be treated as an extension of the presetnt study.

Strictly speaking, McKay's law is only applicable to an elementary reaction or step. The proof of this is very simple. Let the reaction (1) be an elementary reaction. According to the theory of the absolute reaction rate, the rate in the elementary process is given by $\nu\,[Z^*]$, where Z^* denotes the activated complex and ν the frequency of vibration of the activated complexes in the degree of freedom corresponding to their decomposition. Furthermore, there exists a thermodynamic equilibrium between

Z^* and the reactants. Here we consider that X-atoms at two specified positions in the activated complex are interchanged with each other in the course of the decomposition of activated complex, and that one of the exchangeable X-atoms comes from an AX-molecule and is transfered to a BX-molecule while another from a BX to an AX. These exchangeable atoms may be designated by A-site atom and B-site one, respectively. Let us consider the activated complex, Z^{**},whose A-site atom is tagged and B-site atom untagged. The ratio of the number of such tagged activated complexes to the total number of activated complexes becomes equal to $[AX^*][BX]/\{([AX]+[AX^*])([BX]+[BX^*])\}$. Consequently, for the forward reaction of (1), we have

$$\frac{(\text{rate of reaction of tagged molecules})}{(\text{total reaction rate})} = \frac{\nu[Z^{**}]}{\nu([Z^*]+[Z^{**}])} = \frac{x(b-y)}{ab},$$

irrespective of the molecularity of the reaction. Similarly, for the backward reaction of (1), we get

$$\frac{(\text{rate of reaction of tagged molecules})}{(\text{total reaction rate})} = \frac{y(a-x)}{ab}.$$

Thus, the net increase of AX^* is given by the difference of the two, *i. e.*, by Eq. (3).

Complex Reaction. When the reaction (1) is a complex reaction, the validity of Eq. (4) must carefully be examined. Even when applicable for appropirate conditions, Eq. (4) may be only approximate. As there are numerous reaction mechanisms, we cannot arrive at the necessary and sufficient conditions for general applicability of Eq. (4). Some typical cases, however, may be discussed.

Consecutive Reactions. If the reaction kinetics can well be described by assuming the existence of a rate determing step, the reaction scheme may be expressed as

$$AX+BX^* \rightleftarrows CX+DX^* \overset{R}{\rightleftarrows} CX^*+DX \rightleftarrows AX^*+BX,$$

where R designates the over-all rate and consequently that of rate determining step.
Using the notation (2), and further denoting

$$[CX] + [CX^*] = \alpha,\ [CX^*] = \xi$$

and

$$[DX] + [DX^*] = \beta,\ [DX^*] = \eta,$$

we have, irrespective of the molecularity of the reaction,

$$\frac{d(x+\xi)}{dt} = -R\frac{\xi}{\alpha} + R\frac{\eta}{\beta} = -\frac{d(y+\eta)}{dt}, \tag{6}$$

and $x+y+\xi+\eta=\text{const.}$
Since the reaction $AX+BX \rightleftarrows CX+DX$, is very rapid and in equilibrium, it becomes,

$$\frac{\xi}{\alpha} = \frac{x}{a},\ \frac{\eta}{\beta} = \frac{y}{b}.$$

Introducing these into Eq. (6), we get

$$\frac{d(x+\xi)}{dt} = R\left(\frac{y}{b} - \frac{x}{a}\right).$$

As far as the relations

$$\frac{dx}{dt} \gg \frac{d\xi}{dt} \text{ and } x, y, \gg \xi, \eta \tag{7}$$

hold the above relation reduces to

$$\frac{dx}{dt} = R\left(\frac{y}{b} - \frac{x}{a}\right),$$

i. e., Eq. (3) may be applied.

Concurrent Consecutive Reactions. When there exist parallel reaction paths, the typical reaction scheme may be expressed as

$$\begin{array}{ccccccc} & & C_1X + D_1X^* & \overset{R_1}{\rightleftarrows} & C_1X^* + D_1X & & \\ & \nearrow & & & & \searrow & \\ XA + BX^* & \rightleftarrows & C_2X + D_2X^* & \overset{R_2}{\rightleftarrows} & C_2X^* + D_2X & \rightleftarrows & AX^* + BX, \\ & \searrow & & & & \nearrow & \\ & & \cdots\cdots\cdots & & \cdots\cdots\cdots & & \\ & & \cdots\cdots\cdots & & \cdots\cdots\cdots & & \\ & & C_nX + D_nX^* & \overset{R_n}{\rightleftarrows} & C_nX^* + D_nX & & \end{array} \tag{8}$$

where the existence of rate determining step in the respective path is assumed. Then the rate equation is given by

$$\frac{d(x+\xi_1+\cdots+\xi_n)}{dt} = \sum_{i=1}^{n} R_i\left(\frac{\eta_i}{\beta_i} - \frac{\xi_i}{\alpha_i}\right),$$

where

$$\alpha_i = [C_iX] + [C_iX^*],\ \xi_i = [C_iX^*],$$

and

$$\beta_i = [D_iX] + [D_iX^*],\ \eta_i = [D_iX^*].$$

If $x, y \gg \xi_i, \eta_i$, and $dx/dt \gg d\xi_i/dt$, we have, by

virture of the relations $x/a=\xi_t/\alpha_t$ and $y/b=\eta_t/\beta_t$,

$$\frac{dx}{dt}=\left(\frac{y}{b}-\frac{x}{a}\right)\sum_{i=1}^{n}R_i=R\left(\frac{y}{b}-\frac{x}{a}\right)$$

with $$R=\sum_{i=1}^{n}R_i.$$

Since R corresponds to the over-all rate, McKay's law holds.

Rate Determining Step cannot be specified. Let us consider a more general case where the rate of reaction is controlled by several steps which occur in series; namely,

$$\left.\begin{array}{l}A_1X \overset{R_1}{\rightleftarrows} A_2X \overset{R_2}{\rightleftarrows} \cdots \overset{R_{n-1}}{\rightleftarrows} A_nX \\ \qquad\qquad\qquad\qquad + \\ B_1X^* \overset{R'_1}{\rightleftarrows} B_2X^* \rightleftarrows \cdots \overset{R_{m-1}}{\rightleftarrows} B_mX^*\end{array}\right\} \overset{R_n}{\rightleftarrows}$$

$$\left\{\begin{array}{l}A_nX^* \overset{R_{n-1}}{\rightleftarrows} \cdots \rightleftarrows A_1X^* \\ + \\ B_mX \overset{R'_{m-1}}{\rightleftarrows} \cdots \rightleftarrows B_1X.\end{array}\right.$$

Then the rate equations are

$$\frac{dx_1}{dt}=-R_1\frac{x_1}{a_1}+R_1\frac{x_2}{x_2} \tag{9}$$

$$\left.\begin{array}{l}\dfrac{dx_2}{dt}=R_1\dfrac{x_1}{a_1}-R_1\dfrac{x_2}{a_2}-R_2\dfrac{x_2}{a_2}+R_2\dfrac{x_3}{a_3} \\ \cdots\cdots\cdots\cdots \\ \cdots\cdots\cdots\cdots \\ \dfrac{dx_n}{dt}=R_{n-1}\dfrac{x_{n-1}}{a_{n-1}}-R_{n-1}\dfrac{x_n}{a_n}-R_n\dfrac{x_n}{a_n}+R_n\dfrac{y_m}{b_m} \\ \dfrac{dy_m}{dt}=R_n\dfrac{x_n}{b_n}-R_n\dfrac{y_m}{b_m}-R'_{m-1}\dfrac{y_m}{b_m}+R'_{m-1}\dfrac{y_{m-1}}{b_{m-1}} \\ \cdots\cdots\cdots\cdots \\ \cdots\cdots\cdots\cdots\end{array}\right\} \tag{10}$$

$$\frac{dy_1}{dt}=-R'_1\frac{y_1}{b_1}+R'_1\frac{y_2}{b_2}, \tag{11}$$

where

$$[A_iX]+[A_iX^*]=a_i,\quad [A_tX^*]=x_i,$$

and

$$[B_iX]+[B_iX^*]=b_i,\quad [B_iX^*]=y_i.$$

From Eqs. (9)—(11), a $(m+n)$th order differential equation for $x_1(t)$ may be obtained, and its exact solution is to have a different form from Eq. (4). Under appropriate conditions, however, this equation may be reduced approximately to Eq. (3). This is studied in the following.

If the approximation of the steady state reaction[11] is used, *i. e.*, the relations,

$$\frac{dx_2}{dt}=\frac{dx_3}{dt}=\cdots=\frac{dx_n}{dt}=\frac{dy_m}{dt}=\cdots=\frac{dy_2}{dt}=0,$$

are assumed, then Eq. (10) become

$$\left.\begin{array}{l}(R_1+R_2)\dfrac{x_2}{a_2}-R_2\dfrac{x_3}{a_3}=R_1\dfrac{x_1}{a_1}, \\ -R_2\dfrac{x_2}{a_2}+(R_2+R_3)\dfrac{x_3}{a_3}-R_3\dfrac{x_4}{a_4}=0, \\ \cdots\cdots\cdots\cdots \\ \cdots\cdots\cdots\cdots \\ -R_{n-1}\dfrac{x_{n-1}}{a_{n-1}}+(R_{n-1}+R_n)\dfrac{x_n}{a_n}-R_n\dfrac{y_m}{b_m}=0, \\ -R_n\dfrac{x_n}{a_n}+(R_n+R'_{m-1})\dfrac{y_m}{b_m}-R'_{m-1}\dfrac{y_{m-1}}{b_{m-1}}=0, \\ \cdots\cdots\cdots\cdots \\ \cdots\cdots\cdots\cdots \\ -R'_2\dfrac{y_3}{b_3}+(R'_1+R'_2)\dfrac{y_2}{b_2}=R'_1\dfrac{y_1}{b_1}.\end{array}\right\} \tag{10}'$$

Solving Eq. (10)′, we can express x_2/a_2 as a function of x_1/a_1 and y_1/b_1,

$$\frac{x_2}{a_2}=\frac{1}{\Delta}\begin{vmatrix}\dfrac{R_1}{a_1}x_1, & -R_2, & \cdots\cdots\cdots & 0 \\ 0, & R_2+R_3, & -R_3, & \vdots \\ \vdots & -R_3, & R_3+R_4, & -R_4 \\ & & -R'_3, & R'_3+R'_2 \\ \dfrac{R_1}{b_1}y_1, & \cdots\cdots\cdots, & 0, & -R'_2 \end{vmatrix}\begin{matrix} 0 \\ \vdots \\ 0 \\ -R'_2 \\ R'_1+R'_2 \end{matrix}, \tag{12}$$

11) K. J. Laidler, "Reaction Kinetics, Vol. I Homogeneous Gas Reactions," Pergamon Press, Oxford (1963).

where

$$\Delta = \begin{vmatrix} R_1+R_2, & -R_2, & 0 & \cdots\cdots & 0 \\ -R_2, & R_2+R_3, & -R_3 & & \vdots \\ 0, & \ddots & \ddots & \ddots & 0 \\ \vdots & & -R'_3, & R'_3+R'_2, & -R'_2 \\ 0 & \cdots\cdots, & 0, & -R'_2, & R'_2+R'_1 \end{vmatrix} = Q \cdot \frac{1}{R},$$

with

$$\frac{1}{R} = \frac{1}{R_1} + \cdots + \frac{1}{R_n} + \frac{1}{R'_{m-1}} + \cdots + \frac{1}{R'_1}, \tag{13}$$

and

$$Q = R_1 \cdot R_2 \cdot \cdots \cdot R_n \cdot R'_{m-1} \cdot \cdots \cdot R'_1.$$

Eq. (12) becomes

$$\frac{x_2}{a_2} = \frac{1}{\Delta}\frac{R_1}{a_1}x_1 \begin{vmatrix} R_2+R_3, & -R_3, & 0 & \cdots\cdots & 0 \\ -R_3, & R_3+R_4, & -R_4 & & \vdots \\ 0, & -R_4, & \ddots & \ddots & 0 \\ \vdots & & , -R'_3, & R'_3+R'_2, & -R'_2 \\ 0 & \cdots\cdots, & 0, & -R'_2, & R'_2+R'_1 \end{vmatrix} +$$

$$(-1)^{m+n-2}\frac{1}{\Delta}\cdot\frac{R_1}{b_1}y_1 \begin{vmatrix} -R_2, & 0, & \cdots\cdots & & 0 \\ R_2+R_3, & -R_3, & 0, & & \vdots \\ -R_3, & R_3+R_4, & -R_4, & & \\ 0, & \ddots & \ddots & \ddots & \\ \vdots & & , -R'_4, & R'_3+R'_4, & -R'_3, & 0 \\ 0 & \cdots\cdots, & 0, & -R'_3, & R'_2+R'_3, & -R'_2 \end{vmatrix}$$

$$= \frac{1}{\Delta}\frac{R_1}{a_1}x_1(R_2 \cdot R_2 \cdot \cdots \cdot R'_1)\left(\frac{1}{R_2} + \frac{1}{R_3} + \cdots + \frac{1}{R'_1}\right) + \frac{1}{\Delta}\frac{R'_1}{b_1}y_1 \cdot R_2 \cdot R_3 \cdot \cdots \cdot R'_2.$$

Introducing this relation into Eq. (9), we get

$$\frac{dx_1}{dt} = -\frac{R_1}{a_1}x_1 + \frac{R_1}{\Delta}\frac{x_1}{a_1}(R_1 \cdot R_2 \cdot \cdots \cdot R'_1)\left(\frac{1}{R_2} + \frac{1}{R_3} + \cdots + \frac{1}{R'_1}\right) + \frac{Q}{b_1 R_1}y_1$$

$$= -R_1\frac{x_1}{a} + R \cdot R_1\frac{x_1}{a_1}\left(\frac{1}{R_2} + \cdots + \frac{1}{R'_1}\right) + \frac{y_1}{b_1}R = R\left(\frac{y_1}{b_1} - \frac{x_1}{a_1}\right).$$

Thus McKay's law is proved inasmuch as R corresponds, according to Eq. (13), to the rate of the overall reaction.

It may be deduced from these examples, that McKay's law approximately holds, when concentrations of reaction intermediates are negligibly smally as compared to those of reactants and products and consequently changes of concentrations of tagged intermediates are also negligible.

Failure of McKay's Law

Now, two questions may arise: firstly, whether McKay's law necessarily breaks down in the case where concentrations of reaction intermediates cannot be disregarded, and secondly, whether such a case has a practical meaning. In the usual cases, concentrations of reaction intermediates are negligibly small as compared to those of reactants and products, but in some reactions this is not the case. Several such examples are discussed.

Excess Catalysts. The direct observation of reaction intermediates is one of current topics, especially in the field of contact catalysis. Some adsorbed species on solid catalysts constitute reaction intermediates and can be studied by ESR, NMR,

IR, isotope techniques and so on. For the convenience of measurements, in some cases, excess amounts of solid catalyst are used as compared to those of the reactants and products in gaseous phase. Such examples were reviewed by Tamaru.[12] Let us discuss one of the simplest cases.

$$\left.\begin{matrix} AX \overset{R_1}{\rightleftarrows} (AX)_a \\ + \\ BX^* \end{matrix}\right\} \overset{R_2}{\rightleftarrows} \left\{\begin{matrix} (AX^*)_a \overset{R_1}{\rightleftarrows} AX^*, \\ + \\ BX \end{matrix}\right.$$

where the subscript a designates adsorbed species. Using the notation (2), and designating

$$[(AX)_a] + [(AX^*)_a] = \alpha$$

and

$$[(AX^*)_a] = \xi,$$

we have the rate equations

$$\frac{dx}{dt} = -R_1\frac{x}{a} + R_1\frac{\xi}{\alpha},$$

$$\frac{d\xi}{dt} = R_1\frac{x}{a} - R_1\frac{\xi}{\alpha} - R_2\frac{\xi}{\alpha} + R_2\frac{y}{b},$$

and

$$\frac{dy}{dt} = -R_2\frac{y}{b} + R_2\frac{\xi}{\alpha},$$

with $x + y + \xi = \text{const.} = I.$

These equations reduce to

$$\frac{d^2x}{dt^2} + \left(\frac{R_1+R_2}{\alpha} + \frac{R_1}{a} + \frac{R_2}{b}\right)\frac{dx}{dt} + \frac{a+b+\alpha}{ab\alpha}R_1R_2x = \frac{R_1R_2}{b\alpha}I, \tag{14}$$

of which the solution becomes

$$x = x_\infty\left[1 + \frac{\rho_-}{\sqrt{D}}\exp(\rho_+t) - \frac{\rho_+}{\sqrt{D}}\exp(\rho_-t)\right], \tag{15}$$

with

$$\rho_\pm = -\frac{1}{2}\left(\frac{R_1}{a} + \frac{R_2}{b} + \frac{R_1+R_2}{\alpha}\right) \pm \frac{\sqrt{D}}{2},$$

$$D = \left(\frac{R_1}{a} + \frac{R_2}{b} + \frac{R_1+R_2}{\alpha}\right)^2 - \frac{4(a+b+\alpha)}{ab\alpha}R_1R_2,$$

and

$$x_\infty = \frac{a}{a+b+\alpha}I,$$

under the intial condition

$$x = 0,\ \xi = 0 \text{ at } t = 0.$$

Let us consider the case where R_1 is much larger than R_2, *i. e.*, the reaction $AX \rightleftarrows (AX)_a$ is in equilibrium. Then, Eq. (14) reduces approximately to

$$\left(\frac{R_1}{\alpha} + \frac{R_1}{a}\right)\frac{dx}{dt} + \frac{a+b+\alpha}{ab\alpha}R_1R_2x = \frac{R_1R_2}{b\alpha}I,$$

and hence to

$$\frac{dx}{dt} = -\frac{a+\alpha+b}{b(a+\alpha)}R_2x + \frac{a}{b(a+\alpha)}R_2I,$$

and consequently we have

$$-\ln\frac{x_\infty - x}{x_\infty} = \frac{b+a+\alpha}{b(a+\alpha)}R_2t. \tag{16}$$

This is a slight modification of Eq. (4) obtained by replacing a by $a+\alpha$.

In the case where the step $(AX)_a + BX^* \rightleftarrows (AX^*)_a + BX$ is in equilibrium, the same result is obtained. Thus, it may be concluded that in this reaction scheme McKay's law seriously breaks down only if the intermediate rate determining step cannot be specified and further the amount of intermediates cannot be disregarded in comparison with those of reactants and products.

NaCl/HCl System. Now let us show another example, to which McKay's law cannot be applied, *i. e.*, the exchange reaction between sodium chloride crystallites and hydrogen chloride gas.[13] The exchange of ^{36}Cl in this system proceeds layer by layer, and the activation energy of the reaction becomes progressively higher as the reaction proceeds from the first layer to inner layers, approaching that for self-diffusion. The exchange reaction scheme is expressed as

$$HCl + Cl^*(1) \overset{R_1}{\rightleftarrows} HCl^* + Cl(1)$$

$$Cl(1) + Cl^*(2) \overset{R_2}{\rightleftarrows} Cl^*(1) + Cl(2)$$

$$Cl(2) + Cl^*(3) \overset{R_3}{\rightleftarrows} Cl^*(2) + Cl(3)$$

and so on,

where $Cl(i)$ designates a chloride ion in the ith layer. Thus, the rate equation becomes

$$\frac{dx_g}{dt} = -R_1\frac{x_g}{a_g} + R_1\frac{x_1}{a_1},$$

$$\frac{dx_1}{dt} = R_1\frac{x_g}{a_g} - R_1\frac{x_1}{a_1} - R_2\frac{x_1}{a_1} + R_2\frac{x_2}{a_2}, \tag{17}$$

$$\frac{dx_2}{dt} = R_2\frac{x_1}{a_1} - R_2\frac{x_2}{a_2},$$

with $x_g + x_1 + x_2 = \text{const.} = I,$

and $a_1 = a_2,$

when the experiments carried out at such temperatures as that the third layer does not participate in the reaction. Solving Eq. (17) with the initial condition, which is a situation really encountered,[13]

$$x_g = 0 \text{ and } x_2 = 0 \text{ at } t = 0,$$

we get a solution quite simmilar to Eq. (15).

Concluding Remark

We may conclude, from the above considerations, that an isotopic exchange reaction cannot be described by first order kinetics with respect to the isotopic concentration when:

the concentrations of intermediates are significant compared to those of reactants and products and no intermediate step is rate controlling

Otherwise, first order kinetics may hold. First order kinetics contains such a case as Eq. (16), and has a wider meaning than McKay's law. This conclusion cannot be proved strictly in a mathematical sense, but it may presumably be true as judged from the rather wider considerations given in the preceding sections.

As for cases where two or more atoms in the same molecule are exchanged, their reaction kinetics may have various forms[8] and may not be concerned in the present paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1271—1277 (1969)

Thermodynamic Properties and Phase Transitions of Thallous Cyanide Crystal

Takasuke MATSUO, Masayasu SUGISAKI,*1 Hiroshi SUGA and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received October 9, 1968)

The heat capacities of TlCN crystal were measured from 15 to 300°K with an adiabatic calorimeter. Three regions of anomalously high heat capacity were discovered. Thermodynamic functions of the crystal were calculated by the graphical integration of the heat capacity data. ^{205}Tl nuclear magnetic resonance was observed as functions of temperature and applied static magnetic field. Their second moment values could be interpreted in terms of the anisotropic chemical shift tensor.

The alkali cyanides, NaCN, KCN, RbCN and CsCN all crystallize in the cubic system at room temperature and on cooling, they all transform into the less symmetric modifications. Their thermodynamic behaviors were reported in the series of our papers.[1-3] The present investigation deals with thallous cyanide crystal. Thallium belongs to the third group in the periodic table but its monovalent ion behaves much like the alkali ions. Thus, its hydroxide is strongly alkaline in aqueous solution and it forms halide crystals of similar structure. Therefore, its cyanide was expected to exhibit some properties analogous to those of the alkali cyanides.

We present here the results of low temperature heat capacity measurement carried out mainly in order to investigate the phase transition effect.

In addition to the thermodynamic method, thallous compounds can be investigated with the nuclear magnetic resonance. ^{203}Tl and ^{205}Tl nuclei involved with the natural abundance ratio; 29.5%: 70.5%, respectively, have nuclear spin 1/2 with experimentally favorable gyromagnetic ratio. Owing to the large number of electrons which Tl^+ ion has, Tl resonance shows some interesting feature which is absent from the usual proton resonance: we can expect to see the chemical shift and/or indirect nuclear spin coupling in solids.[4]

In spite of its simple composition, very little is known about the property of thallous cyanide crystal, though its chemical reactivity was studied rather extensively.[5] The only relevant works that came into our attention are two structural investigations,[5,6] both dealing with the room temperature cell constant of thallous cyanide crystal. Strada[6] showed that the crystal has the cesium chloride structure with $a=3.83$ Å while Penneman and Staritzky[5] gave $a=3.993$ Å, the latter being in good correlation with other alkali halides and

cyanides. The cesium chloride structure made up of CN^- ions is just the same situation as in the cesium cyanide crystal. That is, there must be some orientational disorder in the ionic configuration of CN^- group, which means there may be phase transitions at lower temperatures. The same line of reasoning resulted in the previous investigations on NaCN, KCN, RbCN and CsCN.

Experimental

The Sample Preparation. The thallous cyanide crystal was prepared according to the reaction

$$TlOH + HCN \rightarrow TlCN + H_2O,$$

in aqueous solution.

Thallous hydroxide was made by oxidation of metallic thallium in water[7] as follows. Metallic thallium of stated 99.9% purity supplied by Nakarai Chemicals Ltd. in a cylindrical form was machined to turnings on a lathe. 75 g of the turnings was put in a pyrex flask, furnished with a polyethylene stirrer, together with 700 cc of water purified by an ion-exchanger. It was then oxidized by bubbling cylinder oxygen gas from which carbon dioxide had been removed with aqueous solution and pellets of potassium hydroxide. No heating of the reaction vessel was employed lest the alkaline solution might react with the glass are at elevated temperatures. After 24 hr of bubbling, undissolved metal was filtered off the solution.

Hydrogen cyanide was prepared in a standard way, *i.e.*, by mixing aqueous solution of KCN with sulfuric acid and trapping the evolving gas in a glass flask chilled with an ice-salt mixture.

About 70 cc of liquid hydrogen cyanide was poured into 700 cc of aqueous solution of thallous hydroxide obtained as above. As soon as the two liquids were mixed, a white crystalline powder precipitated out. The crystal was filtered off the solution and dried in vacuum at 130°C for 4 hr. The X-ray powder photograph of the crystal taken with Cu$K\alpha$ radiation was assignable to CsCl structure with a lattice constant of $a=3.97$Å.*2 This figure may be accurate about to 1%.

The most susceptible impurity was the carbonate ion, on which we tested the sample as follows. Small amount of the sample was dissolved in water. To the solution, $Ba(OH)_2$ aqueous solution was added. If there was sufficient concentration of carbonate ion in the sample, white precipitate of $BaCO_3$ would be formed. In fact no precipitation was observed in the present case. Comparison with an independent test by using K_2CO_3 solutions of known concentration showed that the present TlCN contains less than 0.1 weight per cent of carbonate ion.

Calorimetry. The heat capacities were measured with an adiabatic calorimeter operating from 15 to 300°K. Its detail was reported elsewhere.[8] The weight of sample used for calorimetry was 29.008 g (0.12591 mol). It was packed in a gold calorimeter cell with a small amount of helium gas to facilitate thermal equilibrium.

In a preliminary run, it was found that there are three temperature regions of anomalously high heat capacity. They are around 90, 190 and 260°K. The lowest one supercools easily and causes objectionable thermal effect. In order to prepare the stable lowest temperature phase, the specimen was first cooled down to 65°K and kept at the temperature overnight. Subsequent annealing at 85°K followed by recooling to 58°K produced the stable phase. At 58°K 1st run was initiated.

Temperature step of 1—2°K was usually chosen for one measurement in the normal region. In the transition regions necessarily smaller step was used. After turning off the calorimeter heater, usually 10 min were sufficient for it to attain a thermal equilibrium. But from 79 to 87°K, more than 20 min were needed. Next anomalous region around 190°K remained unnoticed until the data were processed, for it did not cause any anomalous equilibriating behavior. Another anomalous region is around 266°K where the heat capacity becomes drastically large and also the equilibriating times were more than 1 hr. Since the high temperature (cubic) phase was found to be supercooled to 248°K, nearly 20°K below the normal transition temperature, its heat capacities were measured in this metastable region in order to facilitate determination of the "normal heat capacity."

Nuclear Magnetic Resonance. Tl nuclear magnetic resonance experiment was carried out with a Nihon-Denshi electromagnet and a locally designed spectrometer of Pound-Watkins type, followed by a phase sensitive detector and a recorder. The RF coil was housed in a copper cylinder which was suspended in a glass dewar. The specimen in a glass tube was cooled by nitrogen gas which boiled off the liquid at the bottom of the dewar flask. The sample temperature was monitored with a chromel-P constantan thermocouple attached to the specimen glass tube. The ^{205}Tl resonance signal was recorded between the liquid nitrogen and room temperatures at 10.6 MHz. The ^{203}Tl signal was also detected at room temperature but naturally with weaker intensity. On cooling both ^{205}Tl and ^{203}Tl signal broadened considerably and ^{203}Tl signal was scarcely above the noise level. Therefore, only ^{205}Tl resonance was studied in detail. In addition to the temperature dependence, static field dependence of the resonance line was studeid at 8, 10.6, 15 and 17.5 MHz for two fixed temperatures, 210°K and room temperature.

Experimental Results

Heat Capacity. The experimental molar heat capacities are given in Table 1 in the chronological order. They are the ratios of the molar enthalpy

7) F. Bahr, *Z. anorg. Chem.*, **71**, 81 (1911).

*2 Our datum, though not too accurate, favors Penneman and Staritzky's value rather than Strada's. Strada's value is definitely inconsistent when compared with the lattice parameters of alkali halides, and cyanides. Therefore, citations of Strada's value in some books should be corrected. increment ΔH to the temperature rise ΔT. The temperature indicated is the average of the initial and the final temperatures. Also shown is the approximate temperature rises. Figure 1 is the graphical representation of the heat capacity data. There are three regions of anomalously high heat capacity. As stated above, the transitions at 85°K and 266°K are very sluggish, the intermediate one being entirely normal. As a criterion for determining the heat capacity at these temperature range, it was assumed that the temperature variation after turning off the calorimeter heater follows

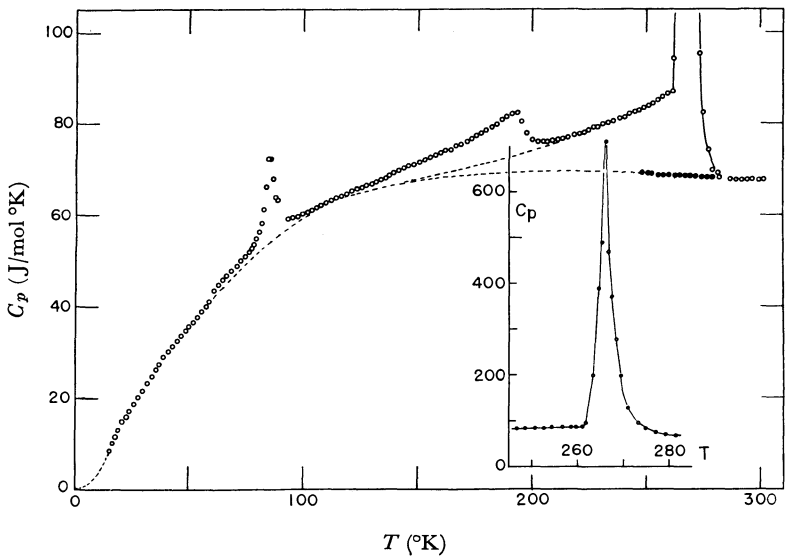

Fig. 1. Molar heat capacity *vs.* temperature of TlCN crystal.
(—○—○—○—; stable phase, —●—●—●—; the metastable cubic phase)

the exponential time dependence. That is

$$T(t) - T(\infty) = [T(0) - T(\infty)] \exp\left(-\frac{t}{\tau}\right),$$

where $T(t)$ is the temperature of the calorimeter at time t measured from the time when the heater is turned off, and τ, a time constant. Differentiation with t gives

$$\frac{dT}{dt} = -[T(0) - T(\infty)]\frac{1}{\tau}\exp\left(-\frac{t}{\tau}\right) = -\frac{1}{\tau}[T(t) - T(\infty)].$$

Therefore, if we plot $T(t)$ against $dT(t)/dt$ extrapolation of the graph to $dT(t)/dt=0$ gives $T(\infty)$. In practice, the resistance $R(t)$ of the platinum thermometer was plotted rather than the temperature.

This method rests entirely on the assumption of the exponential time dependence of the temperature, which is not always the case. Therefore, it is applied solely, for the sake of convenience, to prohibitingly long equilibriation times.

TABLE 2. ENTHALPY AND ENTROPY CHANGES OF THE TRANSITIONS

T_{tr}(°K)	ΔS_{tr}(J/mol °K)	ΔH_{tr} (J/mol)
84.7	2.242	181.3
193.2	1.458	255.7
266.1	11.481	2945.5

The enthalpy and entropy changes of the phase transitions are summarized in Table 2 together with the temperature at which the heat capacity has the peaks. These values are of the corresponding changes associated with the excess heat capacity above the dotted curves in Fig. 1. The dotted curves are assumed to represent the vibrational part of the heat capacity. They are just the extrapolation of the heat capacity of the temperature ranges where anomalous effect seems to be absent. Their significance may be rather obscure in principle, but there are many cases in practice in which the entropy of the phase transition thus obtained can be rationalized in theoretical interpretations.

^{205}Tl NMR. The typical NMR absorption derivatives are shown in Fig. 2 for the room temperature and 210°K. The room temperature absorption is narrow and symmetric in its shape, while it becomes broad and slightly but significantly asymmetric at lower temperatures. Their second moment is shown in Fig. 3 as a function of temperature. The second moment of the asymmetric spectra was approximated by the sum of the lower field and higher halves which are separated by the zero of the absorption derivative. The second moment decreases steadily to about 180 °K and remains rather constant to the upper transition point where it decreases suddenly.

Figure 4 shows the field dependence of the second moment of the absorption at the room temperature

* The units are °K for temperature and J/mol°K for the other quantities.

and 210°K, the latter being a temperature where the second moment retains a rather constant value. The room temperature value is field-independent; this is what is expected for the dipolar and/or exchange broadening. In the low temperature phase, the second moment is definitely larger and depends linearly on the square of the static magnetic field. Similar type of behaviors was observed in Tl_2O_3,[4] Tl,[4] UF_6,[9] XeF_4,[10] $CFCl_2 \cdot CFCl_2$[11] and $CF_2Br \cdot CF_2Br$[11] and may be attributed to the anisotropic

chemical shift.

Discussion

Phase Transitions. The total entropy associated with the three phase transitions is 15.2 J/mol°K. This value may be correlated with the possible eight directions of the cyanide ion on the four body diagonal directions in the cubic phase ($R\ln 8 = 17.2$ J/mol°K). The entropy change at the 266°K transition is approximately equal to $R\ln 4$, which implies that among the eight possible directions of the cyanide ion, two become energetically favored. This is the same situation as in the CsCN crystal. The CsCN crystal has a transition[3] at $T_{tr}=193.1$°K with $\Delta S_{tr}=15.7$ J/mol°K. Its low temperature phase has a distorted CsCl structure with one body diagonal axis elongated. If one assumes that TlCN has the same structure in the temperature region between the upper and the intermediate transitions, one can discuss the phase transition of the two salts comparatively. Among the possible molecular or ionic interactions leading to the transition, the dipole-dipole interaction between the CN^- ions is excluded on the symmetry ground. The next lower multipole is the quadrupole. The quadrupole-quadrupole interaction potential depends on the separation r as r^{-5}. The ratio of the lattice constant of TlCN to that of CsCN is equal to $a_{Tl}/a_{Cs}=3.993/4.25=0.9395$. If this value may be used also for the low temperature structures, its fifth power is expected to be approximately equal to the inverse ratio of the transition temperatures of the two salts. In fact, $(a_{Tl}/a_{Cs})^5=0.7320$ while $T_{Cs}/T_{Tl}=193.1/266.1=0.7257$. This excellent agreement may be rather fortuitous, since the change in the Madelung energy and the repulsive energy must be taken into account. However, before we are able to discuss these effects, it would be necessary to have more detailed structural informations. The scalar quadrupole moment of the CN^- ion was estimated to be $Q=0.7\times10^{-26}$cgs by equating kT_{tr} to the quadrupole-quadrupole interaction potential given by the expression[13]

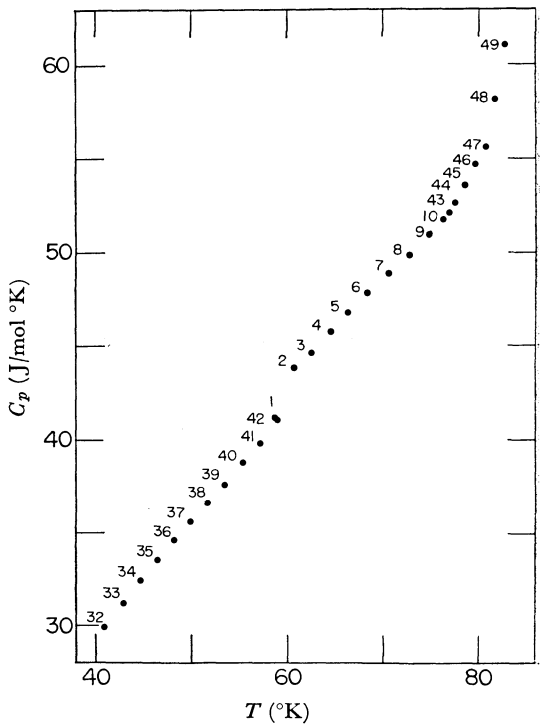

Fig. 5. The portion of the heat capacity diagram of TlCN crystal showing a small step-like anomaly. The numbers in the figure indicate the time order in which the measurements were performed.

$$\Phi_{ab}^{(QQ)} = (3Q_aQ_b/16r^5)[1 - 5\cos^2\theta_a - 5\cos^2\theta_b - 15\cos^2\theta_a \cdot \cos^2\theta_b + \{2\sin\theta_a\sin\theta_b\cos(\phi_a-\phi_b) - 4\cos\theta_a\cos\theta_b\}^2],$$

where r is the intermolecular separation, θ's and ϕ's are polar and azimuthal angles measured from the intermolecular vector. Here, we used for the structural parameters their high temperature values. With regard to the other two phase transitions, no detailed interpretation seems to be possible at the present stage. In addition to these three anomalies, there is another which seems to be associated with the 85°K transition. The detailed diagram of the relevant portion of the heat capacity is shown in Fig. 5. It is not a peak but a steplike increase of the heat capacity. This type of anomaly is observed in many glass forming and other substances.[13,14] The interpretation of the detailed mechanism of this kind of transition remains for further investigations.

Hindered Rotation of the CN^- Ion. The heat capacities of the cubic phase in the stable and the metastable phases continue to each other smoothly as they should. The heat capacity value decreases with increasing temperature. This behavior is not feasible with the harmonic oscillator heat capacity. It is generally agreed that hindered rotation of molecules produces such an effect. There is wealth of literatures dealing with this phenomenon both from experimental and theoretical sides, the most recent and detailed treatment being due to Smith.[15] His investigation might be extended to apply to the present case.

The NMR Second Moment. From the NMR experiment we obtained a qualitatively interesting conclusion. The high temperature value of the second moment is comparable with the Van Vleck value for the dipolar broadening, while below the 266°K transition, it is definitely larger. The width might be due to the $I_1 \cdot I_2$ coupling through the electron and/or anisotropic chemical shift, since the lattice sum $\sum_{ij} 1/r_{ij}^6$ cannot change to this extent through the transition. Also the asymmetric shape of the spectrum suggests an anisotropic chemical shift. The slope of the line in Fig. 4 gives the anisotropy of the chemical shift, $\sigma^{\parallel} - \sigma^{\perp}$.[11] It is about 1000 ppm for the present case. If there are non-equivalent sites for the Tl ions, it may also contribute to the second moment with the similar H_0 dependence. But the asymmetric spectrum does not occur if the non-equivalent sites are same in number. Moreover, the spectrum would exhibit resolved structures if they were mere superpositions of a small number of the narrow spectra shifted from each other.*3

We can, therefore, conclude that the thallium chemical shift tensor changes on the phase transition, which in turn means that there are definite chemical bonds[16-20] among the ions which change on the phase transition. Thermodynamic consequences of such chemical bonds are still to be investigated.

Conclusion

Thallium cyanide crystal has three phase transitions below the room temperature. The uppermost one may be of the same nature as the one observed in cesium cyanide crystal. Interpretation of the other two transitions seems to be difficult at the present stage. The heat capacity of the cubic modification could be measured in the stable and the metastable temperature region and behaves as expected for a hindered rotator. ^{205}Tl NMR line widths in the low temperature phases are definitely larger than the dipolar width and may be attributed to the anisotropic chemical shift. This implies that not only the packing condition of the ions but also the electronic state changes on the phase transition to the extent to be observed in such an experiment.

The authors are grateful to Dr. Nobuo Nakamura, Osaka University, to whom they owe much in performing the NMR experiment. Also the financial support by the Toyo Rayon Co. is greatly acknowledged.

Gas Chromatography of Rare Earth Chelates of Pivaloyltrifluoroacetone*1

Tsunenobu SHIGEMATSU, Masakazu MATSUI and Kei UTSUNOMIYA

Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received August 15, 1968)

The gas chromatographic behavior of Sc, Y, and rare earth chelates of a new β-diketone, pivaroyltrifluoroacetone (PTA), was investigated. PTA was synthesized by a Claisen condensation from pinacolin and ethyltrifluoroacetone. Sc, Y, Nd, Sm, Eu, Gd, Tb, Dy, Er, Yb, and Lu PTA chelates were prepared. Their elemental analyses and infrared spectra indicated that they were anhydrous tris chelates, and the TGA curves of the chelates proved their good volatile characteristics, showing approximately a 100% weight loss. Gas chromatograms of all the chelates and of mixtures of Sc, Y, and several rare earth chelates were obtained. Some relationships were observed between the retention time, the volatilization temperature, and the ionic radius of the central metal: With the decrease in the ionic radius, the retention time of the chelate decreased and the volatilization temperature became lower.

Recently, it has been recognized that the volatile characteristics of a number of metal β-diketone chelates make the gas-chromatographic technique of possible use for the separation of the metals. From this point of view, the chromatographic studies have been carried out on various metal chelates with acetylacetone,[1,2] trifluoroacetylacetone,[3-5] hexafluoroacetylacetone,[6] dipivaloylmethane,[7] 1,1,1,2,2,3,3,-heptafluoro-7,7-dimethyl-4,6-octanedione[8] (FOD), *etc.* By using the latter two β-diketones, Sievers and his co-workers studied the chromatographic behavior of rare earth elements in detail; as a result, they suggested the possibility of the simple and rapid separation of the individual elements.

The present authors have been attracted by the gas chromatography of metal β-diketone chelates, and have performed a systematic investigation with several β-diketones, some of which were synthesized in our own laboratory.

In this paper, the gas-chromatographic behavior of rare earth chelates with a new β-diketone, pivaloyltrifluoroacetone (PTA), will be described. The reagent possesses a trifluoromethyl group and a *t*-butyl group, both of which enhance the volatility of the chelates. Thus, rare earth PTA chelates were eluted by the gas phase, as were the dipivaloylmethane and the FOD chelates.

Experimental

Synthesis of Pivaloyltrifluoroacetone (PTA), (1,1,1-Trifluoro-5,5-dimethyl-3,5-hexanedione). The β-diketone was synthesized by Claisen condensation from pinacolin and ethyl trifluoroacetate.[9]

Ethyl trifluoroacetate was synthesized by trifluoroacetic acid and diethyl sulfate.[10,11] One mole of trifluoroacetic acid was neutralized with a sodium hydroxide solution (1.1 mol in 100 ml of water) and was then treated with diethyl sulfate (0.6 mol). After standing at room temperature for 3 hr, the reaction mixture was refluxed on a water bath, an ester was then obtained by distillation at 55°C. The crude ester, collected in a receiver cooled in ice water, was washed with 100 ml of a cold 5% sodium carbonate solution and dried over 25 g of anhydrous calcium chloride at 0°C. The product was finally purified by distillation after having been treated with concentrated sulfuric acid. In this procedure, 68 g of a pure ester with a boiling point of 60—62°C were produced.

The Claisen condensation was carried out in the following manner. To 0.55 mol of sodium methoxide

suspended in 100 m*l* of dry ether, 0.5 mol of ethyl trifluoroacetate and 0.5 mol of pinacolin were added successively. The mixture was then agitated for 2 hr. After the mixture had stood overnight, the ether and the ethanol were completely removed by evaporation under reduced pressure and by heating at 90°C for 6 hr. The sodium salt of PTA was then treated with 10% sulfuric acid, and the liberated PTA was extracted with ether. The ether solution was dehydrated with anhydrous calcium chloride, and the ether was evaporated off. The PTA was then converted into copper salt, the copper salt was decomposed with 10% sulfuric acid, and finally the PTA was purified by vacuum distillation. The purified product showed a boiling point of 40—41°C/17 mmHg; the yield was about 75%.

Preparation of Rare Earth Metal (III), Sc(III), and Y(III) PTA Chelates. The rare earth chelates were prepared by the method of Sievers *et al.*[8] Rare earth oxides were converted into nitrates, which were dissolved in methanol. Into the rare earth nitrate solution, a PTA methanol solution was then stirred, while the pH of the reacting mixture was maintained between 4 and 5 with a sodium hydroxide solution. The PTA chelates thus precipitated were filtered, air-dried, and recrystallized from benzene. The chelates were finally dried in a vacuum desiccator over phosphorus pentoxide.

The gas chromatograms were obtained with a Yanagimoto GCD-5DH apparatus equipped with a thermal conductivity detector. The column, 75 cm×3 mm i. d. and of stainless steel, was packed with 5% (by weight) of Dow Corning high vacuum silicone grease on Chromosorb W (60—80 mesh). Helium was used as the carrier gas. Chelate solutions were injected with a microsyringe. The thermogravimetric analysis was made with a Shimadzu Thermano Balance. About a 20-mg portion of a sample in a platinum dish was heated at a rate of 10°C/min in a nitrogen stream at a flow rate of 50 ml/min. The infrared spectra were measured with a Perkin-Elmer Model 521 spectrophotometer.

Results and Discussion

The melting points of scandium, yttrium, and rare earth chelates are summarized in Table 1, while the results of elemental analysis for several chelates are shown in Table 2. The carbon and hydrogen contents found are in good agreement with the calculated values of the tris-PTA chelates. In Fig. 1, the infrared spectrum of the erbium chelate (as a representative tervalent rare earth chelate) does not show a band attributable to OH stretching near 3400 cm^{-1}, this fact may prove that the chelates obtained are anhydrous $M^{III}(PTA)_3$-type chelates. The NMR spectrum of $Sc(PTA)_3$ is also presented in Fig. 2.

Figures 3, 4, 5 and 6 show typical chromatograms of some multicomponent mixtures. Samples, which were prepared by dissolving the PTA chelates in

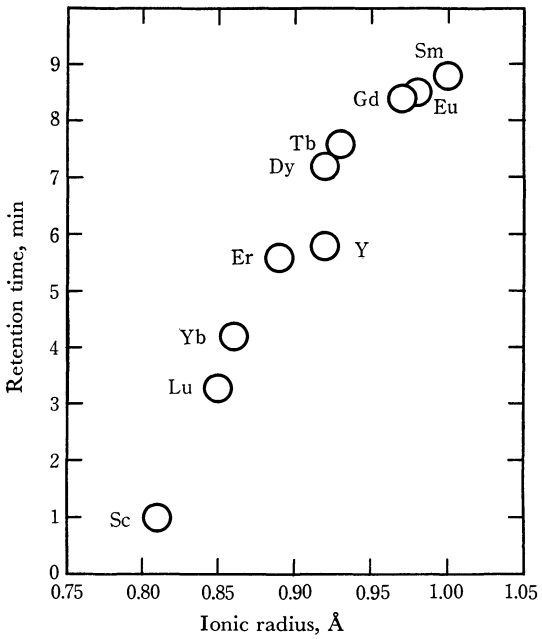

Fig. 7. Retention times for the rare earth PTA chelates as a function of ionic radius. Conditions: same as those in Fig. 3.

25—50 μl of *n*-hexane, were injected (at about 280°C), the column temperature was elevated from 170°C to 260°C at the rate of 12°C/min. For neodymium chelate, a higher injection temperature (*e.g.*, 320°C) was required.

The retention time of each PTA chelate was separately measured under similar condition (see Fig. 3), in Fig. 7, the values are plotted as a function of the ionic radii of the tervalent metal ions. The lower retention time corresponds well to the small ionic radius, as reported by Sievers *et al.* concerning the dipivaroylmethane[7] and FOD[8] chelates. As these figures indicate, it is not yet possible to separate all the rare earth metals individually at the same time. However, there may be a possibility for a group separation or for the separation of mixtures of some rare earth metals which do not contain any neighboring elements.

The thermogravimetric curves are shown in Fig. 8. The chelates of smaller metal ions, which show a shorter retention time, are volatilized at lower temperatures. The weight losses of all the chelates except the neodymium chelate approach 100%; this fact indicates that the PTA chelates are thermally stable in the volatilization process. The TGA curves of heavy rare earth metals and yttrium chelates may represent a combined sublimation-vaporization process, because the curves pass successively through the start of the weight loss, the

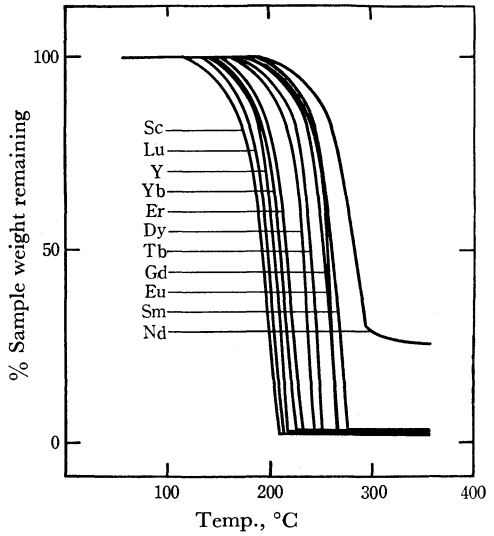

Fig. 8. Thermogravimetric curves of rare earth PTA chelates.

melting temperature of the chelate, and the end of the weight loss.

Sievers and his collaborators[8] mentioned that a fluorocarbon substituent in a ligand markedly increased the volatility of the chelates, and that the volatile ability was also enhanced by substitution with sterically-crowded alkyl groups. Berg and Acosta[12] stated that the thermal stability of β-diketone chelates is related to the hydration (of the chelate), and that anhydrous chelates were much more stable than hydrated ones in the volatilization process.

The authors had previously studied rare earth and several other metal chelates with diisobutyrylmethane,[13] but they could not obtain satisfactory chromatograms for any rare earth metals except lutetium and erbium. Even lutetium and erbium chelates seemed to be hydrated and did not show a 100% weight loss, but one of about 75%, in the TGA curves. On the contrary, dipivaroylmethane and FOD, which possessed a more bulky alkyl group or fluorocarbon group, were proposed as useful chelating reagents for the gas chromatography of rare earth metals. The PTA presented in this investigation has a similar advantage; therefore, rare earth PTA chelates were well eluted by the gas phase. The authors will deal with the participation of the terminal group of β-diketone with the volatile characteristics of the rare earth and other metal chelates in the near future.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1282—1285 (1969)

Coulometric Titration of a Microamount of Water after Conversion to Ammonia

Takayoshi Yoshimori and Syuiti Ishiwari

Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received August 15, 1968)

Sodium amide was used to convert a microamount of water into ammonia in a carrier gas. The ammonia was then titrated with coulometrically generated hypobromite ions. The reaction between water and sodium amide was completed stoichiometrically, and the reaction rate was considerably promoted by heating sodium amide at 80°C. The sample hydrogen was oxidized with copper(II) oxide at 800°C, and the water thus produced was determined by this method. 0.096—0.665 m*l* (8.6—59.8 μg) of hydrogen and 0.055—0.465 mg of water in barium chloride crystals were determined within errors of 3.6% and 3.0% respectively. The water adsorbed on the surfaces of the weights was also determined by this method at various humidities.

Many investigations of the coulometric microdetermination of water are to be found in the literature. Meyer and Boyd[1] proposed first the use of a Karl Fischer reagent for this purpose, and several similar papers have followed theirs.[2-4] In this process, however, the location of the end point of the titration is troublesome for determining a microamount of water. The excess iodine produced after the end point usually disappeared when the reducing material was diffused from the cathode compartment.[2]

Keidel[5] proposed the phosphorous pentoxide cell, which is very useful for the continuous analysis of water in gaseous samples.[6] It was, however, recently pointed out that the cell gave relatively large residual current.[7] This current may disturb the precise determination of microamounts of water. Giegerl[8] proposed a method for the coulometric determination of hydrogen in steel. After the oxidation of the hydrogen, the water was heated with carbon at 1100°C; then the hydrogen and carbon monoxide produced were reoxidized to water and carbon dioxide respectively. The latter was then determined by the coulometric titration method. Martin, Floret, and Lemaitre[9] recommended the following process; the water in the carrier gas was converted into hydrogen chloride with phosphorus pentachloride, and then the gas was allowed to flow through a sodium bicarbonate column. The carbon dioxide thus produced was determined by coulometric titration. These circuitous processes give relatively large blank values, and also a long time is needed to make the values constant.

Sodium amide reacts with water to produce ammonia; this reaction has also been applied to the determination of water.[10] No remarkable advantage can, however, be expected when the ammonia is titrated by the ordinary volumetric method.

In this paper, the authors used the coulometric titration method to determine the ammonia produced by the above reaction; they proved that this process can be adopted to determine a microamount of water or hydrogen in the carrier gas.

Experimental

Apparatus. The apparatus for the dehydration of solid samples is shown in Fig. 1. The heating tube for the dehydration of solid samples was made of Pyrex glass. Two different U-tubes of sodium amide (15 cm × 8 mm i. d. for 20—500 μg H_2O; 10 cm × 5 mm i. d. for less than 20 μg H_2O) were used to convert water into ammonia. The U-tube used was heated in a thermostat (oil bath). In order to pack sodium amide and phosphorus pentoxide in the respective U-tubes, the authors used a moistureless glove box. The air in the U-tube was replaced with argon. Unless these precautions are taken,

their expected effectiveness are considerably shortened. The gas-sampling buret proposed by Gieger1[8] (Fig. 2) was advisable for removing the disturbance due to back-pressure of the carrier gas. Copper(II) oxide was used to oxidize the hydrogen. The temperature of the oxide was kept at 800°C.

The coulometric titration cell is shown in Fig. 3. The generator electrode was a platinum foil of 1 × 1 cm. According to the investigation by Christian, Knoblock, and Purdy,[11] the current density for the generation of hypobromite ions should be less than 9.6 mA/cm² in a solution of 1M of bromide ions. Therefore, a current of less than 19 mA was used in this investigation.

The auxiliary electrode was a platinum wire 5 cm in length and 0.5 cm in diameter. The same platinum wires, 0.5 cm in length, were used as the pair of indicator electrodes. The dead-stop method was used to detect the end point of the titration. The indicator current was measured by a microammeter (full scale: 3 μA). The potential difference between the two indicator electrodes was 0.2 V.

The electronic constant current source reported previously[12] and an electric stop clock driven by a

1. mA meter (full scale 10 and 30 mA), 2. Constant current source, 3. Indicator electrode pair, 4. Generator electrode, 5. Auxiliary electrode 6. Magnetic stirrer

synchronous motor were used to measure the electricity. The total error due to the measurements of the electrolytic current and of the time does not exceed 0.5%.

Reagents. *Sodium Borate Solution.* 38.1 g of sodium borate (Borax) were dissolved in 1 *l* of water; then perchloric acid was added until the pH of the solution decreased to 8.6.

The electrolyte solution was prepared by mixing 25 m*l* of a 5M sodium bromide solution and 50 m*l* of the sodium borate solution, and by then diluting the mixture to 125 m*l* with water. The above mentioned sodium borate solution was used as a catholyte. Sodium amide produced by the Daiichi Pure Chemicals Co., Ltd., could be used without any trouble. All the other reagents used were analytical grade.

Argon was dried with magnesium perchlorate and then with phosphorus pentoxide.

Procedure. *Setup of the Apparatus.* To decrease and to stabilize the blank value quickly, a column of sodium amide was heated at 110°C for half an hour; then it was cooled somewhat and kept at 80°C. During this period, argon was allowed to flow through the apparatus, but it was not introduced into the titration cell. The rate of the flow of argon was 200 or 100 ml/min. Argon was then introduced into the column and the cell by turning a three-way cock. The blank values were determined coulometrically every 5 or 10 min until the values became constant.

Introduction of Sample. The process used for sampling gaseous hydrogen was that shown by Gieger1.[8] First, U-tube buret was filled with mercury; then electrolytically generated hydrogen was introduced into the capillary buret on one side of the U-tube. After the measurement of the volume of hydrogen, a small amount of it was transferred to the tube on the other side by lowering the mercury reservoir. The transferred hydrogen was then introduced into the reaction tube containing copper(II) oxide, after which the volume of hydrogen

11) G. D. Christian, E. C. Knoblock and W. C. Purdy, *Anal. Chem.*, **35**, 2217 (1963).

12) T, Yoshimori, Y. Hino and T. Takeuchi, *Bunseki Kagaku* (*Japan Analyst*), **15**, 1234 (1966).

remaining in the buret was measured again. The difference between the two readings was the volume of hydrogen taken.

A weighed solid sample was dropped into the dried boat in the dehydration tube by the aid of a small glass funnel. The boat was then introduced into a furnace kept at 200°C by the movement of a magnet. After 10 min, the boat was removed from the furnace. Argon was allowed to flow through the apparatus continuously. The rate of the flow of argon should not exceed 200 ml/min. Lower results could be obtained at the rate of 400 ml/min with the sodium amide column mentioned above. By using a longer column, the rate of argon can perhaps be increased.

Coulometric Titration. The electrolyte prepared as above was electrolyzed with a constant current until the indicator current was raised to a definite value smaller than 1.0 μA. After recording the indicator current, argon containing ammonia was introduced into the cell. After 5 or 10 min, the titrant was generated electrolytically with a constant current until the indicator current was increased to the previous value. This titration was repeated at 5- or 10-min intervals until the electricity of the blank experiment. During the entire course of the titration, argon was allowed to flow through the apparatus and the cell continuously.

Results and Discussion

Determination of Hydrogen. Hydrogen was measured into a reaction tube containing copper-(II) oxide and heated at about 800°C using Giegerl's buret.[8] The water thus produced was determined by this method. The results obtained are shown in Table 1.

The reaction of water in a carrier gas with sodium amide is completely stoichiometric. Therefore, a standard sample or a calibration curve is not necessary. This makes it possible to obtain reliable and accurate results in the determination of micro-amounts of water.

To shorten the time required for a single determination, the heating of sodium amide is quite effective. Blank values, however, increase appreciably over 90°C. The relations obtained in the analysis of hydrogen are shown in Fig. 4. The heating of the column at 80°C is preferable.

Table 1. Determination of hydrogen

	mean	99.2
	$\sqrt{V}$	3.6

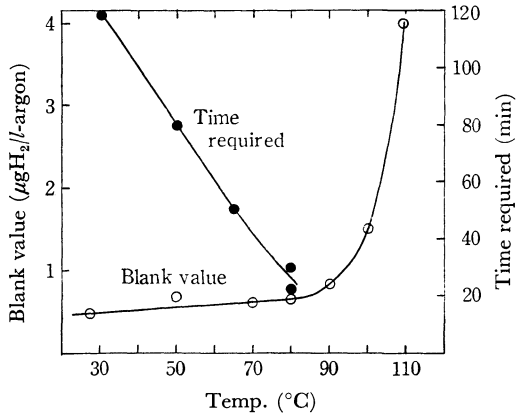

Fig. 4. Effects of heating of $NaNH_2$ column on the blank value and on the time required for single determination of hydrogen.

The increase in the blank value at a temperature higher than 90°C may be based on the some decomposition of the amide.[13] In accounting for the heating effects of the column, the authors considered the following possibility. Some of the water in argon may be adsorbed on the surface of the sodium hydroxide produced by the reaction of water and sodium amide, and the vapor pressure of water on the surface of the hydroxide may be increased at an elevated temperature.[14] These phenomena accelerate the desorption of water on the surface of sodium hydroxide and quickly complete the reaction of water and sodium amide.

In the field of gas chromatography, calcium carbide has sometimes been used for removing the tailing effect due to water in a sample. The present authors tried to use carbide to convert water into acetylene, and then the acetylene was oxidized to carbon dioxide and water. The carbon dioxide thus produced was determined by coulometric titration. This process, however, has the following disadvantages. The calcium hydroxide produced by the reaction between water and the carbide has a relatively high vapor pressure of water. Therefore, it reacts slowly with calcium carbide to produce acetylene. The reaction rate of this process is very slow even at elevated temperatures. More than 3 hr are needed for a single determination even if the carbide has previously been heated at several hundred degrees. The other problem was the purity of the carbide. Different kinds of commercially obtainable carbides and the carbide produced specially by the authors were all used.

13) Gmelin, Handbuch für anorg. Chemie, "Natrium," 8 Aufl., s. 211 (1928).
14) *Ibid.*, s. 255.

The blank values were, however, not decreased enough with these reagents.

Roth and his co-workers[15] has proposed a process to convert water into ammonia with magnesium nitride. This process was also attempted by the present authors with the aid of coulometric titration; they found the same difficulties as in the calcium carbide process.

Since sodium hydroxide does not itself set free water, it is unnecessary to consider these difficulties. By the present method, the time required for a single determination and the blank value of each determination are considerably decreased. Furthermore one mole of water is equivalent to three Faradays of electricity. This ratio is greater than in any of the other processes mentioned above. These advantages show the adaptability of this method to determine microamounts of water and hydrogen in various carrier gases which do not react with sodium amide.

Determination of Water in Hydrated Barium Chloride Crystal. A weighed crystal of hydrated barium chloride was dropped into the boat in the reaction tube, and then the boat was introduced into the heating furnace by the aid of a magnet. The water content in the crystal was determined by this method. The temperature of the furnace was kept at 200°C, and the rate of flow of argon was 200 ml/min. The results obtained are shown in Table 2. In order to recover the water in the crystal completely, a somewhat longer time was needed than for the determination of hydrogen. Because of the water adsorbed on the surface of the crystal, these results were somewhat larger than their theoretical values. Considerably higher results could be obtained when the sample did not consist of a single crystal.

Table 3. Adsorbed water on the surfaces of weights (in μg)

	Kind of weight (mg)	Relative humidity (%) 55	66	76	80

* Surface is somewhat rough.

Determination of Water Adsorbed on the Surfaces of Weights. As an example of the practical use of this method, the water adsorbed on the surfaces of the weights was determined at various humidities. The appratus and the method were the same as in the case of barium chloride. The results obtained for various kinds of weights are shown in Table 3.

These results show that the water adsorbed on the weight depends greatly on the condition of the surface, and not so greatly on the relative humidity. It can be concluded that the water adsorbed on the surfaces of weights does not disturb the ordinary weighings with a microbalance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1286—1291 (1969)

Absorption Spectra and Circular Dichroisms of Metal Complexes. III.*1 *trans*-Dihalogeno-bis-*l*-propylenediamine Complexes of Cobalt(III), Rhodium(III), Palladium(IV) and Platinum(IV)

Haruko Ito, Junnosuke Fujita and Kazuo Saito

Department of Chemistry, Faculty of Science, Tohoku University, Katahiracho, Sendai

(Received August 21, 1968)

Absorption (AB) and circular dichroism (CD) spectra of *trans*-$[MX_2(l\text{-pn})_2]^{n+}$ (where M= Rh^{III}, Pd^{IV}- and Pt^{IV}-, and X=Cl^- and Br^-) have been discussed by comparing them with those of cobalt(III) complexes which had been studied extensively. A positive CD peak was observed at around the so called I_a band region of all the complexes studied except for *trans*-$[PtBr_2(l\text{-pn})_2]^{2+}$. A negative CD peak of this complex ion at 26000 cm^{-1} was assigned to be a split component of the I_a band. The AB peaks at 38000, 28600 and 31100 cm^{-1} for *trans*-$[PtCl_2(l\text{-pn})_2]^{2+}$, *trans*-$[PdCl_2(l\text{-pn})_2]^{2+}$ and *trans*-$[PtBr_2(l\text{-pn})_2]^{2+}$ respectively were assigned to $p_\pi \rightarrow d_{z^2}$ charge transfer transition. An ion association band was observed for *trans*-$[PtBr_2(l\text{-pn})_2]Br_2$ in 1N hydrobromic acid.

In the first paper of this series,[1] the absorption spectra of square planar platinum(II), palladium(II) and gold(III) complexes containing optically active diamines were interpreted on the basis of an analysis of their circular dichroism spectra. The present paper deals with the AB and CD spectra of octahedral platinum(IV) and palladium(IV) complexes of the type, *trans*-$[MX_2(l\text{-pn})_2]^{2+}$ (X=Cl^- and Br^-, *l*-pn=$(-)_D$-propylenediamine).

Since both platinum(IV) and palladium(IV) ions have strong tendency to form diamagnetic d^6 complexes, their AB spectra are expected to resemble those of cobalt(III) and rhodium(III) complexes.

However, assignment of their absorption bands still remains uncertain, partly because both the *d–d* transition and the charge transfer band appear in overlapping regions. The trans complexes in this paper have no optical dissymmetry around the central metal ion, but give CD peaks due to the vicinal effect coming from asymmetric ligands. Usefulness of the examination of these peaks for the band assignment has been demonstrated with various cobalt(III),[2,3] platinum(II) and palladium(II) complexes.[1]

We have attempted, therefore, to assign tentatively the absorption bands of some platinum(IV) and palladium (IV) complexes by comparing their CD spectra with those of cobalt (III) complexes which had been studied extensively.

Experimental

Preparations of the Complexes. Six new complexes were prepared by the following methods.

trans-Dichloro-bis-l-propylenediaminepla tinum(IV) Chloride monohydrate, *trans*-$[PtCl_2(l\text{-pn})_2]Cl_2\cdot H_2O$, *trans-Dichloro-bis-l-cyclohexanediaminepla tinum(IV) Chloride Monohydrate*, *trans*-$[PtCl_2(l\text{-chxn})_2]Cl_2\cdot H_2O$ and *trans-Dibromo-bis-l-propylenediaminepla tinum (IV) Bromide Monohydrate*, *trans*-$[PtBr_2(l\text{-pn})_2]Br_2\cdot H_2O$ were prepared from $[Pt(l\text{-pn})_2]Cl_2$ and $[Pt(l\text{-chxn})_2]Cl_2$ and halogens by Basolo, Bailar and Tarr's method[4] for the corresponding ethylenediamine complexes. The dichloro complexes were recrystallized from an aqueous solution by adding ethanol. The dibromo complex was converted into bromide by dissolving it in 3N hydrobromic acid and evaporating on a water bath. *trans*-$[PtCl_2(l\text{-pn})_2Cl_2$ and *trans*-$[PtBr_2(l\text{-pn})_2]Br_2$ were converted into perchlorate by dissolving them in a small amount of water and adding concentrated perchloric acid. The crystals were filtered off, dried over potassium hydroxide *in vacuo*.

trans-Dichloro-bis-l-propylenediaminepalladium(IV) Nitrate, *trans*-$[PdCl_2(l\text{-pn})_2](NO_3)_2$ was prepared by a similar method to that for *trans*-$[PdCl_2(en)_2](NO_3)_2$[5] in bright yellow crystals.

trans-Dibromo-bis-l-propylenediaminerhodium(III) Perchlorate, *trans*-$[RhBr_2(l\text{-pn})_2]ClO_4$. Seven hundred milligrams of $RhBr_3\cdot 2H_2O$, 1.13 g of *l*-pn·2HCl and 0.43 g of potassium hydroxide were dissolved in 50 ml of water, heated on a water bath with reflux, treated with a solution containing 0.43 g potassium hydroxide in 50 ml of

water dropwise, heated for about 2 hr and filtered. The filtrate was passed through a column containing cation exchanger Dowex 50 W in H form. The column was washed with water and the adsorbed band eluted with 3% hydrobromic acid. The eluate was evaporated to dryness *in vacuo* at 60°C. The residue was extracted with methanol and treated with ether. The precipitate was dissolved in a small amount of water and concentrated perchloric acid was added. The product was recrystallized from methanol solution by adding ether.

Tetrabromo-l-propylenediamineplatinum(IV), $[PtBr_4(l\text{-pn})]$ was obtained by oxidizing $[PtBr_2(l\text{-pn})]$ in water with bromine. Orange crystals were precipitated by concentrating the solution on a water bath.

The other complexes were prepared by the method described in the literatures.[2,3,6,7]

The results of the chemical analysis are given in Table 1.

Measurements. Visible and ultraviolet absorption spectra were obtained by using a Hitachi 124 recording spectrophotometer. The CD curves were recorded with a Model ORD/UV-5 spectrophotometer of Japan Spectroscopic Co. with its CD attachment.

To avoid the aquation of coordinated halides, cobalt and rhodium complexes, *trans*-$[PtCl_2(l\text{-pn})_2](ClO_4)_2$ and *trans*-$[PtBr_2(l\text{-pn})_2](ClO_4)_2$ were dissolved in methanol, and *trans*-$[PtCl_2(l\text{-pn})_2]Cl_2$, *trans*-$[PtCl_2(l\text{-chxn})_2]Cl_2$ and *trans*-$[PdCl_2(l\text{-pn})_2](NO_3)_2$ in 1.0N hydrochloric acid. All the measurements were made at room temperature.

Results and Discussion

The AB and CD spectra of the complexes measured are shown in Figs. 1—5. The CD spectra of *trans*-$[CoX_2(l\text{-pn})_2]^+$ (X=Cl^- and Br^-)[2,3] and *trans*-$[RhCl_2(l\text{-pn})_2]^+$ [6] had been measured only in the region of *d*→*d* transitions of these complexes.

d-d Transition. Since the complex ions, *trans*-$[MX_2(l\text{-pn})_2]^{n+}$ have a pseudo-tetragonal symmetry, the two spin-allowed *d*→*d* transitions expected for a d^6-diamagnetic system, $^1A_1\rightarrow{}^1T_1$ and $^1A_1\rightarrow{}^1T_2$, should split into two components, $^1A_1\rightarrow{}^1A_1+{}^1E^{(a)}$ and $^1A_1\rightarrow{}^1B_2+{}^1E^{(b)}$, respectively. Of these four transitions, only the $^1A_1\rightarrow{}^1B_2$ is magnetically forbidden.

Fairly strong positive CD peaks at 16600 and 15600 cm^{-1} for dichloro- and dibromo-cobalt(III)

complexes, respectively, have been assigned to the $^1A_1 \rightarrow {}^1E^{(a)}$ transition (I_a band), a split component of the so-called first band[2,3,8] (Fig. 1).

The CD and AB spectra of rhodium(III) complexes are very similar to those of cobalt(III) complexes, except that the transition energies are higher in the former complexes (Fig. 2). Therefore, the positive CD bands at 24600 cm^{-1} for dichloro- and at 23500 cm^{-1} for dibromo complexes of rhodium(III) can reasonably be assgined to $^1A_1 \rightarrow {}^1E^{(a)}$ transition (I_a band).

The AB spectrum of *trans*-$[PdCl_2(l\text{-pn})_2]^{2+}$ exhibits no distinct ligand field bands because of the overlapping of strong charge transfer bands (Fig. 3). However, a positive CD shoulder appears at about 24500 cm^{-1} corresponding to a shoulder AB band in the same energy region. Since this frequency value is almost the same as that of I_a band of rhodium(III) complex with an isoelectronic structure, this shoulder band could be assigned to the $^1A_1 \rightarrow {}^1E^{(a)}$ transition (I_a).

Both *trans*-$[PtCl_2(l\text{-pn})_2]^{2+}$ and *trans*-$[PtCl_2(l\text{-chxn})_2]^{2+}$ show two positive CD peaks in the ligand field band region (at around 26500 and 30500 cm^{-1}) (Fig. 3). The absorption intensities of these bands indicate that the positive CD peak at the longer wavelength could correspond to the spin-forbidden transition, and the other positive peak at the shorter wavelength to the spin-allowed $^1A_1 \rightarrow {}^1E^{(a)}$ transition, although the CD intensity is relatively weak. The rhodium(III) complexes and the palladium(IV) complex show also a trace of positive CD band in the region of their spin-forbidden $d \rightarrow d$ transition (see Figs. 2 and 3).

trans-$[PtBr_2(l\text{-pn})_2]^{2+}$ gives no definite AB peak corresponding to the $d \rightarrow d$ transitions, but its CD spectrum exhibits a weak positive and a weak negative band at 23300 and 26000 cm^{-1} respectively (Fig. 4). Comparison with the data for the other complexes described above suggests that the positive CD component would be due to the spin-forbidden $d \rightarrow d$ transition.

The negative CD peak, however, should not be assigned to the I_a band, since the energy difference between this band and the I_a band of *trans*-$[PtCl_2(l\text{-pn})_2]^{2+}$ amounts to about 4500 cm^{-1}, which is somewhat too large as compared with the difference between the I_a band of dichloro- and that of dibromo complex of cobalt(III) (1000 cm^{-1}) and rhodium(III) (1100 cm^{-1}). The actual symmetry of *trans*-$[MX_2(l\text{-pn})_2]^{n+}$ ion should be lower than D_{4h}, and $^1A_1 \rightarrow {}^1E^{(a)}$ transition can split further into two components. Hawkins *et al.*[3] observed another weak negative CD band at longer wavelength side of the strong positive peak (I_a) for *trans*-$[CoCl_2(l\text{-pn})_2]^+$ ion and assigned both of them to the components resulting from the splitting of degenerate $^1A_1 \rightarrow {}^1E^{(a)}$ transition. We also observed a weak negative peak at 18600 cm^{-1} of *trans*-$[RhBr_2(l\text{-pn})_2]^+$ ion in 3N hydrobromic acid solution. Thus, the weak negative CD band of *trans*-$[PtBr_2(l\text{-pn})_2]^+$ at 26000 cm^{-1} may be considered to be a split component of this type. The positive CD component corresponding to I_a band might be hidden by the positive CD peak of charge transfer transition, which is discussed below.

The AB spectra of $[PtCl_4(l\text{-pn})]$ and $[PtBr_4(l\text{-pn})]$ are very similar to those of $K_2[PtCl_6]$ and $K_2[PtBr_6]$, respectively (Fig. 5). Thus, on the basis of the results of spectroscopic study reported by Jørgensen,[9] the positive CD peaks at 24100 cm^{-1} for tetrachloro and 21500 cm^{-1} for tetrabromo complex were assigned to spin-forbidden bands and those at 28700 cm^{-1} for tetrachloro and 26500 cm^{-1} for tetrabromo complexes were assgined to the $^1A_1 \rightarrow {}^1E^{(a)}$ transition (assumed as pseudo D_{4h} symmetry[6]).

Concerning the so-called second absorption bands, a weak negative and a positive CD were observed for *trans*-$[CoCl_2(l\text{-chxn})_2]^+$, which were assigned to be $^1A_1 \rightarrow {}^1B_2$ and $^1A_1 \rightarrow {}^1E^{(b)}$ transition, respectively.[8] On the basis of these data, the positive CD peak at 36500 cm^{-1} of *trans*-$[RhCl_2(l\text{-pn})_2]^+$ is considered to correspond to the $^1A_1 \rightarrow {}^1E^{(b)}$ transition, though its CD intensity is somewhat too large for the magnetically forbidden II band (in O_h symmetry).

Charge Transfer Transition. It is well known that complex ions, $[CoX(NH_3)_5]^{2+}$ and $[CoX_2(NH_3)_4]^+$, where X=Cl^- and Br^-, have two intense bands in the ultraviolet region of their spectra. These are interpreted on the basis of LCAO-MO theory to be charge transfer bands from p orbitals of the halide ion to mainly d_z^2 orbital of the cobalt(III) ion,[10] the one at longer wavelength involving $p_\pi \rightarrow d_z^2$ and the other at shorter wavelength $p_\sigma \rightarrow d_z^2$ transition. Two intense bands were observed for all the complexes studied in this work except for *trans*-$[RhCl_2(l\text{-pn})_2]^+$ in the ultraviolet region, which are expected to be of the same nature as those of cobalt(III) complexes. The energy of $p_\sigma \rightarrow d_z^2$ transition of *trans*-$[RhCl_2(l\text{-pn})_2]^+$ is too high to be measured, and only the $p_\pi \rightarrow d_z^2$ band was observed.

In the CD spectra, three CD peaks appear in the charge transfer band region, a relatively weak positive, a strong negative and a strong positive peak from longer to shorter wavelength. According to Treptow,[8] *trans*-$[MX_2(l\text{-chxn})_2]^{n+}$ ion (approximated as D_{4h} symmetry) can have three charge transfer transitions from halide ions to d_z^2 orbital; of these two are $p_\pi \rightarrow d_z^2$ and one is $p_\sigma \rightarrow d_z^2$.

As can be seen in Figs. 3 and 4, the CD behavior of the bands at 38000 cm^{-1} for *trans*-$[PtCl_2(l\text{-}$

a) in methanol, b) $[RhBr_2(l\text{-pn})_2]Br$ in 3N HBr, c) in 1N HCl, CT: charge transfer band.

pn)$_2$]$^{2+}$, 31100 cm^{-1} for *trans*-[$PtBr_2(l\text{-pn})_2$]$^{2+}$ and 28600 cm^{-1} for *trans*-[$PdCl_2(l\text{-pn})_2$]$^{2+}$ is quite similar to those assigned to $p_\pi \rightarrow d_{z^2}$ charge transfer for the cobalt(III) complexes. Therefore, those CD peaks could be assigned to charge transfer transitions.

The similarity of absorption spectra between $K_2[PtBr_2(CN)_4]$ and $[PtBr_2(l\text{-pn})_2](ClO_4)_2$ will support the above assignment. If the bands at 31100 cm^{-1} of the latter and 29200 cm^{-1} of the former were due to $d \rightarrow d$ transition, the order of the "spectrochemical series" of CN^- and *l*-pn should be reversed, to contradict with the usual observation. Since the d_{z^2} orbital might not be affected by coordinated ligands in the *xy* plane, the energy of charge transfer transition from *p* orbitals of halide ions to d_{z^2} orbital for *trans*-[$PtBr_2(CN)_4$]$^{2-}$ and *trans*-[$PtBr_2(l\text{-pn})_2$]$^{2+}$ should not differ largely.

Consequently, the energies of charge transfer band agree well with the general trend of ligand to metal charge transfer. That is, the energy of a charge transfer band is higher for the metal with larger atomic number, whenever the oxidation number of the central metals is the same (*e. g.* Co(III) and Rh(III) or Pd(IV) and Pt(IV)), and is also higher for the metal of smaller oxidation number with an isoelectronic structure (Rh(III) and Pd(IV)).

The AB and CD data are summarized in Table 2.

Ion Association Band. It is known that $[Pt(en)_3]^{4+}$ associates with Cl^- or $S_2O_3^{2-}$ to change

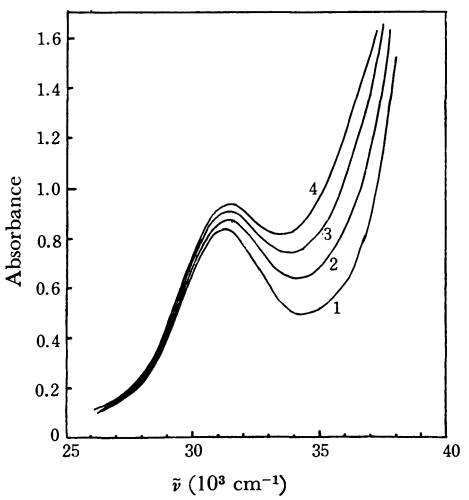

Fig. 6. AB spectra of *trans*-[$PtBr_2(l\text{-pn})_2$]Br_2 (0.664 $\times 10^{-3}$ mol/*l*) in 0.05N perchloric acid containing (1) 0.2M, (2) 0.4M, (3) 0.6M and (4) 0.8M sodium bromide.

the absorption and circular dichroism spectra.[11] Though absorption spectra of *trans*-$[PtCl_2(l\text{-pn})_2]^{2+}$ in methanol and in 1N hydrochloric acid are not very different (see Fig. 3), those of *trans*-$[PtBr_2(l\text{-pn})_2]^{2+}$ in methanol and in 1N hydrobromic acid are significantly different, *i. e.* a new band appears at about 35000 cm^{-1} in 1N hydrobromic acid (Fig. 4). Poë[12] studied the absorption spectra of *trans*-$[PtBr_2(en)_2]^{2+}$ in detail and assigned this band to an ion association band. The absorption spectra of $[PtBr_2(l\text{-pn})_2]Br_2$ in 0.05N perchloric acid (to prevent deprotonation of the coordinated amine) with varying bromide concentration are shown in Fig. 6. The intensity of this band increases with an increase in bromide concentration. The CD spectra of the solutions, however, are quite similar to one another, to indicate that the ion association is not stereoselective.

The authors wish to thank the Ministry of Education for Grand in aid.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1291—1296 (1969)

The Separation of Hexacyanoferrate(II) and Hexacyanoferrate(III) Ions by Reversed-phase Partition Chromatography

Ikuko AKAZA, Toshiyasu KIBA and Minoru TABA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received September 3, 1968)

The separation of hexacyanoferrate(II) and (III) ions with a TBP-HCl extraction system has been carried out by reversed-phase partition column chromatography. TBP adsorbed on Kel-F powder was used as the stationary phase in the column. Elution was performed with hydrochloric acid of various concentrations and with water, both having been saturated with TBP. The actual separation of hexacyanoferrate(II) and (III) ions from each other was successfully achieved, even in a large volume of a sample solution, by carrying out the elution with 3N HCl. The dependencies of the distribution ratio on the acidity of the solution and on the concentration of TBP in the stationary phase were examined on the basis of the elution curves under various conditions. The liquid-liquid batch extraction was also carried out under the same conditions; it was found an identical relation of distribution between the two phases held in both column and batch extractions. The principal extracted species might be assumed to be a large ion-pair hydrated and solvated.

Reversed-phase partition column chromatography is closely related to the liquid-liquid batch extraction of the same system; the former makes possible the effective separation of each component in a mixture even when the separation factor obtained in the latter is very low, because multiple extraction is carried out in the column. Therefore, this chromatographic technique has been applied to inorganic ions difficult to separate, such as rare earths and transition metals.

In the preceding papers, one of the present authors described the liquid-liquid extraction of alkali metal ions as their poly-iodides in nitrobenzene;[1] this extraction was later developed to reversed-phase partition column chromatography, in which Kel-F powder was used to support the organic phase of nitrobenzene-iodine-iodide.[2] The liquid-liquid extraction of alkaline earth metals as their TTA-chelates in MIBK was also investigated;[3] these results were then further applied to the reversed-phase chromatography, in which the stationary phase was a MIBK solution of TTA held on Kel-F.[4] These chromatographic investigations revealed that valuable information concerning reversed-phase partition column chromatography could be given by a study of the identical liquid-liquid extraction system.

In this paper, the separation of hexacyanoferrate-(II) and hexacyanoferrate(III) ions by the reversed-phase partition chromatography will be described; a TBP-(Kel-F) column will be used. It has been reported by Kiba *et al.* that these anions can be

extracted from their hydrochloric acid solution by liquid-liquid extraction with TBP.[5] The present research aims at a more effective separation of these two ions by using reversed-phase chromatography; the relation between the chromatography and the liquid-liquid extraction will also be investigated.

It is noteworthy that reversed-phase partition chromatography has never before been applied to the separation of common anions.

Experimental

Apparatus. *Column.* A glass column, 0.92 cm in diameter and 30 cm long, and with a coarse frit at the bottom, was used during this study. A separating funnel was fitted at the top of the column as a reservoir of the eluting solution.

Fraction Collector. A fraction collector (Model SF 200A of the Toyo Roshi Co.) holding 200 tubes was employed.

Photoelectric Photometer. A photoelectric photometer, Hitachi EPW-4, was employed, along with a 1-cm cell.

Reagents and Materials. *Kel-F.* Kel-F (polytrifluorochloroethylene), a trade-name low-density 300 moulding powder, was imported from the Minnesota Mining and Manufacturing Co., U.S.A. The material was ground with a mixing grinder and sieved through screens; particles between 42 to 80 mesh were collected for use.

TBP. Commercially-available TBP was purified by washing it twice with a 5% sodium carbonate solution of an equal volume in order to remove any dibutyl- or monobutyl phosphate, and by then distilling the solvent at about 178°C and at 25 mmHg.

All the other chemicals used were of an analytical reagent grade.

Organic Solvent Useful for Both the Stationary Phase of the Column and the Organic Phase of the Batch Extraction. The TBP used in each experiment had been pre-equilibrated with hydrochloric acid of the same concentration as that for the mobile phase or the aqueous phase. No diluent such as benzene was used except when, in some experiments, it was necessary to use TBP of varying concentrations.

Eluting Solution of the Column Extraction and Aqueous Phase Solution of the Batch Extraction. Hydrochloric acid of various concentrations and water were used as the eluting solutions; both had been saturated with TBP or, in some experiments, with TBP-benzene. They were also used as the aqueous phases of the batch extraction.

Test Solution. Hydrochloric acid solutions of potassium hexacyanoferrate(II) and potassium hexacyanoferrate(III) in the range of 10^{-1}M to 10^{-4}M were prepared; the concentration of hydrochloric acid had been made up to equal that in the eluting solution of the aqueous phase solution in each case. A mixed test solution was prepared by mixing equal volumes of these solutions.

Experimental Procedure. All the experiments were performed in rooms from which sunlight was kept out and the temperature, except in the experiment of Table 2, was always about 6—10°C.

The Preparation of the Stationary Phase. Six grams of Kel-F were placed in an Erlenmyer flask fitted with a stopper, and then 6 m*l* of an organic solvent prepared as above was poured in. The volume, 6 m*l* to 6 g of Kel-F, was derived from the amount of TBP adsorbable on Kel-F, an amount which had been determined by other experiments.[2,4] The stoppered flask was shaken gently by hand until the contents became homogeneous, and then it was left for over three hours as it was. A small volume of an eluting solution was added, and the slurry was poured little by little into the chromatographic column, taking care not to include any air bubbles. Every time a small portion of slurry was added, gentle press for the column bed was done with a glass rod; the bed length eventually reached about 17.4 cm. About a 50-m*l* portion of the eluting solution was then passed through the column in order to remove any contaminant.

The volume of the mobile phase in the column was found to be 3.6 m*l*. The amount of TBP originally adsorbed on the Kel-F column was 6 m*l*; hence, the volume ratio of the stationary phase to the mobile phase was 6: 3.6.

The Elution and Separation of Hexacyanoferrate(II) and Hexacyanoferrate(III) Ions. Three milliliters of the test solution were poured onto the upper surface of the column and were then percolated through the column at the rate of about 0.25 m*l* per minute; then the inside of the glass tube above the top of the column bed was washed twice with small portions of the eluting solution, letting them flow down at the same rate. On the top of the glass tube, a separatory funnel was placed; then the elution was carried out with eluting solutions of various concentrations of hydrochloric acid supplied from the funnel at the rate of 0.5 m*l*/min. The effluent was collected in suitable fractions with a fraction collector, and the hexacyanoferrate content in each fraction was determined.

A 3-m*l* portion of the test solution was usually employed, but a larger volume, such as 50 m*l*, was also employed in some cases.

Determination of Hexacyanoferrate(II) and Hexacyanoferrate(III) Ions. The $[Fe(CN)_6]^{3-}$ content in each fraction was determined by measuring the absorbance at 420 mμ directly. On the other hand, the concentration of $[Fe(CN)_6]^{4-}$ was determined absorptiometrically after oxidizing it to $[Fe(CN)_6]^{3-}$ by the addition of hydrogen peroxide to the acidic solution. This new determination method will be described here for the first time: Hydrochloric acid and 2% H_2O_2 were added to a solution of $[Fe(CN)_6]^{4-}$, and the mixture was diluted to a definite volume; the concentrations of HCl and H_2O_2 had to be about 1.5N and 0.26% respectively. After the vessel had then been placed at 20°C for 20 min, the yellow color was measured at 420 mμ; its absorbance was invariable, even 5 hr later. The working curve of the $[Fe(CN)_6]^{4-}$ solution coincided exactly with that of $[Fe(CN)_6]^{3-}$, and in both cases the curve could be used up to 5.5×10^{-4} mmol/m*l*; when the concentration of the ions exceeded 5.5×10^{-4} mmol/m*l*, the slope of the curve became gentle.

Results and Discussion

The Chromatographic Behavior of Hexacyanoferrate(II) and Hexacyanoferrate(III) Ions. The chromatographic behavior of the ion may be expected from the results of its liquid-liquid extraction. According to the results obtained in the liquid-liquid extraction of $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$ by Kiba *et al.*,[5] the distribution ratios of both ions increase with the concentration of hydrochloric acid, and the difference in the distribution ratio between the two ions is large in the range from 1N to 3N of hydrochloric acid. Therefore, the authors' experiments were attempted at concentrations of hydrochloric acid within this range.

The States of the Elutions at Various Concentration of Hydrochloric Acid. Solutions of 5×10^{-3}M $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$ in hydrochloric acid of various concentrations were prepared. Both of them, in the same concentration of hydrochloric acid and in equal volumes, were then mixed together. A 3-ml portion of the mixed solution was then eluted with acid of the identical concentration. The results are summarized in Fig. 1. It was found that $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$ cannot be separated from each other by elution with 1N HCl, but can be easily separated with an acid of higher concentration; also, in all cases $[Fe(CN)_6]^{3-}$, which has the smaller distribution ratio, is first eluted. Moreover, the position of the peak of the elution curve shifts backward on the abscissa with an increase in the concentration of HCl—as is clearly shown in the case of $[Fe(CN)_6]^{4-}$; namely, the distribution ratio of the ion increases with the concentration of HCl. In the case of 3N HCl, all the $[Fe(CN)_6]^{4-}$ remains in the column even after an eluting solution of 1*l* has flowed down, but as soon as the 3N HCl eluting solution is replaced by a water eluting solution, $[Fe(CN)_6]^{4-}$ is eluted immediately.

Table 1. The states of the elutions at various amounts of $[Fe(CN)_6]^{3-,4-}$

Concn. of HCl N	Loaded, mmol $[Fe(CN)_6]^{3-}$	Loaded, mmol $[Fe(CN)_6]^{4-}$	Elution range, ml $[Fe(CN)_6]^{3-}$	Elution range, ml $[Fe(CN)_6]^{4-}$
2.0	1.5×10^{-2}	7.5×10^{-3}	0—34	186—395 max. at
2.0	7.5×10^{-3}	1.5×10^{-2}	0—34	167—499
1.5		15×10^{-4}		52—112 82
1.5		15×10^{-3}		43—171 93
1.5		3×10^{-2}		40—207 106

The States of the Elutions at Various Amounts of the Ions. The following two experiments were carried out, one at varying ratios of $[Fe(CN)_6]^{3-}$ to $[Fe(CN)_6]^{4-}$ in 2N HCl, and the other at varying amounts of only $[Fe(CN)_6]^{4-}$ in 1.5N HCl. The results of elution are shown in Table 1. The situation of the peak of each elution curve seems practically unchangeable, though there is a slight shift backward with an increase in the amount of the ions loaded; this is contrary to the cases of alkali polyiodides and alkaline earth-TTA chelates, in which the distribution ratios decrease with an increase in the amount of the substance loaded. This discrepancy may be attributed to the difference between the types of extraction mechanisms: in this extraction system of hexacyanoferrate ions, the extraction is not affected by the relative amounts of the ion and the reactant because the ions transfer, without any reactant, into the TBP phase as their solvated free acids.

The Separation of Hexacyanoferrate(II) and (III). Eluting solutions of from 2N to 3N hydrochloric acid may be useful in separating these two substances, as is shown in Fig. 1. Among

these solutions, the 3N solution was preferred. The sample solution of 3N HCl was loaded, and then an eluting solution with the same HCl concentration was flowed in order to elute $[Fe(CN)_6]^{3-}$. In order to elute the $[Fe(CN)_6]^{4-}$ rapidly, the eluting solution was replaced with water. A satisfactory separation was attained, as is shown in Fig. 2.

Quantitative Separation of $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$ from a Mixed Test Solution of a Large Volume. To show the practical usefulness of the method and a quantitative separation of the ions, a simple process was carried out with a test solution of a 50-m*l* portion of a 3N HCl solution containing each of the two ions in 5×10^{-2} mmol (10.59 mg), and without a fraction collector.

This experiment was carried out at 20°C under a flow rate of 1 m*l*/min, faster than in the other experiments. The effluent of 3N HCl was placed successively in 100-, 50-, and 25-m*l* measuring flasks; the portions were named the first, second, and third fractions respectively. As a result of this process $[Fe(CN)_6]^{3-}$ should flow down. In order to examine if all of the $[Fe(CN)_6]^{4-}$ was left on the column, a new eluting solution of 1.5N HCl-H_2O_2*1 was supplied while about 2 m*l* of the preceding 3N HCl eluting solution still remained on the top of the column; the elution of $[Fe(CN)_6]^{4-}$ was then continued, with the fourth and fifth fractions placed in measuring flasks of 50 m*l* and 25 m*l* respectively. By this elution the $[Fe(CN)_6]^{4-}$ in the column was oxidized to $[Fe(CN)_6]^{3-}$. The absorbancy of each fraction was measured at 420 mμ. Furthermore, the absorbancy of the first and second fractions was measured again after the addition of H_2O_2. This treatment is necessary to certify the absence of $[Fe(CN)_6]^{4-}$ in the fractions of $[Fe(CN)_6]^{3-}$.

The results shown in Table 2 show that all of the $[Fe(CN)_6]^{3-}$ was eluted and recovered in the first 125-m*l* effluent, and $[Fe(CN)_6]^{4-}$ did not appear in this fraction, since the T% of the first and the second fractions after oxidation by H_2O_2 remained the same as before the oxidation. None of the ions could be detected in the next, third fraction. The results from the fourth and fifth fractions showed that $[Fe(CN)_6]^{4-}$ was left in the column quantitatively. This means that comparatively large amounts of $[Fe(CN)_6]^{4-}$ ions can be caught in the column quantitatively from the test solution of a larger volume, even at quite a fast flow rate. In this experiment the water-eluting solution was intentionally not employed for $[Fe(CN)_6]^{4-}$, unlike the ordinary elution presented in Fig. 2. A reason for this treatment is as follows. It was found in a preliminary test that $[Fe(CN)_6]^{4-}$ separated itself, as white, free acid $H_4[Fe(CN)_6]$, when a little TBP was added to a solution containing a large amount of $[Fe(CN)_6]^{4-}$ at a high concentration of hydrochloric acid. On the other hand, in the above column experiment, the concentration of $[Fe(CN)_6]^{4-}$ was be raised remarkably in a small upper part of the column, since adequate extraction conditions, such as 3N HCl, were kept; moreover, a large amount of $[Fe(CN)_6]^{4-}$ was handled here. The spontaneous separation of the free acid could be expected, as in the preliminary test. This free acid seemed unstable in water, and indeed it at once became blue when the hydrochloric acid-eluting solution was displaced with water. Hence, the water-eluting solution was omitted. The fact that $[Fe(CN)_6]^{4-}$ remained near the top of the column, has also the advantage that the separation from $[Fe(CN)_6]^{3-}$ can be achieved successfully without any consideration of the volume of the sample solution and the flow rate of elution. If one desires to take out the $[Fe(CN)_6]^{4-}$ as it is, not according to above procedure, it should be washed down to-

TABLE 2. QUANTITATIVE SEPARATION OF $[Fe(CN)_6]^{3-}$ AND $[Fe(CN)_6]^{4-}$ FROM MIXED TEST SOLUTION OF LARGE VOLUME

Fraction number	Eluant	Effluent collected m*l*	Found mg	Taken mg

gether with the stationary phase of TBP by passing 50 m*l* of a 1N HCl-50% alcohol solution (2N HCl : C_2H_5OH=1:1) through the column.

Some Relation to the Liquid-Liquid Extraction. The mechanism of reversed-phase partition chromatography is very similar to that of the liquid-liquid extraction of the same system, has been clarified by one of the present authors. Now, the extraction of $[Fe(CN)_6]^{4-}$ with TBP was preferentially examined.

The equation for the extraction of $[Fe(CN)_6]^{4-}$ with TBP can be written simply as:

$$nH^+_{(a)} + A^{n-}_{(a)} + m\text{TBP}_{(o)} = H_nA \cdot m\text{TBP}_{(o)} \quad (1)$$

where A^{n-} is the hexacyanoferrate ion. The distribution ratio, D, for this process can be written as:

$$D = K[H^+]^n[\text{TBP}]^m \quad (2)$$

where K is the thermodynamic extraction constant. Therefore, the distribution ratio, D, depends on the activity of both TBP and hydrogen ions. These activities can, for convenience, be displaced by the concentration of an acid and TBP.

The distribution ratio in the column extraction by reversed-phase partition chromatography was calculated, by using Eq. (3), from the elution curve obtained:

$$D = (E - F)/B \quad (3)$$

where E is the volume of the effluent before the emergence of the solute in a maximal concentration; B, the volume of the stationary phase, and F, the volume of the mobile phase.

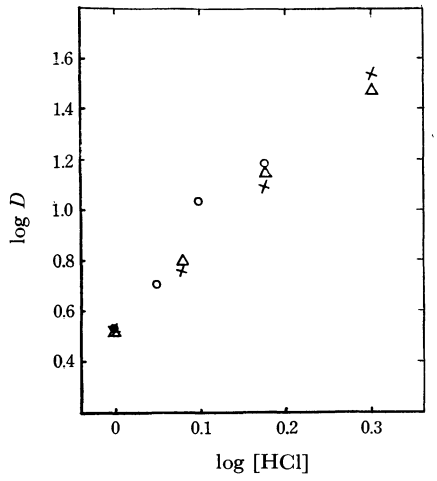

Fig. 3. Dependence of distribution ratio of $[Fe(CN)_6]^{4-}$ upon the concentration of HCl.
○ Column chromatography
△ Liq.-liq. (on Kel-F) batch extraction
× Liq.-liq. batch extraction

First, the dependence of the distribution of $[Fe(CN)_6]^{4-}$ on the concentration of hydrochloric acid was examined. Three-m*l* portions of a 5×10^{-3}M $[Fe(CN)_6]^{4-}$ solution with various concentrations of hydrochloric acid were fed into the column; elution was then carried out with a hydrochloric acid-eluting solution of the same concentration. The distribution ratio of $[Fe(CN)_6]^{4-}$ in each case was calculated by putting a value of E obtained from an elution curve into Eq. (3), and plotted on a graph of log$D$ *vs.* log[HCl] as is shown in Fig. 3.

For comparison with the above results, a series of batch extractions was carried out between (Kel-F)-TBP and an aqueous phase of the eluting solution. In a 100-m*l* glass-stoppered Erlenmyer flask, (Kel-F)-TBP was prepared with TBP pre-equilibrated with HCl of varying concentrations in the manner described above. After the solution had stood for more than three hours, 9 m*l*[*2] of each eluting solution of a definite acidity and 3 m*l*[*2] of a 5×10^{-3}M solution of $[Fe(CN)_6]^{4-}$ were introduced into the flask. The stoppered flask was gently shaken for a while and then set aside. The contents were poured on a coarse glass filter, and the aqueous phase was allowed to drain before it was submitted to photometry for $[Fe(CN)_6]^{4-}$. The results are shown in Fig. 3.

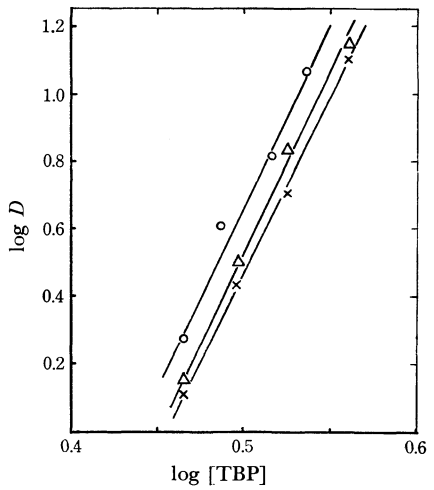

Fig. 4. Dependence of distribution ratio of $[Fe(CN)_6]^{4-}$ upon the concentration of TBP.
○ Column chromatography
△ Liq.-liq. (on Kel-F) batch extraction
× Liq.-liq. batch extraction

[*2] The reason for taking 12 m*l* as the sum of the two aqueous solutions is as follows: If the same volume ratio as in the column, organic phase: aqueous phase= 6 : 3.6, had to be kept, 3.6 m*l* of the aqueous volume would be too small to separate it from the organic solvent adsorbed on Kel-F. In this extraction system, the distribution ratio, D, did not differ upon a change in the volume ratio, so the data from the column extraction carried out at 6 : 3.6 and the batch extraction carried out at 6 : 12 are comparable.

Moreover, another series of liquid-liquid extractions, with Kel-F omitted from the system, was carried out. In this case, not only the organic solvent and the aqueous solutions, but also their volumes, were all identical to those described just above. These results are also shown in Fig. 3.

Next, the dependency of the distribution ratio on the concentration of TBP was examined by three kinds of experiments in the same manner as when the relation of log$D$ to log[HCl] was obtained. However, the concentration of hydrochloric acid was fixed at 1.5N in all these experiments, while that of TBP was varied by diluting the reagent with benzene. Organic solvents containing TBP in various concentrations were used for the stationary phase of the column chromatography, for the batch extraction with TBP-(Kel-F), and also for the liquid-liquid extraction. The data obtained are shown in Fig. 4 as a graph of log$D$ *vs.* log[TBP].

As Fig. 3 and Fig. 4, show all of the slopes showing the relation log$D$ *vs.* log[HCl] are about 3.5 and the dependency of D on the concentration of TBP is about 11 in every series of experiments. The data obtained in the column extraction chromatography and those in the liquid-liquid extraction are thus in good agreement. This shows that the extraction mechanism in the reversed-phase column chromatography is identical with that of the liquid-liquid extraction system.

In the former, however, the distribution ratio was found to be a little higher than in the liquid-liquid batch extraction; this might be caused by a small difference in temperature between the two experimental rooms,*3 not by the extraction mechanisms. Because the data obtained from the liquid-liquid batch extraction and those from the batch extraction with (Kel-F)-TBP are found to be in good agreement on the straight lines in Figs. 3 and 4, it can be said that Kel-F powder does not affect the extraction mechanism. Also, it was observed that this extraction system is readily affected by the temperature; *e.g.*, of the distribution ratios of $[Fe(CN)_6]^{4-}$ at 20°C and 10°C, the latter has a value higher than the former by about 0.5 in logarithm.

The slopes of the lines in Figs. 3 and 4 presumably do not stand directly for n and m in Eq. (2). They only indicate the average reagent-dependence of the species present; furthermore, the experimental conditions are remarkably far from ideal for an infinite dilution system. As has been shown in the papers concerning the extraction mechanism of acids by TBP by Whitney and Diamond[6] and Biddle *et al.*,[7] the principal extracted species may be assumed to be a large species which is an associate of a hexacyanoferrate ion and about four trihydrated hydronium ions, each of the hydronium ions being solvated with three TBP's.

*3 The chromatography was carried out in a room the temperature in which was kept at 6—10°C, while the extraction was done in an anteroom with a temperature slightly higher than the inner room.

Summary

The present authors have developed a liquid-liquid extraction system of hexacyanoferrate(II) and (III) with TBP to a reversed-phase column partition chromatography. In the column, TBP held on Kel-F powder was used as the stationary phase. The separation of each ion from the mixture has been successfully achieved by carrying out the elution with an eluting solution of 3N HCl; tolerable amounts could thus be treated. The relation between the method and the liquid-liquid extraction has been examined; no fundamental difference could be found between them.

Reactions of Metal Chelates. III. The Reactions of Bis(salicylaldehydato)copper(II) with Amides and Esters of Glycine and Glycylglycine

Kazuko HAMADA, Hideo UEDA, Yasuo NAKAO and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received September 5, 1968)

The reactions of bis(salicylaldehydato)copper(II) in acidic, neutral and basic media with glycinamide, glycinester, glycylglycinamide and glycylglycinester have been systematically investigated. The reaction products have, in all cases, been isolated as crystals and characterized. As a result of this investigation, six new copper(II) chelates of Schiff bases derived from salicylaldehyde and glycine- or glycylglycine-amide have been obtained. The interrelation between those chelates has also been disclosed.

In a previous paper[1] it was reported that bis(salicylaldehydato)copper(II), I, reacts readily with glycine or glycylglycine to form salicylideneglycinato- or -glycylglycinato-chelate, respectively, II, III.

We have further reported that the reaction at pH 4.5 between the same chelate, I, and tri-[2] or tetra-glycine[3] results in the hydrolytic cleavage of a peptide linkage, producing salicylideneglycylglycinatocuprate(II), III, and free glycine or glycylglycine, respectively. From biochemical interest, the investigation has been extended to reactions of the same chelate, I, with some derivatives of amino acids and peptides.

This paper describes the reactions of bis(salicylaldehydato)copper(II), I, in acidic, neutral and basic media with glycinamide, glycinester, glycylglycinamide and glycylglycinester. The preparation and properties of six new copper(II) chelates, which have been obtained as a result of this investigation, are also described.

The Reaction of Bis(salicylaldehydato)copper(II), I, with Glycinamide. The reaction between complex, I, and glycinamide varies widely with the hydrogen ion concentration in solutions. Although the reactions proceed rapidly at room temperature both in acidic and basic solutions to form the one-to-one type copper(II)-Schiff base complexes, the resulting chelate from acidic solution is green, while that from basic solution red-purple, indicating that they have different structure from each other. The structure of the green complex is easily concluded to be IV in Fig. 1 in the light of properties of acidamide found in the case of pyridine-2-carboxamide complexes,[4-6] and results of elemental analysis and electrophoretic investigation of the complex. As is clear from the structural formula, IV, the carboxamide group of the glycinamide moiety in the green complex is linked to copper(II) through the oxygen atom, and the ligand at the fourth coordination position around copper(II) is water molecule; hence the complex is a univalent cation, being isolated as chloride, bromide, perchlorate, sulfate, *etc.* On the other hand, the structure of the red-purple complex isolated from a basic solution is somewhat difficult to determine, since the complex shows a considerably subnormal magnetic moment (1.15 B. M. for copper atom). As has been established by Kishita *et al.*,[7] the subnormal magnetic moment of this kind can be elucidated in terms of binuclear structure, V, in which an interaction is expected between copper(II) atoms.

Although there is another possible binuclear structure as represented by V′, in which the bridging atoms are phenolic oxygen atoms, this structure is supposed to be less plausible from a stereochemical point of view. In other words, the steric hindrance between the benzene ring of salicylaldehyde moiety and the carboxamide nitrogen might eliminate the possibility of the structure V′. The binuclear complex, V, can be dissolved in an alkaline solution, but the structure of the complex

(V′)

in the solution has not been determined; hence the structure of the complex in the solution is still uncertain whether the binuclear structure is maintained or not.

In neutral solutions the chelate I reacts less rapidly than in acidic or basic solutions with glycinamide. The resulting compound is not the one-to-one but one-to-two type copper(II)-Schiff base complex, in which the carboxamide groups are free from coordination as illustrated in VI. As is understood from its structural formula, this complex is an uncharged neutral complex.

The interrelation between those chelates, IV, V and VI, has also been clarified to some extent. First, chelate IV changes to V by adjusting the pH of the solution to about 12; this isomerization is almost reversible, and accordingly, chelate IV is reproduced from V by readjusting the pH of the solution to about 4.0. However, the procedure is always accompanied by the precipitation of blue-purple crystalline powder at pH-values near 7.5. Though this precipitate is expected to have an interesting structure, the details on this particular compound is not clarified yet. Secondly, the chelate VI also changes readily to IV or V according to the pH-value of the solution, but these rearrangements are, of course, not reversible.

As has been reported previously,[3] glycylglycine-Schiff base coordinated around copper(II) in the same fashion as that depicted in the structural formula, IV, is easily hydrolyzed into the free glycine and glycine-Schiff base complex in aqueous media at low pH and especially at high temperature. However, in the present case, the hydrolysis of the carboxamide group has not been observed at least under the same condition. Though this finding seems to be inconsistent with the results of Meriwether and Westheimer,[8] who reported the metal ion-promoted-hydrolysis of glycinamide and of phenylalanylglycinamide, their experiments were made in a slightly alkaline solution, while the present datum has been obtained from an investigation on a slightly acidic solution.

Thus it can be said that carboxamide $-CO-NH_2$ linkage is difinitely more stable at low pH against the hydrolytic cleavage reaction than peptide linkage.

The Reaction of Bis(salicylaldehydato)copper(II), I, with Glycinester. This reaction is very monotonous, and always results in the formation of the one-to-two type copper(II)-Schiff base complex, (VII),[1,9] regardless of the hydrogen ion concentration in solutions. The hydrolysis of the ester groups of complex, VII, in aqueous media has not been observed under mild conditions, perhaps because of its poor solubility. At any rate, since the ester groups of glycinester moieties in chelate VII are located away from the central metal ion, the electron-withdrawing effect of metal ion would not reach the ester group to catalyze the hydrolytic reaction.

The Reaction of Bis(salicylaldehydato)copper(II), I, with Glycylglycinamide. This reaction varies also delicately with the hydrogen ion concentration in solutions. In acidic solutions, the reaction product is an olive-green Schiff base complex, in which the glycylglycinamide moiety is linked to copper(II) only through the nitrogen of the terminal amino group and the oxygen of the peptide linkage as indicated in (VIII). The structure is supported not only by the results of elemental analysis but also by the paper chromatographic identification of the glycylglycinamide after decomposing the chelate with hydrogen sulfide. Chelate VIII is easily hydrolyzed into the free glycinamide and the *N*-salicylideneglycinatoaquocopper(II), II, by heating at 70°C and at pH-value near 2.8.[3]

On the other hand, the resulting compounds from the reactions in neutral or basic solutions are copper(II) tetradentate chelates of Schiff base derived from salicylaldehyde and glycylglycinamide. However, the chelate from neutral solution is navy-blue, while that from basic solution is red-brown. The difference is apparently due to a linkage isomerism; the carboxamide group in the navy-blue chelate is considered to be linked to copper(II) through oxygen atom, and the same group in the red-brown chelate through nitrogen atom as illustrated in IX and X, respectively. This consideration is strongly supported by the fact that chelate IX is an uncharged neutral complex, whereas chelate X a univalent anion. Hydrolysis of the terminal carboxamide group has not been observed in either complexes under conditions that would be observed in case of peptide linkage. The results of experiments of paper-electrophoresis clearly indicate that the olive-green complex is a cation, the navy-blue complex an uncharged molecule, and the red-brown complex an anion. The mutual transformation between the three chelates, VIII, IX and X, is readily attained only by changing the pH of solutions.

The Reaction of Bis(salicylaldehydato)copper(II), I, with Glycylglycinester. The reaction

9) P. Pfeiffer, W. Offermann and H. Werner, *J. prakt. Chem.*, **159**, 313 (1942).

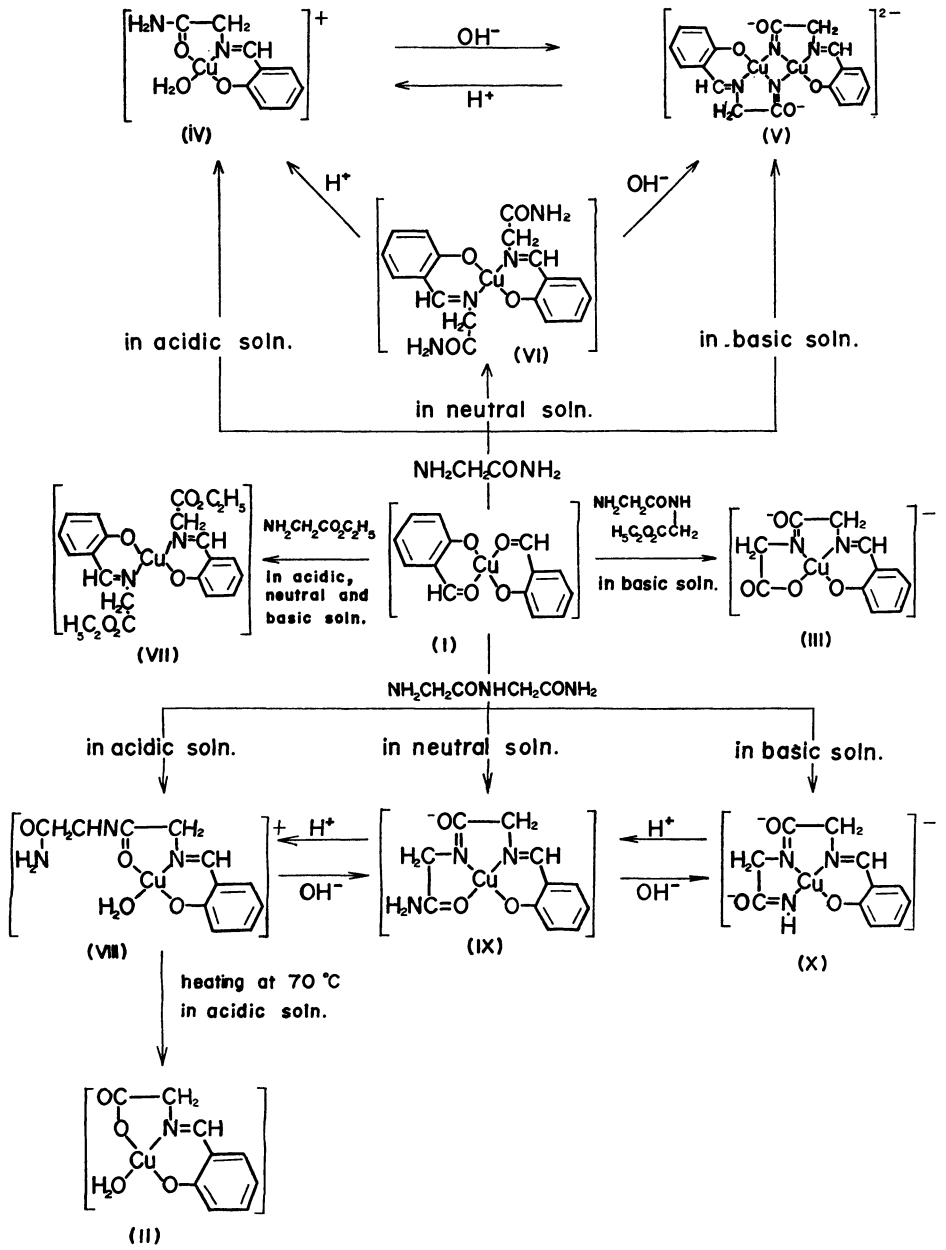

Fig. 1. The reactions of bis(salicylaldehydato)copper (II) with amides and esters of glycine and glycylglycine. The complexes, IV, V, VI, VIII, IX, and X, are new compounds.

product in basic solutions from the system containing chelate I and glycylglycinester is the *N*-salicylideneglycylglycinatocuprate(II), III,[1] indicating that hydrolysis of ester group proceeds quite readily and rapidly.

The phenomenon is understood in terms of a catalytic effect of metal ion as has very often been observed in researches on metal chelates of esters.[10]

Experimental

Preparations of Amides and Esters of Glycine and Diglycine. *Glycinamide* was prepared according to directions of Bergell and Wulfing[11]

Glycylglycinamide was Prepared as acetate according to the method of Fruton and Bergmann.[12] *Glycine-*

11) P. Bergell and H. V. Wulfing, *Z. Physiol. Chem.*, **64**, 348 (1910).

12) J. S. Fruton and M. Bergmann, *J. Biol. Chem.*, **145**, 253 (1942).

and *glycylglycinethylester* were obtained from glycine and glycylglycine, respectively, by treating with absolute ethanol saturated with dried hydrogen chloride. All these amides and esters were identified through the elemental analyses. The preparation and purification of *bis(salicylaldehydato)copper(II)*, I, was performed in the same way as that described in the first paper of this series.[2)]

The Reaction of bis(salicylaldehydato)copper (II), I. *The Reaction of Complex I with Glycinamide.* A one-to-one molar mixture of complex I and glycinamide hydrochloride in aqueous ethanol was divided into three parts. The pH-values of each solution were adjusted to 3.0, 7.0 and 12.0, respectively, by using dilute solutions of sodium hydroxide and hydrochloric acid. Each reaction mixture was then stirred at room temperature for about half an hour.

From the acidic solution, a green crystalline powder was deposited, which was filtered and recrystallized from an aqueous ethanol solution to give a green prism.

The structure of this complex was easily concluded to be IV from coincidence of its decomposing temperature and infrared spectrum with those of complex IV, which can more conveniently be obtained, for the purpose of preparation, from a reaction at pH 3.0 of a system containing 1 : 1 : 1 copper(II) : salicylaldehyde : glycinamide. Mp 178—186°C (decomp.). Found: C, 37.19; H, 3.35; N, 9.44%. Calcd for $CuC_9H_{11}O_3N_2Cl$: C, 36.74; H, 3.77; N, 9.52%. The elemental analysis of sulfate of the same complex was also performed. Found: C, 33.24; H, 3.81; N, 8.43; Cu, 19.87%. Calcd for $CuC_9H_{11}O_3N_2 \cdot \frac{1}{2}SO_4 \cdot H_2O$: C, 33.30; H, 4.00; N, 8.63; Cu, 19.54%. Mp 180—200°C (decomp.). Magnetic moment, $\mu_{eff}=1.84$ B. M. (15°C).

From the reaction mixture of pH-value near 12, a red-purple crystal was isolated. The structure of this complex was concluded to be V, on the basis of the results of elemental analysis and the magnetic datum. Mp 218—220°C (decomp.). Found: C, 36.22; H, 3.73; N, 9.17; Cu, 21.59%. Calcd for $Na_2Cu_2C_{18}H_{14}O_4N_4$: C, 36.30; H, 3.70; N, 9.41; Cu, 21.34%. Magnetic moment, $\mu_{eff}=1.15$ B.M. (15°C).

The reaction mixture of pH-value near 7.0 gave an olive-green precipitate, which was recrystallized from aqueous ethanol to give a one-to-two copper(II)-Schiff base complex. Mp 255—265°C (decomp.). Found: C, 51.63; H, 4.97; N, 13.90%. Calcd for $CuC_{18}H_{18}O_4N_4$: C, 51.73; H, 4.34; N, 13.41%.

Though the two complexes, IV and V, can be prepared either through the reaction between bis(salicylaldehydato)copper(II) and glycinamide or by the direct reaction between copper (II), salicylaldehyde and glycinamide, this particular one-to-two copper(II)-Schiff base complex can be prepared only through the reaction between bis(salicylaldehydato)copper(II) and glycinamide.

The Reaction of the Complex I with Glycylglycinamide. A similar procedure to that employed for the reaction of complex I with glycinamide was adopted. In order to isolate the reaction products it was necessary, in some cases, to concentrate the solution *in vacuo*. Recrystallization was performed by using aqueous ethanol and keeping the pH-value near 3.0, 7.0 and 12.0, respectively. The resulting chelate from the acidic solution is an olive-green crystalline powder, which decomposes at 195—198°C. Found: C, 36.94; H, 3.91; N, 11.57%. Calcd for $CuC_{11}H_{12}O_3N_3Cl \cdot 1.5H_2O$: C, 36.67; H, 4.05; N, 11.66%. The product from the neutral solution is a navy-blue crystalline powder, which decomposes at 262—263°C. Found: C, 42.47; H, 3.69; N, 13.63%. Calcd for $CuC_{11}H_{11}O_3N_3 \cdot H_2O$: C, 41.96; H, 4.13; N, 13.34.% The complex obtained from the basic solution is a red-brown prism, which decomposes at 282—290°C. Found: C, 35.10; H, 4.09; N, 10.82%. Calcd for $NaCuC_{11}H_{10}O_3N_3 \cdot 3H_2O$: C, 35.44; H, 4.33; N, 11.27%.

The Reactions of the Complex I with Glycine- and Glycylglycinester. A one-to-one molar mixture of complex I and glycinester in aqueous ethanol (50% by volume) was stirred and heated at 60°C for half an hour.

The reaction product was soon deposited as an olive-green powder, and was recrystallized from ethanol. No difference in the reaction product was observed within wide range of pH and molar ratio of complex I to glycinester. The resulting complex was identified as the one-to-two type copper(II)-Schiff base chelate as illustrated in VII, from the coincidence in infrared spectrum of the complex with that obtained by Pfeiffer *et al.*[9)]

The reaction of complex I with glycylglycinester was performed only at pH value near 8.5 by a similar procedure as described above. The reaction product was, after recrystallization, a red-purple needle. The structure of this compound was easily concluded as sodium *N*-salicylideneglycylglycinatocuprate(II), III, on the basis of the coincidence of its infrared spectrum with that of the standard sample.[1)]

Magnetic Measurements. The magnetic susceptibility was determined at 15°C by using a Gouy magnetic apparatus. From susceptibilities observed, the magnetic moments were evaluated per copper atom.

Paper-electrophoretic experiments, aminoacid analyses and the measurements of *infrared spectra* were made with the use of a Yanagimoto EC-10, a Yanagimoto LC-5 and a Hitachi EPI-S2, respectively.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1301—1304 (1969)

The Mixed Chromium(III) Complexes containing Acetylacetone and the Halogenations Thereof*1

Yuki FUJII,*2 Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received September 9, 1968)

The following three mixed chromium(III) complexes containing acetylacetone, which had a charge of from -1 to $+1$, were prepared: $NH_4[Cr(acac)(ata)]\cdot H_2O$,*3 $[Cr(acac)(edda)]\cdot 2H_2O$*3 and $[Cr(acac)(edma)(H_2O)]Cl\cdot H_2O$.*3 The halogenations at γ-position of the acetylacetonate ring were attempted in these three mixed complexes with NCS, NBS and ICl respectively in methanol and in acetic acid solutions, where NCS, NBS and ICl are abbreviated forms of *N*-chlorosuccinimide, *N*-bromosuccinimide and iodine monochloride, respectively. From an inspection of UV-spectra of the above halogenation reaction mixtures, all the three mixed complexes were confirmed to be halogenated at the γ-position of the acetylacetonate ring. Of these complexes, $NH_4[Cr(acac\text{-}Cl)(ata)]\cdot \frac{1}{2}H_2O$ and $[Cr(acac\text{-}Br)(edda)]$ were isolated as crystals from the reaction mixtures. IR-spectra measurement was also used to certify the halogen-substitution at γ-position in the above two compounds.

Electrophilic substitution reaction (S_E reaction) at γ-position of metal acetylacetonates is of interest from the view point of the chemical reaction due to the quasi-aromaticity. Based on the experimental results recently reported,[1,2] the predominant factors governing the reactivity of 1,3-dicarbonyl chelate in S_E reaction may be focussed on the following two points: (1) the electron density at the central carbon atom (γ-position) of the chelate ring (2) the degree of the steric hindrance around the central carbon of the chelate ring. Unfortunately, however, there are still very few reports that affirm the factors described above, and most researches on the reactivity of metal acetylacetonate have been focussed only on the non-electrolyte trisacetylacetonate complexes, due to easiness for treatment in organic solvents. Furthermore, there is no report that describes the reactivity of the mixed acetylacetonate complexes, except for that of the complex ion $[Co(en)_2(acac)]^{2+}$.[1,2]

In order to obtain further information on the reactivity of the mixed complexes containing acetylacetone against halogen, such complexes having different charges of -1, 0 or $+1$ were synthesized and the halogenation reaction was investigated.

Experimental

Preparation of Mixed Complexes. *1) Ammonium Acetylacetonatoammoniatriacetatochromate(III) Monohydrate,* $NH_4[Cr(acac)(ata)]\cdot H_2O$ (I).[3] Ammonium hydroxoammoniatriacetatoaquochromate(III) dihydrate, $NH_4[Cr(OH)(ata)(H_2O)]\cdot 2H_2O$ (9.9 g, 0.03 mol), was dissolved in 40 m*l* of water and heated on a water bath. Acetylacetone (3.3 g, 0.033 mol) was added to the solution with stirring and was warmed at 80—90°C for one hour. After adjusting the pH of the solution to 5—6 by adding a small amount of ammonium carbonate, it was cooled to 0°C, when purple crystals were separated out. They were recrystallized from an aqueous solution. Yield, 10.4 g (92.0%).

Found: C, 35.09; H, 4.89; N, 7.14; Cr, 13.52; H_2O, 4.69%. Calcd for $NH_4[Cr(acac)(ata)]\cdot H_2O$: C, 35.21; H, 4.80; N, 7.47; Cr, 13.86; H_2O, 4.80%.

2) Acetylacetonato-N,N′-ethylenediaminediacetatochromium-(III) Dihydrate, $[Cr(acac)(edda)]\cdot 2H_2O$ (II). Ethylenediaminediacetic acid, $eddaH_2$,[4] (8.0 g) was added to a solution of chromium(III) chloride hexahydrate (5.3 g) in 40 m*l* of water. Heating it on a water bath, the pH of the solution was adjusted to about 3 or 4 with ammonium carbonate and then acetylacetone (2.0 g, 0.02 mol) was, with stirring, added to the solution. Adjusting the pH of the resultant solution to about 7, it was cooled to 0°C. Purple crystals were then separated out and recrystallized from 50% methanol-water solution. Yield, 1.6 g (22.2%).

4) M. Mori, M. Shibata, E. Kyuno and F. Maruyama, *ibid.*, **35**, 75 (1962).

Found: C, 36.71; H, 5.74; N, 7.62; Cr, 14.03; H_2O, 10.0%. Calcd for $[Cr(acac)(edda)]\cdot 2H_2O$: C, 36.56; H, 5.78; N, 7.75; Cr, 14.39; H_2O, 9.98%.

3) Acetylacetonatoethylenediaminemonoacetatoaquochromium-(III) Chloride Monohydrate, $[Cr(acac)(edma)(H_2O)]Cl\cdot H_2O$ (III). Ethylenediaminemonoacetic acid dihydrochloride monohydrate, $edmaH\cdot 2HCl\cdot H_2O$*4 (4.2 g, 0.02 mol), was added to the solution of chromium(III) chloride hexahydrate (5.3 g, 0.02 mol) in 30 m*l* of water. Heating the solution on a water bath, the solution was adjusted to about pH 2 or 3 with ammonium carbonate. Acetylacetone (2.0 g, 0.02 mol) neutralized with equimolar ammonium carbonate was added to the solution, and was heated for an hour. After the pH of the solution was adjusted to about 5, it was allowed to stand for about three weeks at room temperature. Reddish purple crystals were separated out and recrystallized from an aqueous solution. Yield, 2.7 g (40%).

Found: C, 31.98; H, 5.85; N, 7.88; Cr, 14.61; H_2O, 5.02%. Calcd for $[Cr(acac)(edma)(H_2O)]Cl\cdot H_2O$: C, 31.81; H, 5.95; N, 8.25; Cr, 15.31; H_2O, 5.30%.

Isolation of Halogenated Mixed Complexes. *1) Ammonium 3-Chloroacetylacetonatoammoniatriacetatochromate(III) Hemihydrate*, $NH_4[Cr(acac\text{-}Cl)(ata)]\cdot \frac{1}{2}H_2O$ (IV). The solution of NCS (5.4 g, 0.04 mol) in 60 m*l* of glacial acetic acid was slowly added to the solution of the complex I (7.5 g, 0.02 mol) in glacial acetic acid at room temperature.[5] After being stirred for 30 min, 150 m*l* of ether was added and the resultant reddish purple precipitates were collected. Washed with ether, the powder obtained was dissolved in 70 m*l* of ethanol at 40°C. Fifty milliliters of ether were added to the solution and the reddish purple precipitates produced were collected. Washed with ether, the precipitates were recrystallized from 20% of methanol solution. Black purple crystals were separated out. Yield, 2.1 g (25.5%).

Found: C, 32.20; H, 4.49; N, 6.70; Cr, 12.36; Cl, 8.26; H_2O, 2.20%. Calcd for $NH_4[Cr(acac\text{-}Cl)(ata)]\cdot \frac{1}{2}H_2O$: C, 32.99; H, 4.28; N, 6.99; Cr, 12.96; Cl, 8.85; H_2O, 2.25%.

2) 3-Bromoacetylacetonatoethylenediaminediacetatochromium-(III), $[Cr(acac\text{-}Br)(edda)]$ (V). One gram (0.003 mol) of the complex II was dissolved in 60 m*l* of methanol and a solution of NBS (0.6 g, 0.003 mol) in methanol was added to it at room temperature. Evaporating off the solvent at room temperature, purple crystals were separated out. These were insoluble in various solvents. Yield, 0.6 g (66.0%).

Found: C, 32.81; H, 4.13; N, 6.95; Cr, 12.88; Br, 19.26%. Calcd for $[Cr(acac\text{-}Br)(edda)]$: C, 32.68; H, 4.00; N, 6.93; Cr, 12.87; Br, 19.77%.

Apparatus. The molar conductivity, the UV and visible absorption spectra and IR spectra were measured with a Yokogawa Universal Bridge BV-Z-13A, a Hitachi EPS Spectrophotometer and a Nippon Bunko DS-301 Infrared Spectrometer, respectively. The quantity of the crystalline water contained in these compounds was estimated from TGA curves measured with Derivatograph.

Results and Discussion

Visible and UV Absorption Spectra. Absorption spectra for the complexes I, II, III and IV are shown in Fig. 1 and the numerical values of the absorption bands for these complexes, including those for the other related compounds halogenated, are summarized in Table 1.

The absorption spectrum of the complex I has a band at 330 mμ which is characteristic of the coordinated acetylacetone but the maximum of the corresponding band in complex IV is shifted to 350 mμ. The spectra measured for the reaction mixtures of the complex I and NBS and those of I and ICl in methanol and in acetic acid solutions also show the shifts of the absorption maxima to 351 mμ and 357 mμ, respectively (These compounds are presumed to have the formulae, $NH_4[Cr(acac\text{-}Br)(ata)]$ and $NH_4[Cr(acac\text{-}I)(ata)]$, respectively.). Such a red shift of the maximum mentioned above which is assigned to $d_\varepsilon \rightarrow \pi_4$ transition[6] will show evidence of halogenation in

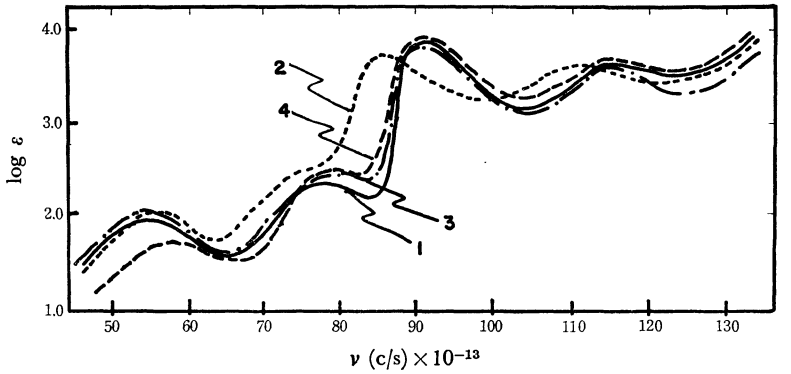

Fig. 1. The absorption spectra of the mixed complexes.

$[Cr(acac\text{-}I)(edma)(H_2O)]Cl$*	359		CH_3OH

* Although these complexes could not be isolated, their compositions were presumed on the basis of IR spectra measurement in the respective mixed solutions.

the acetylacetonate ring[2] and this explanation can be ascertained by the fact that neither acetylacetone nor NCS (also NBS and ICl) has absorption peak near 355 mμ.

The maximum of the characteristic absorption band for the complex II appears at 330 mμ and the spectrum of the bromo-substituent V has a corresponding maximum at 351 mμ. The spectra of the chloro- and iodo-substituents (probably having the formulae, [Cr(acac-Cl)(edda)] and [Cr(acac-I)(edda)], respectively), which were measured for the reaction mixture of the complex II and NCS or ICl in methanol solution, (the reaction in acetic acid made the complex II to $[Cr(eddaH)_2]X\cdot 3H_2O$,*4 where X is halogen anion) have the maxima at 350 mμ and 357 mμ, respectively.

The maximum of the complex III appears at 331 mμ. The spectra for the complexes, which may be considered to be expressed by $[Cr(acac\text{-}X)(edma)(H_2O)]Cl$ (X=Cl, Br and I), were measured for the reaction mixtures of the complex III and halogenating reagents in acetic acid and in methanol. The band of the complex III at 331 mμ is shifted to 350 mμ by chlorination in acetic acid, but in methanol as a solvent only a small distinct shoulder appears at 350 mμ. The band at 331 mμ is also shifted to 351 mμ by bromination and to 359 mμ by iodination in methanol solvent, but in the case of acetic acid solvent, complex III decomposed very rapidly before absorption measurement.

IR Spectra. The predominant bands of IR spectra measured in the region 4000—700 cm^{-1} are listed in Table 2. The strong bands appearing between 1650 and 1670 cm^{-1} in the complexes I and IV indicate the presence of three coordinated carboxyl groups of ata. The strong bands of 1528 and 1570 cm^{-1} in the complex I are assigned to $\nu_{C=C}$ and $\nu_{C=O}$ in the coordinated acetylacetonate, respectively. In the complex IV, however, only one peak at 1560 cm^{-1} for coordinated acetylacetonate is observed in this region. This phenomenon is well known in a number of metal acetylacetonate and is commonly used to check the presence of the γ-substituted chelate ring.[1]

Table 2. IR spectra of the mixed complexes (cm^{-1})

Ccomplex	ν_{O-H}	ν_{N-H}	ν_{COO-Cr}	$\nu_{C=O(acac)}$	$\nu_{C=C}$
I	3620	3060	1650	1570	1528
		3180	1670		
		3380			
IV	3520	3040	1650	1560	
		3180			
		3390			
II	3400	3140	1635	1560	1515
	3500	3260	1675		
V		3100	1670	1550	
		3180			
		3250			
III	3410	3080	1640	1560	1530
		3140			
		3200			
		3270			

The spectra of the complexes II and III indicate the strong bands between 1630 and 1680 cm^{-1} for $\nu_{M\text{-}O\text{-}\overset{O}{\overset{\|}{C}}\text{-}}$ of coordinated edda and edma respectively and also have two strong bands characteristic of coordinated acetylacetone between 1510 and 1560 cm^{-1}. On the other hand, the spectrum of the complex V indicates only one band at 1550 cm^{-1} for acetylacetone, which suggests the substitution at γ-position.

Conductivity Measurements and Behavior toward Ion-exchangers. The values of molar conductivity of the complexes prepared in this work measured in a 1/500 mol aqueous solution at 25°C and the behavior toward ion-exchangers are summarized in Table 3, in which the symbol + indicates the possibility of the adsorption of the complexes by the resin and −, the reverse. It is found from this table that the three complexes I, II and III have the charges of −1, 0 and +1 respectively and the charges are still invariable by halogenation both in I and II.

Reactivity of the Mixed Complexes against Halogenating Agents. It may be concluded from the results obtained above that the three mixed complexes I, II and III are halogenated at

Table 3. Molar conductivity and behavior toward ion exchangers

Complex	Molar conductivity (mho cm^{-1})	Ion exchanger Na-form	Cl-form
I	104.7	−	+
IV	104.2	−	+
II	—	−	−
V	—	−	−
III	102.8	+	−

γ-position of the chelate ring irrespective of the charge in the complex ions themselves from -1 to $+1$. But the complex III which has the charge $+1$ is relatively difficult to be halogenated as compared with complex I or II. This result suggests that the positively charged complex is not as easily attacked by the electrophilic reagent, which also has positive charge, as the negatively charged or non-charged complex. This result coincides with that obtained by Collman for cobalt(III) complex and indicates that the electron density at the γ-position of acetylacetonate ring in the positively charged complex is somewhat more deficient than that of negatively charged or non-charged complexes.[1,2]

Some differences in the reactivity were observed, depending upon the solvent, and the halogenation was more vigorous in acetic acid than in methanol. NCS was milder than NBS or ICl as halogenating reagent in both solvents.

Crystal Growth of the Phosphate Coating on Iron and Steel*1

Takao UMEGAKI and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai

and Keiichi OMORI

Institute of Mineralogy, Petrology and Economic Geology, Tohoku University, Sendai

(Received October 5, 1968)

Crystal growth of the phosphate coating on steel and pure iron was investigated by microscopic observation and X-ray diffraction. β-Hopeite was recognized as a main constituent of the phosphate coating. From the experimental results obtained in this investigation and the crystal structure of β-hopeite proposed by Gamidov and Galovachev (*Dokl. Akad. Nauk, SSSR*, **150**, 2, 381, (1963)), it was concluded that the bonding of the (010) plane of β-hopeite to the (100) plane of iron is most favorable for atomic arrangement of the phosphate coating.

Many attempts have been made to establish a theory of crystal growth since the first research by P. Curie at the end of the 19th century, and the results obtained in the course of those attempts have recently come to be applied to polymer chemistry and electronic engineering. The process of crystal growth has to be taken into account to understand the mechanism that crystals are produced on a metal surface by corrosion. The phosphate coating may be regarded as one of the most excellent utilizations of corrosion products. According to the research by Neuhaus and his coworkers,[1] phosphorus atoms in phosphate ions of the coating combine with iron atoms on the surface in such a manner that is known as Wustite bond. Notwithstanding the comprehensive investigation by Neuhaus, the detailed construction of the boundary layer between iron and phosphate coating has still remained obscure. In the present paper microscopic observation on the crystal growth of phosphates on iron surface and X-ray diffraction patterns of the phosphate coating are described and, based on our experimental results and the crystal structure of β-hopeite determined by Gamidov and Galovachev,[2] an adhesive mechanism between iron and phosphate is presented.

*1 Presented at the 21st Annual Meeting of the Chemical Society of Japan, Osaka, April, 1968.

Experimental

A) Microscopic Observation on Crystal Growth. The compositions of specimens of iron and steel, size of which being 3 mm×5 mm×20 mm, and that of phosphating solution are shown in Tables 1 and 2,

Table 1. Compositions of specimens (wt %)

	O	Si	Mn	F	S	Cu	Cr	Ni
iron	0.007	trace	trace	trace	0.006	0	trace	0
steel	0.20	trace	0.80	0.016	0.024	0.06	0.06	0.03

Table 2. Composition of phosphating solution

Zn^{2+} (g/l)	PO_4^{3-} (g/l)	Na_2CO_3 (g/l)	Total acidity (point)	Free acidity (point)
5.9	15.7	2.74	32.1	2.2

respectively. The specimens were polished with emery paper (0/5) and buff. When necessary, they were further etched with Nital or Picral. About 0.05 ml of the phosphating solution was dropped on the surface of the specimen placed on a deck glass. The visual field of the microscope was fixed at the same position during the observation. Most of the microscopic photographs were taken every 2 min.

B) X-Ray Diffraction. The coating obtained in the phosphating solution was scratched and stripped off with an edge of glass plate. The X-ray diffraction patterns of the powdered coating were taken with the "Geigerflex" manufactured by Rigaku Denki Co., Ltd. The diffraction data were compared with those of ASTM cards.

C) Observation on Phosphate Crystals under Polarized Light. The powdered coating used for X-ray diffraction pattern was also observed with a polarization microscope inserted with a gypsum plate. The directions of optical elasticity axes of β-hopeite were identified by comparison of the refractive indices obtained in this experiment with those in the data shown in ASTM card (9-497). The refractive indices were measured by the immersion method under the polarization microscope.

D) Calculation of the Velocity of Crystal Growth. The velocity of crystal growth of β-hopeite was calculated from the differences of the crystal length shown in microscopic photographs which were taken by the method described above.

Results and Discussion

A series of microscopic photographs from Figs. 1 to 4 shows the crystal growth of phosphate on the buff-polished carbon steel. At first, a certain number of small core crystals appeared. They grew radially, forming dendrites, and finally covered the whole surface of iron. The number of round crystals formed at the beginning remained constant during the phosphating process. A similar behavior of crystal growth was found on the buff-polished pure iron, etched carbon steel and etched pure iron. Figures 5 and 6 show the phosphate crystals which appeared on the buff-polished pure iron. The initiation of crystallization on pure iron surface was considerably delayed, compared with that on carbon steel. In Figs. 7, 8, 9 and 10, the crystals on the etched surfaces of carbon steel and of pure iron are shown. The round phosphate crystals were apt to appear in the neighborhood of grain boundaries or on the scratches of polishing.

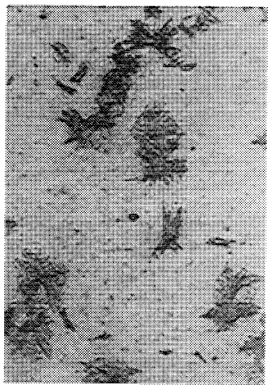

Fig. 2. Crystal growth of phosphate coating on polished carbon steel (6 min). (×180)

Fig. 3. Crystal growth of phosphate coating on polished carbon steel (10 min). (×180)

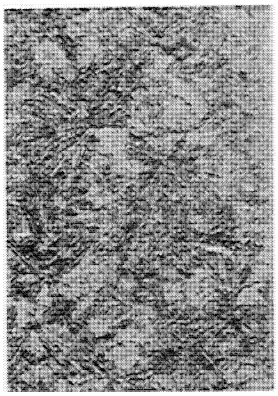

Fig. 4. Crystal growth of phosphate coating on polished carbon steel (24 min). (×180)

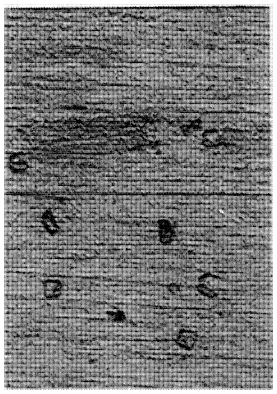

Fig. 5. Crystal growth of phosphate coating on polished pure iron (10 min). (×180)

Fig. 6. Crystal growth of phosphate coating on polished pure iron (26 min). (×180)

The order of increasing size of the phosphate crystal particles on various iron surfaces was obtained as follows: etched carbon steel, etched pure iron, buff-polished carbon steel and buff-polished pure iron. The initiation of crystallization of various iron surfaces was delayed with increasing size of the crystals. The X-ray powder diffraction pattern of the stripped coating is shown in Fig. 11. By comparison of this pattern with that in ASTM card (9-497), β-hopeite was recognized as a main constituent of the phosphate coating and a trace of vivianite was also found on it. Under the polarized microscope the direction of elongation of all β-hopeite crystals was parallel to the direction of wave motion of lower velocity, of which refractive index was 1.580. For β-hopeite two kinds of

optical orientation are shown in the reference:[3] $X=b$, $Y=c$, $Z=a$, or $X=b$, $Y=a$, $Z=c$. The refractive indices of β-hopeite (ASTM card 9-497) are as follows: $\alpha=1.574$, $\beta=1.582$, $\gamma=1.582$. Therefore, it is considered that the direction of elongation and also the c axis were parallel to Z axis with the minimum velocity of wave motion. The optical elasticity axes of the stripped β-hopeite were identified to be $X=b$, $Y=a$ and $Z=c$. The relations between crystal growth of β-hopeite on polished carbon steel and phosphatizing time are shown in Fig. 12. The elongation of the c axis increased linearly with time and the velocity was much greater than that in the direction perpendicular to the c axis. An overlapped projection of the (010) plane of β-hopeite and the (100) plane of iron is schematically shown in Fig. 13. In this mode of adhesion, oxygen atoms located at the apices of tetrahedra of phosphate ion can be transferred into the interstices of an iron lattice. Although some other modes of adhesion in the phosphate coating have already been presented, this mechanism may be most favorable for atomic arrangements of both iron and β-hopeite crystal.

Conclusion

The mechanism of phosphate film formation was studied with the concept that the phosphating reaction may be a kind of corrosion. Conclusions obtained from the present investigation are as follows: (a) In the phosphate coating process, small round phosphate crystals appear at the beginning as nuclei in the neighborhood of grain boundaries corroded by etching solution or on the scratches produced by polishing. (b) The nuclei of phosphate coating grow to form dendrites. The total number of nuclei does not increase during the course of phosphatization. (c) The dendritic crystals are identified as β-hopeite from a comparison of the X-ray diffraction spacings with the data of ASTM card and from the microscopic observation under polarized light. (d) Comparing the crystal structure of β-hopeite proposed by Gamidov with the results obtained in this investigation, it is concluded that the (010) plane of β-hopeite sticks on the (100) plane of iron.

This investigation was partly supported by a grant from Nippon Kokan (Japan Steel and Tube) Corp., for which the authors wish to express their sincere appreciation.

Synthesis of Vitamin B_{12} Model Compounds

Tadashi Sasaki and Fujinao Matsunaga

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received November 10, 1967)

Bis(dimethylglyoximato)cobalt(III) complexes with the general formula: $[CoX(DH)_2B_A]$ (X: CN^-, NO_2^-, $SeCN^-$, SCN^-, Br^-. D: dianion of dimethylglyoxime. B_A: such biologically interesting bases as imidazole, benzimidazole, 5,6-dimethylbenzimidazole, pyridine, γ-picoline, 4-vinylpyridine, nicotinic acid, isoquinoline, 5-amino-4-imidazolecarboxamide, and 6-aminopurine) were prepared from dimethylglyoxime, the base, and an adequate cobalt(III) salt. The treatment of $[CoCN(DH)_2Imd]$ (Imd: imidazole) with boron trifluoride etherate afforded $[Co(CNBF_3)(DBF_2)_2Imd]$ in an 86% yield. The reduction of $[CoCl(DH_2)Imd]$ with sodium borohydride gave a labile $[Co(I)H(DH)_2Imd]$, which was directly converted with phenylacetylene into a stable $[Co(III)(C_6H_5CH{=}CH)(DH_2)Imd]$ in a 60% yield and into $[Co(DH)_2Imd]\cdot H_2O$ in a 30% yield. These products were structurally elucidated on the basis of their spectral data.

It is known that bis(dimethylglyoximato)cobalt(III) complexes uniquely reproduce the fundamental reactions of cobalamins and are thus excellently suited for the study of the mechanisms of vitamin B_{12}-catalyzed biochemical processes.[1,2] Whereas simple alkylcobaloximes are found to be unusually stable, a surprising variation in the reactivity of the cobalt-carbon bond results from the introduction of the substituents into the cobalt-bound alkyl group.[3]

In this paper we wish to describe the preparation of new bis(dimethylglyoximato)cobalt(III) complexes containing such biologically interesting bases as imidazole, benzimidazole, 5,6-dimethylbenzimidazole, nicotinic acid, 5-amino-4-imidazolecarboxamide, and 6-aminopurine. The reactivities of some cobaloximes and the structures of these products are also discussed.

Results and Discussion

Preparation of Cobaloximes. $[CoCN(DH)_2B_A]$-*type Complexes.* Ablov[4] reported the preparation of $[CoCN(DH)_2Pyr]\cdot\frac{1}{2}H_2O$ (Pyr: pyridine) by a sequence of ligand substitution reactions:

$$[CoH_2O(DH)_2NCS] \rightarrow K[CoCN(DH)_2NCS] \rightarrow [CoCN(DH)_2Pyr]\cdot\tfrac{1}{2}H_2O.$$

On the other hand, our present preparative method is shown by:

$$4DH_2 + 2Co(OCOCH_3)_2 + 2KCN + 4B_A + \tfrac{1}{2}O_2 \rightarrow 2[CoCN(DH)_2B_A] + 2B_A\cdot CH_3COOH + 2CH_3COOK + H_2O.$$

A similar procedure has recently been reported by Varhelelyi[5] using several aromatic amines as the basic component. This report prompted us to publish this paper. The yields, compositions, colors, and results of analyses of the products using various bases are summarized in Table 1.

The yields of the products were generally lower than those of the $[CoCl(DH)_2B_A]$-type complexes described in the next paragraph. When 5-amino-4-imidazolecarboxamide or 6-aminopurine was used, the base did not coordinate to the cobalt atom, and the product was $H[Co(CN)_2(DH)_2]\cdot 2H_2O$, which was presumably formed by:

$$4DH_2 + 2Co(OCOCH_3)_2 + 2KCN + \tfrac{1}{2}O_2 \rightarrow 2H[Co(CN)_2(DH)_2] + 2CH_3COOK + H_2O.$$

$[CoCl(DH)_2B_A]$-*type Complexes.* It is well known that stable $[Co(III)Cl(DH)_2NH_3]$ can be prepared readily from DH_2, ammonia, and cobalt(II) chloride.[6] Similarly, several complexes with various bases were prepared by:

$$4DH_2 + 2CoCl_2\cdot 6H_2O + 4B_A + \tfrac{1}{2}O_2 \rightarrow 2[CoCl(DH)_2B_A] + 2B_A\cdot HCl + H_2O.$$

These results are summarized in Table 2.

complex was prepared by:

$$4DH_2+2Co(OCOCH_3)_2\cdot 4H_2O+2KX+4Imd+\tfrac{1}{2}O_2 \rightarrow 2[CoX(DH)_2Imd]+2Imd\cdot CH_3COOH+2CH_3COOK+H_2O.$$

Likewise, the preparation of $[CoBr(DH)_2Imd]$ was followed by:

$$4DH_2+2CoBr_2+2Imd+\tfrac{1}{2}O_2 \rightarrow 2[CoBr(DH)_2Imd]+2Imd\cdot HBr+H_2O.$$

The products are summarized in Table 3.

Some Reactions of Cobaloximes. The treatment of $[CoCN(DH)_2Imd].\frac{1}{2}H_2O$ with boron trifluoride etherate afforded $[Co(CNBF_3)(DBF_2)_2$-Imd] in an 86% yield. Since it is known[7] that vitamin B_{12S}, a two-electron reductant of vitamin B_{12}, shows specific reactivity with electrophilic reagents, giving complexes which are sensitive to light and air, $[CoCl(DH)_2Imd]$ was treated with sodium borohydride in a methanol-water mixture to afford a brownish-green colored, two-electron reductant. This was also unstable in air, so it was confirmed by conversion with phenylacetylene into $[Co(III)(C_6H_5CH{=}CH)(DH)_2Imd]$:

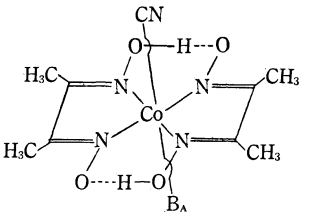
$$4[Co(III)Cl(DH)_2Imd]+NaBH_4 \rightarrow 4[Co(I)H(DH)_2Imd]+NaBCl_4.$$
$$[Co(I)H(DH)_2Imd]+C_6H_5C{\equiv}CH \rightarrow [Co(III)(C_6H_5CH{=}CH)(DH)_2Imd].$$

The side-formation of $[Co(II)(DH)_2Imd]$ in this reaction might be explained by:[2]

$$[Co(III)(C_6H_5CH{=}CH)(DH)_2Imd]+[CoCl(DH)_2Imd] \rightarrow [Co(II)(DH)_2Imd]+C_6H_5CH{=}CHCl.$$
$$[Co(I)H(DH)_2Imd]+[Co(III)(C_6H_5CH{=}CH)\text{-}(DH)_2Imd] \rightarrow [Co(II)(DH)_2Imd]+C_6H_5CH{=}CH_2.$$

These reactivities are similar to those of vitamin B_{12S}.

Structural Elucidation. The ultraviolet and visible spectra of $[CoCN(DH)_2B_A]$-type complexes showed similar absorption patterns regardless of the kind of base, except for triphenylphosphine; the absorption maxima ranged from 240 to 245 mμ ($\log\varepsilon=4.4$), from 280 to 290 (shoulder, 3.7—3.8) and from 330 to 340 (shoulder, 3.1—3.4), as is shown in Figs. 1 and 2 and in Table 4; the strongest absorption due to a coordinated dimethylglyoximate ion[8] was too strong for the other two absorptions to be obvious. Considering their similarity in the spectra of $[Co(DH)_2(NH_3)_2]Cl$, $[CoCl(DH)_2NH_3]$, $H[CoCl(DH)_2]$,[9,10] and $[Co(DH)_2A_2]Cl$[11] (A: butylamine, ammonia, pyridine), we concluded that our $[CoCN(DH)_2B_A]$-type complexes have similar structures, in which two dimethylglyoximate ions are coordinated and are coplanar with the cobalt, taking a cyano group and the base in a *trans*-configuration as is illustrated in Scheme 1. When



Scheme 1

triphenylphosphine was used, the UV pattern was quite different from those of the above compounds, as is shown in Fig. 3; it manifested an absorption at 374 mμ which rather resembled that of $[Co(DH)_2A']Cl$ (A′: aniline and its derivatives),[11] where an absorption at 340—380 mμ is interpreted as a charge-transfer spectrum from aniline to the cobalt atom. Therefore, we interpreted the absorption at 374 mμ as being due to a charge-transfer from triphenylphosphine to the cobalt atom. Furthermore, based on Nakahara's UV spectral data about other bis(dimethylglyoximato)cobalt-(III) complexes,[9] we concluded that the cobalt-

The fact that the characteristic band of a dimethylglyoximate ion in [CoCl$(DH)_2B_A$] showed somewhat bathochromic shifts compared with those of [CoCN$(DH)_2B_A$] can be explained in terms of Tsuchida's spectrochemical series.[12] The same principle can be applied in explaining why the characteristic absorptions at around 250 mμ in [CoX$(DH)_2$Imd] were changed to some extent according to the species of the X ligand, as is shown in Table 6.

12) R. Tsuchida and M. Kobayashi, This Bulletin, **13**, 471 (1938); R. Tsuchida, *ibid.*, **13**, 388, 442 (1938).

The infrared spectra of the dimethylglyoximate moiety in $[CoX(DH)_2B_A]$ are shown in Tables 7, 8, and 9. As may clearly seen from these tables, the weak absorption of ν_{OH} in $[CoX(DH)_2B_A]$ at 1740—1770 cm^{-1} [13] demonstrate that these complexes take a *trans*-configuration between X and B_A; this further substantiates the conclusion from the UV data described above. This was also supported by the chemical behavior of these cobaloximes in readily forming an O–BF_2–O bonding by the interaction of two O–H–O bondings in cobaloximes with boron trifluoride etherate. The other assignments in these tables were made on the basis of Schrauzer's data.[3]

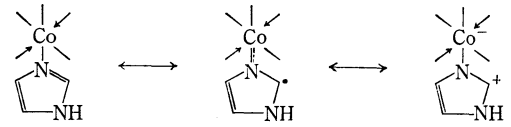
13) A. Nakahara, This Bulletin, **29**, 296 (1956). He concluded that an absorption band at 1725 cm^{-1} of hydrogen dichloro-bis(dimethylglyoximato)cobalt(III) was attributable to an OH stretching frequency when intramolecular O–H···O hydrogen bonds were formed.

The multiple absorption bands due to ν_{NH} in imidazole at 2600—3110 cm^{-1} were changed into a single band at around 3150 cm^{-1} by the complex formation, as is shown in Table 10. This means that the formation of σ- or π-bonding between the nitrogen and the cobalt atom, as is shown in Scheme 2, causes any change in the electron density



Scheme 2

of an N–H bonding or the bond distance. The simplification of ν_{NH} absorption bands by the complex formation can be explained in terms of the prohibition of the tautomerism based on the prototropy of the imidazole ring proton. George[14] has pointed out that an acid dissociation constant of an imino group of a non-coordinated imidazole is less than that of a coordinated one to an iron atom, indicating the prohibition of the ionic structures by the complex formation.

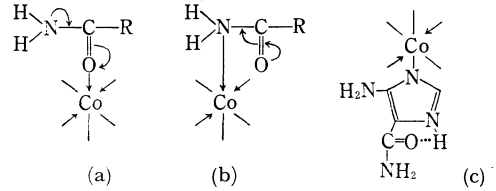
* Strength. m: medium and s: strong.

As for 5-amino-4-imidazolecarboxamide, a question arises regarding to which position the cobalt atom is bound. The infrared spectrum of $[CoCl(DH)_2AICA]$ (AICA: 5-amino-4-imidazolecarboxamide) gives some information on this point; it is expected[15] that if the amidocarbonyl were coordinated to a cobalt atom, as is shown in (a) of Scheme 3, the ν_{NH} absorption of the amidocarbonyl



Seheme 3

14) P. George, I. H. Hanania and D. H. Irvine, *J. Chem. Soc.*, **1964**, 5689.

15) N. Gerrad, *ibid.*, **1960**, 2144.

group would shift to a lower wave number. If it were coordinated to the nitrogen atom of the amide group (b), the ν_{NH} absorption would shift to a lower, but the ν_{CO} absorption of the amide would shift to a higher wave number. Table 11 indicates that the ν_{NH} absorption shifted up by about 10 cm^{-1} and that the ν_{CO} absorption shifted down by about 17 cm^{-1}, indicating that [CoCl-$(DH)_2$AICA] has no such linkages as shown in (a) and (b). The slight shift of the ν_{CONH_2} absorption to a lower wave number can be explained in terms of the prohibition of the prototropy of an imidazole-ring proton by the complex formation, resulting in the easier formation of hydrogen bond than free AICA. This suggests that the cobalt atom is coordinated to the nitrogen atom of the imidazole ring, as is shown in (c) of Scheme 3.

Table 11. Characteristic IR absorption bands of AICA (cm^{-1})

Compound	ν_{CONH_2}	ν_{as-NH_2}	ν_{s-NH_2}	ν_{CONH_2}	δ_{NH_2}
AICA	3430	3300	3220	1680	1624
[$CoCl(DH)_2$-AICA]	3440	3300	3230	1663	1621

The same problem is encountered in 6-aminopurine. The basicity of adenine is not strong enough for the basic center to be the same as the coordination center; therefore, the basic center is not very important in this case. If the cobalt atom were coordinated to an amino group of adenine, the ν_{NH} absorption should shift to a wave number lower by 100—150 cm^{-1}, while the δ_{NH} absorption should not change at all or shift to a slightly higher wave number.[16] The fact that both the γ_{NH} and δ_{NH} absorptions shifted to lower wave numbers, as is shown in Table 12, indicates the absence of any coordination of the amino group to the cobalt atom. The 12 cm^{-1} shift of the $\nu_{C=C,C=N}$ of the purine ring to a higher wave number upon the complex formation may be explained in terms of the lowering of the resonance contribution of the purine ring. Considering that pseudo B_{12}, which is different from B_{12} in containing adenine instead of 5,6-dimethylbenzimidazole, has a coordinate bond between the nitrogen atom of the imidazole ring and the cobalt atom,[17] [$CoCl(DH)_2$Adenine] may be supposed to have the same type of coordinate bond.

Table 12. Characteristic IR absorption bands of adenine (cm^{-1})

	ν_{as-NH_2}	ν_{s-NH_2}	δ_{NH}	$\nu_{C=C,C=N}$
Adenine	3290	3110	1668	1605

16) J. Chatt, L. A. Duncanson and L. M. Venanzi, *ibid.*, **1955**, 4461.

17) E. A. Kaczka, D. E. Wolf, F. A. Kuehl and K. Folkers, *J. Am. Chem. Soc.*, **73**, 3569 (1951).

Table 13 shows the characteristic infrared absorption bands of the chelates involving benzimidazole ($C_7H_6N_2$) and 5,6-dimethylbenzimidazole ($C_9H_{10}N_2$). All had a common strong band at 3120 cm^{-1} upon the complex formation; this band perhaps originated from the prohibition of the tautomerism based on the prototropy of a benzimidazole-ring proton. The fact that the absorptions due to both the ν_{NH} of the imidazole ring and the $\nu_{C=C}$ of the phenyl part did shift to higher wave numbers may be caused by the decrease in the conjugation of the benzimidazole ring, as is shown in (c) of Scheme 3.

Table 13. Characteristic IR absorption bands of chelates involving benzimidazole and 5,6-dimethylbenzimidazole (cm^{-1})

Compound	ν_{NH}	$\nu_{C=N}$	$\nu_{C=C}$
Benzimidazole	3120—2450	1621	1590
[$CoCN(DH)_2C_7H_6N_2$]	3130	1625	1598
[$CoCN(DH)_2C_9H_{10}N_2$]	3130	1630	1952

Table 14 shows the characteristic infrared absorption bands of the chelates involving pyridine derivatives in comparison with those of pyridine derivatives. If a nitrogen-cobalt linkage were formed of σ- and π-bonding, a decrease in the conjugation of the pyridine ring would be expected; such a decrease is, in fact, shown in this table by the 10—30 cm^{-1} shift to a higher wave number of the absorption due to the $\nu_{C=C}$ of the pyridine ring.

Table 15 shows the characteristic infrared absorption bands of X in [$CoX(DH)_2Imd$] (X: NO_2, NCO). As for [$CoNO_2(DH)_2Imd$], there are possible two structures; it can be assigned either to a nitro or to a nitrito complex. Nakamoto[18] has

18) K. Nakamoto, J. Fujita and H. Haruta, *ibid.*, **80**, 4517 (1958).

provided a method of discrimination by means of infrared spectral comparison. As is shown in Table 14, the infrared spectrum of $[CoNO_2(DH)_2Imd]$ was compared with those of known nitro and nitrito complexes. From its similarity to the former, we concluded that $[CoNO_2(DH)_2Imd]$ was a nitro complex. Likewise, our $[CoNCO(DH)_2Imd]$ was concluded to be an isocyanato complex with a cobalt-nitrogen bonding.[19]

Table 15. Characteristic IR absorption bands of $[CoX(DH)_2Imd]$ (cm^{-1})

X: NO_2

Compound	ν_{as-NO_2}	ν_{s-NO_2}	δ_{NO_2}
$[Co(NH_3)_5NO_2]Cl_2$	1428	1310	824
$[Co(NH_3)_5ONO]Cl_2$	1468	1065	825
$[CoNO_2(DH)_2Imd]$	1425	1323	822

X: NCO

Compound	$\nu_{N=C=O}$
$Et_4N[Co(NCO)_4]$	2217(shoulder), 2179(very strong)
$[CoNCO(DH)_2Imd]$	2200 (very strong)

As for thiocyanato- and selenocyanatocobaloxime, these complexes are shown by their microanalyses (Table 3) to consist of 1 mol of $[CoSCN(DH)_2Imd]$ or $[CoSeCN(DH)_2Imd]$ and ½mol of Imd·H_2O. This means that the thiocyanate- and selenocyanate ions and imidazole have some specific characteristics as ligands in these complexes; concerning this subject many papers have been published.[20] As is shown in Table 16, absorptions due to $\nu_{C\equiv N}$ shifted to higher wave numbers in the following sequence:

M-CS(Se)<M-S(Se)CN<M-NCS(Se)-M,M-NCS(Se)-B

where M is the metal and where B is a base such as $PyrH^+$, NH_4^+, or Et_4N^+.

From Table 16, it can be said that:

M-NCS(Se)<2080 cm^{-1} and M-S(Se)CN>2080 cm^{-1}

It is generally believed that Co(III) forms a Co–S(Se) bonding in the thiocyanatocomplexes of B_{12}[21] and in $(NH_4)[Co(SeCN)_2(DH)_2]\cdot 3H_2O$.[22] The presence of an absorption due to ν_{CN} at 2135 cm^{-1} in $[CoSCN(DH)_2Imd]\cdot ½Imd\cdot H_2O$ and at 2120 cm^{-1} in $[CoSeCN(DH)_2Imd]\cdot ½Imd$, both located in the >2080 cm^{-1} region, demonstrates that these two complexes have a bridged structure with a

Co–S(Se) bonding, while the imidazole intervenes, as is shown in Scheme 4. This is supported by the presence of a strong absorption due to the ν_{NH} of the imidazole ring; this absorption is clearly different from those of the other cobaloximes described above.

Table 17. IR absorption bands (cm^{-1})

Compound	$\nu_{C=N}$	ν_{B-O}	ν_{B-F}	δ_{B-O}
$[Ni(DBF_2)_2]$	1648	1193	1026	826
$[Co(CNBF_3)(DBF_2)_2Imd]$	1620	1203	1025	818

In Table 17 the infrared spectrum of $[Co(CNBF_3)(DBF_2)_2Imd]$ is compared with that of known $[Ni(DBF_2)_2]$, which possesses a bridged N–CN–BF_2 structure.[23] Their similar absorption patterns suggest that a bridged Co–CN–BF_2 bonding might also be involved in $[Co(CNBF_3)(DBF_2)_2Imd]$; this is further supported by the presence of an absorption due to ν_{CN} at 2240 cm^{-1}, located at a higher wave number than those of the general cobaloximes at 2155—2160 cm^{-1} described above.

Table 18. Far-infrared spectra of $[CoX(DH)_2B]$-type complexes (cm^{-1})

sh*: shoulder

Table 18 shows the far-infrared spectra due to ν_{Co-N} in $[CoX(DH)_2B_A]$-type complexes; the data are in good accordance with Schrauzer's data,[2] indicating no remarkable change upon a variation in the bases.

Experimental

Materials. Benzimidazole was prepared by the known method.[24] 5,6-Dimethylbenzimidazole was prepared from 4,5-diamino-1,2-dimethylbenzene[25] by the method of Takatori *et al.*[26] Potassium cyanate[27] and selenocyanate[28] were prepared by the usual methods. All the other reagents were commercially available and were used after purification if neccessary.

Preparation of Complexes. $[CoCN(DH)_2B_A]$, B_A: Imd. Into filtered solution*1 of 2.8 g (0.024 mol) of DH_2 and 2.6 g (0.011 mol) of $Co(OCOCH_3)_2\cdot 4H_2O$ in 100 m*l* of hot 80% ethanol, there was stirred 0.7 g (0.01 mol) of KCN*2 at room temperature. To this stirred solution there was then added 1 g (0.015 mol) of imidazole, after which the reaction mixture was aerated for 1 hr. The precipitated yellow-purple powders were collected, washed thoroughly with water, ethanol, and finally with ether, and dried in air. The yield and the results of analysis are given in Table 1.

$H[Co(CN)_2(DH)_2]$: When 5-amino-4-imidazolecarboxamide or 6-aminopurine was used as the base in the above experiments, fine, thin, yellow crystals (mp >300°C) were obtained in a yield of 31 or 43% respectively. They are quite soluble in ethanol.

Found: C, 31.38; H, 4.75; N, 22.23%. Calcd for $H[Co(CN)_2(DH)_2]\cdot 2H_2O$: C, 31.78; H, 5.07; N, 22.22%.

$[CoCl(DH)_2B_A]$: B_A: Imd. To a ho , filtered solution of 2.8 g (0.024 mol) of DH_2 and 2.5 g (0.011 mol) of $CoCl_2\cdot 6H_2O$ in 100 m*l* of 95% ethanol,*3 1 g (0.015 mol) of imidazole was added; the reaction mixture was then kept standing overnight at room temperature. The resulting brown-yellow powder was filtered and worked up as above. The results are summarized in Table 2, together with those obtained using several other bases.*4

$[CoSeCN(DH)_2Imd]\cdot \frac{1}{2}Imd$: To a hot, filtered solution of 1.4 g (0.012 mol) of DH_2 and 1.3 g (0.006 mol) of $Co(OCOCH_3)_2\cdot 4H_2O$ in 50 m*l* of hot ethanol, there was added 0.75 g (0.050 mol) of potassium selenocyanate. After it had been completely dissolved in the reaction mixture, 0.5 g (0.0075 mol) of imidazole was added. The resultant clear solution was aerated for 1 hr, after which the reaction mixture was kept standing overnight at room temperature. The crystalline precipitates were collected and worked up as above to afford a selenocyanatocomplex. Similarly, the corresponding isocyanato- and thiocyanatocomplex were prepared. These results are summarized in Table 3.

$[CoNO_2(DH)_2Imd]$: This was prepared similarly from 2.8 g (0.024 mol) of DH_2, 2.6 g (0.011 mol) of $Co(OCOCH_3)_2\cdot 4H_2O$, 1 g (0.015 mol) of potassium nitrite, and 100 m*l* of hot 80% ethanol. The results are given in Table 3.

$[CoBr(DH)_2Imd]$: To a hot, filtered solution of 1.4 g (0.012 mol) of DH_2 and 1.7 g (0.006 mol) of $CoBr_2\cdot 6H_2O$ in 50 m*l* of 95% ethanol, there was added 0.5 g (0.0075 mol) of imidazole; the reaction mixture was then kept standing overnight at room temperature, after which the precipitates were worked up as above. The results are given in Table 3.

$[Co(CNBF_2)(DBF_2)_2Imd]$: To 15 m*l* of boron trifluoride etherate there was added 0.5 g of $[CoCN(DH)_2Imd]\cdot \frac{1}{2}H_2O$, and the resulting red solution was kept standing overnight at room temperature. The precipitates were collected and worked up as above to give 0.8 g (86%) of fine, thin, yellow crystals, mp >300°C.

28) "Inorganic Syntheses," **2**, 186, 188 (1946).

*1 Without the filtering of the unidentified by-product, the crystallization of the produced complexes did not proceed smoothly.

*2 A desired complex could not be isolated when the base was added to the reaction mixture before potassium cyanide was added.

*3 When nicotinic acid, 5-amino-4-imidazolecarboxamide, or 6-aminopurine was used, a large amount of ethanol should be used for obtaining a clear solution because of the low solubility of these bases in ethanol.

*4 The similar treatment of 2-vinylpyridine did not afford any complex.

Found: N, 17.90%. Calcd for $[Co(CNBF_3)(DBF_2)_2\text{-}Imd]$: N, 17.93%.

$[Co(C_6H_5CH{=}CH)(DH)_2Imd]$ and $[Co(DH)_2Imd]\cdot H_2O$: Air in a suspension of 1.5 g (0.0037 mol) of $[CoCl(DH)_2Imd]$ in 10 m*l* of 80% methanol was completely removed at −70°C under a high vacuum. With strictly excluded air, a solution of 0.15 g (0.004 mol) of sodium tetrahydridoborate in a small amount of water was added to the reaction mixture. The mixture turned greenish-brown. Again, in the absence of air, 0.6 m*l* (0.0049 mol) of phenylacetylene was added to the reaction mixture and the mixture was kept standing overnight at room temperature. The resulting yellow crystals were collected and worked up as above to give 0.4 g (30%) of $[Co(DH)_2Imd]\cdot H_2O$, mp >300°C.

Found: C, 36.07; H, 5.23; N, 22.93%. Calcd for $[Co(DH)_2Imd]\cdot H_2O$: C, 35.93; H, 5.93; N, 22.53%.

The red filtrate was condensed to 30 m*l*, and the resulting orange needles were collected and recrystallized from chloroform to afford 1 g (60%) of $[Co(C_6H_5CH{=}CH)(DH)_2Imd]$, mp 232—233°C.

Found: C, 49.46; H, 5.68; N, 18.22%. Calcd for $[Co(C_6H_5CH{=}CH)(DH)_2Imd]$: C, 49.11; H, 5.52; N, 18.24%.

Measurements. The melting points were determined by a Yanagimoto micromelting-point apparatus and are uncorrected. The infrared spectra were measured in KBr pellets with a JASCO, Model IR-S infrared spectrometer, while the far-infrared were measured with a Perkin-Elmer grating infrared spectrometer, Model 337. All the ultraviolet and visible spectra were taken in methanol with a JASCO recording spectrometer, Model ORD/UV-5.

The authors would like to express their deep thanks to the Takeda Science Research Foundation for supporting this work in part.

A Mechanistic Approach to the Electrolytic Reductive Dimerization of Acrylonitrile

Teruzo ASAHARA, Manabu SENŌ and Takeshi ARAI*1

Institute of Industrial Science, The University of Tokyo, Minato-ku, Tokyo

(Received February 24, 1968)

The electrolytic reductive dimerization of acrylonitrile was investigated extensively especially in order to obtain some mechanistic information. The essential point of this reaction exists in the selective formation of adiponitrile under relatively wide conditions and this cannot be explained by a normal kinetic treatment based on the reaction scheme which has been accepted as probable. The heterogenuity in acrylonitrile concentration in the reaction system is assumed and the kinetic formulas are modified. This treatment explains the experimental results very satisfactorily. In order to confirm this mechanistic scheme, the effects of temperature, pH and solvents on the yield of reaction products were examined. All the results are consistent with the proposed mechanism.

Recently Baizer[1] *et al.* carried out extensive studies on the electro-reductive dimerization of acrylonitrile and other vinyl compounds. Their work is limited to examining the conditions for exclusive preparation of hydro-dimers and the reaction mechanism for this process is not yet clarified in detail. Therefore, the extensive studies have been designed to examine the effect of the experimental conditions on the electro-reductive dimerization of acrylonitrile to get some mechanistic information for this process. In the present paper, the effects of current densities, concentrations of acrylonitrile, temperatures, pH and solvents on the formation of adiponitrile, propionitrile and oligomers from acrylonitrile will be examined and discussed.

Experimental

Apparatus. As shown in Fig. 1, the reaction cell is a cylindrical separable flask of the area of the bottom of 0.3 dm^2, equipped with an inlet tube for N_2 gas, a thermometer, a glass electrode for the measurement of pH value, a platinum anode, a separatory funnel and a cooler with dry-ice acetone mixtures. There are a mercury pool at the bottom as the cathode, and a junction connected with a saturated calomel electrode. The separatory membrane was not used in this apparatus.

Chemicals. Tetraethylammonium *p*-toluenesulfonate (QAS), used as a supporting electrolyte, was prepared according to the method reported by Baizer. It was confirmed by IR spectrum to contain neither amine nor ester. Commercially available acrylonitrile was used after treatment with calcium chloride followed by distillation twice. Calcium sulfate and methylene dichloride were used without further treatments.

Electrolytic Reduction. A QAS solution was placed into the electrolytic cell and, while N_2 gas was passed through, a definite amount of acrylonitrile was added and then the electrolysis was initiated, the temperature being kept constant. The formation of precipitates in a small quantity was observed in a cathode region during electrolysis. After a definite period of electrolysis, the electrolysed soltuion was neutralized, cooled with water and transferred into a separatory funnel. The 200 m*l* of water was added and, after the precipitates were removed, the water layer was extracted four times with each 50 m*l* of methylene dichloride, and the extracts were combined to the acrylonitrile layer. The combined solution was washed with water twice, dried with calcium sulfate, and methylene dichloride was removed by distillation. The residue was analysed by gas chromatography (Shimadzu GC-1C, column Tween 80 on Chromosorb P).

The precipitates were purified twice through reprecipitation with dimethylformamide and water and analysed by IR and vapor pressure osmometer measurements.

Electrolytic Potential and Electrolytic Current. The relation of the electrode potential and the electrolytic current to the applied voltage are shown in Fig. 2 in the cases of the absence and the presence of acrylonitrile. By the addition of acrylonitrile the cathode potential decreases significantly and the electrolytic current increases. There is some difference between the reduction potentials of acrylonitrile and QAS, as shown in Fig. 3.

Conditions of Electrolysis. In all the experiments, the total volume of the reaction solution was 100 m*l*. The current efficiency was calculated under the assumption that the theoretical electric quantity of 2 faradays is required for the formation of each 1 mol of adiponitrile.

Products of Electrolysis. The formation of propionitrile and adiponitrile was detected by GLC and IR measurements. The product precipitated from water was confirmed to be oligomers of acrylonitrile by the

Results and Discussion

Baizer[1] has established the process of electrolytic preparation of adiponitrile from acrylonitrile. The essential point of this method exists in the use of McKee's salt. Acrylonitrile dissolves or disperses into water to 4.5 wt% at room temperature in the presence of McKee's salt and McKee's salt is almost inactive to the electrode reaction even in the range of cathode potential sufficiently high for the reduction of acrylonitrile. The reaction

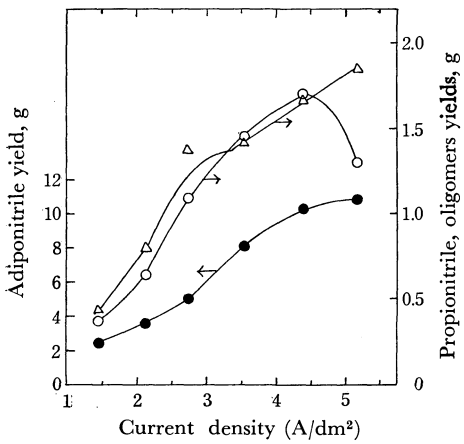

Fig. 4. Relation of yields and current density.
● Adiponitrile, ○ Propionitrile, △ Oligomers

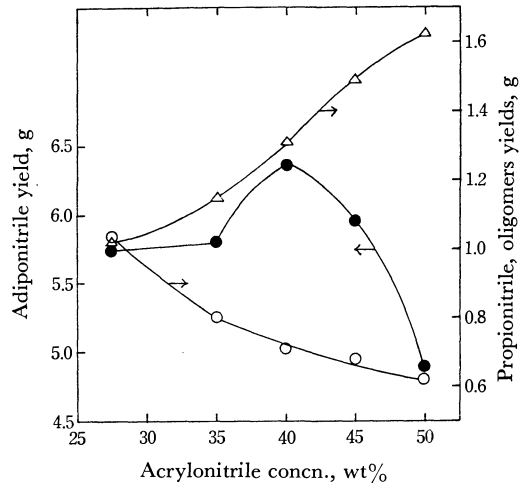

Fig. 5. Relation of yields and acrylonitrile concentration.
● Adiponitrile, ● Propionitrile, △ Oligomers

conditions, under which adiponitrile is a main product, were elucidated by Baizer as follows; the acrylonitrile concentration is in the range from 10 to 40 wt% in water and the cathode potential is about −2.0 V *vs.* SCE.

Although the principal feature of this reaction became clear by Baizer's pioneer work, further examination would be necessary to get some mechanistic information. In Figs. 4 and 5, the effect of current densities and acrylonitrile concentrations on the yields of reaction products are shown in the vicinity of optimum conditions for the adiponitrile formation.

It is considered that these results confirm the following reaction scheme which was originally suggested by Baizer and modified in part in the present work;

$$CH_2CHCN \xrightarrow[k_1]{2e} \overset{\ominus}{C}H_2\overset{\ominus}{C}HCN \longrightarrow$$

$$\begin{cases} \xrightarrow[k_2]{2H^+} CH_3CH_2CN \\ \xrightarrow[k_3]{AN} NC\overset{\ominus}{C}HCH_2CH_2\overset{\ominus}{C}HCN \longrightarrow \end{cases}$$

$$\begin{cases} \xrightarrow[k_4]{2H^+} NCCH_2CH_2CH_2CH_2CN \\ \xrightarrow[k_5]{AN} \text{oligomers} \end{cases}$$

The initial step of 2-electron reduction is confirmed by polarographic examination.[2)]

The kinetic treatment under the assumption of stationary state for the intermediate dianions leads the following formula for the formation rates of propionitrile (PN), adiponitrile (ADN) and oligomers (olig) of acrylonitrile.

$$\frac{d[PN]}{dt} = \frac{k_1k_2[AN][H^+]^2I}{k_2[H^+]^2+k_3[AN]}$$

$$\frac{d[ADN]}{dt} = \frac{k_1k_3k_4[AN]^2[H^+]^2I}{(k_2[H^+]^2+k_3[AN])(k_4[H^+]^2+k_5[AN])}$$

$$\frac{d[olig]}{dt} = \frac{k_1k_3k_5[AN]^3I}{(k_2[H^+]^2+k_3[AN])(k_4[H^+]^2+k_5[AN])}$$

where k_1, k_2,$\cdots$ are the rate constants corresponding to each step of reactions, and I denotes the current density.*2 The effect of the current density and the acrylonitrile concentration as shown in figures above are explained by these formulas. However, there is one important point that is completely inconsistent with these kinetic results, which were derived under the assumption of the uniformity through the reaction system. That is, this treatment leads to the result that the rate of formation of PN is always larger than that of ADN, if the ratio of rate constants k_2/k_3 is comparable to the ratio k_4/k_5, but Baizer's result and the present result show the reverse result; the main product in this reaction system is adiponitrile even when the AN concentration is so low as 10% as shown by Baizer.

2) T. Asahara, S. Hayano, M. Senō and H. Kaneko, *Denki Kagaku (J. Electrochem. Soc. Japan)*, **35**, 882 (1967).

*2 In these equations, the exponent 2 on the proton concentration comes from the overall reaction formula in which one dianion reacts with two protons. But the rate-determining step in this protonation reaction is not clear and, therefore, the reaction order regarding protons is not conclusive.

This experimental result is confirmed more clearly from the investigation for the rates of formation of PN and ADN, the result of which is shown in Fig. 6.

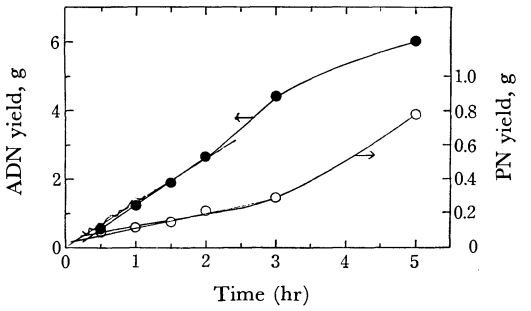

Fig. 6. Rates of formation of propionitrile and adiponitrile.

If the reaction mechanism as mentioned above would be valid, this essential behavior should be interpreted from the following reasons. Propionitrile is formed through the successive attacks of protons or proton donors to the dianion $\overset{\ominus}{C}H_2\overset{\ominus}{C}HCN$ at any positions and, on the other hand, adiponitrile is formed only through the attack of acrylonitrile to the dianion at the β-position to the nitrile group. Therefore, to explain the present result, it should be considered that the protonation ability in this system is very weak or the propionitrile dianion would be easily attacked by acrylonitrile at the β-position under the present circumstance.

In order to examine the first possibility, the effect of pH was investigated. The result is shown in Table 2. In general, the yield of propionitrile is high under the acidic condition and the yield of adiponitrile is high under the basic condition, as expected, but there is no definite quantitative correlation between pH and the product yield, and the property of each reagent used for the adjustment of pH clearly gives rise to a characteristic behavior. For example, acetic acid depresses very strongly the formation of adiponitrile, but sulfuric acid has no remarkable effect. This result reveals that the protonation ability is influenced by the physical situation of proton donors in the present system.

Moreover, it would be considered that this physical situation leads to the result that adiponitrile is formed as a main product in this reaction system. That is, taking this situation into consideration, we must modify the kinetic formula derived above under the assumption of the uniformity of the reaction system. Presumably the concentration of acrylonitrile is different in positions, *i. e.* the electrode surface and the bulk of solution, and the steps 2 and 3 of the reaction occur at the cathode surface and the steps 4 and 5 occur in the bulk. The kinetic treatment affords the following formulas;

Table 2. Effects of pH on electrolysis of acrylonitrile

2) Current efficiency
3) From vapor pressure osmometer
4) Trace of biscyanoethyl ether was dectected.

$$\frac{d[PN]}{dt} = \frac{k_1k_2[AN]^*[H^+]^*I}{k_2[H^+]^*+k_3[AN]^*}$$

$$\frac{d[ADN]}{dt} = \frac{k_1k_3k_4[AN]^{*2}[H^+]^2I}{(k_2[H^+]^{*2}+k_3[AN]^*)(k_4[H^+]^2+k_5[AN])}$$

$$\frac{d[olig]}{dt} = \frac{k_1k_3k_5[AN]^{*2}[AN]I}{(k_2[H^+]^{*2}+k_3[AN]^*)(k_4[H^+]^2+k_5[AN])}$$

where [ ] stands for the concentration in the bulk and [ ]* stands for that at the cathode surface.

If it is assumed from the above consideration that $[AN]^*>[AN]$ and $[H^+]^*<[H^+]$, the experimental behavior is well explained. For instance, if the concentration of acrylonitrile is larger than that of protons in the bulk, the yield ratio of adiponitrile to propionitrile is expressed from the above formulas as follows;

$$\frac{d[ADN]}{d[PN]} = \frac{k_3k_4}{k_2}\frac{[H^+]^2[AN]^*}{[H^+]^{*2}(k_4[H^+]^2+k_5[AN])} \simeq \frac{k_3k_4}{k_2k_5}\left(\frac{[H^+]}{[H^+]^*}\right)^2\left(\frac{[AN]^*}{[AN]}\right)$$

From the assumption that the ratio k_2/k_3 is in a comparable order to the ratio k_4/k_5 it could be expected that adiponitrile becomes a main product in this reaction system if the adsorption of acrylonitrile at the cathode surface takes place to a great extent.

This assumption seems to be probable from the reason that the cathode surface is active for the adsorption of polarizable organic molecules and is consistent with the concept of formation of organic layer at the electrode surface by Tomirov *et al.*[3] The direct measurement on the adsorption is now under examination.

3) L. G. Feoktistov, A. P. Tomirov and I. G. Sevastyanova, *Electrochimiya*, **1**, 1300 (1965).

The effect of the adsorption of acrylonitrile onto the cathode surface is cosidered to appear in many aspects. The effect of reagents for the pH adjustment was mentioned already and the effect of temperature should be examined. The result is shown in Fig. 7. The yield of ADN remains to be almost constant, but the yield of propionitrile increases with the increasing temperature. This result is thought to be probable from the consideration on the adsorption equilibrium; the adsorbed amount of acrylonitrile decreases relatively with the rise in temperature. The constancy in the adiponitrile yield should be attributed to the increasing reactivity of the adsorbed acrylonitrile with temperature.

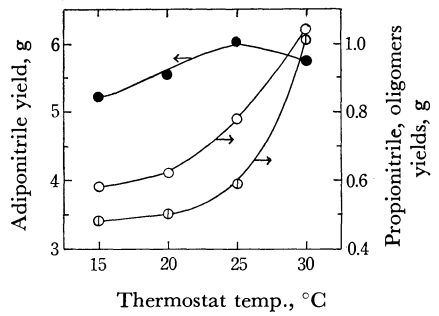

Fig. 7. Relation of yields and temperature.
○ Propionitrile, ● Adiponitrile,
◑ Oligomers

As has been discussed above, this reaction occurs through the anionic intermediates and the reactivity of those anions play an essential role in the present system and thereby the solvent effect should be anticipated. Some examinations were carried out in this respect and the result is shown in Table 3. It is clear that the higher the dielectric constants or the ionization potentials of the solvent, the less

● Adiponitrile, ○ Propionitrile,
◑ Total

the yield of adiponitrile. This shows that the extent of the solvation of ion-pairs influences the reaction. Since the free dianions react with protons more easily than the ion-pairs of the dianions and ammonium cations, this shows also that the dianions react with acrylonitrile in a near-adsorbed state at the vicinity of the cathode.

In the present experiments, the current efficiency for the production of adiponitrile does not exceed 75%. It would be considered that this is owing to the contribution of the electrolysis of QAS, for the reduction potential of QAS is close to that of acrylonitrile.

In this connection, the time change of pH and the product yields were measured and the result is shown in Figs. 8 and 9. Under normal conditions, pH of the system becomes acidic as time passes, but no remarkable changes in the yields of products were observed.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1322—1324 (1969)

Studies of Acetothiolacetate

Shinichi Motoki and Tadao Sato

Department of Chemistry, Faculty of Science, Science University of Tokyo, Shinjuku-ku, Tokyo

(Received April 23, 1968)

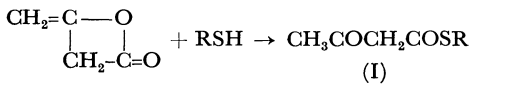
Ketene dimer reacted with mercaptan to give acetothiolacetate (I) in the presence of triethylamine. The ester I underwent a thermal condensation to give dehydroacetic acid (III), with the liberation of mercaptan, merely upon heating, and the reaction was effectively promoted in the presence of triethylamine. The ester I reacted with alkyl halide and acyl halide in dioxane to give α-alkyl and α-acylacetothiolacetate (II) respectively. Ethyl acetothiolacetate, ethyl α-methylacetothiolacetate, and ethyl α-acetylacetothiolacetate reacted with mercuric oxide at a low temperature to give diacetylacetone (VI), methyl ethyl ketone, and dehydroacetic acid (III) respectively.

Although there have been some indications of the differences between esters and thiolesters, acetothiolacetate (I) has been investigated extensively by only a few workers, including Cronyn[1] and Reid.[2]

The present work was undertaken in order to establish an effective way of preparing the ester I and in order to study the chemical properties of I and the related compounds.

In the present study, mercaptans were allowed to react with ketene dimer in the presence of triethylamine; acetothiolacetates (I) were thus conveniently prepared in 30—56% yields.*1

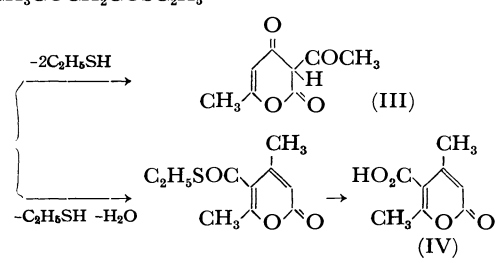
The synthesis of I was unsuccessful when sulfuric acid or *p*-toluenesulfonic acid was used as the catalyst because of contamination by persistent impurities.*2



$$CH_2{=}C(-O)-CH_2-C{=}O \;+\; RSH \;\rightarrow\; CH_3COCH_2COSR \quad (I)$$

Ia) $R=C_2H_5$ Ib) $R=(CH_3)_2CH$
Ic) $R=C_2H_5(CH_3)CH$ Id) $R=(CH_3)_3C$

It has been known that 2 mol of ethyl acetoacetate lose 2 mol of ethanol when heated at about 200°C; giving dehydroacetic acid (III) in a 53% yield.[3] Similarly, it has been found that a considerable amount of Ia can be converted into III even at 100—120°C with the liberation of mercaptan. Since the anion stability of the ethylmercapto group is greater than that of the alkoxyl group, mercaptan is more readily eliminated than alcohol from the corresponding esters.



$$2\,CH_3COCH_2COSC_2H_5 \longrightarrow$$

$-2C_2H_5SH$ → (III)

$-C_2H_5SH\ -H_2O$ → C_2H_5SOC → HO_2C (IV)

The addition of a small amount of triethylamine caused a marked increase in the yield of III, whereas the reaction was not accerelated by sodium acetate. On the other hand, acetic acid rather hindered the reaction and cold concentrated sulfuric acid caused it to give isomeric isodehydroacetic acid (IV).

Table 1. Preparation of acetothiolacetate (CH_3COCH_2COSR)

Table 2. Thermal condensation of Ia

Catalyst	g	Product	Yield %	Recovered ester %
none	—	dehydroacetic acid	38	60
$(C_2H_5)_3N$	0.2		75	20
$NaHCO_3$	0.2		58	35
CH_3CO_2Na	0.2		35	40
CH_3CO_2H	0.2		8	80
H_2SO_4	—	isodehydroacetic acid	23	—

This thermal condensation was also extended to α-alkyl and α-acylacetothiolacetate. The alkylation and acylation of Ia were carried out by ordinary methods with the aid of sodium in dioxane, in which the sodium salt of Ia was readily dissolved. The NMR spectra of the products showed that the *C*-alkylated and *C*-acylated compounds were exclusively obtained. However, since these substituted acetothiolacetates were stable at higher temperatures even in the presence of triethylamine, the expected compounds V were not obtained.

On the other hand, when yellow mercuric oxide was added to Ia at room temperature, a vigorous reaction took place and mercury ethylmercaptide was formed, along with carbon dioxide. At lower temperatures, the reaction proceeded slowly to give a substance melting at 44—46°C. It was not the expected dehydroacetic acid, but was identfied as diacetylacetone (VI) by elementary analysis and by conversion into its bisphenylhydrazone.

Similarly, the reaction of ethyl α-methylacetothiolacetate (IIa) with mercuric oxide gave a small amount of methyl ethyl ketone, whereas ethyl α-acetylacetothiolacetate (IIc) yielded acetylacetone and III.

$$CH_3COCH_2COSC_2H_5 + HgO \longrightarrow$$

Experimental

Acetothiolacetic Acid Esters (I). To 0.35 mol of mercaptan containing 0.2 m*l* of triethylamine, 0.35 mol of the ketene dimer was added, drop by drop, over a 1-hr period at the boiling point of the mercaptan. After 1 hr, the reaction mixture was distilled and the corresponding acetothiolacetate was obtained.

In the case of the ethyl ester, the procedure had to be modified slightly to prevent the evaporation of ethylmercaptan. To 0.35 mol of ethylmercaptan containing 0.2 m*l* of triethylamine, 0.35 mol of the ketene dimer was added, drop by drop, over a 1-hr period at 0—5°C. The mixture was then stirred at room temperature until the odor of the ketene dimer was lost. Then the mixture was distilled. These results are shown in Table 1.

Ethyl α-Alkyl and α-Acylacetothiolacetate (II). To a suspension of 0.17 g atom of sodium in 60 m*l* of dioxane, 0.18 mol of Ia was added, drop by drop, at room temperature. After the sodium had dissolved, 0.18 mol of alkyl halide or acyl halide was stirred in at such a rate that the temperature did not exceed 50°C. The mixture was then stirred at the same temperature for 4 hr. After cooling, the sodium halide was filtered off and the filtrate was concentrated under reduced pressure. The residue was distilled to give ethyl α-alkyl and α-acylacetothiolacetate (II).

Dehydroacetic Acid (III). (Thermal Condensation of Ia). Ten grams of Ia containing 0.2 g of a catalyst were heated in an oil bath at 100—120°C. The evolution of ethylmercaptan was observed. After 2 hrs' heating, the reaction mixture was distilled to give III and recovered Ia. The results are summarised in Table 2.

Isodehydroacetic Acid (IV). The procedure of

the reaction of Ia with sulfuric acid was similar to that described in the preparation of IV from ethyl acetoacetate.[4] The product was recrystallised from benzene; yield, 22.5%; mp 153°C, undepressed upon admixture with an authentic sample of IV.

The Reaction of Ia with Mercuric Oxide. Ia (29 g, 0.2 mol) was added to a suspension of yellow mercuric oxide (21 g, 0.1 mol) in 60 m*l* of ether over a one-hour period between −20°C and −30°C. After the mixture had then been stirred a further 35 hr at the same temperature, mercury mercaptide (mp 85°C recrystallised from ethanol) was filtered off and the ether was evaporated. The residue was distilled to give fractions boiling at 105—118°C/8 mmHg. The distillate solidified on cooling and was recrystallised from petroleum ether to give pure diacetylacetone (VI), mp 44—46°C; yield, 5 g, and bisphenylhydrazone, mp 140—142°C, undepressed by admixture with an authentic sample.*3

Found; C, 58.99; H, 7.12%; mol wt (Cryoscopy in benzene), 140.3. Calcd for $C_7H_{10}O_3$: C, 59.14; H, 7.09%; mol wt, 142.2.

The Reaction of IIc with Mercuric Oxide. IIc (38 g, 0.2 mol) was added, drop by drop, to a suspension of yellow mercuric oxide (21 g, 0.1 mol) in 60 m*l* of ether over a 1-hr period at 0—5°C. After the mixture had then been stirred for 48 hr at the same temperature, the mercaptide thus precipitated was filtered off and the filtrate was distilled. Two fractions, boiling at 120—140°C and at 120—135°C/5 mmHg, were collected. The first fraction was redistilled to give 6 g of acetylacetone, bp 135—138°C. It was identified by the formation of the semicarbazone, mp 108—110°C, undepressed on admixture with a sample prepared from commercial acetylacetone. The second fraction immediately solidified and was recrystallised from ethanol to give 3 g of III, mp 109°C.

The authors wish to thank Professor Yojiro Tsuzuki for his helpful advice and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1324—1328 (1969)

Kinetic Studies of Oxygen Exchange and Racemization Reactions of Diaryl Sulfoxides in Sulfuric Acid of Various Concentrations[1)]

Norio KUNIEDA and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received May 9, 1968)

When ^{18}O-labeled and optically active sulfoxides are dissolved in a concentrated sulfuric acid, one observes the concurrent oxygen exchange and racemization reactions of the sulfoxides, and these reactions were found to proceed through the S_N1-like path (S. Oae *et al.*, Bull. Chem. Soc. Japan, **38**, 546 (1965); **41**, 696 (1968)). We have found that the concurrent oxygen exchangeand racemization reactions also take place even in less concentrated sulfuric acid at somewhat higher temperature, *i. e.* 70% sulfuric acid at 30°C, and proceed through a different mechanistic route, very likely an S_N2-like path. Kinetic investigation on these reactions in sulfuric acid of various concentrations (66.5—96.3%) suggests there is a gradual change of mechanism of the reaction, *i. e.* from S_N2 type in 66.5% to S_N1 type in 96.3% with the increase of the concentration of sulfuric acid.

Sulfoxides, being of stable pyramidal structure, can be resolved to a pair of optically active enantiomers when two substituents on the sulfur atom are different.[2)] Meanwhile, a convenient method of synthesizing optically active sulfoxides has recently been developed.[3)] Therefore one can now study the stereochemistry of reactions of the sulfoxides very readily using these optically active compounds.[4)] The concurrent oxygen exchange and racemization reaction of sulfoxides are particularly useful for the stereochemical studies on nucleophilic reaction on the trivalent sulfur atom, because one can readily prepare both ^{18}O-labeled and optically active

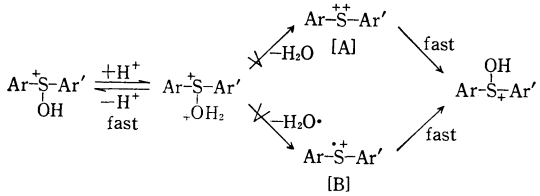
sulfoxides while the analysis of ^{18}O-content in sulfoxides is also quite facile. We have reported previously[5] that the rate of the oxygen exchange of ^{18}O-labeled, optically active *p*-tolyl phenyl sulfoxide was identical to that of the racemization in 95.5% sulfuric acid and the rates of the racemization were nicely correlated with $-H_0$ (slope=1.1) in the range of concentration from 96.3% to 91.8% of sulfuric acid. In the meantime, the polar effect of *p*-substituent on phenyl ring on the rates of both oxygen exchange and racemization in 95.5% or 96.2% sulfuric acid was found to be very small, while a noticeable ESR signal was detected with 96% sulfuric acid solution of a *p,p'*-disubstituted diphenyl sulfoxide.[6] From these observations we have postulated the following S_N1-like mechanism for these reactions, and favored the homolytic cleavage of the S–O bond, the route involving [B].



Previously, a preliminary experiment on the oxygen exchange and racemization reactions of diaryl sulfoxides was conducted in a sulfuric acid of less than 85% concentration at around 0°C[5b] and found to proceed very little. Meanwhile, we have found that these sulfoxides undergo concurrent oxygen exchange and racemization reactions with much weaker acids such as acetic, perchloroacetic acids when heated at much higher temperatures.[7] Accordingly, it was thought that the oxygen exchange reaction should take place even in dilute sulfuric acid at somewhat higher temperatures. In fact, we have found that diaryl sulfoxides undergo oxygen exchange and racemization reactions readily in a sulfuric acid of even less than 85% concentration when the reaction was carried out at considerably higher temperatures (30—50°C). We now have compiled substantial amounts of kinetic data on these reactions of diaryl sulfoxides in sulfuric acid of various concentrations (66.5—96.3%) and hence would like to report detailed accounts of the kinetic results and their implications to the mechanistic interpretations on these reactions.

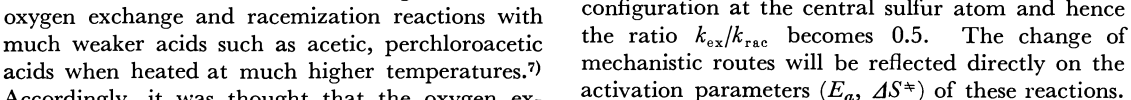
Results and Discussion

At first, careful kinetic experiments were conducted on the rates of both oxygen exchange and racemization reactions of *p*-tolyl phenyl sulfoxide (0.935 atom%-^{18}O, $[\alpha]_D^{25}$ +27.8° in 96% ethanol) in sulfuric acid of various concentrations ranging between 66.5% and 96.3% at several temperatures between 0 and 60°C. The results are shown in Table 1. The sulfoxide was found to be racemized even in 66.5% sulfuric acid at a higher temparature. The mechanistic interpretation of these results will be discussed in the light of first the values of k_{ex}/k_{rac} and activation parameters, the correlation with H_0 (Zucker-Hammett hypothesis), and then the Bunnett's *w*-values.

Variation of k_{ex}/k_{rac} Values and Activation Parameters. The concurrent oxygen exchange and racemization reaction of sulfoxides in acid media may proceed through the following two extreme mechanistic routes as shown below.



When the reaction proceeds through the S_N1-like route, each oxygen exchange will cause racemization, and the ratio k_{ex}/k_{rac} becomes unity. Whereas if it passes through the S_N2-like route each oxygen exchange will result in the inversion of configuration at the central sulfur atom and hence the ratio k_{ex}/k_{rac} becomes 0.5. The change of mechanistic routes will be reflected directly on the activation parameters (E_a, $\Delta S^{\neq}$) of these reactions. Therefore these parameters were estimated and the k_{ex}/k_{rac} values and activation parameters thus obtained in several concentrations are listed in Table 2.

As shown in our previous paper,[5] the k_{ex}/k_{rac} and $\Delta S^{\neq}$ values observed in a concentrated sulfuric acid (95.5% or 95.9%) were 1 and 11.5 *e. u.* respectively, suggesting that the reaction proceeds through a route involving the S_N1-like S–O bond cleavage at the rate determining step. However, in about 75% sulfuric acid, the k_{ex}/k_{rac} and $\Delta S^{\neq}$ values, are 0.5 and −18 *e. u.* respectively, indicating that the reaction proceeds through a different mechanistic route, *i. e.* very likely an S_N2-like process, from that in concentrated sulfuric acid. For example, the $\Delta S^{\neq}$ value of the racemization reaction of (+)-*p*-tolyl phenyl sulfoxide with acetic anhydride which show the typical S_N2-like mechanism is −28.6 *e. u.*[8] One finds in Table 2, that both

k_{ex}/k_{rac} and $\Delta S^{\neq}$ values change with the change of the concentration of sulfuric acid. The gradual increase of both k_{ex}/k_{rac} and $\Delta S^{\neq}$ values with the increase of the acid suggests that there is a gradual shift in the mechanism of the reaction from S_N2-like in about 75% sulfuric acid to S_N1-like in about 95% acid.

The Correlation with H_0-Values. The rates of many acid-catalyzed reactions are dependent on the concentrations of acid. However, the role of acid and solvent, usually water, varies depending on the reaction conditions and reactants. The Zucker - Hammett hypothesis[9] has been most widely used to gain an insight into the mechanisms of these acid-catalyzed reactions. They classified mechanisms of many acid-catalyzed reactions into the following two classes, the one (*i. e.* A-1 type) is a group of reactions which give linear plots of log *k* against $-H_0$, and belongs to a family of S_N1-like processes, and the other (*i. e.* A-2 type) is the group which give linear plots of log *k* against log-[HX], belonging to a family of S_N2-like reactions. A diagram correlating the logarithms of the rates of both oxygen exchange ($\log k_{ex}$) and racemization ($\log k_{rac}$) of *p*-tolyl phenyl sulfoxide against the $-H_0$ values of sulfuric acids of various concentrations ranging from 66.5% to 96.3% are shown in Fig. 1. In concentrated sulfuric acid (86.9% to 96.3%), both $\log k_{ex}$ and $\log k_{rac}$ values are in a

9) M. A. Paul and F. A. Long, *Chem. Revs.*, **57**, 935 (1957); L. Zucker and L. P. Hammett, *J. Am. Chem. Soc.*, **61**, 2791 (1939).

linear relationship with $-H_0$ functions[10] both at 5°C and 30°C, with the slope=1.14, r (correlation coefficient)=0.999 at 5°C. This means that a protonated species is involved in the transition state of the reaction and the reaction is of the A-1 type mechanism. However, as the concentration of sulfuric acid decreases from 86.9%, the plots of $\log k_{ex}$ and $\log k_{rac}$ starts to deviate markedly from the linear slope, suggesting that the reaction is gradually shifted from A-1 type to other with the decrease of the concentration of sulfuric acid. Although we could not find any good relationship of $\log k$ values with those of log[HX], the mechanism of the reaction in less concentrated sulfuric acids is definitely different from that with concentrated sulfuric acid as mentioned in the preceding discussion of both k_{ex}/k_{rac} and $\Delta S^{\neq}$ values.

The Correlation with Bunnett's w-Values. The w-value is an empirical function presented by Bunnett[11] and is defined by the following equation.

$$(\log k + H_0) = w \log a_{H_2O} + C$$

This parameter, w, is associated with characteristic mode of involvement of water at the rate-determining step of a reaction and according to the magnitude of the w-value many acid-catalyzed reaction can be divided into three groups. In the first group of reactions in which w is between -2.5 to 0, water does not participate in the transition state. In the second group, in which w is between $+1.2$ and $+3.3$, water acts as a nucleophile, while in the last where $w>+3.3$, water acts as a proton transfer agent. The actual diagram plotted with $(\log k+H_0)$ against $\log a_{H_2O}$ are shown in Fig. 2. Apparently, there is a gradual shift of mechanism with the change of the concentration of sulfuric acid. In fact, the w-value in the range of concentration from 75.4 to 66.5% sulfuric acid

is $+1.28$ ($r=0.998$) which corresponds to the second group of reactions that belong to S_N2-like mechanism whereas in a sulfuric acid of above 86.9% concentration the w-value is -0.06 ($r=0.990$) which is in the range of S_N1-like mechanism.

Mechanistic Change from S_N1 to S_N2 Type Pathways. The k_{ex}/k_{rac} values, the activation paramaters, the correlation with Hammett's H_0 functions and that with Bunnett's w-values show that the concurrent oxygen exchange and racemization reaction of *p*-tolyl phenyl sulfoxide in the less concentrated sulfuric acids proceed through an S_N2-like pathway which is quite different from an S_N1-like route through which the oxygen exchange and racemization reactions in a cancentrated sulfuric acid proceeds. As described in the previous section the shift of the mechanism of the reaction from

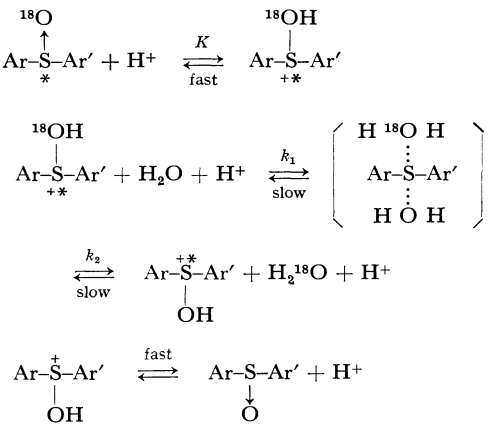
10) M. A. Paul and F. A. Long, *Chem. Revs.*, **57**, 1 (1957). When the H_0 values of Jorgenson and Hartter were used, the slope of this correlation was smaller slightly than 1; J. Jorgenson and D. R. Hartter, *J. Am. Chem. Soc.*, **85**, 878 (1963).

11) J. F. Bunnett, *J. Am. Chem. Soc.*, **82**, 499 (1960); **83**, 4956 (1961); **83**, 4968 (1961); **83** 4973 (1961); **83**, 4978 (1961).

S_N2-like in less concentrated sulfuric acid to S_N1-like in concentrated acid is apparently gradual. This shift of mechanism is caused by the change of the character of sulfuric acid solution, namely, the proton-donating ability of the solution diminishes steadily as acid concentration decreases while the activity of water increases. If the S_N1-like cleavage of S–O bond of the sulfoxide takes place through the diprotonated species ($R_2S^+-{}^+OH_2$) in rate-determining step as we have suggested,[5b] the formation of this diprotonated species will be decreased as the acid concentration decreases.

Polar Effect in a Less Concentrated Sulfuric Acid. The overall scheme of the oxygen exchange reaction of diaryl sulfoxides in a less concentrated sulfuric acid may be formulated as shown below:



In order to comfirm the S_N2 like mechanism for this reaction, we have extended the oxygen exchange reaction on a few *p*-substituted diphenyl sulfoxides in 75.4% sulfuric acid, and the results are shown in Table 3. Except for the *p*-methoxyl compound, there is no difinite trend in the effect of these substituents and the rate varies very little (For σ^+-$\log k_{ex}$; $\rho=0.185$, $r=0.980$) like in case of S_N2 reaction of substituted alkyl halides, while the large negative $\Delta S^{\neq}$ values also suggests a S_N2-like mechanism for this reaction. The small positive value of ρ may be attributed to the fact that the polar effects on the two constants K and k in the equation for the observed rate, $k_{obs}\propto k_1K$, are canceled out considerably, since K is increased by a electron-accepting substituent while k is decreased by the same substitutent. The equilibrium constant (K) of the initial step of protonation is considered to be very large, since the pK_a values of diaryl sulfoxides are very small,[12] *i. e.* *p*-tolyl phenyl sulfoxide (−4.40) and diphenyl sulfoxide (−4.97), while H_0 function of 75.4% sulfuric acid is −6.35 and even that of 66.5% sulfuric acid is −5.20. Since the pK_a values are presumed to be the H_0 values of the half protonation of the sulfoxides, the sulfoxides are considered to be protonated nearly completely. Therefore, the second step of nucleophilic subsitution of the protonated sulfoxide by water (k_1) become the slow rate-determining step of the reaction. Only in the case of the *p*-methoxyl compound a small acceleration of rate observed, and both entropy and enthalpy of activation are off the trend of those of the other substituted sulfoxides. The mechanism of the reaction of this compound is probably different from that of the others, and similar to that of *p*-tolyl phenyl sulfoxide in a concentrated sulfuric acid, proceeding through an A-1 type route.

Experimental

Materials. *^{18}O-Labeled p-Substituted Diaryl Sulfoxides* were prepared by the oxidation of the corresponding sulfides with bromine complex of pyridine and ^{18}O-enriched water (1.63 atom%-^{18}O) in acetic acid by the same procedure as described in our previous paper.[13] *p*-X-C_6H_4-$S^{18}O$-C_6H_5; (X, mp (°C) (lit),[14] atom%-^{18}O). H, 70—71 (71), 0.955. CH_3, 71—71.2 (71—72), 0.935. CH_3O, 60 (55—57), 0.685. Cl, 45—46 (45—46), 1.23. NO_2, 107 (106—107), 0.996 (from 3.50 atom%-^{18}O-water).

Optically Active p-Tolyl Phenyl Sulfoxide was prepared from (−)-menthyl (−)-*p*-toluenesulfinate according to the method developed by Andersen.[3] mp 91.5—92°C, $[\alpha]_D^{25}=+27.8°$ in 96% ethanol ($l=0.5$, $c=1.63$) (lit[15]; mp 92—93°C, $[\alpha]_D=+27.0°$ in 95% ethanol).

Kinetic Procedure. The rates of the oxygen exchange and racemization were measured by the same procedures as described in our previous paper[5] using Yanagimoto OR-10 type polarimeter and Hitachi-RMU-6E type mass-spectrometer.

Sulfuric Acid. Concentrations of sulfuric acid-water media were determined by titration with a standard alkali solution. The H_0 values used here is from the tables of Paul and Long,[10] and the activity of water ($\log a_{H_2O}$) of a sulfuric acid solution was tabulated by Deno and Taft.[16]

Reaction of Salicylamine with α-Dicarbonyl Compounds. I. Transamination Reaction

Hajime KANATOMI and Ichiro MURASE

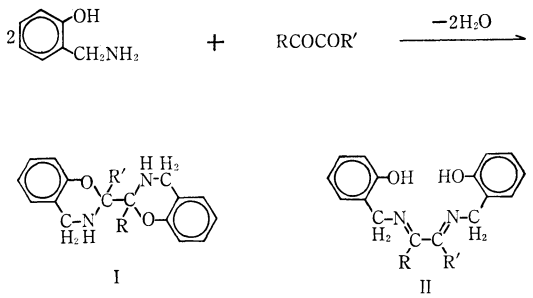
College of General Education, Kyushu University, Fukuoka

(Received July 4, 1968)

The reactions of salicylamine with α-dicarbonyl compounds were examined in the hope of obtaining 2,2′-bibenzoxazine derivatives I or Schiff bases II as two-to-one condensation products; however, salicylidenesalicylamine was isolated in every case. It was found that the reaction proceeded through transamination, followed by *trans*-Schiffization between salicylamine and α-dicarbonyl compounds. The mechanism and the conditions under which the reactions take place were investigated.

It has previously been reported by one of the present authors[1] that the condensation of *o*-aminophenols with α-dicarbonyl compounds proceeded with the formation of 2,2′-bibenzoxazoline and its derivatives, and that it did not afford ordinary Schiff base derivatives. It was further noted that the oxazoline could isomerize to a Schiff base-type anion by ring opening in the presence of bivalent metal ions and formed metal chelates where the anion was coordinated as a tetradentate ligand. Therefore, the Schiff base can exist only as a ligand anion of the metal chelate in this case.

The present investigation was undertaken to study whether a similar type of condensation occurs when salicylamine (*o*-hydroxybenzylamine) reacts with α-dicarbonyl compounds. The compounds expected as the condensation products were 2,2′-bibenzoxazines of the type I or Schiff bases of the type II.

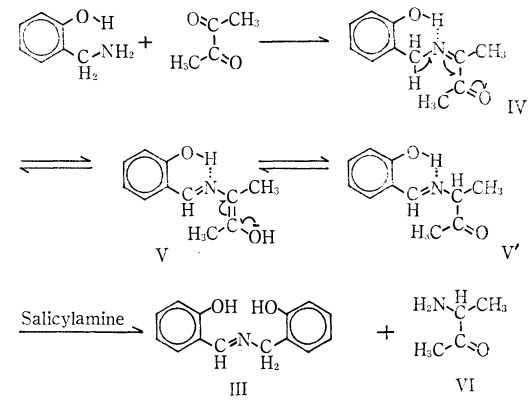


I II

The reaction of salicylamine with diacetyl was examined. When a mixture of two moles of the former and one mole of the latter was heated in methanol, yellow crystals, mp 183—184°C, were isolated. However, the compound with a molecular formula of $C_{14}H_{13}NO_2$, was neither the oxazine I nor the Schiff base II. It was easily confirmed to be salicylidenesalicylamine (III) from its infrared spectrum and by means of a mixed-melting point determination with an authentic sample.[2]

Accordingly, the mechanism of this unexpected reaction was first investigated in this paper.

Seto *et al.*,[3] have reported that salicylidenesalicylamine was isolated from an aqueous methanol solution of salicylamine by prolonged heating. The reaction was found to proceed by air oxidation, in which the amine was converted to aldimine, which was then readily hydrolized to salicylaldehyde. The aldehyde then reacted with unoxidized salicylamine to afford the Schiff base III. Although, in the present experiments, the reaction was carefully conducted under a nitrogen stream to avoid the otherwise inevitable air oxidation, the Schiff base III was always isolated in about a 40% yield.



Scheme I

1) I. Murase, This Bulletin, **32**, 827 (1959); **33**, 59, 607 (1960).

2) M. Yamaguchi, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **74**, 261 (1953).

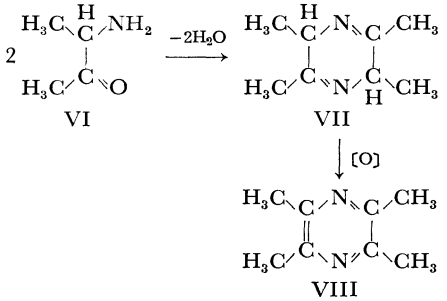
3) A. Takahashi and S. Seto, *Kogyo Kagaku Zasshi* (*J. Chem. Soc. Japan, Ind. Chem. Sect.*), **58**, 796 (1955).

Thus, the reaction did not proceed by the air oxidation of salicylamine; rather, diacetyl must have taken part in this reaction. The postulated reaction mechanisms are shown in Scheme I.

The formation of the Schiff base IV is the first step of an equimolar condensation between salicylamine and diacetyl. IV undergoes deprotonation from the methylenic group and protonation at the carbonyl oxygen, accompanied by a simultaneous electron shift, to form V, which is in equilibrium with its keto form, V'. The amine moiety of the two Schiff bases, V and/or V', is then replaced by unreacted salicylamine to give salicylidenesalicylamine (III). Thus, the overall reaction can be assumed to be transamination, followed by *trans*-Schiffization between salicylamine and diacetyl.

A similar reaction involving salicyamine has been reported by Witkop and Beiler,[4] who also isolated salicylidenesalicylalmine from the reaction mixture of salicylamine and pyridoxal. They claimed that the reaction proceeded through transamination, followed by a Schiff base exchange reaction which they termed "*trans*-Schiffization."

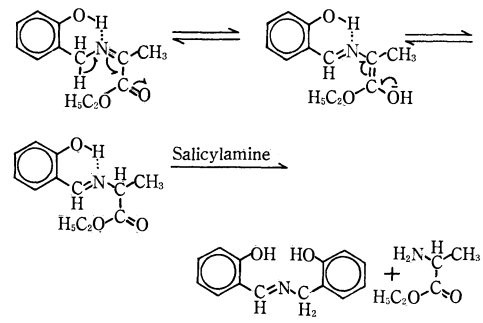
According to our reaction mechanism, the α-aminoketone VI should be liberated as a by-product of the *trans*-Schiffization; the determination of VI is another evidence of this mechanism. It should be noted, however, that an aliphatic α-aminoketone such as VI is, in general, very unstable and readily undergoes self-condensation to form dihydropyrazine VII, which is then readily air-oxidized to a pyrazine VIII. Thus, the formation of the α-aminoketone VI can be proven by the detection of either VII or VIII.



In our experiments, tetramethylpyrazine (VIII) was isolated from the reaction mixture; it was identified with an authentic sample[5] by means of the infrared spectra and by a mixed-melting point determination. The formation and isolation of VIII can be explained as resulting from the air-oxidation of VII, which has been formed from α-aminoketone VI in the reaction mixture, since the isolation and purification were unavoidable in an air atmosphere.

Different α-dicarbonyl compounds were also examined with salicylamine; the same type of reaction was found to proceed with methylglyoxal, acetylpropionyl, acetylisobutylyl, phenylglyoxal, acetylbenzoyl, and benzil, always giving rise to salicylidenesalicylamine. Among these, the reaction proceeded without a solvent for acetylbenzoyl; with the exception of acetylpropionyl and acetylisobutylyl, the others gave salicylidenesalicylamine in poor yields. Glyoxal was also examined, but no crystalline material was isolated. 5-Chlorosalicylamine as well as salicylamine reacted with diacetyl; 5-chlorosalicylidene-5'-chlorosalicylamine was thus obtained in about a 40% yield.

It was also found that the α-keto acid ester, *i. e.*, pyruvic acid ethyl ester, underwent the same type of reaction with salicylamine, and that salicylidenesalicylamine was thus obtained in a good yield. Since the amine moiety after *trans*-Schiffization should consist of the α-amino acid ester in this case, the determination was carried out by paper chromatography; α-alanine was detected in the reaction mixture from which salicylidenesalicylamine was isolated. It is clear that the reactions proceed in the same manner as in the case of the α-diketones. They are shown in Scheme II.



Scheme II

It is interesting with respect to this reaction to note that Nakahara *et al.*[6] have found the transamination reaction to occur from a salicylamine-pyruvic acid Schiff base to a salicylaldehyde-α-alanine Schiff base through the copper chelate. Since both Schiff bases can exist only as metal chelate ligands, the role of the metal ion may be to stabilize the azomethine linkage through the formation of a chelate ring. In the case of the ester, the Schiff base exists without any metal chelate formation; therefore, transamination could occur smoothly in the absence of metal ions.

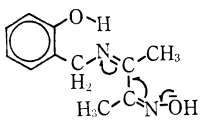
It can be seen from these pieces of evidence that

4) B. Witkop and T. W. Beiler, *J. Am. Chem. Soc.*, **20**, 5589 (1954).

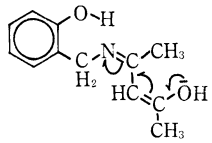
5) H. Gutknecht, *Ber.*, **12**, 2291 (1879); E. Braun, *ibid.*, **22**, 559 (1889).

6) Y. Nakao, S. Sasaki, K. Sakurai and A. Nakahara, This Bulletin, **40**, 241 (1967).

these types of transamination and *trans*-Schiffization proceed between salicylamines and α-dicarbonyl compounds except in the case of α-dialdehyde. The transamination may be due to a mesomeric effect of the carbonyl group in the Schiff base IV; this effect causes simultaneously an electron shift from the azomethine double bond to the C–C bond and deprotonation from the methylenic hydrogen. Accordingly, if there is any substituent to prevent the carbonyl group from exerting the electron-withdrawing effect, the transamination reaction will not occur. This was confirmed by the reaction of salicylamine and diacetyl monoxime, where a Schiff base IX was isolated in a good yield and where no further reactions were observed. It is clear that the electron-withdrawing effect of the carbonyl group was very much weakened by the oximino substitution and that, consequently, a further electron shift was prevented.



IX



X

The significant role of the α-carbonyl group of the Schiff base IV in the transamination was further supported by the fact that transamination did not occur on a Schiff base such as X with a β-carbonyl group. The Schiff base X which was obtained by the reaction of salicylamine with acetylacetone is stable in boiling methanol; the enol structure was suggested from its infrared spectrum which exhibited strong absorptions at 1603 cm^{-1} and 1540 cm^{-1}. Since the enol group enhances the negative charge at the azomethine nitrogen atom, as is shown in the case of X, deprotonation from the methylenic hydrogen becomes difficult.

Metzler *et al.*[7] have extensively studied non-enzymatic transamination between α-amino acid and α-keto acid catalyzed by pyridoxal and by pyridoxamine. They found that the reaction was accelerated by metal chelate formation with the Schiff bases of pyridoxal-amino acid or pyridoxamine-keto acid and claimed that the significance of the nitrogen atom of the pyridine ring of pyridoxal or pyridoxamine was that it caused an electron shift from the azomethine linkage towards the pyridine ring. The role of the metal ion was explained as enhancing the electronegativity of the azomethine nitrogen; however, no mention was made concerning the role of the carboxylate group adjacent to the azomethine linkage.

The fact that the transamination could occur even between salicylamines and α-dicarbonyl compounds in the absence of metal ion may be somewhat inconsistent with their explanation. As has been stated above, the significant role of the α-carbonyl group should be taken into consideration as an electron-withdrawing source towards its own sites.

The presence of the ortho hydroxyl group in salicylamine is favorable for transamination by facilitating the formation of the Schiff base IV through intramolecular hydrogen bonding with the azomethine nitrogen. This was evidenced by the fact that benzylamine with no hydroxyl group, did not react with either the diacetyl or the pyruvic acid ester.

The effect of the metal ion, through chelate formation, on this transamination is now being investigated; the synthesis of the initially-proposed compounds, I and II, will be reported in a subsequent paper.

Experimental

Reaction of Salicylamine with Diacetyl (Transamination and *trans*-Schiffization). Under a nitrogen stream, 3.7 g (0.03 mol) of salicylamine which had been carefully purified by sublimation and by recrystallization from ethanol were dissolved in 70 m*l* of methanol, and then 1.5 g (0.018 mol) of diacetyl were added. The solution was gently refluxed under a nitrogen stream for thirty minutes and then kept in a refrigerator overnight. The resulting yellow needles were filtered, and the filtrate was concentrated to about 15 m*l*; additional crystals were thus obtained. When they were recrystallized from methanol, 1.4 g of a pure sample, mp 183—184°C, were obtained in a yield of 41.3% based on the salicylamine. The mixed-melting point with salicylidenesalicylamine was 183°C, and their infrared spectra were identical, both exhibiting a C=N absorption at 1640 cm^{-1} (KBr disk).

Found: C, 73.39: H, 5.82; N, 6.20%. Calcd for $C_{14}H_{13}NO_2$: C, 73.54: H, 5.72: N, 6.16%.

After salicylidenesalicylamine had been isolated from the reaction mixture, the mother liquor was evaporated to dryness on a water bath; the remaining resinous material was then sublimed at 80°C under reduced pressure (30 mmHg). The colorless sublimates were collected and recrystallized from water. The melting point was 81—82°C; it showed no depression upon being mixed with an authentic sample of tetramethylpyrazine, and their infrared spectra were identical.

The reaction of salicylamine with acetylpropionyl, acetylisobutylyl, methylglyoxal, phenylglyoxal, and benzil were carried out in the same manner as above; salicylidenesalicylamine was isolated in every case. The yields for acetylpropionyl and acetylisobutylyl were almost the same as those cited above; however, those of the last three substances were less than 10%.

For acetylbenzoyl, the reaction proceeded without any solvent; thus, 0.12 g (0.001 mol) of salicylamine and 0.15 g (0.001 mol) of acetylbenzoyl were mixed and heated on a water bath under a nitrogen stream. The mixture soon melted and yellow needles were gradually deposited over a ten-minute period. After the mixture

7) D. E. Metzler, M. Ikawa and E. E. Snell, *J. Am. Chem. Soc.*, **76**, 648 (1954).

had been heated for thirty minutes, the resulting salicylidenesalicylamine was isolated by treating the mixture with ethanol.

Reaction of 5-Chlorosalicylamine with Diacetyl. This reaction was carried out in the same manner as in the case of salicyalmine; 5-chlorosalicylidene-5'-chlorosalicylamine, mp 201—203°C, was isolated in a 40% yield. IR: 1665 cm^{-1} (C=N).

Found: C, 56.88; H, 3.81; N, 4.66%. Calcd for $C_{14}H_{11}NO_2Cl_2$: C, 56.79; H, 3.72; N, 4.73%.

Reaction of Salicylamine with Ethyl Pyruvate. A mixture of 0.12 g (10^{-3} mol) of pure salicylamine and 0.06 g (5×10^{-4} mol) of ethyl pyruvate in 5 m*l* of methanol was gently refluxed under a nitrogen stream for one hour. The solution turned red orange, and salicylidenesalicylamine was crystallized on cooling. The yield was 0.04 g (40% based on the salicylamine) and a mixed-melting point determination with an authentic sample showed no depression (183°C). After the filtrate of salicylidenesalicylamine had been evaporated, the resinous residue was treated with a small amount of water and filtered. To the filtrate there was added one drop of concentrated hydrochloric acid; the mixture was refluxed for one hour and then evaporated to dryness. The residue was dissolved in a small amount of water, and the solution was subjected to paper chromatography. The R_f value of the sample was 0.38, identical with that of *d,l*-alanine ($R_f=0.38$; solvent, butanol : acetic acid : water=4 : 1 : 2).

Schiff Base of Salicylamine with Diacetyl Monoxime IX. A mixture of 0.48 g (0.039 mol) of pure salicylamine and 0.4 g (0.04 mol) of diacetyl monoxime in 25 m*l* of dry benzene was refluxed for one hour under a nitrogen stream. The solution was then concentrated to 10 m*l* under reduced pressure, and the resulting precipitates were recrystallized from benzene. Colorless crystals, mp 106—108°C; yield 0.6 g (80%). IR: 3250 cm^{-1} (NOH), 1645 cm^{-1} (C=N), 1609 cm^{-1} (C=NOH).

Found: C, 63.78; H, 6.79; N, 13.67%. Calcd for $C_{11}H_{14}N_2O_2$: C, 64.06; H, 6.84; N, 13.58%.

Schiff Base of Salicylamine with Acetylacetone (X). A mixture of 1.2 g (0.01 mol) of pure salicylamine and 1 g (0.01 mol) of acetylacetone in 10 m*l* of methanol was refluxed for one hour under a nitrogen stream. On cooling, 1.7 g of an almost pure Schiff base was obtained as colorless needles in a yield of 83%; it was recrystallized from methanol; mp 141—142.5°C. IR: 1603 cm^{-1}, 1540 cm^{-1} (probably C=N and C=C of enol).

Found: C, 69.88; H, 7.27; N, 6.99%. Calcd for $C_{11}H_{13}NO_2$: C, 70.21; H, 7.37; N, 6.84%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1332—1336 (1969)

The Structure of Copolymers of L-Proline with γ-Benzyl-L-glutamate in Organic Solvents

Rume SAKAI, Shoichi IKEDA*1 and Toshizo ISEMURA

Institute for Protein Research, Osaka University, Kita-ku, Osaka and Faculty of Science, Osaka University, Toyonaka, Osaka

(Received July 9, 1968)

The equilibrium conformations of three copolymers of L-proline with γ-benzyl-L-glutamate were studied in 1,2-dichloroethane, *m*-cresol, and dichloroacetic acid by measuring the optical rotatory dispersion and the infrared absorption spectra. In *m*-cresol and dichloroacetic acid, the proline residues take the *trans*-configuration. In *m*-cresol their incorporation into copolymers destroys the right-handed-α-helical conformation of glutamate residues. In 1,2-dichloroethane, the proline residues assume the *cis*-configuration if the sequence of proline residues is long enough. If it is short, they are in the *trans*-configuration. The poly-L-proline-I-helix can never coexist with the α-helix.

Poly-γ-benzyl-L-glutamate (PBLG) can assume the right-handed α-helix in helicogenic solvents, such as 1,2-dichloroethane (DCE), chloroform, and *m*-cresol, while it is a random coil in dichloroacetic acid (DCA) or trifluoroacetic acid.[1] Its helix-coil transition has been extensively investigated by changing the solvent or the temperature.[2] Poly-L-proline (PLP) has two types of conformations.[3] The one, known as the form I, is a right-handed helix with all the peptide bonds in the

cis-configuration,[4] $[\alpha]_D^{25}=+50°$ [5] (immediately after the dissolution of polyproline into acetic acid). The other, the form II, takes a left-handed helix with *trans*-imide bonds,[6] $[\alpha]_D^{25}=ca.\ -500°$, and is stable in acetic acid, formic acid, DCA, and water. The mutual conversion between the forms I and II has also been elucidated in relation to the nature of the solvent. It is known that the PLP-I-helix can be readily transformed into the PLP-II-helix by dissolving it in organic acids, water, and *m*-cresol, and that it can be recovered from these solvents by the addition of aliphatic alcohols.[5]

It is of interest to study the stable conformation of the copolymers of L-proline and γ-benzyl-L-glutamate (γBLG) in various environments. DCE favors the right-handed α-helix of PBLG, it seems also to favor the right-handed PLP-I-helix, because the conformation of PLP in DCE-acetic acid (99.5—0.5%) (DCE-AA) is the form I.[7] *m*-Cresol also favors the right-handed α-helix of PBLG, but folds PLP into a left-handed PLP-II-helix. While DCA disrupts the PBLG helix into the random coil, it keeps PLP in the left-handed PLP-II-helix.[8]

We have previously reported the synthesis and some properties of the copolymers.[7] The copolymers studied were copoly-3:1-(L-proline, γBLG) (Copoly-3:1), copoly-1:1-(L-proline, γBLG) (Copoly-1:1), and copoly-1:3-(L-proline, γBLG) (Copoly-1:3).

In the present investigation, studies have been made of the conformation of these copolymers in three different solvents, DCE, *m*-cresol, and DCA, by measuring the optical rotatory dispersion and the infrared absorption spectra of films cast from those solvents.

Experimental

Materials. The *m*-cresol and DCA used in the present study were twice redistilled in a vacuum. The DCE was distilled under atmospheric pressure. The acetic acid was a JIS special grade acid from Wako Pure Chemical Industries, Ltd., and was used without further purification. All the polymers were the same as those used in the previous investigation.[7]

Optical Rotatory Dispersion (ORD). The ORD of the poly-peptides in *m*-cresol and DCA solutions was measured at room temperature with a Rudolph and Sons Model 200S photoelectric spectropolarimeter. The ORD of the DCE solutions was measured by a Perkin-Elmer Model 141 photoelectric polarimeter. The ORD results were analysed by the Moffitt-Yang equation,[9] assuming λ_0 to be 212 mμ. The a_0 and b_0 are constants. PLP and the copolymers exhibited mutarotation in a *m*-cresol solution, although less mutarotation was observed with copolymers of lower proline contents. All the ORD curves shown below were obtained at room temperature after the mutarotation had been completed. For the measurements, polymer solutions were put in a cell with a 10-cm path.

Infrared Absorption Spectra. The infrared absorption spectra of films cast from the solutions on KBr plates were measured on a Perkin-Elmer Model 221 spectrophotometer at a relative humidity of 40% and at 20°C.

Results

DCE Solutions. The ORD curves of the polymers are shown in Fig. 1, while the plots of a_0 and b_0 against the polymer composition in DCE are shown in Fig. 2.

The values of a_0 and b_0 for PBLG in DCE were found to be 202° and −630° respectively, in good agreement with the values observed by Moffitt and Yang.[9] Those values for PLP in DCE-AA were found to be −280° and +285°. For PLP in DCE-AA, the specific rotation at 589 mμ (the D-line of sodium) was almost the same value as $[\alpha]_{578}=-36°$, which lies between the $[\alpha]_D=+50°$ for the form I and $[\alpha]_D=-100°$. The form IA of PLP was discovered and thus denoted by Sasisekharan;[10] it was later identified as the form I by Traub and Shmueli.[4] Therefore, the conformation of PLP in DCE-AA seems to be the form I. This is supported by the infrared study of a film cast from the solution. A prominent

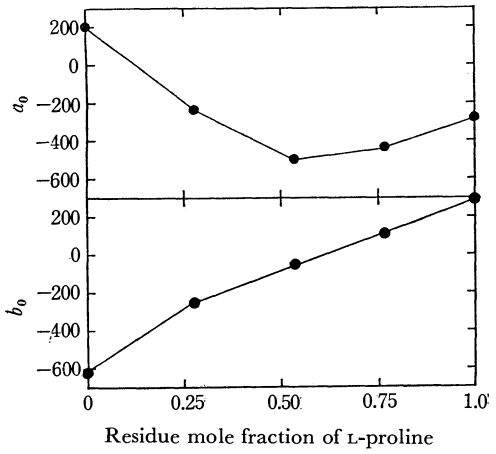

Fig. 2. The relation of a_0 and b_0 in DCE or DCE-AA to the content of proline.

feature of the copolymers is the fact that a minimum a_0 value is found at the proline content of 50%. This feature was also observed for $[m']_{546}$.[7] The inference to be drawn from this observation will be discussed below. As the residue mole fraction of proline increased from 0 to 0.25, the value of b_0 increased more sharply than it did on going from 0.25 to 1.0.

The infrared absorption spectra of polymers cast from DCE or DCE-AA are shown in Fig. 3.

In the spectrum of PLP, the CO stretching frequency of the amide (amide I) was observed at 1653 cm^{-1}, while the characteristic frequencies of the form I were observed at 960 and 1360 cm^{-1}. The last two absorptions clearly indicate that the

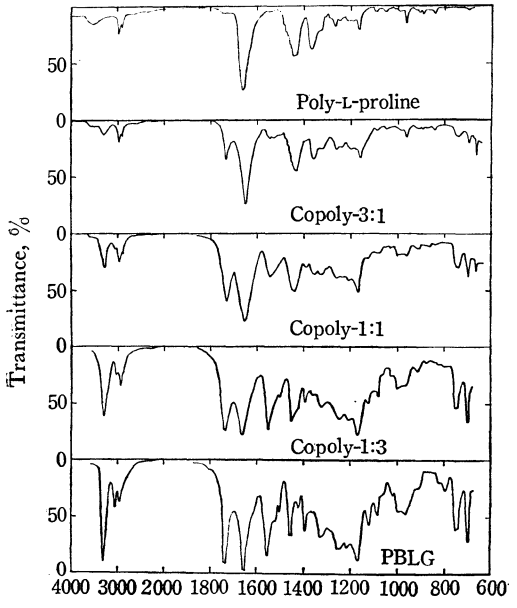

Fig. 3. Infrared absorption spectra of polymers cast from DEC of DCE-AA.

PLP-I-helix is predominant in the DCE-AA solution of PLP. An NH stretching was observed at about 3300 cm^{-1}, and a CO stretching of the γ-ester, at about 1740 cm^{-1}, together with amide I and II bands, as in the spectrum of PBLG.[11] In the neighborhood of 1360 cm^{-1}, however, no absorption was observed. For the copolymers the ratio of the intensity of the amide I to that of the absorption at 1740 cm^{-1}, defining the existence of glutamate, increased with the proline content. The absorption at 960 cm^{-1} was observed for Copoly-3:1, and the absorption at 1360 cm^{-1}, for Copoly-3:1 and Copoly-1:1. These facts suggest that the proline parts in Copoly-3:1 and Copoly-1:1 take the same conformation as in the form I of PLP. The frequencies of the amide I of the polymers are listed in Table 1.

Table 1. The amide I frequencies of polymers cast from *m*-cresol and DCE

Polymer	Solvent	
	m-Cresol cm^{-1}	DCE cm^{-1}
PLP	1637	1653
Copoly-3:1	1642	1650
Copoly-1:1	1661 1650 1642	1653
Copoly-1:3	1658	1661
PBLG	1655	1656 1650

The frequencies of Copoly-1:3 were higher than that of PBLG. The frequency of the amide I is known to be higher than that of the right-handed α-helix if ordinary polypeptides take the left-handed helix.[12–15] Therefore, Copoly-3:1 might contain some left-handed helicies.

m-Cresol Solutions. The ORD curves of the polymers in *m*-cresol are shown in Fig. 4, while the plots of a_0 and b_0 against the polymer composition in *m*-cresol are shown in Fig. 5.

The values of a_0 and b_0 for PBLG in *m*-cresol were +350° and −530° respectively. These values were not compatible with those reported by Cassim and Taylor[16] (a_0=223°, b_0=−650°). Although

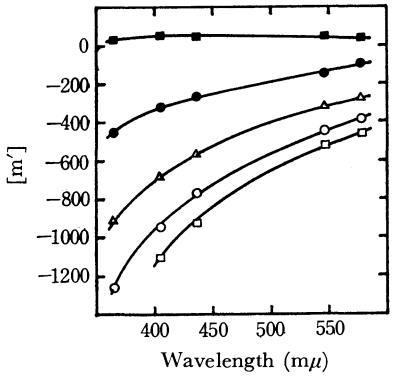

Fig. 4. The optical rotatory dispersion curves of the solutions of polymers in *m*-cresol.
The symbols are the same as in Fig. 1.

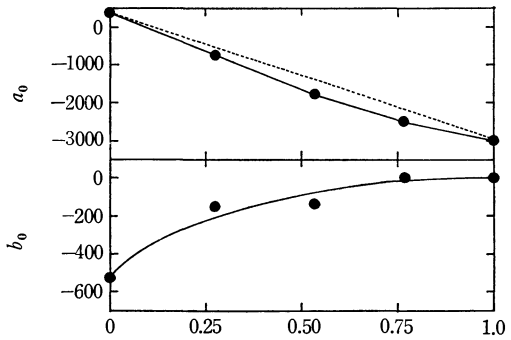

Fig. 5. The relation of a_0 and b_0 in *m*-cresol to the content of proline.

the reason for this discrepancy is not clear, the values fall in the same category as those of PBLG in helicogenic solvents. PLP had an $[\alpha]_{546}$ value of −538° in *m*-cresol, and was found to have the conformation of the form II. The values of a_0 and b_0 of PLP were −3000° and 0° respectively. The plot of a_0 was concave against the residue mole fraction of proline. The plot of b_0 was convex.

In the infrared absorption spectra of polymers cast from *m*-cresol, no absorption band near 1360 cm^{-1} was observed. This fact is to be expected for PLP, for the conformation of PLP in *m*-cresol is the form II and this conformation would be retained in a solution even after regeneration into the solid state. The frequencies of the amide I of polymers cast from *m*-cresol are listed in Table 1. The frequencies increased from PBLG to Copoly-3:1 and Copoly-1:1. This also suggests that Copoly-1:3 and Copoly-1:1 cast from *m*-cresol consist of some parts of the left-handed helices.

DCA Solutions. The ORD curves of the polymers in DCA are shown in Fig. 6, while the plots of a_0 and b_0 against the polymer composition in DCA are shown in Fig. 7.

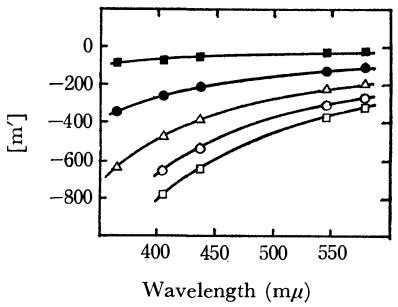

Fig. 6. The optical rotatory dispersion curves of solutions of polymers in DCA.
The symbols are the same as in Fig. 1.

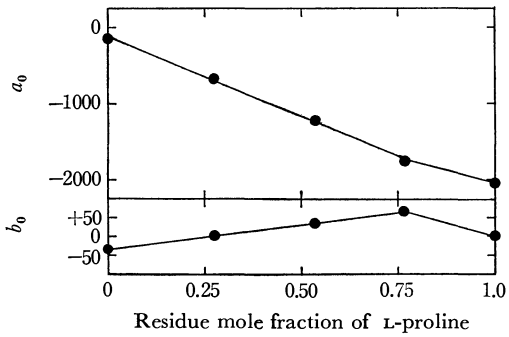

Fig. 7. The relation of a_0 and b_0 in DCA to the content of proline.

The a_0 and b_0 values of PBLG in DCA were −160° and 35°. PBLG is randomly coiled in DCA. PLP in DCA is known to be in the form II,[8] and in the present experiment it was found that $[\alpha]_{546}=-373°$. The observed value was less negative than that for PLP in formic acid or in acetic acid, but the deviation could be caused by some solvent effect or by the smaller molecular weight of our sample. The a_0 and b_0 values of PLP were −2100° and zero respectively. The b_0 value was equal to that in *m*-cresol. The plot of a_0 is concave against the increase of the residue mole fraction of proline, as is shown in Fig. 7. The b_0 value increased linearly as the proline fraction increased from zero to 0.75. However, these b_0 values are nearly zero when the ambiguity of the experiment is considered.

Discussion

The conformation of the copolymers of L-proline with γBLG will be considered as a function of the composition in different solvents, based on the following assumptions. First, the rotatory properties observed for copolymers can be reduced to those of the constituent residues. Second, the a_0 value reflects the configuration of the L-proline residue. Although it ranges from −160° for the random

coil to 400° for the α-helix in PBLG, the a_0 value of PLP changes much more, *i. e.*, from −300° for the form I to −3000° for the form II. Therefore, the second assumption is roughly justified. Third, the b_0 value depends on the conformation of the benzyl glutamate residue alone. The right-handed α-helical conformation of the glutamate residue has $b_0=-600°$, while its random coil conformation has $b_0=0$. Finally, it is assumed that the conformation of copolymers regenerated from solutions is not distinguishable from that in the original solutions when the solvent is either DCE or *m*-cresol. For DCA this assumption is not necessarily true.[17]

DCE Solutions. The observed gradual change in a_0 with the increase in proline content seems to indicate that any peptide bond associated with a proline residue assumes the *cis*-configuration if the proline content is more than 50%. This is supported by the infrared measurements, which reveal the appearance of absorption bands at 1360 and 960 cm^{-1}. In proline-rich copolymers proline residues occur consecutively more frequently, and in such sequences proline have the *cis*-configuration. On the other hand, in the copolymers with proline contents of less than 50%, the chance of finding more than two or three proline residues in a sequence is smaller and more proline residues would be isolated from the others. The change in a_0 with the proline content suggests that the proline residue tends to take the *trans*-configuration. This is consistent with the results on oligomers and low-molecular-weight polymers of proline.[18] *N*-Carbobenzoxy-di-, tri-, and tetra-L-proline had more negative specific rotations at 546 mμ in methanol or acetic acid than the monomer. Mutarotation studies of PLP dodecylamides (PPDA) of different molecular weights in organic acids have also shown that, in the initial conformation, more proline residues exist in the *trans*-configuration as the degree of polymerization decreases. Further, in a mixed solvent, benzene-alcohol, PPDA of a higher degree of polymerization existed in the PLP-I-helix. Even in this solvent, however, PPDA of a lower degree of polymerization had a higher content of *trans*-peptide bonds. Consequently, in a sequence composed of a small number of proline residues in the copolymers, the proline residues will be in the *trans*-configuration, even if they are in DCE, which stabilizes the *cis*-configuration of the peptide bond between prolines, or the form I. Proline residues take the *cis*-configuration in the PLP-I-helix-solvent only if they are included in a long sequence of proline residues.

The b_0 value increases rather markedly even if a small quantity of proline residues is incorporated into PBLG. The right-handed α-helix formed by glutamate residues is partly broken or converted into the left-handed helix by the occasional occurrence of proline residues. The latter suggestion is supported by the infrared spectra, which show a rather high amide I band frequency for the copolymer with a 27% proline content, since the high amide I frequency has thus far been attributed to the left-handed helix.[12–15]

***m*-Cresol Solutions.** All the a_0 values observed for the copolymers are more negative than those calculated from the weighted sum of the proline-II-helix and the glutamate helix. *m*-Cresol is a solvent supporting both the PLP-II-helix and α-helix. Consequently, the proline residues tend to assume the *trans*-configuration. The infrared spectra of the solid film regenerated from *m*-cresol solutions do not have any absorption around 1360 cm^{-1}. This fact also indicates that the *cis*-configuration is absent in the copolymers. The b_0 value increases rather abruptly with as the proline content increases to 27%. Considerable sections of the right-handed helix have been broken in this composition. In the same way as has been discussed in the case of DCE solution, the glutamate residues in the copolymers are considered to be folded together into a helix of the same kind as that of the proline residues, *i. e.*, into a left-handed helix.

DCA Solutions. Proline residues have the *trans*-configuration, and most benzyl glutamate residues are in random coils. The experimental curve for a_0 is lower, *i. e.*, more negative, than that expected for the simple sum of random coil glutamate residues and *trans* proline residues. This can be most adequately interpreted by assuming that the glutamate residues are folded into a PLP-II-helix or a left-handed α-helix. Since, however, b_0 does not change appreciably with the composition, the formation of a left-handed α-helix can be rejected.

In the PLP-II-solvent, proline residues take the *trans*-configuration and interrupt the formation of the right-handed α-helix conformation specific for the glutamate-rich parts in helicogenic solvents. In the PLP-I-solvent, proline residues assume a *cis*-configuration if the series of proline residues is long enough, although they take a *trans*-configuration if the number of proline residues in a sequence is small. Over the whole range of mole fractions of proline to benzyl glutamate, the right-handed α-helix of the glutamate residues and the right-handed PLP-I-helix can never coexist in the copolymers.

The authors wish thank Professor G. D. Fasman, Brandeis University, for his many helpful comments.

The Structure of Copolymers of L-Proline with L-Glutamic Acid in Aqueous Solutions

Rume SAKAI and Toshizo ISEMURA

Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received September 12, 1968)

Three copolymers of L-proline and L-glutamic acid were synthesized, and their equilibrium conformation in an aqueous solution was studied in relation to their composition. The molar ratios of the proline to the glutamic acid residues in the copolymers were about 1:3, 1:1, and 8:1. All the copolymers were soluble in water, as were poly-α,L-glutamic acid and poly-L-proline II. The conformational change was caused by the pH effect on proline-poor copolymers. Evidence was obtained for the possibility of the absence of such a helix as a right-handed poly-L-proline-I-helix in the copolymers examined. The conformation of Copoly-8:1 was not affected by the pH and was identified as the poly-L-proline-II-helix.

Both poly-L-proline (PLP)[1] and poly-α, L-glutamic acid[2] (PLGA) are water-soluble, and their conformations in water have been investigated in great detail. PLP exists in the PLP-I-helix[3] after being isolated from the polymerization medium, but if it is dissolved in water it changes into a left-handed PLP-II-helix[4] with a threefold screw-axis, after a gradual *trans*-conformation from PLP-I to PLP-II.[5] PLGA assumes an α-helix form at the pH of acid or at a low ionization of side-chain carboxyl groups, but is randomly coiled at a neutral or alkaline pH.[6]

The copolymers of L-proline and L-glutamic acid can be effected to be soluble in water, and can be expected to be suitable for the elucidation of the relative stabilities of those various conformations assumed by each residue in relation to its environment. The water-solubility of the copolymers permits the measurment of the circular dichroism (CD) and the optical rotatory dispersion (ORD) in the far-ultraviolet region; these measurements will give us important informations about the conformational stability. The composition of the copolymers will influence the environment of each residue and, consequently, change the conformation of each residue from that found when the residue is located in a long sequence of the same residue, *i. e.*, in a homo-polymer. Also, the change in pH will affect their conformation. These various parameters of the water-soluble copolymers can afford a greater variety of information than can those of such water-insoluble copolymers as copolymers with γ-benzyl-L-glutamate (γBLG).[7,8]

The copolymers of L-proline and L-glutamic acid have been prepared, and their ORD in the visible region and their viscosities have been measured as a function of the pH. These properties of the copolymers rich in glutamic-acid residues have shown the presence of a transition due to pH change similar to that observed for PLGA. The CD and ORD values in the far-ultraviolet region have also been measured at pH's on both sides of the copolymer transitions.

Experimental

Materials. The γBLG was synthesized from L-glutamic acid and benzyl alcohol in 60% H_2SO_4. The *N*-carboxyanhydrides (NCA's) of γBLG and L-proline were synthesized by the methods of Blout *et al.*[9] and Kurtz *et al.*[10] respectively. Polymerization was performed in nitrobenzene with a total NCA con-

centration of 4%, and was initiated by sodium methoxide at molar ratio of the NCA's to the initiator of 100. The mixing ratios of NCA's are shown in Table 1. After the polymerization had been allowed to go on about a week, anhydrous hydrogen bromide was bubbled through all the solutions except for that of PLP. Each solution became turbid or a precipitate separated. After 24 hr standing, the excess hydrogen bromide was removed from the solutions by passing a stream of dry air through the solutions. The polymers were then isolated by the addition of ether to the solution, followed by centrifugation. They were exhaustively washed with anhydrous ether and acetone alternatively and dried *in vacuo*. All the isolated polymers except for the Copoly-8:1 were stored in a desiccator over silica gel. The compositions of the copolymers were determined by amino-acid analysis. PLP, PLGA, and three copolymers were prepared in this way; some of their properties are shown in Table 1. Copoly-8:1 has a very different proline content from that of the mixed ratio of NCA, although the other two copolymers have almost the same ratio. A polymer sample prepared in a proline to glutamate ratio of 3:1 became black and sticky within a few days after isolation. The black material (6 g) was dissolved in water, decolorized by Norit, and filtered, and then acetone was added to separate the purified polymer. It was washed with anhydrous acetone several times and designated as Copoly-8:1 (1.8 g). It seems likely that fractionation according to composition occurred during the above additional procedure.

The ORD of PLP and the copolymers changed with time after they have been dissolved in 0.1M sodium chloride or sodium fluoride. All the physical measurements described below were made on solutions after the mutarotation had ceased. The mutarotation was complete within 24 hr for the copolymers, while it took 7 days for PLP.

Amino-acid Analysis. The copolymers were hydrolysed at 110°C for 20 hr with twice-distilled hydrogen chloride. Amino-acid analysis was performed on a Beckman Spinco Model 120 amino-acid analyzer.

Molecular Weight. The molecular weights of PLP and Copoly-8:1 were determined by the method of sedimentation equilibrium performed in a Spinco E Ultracentrifuge at 26°C for PLP and at 31°C for Copoly-8:1, using a temperature control unit. To correlate the concentration with the fringe scale, a filled Epon double sector synthetic boundary cell was used. The solvent used was a 0.1M sodium chloride solution. The partial specific volume of the two polymers was assumed to be 0.758 ml/g.[11] Equilibrium patterns for both polymers showed that they were relatively homogeneous in molecular weight. The weight-average molecular weight of PLGA was determined from its intrinsic viscosity by using the molecular weight-viscosity relationship provided by the data of Wada.[12] These results are also included in Table 1.

Viscosity. The viscosity was measured using an Ubbelohde-type viscometer, with a flow time of 239 sec for a 0.1M sodium chloride solution at 25±0.01°C.

The ORD in the Visible Region. The ORD in the visible region was measured on a Perkin Elmer Model 141 spectrophotoelectric polarimeter. The measurement was made on a 0.5% solution at 25°C. The data were analyzed in the way described in previous paper.[8] The results followed the Moffitt-Yang equation.[13]

The CD and ORD in the Far Ultraviolet Region. The CD and ORD curves in the far ultraviolet region were recorded on a JASCO Model ORD/UV-5 spectropolarimeter, equipped with a circular dichroism attachment, at room temperature. For both measurements, 0.1 g/dl polymer solutions in 0.1M sodium fluoride were placed in cells of with light paths of 0.2, 1, or 2 mm, depending on the wavelength region scanned. The CD spectra are shown in terms of the residue ellipticity, $[\theta]$:

$$[\theta] = 3300(\varepsilon_L - \varepsilon_R),$$

where $(\varepsilon_L - \varepsilon_R)$ is the difference between the residue mole extinction coefficients of the left and right circularly-polarized lights. The ORD spectra are shown in terms of the residue rotation, [m]:

$$[m] = \frac{M_R}{100}[\alpha],$$

where M_R is the residue weight and [α], the specific rotation. To reduced [θ] and [m] to the residue basis for copolymers, the mean residue weight calculated from the composition of the copolymer was used.

Results

The ORD of a solution of each polymer in 0.1M sodium chloride was observed at various pH's, and the parameters, a_0 and b_0, of Moffitt-Yang's equation were calculated for each solution. The pH dependence of these parameters for each polymer is shown in Fig. 1.

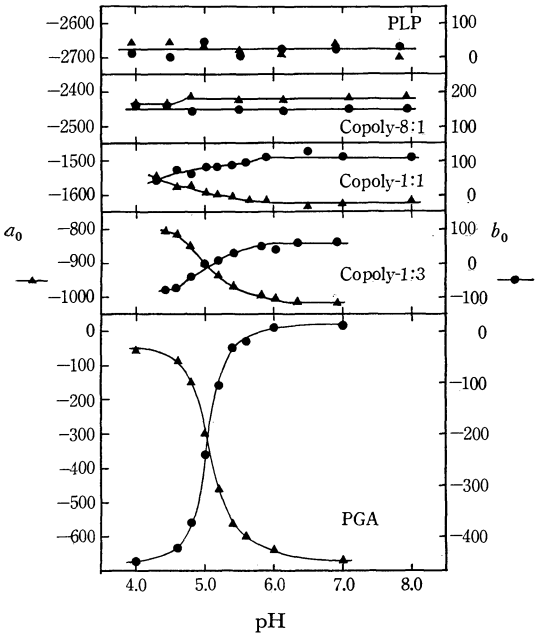

Fig. 1. The effect of pH on the a_0 and b_0 for each polymer in 0.1 M sodium chloride.

It is evident that PLP has no pH dependence of the ORD, while the largest pH dependence is observed for PLGA, which undergoes a helix-coil transition around pH 5.0, as has previously been shown by Doty *et al.*[6] Although a trivial difference in a_0 was observed for the Copoly-8 : 1, no corresponding difference in b_0 as the pH of the solution was observed. The other copolymers have a narrow pH region in which both a_0 and b_0 change with the pH. As the pH increases from 4.3 to 6, the a_0 value decreases and the b_0 value increases. As compared with that of PLGA, it is likely that the pH region observed for the copolymers represents the region where they undergo a conformational change caused by the ionization of side-chain carboxyls of the glutamic-acid residues. The differences in the two parameters, a_0 and b_0, in the two extrema are smaller as the proline content of the copolymer is higher. For example, the b_0 values of PLGA, Copoly-1:3, and Copoly-1:1 are $-450°$, $-77°$, and $44°$ at pH 4.3, while they are 10°, 60°, and 113° at a neutral pH. This is shown in Fig. 2, which clearly indicates that the differences in both a_0 and b_0, especially in the latter, decrease sharply with the proline content, more than expected.

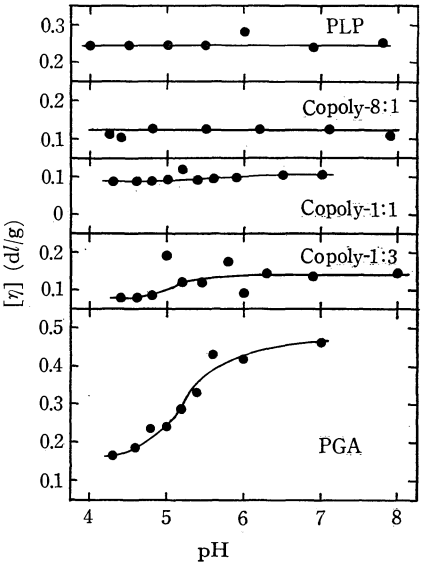

Fig. 3. The effect of pH on intrinsic viscosity.

The effect of the pH on the intrinsic viscosity of each polymer in 0.1M sodium chloride was studied as an alternative method to check the conformational change, the results are shown in Fig. 3. The results are compatible with those to be expected from ORD. The intrinsic viscosity of PLP and Copoly-8:1 are independent of the pH, while a slight pH dependence is observed for Copoly-1:1. Although the viscosity of Copoly-1:3 around the transition pH was variable, it was constant below pH 4.6 and above pH 6.3. The

intrinsic viscosity is higher at a neutral pH than at an acid pH; this finding is opposite to that reported by Doty *et al.*[6] The difference seems to come from the difference in the molecular weight or in the solvent used in the experiments. The inflection point, *i. e.*, the transition pH, on the $[\eta]$-pH curve was, at pH 5.3, slightly higher than that obtained from the ORD.

It is now generally accepted that PLP in an aqueous solution has a form-II helix after mutarotation has ceased; the present ORD and viscosity measurements of PLP at different pH values show that the same helical conformation exists in the pH region between 4 and 8. The helix-coil transition of PLGA is induced by the change in pH. PLGA is in the α-helix conformation at an acid pH, while it is randomly coiled at a neutral pH. The ORD and viscosity profiles against the pH imply that at pH 4.3 the copolymers assume definite conformations characteristic to each of them which differ from those at pH 7.

The CD and ORD, in the far ultraviolet region, of polymers at different pH's are shown in Figs. 4—7. The positions and magnitudes of the dichroic bands are given in Table 2, while the peaks and troughs of the Cotton effect are shown in Table 3.

The CD and ORD spectra of PLP and Copoly-8:1 in Fig. 4 are not influenced by the pH, as was to be expected from the results on ORD in the visible region and from the viscosity studies. The spectra of PLP are almost identical with those reported by Timasheff *et al.*[14] and by Bovey and Hood.[15] As is shown in Fig. 5, the CD of PLGA at pH 4.3 has two negative dichroic bands, while at a neutral pH it has a strong negative band, together with a weak positive and a trivial negative band. The spectra are almost identical with those previously reported.[16] The Cotton effects of PLGA at two pH's (shown in Fig. 5) are also similar to those already found by other workers.[17] It may be noted in Fig. 6 that Copoly-1:1 at an acid pH is associated with a single negative dichroic band similar to PLP, but it does not have any dichroic band near 228 mμ. The CD spectra of Copoly-1:1 change when the pH is raised by the shift of the negative dichroic band to a shorter wavelength and the appearance of weak dichroic bands at longer wavelengths. This change in CD is not clearly manifested in the ORD curve. The CD of Copoly-1:3 does markedly change with the pH, as is shown in Fig. 7. There are two plateau regions, around 220 and 202 mμ, at an acid pH; these regions may correspond to the negative bands of the PLGA α-helix, but the CD pattern at a neutral pH is completely different. The CD curve of Copoly-1:3 at a neutral pH is similar to that of PLGA at a neutral pH, but it is more depressed by the contribution of the proline residue. The same tendency is observed from the ORD curves in Fig. 7.

Discussion

The pH-induced conformational transitions are clearly seen in Copoly-1:3 and Copoly-1:1 as well as in PLGA in Figs. 1 and 3. It is well known that PLGA is a random coil if the side-chain carboxyl groups are highly ionized, while it assumes an α-helix if they are not. The stable form of PLP in 0.1M sodium chloride is a PLP-II-helix, a short sequence of proline residues also tends to assume the *trans*-configuration of the peptide bonds, as in the PLP-II-helix.[8] The peptide bonds of the L-proline residues in the copolymers containing a small quantity of L-proline residues would, therefore, assume the *trans*-configuration in 0.1M sodium chloride. Since the PLP-II-helix has a zero b_0 value,[5] a zero b_0 value can be assigned to a proline residue in the *trans*-configuration. Consequently, the b_0 value of the copolymers can be used as a measure of the conformation of the glutamic-acid residue. As is shown in Fig. 2, the observed difference in the b_0 value of each copolymer between acid and neutral pH values is smaller in magnitude than that to be expected if a linear relation between the difference and the glutamic-acid content is assumed. One of the reasons for the deviation is perhaps the effect of the chain length on the b_0 value. Proline residues cut up the segment composed of glutamic-acid residues. Goodman *et al.*[18] have reported that the b_0 value of the oligo-γ-methyl-L-glutamates in helicogenic solvents abruptly decreases in absolute value with a decrease in the polymerization degree. This may be because the α-helix is unstable in the oligomers or because a considerably long series of residues is necessary to produce a large negative b_0 value for the α-helix, even though oligomers can assume a perfect α-helix. The same reasons are appropriate in explaining the b_0 value of copolymers. Another reason may be that glutamic-acid residues in the copolymers take a definite conformation, *e.g.*, a left-handed helix. Even at higher pH values the copolymers can assume the same conformation as that in an acid pH, because the electric repulsion between glutamic-acid residues is more reduced than that in PLGA.

It would be interesting to ascertain whether or not these copolymers assume a definite conformation under the conditions described above. This question can be partly answered by considering the ORD and CD results in the far ultraviolet region. The results for Copoly-8:1 are very similar to those of PLP, as is shown in Fig. 4. If Copoly-8:1 contains some parts of left-handed α-helices or random coils, the CD spectra or ORD will be different from those of PLP by the inverted CD

or ORD of PLGA at an acid pH or the CD or ORD at a neutral pH. The CD and ORD of Copoly-8:1 show this tendency only a very little. Therefore, the conformation of the copolymers is probably the same as that of the PLP-II-helix.

This inference is also supported by the following facts. The axial ratio, as calculated from the intrinsic viscosity by Simha's equation[19] assuming a partial specific volume and no hydration, 11, is nearly equal to that calculated from the molecular weight on the assumption that the conformation of the copolymers is the same as that of the PLP-II-helix, 13. The CD spectra and ORD of Copoly-1:1 at an acid pH reflect those of PLP to some extent. For example, they have a negative dichroic band in the CD spectra at 205 mμ, the same wavelength as in PLP. The situation is similar in ORD. At a neutral pH, the parts rich in glutamic-acid residues in the copolymers will be in random coils, because the CD pattern is like that of PLGA at a neutral pH, although the CD band around 220 mμ shifts towards a longer wavelength, possibly because of the CD arising from proline residues.

19) R. Simha, *J. Phys. Chem.*, **44**, 25 (1940).

The CD and ORD of Copoly-1:3 at an acid or neutral pH reflect those of PLGA, as is shown in Fig. 7. Some parts in the copolymer assume the α-helix at an acid pH, but they are randomly coiled at a neutral pH.

The above discussion makes it clear that glutamic-acid residues are folded with proline residues into a PLP-II type helix when the proline residue content in the copolymers is high. The positive b_0 values of the copolymers, as is shown in Fig. 1, do not always imply the left-handed α-helix; they might come from such a helix of glutamic-acid residues as the PLP-II-helix.

The presence of no PLP-I-helix-type helix was detected in any of our experiments.

The authors wish to express their deep gratitude to Dr. S. Ikeda, Nagoya University, for his helpful discussions throughout the course of this work. The authors also wish to thank Professor G. D. Fasman, Brandeis University, for many valuable comments. One of the authors (R.S.) was a fellow of the California Foundation for Biochemistry, 1967—1968.

(Received July 15, 1968)

Styrene was polymerized in dimethyl sulfoxide by alcohol-ceric salt containing lauryl sulfuric ions. The rate of polymerization increased with the amount of ethyl alcohol added. A deuterium isotope effect was observed when tetradeuteromethyl alcohol was used as an initiator. Accordingly, the generation of radicals by the elimination of the hydrogen atom from the alcohol molecule was concluded. When styrene was polymerized in the presence of cellulose, graft copolymer was obtained. The grafting efficiency amounted to about 70%.

Many workers have reported the graft copolymerization of vinyl monomers onto cellulose.[1] Previous investigations have, however, dealt almost exclusively with polymerizations in aqueous systems. On the other hand, some reactive monomers react with water rather than graft. No radical initiator which initiates graft copolymerization onto cellulose in an inert organic solvent is yet known.

The author has been studying the polymerization by ceric ions in an organic solvent.[2,3] Ceric salt containing lauryl sulfuric ions (hereafter refered to as CLS) was found to be an effective initiator. As our purpose is to show the effectiveness of CLS in grafting vinyl monomers onto cellulose, the present paper will deal with the polymerization of styrene.

3) K. Kaeriyama, *Polymer* (*London*), **10**, 11 (1969).

Experimental

Material. The styrene, ethyl alcohol, dimethyl sulfoxide (DMSO), and dimethylformamide (DMF) were distilled under reduced pressure just prior to use. The tetradeuteromethyl alcohol was of commercial origin (E. Merck AG.).

The CLS was generally prepared according to the following procedure.[4] To a solution of 32 g of ceric ammonium nitrate in 70 m*l* of water, there was added a solution of 12 g of sodium laurylsulfate in 50 m*l* of water. The slurry was poured into 800 m*l* of water, and the precipitate thus separated was collected on a sintered filter and dried *in vacuo*. The yield was 14.8 g. The CLS thus obtained was not soluble in any of the organic solvents examined except DMSO and DMF. The ceric ion content in CLS was 23.00% by weight.

The cellulose used was 40/1 cotton cloth which had been desized and scoured according to the usual procedure.

Polymerization Procedure. In a glass tube with a capacity of 25 m*l* there was placed a 20 m*l* portion of the polymerizing mixture. After the tube had been degassed by the freeze-thaw-method, it was sealed off. After the tube had then been maintained at 60°C for a given time, the contents were poured into methyl alcohol containing a small amount of benzoquinone. The polystyrene thus precipitated was collected on a sintered filter and dried *in vacuo* to a constant weight.

The grafted cellulose was extracted with benzene until no further polymers could be extracted.

Molecular Weight. The viscometry was carried out at 30°C in a benzene solution. The molecular weight was calculated from the intrinsic viscosity based on the equation:[5]

$$\log[\eta] = -4.013 + 0.74 \log M_n$$

Definitions. In this paper, the polymer yield, the grafting, and the grafting efficiency are defined as follows:

$$\text{Polymer yield (mol/}l\text{)} = \frac{\text{weight of polymer produced per liter}}{\text{molecular weight of the polymer produced}}$$

$$\text{Grafting (\%)} = \frac{\text{weight increase of cellulose after extraction}}{\text{weight of original cellulose}} \times 100$$

$$\text{Grafting efficiency (\%)} = \frac{\text{weight increase of cellulose after extraction}}{\text{weight of polymerized styrene}} \times 100$$

Results and Discussion

Polymerization in DMF. Polymerization was carried out in DMF, in which CLS was soluble.

Table 1. Polymerization in dimethyl formamide

Ethyl alcohol (mol/*l*)	Conversion (%)
1.73	2.46
0.606	2.33
0.173	2.85
0.0346	2.69
0.00692	2.74

[Styrene]=2.18 mol/*l*; [CLS]=8.21×10^{-3} mol/*l*
Solvent: dimethyl formamide
Polymerization: at 60°C for 48 hr

The results are shown in Table 1. Polymerization is not initiated by the ethyl alcohol-CLS system in DMF. The conversion is much lower than that of similar runs in DMSO, which will be described below. In view of the above results, the polymerization was thereafter carried out in DMSO.

Polymerization in DMSO. Polymerization was carried out in DMSO. It can be seen from Table 2 that polymerization is initiated by the ethyl alcohol-CLS system in DMSO.

Table 2. Effects of the concentration of ethyl alcohol

Ethyl alcohol (mol/*l*)	Conversion (%)	$M_n \times 10^{-5}$	Polymer yield (mol/*l*) $\times 10^4$
1.73	22.5	2.4	2.1
0.606	18.9	3.4	1.3
0.173	15.8	3.7	0.97
0.0173	14.7	5.6	0.60
0.00173	10.4	5.7	0.41

[Styrene]=2.18 mol/*l*; [CLS]=8.21×10^{-3} mol/*l*
Solvent: DMSO
Polymerization: at 60°C for 48 hr

Because the polymer yield increases with the amount of ethyl alcohol added, the latter is concluded to participate in the initiation reaction of polymerization. This suggests that a graft copolymerization of styrene onto cellulose may be possible in DMSO.

Deuterium Isotope Effect. Ethyl alcohol participates in the initiation reaction, as is evident from the above results. However, it is not yet clear whether or not the radical is formed by the cleavage of the covalent bond in the alcohol molecule. In order to see how the radical is formed, styrene was polymerized by the CLS-tetradeuteromethyl alcohol system.

In the initiation step, if the reaction involves a rupture of the C–H bond, the rate of the reaction of the deuterated alcohol should be lower than that of the ordinary alcohol because of the difference in

zero-point energy and mass effect.[6] If the step is rate-determining, the difference in rates may actually be observed. In fact, the isotope effect has been observed in the radical oxidation of various alcohols.[7,8]

The results of polymerization in the presence of CH_3OH and CD_3OD and in the absence of any alcohol are shown in Table 3. Styrene was polymerized without any alcohol because of the initiation of polymerization by the CLS-DMSO system and thermal polymerization. In order to observe the effect of the methyl alcohol-CLS system, it is necessary to deduct the moles of polymer produced in the absence of alcohol from the total moles of the polymer produced. Ratios of the moles of the polymers produced by ordinary methyl alcohol to those produced by tetradeuteromethyl alcohol are shown in the last column. The mean value of the ratios is 1.6. This value suggests that a radical is formed by the elimination of a hydrogen atom from methyl alcohol in the rate-determining step; therefore, it may be concluded that it is possible to prepare graft copolymers by the initiator system.

Graft Copolymerization onto Cellulose. The results of graft copolymerization onto cellulose are shown in Table 4. The data show that styrene was graft-copolymerized onto cellulose. The grafting efficiency is high. The percentage of grafting increases with the polymerization time for 40 hr and in the range of the CLS concentration below 13.9×10^{-3} mol/l. The grafting efficiency reaches its maximum at the CLS concentration of 8.21×10^{-3} mol/l and at the polymerization time of 26 hr.

The method developed in this paper will be useful for preparing graft copolymers with functional side chains.

The author is grateful to Dr. R. Murase and Mr. K. Ishino for their interest in this work. The author also wishes to thank Dr. Y. Tanaka for his valuable discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1345—1350 (1969)

Studies of the Derivatives of Epichlorohydrin. III. A New Method of Preparing γ-Alkoxy-γ-butyrolactones

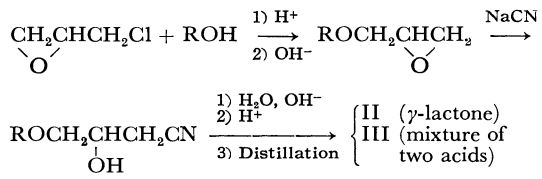
Tsunehiko KUWAMURA and Hideo TAKAHASHI

Department of Synthetic Chemistry, Faculty of Engineering, Gunma University, Tenjin-cho, Kiryu

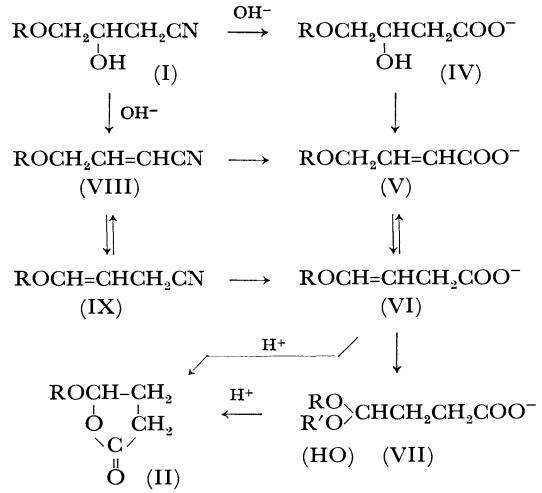
(Received July 25, 1968)

When alkyl glycidyl ethers derived from epichlorohydrin and alcohols were treated with sodium cyanide, the corresponding γ-alkoxy-β-hydroxybutyronitriles (I) were obtained. The hydrolysis of I with aqueous alkali metal hydroxide, followed by acidification and distillation, gave γ-alkoxy-γ-butyrolactones (II). The structure of II was confirmed by chemical and physical means. The reaction paths of I to II were also studied.

In previous papers,[1,2] the synthesis of alkyl glycidyl ammonium salts from epichlorohydrin and amines was described, and their properties as reactive surfactants were discussed. The purpose of this investigation is to develop the study of reactive long-alkyl-chain derivatives of epichlorohydrin. The earlier work[3] on the application of long-alkyl-chain glycidyl ethers prompted the preparation of β-hydroxynitriles, which may be convertible to lactones. Many previous workers have mentioned the lactonization of unsaturated carboxylic acids by the aid of such strong acids as polyphosphoric acid or sulfuric acid.[4] Blout and Elderfield[5] and Newman and Rosher[6] have reported the formation of γ-lactones from β-hydroxycarboxylic acids, the process involving dehydration and subsequent cyclization. Also, Campaigne and Ellis[7] have prepared highly-substituted γ-butyrolactones from unsaturated nitriles. Recently Heiba and Dessau[8] have reported a new radical synthesis of γ-lactones. Although it has been well known that γ-alkoxy-γ-butyrolactones can be prepared from esters of β-formylpropionic acid dialkylacetal, no published investigation has yet described a method of synthesizing γ-lactones directly from β-hydroxynitriles.



The hydrolysis of I yielded predominantly II rather than III. II and III were decided to be, respectively, γ-alkoxy-γ-butyrolactones and a mixture of γ-alkoxy-β-hydroxybutyric acid (IV) and γ-alkoxy-crotonic acid (V), as will be discussed later. From the consideration of these products, it may be predicted that the reaction involves dehydration, the hydrolysis of the cyano group, and a rearrangement of the double bond preceding cyclization. As to the sequence, it was postulated that the course of the reaction may be as is shown in the following scheme:



To confirm this sequence, however, we prepared several presumable intermediates (IV, V, VII, and

VIII) (indicated above) and established that they did indeed exist in the reaction mixture. Furthermore, evidence was obtained that they all afford II. Then the proceeding of the reaction was followed up by measuring the nitrogen content and the hydroxyl number in the reaction mixture in order to establish the reaction path preferred. Unfortunately, however, we had only rough information because of technical difficulties.

Experimental and Results

Preparation of Alkyl Glycidyl Ethers. According to a method described in a previous report,[3] these ethers were prepared from epichlorohydrin and alcohols. Ethyl, butyl, and octyl derivatives were prepared. Their purity, as checked by gas-liquid chromatography (GLC), was satisfactory. The properties and yields are shown in Table 1.

Preparation of γ-Alkoxy-β-hydroxybutyronitriles. Alkyl glycidyl ether (1 mol) was dissolved in an equivalent volume of ethanol containing a few drops of a thymol blue solution as the indicator. Into the resulting solution, a 30% aqueous solution of sodium cyanide (1 mol) was, drop by drop, added with stirring at 30—40°C over a period of about 90 min. During the reaction, the mixture was kept at pH 7.0—7.5 by the drop-by-drop addition of a 30% aqueous solution of acetic acid. After all the sodium cyanide had been added to the reaction mixture, stirring was continued for an additional 3—6 hr at 40—50°C. When the reaction mixture no longer exhibited a color change, it was cooled. Then the separated organic layer and the ether extract of the water layer were gathered and dried over magnesium sulfate. After the ether had been removed, I was isolated by distillation and then purified using a concentric-type fractionator. Their purities were checked by GLC. Table 2 shows their properties and yields. The IR spectrum of the C-2 homologue of I is indicated in Fig. 1. The characteristic absorption band at 2240 cm^{-1} can be ascribed to the $-C\equiv N$ group.

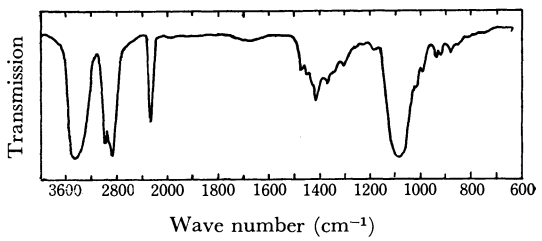

Fig. 1. IR spectrum of γ-ethoxy-β-hydroxybutyronitrile.

Preparation and Identification of II. *a) Hydrolysis of I.* A solution of I (1 mol) in an equivalent volume of ethanol was mixed with a concentrated aqueous solution of sodium hydroxide (1.1 mol). The resulting mixture was heated under reflux for 24—30 hr and then evaporated to dryness. During the first 30 min, ammonia was liberated from the reaction mixture. The residue was then made into a slurry with a small amount of water and acidified to pH 3—4 with a 50% aqueous solution of mineral acid. The separated organic layer and the ether extract from the water layer were combined and dried over magnesium sulfate. After the solvent had then been removed, the residue was distilled under reduced pressure. The substance first distilled out, II, was fractionated and its purity determined by GLC. The one distilled out next, III, was also redistilled, but it did not show a mono peak on the GLC chart. Table 3

* Calculated for γ-alkoxy-γ-butyrolactone.
** The authentic substance prepared by the routine method.
*** They were measured at 20°C.

shows the properties and yields of II.

b) IR Spectra. The IR spectra of II exhibit the characteristic absorption band at 1790 cm^{-1}, indicating the presence of the γ-butyrolactone carbonyl group. Its chart is given in Fig. 2.

c) Identification of II. γ-Butoxy-γ-butyrolactone, the authentic substance, was prepared by a well-known method[9] and then compared with II. β-Formylpropionitrile (1 mol) was dissolved in butyl alcohol (400 ml) containing a small amount of hydrochloric acid. The reaction mixture was heated at 110°C for 3 hr and then allowed to stand at room temperature for several hours. After neutralization with an aqueous solution of potassium carbonate, the corresponding butyl acetal was obtained by distillation; bp 104—106°C/1 mmHg (lit.,[9] 122—123°C/3.4 mmHg). β-Formylpropionitrile butyl acetal was then hydrolyzed in the presence of an alkaline catalyst. The salt thus obtained was purified and acidified. On distilling, carboxylic acid of the acetal type formed γ-butoxy-γ-butyrolactone immediately. The properties and yields are listed in Table 3. The best evidence for the identity of II with this γ-alkoxy-γ-butyrolactone is the fact that the IR spectrum and the GLC retention time of II agreed entirely with the values of the authentic sample. They are shown in Fig. 2.

d) NMR Spectra. The NMR spectra of II provided further information for the structual consideration. In Fig. 3, A and B represent the normal spectra of the C-4 and C-2 homologues of II, while C and D show the spin-spin decoupled spectra of B. As may be seen in the spectrum B, four bands are found, at τ 4.45, and 8.8 and in the regions of τ 6.1—6.6, and 7.4—7.9. The relative heights of the integrated spectrum give the number of protons as in the following ratio in the spectrum B from the low to the high field; 1:2:4:3. The band at

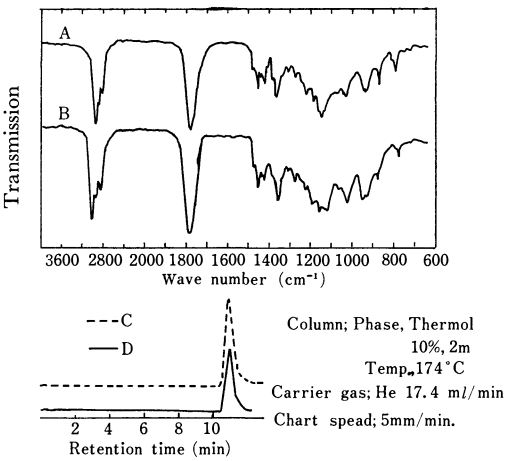

Fig. 2. IR spectra and GLC charts.

C and D; GLC charts of the authentic γ-butoxy-γ-butyrolactone and C_4-II.

τ 4.45, indicating one proton, is attributable to the γ-position proton, which may be the lowest field since it is deshielded by the adjacent oxygen atoms. The two protons appearing in the region of τ 6.1—6.6 may correspond to methylene protons in the substituted ethoxy group, and their chemical shift may be lowered by the adjacent oxygen atom. The band in the region of τ 7.4—7.9 comes from the four protons at the α- and β-methylene groups. They appear as a group of bands, since they are nearly, but not exactly, equivalent protons and split each other complicatedly. The three protons of the methyl group in the side chain resonate at τ 8.8 and are split into a triplet. Spin-spin decoupling was carried out to support these assignments. In the spectrum C, decoupling the multiplet at τ 6.45 causes the triplet at τ 8.8 to collapse to a singlet and somewhat simplifies the multiplet

9) S. Motoki, S. Satsumabayashi and I. Tajima, This Bulletin, **37**, 646 (1964).

in the region of τ 7.4—7.9. On the other hand, decoupling the triplet at τ 8.8, although its spectrum is not shown here, causes a partial collapse in two regions, τ 6.1—6.6 and 7.4—7.9. As the spectrum D indicates, decoupling the multiplet at τ 4.45 partially collapses the multiplet in the region of τ 7.4—7.9, whereas the alternative decoupling in the region of τ 7.4—7.9 serves to simplify the pattern at τ 4.45. As a result, it is apparent that the relative positions of protons in the molecule deduced above are reasonable, and that the complex patterns resulted not only from a simple coupling, but also from a long-range coupling. Therefore, it was not easy to interpret them in a simple way.

e) *Characteristic Reaction of II.* Fife has kinetically studied the hydrolysis of γ-alkoxy-γ-butyrolactone to β-formylpropionic acid and alcohol.[10] In the present work, the C-4 homologue of II was hydrolyzed without any catalyst. The products were detected by GLC under various conditions. The acid product thus obtained was then conveniently converted to its 2,4-dinitrophenylhydrazone, mp 206—207°C. The authentic γ-alkoxy-γ-butyrolactone was treated similarly and gave a derivative with the same melting point. No depression of the melting point was observed when the two samples were mixed. The IR spectrum is shown in Fig. 4. The absorptions at 1715 cm^{-1}, at 1620 cm^{-1}, at 1530 and 1340 cm^{-1}, and at 1080 and 825 cm^{-1} are associated with -C=O, -C=N-, $-NO_2$, and 1,2,4-substituted phenyl groups respectively.

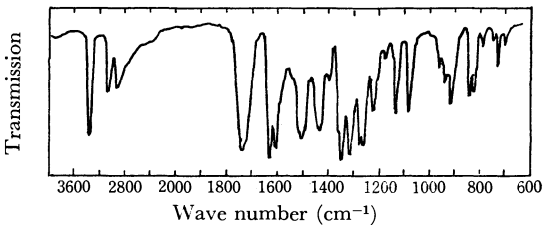

Fig. 4. IR spectrum of 2,4-dinitrophenylhydrazone of β-formylpropionic acid.

Determination of III. The determination of III, obtained as a by-product upon the hydrolysis of I, is helpful in considering the overall reaction. III was regarded as a mixture of IV and V because of its low OH number and its rather high acid value in comparison with IV alone, the separation of the two acids in III was difficult and not completed. Therefore, the mixture was esterified and fractionated effectively. The properties of the esters of IV and V thus isolated agreed with those of the authentic substances listed in Table 4.

Some Aspects of the Reaction Paths. *a*) *Preparation of Intermediates.* As has previously been pointed out, the four intermediates presumed on the reaction paths were synthesized by the following routine methods. I was manipulated with a large excess of ethanol saturated with hydrogen chloride to give the ethyl ester of IV without any significant dehydration.[11] The acetylation of the β-hydroxyl group in I and the subsequent pyrolysis of the acetate over potassium acetate yielded V.[12] According to Wohl's method,[13] the ethyl esters of VII were obtained from β-formylpropionitrile in three steps. Their properties and yields are summarized in Table 4. Their IR spectra are given in Fig. 5. All these products indicated a mono peak on the GLC chart except for the thermally unstable VII.

b) *Determination of Components in the Reaction Mixture.* The C-2 homologue of I was hydrolyzed in the same way as has been described above. The reaction mixture was neutrallized by the use of carbon dioxide and then evaporated to dryness. The residue was then recrystallized from ethanol. The sodium salt thus obtained was treated with an equivalent portion of ethyl iodide in a large amount of ethanol under reflux for 15 hr; this gave the corresponding ethyl ester. However, the esterified product distilled out at 90—120°C/20 mmHg and could not be fractionated. The GLC of this distillant indicates the presence of II and ethyl esters

of IV, V, and VII, for their retention times correspond to those of authentic substances. A similar attempt to establish their presence was made. Thus, the C-4 homologue of I was hydrolyzed in butyl alcohol containing a suitable amount of ethanol to avoid the separation of water and was subsequently esterified to give the corresponding ethyl esters of the intermediates. The results gave evidence of the presence of C-4 homologues of IV, V, VII, and II in the reaction mixture. As is shown in Fig. 5, the IR spectrum of the ester obtained from the reaction mixture can be interpreted. Namely, it was found in the spectrum D that the four characteristic absorption bands near 3580 cm^{-1}, 1790 cm^{-1}, 1680 cm^{-1}, and 1060 cm^{-1}, referrable to the OH, γ-lactone C=O, C=C, and C–O–C–O–C groups respectively, indicate the presence of IV, II, V, and VII in the reaction mixture just before the acidification.

Table 5. Results of the preparation of γ-alkoxy-γ-butyrolactone from intermediates

VIII	1.1	110—120	20	70	—

* Obtained as γ-alkoxy-γ-butyrolactone.
** Obtained as free carboxylic acid.
*** Ethyl ester was used as the starting material.

c) Preparation of γ-Lactone from Intermediates. The experimental procedure was analogous to that used in preparing II from I. The results are summarized in Table 5.

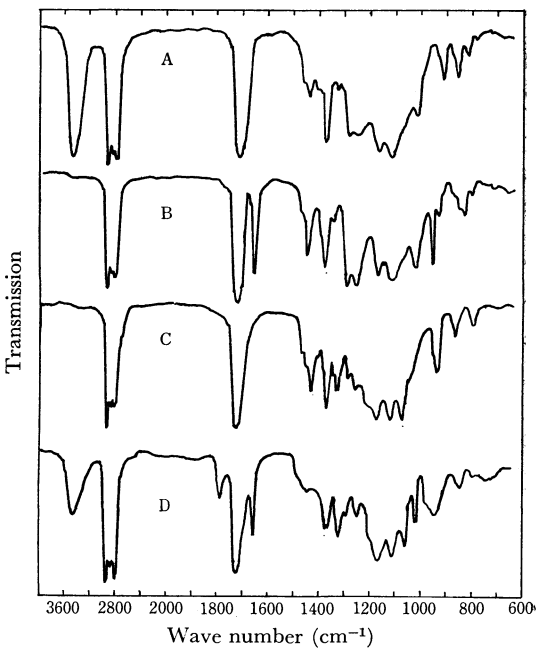

Fig. 5. IR spectra of ethyl esters of intermediates and reaction mixture.
A: γ-Ethoxy-β-hydroxybutyric acid.
B: γ-Ethoxycrotonic acid.
C: γ,γ-Diethoxybutyric acid.
D: Reaction mixture.

The products II obtained were checked by GLC, and their properties were determined. From these results, it seems likely that the predominance of VIII rather than V in the yield of γ-lactone may be attributable to its advantage in the rearrangement of the double bond, since the contribution of the resonance of the conjugate base $(-\ddot{C}H-CH=CH-CN \longleftrightarrow -CH=CH-\ddot{C}H-CN)^-$ must be larger than

that of V.

d) *Tracing of the Process of the Reaction.* The process of the reaction was followed by measuring the OH number and the N%. The sample submitted to analysis was pretreated to exclude difficulties. The neutralization of the alkaline catalyst and of the liberated ammonia with diluted hydrochloric acid, and the removal of the resulting salt and solvent, were carried out carefully. In spite of these cautions, however, there remained some doubt about the values obtained, because the loss of the species to be analyzed, which were assumed to be present, could not be avoided during the procedure. Aside from the point of whether or not the data indicates the absolute values, however, information about the estimated situation was obtained. That is, the decrease in the N% in the sample is relatively faster than that of the OH number. About 5 hr after reflux, 80—90% of the N content with respect to the theoretical amount was consumed. However, the consumption of OH was not so great. Moreover, the rate of the decrease in N% in the hydrolysis of γ-alkoxycrotonitrile is comparable to that of I. Therefore, the comparison between the consumption of OH and that of the N content gives information about the relative rates of the I to VIII and I to IV paths respectively.

Summary

The principal purpose of this investigation, the development of a new route for the synthesis of γ-alkoxy-γ-butyrolactone from epichlorohydrin, has been achieved. The identity of the products obtained with authentic substances prepared by well-known methods, and some proofs for the structure have been indicated by GLC, IR, NMR, and other appropriate procedures. In the experiments concerning the reaction paths, it was confirmed that some of the presumed intermediates indeed exist in the reaction mixture and that these intermediates, treated in the same condition to that of the hydrolysis of I, give γ-alkoxy-γ-butyrolactone. These results suggest that all the postulated paths in a scheme presented early in this paper are possible. To decide the most favorable path, however, was difficult on the basis of the results obtained in the present work. It may still be guessed that the attack on the cyano group is preferrable to the competing elimination of the hydroxyl group. As the sequence, the I→IV→V→VI→(*via* VII)→II path may eventually come to be significant, even though the rearrangement of VIII to IX is more likely than that of V to VI, as has been mentioned. The outline of the synthesis has already been published as a letter to the editor.[14]

The authors wish to thank Professor T. Mukai of Tohoku University for his providing the convenience of the NMR measurements. They are also indebted to Mr. S. Tomidokoro for his assistance in the experimental work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1351—1353 (1969)

Spiro Compound Formation. III.[1] The Formation of Spiro Compounds by the Rearrangement of Bicyclo[5.4.0]-undecene(1,7) and Cyclopentylcyclohexene

Masatomo NOJIMA and Niichiro TOKURA

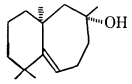
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received July 31, 1968)

The isomerizations of bicyclo[5.4.0]undecene-(1,7) (IV), spiro[5.5]undecene-1 (V), and 1-cyclopentylcyclohexene (VI) were examined with equivalent amounts of perchloric acid in acetic acid or in ethanol at 75°C. In acetic acid, IV, V, and VI all rearranged to form spiro[5.5]-undecan-1-yl acetate (VII) and spiro[5.5]undecan-2-yl acetate (VIII), together with the three olefins IV, V, and VI. No rearranged product has been obtained by the same procedure in ethanol.

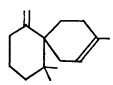
The recent report by Ito[2] on the rearrangement of widdrol (I) or thujopsene (II) to chamigrene (III) under acidic conditions was very suggestive regarding the possibility of spiro-compound formation from bicyclo[5.4.0]undecane derivatives. The formation of 1-cyclopentylcyclohexene (VI) from the reaction of spiro[5.5]undecan-1-ol with zinc chloride had previously been reported by Christol, Jacquier, and Mousseron.[3]

The acetolysis of spiro[5.5]undecan-1-yl tosylate was also examined by Krapcho, McCullough, and Nahabedian[4]; they obtained spiro[5.5]undecane, cyclohexylcyclopentane, and *cis*-bicyclo[5.4.0]undecane in yields of 11, 64, and 25% respectively after the hydrogenation of the reaction mixture.



I

II



III

From these results, it is expected that bicyclo-[5.4.0]undecene(1,7) (IV), sipro[5.5]undecene-1 (V), and 1-cyclopentylcyclohexene (VI) would all rearrange under acidic conditions. Thus, the present authors attempted the isomerization reaction of IV, V, and VI in the presence of one equivalent mole of perchloric acid in both acetic acid and ethanol.

IV, V and VI all rearranged with each other and gave a mixture with VII and VIII as the major products after 24 hr.

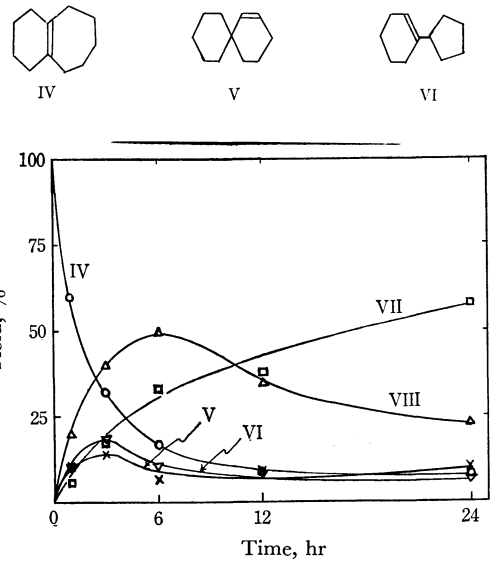


Fig. 1. The Conversion *vs.* reaction time relationship during the isomerization of IV.

The behavior of the isomerization of IV is shown in Fig. 1. At the initial stage of the reaction compound IV rearrange to V, VI, and spiro-[5.5]undecan-1-yl acetate (VII), which is then converted to spiro[5.5]undecan-2-yl acetate (VIII). This reaction probably proceeds by way of the carbonium ion B_2. After 24 hr, VIII increased to become 55.8% of the whole reaction product. Similar results were obtained by the reaction of VI in acetic acid. The fact that VIII was formed by the addition of acetic acid to V (after 24 hr an 82.8% yield of VIII was obtained) is comparable to the results in the preceding paper,[1] where V was formed by the reaction of 1-(Δ^4-pentenyl)-

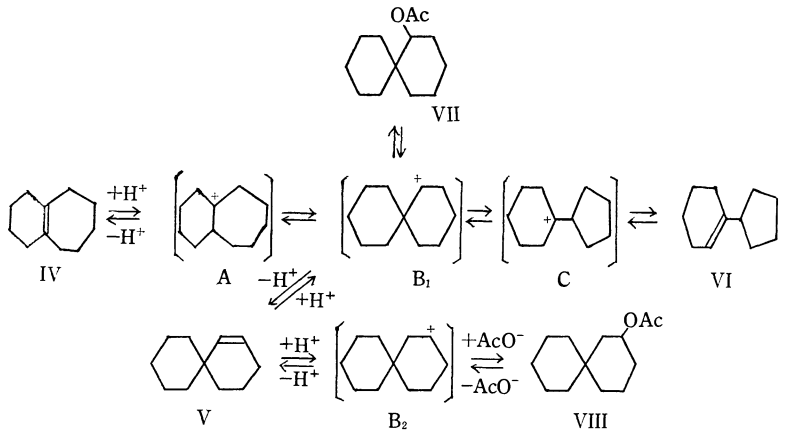

Scheme I

cyclohexanol; it is in equilibrium with VIII in acetic acid in a molar ratio of 4.5 to 95.5.

The instability of VII under these three sets of reaction conditions was confirmed by the finding that VII was converted to VIII in a high yield under the same conditions. This instability of VII may be explained from a sterical point of view.

Scheme I presents what seem to be the most plausible routes for the formation of the products.

The tertiary carbonium ions, A and C, produced by the protonation of IV and VI rearrange to a carbonium ion, B_1, which then affords VII upon the attack of the acetate anion and the compound V upon deprotonation.

The compound VII was also converted to the ion B_1 by the elimination of acetic acid after protonation; the ion was then further rearranged or deprotonated to form the three products, IV, V, and VI. Under the three sets of reaction conditions the tertiary acetate, which may be derived from A and C, is again unstable.

The reactions of IV, V, and VI in ethanol were also attempted. Contrary to the reactions in acetic acid, no rearrangement occurred after 24 hr and the original olefins used were recovered unchanged.

Experimental

Bicyclo[5.4.0]undecene-(1,7) (IV). Bicyclo[5.4.0]-undecan-2-ol was reacted with polyphosphoric acid according to the method of Christol, Jaquier, and Mousseron;[3] bp 107—108°C/25 mmHg. Found: C, 87.90; H, 12.21%. Calcd for $C_{11}H_{18}$: C, 87.92; H, 12.08%.

Spiro[5.5]undecene-1 (V). This compound was prepared from spiro[5.5]undecan-1-yl xanthate according to the procedure described by Alexander and Mudrak;[5] bp 105—106°C/25 mmHg. Found: C, 87.97; H, 11.92%. Calcd for $C_{11}H_{18}$: C, 87.92; H, 12.08%.

1-Cyclopentylcyclohexene. The reaction of cyclopentylcyclohexanol with thionyl chloride and pyridine[6] gave cyclopentylcyclohexene in a 70% yield; bp 104—105°C/25 mmHg, NMR τ=4.8 (broad 1H). Found: C, 87.88; H, 12.19%. Calcd for $C_{11}H_{18}$: C, 87.92; H, 12.08%.

Spiro[5.5]undecan-1-yl Acetate. This acetate was prepared from the corresponding alcohol with acetyl chloride and *N,N*-dimethylaniline according to the procedure of Nevitt and Hammond.[7] The yield was 55%; bp 104—105°C/7 mmHg: NMR τ=7.6 (singlet, 3H), 5.4 (broad 1H). Found: C, 74.50; H, 10.49%. Calcd for $C_{13}H_{22}O_2$: C, 74.30; H, 10.65%.

Isomerization of an Olefin, IV, V, or VI, in Acetic Acid. To 0.5 g (0.33 mmol) of the olefin in 15 m*l* of glacial acetic acid there was added a 5-m*l* portion of an acetic acid solution containing 0.4 g of 60% perchloric acid (d=1.55). The temperature was maintained at 75±2°C, and a 5-m*l* aliquot was withdrawn periodically. The aliquot was rapidly cooled, diluted with 30 m*l* of chilled water, and extracted three times with *n*-hexane. The combined organic layer was washed with saturated brine water and dried over anhydrous sodium sulfate.

The volume of the extract was kept as small as possible so that no concentration was necessary prior to vpc analysis. The products were analyzed on a Hitachi-Perkin Elmer Gas Chromatograph, Model F-6-D, equipped with a hydrogen flame-ionization detector. A 150 ft×0.01 in. column packed with Silicone DC 550 was employed, and nitrogen was used as the carrier gas. The temperature settings were at 150°C for the olefin analysis and at 200°C for the acetate analysis.

The Reaction of VII in Acetic Acid. A solution of 0.6 g of VII and 0.4 g of 60% perchloric acid (d=1.55) was heated at 75°C for 24 hr. The reaction mixture was then extracted and analyzed as above. The residue after the removal of the solvent was chromatographed over 30 g of alumina. Elution with ether (10×50 m*l*) gave 0.4 g of an oil. The infrared and NMR spectra

were identical with those of VIII;[1] however, this product found to be 95% pure by vpc analysis on a silicone DC 550 column.

The Attempted Isomerization of Three Olfefins, IV, V, and VI, in Ethanol. To 0.5 g of the olefin and 15 m*l* of ethanol there was added a 5-m*l* portion of an ethanol solution containing 0.5 g of 60% perchloric acid ($d=1.55$). The reaction temperature was maintained at 75 ± 2°C for 24 hr. The reaction mixture was then treated and analyzed as has been described above.

The Photoreaction of β-Benzoylacrylic Acid

Noboru SUGIYAMA, Hiroshi KATAOKA, Choji KASHIMA and Kazutoshi YAMADA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received August 23, 1968)

The product of the irradiation of *trans*-β-benzoylacrylic acid (**1**) in methanol was proved to be α-methoxy-β-benzoylpropionic acid (**2**), whose methyl ester was identified with an authentic material. On the other hand, the product of the irradiation of methyl *trans*-β-benzoylacrylate (**5**) was the *cis*-isomer. The photoreaction of **1** in various solvents, including EtOH, *iso*-PrOH, *t*-BuOH, ether, and AcOH, was examined from the standpoints of the *cis-trans* isomerization and alcohol addition. The rate of the photoreaction of **1** in methanol was determined, and a reasonable mechanism for the over-all reaction was proposed.

Only a few studies of β-acyl- and β-aroyl-acrylic acids have been found in the literature.[1] Previously we ourselves reported on the structures and the reactions of these systems.[2] Also, we found three kinds of photoproducts from these systems[3]—that is, *cis-trans* isomers, angelica lactones, and alcohol adducts. Lutz[4] first reported the *cis-trans* isomerization of methyl β-benzoylacrylate under sunlight without any solvent or in benzene. Kropp[5] found that the photoaddition of alcohol to an olefinic double bond was limited to six- or seven-membered cyclic olefins; larger ring or acyclic systems capable of easily undergoing *cis-trans* photoisomerization showed no evidence of adduct formation.

Recently it has been found that methanol, when added to *trans*-β-benzoylacrylic acid (**1**) under the irradiation of UV light, gave β-benzoyl-α-methoxypropionic acid (**2**).[3,6] This is the first example of the photoaddition of methanol to acyclic olefins giving a methoxy derivative except in the case of Stoermer's work, which was reinvestigated by Kropp.[5] However, the formation of no adduct was detected. The present paper will deal with the photoreaction of *trans*-β-benzoylacrylic acid (**1**) in various solvents and will discuss the reaction mechanism.

By the external irradiation of **1** in methanol, **2** was obtained almost quantitatively. The product was methylated by diazomethane. The methyl ester was identified with the authentic methyl α-methoxy-β-benzoylpropionate (**3**)[2b] on the bases of the spectral data.

$$C_6H_5COCH_2\underset{\displaystyle R_1}{\underset{|}{C}}HCOOR_2$$

2 $R_1=OCH_3$, $R_2=H$
3 $R_1=OCH_3$, $R_2=CH_3$

It was confirmed that **2** was not obtained without light under the same conditions. Table 1 shows the results of the reactions of **1** in various solvents. Photoaddition was observed only when methanol or ethanol was used as the solvent. The alcohols with larger alkyl groups, *e.g.*, isopropanol or *t*-butanol, did not add to **1**. In ether, acetic acid, or tetrahydrofuran, or without a solvent, **1** was turned to the *cis*-isomer **4** photochemically. From these results, it is clear that the addition of alcohol becomes difficult as the alkyl group of alcohol becomes bulky.

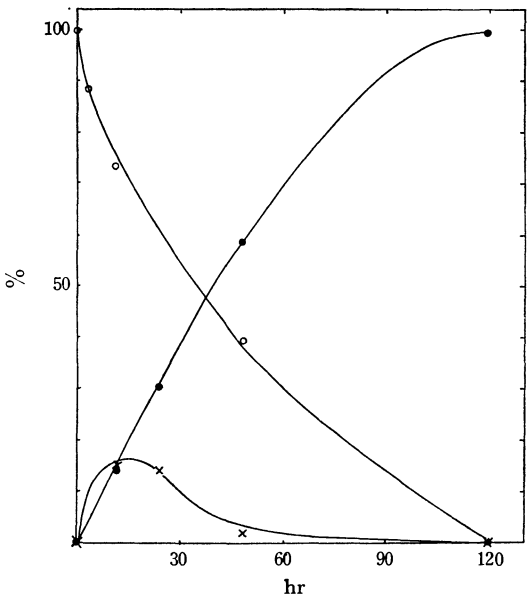

Fig. 1. The rate of the photoreaction of **1** in methanol.
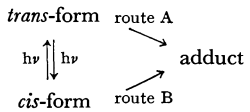
○—○—○ *trans*-form
●—●—● adduct
×—×—× *cis*-form

In order to confirm the structure of the photoproduct, **4**, methyl *cis*-*β*-benzoylacrylate (**6**)[7] was prepared by the irradiation of methyl *trans*-*β*-benzoylacrylate (**5**) in methanol. As the spectral data of **6** have not yet been reported, the UV, IR, and NMR spectra of **6** were measured, as will be shown in the Experimental section. All the spectral data strongly support the structure **6**. The IR spectrum of **4** shows the characteristic *cis*-olefinic bands at 1415 cm^{-1} (CH, in-plane), 745, and 695 cm^{-1} (CH, out-of-plane).[8] The NMR spectrum shows a doublet of olefinic protons at τ 2.89 and 3.68, with a coupling constant of 12.0 Hz. These data support the *cis*-configuration of **4**.

Furthermore, in acetic acid - methanol (1 : 1) or in methanol containing a several drops of ether, methanol did not add, but the *cis*-isomer **4** was obtained. In water-methanol (2:1), the adduct **2** was obtained, indicating that methanol addition took place while water addition did not. In a methanol solution containing a few drops of hydrochloric acid, the adduct was formed, but the yield was low. These results, make it probable that the excess acidic proton disturbs the alcohol addition. Methyl *trans*-*β*-benzoylacrylate **5**, however, did not react with methanol to give the adduct in methanol under irradiation.[3] Therefore, it might be concluded that the presence of a free carboxyl group in **1** is essential for the alcohol addition.

Next, the rate of the formation of products during the irradiation of **1** in methanol was determined, as is shown in Fig. 1. The starting material, **1**, first decreased gradually and then disappeared completely after 5 days. During the course of this period, the adduct **2** gradually increased, while the *cis*-isomer first increased and then gradually decreased.

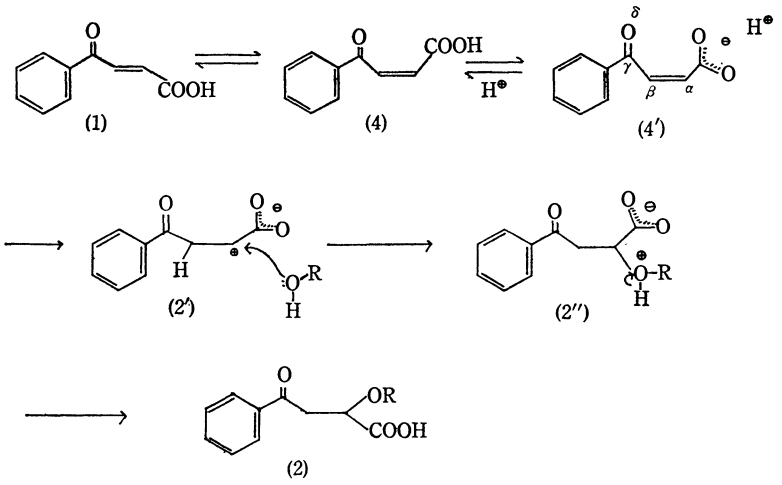


Scheme 1

From these results, it can be presumed that the adduct **2** will be produced *via* route A or B in Scheme 1. When **1** was irradiated in tetrahydrofuran (THF) for 72 hr, a mixture of *trans*- and *cis*-isomers (45:55) was obtained. When the methanol solution of this mixture was left to stand for 5 days in a dark place at room temperature, the adduct **2** and the *trans*-isomer were obtained in 37% and 63% yields respectively, and the *cis*-isomer was not found. These facts suggest that the *cis*-isomer **4**, formed by photochemical *cis*-*trans* isomerization, reacted with methanol to give the adduct **2** (route B).

Now let us presume the reaction route shown in Scheme 2. Scheme 2 explains that the free carboxylic acid is essential for the alcohol addition, and that an excess amount of acid disturbs the reaction. Considering that the *cis*-isomer **4** reacted with methanol to give the adduct **2** in a dark place,

7) G. P. Rice, *J. Am. Chem. Soc.*, **45**, 222 (1923).
8) K. Nakanishi, "Infrared Absorption Spectroscopy," Nankodo Co., Ltd., Tokyo (1962), pp. 24, 124, 125.



Scheme 2

the *cis*-acid **4** might be first produced by light and then dissociated to the carboxylate anion **4'**. In the presence of excess acid, the anion **4'** would change to the non-dissociated acid **4**, and the addition could not proceed. This is the reason why the adduct **2** is not obtained in acetic acid, in acetic acid - methanol (1 : 1), or in methanol containing a trace of hydrochloric acid. Moreover, isopropanol or *t*-butanol disturbed the alcohol addition and only *cis-trans* isomerization occurred. This is because the hydroxy oxygen of isopropanol or *t*-butanol is more negative than those of methanol or ethanol because of the inductive effect of the alkyl group. The dissociated proton coordinates to the hydroxy oxygen of alcohol; therefore, the alcohol cannot attack **4'**, as with **2'** or **2''**. Furthermore, the bulkiness of alcohol may also influence an alcohol attacking olefin. The fact that the *cis*-isomer was obtained in methanol containing a small amount of ether can also be explained by a consideration similar to that ether can stabilize the structure **4'**, but as for this point, more detailed experiments are needed.

Experimental

Matrials. *trans*-β-Benzoylacrylic Acid (1) was prepared by the method of Papa; yellow needles, mp 94—95.5°C (lit. 98—99°C).[9]

UV (λ_{max} nm (ε), in EtOH): 238 (11000), 272 (8900), 357 (86).

Methyl *trans*-β-Benzoylacrylate (5) was prepared by the method described in a previous paper,[2] mp 34°C.

All the solvents were commercially-available Guaranteed Reagents.

Instrumentation. The infrared and ultraviolet spectra were measured on a Hitachi EPI-2-type infrared spectrometer and a Hitachi EPS-3T-type recording spectrometer respectively.

A Taika 500 W high-pressure mercury lamp was used as the irradiation source, while a Pyrex tube was used as the filter and reaction vessel. The NMR spectra were recorded in deuterochloroform, with TMS as the internal standard, with an Hitachi H-60 high-resolution spectrometer.

For paper chromatography we used Toyo Filter Paper No. 53 and *n*-butanol (saturated with a 3% aqeuous ammonia solution).

Irradiation of *trans*-β-Benzoylacrylic Acid (1) in Methanol. One gram of **1** was dissolved in 20 m*l* of methanol, and then the solution was irradiated for 5 days. The solvent was removed under reduced pressure. It was confirmed by a study of the NMR spectrum that the starting material, **1**, did not remain, and that β-benzoyl-α-methoxypropionic acid (**2**) was formed almost quantitatively as a yellow oil.

NMR (τ, in $CDCl_3$): 1.8—2.7 (m, phenyl), 2.55 (broad s, COOH), 5.55 (t, J=6.0 Hz, α-methine), 6.42 (s, $-OCH_3$), 6.48 (d, J=6.0 Hz, β-methylene).

R_f value of paper chromatography: 0.52 (that of **1**: 0.40).

Crude **2** was methylated with diazomethane to give methyl β-benzoyl-α-methoxypropionate (**3**), which was then purified by silica-gel - column chromatography and eluted with benzene - ethyl acetate (19 : 1), as a yellow liquid.

IR (cm^{-1}, liq. film): 1750 ($COOCH_3$), 1685 (Ar–CO–) 1600 (phenyl), 1195 (C–O–C).

UV (λ_{max} nm (ε), in EtOH): 244 (11000), 280 (1100), 323 (66).

NMR (τ, in $CDCl_3$): 1.82—2.66 (m, phenyl), 5.55 (t, J=6.0 Hz, α-methine), 6.23 (s, $COOCH_3$), 6.52 (s, $-OCH_3$), 6.62 (d, J=6.0 Hz, β-methylene).

3 was identified with an authentic sample[2b] by means of its IR, UV, and NMR spectra.

Irradiation of Methyl *trans*-β-Benzoylacrylate (5) in Methanol. A methanol solution of **5** (500 mg/10 m*l*) was irradiated in a Pyrex tube for 5 days, after which the solvent was removed under reduced pressure. The NMR spectrum of this residue showed that 76% of the **5** had changed to methyl *cis*-β-benzoylacrylate

9) D. Papa, E. Schwenk, F. Villani and E. Klingsberg, *J. Am. Chem. Soc.*, **70**, 3356 (1948).

(**6**). The residue was washed with ice-cooled methanol and recrystallized from methanol. Colorless needles, mp 66°C (lit. 67°C).[7]

IR (cm^{-1}, KBr): 1725 (ester C=O), 1675 (Ar–CO–), 1640 (C=C), 1395 (*cis*-olefin, in-plane), 760, 740, 705 (*cis*-olefin, out-of-plane), 735, 690 (phenyl).

UV (λ_{max} nm (ε), in EtOH): 251 (11800), 280 (sh, 3790), 342 (152).

NMR (τ, in $CDCl_3$): 1.9—2.7 (m, phenyl), 3.13 (d, J=12.0 Hz, olefinic proton), 3.76 (d, J=12.0 Hz, olefinic proton), 6.42 (s, ester methyl).

Irradiation of 1 in Ethanol. An ethanol solution of **1** (250 mg/5 m*l*) was irradiated for 10 days. The subsequent evaporation of the solvent under reduced pressure gave β-benzoyl-α-ethoxypropionic acid (**7**), which was then purified by cellulose-powder chromatography and eluted with *n*-butanol saturated with 3% aqueous ammonia; pale yellow needles, mp *ca.* 93°C.

IR (cm^{-1}, KBr): 2800—2300 (COOH), 1715 (COOH), 1675 (Ar–CO–), 1600 (phenyl), 1260, 1210 (C–O–C), 720, 675 (phenyl).

UV (λ_{max} nm (ε), in EtOH): 244 (9300), 273 (sh, 3400), 345 (200).

NMR (τ, in $CDCl_3$): 1.2 (s, COOH), 1.8—2.7 (m, phenyl), 5.39 (t, J=6.0 Hz, methine), 6.24 (q, J=6.0 Hz, –OEt, methylene), 6.51 (d, J=6.0 Hz, methylene), 8.78 (t, J=6.0 Hz, –OEt, methyl).

β-Benzoyl-α-ethoxypropionic Acid (7). A solution of β-benzoylacrylic acid (1 g) in 30 m*l* of ethanol containing 0.1 m*l* of sulfuric acid was refluxed for 4 hr. The reaction mixture was then diluted with water and extracted with ether. The ethereal layer was washed with a sodium carbonate solution and then with water, and dried with anhydrous sodium sulfate. After the solvent had been removed, ethyl β-benzoyl-α-ethoxypropionate (**8**) was obtained; 0.4 g, yellow liquid.

IR (cm^{-1}, liq. film): 1740 (ester C=O), 1685 (Ar–CO–), 1195 (C–O–C).

UV (λ_{max} nm (ε), in EtOH): 243 (15000).

NMR (τ, in $CDCl_3$): 1.9—2.6 (m, phenyl), 5.45 (t, J=6.0 Hz, methine), 5.75 (q, J=6.0 Hz, ester methylene), 6.25 (q, J=6.0 Hz, ether methylene), 6.65 (d, J=6.0 Hz, methylene), 8.70 (t, J=6.0 Hz, ester methyl), 8.80 (t, J=6.0 Hz, ether methyl).

Found: C, 67.19; H, 7.22%. Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25%.

One hundred milligrams of **8** were dissolved in 10 m*l* of 0.5% ethanolic potassium hydroxide, and then the mixture was stirred for 15 hr at room temperature. After hydrochloric acid had been added to the reaction mixture, it was extracted with ether. From the ether solution β-benzoyl-α-ethoxy-propionic acid (**7**) was obtained. This synthetic sample was found by paper chromatography and the spectral data to be identical with the photoproduct, **7**, of the preceding section.

Irradiation of 1 in Various Solvents. In 1 m*l* of a solvent, 50 mg of **1** were dissolved, and the mixture was irradiated for 2—3 days in a Pyrex tube. After irradiation, the solvent was removed under reduced pressure; the NMR spectrum of the residue was immediately measured, and the yields of the products were calculated from the integration of the spectrum.

The Solution of 1 in Methanol with Time. A solution of **1** (300 mg) in 6 m*l* of methanol was divided into six aliquots, which were then irradiated for 0, 3, 12, 24, 48, and 120 hr respectively. On each aliquot, after the removal of the solvent, the NMR spectrum of the residue was measured at τ 3.17 (d, olefinic proton of **1**), 3.65 (d, olefinic proton of **4**) and 5.55 (t, methine proton of **2**); the yields of **1**, **4** and **2** were calculated from the integration of each signal. The results are plotted in Fig. 1.

The Dark Reaction of a Methanol Solution of the Mixture of *cis*- and *trans*-Isomers of β-Benzoylacrylic Acid. Fifty milligrams of **1** were dissolved in 1 m*l* of THF, and the mixture was irradiated for 72 hr. After the solvent had been removed under reduced pressure, a 55:45 mixture of *cis*- and *trans*-β-benzoylacrylic acid was obtained. This mixture was dissolved in 1 m*l* of methanol and then left to stand for 72 hr at a dark place. The adduct **2** and the *trans*-isomer **1** were obtained in 37% and 63% yields respectively.

The authors wish to express their thanks to Mr. Kyuzaburo Furuhashi for his measurement of NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1357—1359 (1969)

A Novel Method for the Synthesis of 1-Phenyl-2,3-dihydro-4-pyridones

Noboru SUGIYAMA, Makoto YAMAMOTO and Choji KASHIMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received August 23, 1968)

The condensation of β-diketones, benzoylacetone (II), acetylacetone (III), or 6-phenyl-2,4-hexanedione (IV) with benzylidenaniline (I), in the presence of three moles of potassium amide in liquid ammonia, was found to give a dihydropyridone or an aminodiketone. Thus, the condensation of II with I afforded aminodiketone, 1-anilino-1,5-diphenyl-3,5-pentanedione (V), which cyclized to 2,3-dihydro-1,2,6-triphenyl-4-pyridone (IX) upon being treated with sulfuric acid. The condensation of III with I gave 2,3-dihydro-1,2-diphenyl-6-methyl-4-pyridone (X) without any treatment with sulfuric acid. IV and I gave 2,3-dihydro-1,2-diphenyl-6-phenethyl-4-pyridone (XI) as the main product, with 3-benzyl-2,3-dihydro-1,2-diphenyl-6-methyl-4-pyridone (XII) as a by-product.

The condensation of β-diketones with ketones or aldehydes in the presence of alkali amide in liquid ammonia has previously been reported.[1,2] It appeared of interest to investigate whether the reaction could be extended to the condensation of β-diketones with Schiff bases. Thus, the reaction of β-diketones, *e. g.*, benzoylacetone (II), acetylacetone (III), or 6-phenyl-2,4-hexanedione (IV), with benzylidenaniline (I), a Schiff base, was carried out in the presence of three moles of potassium amide in liquid ammonia. It was proved that a dihydropyridone or an aminodiketone was produced by this reaction. A few reports of dihydropyridone synthesis have appeared in the literature;[3,4] in these syntheses dihydropyridones have been prepared by the partial reduction of the corresponding pyridones. In our method, however, dihydropyridones are directly prepared from β-diketones and a Schiff base.

Results and Discussion

A β-diketone was condensed one molar equivalent of a Schiff base in the presence of three molar equivalents of potassium amide in liquid ammonia. The condensation of II with I gave 1-anilino-1,5-diphenyl-3,5-pentanedione (V). The structure of V was proved by its IR, UV, and NMR spectra and by the results of elemental analysis.

The treatment of V with sulfuric acid gave 2,3-dihydro-1,2,6-triphenyl-4-pyridone (IX), whose structure was supported by its IR, UV, and NMR spectra as well as by the results of elemental analysis. The NMR spectrum of IX showed a multiplet at τ 6.37—7.35, a triplet centered at τ 4.70 and a singlet at τ 4.42; these can be assigned to C-3 methylene, C-2 methine, and olefinic protons of the 2,3-dihydro-4-pyridone nucleus respectively. The UV maxima at 249 and 353 mμ remained unchanged in either an acidic and an alkaline solution. These facts favor the dihydropyridone structure of IX. The reaction course from V to IX is a cyclization by dehydration and seems analogous to that from an aminodiketone to a 4-pyridone.[5]

III and I were treated under the conditions similar to those described above. In this case, the expected aminodiketone (VI) was not detected, but 2,3-dihydro-1,2-diphenyl-6-methyl-4-pyridone (X) was obtained. The structure of X was supported by the spectral data and by the results of elemental analysis.

It is suggested that VI is the intermediate in the synthesis of X, as V is the intermeidate in the synthesis of IX, and that the intermediate VI is cyclized during the neutralization with ammonium chloride. Thus, the detection of VI was examined before the neutralization. However, X was the only product obtained, and no aminodiketone was detected. These facts indicate that the cyclization

of VI was already accomplished before the neutralization.

The reaction of IV and I was also carried out. Compound IV has a terminal methyl group (C-1 position) and a C-5 methylene group, which can be activated by the vicinal carbonyl group. The treatment of IV and I by the general procedure gave 2,3-dihydro-1,2-diphenyl-6-phenethyl-4-pyridone (XI) and its isomer, 3-benzyl-2,3-dihydro-1,2-diphenyl-6-methyl-4-pyridone (XII), in a molar ratio of 4:1. The structures of XI and XII were supported by the spectral data and by the results of elemental analysis. For the formation of XI and XII, it is also supposed that the VII and VIII intermediates must be formed first. Thus, it is reasonable to suppose that the reaction proceeds not only at the terminal methyl group, but also at the C-5 methylene group of IV. The yield of XI and XII supports the idea that, in IV, the terminal methyl is more reactive than the C-5 methylene group. This might be in agreement with the fact that IV and methyl iodide in the presence of sodium amide in liquid ammonia gave the corresponding methylation products at C-1 and C-5 positions in a ratio of 89:11.[6]

Furthermore, we attempted to perform experiments on the condensation of a β-diketone III with aliphatic Schiff bases, benzylidenemethylamine, and ethylidenaniline. However, neither the corresponding dihydropyridone nor the aminodiketone was obtained, probably because these Schiff bases are unstable under the conditions of the general procedure.

Experimental

General Procedure. In a 500-m*l* three-necked flask, 300 m*l* of anhydrous liquid ammonia were placed. A small amount of potassium was then added and dissolved completely. Into the blue solution there were stirred a catalytic amount of ferric chloride and then 5.85 g (0.15 mol) of potassium in small portions. The resulting blue solution turned dark gray within 90 min. To this solution there was added, in small protions, 0.05 mol of β-diketone in 30 m*l* of anhydrous ether. After stirring for 45—60 min, 0.05 mol of a Schiff base in 30 m*l* of anhydrous ether was added to the solution. After stirring for an additional hour, the reaction mixture was neutralized with ammonium chloride. The liquid ammonia was evaporated rapidly on a water bath, and 100—150 m*l* of ether were added from a dropping funnel. The ethereal layer was separated and reserved. To the remaining layer there were added 150 m*l* of dilute hydrochloric acid, and this solution was extracted with chloroform. After drying over anhydrous sodium sulfate, the ether and the chloroform were evaporated. Both residues gave a crude condensation product.

1-Anilino-1,5-diphenyl-3,5-pentanedione (V). According to the general procedure, V was prepared from 8.1 g (0.05 mol) of II and 9.05 g (0.05 mol) of I. The crude product was recrystallized from a benzene-*n*-hexane (1:1 v/v) mixture to give 7.3 g (43%) of V as colorless plates, mp 116—118°C.

Found: C, 80.05; H, 6.05; N, 4.10%. Calcd for $C_{23}H_{21}NO_2$: C, 80.44; H, 6.16; N, 4.08%.

IR (KBr): 3370 (νNH), 1600 (νC=O), 1570 (νC=C, enol) and 700 cm^{-1} (phenyl).

UV: λ_{max}^{EtOH} 249 mμ (ε 19000) and 311 mμ (ε 17200).
$\lambda_{max}^{HCl\text{-}EtOH}$ 319 mμ (ε 16600).
$\lambda_{max}^{NaOH\text{-}EtOH}$ 247 mμ (ε 22000) and 332 mμ (ε 17800).

NMR (CCl_4): τ 7.10 (doublet, 2H, $COC\underline{H}_2$–CH), τ 5.14 (triplet, 1H, CH_2–C$\underline{H}$–Ph), τ 3.92 (singlet, 1H, Ph–C=C$\underline{H}$–CO), and τ 2.08—3.50 (multiplet, 15H, phenyl).

2,3-Dihydro-1,2,6-triphenyl-4-pyridone (IX). To 2.0 g of V, 15 m*l* of concentrated sulfuric acid were added, and then the mixture was allowed to stand at room temperature for two hours. About 100 g of crushed ice were then added to the reaction mixture, and the solution was neutralized with a cold concentrated potassium hydroxide solution. This solution was extracted with chloroform, and the chloroform layer was washed with water and dried over anhydrous sodium sulfate. The solution was evaporated, and the residue was chromatographed on a silica-gel (Merck 7734) column with a benzene - ethyl acetate (2:1 v/v) mixture. The fraction, which showed a violet color in a ferric chloride test, was collected and concentrated to give crude IX, which was then recrystallized from ether to yield 0.12 g (6.3%) of IX as yellow plates; mp 149—151°C.

Found: C, 84.82; H, 5.97; N, 4.34%. Calcd for $C_{23}H_{19}NO$: C, 84.89; H, 5.89; N, 4.30%.

IR (KBr): 1645 (νC=O) and 1550 cm^{-1} (νC=C).

UV: λ_{max}^{EtOH} 249 mμ (ε 16300) and 353 mμ (ε 21500).

NMR (CCl_4): τ 6.37—7.35 (multiplet, 2H, C-3 methylene), τ 4.70 (triplet, 1H, C-2 methine), τ 4.42 (singlet, 1H, olefinic proton), and τ 2.40—3.20 (multiplet, 15H, phenyl).

2,3-Dihydro-1,2-diphenyl-6-methyl-4-pyridone(X). X was synthesized from 5.0 g (0.05 ml) of III and 9.05 g (0.05 mol) of I by the general procedure. The residue was chromatographed on a silica-gel (Merck 7734) column with a benzene-ethyl acetate (4 : 1 v/v) mixture. The fraction, which showed a brownish violet color in a ferric chloride test, was collected and evaporated to afford crude X, which was then recrystallized from carbon tetrachloride to give 6.5 g (50%) of colorless needles; mp 84—85°C.

Found: C, 81.94; 81,98; H, 6.53, 6.54; N, 5.26%. Calcd for $C_{18}H_{17}NO$: C, 82.10; H, 6.51; N, 5.32%.
IR (KBr): 1645 (νC=O) and 1560 cm^{-1} (νC=C).
UV: λ_{max}^{EtOH} 240 mμ (ε 2180) and 327 mμ (ε 10400).
$\lambda_{max}^{HCl\text{-}EtOH}$ 242 mμ (ε 1640) and 325 mμ (ε 8100).
NMR (CCl_4): τ 8.20 (singlet, 3H, CH_3–C=), τ 6.88—7.62 (ABX-type, 2H, $COCH_2$–CH), τ 5.10 (triplet, 1H, CH–Ph), τ 4.96 (singlet, 1H, olefinic proton), and τ 2.85—2.92 (multiplet, 10H, phenyl).

In order to examine for the presence of the intermediate of VI, the whole procedure was modified as follows. Two grams of V (0.02 mol) were allowed to react with 3.6 g (0.02 mol) of I, and then the liquid ammonia was evaporated without neutralization. To the residue 50 g of crushed ice and 50 g of water were added. After stirring for 10 min, the reaction mixture was extracted with chloroform. The aqueous layer was neutralized with dilute hydrochloric acid, and then again extracted with chloroform. From both solutions, only X was detected, not VI.

2,3-Dihydro-1,2-diphenyl-6-phenethyl-4-pyridone (XI). By the general procedure, XI was prepared from 9.5 g of IV and 9.05 g of I. The residue was chromatographed on a silica-gel (Merck 7729) column with a benzene-ethyl acetate (4 : 1 v/v) mixture; a fraction which showed a violet color in a ferric chloride test was collected. After the evaporation of the solvent, the residue was recrystallized from benzene-*n*-hexane (1:1 v/v) to afford 3.5 g (20%) of XI as colorless plates; mp 99—100°C.

Found: C, 84.79; H, 6.62; N, 4.10%. Calcd for $C_{25}H_{23}NO$: C, 84.95; H, 6.56; N, 3.96%.
IR (KBr): 1635 (νC=O), 1550 (νC=C) and 705 cm^{-1} (phenyl).
UV: λ_{max}^{EtOH} 238 mμ (ε 4500) and 330 mμ (ε 17500).
$\lambda_{max}^{HCl\text{-}EtOH}$ 236 mμ (ε 5200) and 326 mμ (ε 13200).
NMR (CCl_4): τ 7.72—7.10 (multiplet, 4H, Ph–CH_2–CH_2–). τ 7.28 (multiplet, 2H, C-3 methylene), τ 5.10 (triplet, 1H, C-2 methine), τ 4.66 (singlet, 1H, C=CH), and τ 2.60—3.10 (multiplet, 15H, phenyl).

3-Benzyl-2,3-dihydro-1,2-diphenyl-6-methyl-4-pyridone (XII). As in the preceding fractionating chromatography for XI, a fraction which showed a light brown color with ferric chloride was collected, concentrated, and recrystallized from benzene to yield 0.9 g (5.0%) of XII as yellow plates; mp 179—180°C.

Found: C, 84.99; H, 6.71; N, 4.09%. Calcd for $C_{25}H_{23}NO$: C, 84.95; H, 6.56; N, 3.96%.
IR (KBr): 1623 (νC=O), 1555 (νC=C) and 700 cm^{-1} (phenyl).
UV: λ_{max}^{EtOH} 240 mμ (ε 4580) and 333 mμ (ε 16900).
$\lambda_{max}^{HCl\text{-}EtOH}$ 245 mμ (ε 3620) and 331 mμ (ε 13400).
NMR ($CDCl_3$): τ 7.98 (singlet, 3H, CH_3–C=C), τ 6.62—7.23 (multiplet, 4H, C-3 methylene and Ph–CH_2–), τ 5.45 (singlet, 1H, C-2 methine), τ 4.78 (singlet, 1H, CH=C), and τ 2.60—3.10 (multiplet, 15H, phenyl).

Reaction of III with Aliphatic Schiff Bases. By the general procedure, 2.0 g (0.02 mol) of III were condensed with 2.38 g (0.02 mol) of benzylidenemethylamine or with 2.38 g (0.02 mol) of ethylideneaniline. In these reactions, neither the corresponding dihydropyridones nor the corresponding aminodiketones were detected by thin-layer chromatography.

Synthesis and Physical Properties of Long Chain Compounds. X. Studies on the X-Ray Diffraction Patterns of Normal Higher Primary Amines

Akira WATANABE,* Akio ISHIZAWA,** Masao KOSAKA* and Ryōzō GOTŌ**

* *Department of Chemistry, Faculty of Science and Engineering, Ritumeikan University, Kita-ku, Kyoto*

** *Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto*

(Received August 6, 1968)

For the members of *n*-higher primary amines from C_{12} to C_{20} the crystal structure was studied by X-ray powder method. From the values of long spacings and the splitting of (110) reflections it was concluded that the structure is probably similar to that of fatty acids and that the hydrocarbon chains are tilted with respect to the plane formed by end groups. This structure seems to be stable over the temperature range between room temperature and melting points. The dependence of melting points on chain length was discussed.

X-Ray diffraction patterns of long chain compounds were first studied in detail by Müller[1] whose investigation dealt with normal paraffins with the carbon numbers from C_{18} to C_{44}. Malkin,[2] Francis,[3] and other workers also reported X-ray long spacings for the series of several long chain compounds such as alcohols, fatty acids, esters and iodides. In a previous work in this laboratory normal higher primary alcohols were studied in some detail.[4]

No X-ray study for normal higher primary amines can be found in the literature. Moreover a property of the amines in solid state has not been reported except the work of Smyth[5] who studied dielectric behavior of the amines of even carbon numbers from C_{12} to C_{18}. The present investigation was undertaken in order to study the dependence of solid structure of the amines on carbon numbers and on temperatures by X-ray powder method and to compare the results with those of higher alcohols and other compounds. The amines investigated are odd and even compounds with the carbon numbers from C_{12} to C_{20}.

Experimental

Preparation of the Amines and Their Purity.

The preparation has been reported in a preceding paper,[6] then the procedures will be described briefly. Since an extremely small amount of impurity affects the properties of long chain compounds, great care was taken throughout the preparations. Starting materials were commercial fatty acids and alcohol *e.g.*, lauric, myristic, palmitic, stearic acids and octadecyl alcohol. The acids, which had been converted to methyl esters, and the alcohol were purified by fractional distillation followed by several recrystallizations. The amines of C_{12}, C_{14}, C_{16}, C_{19} and C_{20} were synthesized by lithium aluminum hydride reduction of the corresponding acid amides in tetrahydrofuran. Most of the odd carbon numbered amines were prepared by Schmidt reaction or by Hofmann reaction from the next higher fatty acids. Melting points of the amines are given in Table 1 and Fig. 1. Data of the elemental analysis of *N*-acetylamines are recorded in Table 2. Since the melting point measurement or elementary analysis is not a reliable method to check the impurity in such long chain compounds, the efforts were exerted to find the method to establish the purity of the amines synthesized

and to obtain the compounds having a suitable purity for X-ray studies.

After preliminary experiments of gas chromatographic analysis it was found that this method is quite reliable for methyl esters, alcohols as well as acetylamines to check the impurities, especially homologous compounds which have been known to cause an important effect on the properties of solid long chain compounds. Methyl esters of starting fatty acids, alcohols and intermediate methyl esters, that is, the esters of C_{19}, C_{20} acids were effectively analyzed by gas chromatography. For example, by the gas chromatography with a flame ionization detector in the best condition, 0.1 to 0.5% of C_{16} compounds in C_{18} compounds could be detected.

The hydrochlorides of the amines were purified by recrystallizing them four to six times from ether-ethanol mixture. Resulting compounds, after being acetylated with acetic acid anhydride, were referred to gas chromatography. Recrystallizations of the hydrochlorides were repeated until a purity of 99% or better was achieved. Selections of the typical chromatograms are shown in Fig. 2 and Fig. 3. Before the X-ray measurements further purifications were carried out for each material as follows. The compound free from hydrogen chloride was heated in a stream of nitrogen at the temperature slightly above its melting point in order to eliminate any carbon dioxide which had been held in the compound. After about two hours heating the compound was distilled from the vacuum system into a tube. After being filled with nitrogen gas the tube was sealed off.

Measurements of X-Ray Patterns. The X-ray photographs were all taken using Cu*K* radiation which was produced at 40 kV and 30 mA. Camera distance was 10 cm. Exposure times were 1.5 to 2.5 hr depending on the chain length of the compounds.

The samples were melted on an electric heater placed in a glove box filled with nitrogen gas, and then drawn into thin walled glass tubes of about 0.5 mm diameter.

Column: 6 mm×2 m, 5% PEG 20 M on 60—80 mesh Celite 545 for the esters; 5% Apiezon grease L on 80—100 mesh Celite 545 for the alcohols; temp.: 155—225°C; nitrogen flow: 47 ml/min; fuel gas: hydrogen 44 ml/min.

The tubes were sealed off at their both ends. During the exposure the tubes were rotated. A brass furnace in which the tube was inserted was used for the measurements at high temperatures.

Results and Discussion

X-Ray diffraction patterns for the series of amines are presented in Fig. 4. The patterns appear to be similar throughout the series. No differences in crystal forms seem to exist between odd and even compounds nor from lower through higher members. The patterns were measured on long spacing reflections and it was found that the values of the spacings are a linerar function of carbon numbers for the series of either odd or even compounds. The data are summarized in Table 3 and illustrated in Fig. 5 together with those of normal higher alcohols quoted from previous papers.[4] The magnitude of the long spacings suggests that the molecules of the amines may be arranged in double molecules in the direction of the long axes, possibly due to the formation of hydrogen-bonding between the nitrogen atoms.

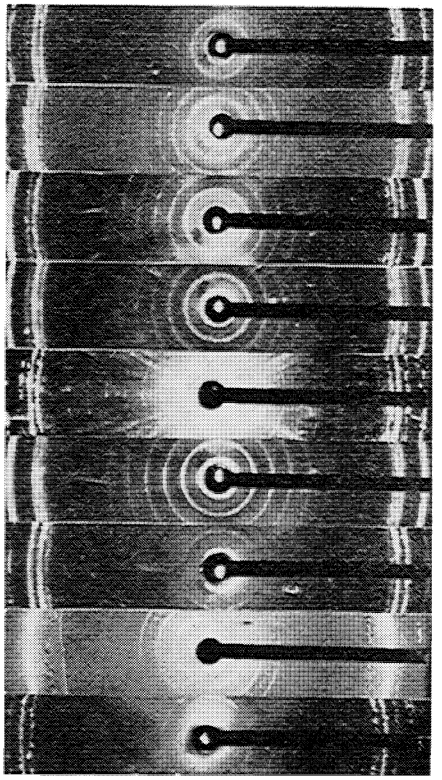

Fig. 4. X-Ray diffraction patterns of amines.
The patterns in discending order are from C_{12}, C_{13}, C_{14}, C_{15}, C_{16}, C_{17}, C_{18}, C_{19}, C_{20} amines.

By inspection of the values indicated in Table 3 it can be found that the long spacings of the amines are shorter by about 3 Å than those of the corresponding alcohols of vertical form. In view of the results of the analysis of other long chain compounds it is quite probable that the molecules of the amines extend themselves in straight zig-zag chains in the crystals, hence the shorter long spacings observed in the amines suggest that here the hydro-

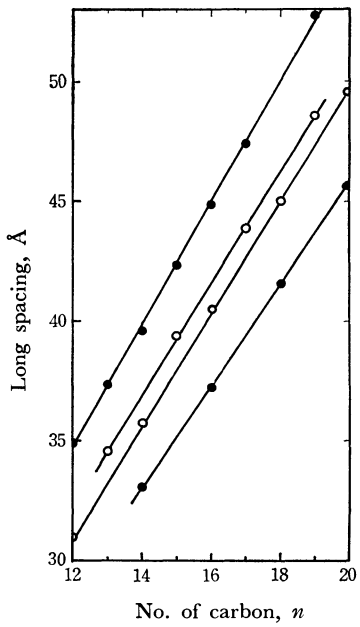

Fig. 5. Long spacings of *n*-higher primary amines and alcohols.
○ amines ● alcohols

carbon chains are inclined to the plane formed by the end groups. Additional evidence of the inclination can be obtained by the inspection of short spacing reflections. As may be seen in Fig. 4, the patterns indicate the splitting of (110) reflections in all the compounds, which is analogous to the case of tilted chain structures of higher alcohols and related compounds. If then, from the fact that the increase of the long spacings by the addition of two carbon atoms is about 4.6 Å, an approximate value of the tilt angle of the amine molecules can be estimated as 60° for both series of odd and even compounds.

Though the results obtained by powder patterns are limited to the general features of the molecular packing, some information on the conformation of the amines may be obtained by considering the intensity of the reflections with long spacings together with that of other compounds which have been analyzed previously. In the vertical form of normal higher alcohol *e. g.*, heptadecyl alcohol, the skew conformation of C–C–C–O bond has been confirmed by Seto.[7] Also it has been shown that, as a result of the existence of the skew conformations, the odd ordered long spacing reflections appear with stronger intensity as compared with those of even order. In the patterns of the amines the intensities of long spacing reflections decay gradually as the order of reflections increase. This behavior is different from that of alcohols mentioned above, and is similar to that of odd carbon numbered paraffin as heneicosane or tricosane which has been confirmed to have a straight zig-zag chain. From the intensity consideration mentioned above it seems probable that the amine molecules in the crystals consist only of transoid conformation of the C–C–C–N bonds.

Transitions in the solid state, which appear at temperatures not far from the melting or freezing points, have been found in paraffins, alcohols, bromides, and fatty acids. Therefore X-ray studies were made at various temperatures, in the hope of finding the same phenomena for the series of amines. However, no abrupt change of spacings was detected in any of the compounds studied. Accordingly, for the amine molecules tilted chain structure seems to be stable over the temperature range between room temperature and melting points.

A well known phenomenon of alternation of melting points could be observed in the series of amines investigated. As may be seen in Fig. 1, melting points of even carbon numbered amines lie on an upper curve similar to the behavior of other long chain compounds. Malkin,[8] in an earlier investigation, postulated a concept that the arrangement of tilted chain molecules makes methyl group packing less tight in odd carbon numbered compounds than in even numbered compounds. Later his concept was verified for the two forms of fatty acids by Sydow[9] with the interpretation based on the structure analysis. As mentioned above, the structure of the amine molecules, existing at the temperature just below their melting points, is the tilted one in both odd and even compounds. From the values given in Table 3 it can be found that the difference in the values of long spacings between odd and even compounds is about 1 Å. This difference will be interpreted reasonably as a result of different orientation of methyl groups, if for the odd numbered amines the C–C bond at the methyl terminal is perpendicular to the plane of methyl groups and if for the even numbered amines the bond in question is inclined at an angle. Thus the general arrangement of the molecules of the normal higher amines may be assumed to be similar to that of fatty acids, and the alternation of the melting points may be accounted for by Malkin's concept.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1364—1367 (1969)

Effects of Substituents on the Chain-transfer Reactivities of Nuclear-substituted Benzaldehydes to Polymer Radicals

Tadahiro YAMAMOTO,*1 Masaru HASEGAWA and Takayuki OTSU

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received September 9, 1968)

In order to study the effect of substituents on the chain-transfer reactivities of nuclear-substituted benzaldehydes toward polymethyl methacrylate (poly-MMA) and polystyryl (poly-St) radicals, the chain transfer constants (C) of six kinds of benzaldehydes in radical polymerizations of these monomers were determined at 60°C. The C values of all the substituted benzaldehydes toward the poly-MMA radical were larger than that of unsubstituted benzaldehyde, regardless of the electron-repelling or electron-attracting nature of the substituents, while those toward the poly-St radical increased with an increase in the electron-attracting nature of the substituents. The relative reactivities toward the poly-MMA radical could not be correlated with the ordinary Hammett equation, but they could be with this modified equation: $\log(k/k_0)=\rho\sigma+\gamma E_R$, with $\rho=+0.2$ and $\gamma=0.7$. On the other hand, the relative reactivities toward the poly-St radical also fit a modified Hammett equation with $\rho=+1.4$ and $\gamma=0.65$.

One of the most interesting problems in vinyl polymerization is to clarify the relationship between the structure and the reactivity toward the attack of a polymer radical. In connection with this problem, we have investigated the effects of substituents on the chain-transfer reactions of the nuclear-substituted cumenes[1] and toluenes[2] toward various polymer radicals. From the results of these investigations, we have found that their chain-transfer reactivities are correlated not with the ordinary Hammett equation, but with a modified Hammett equation[3] including the resonance term:

$$\log(k/k_0) = \rho\sigma + \gamma E_R \quad (1)$$

where σ is the polar substituent constant; E_R, the resonance one, and ρ and γ, reaction constants giving, respectively, the degree of the polar and resonance contributions by the substituents. Clearly these results suggest that neither the resonance effect nor the polar effect of the substituents on these chain-transfer reactions should be disregarded.

The present investigation was undertaken in order to ascertain further the effect of substituents on the chain-transfer reactivities of another substrate toward a polymer radical. As substrates, six kinds of nuclear-substituted benzaldehydes were chosen. It was known that the abstraction of a hydrogen atom on the carbonyl group of benzaldehyde is easier than that on the side-chain atom of hydrocarbons.[4] Since the benzaldehyde has an oxygen atom of the carbonyl group which lies beside the reacting side-chain hydrogen atom, its substituent effect may be expected to be different from those observed in the reactions of cumenes and toluenes.[1,2]

This paper will describe the effect of substituents on the chain-transfer reactivities of nuclear-substituted benzaldehydes toward poly-MMA and poly-St radicals, as evaluated from the results of the polymerizations of methyl methacrylate and styrene in the presence of the benzaldehydes, using α,α′-azobisisobutyronitrile (AIBN) as the initiator.

Experimental

Materials. The nuclear-substituted benzaldehydes used in this study had the following substituents: *p*-methoxy, *p*-chloro, H, *p*-bromo, *m*-chloro, and *p*-cyano. The *m*-chlorobenzaldehyde and *p*-cyanobenazldehyde were synthesized as follows. The *m*-chlorobenzaldehyde was prepared from *m*-aminobenzaldehyde through a Sandmeyer reaction; bp 84—86°C/8 mmHg (lit.,[5]

84—86°C/8 mmHg). The *p*-cyanobenzaldehyde was prepared from *p*-cyanobenzyl bromide according to the procedure of Hass and Bender;[6] mp 95°C (lit.,[6] 95—96°C). The other substituted benzaldehydes were commercial materials used after purification.

All these substituted benzaldehydes except for the *p*-cyano-derivative, methyl methacrylate (MMA), and styrene were redistilled in a stream of nitrogen under reduced pressure before use.

Polymerization Procedure. The polymerizations of MMA and styrene in substituted benzaldehydes were carried out at 60°C in the presence of AIBN (3.32×10^{-3} mol/*l*) as the initiator. After a given reaction time, the resulting polymer was isolated by pouring the polymerizing mixture into an excess of methanol. Polymerization was controlled below 10% conversion.

Calculation of Number-average Degree of Polymerization ($\bar{P}_n$) and Chain-transfer Constant (C). The resulting polymer was purified by reprecipitating it from a benzene solution into a large amount of methanol. The intrinsic viscosty [η] of the polymers was determined by the viscosity measurement of its benzene solution at 30°C using an Ubbelohde viscometer. The $\bar{P}_n$ was calculated from the intrinsic viscosity obtained according to the following equations, (2) and (3):

$$\text{Poly-MMA:}^{7)}\ \log(\bar{P}_n) = 3.420 + 1.13\log[\eta] \quad (2)$$

$$\text{Poly-St:}^{8)}\ \log(\bar{P}_n) = 3.205 + 1.37\log[\eta] \quad (3)$$

The chain-transfer constants ($C=k_{tr}/k_p$) to benzaldehydes were determined by the Mayo equation (4):

$$1/\bar{P}_n = \text{Constant} + C[\text{S}]/[\text{M}] \quad (4)$$

where [S] and [M] are the initial concentrations of benzaldehydes and the monomer respectively.

Results and Discussion

The plots of the $1/\bar{P}_n$ of the polymers obtained against [S]/[M] are shown in Figs. 1 and 2. According to Eq. (4), from the slopes of the straight lines the chain-transfer constants were calculated to be as tabulated in Table 1. This table also shows the σ and E_R constants for the substituents used.

Chain-transfer Reactivities of Benzaldehydes with the Poly-MMA Radical. In Table 1 the resulting C values of substituted benzaldehydes may be seen to be larger than that of unsubstituted benzaldehyde, regardless of the electron-attracting or electron-repelling character of the substituents. The plot of the logarithms of the relative chain-transfer reactivities ($C/C_0=k/k_0$) toward the attack of the poly-MMA radical on the Hammett σ constants of the corresponding substituents is shown

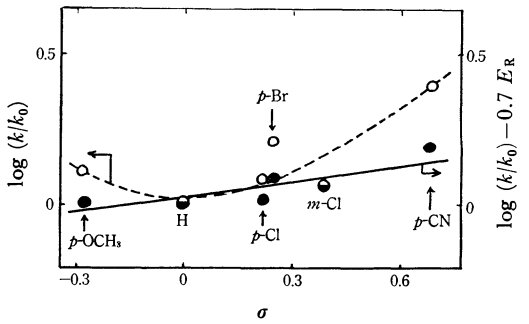

Fig. 3. The plots by the Hammett equation and Eq. (1) for the relative reactivities of benzaldehydes toward poly-MMA at 60°C.

in Fig. 3.

It may be seen that the plot of Fig. 3 gives not a straight line, but a concave curve. Such a parabola-type relation has always been observed in various chain-transfer reactions of cumenes and toluenes toward various polymer radicals[1,2] and in many radical reactions.[3a,10] Therefore, the effect of substituents on the reactivities of benzaldehydes toward the poly-MMA radical, as well as that on the other chain-transfer reactions, can not be explained by only a polar factor.

However, when Eq. (1) was applied to the present chain-transfer reaction, the straight-line relationship illustrated in Fig. 3 was obtained. From the slope of the straight line, the reaction constants, ρ and γ in Eq. (1), were found to be +0.2 and 0.7 respectively. The ρ and γ values indicated that the polar effect of substituens on the present chain-transfer reactivities was rather small, while the resonance effect was relatively important.

In previous papers, the chain-transfer reactivities of the nuclear-substituted cumenes,[1b] toluenes,[2] and acetophenones[11] toward the poly-MMA radical fit not the ordinary Hammett equation, but a modified Hammett equation (1). Tsuda and Otsu[12] reported that the chain-transfer reactivities of substituted dibenzoyl disulfides toward the poly-MMA radical were also correlated with Eq. (1).

For various chain-transfer reactions, it is interesting to compare the magnitude of the reaction constants, ρ and γ, obtained from the application of Eq. (1). Table 2 summarizes the ρ and γ values obtained for various substrates.

As can be seen in Table 2, all of the ρ values for these substrates toward the poly-MMA radical are close to zero, regardless of the substrate structure. In general, the sign and the magnitude of the ρ value are determined by both the polar character

Table 2. The ρ and γ values of the chain-transfer reactions of various substrates toward the poly-MMA radical

Substrate	ρ	γ	Ref.
Benzaldehyde	+0.2	0.7	This work
Cumene	+0.03	0.9	1a)
Toluene	+0.01	0.6	2)
Acetophenone	−0.01	2.0	11)
Diphenyl disulfide	+0.01	0.75	13)
Dibenzoyl disulfide	+0.07	0.75	12)
Phenylacetylene	0.0	1.7	14)

of the attacking radical and the electron density in the reaction center in the substrate. Accordingly, the fact that all of the ρ values in Table 2 are close to zero suggests that the poly-MMA radical has only a small polar character.

On the other hand, the γ values in Table 2 are relatively large and change with the substrate structure. Hence, it may be concluded that the polar factor of the substituents slightly affects the reactivities of these substrates toward the attack of a poly-MMA radical, while the resonance has a significant effect.

Chain-transfer Reactivities of Benzaldehydes with the Polystyryl Radical. The C values of substituted benzaldehydes toward the poly-St radical, shown in Table 1, increases gradually with an increase in the electron-attracting character of their nuclear substituents. The ordinary Hammett plots of these results, shown in Fig. 4, do not give a straight-line relationship.

However, when the σ^- canstant for the *p*-cyano substituent ($\sigma^-=1.00$)[15] was used, a fairly good

linear relationship was observed. This result is understandable if this reaction series is a nucleophilic reaction; the formation of the carbanion in the transition state thus becomes important.

On the other hand, when the plot was made by a modified Hammett equation (1), a much better linear relationship was obtained, as is shown in Fig. 4. From this plot, the ρ and γ values may be found to be $+1.4$ and 0.65 respectively. When we compare these ρ and γ values with those of the attack by the poly-MMA radical, it is noted that the γ values are almost the same, while the ρ values are quite different from each other.

As has been described in a previous paper,[3] the ρ values in Eq. (1) are mainly dependent on the polar natures of both the attacking radical and the substrate structure. Accordingly, the positively-large ρ value in the attack of poly-St, as compared with that of poly-MMA, is understandable, since the poly-MMA radical is less nucleophilic than the polystyryl radical because of its own α-carbomethoxy group.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1367—1373 (1969)

An Improved Synthesis of N,β-Dimethylleucine and the Resolution Thereof*1

Hiroshi KOTAKE, Tomoo SAITO and Kazuo ŌKUBO

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received September 10, 1968)

A diastereoisomeric mixture of racemic β-methylleucine was synthesized by the condensation of 2-benzyl-4(5*H*)-imidazolone with the methyl isopropyl ketone, followed by catalytic hydrogenation and hydrolysis. The separation of the mixture into *threo*-β-methyl-DL-leucine and *erythro*-β-methyl-DL-leucine was mainly achieved by fractional crystallization from water. The resolution of each diastereoisomer was also accomplished through salt-formation with (−)- and (+)-ephedrine alternately before or after the methylation of the amino group. The specific rotation and the NMR and IR spectra of one isomer, *threo*-N,β-dimethyl-L-leucine, corresponded closely with those reported for dimethylleucine isolated from nature.

N,β-Dimethylleucine was isolated from a hydrolysate of Ethamycin by Sheehan and his coworkers,[1] and later from Triostin C by Ōtsuka and Shōji.[2] The configuration at both centers of asymmetry of the amino acid was established as being comparable to that of L-alloisoleucine.[1,3] Although an attempt was made by Sheehan and Howell to synthesize the amino acid,[4],*2 it has not yet been done completely. In this paper, an improved synthesis of N,β-dimethyl-DL-leucine, a synthesis that might be appropriate for a method of preparation, and its favorable optical resolution using ephedrine are described.

Synthesis

2-Benzyl-4(5*H*)-imidazolone[5] (I), which can be easily produced by the condensation of ethyl phenylacetoimidinate with ethyl glycinate, may be expected to be a suitable material for the preparation of the

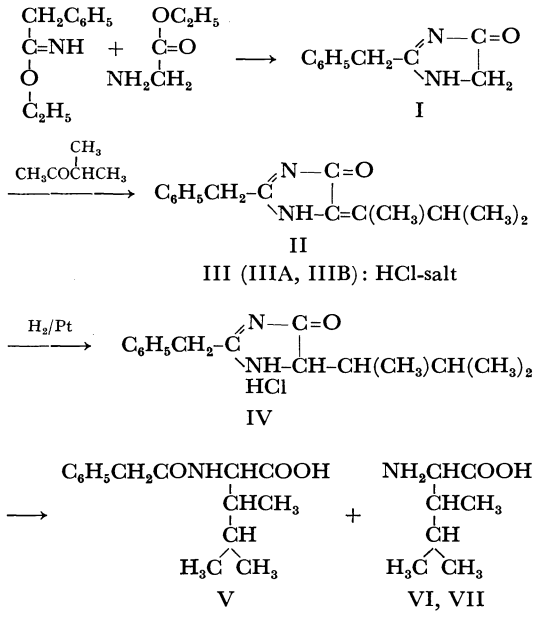
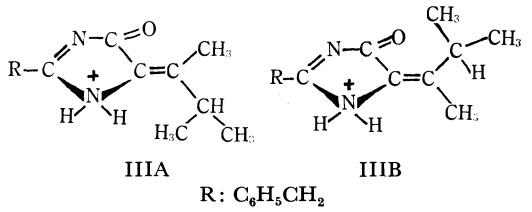
titled compound because of its stability and because its reactivity with the desired ketone is sufficient. The condensation of I with methyl isopropyl ketone was successfully worked up, with the latter in a twofold excess, to give 2-benzyl-5-(α-methyl isobutylidene)-4-imidazolone (II), which was isolated as its stable hydrochloride (III) by passing dry hydrogen chloride through the solution of II in ethyl alcohol. The subsequent catalytic reduction of III over Adams' platinum oxide as a catalyst afforded 2-benzyl-5-(α-methyl isobutyl)-4-imidazolone (IV). In contrast with the favorable use of the above catalyst, palladium black did not respond when used similarly. Upon the hydrolysis of IV with aqueous barium hydroxide, the diastereoisomers of β-methylleucine (VI, VII) and *N*-phenylacetyl-β-methylleucine (V), which was considered to be a hydrolysis intermediate, were given in 52 and 44% yields respectively (Scheme 1). Since the solubility



Scheme 1

of VI in water was much less than that of the other isomer, VII, the isomer VI was obtained in a pure state by repeated fractional crystallization from water. Although it was difficult to isolate the more soluble VII in the pure form, VII was separated from contaminated VI as follows: a reverse relationship in solubility was here observed between the diastereoisomeric amino acids (VI and VII) and their *N*-acetyl derivatives (VI′ and VII′), and the final purification of VII was achieved by the fractional crystallization of its *N*-acetyl derivative (VII′), followed by deacetylation. The above *N*-acetylation was carried out by using a precise equiamount of acetic anhydride in a caustic alkali solution in order to avoid any equalization of asymmetry at the α-carbon atom through the formation of azlactone, which is likely to arise through the action of acetic anhydride in glacial acetic acid.[6],*3 VI was also obtained exclusively from the intermediate V by hydrolysis either with aqueous barium hydroxide or with 6N hydrochloric acid. Thus, the ultimate ratio of fairly pure VI and VII was about 2:1 (in 57 and 28% yields respectively). The predominantly-formed diastereoisomer VI was found to be a racemate of the desired *threo*-form, thus favoring our synthetic purpose. The result is probably due to steric hindrance exerted by the carbonyl group present in the imidazolone on the isopropyl of methyl isobutylidene in the molecule II. In the route from I to IV, IIIA rather than IIIB is preferably formed, followed by the *cis*-addition of hydrogen by catalytic reduction (Scheme 2). Consideration using the Dreiding model led



IIIA IIIB

R: $C_6H_5CH_2$

IIIA: Preferably formed structure, which expected to afford VI by *cis*-addition of hydrogen, followed by hydrolysis.

IIIB: Less prefered structure anticipated to form VII.

Scheme 2

us to understand the condensation containing the above sterically-controlled synthesis and enabled us to predict that, by subsequent catalytic hydrogenation, the preferably-formed VI would be racemic *threo*-β-methylleucine. Characteristic differences between VI and VII are observed from their IR spectra showing absorptions in the region of 1700—1600 cm^{-1}, though there was only a minor difference in the finger-print region; VI has two absorption bands at 1668 and 1628 cm^{-1}, with the former band much stronger than that of the latter, in contrast with the single band, at 1625 cm^{-1}, in VII. In addition, VI′ showed a carboxyl stretching band at 1733 cm^{-1} and a carbonyl band of amide at 1633 cm^{-1}, but the corresponding bands of VII′

6) J. P. Greenstein, S. M. Birnbaum and L. Levinton *Biochem. Prep.*, **3**, 84 (1953).

*3 When excess acetic anhydride in a warm alkali solution was used, epimerization was reported to occur at the α-carbon atom of isoleucine by W. A. H. Huffman and A. W. Ingersoll (*J. Am. Chem. Soc.*, **73**, 3366 (1951)). However, under the conditions described in this paper, VI and VII were acetylated without any considerable epimerization.

shifted to 1708 and 1615 cm^{-1} respectively.*4 There are, moreover, two characteristic bands in the 1200—1300 cm^{-1} region for VI′; one of these, at 1258 cm^{-1}, is much stronger than the other, at 1265 cm^{-1}; there is only the single band at 1418 cm^{-1} in the case of V′.

According to the method of Quitt and his coworkers,[7] the *N*-methylation of VI was accomplished through the formation of an *N*-benzyl derivative (VIII). The *N*-benzyl-*N*-methyl derivative (IX) thus formed was then hydrogenated to give *threo*-*N,β*-dimethyl-DL-leucine (X). Similarly, the other isomer, *erythro*-*N,β*-dimethyl-DL-leucine, was obtained through the isomeric intermediates, corresponding to VIII and IX, from VII. The observation that the relative configurations at the α- and β-carbon atoms of the diastereoisomers are reflected in their NMR spectra[3] was used as a basis for speculation concerning the steric structures of X and its isomer: the coupling constant at the α-proton of compound X, assumed above to be *threo*-form, was 3.9 cps, and that of the latter was 4.8 cps; these values corresponded to the values of the coupling constants (4.05 and 4.80 cps) reported in the literature for *N,γ*-dimethyl-DL-alloisoleucine and *N,γ*-dimethyl-DL-isoleucine. The IR spectra of X was, of course, distinct from that of the other isomer, and it was in good agreement with that of *N,γ*-dimethyl-DL-alloisoleucine over the whole region. The solubility behavior of both the diastereoisomers in such solvents as water, lower alcohols, and acetone was also comparable with that reported in the literature.[4]

Optical Resolution

The resolution of the *N*-benzyloxycarbonyl derivative of X is desirable for the purpose of its peptide formation; it was achieved through salt-formation alternately using (−)- and (+)-ephedrine hemihydrate.*5 *N*-Benzyloxycarbonyl-*threo*-*N,β*-dimethyl-DL-leucine (XI), prepared according to the Schotten-Baumann technique from X with benzyloxycarbonyl chloride, was combined with (−)-ephedrine hemihydrate in ethyl acetate in concentrations of 1.0 and 0.56 M respectively, thus affording exclusively a salt of the L-isomer: *N*-benzyloxycarbonyl-*threo*-*N,β*-dimethyl-L-leucine·(−)-ephedrine salt ($[\alpha]_D = -75.0°$) (XIIL) in over a 90% yield. The further addition of the antipodal base, (+)-ephedrine hemihydrate, to the mother liquor gave an optically-pure *N*-benzyloxycarbonyl-*threo*-*N,β*-dimethyl-D-leucine·(+)-ephedrine salt ($[\alpha]_D = +73.5°$) (XIID). A suspension of XIIL in ethyl acetate was treated with 2N hydrochloric acid to give *N*-benzyloxycarbonyl-*threo*-*N,β*-dimethyl-L-leucine ($[\alpha]_D = -75.9°$) (XIIIL). The XIIIL was dissolved in 30% hydrogen bromide in glacial acetic acid to afford *threo*-*N,β*-dimethyl-L-leucine ($[\alpha]_D = +38.3°$) (XIVL); this was then neutralized with triethylamine in ethyl alcohol. In a similar way, the other isomer, *threo*-*N,β*-dimethyl-D-leucine ($[\alpha]_D = -39.3°$) (XIVD), was obtained from XIID through *N*-benzyloxycarbonyl-*threo*-*N,β*-dimethyl-D-leucine ($[\alpha]_D = +75.3°$) (XIIID). The XIIID isomer, with a specific rotation of +72°, was also obtained directly from the mother liquor of XIIL, without any intermediate formation of salt, XIID. In this case, the effective washing of the solution of ethyl acetate with water to remove a small amount of contaminating salt was essential in order to increase the optical purity of the product. Unlike the case of XI, *N*-benzyloxycarbonyl-*erythro*-*N,β*-dimethylleucine did not react with ephedrine to deposit salt from a solution in such a solvent as ethyl acetate, lower alcohols, acetone, benzene, or ether. The resolution was, however, accomplished in the case of *N*-benzyloxycarbonyl-*erythro*-*β*-methyl-DL-leucine (XV). The salts, *N*-benzyloxycarbonyl-*erythro*-*β*-methyl-L-leucine·(−)-ephedrine ($[\alpha]_D = -17.6°$) (XVIL) and *N*-benzyloxycarbonyl-*erythro*-*β*-methyl-D-leucine·(+)-ephedrine ($[\alpha]_D = +17.7°$) (XVID), were obtained from the ethereal solution by a way similar to that used for the *threo*-form. They were reduced to *erythro*-*β*-methyl-L-leucine ($[\alpha]_D = +38.9°$, in 5N hydrochloric acid) (XVIIL) and its antipode, XVIID ($[\alpha]_D = -39.4°$, in 5N hydrochloric acid), and finally *N*-methylation was performed to afford *erythro*-*N,β*-dimethyl-L-leucine ($[\alpha]_D = +38.0°$) (XVIIIL) and *erythro*-*N,β*-dimethyl-D-leucine ($[\alpha]_D = -38.3°$) (XVIIID) respectively. The L-isomer without an *N*-methyl group, XVIIL, was comparable to β-methyl-L-leucine, with a

Table 1.

Compound	$[\alpha]_D^{23-25}$	Solvent	Coupling constant at the α-proton signal in NMR (cps)
XIVL	+31.5° (+33.15°)[1] (+28.4°)[3]	Water	3.9 (4.0)[3]
	+38.3° (+39.2°)[1] (+41.9°)[3]	5N HCl	
XIVD	−31.8°	Water	3.9
	−39.3°	5N HCl	
XVIIIL	+38.0°	5N HCl	4.8
XVIIID	−38.3°	5N HCl	4.8

*4 Those spectra for VI′ and VII′ are in good agreement in whole region with the corresponding those of Sheehan's.[4]

7) P. Quitt, J. Hellerbach and K. Vogler, *Helv. Chim. Acta*, **46**, 327 (1963). Further studies on the *N*-methylation of amino acids have more extensively been done in the same way by M. Ebata, Y. Takahashi and H. Ōtsuka, This Bulletin, **39**, 2535 (1966).

*5 Extensive studies on the resolution of benzyloxycarbonylamino acids by use of ephedrine will be the subject in next paper.

specific rotation of +38°, prepared by Sheehan from the racemate of the less soluble acetyl derivative in water through digestion by acylase. In this connection, the racemic acetyl derivative VI′, which afforded the desired XIV$_L$, was more soluble in water. All of the four possible optical active isomers have here been successfully prepared, as is indicated in Table 1. Among these, only XIV$_L$ has been found to be identical with natural amino acid in all respects, including optical rotation value and NMR and IR spectra.

Experimental

All melting points are uncorrected. The infrared spectra were recorded with a Koken DS-301 spectrometer using a sodium chloride prism in Nujol mulls. The NMR spectra were taken with a Nihon Denshi JNM-C-60H spectrometer on a solution in deuterium oxide, using sodium 2,2-dimethyl-2-silapentane-5-sulfonate as a reference at room temperature. The optical rotation values were measured with a Jasco DIP-SL-type polarimeter.

2-Benzyl-4(5*H*)-imidazolone (I). Prepared from ethyl phenylacetoimidinate and ethyl glycinate according to the method reported in the literature. I was obtained, in a 70% yield, as needles with a melting point of 142—143°C (lit.[5] mp 143°C).

2-Benzyl-5(*α*-methyl isobutylidene)-4-imidazolone (II). A) A mixture of finely-powdered I (25 g, 0.144 mol) and 25 g (0.288 mol) of methyl isopropyl ketone was refluxed under a nitrogen atmosphere for 6 hr at 120—130°C in an oil bath. After cooling (when the reaction mixture had solidified), the reaction mixture was triturated with 20—30 m*l* of petroleum ether and then filtered to give a crude material (mp 72—79°C) in an 89% yield (30.8 g). The material was dissolved in 300 m*l* of benzene and decolorized with active charcoal. Benzene was removed by concentration *in vacuo* to afford, in an 81% yield, colorless crystals with a melting point of 104—120°C (28.1 g). It was difficult to obtain crystals with a constant melting point, though it was possible to recrystallize them from either ether or ether-petroleum ether.

B) To the reaction mixture obtained from 68 g (0.39 mol) of I and 67 g (0.78 mol) of the ketone under conditions similar to those used in the A) procedure, 400 m*l* of ethyl alcohol were added; then dry hydrogen chloride was passed through the solution obtained above under cooling in a water bath until it was saturated. Then the mixture was sealed tightly with a stopper and stored in a refrigerator. After several hours, the deposited crystals were collected on a glass-fritted funnel and washed with much ether to give an almost pure hydrochloride of II (mp 207—210°C) in a 78% yield (85 g); this substance was designated III. It was recrystallized from ethyl alcohol-ether to afford pure crystals with a melting point of 208—210°C. Found: C, 64.52; H, 6.59; N, 9.96%. Calcd for $C_{15}H_{19}ON_2Cl$: C, 64.22; H, 6.83; N, 10.04%.

Racemic *β*-Methylleucine and Its Separation into Two Diastereoisomers (VI and VII). In a suspension of Adams' platinum oxide (200 mg) in 500 m*l* of alcohol, enough hydrogen was absorbed, and then 55 g (0.197 mol) of III were added. Hydrogenation was continued, with the aid of mechanical shaking, for 40 min, by which time about an equiamount of hydrogen (4400 m*l*) had been absorbed. After the removal of the catalyst by filtration, the filtrate was concentrated *in vacuo* to give an oily product (IV). A solution of the oil in 2000 m*l* of water containing 372 g (1.18 mol) of barium hydroxide octa-hydrate was refluxed for 40—50 hr. After cooling, 351 m*l* of 6N sulfuric acid were slowly added; the precipitate was filtered and washed several times with hot water. The combined filtrate was concentrated *in vacuo* up to about 100 m*l*, and then the solution was washed twice with 100-m*l* portions of ether. The aqueous layer was concentrated *in vacuo* to give a crystalline residue. To the solution of the dried residue in 150 m*l* of ethyl alcohol, there were added about 20 m*l* of triethylamine to afford 15 g (52.4%) of a crystalline solid. The crystals were redissolved by warming them in 70 m*l* of water and decolorized with active charcoal; then the colorless solution obtained was allowed to stand over night at room temperature. The colorless crystals thus deposited were filtered, washed with alcohol, and then recrystallized several times from water to give 3.4 g (11.9%) of fine crystals. This compound did not change over 270°C; it was designated VI. Found: C, 57.64; H, 10.68; N, 9.41%. Calcd for $C_7H_{15}O_2N$: C, 57.90; H, 10.41; N, 9.65%.

To the mother liquor obtained after the removal of VI, there was added about twice as much acetone to give the other crystals. Repeated fractional crystallization from a small amount of water and acetone afforded a somewhat sterically impure material (mp over 270°C) in a 34.2% (9.8 g) yield. The material obtained was designated VII; it differed from VI in its crystalline form. Found: C, 57.73; H, 10.24; N, 9.72%.

The previously-filtered precipitate, after hydrolysis with barium hydroxide and subsequent neutralization with sulfuric acid, was placed in a 1-*l* Erlenmeyer flask; then it was treated by effective shaking with 200 m*l* of 1N sodium hydroxide, filtered, and washed with 1N sodium hydroxide. The combined filtrate was acidified to pH 4 with concentrated hydrochloric acid. The deposited product was collected by filtration and then recrystallized from benzene to give pure *N*-phenylacetyl-*threo*-*β*-methyl-DL-leucine (V), which had a melting point of 151.5—152.5°C, in a 43.5% (21.2 g) yield. Found: C, 68.15; H, 7.69; N, 5.66%. Calcd for $C_{15}H_{21}O_3N$: C, 68.41; H, 8.04; N, 5.32%.

A suspension of 2.9 g (0.011 mol) of V in 40 m*l* of 6N hydrochloric acid was refluxed for 14 hr. After cooling, the deposited crystals were filtered off and the filtrate was concentrated *in vacuo* to give a residue. The residue was dissolved in 15 m*l* of ethyl alcohol and neutralized with 2 m*l* of triethylamine. Then the crystals were filtered and washed with ethyl alcohol to afford VI quantitatively (1.6 g). V also afforded VI exclusively upon further treatment in aqueous barium hydroxide for 31 hr at the refluxing temperature.

Acetylation of Amino Groups of VII and VI. A solution of 4.9 g (0.0337 mol) of sterically-impure VII in 8.48 m*l* of 4N sodium hydroxide was cooled to 0—5°C in an ice bath and stirred mechanically. Then, 8.48 m*l* of 4N sodium hydroxide and 3.18 m*l* (0.0337 mol) of acetic anhydride were added, at rates to maintain a

slight basicity and a temperature of about 5°C, over a 30-min period. Stirring was then continued for a further 30 min at room temperature. The solution was acidified by the addition of about 6 m*l* of 6N hydrochloric acid. White crystals deposited immediately; they were filtered to give an *N*-acetyl derivative (5.95 g, 94%). The product was repeatedly recrystallized from water to give 5.40 g of the less soluble *N*-acetyl-*erythro*-*β*-methyl-DL-leucine (VII′), which had a melting point of 169—170°C (lit.[4] 171.8—172.2°C). Found: C, 57.55; H, 9.34; N, 7.34%. Calcd for $C_9H_{17}O_3N$: C, 57.73; H, 9.15; N, 7.48%. IR: 1708, 1616, and 1553 cm^{-1}.

The combined mother liquor was concentrated to dryness to give a crystalline residue. This was repeatedly recrystallized from water and acetone to afford 0.386 g of the more soluble *N*-acetyl-*threo*-*β*-methyl-DL-leucine (VI′), which had a melting point of 159—160°C (lit.[4] 157—157.5°C). Found: C, 58.05; H, 8.91; N, 7.35%. IR: 1733, 1633, 1550, and 1418 cm^{-1}.

The VII′ and VI′ thus obtained were reduced to pure VII and VI by a usual acid hydrolysis, followed by neutralization with triethylamine. On the other hand, pure VI and VII were also acetylated in a similar way to afford VI′ and VII′ respectively; the yields were in the range of 91—95%, and no epimerization was to be seen in either case.

***N*-Benzyl-*threo*-*β*-methyl-DL-leucine (VIII).** A) According to the method of Quitt,[7] 2.9 g (0.02 mol) of VI was treated with 2.1 m*l* (0.02 mol) of freshly-distilled benzaldehyde and then with 0.23 g (0.006 mol) of sodium borohydride, while the temperature was maintained between 20 and 22°C. Then the same amounts of benzaldehyde and sodium borohydride were added to the reaction mixture; from it 4.7 g (100%) of VIII (mp 205—207°C) were then obtained. Recrystallization from an ethyl alcohol-water mixture (2:1) afforded pure crystals with a melting point of 213°C (4.0 g). Found: C, 71.48; H, 8.87; N, 5.75%. Calcd for $C_{14}H_{21}O_2N$: C, 71.45; H, 9.00; N, 5.95%.

B) When catalytic hydrogenation using palladium black as a catalyst was used instead of reduction with sodium borohydride, VIII was usually obtained in a yield relatively lower (as much as 70%) than in the case of A).

***N*-Benzyl-*erythro*-*β*-methyl-DL-leucine.** In a way similar to the procedure of VIII, A), this compound was obtained in an 87% yield; mp 225°C. The recrystallization was performed from methyl alcohol. A mixed-melting-point determination with VIII was depressed to 200—205°C. Found: C, 71.47; H, 8.76; N, 6.09%.

***N*-Benzyl-*threo*-*N*,*β*-dimethyl-DL-leucine (IX) and Its Dicyclohexylammonium Salt.** According to the method of Quitt,[7] 3 g (0.0128 mol) of finely-powdered VIII were treated with 1.8 m*l* (0.037 mol) of formic acid and 1.5 m*l* (0.018 mol) of 38% formaline. IX was thus obtained almost quantitatively as an oily product; it was often crystallized when left standing for long period of times and furnished crystals with a melting point of 56—57°C. The oil was converted to its dicyclohexylammonium salt from an acetone solution for its characterization. Recrystallization from ethyl alcohol gave a pure product in an 82% yield; mp 139°C. Found: C, 75.16; H, 10.75; N, 6.39%. Calcd for $C_{27}H_{46}O_2N_2$: C, 75.30; H, 10.77; N, 6.51%.

***N*-Benzyl-*erythro*-*N*,*β*-dimethyl-DL-leucine and Its Dicyclohexylammonium Salt.** Similarly, this compound was prepared from *N*-benzyl-*erythro*-*β*-methyl-DL-leucine as crystals with a melting point of 134—135°C in an 87% yield. Found: C, 72.68; H, 9.29; N, 5.66%. Calcd for $C_{15}H_{23}O_2N$: C, 72.25; H, 9.30; N, 5.62%. The dicyclohexylammonium salt of the material was obtained in an 81% yield; mp 127—128°C. A mixed-melting-point determination with the salt of IX was depressed to 120—122°C. Found: C, 75.38; H, 10.43; N, 6.38%.

***threo*-*N*,*β*-Dimethyl-DL-leucine (X).** The oily IX prepared from 3 g (0.0128 mol) of VIII was hydrogenated with palladium black as a catalyst in 60 m*l* of 90% acetic acid; then it was concentrated to afford crystals. Recrystallization from an ethyl alcohol-water mixture (2:1) and then a water-dioxane mixture gave pure X with a melting point of over 270°C in a 98% yield. Found: C, 60.40; H, 11.15; N, 8.89%. Calcd for $C_8H_{17}O_2N$: C, 60.34; H, 10.76; N, 8.80%.

***erythro*-*N*,*β*-Dimethyl-DL-leucine.** The same procedure as in the case of the preparation of X was used. The product was obtained from *N*-benzyl-*erythro*-*N*,*β*-dimethyl-DL-leucine in a 94% yield; mp >270°C. Found: C, 59.87; H, 10.38; N, 8.83%.

***N*-Benzyloxycarbonyl-*threo*-*N*,*β*-dimethyl-DL-leucine (XI).** To a solution of 8.8 g (0.55 mol) of X in 14 m*l* (0.055 mol) of 4N sodium hydroxide, there were added 16.7 m*l* (0.066 mol) of 4N sodium hydroxide and 10 g (0.059 mol) of benzyloxycarbonyl chloride according to the Schotten-Baumann procedure; the subsequent reaction proceeded well with concurrent stirring and cooling at 0—5°C in an ice bath. The reaction was continued for 1 hr at 0—5°C and then for an additional hour at room temperature. The reaction mixture was washed with 15 m*l* of ether, and then the aqueous layer was neutralized with 6N hydrochloric acid to pH 4. The oily product which was thus deposited was extracted twice with 30-m*l* portions of ethyl acetate, and the combined extract was washed with dilute hydrochloric acid and water. The ethyl acetate layer was dried over anhydrous sodium sulfate. The filtrate was evaporated to dryness to give 13.7 g of an oily residue. The oil was purified by redissolving it in an aqueous solution of sodium hydrogen carbonate and by washing it with ether, followed by a treatment similar to that described above. The oily product thus obtained was triturated with petroleum ether to afford a crystalline solid, which was then recrystallized from ether-petroleum ether to give 12 g (75%) of XI with a melting point of 79°C. Found: C, 65.78; H, 7.70; N, 4.94%. Calcd for $C_{16}H_{23}O_4N$: C, 65.51; H, 7.90; N, 4.78%.

***N*-Benzyloxycarbonyl-*threo*-*N*,*β*-dimethyl-L-leucine·(—)-ephedrine Salt (XIIL) and *N*-Benzyloxycarbonyl-*threo*-*N*,*β*-dimethyl-D-leucine (XIIID).** XI (8.3 g, 0.028 mol) and (—)-ephedrine hemihydrate (2.7 g, 0.0155 mol) were dissolved in 28 m*l* of warming ethyl acetate. The mixture was then allowed to stand for 24 hr at room temperature. The deposited crystals were filtered and washed with ethyl acetate to give 6.1 g (94%) of XIIL; mp 157°C. Recrystallization from an ethyl alcohol-ethyl acetate mixture (1:1) afforded 5.7 g of the pure material with a melting point of 160—161°C, $[\alpha]_D^{24} = -75.0°$ (*c* 0.40, in ethyl alcohol). Found: C, 68.26; H, 8.24; N, 6.27%. Calcd for $C_{26}H_{38}O_5N_2$: C, 68.09; H, 8.35; N, 6.11%.

The mother liquor obtained after the removal of XIIL was washed twice with a small amount of 2N hydrochloric acid and water. The organic layer was dried over anhydrous sodium sulfate. The filtrate was concentrated to dryness to give a crystalline residue in a 94% (3.9 g) yield; mp 90—91°C. Recrystallization from benzene - petroleum ether afforded 3.4 g of almost optically-pure XIIID; mp 94—95°C, $[\alpha]_D^{24}=+72°$ (*c* 1.00, in ethyl alcohol).

***N*-Benzyloxycarbonyl-*threo*-*N*,*β*-dimethyl-D-leucine•(+)-ephedrine Salt (XIID).** To a solution of 0.70 g (0.0024 mol) of XIIID ($[\alpha]_D^{24}=+72°$) in 1.5 m*l* of ethyl acetate, there was added a solution of 0.42 g (0.0024 mol) of (+)-ephedrine hemihydrate in 1.0 m*l* of ethyl acetate. The mixture was set aside for 24 hr at room temperature, and then the crystals deposited were filtered, washed with ethyl acetate, and dried to afford XIID (mp 155—157°C) in an 89% (0.975 g) yield. Recrystallization from an ethyl alcohol - ethyl acetate mixture (1 : 1) gave crystals with a melting point of 159—160°C and $[\alpha]_D^{25}=+73.5°$ (*c* 0.30, in ethyl alcohol). Found: C, 67.97; H, 8.31; N, 6.16%.

***N*-Benzyloxycarbonyl-*threo*-*N*,*β*-dimethyl-L-leucine (XIIIL).** To a suspension of 4.8 g (0.0105 mol) of the XIIL salt in 15 m*l* of ethyl acetate, there were added 7.8 m*l* (0.0156 mol) of 2N hydrochloric acid (7.8 m*l*, 0.0156 mol), and the mixture was shaken effectively in a separatory funnel. After washing further with water, the ethyl acetate layer was dried over anhydrous sodium sulfate. The ethyl acetate was evaporated to dryness to afford 3 g (98%) of crystals; mp 94—96°C. Recrystallization from benzene - petroleum ether gave 2.8 g of XIIIL with a melting point of 98—99°C, $[\alpha]_D^{26}=-75.9°$ (*c* 1.10, in ethyl alcohol). Found: C, 65.25; H, 7.99; N, 4.89%. Calcd for $C_{16}H_{23}O_4N$: C, 65.51; H, 7.90; N, 4.78%.

***N*-Benzyloxycarbonyl-*threo*-*N*,*β*-dimethyl-D-leucine (XIIID).** Following the method used for the preparation of XIIIL, from 3.2 g (0.007 mol) of XIID, 1.9 g (93%) of XIIID with a melting point of 98—99°C was obtained. $[\alpha]_D^{25}=+75.3°$ (*c* 0.7, in ethyl alcohol). Found: C, 65.72; H, 8.04; N, 4.79%.

***threo*-*N*,*β*-Dimethyl-L-leucine (XIVL).** A) To 1.0 g (0.0034 mol) of XIIIL, 3.5 g of 30% hydrogen bromide in glacial acetic acid was added. The reaction mixture was then set aside in a tight-stoppered vessel for 1 hr at room temperature. There after 30 m*l* of ether were added to complete the precipitation of the product, which was collected on a glass-fritted funnel and washedwith ether. The yield of the hydrobromide was 0.75 g (92%), and its melting point was 209—210°C. Free amino acid XIVL was obtained by treatment with triethylamine in a solution of 4 m*l* of ethyl alcohol, followed by recrystallization from a water - ethyl alcohol mixture (1 : 1). The yield was 0.43 g (86% from hydrobromide), and it had a melting point of over 270°C; $[\alpha]_D^{25}=+38.3°$ (*c* 0.90, in 5N hydrochloric acid), $[\alpha]_D^{23}=+31.5°$ (*c* 0.50, in water). Found: C, 60.39; H, 10.57; N, 8.93%. Calcd for $C_8H_{17}O_2N$: C, 60.34; H, 10.74; N, 8.80%.

B) A solution of 1.0 g (0.0034 mol) of XIIIL in 10 m*l* of glacial acetic acid was hydrogenated using 200 mg of palladium black as a catalyst under mechanical shaking for 5 hr. After the catalyst had then been removed by filtration, the filtrate was evaporated to dryness to give a crystalline residue and dried in a vacuum desiccator over concentrated sulfuric acid and solid sodium hydroxide. The residue was recrystallized from water and dioxane to give 0.47 g (87%) of XIVL with a melting point of over 270°C; $[\alpha]_D^{25}=+37.3°$ (*c* 0.70, in 5N hydrochloric acid), $[\alpha]_D^{23}=+29.1°$ (*c* 0.90, in water).

***threo*-*N*,*β*-Dimethyl-D-leucine (XIVD).** A way similar to the method A) used in the preparation of XIVL was used. From the reaction of 1.0 g (0.0034 mol) of XIIID and 3.5 g of 30% hydrogen bromide in glacial acetic acid, followed by neutralization with amine, XIVD with a melting point of over 270°C was obtained in almost the same yield. $[\alpha]_D^{25}=-39.3°$ (*c* 0.60, in 5N hydrochloric acid), $[\alpha]_D^{25}=-31.8°$ (*c* 0.40, in water). Found: C, 60.56; H, 10.63; N, 9.01%.

***N*-Benzyloxycarbonyl-*erythro*-*β*-methyl-DL-leucine (XV).** By the usual method of Schotten-Baumann, a pure product with a melting point of 62—64°C was obtained from VII in an 84% yield. The recrystallization was performed from benzene-petroleum ether. Found: C, 64.37; H, 7.42; N, 5.18%. Calcd for $C_{15}H_{21}O_4N$: C, 64.49; H, 7.58; N, 5.01%.

***N*-Benzyloxycarbonyl-*erythro*-*β*-methyl-L-leucine-(−)-ephedrine (XVIL) and *N*-Benzyloxycarbonyl-*erythro*-*β*-methyl-D-leucine•(+)-ephedrine (XVID).** To a solution of 5.58 g (0.02 mol) of XV in 6.0 m*l* of ether, there was added a solution of 1.91 g (0.011 mol) of (−)-ephedrine hemihydrate in 4.0 m*l* of ether. The reaction mixture was then allowed to stand overnight in a refrigerator to form a gelatinous material. The product was collected by filtration after it had been crushed to pieces with a glass rod and a small amount of ether had been added. A somewhat crude (−)-salt (1.6 g) (mp 120—124°C) was thus obtained. The ethereal mother liquor was washed wih 2N hydrochloric acid and then with water, and dried over anhydrous sodium sulfate. The ethereal solution was evaporated to dryness under reduced pressure; then the residue thus obtained was redissolved in 6.0 m*l* of ether. To the solution, there was added a solution of 1.91 g of (+)-ephedrine hemihydrate in 4.0 m*l* of ether. Then (+)-salt (1.4 g) (mp 124—125°C) was obtained by a way similar to that described above. The same treatment was possible again reciprocally with (−)- and (+)-ephedrine hemihydrate. Optically-active (−)-salt consisting of (−)-ephedrine was combined and recrystallized from ethyl acetate to give 2.0 g (45%) of a pure material with a melting point of 124—125°C; $[\alpha]_D^{25}=-17.6°$ (*c* 0.74 in ethyl alcohol). Found: C, 67.50; H, 8.09; N, 6.28%. Calcd for $C_{25}H_{36}O_5N_2$: C, 67.54; H, 8.16; N, 6.30%.

In the same way, optically-pure (+)-salt with a melting point of 124—125°C was obtained in a 49.5% (2.2 g) yield; $[\alpha]_D^{25}=+17.7°$ (*c* 0.95 in ethyl alcohol). Found: C, 67.60; H, 8.14; N, 6.32%. The mixed-melting-point of minus and plus salt was depressed to 101—104°C.

***erythro*-*β*-Methyl-L-leucine (XIIL) and the D-Isomer (XIID).** To a suspension of 1.9 g (0.0034 mol) of (−)-salt in 10 m*l* of ethyl acetate, there were added 3.4 m*l* of 2N hydrochloric acid; then the mixture was shaken in a separatory funnel. The organic layer was treated as usual to give 1.3 g of an oily residue. The oil was dissolved in 3.4 g of 30% hydrogen bromide in glacial acetic acid, after which the mixture was allowed to stand for 1 hr at room temperature and then

for 24 more hour in a refrigerator after the addition of 100 m*l* of ether. The deposited crystals were collected by filtration on a glass-fritted funnel and washed with ether. Recrystallization from ethyl alcohol and ether afforded a pure material with a melting point of 195—196°C in a 69% (0.66 g) yield. Similarly, from 2.18 g of (+)-salt D-isomer hydrobromide was obtained in a 73% (0.8 g) yield; mp 203—205°C. A solution of 0.6g of hydrobromide of the L-isomer in ethyl alcohol was neutralized with triethylamine. The crystals thus obtained were collected and recrystallized from water and dioxane to give 0.28 g (73% from hydrobromide) of the amino acid XVIIL; $[\alpha]_D^{24}=+38.9°$ (*c* 0.485, in 5N hydrochloric acid), $[\alpha]_D^{25}=+29.7°$ (*c* 0.37, in water). Found: C, 57.92; H, 10.38; N, 9.70%. From 0.65 g of the hydrobromide of the D-isomer, free amino acid XVIID was obtained in a 67% (0.3 g) yield; $[\alpha]_D^{25}=-39.4°$ (*c* 0.38, in 5N hydrochloric acid). Found: C, 57.82; H, 10.34; N, 9.62%.

***erythro*-*N*,*β*-Dimethyl-L-leucine (XVIIIL) and the D-Isomer (XVIIID).** The methylation of the amino groups of XVIIL and XVIID was accomplished, step by step, by *N*-benzylation, *N*-methylation, and subsequent catalytic hydrogenolysis, in a way similar to that used for the corresponding racemic *threo*-isomer. *N*-Benzyl-L-isomer: mp 218—219°C, 74% yield. Found: C, 71.62; H, 8.95; N, 5.82%. *N*-Benzyl-D-isomer: mp 218—219°C, 43% yield. Found: C, 71.70; H, 8.93; N, 6.03%. The mixed-melting-point of the two isomers was depressed to 208—210°C. *N*-Benzyl-*N*-methyl-L-isomer: mp 102—105°C, 68% yield. Found: C, 72.41; H, 9.08; N, 5.60%. *N*-Benzyl-*N*-methyl-D-isomer: mp 102—105°C, 74% yield. Found: C, 72.20; H, 9.40; N, 5.55%. The mixed-melting-point of these two isomers was depressed to 76—80°C. *erythro*-*N*,*β*-Dimethyl-L-leucine: mp>270°C, 51% yield; $[\alpha]_D^{25}=+38.0°$ (*c* 0.50, in 5N hydrochloric acid). Found: C, 60.52; H, 10.48; N, 8.91%. *erythro*-*N*,*β*-Dimethyl-D-leucine: mp >270°C, 52% yield; $[\alpha]_D^{25}=-38.3°$ (*c* 0.60, in 5N hydrochloric acid). Found: C, 60.18; H, 10.51; N, 8.76%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1373—1377 (1969)

Studies on Telomerization of Vinyl Chloride with Carbon Tetrabromide

Teruzo ASAHARA and M. C. CHOU

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received September 11, 1968)

The radical telomerization of vinyl chloride with carbon tetrabromide was investigated. The telomers with $n=1$ and 2 in $Br(CHClCH_2)_nCBr_3$ were isolated and identified. The molecular weight distribution of the telomers was determined by thin-layer chromatography (TLC), and it was found that the distribution varied a little with the variation of reaction conditions. From the results of the TLC, the chain transfer constants (C_n) of polylvinyl chloride radical to carbon tetrabromide were calculated, and a monotonous increase in C_n with the increasing n was found. The effects of initial ratio of vinyl chloride to carbon tetrabromide, reaction time and temperature on the conversion of vinyl chloride and the average molecular weight of the telomer were investigated. Bromoform was also used as a telogen instead of carbon tetrabromide, and the results were compared in both systems.

There are few studies on telomerization of vinyl chloride as a taxogen. Akiyoshi *et al.*[1] carried out this reaction using carbon tetrachloride as a telogen and the formation of telomers with 1:1 and 1:2 of the ratio of telogen to taxogen was confirmed. Ali *et al.*[2] investigated this reaction using carbon tetrabromide as a telogen, but liquid telomers were not obtained, probably because the amount of the chain transfer agent was low in this investigation. In order to confirm further the possibility of the preparation of oligo (vinyl chloride), the present investigation was designed under the various reaction conditions such as telogen-taxogen ratio, reaction time and temperature. Further, the separation of products by means of thin-layer chromatography was undertaken. The result will be presented in this paper.

Experimental

Materials. Vinyl chloride was purified by washing with a 30% KOH aqueous solution and drying over calcium chloride. Carbon tetrabromide was prepared from the reaction of acetone and bromine in potassium

hydroxide solutions and purified by recrystallization. α,α′-Azobisisobutyronitrile was purified by recrystallization from methanol before use.

Telomerizations. Into a glass ampoule with a 100 m*l* capacity, definite amounts of carbon tetrabromide and ABIN were taken and a definite amount of vinyl chloride was charged while cooling in dry ice and then sealed. Reactions were carried out in a reaction oven at a given temperature, being shut from light.

Analyses of Products. After the reaction, unreacted vinyl chloride was removed initially at room temperature under atmospheric pressure and completely under reduced pressure. The number-average molecular weights of the products (telomers) were measured cryoscopically. The lower telomers were separated with distillation and the lower and higher telomers were separated by thin-layer chromatography on silica gel.

Results and Discussions

Separation and Identification of Reaction Products. Residues of reaction mixtures after removing the unreacted vinyl chloride are colorless at lower molar ratio, vinyl chloride/carbon tetrabromide, and pale yellow or brown at higher ratios, higher temperatures and prolonged reaction time. However, it is considered that the main components of the residues are telomers of vinyl chloride and carbon tetrabromide, with a small amount of complicated products resulting from the initiator, because the measured mean molecular weights of the residues are in good agreement with those calculated from the results of quantitative analyses of telomers, as will be shown later.

Two fractions were obtained with the distillation at 2 mmHg. Properties of these products are shown in Table 1. From these results and NMR spectra (Fraction 1, 4.0 and 5.9 ppm; Fraction 2, 3.9, 5.7, 6.3 and 7.1 ppm) and IR spectra (CBr; 610; CBr_3, 630; CCl, 685 cm^{-1}), it was confirmed that these fractions are the telomers, $Br(CHClCH_2)_n$-CBr_3, with n=1 and 2 respectively.

Separation of telomers higher than n=3 was impossible by distillation, for they are unstable at elevated temperatures. Thus thin-layer chromatographic separation was carried out. Thin plates (size 20×20 cm^2, depth 0.15 mm) were prepared of Silica Gel G (Merck) and the spots of product mixtures (0.01—0.03 m*l*) were developed with cyclohexane-chloroform (8: 1.5 by volume) on the vertical plates. Detection of developed spots was made by exposure with iodine vapor or by carbonization with 50% sulfuric acid. The results of the TLC analysis are shown in Table 2, in terms of R_f

Table 2. R_f and R_m values of telomer mixture

Spot	R_f	R_m
1	0.837	−0.710
2	0.740	−0.460
3	0.641	−0.250
4	0.530	−0.052
5	0.409	0.160
6	0.287	0.359
7	0.222	0.545

(the ratio of the origin-spot distance to the origin-developing front distance) and $R_m=\log(1/R_f-1)$. It was confirmed from the development of authentic samples that the spots 1 and 2 are the telomers of n=1 and 2, respectively. Although direct identification of the other spots is impossible, it is plausible that they are the telomers with successively increasing n, for the linearity is found between R_m values and spot numbers. Thus, the spots 1, 2, 3, ··· would be assigned to be telomers

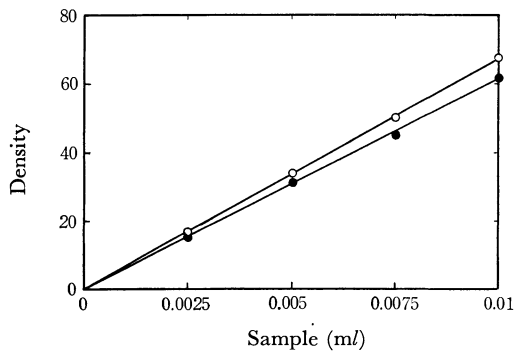

Fig. 1. Relationship between the amounts of telomers and the TLC densities.
○ n=2 telomer; ● n=3 telomer

with $n=1, 2, 3, \cdots$, respectively.

The coloration of spots carbonized with 50% sulfuric acid was measured quantitatively by a TLC densitometer (Seikyo Rika SS-7). The calibration curves for telomers with $n=2$ and 3 were obtained by using the samples separated by distillation as shown in Fig. 1. For the other telomers, it was assumed that the absorption density per mole is proportional to the carbon number in each molecule. This seems to be plausible for molecules in a homolog. The average molecular weights calculated from the results of TLC analysis agree well with the average molecular weights measured cryoscopically.

Effects of Reaction Conditions. From the analyses of the reaction product, it is considered that the telomerization of vinyl chloride with carbon tetrabromide takes place in the present reaction system. Thus, the reaction scheme would be as follows.

$$CBr_4 + R\bullet \rightarrow \bullet CBr_3 + RBr$$

$$\bullet CBr_3 + nCH_2{=}CHCl \rightarrow CBr_3(CH_2CHCl)_{n-1}CH_2\dot{C}HCl$$

$$CBr_3(CH_2CHCl)_{n-1}CH_2\dot{C}HCl + CBr_4 \rightarrow CBr_3(CH_2CHCl)_nBr + \bullet CBr_3$$

$$CBr_3(CH_2CHCl)_n\bullet + CBr_3(CH_2CHCl)_m\bullet \rightarrow CBr_3(CH_2CHCl)_{n+m}CBr_3$$

Total yields, average molecular weights and molecular weight distribution of the telomers are mainly affected by the experimental factors such as the molar ratio of vinyl chloride to carbon tetrabromide, reaction time and temperature. The results for these examinations are summarized in Table 3.

As is expected from the reaction scheme, the conversion of vinyl chloride decreases and the average n value increases with the increasing molar ratio. The increasing reaction time results in slight increases in the conversion and the average n value. Moreover, the increasing temperatures are followed by decreases in the conversion and the average n value. This might be due to the increasing reactivity in telogen molecules at higher temperatures. These results are plausible from the reaction scheme and characterize the telomerization reaction. It should be cited that Bengough *et al.*[3] investigated the telomerization reaction of vinyl chloride and bromotrichloromethane (TBr) and obtained the 1:1 adduct at the molar ratio of vinyl chloride to TBr lower than 10.

a) Molar ratio of vinyl chloride to carbon tetrabromide.

Molecular Weight Distribution. The regulation of molecular weight distribution is essentially important for practical purposes. This is difficult in the present stage but the examination was made to get the information for the effect of reaction conditions. The results at various molar ratios of vinyl chloride to carbon tetrabromide are shown in Table 4. The yield in the mole unit decreases when n increases. This is expected in general for the telomerization where the content of telogen is high. When vinyl chloride/carbon tetrabromide is 3, the telomers with $n=1$—6 are obtained and the higher telomers are formed when the molar ratio

10	0.5	35.43	26.24	17.49	8.75	3.12	0.79

a) Molar ratio of vinyl chloride to carbon tetrabromide.

becomes high. However, the yield of the telomer with $n=1$ is always the largest. When the reaction time is prolonged, the distribution extends to higher telomers. The main products are the telomers with $n=1$ and 2 at the molar ratio 3, 1 hr and 60°C. When the reaction temperature is higher, the distribution shifts into lower telomers. Thus, at the molar ratio 3 and the reaction time 3 hr, he telomers with $n=1$—7, $n=1$—5 and $n=1$—3 are formed at 60, 80 and 100°C, respectively.

It was, therefore, found that the selective formation of the telomer with $n=1$, *i. e.*, Br_3CCH_2CHCl-Br, is possible in the present reaction system under the conditions of the lower mole ratio, vinyl chloride/carbon tetrabromide, shorter reaction time and higher temperature, but the selective formation of the telomers with medium adduct numbers of vinyl chloride is impossible under the reaction conditions examined in the present investigation.

Chain Transfer Constants. The chain transfer constants C_n of poly(vinyl chloride) radicals CBr_3-$(CH_2CHCl)_n^{\cdot}$ to carbon tetrabromide were calculated from the Mayo equation

$$\frac{F_n}{F_{n+1}} = C_n\frac{[S]}{[M]} + \frac{C_n}{C_{n+1}},$$

where F_n is the mole number of active species $CBr_3(CH_2CHCl)_n^{\cdot}$, [S] and [M] are molar concentrations of carbon tetrabromide and vinyl chloride respectively. The conversion must be depressed for the successful use of this relationship. In order to satisfy this requirement and get a wider distribution of molecular weight, experimental data were obtained at the higher mole ratios and the shorter reaction time, the results of which are presented in Table 5. The chain transfer coefficients thus obtained are listed in Table 6. A monotonous increase in C_n with the increasing n is found. This result is consistent with ones obtained by Lewis and Mayo,[4] in different reaction systems and may be attributed to the inductive effect

Table 6. Chain transfer constants

C_1	C_2	C_3	C_4
0.33	1.85	7.45	12.15

of the CBr_3 group as suggested by Walling[5] and Karapetyan.[6]

Telomerization of Vinyl Chloride - Bromoform. Using bromoform instead of carbon tetrabromide as telogen, the telomerization of vinyl chloride was carried out under similar conditions and the results are compared in both systems. The experimental conditions and results are summarized in Table 7.

It was found from the results that both systems show a similar behavior when the taxogen/telogen ratio is lower than unity. That is to say, the conversion of vinyl chloride decreases when the mole ratio increases, the reaction time shortens, and temperature becomes higher. However, when the taxogen/telogen ratio increases over unity, the solid product is formed in a small amount and the conversion increases, making a minimum around unity. The solid product is confirmed to be poly(vinyl chloride). Further, a complicated pattern was found when the product mixture was developed by the thin-layer chromatography. A typical example is shown in Fig. 2. These results are interpreted from the possibilities that the chain transfer of the growing ends is not feasible to bromoform in comparison with carbon tetrabromide and the subtraction by the initiator and growing end radicals takes place at the two alternative positions of bromoform, *i. e.*, H-subtraction and Br-subtraction. For a detailed discussion, identification of products and further examinations under various conditions are necessary and are now in progress.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1377—1379 (1969)

Photooxidation of Anthracene*1

Noboru SUGIYAMA, Masaaki IWATA, Michikazu YOSHIOKA,*2 Kazutoshi YAMADA*3 and Hiromu AOYAMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo

(Received September 12, 1968)

It was found that anthracene (I) was converted to 9,10-anthraquinone (III) and bianthrone (IV) by irradiation *via* anthracene peroxide (II). The reaction proceeded most effectively in carbon disulfide. Also IV was found to be oxidized to III by oxygen in singlet state.

Many reports on the photochemical oxidation of anthracene (I) and its derivatives have been found in literature. Among the photooxidation products of I, its dimer, anthraquinone (III), and anthracene peroxide (II)[1-8] have been reported. We have found that I afforded bianthrone (IV) beside III, the yield being 29% for IV and 21% for III. We have also found that the irradiation of II gave III and IV. This paper deals with the experiments on the formation of III and IV by the photoreaction of I or II, and the intermediacy of II, as well as the photochemical formation of III from IV.

Results and Disscution

When a solution of I in carbon disulfide was irradiated at room temperature with a 500 W high-pressure mercury lamp for 50 hr, five new spots appeared on thin-layer chromatography. These spots showed R_f values of 0.60 (A), 0.54 (B),

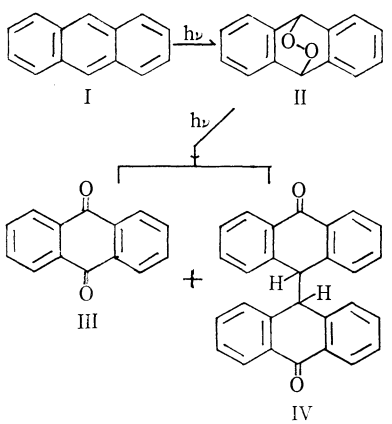
0.43 (C), 0.33 (D), and 0.00 (E), respectively. The products A and B were isolated from the irradiation mixture by silica gel column chromatography. The product A was identified with authentic 9,10-anthraquinone (III) by IR and UV spectra, and mixture melting point. The product B, $C_{28}H_{18}O_2$, showed UV absorption maxima (ε) at 267(26700), 297(8700), and 315(5800) nm, and IR absorption bands at 1658, 1348, 1318 (one strong peak), and 690 cm^{-1}. The NMR spectrum of B showed signals in $CDCl_3$ at 4.74 (singelt), 6.80 (multiplet) and 7.90 (multiplet) at δ from TMS. The mass spectrum of B showed a parent peak at 386 *m/e* and base peak at 193 *m/e* (just half of the parent *m/e*). These physical data, elemental analysis and properties of IV described by Friend and co-worker[9] strongly suggested that B was 10,10′-bianthronyl(bianthrone) (IV).

In order to confirm the intermediacy of II in the photooxidation of I to III and IV, the authentic sample of II[7] saturated in carbon disulfide was irradiated. The reaction was followed at intervals by thin-layer chromatography. After 18 hr irradiation, III and IV were detected. The fact indicates that II is an intermediate in the photooxidation of I.



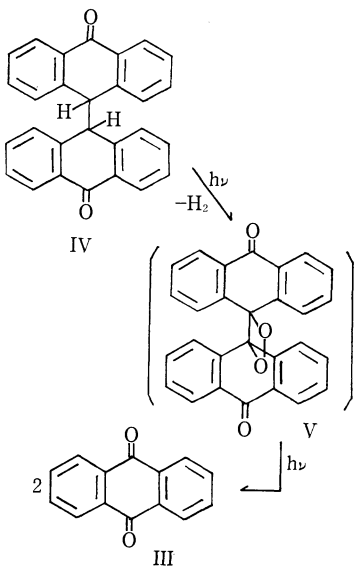
Scheme I

When an acetone solution of I was irradiated for an hour, only II was detected. The irradiation of the same solution for 50 hr gave only III. When a benzene solution of I was irradiated for an hour, II was detected. But if the irradiation period was prolonged for 50 hr, III with other products detected, but not IV.

In the case of the irradiation in ethanol solution, neither II, IIII nor IV was detected. Consequently, the photochemical reaction in an alcohol solution seems to be different from those in the other three solutions.

When a dioxane solution of IV was kept under a scattered light for 10 days, IV was quantitatively converted to III. If the solution was protected from any light with or without bubbling with oxygen, no reaction was observed.

Corey and Taylor[5] reported that I is converted to II with singlet excited O_2 produced by the method of Foner and Hudson.[10] Our experiment shows that IV is converted to III, and this conversion seems to be promoted by visible light. In fact, when IV in a dioxane solution was irradiated with 125 W high-pressure mercury lamp, III was not detected. Therefore, the formation of III from IV might be based on the photooxidation of IV with singlet excited O_2 corresponding to the excitation energy, $^1\Delta_g$ 0.977 eV (12700 Å) and $^1\Sigma_g$ 1.63 eV (7630 Å).[5] The excited oxygen might add to C_{10} and $C_{10'}$ position of IV with elimination of hydrogen to make V as intermediate, and the cleavage of O–O bond and C–C bond of V will take place between C_{10} and $C_{10'}$ position to give III.



Scheme II

Charier and Crippa[11] reported that I in acetic acid containing hydrogen peroxide, as oxidant, was converted to IV accompanying other products by sun-light irradiation for 60 hr. Our result shows that I is oxidized to III and IV without oxidant in fairly good yield, 29%. The qualitative studies of the solvent effect showed that carbon disulfide promoted most effectively the formation of IV. This suggests that the CS radical produced

effectively by irradiation on CS_2 with Hg-vapor lamp,[12] plays an important role for cleavage of the O-O bond of II. Without CS radical II converts solely to III, as in the case of acetone and benzene solutions. This interpretation may be supported by the fact that no formation of III or IV in alcohol solution was detected.

Experimental

As a light source, a Daika 500 W high-pressure mercury lamp was used for the irradiation experiment in carbon disulfide, benzene or ethanol, and a Toshiba 110 V 200 W lamp for the preparation of anthracene peroxide. All solvents were freshly distilled before use. Anthracene was recrystallized twice from benzene.

Anthracene Peroxide (II). The method by Foote *et al.*[7] was modified. A solution of anthracene (0.54 g, 0.003 mol) and methylene blue (50 mg) in 250 m*l* of chloroform was placed in hydrogenation apparatus filled with O_2 gas and irradiated with stirring for 3 hr. The solution temperature was kept below 15°C during the irradiation. The consumed O_2 volume was 43 m*l* (0.00244 mol). The solution was passed through the column of silica gel (Kieselgel, Merck) to remove methylene blue. The colorless solution was obtained and evaporated to dryness under reduced pressure. The residue was chromatographed over silica gel with benzene to give 0.17 g of II, mp 146—147°C, R_f 0.34 (silicagel-benzene), IR (KBr disk) 1460, 1170, 950, 770 and 720 cm^{-1}, UV λ_{max} (Dioxane) (log ε) 270 (2.9) and 278 (2.8) nm.[7,13]

Irradiation of (II) in Carbon Disulfide. A saturated solution of II in carbon disulfide (about 10^{-2} mol/*l*) was sealed in a Pyrex tube and irradiated with a high-pressure mercury lamp for 18 hr. The reaction mixture was chromatographed on silica gel. When benzene (50 m*l*) was passed through the column, 9,10-anthraquinone (III) was eluted. Then the mixture of benzene and ethyl acetate (7:3) was passed through, bianthrone (IV) was eluted. III and IV were respectively identified with an authentic sample by mp, IR, UV, and R_f.

Irradiation of Anthracene (I) in Carbon Disulfide. The saturated solution of I (about 4 g) in 150 m*l* of carbon disulfide was irradiated with the high-pressure mercury lamp for an hour. The thin-layer chromatography of an aliquot from the reaction mixture showed a new spot at R_f 0.39 (benzene), corresponding to that of II. After irradiation for 50 hr, five new spots appeared on the thin-layer chromatogram (benzene-ethyl acetate 7 : 3), while the spot of II could not be found. The reaction mixture was evaporated to dryness, *in vacuo*, and 3.5 g of the mixture was obtained. The mixture (0.3 g) was dissolved in benzene and chromatographed on 20 g of silica gel. The first elution by benzene (120 m*l*) gave 0.063 g (21%) of product A (R_f, 0.62, benzene-ethyl acetate 7:3). The second elution by benzene - ethyl acetate (9:3) gave 0.079 g (29%) of product B (R_f 0.54, benzene-ethyl acetate 7 : 3). Other products, C (R_f 0.43), D (R_f 0.33) and E (R_f 0.00), were also obtained.

The product A showed IR absorption at 1675 (>C=O), 1596 (>C=C<, aromatic), 1355, 1320, 1306, 1285 (=>C=O), and 690 (adjacent four protons of aromatic nuclei) cm^{-1}, UV absorption maxima at 252, 263, 272 and 325 nm in ethanol, and mp 272—282°C. These data were in accord with those of authentic 9,10-anthraquinone (III).[14]

The product B, recrystallized from benzene, light yellow needles, darkened at about 190°C and melted at 250—252°C (decomposition).

Found: C, 86.52; H, 4.66%. Calcd for $C_{28}H_{18}O_2$: C, 87.02; H, 4.69%. UV: λ_{max}^{EtOH} (ε) at 267 (26700), 297 (8700) and 315 (5800) nm, IR: ν_{max}^{KBr} cm^{-1} at 1658 (>C=O), 1600 (>C=C<, aromatic), 1348, 1312 (=>C=O), and 690 (adjacent four protons of aromatic nuclei). NMR: δ^{CDCl_3}, four kinds of signal at 4.74 (s, 2H, 10,10′-protons), 6.80 (m, 4H, 4,4′,5,5′-protons), 7.34 (m, 8H, 2,2′,3,3′,6,6′,7,7′-protons), and 7.90 (m, 4H, 1,1′,8,8′-protons). The mass spectrum gave parent peak at 386 *m/e* and base peak at 193 *m/e* (just half of the parent *m/e*).

Irradiation of I in Acetone. I (0.2 g) dissolved in acetone (14 m*l*), was irradiated at room temperature. In an hour, only the spot of R_f 0.34 (benzene) was detected, and after 50 hr, this spot completely disappeared and the spot of R_f 0.62 (benzene-ethyl acetate 7 : 3) appeared, indicating that II changed into III.

Irradiation of I in Benzene. I (0.2 g) dissolved in benzene (20 m*l*) was irradiated. In an hour, the spot of R_f 0.34 (benzene) was detected, and after 50 hr, five spots appeared, including a small spot of R_f 0.62 (benzene-ethyl acetate 7:3), corresponding to that of III.

Irradiation of I in Ethanol. As I was sparingly soluble in ethanol, the mixture of I and ethanol (60 m*l*) was stirred at boiling point. After the solution was placed for 24 hr at ordinary temperature, the excess of I was filtered and the filtrate was irradiated for 3 hr. II, III or IV was not detected, while the fluorescent of I disappeared.

Irradiation of Bianthrone (IV) in Dioxane. IV (1.3 mg) was dissolved in dioxane (200 m*l*) and the solution was allowed to stand. After 10 days, the UV spectrum showed that IV changed into III and the spot of R_f 0.62 (benzene-ethyl acetate 7:3) was detected. When intercepted from any light with or without oxygen, the reaction from IV to III did not take place.

Reaction of Acyl Oxime with Mercaptan

Rokuro SUDO, Akira KANEDA and Nobuo FURUOYA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received September 14, 1968)

The acyl derivative of oxime, derived from a strong acid, is generally unstable. However, acyl oximes of the ethyl α-oximinoacetate derivative were prepared and were found to be more stable than ordinary acyl oxime. Acetyl, carbethoxy, benzoyl, and even tosyl ester were prepared, and their reactions with the mercaptide anion were investigated.

In general, acyl derivatives of oxime can be readily isolated as long as the acyl group is not derived from a very strong acid.[1] Recently, however, tosyl ester of α-oximinobenzylcyanide[2] and ethyl α-oximinophenylacetate[3] were found to be more stable than ordinary oxime tosylate. In our study[3] of the nucleophilic attack of the mercaptide anion on the carbon of the C=N function, some acyl esters of ethyl α-oximininopropionate (**1**) and ethyl α-oximinophenylacetate (**2**) were prepared, and their reactions with the mercaptide anion were investigated. The characteristics of these acyl oximes, prepared from the corresponding ethyl α-oximinoacetate derivative and acyl chloride, are summarized in Table 1.

TABLE 1. ACYL OXIMES $R-\underset{\underset{N-OR_1}{\|}}{C}-COOC_2H_5$

When acetyl ester (**3**) of ethyl α-oximinopropionate was treated with benzyl mercaptan in benzene, no reaction occurred, but in benzene containing an equivalent amount of triethylamine, it afforded four products: ethyl α-oximinopropionate (**1**), benzyl thioacetate (**9**), ethyl α-benzylsulfeniminopropionate (**11**), and triethylammonium acetate (**12**) (Fig. 1). **11** was characterized by elementary analysis and by a study of its IR and NMR spectra. The IR spectrum had absorptions at 1712 cm^{-1} (C=O of the ester) and at 1586 cm^{-1} (C=N), and the NMR spectrum had a CH_3-singlet at τ 7.88, indicating that the methyl group is attached to carbon, while that of the C=N-CH_3 singlet in the 2-methyliminodithiolane[4] (**13**) is at τ 6.9.

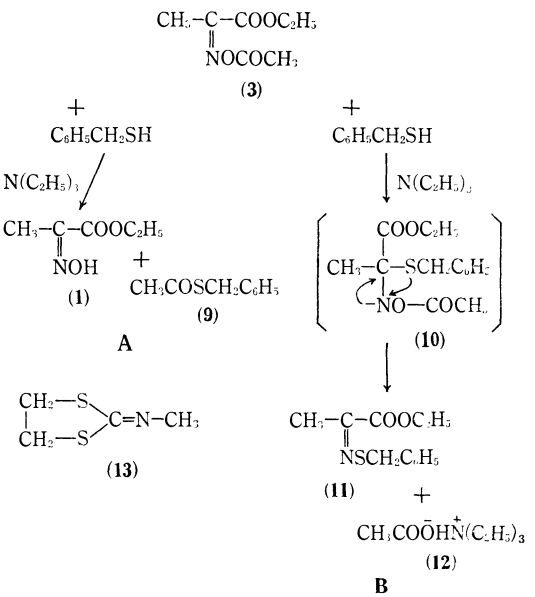

Fig. 1.

Furthermore, the fact that the reaction of this compound with hydrochloric acid in ethanol yielded dibenzyl disulfide (**14**) and ammonium chloride supported the sulfenimino structure of **11**. The presence of **14** and ammonium chloride in the

products indicates that the intermediates of the reaction are ethyl α-iminopropionate (**15**) and benzylsulfenchloride (**16**) (Fig. 2).

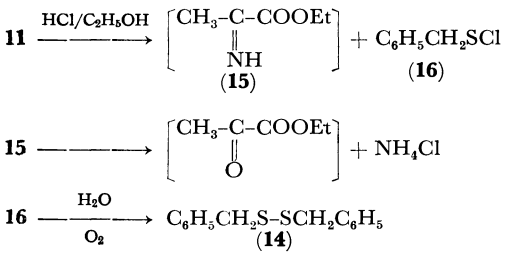

Fig. 2

Thus, acetyl ester of ethyl α-oximinopropionate can be expected to manifest its nucleophilic activity at two sites: at the carbon of the carbonyl in the acyl group, yielding **1** (A route), and at the carbon of the C=N function (B route) yielding ethyl α-benzylmercapto-α-acetoxyaminopropionate (**10**) (B route). **10** seems to have been converted to **11** through a migration of the benzylmercapto group from carbon to nitrogen, accompanied by the elimination of the acetoxy group, instead of through the Beckmann rearrangement, which usually occurs with acyl oxime. Another mechanism is possible, that in which the mercaptide anion attacks nitrogen directly, leading to a nucleophilic substitution. In a similar method, other acyl esters of the ethyl α-oximinoacetate derivative were treated with benzyl mercaptan; these results are summarized in Table 2. In the case of tosyl ester, only the

product from the **B** route was obtained; thus, the reaction with benzyl mercaptan gave the benzylsulfenimino compound, and also ethyl α-ethylsulfeniminopropionate (**17**) with ethyl mercaptan. On the other hand, the ethyl trichloroacetylpropionate **18** and diethyl phosphate **19** of ethyl α-oximinopropionate, which were prepared from **1** and the corresponding acid chloride, were carefully treated with benzyl mercaptan to give the original oxime **1** quantitatively (A route). Because, they appeared to undergo hydrolysis very easily and to give **1**.

It has been reported[3] that the tosyl ester of α-oximinobenzylcyanide (**20**) afforded α-benzylmercapto-α-phenylimino acetonitrile (**21**) through the Beckmann rearrangement in a similar reaction. This is erroneous, for the product was α-benzylsulfeniminobenzyl cyanide (**22**). This compound was very stable even when it was refluxed in an aqueous hydrochloric acid or sodium hydroxide solution, but it was converted to ethyl benzoate, dibenzyl disulfide(**14**), and anmmonium chloride when it was treated with hydrochloric acid in ethanol under cooling. Similarly, the tosyl ester **20′** of ethyl α-oximinophenylacetate afforded ethyl α-benzylsulfeniminophenylacetate (**22′**), which was then converted to ethyl benzoyl formate, dibenzyl disulfide, and ammonium chloride (Fig. 3).

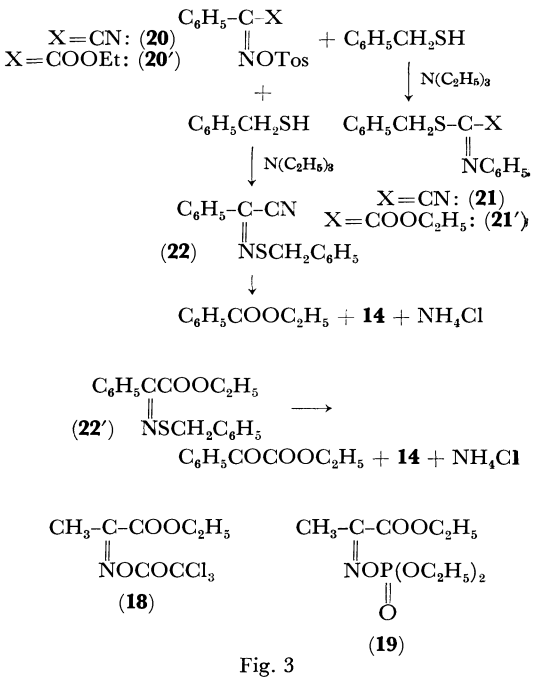

Fig. 3

Experimental

Ethyl α-oximinopropionate (**1**)[5] and ethyl α-oximinophenylacetate (**2**)[6] were prepared by the nitrosation of ethyl α-methylacetoacetate and ethyl phenylacetate; they melted at 96°C and 95—96°C respectively.

Acetylation of the Ethyl α-Oximinopropionate

6) K. E. Hamlin and W. H. Hartung, *J. Biol. Chem.*, **145**, 355 (1942).

Derivatives (3, 4, 5 and 6). To a solution of 0.1 mol of **1** and 0.1 mol of triethylamine in 50 m*l* of ether there was added 0.1 mol of the corresponding acetyl chloride derivative. The mixture was then refluxed for 2 hr and, after cooling, washed with 50 m*l* of water. The ether solution was concentrated to give a crude product, which was purified by distillation or by recrystallization. The physical constants are summarized in Table 1 and Table 3.

Ethyl α-Acetoximinophenylacetate (7). Sodium salt[3] of **2** (21.5 g, 0.1 mol) was suspended in 50 m*l* of benzene. To this solution, which was stirred vigorously, there was then added, drop by drop, 8 g (0.1 mol) of acetyl chloride under cooling. After the addition had been completed, the mixture was warmed at 40°C for 30 min. After cooling, it was poured into water. The benzene layer was separated and dried over anhydrous sodium sulfate. It was concentrated to give an oil, which was distilled at 145°C/1 mmHg, giving **7**. Yield, 17.7 g (75%).

Tosyl Ester of α-Oximinophenylacetate (8). Sodium salt[3] of **2** (21.5 g, 0.1 mol) was suspended in 50 m*l* of benzene. To this solution, which was stirred vigorously, there were then added, drop by drop, 19 g of *p*-toluenesulfonyl chloride dissolved in 30 m*l* of benzene. After the addition was completed, the mixture was refluxed for 1 hr. After cooling, the mixture was washed with water and was dried over anhydrous sodium sulfate. The mixture was concentrated to give crystals which were recrystallized from ethanol. Mp 95—96°C Yield, 12.1 g (35%). The physical constants of **7** and **8** are listed in Table 1 and Table 3.

Reaction of Ethyl α-Acetoximinopropionate (3) with Benzyl Mercaptan. To a solution of 17.3 g (0.1 mol) of **3** in 50 m*l* of dry benzene containing 10.1 g (0.1 mol) of triethylamine, 12.4 g (0.1 mol) of benzyl mercaptan were added. The mixture was then refluxed for 6 hr. After cooling, water was added to the mixture. The benzene layer was dried over anhydrous sodium sulfate and concentrated under reduced pressure; 50 m*l* of ligroin were then added. The precipitated crystals were collected by filtration and were found to be the original oxime (**1**) by a mixed-melting-point procedure. The ligroin filtrate was concentrated to give an oil, which was then purified by distillation and which was identified as ethyl α-benzylmercaptiminopropionate (**11**), bp 135°C/1 mmHg, mp 36—37°C. The yields of **1** and **11** are listed in Table 2. IR bands (KBr): 1712 cm^{-1} (C=O), 1586 cm^{-1} (C=N). NMR spectrum, $CDCl_3$ (TMS as internal reference): τ 8.69 (3H, triplet) for $-CH_2-C\underline{H}_3$, τ 7.88 (3H, singlet) for $-CH_3$, τ 5.74 (2H, quartet) for $-C\underline{H}_2-CH_3$, and τ 5.57 (2H singlet) for $-C\underline{H}_2-C_6H_5$. In a similar procedure, other acyl oximes, (**4**, **5** and **6**), were treated with benzyl mercaptan; the results are summarized in Table 2.

Ethyl α-Ethylsulfeniminopropionate (17). In a procedure similar to **11**, **6** was treated with ethyl mercaptan and was converted to **17**. **17** was distilled at 103°C/8 mmHg. Yield, 96%. IR bands (NaCl): 1712 cm^{-1} (C=O), 1586 cm^{-1} (C=N); NMR ($CDCl_3$, TMS as the internal reference): τ 8.67 (3H, triplet) for $-COOCH_2C\underline{H}_3$, τ 8.59 (3H, triplet) for $-S-CH_2-C\underline{H}_3$, τ 7.81 (3H, singlet) for $-CH_3$, τ 6.83 (2H, quartet) for $-S-C\underline{H}_2-CH_3$, and τ 5.72 (2H, quartet) for $-COOC\underline{H}_2-CH_3$.

Reaction of Ethyl α-Benzylsulfeniminopropionate (11) with Hydrochloric Acid in Ethanol. The propionate, **11** (11.6 g, 0.05 mol), was added under cooling to 30 m*l* of ethanol containing hydrochloric acid. The solution was then kept at room temperature overnight. The precipitated crystals were collected by filtration and found to be ammonium chloride. Yield, 1.8 g. The filtrate was concentrated to one third of the original volume and kept at room temperature. The precipitated crystals were collected by filtration and found to be dibenzyl disulfide (yield, 7 g) by a mixed-melting-point procedure. The filtrate was concentrated to an oil. The isolation of the product from this oil, by either distillation or recrystallization, was not successful.

Reaction of α-Benzylsulfeniminobenzyl Cyanide (22) with Hydrochloric Acid in Ethanol. In a procedure similar to that described above, **22**[3] was treated with hydrochloric acid. Dibenzyl disulfide and ammonium chloride were obtained, and the final oily residue was distilled to give an oil which was identified as ethyl benzoate by a study of its IR spectrum.

Reaction of Ethyl α-Benzylsulfeniminophenylacetate (22′) with Hydrochloric Acid in Ethanol. In a procedure similar to that used in the reaction of **22**, **22′** [3] was treated with hydrochloric acid to give dibenzyl disulfide, ammonium chloride, and ethyl benzoylformate, which was identified by means of the IR spectrum.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1383—1386 (1969)

Oligomerization of Isoprene by Hafnium Catalysts

Akira MISONO, Yasuzo UCHIDA, Ken-ichi FURUHATA and Shohei YOSHIDA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received September 17, 1968)

Oligomerization of isoprene by the catalyst system consisting of hafnium(IV) *n*-butoxide and diethylaluminum chloride was studied. Isoprene was oligomerized to a mixture of dimers, trimers and higher oligomers. The compound, 2,6-dimethyl-1-*trans*-3,6-octatriene, was the main dimer of isoprene in this reaction. The maximum yield of this dimer in the reaction at 130°C for 2 hr was accomplished when the molar ratio of diethylaluminum chloride to hafnium(IV) *n*-butoxide was 4.7. The addition of tetrahydrofuran or triphenylphosphine kept the selectivity for the dimer nearly constant. These results were compared with those obtained by the catalyst system consisting of titanium(IV) *n*-butoxide or zirconium(IV) *n*-butoxide and diethylaluminum chloride.

Many catalyst systems containing transition metals are known to oligomerize olefins. In the course of our studies on the catalytic oligomerization of conjugated dienes, we found the cyclic dimerization of isoprene into a mixture of 1,5- and 2,5-dimethyl-1,5-cyclooctadiene by iron complex catalysts.[1] Some catalyst systems containing titanium[2] or chromium[3] are reported to give a linear dimer of isoprene along with other oligomers.

In the preceding paper,[4] we reported the linear dimerization of isoprene to 2,6-dimethyl-1,*trans*-3,6-octatriene by the catalyst system consisting of zirconium(IV) *n*-butoxide, diethylaluminum chloride and with or without electron donors.

In this paper, we report on the oligomerization of isoprene by the catalyst system consisting of hafnium(IV) *n*-butoxide and diethylaluminum chloride. This catalyst system gave a mixture of oligomers of isoprene, and 2,6-dimethyl-1,*trans*-3,6-octatriene was formed predominantly among dimers of isoprene. The selectivity for this compound in the reaction at 130°C for 2 hr was 43% when the molar ratio of diethylaluminum chloride to hafnium(IV) *n*-butoxide was 4.7. The addition of triphenylphosphine or tetrahydrofuran did not raise the selectivity for the dimer. The reaction of isoprene by the catalyst system consisting of titanium(IV) *n*-butoxide and diethylaluminum chloride was also studied, but our results were different from those reported by Takahashi and Yamaguchi.[2b] These results were compared with those obtained by the catalyst system consisting of zirconium(IV) *n*-butoxide and diethylaluminum chloride.

Experimental

Reactors. A 100 m*l* stainless steel autoclave was used.

Reagents. Isoprene was dried over Drierite, distilled and was deoxygenated by the freeze-thaw method with pumping.

Benzene and tetrahydrofuran were purified by conventional methods and were distilled under a nitrogen stream.

Diethylaluminum chloride and titanium(IV) *n*-butoxide were purified by distillation and were diluted in benzene.

Hafnium(IV) *n*-butoxide was made according to the analogous method for zirconium(IV) *n*-butoxide[5] and was diluted in benzene.

Commercial triphenylphosphine was used without further purification.

Reaction Procedure. In a typical reaction, to an autoclave filled with nitrogen, 5.70 g of benzen, 50 mmol of isoprene, 0.5 mmol of hafnium (IV) *n*-butoxide (16.3 wt% benzene solution) and 2.0 mmol of diethylaluminum chloride (17.6 wt % benzene solution) were charged with injectors under a nitrogen stream. The total amount of benzene was controlled to be 8.3—8.5 g. The autoclave was then heated at 130°C for 2 hr with stirring.

Analysis. The gas chromatography was used for calculating the conversion percent of isoprene and for the quantitative analysis of products. A 2 m stainless steel column, 4 mm in diameter, packed with polydiethylene glycol succinate on Shimalite was used. Operation conditions: column temperature, 112°C and 180°C for dimers and trimers, respectively; flash evaporator, 300°C; carrier gas (helium) speed, 30 m*l*/min. Benzene

was used as an internal standard.

Infrared spectra were taken using a Nihon Bunko Model DS-301.

Nuclear magnetic resonance spectra were recorded on a Nihon Denshi Model C-60.

Molecular weights were measured by the cryoscopic method in benzene.

Results and Discussion

Products obtained in the reaction of isoprene by the catalyst system consisting of hafnium(IV) *n*-butoxide and diethylaluminum chloride were dimers, trimers and higher oligomers. Two dimers were found on gas chromatography and the structure of the dimer with the relative retention time 2.8 was determined to be 2,6-dimethyl-1,*trans*-3,6-octatriene by comparing the retention time with the pure sample obtained by the zirconium catalyst.[4] A small amount of another dimer with the relative retention time 3.4 was found on gas chromatography, but this compound was not studied in detail.

The Effect of the Molar Ratio of Catalyst Components. The effect of the molar ratio of diethylaluminum chloride to hafnium(IV) *n*-butoxide on the reaction of isoprene is shown in Fig. 1. The reaction was

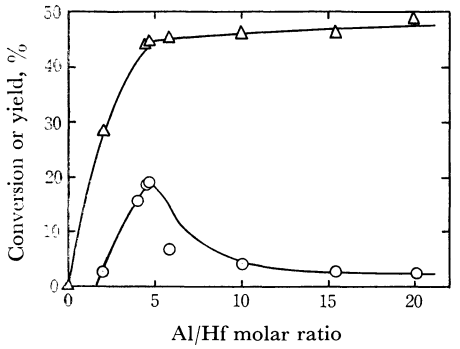

Fig. 1. Effect of the molar ratio of Et_2AlCl to $Hf(OBu)_4$.
—△—: Conversion of isoprene, %
—○—: Yield of 2,6-dimethyl-1, *trans*-3,6-octatriene, %
Reaction temp.: 130°C; reaction time: 2 hr; Isoprene/$Hf(OBu)_4$: 100

carried out at 130°C for 2 hr and the maximum yield of dimers was accomplished when the molar ratio of diethylaluminum chloride to hafnium(IV) *n*-butoxide was 4.7. At this temperature only traces of trimers were formed and the rest were higher oligomers. The infrared spectra of the mixture of these higher oligomers showed absorption bands due to a methyl group (2975, 1450 and 1375 cm^{-1}), a methylene group (2925 and 1450 cm^{-1}), a *trans* double bond (1650 and 965 cm^{-1}), a conjugated double bond (1610 cm^{-1}) and a terminal methylene group (1780 and 885 cm^{-1}). The mean polymerization degrees of liquid oligomers obtained were 6.5, 8.1 and 9.3 when the molar ratios of diethylaluminum chloride to hafnium(IV) *n*-butoxide were 4.0, 6.0 and 15.6, respectively. These data indicate that the excess of diethylaluminum chloride promoted the oligomerization of isoprene to higher oligomers. A similar result was reported in the case of oligomerization of butadiene by iron catalysts.[6,7]

The Effect of the Reaction Temperature. The effect of the reaction temperature on the formation of oligomers of isoprene was examined keeping the molar ratio of diethylaluminum chloride to hafnium(IV) *n*-butoxide constant at 4.0 and the reaction time 2 hr (Fig. 2). The maximum yield of the

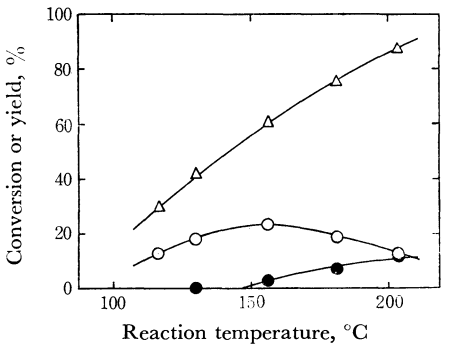

Fig. 2. Effect of the reaction temperature.
—△—: Conversion of isoprene, %
—○—: Yield of 2,6-dimethyl-1, *trans*-3,6-octatriene, %

Reaction time: 2 hr; Isoprene/$Hf(OBu)_4$: 100; $Et_2AlCl/Hf(OBu)_4$: 4.0

dimer was accomplished at about 160°C. The formation of trimers was observed significantly at the temperature higher than 150°C. Four trimers were detected on gas chromatography, and one isomer was predominantly formed. Solid polymers of isoprene were precipitated from the reaction solution at higher temperature when an excess amount of methanol was added, but the higher oligomers formed in the reaction at 130°C remained in the benzene layer.

The Effect of Electron Donors. The effect of electron donors on the oligomerization of isoprene was examined using triphenylphosphine and tetrahydrofuran (Fig. 3). The reactions were carried out at 156°C for 2 hr.

The addition of triphenylphosphine to the catalyst system did not change the selectivity for 2,6-dimethyl-1,*trans*-3,6-octatriene. The same result was observed in the selectivity for the trimer.

In the case of tetrahydrofuran, the selectivity for the dimer decreased slowly as the molar ratio of added tetrahydrofuran to hafnium(IV) *n*-butoxide increased. In this case, no trimer was found when the molar ratio exceeded five.

There was little difference between triphenylphosphine and tetrahydrofuran regarding the influence on the oligomerization of isoprene by the catalyst system consisting of hafnium(IV) *n*-butoxide and diethylaluminum chloride. These electron donors suppressed the conversion of isoprene, but the selectivity for the dimer was nearly constant in both cases, and they did not change the nature of the reaction.

In the oligomerization of olefins catalyzed by transition metals, an alkylaluminum compound acts as an alkylating reagent and the resulting alkyl-transition metal is usually reduced to a low valent state by a homolytic splitting of the transition metal-carbon bond.

In order to examine the reaction of catalyst components in the oligomerization of isoprene by this catalyst system, the nuclear magnetic resonance spectra of catalyst components were studied. Hafnium(IV) *n*-butoxide showed an absorption centered at $\tau=5.5$ ppm (triplet) due to methylene protons next to oxygen in the Hf–O–C linkage. On the other hand, ethylaluminum *n*-butoxide chloride formed by the reaction of equal amounts of diethylaluminum chloride and *n*-butanol showed an absorption centered at $\tau=6.3$ ppm (triplet), which can be assigned to methylene protons next to oxygen in Al–O–C linkage. A mixture of hafnium(IV) *n*-butoxide and diethylaluminum chloride (molar ratio: about 1:4) showed absorptions centered at $\tau=5.7$ (triplet) and 6.4 ppm (triplet) which can be assigned to methylene protons next to oxygen in the linkage of Hf–O–C and Al–O–C, respectively. From this result, it can be said that a ligand exchange reaction between hafnium(IV) *n*-butoxide and diethylaluminum chloride occurred. No significant change was observed after heating this solution at 100°C for 2.5 hr. The solution remained diamagnetic after heating at the reaction temperature and the valency of hafnium was probably four. The ligand exchange reaction could also be observed in the infrared spectra.

Brown precipitates were separated from the benzene solution of hafnium(IV) *n*-butoxide and diethylaluminum chloride after heating at 110°C for 2.5 hr, but when the solution contained a stoichiometric amount of isoprene along with hafnium(IV) *n*-butoxide and diethylaluminum chloride, it remained homogeneous for a long time after the heating. This solution was also diamagnetic before and after the heating.

From these results, it can be said that hafnium is in its four valent state in the oligomerization of isoprene by hafnium(IV) *n*-butoxide and diethylaluminum chloride, and the little difference in the effect of triphenylphosphine and tetrahydrofuran on the catalysis can be explained by the fact that there is no *d*-electron in the four-valent hafnium and thus the back donation can be of little significance in the reaction.

The Oligomerization of Isoprene by Titanium Catalysts. The oligomerization of isoprene by the catalyst system consisting of titanium(IV) *n*-butoxide and diethylaluminum chloride was studied and the results were compared with those mentioned above.

The Effect of the Molar Ratio of Catalyst Components. The effect of the molar ratio of diethylaluminum chloride to titanium(IV) *n*-butoxide is shown in Fig. 4. The reactions were carried out at 35°C for 2 hr. Takahashi and Yamaguchi reported that

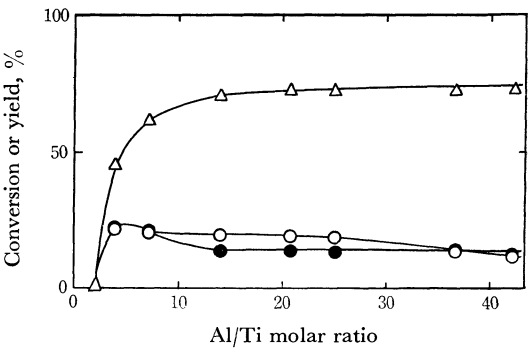

Fig. 4. Effect of the molar ratio of Et_2AlCl to Ti(OBu)$_4$.
—△—: Conversion of isoprene, %
—○—: Yield of 2,6-dimethyl-1, *trans*-3,6-octatriene, %

this catalyst system gave only 2,6-dimethyl-1,*trans*-3,6-octatriene as the dimer of isoprene,[2b] but in our experiment another dimer was found. This dimer was purified by preparative gas chromatography and analyzed. From the infrared and nuclear magnetic resonance spectra, this compound had two methyl groups (IR: 2975, 1450 and 1375 cm^{-1}; NMR: τ=8.37 and 9.02 ppm, 6H), three methylene groups (IR: 2925, 2850, 1440 and 1415 cm^{-1}; NMR: τ=8.02—8.63 ppm, 6H), one vinyl group (IR: 1830, 1645, 1000 and 910 cm^{-1}; NMR: τ=4.17, 4.92 and 5.22 ppm, 3H) and one three-substituted double bond (IR: 1645 and 805 cm^{-1}; NMR: τ=4.69 ppm, 1H). Therefore, this compound was 1,4- and/or 2,4-dimethyl-4-vinylcyclohexene. The boiling point (bp 48—49°C/14 mmHg) and the refractive index (n_D^{26} 1.4638) were very colse to 2,4-dimethyl-4-vinylcyclohexene reported by Zakharkin[2a] (bp 48—48.5 C/14 mmHg; n_D^{20} 1.4646).

Dimers were formed selectively when the molar ratio of diethylaluminum chloride to titanium(IV) *n*-butoxide was 3.6, and at higher molar ratio, reactions to higher oligomers were favored. The yield of dimethylvinylcyclohexene was constant at the higher molar ratio, but that of 2,6-dimethyl-1,*trans*-3,6-octatriene decreased.

The effect of electron donors on this catalyst system was shortly examined keeping the molar ratio of diethylaluminum chloride to titanium(IV) *n*-butoxide at 20. At this molar ratio, the selectivities for 2,6-dimethyl-1,*trans*-3,6-octatriene and dimethylvinylcyclohexene were 24 and 17%, respectively. When triphenylphosphine was added (molar ratio to titanium(IV) *n*-butoxide: 8.2), the selectivities for two dimers lowered to 19 and 16%, respectively. In the case of tetrahydrofuran (molar ratio to titanium(IV) *n*-butoxide: 6.7), the selectivities were 9 and 8%, respectively. An increase in the selectivity for dimers was not observed and the addition of tetrahydrofuran favored the reaction of isoprene to higher oligomers.

In the oligomerization of isoprene by the catalyst system consisting of zirconium(IV) *n*-butoxide and diethylaluminum chloride, the addition of triphenylphosphine or tetrahydrofuran raised the selectivity for 2,6-dimethyl-1,*trans*-3,6-octatriene to more than 90%.[4] The addition of these electron donors to the catalyst system consisting of titanium(IV) *n*-butoxide or hafnium(IV) *n*-butoxide and diethylaluminum chloride suppressed the conversion of isoprene but the increase of the selectivity for the linear dimer was not observed. The adidtion of triphenylphosphine kept the selectivity for the dimer nearly constant in both cases. The addition of tetrahydrofuran to the hafnium catalyst caused a faint decrease in the selectivity for the dimer. In the case of the reaction of isoprene by the catalyst system consisting of titanium(IV) *n*-butoxide and diethylaluminum chloride, the addition of tetrahydrofuran favored the reaction of isoprene to higher oligomers.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1387—1393 (1969)

Specific Association of Riboflavin and Adenine Derivatives in Chloroform Solution and the Effect of Barbiturates on the Association

Yoshimasa KYOGOKU and Byung Sul YU

Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Hongo, Tokyo

(Received September 27, 1968)

Riboflavin-2′,3′,4′,5′-tetraacetate and tetrabutyrate have been found to associate with 9-ethyladenine. They form stronger complexes with each other than with themselves and with other nucleic acid purine and pyrimidine derivatives. The association constants of the formation of the complexes were determined from the infrared spectra to be 130 and 95 M^{-1} respectively. The complex is a 1 : 1 cyclic hydrogen bonded dimer through the imino and the 2-C carbonyl groups of the isoalloxazine ring and the amino group of the adenine residue. 9-Ethyladenine is an effective quencher of the fluorescence of riboflavin tetraacetate. The quenching appears mainly due to the coplanar interaction through hydrogen bonds and partly due to the collision interaction with the purine rings. Some barbiturates were found to prevent the formation of the complex of the adenine and riboflavin derivatives by the formation of more stable complexes with ethyladenine.

The use of infrared spectroscopy has become customary for detecting the specific interaction of biologically important molecules in chloroform solutions. The method was first used for the detection of the specific association of the nucleic acid purine and pyrimidine derivatives.[1-7] It has been extended to the survey of the interaction of other kinds of molecules like drugs and coenzyme derivatives.[8-10] In a previous communication it was reported that riboflavin derivatives show fairly strong association only with an adenine compound and not with other nucleic acid base derivatives.[10] In this paper a detailed analysis of the infrared spectra of the complex will be presented and the structure of the complex will be proposed.

Previous investigators have reported that purine derivatives work as the quenchers of the fluorescence of riboflavin derivatives in aqueous solutions.[11-15] A similar phenomenon has been found in chloroform solutions. The mechanism of the quenching will be discussed in relation to the structure of flavin adenine dinucleotide (FAD).

Barbiturates were found to interact strongly with adenine derivatives.[8] In this paper it will be reported that some of barbiturates can disturb the interaction between riboflavin and adenine derivatives which might be present in the FAD molecule. Barbiturates can inhibit the respiration in mitochondria, which is thought to be related to their sedative activity in the central nervous system.[16,17] The present results might provide a basis for interpreting their mode of action.

Experimental

Materials. Riboflavin-2′,3′,4′,5′-tetraacetate (R) was prepared by the reaction of riboflavin with acetic

anhydride in pyridine. The mixture of anhydrous pyridine (35 ml) and acetic anhydride (4 ml) suspended with dried riboflavin (3 g) was stirred for fifty hours at room temperature. The solution became clear and its color changed to deep orange with green fluorescence. Pyridine was removed by the addition of ethanol and successive evaporation. The sample was recrystallized from the ethanol and chloroform mixture. A yellow flaky crystal was obtained (5 g) (mp 246°C, Found: C, 53.95; H, 5.22; N, 10.41%). 3-*N*-Methylriboflavin-2′,3′,4′,5′-tetraacetate (MeR) was obtained from 3-methylriboflavin by applying the same procedure described above (mp 185°C, Found: C, 55.62; H, 5.49; N, 10.50%). 3-*N*-Methylriboflavin and ribofiavin-2′, 3′,4′,5′-tetrabutyrate (RB) were kindly provided by Professor K. Yagi of Nagoya University and by Professor J. Okuda of Meijo University.

9-Ethyladenine (A), 1-cyclohexyluracil (U), 1-cyclohexyl-5-bromouracil (BrU), 2′,3′-benzylidene-5′-trityl-guanosine (G) and 2′,3′-benzylidene-5′-trityl-cytidine (C) were purchased from Cyclo Chemical Co., Los Angeles, U.S.A. Commercial 5-ethyl-5-phenylbarbituric acid (phenobarbital) (PB) was used after recrystallization from hot water. Crude 1-methyl-5-cyclohexenyl-5-methylbarbituric acid (CB) was obtained by the addition of hydrochloric acid to the commerical sodium salt. Resultant precipitate was recrystallized from hot water.

Procedures. For the measurement of infrared spectra the samples were dissolved in chloroform-*d* (Showa Denko Co., Kawasaki) which was purified by passing through alumina gel column. Infrared spectra were measured with a Perkin Elmer Model 621 infrared spectrophotometer. Fused quartz cells ranging from 1 to 25 mm were used for the measurement in the 3700—3000 cm^{-1} region and potassium bromide cells (including a variable thickness cell) ranging from 0.1 to 5 mm were used for the 1800—1500 cm^{-1} region. The infrared spectra shown in the figures of this paper were given in the absorbance scale, which was calculated from the observed transmission with the aid of the solvent curves as base lines.

From the concentration dependence of the intensity of the monomer bands, association constants were calculated on the theory described previously.[5,6] Six to ten spectra were recorded at different concentrations between 0.1 and 0.001M for the determination of each association constant. It is estimated that the experimental errors of measurement yield relative association constants which are accurate to ±15 per cent.

Non-deuterated chloroform was used as the solvent for the measurements of visible-ultraviolet and fluorescence spectra. The solvent was purified by distillation and by successive passage through alumina gel column. Visible-ultraviolet spectra were recorded with a Hitachi 124 spectrophotometer. The fluorescence measurements were carried out with a Hitachi MPF-2A fluorescence spectrophotometer equipped with a xenon lamp and a grating monochromator. The activating wavelength was set at 360 mμ with a slit width of 10 mμ and the fluorescence was read in the range 380—700 mμ. A fused quartz cell of 1 cm width and 1 cm length with a cap was used. To avoid self quenching at higher concentration, the solution of riboflavin derivatives should have a concentration less than 10^{-4}M.

Results and Discussion

Specific Association of Riboflavin Tetraacetate with Ethyladenine. *Infrared Spectra.* In the spectrum of the 0.02M solution of riboflavin tetraacetate a strong sharp band is observed at 3380 cm^{-1} and a broad band at 3200 cm^{-1} (Fig. 1). Since both of the bands disappear on the deuterium and methyl substitution at the 3-N position, they are associated with the NH stretching vibrations. The apparent extinction coeffecient of the 3380 cm^{-1} band increases and that of the 3200 cm^{-1} band decreases with dilution of the solution. Therefore the former band is assignable to the nonbonded NH stretching vibration and the latter is considered to be related to the bonded NH stretching vibration.

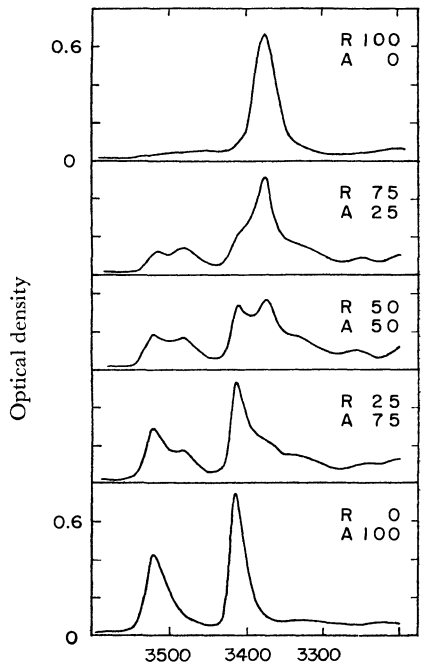

Fig. 1. Infrared spectra of various mixtures of riboflavin tetraacetate (R) and ethyladenine (A). The total concentration of the material is 0.02M and the path length is 2 mm.

The spectrum of 9-ethyladenine shows two strong bands at 3525 and 3414 cm^{-1} which are respectively due to the antisymmetric and symmetric NH stretching vibrations of the nonbonded amino group as discussed previously[5] (Fig. 1). The self-association of the ethyladenine molecules at the 0.02M solution must be negligibly small because the self-association bands at 3485, 3310, 3250 and 3200 cm^{-1} are very weak.

When both the solutions are mixed together, the nonbonded bands decrease in intensity and new

association bands appear at 3485, 3330, 3260, and 3200 cm^{-1}. The positions of some of these bands are different from those of the self-association bands of ethyladenine and riboflavin tetraacetate. It is difficult to assign each association band of the mixture to one or both components. The spectra of various mixtures of riboflavin tetraacetate and ethyladenine are given in Fig. 1. The intensity of the association bands at 3485 and 3330 cm^{-1} changes as a function of the mole ratio and reaches its maximum in the 1 : 1 region (Fig. 2). Similar

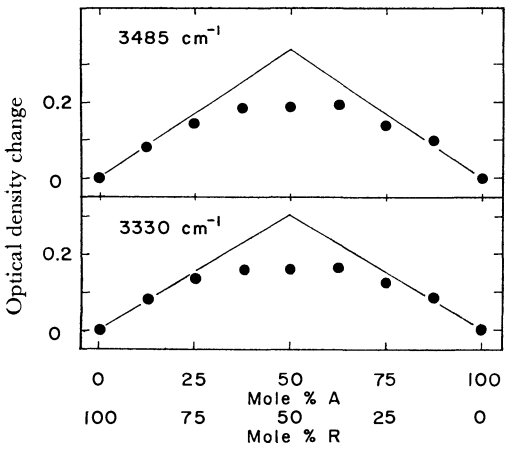

Fig. 2. Change in the optical density of the association bands found at 3485 and 3330 cm^{-1} as a function of the mole ratio of riboflavin tetraacetate and ethyladenine. The optical density of the pure solution is adjusted to zero.

phenomenon was observed for the riboflavin tetrabutyrate and ethyladenine mixture. But the spectrum of ethyladenine does not change to any observable extent by the addition of *N*-methylriboflavin tetraacetate. There is no interaction between them at this concentration.

The association constants for the formation of the R-A complex and the RB-A complex at 25°C were determined to be 130 and 95 M^{-1} respectively. The self-association constant of riboflavin tetraacetate is 4.5 and that of riboflavin tetrabutyrate is 2.3M^{-1}. The monomer band of the riboflavin derivatives at 3380 cm^{-1} and that of ethyladenine at 3525 cm^{-1} were used for the determination.

Although riboflavin tetraacetate and tetrabutyrate associate with ethyladenine fairly strongly, their interaction with other nucleic acid purine and pyrimidine derivatives are negligibly small. Figure 3 shows the infrared spectra of the equimolar mixtures of R-A, R-U, R-C and R-G at 0.008M. Except for the R-A mixture the observed spectra (solid line) are virtually identical to the sum (dotted line) of the component spectra.

In order to get further information on the structure of the R-A complex in solution the spectra in the carbonyl stretching region were studied. In the spectrum of the dilute solution of riboflavin tetraacetate a strong band is observed at 1745 cm^{-1} and two bands with medium intensity at 1710 and 1690 cm^{-1} (Fig. 4). On the deuteration of the 3-N position the strongest band remains unchanged, whereas the 1710 cm^{-1} band moves to 1713 cm^{-1} and the 1690 cm^{-1} band shifts to 1675 cm^{-1}. (The infrared spectrum of 3-*N*-methylriboflavin tetraacetate shows three bands at 1745, 1705 and 1660 cm^{-1}). The 1745 cm^{-1} band which appears at such high frequency region must be the carbonyl stretching band of the acetyl groups. The 1710 cm^{-1} band is considered to arise mainly from the

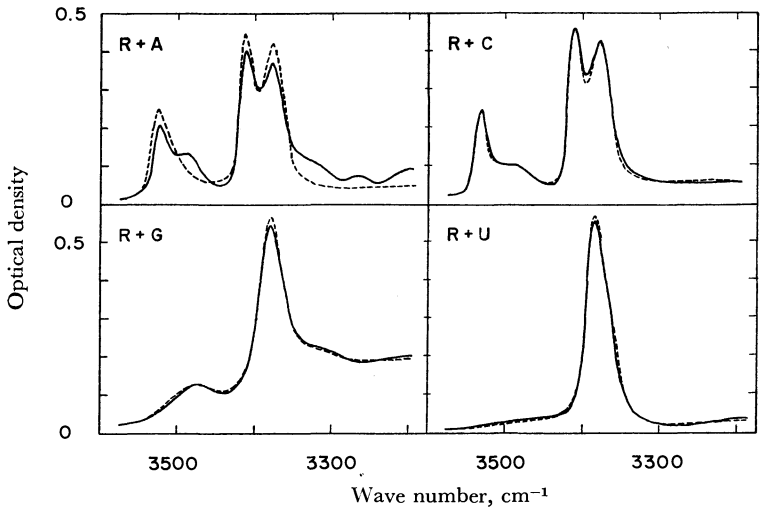

Fig. 3. Infrared spectra of the equimolar mixture solutions of riboflavin tetraacetate and one of the A, U, G and C compounds in chloroform. The total concentration is 0.008M and the path length is 5 mm. See text.

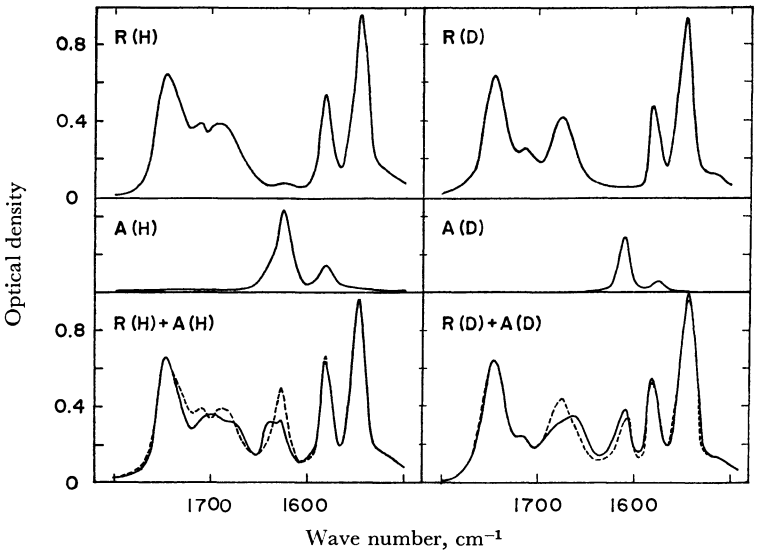

Fig. 4. Infrared spectra of the carbonyl stretching region of riboflavin tetraacetate (R) and ethyladenine (A). The concentration of each solute is 0.05M and the path length is 0.1 mm. H, nondeuterated compound; D, *N*-deuterated compound. Solid line, observed spectra; dotted line, calculated sum of the upper two spectra.

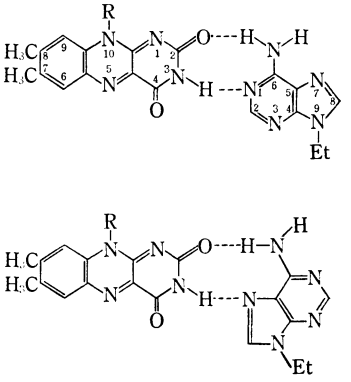
4-C carbonyl group and the 1685 cm^{-1} band from the 2-C carbonyl stretching vibrations coupled with the NH bending mode, since the 2-C carbonyl bond, being conjugated with the C=N bonds, should have lower frequency vibration than the 4-C carbonyl bond. Therefore the bands at 1713 and 1675 cm^{-1} of the *N*-deuterated compound can be assigned to the pure stretching modes of the 4-C and 2-C carbonyl groups respectively.

The spectrum of ethyladenine shows a medium band at 1625 cm^{-1} which was assigned to the coupled vibration of the NH_2 scissors vibration and the ring stretching motions.[5] On the deuteration of the amino group the band moves to 1612 cm^{-1}.

When both the solutions are mixed together, new association bands appear at 1700, 1668 and 1640 cm^{-1} and the bands at 1710, 1685 and 1625 cm^{-1} become weak. The 1745 cm^{-1} band remains unchanged. The 1710 and 1690 cm^{-1} bands of the coupled vibrations of the carbonyl stretching and the NH bending motions of riboflavin tetraacetate shift to 1700 and 1665 cm^{-1} respectively by the formation of hydrogen bonds. The NH_2 scissors vibration at 1625 cm^{-1} of ethyladenine must be moved to 1640 cm^{-1}. On the other hand in the spectrum of the mixture solution of the *N*-deuterated compounds the bands at 1745 and 1713 cm^{-1} of riboflavin tetraacetate are unaffected. Only the 1675 cm^{-1} band of the 2-C carbonyl group decreases in intensity and a new band appears at 1660 cm^{-1}. The 1612 cm^{-1} band of *N*-deuterated ethyladenine shifts to 1615 cm^{-1}.

Since only the 1675 cm^{-1} band of the *N*-deuterated compound shifts to lower frequency by the addition of ethyladenine, the 2-C carbonyl group of riboflavin tetraacetate seems to be used for the formation of the hydrogen bond with ethyladenine. Besides this it is doubtless that the imino group of the riboflavin tetraacetate and the amino group of ethyladenine are employed for the complex formation. Ethyladenine does not interact with *N*-methylriboflavin tetraacetate which is still capable of forming linear hydrogen bond with ethyladenine. This fact indicates the importance of the cyclic dimer formation for the association of riboflavin tetraacetate and ethyladenine. From the present results, however, it can not be concluded which nitrogen atom at the 1 or 7 position of ethyladenine is used for the complex formation.



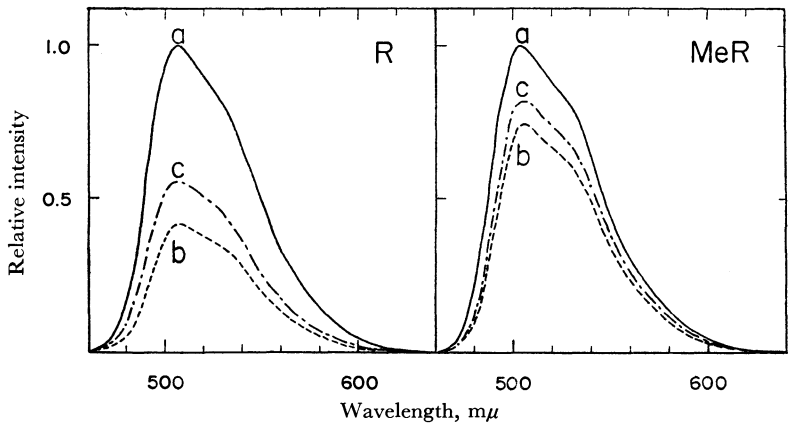


Fig. 5. Fluorescence spectra of riboflavin tetraacetate (R) and *N*-methylriboflavin tetraacetate (MeR) in chloroform solution.

Recently the complex crystals of riboflavin and adenosine monophosphate[18] and of riboflavin and 8-bromoadenosine[19] have been obtained. Although their detailed structure have not yet been reported, such structure as shown above can be expected in those complex crystals.

In dilute solution of organic solvents the existence of the ring stacked complex is less possible as seen by analogy to cases of nucleic acid purine and pyrimidine complexes. The NMR study showed the absence of stacking in the chloroform solution of 9-ethyladenine and 1-cyclohexyluracil,[20] although purine derivatives in the vertical interaction caused by hydrophobic bonds are predominant in the aqueous solution at higher concentration.[21] It is generally believed that there is some kind of interaction between isoalloxazine and adenine moieties of the FAD molecule.[11–15] Not only the stacked model but also the coplanar interaction in the molecule must be taken into consideration.

Fluorescence Spectra. Fluorescence spectra of the 2×10^{-5}M chloroform solution of riboflavin tetraacetate are given in Fig. 5. When the same amount of ethyladenine was added to the solution, there was no change in the fluorescence spectrum of riboflavin tetraacetate. As the concentration of ethyladenine was increased, however, decisive quenching was detected. Sixty per cent quenching was observed for the solution containing 2×10^{-5}M riboflavin tetraacetate and 2×10^{-2}M ethyladenine. The other nucleic acid base derivatives gave smaller quenching effect than ethyladenine did (Table 1). The solubility of the C compound is less than 0.01M and the result obtained by the addition of its 0.01M solution is given in the table.

Table 1. Quenching of the fluorescence of riboflavin tetraacetate and *N*-methylriboflavin tetraacetate by some purine and pyrimidine derivatives in chloroform solution

(The figures in the table are values relative to the intensity of the fluorescence of the pure solution at 25°C. Those in parentheses are intensities relative to that of pure solution at 50°C. The error is estimated less than 2%.)

* 1×10^{-2}M

The quenching appears to be related to the formation of the complex with ethyladenine through hydrogen bonds, because *N*-methylriboflavin tetraacetate shows much smaller quenching effect when it is mixed together with ethyladenine. The number of the complex molecules at a given concentration can be calculated from the association

constant determined by the infrared measurements. In the binary solution of riboflavin tetraacetate (2×10^{-5}M) and ethyladenine (2×10^{-2}M) seventy two per cent of the riboflavin tetraacetate molecules are bound to ethyladenine. Since the association constant for the complex formation of R-U, R-C and R-G are estimated by the infrared measurements to be in the order of magnitude of 10M^{-1}, about ten per cent of riboflavin tetraacetate must be bound to those base derivatives. The amount of quenching is in the same order of the percentage of the riboflavin tetraacetate molecules used for the complex formation. This is another evidence showing that the quenching is mainly caused by the formation of hydrogen bonding.

However, the G compound shows greater quenching effect in both of the mixture solutions of R and MeR than those expected from the infrared measurements. Ethyladenine also shows greater quenching effect than U and C do on the fluorescence of *N*-methylriboflavin which can not form the hydrogen bonded complex. Purine compounds appear to possess a quenching ability without forming a hydrogen bond. It may be caused by a simple collision process between the isoalloxazine and purine rings. To test this idea the temperature dependency of the quenching was measured. The fluorescence of the R-A complex solution at 50°C became stronger than that at room temperature, *i.e.*, the extent of quenching decreased. This may be due to the increase of the number of the free riboflavin molecules at higher temperature. On the other hand the quenching observed for the MeR+A, R+G and MeR+G solutions increased at higher temperature. This phenomenon can be explained by the increase of the thermal collisions of the molecules at higher temperatures.[22]

The intensity of the fluorescence of FAD is about one tenth of that of riboflavin monophosphate.[15] Such big quenching could be caused not only by the vertical interaction of the isoalloxazine and adenine rings[14] but also by the coplanar interaction of the rings in the FAD molecule.

Ultraviolet and Visible Spectra. The spectra of riboflavin tetraacetate and *N*-methylriboflavin tetraacetate in chloroform are given in Fig. 6. Spectra in the same region were recorded for all of the mixture solutions that were examined by the fluorescence measurements. The absorption at 260 mμ of the purine and pyrimidine derivatives solution at 2×10^{-2}M is so strong that the spectra of the mixture solutions could not be recorded below 300 mμ. Neither position nor intensity of the absorption between 300 and 500 mμ of riboflavin tetraacetate changes by the addition of the base derivatives.

The Effects of Barbiturates on the Specific Association. In a previous paper it was reported that ethyladenine forms a stable complex with phenobarbital, the association constant of which is 1200M^{-1}.[8] The equimolar mixture of ethyladenine and phenobarbital gives precipitate, if the concentration of the solution is more than 10^{-3}M. When 10^{-3}M of phenobarbital was added to the chloroform solution containing 10^{-3}M of ethyladenine and riboflavin tetraacetate, phenobarbital-ethyladenine precipitation was still produced. The presence of riboflavin tetraacetate does not affect the formation of the phenobarbital - ethyladenine complex. In such a dilute solution as 10^{-3}M, however, the amount of the riboflavin tetraacetate-ethyladenine complex is negligibly small and most of the ethyladenine molecules exist as monomers when phenobarbital is added to the solution. Therefore 1-ethyl-5-cyclohexenyl-5-methylbarbituric acid whose complex with ethyladenine is quite soluble has been employed. The use of the compound makes it possible for us to see the effect

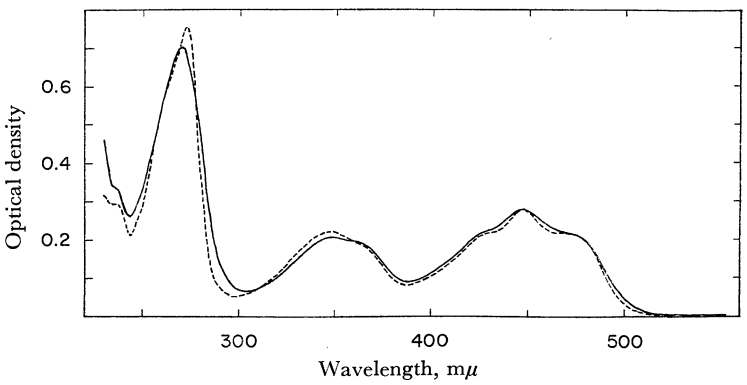

Fig. 6. Ultraviolet and visible spectra of riboflavin tetraacetate (—) and *N*-methylriboflavin tetraacetate (···) in chloroform. The concentration of the solution is 2×10^{-5}M and the path length is 1 cm.

of the addition of barbiturate at a high concentration where the R-A complex is predominant in the solution. The association constant of the CB-A complex has been determined to be $170\,M^{-1}$ which is fairly smaller than that of the PB-A complex.

An infrared spectrum was measured with the solution containing equimolar A, R and CB at 0.04M The observed spectrum is different from the calculated sum of the individual spectrum and the strong association bands are observed. But the positions of the association bands of the R-A and the CB-A complexes are almost the same. It is not possible to distinguish which complex is predominant in the mixture solution from the band position and intensity.

In the fluorescence spectrum of the R-A solution the decrease of quenching by the addition of CB was detected. Twenty per cent increase of the fluorescence of the mixture solution, *i.e.*, eight per cent recovery of the original fluorescence of riboflavin tetraacetate was observed, when $2\times10^{-2}M$ solution of CB was added to the mixture solution containing $2\times10^{-2}M$ of A and $2\times10^{-5}M$ of R. The CB-A complex is more stable than the R-A complex and the added CB releases R from the R-A complex. The binding site of A in the R-A complex appears the same as that in the CB-A complex and the triple complex like CB-(R-A) is not predominant. The enhancement of the fluorescence of the R-A solution, however, is not the special activity of CB. 1-Cyclohexyluracil and 1-cyclohexyl-5-bromouracil, which associate with ethyladenine at the constants 100 and $250\,M^{-1}$,[5,6] respectively, can also increase the fluorescence of the R-A complex. Their ability to disturb the formation of the R-A complex is not parallel with the inhibitory activity in the respiratory chain, since uracil derivatives do not have such activity. Permeability and solubility differences of these compounds in mitochondria must be taken into account.

Increase of the fluorescence of the MeR+A solution by the addition of CB or uracil derivative was also observed. Thermal motion of the ethyladenine molecule may be reduced by the formation of the complex with these compounds.

The authors wish to express their sincere thanks to Professor M. Tsuboi for his valuable discussion and encouragement. Thanks are also due to Drs. K. Nakajima and M. Watanabe for the permission to use fluorescence spectrophotometers. Solvent Effect in a Partial Asymmetric Synthesis. II[1]

Shuji INAMASU

Research Department, Yoshitomi Pharmaceutical Ind. Ltd., Yoshitomi, Fukuoka

and Michio HORIIKE and Yuzo INOUYE

Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received September 27, 1968)

Further evidence for the unambiguous solvent polarity dependence of the stereochemistry in the base-catalyzed Michael type condensation was provided by the systems involving (−)-menthyl chloroacetate and methyl acrylate, and (−)-menthyl chloroacetate and (−)-menthyl acrylate with a modification of the work-up. The electrostatic control of the stereoselectivity was interpreted by the same theorem developed in the previous study and some novel features found for the present systems were discussed.

The first example of an olefin addition in which both the stereochemical outcome and optical yield are solvent polarity-dependent was presented in our earlier work[1a] dealing with the base-catalyzed Michael type condensation of (−)-menthyl chloroacetate with ethyl acrylate to give optically active *trans*-cyclopropane-1,2-dicarboxylic acid plus a trace of the *cis*-acid after removal of the chiral center by

(London)*, **1967**, 1293; c) Y. Inouye, S. Inamasu, M. Horiike and H. M. Walborsky, *Tetrahedron*, **24**, 2907 (1968).

alkaline hydrolysis. The stereochemistry of this asymmetric reaction depended markedly on the solvent: in toluene, the *trans*-diacid obtained was levorotatory whereas in dimethylformamide, this acid had the opposite configuration and the optical yield was higher.

In contrast to this finding, McCoy[2] argued that the actual asymmetric synthesis of the *trans*-diacid was unaffected by a change of solvent but that the change in configuration of the *trans*-acid was due to a possible asymmetric *cis*-to-*trans* isomerization of the diastereomeric (−)-menthyl ethyl *cis*-diesters which were formed in the initial kinetically controlled process. Recent results by the present authors,[1b,c] however, decidedly refuted McCoy's claim and established the solvent effect in the asymmetric synthesis of this type on a more sound basis of kinetic theory. The NaH-catalyzed condensation of (−)-menthyl α-chloropropionate with methyl methacrylate, in which the resulting *cis*- and *trans*-1,2-dimethylcyclopropane-1,2-dicarboxylic acids carry no acidic α-hydrogen and the asymmetric isomerization by alkaline hydrolysis is excluded, was conducted in a binary solvent system of continuously varied dielectric constant. The *cis*/*trans* as well as *trans*-(−)-(R:R)/(+)-(S:S) ratios of the cyclopropane products unequivocally corroborated the dependence of stereoselectivity of the reaction on solvent polarity. That is, the *trans*-isomer predominated in more polar solvents whereas the *cis* in non-polar media and the *trans*-isomer produced in non-polar media exhibited levorotation whereas those in polar media were dextrorotatory. The solvent effect was accommodated fairly well in quantitative terms by the Kirkwood-Onsager theory as shown by the fine linearity of the plots of logarithms of *cis*/*trans* and (−)-(R:R)/(+)-(S:S) ratios against the Kirkwood-Onsager parameter of the reaction media. The stereochemical outcome was nicely explicable in terms of electrostatic stabilization and non-bonded interactions in the postulated transition state conformations which were stabilized by orbital overlap and charge delocalization at the rate-, and therefore, stereochemical-determining cyclization step.

In the present work, further evidence for the unambiguous operation of solvent effect is provided by both the earlier (−)-menthyl chloroacetate-methyl acrylate and the novel (−)-menthyl chloroacetate-(−)-menthyl acrylate systems with the work-up modified so that the final product ratio can represent the kinetically controlled results of the reaction. The conventional alkaline hydrolysis of the resulting diesters was replaced by lithium aluminum hydride reduction capable of converting the diesters into the corresponding stereomeric diols without thermodynamical equilibration and jeopardization of the absolute configurations of the reaction products.

Methods and Results

(−)-Menthyl chloroacetate was condensed with equimolar methyl acrylate or (−)-menthyl acrylate by means of sodium hydride at 25°C in binary solvent system of continuously varied dielectric constant, consisting of dimethylformamide and benzene in 10 : 0 through 0 : 10 by volume and covering the polarity range of ε 37.63 through 2.28. After 2 hr's reaction period, the resulting mixture was worked up as usual[1c] and the mixture of stereomeric cyclopropane-1,2-dicarboxylate esters was reduced with an excess of lithium aluminum hydride. Addition of acetic anhydride to the reaction mixture afforded *cis*-, and *trans*-1,2-bis-(acetoxymethyl)-cyclopropane, which was purified by distillation and separated pure by means of preparative vpc.

Results of the asymmetric reactions conducted in binary solvent system of continuously varied dielectric constant are summarized in Tables 1 and 2.

As can be seen from the data, the *cis*/*trans* ratio of the resulting glycol diacetates in these asymmetric reactions trends to increase as the solvent polarity decreases *i.e.* the *trans*-isomer predominated in more polar media rich in DMF, whereas the *cis* in less-polar media of more benzene composition.

The sign of rotation of the isolated *trans*-diacetates altered on changing the polarity of reaction media: the *trans*-diacetates obtained in less-polar media were found to be levorotatory, whereas those in more polar media were dextrorotatory. These findings, including the *cis*, *trans*-stereoselectivity, are completely consistent with those in the previous system and this fact, in the present systems where the thermodynamical equilibration of the asymmetric reaction product is excluded by the modification of work-up, furnished further cogent evidence for the unequivocal operation of solvent effect in the asymmetric cyclopropane synthesis.

Furthermore, when log (−)-(R:R)/(+)-(S:S) was plotted against the Kirkwood-Onsager parameter of the reaction media, a fine linearity was obtained in both systems (Figs. 1 and 2), as was also the case with log *cis*/*trans* *vs.* $(\varepsilon-1)/(2\varepsilon+1)$. A considerable deviation from the linearity of the regression lines of log *cis*/*trans* plots was observed also in the pure benzene runs of the present systems. This anomalous *cis*-formation in pure benzene may be accounted for by the same heterogeneity effect in this medium, as discussed in the previous paper.[1c]

The linearity of the plots obviously shows the obedience of both *cis*,*trans*-stereoselectivity and asymmetric induction to the Kirkwood equation.

The absolute configuration and maximum rotation of the final product in the present asymmetric reaction, *trans*-1,2-bis(acetoxymethyl)-cyclopropane, were determined by the conversion of (−)-*trans*-cyclopropane-1,2-dicarboxylic acid of the well-

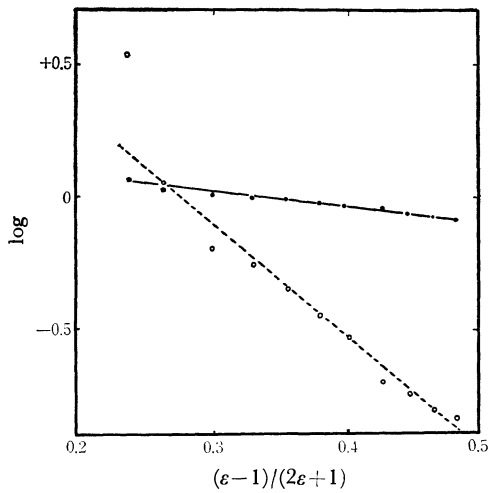

Fig. 1. The plots of log *cis*/*trans* (in dashed line) and log (−)-(R:R)/(+)-(S:S) (in solid line) *vs.* Kirkwood-Onsager parameter of media in methyl acrylate-(−)-menthyl chloroacetate system.

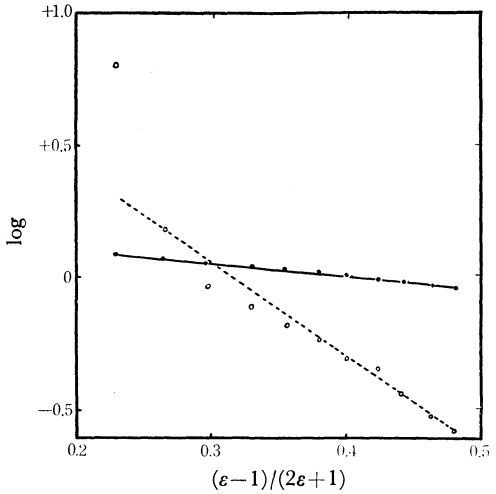

Fig. 2. The plots of log *cis*/*trans* (in dashed line) and log (−)-(R:R)/(+)-(S:S) ratio (in solid line) *vs.* Kirkwood-Onsager parameter of media in (−)-menthyl acrylate-(−)-menthyl chloroacetate system.

defined (R:R)-configuration[3] into (−)-*trans*-1,2-bis(acetoxymethyl)-cyclopropane. Since the starting (−)-(R:R)-acid, $[\alpha]_D^{25}$ −235°, was optically pure, the eventually derived (−)-diacetate, $[\alpha]_D^{25}$ −17.75°, should have the (R:R)-configuration and the rotation found should be maximal.

Discussion

The stereochemical outcome in the present systems is completely consistent with those in the previous system involving the base-catalyzed Michael type condensation of (−)-menthyl α-chloropropionate with methyl methacrylate (for convenience, designated as system A) and accordingly, can be successfully accounted for by the same theorem developed in the previous paper.[1c] Thus, the transition state of the intermediate carbanion is stabilized by orbital overlap and charge delocalization in the postulated sp^2-model conformation[1c] and, the steric factor being comparable in both competing transition state conformers as estimated by model inspection of the non-bonded interactions, then *ceteris paribus*, the electrostatic stabilization which varies depending on the solvent polarity becomes the controlling factor of the steric course of the reaction.

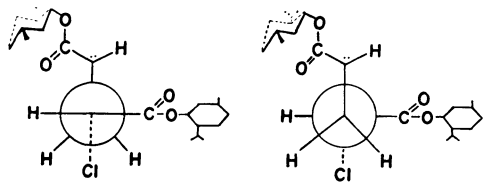
The carbanionic transition state *cis*-conformer with a reduced dipole moment (1.9 D) and a *cis*-compression relieved by the sodium cation chelation is electrostatically more favored in non-polar solvents than the *trans*-counterpart with a greater moment (2.75 D), and the situation is just reversed in polar and strongly solvating media. This naturally leads to the predominant formations of the *cis*-product in non-polar media, and of the *trans*-isomer in polar media. It is surprising to find that the regression line found for the log *cis*/*trans* plots in (−)-menthyl chloroacetate-(−)-menthyl acrylate system (designated as system C) is shifted towards the positive side as compared to that in (−)-menthyl chloroacetate-methyl acrylate (system B). *A priori*, the transition state *cis*-conformer in the system C may well be expected to experience a more serious *cis*-compression between two bulky carbomenthoxy groups than that between carbomenthoxy and carbomethoxy to be felt by the corresponding *cis*-conformer in the system B, and this should naturally disfavor the *cis*-formation in the system C. Despite this, the experiment actually showed that the system C is prone to produce more *cis* relative to *trans* than does the system B. A tentative interpretation of this stereochemical result is as follows. The microscopic dielectric constant (ε') of a cospherical region surrounding a carbanion is considered as being affected by the charge, steric shielding and local polarity of substituent groups of the carbanion, and is duly different from the macroscopic bulk dielectric constant (ε) outside this region. It is within this region that the reaction actually takes place. The polarization of solvent molecules within this region depends on ε' and thus, the degree and type of solvation of carbanion are also dependent on this parameter. The polarity (ε') of cybotactic region of the transition state *trans*-conformer in the system C would be lowered by the more steric shielding and the lower local polarity of the two carbomenthoxy groups than that of the corresponding *trans*-conformer in the system B which would be affected by a less bulky and more polar carbomethoxy and a carbomenthoxy group. The electrostatic stabilization of the *trans*-conformer in the system C by solvation is thus reduced by the lower polarity and steric shielding of its cybotactic region and this contributes more to the relative stability of the *cis*-counterpart with smaller moment in the unsolvated chelate form. The chemical consequence for this situation is the favored *cis*-formation in the double induction system. As a fair approximation, ε' should be a function of the bulk dielectric constant which is conveniently measured with pure solvent, so that the linearity of the log *cis*/*trans* *vs.* $(\varepsilon-1)/(2\varepsilon+1)$ plots in this case is reasonably borne out. For better understanding of this phenomenon, further investigations are needed and this will be the subject of furture publications.

A successful explanation of the solvent effect in the asymmetric synthesis of the *trans*-isomer in the present systems B and C can be made on the same theoretical basis as in the system A and/or the above-mentioned *cis*,*trans*-stereoselectivity. Of conceivable transition state conformations which fulfill the stereoelectronic requirements for orbital overlap and charge delocalization, the *trans*-conformer with a dipole moment of 2.75 D[1c] which, upon cyclization, would lead to the (R:R)-enantiomer, and the other with a slightly greater moment (3.05 D) leading to the (S:S)-product are chosen as sterically the most favored transition state conformer in each diastereomeric series, because of their minimized non-bonded repulsive interactions. Since the electrostatic stabilization of the carbanion by solvation is the controlling factor in the asymmetric induction too, the energy difference between these two transition states in solvents of varying polarity is reflected in the rate-, and consequently, the enantiomer-ratio of the *trans*-products. Reversal in sign and configuration of the *trans*-products was actually observed in the present systems B and C upon changing the solvent polarity. The fine linearity found for the log RR/SS plotted against the Kirkwood-Onsager parameter clearly shows the strict obedience of the asymmetric induction to the Kirkwood equation and provides cogent evidence based on kinetic

3) Y. Inouye, T. Sugita and H. M. Walborsky, *Tetrahedron*, **20**, 1695 (1964).

theory for the solvent effect in the asymmetric induction of this type.

By superimposing the Figs. 1 and 2, one is aware of a slight shift of the log RR/SS plots in the double induction system C towards the positive side as compared to that in the system B. This implies that the levorotatory (R:R)-enantiomer is inclined to form to a more extent relative to the (S:S)-enantiomer in the double induction system than does in the system B. This may be rationalized by the steric advantage of the (R:R)-carbanion over the (S:S)-counterpart.



Model inspection reveals that the steric strain is comparable in the competing (R:R)- and (S:S)-transition state conformers in the system B (as was also the case in the system A), whereas in the double induction system C, the (R:R)-conformer (2.75 D) is sterically more favored than the (S:S)-counterpart (3.05 D). Upon intramolecular nucleophilic displacement, the latter carbanion has to experience more steric hindrance with the more bulky side (extended isopropyl branch) of (−)-menthyl grouping oriented towards the γ-carbon carrying the leaving chlorine atom, whilst in the former (R:R), this can be done with less hindered side of the menthyl. The (R:R)-conformer is thus sterically more favored than in the case of the system B, but this steric advantage *per se* is not great enough to control the steric course of the asymmetric induction and the electrostatic factor still remains dominant, so that the enantiomer ratio varies depending upon the solvent polarity and the sign of rotation of the products alters at ε 9.45. Although the point of the reversal of rotation was found at ε 3.87 for the system B and at ε *ca.* 2.4 for A, it is noteworthy that all the regression lines in the three asymmetric systems have nearly the same slope. In contrast to expectation, the optical yields in the double induction system C were not so high, as compared with those in the system B. This may well be understood by reasoning that the transition state in the double induction sees quite a different stereochemical environment from that in the individual asymmetric induction.

Experimental

The Asymmetric Synthesis of 1,2-Bis-(acetoxymethyl)-cyclopropane. The synthetic procedure is exemplified by a typical run of the (−)-menthyl chloroacetate-methyl acrylate system in a mixture of DMF and benzene (1 : 9 by volume). The reactions were repeated in exactly the same manner except the solvent composition. For the (−)-menthyl chloroacetate-(−)-menthyl acrylate system, the identical procedure was followed with one of the reactants changed.

Methyl acrylate (10.5 g; 0.12 mol) and (−)-menthyl chloroacetate (23.3 g; 0.1 mol) were condensed in the presence of sodium hydride (dispersed in a mineral oil from Metal Hydrides Inc., a commercial grade of 50% purity: 4.8 g; 0.1 mol) in 60 m*l* of the mixed solvent (DMF : benzene=1 : 9 by volume) at 25°C for 2 hr with stirring. The reaction temperature was maintained constant throughout the reaction by cooling with ice-water if necessary. After the duration, a small amount of methanol (*ca.* 3 g) was added dropwise to the reaction mixture with stirring and cooling to decompose any residual hydride, and then sufficient water was added to dissolve sodium chloride. The organic layer was taken up in benzene, washed with saturated sodium chloride solution and dried by means of molecular sieves. Removal of solvent *in vacuo* yielded a mixture of crude, isomeric (−)-menthyl methyl cyclopropane-1,2-dicarboxylates, which weighed *ca.* 26 g. According to the Blomquist procedure,[4] the crude diester was reduced with lithium aluminum hydride (12 g; 0.3 mol) in absolute ether (300 m*l*). Acetic anhydride (100 m*l*) was added to the reaction mixture and ether was replaced with further anhydride to facilitate stirring and refluxing. After 10 hr, acetic acid, residual anhydride and (−)-menthyl acetate were driven in steam and the residue was extracted with ether. After drying, ether was removed to give crude, isomeric 1,2-bis-(acetoxymethyl)-cyclopropanes (*ca.* 9.5 g). This was distilled on a column packed with dixone to remove (−)-menthyl acetate and a fraction boiling at 108—125°C/17 mmHg was collected (*ca.* 8.4 g). Isomeric glycol diacetates were separated by means of preparative scale vpc (Wilkins Autoprep. 700) under the following conditions*1: column 3/8 in ×10 ft, Apiezon grease 30% impregnated Diasolid L, helium gas at the flow rate 200 m*l*/min, column temp. 180°C, detector temp. 220°C, injector temp. 210°C. The retention time found for the *cis*-diacetate was 11 min; for the *trans*, 10 min. *cis*-Diacetate, bp 125—126°C/22 mmHg, n_D^{20} 1.4456, 4.43 g (23.8%). (Found: C, 58.13; H, 7.46%. Calcd for $C_9H_{14}O_4$: C, 58.05; H, 7.58%). *trans*-Diacetate, bp 130—132°C/24 mmHg, n_D^{20} 1.4406, 3.98 g (21.4%). (Found: C, 58.27; H, 7.38%. Calcd for $C_9H_{14}O_4$: C, 58.05; H, 7.58%). $[\alpha]_D^{25}$ −0.73° (*c* 4.0, EtOH). The IR- and NMR-spectra of the *cis*- and *trans*-diacetates were identical in every respect with those of the authentic specimens.[4]

Resolution of *trans*-1,2-Cyclopropanediacarboxylic Acid. The racemic *trans*-acid, mp 174—175°C. (Found:C, 46.25; H, 4.59%. Calcd for $C_5H_6O_4$: C, 46.16; H, 4.65%). (60 g; 0.46 mol) was dissolved in

4) A. T. Blomquist and D. T. Longone, *J. Am. Chem. Soc.*, **81**, 2012 (1959).

*1 McCoy described in Ref. 2 that the *cis*-isomer peak appeared as an incompletely resolved small shoulder on the long retention time side of the *trans*-peak on his qualitative VPC column, but on our column under the conditions specified above, a clear-cut separation was obtained.

boiling water (3500 ml) and cinchonidine (136 g; 0.46 mol) was added and the mixture was allowed to stand still overnight at room temperature, when the cinchonidine salt crystallized out. After fractional triangular crystallization of the salt from 20% ethanol, the salt with a constant rotation was decomposed with dilute sulfuric acid to afford the optically active (−)-acid (6.9 g). Further recrystallization of the free acid from acetonitrile gave the optically pure acid, mp 171—173°C. (Found: C, 46.21; H, 4.53%. Calcd for $C_5H_6O_4$: C, 46.16; H, 4.65%). $[\alpha]_D^{25}$ −235° (*c* 2.0, water).

Conversion of (−)-*trans*-Cyclopropane-1,2-dicarboxylic Acid into (−)-*trans*-1,2-Bis-(acetoxymethyl)-cyclopropane. The (−)-acid (2.6 g) obtained by the resolution described above was converted by the standard method with diazomethane into the corresponding dimethyl ester. According to the Blomquist procedure,[4] the (−)-diester was transformed into (−)-*trans*-1,2-bis-(acetoxymethyl)-cyclopropane, bp 130—132°C/23 mmHg, n_D^{20} 1.4408. (Found: C, 58.06; H, 7.40%. Calcd for $C_9H_{14}O_4$: C, 58.05; H, 7.58%). $[\alpha]_D^{25}$ −17.75° (*c* 2.0, EtOH). The IR- and NMR-spectra were identical in every respect with those of the authentic racemic specimen.[4] The dielectric constants of the binary solvent system consisting of DMF and benzene in continuously varied volume ratios were computed by the mixing rule and the data were given in the previous paper.[1c]

The authors are indebted to Drs. M. Ohno, M. Nakanishi and T. Mukai for their encouragement and interest in this work. Partial support of this study by grant D86547 from the Ministry of Education is gratefully acknowledged (Y. I.).

Synthetic Studies of the Flavone Derivatives. X.*1 The Synthesis of 3,4′,5-Trihydroxy-3′,6,7-trimethoxyflavone and the Structures of Chrysosplenin and Chrysosplenetin

Kenji FUKUI, Takashi MATSUMOTO and Sachihiko TANAKA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received September 28, 1968)

The acid-catalyzed isomerization of 4-benzyloxy-2′-hydroxy-3,4′,5′,6′-tetramethoxychalcone gave 4′-benzyloxy-3′,5,6,7-tetramethoxyflavanone, which was then converted by oxidation to 4′-benzyloxy-3-hydroxy-3′,5,6,7-tetramethoxyflavone. This, after debenzylation to 3,4′-dihydroxy-3′,5,6,7-tetramethoxyflavone, was partially demethylated with aluminum chloride or aniline hydrochloride to give 3,4′,5-trihydroxy-3′,6,7-trimethoxyflavone (I) (mp 213—214°C), the structure proposed previously for the chrysosplenetin (mp 177—178°C) isolated from *Chrysosplenium japonicum* Makino. However, the synthetic flavone was found to be different from natural chrysosplenetin by a mixed melting point determination and by a comparison of the spectra. Finally, the structures of chrysosplenetin and chrysosplenin were established by the spectroscopic studies to be 4′,5-dihydroxy-3,3′,6,7-tetramethoxyflavone (XIII) and its 4′-glucoside (XIV) respectively. The revised structure for chrysosplenetin has been fully confirmed by direct comparison with an authentic sample.

Chrysosplenin, yellow glycoside, has been isolated from the dried whole herb of *Chrysosplenium japonicum* Makino by Nakaoki and Morita.[1] The hydrolysis of this glycoside with dilute sulfuric acid afforded an aglycone, chrysosplenetin. On the basis of analytical and chemical studies, those authors proposed that structures of chrysosplenetin and chrysosplenin ere 3,4′,5-trihydroxy-3′,6,7-trimethoxyflavone (I) and its 3-(or 5-)glucoside respectively.

Although Mani and Venkataraman[2] reported a synthesis of I which involved a partial demethylation of the 5-methoxyl group of 3,4′-dihydroxy-3′,5,6,7-tetramethoxyflavone (II) with anhydrous aluminum chloride in ether, a similar selective demethylation of 3-hydroxy-5,7-dimethoxyflavone

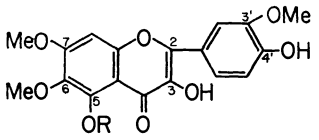
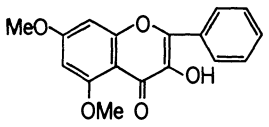
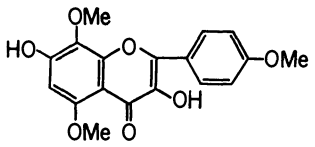
(III) in this laboratory was unsuccessful.[3] Recently, an unsuccessful demethylation of 3,7-dihydroxy-4′,5,8-trimethoxyflavone (IV) under similar reaction conditions has also been reported by Krishnamurti *et al.*[4]



I R = H
II R = Me



III



IV

For this reason, it was thought worthwhile to study further the selective demethylation of the 5-methoxyl group of II.

The present paper will describe a synthesis of I, which was found to be different from the natural pigment, and will present revised structures for chrysosplenin and chrysosplenetin.

According to the method of Hörhammer *et al*,[5] 4′-benzyloxy-3-hydroxy-3′,5,6,7-tetramethoxyflavone (V) was prepared from 2-hydroxy-4,5,6-trimethoxyacetophenone (VI) *via* 4-benzyloxy-2′-hydroxy-3,4′,5′,6′-tetramethoxychalcone (VII); it was obtained in a yield of 83% (lit.[5] 49%). The flavonol (V) was also obtained by a similar oxidation of 4′-benzyloxy-3′,5,6,7-tetramethoxyflavanone (VIII), which had been prepared by the acid-catalyzed isomerization of VII. The catalytic debenzylation of V gave II; mp 236—237°C (lit.[2] mp 235°C).

Now, an attempt at the selective demethylation of the 5-methoxyl group of II with anhydrous aluminum chloride in ether, using the method of Mani and Venkataraman[2] or a modification of it, failed, but, not unexpectedly, it did lead to the recovery of the starting material. Therefore, the other effective methods were used on II; a) leaving it with anhydrous aluminum chloride in nitrobenzene at room temperature, and b) fusion with aniline hydrochloride.

When II in nitrobenzene was treated with anhydrous aluminum chloride at room temperature for 5 hr, a demethylated flavone was isolated as yellow needles, mp 213—214°C, in a yield of 52%. The same flavone was also obtained in a yield of 19% by the fusion of II with aniline hydrochloride at 180°C for 1 hr. The mass spectrum of this demethylated flavone showed a molecular ion peak at *m/e* 360, supporting the molecular formula of $C_{18}H_{16}O_8$ (Mwt 360.31); the NMR spectrum in dimethyl sulfoxide-d_6 showed the presence of three methoxyl groups, at δ 3.74, 3.85, and 3.91 (each 3H singlet), three hydroxyl groups, at δ 9.47, 9.73, and 12.42 (each 1H singlet), and four aromatic protons, at δ 6.88 (C_8–H singlet), 6.95 ($C_{5'}$–H, doublet, J=9 cps), 7.77 ($C_{6'}$–H, double doublet, J=2 cps and 9 cps), and 7.81 ($C_{2'}$–H, doublet, J=2 cps). The demethylated flavone was also characterized as its triacetate (IX), which gave the original flavone (mp 213—214°C) (by acid hydrolysis), its dibenzyl ether (X), and its dimethyl ether, 5-hydroxy-3,3′,4′,6,7-pentamethoxyflavone (XI). The compound XI was further methylated to 3,3′,4′,5,6,7-hexamethoxyflavone (XII), which was identical with a sample prepared by the methylation of II. The structures of XI and XII were confirmed by direct comparisons with authentic sample[6]; this proved that there was no isomeric

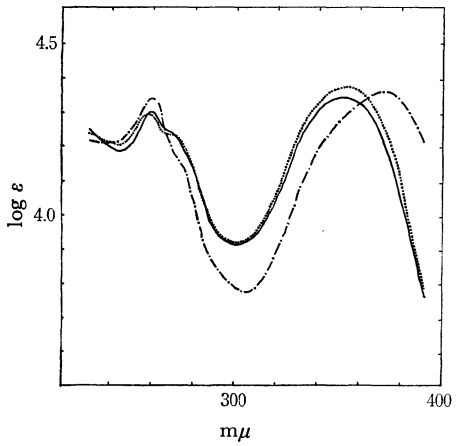

Fig. 2. Ultraviolet spectra of I (·—·—·), XIII (·····) and chrysosplenetin (——) in ethanol.

change during the demethylation of II. As is shown in Table 1, a long-wavelength band in the UV spectrum of X undergoes a bathochromic shift (29 mμ) upon the addition of aluminum chloride;[7] this shows the presence of a free 5-hydroxyl group.

From these facts, the structure of the demethylated flavone was established to be 3,4′,5-trihydroxy-3′,6,7-trimethoxyflavone (I); this identification was also supported by the UV spectra (see Table 1). The synthetic flavone (I) was found not to be identical with natural chrysosplenetin, mp 177—178°C*2 (lit.[1] mp 158—159°C) by a mixed-melting-point determination and by a comparison of their IR, UV, NMR, and mass spectra.

Consequently, the correct structures of chrysosplenetin and chrysosplenin*2 were studied further. We used spectroscopic methods because of the small amount of the natural sample available.

a) Chrysosplenetin. The NMR spectrum of chrysosplenetin in pyridine-d_5 showed the presence of four methoxyl groups, at δ 3.86 (6H singlet) and 4.01 (6H singelt), and four aromatic protons, at δ 6.87 (C_8–H, singelt), 7.37 ($C_{5'}$–H, doublet, J=9 cps), 7.93 ($C_{6'}$–H, double doublet, J=2 cps and 9 cps), and 8.00 ($C_{2'}$–H, doublet, J=2 cps). In the UV spectra (Table 1), a free 5-hydroxyl group is indicated by the bathochromic shift (31 mμ) of the long-wavelength band in the presence of aluminum chloride. The large bathochromic shift (67 mμ or 57 mμ) of the long-wavelength band in ethanol upon the addition of fused sodium acetate[8] or sodium hydroxide[7] suggests the presence of a free 4′-hydroxyl group. Chrysosplenetin is stable in an alkaline solution, for when the alkaline solution is acidified, the spectrum changes to the parent one in ethanol. This suggests the absence of a free 3,4′-dihydroxyl group. The absence of a free *o*-dihydroxyl group is also indicated by effects of the addition of boric acid and sodium acetate.[8,9] It has already been made clear that chrysosplenetin is a quercetagetin derivative.[1] Therefore, the structure of chrysosplenetin must be 4′,5-dihydroxy-3,3′,6,7-tetramethoxyflavone (XIII). In addition, the molecular ion peak in the mass spectrum of chrysosplenetin was observed at *m/e* 374, supporting the XIII structure, $C_{19}H_{18}O_8$ (Mwt 374.33). Finally, chrysosplenetin was compared with authentic XIII specimens which had previously been synthesized by Hörhammer *et al.*[5] and by Fukui *et al.*[6] by the different routes; all the samples were shown to be identical by a mixed-melting-point determination and by a comparison of their IR, UV, NMR, and mass spectra.

b) Chrysosplenin. The NMR spectrum of chrysosplenin in dimethyl sulfoxide-d_6 showed the presence of four methoxyl groups, at δ 3.75, 3.84,

		420 (3.77)				

3.90, and 3.93 (each 3H singlet), of four aromatic protons, at δ 6.96—7.85 (multiplet), and one hydrogen-bonding hydroxyl group, at δ 12.58 (1H broad singelt), which latter suggests the presence of a 5-hydroxyl group. In the UV spectra (Table 1), a free 5-hydroxyl group is also supported by the bathochromic shift (23 mμ or 36 mμ) of the long-wavelength band upon the addition of aluminum chloride or sodium hydroxide. The absence of a free 3- or 4'- or 7-hydroxyl group, a free 3,4'-dihydroxyl group, and a free *o*-dihydroxyl group is also indicated by the spectra summarized in Table 1. The above spectral evidence leads to the identification of chrysosplenin as the 4'-glucoside (XIV) of chrysosplenetin.

4-Benzyloxy-2'-hydroxy-3,4',5',6'-tetramethoxychalcone (VII). A mixture of 2-hydroxy-4,5,6-trimethoxyacetophenone (VI)[10] (5.5 g), 4-benzyloxy-3-methoxybenzaldehyde (13.5 g), aqueous sodium hydroxide (50%, 140 g), and ethanol (400 m*l*) was treated by a method similar to that of Hörhammer *et al.*[5] The crude product was recrystallized from a benzene-methanol mixture to give VII, mp 158—159°C, which gave a brown ferric chloride reaction in ethanol; yield 9.0 g (83%) (lit.[5] mp 158—159°C, yield 49%).

Found: C, 69.58; H, 5.61%. Calcd for $C_{26}H_{26}O_7$: C, 69.32; H, 5.82%.

4'-Benzyloxy-3', 5, 6, 7-tetramethoxyflavanone (VIII). A mixture of VII (16.0 g) and ethanolic sulfuric acid (3%: 1.6 *l*) was refluxed for 9 hr. Most of the solvent was evaporated under a vacuum, and the residue was poured into water (2 *l*). The precipitate was collected, washed with water, and then treated with methanol. From the sparingly-soluble part, the starting material (VII) (6.6 g, 41%) was recovered; the soluble part was recrystallized from methanol to give VIII as colorless needles, mp 126°C, which gave a negative

*7 All melting points are uncorrected. The NMR spectra were taken on a Hitachi Model R-20 NMR spectrometer (60 Mc/sec), using tetramethylsilane as the internal standard; their chemical shifts are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, dd: double doublet, m: multiplet.

10) V. D. N. Sastri and T. R. Seshadri, *Proc. Indian Acad. Sci.*, **23A**, 262 (1946).

ferric chloride reaction; yield 6.4 g (40%).

Found: C, 69.47; H, 5.79%. Calcd for $C_{26}H_{26}O_7$: C, 69.32; H, 5.82%.

4'-Benzyloxy-3-hydroxy-3',5,6,7-tetramethoxyflavone (V). To a boiling solution of VIII (0.6 g) in methanol (50 ml) there were added hydrogen peroxide (30%: 3.0 ml) and then aqueous potassium hydroxide (20%: 10 ml). After the refluxing had been continued for 1.5 min, the mixture was poured onto ice (200 g), and the alkaline solution was acidified with dilute hydrochloric acid. The yellow precipitate was collected, washed with water, and then recrystallized from acetone to give V as yellow needles, mp 201—202°C, which gave a brown ferric chloride reaction in ethanol; yield 0.1 g (16%). This substance was identical with a sample (mp 201—202°C) (lit.[5] mp 202°C) prepared by the method of Hörhammer *et al.*[5] UV: λ_{max}^{EtOH} mμ (log ε); 237*[6] (4.29), 255 (4.37), 360 (4.39).

Found: C, 67.34; H, 5.25%. Calcd for $C_{26}H_{24}O_8$: C, 67.23; H, 5.21%.

Benzyl Ether of V. A mixture of V (460 mg), benzyl chloride (140 mg), anhydrous potassium carbonate (700 mg), and dimethylformamide (4.0 ml) was gently refluxed for 1 hr. After the mixture had been poured into water, the precipitate was collected, washed with water, and then recrystallized from ethanol to give colorless needles, mp 105.5—106.5°C, which gave a negative ferric chloride reaction; yield 490 mg (88%).

Found: C, 71.63; H, 5.50%. Calcd for $C_{33}H_{30}O_8$: C, 71.47; H, 5.45%.

3,4'-Dihydroxy-3',5,6,7-tetramethoxyflavone (II). A solution of V (700 mg) in ethyl acetate (700 ml) was submitted to catalytic hydrogenolysis at room temperature in the presence of Pd-C (5%; 700 mg). After the catalyst had been filtered off, the filtrate was evaporated, and then the residue was recrystallized from ethyl acetate to give II as yellow needles, mp 236—237°C (lit.[2] mp 235°C), which gave a brown ferric chloride reaction in ethanol; yield 510 mg (91%). UV: λ_{max}^{EtOH} mμ (log ε); 237*[6] (4.24), 255 (4.33), 364 (4.37). NMR in DMSO-d_6: 3.78 (s, MeO), 3.86 (s, 2MeO), 3.95 (s, MeO), 6.97 (d, J_{ortho}=9 cps, $C_{5'}$–H), 7.17 (s, C_8–H), 7.73 (dd, J_{ortho}=9 cps, J_{meta}=2 cps, $C_{6'}$–H), 7.79 (d, J_{meta}=2 cps, $C_{2'}$–H), 8.94 (bs) and 9.63 (bs) (C_3–OH and $C_{4'}$–OH). Mass spectrum: *m/e* 374 (M^+).

Found: C, 61.04; H, 4.87%. Calcd for $C_{19}H_{18}O_8$: Mwt, 374.33; C, 60.96; H, 4.85%.

Diacetate of II. Hot acetic anhydride-pyridine method; mp 169—170°C (from ethanol). NMR in $CDCl_3$: 2.35 (s, 2AcO), 3.89 (s, 2MeO), 3.98 (s, 2MeO), 6.75 (s, C_8–H), 7.15 (d, J_{ortho}=9 cps, $C_{5'}$–H), 7.41 (m, $C_{2'}$–H and $C_{6'}$–H).

Found: C, 60.13; H, 4.88%. Calcd for $C_{23}H_{22}O_{10}$: C, 60.26; H, 4.84%.

3,4',5-Trihydroxy-3',6,7-trimethoxyflavone (I). *a) With Aluminum Chloride in Nitrobenzene.* The flavone (II) (400 mg) was added to a mixture of anhydrous aluminum chloride (4.0 g) and dry nitrobenzene (40 ml). After the mixture had stood at room temperature for 5 hr, ice (25 g) and then concentrated hydrochloric acid (25 ml) were stirred into the mixture and cooled in an ice-water bath. The nitrobenzene was removed by steam distillation, and the residual precipitate was collected, washed with water, and then recrystallized from methanol to give I as yellow needles, mp 213—214°C, which gave a dark green ferric chloride reaction in ethanol; yield 200 mg (52%). The mixed melting point with natural chrysosplenetin (mp 177—178°C) was 163—174°C.

Found: C, 60.20; H, 4.41%. Calcd for $C_{18}H_{16}O_8$: C, 60.00; H, 4.48%.

b) With Aniline Hydrochloride. A mixture of II (700 mg) and aniline hydrochloride (1.50 g) was heated at 180°C for 1 hr, and then cooled. After the addition of water (40 ml), the precipitate was collected, washed with water, and recrystallized from methanol to give yellow needles, mp 213—214°C, which was shown to be identical with that of the sample of a) by a mixed-melting-point determination and by a comparison of the IR spectra; yield 130 mg (19%).

c) Hydrolysis of IX. A mixture of IX (200 mg), concentrated hydrochloric acid (20 ml), and ethanol (80 ml) was refluxed for 1.5 hr. After the evaporation of the solvent under a vacuum, the residue was poured into an ice-water mixture (*ca.* 80 ml). The precipitate was collected, washed with water, and then recrystallized from methanol to give yellow needles, mp 213—214°C, which was identical with that of the sample of a); yield 105 mg (71%).

3,4',5-Triacetoxy-3',6,7-trimethoxyflavone (IX). A mixture of I (300 mg), acetic anhydride (4.0 ml), and dry pyridine (6.0 ml) was refluxed for 1.5 hr. The crude product was then recrystallized from acetone to give the triacetate (IX) as colorless needles, mp 228—230°C, which gave a negative ferric chloride reaction; yield 320 mg (79%). UV: λ_{max}^{EtOH} mμ (log ε); 241 (4.29), 308 (4.13). NMR in $CDCl_3$: 2.30 (s, AcO), 2.33 (s, AcO), 2.46 (s, AcO), 3.84 (s, MeO), 3.87 (s, MeO), 3.97 (s, MeO), 6.88 (s, C_8–H), 7.14 (d, J_{ortho}=9 cps, $C_{5'}$–H), 7.40 (overlap, $C_{2'}$–H), 7.42 (dd, J_{ortho}=9 cps, J_{meta}=2 cps, $C_{6'}$–H). Mass spectrum: *m/e* 486 (M^+).

Found: C, 59.20; H, 4.67%. Calcd for $C_{24}H_{22}O_{11}$: Mwt., 486.42; C, 59.26; H, 4.56%.

3,4'-Dibenzyloxy-5-hydroxy-3',6,7-trimethoxyflavone (X). A mixture of I (90 mg), benzyl chloride (145 mg), anhydrous potassium carbonate (1.5 g), and dry acetone (30 ml) was refluxed for 15 hr. The crude product was then recrystallized from methanol to give the dibenzyl ether (X) as yellow needles, mp 141—142°C, which gave a green ferric chloride reaction in ethanol; yield 32 mg (24%).

Found: C, 71.05; H, 5.17%. Calcd for $C_{32}H_{28}O_8$: C, 71.10; H, 5.22%.

5-Hydroxy-3,3',4',6,7-pentamethoxyflavone (XI). To a solution of I (800 mg) in acetone (100 ml), an ethereal diazomethane solution was added; then the mixture was allowed to stand at room temperature for 3.5 hr. After the solvent had been evaporated, the residue was recrystallized from methanol to give XI as yellow needles, mp 161—162°C, which gave a green ferric chloride reaction in ethanol; yield 600 mg (70%). The melting point was undepressed on admixture with an authentic sample[6] (mp 161—162°C). UV: λ_{max}^{EtOH} mμ (log ε); 239 (4.12), 255.5 (4.27), 272.5 (4.23), 345 (4.35). NMR in $CDCl_3$: 3.85 (s, MeO), 3.90 (s, MeO), 3.95 (s, 3MeO), 6.51 (s, C_8–H), 7.00 (d, J_{ortho}=9 cps, $C_{5'}$–H), 7.75 (dd, J_{ortho}=9 cps, J_{meta}=2 cps, $C_{6'}$–H), 7.71 (d, J_{meta}=2 cps, $C_{2'}$–H), 12.60 (s, C_5–OH).

Found: C, 61.70; H, 5.33%. Calcd for $C_{20}H_{20}O_8$: C, 61.85; H, 5.19%.

3,3′,4′,5,6,7-Hexamethoxyflavone (XII). *a) From II.* A mixture of II (300 mg), dimethyl sulfate (200 mg), anhydrous potassium carbonate (2.0 g), and dry acetone (250 m*l*) was refluxed for 15 hr. After the mixture had been filtered, the filtrate was evaporated, washed successively with aqueous sodium hydroxide, and water, and then recrystallized from methanol to give XII as colorless needles; mp 142—143°C, which was identical with that of an authentic sample[6] (mp 142—143°C); yield 210 mg (65%). It gave a negative ferric chloride reaction. NMR in $CDCl_3$: 3.84 (s, MeO), 3.89 (s, MeO), 3.94 (s, 3MeO), 3.99 (s, MeO), 6.75 (s, C_8–H), 6.98 (d, J_{ortho}=9 cps, $C_{5'}$–H), 7.71 (dd, J_{ortho}=9 cps, J_{meta}=2 cps, $C_{6'}$–H), 7.70 (d, J_{meta}=2 cps, $C_{2'}$–H).

Found: C, 62.54; H, 5.37%. Calcd for $C_{21}H_{22}O_8$: C, 62.68; H, 5.51%.

b) From XI. A mixture of XI (370 mg), dimethyl sulfate (150 mg), anhydrous potassium carbonate (2.0 g), and dry acetone (150 m*l*) was refluxed for 60 hr. The reaction mixture was then treated by the method of a) to give XII; mp 142—143°C, which was identical with that of the sample of a); yield 280 mg (73%).

4′,5-Dihydroxy-3,3′,6,7-tetramethoxyflavone(XIII). The flavone (XIII: mp 181—182°C) was prepared by the method of Hörhammer *et al.*[5]; it was proved to be identical with a sample prepared by the method of Fukui *et al.*.[6] NMR in pyridine-d_5: 3.86 (s, 2MeO), 4.01 (s, 2MeO), 6.87 (s, C_8–H), 7.37 (d, J_{ortho}=9 cps, $C_{5'}$–H), 7.93 (dd, J_{ortho}=9 cps, J_{meta}=2 cps, $C_{6'}$–H), 8.00 (overlap, $C_{2'}$–H). NMR in DMSO-d_6: 3.73 (s, MeO), 3.82 (s, MeO), 3.88 (s, MeO), 3.92 (s, MeO), 6.90 (s, C_8–H), 6.99 (d, J_{ortho}=9 cps, $C_{5'}$–H), 7.65 (dd, J_{ortho}=9 cps, J_{meta}=2 cps, $C_{6'}$–H), 7.72 (overlap, $C_{2'}$–H), 9.87 (bs, $C_{4'}$–OH), 12.62 (s, C_5–OH). Mass spectrum: *m/e* 374 (M^+).

Found: C, 60.79; H, 4.76%. Calcd for $C_{19}H_{18}O_8$: Mwt., 374.33; C, 60.96; H, 4.85%.

The mixed melting point of XIII with natural chrysosplenetin (mp 177—178°C) was 178—180.5°C.

Diacetate of XIII. Mp 191—192°C, identical with that of an authentic sample[6] (mp 191—192°C). NMR in $CDCl_3$: 2.31 (s, AcO), 2.47 (s, AcO), 3.77 (s, MeO), 3.83 (s, MeO), 3.87 (s, MeO), 3.95 (s, MeO), 6.85 (s, C_8–H), 7.16 (d, J_{ortho}=9 cps, $C_{5'}$–H), 7.65 (dd, J_{ortho}=9 cps, J_{meta}=2 cps, $C_{6'}$–H), 7.74 (overlap, $C_{2'}$–H). Mass spectrum: *m/e* 458 (M^+).

Found: C, 60.03; H, 4.76%. Calcd for $C_{23}H_{22}O_{10}$: Mwt., 458.41; C, 60.26; H, 4.84%.

Chrysosplenetin. Mp 177—178°C*[2]. Mass spectrum: *m/e* 374 (M^+) ($C_{19}H_{18}O_8$: Mwt=374.33). NMR in pyridine-d_5: 3.86 (s, 2MeO), 4.01 (s, 2MeO), 6.87 (s, C_8–H), 7.37 (d, J_{ortho}=9 cps, $C_{5'}$–H), 7.93 (dd, J_{ortho}=9 cps, J_{meta}=2 cps, $C_{6'}$–H), 8.00 (d, J_{meta}=2 cps, $C_{2'}$–H). UV: λ_{max}^{EtOH} mμ (log ε); 259 (4.28), 271*[6] (4.23), 353 (4.34).

The authors are grateful to Professor N. Morita, Toyama University, for his gifts of natural chrysosplenetin and chrysosplenin. Thanks are also due to the Toyo Soda Co., Ltd., for the mass spectral measurements. This work was supported by a grant-in-aid from the Ministry of Education.

Appendix. Since this paper had been submitted, Shimizu and Morita reported on the structure of chrysosplenin in a communication form (*Chem. Pharm. Bull. Japan*, **16**, 2310 (1968)), and those authors concluded that chrysosplenin was a mixture of 4′,5-dihydroxy-3,3′,6,7-tetramethoxyflavone-4′-monoglucoside (XIV, chrysosplenoside-B) and 3′ or 4′-monoglucoside of 3′,4′,5-trihydroxy-3,6,7-trimethoxyflavone (chrysosplenoside-D) in a 68 : 32 ratio.

Reaction of Vetivazulene with Sulfur. 3,5,9-Trimethylazuleno-[1,2-*b*]thiophene

Shûichi HAYASHI, Shinji KUROKAWA*1 and Tamon MATSUURA

Department of Chemistry, Faculty of Science, Hiroshima University, Senda-machi, Hiroshima

(Received September 30, 1968)

Vetivazulene was heated with sulfur to give a new sulfur-containing azulene, 3,5,9-trimethylazuleno[1,2-*b*]thiophene. On Vilsmeier formylation, the compound normally resulted in the formation of 4-formyl derivative, while the acetylation according to the Vilsmeier procedure proceeded abnormally to produce 4-dimethylamino-3,5,9-trimethylazuleno[1,2-*b*]thiophene.

In previous papers[1,2] it has been reported that the reaction of S-guaiazulene with sulfur formed a sulfur-containing azulene, 3,5,8-trimethylazuleno-[6,5-*b*]thiophene. We will describe here how the reaction of vetivazulene with sulfur formed a new sulfur-containing azulene, whose structure was determined to be 3,5,9-trimethylazuleno[1,2-*b*]-thiophene (II). This is a condensed ring compound consisting of azulene and thiophene nuclei; an α-bond of an azulene nucleus and a *b*-bond of a thiophene nucleus were common between the two nuclei, as in the azuleno[2,1-*b*]thiophene synthesized by Matsui,[3] but the relative configurations of the two nuclei are opposite. We also attempted to compare the reactivity in the electrophilic substitution by means of Vilsmeier acylation.

Results and Discussion

The Structure of the Sulfur-containing Azulene. Vetivazulene was heated with sulfur; dark blue prisms, mp 93.5—94.0°C, with the molecular formula of $C_{15}H_{14}S$ were obtained.

When the compound was subjected to reductive desulfurization with the Raney nickel catalyst (W-2 type) and subsequent dehydrogenation by means of chloranil or 30% palladium-on-charcoal, vetivazulene, the starting material, was regenerated in a good yield. Hence, the compound is certain to retain the vetivazulene skeleton in the molecule.

In the NMR spectrum of this compound (Fig. 1-B) the isopropyl signals (methyl doublet at 1.42 ppm and methine multiplet at 3.31 ppm) which are clearly observed in that of vetivazulene (Fig. 1-A) can not be seen; the disappearnace of the isopropyl group is also observed in the IR spectrum, and the proton signals assignable to aromatic methyl groups increase from two methyl equivalents in vetivazulene to three equivalents in the compound. Such a

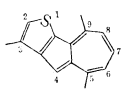
*2 The skeleton numbering of the compound according to the IUPAC nomenclature is:



For convenience in comparing it with vetivazulene, the numbering system in the azulene compounds was adopted in this paper, though not the name of the compound.

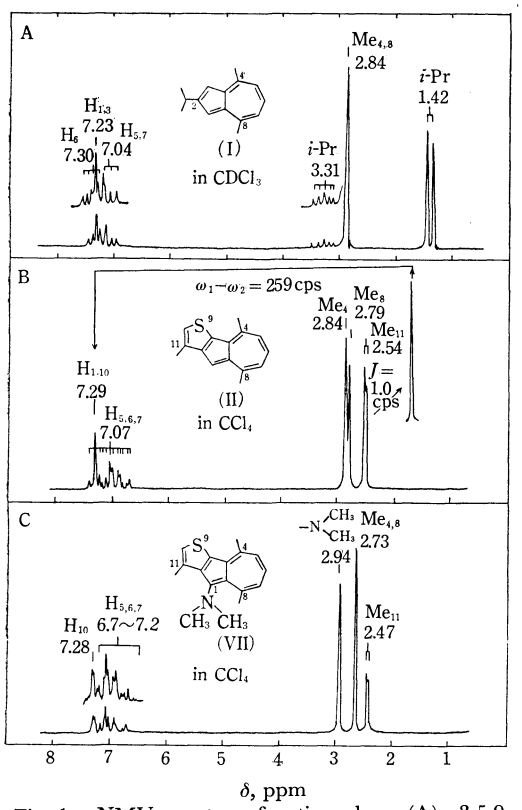


Fig. 1. NMV spectra of vetivazulene (A), 3,5,9-trimethylazuleno[1,2-*b*]thiophene (B) and 4-dimethylamino derivative (C).

change in the substituents between the starting and resulting compounds indicates that one end of the isopropyl group in vetivazulene participated in the reaction with sulfur.

The UV spectrum has an absorption maximum at 325 mμ the value of which corresponds to the bathochromic shift of 34 mμ from that of vetivazulene (291 mμ); this fact suggests that the conjugate system was elongated in the present compound. The absorption pattern of the IR spectrum in the $\nu_{C=C}$ region well resembles that of Matsui's azuleno-[2,1-*b*]thiophene.[3] The evidence of UV and IR spectroscopy thus suggests that the compound is 3,5,9-trimethylazuleno[1,2-*b*]thiophene (II).

The detailed inspection of the NMR spectrum affords reliable support for the proposed structure. An aromatic methyl doublet of 2.54 ppm (3H, J=1.0 cps) can be assigned to Me_{11} by comparison with the spectra of 3,5,8-trimethylazuleno[6,5-*b*]-thiophene,[1,2] and 3-methylbenz[*b*]thiophene,[4] and the doublet was decoupled, as expected, by irradiation upon an aromatic ring proton of 7.29 ppm (2H, singlet*3). The other two methyl singlets at 2.79 and 2.84 ppm are assigned to Me_8 and Me_4 respectively, because the groups overlapping at the same chemical shift in the spectrum of vetivazulene are considered to be resolved by the paramagnetic effect of the sulfur atom. Regarding the aromatic ring protons, one proton present in the singlet of 7.29 ppm (2H) can be assigned to H_{10} on the basis of the results of the above double-resonance experiment.

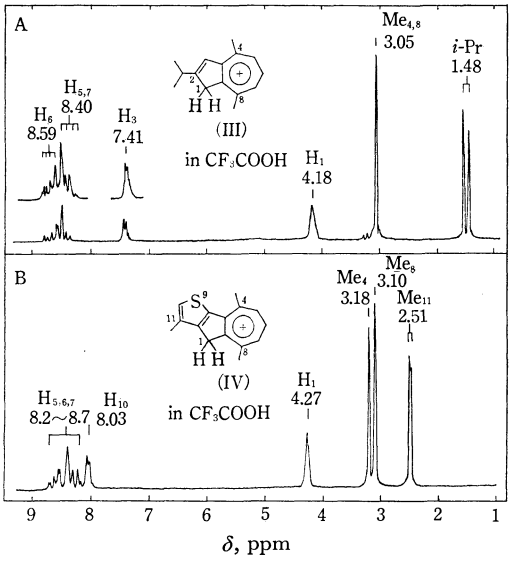

Fig. 2. NMR spectra of conjugate acids of vetivazulene (A) and 3,5,9-trimethylazuleno[1,2-*b*]thiophene (B).

If another proton of this singlet is now assigned to H_1 on the basis of comparison with the spectrum of vetivazulene, the remaining aromatic proton signals (nine lines centered at 7.07 ppm, 3H) can be assigned to H_5, H_6, and H_7 without any difficulty, for the signal pattern in nearly identical with such a spectrum of an ABC coupling system approaching an AB_2-type pattern as seen in 3-chloro-2-toluidine.[5]

The NMR spectrum (Fig. 2-B) taken in trifluoroacetic acid also supports the structure (II). A methylene singlet (2H, 4.27 ppm) which was absent in the spectrum taken in carbon tetrachloride (Fig. 1-B) can be attributed to two protons of a C_1-methylene group of the conjugate acid (IV) expected for the structure (II) on the basis of a comparison with the spectrum (Fig. 2-A) of a vetivazulenium cation. The other signals are also easily assigned as in Fig. 2-B. Regarding the conjugate acid formula (IV), the allylic coupling is expected between Me_{11} and C_{10}-ring protons, and the homoallylic coupling, between Me_8 and $2H_1$.

4) J. A. Elvidge and R. G. Foster, *J. Chem. Soc.*, **1964**, 981.

*3 Since a proton-signal of H_{10} is expected to be split into a quartet as a result of its spin-coupling with Me_{11}, this singlet may be due to the overlapping of H_{10} and H_1 signals.

5) R. E. Richards and J. Schaefer, *Mol. Phys.*, **1**, 331 (1958).

These were confirmed by double-resonance experiments; the Me_{11}-doublet at 2.51 ppm was decoupled by the saturation of H_{10}, and the half-band width (1.5 cps) of the Me_8-singlet at 3.10 ppm was reduced to two-thirds (1.0 cps) by the irradiation of H_1.

The authors have previously pointed out that Plattner's rule regarding the calculation of the visible absorption maxima of the alkylazulenes can also be applied to alkyl-substituted azulenothiophenes by replacing the standard value (17265 cm^{-1}=579 mμ) with the absorption maximum (615 mμ) of benz[*a*]azulene which has the same condensing mode.[2] The absorption maximum (592 mμ) thus calculated of the present compound*4 is in good agreement with the observed value (593 mμ). This also supports the proposed structure (II).

Electrophilic Substitution of 3,5,9-Trimethylazuleno[1,2-*b*]thiophene. Matsui has reported that azuleno[2,1-*b*]thiophene undergoes electrophilic substitution at the same position regarding the azulene nucleus, C_1 or C_3, as in the case of alkyl azulenes.[3] For confirmation of this, Vilsmeier formylation and acetylation[6] were attempted.

Formylation: Formation of 4-Formyl-3,5,9-trimethylazuleno[1,2-*b*]thiophene (V). In the presence of phosphorus oxychloride the condensation of *N*,*N*-dimethylformamide with 3,5,9-trimethylazuleno[1,2-*b*]thiophene was carried out; brown needles, mp 136—141°C, were thus obtained in a nearly theoretical yield.

The compound exhibited a strong absorption band due to an aldehyde group at 1632 cm^{-1} in the IR spectrum and formed an oxime of green needles, mp 193.0—194.5°C. The formyl derivative, upon reduction with sodium borohydride, gave dark blue crystals of a primary alcohol (VI) (ν_{OH} 3408—3584 cm^{-1}), mp 122.5—123.5°C. Although the NMR spectrum of this alcohol exhibited a hydroxyl proton signal at 3.37 ppm and methylene protons attached to the hydroxyl group at 4.97 ppm the remaining portion of the spectrum had a remarkable resemblance to that of original azulenothiophene, except that the integral strength of the signal of 7.29 ppm was reduced by half. This NMR spectrum indicates the introduction of a hydroxymethyl group into a C_1- or C_{10}-position. Of these positions, the C_1-position is adopted because the signal of Me_{11} is a doublet. Accordingly, it is certain that the formylation product has the structure of 4-formyl-3,5,9-trimethylazuleno[1,2-*b*]-thiophene (V), and that Vilsmeier formylation in the azulenothiophene takes place at the same position as in Matsui's azulenothiophene.

Acetylation: Formation of 4-Dimethylamino-3,5,9-trimethylazuleno[1,2-*b*]thiophene (VII). The acetylation of the azulenothiophene was carried out by using *N*,*N*-dimethylacetamide in the presence of phosphorus oxychloride; a green, oily substance was thus obtained. This compound, contrary to expectations, had an empirical formula of $C_{17}H_{19}NS$ containing one nitrogen atom, and its IR spectrum had no absorption band which could be assigned to a carbonyl group. The UV and visible absorption spectra are quite similar to those of the original azulenothiophene, except that their fine structures were reduced. Hence, it may be deduced that the resulting green oil is not a normal acetyl derivative.

These facts and the NMR spectrum (Fig. 1-C) can be reasonably explained when the dimethylamino group is directly introduced into an azulenothiophene nucleus. The methyl signals observed in the aromatic methyl region (2.47 ppm, doublet, 3H; 2.73 ppm, singlet, 6H; 2.94 ppm, singlet, 6H) can be assigned to three methyl groups located originally and two methyl groups of the dimethylamino group[7] newly introduced. The aromatic-ring-proton region of the spectrum shows a remarkable resemblance to that of the preceding formylated product. Accordingly, the obtained compound may be certainly said to have the structure of 4-dimethylamino-3,5,9-trimethylazuleno[1,2-*b*]thiophene(VII). Thus, the Vilsmeier acetylation of the azulenothiophene does not result in the introduction of an acetyl group, but the substituion of a dimethylamino group at the C_1-position in the azulene moiety. This is the first example of a dimethylamino derivative being produced in the Vilsmeier acetylation procedure.

Experimental

The melting points in this paper were uncorrected. The UV and visible absorption spectra were taken in cyclohexane. The gas chromatography was carried out at 170°C, using a column (1 m in length) of Diasolid-L impregnated by DEGS (10%).

Reaction of Vetivazulene (I) and Sulfur. A mixture of 2.50 g of vetivazulene and 1.25 g of powdered sulfur was heated at 200°C, for 4 hr with shaking under a nitrogen atomosphere. The reaction mixture, after being cooled at room temperature to solidify it, was crushed into small fragments. The fragments were then thoroughly ground together with petroleum ether in a mortar; 1.03 g of a dark violet, oily substance were extracted and chromatographed on a silica-gel column with petroleum ether. From a quickly-eluted fraction, 450 mg (18%) of unchanged vetivazulene were re-

*4 The contribution of the substituents held in the thiophene moiety is neglected (*cf.* Ref. 2).

Benz[*a*]azulene	16260 cm^{-1} (615 mμ)
4,8-Me	318×2 cm^{-1}
11-Me	0 cm^{-1}
Sum	16896 cm^{-1} (592 mμ)

covered, and from a slowly-eluted fraction, 310 mg (12.4%) of 3,5,9-trimethylazuleno[1,2-*b*]thiophene (II) were obtained as dark blue prisms, mp 93.5—94.0°C, after being purified by repeated recrystallizations from methanol.

Found: C, 79.54; H, 6.36; S, 14.16%. Calcd for $C_{15}H_{14}S$: C, 79.60; H, 6.23; S, 14.17%. Mass spectrum: $M^+=226$.

Desulfurization of 3,5,9-Trimethylazuleno[1,2-*b*]thiophene (II). A solution of 30 mg of the azulenothiophene (II) in 20 m*l* of absolute methanol was mixed with 0.6 mg of a W-2 Raney nickel catalyst freshly prepared; the mixture was then warmed at 60°C for 30 min under stirring. During this warming procedure the original blue color of the solution faded away. The reaction mixture was then filtered, and the nickel catalyst was repeatedly washed with ether. The filtrate and the washing were then combined; when the solvent was distilled off under reduced pressure, 20 mg of a colorless oily substance were obtained.

Dehydrogenation of the Desulfurized Product. *a) Dehydrogenation with Chloranil.* A solution of 20 mg of the desulfurized substance in 2 m*l* of isoamyl alcohol was mixed with 50 mg of chloranil, and then the mixture was refluxed in an oil bath for 2 hr. After the dark brown reaction mixture had been diluted by adding 30 m*l* of *n*-hexane, the solution was washed with water, dried, and the solvent distilled off under reduced pressure. The dark brown oil (60 mg) thus obtained was then eluted over silica gel with *n*-hexane to separate it into 20 mg of a colorless oil which eluted quickly and 0.7 mg of a violet oil which eluted slowly. The latter oil was confirmed through thin layer and gas chromatography to be identical with authentic vetivazulene.

b) Catalytic Dehydrogenation. The colorless oil (20 mg) eluted quickly in the preceding chromatography was sealed along with 20 mg of 50% palladized charcoal in a glass tube, and the mixture was heated at 300°C for 10 min. The dehydrogenated mixture was treated with 85% phosphoric acid in the usual manner; a violet oil (10 mg) was isolated which was found to be identical with vetivazulene by gas chromatography and by UV and visible absorption spectroscopy.

Vilsmeier Formylation of 3,5,9-Trimethylazuleno[1,2-*b*]thiophene (II). To a mixture of 30 mg of 3,5,9-trimethylazuleno[1,2-*b*]thiophene and 1 m*l* of *N,N*-dimethylformamide, 0.5 m*l* of *N,N*-dimethylformamide containing 0.1 g of phosphorus oxychloride was added, drop by drop, under ice cooling; the mixture was then allowed to stand overnight. The reaction mixture was then poured into 50 m*l* of water, kept slightly alkaline (*ca.* pH 9) by the addition of powdered potassium carbonate, and extracted with benzene. The 40 mg of a 4-formyl derivative (V) in the form of brown needles, mp 136—141°C, thus obtained showed a single brown spot ($R_f=2.5$) in thin-layer chromatography carried out using methylene chloride as the solvent. This spot turned yellow when sprayed with an acidic solution of 2,4-dinitrophenylhydrazine in alcohol.

Oxime. From 10 mg of 4-formyl-3,5,9-trimethylazuleno[1,2-*b*]thiophene, 10 mg of crude oxime was prepared using pyridine as a solvent; it was recrystallized from methanol to give green needles, mp 193.0—194.5°C.

Reduction of 4-Formyl-3,5,9-trimethylazuleno-[1,2-*b*]thiophene (V). Twenty-five milligrams of the 4-formyl derivative (V) were reduced with 50 mg of sodium borohydride in 5 m*l* of methanol by stirring at room temperature for 40 min. When the reaction mixture turned from brown to blue, a large amount of water was added; 30 mg of the 4-hydroxymethyl derivative (VI) were thus obtained as blue crystals. The crystals thus obtained were purified by recrystallization from ethanol to dark blue needles (3.0 mg), mp 122.0—123.5°C, which showed one blue-colored spot ($R_f=3.2$) in thin-layer chromatography using a *n*-hexane-ether (2 : 3) mixture.

$\delta_{TMS}^{CCl_4}$: Me_{11}, 2.65 (3H, doublet, $J=1.0$ cps); Me_4, 2.90 (3H, singlet); Me_8, 3.06 (3H, singlet); -OH, 3.37 (1H, singlet); $-CH_2(OH)$, 4.97 (2H, singlet); $H_{5,6,7}$, 6.88—7.16 (3H); H_{10}, 7.27 (1H, multiplet).

Acetylation of 3,5,9-Trimethylazuleno[1,2-*b*]thiophene (II). To 100 mg of azuleno[1,2-*b*]thiophene and 110 mg of *N,N*-dimethylacetamide dissolved in 1 m*l* of dry tetrahydrofuran, there was slowly added 1 m*l* of a dry tetrahydrofuran solution containing 200 mg of phosphorus oxychloride. The mixture was then refluxed on a water bath for 3 hr and treated in the same manner as in the formylation to afford 170 mg of a green oil, 39.3 mg of which was then chromatographed over an alumina column (Merck II-III) using an ether-*n*-hexane (1 : 9) mixture. The 4-dimethylamino derivative (VII) (19.3 mg) was thus obtained as a greenish-blue oil.

Found: N, 5.17; S, 11.80%. Calcd for $C_{17}H_{19}NS$: N, 5.20; S, 11.90%.

$\lambda_{max}^{cyclohexane}$ mμ (log ε): 240 (3.68), 288.5 (4.30), 310 sh (4.42), 318 (4.49), 330 sh (4.36), 364.5 (3.62), 382 (3.65), 398.2 (3.43). $\lambda_{max}^{cyclohexane}$ mμ (ε): 552 sh (371), 559 (460), 630 (405), 690 (189), 710 (158).

The authors are indebted to Professor Shô Itô of Tohoku University for his kind measurement of the mass spectra and to Dr. Hitoshi Minato of Shionogi Research Laboratory of Shionogi & Co., Ltd. for his measurement of the NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1408—1411 (1969)

Syntheses of Pterocarpans. II.*1 The Synthesis of (±)-Pterocarpin*2

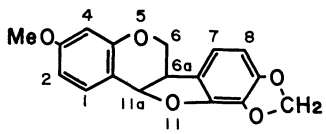
Kenji FUKUI and Mitsuru NAKAYAMA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi Sendamachi, Hiroshima

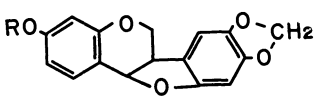
(Received September 30, 1968)

The reduction of medicagol methyl ether with lithium aluminum hydride in tetrahydrofuran yielded a diol. The dehydration of the diol in boiling diethylene glycol gave an ether (anhydropisatin, *O*-methyl anhydrosophorol). Then, the above ether was hydrogenated with 10% Pd-C to (±)-pterocarpin.

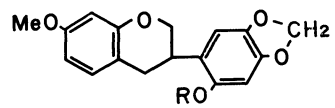
(−)-Pterocarpin was first isolated from the heartwood of the red sandalwood tree (*Pterocarpus santalinus*).[1] It was initially proposed by Robertson *et al.*[2] that in chemical structure it was a 3-methoxy-9,10-methylenedioxypterocarpan (I).*3 Lately, on the basis of NMR spectral analysis[3] and by a comparison[4] of synthetic (±)-dihydropterocarpin methyl ether ((±)-7,2′-dimethoxy-4′,5′-methylenedioxyisoflavan) (II) with the (−)-compound II derived from (−)-pterocarpin, the structure was revised and it was regarded as a 3-methoxy-8,9-methylenedioxypterocarpan (III).



I



III R=Me IX R=H



II R=Me X R=H XI R=CH_3CO

In a previous preliminary communication,[5] the present authors have already reported the total synthesis of (±)-pterocarpin*4 and confirmed the revised structure, III. The present paper will be concerned with providing a full account of the experiments. Another synthesis of (±)-pterocarpin *via* a different route has been reported.[7]

The reduction of the methyl ether (IV)[8] of medicagol (V),[9] which had been obtained by the procedure of Wanzlick's benzofurano(3′,2′ : 3,4)-coumarin synthesis,[10] with lithium aluminum hydride in tetrahydrofuran yielded 2-(2-hydroxy-4-methoxyphenyl)-3-hydroxymethyl-5,6-methylenedioxybenzo[*b*]furan (VI), with absorptions at 3350 and 3100 cm^{-1} in the infrared spectrum, in a 60% yield. This was readily transformed to a diacetate. The removal of water from the diol VI in boiling diethylene glycol gave a product (VII), $C_{17}H_{12}O_5$, which melted at 179—180°C, in a 83% yield. The

absence of a hydroxyl band in its infrared spectrum, and the close similarity of its ultraviolet spectrum (Fig. 1) of those of anhydrosophorol[11] and anhydropisatin[12] previously reported, indicated that this compound was an ether derivative. Moreover, the NMR spectrum*5 (Table 1) of VII suggested the presence of aromatic protons (5H, complex peaks from 6.5 to 7.4), methylenedioxyl protons (2H, 5.97), and methoxyl protons (3H, 3.78). The singlet peak at 5.51 (2H) is due to the ring protons. Accordingly, the structure VII is formulated: 3-methoxy-8,9-methylenedioxy-6*a*,11*a*-dehydropterocarpan (anhydropisatin,[12] *O*-methyl anhydrosophorol[13]). The identity of this product with *O*-methyl anhydrosophorol,*6 which had been obtained from sophorol (VIII)[11] by the action of acid, followed by methylation, was confirmed by a mixed-melting-point determination and by spectral comparisons. Then, VII was hydrogenated over 10% palladium-charcoal in acetic acid; this produced a product in a 60% yield. The synthetic product was found to be identical with (±)-maackiain methyl ether ((±)-pterocarpin) (III)*7 which had

been derived from natural (±)-maackiain (IX)[6] by a mixed-melting-point determination and by infrared, ultraviolet, and NMR spectral comparisons. The infrared and ultraviolet spectra of synthetic and natural (±)-pterocarpin are superimposable, as is shown in Figs. 2 and 3. The data of the NMR spectra was in good accordance with those of (−)-pterocarpin reported by Bredenberg and Shoolery (Table 1).

The catalytic hydrogenolysis of III with either 15% palladium-charcoal or 10% palladium-charcoal at an elevated temperature in acetic acid gave (±)-2′-hydroxy-7-methoxy-4′,5′-methylenedioxyisoflavan ((±)-dihydropterocarpin (X). An acetate (XI) of X was easily prepared. Also, the methyl ether of X is identical with (±)-II reported earlier by Suginome.[4] The NMR spectra of II and XI were assigned as is shown in Table 1.

The partial synthesis of the racemate of (−)-pisatin (XII)[12] has been carried out from (−)-pterocarpin by Bevan *et al.*[14] Thus, the synthesis of (±)-XII has been now totally accomplished.

2-(2-Hydroxy-4-methoxyphenyl)-3-hydroxymethyl-5,6-methylenedioxybenzo[*b*]furan (VI). A suspension of medicagol methyl ether (1.0 g) (mp 269—270°C)[8] (V) in absolute tetrahydrofuran (150 m*l*) was stirred into a suspension of lithium aluminum hydride (600 mg) in absolute tetrahydrofuran (150 m*l*); the mixture was then refluxed for 3 hr. The excess lithium aluminum hydride was destroyed by the careful addition of ethyl acetate (2 m*l*) and water (50 m*l*). The cooled mixture was acidified with dilute hydrochloric acid and extracted with ether. After the removal of the solvent under diminished pressure, the resulting solid was recrystallized from benzene to give colorless prisms of VI; mp 186—187°C; yield, 600 mg (60%). IR: 3350, 3100 (OH); 1026, 941 cm^{-1} (O–CH$_2$–O). UV: λ_{max} mμ (log ε); 271 (4.11), 322 (4.36).

*8 s, singelt; d, doublet (J_{ortho}=8.5 Hz); d′, doubelt (J_{meta}=2.5 Hz); q, quartet (J_{ortho}=8.5 Hz; J_{meta}=2.5 Hz); m, multiplet.

(Received October 22, 1968)

The present work was carried out in order to elucidate the reaction mechanism in the polymerization of formaldehyde in liquid carbon dioxide. Methylene glycol methylether acetate with a structure similar to that of methylene glycol monocarboxylate, which was assumed to be an initiator, exhibited a catalytic activity. On the other hand, methyl acetate terminated the polymerization. Moreover, the resulting polymer, which was terminated by the addition of methyl-$^2H_3$-acetate, contained deuterium originating from the terminator used. On the basis of these experimental results, a reaction mechanism of the elementary processes is discussed.

In our previous papers[1,2] it has been disclosed that formaldehyde, prepared by the thermal decomposition of α-polyoxymethylene, followed by no additional purification, is polymerized by a carboxylic acid catalyst in a liquid carbon dioxide solution to produce a high-molecular-weight polyoxymethylene, and that the polymerization is a cationic mechanism and belongs to a type of stationary successive polymerization with rapid initiation and no termination. Acetic anhydride added to the reaction system in advance of the polymerization reaction acetylates the endgroups of the polymer chain by means of heating the resulting polymer after the polymerization.[3] On the other hand, acetic anhydride added to a reaction system in which the polymerization was initiated by acetic acid terminates the propagation; the rate of termination was proportional to the square of the concentration of the growing polymer chain.[4]

The present paper will describe a study which was carried out in order to elucidate the role of acetic anhydride in the termination reaction and in order to discuss, in detail, the mechanism of the elementary processes in the polymerization.

Experimental

Procedure and Materials. The formaldehyde monomer was prepared and the experimental procedure of polymerization was carried out in the manner described in a previous paper.[1] The monomer concentration in each polymerization experiment was 60 wt% in liquid carbon dioxide solution, while the loading density was 10 g/30 ml.

In order to remove the contained acetic acid, acetic anhydride was purified by using the reaction with carbodiimide previously described.[3] The acetic acid content in the acetic anhydride thus prepared was less than 0.1 wt%.

Commercially-available methyl acetate and methyl formate were purified by distillation before use. Isoamyl acetate was prepared by the reaction of isoamyl alcohol with acetic acid in the presence of concentrated sulfuric acid, and was purified by distilltion under reduced pressure. Methylene glycol methylether acetate was synthesized by the reaction of potassium acetate with monochloromethyl ether[5] and was purified by distillation (bp 117—118°C). Methyl-$^2H_3$-acetate was prepared by the reaction of pure tetradeuteromethanol with acetic acid in the presence of sulfuric acid, and it was purified by distillation.

Analytical Procedures. The deuterium content in the polymer was determined by quantifying the concentration of deuterium in hydrogen gas which had been prepared from the polymer as follows.[6] The polymer was placed in a combustion tube packed with palladium

black and was decomposed by heating under a stream of oxygen; it was thus converted into water and carbon dioxide. The water produced was frozen out in a trap at −78°C. After evacuating the system to eliminate the carbon dioxide, the evaporated water was reduced to hydrogen gas by placing it in contact with metallic zinc heated at 400°C. The hydrogen, which was collected by the use of Toepler pump, was then analyzed by a mass spectrometer (Hitachi, Model RMU-5B).

The acetyl and hydroxyl groups of the polymer were quantified by means of a study of the infrared spectrum of the polymer film, as has already been described.[3]

Methyl acetate, acetic anhydride, and other substances were quantified by using a Perkin-Elmer Model 154D gas chromatograph equipped with a Golay column and a flame-ionization detector. The operating temperature was 80°C, and the flow rate of nitrogen as the carrier gas was 0.97 ml/min.

Results and Discussion

Endgroups of the Polymer Which Results from the Polymerization Initiated by An Acetic Acid Catalyst. When we studied the infrared spectrum of the polymer produced by the acetic-acid-initiated polymerization in a liquid carbon dioxide solution, an acetyl group was found in the polymer chain. Acetyl group in the polymer resulting from the polymerizations initiated by acetic acid both in the presence and in the absence of acetic anhydride, was quantified. The results are shown in Table 1. Here, the degree of acetylation is defined as the molar ratio of the acetyl group to the total endgroup, as has been described in a previous paper.[3] It was found that the degree of acetylation was independent of the polymer yield and the degree of polymerization in the polymerizations, both in the presence and in the absence of acetic anhydride. This fact indicates that the acetyl group in the polymer originates from acetic acid as the initiator.

Table 1. Acetyl group at chain end of the resulting polymer

—	60	70.7	2200	22

acetic acid/monomer molar ratio, 1×10^{-3}; reaction temp., 30°C

Initiation by Methylene Glycol Methylether Acetate. It has been disclosed that carboxylic acid initiates the polymerization of formaldehyde in a liquid carbon dioxide solution.[1,2] The initiator of the present polymerization was assumed to be methylene glycol monocarboxylate, produced by the following reaction between the monomer and carboxylic acid;

$$HCHO + RCOOH \rightarrow HOCH_2O\overset{O}{\overset{\|}{C}}R \qquad (1)$$

In order to verify this assumption, the catalytic activity of methylene glycol methylether acetate, $CH_3OCH_2O\overset{O}{\overset{\|}{C}}CH_3$, which has a structure similar to that of the supposed initiator, was studied in the polymerization in the absence of acetic anhydride. The effects of isoamyl acetate and methyl formate on the polymerization were also investigated for the sake of comparison. The results are shown in Table 2. Only methylene glycol methylether acetate exhibited a catalytic effect.

Table 2. Effect of esters on the polymerization[a]

Ester	Polymer yield wt%	$\bar{P}_n$	N_p[b] mol/$l\times10^2$
EA[c]	63.7	680	21
EA	42.6[d]	3400	2.8
Isoamyl acetate	7.1	370	5.5
Methyl formate	5.4	400	3.0
none	5.8	410	3.1

a) ester/monomer molar ratio, 1×10^{-3}; reaction temp., 30°C; reaction time, 10 min.
b) number of moles of polymer chain, which is defined as a ratio of the polymer yield (mol)/ the degree of polymerization.
c) methylene glycol methylether acetate
d) ester/monomer molar ratio, 1×10^{-4}

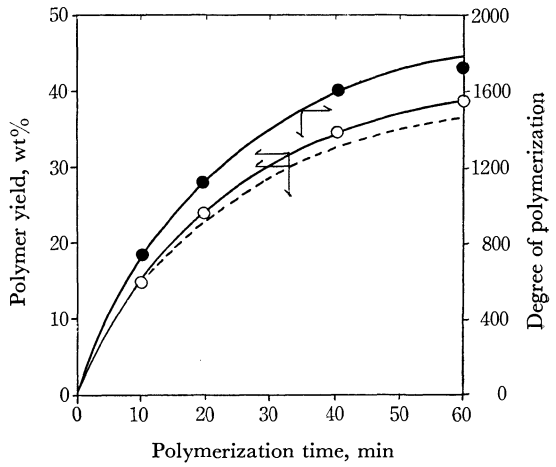

Fig. 1. Effect of methylene glycol methylether acetate on the polymerization in the presence of acetic anhydride; catalyst/monomer molar ratio, 1×10^{-3}; acetic anhydride/monomer molar ratio, 0.05; temp., 30°C; broken line, by acetic acid (quoted from the previous paper[2]).

Figure 1 shows the reaction time *versus* the polymer yield and the degree of polymerization in the polymerization which was initiated with methylene glycol methylether acetate in the presence of acetic anhydride. In the figure this polymerization is compared with the polymerization initiated by acetic acid. The results show that methylene glycol methylether acetate has almost the same catalytic activity as does acetic acid.

Formation of Methyl Acetate and the Influence of Methyl Acetate on the Polymerization. It has been already found that the termination reaction occurs only in the polymerization which is initiated with acetic acid in the presence of acetic anhydride, and that the rate of termination is proportional to the square of the concentration of the active initiating species.[4] On the other hand, the polymerization initiated with dichloroacetic acid is not terminated even in the presence of acetic anhydride.[4] Accordingly, it may be inferred that acetic acid plays an important part in the formation of a terminator. We also assumed that the methanol present in formaldehyde was another reactant in the reaction.

TABLE 3. EFFECT OF ACETIC ANHYDRIDE ON THE REACTION OF CARBOXYLIC ACIDS WITH METHANOL AT ROOM TEMPERATURE

DCAA,	1	1	10	60	0 as MCA

AA, acetic acid; FA, formic acid; DCAA, dichloroacetic acid; MA, methyl acetate; MF, methyl formate; MCA, methyl dichloroacetate

In order to ascertain the above-mentioned assumptions, the influence of acetic anhydride on the esterification reaction of carboxylic acid and methanol was studied; the results are shown in Table 3. In the reaction of acetic acid with methanol, methyl acetate was not formed even after 60 min in the absence of acetic anhydride, whereas most of the acetic acid changed into methyl acetate within 30 min in the presence of acetic anhydride. The results indicate that the formation of methyl acetate is quite slow in a system in which acetic acid is absent. On the other hand, even in a reaction system in which acetic anhydride is present, formic and dichloroacetic acids, which have a stronger acidity than acetic acid, produced only a small quantity of esters. Based on the assumption that methyl acetate acts as a terminator, the above experimental results explain the extraordinary fact that the termination reaction occurred only in the polymerization initiated by acetic acid in the presence of acetic anhydride.

The reaction of methyl acetate with methylene glycol methylether acetate, which has a structure similar to that of the growing polymer chain, was studied in order to ascertain the termination reaction in which methyl acetate attacks the active chain end of the growing polymer. The results, shown in Table 4, indicate that methyl acetate reacted with methylene glycol methylether acetate to produce methylal and acetic anhydride in the following manner;

$$CH_3OCH_2O\overset{O}{\overset{\|}{C}}CH_3 + CH_3COOCH_3 \rightarrow CH_3OCH_2OCH_3 + CH_3\overset{O}{\overset{\|}{C}}O\overset{O}{\overset{\|}{C}}CH_3 \quad (2)$$

Methyl formate also produced methylal, but its yield was smaller than in the case of methyl acetate. These results support the assumption that methyl acetate terminates the propagation by means of reacting with the growing polymer chain to give a stable methoxy endgroup.

As is shown in Table 5, the addition of methyl acetate to the polymerization, which was carried out in the absence of acetic anhydride, caused the same extent of decrease in the rate of polymerization as in the polymerization which was carried out in the presence of acetic anhydride without methyl acetate, but it did not decrease the number

TABLE 4. REACTION OF ESTERS WITH METHYLENE GLYCOL METHYLETHER ACETATE AT ROOM TEMPERATURE

of moles in the resulting polymer chain. These facts lead to the conclusion that methyl acetate affects the polymerization as a terminator.

In order to confirm the terminating effect of methyl acetate, the origin of the endgroup of the polymer chain was studied by analyzing the deuterium content in the polymer which resulted from the polymerization terminated by methyl-$^2H_3$-acetate. When the amount of the deuterated methyl acetate was increased, the deuterium content increased, but both the polymer yield and the degree of polymerization decreased, as is shown in Table 6. Consequently, it was concluded that a part of the polymer chain was ended with the deuterated methyl group. This fact means that the carboxylate anion, which is a counter anion of the growing polymer chain, was replaced with a methoxy group of methyl acetate because of the termination by methyl acetate.

Table 6. Effect of methyl-D_3-acetate on the polymerization[a] and deuterium content in the resulting polymer

a) acetic acid/monomer molar ratio, 1×10^{-3}; temperature, 30°C. time, 30 min.

Mechanism of Polymerization. It has already been disclosed in the previous works of the present series[1-3] that formaldehyde is polymerized by a carboxylic acid initiator in liquid carbon dioxide solution to produce a high-molecular-weight polyoxymethylene and that the catalytic activity of carboxylic acid increases with an enhancement of the acidity of the acid used. The methanol and water present in the monomer have a chain transfer effect, but the rate of chain transfer is smaller than that of initiation or of propagation. In the polymerization which is initiated with acetic acid in the presence of acetic anhydride, acetic anhydride accelerates the formation of methyl acetate from acetic acid and methanol, and the methyl acetate thus formed attacks the active chain end of the growing polymer to terminate the propagation. Therefore, the following cationic mechanism of the polymerization in a liquid carbon dioxide solution may be presented:

Initiation: In view of the fact that methylene glycol methylether acetate showed the same catalytic activity as acetic acid, it was considered that the intiator of polymerization was methylene glycol monocarboxylate, which was formed by the loose addition reaction of formaldehyde and carboxylic acid.

$$CH_2O + RCOOH \rightarrow HOCH_2O\overset{O}{\overset{\|}{C}}R \rightarrow HOCH_2^{\oplus} \cdots {}^{\ominus}O\overset{O}{\overset{\|}{C}}R \qquad (3)$$

The ion pair formed by the dissociation of the addition compound is the initiating species. It has been reported that the rapid initiation takes place in this polymerization.[2,4] Accordingly, the dissociation of methylene glycol monocarboxylate rapidly reaches equilibrium.

Propagation: The propagation proceeds by forming a co-ordinated compound from the monomer and the initiating species as follows:

$$HOCH_2^{\oplus}\cdots{}^{\ominus}O\overset{O}{\overset{\|}{C}}R + CH_2O \longrightarrow \qquad (4)$$

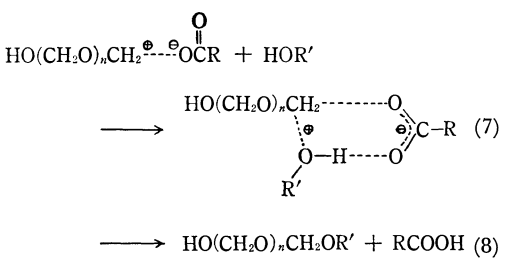
$$\longrightarrow HOCH_2OCH_2^{\oplus}\cdots{}^{\ominus}O\overset{O}{\overset{\|}{C}}R \qquad (5)$$

$$\rightleftharpoons HO(CH_2O)_nCH_2^{\oplus}\cdots{}^{\ominus}O\overset{O}{\overset{\|}{C}}R \qquad (6)$$

The carboxylic acid with a larger dissociation constant gave the faster rate of propagation.[2,4] Therefore, the stability of the counter anion affects the rate of propagation.

Chain Transfer: The chain transfer reaction by methanol or water is illustrated by the following

scheme:



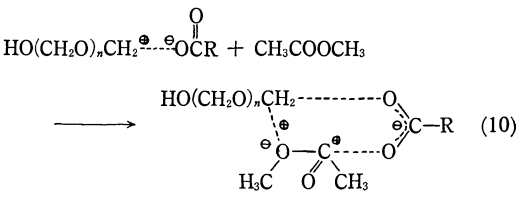
(7)

(8)

Here, R′ is the hydrogen atom or the methyl group. It has been experimentally confirmed that the rate of chain transfer caused by water or methanol is comparatively small. This fact is probably attributable to the depression in the activity of the chain transfer agent because of the solvation of liquid carbon dioxide to water and methanol, which are basic. The retardation effect of carbon dioxide on the chain transfer may be the chief reason for the high-molecular-weight polymer being produced by the cationic polymerization process at room temperature, even though the crude monomer prepared by the thermal decomposition of α-polyoxymethylene, and not additionally purified, is used as the starting material.

Termination: As has been mentioned above, the esterification of methanol and acetic acid to produce methyl acetate is remarkably accelerated in the presence of acetic anhydride. Moreover, the addition of methyl acetate terminates the propagation, with the result that the polymer produced contains methoxy endgroup originating from methyl acetate. These facts lead to the following scheme for the termination, which, extraordinarily, takes place only in the polymerization initiated with acetic acid in the presence of acetic anhydride:

(9)



(10)

(11)

(1) The not-extremely-purified monomer, which is prepared by the thermal decomposition of α-polyoxymethylene without additional purification, can be used as the starting material to produce a high-molecular-weight polymer.

(2) The polymerization initiated by carboxylic acid proceeds by a cationic mechanism.

(3) The polymerization belongs to a successive polymerization with rapid initiation. The chain transfer caused by water or methanol present in the monomer is slower than the other elementary reactions. The rate of propagation and the number of moles of the resulting polymer chain increase with an enhancement of the acidity of the acid used as a catalyst. The termination reaction is, in general, negligible except for the polymerization to be described below.

(4) Methyl acetate, which is formed from acetic acid and methanol because of the catalytic effect of acetic anhydride, terminates the propagation only in the polymerization initiated by acetic acid in the presence of acetic anhydride.

Summary. In concluding the present series, the following summary of the characteristics of the polymerization of formaldehyde in liquid carbon dioxide and the succeeding stabilization process may be given.

The authors wish to thank Dr. K. Fujimura, Director of the Takarazuka Radiation Laboratory, for his encouragement and for permission to publish this paper. They also wish to express their gratitude to Mr. S. Nakao for his skillful measurements in the analytical procedures.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1417—1424 (1969)

Characteristic Chemical Constitution of Pitch Materials Suitable for the MP Carbon Fiber

Sugio Ōtani and Akira Yokoyama*1

Faculty of Technology, Gunma University, Kiryu, Gunma

(Received September 16, 1968)

Pitch materials suitable for the MP carbon fiber were prepared from petroleum asphalt, coal tar pitch, and polyvinylchloride. The present investigation was undertaken to clarify the characteristic chemical constitution of each suitable pitch material and to define the significance of the special treatment required to prepare the pitch materials. The suitable pitch materials are generally composed of several structural units with aromatic fused rings and more or less alkyl side chains. The suitable pitch material finally obtained from the petroleum asphalt is characterized by a relatively high molecular weight and many quite long alkyl side chains. Special treatment is required to increase the aromaticity and the removal of the low-molecular-weight component. The suitable pitch material from the coal tar pitch is characterized by aromatic fused rings of the condensed type and only a few alkyl side chains, such as, the methyl group. The most desirable effect of the treatment is to accelerate the condensation between molecules without increasing the insoluble matter and to remove the low-molecular-weight component. The results concerning the polyvinylchloride pitch lend some support to the scheme suggested before.

In previous papers,[1-3] it has been reported that carbon fibers were prepared from polyvinylchloride (PVC), petroleum asphalt, coal tar pitch, and other pitch-like materials. We refer to the fiber so produced as the MP carbon fiber.

Pitch materials suitable for MP carbon fibers must have at least two characteristics - excellent spinnability and the ability to be easily converted into an infusible form by oxidation in the low-temperature range. The above raw materials than PVC pitch leave much to be desired. Some special treatment, therefore, is required to achieve the desirable characteristics. Up to now, only an experimental approach seems useful in discovering suitable pitch materials, because the relation between the desirable characteristics and the structures of the pitch materials is still obscure. From this point of view, it appeared of interest to investigate further the fundamental features of the pitch materials in order to improve the preparation method and the properties of the MP carbon fiber.

The present investigation was undertaken in order to clarify the following two questions the characteristic chemical constitution of the suitable materials prepared from a petroleum asphalt and coal tar pitch, and the significance of the special treatment required.

For these purposes, the pitch materials at each stage of the treatment were fractionated by extraction in turn with several solvents, and then use was made of the NMR, IR and UV spectra as well as of elemental analysis and the measurement of the mean molecular weight by the vapor-pressure osmometer method.

Experimental and Results

Raw Materials and Special Treatment. The starting raw materials and the special treatments used in this experiment are shown in Fig. 1. The PVC powder was supplied by the Kureha Chemical Ind. Co., while the PVC pitch was the pyrolyzed residue itself and was used without any further treatment. The petroleum asphalt was treated according to a procedure described previously.[2,3] In the case of the coal tar pitch, the treatment procedure was modified as is shown in Fig. 1, since the present method, in comparison with the previous method,[3] gave a better spinnability of the pitch and better mechanical properties of the carbon fiber finally obtained. The modification is characterized by the removal of the insoluble matter from the raw coal tar pitch and by heat

treatment with five percent of tetramethylthiuram disulfide (TMTD) in a low-temperature range.

The chemical composition and the mean molecular weights of the pitch materials at each stage of the above special treatments are presented in Table 1.

In Table 1, DDR is an abbreviation of the dry distilled residue, while VDR is that of the vacuum-distilled residue finally obtained. EXT is the soluble matter obtained by chloroform extraction, and TMD indicates the pitch materials heated together with TMTD. The value of the H/C atomic ratio for PVC pitch lies between those of the asphalt group and of the coal tar group. In the course of the treatment, especially during the final treatment under a vacuum. the H/C atomic ratio decreases and the mean molecular weight increases. In spite of the addition of the sulfur compound (TMTD) during the treatment, the sulfur content in the coal tai pitch material finally obtained is less than one percent. Therefore, the presence of sulfur and the other heteroatoms in the coal tar pitch material was disregarded and will not be discussed any further.

Solvent Analysis. A flow chart of the fractionation is shown in Fig. 2. The extraction was carried out at room temperature in order to prevent any possible change in quality. The bar graphs in Fig. 3 depict the results.

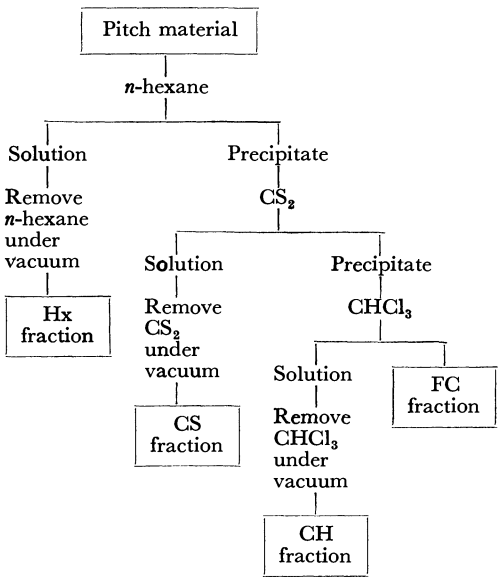

Fig. 2. Flow chart of extraction method.

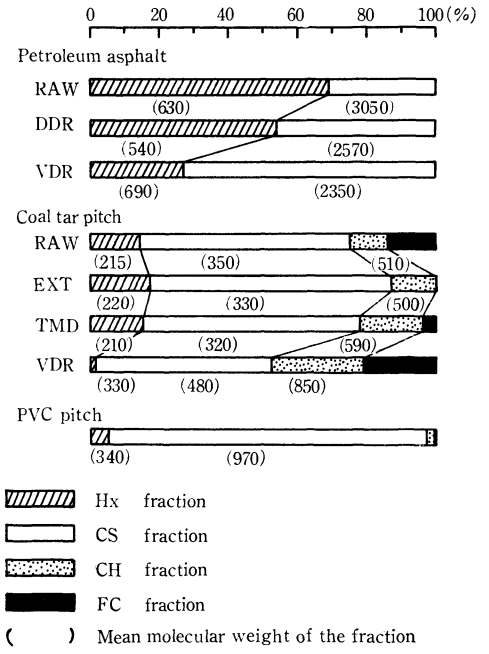

Fig. 3. Result of the solvent analysis.

The PVC pitch is characterized by a large CS fraction, and the CS fraction of the petroleum asphalt was increased to 73% by the treatment. In the case of the coal tar pitch, the mean molecular weight of each fraction increased, especially during the final treatment, and the low-molecular-weight component, the Hx fraction, vanished finally.

Chemical Composition of Each Fraction. The diagrams of the H/C atomic ratio *vs.* the stages of the treatment are shown in Figs. 4 and 5.

Figure 4 indicates that the final treatment under a vacuum for the coal tar pitch prompts a slight decrease in the atomic ratio of CH and FC. In the cases of both the fractions of the petroleum asphalt (Fig. 5), the decrease in the ratio is limited to the first step. However, the value of the entire

—— Hx
---- CS

sample continues to decrease during the final stage as a result of the increase in the CS content.

Spectroscopic Observations. *Infrared Spectra* Figure 6 indicates the infrared spectra of the samples before fractionation at each step of the treatments. These spectra consist of the absorption bands due to a saturated alkyl and an aromatic structure; no other band showing the presence of a hetero-atom or of unsaturated double bond is observed. Moreover, it seems that the asphalt is rich in an alkyl hydrogen, while, on the other hand, the coal tar pitch is rich in an aromatic hydrogen.

PVC pitch lies midway between the asphalt and the coal tar pitch in this case, too. Each VDR

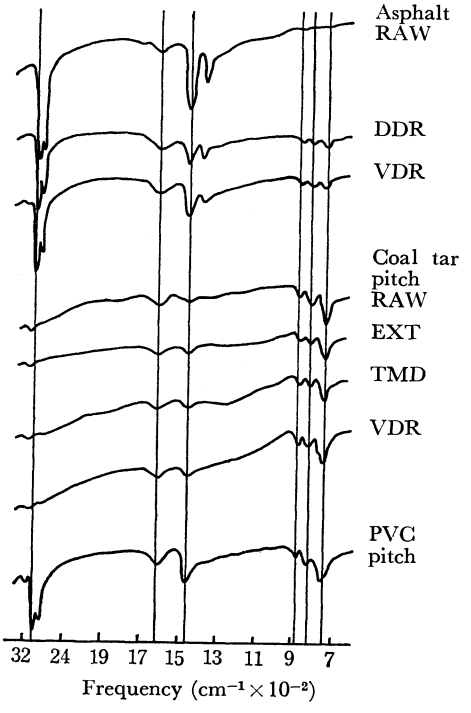

Fig. 6. Infrared spectra of the pitch materials before fractionation.

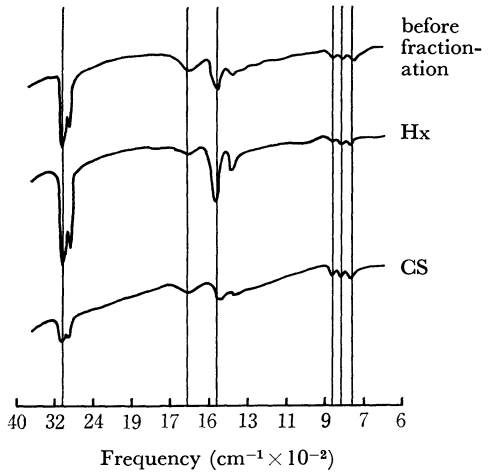

Fig. 7. Infrared spectra of petroleum asphalt (VDR).

fraction of the coal tar pitch was almost identical in infrared spectra with the sample before fractionation. In the case of the petroleum asphalt (Fig. 7), Hx exhibited a larger absorption band due to an alkyl structure than that of CS.

The Hx fraction of PVC pitch, although their content is only less than 6%, had the same tendency.

Ultraviolet Spectra. In order to get some useful information about the structure of the aromatic part, we have observed the ultraviolet and visible spectra. The spectrum of PVC pitch has been reported in our previous work,[1,4,5] in one paper,[1] we attempted to isolate the unit aromatic component by decomposition with nitric acid. On the basis of the data thus obtained and the other general information available, we concluded[1] that the spectrum of PVC pitch gives evidence of the presence of condensed aromatic nuclei composed of three or four rings, such as anthracene, chrysene, and phenanthrene. When the spectra of the two other pitch materials shown in Fig. 8 are compared with that of PVC pitch, the spectrum of coal tar pitch, VDR, is seen to be characterized by the presence of some obvious absorption bands in the range over 300 mμ.

It may be assumed that these bands are due to a sort of pyrene (250 and 340 mμ), benzpyrene (370, 380, and 390 mμ), coronene (300, 340, and 400 mμ), perylene (400 and 430 mμ), and other similar aromatic compounds. On the other hand, the spectrum of the petroleum asphalt has only one broad absorption band, that centering around 270 mμ. The two fractions (CS and Hx) of the petroleum asphalt treated at each stage were identical in ultraviolet spectra, although some general difference

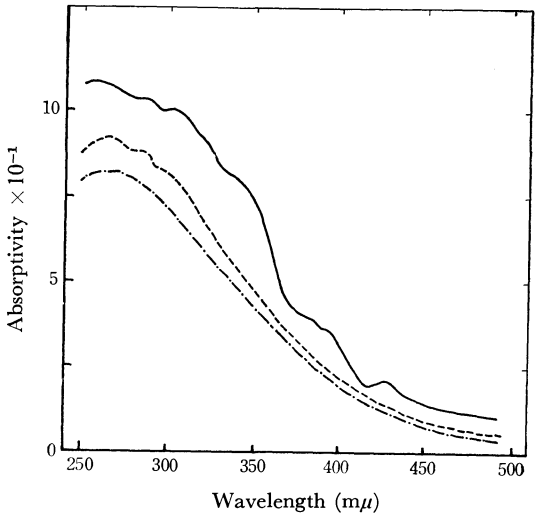

Fig. 8. UV and Vis. spectra of the pitch materials finally obtained.
----- Asphalt (VDR)
—— Coal tar piteh (VDR)
------ PVC pitch

in intensity was found throughout the wavelengths of the spectrum. When cyclohexane was used as a solvent, it was found that Hx exhibits another broad band in the range of 210—240 mμ in addition to the band at 270 mμ. The two fractions (CS and Hx) of the coal tar pitch treated at each stage were also identical in ultraviolet spectra except in intensity to that of the each entire sample before fractionation. However, the profile of the spectra changed considerably during the final treatment under a vacuum, as is shown in Fig. 9.

When the spectrum of the Hx of PVC pitch is compared with that of CS, the displacement of the wavelength of the maximum absorption is not

observed. However, the absorption in the range over 300 mμ apparently decreases in intensity.

Proton Magnetic Resonance Spectra. Some typical spectra are shown in Fig. 10.

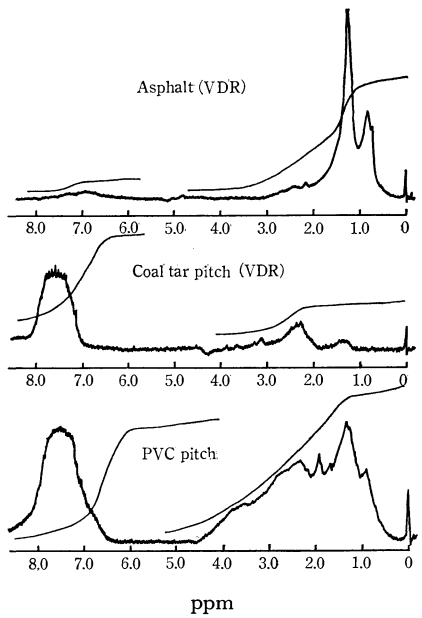

Fig. 10. Typical spectra of proton magnetic resonance.

The left-side peaks are due to an aromatic hydrogen, while the right-side peaks indicate the presence of some kinds of aliphatic hydrogen. The contents of aromatic and aliphatic hydrogen, as calculated from the peak area, are listed in Table 2.

The values in Table 2 clearly show the characteristics of each material. The treatment of the asphalt causes a slight increase in the aromatic hydrogen content. In the case of the coal tar pitch, the content remains almost constant throughout the whole process. No difference in the content is observed between the fractions of the coal tar pitch; however, in the cases of the other two materials, some difference is observed, as is shown in Table 3.

	CS	40	60

A further classification of the alkyl hydrogen atoms has been attempted on the basis of the chemical shifts, and the content of each class has been calculated from the peak area. The results obtained are listed in Table 4. Some errors are, of course, unavoidable in this classification, but they are not serious, we think. In the case of the asphalt, Hx exhibits a larger content of II-type hydrogen and a smaller content of V-type hydrogen than does CS. This fact probably indicates that Hx has a longer side chain. The coal tar pitch is only 20% aliphatic hydrogen, and all the fractions are almost identical in their spectra.

Effect of the Improvement on the Procedure Used for Coal Tar Pitch. We pointed out previously[3] that the pitch material prepared from a coal tar pitch material leaves something to be desired. The procedure of the treatment has since been improved to some extent by the addition of the two steps of the extraction and TMTD treatment shown in Table 1. Table 5 shows the effect of these changes. By the removal of the insoluble residue from the raw material, the FC of the final is reduced to about half and the spinnability is doubled. The addition of TMTD results in a remarkable increase in the mean molecular weight.

Discussion

Characteristic Chemical Constitution of the Pitch Materials. Even when the pitch materials are treated by the method above described, the pitch materials are, of course, very complex mixtures composed of many kinds of molecules. The pitch materials are, indeed, too complex for their chemical structure to be determined in detail, and so the data obtained in our experiment are limited. However, the results obtained seem to lead to some significant conclusions concerning the characteristic chemical constitution of each suitable pitch material finally obtained. Moreover we feel that the presentation of the scheme of each pitch material, including most of the configurations mentioned above, will be helpful in clarifying the characteristic nature of the suitable pitch materials.

The major portion (94%) of the PVC pitch is CS, so it may be considered that this fraction represents the entire PVC pitch. On the basis of the proton magnetic resonance spectra, the atomic ratio of the aromatic hydrogen to the aliphatic hydrogen of CS is about 40/60. This value and the results presented in Table 4 are in good agreement with that calculated from the scheme (structural model) suggested previously.[1] The other results obtained in the present experiment are essentially identical with those previously reported. However, in the infrared spectra of the range from 700 cm^{-1} to 900 cm^{-1}, the absorption band at 740 cm^{-1} which is due to the four adjacent ring hydrogen atoms is the greatest in intensity. In order to ex-

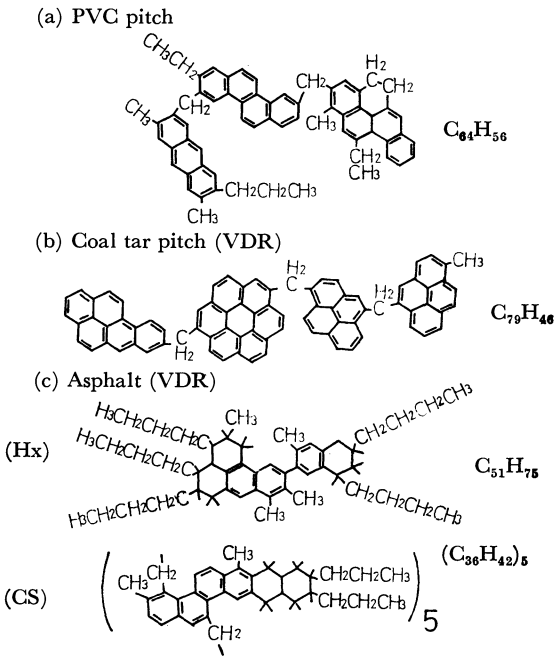

Fig. 11. Schemes including most of the characteristic configuration obtained.

plain this, it seems most reasonable to correct the model as shown in Fig. 11-a.

The pitch material finally obtained from the coal tar pitch is characterized by a small H/C atomic ratio, and its UV spectra indicates the existence of some condensed type of aromatic nuclei, such as pyrene, perylene, and coronene. The results of the proton magnetic resonance spectra (Table 4) suggest that only one methyl group is substituted in each molecule. From the results concerning the chemical composition of the entire VDR and its mean molecular weight, the experimental formula seems to correspond to $C_{79}H_{46}$. The proposed structural model is presented in Fig. 11-b. No remarkable difference has been found between fractions throughout the treatment with the exception of the mean molecular weight. Therefore, it seems reasonable to conclude that each fraction is distinguished by the number of the aromatic nuclei in a molecule. The most characteristic feature of the pitch materials prepared from the petroleum asphalt is the small value of the ratio of the aromatic hydrogen to the aliphatic hydrogen. From the UV spectra, it seems reasonable to assume that the aromatic nuclei of these materials are composed of similar aromatic fused rings to that of PVC pitch and/or some smaller aromatic fused rings such as naphthalene. When Hx is compared with CS in Table 4, it may be found that the content of II-type hydrogen of Hx is larger and the content of V-type hydrogen is smaller. These facts probably indicate that Hx has longer side chains than CS. The results of the IR spectra lend some support to this assumption. The existence of sulfur atoms in the petroleum asphalt causes some knotty problems in making up the structural model of the material. Previous investigations of sulfur in a heavy component of petroleum have given no information on its definite position in a molecule. It is said, in general, that sulfur atoms often form a C–SH (thiol) group in a side chain and/or a heterocyclic structure such as thiophene. Although the sulfur content of VDR is 3.9% corresponding to three or four atoms in a molecule, in the present spectroscopic examination, no clear characteristic information as to the presence of a sulfur atom is obtained. If the experimental formulae of CS and Hx are determined on the basis of the H/C atomic ratio and the mean molecular weight, that is, ignoring the possible presence of sulfur and other hetero-atoms, they correspond to $C_{51}H_{75}$ and $C_{180}H_{210}$ respectively. The structural models shown in Fig. 11-c are designed to satisfy the experimental formulae and the results of our spectroscopic observation. If the possible presence of sulfur atoms in taken into consideration, it seems most reasonable to correct by introducing three of four sulfur atoms into a molecule of CS in the form of thiophene and/or thiol; the atoms may then be converted to a C–S–C bond by heat treatment. In the case of Hx, one sulfur atom is introduced in the same form.

In Table 6, the values calculated from the structural models shown in Fig. 11 are listed together with those observed. As has been described above, the pitch materials are very complex mixtures and it is, of course, impossible to represent the molecules in all the pitch materials by the use of one molecular formula. However, on the basis of the results shown in Table 6 and described above, it may be concluded that these structural models express consistently the characteristic features of the pitch materials.

The Significance of the Special Treatment. *Petroleum Asphalt:* The most noticeable changes observed with the treatment are the increase in the CS content, the decrease in the H/C atomic ratio, and the variation in the mean molecular weight. The increase in CS content, of course, is mainly due to the removal of the Hx. However, the results for the fractions make it apparent that Hx and

CS change in quality. The nature of CS changes to a much larger extent through the first distillation process at 380°C than through the vacuum-distillation process at 300°C. In the first step, for example, it has been found that the mean molecular weight, 3050 in the original, decreases to 2570; the H/C ratio, 1.57 in the original, decreases to 1.46, and the three absorption bands in the range from 700 to 900 cm^{-1} of the IR spectrum become apparent with the decrease in intensity of the bands due to an alkyl group. In view of these facts, it seems that the treatment causes, to some extent, the abscission and the aromatization of the alkyl side chains of the molecules in CS. No remarkable change in any fraction has been observed in the final step; the most important role of the step seems to be the removal of the lower-molecular-weight components which are present in the original and which are formed by the treatment.

Coal Tar Pitch: Even in the original pitch material itself, the aromaticity is satisfactory for our purposes. However, it is a great defect that the major portion of the material has a very low molecular weight and a low softening point below 80°C. It is possible to elevate the softening point and to increase the mean molecular weight by various heat treatments. However, heat treatment at higher temperatures often causes a remakable increase in FC. In general, the use of pitch materials with a large FC content results in less spinnability and in the formation of rough carbon fiber. It is desirable, therefore, to elevate the mean molecular weight without increasing the FC. In view of the results described above, the present procedure seems to fulfil the purpose quite well. Although the mechanism of the reaction with TMTD is not obvious even after the present experiments, it is certain that the addition of TMTD accelerates the condensation between the molecules. The condensation occurs more remarkably in the final treatment under a vacuum at 300°C. (Figs. 3, 4, and 9 and Table 5) The unavoidable formation of FC in this step may indicate that the treatment temperature is still too high.

Conclusion

Suitable pitch materials for MP carbon fiber are generally composed of several structural units with an aromatic fused ring and more or less alkyl side chains, as is shown in Fig. 11.

The suitable pitch finally obtained from the petroleum asphalt is characterized by a relatively high molecular weight and by many relatively long alkyl side chains.

The special treatment required promotes the increase in the aromaticity and the removal of the low-molecular-weight component.

The suitable pitch material from the coal tar pitch is characterized by aromatic fused rings of the condensed type and only a few alkyl side chains, such as, the methyl group.

The most desirable effect of the treatment is to accelerate the condensation between molecules without increasing the insoluble matter and to remove the low-molecular-weight component.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1425—1428 (1969)

Effect of Pressure on Graphitization of Carbon. VI. Normal Pressure Heat Treatment of Soft Carbon Pre-Heat-Treated under High Pressure

Kan-ichi KAMIYA, Michio INAGAKI and Hajime SAITO

Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received September 24, 1968)

Three different samples of polyvinylchloride coke (designated as N-1, N-2, and N-3 which were pre-heat-treated at 1470, 1590, and 1620°C, respectively, under 5 kbar) were heat-treated in a flow of nitrogen under normal pressure. Process of graphitization in these samples was investigated by analyzing (004) diffraction profile. Sample N-1 has a symmetrical profile and consists only of the trubostratic component A_S. Samples N-2 and N-3 have a composite profile and are composed of the turbostratic component A_S and the graphitic component G_S. Only the profiles corresponding to the turbostratic component A_S of these samples shift gradually to higher angle together with sharpening when the heat treatment temperature under normal pressure increases. Changes in c_0-spacing and crystallite size L_C of the component A_S with heat treatment temperature follow the same course of change as in those of the original polyvinylchloride coke. However, heat treatment of the sample under normal pressure did not affect the quality and quantity of the component G_S which had been formed by the pre-heat-treatment under high pressure. These results indicate that the pre-heat-treatment of soft carbon under high pressure has no accelerating effect on the graphitization of the carbon in the subsequent heat treatment under normal pressure.

Polyvinylchloride coke PV-7, a soft carbon, has been found to be graphitized very rapidly at as relatively low a temperature as 1400—1500°C under high pressure above 3 kbar.[1-3] The process of its graphitization is divided into two stages on the basis of the change in the profile of (00*l*) diffraction line.[2,3] In the first stage, the structural component of the carbon is the turbostratic one A_S, of which the c_0-spacing is larger than 6.85 Å. In the second stage, however, two components A_S and G_S, having the turbostratic and graphitic structures, respectively, coexist in the sample and no component having an intermediate structure is observed. In this stage, the graphitization proceeds through the direct transformation from turbostratic carbon to graphite, which can be detected by the composite structure of the profile of (00*l*) diffraction line.[2,3] Such a change in the profile of (00*l*) diffraction line contrasts with that observed by the heat treatment under normal pressure.[4] It was confirmed that the composite profile observed in the sample heat-treated under pressure was not due to the temperature and pressure gradients in the specimen.[5] A similar abrupt transformation was also observed on a hard carbon PH-7 prepared from phenolformaldehyde resin.[6,7]

In the present work, in order to know whether the after-effect of high pressure heat treatment of carbon can be detected in the graphitization under normal pressure, the soft carbon PV-7 pre-heat-treated at several temperatures under 5 kbar was re-heat-treated under normal pressure. Structural changes by the re-heat-treatment were followed by X-ray diffraction.

Experimental

Pre-heat-treatment under High Pressure. A simple piston-cylinder type high pressure vessel made of tool steel was used. Its bore diameter was 30 mm. The pressure cell arrangement was similar to that previously reported,[2] except that the graphite tube heater used was larger, *i. e.* inner diameter 8 mm, outer diameter 10 mm and length 21 mm, and that the glassy carbon tube in the graphite heater was not used. The weight of the sample was about 450 mg, almost four

times the previous one. The contamination of the heat-treated samples was scarcely detected by X-ray analysis. Heat treatment temperature was estimated from the input power by using the relation between input power and temperature, which was determined especially for the present cell arrangement.

The coke PV-7 was heat-treated at three different temperatures of 1470, 1590, and 1620°C for the residence

time of 20 min under a quasi-hydrostatic pressure of 5 kbar. The heat-treated specimens were obtained as sintered cakes *ca.* 8 mm in diameter and *ca.* 6 mm long. A tablet 8 mm in diameter and 2 mm thick was sampled from the central part of the sintered cake of each heat-treated specimen. For this central part, temperature gradient during the heat treatment under 5 kbar was scarcely observed.[5] To minimize the effect of the possible gradients of temperature and pressure along the radial direction of the tablet on the final results, each tablet of the specimen was cut into eight small pieces through the center of the tablet and these small pieces were used for the re-heat-treatment under normal pressure at different temperatures. The 1470°C-, 1590°C-, and 1620°C-treated samples were designated as N-1, N-2, and N-3, respectively, in the present work.

Re-heat-treatment under Normal Pressure. The re-heat-treatment under normal pressure was conducted at temperatures ranging from 1190 to 2630°C for the residence time of 60 min in a flow of nitrogen by using a graphite tube resistance furnace. During the heat treatment, small pieces of the samples N-1, N-2, and N-3, and the original coke PV-7 were placed in graphite crucibles separately and the crucibles were put in a large graphite container.

Heat treatment under normal pressure was performed as follows. After the central part of the graphite heater was heated to a desired temperature, the graphite container, which contained the four samples and was placed beforehand in a cold part of the heater, was pushed into the central part. It required about 10 min to heat the crucible to the desired temperature. After 60 min residence, the graphite container was pushed out to a cold part on the opposite side of the heater and then the temperature of the furnace was raised in order to perform another heat treatment. The temperature of heat treatment was determined by focusing an optical pyrometer on the surface of the graphite crucible through a hole drilled in the container wall. The optical pyrometer used was calibrated to the standard lamp for pyrometry. The temperature of the furnace was kept constant within ± 10°C by adjusting the input power manually.

X-Ray Analysis. The profiles of (004) diffraction line of all heat-treated samples were measured by using Ni-filtered Cu*Ka* radiation and a recording goniometer. The specimens for X-ray analysis were 0.2 mm thick. The heat-treated samples of PV-7 and N-1 had symmetrical profiles of (004) diffraction line, as can be seen in Fig. 1-a) and b). For the sample producing such a symmetrical profile, c_0-spacing and crystallite size L_c were measured by the usual method[8] referring to the inner standard of silicon. However, profiles of all samples derived from N-2 and N-3 had a composite structure, as can be seen in Fig. 1-c) and d). The composite profile was separated into the profiles of two components A_S and G_S, which were on low and high angle side, respectively.*1 A similar procedure to that reported previously[3] was applied to the separation of the composite profile. In the present work, the angular position of the component profile on low angle side could not be fixed at a constant value, but estimated very easily because the separation of two component profiles was relatively large. Almost all the composite profiles could be separated into two symmetrical component profiles after one or two trials. For each separated component profile, c_0-spacing and crystallite size L_c were measured by referring to the inner standard of silicon. The content of the component G_S was evaluated by measuring the ratio of area under the profile of G_S to the total area of the composite profile and correcting it for the crystallite orientation.[2,3]

Results

Changes of the profile of (004) diffraction line with temperature of heat treatment under normal pressure (HTT) for the samples PV-7, N-1, N-2, and N-3 are shown in Figs. 1-a), b), c) and d), respectively. For the sample PV-7, all the profiles are symmetrical and shift to a higher angle together with sharpening as HTT increases. Sample N-1 is found to have almost the same tendency of change in the profile as that of the sample PV-7. For samples N-2 and N-3 of which the originals have composite profiles, only the profile corresponding to the component A_S shift to a higher angle with sharpening as HTT increases, but the profile corresponding to the component G_S does not seem to change in position, relative intensity and sharpness with heat treatment.

Changes of c_0-spacing and crystallite size L_C with HTT for the samples are shown in Figs. 2-a) and b), respectively. Sample PV-7 becomes to have almost the same values of c_0 and L_C as those of the component A_S of the other samples at about 2000°C and above that temperature the changes in c_0 and L_C of A_S of the samples N-1, N-2, and N-3 as well as PV-7 follow the same course of change with HTT. On the other hand, the graphitic component G_S which has been formed by the pre-heat-treatment under high pressure has the constant c_0-spacing of 6.72 Å and the crystallite size L_C of around 300 Å during the heat treatment under normal pressure.

Changes of content of the component G_S with HTT are shown in Fig. 3. The content of the component G_S does not change by the re-heat-treatment under normal pressure. Sample N-1 does not have any amount of the component G_S originally.

Discussion

The graphitization under pressure above 3 kbar proceeds in two stages.[2,3] In the first stage the c_0-spacing of carbon decreases to *ca.* 6.85 Å and in the second stage a new component having graphitic structure develops in the original turbostratic car-

8) M. Inagaki and T. Noda, This Bulletin, **35**, 1652 (1962).

*1 In a previous work,[2] the component A_s had the c_0-spacing larger than 6.85Å. In the present work, however, the component corresponding to the separated profile on low angle side was designated as A_s, even if it has the c_0-spacing smaller than 6.85 Å.

Fig. 2-a)

●: N-1, △: N-2, ○: N-3

bon, *i.e.*, a sharp peak corresponding to c_0 of 6.72 Å develops besides the original broad peak of turbostratic carbon, making (00*l*) diffraction profile composite. This direct transformation of turbostratic carbon to graphite indicates that graphitization under high pressure proceeds heterogeneously on the scale of crystallite and can be called a heterogeneous graphitization. On the other hand, the graphitization under normal or reduced pressure proceeds homogeneously. The c_0-spacing decreases continuously to the value of graphite, and this change is detected as a continuous shift of a symmetrical profile of (00*l*) diffraction line to higher angle.

The sample N-1 has a symmetrical profile and its c_0-spacing is 6.856 Å, *i.e.*, it is on the first stage of graphitization process and consists only of turbostratic component A_S. The samples N-2 and N-3 give composite profiles and consist of turbostratic component A_S and graphitic component G_S, *i.e.*, they are on the second stage of graphitization process. The component A_S, which did not transform directly to graphitic component during the pre-heat-treatment under high pressure, was found to be graphitized homogeneously when the samples N-1, N-2 and N-3 were re-heat-treated under normal pressure. However, the re-heat-treatment of the samples under normal pressure did not affect the quality and quantity of the component G_S which has been formed by the pre-heat-treatment under high pressure.

These results indicate that the pre-heat-treatment of a soft carbon under high pressure has no accelerating effect on the graphitization of the carbon in the subsequent heat treatment under normal pressure, and that the direct transformation of the turbostratic component to graphitic component by the application of external stress causes the observed heterogeneous graphitization of soft carbon.

The authors wish to thank Dr. T. Noda, President of Mie University, for his valuable discussions and thorough review of the paper. The graphite materials used were supplied by Tokai Electrode Mfg. Co.

Some Observations of the Water Activity in Uni-uni Valent Electrolyte Solutions

Yuko HASEGAWA

Department of Chemistry, Science University of Tokyo, Kagurazaka Shinjuku-ku, Tokyo

(Received April 24, 1968)

The association or dissociation of various ionic species has sometimes been determined in aqueous electrolyte solutions at high concentrations. In such experiments, the constant ionic medium method has usually been employed for the control of the activity coefficients. The validities and the limitations of this method have been discussed by Rossotti and Rossotti.[1]

As the association or the dissociation of ions in aqueous solutions is accompanied by hydration or dehydration, the activity of water as well as the activity coefficients of the ionic species should be controlled in order to obtain reasonable chemical constants; information about the water activity in various constant ionic media is desirable for this purpose.

For the present study, the water activity in some very common uni-uni valent electrolyte solutions has been determined by a Karl Fischer titration method based on the principle that the water concentration in a benzene phase in an equilibrium with an aqueous phase is approximately proportional to the water activity in the latter.[2] The results thus obtained were then compared with the values calculated from the previous osmotic data,[3] and some consideration was done of the validities of the constant ionic media from this point of view.

Experimental

All of the reagents used were of a reagent grade. The concentrations of thiocyanate solutions were determined by argentometry, but the other concentrations were determined by gravimetry.

All of the procedures were carried out in the manner described in a previous paper.[2]

Results and Discussion

As has been described,[2] the water activity, A_w, of an aqueous solution can be calculated from the water concentration in a benzene phase in an equilibrium with the sample solution (which will be denoted by C_w), and that in an equilibrium with pure water (which will be denoted by C_{wo}), by using the following equation:

$$A_w = C_w/C_{wo}$$

The value of C_{wo} experimentally determined at 25°C is 0.034M.[2]

Table 1 shows the water activities determined by the titration method in the present study and those calculated from the molal osmotic coefficients by using the following equation:[3]

$$\ln A_w = -\frac{mW_w\nu\phi}{1000}$$

Here, ν is the number of ions formed from one mole of electrolyte; m is the concentration of electrolytes in the molality unit; W_w is the molecular weight of water, and ϕ is the molal osmotic coefficient.

In most salt solutions, the values calculated from the osmotic coefficients on the assumption that the salts are completely dissociated in the

aqueous solutions agree with the values determined by the present titration method. However, in a few solutions (for example, in the thiocyanate solution, as we can see from Table 1), the values are rather larger than the values from the osmotic coefficient method. From these results, the following conclusions may be drawn:

As the values obtained by these two independent methods are consistent, many strong electrolytes may be considered to be dissociated completely, and both of these methods are applicable for the determination of water activities, even when the electrolyte concentration is very high. The difference between the values obtained by these two methods could be explained by that the ν in the equation is smaller than the values calculated by assuming complete dissociation; that is, sodium ions and thiocyanate ions might be associated to some extent.

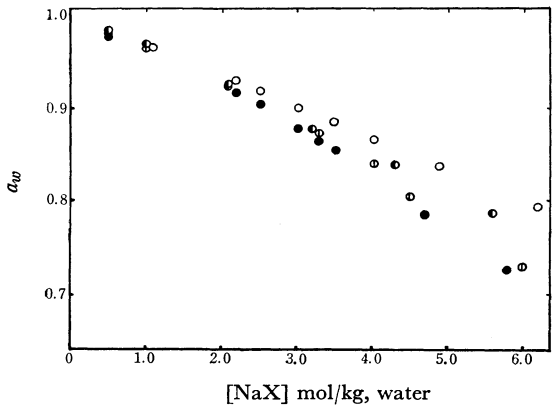

Fig. 1. Change in the water activity of four sodium salt solutions as a function of concentration of NaX.

○ Sodium perchlorate
◐ Sodium chloride
◑ Sodium bromide
● Sodium iodide

Figure 1 shows the water activities in solutions of four salts as a function of the salt concentration (molal units). We can see from Fig. 1 that, although the differences at a certain concentration are rather small, still the following decreasing order of the values of the water activity can be estimated in these sodium salt solutions:

$$A_{w_{NaClO_4}} > A_{w_{NaCl}} > A_{w_{NaBr}} > A_{w_{NaI}}$$

The water activity in aqueous salt solutions may be influenced by many factors. Robinson and Stokes[3] pointed out that the hydration of univalent anions decreases with an increase in the ionic radius. As the ionic radii of these anions decrease in the following order;

$$r_{ClO_4^-} > r_{I^-} > r_{Br^-} > r_{Cl^-}$$

the water activity in the solutions should decrease in the same order as long as we consider this problem in terms of hydration.

On the other hand, the following "*destroying-order*" of the water structure by solute anions was proposed, on the basis of IR measurements of various aqueous solutions, by Yamatera and Gordon[4] and Choppin and Buijs:[5]

$$ClO_4^- > I^- > Br^- > NO_3^- > Cl^-$$

If the water structure of these solutions is destroyed in this order, the water activity should decrease in the same order. However, the experimental observations gave just the reverse order except that the perchlorate solutions gave the largest values of water activity. Thus, factors other than the hydration or the destruction of the structure of water must be taken into account in formulating a reasonable explanation of these results.

Some more data on the water activities which will be useful in various discussions of solution chemistry are given in Table 2 by molarity and molality.

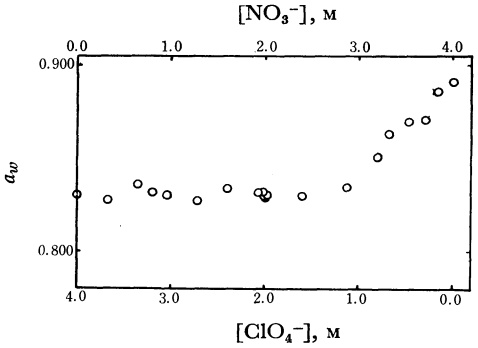

Fig. 2. Water activity in 4M Na (NO_3, ClO_4) solutions as a function of perchlorate or nitrate concentration.

Further study was carried out in mixed salt solutions in order to ascertain the ability of the constant ionic method to control the water activity. Mixtures of sodium perchlorate and nitrate were chosen as the representatives of the mixed electrolyte solutions because the difference in the water activity at 4M, for example, is largest between perchlorate and nitrate solutions.

Figure 2 shows the water activity in solutions containing sodium perchlorate and nitrate mixtures. We can seen from Fig. 2 that even when the sodium ion concentration is kept at 4M, the water activity changes continuously from 0.83 in 4M sodium perchlorate to 0.89 in 4M sodium nitrate; the water activity is almost constant until the nitrate concentration reaches 2.8M, but it increases abruptly beyond 2.8M. For the determination of very weak metal complexes, it is necessary to add a very large amount of ligand anions to the ionic media; that is, a large portion of the perchlorate ions should be replaced by the ligand anions. For example, when we examined europium(III) nitrate complexes ($K_1=1.3$ and $\beta_2=0.30$ in 4M Na(ClO_4, NO_3)),[6] it was necessary to replace almost 70% of the perchlorate ions in 4M sodium perchlorate media with nitrate ions in order to determine the second stability constants accurately. The present results indicate that even when such a large alternation of the medium is made the change in the water activity is still not very large; in view of this, the author regards the nature of the medium as still being kept constant.

The author is grateful to Dr. Tatsuya Sekine for many invaluable discussions.

The Synthesis and the Properties of Some New Boroarsenites

Narayani Prasad SINGH

Radiochemistry Division, Bhabha Atomic Research Centre, Trombay, Bombay-74, India

(Received June 19, 1968)

Though heteropoly salts of boron such as borotungstates[1,2] and borotungstovanadates[3] are reported in literature, very little work has been done on boroarsenites. Lery and Curty[4] found that, borophosphoric and boroarsenic acids exist in solution provided the solutions are sufficiently concentrated, even in the presence of vigorous hydrolyzing agent such as steam. In this note the preparation of ammonium boroarsenite and there-from the boroarsenite salts of silver, lead, zinc, cadmium and iron(II) are reported. Some of the physical properties of a few of these compounds are also studied.

Experimental

Synthesis of Ammonium Boroarsenite. Boric acid (9.27 g) and arsenious oxide (9.89 g) were dissolved in aqueous ammonia separately. The solutions were mixed together and then refluxed for ten to twelve hours. The solution was then concentrated to small volume and kept in a refrigerator, when ammonium boroarsenite separated out. It was recrystallized from water two to three times and dried in a vacuum desiccator.

The other salts were prepared by adding solutions of $AgNO_3$, $Pb(CH_3COO)_2$ $Zn(CH_3COO)_2$, $Cd(CH_3COO)_2$ and $FeSO_4$ to the ammonium salts solution. The analytical results are recorded in Table 1.

Analytical. Boron was estimated by a volumetric method in the presence of mannitol using phenolphthalein as an indicator. Nitrogen was estimated by the Kjeldahl method and the percentage expressed in terms of $(NH_4)_2O$. Other metals were estimated by standard

methods. Water was found by difference.

Spectroscopic Studies. The infrared spectra in the range 2—15μ of ammonium boroarsenite and zinc boroarsenite were recorded on a Perkin-Elmer infrared spectrometer in KBr discs.

Discussion

It is very difficult to assign definite structures to the heteropoly acids and their salts owing to the complexity of the molecules involved. The compositions of the salts have been arrived at on the basis of analytical results. The analytical results have given the empirical formula $5(NH_4)_2O \cdot B_2O_3 \cdot 4As_2O_3 \cdot 25H_2O$ for ammonium boroarsenite. When a freshly prepared solution of this salt was subjected to ion exchange (Dowex-50 cation resin), it gave a stable free acid thus confirming the stability of boroarsenite ion in the solution. Several unsuccessful attempts were made to crystallize the acid out.

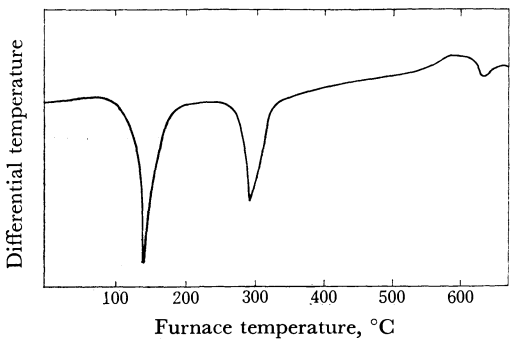

Fig. 1. Differential thermal analysis curve of ammonium boroarsenite.

The differential thermal analysis (DTA) curve reveals two endotherms one at 140°C and the other at 294°C, corresponding to the dehydration of the compound. This indicates the presence of two types of bound water molecules.

In the infrared spectra of zinc boroarsenite and ammonium boroarsenite one peak is observed in the 3μ region (3231, 3403 cm^{-1} respectively) corresponding to the –OH stretching vibrations of water molecules. The peak at 3403 cm^{-1} in case of ammonium boroasenite is broad which may due to the overlapping of –NH and –OH stretching frequencies. In the case of ammonium boroarsenite one peak is found at 1634 cm^{-1} which may be assigned as –NH bending. Peaks at 1198 cm^{-1} and 793 cm^{-1} in the case of ammonium boroarsenite and 1191 and 802 cm^{-1} in the case of zinc boroarsenite have been assigned to –BO group, though. White *et al.*[5] have reported absorption bands at 1300 and 762 cm^{-1} for –BO group in their studies on simple B_2O_3 molecule. The variation in the frequencies observed may be due to the involvement of BO group in complex formation. Bands have been observed at 1044 cm^{-1} and 1052 cm^{-1} respectively for ammonium boroarsenite and zinc boroarsenite which are attributed to As–O stretching frequency. Confirmation to this was obtained in the infrared spectrum of As_2O_3 taken by the author which showed band at 1045 cm^{-1} which can be attributed to As–O stretching frequency.

The slight differences observed in the position of the corresponding IR bands of the two salts studied may be due to the differences in their crystal structure environments.

Author's sincere thanks are due to the authorities of Banaras Hindu University for the necessary facilities provided and the C.S.I.R., New Delhi for financial assistance.

Fluorescence Spectra of Some Benzimidazoles in Acid Media

Michio KONDO and Harumitsu KUWANO

Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo

(Received June 20, 1968)

Few papers have been published on the fluorescence spectra of benzimidazole in the protonated state.[1,2] For benzimidazole perchlorate, two fluorescence bands were observed in an ethanol solution at a low temperature. The weak, broad, structureless band observed at about 29000 cm^{-1} was assigned to the emission from the excited singlet state, ^1L_a, on the basis of the results of fluorescence polarization experiments.[2] This indicates the reversal of the excited energy levels, ^1L_a and ^1L_b. The present note will report on the fluorescence of some benzimidazole derivatives in acid and neutral media.

The benzimidazoles studied have pK_a values ranging from 4.9 to 6.8. The absorption spectra of these compounds show two separated absorption bands, ^1L_a and ^1L_b, in neutral and acid solutions. The protonation causes slight blue shifts in the two absorption bands for each compound.

Neutral benzimidazole molecules show an emission band at about 34500 cm^{-1}, whereas the cations give rise to a broad, structureless emission band peaking at about 27800 cm^{-1}.

Neutral molecules of 2-methylbenzimidazole give an emission band at 34250 cm^{-1}. However, two emission bands are observed in acid media where the molecules are presumed to be completely protonated. This is in marked contrast to the fact that benzimidazole cations exhibit only one emission band. One of the two emission bands of the 2-methylbenzimidazole cations is located at 34840 cm^{-1} and it has unresolved structure, whereas the other is a broad, structureless band peaking at about 27800 cm^{-1}. The former emission bands shifts 590 cm^{-1} to higher frequencies relative to the emission band observed for neutral molecules and is observed to a considerable extent even in a 10 N sulfuric acid solution. These facts suggest that this fluorescence originates not from neutral but from cationic species.

It is possible to ascribe this emission band to the neutral species which could be present in the excited state if the pK_a^* value were assumed to be much smaller than pK_a. However, it is very difficult to imagine a large difference between the pK_a^* values of benzimidazole and 2-methylbenzimidazole in the excited state, for they are very similar in physical and chemical properties.

Another derivative of benzimidazole, 5-chlorobenzimidazole, behaves quite differently from the two compounds mentioned above. Neutral molecules show an emission band at 32890 cm^{-1}. An emission band from the cations is observed at 33900 cm^{-1} with no accompanying band at lower frequencies. In this case, the protonation causes a blue shift in both absorption and emission spectra. Even in a solution of 10N sulfuric acid, no emission band was observed at about 27800 cm^{-1}. This fact suggests that the normal emission band from the protonated species should not be far apart from the absorption band, and that the broad, structureless emission observed for benzimidazole and 2-methylbenzimidazole cations is abnormal.

From the large red shift of the broad, structureless emission band of the 2-methylbenzimidazole cations, one can suspect that the emission band is attributable to the formation of a kind of excimers.[3] However, this possibility can be ruled out for the following

TABLE 1. CLASSIFICATION OF FLUORESCENCE SPECTRA OF SOME BENZIMIDAZOLES

Cation	pK_a	Emission band ~34000 cm^{-1}	Emission band 27800 cm^{-1}	Class*

reasons: (i) the concentration change (10^{-4} mol/l to 10^{-6} mol/l) caused no variation in the relative intensity of the two bands or in the shape of the emission spectrum, (ii) the emission spectrum was independent of the viscosity of the media, as was seen from the fact that the emission spectrum obtained in an aqueous solution was essentially the same as that obtained in aqueous glycerol (60 vol%). Furthermore, in different acids, (0.1N sulfuric, hydrochloric, perchloric, and acetic acid), the emission spectra of the two bands were essentially the same in shape and in intensity ratio. These facts suggest that the appearance of the second emission band is not due to some bimolecular or multimolecular mechanism, but to unimolecular mechanism.

The other benzimidazole derivatives studied can be classified into the three types described above on the basis of their fluorescence spectra. Table 1 presents this classification. From this table, it can be concluded definitely that there is no close relationship between the pK_a values and the appearance of the broad emission band at lower wave numbers. It is of interest to note, however, that 2-methylbenzimidazole gives an emission spectrum consisting of two components, whereas 5-methylbenzimidazole gives a single, broad, structureless fluorescence band at about 27800 cm^{-1}. This observation suggests that the introduction of a methyl group at the position 2 has a greater effect in producing the broad emission at lower frequencies than does the introduction of a methyl group at the position 5.

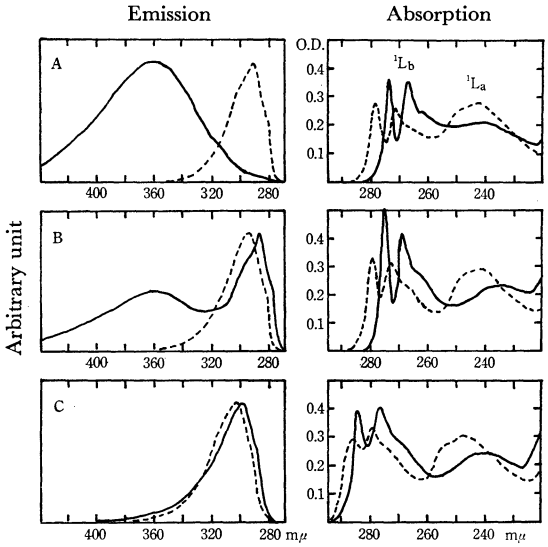

Fig. 1. Absorption and emission spectra of three benzimidazole derivatives in neutral (pH=9.3) —— and acid (0.1N H_2SO_4) —— media.
A: benzimidazole; B: 2-methylbenzimidazole; C: 5-chlorobenzimidazole.

The emission and absorption spectra are shown in Fig. 1 for the three benzimidazole derivatives in neutral and acid media. A correlation between the absorption and emission spectra in acid media can be obtained. In the case of the benzimidazole cation, the separation between the absorption bands is small and the emission is broad and is shifted to lower wave numbers. In contrast with this, two clearly-split absorption bands are observed for 5-chlorobenzimidazole cations, which show a single emission band with a small Stokes shift. For the compound with two emission bands, an intermediate splitting of the two absorption bands is observed. On the other hand, in neutral media, the two absorption bands are clearly split and only one emission band is observed for each compound. These observations suggest that the magnitude of the separation between the two excited singlet states, ^1L_a and ^1L_b, is an important factor in producing the broad emission band.

It is sure that the fluorescence originates from the equilibrium excited-state configuration, because the viscosity has no effect on the emission spectra. The relaxation process, through which the excited molecules in the Franck-Condon state change into the equilibrium-excited state, includes the reorientation of the polar solvent molecules to their equilibrium orientation in the field of the excited state of the polar solute molecules. For benzimidazole perchlorate, the emission from the ^1L_a state was observed at lower frequencies than that from the ^1L_b state.[2] This indicates that the ^1L_a state was much more stabilized than the ^1L_b state, perhaps due to the more polar character of the ^1L_a state. For the compounds, therefore, it may be possible to say that the ^1L_a states are more polar than the ^1L_b states. It is expected that the ^1L_a states are strongly stabilized by the interaction with polar solvent molecules, while the ^1L_b states are not, and that the reversal of the two excited energy levels can occur when the separation between them is small. In the case of the benzimidazole cation, the lowest vibration energy levels of the ^1L_a and ^1L_b states seem to be close to each other, and the reversal of the two energy levels could occur through the relaxation mentioned above. However, it may be difficult for the reversal to occur in the 5-chlorobenzimidazole cation because of its well-separated levels. The compounds with two excited levels intermediately split will give emission spectra consisting of two components as a result of a competitive emission from the two levels, ^1L_a and ^1L_b, which lie very close to each other after the stabilization mentioned above. Such a reversal of the two excited states has been reported for *p*-cyano-*N*,*N*-dimethylaniline,[4] for example.

Experimental

Several benzimidazole derivatives were prepared by refluxing *o*-phenylenediamine and appropriate carboxylic acids in dilute hydrochloric acids.

The absorption spectra were measured with a Cary spectrophotometer Model 14. The fluorescence spectra were recorded on a Hitachi fluorescence spectrophotometer Model MPF-2.

In acid media, these compounds were stable, so the same absorption and emission spectra were obtained again on the next day. Prolonged irradiation did not cause any change in the absorption and emission spectra of benzimidazole. When the observing fluorescence was fixed at the higher-frequency band, the apparent excitation spectrum of 2-methylbenzimidazole cations was essentially the same as that obtained when the fluorescence was observed at the lower-frequency band. This is consistent with the fact that there only the protonated species are present in the solution.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1435—1437 (1969)

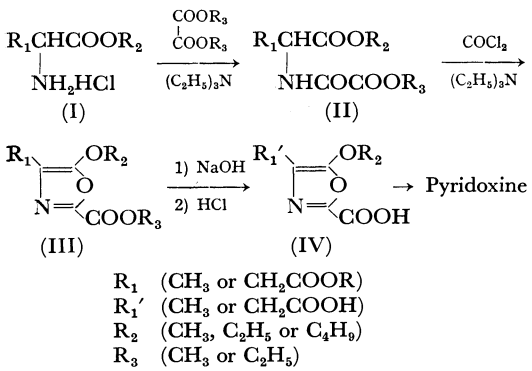
The Synthetic Intermediate of Pyridoxine. I. A Novel Synthesis of 5-Alkoxy-2-carboxy-4-methyloxazole

Itsutoshi MAEDA, Masahiro TAKEHARA, Kazushi TOGO, Soichiro ASAI and Ryonosuke YOSHIDA

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki

(Received July 2, 1968)

Recently, a few attempts have been reported to develop a new route to pyridoxine by modifying the original Harris report.[1] Most of these methods have dealt with the Diels-Alder reaction of 5-alkoxy-4-methyloxazole with various dienophiles except a few reports.[2,3] This 5-alkoxy-4-methyloxazole has been prepared from alkyl *N*-formylalaninate with phosphorus pentoxide.[4,5] However, the procedure is troublesome, for the reaction mixture forms a hard mass in the vessel.



R_1 (CH_3 or CH_2COOR)
R_1' (CH_3 or CH_2COOH)
R_2 (CH_3, C_2H_5 or C_4H_9)
R_3 (CH_3 or C_2H_5)

The present authors have found an excellent method for preparing a new oxazole, 5-alkoxy-2-alkoxycarbonyl-4-methyloxazole, as an intermediate of pyridoxine. Namely, 5-alkoxy-2-alkoxycarbonyl-4-methyloxazole was prepared from alkyl *N*-alkoxalylalaninate with phosgen and triethylamine as the dehydrating agents. Other dehydrating agents

gave unsatisfactory results, as is shown in Table 1. No method of synthesizing oxazole derivatives by a reaction with phosgen and triethylamine has yet been reported.

Alkyl DL-alaninate hydrochloride (Ia, $R_1=CH_3$) reacted with alkoxalylchloride to produce alkyl *N*-alkoxalylalaninate (IIa, $R_1=CH_3$),[6] but the following improved method was adopted. A mixture of 1 mol of alkyl DL-alaninate hydrochloride, 2 mol of dialkyl oxalate, and 1 mol of triethylamine was heated to give compound IIa. Compound IIa then reacted with phosgen and triethylamine to give 5-alkoxy-2-alkoxycarbonyl-4-methyloxazole (IIIa, $R_1=CH_3$). The results are summarized in Table 2. Compound IIIa was saponified with sodium hydroxide and neutralized with hydrochloric acid to crystallize 5-alkoxy-2-carboxy-4-methyloxazole (IVa, $R_1=CH_3$), as is shown in Table 3.

In a similar manner, the oxazole derivative could be obtained from dialkyl aspartate hydrochloride (Ib, $R_1=CH_2COOR$). The results are shown in Table 2 and Table 3.

Pyridine derivatives were obtained by Diels-Alder reactions with 5-alkoxy-2-carboxy-4-methyloxazole (IVa) or 5-alkoxy-2-carboxy-4-carboxymethyloxazole (IVb) and with such dienophiles as diethyl maleate, fumaronitrile, 2,5-dihydrofuran, and 4,7-dihydro-1,3-dioxepine. These pyridine derivatives were introduced to pyridoxine by the usual methods.

Experimental*1

Ethyl *N*-Ethoxalylalaninate (Iae). Ethyl DL-alaninate hydrochloride (12.3 g, 0.08 mol) was dissolved in ethanol, and then diethyl oxalate (23.4 g, 0.16 mol) and triethylamine (8.1 g, 0.08 mol) were added. After the mixture had been heated at 50°C for 5 hr, the solvent was removed by distillation and chloroform was added to the residue. The triethylamine hydrochloride was removed by washing with water. On fractional distillation, ethyl *N*-ethoxalylalaninate was obtained (bp 127°C/2 mmHg, yield, 15.7 g, 90.5%). Similarly, alkyl *N*-alkoxalylalaninate and alkyl *N*-alkoxalylaspartate were obtained.

5-Ethoxy-2-ethoxycarbonyl-4-methyloxazole (IIIae). In 100 m*l* of chloroform, ethyl *N*-ethoxalylalaninate (21.7 g, 0.1 mol) and triethylamine (30.0 g, 0.3 mol) were dissolved. Into the solution, a 100-m*l* portion of chloroform solution containing phosgen (14.8 g, 0.15 mol) was then stirred, drop by drop, at 20°C, and the mixture was heated to 50°C for 1 hr. After the reaction mixture had been washed with water to remove the triethylamine hydrochloride, the chloroform was distilled off; on fractional distillation, 5-ethoxy-2-ethoxycarbonyl-4-methyloxazole was obtained (bp 128°C/4 mmHg; yield, 13.9 g, 70.0%). Similarly, 5-alkoxy-2-alkoxycarbonyl-4-methyloxazole and 5-alkoxy-2-alkoxycarbonyl-4-alkoxycarbonylmethyloxazole were obtained from alkyl *N*-alkoxalylalaninate and alkyl *N*-alkoxalylaspartate.

2-Carboxy-5-ethoxy-4-methyloxazole (IVae). Into 9.9 g (0.05 mol) of 5-ethoxy-2-ethoxycarbonyl-4-methyloxazole, an 11.4-m*l* portion of a 5N aqueous sodium hydroxide solution (0.057 mol) was stirred. After 20 min, 9.56 m*l* of 5.95N hydrochloric acid (0.057 mol) were added to the mixture. Crystals of 2-carboxy-5-ethoxy-4-methyloxazole were filtered out and dried over phosphorus pentoxide at 30°C under reduced pressure (mp 83—84°C; yield, 7.7 g, 90%). Similarly, 5-alkoxy-2-carboxy-4-methyloxazole and 5-alkoxy-2-carboxy-4-carboxymethyloxazole were obtained.

The Diels-Alder Reaction of 2-Carboxy-5-ethoxy-4-methyloxazole. *With Diethyl Maleate.* A mixture of 2-carboxy-5-ethoxy-4-methyloxazole (IVae, 1.7 g) and

6) W. Kerp and K. Unger, *Ber.*, **30**, 579 (1897).

*1 The boiling and melting points are uncorrected.

diethyl maleate (5.2 g) was kept at 100°C for 6 hr. Upon the addition of ethanol containing hydrogen chloride and upon the further addition of ether to the reaction mixture, crystals of 4,5-diethoxycarbonyl-3-hydroxy-2-methylpyridine hydrochloride (V) were formed (mp 144—145°C; yield, 2.5 g, 86.2%).

Found: C, 49.63; H, 5.34; N, 4.88%. Calcd for $C_{12}H_{15}NO_5HCl$: C, 49.74; H, 5.57; N, 4.84%.

Similarly, a mixture of 2-carboxy-4-carboxymethyl-5-ethoxyoxazole (IVbe, 2.2 g) and diethyl maleate (5.2 g) was kept at 130°C for 4 hr. From the reaction mixture, V was obtained (mp 145—146°C; yield, 1.1 g).

With Fumaronitrile. A mixture of IVae (1.7 g), fumaronitrile (0.78 g), and methanol (20 m*l*) was refluxed for 5 hr. After the reaction mixture had then cooled, 4 m*l* of concentrated hydrochloric acid were added. The solvent was then distilled off, and the residue was dried with benzene. When recrystallized from a mixed solvent of methanol and benzene, it formed yellow crystals, 4,5-dicyano-3-hydroxy-2-methylpyridine (mp 187—188°C; yield, 0.9 g).

Found: C, 60.54; H, 3.08; N, 26.49%. Calcd for $C_8H_5N_3O$: C, 60.37; H, 3.17; N, 26.41%.

With 4,7-Dihydro-1,3-dioxepine. A mixture of 4,7-dihydro-1,3-dioxepine (20.3 g) and IVae (1.7 g) was kept at 190°C for 3 hr. After the unreacted compounds had been distilled off, a 120-m*l* portion of 2N hydrochloric acid was added to the residue and the mixture was refluxed for 2 hr. After the solvent had been distilled off, crystals of pyridoxine hydrochloride were obtained when ethanol and acetone were added to the residue (mp 202—204°C; yield, 1.0 g).

Found: C, 46.89; H, 6.15; N, 6.76%. Calcd for $C_8H_{11}NO_3HCl$: C, 46.72; H, 5.88; N, 6.81%.

Hot-Atom Chemistry of Bromine. I. Distribution of Bromine-82 Recoiled by the Bromine-82m Isomeric Transition Process in Aqueous Potassium Bromate

Chiro SHINOMIYA, Akira OYOSHI and Toshiaki KISHIKAWA

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto

(Received July 4, 1968)

In spite of a number of investigations of the chemical state of recoil bromine atoms arising from radiative neutron capture in bromate,[1-3] the discovery of ^{82m}Br in independent studies[4,5] has prompted a re-evaluation of the ^{82}Br hot-atom data. Saito *et al.*,[2] in 1967, discussed isotope effects with regard to the isomeric transition-induced reaction of ^{82m}Br after (n, γ) reactions in various solid bromates.

To study the chemical state of radioactive bromine atoms after (n, γ) and (I. T.) reactions in aqueous media, the present authors irradiated an aqueous (0.1M) potassium bromate solution in a reactor for one minute (thermal neutron flux of 5×10^{12} n/cm^2/-sec and attendant γ-dose rate of 2.7×10^7 R/hr) and then investigated the distribution of ^{82}Br atoms arising from both (n, γ) and (I. T.) reactions by means of paper electrophoresis (on Toyoroshi No. 50 with a potential gradient of 50 V/cm and with 0.1M $NaClO_4$ as the electrolyte). It was found that most of the activities in the form of BrO_3^- and Br_2[6] at the end of irradiation decayed with a half-life of ^{82m}Br, while the activities in the form of Br^- grew simultaneously.

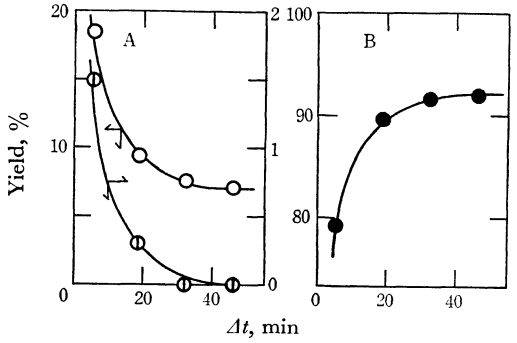

Fig. 1. Decays and growth of ^{82}Br-recoil species in irradiated aqueous BrO_3^-.
○: BrO_3^-, ◑: Br_2, ●: Br^-

Figures 1A and 1B show plots of the activities

1) The literature has been well surveyed by Saito *et al.* in Ref. 2.

5) J. F. Emery, *J. Inorg. Nucl. Chem.*, **27**, 903 (1965).

6) Activities remained on the point of origin on a paper strip. The neutral bromine species which could have been thought to be present in the solution after stabilization was Br_2.

of BrO_3^-, Br_2 and Br^- in percentages obtained from a neutron-irradiated aqueous potassium bromate solution which has been left to stand for various periods of time, Δt, after the end of irradiation. The curves of BrO_3^- and Br_2 decrease with an increase in the standing time, while that of Br^- increases.

About 91% of the initial radioactive bromine when the ^{81}Br atoms have been captured with neutrons is the 6.2 min ^{82m}Br isomer,[5] which decays primarily (*i.e.*, 99.8%) by means of a highly-converted transition from the 46 keV level (internal conversion coefficient $\alpha_k=268$) to the ^{82}Br ground state. This means that, in the process of the isomeric transition the ^{82}Br atom gains a highly positively-charged state as a result of the emission of a conversion electron and accompanying Auger electrons. The high positive charge results in a Coulomb repulsion. Bromine-82, which combines with oxygens to form the bromate ion, will then recoil into the aqueous medium. The chemical form in which the bromine finally remains will be the bromide ion. Early work by Libby and his co-worker[7] has shown that, if the bromate ion in solution is labeled with ^{80m}Br, the isomeric transition produces a disruption of the bromate molecule. Then the recoil ^{80}Br becomes a bromide ion.

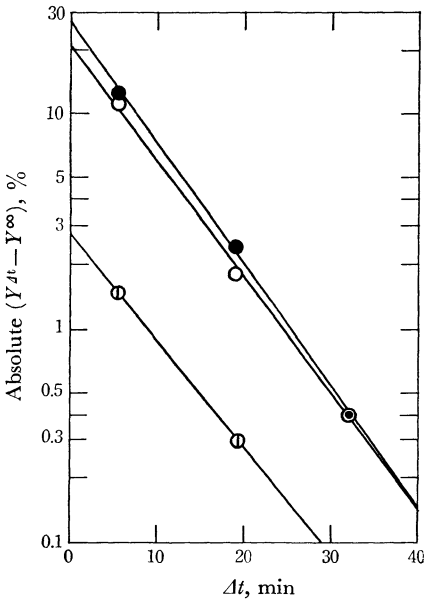

Fig. 2. ^{82}Br-recoil species as a result of isomeric transition in aqueous BrO_3^-.
○: BrO_3^-, ◑: Br_2, ●: Br^-

If the observed decrease or increase in the ^{82}Br yields of subjecting species were a result of chemical excitation by the isomeric transition alone, the rate of the decay or growth of the yield should be dependent only on the decay of ^{82m}Br and should be related to the half-life of the ^{82m}Br. Therefore, if Y^∞ represents the yield of a species reached in the solution after all the ^{82m}Br has decayed to the ^{82}Br ground state, and if Y^0 represents the yield produced at the end of neutron irradiation, the yield, $Y^{\Delta t}$, at any time before the ^{82m}Br has completely decayed minus Y^0 would be $(Y^\infty-Y^0)$ multiplied by the fraction of ^{82m}Br atoms, present when the sample was separated, which had decayed to ^{82}Br. The fraction remaining would be $\exp(-\lambda\Delta t)$, where λ is the decay constant of ^{82m}Br. The decay of ^{82m}Br in BrO_3^- or Br_2 is then given by $Y^{\Delta t}-Y^\infty=(Y^0-Y^\infty)\cdot\exp(-\lambda\Delta t)$. A plot of $Y^{\Delta t}-Y^\infty$ *vs.* Δt on a semilogarithmic scale should yield a straight line with a slope of $-0.693/2.303T_{1/2}$ (Fig. 2). The fraction which had decayed is $1-\exp(-\lambda\Delta t)$. Similarly, the growth of ^{82}Br in Br^- will be given by $Y^{\Delta t}-Y^0=(Y^\infty-Y^0)(1-\exp(-\lambda\Delta t))$. By rearranging the equation, we can see also that a plot of $Y^\infty-Y^{\Delta t}$ *vs.* Δt on the same scale should yield a straight line (Fig. 2). The ^{82m}Br half-life values were determined to be 5.53, 5.57 and 5.29 min using the yields of BrO_3^-, Br_2, and Br^- respectively. These values are in fairly close agreement with the values of 363 sec and 6.2 min reported in Refs. 4 and 5 respectively. The agreed relative rates of decrease or increase in the BrO_3^-, Br_2, or Br^- yields can be attributed to ^{82m}Br isomeric transition-excited reactions.

The Y^∞ values in BrO_3^-, Br_2, and Br^- were 7.7%, 0%, and 92.1%, and the (Y^0-Y^∞) values in them were 21.3%, 2.9%, and 27.3% respectively. By adding; $(Y^0-Y^\infty)(BrO_3^-)+Y^\infty(BrO_3^-)$; here, the latter term must be due, for the most part, to the direct formation of ^{82g}Br from the (n, γ) process; the experimentally-determined retention in BrO_3^- at the end of neutron irradiation was 29.0%, the 21.3/29.0=0.78 fraction of which was estimated to be $BrO_3^-(^{82m}Br)$. The yields of ground- and metastable-state bromine-82 in bromate at the end of irradiation arising directly from the (n, γ) reaction were distinguished.

The authors wish to express their appreciation to Dr. Shiro Iwata, Dr. Yoshiyuki Kiso, and the personnel of the Research Reactor Institute, Kyoto University, for their assistance in the irradiation. Thanks are also due to Mr. Shin'ichi Toyama for helping with the experimental work.

A Band Model of the Charge-Transfer Complexes

Hisanao SATO and Chisato OKAZAKI

Wireless Research Lab., Matsushita Electric Industrial Co., Ltd., Kadoma, Osaka

(Received July 13, 1968)

The purpose of this note is to propose a theoretical model to explain the high electrical conductivities of some charge-transfer complexes. The complexes of aromatic hydrocarbons with iodine are found to show low resistivities when the mole ratio deviates from 1 : 1, while those of the 1 : 1 complexes are high.[1] For example, the resistivity of the pyrene-iodine (1 : 2) complex is 75 ohm-cm at room temperature[2] and the coronene-iodine (1 : 1) complex has a resistivity of about 10^8 ohm-cm.[3] For a complex in which the ionization energy of the donor is much larger than the electron affinity of the acceptor, the ground state is mainly expressed as a non-bonding structure and the band gap may be presumed to be large. Since the ionization energy of pyrene is nearly equal to that of coronene,[1] the reason for the low resistivity of the pyrene-iodine complex must be discussed.

Since no data are available on the crystal structure of the 1 : 2 complexes, the linear chain indicated in Fig. 1 is assumed[4] in order to calculate the energy bands for the simplest case. In Fig. 1, D is a donor molecule and A is an acceptor molecule. In this arrangement two acceptors (A_1 and A_2) in a unit cell are assumed to occupy equivalent sites. Assuming that the one-electron Hamiltonian, H, has properly been chosen for the linear chain, we define the Bloch orbitals, $\phi_D(\boldsymbol{k})$, $\phi_{A_1}(\boldsymbol{k})$, and $\phi_{A_1}(\boldsymbol{k})$, as follows:

$$\phi_D(\boldsymbol{k}) = \sum_j \exp(i\boldsymbol{k}\boldsymbol{R}_{jD})\ \chi_D(r - \boldsymbol{R}_{jD}), \quad (1)$$

$$\phi_{A_1}(\boldsymbol{k}) = \sum_j \exp(i\boldsymbol{k}\boldsymbol{R}_{jA_1})\ \chi_A(r - \boldsymbol{R}_{jA_1}), \quad (2)$$

$$\phi_{A_2}(\boldsymbol{k}) = \sum_j \exp(i\boldsymbol{k}\boldsymbol{R}_{jA_2})\ \chi_A(r - \boldsymbol{R}_{jA_2}). \quad (3)$$

Here $\boldsymbol{R}_{jD}$, $\boldsymbol{R}_{jA1}$, and $\boldsymbol{R}_{jA2}$ are the coordinates of the molecules D, A_1, and A_2 respectively in the jth cell, and $\boldsymbol{k}$ is the wave vector of an electron. χ_D is the wave function for the highest occupied level of the donor, and χ_A is that for the lowest unoccupied level of the acceptor.

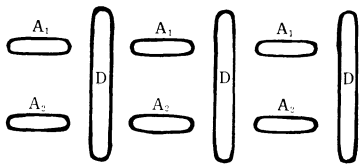

Fig. 1. Assumed structure of 1 : 2 complex. D is a donor and A is an acceptor.

It can be seen from the symmetry that the state:

$$\phi_A^- = 2^{-1/2}(\phi_{A_1} - \phi_{A_2})$$

does not combine with ϕ_D and that it is, therefore, the eigen-state. The corresponding energy, $E^{(-)}(\boldsymbol{k})$, is nearly independent of the wave vector, $\boldsymbol{k}$, since the overlap of χ_A in different cells may be neglected. The other eigen-states are obtained by taking linear combinations of ϕ_D and

$$\phi_A^+ = 2^{-1/2}(\phi_{A_1} + \phi_{A_2})$$

The energies are determined by:

$$\begin{vmatrix} H_D - E, & H_1 \\ H_1^*, & H_A - E \end{vmatrix} = 0, \quad (4)$$

where, for simplicity, the overlap integral is neglected and where:

$$H_D = \int \phi_D^* H \phi_D d\tau, \quad (5)$$

$$H_A = \int \phi_A^{+*} H \phi_A^+ d\tau, \quad (6)$$

$$H_1 = \int \phi_D^* H \phi_A^+ d\tau. \quad (7)$$

If $(H_A - H_D)^2 \gg 4|H_1|^2$, the ground state energy, $E_0(\boldsymbol{k})$, and the excited state energy, $E^{(+)}(\boldsymbol{k})$, may be written as:

$$E_0(\boldsymbol{k}) = H_D - \Delta E, \quad (8)$$

$$E^{(+)}(\boldsymbol{k}) = H_A + \Delta E, \quad (9)$$

where: $$\Delta E = |H_1|^2/(H_A - H_D). \quad (10)$$

These energies are shown in Fig. 2, where $E^{(-)}(\boldsymbol{k})$ and the magnitudes of the integrals (5), (6), and (7) are chosen arbitrarily. The band $E_0(\boldsymbol{k})$ is filled with electrons, since there are two electrons

per molecule; hence, the smallest band gap is equal to $H_A - H_D$ at the zone boundary.

ΔE represents the part of the binding energy due to the electron transfer from D to A. This charge-transfer energy, ΔE, depends on the distance, R_A, between A_1 and A_2 through H_A. If the magnitude of $|H_1|^2$ does not decrease with R_A, R_A becomes shorter than the van der Waals distance between the two acceptors in order to lower the energy of the state $\phi_A{}^+; H_A$. Therefore, the binding energy of the lattice is expected to increase with a decrease in R_A, although the repulsive force between A_1 and A_2 causes some energy loss. Therefore, the band gap, $H_A - H_D$, may be small even if the difference between the donor ionization energy and the electron affinity of the acceptor is large. The difference between coronene and pyrene may lie in the difference between their highest occupied states, χ_D. Presumably, the χ_D of coronene spreads on a large molecular plane, so a decrease in R_A results in the reduction of the overlapping of ϕ_D and $\phi_A{}^+$.

The Nuclear Magnetic Resonance and Infrared Spectra of Aromatic Azomethines

Katsumi TABEI and Etsurou SAITOU

Tokyo College of Pharmacy, 4-600, Kashiwagi, Shinjuku-ku, Tokyo

(Received July 24, 1968)

Theoretical and experimental studies have suggested that the molecular structure of benzalaniline is not planar and that the benzene ring of the aniline part is distorted from the plane of the *trans*-benzalamino skeleton, as is shown in Fig. 1; it has

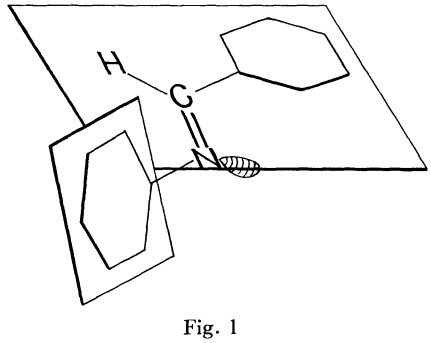

Fig. 1

also been disclosed that the substituent in the benzaldehyde ring has more effect on the electronic structure of azomethine group than that in the aniline part does.[1-7] Although a few papers suggest the above molecular geometry from the point of view of infrared spectral studies, there has been very little work on the nuclear magnetic resonance spectra of aromatic azomethines.

In the present work, the nuclear magnetic resonance spectra of more than twenty kinds of *p*-substituted benzalaniline were newly measured; the characteristic Hammett relation in the NMR and

IR spectra of the azomethine group will be discussed in order to clarify the molecular geometry.

Experimental

Materials. Twenty-nine kinds of benzalaniline were prepared by the usual condensation reaction either from aniline and *p*-substituted benzaldehydes or from *p*-substituted anilines and benzaldehyde.[8,9] The crystalline compounds were purified by repeated recrystallization from methanol or ethanol, but *N*-(*p*-methylbenzal)-aniline, *N*-benzal-*p*-toluidine, and ethyl *p*-(*N*-benzalamino)-benzoate were distilled under reduced pressure. The purity of the products was checked by thin-layer chromatography.

Nuclear Magnetic Resonance Spectra. The NMR spectra of the above compounds were measured by using a JNM-4H-100 NMR spectrometer in a deuteriochloroform solution at a 0.2—0.5 mol/*l* concentration. The spectra of the hydroxyl, carboxyl, and sulfonamido derivatives, however, could not be measured, since the compounds are not satisfactorily soluble in deuteriochloroform.

Infrared Spectra. The IR spectra of the above benzalanilines were also measured by using a JASCO DS-301 infrared spectrophotometer in a carbon tetrachloride or chloroform solution and in a disk of potassium bromide. The spectra of *p*-(*N*-benzalamino)-benzoic acid and *p*-(*N*-benzalamino)-benzenesulfonamide were not measured in the solution because of their poor solubility in the above solvents.

The τ values and the wave numbers so measured are listed in Table 1, together with the physical constants.

Results and Discussion

***N*-(*p*-Substituted-benzal)-anilines (Type-A compounds).** The NMR proton signals of the azomethine group of the *N*-(*p*-substituted-benzal)-anilines appear in the region of 1.46 τ (*p*-nitrobenzalaniline)- 1.73 τ (*p*-*N,N*-dimethylaminobenzalaniline) as a singlet peak; the introduction of an electron-donating or of an electron-withdrawing group into the para position of the benzaldehyde ring of a type-A compound brings about a small shift of the signal to a higher or to a lower field respectively.

The plot of the τ values against Hammett's σ_p constant (Fig. 2) shows a characteristic Hammett relationship between the chemical shift of an azomethine proton signal and the electronic effect of a substituent in type-A compounds.

The present NMR data permit only a qualitative discussion; however, it seems reasonable that the chemical shift of an azomethine proton signal is

8) L. Gattermann, "Die Praxis des Organischen Chemikers," 40 Aufl., 150 (1961).
9) H. Gilman, "Organic Syntheses," Coll. Vol. I, p. 80 (1956).

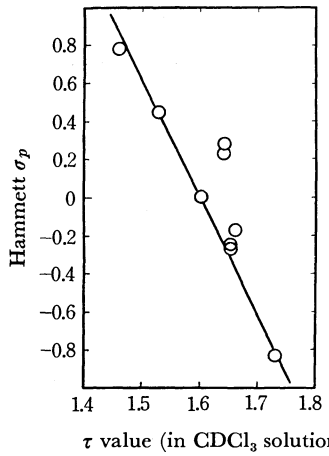

Fig. 2. τ value of azomethine proton *vs.* Hammett's σ_p in type A compounds.

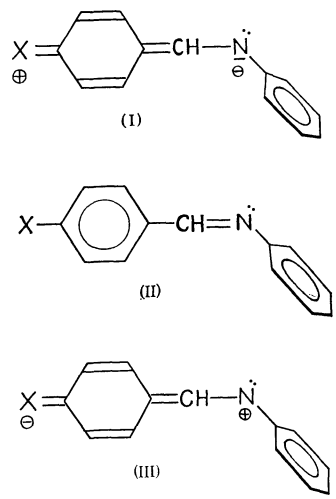
mainly determined by the change in the electron density on the carbon atom in the azomethine double bond, supposing that the magnetic anisotropy of a substituent can be neglected as in the case of styrene and phenylacetylene derivatives.[10,11]

Consequently, the present chemical shift of the azomethine proton signal can be understood by taking the following resonance structures (I)—(III) into account; since an increase in the contribution of the polar structure (I) to the ground state (II) makes for an increase in the electron density of the azomethine carbon as well as in that of nitrogen,[12] the introduction of an electron-donating group to the para position of the benzaldehyde ring makes for a small shift of the azomethine proton signal to the higher-field side. The substituent effect of an electron-withdrawing group corresponding to the increase in the contribution of the polar structure (III), on the other hand, decreases the electron density at the azomethine group and, therefore, makes for a small shift of the signal to the lower-field side.



From the above discussion, it can also be expected that an increase in the contribution of either polar structure will bring about a decrease in the carbon-nitrogen bond order of the azomethine group. Previous infrared studies have not satisfactorily treated the substitution effect upon the change in the C=N bond order; therefore, the C=N stretching frequency of many kinds of type-A compounds were also measured.

When an electron-donating or electron-withdrawing group is introduced into the para position of the benzaldehyde ring, the C=N stretching band of benzalaniline, 1635 cm^{-1} in a CCl_4 solution and 1629 cm^{-1} in a KBr disk, is, as expected, shifted more or less to the longer wavelength side. The present characteristic trend is confirmed by plotting the $\nu_{C=N}$ against the Hammett's σ_p constant, as is shown in Fig. 3. The relationship obtained can also safely be explained by taking the polar structures (I) and (III) into consideration, as has been mentioned previously.

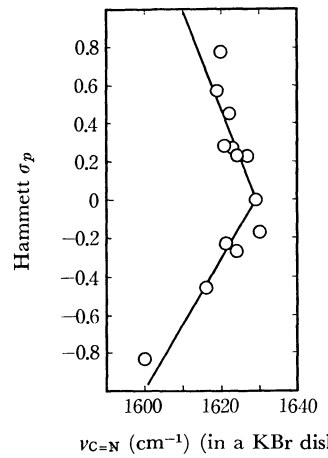


Fig. 3. $\nu_{C=N}$ *vs.* Hammett's σ_p constant in type A compounds.

***p*-Substituted *N*-benzalanilines (Type-B Compounds).** The preceding discussion does not take the effect of the aniline part into account, since the aniline ring may be distorted from the plane of the benzalamino skeleton. In order to substantiate the above description, the NMR and IR spectra of *p*-substituted *N*-benzalanilines were also studied. It was revealed that the proton signal and the C=N stretching band of the azomethine group of type-B

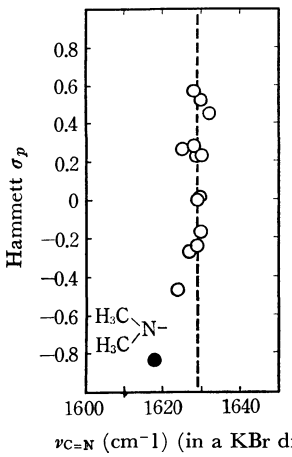

Fig. 5. $\nu_{C=N}$ *vs.* Hammett's σ_p constant in type B compounds.

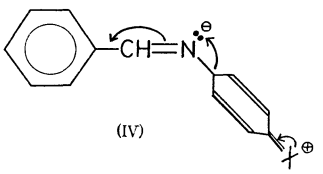
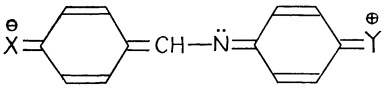
compounds appear within a narrower range than those of type-A compounds do. That is, a substituent in the para position of the aniline ring can not exert any appreciable electronic effect upon the azomethine group, and the Hammett relation is not obtained, as is depicted in Figs. 4 and 5. The present results can reasonably be understood by accepting the previous non-planar structure for the benzalaniline molecule in which an aniline ring can not conjugate with a benzalamino π system.

A strong electron-donating group such as *N,N*-dimethylamino, however, shifts the proton signal considerably to the lower-field side, and at the same time shifts the C=N stretching band to the longer wavelength side. The above rather exceptional shift found in the dimethylamino derivative can be understood by considering the electron-repelling effect of the electron-rich azomethine nitrogen atom. Since an electron is concentrated on one of the sp^2 lobes, the lone-pair lobe, from the dimethylaminophenyl group, the electron-rich azomethine nitrogen atom can repel its π-electron to the benzaldehyde part inductively, as in the structure (IV), and can, therefore, increase the electron density at the azomethine carbon and at the same time decrease the bond order of the azomethine bond.



(IV)



(V)

If an electron can transfer from an aniline part to a benzaldehyde one conjugatively, as is shown in the planar structure (V), the azomethine proton signal and the C=N stretching band of *N*-(*p*-nitrobenzal)-*N'*,*N'*-dimethyl-*p*-phenylenediamine can be expected to appear in a far lower-field side and in a far longer wavelength region than those of other benzalanilines. The observed values, however, are 1.42 τ in the $CDCl_3$ solution, 1629 cm^{-1} in the $CHCl_3$ solution, and 1619 cm^{-1} in the KBr disk. The present shifts are merely larger than those of *p*-nitrobenzalaniline; 1.46 τ in the $CDCl_3$ solution, 1630 cm^{-1} in the $CHCl_3$ solution, and 1621 cm^{-1} in the KBr disk.

The above results suggest that dimethylamino, a strong electron-donating group, in the para position of the aniline ring can not conjugate directly with the nitro group through the benzalaniline skeleton and that it can not greatly change the electron density and bond order of the azomethine bond. Thus, the non-planar structure of benzalaniline, the so-called Brocktehurt model, is also supported with respect to the Hammett relationship in NMR and IR spectra.

The authors wish to express their deep thanks to Mr. Toshio Ono and Mrs. Moriharu Nagase of the Tokyo College of Pharmacy for their helpful measurements of the NMR and IR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1444—1446 (1969)

Studies on 6-Bromo-2-mercapto-3-substituted 4-(3*H*)-Quinazolinones

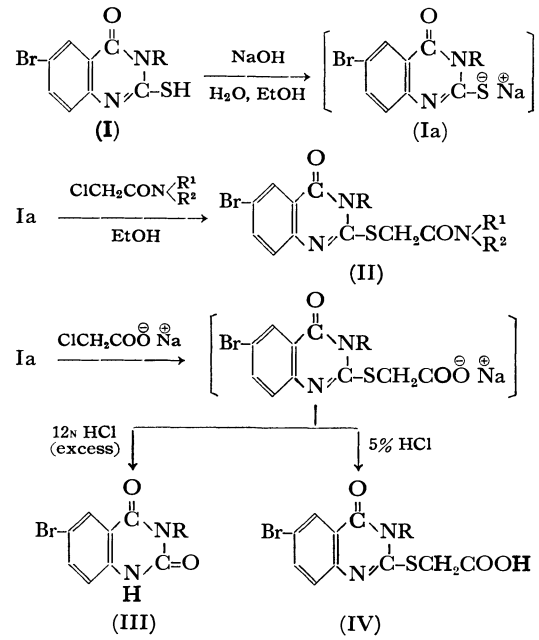
P. N. Bhargava and R. Lakhan

The Chemistry Department, Faculty of Science, Banaras Hindu University, Varanasi-5, India

(Received July 26, 1968)

In continuation of our earlier work on heterocyclic sulphur compounds of interest as antimalarials and ataractic agents,[1] we have extended the alkylation of the sodium salts of 6-bromo-2-mercapto-3-aryl(or alkyl)-4(3*H*)-quinazolinones in alcoholic alkali solution with typical halogen compounds (prepared by the interaction of chloroacetyl chloride and secondary amines in benzene) and also with monochloroacetic acid.

In the present communication, for example, when 6-bromo-2-mercapto-3-substituted 4(3*H*)-quinazolinone (I) was treated with aqueous alcoholic alkali, the sodium salt (Ia) was formed (soluble in aqueous ethanol) which without isolation was converted to the *S*-substituted derivative (II) by reaction with *N,N*-disubstituted chloroacetamides as shown in the reaction scheme.



An interesting point was observed when the sodium salt (Ia) was treated in cold with sodium monochloroacetate and the precipitate obtained was kept in contact with excess of concentrated hydrochloric acid. The product was then found to be the corresponding 2-hydroxyquinazolinone (III) and not the expected 2-carboxymethylthio derivative (IV). The structure of the 2,4-diketo derivative (III) was confirmed by preparing it from 5-bromoanthranilic acid and the corresponding urea.[2]

However, the 2-carboxymethylthio derivative (IV) was obtained by a modified procedure. The solution of the sodium salt (Ia) on treatment with sodium monochloroacetate and subsequent acidification with 5% hydrochloric acid gave the desired product (IV).

Experimental

6-Bromo-2-mercapto-3-substituted 4-(3*H*)-Quinazolinones (I). These were prepared by the condensation of 5-bromoanthranilic acid and various isothiocyanates as described earlier.[1]

6-Bromo-2-(*N,N*-diethylcarbamoyl)methylthio-3-phenyl-4-(3*H*)-quinazolinone (II). 6-Bromo-2-mercapto-3-phenyl-4-(3*H*)-quinazolinone (I,R = C_6H_5 6.66 g) was dissolved in minimum amount of 10% sodium hydroxide solution (prepared in 50% ethanol). The solution was filtered and treated with 3.3 g of *N,N*-diethylchloroacetamide dissolved in 10 m*l* of ethanol. The reaction mixture was stirred at room temperature for about 4 hr when a precipitate was obtained. It was filtered, washed with water, ethanol and recrystallized from ethanol into colourless crystals.

Following the same procedure other 6-bromo-2-(*N,N*-disubstituted carbamoyl)methylthio-3-substituted 4-(3*H*)-quinazolinones have been prepared. Their yields, melting points and analytical data are recorded in Tables 1—4.

6-Bromo-3-phenyl-2,4-(1*H*, 3*H*)-quinazolindione (III). 6-Bromo-2-mercapto-3-phenyl-4-(3*H*)-quinazolinone (0.01 mol) was dissolved in 2.1 equivalents of 1N sodium hydroxide solution (in 50% ethanol) and the resulting solution was treated in cold with monochloroacetic acid (0.011 mol). The reaction mixture was stirred for 4—6 hr when a precipitate was obtained. It was filtered and the residue was kept in contact with excess of 12N hydrochloric acid at room temperature for 2 hr. The reaction mixture was then filtered and washed several times with water to remove the acid and dried. It was crystallized from acetone-ethanol mixture (1 : 1) into colourless needles to give 68% yield of 6-bromo-3-phenyl-2,4-(1*H*,3*H*)-quinazolindione.

Liquid-phase Selective Hydrogenation of an Aliphatic α,β-Unsaturated Aldehyde over Raney Cobalt Catalyst Modified with Ferrous Chloride

Kazuhiko HOTTA and Teruo KUBOMATSU

The Osaka Municipal Technical Research Institute, Kita-ku, Osaka

(Received August 10, 1968)

It is comparatively difficult to hydrogenate selectively an α,β-unsaturated aldehyde to an unsaturated alcohol by heterogeneous catalytic reaction. This hydrogenation can, however, be performed over the noble metal catalysts or over less active catalysts under severe conditions.[1-6] Hydrogenation under mild conditions, however, was not successful over Raney-type catalysts, except over the Raney zinc and the Raney zinc-copper catalysts.[7,8]

The present authors have studied the selectivities of Raney-type catalysts modified with various compounds. It has been found that no unsaturated alcohols can be obtained by the hydrogenation of such unsaturated aldehydes as 2-methyl-2-pentenal and cinnamaldehyde over the Raney nickel catalyst, and that the addition of such modifiers as ferrous chloride, cadmium chloride, cobalt chloride, and citric acid was not effective in producing unsaturated alcohols.[9]

On the other hand, it is interesting that unsaturated alcohols was obtained over the Raney *cobalt* catalyst under the normal hydrogen pressure at 55°C, and that the addition of ferrous chloride to the reaction mixture increased the yield of the unsaturated alcohol.

Experimental

A commercial Raney cobalt-aluminum alloy (Co: 50 wt%) was developed with a 15 % sodium hydroxide solution at 50°C, and the resulting catalyst was washed with water and then with 2-propanol. The catalyst thus prepared was stirred with ferrous chloride in 2-propanol under a hydrogen atmosphere, then the substrate was added to the solution and the mixture was stirred with a magnetic stirrer under the normal pressure of hydrogen at 55°C. 2-Methyl-2-pentenal, used as the substrate, was prepared from propionaldehyde; its purity was indicated to be more than 99% by gas chromatography. The reaction products were analyzed by gas chromatography. The amount of hydrogen adsorbed on the catalyst was estimated by methods described previously.[10,11]

Results and Discussion

The selectivity of the catalyst, which is defined as the mole percent of the unsaturated alcohol in all the products, depended on the temperature at which the development of the Raney cobalt alloy was carried out. The best selectivity was obtained with the catalyst developed at 50°C, so this catalyst was used for this hydrogenation.

The hydrogenation of 2-methyl-2-pentenal (UD) is shown in Fig. 2. 2-Methyl-2-pentene-1-ol (UA) was obtained as the main product. The rate of

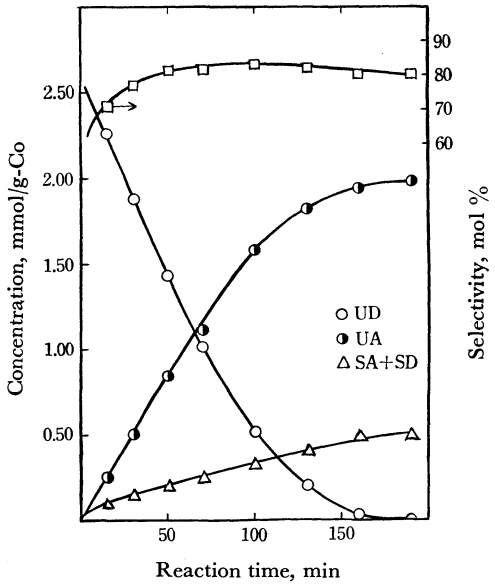

Fig. 2. Hydrogenation of 2-methyl-2-pentenal. Catalyst: 1.0 g cobalt, solvent: 2-propanol 5 m*l*, concentration of substrate: 2.60 mmol/g-Co, amount of ferrous chloride added : 0.18 mmol/g-Co.

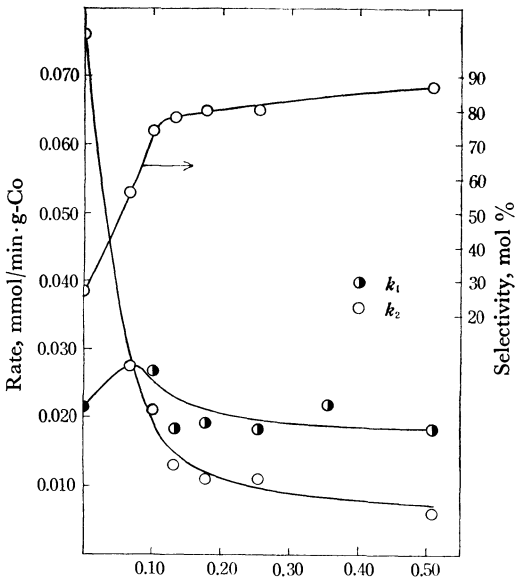

Fig. 3. Dependence of selectivity and initial rate on amount of ferrous chloride added. Catalyst: 1.0 g cobalt, solvent: 2-propanol 5 m*l*, concentration of substrate: 2.60 mmol/g-Co.

the production of UA was constant during the first period of the reaction, and the total rate of the production of the saturated compounds, 2-methylpentan-1-ol (SA) and 2-methylpentanal (SD), which were obtained as the by-products, decreased gradually. A similar situation was observed when ferrous chloride of less than 0.36 mmol/g-Co was added. The rate of the production of UA showed a progressive decrease in the course of the reaction when more than 0.51 mmol/g-Co of ferrous chloride was added.

Each hydrogenation step is supposed to be irreversible, judging from the fact that the dehydrogenation of the produced alcohols did not occur under these conditions. The isomerization of UA to SD almost did not occur at all and SD was consumed preferentially on the hydrogenation of a mixture of UA and SD. Judging from the facts mentioned above, the produced SD is readily hydrogenated to SA and the produced UA does not react further; thus, most of the SA is supposed to be produced through SD.

The yield of UA increased with an increase in the amount of ferrous chloride added, as is shown in Fig. 3. It is also shown in Fig. 3 that the rate of the hydrogenation of the carbon-carbon double bond (C=C), k_2, decreased remarkably, and that the rate of the hydrogenation of the aldehyde group, k_1, decreased only slightly, with an increase in the amount of ferrous chloride added. Thus the promotion of the selectivity of the catalyst in the hydrogenation of the unsaturated aldehyde seems to be caused by the decrease in the rate of the hydrogenation of the carbon-carbon double bond.

It was found that the color of the reaction solution changed to the blue of the cobalt(II) ion when it was stirred for about 5 min. This indicates that the cobalt of the catalyst was substituted rapidly by the iron when ferrous chloride was added. A part of the remaining ferrous chloride might be adsorbed on the catalyst surface and might react further with the Raney cobalt catalyst, judging from the fact that the concentration of ferrous chloride decreased gradually during the last period of the reaction.

It has been found that there are two types of hydrogen on the Raney nickel catalyst.[10,11] One of these is the hydrogen adsorbed weakly on the catalyst, and the other is the strongly-adsorbed hydrogen, the amount of which is termed the hydrogen content of the catalyst. These two types of adsorbed hydrogen were also found on the Raney cobalt cotalyst. The weakly-adsorbed hydrogen decreased to 40% of the original value, and the hydrogen content of the catalyst decreased to 8%, when 0.18 mmol/g-Co of ferrous chloride was added.

It seems that the selective hydrogenation could be carried out because the addition of ferrous chloride to the reaction mixture decreased the amount of the strongly-adsorbed hydrogen more than that of the weakly-adsorbed hydrogen, and thus the decrease in the rate of hydrogenation

became much greater for the carbon-carbon double bond than for the aldehyde group, assuming that the carbon-carbon double bond reactes more readily with the strongly-adsorbed hydrogen than with the weakly-adsorbed hydrogen, as has been reported by Takeuchi and Asano.[12)]

A more detailed discussion will be reserved until the results of experiments now in progress are available.

The Cerimetric Determination of Hypophosphite after Oxidation with Iron(III)

Kin'ya OGAWA

Hitachi Research Laboratory, Hitachi, Ltd., Kuji-machi, Hitachi, Ibaraki

(Received August 28, 1968)

Because hypophosphite has come to have a number of commercial applications as a reducing agent, and because phosphite is frequently an intermediate product in the oxidation of hypophosphite, it is desirable to establish an analytical procedure for the determination of hypophosphite in the presence of phosphite. For this purpose, volumetric methods with iodometric or cerimetric procedures have been described by Jones and Swift,[1] Bernhart,[2] and Rao and Rao.[3] These procedures, however, are all inapplicable to rapid analyses because of their complexity and difficulty. On the other hand, Sastri and Radhákrishnamurthi[4] found that an excess of hypophosphite reduces iron(III) quantitatively in hydrochloric acid solutions upon boiling:

$$H_3PO_2 + 2Fe^{3+} + H_2O \rightarrow H_3PO_3 + 2Fe^{2+} + 2H^+ \quad (1)$$

Sastri and Kalidas[5] later applied this reaction to the determination of hypophosphite in the presence of phosphite; their procedure consisted of boiling, for 20 min, hypophosphite with approximately twice as much iron(III) as was required for the stoichiometric reaction in a 1.0-to-2.0N hydrochloric acid medium and of titrating the iron(II) thus formed with a standard solution of cerium(IV) sulfate. This Sastri-Kalidas procedure has the advantages of simplicity and rapidity, for it requires only one standard solution which is very stable. However, it has been observed in preliminary experiments that the reaction does not reach quantitative completion, even when the Sastri-Kalidas procedure is followed completely. In this paper, therefore, the reaction between hypophosphite and iron(III) at the boiling temperature is re-examined, and the applicability of this reaction to the determination of hypophosphite in the presence of phosphite is discussed.

Experimental

Reagents. All the chemicals were of a reagent grade. The standard solutions of hypophosphite and phosphite were prepared by dissolving monosodium hypophosphite monohydrate and disodium phosphite pentahydrate respectively in distilled water. The concentrations of these solutions were determined by the Rao-Rao procedure.[3] A standard solution of cerium(IV) sulfate was prepared and standardized by the conventional method. A solution of iron(III) was prepared by dissolving ammonium iron(III) sulfate in distilled water. For the detection of the end point of titration, one drop of a 0.025M ferroin indicater solution was used.

Procedure. A solution containing hypophosphite alone or both hypophosphite and diverse salts was transferred to a 300-m*l* flask equipped with a reflux cooler. The calculated volumes of the iron(III) solution and of the hydrochloric acid were added, and then the whole was diluted to about 100 m*l*. The resulting solution was boiled on an electric heater for the required time. After cooling, the solution was titrated with the standard solution of cerium(IV) sulfate to the blue-yellow end point of the ferroin indicator.

Results and Discussion

Conditions for the Determination of Hypophosphite. The effects of the mole ratio of iron(III) to hypophosphite on the oxidation of hypo-

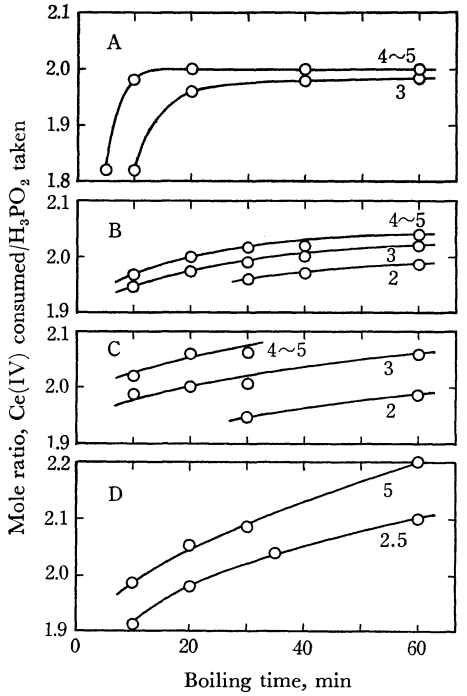

Fig. 1. Oxidation of 0.25 mmol of hypophosphite in (A) 1.6, (B) 1.2, (C) 0.8 and (D) 0.4N hydrochloric acid solutions. Numericals on curves represent amounts of iron(III) added in mmol.

phosphite at the boiling temperature were observed at different concentrations of hydrochloric acid; the results are shown in Fig. 1. When a hydrochloric acid concentration between 0.4 and 1.2N is selected, the oxidation of hypophosphite is greatly affected by the boiling time; if the solution is boiled to excess, some hypophosphites may be oxidized beyond phosphite to phosphate, while if boiling is insufficient, the oxidation to phosphite does not reach quantitative completion. In a 1.6N hydrochloric acid medium, however, 0.25 mmol of hypophosphite can be quantitatively oxidized to phosphite, without being oxidized to phosphate, with 5 mmol of iron(III) by boiling it for at least 20 min.

For the determination of hypophosphite, therefore, approximately ten times as much iron(III) as the amount required for the stoichiometric reaction was added, the final acidity was adjusted with hydrochloric acid to approximately 1.6N, and the mixture was boiled for about 20 min.

The Effects of Phosphate, Acetate, and Citrate on the Determination of Hypophosphite. Sample solutions containing about 0.2 mmol of hypophosphite and from 0.1 to 2 mmol of phosphite, acetate, or citrate were analyzed by the proposed procedure. The data in Tables 1 and 2 show an accuracy and precision of better than one percent in the presence of these anions.

The author wishes to express his deep gratitude to Dr. Takeshi Nakatogawa and Dr. Natsuki Kawashima of the Hitachi Rasearch Laboratory, Hitachi, Ltd., for thoir guidance and ercouragement throughout this work.

Catalytic Hydrogenation of 1,3-Diphenylpropane-1,2-dione and 2-Hydroxy-1,3-diphenylpropan-1-one

Akiko SOHMA*1 and Sekio MITSUI

Department of Applied Science, Faculty of Engineering, Tohoku University, Aoba, Sendai

(Received September 14, 1968)

In the catalytic hydrogenation of 1,3-diphenylpropane-1,2-dione (I) and 1-hydroxy-1,3-diphenylpropan-2-one (II), 1,3-diphenylpropane-1,2-diol (III), mp 65—66°C, was produced by Ruggli and Lutz.[1] Bonner and Raunio[2] considered that the diol must have been *threo*-III, and they speculated that, if I is absorbed on the catalyst surface in such a way as to orient the two polar carbonyl functions and the bulky phenyl and benzyl groups as far apart as possible, the *cis* hydrogenation of the two carbonyl groups would lead to *threo*-III. In the case of the catalytic hydrogenation of benzalacetophenone oxide (IV) over palladium-charcoal containing a small amount of sodium hydroxide, IV was isomerized to the diketone I prior to reduction. The initial main product was II, whose hydrogenation gave *erythro*-III, although it proceeded with great difficulty.

In connection with the stereochemistry of the molecules when absorbed on the catalyst surface, we have undertaken a study of the catalytic hydrogenation of 1,3-diphenylpropane-1,2-dione (I) and 2-hydroxy-1,3-diphenylpropan-1-one (V) in ethanol at an ordinary temperature and at atmospheric pressure. The reduction products were analyzed by gas chromatography and by thin-layer chromatography. The authentic samples, *erythro*- and *threo*-III, were synthesized by the procedure of Bonner and Raunio.[2]

In the catalytic hydrogenation of I over palladium-charcoal, it was found by thin-layer chromatography that two isomeric hydroxy ketones, II and V, were the primary products, in further reduction yielded 1,2-diols, but II, which was not the phenyl ketone, was not hydrogenated under our conditions. In the catalytic hydrogenation of I over palladium-charcoal containing a small amount of sodium hydroxide, II was the main product and the reduction of it did not proceed further. In the catalytic hydrogenation of I over Raney nickel and platinum oxide, the two isomeric ketones, II and V, were produced in almost equal amounts as the primary products, as analyzed by thin-layer chromatography, the 1,2-diols which were rich in the *erythro* form were further products.

The catalytic hydrogenation of V over palladium charcoal, Raney nickel, or platinum oxide, or catalysts containing a small amount of sodium hydroxide, yielded mainly *erythro*-III, which was also the main product of the catalytic hydrogenation of II.

Our results show that the catalytic hydrogenation would not proceed directly in the I→III fashion, so that the isomeric ratio of the 1,2-diols (*erythro*-III *vs.* *threo*-III) must reflect the stereochemistry of the hydroxy ketones, the primarily-desorbed products, on the catalyst surface. As there are many factors which control the orientation, we are now investigating them.

Experimental

1,3-Diphenylpropane-1,2-dione (I). I was prepared by the method of Kohler[3] by the isomerization of benzalacetophenone oxide; bp 132—138°C/1 mmHg, 40% yield.

1,3-Diphenylpropane-1,2-diol (III). *threo*-III was synthesized by the method of Bonner *et al.*[2] by the *cis* hydroxylation of *trans*-1,3-diphenylpropane[4]; mp 62°C, 80% yield, *erythro*-III was prepared by the catalytic hydrogenation of benzalacetophenone oxide

(IV) over palladium-charcoal; mp 82°C, 62% yield.

2-Hydroxy-1,3-diphenylpropan-1-one (V). V was prepared by the catalytic hydrogenation of benzalacetophenone oxide (IV). IV, palladium-charcoal, and ethanol were stirred with hydrogen at an ordinary temperature and at atmospheric pressure. After one mole of hydrogen had been absorbed, the catalyst was filtered and the product (V) was recrystallized from petroleum benzine containing a small amount of benzene; mp 66°C, 50% yield.

Catalytic Hydrogenation of I or V. I or V (450 mg), the catalyst, and 30 m*l* of ethanol were stirred with hydrogen at an ordinary temperature and at atmospheric pressure. After the hydrogenation was over, the catalyst the filtered, the products were acetylated with acetic anhydride in pyridine, and the acetyl derivatives were analyzed by vapor-phase chromatography. In the course of hydrogenation, the partial reduction products were analyzed by thin-layer chromatography. The results are summarized in Table 1.

Die Absolutkonfiguration des (−)-Isosakuranetins

Hisao ARAKAWA und Yukio MASUI

Science Education Institute of Osaka Prefecture, Karita-cho, Sumiyoshi-ku, Osaka

(Eingegangen am 18. September, 1968)

In der letzten Mitteilung[1] ist die Absolutkonfiguration der optisch aktiven Flavanone, (−)-Hesperetin(III), (−)-Liquiritigenin(IV) und (+)-Sakuranetin(I), bestimmt worden. Als die Flavanone wurden die Aglykone der schwer löslichen, durch fraktioniertes Umkristallisieren erhaltenen Glykoside benutzt.[2]

In dem vorliegenden Bericht sind die Bestimmung der Absolutkonfiguration des als optisch aktives Flavanon bekannten Isosakuranetins, das durch säure Hydrolyse von Poncirin zu gewinnen ist,[3]

2) S. Hishida, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **79**, 709 (1958).

3) S. Hattori, M. Hasegawa und M. Shimokoriyama, *ibid.*, **65**, 61 (1944).

thanol) übergeführt. Aus dem Ester wurde mit Hydrazinhydrat in Äthanol L-(−)-Äpfelsäure-dihydrazid von $[\alpha]_D^{25}=-51.3°$ (50-proz. Äthanol), Schmp. 173–174.5°C erhalten. Das Dihydrazid wurde durch $[\alpha]_D$, Misch-Schmelzpunkt und IR-Spektrum identifiziert.

Damit ist (−)-Isosakuranetin als (2S)-konfiguriert (II) bestimmt worden. Diese Tatsache zeigt, dass, wie der Verfasser schon annahm[1], alle (−)-Flavanone (S)-Konfiguration haben müssen. Das CD der (S)-(−)-Flavanone (II, III, IV) in Methanol zeigte bei 330 mμ einen positiven Cotton-Effekt und bei 280—303 mμ einen negativen Cotton-Effekt. Das CD des (+)-Sakuranetins (I) in Methanol zeigte umgekehrtes Vorzeichen. Diese Tatsache stimmt mit Gaffields u.a.[4] Kenntnissen von ORD des (+)-Naringenins überein.

Beschreibung der Versuche*1

Isolierung des Isosakuranetins. Aus 6 kg frischen Blütenblättern von *Poncinustri foliata* Refinesque wurden 4.1 g Poncirin von Schmp. 208—209°C isoliert.[3] Die erhaltene Kristalle wurden mit 1 ccm konz. Schwefelsäure/500 ccm Methanol verseift.[1,2] Man erhielt 1.9 g Isosakuranetin von Schmp. 174—175°C, $[\alpha]_D^{26}=-25.0°$ (*c* 2.2, in Äthanol).

Gef.: C, 63.08; H, 5.34%. Ber. für $C_{16}H_{14}O_5\cdot H_2O$: C, 63.05; H, 5.30%.

L-Äpfelsäuredihydrazid aus (−)-Isosakuranetin. Durch eine Lösung von 1.3 g (−)-Isosakuranetin von $[\alpha]_D=-25.0°$ in 35 ccm 95-proz. Methanol wurde bei Zimmertemperatur 3-proz. Ozon enthaltender Sauerstoff geleitet. Nach 10 Stdn. wurde das Losungsmittel fast abgedampft. Dann versetzte man mit 90-proz. Essigsäure und liess nochmals Ozon durchströmen. Nach insgesamt 28 Stdn. wurde die Lösung farblos. Man setzte 3 ccm 30-proz. Perhydrol zu und behandelte dann mit Palladium/Kohle, Calciumacetat und Ionenaustauscher.[5,6] Die so von Peressigsäure und Oxalsäure befreite wässerige Lösung wurde i. Vak. eingedampft, der Rückstand in 50 ccm Wasser gelöst und mit Äther kontinuierlich extrahiert. Durch Verdampfen des Lösungsmittels wurde ein Sirup erhalten. Verestern mit Diazomethan und Gaschromatographieren an Bernsteinsäureglykolester lieferte 40 mg L-Äpfelsäuredimethylester von $[\alpha]_D^{20}=-5.75°$ (*c* 0.957, Methanol). 30 mg Methylester wurde mit 150 mg Hydrazinhydrat in 2.5 ccm Äthanol 1 Std. gekocht. Nach dem Erkalten wurde Nadeln erhalten. Umkristallisieren aus Äthanol-Wasser lieferte farblose Nadeln vom Schmp. 173—174.5°, $[\alpha]_D^{25}=-51.3°$ (*c* 0.95, in 50-proz. Äthanol). Der Misch-Schmp. mit authentischem L-Äpfelsäuredihydrazid vom Schmp. 177—179°, $[\alpha]_D^{25}=-52.0°$ (*c* 1.50, in 50-proz. Äthanol) zeigte keine Depression. Beide IR-Spektren sind praktisch ganz identisch.

Gef.: C, 29.95; H, 6.25; N, 33.85%. Ber. für $C_4H_{10}O_3N_4$: C, 29.63; H, 6.22; N, 34.56%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1453—1454 (1969)

A New Synthesis of Tris(triphenylsilyl) Vanadate

Shizen SEKIGUCHI and Akira KURIHARA

Department of Chemistry, Gunma University, Kiryu, Gunma

(Received September 20, 1968)

In 1958 Orlov *et al.*[1] reported the preparation of tris(triphenylsilyl) vanadate (III) by the reaction of tri-*n*-butyl vanadate and triphenylsilanol.

Chamberlain *et al.*[2] later reported the preparation of the title compound by the reaction of triphenylsilanol and vanadium oxytrichloride in the presence of ammonia.

The present authors have now found that the title compound can be synthesized by transesterification between triphenylacetoxysilane (I) and triisopropyl vanadate (II):

$$\underset{\text{I}}{3CH_3COOSiPh_3} + \underset{\text{II}}{OV\{OCH(CH_3)_2\}_3} \rightleftarrows \underset{\text{III}}{OV(OSiPh_3)_3} + 3CH_3COOCH(CH_3)_2 \quad (1)$$

As part of our work on the preparation of metal alkoxides as polymerization catalysts, we will report

1) N. F. Orlov, B. N. Dolgov and M. G. Voronkov, *Doklady Akad. Nauk S. S. S. R.*, **122**, 246 (1958).

2) M. M. Chamberlain, G. A. Jobs and B. B. Wayland, *J. Org. Chem.*, **27**, 3321(1962).

on this new synthesis of this compound.

Experimental

Preparation of Triphenylacetoxysilane (I). Triphenylacetoxysilane was prepared by the reaction of triphenylchlorosilane and acetic anhydride.[3]

In a typical experiment, 20.0 g (0.067 mol) of triphenylchlorosilane was added to 34.2 g (0.335 mol) of acetic anhydride. After the triphenylchlorosilane had been dissolved in acetic anhydride upon heating, the mixture was refluxed for 4 hrs, then it was concentrated by distilling the excess acetic anhydride and allowed to stand at about −20°C in a dry ice-acetone bath. The crude product was precipitated, filtered, washed with cooled ether, and recrystallized from dry ether; mp 96—97°C (lit.[3] mp 97°C) The yield was 17.2 g (79%) based upon the triphenylchlorosilane.

Preparation of Triisopropyl Vanadate (II). The vanadate was prepared from 30.0 g of commercial ammonium metavanadate and isopropyl alcohol in a large excess by the procedure described by Cartan and Caughlan,[4] using the following reaction:

$$NH_4VO_3 + 3(CH_3)_2CHOH \rightleftarrows \{(CH_3)_2CHO\}_3VO + NH_3 + 2H_2O \quad (2)$$

The azeotrope was removed as it was formed. After several days, the majority of the excess alcohol was distilled. The contents in the flash were then centrifuged to remove the unreacted solids and the decomposition products. Repeated vacuum distillation gave 32.1 g (51.1%) of II; bp 75°C/2 mmHg and n_D^{25} 1.4782 (lit.[4] n_{15}^{D} 1.478).

Preparation of Tris(triphenylsilyl) Vanadate (III). This vanadate was prepared by Eq. (1). Nine grams (0.028 mol) of I and 2.1 g (0.009 mol) of II were dissolved in 100 m*l* of benzene. The mixture was refluxed for 90 hr and washed with water several times; the benzene layer was then separated and dried over anhydrous sodium sulfate overnight.

The crude product was precipitated, filtered, and recrystallized from benzene. The yield was 3.9 g (51%); mp 223—234°C (lit.[2] mp 225—226°C).

Found: C, 72.83; H, 5.29; V, 5.66; Si, 9.26%. Calcd for $C_{54}H_{45}O_4Si_3V$: C, 72.62; H, 5.08; V, 5.70; Si, 9.43%.

The NMR spectrum (60 Mc, room temperature) of this compound showed only the signals at τ near 2.75 assignable to the protons of the phenyl group and no signal characteristic for the isopropyl group.

The infrared spectrum indicated the characteristic bands of the phenyl group at 3060, 3025 (ν_{C-H}), and 1529 cm^{-1} ($\nu_{C=C}$).

In contrast, no band characteristic of the isopropyl group appeared. The strong absorption bands at 1430 and 1120 cm^{-1} are associated with the Si-phenyl group, while that at 1005 cm^{-1} can be attributed to the vanadyl group (V=O).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1454—1456 (1969)

Synthesis of 4,8-Diaminopyrimido[5,4-*d*]pyrimidine from Hydrogen Cyanide in Liquid Ammonia[1]

Yoshitaka YAMADA, Ichiro NODA, Izumi KUMASHIRO and Tadao TAKENISHI

Central Research Laboratories, Ajinomoto Company, Inc., Kawasaki

(Received September 25, 1968)

In a previous paper,[2] the present authors have reported that adenine and 4,5-dicyanoimidazole are formed by heating anhydrous hydrogen cyanide in excess liquid ammonia. Furthermore, a precise investigation revealed that another product, 4,8-diaminopyrimido[5,4-*d*]pyrimidine (III) is also present in the reaction mixture.

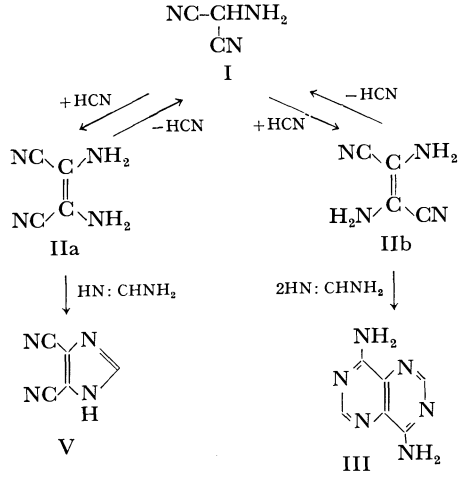
In the present paper, the identification of the compound (III) and some discussions of the course of its formation are presented. The compound (III) was not at all soluble, or only a little so, in dilute hydrochloric acid, aqueous ammonia, and most usual organic solvents. Although III was not extracted directly from the reaction mixture of hydrogen cyanide with liquidammonia, the N^4,N^8-diacetyl derivative (IV) of III was found to dissolve in hot acetic anhydride. IV was easily deacetylated by aqueous ammonia to give the free base. The structure of III was determined by elementary analysis, by a study of its ultraviolet and infrared absorption spectra, and by means of the molecular ion peak of the mass spectrum, while it was identified by comparing it with an authentic sample

1) Presented at the 21st Annual Meeting of Chemical Society of Japan, Osaka, 1968.

2) H. Wakamatsu, Y. Yamada, T. Saito, I. Kumashiro and T. Takenishi, *J. Org. Chem.*, **31**, 2035 (1966).

of 4,8-diaminopyrimido[5,4-*d*]pyrimidine.[3] By acetylation with acetic anhydride, followed by deacetylation with aqueous ammonia, III was isolated in an 11% yield (based on the hydrogen cyanide used).

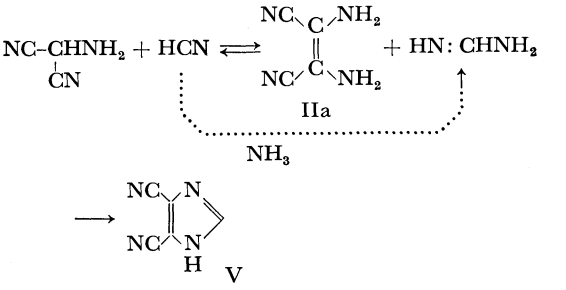
In a previous paper[4] the authors presumed that III would be derived from the postulated trans-isomer of the hydrogen cyanide tetramer, diaminofumaronitrile (IIb).[5] However, when diaminomaleonitrile (IIa) and formamidine acetate were heated in liquid ammonia at 120°C, III was obtained in a 10% yield (based on the IIa). As an interpretation of the formation of III from the cis-tetramer (IIa) in the liquid ammonia system, an equilibrium between aminomalononitrile (I) and both tetramers of hydrogen cyanide, IIa and IIb, may be assumed



In order to demonstrate the existence of an equilibrium between I and the two tetramers, IIa and IIb, the following experiment was carried out.

When a solution of IIa in a large amount of liquid ammonia was heated in a sealed vessel, 4,5-dicyanoimidazole (V) was obtained, together with azulmic acids, but III was not isolated, probably because of its low yield. Therefore, the formation of V from IIa may be attributed to the conversion of IIa into I by dehydrocyanation prior to the cyclization to V. The hydrogen cyanide thus formed would react with ammonia to give formamidine, which may serve as a ring-closing agent.

IIa is usually obtained by the base-catalyzed oligomerization[6] of hydrogen cyanide, or as an



addition product[7] of I with hydrogen cyanide. However, IIb has not been found in these reaction mixtures because of its extreme lability in the presence of an acid or a base, although it has been prepared by the photochemical rearrangement of IIa.[5] Therefore, the effect of an added acid or a base on the formation of III in liquid ammonia was investigated.

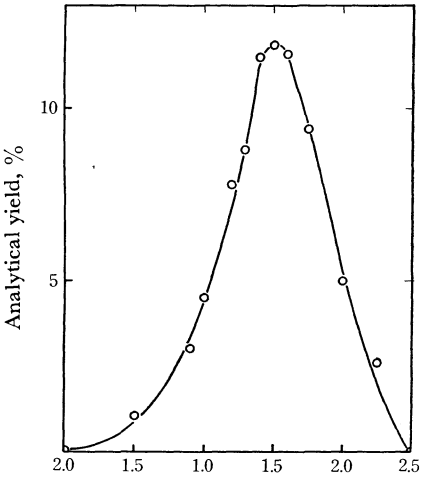


Fig. 1. The formation of III from mixtures of 20 m*l* of liquid ammonia and different amounts of sodium cyanide and ammonium chloride (120°C, 3 hr).

Although IIb is found to be most stable in a neutral medium,[5] a weakly basic region has apparently been observed to be most suitable for the formation of III.

ml (at 20°C) of liquid ammonia was heated at 120°C for 8 hr in a 500-ml stainless-steel pressure vessel. After removing the ammonia and unchanged hydrogen cyanide, adenine and 4,5-dicyanoimidazole were extracted several times with hot dilute aqueous ammonia from the resulting residue. The dry extracted residue was heated under refluxing with acetic anhydride (250 g, 2.45 mol) and filtered while hot. The brown precipitate gradually formed when the filtrate stood. The crude crystals were collected by filtration and recrystallized from acetic anhydride to give 4.55 g (11%) of IV, mp 277—278°C (dec.).

Found: C, 48.75; H, 4.58; N, 34.48%. Calcd for $C_{10}H_{10}N_6O_2$: C, 48.78; H, 4.09; N, 34.14%.

4,8-Diaminopyrimido[5,4-*d*]pyrimidine (III). When IV was, at room temperature, stirred into dilute aqueous ammonia, white crystals were immediately formed. The crystals were filtered and washed with water to give III quantitatively. ν_{max}^{KBr} 3380, 3200, 1665, 1555, 1540, 1440 and 1430 cm^{-1}.

Found: C, 44.25; H, 3.95; N, 51.66%. Calcd for $C_6H_6N_6$: C, 44.44; H, 3.73; N, 51.83%.

Although a detailed study was not made, a reversible hydration phenomenon,[9] which has also been observed in some pteridines, was found from its ultraviolet absorption spectra to occur in III.

The authors wish to express their deep thanks to Dr. Toichi Yoshida, Director of these Laboratories, for his kind encouragement.

Manganic Acetate Oxidation of 2′-Hydroxychalcones

Kazu KUROSAWA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

(Received September 30, 1968)

Although manganic acetate has received less attention than lead tetraacetate, several oxidation reactions of phenols,[1] ketones,[2] aromatic hydrocarbons,[3] and phenyl ethers[4] by a reagent have been reported recently. During my investigation of the oxidation of various organic compounds, it was demonstrated that manganic acetate reacted with 2′-hydroxychalcones in acetic acid to give aurones in fairly good yield. Aurones have so far been prepared either by dehydrobromination of dibromochalcones or by the condensation of 3-benzofuranones with benzaldehydes. This oxidation of 2′-hydroxychalcones gave an alternative way to make aurones.

* Elemental analysis gave a satisfactory agreement with the calculated value.

which was identified with its melting point and IR spectrum (ν_{max} 1700 cm^{-1}, a characteristic carbonyl band of 3-benzofuranone), compared with those of an authentic sample. The resultes are shown in Table 1.

A chalcone having hydroxyl group other than at 2′-position was also subjected to oxidation. However, this resulted in a variety of products, none of which was isolated as a pure crystalline form.

The reaction mechanism could be written similarly to the reaction of lead tetraacetate with phenols. The first step in the reaction is the formation of Ar–O–$Mn(OAc)_2$ group.[17] Homolysis of O–Mn bond gives a radical, Ar–$\dot{O}$, and manganese diacetate as shown in Fig. 2. Heterolysis of the bond is unlikely to occur as manganic acetate is

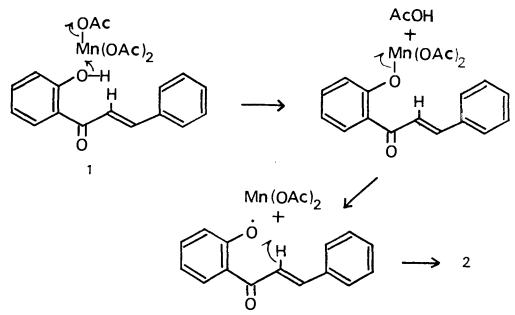

Fig. 2

one electron oxidizing reagent. Then, the radical attacks C–H bonds in suitable spatial position,[18] which is α-hydrogen in this case, to give aurone (2). Further studies on solvent effects and temperature dependence of the reaction are now in progress.

Experimental

Measurements. Melting points were determined with Mitamura Melting Point Measuring Apparatus. The IR spectra were obtained with a Shimadzu IR spectrometer in chloroform.

Chalcones. One equivalent each of 2′-hydroxyacetophenone and benzaldehyde was dissolved in a small volume of ethanol and the solution was treated with 50% aqueous potassium hydroxide with stirring. The mixture was poured into cold dilute hydrochloric acid. The precipitates were collected by filtration and recrystallized from ethanol.

Manganic Acetate. Manganic acetate was prepared according to Dewer's method.[4]

Manganic Acetate Oxidation of Chalcones. A chalcone (1 mmol), dissolved in acetic acid (15 m*l*) was heated with manganic acetate (2 mmol) at 100°C

until a dark solution turned into clear orange. After removal of the acetic acid *in vacuo*, the resulting solid was treated with water (10 m*l*) and then extracted with chloroform (20 m*l*). The chloroform layer was separated from aqueous solution and evaporated. The residue was dissolved in a small amount of chloroform and separated on silica gel plates (Wako gel B, 10 g × 5) with chloroform as an eluant. A yellow band running below the unchanged chalcone was scraped out and extracted with chloroform. The chloroform was distilled off and the crude aurone was recrystallized from ethanol.

The author wishes to thank Professor H. Matsumura of Kumamoto University for his helpful discussions and encouragement throughout the work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1458—1460 (1969)

Effect of the Deuterium Atom Fraction on the Stability Constant of the Main Hydrolysis Product of the Beryllium Ion

Hidetake KAKIHANA and Masunobu MAEDA

Research Laboratory of Nuclear Reactor, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 14, 1968)

It has been confirmed by several investigators that $Be_3(OH)_3^{3+}$ is the main hydrolysis product of the beryllium ion.

The present work was carried out in order to examine the variation in the stability constant of the main hydrolysis species with a variation in the deuterium atom fraction.

First, the composition and the stability constant of the main hydrolysis species were evaluated in 20% and 80% heavy water; next, the variation in the stability constant of the main species with a variation in the deuterium atom fraction(0—0.8) was studied.

Symbols

B total concentration of beryllium
L total excess concentration of lyonium ions*
l total concentration of free lyonium ions
Z average number of lyonium ions split off per beryllium
$\bar{p}$ and $\bar{q}$ average number of OL groups and beryllium atoms respectively in hydrolyzed species
$\beta_{3,3}$ stability constant of the following reaction:

$$3\,Be^{2+} + 3\,L_2O = Be_3(OL)_3^{3+} + 3\,L^+$$

* Besides, L will be used throughout to mean both H and D.

Experimental

All the reagents used were prepared and analyzed by procedures similar to those described in Ref. 1 and Ref. 2.

Heavy water was redistilled from an alkaline permanganate solution.

A Wilhelm-type half cell[3] was used for the emf measurements.

Glass electrodes of the Beckman type No. 40498 were used in combination with **a Radiometer PHM-4C(Copenhagen)**.

Silver - silver chloride electrodes were used as references.

Procedures. The hydrolysis was investigated by measurements of the total concentration of free lyonium ions using a glass electrode. $NaClO_4$ was added to all the test solutions so that they contained 3M ClO_4^-. The lyonium ion concentration was measured by the use of the cell assembly described in Ref. 3.

It was proved experimentally that the emf of the cell could be denoted as follows:

$$E = E_0 + 59.15 \log l + E_j \text{ (at 25°C)} \qquad (1)$$

where E_0 is a constant, and E_j a liquid junction potential, which was found to be approximated by $E_j = -13\,l$ for the system of 20% heavy water and by $-8\,l$ for the system of 80% heavy water.

In the present work, two kinds of experiments were carried out.

The first were "constant B titrations," the experimental details of which were similar to those presented in Ref. 1.

The second were "constant B and Z titrations," where B was maintained at 20 mM and 40 mM and where Z was adjusted to around 0.5, while only the deuterium atom fraction was varied from 0 to 0.8.

All the measurements were made in a paraffin-oil thermostat kept at 25.00±0.01°C in a room kept by a thermostat at 25±1°C.

Results and Discussion

(1) The Composition and the Stability

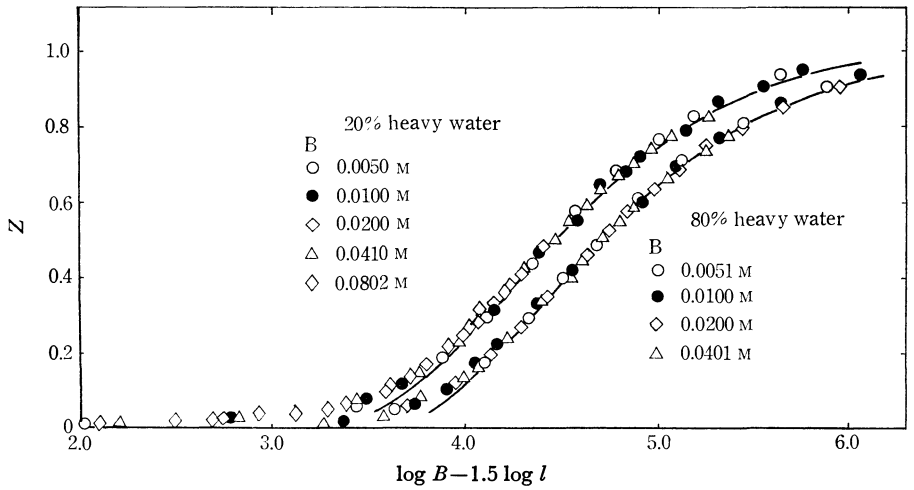

Fig. 1. Z as a function of (log B−1.5 log l).
The drawn curves for the system of 20% heavy water and 80% heavy water were calculated for $-\log \beta_{3,3}$=8.75 and 9.28 respectively.

Constant of the Main Species in 20% Heavy Water and 80% Heavy Water. From the $Z(\log l)_B$ data which were calculated from the potentiometric measurements by the use of Eq.(1), the composition of the hydrolysis species was estimated by the integration method presented by Sillén.[4]

A plot of $\bar{q}$ *vs.* $(2\bar{q}-\bar{p})$[5] suggested the presence of the (3,3) species as the main one in the region of $0.2<Z<0.8$. From this evidence, it may be said that the composition of the main species in H_2O-D_2O mixed solvents is the same as that in light water.

The values of the stability constant of the (3,3) species were calculated by the curve-fitting method described in Ref. 2.

If only the (3,3) species is present in appreciable amounts, the following equation can be derived:

$$\log X = 1/2 \log Z - 3/2 \log(1-Z)$$
$$= 1/2 \log 3 + 1/2 \log \beta_{3,3} + \log B - 3/2 \log l \quad (2)$$

A plot of Z as a function of (log B−3/2 log l) should lie on a single curve, independent of B; the experimental plots are shown in Fig. 1. The experimental plots in Fig. 1 can be fitted with a normalized curve of Z *vs.* log X.

The values of the stability constant for the system of 20% and 80% heavy water were found to be $-\log \beta_{3,3}=8.75\pm0.05$ and 9.28 ± 0.05 respectively.

(2) The Variation in the Stability Constant of the Main Species with the Deuterium Atom Fraction from 0 to 0.8. The differentiation of

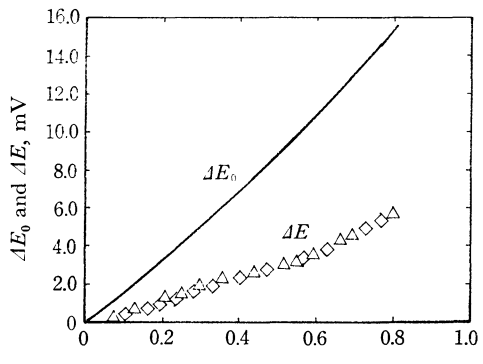

Fig. 2. The plots of ΔE_0 and ΔE *vs.* deuterium atom fraction.
△ B=0.040M, Z=0.499
◇ B=0.020M, Z=0.516

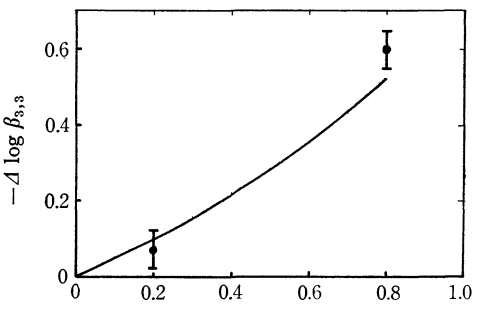

Fig. 3. The change in the stability constant with varying deuterium atom fraction.
The symbol ⊕ denotes the values calculated from Fig. 1.
The value of the stability constant of the (3,3) species in light water was assumed to be $-\log \beta_{3,3}$ =8.68, which was obtained by the authors.

4) L. G. Sillén, *ibid.*, **15**, 1981 (1961).
5) H. S. Dunsmore, S. Hietanen and L. G. Sillén *ibid.*, **17**, 2644 (1963).

Eq. (2) with respect to the deuterium atom fraction at constant B and Z values give the following equation:

$$\partial \log \beta_{3,3} = 3\, \partial \log l \qquad (3)$$

The variation in the stability constant can be calculated by the use of Eq. (3) if the change in l with the deuterium atom fraction is measured.

The variation in E_0, ΔE_0, with the deuterium atom fraction is graphed in Fig. 2. The change in E, ΔE, with a variation in the deuterium atom fraction at constant B and Z values is also shown in Fig. 2. The variation in the stability constant, $\Delta \log \beta_{3,3}$ was evaluated from Fig. 2 by the use of Eq. (3), which is shown graphically in Fig. 2.

From the above results, it may be said that the value of the stability constant of the (3,3) species decreases gradually with an increase in the deuterium atom fraction.

SHORT COMMUNICATIONS

Reductive Dehalogenation of Halobenzenes with Hydrosilanes in the Presence of Free-Radical Initiators[1]

Hideki SAKURAI, Mineo YAMAGATA, Akira HOSOMI and Makoto KUMADA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received January 28, 1969)

Reductive dehalogenation of unactivated aromatic halides is not easy, drastic reaction conditions being usually required.[2] In this communication, we present preliminary results of facile and mechanistically interesting reduction of halobenzenes with hydrosilanes involving free silyl radicals as intermediates.[3] To date, an example of the peroxide-catalyzed reaction of chlorobenzene with triphenylhydrosilane has been reported,[4] but no reduction product nor condensation product was detected.

In a typical experiment, 9.06 mmol of chlorobenzene, 8.94 mmol of triethylsilane, and 5.02 mmol of di-*t*-butyl peroxide were mixed and sealed in a small ampoule, and were allowed to react at 135±1°C for 15 hr. Examination of the products by GLC revealed that benzene (3.16 mmol, 35.3%), phenyltriethylsilane (0.325 mmol, 3.6%), and hexaethyldisiloxane (2.57 mmol, 57.5%) were present along with a small amount of unchanged chlorobenzene, acetone, and *t*-butyl alcohol. Bromobenzene (5.15 mmol) was also reduced to benzene (3.08 mmol, 59%) with triethylsilane (5.13 mmol), and di-*t*-butyl peroxide (2.57 mmol). The product contains also unchanged bromobenzene (1.34 mmol, 26%), acetone, and *t*-butyl alcohol. In both cases, triethylsilane was consumed completely. It is also established that no reaction took place without an initiator in otherwise the same reaction conditions.

Only a trace amount of biphenyl was detected. Therefore, intermediacy of phenyl radicals may not be excluded completely, but in the present reaction, direct abstraction of a halogen atom by free silyl radicals seems less plausible as a main reaction since no chlorobiphenyl was detected in spite of careful examination. Furthermore, recent observation in this laboratory[5] has demonstrated that silyl radicals produced by the reaction of trialkylhydrosilane with peroxide undergo successful homolytic substitution with aromatic solvents such as benzene and toluene.

These facts suggest therefore that more plausible process of reduction involves addition-elimination reactions of free silyl radicals.

(I)

$$I \longrightarrow Et_3SiPh + Cl\cdot$$

$$Cl\cdot + Et_3SiH \longrightarrow Et_3Si\cdot + HCl$$

$$Et_3SiPh + HCl \longrightarrow Et_3SiCl + PhH$$

$$I + Et_3Si\cdot \longrightarrow Et_3SiCl + Et_3SiPh$$

$$Et_3SiCl + t\text{-}BuOH \rightarrow\rightarrow Et_3SiOSiEt_3$$

It should be noted, however, that no substitution product, (chlorophenyl)triethylsilane, was obtained contrary to the cases of other aromatic solvents. This may be rationalized by the explanation that intermediate free radicals, I, could be fluxional[6] at the reaction temperature, like (trimethylsilyl)-cyclopentadiene,[7] and, moreover, elimination or abstraction of the chlorine atom from the intermediate, Ia, would be faster than hydrogen abstraction to give substitution products.

Infrared Spectra of BF_3-NO Mixed Solids

Shun-ichi IKAWA and Shiro MAEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 13, 1968)

It has been reported that nitric oxide and boron trifluoride form an addition complex at the temperature of liquid N_2.[1] Recently we studied the infrared spectra of BF_3-NO mixed solids, which were deposited from a mixed gas onto a cold CsI window.

When a BF_3-rich mixture is deposited very slowly, the spectrum of Fig. 1 (solid line) is obtained; however, the deposit of the same sample at a higher rate gives the absorption bands of the NO dimers[2] at the same time, as is shown in Fig. 2. Such a difference seems mainly due to the blanket effect[3] in the latter case. The results for NO-rich samples are essentially the same as those of Fig. 2 except that no splitting is observed in the $(NO)_2$ absorption at 1760 cm^{-1}.

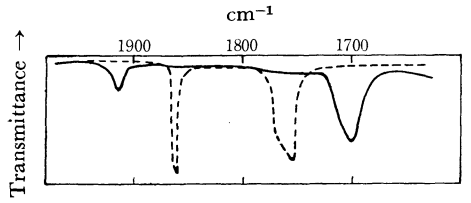

Fig. 1. Solid line; Slow deposit of a BF_3 rich (5 : 1) sample. (65°K) Dotted line; Solid NO. (65°K)

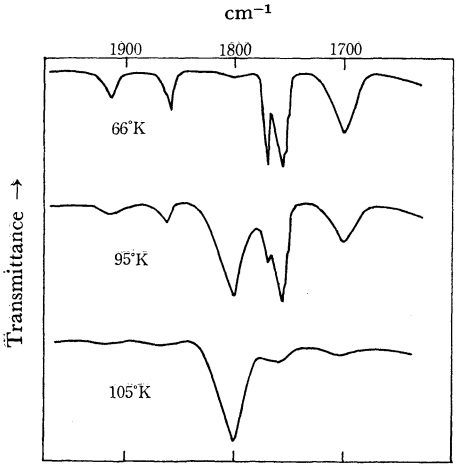

Fig. 2. Fast deposit of a BF_3 rich (5 : 1) sample, and its change by annealing.

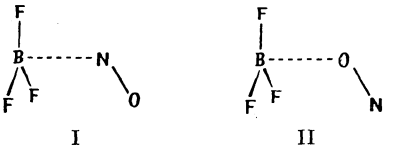
When the sample temperature is allowed to rise slowly, an interesting spectral change occurs, as is also shown in Fig. 2. As the temperature goes up, all the bands shown at the top of Fig. 2 gradually lose their intensities, but a new absorption appears at 1800 cm^{-1} and grows up rather quickly. At about 105°K, the initially-observed bands almost disappear, but the new 1800 cm^{-1} absorption holds its maximum intensity at this temperature and is still observable at 130°K, where the individual components are never able to remain on the window. The spectral change is irreversible and common to both BF_3- and NO-rich samples.

As the transient bands at 1915 cm^{-1} and 1700 cm^{-1} are definitely different in frequency from those of gaseous or solid NO, they may be interpreted as due to the complexed states existing in the lattice of excess NO or BF_3, most likely in such a form as:



In either case, donor-acceptor interactions are conceivable between vacant orbitals of BF_3 (A_1' and A_2'') and π-electrons, as well as σ-lone pairs, of NO. Of the two principal resonance structures, $:\dot{N}::\ddot{O}:$ and $:\ddot{N}^-::\dot{O}^+:$, the former is more favorable for II, and the latter, for I, in the donation of π-electrons. This suggests that the higher frequency, 1915 cm^{-1}, should be assigned to I, and the lower, 1700 cm^{-1}, to II. The donation of σ lone pairs may be of comparable importance, so the oblique forms, as above, may be most probable.

On the other hand, the 1800 cm^{-1} band may be of a stable complex. The fact that the frequency is nearly equal to the mean value of the transient bands suggests the following n : n structure:

Chromium(III) Complexes Containing Bis(salicylaldehyde)ethylenediiminate as a Ligand

Shoichiro YAMADA and Katsumoto IWASAKI

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received January 28, 1969)

Numerous metal complexes containing bis(salicylaldehyde)ethylenediiminate as a quadridentate ligand (Fig. 1)*1 have been reported in literature.[1-3] However, synthesis of the corresponding chromium(III) complexes has been unsuccessful. In general, synthesis of chromium(III) complexes with *C,N*-disubstituted salicylideneiminate ions*2 is known to be very difficult, and the complexes of the type $Cr(X\text{-}SAL.R)_3$, for example, have only recently been isolated.[4,5] A recent attempt to produce the bis(salicylaldehyde)ethylenediiminatochromium(III) complex by treating tris(salicylaldehydato)-chromium(III) with ethylenediamine was not successful, yielding only bis(*N*-α-aminoethylsalicylideneiminato)chromium(III) series.[4]

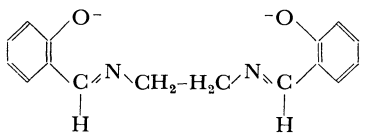

Fig. 1

By employing a method similar to that used for the synthesis of $Cr(X\text{-}SAL.R)_3$,[5] we have succeeded in preparing the chromium(III) complexes containing bis(salicylaldehyde)ethylenediiminate as a quadridentate ligand. The new chromium(III) complexes, together with analytical data, are given in Table 1. The compound $[Cr(SAL_2en)(H_2O)_2]Cl$ was prepared in the following way. To a solution of chromium(III) chloride hexahydrate (0.1 mol) in ethylene glycol-water-methanol (1:1:3, 300 m*l*) were added salicylaldehyde (0.2 mol) and ethylenediamine (0.1 mol). After the mixture was heated at about 110°C on an oil-bath for about thirty minutes, sodium carbonate (0.06 mol) was gradually added to the solution, followed by reflux of the solution for about three to four hours. Concentrating the solution yielded a reddish brown precipitate, which was recrystallized from 80% methanol to give reddish orange crystals.

The complexes II—V in Table 1 were obtained as orange crystals by reaction of $[Cr(SAL_2en)(H_2O)_2]Cl$ with an appropriate amine in methanol, followed by addition of benzene or ethyl ether. The complex VI, $K[Cr(SAL_2en)(CN)_2]\cdot H_2O$, was obtained as orange crystals by heating at about 60°C a mixture of the complex I and potassium cyanide in 80% methanol for about one hour.

All these chromium(III) complexes are soluble in methanol, ethanol and water, but insoluble in ethyl ether and benzene. The complexes at room temperature show magnetic moments of 3.80 to 3.85 B. M., which correspond to three unpaired electrons for the chromium(III) ion. Infrared spectra of these complexes are similar to those of the corresponding cobalt(III) complexes of the type $[Co(SAL_2en)\text{-}L_2]X$, where L denotes various ligands.[6]

TABLE 1. ANALYTICAL DATA OF $[Cr(SAL_2en)L_2]X\cdot nH_2O$

	L	X	*n*	Calcd, %			Found, %		
				C	H	N	C	H	N

Acidic Cleavage of Anispinacolone. Formation of a Substituted Benzofuran *via* an Acylcarbonium Ion Intermediate

Kunio OKAMOTO, Issei NITTA and Haruo SHINGU

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

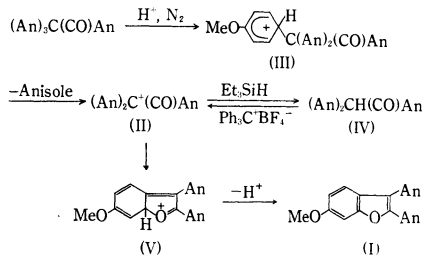
(Received February 17, 1969)

The acidic cleavage of anispinacolone (ω,ω,ω-tris(*p*-methoxyphenyl)-*p*-methoxyacetophenone) in 1,2-dichloroethane has been studied by Buckles and his collaborators;[1] the major product has been identified as the tris(*p*-methoxyphenyl)methyl cation on the basis of the visible and IR spectra of the reaction mixture. Following their method, we have found that this cleavage is accelerated by the interaction of molecular oxygen and proceeds *via* a radical (presumably a cation radical) intermediate; we have ascertained this by studying the ESR spectrum of the reaction mixture.[2]

In contrast, we will now show that, under an atmosphere of nitrogen or in an evacuated system, the acidic cleavage of the titled compound proceeds in an unexpected way, affording 2,3-bis(*p*-methoxyphenyl)-6-methoxybenzofuran (I) and anisole.

A 0.1 M solution of anispinacolone in 1,2-dichloroethane was allowed to react with twenty molar equivalents of trifluoroacetic acid in a sealed tube filled with nitrogen at 50°C for 24 hr; the reaction mixture was then washed with an aqueous alkaline solution, from which a small amount of anisic acid (4.2%)[3] was later isolated. After the usual working-up of the remaining organic layer and subsequent chromatography over silica gel, we isolated anisole (40%), the substituted benzofuran I (87%), tris(*p*-methoxyphenyl)carbinol (4.5%), and small amount of unchanged anispinacolone (9.0%).

In view of the facile elimination of *m*-dimethoxybenzene from 2,6,2′,6′,2″,6″-hexamethoxytriphenylmethane in dichloromethane in the presence of trifluoroacetic acid,[4] it is most probable that an acylcarbonium ion (II) would be formed as a result of the facile elimination of anisole from anispinacolone, protonated on its *p*-methoxyphenyl group (III).



(An = *p*-methoxyphenyl)

In order to trap the supposed acylcarbonium ion II, the acidic cleavage was carried out in the presence of a hydride donor, *i. e.*, triethylsilane,[4] with the reaction conditions being otherwise the same as above; ω,ω-bis(*p*-methoxyphenyl)-*p*-methoxyacetophenone (IV) (85%) and anisole (75%) were isolated, along with a small amount of I (3.4%), by elution chromatography over silica gel. This indicates that the acylcarbonium ion II is a common precursor to IV and I.

The intramolecular cyclization of the acylcarbonium ion II to the substituted benzofuran I was confirmed by the fact that, when the ketone IV was treated with two molar equivalents of triphenylmethyl tetrafluoroborate in 1,2-dichloroethane at 50°C for 22.5 hr, I was obtained in a 3.7% yield *via* II, produced by hydride abstraction from IV. The other compounds isolated from the reaction mixture were triphenylmethane (2.2%) and unchanged ketone IV (95%); they were obtained after the usual working-up and after subsequent t.l.c. separation over silica gel. This cyclization conceivably proceeds *via* a substituted 1-oxonia-7a*H*-indene (V).[5]

Experiments with other substituted benzopinacolones are under way in order to clarify the scope of this novel reaction.

Synthesis of 1-Oxygenated 5β-Cholestanes

Yasuo SATOH, Tomoyoshi TAKAHASHI, Toshiji AOKI and Akira HAGITANI

Department of Chemistry, College of Science, St. Paul's University (Rikkyo Daigaku), Nishi-Ikebukuro, Toshima-ku, Tokyo

(Received February 21, 1969)

Although the synthesis of 1-oxygenated 5α-steroids has been studied by several groups,[1] little has been found in literature concerning the synthesis of 1-oxygenated 5β-steroids except for the preparation of 1-oxoetianic acid from acovenosigenin A, which has two hydroxy groups in C-1 and -3.[2]

The present communication deals with a study on the synthesis of 1-oxygenated 5β-cholestanes from 4β-bromo-3-oxo-5β-cholestane. As a key intermediate in this synthesis, we chose 3-oxo-5β-cholest-1-ene. The synthesis of this derivative in circuitous route or in the method using a special reagent has already been reported by a few groups.[3] We wish to present a more practical method for the synthesis of 3-oxo-5β-cholest-1-ene.

In a previous paper, it was reported that the substitution reaction of 4β-Br in 3-oxo-5β-steroids with AcOK/AcOH is accompanied by a new rearrangement of the substituent from C_4 to C_2 resulting in the formation of the 2β-acetoxy-3-oxo derivative in good yield.[4] In the reaction using piperidine/piperidine hydrobromide/dioxane as reagents instead of AcOK/AcOH, we have found that the 1-en- and 4-en-3-oxo derivatives were formed in the ratio of 1 : 1. Chromatographical separation and recrystallization of the product from methanol gave needles of 3-oxo-5β-cholest-1-ene, mp 103°C, in over 35% yield.

When the 4β-bromo-3-oxo derivative was refluxed with pyridine, 1-[2-(3-oxo-5β-cholestanyl)]pyridinium bromide was formed. Needles, mp 266—268°C (decomp.), ν_{max}^{KBr} cm^{-1}: 1725 (C=O), 1633, 1493 (C=C, C=N), 789, 763 (=C–H), λ_{max}^{EtOH} 261 mμ (ε 3700). On the pyrolysis of the pyridinium bromide at 480—500°C, 3-oxo-5β-cholest-1-ene was also obtained. The total yield of this α,β-unsaturated ketone from the 4β-bromo-3-oxo-5β-cholestane was 43%.

The synthesis of 1-oxygenated 5β-cholestane from this derivative was carried out using the procedure of Djerassi *et al.*[5] for the syntehsis of 1-oxygenated 5α-steroids. The physical constants of the products in this synthetic pathway are as follows:

Epoxidation of the 1-en-3-oxo derivative gave needles of 1β,2β-epoxide, mp 107—108.5°C, from methanol. ν_{max}^{KBr} cm^{-1}: 1702 (C=O), 856, 844 (C–O), ORD (*c* 0.19, Di) at 22°C: $[\alpha]_{589}$ − 5°, $[\alpha]_{333}$ −697° (trough), $[\alpha]_{329}$ −678° (peak), $[\alpha]_{325}$ −687° (trough), $[\alpha]_{280}$ +1355° (peak), NMR ($CDCl_3$) τ: 6.57 (d., J=4.5 cps, 1H), 6.72 (d., J=4.5 cps, 1H). Configuration of this product was established by analysis, IR, ORD and NMR spectra, conversion to 1β,3α-dihydroxy-5β-cholestane with lithium aluminum hydride, and conversion to the 2-halo-3-oxo-1-ene derivatives by cleavage of the epoxy ring with hydrogen halides.*1 The result of this epoxidation of 3-oxo-5β-cholest-1-ene is contrary to that reported for 5α-series which gives the α-epoxide from the 1-en-3-oxo derivative.[1]

1β-Hydroxy-5β-cholest-2-ene: mp 95—96°C, ν_{max}^{KBr} cm^{-1}: 3320 (O–H), 1655 (C=C), 740, 724 (=C–H), NMR ($CDCl_3$) τ: 4.16 (b.d., 2H), 6.16 (m., $W_{h/2}$=7 cps, 1H).

1β-Hydroxy-5β-cholestane: oil, ν_{max}^{Film} cm^{-1}: 3330 (O–H).

1β-Acetoxy-5β-cholestane: needles, mp 104—105.5°, ν_{KBr}^{max} cm^{-1}: 1720 (C=O), 1240 (C–O), $[\alpha]_D^{25}$ −10.0° (*c* 1.01, $CHCl_3$), NMR ($CDCl_3$) τ: 5.00 (b.s., $W_{h/2}$=6 cps, 1H), 7.98 (s., 3H).

1-Oxo-5β-cholestane: needles, mp 101—102°C, ν_{max}^{KBr} cm^{-1}: 1702 (C=O), ORD (*c* 0.43, Di) at 25°C: $[\alpha]_{589}$ − 69°, $[\alpha]_{322}$ −1681° (trough), $[\alpha]_{313}$ −1290° (sh.), $[\alpha]_{280}$ +1470° (peak). This derivative showed a negative Cotton effect curve having a shoulder at near 310 mμ similar to 2-oxo-5β-cholestane[6] in ORD spectrum. This 1-oxo derivative was obtained in 55% over-all yield from 3-oxo-5β-cholest-1-ene.

Further details will be published later.

Synthesis and Use of N^{im}-Tosyl-L-histidine*1

Shumpei SAKAKIBARA and Toshiyuki FUJII*2

Peptide Center, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received March 3, 1969)

Recently, great progress has been made in peptide synthesis, but the synthesis of histidine peptides requires further improvement.[1] This paper will describe a new procedure for the protection of the imidazole residue with a tosyl group. Generally, the tosyl group in peptide derivatives is stable and can only be removed by treatment with sodium in liquid ammonia.[2] However, a tosyl group attached to a guanido group in an arginine residue can, exceptionally, be removed by treatment with anhydrous HF at 0°C for 30 min, although it is stable with HBr in acetic acid.[3] The N^{im}-tosyl group was found to be removed more easily, not only by short treatment with anhydrous HF, but also under the conditions used for ester saponification. This group was also partially decomposed with anhydrous HCl or HBr in organic solvents. Further, the N^{im}-tosyl group was found to be unaffected by treatment with trifluoroacetic acid at room temperature under the conditions used for removing Nps-, Boc-, Aoc-, or Z(OMe)-groups. These properties all suggest that this group might be used for the synthesis of histidine peptides.

The tosyl group was introduced into N^{α}-protected histidine derivatives with tosyl chloride under the conditions of the Schotten-Baumann reaction, using sodium carbonate as the base. Thus the following compounds were synthesized and obtained as crystals: Z-L-His(Tos)-OH·DCHA, yield 62%, mp 150—152°C (decomp.), $[\alpha]_D^{17}$ +19.2° (*c* 1, DMF); Aoc-L-His(Tos)-OH (I), yield 75%, mp 109—111°C (decomp.), $[\alpha]_D^{17}$ +10.0° (*c* 1, pyridine); Nps-L-His(Tos)-OH (II), yield 75%, mp 140—141°C (decomp.), $[\alpha]_D^{17}$ +39.9° (*c* 1, DMF). Elemental analyses gave correct values for these compounds within the expected limits of error. These compounds were soluble in the organic solvents for usual acylated amino acids. Compounds I and II were coupled with the glycine benzyl ester by the DCC method and by the mixed anhydride method; Aoc-L-His(Tos)-Gly-OBzl (III) and Nps-L-His(Tos)-Gly-OBzl (IV) were thus both obtained in 80% yields. III: oily compound. IV: mp 164—165°C, $[\alpha]_D^{18}$ +57.5° (*c* 1, DMF). Found: C, 55.03; H, 4.19; N, 11.24; S, 10.44%. Calcd for $C_{28}H_{27}N_5O_7S_2$: C, 55.16; H, 4.46; N, 11.48; S, 10.51%. The Aoc- or Nps-group was removed by dissolving III or IV in trifluoroacetic acid in a presence of anisole at room temperature; after 30 min, the product was coupled with Nps-L-alanine using DCC. The product, Nps-L-Ala-L-His(Tos)-Gly-OBzl, was recrystallized from ethyl acetate and *n*-hexane as needles; yield 50%, mp 88—89°C, $[\alpha]_D^{17}$ −30.0° (*c* 1, AcOEt). Better results were obtained by the *N*-hydroxysuccinimide method, in which case the yield was 75%. Found: C, 54.43; H, 4.53; N, 12.35; S, 9.43%. Calcd for $C_{31}H_{32}N_6O_8S_2$: C, 54.69; H, 4.73; N, 12.34; S, 9.42%. All the protective groups could be removed from IV by treatment with anhydrous HF[4] at 0°C for 1 hr; L-His-Gly·½H_2O was thus obtained, as expected; yield 55%, mp 190°C (decomp.), $[\alpha]_D^{17}$ +24.6° (*c* 1, water). Reported,[5] mp 190°C (decomp.), $[\alpha]_D$ +25±1° (*c* 2, water).

Thus, the procedure was demonstrated to be useful for histidine peptide syntheses. The new histidine derivatives, I and II, should be especially useful in the solid-phase method. This possibility is now being investigated in our laboratory.

The Electronic Structures of Base Components of Nucleic Acids and Their Tautomers Calculated by CNDO Method

Hiroko FUJITA, Akira IMAMURA and Chikayoshi NAGATA

Biophysics Division, National Cancer Center Research Institute, Tsukiji, Chuo-ku, Tokyo

(Received March 3, 1969)

The relative stability of the DNA bases and their tautomers is of interest in connection with the mechanism of mutation in which the conversion of the DNA bases into their tautomers has been supposed to be involved. By means of infrared spectra and X-ray diffraction *etc.*, the amino and the keto forms (usual forms) of the DNA bases have been confirmed to be more stable than the imino and the enol forms (rare forms) in solid state or in solution. Comparison of the energies for the usual and the rare forms obtained by the molecular orbital calculation was made by some investigators,[1,2] and the usual forms were found to be more stable than the rare forms for all bases. In these calculations, however, the electronic repulsion is not explicitly taken into account. In such circumstances, CNDO method[3] was considered to be more reliable in discussing the relative stability of molecules,[4] and it was applied to the four tautomers of purine.[5]

In the present communication, the total energies calculated by means of CNDO/2 method[3] for the usual and the rare forms of the bases of nucleic acids and a base analog, were compared and the relative stability among these compounds was discussed in relation to the mutagenesis. Bond lengths and bond angles for the usual forms of bases and a base analog were obtained from Spencer's data.[6] For the rare tautomeric forms, the geometry of the purine and pyrimidine rings was assumed to be the same as the usual form. Bond lengths for C–N and N–H bonds in the imino form were taken as 1.27 Å and 1.0 Å, respectively, and for C–O and O–H in the enol form, as 1.47 Å and 0.96 Å, respectively. The calculated total energies of the bases and the base analog in the usual and the rare forms are listed in Table 1. Except guanine,

TABLE 1. TOTAL ENERGIES FOR THE USUAL AND THE RARE FORMS OF THE BASES OF NUCLEIC ACIDS AND A BASE ANALOG (IN eV)

Bases	Usual form	Rare form	Difference
A	−2655.09	−2652.97	−2.12
G	−3156.11	−3156.68	+0.57
T	−2726.04	−2725.53	−0.51
C	−2326.68	−2325.53	−1.15
U	−2489.58	−2489.13	−0.45
FU	−3223.42	−3222.99	−0.43

the usual forms are more stable than the rare forms in agreement with the experimental results. For guanine, the rare form is found to be more stable than the usual form. But from X-ray diffraction and infrared spectra, guanine was shown to exist predominantly as the keto form in water and solid state. In connection with this, the following fact should be remarked; from the total energies calculateld by means of CNDO method for the zwitter ion and neutral form of glycine, it was predicted that the latter form was more stable than the former.[7] In fact, glycine is known to exsit as neutral molecule in gaseous state, although it exists as zwitter ion in water and solid state. Bearing this fact in mind, it may not be unreasonable to suppose that the predominant form of guanine in gaseous state is the so-called rare form, *i. e.*, the enol form. The ease of the conversion of the usual tautomeric form into the rare form decreased in the order, guanine>fluorouracil>uracil>thymine >cytosine>adenine, and this order is in accordance with Danilov's result.[2] It is interesting that fluorouracil is found to be more easily converted into the rare form than uracil and thymine in reference to the fact that fluorouracil is known to be mutagenic.

Natural Occurrence of α-Cadinene

Yoko NAYA and Munio KOTAKE

The Institute of Food Chemistry, 2-Chome 43, Dojimanaka, Kita-ku, Osaka

(Received March 6, 1969)

The sesquiterpene hydrocarbon, α-cadinene (I) has been isolated from Japanese hop (*Humulus lupulus* L.) for the first time.

The hydrocarbon (I) is a colorless oil, $C_{15}H_{24}$, $[\alpha]_D^{24}$ $-62.4°$ (c 0.868, $CHCl_3$). Its NMR (CCl_4) spectrum shows two vinyl protons at δ (ppm) 5.32 (1H), and 5.52 (1H). Besides the signals of isopropyl group at δ 0.78 (3H, d. $J=7$ cps), and 0.91 (3H, d. $J=7$ cps), the spectrum shows six protons at 1.65 (broad s.) corresponding to two vinyl methyl groups. The MS spectrum exhibits the molecular ion peak at m/e 204 and the base peak, at m/e 105 together with a considerably abundant peak at m/e 161 (M−43).

On partial hydrogenation with platinum oxide in a mixture of methanol and ether, a single product was provided. The IR spectrum of the product was identical with that of the dihydrocadinene prepared from γ-cadinene. The hydrocarbon (I) yielded crystalline dihydrochloride, $[\alpha]_D^{24}$ $-38.1°$ (c 1.608, $CHCl_3$), mp 115—116°C, by treating with dry hydrogen chloride in ether solution. The product showed no depression of the mixed melting point with an authentic sample of (−)-cadinene dihydrochloride[1-3] of known absolute configuration. In addition, the IR spectrum of I is different from that of β-cadinene[4,5] as shown in Fig. 1.

The above evidence leads to α-cadinene structure (I) for this hydrocarbon.

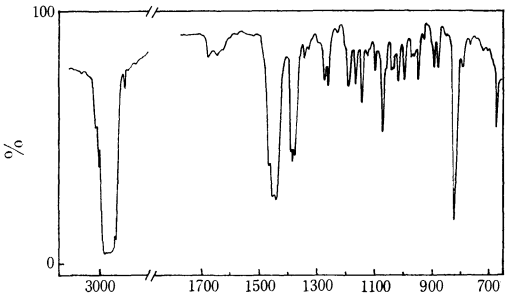

Fig. 1. IR spectrum of I.

Polarographic Studies of the Solubilization of Disperse-dyes

Shigeo HAYANO and Noriko SHINOZUKA

Institute of Industrial Science, The University of Tokyo, Roppongi, Tokyo

(Received June 20, 1968)

The apparent mean particle size of the solubilized dye in nonionic surfactant solutions is determined from the polarographic diffusion coefficient. The diffusion coefficient and the particle size obtained are in good agreement with those of the nonionic surfactant micelle reported in the literature. For the system of polyoxyethylene nonylphenyl ether (NP-$\overline{19}$) and 1,4-diaminoanthraquinone, the particle size increases with the dye concentration; however, the particle size is almost constant for the system of NP-$\overline{19}$ and 1,4,5,8-tetraaminoanthraquinone (TAA). When a certain quantity of TAA is solubilized into the 10^{-3}—10^{-2} M NP-$\overline{19}$ solution, the particle size is also constant. In the case of the polyoxyethylene lauryl ether (LA-$\overline{14}$) and TAA system, the particle size markedly decreases with the increase in the dye concentration. This tendency suggests that the numbers of micelles increase with the concentration of the solubilizate. The fact that the half-wave potential of the dye reduction is independent of the concentration of the surfactants is explained in terms of the similarity between the electrode process of the solubilized dye and that of the dissolved dye.

The solubilization of disperse-dyes has been the subject of many investigations.[1-3] Among the various methods used in the studies of solubilization, the spectroscopic method is most popular.[3-7] Few polarographic measurements have been made of the solubilization because such measurements need a large concentration of supporting electrolyte, and such a concentration has been thought to disturb the system.

To determine the CMC's, the polarographic technique was applied to anionic and nonionic surfactants,[8-10] but the polarographic CMC's sometimes did not agree with those obtained by other methods. The CMC's are found to be greatly affected by added electrolytes[11-13]: this is the reason for the above discrepancy. On the contrary, the size of the micelle is found not to change with the addition of electrolytes.[14]

Craven and Datyner[15] investigated the interaction between some acid wool dyes and nonylphenol-ethyleneoxide derivatives by means of diffusion measurements in which they calculated the apparent mean particle size of the dye-surfactant complex.

In this paper, the apparent mean particle size of the solubilized dye is determined by means of the polarographic diffusion coefficient, and the effects of the addition of nonionic surfactants are investigated. The electrode process of the solubilized-dye particle is also discussed.

Experimental

Materials. 1,4-Diaminoanthraquinone and 1,4,5,8-tetraaminoanthraquinone were used as the disperse-dyes. 1,4-Diaminoanthraquinone was recrystallized from ethyl alcohol, and 1,4,5,8-tetraaminoanthraquinone, from acetone; the melting points were 264°C and 324°C respectively.

Polyoxyethylene nonylphenyl ether (NP-$\overline{10}$,-$\overline{19}$) and polyoxyethylene lauryl ether (LA-$\overline{14}$) were received

through the courtesy of Lion Oil and Fats Co. and the Meisei Chemical Co., and were used without further purification.

Procedure. A solution containing a nonionic surfactant, a 0.1 N acetic acid - sodium acetate buffer solution (pH=4.7), and a dye was irradiated with a 21.6 kHz surpersonic wave for 5 min, and then agitated in a water bath at 25±0.1°C for 24 hr. The solution was then stored for a week at the same temperature. The equilibrium of the solution was thus confirmed. The excess dye was removed by filtration through a G4 glass filter. The solid dye remaining on the filter was dissolved with acetone, and its quantity was determined by means of the absorption at 620 mμ.

The polarographic measurements were carried out at 25°C for a filtrate, the dye concentration of which had been corrected. Yokogawa POL-11 and POL-21 polarographs were used, and a saturated calomel electrode was used as a reference electrode. The DME had the following characteristics; $m=1.70$ mg/sec (in pure water at zero applied potential *vs.* SCE) and $t=3.9$ sec (in 10^{-2} M NP-$\overline{19}$ buffer solution at −0.64 V *vs.* SCE). The height of the mercury head was 77.5 cm.

The viscosity of the basic solution was measured with an Ostwald viscometer.

Results and Discussion

Polalographic Measurements. Dye-solubilized aqueous nonionic surfactant solutions all showed a well-defined wave corresponding to the dye reduction (Fig. 1). If the current is diffusion-controlled, the diffusion coefficient of the reductive particle can be obtained from the Ilkovic[16] equation. The relation between the current and the square root of the mercury head is shown in Fig. 2. A linear relationship was obtained in all the cases of nonionic surfactant solutions and a 50% alcoholic solution. The half-wave potentials of the dye-solubilized solutions did not change with either the concentration or the kind of surfactants.

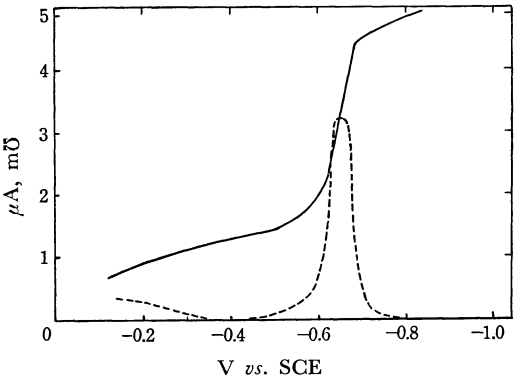

Fig. 1. DC and AC polarograms of the solubilized 1,4,5,8-TAA in NP-$\overline{19}$ solution.

16) D. Ilkovic, *Collection Czechoslov. Chem. Commun.*, **6**, 498 (1934).

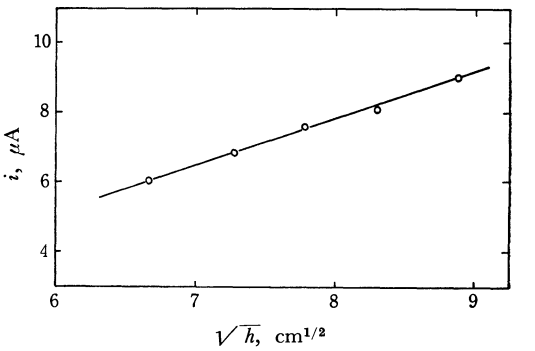

Fig. 2. Dependence of current on mercury height.

From these results, the limiting current is found to be a diffusion current, so the Ilkovic equation is applicable.

The water of hydration in the micelle has not been taken into account.

The diffusion coefficient calculated from the polalographic data is affected by the composition of the solution,[17] the ionic strength, and the species of the solvent. However, the polarographic measurement is a very convenient and simple method when the following assumptions are made: 1) the diffusion current has a linear relationship with the dye concentration; 2) the diffusing particles contain dye molecules only, and 3) the number of electrons transferred is known.

The number of electrons involved in the reduction of the dye is estimated to be 2 on the basis of the following results: 1) the AC polarograms and the cyclic voltammograms indicate a reversible dye reduction process (this makes possible the calculation of "n" from the log-plot of the currents; $n=2$ is obtained), and 2) the anthraquinone derivatives are reduced in a 2-electron step.

Concerning the diffusion coefficients from the polarographic data, an uncertainty of about ±10% usually appears, but the polarographic diffusion coefficients which are calculated in this study are in good agreement with the known values for nonionic surfactant micelles.[18]

Apparent Radii of Dye Particles in the Presence of Different Concentrations of Surfactants. By means of Stockes-Einstein's law for diffusion coefficients that the particles are spherical,[19] the apparent mean radii of dye particles at different concentrations of surfactant solutions are obtained; they are shown in Table 1. When a 0.446×10^{-4} M dye is solubilized into a 10^{-4} M surfactant solution, the particle size observed is 16 Å. This value is very small compared with

Table 1. Apparent mean particle radii of 1,4,5,8-tetraaminoanthraquinone in NP-$\overline{19}$ solutions

Surfactant concn. (M)	Dye concn. (10^{-4} M)	Diffusion coefficient (10^{-7} cm^2/sec)	Particle radius (Å)
1×10^{-1}	1.000	2.26	38
5×10^{-2}	1.000	2.41	63
1×10^{-2}	0.922	2.45	85
5×10^{-3}	0.865	2.57	84
1×10^{-3}	0.732	3.04	73
5×10^{-4}	0.619	2.83	79
3×10^{-4}	0.451	4.41	51
1×10^{-4}	0.446	13.6	16
50% Alcoholic solution	0.718	36.5	2.5

that in a 5×10^{-4} M surfactant solution. Since the CMC of NP-$\overline{19}$ is near 10^{-4} M, small, incomplete micelles may be formed at this low surfactant concentration.[20]

As the surfactant/dye ratio increases, the apparent mean radii become constant at about 80 Å in the range of surfactant concentration of 5×10^{-4}M —10^{-2} M. The corresponding diffusion coefficient, about 3×10^{-7} cm^2/sec, is in good agreement with that of the nonionic surfactant micelle.[18]

At a surfactant concentration of 10^{-1} M, the apparent radius decreases to about 40 Å. In this case, the reproducibility of the polarographic data is improved, because of the increase in the homogeniety of the solution. The more homogeneous state than micelle formation can be regarded as the reason.[21]

The radius in a 50% alcoholic solution is 2.5 Å; the value does not change when a 10^{-2} M surfactant was added. This may be compared with the results of Becher,[22] who found that in polyoxyethylene lauryl ether solutions micelle formation does not occur when the concentration of ethanol reaches approximately 30%.

Effect of Dye Concentration on the Apparent Radii. The apparent mean radii of the particle at various dye concentrations are given in Table 2, Fig. 3, and Fig. 4. With the system of 1,4-diaminoanthraquinone and 10^{-1} M NP-$\overline{19}$, the radius of the particle increases with the dye concentration (Fig. 3). On the other hand, in the case of 1,4,5,8-tetraaminoanthraquinone solubilized in a 10^{-2} M NP-$\overline{19}$ solution, the dye particle size seems to be independent of the dye concentration. In the above NP-$\overline{19}$ systems, the diffusion coefficients are also of the same degree as those of nonionic surfactant micelles. From the polarographic diffusion coefficient, the aggregation number of NP-$\overline{19}$ can be estimated to be about 50. The above result is acceptable in comparison with the reported value of 62 for NP-$\overline{20}$.[12]

The radius of the dye particle solubilized into a polyoxyethylene lauryl ether surfactant solution markedly decreases with the dye concentration

Table 2. Apparent mean particle radii of 1,4,5,8-TAA in 10^{-2} M NP-$\overline{19}$ solution

Dye concn. (mM)	Diffusion coefficient (10^{-7} cm^2/sec)	Particle radius (Å)
0.47	3.56	60
0.92	2.45	85
1.59	3.14	67
1.91	3.22	65
3.22	3.10	69

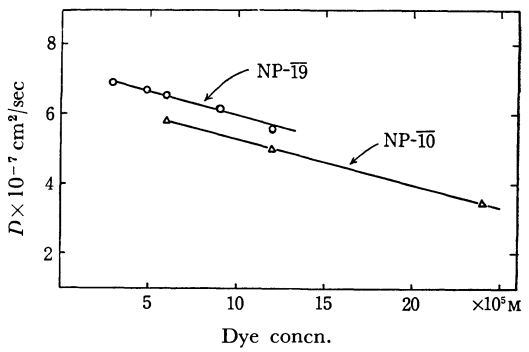

Fig. 3. Dependence of diffusion coefficient on dye concentration (1,4-DAA).

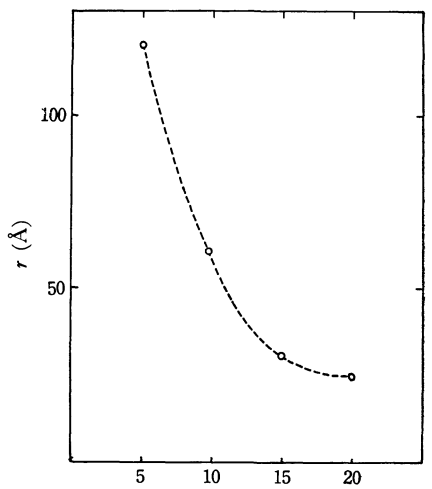

Fig. 4. Dependence of apparent mean particle radii on dye concentration (1,4,5,8-TAA in LA-$\overline{14}$ solution).

20) S. Kuroiwa, *Hyōmen (Surface)*, **3**, 690 (1965).
21) S. Kuroiwa, *Yukagaku (J. Japan Oil Chem. Soc.)*, **17**, 125 (1968).
22) P. Becher, *J. Colloid. Sci.*, **20**, 728 (1965).

(Fig. 4). The aggregation number of LA-$\overline{14}$ may be about 125; a large micelle ($r = ca.$ 40 Å) may be expected from this value. In this case, the radius of the particle falls from 60 Å to 25 Å when the 2.0×10^{-4} M dye is solubilized. This effect of the solubilizate concentration on the particle size appears to be due to the influence of the linear alkyl chain of the surfactant. The above tendency is similar to that found by Craven and Datyer,[7] but it is not ascribed to complex formation because of the constancy of the half-wave potentials. The mechanism of this phenomenone has not yet been explained.

Electrode Process of the Solubilized Dye. The fact that the half-wave potential of the dye reduction does not change when the dye is solubilized in a micellar solution indicates the similarity between the electrode process of the solubilized dye and that of the dissolved dye. It is clear that the diffusing particle is the micelle with the dye; this causes the diffusion current. The complex formation between dye and surfactant is inconceivable in this case; if it occurred, the half-wave potential might change with the concentration of the surfactant.

The rates of electron transfer are estimated by the method of Kambara-Ishii.[23] The rate constant of the solubilized dye is about 2×10^{-3} cm/sec; on the other hand, the dye dissolved into a 50% ethanolic aqueous solution has value of about 2×10^{-2} cm/sec. This difference may be attributed to the influence of the walls of the micelles near the electrode.

The authors wish to express their gratitude to Mr. O. Murakami for measuring the polarograms and to Professor S. Kuroiwa for his helpful discussions.

Molecular Orbital Treatment of Nitric Oxide Radicals. III. Spin Distributions and *g* Factors of Aromatic Nitric Oxide Radicals

Osamu KIKUCHI

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received July 25, 1958)

The spin distributions and *g* factors have been calculated for several aromatic nitric oxide radicals. The spin distributions calculated by the open-shell SCF method with configuration interaction, and by the unrestricted SCF method with the annihilation of the quartet component from the single determination wave function, agreed with the experimental values estimated from the ESR spectra. The contributions of the lone-pair orbital of the oxygen and of the N–O σ-bonding orbital to the *g* factor were calculated, the calculated *g* factors in solution being in the range of 2.005—2.006; these values were then discussed on the basis of the electronic structures of nitric oxide radicals.

In preceding papers,[1,2] the electronic structure and the spectrum of the H_2NO radical, and the ESR spectra of aliphatic nitric oxide radicals were discussed quantitatively on the basis of a SCF MO method in which all the valence electrons were explicitly considered. One purpose of this paper is to calculate the spin distributions for the phenyl nitric oxide, the diphenyl nitric oxide, and the carbazole *N*-oxide radicals by the open-shell SCF procedure of Longuet-Higgins and Pople[3] with configuration interaction, and also by the unrestricted Hartree-Fock method,[4] and to compare the calculated spin distributions with the experimental values estimated from the ESR spectra. The π-electrons of aromatic molecules delocalize upon a large conjugated system; nevertheless, some experimental results have shown that the aromatic nitric oxide radical reveals a *g* factor

4) J. A. Pople and R. K. Nesbet, *J. Chem. Phys.*, **22**, 571 (1954); A. Brickstock and J. A. Pople, *Trans. Faraday Soc.*, **50**, 901 (1954); A. T. Amos and L. C. Snyder, *J. Chem. Phys.*, **41**, 1773 (1964).

similar to that of the aliphatic nitric oxide radical.[5] The second purpose of this note is to estimate the g factor of the aromatic nitric oxide from the spin density on the N-O group and the orbital energy of the odd π-orbital. The results will be discussed on the basis of the electronic structures of aromatic nitric oxides.

Calculation Procedure

The calculation procedure and all the parameters except the core resonance integrals were the same as those reported elesewhere.[6] The g factor was calculated by means of the equation presented by Stone.[7] The core resonance integrals were computed by the relations:[8]

$$\left.\begin{aligned}\beta_{rs} &= -0.4172 S_{rs}(I_r+I_s) \quad (R_{rs} \leq 3\text{Å}) \\ &= 0 \qquad\qquad\qquad\quad (R_{rs} > 3\text{Å})\end{aligned}\right\} \tag{1}$$

where R_{rs} is the distance between the rth and sth atoms; S_{rs}, the overlap integral between two $2p_z$ Slater-type atomic orbitals, and I_r, the ionization potential for the valence atomic orbital, r. For all the C-C and C-N bonds, the bond lengths were assumed to be 1.40 Å, while for the N-O bonds, they were assumed to be 1.23 Å.[9] The bond angles were also assumed to be 120° and 108° for the benzene rings and the pyrol ring respectively. The overlap integrals were computed using the formula given by Mulliken, Rieke, Orloff, and Orloff[10] with the effective nuclear charges determined from the electron densities by

each iteration.

Results and Discussion

The spin densities calculated for the phenyl nitric oxide, the diphenyl nitric oxide, and the carbazole *N*-oxide radicals are listed in Table 1. The spin densities of the phenyl nitric oxide agree well with the experimental values; the II and IV methods give a better agreement. From the theoretical point of view, the spin distributions calculated either by the method with configuration interaction (II) or by the annihilation of the quartet component of a single Slater-determinant (IV) are satisfactory. The ESR study of some substituted phenyl nitric oxide radicals has shown that the hyperfine splitting constants of two protons at the 2 and 4 positions differ from each other.[12] The present results (IV) show that $\rho_2 > \rho_4$; this is the relation observed in the experiment. The spin densities of the carbazole *N*-oxide radical also agree with the experimental values. The nitrogen hyperfine splitting constant (3.5—7.0 gauss[11]) of the carbazole *N*-oxide, small in comparison with that of the diphenyl nitric oxide (9.5 gauss[5]), can be explained by the calculated spin densities on the nitrogen and oxygen atoms of these two radicals.[13]

It has been shown that, in nitric oxide radicals, the deviation of the *g* factor from the value of the free spin is caused mainly by the lone-pair orbital of the oxygen atom and by the N–O σ-bonding orbital.[2] In the calculation of the *g* factor, it is necessary to estimate not only the spin distribution, but also the excitation energies from the σ-orbitals to the odd π-orbital. It is troublesome to calculate the electronic structure for the valence electron system of an aromatic radical. In the present investigations, therefore, these excitation energies were estimated by employing some assumptions based on the electronic structure of aliphatic nitric oxide radicals. The excitation energy from the σ-orbital to the odd π-orbital is given by:

$$\Delta E_{\sigma\to\pi^\circ} = \varepsilon_{\pi^\circ} - \varepsilon_\sigma - J_{\sigma\pi^\circ} + \frac{1}{2}J_{\pi^\circ\pi^\circ} + \frac{1}{2}K_{\sigma\pi^\circ} \quad (2)$$

where ε_{π° and ε_σ are the molecular orbital energies for the odd π-orbital and for the σ-orbital respectively. The LCAO approximation and the zero-differencial overlap approximation reduce the two-electron integrals in Eq. (2) to:

$$\left.\begin{aligned} J_{\sigma\pi^\circ} &= \sum_{r,s} C^2_{r\sigma} C^2_{s\pi^\circ} (r_\sigma r_\sigma \mid ss) \\ J_{\pi^\circ\pi^\circ} &= \sum_{r,s} C^2_{r\pi^\circ} C^2_{s\pi^\circ} (rr \mid ss) \\ K_{\sigma\pi^\circ} &= 0 \end{aligned}\right\} \quad (3)$$

These equations show that the integral values depend largely on the spin distribution of a radical, while for the nitric oxide radical the contribution of the spin density on the N–O group to the integral value is most important. The problem is treated as a "three-atom problem" in which the spin desnity $(1-\rho_{NO})$ is on the third atom, X, bonded to the nitrogen atom, where ρ_{NO} is the sum of the spin densities on the nitrogen and oxygen atoms. The localization of the lone-pair electrons on the oxygen atom is assumed;[14] we then obtain:

$$J_{n\pi^\circ} = \rho_O(nn \mid OO) + \rho_N(nn \mid NN) + (1-\rho_{NO})(nn \mid XX) \quad (4)$$

The one-center integral of the nitrogen, (NN|NN), is taken to be approximately equal to that of the oxygen, (OO|OO);[15] the value of the two-center integrals, γ, in this equation are taken to be approximately a half of the one-center integral.[15] Therefore,

$$J_{n\pi^\circ} = \gamma(1+\rho_O) \quad (5)$$

Similarly,*1

$$J_{\pi^\circ\pi^\circ} = \gamma(1 + \rho_O^2 + \rho_N^2) \quad (6)$$

From Eqs. (5) and (6), the excitation energy for the $n\to\pi$ excitation is given by:

$$\Delta E_{n\to\pi^\circ} = \varepsilon_{\pi^\circ} - \varepsilon_n - \frac{\gamma}{2}(1+2\rho_O - \rho_O^2 - \rho_N^2) \quad (7)$$

A simpler relation between the excitation energy and the spin density on the N–O group is obtained by setting $\rho_N = \rho_O = \frac{1}{2}\rho_{NO}$:

$$\Delta E_{n\to\pi^\circ} = \varepsilon_{\pi^\circ} - \varepsilon_n - \frac{\gamma}{4}(2+2\rho_{NO} - \rho_{NO}^2) \quad (8)$$

When the electrons in the N–O σ-bonding orbital are shared equally on the nitrogen and the oxygen atoms,[16] the same relation (8) is obtained for the excitation from the N–O σ-bonding orbital to the odd π-orbital. For the values of ε_n and $\varepsilon_{\sigma(N-O)}$, the preceding results concerning the H_2NO radical were used: $\varepsilon_n = -14.75$ eV and $\varepsilon_{\sigma(N-O)} = -19.20$ eV.[1] The value of the two-center integral, γ,

12) Th. A. J. W. Wajer, A. Mackor, Th. J. de Boer and J. D. W. van Voorst, *Tetrahedron Letters*, **20**, 1941 (1967).

13) A nitrogen hyperfine splitting constant of an aromatic nitric oxide radical can be estimated by the relation,

$$a_N = \rho_N|Q_N| - \rho_O|Q_O|.$$

14) Strictly speaking, the lone-pair electron of the oxygen atom is not completely localized on the oxygen atom (see Ref. 1.)

15) In the calculation for the H_2NO radical, the electron repulsion integrals were $\gamma_{NN}=19.3$, $\gamma_{OO}=22.5$, and $\gamma_{NO}=11.3$ eV (see Ref. 1).

*1 Equation (3) is expanded as:

$$J_{\pi\pi} = \rho_N^2(NN \mid NN) + \rho_O^2(OO \mid OO) + 2\rho_N\rho_O(NN \mid OO) + c(1-\rho_{NO}^2)$$

where the constant, *c*, corresponds to the mean value of (tt/uu) (t=C, u=C, N, O); this value is approximately equal to the two-center integral, γ.

16) For the H_2NO radical, this is correct (see Ref. (1)).

TABLE 2. CALCULATED g FACTORS FOR AROMATIC NITRIC OXIDE RADICALS

	Odd orbital energy*1 (eV)	Excitation energy (eV)		$\Delta g_{xx}\times10^{-5}$	$\Delta g_{yy}\times10^{-5}$	g, Factor*2		
		$n\rightarrow\pi^\circ$	σ(N-O)$\rightarrow\pi^\circ$			g_{xx}	g_{yy}	g_{av}*3
H_2NO radical	−3.63	2.77	7.22	388	678	2.0062	2.0091	2.0059
Phenyl nitric oxide	−4.94	1.89	6.34	265	674	2.0050	2.0091	2.0055
Diphenyl nitric oxide	−5.18	1.87	6.32	225	617	2.0046	2.0086	2.0051
Carbazole *N*-oxide	−5.64	1.47	5.92	226	798	2.0046	2.0103	2.0057

*1 Obtained from the calculation I

*2 The most important excited states correspond to the excitations from the non-bonding orbital to the odd π-orbital and from the N-O σ-bonding to the odd π-orbital and only these excitations were considered. The contributions from the other excited states are small.[2] N-O axis taken as y axis; z axis perpendicular to molecular plane.

*3 Obtained by $g_{av}=\frac{1}{3}(g_{xx}+g_{yy}+g_{zz})$ with $g_{zz}=2.0023$

is determined so that the $n\rightarrow\pi$ excitation energy of the H_2NO radical calculated from Eq. (8) agrees with the experimental $n\rightarrow\pi$ transition energy of the aliphatic nitric oxide radical (2.76 eV[17]). The relations obtained are:

$$\left.\begin{aligned}&\Delta E_{n\rightarrow\pi^\circ}(\mathrm{eV}) = \\ &\quad \varepsilon_{\pi^\circ} + 14.75 - 2.79(2+2\rho_{NO}-\rho_{NO}^2) \\ &\Delta E_{\sigma(N-O)\rightarrow\pi^\circ}(\mathrm{eV}) = \\ &\quad \varepsilon_{\pi^\circ} + 19.20 - 2.79(2+2\rho_{NO}-\rho_{NO}^2)\end{aligned}\right\} \quad (9)$$

Using the spin density on the N-O group and the orbital energy of the odd π-orbital, the excitation energies and the g factors of aromatic nitric oxide radicals were calculated; they are tabulated in Table 2. The averaged g factors for aromatic nitric oxide radicals were in the range of 2.005—2.006; they agree with the experimental values in solution.[5] It may be concluded that, in aromatic nitric oxide radicals, the spin density on the N-O group is smaller than that for the aliphatic nitric oxide radical, but the excitation energy from the σ-frame to the odd π-orbital is lower than that for the aliphatic nitric oxide, mainly because of the lower energy of the odd π-orbital. As a result, aromatic nitric oxide radicals reveal g factors similar to those of aliphatic nitric oxide radicals.

The author wishes to express his thanks to Professor Keizo Suzuki, Tokyo Kyoiku University, and to Dr. Kazuo Someno, Government Chemical Industrial Research Institute, Tokyo, for their helpful suggestions and encouragement during the course of this work. Nature of Acid Sites on the Surface of Silica-alumina. I. The Relation between the Acid Property of Sites and the Heat of Immersion

Masaji MIURA, Yukio KUBOTA,*1 Toru IWAKI, Kazuto TAKIMOTO and Yoshinori MURAOKA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received September 20, 1968)

The acidity and the acid strength of the sites of such solid catalysts as silica gel, alumina, and silica-alumina were determined by the *n*-butylamine titration method using the Hammett indicators. The distribution of the acid sites on the surfaces of these catalysts was found to vary with the outgassing temperature, and also with the alumina content in the case of silica-alumina. The heats of immersion of these catalysts in water and in an aqueous solution of *n*-butylamine were measured. The heat value corresponding to the difference between these two cases, as well as the number of acid sites, showed a maximum at contents of 10—20%. These phenomena are discussed with reference to the results of the diffuse reflection measurements.
