Syntheses of Optically Active Amino Acids by Reduction of Schiff Bases with Sodium Borohydride[1)]

Kaoru HARADA and Jun-ichi OH-HASHI

Institute of Molecular Evolution and Department of Chemistry, University of Miami, Coral Gables, Florida 33134, U.S.A.

(Received September 29, 1969)

Several nonenzymatic asymmetric syntheses of α-amino acids from their corresponding α-keto acids have been reported.[2-12)] An asymmetric synthesis of α-amino acids by catalytic hydrogenation and subsequent hydrogenolysis of the Schiff bases of

and electrolytic reduction.[19] In the present study, the Schiff bases of α-keto acids with optically active α-alkylbenzylamines were reduced with sodium borohydride. The reduced compounds were further hydrogenolyzed and hydrolyzed to afford α-amino acids. The α-keto acid esters used were: ethyl pyruvate, ethyl α-ketobutyrate, and benzyl pyruvate. The optically active α-alkylbenzylamines used were: S(−)-α- and R(+)-α-methylbenzylamine, S(−)-α- and R(+)-α-ethylbenzylamine. Solvents used were: diglyme, tetrahydrofuran, and ethanol. The Schiff base was dissolved in a solvent and was reduced with sodium borohydride at room temperature (or at 0°C). After the reaction was over, the boron complex was decomposed with hydrochloric acid. The resulting *N*-alkyl amino acid ester was hydrolyzed and then hydrogenolyzed by the use of palladium hydroxide on charcoal. A part of the reduction product was applied to an amino acid analyzer to estimate the yield of amino acid. The other part was desalted and then applied to a Dowex 50×2 column (H form). Free amino acids were obtained by elution with aqueous ammonia. The resulting amino acids still contained some impurities, so that the measurements of optical rotation at this stage were meaningless. The crude amino acids were converted to their corresponding DNP-amino acids by the use of 2,4-dinitrofluorobenzene in a conventional manner.[20] The resulting DNP-amino acids were purified without fractionation of optical isomers by the use of Celite column chromatography,[21] as reported in the previous papers.[5,6] Results are summarized in Tables 1 and 2.

The yields of the asymmetric synthesis were rather low (5—27%). The optical purity of synthesized amino acids was in a range of 9—36%. When (S)-α-alkylbenzylamines were used, (S)-amino acids were synthesized. Yields of amino acids prepared at lower temperature (0°C) were smaller than that prepared at room temperature. However, optical purities of amino acids prepared at 0°C and at room temperature (25°C) were found to be the same (Table 1, 15—20). Yields of amino acids were almost constant dependent on the amount of sodium borohydride used (Table 1, 15—20). When α-methylbenzylamine was used, higher optical activity of amino acid was obtained than by the use of α-ethylbenzylamine. The optical purities of alanine were generally higher than that of α-amino butyric acid. These results are similar to those obtained by the hydrogenolytic asymmetric transamination of α-keto acids,[9,10] or α-keto acid esters,[12] with optically active α-alkylbenzylamine.

Experimental

Amino Acids from Benzyl Esters of α-Keto Acids. Benzyl pyruvate (1.78 g, 0.01 mol) and S(−)-α-methylbenzylamine (1.21 g, 0.01 mol) were dissolved in 50 ml of benzene and the solution was gently refluxed for 30 min using a Dean and Stark distillation tube. After dehydration was over, benzene was evaporated under reduced pressure. The residual syrup was dissolved in 30 ml of tetrahydrofuran. To this, sodium

borohydride (0.380 g, 0.01 mol) was added under stirring at room temperature. No heat generation was observed. After 2 hr of stirring, 10 m*l* of 2N hydrochloric acid was added to decompose unreacted sodium borohydride and boron complex. The solvent was removed under reduced pressure. The residual material was dissolved in a mixture of 10 m*l* of water and 5 m*l* of methanol. Sodium hydrogencarbonate was added to the solution to adjust the pH to about 8.0. Palladium hydroxide on charcoal (0.50 g) was added to the solution and hydrogenolysis was carried out for 30 hr. After hydrogenolysis was over, the catalyst was filtered and washed with water. A part of the combined solution was used for amino acid analysis to determine the yield of amino acid.

To the main reaction mixture, 10 m*l* of 2N hydrochloric acid was added and the solution was evaporated to dryness under reduced pressure. To the residual material, absolute ethanol (20 m*l*) was added to extract amino acid hydrochloride. Undissolved sodium chloride was removed by filtration. The alcoholic solution was evaporated to dryness *in vacuo* and the residue was dissolved in 10 m*l* of water. The amino acid solution was applied to a Dowex 50×2 column (H form, 2× 15 cm). The column was washed with water until the effluent became neutral. Then amino acid was eluted with 5% pyridine (*v*/*v*). Fractions containing alanine were combined and evaporated, 0.16 g (18%).

The crude alanine was treated with 2,4-dinitrofluorobenzene in a conventional manner.[20] The resulting DNP-alanine was purified by the use of a Celite column treated with pH 7.0 buffer as described in the earlier reports.[5,6] Results are listed in Table 1.

DNP-(S)-Alanine (reaction 3): $[\alpha]_D^{25}$ +41.5° (*c* 0.46, 1N NaOH).

Found: C, 42.48; H, 3.63; N, 16.38%. Calcd for $C_9H_9N_3O_6$: C, 42.36; H, 3.55; N, 16.47%.

DNP-(R)-Alanine (reaction 4): $[\alpha]_D^{25}$ −40.8° (*c* 0.56, 1N NaOH).

Found: C, 42.53; H, 3.67; N, 16.30%. Calcd for $C_9H_9N_3O_6$: C, 42.36; H, 3.55; N, 16.47%.

Amino Acids from Ethyl Esters of α-Keto Acids. When ethyl esters of α-keto acids were used, the reaction mixture was hydrolyzed with 50 m*l* of 2N hydrochloric acid for 3 hr after reduction and evaporation of the solvent.

DNP-(S)-α-Aminobutyric acid (reaction 21): $[\alpha]_D^{25}$ +15.3° (*c* 0.42, 1N NaOH).

Found: C, 44.68; H, 4.18; N, 15.58%. Calcd for $C_{10}H_{11}N_3O_6$: C, 44.62; H, 4.12; N, 15.61%.

DNP-(R)-α-NH_2-Butyric acid (reaction 22): $[\alpha]_D^{25}$ −15.2° (*c* 0.52, 1N NaOH).

Found: C, 44.73; H, 4.13; N, 15.57%. Calcd for $C_{10}H_{11}N_3O_6$: C, 44.62; H, 4.12; N, 15.61%.

Amino Acids from Sodium Salts of α-Keto Acids. The experimental procedures using α-keto acid sodium salt are similar to those described above. The results are summarized in Table 2.

Amino Acid Analysis of the Products. Synthesized amino acids were analyzed by the use of a Phoenix 5000 K automatic amino acid analyzer. Alanine and α-aminobutyric acid appeared in the ranges of elution volume 148—159 m*l* and 157—159 m*l*. In each of the reactions using benzyl and ethyl esters of α-keto acid and also the α-keto acid sodium salt, few unknown peaks signifying trace amounts were observed in both long (for acidic and neutral amino acid) and short column (for basic amino acid) analyses. The elution volume of alaninol is in a range of 88—90 m*l* in the short column. Because trace amounts of a peak which might correspond to alaninol were found in the reduction products, the low yield of amino acid in this reduction could not be due to the formation of alaninol.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 963—965 (1970)

Reaction of Acetonitrile with Carboxylic Esters

Akira UCHIDA, Akio DOYAMA and Sumio MATSUDA

Faculty of Engineering, Osaka University, Yamadakami, Suita

(Received June 21, 1969)

Acetonitrile is metalated by means of alkali amide,[1,2] sodium,[2] alkyllithium,[3] lithium diethylamide[4] or sodium with naphthalene,[5] using ether, petroleum ether, benzene or ethylene glycol dimethyl ether as the solvent.

In a previous paper, a large excess of acetonitrile was treated with sodium, and then the reaction of the resultant cyanomethylsodium with aromatic carbonyl compounds was attempted.[7]

It is well known that cyanomethyl carbanion

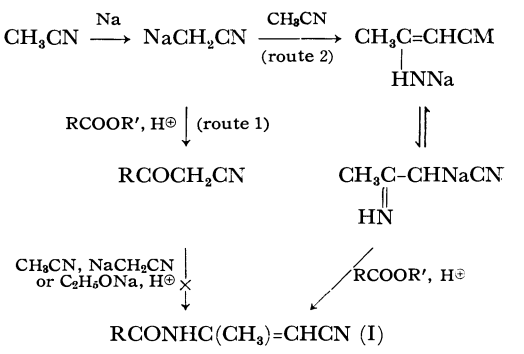
adds to acetonitrile to form diacetonitrile (β-aminocrotononitrile or β-iminobutyronitrile),[2,4,5] and that diacetonitrile condenses with carbonyl compounds.[6] However, when the reaction of cyanomethylsodium with aromatic carbonyl compounds was attempted in acetonitrile, the derivatives of hydroxypropionitrile or the derivatives of cinnamonitrile were obtained.[7] These results suggest that the cyanomethyl carbanion in acetonitrile did not add to the solvent molecule, but instead reacted predominantly with aromatic carbonyl compounds.

The present study will deal with the reaction of cyanomethyl carbanion (or cyanomethylsodium) with carboxylic esters in acetonitrile.



Results and Discussion

Lettré *et al.* attempted the condensation reaction of acetonitrile with various esters using sodium amide in ether and obtained the derivatives of acylacetonitrile.[1] According to the results described in a previous paper,[7] the formation of acylacetonitrile can be expected in the reaction of cyanomethylsodium with esters in acetonitrile.

When a solution of ethyl acetate and cyanomethylsodium in acetonitrile was heated under reflux for an hour, a crystalline solid was formed in a fairly good yield. This solid was identified as β-acetamidocrotononitrile from the spectroscopic data and from the results of elementary analysis, although the mp was not identical with that reported in the literature.[8] Similarly, β-benzamidocrotononitrile was obtained by the reaction of methyl benzoate.

The reaction of diethyl carbonate with acetonitrile in ether or alcohol, using sodium amide[9,10] or sodium ethoxide[11] as the catalysts, has been reported to give ethyl cyanoacetate. The reaction of diethyl carbonate with cyanomethylsodium in acetonitrile, however, resulted in the production of β-ethoxycarbonylaminocrotononitrile. These results are completely different from those to be expected on the basis of the previous paper.[7]

There might be at least two possible routes for the formation of β-acylaminocrotononitrile (I) by the reaction of an ester with cyanomethylsodium in acetonitrile.

If acylacetonitrile is formed by the reaction of cyanomethylsodium with esters, and if the resultant acylacetonitrile is added to a solvent molecule, any rearrangement will give I (route 1). On the other hand, if the reactivities of esters towards cyanomethylsodium are less than that of acetonitrile, cyanomethylsodium will add to acetonitrile preferentially to form diacetonitrile and the reaction of diacetonitrile with the esters will give I (route 2).

When a mixture of acetonitrile, acylacetonitrile (α-cyanoacetophenone or ethyl cyanoacetate,) and sodium ethoxide or cyanomethylsodium was heated under reflux for an hour, almost all of the acylacetonitrile was recovered. This means that the most plausible process is not the route 1 but the route 2. The discrepancies which exist between the aromatic carbonyl compounds and the esters may be supposed to be due to the differences in the reactivities of these two kinds of reactants towards cyanomethyl carbanion.

In the case of the reaction of the α,β-unsaturated ester with cyanomethylsodium in acetonitrile, the Michael-type addition was expected to occur. However, no Michael-type addition product was obtained; only the derivative of dihydropyridone (II) was obtained.

		R^1	R^2	R^3
II, III	a	H	H	CH_3
	b	H	CH_3	C_2H_5
	c	C_6H_5	H	CH_3
	d	CH_3	H	C_2H_5
	e	CH_3	$COOC_2H_5$	C_2H_5

Although the mechanism of the reaction (1) is not clearly known, the following process seems plausible.

Experimental

The same instruments as those described in the previous paper[7] were used for the spectroscopic measurements.

The esters (unless otherwise noted, 0.5 mol per 1.0-g atom of sodium) was added to a solution which had previously been prepared by the dissolution of sodium in acetonitrile (375 m*l* per 1.0-g atom of sodium)and was cooled in an ice-water bath. Then the mixture was heated under reflux for an hour and neutralized with dilute sulfuric acid. The organic phase was separated and dried over anhydrous magnesium sulfate, and the solvent was removed by distillation. From the residues, the following products were isolated.

β-Acetamidocrotononitrile, from ethyl acetate, in a 64% yield; mp 107—110°C (ethanol-water) (lit,[8] mp 53°C); IR (KBr Disk) 2220 cm^{-1} (CN), 1720 cm^{-1} (CO), 1640 cm^{-1} (C=C); NMR ($CDCl_3$) τ 7.89, 7.85 (3H×2, s, $C\underline{H}_3$), 3.60 (1H, s, C=C$\underline{H}$), 1.79 (1H, broad, CON$\underline{H}$).

Found: C, 57.82; H, 6.75; N, 22.72%; M^+, 124. Calcd for C_6H_8ON: C, 58.05; H, 6.50; N, 22.75%; mol wt, 124.14.

β-Benzamidocrotononitrile, from 0.46 mol of methyl benzoate per 1.0-g atom of sodium, in an 88% yield; mp 81—83°C (benzene); IR (KBr Disk) 2220 cm^{-1} (CN), 1685 cm^{-1} (C=C); NMR ($CDCl_3$) τ 7.75 (3H, s, $C\underline{H}_3$), 3.47 (1H, s, C=C$\underline{H}$CN), 2.5 (6H, m, aryl $\underline{H}$+N$\underline{H}$).

Found: C, 70.67; H, 5.46; N, 15.09%; M^+, 186. Calcd for $C_{11}H_{10}ON_2$: C, 70.95; H, 5.41; N, 15.05%; mol wt, 186.21.

β-Ethoxycarbonylaminocrotononitrile, from diethyl carbonate, in a 69% yield; mp 87—90°C(acetone); IR (KBr Disk) 2200 cm^{-1} (CN), 1750 cm^{-1} (CO), 1640 cm^{-1} (C=C); NMR ($CDCl_3$) τ 8.71 (3H, t, J=7 Hz, $C\underline{H}_3CH_2$), 7.82 (3H, s, $C\underline{H}_3$), 5.81 (2H, q, J=7 Hz, $CH_3C\underline{H}_2$), 4.04 (1H, s, C$\underline{H}$CN), 2.65 (1H, broad, CON$\underline{H}$).

Found: C, 54.67; H, 6.86; N, 18.17%; M^+, 154. Calcd for $C_7H_{10}O_2N_2$: C, 54.53; H, 6.54; N, 18.17%; mol wt, 154.17.

3,4-Dihydro-5-cyano-6-methyl-2-pyridone (IIa), from methyl acrylate, in a 69% yield; mp 213—214°C (THF); IR (KBr Disk) 3200, 3150 cm^{-1} (NH), 2200 cm^{-1} (CN), 1690 cm^{-1} (CO), 1650 cm^{-1} (C=C); NMR ($CDCl_3$) τ 7.88 (3H, s, $C\underline{H}_3$), 7.57 (4H, s, $C\underline{H}_2C\underline{H}_2$), 1.50 (1H, broad, CON$\underline{H}$).

Found: C, 61.58; H, 6.05; N, 20.43%; M^+, 136. Calcd for $C_7H_8ON_2$: C, 61.75; H, 5.92; N, 20.85%; mol wt, 136.15.

3,4-Dihydro-3,6-dimethyl-5-cyano-2-pyridone (IIb), from ethyl methacrylate, in a 75% yield; mp 148—150°C (ethanol); IR (KBr Disk) 3200, 3100 cm^{-1} (NH), 2200 cm^{-1} (CN), 1690 cm^{-1} (CO), 1650 cm^{-1} (C=C); NMR ($CDCl_3$) τ 8.77 (3H, d, J=6.0 Hz, $C\underline{H}_3$-CH), 7.86 (3H, s, $C\underline{H}_3$), 7.1—7.7 (3H, m, $C\underline{H}_2C\underline{H}$), 1.10 (1H, broad, CON$\underline{H}$).

Found: C, 64.00; H, 7.02; N, 18.77%; M^+, 150. Calcd for $C_8H_{10}ON_2$: C, 63.98; H, 6.71; N, 18.65%; mol wt, 150.18.

3,4-Dihydro-4-phenyl-5-cyano-6-methyl-2-pyridone (IIc), from 0.4 mole of methyl cinnamate per 1.0-g atom of sodium, in a 72% yield; mp 188—190°C (methanol); IR (KBr Disk) 3200, 3100 cm^{-1} (NH), 2200 cm^{-1} (CN), 1685 cm^{-1} (CO), 1634 cm^{-1} (C=C); NMR ($CDCl_3$) τ 7.86 (3H, s, $C\underline{H}_3$), 7.16 (2H, m, $C\underline{H}_2$), 6.12 (1H, m, $C_6H_5C\underline{H}$), 2.73 (5H, m, aryl $\underline{H}$), 1.12 (1H, broad, CON$\underline{H}$).

Found: C, 73.65; H, 5.45; N, 13.23%; M^+, 212. Calcd for $C_{13}H_{12}ON_2$: C, 73.56; H, 5.70; N, 13.20%; mol wt, 212.24.

3,4-Dihydro-4,6-dimethyl-5-cyano-2-pyridone (IId), from ethyl crotonate, in a 57% yield; mp 130—132°C (acetonitrile); IR (KBr Disk) 3200, 3100 cm^{-1} (NH), 2200 cm^{-1} (CN), 1670 cm^{-1} (CO), 1620 cm^{-1} (C=C); NMR ($CDCl_3$) τ 8.78 (3H, d, J=6.3 Hz, $C\underline{H}_3$-CH), 7.87 (3H, s, $C\underline{H}_3$C=C), 7.85—7.04 (3H, m, C$\underline{H}$-$C\underline{H}_2$), 1.02 (1H, broad, CON$\underline{H}$).

Found: C, 64.04; H, 7.08; N, 19.07%; M^+, 150. Calcd for $C_8H_{10}ON_2$: C, 63.98; H, 6.71; N, 18.69%; mol wt, 150.18.

3,4-Dihydro-3-ethoxycarbonyl-4,6-dimethyl-5-cyano-2-pyridone (IIe), from 0.4 mole of diethyl ethylidenemalonate per 1.0-g atom of sodium, in 60% yield; mp 91—93°C (ethanol-water); IR (neat) 3250 cm^{-1} (NH), 2200 cm^{-1} (CN), 1700 cm^{-1} (CO), 1640 cm^{-1} (C=C); NMR ($CDCl_3$) τ 8.73 (3H, d, J=7.0 Hz, $C\underline{H}_3CH$), 8.70 (3H, t, J=7.0 Hz, $C\underline{H}_3CH_2$), 7.83 (3H, s, $C\underline{H}_3$ C=C), 6.6—7.2 (2H, m, $CH_3C\underline{H}C\underline{H}COOC_2H_5$), 5.73 (2H, q, J=7.0 Hz, $CH_3C\underline{H}_2$), 1.20 (1H, broad, CON$\underline{H}$).

Found: C, 59.17; H, 6.40; N, 12.60%; M^+, 222. Cacld for $C_{11}H_{14}O_3N_2$: C, 59.45; H, 6.35; N, 12.60%; mol wt, 222.24.

SHORT COMMUNICATIONS

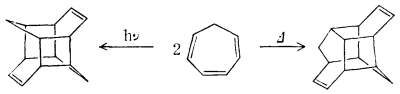
Thermal Dimerization of Tropilidene*1

Keigo TAKATSUKI,*2 Ichiro MURATA*2 and Yoshio KITAHARA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received December 12, 1969)

We have found an example of a [6+4] combination between two hydrocarbon molecules[1] in the Diels-Alder reaction for the first time. Although the photochemical dimerization of tropilidene (I) to give a dimer (II)[2] is known, comparable studies with thermal reactions have not hitherto been reported. In the course of our research on the Diels-Alder reactions of tropilidene, we have found that the thermal reaction of I gave a dimer (III).



(II) (I) (III)

Fig. 1

When I was heated in an ampoule at 170°C for 100 hr, vacuum distillation (40—43°C/1 mmHg) of the product followed by silicagel chromatography (pentane) gave colorless prisms (from methanol), mp 157—162°C, $C_{14}H_{16}$, in 26% yield, IR, 3020, 2910, 1641, 1436, 889, 731 cm^{-1}; UV, end absorption; MS, *m/e* 184 (M^+), the base peak was found at *m/e* 92 corresponding to the tropilidene ion $C_7H_8^+$ and the second intense peak at *m/e* 91 (79%) corresponding to the tropylium ion $C_7H_7^+$. The NMR specrtum[3] showed the asymmetric complex olefinic protons multiplet at 6.4—5.2 (4H) and the three groups of multiplets centered at 2.8 (4H, allylic methine), 2.3 (4H, methine) and 1.9 (4H, methylene) respectively. These data strongly suggest the structure of pentacyclo[7,5,0,$0^{2,7}$,$0^{5,13}$, $0^{6,12}$]tetradeca-3,10-diene (III) for this dimer. III was identical in all respects with the authentic sample[4] which was obtained by the Wolf-Kishner reduction of the cycloaddition product of tropone and I.[5]

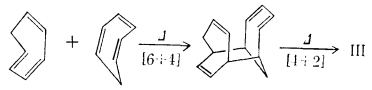


Fig. 2

The formation of III, which may be considered as a concerted [6+4]-cycloaddition[6] followed by an intramolecular Diels-Alder addition, is an additional evidence for the *trans*-[6+4]-cycloaddition.[5,7]

Fluorescence Spectrum of Pyrene Vapor: Emission from the Second Excited Singlet State*[1]

Akira NAKAJIMA and Hiroaki BABA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received November 22, 1969)

It is generally believed that in isolated polyatomic organic molecules, with the exception of azulene, internal conversion occurs at such a high efficiency that fluorescence cannot be observed from excited singlet states other than the first.[1-5] We have recently measured the fluorescence spectrum of pyrene vapor and detected an emission which can be assigned to fluorescence from the second excited singlet.

Fluorescence and excitation spectra were measured with a Hitachi fluorescence spectrophotometer of type MPF-2A, to which an electric furnace was attached. All the spectra were corrected for instrumental factors. Pyrene was highly purified by chemical treatment, chromatography, vacuum sublimation and zone melting.

Figure 1 shows fluorescence spectra of pyrene vapor. In the near ultraviolet region, pyrene has four electronic absorption bands denoted by I, II, III and IV. In Fig. 1, the wavelengths of the exciting light, 323, 268 and 236 mμ correspond

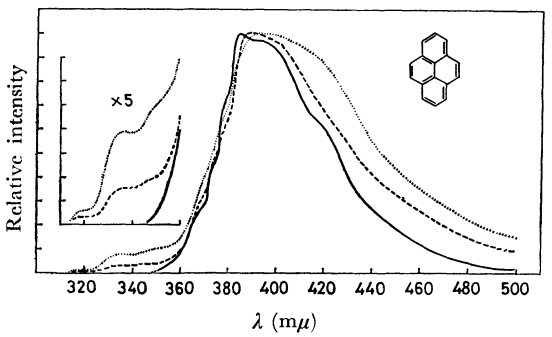

Fig. 1. Fluorescence spectra of pyrene vapor at 200°C and ~3 mmHg obtained by excitation at different wavelengths: solid line, 323 mμ; dashed line, 268 mμ; dotted line, 236 mμ.

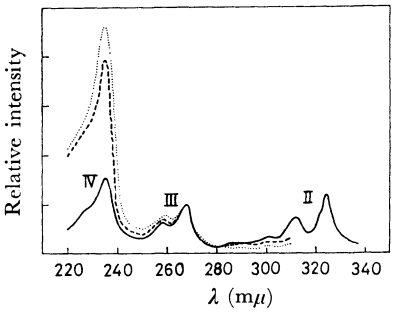

Fig. 2. Excitation spectra of pyrene vapor at 205°C and ~3 mmHg obtained by monitoring at different wavelengths: solid line, 370 mμ; dashed line, 340 mμ; dotted line, 330 mμ.

to the 0–0 transitions for II, III and IV, respectively. It is seen that excitation into the third or fourth excited singlet gives rise to an additional emission between 320 and 360 mμ, *i. e.*, in the region adjacent to the absorption band II. The fluorescence excitation spectrum obtained by monitoring the emission in the above region was different from that obtained by monitoring at a wavelength longer than 360 mμ (Fig. 2). The excitation spectrum monitored at 370 mμ is normal and is in agreement with the absorption spectrum. On the contrary, the excitation spectrum monitored at 340 or 330 mμ differs markedly from the absorption spectrum in intensity distribution, although both spectra have essentially the same vibrational structure. Thus, the quantum yield of the emission between 320 and 360 mμ increases rapidly with excitation into successively higher singlet states. These experimental results can be explained by attributing the emission in the 320—360 mμ region to the fluorescence which originates from the second excited singlet of the pyrene molecule.

Thiocarbonyl Compounds as Potential Scavengers of Carbon Radicals

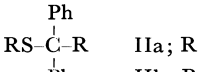
Gen-ichi TSUCHIHASHI, Makiko YAMAUCHI and Atsuyoshi OHNO

Sagami Chemical Research Center, Ohnuma, Sagamihara-shi, Kanagawa

(Received December 15, 1969)

Stable free radicals, such as di-*t*-butylnitroxide,[1] garvinoxyl,[2] or DPPH,[3] are known to act as scavengers for carbon radicals. We would like to report that thiocarbonyl compounds function as powerful, *molecular-type* scavengers toward carbon radicals.

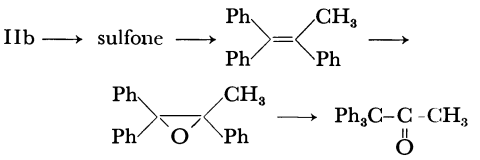
When azobisisobutyronitrile (AIBN) was decomposed in refluxing toluene containing an equimolar amount of thiobenzophenone (I), the yield of tetramethylsuccinonitrile (TMSN), a dimerization product of 1-cyano-1-methylethyl radicals, decreased from 89% (without I) to 21%. 1-Cyano-1-methylethyl radicals were efficiently captured by I, and as a result the adduct IIa was produced in 78% yield. IIa[4]: mp 168°C; IR 2200 and 2240 cm^{-1} (CN); NMR[5] 1.17 (s,6H), 1.34 (s,6H), and 7.3—7.8(m,10H); mass M^+ 334.



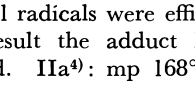
IIa; R=1-cyano-1-methylethyl

IIb; R=1-phenylethyl

Similarly, the addition of I for the decomposition of azobis(1-phenylethane) in toluene resulted in a marked decrease of the formation of 2,3-diphenylbutane:[6] 90% (without I) and 12% (with I). 1-Phenylethyl radicals were trapped by I and the addition product was obtained in 80% yield. This addition product proved to be a 1 : 1 mixture of two diastereomers of IIb, as shown by NMR: 0.86 (d,3H), 1.25(d,3H), 3.10(q,1H), 4.12(q, 1H), and ~7.1(m, 20H) for one isomer and 1.15(d,3H), 1.23(d,3H), 3.06(q,1H), 4.14(q,1H), and ~7.1 (m, 20H) for the other. The mass spectrum was also consistent with this structure, but the most convincing evidence is that oxidation of IIb with hydrogen peroxide in acetic acid produces soley methyl triphenylmethyl ketone in 98% yield. This presumably arises from oxidation of IIb to the sulfone, elimination of the sulfinic acid to form the olefin, and epoxidation, followed by rearrangement of the epoxide:



Thioacetophenone (III) also appears to be an efficient radical-capturing agent. Thus, when AIBN was decomposed in toluene with two molar equivalents of III, TMSN was formed in only 23% yield and the adduct (IVa) was produced instead of the dimer in a yield of 71%.



IVa; R=1-cyano-1-methylethyl

IVb; R=1-phenylethyl

IVa: mp 176°C; IR 2230 cm^{-1} (CN); NMR 0.97 (s,6H), 1.62(s,6H), 2.27(s,6H), and ~7.1(m,10H). Desulfurization of IVa with Ra-Ni(W-2) in ethanol gave *trans*-2,3-diphenyl-2-butene (79%). By a similar reaction of azobis(1-phenylethane) with III, adduct (IVb) was formed in 69% yield and the formation of 2,3-diphenylbutane was reduced to 27%. IVb: mp 204—205°C; NMR 1.30(d,6H), 1.45(s,6H), 3.26 (q,2H), and 6.9—7.2(m, 20H). Desulfurization of IVb with Ra-Ni(W-2) gave *trans*-2,3-diphenyl-2-butene(57%), *meso*-2,3-diphenylbutane (18%), and ethylbenzene(42%).

Hence these thioketones appear as potential radical scavengers. The capturing power is particularly strong toward a neutral carbon radical. 1-Phenylethyl radicals were trapped by I (five-fold excess)[7] and III (five-fold excess)[7] quite effectively, cutting down the yields of dimer to 6.0 and 8.2%, respectively, whereas the addition of thiophenol, in place of thioketones, to the system allowed formation of the dimer in a higher yield of 28%.[8] Apparently, these thioketones are much better scavengers than thiophenol. The use of these thioketones is further advantageous, because they possess visible absorption maxima at around 600 mμ. The extent of scavenged radical can be followed easily by measuring the disappearance of this visible absorption.

Studies on the relationship between the radical capturing power and the structure of thiocarbonyl compounds are in progress.

The Structures of Nigakilactones E and F

Tatsushi MURAE, Tôru IKEDA, Takahiko TSUYUKI, Tadaaki NISHIHAMA and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received December 16, 1969)

The isolation and determination of the structure of bitter principles (nigakilactones A, B, C and D (quassin)) of *Picrasma ailanthoides* Planchon have already been reported.[1] Two additional bitter principles have now been isolated from the same plant. These new bitter principles, nigakilactones E ($C_{24}H_{34}O_8$) and F($C_{22}H_{32}O_7$), contain one hydroxyl group more than nigakilactones C and B, respectively.

Nigakilactone F (I, R_1=OH, R_2=H, R_3=OH), mp 265—265.5°C, M^+ 408, $[\alpha]_D$ +46° (*c* 0.20, in EtOH), λ_{max}^{MeOH} 272 nm (ε 4500), IR (Nujol): 3530, 3470 sh, 3450, 1732, 1684, 1675, 1642, 1634 cm^{-1}, was obtained by the alkaline hydrolysis of nigakilactone E (I, R_1=OAc, R_2=H, R_3=OH), mp 280°C, M^+ 450, $[\alpha]_D$ +36° (*c* 0.22, in EtOH), λ_{max}^{MeOH} 264 nm (ε 4600), IR (Nujol): 3460, 1740, 1725 sh, 1717, 1642, 1255 cm^{-1}, which was not acetylated with acetic anhydride and pyridine.

The NMR spectra (Table 1) of nigakilactones E and F are best interpreted on the basis of the skeletal structures of two known nigakilactones C (I, R_1=OAc, R_2=H, R_3=H) and B (I, R_1=OH, R_2=H, R_3=H), respectively. The spectra of nigakilactones C and B show the presence of two secondary and two tertiary methyls. However, those of nigakilactones E and F indicate the presence of one secondary and three tertiary methyls.

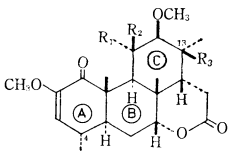
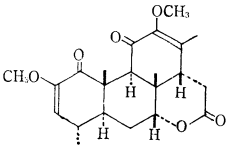
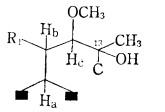
On oxidation with $Na_2Cr_2O_7$ in acetic acid, nigakilactone F yielded a ketone (I, R_1, R_2=O, R_3=OH), mp 256.5—257°C, $C_{22}H_{30}O_7$, M^+ 406, λ_{max}^{MeOH} 264 nm (ε 5700), IR (Nujol): 3550, 3480, 1730, 1696, 1630 cm^{-1}, which was then converted to quassin (II)[2] by dehydration with acetic anhydride and sodium acetate.



I



II



III-a: R_1=OAc
III-b: R_1=OH
(■ indicates carbon with no proton)

These observations, along with the spectral data (Table 1), show that a hydroxyl group is located on C-13 (not on C-4) and lead to partial structures of III-a and -b for the ring C of nigakilactones E and F, respectively. The coupling costants of H_a–H_b (J=11 Hz) and H_b–H_c (J=9 Hz) indicate that two adjacent protons are in axial-axial relationships. One secondary methyl of nigakilactone E (and F) should be located on C-4. The facile dehydration of the ketone (I, R_1, R_2=O, R_3=OH) to yield II suggests that the hydroxyl group at C-13 is in axial conformation.

Thus, the structures of nigakilactones E and F are shown to be I (R_1=OAc, R_2=H, R_3=OH) and I(R_1=OH, R_2=H, R_3=OH), respectively.

Vapor-phase Sample Supply of Metals as β-Diketonates in Atomic Absorption Spectroscopy[1]

Hisao KAWAMURA,* Giichiro TANAKA,* Norio KURITA** and Yoshihiko OHYAGI**

*Division of Environmental Contamination, National Institute of Radiological Sciences, Anagawa, Chiba
**Department of Chemistry, Faculty of Science, Chiba University, Yayoi-cho, Chiba

(Received December 27, 1969)

In atomic absorption and other flame spectroscopy, the nebulization technique has been widely employed to supply the analytical flame with liquid samples. Instead of the conventional nebulization, though, methods have recently been reported in which metal fumes or vapors are introduced to flames or absorption cells.[2] In the present work a volatilizer-premix burner system has been developed and a vapor-phase sample supply has been extended by the use of some β-diketonates of metals.[3]

The volatilizer-premix burner was constructed with a volatilizer unit and a pre-heated mixing chamber-type premix burner unit, which were connected to each other in a gas-tight manner. The volatilizer unit consisted of a volatilization chamber (a Pyrex tube, 1 cm I.D. × 13 cm L.) and an electric heater. This chamber was used with or without a small column packed in its rear end which worked as a "spoiler." The temperature inside the volatilization chamber was adjusted to any level between 100 and 250°C. The premix burner unit consisted of a metal mixing chamber with an electric heater and a 5 cm-slot burner head. The mixing chamber was heated to any temperature in the 150—250°C range. Dried nitrogen (up to 170 ml/min) was supplied to the volatilization chamber. Air (4.8 l/min) and acetylene (1.2 l/min) were supplied to the mixing chamber. A Perkin-Elmer Model 303 atomic absorption spectrophotometer was used to record the absorptions at the most sensitive line of each metal. Samples were prepared by dissolving the laboratory-prepared trifluoroacetylacetonates of copper, chromium and iron[4] in chloroform and commercially obtained acetylacetonates of copper and chromium in a chloroform-methanol mixture. Samples of 0.2—10 μl (containing about 0.1—5 μg metal) were injected by a microsyringe into the volatilization chamber through a silicone rubber septum.

Higher temperatures of the volatilization and mixing chamber, and larger nitrogen flow rates, generally gave higher peak absorptions. The analytical curves obtained with a 1 cm glass-microbead column spoiler are shown in Fig. 1. The absolute sensitivity was found to be considerably higher than that estimated with the conventional nebulization (about eight-fold in the case of chromium). With a 4 cm gas-liquid partition column spoiler (30% SE-30 on Shimalite W), the metal β-diketonates were completely separated from the solvent and from each other. Background absorption caused by chloroform was eliminated. These results indicate that the vaporphase sample supply in atomic absorption spectroscopy makes possible a rapid, highly sensitive, and interference-free determination of metals as volatile β-diketonates and possibly also as organometallic compounds. We have also noted the possibility of identifying any particular ligand of metal chelates.

The Crystal and Molecular Structure of 2,2′-Bipyridinium Tetrabromocobaltate(II)

Shigetaka KODA, Shun'ichiro OOI and Hisao KUROYA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received December 29, 1969)

2,2′-Bipyridine (=bip) reacts with $CoBr_2$ in a HBr solution to yield a moderately stable crystalline compound. Elemental analysis indicates the composition $[bipH_2][CoBr_4]$; this formula was confirmed by the X-ray analysis. We wish here to report the structural features of the $[CoBr_4]^{2-}$ ion and the conformation of the bipyridinium ion in the crystal.

Crystal data: monoclinic, space group $P2_1/c$: $a=8.420\pm0.005$, $b=14.00\pm0.01$, $c=12.878\pm0.006$ Å, $\beta=98.6\pm0.1°$; $Z=4$, $Dc=2.34$ g·cm^{-3}, $\mu=187.0$ cm^{-1} (for Ni$K\alpha$). Multiple-film equi-inclination Weissenberg photographs were taken with Ni$K\alpha$ radiation about the a and c axes, while the intensities of 1551 independent reflections were obtained by visual estimation.

The structure was solved by Patterson and Fourier methods, and the positional and isotropic thermal parameters were refined by the least-squares procedure. The conventional R-factor is 15.7% at this stage; further refinements are now in progress.

The crystal consists of bipyridinium cations and $[CoBr_4]^{2-}$ anions. In the anions, each cobalt atom is surrounded tetrahedrally by four bromine atoms. The mean value of the four Co–Br bond distances is 2.42 Å; this is presumably the first example found for the Co(II)–Br length. It is known that the configuration of the 2,2′-bipyridine molecule in the crystalline state is planar, the two nitrogen atoms being in the *trans* positions with respect to the C–C bond connecting the two pyridine rings.[1] However, this is not the case for our bipyridinium ion. As is shown in the figure, the pyridine rings are inclined toward one another, thus departing from the *trans*-coplanar configuration; the dihedral angle between the ring planes is 37.4°. The bipyridinium cation is isoelectronic with biphenyl, in which the angle of twisting is 45°.[2] The small discrepancy in those values may be attributable to the formation of rather strong hydrogen bonds between the two N^+–H groups in the cation and bromine atoms (N^+–H···Br^-=3.24 and 3.32 Å respectively). The bond distances and angles in the rings are normal within the range of standard deviation (~0.06 Å).

An Unusual Photochemical Reaction of Friedelin

Makoto TAKAI, Reiko AOYAGI, Shūzō YAMADA, Takahiko TSUYUKI and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received January 6, 1970)

The photochemical reaction of friedelin has already been reported.[1-3] We now wish to describe a photochemical cleavage of friedelin to form an unusual product whose formation is not known.

Photochemical Cleavage of Friedelin in *n*-Hexane. The suspension of friedelin (I, 1.00 g) in *n*-hexane (500 g) was heated under reflux with bubbling of argon for 1 hr. The solution was then irradiated with a high pressure mercury lamp (100 W) under an argon atmosphere for 8 hr at room temperature. After the solvent was distilled off under reduced pressure, the products were separated to hydrocarbon, aldehyde, ketene, ketone and carboxylic acid with silica gel chromatography.

From TLC examination (SiO_2; PhH : Et_2O, 10 : 1), the carboxylic acid was shown to be a mixture of two components. One of the components, with a lower R_f value, was identical with 3,4-secofriedelan-3-oic acid (II, R=H),[1,2] and the other was an unknown carboxylic acid.

After the ketene fraction was dissolved in benzene and heated with water for 2 hr, the same mixture was obtained as an acid fraction. The carboxylic acids were then esterified with diazomethane and separated to methyl 3,4-secofriedelan-3-oate (II, R=Me, 135 mg) and the other methyl ester (105 mg, about 10 per cent based on I). On mass spectra, the molecular ion peak of the latter appeared at *m/e* 444, which was 14 mass units (due to CH_2) lower than that of II(R=Me). Moreover, the peaks of $(M-56)^+$ were seen in the spectra of the two methyl esters. A loss of 56 mass units could be interpreted by the fragmentation 'a' (Fig. 1).

From these facts, the latter ester was inferred to be 5α-ethyl-10β-carbomethoxymethyl-des-A-friedelane (III, R=Me). This material was identical (mp, GLC, IR, mass and NMR spectra) with the authentic sample, obtained by the following method (Barbier-Wieland degradation) from ethyl 3,4-secofriedelan-3-oate (II, R=Et).

Synthesis of 5α-Ethyl-10β-carbomethoxymethyl-des-A-friedelane (III, R=Me). Irradiation of friedelin in ethanol gave ethyl 3,4-secofriedelan-3-oate (II, R=Et),[2] which afforded 3,3-diphenyl-3,4-secofriedelan-3-ol (IV) [mp 189—190°C, ν_{O-H} 3560 cm^{-1}, $C_{42}H_{62}O$] on Grignard reaction with phenylmagnesium bromide in tetrahydrofuran. IV gave 3,3-diphenyl-3,4-secofriedel-2-ene (V) [mp 202—203°C, $C_{42}H_{60}$] by dehydration with iodine and benzene. On oxidation of V with acetic acid and chromium trioxide, 5α-ethyl-10β-carboxymethyl-des-A-friedelane (III, R=H) [mp 249—250°C, $\nu_{C=O}$ 1695 cm^{-1}, $C_{29}H_{52}O_2$] was obtained. III(R=H) was esterified with diazomethane to give 5α-ethyl-10β-carbomethoxymethyl-des-A-friedelane (III, R=Me) [mp 173—174°C, $\nu_{C=O}$ 1735 cm^{-1}, mw 444 (mass). Found: C, 81.27; H, 11.81%. Calcd for $C_{30}H_{52}O_2$: C, 81.02; H, 11.79%].

Thus the unknown carboxylic acid was confirmed to be 5α-ethyl-10β-carboxymethyl-des-A-friedelane (III, R=H). This type of photochemical process giving rise to III(R=H) has never been reported. Studies to clarify this process are under way.

COS as an Electron Scavenger in Liquid-phase Radiolysis

Shun-ichi HIROKAMI, Seishi SHISHIDO and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received January 16, 1970)

Although many compounds such as alkyl halides are known to dissociate after capturing an electron,[1] there are a few compounds which produce stable products after the dissociation.[2] Nitrous oxide is one such exceptional compound and has been extensively used in radiation chemistry.[3] The discovery of more such compounds is eagerly desired.

In the study of the γ-radiolysis of benzene, we have recently used COS as one of the solutes and have found that this compound produces CO as much as N_2 when nitrous oxide is used as a solute. Figure 1 shows the results obtained when the competition of COS and N_2O was examined. Obviously, the CO production from a COS-benzene solution decreased as the concentration of N_2O increased; the decrease in CO was about a half of the difference between the amounts of N_2 produced in the absence and in the presence of COS.*1 Since the G-value of N_2 from a N_2O-benzene solution is known to be approximately twice that of the electrons captured by N_2O,[4] the above observation can easily be explained by assuming the following reaction:

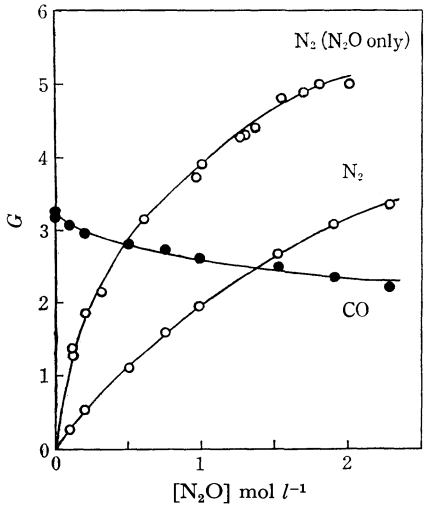

Fig. 1. The competition of COS and N_2O in the radiolysis of a benzene solution. The COS concentration is about 0.4 mol l^{-1}. (Direct decomposition of solutes is not corrected.)

$$e^- + COS \longrightarrow CO + S^-$$

or:

$$e^- + COS \longrightarrow COS^-$$

$$COS^- + C_6H_6^+ \longrightarrow CO + \text{residue}$$

At higher concentrations of N_2O, however, the amount of CO produced did not approach zero, but seemed to level off at a certain value. This is probably due to the reaction of COS with excited benzene molecules. If so, quantitative measurements will help the estimation of the ratio of ionization to excitation in the radiolysis of benzene.

We are now experimenting with COS as an electron scavenger in the radiolysis of saturated hydrocarbons. The results suggest that this compound is a little reactive to the radicals produced. This may cause some complications when analyzing the data. The details will be reported shortly.

Mechanism of the H_2–D_2 Exchange Reaction over ZnO—Dynamic Behaviour of Chemisorbed Hydrogen as a Reaction Intermediate during the Course of the Reaction

Shuichi NAITO, Hazime SHIMIZU, Etsuko HAGIWARA, Takaharu ONISHI and Kenzi TAMARU

Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received November 24, 1969)

The mechanism of the H_2–D_2 exchange reaction over ZnO at lower temperatures (from −70°C to room temperature) was studied by measuring the adsorption during the course of the reaction by the volumetric method as well as by the infrared spectroscopic technique.[1)]

The zinc oxide employed was Kadox 15 and Kadox 25 of the New Jersey Zinc Company; it was evacuated for more than five hours at 400°C prior to the reaction. The infrared spectra of the adsorbed hydrogen and deuterium on ZnO were observed at 3490 (ZnOH), 2584 (ZnOD), 1712 (ZnH), and 1233 (ZnD) cm^{-1}, as has been reported by Eischens, Pliskin and Low.[2)]

Below room temperature, the rate of hydrogen chemisorption over ZnO was rapid, while the rate of desorption was slow. No isotope effect was detected, within the limits of experimental error, in the rate of hydrogen and deuterium chemisorption or in the adsorption equilibrium over ZnO, as has been reported previously.[3)]

When H_2 (9.4 cmHg) was pre-adsorbed over ZnO and D_2 (9.6 cmHg) was then added to the system, the pre-adsorbed H(a) was displaced by D(a) as the exchange proceeded. The rate of HD formation obeyed the first-order rate equation as to H(a), a uniform reactivity of H(a) being demonstrated. Similar experiments were carried out by the infrared technique. The rate of the total decrease in the ZnH and ZnOH-band intensities was equal to that of the increase in the ZnD and ZnOD-band intensities, and it was revealed that the rate of HD formation is proportional to the amount of exchangeable hydrogen chemisorbed which is observed by the infrared technique, and to the D_2 pressure in the ambient gas. At 0°C, the rate of HD formation in the volumetric experiment and the rate of the total decrease in the ZnH and ZnOH-band intensities in the infrared spectroscopic technique were in reasonable agreement. These results lead to the conclusion that the chemisorbed hydrogen observed by the infrared technique exhibits a behaviour similar to that measured volumetrically and that it is the real intermediate of the exchange reaction.

When a mixture of H_2 and D_2 (1 : 1) (total 22.2 cmHg) was introduced, the amounts of ZnH, ZnOH, ZnD, and ZnOD were equal at the beginning of the adsorption, but as the exchange reaction proceeded the amounts of ZnH and ZnOD increased at different rates, whereas those of ZnD and ZnOH decreased correspondingly; this demonstrated the rearrangement of the chemisorbed species through the exchange reaction. No such rearrangement was detected in the absence of the ambient gas, which shows no appreciable mobility to be involved between the hydrogen on zinc and that on oxygen. When one mixture of H_2 and D_2 (2 : 1) (total 24.2 cmHg) was introduced over ZnO, the rate of HD formation was about one and half times as great as that when another H_2 and D_2 (1 : 2) (total 24.3 cmHg) mixture was introduced. Consequently, though no isotope effect is involved in the chemisorption, as has been described above, a considerable kinetic isotope effect is observed in the rate of the exchange reaction.

As the behaviour of the four chemisorbed species, ZnH, ZnD, ZnOH, and ZnOD, may be separately examined by the infrared technique over a wide range of ambient pressures and chemisorbed amounts, and with various isotope contents, the exchange reaction through one of those species and ambient molecules, or through their recombinations, may be studied. It was, consequently, concluded that the rate of the HD formation from the recombination of the chemisorbed species (the Langmuir mechanism), which corresponds to the desorption rate, is at least one or two orders of magnitude slower than the exchange reaction between the molecular hydrogen in the ambient gas and the chemisorbed species (the Eley-Rideal mechanism).

If the repetition of the dissociative chemisorption and desorption of hydrogen results in the H_2–D_2 exchange reaction, as neither process has any kinetic isotope effect, the exchange reaction rate would exhibit no kinetic isotope effect. The marked isotope effect demonstrated in the exchange reaction proves this not to be the case.

Statistical Thermodynamics of Binary Liquid Mixtures

Kiyoshi ARAKAWA and Osamu KIYOHARA

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received May 29, 1969)

By means of the cell method and using the Sutherland type potential function for pair interactions between molecules, a statistical theory was formulated for binary liquid mixtures consisting of rigid spherical molecules differing in size. A formula was derived for cohesive energy as a function of the volume of liquid, and studied in combination with the radial distribution function. The applicability of the square-well type potential function within a cell was also examined. Formulas for excess thermodynamic functions were derived and their applicability investigated. For 22 binary systems consisting of nearly spherical molecules, excess thermodynamic functions were calculated and compared with data in literature. The results show that the theory is applicable to the mixtures.

The present paper deals with the statistical theory of non-electrolyte solutions. The principal problem in the statistical thermodynamics of liquid mixtures is to calculate the thermodynamic properties of mixtures from the forces between molecules. Many attempts have been made since the designation of "regular solutions" by Hildebrand[1] and Scott.[1,2] The following theories are remarkable: "strictly regular solution theory" based on the lattice model developed by Guggenheim[3] and Rushbrooke,[4] the "conformal solution" theory by Longuet-Higgins,[5] theories by the cell method developed mainly by Prigogine and co-workers,[6-9] by Salsburg and Kirkwood,[10] and by Scott,[11] theories based on the explicit combination of the cell method and the "corresponding state theorem" developed by Prigogine and coworkers[12] and by Scott,[11] and the significant structure theory by Eyring and coworkers.[13]

Recently, Flory and Abe have presented a simple corresponding state theory of liquid mixtures of nonpolar molecules,[14] which is applicable to mixtures of molecules differing in size, based on Prigogine's treatment of *r*-mer molecules.[15]

Theories based on the radial distribution function, which have been developed by Kirkwood, Born, Green, and others,[16] are more rigorous than the theories described above, but they are mathematically laborious, and inconvenient for practical use.

The present statistical theories of solutions are unsatisfactory as a whole, as the agreement between calculated and observed values is only qualitative, and the underlying assumptions need further examination.

The authors present a statistical theory of binary liquid mixtures by the cell method in combination with the radial distribution function, where the interaction potential between molecules is assumed to be of Sutherland type.

Field for a Molecule within a Cell. In the following treatment we assume that molecules are rigid spheres, and the potential of interaction between two molecules is a function of the intermolecular separation. As the potential function for two molecules a distance a apart, a Sutherland type function, $\varepsilon(a)$, is used,[17] where a is the average distance between the centers of nearest neighbors.

$$\varepsilon(a) = \begin{cases} -\varepsilon^*\left(\frac{r^*}{a}\right)^6 & \text{for } a>r^* \\ \infty & \text{for } a<r^* \end{cases} \quad (1)$$

where ε^* is an energy constant. For a pure liquid, a molecule with a diameter r* is assumed to be wandering in a spherical cell of radius a. The average potential function of mutual interaction, $\bar{\varepsilon}(r)$, in the cell is evaluated according to the same averaging procedure as made by Lennard-Jones and Devonshire,[18] where r is the distance from the center of the cell.*1.

$$\bar{\varepsilon}(r) = \frac{1}{2}\int_0^\pi \varepsilon((r^2+a^2-2ar\cos\theta)^{1/2})\sin\theta \mathrm{d}\theta = \begin{cases} -\varepsilon^*(r^*/a)^6 & \text{for } r=0 \\ -\varepsilon^*\dfrac{r^{*6}(a^2+r^2)}{(a^2-r^2)^4} & \text{for } r<a-r^* \\ \infty & \text{for } r>a-r^* \end{cases} \quad (2)$$

The shape of the function is of nearly square-well type.

We have calculated the magnitude of $\bar{\varepsilon}(a-r^*)/\bar{\varepsilon}(0)$ (the ratio between the depth of the potential at the center and that at its periphery) in order to investigate the extent of deviations of the potential function $\bar{\varepsilon}(r)$ from the perfect square-well type. The results are given in Table 1 for various magnitudes of (a/r^*). In ordinary liquids, the ratio $(a/r^*)^3$ is believed to be not larger than 1.3.

Thus the function $\bar{\varepsilon}(r)$ could be approximated by a perfect square-well type whose depth is given in Eq. (2)

Table 1. Potential field within a cell

a/r^*	$(a/r^*)^3$	$\bar{\varepsilon}(a-r^*)/\bar{\varepsilon}(0)$
1.05	1.16	1.01
1.1	1.33	1.04
1.2	1.73	1.15

In order to obtain the average potential, $\omega(r)$, for a wandering molecule within a cell for $r<a-r^*$, the influence of the outer neighbors is taken into account, and the following integration has been made, where $g(l)$ is the radial distribution function[16,19] at distance l in the liquid consisting of N molecules and occupying a volume V.

$$\omega(r) = \int_{r^*}^\infty \bar{\varepsilon}(r)\cdot 4\pi l^2 \frac{Ng(l)}{V}\mathrm{d}l = -\int_{r^*}^\infty \varepsilon^*\frac{r^{*6}(l^2+r^2)}{(l^2-r^2)^4}\cdot\frac{4\pi l^2}{V}Ng(l)\mathrm{d}l = -\gamma\varepsilon^*\left(\frac{N\cdot\frac{4}{3}\pi r^{*3}}{V}\right)\times\left[1+3\left(\frac{\gamma'}{\gamma}\right)\left(\frac{r}{r^*}\right)^2+\mathrm{O}\left(\left(\frac{r}{r^*}\right)^4\right)\right] \quad (3)$$

where

$$\gamma = \int_{r^*}^\infty \frac{g(l)}{l^4}\mathrm{d}l \Big/ \int_{r^*}^\infty \frac{\mathrm{d}l}{l^4}, \qquad \gamma' = \int_{r^*}^\infty \frac{g(l)}{l^6}\mathrm{d}l \Big/ \int_{r^*}^\infty \frac{\mathrm{d}l}{l^6} \quad (4)$$

As described above, $r/r^* \lesssim 0.1$ for ordinary liquids, and γ and γ' are of the same order (Table 2). Therefore, $\omega(r)$ can be approximated by the first term in Eq. (3), similar to the case of the mutual potential energy $\bar{\varepsilon}(r)$. Throughout the present calculations the potential energy function $\omega(r)$ of square-well type, as given in the following, is used for a wandering molecule within a cell.

$$\omega(r) = \begin{cases} -\gamma\varepsilon^*\left(\frac{\frac{4}{3}\pi r^{*3}N}{V}\right) & \text{for } r<a-r^* \\ \infty & \text{for } r>a-r^* \end{cases} \quad (5)$$

The wandering molecule behaves like a gas molecule within a cell. The depth of the potential well, $\omega(0)$, is related to the heat of vaporization ΔH_V for the liquid as shown by

$$-\frac{N}{2}\omega(0) = \frac{2}{3}\pi N^2\gamma\varepsilon^* r^{*3}\frac{1}{V} = \Delta H_V - \boldsymbol{R}T, \quad (6)$$

where $\boldsymbol{R}$ is gas constant and T temperature.

Partition Function for a Binary Liquid Mixture. Thermodynamic properties of a solution consisting of N_A molecules of species A and N_B molecules of species B, are derived from the following partition function Z formulated by the cell method assuming the square-well type potential within each cell in the solution.

$$Z = \frac{N!}{N_A!N_B!}f_A^{N_A}f_B^{N_B}\times\exp\left[-\frac{1}{2\boldsymbol{k}T}(N_A\omega_A(0)+N_B\omega_B(0))\right]$$

$$f_A = \frac{4\pi}{3}(a_A-r_A^*)^3 j_A, \quad f_B = \frac{4\pi}{3}(a_B-r_B^*)^3 j_B \quad (7)$$

where $j_A(T)$ and $j_B(T)$ are internal partition functions for each molecule of species A and B, and

17) J. O. Hirshfelder, C. F. Curtiss and R. B. Bird, "Molecular Theory of Gasses and Liquids," Wiley, New York (1954), p. 32.

18) J. E. Lennard-Jones and A. F. Devonshire, *Proc. Roy. Soc.*, **A163**, 53 (1937), **A165**, 1 (1938).

*1 Readers should refer to "Theory of Liquids," A. Harashima (Iwanami), pp. 41—42, Fig. 8—1 (1954).

19) J. G. Kirkwood, E. K. Maun and B. J. Alder, *J. Chem. Phys.*, **18**, 1040 (1950).

$\omega_A(0)$ and $\omega_B(0)$ are the depth of the potential well for the molecules of species A and B in each cell, respectively. a_A and a_B are the radius of the spherical cell for each species in the solution. They are related to the volume per molecule v by the formula

$$\frac{V}{N} = v(a_A, a_B) = x_A\beta a_A^3 + x_B\beta a_B^3, \tag{8}$$

where x_A and x_B are the mole fraction for each species. The applicability of the common packing parameter β is assumed. r_A^* and r_B^* are the collision diameter of the molecule within each cell. They are assumed to be related to the diameters of each species in the pure state r_{AA}^* and r_{BB}^* by the formula

$$r_A^* = x_A r_{AA}^* + x_B r_{AB}^*, \quad r_B^* = x_A r_{AB}^* + x_B r_{BB}^*, \tag{9}$$

where

$$r_{AB}^* = \frac{1}{2}(r_{AA}^* + r_{BB}^*).$$

The energy $\omega_A(0)$ and $\omega_B(0)$ for the molecules within cell, and $\omega_A^\circ(0)$ and $\omega_A^\circ(0)$ for the molecules within cells in each pure liquid, are given by

$$\begin{aligned}
\omega_A(0) &= -\gamma\varepsilon_A^*\left(\frac{\frac{4}{3}\pi r_A^{*3}}{v}\right),\\
\omega_B(0) &= -\gamma\varepsilon_B^*\left(\frac{\frac{4}{3}\pi r_B^{*3}}{v}\right),\\
\omega_A^\circ(0) &= -\gamma\varepsilon_{AA}^*\left(\frac{\frac{4}{3}\pi r_{AA}^{*3}}{v_A^\circ}\right),\\
\omega_B^\circ(0) &= -\gamma\varepsilon_{BB}^*\left(\frac{\frac{4}{3}\pi r_{BB}^{*3}}{v_B^\circ}\right)
\end{aligned} \tag{10}$$

according to Eq. (5),
where v_A° and v_B° are the volume per molecule in each pure state. The energy parameters ε_A^* and ε_B^* are given by

$$\varepsilon_A^* = x_A\varepsilon_{AA}^* + x_B\varepsilon_{AB}^*, \quad \varepsilon_B^* = x_A\varepsilon_{AB}^* + x_B\varepsilon_{BB}^*, \tag{11}$$

where ε_{AB}^* is the energy parameter of the Sutherland type pair interaction between species A and B (Eq. (1)) in the solution.

Determination of Parameters a_A and a_B, and the Equation of State. The two parameters a_A and a_B, which are the radius of the spherical cell for each species in the solution, are determined by the minimization of the Helmholtz energy A under the condition of a given volume (Eq. (8)) as well as that of vanishing external pressure by procedures similar to those adopted by Prigogine and Bellemans.[9]

$$A = A(a_A, a_B, T) = A(a_A, v, T) = -kT\ln Z \tag{12}$$

$$\left(\frac{\partial A}{\partial a_A}\right)_{v,T} = \left(\frac{\partial A}{\partial a_A}\right)_{a_B,T} + \left(\frac{\partial A}{\partial a_B}\right)_{a_A,T}\left(\frac{\partial a_B}{\partial a_A}\right)_v = 0 \tag{13}$$

$$-p = \left(\frac{\partial A}{\partial v}\right)_{T,a_A} = \left(\frac{\partial A}{\partial a_B}\right)_{a_A,T}\left(\frac{\partial a_B}{\partial v}\right)_{a_A} = 0 \tag{14}$$

Combinining Eqs. (13) and (14), we obtain

$$\left(\frac{\partial A}{\partial a_A}\right)_{a_B,T} = \left(\frac{\partial A}{\partial a_B}\right)_{a_A,T} = 0. \tag{15}$$

From Eqs. (7) and (12), the Helmholtz energy A is expressed as follows.

$$\begin{aligned}
A = {} & \frac{N}{2}(x_A\omega_A(0) + x_B\omega_B(0))\\
& + NkT(x_A\ln x_A + x_B\ln x_B)\\
& - NkT(x_A\ln f_A + x_B\ln f_B)
\end{aligned} \tag{16}$$

Introducing Eq. (16) into Eq. (15), and assuming $(\partial\gamma/\partial v)=0$,[*2] we obtain

$$\begin{aligned}
a_A^2(a_A - r_A^*) &= a_B^2(a_B - r_B^*)\\
&= \frac{3v^2kT}{2\pi\gamma\beta(x_A\varepsilon_A^* r_A^{*3} + x_B\varepsilon_B^* r_B^{*3})}.
\end{aligned} \tag{17}$$

In principle, we can determine the magnitude of a_A and a_B from Eq. (17). However, it is difficult to obtain analytical solutions of a_A and a_B because Eq. (17) is 3rd power with respect to a_A and a_B. Thus putting

$$\frac{a_A - r_A^*}{r_A^*} = \rho_A, \quad \frac{a_B - r_B^*}{r_B^*} = \rho_B \tag{18}$$

and using the conditions $\rho_A < 1$, $\rho_B < 1$ for ordinary liquids, we obtain the following relation, where Eq. (8) is used and higher order terms than the first with respect to ρ_A and ρ_B are ignored.

$$\frac{v - \beta(x_A r_A^{*3} + x_B r_B^{*3})}{v^2} = \frac{9kT}{2\pi(x_A\gamma\varepsilon_A^* r_A^{*3} + x_B\gamma\varepsilon_B r_B^{*3})} \tag{19}$$

$$\begin{aligned}
\rho_A &= \frac{3v^2kT}{2\pi\beta r_A^{*3}(x_A r_A^{*3}\gamma\varepsilon_A^* + x_B r_B^{*3}\gamma\varepsilon_B^*)}\\
\rho_B &= \frac{3v^2kT}{2\pi\beta r_B^{*3}(x_A r_A^{*3}\gamma\varepsilon_A^* + x_B r_B^{*3}\gamma\varepsilon_B^*)}.
\end{aligned} \tag{20}$$

Excess Thermodynamic Functions of the Binary Liquid Mixture. Various excess thermodynamic functions can be obtained from the equations described above. The excess Helmholtz energy $A_E = A - x_A A_A^\circ - x_B A_B^\circ - T\Delta S_{\text{mix}}^{\text{id.}}$ is given in Eq. (21) from Eq. (16).

$$\begin{aligned}
A_E = {} & \frac{N}{2}\{x_A(\omega_A(0) - \omega_A^\circ(0)) + x_B(\omega_B(0) - \omega_B^\circ(0))\}\\
& - NkT\left(x_A\ln\frac{f_A}{f_A^\circ} + x_B\ln\frac{f_B}{f_B^\circ}\right)
\end{aligned} \tag{21}$$

where $\omega_A(0)$, $\omega_B(0)$, $\omega_A^\circ(0)$, $\omega_B^\circ(0)$, f_A, and f_B are given in Eqs. (7) and (10). The superscript $^\circ$ represents the values for pure liquids. The excess

[*2] As will be discussed later, γ is slightly dependent on volume. However, in the present treatment γ is replaced by its average value.

energy $E_E=E-x_AE_A^\circ-x_BE_B^\circ$ is obtained from Eq. (21) and the thermodynamical relations, assuming $(\partial\gamma/\partial T)_V=0$ and the invariance of internal partition function by the transfer from pure liquid to solution.

$$E_E=\frac{N}{2}\{x_A(\omega_A(0)-\omega_A^\circ(0))+x_B(\omega_B(0)-\omega_B^\circ(0))\} \tag{22}$$

Introducing Eq. (10) into Eq. (22), we obtain

$$E_E=-\frac{2\pi N}{3}\left\{\frac{1}{v}(x_Ar_A^{*3}\gamma\varepsilon_A^*+x_Br_B^{*3}\gamma\varepsilon_B^*)-\left(\frac{x_Ar_{AA}^{*3}\gamma\varepsilon_{AA}^*}{v_A^\circ}+\frac{x_Br_{AA}^{*3}\gamma\varepsilon_{BB}^*}{v_B^\circ}\right)\right\} \tag{22'}$$

The excess entropy $S_E=S-x_AS_A^\circ-x_BS_B^\circ-\Delta S_{\text{mix}}^{\text{id.}}$ is obtained as follows.

$$S_E=-3Nk\left(x_A\ln\frac{a_A^\circ-r_{AA}^*}{a_A-r_A^*}+x_B\ln\frac{a_B^\circ-r_{BB}^*}{a_B-r_B^*}\right)=-3Nk\left(x_A\ln\frac{\rho_A^\circ r_{AA}^*}{\rho_Ar_A^*}+x_B\ln\frac{\rho_B^\circ r_{BB}^*}{\rho_Br_B^*}\right) \tag{23}$$

The excess volume $V_E=V-x_AV_A^\circ-x_BV_B^\circ$ is obtained from Eq. (19)

$$V_E=N\left[\beta\{x_A(r_A^{*3}-r_{AA}^{*3})+x_B(r_B^{*3}-r_{BB}^{*3})\}+\frac{9kT}{2\pi}\left\{\frac{(x_Av_A^\circ+x_Bv_B^\circ)^2}{x_A\gamma\varepsilon_A^*r_A^{*3}+x_B\gamma\varepsilon_B^*r_B^{*3}}-\frac{x_Av_A^{\circ2}}{\gamma\varepsilon_{AA}^*r_{AA}^{*3}}-\frac{x_Bv_B^{\circ2}}{\gamma\varepsilon_{BB}^*r_{BB}^{*3}}\right\}\right]\Big/\left[1-\frac{9kT}{\pi}\left(\frac{x_Av_A^\circ+x_Bv_B^\circ}{x_A\gamma\varepsilon_A^*r_A^{*3}+x_B\gamma\varepsilon_B^*r_B^{*3}}\right)\right]. \tag{24}$$

From Eq. (19) we obtain the following equation, when $x_A=1$ and $x_B=0$.

$$\gamma\varepsilon_{AA}^*=\frac{9kT}{2\pi}\cdot\frac{v_A^\circ}{r_{AA}^{*3}}\cdot\frac{v_A^\circ}{v_A^\circ-\beta r_{AA}^{*3}} \tag{25}$$

Introducing Eqs. (10) and (25) into Eq. (22), the approximate relation between E_E and V_E is derived.

$$\frac{E_E}{3NkT}=\left\{\left(\frac{x_Av_A^\circ}{v_A^\circ-\beta r_{AA}^{*3}}+\frac{x_Bv_B^\circ}{v_B^\circ-\beta r_{BB}^{*3}}\right)-\left(\frac{\bar v_0}{\bar v_0-\bar v^*}\right)\right\}+\left\{\frac{\bar v^*}{(\bar v_0-\bar v^*)^2}\right\}v_E \tag{26}$$

where $\bar v_0=x_Av_A^\circ+x_Bv_B^\circ$ and $\bar v^*=x_A(\beta r_{AA}^{*3})+x_B(\beta r_{BB}^{*3})$, and the conditions $v_E\ll\bar v_0$ and $v_E\ll\bar v_0-\bar v^*$ are satisfied.

Discussion on the Potential $\omega(r)$ and the Physical Meaning of the Parameter γ. *Volume Dependency of the Potential within a Cell.* For the volume dependency of the potential energy the inverse first power relation has been proposed by Hildebrand *et al.*,[20] and adopted by Flory and Abe[14] in their solution theory. Assuming that the energy is proportional to V^{-n}, Hildebrand and co-workers showed the power n for various organic liquids to be not far from unity. Their result was confirmed experimentally by Beninga and Scott.[21]

We have derived the average potential as a function of the volume of liquid on the basis of the Sutherland type interaction, and have obtained an explicit representation of the potential with molecular parameters using the radial distribution function $g(l)$.

In the derivation of the equation of state, Eq. (17), from Eq. (15), we have assumed that γ is independent of volume. The potential function $\omega(r)$ (Eq. (5)) within a cell is found to be proportional to $(1/V)$ in accordance with the earlier results.[20,21] The value of γ is maintained to be 2.0 within the range of fluctuation of 0.1 for ordinary liquids (Table 3 and Appendix). The underlying assumption is regarded to be reasonable as an approximation. However, as seen in Table 2 γ decreases gradually with volume. This means that $n>1$. Recently, it has been found experimentally that n is 1.4 for alkanes which are non-spherical in molecular shape.[22]

Temperature Dependence of the Parameter γ. Using the values of $g(l)$ calculated by Kirkwood *et al.*[19] for liquids consisting of rigid spherical molecules, we have determined the magnitude of γ (Table 2) for various magnitudes of a parameter λ which is related to density.[19]

Table 2. Values of parameter γ

	Rigid sphere with no attractive forces*[19]				
λ	5	10	20	27.4	33
V/V^*	5.15	3.20	2.10	1.73	1.53
γ	1.19	1.36	1.59	1.72	1.82
γ'	1.29	1.50	1.81	1.99	2.13

	Lennard-Jones fluid, (Kirkwood *et al.*[23])		
	$\lambda=27.4$	$V/V^*=1.73$	
kT/ε	0.833	1.111	1.667
γ	1.63	1.69	1.78

	Lennard-Jones fluid (Verlet[24])		
		$V/V^*=1.885$	
kT/ε	0.827		1.304
γ	1.49		1.49
		$V/V^*=1.663$	
kT/ε	0.719	0.880	1.273
γ	1.60	1.60	1.57

* $V^*=N\beta r^{*3}$

As seen from Eq. (4), γ is dependent on temperature through the temperature dependence of $g(l)$. In the derivation of Eq. (22) the temperature dependence of γ is ignored. Taking the temperature dependence into account, the excess energy E_E is obtained as

20) Ref. 17, p. 280; Ref. 1, Chapter V.

21) H. Beninga and R. L. Scott, *J. Chem. Phys.*, **23**, 1911 (1955).

22) V. Fried and G. B. Schneider, *J. Phys. Chem.*, **72**, 4688 (1968).

$$E_E = \frac{\partial(A_E/T)}{\partial(1/T)_V} = E_E^\circ\left(1-\left(\frac{\partial \log \gamma}{\partial \log T}\right)_V\right), \quad (27)$$

where E_E° is the excess energy given in Eq. (22), and the same temperature dependence of γ is assumed for all species.

According to the Kirkwood-Born-Green theory[16,19] the temperature dependence of the radial distribution function g for a fluid of rigid spheres with no attraction comes from that of a parameter λ, which is related to only density, and thus, only from the temperature dependence of (V^*/V). Thus, for a fluid consisting of rigid spherical molecules with no attractive pair interactions, we have

$$(\partial g/\partial T)_V = 0$$

and

$$(\partial \ln \gamma/\partial \ln T)_V = 0. \quad (28)$$

Thus Eq. (27) reduces to Eqs. (22) and (22′).

In all the theories based on a cell model, the number of nearest neighbors was always assumed to be constant. This is equivalent to the assumption that γ is independent of temperature.

When attractive forces act between molecules, it is difficult to calculate $(\partial \log \gamma/\partial \log T)_V$ analytically. The values of γ are calculated numerically for fluids in which the interaction potential between molecules is of Lennard-Jones type, using the values of g given by Kirkwood *et al.*[23] and Verlet.[24] The results are given in Table 2. It is seen that the temperature dependence of γ, is very small. Thus, the application of condition (28) is justified.

Recently Fried and Schneider[22] have reported from experimental grounds that the parameter a (the cohesive energy is given by $-a/V^n$ in their paper) is slightly temperature-dependent at ordinary temperatures, and that the variation of a is less than 3% over a wide range of temperature. The parameter a is supposed to be proportional to our parameter γ. Thus, their results seem to support our result with respect to the temperature dependence of γ.

Estimation of Parameters λ and γ. The values of parameter λ are determined for liquids consisting of rigid spherical molecules with no attractive interactions, by means of the formula[16]

$$\lambda = 3((2\Delta H_V)/(NkT) - \log (V_g/V_l)) \quad (29)$$

where V_l and V_g are the volume of liquid and gas respectively.[16] It is difficult to determine λ for fluids in general. Thus, we use Eq. (29) as an approximate formula for the determination of λ. Values of λ for various liquids are given in Table 3, together with values of γ determined by extrapolation along the γ *vs.* λ curve given in Fig. 1. It is shown in the appendix[25,26] that the estimation of γ is reasonable.

Table 3. Values of parameters λ and γ for various liquids

	T (°K)	V^l (cm³)	ΔH_v (cal/mol)	λ	γ

Part II. Numerical Computations.

We present here with an analysis of excess functions V_E, E_E, and S_E for binary liquid mixtures. The binary systems consist of pairs of molecules which are approximately spherical and not greatly different in size. Random mixing is assumed. The excess thermodynamic functions for 22 binary liquid mixtures are calculated.

Procedure of Calculation. *Excess Thermodynamic Function.* Combining Eq. (22) with Eqs. (19) and (25), we have

$$E_E = 3RT\left\{\left(\frac{x_A v_A^\circ}{v_A^\circ-\beta r_{AA}^{*3}}+\frac{x_B v_B^\circ}{v_B^\circ-\beta r_{BB}^{*3}}\right) - \frac{v}{v-\beta(x_A r_A^{*3}+x_B r_B^{*3})}\right\}. \quad (30)$$

For the excess volme V_E, we obtain from Eq. (30)

$$\frac{V_E}{N} = \beta(x_A r_A^{*3}+x_B r_B^{*3})\left(\frac{K-E_E}{K-E_E-3RT}\right)-\bar{v}_0 \quad (31)$$

23) J. G. Kirkwood, V. A. Lewinson and B. J. Alder, *J. Chem. Phys.*, **20**, 929 (1952).

24) L. Verlet, *Phys. Rev.*, **165**, 201 (1968).

25) A. Harashima, "Theory of Liquids," Iwanami (1954), p. 42.

26) A. Eisenstein and N. S. Gingrich, *Phys. Rev.*, **62**, 261 (1942).

where

$$K = 3RT\left\{\left(\frac{x_A v_A^\circ}{v_A^\circ - \beta r_{AA}^{*3}}\right) + \left(\frac{x_B v_B^\circ}{v_B^\circ - \beta r_{BB}^{*3}}\right)\right\}.$$

From Eqs. (19), (20) and (23), we obtain the following equation for TS_E.

$$TS_E = 3RT\left[x_A \ln\left\{\left(\frac{v_A^\circ - \beta r_{AA}^{*3}}{v - \beta(x_A r_A^{*3} + x_B r_B^{*3})}\right)\left(\frac{r_A^*}{r_{AA}^*}\right)^2\right\} + x_B \ln\left\{\left(\frac{v_B^\circ - \beta r_{BB}^{*3}}{v - \beta(x_A r_A^{*3} + x_B r_B^{*3})}\right)\left(\frac{r_B^*}{r_{BB}^*}\right)^2\right\}\right] \quad (32)$$

Determination of Parameters for Pure Components. From Eq. (17) we obtain the following equation for $\gamma\varepsilon_{AA}^*$ of pure component A, when $x_A=1$ and $x_B=0$.

$$N\gamma\varepsilon_{AA}^* = \frac{3NkT}{2\pi}\left(\frac{v_A^\circ}{r_{AA}^{*3}}\right)\left(\frac{v_A^{\circ 1/3}}{v_A^{\circ 1/3} - (\beta r_{AA}^{*3})^{1/3}}\right) \quad (33)$$

$\gamma\varepsilon_{AA}^*$ is related to the heat of vaporization ΔH_V in Eq. (6). Eq. (25) is regarded as an approximate representation of Eq. (33).

Differentiating Eq. (33) with respect to temperature assuming that $(d\gamma/dT)_V=0$, we obtain

$$v_A^* = \beta r_{AA}^{*3} = v_A^\circ\left(\frac{1+\alpha_A T}{1+\frac{4}{3}\alpha_A T}\right)^3, \quad (34)$$

where α_A is the thermal expansion coefficient for pure component A. Eq. (34) is found to be similar to that given by Abe and Flory.[14] This may be due to the similarity in the volume dependence of energy.

By means of Eq. (34), $\beta r_{AA}{}^{*3}$ is obtained from thermal expansion coefficient. $N\gamma\varepsilon_{AA}^*$ is determined using Eq. (33). When ΔH_V is known, we can obtain $N\gamma\varepsilon_{AA}^*$ directly by means of Eq. (6). The results are given in Table 4 for 15 liquids. The values given in column 7 are calculated by means of Eq. (33) and those in column 8 by means of Eq. (6). The values in column 7 and those in column 8 are in good agreement with each other. This shows applicability of the present theory. For the calculation of excess thermodynamic functions the values in column 7 are used.

Calculation of Excess Thermodynamic Functions for Equimolar Binary Mixtures. Substituting the observed values of excess energy*3 given in Table 5

into Eq. (31), the excess volume V_E for 22 equimolar binary mixtures is calculated. From the values of V_E calculated and those of βr_{AA}*[3] given in Table 4, the values of TS_E are calculated using Eqs. (32) and (9). The values obtained are given in Table 5, and compared with the observed values.

The agreement between calculated and observed values for V_E and TS_E in satisfactory, as seen in Table 5. The standard deviation of the calculated values from the observed values with respect to V_E, is calculated to be 0.12_5 cc/mol*[4] for the binary mixtures given in Table 5.

It is seen that the calculated entropy is less than the value observed. This is especially remarkable for the systems which include aromatic species as a constituent.

From the observed values of E_E and V_E, substituting the values of $\gamma\varepsilon_{AA}$* and $\gamma\varepsilon_{BB}$* given in Table 4 into Eq. (22′), we can determine the magnitude of the parameter θ defined as follows.

$$\theta = (\varepsilon^*_{AB} - (\varepsilon^*_{AA} + \varepsilon^*_{BB})/2)/\varepsilon^*_{AA} \tag{35}$$

The values of θ thus obtained are given in column 8 of Table 5, together with those of θ_{disp}, in column 9 which are calculated by assuming the Bertholet relation

$$\varepsilon^*_{AB} = (\varepsilon^*_{AA}\varepsilon^*_{BB})^{1/2}. \tag{36}$$

It is observed that for nearly all systems given in Table 5, the sign of θ is negative and $\theta < \theta_{\text{disp}}$. This means that the mutual interactions between different species are less attractive than those within each species in the systems, and that the interactions between molecules can not be ascribed only to dispersion forces.

From Eq. (24) we can divide the excess volume V_E into two terms,[27] $V_{E,\text{size}}$ and $V_{E,\text{int}}$, where $V_{E,\text{size}}$ corresponds to the first term in the numerator in Eq. (24) and $V_{E,\text{int}}$ to the second term:

$$V_E = V_{E,\text{size}} + V_{E,\text{int}}. \tag{37}$$

The values of $V_{E,\text{size}}$ and $V_{E,\text{int}}$ are calculated using the values of θ in Table 5, and are also given in Table 5. The formula for $V_{E,\text{size}}$ is transformed as follows.

$$\begin{aligned} V_{E,\text{size}} &= \beta N\{x_A(r_A{}^{*3} - r^{*3}_{AA}) + x_B(r_B{}^{*3} - r^{*3}_{BB})\}/ \\ &\quad \left[1 - \frac{9kT}{\pi}\left(\frac{x_A v_A{}^\circ + x_B v_B{}^\circ}{x_A\gamma\varepsilon_A{}^* r_A{}^{*3} + x_B\gamma\varepsilon_B{}^* r_B{}^{*3}}\right)\right] \\ &= -\frac{\beta N}{4} x_A x_B (r^*_{AA} - r^*_{BB})^2 \left[\left(4 + \frac{3x_A - x_B}{2}\right) r^*_{AA} \right. \\ &\quad \left. + \left(4 + \frac{3x_B - x_A}{2}\right) r^*_{BB}\right] \Big/ \\ &\quad \left[1 - \frac{9kT}{\pi}\left(\frac{x_A v_A{}^\circ + x_B v_B{}^\circ}{x_A\gamma\varepsilon_A{}^* r_A{}^{*3} + x_B\gamma\varepsilon_B{}^* r_B{}^{*3}}\right)\right] \end{aligned} \tag{38}$$

As is evident in Eq. (38), we have

$$\begin{aligned} V_{E,\text{size}} &< 0 \quad \text{for} \quad r^*_{AA} \neq r^*_{BB} \\ &= 0 \quad \text{for} \quad r^*_{AA} = r^*_{BB} \end{aligned} \tag{39}$$

where the denominator in Eq. (38) has turned out to be always positive for the systems. The values of $V_{E,\text{size}}$ and $V_{E,\text{int}}$ calculated are given in columns 10 and 11 of Table 5.

The numerator in Eq. (38) is regarded to represent the excess volume for the mixture of rigid spherical particles with no mutual attraction. Thus, the fact that the values of $V_{E,\text{size}}$ can not be positive means that the excess volume for the mixture of rigid spherical particles with no attractive forces is always negative or zero. This is supported by the experimental results reported by Westman and Huggil.[28]

The values of $V_{E,\text{int}}$ are observed to be positive or negative. This term is regarded as the excess volume which occurs from an interaction*[5] between molecules.

In order to investigate the relation between E_E and V_E, the second term in Eq. (26) which is taken for the part of E_E apparently attributable to V_E, is calculated using the observed values of V_E, and given in column 12 of Table 5.

Comparison with Other Theories. The calculated values of various excess thermodynamic functions for three equimolar mixtures, benzene-carbon tetrachloride, carbon tetrachloride-cyclohexane and cyclohexane-benzene are given in Table 6(a), and those for equimolar mixtures of aromatic-alicyclic systems in Table 6(b) for comparison with calculated values from other theories. In Table 6(a) the values calculated by means of various theories which were reported previously,[5,9,10,11,14,16] are given together with our results. The Bertholet relation has been assumed in the calculation given in rows (a) to (d), but not in rows (e) to (g) where the calculation was made using the observed values of H_E.

There is not such a large difference in the calculated quantities, A_E, E_E and TS_E by various theories. The difference in the values of V_E is found to the most remarkable. Thus, it seems that the excess volume gives the most sensitive test to the applicability of the theory. With respect to excess volume, the results of Salsburg and Kirkwood,[10] and those of Chung and Espensheid[16] are too large. The results of Scott,[11] Abe and Flory[14] and the authors are of the same order of magnitude compared with the observed values.

In Table 6(b) the values of V_E and θ, calculated

*[4] The value for the system C_6H_6-c-C_7H_{14} is excluded, where an extraordinary large deviation is observed.

[5] The designation of $V_{E,\text{size}}$ and $V_{E,\text{int}}$ is conventional, as an interaction parameter ε_{AB} is included in the common denominator of the two parts of V_E.

that the agreement between calculated and observed values is better in the present theory than in Prigogine's theory. The present theory gives slightly smaller values than the observed, while Prigogine's theory gives larger values.

Discussion on the Results of Numerical Computations. In Table 5 the values of θ which are calculated for the observed values of E_E and V_E are compared with those obtained from the Bertholet relation. The former are larger than the latter in absolute magnitude.

In Table 5 appreciable differences are observed between the systems containing an aromatic constituent and other systems. For aromatic-alicyclic systems the values of $|\theta|$ are 0.02—0.03, and are seen to be larger by one order than those of other systems. Benson and coworkers have reported[29] that the values of $|\theta|$ calculated using Scatchard-Hildebrand theory[31] and Barker's quasi-lattice theory[32] are about 0.03 for aromatic-alicyclic systems. Their results agree with our results. The values of θ calculated by Prigogine's theory, shown in column 6, Table 6(b) (cited from Benson *et al.*[29]) vary greatly. This is unreasonable when the similar properties of these systems are taken into account.

For the aromatic-alicyclic systems the observed values of H_E are positive and large compared with those of other systems in Table 5, which correspond to fairly large values of $|\theta|$. We see that the excess entropy calculated is larger for the aromatic-alicyclic systems than for the other systems, and that the observed values of excess entropy for the systems are larger than for the calculated values. A certain ordered arrangement seems to be present in liquid benzene and disturbed by the addition of non-aromatic constituents.[14]

For aromatic-carbon tetrachloride systems the values of $|\theta|$ and those of TS_E are very small. It seems that the systems are to some extent ideal from a thermodynamical point of view, compared with the non-ideal behavior of aromatic-alicyclic systems.

For the benzene-ethylene dichloride system,[33] the situation is different, compared with other systems containing one aromatic constituent. In spite of some positive values of V_E observed, the value of TS_E is small, and the value of θ is positive. The calculated values given in column 12, Table 5, are seen to be fairly larger than the observed value of H_E in column 3. For the aromatic-alicyclic systems in Table 5, the values in column 3 are nearly equal to those in column 12. From the results it seems that an ordered arrangement between benzene and ethylene dichloride molecules occurs in the mixture, and that it reduces the magnitude of TS_E and H_E in spite of the observed positive value of V_E. This explains the fact that the value of V_E calculated from the observed value of H_E is fairly smaller than the observed value of V_E.

The authors wish to thank Miss Yuko Endo of the laboratory for her co-operation in carrying out this study.

Appendix

Estimation of the Number of Nearest Neighbors for Pure Liquid. From Eq. (5) we can estimate the effective number of nearest neighbors, $Z_{\text{eff.}}$ for pure liquid, as follows.

$$\omega(0) = \gamma\varepsilon^* - \left(\frac{N\cdot\frac{4}{3}\pi r^{*3}}{V}\right) = -\gamma\left(\frac{4\sqrt{2}\,\pi}{3}\right)\left(\frac{r^*}{a}\right)^3\varepsilon^* \tag{40}$$

where

$$V = Na^3/\sqrt{2}.$$

On the other hand we can put

$$\omega(0) = -Z_{\text{eff.}}\varepsilon^*\left(\frac{r^*}{a}\right)^6 \tag{41}$$

where $Z_{\text{eff.}}$ is the effective number of nearest neighbors, which includes the influence of outer neighbors.

Equating Eq. (40) and Eq. (41), we have

$$Z_{\text{eff.}} = \gamma\left(\frac{4\sqrt{2}\,\pi}{3}\right)\left(\frac{a}{r^*}\right)^3 = \gamma\left(\frac{4\sqrt{2}\,\pi}{3}\right)\left(\frac{V}{V^*}\right) \tag{42}$$

where V^* is a "hard core volume"[14] and is taken to be equal to $N\beta r^{*3}$.

The influence of outer neighbors is estimated to increase the potential energy within a cell by about 20%, compared with the potential occuring from the first nearest neighbors only.[18,25] Thus, we can estimate the number of the first nearest neighbors approximately equal to $Z = Z_{\text{eff.}}/1.2$.

From the values of γ given in Table 3, estimating the values of (V/V^*) to be 1.3 for ordinary conditions of liquids, we can determine the values of Z to be 11.8 for liquid argon and to be 12.8 for C_6H_6, c-C_6H_{12}, and CCl_4. The values are supposed to be of reasonable magnitudes, though slightly larger than the observed.[26] This seems to support the adequacy of the present theory.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 985—991 (1970)

Phosphorescence of Quinoxaline-Durene Mixed Crystal — Analysis of Fine Structures and Decay Characteristics

Yasuko NAKANO*1 and Tohru AZUMI*2

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received July 26, 1969)

The phosphorescence spectrum of quinoxaline doped in durene crystal is observed at 4.2°K. The spectrum is composed of a number of sharp bands, many of which being interpreted as arising from the coupling with the ground state molecular vibrations of quinoxaline. Associated with the 0,0 and vibronic bands three weak bands were observed which are separated from the vibronic band by 19, 30 and 52 cm^{-1}. The nature of these three bands is not well understood, but it is certain that they are not due to the lattice vibrations of the durene host. The decay of the phosphorescence is investigated at fifteen different temperatures between 4.21 and 1.59°K. Above 2.41°K the decay is single exponential with a lifetime of 0.246 sec. Below 2.19°K, however, the decay is expressed as a sum of two exponential decays whose lifetimes are 0.757 and 0.093 sec. The shorter one is approximately one third of the lifetime at 4.21°K. The change of the decay characteristics at a temperature between 2.19 and 2.41°K is interpreted to be associated with the spin alignment. In terms of these data, together with the polarization ratio observed by Chaudhuri and El-Sayed, radiative and radiationless rate constants are estimated for each of the three magnetic subcomponents of the triplet state. The experimental results and their interpretation are partly in disagreement with the work by de Groot, Hesselmann and van der Waals, and the source of the discrepancy is analyzed.

Quinoxaline exhibits relatively intense phosphorescence of π,π^* nature. As is revealed from the polarization measurements carried out for rigid glass solution by El-Sayed and Brewer,[1] the phosphorescence is polarized normal to the molecular plane. This out-of-plane polarization of the phosphorescence is in line with the π,π^* nature of the phosphorescence.[2] Namely, if the contribution from the two-electron operators for spin-orbit coupling is neglected, the π,π^* triplet state of a planar aza-aromatic molecule mixes only with π,σ^* or σ,π^* singlet states, from which the transition to the ground state is polarized normal to the molecular plane.

The situation is more complicated when quinoxaline is doped in durene host. As Chaudhuri and El-Sayed[3] showed, a significant part of the phosphorescence is polarized in-plane along the long axis of the molecule. This abnormal in-plane polarization was interpreted by Chaudhuri and El-Sayed to be due to the host-guest interaction. The exact nature of the host-guest interaction is, however, not well understood.

Vibrational analysis of the phosphorescence might give us more information on the host-guest interaction. The phosphorescence spectrum at 77°K or above is, however, broad and detailed fine structure analysis is not feasible. In the present paper, effort was made to accomplish the detailed fine structure analysis for the phosphorescence spectrum observed at 4.2°K.

The path of excitation and deexcitation of the triplet state were analyzed with emphasis on the three individual magnetic subcomponents of the triplet state. For this purpose analysis of the phosphorescence decays at very low temperatures was carried out in some detail.

At temperatures not very low, the decay constant of the phosphorescence is a population weighted average of the three individual rate constants for the three magnetic subcomponents. Specifically, the rate constant k for the triplet state as a whole is expressed as

$$k = \sum_i^3 n_i k_i \qquad (1)$$

where n_i and k_i are the fraction of the population and the decay constant for the ith subcomponents, respectively. This averaging results from the fact that, in ordinary condition, spin-lattice relaxation

*1 Present Address: Government Chemical Industrial Research Institute, Tokyo.

time is much shorter than the phosphorescence lifetime and that the population of any one sublevel is strayed over all the three levels. However, at very low temperatures, the spin-lattice relaxation time is expected to become longer than the phosphorescence lifetime. If this condition is realized, the phosphorescence emission would now start from each sublevel independently. The decays observed under this condition directly reflect the rate constants for the individual subcomponents. One may also obtain information regarding the population of the sublevels too.

The notations for states, rate constants and axes to be used in the following discussion are schematically shown in Fig. 1. Three magnetic subcomponents are denoted by T_x, T_y and T_z, which transform like rotations around x, y and z axis, respectively. The energy separations among three sublevels are obtained from the results of the ESR studies of Vincent and Maki.[4] The ordering of energies is consistent with the assumption of positive D and negative E. The radiative and radiationless decay constants for T_x are denoted by k_{px} and k_{qx}, respectively, and the sum of these two simply by k_x. Similar notations are adopted for decay constants for T_y and T_z. In C_{2v} point group, if the lowest triplet state is assumed to be of π,π^* $^3B_2$, the emission from T_x, T_y and T_z should be z-polarized, forbidden and x-polarized, respectively.

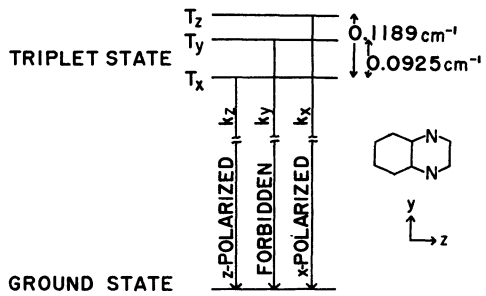

Fig. 1. Notation for states, rate constants and axes concerned with quinoxaline phosphorescence.

Experimental

Quinoxaline was purified by sublimation in a vacuum. Durene was purified by recrystallization from ethanol and by zone refining. Emission was observed for mixed crystals of 10^{-3} mol/mol in a polycrystalline form.

Emission spectra were obtained by a Spex 1700-II grating monochromator (reciprocal dispersion of 11 Å/mm) either photographically with a Kodak 103a-F plate or photoelectrically with an EMI 6256S photomultiplier tube. The locations of phosphorescence bands are determined from the photographic plates by reference to the iron arc spectrum.

The decays of the phosphorescence were measured at 462 nm using a JASCO CT-50 grating monochromator with an EMI 9529 A photomultiplier tube connected to an oscilloscope. In measurements of both spectra and decays, the exciting radiation was obtained from a 500 W high pressure mercury lamp. A Becquerel type phosphoroscope was used to separate the phosphorescence from the exciting light.

Temperature below 4.2°K was obtained by reducing the pressure above boiling helium, and the temperature was estimated from the known temperature-pressure curve.[5]

Infrared spectra of quinoxaline crystal were measured[6] at room temperature by a JASCO 402G spectrometer for the range from 4000 to 650 cm^{-1}, a Hitachi EPI-L spectrometer for the range from 700 to 250 cm^{-1}, and a Hitachi FIS-I spectrometer for the range from 300 to 50 cm^{-1}. Raman spectra of quinoxaline crystal were measured at 77°K in these laboratories by a three prism spectrograph by Yoko Kaizu, a low pressure mercury lamp being used as an exciting source.

Fine Structure Analysis

The phosphorescence spectrum of quinoxaline in durene host observed at 4.2°K is shown in Fig. 2a. The highest energy band at 21639 cm^{-1} is quite sharp and intense, and, in view of the vibrational analyses discussed below, is considered as the 0,0 band. Following this band, three relatively broad and weak bands were observed which are 19, 30 and 52 cm^{-1} apart from the 0,0 band (see Fig. 2b). As seen in Fig. 2, these four bands appear repeatedly in the whole spectral region. The fine structure analysis of the spectrum is attempted in Table 1, in which the wavenumber differences from the 21639 cm^{-1} band are compared with the molecular vibrations observed in infrared and Raman spectra. As shown in Table 1, the wavenumber separations among groups of the above mentioned four bands are in good agreement with the intramolecular vibrations of quinoxaline. Thus, as far as progressions of intramolecular vibrations are concerned, no immediate influence of the host-guest interaction is revealed.

The nature of the three weak bands always accompanied by the intense and sharp bands, however, remains unsolved. The energy separations of 19, 30 and 52 cm^{-1} are, of course, too small to be ascribed to intramolecular vibrations. One might then suppose that these fine structures are due to lattice vibration of the durene host. In fact, Hochstrasser and Small[7] interpreted some

of the fine structures observed in phenanthrene fluorescence in biphenyl host to be due to the lattice vibrations of the biphenyl. Similar interpretations have also been given by Shigeoka, Koyanagi and Kanda[8] for fine structures observed in the phosphorescence of pyrazine in various hosts. In order to see if such supposition is also applied in this case, we compare the above mentioned energy intervals with the observed lattice vibrations. Raman spectra of durene crystal observed by Ito, Suzuki and Yokoyama[9] are at 50, 84 and 116 cm^{-1}; in each of these bands two rotational lattice vibrations are considered to be overlapped. As is evident, the intervals of 19 and 30 cm^{-1} are too small even compared with the rotational lattice vibrations. The translational lattice vibrations have not been observed. These frequencies may be a little smaller than the rotational lattice vibrations, but never as low as 19 cm^{-1}. If a lattice vibration of such low frequency existed, because of too large amplitude, it would manifest some unexpected specific heat properties, but such is not the case. All of these considerations lead us to conclude that the fine structures with small frequency intervals observed in the phosphorescence spectrum are not due to the lattice vibrations of the durene host.

A question still remains as to what the fine structures are due to, but cannot be answered at the moment. However, from our efforts in the defect phosphorescence observed in the crystalline states of azaaromatics[10] we regard it not meaningless to surmise that, in this case too, the phosphorescence originates from various perturbed quinoxaline molecules. It might be the guest-host interaction which causes this perturbation. Researches focussing on this point are under way and will be discussed in later publications.

Whatever the origins of the three weak bands associated with the 0,0 and other vibronic bands, the fine structure analysis presented in Table 1 clearly demonstrates that the phosphorescence

comes from the quinoxaline molecules and not from any impurities. This conclusion is important in interpreting the decay results discussed in the following section, especially in analyzing the discrepancies of experimental results from the work by other workers; any possible complication due to impurity emissions is eliminated.

Spin Alignment as Revealed from Decay Characteristics

The decay of the phosphorescence was measured at fifteen different temperatures between 4.21 and 1.59°K. At any temperature above 2.41°K (and below 4.21°K) decay is found to be identical; it is single exponential decay with lifetime of 0.246 sec. These lifetime data indicate that the phosphorescence is of π,π^* nature, and validate the sublevel specifications shown in Fig. 1. The shortening of lifetime, by a factor of about 10, as compared with the lifetime of π,π^* phosphorescence of aromatic hydrocarbons, say, naphthalene, is due to the presence of n,π^* singlet states, which enhance the spin-orbit coupling.[11]

Below 2.19°K, however, a drastic change in decay characteristics is observed. First, the significant part of intensity is decayed with a rate approximately three times as fast as the decay rate at 4.21°K. In addition to this decay, there exists some component of longer lifetime. At all the temperatures observed below 2.19°K, the decay is expressed as a sum of two exponential decays with lifetimes of 0.757 and 0.093 sec, the component of shorter lifetime emitting more intensely. The manner in which decay is separated into two exponential decays is shown in Fig. 3b.

Such decay behavior at lower temperatures is due to spin alignment as has already been discussed by de Groot, Hesselmann and van der Waals[12] and by Hall, Armstrong, Moomaw and El-Sayed.[13] At very low temperatures, the spin-lattice relaxation time becomes much longer than the phosphorescence lifetime, and consequently "straying" among the spin states is frozen. For quinox-

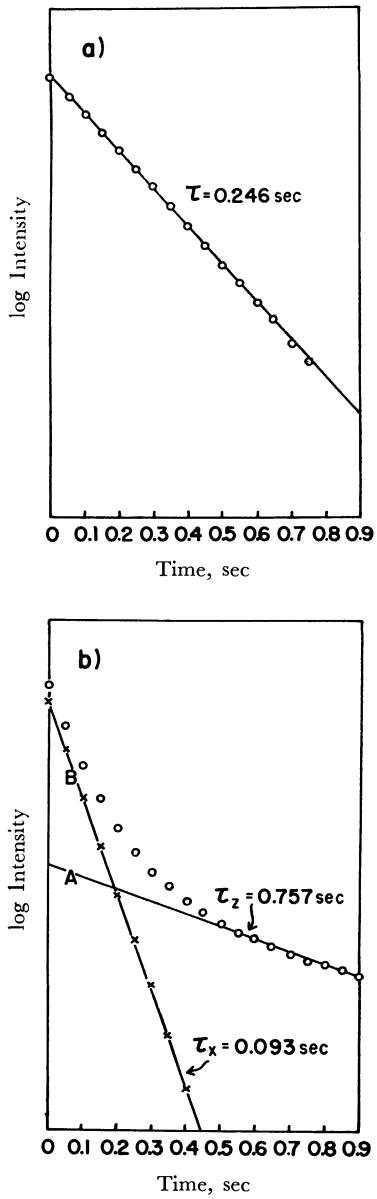

Fig. 3. Decay of phosphorescence in semilogarithmic plot. The points are experimental.
a) Observation at 77, 4.21, 4.00, 3.80, 3.45, 2.74, 2.58 and 2.41°K. The decay is single exponential, and the lifetime is 0.246 sec.
b) Observation at 2.19, 2.02, 1.97, 1.94, 1.84, 1.81, 1.74 and 1.59°K. The decay is expressed as a sum of two exponential decays whose lifetimes are 0.093 and 0.757 sec. Line A is as extrapolation from the long-time decay region. The × marks on the lower curve are differences between the experimental points and the corresponding points on Line A. Line B is drawn through these latter difference intensities.

aline-durene mixed crystal, de Groot *et al.* found that the inversion in magnitude between the spin-lattice relaxation time and the phosphorescence lifetime takes place at a temperature between 4.21 and 1.56°K. Our data indicate that this takes place somewhere between 2.19 and 2.41°K. The fact that the complete inversion of the order of the lifetimes at some temperatures in the narrow range of 0.2° may indicate that the spin-lattice relaxation time is very strongly dependent on temperature.

We shall next see if the above data could be used to estimate the decay constants for each of the magnetic subcomponents. First we note that the decay characteristics are identical at any temperatures between 1.59 and 2.19°K and also between 2.41 and 4.21°K. The identity of the decays indicates that decay constants are unchanged in the two temperature ranges. Thus we could assume that they keep constant all through 1.59 to 4.21°K.

The lifetime observed at temperatures above 2.41°K should be expressed by Eq. (1), thus

$$(k_x+k_y+k_z)/3 = 1/0.246 \tag{2}$$

Since the emission from T_y is forbidden, the two phosphorescence components observed at lower temperatures should be associated with the emission from T_x and T_z. The correspondence between the two components and the two emitting states is not determined uniquely. However, in view of the observation by Chaudhuri and El-Sayed[3] that the significant part of intensity comes from T_x, we shall assign the component of shorter lifetime as the emission from T_x.
Thus

$$k_x = 1/0.093 \tag{3}$$

$$k_z = 1/0.757 \tag{4}$$

From Eqs. 2—4, we obtain

$$\begin{aligned} k_x &= k_{px} + k_{qx} = 10.72\ \text{sec}^{-1} \\ k_y &= k_{qy} = 0.15\ \text{sec}^{-1} \\ k_z &= k_{pz} + k_{qz} = 1.32\ \text{sec}^{-1} \end{aligned} \tag{5}$$

Note that even though the emission from T_y is forbidden, the radiationless decay from this state takes place with a rate of $k_y=0.15\ \text{sec}^{-1}$.

We shall next separate the above rate constants into the radiative and radiationless parts. The polarization ratio observed by Chaudhuri and El-Sayed[3] indicates that

$$k_{px}/k_{pz} = 9 \tag{6}$$

We assume that the rates of radiationless decays are indentical for the three subcomponents. This assumption is only based upon the observation that the rates of radiationless transitions are mostly governed by energy difference.[14] No further justification exists and we admit that the assumption might not represent reality. However, we shall examine what information we could get.

14) R. E. Kellogg and N. C. Wyeth, *J. Chem. Phys.*, **45**, 3156 (1966); W. Siebrand, *ibid.*, **47**, 2411 (1962).

We obtain

$$k_{qx} = k_{qz} = 0.15 \text{ sec}^{-1} \tag{7}$$

which coincides with the k_{qy} value obtained independently. The coincidence is consistent with the above assumption that all of the three radiationless decay rates are the same. The radiative rate constants are then obtained as

$$\begin{aligned} k_{px} &= 10.75 \text{ sec}^{-1} \\ k_{pz} &= 1.17 \text{ sec}^{-1} \end{aligned} \tag{8}$$

From the above estimation, we view the path of excitation and deactivation in the following way: The T_y component is non-emissive, but radiationless deactivation from this state is not nonexisting. Both of the other two states, T_x and T_z, are emissive. Observation of emission from the two states in lower temperatures reveals that at least two subcomponents are populated by intersystem crossing from singlet excited states. Contrary to our view, however, de Groot *et al.*[15] concluded, for the same system, that only the T_z component is populated by intersystem crossing and phosphorescence comes exclusively from the same states. This discrepancy is puzzling, and we try to analyze the source of the discrepancy in the following.

Comparison with, and Comment on, the Work by de Groot, Hesselmann and van der Waals. The most significant source of discrepancy between the two groups of authors is apparently the difference in experimental results. Specifically, we found, at the temperatures where spins are aligned, decays consisted of *two* different exponential decays, whereas de Groot *et al.*[12,15] reported that the decay is always *single* exponential. A question immediately arises why the two sets of experiments, both concerned with apparently the same quinoxaline-durene mixed crystals, give different results. In the experiment of de Groot *et al.*, excitation is effected for a period of 1 msec by a xenon flash lamp, whereas in our case excitation is continued for about 10 sec until further irradiation does not increase the phosphorescence signals. Apparently, excitation is more efficient in our case. We believe that this difference in excitation efficiency is the primary cause of the differences in the observed decay behaviors.

In general, the rise time of the phosphorescence is shorter than or equal to the decay time; lower efficiency in the excitation leads to longer rise time.[16] Now, suppose we have two emitting states characterized by two different decay constants. When excitation is carried out for a sufficiently long time, the population of the two states are increased to their maximum (saturated) values, and consequently the decays from the two states may be separated without much difficulty. On the other hand, if excitation is interrupted after a very short time, as in the case of flash excitation, the state of the longer lifetime is not populated as much as in that of the shorter lifetime. Consequently the emission from the state of longer lifetime may be hidden under the emission from the state of shorter lifetime. It is probably due to this latter effect that de Groot *et al.* did not find the phosphorescence component of longer lifetime. From this viewpoint we emphasize that the phosphorescence decay measurement for a system of more than one emitting states must be carried out with high efficiency of excitation.

In view of what is discussed above, let us for a moment disregard the results of the decay measurements by de Groot *et al.* and see what information concerning the decay rates is available from other data. The most meaningful experiment in this regard is the optical detection of magnetic resonance (hereafter abbreviated as ODMR) carried out by Schmidt, Hesselmann, de Groot and van der Walls[15] for perdeuterated quinoxaline and also by Forman and Kwiram[17] for perhydrated quinoxaline. In this experiment one sees how application of microwave corresponding to magnetic resonance varies the phosphorescence intensity. Both of the above two groups of authors obtained identical results. Analysis of their experimental results leads to the following three inequalities:

$$\begin{aligned} 2k_{pz} &> k_{px} + k_{py} \\ k_{py} + k_{pz} &> 2k_{px} \\ k_{px} + k_{pz} &> 2k_{py} \end{aligned} \tag{9}$$

where no assumptions or preliminary knowledge regarding the values of the rate constants are introduced. If now, in view of our experimental results, k_{py} is set equal to zero, then inequality (9) is reduced to

$$k_{pz} > 2k_{px} \tag{10}$$

This indicates that k_{pz} is larger than twice of k_{px}; it does not indicate that k_{px} is zero. It is therefore not correct to conclude that emission comes exclusively from the T_z component. If, and only if, it becomes certain that only one of the three states is emissive, then conclusion that only k_{pz} is non-zero is justified. From this viewpoint, we suggest that when one tries to see the path of deexcitation from experiments on ODMR, other data such as polarization measurements or decay measurements followed by high efficiency of excitation should be consulted.

One more comment should be added with regard to inequality (10). The inequality, which was derived from the analysis of experimental results

on ODMR, clearly contradicts the polarization results, Eq. 6, reported by Chaudhuri and El-Sayed. At this moment we have no way of judging which of the results are correct; however, if the polarization data be erroneous, the rate constant estimate given in this paper would be meaningless.

The unambiguous determination of the x and z axes of quinoxaline molecule is not an easy task since in durene host x axis of a molecule is nearly parallel to the z axis of another molecule in the same cell.[18] Nonetheless attempts to decide which of the conflicting results are correct are under way and will be treated in the future.

We wish to express our appreciation to Professor Saburo Nagakura, Professor Mitsuo Ito and Mr. Yasuo Udagawa for fruitful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 991—995 (1970)

Conformers and Intramolecular Hydrogen Bond of *trans*-2-Halocyclohexanols

Etsuko FUJIMOTO, Yoshiko TAKEOKA*1 and Kunio KOZIMA

Laboratory of Molecular Spectroscopy, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received August 19, 1969)

By infrared studies it has been ascertained that *trans*-2-halocyclohexanols possess two conformers, namely, the ee-isomer and the aa-isomer, both in the liquid and in a solution, while only the ee-isomer exists in the solid. In a dilute solution the ee-isomer is more stable and exists exclusively in the form with an intramolecular hydrogen bond. The values of the energy difference between the two isomers are 1.3, 1.9, and 2.2 kcal/mol for the chloro-, the bromo-, and the iodo-derivative respectively. The magnitude of the frequency shifts of the O–H stretching bands increases in the order: Cl<Br<I. These facts show that the intramolecular hydrogen bond stabilizes the ee-isomer and that the strength of the hydrogen bond increases in the order: Cl<Br<I. The electrostatic energy increases in the order: Cl>Br>I, while the delocalization energy due to the charge-transfer increases in the opposite order. Therefore, it can be concluded that the energy due to the charge-transfer contributes dominantly to the energy of the intramolecular hydrogen bond formed in the ee-isomer of *trans*-2-halocyclohexanols.

It is very probable that *trans*-2-halocyclohexanols possess two conformers which are interconvertible by the inversion of the ring, and that both the halogen X and the O–H group attach to the e-positions of a ring in one conformer and to the a-positions of a ring in the other, as in the case of *trans*-1,2-dihalocyclohexanes.[1] The conformers hereafter will be referred to as the ee-isomer and the aa-isomer respectively.

Since, of the two isomers, only the ee-isomer is expected to have an intramolecular hydrogen bond between the X atom and the H atom of the O–H group, as in the case of ethylene chlorohydrin,[2] it seemed that it would be interesting to study the energy differences between the isomers.

Experimental

Materials. *trans*-2-Chlorocyclohexanol was prepared[3] by adding hypochlorous acid to cyclohexene obtained according to the method of Osterberg and Kendall.[4] The product was then purified by fractional distillation; bp 71.2—72.5°C/10 mmHg.

trans-2-Bromocyclohexanol was prepared according to the method of Winstein[5] by adding 1,2-epoxycyclohexane to 48% hydrobromic acid, the reaction temperature being maintained below 5°C over a period of about an hour. The product was purified by fractional distillation; bp 61.5—61.8°C/2 mmHg.

trans-2-Iodocyclohexanol was prepared by a method[6]

similar to that used for *trans*-2-bromocyclohexanol. The product was recrystallized from petroleum ether; mp 40.0—41.7°C.

Carbon disulfide of an extra pure grade was used as a solvent after distillation.

Infrared Spectra. The spectra were measured with a Perkin-Elmer 112 spectrometer equipped with a potassium bromide, a sodium chloride, or a lithium fluoride prism. To study the solid-state spectra, the chloro-derivative was cooled by ice,*2 and the bromo-derivative by a mixture of dry ice and ethyl alcohol. The temperature of the samples was determined by means of a copper-constantan thermocouple. The thickness of the cell used for the infrared studies of dilute solutions was 6 mm.

The wavenumber readings for the liquid- and the solid-state spectra are listed in Table 1.

Measurements of the Integrated Intensities. As the contours of the bands used in the intensity measurements were usually represented by Lorentz's curve, the true integrated absorption intensity per mole, a, corrected for finite slit widths was calculated by means of the equation:

$$a = K(1/CL)\log_e(T_0/T)_{max}\Delta\nu^a_{1/2}$$

where the letters have their usual meanings.[7] The values of K were obtained from the table of Ramsay.[7]

In order to determine the energy difference between the isomers, the relative intensities of bands due to the two isomers as a function of temperature were measured in a dilute carbon disulfide solution. The O–H stretching band due to the intramolecular hydrogen bond overlaps with the free O–H stretching band for the three derivatives. However, these bands could be separated only for the iodo-derivative by assuming that the band shapes are given by Lorentz's equation. The measurements for such compounds having an O–H group should be made in a very dilute solution, for which no band assigned to the intermolecular hydrogen bond can be detected in the 3 μ region spectra, because even a small amount of the intermolecular hydrogen bond markedly affects the observed energy difference.

By using the data of the change in the relative intensity with the temperature, the energy difference between the isomers could be estimated by the following equation, as has been described in a previous paper:[8]

$$\log_e \frac{(C_1a_1/C_2a_2)_{T'}}{(C_1a_1/C_2a_2)_{T''}} = -\frac{\Delta E}{R}\left(\frac{1}{T'} - \frac{1}{T''}\right)$$

where ΔE denotes $E_1 - E_2$, $(C_1a_1/C_2a_2)_{T'}$, and $(C_1a_1/C_2a_2)_{T''}$ denote the relative intensities at the T' and T'' °K temperatures, and where the suffixes 1 and 2 refer to the value of each isomer. The results obtained are shown in Tables 3.

Results and Discussion

Since several bands of the liquid-state spectra of these compounds disappear on passing from the liquid to the solid, as is shown in Table 1, it is sure that the two isomers, the ee-isomer and the aa-isomer, exist in the liquid and that the equilibrium between them breaks down in the course of crystallization until only one isomer persists in the solid, as in the cases of *trans*-1,2-dichloro- and *trans*-1,2-dibromocyclohexane.[1]

The infrared spectra of *trans*-2-halocyclohexanols in a dilute carbon disulfide solution were measured in the 3 μ region. As can be seen in Table 2, there are two absorption bands in this region. Concerning the iodo-derivative, in the spectra of which the frequency difference between these bands is relatively large, it was ascertained that the relative intensity of these bands changes with the dilution and that it becomes constant when the concentration is less than 0.03 mol/l. This shows that there are intramolecular hydrogen-bonded molecules in this solution. The lower frequency band can be assigned to the O–H stretching vibration of the hydrogen-bonded molecules, and the other to that of the non-bonded molecules. This behavior of the iodo-derivative is similar to that in the cases of the chloro-derivative and the bromo-derivative. It can be safely assumed that the lower frequency band is due to the ee-isomer, while the higher one may be due to the aa-isomer, because, in view of its molecular geometry, only the ee-isomer is able to form an intramolecular hydrogen bond.

In both the liquid- and the solid-state spectra for these three compounds, we could observe a very broad and weak band extending from 800 to beyond 550 cm^{-1}. Since this band disappears in the spectra of the dilute solution, it may be safely assigned to the out-of-plane deformation vibration of the intermolecular hydrogen-bonded O–H group.[9]

In order to determine the energy difference between the two isomers of the iodo-derivative, we selected a pair of bands, namely the 1030-cm^{-1} band which persists in the solid and the 1001-cm^{-1} band which disappears on passing from the liquid to the solid, and measured the temperature dependence of the relative intensity; the results are shown in Table 3—3a. From these data, the energy difference is calculated to be 2.2 kcal/mol, the isomer which exists in the solid being more stable.

To determine the stable isomer, the change in the relative intensity of the two O–H stretching bands, one of which is due to the intramolecular hydrogen bond, and the other of which is due to the free O–H bond, was measured with the change in the temperature in the dilute solution. The results obtained are shown in Table 3—3b. From these data the energy difference between the two isomers is calculated to be 2.4 kcal/mol, the intramolecular hydrogen-bonded isomer being more

*2 In order to avoid supercooling, this refrigerant is used; it is adequate for this substance.

$C_6H_{10}I(OH)$	3599	3558	41

stable. When taking into account the experimental error usually introduced in the intensity measurements, the two values of the energy difference are considered to agree with each other. This fact indicates that the isomer which exists in the solid is the ee-isomer and that it exists exclusively in the form having the intramolecular hydrogen bond in the dilute solution.

For the bands assigned to the C-halogen stretching vibration of various halogen derivatives of cyclohexane, one of the present authors has previously pointed out the empirical rule[10] that the frequencies of the bands which are due to the halogen atoms attached to the e-positions of the ring are higher than those of the bands due to the same halogen atoms attached to the a-positions. For the iodo-derivative, the 632- and the 657-cm^{-1} band can be

$E_f-E_h=2.4$ kcal/mol

safely assigned to the C-I stretching vibrations. Therefore, according to this rule, the same conclusion as that described above for the stable isomer can be drawn, since only the higher frequency band persists in the solid.

The liquid-state spectrum of the chloro- or the bromo-derivative was divided into two groups according to whether or not the band persists in the solid. For the chloro- or the bromo-derivative, an adequate band for the intensity measurements was selected from each group and the change in the relative intensity with the temperature was measured. The results are shown in Tables 3—1 and 3—2. From these data, the energy differences are calculated to be 1.3 and 1.9 kcal/mol for the chloro- and the bromo-derivative respectively, the isomer which exists in the solid being more stable. By comparing the two groups of the bands of the three compounds, it can be seen that the spectra show striking similarities. Therefore, it is very probable that the stable isomer is the ee-isomer for the chloro- or the bromo-derivative, as is the case for the iodo-derivative. Furthermore, additional evidence is obtained by the following considerations. The 735 and 705-cm^{-1} band of the chloro-derivative, and the 688 and the 650-cm^{-1} band of the bromo-derivative, can be safely assigned to the C–Cl and the C–Br stretching vibrations respectively. According to the rule described above, the same conclusion can be drawn from the fact that the higher frequency bands persist in the solid for the two derivatives.

The energy differences between the two isomers of *trans*-2-halocyclohexanols, $\Delta E=E_{aa}-E_{ee}$, increase in the order: Cl<Br<I. For *trans*-1,2-dihalocyclohexanes it has been reported[1] that the energy difference between the two isomers is 50 cal/mol or 500 cal/mol in the dilute carbon tetrachloride solution for the dichloro- or the dibromo-derivative respectively, the aa-isomer being the more stable. Comparisons of the energy differences show that the ee-isomer of the dibromo-derivative is less stable than that of the dichloro-derivative. This is contrary to the case of *trans*-2-halocyclohexanols. These facts suggest that the intramolecular hydrogen bond formed in the ee-isomer of *trans*-2-halocyclohexanols stabilizes the ee-isomer and that the strength of the hydrogen bond increases in the order: Cl<Br<I. This suggestion is supported by the following experimental evidence.

The magnitude of the frequency shifts of the O–H stretching band, which may be considered to be a measure of the strength of the hydrogen bond, increases in the order: Cl<Br<I. Since the sequence of the hydrogen-bonding power of halogens is opposite to the sequence of electronegativity, the energy due to the electrostatic interaction between the halogen and the hydrogen of the O–H group, which may increase with an increase in the electronegativity of halogens, does not seem to be dominant in this system.

It is well known[11] that, for a proper understanding of the hydrogen bond, we must use the charge-transfer theory. For this it may be assumed that the delocalization effect can be represented as due

11) C. A. Coulson, "Valence," 2nd Ed., Oxford Univ. Press (1961), p. 352.

to the existence of terms corresponding to two structures, namely:

(i) —O—H X—; no bond structure

(ii) —O$^-$ H—X$^+$—; dative structure.

According to Mulliken's theory,[12] the delocalization energy, ε, for these charge-transfer systems of a common electron acceptor can be represented approximately as follows:[13]

$$\varepsilon \propto \frac{S^2_{HX}}{I_D - k}$$

where S_{HX} is the overlap integral over the lone-pair AO of halogen, φ_X, and hydrogen 1*s*-AO, φ_H, *viz.*, $S_{HX}=\int\varphi_H\varphi_X d\tau$, I_D is the ionization potential of the electron donor, and k is taken to be a constant for the three compounds. Therefore, the delocalization energy increases as S_{HX} increases or I_D decreases.

In order to estimate the values of the overlap integrals, we calculated the H---X distance (r_{HX}) and the angle between the C–X bond and the hydrogen bond ($\pi/2-\alpha$), assuming that the most stable hydrogen bond is formed in the position where r_{HX} is at a minimum. The result are shown in Table 4. When we assume the structure of the hydrogen-bonded system shown in Fig. 1, an orbital of the lone-pair of the halogen can be represented as follows:

$$\varphi_X = \sqrt{\frac{1}{3}}\{\sqrt{1-s^2}\,\psi_s + (\sqrt{2}\cos\alpha - s\sin\alpha)\psi(p_x) - (\sqrt{2}\sin\alpha + s\cos\alpha)\psi(p_y)\}.$$

Here s^2 denotes the *s* character of the *s*–*p* hybridization of the halogen-bonding orbital, while ψ_s, $\psi(p_x)$, and $\psi(p_y)$ denote, respectively, the *ns*-, np_x-, and np_y-AO's of the electrons of the halogen atom, where *n* is the principal quantum number. When Slater's AO's are tentatively assumed and the *s* character is assumed to be 18%,[14] the overlap integrals are calculated to be 0.143 and 0.188 for the chloro- and the iodo-derivative respectively.

Although the r_{HX} value of the iodo-derivative is larger than that of the chloro-derivative, the value of the overlap integral of the iodo-derivative is not less than that of the chloro-derivative. By considering this result and the fact[15] that the first ionization potentials of alkyl halides decrease in the order: Cl>Br>I, it can be concluded that the delocalization energies due to the charge-transfer increase in the following order: the chloro- <the bromo- <the iodo-derivative. This conclusion is in accord with the experimental results.

Therefore, it can be concluded that the delocalization energy due to the charge-transfer contributes dominantly to the energy of the intramolecular hydrogen bond formed in the ee-isomer of *trans*-2-halocyclohexanols.

Table 4. Intramolecular hydrogen-bonded system formed in the ee-isomer

Compound	r_{HX} (Å)	α	S_{HX}

The Catalytic Oxidation of Carbon Monoxide on Titanium Dioxide; Anatase and Rutile

Yoshito ONISHI and Takuya HAMAMURA

Department of Chemistry, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto

(Received September 16, 1969)

For the purpose of investigating the correlation between the crystal structure of titanium dioxide and its catalytic activity, the catalytic oxidation rate of carbon monoxide and the desorption rate of oxygen from the sample surface have been measured on anatase, rutile, and an anatase-rutile mixture. The oxidation of carbon monoxide was investigated by a static method at temperatures of 250—550°C and under gas pressures of 10^{-2}—150 mmHg. The desorption of oxygen was carried out at 600—750°C. The reaction rate was proportional to P_{CO} and did not depend on either P_{O_2} or P_{CO_2}. The activation energy was 16.0 kcal/mol for anatase and 6.7 kcal/mol for rutile. The catalytic activity per unit of the surface area of rutile was 3—6 times as much as that of anatase. The reaction rate almost coincided with the rate of the reduction of titanium dioxide by carbon monoxide. The electric resistance of the sample was little affected by the P_{O_2}. The following reaction mechanism is proposed to explain the results. The rate-determining step is the reaction between the surface oxygen of the sample and the carbon monoxide physisorbed or that which has just collided with the surface coming from the gas phase; the oxygen vacancy thus formed on the surface is quickly filled with oxygen of the gas phase. The difference in the activation energy of the catalytic action between the two structures is based upon the difference in the activation energy of the oxygen desorption from the surface structure; the activation energies are 57.8 kcal/mol for anatase and 38.4 kcal/mol for rutile.

It is generally accepted that there is an intimate relationship between the catalytic activity of a solid catalyst and its crystal structure. Many investigations[1-4] as to these points have been carried out on the metals, but few on metallic oxide catalysts; thus, we have chosen titanium dioxide, TiO_2, as the subject of the present investigation. Titanium dioxide has three polymorphic forms, that is, anatase, rutile, and brookite; among these, rutile can be transformed from anatase by heating it to high temperatures, and so it is easy to obtain samples with the same chemical constitutions but different polymorphic forms. Therefore, titanium dioxide is suitable as a sample to investigate the relationship between the catalytic activity and the crystal structure.

The aim of this series of investigations is to ascertain the difference between anatase and rutile in their catalytic activity in response to the oxidation reaction. This paper will be concerned with the oxidation of carbon monoxide on the surface of titanium dioxide.

There have been several reports[5] on the pure or doped titanium dioxide catalyst used for the CO-oxidation, but there seems to have been no systematic investigation of the catalyst relating to the polymorphic forms. Moreover, most of the investigations of the catalytic reactions reported so far were carried out using an apparatus with greased stop cocks; these might contaminate the catalyst and so might cause some errors in the results. For this reason, the present experiments were performed with strict care taken to prevent the sample from contamination with grease vapor.

Experimental

The samples used in the present experiment are listed in Table 1. The sample A_1 was a reagent of a guaranteed grade obtained from the East Merck Company. Anatase transforms into rutile[6] and decreases in specific surface area when it is heated to high temperatures, so the samples of anatase, rutile, or an anatase-rutile mixture with the desired surface areas were obtained by selecting a suitable temperature and period

AR_2	Mixture of A_1 and R_2		Anatase Rutile	87.4 12.6	4.7

of heat treatment. The heat treatments were carried out as follows. The sample A_1 (about 60 g) in a fused quartz tube 3 cm in diameter was put in an electric furnace which had been preheated to a desired temperature, and kept there for the desired period. It was then taken out of the furnace, quenched in air, and pulverized by using an agate mortar. The temperature, time of heating, weight percentages of anatase and rutile, and specific surface areas of the samples are listed in Table 1. The weight percentages of anatase and rutile were estimated by the ordinary method of X-ray analysis, while the specific surface areas were determined by the B.E.T. method,[7,8] using nitrogen as the adsorbate. The crystal structures of A_2 and A_3 are the same as that of A_1, but the specific surface areas of A_2 and A_3 are less than that of A_1. The crystal structures of R_1 and R_2 are rutile, but the specific surface areas differ from each other. The AR_1 is A_1 partly transformed into rutile.

Carbon monoxide prepared by the decomposition of sodium formate by sulfuric acid, and oxygen prepared from a commercial bomb, were purified by fractional distillation using liquid nitrogen.

The apparatus shown schematically in Fig. 1. was used for the experiment under pressures of 10—150 mmHg. It was made of glass and had a circulating pump of the piston type. The stop cocks, A, B, and C, were metallic cocks, with Viton used as the sealing material to keep grease vapor out. The trap T_1 was cooled by liquid nitrogen in order to collect the reaction product, (CO_2), while the trap T_2 was cooled to keep grease and mercury vapor out of the sample. This apparatus could be evacuated to a pressure lower than 10^{-6} mmHg by means of a mercury-diffusion pump. A sample tube of fused quartz, in which a pair of electrodes of gold were mounted, was connected with the glass system by means of a graded seal.

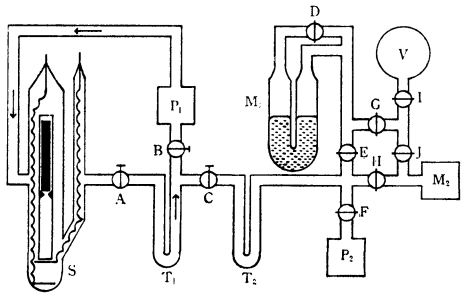

Fig. 1. The apparatus.

The electric resistance of the catalyst was measured as follows. The catalyst (about 10 g) was put between two electrodes, about 1 cm apart, and was loaded with an iron rod (about 80 g) enclosed in a glass tube; then a constant D.C. voltage was applied, and the current was measured with an electric micro-micro ammeter produced by Takeda-Riken, type TR-16. The voltage was applied only when the current was to be measured.

By preliminary experiments, the followings were confirmed: the electric resistance of the sample was proportional to its length, the contact resistance between the electrodes and the catalyst was negligible, and both the catalytic reaction on the gold electrodes and the gas-phase reaction were negligible.

The apparatus used for the experiments under a gas pressure of about 10^{-2} mmHg consisted of a reaction tube, a Pirani gauge, and a liquid nitrogen trap. Under such low pressures, the diffusion velocity of gas was fast enough, so the circulating pump was not used.

When a mixture of carbon monoxide and oxygen was introduced into the reaction system, a catalytic oxidation reaction occurred to form carbon dioxide, which then condensed in the trap; the rate of reaction could be determined by measuring the rate of decrease of the total pressure. When the reaction rate was too small, however, the following method was employed to get the reaction rate: at the end of the run, the residual carbon monoxide and oxygen were pumped out, the carbon dioxide condensed in the trap was vaporized to a definite volume, and the pressure was measured. The rate of the reaction was obtained from the amount of carbon dioxide thus determined.

In the experiment with a powder catalyst, the rate of reaction is, in general, apt to be affected by the rate of the diffusion of gas into the catalyst, so the rate of the reaction should vary with the amount of the catalyst and this effect should become more remarkable as the reaction rate becomes faster. In order to examine this effect, the rate of reaction per unit amount of the catalyst was estimated from the results of runs using different amounts of the catalyst; it was thus found that, in the present experiment, the effect of the amount of the catalyst is negligible. However, the same amount of the catalyst was used in each of the series of experiments.

Gebhardt and Herrington[9] reported that, in order to clean the rutile surface, it was necessary to heat it at 600°C in oxygen for 30 min. In the present experiments, too, this fact was confirmed on both rutile and anatase. The pretreatment carried out in the present

experiment was to heat the sample at 600°C for 3 hr in circulating oxygen at a pressure of 70 mmHg until the electric resistance became constant. In the experiment under the lower pressure, the gas could not be forced to circulate in the apparatus, so the pretreatment of the sample was carried out by renewing the oxygen several times.

For obtaining reproducible results with a sample of a low catalytic activity, such as titanium dioxide, it seems necessary to use an apparatus without greased stop cocks and to clean the sample with oxygen prior to the experiment.

Results and Discussion

The Relation of Catalytic Activities to Specific Surface Areas and Polymorphic Forms. The catalytic activity of each sample was measured by using reacting gas with a composition of $CO/O_2=2/1$. At temperatures of 250—550°C and under gas pressures of 10^{-2}—150 mmHg, the reaction rates were found to be proportional to the total pressure of the reacting gas; they can be expressed by the following equation:

$$d(CO_2)/dt = 2/3\, k \cdot P \qquad (1)$$

where k is a constant. The Arrhenius plots of each sample are shown in Fig. 2. It can be seen from the figure that the k value of the sample A_1 is almost equal to that of the smaple A_3 and that the k value of R_1 is almost equal to that of R_2. Therefore, the catalytic activity per unit of the surface area is the same for all samples with the same crystal form, even when they have different surface areas per unit of weight. The sample AR_1 consists of particles with both anatase and rutile forms in each particle. The ratio of the area of anatase-type faces to that of rutile-type faces in the sample may be estimated on the assumption that the catalytic activity of an anatase-type face in AR_1 is equal to that in A_1 and that the catalytic activity of a rutile-type face in AR_1 is equal to that in R_2. From the data at 550°C, the ratio was estimated to be: anatase/rutile=86.8/13.2. At temperatures other than 550°C, the k values of AR_1 can be calculated by using the surface-area ratio presented above, assuming that the k values of the two crystalline faces on AR_1 are equal to those of A_1 and R_2 respectively. These calculated values are plotted as the curve AR_1 in Fig. 2; this curve is convex downward. On the other hand, the measured values of k are plotted in Fig. 2 by the mark ○; this mrak shows that the calculated values agree well with the measured values at every temperature.

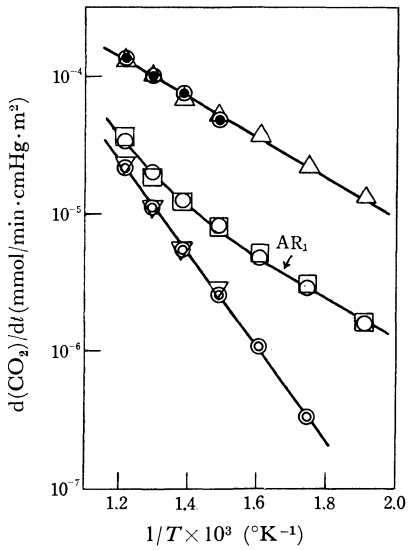

Fig. 2. Effect of temperature on the reaction rate constant.
◎: A_1 ▽: A_3 ⊙: R_1: △: R_2 ○: AR_1
□: AR_2

From these results, it was found that the k value was characteristic for the crystal form and was not affected by the value of the specific surface area nor by the coexistence of two crystalline faces.

The Relation between the Reaction Rate and the Partial Pressure of Carbon Monoxide. The effect of the partial pressures of oxygen and carbon monoxide upon the reaction rate was studied at temperatures of 350—550°C and under gas pressures of 10^{-2}—100 mmHg by changing the CO/O_2 ratio at each pressure. It follows that the reaction rate is proportional to P_{CO} and that it does not depend on the P_{O_2} for all samples and does not change even if a small amount of CO_2 is intentionally introduced into the reaction system. From these results, together with Eq. (1), the following equation can be obtained:

$$d(CO_2)/dt = k \cdot P_{CO} \qquad (2)$$

The activation energies of the reaction using anatase and rutile, as calculated from Fig. 2, are 16.0 kcal/mol and 6.7 kcal/mol respectively.

The Reaction of Carbon Monoxide with the Surface Oxygen of Titanium Dioxide. The catalyst pretreated in oxygen at 600°C was cooled down to the reaction temperature and evacuated.*1 When carbon monoxide, at a pressure of about 10^{-2} mmHg, was introduced into the reaction system, it reacted slowly with the surface oxygen of the catalyst and the carbon dioxide thus formed was caught in the trap. In this experiment, the amount of carbon monoxide which disappeared from the gas phase agreed well with that of the carbon dioxide caught in the trap, showing that the consumed carbon monoxide is entirely converted to carbon dioxide and that the amount of carbon monoxide adsorbed on the surface of the catalyst is negligible compared with that of the carbon monoxide oxidized to carbon dioxide. It was found that the rate of the formation of carbon dioxide

*1 At this time, the electric resistance of the catalyst did not change upon the evacuation.

is proportional to P_{CO}:

$$d(CO_2)/dt = k' \cdot P_{CO} \quad (3)$$

The k' values determined for all the samples are shown in Fig. 3. On the other hand, when reacting

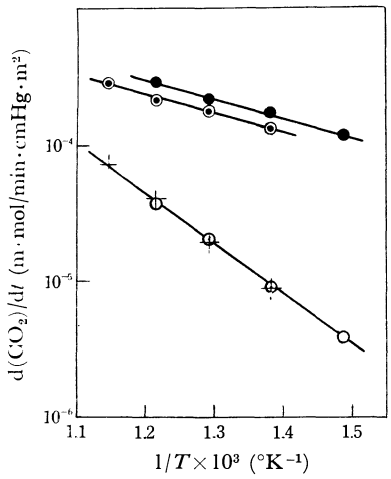

Fig. 3. Effect of temperature on the reaction rate constant.
Anatase, +: k' ○: k Rutile, ⊙: k' ●: k

gas with the composition of $CO/O_2=2/1$ is introduced into the reaction system at a pressure of 10^{-2} mmHg, catalytic oxidation occurs. The k values of this reaction, as calculated by Eq. (1), are shown in Fig. 3. It is clear that the rate constant of the catalytic oxidation of carbon monoxide, k, almost agrees with that of the reaction of carbon monoxide with the surface oxygen of titanium dioxide, k'.

On the catalytic oxidation of carbon monoxide on cupric oxide and nickel oxide,[10-15] it has been reported that the rate of the formation of carbon dioxide is proportional to P_{CO} and independent of P_{O_2}, and that the reaction consists of two processes: 1) carbon monoxide which collides with the surface of the catalyst or is physisorbed on the surface reacts with the surface oxygen of the catalyst, and the carbon dioxide thus formed is desorbed immediately, leaving an oxygen vacancy on the surface, and 2) the oxygen vacancy thus formed is filled with oxygen from the gas phase. Therefore, the reaction mechanism can be expressed as follows:

$$CO(g) + O(s) \rightarrow CO_2\uparrow + (s) \quad (4)$$

$$(s) + 1/2\ O_2 \rightarrow O(s) \quad (5)$$

where O(s) refers to the surface oxygen of the catalyst and (s), to the oxygen vacancy on the surface. The rate of step (5) is much faster than that of step (4); therefore, the overall reaction rate is proportional only to P_{CO}.

In the present investigation, it is believed that the catalytic oxidation of carbon monoxide on titanium dioxide proceeds through the steps (4) and (5), as is the case with cupric oxide or nickel oxide, because the rate of the formation of carbon dioxide is proportional to P_{CO} and the uptake rate of oxygen on the catalyst is much faster than that of carbon monoxide, as will be discussed below.

The Pressure of Oxygen and the Amount of Surface Oxygen. The electric resistance of the catalyst which had been pretreated in oxygen at 600°C was measured under the oxygen pressures from 10^{-2} to 100 mmHg, with the temperature kept constant. The results, given in Fig. 4, can be represented by:

$$R = R_0 \cdot P_{O_2}^n$$

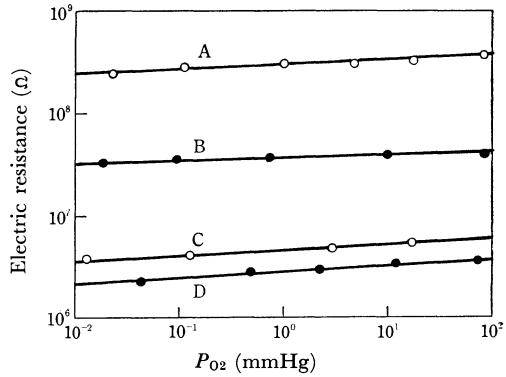

Fig. 4. Effect of oxygen pressure on electric resistance of the catalyst under the constant temperature.
A: 350°C (n=0.04) B: 450°C (n=0.02) C: 550°C (n=0.09) D: 600°C (n=0.10)

where R_0 is a constant at each temperature and n is 0.02—0.10. It is clear from this result that the electric resistance at a fixed temperature is practically independent of the oxygen pressure; this shows that the surface of the catalyst is saturated with oxygen, even at a pressure as low as 10^{-2}mmHg, so the amount of surface oxygen is almost constant, independent of the oxygen pressure. This fact seems to show that the uptake rate of oxygen is extremely fast.

The Desorption of the Surface Oxygen. The catalyst pretreated in oxygen at 600°C was evacuated at this temperature until the gas desorption became almost imperceptible. When the catalyst thus pretreated was heated to a temperature above 600°C, the oxygen desorption was detected and the desorption rate of oxygen could be deter-

mined by measuring the pressure of the oxygen, which was collected in a fixed volume by a compressing pump. In this experiment, reproducible results could be obtained as long as the catalyst was pretreated in oxygen for each run and the desorption rate was not too large. The experimental results on anatase and rutile are shown in Fig. 5. The activation energies for anatase and rutile are 57.8 kcal/mol and 38.4 kcal/mol respectively. The difference in activation energy between anatase and rutile is about 20 kcal/mol.

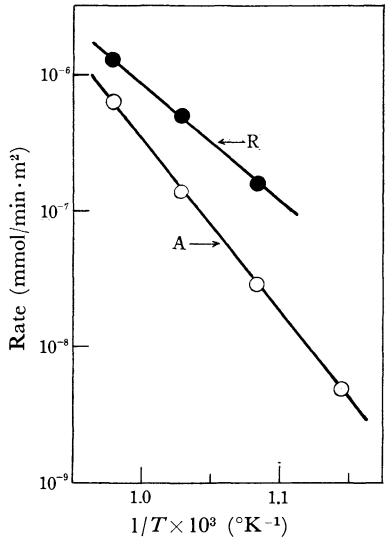

Fig. 5. Effect of temperature on the oxygen desorption rate.

As it is believed[1,16] that the surface oxygen of catalyst exists in the form of O^{2-} at these high temperatures, the desorption of the surface oxygen can be expressed by $2\ O^{2-} \rightarrow O_2(g) + 4e$; the difference of 20 kcal/mol mentioned above would result from this process. Therefore, the difference becomes about 10 kcal/mol for the process $O^{2-} \rightarrow 1/2\ O_2(g) + 2e$. This value is comparable to the 10 kcal/mol difference between the activation energy of anatase and that of rutile which was found in the catalytic oxidation of carbon monoxide and also in the reaction of carbon monoxide with the surface oxygen of the catalyst.

The authors wish to express their deep thanks to Professor Kumasaburo Kodera of Kyoto University for his kind advice and discussions.

Amylase Action in Maltodextrin-Sodium Dodecylsulfate Solution

Ken-ichi SAKON,*1 Takehiko WATANABE and Sôzaburo ONO

Laboratory of Biophysical Chemistry, College of Agriculture, University of Osaka Prefecture, Sakai, Osaka

(Received September 19, 1969)

Enzyme catalyzed hydrolysis of maltodextrin was studied with enzyme-maltodextrin and enzyme-maltodextrin-sodium dodecylsulfate systems. Sodium dodecylsulfate (SDS) is a complex forming agent for maltodextrin. When endo-enzyme such as Taka-amylase A was used as the enzyme, ratio of the initial velocity of the hydrolysis of the system containing SDS to that without SDS decreases with the increase of degree of polymerization (D.P.) of the maltodextrin and becomes zero with the maltodextrin of D. P. above about 60. When the liquefying α-amylase of Bacillus subtilis was used as an endo-enzyme, a similar result was also obtained. When exo-enzyme such as Glucoamylase of Rh. Delemar was used, the ratio decreases gradually with the increase of D.P. of maltodextrin, and remains in a relatively high level even in the case of maltodextrin of D.P. above 60. In the case of Taka-amylase A, the enzyme action is suppressed by the presence of the stiff helical segments of SDS complex and the initial velocity of the system with SDS decreases compared with the one without SDS. In the case of Glucoamylase, the presence of the stiff helical segment does not distinctively induce such a depression of the enzyme action as that in the case of Taka-amylase A. The depression is partly dependent on the inhibitory interaction of SDS with the enzyme.

According to recent studies on the conformation of amylose (or maltodextrin*2) molecules in

*1 Permanent address: Research Laboratory, Nakayama Taiyodo Co., Ltd., Mizusaki-cho, Naniwa-ku, Osaka.

*2 Maltodextrin is a degraded amylose, *i. e.* a relatively low molecular weight linear polysaccharide linked by α-1,4 glucosidic linkages.

water,[1-4] amylose behaves like a random coil, while a relatively large percentage of molecule has a helical structure, the individual helical segments being connected by random segments. The amylose-iodine complex in solution is assumed to have a similar structure as stated above in which the polyiodine chain is formed in the axis of the helical segment. The amylose-sodium dodecylsulfate complex[3,5,6] is assumed to have a similar structure as the iodine complex. The character of the helical segment of amylose in the absence of the complexing agent is different from that of the complex. In the absence of the complexing agent, the thermal fluctuation in the conformation of the molecular chain occurs between the helical and random segments. Thus the helical segment has a relatively flexible character and the conformation is designated as deformed helix.[1,2,7] The helical segment in the complex is assumed to be relatively stiff owing to the holding of the iodine or sodium dodecylsulfate molecules inside the helical segment.

Studies have been carried out to elucidate the difference in the characteristics of the enzyme actions of two types of amylases (*i.e.* endo type and exo type) in enzyme-maltodextrin-sodium dodecylsulfate system.

Experimental

Enzyme. Endo-type: Taka-amylase A (TAA) (molecular weight, 53000) was prepared from "Taka-diastase Sankyô" according to the method of Akabori *et al.*[8] and kept as 4.25% aqueous solution containing 0.02M calcium acetate.

Liquefying α-amylase of Bacillus subtilis (BLA) (molecular weight, 45000) was supplied by Ueda Chemical Industry.

Exo-type: Glucoamylase of Rh. Delemar (GA) (molecular weight, 47000) was supplied by Professor J. Fukumoto of Osaka City University and Dr. Y. Tsujisaka of Osaka Municipal Technical Research Institute.

Concentration of these enzymes was determined by absorbance at 280 mμ, assuming $E^{1\%}_{1cm}$=22.0, 25.0 and 14.0 for TAA, BLA and GA, respectively.

Substrate. Maltodextrins: fractionated maltodextrins were prepared according to Hiromi *et al.*[9] A commercial product of potato amylose from Pierce Chemical Co., Illinois was partially hydrolyzed by using TAA at pH=4.5 and at 35°C for 45 min. The partially degraded amylose was precipitated by the addition of ethanol and washed with distilled water and dried. Using this preparation, the fractionation was carried out according to Everett and Foster[10] by employing dimethyl sulfoxide as solvent and ethanol as precipitant. Five subfractions were obtained and designated as maltodextrin I, II, III, IV and V. Maltodextrin VI was prepared according to the method of Hizukuri *et al.*[11] as a crystalline product from a highly concentrated aqueous solution (about 70%) of an acid hydrolyzed dextrin mixture. Determination of the carbonyl groups as the reducing end of each maltodextrin was made by a modified Somogyi-Nelson method.[12] The values of number-average molecular weight and degree of polymerization (D.P.) are listed in Table 1. These maltodextrins were the same as those used for the polarographic studies of starches by Takagi *et al.*[13]

Table 1. Number-average molecular weight ($\bar{M}_n$) and degree of polymerization (D.P.) of substrates

Substrate	$\bar{M}_n$	D.P.
Maltodextrin I	19000	116.6
II	12000	71.5
III	8200	50.5
IV	6200	38.4
V	4600	28.4
VI	2040	12.6
Maltoheptaose	1150	7.0
Maltose	342	2.0

Maltoheptaose was prepared from β-Shardinger's dextrin according to the method of French *et al.*[14]

Maltose was a commercial product and was used after recrystallization four times.

Helical Complex Forming Agent. Sodium dodecylsulfate (SDS), used as the complex forming agent with the substrate molecules, was a commerical product of Ishizu Pure Chemicals and was extracted by ethyl ether using Soxhlet extractor for 15 hr in order to remove unreacted higher alcohol.

Procedure. For the preparation of the reaction mixture suitable to the present experiment, the following three factors were considered.

(1) There should be a linear relationship between the increase of the number of reducing ends produced

and the reaction time.

(2) The amount of SDS in reaction mixture must be high enough for the formation of a sufficient quantity of helical complex in order to detect the influence of the presence of the complex on the reaction velocity.

(3) The concentration of SDS must be lower than the one where inactivation of enzyme owing to the interaction between SDS and enzyme, and/or the formation of aggregates or precipitates of the SDS-maltodextrin complex occurs.

The procedure adopted for following the reaction of the TAA-substrate-SDS system was as follows. Twenty m*l* of 0.05% substrate solution with or without 0.015% SDS was taken into a reaction vessel immersed in a constant-temperature water bath controlled at 25°C. After about 30 min the reaction was commenced by introducing 10 μl of 2.5×10^{-2}% TAA solution to the substrate solution, and at 2 min intervals the reaction mixture was pipetted into 3 m*l* of Somogyi's reagent, and the reaction was stopped. The number of reducing ends produced was determined by means of Somogyi-Nelson method and was expressed by the value of absorbance observed at the wavelength of 530 mμ. A similar procedure as stated above was adopted for the other enzyme reaction systems. The final recipes for the reaction mixtures were as follows: TAA; 2.0×10^{-9}M, substrate; 0.05%, SDS; 0.5×10^{-3}M, and pH=5.3 for TAA system; BLA; 2.8×10^{-9}M, substrate; 0.1%, SDS; 1.0×10^{-3}M, and pH=5.85 for BLA system; GA; 1.0×10^{-8}M, substrate; 0.05%, SDS; 0.5×10^{-3}M, and pH=4.5 for GA system.

The amount of SDS in the above reaction mixture satisfies the condition of one SDS molecule per one helical turn, provided that all anhydroglucose units of maltodextrin (or amylose) take part in helix formation and 6 anhydroglucose units form one helical turn. Under this condition the complex, SDS-maltodextrin I, II or III showed a slight tendency to form an aggregate in solution, and the reaction was made under continuous stirring to prevent the formation of a large visible aggregate.

Results and Discussion

Typical examples of the change in absorbance with reaction time are shown in Figs. 1, 2 and 3. Each plot was found to show a good linear relationship within the interval of 18 min. The initial velocity was obtained from the slope of the plot shown in these figures. The ratio of the initial velocity of the system containing SDS to that without SDS was expressed in % and designated as "reactivity factor" or *R*. The value of *R* may be primarily determined by the ratio of the number of hydrolyzable α-1,4 glucosidic linkage present in the reaction mixture at the initial stage of reaction

in the system containing SDS to that without SDS.

Figures 4,5 and 6 and Table 2 show the change of R with D.P. of substrate. In TAA (endo-enzyme) system where TAA can hydrolyze α-1,4 glucosidic linkage at random along the linear chain of substrate, the initial velocity of TAA-low D.P. substrate (maltoheptaose)-SDS system was as high as that without SDS, and the value of R

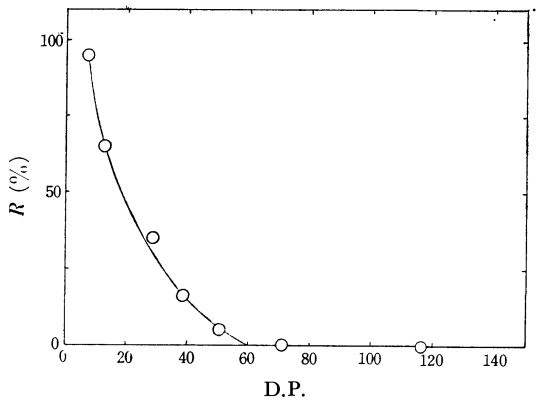

Fig. 4. The plot of R *vs.* D.P. with TAA-Maltodextrin-SDS system (TAA: 2.0×10^{-9}M, SDS: 0.5×10^{-3}M, Substrate: 0.05%, pH: 5.3, at 25°C).

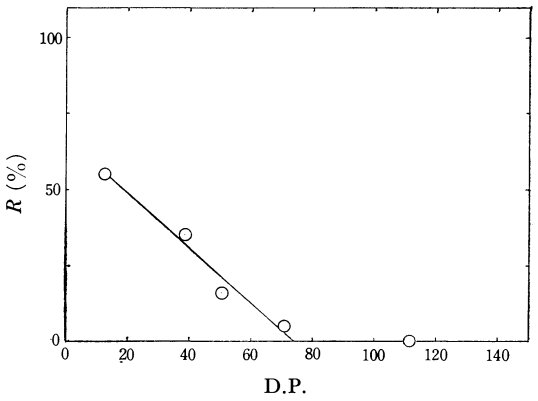

Fig. 5. The plot of R *vs.* D.P. with BLA-Maltodextrin-SDS system (BLA: 2.8×10^{-9}M, SDS: 1.0×10^{-3}M, Substrate: 0.10%, pH: 5.85, at 25°C).

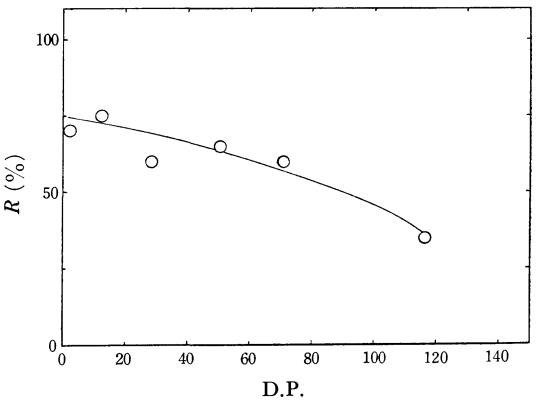

Fig. 6. The plot of R *vs.* D.P. with GA-Maltodextrin-SDS system (GA: 1.0×10^{-8}M, SDS: 0.5×10^{-3}M, Substrate: 0.05%, pH: 4.5, at 25°C).

Table 2. The relation between R and D.P. of substrate with three kinds of systems using TAA, BLA and GA as enzyme, respectively

D.P.	R (%)		
of substrate	TAA	BLA	GA
116.6	0	0	35
71.5	0	5	60
50.5	5	17	65
38.4	20	35	60
28.4	30	—	—
12.6	70	55	75
7.0	95	—	70

was as high as 95%. The value of R decreases rapidly with the increase of D.P. of the substrate and tends to 0% at the D.P. value of about 60 (molecular weight, 1×10^4). In the presence of SDS, the substrate having higher D.P. value than

60, was not hydrolyzed by TAA within the reaction time of 18 min.

As shown in Fig. 5, in BLA (endo-enzyme) system, a similar result was obtained between R and D.P. of substrate as in the case of TAA system.

In GA system (Fig. 6) where GA is an exo-enzyme which catalyzes the hydrolysis of maltodextrin producing glucose from its non-reducing end, the value of R for the substrate of low D.P. value was lower than that in the case of TAA system. However, the rate of decrease of R with the increase of D.P. was slight compared with that in the case of TAA, and a fairly high value of R of 60—65% was obtained with the substrate of D.P. 60—70 to which TAA and BLA could not react in the presence of SDS.

The difference in the characteristics of the enzyme action between the endo-enzyme and exo-enzyme as described above is expected to be brought about primarily by the difference in the contribution of the helical segments of the SDS complex on the reaction. The following experiments on the iodine complex of maltodextrin were carried out to elucidate the conformation of maltodextrin and the SDS complex in solution.

The absorption spectra of the maltodextrin-iodine complex were recorded by a Hitachi Recording Spectrophotometer Model EPS-3 at 25°C. Figure 7 shows the relation between λ_{max} (wave-

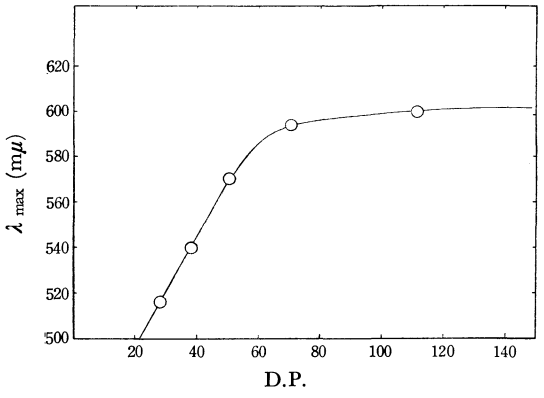

Fig. 7. The relation between the λ_{max} and D.P. of maltodextrin; maltodextrin: 3.7×10^{-3}%, KI: 8.0×10^{-3}M, I_2: 8.0×10^{-5}M, pH: 5.3, at 25°C. (This composition corresponds to the one containing minimum amount of iodine, where the value of λ_{max} takes the longest wavelength, irrespective of the values of D.P. of maltodextrins.)

length of the maximum of absorption spectra observed in the range of wavelength of 400—600 mμ) and D.P. at pH=5.3. As shown in Fig. 7, with increasing D.P. the value of λ_{max} shows a remarkable shift toward longer wavelength up to the D.P. value of about 60, and the plot of λ_{max} *versus* D.P. revealed a break point at about D.P.=60. Above D.P.=70 the value of λ_{max} changes only slightly with the increase of D.P. and the same result was also obtained at pH 4.5. In a previous publication[15] one of the present authors (S.O.) showed that the λ_{max} of the iodine complex shifts toward longer wavelength with the increase of the length of the polyiodine chain. Thus the shift of λ_{max} with the increase of D.P. up to about 60, corresponds to the increase of the length of the single polyiodine chain in the complex. We (T.W. and S.O.) also showed that the helical segments of amylose molecule (molecular weight: 1×10^6) were composed of 66 anhydroglucose units.[16] Therefore the value of about 60 corresponds to the maximum number of anhydroglucose units which take part in the formation of the helical segment.

From the results obtained with the iodine complex, the conformation of the maltodextrin of D.P. above 60—70 in the absence of complexing agent in acidic solution may be a deformed helix. The individual helical segments are connected by random segments which are composed of a certain number of the anhydroglucose units. There are the freely rotating endgroups of a certain number of anhydroglucose units which do not take part in the helix formation. The maltodextrin of D.P. below about 60 consists of a single helix with the freely rotating endgroups.

As shown in Fig. 4, in the case of TAA-substrate-SDS system, the substrates of D.P. from 7 to 60 were hydrolyzed by the enzyme. The initial velocity obtained with the system of low D.P. substrate as maltoheptaose in the presence of SDS was essentially the same as the one without SDS. It may be assumed that the SDS molecules do not inhibit the TAA action under the present experimental conditions. The decrease in the value of R with the increase of D.P. of substrate shows that the SDS complex is difficult to be hydrolyzed by TAA compared with maltodextrin uncoupled with SDS. When the length of the freely rotating endgroups is assumed to be constant independent of the D.P. of the substrate, the ratio of the number of anhydroglucose units in endgroups to that of the helical segment decreases with the increase of D.P. of substrate. Therefore the number of hydrolyzable α-1,4 glucosidic linkage decreases with the increase of D.P. and the value of R decreases with the increase of D.P. In the case of substrate of D.P. above 60 where the helical segments are stabilized by the complex formation, both random segments and endgroups which can be hydrolyzed by TAA in the absence of SDS, would not be hydrolyzed by TAA due to the steric hindrance of the stiff helical segments.

As shown in Fig. 6, in the case of GA-substrate-

15) S. Ono, S. Tsuchihashi and T. Kuge, *ibid.*, **75**, 3601 (1953).

16) T. Watanabe, K. Ogawa and S. Ono, This Bulletin, **43**, 950 (1970).

SDS system, the enzyme action can be assumed to be inhibited by free SDS in solution to some extent, since the value of R was only 70% with the system using maltose as the substrate which can not form the helical complex with SDS. The inhibition of the enzyme action of GA by SDS can be suggested by the result of the measurement of difference spectra.

Absorption spectra obtained with GA solution and GA-SDS solution are shown in Fig. 8. A

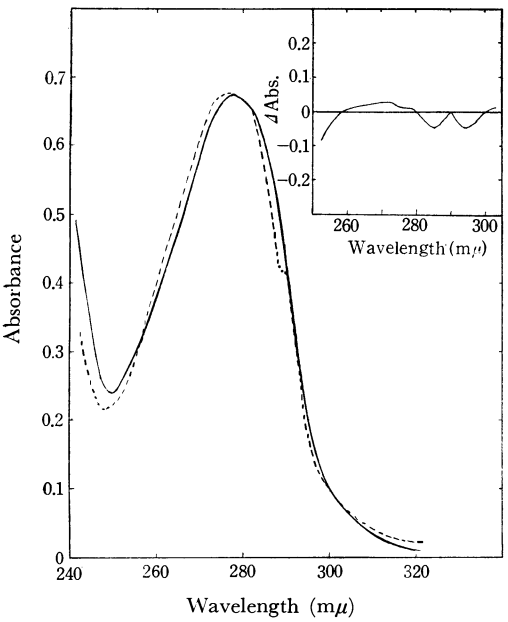

Fig. 8. Absorption spectra of 0.453% GA solution (solid line) and 0.453% GA and 0.2% SDS solution (broken line) at 25°C and difference spectrum (inset).

distinct difference in shape was observed between the two curves. The difference spectrum was recorded by a Hitachi Recording Spectrophotometer Model EPS-3, using four cells; two of them were put on one side of the light path in series, one containing enzyme solution and the other SDS solution, respectively, and on the other side were put the other two cells containing a mixture of enzyme and SDS in one cell, and the buffer solution only in the other, respectively. The spectrum is shown in the inset of Fig. 8. From these results, some interaction is expected to occur between GA and SDS. This interaction suggests the inhibition of the enzyme action of GA. The difference in absorption spectra as in the case of GA was not observed between TAA and TAA-SDS solutions.

In spite of the inhibition of GA action by SDS, the enzyme GA still hydrolyzed the SDS complex of the substrate of D.P. above 60, *i.e.* the values of R are 60% for D.P. 70 and 35% for D.P. 117 (Table 2). These results are markedly different from those obtained with TAA and BLA. When the number of anhydroglucose units of the freely rotating endgroups of maltodextrin chain is assumed to be constant independent of chain length, the ratio of the number of anhydroglucose units in the helical segment to that in whole molecule would become larger with the increase in D.P. in the case of the substrate of D.P. below 60. Thus the amount of SDS combined with the substrate would be smaller and that of SDS free in solution larger in the lower D.P. substrate system compared with the case of the higher D.P. system. In the system containing substrate of D.P. above 60, the concentration of free SDS is assumed to be constant according to the results obtained with the iodine complex as shown in Fig. 7. Thus the enzymatic activity would be more inhibited by free SDS with the system containing lower D.P. substrate, and the value of R is expected to increase with the increase of D.P. of the substrate up to about 60 and become constant with the further increase of D.P. Contrary to expectation, the value of R actually observed decreases gradually with the increase of D.P. of the substrate, though it is fairly high with the complex of high D.P. substrate which was not hydrolyzed by TAA and BLA. The fact that a relatively high value of R was obtained with the system of higher D.P. substrate may support the assumption that the endgroups of the complex are freely rotating and can be hydrolyzed by GA, irrespective of the value of D.P. of the substrate. The decrease in the value of R with the increase of D.P. of the substrate may be explained by the following reasons.

(1) The length of the endgroups of the substrate molecule becomes shorter with the increase of D.P. and consequently the affinity of the substrate for GA becomes smaller.

(2) Even though the length of the endgroups is constant, the stiff helical structure of the complex interferes with the enzymatic action.

(3) Effective concentration of the substrate decreases, which has endgroups with favorable number of anhydroglucose units to be hydrolyzable with GA.

The authors are grateful to Professor Juichiro Fukumoto of Osaka City University and Dr. Yoshio Tsujisaka of Osaka Municipal Technical Research Institute and to Ueda Chemical Industry for the gift of amylase and to Sankyô Co., Ltd. for the supply of "Taka-diastase Sankyô." We are also greatly indebted to Dr. Keitaro Hiromi of Kyoto University and Dr. Masanosuke Takagi for their interest and helpful discussions and to Mr. Yasunori Nitta for his technical assistance.

The Three-dimensional Structure of Macromolecules. I. The Conformation of Ethylene Polymers by the Monte Carlo Method

Keizo SUZUKI and Yoshiro NAKATA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received October 3, 1969)

The Monte Carlo method is employed on a high-speed digital computer in order to generate non-intersecting random chains simulating polymer molecules. For this purpose the GT-model of polyethylene is used. Suitable potential functions are used to calculate the energy and the probability of each chain conformation thus generated. The nonbonded-interaction energy is calculated by the Lennard-Jones "6—12" potential function. The average dimensions are then calculated by using this energy. It is suggested that the hydrogen atoms contribute largely to the statistical properties of the ethylene polymers.

The Monte Carlo procedure is used to simulate non-self-intersecting random walks on a high-speed digital computer. Most of the works up to this time have considered the restricted walks confined to a multidimensional lattice,[1] but the stability of the real molecule (intramolecular energy) is not considered.

Using a more realistic model, we estimate the intramolecular conformational energy of each conformation. The average dimensions are calculated by using this energy.

The lower members of the normal hydrocarbon series have been fully discussed in terms of "Conformation Analysis,"[2] "Molecular Geometry,"[3] *etc.* We use the results of these discussions, and then consider the higher members of the normal hydrocarbon series by means of the Monte Carlo Method.

Model

In this paper we discuss the GT-model of polyethylene. The fully-extended conformation of polyethylene is shown in Fig. 1. The hydrogen atoms are bonded to the ith carbon atom as H_i and H_i'. The backbone of the molecule is considered to begin with the atom H_0, continue on through n carbon atoms, and end with the atom H_{n+1}. All the bond lengths and bond angles are kept constant. The bond lengths are taken to be 1.08 Å for the C–H bonds and 1.54 Å for the C–C bonds, while all the bond angles are taken to be tetrahedral. We assume that each bond in a polyethylene molecule can exist in three rotational isomeric states, *trans*(180°), *gauche*(60°), and *gauche'*(300°). This model is equal to the diamond lattice model if we consider only the skeletal carbon atoms. The *trans* form is chosen with the probability of $p_T=1/2$, and the *gauche* forms, with the probabilities, $p_G=p_G'=1/4$.*1

Calculation

Steric hindrances are examined on the basis of

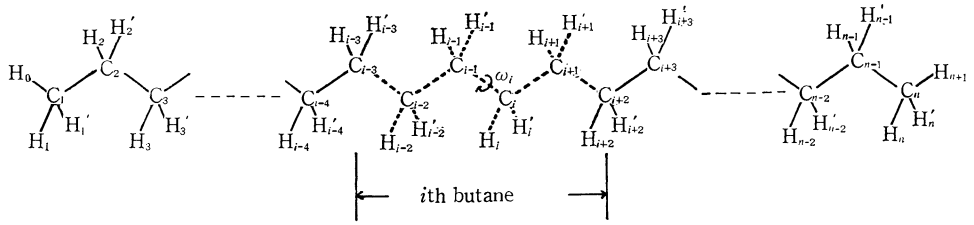

Fig. 1. The polyethylene molecule in the fully extended state.

1) F. T. Wall, S. Windwer and P. J. Gans, *Methods Computation Phys.*, **1**, 217 (1963).

2) R. A. Scott and H. A. Scheraga, *J. Chem. Phys.*, **44**, 3054 (1966).

3) E. J. Jacob, H. B. Thompson and L. S. Bartell, *ibid.*, **47**, 3736 (1967).

*1 This operation is a method to get long chains rapidly, but the generated chain has an unequal *a priori* probability. This inequality is corrected when we calculate the average quantities (see Eq. (4)). However the inequality corresponds roughly to the energy difference between the *trans* and *gauche* forms so that the generated chains have comparable weights.

the van der Waals radii. When the nonbonded interaction energy (see next section) becomes positive, the whole molecule is discarded. Long, non-self-intersecting random walks are difficult to achieve even when the walks are confined to a lattice.[4] When the walks are off the lattice, this problem is much greater. In order to overcome this extreme attrition, use is made of the enrichment technique previously developed by one of the present authors.[5] The scheme of the program is as follows:

1) MAKE AN M-BOND CHAIN AT RANDOM. ($M=12$, FOR EXAMPLE).
2) IF THE NONBONDED INTERACTION ENERGY IS POSITIVE, GO TO 1.
3) $N=M$.
4) IF ANOTHER N-BOND CHAIN IS NOT STORED, STORE THE NEW CHAIN AND GO TO 1.
5) CONNECT THE STORED CHAIN TO THE NEW CHAIN AND MAKE A $2N$-BOND CHAIN.
6) IF THE NONBONDED INTERACTION ENERGY IS POSITIVE, OUTPUT AND CLEAR BOTH THE N-BOND CHAINS AND THEN GO TO 1.
7) $N=2N$, AND GO TO 4.

Energy Equations

The intramolecular conformational energy of each conformation is calculated by using the semi-empirical potential functions. The energy equation is:

$$E = U_{rot} + U_{nb} \tag{1}$$

where:

$$U_{rot} = \sum_i U_{rot}(\omega_i) \tag{2}$$

$$U_{nb}=\sum_{i<j}(a_{ij}/r_{ij}^{12}-b_{ij}/r_{ij}^{6}) \quad (3)$$

We assume that the polyethylene molecule (C_nH_{2n+2}) is formed by overlapping $n-3$ butanes in regard to the internal rotation energy. The energy difference between the one *trans* and the two *gauche* forms is taken as 0.8 kcal/mol from the experimental values of butane. The first term in Eq. (1) is a sum over this energy difference. The second term in Eq. (1) is a sum over the nonbonded interactions between atoms separated by six or more bonds (long-range interaction). In treating the nonbonded interaction, we have used the Lennard-Jones "6—12" potential functions.

The sets of constants[6] in Eq. (3) are summarized in Table 1.

Results and Discussion

The influence of the nonbonded interaction energy on the total intramolecular energy is shown in Fig. 2. The unstabilization by *gauche* forms is fully compensated by the nonbonded interaction energy.

$\langle R_N^2 \rangle$ and $\langle S_N^2 \rangle$. The mean-square end-to-end distance, $\langle R_N^2 \rangle$, and the mean-square radius of gyration, $\langle S_N^2 \rangle$, are calculated by an equation of the form:

$$\langle J_N^2 \rangle = \sum_i J_i^2 g_i \exp(-E_i/kT)/\sum_i g_i \exp(-E_i/kT) \quad (4)$$

where N is the number of C–C bonds and is equal to $n-1$, where J represents R or S, and where g is the weight which corrects the uneven selection.*2

These values are calculated only with carbon atom coordinates. The variation in the molecular dimension with the temperature is calculated by changing the temperature in the Boltzmann factor, $\exp(-E_i/kT)$.

These results fit an equation of the form:

$$\langle J_N^2 \rangle = kN^{\alpha} \quad (5)$$

where k and α are constants.

The results are summarized in Tables 2 and 3. Figure 3 shows plots of $\log\langle S_N^2 \rangle$ *vs.* $\log N$ at

$T=\infty$ and at $T=300$°K.

α, the exponent in Eq. (5), is calculated by the equation:

$$\alpha = (\log\langle J_{2N}^2\rangle - \log\langle J_N^2\rangle)/\log 2. \quad (6)$$

These values are summarized in Table 4.

$\langle S_N^2\rangle/\langle R_N^2\rangle$. Table 5 lists the $\langle S_N^2\rangle/\langle R_N^2\rangle$ ratios for the different values of N obtained in this study. These values are small compared with the values determined in a previous investigation.[7] The major reason for this may be the influence of hydrogen atoms.

The variation in R^2 with S^2 is shown in Fig. 4.

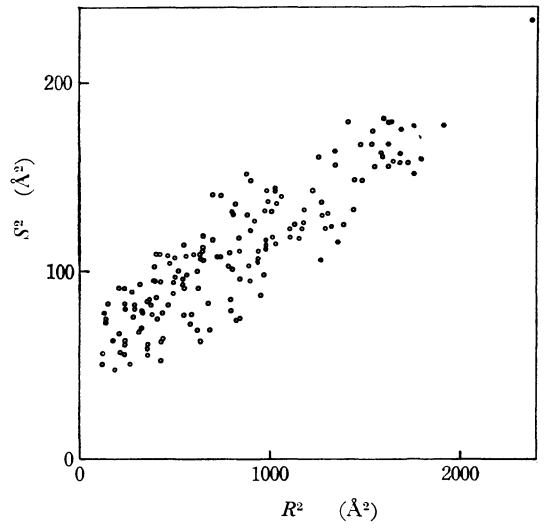

Fig. 4. Plot of S^2 against R^2 at $N=48$.

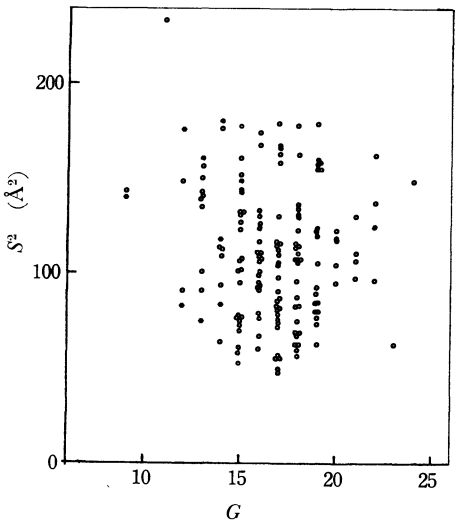

Fig. 5. Plot of S^2 against number of *gauche* forms at $N=48$.

7) S. Windwer, *J. Chem. Phys.*, **43**, 115 (1965).

It is noticeable in Fig. 3 that the temperature coefficient of the dimensions is reversed between $N=24$ and $N=48$. This means that the average dimensions of the long ethylene polymer are affected more strongly by the "long range" interaction than by the "short range" interaction. In this case the van der Waasl attraction is stronger than the *trans-gauche* energy difference. Figure 5 shows that the number of *gauche* forms has little effect on the dimensions.

Our model is a simple one compared with real molecules, but the use of much more realistic models would not alter the general features of the result; the long-range interaction, including interactions by the solvent, will overcome the short-range interaction at the early stage of the chain length.

Electronic Structures of Unsaturated Molecules Containing Hetero-atoms, — Configuration Interaction Treatment Including Doubly Excited Configurations

Fumihiko HIROTA and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received October 14, 1969)

The π-electron structures of several unsaturated molecules containing hetero-atoms were studied by SCFMO-CI scheme employing the Pariser-Parr-Pople method, special attention being paid to the effect of doubly excited configurations upon calculated transition energies, transition moments and π-electron distributions in the ground and lower excited states. The transition energies and oscillator strengths calculated for pyridine, phenol, aniline, pyrrole and furan were compared with their experimental values. Consequently, the inclusion of doubly excited configurations was found to improve the coincidence between the theoretical and observed values and to remove some difficulties in the application of the Pariser-Parr-Pople method to molecules containing hetero-atoms. One-center integrals W_P and γ_{PP} for hetero-atoms were taken as parameters in the calculations of phenol and aniline. Their fittest values were determined reasonably to be $W_N=-24.71$, $W_O=-30.08$, $\gamma_{NN}=13.75$, and $\gamma_{OO}=16.78$ eV.

The Pariser-Parr-Pople (P-P-P) method[1,2] has been successfully applied to many unsaturated organic molecules. The adequateness of several approximations adopted in this method has been discussed from several points of view. For example, the adequateness and limitations of the zero differential overlap approximation have been studied by use of the Löwdin orbitals.[3,4] Furthermore, the *I-A* approximation for the one-center Coulomb repulsion integrals has been discussed on the basis of the correlation effect,[5] the σ-π interaction,[6] and the expansion of excited orbitals.[7]

One of the fundamental problems of the P-P-P method is the treatment of the σ-π interaction, especially of the change in the σ-core caused by π-electron excitation. The development of the CNDO method[8] and other theoretical calculations including both σ and π electrons has brought about some progress in the direction of overcoming this difficulty.

Another important problem is concerned with the application of the P-P-P method to molecules containing hetero-atoms. The results calculated for them are generally sensitive to parameters. Several methods have been presented for the purpose of improving the prediction and interpretation of charge distributions in the ground states of the molecules. They include the VESCF method by Brown and Heffernan[9] and the method of in-

cluding penetration integrals.[10] Furthermore, continuing efforts have made to find improved methods which give reliable results to excitation energies of molecules containing hetero-atoms, and consequently some progress has been achieved in the direction of determining appropriate core resonance integrals[11,12] and of considering the influence of electron cloud polarization upon the two center Coulomb integrals.[13] In the present study we undertake to make some contribution to this problem from the standpoint of attaching some importance to the configuration interaction (CI).

In the P-P-P type calculation, the CI procedure is usually made only among singly excited configurations (SECI treatment). The results in benzene[14-20] and other several hydrocarbons,[18-21] however, point out the importance of some doubly excited configurations. The CI procedure may be expected to have an important meaning in theoretical studies of the π-electron structures of molecules containing hetero-atoms. For example, if the core potential of a hetero-atom is too deep, the single configuration picture gives too large electron density on that atom, but the CI procedure relieves obviously this tendency. In addition, in molecules containing hetero-atoms, the charge distribution is not uniform, and is reorganized by a π-electron excitation. This reorganization in the molecules gives relatively larger effect on charge distributions in excited states and on π-electron levels than on those in hydrocarbons. This effect can be taken into account by the CI procedure. In the present paper, we study the effect of CI including the doubly excited configurations upon the calculated results of π-electron levels, transition moments and electron distributions in some molecules, paying a special attention to the parameters associated with hetero-atoms.

Method of Calculation

In the present study, pyridine, aniline, phenol, pyrrole and furan were taken as the typical molecules containing hetero-atoms and their π-electron structures were calculated by the P-P-P method combined with CI including doubly excited configurations (DECI treatment).

In the evaluation of SCF orbitals of pyridine, the Pariser-Parr parameters[1,2] were employed; that is to say, one-center Coulomb integral γ_{pp} was taken to be the difference between the ionization potential I_p and the electron affinity A_p for an appropriate valence state, and the two-center Coulomb integral γ_{pq} was calculated by the uniformly charged sphere model with the effective nuclear charge Z_p determined by Salter's rule. Concerning W_p representing the diagonal matrix element of the χ_p atomic orbital with respect to the one-electron Hamiltonian consisting of the kinetic energy and the core attraction due to atom p, its absolute value was taken to be equal to the ionization potential of an appropriate valence state.

Several discussions have been made concerning the problem which $|W_p|$ value should be adopted for the nitrogen atoms of aniline and pyrrole, the first or second ionization potential. We have the same problem for the oxygen atoms of phenol and furan, too. Some authors insisted upon the superiority of using the first ionization potentials as the $|W_p|$ values of these atoms.[22,23] Our opinion is that the most suitable $|W_p|$ value for each of these atoms exists between the first and second ionization potentials. Therefore, we carried out several calculations for each of the aniline and phenol molecules, regarding the W_p and γ_{pp} values of the heteroatoms of these molecules as parameters. The best values determined for aniline and phenol were used for the calculation of pyrrrole and furan, respectively. The W_p and γ_{pp} values for the carbon atom and the γ_{pq} values necessary for the calculation of these four molecules were evaluated by the same procedures as described in the case of pyridine.

The core resonance integral (β_{CC}) for the carbon-carbon bond of the benzene and pyridine rings was taken to be equal to -2.61 eV. This value is the optimum one for interpreting the observed benzene spectrum.[24] The core resonance integrals necessary for the calculation of pyrrole and furan were evaluated by two formulas presented by

Mulliken[25] and by Ohno.[26] For the other molecules, the core resonance integral (β_{cx}) for the bond including the hetero-atom was regarded as a parameter.

In the CI calculation, we took all the singly and doubly excited configurations for pyridine, pyrrole and furan, but for phenol and aniline disregarded several doubly excited configurations which include the excitation from the lowest occupied orbital.*1 These configurations are higher than the ground configuration by more than 16 eV and seem to have only little influence on lower excited states.

There are five types of doubly excited configurations,[27] and the total numbers of configurations taken in the actual calculation are 55 for pyridine, 58 for aniline and phenol, and 37 for pyrrole and furan.

In actual calculations we need the data on the geometrical configurations of the molecules under consideration. Pyridine and the benzene rings of aniline and phenol were assumed to have the same geometrical configurations as benzene, that is, all the bond lengths were taken to be 1.397 Å.*2 The C–N and C–O bond lengths in aniline and phenol were assumed to be 1.38 Å and 1.36 Å, respectively, from those of similar compounds given in Sutton's table.[28] The structure of pyrrole was also taken from the same table. The calculation of furan was caried out on the basis of its geometrical structure determined by Bak *et al.*[29]

The computation was carried out by a HITAC 5020E located at the Computer Center, the University of Tokyo.

Results and Discussion

Effect of Parameters. The DECI treatment reduces somewhat the effect of the W_p value upon the calculated energy levels of lower excited states compared with the SECI treatment, (at least) when the change of W_p is limited to ± 4 eV. This is clear form Fig. 1 which exhibits, taking aniline as an example, the W_p dependency of lower excited levels calculated by the P–P–P method without CI and with the SECI and DECI procedures. The same tendency was found for the other molecules under consideration. It is noteworthy that the effect of W_p upon the calculated results is reduced by the DECI treatment.

The effect of one-center Coulomb integrals, γ_{pp}'s upon the calculated energy levels is scarcely reduced by the DECI treatment. Some energy levels are more sensitive to γ_{pp} in the DECI treatment than in the SECI one. This may conceivably be attributed to the fact that γ_{pp} contributes directly to the matrix element of the DECI calculation.

Concerning aniline and phenol, calculations were carried out by the use of several sets of the parameters, W_p and γ_{pp}, with the step of about 2 and 1 eV, respectively, and we looked for the most suitable set which gives the best agreement with the observed transition energies. Consequently, we obtained the values given in Table 1. The selected W_p values, as expected, are the intermediates between the first and the second ionization potentials. Kwiatokowski[22,23] calculated the tran-

sition energies of aniline by the P-P-P method with the SECI treatment and using Nishimoto-Mataga's formula[30] for γ_{pp}, and obtained the results coincident with the observed transition energies by adopting the $|W_N|$ value (22.49 eV) lower than the second ionization potential of nitrogen, and γ_{pp} for the neutral atom.*3 His parameter values are similar to ours, although the γ_{pp} value in the present calculation is a little greater than that of Kwiatokowski. Since in the SCF calculation the $(W_p + 1/2P_{pp}\gamma_{pp})$ is (P_{pp} is the π-electron density on atom p) mainly effective for the evaluated energies, there may be several sets of W_p and γ_{pp} to give a good agreement between the theoretical and experimental transition energies.

The absolute value of the core resonance integral β_{C-X} for aniline and phenol is somewhat larger in the DECI treatment than in the SECI one. The same tendency was found for β_{C-C}.[15] For pyrrole and furan, the better results were obtained with the aid of the core resonance integrals derived by Ohno's formula than by Mulliken's formula, although the difference is rather small and too much

importance should not be attached to it.

Energy Levels. The energy levels calculated by the DECI method are shown in Tables 2—6, together with the experimental values and the results obtained by the SECI method. In these tables, the results obtained by other authors are also given for the purpose of compariosn, only one example being taken from many calculations for each molecule. The comparison of the energy levels calculated by the DECI method with those by the SCF scheme and by the SECI method are schematically shown in Figs. 2—5[*4] for pyridine, aniline, phenol and pyrrole. From these figures, it is clear that the energy levels changes to a considerable extent by the DECI treatment compared with the results by the SECI calculation. The DECI calculation stabilizes the ground states of these molecules by 0.5—1 eV and improves greatly the agreement between the theoretical and experimental excitation energies.

The most remarkable effect of the DECI treatment is found for the separation between the lowest and the second lowest excited states. In the case

[*4] For the convenience of comparison, in these figures the energy levels calculated by the DECI treatment are corrected in such a way as the ground state is equal to that calculated by the SECI treatment.

of the SECI method, the calculated separation is too small compared with the observed value for pyridine, aniline and phenol. The DECI treatment improves this point to a great extent and gives the reasonable values. This is also the case for benzene.[15] In this connection, it is worth noticing

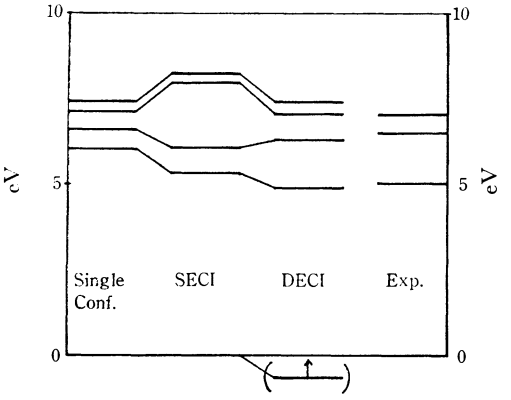

Fig. 2. Calculated Energy Levels of Pyridine.

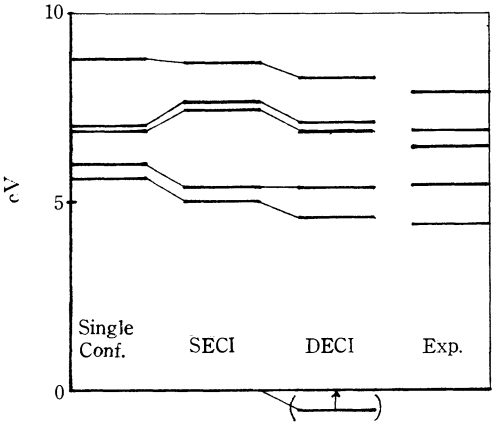

Fig. 3. Calculated and observed energy levels of aniline.

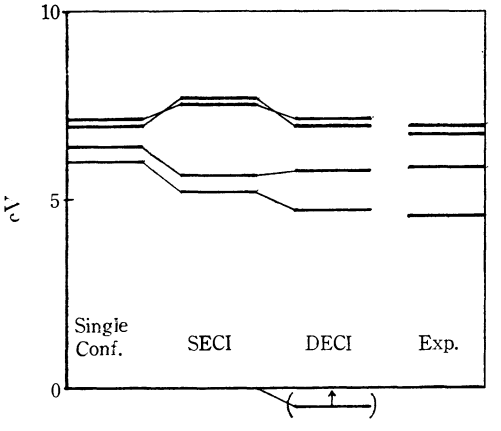

Fig. 4. Calculated and observed energy levels of phenol.

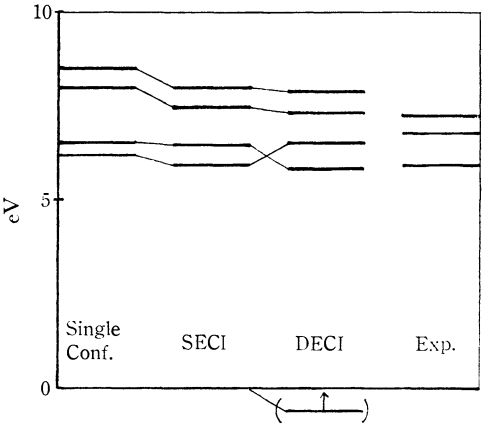

Fig. 5. Calculated and observed energy levels of pyrrole.

that the great separtion between these two states can be obtained[29] by the SECI treatment, when we use Nishimoto-Mataga's formula[31] for γ_{pq} instead of the uniformly charged sphere model. The former gives the smaller γ_{pq} value by 1—2 eV than the latter in the important region of interatomic distance. This seems to mean that the inclusion of the doubly excited configurations has effectively the effect similar to that of the decrease in γ_{pq}. This may be a correlation effect by screening.*5

In phenol, the third and fourth excited levels are inverted in the DECI calculation compared with the result by the SECI treatment. Since the composite-molecule method[32] and also the modified P-P-P method[12] support the results of the DECI treatment, this inversion is thought to be rather important.

In our calculation, the higher excited levels evaluated for aniline and phenol have a tendency to be a little higher than the observed ones. In order to lower these levels, it may be necessary to take doubly excited configurations higher than those taken in the present calculation.

In pyrrole and furan the inversion occurs between the lowest and second lowest levels more vividly than in phenol. We explain the details taking pyrrole as an example. In this case, the first excited state which is of the B_1 character in the SECI calculation turns out to be of the A_1 character in the DECI treatment. Dahl and Hansen[10] obtained by the SECI treatment the same result concerning the order of the excited levels as the present DECI calculation, adopting Nishimoto-Mataga's formula for γ_{pq} and including the penetra-

31) See, for example, K. Nishimoto and L. S. Forster, *Theor. Chim. Acta*, **3**, 407 (1965).

*5 There is a possibility that this is due to the other effects, such as the effective σ-core change and the expansion of π-orbitals.

32) K. Kimura, H. Tsubomura and S. Nagakura, This Bulletin, **37**, 1336 (1964).

tion integrals. Here, again, the DECI treatment shows the effect effectively similar to that of reducing γ_{pq}. In this case, however, the relative change between the two levels (1.5 eV) caused by the inclusion of the doubly excited configurations is too large to be attributed to the correlation effect. Furthermore, Chiorboli *et al.*[33] showed that, in spite of the adoptation of Nishimoto-Mataga's formula, the SECI calculation gives the order of the excited levels different from that of Dahl and Hansen when the penetration integrals are different from theirs. From these facts it is revealed that the effect of the doubly excited configurations upon the calculated energy levels is more complicated for pyrrole than for phenol and aniline.

Transition Moment. As is well known, the transition moment or oscillator strength calculated by the P-P-P method including SECI is usually too large (2—3 times) compared with the experimental value. This is corrected to a great extent by the DECI treatment. This improvement is mainly attributed to the fact that in the DECI treatment excited wavefunctions include many doubly excited configurations, the transition moments from the ground configuration to which are zero. This tendency is vivid in the transitions to higher excited levels of aniline and phenol, and the moments calculated for them are sometimes smaller than the observed values.

π-Electron Densities and Dipole Moments of Aniline. By the aid of the wavefunctions calculated by the present study, π-electron densities were evaluated for the ground state of aniline as shown in Fig. 6. This figure shows that the

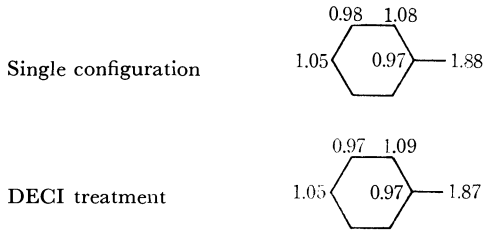

Fig. 6. Electron densities in the ground state of aniline.

nonbonding electrons of the nitrogen atom migrate by 0.12—0.13 *e* toward the benzene ring and consequently the carbon atoms at the *o*- and *p*-positions turn out to have excess π-electrons by 0.08—0.09 *e* and 0.05 *e*, respectively. From these π-electron densities we calculated the dipole moment due to the π-electrons to be 1.82—1.89 D. The values are close to the π-electron moment estimated by analyzing the observed dipole moment of aniline, 1.41—1.52 D.[34,35]

The calculated π-electron densities in the first excited state of aniline are shown in Fig. 7. The

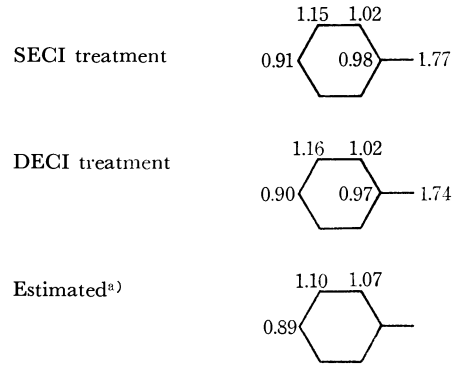

Fig. 7. Electron densities in the first excited state of aniline.

corresponding quantities were estimated[36] from the analysis of the peak positions of the absorption band observed for various aminopyridines. The estimated values are also shown in Fig. 7 for the purpose of comparison, although the estimation includes much ambiguity and therefore too much importance should not be attached to them. The theoretical π-electron densities in the first excited state are qualitatively coincident with the estimated ones in the sense that excess amounts of π-electrons are located on the carbon atoms of *o*- and *m*-positions. In this connection, it may be noticed that the difference ($\Delta\mu_\pi$) in the π-electron moment between the ground and the first excited state was estimated to be~5 D from the analysis of the solvent effect on the absorption and fluorescence spectra observed for aniline.[36] The corresponding quantity was calculated by the SECI and DECI treatment to be 1.45 D and 2.44 D, respectively. The calculated $\Delta\mu_\pi$ values are smaller than the estimated value, although the latter includes much ambiguity. From this it is revealed that the present calculation underestimates a little the π-electron migration from the nitrogen atom toward the benzene ring and therefore that a little smaller $|W_p|$ value than that in the present calculation may give better results for the π-electron distribution. Anyhow, it may be concluded from the both theoretical and experimental points of view that the π-electron migration from the nitrogen atom toward the benzene ring much increases in the first excited state compared with in the ground state.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1017—1022 (1970)

Excitation Transfer in the Radiolysis of Solid Hydrocarbons as Studied by ESR Spectroscopy and Product Analysis

Terunobu WAKAYAMA, Toyoaki KIMURA, Tetsuo MIYAZAKI, Kenji FUEKI and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received October 17, 1969)

The effect of carbon tetrachloride on the radiolysis of isobutane and methylcyclohexane at 77°K is studied by ESR spectroscopy and by product analysis. The yields of solvent radicals from the γ-irradiation of isobutane and methylcyclohexane are not changed by the presence of conventional electron scavengers. This indicates that solvent radicals are not formed by the neutralization of solvent cations with electrons. On the contrary, the yields of solvent radicals decrease remarkably upon the addition of CCl_4. Though the yield of propylene from the γ-irradiation of isobutane is not affected by the addition of electron scavengers, it decreases significantly upon the addition of CCl_4. Though the decrease in the hydrogen yield in the radiolysis of methylcyclohexane at 77°K upon the addition of electron scavengers is only about 1G-unit, it amounts to more than 3.5G-units upon the addition of CCl_4. These characteristic effects of CCl_4 can possibly be explained in terms of excitation transfer from the excited solvent molecule to CCl_4. A kinetic treatment suggests that its mechanism may be an exciton transfer.

Product analysis and the observation of reaction intermediates have been two major methods for the study of the reaction mechanism of radiolysis. Since these two methods reveal different aspects of mechanisms, however, it is desirable to make a study of the radiolysis mechanism using both methods. Along this line we have previously studied the reaction of nitrous oxide with electrons in organic glass[1] and the radiolysis of phenylacetate in the solid states[2] at −196°C.

We reported in a previous communication[3] that the yield of the isobutyl radical produced in γ-irradiated isobutane at −196°C decreases upon the addition of carbon tetrachloride, while it is not affected by the addition of other electron scavengers, such as nitrous oxide, sulfur hexafluoride, and ethyl iodide. Here we will study in more detail, by ESR spectroscopy and by product analysis, the characteristic effect of carbon tetrachloride in the radiolysis of isobutane and methylcyclohexane at −196°C.

Experimental

The isobutane and the methylcyclohexane were more than 99.9% pure. The gas-chromatographic analysis did not show any detectable impurity. They were used after degassing and distillation on a vacuum line. The carbon tetrachloride (99.9%) was used after vacuum distillation. The additives, such as phenyl iodide, ethyl iodide, nitrous oxide, sulfur hexafluoride, *n*-butyl chloride, carbon dioxide, and ethylene, were all of a high purity and were used after vacuum distillation.

The samples were irradiated with γ-rays from Co-60 at a dose rate of 4.2×10^5 rad/hr. The photobleaching of the γ-irradiated samples was carried out at 77°K with the light from a tungsten lamp.

The ESR measurements were made on a JES-3BX ESR spectrometer. The gaseous products not condensable at the temperature of liquid nitrogen were analyzed by a gas burette connected to a Toepler pump and a cupric oxide furnace kept at 240°C. The hydrocarbon products were analyzed by a Hitachi K53 gas chromatograph equipped with a flame-ionization detector (activated alumina column, 2 m, 100°C).

The *G*-value is expressed here by the number of product molecules per 100 eV absorbed in isobutane or methylcyclohexane. The *G*-values of the radicals were determined by ESR measurements by assuming $G(\text{radical})=1.6$ for the radicals produced in the γ-irradiated 3-methylpentane at −196°C.[4]

Results and Discussion

Radiolysis of Isobutane. *A) The Effect of Carbon Tetrachloride on Solvent Radical Formation.* Isobutane forms a polycrystal at −196°C, and when irradiated with γ-rays it produces the isobutyl

△ C_6H_5I
□ C_2H_5I
▲ N_2O
■ SF_6
} Additives
Yields of CCl_3 radical in the radiolysis of i-C_4H_{10}-CCl_4 system are also shown by plots (●).

radical whose ESR spectrum is shown in Fig. 1(A). The yield of the isobutyl radical is not affected by the addition of electron scavengers, such as phenyl iodide, C_2H_5I, N_2O, and SF_6 (Fig. 2). When isobutane containing ethyl iodide was γ-irradiated at −196°C, an ethyl radical was observed by ESR measurement. The ethyl radical is produced by dissociative electron attachment to ethyl iodide (reactions (1) and (2)).

$$C_4H_{10} \rightsquigarrow C_4H_{10}^+ + e^- \quad (1)$$

$$e^- + C_2H_5I \longrightarrow C_2H_5 + I^- \quad (2)$$

Nitrous oxide suppresses the formation of the toluene anion in the γ-irradiated isobutane-toluene system, as will be described in the next section, and it also acts as an effective electron scavenger.

Therefore, it can be said that the isobutyl radical is not produced by the neutralization reaction in the radiolysis of solid isobutane. The effect of CCl_4 on the formation of isobutyl radical is shown in Fig. 2. Here the remarkable points are the rapid decrease in the yield of the solvent radical and the increase in the yield of the CCl_3 radical with the increase in the concentration of CCl_4. The yield of the CCl_3 radical amounts to 6.5G-units at $[CCl_4]=5$ mol/100 mol of i-C_4H_{10}. The large yield of the CCl_3 radical cannot be explained only by the dissociative electron attachment:

$$e^- + CCl_4 \rightarrow CCl_3 + Cl^- \quad (3)$$

but suggests the participation of some other reactions. Since the ionization potential of isobutane (10.8 eV) is lower than that of carbon tetrachloride (11.5 eV), isobutane ion in the ground state cannot transfer its charge to CCl_4. The quantity of mobile excited butane ions is considered to be rather small because of the fact that the toluene cation was not formed in the γ-irradiated isobutane matrix containing toluene (*cf.* next section). Therefore, the effect of CCl_4 on the formation of the isobutyl radical may not be due to charge transfer from the excited isobutane ion to carbon tetrachloride.

Let us tentatively ascribe this effect to excitation transfer from the excited isobutane molecule to carbon tetrachloride and the suppression of the decomposition of the excited isobutane (reactions (4)—(6)):

$$C_4H_{10} \rightsquigarrow C_4H_{10}^* \quad (4)$$

$$C_4H_{10}^* \longrightarrow C_4H_9 + H \quad (5)$$

$$C_4H_{10}^* + CCl_4 \longrightarrow C_4H_{10} + CCl_4^* \quad (6)$$

A portion of CCl_4^* may decompose further to produce CCl_3 and Cl radicals:

$$CCl_4^* \rightarrow CCl_3 + Cl \quad (7)$$

The presence of H atoms produced in reaction (5) is demonstrated by the fact that the ethyl radical is observed by ESR measurements in the γ-irradiated isobutane-ethylene system (Fig. 1(B)):

$$H + C_2H_4 \rightarrow C_2H_5 \quad (8)$$

B) The Effect of Toluene on Solvent Radical Formation. The effect of toluene on the formation of the isobutyl radical is shown in Figs. 3 and 4. Here the remarkable points are the rapid decrease in the yield of the solvent radical and the appearance of a new ESR spectrum with the increase in the concentration of toluene. The new spectrum disappears easily upon illumination with light from a tungsten lamp, and it decreases upon the addition of nitrous oxide to the i-C_4H_{10}-$C_6H_5CH_3$ system (Fig. 4a, b and c). These results suggest that the species responsible for this spectrum may be assigned to the toluene anion. The spectrum consists of five lines with a splitting constant of 4.2 G.

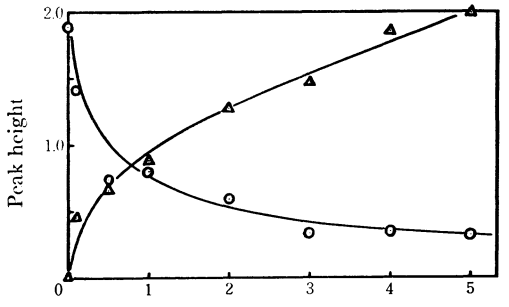

Fig. 3. Effect of toluene on the formation of radical in the radiolysis of isobutane at 77°K studied by ESR.
Dose: 1.7×10^5 rad.
○, isobutyl radical; △, toluene anion

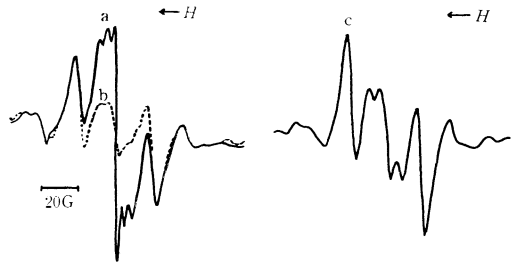

Fig. 4. a) ESR spectrum of γ-irradiated isobutane containing 4.8 mol% toulene at 77°K.
b) The same sample as (a) after 5 min illumination with visible light.
c) ESR spectrum of γ-irradiated isobutane - toluene (4.8 mol%) - nitrous oxide (0.9 mol%) system at 77°K.
Dose: 1.7×10^5 rad.

The ESR spectrum of the toluene anion produced chemically consists mainly of five lines with a splitting constant of 4.0 G,[5] these lines arising from hyperfine interactions with ortho- and meta-protons. The formation of the toluene anion and the related reactions may be written as follows:

$$i\text{-}C_4H_{10} \rightsquigarrow C_4H_{10}^+ + e^- \quad (9)$$

$$e^- + C_6H_5CH_3 \rightarrow C_6H_5CH_3^- \quad (10)$$

$$C_6H_5CH_3^- \xrightarrow[\text{(visible light)}]{h\nu} C_6H_5CH_3 + e^- \quad (11)$$

$$e^- + N_2O \rightarrow N_2 + O^- \quad (12)$$

The absence of the toluene cation suggests that the amount of the mobile excited ion may be negligibly small in the γ-irradiated solid isobutane. Since the yield of isobutyl radical is not altered by the photodetachment of an electron from a toluene anion (reaction (11)), the isobutyl radical is not formed by the neutralization of an electron with an isobutane cation.

5) S. P. Solodovnikov, *Zh. Strukt. Khim.*, **2**, 282 (1961).

Since the addition of toluene suppresses the formation of the isobutyl radical, as does carbon tetrachloride, toluene may also act as an acceptor of excitation energy:

$$C_4H_{10}^* + C_6H_5CH_3 \rightarrow C_4H_{10} + C_6H_5CH_3^* \quad (13)$$

C) The Effect of Carbon Tetrachloride on the Final Products. The fragment products in the radiolysis of isobutane at −196°C are mainly hydrogen, methane, propane, propylene, and isobutene. The hydrogen and propylene decrease in amount upon the addition of CCl_4 (Figs. 5 and 6). The

○, H_2; △, CH_4

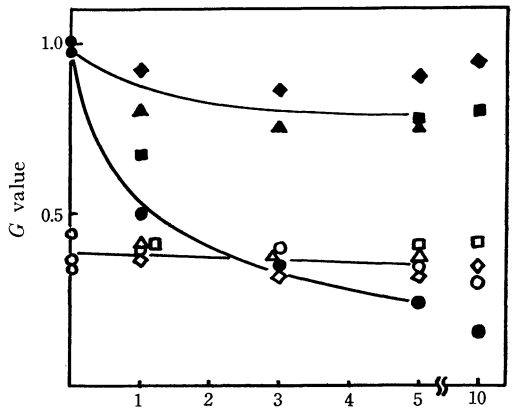

Fig. 6. Effect of additives on the formation of propylene and propane in the radiolysis of isobutane at 77°K.
Dose: 3.4×10^6 rad.

Yields of C_3H_6	Yields of C_3H_8
● CCl_4	○ CCl_4
▲ C_2H_5I	△ C_2H_5I
■ SF_6	□ SF_6
◆ N_2O	◇ N_2O

fact that the yield of propylene is not affected by the addition of electron scavengers, such as N_2O, SF_6, and C_2H_5I, indicates the absence of the follow-

ing neutralization reactions:

$$C_4H_{10}^+ + e^- \rightarrow C_3H_6 + CH_4 \quad (14)$$

$$C_3H_7^+ + e^- \rightarrow C_3H_6 + H \quad (15)$$

The yield of propane in the radiolysis of isobutane at −196°C are 0.3—0.4 G-unit in the presence of SF_6, while the yields amount to 1.4 in the radiolysis in the liquid phase.[6] This is because the fragmentation of the electronically-excited isobutane ion (reaction (16)) may be suppressed in the solid state by the dissipation of the electronic excitation energy to the solvent matrix; thus, the reaction of the $C_3H_7^+$ ion, reaction (15), for example, may play a minor role in the radiolysis of solid isobutane:

$$C_4H_{10}^{+*} \rightarrow C_3H_7^+ + CH_3 \quad (16)$$

The possibility that propylene may be produced directly from the fragmentation of the excited isobutane ion may be unimportant for two reasons. (i) The amounts of the CH_4^+ and $C_3H_5^+$ ions are rather small in the mass spectrum of isobutane, which may be correlated to C_3H_6 (reactions (17)—(20)):

$$C_4H_{10} \rightsquigarrow C_4H_{10}^{+*} + e^- \quad (17)$$

$$C_4H_{10}^{+*} \longrightarrow C_3H_6 + CH_4^+ \quad (18)$$

$$\searrow\ C_3H_5^+ + CH_3 + H_2 \quad (19)$$

$$C_3H_5^+ + C_4H_{10} \longrightarrow C_3H_6 + C_4H_9^+ \quad (20)$$

(ii) Even if $C_4H_{10}^{+*}$ is formed, its fragmentation may be suppressed in the condensed phase by collisional deactivation (reaction (21)).[7]

$$C_4H_{10}^{+*} + C_4H_{10} \rightarrow C_4H_{10}^+ + C_4H_{10} \quad (21)$$

It is suggested, therefore, that propylene is formed mainly by the fragmentation of the excited isobutane molecule:

$$C_4H_{10} \rightsquigarrow C_4H_{10}^* \quad (4)$$

$$C_4H_{10}^* \longrightarrow C_3H_6 + CH_4 \quad (22)$$

$$\searrow\ C_3H_6 + CH_3 + H \quad (23)$$

Lias and Ausloos[8] have reported that propylene is one of the main products in the fragmentation of excited or superexcited isobutane molecules in the photolysis of isobutane in the gas phase.

The addition of carbon tetrachloride suppresses the formation of propylene in the radiolysis of solid isobutane. When ethylene (3 mol/100 mol of i-C_4H_{10}) is added to the i-C_4H_{10}-CCl_4 system in order to protect propylene from the occurrence of reaction (24) while the irradiated sample is being warmed to room temperature, CCl_4 suppresses the formation of propylene to the same extent as in the absence of ethylene. This confirms that the effect of CCl_4 is not due to the secondary reaction of propylene with CCl_3 radicals.

$$C_3H_6 + CCl_3 \rightarrow C_3H_6CCl_3 \quad (24)$$

Therefore, the excitation transfer from the excited isobutane molecule to carbon tetrachloride (reaction (6)) may compete with Reactions (22) and/or (23). Since the yield of methane is not affected by the addition of carbon tetrachloride, Reaction (22) may be unimportant in the formation of propylene. The failure to detect the methyl radical, which would be produced by Reaction (23), may be due to its rapid combination with other radicals, for example butyl radicals, in a spur.

Radiolysis of Methylcyclohexane. As is shown in Fig. 7, the yield of solvent radicals decreases

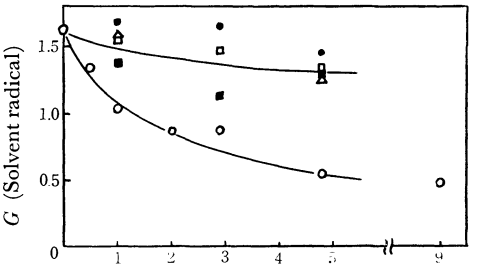

Fig. 7. Effect of additives on the formation of solvent radical in the radiolysis of methylcyclohexane at 77°K studied by ESR.
Dose: 2.1×10^5 rad.
○, CCl_4; □, n-C_4H_9Cl; △, CO_2; ●, N_2O; ■, SF_6

upon the addition of CCl_4. The reaction scheme for the radiolysis of methylcyclohexane may be depicted as follows:

$$C_7H_{14} \rightsquigarrow C_7H_{14}^+, C_7H_{14}^{+*}, C_7H_{14}^*, e^- \quad (25)$$

$$\left.\begin{matrix} C_7H_{14}^+ \\ C_7H_{14}^{+*} \end{matrix}\right\} + e^- \longrightarrow C_7H_{14}^* \quad (26)$$

$$C_7H_{14}^* \longrightarrow C_7H_{13} + H \quad (27)$$

$$\searrow\ C_7H_{12} + H_2 \quad (28)$$

$$2H \longrightarrow H_2 \quad (29)$$

The electron scavengers, such as CO_2, N_2O, SF_6, and n-C_4H_9Cl, but not CCl_4, do not suppress the yield of the solvent radical (Fig. 7). In these cases it was found, by ESR or product analysis, that CO_2^-, N_2,[9] and n-C_4H_9 radicals are formed by electron attachement to CO_2, N_2O, and n-C_4H_9Cl respectively. Moreover, when the trapped electron is bleached by infrared light, the solvent radical does not increase. Therefore, it can be said that the solvent radical is not produced by the neutralization reaction, (26).

9) T. Kimura, T. Miyazaki, K. Fueki and Z. Kuri, This Bulletin, **41**, 2861 (1968).

The characteristic effects of CCl_4 in the radiolysis of methylcyclohexane at 77°K were also observed on the production of hydrogen (Fig. 8). The

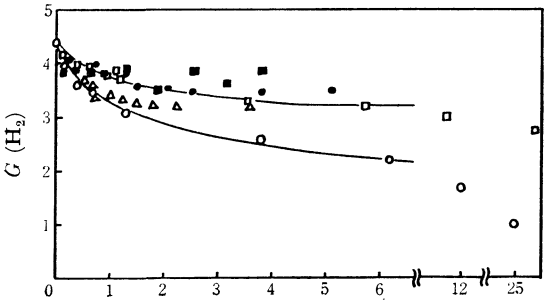

Fig. 8. Effect of additives on the formation of hydrogen in the radiolysis of methylcyclohexane at 77°K.
Dose: 3.6×10^5 rad.
○, CCl_4; □, n-C_4H_9Cl; △, C_6H_5I; ■, SF_6; ●, N_2O

decrease in the amount of hydrogen upon the addition of CCl_4 exceeds 3.5 G-units at the highest concentration, while the decreases upon the addition of n-C_4H_9Cl, SF_6, N_2O,[9] and C_6H_5I[9] are 1.3, 0.7, 0.8, and 1.3 G-units respectively.

Since the ionization potential of methylcyclohexane (9.9 eV) is lower than that of carbon tetrachloride (11.5 eV), the methylcyclohexane ion in the ground state cannot transfer its charge to CCl_4. Though the excited methylcyclohexane ion might transfer its charge to CCl_4, let us tentatively ascribe the effect of CCl_4 to the excitation transfer (reaction (30)):

$$C_7H_{14}^* + CCl_4 \longrightarrow C_7H_{14} + CCl_4^* \qquad (30)$$

Mechanism of Excitation Transfer. From the above results it can be assumed that the isobutyl radical is formed mainly by the decomposition of excited molecules in the radiolysis of solid isobutane and that CCl_4 acts as an acceptor of the excitation energy. Recently it was found, in a study of ultraviolet-induced luminescence of benzene, that CCl_4 is an efficient excitation quencher.[10] The mechanism of excitation transfer will now be discussed on the basis of the effect of CCl_4 on the formation of the isobutyl radical. A possible kinetic scheme is the following:

$$C_4H_{10} \overset{I}{\rightsquigarrow} C_4H_{10}^* \qquad (4)$$

$$C_4H_{10}^* \overset{k_d}{\longrightarrow} C_4H_9 + H \qquad (5)$$

$$C_4H_{10}^* + CCl_4 \overset{k_q}{\longrightarrow} C_4H_{10} + CCl_4^* \qquad (6)$$

where I is the rate of reaction (4) and where k is the rate constant. The rate of excitation transfer (reaction (6)) cannot be expressed *a priori* as that of the bimolecular reaction. Therefore, the following expression may be adopted:[11]

$$R_q = k_q\,[C_4H_{10}^*][CCl_4]^{n/3} \qquad (I)$$

where R_q is the rate of reaction (6). Since the rate of excitation transfer is usually some integral power function of the distance between two interacting molecules, it is natural to assume $R_q \propto [CCl_4]^{n/3}$, where n is an integer. $[CCl_4]^{1/3}$ is proportional to the reciprocal of the average distance between the molecules of carbon tetrachloride and excited butane.

The rate of excitation transfer for various theoretical models may be expressed as follows:[12]

a) Exciton transfer:

$$R_q \propto \frac{1}{r^3}$$

b) Vibrational-relaxation resonance transfer:

$$R_q \propto \frac{1}{r^6}$$

c) Polak's treatment:[11]

$$R_q \propto \frac{1}{r^2}$$

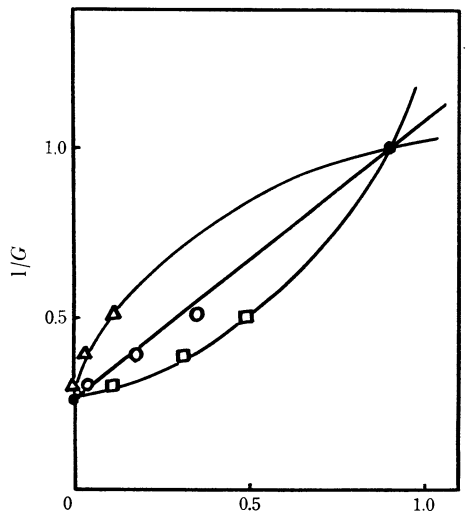

Fig. 9. Relations between $1/G(C_4H_9)$ and $[CCl_4]$. When $[CCl_4]=0.45$M, $[CCl_4]^{n/3}$is normalized to be 1.

where r is the distance between interacting molecules.

The steady-state treatment leads to:

$$\frac{1}{G(C_4H_9)} = \frac{1}{I} + \frac{k_d}{Ik_q}[CCl_4]^{n/3} \qquad (II)$$

where n is taken to be 2, 3, or 6, depending upon the models. Kinetic plots of our data for these cases are shown in Fig. 9. The experimental points fall reasonably well on a straight line for $n=3$; thus,

$$R_q \propto [CCl_4] \propto \frac{1}{r^3}$$

The kinetic treatment suggests that the mechanism of excitation transfer in our system is exciton transfer.

The slope-to-intercept ratio gives $k_q/k_d = 7.3\,\text{M}^{-1}$. The C–H bond rupture of the excited butane molecule may occur in the period of one vibration (10^{-12}—10^{-13} sec). It seems reasonable to assume $k_d = 10^{12}$—$10^{13}\,\text{sec}^{-1}$. Therefore, we obtain:

$$k_q = 7 \times 10^{12}\text{—}10^{13}\ \text{M}^{-1}\text{sec}^{-1}$$

This suggests that the rate of excitation transfer is extremely high as compared with the rate of diffusion-controlled reactions in the liquid phase ($\sim 10^{10}\ \text{M}^{-1}\text{sec}^{-1}$). k_q is of approximately the same order of magnitude as the theoretical value[12] (10^{12}—$10^{13}\,\text{M}^{-1}\,\text{sec}^{-1}$) of the transfer rate of the localized exciton.

Solvent Effects on the *g* Factors of Semiquinones

Teijiro YONEZAWA, Takashi KAWAMURA, Masaru USHIO and Yukimichi NAKAO

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received October 17, 1969)

The dependence of the *g* factors of *p*-benzosemiquinone and its tetrahalogenated derivatives on the solvent composition has been studied in the dimethyl sulfoxide-water system. When the water content of the solvent increases, the *g* factor of *p*-benzosemiquinone decreases, that of tetrachloro-*p*-benzosemiquinone scarcely changes, and the *g* factors of tetrabromo- and tetraiodo-*p*-benzosemiquinones increase. These phenomena are interpreted qualitatively by assuming that the water molecule solvates to the carbonyl oxygen atom of semiquinones and by using Stone's equation for the *g* factor of the polyatomic radical. The dependence of the *g* factor of *p*-benzosemiquinone on the solvent composition is quantitatively studied by means of the theory of solvent effects proposed by Gendell, Freed and Fraenkel and by using the 2-site model of Stone and Maki and also the 4-site model. The former model assumes that one carbonyl oxygen atom has one site occupied by a solvent molecule, thus resulting in a dominant *g* shift. In the later model, two solvent molecules interact with one carbonyl oxygen atom. Both models predict the same relation between the *g* shift and the solvent composition; this experiment cannot confirm which model is more adequate, although the deduced values of the equilibrium constants indicate that the 4-site model is preferable.

In two previous papers[1,2] we have studied the effects of solvents on the *g* factors of diphenyl nitric oxide and di-*t*-butyl nitric oxide; these investigations gave useful information about solvent-solute interactions, especially regarding the hydrogen-bond.

Although the solvent effects on the hyperfine coupling constants of the proton, carbon-13, and oxygen-17 of semiquinones have been extensively investigated,[3-7] the solvent effects on their *g* factors have attracted little attention[8]; therefore, a further extensive investigation of the solvent

effect on the g factors of semiquinones seems to be required.

p-Benzosemiquinone and its tetrahalogenated derivatives are generated electrochemically in the mixed solvent system of water and dimethyl sulfoxide (DMSO). The g factors of these radicals are measured in solvents of various compositions. These data are quantitatively explained in terms of the Gendell, Freed, and Fraenkel (GFF) theory;[4] this procedure accounts for these solvent effects on the assumption that the solvent forms localized complexes with oxygen atoms in carbonyl groups. Moreover, the shifts in the g factors of these semiquinones can be quantitatively explained by means of Stone's theory[9] regarding g factor of the polyatomic radical.

Experimental

p-Benzoquinone and chloranil were obtained commercially and were purified by recrystallization. The bromanil and iodanil were synthesized by the method of Torrey and Hunter[10] and were subsequently purified by recrystallization.

Semiquinones were generated by diffusion-controlled electroreduction within the microwave cavity of a 10^{-3} mol/l solution of quinone in DMSO, water, and various mixtures of both solvents under a vacuum. The reduction potential was controlled as the yellow color of the semiquinone arose near the mercury cathode. The supporting electrolyte was 0.05M tetraethylammonium perchlorate or sodium perchlorate in solutions with mole fractions of water less than or greater than 0.5 respectively.[5]

The water content of the mixed solvent was determined by means of the Karl-Fisher method.[11]

The electron spin resonance (ESR) spectra were observed by means of a JEOL JES-3BSX instrument with a 100 kHz field modulation and operating at a nominal frequency of 9.4 GHz.

For the measurement of the g factor, a glass capillary was attached to the sample tube. The capillary was filled with a reference compound, an alkaline aqueous solution of the potassium peroxylamine disulfonate or the tetracene cation radical in concentrated sulfuric acid, the g factors of which were assumed to be 2.005590 or 2.002604[12] respectively.

Results and Discussion

Table 1 lists the experimental values of the g factor of *p*-benzosemiquinone (I) for various mole fractions of water, designated by N_W, in mixture with DMSO. The values of the g factors decrease

with the increase in N_W.

The experimental values of the g factors of tetrachloro-p-benzosemiquinone (II), tetrabromo-p-benzosemiquinone (III), and tetraiodo-p-benzosemiquinone (IV) are summarized in Tables 2, 3, and 4 respectively. Since tetrahalogenated derivatives of p-benzoquinone do not dissolve in water, the g factors of semiquinones derived from these quinones can not be obtained for high values of N_W.

Shifts of the g Factors of p-Benzosemiquinone and Its Tetrahalogenated Derivatives. Figure 1 shows plots of the g factors of p-benzosemiquinone and its tetrahalogenated derivatives against N_W. As N_W increases, the g factor of I decreases, and that of II scarcely changes, while that of III increases and the g factor of IV increases even more steeply than that of III.

According to Stone's equation for the g factor of a polyatomic radical,[9] the g factors of these semiquinones can be approximately given as:[13]

$$g \simeq 2.00232 + 2\Delta g_O + 4\Delta g_X \qquad (1)[14]$$

$$\Delta g_O = \frac{a\zeta_O C_{O\sigma}^2 \rho_O^{\pi}}{\Delta E_O} \qquad (2)$$

$$\Delta g_X = \frac{b\zeta_X C_{X\sigma}^2 \rho_X^{\pi}}{\Delta E_X} \qquad (3)$$

where a and b are positive constants; ζ_O and ζ_X are the L–S coupling constants about oxygen and halogen nuclei; $C_{O\sigma}^2$ or $C_{X\sigma}^2$ implies the square of the coefficient of the p_σ atomic orbitals of oxygen or halogen in lone-pair orbitals on it, and ρ_O^{π} and ρ_X^{π} denote the odd-electron density on the oxygen and on the halogen atoms respectively. ΔE_O or ΔE_X is the energy for a transition of a lone pair electron localized on oxygen or halogen atoms to the odd electron π orbital, respectively.

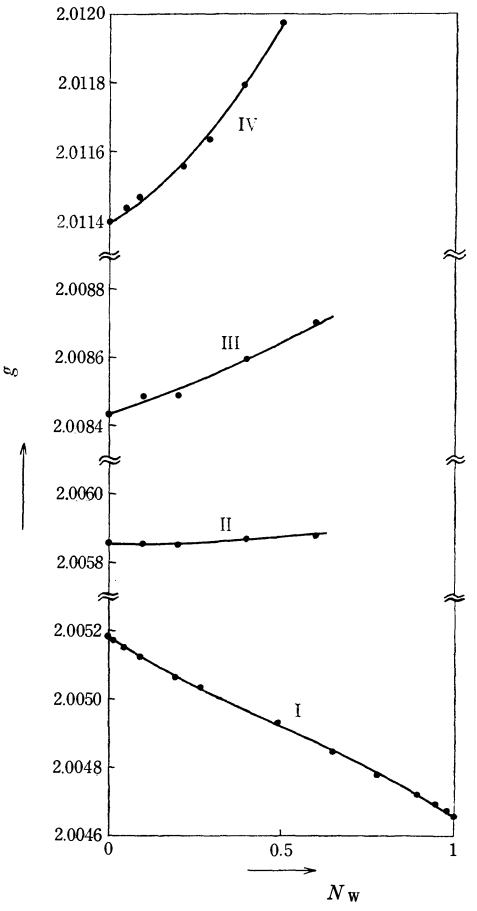

Fig. 1. Observed g factors of p-benzosemiquinone (I), tetrachloro-p-benzosemiquinone (II), tetrabromo-p-benzosemiquinone (III), and tetraiodo-p-benzosemiquinone (IV) *vs.* mole fraction of water in solution of DMSO-water.
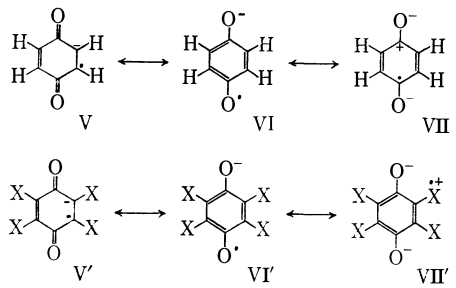
The curve for I expresses calculated behavior (See text).

Δg_X and Δg_O then, indicate the contributions of lone parirs on oxygen and halogen respectively to the g factor. The L–S coupling constants of oxygen and halogen are greater than that of carbon (ζ_C=28 cm^{-1}, ζ_O=152 cm^{-1} ζ_{Cl}=587 cm^{-1}, ζ_{Br}=2460 cm^{-1}, ζ_I=5060 cm^{-1}),[15] and the σ-π* and π-σ* transition energies are greater than ΔE_O and ΔE_X; hence, the other terms contribute only a little to the g factors of semiquinones and are neglected in this discussion. Changes in the electronic structure and a resulting shift in the g factor, accompanied by a change in the solvent from DMSO to water, are denoted by δ. For example, when g is the g factor in DMSO, $g+\delta g$ is that in water.

13) See also H. M. McConnell and R. E. Robertson, *J. Phys. Chem.*, **61**, 1018 (1957).
14) In the case of p-benzosemiquinone, the last term in Eq. (1) should be ignored.
15) D. S. McClure, *J. Chem. Phys.*, **17**, 905 (1949).

We assume that semiquinones in water form a hydrogen bond between their lone pairs on the oxygen atom and the solvent molecule, but not between their halogen atoms and the water molecule. Hydrogen-bond formation to the oxygen atom in a carbonyl group affects the odd-electron distribution through increasing the effective electronegativity of oxygen, while it decreases the odd-electron density on oxygen and increases that on halogen.



(X: halogen) (4)

When the effective electronegativity of oxygen increases, the weight of the structure VII or VII′ can be expected to increase in resonance (4). Therefore, as to the changes in ρ_0^{π} and ρ_X^{π},

$$\delta\rho_0^{\pi} < 0 \tag{5}$$

$$\delta\rho_X^{\pi} > 0 \tag{6}$$

are expected. Broze, Luz, and Silver[16] have reported that the absolute values of the oxygen-17 hyperfine coupling constants of p-benzosemiquinone and tetrachloro-p-benzosemiquinone in aprotic solvents are larger than those in protic solvents. These results also confirm the inequality (5).

A hydrogen-bond formation changes ΔE_0 and $\Delta C_{0\sigma}^2$ thus:

$$\delta\Delta E_0 > 0 \tag{7}$$

$$\delta C_{0\sigma}^2 < 0, \tag{8}$$

these phenomena are known as the blue-shift of the n–π^* transition and the delocalization of lone-pair electrons onto hydrogen respectively.[17] By comparing Eqs. (2) and (3) and the inequalities, (5)—(8), we obtain:

$$\delta\Delta g_0 < 0 \tag{9}$$

$$\delta\Delta g_X > 0. \tag{10}$$

Since the L–S coupling constants of halogens decrease in the following order:

$$\zeta_{Cl} < \zeta_{Br} < \zeta_I, \tag{11}$$

we may expect:

$$0 < \delta\Delta g_{Cl} < \delta\Delta g_{Br} < \delta\Delta g_I.$$

The discussion above can explain the interesting feature shown in Fig. 1, since:

$$\delta g_I = 2\delta g_0 < 0$$

$$\delta g_{II} = 2\delta g_0 + 4\delta\Delta g_{Cl} \simeq 0$$

$$\delta g_{III} = 2\delta\Delta g_0 + 4\delta\Delta g_{Br} > 0$$

$$\delta g_{IV} = 2\delta\Delta g_0 + 4\delta\Delta g_I > \delta g_{III}.$$

Analysis of the Dependence of the g Factor of p-Benzosemiquinone on N_W. Gendell, Freed, and Fraenkel[4] assume that the electronic structure of a radical is affected by radical-solvent complexing, and that each type of complex is characterize by a unique value of the coupling constant, a. The formation and decomposition of complexes is so rapid in our case, however, that only a single averaged coupling constant, $\bar{a}$, is observed, *i. e.*:

$$\bar{a} = \sum_i p_i a_i \quad (\text{with } \sum_i p_i = 1) \tag{12}$$

where a_i is the coupling constant characteristic of the ith solvent-radical complex, with represents a fraction, p_i, of the total concentration of the radical. The p_i can be evaluated in terms of a series of solvent-radical association equilibria. Although the GFF theory has been proposed in accounting for solvent effects on the coupling constant, this theory is also applicable at discussion of solvent effects on the g factor, for

$$\bar{g} = \sum_i g_i p_i, \tag{13}$$

where $\bar{g}$ is an observed g factor, g_i denotes the g factor of the ith complex, and p_i has the same meaning as in Eq. (12).

Stone and Maki[5] studied the ^{13}C coupling constant of p-benzosemiquinone-1-^{13}C in a DMSO-water mixed solvent and explained their data quantitatively by assuming three types of solvated species, DRD, WRD, and WRW, where R is the radical anion, D is a DMSO molecule, and W is a water molecule. Their model for solvated complexes assumes that two solvent molecules solvate to one semiquinone molecule; it is referred to as the 2-site model in this work. We used this model in discussing solvent effects on the g factor of p-benzosemiquinone. We also analyzed the present data with the 4-site model. This model assumes that 4 solvent molecules solvate to one semiquinone molecule.

2-Sitie Model. The equilibria proposed by Stone and Maki[5] are:

$$\text{DRD} + \text{W} \overset{K_1}{\rightleftarrows} \text{DRW (and WRD)} + \text{D}$$

$$\text{DRW} \overset{K_3}{\rightleftarrows} \text{WRD}$$

$$\text{W} + \text{DRW (and WRD)} \overset{K_2}{\rightleftarrows} \text{WRW} + \text{D}. \tag{14}$$

They assumed, in the complex formation, that one carbonyl group of the radical has one site occupied by a solvent molecule and that the electronic state of the radical is perturbed. In Eq. (14), DRW

16) M. Broze, Z. Luz and B. L. Silver, *J. Chem. Phys.*, **46**, 4891 (1967).

17) G. C. Pimentel and A. L. McClellan, "The Hydrogen Bond," Freeman Co., San Francisco (1960).

or WRD refers to a complex in which the water molecule is complexed with one carbonyl or with the other carbonyl respectively, and it is assumed that $K_3=1$. When the equilibria in (14) are assumed to explain the solvent effects on the g factor of p-benzosemiquinone, the g factor is given by:

$$\bar{g}=\frac{g_1+K_1g_2S+K_1K_2g_3S^2}{1+K_1S+K_1K_2S^2} \tag{15}$$

where $S=[W]/[D]$ is the ratio of the mole fraction of water and DMSO. The notations, g_1, g_2, and g_3, are the g factors of DRD, of the average of DRW and WRD, and of WRW respectively.

If these radical-solvent complexes are assumed, g_2 becomes

$$g_2=(g_1+g_3)/2$$

and Eq. (15) simplifies to:

$$\bar{g}=\frac{g_1(2+K_1S)+g_3(K_1S+2K_1K_2S^2)}{2(1+K_1S+K_1K_2S)} \tag{16}$$

Since we have taken three types of equilibria (14) into consideration, g_1 and g_3 may be interpreted as the experimental g factors in nonaqueous DMSO and in pure water respectively.

According to Stone and Maki's treatment, an equation equivalent to Eq. (16) is given with the $Q\equiv S^{-1}$ parameter as the variable:

$$\bar{g}=\frac{g_3(2+K_2^{-1}Q)+g_1[2(K_1K_2)^{-1}Q^2+K_2^{-1}Q]}{2[1+K_2^{-1}Q+(K_1K_2)^{-1}Q^2]} \tag{17}$$

Taking the experimental values of 2.005182 and 2.004659 for g_1 and g_3 respectively, we obtain $K_1=2.6$ from the initial slope of Eq. (16):

$$\left(\frac{d\bar{g}}{dS}\right)_{S=0}=K_1(g_3-g_1)/2$$

and $K_2=0.41$ from the initial slope of Eq. (17):

$$\left(\frac{d\bar{g}}{dQ}\right)_{Q=0}=K_2^{-1}(g_1-g_3)/2.$$

By adopting the equilibrium constants thus obtained, we have plotted the g factors calculated by means of Eqs. (16) and (17) in Fig. 1, with N_W as the abscissa. The experimental plots agree with Eqs. (16) and (17) over the entire range of solvent composition.

The obtained values of the equlibrium constants of $K_1=2.6>1$ and $K_2=0.41<1$ show that the first solvation of the water molecule to one carbonyl group of the semiquinone tends to occur and that the second solvation of the water molecule to the other carbonyl group of the radical is, rather, prevented. The distance between the two carbonyl oxygen atoms is 5.4 Å.[18] The interaction of the hydrogen bond is a rather localized one. Therefore, the results of $K_1>1$ and $K_2<1$ obtained with Stone and Maki's 2-site model of solvent-radical complexing seems somewhat unreasonable.

4-Site Model. Senti and Harker[19] and Pasternak[20] showed that, in a crystal of acetoamide or succinamide, two N–H hydrogen atoms interact with one carbonyl oxygen atom to form a planar hydrogen-bond structure. On the basis of the infrared spectroscopic study of a hydrogen-bond formation between p-benzoquinone and phenol in a carbon tetrachloride solution, Fritzsche[21] reported that each carbonyl group of p-benzoquinone has two sites occupied by a phenol molecule forming a hydrogen-bond between its OH hydrogen and the lone-pair electrons of the quinone.

On the basis of these experimental observations, we attempted to analyze solvent effects on the g factor of p-benzosemiquinone with a model (4-site model) in which each carbonyl group has two sites which the solvent molecule occupies, thus shifting the g factor of the radical dominantly. The postulated equilibria are:

$$\begin{aligned}
&\text{DDRDD} + \text{W} \overset{K_1'}{\rightleftharpoons} \text{WDRDD (DWRDD, DDRWD, and DDRDW)} + \text{D}\\
&\text{DWRDD (WDRDD, DDRWD, and DDRDW)} + \text{W} \overset{K_2'}{\rightleftharpoons} \text{WWRDD (and DDRWW)} + \text{D}\\
&\text{DWRDD (WDRDD, DDRWD, and DDRDW)} + \text{W} \overset{K_1'}{\rightleftharpoons} \text{DWRDW (DWRWD, WDRDW, and WDRWD)} + \text{D}\\
&\text{WWRDD (and DDRWW)} + \text{W} \overset{K_1'}{\rightleftharpoons} \text{WWRWD (WWRDW, DWRWW, and WDRWW)} + \text{D}\\
&\text{DWRDW (WDRDW, DWRWD, and WDRWD)} + \text{W} \overset{K_2'}{\rightleftharpoons} \text{WWRDW (WWRWD, DWRWW, and WDRWW)} + \text{D}\\
&\text{WWRWD (WWRDW, DWRWW, and WDRWW)} + \text{W} \overset{K_2'}{\rightleftharpoons} \text{WWRWW} + \text{D},
\end{aligned} \tag{17}$$

where WWRWD refers to the complex in which two water molecules solvate to one carbonyl group and in which the other carbonyl group interacts with one water molecule and one DMSO molecule. It is assumed that solvent molecules complexed with one carbonyl group do not affect the equilibrium constants concerned in the solvation of the other carbonyl, and that the number of solvated water molecules determines the g factor of the com-

plex and is proportional to the shift of the g factor; for example,

$$g_{WWRDD} = g_{WDRWD} = g_{DDRDD} + \frac{1}{2}(g_{WWRWW} - g_{DDRDD}).$$

g_{WWRWW} and g_{DDRDD} may be interpreted as the experimental g factors in pure water, g_W, and in nonaqueous DMSO, g_D, respectively.

On the assumptions stated above, the (17) equilibria and Eq. (13) give, as the g factor in the mixed solvent:

$$\bar{g} = g_D + \frac{K_1'K_2'S^2 + K_1'S}{K_1'K_2'S^2 + 2K_1'S + 1}(g_W - g_D). \qquad (18)$$

Eq. (18) coincides with the equation of the 2-site model, Eq. (15), when $K_1' = K_1/2$ and $K_2' = 2K_2$; that is, $K_1' = 1.3$ and $K_2' = 0.82$.

In the 4-site model, the obtained values of K_1' and K_2' are reasonable. $K_2' < 1$ shows that the second solvation of the water molecule, forming a hydrogen bond between an oxygen atom of a carbonyl group and a hydrogen atom of water, is hindered by the water molecule which has solvated to the same oxygen atom.

Stone and Maki's[5] data on the solvent effects on ^{13}C coupling constants can be interpreted by means of the 4-site model as well as by means of their 2-site model. They reported that the solvation to the nonlabeled carbonyl group scarcely changes the odd-electron distribution near the labeled carbonyl of *p*-benzosemiquinone-1-^{13}C (see Eq. (5) of Ref. 5). Therefore, their a_1 value, the ^{13}C coupling constant in DMSO, may be regarded as the constants of the DDRSS complexes; their a_3 value, the ^{13}C coupling constant in water, as those of the WWRSS complexes, and their a_2 value, as those of the DWRSS and WDRSS complexes, where S denote D or W. In the complex representation above, the two prefixed letters refer to the solvent molecules solvated to the labeled carbonyl. With the approximations above, the equation derived from the 4-site model coincides with the 2-site model equation of solvent effects on the ^{13}C coupling constant.

Both Stone and Maki's 2-site model and the present 4-site model can interpret solvent effects on the g factor as well as on the ^{13}C coupling constant of *p*-benzosemiquinone. Although the 4-site model may be preferred on the basis of the physical meaning of the obtained values of K_2 and K_2', which are smaller than 1, neither the present experimental data on solvent effects on the g factor nor Stone and Maki's study of the ^{13}C coupling constant can experimentally confirm which model is more adequate.

The further study of such things as solvent effects on the ESR parameters of 2,6-di-*t*-butyl-*p*-benzosemiquinone and 2,5-di-*t*-butyl-*p*-benzosemiquinone seems to be desirable in order to ascertain how many water molecules, one or two, can solvate to one carbonyl oxygen atom forming hydrogen-bond in solution.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1027—1032 (1970)

A One-dimensional Model of a Conduction Calorimeter*1

Masaru HATTORI

Department of Machine Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

and Satohiro TANAKA and Kazuo AMAYA

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received October 17, 1969)

An idealized one-dimensional model of a conduction calorimeter, composed of a container in which thermal change occurs, a thermal bath, and a solid thermal conductor connecting the container with the thermal bath, is presented. The boundary-value problem of heat conduction in the model calorimeter is solved by the Laplace transformation method. A proportionality relation between the quantity of heat evolved in the calorimeter container and the area enclosed by the recorded temperature curve and the time axis is established.

The quantity of heat given off in a reaction or process can be determined by various types of calorimeters.[1-3] One of these types consists of

1) "Experimental Thermochemistry," Vol. 1, ed. by F. D. Rossini, Interscience Publishers, New York, N. Y. (1956).

conduction or heat-flow calorimeters which have already found successful application in measurements of the quantity of heat and in studies of thermokinetics.[4-14]

A calorimeter consists essentially of a container in which the thermal phenomena under investigation are carried out and studied. In general, this container is placed in a cavity the walls of which are kept at a constant temperature (a "constant temperature environment" calorimeter) or, alternatively, at a temperature which can be varied at will (an "adiabatic" calorimeter). Calvet and Prat refer to the walls of the calorimeter container as the "internal boundary," and to the walls of the surrounding cavity as the "external boundary.[7]"

In the conduction calorimeter, all or nearly all of the heat evolved or absorbed in the calorimeter container is conducted to or from the surrounding "external boundary," which is kept at a constant temperature. The measurement of the quantity of heat or the study of thermokinetics depends entirely on the calculation of the heat exchange. This, in turn, depends on a knowledge of the temperatures of the calorimeter container and the surrounding external boundary at all times during the measurement and on a knowledge of the rate of heat transfer as a function of these temperatures.

In the case of processes which cause only slow variations in the temperature of the container, the simplified theory of Tian is very useful.[4,5,7] In the theory of Tian, the rate of the heat transfer, ϕ, between the calorimeter container and the surrounding external boundary is assumed to be given by Newton's cooling law; thus:

$$\phi = p(\theta_i - \theta_e) = p\theta, \tag{1}$$

where θ_i=container temperature, θ_e=external boundary temperature, $\theta=\theta_i-\theta_e$, and p=leakage modulus of the system. Let W be the calorific power developed in the container at time t. During the dt time, the quantity of heat given off is $W\mathrm{d}t$. This heat, $W\mathrm{d}t$, is in part lost from the container as a flow of heat, represented by $\phi\mathrm{d}t=p(\theta_i-\theta_e)\mathrm{d}t$; the remaining part of the $W\mathrm{d}t$ causes an increase, $\mathrm{d}\theta$, in the container temperature (assuming that the temperature, θ_e, is basically constant). If the thermal capacity of the container is μ, the container heating consumes power by $\mu\mathrm{d}\theta$. Hence, it follows that:

$$\begin{aligned} W\mathrm{d}t &= p(\theta_i-\theta_e)\mathrm{d}t + \mu\mathrm{d}\theta \\ &= p\theta\mathrm{d}t + \mu\mathrm{d}\theta \end{aligned} \tag{2}$$

or that:

$$W = p\theta + \mu\frac{\mathrm{d}\theta}{\mathrm{d}t}\ , \tag{3}$$

(the later is called "Tian's equation").

The finite quantity of heat, $Q=\int W(t)\mathrm{d}t$, produced in the time interval, $[0,\infty)$, is obtained from Eq. (2) by integration:

$$Q = \int_0^\infty W\mathrm{d}t = p\int_0^\infty \theta\mathrm{d}t + \mu(\theta_\infty-\theta_0), \tag{4}$$

where $\theta=\theta_0$ at $t=0$ and $\theta=\theta_\infty$ at $t=\infty$. In an experiment, it is possible to make $\theta_0=\theta_\infty$. Therefore, a very simple relation

$$Q = p\int_0^\infty \theta dt = pA \tag{5}$$

can be obtained. The integral, $\int_0^\infty \theta\mathrm{d}t$, is equal to the area, A, under the recorded curve and the time-axis over the interval $[0,\infty)$. The expression (5) relates the heat of the reaction of the sample to the area of the recorded curve through the use of the proportionality constant, p, which is independent of the heat capacity of the sample. This expression is perhaps one of the most simple, useful and, fundamental theorems in calorimetry by means of the conduction method.

The above expressions by Tian are, however, only approximate relationships. One of the inherent limitations of Tian's theory is the assumption that the rate of heat transfer between the container and the external boundary is given by Newton's cooling law (1). Newton's law of cooling has been proposed for the transfer of heat from the surface of a solid to a fluid flowing past; in fact, the expression is a rather approximate one, and the coefficient, p, in (1) depends not only on the fluid but on the temperature differences $(\theta_i-\theta_e)$.[15,16] This limitation is considered to be very important

when the heat flow from or to the container is conducted by a solid thermal conductor and when the thermal process is rapid one. In actuality, nearly all of the heat flux is conducted away by the thermocouple wires (Tian-Calvet calorimeter)[4,7] or by the thermoelement (Amaya-Hagiwara calorimeter).[8-12]

Calvet has developed a theory of a more general form applicable to the study of a rapid process.[5,7] He has proposed the expression:

$$\theta = a_1\int_0^t W(u)e^{-\omega_1(t-u)}du + a_2\int_0^t W(u)e^{-\omega_2(t-u)}du + \cdots \tag{6}$$

for the temperature of the calorimeter container, θ, where $W(t)$ is the calorific power produced in the container as a function of the time t and where the heating time extends from $u=0$ to $u=t$. The coefficients, a_1, a_2, $\cdots$ and ω_1, ω_2, $\cdots$, are constants of the calorimeter for a given arrangement. However, the model on which his theory is based and the mechanism of the heat transfer are both obscure; therefore, the parameters, a_1, a_2, $\cdots$ and ω_1, ω_2, $\cdots$, must be determined from a calibration experiment and cannot be evaluated *a priori* before the construction of the calorimeter.

It is, then, necessary to develop a definite model of the calorimeter considering a distinct mechanism of heat transfer.

An Idealized One-dimensional Model of a Conduction Calorimeter

In the actual case of a conduction calorimeter, a heat flux from or to the container is conducted in part by conduction and in part by convection and radiation through the space formed by the internal and external boundaries of the calorimeter. To obtain a precise theory, it is necessary to consider all these processes. However, it is so difficult to take into account all the mechanism of the heat transfer and the complex shape of the boundaries of a calorimeter that the calculation must start from a simplified model. As a first step, an idealized one-dimensional model, in which heat transfer by only conduction is considered, can be adopted; it may be a fairly good approximation for a calorimeter in which a considerable amount of the heat flux is conducted by such solid thermal conductors, as thermocouple wires (Tian-Calvet's calorimeter) or a thermoelement (Amaya-Hagiwara's calorimeter).

Figure 1 illustrates a one-dimensional model

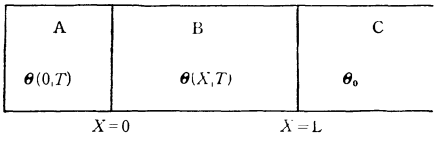

Fig. 1. A one-dimensional model of conduction calorimeter.

of a conduction calorimeter with a container, A, a solid thermal conductor, B, and a thermal bath, C, kept at a constant temperature. The following assumptions are adopted:

1) Calorific power, $W(T)$, is developed in the container at time T, and the temperature of the container is uniform. Let C_0 be the thermal capacity of the container.

2) The solid thermal conductor is a bar with its lateral surface insulated against the flow of heat; the area of its cross section is S, and its ends are $X=0$ and $X=L$. Let $\Theta(X,T)$ denote the temperature at any point in the thermal conductor, and K, the thermal diffusivity of the material.

3) The container is in perfect thermal contact with the $X=0$ side face of the thermal conductor. Heat transfer from or to the container takes place only through the $X=0$ side face of the conductor according to the basic postulate for the conduction of heat in solids, so the quantity of heat per unit of time transferred across the $X=0$ face is given by:

$$-\Lambda S\left(\frac{\delta\Theta}{\delta X}\right)_{X=0},$$

where Λ is the thermal conductivity of the conductor.

4) The thermal bath kept at a constant temperature, Θ_0, is in perfect thermal contact with the $X=L$ side face of the thermal conductor, so that:

$$\Theta_{X=L} = \Theta_0.$$

5) The initial temperature of the calorimeter, $\theta_{T=0}$, is Θ_0 throughout the container, the conductor, and the thermal bath.

6) The C_0, K, and Λ quantities are always constant while the thermal change in the container is taking place. The boundary-value problem for this calorimeter is then:

$$\frac{\partial\Theta}{\partial T} = K\frac{\partial^2\Theta}{\partial X^2} \qquad (0<X<L,\ T>0), \tag{7}$$

$$W(T) = C_0\left(\frac{\partial\Theta}{\partial T}\right)_{X=0} - \Lambda S\left(\frac{\partial\Theta}{\partial X}\right)_{X=0} \tag{8}$$

$$\Theta_{X=L}=\Theta_0, \tag{9}$$

$$\Theta = \Theta_0 \qquad (T\leqq 0). \tag{10}$$

It is convenient to introduce the following dimensionless reduced variables and quantities for the universal forms of the solution of the problem:

$$\left.\begin{aligned} x &= \frac{X}{L} \\ t &= \frac{K}{L^2}T \\ \theta(x,t) &= \frac{\Theta(X,T)-\Theta_0}{\Theta_0} \\ w(t) &= \frac{L^2}{KC_0\Theta_0}W(T) \\ h &= \frac{L\Lambda S}{KC_0}. \end{aligned}\right\} \tag{11}$$

The boundary-value preblem can, then, be written;

$$\frac{\partial\theta}{\partial t} = \frac{\partial^2\theta}{\partial x^2} \qquad (0<x<1,\ t>0) \tag{12}$$

$$w(t) = \left(\frac{\partial\theta}{\partial t}\right)_{X=0} - h\left(\frac{\partial\theta}{\partial x}\right)_{X=0} \tag{13}$$

$$\theta = 0,\ x = 1 \tag{14}$$

$$\theta = 0,\ t = 0. \tag{15}$$

Solution of the Boundary-value Problem by the Laplace Transformation Method[17,18]

Let $\bar{\theta}(x,s)$ be the Laplace transform of $\theta(x,t)$;

$$\bar{\theta}(x,s) = \int_0^\infty e^{-st}\theta(x,t)dt, \quad \mathrm{Re}\{s\}>0.$$

If the Laplace transformation is applied to (12), the transformed equation is:

$$\int_0^\infty e^{-st}\frac{\partial\theta}{\partial t}\,dt = \int_0^\infty e^{-st}\frac{\partial^2\theta}{\partial x^2}\,dt. \tag{16}$$

This becomes, in view of the initial condition (15), and by a formal integration by parts:[19]

$$s\bar{\theta}(x,s) = \frac{d^2}{dx^2}\bar{\theta}(x,s). \tag{17}$$

The boundary conditions, (13) and (14), treated in the same way, give:

$$\bar{w}(s) = s\bar{\theta}(0,s) - h\frac{d}{dx}\bar{\theta}(0,s), \tag{18}$$

$$\bar{\theta}(1,s) = 0, \tag{19}$$

where $\bar{w}(s)$ is the Laplace transform of $w(t)$.

A convenient form of the general solution of Equation (17) is:

$$\bar{\theta}(x,s) = Ae^{\sqrt{s}x} + Be^{-\sqrt{s}x}, \tag{20}$$

where A and B may be functions of s. When this equation is substituted into Eqs. (18) and (19), these equations become:

$$\bar{w}(s) = A(s-\sqrt{s}) + B(s+\sqrt{s}), \tag{21}$$

$$Ae^{\sqrt{s}} + Be^{-\sqrt{s}} = 0. \tag{22}$$

From (21) and (22), the values of A and B are found to be:

$$A = \bar{w}(s)\frac{e^{\sqrt{s}}}{(s-h\sqrt{s})e^{-\sqrt{s}} - (s+h\sqrt{s})e^{\sqrt{s}}}, \tag{23}$$

$$B = -\bar{w}(s)\frac{e^{\sqrt{s}}}{(s-h\sqrt{s})e^{-\sqrt{s}} - (s+h\sqrt{s})e^{\sqrt{s}}}. \tag{24}$$

When these values are substituted into (20), Eq. (20) can be written as:

$$\bar{\theta}(x,s) = \bar{w}(s)\frac{\sinh\sqrt{s}(1-x)}{\sqrt{s}(\sqrt{s}\sinh\sqrt{s}+h\cosh\sqrt{s})} = \bar{w}(s)\bar{f}(s), \tag{25}$$

where:

$$\bar{f}(s) = \frac{\sinh\sqrt{s}(1-x)}{\sqrt{s}(\sqrt{s}\sinh\sqrt{s}+h\cosh\sqrt{s})}. \tag{26}$$

Now the inverse transform of the $\bar{\theta}(x,s)=\bar{w}(s)\bar{f}(s)$ gives $\theta(x,t)$ as the convolution[20] of the $w(t)$ and $f(t)$ functions:

$$\theta(x,t) = \int_0^t w(\tau)f(t-\tau)d\tau. \tag{27}$$

The $f(t)$ function is the inverse transform of $\bar{f}(s)$ and is given by the use of the Inverse Theorem for the Laplace transformation.[21]
This states that:

$$f(t) = \frac{1}{2\pi i}\lim_{\beta\to 0}\int_{\gamma-i\beta}^{\gamma+i\beta} e^{zt}\bar{f}(z)dz = \sum_{n=1}^{\infty}\rho_n(t), \tag{28}$$

where:

$\rho_n(t)$ = the residue of $e^{zt}\bar{f}(z)$ at $z=s_n$

and where:

$z = s_n$ = the singular point of $\bar{f}(z)$.

The singular points $\bar{f}(z)$are:

$$z = 0 \tag{29}$$

and the roots of the equation are:

$$\sqrt{s}\sinh\sqrt{s} + h\cosh\sqrt{s} = 0. \tag{30}$$

The roots of Eq. (30) are given by[22]:

$$s = -\alpha_n^2, \tag{31}$$

where α_n are the positive roots of the equation:

$$\alpha\sin\alpha - h\cos\alpha = 0. \tag{32}$$

The residue for the singular point, $z=0$, is given by:

$$\lim_{s\to 0} s\bar{f}(x,s)e^{st} = 0, \tag{33}$$

while the residues, ρ_n, for the singular points, $z=-\alpha_n$ are given by:[21]

$$\begin{aligned}\rho_n(t) &= \lim_{s\to-\alpha_n^2}(s+\alpha_n^2)\bar{f}(x,s)e^{st}\\ &= \left[\frac{\sinh\sqrt{s}(1-x)}{\frac{d}{ds}\sqrt{s}(\sqrt{s}\sinh\sqrt{s}+h\cosh\sqrt{s})}e^{st}\right]_{s=-\alpha_n^2}\\ &= \frac{2\sin\alpha_n(1-x)}{(1+h+\frac{\alpha_n^2}{h})\sin\alpha_n}e^{-\alpha^2 nt}.\end{aligned} \tag{34}$$

Thus, from (27), (28), (33) and (34), the expression for $\theta(x,t)$ can be obtained as:

17) H. S. Carlslaw and J. C. Jager, "Conduction of Heat in Solids," 2nd Ed., Oxford (1959), Chap. XII.
18) R. V. Churchill, "Operational Mathematics," 2nd Ed., McGraw-Hill, New York, N. Y. (1958).
19) R. V. Churchill, *ibid.*, p. 112.
20) R. V. Churchill, *ibid.*, p. 37.
21) R. V. Churchill, *ibid.*, Chap. 6.
22) H. S. Carlslaw and J. C. Jager, *ibid.*, p. 119.

$$\theta(x,t)=\sum_{n=1}^{\infty}\frac{2\sin\alpha_n(1-x)}{(1+h+\frac{\alpha_n^2}{h})\sin\alpha_n}\int_0^t w(\tau)e^{-\alpha_n^2(t-\tau)}\,d\tau, \tag{35}$$

where α_n are the positive roots of the equation:

$$\alpha\sin\alpha - h\cos\alpha = 0.$$

The final result (35) thus obtained is in a form similar to that of Calvet's general expression (6). The coefficients, a_n and ω_n, in Calvet's expression correspond to those in (35) as follows:

$$a_n \sim \frac{2\sin\alpha_n(1-x)}{(1+h+\frac{\alpha_n^2}{h})\sin\alpha_n}$$

$$\omega_n \sim \alpha_n^2.$$

The coefficients in (35) are physically clear and can be evaluated a priori from the materials and the dimensions of the calorimeter, while a_n and ω_n in Calvet's expression are experimental and physically obscure.

Let us now deduce a property of the series on the right hand of (35), which can be useful in proving the proportionality relation (5). When the quantity $w(t)$ is constant and equals w_0, the series (35) becomes:

$$\theta(x,t)=\sum_{n=1}^{\infty}\frac{2\sin\alpha_n(1-x)}{(1+h+\frac{\alpha_n^2}{h})\sin\alpha_n}\int_0^t w_0e^{-\alpha_n^2(t-\tau)}d\tau$$

$$=\sum_{n=1}^{\infty}\frac{2w_0\sin\alpha_n(1-x)}{\alpha_n^2(1+h+\frac{\alpha_n^2}{h})\sin\alpha_n}(1-e^{-\alpha_n^2t}).$$

The steady temperature, $\theta(x,\infty)$, is obtained as:

$$\theta(x,\infty)=\lim_{t\to\infty}\theta(x,t)$$

$$=\sum_{n=1}^{\infty}\frac{2w_0\sin\alpha_n(1-x)}{\alpha_n^2(1+h+\frac{\alpha_n^2}{h})\sin\alpha_n}. \tag{36}$$

On the other hand, the steady temperature, $\theta(x,\infty)$, can be easily obtained from the steady-state solution of the boundary-value problem, (12), (13), (14), and (15), as:

$$\theta(x,\infty)=w_0\frac{(1-x)}{h}. \tag{37}$$

From (36) and (37), the relation:

$$\sum_{n=1}^{\infty}\frac{2\sin\alpha_n(1-x)}{\alpha_n^2(1+h+\frac{\alpha_n^2}{h})\sin\alpha_n}=\frac{1-x}{h} \tag{38}$$

is obtained.

Proof of Proportionality Relation between the Quantity of Heat and the Integral, $\int_0^\infty\theta dt$

When the rate of heat transfer between the calorimeter container and the thermal bath is given by Newton's cooling law (1), it has easily been shown that the proportionality relation (5) between the quantity of heat, Q, and the "area", $\int_0^\infty\theta dt$, holds. On the other hand, when the container is connected with the thermal bath by a solid thermal conductor, as has been discussed above, and when the rate of heat transfer given by Fourier's Eq. (12), we cannot expect a clear answer to the question of whether the proportionality relation (5) holds or not. However, it will be proved below that the relation is also valid in this case.

The area enclosed by the recorded curve and the time axis is:

$$\int_0^\infty\theta dt=\sum_{n=1}^{\infty}\frac{2\sin\alpha_n(1-x)}{(1+h+\frac{\alpha_n^2}{h})\sin\alpha_n}\int_0^\infty\int_0^t w(\tau)e^{-\alpha_n^2(t-\tau)}d\tau dt. \tag{39}$$

By a formal integration by parts, the integral part on the right hand of (39) becomes:

$$\int_0^\infty\int_0^t w(\tau)e^{-\alpha_n^2(t-\tau)}d\tau dt$$

$$=\frac{1}{\alpha_n^2}\left\{-\lim_{t\to\infty}e^{-\alpha_n^2t}\int_0^t w(\tau)e^{-\alpha_n^2\tau}d\tau+\int_0^\infty w(t)dt\right\}. \tag{40}$$

Now, it can be shown that the first term on the right-hand side of Eq. (40) becomes zero if the total quantity of heat, either evolved or absorbed in the container, has a limited value:

$$Q=\int_0^\infty w(t)dt. \tag{41}$$

A necessary and sufficient condition[23] for the convergence of $\int_0^\infty w(\tau)d\tau$ is that, corresponding to any one positive number, ε, another positive number T should exist so that:

$$\left|\int_T^t w(\tau)d\tau\right|<\varepsilon \tag{42}$$

wherever $t>T$. Therefore,

$$\left|e^{-\alpha_n^2t}\int_0^t w(\tau)e^{\alpha_n^2\tau}d\tau\right|$$

$$=\left|e^{-\alpha_n^2t}\left\{\int_0^T w(\tau)e^{\alpha_n^2\tau}d\tau+\int_T^t w(\tau)e^{\alpha_n^2\tau}d\tau\right\}\right|$$

$$\leqq\left|e^{-\alpha_n^2t}\int_0^T w(\tau)e^{\alpha_n^2\tau}d\tau\right|+\left|e^{-\alpha_n^2t}\int_T^t w(\tau)e^{\alpha_n^2\tau}d\tau\right| \tag{43}$$

The function $e^{\alpha^2n\tau}$ is a positive increasing function and has an upper boundary., e^{α^2nt}, in the $[T,t]$ range:

$$e^{-\alpha_n^2t}\left|\int_T^t w(\tau)e^{\alpha_n^2\tau}d\tau\right|\leqq e^{-\alpha_n^2t}\left|\int_T^t w(\tau)e^{\alpha_n^2t}d\tau\right|$$

$$=e^{-\alpha_n^2t}\left|e^{\alpha_n^2t}\int_T^t w(\tau)d\tau\right|$$

$$=\left|\int_T^t w(\tau)d\tau\right|<\varepsilon.$$

23) E. T. Whittaker and G. N. Watson, "A Course of Modern Analysis," 4th Ed., Cambridge University Press (1965), p. 70.

Therefore, (43) becomes:

$$\left|e^{-\alpha_n^2 t}\int_0^t w(\tau)e^{\alpha_n^2\tau}d\tau\right| < e^{-\alpha_n^2 t}\left|\int_0^T w(\tau)e^{\alpha_n^2\tau}d\tau\right| + \varepsilon. \quad (44)$$

As $t\to\infty$, (44) becomes:

$$\lim_{t\to\infty}\left|e^{-\alpha_n^2 t}\int_0^t w(\tau)e^{\alpha_n^2\tau}d\tau\right| < \varepsilon,$$

or, by the definition of the limit,

$$\lim_{t\to\infty} e^{-\alpha_n^2 t}\int_0^t w(\tau)e^{\alpha_n^2\tau}d\tau = 0. \quad (45)$$

From (38), (39), (40), and (45), it can be shown that:

$$\int_0^\infty \theta(x,t)dt = \sum_{n=1}\frac{2\sin\alpha_n(1-x)}{\alpha_n^2(1+h+\frac{\alpha_n^2}{h})\sin\alpha_n}\int_0^\infty w(t)dt$$

$$= \frac{(1-x)}{h}\int_0^\infty w(t)dt$$

$$= \frac{(1-x)}{h}Q. \quad (46)$$

This is what we desired to prove. It can thus be concluded that the simple method of evaluating the total quantity of heat generated in a thermal process by the simple proportionality relation (5) can well be used when using a conduction calorimeter in which the heat transfer between the container and the surrounding external boundary is effected by conduction.

The authors wish to thank Mrs. K. Sasaki and Mr. I. Takeda of this Institute for their interest and discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1032—1035 (1970)

Verification of the Conduction Method in Calorimetry

Satohiro TANAKA and Kazuo AMAYA

Government Chemical Industrial Reaserch Institute, Tokyo, Shibuya-ku, Tokyo

(Received November 18, 1969)

An ideal three-dimensional model of a conduction calorimeter is presented. In the model, the heat transfer takes place only by conduction. The proportionality relation between the quantity of heat and the area enclosed by the recorded temperature curve and the time axis is proved under several sets of ideal conditions under which the proportionality relation is valid are examined, and thermal compensation is recommended for more precise measurements of heat and for convenience in obtaining thermogenesis curves.

Calorimetric studies are now made of various systems under a wide range of conditions. The wide range of systems and conditions studied in calorimetry requires a large variety of specific calorimeters and techniques. One of these calorimeters is the conduction or heat-flow calorimeter, which has been used for a long time by many investigators. The technique which the calorimeter requires may be called the "conduction method"; it has also been widely not only for static but also for dynamic calorimeters. Some popular calorimeters of this type are the Tian-Calvet calorimeter,[1] the Benzinger-Kitzinger microcalorimeter,[2] the Amaya-Hagiwara calorimeter,[3] and Ozawa's quantitative differential thermal analyzer.[4] Of these calorimeters, Ozawa's is of the dynamic type.

In the conduction method, all or nearly all of the heat evolved or absorbed in the calorimeter container is conducted to or from the jacket through the space formed by the walls of the container and the jacket. The space between the walls of the container and the jacket is sometimes called the cavity[1] or the thermal barrier.[4] The measurement of the heat depends on the calculation of the heat exchange between the container and the jacket. This depends on a knowledge of the temperatures of the jacket and the container at all times during the measurement and on a knowledge of the rate of heat transfer as a function of these temperatures. The rate of the transfer of heat from the jacket to

the container, ϕ, is nearly always represented by Newton's cooling law:

$$\phi = p_c(\theta_c - \theta_j) = p\theta, \tag{1}$$

where θ_c = the temperature at a point on the outside surface of the container, θ_j = the temperature at a point on the inside surface of the jacket, $\theta = \theta_c - \theta_j$, and p = the leakage modulus of the system. If once Newton's law (1) is adopted as the expression for the rate of the heat transfer, it is easy to show that the total quantity of heat evolved or absorbed in the container, Q, is proportional to the area under the curve of the temperature difference, θ, and the time axis;[1-3]

$$Q = p\int_0^\infty \theta \mathrm{d}t, \tag{2}$$

where t = time and p = the leakage modulus of the calorimeter, independent of the heat capacity of the calorimeter container.

In the dynamic experiment of DTA, the proportionality relation (2) also holds approximately; in this case, θ denotes the temperature difference between the sample and the thermally inert reference substance rather than the difference between the container and the jacket.[5]

Although Newton's law (1) is widely used as an expression for the rate of heat transfer in a calorimeter, it is only an approximate one, since the value of the coefficient, p, depends on the temperature difference, θ, the nature of the fluids, and other factors.[6,7] In particular, when the heat flow between the container and the jacket is conducted mainly by conduction in solids, as in the case of the Amaya-Hagiwara calorimeter and Ozawa's quantitative differential thermal analyzer, we must use Fourier's law for the conduction of heat rather than Newton's law.

Hattori *et al.*[8] have presented a one-dimensional model of a conduction calorimeter, solved the boundary-value problem of the heat conduction in the model, and verified that the proportionality relation (2) is also valid in the case of heat flow conducted by conduction in solids. Ozawa[4] also solved the boundary-value problem of a cyrindrical model of the differential thermal analyzer and also concluded that the proportionality relation holds in good approximation if some devices are used to decrease the temperature gradient in the sample cell. The present work to be descrived in this paper was undertaken to see if the proportionality relation hold in a three-dimensional model of a conduction calorimeter and to investigate the foundation of the conduction method in calorimetry.

An Idealized Three-dimensional Model of a Conduction Calorimeter

Figure 1 illustrates an idealized three-dimensional

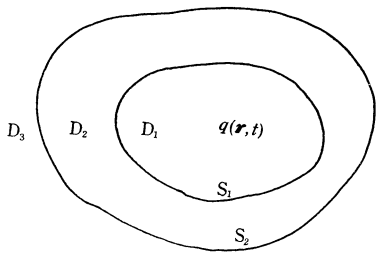

Fig. 1. Three-dimensional model of conduction calorimeter.

model of a conduction calorimeter composed of three solid domains, D_1, D_2, and D_3. The D_1 domain, in which heat is evolved or absorbed, is surrounded by the D_2 domain. The D_2 domain is surrounded by the D_3 domain, the temperature of which is kept constant. The three domains, D_1, D_2, and D_3 correspond, respectively, to the calorimeter container, the space of the solid thermal conductor between the surfaces of the container and the jacket, and the jacket.

The boundary value problem may then, in this case, be written as follows:

1. the D_1 domain:

$$c_1\rho_1\frac{\partial\theta_1}{\partial t} = \lambda_1\Delta\theta_1 + q \tag{3}$$

2. the D_2 domain:

$$c_2\rho_2\frac{\partial\theta_2}{\partial t} = \lambda_2\Delta\theta_2 \tag{4}$$

3. the D_3 domain:

$$\theta_3 = 0 \tag{5}$$

4. the S_1 boundary surface:

$$\theta_1 = \theta_2 \tag{6}$$

$$\lambda_1\frac{\partial\theta_1}{\partial n_1} = \lambda_2\frac{\partial\theta_2}{\partial n_1} \tag{7}$$

5. the S_2 boundary surface:

$$\theta_2 = \theta_3 = 0 \tag{8}$$

6. the initial conditions:

$$\theta_1 = \theta_2 = \theta_3 = 0 \qquad t \leqq 0,\ t = \infty \tag{9}$$

$$q(\boldsymbol{r}, t) = 0 \qquad t \leqq 0,\ t > t_0 \tag{10}$$

$$q(\boldsymbol{r}, t) \neq 0 \qquad 0 < t < t_0, \tag{11}$$

θ = temperature measured from the temperature of D_3,
t = time,
r = coordinate vector,
q = the heat evolved or absorbed per unit of time and unit of volume in D_1.
c = the specific heat capacity,
ρ = the density,
λ = the thermal conductivity,
$\partial/\partial n_1$ = differentiation in the direction of the out-ward normal to the surface,
Δ = the Laplacian,

The subscripts, 1, 2, and 3, denote the quantity in the D_1, D_2, and D_3 domains respectively.

Treatments of the Boundary-value Problem and the Proportionality Relation

Let the volume integral extended throughout D_1 apply to (3). Equation (3) then becomes:

$$c_1\rho_1\int_{D_1}\frac{\partial\theta_1}{\partial t}\mathrm{d}v=\lambda_1\int_{D_1}\Delta\theta_1\mathrm{d}v_1+\int_{D_1}q(\boldsymbol{r},t)\mathrm{d}v,$$

where it is assumed that the values of c, ρ, and λ are constant throughout the process of the thermal change. By Green's theorem,

$$\int_{D_1}\Delta\theta_1\mathrm{d}v=\int_{S_1}\frac{\partial\theta_1}{\partial n_1}\mathrm{d}s.$$

The quantity

$$w(t)=\int_{D_1}q(\boldsymbol{r},t)\mathrm{d}v$$

denotes the quantity of heat evolved or absorbed per unit of time in the D_1 domain. Therefore,

$$c_1\rho_1\int_{D_1}\frac{\partial\theta_1}{\partial t}\mathrm{d}v=\lambda_1\int_{S_1}\frac{\partial\theta_1}{\partial n_1}\mathrm{d}s+w(t). \tag{12}$$

The integration of (12) with respect to t from zero to infinity gives:

$$c_1\rho_1\int_0^\infty\int_{D_1}\frac{\partial\theta_1}{\partial t}\mathrm{d}v\mathrm{d}t=\lambda_1\int_0^\infty\int_{S_1}\frac{\partial\theta_1}{\partial n_1}\mathrm{d}s\mathrm{d}t+\int_0^\infty w(t)\mathrm{d}t.$$

When the order of integration can be interchanged, the left-hand side of the above equation becomes:

$$\begin{aligned}c_1\rho_1\int_0^\infty\int_{D_1}\frac{\partial\theta_1}{\partial t}\mathrm{d}v\mathrm{d}t&=c_1\rho_1\int_{D_1}\mathrm{d}v\int_0^\infty\frac{\partial\theta_1}{\partial t}\mathrm{d}t\\&=c_1\rho_1\int_{D_1}\{\theta_{1,t=\infty}-\theta_{1,t=0}\}\mathrm{d}v\\&=0,\end{aligned}$$

considering the initial condition (9). The quantity

$$Q=\int_0^\infty w(t)\mathrm{d}t=\int_0^\infty\int_{D_1}q(\boldsymbol{r},t)\mathrm{d}v\mathrm{d}t$$

is the total quantity of heat evolved or absorbed in D_1. Therefore, the integration of (12) becomes:

$$0=\lambda_1\int_0^\infty\int_{S_1}\frac{\partial\theta_1}{\partial n_1}\mathrm{d}s\mathrm{d}t+Q. \tag{13}$$

By applying the same calculation to (4) in D_2 we obtain:

$$\begin{aligned}0&=\lambda_2\int_0^\infty\int_{S_1+S_2}\frac{\partial\theta_2}{\partial n}\mathrm{d}S\mathrm{d}t\\&=-\lambda_2\int_0^\infty\int_{S_1}\frac{\partial\theta_2}{\partial n_1}\mathrm{d}S\mathrm{d}t+\lambda_2\int_0^\infty\int_{S_2}\frac{\partial\theta_2}{\partial n_2}\mathrm{d}S\mathrm{d}t.\end{aligned} \tag{14}$$

From (7), (13) and (14),

$$\begin{aligned}Q&=-\lambda_1\int_0^\infty\int_{S_1}\frac{\partial\theta_1}{\partial n_1}\mathrm{d}S\mathrm{d}t\\&=-\lambda_2\int_0^\infty\int_{S_1}\frac{\partial\theta_2}{\partial n_1}\mathrm{d}S\mathrm{d}t\\&=-\lambda_2\int_0^\infty\int_{S_2}\frac{\partial\theta_2}{\partial n_2}\mathrm{d}S\mathrm{d}t.\end{aligned} \tag{15}$$

The main purpose of calorimetry is to obtain the Q quantity; Equation (13) shows that the measurement of the $\partial\theta/\partial n$ quantity over the boundary surface enables us to obtain the Q quantity. However, it is not easy to measure the $\partial\theta/\partial n$ quantity.

On the other hand, from Green's formula the temperature at a point, P, inside D_2, $\theta_2(\mathrm{P})$, is given by:

$$4\pi\theta_2(\mathrm{P})=-\int_{D_2}\frac{\Delta\theta_2}{r}\mathrm{d}v+\int_{S_1+S_2}\left\{\frac{1}{r}\frac{\partial\theta_2}{\partial n}-\theta_2\frac{\partial}{\partial n}\left(\frac{1}{r}\right)\right\}\mathrm{d}S, \tag{16}$$

where r is the distance from P to points on the boundary surfaces, S_1 and S_2. The integration of $\theta_2(\mathrm{P})$ with respect to t from zero to infinity then gives:

$$\begin{aligned}4\pi\int_0^\infty\theta_2(\mathrm{P})\mathrm{d}t=&-\int_0^\infty\int_{D_2}\frac{1}{r}\Delta\theta_2\mathrm{d}v\mathrm{d}t\\&+\int_0^\infty\int_{S_1+S_2}\left\{\frac{1}{r}\frac{\partial\theta_2}{\partial n}-\theta_2\frac{\partial}{\partial n}\left(\frac{1}{r}\right)\right\}\mathrm{d}S\mathrm{d}t.\end{aligned} \tag{17}$$

The first term on the right-hand side of Eq. (17) becomes zero, because, from (4) and (9);

$$\begin{aligned}\int_0^\infty\int_{D_2}\frac{1}{r}\Delta\theta_2\mathrm{d}v\mathrm{d}t&=\int_{D_2}\frac{\mathrm{d}v}{r}\int_0^\infty\Delta\theta_2\mathrm{d}t\\&=\int_{D_2}\frac{\mathrm{d}v}{r}\int_0^\infty\frac{c_2\rho_2}{\lambda_2}\frac{\partial\theta_2}{\partial t}\mathrm{d}t\\&=\frac{c_2\rho_2}{\lambda_2}\int_{D_2}\frac{\mathrm{d}v}{r}\{\theta_{2,t=\infty}-\theta_{2,t=0}\}\\&=0.\end{aligned}$$

Therefore, (17) becomes:

$$\begin{aligned}4\pi\int_0^\infty\theta_2(\mathrm{P})\mathrm{d}t&=\int_0^\infty\int_{S_1+S_2}\left\{\frac{1}{r}\frac{\partial\theta_2}{\partial n}-\theta_2\frac{\partial}{\partial n}\left(\frac{1}{r}\right)\right\}\mathrm{d}S\mathrm{d}t\\&=\int_0^\infty\int_{S_1}\left\{\frac{1}{r}\frac{\partial\theta_2}{\partial n}-\theta_2\frac{\partial}{\partial n}\left(\frac{1}{r}\right)\right\}\mathrm{d}S\mathrm{d}t\\&\quad+\int_0^\infty\int_{S_2}\left\{\frac{1}{r}\frac{\partial\theta_2}{\partial n}-\theta_2\frac{\partial}{\partial n}\left(\frac{1}{r}\right)\right\}\mathrm{d}S\mathrm{d}t\\&=\int_0^\infty\int_{S_1}\left\{-\frac{1}{r}\frac{\partial\theta_2}{\partial n_1}+\theta_2\frac{\partial}{\partial n_1}\left(\frac{1}{r}\right)\right\}\mathrm{d}S\mathrm{d}t\\&\quad+\int_0^\infty\int_{S_2}\frac{1}{r}\frac{\partial\theta_2}{\partial n_2}\mathrm{d}S\mathrm{d}t,\end{aligned} \tag{18}$$

considering $\theta_2=0$ on the S_2 surface, as (8) shows.

Now, if we assume that:

(1) $\partial\theta_2/\partial n_1$ and θ_2 are equal everywhere over the S_1 boundary surface and are functions of the time, t, only, and that
(2) $\partial\theta_2/\partial n_2$ is equal everywhere over the S_2 boundary surface and is a function of t, (19)

Equation (15) becomes:

$$\begin{aligned} Q &= -\lambda_1 S_1 \int_0^\infty \frac{\partial\theta_1}{\partial n_1}\mathrm{d}t \\ &= -\lambda_2 S_1 \int_0^\infty \frac{\partial\theta_2}{\partial n_1}\mathrm{d}t \\ &= -\lambda_2 S_2 \int_0^\infty \frac{\partial\theta_2}{\partial n_2}\mathrm{d}t, \end{aligned} \tag{20}$$

where S_1 and S_2 are the areas of the S_1 and S_2 surfaces respectively. Also (18) becomes, considering (20):

$$\begin{aligned} 4\pi\int_0^\infty \theta_2(\mathrm{P})\mathrm{d}t &= -\int_{S_1}\frac{\mathrm{d}S}{r}\int_0^\infty \frac{\partial\theta_2}{\partial n_1}\mathrm{d}t - \int_{S_1}\frac{\partial}{\partial n}\left(\frac{1}{r}\right)\mathrm{d}S\int_0^\infty \theta_2\mathrm{d}t \\ &\quad + \int_{S_2}\frac{\mathrm{d}S}{r}\int_0^\infty \frac{\partial\theta_2}{\partial n_1}\mathrm{d}t \\ &= \frac{Q}{\lambda_2 S_1}\int_{S_1}\frac{\mathrm{d}S}{r} - \int_{S_1}\frac{\partial}{\partial n}\left(\frac{1}{r}\right)\mathrm{d}S\int_0^\infty \theta_2\mathrm{d}t \\ &\quad - \frac{Q}{\lambda_2 S_2}\int_{S_1}\frac{\mathrm{d}S}{r} \\ &= \frac{Q}{\lambda_2}\left\{\frac{1}{S_1}\int_{S_1}\frac{\mathrm{d}S}{r} - \frac{1}{S_2}\int_{S_2}\frac{\mathrm{d}S}{r}\right\} \\ &\quad - \int_{S_1}\frac{\partial}{\partial n}\left(\frac{1}{r}\right)\mathrm{d}S\int_0^\infty \theta_2\mathrm{d}t, \end{aligned} \tag{21}$$

where the integrals, $\int_S \frac{\mathrm{d}s}{r}$ and $\int_S \frac{\partial}{\partial n}\left(\frac{1}{r}\right)\mathrm{d}S$, are not functions of t but are determined by the geometric shapes of the boundary surfaces. The boundary surfaces, which fulfill the assumptions (19), are symmetrical surfaces, for example, the surface of a sphere, a circular cylinder, or a plane.

If the P point is taken on the S_1 surface, $\theta_2(\mathrm{P})=\theta_2$, and if the S_1 and S_2 surfaces do not coincide, the rearrangement of (21) gives:

$$\begin{aligned} Q &= \frac{\lambda_2\left\{4\pi + \int_{S_1}\frac{\partial}{\partial n}\left(\frac{1}{r}\right)\mathrm{d}S\right\}}{\frac{1}{S_1}\int_{S_1}\frac{\mathrm{d}S}{r} - \frac{1}{S_2}\int_{S_2}\frac{\mathrm{d}S}{r}}\int_0^\infty \theta_2\mathrm{d}t \\ &= p\int_0^\infty \theta_2\mathrm{d}t, \end{aligned} \tag{22}$$

where the coefficient:

$$p = \frac{\lambda_2\left\{4\pi + \int_{S_1}\frac{\partial}{\partial n}\left(\frac{1}{r}\right)\mathrm{d}S\right\}}{\frac{1}{S_1}\int_{S_1}\frac{\mathrm{d}S}{r} - \frac{1}{S_2}\int_{S_2}\frac{\mathrm{d}S}{r}} \tag{22'}$$

is a constant determined only by the shape of the boundary surface of the calorimeter.

Conditions for the Reliability of the Proportionality Relation

Let us summarize the main conditions under which the proportionality relation (22) is valid and the conduction method in calorimetry is possible:

(1) The heat transfer in the calorimeter takes place by conduction.

(2) The boundary surfaces of the calorimeter should be symmetrical.

(3) The c, ρ, and λ values of the materials of which the calorimeter is constructed are constant throughout the process of the thermal change in the container.

In the case of an actual conduction calorimeter, none of these conditions are fulfilled. The heat is conducted not only by conduction but by convection and radiation. The surface of the calorimeter container and the inner surface of the jacket are not perfectly symmetrical. Moreover, the values of c, ρ, and λ sometimes change considerably during the process of a thermal change, *e. g.*, phase-change or chemical reactions.

Therefore, the proportionality relation fundamental in conduction calorimetry is only an approximate one in any actual experiment; this is thought to be one of the main causes of the accuracy being less than with an isothermal or adiabatic jacket calorimeter.

For precise heat measurement, it is necessary to compensate the heat of the process being studied.[9] Although it is difficult to achieve a precise thermal compensation, recent progress in servo mechanism and electronic devices favors a precise compensation. When the calorimeter is compensated, it then behaves essentially as an isothermal calorimeter. Since the heat compensated is equal to the rate of heat production or absorption, $w(t)$, it is not necessary to use Calvet's complex method[10] of transforming the recorded curve $\theta=\theta(t)$ into a thermogenesis curve $w=w(t)$.

The authors wish to thank to Miss K. Sasaki and Mr. I. Takeda of this Institute for their interest and discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1036—1040 (1970)

The Density and Molar Volume of a Binary Liquid, B_2O_3-H_2O

Hiroshi KODAMA,*1 Toshio YOKOKAWA and Kichizo NIWA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received October 22, 1969)

The density of the binary B_2O_3-H_2O liquid system with concentrations of from 4.9 to 83.0 mol% B_2O_3 has been measured, and the mean volume expansivity has been calculated. The molar volume and the expansivity of this system has then been compared with those of other binary borates. The experimental results suggest a change in the boron-to-oxygen coordination number between the $3B_2O_3 \cdot H_2O$ and $B_2O_3 \cdot H_2O$ compositions. The thermal expansivity of this system shows a different trend from those of alkali borate melts.

On the structure of B_2O_3 in glass and liquid states many investigations[1] have been made. While the presently-available data are insufficient for any structural conclusions to be drawn particularly for the molten state, it can be said that the oxide is formed from a random network structure constructed of planar BO_3 triangular units in the two states except for the high-temperature range, *e.g.*, the temperature range far above the liquidus. The network link is gradually disrupted by the addition of alkali oxides, alkaline earth oxides[1] and other basic oxides.[2,3] These are, therefore, called "network modifiers." The thermodynamic and kinetic properties of the binary oxidic melts change continuously with their composition. In addition to this trend, binary metal borate melts show a so-called boron anomaly, which has been interpreted in terms of the structural change from BO_3 triangular to BO_4 tetrahedral units in the network.[4-6] This change in coordination number also takes place on binary alkali germanates.[7]

As to the binary B_2O_3-H_2O system, so far the experimental investigations have been restricted to a dilute aqueous solution of boric acid, on the one hand, and to a boron trioxide melt with trace of water, on the other hand. On the basis of the experimental evidence on the latter, such as the B–OH absorption band and the dependence of the solubility of water on its partial pressure, it seems that the dissolution can be expressed by the following equation:[8]

$$\rangle B\text{–}O\text{–}B\langle + H_2O = 2\,\rangle B\text{–}O\text{–}H \qquad (1)$$

Thus, the water molecule modifies the network as do alkali metal oxides. The solubility decreases with the alkali content in the melt. In other works, water behaves as a base weaker than the alkali oxides. On the other hand, boric acid dissociates at three steps in a dilute aqueous solution, the dissociation being, respectively, promoted and inhibited by the presence of a basic and a strong acid substance.

The purpose of the present study is to make a structural examination of this binary system over the whole composition range by studying the molar-volume trend especially. The electrical conductivity of this system is now being studied.

Experimental

Materials and Reagent. Specimens with the desired compositions were prepared by mixing proper amounts of two reagents from among boric acid, metaboric acid, and boron trioxide of a guaranteed reagent grade, and distilled water. It was useful to start from combinations of H_3BO_3 and B_2O_3, and of HBO_2 and B_2O_3 corresponding to the desired composition except in the range of water content higher than 75 mol% (boric acid). The mixture was heated in a sealed Pyrex glass tube in order to make a uniform solution. The melts' compositions were determined from the quantities of chemicals employed over the H_2O and H_3BO_3 range. Otherwise, the quenched samples were analyzed by volumetric titration with NaOH in the presence of manitol.

Apparatus and Procedure. In order to cover the melt of the whole composition, the temperature had to be raised to a point where the vapor pressure was

as high as seven atm.[9] A diagramatic sketch of the apparatus for measuring the density is given in Fig. 1. The Pyrex glass tube shown in Fig. 2 was employed as a densimeter. Figure 1 shows how it was wound with a copper wire and set at the center of an electric resistance furnace, through the windows of which the liquid level could be observed. The densimeter tube was moved up and down at the rate of 2.11 mm/min by means of a lifting device equipped with a synchronus motor. The time needed to drive the motor to reach a given liquid level gave the height. The relation between the height of the liquid column and its volume was calibrated with distilled water at room temperature.

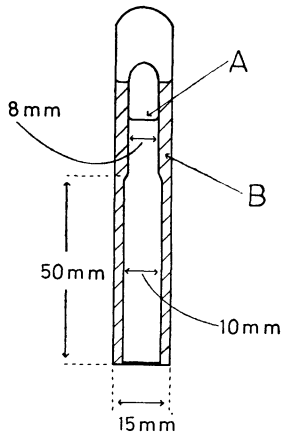

Fig. 2. Specimen cell.
A: liquid level of sample after melting.
B: octhyl alcohol or air

As is shown in Fig. 2, the densimeter was sealed in a second Pyrex tube in order to moderate the stress due to differences in pressure. Sometimes a third enclosure was employed. The measurements were carried out in the temperature range from the liquidus points to 50—150°C above them. The temperature was controlled within ±1°C. The accuracy of the measured density was found to be 99.5% by the use of distilled water at 153°C.

Results

The data on the density isotherms for the B_2O_3-H_2O system are presented in Fig. 3. They were obtained by the intra- or by the extrapolation of the density temperature relations. The densities

at two temperatures are summarized in Table 1. For the density of liquid B_2O_3, numerous values have been reported.[10-13] Among them, the value of Napolitano *et al.* is quoted in Fig. 1. The density of water was quoted from "The Chemical Handbook."[14] The measurement could not be done with a B_2O_3 content of over 83.0 mol%, because of the considerable difficulty of obtaining a uniform solution due to the high viscosity. Although a small contamination from the glass tube was observed with melts of a high B_2O_3 content, the amounts of the impurity were less than 1.5 wt%, and so the effect on the density was neglected. The mean volume expansivities of the melts for the temperature range covered are shown in Fig. 4. The value for the liquid B_2O_3 was estimated for the 450—600°C temperature range from the data of Napolitano *et al.*

Discussion

Molar and Partial Molar Volume. The molar volume isotherms presented in Fig. 5 were calculated from Eq. (2).

$$MW = X_{B_2O_3} MW_{B_2O_3} + X_{H_2O} MW_{H_2O} \quad (2)$$

where X is the mole fraction of each component and where MW is the molecular weight. The molar volume is defined by:

$$V_M = MW/\rho \quad (3)$$

where ρ is the density (g/cm³). The addition of H_2O to molten B_2O_3 decreased the molar volume of this mixture below the 41.7 cm³/mol value for B_2O_3. Attention should be paid to the abrupt change in the rate of decrease in the vicinity of the $3B_2O_3 \cdot H_2O$ composition. This suggests some structural change near this composition. There are, generally

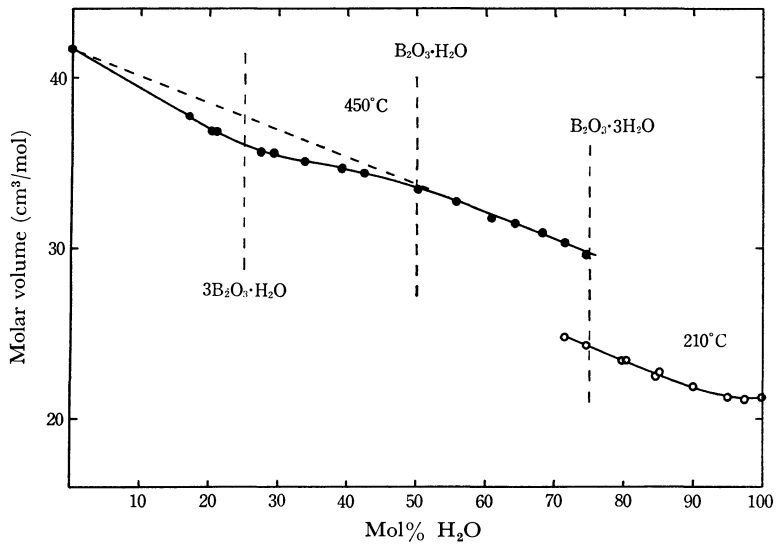

Fig. 5. Molar volume isotherms for B_2O_3-H_2O.

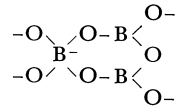
speaking, two types of molar volume decrease arising from the addition of another oxide to molten B_2O_3. One type is seen in the systems of borosilicate,[15] borogermanate[15] and aluminoborate,[16] in which the added oxide can be called a "network former." In these systems, the molar volume changes almost linearly with the addition of the second oxide. That is, the partial molar volume of B_2O_3 in the solution is nearly the same as that of B_2O_3. The coordination number probably remains unchanged. The other type is observed in the alkali,[10] alkaline earth borate,[5] and silver borate[17] systems, in which the decrease in the molar volume results in a convex curve downward. That is, the partial molar volume of B_2O_3 decreases rapidly below the volume of the pure B_2O_3. The latter type can be interpreted by the change in coordination from BO_3 to BO_4. In our system, the linear decrease in the molar volume over the B_2O_3·H_2O range belongs to the former type in spite of the fact that H_2O has been regarded as a network modifier. Therefore, there is no change in coordination number over that range. Milberg and Meller[18] studied the structure of vitreous B_2O_3·H_2O, glass with a composition of B_2O_3, B_2O_3·0.42 H_2O-B_2O_3·0.5H_2O and B_2O_3·0.63H_2O by means of the X-ray scattering method. They indicated that the fundamental triangle coordination characteristic of vitreous B_2O_3 was maintained in the water-containing glasses, although the possibility that a small fraction of the boron atoms was coordinated by four oxygen atoms could not be completely excluded. Their results coincide well with the present result. With the increase in the water content to near the composition of 3B_2O_3·H_2O, the partial molar volume of B_2O_3, which is read out from the intercept of the tangential line with the B_2O_3 axis, decreases abruptly to about 38 cm³/mol, then it returns gradually to the starting value. The decrease might be explained by the change in the coordination number, as in the case of binary metal borate. Silver[19] investigated the system over the B_2O_3 to B_2O_3·3H_2O range by the NMR method and confirmed that all the substances contained a planar BO_3 triangular unit. He also concluded that the BO_4 tetrahedral unit existed only in B_2O_3·0.6H_2O and B_2O_3·0.5H_2O glass samples and in monoclinic acid, not in B_2O_3 and B_2O_3·0.4H_2O. Thus, there is a good correspondence between his results in glass and the present results in liquid. The partial molar volume of the B_2O_3·3H_2O composition returns exactly to that of pure B_2O_3.

The change in the coordination number may be expressed by the following process:

$$\rangle B\text{–}O\text{–}B\langle + Na_2O = 2\,\rangle B\text{–}O^- + 2Na^+ \qquad (4)$$

$$\rangle B\text{–}O^- + -B\langle = \rangle B\text{–}O\text{–}\underset{|}{\overset{|}{B}}\text{–} \qquad (5)$$

Krogh-Moe[20] observed an example in solid Cs_2O·3B_2O_3. That is,



Likewise, a similar equation can be written for the

B_2O_3-H_2O system;

$$\rangle B\text{–}O\text{–}B\langle + H_2O = 2\,\rangle B\text{–}O\text{–}H \quad (6)$$

$$\rangle B\text{–}O\text{–}H = \rangle B\text{–}O^- + H^+ \quad (7)$$

$$\rangle B\text{–}O^- + -B\langle = \rangle B\text{–}O\text{–}\overset{|}{\underset{|}{B}}\text{–} \quad (5)$$

or equivalently to the last two equations:

$$B\text{–}O\text{–}H + -B\langle = \rangle B\text{–}O\text{–}\overset{|}{\underset{|}{B}}\text{–} + H^+ \quad (8)$$

The above experimental results suggest that, while the (4) and (5) reactions proceed at the same time on the addition of Na_2O to B_2O_3, the (7) and (5) reactions preceed appreciably only after the H_2O content becomes higher than $3B_2O_3 \cdot H_2O$.

Thermal Expansivity. The volume expansivity (the mean values over the measured temperature) is shown in Fig. 4. The corresponding data on the binary alkali borates show a different trend. Any alkali oxide keeps a low expansivity at first as a result of BO_4 formation, and then it rises, probably because of the ionic nature of the melt. Water steadily increases the expansivity. The comparatively moderate increase in the range between $3B_2O_3 \cdot H_2O$ and $B_2O_3 \cdot H_2O$ confirms the notion that BO_4-unit formation occurs in this range.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1040—1048 (1970)

The Crystal and Molecular Structure of Bis(2-hydroxyethyliminosalicylaldehydato)copper(II)

Kinya IIJIMA,*1 Isao OONISHI, Fumio MUTO, Akitsugu NAKAHARA* and Yoshimichi KOMIYAMA*2

Department of Applied Chemistry, Faculty of Engineering, Yamanashi University, Kofu

* *Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka*

(Received October 30, 1969)

The crystal structure of bis(2-hydroxyethyliminosalicylaldehydato)copper(II) has been determined by means of an X-ray diffraction study of a single-crystal specimen. Four formula units are contained in the monoclinic unit cell, the $P2_1/c$ space group, with lattice parameters of: $a=18.41$ A, $b=4.82$ Å, $c=19.86$ Å, and $\beta=99.1°$ ($Dm=1.50$ g·cm^{-3}; $Dx=1.50$ g·cm^{-3}). The structure has been refined, by means of three-dimensional difference syntheses and the least-squares method, to $R=0.095$. It has been confirmed that copper(II) links to the 2-hydroxyethyliminopyruvate anion through the phenolic oxygen and the nitrogen of the Schiff base linkage, while the alcoholic oxygen in the ethanol-amine moiety is free from coordination. The two Schiff-base ligands are coordinated around copper(II) in the *trans*-configuration. All the bond distances and angles in the complex are within the range of normal values. The N-Cu-O angles (91.3 and 91.8°) in the chelate rings are close to a right angle, showing that there is less strain in the chelate structure than in the case of a similar chelate of the pyruvate Schiff base (84.6°).

Although the ethanolamine molecule is provided with two functional groups for chelate formation, it can not always be coordinated as a bidentate ligand around a metal ion. The Schiff base derived from salicylaldehyde and ethanolamine is, for instance, coordinated around copper(II) to produce not only a one-to-one-type, but also a one-to-two-type, copper(II) Schiff-base complex, (I), in which the two hydroxyl groups of the ethanol-amine moieties are free from coordination.[1] In addition, the Schiff base derived from pyruvic acid and ethanolamine reacts with copper(II) to form, exclusively, a one-to-two-type copper(II) Schiff base complex, (II); consequently, the corresponding one-to-one-type complex is hardly ever obtained regardless of the molar ratio of copper(II) to the Schiff base employed in the preparation.[2] These findings can be explained by taking into account the rather weak binding ability of alcoholic oxygen, on the one hand, and, on the other hand, the geometrically unfavorable structure[3] of the fused

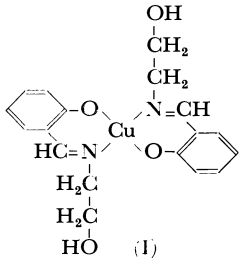
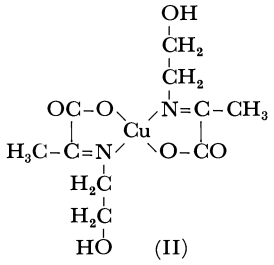
chelate ring in the imaginary one-to-one-type complex of copper(II) 2-hydroxyethyliminopyruvate. In order to estimate the validity of the latter assumption, a comparison of the molecular structure of the copper(II) chelates, I and II, seemed valuable. From this point of view, X-ray studies of the two complexes have recently been performed; the crystal structure of II has already been descrived.[2] This paper will describe the molecular and crystal structure of bis(2-hydroxyethyliminosalicylaldehydato)-copper(II).



(I)

Bis(2-hydroxyethylimino-salicylaldehydato) copper-(II)



(II)

Bis(2-hydroxyethyl-iminopyruvato)copper(II)[2]

Experimental

Bis(2-hydroxyethyliminosalicylaldehydato)copper(II) was prepared and purified according to the procedure described in a previous paper.[1] The final pure product appears as thin yellow-brown needles elongated along the *b*-axis. The unit-cell dimensions were determined from the higher-order reflections of Weissenberg photographs (Cu$K\alpha$, λ=1.5418 Å). The systematic absences were *h0l* for *l* odd and 0*k*0 for *k* odd. Hence, the space group was unequivocally determined. The crystal data are listed in Table 1. Sets of multiple-film equi-inclination Weissenberg photographs were taken about the *b*-axis (0 to 4th layers), the *a*-axis and the *c*-axis (0th layer). Cu$K\alpha$ radiation was used throughout. The crystal used was a rod with dimensions of 0.07×0.16×0.46 mm. The intensities were estimated visually with a standard film strip and were converted to $|F_o(hkl)|^2$ and $|F_o(hkl)|$ by applying the usual Lorentz, polarization, and spot-shape corrections. No correction was made for absorption and extinction. The range of relative intensities was from 1 to 30000. 2243 independent reflections fell within this range, whereas 1092 others were too weak to be observed.

Structure Analysis

At first, two-dimensional Patterson syntheses projected along the *b*-axis and the *c*-axis were calculated. From these Patterson projections it was apparent that the copper atoms occupy two sets of two-fold positions. They could easily be placed at (000 and $\frac{1}{2}\frac{1}{2}\frac{1}{2}$) and at ($\frac{1}{2}\frac{1}{2}0$ and $\frac{1}{2}0\frac{1}{2}$). Attempts were made to deduce the x and y parameters of the lighter atoms from a three-dimensional Patterson function and from Fourier syntheses of the electron density, $\rho(x,z)$, the signs of which were calculated from the parameter values of the copper atoms. It was possible to locate all the atoms except those belonging to ethanol groups. Two-dimensional difference syntheses revealed ethanol groups, and all the x and y parameters of the lighter atoms were refined by a series of two-dimensional Fourier and difference syntheses to R_{h0l}=0.17. Consideration of the projected bond lengths made the estimation of approximate y coordinates possible. With these coordinates, a subsequent series of three-dimensional Fourier syntheses and difference syntheses reduced the R value to 0.15.

The structure thus obtained was refined by a block-diagonal, least-squares method with a HBLS-4 program written by T. Ashida. In this least-squares calculation, anisotropic temperature factors were introduced and four cycles of refinement were carried out. The following weighting scheme was employed:

$w = 0.2$ if $F_o \leqq F_{\min.}$ (=4.0)
$w = 1.0$ if $F_{\min.} < F_o \leqq F_{\max.}$ (=100.0)
$w = F_{\max.}/F_o$ if $F_o > F_{\max.}$

The final discrepancy factor, $R=\sum||F_o|-|F_c||/\sum|F_o|$, was 0.095 for all the observed reflections. The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[4] The final atomic parameters and their estimated standard deviations are summarized in Table 2. The agreement between the observed and calculated structure amplitudes is reasonable (Table 3).

Description of the Structure and Discussion

The structure projected upon a plane normal to the *b*-axis is shown in Fig. 1. The intramolecular distances and angles are listed with their estimated standard deviations in Tables 4 and 5, and are shown in Figs. 2 and 3. The intramolecular distances and angles were calculated by using program DAPH written by T. Ashida.

The new complex, bis(2-hydroxyethyliminosalicylaldehydato)copper(II) is in a *trans*-configuration. The 2-hydroxyethyliminosalicylaldehyde groups are coordinated to copper(II) as a bidentate chelate, through the terminal phenolic oxygen and the nitrogen of the Schiff-base linkage, while the alcohol groups are free from coordination. This is quite reasonable since the donating tendency of the alcohol oxygen has been estimated to be comparatively weak, as in bis(2-hydroxyethyliminopyruvato)-copper(II) tetrahydrate.[2]

The coordination configurations about the copper atoms in the molecules I and II are both square-planar. Square-planar configurations are also found in bis(salicylaldiminato)copper(II),[5] bis(*N*-*n*-butylsalicylaldiminato)copper(II),[6] and bis(*N*-phenylsalicylaldiminato)copper(II),[7] in which all the Cu(II) atoms occupy the positions of a center of symmetry.

The Cu–O distances of 1.872 and 1.869 Å are shorter than the value of 1.92 Å found in bis(2-hydroxymethyliminopyruvato)copper(II) tetrahydrate.[2] The Cu–N distances of 2.011 and 2.015 Å agree with the value of 2.00 Å in bis(2-hydroxymethyliminopyruvato)copper(II) tetrahydrate.[2] The N–Cu–O angles of 91.7 and 91.3° in the chelate rings are close to a right angle, showing that there is less strain in the chelate structure than the case of the similar chelate of the pyruvate Schiff-base (84.6°),[2] because the chelate rings in this Cu(II) complexes are six-membered, while it is five-membered in the latter.[2] The C–C and C–O bond distances in the ethanol moieties agree well with those in bis(2-hydroxymethyliminopyruvato)copper-(II) tetrahydrate,[2] but the N–C bond distances appear to be longer than that observed in the latter. It is interesting to note here that the distances of C(8)–O(1′) and C(17)–O(3′) (both 2.77 Å) are shorter than the corresponding value (3.10 Å) in bis(2-hydroxymethyliminopyruvato)copper(II) tetrahydrate. These differences in the interatomic distances seem to be caused by the difference in the chelate structure described above.

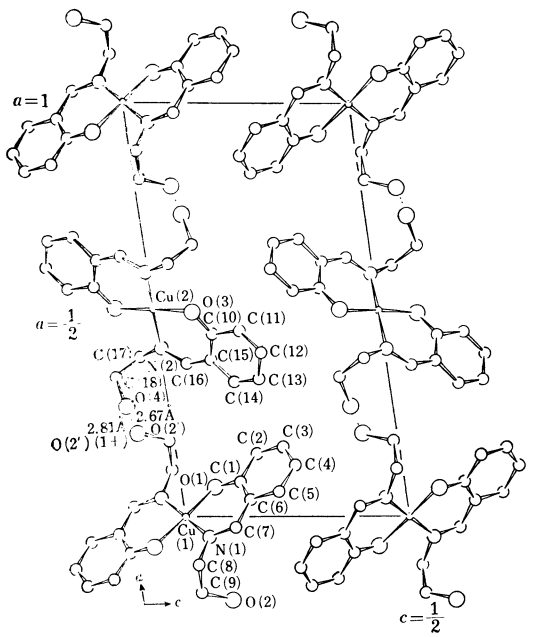

Fig. 1. Projection of the unit cell contents on the (010) plane.

In Table 5 the distances in various related complexes are compared with the values obtained in the present work. These latter values generally agree well with those found in the related compounds. The molecules may be described in terms of a set of various planar groups. Tables 6 (molecule I) and 7 (molecule II) list the equations for various least-square planes, the angles between them, and the deviations of the atoms therefrom. The benzene rings in salicylaldimine groups are almost planar (the maximum deviations of the atoms from the mean planes are 0.007 Å in the molecule I and 0.014 Å in the molecule II), but the nitrogen atoms are slightly, but significantly, out of the plane (0.104 and 0.092 Å). The two salicylaldimine groups in the molecules I and II are, of course, parallel, as is required by the centrosymmetry, but they are far from coplanar. The perpendicular distances between the two parallel salicylaldimine planes in the molecules I and II are 0.29 and 0.50 Å, while these range from 0.13 to 0.89 Å in other, similar complexes with planar configurations about Cu(II) atoms.[5-7] Each salicylaldimine group makes an angle of 5.5° (in the molecule I) and 9.9° (in the molecule II) with the coordination plane. Thus, the planarity of the molecule I is slightly better than that of the molecule II. This difference seems to be caused by the

difference in the packing of the molecules. The C(8) (in the molecule I) and C(17) (in the molecule II) of ethanolamine groups are displaced from the planes of the chelate ring, the deviations being 0.049 and 0.026 Å. The angles between the C–C single bonds in ethanolamine groups and the planes are 62 and 67° respectively.

The closest approach, less than 3.5 Å, between adjacent molecules occurs between the free alcoholic oxygens of the adjacent molecules. The distances of O(2′)–O(4) and O(2′)–O(4) $(x,-1+y,z)$ are 2.67 and 2.81 Å, as is shown in Fig. 1. These short distances suggest the presence of hydrogen bonds between them. By these hydrogen bonds, the complexes are held together to form layers parallel to the (001) plane. Between adjacent layers there exists no hydrogen bond.

The numerical calculations were carried out on the FACOM231 computer at this University and the HITAC5020E computer at the Computer Center, Tokyo University.

Part of the costs of this investigation has been defrayed by a Scientific Research Grant of the Ministry of Education, to which the authors' thanks are due.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1049—1053 (1970)

The Zero-point Average Structure of Acetone

Takao IIJIMA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received November 4, 1969)

The zero-point average structure of acetone has been determined from the moments of inertia obtained by means of microwave spectroscopy by Nelson and Pierce, as incorporated with the average distances from gas-electron diffraction by Kato *et al.* In addition to the normal species $(CH_3)_2CO$, three isotopically-substituted species, $(^{13}CH_3)_2CO$, $(CH_3)_2C^{18}O$, and $(CD_3)_2CO$, have been used in the analysis. The following values of the r_Z-parameters have been determined: C=O, 1.2122±0.0025 Å; C–C, 1.5190±0.0008 Å; C–H, 1.0614±0.0010 Å; ∠HCH, 108°30′± 6′; and ∠CCC, 116°9′±10′ (∠CCC for $(CD_3)_2CO$, 115°51′±10′). The slightly smaller value of ∠CCC found for the deuterated species has been reasonably attributed to the anharmonicity associated with the symmetric rocking motion of the two methyl tops. The equilibrium values for C–H(D) and ∠CCC have also been estimated to be 1.078 Å and 115°0′ respectively.

The molecular structure of acetone was studied by Nelson and Pierce[1] by means of microwave spectroscopy. They obtained the moments of inertia of $(CH_3)_2CO$ and three isotopically-substituted molecules $(^{13}CH_3)_2CO$, $(CH_3)_2{}^{18}O$ and $(CD_3)_2CO$, and determined the so-called r_s-structure of this molecule. For the deuterated species $(CD_3)_2CO$, they used the spectra which had previously been observed by Swalen and Costain.[2] The moments of inertia calculated by the use of their r_s-parameters differed from the observed moments by as much as 0.4 amu.Å^2. This is not surprising, however, because correction is necessary for the vibrational effect on the observed effective moments of inertia in order to find a set of parameters which will account for all the moments of inertia of isotopically-substituted species.

In the present study, the observed effective moments of inertia for the ground vibrational state have been reduced to the zero-point moments of inertia by applying vibrational correction, and the zero-point average structure has been determined. In the process of the structure determination, the previous electron-diffraction results by the present author and his collaborators[3] have also been used. As a result, an isotope effect has been found in the zero-point average values of the CCC angles.

Determination of r_z-Parameters

The procedure of applying the vibrational correction to the observed effective moments of inertia, $I_\alpha^{(0)}$, in order to obtain the zero-point moments of inertia, $I_\alpha^{(z)}$, is the same as that reported in the previous paper on the zero-point average structure of acetaldehyde.[4] Accordingly, only the results are shown in the present paper (Table 1). The

quadratic force field by Cossee and Schachtschneider[5] (the set VF3) was used in the calculation of the vibrational correction. The vibrational averages of the linear displacements along the equilibrium bond direction were also calculated for the C–H and C–D bonds in order to estimate the possible isotope effect on the r_z(C–H), or r_z(C–D) value of each isotopically-substituted species. As

$(^{13}CH_3)_2CO$	−0.016
$(CH_3)_2C^{18}O$	−0.017
$(CD_3)_2CO$	−0.010

a) Morse anharmonicity constant a_3 was assumed to be 1.98 Å^{-1}.

The angle between the axes of the two methyl tops is denoted by 2θ; it was determined by Nelson and Pierce[1] as 119° 54′±30′*1 by an analysis of the multiplet separation of the spectrum caused by the coupling between the internal rotation and the overall rotation of the molecule. Since the value of 2θ was determined independently of the other structure parameters, the Nelson and Pierce value, namely, 119°54′, has been assumed in the present study.

The r_g distances of C–C and C=O, as determined by gas-electron diffraction, were converted to the r_z values shown in Table 3 in order to afford additional information for the structure determination. The details of the process of conversion have been reported in a previous paper.[4]

Table 3. Conversion from r_g to r_z (in Å units)

	r_g	l_T^2	l_0^2	K_0

C=O	0.0002	2.4	1.208

a) assumed.
b) Morse anharmonic constant.

We assumed that the molecule including the methyl hydrogens had a C_{2v} symmetry and that the outer two hydrogens were on the plane formed by the molecular frame. However, the results of the present study are independent of the assumed conformation of the methyl hydrogens. In other words, no definite information has been obtained on the conformation of the methyl hydrogens by either the present analysis or the previous studies.[1-3]

For the value of $I_a^{(z)}+I_b^{(z)}-I_c^{(z)}$, the out-of-plane coordinate (c-coordinate) of the hydrogen atom was determined for each isotopically-substituted species. As is shown in Table 4, the coincidence between the c-coordinates of the H-atoms is quite satisfactory, while the larger value for the D-atom is well accounted for by assuming that r_z(C–D) is longer than r_z(C–H) by 0.006 Å. This amount of difference between r_z(C–D) and r_z(C–H) is in good agreement with the expected value, 0.007 Å, estimated by the use of $\langle \Delta z \rangle_0$, shown in Table 2. A similar situation has already been reported in the cases of ethane[6] and acetaldehyde.[4]

Table 4. Out-of-plane coordinates of H and D atoms[a] (in Å units)

$(CH_3)_2CO$	0.8616
$(^{13}CH_3)_2CO$	0.8609

$(CD_3)_2CO$	0.8664

a) Calculated from $I_a^{(z)}+I_b^{(z)}-I_c^{(z)}$.

By keeping 2θ fixed at 119°54′, we tried to adjust the five structure parameters, r_z(C–O), r_z(C–C), r_z(C–H), α_z(CCC), and α_z(HCH), so as to make the calculated moments of inertia fit all the observed moments well, with the additional condition that r_z(C–D) was longer than r_z(C–H) by 0.006 Å. The α_z(DCD) was assumed to be equivalent to α_z(HCH). However, it was revealed that no satisfactory set of parameters could be obtained as long as the moments of inertia of the deuterated species were included. This implies that, in addition to r_z(C–D), at least one r_z-parameter of the deuterated species should take different values from those of other species provided the procedure of data handling is appropriate. Accordingly, the structure parameters were determined without the moments of inertia of the deuterated molecule.

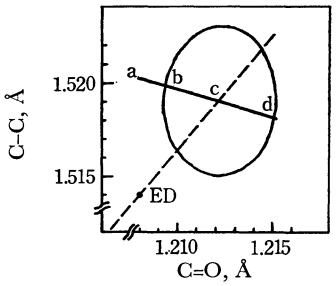

Fig. 1. The parameters r_z(C=O) *vs.* r_z(C–C) of acetone. The solid line gives sets of parameters which account almost equally well for the observed moments of inertia. The diffraction values are denoted by ED, which may vary along the broken line if an uncertainty of the scale factor is allowed for. The circle shows the errors of the ED-values without those originating in the scale factor.

*1 The values of 2θ for $(^{13}CH_3)_2CO$ and $(CD_3)_2CO$ were also determined by them to be 119° 42′ and 119° 54′ respectively.

a) Values of (obs'd)—(calc'd) are tabulated.
b) With CCC angle reduced by 18′.

As is shown in Fig. 1 and Table 5, a rather wide range of variation in parameters accounts equally well for the observed values of $I_a^{(z)}$ if the mutual correlation between the parameters is properly taken into account. The situation graphically shown in Fig. 1, where a point on the solid line indicates a definite set of parameters which gives a good fit between the calculated $I_a^{(z)}$ and observed $I_a^{(z)}$ values. Although the values of the parameters other than r_z(C–O) and r_z(C=C) are not explicitly shown in Fig. 1, a definite value for each parameter corresponds to each point on the solid line.

The strong correlation between parameters was alleviated by the use of electron-diffraction results as additional information, as has been successfully done in the cases of acetaldehyde[4] and also several other molecules.[7] The point ED in Fig. 1 shows the diffraction values. By allowing for an uncertainty in the scale factor of the ED data, the set ED may vary along the broken line. Therefore, the cross point of the broken line and the solid line, namely, the set c, was obtained as the most reliable set of structure parameters.*2 The region of the solid line cut out by the error circle of the ED data determines the error of the parameters of the set c. The error circle does not, however, include the error associated with the uncertainty of the scale factor. The values of the parameters of the set c are listed in Table 6.

Table 6. The r_z-parameters of acetone (in Å units)

C–C	1.5190±0.0008
C=O	1.2122±0.0025
C–H	1.0614±0.0010[a]
∠HCH	108°30′±6′
∠CCC	116°9′±10′[b]
2θ	119°54′±30′ (assumed)

a) 1.0674 for C–D of $(CD_3)_2CO$
b) 115°51′ for CCC of $(CD_3)_2CO$

For the deuterated species which has been left out, the set c still leaves a rather large deviation of the calculated $I_a^{(z)}$ value from the observed value, as is shown in Table 5. This deviation, however, can be eliminated only if α_z(CCC) is reduced by 18′ for the deuterated species.*3 Accordingly, the present author takes the view that the zero-point average value of the CCC angle of $(CD_3)_2CO$ is less than that of $(CH_3)_2CO$ by 18′. This can most easily be understood as an effect of the bending anharmonicity, which makes it harder for the CCC angle to narrow than to widen. The anharmonicity will be discussed further below.

The above conclusion on the isotope effect found in the CCC angle is not vulnerable to the ambiguity of the value of 2θ. Even if the value of 2θ for $(CD_3)_2CO$ were 1° less than that of $(CH_3)_2CO$, the CCC angle of the deuterated species would be required to be only 1.4′ smaller from I_a value and 1.5′ larger from I_b value; that is, substantially no change would be required in the sense of a least-squares fitting. It should be noted, however, that the question of whether the 2θ value obtained by the spectroscopic analysis can be interpreted as $2\theta_z$, *i. e.*, the angle between the two top-axes in the zero-point average structure, is still unsettled. The equivalence of 2θ and $2\theta_z$ within the reported area of uncertainty has been assumed in the present study.

From the difference between 2θ and α_z(CCC), it is seen that the methyl tops are tilted outwards by nearly 2°.

Discussion

The Effect of Bending Anharmonicity on α_z(CCC). If it is assumed that a cubic term of the kth symmetry coordinate is present in the intramolecular potential function in such a form as:

$$V' = F_k^{(3)} S_k^3, \qquad (1)$$

the zero-point average of the lth symmetry coordinate can be given by a rather simple relation (see

7) References 6 through 10 cited in the reference 4: S. Konaka and M. Kimura, "Determination of the molecular structures of AsF_3 and $AsCl_3$ by gas electron diffraction." This Bulletin, to be published.

*2 It may be seen in Fig. 1 that an error of 0.3% was included in the scale factor of the ED value. This is slightly larger than the limit of error reported in current ED studies. Since there is evidence which strongly suggests that the stabilizing circuit of the accelerating voltage of the electron beam was in a threatening condition at the time acetone was studied, a reinvestigation of this molecule by electron diffraction is now under way.

*3 A similar situation was observed by Swalen and Costain[2] in their determination of r_0-parameters. The difference between the CCC angles of the normal and the deuterated species was 32′ in their case.

Appendix for the derivation) as:

$$\langle S_l \rangle_0 = -3F_k^{(3)}(F^{-1})_{lk}\langle S_k^2 \rangle_0, \quad (2)$$

where F^{-1} is the inverse of the symmetrized F matrix. The symmetry coordinates, S_l and S_k, must belong to the totally symmetric species.

In the case of acetone, the average of the vibrational displacement of the CCC angle is expressed as*4:

$$\langle \Delta\alpha(\mathrm{CCC}) \rangle_0 = \frac{2}{\sqrt{6}}\langle S_8 \rangle_0 = -\sqrt{6}F_k^{(3)}(F^{-1})_{8k}\langle S_k^2 \rangle_0. \quad (3)$$

It can be seen from Eq. (3) that the difference in α_z between the normal and the deuterated species must be caused by the difference in $\langle S_k^2 \rangle_0$, if any. By rewriting Eq. (3) simply as:

$$\langle \Delta\alpha \rangle_0 = a\langle S_k^2 \rangle_0, \quad (4)$$

a relation which enables one to estimate $\langle \Delta\alpha \rangle_0$ values from the difference in α_z, that is, the difference in $\langle \Delta\alpha \rangle_0$, between the normal and the deuterated species, can be obtained as:

$$\langle \Delta\alpha \rangle_0^{\mathrm{H}} = [\langle \Delta\alpha \rangle_0^{\mathrm{H}} - \langle \Delta\alpha \rangle_0^{\mathrm{D}}] \cdot \frac{\langle S_k^2 \rangle_0^{\mathrm{H}}}{\langle S_k^2 \rangle_0^{\mathrm{H}} - \langle S_k^2 \rangle_0^{\mathrm{D}}}. \quad (5)$$

The mean square values, $\langle S_k^2 \rangle^{\mathrm{H}}$ and $\langle S_k^2 \rangle^{\mathrm{D}}$, are quantities which are easily calculated, and the $\langle \Delta\alpha \rangle_0^{\mathrm{H}} - \langle \Delta\alpha \rangle_0^{\mathrm{D}}$ has been estimated to be 18′. The superscripts H and D denote the normal and the deuterated species respectively. The values of $\langle \Delta\alpha \rangle_0^{\mathrm{H}}$ have been calculated by Eq. (5) for each of the k-numbers, from 5 through 9, corresponding to the bending symmetry coordinates of the totally symmetric species of this molecule. The results are tabulated in Table 7.

TABLE 7. ESTIMATED VALUES OF $\langle \Delta\alpha \rangle_0^{\mathrm{H}}$

k	Mode of vibration	$\langle \Delta\alpha \rangle_0^{\mathrm{H}}$
5	HCH bending (nearly redundant)	1°7′
6		1°16′
7		1°16′
8	CCC bending	9°
9	CH_3 rocking	1°9′

If it is accepted as a reasonable judgment that a value of 9° is too large for $\langle \Delta\alpha \rangle_0^{\mathrm{H}}$, the coordinate of CCC bending ($k=8$) is excluded as a possible source of the anharmonicity. Among the rest, the coordinates with the k numbers of 5, 6, and 7 all represent an intra methyl-top bending motion.

*4 The correspondence between the vibrational mode and the sequence number of the symmetry coordinate is arbitrary. In the present treatment, the number 8 has happened to be assigned to the symmetry coordinate of the CCC bending.

In the present results, as well as in the case of acetaldehyde, the zero-point average values of the HCH angle and the DCD angle of the methyl top have been found to be equivalent. Therefore, it is implausible that an appreciable amount of anharmonicity is associated with the intra-methyl bending motion. Accordingly, the coordinate of the rocking motion of the tops ($k=9$) must be the source of the anharmonicity which brings about the difference between $\langle \Delta\alpha \rangle_0^{\mathrm{H}}$ and $\langle \Delta\alpha \rangle_0^{\mathrm{D}}$. A strong anharmonicity of the rocking motion is the most plausible in view of the fact that the methyl tops are tilted outwards, most probably by mutual repulsive interaction.

From the $\langle \Delta\alpha \rangle_0^{\mathrm{H}}$ value thus estimated, the equilibrium value, α_e(CCC), has been evaluated to be 115°0′ by the relation:

$$\alpha_z = \alpha_e + \langle \Delta\alpha \rangle_0. \quad (6)$$

The numerical value of the cubic constant, $F_9^{(3)}$, could be calculated if $(F^{-1})_{89}$ were known. In the present case, however, $(F^{-1})_{89}$ is simply zero because the quadratic force field used is a rather simplified one. Accordingly, $F_9^{(3)}$ is left undetermined, although it would be very interesting to evaluate it by the use of a more sophisticated set of quadratic force constants.[8]

Equilibrium C-H(D) Bond Length. From the r_z-values thus determined and from the $\langle \Delta z \rangle_0$ values in Table 2, the equilibrium bond length, r_e, can be estimated by the relation:

$$r_z = r_e + \langle \Delta z \rangle_0. \quad (7)$$

From both r_z(C–H) and r_z(C–D), the r_e-value of 1.077—1.078 Å was obtained. This is close to the value, 1.078 Å, obtained for the methyl C–H of acetaldehyde.[4] It should be noted that the rather smaller value of the r_z(C–H) of acetone is simply due to the environment effect, that is, the larger torsional amplitude of the methyl top around the axis.

The author wishes to thank Professor M. Kimura for his helpful advice and Mr. C. Kato for his help in the early stages of this study. The numerical calculations were performed on a HITAC 5020E of the Computing Center of the University of Tokyo and on a FACOM 270-20 in the laboratory of Professor Kimio Ohno, Hokkaido University, to whom the author's thanks are also due.

Appendix

Derivation of Eq (2). By applying the theorem that the expectation value of the force with respect to any coordinate should be zero for a system in a stationary state,[9] the following simultaneous linear equations for

8) G. Dellepiane and J. Overend, *Spectrochim. Acta*, **22**, 593 (1966).

9) L. S. Bartell, *J. Chem. Phys.*, **38**, 1827 (1963).

$<S_l>$'s are obtained:

$$\left\langle \frac{\partial V}{\partial S_j} \right\rangle = \sum_l F_{jl}\langle S_l\rangle + 3F_k^{(3)}\langle S_k^2\rangle\delta_{kj} = 0 \qquad (A1)$$

$$(j = 1, 2, \cdots)$$

where the potential function, V, is given as:

$$V = \frac{1}{2}\sum_{j,l} F_{jl}S_lS_j + F_k^{(3)}S_k^3 \qquad (A2)$$

in terms of the symmetry coordinates. By solving Eq. (A1) for $<S_l>$, this relation:

$$\langle S_l\rangle = -3F_k^{(3)}(F^{-1})_{lk}\langle S_k^2\rangle \qquad (A3)$$

can easily be derived. In the event that the cubic potential is given by such a sum of terms as $\sum_k F_k^{(3)} S_k^3$, $<S_l>$ is obtained simply by taking a sum of the right-hand side of Eq. (A3) over k.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1053—1056 (1970)

Solvent Effect on the Electronic Spectra of Bis(8-quinolinolato)-nickel(II) at 80°C*1,2

Yoshiki MORIGUCHI*3 and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received June 11, 1969)

The visible absorption spectra were observed on bis(8-quinolinolato)nickel(II) in molten 8-quinolinol as well as in other solvent systems such as molten naphthalene, molten β-methoxynaphthalene or toluene containing various amounts of 8-quinolinol at 80°C. Little interaction was found between the solute and naphthalene or toluene. However, a weak interaction was observed between the solute and β-methoxynaphthalene or 8-quinolinol. The extent of interaction between the solute and 8-quinolinol in toluene was evaluated spectrophotometrically.

Concerning the zone-melting process of the systems containing metal chelates of 8-quinolinol,[1] we are interested in the behavior of 8-quinolinolato metal chelates in molten 8-quinolinol or other solid solvents such as naphthalene or β-methoxynaphthalene. Bis(2,4-pentanedionato)nickel(II) exists as a hexa-coordinate trimeric form in a solid state, but exists as a solvated octahedral monomeric form in donating solvents and as a polymeric or a tetrahedral monomeric form in non-donating solvents.[2] In this connection, it is of interest to study the interaction between the solute, bis(8-quinolinolato)nickel(II), and the solvents such as molten 8-quinolinol or other solvents.

The visible absorption spectra were observed on bis(8-quinolinolato)nickel(II) in molten 8-quinolinol as well as in other solvent systems such as molten naphthalene, molten β-methoxynaphthalene or toluene containing various amounts of 8-quinolinol at 80°C. The analysis of the spectra showed that there was definitely a weak interaction between the dissolved chelate and β-methoxynaphthalene or 8-quinolinol. As the observed absorption bands are due to d–π transition, and as the d–d band was too weak to be observed no significent discussion could be made on the coordinating structure of dissolved 8-quinolinolato metal chelate.

Experimental

Materials. 8-Quinolinol was purified by steam distillation and was dried over phosphorus pentoxide. Bis(8-quinolinolato)nickel(II) was obtained according to the standard procedure as dihydrate,[3] which was then dehydrated by heating at 100°C for 6 hr in a vacuum over phosphorus pentoxide. The dehydrated sample was found to have a composition of $Ni(ox)_2 \cdot 1/2H_2O$. It was a brownish yellow powder relatively soluble in hot toluene or in pyridine at room temperature. Although we tried to obtain a completely dehydrated sample,[4] further dehydration under severer conditions

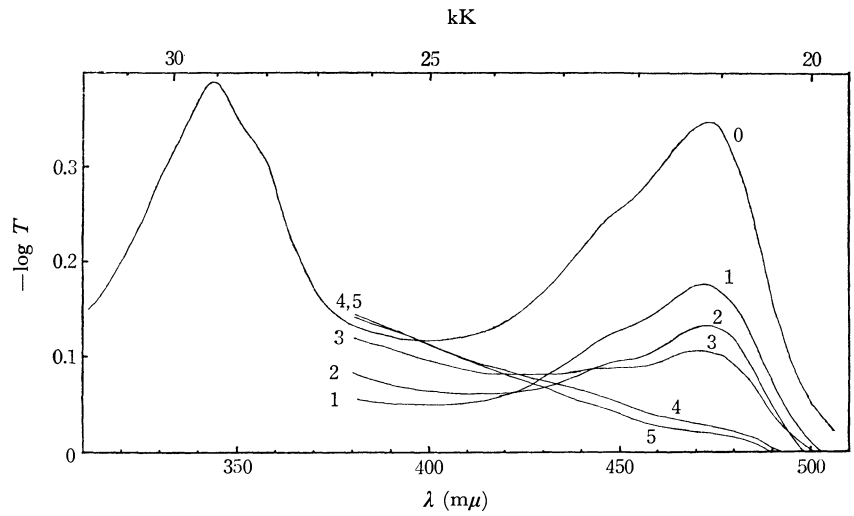

Fig. 1. Absorption spectra of bis(8-quinolinolato)nickel(II) in toluene containing various amounts of 8-quinolinol at 80°C. Concentration of nickel chelate 2.76×10^{-5}M. Concentration of 8-quinolinol increases from curve 0 to 5; zero, 1.95×10^{-4}M, 1.01×10^{-3}M, 1.95×10^{-3}M, 1.08×10^{-2}M and 1.95×10^{-2}M respectively.

resulted in the decomposition of the chelate.

Other solvents were purified and dried according to standard procedures.

Apparatus. Absorption spectra in a visible region were measured with a Hitachi Model 124 recording spectrophotometer, and the optical densities at controlled temperature were measured with a Hitachi-Perkin Elmer Model 139 spectrophotometer equipped with a constant temperature cell compartment which was heated by circulating silicone oil. The temperature fluctuation in the compartment was kept within ±1°C. The spectra were measured against the composite solvent which has exactly the same composition as the solution. However, no reliable specrta could be observed in a region shorter than 390 mμ where a strong absorption of 8-quinolinol was observed, since both solvent and solution contained relatively high concentration of 8-quinolinol.

The molecular weight of 8-quinolinol in toluene was determined by a Mechrolab Model 301A vapour pressure osmometer.

Result and Discussion

The absorption spectrum of bis(8-quinolinolato)-nickel(II) in toluene at 80°C is shown in Fig. 1. The spectrum is characterized by a peak at 473 mμ with an intensity of log $\varepsilon\approx4$, and is interpreted as a d–π transition band of the chelate.[5] Almost similar spectrum was observed for the nickel chelate in molten naphthalene at 83°C. Thus, this spectrum may represent the chelate species which is dissolved in non-donating solvents. On the other hand, when 8-quinolinol is added to the toluene solution of nickel chelate, the peak at 473 mμ diminishes with increasing concentration of 8-quinolinol as illustrated in Fig. 1. Further increase of 8-quinolinol concentration does not change the spectrum appreciably. The spectrum is almost the same as that of nickel chelate in molten 8-quinolinol at 82°C.

When the spectra of nickel chelate are observed in weak donating solvents such as β-methoxynaphthalene, dioxane, cyclohexanol or toluene-methanol, a similar diminution of the 473 mμ peak is noticed, but to a lesser extent than in the case of 8-quinolinol as illustrated in Fig. 2. When the spectra are observed in strong donating solvents, such as pyridine or benzylamine, the spectra changed completely and a new band appeared at 410 mμ. Thus, the absorption band of nickel chelate at 473 mμ was found to be rather sensitive against the donating solvents. The curve 5 in Fig. 1 may be assumed to represent the chelate species which is fully solvated with 8-quinolinol.

In order to estimate the extent of interaction between the nickel chelate and 8-quinolinol, an equilibrium constant of the reaction

$$\mathrm{Ni(ox)_2\cdot\tfrac{1}{2}H_2O} + n\,\mathrm{Hox} \overset{K}{\rightleftharpoons} \mathrm{Ni(ox)_2\cdot(Hox)_n\cdot\tfrac{1}{2}H_2O} \qquad (1)$$

was determined by means of a modified Benesi-Hildebrand method[6] using the spectrophotometric data of Fig. 1.

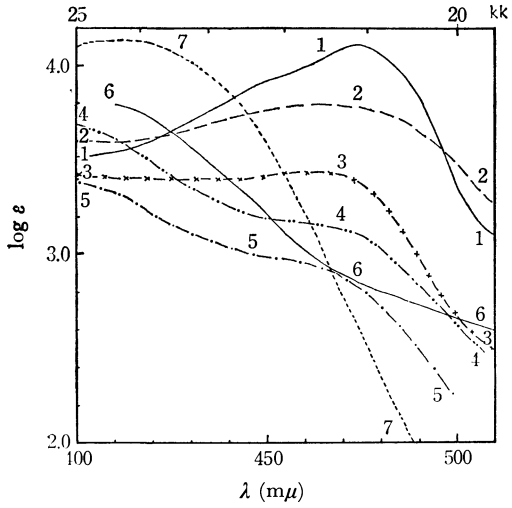

Fig. 2. Absorption spectra of bis(8-quinolinolato)-nickel(II) in various solvents.
Curve 1, in toluene at 80°C; Curve 2, in β-methoxynaphthalene at 77°C; Curve 3, in dioxane at 80°C; Curve 4, in toluene containing 0.5M methanol at 80°C; Curve 5, in cyclohexanol at 60°C; Curve 6, 8-quinolinol at 82°C, Curve 7, in pyridine at room temperature. The values of ε are approximate for the solution of β-methoxy-naphthalene (curve 2) and of 8-quinolinol (curve 6), because no volume corrections were made for those solutions. However, these values are still meaningful for the sake of comparison with other solvent systems.

As we did not succeed in obtaining the completely dehydrated nickel chelate, we could not confirm whether the 8-quinolinol adduct still holds water ($Ni(ox)_2\cdot(Hox)_n 1/2H_2O$) or the chelate releases water when the adduct is formed ($Ni(ox)_2\cdot(Hox)_n$). Thus, the equilibrium constant under discussion is merely an apparent one. However, it may still be useful to estimate the extent of interaction between the nickel chelate and 8-quinolinol.

The equilibrium constant, K, for Eq. (1) is defined by

$$K = \frac{x}{(a-x)(b-nx)^n}, \qquad (2)$$

where a and b are the initial molar concentrations of nickel chelate and 8-quinolinol, respectively, and x is the molar concentration of nickel chelate-8-quinolinol adduct in the equilibrium solution. Eq. (2) may be simplified to

$$K = \frac{x}{(a-x)b^n}, \qquad (3)$$

under the conditions, $b \gg a$ and $b \gg x$.

On the other hand, the optical density of the above system at the given wave length, A_s, can be expressed by

$$A_s = (a-x)\varepsilon_1 + (b-nx)\varepsilon_2 + x\varepsilon_3, \qquad (4)$$

where ε_1, ε_2, and ε_3 are the molar absorption coefficients of nickel chelate, 8-quinolinol and the adduct, respectively.

Thus, we have

$$\frac{a}{(A_s-A_{s_1}-A_{s_2})} = \frac{1}{(\varepsilon_3-\varepsilon_1-n\varepsilon_2)} + \frac{1}{(\varepsilon_3-\varepsilon_1-n\varepsilon_2)K}\cdot\frac{1}{b^n} \qquad (5)$$

by eliminating x from Eqs. (3) and (4), where, $A_{s_1}=a\varepsilon_1$ and $A_{s_2}=b\varepsilon_2$.

Equation (5) can be written as follows, because the molar absorption coefficient of 8-quinolinol, ε_2, at 476 mμ in toluene solution is assumed to be zero.

$$\frac{a}{(A_s-A_{s_1})} = \frac{1}{(\varepsilon_3-\varepsilon_1)} + \frac{1}{(\varepsilon_3-\varepsilon_1)K}\cdot\frac{1}{b^n} \qquad (6)$$

As illustrated in Fig. 3, the plot of $a/(A_s-A_{s_1})$ *vs.* $1/b^n$ becomes a straight line when n is assumed to be 0.5. From the slope of the line, the apparent equilibrium constant is obtained as 5.0 which is comparable to that of hydrogen bond formation in systems such as phenol-dioxane-iso-octane.[7]

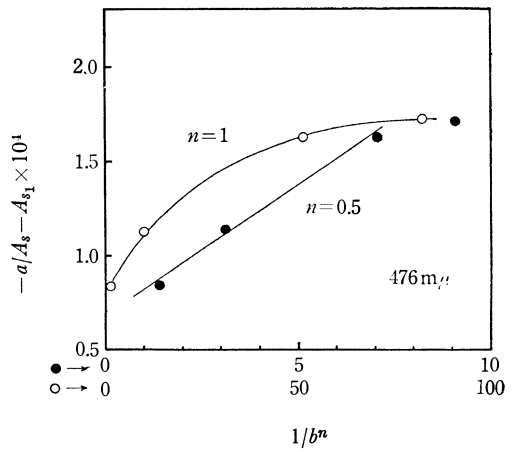

Fig. 3. Determination of equilibrium constant by the modified Benesi-Hildebrand plots.

The combining ratio of 0.5 suggests that one half mole of dimeric 8-quinolinol in toluene interacts with one mole nickel chelate. However, this was denied by the fact that 8-quinolinol exists as monomeric species in toluene as proved by the molecular weight determination.

Formation of 8-quinolinol adducts with 8-quinolinolato metal chelate was reported for several metals, and the equilibrium constant for the reaction

$$Zn(ox)_2 + Hox \rightleftharpoons Zn(ox)_2\cdot(Hox) \qquad (7)$$

in water-chloroform system, was studied by means

7) S. Nagakura and H. Baba, *J. Amer. Chem. Soc.*, **74**, 5693 (1952).

of the solvent extraction technique, and was found to be larger than $10^{2.6}$ at 25°C.[8] The value we obtained is much lower.

Thus, it may be concluded that the extent of interaction of bis(8-quinolinolato)nickel(II) and 8-quinolinol in toluene at 80°C is an order of hydrogen bond formation if the entropy effect is small enough to be neglected.

The authors wish to thank the Ministry of Education, Japanese Government, for financial support of this work. They are also grateful to Miss A. Itoh for the molecular weight determination.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1056—1061 (1970)

Optimum Geometric Position for Radioactivation by Fast Neutron with a Neutron Generator

Toshiaki KISHIKAWA and Chiro SHINOMIYA

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami-cho, Kumamoto

(Received June 19, 1969)

With a 14 MeV neutrol generator the optimum irradiation position of disk or square samples of appropriate numbers are given as a function of the configuration of the sample relative to the source. Calculated values are compared with experimental data.

In working with a 14 MeV neutron generator, the need arose to irradiate simultaneously several samples at the same flux. When only one sample is irradiated, the position nearest the deuteron beam spot provides the highest neutron flux.[1,2] When several samples are irradiated, the optimum irradiation position should be chosen at which the neutron flux gives the maximum value, and the radioactivation reaction gives the highest induced activity.

In a previous paper[1] geometry of irradiation was derived and calculated as a function of a generator-sample configuration. The calculated values were compared with the measured values of relative neutron flux. The geometry of irradiation is essentially the same as the geometry of radioactivity measurement. Extensive calculation of solid angles has been carried out.[3-9]

In this paper we report the optimum irradiation position of plane samples as a function of generator-sample configuration. Calculated values are compared with experimental data.

Theoretical

The following assumptions are made:

1. The shape of the neutron source is a point or a disk, emitting neutrons which are distributed uniformly throughout the source.
2. Mono-energetic neutrons (14 MeV) are emitted isotropically.
3. Thermalization and absorption by target holder, water cooling cap and air are neglected.

Geometry of Irradiation and Its Calculation. Neutron flux is different in various irradiation configuration. The flux to be measured is proportional to the numbers of neutron passing through the sample. The fraction of the flux ϕ in n/cm^2-sec to the neutron output N in n/sec is equal to the relative solid angle $\Omega/4\pi$ subtended by the sample. This is defined as the geometry G of irradiation corresponding to the geometry of instruments to measure radioactivity.

$$G = \phi/N = \Omega/4\pi \tag{1}$$

The solid angle Ω_P at a point source P subtended by the sample is given by

$$\Omega_P = \int_A \cos\gamma \frac{dA}{r^2} \tag{2}$$

Table 1. Typical classification of geometry calculation

Sample form	Source	Distance from Axis[a)]	Calculation		Ref.
			Equation	Solution	
Disk	Point	On axis	5	Given	5
Disk	Point	Off axis	6	Numerically integrated	
Square	Point	On axis	8	Solved	
Square	Point	Off axis	10	Solved	
Disk	Spread	On axis	11	Numerically integrated	
Disk	Spread	Off axis			1
Square	Spread	On axis			1
Square	Spread	Off axis			1

a) The expression "axis" means the direction which passes through a point or the center of a spread source, and which is normal to sample plane (see Fig. 1).

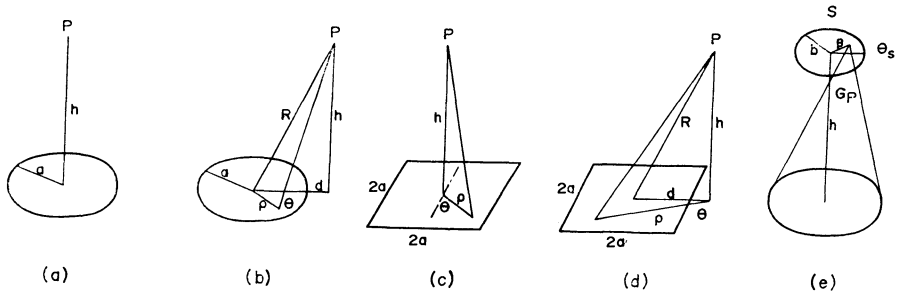

Fig. 1. Typical assemblies of source (point P or spread S) and a sample.

where

A = surface bounded by the sample.
r = distance from the source to a point Q on the sample.
γ = angle between the normal to the surface element dA at Q and the line PQ.

Substituting Eq. (2) into Eq. (1), we obtain

$$G_P = \frac{1}{4\pi}\int_A \cos\gamma \frac{dA}{r^2} \tag{3}$$

If the area of the source is too large to be approximated by a point, the average value of the geometry G_S of a spread source may be calculated by the equation[6)]

$$G_S = \frac{1}{N_S}\int_S G_P N_P dS \tag{4}$$

where

S = surface bounbed by neutron generation.
N_P = relative neutron output at a point P.
N_S = total neutron output.
G_P = geometry at a point P (Eq. 3).

It is possible only in a few cases to carry out the integration analytically where the symmetry of the configuration simplifies the calculation.

Geometry equations were derived for disk and square as functions of the generator-sample configuration in orthogonal coordinates. Typical classification of the geometry calculation is given in Table 1. The schematic configuration and summary of symbol definitions are given in Fig. 1.

The results of the derivation are as follows. Results which cannot be evaluated in closed form are expressed in integral forms.

A. Geometry of a point source coaxial with a disk (Fig. 1a) is derived by means of solid geometry elsewhere[5)]

$$G_P = \tfrac{1}{2}\left\{1 - \frac{h}{(a^2+h^2)^{1/2}}\right\} \tag{5}$$

B. Geometry in which the normal to the center of the disk does not pass the point source (Fig. 1b), is found to be

$$G_P = \frac{1}{4\pi}\int_0^a\int_0^{2\pi} \frac{\rho h d\rho d\theta}{(d^2+\rho^2+h^2-2d\rho\cos\theta)^{3/2}}$$

or

$$G_P = \frac{h}{2\pi}\int_0^{\pi} d\theta \left\{\frac{ad\cos\theta + R^2}{(d^2\cos^2\theta - R^2)(R^2+a^2-2ad\cos\theta)^{1/2}} - \frac{R}{d^2\cos^2\theta - R^2}\right\} \tag{6}$$

where

$$R^2 = d^2 + h^2$$

If the sample is on the axis of the source, *i.e.* d is 0 in Eq. (6), then Eq. (6) can be reduced to Eq. (5).

C. Geometry of a point source coaxial with the

square (Fig. 1c) is given by

$$G_P = \frac{2}{\pi}\int_0^{a\sec\theta}\int_0^{\pi/4}\frac{\rho h\,d\rho\,d\theta}{(\rho^2+h^2)^{3/2}} \tag{7}$$

Equation (7) is then reduced to

$$G_P = \frac{1}{2} - \frac{2}{\pi}\sin^{-1}\frac{h}{(2a^2+2h^2)^{1/2}} \tag{8}$$

D. Geometry in which the normal to the center of the square dose not pass the point source (Fig. 1d) is found to be

$$G_P = \frac{1}{2\pi}\left[\int_{(d-a)\sec\theta}^{(d+a)\sec\theta}\int_0^{\tan^{-1}a/(d+a)}\frac{\rho h\,d\rho\,d\theta}{(\rho^2+h^2)^{3/2}} + \int_{(d-a)\sec\theta}^{a\operatorname{cosec}\theta}\int_{\tan^{-1}a/(d-a)}^{\tan^{-1}a/(d+a)}\frac{\rho h\,d\rho\,d\theta}{(\rho^2+h^2)^{3/2}}\right] \tag{9}$$

Equation (9) is then reduced to

$$G_P = \frac{1}{2\pi}\left[\sin^{-1}\frac{ah}{\{(d-a)^2+h^2\}^{1/2}\{(d-a)^2+a^2\}^{1/2}} - \sin^{-1}\frac{ah}{\{(d+a)^2+h^2\}^{1/2}\{(d+a)^2+a^2\}^{1/2}} + \sin^{-1}\frac{(d-a)h}{(a^2+h^2)^{1/2}\{(d-a)^2+a^2\}^{1/2}} - \sin^{-1}\frac{(d+a)h}{(a^2+h^2)^{1/2}\{(d+a)^2+a^2\}^{1/2}}\right] \tag{10}$$

E. Geometry of a spread source coaxial with a disk (Fig. 1e) is given from Eqs. (4) and (6) by replacing d with β in Eq. (6). We have

$$G_S = \frac{2}{b^2}\int_0^b \beta G_P(\beta)\,d\beta$$

or

$$G_S = \frac{h}{\pi b^2}\int_0^b\int_0^\pi \beta\,d\beta\,d\theta_S \times\left[\frac{\beta^2+h^2-2a\beta\cos\theta_S}{\{\beta^2\cos^2\theta_S-(\beta^2+h^2)\}\{a^2+\beta^2+h^2-2a\beta\cos\theta_S\}^{1/2}} - \frac{(\beta^2+h^2)^{1/2}}{\beta^2\cos^2\theta_S-(\beta^2+h^2)}\right] \tag{11}$$

Numerical data of the derivations A—E and a summary of the geometry (F) in which the normal to the center of the disk does not pass the center of the source, (G) in which the normal to the center of the square passes the center of the source, and

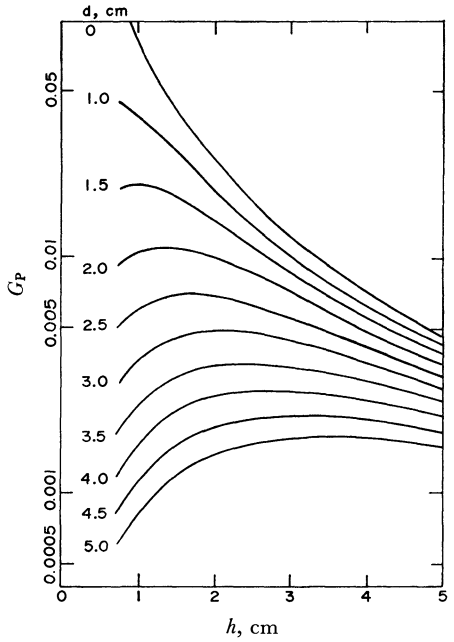

Fig. 2. Geometry value G_P of a point source of a disk (radius 0.665 cm). The G_P curve is given for each distance from axis d.

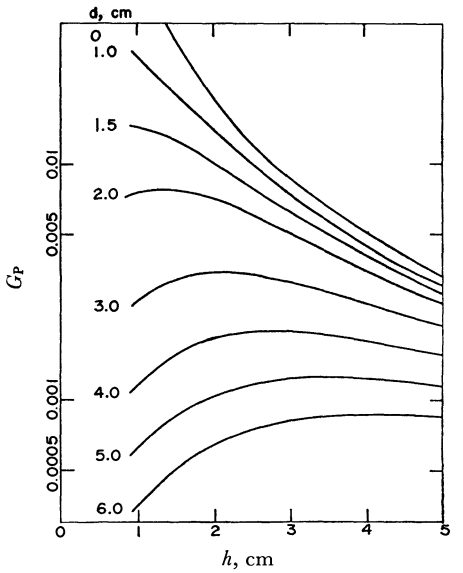

Fig. 3. Geometry value G_P of a point source of a square (side 1 cm). The G_P curve is given for each distance from axis d.

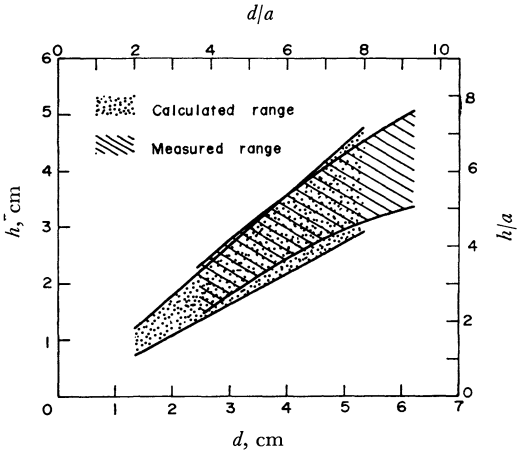

Fig. 4. The optimum geometric position of 97% confidence range of a disk sample with a radius of a=0.665 cm or with an unit radius.

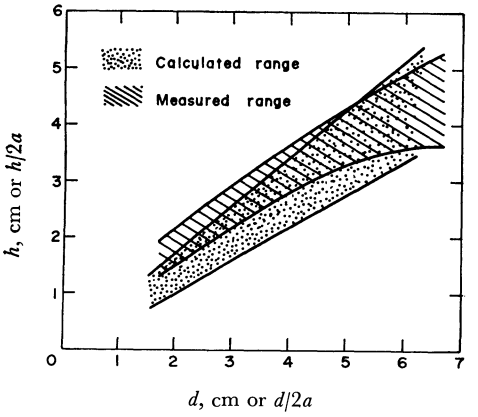

Fig. 5. The optimum geometric position of 97% confidence range of a square sample with a side of $2a=1$ cm or with an unit side.

(H) in which the normal to the center of the square dose not pass the center of the source, have been reported.[1)]

For disk (radius $a=0.665$ cm) and square (side $2a=1$ cm) the geometry values of the series A—D are numerically integrated and shown in Figs. 2 and 3.

The optimum geometry with respect to h can be given analytically by solving the equation $(\partial G/\partial h)_{a,b,d}=0$. This was obtained graphically in Figs. 2 and 3. The optimum geometric position of 97% confidence range in (d, h) with a radius of $a=0.665$ cm or with a side of $2a=1$ cm, so obtained, are shown in Figs. 4 and 5.

Experimental

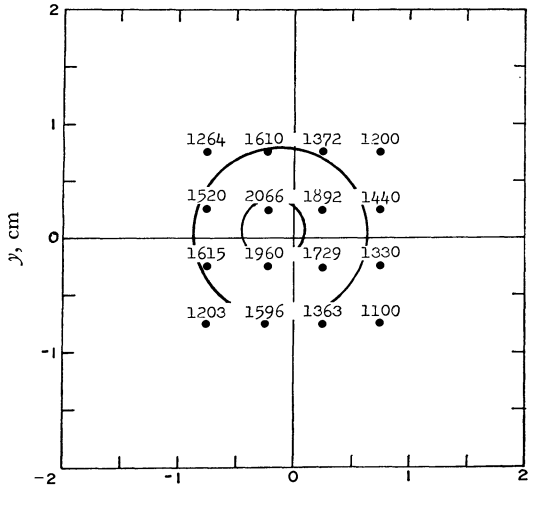
Neutron Generator. Monochromatic 14 MeV neutrons were produced by $^{3}H(d, n)^{4}He$ reaction with a vertical-type neutron generator made by Hitachi Ltd. A thin tritiated titanium target (*ca.* 5 Ci; copper based) was bombarded with a deuteron beam of *ca.* 200 μA and *ca.* 100 kV. The neutron output was kept constant by controlling the accelerating voltage of the generator. The output was recorded by a BF_3 counter with a counting-rate meter.

Determination of Deuteron Beam Position. It was important to keep the position of deuteron beam spot, or the center of the neutron emission constant. The determination was made by irradiating a small copper foil. The foils ($5\times5\times0.5$ mm) were placed square or crosswise on the cooling cap in the plane parallel to the tritiated target. From the distribution of the induced activity of the foils, the center of the neutron emission was determined by plotting the activity *versus* position. Typical examples are shown in Figs. 6a and 6b.

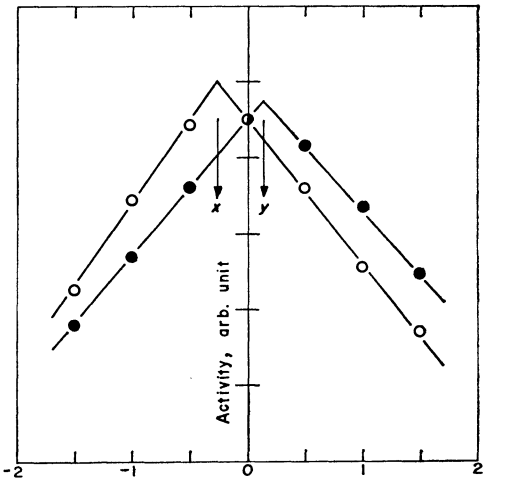
In the case of the squares method, a contour map (see Fig. 6a) was obtained. The limited numbers of the foil made it difficult to draw a contour of an appropriate level of activity. In the case of the cross method, the plot of activity against position axes gave bloken lines. The ordinates of the folds showed the center (see Fig. 6b). The method was found to be useful.

Determination of Irradiation Geometry. Variation of neutron flux at the irradiation position with respect to the generator-sample configuration was determined by measuring the induced activity of the sample. Copper foil was chosen as a sample. It was a disk (radius 0.665 cm) or a square (side 1 cm).

In order to determine flux at a particular position,



(a) Squares method; center $(-0.2_0, 0.0_6)$



(b) Cross method; center $(-0.2_5, 0.1_3)$

Fig. 6. Determination of the center of the deuteron beam spot, or the center of neutron emission by activating copper foils. In the figure (a) activity values in cpm are superimposed. Contours are 1500 and 2000 cpm level.

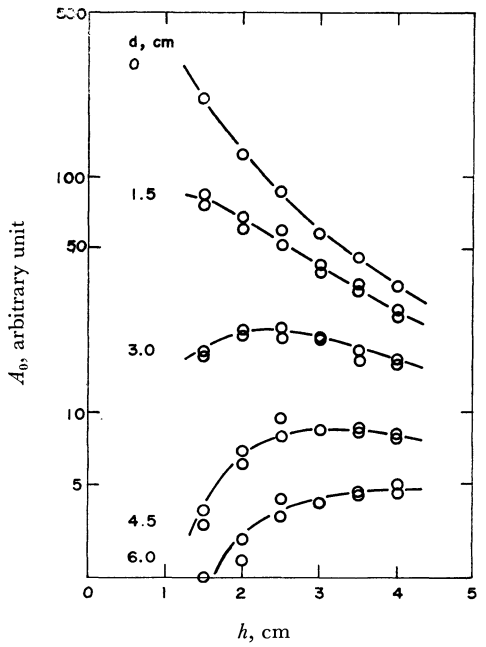


Fig. 7. Induced activity values of disk samples. The radius is 0.665 cm.

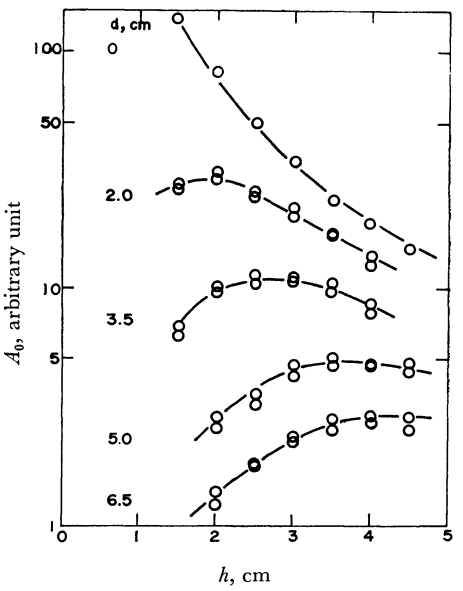

Fig. 8. Induced activity values of square samples. The side is 1 cm.

TABLE 2. RATIO OF INDUCED ACTIVITY TO GEOMETRY OF SPREAD SOURCE COAXIAL WITH A DISK SAMPLE

Axial distance h, cm	Induced activity A_0, cpm	A_0/G_S values $\times 10^{-5}$ at b in cm					
		0[a)]	0.1	0.2	0.3	0.4	0.5

a) Point source, A_0/G_P values.

the foils were placed normal to the direction of deuteron beam and irradiated for several minutes. In order to give uniform neutron emission to the foils, they were rotated with the sample mounting. The induced activity of each foil was then measured in turn to follow its decay with an end-window G-M counter. The decay curve showed the presence of ^{62}Cu (half-life 9.8 min). Possible influence of ^{66}Cu (half-life 5.1 min) produced from ^{65}Cu(n, γ)^{66}Cu reaction and the other nuclides (^{64}Cu and ^{65}Ni) produced from the fast neutron activation could be neglected. Counting rates of the individual samples were corrected for slight weight differences. All the samples were not irradiated at the same time. A comparator technique was used to correlate separate irradiation at different output levels.

The relation between induced activity A_0 at the end of irradiation and flux ϕ can be given by

$$A_0 = N_0\phi\sigma(1-e^{-\lambda t}) \qquad (12)$$

When a foil with known N_0 is irradiated for a certain time t, the term $N_0\sigma(1-e^{-\lambda t})$ in Eq. (12) remains constant. Thus the induced activity is proportional to the neutron flux at the irradiation position or the irradiation geometry. The results are shown in Figs. 7 and 8.

Size of Deuteron Beam Spot. If samples along the direction of the deuteron beam are irradiated (radius of the focus b in cm), the ratio of induced activity to geometry $A_0(h)/G_S(h)$ may remain constant independent of the irradiation distance h. The calculated ratio with the values of $G_S(h)$ given previously[1] at appropreate values of b are listed in Table 2. In the case that b is 0.0, the ratio is equal to $A_0(h)/G_P(h)$. If the value of b is equal to the radius of the neutron emitting spot at which the percent standard deviation of the values of $A_0(h)/G_S(h)$ is minimized, the radius of *ca.* 0.1 cm can be obtained.

The actual size of the focus of the deuteron beam can be seen directly by replacing the tritiated target with a quartz plate. Induced fluorescence showed an

ellipse-like figure, whose diameters are found to be *ca.* 3 mm and *ca.* 5 mm. Its color showed non-uniform intensity. With quartz plate the calculated value was smaller than the observed value. It is probably because (1) the neurton emission is assumed to be distributed unformly throughout the beam spot, and (2) the shape of the spot is assumed to be a disk.

Optimum Irradiation Geometry. The observed values of induced activity at various distances d against distance h shown in Figs. 7 and 8 indicate the presence of maximum values of A_0 and that at d is zero. The experimentally obtained optimum position of 97% confidence range expressed in the coordinates (d, h) which can be found in Figs. 7 and 8 are shown in Figs. 4 and 5. The ranges obtained are in fairly good agreement with the theoretically derived ranges which are shown in the same figures.

As the value of geometry is only a function of the source-sample configuration, the ratio $a : d : h$ is constant. (If the radius of a disk is greater than or equal to 0.665 cm, the value of $G_S(h)$ becomes nearly equal to the value of $G_P(h)$ for $h=1.5$ cm.[1]) This indicates that it is sufficient, under the appropriate empirical conditions, to assume the beam focus to be a point.) This leads to the homologous relation. If the value of a is set up, an optimum position (d, h) is found in scale of d/a and h/a respectively in Fig. 4 or 5. If definite numbers n of disk or square sample (appropreate size a) are irradiated simultaneously under the same neutron flux, the optimum distance d from the axis can be found by means of the relation

$$d = a\mathrm{cosec}\pi/n \quad \text{for disk} \tag{13}$$

or

$$d = \mathrm{a}(1+\cot\pi/n) \quad \text{for square} \tag{14}$$

Hence the optimum configuration can be obtained in Fig. 4 or 5.

As the capsule used for the irradiation of powder or liquid is cylindrical, and the optimum range of irradiation geometry is fairly wide, the present data can be utilized for the choice of the generator-cylindrical sample configuration.

The authors wish to express their gratitude to Dr. Shoichi Sato, Dept. of Mathematics, for his advice and encouragement, and to Professor Kimikazu Matsuyama, Dept. of Electrical Engineering, Chief of the Computing Center, for providing facilities of FACOM-231 computer and for his help with programming. Thanks are also due to Mr. Masaya Tanizaki for the operation of the neutron generator.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1061—1065 (1970)

Cobalt(III) Complexes with Nitrilotriacetic Acid, Nitrilopropionicdiacetic Acid and Nitriloisopropionicdiacetic Acid*1

Mitsuo TACHIBANA, Akira UEHARA, Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received August 13, 1969)

The following cobalt(III) complexes containing nitrilotriacetic acid (NTA), nitrolopropionicdiacetic acid (NPDA) and nitriloisopropionicdiacetic acid (NIPDA) were prepared: $(NH_4)_3[Co(nta)_2]\cdot 2H_2O$ (pink) (I), $NH_4[Co(Hnta)_2]\cdot 2H_2O$ (pale pink) (II), $K_3[Co(npda)_2]\cdot 2H_2O$ (pink) (III), $K[Co(Hnpda)_2]\cdot 3H_2O$ (pale pink) (IV), [Co(npda)(*o*-phen)]·H_2O (reddish violet) (V), [Co(npda)(bipy)] (reddish violet) (VI), $K[Co(OH)(nipda)(H_2O)]\cdot H_2O$ (bluish violet) (VII) and [Co(nipda)(*o*-phen)] (reddish violet) (VIII); where nta, npda, nipda, *o*-phen and bipy are the abbreviations of nitrilotriacetate-, nitrilopropionicdiacetate-, nitriloisopropionicdiacetate-ion, *o*-phenanthroline and 2,2′-bipyridyl, respectively. On the basis of electronic spectra, it was found that complexes I to IV have the *trans* form, while complexes V, VI and VIII have the *mer* form structure with respect to the nitrogen atoms in the coordinating ligands. Complex VII showed a dehydration-dimerization reaction on heating by "Derivatograph". Comparison of chemical and physical properties of the complexes with those of the corresponding chromium(III) complexes was made.

All the chelating agents discussed in this paper, NTA, NPDA and NIPDA,*2 can behave as $(N\text{–}O_3)$, $(N\text{–}O_2)$ or (O_3) type ligands toward metals. Some behaviors of NTA in cobalt(III)[1] and chromium(III) complexes[2] have been reported. Several

*1 Presented at the 22nd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1969.

*2 The abbreviations used in this paper, NTA, NPDA and NIPDA, correspond to ATA in Ref. 2, APDA in Ref. 11 and AIPDA in Ref. 12 respectively.

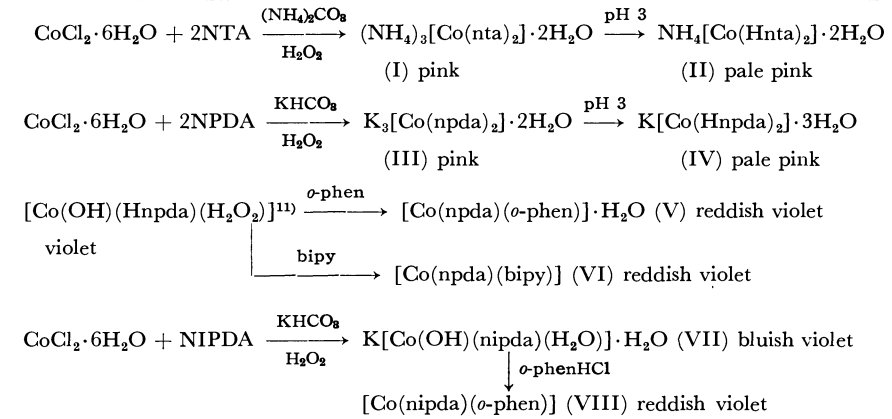
2) A. Uehara, E. Kyuno and R. Tsuchiya, *ibid.*, **40**, 2317 (1967).

Table 1. Preparative schemes of complexes



mixed complexes of cobalt(III) with NTA and with natural amino acids have been prepared and discussed in relation to the structural isomers.[3] The bis type complexes of cobalt(III)[4-7] and chromium(III)[8,9] with aminodicarboxylic acids have been reported by many workers, and speculations for their geometrical isomers have also been made. The chromium(III) complexes with aminotricarboxylic acids such as NTA or NPDA have been reported by the authors,[10-12] who pointed out that the coordinating behaviors of these agents toward chromium appreciably vary with each other due to the difference of their structures and properties. However, no report has been given about the corresponding cobalt(III) complexes.

In this study we have undertaken to (1) prepare various kinds of the cobalt(III) complexes with these ligands, (2) ascertain the coordinating behaviors of these ligands toward cobalt(III), (3) predict their structures, especially those of bis type complexes, and (4) compare the structures of the cobalt(III) complexes with those of the corresponding chromium(III) complexes.

Experimental

Preparation of Ligands. NTA,[2] NPDA,[11] and NIPDA[12] were prepared by the methods given in literature.

Preparation of Complexes. The preparative methods of the complexes are schematically shown in Table 1.

Ammonium Bis-(nitrilotriacetato)cobaltate(III) Dihydrate, $(NH_4)_3[Co(nta)_2]\cdot 2H_2O$ (pink) (I). 100 m*l* of water containing 38 g of NTA was gradually neutralized with 17 g of ammonium carbonate. To this solution, 100 m*l* of aqueous solution containing 24 g of cobalt(II) chloride hexahydrate was added. After the pH of the mixed solution was adjusted to 6—7 by means of ammonium carbonate, 10 m*l* of 28% hydrogen peroxide solution was added in order to oxidize the cobalt(II) solution. On being heated on a water bath, the solution turned to pink from violet. The pink crude crystals were obtained from the resulting solution evaporated almost to dryness. The crude products were recrystallized from 5% ammonium carbonate solution. Yield about 8 g.

Found: N, 13.53; C, 27.30; H, 5.21%. Calcd for $(NH_4)_3[Co(nta)_2]\cdot 2H_2O$: N, 13.32; C, 27.41; H, 5.34%.

Ammnoium Bis-(hydrogennitrilotriacetato)cobaltate(III) Dihydrate, $NH_4[Co(Hnta)_2]\cdot 2H_2O$ (pale pink) (II). Five grams of complex I was dissolved in about 50 m*l* of water. When the pH of the solution was adjusted to 3 by adding a few drops of hydrochloric acid, pale pink crystals came out easily. Recrystallization was achieved from an aqueous solution. Yield about 3 g.

Found: N, 8.58; C, 27.78; H, 4.62%. Calcd for $NH_4[Co(Hnta)_2]\cdot 2H_2O$: N, 8.55; C, 27.31; H, 4.48%.

Potassium Bis-(nitrilopropionicdiacetato)cobaltate(III) Dihydrate, $K_3[Co(npda)_2]\cdot 2H_2O$ (pink) (III). These crystals were prepared by a procedure analogous to that in complex I except for the use of 40 g of NPDA and 9 g of potassium hydrogen carbonate instead of 38 g of NTA and 17 g of ammonium carbonate. Yield 6 g.

Found: N, 4.73; C, 27.89; H, 3.13%. Calcd for $K_3[Co(npda)_2]\cdot 2H_2O$: N, 4.54; C, 27.25; H, 3.24%.

Potassium Bis-(hydrogennitrilopropionicdiacetato)cobaltate-(III) Trihydrate, $K[Co(Hnpda)_2]\cdot 3H_2O$ (pale pink)

(IV). These crystals were also prepared by a procedure similar to that in complex II except that complex III was used instead of complex I as the starting material.

Found: N, 5.11; C, 29.96; H, 4.60%. Calcd for $K[Co(Hnpda)_2]\cdot 3H_2O$: N, 5.00; C, 30.11; H, 4.30%.

Nitrilopropionicdiacetato-o-phenanthrolinecobalt(III) Monohydrate, $[Co(npda)(o\text{-phen})]\cdot H_2O$ (reddish violet) (V). Two grams of hydroxonitrilopropionicdiacetatodiaquocobalt(III)[13] was dissolved in 100 m*l* of water and 1 g of *o*-phenanthroline was then added. On heating the color of the solution gradually turned to reddish violet from violet. From the resulting solution which was kept in a refrigerator, reddish violet crystals were obtained. Recrystallization was achieved from water. Yield 1 g.

Found: N, 9.37; C, 49.58; H, 4.02%. Calcd for $[Co(npda)(o\text{-phen})]\cdot H_2O$: N, 9.15; C, 49.69; H, 3.95%.

Nitrilopropionicdiacetato-2,2′-bipyridylcobalt(III), [Co(npda)(bipy)] (reddish violet) (VI). The preparative method is similar to that described in the case of complex V except that 1 g of 2,2′-bipyridyl was used in place of *o*-phenanthroline. Yield 1 g.

Found: N, 10.01; C, 47.16; H, 3.82%. Calcd for [Co(npda)(bipy)]: N, 10.07; C, 47.93; H, 3.86%.

Potassium hydroxonitriloisopropionicdiacetatoaquocobaltate-(III) Monohydrate, $K[Co(OH)(nipda)(H_2O)]\cdot H_2O$ (bluish violet) (VII). 200 m*l* of water containing 20 g of NIPDA was neutralized with 24 g of potassium hydrogen carbonate. To the solution, 24 g of $CoCl_2\cdot 6H_2O$ was added. After the pH of the solution was adjusted to 6—7 by the addition of potassium hydrogen carbonate, 10 m*l* of 28% hydrogen peroxide solution was added in order to oxidize cobalt(II) solution. From the resulting solution kept at room temperature for a few days, bluish violet crystals were obtained. They were recrystallized from water. Yield 8 g.

Found: N, 3.74; C, 24.02; H, 3.92%. Calcd for $K[Co(OH)(nipda)(H_2O)]\cdot H_2O$: N, 3.98; C, 23.80; H, 3.71%.

Nitriloisopropionicdiacetato-o-phenanthrolinecobalt(III) Monohydrate, $[Co(nipda)(o\text{-phen})]\cdot H_2O$ (reddish violet) (VIII). After two grams of complex VII was dissolved in 100 m*l* of hot water, 1 g of *o*-phenanthroline neutralized with hydrochloric acid was added. The color of the solution turned from violet to reddish violet. From the cooled solution, reddish violet crystals separated. Recrystallization was carried out from water. Yield 0.4 g.

Found: N, 8.58; C, 47.48; H, 4.28%. Calcd for $[Co(nipda)(o\text{-phen})]\cdot H_2O$: N, 8.80; C, 47.82; H, 4.22%.

Apparatus. The same apparatus as described previously was used.[11]

Results and Discussion

Magnetic Properties and Molar Conductivities. Magnetic susceptibilities were measured by the Gouy method in order to ascertain whether the cobalt in the complexes is tervalent or not. The results are listed in Table 2 together with the values of molar conductivities. All the complexes showed diamagnetic properties, indicating that the tervalent cobalt of low-spin type participates in coordination in these complexes.

Table 2. Magnetic properties and molar conductivities

Complexes	Magnetic Properties*	Molar Conductivities** (mho cm^{-1})
I	diamagnetic	325
II	diamagnetic	366
III	diamagnetic	333
IV	diamagnetic	372
V	diamagnetic	<10
VI	diamagnetic	<10
VII	diamagnetic	102
VIII	diamagnetic	<10

* measured at 293°K
** 10^{-3} mol/*l* of aqueous solution was used.

Molar conductivities were measured to investigate to what valency-type the complexes belong in an aqueous solution. As can be seen from Table 2, the values for complexes I and III are 325 and 333 mho cm^{-1}, showing that they are 1 : 3 valency-type electrolytes. The larger values for complexes II (366 mho cm^{-1}) and IV (372 mho cm^{-1}) than those for I and III may be due to the partial dissociation of the hydrogen ion of free carboxylic acid. The very small conductivities of V, VI and VIII suggest that they are non-electrolytes. The value 102 mho cm^{-1} for complex VII is fairly reasonable for the 1 : 1 type electrolyte.

IR Spectra. The infrared absorption spectra of the complexes were measured at a nujol mull state to inspect how the carboxylic groups in the ligands behave toward metals. The numerical data of the absorption bands arising from the free carboxylic (–COOH), the coordinated carboxylic (–COO–M) and the ionic carboxylic groups ($-COO^-$) are given in Table 3 together with the values assigned to the other ligands coordinated. Assignments of the bands were also followed

Table 3. IR data (cm^{-1})

Complexes	–COOH	COO–M	COO^-	Complements
I		1620 (vs)	1595 (sh)	
II	1753 (s)	1610 (vs)		
III		1628 (vs)	1598 (sh)	
IV	1715 (s)	1626 (vs)		
V		1655 (vs)		850, 1590*
VI		1665 (vs)		780, 1590**

VIII		1658 (vs)		865, 1595*

* The absorptions arising from *o*-phenanthrolorine
** Those from 2,2′-bipyridyl

13) R. Tsuchiya, A. Uehara and E. Kyuno, This Bulletin, **42**, 1886 (1969).

by Busch and Bailar.[14] In the spectra of all the complexes, the bands assigned to the coordinated carboxylic group are confirmed. The bands arising from the free carboxylic acid appeared in both the spectra of complexes II and IV. The spectra of complexes I and III show the bands due to the ionic carboxylic groups.

Coordinating Structures of the Complexes. From the results, the coordinating structures of the complexes are discussed.

It has been mentioned from MO treatments that in the cobalt(III) complexes of N_2–O_4 type, the *trans* form with respect to nitrogen atoms shows the splitting in the first absorption band at the longer wave length region,[15] and it has been established in the complexes such as K[Co(ox)(gly)$_2$][16] and K[Co(ida)$_2$].[7]

The numerical data of the absorption maxima of the complexes due to *d–d* transitions are summarized in Table 4.

TABLE 4. ABSORPTION MAXIMA

Complexes	$\nu_1(10^{13}/\text{sec})$ (log ε_1)	$\nu_2(10^{13}/\text{sec})$ (log ε_2)
I	57.58 (1.83)	81.97 (2.27)
II	57.58 (1.81)	81.74 (2.25)
III	58.71 (1.90)	82.87 (2.10)
IV	58.71 (1.91)	82.64 (2.15)
V	56.29 (2.34)	77.92 (2.34)
VI	55.76 (2.36)	77.92 (2.34)
VII	53.00 (2.23)	75.95 (2.31)
VIII	56.07 (2.35)	78.13 (2.36)

The spectral data are obtained in an aqueous solution unless otherwise stated. Figure 1 shows the spectra of complex I, *cis*-K[Co(ida)$_2$] and *trans*-K[Co(ida)$_2$]. The splitted first band of complex I suggests that it takes the *trans* structure with respect to the nitrogen atoms. As regard to these *trans* structures, two possible coordinating structures can be assumed, *i. e.*, facial configuration (Fig. 2 (A)) with respect to O–N–O and meridional one. However, the former seems to be more reasonable than the latter because the observations of NMR[5,6] and electronic spectra[9] and the consideration on the favorable bond angles[7] in the *trans* IDA or MDA complexes suggests that the *trans* facial is prefered to *trans* meridional configuration.

The shapes of the absorption bands of the complexes II, III and IV are essentially analogous to that of complex I. It is reasonable from these facts to consider that complexes II, III and IV

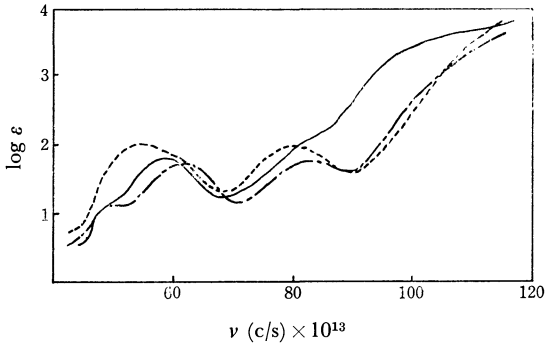

Fig. 1. Absorption spectra for complex I (——), *trans*-K[Co(ida)$_2$](— · —) and *cis*-K[Co(ida)$_2$] (·····).

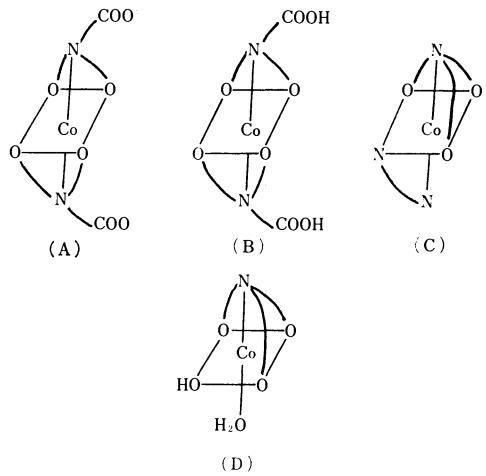

Fig. 2. Possible structures.

may also have the *trans* structure. The IR data show the existence of free carboxylic acid in complexes II and IV, and they seem to have (B) structure as given in Fig. 2.

As for complexes V, VI and VIII, only the *mer* structure with respect to the nitrogen atoms as shown in Fig. 2 (C) can be considered.

Two possible coordinating structures are considered for the structure of complex VII. In the one, the OH group is situated in the *cis* position in relation to the nitrogen atoms of NIPDA, and in the other, in the *trans* position. It has been suggested that K[Co(OH)(nta)(H$_2$O)] has such two isomers; the isomer corresponding to the former was named α type (*cis*) and that corresponding to the latter named β type (*trans*).[1] Comparison of IR spectrum for Complex VII with that for the α or β type of NTA complex indicates that the spectrum of complex VII resembles the former type, and it would be better to assign the *cis* structure to complex VII as shown in Fig. 2 (D).

Comparison of the Properties of Cobalt(III)- with Those of Chromium(III)-Com-

14) D. H. Busch and J. C. Bailar, Jr., *J. Amer. Chem. Soc.*, **75**, 4574 (1953).

16) N. Matsuoka, J. Hidaka and Y. Shimura, This Bulletin, **40**, 1868 (1967).

plexes. It will be of interest to compare the difference in properties between the cobalt(III)- and the corresponding chromium(III) complexes.

It has been stated on the basis of electronic spectra that the chromium(III) complex corresponding to I is successively aquated as follows:

$$[Cr(nta)_2]^{3-} \rightarrow [Cr(OH)(nta)(H_2O)]^- \rightarrow [Cr(OH)(nta)(H_2O)_2]^-.$$ [2]

Complex I does not undergo such an aquation. It has been found that the chromium(III) complex corresponding to complex VII turns from $[Cr(OH)(nipda)(H_2O)]^-$ to $[Cr(OH)(nipda)(H_2O)_2]^-$ in an aqueous solution.[12] Complex VII does not show such a change. These facts suggest that the chromium(III) complexes more easily undergo an aquation than the corresponding cobalt(III) complexes in these cases, probably due to the stronger affinity of the metal ion aganist oxygen than aganist nitrogen in the chromium(III) complexes, and *vice versa* in cobalt(III) complexes.

The Coordination Behaviros of the Ligands Toward Chromium(III) or Cobalt(III) Ions. On the basis of the above consideration, the coordinating behaviors of NTA, NPDA and NIPDA toward the metals are summarized in Table 5. The symbol ○ means the possibility of coordination to metals and × the reverse. As seen in Table 5, all the ligands can act as N_1–O_3 type to both cobalt(III) and chromium(III). NIPDA can not behave as N_1–O_2 type for both metals. This may be due to some steric hindrance of CH_3 group and/or the lesser acidities of NIPDA than the other two. NPDA can not behave as O_3 type. This is because the ligand of the 5,5 and 6 membered rings (NPDA) makes the more stable complex than that of 5,5 and 5 membered rings (NTA and NIPDA).[11,17] However, NTA and NIPDA can not act O_3 type to cobalt(III). This may mean that the cobalt has greater affinity to nitrogen than to oxygen.

Table 5. Chelating behaviors of ligands

Ligands	Type	Number of coordinated doner atoms	Chromium(III)	Cobalt (III)
NTA	N_1–O_3	4	○	○
	N_1–O_2	3	○	○
	O_3	3	○	×
NIPDA	N_1–O_3	4	○	○
	N_1–O_2	3	×	×
	O_3	3	○	×
NPDA	N_1–O_3	4	○	○
	N_1–O_2	3	○	○
	O_3	3	×	×

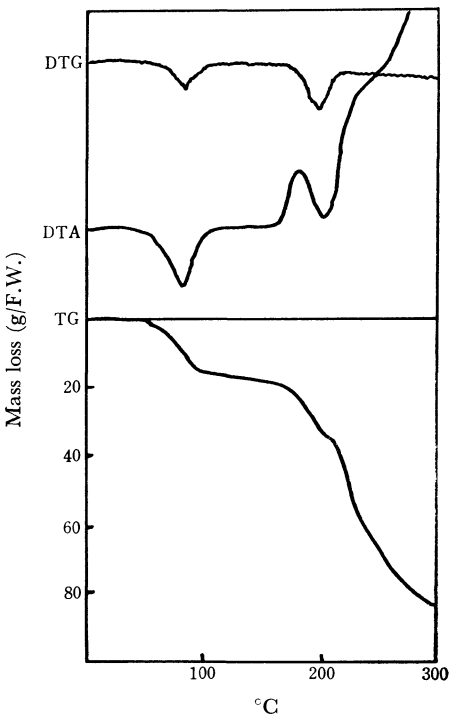

Fig. 3. Derivatogram for complex VII.

Observations of Thermal Decomposition Processes on Complex VII. The thermal decomposition processes of the complex VII were investigated by means of Derivatograph. The measurement was carried out in a constant nitrogen stream at a heating rate of 1°C/min. 500 mg of the samples was used. The derivatogram is shown in Fig. 3. Complex VII lost one mole of crystalline water at 100°C, and the mass loss corresponding to one mole of water is detected at *ca.* 180—200°C. It is of interest to note that the exothermic reaction is detected on DTA curve even in the dehydration process. At this step the color of the sample changed from bluish violet to reddish violet as in the case of the corresponding LDA complex (LDA: *l*-leucine-*N*,*N*-diacetic acid).[18] From this result, it is considered that dimerization may occur at this step, and result in the formation of diol complex such as $K_2[(nipda)Co\langle^{OH}_{OH}\rangle Co(nipda)]$.

The authors wish to thank the Ministry of Education for the financial support granted for this research.

(Received September 16, 1969)

We have prepared a variety of binuclear and trinuclear complexes of the composition Cu(TDSB)·MX_2 and 2Cu(TDSB)·$M(ClO_4)_2$, where Cu(TDSB)=*N,N'*-ethylenebis(salicylideneiminato)copper(II) or *N,N'*-1,2-propylenebis(salicylideneiminato)copper(II), and M=Co, Ni, Cu and Zn. A few higher polynuclear species were also prepared. The previously reported empirical rule found in binuclear copper(II) complexes, where the two copper ions are in the same environment, that the "higher energies of *d–d* bands - lower magnetic moments," was proved to hold in the binuclear copper complexes of the present study, even though the two copper ions are in different environments. For a series of complexes with M = Cu or other metals, and with X = NO_3 or ClO_4, it was observed that "*d–d* bands of Cu(TDSB) apperas at the shortest wavelengths when M = Cu." For perchlorate complexes, the energy of the *d–d* band is in the order, Co<Ni<Cu>Zn, the same as the Irving and Williams' order of complex stability. It can then be generalized that in a hetero-polynuclear complex molecule, the strengthening of the coordinate bonds around one metal ion strengthens the coordinate bonds around the other metal ion or ions.

Previously we reported the correlation between the magnetism and spectra in binuclear copper(II) halide complexes with pyridine *N*-oxides or salicylideneimines.[1-4] As an extension of these investigations we have been studying a variety of polynuclear complexes derived from copper(II) chelates with tetradentate salicylaldimine-Schiff's base and one of the following metal salts: Cu(II), Ni(II), Co(II) and Zn(II) as the chloride, nitrate, and perchlorate. About the time of the completion of this study, Gruber reported magnetic and spectral studies of similar polynuclear complexes.[5-8]

We are therefore reporting in this paper only the data of the complexes which were not included in their papers except those which are necessary for our discussion. Many of Gruber's and our complexes are adducts with different solvent molecules. Often, too, the numerical values of the data differ in details from each other. The spectral data necessary for the discussion of the stereochemistry are shown in the attached figures.

The present study was initiated to investigate the change in magnetic interaction or spectral properties of binuclear copper(II) complexes when the two copper ions were present in different environments. The rule, "higher energies of *d–d* band - lower magnetic moments," previously observed for the homo-binuclear copper(II) complexes, was to be tested for hetero-binuclear copper(II)

$2Cu(Pn\text{-}Sal)\cdot Cu(ClO_4)_2$	$2H_2O$	$2H_2O$ (dark violet)
$2Cu(Pn\text{-}Sal)\cdot Cu(ClO_4)_2$	X	en (greyish green)
Cu(En-AcAc)		non-adduct (dark violet)
$2Cu(En\text{-}AcAc)\cdot Cu(NO_3)_2$	X	H_2O (greyish brown)

†1 The symbol(X) in column of Gruber's indicates the complexes which are reported in the present study but not described by Gruber and co-workers.

†2 Cu(En-Sal), Cu(Pn-Sal) and Cu(En-AcAc) are used as abbreviations for *N,N'*-ethylenebis (salicylideneiminato)copper(II), *N,N'*-1,2-propylenebis (salicylideneiminato) copper (II) and *N,N'*-ethylenebis (acetylacetoneaminato) copper (II) respectively. en=ethylenediamine, py=pyridine

†3 Color of the complexes was given in parentheses in the third column.

complexes.*2 The mutual stereochemical interaction between local metal complexes which may occur when more than two metal atoms were present in a molecule, was another interesting point under examination.

The complexes of this study is given in Table 1; some of Gruber's complexes are also included to indicate the difference in the solvation.

Experimental

I. Preparation of Complexes. *A. Materials.* Salicylaldehyde, ethylenediamine, 1,2-propylenediamine (Tokyo Kasei Kogyo's Guaranteed Reagent), metal nitrates, chlorides (Wako Pure Chemical Industries' JIS Special Grade), anhydrous cupric chloride (Fisher Certified Reagent) and perchlorates (K & K Laboratories) were obtained commercially.

B. General Method of Preparation. In a typical preparation, an ethanolic solution of a metal salt was added through a quantitative filter paper to one of the recrystallized parent copper(II) complexes, Cu(En-Sal), Cu(Pn-Sal) or Cu(En-AcAc) in a flask equipped with a condenser. For binuclear complexes, the mole ratio of a chloride or a nitrate to parent complex was 1.1 : 1, *i. e.*, ten per cent excess of the metal salt over the stoichiometric quantity. For the preparation of trinuclear complexes, the mole ratio of the perchlorate or nitrate to the parent complex was 1.1 : 2. The ethanolic mixture in the flask was stirred on a hot plate for two hours to complete the reaction. The product was

*2 In this paper, the words, hetero- and homo-, are used to indicate the ligand field environments in a polynuclear complex molecule which are essentially different and the same respectively.

filtered off on a glass filter, washed several times with ethanol and once with ether, and dried at 40—50°C.

C. Preparation of Specific Complexes. a) Cu(En-Sal). $Cu(NO_3)_2$. A crude product was prepared by stirring a mixture of Cu(En-Sal) and $Cu(NO_3)_2 \cdot 3H_2O$ in a 1 : 1 mole ratio in ethanol at room or at an elevated temperature. The product was filtered off, washed with a mixture of ether and ethanol, and dried at 50°C. The pure compound can be prepared by refluxing a recrystallized Cu(En-Sal)·$Cu(NO_3)_2 \cdot 1.5CH_3OH$ in ethanol.

b) Cu(En-Sal)·$Cu(NO_3)_2 \cdot 1.5CH_3OH$. Crude Cu(En-Sal)·$Cu(NO_3)_2$(5 g) was dissolved by heating in 150 m*l* of methanol containing one gram of $Cu(NO_3)_2 \cdot 3H_2O$. The hot solution was filtered through a quantitative filter paper into a flask. To the filtrate were slowly added 30 m*l* of ether and then 120 m*l* of petroleum ether. The precipitated complex was filtered off, washed with ether containing a small amount of methanol and then with a large amount of ether, and dried at 40—45°C. Yield 2.4 g.

c) Cu(En-Sal)·$Cu(NO_3)_2 \cdot 1.5CH_3OH \cdot H_2O$. Crude Cu(En-Sal)·$Cu(NO_3)_2$(5 g), dissolved in 190 m*l* methanol on a hot plate and the hot solution was passed once through a quantitative filter paper. To the filtrate, 15 m*l* of ether and then 130 m*l* of petroleum ether were slowly added. The product was collected on a glass filter, methanol and ether were added with stirring, and then sucked off. After washing with ether it was dried at 40—45°C, yield 2.9 g.

d) Cu(En-Sal)·$Cu(NO_3)_2 \cdot 4Py$. Three grams of Cu(En-Sal)·$Cu(NO_3)_2$, dissolved in 190 m*l* of pyridine on a hot plate were filtered through a quantitative filter paper into a flask. Petroleum ether was added until precipitation just occurred. The mixture was allowed to stand for one to two weeks at room temperature with occasional shaking. The product was washed with ether several times, and dried at 50°C,

yield 1.9 g.

e) $2Cu(Pn\text{-}Sal)\cdot Cu(ClO_4)_2\cdot en$. To a mixture of recrystallized $Cu(en)_2(ClO_4)_2$(2.8 g) and Cu(Pn-Sal) (5.2 g) in a flask, was added a solution of $Cu(ClO_4)_2\cdot 6H_2O$ (3 g) in methanol (130 m*l*). The methanolic mixture was stirred on a hot plate under reflux for three hours. The reaction product was carefully poured into another flask in order to separate it from the small amount of unreacted $Cu(en)_2(ClO_4)_2$. To this, was added 0.2 g of pure $Cu(Pn\text{-}Sal)\cdot Cu(ClO_4)_2\cdot 2H_2O$ and, with stirring, refluxed for five hours more. The dark green fine crystals were washed on a glass filter several times with methanol and once with ether and dried at 80°C, yield 6 g.

f) $2Cu(Pn\text{-}Sal)\cdot Zn(NO_3)_2\cdot 1.5CH_3OH\cdot 2H_2O$. Cu-(Pn-Sal) (2.5 g) and $Zn(NO_3)_2\cdot 6H_2O$ (2.5 g), dissolved in methanol (25 m*l*) by heating gently, was filtered into a flask and allowed to stand until precipitation started. Ether was added to the supernatant to complete the precipitation. The crude material (3.2 g), after dissolving by warming in methanol (20 m*l*), and filtering through a quantitative filter paper into a flask, was placed in a vacuum desiccator. The filtrate was concentrated to one third of its original volume by warming gently under gentle suction. Ether was added to it and the precipitated violet powder was washed on a glass filter with a mixture of ether and methanol several times and once with ether, and dried at 40°C. Yield 2.5 g.

g) $Cu(Pn\text{-}Sal)\cdot Zn(NO_3)_2$. The crude material was prepared by treating a mixture of Cu(Pn-Sal) (3 g) and $Zn(NO_3)_2\cdot 6H_2O$ (3 g) in 30 m*l* of ethanol according to the method of (f). Yield 3.8 g. This was dissolved in methanol (30 m*l*) and filtered through a quantitative filter paper into a flask. By alternatively adding small portions of ether and petroleum ether in volume ratio of 2 : 1 at a time precipitation occurred. The precipitate was filtered, washed with a mixture of ether and methanol twice and once with ether, dried at 95°C, yield 2.7 g.

h) $2Cu(En\text{-}AcAc)\cdot Cu(NO_3)_2\cdot H_2O$. A mixture of Cu(En-AcAc) and $Cu(NO_3)_2\cdot 3H_2O$ in mole ratio of 2 : 1 was dissolved in methanol. The brown solution was concentrated to a certain volume in an evaporator and ether was added to it. The crude product (2.7 g) was dissolved in hot methanol (13 m*l*), filtered through a quantitative filter paper into a flask, and concentrated in an evaporator until precipitation began to occur. After slowly adding 20 m*l* of ether to it, the product was washed with a mixture of ether and methanol several times and once with ether, and dried at 40°C, yield 2 g.

The analytical data for all the complexes are listed in Table 2.

II. Magnetic Susceptibility Determinations. These data were obtained by the Gouy method at room temperature. The molar susceptibility, χ_M, was corrected using Pascal's constants, for the diamagnetism

*) vs=very strong s=strong w=weak vw=very weak sh=shoulder br=broad dp=double peak, two bands in succession

*, † =the main *d–d* bands of copper(*) and of metal other than copper (†) which were employed in the discussion of the structure of complexes.

of all the atoms in the complexes.[9,10] For the complexes containing only copper atom as paramagnetic ions, the magnetic moments were calculated per copper atom from the expression $\mu_{eff}=2.83\sqrt{\chi_M/n\cdot T}$ B.M., where n is the number of copper atoms in a molecule. For the complexes in which paramagnetic ions other than copper are present, the magnetic moments were calculated using $\mu_{eff}=2.83\sqrt{\chi_M\cdot T}$ B.M. The temperature-independent paramagnetism associated with the paramagnetic ions was not included in the calculation of μ_{eff} throughout this work. For binuclear copper(II) complexes with subnormal magnetic moments, the moments observed at room temperature were corrected for minor room temperature variations to those at 25°C, $\mu_{ref}^{25°C}$, by using Bleaney and Bowers' equation assuming $g=2.2$.[11,12] These results are given in Table 3.

III. Diffuse Reflectance Spectral Measurements. The 340—2000 mμ region was investigated on a Hitachi EPS-3T recording spectrophotometer with the use of a reflectance attachment, and optical grade lithium fluoride was used as the standard of light reflectance. Instead of diluting the compounds with the reference material, appropriate absorbancy ranges were selected by controlling the sensitivity knobs on the spectrophotometer. The band maxima of these complexes are recorded in Table 4.

IV. Infrared Spectral Measurements. Infrared spectra were taken in 4000—1200 cm^{-1} region on Low-Polymerized Trifluoroethylene mulls and in 1300—400 cm^{-1} region on Nujol mulls on a Hitachi EPI-G2 model of infrared spectrophotometer. A part of the data are given in Table 5.

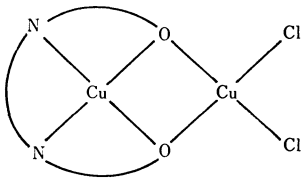
** sp=sharp For other symbols, see the footnote of Table 4. The band(†) was assigned to the C–O stretching vibration in chelation by K. Ueno and A. E. Martell (*J. Phys. Chem.*, **59**, 998 (1955)).

Results and Discussion

I. General Discussion of Complex Structures. One of the interesting points of studies of polynuclear complexes would be in the observation of the reaction conditions whose minor difference yields different type of complexes (*cf. e. g.*, C-(f) and -(g), the formation of a binuclear and trinuclear complex by reaction of Cu(Ph-Sal) and $Zn(NO_3)_2$). Sometimes, even minor change in the structure of a parent complex or difference in anion part of salts with the same metal gives rise to occurrence of metal exchange reactions; *e. g.*, the copper atom in Cu(Pn-Sal) was exchanged with nickel in ethanol when nickel chloride was employed but no such reaction occurred when nickel nitrate or perchlorate was used under the same reaction condition.

Although the structure of these complexes is unknown at present, Gruber and his co-workers fully discussed probable structures from the con-

sideration of steric hindrance.[7] They proposed the following type of binuclear structure for complexes with the chemical formula, Cu(TDSB)·$CuCl_2$.*3



(i)

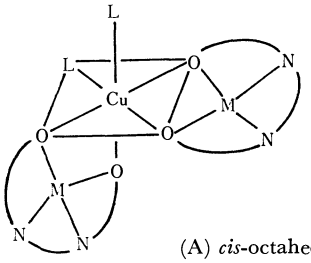
The most powerful supporting evidence for the binuclear structure is the conformation of the magnetic properties of these complexes to the Bleaney and Bowers' equation.[5-7,11]

The complexes with the chemical formula, Cu(TDSB)·$Cu(NO_3)_2$ (*cf.* Table 1) have not been reported by Gruber and co-workers. We assume for these nitrato complexes a binuclear structure of the same type as the chloro complexes based upon the following observations:

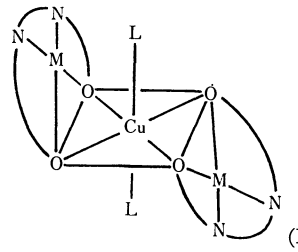
1. The observed subnormal magnetic moments are even lower than those of the corresponding chloro complexes.

2. The appearance of C–O stretching vibration near 1550 cm^{-1}, which is a powerful indication of the presence of bridging phenolic oxygens.[7,13,14] The properties of Cu(TDSB)·$M(NO_3)_2$(M=Ni, Co and Zn) will be discussed assuming that their structures are the same as those of Cu(TDSB)·$Cu(NO_3)_2$.

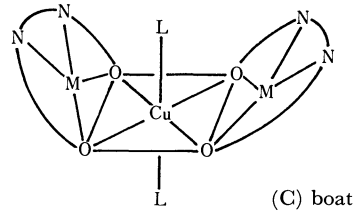
To complexes with formula, 2Cu(TDSB)·$M(ClO_4)_2$(M=Cu, Ni, Co, Zn and other metals), Gruber and co-workers proposed three probable trinuclear structures shown below (ii-A, B and C).



(A) *cis*-octahedral type



(B) chair type



(C) boat type

(ii)

L = solvent molecule attached to the central copper atom

They preferred the *cis*-octahedral type (ii-A). Their recent study of temperature variations of magnetic susceptibilities supported the trinuclear structure for this series of complexes; no appreciable magnetic interaction exists between terminal magnetic ions.[8] However, such magnetochemical studies do not distinguish among a number of probable trinuclear structures.

II. Binuclear Complexes. *A. Infrared Spectra.* a) Band of Bridging Phenolic Oxygen. A shift of the phenolic C–O stretching band of Schiff's base complexes from 1530 cm^{-1} to near 1550 cm^{-1}, can be taken as diagnostic of the formation of polynuclear complexes with bridging phenolic oxygen. Such shift of C–O stretching band toward higher wave numbers was also observed for these complexes.

b) Band of Nitrato Group. The following bands due to coordinately bound nitrato groups[15-22] were observed for Cu(TDSB)·$M(NO_3)_2$,

*3 In this paper, Cu(TDSB) is used for the abbreviation for a copper(II) complex with a tetradentate Schiff's base, and it is schematically expressed as

ν_4 1490—1510 cm^{-1}

ν_1 1290—1310 cm^{-1}

ν_2 1000—1020 cm^{-1}

ν_6 805— 825 cm^{-1}

The band designation follows Gatehouse and others.[16-18] In most cases, two peaks appeared in the respective absorption regions. This may be due to one of the following:

1. Further splitting of the respective bands may be caused because of a lower symmetry of the nitrato group in complexes possibly due to solid state effects.

2. Two differently bound nitrato groups may be present in the complex. According to Curtis and Curtis,[21] the band (ν_4) of a bi-dentate nitrato region appears at a higher frequency than that of a mono-dentate nitrato group. The other bands (ν_1, ν_2 and ν_6) of a bi-dentate nitrato group appear at lower frequencies compared to those of a mono-dentate nitrato group.

At present infrared spectral study in the NaCl region alone can not distinguish between these possibilities.

The (ν_2) band was taken by Nyholm *et al.* as a criterion of the degree of covalency of metal-nitrate bond.[16,17] A low frequency of this band indicates a high degree of covalency of the bond and *vice versa*. The observed frequency range of the band (ν_2) of the complexes in the present study, near 1000 cm^{-1}, indicates a fairly strong covalent character of the metal-nitrate bond in these complexes.

B. Magnetic Moments and d-d Bands. a) General Consideration for Chloro and Nitrato Complexes. These copper(II) complexes showed, in general, two *d-d* bands which appeared at two distinctly different wavelength regions (*cf.* Fig. 1 and Table 4). These two *d-d* bands are assigned to the two copper ions which are placed in different environments. From the spectrochemical series the *d-d* bands of higher energies of the chloro and nitrato complexes are assigned to Cu_1 and those of lower energies to Cu_2.[23]

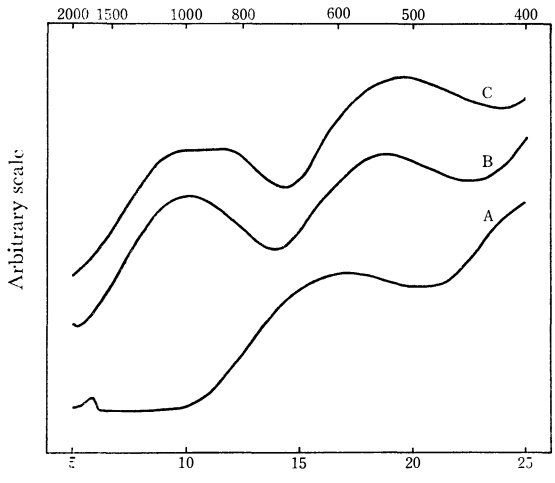

Fig. 1. Reflectance spectra of Cu(En-Sal) (curve A), Cu(En-sal)·$CuCl_2$·0.$5C_2H_5OH$ (curve B) and Cu(En-Sal)·$Cu(NO_3)_2$ (curve C).

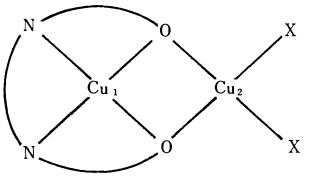
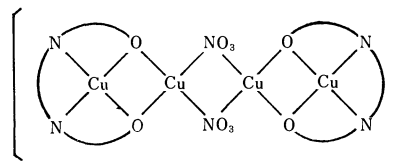


(X=Cl and NO_3) (iii)

Gruber's χ-T study have indicated that the chloro complexes should have a dimeric structure. At present, no χ-T data are available for the nitrato complexes. The complexes with the chemical formula, Cu(TDSB)·$Cu(NO_3)_2$, could be higher polymers such as [Cu(TDSB)·$Cu(NO_3)_2$]$_n$(n=2,3, ···). When n=2, one probable structure is as such given in (iv), where outer nitrate groups may be bound weakly to the metal atoms in the complex ion. Even though such a structure is not inconsistent with the infrared spectral data (*cf.* II-A-b), we



(iv)

shall assume a dimeric structure resembling to those of the chloro complexes.

Gruber and co-workers pointed out that when Cu(TDSB) complexes with metal halides or metal perchlorates, the main ligand field transitions shift to higher energies. This was confirmed in the present study and shown to hold also for complexes with metal nitrates. The main *d-d* band of Cu(En-Sal) appears at a much longer wavelength (590 mμ). This fact is consistent with its dimeric structure in which each copper atom is five coordinated with a pyramidal arrangement.[24] The band of Cu(Pn-Sal) appears at 566 mμ.

On complexing, the main *d-d* band of these Cu(TDSB) shifts towards 540—505 mμ, which is at shorter wavelengths than that of bis(ethylenediamine)copper(II) ions in various ligand field

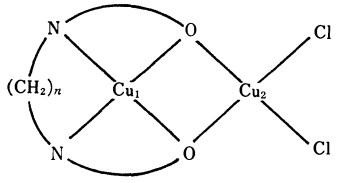
23) C. K. Jørgensen, "Absorption Spectra and Chemical Bonding in Complexes," Pergamon Press, New York, N. Y. (1962), p. 107.

24) D. Hall and T. N. Waters, *J. Chem. Soc.*, **1960**, 2644.

environments,[25,26] and quite close to that of the copper(II) complexes of planar type.[27-29]

The *d–d* transitions of Cu_1 and Cu_2 occur at 515—536 and 945—983 mμ for the chloro complexes and at 506—516 and 855—910 mμ for nitrato complexes respectively. The *d–d* band energy of Cu_2 is greater for nitrato complexes than for chloro complexes in line with their relative positions in the spectrochemical series.[22,23,30]

The magnetic moments of nitrato complexes ranging from 1.25 to 1.45 B. M., are apparently smaller than those of chloro complexes. The empirical rule "higher energies of *d–d* bands - lower magnetic moments" established for dimeric copper(II) halide complexes with pyridine *N*-oxides[3] or salicylideneimines[2,4] where the two copper ions are in essentially the same environment, is apparently also valid for the complex systems of the present study even though each copper ion is placed in a different environment in a dimeric molecule. Gruber and co-workers[7] showed that, for the system,



(n=2, 3,···) (v)

as n increases, the deviation of the stereochemistry of Cu_1 from planarity increases thus bringing about a shift of the *d–d* bands of both Cu_1 and Cu_2 to lower energies indicating "mutual influence of complex moieties in a molecule" in the direction $Cu_1 \rightarrow Cu_2$. However, the present study indicates that the influence in the reverse direction $Cu_1 \leftarrow Cu_2$ also occurs. A shift of *d–d* band of copper(II) complexes to lower energy is correlated with the deviation of stereochemistry of the copper ion from planar to tetrahedral symmetry.[30-33] These are in line with the fact that the more planar the copper(II)-stereochemistry in a binuclear complex, the greater the orbital overlap effective for superexchange interaction between copper ions.[3,4]

b) $Cu(TDSB)\cdot M(NO_3)_2$ (M=Ni, Co and Zn). A binuclear structure of the same type as that for copper(II) nitrate complexes shall be assumed for these nitrato complexes since all showed bridging phenolic oxygen band.[7,13,14] The stereochemistry of M greatly influences the properties of these compounds. Reflectance spectra give reasons for many of these properties.

1) M=Ni(II): Spectral data rule out square-planar, tetrahedral[34-40] and the five coordinated configurations.[34-36,41-44] The spectra best fit those

of Ni(II) complexes with octahedral configurations (*cf.* Fig. 2).[35,45-47] The bands at *ca.* 1200 mμ were assigned to $^3A_{2g}\rightarrow{}^3T_{2g}$ transition and those at 740—750 mμ to $^3A_{2g}\rightarrow{}^3T_{1g}$(F). The characteristic feature of the latter band, which occurs often in double peaks ($^3A_{2g}\rightarrow{}^3T_{1g}$(F) and $^3A_{2g}\rightarrow{}^1E_g$), has become partly hidden by the absorption end of the stronger band of the Cu(TDSB) moiety. The band due to transition, $^3A_{2g}\rightarrow{}^3T_{1g}$ (P), expected at *ca.* 400 mμ, could not be observed, being hidden by the stronger absorption due to *d–d* transition of Cu(TDSB) as well as the strong absorption of charge transfer region.

2) M=Co(II): For Co(II) complexes with nitrato groups, the most probable stereochemical environment of Co(II) is octahedral based on a similar consideration to that for Ni(II).[20,34-36,42,46-60] The bands at *ca.* 1200 mμ were assigned to $^4T_{1g}$(F)$\rightarrow{}^4T_{2g}$(F). The absorption due to transition, $^4T_{1g}$(F)$\rightarrow{}^4T_{1g}$(P) which is expected at *ca.* 500 mμ, was not observed, being hidden by the stronger copper(II) band at 520 mμ.

3) M=Zn(II): Surprisingly the *d–d* band of Cu(TDSB) of this compound appeared at a shorter wavelength (520 mμ) than those for Co(II) and Ni(II) complexes (540—532 mμ). The same trend was observed for Cu(TDSB)·$ZnCl_2$ (*cf.* Table 4 and Fig. 4). The "mutual influence of complex moieties" is out of line here compared to that observed in Cu(TDSB)·CuX_2 (X=Cl and NO_3). It is rather difficult to give a clear-cut explanation for this inconsistency. However, a conceivable mechanism for this conflict may be found in the tetrahedral coordination of the Zn(II) ion and subsequent steric influences. This may decrease the ligand field exerted from neighboring molecules or ions on the fifth or sixth coordination positions of the copper(II) ion in Cu(TDSB).[3,4] Such steric effect might then exceed the effect of the "mutual influence of complex moieties" in a dimeric complex molecule.

c) Other Nitrato Complexes. 1) Cu(En-Sal)·$Cu(NO_3)_2\cdot 1.5CH_3OH\cdot H_2O$: The band ν_{C-O} of this compound appeared at 1544 cm^{-1}. This frequency is somewhat low compared to the band due to bridging phenolic oxygen present in the most binuclear complexes (*ca.* 1550 cm^{-1}).[7,13,14] The *d–d* band appearance of this compound makes it difficult to distinguish between Cu_1 and Cu_2 bands.

The spectral feature of this compound differes from that of most binuclear chloro and nitrato copper(II) complexes but resembles that of the pseudo-tetrahedral binuclear complexes, $[Cu(\overset{1}{O}\cdot C_6H_4\cdot\overset{2}{C}H{=}N{-}R)Cl]_2$ (R=alkyl or aryl groups) (*cf.* Fig. 3).[4,30-33,37,53] The magnetic moment of this compound, 1.75 B.M., is consistent with these facts.

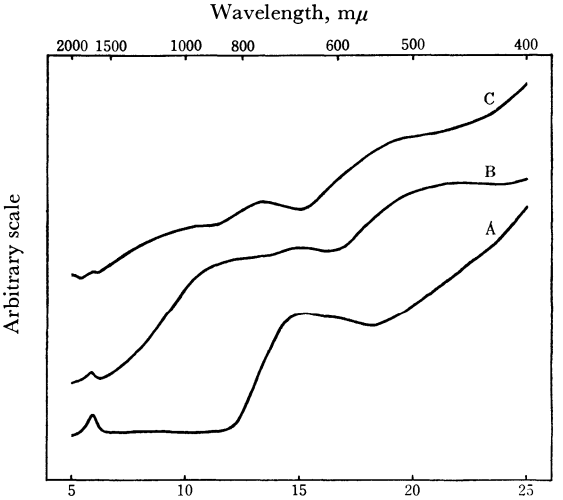

Fig. 3. Reflectance spectra of Cu(Sal·N-CH_3)$_2$ (curve A), [Cu(Sal·N-CH_3)Cl_2] (curve B) and Cu(En-Sal)·$Cu(NO_3)_2\cdot 1.5CH_3OH\cdot H_2O$ (curve C). Sal·N-$CH_3{=}\overset{1}{O}\cdot C_6H_4\cdot\overset{2}{C}H{=}N{-}CH_3$

2) Cu(En-Sal)·$Cu(NO_3)_2$·4Py: The ν_{C-O} frequency of this compound (1530 cm^{-1}) indicates the absence of bridging phenolic oxygen. The magnetic moment, 1.87 B.M., is consistent with this observation. This compound showed two main *d–d* bands at 585 and 1005 mμ due to two copper(II) ions in different ligand fields.

d) Cu(TDSB)·MCl_2(M=Co and Zn). 1) M=

Co(II): These greyish violet complexes showed three main absorption bands in the 340—2000 mμ region near 565, 660 and 1520 mμ respectively. No peak was observed in the 520 mμ region where most of these complexes showed a broad band due to the *d–d* transition of Cu(TDSB). Instead, a sharp band appeared in the region at *ca.* 565 mμ. This band can not be assigned to the *d–d* band of Cu(TDSB) because of its shape and absorption position (*cf.* Fig. 4). It seems reasonable that in

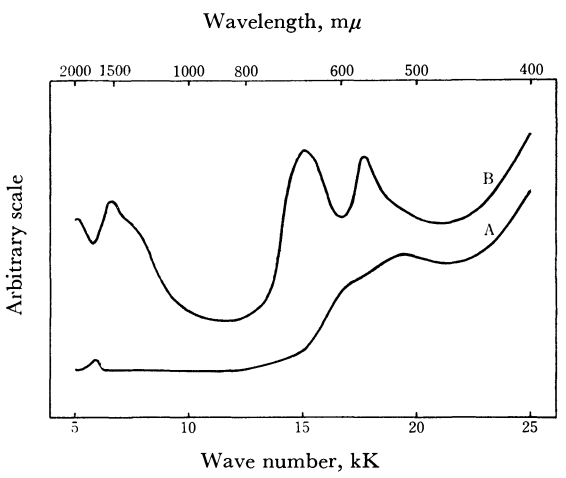

Fig. 4. Reflectance spectra of $Cu(En\text{-}Sal)\cdot ZnCl_2$ (curve A) and $Cu(En\text{-}Sal)\cdot CoCl_2\cdot 0.5C_2H_5OH$ (curve B).

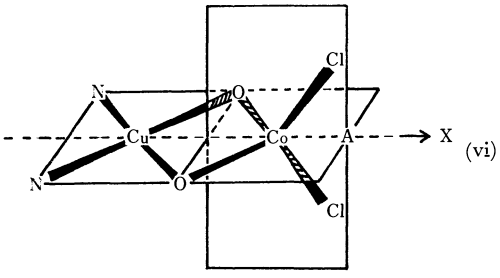
these complexes the band of Cu(TDSB) is hidden under the stronger absorption of Co(II).[50,52] The observed spectra are different from those of octahedral and planar cobalt(II) complexes[35,36,46,47] and are similar to that of tetrahedral Co(II);[34,35,48-55] they have also a resemblance to those of trigonal bipyramidal Co(II).[36,41,42,44,56-60] X-ray analysis of metal complexes often shows them as an intermediate of fundamentally different geometries.[42] An environment of Co(II) for such an intermediate of tetrahedral and trigonal bipyramidal configurations in the presence of ligand A is shown below.

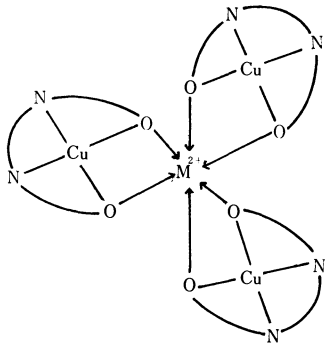


(vi)

Here, A=a solvated molecule or a neighboring molecule or ion which exerts a ligand field on the Co(II) ion in the x direction.

2) M=Zn(II): discussed previously (*cf.* (b)-3).

III. $2Cu(TDSB)\cdot M(ClO_4)_2$. *A. Formation.*[*4] The ease of formation of trinuclear complexes from metal perchlorate and Cu(TDSB) in alcoholic solution is partly due to the very weak coordinating ability of perchlorate ion. In complex formation from Cu(TDSB) and $M(ClO_4)_2$, the ligands to coordinate to M^{2+} are firstly the complex ligand (Cu(TDSB)) and secondly solvent molecules. In a metal with coordination number of six, two molecules of Cu(TDSB) acting as a bidentate ligand, will occupy four positions, and the remaining two coordinating sites will be occupied by solvent molecules. Steric consideration does not allow three molecules of Cu(TDSB) to attach to one metal without a large amount of strain, *i. e.*, the formation of a tetranuclear complex of the following type does not seem possible for the first transition elements.[7] Such steric condition encountered here



(vii)

is similar to that observed for complex formation of nickel (II) with 2,9-dimethylphenanthroline, where even a large excess of the ligand gave only a bis-complex for steric reason.[61]

Recent X–T studies by Gruber and co-workers supports the trinuclear formation for these perchlorate complexes.[8] For metal chloride or nitrate, the anions have a much greater coordinating ability than the perchlorate ion, and the central metal coordinates with either of the complex ligand and chloride or nitrate ion. Under such conditions, it becomes difficult for one central metal ion to combine with more than a molecule of the complex ligand, leading to the formation of a binuclear complex rather than a trinuclear one. However, in some cases metal nitrates can form trinuclear

[*4] Metal analysis does not distinguish between the chemical compositions of a binuclear and a trinuclear complex. For instance, per cent of copper is 19.36% for $Cu(En\text{-}Sal)\cdot Cu(ClO_4)_2\cdot 2CH_3OH$(dimer) and 19.26% for $2Cu(En\text{-}Sal)\cdot Cu(ClO_4)_2\cdot CH_3OH\cdot 2H_2O$(trimer) respectively, practically the same values within the accuracy of our metal analysis, ±0.5%. At the meeting[*1-b] this was pointed out and a trimeric formula was presented for the dimeric one in the proceedings based on Cu and C.H.N. analysis.

61) K. Sone and M. Kato, *Naturwissenschaften*, **45**, 10 (1958).

complexes as in 2Cu(Pn-Sal)·$Zn(NO_3)_2$ or 2Cu(En-AcAc)·$Cu(NO_3)_2$, where nitrate ion has a stronger coordinating ability than chloride ion in line with the spectrochemical series. This suggests that coordinating ability of the anions is not the only factor determining the formation of these polynuclear complexes. Packing or steric effect, or other factors must be considered to be cooperating in this phenomenon.

B. Spectral Features. The spectra of complexes with Cu(En-Sal) are given in Fig. 5. Of all the

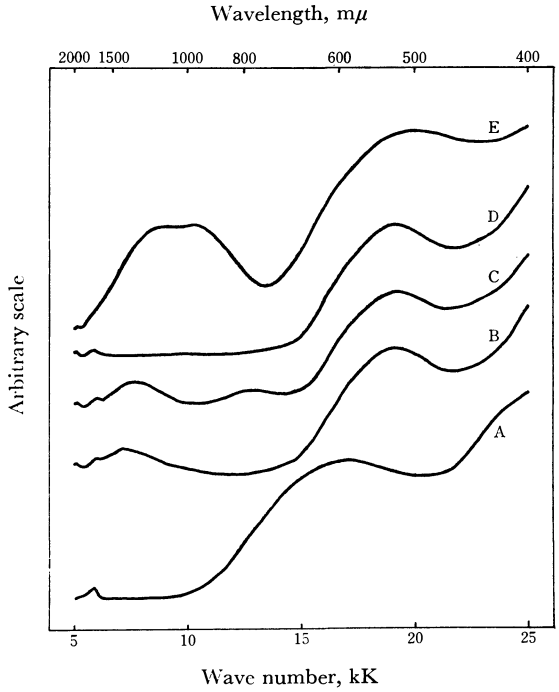


Fig. 5. Reflectance spectra of Cu(En-Sal) (curve A), 2Cu(En-Sal)·$Co(ClO_4)_2$·$2H_2O$ (curve B), 2Cu(En-Sal)·$Ni(ClO_4)_2$·$2H_2O$ (curve C), 2Cu(En-Sal)·$Zn(ClO_4)_2$·$2.5H_2O$ (curve D) and 2Cu(En-Sal)·$Cu(ClO_4)_2$·CH_3OH·$2H_2O$ (curve E).

chloride, nitrate and perchlorate complexes, the *d–d* transitions of Cu(TDSB) always occur at shortest wavelengths when they combine with copper(II) salts. The spectral features of Co(II) and Ni(II) complexes indicate octahedral complexes though the absorptions at wavelengths shorter than 600 mμ are hidden by the stronger absorption of the complex ligand (Cu(TDSB)).

The bands of the central metal ions in perchlorate complexes appear at a lower energy than those of the nitrate complexes. This makes it possible to observe the familiar doublet band of nickel(II) complexes (near 700 mμ) separate from the absorption due to the complex ligand. It is noteworthy that for the perchlorate complexes the *d–d* transitions due to Cu(En-Sal) are in the order from lower to higher energy, Co<Ni<Cu>Zn or Co<Zn<Ni<Cu, the same as the Irving and Williams' sequence for complex stability.[62]

The antiferromagnetic exchange interaction of trinuclear perchlorate complexes, 2Cu(TDSB)·$M(ClO_4)_2$ increases in the order, M=Co<Ni<Cu,[8] is the same as observed for the energy of copper(II) band of Cu(TDSB) in trinuclear complexes of the same type.

C. Some Specific Complexes. a) 2Cu(Pn-Sal)·$Cu(ClO_4)_2$·en. This compound has a chemical formula in which the two water molecules in 2Cu(Pn-Sal)·$Cu(ClO_4)_2$·$2H_2O$ are replaced with one ethylenediamine molecule. Such an apparently minor change in the chemical formula, however, gives rise to a great deal of change in its properties. The ethylenediamine compound is greyish green, and the dihydrate compound is violet. The former has only one *d–d* band due to copper(II) at 583 mμ but the dihydrate, as most polynuclear copper(II) complexes of the present study, has two copper(II) bands at greatly different wavelengths, *i.e.*, at *ca.* 520 and 900—1000 mμ respectively (*cf.* Fig. 6).

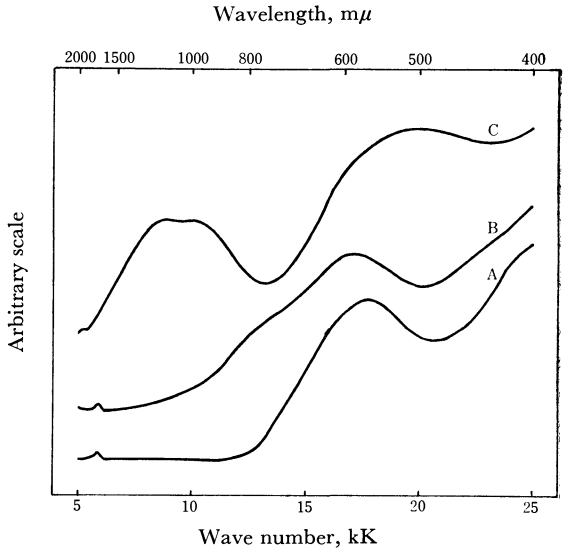

Fig. 6. Reflectance spectra of Cu(Pn-Sal) (curve A), 2Cu(Pn-Sal)·$Cu(ClO_4)_2$·en (curve B) and 2Cu(Pn-Sal)·$Cu(ClO_4)_2$·$2H_2O$ (curve C).

This suggests that in the ethylenediamine complex the copper ions are in practically the same environment whereas in the dihydrate the environment is greatly different for each copper(II) ion. The mechanism by which the two copper(II) ion bands merge into one absorption, and the coordination behavior of ethylenediamine in this complex are under study.[63]

62) F. J. C. Rossotti, "Modern Coordination Chemistry," ed. by L. Lewis and R. G. Wilkins, Interscience Publishers, New York, N. Y. (1960), p. 1.
63) Ref. 15, p. 186.

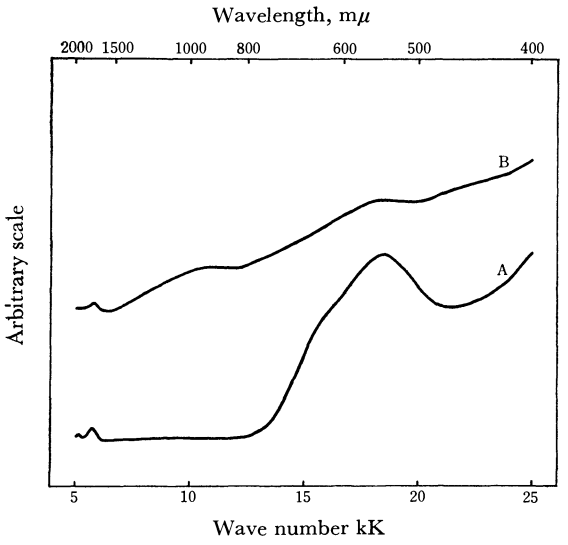

Fig. 7. Reflectance spectra of Cu(En-AcAc) (curve A) and $2Cu(En\text{-}AcAc)\cdot Cu(NO_3)_2\cdot H_2O$ (curve B).

b) $2Cu(En\text{-}AcAc)\cdot Cu(NO_3)_2\cdot H_2O$. The spectral features of this compound indicate a pseudo-tetrahedral copper(II) complex (*cf.* Fig. 7).[30-33,37] The structures of Cu(En-Sal)[24] and Cu(En-AcAc)[64] determined by X-ray analysis indicate that the steric hindrance due to these complex ligands in the formation of the polynuclear complexes is greater in Cu(En-AcAc) than in Cu(En-Sal). The magnetic moment, 1.76 B.M. suggests the existence of an antiferromagnetic interaction in this compound.[3,4]

One area of the further development of the present study will involve the systematic research for the conditions under which even minor changes in the structure of the parent compound lead to the formation of different type of polynuclear complexes, bi-nuclear or tri-nuclear ones, in the cooperation of the specific property of the respective anion of the metal salt employed in the preparation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1078—1083 (1970)

ESR Studies of Some Copper(II) β-Diketone Chelate Complexes in Heterocyclic Basic Solvents

Hiroshi Yokoi, Mitsuru Sai and Taro Isobe

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received September 9, 1969)

Three representative copper(II) β-diketone chelate complexes, bis-(ethylacetoacetato)copper-(II), bis-(salicylaldehydato)copper(II), and bis-(acetylacetonato)copper(II), have been investigated by the ESR method in order to estimate their structures in various solvents. The super-hyperfine structures due to the equal coupling of the unpaired electron with two nitrogen atoms were clearly observed for the first two complexes dissolved in pyridine or γ-picoline. The structures of these two complexes in pyridine or γ-picoline could be estimated to be as follows; a new square-planar coordination occurs through two nitrogen atoms of these basic solvent molecules and two oxygen atoms of the four originally-coordinating ligand oxygen atoms, and the other oxygen atoms are coordinated as apical ligand atoms with less strength. On the other hand, the ESR spectra of the latter complex dissolved in pyridine or γ-picoline show a significantly strong ligand field only in the axis normal to the molecular plane; this indicates that the coordination of the basic solvent molecules along the axis normal to the molecular plane occurs.

It has been reported by several authors that the reaction of copper(II) β-diketone chelate complexes with some heterocyclic bases generally produces 1 : 1- or 1 : 2-adducts.[1-3] The absorption spectral features of bis-(ethylacetoacetato)copper(II), one of the copper(II) β-diketone chelate complexes, in pyridine and piperidine are quite different from those in other ordinary solvents.[4] The ESR is a powerful and unique technique for the structural

investigation of the copper(II) complexes in the following specific points: it gives much information about the strength and symmetry of the ligand field of the complexes,[5-8] and it is a method of determining decisively whether or not coordination occurs through nitrogen atoms.[9] The purpose of this paper is to estimate the structures of some copper(II) β-diketone chelate complexes in various solvents by the ESR method.

Experimental

Materials. The copper(II) β-diketone chelate complexes employed in this study are bis-(acetylacetonato)-copper(II), bis-(ethylacetoacetato)copper(II), and bis-(salicylaldehydato)copper(II); they are abbreviated as $Cu(acac)_2$, $Cu(acest)_2$, and $Cu(sal)_2$ respectively. Commercially-available $Cu(acac)_2$ was recrystallized from chloroform. The $Cu(acest)_2$ was prepared and purified according to the method in the literature.[2] The $Cu(sal)_2$ was obtained in the usual way reported in the literature by mixing an aqueous solution of cupric acetate with an ethanolic solution of salicylaldehyde, the green product being then filtered off, washed, and dried.[3,10] The adduct of $[Cu(acest)_2(\gamma\text{-picoline})_2]$ was prepared according to the method of Graddon and Watton.[2]

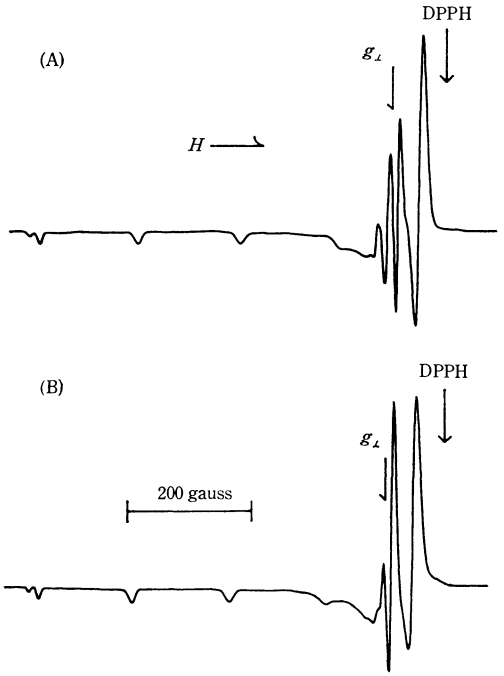

Fig. 1. The X-band ESR spectra of $Cu(acac)_2$ at 77°K.
(A) in 50% chloroform - 50% ethanol
(B) in 20% pyridine - 40% chloroform - 40% ethanol

Measurements. The ESR spectra were measured in solutions at the temperature of liquid nitrogen with a Hitachi X-band ESR spectrometer, Model MES-4001, equipped with a 100 kHz field modulation unit. Furthermore, the second derivative ESR spectra were obtained using 100 kHz-40 Hz field modulations in order to resolve the nitrogen super-hyperfine structure clearly. The field was calibrated with an NMR probe and then with a benzene solution of vanadyl acetylacetonate or with Mn(II) ions in MgO powder. Some of the ESR spectra observed are shown in Figs. 1—7, while the analyzed results are listed in Table 1. All the solvents used were mixed solvents. Almost no change in the ESR results was observed when we varied to some extent the mixing ratios of the solvents listed in Table 1.

Results and Discussion

$Cu(acac)_2$. It has been suggested, on the basis of the optical absorption and ESR spectra, that the physical and chemical properties of the β-diketone copper(II) chelate complexes in solution vary to an appreciable extent according to the kind of solvent used.[4, 11-14] The ESR data of Table 1 also clearly support the above description.

(A) in Fig. 1 shows the ESR spectrum of $Cu(acac)_2$ in 50% chloroform - 50% ethanol (volume %). This spectrum is sharp in its line width and is typical of an axial symmetry in the ligand field. (B) in Fig. 1, where the solvent is 20% pyridine - 40% chloroform - 40% ethanol, is also sharp in its absorption line width and shows the ligand field of an axial symmetry. The ESR spectrum of the complex in 10% pyridine - 90% toluene was quite similar to the (B) in Fig. 1. The absorption line shapes of these spectra indicate that there are not two or more molecular species in solution.

The ESR results of $Cu(acac)_2$ in Table 1 indicate that the addition of pyridine causes the g values to increase and the $|A_{//}|$ value to decrease. This

tendency of the g and $A_{//}$ values means that the ligand field of the complex on the axis normal to the molecular plane is strengthened on the addition of pyridine; the pyridine molecules coordinate to the complex as apical ligands.[8, 13, 14]

$Cu(acest)_2$ and $Cu(sal)_2$. The ESR spectra of $Cu(acest)_2$ and $Cu(sal)_2$ in 50% chloroform-50% ethanol are sharper in absorption line width than are those in other solvents, as may be seen in Figs. 2—5. An exception is the ESR spectrum of $Cu(acest)_2$ in toluene, which is shown in (B) in Fig. 2. This spectrum is different in its absorption line shape from the other spectra; it consists of a very sharp absorption-line spectrum and a broad one superposed upon each other. The former spectrum could be analyzed in the usual way; the results are listed in Table 1. The latter spectrum may be due to the triplet dimer of the complex. The observation of the broad signal at $g \fallingdotseq 2.0$ for the triplet dimers of some copper(II) complexes has been reported.[15] Many planar copper(II) complexes are known to have a dimer structure in the crystal,[16,17] and the dimer formation of those complexes seems to be possible in such a non-coordinating solvent as toluene. A similar spectrum

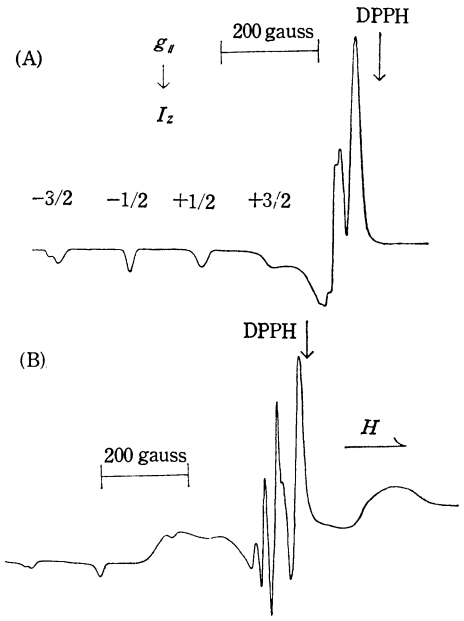

Fig. 2. The X-band ESR spectra of $Cu(acest)_2$ at 77°K.
(A) in 50% chloroform-50% ethanol
(B) in toluene

was observed for $Cu(acac)_2$ in toluene. A detailed investigation of these problems is now in progress.

The addition of pyridine causes the absorption line width to broaden. The (A) of Fig. 3 is very broad in line width, in contrast with the (A) of

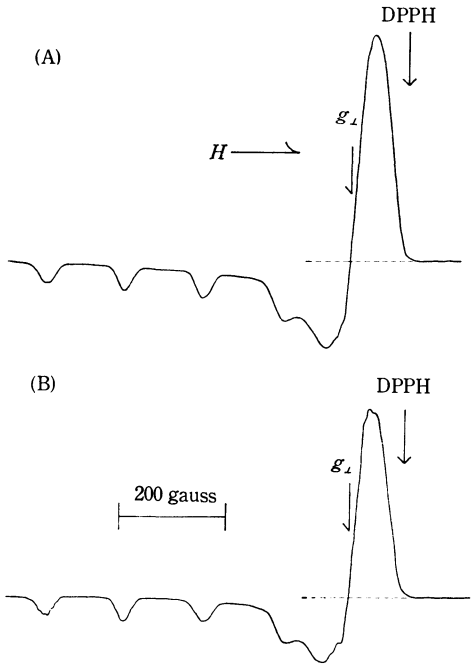

Fig. 3. The X-band ESR spectra of $Cu(acest)_2$ at 77°K.
(A) in 20% pyridine - 40% chloroform - 40% ethanol
(B) in 20% pyridine - 80% chloroform

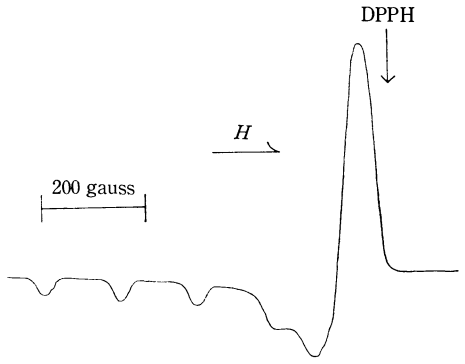

Fig. 4. The X-band ESR spectrum of $Cu(acest)_2$ in 20% γ-picoline - 80% toluene at 77°K. This spectrum was quite the same as the one of [$Cu(acest)_2(\gamma\text{-picoline})_2$] in toluene at 77°K.

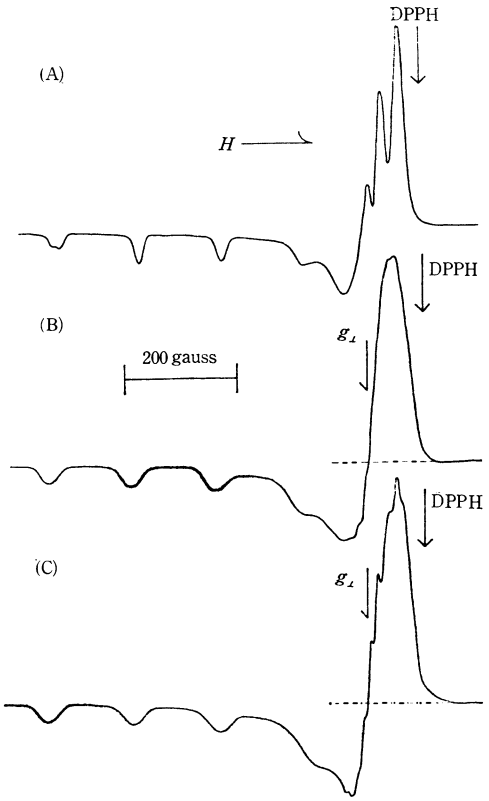

Fig. 5. The X-band ESR spectra of $Cu(sal)_2$ at 77°K.
(A) in 50% chloroform - 50% ethanol
(B) in 20% pyridine - 40% chloroform - 40% ethanol
(C) in 20% γ-picoline - 80% chloroform

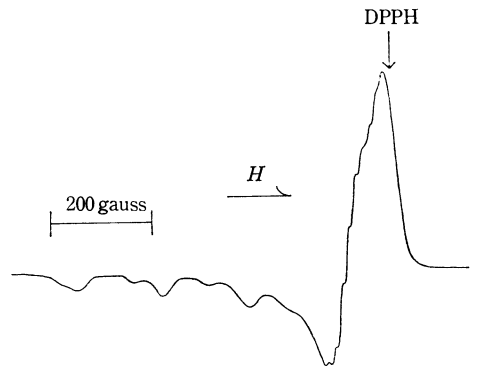

Fig. 6. The X-band ESR spectrum of $Cu(acest)_2$ in 20% piperidine - 40% chloroform - 40% ethanol at 77°K.

Fig. 2. On the other hand, piperidine, which is more basic than pyridine and γ-picoline, has a different effect on the complexes; for example, the ESR spectrum of $Cu(acest)_2$ in 20% piperidine - 40% chloroform - 40% ethanol, as is shown in Fig. 6, is due to two molecular species.

(B) in Fig. 3 shows the ESR spectrum of $Cu(acest)_2$ in 20% pyridine - 80% chloroform; this spectrum has almost the same absorption-line shape as the (A) in Fig. 3. However, the former spectrum shows more clearly than the latter one that the super-hyperfine structures appear at the most intense absorption line in the high-field part and in the hyperfine components of $I_z = -3/2$ and $-1/2$ in the low-field part. These super-hyperfine structures are considered most likely to be due to

nitrogen nuclei.

The second derivative ESR spectra were measured in order to observe the super-hyperfine structures more clearly; some of them are shown in Fig. 7.

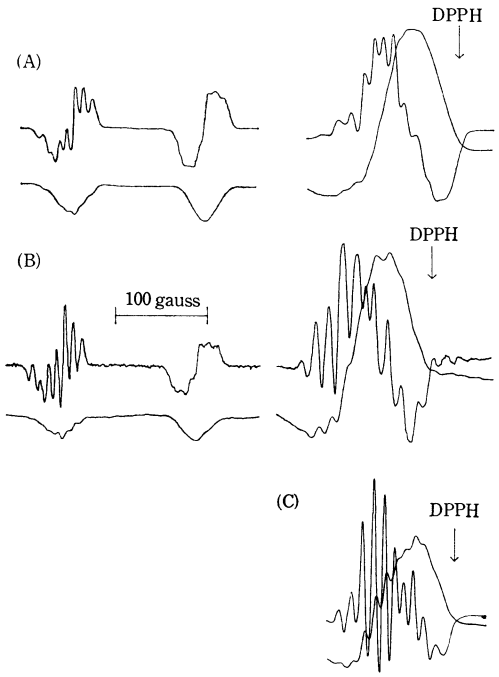

Fig. 7. The second derivative X-band ESR spectra at 77°K.
(A) $Cu(acest)_2$ in 20% pyridine-80% chloroform
(B) $Cu(acest)_2$ in 20% γ-picoline-80% chloroform
(C) $Cu(sal)_2$ in 20% γ-picoline-80% chloroform

The hyperfine and super-hyperfine structures at the most intense absorption line in the high-field part are too complex to be analyzed completely. On the other hand, the super-hyperfine structure in the hyperfine absorption lines of $I_z=-3/2$ and $-1/2$ in the low-field part were analyzed on the assumption of an equal coupling of the unpaired electron with two nitrogen atoms. The results are shown in Fig. 8, which shows a fairly good correspondence in the position and intensity of the super-hyperfine absorption line between the second derivative spectrum and its reconstruction.

The ESR spectrum of (B) in Fig. 3 shows that the ligand field of $Cu(acest)_2$ in 20% pyridine (or γ-picoline) - 80% chloroform is of an axial symmetry; the complex dissolved in the solvent has a square-planar structure. As has been described in the foregoing paragraph, the ESR spectra of $Cu(acac)_2$ in the solvents containing pyridine or γ-picoline also showed the ligand field of an axial symmetry; furthermore, it was concluded that, in the solvents, pyridine or γ-picoline molecules coordinate to the complex as apical ligands. However, no super-hyperfine structure could be observed in these spectra of $Cu(acac)_2$.

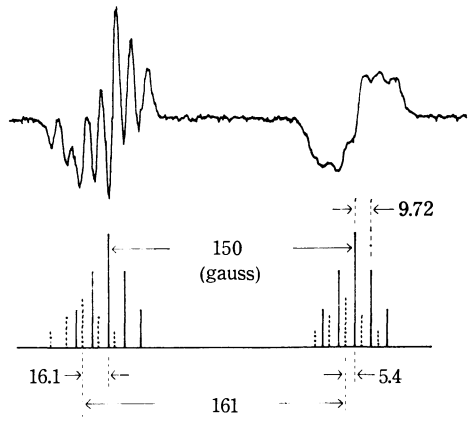

Fig. 8. The second derivative ESR spectrum (the hyperfine absorption lines of $I_z=-3/2$ and $-1/2$) of $Cu(acest)_2$ in 20% γ-picoline - 80% chloroform at 77°K and its reconstruction (solid line : ^{63}Cu dotted line : ^{65}Cu; the hyperfine intensity ratio of ^{63}Cu to ^{65}Cu of 7 : 3 was assumed).

The super-hyperfine interaction between the unpaired electron spin and the nuclear spin of the surrounding ligand atoms is mainly due to the dipole interaction and Fermi contact interaction with the spin density produced in the ligands by the covalent mixing of ligand wavefunctions into the antibonding orbitals.[18-21] The super-hyperfine interaction energies listed as $A_N//$ in Table 1, which were determined from the super-hyperfine structure observed in the hyperfine absorption lines of $I_z=-3/2$ and $-1/2$ in the low-field part, are comparable in magnitude to those previously reported for the square-planar copper(II) complexes containing nitrogen atoms as coordinating ligand atoms.[6,9,22] When the unpaired electron orbit is on the molecular plane, the super-hyperfine interaction between the electron spin and the nuclear spin of the apical

22) A. G. Gersmann and J. D. Swalen, *J. Chem. Phys.*, **36**, 3221 (1962); S. E. Harrison and J. M. Assour, "Paramagnetic Resonance," Vol. 2, ed. by W. Low, Academic Press, New York (1963), p. 855; W. Schneider and A. V. Zelewsky, *Helv. Chim. Acta*, **48**, 1529 (1965).

ligand atoms which are 2 Å or more from the metal atom, such interaction proceeding by means of direct dipole interaction or other possible mechanisms, can be estimated to be of an order of magnitude lower than the observed energies.[18-21] Therefore, it can be concluded that, in the system under discussion, two nitrogen atoms are equally introduced into the unpaired electron orbital of the complex and that a new square-planar coordination occurs through the two nitrogen atoms and the two oxygen atoms of the four originally-coordinating oxygen atoms. Needless to say, the two nitrogen atoms are those of the pyridine or γ-picoline used as the solvent.

The question next arises: what are the apical ligands in these systems. Figure 4 shows the ESR spectrum of $Cu(acest)_2$ in 20% γ-picoline - 80% toluene; this spectrum was in complete agreement with the ESR spectrum of $[Cu(acest)_2(\gamma\text{-picoline})_2]$ in toluene. This experimental fact establishes that the apical ligands are not γ-picoline molecules in either of the solutions. Furthermore, all the ESR spectra of $Cu(acest)_2$ in 20% pyridine - 80% chloroform, 20% pyridine - 40% chloroform - 40% ethanol, and 10% pyridine - 90% toluene are almost the same in line shape. This indicates that the apical ligands of the complex are same in all these solutions. From all the above discussion, it can be concluded that the apical ligand atoms are the two oxygen atoms of the four originally-coordinating oxygen atoms of $Cu(acest)_2$, whereas, as has been described above, the other oxygen atoms form a square-planar coordination. Therefore, the structure of $Cu(acest)_2$ in pyridine or γ-picoline can be visualized as is shown in Fig. 9. Such is also the case with $Cu(sal)_2$, since $Cu(acest)_2$ and $Cu(sal)_2$ are quite similar in their ESR spectral behavior.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1083—1087 (1970)

Determination of Niobium by Photon-Activation Analysis Based on Internal-Reference Method*1

Yoshinaga OKA, Tong-Chuin PUNG and Tatsuya SAITO

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received September 27, 1969)

The internal-reference method proposed previously has been applied to the photon-activation analysis of niobium using molybdenum as the reference element. For the determination of niobium, ^{92m}Nb produced by the (γ,n) reaction was utilized and ^{95m}Nb or ^{96}Nb activities coming from molybdenum by the (γ,p) processes were used as reference. A series of molybdenum and niobium mixtures with known compositions were irradiated by bremsstrahlung photons with a maximum energy of 17 MeV for an hour. After niobium activities were separated chemically, their γ-ray spectra were measured with a lithium-drifted germanium detector. A good proportionality was obtained between the activity ratio, R_{A_0}, and the weight ratio, R_W. Niobium down to 50 μg can be determined with a relative error within $\pm 3\%$ under the present experimental conditions.

Thermal neutron activation analysis for niobium has been studied by several workers.[1-3] Kim and

*1 Study on the Activation Analysis using Internal-Reference Method. XII., Part XI: Y. Oka, T. Kato and Y. Konami, *Bunseki Kagaku*, **18**, 971 (1969).

1) C. K. Kim, "Production and Use of Short-lived Radioisotopes from Reactors," I.A.E.A., 1963, Vol. II, 73.

Meinke,[2] and Verbeek[3] measured the 16.6 KeV X-ray of 6.3 min-^{94m}Nb produced by (n,γ) reaction. Rapid separation is necessary in their methods, and low energy of the X-ray makes the measurement difficult. Athavale *et al.*[4] have taken advantage of the reaction ^{93}Nb(n,α)^{90}Y induced by fast neutrons in a pile. Tomita and Saisho[5] used the ^{93}Nb(p,n)^{93m}Mo reaction for the same purpose.

In the present paper we describe a method of photon-activation analysis using molybdenum as the internal-reference element.

Experimental

Materials and Irradiation. Niobium, in the form of metallic powder of analytical-reagent grade was supplied from Johnson Mathey Co. Molybdenum was metallic powder of 99.9% purity from Wako Pure Chemical Industries, Ltd.

A linear electron accelerator of the Tohoku University and that of the Japan Atomic Energy Research Institute were the bremsstrahlung sources.

0.1—1.5 g of each element or mixtures of known compositions were sealed either in small quartz or pyrex tubes with an internal diameter of 6 mm. They were placed in a target holder immediately behind the converter*2 and irradiated. Typical irradiation was performed for an hour.

Measurement of Radioactivity. For measurements of γ-ray spectra a lithium-drifted germanium detector with a sensitive volume of 36 cm^3 coupled to a TMC 1024-channel pulse-height analyzer was used. Nuclide identification was made by energies and decay curve analysis of the specified γ-ray photopeaks.[6]

Separation of Niobium. Niobium activities were separated from irradiated samples with anion exchange

resin using hydrofluoric acid-hydrochloric acid mixture as the eluting agent.[8] The irradiated sample was dissolved in 3 m*l* of 40 (w/v) % hydrofluoric acid containing a few drops of nitric acid in a teflon beaker, and the content was evaporated to dryness under an infrared lamp. After dissolving the residue with 5 m*l* of 1N hydrofluoric acid, 9.711 mg of niobium in 1N hydrofluoric acid solution was added as carrier. The resulting solution was poured into a Dowex 1×8 column.*3 Yttrium activities were eluted with 1N hydrofluoric acid, and zirconium activities were eluted with 80 m*l* of 0.01N hydrofluoric acid-9N hydrochloric acid mixture. Niobium was then eluted with 80 m*l* of 0.2N hydrofluoric acid-9N hydrochloric acid mixture. To this niobium fraction, 5 m*l* of saturated boric acid solution was added. The solution was heated nearly to boiling for about 1 min and niobium was precipitated by the addition of aqueous ammonium hydroxide solution. The precipitate was filtered and washed with dilute ammonium hydroxide solution and then ignited to obtain niobium oxide. The chemical yield of niobium was 90—95%.

Results and Discussion

Photonuclear Reaction. The photonuclear reactions on niobium and molybdenum were studied with Bremsstrahlung of several different maximum energies. The nuclear characteristics of radionuclides of present importance, mass threshold energies of possible reactions and the Coulomb barrier heights are summarized in Table 1.

When niobium samples were irradiated with Bremsstrahlung, with maximum energies 17, 30, 45 and 60 MeV, the γ-ray spectra of the resultant activities were obtained as shown in Fig. 1. As shown in spectrum I in Fig. 1, an intense photopeak at 0.934 MeV was observed. Minor peaks at 0.90 and 1.83 MeV were also measured. From the γ-ray energies and decay curve analysis, the production of ^{92m}Nb could be confirmed. This might be acceptable from the threshold consideration listed in Table 1. With 30 MeV bremsstrahlung, the production of ^{91m}Nb by (γ,2n) reaction could also be expected. However, as seen in spectrum II in Fig. 1, the activity strength of the 1.21 MeV γ-ray photopeak was very weak. This would be due to the fact that the irradiation period was too short to produce enough 62 d-^{91m}Nb activity and that the branching decay ratio of the 1.21 MeV γ-ray is only 3%. From mass threshold energy, the ^{93}Nb (γ,3n) ^{90}Nb reaction may not be expected at 30 MeV, but it was apparent with 45 and 60 MeV bremsstrahlung.

It should be noted that knowledge of a mass threshold energy of a given photonuclear reaction gives only the possibility of its production: The relative probability of forming each product by the (γ,*x*n) reactions depends on the shape of the excitation functions which determines the yield value over the energy range of given Bremsstrahlung.

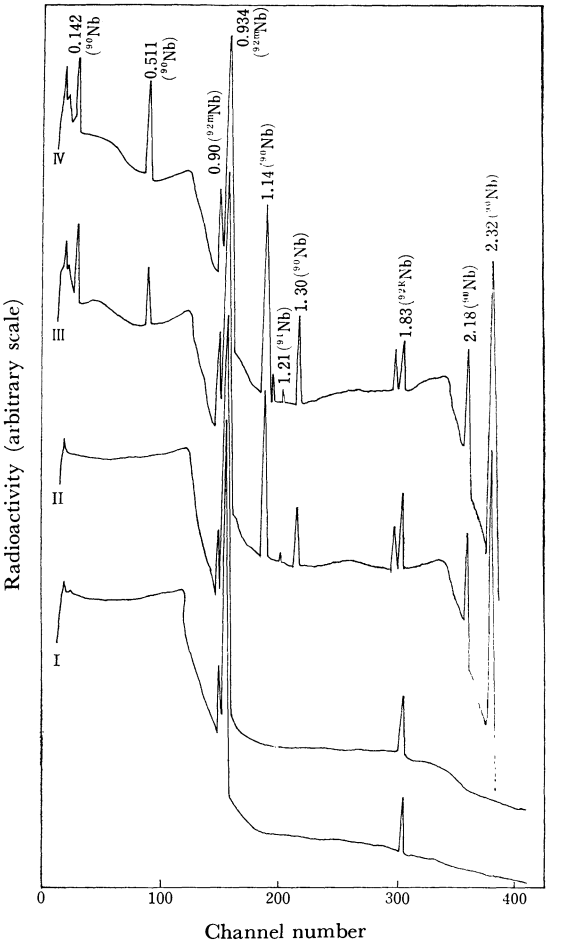

Fig. 1. γ-Ray spectra of niobium targets irradiated by Bremsstrahlung with various maximum energies.
I: 17 MeV bremsstrahlung for 60 min, 10.4 d after irradiation
II: 30 MeV bremsstrahlung for 100 min, 2.0 hr after irradiation
III: 45 MeV bremsstrahlung for 60 min, 1.8 d after irradiation
IV: 60 MeV bremsstrahlung for 105 min, 1.9 d after irradiation

Studies have been done on the niobium activities produced by the (γ,p*x*n) reactions in molybdenum samples irradiated with bremsstrahlung of maximum energies varying from 17 MeV to 65 MeV. Their γ-ray spectra are given in Fig. 2. In spectrum I in Fig. 2, the productions of ^{95m}Nb and ^{96}Nb can be seen. The former can be formed by the ^{96}Mo (γ,p), ^{97}Mo (γ,pn) or ^{97}Mo (γ,d) reactions, and the latter by the ^{97}Mo (γ,p), ^{98}Mo (γ,pn) or ^{98}Mo (γ,d) reactions. From mass threshold and Coulomb barrier consideration as given in Table 1,

*3 1 cmϕ×40 cm, 100—200 mesh.

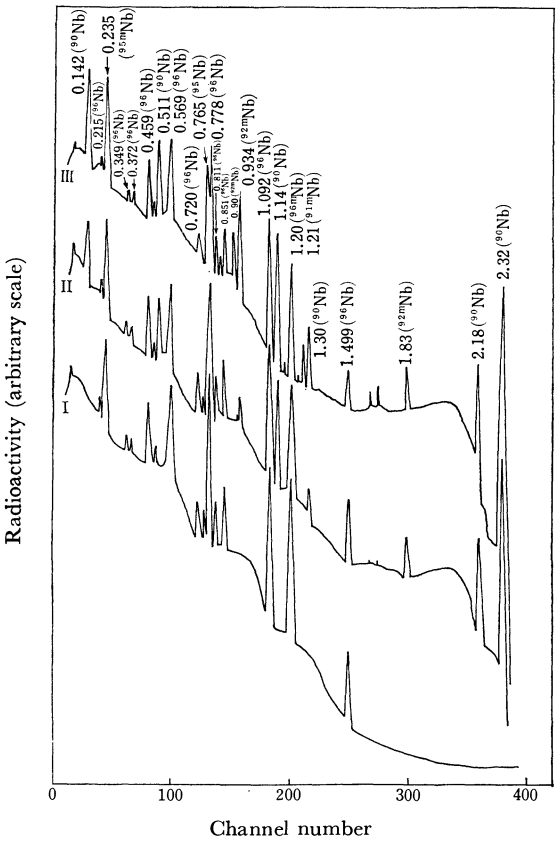

Fig. 2. γ-Ray spectra of niobium fractions separated from irradiated molybdenum targets.
I: Irradiated with 17 MeV bremsstrahlung for 60 min, spectrum obtained 1.33 d after irradiation
II: Irradiation with 30 MeV bremsstrahlung for 30 min, spectrum obtained 3.03 d after irradiation
III: Irradiated with 65 MeV bremsstrahlung for 25 min, spectrum obtained 3.96 d after irradiation

the possible reactions to produce ^{95m}Nb and ^{96}Nb can be concluded to be (γ,p) reactions on ^{96}Mo and ^{97}Mo respectively at 17 MeV. From a similar consideration, ^{95}Nb may be formed only by the (γ,p) reaction on ^{96}Mo at 17 MeV. Its production rate would not be appreciable in a short irradiation period. With bremsstrahlung maximum energies above 30 MeV, the formation of ^{90}Nb, ^{92m}Nb and small amount of ^{95}Nb can be found as shown in Fig. 2.

As has been stated on the yields of the (γ,n), (γ,p), (γ,2n), (γ,pn) and (γ,α) reactions with 20 MeV Bremsstrahlung, the (γ,n) reaction gives the highest yield for most of nuclei in the medium-to-heavy mass region.[9-11] Accordingly, ^{92m}Nb, the (γ,n) reaction product, should be preferably used for the determination of niobium with respect to sensitivity. The formation of ^{92m}Nb, therefore, should be necessarily avoided in an irradiated molybdenum sample. As seen in Table 1, the possible reactions leading to the production of ^{92m}Nb from molybdenum are the (γ,pn) or the (γ,d) reaction on ^{94}Mo. The sum of their mass threshold energies and Coulomb barrier heights are 24.15 and 21.75 MeV, respectively, which are both well beyond an excitation energy of 20 MeV. Hence interference of this sort could be avoided in the irradiation with 20 MeV bremsstrahlung, provided that the tunnel effect was not taken into account. Figure 3 shows the experimental results.

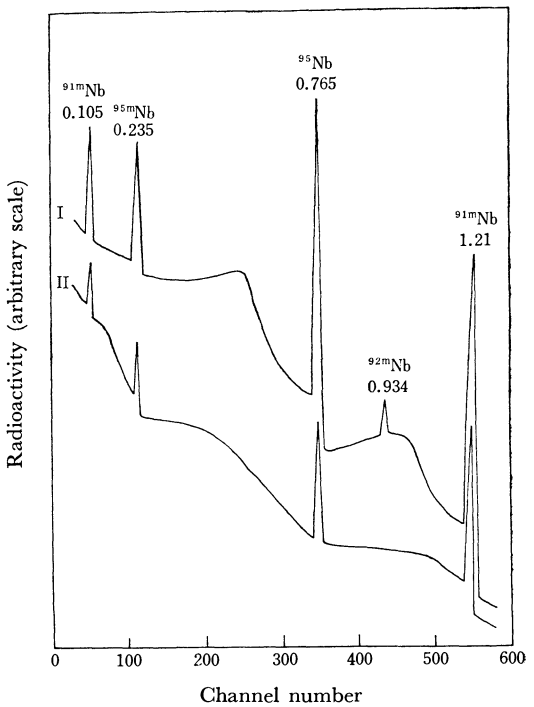

Fig. 3. γ-Ray spectra of niobium fractions separated from irradiated molybdenum targets.
I: Irradiated with 20 MeV bremsstrahlung for 1 hr, spectrum obtained 1.83 d after irradiation
II: Irradiated with 17 MeV bremsstrahlung for 1 hr, spectrum obtained 10.4 d after irradiation

The 0.934 MeV γ-ray of ^{92m}Nb can still be found as shown in spectrum I but its formation was completely suppressed at 17 MeV. Consequently, the irradiation was performed by 17 MeV bremsstrahlung in the determination of niobium using

molybdenum as the internal-reference element.

The Determination of Niobium. The synthetic niobium-molybdenum mixtures were irradiated with 17 MeV Bremsstrahlung for an hour at a photon flux of 4.3×10^5 roentgens/min. After irradiation, niobium activities were separated chemically as described above. In Fig. 4, a typical γ-ray spectrum of niobium fraction is shown. Photopeak area under the 0.934 MeV photopeak of ^{92m}Nb was measured against that of either the 0.235 MeV photopeak area from ^{95}Nb or the 1.092 MeV photopeak area from ^{96}Nb.

The results are shown in Table 2. In each case, a good proportionality was obtained between R_W and R_{A_0}, where R_W is the weight ratio of niobium to molybdenum and R_{A_0} is the ratio of photopeak activities corrected at the end of one hour irradiation. The determination of niobium content in a sample can be achieved by using this relationship.

When a 10 cpm of photopeak activity is selected as the limit of determination, niobium content down to about 50 μg in a 1.5 g sample of molybdenum will be determined with a relative error within $\pm3\%$. Further applicability of this method will be found in the determination of niobium content in various samples by adding a proper amount of molybdenum as internal-reference element. An increase in sensitivity would be expected by using the higher bremsstrahlung dose and with a longer period of irradiation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1088—1093 (1970)

Syntheses and Properties of Metal Chelates of Ethanediylidenetetrathiotetraacetic Acid (ETTA) and Some Other Thioglycolic Acid Derivatives

Akira Ouchi, Yayoi Ohashi, Toshio Takeuchi and Yukichi Yoshino

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received October 17, 1969)

Some new metal chelate compounds of ethanediylidenetetrathiotetraacetic acid (H_4ETTA), $Co_2L\cdot 5H_2O$, $Cu_2L\cdot 4H_2O$, $Zn_2L\cdot 3H_2O$, $Ni_2L\cdot 6H_2O$, and $FeHL\cdot 3.5H_2O$, where H_4L is H_4ETTA, were obtained. The infrared spectra and other properties of these compounds were compared with those of the metal complexes of other thioglycolic acid derivatives, some of which are also new compounds. Judging from the wave numbers of the stretching bands, the carboxyl group of these complexes can be said to be rather ionic. Though the bond is not very strong, thioglycolic acid derivatives seem to bond with the central metal ion with both the sulfur atom and the carboxyl group.

Many kinds of chelate compounds of various metals with ethylenediaminetetraacetic acid (H_4EDTA) and its analogous ligand have already been synthesized and their properties investigated.[1] Recently many ligands which bond with the central metal ion by one or more sulfur atoms, or by one sulfur atom and some others, such as nitrogen or oxygen atoms, have been investigated very actively.[2,3] Therefore, it seemed that it would be interesting to study multidentate sulfur containing ligands and their metal complexes. The ethanediylidenetetrathiotetraacetic acid (H_4ETTA) is one of the ligands in this line of the research; moreover, as the structure of ETTA resembles that of EDTA, it led us to study the synthetic method and the properties of the metal chelates of this ligand. Only a few reports have been published about ETTA metal chelates. Longo and others have, though, prepared H_4ETTA and its chelate compounds of silver(I), iron(III), and mercury(II).[4] Saini and others have reported that the mole ratio of copper to ETTA in the chelate is 1 : 1 in the solution.[5]

Therefore, we have newly synthesized solid ETTA chelates of other metals; nickel(II), cobalt(II), copper(II), zinc(II) and cadmium(II). The iron(III) complex was also synthesized. The mole ratio of ETTA to iron was 1 : 1, unlike Longo's product, which had the mole ratio of 1 : 2.

In order to study the structure of the ETTA complexes and of the several thioglycolic acid derivatives shown below, their metal complexes were synthesized and investigated; they were benzylidenebisthioglycolic acid $C_6H_5CH(SCH_2CO_2H)_2$ (H_2BzS_2), ethylidenebisthioglycolic acid $CH_3CH(SCH_2CO_2H)_2$ (H_2EtS_2), methylenebisthioglycolic acid $CH_2(SCH_2CO_2H)_2$ (H_2MeS_2), benzylthioglycolic acid $C_6H_5CH_2SCH_2CO_2H$ (H_1BzS_1), and ethylthioglycolic acid $C_2H_5SCH_2CO_2H$ (H_1EtS_1). Their structure are shown in Fig. 1. The metal chelates of some of these compounds were studied by the solution-chemistry method. Ethylthioglycolic acid,

for example, has been studied by several authors;[6,7] according to their results, the ligand bonds to the central metal ion not only by its carboxyl group, but also by its sulfur atom. Although Yamasaki and Suzuki[8] have reported that the sulfur atom of phenylthioacetic acid seems not to be bonded with the metal ion in their metal complexes, the same authors wrote that ethylenedithiodiacetic acid seems to coordinate to a metal ion by means of sulfur atoms. The behavior of the former may be partly due to some steric interference with the chelate formation.

The chemical properties and the infrared spectra of the metal chelates of H_4ETTA and these thioglycolic acid derivatives resemble each other; accordingly, the structure of all of these chelates seem to be similar. The results obtained below seem to show that these ligands bond to the central metal ion as a multidentate, using both the sulfur atom and the carboxyl group, though the sulfur-metal bond is not very strong.

Experimental

Instruments. The infrared spectra were obtained by the Nujol or hexachloro-1,3-butadiene mull procedure, using a DS 301-type infrared spectrophotometer of the Japan Spectroscopic Co., Ltd. The electronic spectra were obtained with a Hitachi EPS-2-type automatic recording spectrophotometer. The reflectance spectra were obtained by using a reflectance attachment and a magnesium oxide standard. The magnetic moments were measured with a Gouy balance at room temperature (25°C).

Materials. The H_4ETTA was synthesized by Longo's method[4] by means of a condensation reaction between glyoxal and thioglycolic acid. The bisthioglycolic acid derivatives, H_2BzS_2, H_2EtS_2, and H_2MeS_2, were synthesized by Bongartz's method[9] and by Mattisson's method.[10] The monothioglycolic acid derivatives, $HBzS_1$ and $HEtS_1$, were synthesized by Larsson's method.[11]

The Syntheses of the Metal Chelates of ETTA. *(i) Cobalt(II), Copper(II), Nickel(II), Zinc(II) and Cadmium(II) Complexes.* The metal hydroxide of these metals was made from their nitrate and sodium hydroxide. It was suspended in water, about one fourth (mol/mol) of H_4ETTA was added, and the mixture was stirred for about 10 to 30 min at room temperature. The residue was then filtered off, and to the filtrate an equivolume of ethanol was added. The precipitate thus obtained was filtered off and washed by ethanol and acetone, in that order, before being dried in a vacuum desiccator at room temperature.

(ii) Iron(III) Complex. 1.3 g (1/300 mol) of H_4ETTA and 0.53 g (4/300 mol) of sodium hydroxide were dissolved in water. In a separate vessel, an aqueous solution of 2.7 g (1/100 mol) of iron(III) chloride hexahydrate was prepared; the pH of this solution was kept lower than 1 by perchloric acid. The two solutions were then mixed and stirred. The pH of the supernatant fluid was kept at 0.8 by adding perchloric acid. A precipitate thus appeared. It was filtered off, washed by acetone and ether, and dried in a vacuum desiccator at room temperature.

The Syntheses of Metal Complexes of Other Thioglycolic Acid Derivatives. The method of synthesizing the ETTA chelates can be used with slight modifications. Some examples are shown as follows.

(i) Copper(II) Complex of H_1BzS_1. Copper(II) hydroxide was obtained from 1 g of copper(II) chloride dihydrate. After suspending it in water, 2 g of H_1BzS_1 were added; the mixture was stirred well and boiled, and the insoluble residue was filtered off while hot. When the filtrate was cooled in an ice bath, pale blue $Cu(BzS_1)_2 \cdot 2H_2O$ deposited. The $Cu(BzS_1)_2 \cdot 2H_2O$, when boiled with an equivolume mixture of absolute ethanol and benzene, produced a green precipitate, $Cu(BzS_1)_2$. This was washed repeatedly with benzene and dried in a vacuum desiccator at room temperature.

(ii) Nickel(II) Complex of H_2EtS_2. Newly-made wet nickel(II) hydroxide obtained from 0.5 g of nickel(II) chloride hexahydrate and alkali was mixed with 0.7 g of H_2EtS_2(liquid). Ethanol was added to the mixture, after which the mixture was stirred, warmed, and filtered. The solid product thus obtained was washed well with ethanol and ethyl ether successively and then dried in a vacuum desiccator at room temperature.

Results and Discussion

The elemental analyses and the chemical formulae of the complexes thus obtained are shown in Table 1. Judging from these analytical results, many of these complexes can be said to contain water molecules and some of them seem to be coordinated complexes though the coordination number of the metals of these complexes cannot be determined from only these data.

The magnetic moments of these complexes, as measured by Gouy's balance at 25°C, are shown in Table 2. The cobalt complexes show magnetic moments of 4.5—4.9 B.M. per mole of metal. As these complexes are pink in color and have the oxidation number of +2, these cobalt(II) complexes can be said to be in a d^7 high spin configuration. Because of the orbital contribution, the observed magnetic moments are always higher than the spin-only values; they are 4.7—5.2 B.M. for octahedral- and 4.4—4.8 B.M. for tetrahedral-configuration complexes.[12] Consequently, the cobalt(II) complexes of ETTA and thioglycolic acid derivatives probably have an octahedral configuration.

In the case of nickel complexes, the observed magnetic moment values are in the range of 3.0—3.7 B.M. The nickel(II) complexes in an octahedral configuration show magnetic moments of 2.9—3.4 B.M., whereas the tetrahedral-configuration complexes show 3.5—4.2 B.M.[12] Therefore, these complexes are possibly in an octahedral configuration too, not in the planar or tetrahedral configurations. Although this method cannot be used with the complexes of other metals, they are probably in a hexacoordinated octahedral form, too, for the properties of all of these complexes resemble each other. Therefore, in order to make a hexacoordinate configuration not only the carboxyl group, but also the sulfur atoms and water should be coordinated to the central metal ion.

In the case of copper(II) complexes, the magnetic moments are about 1.7—1.9; therefore, the metal-metal bond of copper(II) acetate-type compounds does not exist. In the case of the copper(II)

complex of benzylthioacetic acid, both $Cu(BzS_1)_2\cdot 2H_2O$ and $Cu(BzS_1)_2$ were obtained. The extraordinarily low magnetic moment of the iron(III) ETTA complex seems to be due to the low spin-high spin equilibrium reported by Ewald and others.[13]

The visible spectral data, absorption as well as reflection spectra data, of colored complexes are shown in Table 3. Some of these complexes are not soluble in water or other organic solvents, and so it is difficult to study their absorption spectra. The spectra of soluble samples show relatively low absorption peaks in the visible region; the log ε is about 1, except for those in the ultra-violet region, which seem to be the absorptions of the ligands themselves. Consequently, from the visible spectral data, too, the complex species in the solution seem to be in a hexacoordinate octahedral configuration, although some solvolysis may change the configuration in the solution from that in the solid state. The solid complex salts are not deeply colored, either, and the tetrahedral configuration is less probable even in the solid state. The d–d bands of the cobalt(II) and nickel(II) complexes are observed at about 7.5—8.0 kK and about 9 kK respectively. Therefore, the coordination bond strength of the chelates is not very strong; possibly it is comparable to those of water or of usual amino acids in the spectrochemical series.

The infrared absorption bands of the carboxyl group are most useful for a study of the coordination structure of these complexes. The wave numbers of the antisymmetric and symmetric stretching bands of the carboxyl group of the metal complexes as well as of the free acids, H_4ETTA, and other thioglycolic acid derivatives are shown in Table 4. The antisymmetric stretching bands of the free acids appear at about 1700 cm^{-1}; they shift to about 1570 to 1600 cm^{-1} in the cases of metal chelates. In some cases, the band splits into two peaks. For example, the bands appear at 1715 cm^{-1} as well as at 1610 cm^{-1} in the case of the Fe(III) HETTA complex. Therefore, some carboxyl groups of the ligand bond to the central metal ion, while others are in a free –COOH form. As the wave numbers of the peaks of metal chelates make such a big shift to the lower-wave number side, the carboxyl group of the ligand must have an ionic character in these compounds. Therefore the group seems to bond with the central metal ion, but the bond seems not to be a purely

covalent one.[14,15] The symmetric stretching band of the carboxyl group of the free acids appeared at about 1400 cm^{-1}; the shift of the band of metal complexes should be another index of the bond type. According to Nakamoto,[16] the direction of the shift of the band depends on the symmetry of the carboxyl group in the metal complexes. If the carboxyl group in the complexes is not symmetric, antisymmetric and symmetric stretching bands shift to the higher- and lower-wave number sides respectively. On the other hand, if the coordination occurs symmetrically, both stretching bands shift in the same direction. Thus, the difference in the wave numbers of the antisymmetric and symmetric stretching bands of the carboxyl group of these compounds is useful for judging the structure of the chelate compounds.[17,18] Therefore, the observed values are also shown in Table 4. The values of carboxylic acid complexes increase in the following order of the central metals:

$$Ni(II) < Zn(II) < Cu(II) < Co(II).$$

The covalent character of the M–O bond also seems to increase in this order.[16]

In this case, however, the direction of the shift of the symmetric stretching band is not clear, and the values of the complexes of different metals are almost random; therefore, no meaningful conclusion could be drawn from the results. Two reasons for this are that the bonds between the metal-ligand bonds of all of these compounds are weak and that the bond strengths by different central metal ions are not very different. Moreover, if the sulfur atom bonds with the metal ion and forms a chelate ring, the order of the coordination bond strength of the simple carboxyl acid complexes should be modified. Whether or not sulfur is bonded to the central metal ion is not clear from the infrared spectral data in the 4000—600 cm^{-1} region, because the sulfur atoms in thio-ether-type compounds do not give strong bands in this region and so it is difficult to distinguish them from other bands. The weak band near 2550 cm^{-1} of the H_4ETTA seems to be due to dimerization by the hydrogen bond. It was not recognized in the spectra of its metal complexes.

Conclusions

From these data it may be concluded that the stabilities of the first-transition metal complexes of H_4ETTA and other thioglycolic acid derivatives are

not high. Even ETTA acts at most as a tetradentate for each metal ion, and the chelate is not very stable. This is probably due to the weak coordination ability of the sulfur atoms of the thio-ether-type compounds. Moreover, the steric configuration of ETTA also shows that it finds difficult to act as a octadentate ligand for one metal atom with each four sulfur atoms and carboxyl groups. All of these metal complexes, however, are probably hexa-coordinated octahedral complexes, and the ligand bonds with the central metal ion by means of sulfur atoms and an ionized carboxyl group. Sometimes water molecules are also coordinated. In some cases, the polymerized form where a carboxyl group is coordinated with two metal ions is also possible.

The authors wish to express their appreciation to Professor Kunihiko Watanuki and to their colleagues of our laboratory for their helpful discussions.

Mössbauer Studies of the Thermal Decomposition of Iron(II) Pyridine and Picoline Complexes

Takeshi TOMINAGA, Masuo TAKEDA, Takeshi MORIMOTO and Nobufusa SAITO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received October, 20, 1969)

The thermal decomposition of tetrakispyridineiron(II) chloride, tetrakis(γ-picoline)iron(II) chloride, and tetrakispyridineiron(II) isothiocyanate has been studied in nitrogen. These complexes presumably decompose in the following sequences:

$Fe(py)_4Cl_2 \rightarrow Fe(py)_2Cl_2 \rightarrow Fe(py)Cl_2 \rightarrow Fe(py)_{2/3}Cl_2 \rightarrow FeCl_2$,
$Fe(\gamma\text{-pic})_4Cl_2 \rightarrow Fe(\gamma\text{-pic})Cl_2 \rightarrow FeCl_2$ and $Fe(py)_4(NCS)_2 \rightarrow Fe(py)_2(NCS)_2 \rightarrow Fe(NCS)_2$.

The Mössbauer spectra of these complexes and of their decomposition products have been studied in terms of the structural change about the iron atom during the thermal decomposition process.

The Mössbauer spectroscopy has become a useful technique to investigate the oxidation state and the electronic configuration of iron in iron compounds. Since the Mössbauer study of the radiolysis and photolysis of ferric oxalate[1] indicated that this new technique was useful for directly investigating the chemical changes induced in solids, we applied this method to the study of the thermal decomposition of tetrakispyridineiron(II) chloride.[2]

After our preliminary work had been submitted for publication, we learned of an earlier Mössbauer work on some complex oxalates of iron(III).[3] In those iron oxalates, the oxidation state of iron was found to fluctuate between +2 and +4 during the course of the thermal decomposition.

According to our work on the thermal decomposition behavior of the iron(II) pyridine complexes,[2] the oxidation state of iron remains unchanged during the process in nitrogen. The thermal decomposition of these complexes proceeds through the step-by-step formation of octahedral polymers. Therefore, the purpose of our present work is to study the change in the Mössbauer parameters at different phases of the thermal decomposition in terms of the structural change about the iron atom, or the growth of the polymer structure during the decomposition process.

In the present paper, we will give a more complete report on the system which was studied in our earlier work,[2] as well as new data on some other complexes which have been studied recently.

Experimental

Samples. Tetrakispyridineiron(II) chloride, tetrakis(γ-picoline)iron(II) chloride, and tetrakispyridineiron(II) isothiocyanate were prepared and used for the thermal decomposition studies.

(i) $Fe(py)_4Cl_2$. Tetrakispyridineiron(II) chloride was prepared as has been described in the literature.[4,5]

5) H. S. Booth, "Inorganic Syntheses," Vol. 1, McGraw-Hill Book Co. Inc., New York (1939), p. 184.

Intense yellow crystals were obtained and dried in a vacuum desiccator containing pyridine vapor. Found: Fe, 12.6; Cl, 15.0%. Calcd for $Fe(py)_4Cl_2$: Fe, 12.6; Cl, 14.2%.

(ii) $Fe(\gamma\text{-pic})_4Cl_2$. This was prepared by a procedure similar to (i). To 20 m*l* of γ-picoline we added 5 m*l* of a saturated $FeCl_2$ solution. Yellow crystals of the complex were obtained. Found: Fe, 11.3: Cl, 16.5%. Calcd for $Fe(\gamma\text{-pic})_4Cl_2$: Fe, 11.2; Cl, 16.0%.

(iii) $Fe(py)_4(NCS)_2$. This compound was prepared by the method described in the literature.[6] The yellowish white crystals obtained were dried in a vacuum desiccator. Found: Fe, 11.5; C, 54.1; H, 4.28; N, 17.2%. Calcd for $Fe(py)_4(NCS)_2$: Fe, 11.5; C, 54.1; H, 4.14; N, 17.2%.

Thermal Decomposition. The thermal decomposition studies were carried out on a Shimadzu Thermal Balance at a rate of heating of 2°C/min. All the thermal decompositions were carried out in a nitrogen atmosphere.*1

The powder X-ray patterns of tetrakispyridineiron(II) chloride, isothiocyanate, and their thermal decomposition products were made using a Rigaku Denki Geigerflex and Fe$K\alpha$ radiation.

The infrared spectra of these compounds were measured by using Hitachi EPI-G2 and EPI-L Spectrophotometers and a Hitachi FIS-1 Far-infrared Spectrophotometer.

Mössbauer Measurements. The Mössbauer absorption spectra of the starting materials and of the thermal decomposition products were obtained at room temperature and at lower temperatures*2 (163°K or 100°K) by using a mechanical constant-velocity drive spectrometer with a source of ^{57}Co diffused into copper or platinum foil. The spectrometer was calibrated with sodium nitroprusside dihydrate powder.

Results and Discussion

Thermal Decomposition of the Iron(II) Pyridine and γ-Picoline Complexes. Although several studies have been made of the thermal decomposition of various metal complexes of pyridine and its derivatives,[7-11] the thermal decomposition of the iron pyridine complexes had never been reported before our preliminary work on $Fe(py)_4Cl_2$[2] was published.

As may be seen in Fig. 1, the thermal decomposition of $Fe(py)_4Cl_2$ in air produced no distinct intermediate phase other than $Fe(py)_2Cl_2$, presumably because of the oxidation taking place at about 100°C or higher temperatures. This was verified by the Mössbauer spectrum of the decomposition product obtained at 150°C (above the temperature for the formation of $Fe(py)_2Cl_2$), which indicated the presence of Fe(III) (δ ~0.5 mm/sec; ΔE_Q

~0.5 mm/sec). Accordingly, all the thermal decompositions of the iron(II) complexes were carried out in a nitrogen atmosphere.

Figures 1 to 3 show the weight-loss curves of $Fe(py)_4Cl_2$, $Fe(\gamma\text{-pic})_4Cl_2$, and $Fe(py)_4(NCS)_2$, respectively. Four distinct phases can be observed during the thermal decomposition of $Fe(py)_4Cl_2$ in a nitrogen atmosphere (Fig. 1). These four phases correspond to the products which can be obtained by the successive loss of two, one, one-third and two-thirds molecules of pyridine from the starting material, $Fe(py)_4Cl_2$. The results of analyses for the iron and chlorine contents were in good agreement with the values calculated for the assumed products. The X-ray powder patterns and Mössbauer spectra confirmed that all of these phases are separate and distinct entities. Therefore, it may be concluded that the thermal decomposition of $Fe(py)_4Cl_2$ proceeds in a nitrogen atmosphere as follows:

$$Fe(py)_4Cl_2 \rightarrow Fe(py)_2Cl_2 \rightarrow Fe(py)Cl_2 \rightarrow Fe(py)_{2/3}Cl_2 \rightarrow FeCl_2.$$

Similarly, the thermal decompositions of $Fe(\gamma\text{-pic})_4Cl_2$ and $Fe(py)_4(NCS)_2$ were found to proceed according to the sequences:

$$Fe(\gamma\text{-pic})_4Cl_2 \rightarrow Fe(\gamma\text{-pic})Cl_2 \rightarrow FeCl_2,$$

and

$$Fe(py)_4(NCS)_2 \rightarrow Fe(py)_2(NCS)_2 \rightarrow Fe(NCS)_2.$$

In addition, it may be worthwhile mentioning that, according to our preliminary work,[12] $Fe(py)_4Br_2$ and $Fe(\gamma\text{-pic})_4Br_2$ decompose through the following steps:

$$Fe(py)_4Br \rightarrow Fe(py)Br_2 \rightarrow FeBr_2,$$

and

$$Fe(\gamma\text{-pic})_4Br_2 \rightarrow Fe(\gamma\text{-pic})Br_2 \rightarrow FeBr_2.$$

Structures of the Decomposition Products. No X-ray study of the structure of $Fe(py)_4Cl_2$ has been reported to date. However, the electronic spectra[13] suggest that $Fe(py)_4Cl_2$ has a trans-octahedral configuration about the iron atoms. We confirmed this conclusion, since the powder X-ray patterns of $Fe(py)_4Cl_2$ are quite similar to those of $Co(py)_4Cl_2$ and $Ni(py)_4Cl_2$, whose structures are known.[14,15] The X-ray powder photography[16] indicated that $Fe(py)_2Cl_2$ has a structure analogous to that of $\alpha\text{-}Co(py)_2Cl_2$, an octahedral polymer with bridging chloride ions.[17] This conclusion was also confirmed by our powder X-ray data. The electronic spectra[13] suggest that $Fe(py)Cl_2$ also has an octahedral polymeric structure. Our powder X-ray data indicate that $Fe(py)_{2/3}Cl_2$ is isomorphous with $Co(py)_{2/3}Cl_2$, which may, according to the electronic spectra,[18] be supposed to have an octahedral polymer structure. Therefore, the thermal decomposition of $Fe(py)_4Cl_2$ proceeds with the formation of the polymer structure: the successive removal of pyridine molecules from the complex gives single, double, and triplechain polymers, and finally the chains are converted to the infinite plane structure of $FeCl_2$.[19] The structural changes which might take place during the thermal decomposition of $Fe(py)_4Cl_2$ are shown in Fig. 4. The structure of

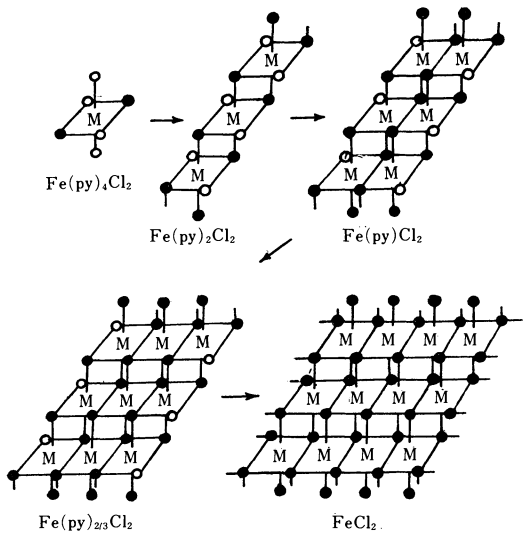

Fig. 4. Structures of $Fe(py)_xCl_2$.
M: Fe; O: py; ●: Cl.

$Fe(py)_4(NCS)_2$ was determined by the X-ray investigation.[20] It has a trans-octahedral arrangement about the iron atoms (nitrogen atoms are bonded to iron). Since the powder X-ray patterns of $Fe(py)_2(NCS)_2$ were found to be quite similar to those of $Co(py)_2(NCS)_2$, whose structure is known,[21] we assume that $Fe(py)_2(NCS)_2$ has an octahedral polymeric structure with bridging NCS ions (sulfur atoms occupy trans positions to iron). The comparison of the IR spectra of $Fe(py)_4(NCS)_2$ and

$Fe(py)_2(NCS)_2$ also suggests the presence of bridging thiocyanate groups.

The Mössbauer Spectra of the Decomposition Products. The Mössbauer spectra (room temperature) of $Fe(py)_4Cl_2$, $Fe(\gamma\text{-pic})_4Cl_2$, $Fe(py)_4(NCS)_2$ and their decomposition products are represented in Figs. 5 to 7. All the Mössbauer spectra are composed of two absorption peaks. The isomer shifts and quadrupole splittings of these compounds obtained at various temperatures are summarized in Table I.

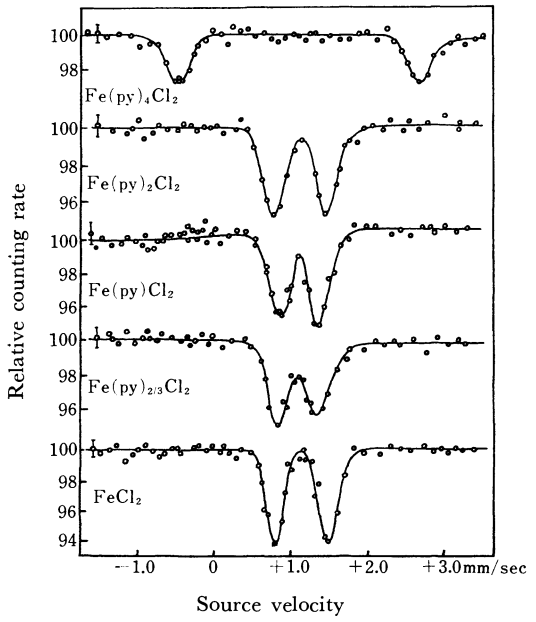

Fig. 5. Mössbauer spectra of $Fe(py)_xCl_2$.

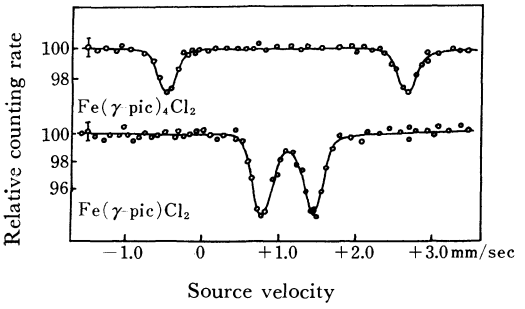

Fig. 6. Mössbauer spectra of $Fe(\gamma\text{-pic})_xCl_2$.

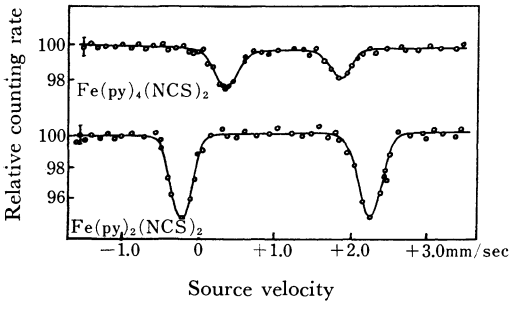

Fig. 7. Mössbauer spectra of $Fe(py)_x(NCS)_2$.

* Vs. stainless steel (310SS) ** Obtained at 100°K

From the Mössbauer data on $Fe(py)_4Cl_2$ and its thermal decomposition products, we may draw the following conclusions:

(1) The isomer shifts (δ) of the different phases show only small variations during the thermal decomposition process in a nitrogen atmosphere. All the δ values fall within the range of δ values for a typical high-spin Fe(II) state. Thus, it is obvious that the oxidation state of iron in the starting material, $Fe(py)_4Cl_2$, remains unchanged throughout the decomposition process.

(2) The quadrupole splitting (ΔE_Q) is appreciably changed as the thermal decomposition proceeds; at room temperature, the quadrupole splitting of $Fe(py)_4Cl_2$ is 2.94 mm/sec, whereas the quadrupole splittings of the decomposition products are significantly decreased and fall within a range between 0.38 and 0.75 mm/sec. The changes in the quadrupole splitting may reflect the structural changes about the iron atoms.*3

(3) The intensities of absorption peaks are generally larger for the polymeric compounds than for the monomer, $Fe(py)_4Cl_2$. This may be due to the "polymer effect" suggested for organotin

*3 Since the quadrupole splitting of these high spin iron(II) compounds is closely related to the ligand-field splitting of d_ε orbitals, the temperature dependence of the quadrupole splittings of various iron pyridine complexes is now being studied in our laboratory. The results will be published elsewhere.

compounds[22-25] and α-$Co(py)_2Cl_2$[26]; the polymer structures may restrict the motion of the iron atoms and give higher recoilless fractions.

(4) In order to examine the mechanism of the primary step of decomposition, *i. e.*, $Fe(py)_4Cl_2 \rightarrow Fe(py)_2Cl_2$, the Mössbauer spectra were taken of the products obtained at intermediate stages before the $Fe(py)_2Cl_2$ phase was completely attained (Fig. 8). As may be seen in Fig. 8, only the absorption peaks of $Fe(py)_4Cl_2$ and $Fe(py)_2Cl_2$ are observed in the intermediate stages. The intensities of the $Fe(py)_4Cl_2$ peaks are decreased, whereas the intensities of the $Fe(py)_2Cl_2$ peaks are increased, as the decomposition proceeds. Therefore, it seems unlikely that any stable entity such as $Fe(py)_3Cl_2$ could exist as an intermediate phase for the $Fe(py)_4Cl_2 \rightarrow Fe(py)_2Cl_2$ transition. This suggests the possibility of the application of the Mössbauer spectroscopy to the study of the kinetics and the mechanism of solid-phase reactions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1097—1100 (1970)

The Hydrolysis of the Uranyl Ion in Heavy Water*1

Masunobu MAEDA and Hidetaka KAKIHANA

Research Laboratory of Nuclear Reactor, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October, 24, 1969)

The hydrolysis equilibria of the UO_2^{2+} ion in heavy water containing 3M $NaClO_4$ as an ionic medium were studied at 25°C by potentiometric titrations, employing a technique of constant-current coulometry. The deuterium-ion concentration was measured by means of a glass electrode. The most probable hydrolysis scheme chosen in the range of the total uranyl concentration from 1 to 10 mM was: $(UO_2)_2(OD)_2^{2+}-(UO_2)_3(OD)_4^{2+}-(UO_2)_3(OD)_5^{+}$; the respective stability constants were $-\log \beta_{2,2}=6.80\pm0.02$, $-\log \beta_{4,3}=14.00\pm0.07$, and $-\log \beta_{5,3}=18.63\pm0.02$. The above results reveal that the composition of the hydrolysis species in heavy water are generally the same as those in light water, while the values of the stability constants are smaller in heavy water than in light water.

In a previous paper[1] we described the hydrolytic reaction of the beryllium ion in heavy water and concluded that the compositions of the hydrolysis species are the same in heavy water as in light water and that the values for the stability constants in heavy water are smaller than those in light water.

In this work, the hydrolytic reaction of the uranyl ion was studied, and the results obtained were compared with those in light water.

*1 Ionic Equilibria in Heavy Water, Part IV.

1) H. Kakihana and M. Maeda, This Bulletin, **43**, 109 (1970).

Symbols

The symbols used are the same as those described in Part II of this series.[1]

Expermental

Reagents and Apparatus. *The reagents used* were, unless otherwise stated, prepared and analyzed as has been described in Refs. 1 and 2.

Uranyl perchlorate in heavy water was prepared by the repeated evaporation of uranyl perchlorate in light water (which had been prepared and analyzed as has been described in Ref. 3), under an infrared lamp, while adding heavy water.

NaOD solution was prepared by the electrolysis of sodium perchlorate in heavy water, using a procedure similar to that described in Ref. 4.

All the apparatuses employed were the same as those used in Refs. 1 and 2.

Experimental Procedures. The hydrolysis of the UO_2^{2+} ion was investigated by measuring the deuterium-ion concentration using a glass electrode. $NaClO_4$ was added to all the test solutions so that they contained 3M ClO_4^-; the total UO_2(II) concentration was maintained within the 1—10 mM range.

The deuterium-ion concentration and the generation of the deuterium ions in a test solution were measured by the use of the same cell assembly as that employed in Part II[1] of this series.

The emf of the cell at 25°C can be denoted by Eq. (1),[5] since the concentration of the deuterium ions was maintained at less than 0.01M in the present work:

$$E = E_0 + 59.15 \log d \qquad (1)$$

The potentiometric titrations were carried out as follows. First, a partially-hydrolyzed solution of the uranyl ion was made by adding the solutions T_1 and T_2 to a test solution, S. The compositions of the solutions T_1, T_2, and S were as follows;

$$T_1 = A\text{M NaOD} + 3\text{M NaClO}_4$$

$$T_2 = 2B\text{M UO}_2(\text{ClO}_4)_2 + X\text{M DClO}_4 + (3-4B-X)\text{M NaClO}_4$$

$$S = B\text{M UO}_2(\text{ClO}_4)_2 + D\text{M DClO}_4 + (3-2B-D)\text{M NaClO}_4.$$

The partially-hydrolyzed solution made thereby was kept standing overnight, while nitrogen gas was passed through the solution; the next morning no precipitate was detected in the test solution.

The partially-hydrolyzed solution was gradually acidified by generating the deuterium ions coulometrically.

During the measurements, the test solution was stirred by a stream of nitrogen gas which had been purified by leading it through heavy water and 3M $NaClO_4$ in heavy water.

All the measurements were carried out in a paraffin-oil thermostat kept at 25.00±0.01°C in a room kept by a thermostat at 25±1°C.

Results and Discussion

The values of Z and $\log d$ in each series of B, which were calculated from the potentiometric measurements by the use of Eq. (1), are represented graphically in Fig. 1.

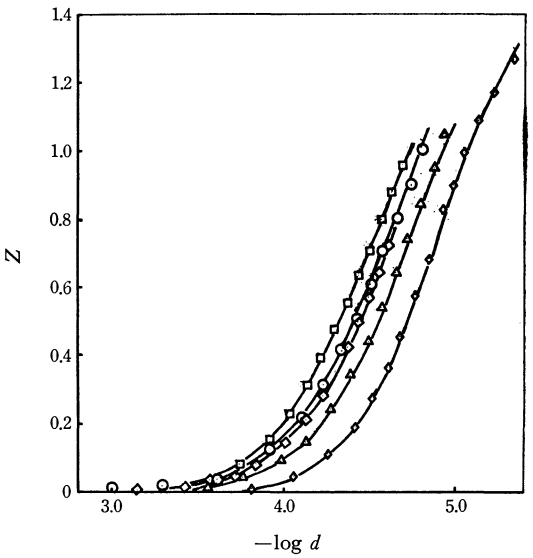

Fig. 1. Average number, Z, of OD bound per UO_2, as a function of $\log d$. Drawn curves were calculated with the stability constants given in Table 2.

B

The experimental data were analyzed by a graphical method and by computer calculations.

First, the hydrolysis data were submitted to graphical analysis in order to obtain some preliminary information on the composition of the hydrolysis species formed; then, on the basis of the information thus obtained, computer analysis was made in order to evaluate the most probable hydrolysis scheme and the stability constants of the species formed.

1) The Evaluation of the Composition of the Hydrolysis Products by Graphical Analysis. In order to ascertain the mean composition of the polynuclear species formed, *i. e.*, $\bar{p}$ and $\bar{q}$, the general integration method presented by Sillén[6] was employed. The results of the calculations are

shown in Fig. 2 as $\bar{q}$ *vs.* $(2\bar{q}-\bar{p})$.[7] From this figure, it may be seen that the (2,2) species exists at low Z values, while the (5,3) species may be present at high Z values, judging from the directions of the plots.

2) The Evaluation of the Composition and the Stability Constants of the Hydrolysis Products by Computer Analysis. The generalized, least-squares method was, with the help of an electronic computer (HITAC 5020), used to determine the most probable hydrolysis scheme containing the lowest number of species which would suffice to account for the experimental data and for the stability constants of the species formed. The least-squares calculations on the electronic computer were carried out using same procedure as that described in Ref. 1.

Several combinations of the hydrolysis species were attempted by starting with the species which had been suggested by the graphical analysis of the present work and by the investigations previously made by several researchers[8] in light water with the ClO_4^- anion. The results of the computations for several combinations of these species are shown in Table 1.

Table 1. The error square sums and the values of the stability constants for the schemes chosen

$\beta_{1,1}$ $\times 10^7$	$\beta_{2,2}$ $\times 10^7$	$\beta_{4,3}$ $\times 10^{14}$	$\beta_{5,3}$ $\times 10^{19}$	$\beta_{6,4}$ $\times 10^{22}$	U $\times 10^2$
—	1.89	—	3.14	—	1.72
17.8	1.71	—	3.16	—	1.70
—	1.58	1.02	2.32	—	1.27
8.26	1.33	1.56	1.95	—	1.73
—	1.58	0.969	2.29	1.46	1.30

7) H. S. Dunsmore, S. Hietanen and L. G. Sillén, *ibid.*, **17**, 2644 (1963).
8) "Stability Constants," ed. by L. G. Sillén and A. E. Martell, The Chemical Society, London (1964).

The (2,2) - (4,3) - (5,3) species scheme had the least error-square sum and the least systematic errors of the schemes chosen; also, it showed a satisfactory agreement with the experimental data. It is shown in Fig. 1 as solid lines superimposed on the experimental data. The (2,2) - (4,3) - (5,3) - (6,4) species scheme, which had the second least error-square sum, gave rise to slight larger systematic errors than the (2,2) - (4,3) - (5,3) species scheme at higher Z values.

In the present work, no further attempt was made to search for new species other than those listed in Table 1.

From the results described above, it was concluded that the present experimental data in heavy water could be explained by assuming the (2,2) - (4,3) - (5,3) species scheme within the limits of experimental error.

The final values for the stability constants for the system of heavy water are listed in Table 2, together with those for the system of light water described by Dunsmore, Hietanen, and Sillén.[7]

3) Distribution of the Species. The distribution of the hydrolysis species in heavy water and in light water, calculated at the total uranyl concentration of 10 mM, and assuming the values of the stability constants in Table 2, is represented

Table 2. The values for the stability constants of the hydrolysis species of the beryllium ion in heavy water and in light water containing 3M $NaClO_4$ as an ionic medium

	Present work* (in heavy water)	Ref. 7** (in light water)
$-\log \beta_{2,2}$	6.80±0.02	6.04±0.02

graphically in Fig. 3. There is a general shift toward less hydrolysis in heavy water at a given pH. The dominance of the (2,2) and (5,3) species in the accessible pH region is apparent in both heavy water and light water.

In the present work, it has been found that the compositions of the species formed in heavy water, *i.e.*, $(UO_2)_2(OD)_2^{2+}$, $(UO_2)_3(OD)_4^{2+}$, and $(UO_2)_3(OD)_5^+$, are generally the same as those in light water, although the (1,1) species or of the (6,4) species, which had previously been found, was not found in the present heavy water - system. It has also been found that the values of the stability

Circular Dichroism of Chromium(III) Complexes. II.[1] Correlation between Behavior in the Spin-forbidden Absorption Band Region and Absolute Configurations

Sumio KAIZAKI, Jinsai HIDAKA and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received October 31, 1969)

The absorption and circular dichroism (CD) spectra of twelve optically active chromium(III) complexes containing three bidentate ligands have been measured in the near-infrared to ultraviolet region. CD spectra in the spin-forbidden *d–d* absorption band region have been considered mainly in relation to the CD bands in the first spin-allowed *d–d* absorption band region. It has been concluded that the absolute configurations of chromium(III) complexes can be determined on the basis of the signs of the CD bands in the spin-forbidden band region. The splitting components of the CD bands in the spin-forbidden band region have been discussed considering the crystal field treatment by Macfarlane.

There have been a number of studies concerning the relationship between the absolute configurations of dissymmetric d^3 and d^6 metal complexes and their CD spectra in the region of *d–d* absorption bands.[2-5] In these cases, the absolute configurations have been assigned from a comparison of the signs of the CD bands in the spin-allowed *d–d* absorption band region with those of the electronically corresponding CD bands of a reference complex, *e. g.* $(+)_{546}$-$[Co(en)_3]^{3+}$, whose absolute configuration had been conclusively determined by an

X-ray method.[6] However, it was difficult to decide which band corresponded electronically to the key band of the reference complex. As a means to solve the problem the ion-pairing effect on the CD bands by selenite or phosphate ion in solutions has been proposed by Mason *et al.*

Kling and Woldbye[7] obtained the rotatory dispersion of $(+)_{546}$-$[Cr(en)_3](ClO_4)_3$ and $(+)_{546}$-$[Cr(tn)_3]Cl_3$ in their spin-forbidden band region and found many inversive dispersions superimposed with each other. McCaffery and Mason[2] reported the CD spectra of tris(L-tartrato)chromium(III) ion in the spin-forbidden band region. In the corresponding region, Mason[8] found the splitting of the CD bands due to the ^2E_g transition of $(-)_{546}$-$[Cr_2(OH)_2(dip)_4]^{4+}$ and $(-)_{546}$-$[Cr_2(OH)_2(phen)_4]^{4+}$, and suggested the spin-spin coupling in these binuclear complexes. In a previous paper,[1] we reported the CD spectra of three oxalato- and two L-tartratochromium(III) complexes in the spin-forbidden band region and proposed a tentative assignment of the sharp but weak CD bands observed.

In this paper, the CD and electronic absorption spectra of twelve optically active tris-chelate chromium(III) complexes, which belong to the types, $[Cr(N)_6]$, *cis*-$[Cr(O)_2(N)_4]$ and *cis*-$[Cr(O)_4(N)_2]$, will be reported and the assignment of the CD bands in the spin-forbidden band region will be confirmed on the basis of the ion-pairing effect on the CD bands of the tris-diamine chromium(III) complex ions. The correlation of the CD bands in the spin-forbidden band region with those in the spin-allowed absorption band region as well as with the exciton CD bands of tris- or bis-α-diimine metal complexes will be discussed in connection with the absolute configurations. Macfarlane's analysis[9] using the crystal field model will be applied to the splitting components of the CD spectra in the spin-forbidden band region. The values for the electron repulsion parameter B and the trigonal parameter v and v' will be estimated and considered.

Experimental

Preparation and Optical Resolution. 1) $(+)_{546}$-$[Cr(ox)(en)_2]Cl$. This complex was prepared by Werner's method[10] and resolved by the method of Vaughn and Walkwitz.[11]

2) $(+)_{546}$-$[Cr(ox)(dip)_2]Cl$ and $(+)_{546}$-$[Cr(ox)(phen)_2]ClO_4 \cdot 2.5H_2O$. These 2,2′-dipyridyl(=dip) and 1,10-phenanthroline(=phen) complexes were prepared and resolved by the method of Broomhead *et al.*[12] The CD spectra of $(+)_{546}$-oxalatobis(dip)chromium(III) complex were measured after converting the diastereomer, $(+)_{546}$-$[Cr(ox)(dip)_2] \cdot (+)_{546}$-$[Cr(ox)_2(phen)]$, into the chloride with anion exchange resin of chloride type.

3) $(+)_{546}$-$[Cr(en)_3](ClO_4)_3$. Trisethylenediaminechromium(III) perchlorate was prepared by the method of Linhard and Weigel[13] and resolved by the method of Werner.[14]

4) $(+)_{546}$-$[Cr(tn)_3](ClO_4)_3$. The preparation and optical resolution of this complex was performed by the method of Schläfer and Kling.[15]

5) $(-)_{546}$-$[Cr(BH)_3]Cl_3$.*1 The trisbiguanide complex was obtained by the reaction with potassium chromium(III) alum and biguanide sulfate in an alkaline solution.[16] The optical resolution of this complex was carried out by Michelsen's method.[17]

6) $(+)_{546}$-$[Cr(phen)_3](ClO_4)_3$. The synthesis of optically active tris(1,10-phenanthroline)chromium(III) complex was performed by the second order asymmetric process of Lee *et al.*[18]

7) $(+)_{546}$-$K[Cr(ox)_2(dip)] \cdot 3H_2O$, $(+)_{546}$-$K[Cr(ox)_2(phen)] \cdot 4H_2O$, $(+)_{546}$-$K[Cr(ox)_2(en)] \cdot 2H_2O$, $Ba[Cr_2(L\text{-}tart_2H)(dip)_2]_2 \cdot 9H_2O$ and $NH_4[Cr_2(L\text{-}tart_2H)(phen)_2] \cdot 6.5H_2O$. The preparation and optical resolution of these bisoxalato complexes and the syntheses of the L-tartrato complexes have been described in Part I of this series.[1]

8) Sodium $(+)_{589}$-Nitrocamphoronate. The resolving agent with which $[Cr(en)_3]^{3+}$ and $[Cr(tn)_3]^{3+}$ were resolved was prepared from $(+)_{589}$-camphor.[19] Preparation of $(+)_{589}$-bromocamphor as a starting material was carried out by treating $(+)_{589}$-camphor with bromine. The $(+)_{589}$-bromonitrocamphor was obtained by refluxing with nitric acid for about 50 hr. The resulting $(+)_{589}$-bromonitrocamphor was treated with sodium alcoholate and the crude product obtained was recrystallized from alcohol. The pure sodium $(+)_{589}$-nitrocamphoronate was obtained as pale yellow crystals.

Measurements. Absorption spectra were measured by a Beckman DU spectrophotometer. CD spectra were recorded with a Roussel-Jouan dichrograph. The CD spectra of $(+)_{546}$-$[Cr(en)_3](ClO_4)_3$ in the second spin-allowed *d–d* absorption band region were recorded with a Jasco Model ORD/UV-5 spectrophotometer. The concentrations of complexes for the CD measurements in the spin-forbidden absorption band region were 10^{-1}—10^{-2} F, and the cell lengths employed were 5 and 7 cm.

The CD measurements for the ion-pairing effect were made throughout the spin-forbidden and first spin-allowed absorption band region in solutions with the constant molar concentrations of both the complex perchlorates and sodium selenite, using cells with 7, 5, 2 and 1 cm path-length. The solvent employed was water for the complexes except $(+)_{546}$-$[Cr(ox)(phen)_2]$-ClO_4. The absorption and CD spectra of this 1,10-phenanthroline complex were measured in 70% $HClO_4$, because of very small solubility in water to measure the CD spectrum in the spin-forbidden band region. In the first spin-allowed *d–d* absorption band region, the CD spectra in water show only one positive CD band, whereas the CD spectra in 70% $HClO_4$ show two CD bands, (−) and (+), listing from the longer wavelength side. In 70% $HClO_4$, however, the absorption spectra and the exciton CD bands in the ultraviolet region corresponding to the ligand transition (300—250 mμ) are similar to those in water. This fact indicates that the geometrical sturcture and absolute configuration are retained in 70% $HClO_4$ as they were in water.

Results and Discussion

General Features of the Spin-forbidden Bands. The absorption and CD spectra of the present complexes are shown in Figs. 1—8. Their characteristics are summarized in Table 1. In the spin-forbidden *d–d* absorption band region, the CD spectra of the complexes show a group of sharp and narrow peaks with weak intensity as may be seen in Figs. 1, 2 and 5—8. The intensities of the CD bands in this region are found to be one fraction of a few hundred times as weak as those in the first spin-allowed *d–d* absorption band region as shown in Table 1. The half-widths of these CD bands are found to be about 200 to 400 cm^{-1} with the exception of the case of $(-)_{546}$-$[Cr(BH)_3]Cl_3$, whose half-width is about 800 cm^{-1}. The experimental

rotational strengths of the spin-forbidden transitions are found to be about 0.1% of that of the first spin-allowed transitions. This value is about one tenth of the value estimated for cobalt(III) complexes by Ballhausen.[20] The anisotropy factor, *g*, for the CD bands in the spin-forbidden band region is nearly equal to that of the CD bands in the first spin-allowed *d–d* absorption band region. This fact suggests that the rotational strength of the spin-forbidden transition originates from that of the first spin-allowed transition which is magnetically dipole allowed in O_h symmetry, rather than from that of the second spin-allowed transition which is magnetically dipole forbidden in O_h symmetry.

The CD bands of trisoxalato- and trismalonato-chromium(III) complexes were also observed in the spin-forbidden band region. However, the CD spectra of both complexes in this region are very complicated, because of the superposition upon the minor but broad CD band related to the longest wavelength component of the first spin-allowed absorption band.

According to the crystal field theory,[21] the

narrow and sharp absorption bands of chromium(III) complexes appearing at 800—600 mμ are considered to be due to the spin-forbidden transitions within the t_{2g} shell and to be assigned to the $^4A_{2g}$–^2E_g and $^4A_{2g}$–$^2T_{1g}$ transitions in O_h symmetry. Furthermore, the ^2E_g state seems to occur at the longer wavelength side and to be of stronger intensity than the $^2T_{1g}$ state.[21] On the other hand, Schläfer *et al.*[22-24] have extensively studied the phosphorescence spectra of a number of chromium(III) complexes. It has been revealed that the relatively intense spin-forbidden absorption band lying at the longest wavelength side are the zero-zero band of the ^2E_g transition and the remaining bands are due to the vibrational transitions associated with the electronic transition to the ^2E_g state rather than the electronic transitions to the $^2T_{1g}$ state. Now, in D_3 symmetry, to which most of the present complexes belong, the T_{1g} state breaks down into the E_b and A_2 states and the E_g state remains as the E_a one. Accordingly, from the fact that most of the complexes studied here exhibit a close correspondence between the positions of the lowest frequency CD band and those of the absorption and phosphorescence bands in the spin-forbidden band region,[22-24] the lowest frequency CD band may be assigned to the ^2E_a transition. Assuming that the remaining CD bands are due to the electronic transitions to the $^2T_{1g}$ state in O_h symmetry, these CD bands may be tentatively assigned to the $^2A_2$ and ^2E_b states in D_3 symmetry.[1] However,

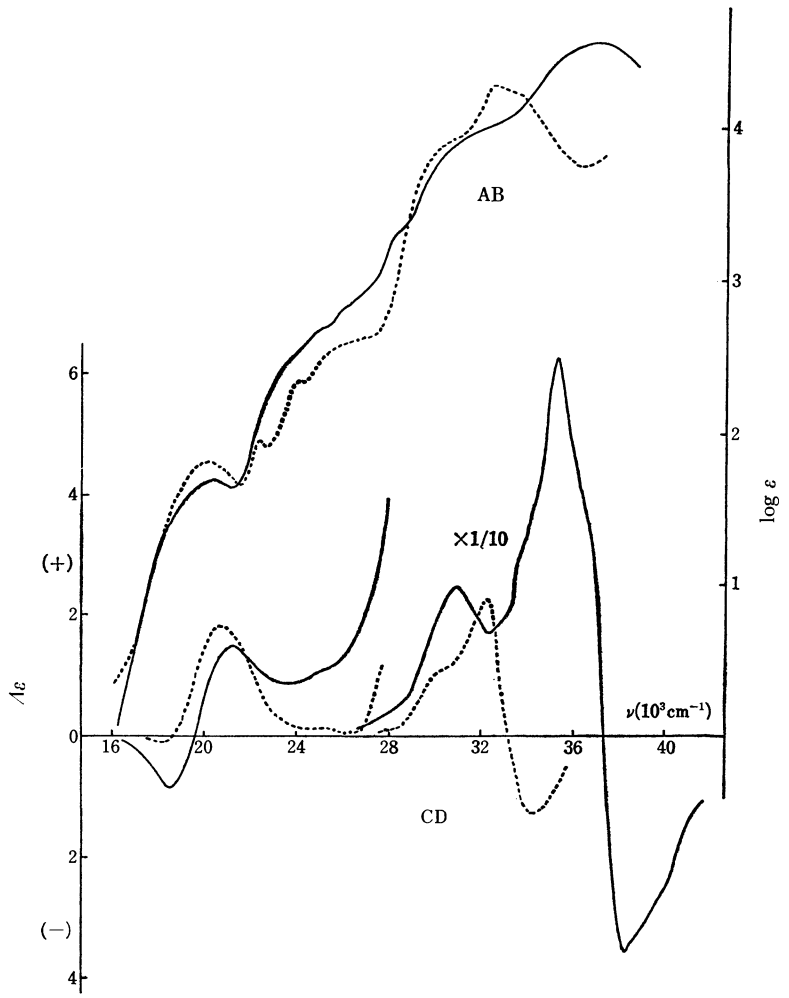

Fig. 4. Absorption (AB) and CD curves of $(+)_{546}$-[Cr(ox)(phen)$_2$]ClO_4 (———) in 70% $HClO_4$ and $(+)_{546}$-[Cr(ox)(dip)$_2$]Cl (·····) in water.

it is difficult to determine whether these CD bands are due to the vibrational transitions associated with the electronic transitions to the $^2E_g(O_h)$ state or to the electronic transitions to the $^2T_{1g}(O_h)$ state from the following reasons. Firstly, the ^2E_g and $^2T_{1g}$ states with $(t_{2g})^3$ configuration are theoretically expected to be split neither to the first order by means of the spin-orbit coupling nor in terms of lowering of symmetry.[21] Secondly, these CD bands in the spin-forbidden band region show rather simpler patterns than the corresponding absorption bands.

$(+)_{546}$-[Cr(en)$_3$]$(ClO_4)_3$ and $(+)_{546}$-[Cr(tn)$_3$]-$(ClO_4)_3$. The absorption spectra of trisethylenediamine- and tristrimethylenediaminechromium-(III) complexes coincide with those reported.[15] The CD spectra of $(+)_{546}$-trisethylenediamine complex in the first spin-allowed *d–d* absorption band region coincide with those reported by Mathieu.[25] In the second spin-allowed *d–d* absorption band region, however, the CD spectra of the complex obtained here are quite different from those reported by Mathieu.[25] According to the present measurement, three weak CD peaks, (+), (−) and (+) listing from the longer wavelength side, are evidently observed in the corresponding region as may be seen in Fig. 1. This result is inconsistent with the theory[26] that the d^3 or d^6 complex with D_3 symmetry should give only one CD component in the second absorption band region.

Mason *et al.*[27-29] have intensively studied the

ion-pairing effect on the CD spectra of trisdiamine metal complexes. It has been reported that the diminution or increase of the intensity of the CD bands by the ion-pairing effect are observed in the first spin-allowed absorption band region, and it has been proposed that the diminished CD band is assigned in the case of chromium(III) complexes to the ^4E component and the increased CD band to the $^4A_1$ in D_3 symmetry. In the first spin-allowed *d–d* absorption band region, the intensity of the positive CD band of $(+)_{546}$-trisethylenediaminechromium(III) complex is diminished with the addition of sodium selenite to the solution as may be seen in Fig. 1 and Table 1.[27] Since the diminished positive CD band is due to the ^4E component, the $(+)_{546}$-isomer of trisethylenediamine complex seems likely to have a $\Delta(C_2)$ absolute configuration. The same CD behavior due to the ion-pairing effect is also more markedly observed for the $(+)_{546}$-tristrimethylenediamine complex as seen in Fig. 2.

In this complex, the intensity of a positive CD band at 477 mμ is diminished and a new CD band appears at 435 mμ with the addition of sodium selenite to the solution.[28] Thus, the diminished positive band is assigned to the ^4E component and the newly appearing negative band to the $^4A_1$ component.[28] From this fact, the $(+)_{546}$-tristrimethylenediaminechromium(III) complex was determined to have a $\Delta(C_2)$ absolute configuration. The CD spectra in the region corresponding to the spin-forbidden transitions for the $(+)_{546}$-trisethylenediamine- and tristrimethylenediaminechromium(III) complexes with a $\Delta(C_2)$ configuration show three sharp and narrow peaks, (+), (−) and (+). For the $(+)_{546}$-trisethylenediamine complex, the CD intensity of the positive component at the longest wavelength side is diminished by the ion-pairing effect as shown in Table 1. The CD behavior in the corresponding region for the tristrimethylenediamine complex is similar to that for the ethylenediamine complex. That is, the CD intensity of the positive band due to the ^2E_a transition of the trimethylenediamine complex is markedly reduced with the addition of sodium selenite as shown in Fig. 2 and Table 1. From this parallel reduction in the CD intensity by the ion-pairing effect between the ^4E and ^2E_a transitions and from the above-mentioned anisotropy factor, it is suggested that the excited doublet and quartet states with the same orbital symmetry are mixed with

each other by means of the spin-orbit coupling, which allows the ^2E_a transition to acquire a rotational strength by borrowing both the magnetic and electric transition dipole moments from the upper ^4E transition and to have the same sign of rotational strength as that of the ^4E transition. The central negative and the highest frequency positive CD bands in the spin-forbidden band region may be tentatively assigned to the $^2A_2$ and ^2E_b transition with octahedral $^2T_{1g}$ parentage, respectively, though for the $^4A_2$–$^2A_2$ transition the corresponding spin-allowed transition ($^4A_2$–$^4A_2$) is both electrically and magnetically dipole forbidden. From this consideration, it can be proposed that chromium(III) complexes with the positive ^4E CD band of the first spin-allowed *d–d* transition exhibit the positive ^2E_a CD band and have a $\Delta(C_2)$ configuration. This proposal is consistent with the result from the determination of absolute configurations on the basis of the exciton CD bands and of stereospecificity as will be mentioned below.

1,10-Phenanthroline and 2,2′-Dipyridyl Complexes. Mason *et al.*[30-32] and Bosnich[33] have developed the nonempirical method for determining the absolute configurations of tris- or bis-α-diimine metal complexes on the basis of CD spectra in the ultraviolet region, where long-axis-polarized π–π* ligand transition occurs. According to their consideration, the simple electrostatic treatment of the exciton theory neglecting the central metal ion predicts that tris- or bis-α-diimine metal complexes should take a $\Delta(C_2)$ configuration, if these complexes show a positive and a negative CD band at the longer and shorter wavelength side, respectively, in the exciton band region. This prediction has been recently confirmed by X-ray determination[34] of the absolute configuration of $(-)_{589}$-$[Fe(phen)_3]^{2+}$ and has been shown to be consistent with the result of the empirical method on the basis of the CD bands in the first spin-allowed *d–d* absorption band region.[8,31] In the region from 300 mμ to 250 mμ, the CD spectra of tris- or bis-1,10-phenanthroline- and bis-2,2′-dipyridylchromium(III) complexes studied show two large typical exciton bands, which have signs opposite each other and are of nearly equal intensity. As may be seen in Figs. 3 and 4, $(+)_{546}$-$[Cr(phen)_3](ClO_4)_3$, $(+)_{546}$-$[Cr(ox)(phen)_2]ClO_4$ and $(+)_{546}$-$[Cr(ox)(dip)_2]Cl$ give two exciton CD bands, namely, (+) and (−) bands, and a positive major CD band in the first spin-allowed *d–d* absorption band region.[8,35] Consequently, on the basis of the CD bands, the absolute configuration of these phen and dip complexes

will be determined to be a $\Delta(C_2)$ configuration.*2 The CD spectra in the spin-forbidden band region show two peaks, (+) and (−), for $(+)_{546}$-[Cr(phen)$_3$]$^{3+}$ and $(+)_{546}$-[Cr(ox)(phen)$_2$]$^+$ and four peaks, (+), (−), (−) and (+), for $(+)_{546}$-[Cr(ox)(dip)$_2$]$^+$, listing from the longer wavelength side as may be seen in Fig. 5. That is, the sign of the lowest frequency CD band due to the ^2E_a transition for the phen and dip complexes having the $\Delta(C_2)$ absolute configuration is always positive. In the case of $(+)_{546}$-[Cr(ox)(en)$_2$]Cl, which has a *cis*-[Cr(O)$_2$(N)$_4$] type structure similar to that of bis(phen)- and bis(dip)oxalato complexes, the CD band in the region of the spin-forbidden band is also related to that in the first spin-allowed absorption band region. Namely, the CD spectra of $(+)_{546}$-[Cr(ox)(en)$_2$]Cl show a positive band in the first absorption band region and three sharp peaks, (+), (−) and (+), in the spin-forbidden band region, as seen in Fig. 5. Thus, it can be determined that $(+)_{546}$-[Cr(ox)(en)$_2$]Cl giving the positive ^4E and ^2E_a CD components take a $\Delta(C_2)$ configuration.

L-*Tartrato and Oxalato Complexes.* We have revealed that the L-tartratochromium(III) (1:1)-complexes, Ba[Cr$_2$(L-tart$_2$H)(dip)$_2$]$_2\cdot 9H_2O$ and NH_4[Cr(L-tart$_2$H)(phen)$_2$]$\cdot 6.5H_2O$, are formed completely stereospecifically to have a bis(L-tartrato)-bridged binuclear structure with a $\Lambda(C_2)$–$\Lambda(C_2)$ configuration. The L-tartrato complexes gave apparently positive weak CD bands in the spin-forbidden band region superimposing on the positive CD component related to the first spin-allowed absorption band.[1] Upon detailed remeasurements, however, another sharp but weak negative CD bands are observed at longer wavelengths in the spin-forbidden band region as shown in Fig. 6. It is evident that the L-tartrato complexes with the $\Lambda(C_2)$ absolute configuration give the negative CD peaks at the longest wavelength side in the spin-forbidden band region and the negative major CD band in the first spin-allowed *d–d* absorption band region. The L-tartrato complex containing 1,10-phenanthroline exhibits splitting of the negative CD band of the spin-forbidden transition (Fig. 6). This fact suggests the existence of the spin-spin coupling between the two chromium(III) ions also in this binuclear complex as reported by Mason[8] in the case of $(-)_{546}$-[Cr$_2$(OH)$_2$(dip)$_4$]$^{4+}$ and $(-)_{546}$-[Cr$_2$(OH)$_2$(phen)$_4$]$^{4+}$. For the oxalato complexes, $(+)_{546}$-K[Cr(ox)$_2$(dip)], $(+)_{546}$-K[Cr(ox)$_2$(phen)] and $(+)_{546}$-K[Cr(ox)$_2$(en)], which have the geometrical structure identical to that of the L-tartrato complex, *cis*-[Cr(O)$_4$(N)$_2$] type, the major CD band in the first spin-allowed absorption band region and the lowest frequency CD band in the spin-forbidden band region have a positive sign, as seen in Fig. 7. Thus, the oxalato complexes take a $\Delta(C_2)$ absolute configuration.

Trisbiguanide Complex. The biguanide complex, $(-)_{546}$-[Cr(BH)$_3$]Cl$_3$, shows two intense CD bands in the first spin-allowed absorption band region, (+) one at 460 mμ and (−) one at 520 mμ.[17] In the region of the spin-forbidden band, this complex gives two weak and broad CD bands, (−) and (+), as seen in Fig. 8. The absolute configuration of this complex may be assumed to be a $\Delta(C_2)$ one on the basis of the sign of the major CD band in the first spin-allowed band region.[17] On the contrary, a $\Lambda(C_2)$ configuration may be assumed from the theory that the ^2E_a CD component is at the longest wavelength side. However, this contradiction may be solved as follows. Since a biguanide forms a six membered chelate ring, the energy ordering of the trigonal splitting for this complex is assumed to be similar to that of tristrimethylenediamine complex with six membered chelate rings. Thus, the positive major CD component at the shorter wavelength side may be assigned to the $^4A_1$ and the negative minor CD component at the longer wavelength side to the ^4E component. Therefore, the ^4E CD component has a negative sign similar to the ^2E_a CD component. It is thus concluded that the $(-)_{546}$-trisbiguanidechromium(III) complex has a $\Lambda(C_2)$ absolute configuration.

It is concluded that the absolute configurations of tris-chelate chromium(III) complexes can be determined on the basis of the sign of the lowest frequency CD component corresponding to the ^2E_a transition derived from the octahedral ^2E_g parentage. Namely, if the ^2E_a CD component show a positive sign, the absolute configuration of the complexes can be determined to be a $\Delta(C_2)$.

Analysis of the CD Bands. On analysis of the spectra of d^3 ions in a trigonal field in terms of the weak field perturbation, Macfarlane[9] has estimated the contribution of the ligand field parameter Δ, the trigonal parameters v and v', and the electronic repulsion parameters B and C, to the transition energies of the doublet states as shown in Table 2.

*2 When the metal-ligand and ligand-ligand bonding are taken into consideration, the relative energies of the exciton splitting are affected by the central metal ion and also by the kind of conjugated ligand. According to Ferguson *et al.*,[35] the sign of the exciton splitting has been experimentally determined on the basis of analysis of the ligand absorption bands and it has been found that the sign for $(+)_{546}$-[Cr(ox)(dip)$_2$]$^+$ is opposite that of $(+)_{546}$-[Cr(ox)(phen)$_2$]$^+$.

In consequence, it has been concluded that the two $(+)_{546}$-isomers have been assigned to have opposite configurations to each other. It is doubtful, however, that the difference in the π-bonding between 2,2′-dipyridyl and 1,10-phenanthroline gives rise to such drastic modification of the relative energies of the exciton splitting, because the contributions of the metal-ligand or ligand-ligand bonding to the exciton splitting are expected to be small and almost the same for the dip and phen chromium(III) complexes.[8,32] Therefore, the simple dipole-dipole interaction theory may be adopted here as a good approximation.

Table 2. Representation of the transition energies of the doublet states

$$\nu(^2E_a) = 0.0317\Delta - 0.241v - 0.178v' + 6.54B + 3.06C$$
$$\nu(^2A_2) = 0.0250\Delta - 0.217v' + 7.63B + 3.00C$$
$$\nu(^2E_b) = 0.0176\Delta - 0.052v - 0.109v' + 7.81B + 3.01C$$

A similar treatment neglecting the spin-orbit coupling was applied for the trisdiamine complexes on the basis of the above-mentioned assignment for three CD peaks observed in the spin-forbidden band region, on the assumption that the ligand field splitting Δ equals the energy of the first absorption band maximum and that the Racah parameter C is equal to 4B. The values of the parameters B, v and v' obtained are given in Table 3. The values obtained for the parameter B are so reasonable that they are closer to those from Schäffer's treatment[36] including the non-diagonal elements rather than values from strong field approximation with only diagonal elements.[23] The sign of the trigonal parameter v of $[Cr(tn)_3]^{3+}$ obtained is in agreement with the result from the CD measurement. However, the sign for $[Cr(en)_3]^{3+}$ is opposite that from the polarized crystal spectra.[37]

Table 3. Values for the parameters (cm^{-1})

Complexes	B	v	v'
$[Cr(en)_3]^{3+}$	772	+104	+912
$[Cr(tn)_3]^{3+}$	776	+303	+862

Imidazole Catalyses in Aqueous Systems. III. Formation of the Catalyst-Substrate Complex in the Hydrolysis of a Phenyl Ester Catalyzed by a Naphthylimidazole Derivative*1

Toyoki KUNITAKE, Seiji SHINKAI and Chuji ASO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka

(Received June 7, 1969)

Catalytic hydrolysis of *p*-acetoxybenzoic acid by 1-[4(5)-imidazolyl]-4-aminomethylnaphthalene was carried out at 30°C in aqueous systems using a pH-stat. The catalytic rate leveled off at high substrate concentrations and increased remarkably at high pH. The data indicated that both the neutral catalytic species (AmIm) and the monoprotonated catalytic species (Am^+Im) acted as enzyme-like catalysts, the catalytic rate conforming to the Michaelis-Menten kinetics, although their catalytic efficiencies were quite different: K_m (dissociation constant of the catalyst-substrate complex)$=0.011$ M and k_3 (pseudo-intramolecular rate constant of the product-formation)$=0.19$ min^{-1} for AmIm, and $K_m=0.041$ M and $k_3=0.036$ min^{-1} for Am^+Im. The binding function was attributed to hydrophobic interaction, on the ground that K_m was smaller for AmIm than for Am^+Im and that an increase in the ionic strength of the medium caused rate enhancement. The hydrolysate showed an inhibitory action. The wide variation of the catalytic efficiency between AmIm and Am^+Im may be related to the structural difference of the Michaelis complexes. 1-Aminomethylnaphthalene similarly catalyzed the hydrolysis and showed a substrate binding phenomenon, though the saturation phenomenon was much less pronounced as compared with the imidazole catalyst.

In the previous publications of this series, it was shown that imidazole-containing copolymers (I and II) catalyzed the hydrolysis of 3-nitro-4-acetoxybenzoic acid according to the Michaelis-Menten kinetics as in enzymatic reactions.[1)]

*1 Contribution No. 169 from this department. Presented at the 22nd Annual Meeting of the Chemical Society of Japan, March, 1969, Tokyo, Japan. A preliminary account of this work was given in C. Aso, T. Kunitake and S. Shinkai, *Chem. Commun.*, **1968**, 1483.

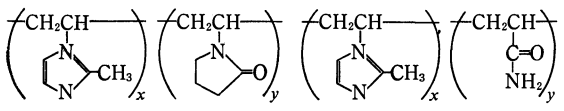
$$\text{catalyst} + \text{substrate} \overset{K_m}{\rightleftarrows} \text{catalyst}\cdot\text{substrate} \xrightarrow{k_s} \text{catalyst} + \text{product} \quad (1)$$



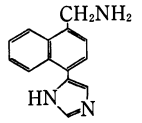
I II

The influence of the copolymer composition of I on the catalytic behavior was accounted for by assuming that the catalytic site was made of a loop of a polymer segment surrounding a substrate molecule. The binding function of the catalytic site was attributable to hydrophobic forces. It was shown that the catalytic action was inhibited competitively by several organic compounds, supporting its enzyme-like catalytic behavior.[2] In the case of catalysis by II, it was not necessary to consider loop formation. The binding function was similarly attributed to the hydrophobic interaction.[1b]

Molecular associations of organic compounds due to hydrophobic forces are frequently encountered in aqueous systems. Dye associations and the micelle formation of detergents are typical examples.

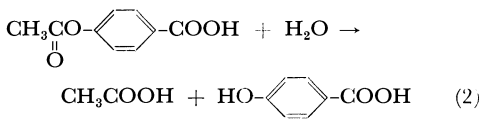
Apart from polymeric systems, there have been several investigations in which formation of catalyst-substrate complexes preceded the chemical transformation of substrates. For instance, Cramer and coworkers found that cyclodextrins catalyzed decarboxylation of substituted cyanoacetates and acetoacetates[3] and fission of pyrophosphates[4] in enzyme-like manners (Eq. (1)). Bender *et al.*[5,6] studied in detail phenyl ester cleavages catalyzed by cycloamyloses. The formation of a 1 : 1 complex between catalyst and substrate molecules with detergent-like structures of opposite charge has been proposed by Wagner *et al.*[7]

Thus, it was expected that small molecules which consist of hydrophobic and catalytic groups might show an enzyme-like catalytic behavior. The first compound we selected for this purpose was 1-[4(5)-imidazolyl]-4-aminomethylnaphthalene (III). The naphthalene ring is considered to show sufficiently strong hydrophobic interaction, since naphthalenesulfonic acid was shown by NMR spectroscopy to associate with acetone or methanol in an aqueous system,[8] and the imidazole group is known to be present in the active site of many hydrolytic enzymes.[9a]



III

In the following we describe an investigation of the enzyme-like catalysis by III for hydrolysis of 4-acetoxybenzoic acid into 4-hydroxybenzoic acid and acetic acid.



(2)

Experimental

Preparation of 1-Acetyl-4-bromonaphthalene (IV).[10,11] α-Bromonaphthalene was prepared in 70% yield from naphthalene and bromine in CCl_4,[12] and subsequently acetylated with acetyl chloride and $AlCl_3$ in CS_2 at room temperature. Yield 71%, mp 47.0—47.5°C (lit,[10] 47.0—47.5°C).

Preparation of 1-Acetyl-4-cyanonaphthalene (V). The reaction was carried out following the preparative method of 1-cyanonaphthalene.[13] Into a 300-m*l* three-necked flask equipped with a mechanical stirrer, a reflux condenser and a thermometer were added 83 g (0.33 mol) of IV, 35 g (0.38 mol) of cuprous cyanide and 65 m*l* of dimethylformamide (DMF). The reaction mixture was stirred for 6 hr with gentle refluxing at 150—160°C. A warm solution of 133 g (0.50 mol) of ferric chloride in 33 m*l* of concentrated hydrochloric acid and 200 m*l* of water was added to the reaction mixture. Some solid residues left in the flask were dissolved in warm DMF. The solutions were combined and maintained for 20 min at 60—70°C. Black precipitates were filtered and the solution was extracted with 750 m*l* (in three portions) of toluene. After distilling toluene,

red-brown needles were obtained on cooling. Recrystallization from methanol gave 7 g (11% yield) of yellow needles: mp 130—132°C. The black precipitate was extracted with toluene in a Soxhlet extractor. Solvent removal from the extract gave red-brown needles, which were recrystallized from methanol to yield yellow needles. The combined yield amounted to 90%. Elemental analysis. Found: C, 80.30; H, 4.56; N, 7.09%. Calcd for $C_{13}H_9NO$: C, 79.98; H, 4.65; N, 7.17%. The infrared spectrum showed peaks at 2220 ($\nu_{C\equiv N}$), 1695 ($\nu_{C=O}$, conjugated), 833 (δ_{CH}, aromatic, out of plane) and 758 cm^{-1} (δ_{CH}, aromatic, out of plane).

Oxidation of V with SeO_2. The reaction was carried out by modifying the preparative method of naphthylglyoxal.[14] In a 100-m*l* three-necked flask equipped with a mechanical stirrer, a reflux condenser and a thermometer, 11.1 g (0.1 mol) of SeO_2 was dissolved in 50 m*l* of dioxane containing 2 m*l* of water at 50—55°C. 19.5 g (0.1 mol) of V was then quickly added and the reaction mixture was refluxed with stirring for 6.5 hr, and stirred at room temperature for additional 12 hr. The precipitated selenium metal and filtered and the solvent removed *in vacuo*. The residue was dissolved while still warm in 30 m*l* of acetone and the precipitate formed (Se metal) was filtered. Acetone was evaporated and the resulting brown residue (1-(4-cyanonaphthyl)-glyoxal, VI) dissolved in 200 m*l* of methanol was used for the next step without further purification. When a shorter oxidation period was employed (refluxing for 4 hr and stirring for 2 hr), the yield of the copper complex in the next step did not decrease.

Preparation of 1-[4(5)-Imidazolyl]-4-cyanonaphthalene (VII). The general procedure for preparation of imidazoles from glyoxals[15] was followed. To a 300-m*l* three-necked flask equipped with a mechanical stirrer, a reflux condenser and a thermometer was added 140 m*l* of 28% aqueous ammonia and 8 m*l* of 37% formalin. The mixture was warmed to 40°C on a water bath, and 20 g of cupric acetate and 100 m*l* of a methanol solution of VI were added with stirring. Stirring was further continued for 40 min at 55—58°C, and the copper salt of the imidazole compound was obtained as precipitates. The crude copper complex was purified by refluxing for 1 hr each in the following solvents: a. 1 : 1 aqueous methanol; b. ethyl acetate, twice; c. acetone, twice; d. chloroform, twice. The yield of the purified copper complex was 15 g (30% based on V).

The imidazole was freed from copper by treating with H_2S. The copper complex (50 g) was suspended in 2 *l* of 1 : 1 aqueous methanol and H_2S gas was introduced for 4 hr with gentle refluxing. The hot mixture was filtered, and, on cooling, 40 g of crude VII was obtained as red-brown precipitates. The crude VII was dissolved in dilute hydrochloric acid, and the hydrochloride of VII (VII-HCl) was recovered by concentration and purified by recrystallization from water with charcoal treatment. The overall yield of VII-HCl from V was approximately 10%. Colorless needles, mp 219—220°C. Found: C, 57.68; H, 4.88; N, 13.75%. Calcd for $C_{14}H_{10}N_3Cl\cdot 2H_2O$: C, 57.63; H, 4.83; N, 14.41%.

Its infrared spectrum showed a broad peak characteristic of the imidazole group at 2800—3200 cm^{-1}, a sharp peak at 2220 cm^{-1} ($\nu_{C\equiv N}$), and peaks at 762 and 833 cm^{-1} (δ_{CH} aromatic, out of plane).

The free imidazole derivative, VII, was obtained by treating VII-HCl with concentrated aq. $NaHCO_3$: Colorless crystals, mp 216—218°C. Its infrared spectrum was consistent with what was expected for VII.

Reduction of VII with $LiAlH_4$. In a 300-m*l* three-necked flask equipped with a mechanical stirrer, a dropping funnel and a reflux condenser connected to a soda lime tube were placed 100 m*l* of carefully-purified tetrahydrofuran (THF) and 1.2 g of $LiAlH_4$. Finely powdered VII (0.6 g) was suspended in 50 m*l* of THF and slowly added over 30 min from the dropping funnel. The color of the mixture turned green. The reaction mixture was refluxed during the addition and for the subsequent 90 min. Excess $LiAlH_4$ was decomposed with 50 m*l* of water, and 70 m*l* of 10% aqueous NaOH was added. The pale yellow organic layer was separated and acidified with 10 m*l* of 4N hydrochloric acid, and THF was removed *in vacuo*. When separation of the two layers was difficult, addition of concentrated aqueous NaOH or of an aqueous solution of Rochelle salt was effective for the phase separation. Slow addition of concentrated aqueous alkali to the organic residue gave rise to white precipitates, which again went into solution on standing. When the dissolution became sluggish, an aqueous solution of excess Na_2CO_3 was added to yield 0.4 g of white precipitates (III). mp 172—175°C. Yield 70%. Reprecipitation was carried out by neutralization of an acidic aqueous solution as metioned above, and the precipitate was dried *in vacuo*.

Found: C, 75.03; H, 5.85; N, 17.75%. Calcd for $C_{14}H_{13}N_3$: C, 75.31; H, 5.87; N, 18.82%.

Its infrared spectrum showed the presence of a broad peak between 2900—3400 cm^{-1} (imidazole). The peak at 2220 cm^{-1} was absent, indicating disappearance of the cyano group. Peaks at 827 and 756 cm^{-1} showed that the naphthalene ring remained intact. Titration of III (10.9 mg) was carried out as described below (30°C, 1M KCl) and the alkali consumption to neutralize the protonated imidazole group was 95±3% of the calculated amount.

Preparation of 1-Aminomethylnaphthalene (VIII). Naphthalene was reacted with paraformaldehyde and concentrated hydrochloric acid to give 1-chloromethylnaphthalene[16] in 83% yield: bp 168—172°C/25 mmHg (lit,[16] 148—153°C/14 mmHg). 1-Chloromethylnaphthalene was converted to 1-aminomethylnaphthalene by treating with hexamethylenetetramine in chloroform.[17] Bp 192—198°C/25 mmHg (lit,[17] bp 200—205°C/30 mmHg). Yield 61%. 1-Aminomethylnaphthalene hydrochloride (VIII-HCl) was obtained by introducing dry HCl gas into an ether solution of VIII. Colorless plates, mp 261—263°C (lit,[17] 260—262°C).

Preparation of *p*-Acetoxybenzoic Acid. Commercial *p*-hydroxybenzoic acid, 27.6 g (0.2 mol), was dis-

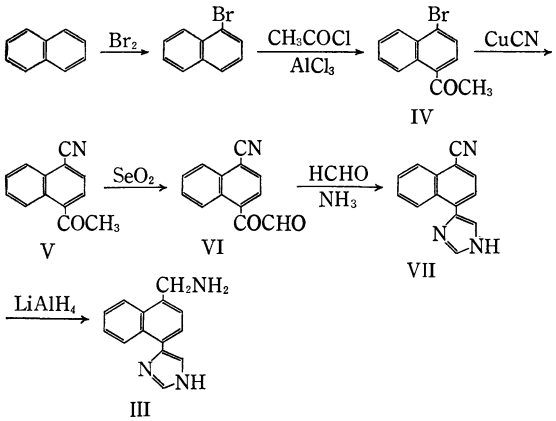
solved in 80 ml (0.8 mol) of acetic anhydride and the solution was refluxed for 3 to 4 hr. The reaction mixture was poured into ice water, and the white precipitates formed were recrystallized twice from water and dried. Additional recrystallization from benzene gave colorless flakes in 85—92% yield. Mp 192—194°C (lit,[18] 186°C).

Titration and Hydrolysis Procedures. Titration and hydrolysis were carried out at 30.0±0.05°C using a pH-stat connected with a recorder (TOA Electronics Ltd., Models HS-1B and EPR-2T, respectively). Details of the procedures have been described previously.[1b]

Miscellaneous. Imidazole and KCl, guaranteed reagents, were dried and used without further purification. Infrared spectra were obtained with a Jasco DS 301 spectrometer.

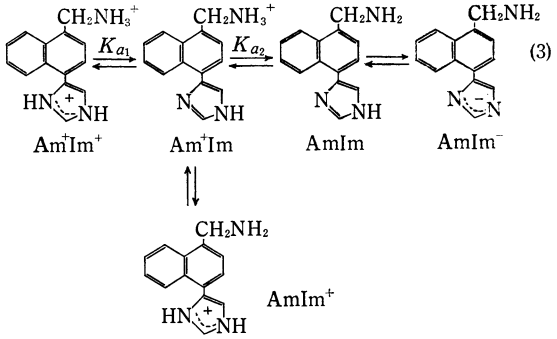
Results

Synthesis of 1-[4(5)-Imidazolyl]-4-aminomethylnaphthalene (III). III was synthesized by the following sequences.



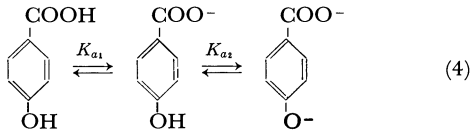
IV was obtained in good yields by acetylating 1-bromonaphthalene with acetyl chloride and $AlCl_3$ in CS_2 at 15—17°C. The conversion from IV to V proceeded smoothly with CuCN in DMF. Oxidation of V was carried out with SeO_2. Since the resulting glyoxal, VI, was unstable in air, a methanol solution of VI was used for the next step without purification. Formation of the imidazole ring was done with HCHO and NH_3 from VI. In order to obtain pure VII, extensive solvent extraction of the VII-copper complex was necessary. Otherwise, VII was accompanied by tarry materials which were difficult to remove. Reduction of the cyano group of VII was readily carried out using $LiAlH_4$. III was rather unstable in air and underwent ready discoloration, while III-HCl was sufficiently stable.

Titration. The titration behavior of the catalysts and the substrate were investigated at 30.0±0.05°C in 1M aqueous KCl. The free naphthylimidazole catalyst (III) was dissolved in 1M aqueous KCl at 30°C and the solution was adjusted to pH 3 by adding a small amount of hydrochloric acid. Titration was carried out by adding aqueous alkali in small portions. When pH of the solution reached approximately 9.8, the catalyst started to precipitate. This compound can exist in the form of the following species:



The titration curve of this compound shown in Fig. 1 indicates the presence of two dissociation steps. Since species $AmIm^-$ need not be considered in this pH range and the amount of $AmIm^+$ appears negligible, the two dissociation steps observed were concluded to correspond to processes Am^+Im^+ to Am^+Im and Am^+Im to AmIm. pK_a values determined from the titration curve by the method of Noyes[19] are given in Table 1.

The hydrolysis product, *p*-hydroxybenzoic acid, similarly gives the following two dissociation steps.



The pK_a values of III obtained from the titration curve of Fig. 1 are shown in Table 1. The titration of imidazole and 1-aminomethylnaphthalene was carried out in the same way and the pK_a (half neutralization point) is given in Table 1. The titration curve of the latter compound (Fig. 1), however, did not show a sharp transition, and the estimation of pK_a was less precise.

The pH dependence of the fractions of each species of III present in the system was calcluted as shown in Fig. 2 from the pK_a values obtained.

Spontaneous Hydrolysis. The substrate underwent spontaneous hydrolysis at higher pH. The results of the spontaneous hydrolysis at pH 8.0 are given in Fig. 3. Its rate was proportional to the substrate concentration, *viz.*,

$$v_{spont} = k_{spont} \cdot [S] \quad (5)$$

k_{spont} determined by the least square method was

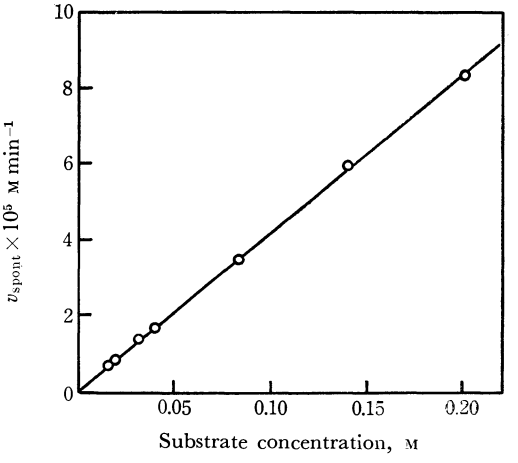

Fig. 3. Spontaneous hydrolysis.
30°C; pH 8.0; 1.0M KCl

$(4.23\pm0.02) \times 10^{-4}$ min^{-1}. The spontaneous hydrolysis was not detectable at pH 7.0.

Catalytic Hydrolysis. The overall rate of hydrolysis is the sum of the rates of the catalytic hydrolysis and of the spontaneous hydrolysis, *viz.*,

$$v_{total} = v_{cat} + v_{spont} \quad (6)$$

The amount of the substrate which was spontaneously hydrolyzed prior to the addition of the catalyst solution was determined by estimating the amount of substrate and alkali used for neutralization. The extent of the spontaneous hydrolysis was 0.8% for 0.04M substrate and about 4% for 0.20M substrate

at pH 8.0. This decrease in the substrate concentration was taken into account. The inhibitory effect of the hydrolysate was rather small and neglected in the determination of the initial rate of the catalytic hydrolysis (see below).

These corrections were not necessary at pH 7.0, because spontaneous hydrolysis was not detected. The amount of alkali necessary to compensate the acid formed by hydrolysis depends upon the pH of the system and on pK_a of the substrate. For instance, 1.063 mol of alkali is required for hydrolysis of 1.000 mol of the substrate at pH 8.0.

The relationships between v_{cat} and [S] at pH 7.0 and 8.0 are shown in Fig. 4. In both cases, v_{cat} showed substrate saturation phenomena. As already shown for polymer catalysts in previous publication,s[1,2] these kinetic patterns are typical of the enzyme-catalyzed reaction, indicating formation of the Michaelis complex between catalyst and substrate (Eq. (1)). The correspondin catalytic rate is given by

$$v_{cat} = \frac{k_3 \cdot [C][S]}{K_m + [S]} \tag{7}$$

As mentioned in the previous publication,[1b] k_3 values for the imidazole catalysts studied so far are rather small, and the Michaelis constant K_m may be considered to represent the true dissociation constant in the following discussion. The kinetic constants in this equation are determined from the following equation by plotting $1/v_{cat}$ *vs.* 1/[S] (the Lineweaver-Burk plots[20]).

$$\frac{1}{v_{cat}} = \frac{K_m}{V_{max}} \cdot \frac{1}{[S]} + \frac{1}{V_{max}} \tag{8}$$

where

$$V_{max} = k_3[C].$$

Since III is present in various forms, depending on pH of the system (Eq. (3)), the large difference between v_{cat} values at pH 7.0 and 8.0 suggests that catalytic efficiencies among various species of III vary to an appreciable extent. In the pH range studied, the catalytic species can be limited to Am^+Im and AmIm. If these two species show the enzyme-like catalysis indepnedently, the overall rate consists of the two terms as follows:

$$v_{cat} = \frac{k_3[C][S]}{K_m + [S]} + \frac{k_3'[C'][S]}{K_m' + [S]} \tag{9}$$

where the first term of the right side refers to AmIm and the second term to Am^+Im.

At $[S] \gg K_m, K_m'$, the maximum rate is given by

$$V_{max} = k_3[C] + k_3'[C'] \tag{10}$$

The Lineweaver-Burk plots of the data of Fig. 4 are given in Figs. 5 and 6. The reciprocal rela-

20) H. Lineweaver and D. Burk, *J. Amer. Chem. Soc.*, **56**, 658 (1934).

tionships were seemingly linear,*2 and the values of V_{max} at the respective pH were determined from the intercepts. Since the fractions of each catalytic species are known from Fig. 2, k_3 and k_3' were determined to be 1.9×10^{-1} and 3.6×10^{-3} min^{-1}, respectively, by solving Eq. (10) for two values of pH.

The determination of the Michaelis constants was done by a computational trial and error as follows: K_m and K_m' were varied by an interval of 0.001M in Eq. (9) and the corresponding v_{cat} was calculated for respective substrate concentrations (v_{calcd}) from the known k_3, k_3', [C] and [C'] values. v_{calcd} was then compared with the observed rate of the catalytic hydrolysis (v_{obsd}). A set of K_m and K_m' was obtained which minimized the relative error.

$$E_{rel} = \{[\sum_{i=1}^{N}((v_{obsd})_i/(v_{calcd})_i-1)^2]/N\}^{1/2} \quad (11)$$

where N is the number of experimental runs.

When these procedures were carried out for the hydrolysis data at pH 8.0, E_{rel} was minimal (2.7%) for K_m=0.011M and K_m'=0.041M. In Table 2 are given the kinetic constants for the two catalytic species, together with the apparent kinetic constants at the two values of pH as obtained from the overall Lineweaver-Burk plots (Figs. 5 and 6). The kinetic constants obtained for catalysis of 1-aminomethylnaphthalene (see below) were also included in the table. Using these kinetic constants and the fractions of the catalytic species present, the substrate saturation curves were calculated as shown by the solid curve in Fig. 4. The agreement between v_{obsd} and v_{calcd} was satisfactory at pH 8.0 while v_{calcd} was somewhat lower than v_{obsd} at pH 7.0.

The solid line was obtained by the least squares method.

*2 The Lineweaver-Burk plots of the overall catalytic rate are not necessarily linear, when more than one catalytic species with different K_m values are present.[1b] In the present case, K_m values for AmIm and Am$^+$Im are fairly close and the Lineweaver-Burk plotting of the overall catalytic rate did not deviate much from linearity. Thus, the linear extrapolation of the reciprocal plots to obtain k_3 values at 1/[S]=0 (Eq. (10)) may be justified.

rate was much greater at higher pH, supporting the higher catalytic efficiency of AmIm as compared with Am+Im. When v_{cat} was calculated from the kinetic constants of Table 2 for $[C]=1.39\times10^{-3}$M, the calculated rate was greater at higher pH and somewhat lower at lower pH than the observed rate. They were comparable at pH 7 to 8.

The influence of ionic strength on v_{cat} is shown in Table 3. v_{cat} decreased with decrease in the ionic stregth.

b) The sum of KCl added and NaCl formed by neutralization by the time at which the initial rate was measured.

Product Inhibition. Figure 8 shows the rate-depressing effect of *p*-hydroxybenzoic acid (product of hydrolysis). v_{cat} decreased with increase in the amount of the product added, and the rate decrease was appreciable when the amount of the product was greater than 4 mM. Addition of 8 mM of the product lowered v_{cat} to about 30% of the original value. Further analysis of the inhibition was not attemped considering the kinetic complexity of this system.

It was mentioned above that the substrate underwent spontaneous hydrolysis during its dissolution process in the reaction mixture at pH 8.0. However, considering the limited extent of spontaneous hydrolysis and the small rate-depressing effect at low concentrations of *p*-hydroxybenzoic acid (Fig. 8), it was concluded that the correction of v_{cat} due to the inhibitory action of the product was not necessary.

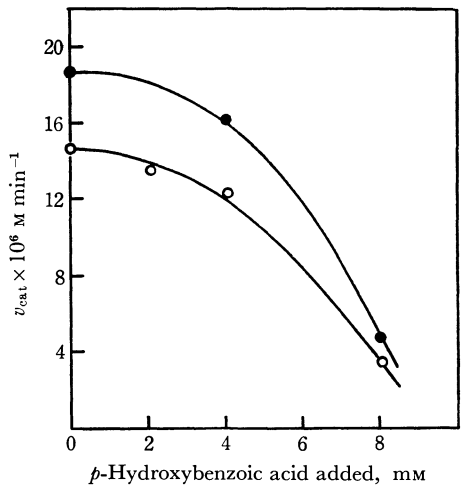

Fig. 8. Effect of *p*-hydroxybenzoic acid on v_{cat}
30°C; pH 8.0; μ=1.0M KCl; catalyst, III 1.39×10^{-3}M; ○, substrate 0.020M; ●, substrate 0.010M.

Recovery of the Catalyst. The imidazole catalyst III was precipitated from the reaction mixture by adding a few drops of 1.7N aqueous NaOH (pH>10). The precipitate was separated by centrifugation and subjected to infrared analysis. Hydrolysis was carried out under standard conditions with $[C]=1.39\times10^{-3}$M and [S]=0.010M. On an average, one mole of the catalyst had hydrolyzed 0.47 mol of the substrate when the catalyst was recovered. No amide absorption was found for the recovered catalyst, indicating that the amino group of the catalyst was not acetylated.

Catalytic Hydrolysis by 1-Aminomethylnaphthalene. The relationship between v_{cat} and [S] is shown in Fig. 9 for the catalytic hydrolysis by 1-aminomethylnaphthalene. A tendency of substrate saturation was observed, although it was much less pronounced than that observed for catalysis of III. The corresponding Lineweaver-Burk plots (Fig. 10) were linear and yielded the following data: $K_m=0.28$M and $V_{max}=5.7\times10^{-5}$M min^{-1}. Since the fraction of the non-protonated catalyst was calculated to be 2.2% at pH 8.0 from its pK_a value, k_3 for the neutral species was 1.8 min^{-1}.

In order to see the catalytic role of the amino group, hydrolysis was carried out at a higher catalyst concentration: $[C]_{total}=0.010$M, [S]=0.044M, μ= 1.0M KCl, 30°C, pH 8.0. The reaction was stopped

when the amount of phenyl ester hydrolyzed reached 4.5×10^{-3}M (0.005M alkali consumption). The catalyst was recovered by ether extraction, drying and evaporation of ether. An IR spectrum of the recovered material (brown oil) did not show amide absorption.

Catalytic Hydrolysis by Imidazole. When imidazole was used as a catalyst, the catalytic rate of hydrolysis was first order with respect to the substrate concentration, as shown in Fig. 11. The fraction of the neutral imidazole was 88.1% at pH 8.0. The second-order rate constant obtained from the slope was 0.325M^{-1} min^{-1}.

Discussion

Validity of the Enzyme-like Catalytic Mechanism. Catalytic hydrolysis with the naphthylimidazole derivative, III, showed substrate saturation phenomena, one of the important characteristics of enzyme-catalyzed reactions, as shown in Fig. 4.

The substrate saturation phenomenon, however, cannot exclude the possible coexistence of the common bimolecular catalysis by the uncomplexed imidazole catalyst (Eq. (12)) with the enzyme-like process (Eq. (1)).

$$\text{catalyst} + \text{substrate} \xrightarrow{k'} \text{catalyst} + \text{product} \qquad (12)$$

When these two catalytic processes coexist,[1b] the overall catalytic rate is given by

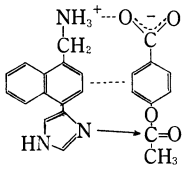
$$v_{cat} = k_3[CS] + k'[C]_{uncomplexed} \cdot [S] \qquad (13)$$

$$= (k_3 + k'K_m) \cdot \frac{[C]_{total} \cdot [S]}{K_m + [S]} \qquad (14)$$

This means that substrate saturation phenomena will be observed even in the presence of the second-order process (Eq. (12)), as long as the complexation occurs, and the relative importance of the two processes is determined from a comparison of k_3/K_m and k'. The catalytic hydrolysis of the substrate by imidazole was first-order with respect to substrate, the second-order rate constant being 0.325 $M^{-1}min^{-1}$. Since the nucleophilic reactivity of imidazole derivatives towards *p*-nitrophenyl acetate increased exponentially with the increases in pK_a,[21] the hypothetical second-order reactivity (k') of the imidazole group in III ($pK_a = 5.92$) would be much smaller than that of imidazole ($pK_a = 7.13$, $k' = 0.325$ $M^{-1}min^{-1}$). Therefore, the overall second-order reactivity of III expressed by the k_3/K_m term (0.32 at pH 7 and 18 at pH 8) may be assumed to be much greater than the hypothetical second-order reactivity of the imidazole group in III. Thus, the enzyme-like process (Eq. (1)) is concluded to be the major pathway of the catalytic hydrolysis under the present experimental conditions.

Substrate Binding. In the hydrolysis of a phenyl ester catalyzed by imidazole-containing copolymers,[1] the binding function of the catalyst was ascribed to hydrophobic forces. The results in the present system point to the same conclusion.

There are several investigations which showed rate enhancement[22-24] and substrate saturation[25,26] due to the electrostatic interaction of catalysts and substrates. Recently, Bruice *et al.*[27] considered the possible cooperative action of electrostatic and hydrophobic forces between catalysts and substrates of the detergent-like structure. Similarly, at the biginning of the present study, we assumed that an analogous cooperative action for III, as shown by IX, would be observed. However, the Michaelis constant K_m for species AmIm was smaller than that of Am$^+$Im (11 mM *vs.* 41 mM), indicating that



IX

protonation of the aminomethyl group resulted not in an electrostatic attraction toward the anionic substrate but in a decrease of the binding capacity of the catalyst. Thus, the hydrophobic interaction must be responsible for formation of the Michaelis complex for both of the catalytic species (AmIm and Am$^+$Im) at least under the hydrolysis conditions used. This conclusion was further supported by the fact that v_{cat} decreased when the ionic strength of the reaction system decreased (Table 3). If the electrostatic interaction were responsible for the substrate binding, a decrease in the ionic strength would have caused rate enhancement.

Pseudo-Intramolecular Process. The chemical nature of the product-forming step in the present catalytic system remains to be elucidated.

Since III was recovered after hydrolysis at pH 8.0 without undergoing acetylation of its amino group, it is clear that the naphthylimidazole derivative acted as a true catalyst. The imidazole group in III may act as either a nucleophilic or general-base catalyst,[9b] and these two processes are indistinguishable from the kinetic data alone. The amino group, protonated and unprotonated, can also reinforce the catalytic action of the imidazole group as a general-acid and general-base catalyst, respectively. Involvement of the protonated amino group in catalysis, however, appears less likely, considering the much smaller k_3 for Am$^+$Im as compared with that for AmIm (0.0036 min^{-1} *vs.* 0.19 min^{-1}).

This large difference in k_3 is interesting, and is conceivably related to the structural variation of the Michaelis complex. The greater pseudo-intramolecular catalytic efficiency of AmIm may be explicable on the basis of either or both of the following hypotheses: a) The spacial arrangement of the imidazole and ester groups in the Michaelis

complex is less favorable for catalysis when the amino group is protonated than when it is not; b) the imidazole and amino groups in AmIm catalyze the ester cleavage cooperatively, while the protonated amino group in Am^+Im cannot be involved in catalysis.

In the above discussion, the catalyst molecules were assumed to be molecularly dispersed. Considering the poor solubility of III it is possible that the catalyst molecules, AmIm in particular, were extensively associated. If the associated catalytic species show different catalytic activities from those of the molecularly dispersed species, the simple allotment of the overall catalytic activity to the two species AmIm and Am^+Im becomes questionable. In fact, as shown in Fig. 7, there was considerable discrepancy between the pH dependence of the observed and calculated catalytic rates. Since AmIm would associate more readily than Am^+Im in the case where the catalyst molecules are not molecularly dispersed, the pH dependence of v_{cat} would be correspondingly complex. Then association of the catalyst molecules could be the cause for the discrepancy. However, the fact that v_{cat} did not vary with the catalyst concentration at pH 7 and 8 (Fig. 7) speaks against this hypothesis, since association of the catalyst molecules, if any, must be concentration dependent, leading to the dependence of $v_{cat}/[C]$ on the catalyst concentration. Another possible cause for the discrepancy might be either or both of underestimation of the catalytic activity of AmIm and of overestimation of the catalytic activity of Am^+Im. At present, experimental data are not sufficient to warrant further discussion on these problems. However, the remarkable variation of the catalytic efficiency with pH (hence the nature of the catalytic species) suggests that catalytic efficiency is much more widely variable when the enzyme-like kinetics are observed than when the common second order kinetics are observed.

Catalysis of 1-Aminomethylnaphthalene. K_m for 1-aminomethylnaphthalene, VIII, was quite large (280 mM), showing the small binding capacity of this catalyst as compared with those of the imidazole derivatives. Since the substrate saturation phenomenon was not very clear in this system, it is not certain if the catalytic action consisted only of the enzyme-like process (Eq. (1)), in spite of the linear Lineweaver-Burk plots obtained. Assuming that the enzyme-like pathway is predominant, the large difference in K_m between III and VIII suggests that the imidazole group made an important contribution to the binding function. It is interesting that the primary amino group in VIII acted as a catalyst without undergoing acetylation. This was also the same with AmIm. The lack of acetylation indicates that VIII was a general-base catalyst, in marked contrast with the commonly observed nucleophilic reaction of the primary amino group with phenyl acetates. This result may be an indication of the particular geometry of the Michaelis complex, in which the nucleophilic attack of the amino group toward the ester group is not favored. The large k_3 value (1.8 min^{-1}) is probably related to the high basicity of the amino group ($pK_a = 9.95$) as well as to the particular geometry of the complex. Although high K_m and k_3 values observed for VIII catalysis is in sharp contrast to those for the imidazole catalysts, it is not warranted to discuss the difference more fully, since substrate saturation with VIII was not sufficient and its catalytic behavior can be more complex than it appears.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1120—1126 (1970)

On the Photochemical Hydrogen Shifts in Arylcycloheptatrienes*1

Takahiro TEZUKA, Masaru KIMURA, Aiya SATO and Toshio MUKAI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received June 6, 1969)

Photochemically-induced hydrogen shifts in 7-(*p*-chlorophenyl), 7-phenyl, 7-(*p*-methoxyphenyl) and 7-*p*-tolylcycloheptatrienes (Ia—d) were studied. The possibility of hydrogen 1,7 and 1,3 shifts in these compounds was examined on both experimental and theoretical grounds. It was concluded that the hydrogen 1,7 shift is the only suprafacial hydrogen shift possible in the excited cycloheptatriene system. In this study all the isomers of *p*-chlorophenylcycloheptatriene were separated by applying the Diels-Alder reaction to the photo-reaction mixture; the method of preparing each of those isomers will also be described.

The specific hydrogen shifts in substituted cycloheptatrienes have been one of the most interesting topics in photochemistry.[1-5] In 1965 Woodward and Hoffmann[6] successfully interpreted the specific mode of the hydrogen shift in the conjugated allyl system on the basis of molecular orbital symmetry considerations; they implied that the suprafacial hydrogen 1,3 and 1,7 shifts are permitted photochemically in the cycloheptatriene. ter Borg and Kloosterziel,[3] in 1965, reported the unexpected formation of 2-phenylcycloheptatriene (IIIb) from 7-phenylcycloheptatriene (Ib) upon irradiation with a high-pressure mercury lamp. They explained this transformation as a consequence of successive hydrogen 1,7 shifts *via* 1-phenylcycloheptatriene (IIb). However, Murray and Kaplan[5] have recently suggested this to be a possible case of a symmetry-allowed suprafacial hydrogen 1,3 shift.

We now wish to report on our studies of photohydrogen shifts in 7-arylcycloheptatrienes (Ia—Id); these studies have led us to the conclusion that the 1,3 shift is not a favorable mode of the hydrogen shift, while the hydrogen 1,7 shift is the only probable mode in the 7-substituted cycloheptatrienes when a Xenon or mercury lamp is used as the light source.

Results

Upon the irradiation of an ethereal solution of 7-(*p*-substituted-phenyl)cycloheptatriene (Ia—Id) in a quartz vessel with 150 W Xenon lamp, Ia and Ib afforded the isomers IIIa and IIIb, while Ic and Id yielded IIc and IId respectively. The formation of IIc from Ic, and that of IId from Id, can be interpreted in terms of the photo-hydrogen 1,7 shift. Such a type of photoisomerization reaction has been found to occur commonly in 7-methoxy, 7-ethoxy,[4] and 7-deuterio-cycloheptatrienes.[2] However, interpretation of the formation of IIIa from Ia, and that of IIIb from Ib, seems to be more complicated.

Two possible mechanisms can be assumed for the formation of IIIa from Ia and/or IIIb from Ib: (1) the hydrogen migrates from C_7 to C_2 in one step by the suprafacial hydrogen 1,3 shift; or (2) the hydrogen migrates from C_7 to C_1, and then from C_1 to C_2 by pepeating the suprafacial hydrogen 1,7 shift. ter Borg and Kloosterziel[3] have proposed the second mechanism, while Murray and Kaplan[5] suggested the first mechanism for the formation of IIIb from Ib.

In order to elucidate this point we investigated the photochemical isomerization of 7-(*p*-chlorophenyl)cycloheptatriene (Ia) and of 7-phenylcycloheptatriene (Ib) in detail. As 7-(*p*-chlorophenyl)-cycloheptatriene was easier to work with, we studied the photoisomerization reaction of this compound first.

The isomer IIIa formed from Ia on the photolysis was separated as a pure form by applying the Diels-Alder reaction. When a benzene solution of the reaction mixture of the photolysis of Ia was heated with maleic anhydride, only Ia afforded the Diels-Alder adduct (V). An unreacted oil was purified by vacuum distillation to give IIIa. The structure

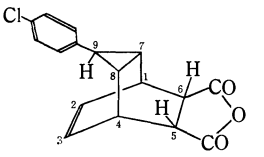
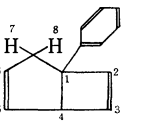
of IIIa was established on the basis of the following physical properties: mass spectrum, *m/e* 202 (M); ultraviolet spectrum, λ_{max}^{MeOH} (log ε), 247 (3.61) with tailing up to 310 mμ; infrared spectrum (oil), 3030, 2841, 1495, 1006, 820, 747, 707 cm^{-1}; NMR spectrum (in $CDCl_3$), 7.65 ($2\times H_7$; triplet, $J_{1,7}=7.0$ Hz), 4.40 (H_1; triplet), 4.47 (H_6; broad quartet), 3.75 (H_5; multiplet), 3.20 (H_3 and H_4; multiplet), 2.7 τ (aromatic protons) (Fig. 2). The isomer IIIa could be differentiated from the other isomers, IIa and IVa, by a comparison of their physical properties. IIa; ultraviolet spectrum, λ_{max}^{MeOH} (log ε), 303 (3.88), 242 (4.24) mμ; infrared spectrum (oil), 3040, 2849, 1490, 1009, 826, 736, 719 cm^{-1}; NMR spectrum (in $CDCl_3$), 7.35 ($2\times H_7$; doublet, $J_{6,7}=$ 7.1 Hz), 4.60 (H_6) around 3.60 τ (H_2, H_3, H_4 and H_5; complex multiplet) (Fig. 3). IVa; ultraviolet spectrum, λ_{max}^{MeOH} (log ε), 285 (3.96), 241 (4.17) mμ; infrared spectrum (oil), 3030, 2833, 1493, 1092, 1014, 824, 744 cm^{-1}; NMR spectrum (in benzene), 7.85 ($2\times H_7$; triplet, $J_{1,7}=7.0$ Hz), 4.75 (H_1; doublet of triplet, $J_{1,2}=9.1$ Hz), 4.65 (H_6; doublet of triplet, $J_{5,6}=9.1$ Hz), 3.75 (H_2; doublet, $J_{1,2}=9.1$ Hz), 3.85 (H_5; quartet), 3.29 τ (H_1; doublet, $J_{4,5}=4.6$ Hz) (Fig. 4).*2

The isomer IVa was obtained by heating Ia at 150°C, as has been described in literatures,[7] while IIa was obtained by the irradiation of Ia for a short period of time with a 6 W low pressure mercury lamp (*vide infra*), followed by the application of the Diels-Alder reaction as described in the case of the isolation of IIIa.





If the first mechanism (1) is correct, there are no intermediate products to be trapped. On the other hand, if the second mechanism (2) is correct, the isomer IIa must be trapped as an intermediate when appropriate photolysis conditions are used. In addition, the isomer IIIa must be formed from IIa at a rate faster than that of the formation of IIa from Ia, or of IIIa from Ia. With these facts in mind the photolysis of Ia and IIa was monitored under several sets of conditions.

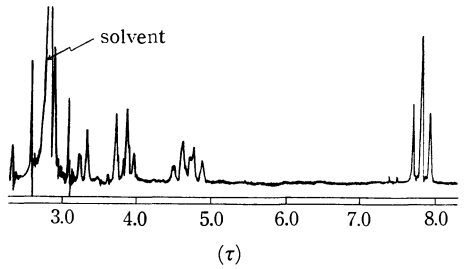

Fig. 4. NMR spectrum of 3-(*p*-chlorophenyl)cycloheptatriene (IVa) in benzene.

In order to trap the intermediate IIa, the Xenon lamp was replaced by a 6 W low-presure mercury lamp with very weak emission bands around 3000 Å, where the intermediate (IIa) has an absorption maximum. Under this condition the formation of IIIa was suppressed, and the only product identified by NMR spectroscopy during the first period of irradiation was the isomer IIa. For further confirmation of the isomer, the product (IIa) was separated from the reaction mixture by applying the Diels-Alder reaction and its structure was established by means of spectral data (*vide supra*). On prolonged irradiation, however, the gradual formation of IIIa was observed at consumption of IIa. The relative ratio of the formations of Ia, IIa, and IIIa under this irradiation condition, which was estimated from the methine or methylene signal in the NMR spectra, was plotted *vs.* the irradiation time (Fig. 5). The plot indicates that the isomer IIIa was apparently produced after the formation of IIa; *i. e.*, IIa must be the precursor of the isomer IIIa. This was supported by the fact that when Ia was irradiated with filtered 2537 Å light, IIa was produced selectively and the formation of IIIa was suppressed. In addition, the irradiation of IIa with a Xenon lamp gave the isomer IIIa at a rate approximately

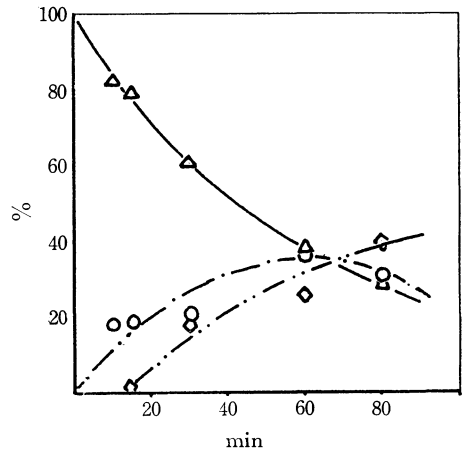

Fig. 5. Relative yields of Ia (△), IIa (○) and IIIa (◇) *vs.* time.

ten times as fast as that of the formation of IIIa from Ia.

These evidences support the second mechanism (2), and the formation of IIIa from Ia can be interpreted in terms of successive hydrogen 1,7 shift. By absorbing light around 2500 Å, Ia isomerizes to IIa, and this is, in turn, rapidly converted into IIIa upon the further absorption of light above 3000 Å by the hydrogen 1,7 shift. Therefore, the fact that the isomer IIa was not identified by NMR spectroscopy in the case of the irradiation of Ia with a Xenon lamp can be explained as a consequence of the rapid transformation of IIa to IIIa.

A similar trend of photoisomerization was observed in the case of 7-phenylcycloheptatriene (Ib). The only isomer identified by NMR spectoscopy was IIIb when Ib was irradiated with a Xenon lamp. On the other hand, the irradiation of Ib with a 6 W low-pressure mercury lamp afforded IIb after a short period of irradiation. On prolonged irradiation, however, the isomer IIIb and the bicyclic compound,[3] for which the structure (VI) is tentatively assigned from the NMR analysis were formed.

Plots of the relative ratio of Ib, IIb, and IIIb *vs.* the irradiation time indicated that the isomer IIIb was formed from IIb, which was itself produced from Ib by the hydrogen 1,7 shift. The bicyclic compound (VI) may arise from the isomer IIa.[4] This may be supported by the fact that the VI was formed after the formation of IIa, which was identified by means of gas chromatographic analysis.

The irradiation of IIb with a Xenon lamp gave IIIb very rapidly. The formation of IIIb from Ib *via* IIb is sensitive to the light source used. Thus, when filtered 2537 Å light was used the formation of IIIb from IIb was suppressed; even after the irradiation of Ib for more than ten hours, the isomer IIIb was not detected; the only isomer detected by NMR spectrum was IIb.

Therefore, it may be concluded that the 1,7 shift is the only mode of hydrogen shift occurring on the photolysis of Ia—Id. This is in accord with the conclusion reached by ter Borg and Kloosterziel[3] regarding the photolysis of Ib, but it is inconsistent with Murry and Kaplan's suggestion[5] that IIIb may be formed from Ib by the hydrogen 1,3 shift.

It may be noted that in both cases, the isomers III and IV were relatively stable to Xenon light and did not afford the other isomers during several hours irradiation.[3,14] This may be due to the electronic effect of the aryl group on the excited triene system, but the details of this effect are not clear at present.

Discussion

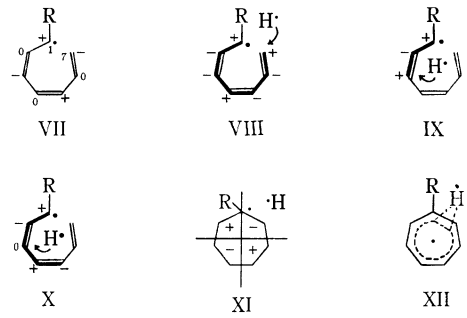
Woodward and Hoffmann's selection rule has predicted that the symmetry-allowed suprafacial hydrogen 1,3 and 1,7 shifts would occur photochemi-

cally while the 1,5 shift would occur thermally, in the cycloheptatriene.[6] The process of the thermal 1,5 hydrogen shift has been established in many cycloheptatriene derivatives.[5,7,8] However, there are some problems as to the photochemical hydrogen shifts in the cycloheptatriene series. One of the problems is that only the hydrogen 1,7 shift has been identified experimentally, though the possibility of the occurrence of the hydrogen 1,3 shift has been suggested theoretically[6,12] for the photochemical isomerization of the cycloheptatrienes.

Perhaps the photochemically induced suprafacial hydrogen 1,3 shift has not occurred in the cycloheptatriene for either of following two reasons: (1) geometrical, (2) the molecular orbital symmetry relationship. Geometrically, however, the suprafacial hydrogen 1,3 shift is possible, since the distance between C_7 and C_2, through which the hydrogen 1,3 shift could occur, is approximately 2.8 Å.[9] This distance is comparable with that between C_7 and C_3, through which the hydrogen 1,5 shift occurs. In fact, a base-catalyzed hydrogen 1,3 migration has been observed in 7-cyanocycloheptatriene.[10] Therefore, it is necessary to reexamine whether or not the photo-hydrogen 1,3 shift is really a symmetry-allowed mode in the excited cycloheptatriene.

Woodward and Hoffmann's selection rule[6] for the sigmatropic rearrangement of the order $[1,j]$ is based on the molecular orbital symmetry relation of the terminal carbon atoms C_1 and C_j, in the conjugated allyl radical system containing j π-electrons. It has been stated[6] that a reverse symmetry relation exists between the highest occupied and the first excited molecular orbital at C_j. This relation always holds when C_j is located in the terminal position in the j π-electron system, but it does not hold when C_j is in a half-way position of the π-electron system containing more than j electrons. This may be seen, for example, in the heptatrienyl radical system, which is a model system taken by Woodward and Hoffmann for explaining the specific hydrogen shifts in the cycloheptatriene. The reverse relation between the highest occupied (VII) and the first excited molecular orbitals (VIII) of the heptatrienyl radical exists at the terminal position, C_7, while this relation does not exist at the C_3 position. This implies that the suprafacial hydrogen 1,3 shift is not a symmetry-allowed mode, while the 1,7 shift is the only symmetry-allowed mode of the suprafacial hydrogen shift when the excited heptatrienyl radical system (VIII) is produced by excitation in the cycloheptatriene. Jones also pointed out this point in the photochemical methyl migration of 7,7′,3-trimethylcycloheptatriene.[11]

The suprafacial hydrogen 1,3 shift, however, may schematically become a symmetry-allowed mode if an excited propenyl radical (IX) or an excited pentadienyl radical (X) is produced in the cycloheptatriene molecule. Here, such an excited radical exists as an independent part in the molecule. Practically, however, the introduction of such a limited excited radical system in the cycloheptatriene molecule may be difficult, since the excitation of the



VII VIII IX

X XI XII

triene chromophore occurs preferentially in the cycloheptatriene molecule when 2537 Å light is absorbed and, as a concequence the excited heptatrienyl radical system (VIII) is produced in the molecule.

In general, the selection rule for the photochemical hydrogen shift must be used in terms of the excited radical system, but not in terms of the length of the conjugation in the ground state molecule. Such hydrogen shifts in terms of several excited radical systems can be deduced on the basis of the symmetry relation of the Hückel molecular orbital of the acyclic model.[6] Several such are presented in Table 1. Here, the length of the conjugation of double bonds in a ground state molecule is not a decisive factor, but the nature of a specific excited radical system introduced in this

Table 1

Excited radical system	Type of permissive suprafacial hydrogen shift
Propenyl	1,3
Pentadienyl	1,3
Heptatrienyl	1,7
Nonatetraenyl	1,5 1,7

8) The occurrence of the thermal hydrogen 1,5 shift in Ia, Ic, and Id at 120—150°C, giving IVa, IVc, and IVd respectively, was confirmed by the present work.

9) This is the distance of the ground-state molecule as estimated by the Dreiding model. In the excited state the distance may be somewhat different from what it is in the ground state. However, in a rigid system such as cycloheptatriene the geometrical difference between the two states may be small.

11) L. B. Jones and V. K. Jones, *J. Amer. Chem. Soc.*, **89**, 1880 (1967).

molecule by excitation is important in determining the mode of the photochemical hydrogen shift. Whether or not such a specific excited radical system can be produced in the conjugated allyl depends on the irradiation conditions (the wave length of light used) and the geometrical conditions (the inhibition of the full conjugation of the double bonds in the molecule).

Recently, Anastassiou[12] has proposed a cyclic model (XI) for predicting the specific mode of the hydrogen shifts in the cycloheptatriene. According to Anastassiou's selection rule, all of the hydrogen 1,3 and 1,5 and 1,7 shifts can occur photochemically in the cycloheptatriene. However, this selection rule is not consistent with the observation that the photochemical hydrogen 1,3 and 1,5 shifts have not been found in the cycloheptatriene series.

It is instructive to reconsider the model system of the transition state of the hydrogen shift in the cyclic conjugated allyl system. Anastassiou has mentioned that the acyclic model employed in the derivation of Woodward and Hoffmann's selection rule is incapable of allowing for the necessary cyclic π-interaction introduced by the developing p-orbital at the migration origin of the cyclic system. In this we agree with Anastassiou's comments. However, it seems that Anastassiou's cyclic model does not consider the interaction between a migrating hydrogen and a remnant conjugated system. On the basis of a theoretical consideration including the above discussion, we would like to propose, for the hydrogen shift in the cyclic allyl system, new model system in which the interaction of the migrating hydrogen and the cyclic π-interaction is taken into consideration. For example, according to this treatment the transition state of the hydrogen 1,7 shift in the cycloheptatrienes is represented as XII, where a three-member part including a hydrogen atom, interacts with a dienyl radical system. With this model several modes of the hydrogen shift in the cyclic allyl system can be interpreted. A detailed interpretation and application will not be made in this report, but will appear elsewhere.

It is interesting to consider the substituent effect upon the relative rate of the formation of the bicyclic compound from 1-substituted cycloheptatriene. It has been reported that 1-methoxy- and 1-ethoxycycloheptatrienes isomerize very rapidly to 1-methoxy- and 1-ethoxy-bicyclo[3.2.0]hepta-3,6-dienes upon irradiation by light above 3000 Å.[4] In these cases, the formation of 2-methoxy- and 2-ethoxycycloheptatriene by the hydrogen 1,7 shift has not been observed.[4] On the contrary, the photolysis of 1-phenyl-, 1-(p-chlorophenyl)-, and 1-deuterio-cycloheptatrienes[3] afforded preferentially 2-phenyl-, 2-(p-chlorophenyl)-, and 2-deuterio-cycloheptatrienes respectively, instead of the bicyclic compounds. It may be noted that the substituent at the C_1 position of the cycloheptatrienes potentially affects the rate of the bond formation between C_1 and C_4 as well as the rate of the hydrogen shift. These substituent effects may be electronic in nature; electron-donating substituents facilitate the bond formation at C_1 and C_4, while electron-attracting substituents tend to retard it. However, a detailed interpretation of the mechanism of the substituent effect on the excited state must await further study.[14]

Experimental

Preparation of 7-(p-Chlorophenyl)cycloheptatriene (Ia). To a solution of p-chlorophenylmagnesium bromide which had been prepared from p-bromochlorobenzene (16.89 g) and magnesium (2.14 g) in absolute ether (50 m*l*), there was added a solution of 7-ethoxycycloheptatriene (10.0 g) in absolute ether (50 m*l*) at 0°C; the mixture was then stirred continuously for several hours. The reaction mixture was then treated with 2N hydrochloric acid and extracted with ether. The resultant oil was distilled to give a colorless oil, bp, 107°C/0.2 mmHg (9 g), which crystallized on standing at 0°C; after recrystallization from petroleum ether it gave colorless needles, mp 41—42°C. Ultraviolet spectrum, $\lambda_{max}^{cyclohexane}$ (log ε), 265 mμ (3.52); infrared spectrum (KBr), 3012, 2857, 1492, 1026, 826, 754, 709 cm^{-1}; mass spectrum (*m/e*), 202 (M); the NMR spectrum is shown in Fig. 1.

Found: C, 77.18; H, 5.48%. Calcd for $C_{13}H_{11}Cl$: C, 77.10; H, 5.48%.

The Formation of 1-(p-Chlorophenyl)cycloheptatriene (IIa) from Ia by Irradiation with a Low-pressure Mercury Lamp. a) A solution of 7-(p-chlorophenyl)cycloheptatriene (Ia) (1.5 g) in absolute ether (180 m*l*) was irradiated with an internal 6 W low-pressure mercury lamp for 15 min under a nitrogen stream; 15% of Ia was thus converted to IIa, which was estimated by means of the doublet signal due to methylene protons of IIa at 7.35 τ in NMR spectroscopy. The oily reaction mixture was heated with maleic anhydride (500 mg) in absolute benzene (10 m*l*) for 1 hr. The evaporation of the solvent afforded an Diels-Alder adduct of Ia as white crystals; mp, 186.5°C (V) (300 mg). Infrared spectrum (KBr), 3039, 2985, 1869, 1824, 1785, 1226, 1089, 918, 792, 755 cm^{-1}; NMR spectrum (in $CDCl_3$), 2.95 (aromatic protons; quartet), 3.96 (H_2 and H_3; sextet), 6.38 (H_1 and H_4; multiplet), 6.76 (H_5 and H_6; triplet, $J_{1,5}=J_{4,5}=2.5$ Hz), 8.36 (H_9; triplet, $J_{8,9}=J_{7,9}=3.2$ Hz), 8.60 τ (H_7 and H_8; $J_{1,7}=J_{4,8}=5.0$ Hz).

12) A. G. Anastassiou, *Chem. Commun.*, **1968**, 15.

13) a) Concerning the substituent effects, Professor ter Borg has found that the substituents which facilitate the valence-isomerization reaction end to retard the hydrogen-migration reaction in 1-substituted cycloheptatrienes. The authors wish here to thank Professor ter Borg for his communication on this point prior to publication. b) A. P. ter Borg, E. Razenberg and H. Kloosterziel, *Chem. Commun.*, **23**, 1210 (1967).

14) For example, the photochemical 1,7 migration of the phenyl group in competition with the hydrogen 1,7 shift in 7-phenylcycloheptatriene has recently been reported. *Cf.* K-W Shen, W. E McEwen and A. P. Wolf, *Tetrahedron Lett.*, **1969**, 827.

Found: C, 68.11; H, 4.42%. Calcd for $C_{17}H_{13}O_3Cl$: C, 67.89; H, 4.36%.

The filtrate was purified by alumina chromatograpy, followed by vacuum distillation, to give a colorless oil (IIa); bp, 120—125°C/0.5 mmHg (80 mg).

Found: C, 77.24; H, 5.43%. Calcd for $C_{13}H_{11}Cl$; C, 77.10; H, 5.48%.

b) The photolysis of Ia under the same conditions was monitored, and the amounts of isomers formed was estimated by NMR spectroscopy. The relative ratio of the isomers *vs.* the time was estimated by the integration of the triplet at 7.31 (for Ia), the doublet at 7.33 (for IIa), and the triplet at 7.69 τ (for IIIa), in the NMR spectrum. The results are shown in Fig. 5.

The Formation of 2-(*p*-Chlorophenyl)cycloheptatriene (IIIa) from Ia by Irradiation with a Xenon Lamp. a) A solution of 7-(*p*-chlorophenyl)cycloheptatriene (Ia) (954 mg) in absolute ether (180 m*l*) in a quartz vessel was irradiated with a Xenon lamp (Toshiba XD-150) for 16 hr under a nitrogen stream. The reaction was followed by the appearance of the triplet signal due to IIIa at 7.69 τ in the NMR spectroscopy. The reaction mixture was treated with maleic anhydride (300 mg) as has been described in the case of IIa. The filtrate was purified by alumina chromatography, and subsequent vacuum distillation afforded a colorless oil, bp, 130—135°C/0.2 mmHg (246 mg), which on standing at −60°C afforded colorless needles; mp, 41—42°C (IIIa).

Found: C, 77.44; H, 5.45%. Calcd for $C_{13}H_{11}Cl$; C, 77.10; H, 5.48%.

b) A solution of Ia (20 mg) in absolute ether (5 m*l*), saturated with nitrogen, was irradiated in a sealed quartz vessel with a Xenon lamp for a few hours. The reaction mixture was analyzed by means of NMR spectroscopy, which indicated that the only isomer produced during the irradiation was IIIa. Within 90 min the Ia was converted to IIIa in 50% yield.

Irradiation of 1-(*p*-Chlorophenyl)cycloheptatriene (IIa) with a Xenon Lamp. A solution of 1-(*p*-chlorophenyl)cycloheptatriene (IIa) (20 mg) in absolute ether (5 m*l*) saturated with nitrogen was irradiated in a sealed quartz vessel with a Xenon lamp. The reaction was followed by NMR spectroscopy. The amounts of the isomers IIIa and IIa was estimated from the integrated signals at 7.69 (triplet for IIIa) and 7.35 τ (doublet for IIa) in the NMR spectrum. Within 90 min the IIa was converted into IIIa in 43% yield.

Irradiation of Ia with a 2537 Å Light. A solution of Ia (20 mg) in absolute ether (5 m*l*) saturated with nitrogen was irradiated in a sealed quartz vessel with a 2537 Å light. The reaction was followed by NMR spectroscopy. Within 6 hr the Ia was converted into IIa in 17% yield. No formation of IIIa was detected even after 14 hr of irradiation.

Irradiation of IIa with a High-pressure Mercury Lamp through a Pyrex Filter. A solution of IIa (20 mg) in absolute ether (5 m*l*) saturated with nitrogen was irradiated in a sealed quartz vessel with high pressure mercury lamp through Pyrex filter. The reaction was followed by NMR spectroscopy. Within 25 min the IIa was canverted to IIIa in a 70% yield.

Preparation of 3-(*p*-Chlorophenyl)cycloheptatriene (IVa). 7-(*p*-Chlorophenyl)cycloheptatriene (Ia) (757 mg) was heated at 150—155°C for 90 min. The crude oil was distilled to give a colorless oil, bp 120—125°C/0.5 mmHg (650 mg), which was identified by NMR spectroscopy as a mixture composed of 98% of IVa and 2% of IIa.

Found: C, 77.49; H, 6.05%. Calcd for $C_{13}H_{11}Cl$: C, 77.10; H, 5.48%.

Irradiation of 3-(*p*-Chlorophenyl)cycloheptatriene (IVa) with a Xenon Lamp. A solution of 3-(*p*-chlorophenyl)cycloheptatriene (IVa) (20 mg) in absolute ether (5 m*l*) saturated with nitrogen, was irradiated in a sealed quartz vessel with a Xenon lamp for several hours. The reaction was followed by NMR spectroscopy. No change around the methylene proton region in the NMR spectrum was observed even after 6 hr of irradiation.

Irradiation of 2-(*p*-Chlorophenyl)cycloheptatriene (IIIa) with a Xenon Lamp. A solution of 2-(*p*-chlorophenyl)cycloheptatriene (IIIa) (20 mg) in absolute ether (5 m*l*) saturated with nitrogen, was irradiated in a sealed quartz vessel with a Xenon lamp for 12 hr. No change around the methylene proton region in the NMR spectrum was observed during the time of irradiation.

Preparation of 7-Phenylcycloheptatriene (Ib). To a solution of phenylmagnesium bromide which had been prepared from bromobenzene (41.6 g) and magnesium (6.44 g) in absolute ether (129 m*l*), there was added a solution of 7-ethoxycycloheptatriene (30 g) in absolute ether (100 m*l*) at 0°C; the mixture was then continuously stirred for several hours. The reaction mixture was then treated with a 2N ammonium chloride solution and extracted with ether. The crude oil was distilled to give a pale yellow oil, bp 99—103°C/0.9 mmHg (23 g). This oil crystallized on standing at 0°C; recrystallization from petroleum ether gave colorless needles, mp, 32°C (Ib). The structure of Ib was identified by means of the following physical properties.[15,16] Ultraviolet spectrum, λ_{max}^{MeOH} 262 mμ (logε 3.53); infrared spectrum (KBr), 2994, 1592, 1493, 746, 704 cm^{-1}; mass spectrum (*m/e*), 202 (M).

Irradiation of 7-Phenylcycloheptatriene (Ib) with a Low-pressure Mercury Lamp. a) A solution of 7-phenylcycloheptatriene (Ib) (1.5 g) in absolute ether (180 m*l*) was irradiated with a 6 W low pressure mercury lamp under a nitrogen stream for 30 hr. The reaction products were then separated by means of gas chromatography (Silicon Grease), 1-phenylcycloheptatriene (IIb) (300 mg) and bicyclic product (VI) (35 mg) were thus obtained. The structure of these products was suggested on the basis of the NMR spectrum.

IIb: Infrared spectrum (oil), 3031, 2941, 1600, 1477, 1449, 759, 711, 698 cm^{-1}; NMR spectrum (in $CDCl_3$), 7.34 (H_7 and H_7; doublet, $J_{6,7}=J_{1,7}=7.1$ Hz) 4.72 (H_6; multiplet, $J_{5,6}=9.2$ Hz), 3.60 τ (H_2 and H_5, multiplet).

Bicyclic compound(VI): NMR spectrum*[3] (in $CDCl_3$), 6.87 (H_4), 6.18 (H_7; doublet with small coupling), 6.42 (H_8; doublet with small coupling), 4.35 (H_5; doublet with small coupling, $J_{5,6}=5$ Hz), 4.02 (H_6; doublet

Preparation of 7-(*p*-Methoxyphenyl)cycloheptatriene (Ic). To a Grignard solution of *p*-methoxyphenylmagnesium bromide which had been prepared from *p*-bromoanisole (8.25 g) and magnesium (1.07 g) in absolute ether (50 m*l*) was added 7-ethoxycycloheptatriene (5 g) in absolute ether (30 m*l*) at 0°C; the mixture was continuously stirred for 5 hr. The reaction mixture was treated as has been described in the case of Ib. The oily product was distilled to give a yellow oil, bp, 114—115°C/0.3 mmHg (5.6 g), which crystallized on standing at −60°C to give, after recrystallization from petroleum ether, colorless needles, mp, 28°C.

Found: C, 84.58; H, 7.35%. Calcd for $C_{13}H_{14}O$; C, 84.81; H, 7.12%.

Mass spectrum (*m/e*), 198 (M); ultraviolet spectrum, $\lambda_{max}^{cyclohexane}$ (log ε), 270 mμ (3.70); infrared spectrum (oil) 3002, 2994, 1605, 1508, 1250, 1176, 1034, 830, 747, 707 cm^{-1}; NMR spectrum (in $CDCl_3$), 7.34 (H_7 and H_7; triplet, $J_{1,7}=J_{6,7}=6.0$ Hz), 6.30 (OCH_3; singlet), 4.65 (H_1 and H_6; quartet, $J_{5,6}=J_{1,2}=9.1$ Hz), 3.82 (H_2 and H_5; multiplet), 3.32 (H_3 and H_4; multiplet), 2.96 τ (aromatic; quartet).

Irradiation of 7-(*p*-Methoxyphenyl)cycloheptatriene (Ic) with a Xenon Lamp. A solution of 7-(*p*-methoxyphenyl)cycloheptatriene (Ic) (20 mg) in absolute ether (5 m*l*), saturated with nitrogen, was irradiated in a sealed quartz vessel with a Xenon lamp for several hours. The reaction was followed by NMR spectroscopy. The only product identified by means of the NMR spectrum was IIc, which showed a doublet peak at 7.37 τ (in $CDCl_3$).

Preparation of 7-*p*-Tolylcycloheptatriene (Id). To a Grignard solution which had been prepared from *p*-bromotoluene (7.64 g) and magnesium (1.0 g) in absolute ether (20 m*l*) was added 7-ethoxycycloheptatriene (5 g) in absolute ether (20 m*l*) at 0°C; the mixture was then stirred continuously for several hours. The reaction mixture was treated as had been described in the case of Ib. The resultant oil was distilled to give a yellow oil, bp 85—89°C/0.5 mmHg (4 g), which crystallized on standing at −60°C to give, after recrystallization from petroleum ether, yellow needles, mp, 31°C.

Found: C, 91.98; H, 7.68%. Calcd for $C_{14}H_{14}$; C, 92.26; H, 7.74%.

Mass spectrum (*m/e*), 182 (M); ultraviolet spectrum, $\lambda_{max}^{cyclohexane}$ 265 mμ (logε 3.569); infrared spectrum, (KBr) 3040, 1603, 1520, 1391, 814, 746, 704 cm^{-1}; NMR spectrum (in $CDCl_3$) 7.70 (CH_3; singlet), 7.33 (H_7 and H_7; triplet, $J_{1,7}=J_{6,7}=5.5$ Hz), 4.66 (H_1 and H_6; quartet, $J_{5,6}=J_{1,2}=6.0$ Hz), 3.82 (H_2 and H_5; multiplet), 3.34 (H_3 and H_4; multiplet) and 2.89 τ (aromatic; multiplet).

Irradiation of 7-*p*-Tolylcycloheptatriene (Id) with a Xenon Lamp. A solution of 7-*p*-tolylcycloheptatriene (Id) in absolute ether (5 m*l*), saturated with nitrogen, was irradiated in a sealed quartz vessel with a Xenon lamp for several hours. The only product identified by NMR spectroscopy was IId, which showed a doublet peak at 7.40 τ (in $CDCl_3$).

Telomerization of Vinyl Chloride with Carbon Tetrachloride Using Amine-Cupric Chloride. Effects of Amines and Solvents[1]

Teruzō Asahara, Manabu Senō and Cheng-Ching Wu*1

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received July, 3 1969)

Telomerization of vinyl chloride with carbon tetrachloride was investigated in reaction systems containing amines and cupric chloride. The yield of telomers $CCl_3(CH_2CHCl)_nCl$ and the content of the telomer with $n=1$ were high when aliphatic amines with relatively long chains were used. An increase in basicity of amines raised the yield of telomers. When bifunctional amines such as diamines and alkanolamines were used, the yield of telomers was low and the content of higher telomers was high. The effect of added solvents on the yield of telomers was not so remarkable and an increase in the dielectric constant of solvents decreased the yields. The results were examined on the basis of Asscher-Vofsi mechanism, but could not be explained satisfactorily. A partly modified scheme was proposed for the radical addition in the cage complex stabilized with amine.

In a previous paper,[1] we reported that the telomerization of vinyl chloride and carbon tetrachloride was initiated by *n*-butylamine in the presence of metals (cupper and iron) and metallic salts (Cu(I) or Cu(II) chloride and Fe(II) or Fe(III) chloride). While the reactions initiated by ordinary radical initiators such as benzoyl peroxide and azobisisobutyronitrile afford telomers with higher average molecular weights, the main products obtained in the *n*-butylamine - metallic salt systems were telomers lower average molecular weights. The content of $CCl_3CH_2CHCl_2$, the 1 : 1 adduct of vinyl chloride with carbon tetrachloride, is as high as 80%.

Since Collins noticed that amines change into amine hydrochlorides in carbon tetrachloride under day-light, the reaction of amines with carbon tetrachloride under mild conditions has been investigated by many authors.[2] Amines form charge-transfer complexes with carbon tetrachloride. However, the formation constants are rather small. The complexes decompose with the formation of trichloromethyl radicals under the influence of light or metallic salts.[3-5]

Miller[5] proposed the following mechanism for the photo-decomposition:

$$RNH_2 \cdot CCl_4 \xrightarrow{h\nu} RNH_2^+Cl^- + \cdot CCl_3$$

On the other hand, Asscher and Vofsi[6] proposed the following redox mechanism with participation of metallic ions, *e. g.* cupper ions:

$$RNH_2 \cdot CCl_4 + Cu^+ \rightarrow [Cu^{(+)} \cdot Cl]RNH_2 + \cdot CCl_3$$

When a vinyl compound is present in such a system, trichloromethyl radicals enter into polymerization. However, this mechanism has not been confirmed to be plausible through our investigation on the telomerization of vinyl compounds with carbon tetrachloride in amine-metallic salt systems.[1] In the present paper, the results on the effect of amines on the reaction will be presented.

Experimental

Amines and cupric chloride of commercial special grade were used without purification. Carbon tetrachloride was purified by distillation and vinyl chloride was washed with a 5% sodium hydroxide solution and dried by passing through a calcium chloride tube.

Telomerization was carried out in a stainless steel autoclave with a magnetic stirrer. Definite amounts of carbon tetrachloride, amine and $Cu(II)Cl_2$ were placed in the autoclave chilled with dry ice-acetone, and vinyl chloride which had been liquified was added.

* Added amount of amine, 0.01 mol/mol CCl_4; Added amount of $CuCl_2$, 0.0025 mol/mol CCl_4; Reaction time, 2.5 hr; Reaction temperature, 130°C; Molar ratio CCl_4/vinyl chloride, 4.

** Determined by gas chromatography.

The autoclave was then sealed and the air inside was replaced several times by nitrogen gas. The autoclave was heated up to the desired temperature and kept for 2.5 hr.

The reaction conditions were as follows. The molar ratio of carbon tetrachloride to vinyl chloride was 4, cupric chloride 0.0025 mol/mol CCl_4, amine 0.01 mol/mol CCl_4, temperature 130°C and reaction time 2.5 hr.

After the autoclave was cooled to room temperature, the reaction mixture was filtered, washed with water to remove soluble amine hydrochloride and the solvent and carbon tetrachloride were recovered by distillation. The mixture of telomers was fractionated into $n=1$, $n=2$ and $n=3$ fractions by distillation. Each fraction was examined by gas chromatography, infrared and NMR spectroscopy to confirm its structure.

Results

Effect of Amines. Telomerization was carried out in the presence of various amines. The result is shown in Table 1. When the amine with lower value of pK_B is used, the yield of telomers becomes higher. The following order which gives higher yields of telomers should be noted; diethylamine<di-*n*-propylamine<di-*n*-butylamine and *n*-butylamine <tri-*n*-butylamine<di-*n*-butylamine. When amines with two functional groups such as diamines and alkanolamines are used, the yield of telomers becomes lower. The result is inconsistent with that obtained on the telomerization of ethylene with carbon tetrachloride, where the presence of alkanolamines raises the yield of telomers.[7] When the yield of total telomers is high, the composition ratio of the telomer with $n=1$ is also high in most cases. However, some heterocyclic amines such as pyridine, piperidine and pyrrolidine give lower yield of telomers, but higher ratio of telomer with $n=1$.

The effect of added amount of di-*n*-butylamine on the yield of telomers is shown in Fig. 1. We see that the yield of telomers increases rapidly at first, then slowly with the increase of added amounts

of di-*n*-butylamine.

Effect of Reaction Temperature and Time. The effects of reaction temperature on the yield of telomers when di-*n*-butylamine and *n*-butylamine are used are shown in Fig. 2. The yield of telomers increases abruptly in a relatively low temperature range and shows a maximum at 90 and 120°C in the cases of *n*-butylamine and di-*n*-butylamine, respectively. The composition ratio of the 1 : 1 telomer exhibits a similar behavior.

The effect of reaction time in the system of di-*n*-butylamine and cupric chloride is shown in Table 2. The yield of telomers increases abruptly within 1 hr of the initial stage of reaction. The composition of telomers does not change remarkable during the course of the reaction.

Effect of Solvents. The basicity and ability of complex formation of amines are affected by the solvent. Thus it is probable that telomerization is affected in various stages by addition of solvents. The effect of solvent on the yield and composition of telomers was examined by using mixtures of carbon tetrachloride and various solvents. The

results are shown in Table 3. As shown in this table, the effect of solvent is not remarkable, except for the cases where solvents take part in reactions.

Discussion

The amine-metallic salt initiating systems afford a high yield of lower telomers. This might be due to an effective chlorine-transfer mechanism. Asscher and Vofsi supposed some complexes consisting of cuprous ions and chlorine radicals or cupric ions and chloride ions with coordinated amines for a reaction intermediate to take an essential role in this chlorine-transfer mechanism. Assuming the existence of such complexes the following reaction scheme would follow.

$$M^{(+)} + nRNH_2 \rightarrow M^{(+)}(RNH_2)_n$$

$$M^{(+)}(RNH_2)_n + CCl_4 \rightarrow [M^{(+)}\cdot Cl](RNH_2)_n + \cdot CCl_3$$

$$\cdot CCl_3 + CH_2CHCl \rightarrow CCl_3CH_2CHCl\cdot$$

$$CCl_3CH_2CHCl\cdot + [M^{(+)}\cdot Cl](RNH_2)_n \rightarrow CCl_3CH_2CHCl_2 + M^{(+)}(RNH_2)_n$$

The result of kinetic treatments based on this scheme is inconsistent with experimental result. As an example, the increasing stability of the complex $[M^{(+)}\cdot Cl](RNH_2)_n$ gives rise to the increase in the rate of formation of trichloromethyl radicals, and the decrease in the rate of abstraction of chlorine radical from the complex. This conflicts with the result where the increasing yield of total telomers is accompanied by the increasing content of the telomer with $n=1$.

Thus the above reaction scheme should be modified. It seems most probable that the reaction step to form the telomer with $n=1$ takes place in cages stabilized by amines. The reaction scheme is written as follows:

$$M^{(+)} + nRNH_2 \overset{K_1}{\rightleftharpoons} M^{(+)}(RNH_2)_n$$

$$M^{(+)}(RNH_2)_n + CCl_4 \overset{K_2}{\rightleftharpoons} [M^{(+)}Cl\cdot\cdot CCl_3](RNH_2)_n$$

$$[M^{(+)}Cl\cdot\cdot CCl_3](RNH_2)_n + CH_2CHCl \overset{k_1}{\longrightarrow} CCl_3CH_2CHCl_2 + M^{(+)}(RNH_2)_n$$

$$[M^{(+)}Cl\cdot\cdot CCl_3](RNH_2)_n \overset{k_2}{\longrightarrow} (M^{(2+)}Cl^-)(RNH_2)_n + \cdot CCl_3$$

$$\cdot CCl_3 + CH_2CHCl \overset{k_3}{\longrightarrow} CCl_3CH_2CHCl\cdot$$

$$CCl_3CH_2CHCl\cdot + CH_2CHCl \overset{k_4}{\longrightarrow} CCl_3(CH_2CHCl)_2\cdot$$

$$CCl_3CH_2CHCl\cdot + CCl_4 \overset{k_5}{\longrightarrow} CCl_3CH_2CHCl_2 + \cdot CCl_3$$

The following reactions are induced by trichloromethyl radicals:

$$\cdot CCl_3 + \cdot CCl_3 \overset{k_6}{\longrightarrow} C_2Cl_6$$

$$\cdot CCl_3 + RNH_2 \overset{k_7}{\longrightarrow} \dot{R}NH + CHCl_3$$

$$\dot{R}NH + CCl_4 \overset{k_8}{\longrightarrow} RNClH + \cdot CCl_3$$

$$RNClH + RNH_2 \overset{k_9}{\longrightarrow} R'CHNH + RNH_3Cl$$

By kinetic treatment of this reaction scheme, the following formulas are derived on the assumption that reaction intermediate $\cdot CCl_3$, $CCl_3CH_2CHCl\cdot$ and $\dot{R}NH$ are in stationary states.

If the condition $k_3k_4[V]^2/(k_4[V]+k_5[C]) < 4k_2k_6 \times [com]$ is satisfied, the rate of formation of the telomer with $n=1$ is given by

$$\frac{d[CCl_3CH_2CHCl_2]}{dt} = k_1[V][com] + \frac{k_2^{1/2}k_3k_5[C][V]}{k_6^{1/2}(k_4[V]+k_5[C])}[com]^{1/2} \quad (1)$$

and the rate of formation of the telomers with $n \geq 2$, by

$$\frac{d[CCl_3(CH_2CHCl)_nCl]}{dt} = \frac{k_2^{1/2}k_3k_4[V]^2}{k_6^{1/2}(k_4[V]+k_5[C])}\cdot[com]^{1/2} \quad (2)$$

On the other hand, if the reverse condition

$$k_3k_4[V]^2/(k_4[V] + k_5[C]) > 4k_2k_6[com]$$

is satisfied, the corresponding equations are obtained as follows:

The rate of formation of the telomer with $n=1$,

$$\frac{d[CCl_3CH_2CHCl_2]}{dt} = [com]\left(k_1[V]+\frac{k_2k_5[C]}{k_4[V]}\right) \quad (3)$$

and the rate of formation of the telomers with $n \geq 2$,

$$\frac{d[CCl_3(CH_2CHCl)_nCl]}{dt} = k_2[com] \quad (4)$$

In these equations, the following abbreviations are used,

V: CH_2=CHCl, C: CCl_4

and com: $[M^{(+)}Cl\cdot\cdot CCl_3](RNH_2)_n$

and the concentration of this complex is

$$[com] = K_1K_2[M^{(+)}][CCl_4][RNH_2]^n \quad (5)$$

The cage complex as a reaction intermediate would be formed through the interaction of chlorine radical with metal ion and the stabilization by coordinated amines. The attack of vinyl chloride on this cage complex affords tetrachloropropyl radical, and the resulting radical instantly abstracts chlorine radical from the complex. The presence of such cage complexes greatly decreases activation energy for the insertion of vinyl chloride into the Cl–CCl_3 bond.

This scheme gives a plausible explanation for the effect of amines as shown in Table 1. The increasing basicity of amines enhances the stabilization of cage complexes and decreases the activation energy for the insertion reaction. On the other hand, bifunctional amines possess strong chelating ability to Cu(II) ions and, therefore, make the decomposition of cage complexes feasible. Bulkiness of amines do not show any steric hindrance, for the site of reaction is not on the metallic ions and mechanically stabilize the cage complex. This is the reason why the amine with two or three long alkyl chains is effective.

The slight effect of solvents is understandable if the reaction proceeds primarily in cages. However, the increase in dielectric constants might decrease the stability of cages.

Of the alternative conditions mentioned above, the latter would be satisfied in most cases, because k_2 and [com] are relatively small. In this case, from Eqs. (1) and (2), the product ratio of the telomers with $n=1$ and $n\geq 2$ is given by

$$\frac{[CCl_3CH_2CHCl_2]}{[CCl_3(CH_2CHCl)_nCl]} = \frac{k_1}{k_2}[V] + \frac{k_5[C]}{k_4[V]} \simeq \frac{k_1}{k_2}[V] \quad (6)$$

Table 1 shows that the ratio $k_1[V]/k_2$ is 3—5.

The high reaction rate observed in this system supports the mechanism. In telomerization of vinyl chloride and chloroform, the main product of the 1 : 1 adducts is $CCl_3CH_2CH_2Cl$ when benzoyl peroxide or azobisisobutyronitrile is used as an initiator, but the main product is $CHCl_2CH_2CHCl_2$ when the amine-$CuCl_2$ is used.[8] This observation supports the mechanism proposed in this paper. However, further examination would be necessary in order to establish this mechanism. The EPR measurement on copper ion-amine-carbon tetrachloride systems and a detailed analysis on the distribution of products in the reaction of vinyl chloride with chloroform are now in progress. The results will be presented in the near future.

Aromatic Arylation with Aryl Radicals. I. A Novel Method for Generating Aryl Free Radical

Michio KOBAYASHI, Hiroshi MINATO, Nobumasa KOBORI and Eiichi YAMADA

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

(Received July 15, 1969)

Benzenediazonium tetrafluoroborate in DMSO decomposed instantaneously with evolution of nitrogen upon addition of a DMSO solution of sodium nitrite. Orientations and partial rate factors for phenylation of substituted benzenes indicated that not phenyl cation but phenyl radical was produced as an intermediate. Hammett's plots of partial rate factors of meta and para positions yielded good straight lines with $\rho_m = 0.46$ and $\rho_p = 1.67$. Plausible mechanisms were discussed. From *m*-dinitrobenzene 2,6- and 2,4-dinitrobiphenyl were produced in 47 and 23% yields, respectively, and the synthetic value of this method was pointed out.

Aryldiazonium salts decompose with evolution of nitrogen in aprotic polar solvents, and phenyl cation is considered to be the intermediate on the basis of the kinetic studies[1] and the partial rate factors for arylation of substituted benzenes.[2]

$$ArN_2^+ \rightarrow Ar^+ + N_2$$

However, it has been reported that aryldiazonium salts undergo homolytic decomposition in methanol[3] or pyridine.[4]

$$ArN_2^+ + CH_3O^- \rightarrow Ar\text{–}N{=}N\text{–}OCH_3 \rightarrow Ar\cdot + N_2 + \cdot OCH_3$$

or

During a systematic investigation on the decomposition of aryldiazonium salts in aprotic polar solvents in our laboratories, it has been found that aryldiazonium salts decompose instantaneously with evolution of nitrogen upon addition of sodium nitrite in dimethyl sulfoxide (DMSO) at room temperature. In this paper, the results of this investigation will be described, and the evidence for the homolytic nature of the decomposition will be presented. Synthetic utility of this reaction will be also pointed out.

Experimental

Materials. Preparation of benzenediazonium tetrafluoroborate and substituted biphenyls, and purification of DMSO and substituted benzenes were described in our previous paper.[2b] *m*-Dinitrobenzene, *p*-nitrotoluene, *p*-chloronitrobenzene, 1,3,5-trinitrobenzene and sodium nitrite were the first grade chemicals of Wako Pure Chemical Industries, and were used without further purification.

Phenylation of Monosubstituted Benzenes. Under nitrogen atmosphere a solution of 2.00 g of benzenediazonium tetrafluoroborate in 20 g of DMSO was added drop by drop at 10°C into a vigorously stirred solution of sodium nitrite (3 mol/mol of PhN_2BF_4) and a substituted benzene (50 mol/mol of PhN_2BF_4) in 60 g of DMSO. Evolution of nitrogen was instantaneous upon addition of each drop of the diazonium salt solution, and the addition was completed in about ten minutes. Ether was added to the solution, and the mixture was washed with water in order to remove DMSO and excess sodium nitrite. After it was dried over magnesium sulfate, ether and about 70% of the remaining substituted benzene was evaporated, and biphenyl isomers in the residue was analyzed by a Hitachi Gas-Chromatograph K-53. Biphenyl isomers were identified by comparison of the retention times with those of the authentic samples on a 1 m to 6 m-column (depending upon the ease of separation) packed with Chromosorb W (10% Apiezon L). Quantitative determinations were made by use of calibration curves.

Not benzene but chlorobenzene was used as the standard for the competitive phenylation, since non-substituted biphenyl easily sublimes and the evaporation of a remaining substituted benzene will bring forth a great error. The reactivity of each position of substituted benzenes was calculated relative to the reactivity of the ortho position of chlorobenzene. A competitive phenylation between benzene and chlorobenzene was carried out without evaporation in order to determine the partial rate factor of the ortho position of chlorobenzene. The partial rate factors of various substituted benzenes were calculated by the following equation.

$$k_X/k = (k_X/k_{o\text{-}Cl}) \times (k_{o\text{-}Cl}/k)$$

Phenylation of Poly-substituted Benzenes. The experimental procedure was the same as that described for mono-substituted benzenes except where otherwise stated.

***p*-Nitrotoluene.** A solution of *p*-nitrotoluene (10.0 g) and sodium nitrite (2.5 g) in DMSO (30 g) was added to a stirred solution of benzenediazonium tetrafluoroborate (3.717 g) in DMSO (30 g). Biphenyl isomers were separated by a gas chromatograph, and the fractions isolated were identified by infrared spectroscopy, NMR spectroscopy (in $CDCl_3$) and elemental analyses, and quantitative determinations were made by gas chromatography. 3-Methyl-6-nitrobiphenyl. H^2: 2.64 τ (singlet); H^4: 2.71 τ (doublet, J_{45}=9.0 Hz); H^5: 2.20 τ (doublet, J_{54}=9.0 Hz). Found: C, 73.75; H, 5.72%. Calcd for $C_{13}H_{11}O_2N$: C, 73.22; H, 5.20%. 2-Methyl-5-nitrobiphenyl. H^3: 2.76 τ (multiplet); H^4 and H^6: 1.90 τ (multiplet). Found: C, 73.46; H, 5.50%. Calcd for $C_{13}H_{11}O_2N$: C, 73.22; H, 5.20%.

***p*-Nitrochlorobenzene.** A solution of *p*-nitrochlorobenzene (16.0 g) and sodium nitrite (4.0 g) in DMSO (30 g) was added to a stirred solution of benzenediazonium tetrafluoroborate (3.445 g) in DMSO (20 g). Biphenyl isomers were separated by a gas chromatograph, and the fractions isolated were identified by infrared spectroscopy, NMR spectroscopy (in $CDCl_3$) and elemental analyses, and determined quantitatively by gas chromatography. 3-Chloro-6-nitrobiphenyl. H^2: 2.24 τ (singlet); H^4: 2.55 τ (doublet, J_{45}=9.0 Hz); H^5: 2.16 τ (doublet, J_{54}=9.0 Hz). Found: C, 61.29; H, 3.46%. Calcd for $C_{12}H_8O_2NCl$: C, 61.69; H, 3.45%. 2-Chloro-5-nitrobiphenyl. H^3: 2.37 τ (doublet, J_{34}=9.0 Hz); H^4: 1.86 τ (doublet, J_{43}=9.0 Hz); H^6: 1.77 τ (singlet). Found: C, 61.9; H, 3.14%. Calcd for $C_{12}H_8O_2NCl$: C, 61.69; H, 3.45%.

***m*-Dinitrobenzene.** A solution of *m*-dinitrobenzene (10.0 g) and sodium nitrite (5.0 g) in DMSO (22 g) was added to a stirred solution of benzenediazonium tetrafluoroborate (4.237 g) in DMSO (10 g). Chloroform instead of ether was used for extraction. Substituted biphenyl isomers were separated on an alumina column with hexane-benzene as the eluant, and recrystallized from ethyl acetate. 2,4-Dinitrobiphenyl, 2.1 g (47%), mp 108°C (lit,[5] 110°C). 2,6-Dinitrobiphenyl, 1.1 g (23%), mp 186—187°C (lit,[6] 188—189°C).

1,3,5-Trinitrobenzene. A solution of 1,3,5-trinitrobenzene (4.0 g) and sodium nitrite (5.0 g) in DMSO (30 g) was added to a stirred solution of benzenediazonium tetrafluoroborate (4.50 g) in DMSO (10 g). Chloroform was used for extraction. 2,4,6-Trinitrobiphenyl was isolated by elution chromatography on a silica gel column with hexane-benzene as the eluant; 2.55 g (55%), mp 129°C (lit, 130°C).[5]

Results and Discussion

Benzenediazonium tetrafluoroborate in DMSO decomposed instantaneously with evolution of nitrogen upon addition of a DMSO solution of sodium nitrite. Since in the absence of sodium nitrite the diazonium salts slowly undergoes a first-order decomposition *via* phenyl cation,[2b] the mechanism of this rapid decomposition must be different from that involving phenyl cation. The difference of the mechanism is also suggested from the absence of 1,3-benzoxathian in the products, which was always produced when phenyl

b) Reaction was carried out in water under heterogeneous conditions.

cation was generated in DMSO.[2b]

Table 1 shows the orientations and partial rate factors for phenylation of substituted benzenes with benzenediazonium tetrafluoroborate and sodium nitrite in DMSO. All the substituents behaved as *o,p*-directors, and partial rate factors were always larger than 1. These data are similar to those of phenylation with phenyl radical produced from benzoyl peroxide[7a] or *N*-nitrosoacetanilide[7b] and quite different from those of phenylation with phenyl cation.[2,8] These findings indicate that the benzenediazonium salt reacts with sodium nitrite and produces phenyl radical. Plausible mechanisms are the following two.

$$PhN_2^+ + {}^-O\text{-}N{=}O \rightarrow Ph\text{-}N{=}N\text{-}O\text{-}N{=}O \quad (I)$$

Scheme 1

$$Ph\text{-}N{=}N\text{-}O\text{-}N{=}O \rightarrow Ph\cdot + N_2 + NO_2$$

Scheme 2

$$2Ph\text{-}N{=}N\text{-}O\text{-}N{=}O \rightarrow Ph\text{-}N{=}N\text{-}O\text{-}N{=}N\text{-}Ph + N_2O_3 \quad (II)$$

$$Ph\text{-}N{=}N\text{-}O\text{-}N{=}N\text{-}Ph \rightarrow Ph\cdot + N_2 + Ph\text{-}N{=}N\text{-}O\cdot$$

Since NO_2 and $PhN{=}NO\cdot$ are rather stable radicals, it is possible that compound I or II decomposes quickly as they are formed.

It is generally recognized that excess sodium nitrite should not be present when aryldiazonium salts are prepared, but no satisfactory explanation for the harmful action of nitrites has been proposed yet. The results of this investigation show that the excess nitrite not only decompose the aryldiazonium salts but also produce very reactive phenyl radical, which attacks various compounds present in the medium, producing a mixture of complicated products.

the Hammett's plots of partial rate factors obtained by Ito, Migita, Morikawa and Simamura[7b] for phenylation with *N*-nitrosoacetanilide (without consideration of the conjugative effect τ_p). It is a satisfactory linear relationship of V-shape with $\rho_m=0.07$ and $\rho_p=1.27$. Both ρ_m and ρ_p of this investigation were greater than those of *N*-nitrosoacetanilide. The difference might be ascribed to solvent effect, *i.e.*, the use of the polar solvent, DMSO, in this investigation. However, it has been found in our laboratories that the ρ value for the partial rate factors for phenylation with phenyl radical generated from phenylazotriphenylmethane in PhX-DMSO is not greater than that in PhX alone,[9] and this finding shows that the greater ρ value in this investigation is not due to solvent effect. Since sodium nitrite is insoluble in less polar organic solvents, it is not possible to investigate the reaction between benzenediazonium tetrafluoroborate and sodium nitrite in other solvents.

The greater ρ values may be ascribed to the difference in the species abstracting hydrogen from the intermediate phenylcyclohexadienyl radicals. The hydrogen abstractor in Scheme 1 is NO_2, and that in Scheme 2 is PhN=N-O· or N_2O_3. As for the hydrogen abstractor for *N*-nitrosoacetanilide, Ruchardt and his coworkers reported that PhN=NO· is the species which abstracts hydrogen,[10] whereas Chalfont and Perkins reported that Ph(Ac)N-(Ph)N-O· abstracts hydrogen.[11] If the hydrogen abstractor in the case of *N*-nitrosoacetanilide is Ph(Ac)N-(Ph)N-I·, the difference in the ρ values may be ascribed to the difference in the hydrogen-abstracting species. If the hydrogen abstractor in the case of *N*-nitrosoacetanilide is is PhN=N-O·, the difference in the ρ values can be ascribed to the difference in the hydrogen-abstracting species only when the hydrogen abstractor in the PhN_2BF_4-$NaNO_2$ system is NO_2 or N_2O_3, and not PhN=N-O·. At present it is not possible to determine what the true hydrogen abstractor in this system is. In our laboratories phenylation with phenylazotriphenylmethane in the presence of N_2O_4 is being investigated and the capacity of N_2O_4 as a hydrogen abstractor is being examined.[9]

It is interesting to note that the values of $\rho_p-\rho_m$ are approximately the same in both cases (1.27−0.07=1.20 for *N*-nitrosoacetanilide and 1.67−0.46=1.21 for PhN_2BF_4-$NaNO_2$). This fact seems to indicate that the contributions of the direct conjugative effect of *p*-substituents are similar in both cases.

Table 1 shows that the yield of phenylation of nitrobenzene is 76.3%, which is much better than those of chlorobenzene. Williams and his coworkers observed that in the decomposition of benzoyl peroxide in benzene the yield of biphenyl increased from 50% to 90% when aromatic compounds with nitro group were added to the media, and they called the phenomenon "nitro group effect.[12]" However, in Fig. 1 the nitro group

does not appear to be peculiar on the straight line representing a satisfactory Hammett relationship, and it seems that the high yield of nitrobiphenyl can be explained in terms of the conjugative effect alone.

This phenylation reaction appears to be a good method for the syntheses of substituted biphenyls. This method is more advantageous than Gomberg reaction in that even solid substrates can be phenylated in homogeneous media under very mild and non-alkaline conditions. The phenylations of several solid aromatic compounds were investigated, and the results are summarized in Table 2. Yields are fairly large and better than those of Ullmann reaction. It is interesting to note that the substitution with phenyl group takes place at the position ortho to sterically large nitro group in good yields. As an example, phenylations of *m*-dinitrobenzene by several methods[13] are compared above, and the comparison reveals the synthetic utility of the phenylation with PhN_2BF_4-$NaNO_2$ in DMSO.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1135—1138 (1970)

Formation of 4-Hydroxycarbostyrils in the Reaction of Carbon Suboxide with Aromatic Amines

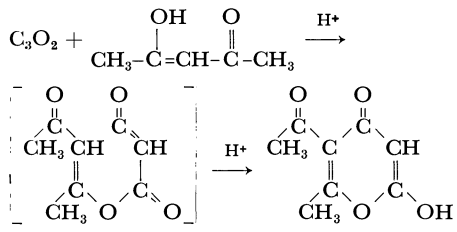
Akira Omori, Noboru Sonoda and Shigeru Tsutsumi

Department of Chemical Technology, Faculty of Engineering, Osaka University, Yamadakami, Suita

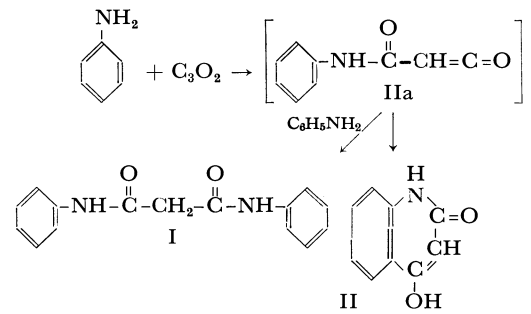
(Received July 18, 1969)

The reactions of carbon suboxide with aromatic amines were found to give various 4-hydroxycarbostyril derivatives. The reaction between aniline and carbon suboxide usually gives malonanilide. However, it was found that the reaction of aniline with carbon suboxide in ether in the presence of aluminum chloride produced phenylcarbamoylacetic acid in a good yield and that cyclization to 4-hydroxycarbostyril occurred when the solvent was replaced by benzene before the decomposition of the reaction mixture with water. The solvent effect on the formation of 4-hydroxycarbostyrils and the possible reaction mechanism were discussed.

The reaction between carbon suboxide and several enolizable ketones have been reported to give pyrone and pyronopyrone derivatives.[1-3] In our recent publications,[3,4] we have reported the reaction of carbon suboxide with acetylacetone in the presence of sulfuric acid, thus producing 3-acetyl-6-hydroxy-2-methyl-4-pyrone. The reaction includes the cyclization of the *O*-acetylated ketenic intermediate to the pyrone, as is indicated below:



It has been reported that the reaction of carbon suboxide with aniline[5] gave malonanilide (I) quantitatively. In this case, the reaction may proceed *via* the *N*-acylated ketenic intermediate (IIa), which may be expected to produce 4-hydroxycarbostyril (II) if the intramolecular cyclization occurs.



In the present paper, we wish to report on the formation of various 4-hydroxycarbostyril derivatives in the reaction of carbon suboxide with aromatic amines.

Results and Discussion

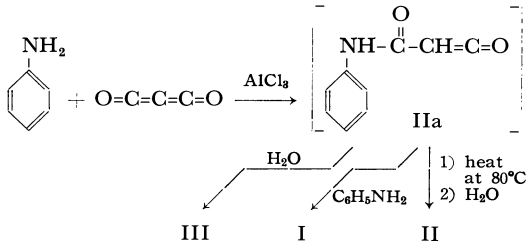
Reaction with Aniline. The reaction of carbon suboxide with aniline in ether gave I quantitatively. The presence of a catalytic amount of sulfuric acid did not affect the reaction, and no II was obtained. A further attempt with aluminum chloride in carbon disulfide failed to give either II or phenylcarbamoylacetic acid (III), only I was isolated. However, the reaction of carbon suboxide with aniline in the presence of aluminum chloride in ether at room temperature gave III in a 78% yield when the reaction mixture was decomposed with water. On the other hand, II was obtained in a 17.3% yield when, before the decomposition of the reaction mixture with water, benzene was used in the place of ether and the benzene solution was refluxed at 80°C. The structures of II and III were confirmed by comparison with authentic samples in terms of their mass, infrared, and ultraviolet spectra. The results obtained in the reaction of carbon suboxide with aniline are summarized in Table 1.

Table 1. Reaction of carbon suboxide with aniline under various conditions

Reactant $C_6H_5NH_2$/ C_3O_2	Solvent	Catalyst	Reaction temp.	Product (yield)
1/1	CS_2	$AlCl_3$	r. t.	I (95%)
1/2	CS_2	$AlCl_3$	r. t.	I (100%)
1/2	Et_2O	none	r. t.	I (100%)
1/2	Et_2O	H_2SO_4	r. t.	I (100%)
1/2	Et_2O	$AlCl_3$	r. t.	III (78%)
1/3	$Et_2O \rightarrow C_6H_6$	$AlCl_3$	80°C	II(17.3%)

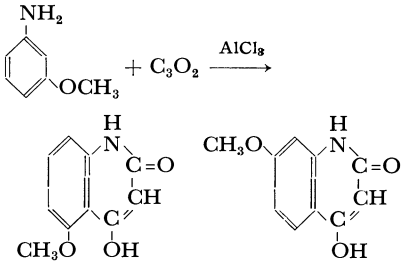
* Mole ratio

A possible reaction path for the formation of II is illustrated below. The first step in the reaction is considered to be the *N*-acylation to give an *N*-acylated intermediate (IIa), which, on cyclization, gives II and which, on reaction with one molecule of aniline and with water, gives I and III respectively.



As is shown in Table 1, the solvent effect on the reaction with aniline is remarkable. In the first two cases in Table 1, I was formed quantitatively in carbon disulfide with aluminum chloride. However, in ether III was produced in a 78% yield under similar conditions. The reason for this solvent effect is that aluminum chloride may be catalytically inactive for the formation of I due to the formation of a complex ($\overset{\delta+}{Et_2O} \rightarrow \overset{\delta-}{AlCl_3}$); since no such complex is formed when carbon disulfide is used, it is thought that the activity of aluminum chloride remains such as to give I.

Reaction with Anisidines. The reaction of carbon suboxide with *o*,- *p*-, and *m*-anisidines (IV, V, and VI respectively) gave 4-hydroxy-methoxycarbostyrils in 29—67% yields under conditions similar to those used in the case of aniline. In the reaction with IV, 4-hydroxy-8-methoxycarbostyril (VII) was obtained in a 28.5% yield. With V, 4-hydroxy-6-methoxycarbostyril (VIII) was obtained in a 58.7% yield. The structures of VII and VIII were confirmed by comparison with authentic samples in terms of their infrared, ultraviolet, and mass spectral data. In the reaction of carbon suboxide with VI, a carbostyril derivative (mp 330°C) (IX) was obtained. In this case, 4-hydroxy-5-methoxy- and/or 4-hydroxy-7-methoxycarbostyril would normally be expected.



The structure of IX was examined by a comparison of its infrared and ultraviolet spectra with

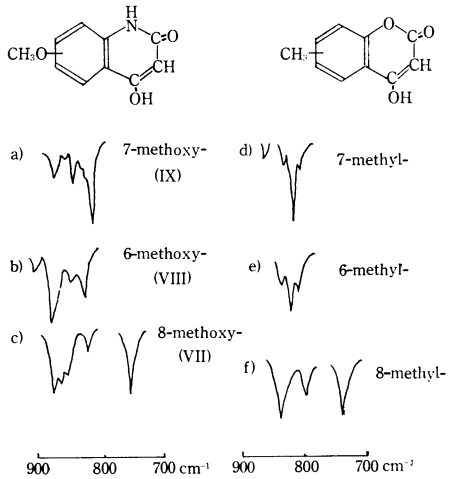


Fig. 1. The IR spectra between 900 cm^{-1} and 700 cm^{-1} of carbostyrils and coumarins.

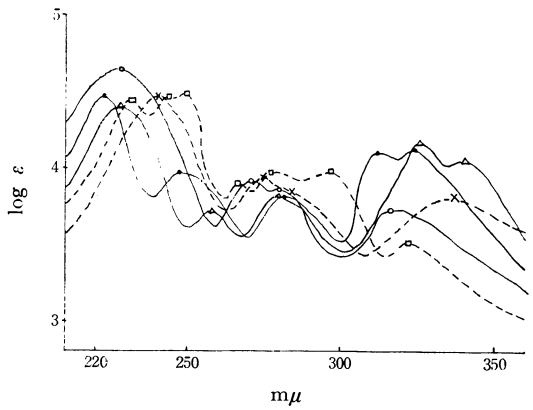

Fig. 2. The UV spectra of carbostyril derivatives.

2) $R_1=OH$, $R_2,R_3,R_4=H$, $R_5=OCH_3$ (—□—□)
3) $R_1=OH$, $R_2,R_4,R_5=H$, $R_3=OCH_3$ (—×—×)
4) $R_1=OH$, $R_2,R_3,R_4,R_5=H$ (—○—○)
5) IX (—●—●)

those of other 4-hydroxycarbostyril and 4-hydroxycoumarin derivatives (Fig. 1 and Fig. 2).

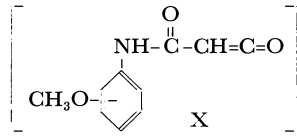
The 1,2,3-trisubstituted benzene rings of 4-hydroxy-methylcoumarin and 4-hydroxy-methoxycarbostyril show characteristic absorption bands due to hydrogen on the benzene ring between 800 cm^{-1} and 700 cm^{-1}. However, IX shows no absorption bands in this region, and the spectrum between 900 cm^{-1} and 800 cm^{-1} can be interpreted rather as that for the 1,2,4-trisubstituted benzene derivative. The spectral data of some 1,2,4-trisubstituted benzene derivatives related to 4-hydroxycarbostyril are also shown in Fig. 1. This speculation is also supported by the ultraviolet spectral data shown in Fig. 2. On the basis of these facts, the structure of IX was assigned to 4-hydroxy-7-methoxycarbostyril. The results obtained in the reactions of anisidines are shown in Table 2.

Table 2. Reaction of carbon suboxide with anisidines

Reactant	Solvent	Catalyst	Reaction temp.	Product (yield)
IV	$Et_2O \rightarrow C_6H_6$	$AlCl_3$	80°C	VII(28.5%)
V	$Et_2O \rightarrow C_6H_6$	$AlCl_3$	80°C	VIII(58.7%)
VI	$Et_2O \rightarrow C_6H_6$	$AlCl_3$	80°C	IX (66.8%)

The reaction path for the formation of 4-hydroxy-methoxycarbostyrils may also include the cyclization of the *N*-acylated intermediate (X).

The better yields of carbostyril derivatives from anisidines than from aniline may be ascribed to



the electron-donating effect of the methoxyl group on the benzene ring in X. In the case of VI, the steric interaction between the methoxyl group and the ketenic group in the intermediate may affect the course of cyclization so as to favor the production of the 7-methoxycarbostyril rather than the 5-methoxy derivative.

Experimental

Preparation of Carbon Suboxide. Carbon suboxide was prepared by the pyrolysis[6] of diacetyltartaric anhydride at about 700°C and trapped at −78°C (a dry ice-methanol bath), and it was purified by distillation from trap to trap. The identification was established by the preparation of malonanilide by means of a reaction with aniline.

Reaction of Carbon Suboxide with Aniline in Carbon Disulfide. Into a suspension of aluminum chloride (15.2 g, 0.14 mol) in carbon disulfide (15 m*l*), we stirred a solution of carbon suboxide (8.8 g, 0.14 mol) in carbon disulfide (20 m*l*) at −70°C under nitrogen. Then a solution of aniline (11.8 g, 0.14 mol) in carbon disulfide (50 m*l*) was stirred, drop by drop, into this reaction mixture over a period of one hour. The reaction mixture was then maintained at −70°C for 6 hr, at 0°C for 9 hr and at room temperature for 9 hr. The reaction mixture was then poured into ice-water. The solid (19.5 g, 95%) which was deposited was recrystallized from ethanol to give I, mp 225°C.

Reaction of Carbon Suboxide with Aniline in Ether. The same procedure as described above was applied using aluminum chloride (6.9 g, 0.05 mol), carbon suboxide (3.4 g, 0.05 mol), and aniline (1.7 g, 0.017 mol), and ether (170 m*l*) instead of carbon disulfide. The reaction mixture was poured into ice water. The ether layer was dried over anhydrous magnesium sulfate, and the solid residue was recrystallized from chloroform to give III (2.2 g, 78%); mp 128°C; ν_{max}^{KBr} 1730 (C=O), 1670 (–NH–C(=O)–) cm^{-1}; an acidic test by $NaHCO_3$ was positive.

Found: C, 60.25; H, 4.90; N, 7.86%. Calcd for $C_9H_9NO_3$: C, 60.33; H, 5.06; N, 7.82%.

4-Hydroxycarbostyril (II). The same procedure as described above was applied using aluminum chloride (6.5 g, 0.04 mol), carbon suboxide (3.3 g, 0.049 mol), aniline (1.5 g, 0.016 mol), and ether (250 m*l*). After mixing the reactants, benzene (150 m*l*) was added, drop by drop, to the mixture, and at the same time the ether was evaporated by warming. After the ether had been removed completely, the benzene solution was refluxed at 80°C for 4 hr and then poured into ice water. A yellow solid, extracted with methanol from the solid deposited, was recrystallized from ethanol to give II; 0.46 g (17.3%); mp 333—335°C (decomp.); ν_{max}^{KBr} 2900 (–OH, –NH), 1680 (C=O), 1600 (C=C)

The Optical Rotatory Dispersion and Circular Dichroism of Aromatic Amino Acids*1,2

Naokazu SAKOTA, Kozo OKITA and Yasuhiko MATSUI

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Bunkyo-cho, Matsuyama

(Received August 8, 1969)

The CD and ORD of D-phenylglycine and L-phenylalanine were measured at various pH's. The superficial small pH dependence of the CD maximum around 220 mμ and the anomalous large $[\theta]$ value at the CD maximum in both aromatic amino acids suggest an interaction between the ^1L_a transition of the benzene ring and the $n\rightarrow\pi^*$ transition of the carboxyl group. The ORD and CD of L-α-amino-β-benzalpropionic acid, L-α-amino-β-benzylpropionic acid, and L-2-amino-4-phenyl-butanol-1 were also measured, and the screening effect of the methylene groups which exist between a benzene ring and an asymmetric carbon atom was discussed.

Studies of the optical rotatory dispersion (ORD) and circular dichroism (CD) of optically active aromatic compounds have revealed that in some compounds, ^1L_a and ^1L_b transitions of the benzene ring in Platt's notation[1] are optically active.[2,3] It has also been reported that the ^1L_b transition of the benzene ring is optically active in such aromatic amino acids as tyrosine,[3] tryptophan,[3] and phenylalanine.[4] However the absorption maximum corresponding to the ^1L_a transition is situated so close to that of the $n\rightarrow\pi^*$ transition of the carboxyl group that it is not obvious whether the ^1L_a transition of aromatic amino acid is optically active or not.

Sakota (one of the present authors) has previously shown[5] that the CD curve of an aromatic amino acid is closely related to that of its acryloyl derivative, although a new CD maximum around 230 mμ appears in the acryloyl derivatives of aliphatic amino acids. These facts suggest that a Cotton effect in 220 mμ regions of aromatic amino acids corresponds to the phenyl chromophore rather than to the carboxyl chromophore. Furthermore, in comparing the ORD curves of phenylalaninol and tyrosinol with those of the corresponding amino acids, Rosenberg[6] has suggested that the ^1L_a transition of the benzene ring is optically active.

In the present experiment, the present authors have measured the ORD and CD curves of D-

phenylglycine and L-phenylalanine at various pH's, and also, the ORD and CD curves of three more optically active aromatic amino acids synthesized. The results gave direct support to the above-mentioned suggestions, indicating the screening effect of the methylene groups which exist between an asymmetric carbon atom and a benzene ring in aromatic amino acids.

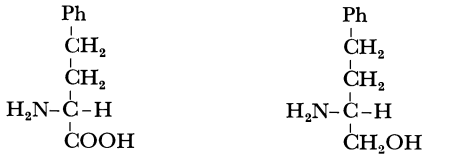
D-Phenylglycine (I) | L-Phenylalanine (II) | L-α-Amino-β-benzalpropionic acid (III)



L-α-Amino-β-benzylpropionic acid (IV) | L-2-Amino-4-phenylbutanol-1 (V)

Experimental

Materials. Chromatographically- and optically-pure D-phenylglycine (I) and L-phenylalanine (II) were purchased from the Yoneyama Chemical Industry Co., Ltd.

Preparations. *L-α-Amino-β-benzalpropionic Acid (III).* DL-α-Amino-β-benzalpropionic acid (11 g, 0.0615 mol), prepared from cinnamaldehyde and sodium cyanide by the method of Ref. 7, was dissolved in 32 m*l* of 2N NaOH (0.062 mol). To this solution 6.4 g (0.062 mol) of acetic anhydride and 32 m*l* (0.062 mol) of 2N NaOH were added at 0°C over a period of about 1 hr. Then, the mixture was stirred for one more hour, after which the pH of the solution was adjusted with 6N HCl to 2.0 and the acetyl-DL-α-amino-β-benzalpropionic acid thus precipitated was filtered out in order to dry it. The yield was 11 g (81%), mp 133—134°C. Acetyl-DL-α-amino-β-benzalpropoinic acid (11 g, 0.05 mol) was dissolved in 25 m*l* of 2N LiOH and adjusted to pH 7.5, the clear upper solution of a suspension of 2.5 g of Biodiastase (purchased from the Amano Pharmaceutical Co., Ltd.) in 10 m*l* of water was then added. After the mixture had stood at 37°C for 5 hr, the crystalline precipitate (III) was filtered off and recrystallized from methanol-water. Yield 3 g (75%), $[\alpha]_D^{20}$ −20° (*c* 1, 0.1N HCl).

Found: C, 67.50; H, 6.10%. Calcd for $C_{10}H_{11}O_2N$: C, 67.77; H, 6.45%.

L-α-Amino-β-benzylpropionic Acid (IV). L-α-Amino-β-benzalpropionic acid (2.5 g, 0.014 mol) was dissolved in 10% acetic acid, 200 mg of 10% palladium charcoal (purchased from the Kawaken Fine Chemical Co., Ltd.) was added, and the mixture was hydrogenated at room temperature for 5 hr. Then, the catalyst was filtered off and the filtrate was concentrated *in vacuo*. IV was precipitated by the addition of methanol and filtered off. Yield 2.3 g (95%), $[\alpha]_D^{20}$ −18° (*c* 1, 0.1N HCl). Ref.[8] $[\alpha]_D^{20}$ −17.7° (*c* 1, 0.1N HCl).

L-2-Amino-4-phenylbutanol-1 (V). L-α-Amino-α-benzylpropionic acid (2 g, 0.012 mol) was added to a solution of 1.2 g (0.032 mol) of $LiAlH_4$ in 30 m*l* of ether over a 20-min period. Stirring was continued for 30 more min, and then water was added to decompose the unreacted $LiAlH_4$. The precipitate was filtered off and washed with ether. The ether solution was dried over anhydrous magnesium sulfate and concentrated *in vacuo*. The crystalline material was filtered off and recrystallized from ethyl acetate. Yield 0.4 g (24.4%), mp 95—96°C, $[\alpha]_D^{20}$ −12° (*c* 1, MeOH).

Found: C, 72.60; H, 9.21%. Calcd for $C_{10}H_{15}ON$: C, 72.65; H, 9.28%.

Measurements. The optical rotatory dispersion and circular dichroism were measured at room temperature with a Jasco-model ORD/UV-5 optical rotatory dispersion recorder with a CD attachment. The cells used were 1 mm long except for III (0.1 mm). Samples of I and II were dissolved in distilled water (about 0.1—0.5 mg/m*l*), and the pH was adjusted with aqueous sodium hydroxide or hydrochloric acid.

Results and Discussion

The CD curves of D-phenylglycine (I) and L-phenylalanine (II) are shown in Fig. 1 and Fig. 2 respectively. The pH-dependent CD measure-

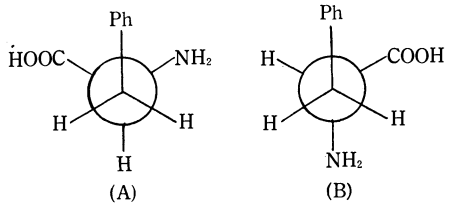
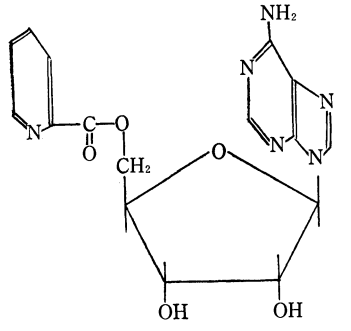
ments had little influence on the wavelength of the CD maximum in the 220 mμ region, though in the case of aliphatic amino acids dramatic changes have been reported.[9] These facts suggest that the CD maximum in the 220 mμ region for I and II is attributable to the aromatic chromophore rather than to the carboxyl chromophore. However, the 220 mμ CD maximum should be partly ascribed to the carboxyl $n\rightarrow\pi^*$ transition, because the superficial small pH dependence of the 220 mμ CD maximum observed in these two aromatic amino acids is presumably associated with the anomalous large contribution of the ^1L_a transition of the aromatic chromophore.

In fact, the molecular ellipticities [θ] at the 220 mμ CD maximum of I and II are about 20000—23000 and 11000—13000 respectively, though the aliphatic amino acids show the value of 3000—5000,[9] and the aromatic compounds without a carboxyl group, about 3000.[6] Therefore, it may be deduced that the 220 mμ CD maximum in aromatic amino acids should not be ascribed to the mere sum of the contributions of an aromatic chromophore and a carboxyl chromophore, but, rather, to the results of the interaction of the two chromophores.

Lucas[10] measured the UV spectra of the compounds with the general formulae of $C_6H_5(CH_2)_n$-$CH{:}CH_2$ and $C_6H_5(CH_2)_nCH(COOH)CH_2COOH$; he suggested the presence of the interaction of the two chromophores in the case of $n=1$. As in the case of I, there exists an aromatic chromophore interacted with a carboxyl group through an asymmetric carbon atom, it can be proved that I should show a [θ] value larger than the sum of the contributions of the two chromophores.

On the other hand, II contains a methylene group and an asymmetric carbon atom between carboxyl and phenyl chromophores, so it is difficult to explain the relatively large [θ] value at 220 mμ by Lucas's theory. Recently, Cavanaugh[11] mentioned that in light of the NMR measurements, the conformer, (A) or (B), in which the phenyl group





(C)

10) R. Lucas, *ibid.*, **1932**, 51, 289, 965.
11) J. R. Cavanaugh, *J. Amer. Chem. Soc.*, **90**, 4533 (1968).

is gauche to the carboxyl group is considerably predominant in the phenylalanine anion and in the dipolar ion. Urry[12] has also concluded that the large molecular ellipticity for adenosine-5′-mononicotinate (C) is caused by the reciprocal relation between the adenine and the nicotinic acid residue. In phenylalanine, it may be suggested that the benzene-ring plane can run nearly parallel to the carboxyl group, therefore, the $[\theta]$ value at 220 mμ becomes larger by means of interaction between the aromatic ^1L_a transition and the carboxyl $n\rightarrow\pi^*$ transition.

Figure 3 shows the ORD, CD, and UV spectra in the 260 mμ region for L-α-amino-β-benzalpropionic acid (III) and L-α-amino-β-benzylpropionic acid (IV) in 0.1N HCl. III reveals a multiple-humped positive CD maximum corresponding to the 250—265 mμ absorption maximum, and a weak Cotton effect in the ORD curve, these characteristics show that the ^1L_b transition of III is optically active. Although IV also shows the multiple-humped absorption band of the ^1L_b transition in 250—265 mμ, neither the CD maximum nor the anomalous dispersion curve are observed. The results imply that the ^1L_b transition is not optically active in the case of IV. From these facts, it is evident that the ^1L_b transition of the compounds with the $C_6H_5(CH_2)_nCH(NH_2)COOH$ formula is optically active in $n=0$ or $n=1$, but inactive in $n=2$.

The ORD, CD and UV spectra for III and IV in the 220 mμ region are shown in Fig. 4. The ORD and CD curves of III shows the CD maximum and an anomalous dispersion, these characteristic may be explained in a manner similar to that used for I. Although IV has a CD maximum at 207 mμ, it is not obvious that this CD maximum is to be attributed to either the ^1L_a transition of the aromatic chromophore or to the $n\rightarrow\pi^*$ transition of the carboxyl chromophore. The CD, ORD and UV spectra of L-2-amino-4-phenylbutanol-1 (V), which was synthesized from IV by the reduction of the carboxyl group, were measured in 0.1N HCl (Fig. 5).

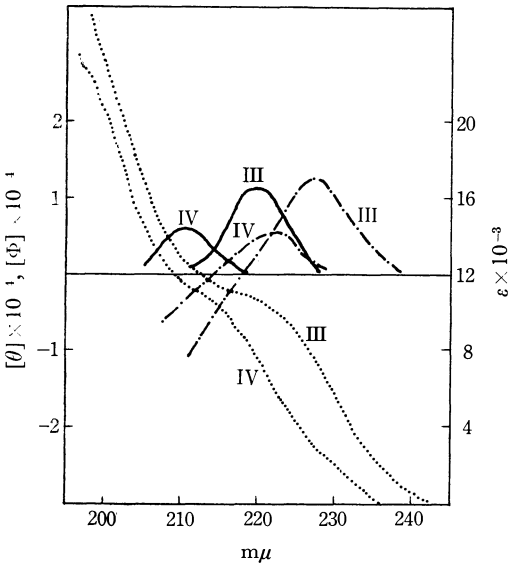

Fig. 4. CD (———), ORD (—·—) and UV (·····) spectra of L-α-amino-β-benzalpropionic acid (III) and L-α-amino-β-benzylpropionic acid (IV).

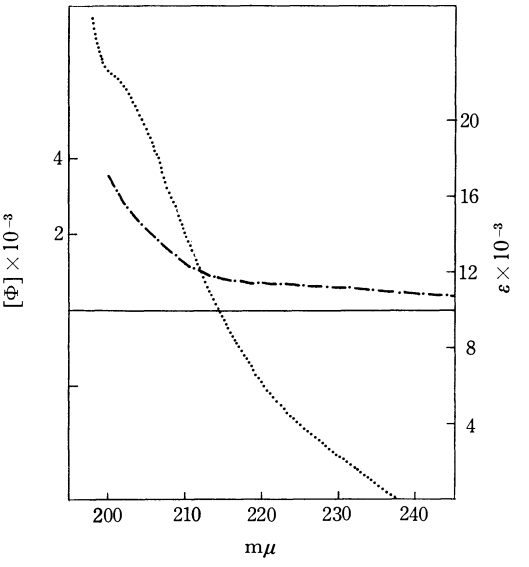

Fig. 5. ORD (—·—) and UV (·····) spectra of L-2-amino-4-phenylbutanol-1 (V) (in 0.1N HCl).

V had a large shoulder of ^1L_a transition in the 200—205 mμ region of the UV absorption spectrum, but no anomalous dispersion was observed. Therefore, it is evident that the ^1L_a transition of V is not optically active; this implies that the 207 mμ CD maximum of IV is to be attributed not to the ^1L_a transition of the benzene ring but to the carboxyl $n\rightarrow\pi^*$ transition.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1142—1147 (1970)

Syntheses and NMR Spectra of the Substituted Methylferrocenes

Masaru SATO, Michinao KOGA, Izumi MOTOYAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received September 8, 1969)

Several 1′- and 2-substituted 1-methylferrocenes were prepared, and their NMR spectra were measured. From the consideration of the chemical shifts, the transmission coefficient of the electronic effect through the ferrocene nucleus was calculated to be 0.28. 1′-Substituted 1-acetylferrocenes were also prepared, and their NMR spectra were discussed in connection with those of methylferrocenes.

Since the discovery of the fact that the unsubstituted ring of acetylferrocene was acetylated about 10^4 times slower than those of ferrocene itself,[1] the transmissivity of the electronic effect of substituents through the ferrocene system has been widely studied. For example, linear relationships have been observed between the Hammett σ constants and various reaction constants, such as the dissociation constants of various heteroannularly-substituted ferrocenecarboxylic acids,[2,3] the quarter-wave potentials in the chronopotentiometric oxidation of mono- and disubstituted ferrocenes,[4] the shifts of the carbonyl stretching frequencies in the IR spectra of substituted ferrocenecarboxylic acids and esters,[5] the rates of the esterification of heteroannularly-substituted ferrocenecarboxylic acids with diphenyldiazomethane,[6] the rates of the desilylation of 1′-alkyl-1-(trialkylsilyl)ferrocenes,[7] the rates of the protodemercuration of bis(1′-substituted ferrocenyl)mercury,[8] and the rates of the solvolysis of 1′-substituted ferrocenylmethylcarbinyl acetates.[9] However, the electronic effect of homoannular substituents has been little studied. Only a few investigations concerning the chemical shifts of the ring protons in monosubstituted ferrocenes[10] and *p*-substituted phenylferrocenes,[11] and the rates of the acetylation of alkylferrocenes[7] are available.

The chemical shifts of the benzene protons or the side-chain protons in the substituted benzene derivatives have been reported to correlate with Hammett σ constants. For example, the chemical shifts of the methyl groups in *p*-substituted toluenes have linear correlations with the σ^+ constants.[12] In the present study, the NMR spectra of 1′- and 2-substituted methylferrocenes and of 1′-substituted acetylferrocenes were measured in order to get some information about the transmission of the electronic effect through the ferrocene system. An improved method for preparing these compounds will be presented, together with a discussion of the NMR spectra.

Results and Discussion

Syntheses of 1′-Substituted Methylferrocenes. Since methylferrocene is more reactive toward electrophilic reagents than is ferrocene itself, it always affords a mixture of three isomers on acetylation, dimethylaminomethylation, and chloromercuration.[13] Because of the difficulty of separating the isomers each other, some indirect routes which lead selectively to 1′-isomers were devised in the following manner. When formyl-

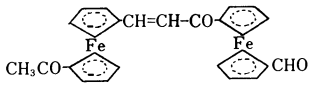
ferrocene was acetylated with three molar amounts of acetyl chloride and aluminum chloride in dichloromethane under cooling, only 1′-acetyl-1-formylferrocene was obtained in a 41% yield. Under somewhat severer conditions, two additional products were isolated. The minor product of the two, which was eluted ahead of 1′-acetyl-1-formylferrocene on chromatographic separation on alumina, seemed to be 3-acetyl-1-formylferrocene, judging from its IR and NMR spectra. The other (1.2% yield), which was eluted after 1′-acetyl-1-formylferrocene, was identified to be 1-(1′-formylferrocenyl)-3-(1″-acetylferrocenyl)-2-propen-1-one (**1**) on the basis of its IR and NMR spectra and



(**1**)

its elemental analysis. In view of the large coupling constant (15.7 Hz) of the vinyl protons of **1**, it can be concluded that **1** has a *trans* configuration with respect to the olefinic double bond. On the reduction of 1′-acetyl-1-formylferrocene by lithium aluminum hydride-aluminum chloride compelx,[14] 1′-ethyl-1-methylferrocene was obtained in a good yield.

We have reported in a previous paper[15] that when 1,1′-diiodoferrocene was treated with copper(I) cyanide in boiling pyridine, 1′-iodo-1-cyanoferrocene was exclusively obtained. This compound proved to be useful as a starting material for the preparation of 1′-substituted methylferrocenes. On the hydrolysis of 1′-iodo-1-cyanoferrocene in a boiling 40% aqueous potassium hydroxide solution for 15 hr, 1′-iodo-1-ferrocenecarboxylic acid was obtained in a 74% yield, whereas the reaction for 4 hr gave 1′-iodo-1-ferrocenecarboxamide as the main product (77% yield). This can be explained by assuming that the reaction may be suppressed by the electron-attracting effect of the iodo group, since 1′-ethyl-1-cyanoferrocene can be hydrolyzed within a shorter period to give, quantitatively, 1′-ethyl-1-ferrocenecarboxylic acid.[16] 1′-Iodo-1-ferrocenecarboxylic acid gave its methyl ester when treated with diazomethane in an ice bath. The reduction of the ester with lithium aluminum hydride and aluminum chloride afforded 1′-iodo-1-methylferrocene in a poor yield. Since no dehalogenated product was detected, this low yield seems to be due to the decomposition of the starting material by the action of the reducing agent. 1′-Iodo-1-methylferrocene was converted into 1′-cyano- and 1′-chloro-1-methylferrocene when treated with copper(I) cyanide and chloride respectively.[15]

Syntheses of 2-Substituted 1-Methylferrocenes. It has recently been reported that 2-haloferrocenylmethanol[17] could be obtained from 2-lithio-1-(dimethylaminomethyl)ferrocene.[18,19] This procedure has now been applied to the synthesis of 2-halo-1-methylferrocenes; 2-bromo- and 2-chloro-1-ferrocenylmethanol thus obtained were reduced with lithium aluminum hydride-aluminum chloride complex to give the corresponding 2-halo-1-methylferrocene in a moderate yield. When 2-chloro-1-methylferrocene was heated with copper(I) cyanide in γ-picoline at 145°C, 2-cyano-1-methylferrocene was obtained in a 22% yield. On the other hand, 2-ethyl-1-methylferrocene was obtained in a good yield on the Clemmensen reduction of 2-acetyl-1-methylferrocene.[20]

NMR Spectra. The NMR spectra of 2- and 1′-substituted methylferrocenes thus obtained were measured as about a 20% solution in carbon tetrachloride, while those of 1′-substituted acetylferrocenes were measured in deuteriochloroform.

	$COCH_3$	134.3	17.1

The chemical shifts of these methyl and acetyl protons are summarized in Tables 1, 2, and 3.

In order to examine the substituent effects, the relative chemical shifts ($\Delta\delta$) of the protons in each series were plotted *versus* the Hammett σ_p constants. These results are shown in Fig. 1 for 1′-substituted acetylferrocenes and in Fig. 2 for 1′- and 2-substituted methylferrocenes. It is clear from Fig. 1 that an excellent linear correlation is present between the Hammett σ_p constants and the chemical shifts of the acetyl protons of 1′-substituted 1-acetylferrocenes and acetylferrocene itself, except for those of 1′-acetyl- and 1′-methoxycarbonyl-1-acetylferrocene. An irregularity observed in the compounds containing an extra carbonyl substituent is considered to be due to the large magnetic anisotropy of the carbonyl group.[21] Therefore, the substituent effects will be discussed on the basis of the shifts observed with substituents other than the carbonyl-containing substituent. The same limitation was applied in the consideration of the chemical-shift differences between 1′- and 2-substituted methylferrocenes, and good correlations were observed between the chemical shifts of the methyl protons and the

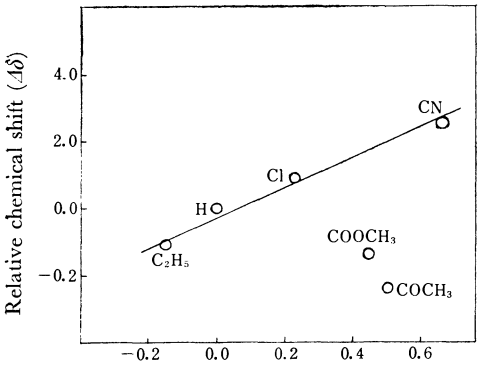

Fig. 1. Plot of the relative chemical shifts of 1′-substituted 1-acetylferrocenes against Hammett σ_p constant.

21) M. I. Levenberg and J. H. Richards, *J. Amer. Chem. Soc.*, **86**, 2634 (1964).

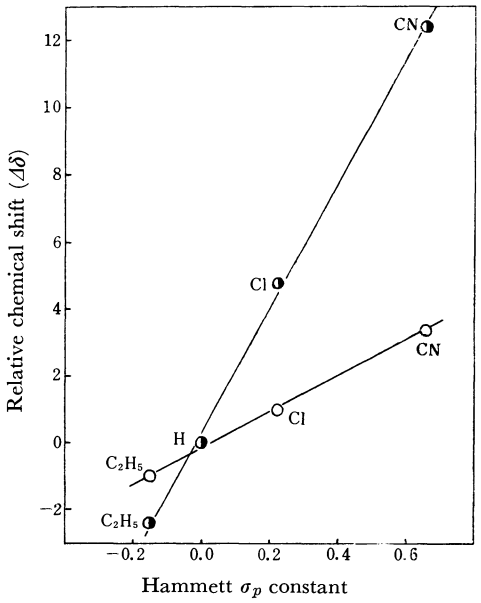

Fig. 2. Plot of the relative chemical shifts of substituted methylferrocenes against Hammett σ_p constant: ◑, 2-derivatives; ○, 1′-derivatives.

Hammett σ_p constants in either series. The following equations are those of the regression lines, shown in Figs. 1 and 2, which were calculated by the method of least squares:

$$\Delta\delta = 4.4\,\sigma_p + 0.1$$

for 1′-substituted 1-acetylferrocenes,

$$\Delta\delta = 5.2\,\sigma_p - 0.2$$

for 1′-substituted 1-methylferrocenes, and

$$\Delta\delta = 18.3\,\sigma_p + 0.3$$

for 2-substituted 1-methylferrocenes.

It is quite interesting that an excellent linear relationship, one with a correlation coefficient more than the 0.99 for the methylferrocene series, was found between the chemical shifts in the acetylferrocenes or methylferrocenes and the Hammett σ_p constants, while good correlations were not found with the other σ constants, such as σ_m, σ^+, and σ^*. In accordance with these observations, there have been reported many findings that various chemical behaviors of ferrocene derivatives correlated with Hammtt σ_p constants.[2-9]

As may be seen in Fig. 2, the chemical shifts of methyl protons in 2-substituted 1-methylferrocenes were found to correlate with Hammett σ_p constants, while no linear correlation was found with the σ^+ constants. A similar tendency had already been reported for those of the cyclopentadienyl ring protons in *p*-substituted phenylferrocenes, but without any detailed discussion.[11] On the other hand, it has been found that the chemical shifts of methyl protons in *p*-substituted toluenes and acetyl protons in *p*-substituted acetophenones correlated linearly

with the σ^+ constants.[12] The difference between the observations of ferrocene derivatives and of benzene derivatives suggests that the transmission of an electronic effect in 2-substituted methylferrocene might be through some way different from such a resonance effect of the substituent as was seen in benzene derivatives. The transmission of an electronic effect in ferrocene derivatives is probably through the total electron density of the ferrocene nucleus, without the loss of its stability due to the aromaticity.

It is clear from Fig. 2 that the regression lines for 1′- and 2-substituted methylferrocenes have different slopes. These differences can undoubtedly be attributed to the differences in the transmissivity of the electronic effect of the substituent. Hence, the ratio of these slopes, 0.28, may be considered to be the transmission coefficient of the electrnoic effect through the ferrocene nucleus. A similar value (0.22) was reported by Butter and Beachell,[22] who calculated it on the basis of the data reported by Nagai *et al.*[23] On the other hand, a transmission coefficient through a benzene ring was reported to be 0.37;[24] this was calculated on the basis of the dissociation constants of substituted 4-biphenylcarboxylic acids. In view of the intervention of an iron atom in the transmission of the electronic effect through the ferrocene ring, a smaller value is to be expected for the transmission coefficient through the ferrocene nucleus than for that through the benzene ring. Therefore, the value (0.28) obtained in this investigation seems reasonable.

Experimental

1′-Iodo-1-ferrocenecarboxylic Acid. 1′-Iodo-1-cyanoferrocene (1.12 g), which had been prepared from 1,1′-diiodoferrocene by a procedure reported previously,[15] was refluxed for 15 hr with 7.5 m*l* of a 40% aqueous potassium hydroxide solution and 16 m*l* of ethanol. The dark reaction mixture was then filtered out. The filtrate was acidified with dilute hydrochloric acid and extracted with ether, and then the ethereal solution was dried over anhydrous magnesium sulfate. The evaporation of the solvent gave red-orange crystals of 1′-iodo-1-ferrocenecarboxylic acid in a 73.7% yield; the acid was then recrystallized from benzene, mp 138.5°C (decomp.).

Found: C, 37.43; H, 2.42%. Calcd for $C_{11}H_9IFe$: C, 37.08; H, 2.52%.

The dark orange solid remaining after the filtration of the reaction mixture was dissolved in chloroform. After the insoluble matters had been filtered off, the filtrate was washed with water and dried over anhydrous magnesium sulfate. By evaporating the solvent, orange crystals of 1′-iodo-1-ferrocenecarboxamide were obtained (0.21 g, 18.7% yield); these were recrystallized from *n*-hexane, mp 136—137.5°C.

Found: C, 37.76; H, 3.17; N, 4.11%. Calcd for $C_{11}H_{10}ONIFe$: C, 37.18; H, 2.82; N, 3.94%.

When the same reaction was stopped after 4 hrs' heating, the main product was the amide (77.1% yield), while the minor product was the acid (14.6%). No recovery of unchanged nitrile was observed in either reaction.

Methyl 1′-Iodo-1-ferrocenecarboxylate. A solution of 1′-iodo-1-ferrocenecarboxylic acid (1.27 g) in 20 m*l* of ether was added, drop by drop, with vigorous stirring into an ethereal solution of diazomethane prepared from 1.0 g of nitrosomethylurea. After the addition of the acid had been completed, stirring was continued further an additional hour. After the solvent had been removed under reduced pressure, the residue was dissolved again in ether. The solution was washed successively with an aqueous sodium hydroxide solution and with water, and then dried. After the removal of the solvent, the residue was chromatographed on alumina to give methyl 1′-iodo-1-ferrocenecarboxylate in a 75.8% yield; the ester was recrystallized from *n*-hexnae, mp 71—72.5°C.

Found: C, 39.19; H, 3.03%. Calcd for $C_{12}H_{11}O_2$-IFe: C, 38.92; H, 3.00%.

From the sodium hydroxide solution, 0.30 g (23.6%) of the starting material was recovered.

1′-Iodo-1-methylferrocene. Methyl 1′-iodo-1-ferrocenecarboxylate (1.2 g, 3.2 mmol) was added, little by little, to a suspension of 0.25 g (6.5 mmol) of lithium aluminum hydride in 20 m*l* of dry ether, and then a solution of 0.47 g (3.5 mmol) of aluminum chloride in 15 m*l* of dry ether was added, drop by drop, to the reaction mixture under a nitrogen atmosphere and in an ice-water bath. After stirred for 15 min, the mixture was poured into cold water and the aqueous layer was extracted with ether. The combined ethereal solution was washed with dilute hydrochloric acid and dried over anhydrous magnesium sulfate. After the removal of the solvent, the residue was chromatographed on alumina to give an orange liquid which was then distilled under reduced pressure, bp 102—104°C/0.2 mmHg. The yield of 1′-iodo-1-methylferrocene was 0.49 g (18.8%).

Found: C, 40.62; H, 3.65%. Calcd for $C_{11}H_{11}IFe$: C, 40.49; H, 3.37%.

1′-Chloro-1-methylferrocene. 1′-Iodo-1-methylferrocene (0.2 g, 0.6 mmol) and copper(I) chloride (0.12 g, 1.2 mmol) were refluxed in 2 m*l* of pyridine for 2 hr. After the reaction had been completed, a small amount of pyridine was added; then the reaction mixture was cooled. The cooled mixture was diluted with ether and filtered. The residue was then washed with ether. The combined ethereal solution was washed several times with dilute hydrochloric acid, and finally with water; it was then dried over anhydrous magnesium sulfate. After the removal of the solvent, the residue was purified by chromatography on alumina with *n*-hexane to give 0.07 g (51% yield) of 1′-chloro-1-methylferrocene, which was recrystallized from methanol, mp 47.5—48.5°C.

Found: C, 56.54; H, 5.11%. Calcd for $C_{11}H_{11}ClFe$: C, 56.38; H, 4.69%.

1′-Cyano-1-methylferrocene. After a mixture of 0.129 g (0.4 mmol) of 1′-iodo-1-methylferrocene, 0.180 g

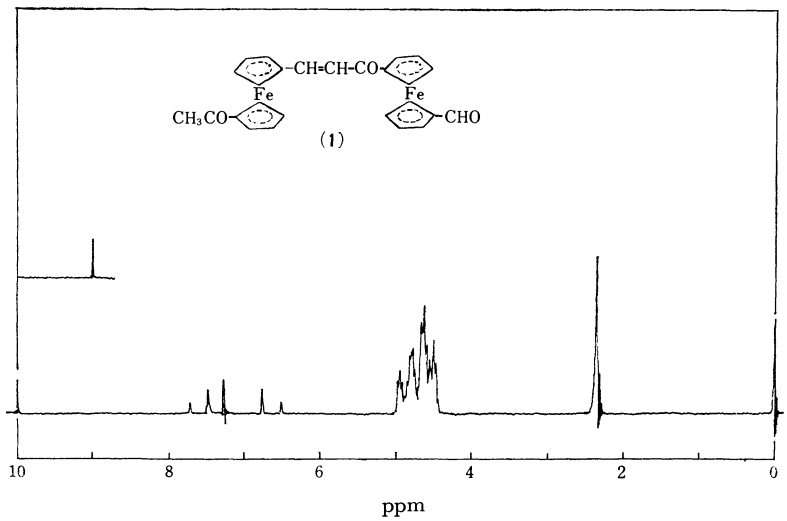

Fig. 4. NMR spectrum of compound **1** (in $CDCl_3$).

(2 mmol) of copper(I) cyanide, and 1 m*l* of pyridine had been heated at 120°C for 2.5 hr in a sealed tube, the mixture was treated in the manner described above to give 0.041 g (52% yield) of 1′-cyano-1-methylferrocene, mp 72.5—73.5°C (lit,[25] mp 72—73°C).

1′-Acetyl-1-formylferrocene. A solution of the complex, which had been prepared in advance from 2.2 m*l* (0.03 mol) of acetyl chloride and 4.0 g (0.03 mol) of anhydrous aluminum chloride in 20 m*l* of dichloromethane, was added to a solution of 2.2 g (0.01 mol) of formylferrocene in 50 m*l* of dichloromethane over a period of 15 min in an ice bath and with stirring under a nitrogen atmosphere. In order to keep the reaction out of the light, the flask was covered with aluminum foil during the reaction. After being stirred for 4 hr in the ice bath, the reaction mixture was hydrolyzed by ice and water containing tin(II) chloride as a reducing agent. The aqueous layer was extracted with dichloromethane, and then the combined dichloromethane solution was washed with water and dried over anhydrous magnesium sulfate. After the removal of the solvent under reduced pressure, the residue was chromatographed on alumina which had previously been deactivated by exposure to the air for 0.5 hr. The chromatography gave 0.62 g (28.2% recovery) of formylferrocene from the first fraction, eluted by ether-*n*-hexane (1 : 1), and then 1.08 g (41.1% yield) of 1′-acetyl-1-formylferrocene from the second fraction, eluted by ether. The product was recrystallized from *n*-hexane-ether, mp 94—95°C (lit,[26] mp 90—93°C).

When the same reaction was carried out initially in

an ice bath for 1 hr, and subsequently at room temperature for 3 hr, the chromatographic separation of the product gave different results. After the recovery of the starting material (40.4%), the second fraction with *n*-hexane–ether (1 : 1) gave a trace of orange crystals. This compound was identified to be 3-acetyl-1-formyl ferrocene, mp 106—107.5°C, by a study of its IR and NMR spectra. The NMR spectrum is shown in Fig. 3.

Found: C, 60.70; H, 4.69%. Calcd for $C_{13}H_{12}O_2Fe$: C, 60.94; H, 4.69%.

From the third fraction, which was eluted with ether, 1′-acetyl-1-formylferrocene was obtained in a 33% yield. Further elution with ether gave a fourth fraction consisting of reddish-violet crystals (1.2% yield), which were then recrystallized from benzene–dichloromethane, mp 163°C (decomp.). This compound was identified to be 1-(1′-formylferrocenyl)-3-(1″-acetylferrocenyl)-2-propen-1-one (**1**) by means of its IR and NMR spectra. The NMR spectrum is shown in Fig. 4.

Found: C, 63.26; H, 4.43%. Calcd for $C_{26}H_{22}O_3Fe$: C, 63.16; H, 4.45%.

1′-Ethyl-1-methylferrocene. A solution of 1′-acetyl-1-formylferrocene (190 mg, 0.75 mmol) in 10 m*l* of dry ether was added, drop by drop, to a solution of lithium aluminum hydride (280 mg, 7.4 mmol) and aluminum chloride (1.0 g, 7.5 mmol) in 10 m*l* of dry ether in an ice bath and under an atmosphere of nitrogen. After being stirred for 0.5 hr, the mixture was poured into cold water. Then the ethereal layer was separated, and the aqueous layer was extracted with ether. The combined ethereal solution was then washed with dilute hydrochloric acid and dried over anhydrous magnesium sulfate. After the removal of the solvent, the residue was chromatographed on alumina to give an orange liquid; the liquid was then distilled under reduced pressure, bp 75—77°C/0.21 mmHg. The yield of 1′-ethyl-1-methylferrocene was quantitative.

Found: C, 68.87; H, 6.92%. Calcd for $C_{13}H_{16}Fe$: C, 68.44; H, 7.08%.

2-Chloro-1-methylferrocene. 2-Chloro-1-ferrocenylmethanol (1.45 g, 6 mmol), prepared by Marr's method,[17] was treated for half an hour with a solution of a complex composed of 0.46 g (12 mmol) of lithium aluminum hydride and 0.80 g (6 mmol) of aluminum chloride in 40 m*l* of dry ether under a nitrogen atmosphere. The chromatographic purification of the crude product thus obtained gave 0.94 g (69% yield) of 2-chloro-1-methylferrocene, which was recrystallized from methanol, mp 55.2—56.0°C.

Found: C, 56.68; H, 4.80%. Calcd for $C_{11}H_{11}ClFe$: C, 56.38; H, 4.69%.

2-Bromo-1-methylferrocene. Similarly, 1.01 g (3.4 mmol) of 2-bromo-1-ferrocenylmethanol[17] was converted into 0.57 g (59.7% yield) of 2-bromo-1-methylferrocene, which was then recrystallized from methanol, mp 64—65°C.

Found: C, 47.31; H, 3.94%. Calcd for $C_{11}H_{11}BrFe$: C, 47.45; H, 4.19%.

2-Cyano-1-methylferrocene. 2-Chloro-1-methylferrocene (0.47 g, 2 mmol) was refluxed with 1.8 g (0.02 mol) of copper(I) cyanide for 4 hr in the presence of 1 m*l* of γ-picoline. After the reaction mixture had been treated as has been described for the preparation of 1′-cyano-1-methylferrocene, 0.10 g (22.2% yield) of 2-cyano-1-methylferrocene was obtained and subsequently recrystallized from *n*-hexane, mp 49—50.0°C (lit,[25] mp 51—52°C).

2-Ethyl-1-methylferrocene. A solution of 0.145 g (0.6 mmol) of 2-acetyl-1-methylferrocene in 2 m*l* of acetic acid and 2 m*l* of concentrated hydrochloric acid was added, drop by drop, to amalgamated zinc dust, after which the mixture was refluxed for 5 min. After cooling, the reaction mixture was filtered and the residual zinc dust was thoroughly washed with ether. The filtrate, diluted with water, was also extracted with ether. The combined ethereal solution was washed with a dilute aqueous sodium hydroxide solution and then with water, and subsequently dried over anhydrous magnesium sulfate. After the removal of the solvent, the residue was chromatographed on alumina to give 2-ethyl-1-methylferrocene in an 87% yield as a yellow liquid, bp 68—69°C/0.16 mmHg (lit,[27] bp 70—80°C/0.02 mmHg).

NMR Spectra. The NMR spectra were measured on a Varian Associates A-60 NMR spectrometer.

Reaction of Olefin-Palladium(II) Chloride Complexes with *n*-Butylamine

Hidefumi HIRAI, Hiroaki SAWAI and Shoji MAKISHIMA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo

(Received September 12, 1969)

Olefin-palladium(II) chloride complexes reacted with *n*-butylamine to form Schiff's bases. *N*-Ethylidene-*n*-butylamine was obtained by the reaction of the ethylene complex with *n*-butylamine, accompanied by reduction of palladium(II) to the metal. A tris(*n*-butylamine)palladium chloride complex was formed simultaneously by ligand substitution reaction. The yield of *N*-ethylidene-*n*-butylamine was 15—19 mol% (calcd on palladium) in 2.5 hr at 25°C, and decreased at temperatures higher than 60°C with increasing reduction of palladium(II), owing to conversion of *N*-ethylidene-*n*-butylamine into either *N*-crotylidene-*n*-butylamine or a tarry polymeric substance by aldol type condensation reaction. The *n*-butylamine-palladium(II) chloride complex did not react with ethylene at 25°C, but reacted with ethylene at 150°C to form a large amount of tarry polymer and a small amounts of *N*-ethylidene-*n*-butylamine and *N*-crotylidene-*n*-butylamine. The propylene complex and the cyclohexene complex reacted with *n*-butylamine to yield both 2- and 1-*N*-propylidene-*n*-butylamine, and *N*-cyclohexylidene-*n*-butylamine respectively. The yield of Schiff's bases from olefin complex decreased in the order, ethylene$>$propylene$\gg$cyclohexene.

The reaction of olefin-palladium(II) chloride complexes with nucleophilic reagents have been studied by many workers[1,2] in recent years. Aldehydes,[3] ketones,[3] vinyl ethers[4,5] and vinyl acetates[4,5] were sythesized by the reaction of the olefin complex, or by the reaction of olefin in the presence of palladium(II) salt as catalyst, with nucleophilic reagents such as water, alcohols and acetic acid. These reagents containing nucleophilic oxygen atoms attack on a positively charged carbon atom of the olefin to give the product containing a C–O bond. Olefin-palladium(II) complexes were also reported to react with benzene,[6] cyanide,[7] ethylmalonate[8] and carbon monoxide[9] to yield styrene derivatives, unsaturated nitriles, malonate derivatives and carbonyl compounds, respectively. In these cases the nucleophiles attack with their negatively charged carbon atoms to form C–C bond.

Reaction of olefin-palladium(II) complexes with nucleophiles containing nitrogen, however, has been very scantily reported. Stern and Spector reported briefly the formation of *n*-butylisopropylamine by the reaction of propylene and palladium chloride with *n*-butylamine in the presence of disodium hydrogen phosphate with subsquent hydrogenation.[5] There has been, however, very little information on the reaction of olefin complexes with the compounds containing nitrogen on account of the complicatedness of the reaction. The nucleophilic reagents containing nitrogen such as amines and amides make stable complexes with metal satls. This is a great difference from the case of the reagents containing oxygen such as water or alcohols. Further, both the nucleophiles and the reaction products would form the stable complexes with palladium chloride, which prevent the occurrence of the expected reaction making the analysis of the products complicated. On the other hand, these complex formations can be expected, in view of coordination chemistry, to be useful for elucidation of the mechanism of the reaction where palladium(II) complexes play an important role. Paiaro, Renzi and Polumbo reported the reaction of diene-palladium(II) chloride complex with primary amines, in which a new amine-palladium(II) complex containing a Pd–C bond was formed quantitavely at room temperature.[10] Independently,

we have found the formation of Schiff's bases on the reaction of olefin-palladium(II) chloride complexes with *n*-butylamine.[11] In the present paper, the formation of the Schiff's bases will be described under various temperature, pressure and amount of *n*-butylamine. The reaction mechanism will be discussed on the basis of the results.

Results and Discussion

Reaction of Ethylene-Palladium(II) Chloride Complex with *n*-Butylamine. Ethylene-palladium(II) chloride complex reacted with *n*-butylamine at 25°C for 2.5 hr under 5 atm of ethylene pressure. *N*-Ethylidene-*n*-butylamine (**1**) was obtained in 16 mol% yield based on palladium(II) chloride, accompanying the formation of palladium metal. The reddish brown solution of reaction mixture turned white-yellow forming tris(*n*-butylamine)palladium(II) chloride complex (**2**), the structure of which was confirmed by elemental analysis. These facts indicate two types of reaction, a Schiff's base formation and a ligand substitution.

$$\tfrac{1}{2}\,[PdCl_2(C_2H_4)]_2 + n\text{-}C_4H_9NH_2 \rightarrow \underset{\mathbf{1}}{CH_3CH{=}NC_4H_9} + Pd + 2HCl \quad (1)$$

$$\tfrac{1}{2}\,[PdCl_2(C_2H_4)]_2 + 3\ n\text{-}C_4H_9NH_2 \rightarrow [PdCl(n\text{-}C_4H_9NH_2)_3]Cl + C_2H_4 \quad (2)$$

Hydrochloric acid formed by reaction(1) was mostly caught by an excess of *n*-butylamine as *n*-butylamine hydrochloride.

The effect of the reaction temperature on the yield of the reaction products is shown in Table 1. Compound **1** was obtained at 25°C in a yield nearly equal to that of palladium metal. The formation of the palladium metal increased at temperatures higher than 60°C, and palladium(II) was reduced almost completely to metal at 150°C. The yield of **1**, however, decreased with increasing temperature and only a trace amount was obtained at 150°C, while *N*-crotylidene-*n*-butylamine (**3**) and a tarry reddish substance were obtained in fairly good yields. The infrared spectrum of the tarry substance was essentially the same as that of the tarry substance which was prepared by heating **1**. The molar amount of **2** decreased with the elevation of temperature and was in good agreement with the moles of palladium(II) which was not reduced.

Formation of amine complex by ligand substitution seems to be favored, and a *n*-butylamine-palladium(II) chloride complex was too stable to react with ethylene at room temperature. Thus, the extent of the Schiff's base formation (1) at 25°C was not very high. Formation of **3** and tarry substance at elevated temperature can be explained by the reaction.

Table 1. Effect of temperature on the reaction of ethylene-palladium(II) chloride complex with *n*-butylamine

Temp. °C	Yield mol%				Tarry substance[b] mg
	CH_3-CH=NBu	CH_3CH=CHCH=NBu	Pd (metal)	[PdCl(*n*-BuNH$_2$)$_3$]Cl	
25	16	0	14	86	0
65	16	4	19	81	trace
85	13	5	35		
100	15	15	59	44	190
150	1	42	99	0	510

a) Molar conversion based on palladium chloride.
b) Crude substance.
Conditions: Initial pressure of ethylene, 5 atm; Reaction time, 2.5 hr; Palladium chloride, 0.005 mol; *n*-Butylamine, 0.02 mol.

$$\underset{\mathbf{1}}{CH_3CH{=}NC_4H_9} \xrightarrow{\Delta} \underset{\mathbf{3}}{CH_3CH{=}CHCH{=}NC_4H_9} \xrightarrow{\Delta} CH_3CH(=CH\text{-}CH)_n{=}NC_4H_9$$

Elevation of temperature promoted not only the formation of **1** by reaction (1), but also the conversion of **1** either into **3** or into tarry substance through aldol type condensation reaction. Aliphatic Schiff's bases containing α-methylene group have been reported to undergo aldol type condensation easily at elevated temperature.[12] The formation of palladium metal indicates the extent of the Schiff's base formation reaction (1). Thus, the difference between the yield of palladium metal and that of **1** means the extent of the aldol type condensation. The condensation reaction was not observed at 25°C in 2.5 hr. However, it increased with elevating temperature becoming predominant at 150°C.

Table 2 shows the effect of molar ratio of *n*-butylamine to palladium(II) chloride on the yield of **1** and on the species of *n*-butylamine-palladium(II) chloride complex. The yield of **1** determined by g.l.p.c. increased with the molar ratio and saturated at a ratio of four. In the range of ratios smaller than four, the yield of **1** increased by addition of pyridine to the mixture of reaction products, bacause a part of **1** which had formed a complex with palladium(II) could be made free by pyridine.

The composition of *n*-butylamine-palladium(II) complex changed with the amount of *n*-butylamine as shown in Table 2. Bis(*n*-butylamine)palladium(II) chloride (**4**) was produced at the molar ratio of two, while the complex **2** was obtained at that of more than four. The formation of **2** and **4**

d) Yield of CH$_3$CH=NBu analyzed by gaschromatography on reaction mixture after addition of pyridine.
Conditions: Initial pressure of ethylene, 5 atm; Reaction time, 2.5 hr; Reaction temperature, 25°C; Palladium chloride, 0.005 mol.

respectively is nearly equal to the remaining amount of palladium(II). At the molar ratio of one, *n*-butylammonium tetrachloropalladate(II) (**5**) was obtained in a yield approximately equal to that of **1**. Palladium(II) chloride reacted with both *n*-butylamine and hydrochloric acid to form **5**.

The ethylene-palladium(II) chloride complex was prepared either by the reaction of palladium(II) chloride with ethylene under 50 atm in 6 hr, or by the reaction of bis(benzonitrile)palladium(II) chloride complex with ethylene under 10 atm in 1 hr. These two methods were approximately equal in yields of **1** on reaction with *n*-butylamine at 25°C under 5 atm of ethylene pressure. Table 3 shows

TABLE 3. EFFECT OF PESSURE OF ETHYLENE ON THE YIELD OF *N*-ETHYLIDENE-*n*-BUTYLAMINE

Pressure atm[a]	Time[a] hr	Reaction pressure[b] atm	Yield mol%
50	6	1	15
50	6	5	16
50	6	10	18
50	6	25	19
50	6	50	19
10	1	1	4
10	2	25	10
10	1	5	16[c]

a) Pressure of ethylene and reaction time for preparation of the ethylene complex from palladium chloride with ethylene.
b) Pressure of ethylene for the reaction of ethylene complex with *n*-butylamine.
c) Bis(benzonitrile) palladium chloride complex was used instead of palladium chloride.
Conditions: Temperature, 25°C; Reaction time, 2.5 hr; Palladium chloride, 0.005 mol; *n*-Butylamine, 0.02 mol.

that the ethylene complex was prepared completely from palladium(II) chloride in 6 hr under 50 atm, but incompletely in 1 hr under 10 atm. The yield of **1** increased with increasing pressure of ethylene on reaction with *n*-butylamine up to 50 atm as shown in Table 3. The promotion of the yield of **1** can be explained by assuming that the pressure of ethylene not only promoted the coordination of ethylene but also suppressed the ligand substitution reaction resulting in a small acceleration of Schiff's base formation.

Reaction of Tris(*n*-butylamine)palladium-(II) Chloride Complex with Ethylene. *n*-Butylamine-palladium(II) chloride complex **2** was very stable and did not react with ethylene at room temperature. This complex, however, was found to react easily with ethylene at a higher temperature; for example, 95% of palladium (II) in the complex was reduced to the metal at 150°C, yielding **1**, **3** and tarry polymeric substance, as shown in Table 4. These products were consistent with those obtained by the reaction of the ethylene-palladium(II) chloride complex with *n*-butylamine.

TABLE 4. REACTION OF TRIS (*n*- BUTYLAMINE)-PALLADIUM CHLORIDE COMPLEX WITH ETHYLENE

Reaction of Other Olefin-Palladium(II) Chloride Complexes with *n*-Butylamine. The reaction of propylene-palladium(II) chloride complex with *n*-butylamine gave 2- and 1-*N*-propylidene-*n*-butylamine as shown in Table 5. The yield of 2- and 1-*N*-propylidene-*n*-butylamine were in the ratio of the yield of 6 : 1 approximately, which is in fair agreement with the ratio of the yield of acetone to that of propionaldehyde obtained by reaction of palladium(II) chloride with propylene and water.[3]

$$\tfrac{1}{2}\,[PdCl_2(C_3H_6)]_2 + n\text{-}C_4H_9NH_2$$

$$\swarrow \qquad \searrow$$

$CH_3CH_2CH{=}NC_4H_9$ (1-*N*-proylidene-*n*-butylamine) $\qquad$ $(CH_3)_2C{=}NC_4H_9$ (2-*N*-propylidene-*n*-butylamine)

Cyclohexene-palladium(II) chloride complex yielded a small amount of *N*-cyclohexylidene-*n*-butylamine. Schiff's base formation proceeded to remarkably smaller extent in the case of higher

olefins than in that of ethylene. This tendency is greater than that of aldehydes or ketones obtained by the reaction of palladium(II) chloride with higher olefins and water.[3]

Table 5. Reaction of olefin - palladium(II) chloride complexes with *n*-butylamine at 25°C

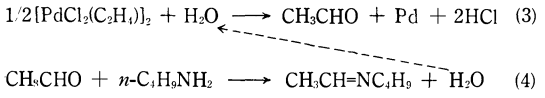
			$(CH_3)_2C{=}NBu$	7.6
C_6H_{10}	5	5		trace[b]

[a] Pressure, 5 atm.
[b] Less than 1 mol%.

Effect of Small Amount of Water on the Reaction. Schiff's bases are usually obtained from aldehydes and primary amines. Acetaldehyde can be formed from ethylene-palladium(II) chloride complex with water,[3] which remains in a very small amount in the reaction system in spite of careful treatment to prevent contamination with water. Consequently, **1** could be formed by reaction of the acetaldehyde with *n*-butylamine as follows.



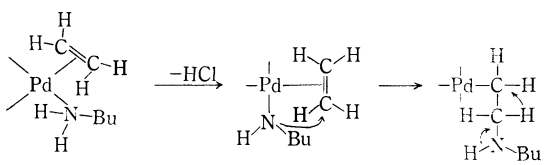
$$1/2[PdCl_2(C_2H_4)]_2 + H_2O \longrightarrow CH_3CHO + Pd + 2HCl \quad (3)$$

$$CH_3CHO + n\text{-}C_4H_9NH_2 \longrightarrow CH_3CH{=}NC_4H_9 + H_2O \quad (4)$$

For examination of this possibility, the formation of acetaldehyde was determined by g.l.p.c. before addition of *n*-butylamine. The result shows that the amount of acetaldehyde is less than 0.8 mol% based on palladium(II) chloride. If **1** were formed by reactions (3) and (4), water should be used twenty times repeatedly to obtain **1** in 16 mol% yield at 25°C, and the yield of **1** could be expected to increase on addition of a small amount of water with *n*-butylamine. The yield, however, decreased from 16 mol% to 9 mol% by the use of *n*-butylamine which contained water in equimolar amount to palladium(II) chloride, instead of dried *n*-butylamine. The fact that the added water played a role of inhibitor indicates that the most of **1** was not formed by reactions (3) and (4), but formed by the direct reaction of *n*-butylamine with ethylene complex. This is consistent with the fact that the ethylene-palladium(II) chloride complex yields *N*-vinylpyrrolidone on reaction with pyrrolidone, which attacks coordinated ethylene with its >NH group to form C–N bond.[13,14] Pyrrolidone cannot react with acetaldehyde under such mild conditions as used in this study.

Reaction Mechanism. The reaction mechanism of direct attack of *n*-butylamine on ethylene-palladium(II) chloride complex will be discussed. The ethylene-palladium(II) chloride complex with equimolar *n*-butylamine was a homogeneous solution under ethylene pressure, and evolved a gas of ethylene with precipitation of complex **5** on standing for several minutes under ordinary pressure of air. Addition of methanol to the homogeneous solution produced palladium metal and methyl vinyl ether. The results indicate the presence of some ethylene-palladium(II) complex in the homogeneous solution. On the other hand, an amine has a stronger coordinating affinity to palladium(II) than ethylene. It is reasonable to suppose that both *n*-butylamine and ethylene coordinate palladium (II) under ethylene pressure to form a complex such as $PdCl_2$(olefin)(amine), which is so unstable as to evolve ethylene under ordinary pressure of air. A platinum complex such as $PtCl_2$(olefin)-(amine) is well known,[15] while a corresponding palladium(II) has never been isolated. The fact that the *n*-butylamine-palladium(II) complex can react with ethylene to give **1** at 150°C indicates the coordination of ethylene to *n*-butylamine-palladium-(II) complex. The complex coordinating both ethylene and *n*-butylamine can be considered to be a reaction intermediate of Schiff's base formation. That the formation of this intermediate is essential for the reaction has been supported also by the results of the allylamine-palladium(II) chloride complexes in dry tetrahydrofuran.[16] The 1 : 1 allylamine-palladium(II) complex which can coordinate olefinic double bond besides amino group could react at 50°C to form palladium metal and Schiff's base, while the 3 : 1 allylamine-palladium-(II) chloride complex, which coordinates only amino group, could not.

The following reaction scheme can be proposed



$\xrightarrow{-HCl}$ $CH_3CH{=}NBu + Pd$

1

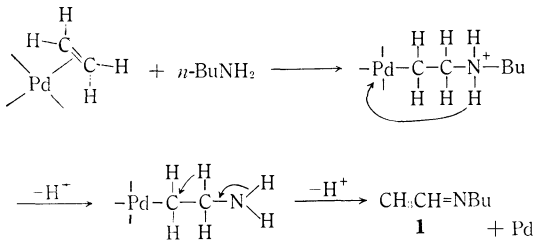
involving an ethylene-*n*-butylamine-palladium(II) complex as the intermediate. The proton of coordinated *n*-butylamine would be withdrawn by palladium(II) to form amido-palladium(II) complex. Then the coordinated ethylene would enter the Pd–N bond to form Schiff's base **1**. The withdrawal of proton of coordinated amine has been proposed by Tsuji and Iwamoto for the carbonylation reaction of amine catalyzed by palladium(II) chloride.[17]

The following reaction scheme can be also considered.



In this case uncoordinated *n*-butylamine attacks coordinated ethylene to form an intermediate complex which is an alkyl palladium derivative containing a quaternary ammonium group. Palladium(II) withdraws two protons from the ammonium group to form Schiff's base. The metal alkyl derivative containing a quaternary ammonium group was isolated in the case of platinum complex prepared from dichloro(olefin)(*t*-phosphine)platinum complex with amine.[18]

The facts that amines have strong coordinating affinity to palladium(II) chloride, and that *n*-butylamine-palladium(II) chloride complex reacts with ethylene at 150°C, suggest that the former scheme is preferable. In either scheme, the elevation of reaction temperature is expected to make the *n*-butylamine complex so labile that the coordination of ethylene becomes possible, and to promote both the withdrawal of proton of *n*-butylamine and the formation of Schiff's base **1** with the subsequent aldol type condensation. These tendencies are supported by the fact that total yield of Schiff's base including the products of condensation increased extensively at higher temperatures and that *n*-butylamine-palladium(II) chloride complex which could not react with ethylene at room temperature reacted at 150°C in a high yield.

Experimental

Materials. Bis(benzonitrile)palladium chloride complex was prepared as described by Kharasch.[19] Ethylene and propylene were from Nihon Petrochemical Co. and used without further purification. Cyclohexene and *n*-butylamine were obtained commercially, dried over calcium hydride and distilled. Tetrahydrofuran used as solvent was dried over calcium hydride and distilled over sodium immediately before use.

Reaction of Ethylene-Palladium(II) Chloride Complex with *n*-Butylamine. Palladium chloride (0.9 g, 0.005 mol) and tetrahydrofuran (20 m*l*) were put into in a magnetically stirred 100 m*l* autoclave in a slow stream of nitrogen. A glass reaction tube containing the reaction mixture was used in the autoclave. The stirrer was gilded with gold to prevent palladium(II) chloride from reacting with steel. Ethylene-palladium(II) chloride complex was prepared under 50 atm of ethylene pressure for 6 hr. The autoclave was then opened and *n*-butylamine (2 m*l*, 0.02 mol) was added. The reaction was carried out at a given pressure of ethylene (1—50 atm) and temperature (25—150°C) by stirring for 2.5 hr. The formation of the ethylene-palladium(II) chloride complex depended on pressure of ethylene and reaction time. To confirm the complete formation of the ethylene complex, bis(benzonitrile)palladium chloride complex was used instead of palladium chloride. In this case the ethylene complex was prepared completely.[19]

The reaction products were analyzed by gaschromatography; 3 m Carbowax 1500 on Diasolid A column at 65°C and a nitrogen flow rate of 60 m*l*/min; 2 m Apiezon Grease L on Diasolid A column at 50°C and a nitrogen flow rate of 50 m*l*/min. Identification of product **1** was carried out by comparison of gas chromatogram and infrared spectrum with that of the authentic sample prepared according to Campbell.[20] Yield data were obtained by gas chromatography using cyclohexane as an internal standard. White crystalline insoluble in tetrahydrofuran was obtained remarkably at elevated temperature. Recrystallization from methanol gave purified *n*-butylamine hydrochloride (mp 195—197°C). Infrared spectrum and melting point of this crystals were identical with those of the authentic sample prepared from *n*-butylamine and hydrochloric acid. The soluble reaction mixture was evaporated to dryness and recrystallization from methanol gave cream yellow crystals, which was **2**, $[PdCl(n\text{-}C_4H_9NH_2)_3]Cl$; mp 149.5—150.5°C.

Found: C, 36.30; H, 8.56; N, 10.16%. Calcd for $PdCl_2C_{12}H_{33}N_3$: C, 36.38; H, 8.38; N, 10.60%.

Analysis of Reaction Products at Elevated Temperature. Product **3** was analyzed by gaschromatography under the same conditions as in **1**. Tarry substance was obtained as follows. The reaction mixture was evaporated and **2** was removed by crystallization from methanol. The black red filtrate was evaporated to dryness under reduced pressure at 60°C for 8 hr and weighed without further purification. Identification of **3** and the tarry substance was made by comparison of gaschromatogram and infrared spectra with those of authentic sample prepared from **1** by heating.[12] The infrared spectrum of the tarry substance showed a broad absorption at 1600—1650 cm^{-1} referred to $\nu_{C=C}$ and $\nu_{C=N}$, but no clear absorption at 3200—3300 cm^{-1} referred to ν_{N-H}.

Analysis of Reaction Products with a Small Amount of *n*-Butylamine. Analysis of **1** was carried out by gas chromatography before and after the addition of pyridine. *n*-Butylamine-palladium(II) chloride complexes which were obtained at molar ratios of *n*-butylamine to palladium chloride of 1 and 2 were different from **2**. When the molar ratio of *n*-butylamine to palladium chloride was 1, *i. e.* $[n\text{-}C_4H_9NH_2]/[PdCl_2]=1$, the reaction mixture was reddish orange and homogeneous immediately after the reaction. In a few minutes copper-red crystals precipitated evolving gas of ethylene. Recrystallization from methanol gave **5**: $(PdCl_4)(n\text{-}C_4H_9NH_3)^+_2$; mp (decomp.) 240—260°C.

Found: C, 24.14; H, 6.07; N, 9.06%. Calcd for $PdCl_4C_8H_{24}N_2$: C, 24.14; H, 6.05; N, 9.05%.

The infrared spectrum was similar to that of *n*-butylamine hydrochloride. Isolation of other complexes was unsuccessful.

At the molar ratio of 2, *i. e.* $[n\text{-}C_4H_9NH_2]/[PdCl_2]=2$, the reaction mixture was yellow and homogeneous. Orange yellow crystals was obtained by the same method as **2**. Recrystallization from methanol gave **4**; $PdCl_2(n\text{-}C_4H_9NH_2)_2$: mp 146—147°C.

Found: C, 29.74; H, 6.66; N, 8.60%. Calcd for $PdCl_2C_8H_{22}N_2$: C, 29.72; H, 6.81; N, 8.67%.

Complex **3** was obtained at the ratio of more than **4**.

Reaction of Tris(*n*-butylamine)palladium(II) Chloride Complex 2 with Ethylene. Both 1.834 g of **2** and 20 m*l* of dry tetrahydrofuran were placed in the autoclave. Ethylene was compressed to 50 atm and stirred for 2.5 hr at 25°C or 150°C. Analysis of the products was carried out by the same method as described in the reaction of ethylene complex.

Reaction of Propylene-Palladium(II) Chloride Complex with *n*-Butylamine. Bis(benzonitrile)palladium chloride complex (1.9 g) and dry tetrahydrofuran (20 m*l*) were put into the autoclave. Propylene was compressed to 10 atm and stirred for 30 min to prepare the propylene complex. The autoclave was opened and *n*-butylamine (2 m*l*) was added. The reaction was carried out under 5 atm of propylene pressure by stirring for 5 hr at 25°C. Analysis of the reaction products was carried out by gas chromatography; 2 m Apiezon Grease L on Diasolid A column at 74°C and a nitrogen flow rate of 50 m*l*/min. Identification of the products was carried out by comparison of gaschromatogram with an authentic sample prepared according to Campbell.[20] Yield data were obtained by gaschromatography using toluene as an internal standard.

Reaction of Cyclohexene-Palladium(II) Chloride Complex with *n*-Butylamine. In a 30-m*l* conical beaker, 0.394 g of bis(benzonitrile)palladium chloride complex, 10 m*l* of dry tetrahydrofuran and 1 m*l* of cyclohexene were stirred by magnetic stirrer for 10 min to prepare the cyclohexene complex. To this reaction mixture 0.4 m*l* of *n*-butylamine was added gradually with stirring. Reaction was carried out at 25°C by stirring for 5 hr. The reaction product was analyzed by gaschromatography; 2 m Apiezon Grease L on Diasolid A column at 144°C and a nitrogen flow rate of 50 m*l*/min. Identification of the product was carried out by comparison of gas chromatogram with an autnentic sample prepared from cyclohexanone and *n*-butylamine.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1153—1157 (1970)

Oxidation by Transition Metal Complexes. I. Oxidation of Styrene and Triphenylphosphine Catalyzed by O_2-Ir Complex

Kiyotomi TAKAO, Yuzo FUJIWARA, Toshinobu IMANAKA and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka

(Received September 16, 1969)

In order to investigate the oxidation reaction which is catalyzed by transition metal complexes in a homogeneous system under mild conditions, the oxidation reactions of styrene and triphenylphosphine catalyzed by various iridium complexes have been studied. The Vaska complex ($IrX(CO)(PPh_3)_2$) and the biphosphine chelate complex have been found to be effective as oxidation catalyst. It was found that the $SnCl_3$ ligand which has a strong *trans* effect promotes the oxidation of styrene. For the sake of comparison with the iridium compounds, oxidation with palladium salts was also studied.

Extensive studies on heterogeneous oxidation reactions by means of various metal oxides or inorganic metal salts have been carried out.[1] Much less is known about oxidation reactions involving organo-transition metal compounds as a catalyst in homogeneous systems.

Recently, some transition metal complexes having

1) See, for example, K. B. Wiberg, Ed., "Oxidation in Organic Chemistry," Academic Press, New York (1965).

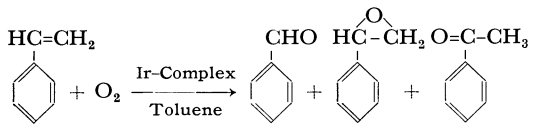
an oxygen molecule as a ligand were prepared.[2-6] These complexes could thus be expected to be effective as oxidation catalyst.

However, only a few workers have studied the homogeneous catalyzed oxidation reaction in the presence of these metal-oxygen complexes.[4-7] Collman has reported briefly that cyclohexene can be oxidized to cyclohexanone and cyclohexene oxide in the presence of the Vaska compelx.[7]

In order to investigate the oxidation reaction which is catalyzed by the transition metal-O_2 complexes in a homogeneous system under mild conditions, we have studied the oxidation reactions of styrene and triphenylphosphine catalyzed by various iridium complexes prepared by Vaska *et al.*[3,8] and others.[9-11]

It has been found that some organoiridium complexes can cause the oxidation reaction of styrene in the presence of oxygen to give styrene oxide, benzaldehyde or acetophenone catalytically. In addition, triphenylphosphine has been found to be easily oxidize to give triphenylphosphine oxide catalytically.

We report in this paper a study on oxidation reactions of styrene and triphenylphosphine by means of iridium complexes under an oxygen atmosphere.



Results and Discussion

The oxidation reactions catalyzed by the iridium complexes were carried out under conditions where homogeneous solutions of reactant styrene (or triphenylphosphine) and iridium complexes in a solvent such as benzene or toluene are heated with a constant bubbling of oxygen for 8 hr.

Oxidation of Triphenylphosphine. Triphenylphosphine has been oxidized easily by the Vaska complexes ($IrX(CO)(PPh_3)_2$; X=Cl, Br, I) to afford triphenylphosphine oxide catalytically, and the catalyst is recovered without decomposition after the reaction. The results are summarized in Table 1.

Table 1. Oxidation of triphenylphosphine with Vaska complex

Catalyst	Reaction temp. °C	Time, hr	Solvent	Triphenylphosphine oxide Yield[a] %
$IrClCO(PPh_3)_2$	110	9	Toluene	426
$IrBrCO(PPh_3)_2$	110	9	Toluene	854
$IrICO(PPh_3)_2$	110	9	Toluene	737

a) Yields are based on catalyst used.

Although it is well known that nickel, palladium, or platinum complexes are effective catalysts for the oxidation of phosphine,[4,5] the present result is the first example of the oxidation by iridium complex catalysts.

Of Vaska complexes, the yield of triphenylphosphine oxide increases in the order: X=Cl<I<Br as shown in Table 1. The fact that the Vaska complexes coordinate with the oxygen molecule easily under oxygen atmosphere, suggests that the present oxidation reaction proceeds *via* an Ir-O_2 complex.

According to La Placa and Ibers[12], and McGinnety *et al.*,[13] the O–O bond lengths of the Ir-O_2 complexes prepared by Vaska *et al.* are 1.30 Å and 1.51 Å for the chloride complex and the analogous iodide complex respectively. That increasing bond length of O–O increases the yield of the oxide formed seems to show that the oxygen molecule is highly activated by coordinating with iridium(I) metal. Heating of Ir-O_2 complex resulted in the formation of triphenylphosphine oxide in the absence of oxygen.

From these results, it appears that the Vaska complex-catalyzed oxidation may proceed through the coordination of both oxygen and triphenylphosphine to iridium(I) metal as is shown in the following scheme:

$IrCl_3$	110	8	Acetic acid	1385	51	89

a) Yields are based on the catalyst utilized.
b) A mixture of 250 m*l* of toluene and 50 m*l* of ethanol was used.
c) Phenylethyleneglycol was also obtained in 102% yield.
d) $[Ir(PPh_2CH_2CH_2PPh_2)_2]Cl$

Oxidation of Styrene. Since the Vaska complexes have been found to be active catalysts for the oxidation of triphenylphosphine, we have undertaken a further study on the oxidation of olefins which are not easily oxidized especially under mild conditions.

It has been found that styrene can be smoothly oxidized by the use of iridium complexes under an oxygen atmosphere. The results are given in Table 2.

As apparent from Table 2, the Vaska complexes (X=Cl, and Br) can cause the oxidation of styrene to give acetophenone in considerable yields. In the absence of the complexes, no oxidation product was formed indicating that these complexes function as a catalyst for the oxidation of styrene.

Solvent Effect. The oxidation of styrene catalyzed by the iridium complexes appears to suffer no solvent effect. That is, styrene gave acetophenone in almost similar yields as in the cases of toluene, a non-polar solvent, ethanol, a protic solvent, or dioxane, a polar solvent. However, in the case of acetic acid, a different result was obtained, namely benzaldehyde was formed as a major product in 1280% yield and acetophenone in 152% yield.[14] This peculiar effect of acetic acid will be discussed in the following publication.

Ligand Effect. *1. Halide Ligand.* The effects of varying the halide ligands of the Vaska complex upon the styrene oxidation are shown in Table 2. The yield of acetophenone increases in the order: X=I<Br<Cl which is different from that observed in the oxidation of triphenylphosphine. This may be explained in the following way: Styrene is a weaker ligand than triphenylphosphine, and the steric hindrance of the halide ligand of the Vaska complex increases in the order, Cl<Br<I. Thus styrene is greatly hindered from coordinating with iridium metal because its forming an iridium-styrene-oxygen complex.

2. $SnCl_3$ and HgCl Ligand. The ligand effects are more clearly obtained when $SnCl_3$[15] or HgCl ligand is introduced to the iridium metal (Table 2).

With the iridium-tin chloride complex,[10] styrene gave 1212% yield of benzaldehyde, 477% yield of styrene oxide and a trace of acetophenone. The higher reactivity of the complex might arise from the strong *trans* effect of the $SnCl_3$ ligand which promotes the formation of an iridium-styrene-oxygen complex intermediate.

It is of interest that the oxidative cleavage of the C=C double bond of styrene takes place easily by the iridium complex catalyst under mild conditions indicating that oxygen is highly activated by coordinating with the iridium metal.[12,13] A similar result was obtained in the case of the HgCl ligand[11] though less reactive than the former.

An interesting aspect of the oxidation is that no benzoic acid is formed even under such an oxidative condition, though benzaldehyde is formed in a high

14) Yields of the oxidation products which appear hereafter in this paper are all based on the amount of the complexes ultilized.

15) $SnCl_3$ ligand is known to have a large *trans* effect and to be a strong π-accepter and a weak donor.[16]

16) R. V. Lindsey, Jr., G. W. Parshall and V. G. Stolberg, *J. Amer. Chem. Soc.*, **87**, 658 (1965).

Table 3. Oxidation of styrene with palladium salts

Catalyst	Reaction		Solvent	Product and yield[a] %		
	Temp.°C	Time, hr		Benzaldehyde	Styrene oxide	Acetophenone
$PdCl_2$[b]	110	8	Toluene	1098	184	17
$PdCl_2$	110	8	Acetic acid	969	19	60
$Pd(OAc)_2$	110	8	Toluene	103	68	7
$Pd_2(C_8H_8)Cl_4$[c]	110	8	Toluene	23	9	2

a) Yields are based on the catalyst used.
b) *trans*-Stilbene (64%) and unidentified compound (0.24 g, mp 77—79°C) were also obtained.
c) 1,3-Diphenylbutene (104%) and *trans*, *trans*-1,4-diphenylbutadiene (44%) were also formed.

yield. This was confirmed by the fact that when benzaldehyde was treated with $IrCl_3$ under the oxygen atmosphere, no benzoic acid was detected.

3 *Bisdiphenylphosphinoethane Ligand.* In the oxidation reaction catalyzed by the four coordinated biphosphine chelate complex,[3] bis,bis(1,2-diphenylphosphine)ethane *iridium(III)* monochloride, $[Ir(PPh_2CH_2CH_2PPh_2)_2]Cl$, styrene was also oxidized easily to give a similar result as above. In this case, an oxygen molecule will be also activated through coordination to iridium metal.[17]

Oxidation with $IrCl_3$. Oxidation of styrene catalyzed by iridium trichloride resulted in the formations of benzaldehyde, styrene oxide and acetophenone in high yields suggesting that the Vaska type complex is formed as an intermediate species[9] which causes the oxidation.

Oxidation with Palladium Salts. For the sake of comparison, the oxidation reactions of styrene using palladium(II) salts were performed. The data in Table 3 show that palladium(II) salts such as palladium(II) chloride can cause the oxidation of styrene to afford benzaldehyde, styrene oxide and acetophenone in excellent yields.

It is well known that acetophenone is obtained by the nucleophilic attack of the hydroxyl anion on the olefinic carbon atom of styrene in the presence of palladium(II) chloride and water.[19] The present oxidation reaction was carried out in the absence of water. Thus acetophenone formed can not be derived from the nucleophilic attack of the hydroxy anion on styrene suggesting that in the present system, an oxygen-palladium complex[4,5] is also formed which behaves as an oxidation catalyst.

In conclusion, it has been revealed that the Vaska complexes and some iridium complexes have a catalytic function for the oxidation of triphenylphosphine and styrene under an oxygen atmosphere.

17) The O_2-complex of this biphosphine chelate was synthesized by Vaska, and it has been reported that the O-O bond length in this complex is 0.45 Å larger than in free oxygen molecule.[18]

Experimental

Materials and Analysis. All temperatures were uncorrected. The IR-spectra were recorded on a Hitachi EPI-S2 spectrometer and NMR spectra were measured on a Japan Electron Optics JNM-4H-100 spectrometer. Chemical shifts are given in τ units together with splitting patterns and relative integrated area. The VPC analysis was made by a Yanagimoto GCG-3 gaschromatograph using an Apiezon L column. Iridium trichloride and palladium chloride were of commercial grade. $Pd(OAc)_2$ was prepared according to the method of Stephenson *et al.*[20] The styrene-$PdCl_2$ complex was prepared according to the method of Kharasch *et al.*[21]

Toluene was refluxed with sodium metal and distilled. Acetic acid was dried over phosphorus pentoxide and distilled. Styrene was dried over anhydrous magnesium sulfate and distilled.

Preparation of Complexes. (1) *trans*-Chloro(carbonyl)bis(triphenylphosphine)iridium. *The Vaska Complex.* *trans*-$IrCl(CO)(PPh_3)_2$ was prepared by a modification of the method of Vaska.[8] Iridium trichloride was dissolved in a mixture of triethyleneglycol and a ten fold excess triphenylphosphine. After heating the mixture at 280°C for 24 hr, the solvent was evaporated to dryness. The residue was recrystallized twice from benzene, affording a yellow crystalline complex (80%). IR: ν(Nujol) 1950 cm^{-1} (C=O) (lit,[8] 1950 cm^{-1}). NMR ($CDCl_3$): 2.00—2.90 (m).

Found: C, 57.23; H, 4.16%. Calcd for $C_{37}H_{30}OClP_2Ir$: C, 56.91; H, 3.88%.

(2) *trans*-Bromo(carbonyl)bis(triphenylphosphine)iridium. *trans*-$IrBr(CO)(PPh_3)_2$ was prepared by the method of Chock *et al.*[9] IR: ν(Nujol) 1955 cm^{-1} (C=O) (lit,[9] 1955 cm^{-1}). NMR ($CDCl_3$): 2.00—3.00 (m).

Found: C, 54.11; H, 3.95; Br, 9.34%. Calcd for $C_{37}H_{30}OBrP_2Ir$: C, 53.89; H, 3.67; Br, 9.69%.

(3) *trans*-Iodo(carbonyl)bis(triphenylphosphine)iridium. *trans*-$IrI(CO)(PPh_3)_2$ was prepared by the

method of Chock *et al.*[9] IR: ν (Nujol) 1973 cm^{-1} (C=O) (lit, 1975 cm^{-1}). NMR ($CDCl_3$): 2.05—2.80 (m).

Found: C, 50.66; H, 3.55%. Calcd for $C_{37}O_{30}OIP_2Ir$: C, 50.98; H, 3.47%.

(4) Bis,bis(1,2-diphenylphosphino)ethane Iridium Monochloride. $[Ir(Ph_2PCH_2CH_2PPh_2)]Cl$ was prepared according to the method of Vaska and Coton.[3] Mp 225—227°C (lit,[3] 225°).

Found: C, 60.62; H, 4.86; Cl, 3.80%. Calcd for $C_{52}H_{48}ClP_2Ir$: C, 60.94; H, 4.72; Cl, 3.46%.

(5) *trans*-Dichloro(carbonyl)bis(triphenylphosphine)chloromercuryl Iridium. *trans*-$IrCl_2(CO)(PPh_3)_2HgCl$ was prepared by the method of Nyholm and Vrieze.[11] IR: ν (Nujol) 2020 cm^{-1} (C=O) (lit,[11] 2030 cm^{-1}).

Found: C, 42.58; H, 3.42%. Calcd for $C_{37}H_3OCl_3P_2HgIr$: C, 42.25; H, 2.88%.

(6) Dichloro(carbonyl)triphenylphosphine Trichlorostanato Iridium. $IrCl_2(CO)(PPh_3)(SnCl_3)$ was prepared by the method of Taylor *et al.*[10] IR: ν (Nujol) 2070 cm^{-1} (C=O) (lit,[10] 2077, 2072 cm^{-1}). Mp 268—272°C (lit,[10] 270—275°C).

Found: C, 28.91; H, 2.16; Cl, 23.53%. Calcd for $C_{19}H_{15}OCl_5PSnIr$: C, 29.31; H, 1.95; Cl, 22.77%.

General Procedure for Oxidation by the Iridium Complexes Catalysts. The iridium complex and styrene (or triphenylphosphine) were dissolved in a solvent (usually, toluene). Oxygen was bubbled through the solution at reflux for 8 hr (in case of triphenylphosphine, 9 hr). After the evaporation of the solvent, the products were isolated by column or gaschromatography. Specific examples of reaction are given in detail below.

Reaction of Vaska Complex with Triphenylphosphine. In a 500-m*l*, three necked, round-bottomed flask, provided with condenser with a calcium chloride tube at the top and an oxygen inlet tube reaching nearly to the bottom, was placed a solution containing 300 m*l* of toluene, 2.00 g (7.6 mmol) of PPh_3 and 0.50 g (0.64 mmol) of $IrCl(CO)(PPh_3)_2$. The solution was refluxed with continued bubbling of oxygen for 9 hr and then the solvent was evaporated to dryness. The residue was subjected to a column chromatography of alumina (100 g). Elution with 500 m*l* of methanol resulted in 0.76 g (426%) of colorless crystals (I), which was assigned as triphenylphosphine oxide by comparison of IR spectrum and mixture melting point with those of an authentic sample. IR: ν (Nujol) 1420, 1185, 1115, 745, 692 and 535 cm^{-1}. After the reaction the Vaska complex catalyst used was recovered quantitatively.

Reaction of Vaska Complex with Styrene. In a flask similar to that mentioned above was placed a mixture containing 0.50 g (0.64 mmol) of $IrCl(CO)(PPh_3)_2$, 10.0 g (97 mmol) of styrene and 300 m*l* of toluene. The solution was refluxed with continued bubbling of oxygen for 8 hr. After evaporation of solvent under reduced pressure, the residual material was chromatographed on alumina (80 g). Elution with 500 m*l* of methanol and recrystallization gave 0.28 g (79%) of triphenylphosphine oxide (I). Although further elution with methanol resulted in no product, 0.2 g of an iridium complex remained at the upper part of the column, which was not further examined. From the solvent evaporated, we obtained styrene and 0.065 g (84%) of liquid substance (IIa) which was assigned as acetophenone by comparison of the IR spectrum and retention time with those of an authentic sample. IR: ν (neat) 1675, 1262, 759, 688, and 587 cm^{-1}.

Reaction of Biphosphine Chelate Complex with Styrene. In a 100 m*l* flask similar to that described above, was placed a mixture containing 0.66 g (0.64 mmol) of $[Ir(PPh_2CH_2CH_2PPh_2)_2]Cl$, 10.0 g (97 mmol) of styrene and 60 m*l* of *n*-propanol. The solution was refluxed with continued bubbling of oxygen for 8 hr. Resulting reaction mixture was treated as usual, and the liquid phase was analysed and separated by VPC to give IIa (0.065 g), IIb (0.32 g) and IIc (0.24 g). IIb was assigned as benzaldehyde by comparison of NMR spectrum, IR spectrum and retention time with those of an authentic sample. IR: ν (neat) 1675, 1573, 1200, 825, 744, 685 and 647 cm^{-1}. NMR (CCl_4): 0.15 (s,1) and 2.10—2.70 (m,5). IIc was assigned as styrene oxide by comparison of retention time with that of an authentic sample.

The solid substance was recrystallized from petroleum ether-benzene to give 0.46 g of white crystalline complex containing iridium metal. Its structure is not yet established.

Scrambling of Oxygen in the Diester Produced from Labeled Diacyl Peroxide-Olefin Reaction

Michio KOBAYASHI, Hiroshi MINATO and Yoshikuni OGI

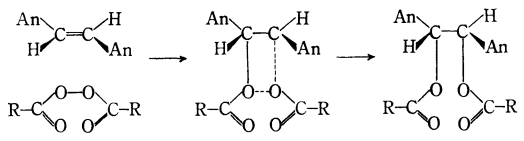
Department of Chemistry, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received September 17, 1969)

dl-Dihydroanisoin bis-*m*-bromobenzoate produced from the reaction between *p,p'*-dimethoxy-*trans*-stilbene and *m,m'*-dibromobenzoyl peroxide labeled with oxygen-18 at the carbonyl oxygen was found to possess completely equilibrated oxygens, and this finding indicated that a four-centerd mechanism was unlikely.

Formation of cyclohexyl acetate from the decomposition of diacetyl peroxide in cyclohexene was explained by the direct attack of cyclohexene on peroxidic oxygen,[1] but such mechanism was ruled out by a later publication describing the formation of cyclohexyl acetate and 1,2-diacetoxycyclohexane having completely scrambled oxygen-18 from the acetyl peroxide labeled specifically at the carbonyl oxygen.[2]

We have recently reported that phenyl benzoate formed from the photochemical decomposition in benzene of the benzoyl peroxide labeled with oxygen-18 at the carbonyl oxygen possesses completely scrambled oxygen and that direct reaction between benzoyl peroxide and benzene must be denounced.[3] Greene, Adam and Cantrill studied the decomposition of *m,m'*-dibromobenzoyl peroxide in benzene containing, *p,p'*-dimethoxy-*trans*-stilbene, isolated *meso*-dihydroanisoin bis-bromobenzoate (28%) and the *dl*-diester (57%), and proposed that the major course of the reaction proceeded by direct reaction between peroxide and olefin according to the four-centered mechanism shown below.[4]



dl-diester

(An=*p*-CH_3O-C_6H_4, R=*m*-Br-C_6H_4)

We have investigated this reaction by use of oxygen-18, and have obtained evidence against such four-centered mechanism.

Experimental

m-Bromobenzaldehyde-^{18}O. *m*-Bromobenzylideneaniline (bp 135°C/0.5 mmHg) was prepared by the reaction with *m*-bromobenzaldehyde and aniline. When a mixture of $H_2{}^{18}O$ (5 g) (^{18}O atom % 1.52) and 9.8 g of concentrated sulfuric acid was added to 26.5 g of *m*-bromobenzylideneaniline, a slightly exothermic reaction took place and white crystals of anilinium sulfate precipitated. After the precipitates were filtered off, 50 m*l* of benzene was added. The organic layer was separated and dried over magnesium sulfate. After the solvent was removed in vacuum, the residual yellow-brown liquid was distilled under reduced pressure and 15.2 g of *m*-bromobenzaldehyde-^{18}O (bp 80.5°C/5 mmHg) was obtained.

m,m'-Dibromobenzoyl Peroxide Carbonyl-^{18}O. Chlorine gas was bubbled through a mixture of 50 m*l* of carbon tetrachloride and 15.2 g of *m*-bromobenzaldehyde-^{18}O at room temperature for 85 min. After the solvent was removed in vacuum, the residual liquid was distilled to give 13 g of *m*-bromobenzoyl chloride-^{18}O; yield, 73.0%.

According to the procedure described by Doering, Okamoto and Krauch[5] 13 g of *m*-bromobenzoyl chloride-^{18}O was let to react with sodium peroxide, and 8.7 g of *m,m'*-dibromobenzoyl peroxide was obtained; mp 117.8°C, yield, 79.5%.

Reaction between m,m'-Dibromobenzoyl Peroxide Carbonyl-^{18}O and p,p'-Dimethoxy-*trans*-stilbene. A benzene solution (35 m*l*) containing *m,m'*-dibromobenzoyl peroxide-^{18}O (1.33 g) and *p,p'*-dimethoxy-*trans*-stilbene (0.88 g) was frozen and degassed for three times in vacuum (10^{-2}—10^{-3} mmHg), and then was heated in a sealed ampoule at 78°C for 24 hr. According to the procedure described by Greene *et al.*,[4] the reaction mixture was treated with alkali for removal of *m*-bromobenzoic acid, and the *meso*-diester was obtained as crystals from ether. The main component of the residue was the *dl*-diester which was then purified by elution chromatography on silica gel. The carbonyl oxygen of the *dl*-diester was separated from the ether

5) W. E. Doering, K. Okamoto and H. Krauch, *ibid.*, **82**, 3579 (1960).

oxygen by reaction with hydrazine in ethanol.[6] The content of oxygen-^{18}O was determined by mass-spectrometric analysis of the carbon dioxide obtained by pyrolysis of a sample.

Results and Discussion

The oxygen-18 analysis were performed for the starting peroxide, two products of the peroxide-olefin reaction (*m*-bromobenzoic acid and the *dl*-diester) and *m*-bromobenzhydrazide derived from the *dl*-diester. The results are summarized in Table 1.

Table 1. Specificity of ^{18}O labeling

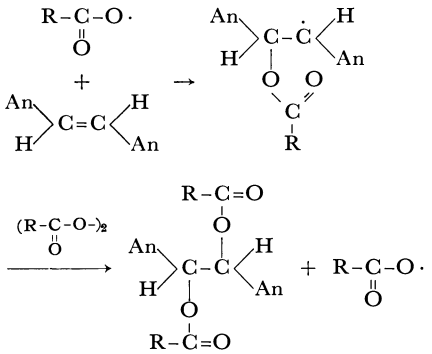
Sample	Atom % ^{18}O-excess	% ^{18}O-calcd
Starting peroxide	0.516	(0.516)
m-Br-C_6H_4COOH	0.518	0.516
dl-Diester	0.459	0.516**
m-Br-$C_6H_4CON_2H_3$*	0.525	1.032**

* Derived from the *dl*-diester by reaction with N_2H_4.
** Calculated according to Greene's mechanism.

The fact that oxygen-18 content of the benzhydrazide is approximately the same as that of the *dl*-diester indicates that carbonyl oxygen and ether oxygen of the *dl*-diester are almost completely equilibrated. If the peroxide decomposes *via* the four-centered mechanism corresponding to the direct reaction, the oxygen-18 of the peroxide must be completely retained at the carbonyl oxygen of the *dl*-diester, and the ^{18}O content of the benzhydrazide must be twice that of the *dl*-diester.

The possibility of the scrambling of the ^{18}O of the starting peroxide due to the recombination of benzoyloxy radicals in cage must be considered since such scrambling occurs in the cage of acetyl peroxide,[7] but we have recently demonstrated that such scrambling does not take place in the case of benzoyl peroxide labeled with oxygen-18 at the carbonyl oxygen.[8]

Thus the mechanism of the molecule-induced homolysis does not appear to be so straightforward as usually written.[9] The following radical-induced mechanism is rejected, at least as the major reaction, of the basis of the isotopic results in Table 1 and the finding of Greene *et al.* that in the presence of galvinoxyl the rate of the peroxide-olefin reaction was reduced by only 25%.



A mechanism which is consistent with various data obtained so far seems to be the following one, in which the diester is produced by combination of two radicals in a cage.

Certainly more detailed study is necessary in order to clalify the mechanism of this reaction completely. However, the above mechanism is consistent with the finding of Greene *et al.* that an

almost identical products mixture (29% *meso*-diester and 57% *dl*-diester) was obtained from the reaction between *p,p'*-dimethoxy-*cis*-stilbene and *m,m'*-dibromobenzoyl peroxide. The above mechanism is also similar to the mechanism proposed for the reaction between acetyl peroxide and cyclohexene.

The Preparation and Reaction of Disubstituted Aminophosphonium Bromide. Reaction of Triphenylphosphine Dibromide with Secondary Amines

Kiyoshi FUKUI and Rokuro SUDO

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 19, 1969)

Disubstituted aminotriphenylphosphonium bromides were obtained in excellent yields from the reaction of triphenylphosphine dibromide and the secondary amines using simple procedures. This method has an advantage in the preparation of cyclic aminophosphonium salts, such as those of morpholine or piperidine. The treatment of the disubstituted aminophosphonium salt with bases resulted in dehydrohalogenation, followed by a Hofmann-like decomposition, and gave imine and triphenylphosphine.

Triphenylphosphine dihalide (**1**) has been used as a halogenation reagent, like phosphorus pentachloride, or as a dehydrating reagent.[1] There have also been several reports on the use of this reagent for the activation of compounds like the malonic ester[2] or primary amines[2b,3] in the form of phosphonium salt or ylide.

In this paper, the preparation of the salt by the reaction of triphenylphosphine dibromide with secondary amines will be reported; the activation of the carbon adjacent to the amino group was also attempted by converting the salt to ylide through the elimination of hydrogen bromide (Eq. (1)).

$$\underset{(\mathbf{1})}{Ph_3PBr_2} + \underset{(\mathbf{2})}{HN\begin{matrix}R^1\\ \diagdown\\ CH_2R^2\end{matrix}} \longrightarrow \underset{Br^-}{Ph_3P^+}\text{–}\underset{(\mathbf{3})}{N\begin{matrix}R^1\\ \diagdown\\ CH_2R^2\end{matrix}}$$

$$\cdots\cdots\rightarrow Ph_3P^+\text{–}N\begin{matrix}R^1\\ \diagdown\\ \underline{C}HR^2\end{matrix} \quad (\mathbf{4}) \qquad \text{Eq. (1)}$$

Disubstituted aminophosphonium salt was obtained by Staudinger[4] through the addition of alkyl halide to phosphoimine, and the scope and the limitations of the dialkylaminophosphonium salt were studied by Zimmer.[3] The disubstituted aminophosphonium salt is obtained by the method used in the preparation of monosubstituted aminophosphonium salt, *i.e.*, directly by the reaction of triphenylphosphine dibromide and secondary amine in the presence of triethylamine.

The reaction of triphenylphosphine dibromide with *N*-ethylaniline (**2a**) in acetonitrile in the presence of an equimolar amount of triethylamine gave *N*-ethylanilinotriphenylphosphonium bromide (**3a**) in an 82% yield. On the other hand, the addition of ethyl bromide or ethyl iodide to tetraphenylphosphoimine gave the corresponding salts in 29% and 73% yields respectively, even after refluxing in benzene for 24 hr. When diethylamine (**2b**), *N*-methylbenzylamine (**2c**), piperidine (**2d**), or morpholine (**2e**) was used as the secondary amine, the corresponding salts were obtained almost quantitatively by this method. In the case of *N*-benzylaniline (**2f**), which would exert a rather large steric hindrance in the salt, there was only a 19% yield of salt after 5 hr refluxing.

In sum, except for the case of bulky amines, the preparations of disubstituted aminophosphonium

* This compound seems to be contaminated with triethylamine salt, and the purification from the triethylamine salt was extremely difficult because of the solubility of both the salts in water.

salts by the reaction of triphenylphosphine dibromide (**1**) with secondary amines (**2**) quantitatively proceed readily and under mild conditions. The cyclic aminophosphonium salts can be also obtained by this procedure. The results are summarized in Table 1.

In an attempt to obtain β-phosphonium ylide (**4**), *N*-methyl-*N*-benzylaminotriphenylphosphonium bromide (**3c**) was treated with sodium methoxide in methanol. However, the products were triphenylphosphine oxide and dimethylamine; this was similar to the case of the hydrolysis of disubstituted aminophosphonium salt with sodium hydroxide.[3] *N*-Methylbenzylamine was also obtained; it is probably a hydrolysis product.

When *N*-methyl-*N*-benzylaminotriphenylphosphonium bromide (**3c**) was treated with an equimolar amount of butyllithium in THF, triphenylphosphine (**6**; 40%), benzylidenemethylamine (**7**; 25%), an unidentified amine, and two hydrolysis products, triphenylphosphine oxide (**5**; 14%) and

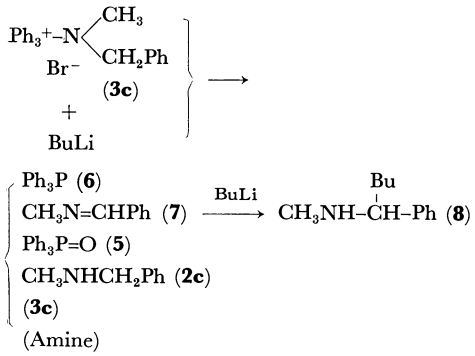

Fig. 1

N-methyl-*N*-benzylamine (**2c**; 41%), were obtained. Thirteen per cent of the unreacted phosphonium salt was recovered.

The unidentified amine is probably the reaction product from benzylidene-methylamine (**7**) and butyllithium, because the treatment of *N*-methyl-*N*-benzylaminotriphenylphosphonium bromide (**3c**) with two mole equivalents of butyllithium gave *N*-methyl-*N*-(1-phenylpentyl)amine (**8**).

These results indicate that the following processes take place in the reaction:

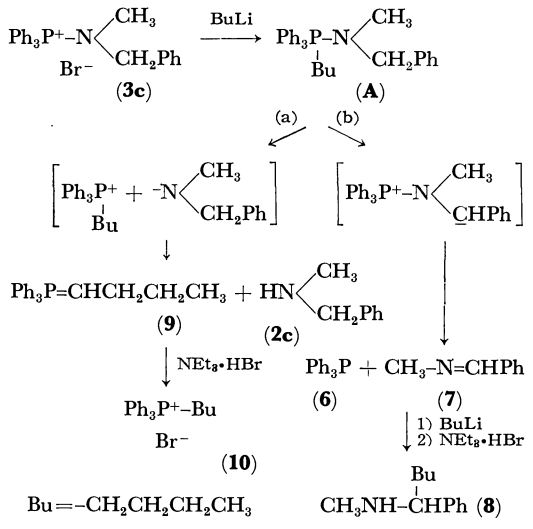

Fig. 2

In the first step, an intermediate, **A**, is formed from the reaction of *N*-methyl-*N*-benzylaminotriphenylphosphonium bromide (**3c**) and butyllithium.

Two different reaction paths from **A** may be considered:

a) The decomposition of **A** produces the amine (**2c**) and butylidenetriphenylphosphorane (**9**), which then, yield phosphonium salt (**10**) after treatment with triethylamine hydrobromide. In this case, the most stable anion, the *N*-methylbenzylamide anion, would leave from the five ligands around the phosphorus atom in **A**.[5]

b) The β-deprotonation of **A** by the butyl anion, followed by a Hofmann-like decomposition gives benzylidenemethylamine (**7**). A similar decomposition of phosphonium salt has been reported by Trippett and[6] Bestmann.[7] The last compound (**7**) was converted to amine (**8**) by the excess butyllithium. If a trace of water is present in the reaction mixture, a portion of the butyllithium will be changed to lithium hydroxide, which will then hydrolyze the phosphonium salt (**3c**) to triphenylphosphine oxide (**5**) and *N*-methylbenzylamine (**2c**).

$$\mathbf{3c} \xrightarrow{\text{LiOH}} \underset{(\mathbf{5})}{Ph_3PO} + HN\begin{matrix}CH_3\\ CH_2Ph\ (\mathbf{2c})\end{matrix}$$

The expected ylide from the elimination of the hydrogen halide of disubstituted aminophosphonium salt was found to be very unstable; as a result, the activation of the carbon adjacent to the amino group as an anion was unsuccessful. However, the results indicate the possibility of the use of this reaction in the preparation of imines and in the reduction of triphenylphosphine dihalide to triphenylphosphine.

In fact, the treatment of *N*-methyl-*N*-benzylaminotriphenylphosphonium bromide with sodium hydride in acetonitrile at room temperature gave triphenylphosphine (**6**; 42%) and benzylidenemethylamine (**7**; 25%). Sodium hydride was used in place of butyllithium to avoid the side reaction of the reagent with the imines.

Experimental

Preparation of Disubstituted Aminophosphonium Salts. *a) From Triphenylphosphine Dibromide (**1**) and Secondary Amines.* Into a solution of triphenylphosphine (2.62 g, 10 mmol) in acetonitrile (50 m*l*), a solution of bromine (1.60 g, 10 mmol) in the same solvent (15 m*l*) was stirred, drop by drop, at room temperature. A solution of *N*-ethylaniline (**2a**) (1.21 g, 10 mmol) in acetonitrile (15 m*l*) and a solution of triethylamine (1.01 g, 10 mmol) in 15 m*l* of the same solvent were then added to the mixture from a dropping funnel. After stirring at room temperature for 8 hr the solvent was removed under reduced pressure at 40—50°C. The concentrated residue was triturated with benzene, and the precipitates were collected by filtration. The precipitates were dissolved in 50 m*l* of water, and the insoluble solids were filtered off. *N*-Ethylanilinotriphenylphosphonium bromide (**3a**) was obtained in an 82% (3.8 g) yield. The crude product was recrystallized from chloroform-ethyl acetate and gave white crystals, mp 242—242.5°C.

The reactions of **1** with all the other secondary amines were carried out by a similar procedure under the reaction conditions shown in Table 1. The solvent for the recrystallization of the crude products was chloroform-ethyl acetate, except for the case of *N*-benzylanilinotriphenylphosphonium salt (**3f**), where water was used as the solvent. The results of elementary analysis and the melting points are listed in Table 1.

b) From the Addition Reaction of Alkyl Halide to Tetraphenylphosphoimine. A solution of tetraphenylphosphoimine[2] (3.53 g) and ethyl bromide (15 m*l*) in benzene (30 m*l*) was refluxed for 24 hr, and then the precipitated crystals were collected at room temperature. **3a** was obtained in a 29% (1.3 g) yield. The crude product was recrystallized from a chloroform-ethyl acetate mixture. The melting point was 242—242.5°C, and there was no depression shown in a mixed-melting point determination with the product from a). Unreacted tetraphenylphosphoimine (2.2 g; 62%) was recovered from the concentrated benzene solution by the addition of isopropyl alcohol.

In a similar fashion, the reaction of ethyl iodide or benzyl chloride with tetraphenylphosphoimine was carried out. The resulting salts were recrystallized from water. The melting points and the results of elementary analysis are as follows: *N*-Ethylanilinotriphenylphosphonium iodide, mp 221—221.5°C. *N*-Benzylanilinotriphenylphosphonium chloride, mp 205—206°C. Found: C, 77.07; H, 5.88; N, 2.92%. Calcd for $C_{31}H_{27}ClNP$: C, 77.60; H, 5.84; N, 2.92%.

Reaction of *N*-Methyl-*N*-benzylaminophosphonium Bromide (3c) with Sodium Methoxide. To a methanol (50 m*l*) solution of sodium (0.5 g), **3c** (9.46 g) in methanol (50 m*l*) was added under cooling. After standing at room temperature for one day, the mixture was refluxed for 3 hr and then concentrated under reduced pressure. Benzene and water were added to the residue. The benzene layer was washed with water and dried over anhydrous sodium sulfate. The solvent was removed to give an oily product, which was then dissolved in *n*-hexane. The insoluble solids were filtered off. Triphenylphosphine oxide was thus obtained in a 97% (5.4 g) yield. The *n*-hexane solution was concentrated and subsequently distilled. A distillate with a bp 80—83°C/26 mmHg was analyzed by gas-liquid chromatography, using an Apiezon Grease M column (10%, 3 mm×2 m); column temperature, 100°C, carrier gas, He. It gave two peaks, whose relative retention times were equal to those of authentic dimethylamine and *N*-methylbenzylamine (**2c**).

Reaction of 3c with Equimolar Butyllithium. To a suspension of **3c** (6.95 g) in THF (50 m*l*) cooled by ice, a *n*-hexane solution of butyllithium (10.5 m*l*) was added, drop by drop, under a nitrogen atmosphere. The mixture was then stirred at room temperature for one day. The precipitated crystals were collected. **3c** (0.9 g, 13%) was recovered. The filtrate was concentrated to give an oily residue. The residue was dissolved in methanol,

5) A. W. Johnson, "Ylid Chemistry," Academic Press, N. Y. and London (1966), pp 59—61.

6) S. Trippett, *Proc. Chem. Soc.*, **1963**, 19.

7) H. J. Bestmann and R. Zimmerman, *Chem. Ber.*, **101**, 2185 (1968).

and the insoluble products were filtered off. By repeating these procedures twice, triphenylphosphine was obtained in a 40% (1.65 g) yield. The filtrate was concentrated and distilled. Benzylidenemethylamine (**7**) was thus obtained in a 40% (0.6 g) yield. The IR spectrum of **7** was equal to that of an authentic sample. The residue of the distillation was dissolved in *n*-hexane. Insoluble solids were thus collected. Triphenylphosphine oxide (**5**) was obtained in a 14% (0.6 g) yield.

Reaction of 3c with 2 Molar Equivalents of Butyllithium. To a suspension of **3c** (23.1 g) in THF (100 m*l*) cooled by a dry ice-acetone mixture, a *n*-hexane solution of butyllithium (68 m*l*) was added, drop by drop, under a nitrogen atmosphere. After keeping the mixture under 0°C for 8 hr, triethylammonium bromide (9 g) and then 50 m*l* of ethanol was added. The crystals were filtered off after 2 hr and washed with water. Butyltriphenylphosphonium bromide (**10**) (8 g, 40%) was thus obtained. The product was recrystallized from water; mp 238°C. Found: C, 65.82; H, 5.99%. Calcd for $C_{22}H_{24}BrP$: C, 66.1; H, 6.01%.

The filtrate was then concentrated and distilled. *N*-Methylbenzylamine (**2c**) (bp 87°C/20 mmHg, 2.5 g, 41%) was thus obtained. Benzene and water was added to the residue of distillation. The precipitated crystals were **10** (2.15 g, 10%). The separated benzene solution was washed with water and dried over anhydrous sodium sulfate. The benzene solution was concentrated and distilled. The distillate with a bp 107—142°C/17 mmHg was identified as *N*-methyl-*N*-(1-phenylpentyl)amine (**8**) (0.55 g, 7%) by IR, bp, and elemental analysis. Found: C, 81.31; H, 10.55; N, 7.91%. Calcd for $C_{12}H_{19}N$: C, 81.3; H, 10.72; N, 7.91%.

Reaction of 3c with Sodium Hydride. To a mixture of **3c** (9.24 g) and sodium hydride (1.0 g), acetonitrile (50 m*l*) was added. A violent gas evolution was observed. The mixture was stirred at room temperature for 8 hr, and then triethylammonium bromide (3.64 g) was added and the mixture was stirred for 2 more hours. After the precipitate had been removed the filtrate was concentrated. To the residue, 2 *N*-hydrochloric acid (10 m*l*), water (20 m*l*), and benzene (30 m*l*) were added, and the two layers were separated. The aqueous solution was neutralized with a sodium bicarbonate solution and was made alkaline by sodium hydroxide. The precipitates were extracted with benzene, washed with water, and dried over anhydrous sodium sulfate. HCl gas was passed through the solution, and the precipitated crystals were collected. The crystals (0.75 g, 24%) showed an IR spectrum identical with that of *N*-methylbenzylammonium chloride prepared from **2c** and hydrogen chloride. The benzene filtrate was washed with water, dried over anhydrous sodium sulfate, and concentrated under reduced pressure. *n*-Hexane (30 m*l*) was added to the residue, and the precipitated crystals were collected. **5** (2.2 g, 40%) was thus obtained. The *n*-hexane solution was concentrated under reduced pressure, the residue was triturated with isopropyl alcohol, and the precipitated crystals were collected by filtration. By repeating these procedures twice, 2.2 g (42%) of triphenylphosphine (**6**) were obtained.

Synthesis of Corticotropin Peptides. XI. Synthesis and Biological Properties of [1-β-Alanine]-ACTH(1-18)-Octadecapeptide Amide

Ken INOUYE, Akira TANAKA and Hideo OTSUKA

Divisions of Biochemistry and Pharmacology, Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received September 24, 1969)

The synthesis is described of an octadecapeptide amide, β-alanyl-tyrosyl-seryl-methionyl-glutamylhistidyl-phenylalanyl-arginyl-tryptophyl-glycyl-lysyl-prolyl-valyl-glycyl-lysyl-lysyl-arginyl-arginine amide, corresponding to the first eighteen amino acid residues of corticotropin except for the amino end which has been substituted by a β-alanine for the serine in native hormone. The adrenalstimulating activities of the octadecapeptide amide are compared with those of the corresponding l-serine or l-glycine octadecapeptide amide to show that the l-β-alanine peptide is remarkably more active than the latter when assayed by *in vitro*, subcutaneous and intamuscular approaches, and that the activities of the former are maintained for a longer period of time than those of the latter. The l-β-alanine peptide as a lipotropic agent is also shown to be more active than the synthetic analogs and a native corticotropin on rat adipose tissue. The differences among these octadecapeptide analogs in the biological properties are discussed in terms of their susceptibility toward the action of aminopeptidase.

Syntheses of a large number of highly active corticotropin (ACTH) peptides have been reported from various laboratories. Among these studies it is of special interest that the amino end can be

Z, benzyloxycarbonyl; Boc, *t*-butyloxycarbonyl; Me, methyl; Bu^t, *t*-butyl; ONp, *p*-nitrophenoxy; M.A., mixed acid anhydride method; DCC, *N,N'*-dicyclohexycarbodiimide method.

replaced by D-serine[1,2] or D-alanine[2] for the native L-serine in corticotropin peptides resulting in a marked increase in the biological activities. Since hormones generally require the cellular organization to exert their biological properties, there must be a number of factors affecting the observed level of activities. It seems, however, most likely that the apparent increase in activities observed with the 1-D-serine and 1-D-alanine analogs of corticotropin peptides is a consequence of the decreased susceptibility of peptides toward the action of aminopeptidase owing to the presence of D-amino acid at the amino end. This is also suggested by the fact that the replacement by glycine of the amino-terminal serine in porcine corticotropin,[3] ACTH-(1-18)-NH_2[4] and ACTH(1-23)-NH_2[5] has made no remarkable change in the adrenal-stimulating activity. If this is correct, such an amino acid, which forms amide bonds resisting the aminopeptidase action, should as well improve the biological properties of a corticotropin peptide as do the D-amino acids, when it is substituted for the amino terminal residue of peptide. In order to confirm this of view, the synthesis of an octadecapeptide amide, β-alanyl-tyrosyl-seryl-methionyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycyl-lysyl-prolyl-valyl-glycyl-lysyl-lysyl-arginyl-arginine amide (I), [β-Ala^1]-ACTH(1-18)-NH_2,[6] corresponding to the first eighteen amino acid residues of corticotropin with the exception of amino end was undertaken. β-Alanine is one choice, because it is known to form acid amides which are not hydrolyzed by hog kidney leucine aminopeptidase.[7] Biological properties of I were then compared with those of the corresponding 1-L-serine and 1-glycine

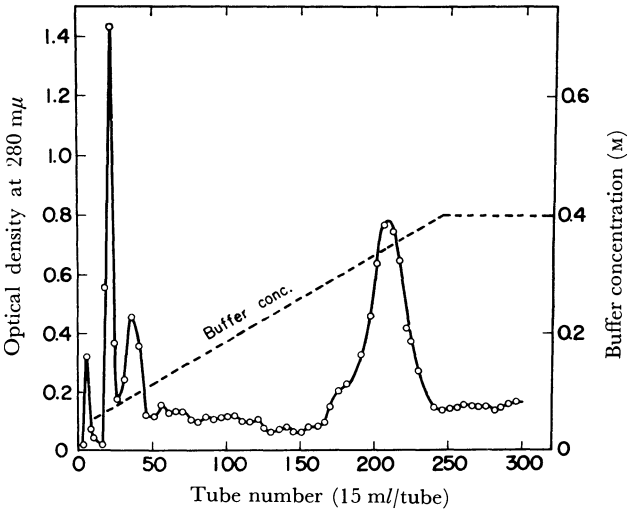

Fig. 2. Chromatography of synthetic octadecapeptide amide. Material: crude [β-Ala[1]]-ACTH(1-18)-NH_2 (I), 0.513 g. Column: carboxymethyl cellulose (Serva, 0.6 meq/g), 2.7×12 cm. Buffer: ammonium acetate (pH 6.84). Flow rate: 6 ml/min.

analogs, ACTH(1-18)-NH_2 (Ia) and [Gly[1]]-ACTH-(1-18)-NH_2 (Ib), whose syntheses were reported previously.[4,8]

A synthetic procedure of the decapeptide intermediate corresponding to the positions 1—10 of I is shown in Fig. 1. The procedure involves a new synthesis of H-Glu(OBu[t])-His-Phe-Arg-Trp-Gly-OH (VIII),[9] in which *t*-butyloxycarbonyl (Boc) groups were removed from Boc-Arg(NO_2)-Trp-Gly-OMe (II) and Boc-Phe-Arg(NO_2)-Trp-Gly-OMe (III) by treatment with formic acid[10] instead of trifluoroacetic acid formerly used,[9] and the conversion of Z-His-Phe-Arg(NO_2)-Trp-Gly-OH (V) into a pentapeptide VI was carried out in anhydrous hydrogen fluoride.[11] In these deprotection steps it was found that no detectable decomposition of the tryptophan residue occurred. The coupling of Z-Glu(OBu[t])-ONp with VI led to the formation of a protected hexapeptide (VII), which was readily converted into VIII by catalytic hydrogenolysis. Boc-β-Ala-Tyr-Ser-Met-$NHNH_2$ (XII) was synthesized by the same procedure as that described for Boc-Gly-Tyr-Ser-Met-$NHNH_2$,[12] except that a mixed acid anhydride method was used to prepare Boc-β-Ala-Tyr-OMe (IX). The azide derived from XII was then coupled with VIII to give a decapeptide Boc-β-Ala-Tyr-Ser-Met-Glu-(OBu[t])-His-Phe-Arg-Trp-Gly-OH (XIII).

In the final coupling step leading to the formation of a protected octadecapeptide amide, Boc-β-Ala-Tyr-Ser-Met-Glu(OBu[t])-His-Phe-Arg-Trp-Gly-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-Lys(Boc)-Arg-Arg-NH_2 (XV), compound XIII was esterified with *N*-hydroxysuccinimide by the carbodiimide method[13] and the resulting active ester, which was isolated, was allowed to react with a partially protected octapeptide amide (acetate), H-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-Lys(Boc)-Arg-Arg-NH_2 (XIV),[14] in the presence of triethylamine. The product, without further purification, was treated with 90% trifluoroacetic acid to remove all the protecting groups. The deprotection has been found to be achieved by the anhydrous hydrogen fluoride treatment;[15] formic acid may also be useful for the same purpose. The crude octadecapeptide amide (I, trifluoroacetate) was converted by treatemnt with Amberlite CG-400 (acetate) into the acetate form, which was, after having been incubated with mercaptoethanol, submitted to chromatography on a carboxymethyl cellulose (CMC) column using an ammonium acetate buffer (pH 6.8) with a linear concentration gradient. The results of chromatography are shown in Fig. 2. An over-all yield of peptide I for the final coupling step was 54%.

TABLE 1. ADRENAL-STIMULATING ACTIVITIES OF ACTH AND RELATED SYNTHETIC OCTADECAPEPTIDE AMIDES*

Method	Administration route	Peptide			
		Ia	Ib	I	α_s-ACTH
Adrenal ascorbic acid depletion[19]	subscutaneous	45.4	25.6 (3)	135 (2)	120
In vitro steroidogenesis[20]	*in vitro*	13.7 (3)	20.8 (3)	237 (3)	120
In vivo steroidogenesis[21]	intravenous	92.0 (9)	167 (11)	125—285 (4)	100—180
In vivo steroidogenesis in:					
dexamethasone-Nembutal-mouse[22]	intravenous	139	70—168 (2)	259 (2)	—
hypophysecotomized rat peripheral blood	intramuscular	—	35.4 (4)	124	—

* The activities are expressed in USP units/mg, relative to the Third USP Corticotropin Reference Standard. The figures in parentheses are the number of independent assays. Ia: ACTH(1-18)-NH_2, Ib:[Gly^1]ACTH(1-18)-NH_2, I:[β-Ala^1]-ACTH(1-18)-NH_2, and α_s-ACTH: native sheep ACTH

A rechromatography on CMC afforded in an 86% recovery the pure material of I, which was found to be homogeneous to ninhydrin, Pauly, Ehrlich, Sakaguchi and methionine (PtI_6'') reagents in paper chromatography and paper electrophoresis. Quantitative amino acid analysis[16] showed that an acid hydrolysate of the product contained individual amino acids in the ratios expected by theory with the exception of tryptophan. The tryptophan-tyrosine ratio of intact I was determined spectrophotometrically to be unity.[17]

The susceptibility of β-Ala^1-octadecapeptide amide (I) toward the action of hog kidney leucine aminopeptidase (LAP) is compared in Fig. 3 with those of the corresponding Ser^1-analog (Ia) and Gly^1-analog (Ib). A commercial LAP preparation was found to hydrolyze [β-Ala^1]-ACTH(1-10)-OH and I, but not β-Ala-Tyr-Ser-Met-$NHNH_2$. Since there was no β-alanine detected in the enzymic digests on an amino acid analyzer,[16] the observed hydrolysis may be due to the presence of an endopeptidase in the LAP preparation. This apparent susceptibility of β-alanyl peptides to LAP was completely lost when the enzyme preparation had been treated with diisopropyl fluorophosphate (DFP). By the DFP-treated LAP, Ser^1-peptide (Ia) was hydrolyzed faster than Gly^1-peptide (Ib) and no hydrolysis was observed with β-Ala^1-peptide (I) within the error of measurements (Fig. 3). The results confirm and extend the finding of Spackman *et al.*[7] that hog kidney LAP does not split β-alanyl amide bonds.

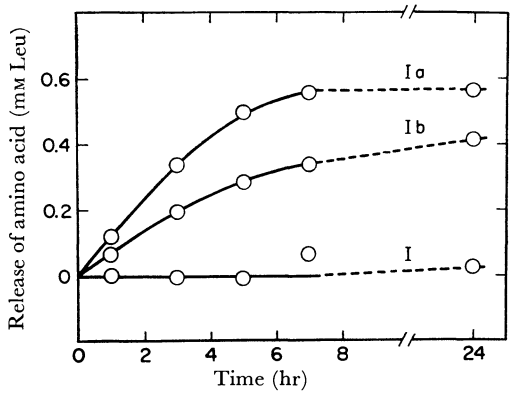

Fig. 3. Action of DFP-treated leucine aminopeptidase on synthetic octadecapeptide amides. Enzyme: DFP-treated hog kidney leucine aminopeptidase, 1.95 units/ml (see Experimental section for the definition of unit). Substrates: I, [β-Ala^1]-ACTH(1-18)-NH_2; Ia, ACTH(1-18)-NH_2; Ib, [Gly^1]-ACTH(1-18)-NH_2; concentration, 0.04 mM. Reactions were carried out in 0.02M Tris buffer (pH 8.3) at 37°C.

The adrenal-stimulating activities of β-Ala^1-octadecapeptide amide (I) were compared with those of the synthetic analogs (Ia and Ib) and sheep corticotropin (α_s-ACTH)[18] by five different assay procedures: 1) adrenal ascorbic acid depletion,[19] 2) *in vitro* steroidogenesis,[20] 3) *in vivo* steroidogenesis,[21] 4) *in vivo* steroidogenesis in the dexamethasone-pentobarbital-blocked mouse[22] and 5) steroidogenesis in the hypophysectomized rat by the intramuscular administration. The results are summarized in

Table 1, in which some of the data for peptides Ia and Ib are revised by the present assays from those reported previously.[4] As shown in Table 1, peptide I is highly active in any respect to the adrenal-stimulating properties. The *in vivo* steroidogenic activity of I is in the same order of magnitude as those of Ia, Ib and α_s-ACTH, when administered by intravenous injection. However, peptide I exhibited a strikingly higher activity than those of Ia and Ib, when assayed by *in vitro* steroidogenesis and adrenal ascorbic acid depletion methods. It is noteworthy that the potency ratios of subcutaneous or *in vitro vs.* intravenous administration are 1—0.5 for peptide I, whereas the ratios for peptides Ia and Ib are 1/7—1/8. Peptide I is, in this respect, much closer than Ia and Ib to the native hormone (α_s-ACTH) which gives the ratio of unity. Figure 4 shows that the β-Ala^1-peptide (I) can remain active for a longer period of time than Gly^1-peptide (Ib), when administered by intramuscular injection; the steroidogenic activity is expressed in terms of the 11-hydroxycorticosteroid (11-OHCS) level in plasma.

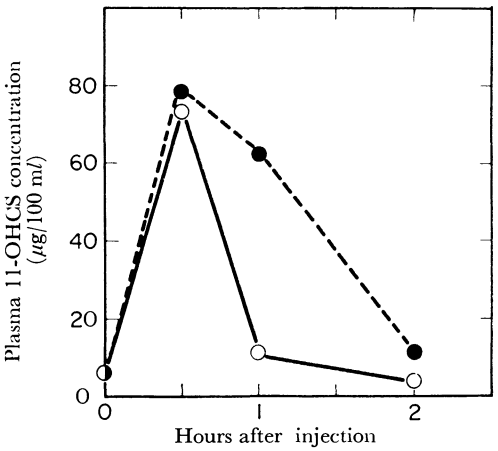

Fig. 4. Time course of synthetic octadecapeptide amides in steroidogenesis.
○—○, [Gly^1]-ACTH(1-18)-NH$_2$ (Ib); ●---●, [β-Ala^1]-ACTH(1-18)-NH$_2$ (I). Peptide (5 μg/rat) was administered into the thigh muscle of hypophysectomized rat and 11-OHCS concentration in blood was measured. See Experimental section for details.

TABLE 2. *In vitro* LIPOTROPIC ACTIVITY OF ACTH AND RELATED SYNTHETIC OCTADECAPTIDE AMIDES[23]

	Minimal effective dose (10^{-6} mg/50 mg tissue)			
	Ia	Ib	I	α_s-ACTH
Rat adipose tissue	3.0	6.3	0.62	6.0
Rabbit adipose tissue	0.004	0.35	0.065	7.1
Rat/rabbit ratio, approx.	750	20	10	1

Ia: ACTH(1-18)-NH$_2$, Ib: [Gly^1]-ACTH(1-18)-NH$_2$, I: [β-Ala^1]-ACTH(1-18)-NH$_2$, and α_s-ACTH: native sheep ACTH.

Peptide I also exhibits a high lipotropic activity, which is compared in Table 2 with the activities of synthetic peptides Ia and Ib, and a native hormone (α_s-ACTH).[23] β-Ala^1-peptide (I) was roughly ten times more active than Ia, Ib and α_s-ACTH, when assayed in the rat. A lesser amount of I can exert the activity in the rabbit as compared to that in the rat. This is the case with the other peptides as well. However, it is to be noted that the ratio of the minimal effective dose in rat fat *vs.* that in rabbit fat is smaller for I than those for Ia and Ib. Figures 5A and B show the inactivation patterns of I and Ib as lipotropic agents in the fresh plasma and in the buffer containing rat muscle fragments, respectively. There was no significant difference between I and Ib in the case of plasma,

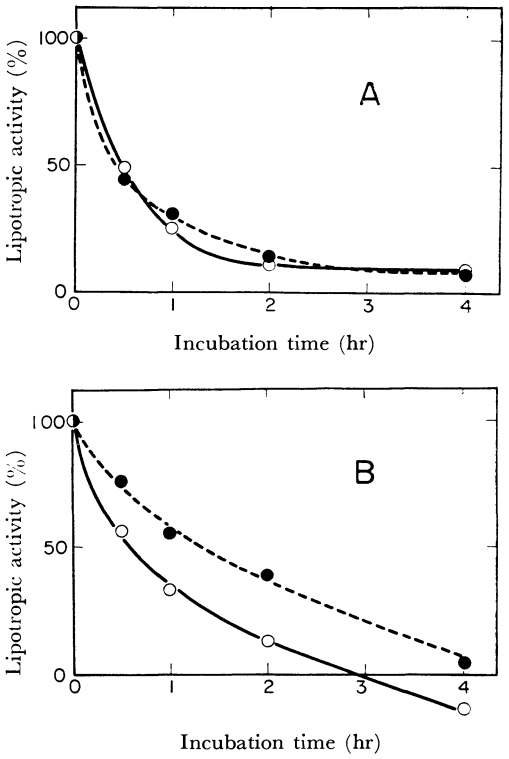

Fig. 5. Inactivation of the lipotropic activity of synthetic octadecapeptide amides.
A: by plasma. B: by tissue. ○—○, [Gly^1]-ACTH(1-18)-NH$_2$ (Ib) 1 μg/fat pad; ●---●, [β-Ala^1]-ACTH(1-18)-NH$_2$ (I) 0.1 μg/fat pad. Incubations were carried out at 37°C in the plasma of anesthetized rat in A and in the buffer containing rat muscle fragments in B. See Experimental section for details.

whereas the inactivation of I was markedly delayed compared with that of Ib in the case of tissue.

The results described above clearly demonstrate that the introduction of β-alanine into the amino terminal position of ACTH(1-18)-octadecapeptide amide causes not only remarkable enhancement but also prolonged duration of the adrenocorticotropic and the lipotropic activities of the peptide. Whether a similar effect as that produced by β-alanine is expected by other amino fatty acids, such as aminobutyric acids and aminovaleric acids, remains to be examined. In any case, one can not exclude the possibility that the distance between the terminal amino group and the center of active site of the hormone peptide may become another important factor which affects the activities. Since no direct comparison has been made between the β-Ala^1-peptide and its corresponding D-Ala^1-analog in the present studies, it is not clear whether the former differes from the latter in the activity levels, solely owing to the fact that the terminal amino group of the former is located one methylene unit away from the regular position.

The present results also indicate that the remarkable changes in activities, which are produced when the amino terminal residue of octadecapeptide amide (Ia or Ib) is replaced by a β-alanine, are quite smilar in characteristics to those which were reported to occur when the relpacement was made by a D-amino acid for the amino end of the corticotropin peptides.[1,2,24] On the other hand, it is known that the adrenocorticotropic activity of corticotropin peptides is little affected by the replacement by glycine[3-5] and even by the deletion[5] of the amino terminal residue. The present results as well as the other observations support the view that the increased biological activities and their prolonged duration, which were found with the analogs bearing a D-amino acid[1,2] or a β-alanine at the amino end, are the consequence of the diminished susceptibility of peptides toward the action of intracellular aminopeptidase. By analogy, the findings that the peptide amides[8,25] and the peptide terminating with a prolinol[26] are more active than the corresponding acids and the proline amide analog, respectively, would be partly explained by the fact that an amide group at the carboxyl end protects the peptide from the action of carboxypeptidase, and by assuming that a prolinol residue assures the resistance of peptide toward the prolidase action.

As has been pointed out above, the potency ratio of subcutaneous *vs.* intravenous administration in the assay for adrenocorticotropic activity changes from 1/8—1/7 up to 0.5—1, when the amino end of octadecapeptide amide (Ia or Ib) is replaced by a β-alanine, approaching the ratio of α_s-ACTH (Table 1). This probably means that the difference in *s.c./i.v.* ratio between the synthetic peptide (Ia or Ib) and the native hormone mostly depends on the inactivation rate of peptide in the tissue, where an aminopeptidase must act predominantly on the peptide. In blood the inactivation seems to involve another type of enzyme, by which both the synthetic and the native peptides are attacked fairly equally. An enzyme inactivating thenative hormone in blod has been suggested to be an endopeptidase.[27] However, the above view remains to be elucidated by comparing the inactivation patterns of the synthetic peptides (I, and Ia or Ib) and the native hormone. Such work is in progress in this laboratory.

Experimental

All melting points were uncorrected.

***t*-Butyloxycarbonyl-β-alanine.** β-Alanine (8.91 g, 0.1 mol) was dissolved in N sodium hydroxide (100 m*l*), and sodium bicarbonate (21 g) and dioxane (70 m*l*) were added. To this was slowly added a solution of *t*-butyl azidoformate (11.2 g, 0.12 mol) in dioxane (30 m*l*) and the mixture was stirred at 50°C for 42 hr. After removal of dioxane by evaporation *in vacuo*, the residue was acidified at 0°C with ice-cold 4N hydrochloric acid to pH 2 and the desired product was extracted with cold ethyl acetate. The extracts were combined, dried over sodium sulfate and evaporated *in vacuo* to give a sirupy residue which crystallized from ethyl acetate-petroleum ether; yield 12.7 g (67%), mp 77—78°C. Recrystallization from the same solvent did not alter the melting point.

Found: C, 50.99; H, 8.06; N, 7.47%. Calcd for $C_8H_{15}NO_4$: C, 50.78; H, 7.99; N, 7.40%.

***t*-Butyloxycarbonyl-β-alanyl-tyrosine Methyl Ester (IX).** To a solution of *t*-butyloxycarbonyl-β-alanine (1.89 g, 0.01 mol) and tri-*n*-butylamine (2.04 g, 0.01 mol) in anhydrous tetrahydrofuran was added dropwise ethyl chloroformate (1.19 g, 0.01 mol) at an ice-salt bath temperature and the mixture was stirred for 10 min, and a suspension of tyrosine methyl ester (1.95 g, 0.01 mol) in tetrahydrofuran was then introduced. The reaction mixture was stirred at the above temperature for 30 min and at room temperature for 3 hr. After removal of the solvent by evaporation *in vacuo* the residue was dissolved in ethyl acetate. The solution was washed with ice-cold N hydrochloric acid, 5% sodium bicarbonate and water, dried over sodium

sulfate and evaporated *in vacuo* to afford a sirupy residue, which crystallized upon addition of ether; yield 2.99 g (82%), mp 139—141°C. Recrystallization from methanol-ether afforded the product with mp 141—142°C, $[\alpha]_D^{23}$ +8.2±0.5° (*c* 1.020, methanol).

Found: C, 59.03; H, 7.12; N, 7.63%. Calcd for $C_{18}H_{26}N_2O_6$: C, 59.00; H, 7.15; N, 7.65%.

***t*-Butyloxycarbonyl-β-alanyl-tyrosine Hydrazide (X).** To a solution of IX (2.56 g) in ethanol (25 m*l*) was added hydrazine hydrate (1.7 m*l*) and the mixture was kept at room temperature for 5 hr. Crystals which separated were, after having been kept in a refrigerator overnight, filtered off, washed with cold ethanol and ether and dried; yield 2.54 g (99%), mp 210—212°C. These crystals were recrystallized from water in an 85% recovery, mp 214—215°C, $[\alpha]_D^{23}$ +3.6±0.6° (*c* 0.978, 50% acetic acid).

Found: C, 55.74; H, 7.11; N, 15.30%. Calcd for $C_{17}H_{16}N_4O_5$: C, 55.72; H, 7.15; N, 15.29%.

***t*-Butyloxycarbonyl-β-alanyl-tyrosyl-seryl-methionine Methyl Ester (XI).** Compound X (1.10 g, 3 mmol) was dissolved in ice-cold N hydrochloric acid (7.5 m*l*) and to this was added 2M sodium nitrite (1.6 m*l*) at an ice-salt bath temperature. The azide which separated was extracted with ice-cold ether. The ethereal extracts were combined, washed with ice-cold M sodium bicarbonate, dried over sodium sulfate and evaporated *in vacuo*. The residue was dissolved in ice-cold acetonitrile together with seryl-methionine methyl ester (0.76 g, 3 mmol)[14] and the mixture was kept at 4°C for 2 days. The solvent was removed by evaporation *in vacuo* and the residue was dissolved in a mixture of ethyl acetate and water. The organic phase was washed successively with ice-cold N hydrochloric acid, 5% sodium bicarbonate and water, dried and evaporated *in vacuo* to yield a gelationous residue, which was twice reprecipitated from ethyl acetate; yield 1.04 g (60%), mp 121—123°C, $[\alpha]_D^{23}$ −13.0±0.6° (*c* 0.997, methanol).

Found: C, 52.94; H, 6.85; N, 9.65; S, 5.48%. Calcd for $C_{26}H_{40}N_4O_9S$: C, 52.41; H, 6.90; N, 9.58; S, 5.48%.

***t*-Butyloxycarbonyl-β-alanyl-tyrosyl-seryl-methionine Hydrazide (XII).** To a solution of XI (0.97 g) in dimethylformamide (6 m*l*) was added hydrazine hydrate (0.5 m*l*) and the mixture was kept at 4°C for 2 days. Addition of ethyl acetate yielded gelatinous precipitates, which were washed with cold ethyl acetate and dried *in vacuo* (1.01 g). The product cyrstallized upon heating with water; yield 0.85 g (88%), mp 187—188°C, $[\alpha]_D^{23}$ −20.1±0.5° (*c* 1.346, 50% methanol).

Found: C, 49.72; H, 7.04; N, 14.50; S, 5.15%. Calcd for $C_{25}H_{40}N_6O_8S\cdot H_2O$: C, 49.82; H, 7.02; N, 13.94; S, 5.32%.

Nitroarginyl-tryptophyl-glycine Methyl Ester Formate. *t*-Butyloxycarbonyl-nitroarginyl-tryptophyl-glycine methyl ester (II, 5.77 g)[28] was dissolved in formic acid (98—100%, 50 m*l*) and the solution was allowed to stand for 3.5 hr. The formic acid was removed by evaporation at 40—45°C and the residue was dissolved in water. The solution was washed with ether and lyophilized; yield 4.76 g (91%), mp 107—111°C, $[\alpha]_D^{23}$ +13.0±0.5° (*c* 2.062, methanol).

Found: C, 47.25; H, 6.03; N, 20.90%. Calcd for $C_{20}H_{28}N_8O_6\cdot HCOOH\cdot \frac{1}{2}H_2O$: C, 47.45; H, 5.88; N, 21.08%.

***t*-Butyloxycarbonyl-phenylalanyl-nitroarginyl-tryptophyl-glycine Methyl Ester (III).** This compound was synthesized in exactly the same manner as described previously, except for using the tripeptide ester formate obtained above instead of the trifluoroacetate.[9] Mp 176—177°C, $[\alpha]_D^{23}$ −20.4±0.2° (*c* 2.040, methanol); lit,[9] mp 172—173°C, $[\alpha]_D^{25}$ −20.1±1° (*c* 2.054, methanol).

Found: C, 56.34; H, 6.22; N, 17.58%. Calcd for $C_{31}H_{45}N_9O_9$: C, 56.42; H, 6.27; N, 17.42%.

Phenylalanyl-nitroarginyl-tryptophyl-glycine Methyl Ester Formate. Compound III (1.81 g) was dissolved in formic acid (98—100%, 18 m*l*) and the solution was kept at room temperature for 3.5 hr. After removal of the formic acid the residue was crystallized from *n*-butanol. The crystalline product was filtered off, washed with ether and dried *in vacuo*; yield 1.71 g (92%), mp 124—125.5°C, $[\alpha]_D^{23}$ −9.0±0.5° (*c* 0.977, methanol).

Found: C, 53.00; H, 6.10; N, 17.79%. Calcd for $C_{29}H_{37}N_9O_7\cdot HCOOH\cdot \frac{1}{2}C_4H_9OH$: C, 54.38; H, 6.28; N, 17.84%.

***N*$^{\alpha}$, *N*$^{\mathrm{Im}}$-Dibenzyloxycarbonyl-histidyl-phenylalanylnitroarginyl-tryptophyl-glycine Methyl Ester (IV).** This compound was synthesized in exactly the same manner as described previously, except for using the tetrapeptide ester formate obtained above instead of the corresponding trifluoroacetate,[9] in a 75% yield; $[\alpha]_D^{27}$ −22.3±0.3° (*c* 2.084, dimethylformamide). Lit,[9] $[\alpha]_D^{25.5}$ −21.5±0.5° (*c* 2.429, dimethylformamide).

Found: C, 58.63; H, 5.70; N, 15.89%. Calcd for $C_{51}H_{56}N_{12}O_{12}\cdot H_2O$: C, 58.50; H, 5.58; N, 16.05%.

Histidyl-phenylalanyl-arginyl-tryptophyl-glycine Monoacetate (VI). Benzyloxycarbonyl-histidyl-phenylalanyl-nitroarginyl-tryptophyl-glycine (V, 0.72 g)[9] and anisole (0.72 m*l*) were dissolved in anhydrous hydrogen fluoride (7—8 m*l*) at a dry-ice-acetone bath temperature and the mixture was stirred at 0°C for 30 min. After removal of hydrogen fluoride by evaporation the residue was dried over sodium hydroxide pellets overnight *in vacuo*. The residue was dissolved in water (20 m*l*) and the solution was washed thoroughly with ethyl acetate and then passed through a small column of Amberlite CG-400 (acetate form). The column was washed with portions of water. The aqueous effluents were combined and lyophilized; yield 0.64 g (98.5%), $\lambda_{max}^{0.1N\ HCl}$=279 mμ ($E_{1cm}^{1\%}$ 66.2), 288 mμ ($E_{1cm}^{1\%}$ 53.5) and $\lambda_{max}^{0.1N\ NaOH}$=280 mμ ($E_{1cm}^{1\%}$ 65.0), 288 mμ ($E_{1cm}^{1\%}$ 54.5). Paper chromatography (*n*-butanol : acetic acid : pyridine : water=30 : 6 : 20 : 24 by volume, BAPW, as solvent) showed the presence of one major component (R_f=0.47—0.53) and two traces, all of which were reactive to ninhydrin, Pauly and Ehrlich reagents; only the major one was reactive to Sakaguchi reagent. The product was used in the subsequent coupling reaction without further purification.

Benzyloxycarbonyl-γ-*t*-butyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine Monoacetate (VII). A solution of compound VI (0.83 g, 1 mmol) and triethylamine (0.28 m*l*, 2 mmol) in 90% dimethyl-

28) In a previous communication compound II was reported as amorphous solid with mp 112—114°C.[9] Later it was obtained in a crystalline state from methanol, mp 189—190°C, $[\alpha]_D^{23}$ −13.6±0.5° (*c* 1.026, dimethylformamide). Found: C, 51.94; H, 6.23; N, 19.26%. Calcd for $C_{25}H_{36}N_8O_8$: C, 52.07; H, 6.29; N, 19.53%.

formamide (10 ml) was stirred at 0°C and to this was added benzyloxycarbonyl-γ-*t*-butyl-glutamic acid *p*-nitrophenyl ester (0.46 g, 1 mmol),[29] and the mixture was stirred at 4°C overnight. An additional quantity (0.46 g) of the active ester was introduced and the mixture was kept at 4°C until the peptide VI became indetectable in thin-layer chromatography (BAPW as solvent). The reaction mixture was then added dropwise into ice-cold ethyl acetate (100 ml) to afford gelatinous precipitates, which were filtered off, washed with ethyl acetate and dried *in vacuo*. The product was reprecipitated from acid-water to give the desired hexapeptide (VII); yield 0.84 g (70%), $[\alpha]_D^{23}$ −26.6±0.5° (*c* 1.377, 50% acetic acid). Lit,[30] $[\alpha]_D$ not given.

Found: C, 52.86; H, 6.74; N, 13.98%. Calcd for $C_{51}H_{64}N_{12}O_{11}\cdot CH_3COOH\cdot 7H_2O$: C, 52.73; H, 6.85; N, 13.92%.

γ-*t*-Butyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine Monoacetate (VIII). Compound VII (0.265 g) in 50% acetic acid (10 ml) was hydrogenolyzed in the presence of palladium black for 2.5 hr. After the catalyst had been removed by filtration the filtrate was evaporated *in vacuo* at a bath temperature of 45—50°C. The residue was lyophilized from acetic acid and dried over sodium hydroxide pellets *in vacuo*; yield 0.22 g. The product behaved as a single component in paper chromatography (*n*-butanol: acetic acid : water=4 : 1 : 2 by volume, BAW, as solvent).

Found: C, 49.46; H, 6.77; N, 15.49%. Calcd for $C_{43}H_{58}N_{12}O_9\cdot CH_3COOH\cdot 8H_2O$: C, 49.53; H, 7.21; N, 15.40%.

***t*-Butyloxycarbonyl-β-alanyl-tyrosyl-seryl-methionyl-γ-*t*-butyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl glycine (XIII).** To a solution of XII (0.45 g, 0.75 mmol) in 90% dimethylformamide (4.5 ml), which had been chilled in an ice-salt bath, were added ice-cold N hydrochloric acid (2.0 ml) and ice-cold M sodium nitrite (0.83 ml) and the mixture was stirred for 4 min. Ice-cold saturated sodium chloride (20 ml) and ice-cold ethyl acetate were then introduced. The aqueous layer which separated was extracted twice with ethyl acetate. The organic solutions were combined, washed with cold 5% sodium bicarbonate, dried over sodium sulfate and added to a solution of VIII (0.50 g, 0.5 mmol) and triethylamine (0.21 ml, 1.5 mmol) in dimethylformamide (15 ml) and the mixture was evaporated at a bath temperature of 10—15°C *in vacuo* to remove ethyl acetate. The resulting clear solution was kept at 4°C overnight. An additional quantity of the azide (prepared from 0.23 g of XII as has been described above) was introduced and the reaction mixture was kept at 4°C for one more day. It was then added dropwise into ice-cold ethyl acetate (200 ml) to afford amorphous precipitates, which were filtered off, washed with ethyl acetate and dried *in vacuo*; yield 0.69 g (94%). Reprecipitation from dimethylformamide-methanol (2 : 5) gave the pure decapeptide derivative (XIII) in a 66 per cent recovery; $[\alpha]_D^{23}$ −19.4± 0.7° (*c* 0.882, dimethylformamide). The product behaved as a single component (R_f=0.54—0.57) in thin-layer chromatography (dimethylformamide : ethyl acetate : acetic acid=15 : 10 : 2 by volume as solvent).

Found: C, 51.62; H, 6.66; N, 14.06; S, 2.64%. Calcd for $C_{68}H_{94}N_{16}O_{17}S\cdot 8H_2O$: C, 51.57; H, 7.00; N, 14.15; S, 2.02%.

β-Alanyl-tyrosyl-seryl-methionyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycyl-lysyl-prolyl-valyl-glycyl-lysyl-lysyl-arginyl-arginine Amide, [β-Ala[1]]-ACTH(1-18)-NH_2 (I). To a solution of compound XIII (0.37 g, 0.25 mmol) in dimethylformamide (10 ml) was added ice-cold N hydrochloric acid (0.25 ml) at 0°C and the solution was immediately added to ice-cold ethyl acetate-ether (1 : 1, 200 ml). The resulting precipitates were filtered off, washed with ether and dried *in vacuo*; 0.36 g. These precipitates were dissolved in dimethylformamide (5 ml) and to this were added *N*-hydroxysuccinimide (0.115 g, 1 mmol) and *N*,*N*′-dicyclohexylcarbodiimide (0.21 g, 1 mmol) successively and the mixture was stood at 4°C overnight. After removal of the urea which separated, the filtrate was introduced into ice-cold ethyl acetate-ether (1 : 1, 200 ml). The precipitates were filtered off, washed with ether and dried *in vacuo* to give the decapeptide active ester; 0.39 g.

The triacetate of N^{ε}-t-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-arginyl-arginine amide (0.23 g, 0.155 mmol)[14] was dissolved in dimethylformamide (3 ml) and triethylamine (0.24 ml) was added. To this was then added a solution of the decapeptide active ester obtained above (0.39 g, 0.24 mmol) in dimethylformamide and the reaction mixture (total volume *ca.* 5 ml) was allowed to stand at 4°C for 60 hr. The crude protected octadecapeptide was obtained as amorphous solid when the reaction mixture was introduced into cold ethyl acetate (100 ml); yield 0.55 g.

The protected peptide obtained above (0.55 g) was dissolved, for deprotection, in 90% trifluoroacetic acid (6 ml) and the solution was kept at room temperature for 60 min, after which the solvent was removed by evaporation *in vacuo*. The residue was dissolved in water and the solution was passed through a column (2.2×7 cm) of Amberlite CG-400 (acetate form); the column was washed with portions of water. The aqueous solutions were combined and concentrated to 10—15 ml *in vacuo*. To the concentrate was added M mercaptoethanol (1 ml) and the mixture was incubated at 37°C overnight and lyophilized. The crude deblocked peptide (0.51 g) thus obtained was subejcted, for purification, to chromatography on a column (2.7×12 cm) of carboxymethyl cellulose (CMC, Serva, 0.6 meq/g) using an ammonium acetate buffer (pH 6.8, 4000 ml) with a linear concentration gradient of 0.05—0.4M.[31] The results of chromatography are shown in Fig. 2. The fractions (15 ml/tube) corresponding to a main peak (tubes 166—245) were combined and the bulk of the solvent was removed *in vacuo*. The residue was lyophilized repeatedly to constant weight to give the partially purified I; 0.22 g (54%). The product (0.2 g) was chromatographed, for further purification, on a column (2.2×18 cm) of CMC (Serva, 0.6 meq/g) using an

31) A buffer with a particular concentration, for example 0.05M, was prepared by adding the reagent grade aqueous ammonia (28%, w/w) to 0.05N acetic acid until the desired pH was obtained.

ammonium acetate buffer (pH 6.8, 2000 m*l*) with a linear cocentration gradient of 0.05—0.8M. The fractions (7.5 m*l*/tube) corresponding to a main peak (tubes 125—160) were combined, concentrated and lyophilized to obtain the pure peptide I; 0.17 g, $[\alpha]_D^{27}$ $-54.0\pm1.8°$ (*c* 0.515, 0.1N acetic acid). $\lambda_{max}^{0.1N\ HCl}$=280 m$\mu$ ($E_{1cm}^{1\%}$ 23.0), $\lambda_{shoulder}^{0.1N\ HCl}$=288.5 m$\mu$ ($E_{1cm}^{1\%}$ 17.5) and $\lambda_{max}^{0.1N\ NaOH}$= 281.5 m$\mu$ ($E_{1cm}^{1\%}$ 24.9), 288 mμ ($E_{1cm}^{1\%}$ 24.3). The peptide behaved as a single component to ninhydrin, Pauly, Ehrlich, Sakaguchi and methionine (PtI_6'') reagents in paper chromatography (BAPW as solvent) and in paper electrophoresis (600 V/36 cm, in 2N acetic acid). Amino acid ratios in acid hydrolysate:[16] Ser 0.75, Glu 0.90, Pro 0.91, Gly 1.89, Val 1.00, Met 0.96, Tyr 1.01, Phe 0.97, β-Ala 1.00, Lys 2.83, His 0.92, Arg 2.82, Trp 0.55, NH_3 1.42. The Trp/Tyr ratio in intact I was determined spectrophotometrically to be 1.16.[17]

Enzymic Studies. A commercial preparation of hog kidney leucine aminopeptidase (LAP) was obtained from Worthington Biochemical Corporation, Freehold, New Jersey, U. S. A.; LAP-C 7HB.[32]

The enzyme preparation (a suspension in 75% saturated ammonium sulfate) was dialyzed against 0.005M trishydroxymethyl aminomethane (Tris) buffer (pH 8.0, 0.005M $MgCl_2$) at 4°C before use. A DEP-treated LAP was obtained in the following way: the LAP suspension (5 mg enzyme) was diluted five fold with 0.005M Tris buffer and to this was added 0.08 m*l* of M diisopropyl fluorophosphate (DFP) in isopropyl alcohol, and the mixture was incubated at 37°C for 45 min and then dialyzed against 0.005M Tris buffer at 4°C. The LAP activity of the enzyme solutions was determined at pH 8.3 and 25°C according to Tuppy *et al.*[33] with some modifications, using L-leucine *p*-nitroanilide (LNA) as substrate. One LAP unit was temporarily defined as the amount of enzyme that produced, in the present assay procedure,[34] an increase in absorbance at 400 mμ of 0.001 per minute above the blank, using 1-cm cells in a Hitachi photoelectric spectrophotometer.

The syntheses of ACTH(1-18)-NH_2 (Ia) and [Gly^1]-ACTH(1-18)-NH_2, (Ib), used as substrates, were described previously.[4,8] [β-Ala^1]-ACTH(1-4)-$NHNH_2$ and [β-Ala^1]-ACTH(1-10)-OH as substrates were prepared from compounds XIV and XIII, respectively, by the treatment with formic acid.[10]

For the measurements of the cleavage of synthetic substrate by LAP, a mixture comprising one part of 0.1 mM substrate (in water), one part of 0.05M Tris buffer (pH 8.3) and a half part of enzyme (4.88 units/m*l*, LNA as substrate) was incubated at 37°C. From the incubation mixture 0.5-m*l* samples were withdrawn and immediately mixed with 0.5 m*l* of ninhydrin reagent[35] and the mixture was then heated in a boiling water bath for 15 min and chilled; after appropriate dilution with 50% ethanol, the absorbance at 570 mμ was determined in a Hitachi spectrophotometer. For each run, control incubation mixtures without substrate or without enzyme were analyzed. In the ninhydrin reaction a standard solution of L-leucine was also checked every time as a reference. The results of the enzymic cleavage of peptides, I, Ia, and Ib, by DFP-treated LAP are shown in Fig. 3, where the release of amino acids is expressed in terms of the leucine concentration.

Characterization of Biological Properties. *1) Adrenal-stimulating Activity.* Assays for adrenal-stimulating activities were carried out according to five different procedures. The adrenal ascorbic acid depleting activity in the hypophysectomized rat was assayed by the method of United States Pharmacopeia, XVII.[19] The *in vitro* steroidogenic activity was assayed by the Saffran and Schally method.[20] The *in vivo* steroidogenic activity by the intravenous administration to hypophysectomized rat was assayed by the method of Lipscomb and Nelson[21] with a minor modification.[36] The *in vivo* steroidogenic activity was also assayed in the dexamethasone-pentobarbital-primed mouse.[22] In addition, the steroidogenic activity by the intramuscular administration to hypophysectomized rat was determined, where a preparation (0.05 m*l*/rat) was injected into the thigh muscle and a blood sample was collected from the abdominal aorta 30 min after the injection. Throughout the experiments, the Third USP Corticotropin Reference Standard was used as a standard and the production of 11-hydroxycorticosteroids (11-OHCS) was determined by the fluorophotometric method of Peterson.[37] For each assay method several determinations were performed and the data obtained independently were submitted to statistical treatment by the Sheps and Moore procedure.[38] The results of these assays are summarized in Table 1.

2) Time Course of Steroidogenesis. The change in steroidogenic activity of the peptides I and Ib, administered by intramuscular injection, was followed: 5-μg/rat samples (1 mg peptide/m*l*) were injected into the thigh muscle of the hypophysectomized rats and blood samples were collected from the abdominal aorta in appropriate time intervals starting 30 min after the injection. The plasma 11-OHCS level was determined fluorophotometrically.[37] The results are shown in Fig. 4.

3) Lipotropic Activity. Assays were carried out according to the method described by Tanaka *et al.*[23] with the rat epididymal and the rabbit perirenal adipose tissues. The increase of nonesterified fatty acid concentration in both medium and tissue is the parameter. The results are summarized in Table 2, in which the activity is expressed in terms of the minimal effective dose per 50 mg itssue.

32) The manufacturer denotes that the preparation has an activity of 150 units/mg (L-leucine amide as substrate) and is free from the activities toward benzoyl-L-tyrosine ethyl ester and benzoyl-L-arginine ethyl ester or tosyl-L-arginine methyl ester.

33) H. Tuppy, U. Wiesbauer and E. Wintersberger, *Z. Physiol. Chem.*, **329**, 278 (1962).

34) A 10-m*l* assay medium is composed of 0.625 mM substrate solution (4 m*l*), 0.1M phosphate buffer (pH 8.3, 4 m*l*) and an enzyme test solution (2 m*l*), which has been prepared from a stock solution by appropriate dilution with 0.005M Tris buffer (pH 8.0, 0.005M $MgCl_2$). With a single run in this assay medium four consecutive determinations are usually possible in appropriate time intervals.

A Novel Reduction in the Presence of Precipitated Metals. II. The Behavior of Precipitated Metals and Water in Catalytic Reduction

Koji SAKAI, Masayoshi ISHIGE,*1 Ken-ichi WATANABE and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received September 26, 1969)

The ppt-metal-catalyzed reduction, which is performed by refluxing the substrates with water in the presence of ppt-metals, was investigated in detail. The participation of water as a hydrogen donor was demonstrated by the fact that benzaldehyde was reduced to the corresponding deuterated alcohols when heated with D_2O in the presence of ppt-Ni. The scope of the reduction was established by the reaction of cyclohexanone with ppt-metals and water. The most preferable H_2O/cyclohexanone molar ratio was found to be about 15 : 1. The reaction was accelerated when a 0.25N aqueous solution of sodium chloride was used instead of water. It was found that the order of the abilities of various ppt-metals to decompose water is different from that of the abilities to catalyze the reduction of cyclohexanone. The values of the activation energies for the reduction catalyzed by ppt-Ni and ppt-Ni,Co were found to be 4.0 kcal/mol and 7.5 kcal/mol respectively. From these facts, it was concluded that the ppt-metal-catalyzed reduction consists of two steps: the reaction of water with zinc or zinc compounds to supply a hydrogen source necessary for the hydrogenation, followed by ordinary catalytic hydrogenation.

In previous papers,[1,2] the utilization of precipitated metals (abbreviated as ppt-metals) as catalysts for the reduction of various compounds, with water as the hydrogen donor, has been described. The reduction was easily attained by refluxing with water in the presence of ppt-metal, the co-existence of any acids or bases being unnecessary. It has already been proposed[2] that this catalytic reaction might involve a reaction step similar to that in the ordinary catalytic hydrogenation. The present paper will deal with an extensive study of this reaction, a study covering the behavior of water and the function of catalyst metals.

Results

Deuteration of Benzaldehyde with D_2O. In order to provide direct evidence for the participation of water as a hydrogen donor, the reduction of benzaldehyde with D_2O in the presence of ppt-Ni was investigated.

The experiment was carried out in a sealed tube by heating benzaldehyde with 99.75% D_2O in the presence of ppt-Ni; deuterated benzyl alcohol was thus obtained in a good yield. However, the attempt to determine the deuterium distribution in the product by the spectroscopic method failed because of the rapid exchange between the D and H in the hydroxyl group by means of the moisture in the air. Therefore, the product, which was assumed to be a mixture of C_6H_5-CHD-OD and

*1 Present address: Chemical Laboratory, Ochanomizu University, Ootsuka, Bunkyo-ku, Tokyo.

2) K. Sakai, M. Ishige, H. Kono, I. Motoyama, K. Watanabe and K. Hata, *ibid.*, **41**, 1902 (1968); M. Ishige, K. Sakai, K. Watanabe and K. Hata, *Shokubai (Catalyst)* (Tokyo), **11**, 50 (1969).

C_6H_5–CD_2–OD, was completely changed to C_6H_5–CHD–OH and C_6H_5–CD_2–OH by vigorous shaking with a large amount of water. The NMR spectrum of the sample thus obtained showed only three sharp singlets, at τ 2.85, 5.60, and 6.35; these singlets are assignable to phenyl, methylene, and hydroxyl protons, and the intensities correspond to 5, 0.4, and 1 protons respectively. From the proton intensities in NMR, the ratio between C_6H_5–CHD–OH and C_6H_5–CD_2–OH was estimated to be approximately 40 : 60. The IR spectram of the deuterated alcohols showed an intense band at 2200 cm^{-1} assignable to the stretching vibration of the CD group. The disappearance of the OD band at 2510 cm^{-1} showed the complete exchange of the D in the hydroxyl group for H. The absorption bands in the 650—900 cm^{-1} region, observed in a *n*-hexane solution (0.014 mol/*l*), distinctly showed the presence of a monosubstituted benzene ring, thus demonstrating that no deuterium exchange of ring protons had occurred during the reduction.

These experimental results prove that water acts as a hydrogen donor as well as a solvent in this reduction. This participation of D_2O as a hydrogen donor in the reduction led to the suggestion that this reduction with D_2O would be useful for the synthesis of various deuterated organic compounds as a simpler method than the well-known reduction with $LiAlD_4$ or $NaBD_4$.

The Reduction of Cyclohexanone Using a Varying Amount of Water. Though the presence of water is indispensable for the reduction, the use of an excess of water may be unfavorable because of the low concentration of the reactants. We tried to ascertain the adequate quantity of water suitable for the reduction by using cyclohexanone as a substrate. The reduction reaction of cyclohexanone to cyclohexanol in the presence of ppt-Ni was apparently first-order in the disappearance of the ketone. Typical examples of the apparent first-order rate constants of cyclohexanone in the reactions with various quantities of water are summarized in Table 1. In order to keep the reaction mixture homogeneous, a given quantity of dioxane was added to the aqueous solution. As is shown in Table 1, when a comparatively small quantity of water is used the rate constant increases with the increase in the quantity of water used. However, the reaction rate gradually decreased when the quantity of water exceeded a certain limit, as had been expected from the decreased concentration of cyclohexanone. The most favorable result was obtained when the H_2O/cyclohexanone mole ratio was about 15 : 1 (Exp. 3).

6	43.2	2.4	20	13.3	9.34

The Promoting Effect of Sodium Chloride[2,3] on the Reduction of Cyclohexanone. The ppt-Ni is generally prepared by the rapid addition of a hot aqueous solution of nickel chloride to slushy zinc dust. When nickel nitrate was used in place of nickel chloride, a ppt-Ni with a lower catalytic activity was obtained. On the other hand, when a nickel chloride solution containing a suitable amount of sodium chloride was used, the activity of the ppt-Ni increased. These findings suggest that the catalytic properties are greatly affected by a small amount of contaminant in the catalyst. In order to get further information on the effect of the chloride ion, the rates of the reduction of cyclohexanone with ppt-Ni in the presence of an aqueous sodium chloride solutions of various concentrations were compared with each other. The results are given in Table 2. As is shown in the table,

Table 2. The effect of NaCl on the reduction of cyclohexanone

Cyclohexanone 9.8 g; Dioxane 13 m*l*; Aqueous NaCl solution 18 m*l*; ppt-Ni 20 g

Exp. No.	Concentration of NaCl N	Rate constant $k(\times 10^2)$ (hr^{-1})
7	0.000	5.21
8	0.080	5.40
9	0.165	4.31
10	0.250	8.58
11	0.500	6.74

the reaction was accelerated by the addition of sodium chloride, the most favorable concentration found to be 0.25N. On the other hand, no promoting effect on the reaction was observed when a potassium chloride was used instead of sodium chloride.

X-Ray diffraction studies revealed the composition of the ppt-Ni. As is shown in Fig. 1, the X-ray diffraction diagram[1,4] of ppt-Ni showed several sharp bands assignable to Zn, Zn(OH)Cl, and ZnO. Besides these constituents, ppt-Ni

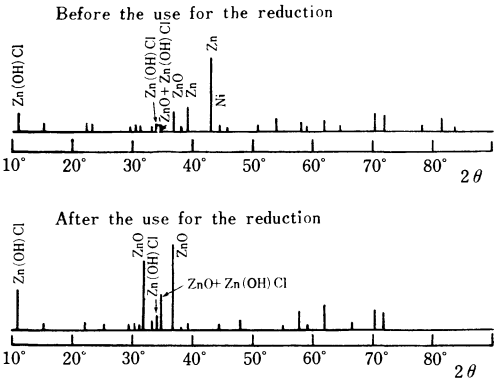

Fig. 1. X-ray diffraction diagrams of ppt-Ni.

also contains Ni, $ZnCl_2$, and $Zn(OH)_2$, though they are not revealed in the X-ray diffraction diagram. On the other hand, a ppt-Ni recovered after being used for the reduction by refluxing with water showed a different diffraction diagram, one in which the bands of Zn disappeared almost completely, while those of ZnO and Zn(OH)Cl were enhanced. This implies that the Zn and $ZnCl_2$ in the ppt-Ni were converted into ZnO, $Zn(OH)_2$, and Zn(OH)Cl in the course of the reaction. It is noteworthy that, when the reaction was carried out in a sodium chloride solution, a remarkable increase in Zn(OH)Cl was observed in the recovered ppt-Ni. From these experimental results, it is concluded that the reaction of water with zinc or zinc chloride is responsible for the supply of hydrogen necessary for the hydrogenation.

The Relationship between the Volume of Generated Hydrogen and That of the Reacted Hydrogen in the Reduction of Cyclohexanone. The reduction with water in the presence of ppt-Ni may be supposed to be composed of two steps: the generation of hydrogen from water and the reduction of organic compounds with the hydrogen.

It has been shown that the generation of hydrogen from water is attributable to the reaction of zinc in the catalyst with water, and also to the difference in ionization potential between zinc and other metals, such as nickel, in the ppt-metal, because the reaction of water with zinc dust alone is extraordinarily slow. Therefore, the amount of hydrogen generated during the reaction depends greatly upon the kind of ppt-metal used. It has previously been reported that the ppt-metal is not useful for ordinary catalytic hydrogenation.[2] However, it has been found*2 that cyclohexene can be hydrogenated under an ordinary pressure of hydrogen in the presence of ppt-Ni, though the reaction velocity is slow. In this hydrogenation, the activity of the catalyst was found to be dependent on the procedure of its preparation and on the amount of nickel in it. Therefore, it may be presumed that the behavior of ppt-metals in the reduction step is analogous to that of the ordinary hydrogenation catalysts. In this step, metals other than zinc in the ppt-metals, such as nickel or cobalt, may play an important part, while zinc may serve for the step of decomposing water.

In the present study, the activities of several ppt-metals were compared for each of the two steps. The hydrogen gas generated when water was refluxed with the ppt-metal alone was introduced into a gas burette and then estimated volumetrically. The volume of hydrogen gas generated when the reaction was carried out in the presence of cyclohexanone under the same conditions was measured in a similar way. Then the volume of hydrogen reacted with cyclohexanone was calculated and compared with the amount of cyclohexanol, determined by gas chromatography. The results are listed in Table 3.

As may be seen in the table, the abilities of the ppt-metals to decompose water were found to increase in the order: ppt-Ni<ppt-Cu<ppt-Ni, Co<ppt-Ni,Cu. This order may be expected if the ability of the ppt-metal to produce hydrogen originates mainly in the difference in ionization potential between the metal in question and zinc.

On the other hand, the ability of each ppt-metal to catalyze the reduction of cyclohexanone was considered to be represented by the ratio of the amount of hydrogen reacted with cyclohexanone

TABLE 3. THE RELATIONSHIP BETWEEN VOLUME OF GENERATED HYDROGEN AND OF THE REACTED HYDROGEN

ppt-metal 0.8 g; H_2O 1.4 m*l*; dioxane 1 m*l*; cyclohexanone 0.5 g; reaction time 2.5 hr

Catalyst	Volume of generated H_2		Hydrogen reacted V_1-V_2	Ratio of reacted hydrogen	Yield of cyclohexanol
	in the absence of cyclohexanone V_1 (m*l*)	in the presence of cyclohexanone V_2 (m*l*)	V_3 (m*l*)	V_3/V_1 (%)	(%)
ppt-Ni	90.6	56.5	34.1	38	24
ppt-Cu	120.6	106.4	14.2	12	15
ppt-Ni,Co	138.3	96.4	41.9	30	25
ppt-Ni,Cu	160.5	142.8	17.7	11	9

*2 A private communication from Y. Urushibara and H. Tomoda.

to the total amount of hydrogen generated by the decomposition of water. The catalytic activity may also be represented by the yield of cyclohexanol. As may be seen in Table 3, the ratio of the amount of reacted hydrogen was approximately parallel to the yield of cyclohexanol. Thus, the catalytic abilities of the ppt-metals were found to increase in the order: ppt-Ni,Cu<ppt-Cu<ppt-Ni <ppt-Ni,Co. This order coincides with that of the catalytic activities of the corresponding Urushibara catalysts which are prepared from these ppt-metals. The fact suggests that the reduction step of the ppt-metal-catalyzed reaction may be similar to that of oridnary catalytic hydrogenation.

The Relative Activities of ppt-Metals in the Reduction of Cyclohexanone.[2] The rate constant was determined for the reduction of cyclohexanone by water in the presence of several ppt-metals. The results are summarized in Table 4 and Fig. 2.

TABLE 4. THE RATE CONSTANTS OF THE REDUCTION OF CYCLOHEXANONE AT 111.5±2°C CATALYZED BY VARIOUS PPT-METALS

Cyclohexanone 0.26 m*l*; H_2O 0.68 m*l*; dioxane 0.50 m*l*; ppt-metal 0.4 g; in a sealed tube

Catalyst	Rate constant $k(\times 10^2)(hr^{-1})$
ppt-Ni,Co	24.5
ppt-Ni,Fe	17.1
ppt-Ni	14.8
ppt-Co	7.17
ppt-Cu	3.76
ppt-Ni,Cu	1.75
ppt-Fe	0.924

The relative activities are found to be in the order: ppt-Fe<ppt-Ni,Cu<ppt-Cu<ppt-Co<ppt-Ni<ppt-Ni,Fe<ppt-Ni,Co. This order is approximately analogous to what has been proposed on the basis of a comparison of the yields of the reduction products.[2]

The Effect of Temperature on the Reduction of Cyclohexanone. The rate constant of the reduction of cyclohexanone was observed at various reaction temperatures; the results are shown in Table 5. Figure 3 shows the Arrhenius plots of the rate constants shown in Table 5. The values of the activation energies and the activation entropies were calculated (from Fig. 3) to be 4.0 kcal/mol and −72 e.u./mol, and 7.5 kcal/mol and −59 e.u./mol, respectively, for the reductions catalyzed by ppt-Ni and by ppt-Ni,Co.

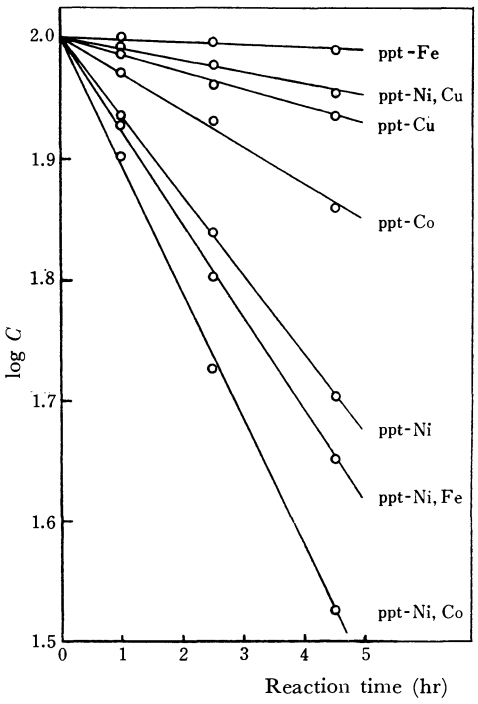

Fig. 2. The first order rate plots for the reduction of cyclohexanone.

$$C=\frac{[\text{cyclohexanone}]}{[\text{cyclohexanone}]+[\text{cyclohexanol}]}\times 100,$$

where [ ] denotes the molar concentration.

Discussion

A mixture of dioxane and water has proved to be an excellent solvent for studies of the ppt-metal-catalyzed reaction because dioxane is almost entirely indifferent to the reaction. Besides the indifference of dioxane to the reaction, the dioxane-water mixed

solvent*3 has the following merits: (1) it can dissolve almost all organic compounds, (2) it can easily be separated from the reaction mixture in most cases, and (3) the closeness of the boiling points of the two components of the solvent makes it easy to keep the reaction temperature constant, even during refluxing over a long period.

It has been demonstrated, by an X-ray diffraction study, that ZnO and Zn(OH)Cl are produced during the reduction reaction by refluxing with water.*4 The increase in ZnO suggests that the difference in ionization potentials between a catalyst metal, such as nickel, and zinc may lead to the decomposition of water through a coordination of the water to the zinc. The increase in Zn(OH)Cl may be explained in terms of the participation of $ZnCl_2$, which is necessarily present in ppt-metal. The catalytic behavior of such metal halides as Lewis acids is well known.[5] In a ppt-metal-catalyzed reduction, a donor-acceptor complex may be formed by the combination of water, as a Lewis base, with zinc chloride in the ppt-metal, thus, leading to a protonic acid,[6] for example:

$$H_2O + ZnCl_2 \rightarrow \begin{matrix} H \\ H \end{matrix}\!\!>\!O \rightarrow ZnCl_2 \rightarrow H^+[Zn(OH)Cl_2]^-$$

The formation of Zn(OH)Cl during the reaction may be through this protonic acid.

The activation energy of the catalytic hydrogenation of cyclohexanone with U-Ni-B at room temperature under an ordinary pressure was reported by Nishimura to be 5.3 kcal/mol.[7] The value resembles that of the ppt-Ni-catalyzed reduction of cyclohexanone by water. This fact suggests that the function of ppt-Ni as a catalyst is similar to that of the ordinary hydrogenation catalysts.

Whereas the Clemmensen-type reduction of a ketone often affords dimerization of rearrangement products, the ppt-Ni-catalyzed reduction never produces such by-products. However, when the reduction of ketones in the presence of ppt-Ni was carried out in an acidic or an alkaline solution,*5 a different result, one which rather resembles that of the Clemmensen reduction, was observed.

In ppt-metals used as catalysts, active sites for hydrogenation are presumably arranged on the surface of such metals as nickel and cobalt, not on the surface of zinc. This presumption is supported by the facts that, on the one hand, the rate of reduction is dependent on the kind of ppt-metal, and that, on the other hand, the rate stays constant in spite of the consumption of zinc during the reaction.

The fact that the activation energy for ppt-Ni differs from that for ppt-Ni,Co suggests the intervention of a transition state in which cyclohexanone forms a certain complex with the catalyst metal. Thus, the mechanism of the reduction may be considered to be as follows. The coordination of water to zinc or zinc chloride leads to a protonic acid, through which hydrogen is then transferred to active sites for the hydrogenation on the surface of nickel or cobalt. The following step is the reaction of cyclohexanone and hydrogen, each of which is adsorbed on the active sites of the catalyst metal, in just the same way as in ordinary catalytic hydrogenation.

Experimental

Materials. *Benzaldehyde.* Commercial benzaldehyde was purified by fractional distillation under reduced pressure.

Deuterium Oxide. Commercial 99.75% D_2O (Showa Denko K. K.) was used.

Cyclohexanone. Commercial cyclohexanone was purified as follows. About 100 m*l* of commercial cyclohexanone was stirred with a solution of potassium dichromate (4 g) and concentrated sulfuric acid (5 m*l*) in 50 m*l* of water at room temperature. When the color of the

solution turned dark green (after about 30 min), the cyclohexanone layer was separated, washed with water several times, dried over anhydrous magnesium sulfate, and distilled. A fraction boiling at 153—154°C was collected. The purity of the sample was verified by gas-chromatographic analysis to be over 99%.

The Reduction of Benzaldehyde with D_2O. A mixture of 1 m*l* of benzaldehyde, 4 m*l* of D_2O, and 3 g of ppt-Ni was heated at 100°C in a sealed tube for 12 hr. After the reaction was over, the reaction mixture was filtered quickly. The filtrate was extracted with ether, and the solid on the filter was washed with ether. All the ethereal solution was combined, and the ether was carefully evaporated away. The residue was shaken vigorously with an excess of water to exchange the D in the hydroxyl group for H, and the deuterated benzyl alcohol was extracted with ether.

Kinetic Measurements. *(1) The Reduction of Cyclohexanone with H_2O* (Table 1). In a 100-m*l*, three-necked, round flask equipped with a reflux condenser, a given amount of water and dioxane (shown in Table 1) was placed together with 9.8 g of cyclohexanone (0.1 mol). The solution was heated to 92.5°C, and then 20 g of ppt-Ni (containing 2 g of nickel) was rapidly added. While the mixture was kept at a constant temperature, 0.2—0.3 m*l* portions of the suspending solution were pipetted out at appropriate intervals. Each sample was kept standing for a while until a small amount of the suspending particles had settled, and was then analyzed by gas chromatography.

(2) The Activity of ppt-Metals (Table 4). For each run of the experiment, several sealed ampoules were prepared, each of them containing 0.26 m*l* of cyclohexanone, 0.50 m*l* of dioxane, 0.68 m*l* of water, and 0.4 g of ppt-metal. The tubes were immersed side by side in an oil bath which had been previously kept at 111.5 ± 2°C. At definite intervals tubes were taken out, one after another, and cooled to 0°C with ice. The composition of the reaction mixture was analyzed immediately by gas chromatography. The decrease in the concentration of cyclohexanone was plotted on a graph for each ppt-metal (Fig. 3).

(3) Measurement of the Hydrogen Gas Liberated (Table 3). In a round, 20-m*l* flask connected to a gas-burette through a reflux condenser, 1 m*l* of dioxane and 1.4 m*l* of water were placed. The mixture was heated to boiling, and then 0.8 g of a ppt-metal was rapidly added. After heating for 2.5 hr, the volume of hydrogen generated was measured by a gas-burette. Another run was carried out by the same procedure and under the same conditions except that it was in the presence of 0.50 g of cyclohexanone. Besides the measurement of the volume of the hydrogen generated, cyclohexanol produced in the solution was analyzed by gas chromatography.

The authors wish to express their hearty thanks to Professor Dr. Michio Kobayashi for his helpful advice and discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1177—1181 (1970)

The Photosensitized Reaction of Deoxyguanosine in the Presence of Methylene Blue*1

Hitoshi FUJITA and Hideo YAMAZAKI*2

Chemistry Division, National Institute of Radiological Sciences, Anagawa, Chiba

(Received September 27, 1969)

The kinetics of the photosensitized decomposition of deoxyguanosine with methylene blue was studied by means of spectrophotometric measurements. The reaction rate increased with an increase in the concentration of the reactant or of oxygen up to a saturation level for each case at a given concentration of the dye. In a buffer solution of a lower phosphate concentration, a larger rate was observed. On the basis of these dependencies of the rate, the reaction scheme was discussed, and the ratios of some rate constants were estimated based on Schenck's mechanism. A preliminary NMR measurement of the protons of deoxyguanylic acid in D_2O suggested that the base-part of the nucleotide was specifically attacked by this photosensitized reaction.

Photodynamic action, namely, a dye-sensitized reaction of biological systems, is known in a wide variety of organisms.[1,2] For example, the muta-

tions of bacteria and viruses are induced,[3,4] and the transforming DNA of *Diplococcus pneumoniae* is inactivated by the photodynamic action with methylene blue, acridine orange, *etc.*[5,6] Thus, deoxyribonucleic acid (DNA) seems to be a main target for this action in living organisms. In order to interpret the photosensitivity of organisms, knowledge about the relationship between the chemical alterations of DNA and the resultant biological phenomena is required. Studies of the dye-sensitized reaction of the components of nucleic acids would give basic information. Simon and van Vunakis[7-9] found that guanine derivatives in the components of DNA or RNA were preferentially destroyed by the sensitization of methylene blue. Each derivative consumes one mole of oxygen for each mole of substrate (reactant), accompanied by the loss of ultraviolet absorbance,[7] and the destructive reaction of deoxyguanosine is of the first-order.[8] They also studied the effects of dye concentration, light intensity, temperature, and pH on this reaction.[8]

In this article, we will discuss the reaction kinetics of the methylene blue-sensitized destruction of deoxyguanosine, with an emphasis on the effects of the concentrations of the substrate, oxygen, and the phosphate buffer on the reaction rate.

Experimental

Materials. Methylene blue was obtained from E. Merck Ag., while deoxyguanosine, deoxyadenosine, deoxycytidine, thymidine, deoxyguanylic acid, and 2-deoxy-D-ribose were from Sigma Chemical Co. All the reagents were used without purification. The molar extinction coefficient of methylene blue was measured to be 74000 at 665 mμ.

Irradiation. Methylene blue and the substrate were dissolved in a phosphate buffer. This mixed solution in silica cuvettes (1 cm in path length) was irradiated with visible light. Four photoflood lamps (500 W—100 V) were used at 75 V. Circulating-water filters (5 cm thick) were interposed between the lamps and the cuvettes to absorb thermic rays. The alignment for irradiation is shown in Fig. 1. The light intensity was adjusted so as to be the same at each cuvette. The reaction temperature was not controlled, since the rate constant of the destruction of deoxyguanosine did not vary between 6 and 58°C.[8]

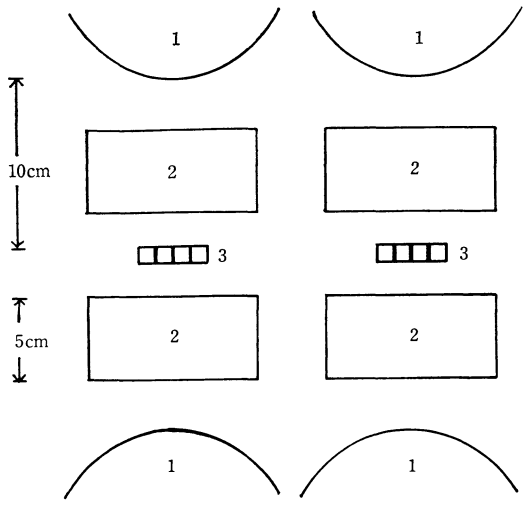

Fig. 1. Alignment of lamps (1), water-filters (2) and cuvettes (3).

Control of the Oxygen Concentration. Some cuvettes were designed to have provisions for bubbling mixtures of air and nitrogen gas in various ratios through sample solutions prior to and during irradiation. The concentration of oxygen in a solution was estimated from the solubility of gas at the experimental temperature. Nitrogen gas was passed through an alkaline-pyrogallol solution to eliminate the contaminating oxygen, and then through water, before being led into the reaction mixture.

Analysis. After irradiation, twenty mg of cation exchange resin (Dowex-50, Na-form) were added to the reaction mixture (3 m*l*) in order to remove methylene blue. The resin was added before the irradiation for the reference sample. The concentration of the substrate in the supernatant solution was measured with a Cary-14-spectrophotometer.

NMR Measurements. Deoxyguanylic acid and methylene blue were dissolved in D_2O to be 5% ($=1.7\times10^{-1}$M) and 3.3×10^{-4}M respectively. One milliliter of this mixed solution was poured into a cylindrical Pyrex reaction vessel (2.6 cm in diameter, 1.7 cm deep) with an inlet and an outlet tube. The thickness of the solution in this vessel was only 1.9 mm. After the inlet and the outlet had been sealed, the solution was irradiated using a photoflood lamp (500 W—100 V) working at 80 V at a distance of 8 cm over the vessel. The circulating water filter was also used in this case. The NMR spectra of the solution before and after the irradiation were measured with a Varian NMR spectrometer, HR-100. The relative signal intensity was determined by measuring the area of each signal on recording paper.

Results

Specificity of the Reaction. Our first interest was in ascertaining whether all the nucleosides constituting DNA submit to the sensitizing reaction of methylene blue. The specific destruction of deoxyguanosine in an aerated aqueous solution was confirmed by measuring the ultraviolet absorp-

tion; this is in agreement with the finding of Simon and van Vunakis.[8] In connection with the specificity, the red shift of the visible absorption peak of the dye upon the addition of various nucleosides was measured (Fig. 2). The interaction of methylene blue with deoxyadenosine or deoxyguanosine is stronger than that with deoxycytidine or thymidine.

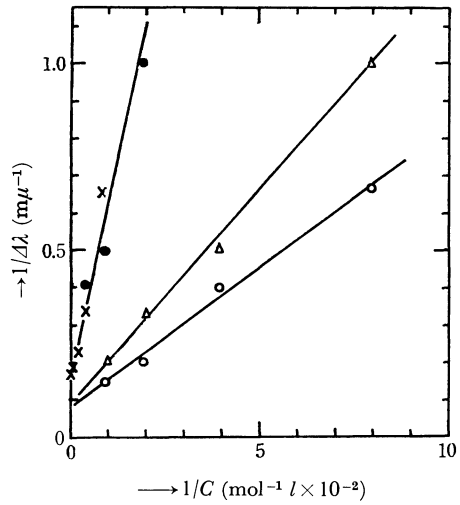

Fig. 2. Reciprocal plottings of extents of red shift ($\Delta\lambda$) and concentrations of nucleosides.
methylene blue, 5×10^{-6}M; phosphate, 1/15M. (pH 6.8); ×, thymidine; ●, deoxycytidine; △, deoxyguanosine; ○, deoxyadenosine.

The remaining concentration of the substrate decreased exponentially with an increase in the irradiation time up to 20 min, at least under the present conditions. Each reaction rate was estimated from the initial slope of the curve in the semi-logarithmic plotting. Deoxyguanylic acid was also decomposed by the irradiation of visible light in the presence of methylene blue when air was dissolved in the solution. Its reaction rate was found to be lower than that of deoxyguanosine (Fig. 3).

It was confirmed that the reaction rate of deoxyguanosine was independent on the pH between 5.4 and 6.6; this is consistent with the data of Simon and van Vunakis.[8] Thus, all the experiments below were performed with solutions in this pH range.

Effects of the Concentrations of Phosphate, the Substrate, and Oxygen. The reaction of deoxyguanosine was examined in 1×10^{-3} and 1×10^{-2}M phosphate buffers. The reaction rate increased with an increase in the concentration of the substrate up to a saturation level at a constant concentration of methylene blue (1×10^{-5}M), as may be seen in Fig. 3. In the solution with a lower phosphate concentration, a larger rate was observed. The phosphate anion may be connected with some irreversible reaction(s) of methylene blue in an aerated solution as well as in a deaerated solution.[10] The present finding may be interpreted as a result of competition between deoxyguanosine and phosphate.

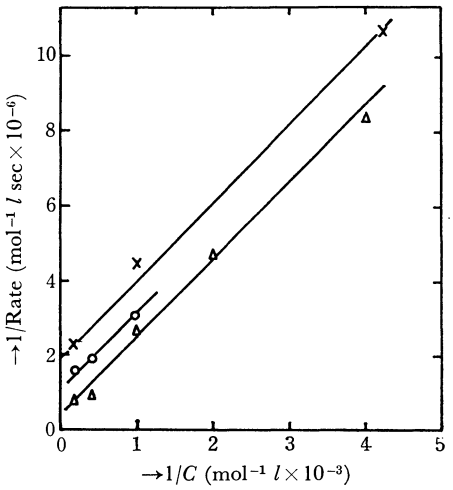

Fig. 3. Dependency of the reaction-rate on the concentration of substrate.
methylene blue, 1×10^{-5}M; air saturated; △ and ○, deoxyguanosine in 1×10^{-3} and 1×10^{-2}M phosphate buffer respectively; ×, deoxyguanylic acid in 1×10^{-2}M phosphate buffer.

It was also observed that the reaction proceeded with a larger rate with an increase in the concentration of oxygen up to a saturation level (Fig. 4). The reaction did not take place in a deaerated solution.

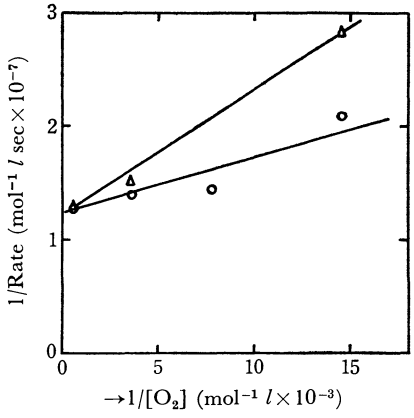

Fig. 4. Oxygen-effect on the reaction-rate.
methylene blue, 1×10^{-5}M; deoxyguanosine, 1×10^{-4}M; phosphate, 1×10^{-3}M (○) and 1×10^{-2}M (△).

Independency on Added 2-Deoxy-D-ribose. Varying amounts of 2-deoxy-D-ribose, which is

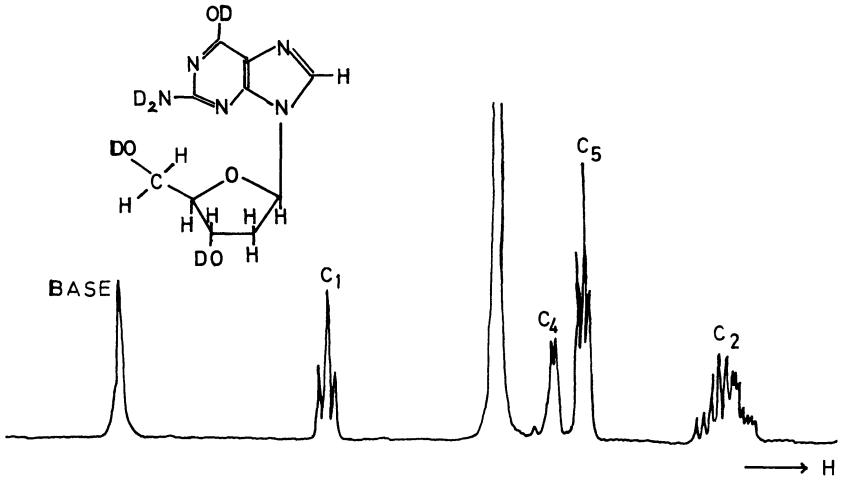

Fig. 5. NMR-Spectrum of deoxyguanylic acid in D_2O.

a component of deoxyguanosine, were added to a reaction mixture of deoxyguanosine (5×10^{-5}M) and methylene blue (1×10^{-5}M) in a phosphate buffer (1×10^{-3}M). Even if the additive was increased as high as 1×10^{-3}M, it however did not affect the photosensitized reaction.

NMR Measurements. As a preliminary experiment, the reaction of deoxyguanylic acid in D_2O was followed by NMR measurements. It did not have an adequate quantitative accuracy, but the decrease in the proton signal from the guanine base caused by the reaction was remarkable compared with that of the C_1-proton of the deoxyribose ring (See Fig. 5). The ratio between the signal intensity of the base and that of C_1 is plotted against the irradiation time in Fig. 6. Since methylene blue itself is also decomposed by such a long irradiation, this curve does not correspond to an actual dose-response of the reaction.

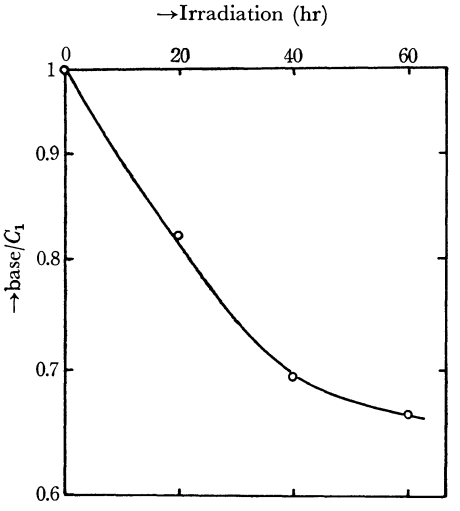

Fig. 6. Decrease of the ratio of NMR-signals, base to C_1, by the photosensitized reaction.
methylene blue, 3.3×10^{-4}M; deoxyguanylic acid, 5%.

Discussion

It was confirmed from spectral shifts that methylene blue interacts more strongly with purine nucleosides than with pyrimidine nucleosides. This is consistent with the results of Kodama *et al.*,[11] who observed that the spectral shifts of proflavine, acridine orange, and methylene blue are larger in the presence of apyrimidic acid than in the presence of apurinic acid, and who ascertained the base specificity of proflavine at the nucleoside level as well as at the polymer level on the basis of a measurement of the difference spectra. The specific destruction of deoxyguanosine, however, can not be accounted for by the specific interaction of methylene blue with deoxyguanosine, since deoxyadenosine was not destroyed by the present reaction and since the photosensitized reaction of deoxyguanosine was carried out at such a low concentration that the red shift was not observed.

Oster *et al.*[12] reported the photo-oxidation of 2,5-diaminotoluene using proflavine as a sensitizer, and postulated that the long-lived, electronically-excited (probably triplet) state of the dye reacted with oxygen to form some dye peroxide, which in turn oxidized the substrate. The reaction scheme for the present system can be built up in the same way:

$$D + h\nu \rightarrow D^* \quad (1)$$

$$D^* \rightarrow D + h\nu_f \quad (2)$$

$$D^* \rightarrow D' \quad (3)$$

11) M. Kodama, Y. Tagashira and C. Nagata, *J. Biochemistry.*, **64**, 167 (1968).

12) G. Oster, J. S. Bellin, R. W. Kimball and M. E. Schrader, *J. Amer. Chem. Soc.*, **81**, 5095 (1959).

$$D' \rightarrow D + h\nu_p \quad (4)$$

$$D' + D \rightarrow 2D \quad (5)$$

$$D' + P \rightarrow \text{product} \quad (5')$$

$$D' + O_2 \rightarrow DO_2 \quad (6)$$

$$DO_2 \rightarrow D + O_2 \quad (7)$$

$$DO_2 + D \rightarrow 2D + O_2 \quad (8)$$

$$DO_2 + P \rightarrow D + \text{product} \quad (8')$$

$$DO_2 + S \rightarrow D + SO_2 \quad (9)$$

where D is the ground state of the dye; D*, the singlet excited state of the dye; D′, the triplet excited state of the dye; P, phosphate; S, the substrate; $h\nu_f$, fluorescence and $h\nu_p$, phosphorescence. If the steady-state treatment is applied to each intermediate, namely, D*, D′, and DO_2, the rate formula may be expressed as follows;

$$-d[S]/dt = k_1 \cdot [D] \Big/ \left[\left(1 + \frac{k_7}{k_9 \cdot [S]} + \frac{k_8 \cdot [D] + k_{8'} \cdot [P]}{k_9 \cdot [S]} \right) \times \left(1 + \frac{k_4}{k_6 \cdot [O_2]} + \frac{k_5 \cdot [D] + k_{5'} \cdot [P]}{k_6 \cdot [O_2]} \right) \cdot \left(1 + \frac{k_2}{k_3} \right) \right]$$

where each k is the rate constant at the elementary process expressed by the subscript. This means that the plot of 1/rate *vs.* 1/[S] should be a straight line when [D], [O_2] and [P] are constant, while the plot of 1/rate *vs.* 1/[O_2] should be linear when [D], [S] and [P] are constant. The reciprocal plot of the experimental values approximately satisfied the above scheme.

Since the quantum yields of the fluorescence and the phosphorescence of methylene blue might be rather small, it may be postulated that $k_2 \ll k_3$ and $k_4 \ll k_6 \cdot [O_2]$. Furthermore, since the slope in the reciprocal plotting on the effect of the substrate concentration at $[P] = 1 \times 10^{-2}$M was nearly the same as that at $[P] = 1 \times 10^{-3}$M, the $k_{8'} \cdot [P] \ll k_7 + k_8 \cdot [D]$ relation is plausible. Thus, the following ratios of the rate constants could be roughly estimated. Comparing the above formula with the results on the effect of the oxygen concentration at different concentration of phosphate ions, we obtained $k_5/k_6 \approx 2.5$ and $k_5/k_{5'} \approx 4 \times 10^2$; that is, the difference between the probabilities of the deactivation of long-lived excited dye molecules (D′) by unexcited ones and of the reaction of D′ with molecular oxygen is not large, and the probability of reaction 5′ is very small. From the dependency on the substrate concentration at two concentrations of the dye, *i.e.*, 1×10^{-5} and 5×10^{-6}M, $k_7/k_8 \approx 2 \times 10^{-5}$M, $k_8/k_9 \approx 3 \times 10$, and $k_7/k_9 \approx 5 \times 10^{-4}$M.

In the reaction mechanism described above, the conception of the molecular complex (DO_2) was accepted as an intermediate on the basis of the reaction scheme proposed by Schenck.[13] However, even if one considers that the singlet excited state of the oxygen molecule, $O_2(^1\Delta_g)$[14,15] or $O_2(^1\sum_g)$,[15] is produced by process (6), the final formula for the kinetics is the same.

The results of the NMR measurements were not incompatible with the study of the kinetics. It may be concluded that, in the reaction of deoxyguanosine or deoxyguanylic acid with methylene blue, the guanine residue is preferentially subjected to the reaction, whereas the deoxyribose residue is rather stable.

According to Waskell *et al.*,[16] guanosine was decomposed by the sensitization of methylene blue to ribosyl urea, free ribose, guanidine, and traces of urea in the earlier stage of irradiation, while the ribose moiety disappeared in the latter stage. The preferential destruction the base component suggests that the secondary reaction of such intermediates as radicals, which may be formed in the primary process, with the sugar component is not appreciable.

The reaction kinetics of deoxyguanosine was studied as a sole solution in the present case. If its reaction is followed in the presence of the three other nucleosides, information about the reaction mechanism as a state closer to the actual system can be obtained. Furthermore, if a competitive reaction between DNA and deoxyguanosine is studied, the $k_{DNA}/k_{nucleoside}$ ratio must be estimated. The biological significance of the selective destruction of the guanine derivatives in DNA or RNA will be thus confirmed.

Studies on the Baudisch Reaction. III. A Possible Intermediate in the Reaction[1)]

Iwao TANIMOTO

Faculty of Home Economics, Kyoto Women's University, Higashiyama-ku, Kyoto

(Received September 29, 1969)

The Baudisch reaction was applied to 1- and 2-naphthols, and 2-nitroso-1-naphthol was obtained as the sole product in both reactions. In a reinvestigation of the products obtained from phenols, it was also found that in some cases the nitroso group replaced the hydroxy group and a hydroxy group was newly introduced into the position *ortho* to the nitroso group. These results indicate that a copper(II)-hydroxylamine-catechol complex will be a possible intermediate of the reaction of phenol. The product studies on the reaction of catechols support the assumption. Kinetically, the formation of the complex seems to be the rate-determining step in the reaction of phenols.

Baudisch[2)] and Cronheim[3)] obtained various *o*-nitrosophenols from phenols by the reaction with hydroxylamine hydrochloride, hydrogen peroxide and copper(II) salt. At first we intended to extend this reaction to naphthols. However, the reaction of 2-naphthol gave an unexpected product, and it became necessary to reinvestigate the products from some substituted phenols. In the present paper, a possible intermediate of the Baudisch reaction is discussed on the basis of experimental results.

Results and Discussion

The Reactions of Naphthols. In methanol, 1- and 2-naphthols reacted with copper(II) nitrate, hydroxylamine hydrochloride and hydrogen peroxide at room temperature, though the reactions proceeded slower than that of phenol. The reaction mixture was poured into water, then the copper salt of the product precipitated. Nitrosonaphthol was liberated from precipitate by an acid. The product from 1-naphthol was 2-nitroso-1-naphthol. Unexpectedly, however, 2-naphthol also gave 2-nitroso-1-naphthol; the hydroxy group of 2-naphthol was replaced by the nitroso group and a hydroxy group was introduced into position 1. Identification of the products was carried out by means of elementary analysis, determination of mixed melting point with the authentic sample and measurement of the NMR spectrum.

Reexamination of the Products from Some Phenols. It was accepted without proof that the position of the hydroxy group does not change in the reactions of phenols.[2,3)] However, the results in the preceding section required reinvestigation of the configurations of *o*-nitrosophenols which were produced from substituted phenols. As *o*-nitrosophenols are volatile, *o*-nitrophenols obtained by oxidation of the products were identified. The results are tabulated in Table 1. Obviously the hydroxy groups of *p*-cresol and 3,5-dimethylphenol were replaced by nitroso groups.

Reactions of Catechols. It was demonstrated in a previous paper that catechol was found when the reaction of phenol was performed under higher pH and that the production of catechol would also be controlled by the copper-hydroxylamine complex.[1b)] However, the mechanistic relationship between the formation of catechol and that of *o*-nitrosophenol has not yet been established. A mixture of catechol, hydroxylamine hydrochloride and copper(II) nitrate in a buffered aqueous solution (pH 2.5) was blue and showed no change in color under a nitrogen atmosphere, but with the addition of a hydrogen peroxide solution the reaction started and proceeded very fast. The red reaction mixture was acidified and the product was extracted with petroleum ether. The product was oxidized and the resulting *o*-nitrophenol was identified. Thus it was confirmed that the reaction product from catechol under the Baudisch reaction conditions was *o*-nitrosophenol. Under the same conditions, 3,4-dihydroxytoluene selectively changed into 5-methyl-2-nitrosophenol which was the sole reaction product from both *m*- and *p*-cresols (Table 1).

Kinetic Measurements for Catechols. In Fig. 1, the kinetic plot for the reaction of catechol is shown, together with that for phenol. The concentration of catechol at any time was assumed

a) All reactions were conducted under a nitrogen atmosphere. Catechol (1×10^{-3} mol), copper(II) nitrate (1×10^{-3} mol) and hydroxylamine hydrochloride (2×10^{-3} mol) were stirred in 198 m*l* of a Walpole buffer (pH 2.50) after addition of a hydrogen peroxide solution (1.0M)(2 m*l*). Temperature was controlled within ±0.1°C.
b) Entropy of activation was calculated at10.0°C.
c) The data was taken from that shown in Part II of this series.[1b)]

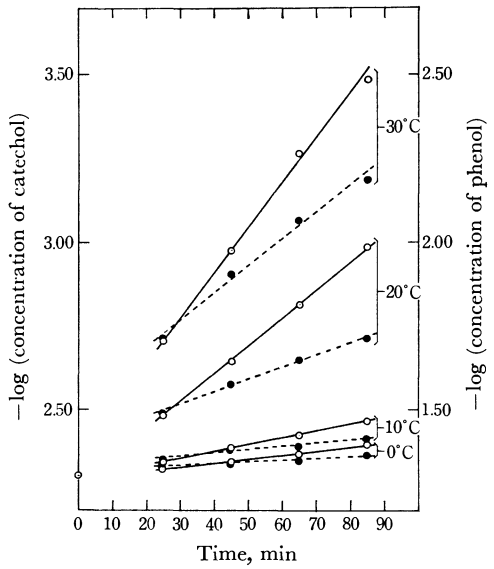

Fig. 1. First-order plots for the Baudisch reaction of catechol and of phenol.
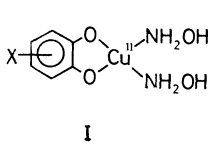
The plot for the reaction of phenol was based on the data shown in the Part II of this series.[1b)]
Initial concentration of catechol (—○—): 5×10^{-3}M.
Initial concentration of phenol (—●—): 5×10^{-2}M.

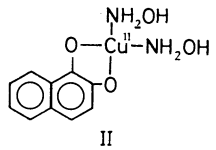
to be given by the difference between its initial concentration and the concentration of *o*-nitrosophenol. Apparently the reaction of catechol is first-order in catechol, and from this plot the rate constants and thermodynamic quantities can be calculated. The results of the calculation are shown in Table 2, together with the data for the reaction of phenol. The rate constants for catechol are about twice those for phenol.

The reaction of 3,4-dihydroxytoluene proceeded much faster than that of both *m*- and *p*-cresols, but reliable kinetic data could not be obtained.

Discussion. The copper-hydroxylamine complex combined with the phenoxy group plays an important role in the reaction of phenol.[1b)] If the complex is responsible for the direct nitrosation of benzene ring, the position of the hydroxy group in the resulting *o*-nitrosophenol should not change from that of the hydroxy group in phenol. However, the formation of 5-methyl-2-nitrosophenol from 3,4-dihydroxytoluene, *m*- and *p*-cresols rejects this mechanism. A reasonable explanation for this may be given by the assumption that complex I is formed in each of the reactions as a common intermediate, because the isokinetic plots shown in the previous paper indicated a constant mechanism for the related series of reactions.[1b)] In Table 2, it is shown that catechol has a higher reaction rate



I



II

than phenol. Since catechol easily changes into complex I, it may be concluded that the kinetic data shown in Table 2 indicate the high reactivity of complex I. Thus the rate-determining step in the reaction of phenol would be the formation of complex I. In the reactions of naphthols, complex II will be formed as a common intermediate. This explains the production of 2-nitroso-1-naphthol from both 1- and 2-naphthols. There are two possible mechanisms by which complex I changes into *o*-nitrosophenol; the one involves the cleavage of the C–O bond and the attack of hydroxylamine moiety on the carbon atom, and the other the formation of *o*-quinone and subsequent oximation. Studies are in progress to establish the mechanism.

Experimental

Materials. Reagent grade 30% hydrogen peroxide solution and *p*- and *m*-cresols were the same as described.[1b] Other reagents were of the best available grade and, if necessary, were used after further purification. Some of the authentic samples were prepared according to directions in literature and others were of the best commercially available grade (Table 3).

2-Nitroso-1-naphthol. In a 1 *l* round-bottomed, threenecked flask provided with a stirrer, 12 g (0.05 mol) of copper(II) nitrate was dissolved with 100 m*l* of methanol, and the solution was mixed with a solution of 8 g (0.12 mol) of hydroxylamine hydrochloride in 100 m*l* of methanol. The flask was then well cooled with ice and stirred at 0°C under a nitrogen atmosphere. After 30 min, 4 g (0.028 mol) of 2-naphthol was added to the solution and stirring was continued for 10 min. A dilute solution of hydrogen peroxide which was obtained from 10 m*l* of 30% hydrogen peroxide solution and 30 m*l* of hydrochloric acid-sodium acetate buffer (pH 2.5) was added to the reaction mixture in about 1 hr. The mixture was then warmed to 20°C gradually and the reaction was continued for 4 hr. After the reaction was completed, the mixture was poured into 200 m*l* of water and allowed to stand in an ice-box overnight. The precipitate was filtered, washed twice with a small amount of ether, and suspended in a mixture of methanol (100 m*l*) and concentrated hydrochloric acid (100 m*l*). The suspension was added to chloroform in a 1 *l* separatory funnel, shaken well, and then separated into two layers by addition of water. The aqueous layer was repeatedly extracted with fresh chloroform. All of the chloroform extract was washed with 6N hydrochloric acid and twice-distilled water. The extract was dried over anhydrous sodium sulfate and the solvent was removed under reduced pressure. By recrystallization of the residue from ethanol-water, 1.6 g of 2-nitroso-1-naphthol of mp 160—162°C (lit, mp 162—164°C) was obtained. The yield was *ca.* 35% of the theoretical value.

Found: C, 69.64; H, 4.02; N, 7.84%. Calcd for $C_{10}H_7O_2N$: C, 69.36; H, 4.07; N, 8.09%.

With the same procedure 1-naphthol gave 0.3—0.4 g of 2-nitroso-1-naphthol, mp 166—167°C.

Found: C, 69.64; H, 4.07; N, 8.05%.

Nitrosophenols from Phenols and Catechols. As *o*-nitrosophenol is very volatile and difficult to identify, the product of the reaction was oxidized to nitrophenol and its identification was conducted. As a typical example of the procedure, the formation of 5-methyl-2-nitrosophenol from *p*-cresol will be described.

In a 1 *l* three-necked flask, equipped with a stirrer, was placed copper(II) nitrate (7.2 g, 0.03 mol) and 200 m*l* of hydrochloric acid-sodium acetate buffer (pH 2.5). To this was added a mixture of hydroxylamine hydrochloride (4.2 g, 0.06 mol) and *p*-cresol (3.24 g, 0.03 mol) dissolved in 400 m*l* of water. The solution was stirred for 6 hr at 30°C after the addition of 6 m*l* of hydrogen peroxide solution. The reaction mixture was acidified and extracted with petroleum ether. *o*-Nitrosophenol in the petroleum ether was extracted with aqueous solution of copper(II) sulfate as a copper salt. The red solution was acidified and extracted with petroleum ether. The petroleum ether solution of pure *o*-nitrosocresol was added with 40 m*l* of glacial acetic acid and evaporated at about 50°C. To the resulting acetic acid solution of *o*-nitrosocresol was added a mixture of glacial acetic acid (15 m*l*) and 30% hydrogen peroxide (15 m*l*) and the solution was allowed to stand at 70—80°C for about 20 min. Completion of oxidation was confirmed by observing that a drop of the acetic acid solution did not turn red with the addition of methanolic copper(II) nitrate solution. To the acetic acid solution was then added a large amount of ice-water and extraction was carried out with ethyl ether. The ether extract was washed with water and extracted with 2N sodium hydroxide solution. Steam distillation of the solution after acidification gave 75 mg of yellow crystalline needles with mp of

49.5—52°C. Recrystallization from aqueous ethanol gave 5-methyl-2-nitrophenol, mp 55°C (lit, mp 56°C), undepressed by admixture with an authentic sample.

Kinetic Studies. The general procedure for phenols was used.[1b)]

The work was supported in part by a Research Grant from Kyoto Women's University. The author wishes to express his gratitude to Professor Kazuhiro Maruyama, Kyoto University, for stimulating suggestions and discussions. The continued encouragement of Professor Ryōzō Gotō of Kyoto University is gratefully acknowledged.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1185—1189 (1970)

A New Synthesis of Aziridines from β-Amino Alcohols with Triphenylphosphine Dibromide

Itaru OKADA, Kunihiro ICHIMURA and Rokuro SUDO

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 29, 1969)

The reaction of β-amino alcohols with triphenylphosphine dibromide was found to give the corresponding aziridines in good yields. The reaction opened a new route to the synthesis of aziridine compounds which seems to be more convenient than the Gabriel and Wenker methods. In the ring closure of ephedrine, a Walden inversion was observed. A possible mechanism is suggested.

Aziridine derivatives are usually prepared from β-amino alcohols by the Gabriel method or by the Wenker method,[1] but both methods are inconvenient because they involve two-step syntheses *via* β-amino hydrogen sulfates or β-haloamines.

In the present paper, a new one-step method is reported; by means of this method β-amino alcohols were rapidly converted to aziridines by using triphenylphosphine dibromide under mild reaction conditions.

Results and Discussion

The amino alcohols (**1**) used were prepared by the reactions of amines with epoxides; the results are summarized in Table 1.

First, the reaction of β-amino alcohols (**1**) with phosphorus pentachloride in the presence of triethylamine was attempted, but the attempt to isolate aziridines (**2**) was unsuccessful.[2]

Triphenylphosphine dibromide (**3**), prepared by Horner and his co-workers, has a considerable advantage over phosphorus pentachloride in the preparation of alkyl and aryl halides from alcohols or phenols.[3]

By using this reagent (**3**), instead of phosphorus pentachloride, the expected aziridines (**2**) were readily obtained in good yields.

In the reaction of 1-phenyl-2-butylaminoethanol (**1a**) with triphenylphosphine dibromide (**3**) in the presence of two equivalents of triethylamine in dry acetonitrile at room temperature, 1-butyl-2-phenyl-aziridine (**2a**) was isolated in a 60% yield, along with 1,4-dibutyl-2,5-diphenylpiperazine (**4a**) as a by-product.

2a was identified by elemental analysis and by means of a study of the NMR spectrum, and its IR spectrum shows neither NH or OH stretching vibrational absorption bands (3280, 1300 cm^{-1}). The structure of **4a** was established by the results of elemental analysis and by a comparison of its infrared spectrum with that of the authentic sample prepared by a procedure similar to that used in a previous paper.[9] A variety of 1,2-disubstituted aziridine derivatives (**2b**—**2g**) were prepared from β-amino alcohols (**1b**—**1g**) in the same way. The results are summarized in Table 2.

The application of this procedure to the synthesis of 1-monosubstituted aziridines was unsuccessful; in the case of 2-cyclohexyl-(**1h**) and 2-benzylamino-ethanol (**1i**), the products isolated were only the

obtained, the structure was confirmed by a comparison of its NMR spectrum with that of the authentic sample reported in the literature.[10] The $[\alpha]_D^{28}-134°$ (EtOH), of the product (**2j**) indicates the occurrence of Walden inversion during the ring closure. On the other hand, in the reaction of *erythro*-ephedrine (**1k**) with **3**, the expected D(+)-*trans*-1,2-dimethyl-3-phenylaziridine (**2k**) was not isolated, and only a polymeric material was obtained. Taguchi and Kojima observed an analogous polymerization of the *trans*-isomer (**2k**) in the application of the Wenker synthesis to *erythro*-ephedrine (**1k**).[12] It seems probable that the *trans*-isomer (**2k**) is easily polymerized during the isolation. Therefore, immediately after the reaction was over, hydrogen chloride gas was introduced into the reaction mixture. The product isolated was the expected L(−)-*erythro*-1-chloro-1-phenyl-2-methylaminopropane hydrochloride (**5k**), which would suggest the formation of **2k**. Although the melting point of this product, 186—188°C, was slightly lower than the literature value,[8] 198°C, $[\alpha]_D^{23}-68.6°$ (EtOH), the infrared spectrum supported the structure.

On the basis of the results described above, in the cases of both *threo*- (**1j**) and *erythro*-ephedrine (**1k**), a Walden inversion should occur in the ring-closure process. This fact supports the idea of the 1,2-*trans*-elimination in path A postulated in Scheme 2; the five-membered ring intermediate shown in path B, which should afford a *cis*-isomer, can thus be eliminated.

Experimental

The acetonitrile used was distilled from phosphorus pentoxide and dried over calcium hydride. The triethylamine was distilled and dried over sodium. All the melting points and boiling points are uncorrected.

β-Amino Alcohols (1). These compounds were prepared by the methods of Emerson,[4] Stolberg,[6] and Bottini;[7] their physical constants are summarized in Table 1.

1-Butyl-2-phenylaziridine (2a). The general procedure for the reaction of β-amino alcohols (**1**) with triphenylphosphine dibromide (**3**) was as follows. To a solution of **3**, prepared from 10.48 g (0.04 mol) of triphenylphosphine in 100 m*l* of acetonitrile and 6.40 g (0.04 mol) of bromine in 40 m*l* of acetonitrile, 7.72 g (0.04 mol) of **1a** was added under ice cooling. A solution of 8.08 g (0.08 mol) of triethylamine in 10 m*l* of acetonitrile was then stirred, drop by drop, into the above mixture. After this mixture had stood overnight at room temperature, the precipitated triethylamine hydrobromide was filtered off (8.90 g, 62%). The filtrate was concentrated by rotary evaporation. The residue was extracted several times with *n*-hexane, and the extract was concentrated by rotary evaporation to about 5 m*l*. The triphenylphosphine oxide thus separated was removed by filtration, and the filtrate was further concentrated. The yellow residue (5.90 g) was distilled to give **2a**; bp 88—89.5°C/2 mmHg. Yield, 4.15 g (60%). The analytical sample was obtained by redistillation as a colorless liquid; bp 80—81°C/1 mmHg. IR (NaCl): 3030, 2920, 1600, 1495, 1450, 1205, 1080, 1025, 740, 720, and 690 cm^{-1}; NMR ($CDCl_3$): τ 2.8 (5H, singlet) due to aromatic protons, τ 7.5—7.9 (3H, multiplet) due to $>N-C\underline{H}_2-CH_2-$ and $C_6H_5-C\underline{H}$, τ 8.1—9.0 (6H, multiplet) due to $C_6H_5-CH-C\underline{H}_2$ and $CH_3-C\underline{H}_2-C\underline{H}_2-$, and τ 9.1 (3H, triplet) due to $-CH_3$. The oily, brown distillation residue was treated with a small quantity of ethanol to give 1,4-dibutyl-2,5-diphenylpiperazine (**4a**) as needle crystals. Yield, 0.85 g (12%). Recrystallization from acetonitrile afforded colorless needles; mp 109.5—110.5°C. Benzene and water were added to the residue resulting from *n*-hexane extraction. The organic layer was concentrated to give 10.60 g (96%) of triphenylphosphine oxide. The evaporation of the aqueous layer afforded 5.90 g (41%) of triethylamine hydrobromide. The total yield of this compound was 93%.

D(+)-*threo*-Ephedrine (1j). This compound was prepared from L(−)-*erythro*-ephedrine hydrochloride (**1k**) by the procedure of Tanaka.[8] The ratio of D(+)-*threo*- to L(−)-*erythro*-ephedrine in the product was 65 : 35.

L(−)-*cis*-1,2-Dimethyl-3-phenylaziridine (2j). 2j was prepared in a manner analogous to that described for the preparation of **2a**. Bp 82°C/14 mmHg. Yield, 74% $[\alpha]_D^{23}$ −134° (EtOH). (Lit, $[\alpha]_D^{11}$ −127°, EtOH). NMR ($CDCl_3$): τ 2.75 (5H, singlet) due to aromatic protons, τ 7.55 (3H, singlet) due to $>N-CH_3$, τ 7.65 (1H, doublet) due to $C_6H_5-C\underline{H}$, τ 8.4 (1H, quintet) due to $-C\underline{H}CH_3$, and τ 9.15 (3H, doublet) due to $-CH-C\underline{H}_3$. IR (NaCl): 2950, 1600, 1500, 1460, 1400, 1120, 730, and 700 cm^{-1}.

Reaction of L(−)-*erythro*-Ephedrine Hydrochloride (1k) with Triphenylphosphine Dibromide (3). 4.03 g (0.02 mol) of **1k** was added, under ice cooling, to a solution of **3** which had been prepared from 5.24 g (0.02 mol) of triphenylphosphine in 25 m*l* of acetonitrile and 3.20 g (0.02 mol) of bromine in 10 m*l* of acetonitrile. A solution of 6.06 g (0.06 mol) of triethylamine in 10 m*l* of acetonitrile was then stirred, drop by drop, into the mixture. After 0.5 hr, the triethylamine hydrobromide and hydrochloride thus precipitated were filtered off (7.50 g, 75%). This filtrate was treated with water or hydrogen chloride.

a) Treatment with Water. The filtrate was concentrated by rotary evaporation. The residue was treated with water, and the insoluble product was collected by filtration, washed with ethanol, and dried (1.30 g); mp 270—290°C. This compound could not be recrystallized from normal solvents. IR (KBr): 2950, 1600, 1490, 1450, 1025, 750, and 700 cm^{-1}.

b) Treatment with Hydrogen Chloride. Hydrogen chloride was introduced into the filtrate. The mixture was concentrated by rotary evaporation, and the residue was treated with 40 m*l* of benzene and 40 m*l* of water. The evaporation of the organic layer afforded 5.00 g (89%) of triphenylphosphine oxide. The aqueous layer was concentrated to give 2.90 g of L(−)-*erythro*-1-chloro-1-phenyl-2-methylaminopropane hydrochloride (**5k**). Recrystallization from ethanol gave colorless plates; mp

1,4-Dibutyl-2,5-diphenylpiperazine (4a). A mixture of 1.75 g (0.01 mol) of **2a**, a catalytic amount of aluminum chloride, and 20 m*l* of methanol was refluxed for 7 hr. The solvent was then evaporated, and the residue was treated with a slight excess of potassium hydroxide and water. The solution was then extracted several times by ether. The ether layer was dried over anhydrous potassium carbonate and evaporated. The crude product, 1.20 g (69%), was recrystallized from acetonitrile to give colorless needles; mp 109.5—110.5°C. IR (KBr): 2950, 2800, 1600, 1490, 1450, 1140, 1110, 750, and 700 cm^{-1}.

Found: C, 82.29; H, 9.59; N, 8.06%. Calcd for $C_{24}H_{34}N_2$: C, 82.23; H, 9.78; N, 7.99%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1189—1196 (1970)

Rearrangement of Aryl Sulfides in the Presence of Aluminum Chloride*1

Tamotsu FUJISAWA, Noriko OHTSUKA and Gen-ichi TSUCHIHASHI

Sagami Chemical Research Center, Ohnuma, Sagamihara-shi, Kanagawa

(Received October 1, 1969)

Aluminum chloride-catalyzed rearrangement of aryl sulfides leads to thermodynamically controlled equilibrium mixtures at room temperature. On treatment of *o*-, *m*- or *p*-tolyl phenyl sulfide without solvent, the isomer distribution converges to an equilibrium point, 17% *ortho*, 47% *meta* and 36% *para* isomer by intramolecular isomerization. Intermolecular disproportionation by methyl-group exchange to produce diphenyl sulfide and ditolyl sulfide accompanied isomerization. In addition, a new type of aromatic rearrangement, intermolecular disproportionation by exchange of the arylthio group, was found to occur simultaneously giving benzene, toluene and thianthrene derivatives. The rate of this reaction is slower than that of the methyl rearrangement. A similar treatment of α-naphthyl phenyl sulfide gave the β-isomer from intramolecular isomerization and diphenyl sulfide, naphthalene, thianthrene and benzene from intermolecular disproportionation. The mechanisms of the rearrangement of aryl sulfides are discussed.

In recent years, several kinds of aromatic rearrangement have been elucidated with the development of analytical methods such as gas chromatography and infrared spectroscopy. Various types are recorded in reports and monographs.[1] In particular, the acid-catalyzed rearrangements of alkyl groups in aromatic hydrocarbons and of halogen atoms in halogenoaromatic compounds, involving the Reverdin and Jacobsen rearrangements, have been discussed in detail. However, no rearrangement of aryl sulfides has yet been described.

Preceding communications on iron catalyzed aromatic sulfuration have shown that the direct sulfuration of the aromatic nucleus with sulfur chlorides in the presence of a trace amount of ironpowder provides a convenient method for the preparation of symmetrical sulfides, and the reaction proceeds through thiosulfenyl chloride and sulfenyl chloride as intermediates.[2-3]

$$ArH + S_xCl_2 \xrightarrow{Fe} ArSSCl \longrightarrow ArSCl \xrightarrow[Fe]{ArH} ArSAr$$

$x = 1$ or 2

Similarly the iron-catalyzed reaction with various types of sulfenyl chlorides as starting materials provides a facile synthetic route for unsymmetrical aryl sulfides.[4] During the course of an extensive study on aromatic sulfuration with various types of catalysts, methyl and arylthio substituents in tolyl

*1 This investigation was presented at the 22nd Annual Meeting of the Chemical Society of Japan, Tokyo, March, 1969.

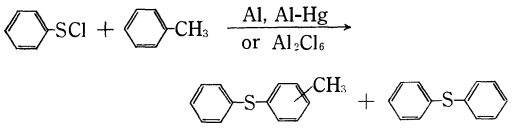
phenyl sulfides were found to rearrange in the presence of aluminum chloride. In the present experiments the rearrangement of aryl sulfides in the presence of aluminum chloride was investigated.

The products and isomer ratios from the reaction of toluene with benzenesulfenyl chloride depend on the kind and amount of the catalysts used. When iron catalysts such as iron powder or ferric chloride, are used, the products are *o*- and *p*-tolyl phenyl sulfides. The total yield increases with the increase of the amount of catalyst, and the *ortho-para* isomer ratio remains unchanged. On the other hand, in the case of aluminum catalysts such as aluminum metal, aluminum amalgam or aluminum chloride, the *meta* isomer is formed along with the other isomers, while the isomer ratios vary with the amount of the catalyst used. The formation of diphenyl sulfide in fair yield was simultaneously observed. The data for the reaction of toluene



with benzenesulfenyl chloride in the presence of various types of catalysts are shown in Table 1. The product yields and isomer ratios were determined by glpc. The results suggest that intramolecular and intermolecular methyl group migration in the initially formed product mixture lead to the observed mixture of tolyl phenyl sulfide isomers and diphenyl sulfide. To confirm this hypothesis, each isomer of tolyl phenyl sulfide was chosen as a starting material and its rearrangement in the presence of aluminum chloride was studied.

Several common solvents were investigated under various conditions to determine how readily the dissolved tolyl phenyl sulfides undergo rearrangement. Representative runs are collected in Table 2. It is worth noting that no rearrangement took place in certain solvents under mild conditions (at room temperature).

Thus, *p*-tolyl phenyl sulfide was recovered after treatment in ether or acetonitrile and only very slowly changed in carbon tetrachloride or nitrobenzene. In petroleum ether, although the products after a 20 hr reaction time could be clearly distinguished by glpc analysis, other peaks appeared at the same region of the peaks of the tolyl phenyl sulfides in the glpc chart after a 40 hr reaction time and quantitative analysis became impossible. This seemed to be attributable to disproportionation between the sulfides and the petroleum ether. The intramolecular rearrangement was readily observed in diphenyl sulfide as solvent, but intermolecular rearrangement, disproportionation, could not be detected in this case. The equilibrium amounts of the sulfide isomers found after a 40 hr reaction time may characterize the equilibrium point when only the intramolecular isomerization took place. Since the tolyl phenyl sulfide isomer compositions were different when the disproportionation was occurring simultaneously, the rearrangements were carried out without solvent in order to observe both features of the reaction. Although the rearrangement occurred readily without solvent at room temperature, addition of a trace amount of water as cocatalyst resulted in an extremely rapid reaction lasting 30 min. After 2 hr, results were the same with or without the addition of water.

Thus, the tolyl phenyl sulfide isomer compositions were obtained by treating stirred mixtures of the sulfides with aluminum chloride (20 : 1 molar ratio) at room temperature in the presence of a drop of water, added by a microsyringe. The mixtures soon became homogeneous liquids and changed to viscous liquids after 72 hr making stirring by magnetic stirrer very difficult. At certain intervals, samples were withdrawn from the reaction mixtures,

Table 2. Solvent effect in rearrangement of *p*-tolyl phenyl sulfide with Al_2Cl_6 catalyst at room temperature

hydrolyzed by addition of water and extracted with ether. The samples were then analyzed by glpc.

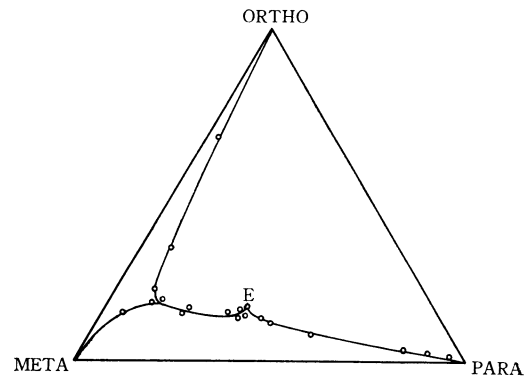

Fig. 1. *Ortho*, *meta* and *para* isomer equilibrations in isomerization of neat tolyl phenyl sulfides with $Al_2Cl_6 \cdot H_2O$ catalyst at room temperature.

The results are given in Table 3. Three runs are plotted in triangular coordinates[5] in Fig. 1.

The *ortho* isomer trajectory starts asymptotically to the 0% *para*-isomer side and the *meta* isomer trajectory starts asymptotically to the 0% *para* isomer side. Both trajectories combine after a 1-hr reaction time and then drift toward the *para* isomer side. After 168 hr, the joint trajectory meets the *para* trajectory at the thermodynamically controlled equilibrium point, in which the sulfide isomer compositions were *ortho* 17%, *meta* 47% and *para* 36%. This corresponds to a *meta*/*para* ratio of 1.3 and *ortho*/*para* ratio of 0.5. The most rapid rearrangement is shown to be the *ortho*→*meta* migration. The pattern of the triangular composition diagram resembles that for the acid-catalyzed isomerization of xylene[6] rather than that for isomerization of bromotoluene,[7] previously reported.

The initial point at which the two *ortho* and *meta* trajectories become associated is considered to be close to the equilibrium point which would be observed if intramolecular rearrangement only took place.

A comparison of the rearrangement of tolyl phenyl sulfides to that of other disubstituted benzenes, which have been previously described, is summarized in Table 4.

The rearrangement of an alkyl group on the benzene nucleus in the presence of an acid-catalyst is well known: Xylenes are isomerized at room temperature and give a *meta/para* ratio of 4.5. This reaction has been shown to proceed by an intramolecular 1,2-shift mechanism.[6] Attachment of more bulky alkyl groups to the benzene nucleus gives a smaller *meta/para* ratio. Thus, the value became smaller in the order methyl, ethyl, isopropyl, *t*-butyl. When two *t*-butyl groups are substituted on the nucleus, the *meta/para* ratio is 1.1. In this case, the reaction is known to proceed by intermolecular rearrangement involving a π-complex at the transition state.[8] Halogen atoms can also move their position on the benzene nucleus in the presence of acid-catalysts by an electrophilic attack mechanism of halogen cation.[9] In the case of bromotoluene, the *meta/para* ratio is 2.5.

The value 1.3 for the *meta/para* ratio in the rearrangement of tolyl phenyl sulfides is fairly close to that for di-*t*-butylbenzenes mentioned above. This indicates that isomerization and disproportionation occur simultaneously in the rearrangement. The relative amounts of tolyl phenyl sulfide and of diphenyl sulfide and ditolyl sulfide, which are products of the intermolecular exchange of the methyl group, *versus* the reaction time (taking the sum of the amounts of the three compounds concerned as 100%) are summarized in Figs. 2—4.

The amount of diphenyl sulfide increases with reaction time, but the yield of the corresponding ditolyl sulfide is maximal at a 6-hr reaction time and thereafter diminishes. The ratio of diphenyl sulfide to tolyl phenyl sulfides converges to about 3.9. This failure in material balance of the methyl group

may be due to the formation of polymethyl derivatives of the sulfides, which also occurs in the case of the Jacobsen rearrangement.[10] In fact, the formation of trimethyldiphenyl sulfide and tetramethyldiphenyl sulfide could be observed on glpc analyses, but they also gradually diminished after a maximum at 6-hr reaction time.

The poor material balance for the methyl group might also suggest other products. Careful examination of the product analyses revealed bond fission between the aryl group and the sulfur atom of the sulfide as well as rearrangement of the methyl group: thianthrene, toluene and benzene were observed among the products from the tolyl phenyl sulfides. The relative amounts of these compounds are shown in Figs. 5—7.

Among the products, the proportion of polymethyl derivatives of thianthrene increased with long reaction times. Although these compounds were obtained by glpc separation, each isomer could not be isolated and the methyl-group positions could not be determined.

As mentioned above, the intermolecular methyl group rearrangement of tolyl phenyl sulfide gives diphenyl sulfide and ditolyl sulfide (Eq. (1)), while a similar arylthio group rearrangement affords benzene, toluene and thianthrene derivatives (Eq. (2)). Thus, in order to compare the rates of these two rearrangements, the ratio of the sum of mole fractions of benzene and toluene, which are formed by the arylthio migration, to the mole fraction of

diphenyl sulfide, which results from the methyl migration, was calculated and is given in Table 5. The values of the ratio converge to about 0.9 after long reaction times in all cases, regardless of the choice of the isomer of tolyl phenyl sulfide as starting material. Table 5 also indicates that the amount

TABLE 5. RATIO OF THE SUM OF MOLE FRACTIONS OF BENZENE AND TOLUENE TO THE MOLE FRACTION OF DIPHENYL SULFIDE IN THE ALUMINUM CHLORIDE CATALYZED DISPROPORTIONATION OF TOLYL PHENYL SULFIDES

Reaction time	Tolyl phenyl sulfides

48	0.7	0.7	0.7
168	0.9	0.9	0.9

of diphenyl sulfide formed is larger than that of arenes in the initial stages of the reaction, which shows that the methyl rearrangement proceeds faster than the arylthio rearrangement in the disproportionation of tolyl phenyl sulfide.

This Lewis acid-catalyzed arylthio group rearrangement has not been reported and is thus a new type of aromatic rearrangement. The most striking characteristic of this rearrangement is that it proceeds at room temperature. In order to make a further study of it, the rearrangement of α-naphthyl phenyl sulfide in the presence of aluminum chloride at room temperature was tried. β-Naphthyl phenyl sulfide, the product of intramolecular rearrangement, increased rapidly at first (α/β=59/41 at 1 hr), then exceeded the amount of α isomer (11/89 at 24 hr), but the ratio of α and β isomers eventually approached 50 : 50 after about 72 hr (Table 6).

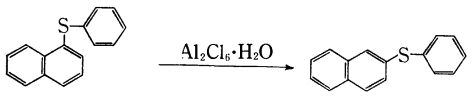

TABLE 6. ISOMERIZATION OF α-NAPHTHYL PHENYL SULFIDE WITH $Al_2Cl_6 \cdot H_2O$ CATALYST AT ROOM TEMPERATURE

Time, hr	0	1	6	24	72
α/β	100/0	59/41	15/85	11/89	50/50

As regards intermolecular rearrangement, the formation of diphenyl sulfide, naphthalene, thianthrene, diphenyl disulfide and benzene were ob-

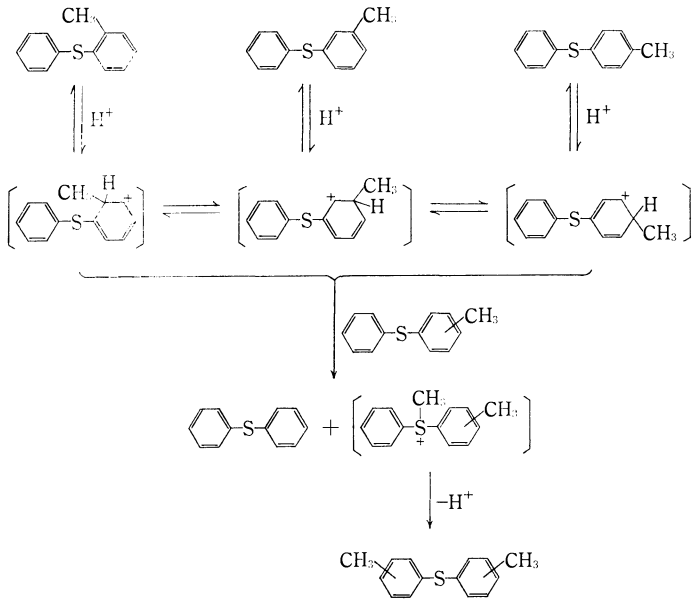
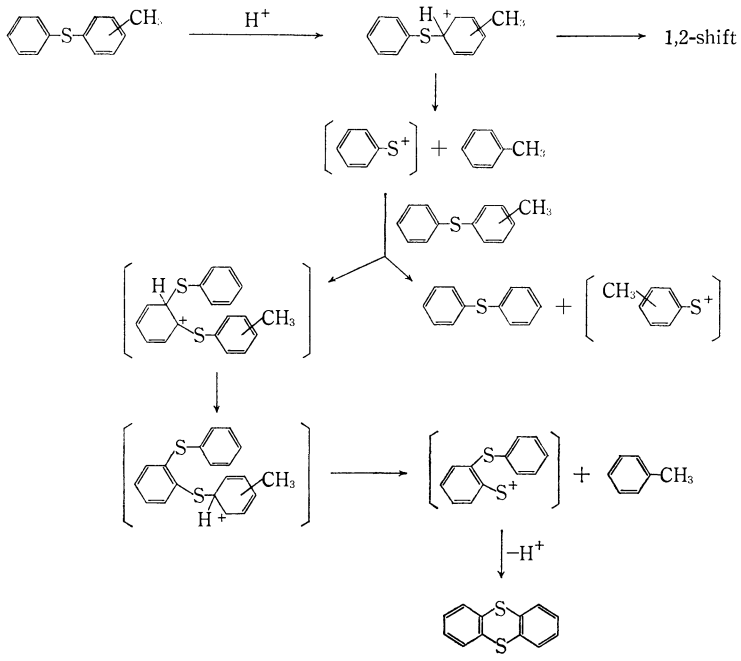
served, together with the decrease of naphthyl phenyl sulfide, as shown in Fig. 8. Other unidentified products observed by glpc, are probably thianthrene type products of naphthalene, and dinaphthyl sulfide, *etc.*

From the results, the isomerization and disproportionation of methyl and arylthio substituents were found to take place simultaneously on treatment of aryl sulfides with aluminum chloride. The mechanisms of the migrations may be as follows:



The proton attacks the position bonded to the methyl group of the aromatic nucleus to make σ-complexes, which are in equilibrium with each other *via* intramolecular 1,2-methyl shifts. In the case of intermolecular rearrangement, the complexes react with another tolyl phenyl sulfide to give diphenyl sulfide and ditolyl sulfide, which proceeds by way of a sulfonium-cation type intermediate.

On the other hand, the protonation at the position of the nucleus bonded to the sulfur atom may promote the intramolecular 1,2-arylthio shifts. The simultaneous bond fission between aryl group and



sulfur atom takes place yielding sulfenium cation.[11] This might be explained partly by the attack on a sulfur bearing carbon to yield another sulfenium cation and partly by the attack on the position *ortho* to the sulfur atom of another sulfide to give thianthrene derivatives, according to the above described routes.

The facility of the rearrangement is considered to be due to the easy protonation by electron-releasing effect of sulfur atom, and the sulfonium type intermediate through which the mobile substituents are able to migrate to the adjacent aromatic nucleus.

Experimental

Materials. Benzenesulfenyl chloride was prepared from thiophenol and chlorine according to the method of Lecher and Holschneider.[12] Most of the aryl sulfides, for reaction and for product analyses were prepared by the condensation of the aryl diazonium salt and the corresponding thiophenols, with modification of the procedure for diphenyl sulfide.[13] α-Naphthyl phenyl sulfide was prepared from α-bromonaphthalene and thiophenol.[14] Thianthrene was obtained as a by-product of the preparation of diphenyl sulfide.[15] The purity of all sulfides was determined by glpc. The following boiling points (melting points) for the sulfides are given: tolyl phenyl sulfides, *o*-, 104°C/0.15 mmHg; *m*-, 98°/0.1; *p*-, 99°/0.09; ditolyl sulfide, *p,p*-, (56—57°); *m,p*-, 114—124°/0.2; *o,p*-, 120—124°/0.15; *o,m*-, 118—124°/0.3; *m,m*-, 124—128°/0.2; naphthyl phenyl sulfides, α-, (42—43°); β-, (52—54°); thianthrene, (155—156°). Aluminum chloride was used as it was.

Reactions of Toluene with Benzenesulfenyl Chloride in the Presence of Various Types of Catalysts. To a solution of 46.0 g (0.5 mol) of toluene and 7.2 g (0.05 mol) of benzenesulfenyl chloride was added the catalyst given in Table 1. The reaction mixture was allowed to stand at room temperature with stirring for 7 hr. After removal of excess toluene, the residual oily product was fractionated by vacuum distillation and then analyzed by glpc (10% carbowax 20M, 1 m, 220°).

General Rearrangement Procedure. Aluminum chloride (0.0005 mol) was added to 0.01 mol of each isomer of tolyl phenyl sulfide in a flask equipped with magnetic stirrer and calcium chloride tube. One microliter of water was added as promoter. The reaction mixture was kept standing at room temperature with constant agitation. Samples were withdrawn periodically; the reaction was stopped by quenching with water. The organic materials were extracted with ether. The extracts were analyzed by glpc (10% carbowax 20M, 2m 220°). When a solvent was used, the concentration was 5×10^{-1}M and molar ratio of the sulfide to the catalyst 10 : 1.

In the case of rearrangement of α-naphthyl phenyl sulfide, carbon disulfide was used to obtain homogeneous liquid. Glpc analytical conditions were 10% QF-1, 1m, 180°.

Gas-liquid Partition Chromatographic Analysis. All analyses were carried out on a Hitachi Model K-53 Fractometer using a hydrogen flame-ionization detector. The accuracy of the gas-liquid partition chromatographic analytical method, as established from the analysis of isomer mixtures of known composition, was better than ±5 relative % for all products.

11) An alternative mechanism may involve an intermediate π-complex, analogous to that proposed for the migration of *t*-butyl group (Ref. 8).

Studies of Peptide Antibiotics. XVI. Analogs of Gramicidin S Containing β-Alanine in Place of L-Proline[1]

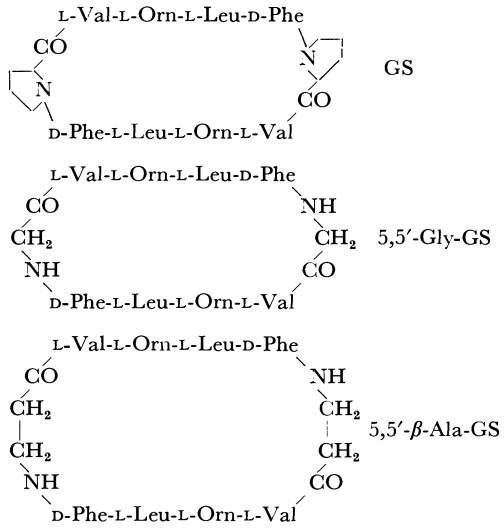
Shuji MATSUURA, Michinori WAKI, Satoru MAKISUMI and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received October 11, 1969)

5,5′-β-Alanine-gramicidin S having a larger ring size by two methylene groups than that of gramicidin S was synthesized to investigate the contribution of the ring size of gramicidin S to antibacterial activity. Cyclization of a protected linear decapeptide active ester in pyridine gave the protected 5,5′-β-alanine-gramicidin S in a good yield. The product obtained after the cyclization of a protected linear pentapeptide active ester consisted of the protected 5-β-alanine-cyclosemi- and 5,5′-β-alanine-gramicidin S. Pure compounds were obtained by column chromatographic separation of Sephadex LH-20. Hydrogenolysis of these protected cyclic peptides in the presence of hydrogen chloride afforded crystalline hydrochlorides of cyclic deca- and pentapeptide. These hydrochlorides exhibited no antibacterial activity against any of the microorganisms tested. Optical rotatory dispersion measurements of these peptides were also carried out.

For a study of the relationship between chemical structure and biological activity of gramicidin S, various analogs have been synthesized in this laboratory. Particularly in regard to ring size, a number of synthetic cyclic peptides, dipeptide anhydrides,[2] cyclo-L-valyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolyl-glycyl,[3] cyclo-L-valyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolyl-glycyl-glycyl[4] and cyclo-D-phenylalanyl-D-leucyl-L-ornithyl-L-valyl D-ornithyl-L-prolyl,[5] were found to be devoid of antibacterial activity. These results seemed to show that a certain minimum ring size and/or a specific amino acid sequence are necessary for the exhibition of antibacterial activity. On the other hand, 5,5′-glycine-gramicidin S[6] possessed activity five times higher than that of natural gramicidin S. Thus it is of interest to investigate the influence of a change in the ring size of gramicidin S or 5,5′-glycine-gramicidin S molecule on biological activity. Replacement of proline or glycine residues in gramicidin S or 5,5′-glycine-gramicidin S molecule by β-alanine residues, which results in the insertion of two methylene groups into the thirty-members ring structure of gramicidin S, may cause considerable change in the conformation and biological activity. The present paper will describe the synthesis, antibacterial properties and optical rotatory dispersion data of 5,5′-β-alanine-gramicidin S and 5-β-alanine-cyclosemigramicidin S.



The sequence of reaction employed for the synthesis of XIII·2HCl is shown in Fig. 1. Acylpentapeptide acid (VIII) was prepared efficiently as follows. Acyltripeptide ester (IV) was prepared by stepwise elongation by means of the dicyclohexylcarbodiimide method. Saponification of IV gave acyltripeptide acid (V), which was then transformed into free tripeptide (VI). Condensation of azide (VII) with VI afforded the acylpentapeptide acid (VIII) in a good yield. Condensation of active ester (IX) derived from VIII with penta-

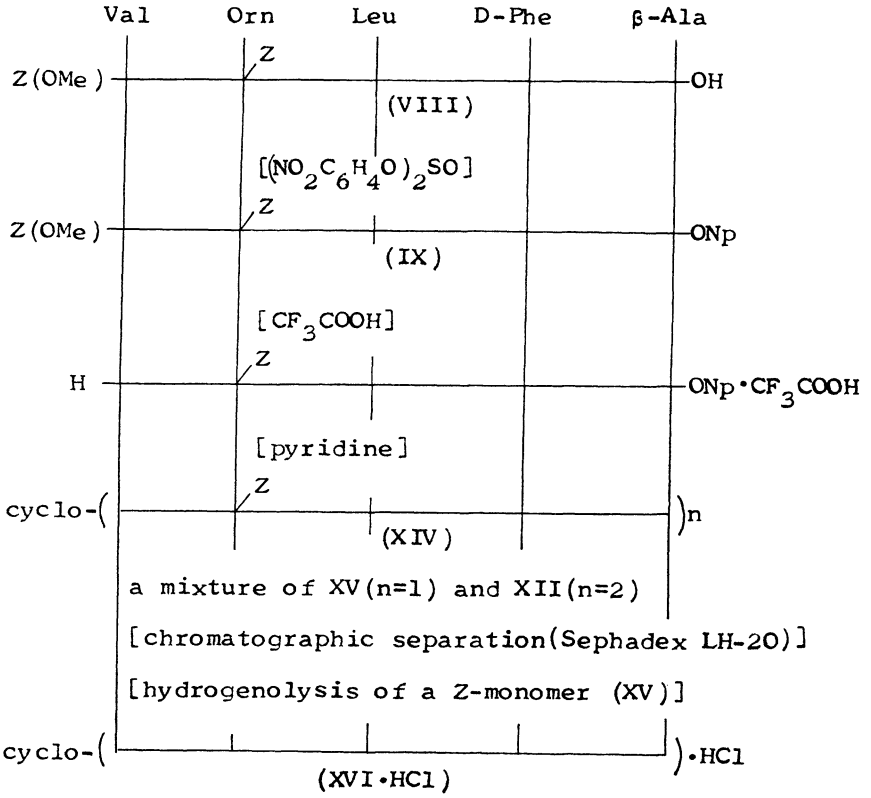

Fig. 2. Synthesis of 5-β-alanine-cyclosemigramicidin S.

peptide hydrochloride (X), which had been obtained from VIII by treatment with hydrogen chloride in dioxane, gave acyldecapeptide acid (XI). Successive treatment of XI with di-*p*-nitrophenyl sulfite, trifluoroacetic acid and excess pyridine afforded the benzyloxycarbonyl-substituted cyclic decapeptide (XII) in a good yield (42% from XI). Hydrogenation of XII in the presence of two equivalents of hydrogen chloride yielded the desired 5,5′-β-alanine-gramicidin S dihydrochloride. Synthesis of the protected cyclic decapeptide (XII) was also attempted by the possible dimerization reaction of acylpentapeptide active ester (IX) (Fig. 2). Active ester (IX) was treated successively with trifluoroacetic acid and excess pyridine. After evaporation, the reaction mixture was passed through Dowex 1 and 50 columns; the subsequent evaporation of the effluent yielded a semi solid residue. This was found to be a mixture of two components by analyzing the hydrogenated product of a small part of the residue (see, Figs. 3 and 4). The remains were subjected to a Sephadex LH-20 column to be separated into components; dimer (XII) was obtained in a yield of 3.7% and monomer (XV) obtained in 29.3%. Thus, the weight ratio of XII and XV is calculated as 11 : 89; the results indicate that the cyclization from acylpentapeptide active ester is favored for the formation of the cyclic monomer.

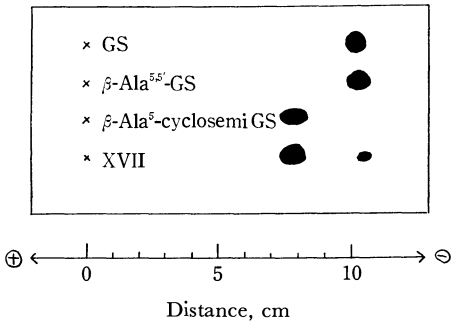

Fig. 3. Paper electrophoresis of the compounds. GS, gramicidin S; XVII; hydrogenated material after cyclization of pentapeptide ester.

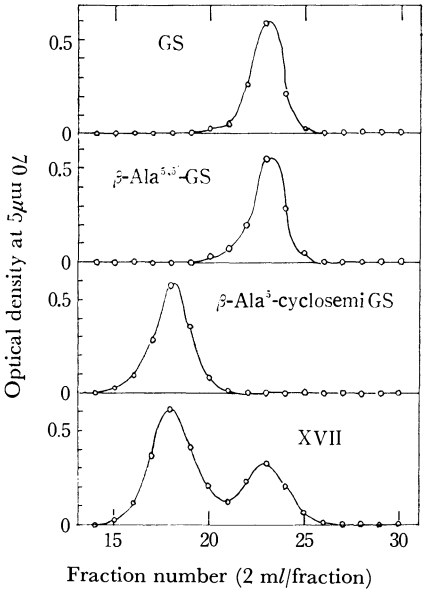

Fig. 4. Carboxymethylcellulose column chromatography of the compounds.

The antibacterial activity of gramicidin S, 5,5′-β-alanine-gramicidin S and 5-β-alanine-cyclosemi-gramicidin S toward several microorganisms was examined. Both monomer (XVI·HCl) and dimer (XIII·2HCl) showed no activity for any of the microorganisms even at 100 γ/ml of the assay medium, whereas minimum concentration of growth inhibition for *B. subtilis* was found to be 3 γ/ml with gramicidin S.

These results suggest that the replacement of proline or glycine residues in gramicidin S or 5,5′-glycine-gramicidin S molecule by β-alanine residues causes change in the conformation of the molecule. We measured the optical rotatory dispersion (ORD) of XIII·2HCl and XVI·HCl in ethanol for comparison with that of gramicidin S[7] (see Fig. 5). The result indicates that the conformation of XIII differs apparently from that of gramicidin S in ethanol. The relationship between ORD patterns and biological activity of gramicidin S analogs is now under investigation.

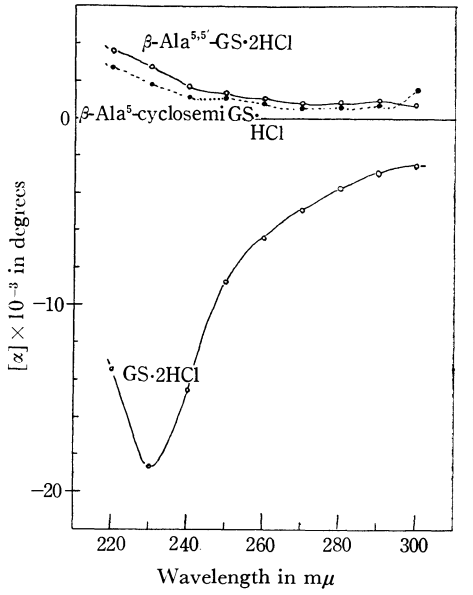

Fig. 5. Optical rotatory dispersion curves of the three compounds.

Experimental

All the melting points are uncorrected. Prior to analysis, the compounds were dried over phosphorus pentoxide to a constant weight at 80°C and 2 mmHg, except for the cyclic peptide hydrochlorides.

H-β-Ala-OEt·p-TsOH (I·p-TsOH).[8] This compound was prepared according to the general procedure of Kato *et al.*[9] A solution of β-alanine (4.45 g, 50 mmol) and *p*-toluenesulfonic acid monohydrate (9.51 g, 55 mmol) in a mixture of ethanol (40 m*l*) and carbon tetrachloride (200 m*l*) was refluxed azeotropically for 64 hr in an oil bath. The reaction mixture was concentrated *in vacuo*, and the residual oil was solidified by treatment with ether and petroleum ether. The hygroscopic product was collected by filtration in a cold room and dried. Recrystallization from hot acetone-ether gave 12.1 g (83.5%); mp 49—51°C; R_f 0.75.[10]

Found: C, 49.23; H, 6.61; N, 5.05%. Calcd for $C_{12}H_{19}O_5NS \cdot \frac{1}{4}H_2O$; C, 49.06; H, 6.69; N, 4.77%.

Z-D-Phe-β-Ala-OEt (II). Dicyclohexylcarbodiimide[11] (4.26 g, 20.6 mmol) was added to a solution of benzyloxycarbonyl-D-phenylalanine (6.18 g, 20.6 mmol) in anhydrous tetrahydrofuran (40 m*l*) with stirring at 0°C. After 30 min, to this mixture was added a solution of β-alanine ethyl ester *p*-toluenesulfonate (6.56 g, 22.7 mmol) and triethylamine (3.49 m*l*, 22.7 mmol) in chloroform (40 m*l*). The reaction mixture was stirred for 3 hr at 0°C and was then allowed to stand in a refrigerator overnight. The mixture was evaporated *in vacuo*, and ethyl acetate (60 m*l*) was added to the residue. The insoluble dicyclohexylurea was removed by filtration and the filtrate was washed successively with water, a 4% sodium bicarbonate solution, 2% hydrochloric acid and water. The organic layer was dried over anhydrous sodium sulfate and was then evaporated *in vacuo*. The residual oil was solidified by addition of ether and petroleum ether. The product was recrystallized from ethyl acetate-ether-petroleum ether; yield, 6.83 g (87%); mp 102—104°C; $[\alpha]_D^{20}$ +12.5° (*c* 1.04, DMF); R_f 0.98.[10]

Found: C, 66.40; H, 6.77; N, 7.35%. Calcd for $C_{22}H_{26}O_5N_2$: C, 66.31; H, 6.58; N, 7.03%.

HCl·H-D-Phe-β-Ala-OEt (III). A solution of II (3.38 g, 8.49 mmol) in methanol (30 m*l*) was subjected to hydrogenolysis in the presence of palladium black and 2.48N methanolic hydrogen chloride (4.13 m*l*) for 8 hr. The filtrate from the catalyst was evaporated to dryness *in vacuo*. The product was obtained as an oil; yield, 2.25 g (100%). R_f 0.82.[10]

Z-Leu-D-Phe-β-Ala-OEt (IV). Benzyloxycarbonyl-leucine dicyclohexylammonium salt (2.25 g, 5.04 mmol) was coupled with III (1.52 g, 5.04 mmol) by dicyclohexylcarbodiimide (1.04 g, 5.04 mmol) following the procedure employed for the preparation of II. Recrystallization from ethyl acetate-ether gave 1.32 g (81%); mp 130—132°C; $[\alpha]_D^{20}$ +15.8° (*c* 1.04, DMF); R_f 0.98.[10]

Found: C, 65.50; H, 7.47; N, 8.51%. Calcd for $C_{28}H_{37}O_6N_3$: C, 65.73; H, 7.29; N, 8.21%.

Z-Leu-D-Phe-β-Ala-OH (V). To a solution of IV (1.65 g, 3.21 mmol) in a mixture of methanol (10 m*l*) and dioxane (5 m*l*) was added 1.0N sodium hydroxide (4.05 m*l*), and the solution was allowed to stand for 4 hr at room temperature. After the addition of water (30 m*l*) and 1.0N hydrochloric acid (4.68 m*l*), the solution was concentrated *in vacuo* at a low temperature, and the residual oily product was extracted with ethyl acetate (50 m*l*). The organic layer was dried over anhydrous sodium sulfate and was then evaporated *in vacuo*. The residual foam weighed 1.7 g (100%). R_f 0.90.[10]

H-Leu-D-Phe-β-Ala-OH (VI). A solution of V (1.5 g, 3.22 mmol) in a mixture of methanol-water-acetic acid (3 : 1 : 6, v/v, 20 m*l*) was subjected to hydrogenolysis in the presence of palladium black for 6 hr. The filtrate from the catalyst was evaporated to dryness *in vacuo* and the oily residue was triturated with ether-petroleum ether. The crystals were collected by filtration in a cold room and dried *in vacuo*; yield, 1.17 g (95%); mp 189—191°C; $[\alpha]_D^{25}$ +57.7° (*c* 0.44, methanol); R_f 0.85.[10]

Found: C, 60.91; H, 7.84; N, 11.49%. Calcd for $C_{18}H_{27}O_4N_3 \cdot 1/3H_2O$: C, 60.82; H, 7.84; N, 11.82%.

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Phe-β-Ala-OH (VIII). To a chilled solution of Z(OMe)-Val-Orn(δ-Z)-$NHNH_2$ (VII)[12] (1.68 g, 3.21 mmol) in glacial acetic acid (40 m*l*) were added successively with stirring 1.0N hydrochloric acid (6.42 m*l*) and sodium nitrite (265.8 mg) in 9 m*l* of water. After 6 min, cold water (520 m*l*) was added to the solution. The azide which precipitated as a white mass was collected by filtration and washed with cold water (200 m*l*), a 9% sodium bicarbonate solution (200 m*l*) and cold water (200 m*l*), and then dried in a vacuum in a desiccator. The azide was added to a solution of VI (1.35 g, 3.12 mmol) and triethylamine (0.87 m*l*) in dimethylformamide (25 m*l*), and the reaction mixture was stirred for 3 days at 0°C. The precipitate formed by the addition of 10% citric acid (15 m*l*) was collected, washed with 10% citric acid and water and then dried. Recrystallization from methanol-ether-petroleum ether gave 2.32 g (86%); mp 181—183°C; $[\alpha]_D^{20}$ +11.6° (*c* 0.53, DMF); R_f 0.87.[10]

Found: C, 62.52; H, 7.20; N, 9.68%. Calcd for $C_{45}H_{60}O_{11}N_6$: C, 62.77; H, 7.02; N, 9.76%.

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Phe-β-Ala-ONp (IX). To a solution of VIII (600 mg, 0.69 mmol) in pyridine (10 m*l*) was added di-*p*-nitrophenyl sulfite[13] (2.25 g, 6.96 mmol), and the reaction mixture was allowed to

stand for 24 hr at room temperature. After evaporation of the mixture to dryness, the oily product was triturated with petroleum ether and washed repeatedly with a mixture of ether-petroleum ether (1 : 1) by decantation until no yellow color could be discerned upon the addition of a sodium hydroxide solution to the washings. The resulting product was collected by filtration, washed with a mixture of ether-petroleum ether (1 : 1) and dried. The yield was 694 mg (108%); the *p*-nitrophenyl ester content in the product was estimated to be 95% spectrophotometrically by measuring the optical density of the solution of the compound in dimethylformamide - N sodium hydroxide (1 : 1) at 404 mμ.[14]

HCl·H-Val-Orn(δ-Z)-Leu-D-Phe-β-Ala-OH (X). To a solution of VIII (700 mg, 0.814 mmol) in dioxane (6 ml) were added anisole (0.6 ml) and 2.0N hydrogen chloride in dioxane (16.28 ml). The reaction mixture was allowed to stand for 7.5 hr at room temperature. After removal of the solvent *in vacuo*, the residue was triturated with ether. The product solidified was collected by filtration, washed with ether and dried in a vacuum in a desiccator; yield, 580 mg (97%); mp 144—146°C; $[\alpha]_D^{25}$ +22.4° (*c* 0.5, DMF); R_f 0.80.[10]

Found: C, 56.45; H, 7.50; N, 11.00%. Calcd for $C_{36}H_{53}O_8N_6Cl \cdot 2H_2O$: C, 56.20; H, 7.46; N, 10.93%.

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Phe-β-Ala-Val-Orn-(δ-Z)-Leu-D-Phe-β-Ala-OH (XI). To a solution of X (273 mg, 0.37 mmol) and triethylamine (0.05 ml) in a mixture of pyridine (5 ml) and dimethylformamide (5 ml) was added IX (367 mg, 0.37 mmol), and the reaction mixture was stirred for 8 days at room temperature. The precipitate formed by the addition of 10% citric acid (30 ml) was collected, washed with 10% citric acid and water and then dried. Recrystallization from dimethylformamide-ether gave 464 mg (81%); mp 237—240°C; $[\alpha]_D^{20}$ +9.2° (*c* 0.5, DMF); R_f 0.99.[10]

Found: C, 62.53; H, 7.22; N, 10.41%. Calcd for $C_{81}H_{110}O_{27}N_{12} \cdot H_2O$: C, 62.45; H, 7.24; N, 10.79%.

***cyclo*-(Val-Orn(δ-Z)-Leu-D-Phe-β-Ala-)$_2$ (XII).** *From XI.* To a solution of XI (358 mg, 0.23 mmol) in pyridine (8 ml), di-*p*-nitrophenyl sulfite (3.01 g, 9.30 mmol) was added. After the mixture had been allowed to stand for 5 days at room temperature, it was evaporated *in vacuo*. The residual solid was collected by filtration with the aid of a mixture of ether and petroleum ether (1 : 1); yield, 476 mg. The *p*-nitrophenyl ester content for this product was estimated to be 100% by measuring the optical density of the compound at 404 mμ. To the active ester thus obtained, anisole (0.3 ml) and trifluoroacetic acid (4.5 ml) were added at 0°C. The solution was evaporated *in vacuo*, and the residual powder was collected by filtration with the aid of ether. This decapeptide *p*-nitrophenyl ester trifluoroacetate was dissolved in dimethylformamide (8 ml) and acetic acid (0.1 ml). The solution was added drop by drop over a period of 6 hr to pyridine (100 ml) which had been kept at 60°C; stirring was then continued for an additional 2 hr at the same temperature. After removal of the solvent by evaporation *in vacuo*, the residue was dissolved in a mixture of methanol (50 ml), dioxane (20 ml) and water (15 ml). The insoluble substance was removed by filtration, and the filtrate was successively passed through columns (1.8×15 cm, each) of Dowex 1 (OH^- form) and Dowex 50 (H^+ form). The columns were washed with the same solvent (400 ml), and the combined effluent was evaporated *in vacuo* to yield a crystalline product. The product was collected by filtration with the aid of water, and recrystallized from methanol-ether-petroleum ether; yield, 132 mg (42% from XI); mp 231—234°C (decomp); $[\alpha]_D^{25}$ −5.3° (*c* 0.6, acetic acid).

Found: C, 62.43; H, 7.44; N, 12.07%; mol wt, 1407.[15] Calcd for $C_{72}H_{100}O_{14}N_{12} \cdot 2H_2O$: C, 62.04; H, 7.53; N, 12.06%; mol wt, 1394.

From VIII. The acylpentapeptide VIII (1.82 g, 2.1 mmol) was converted to the pentapeptide *p*-nitrophenyl ester trifluoroacetate following the same procedure as described above, and then added to pyridine (300 ml). After the filtrate was passed through columns of Dowex 1 and Dowex 50 in the same way as described above, the effluent was evaporated to dryness, and the residual powder was collected by filtration with the aid of water; yield of the crude product (XIV), 482 mg. The solution of XIV (107 mg) in methanol (2 ml) was applied to a column (2.7×110 cm) of Sephadex LH-20, and development was continued with methanol. Elution was carried out at room temperature, and 3 ml fraction were collected under a flow rate 30 ml per hr. When the peptide content in the fractions was determined on a thin-layer plate, the peak of XII appeared from the test tube numbers 41 to 80 and the peak of XV from 90 to 130. The same chromatography was repeated further three times; thus, 430 mg of XIV was separated into two components. The four groups of the fractions of 41—80 were combined, evaporated *in vacuo* and the crystals (44 mg, 3.7% from VIII) of XII were obtained; yield after recrystallization, 40 mg; mp 230—233°C (decomp); $[\alpha]_D^{25}$ −5.0° (*c* 0.58, acetic acid).

***cylco*-(Val-Orn(δ-Z)-Leu-D-Phe-β-Ala-) (XV).** The four groups of the fractions of 90—130 obtained above were combined and evaporated *in vacuo* to afford the crystals (363 mg, 29.3% from VIII). It was recrystallized from methanol-ether-petroleum ether, yield, 358 mg; mp 213—215°C (decomp); $[\alpha]_D^{25}$ −12.5° (*c* 0.68, acetic acid).

Found: C, 61.00; H, 7.52; N, 11.34%; mol wt, 636.[15] Calcd for $C_{36}H_{50}O_7N_6 \cdot 3/2H_2O$: C, 61.16; H, 7.56; N, 11.80%; mol wt, 678.

5,5′-β-Alanine-gramicidin S, *cyclo*-(Val-Orn-Leu-D-Phe-β-Ala-)$_2$ (XIII). A solution of XII (51.6 mg, 0.038 mmol) in ethanol (6 ml) and 0.25N methanolic hydrogen chloride (0.37 ml), was subjected to hydrogenolysis in the presence of palladium black for 6 hr. The solution, after being filtered from the catalyst, was evaporated *in vacuo*. The residual product was recrystallized from methanol-ether-petroleum ether; yield of the air-dried product, 38 mg (86%); mp 280—282°C (decomp); $[\alpha]_D^{25}$ +43.2° (*c* 0.32, ethanol); R_f 0.77.[10]

Found: C, 52.46; H, 7.77; N, 12.66%. Calcd for $C_{56}H_{88}O_{10}N_{12} \cdot 2HCl \cdot 7H_2O$: C, 52.19; H, 8.12; N, 13.04%.

β-Alanine-cyclosemigramicidin S, *cylco*-(Val-Orn-Leu-D-Phe-β-Ala-) (XVI). XV (50.4 mg, 0.074 mmol) was treated as described for the preparation of XIII·2HCl; yield, 41 mg (95%); mp 250—252°C (dec.); $[\alpha]_D^{25}$ −13.4° (*c* 0.55, ethanol); R_f 0.70.[10]

Found: C, 51.61; H, 7.89; N, 12.60%. Calcd for

Electrophoresis and Carboxymethylcellulose (CMC) Chromatography. These experiments were carried out as previously described.[16] A part of the crude product (XIV), which was obtained after the cyclization reaction of the acylpentapeptide *p*-nitrophenyl ester (IX), was hydrogenated, and the product obtained was designated as XVII. As shown in Figs. 3 and 4, 5,5′-β-alanine-gramicidin S and 5-β-alanine-cyclosemigramicidin S were clearly separated in paper electrophoresis and in CMC chromatography.

Optical Rotatory Dispersion (ORD).[7,17] ORD measurements were performed with a Jasco Model ORD/UV5 spectropolarimeter. Cell of path length 1.0 cm was used and the runs were made at ambient temperature. As shown in Fig. 5, the ORD curve of gramicidin S is similar to that obtained by Balasubramanian,[7] and a trough is encountered at 230 mμ with a trough specific rotation of $-18560°$. 5,5′-β-Alanine-gramicidin S and 5-β-alanine-cyclosemigramicidin S showed the monotonic change toward positive at 230 mμ.

Microbiological Assays.[18] The microorganisms employed are listed in Table 1. Minimum amount of the compound necessary for the complete inhibition of growth was determined by the dilution method. As shown in Table 1, 5,5′-β-alanine-gramicidin S and 5-β-alanine-cyclosemigramicidin S were found to exhibit no antibacterial activity against the microorganisms tested, whereas gramicidin S exhibited activity against *Bacillus subtilis* and *Staphylococcus aureus*.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1202—1207 (1970)

Studies of Peptide Antibiotics. XVII. Analogs of Gramicidin S Containing Glycine or Alanine in Place of Leucine

Okitoshi ABE[1] and Nobuo IZUMIYA[2]

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received October 11, 1969)

In order to investigate the contribution to antibacterial activity of the leucine residues at 3- and 3′-position in gramicidin S, 3,3′-glycine- and 3,3′-L-alanine-gramicidin S (XII-G and XII-A) were prepared and tested for antibacterial properties. A crude product obtained after cyclization of a linear pentapeptide active ester consisted of a protected monomer and a dimer. The pure protected dimer was obtained by a Sephadex LH-20 column from the crude product. Hydrogenolysis of the pure protected dimer afforded the crystalline hydrochloride of XII-G or XII-A. It was found that XII-G showed no activity in any of the microorganisms tested, whereas XII-A exhibited substantial activity though weaker than that of gramicidin S.

Regarding the relationship between the chemical structure and the biological activity of gramicidin S (GS) (Fig. 1), it was reported in previous papers that 5,5′-glycine-GS[3] possessed higher activity than GS against several microorganisms, whereas 1,1′-

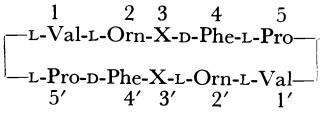

Fig. 1. Structure of gramicidin S (GS) and its analogs. X represents an amino acid residue such as L-Leu (GS), Gly (XII-G) or L-Ala (XII-A).

glycine-GS[4] and 4,4′-glycine-GS[5] exhibited no activity. Contrary to the inactivity of 1,1′-glycine-GS, it was found that 1,1′-L-alanine-GS was as active as GS.[4] These results indicate that the side chains, the isopropyls, of the valine residues in GS molecule can be replaced by smaller aliphatic side chains, the methyls, without influencing the activity, while glycine residues are too small to maintain it. In order to investigate to what extent the leucine residues in 3- and 3′-position of GS molecule contribute to the biological activity, we attempted to prepare several analogs of GS.

This paper deals with the syntheses and antibacterial properties of 3,3′-glycine- and 3,3′-L-alanine-GS besides the preparation of the cyclic pentapeptides, 3-glycine- and 3-L-alanine-cyclo-semiGS.

As shown in Fig. 2,[6] the acylpentapeptide ethyl ester (III-G or -A) was prepared by the coupling reaction of acyldipeptide azide derived from XIII with the tripeptide ester (II-G or -A). However, the ester (III-G or -A) showed considerable resistance to saponification. Hence, in the preparation of the acylpentapeptide acid (VI-G or -A), the azide from XIII was coupled with neutral free tripeptide (V-G or -A), as shown in Fig. 3.

Synthesis of the protected cyclic decapeptide (X-G or -A) was attempted by possible dimerization reaction of the pentapeptide active ester (VIII-G or -A) which was derived from the acylpentapeptide acid (VI-G or -A) (Fig. 3). Treatment of the active ester with a large amount of pyridine afforded a mixture of the protected monomer (IX-G or -A) and dimer (X-G or -A). Attempts to separate two components from the crude mixture by fractional recrystallization with methanol-ether failed because of no appreciable difference in solubility between the components. Separation of the components was achieved by the use of a Sephadex LH-20 column with methanol as an eluting solvent. The protected dimer was obtained from the faster eluting fraction, and the monomer from the slower fraction as shown in Fig. 4.

The weight of both components calculated are shown in Table 1 with the previous results. It is of interest to note that the ratio of formation of the protected monomer increased stepwise as 32→43→59 when the leucine residue in the active ester is replaced with alanine and glycine. The results indicate that a spacial conformation of a pentapep-

6) The following abbreviations are used; Z-, benzyloxycarbonyl; Z(OMe)-, *p*-methoxybenzyloxycarbonyl; -ONp, *p*-nitrophenoxy; -$NHNH_2$, hydrazide; -N_3, azide; MA, mixed anhydride method; DMF, dimethylformamide. Amino acid symbols except for D-Phe denote L-configuration.

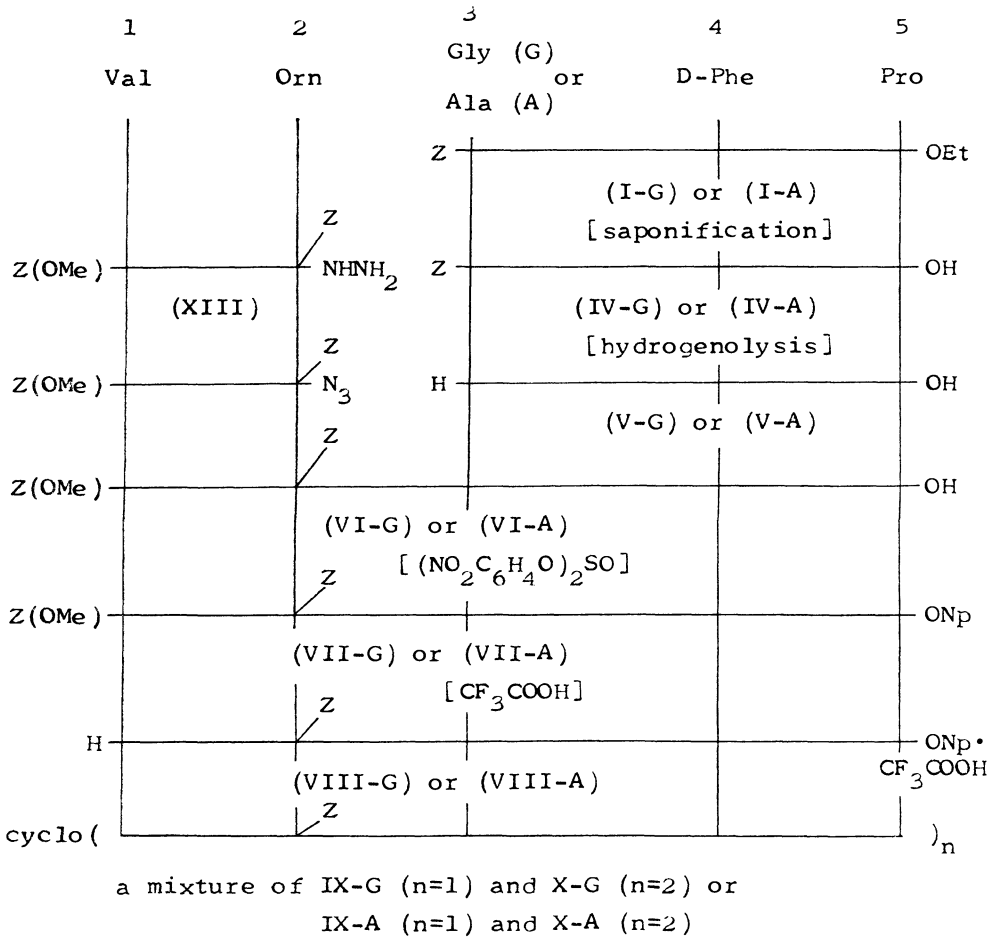

Fig. 3. Cyclization of linear pentapeptide active ester.

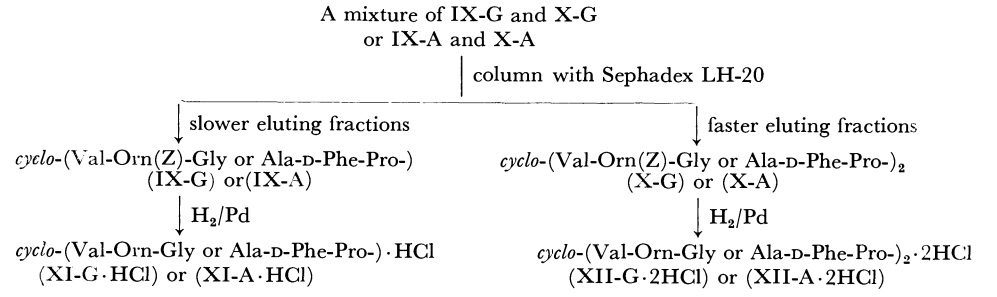

Fig. 4. Separation of the protected monomer and dimer, and preparation of the analogs of GS and cyclosemiGS.

tide active ester in pyridine is favorable for causing a monomerization reaction preferably when a small amino acid, glycine, occupies the third position in the pentapeptide active ester.

Hydrogenolysis of each of the protected cyclic peptides (IX and X) in the presence of hydrogen chloride yielded a crystalline hydrochloride of the required cyclic peptide (XI or XII). The antibacterial activities of these peptides toward several microorganisms were examined (Table 2). The two cyclosemiGS analogs (XI-G and -A) exhibited no activity as in the case of cyclosemiGS itself.[7] It was also found that 3,3′-glycine-GS (XII-G)

Table 1. Ratio of protected monomer and dimer after cyclization of linear pentapeptide active esters

p-Nitrophenyl ester of[a]	Ratio of compounds in product[b]	
	Z-cyclic monomer	diZ-cyclic dimer
H-Val-Orn(δ-Z)-Leu-D-Phe-Pro-OH[7]	32	68
-Gly-[4]	100	0
-Ala-[4]	91	9
-Gly-	59	41
-Ala-	43	57
-Gly-[5]	0	100
-Gly-[3]	79	21

a) After H-Val-Orn(δ-Z)-Leu-D-Phe-Pro-OH listed, only variation of the residue is shown.
b) The concentrations of linear pentapeptide *p*-nitrophenyl esters in pyridine were of approximately 3×10^{-3}M.

exhibited no activity, whereas the alanine analog (XII-A) exhibited substantial activity toward two kinds of microorganisms though the degree of activity was weaker than that of GS (Table 2). These results indicate that the glycine residues which occupy the leucines are too small to maintain activity, while the alanines can replace the leucines without appreciable drop in activity.

Experimental

All melting points are uncorrected.

Z-Gly-D-Phe-Pro-OEt (I-G). To a solution of benzyloxycarbonyl-glycine (0.596 g, 2.85 mmol) and triethylamine (0.40 m*l*, 2.85 mmol) in tetrahydrofuran (5.8 m*l*), isobutyl chloroformate (0.37 m*l*, 2.85 mmol) was added at −5°C. After 15 min, a mixture of H-D-Phe-Pro-OEt·HCl[8] (0.932 g, 2.85 mmol) and triethylamine (0.40 m*l*, 2.85 mmol) in chloroform (5.8 m*l*) was added. The mixture was left to stand overnight at room temperature and then evaporated *in vacuo*. The oily residue was dissolved in ethyl acetate. The solution was washed successively with 4% sodium bicarbonate, 2% hydrochloric acid and water, and dried over sodium sulfate. The filtrate was evaporated *in vacuo*; yield of oil, 1.01 g (74%); R_f, 0.97.[9]

Z-Ala-D-Phe-Pro-OEt (I-A). This was obtained from benzyloxycarbonyl-alanine (3.21 g, 14.4 mmol) and H-D-Phe-Pro-OEt·HCl (4.70 g, 14.4 mmol) as described above; yield of oil, 6.48 g (91%); R_f, 0.97.[9]

H-Gly-D-Phe-Pro-OEt·HCl (II-G·HCl). A solution of I-G (2.54 g, 7.34 mmol) dissolved in 0.52N ethanolic hydrogen chloride (15.5 m*l*) was subjected to hydrogenolysis in the presence of palladium black. The filtrate from the catalyst was evaporated to dryness *in vacuo*; yield of oil, 1.82 g (100%); R_f, 0.73.[9]

9) The R_f values refer to the thin-layer chromatography with Merck silica gel G and to the *n*-butanol - acetic acid - pyridine - water (4 : 1 : 1 : 2, v/v) system. Compounds possessing a free amino group were detected by spraying them with ninhydrin, and those with blocked amino groups, by spraying them with 48% hydrobromic acid, and then with ninhydrin.

H-Ala-D-Phe-Pro-OEt·HCl (II-A·HCl). This was obtained from I-A (6.36 g, 12.8 mmol) as described above; yield of oil, 5.22 g (103%); R_f, 0.74.[9]

Z(OMe)-Val-Orn(δ-Z)-Gly-D-Phe-Pro-OEt (III-G). To a solution of Z(OMe)-Val-Orn(δ-Z)-$NHNH_2$ (XIII)[10] (1.71 g, 3.15 mmol) dissolved in a mixture of acetic acid (50 ml), DMF (10 ml) and 1.92N hydrochloric acid (4.1 ml) was added sodium nitrite (261 mg). After 15 min, cold water (300 ml) was added to the solution. The azide which precipitated was collected by filtration, washed with 4% sodium bicarbonate and water, and then dried *in vacuo*. The azide was added to a solution of II-A·HCl (0.781 g, 3.15 mmol) and triethylamine (0.44 ml) in DMF (25 ml). The mixture was stirred for 2 days at 0°C and evaporated *in vacuo*. The precipitate which formed upon the addition of water was collected, washed successively with 4% sodium bicarbonate, 10% citric acid and water. It was recrystallized from dioxane-methanol-ether; yield, 1.92 g (70%); mp 151—154°C; $[\alpha]_D^{20}$ −18.0° (*c* 1, DMF); R_f, 0.95.[9]

Found: C, 62.65; H, 6.80; N, 9.80%. Calcd for $C_{45}H_{58}O_{11}N_6$: C, 62.91; H, 6.82; N, 9.78% .

Z(OMe)-Val-Orn(δ-Z)-Ala-D-Phe-Pro-OEt (III-A). The azide derived from XIII (2.18 g, 4.0 mmol) was condensed with II-A·HCl (1.59 g, 4.0 mmol) and triethylamine (0.56 ml) as described above. The crude product was recrystallized from ethanol-dioxane-ether; yield, 3.16 g (91%); mp 165—170°C; $[\alpha]_D^{20}$ −14.0° (*c* 1, DMF); R_f, 0.95.[9]

Found: C, 63.51; H, 6.70; N, 9.86%. Calcd for $C_{46}H_{60}O_{11}N_6$: C, 63.27; H, 6.94; N, 9.63%.

Z-Gly-D-Phe-Pro-OH (IV-G). To a solution of I-G (1.88 g, 3.9 mmol) in a mixture of dioxane (8 ml) and methanol (8 ml), N sodium hydroxide (8.15 ml) was added; the solution was then allowed to stand for 1.5 hr at room temperature. After the addition of water, the solution was evaporated *in vacuo*. The residue was acidified with N hydrochloric acid and extracted with ethyl acetate. The extract was dried over sodium sulfate and evaporated *in vacuo*. The residual oil was solidified by the addition of ether; yield of powder, 1.23 g (69%); R_f, 0.79.[9]

Z-Ala-D-Phe-Pro-OH (IV-A). This was obtained from I-A (1.94 g, 3.9 mmol) as described for the preparation of IV-G; yield of powder, 1.31 g (72%); R_f, 0.84.[9]

H-Gly-D-Phe-Pro-OH (V-G). A solution of IV-G (0.722 g, 1.6 mmol) in a mixture of acetic acid (10.8 ml), methanol (5.4 ml) and water (1.8 ml) was treated with hydrogen in the presence of palladium black. The filtrate from the catalyst was evaporated *in vacuo* to dryness. The hygroscopic crystals were collected with the aid of ether; yield, 0.52 g (102%); R_f, 0.46.[9]

H-Ala-D-Phe-Pro-OH (V-A). This was obtained from IV-A (1.31 g, 2.8 mmol) as described for the preparation of V-G; yield, 0.71 g (76%); $[\alpha]_D^{20}$ −36.0° (*c* 1, DMF); R_f, 0.46.[9]

Z(OMe)-Val-Orn(δ-Z)-Gly-D-Phe-Pro-OH (VI-G). The azide derived from XIII (1.31 g, 2.4 mmol) was added to a solution of V-G (0.765 g, 2.4 mmol) and triethylamine (0.34 ml) in DMF (25 ml). The mixture was stirred for 2 days at 0°C and evaporated *in vacuo*. The residue was triturated with 0.5M citric acid, and the precipitate was collected by filtration and washed with water. It was recrystallized from dioxane-ethanol-ether; yield, 1.54 g (77%); mp 110—112°C; $[\alpha]_D^{20}$ −30.0° (*c* 1, DMF); R_f, 0.83.[9]

Found: C, 61.05; H, 6.80; N, 10.19%. Calcd for $C_{43}H_{54}O_{11}N_6 \cdot H_2O$: C, 60.83; H, 6.60; N, 9.90%.

Z(OMe)-Val-Orn(δ-Z)-Ala-D-Phe-Pro-OH (VI-A). The azide derived from XIII (0.936 g, 1.72 mmol) was condensed with V-A (0.570 g, 1.72 mmol) and triethylamine (0.24 ml) as described for the preparation of VI-G. The crude product was recrystallized from dioxane-methanol-ether; yield, 1.22 g (84%); mp 150—153°C; $[\alpha]_D^{20}$ −20.0° (*c* 1, DMF); R_f, 0.77.[9]

Found: C, 61.35; H, 6.69; N, 9.76%. Calcd for $C_{44}H_{56}O_{11}N_6$: C, 61.23; H, 6.79; N, 9.74%.

Z(OMe)-Val-Orn(δ-Z)-Gly-D-Phe-Pro-ONp (VII-G). To a solution of VI-G (1.08 g, 1.3 mmol) in pyridine (25 ml), di-*p*-nitrophenyl sulfite (4.21 g, 1.3 mmol) was added. After the mixture had been allowed to stand overnight at room temperature, it was evaporated *in vacuo*. The residual solid was collected with the aid of a mixture of ether and petroleum ether; yield, 1.50 g. The *p*-nitrophenyl ester content was estimated to be 91% by measuring the optical density at 412 mμ.

Z(OMe)-Val-Orn(δ-Z)-Ala-D-Phe-Pro-ONp (VII-A). The compound VI-A (0.423 g, 0.5 mmol) was converted to VII-A (0.663 g) as described above in which *p*-nitrophenyl ester content was estimated to be 107%.

Mixture of *cyclo*-(Val-Orn(δ-Z)-Gly-D-Phe-Pro-) (IX-G) and *cyclo*-(Val-Orn(δ-Z)-D-Phe-Pro-)$_2$ (X-G). The compound VII-G (1.49 g) was treated with anisole (1 ml) and trifluoroacetic acid (6 ml) at 0°C. After 40 min, the solution was evaporated, and the solid was collected with the aid of a mixture of ether and petroleum ether. The compound VIII-G·CF_3COOH thus obtained was dissolved in DMF (13 ml) and acetic acid (0.5 ml). The solution was added dropwise into pyridine (650 ml) at 55—60°C during 5 hr and the stirring was continued for additional 2 hr. The solution was evaporated, and the residue was dissolved in a mixture of methanol (150 ml) and water (30 ml). The solution was treated with column (1.8×15 cm) of Dowex 1 (OH^- form) and Dowex 50 (H^+ form). The columns were washed with the same solvent (450 ml), and the combined effluent was evaporated to dryness. The residual product was collected by filtration with the aid of water; yield, 0.51 g.[11] A part (0.1 g) of the product was dissolved in methanol (1.5 ml) and applied to a column (2.5×35 cm) with Sephadex LH-20, and the development continued with methanol. Elution was carried out at room temperature, at a flow rate of 30 ml per hour; a 2 ml fraction was collected. The peptide content in the fractions was determined as described previously.[7] The first peak appeared from tube number 31 to 51, and the second, from 56 to 70. The fractions 52 to 55 contained both components. The fractions were treated as follows.

***cyclo*-(Val-Orn(δ-Z)-Gly-D-Phe-Pro-) (IX-G).** The fractions 56—70 were combined and evaporated *in*

11) A few mg of this crude product was dissolved in methanol and subjected to hydrogenolysis. The paper electrophoresis of the hydrogenated material showed two spots.

vacuo, and the product was collected by filtration with the aid of water (yield, 39 mg). It was recrystallized from ethanol-ether; yield, 34 mg (20% from VI-G); mp 117—120°C; $[\alpha]_D^{20}$ −82.8° (*c* 0.5, MeOH); R_f, 0.98.[9]

Found: C, 62.03; H, 6.85; N, 12.90%; mol wt, 640.[12] Calcd for $C_{34}H_{44}O_7N_6 \cdot H_2O$: C, 62.07; H, 6.91; N, 12.78%; mol wt, 667.

***cyclo*-(Val-Orn(δ-Z)-Gly-D-Phe-Pro-)$_2$ (X-G).** The fractions 31—51 were treated as described above (yield, 27 mg). Recrystallization from ethanol-ether gave 25 mg (15% from VI-A); mp 208—210°C; $[\alpha]_D^{20}$ −232° (*c* 0.5, MeOH); R_f, 0.98.[9]

Found: C, 62.80; H, 6.83; N, 12.73%; mol wt, 1260. Calcd for $C_{68}H_{88}O_{14}N_{12}$: C, 62.93; H, 6.85; N, 12.96%; mol wt, 1298.

Mixture of *cyclo*-(Val-Orn(δ-Z)-Ala-D-Phe-Pro-) (IX-A) and *cyclo*-(Val-Orn(δ-Z)-Ala-D-Phe-Pro-)$_2$ (X-A). The compound VIII-A·CF_3COOH obtained from VII-A (0.662 g) was added to pyridine (250 ml) as described for the preparation of a mixture of IX-G and X-G. Yield of the crude product was 149 mg. A part (0.1 g) of the product was dissolved in methanol (2 ml) and applied to a column (2.5×35 cm) with Sephadex LH-20 as described. The first peak appeared from tube number 32 to 48, and the second 54 to 81. The fractions from 49 to 53 contained both components.

***cyclo*-(Val-Orn(δ-Z)-Ala-D-Phe-Pro-) (IX-A).** The fractions 54 to 81 were treated as described for the preparation of IX-G (yield, 26 mg). It was recrystallized from ethanol-ether; yield, 23 mg (10% from VI-B); mp 138—140°C; R_f, 0.98.[9]

Found: C, 61.62; H, 6.95; N, 12.30%; mol wt, 730.[12] Calcd for $C_{35}H_{46}O_7N_6 \cdot H_2O$: C, 61.74; H, 7.12; N, 12.35%; mol wt, 681.

***cyclo*-(Val-Orn(δ-Z)-Ala-D-Phe-Pro-)$_2$ (X-A).** The fractions 32 to 48 were treated as described above (yield, 35 mg). It was recrystallized from ethanol-ether; yield, 32 mg (15% from VI-B); mp 255—258°C; $[\alpha]_D^{20}$ −212° (*c* 0.5, MeOH); R_f, 0.98.[9]

Found: C, 61.38; H, 6.98; N, 11.97%; mol wt, 1320.[12] Calcd for $C_{70}H_{92}O_{14}N_{12} \cdot 2H_2O$: C, 61.74; H, 7.12; N, 12.35%; mol wt, 1362.

***cyclo*-(Val-Orn-Gly-D-Phe-Pro-)·HCl (XI-G·HCl).** A solution of IX-G (20 mg 0.03 mmol) dissolved in 0.01N methanolic hydrogen chloride (3.36 ml) was subjected to hydrogenolysis in the presence of palladium black. The filtrate was evaporated to dryness *in vacuo*. The crystals were collected with the aid of ether; yield of air-dried product, 16.0 mg (96%); mp 135—137°C (decomp); $[\alpha]_D^{20}$ −68.0° (*c* 0.5, MeOH); R_f, 0.84[9] and 0.76.[13]

Found: C, 51.30; H, 7.53; N, 13.86%. Calcd for $C_{26}H_{39}O_5N_6Cl \cdot 3H_2O$: C, 51.61; H, 7.50; N, 13.89%.

***cyclo*-(Val-Orn-Ala-D-Phe-Pro-)·HCl (XI-A·HCl).** The compound IX-A (20 mg 0.03 mmol) was converted to XI-A·HCl as described above; yield of air-dried product, 15.8 mg (95%); mp 140—142°C (decomp); $[\alpha]_D^{20}$ −55.3° (*c* 0.5, MeOH); R_f, 0.82[9] and 0.96.[13]

Electrophoresis. Electrophoresis on Toyo Roshi No. 52 paper was carried out with a solvent system, formic acid-acetic acid-methanol-water (1 : 3 : 6 : 10, v/v; pH 1.8) for 2 hr at 500 V/30 cm. Figure 5 shows

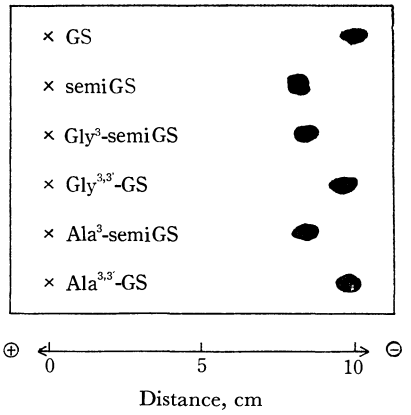

Fig. 5. Paper electrophoresis of the compounds.

that *cyclo*-decapeptides (XII-G and XII-A) migrate toward the cathode faster than *cyclo*-pentapeptides (XI-G and XI-A) and that mobilities of XII-G and XII-A are comparable with that of GS.

Microbiological Assays.[14] The minimum amount of the compounds necessary for the complete inhibition of growth was determined by a dilution method using a bouillon agar medium and a synthetic medium. As shown in Table 2, 3,3'-alanine-GS (XII-A) was found to exhibit weak antibacterial activity against *Staphylococcus aureus* and *Bacillus subtilis*, whereas 3,3'-glycine-GS (XII-G) and cyclosemiGS analogs (XI-G and XI-A) exhibited no activity against the microorganisms tested.

12) The molecular weight was determined on a Hitachi Osmometer, type 115, using methanol as the the solvent.

13) The R_f value of the paper chromatography with Toyo Roshi No. 52 refers to the *n*-butanol-acetic acid-pyridine-water (4 : 1 : 1 : 2, v/v) system.

14) We are indebted to Dr. M. Shibata of Takeda Chemical Industries, Ltd., for the assay.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1208—1211 (1970)

The Graft Copolymerization of a Vinyl Monomer Containing a Glucose Residue onto Polypropylene Fiber

Yoshio IWAKURA, Keikichi UNO, Takakazu KOJIMA and Akihiko UENO

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bukyo-ku, Tokyo

(Received October 13, 1969)

The graft copolymerization of 3-*O*-methacryloyl 1,2; 5,6-diisopropylidene-α-D-glucofuranose (MDG) onto polypropylene fibers was carried out by the γ-ray pre-irradiation technique in the presence of oxygen. The isopropylidene groups of the glucose residue grafted on the copolymer were removed by hydrolysis in aqueous formic acid, and the hydroxyl and hemiacetal groups were regenerated. The deacetonated fibers exhibited a considerable affinity for water vapor and could be dyed with a reactive dye.

In our laboratory, several polymers containing sugar residues were synthesized and their graft copolymerizations onto polymers were studied in a series of studies of the reactive polymer,[1,2] because the polymers containing sugar residues was expected to have a high affinity for water vapor and chemical reactivities through the hydroxyl and hemiacetal groups of the sugar residue. Polypropylene is known to have no affinity for water vapor because it has no hygroscopic groups and little chemical reactivities through the lack of an active center such as hydroxyl groups except hydrogen atoms on the tertiary carbons in the main chain. If hydroxyl groups are introduced into polypropylene by grafting a vinyl monomer with a sugar residue, the physical and chemical character of the grafted polypropylene is modified.

In the present study, 3-*O*-methacryloyl 1,2;5,6-diisopropylidene-α-D-glucofuranose (MDG), prepared from 1,2;5,6-diisopropylidene-α-glucose (DG) and methacryloyl chloride as a vinyl monomer, was used to modify polypropylene. Graft copolymerization was carried out by means of a pre-irradiation process in air. It is well known that when a polymer is irradiated in air, hydroperoxides and peroxides are generally formed on the polymer chain. Therefore, the pre-irradiated polypropylene fiber was heated in MDG to give a MDG-grafted polypropylene fiber. The polypropylene fiber grafted with MDG was hydrolyzed by acid at the acetal linkages of its sugar residue in order to generate the hydroxyl group. The behavior of the hydrolyzed grafted fiber in reaction to water vapor and its dyeability were examined. The hydrolyzed grafted fiber could be dyed with a reactive dye through chemical bonding.

Experimental

Preparation of 3-*O*-Methacryloyl-1,2;5,6-diisopropylidene-α-D-glucofuranose (MDG). MDG was prepared by the method described in the literature,[3,4] and was recrystallized from *n*-hexane at 0°C. Mp 40.5—41.5°C, $[\alpha]_D = -28.96°$ in benzene. ($[\alpha]_D = -28.8°$ in benzene[4]).

Graft Copolymerization. Unstretched polypropylene fiber, a product of the Chisso Co., was extracted with acetone for 5 hr in a Soxhlet apparatus and then irradiated by ^{60}Co in air at room temperature. An ampoule containing the irradiated fiber and the MDG-benzene solution was sealed, after having degassed by the freeze-and-thaw method under 10^{-4} mmHg. Graft copolymerization was carried out by heating the ampoule at a definite temperature. After the reaction, the resulting viscous solution was poured into a large amount of methanol, and the homopolymer thus precipitated was collected by filtration. The grafted fiber was extracted with benzene in a Soxhlet apparatus.

The percentage of grafting (G) and the grafting efficiency (F) were given by:

$$G = \frac{100(W_g - W_0)}{W_0}$$

$$F = \frac{100(W_g - W_0)}{(W_g - W_0) + H}$$

where W_0 is the initial weight of the polypropylene fiber, W_g is the weight of the grafted fiber, and H is the weight of the homopolymer produced during the graft copolymerization.

Hydrolysis.[5] The isopropylidene groups were removed from the MDG units of the grafted fiber by heating the fiber in aqueous formic acid (70 wt%) at

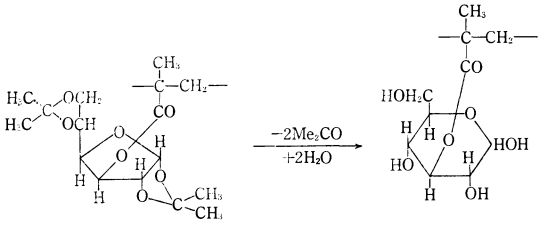
65°C for 6 hr. After the reaction, the fiber was washed with water and acetone, and then dried *in vacuo* at 60°C. Through hydrolysis, two moles of acetone can be eliminated from the MDG (molecular wt 328) unit by the addition of two moles of water. Thus, the extent of deacetonation (D) can be calculated by the following equation:

$$D = \frac{W_g - W_d}{\frac{80}{328}(W_g - W_0)}$$

were W_d is the weight of the polypropylene fiber after hydrolysis.



Dyeing. Mikacion Brilliant Red, a product of Mitsubishi Chemical Industries, Ltd., was used as the reactive dye. A solution of 0.3 g of the reactive dye, 1 g of sodium sulfate, 0.3 g of sodium carbonate, 2 m*l* of toluene, 1 m*l* of pyridine, a small amount of an emulsifier (Scourol 400), and 40 m*l* of water was prepared as the dyeing solution. Dyeing was carried out by dipping 0.1 g of the fiber into 3 m*l* of the above solution at room temperature. After standing overnight, the fiber was extracted with water in a Soxhlet apparatus.

Results and Discussion

In general, the variables which seemed to be important in a graft copolymerization carried out by the pre-irradiation method are the dose rate of irradiation, the total dose delivered to a polymer, the monomer concentration, the reaction temperature, the crystallinity of a polymer, and the time interval between irradiation and grafting. The effects of some of these variables on the pre-irradiation of the grafting of MDG to polypropylene were examined. The percentage of grafting and the grafting efficiency are plotted against the total doses in Fig. 1. It is well known that the characteristics of some polymers, such as polyethylene and polypropylene are changed by irradiation with γ-rays because of the formation of cross linkings.[6] It has also been reported that the monomer diffusion into the irradiated polymer is, in some cases, the rate-determining step in graft copolymerization by means of the pre-irradiated method.[7]

In this study, the fiber which was irradiated with a total dose of 3 Mrad was hard and brittle and was, further, not soluble in any solvent. This change in property was considered to be caused by cross-linking. As is shown in Fig. 1, the percentage of grafting increased with an increase in the total dose, whereas the grafting efficiency decreased.

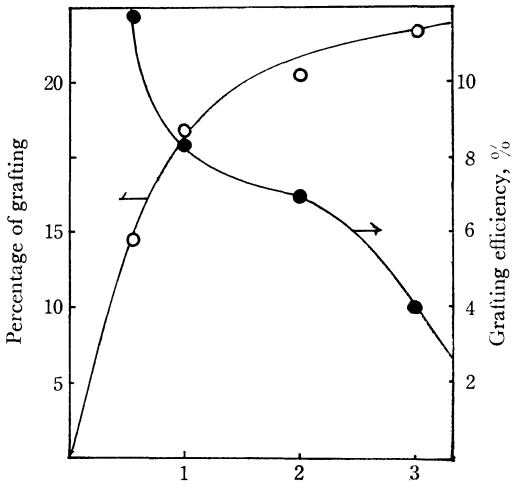


Fig. 1. Influence of irradiation total dose.
Dose rate: 2×10^5 r/hr; monomer concentration: 40 wt%; grafting temperature: 85°C; reaction time: 4 hr

The results obtained may be interpreted as follows. The cross-linked region of the fiber increased with an increased in the total dose, while the rate of the diffusion of the bulky monomer into the fiber decrease with an increase in the cross-linked region. On the other hand, the rate of the diffusion of the hydroxyl radical produced by the decomposition of hydroperoxide into the solution from cross-linked fiber is not much affected; as a result, a depression in grafting efficiency is observed.

Both the percentage of grafting and the grafting efficiency increased with an increase in the monomer concentration, as is shown in Fig. 2.

This fact can also be interpreted in terms of the diffusion of the monomer as follows. When the monomer concentration in the solution is high, the monomer concentration in the solid fiber will be high and the diffusion of the monomer from the solution into the fiber will also be high. This increases the propagation rate and results in the increase in the percentage of grafting. When the diffusion rate of the monomer from the solution into the fiber increases, the amount of homopolymer in the fiber which is polymerized by hydroxyl radical still in the fiber may be considered to increase also, because the diffusion rate of the hydroxide ion produced in the fiber into the solution is influenced by the monomer concentration in the solution. As the diffusion of the homopolymer produced in the fiber into the solution is usually very difficult, the result here obtained, the increase in the grafting

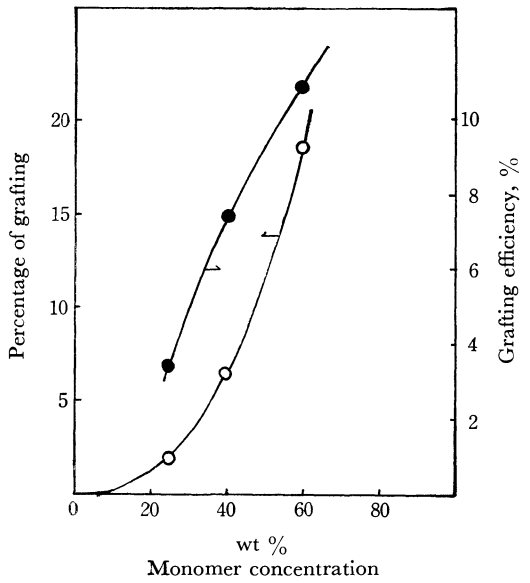

Fig. 2. Influence of monomer concentration.
Irradiation total dose: 2.0 Mrad; reaction condition: 85°C, 50 min
○ percentage of grafting
● grafting efficiency

efficiency, may be interpreted in the above terms.

The temperature dependency on the percentage of grafting is shown in Fig. 3.

The percentage of grafting increased with an increase in the temperature, whereas the grafting efficiency showed little change. These phenomena may indicate that the grafting is controlled by the diffusion of the monomer into the solid fiber. The diffusion rate of the monomer into the fiber from the solution, as well as that of the hydroxyl radical produced in the fiber, into the solution was accelerated by the increase in the reaction temperature. This results in an increase in the percentage of grafting for the reason described above, but it has almost no influence on the efficiency of the grafting.

The grafted fiber and the deacetonated fiber were

TABLE 1. RESULT OF DEACETONATION

Grafting reaction					Deacetonation
Total irradiation Mrad	Monomer concentration wt %	Temperature °C	Time hr	Percentage of grafting %	Extent of deacetonation %
0.55	40	85	4	11.7	34
1.0	40	85	4	17.4	47
2.0	40	85	4	20.3	89
2.0	40	85	5/6	6.5	53
2.0	60	85	5/6	18.6	93
2.0	25	75	5	3.8	101
2.0	25	80	5	7.3	92
2.0	25	90	5	10.0	84

smashed to powder in liquid nitrogen and then analyzed by means of the infrared absorption spectra. The grafted polypropylene showed an absorption characteristic of the carbonyl group at 1730 cm^{-1} and a new absorption of the hydroxyl group at 3400 cm^{-1} after hydrolysis, as is shown in Fig. 4.

This indicates that the isopropylidene groups were removed. The results of the hydrolysis are summarized in Table 1.

The extent of deacetonation was calculated from the weight loss of the fiber.

The introduction of MDG units onto the polymer changed the physical properties of the fiber. A fiber grafted over 200% with MDG was obtained when the grafting reaction was carried out at 85°C for 9.5 hr. The fiber thus obtained was very brittle and was easily torn to pieces. The water-vapor adsorption aspect of the deacetonated homopolymer was also examined. The deacetonated homopolymer, when placed in air saturated with water vapor, adsorbed the water vapor in time and gradually became a viscous mass. The water adsorbed by a deacetonated grafted fiber placed in air saturated with water vapor increased with an increase in the percentage of grafting, as is shown in Fig. 5.

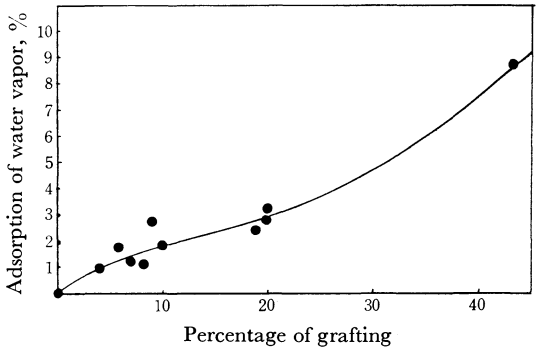

Fig. 5. Water vapor adsorption by the deacetonated grafted fiber at saturated vapor pressure

The amount of water adsorbed by the MDG units of the deacetonated grafted fiber is plotted against the percentage of grafting in Fig. 6.

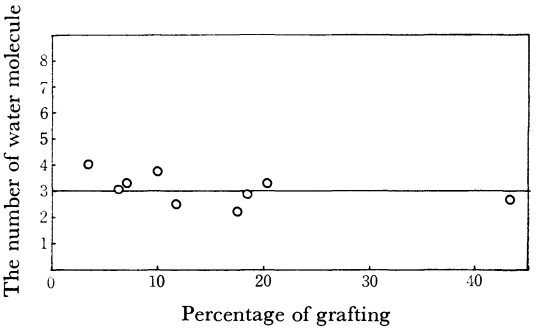

Fig. 6. The number of water molecule adsorbed by each MDG unit of deacetonated grafted fiber

Though no clear conclusion can be deduced from this figure, it can be pointed out that one MDG monomer unit adsorbs about three water molecules on the average.

Reactive dyes generally react with compounds containing hydroxyl groups, such as cellulose, by making covalent bond. The dyeability of the deacetonated fibers was examined with Mikacion Brilliant Red (MBR) as the reactive dye; this was the same kind of dye as Procion M. The shade of the colored fiber was responsible for the percentage of grafting. The observation of the cross-section of the dyed fiber by means of a microscope showed that the dyeing reaction occurred evenly in the fiber.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1212—1218 (1970)

Studies on the Formation of Deoxy Sugars by Detosyloxylation with Lithium Aluminum Hydride*1

Sumio UMEZAWA, Tsutomu TSUCHIYA and Hirokuni HINENO

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received October 29, 1969)

The reduction of a number of tosylated, mesylated, sometimes further-benzoylated derivatives of methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (I) with lithium aluminum hydride in tetrahydrofuran has been investigated; it has thus been found that methyl 4,6-*O*-benzylidene-2,3-di-*O*-tosyl-α-D-glucopyranoside (II) gave methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*ribo*-hexopyranoside (III, major), methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*arabino*-hexopyranoside (IV, minor), and methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*ribo*-hexopyranoside (V, minor) as deoxy derivatives through two kinds of monotosyl derivatives (VIII and X), and that methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-3-*O*-tosyl-α-D-glucopyranoside (VII) and methyl 3-*O*-benzoyl-4,6-*O*-benzylidene-2-*O*-tosyl-α-D-glucopyranoside (IX) gave VIII and X respectively, as intermediates. 2-*O*-Methyl-3-*O*-tosyl (XI) and 2-deoxy-3-*O*-tosyl derivatives (XIII) gave detosylated derivatives, (XII) and (IV) respectively. These and other results suggest, for detosyloxylation, a mechanism through the formation of an alkoxy-aluminum hydride.

The reduction of a secondary sulfonyl ester group with lithium aluminum hydride (hereafter abbreviated to LAH) sometimes provides a facile method for the synthesis of deoxysugars; in recent years, this kind of reaction has been studied fairly extensively. In connection with other work in progress in our laboratory, it became desirable to investigate further the scope and the mechanism of this kind of reaction. This report will deal with the reduction, with LAH in boiling tetrahydrofuran, of secondary sulfonyl groups in methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (I).

In general, the reduction of a sulfonate of a secondary hydroxyl group with LAH causes desulfonylation, thus giving a corresponding secondary alcohol,[1] while a primary sulfonic ester is reduced to give a corresponding methyl group. In some cases,[2] however, a secondary sulfonyloxy group is eliminated to form a deoxy derivative, by the reduction with LAH, as in the usual case of a primary sulfonyloxy group.

Vis and Karrer[3] reported that the reduction of methyl 4,6-*O*-benzylidene-2,3-di-*O*-tosyl-α-D-glucopyranoside (II) with LAH in tetrahydrofuran caused both desulfonylation and desulfonyloxylation, thus giving a 3-deoxy sugar, namely, methyl 4,6-*O*-benzylidene-3-deoxy-α-D-*ribo*-hexopyranoside (III), apparently through a reaction intermediate epoxide, methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside (VI). However, the reduction[4] of VI with LAH in ether gave methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*ribo*-hexopyranoside (V), indicating that the epoxide (VI) may not be the intermediate.

On the other hand, Allerton and Overend[5] observed that the reduction of methyl 2-*O*-tosyl-β-L-arabinopyranoside with LAH in ether afforded two kinds of deoxy derivatives, namely, methyl 2-deoxy-β-L-*erythro*-pentopyranoside and methyl 3-deoxy-β-L-*erythro*-pentopyranoside, and methyl 2,3-anhydro-β-L-riboside, the last epoxy-compound being considered to be the intermediate for the formation of 2-deoxy- and 3-deoxy-pentosides.

As has been mentioned above, the behavior of a sulfonate group towards the reduction with this hydride is critically dependent upon its position in, and the stereochemistry of, the carbohydrate molecule.

Experimental Results

A number of tosylated, mesylated, sometimes

further-benzoylated derivatives of 4,6-*O*-benzylidene-α-D-glucopyranoside were caused to react with LAH in tetrahydrofuran. At the beginning, the structure of the 3-deoxy derivative (III) obtained from II (see Chart 1) by the method of Vis and Karrer[3] was confirmed by NMR spectroscopy. Then, a derivative, in which one of the tosyloxy groups of II is replaced by a benzoyloxy group, namely, methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-3-*O*-tosyl-α-D-glucopyranoside (VII), was prepared and subjected to reduction with LAH for 20 hr. The separation of the resultant products by column chromatography with silica gel gave a mixture of deoxy products (A mixture, 73%) and a desulfonated product, methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (I, 6.3%), which was expected to be produced by the desulfonylation typical for secondary sulfonyloxy groups. The examination of the A mixture by NMR spectroscopy (see Experimental) suggested that it was composed of a 3-deoxy derivative (III, about 93%) and a 2-deoxy derivative, methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*ribo*-hexopyranoside (V, about 7%). When the reaction was pursued by thin-layer chromatography, it was found that the starting material (VII, R_f 0.95*[2]) disappeared rapidly and that, after 30 min, a product (R_f 0.8) became the main product; this was then gradually transformed to the above-mentioned three products constituting the A mixture, (III, V, and I). The intermediate proved to be methyl 4,6-*O*-benzylidene-3-*O*-tosyl-α-D-glucopyranoside (VIII); this pathway was supported by reducing VIII with LAH to give almost the same results as those obtained above.

Next, a positional isomer of VII, namely, methyl 3-*O*-benzoyl-4,6-*O*-benzylidene-2-*O*-tosyl-α-D-glucopyranoside (IX), was prepared and caused to react with LAH in the same manner. In this case, a 2-deoxy product, methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*arabino*-hexopyranoside (IV), was produced in a 29% yield, together with compound I (54%). The structure of IV was confirmed by its melting point and by its NMR spectrum. In this reaction, contrary to the case of VII, the deoxy sugar (IV) was produced in a low yield but was not contaminated by the formation of other deoxy sugars, as in the case of the A mixture. Here again the formation of an epoxy intermediate was not likely.

Hereupon, we made a further investigation of the above-mentioned Vis and Karrer's experiment, and a similar pursuit of the reaction and the identification technique described above was carried out. In a 40-hr reaction, the ditosylated starting material (II) was changed into a mixture of deoxy products (B mixture, 61%) and compound I (15%).

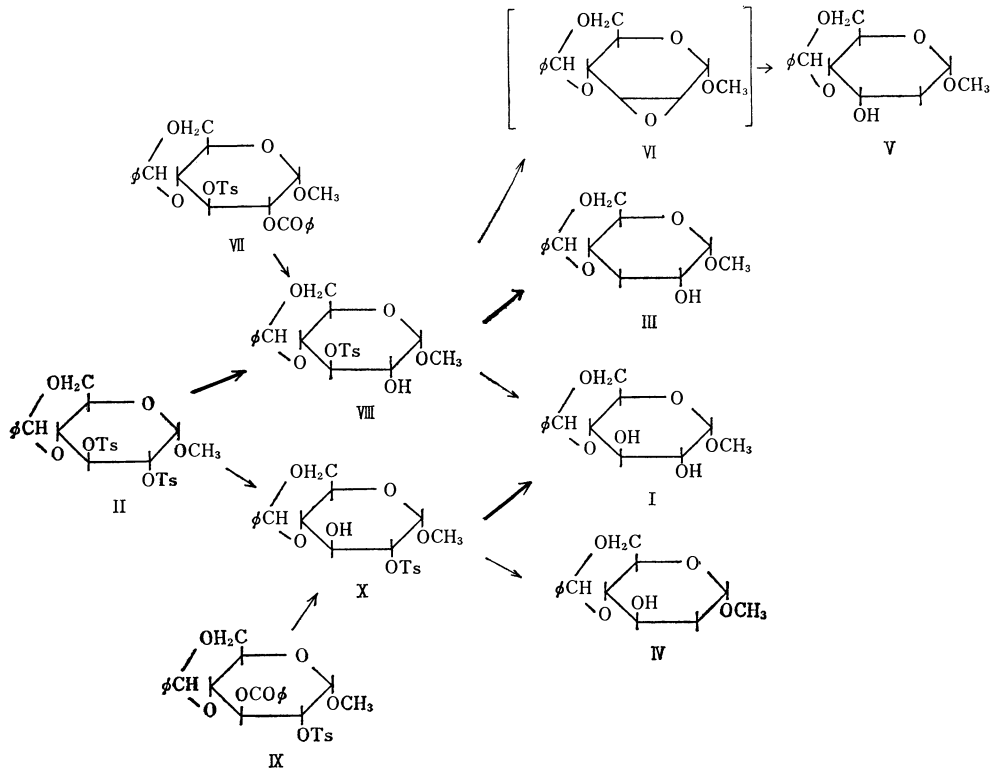

Chart 1

*[2] See Experimental.

An inspection of the NMR spectrum of the B mixture (see Experimental) indicated that the mixture was composed of three components: a 3-deoxy derivative (III, ~75%), a 2-deoxy derivative (V, ~12%), and another 2-deoxy derivative (IV, ~12%); the former two were identical with the components of the A mixture, while the latter was identical with the compound obtained from IX. When the reaction was stopped after 3.5 hr, the formation of two monotosylated products, namely, methyl 4,6-*O*-benylidene-3-*O*-tosyl and 2-*O*-tosyl-α-D-glucopyranoside (VIII and X, respectively), was revealed. Thus, it necessarily follows that the reaction of the ditosylated compound (II) with LAH may involve reactions of two kinds of monotosylated compounds (VIII and X) with LAH. The overall reaction pathway from II is depicted in Chart 1, as are those from VII and IX.

We then went on to prepare several compounds bearing methanesulfonyl (mesyl) groups instead of tosyl groups, namely, methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-3-*O*-mesyl-[6] (XVII), 4,6-*O*-benzylidene-2,3-di-*O*-mesyl-[6,7] (XVIII), 4,6-*O*-benzylidene-2-*O*-mesyl-[6] (XIX), and 4,6-*O*-benzylidene-2-*O*-mesyl-3-*O*-tosyl-α-D-glucopyranoside (XX), and these compounds were caused to react with LAH under reaction conditions similar to those described above. It was found that, except for XX, the three compounds exclusively afforded the desulfonated compound I in high yields; on the contrary, XX gave a result analogous to that from VII. In conclusion, so far as this kind of reactions is concerned, a mesyloxy group acts similarly to that of a benzoyloxy group.

Preparation of the Samples

Methyl 2-*O*-benzoyl- and 3-*O*-benzoyl-4,6-*O*-benzylidene-α-D-glucopyranoside (XIV and XV respectively) were prepared from methyl 4,6-*O*-benzylidene-α-D-glucopyranoside (I) by modifying the method of Jeanloz[6]; the yield of XIV and XV was fairly well improved. The tosylation of XIV and XV was performed with tosyl chloride in pyridine, and the structural proofs of the products (VII and IX) were obtained from their NMR spectra. The debenzoylation of VII and IX were performed with sodium in methanol without the formation of any epoxy compounds to give methyl 4,6-*O*-benzylidene-3-*O*-tosyl- and 2-*O*-tosyl-α-D-glucopyranoside (VIII and X respectively). The methylation of VIII was performed by methyl iodide and silver oxide, thus giving methyl 4,6-*O*-benzylidene-2-*O*-methyl-3-*O*-tosyl-α-D-glucopyranoside (XI) in a high yield. The mesylation of I to methyl 4,6-*O*-benzylidene-2-*O*-mesyl-α-D-glucopyranoside (XIX) was performed by modifying the method of Jeanloz,[6] while XIX was tosylated to methyl 4,6-*O*-benzylidene-2-*O*-mesyl-3-*O*-tosyl-α-D-glucopyranoside (XX) in a good yield in a usual way. Methyl 4,6-*O*-benzylidene 2-deoxy-3-*O*-tosyl-α-D-*arabino*-hexopyranoside[8] (XIII) was prepared from methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*arabino*-hexopyranoside (IV), which had itself been prepared from methyl 3-*O*-benzoyl-4,6-*O*-benzylidene-2-*O*-tosyl-α-D-glucopyranoside (IX) by reduction with LAH. The identification and the differentiation of methyl 4,6-*O*-benzylidene-2- or 3-deoxy-α-D-hexopyranosides (III, IV, and V), which all have the same R_f value in thin-layer chromatography, were conveniently performed by an inspection of their NMR spectra, which differ in τ-values and in the splitting patterns of anomeric, *O*-methyl, and benzylic hydrogens.

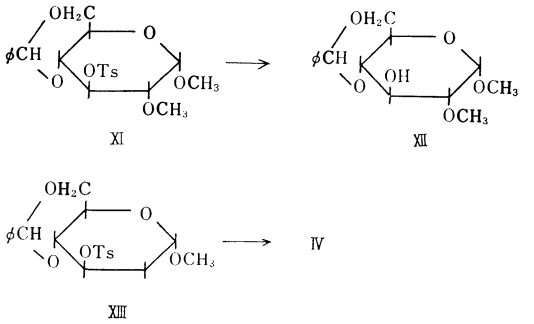

Chart 2

Discussion

In view of the above experimental results, it seems that any tosyl derivative desulfonyloxylated to a methylene-type deoxy compound by the action of LAH has a hydroxyl group, or a group easily changeable to a hydroxyl group by LAH, in the proximity of the secondary tosyloxy group in question. This suggests that the adjacent hydroxyl group may participate in this kind of reaction. To examine this point further, an *O*-methylated derivative (XI) of VIII was prepared and caused to react with LAH by the usual procedure; as expected, it has been found that this derivative was detosylated exclusively to give XII, while no trace of a detosyloxylated derivative was detected. Furthermore, a deoxy derivative of VIII, namely, methyl 4,6-*O*-benzylidene-2-deoxy-3-*O*-tosyl-α-D-*arabino*-hexopyranoside (XIII), was examined for this reaction; again, it has been found that no detosyloxylation, but rather detosylation, occurred to give IV. From these results, the important role of the adjacent

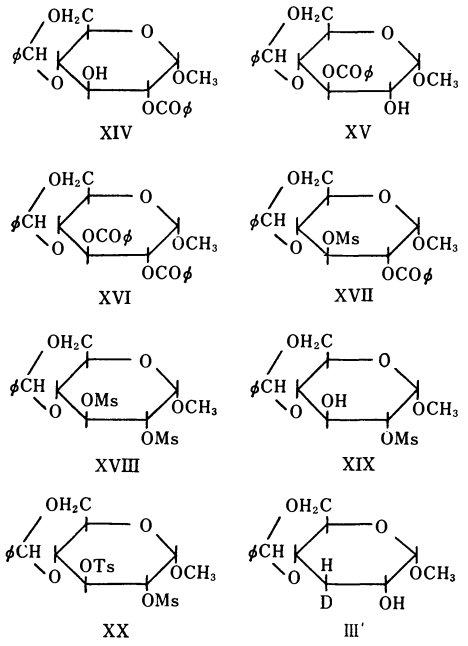

Chart 3. 4,6-*O*-Benzylidene derivatives used in this study other than those depicted in charts 1 and 2.

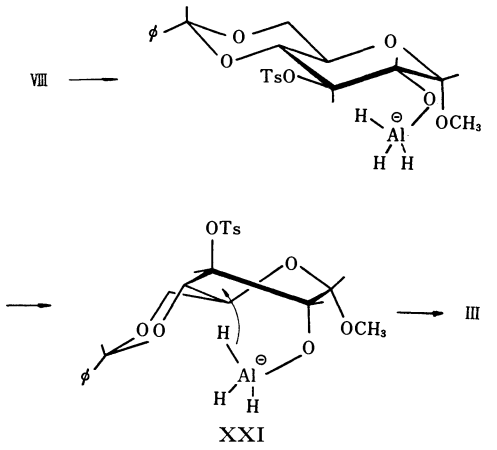
hydroxyl group in this kind of reaction became obvious. In this connection, Hedgley, Meresz, and Overend[9] found, in their synthesis of 5-deoxy-D-*xylo*-hexose, that 6-*O*-benzoyl-1,2-*O*-isopropylidene-5-*O*-tosyl-α-D-glucofuranose was converted mainly to 5-deoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hexofuranose by the reaction with LAH in ether (or in tetrahydrofuran); they therefore suggested that the product might be formed favourably through a *C*-3-alkoxy-aluminum hydride intermediate. A similar kind of mechanism of desulfonyloxylation would be very likely in our experiments, though the conversion of compound II, VII, or VIII to III requires a higher reaction temperature (in boiling tetrahydrofuran) and a small volume of tetrahydrofuran; when the reaction is performed in ether, ether-tetrahydrofuran, benzene-tetrahydrofuran, or dioxane, the reaction is very slow or the ratio of the yield of III to I becomes small, while when a larger volume of tetrahydrofuran than such described in the Experimental section is used, the ratio of the yield of III to I is considerably decreased. The mechanism shown in the following chart may be reasonable for the conversion of VIII to III.

Conformational change will be required to force one of the hydrogens of the metal hydride part of the intermediate to come close to carbon-3; the proximity of the hydrogen will be the driving force of the reaction. The backside attack of the metal hydride was supported by the result obtained



by means of lithium aluminum deuteride, which afforded methyl 3-deoxy-3-deuterio-4,6-*O*-benzylidene-α-D-allopyranoside (III').

In like manner, the formation of methyl 2-deoxy-β-L-*erythro*-pentopyranoside from methyl 2-*O*-tosyl-β-L-arabinopyranoside reported by Allerton and Overend[5] can be understood by the above-mentioned mechanism instead of that through an epoxy intermediate.

As for the mesyl derivatives (XVII, XVIII, and XIX), their desulfonylation may be ascribed to the fact that a mesyloxy group is more basic than a tosyloxy group and less functional as a leaving group in a transition state such as XXI.

Experimental

The NMR spectra were measured with a Varian A-60D spectrometer or a Japan Electron Optics 4H-100 spectrometer. Tetramethylsilane (τ 10.0) was used as the internal standard. The following abbreviations were used: p: proton, s: singlet, d: doublet, t: triplet, q: quartet, m: multiplet. Thin-layer chromatography (TLC) was carried out on microscope slides coated with silica gel, and the spots were visualized by spraying with 95% sulfuric acid and then heating at 110°C.

Methyl 2-*O*-Benzoyl-4,6-*O*-benzylidene-α-D-glucopyranoside (XIV) and Methyl 3-*O*-Benzoyl-4,6-*O*-benzylidene-α-D-glucopyranoside (XV). The method of Jeanloz and Jeanloz[6] was used; when the quantity of pyridine was increased about 20-fold, XIV was obtained in a higher yield as follows. To an ice-cold solution of I (5.0 g) in dry pyridine (100 m*l*) benzoyl chloride (2.1 m*l*) was gradually added; the mixture was allowed to stand under cooling for 4 hr and then at room temperature overnight. The reaction mixture was then treated as has been described in the literature[6] to give a crude syrup, which showed four spots on TLC (benzene-ethyl acetate 6 : 1): R_f 0.87 (XVI, a dibenzoylated derivative), 0.71 (XIV), 0.44 (XV), and 0.06 (I). The syrup was chromatographed on a silica-gel column (500 g, 4.7×54 cm) and then eluted with the same solvent system. After the first fraction (500 m*l*), the eluate was cut into 15-g portions. A dibenzoylated compound (XVI) was eluted between Nos. 12—20

9) E. J. Hedgley, O. Meresz and W. G. Overend, *J. Chem. Soc., C*, **1967**, 888.

(1.14 g, 13%); another, XIV, between Nos. 29—52 (3.47 g, 51%); a third, XV, between Nos. 110—154 (0.50 g, 7%). The starting material (I, 1.3 g, 26%) was eluted after the solvent had been changed to ethyl acetate. The dibenzoylated product (XVI) was recrystallized from benzene-*n*-hexane; mp 155°C (lit,[6] 154°C), $[\alpha]_D^{20}$ +97° (*c* 1, $CHCl_3$) (lit,[6] +94°); IR: 1725, 1275, 1095, 756, 707, 697 cm^{-1}.

Compound XIV was recrystallized from benzene-ether; mp 170—172°C (lit,[6] 169—170°C), $[\alpha]_D^{20}$ +112° (*c* 1, $CHCl_3$) (lit,[6] +111°); IR: 3450, 1735, 1270, 750, 713, 697 cm^{-1}; NMR (60 MHz, in pyridine-d_5): τ: 6.64 (3-p. s., OCH_3), 4.69 (1-p. d., H-1), 4.44 (1-p. q., H-2), 4.21 (1-p. s., benzylic); $J_{1,2}$ 3.5 Hz, $J_{2,3}$ 9.5 Hz.

Compound XV was recrystallized from benzene; mp 225—226°C (lit,[6] 219—220°), $[\alpha]_D^{20}$ +34° (*c* 1, $CHCl_3$) (lit,[6] +34°); IR: 3380, 1725, 1275, 750, 705, 695 cm^{-1}; NMR (60 MHz, in pyridine-d_5): τ: 6.62 (3-p. s., OCH_3), 4.89 (1-p. d., H-1), 4.23 (1-p. s., benzylic), 3.79 (1-p. t., H-3); $J_{1,2}$ 3.5 Hz, $J_{2,3}$—$J_{3,4}$ ~9.3 Hz.

Compound XIV was clearly differentiated from XV by comparing their NMR spectra. When $CDCl_3$ was used instead of pyridine-d_5, the separation of signals was indistinct.

Methyl 2-*O*-Benzoyl-4,6-*O*-benzylidene-3-*O*-tosyl-α-D-glucopyranoside (VII). Prepared by the usual method (yield 90%); mp 190°C (lit,[10] 188—189°C), $[\alpha]_D^{20}$ +89° (*c* 1, $CHCl_3$) (lit,[10] +88.5°); IR: 1730, 1600, 1365, 1270, 1175, 830, 750, 712 cm^{-1}; NMR (100 MHz, $CDCl_3$): τ: 7.87 (3-p. s., $TsCH_3$), 6.65 (3-p. s., OCH_3), 4.95—4.8 (2-p. m., H-1, H-2), 4.62 (1-p. s., benzylic), 4.58 (1-p. t., H-3); $J_{2,3}$—$J_{3,4}$ ~9.7 Hz.

Methyl 4,6-*O*-Benzylidene-3-*O*-tosyl-α-D-glucopyranoside (VIII). To a suspension of VII (594 mg) in dry methanol (60 m*l*) we added a piece of sodium metal; the mixture was then stirred at room temperature for several hours. If the suspension did not become clear, a little more of sodium was added and the mixture was treated as above. The resultant clear solution was neutralized with carbon dioxide and evaporated *in vacuo*. A chloroform solution of the residue was washed with water, dried over sodium sulfate, and evaporated to give a solid which contained a slight amount of an epoxy product (VI, R_f 0.55 on TLC) as a contaminant. Recrystallization from chloroform-*n*-hexane gave pure VIII; 398 mg (83%); R_f 0.30 (VII, R_f 0.72) by TLC (benzene-ethyl acetate 5 : 1); mp 164°C (lit,[7],*3 164°C), $[\alpha]_D^{22}$ +32° (*c* 1, $CHCl_3$) (lit,[7] +32.5°); NMR (60 MHz, $CDCl_3$): τ: 7.72 (3-p. s., $TsCH_3$), 6.55 (3-p. s., OCH_3), 5.18 (1-p. d., H-1), 5.10 (1-p. t., H-3), 4.67 (1-p. s., benzylic), 2.27 and 3.01 (4-proton AB quartet, *J* 8.3 Hz, Tosyl), ~2.65 (5-p., Ph.); $J_{1,2}$ 3.5 Hz, $J_{2,}$—$_3J_{3,4}$ ~9.5 Hz.

Methyl 4,6-*O*-Benzylidene-2-*O*-methyl-3-*O*-tosyl-α-D-glucopyranoside (XI). To a solution of VIII (586 mg) in dry acetone (6 m*l*) we added methyl iodide (1 m*l*), silver oxide (1.2 g), and freshly-prepared Drierite (1 g), after which the mixture was stirred overnight. The filtrate was evaporated, and the residue was dissolved in chloroform. The solution was then washed with water, dried over sodium sulfate, and evaporated. The residue was recrystallized from benzene-ethyl acetate (5 : 1), 591 mg (98%); mp 163—164°C, $[\alpha]_D^{20}$ +26° (*c* 1, $CHCl_3$); R_f 0.56 by TLC (benzene-ethyl acetate 5 : 1); IR: 2930, 1600, 1365, 1175, 1090, 975, 842, 750, 725, 700 cm^{-1}; NMR (60 MHz, $CDCl_3$): τ: 7.72 (3-p. s., $TsCH_3$), 6.63 (3-p. s., $O(2)CH_3$), 6.57 (3-p. s., $O(1)$-CH_3), 5.12 (1-p. d., H-1), 4.91 (1-p. t., H-3), 4.63 (1-p. s., benzylic), ~2.63 (5-p., Ph.), 2.27 and 2.99 (4-proton AB quartet, *J* 8.3 Hz, Tosyl); $J_{1,2}$ 3.5 Hz, $J_{2,3}$—$J_{3,4}$ ~9 Hz.

Found: C, 58.75; H, 5.75; S, 7.16%. Calcd for $C_{22}H_{26}O_8S$: C, 58.65; H, 5.82; S, 7.12%.

Methyl 4,6-*O*-Benzylidene-2-*O*-tosyl-α-D-glucopyranoside (X). Prepared from IX[10] in a manner similar to that described in VIII; yield 91%; mp 155°C (lit, 155°C,[7] 154°C[11]); $[\alpha]_D^{23}$ +63° (*c* 1, $CHCl_3$) (lit, +63.5°,[7] +62.9°[11]); NMR (60 MHz, $CDCl_3$): τ: 7.35 (1-p. broad singlet, disappeared on deuteration, OH), 7.58 (3-p. s., $TsCH_3$), 6.67 (3-p. s., OCH_3), 5.60 (1-p. q., H-2), 5.15 (1-p. d., H-1), 4.50 (1-p. s., benzylic); $J_{1,2}$ 3.2 Hz, $J_{2,3}$ 9.0 Hz.

Methyl 4,6-*O*-Benzylidene-2-*O*-mesyl-α-D-glucopyranoside (XIX). The method of Jeanloz and Jeanloz[6] was followed; when the quantity of pyridine was increased, a higher yield was obtained. To an ice-cold solution of I (2.82 g) in dry pyridine (56 m*l*), we added methanesulfonyl chloride (1.2 m*l*), after which the mixture was allowed to stand at 5°C overnight. A few drops of water were then added, and the solution was evaporated *in vacuo*. A chloroform solution of the resultant residue was washed successively with water, a potassium bisulfate solution, a saturated bicarbonate solution, and water again. After drying over sodium sulfate, the solution was evaporated to give a syrup; the syrup was chromatographed on a silica-gel column (250 g, 4.7×32 cm) and eluted with benzene-ethyl acetate (5 : 1). The dimesylated product (R_f 0.61 by TLC with the same solvent system; 0.81 g) was eluted from a portion between 700 and 800 m*l*, while XIX (R_f 0.47; 2.68 g, 74%) was eluted from a 850-m*l* portion with tailing. XIX was recrystallized from benzene-ethyl acetate (5 : 1); mp 134—135°C (lit, 135—136°C,[6] 132—133°C[7]), $[\alpha]_D^{20}$ +73° (*c* 1, $CHCl_3$) (lit, +73°,[6] +72°[7]); NMR (60 MHz, $CDCl_3$): τ: 5.54 (1-p. q., H-2), $J_{1,2}$ 3.5 Hz, $J_{2,3}$ 9.7 Hz, collapsed to a doublet when irradiated at H-1; 5.07 (1-p. d., H-1), 4.49 (1-p. s., benzylic).

Methyl 4,6-*O*-Benzylidene-2-*O*-mesyl-3-*O*-tosyl-α-D-glucopyranoside (XX). Prepared from XIX (5.08 g) by the usual method; yield 6.62 g (91%); mp 194—195°C, $[\alpha]_D^{20}$ +11° (*c* 1, $CHCl_3$), R_f 0.73 by TLC (benzene-ethyl acetate 5 : 1); IR: 1600, 1365, 1320, 1175, 1095, 1050, 985, 747, 720, 700 cm^{-1}; NMR (60 MHz, $CDCl_3$): τ: 7.76 (3-p. s., $TsCH_3$), 6.87 (3-p. s., SO_2CH_3), 6.50 (3-p. s., OCH_3), 5.40 (1-p. q., H-2), 4.95 (1-p. d., H-1), 4.80 (1-p. t., H-3), 4.71 (1-p. s., benzylic), 2.8—2.5 (5-p. m., Ph), 3.07 and 2.33 (4-p. AB quartet, Ts); $J_{1,2}$ 3.5 Hz, $J_{2,3}$ 9.7 Hz, $J_{3,4}$ ~9.3 Hz.

Found: C, 51.31; H, 5.13; S, 12.65%. Calcd for $C_{22}H_{26}O_{10}S$: C, 51.35; H, 5.09; S, 12.46%.

Methyl 4,6-*O*-Benzylidene-2-deoxy-α-D-*ribo*-hexopyranoside (V). Prepared from methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranoside[12] (VI) as has

been described by Richardson[4b]; mp 129—131°C (lit,[4b] 127—129°C), $[\alpha]_D^{20}$ +140° (*c* 1, $CHCl_3$) (lit,[4b] +140°); R_f 0.72 (VI: R_f 0.82) by TLC (benzene-ethyl acetate 1 : 2).

NMR (60 MHz, $CDCl_3$): τ: 8.3—7.6 (2-p. m., H-2, H-2′), 6.98 (1-p. d., disappeared on deuteration, OH), 6.61 (3-p. s., OCH_3), 5.23 (1-p. q., J 3.3 and 1.5 Hz, H-1), 4.38 (1-p. s., benzylic).

Methyl 4,6-*O*-Benzylidene-2-deoxy-3-*O*-tosyl-α-D-*arabino*-hexopyranoside (XIII). Prepared in the usual way from IV; mp 97°C (lit,[8] 95°C), $[\alpha]_D^{24}$ +46° (*c* 1, $CHCl_3$).

Treatment of Methyl 4,6-*O*-Benzylidene-2,3-di-*O*-tosyl-α-D-glucopyranoside (II) with Lithium Aluminum Hydride for 40 hr. The method of Vis and Karrer[3] was followed essentially. Lithium aluminum hydride (1.13 g) was refluxed in dry tetrahydrofuran (THF, 13 m*l*) for 2 hr, and then well-dried II (3.12 g) was added to the mixture. After refluxing for 40 hr, the reaction mixture was cooled and shaken with ethyl acetate (3 m*l*) for a while. Ether (400 m*l*) and an aqueous solution (150 m*l*) of Rochelle salt (15 g) were added under shaking. The aqueous layer was separated and extracted with ether (100 m*l*×5). The ethereal extract was dried over potassium carbonate and evaporated to give a solid (1.3 g), which was then chromatographed on a silica-gel column (150 g, 3.3×35 cm) with benzene-ethyl acetate (1 : 2). A mixture (0.2 g) of the starting material (II) and an unidentified substance (R_f 0.90 and 0.85 respectively, as determined by TLC with the same solvent system) was eluted in a portion between 200—250 m*l*; then a mixture of the products (the B mixture, all having the same R_f-value of 0.72) was eluted in a portion between 330—460 m*l*; 0.86 g; 61%; mp 168—173°C, $[\alpha]_D^{24}$ +128° (*c* 1, $CHCl_3$). Finally I was eluted in a portion between 820—1200 m*l*; 0.23 g (15%); mp 163—164°C (lit,[12] 163—164°C), $[\alpha]_D^{25}$ +109° (*c* 1, $CHCl_3$) (lit,[12] +110°), R_f 0.3 (the same value as that of the authentic I sample).

The fractional crystallization of the B mixture from ethyl acetate and petroleum ether gave pure III; mp 186°C (lit, 186.5—187.5°C,[3] 190—192°C[13]), $[\alpha]_D^{24}$ +126° (*c* 1, $CHCl_3$) (lit, +126.9°,[3] +116°[13]).

NMR (100 MHz, $CDCl_3$): τ: 8.16 (1-p. q., H_{ax}-3, $J_{3e,3a}$—$J_{2,3a}$—$J_{3a,4}$ ~11 Hz), 7.75 (1-proton doublet of triplets, H_{eq}-3; $J_{3e,3a}$ 11.0 Hz, $J_{2,3e}$—$J_{3e,4}$ ~4.5 Hz), 6.55 (3-p. s., OCH_3), 5.33 (1-p. d., $J_{1,2}$ 3.2 Hz, H-1), 4.49 (1-p. s., benzylic), 2.75—2.4 (5-p. m., Ph.). The results confirm the structure of III.

A comparison of the NMR spectrum of the intact A mixture with those of the standard substances (III, IV, and V) showed that the mixture was composed of three components: III (~75%), V (~12%), and another substance (IV, ~12%), the last of which has the same NMR pattern as the substance produced by the action of LAH on methyl 3-*O*-benzoyl-4,6-*O*-benzylidene-2-*O*-tosyl-α-D-glucopyranoside (IX), which will be described later. NMR (here, τ-values are indicated in the order of III (main), V, and IV): τ 6.55, 6.61, 6.68 (each singlet, OCH_3); τ 5.33 (d.), 5.24 (q.), 5.25 (q.)(H-1); τ 4.49, 4.38, 4.46 (each singlet, benzylic).

Treatment of II with Lithium Aluminum Hydride for 3.5 hr. Compound II (1.45 g) was caused to react with LAH in the same manner as has been described above, except that the time of reaction was 3.5 hr. The ethereal extracts thus obtained were evaporated to give a solid (0.85 g). On TLC (benzene-ether 5 : 1), the solid showed the presence of four components: the starting material (II, major, R_f 0.71), X (minor, R_f 0.51), a monotosylated (?) compound (minor, R_f 0.26), and III (major, R_f 0.28). The monotosylated compound had the same R_f-value and the same color-change as methyl 4,6-*O*-benzylidene-3-*O*-tosyl-α-D-glucopyranoside (VIII) when sprayed with sulfuric acid. The attempted isolation of VIII by preparative TLC[14] was, however, unsuccessful because of the concomitance of the 3-deoxy derivative (III). Another minor substance (R_f 0.51) was separated by preparative TLC[14] to give methyl 4,6-*O*-benzylidene-2-*O*-tosyl-α-D-glucopyranoside (X, 0.04 g, mp 154°C, $[\alpha]_D^{23}$ +63°). The identity was confirmed by the IR and NMR patterns.

Treatment of Methyl 2-*O*-Benzoyl-4,6-*O*-benzylidene-3-*O*-tosyl-α-D-glucopyranoside (VII) with Lithium Aluminum Hydride for 20 hr. Lithium aluminum hydride (1.04 g) was refluxed in dry THF (12 m*l*) for 2 hr; well-dried VII (3.04 g) was then added, and the mixture was refluxed for 20 hr. A crude solid (1.4 g) was obtained by the procedure described for the corresponding reaction of II. Column chromatography with silica gel (140 g) and benzene-ethyl acetate (1 : 2) gave a monotosylated product (VIII, R_f 0.8) in a fraction between 210—240 m*l* (0.09 g (3.7%), mp 163°C, $[\alpha]_D^{23}$ +33° (*c* 1, $CHCl_3$)), which showed IR and NMR patterns identical with those of authentic VIII. A mixture of deoxy derivatives (the A mixture, R_f 0.72) was eluted in a portion between 270—350 m*l* (1.09 g (73%); mp 180—184°C, $[\alpha]_D^{24}$ +121° (*c* 1, $CHCl_3$)), and compound I (R_f 0.3) in a portion between 550—850 m*l* (0.10 g (6.3%); mp 163—164°C, $[\alpha]_D^{25}$ +110° (*c* 1, $CHCl_3$)).

The fractional crystallization of the A mixture from ethyl acetate and petroleum ether gave pure III; mp 187°C, $[\alpha]_D^{24}$ +126°. A comparison of the NMR pattern of the intact A mixture with those of III and V in respect to *O*-methyl, anomeric, and benzylic hydrogens indicated that the mixture consisted of two components: III (~93%) and a 2-deoxy derivative (V, ~7%).

Treatment of VII with Lithium Aluminum Hydride for 30 min. A mixture of VII (206 mg) and LAH (78 mg) in dry THF (4 m*l*) was refluxed as has been described above. When the reaction was pursued by TLC (benzene-ethyl acetate 1 : 2), it was found that the starting material (R_f 0.95) disappeared fairly rapidly and that after 30 min of the reaction only the debenzoylated product (VIII, R_f 0.8) could be detected, the deoxy products (R_f 0.72) being then produced gradually. When the reaction was stopped after 30 min, the usual isolation procedure gave VIII (145 mg, 87%); mp 165°C, $[\alpha]_D^{22}$ +33° (*c* 1, $CHCl_3$). Its IR and NMR spectra were identical with those of an authentic sample.

Treatment of Methyl 2-*O*-Benzoyl-4,6-*O*-benzylidene-3-*O*-tosyl-α-D-glucopyranoside (VII) with Lithium Aluminum Deuteride. Formation of Methyl 3-Deoxy-3-deuterio-4,6-*O*-benzylidene-α-D-allopyranoside (III′). Lithium aluminum deuteride (0.46 g) was refluxed in dry THF (6 m*l*) for 2 hr, well-

13) D. A. Prins, *Helv. Chim. Acta*, **29**, 1 (1946).

14) D. Horton and T. Tsuchiya, *Carbohyd. Res.*, **5**, 426 (1967).

dried VII (1.49 g) was added, and then the mixture was refluxed for 20 hr. The reaction product was purified by a usual procedure. The crude product (0.73 g) obtained from the ethereal extract was chromatographed on a silica-gel column (100 g) with benzene-ethyl acetate (1 : 2). The monotosylated product (VIII), a mixture of deoxy derivatives and compound I were obtained in yields of 0.03 g (3%), 0.57 g (78%), and 0.05 g (6%) respectively. The recrystallization of the mixture of deoxy derivatives from ethyl acetate-petroleum ether gave pure III'; mp 186°C, $[\alpha]_D^{22}$ +125° (*c* 1, $CHCl_3$); NMR (60 MHz, $CDCl_3$): τ: 7.8—7.65 (1-proton broad singlet, H_{eq}-3); no signals corresponding to H_{ax}-3 were observed. The other signals were quite identical with those of III.

Treatment of Methyl 4,6-*O*-Benzylidene-3-*O*-tosyl-α-D-glucopyranoside (VIII) with Lithium Aluminum Hydride. A mixture of VIII (0.72 g) and LAH (0.27 g) in dry THF (2.8 m*l*) was refluxed for 20 hr. The extraction of the resultant products by a usual method was followed by column chromatography with silica gel and benzene-ethyl acetate (1 : 2) to give a mixture of deoxy derivatives (0.31 g, 71%; mp 180—183°C) and compound I (0.07 g, 15%). A comparison of the NMR spectrum of the former mixture with that of above-mentioned A mixture indicated that the former mixture consisted of III (major) and the 2-deoxy derivative (V, minor).

Treatment of Methyl 4,6-*O*-Benzylidene-2-*O*-methyl-3-*O*-tosyl-α-D-glucopyranoside (XI) with Lithium Aluminum Hydride. A mixture of XI (591 mg) and LAH (260 mg) in dry THF (3.1 m*l*) was refluxed for 40 hr, and the product was extracted as before. A crude solid (293 mg) thus obtained was passed through a short column of silica gel with benzene-ethyl acetate (1 : 2), and the product (XII) was recrystallized from the same solvent; 244 mg (63%); mp 170°C (lit, 166°C,[15] 168°C[10]), $[\alpha]_D^{22}$ +95° (*c* 1, $CHCl_3$) (lit, +95.4°[15] ($CHCl_3$), +74.5°[10] (ethanol)); NMR (60 MHz, $CDCl_3$) τ: 7.1 (1-p., disappeared on deuteration, OH), 6.57 (3-p. s., OCH_3), 6.49 (3-p. s., OCH_3), 5.13 (1-p. d., $J_{1,2}$ 3.5 Hz), 4.48 (1-p. s., benzylic).

Found: C, 60.40; H, 6.71%. Calcd for $C_{15}H_{20}O_6$: C, 60.80; H, 6.80%.

Treatment of Methyl 3-*O*-Benzoyl-4,6-*O*-benzylidene-2-*O*-tosyl-α-D-glucopyranoside[10] (IX) with Lithium Aluminum Hydride. A mixture of IX (1.10 g) and LAH (0.36 g) in dry THF (4 m*l*) was refluxed for 20 hr, and the resulting products were extracted by a usual procedure. The crude product (0.52 g) was chromatographed on silica gel (50 g) with benzene-ethyl acetate (1 : 2). Methyl 4,6-*O*-benzylidene-2-deoxy-α-D-*arabino*-hexopyranoside (IV) was eluted in a portion between 70—90 m*l* (R_f 0.72 by TLC with the same solvent mixture); 0.16 g (29%); mp 150—151°C (lit, 151—152°C,[16] 149—150°C[17]), $[\alpha]_D^{23}$ +95° (*c* 1, $CHCl_3$) (lit, +90°[16] (acetone), +83.8°[17] (ethanol)). Compound I was eluted in a portion between 150—270 m*l* (R_f 0.3, 0.31 g, 54%); mp 163—164°C, $[\alpha]_D^{24}$ +110° (*c* 1, $CHCl_3$).

NMR of IV (100 MHz, $CDCl_3$): τ: 8.23 (1-proton quartet of doublets, H_{ax}-2), 7.83 (1-proton quartet of small doublets, H_{eq}-2), 7.25 (1-proton broad singlet, disappeared on deuteration, OH), 6.69 (3-p. s., OCH_3), 6.58 (1-p. t., J~9.5 Hz, H-4), 6.28 (2-p. m., H-6, 6'?), 5.90 (1-p. m., H-3?), 5.77 (1-p. m., H-5?), 5.24 (1-proton doublet of small doublets, H-1), 4.47 (1-p. s., benzylic), 2.8—2.45 (5-p. m., Ph); $J_{1,2_a}$ 3.6 Hz, $J_{1,2_e}$~1.2Hz, $J_{2_a,2_e}$ 13 Hz, $J_{2_a,3}$ 11Hz, $J_{2_e,3}$ 5.5 Hz; irradiation at H-1 collapsed H_{ax}-2 to a quartet (J, 13 Hz and 11 Hz) and H_{eq}-2 to a quartet (J, 13 Hz and 5.5 Hz); irradiation at H_{ax}-2 collapsed H-1 to a singlet in appearance, and irradiation at H_{eq}-2 collapsed H-1 to a sharp doublet (J, 3.6 Hz). These values showed a fairly good agreement with those measured at 60 MHz by Coxon.[17]

Treatment of Methyl 4,6-*O*-Benzylidene-2,3-di-*O*-mesyl-α-D-glucopyranoside[6] (XVIII) with Lithium Aluminum Hydride. A mixture of XVIII (3.08 g) and LAH (1.17 g) in dry THF (12 m*l*) was refluxed for 20 hr, and then the product was extracted by a usual procedure. However, in this case, purification by column chromatography was not necessary. The crude product (1.9 g; R_f 0.3 by TLC with benzene-ethyl acetate 1 : 2) contained only a trace of the deoxy product (R_f 0.72). Recrystallization from chloroform-ether gave I (1.80 g, 91%); mp 163—164°C.

Treatment of Methyl 2-*O*-Benzoyl-4,6-*O*-benzylidene-3-*O*-mesyl-α-D-glucopyranoside[6] (XVII) with Lithium Aluminum Hydride. A mixture of XVII (2.93 g) and LAH (1.11 g) in dry THF (12 m*l*) was refluxed for 20 hr and then treated as above. The crude product (1.7 g), which was not contaminated by any deoxy product, was recrystallized from chloroform-ether to give I (1.16 g, 90%); mp 163—164°C.

Treatment of Methyl 4,6-*O*-Benzylidene-2-*O*-mesyl-3-*O*-tosyl-α-D-glucopyranoside (XX) with Lithium Aluminum Hydride. A mixture of XX (1.40 g) and LAH (0.47 g) in dry THF (6 m*l*) was refluxed for 20 hr, and then the reaction mixture was treated by a usual procedure. The crude product (0.70 g) obtained from the ethereal extract was chromatographed on silica gel (100 g) with benzene-ethyl acetate (1 : 2). At first, unidentified substances (0.08 g; TLC with benzene-ethyl acetate 5 : 1, R_f 0.59 and 0.49) were eluted, and then deoxy derivatives (R_f 0.72) were eluted, 0.43 g (59%); mp 172—175°C. Finally I was eluted (0.13 g (17%)). The deoxy derivatives were proved by a study of the NMR spectrum to be a mixture of the 3-deoxy compound (III, ~80%) and the 2-deoxy compound (V, ~20%).

The authors wish to thank Mr. Kohei Watanabe for his technical assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1219—1223 (1970)

Proton Magnetic Resonance Studies on Specifically Deuterated Sucrose Acetates[1)]

Tetsuo SUAMI, Toshiki OTAKE,* Seiichiro OGAWA, Tadao SHOJI and Naoyuki KATO

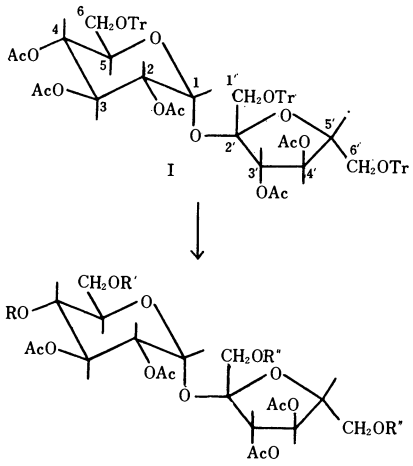
Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

* *Nippon Electric Varian Co. Ltd., Azabu Iigura-cho, Minato-ku, Tokyo*

(Received October 31, 1969)

In the proton magnetic resonance spectrum of octa-*O*-acetylsucrose, an individual acetoxy group signal was assigned by direct comparisons of the spectra of specifically deuterated octa-*O*-acetylsucroses and that of nondeuterated one. The structures of 2,3,6,3′,4′-penta-*O*-acetylsucrose and 2,3,4,3′,4′-penta-*O*-acetylsucrose were further confirmed definitively by the present studies.

Penta-*O*-acetylsucrose of mp 156°C (II) was first prepared in a crystalline form by McKeown and his co-workers[2)] by detritylation of penta-*O*-acetyl-tri-*O*-tritylsucrose (I) in boiling aqueous acetic acid. The structure of I was assigned to be 2,3,4,3′,4′-penta-*O*-acetyl-6,1′,6′-tri-*O*-tritylsucrose[3)] by the relatively higher reactivity of the primary hydroxyl groups, compared with the secondary ones, towards trityl chloride,[2,4)] and soon after this structure was confirmed by methylation of tri-*O*-tritylsucrose.[5)]



II R=H, R′=Ac, R″=H
III R=Ac, R′=R″=H
IV R=$COCD_3$, R′=Ac, R″=$COCD_3$
V R=Ac, R′=R″=$COCD_3$
Ac=$COCH_3$, Tr=$(C_6H_5)C$

Accordingly the structure of II was first supposed to be 2,3,4,3′,4′-penta-*O*-acetylsucrose,[2)] but on the way to establish the structure by methylation of its free hydroxyl groups, it was suspected that an acetyl migration from C-4 to C-6 might occur in a glucose moiety during the reaction leading to 2,3,6,3′,4′-penta-*O*-acetyl-4,1′,6′-tri-*O*-methylsucrose from II.[2,3)]

Later Lemieux and Barrette[6)] reexamined the structure of II and described that II seemed to be 2,3,6,3′,4′-penta-*O*-acetylsucrose, judging from the results of careful treatments of tritosylate of II with sodium iodide and sodium ethoxide.

While Bredereck and his co-workers[7)] prepared another penta-*O*-acetylsucrose of mp 122°C (III) by detritylation of I with hydrobromic acid in glacial acetic acid under ice cooling and described that III was 2,3,4,3′,4′-panta-*O*-acetylsucrose on the bases of its chemical behaviors.

The present authors wish to establish the structural differences between II and III by a definitive method and to open a new field for further synthetic works in sucrose chemistry.

Proton magnetic resonance (PMR) spectroscopy had been proved to be a powerful tool for structural studies of sugar derivatives,[8,9)] and so if it could be possible to distinguish an individual PMR signal arisen from each acetoxy group in octa-*O*-acetylsucrose, the structures of the two different penta-

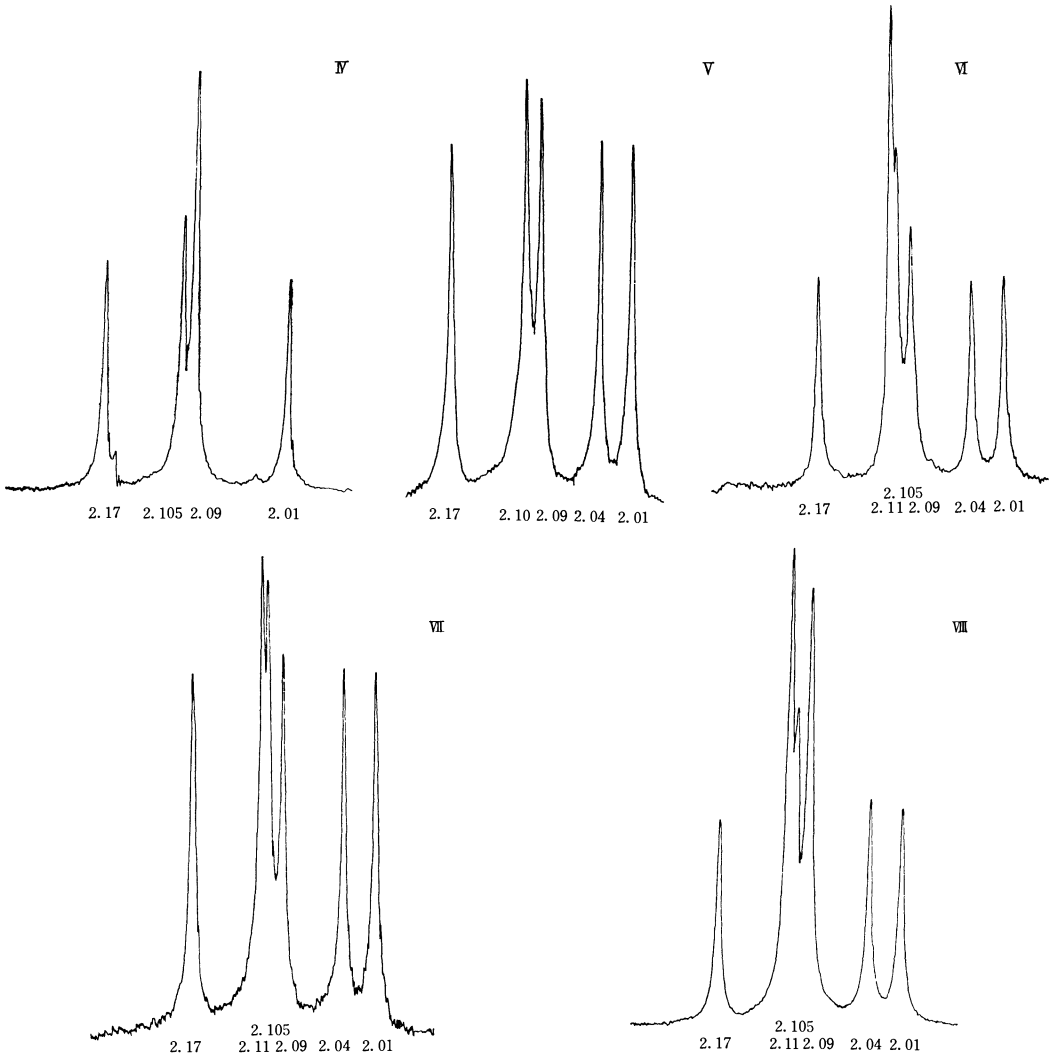

Fig. 1. The acetoxy group signals in the PMR spectra of specifically deuterated derivatives.

O-acetylsucroses would be established by PMR spectroscopy. For this aim, deuteration of an individual acetyl group seemed to be feasible, which had been used successfully by Horton and his co-workers for glucosamine derivatives[10,11] and by the present authors for diazabicyclo[3.2.1.]octanetetrol derivatives.[12]

In the present article, it will be described that some of the individual acetoxy group signals are assigned by the PMR (100 MHz) spectroscopic studies of specifically deuterated octa-*O*-acetylsucrose and it enables us to establish the structures of II and III unambiguously.

The compound II was prepared by the method of McKeown and his co-workers[2] and subsequently acylated with acetic anhydride-d_6 in pyridine, giving penta-*O*-acetyl-tri-*O*-trideuterioacetylsucrose (IV). The PMR spectrum of IV in deuteriochloroform revealed four sharp signals at δ 2.01 (3H), 2.09(6H), 2.105(3H) and 2.17(3H), which were attributed to the five acetoxy groups. When this spectrum was compared with the spectrum of nondeuterated octa-*O*-acetylsucrose (VIII)[13-15] which showed six sharp signals at δ 2.01(3H), 2.04(3H), 2.09(6H), 2.105(3H), 2.11(6H) and

2.17(3H), it was obvious to see that the two signals at δ 2.04(3H) and 2.11(6H) were missing in the former spectrum (Fig. 1).

Then the compound III was obtained by the method of Bredereck and his co-workers[7] and was acetylated analogously with acetic anhydride-d_6 in pyridine to give another penta-*O*-acetyl-tri-*O*-trideuterioacetylsucrose (V). In the spectrum of V in deuteriochloroform, the two signals at δ 2.09 (3H) and 2.11(6H) were missing, compared with the spectrum of VIII (Fig. 1).

In the two spectra of IV and V, the same acetoxy group signals at δ 2.11 with the same intensity of six protons were missing, and accordingly these signals should be arisen from the two acetoxy groups in the common positions. To find out these two acetoxy group, 2,3,4,1′,3′,4′,6′,-hepta-*O*-acetylsucrose[16] was acetylated with acetic anhydride-d_6 giving 2,3,4,1′,3′,4′,6′-hepta-*O*-acetyl-6-*O*-trideuterioacetylsucrose (VI). The PMR spectrum of VI showed a remarkable decrease of the intensity (1/2) of the signal at δ 2.09, compared with the spectrum of the nondeuterated octaacetate. Hence, the signal at δ 2.09 with an intensity of three protons was attributed to the acetoxy group at C-6 in the glucose moiety of sucrose. This assignment of the signal was agreeable with the fact that an acetoxy group at C-6 in methyl α-D-glucopyranoside tetraacetate revealed the signal at δ 2.09.[17]

VII R=R′=$COCD_3$
VIII R=R′=Ac

To substantiate the above mentioned assignment 2,3,4,1′,3′,4′-hexa-*O*-acetylsucrose[18] was analogously trideuterioacetylated to give 2,3,4,1′,3′,4′,-hexa-*O*-acetyl-6,6′-di-*O*-trideuterioacetylsucrose (VII). The spectrum of VII revealed the marked decreases of intensities of the signals at δ 2.09 (3H) and 2.11(3H), compared with the spectrum of VIII. Thus the signal of an intensity of three protons at δ 2.09 was ascribed to the acetoxy group at C-6 in the glucose moiety and the signal of an intensity of three protons at δ 2.11 was due to the acetoxy group at C-6′ in the fructose moiety.

Also, the signal patterns in a lower field in the spectrum of McKeown's penta-*O*-acetylsucrose II which were attributed to the ring protons gave a valuable information on its structure. The signal at δ 5.07 which was arisen from the ring proton at C-4[13] in octa-*O*-acetylsucrose was markedly shifted to a higher field (δ 3.5—4.2) in the spectrum of II (Fig. 2). This fact provided a strong evidence that an acetoxy group at C-4 was absent in the compound II.

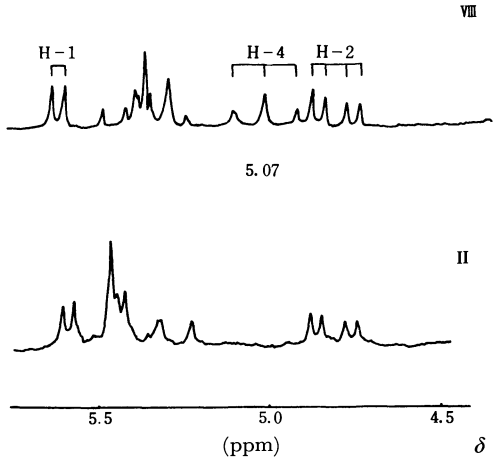

Fig. 2. Partial PMR spectra of II and VIII.

Accordingly the remaining half of the signal at δ 2.11 was due to the acetoxy group at C-4 or C-1′. So if it were arisen from C-4, the diminished signals in the spectrum of V were attributed to three acetoxy groups at C-4, C-6 and C-6′. This caused a big contradiction with the structure of I.

Therefore, the diminished signals at δ 2.11(6H) in the spectra of IV and V should be attributed to the two acetoxy groups at C-1′ and C-6′. Now the structure of V was established to be 2,3,4,3′,4′-penta-*O*-acetyl-6,1′,6′-tri-*O*-trideuterioacetylsucrose and consequently, III was assigned to be 2,3,4,3′4′-penta-*O*-acetylsucrose.

On the other hand, the signal at δ 2.04(3H) disappeared in the spectrum of IV from that of VIII, instead of the diminished signal at δ 2.09(3H) in the spectrum of V. Since Horton and his coworkers[17] described that the signal at δ 2.03 was attributed to the acetoxy group at C-4 of acetylated methyl glucoside, the signal at δ 2.04 in the spectrum of IV was reasonably attributed to the acetoxy group at C-4 of the glucose residue of sucrose. Thus, the structure of IV was assigned to be 2,3,6,3′,4′-penta-*O*-acetyl-4,1′,6′-tri-*O*-trideuterioacetylsucrose and accordingly the structure of II was established to be 2,3,6,3′,4′-penta-*O*-acetylsucrose.

Now four individual acetoxy group signals of the

TABLE 1. CHEMICAL SHIFTS OF ACETYL GROUPS OF SPECIFICALLY DEUTERATED DERIVATIVES

Compound		4-OAc	6-OAc		1′-OAc 6′-OAc	
IV	2.01(1)*	—	2.09(2)	2.105(1)	—	2.17(1)
V	2.01(1)	2.04(1)	2.09(1)	2.10(1)	—	2.17(1)
VI	2.01(1)	2.04(1)	2.09(1)	2.105(1)	2.11(2)	2.17(1)
VII	2.01(1)	2.04(1)	2.09(1)	2.105(1)	2.11(1)	2.17(1)
VIII	2.01(1)	2.04(1)	2.09(2)	2.105(1)	2.11(2)	2.17(1)

* Chemical shifts are expressed in δ-values. Values in parenthesis show number of acetyl groups.

eight ones were assigned in the PMR spectrum of VIII, and the assignments of other four ones are still under way.

But it was readily recognized that the acetoxy group at C-6 in the glucose moiety of sucrose revealed the signal at the same field as was shown by the acetoxy group at C-6 of methyl α-D-glucopyranoside tetraacetate[17] and this was true in the one at C-4. Therefore the two signals at δ 2.01 and 2.09 in the spectrum of VIII might be attributed to the acetoxy groups at C-3 and C-2 respectively in accordance with the Horton's assignment.[17]

The remaining two signals at δ 2.09 and 2.17 could be due to the two acetoxy groups in the fructose residue other than C-1′ and C-6′. The conformations of sucrose and sucrose sodium bromide dihydrate in crystalline states had been described by Brown and Levy,[19] but the conformation of sucrose in a solution is still unfamiliar. But the acetoxy group on C-4′ seemed to widely spread to an outside of the molecule and to be not affected by a deshielding effect of its environments. Therefore this acetoxy group might reveal its signal in a similar position as was shown by an acetyl group on a primary hydroxyl group.

In the low-field regions of the spectra of IV, V, VI, VII and VIII, the same pattern of the signals were observed, which were attributed to the methine and methylene protons[13] and a deuterium isotope effect on the chemical shifts of acetoxy, methine and methylene protons was not distinguished in these 100 MHz spectra.

Thus, Lemieux's[6] and Bredereck's structural assignments[7] of II and III were further confirmed definitively by the present studies.

Experimental

The melting points were determined on a Mitamura Riken micro hot stage. The PMR spectra were determined with a Varian HA-100D (100 MHz) instrument. All the spectra were measured in deuteriochloroform at a concentration of 10% (w/v) at 35°C with tetramethylsilane as an internal standard and the peak positions were expressed in δ-values. Thin layer chromatography (TLC) was run on a glass plate coated with silica gel (Wakogel B-10, Wako pure chemical industries Ltd.) in a solvent system with toluene-methyl ethyl ketone (4 : 1). The spots were detected by spraying a mixture of concd. H_2SO_4 and glacial acetic acid (1 : 1) and heating at 100°C for 30 min. Evaporations were accomplished under reduced pressure with a Tokyo Rikakikai rotary evaporator.

2,3,6,3′,4′-Penta-*O*-acetyl-4,1′,6′-tri-*O*-trideuterioacetylsucrose (IV). 2,3,6,3′,4′-Penta-*O*-acetylsucrose (II), mp 152.5—153.5°C, was prepared by the method of McKeown *et al.*[2] A 170 mg portion of II was acetylated with 0.4 m*l* of acetic anhydride-d_6 in 0.6 m*l* of pyridine and the solution was settled overnight at room temperature. The mixture was evaporated at 60—65°C. Crystallization of the residue from aqueous ethanol gave IV as fine needles, mp 83.5—87°C, yield, 52 mg. The mother liquor was evaporated and the residue was dissolved in chloroform. The chloroform solution was decolorized through a short column of active alumina and then evaporated. The residue was crystallized from aqueous ethanol giving a second crop of IV, mp 83.5—87°C, yield, 127 mg. Total yield was 179 mg (91%). TLC showed the product to be homogeneous with R_f 0.32 (R_f of octa-*O*-acetylsucrose=0.32).

2,3,4,3′,4′-Penta-*O*-acetyl-6,1′,6′-tri-*O*-trideuterioacetylsucrose (V). 2,3,4,3′,4′-Penta-*O*-acetylsucrose (III), mp 128°C, was prepared by the modified method of Bredereck *et al.*[7] A 2.0 g portion of 2,3,4,3′,4′-penta-*O*-acetyl-6,1′,6′-tri-*O*-tritylsucrose[2] was dissolved in a mixture of 7 m*l* of glacial acetic acid and 3 m*l* of chloroform. To the solution, 0.7 m*l* of glacial acetic acid previously saturated with hydrogen bromide was added under ice-cooling with an occasional shaking. After 10 min, the mixture was poured into ice-cold water. The aqueous solution was extracted two times with 10 m*l* of chloroform. The combined chloroform extract was washed with cold water, and evaporated. The residue was dissolved in 10 m*l* of toluene and chromatographed on a column of 10 g of silica gel (Kanto Chemical Co. Ltd. 60—80 mesh). The column was eluted with 150 m*l* of toluene, 200 m*l* of methyl ethyl ketone-toluene (1 : 5), 200 m*l* of methyl ethyl ketone-toluene (3 : 10) and 200 m*l* of methyl ethyl ketone-toluene (1 : 1). The fraction of the last solvent was evaporated to give 470 mg of the residue. The residue was dissolved in 3 m*l* of chloroform and 7 m*l* of ether was added to the solution. The mixture was kept in a refrigerator for 24 hr to give 362 mg of the crystalline product of III, mp 128°C. A 143 mg portion of III was acetylated with 0.2 m*l* of acetic anhydride-d_6 in 1 m*l* of pyridine by the procedure described for the preparation of IV, giving 85 mg of V, mp 83.5—87.5°C. TLC showed practically a single spot of R_f 0.32.

19) G. M. Brown and H. A. Levy, *Science*, **141**, 921 (1963): G. A. Jeffrey and R. D. Rosenstein, *Advan. Carbohydrate Chem.*, **19**, 11 (1964).

2,3,4,1′,3′,4′,6′-Hepta-*O*-acetyl-6-*O*-trideuterioacetylsucrose (VI). A 135 mg portion of 2,3,4,1′,3′,4′,6′-hepta-*O*-acetylsucrose[16] was acetylated with acetic anhydride-$_{f_6}$ in pyridine by an analogous procedure of the preparation of IV to give 95 mg of crystalline product of VI, mp 84.5—88°C. TLC showed a single spot of R_f 0.32.

2,3,4,1′,3′,4′-Hexa-*O*-acetyl-6,6′-di-*O*-trideuterioacetylsucrose (VII). To a solution of 2,3,4,1′,3′,4′-hexa-*O*-acetylsucrose (169 mg)[18] in 1 m*l* of pyridine, 0.12 m*l* of acetic anhydride-d_6 was added and the mixture was treated analogously as described in the preparation of IV to give 11.6 mg of the crystalline product, mp 83—87°C. TLC showed a single spot of R_f 0.32.

Octa-*O*-acetylsucrose (VIII). The product was prepared by the method of Hudson and Johnson[15] and recrystallized two times from aqueous ethanol, mp 84—88°C.

The authors wish to thank Professor Sumio Umezawa for his helpful advice, and Mr. Iwao Miura for determination of PMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1223—1229 (1970)

The Reaction of Sulfenyl Chlorides with Thioethers. I. The Scope of the Reactions

Michinori Ōki and Keiji Kobayashi

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received November 17, 1969)

It was found that thioethers reacted with sulfenyl chlorides to give four kinds of products. When the alkyl part of the thioether is capable of producing a rather stable carbonium ion, the thioether gives the chloride and an olefin, which are derived from the cation, the latter reacting also with the sulfenyl chloride to give adducts. There is another path to afford alkyl chloride; that is, an S_N2-type reaction takes place when the alkyl part gives a less stable carbonium ion. The third and fourth products are α-chloro sulfide and α,β-unsaturated sulfide, which are seemingly produced *via* a common intermediate. The latter may react further with the sulfenyl chloride to give enedithiol derivatives.

During the course of other investigations in this laboratory, a rather unexpected reaction was encountered.[1] Namely, when stilbene (I) and an excess of methanesulfenyl chloride were allowed to react, the product was not the one expected from the mere addition, but α-methylthio-α'-chlorostilbene (III). The treatment of 1,2-diphenyl-1-

$$C_6H_5CH{=}CHC_6H_5 \xrightarrow{CH_3SCl} C_6H_5\underset{\displaystyle CH_3S}{\underset{|}{C}}H-\underset{\displaystyle Cl}{\underset{|}{C}}HC_6H_5$$

$$\xrightarrow{CH_3SCl} C_6H_5C{=}\underset{\displaystyle Cl}{\underset{|}{C}}C_6H_5$$

CH_3S (III)

methylthio-2-chloroethane (II) with methanesulfenyl chloride resulted in the formation of III. Thus, II seemed to be an intermediate in the formation of III when I was treated with methanesulfenyl chloride.

Since it is rather unusual for methanesulfenyl chloride to dehydrogenate, a series of reactions of sulfenyl chlorides with thioethers has been investigated in order to clarify the nature and the limitations of the reaction. A search of the literature at the outset indicated that, although there were some examples[2] of the reaction of disulfides with sulfenyl chlorides, there was only one paper concerning the reaction between thioethers and sulfenyl chloride;*1 Moor and Porter[3] reported the formation of alkyl chlorides as the major product when thioethers were treated with 2,4-dinitrobenzenesulfenyl chloride in acetic acid.

$$O_2N\text{-}C_6H_3(NO_2)\text{-}SCl + RSR' \rightarrow O_2N\text{-}C_6H_3(NO_2)\text{-}SSR + R'Cl$$

The purpose of this paper is to discuss the scope of the reaction, showing the various aspects of the reaction which result from the structural influences.

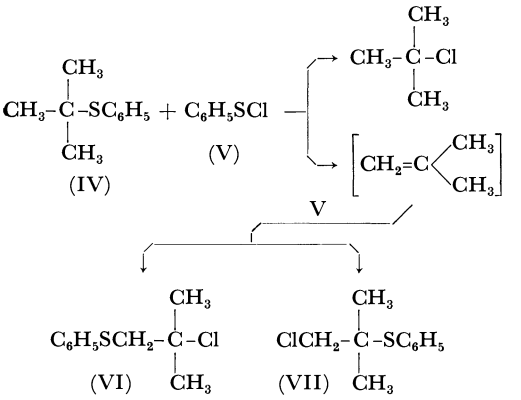
Results and Discussion

Various unsymmetrical thioethers were allowed to react with *ca.* 2 mol benzenesulfenyl chloride (V) in carbon tetrachloride at room temperature. A spontaneous reaction set in, and the evolution of hydrogen chloride was observed. At the completion of the reaction, the red color of the solution of benzenesulfenyl chloride changed to a pale yellow and then did not change any more. The reaction products were analyzed, together with the yields based on the starting thioethers, by intergrating the NMR spectra and gas chromatography of the crude reaction mixture, the behavior of each reaction product being examined beforehand. When possible, the products were isolated by fractional distillation or column chromatography and were subjected to NMR, IR, and elementary analyses.

At the outset, it was expected that *t*-butyl phenyl sulfide (IV) might give the simpler results because of its structure, which would also make analyses by NMR easier. The treatment of *t*-butyl phenyl sulfide with benzenesulfenyl chloride gave 71% *t*-butyl chloride, as was anticipated from an earlier work,[3] and 29% *β*-chloro sulfides, VI and VII, in approximately 2 : 3 ratio. The formation of VI and VII may be expected if it is assumed that the reaction proceeds *via* the *t*-butyl cation, since the cation will give isobutylene together with the substitution product. The addition of benzenesulfenyl chloride to isobutylene will result in the formation of 2-chloro-2-methyl-1-phenylthiopropane (VI) and of 1-chloro-2-methyl-2-phenylthiopropane (VII).

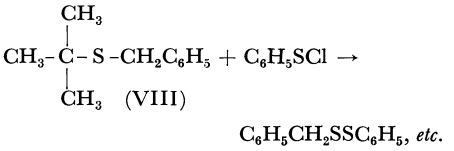


Indeed, the addition of benzenesulfenyl chloride to isobutylene in carbon tetrachloride at room temperature took place exothermally, and the resulting product distribution of VI and VII was in fair agreement with that of the products derived from the reaction of benzenesulfenyl chloride with *t*-butyl phenyl sulfide. The structures of the addition products, which were isomeric mixtures of Markownikoff and anti-Markownikoff adducts, were confirmed by the spectral evidence and by the treatment of the distilled product with potassium *t*-butoxide. On the distillation of the mixture under reduced pressure, isomerization took place and the only isolable compound was 2-chloro-2-methyl-1-phenylthiopropane (VI). Thus, treating the distillate with the base yielded pure 2-methyl-1-phenylthiopropene as a result of dehydrochlorination.

$$\text{VI} + \text{VII} \xrightarrow{\Delta} \text{VI} \xrightarrow{t\text{-BuOK}} C_6H_5SCH{=}C\begin{matrix}CH_3\\CH_3\end{matrix}$$

The facts suggest that the adduct VII is formed by the kinetic control and that VII then rearranges to the thermodynamically more stable VI, probably *via* the episulfonium ion intermediate, as has been suggested in an earlier paper,[4] although the reason for the stability of VI is not well understood at present.

The cleavage of the carbon-sulfur bond observed in the reaction of *t*-butyl phenyl sulfide with sulfenyl chloride should be generally observed if the reaction involves the formation of relatively stable carbonium ion. Thus, benzyl *t*-butyl sulfide (VIII) was treated with benzenesulfenyl chloride to give *t*-butyl chloride and the two adducts, VI and VII, in *ca.* 30% and 57% yields respectively. The stoichiometry of the reaction suggests that benzyl phenyl disulfide should be formed, and, indeed, the unsymmetric disulfide was isolated by column chromatography.



The carbon-sulfur cleavage in benzyl *t*-butyl sulfide occurs predominantly on the *t*-butyl side, giving only 8% benzyl chloride at most. The results conform with the other data on solvolysis,[5] which suggest that the *t*-butyl cation is more easily formed than the benzyl cation. Therefore, it seemed that it would be interesting to ascertain what happens with a sulfide having two alkyl groups which are both poor in giving stable carbonium ions. Benzyl methyl sulfide was, then, treated with benzenesulfenyl chloride. The result was the formation of 9% benzyl chloride and 30% *α*-chlorobenzyl methyl sulfide. A compound of the latter type is known to be a common product when sulfides are treated with chlorinating agents, such as chlorine,[6] sulfuryl chloride,[7] thionyl

chloride,[8] and *N*-chlorosuccinimide.[9]

$$C_6H_5CH_2\text{-}S\text{-}CH_3 + C_6H_5SCl \rightarrow C_6H_5CH_2Cl + C_6H_5\underset{\displaystyle Cl}{\underset{|}{C}}HSCH_3$$

When methanesulfenyl chloride was used in place of V, α-chlorobenzyl methyl sulfide was obtained in a better yield (78%) than in the case of V, and benzyl chloride was also obtained in a 10% yield. Oda and Hayashi have also reported similar results during the course of this study.[10]

The treatment of methyl α-phenethyl sulfide (IX) with V gave 55% α-phenethyl chloride (X). However, neither styrene nor α-chloro-β-phenylthioethylbenzene, which would be expected if styrene were formed and if the addition of V were to follow, was detected in the products. Instead, two unexpected olefins were found by NMR spectra: signals at τ 3.53 and τ 3.83 with relative intensities of *ca.* 3 : 1 and in a 45% yield. Since the elementary analyses of the mixture isolated by alumina chromatography agreed with the $C_{15}H_{14}S_2$ formula, it was assumed that this oily product was an isomeric mixture of the *cis* and *trans* olefinic compounds (XI). The NMR data (τ 3.53, 8.08 and τ 3.83, 8.02 besides the aromatic protons) also agreed with the above.

$$C_6H_5\underset{\displaystyle SCH_3}{\underset{|}{C}}HCH_3 + C_6H_5SCl \rightarrow$$

(IX)

$$C_6H_5\underset{\displaystyle Cl}{\underset{|}{C}}HCH_3 + CH_3SSC_6H_5 \quad (1)$$

(X) 55%

$$C_6H_5\underset{\displaystyle SCH_3}{\underset{|}{C}}HCH_3 + 3C_6H_5SCl \rightarrow C_6H_5\underset{\displaystyle SCH_3}{\underset{|}{C}}=CHSC_6H_5 + 3HCl + C_6H_5SSC_6H_5 \quad (2)$$

(XI) *cis* and *trans* 45%

The structure of XI was unambiguously determined by a comparison of the spectra with an authentic specimen prepared from α-phenylthioacetophenone dimethylmercaptal and dimethyl sulfate according to the published directions:[11]

$$C_6H_5\text{-}\underset{\displaystyle SCH_3}{\underset{|}{\overset{\displaystyle SCH_3}{\overset{|}{C}}}}\text{-}CH_2SC_6H_5 \xrightarrow{(CH_3O)_2SO_2} C_6H_5\underset{\displaystyle SCH_3}{\underset{|}{C}}=CHSC_6H_5 \quad (XI)$$

In order to examine the stoichiometry of this unusual olefin-forming reaction, the yields of the products were determined. Typical results from 0.030 mol of methyl α-phenethyl sulfide and 0.079 mol of benzenesulfenyl chloride are presented in Table 1. One point which warrants special attention is the formation of 149% of the hydrogen chloride. Since the formation of α-phenethyl chloride (Eq. (1)) does not need to liberate hydrogen chloride, the formation of 1 mol of the olefin should liberate 3 mol of hydrogen chloride. This treatment of the results also agrees with the distribution of the other products. Thus, Eq. (2) can be written for the formation of the olefin XI.

Table 1. Product distribution of the reaction between benzenesulfenyl chloride and methyl α-phenethyl sulfide in carbon tetrachloride at O°C

Compound	Yield[a] (%)
$C_6H_5CHClCH_3$	55 (b)
$CH_3SSC_6H_5$	55 (b)
HCl	149 (c)
$C_6H_5C(SCH_3):CHSC_6H_5$	45 (b)
$C_6H_5SSC_6H_5$	18 (d)

a) Yields based on methyl α-phenethyl sulfide.
b) NMR analysis.
c) Determined by titration.
d) Isolated yield based on benzenesulfenyl chloride. This does not have much significance, since excessive benzenesulfenyl chloride gives diphenyl disulfide during the work up.

Although the formation of the olefin XI may seem very curious, it can be explained by considering the process to involve the addition of the sulfenyl chloride or sulfenyl cation to α-methylthiostyrene, followed by dehydrochlorination or by the removal of a proton. In fact, the treatment of α-methylthiostyrene with equimolar benzenesulfenyl chloride in carbon tetrachloride at room temperature readily afforded a *cis* and *trans* mixture*[2] of the olefin XI, the distribution of which closely agreed with that formed in the reaction of methyl α-phenethyl sulfide. Hydrogen chloride was evolved during the course of the reaction. The above assumption can, then, be fairly well verified if the formation of α-methylthiostyrene during the reaction can be proved.

$$C_6H_5\underset{\displaystyle SCH_3}{\underset{|}{C}}=CH_2 + C_6H_5SCl \rightarrow C_6H_5\underset{\displaystyle SCH_3}{\underset{|}{C}}=CHSC_6H_5 + HCl \quad (XI)$$

The above discussion leads to the idea that some sulfides are dehydrogenated to form vinyl sulfide derivatives. This is in conformity with the observation in the reaction of stilbene and an excess of methanesulfenyl chloride[1] and suggests that the

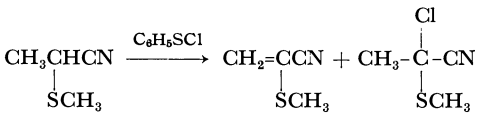
*2 As for the assignment of the configuration, see This Bulletin, **43**, 1234 (1970).

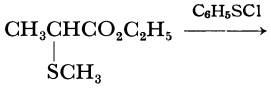
dehydrogenation of thioethers by sulfenyl chlorides is a fairly general reaction. However, in order to isolate the olefin intermediate, the olefin must be fairly inert toward the addition reaction of sulfenyl chloride. Thus, some other sulfides were treated with benzenesulfenyl chloride in an attempt to isolate the intermediate.

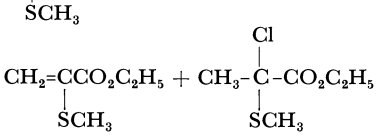
The olefinic linkage in an α,β-unsaturated carbonyl compound will be less reactive than the ordinary olefins toward the electrophilic attack because of the lower electron density. Thus, some α-methylthio ketone would give the α-methylthio-α,β-unsaturated ketone in the reaction with sulfenyl chloride. α-Methylthiocyclohexanone (XII) was treated with benzenesulfenyl chloride; as expected, 2-methylthio-2-cyclohexen-1-one (XIII) was isolated in a 40% yield. The structue of XIII was established on the basis of the spectral evidence and by the characterization of its 2,4-dinitrophenylhydrazone.

(XII) (XIII)

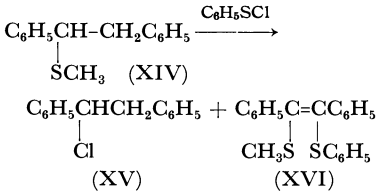
Other electron-deficient olefins, such as α-methylthioacrylonitrile and ethyl α-methylthioacrylate, were also detected when the corresponding nitrile and ester were treated with the sulfenyl chloride, although, in these cases, substitution by chlorine at the α-position was the main reaction.







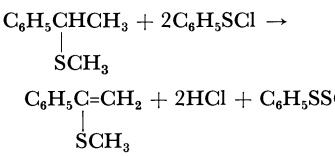
If 1,2-diphenylethyl methyl sulfide (XIV) is analogously dehydrogenated, it will give α-methylthiostilbene. However, XIV gave 30% corresponding chloride (XV) and 65% *cis*- and *trans*-α-methylthio-α'-phenylthiostilbene (XVI), the latter being formed by the addition of benzenesulfenyl chloride to α-methylthiostilbene, followed by dehydrochlorination (or by the addition of the sulfenyl cation, followed by the removal of the proton). These results indicate that the intermediate α-methylthiostilbene is too reactive to be isolated.



(XIV)

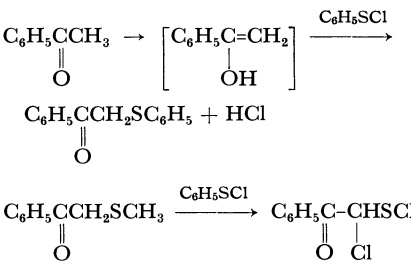
(XV) (XVI)

From these data it is now apparent that the vinyl sulfide derivative intervenes in these reactions and that the following equation, Eq. (3), can be written as a part of the reaction represented by Eq. (2):



(3)

As to the oxidative chlorination of thioethers by sulfenyl chloride, there is another interesting example of the reaction. That is, α-methylthioacetophenone, which is not capable of undergoing dehydrogenation because of its structure, gives an almost quantitative yield of α-chloro-α-methylthioacetophenone. This is very interesting in that, while acetophenone gives α-phenylthioacetophenone when treated with benzenesulfenyl chloride, α-methylthioacetophenone does not give α-phenylthio-α-methylthioacetophenone. If only the enolization and addition are taken into account, α-methylthioacetophenone should have given α-phenylthio-α-methylthioacetophenone more easily. It seems that the sulfur atom in thioether is more vulnerable to attack in this case.



This oxidative chlorination may be classified as a Pummerer-type reaction,[12] which now seems to be a general term for a whole class of reactions involving the reduction of a sulfonium salt with the concomitant oxidation of the α-carbon.

It is thus established that three general types of reactions can occur for thioethers when they are treated with sulfenyl chlorides.

The first is an S_N1-type reaction on the sp^3 carbon atom where the cleavage of the carbon-sulfur bond takes place to produce the carbonium ion, followed by a nucleophilic attack by the chloride ion or by the removal of one of the α-hydrogens as a proton. This type of reaction was observed in the thioethers which carry alkyl groups which tend to give stable carbonium ions, such as the *t*-butyl cation. However, there is definitely another S_N2-type displacement of the alkylthio group by chlorine, for the treatment of optically active 1-phenyl-1-methylthiopropane with methanesulfenyl chloride gave

12) G. A. Russell and G. J. Mikol, "Mechanisms of Molecular Migrations," Vol. 1, Interscience Publishers, New York (1968), p. 157.

1-phenyl-1-chloropropane with an inverted configuration (see the Experimental part). The failure to detect styrene or its adduct in the reaction of methyl α-phenethyl sulfide could lend support to this proposition. This reaction seems to occur when the alkyl part gives a less stable carbonium ion.

$$C_6H_5\underset{\underset{SCH_3}{|}}{C}HC_2H_5 + CH_3SCl \rightarrow C_6H_5\underset{\underset{Cl}{|}}{C}HC_2H_5 + CH_3SSCH_3$$

inversion of configuration

The second type of reaction is the displacement of the α-hydrogen of the thioethers by chlorine to give α-chloro sulfide *i. e.*, oxidative chlorination. This reaction seems to take place when the carbonium ion alpha to sulfur is rather unstable and picks up the chloride anion before losing the proton. If the carbonium ion cannot lose the proton due to its inherent structure, this reaction takes place almost quantitatively.

The third type of reaction is the dehydrogenation which takes place competitively with the second type. It seems that dehydrogenation takes place preferentially when the carbonium ion alpha to sulfur is rather stable or when the product is stabilized by conjugation.

These three reactions may be summarized as in Eq. (4):

$$CH_3\text{-}\underset{|}{C}\text{-}SR \xrightarrow{R'SCl} \begin{cases} \rightarrow CH_3\text{-}\underset{|}{C}\text{-}Cl + CH_2{=}C\diagup \\ \rightarrow CH_3\text{-}\underset{|}{C}\text{-}Cl \\ \rightarrow CH_3\text{-}\underset{|}{\overset{Cl}{C}}\text{-}SR + CH_2{=}C\diagup\!\!\diagdown SR \end{cases} \quad (4)$$

It is not well understood what type of atom is necessary to induce these types of reactions with sulfenyl chlorides. However, the data accumulated in this laboratory indicate that chlorine and oxygen do not induce these reactions. That is, stilbene dichloride, α-phenethyl chloride, and benzyl ethyl ether failed to react with either benzene- or methanesulfenyl chloride.

Experimental

Starting Materials. Benzenesulfenyl chloride was prepared according to the published directions[13] and was always distilled prior to use. The thioethers, other than those indicated below, were prepared by methods that have already been described, and their physical constants were checked.

α-Methylthiostyrene. 1,2-Bis(methylthio)ethylbenzene[14] (45 g) was added to a solution of potassium *t*-butoxide prepared from 10 g of potassium and 400 m*l* of *t*-butyl alcohol, after which the mixture was heated under reflux for 3 hr. After the *t*-butyl alcohol had mostly been removed by distillation from the mixture, the remaining liquid was poured into 300 m*l* of water and extracted with ether. The ethereal extract was dried over anhydrous sodium sulfate and distilled to give 25 g of α-methylthiostyrene; bp 69—70°C/2 mmHg, n_D^{25} 1.5905 (lit,[14] n_D^{25} 1.5910). NMR (τ); 7.83 (3H, s), 5.16 (1H, s), 4.68 (1H, s), 2.5—2.9 (5H, m). IR (cm^{-1}); 1226, 1068, 1025, 848, 770, 699.

1,2-Diphenylethyl Methyl Sulfide. Methyl mercaptan (0.2 mol) was introduced at 0°C into a solution prepared from 4.6 g of sodium and 200 m*l* of ethanol. To this solution there was then added, drop by drop, 40 g of 1,2-diphenylethyl chloride in 100 m*l* of ethanol, after which the mixture was stirred under reflux for 10 min. The major portion of the solvent was removed under reduced pressure, and the residual mixture was extracted with ether after pouring it into 300 m*l* of water. The extract was dried over anhydrous sodium sulfate and distilled to afford 34 g of 1,2-diphenylethyl methyl sulfide; bp 151—152°C/3 mmHg, n_D^{28} 1.5938. NMR (τ); 8.29 (3H, s), 6.22 (1H) and 6.95 (2H) A_2X pattern, J_{AX}=8 Hz, 2.88 (5H, s), 3.0 (5H, m). IR (cm^{-1}); 1073, 1032, 768, 750, 730, 700, 543, 530. Found: C, 78.94; H, 7.06%. Calcd for $C_{15}H_{16}S$: C, 78.89; H, 7.07%.

General Procedure for the Reaction and the Product Analyses. To an approximately 0.2 M solution of the thioether in carbon tetrachloride, *ca.* 2 mol benzenesulfenyl chloride was added at room temperature under anhydrous conditions. After the reaction had been completed, the reaction mixture was poured into an aqueous solution of sodium bicarbonate and extracted with additional carbon tetrachloride. After the removal of most of the solvent under reduced pressure, the crude products were analyzed by NMR spectroscopy, and then any unknown products were isolated by distillation or by column chromatography. The reaction mixture before the removal of the solvent was examined by gas chromatography as required. An essentially quantitative consumption of the thioether was observed. Each product other than the known products was identified as will be described below.

Adducts of Benzenesulfenyl Chloride to Isobutylene. Isobutylene was slowly introduced into a carbon tetrachloride solution of benzenesulfenyl chloride at −10—0°C. The complete fading of the orange color indicated the completion of the reaction. After the solvent had then been removed under reduced pressure, the crude reaction mixture showed NMR signals for two isomers with a relative intensity of *ca.* 3 : 2; this was in fair agreement with that of the products from *t*-butyl phenyl sulfide and benzenesulfenyl chloride. In order to obtain analytical samples of the isomeric mixture, the adducts were distilled *in vacuo* when the distillate contained only one isomer. This isomer was found to be the Markownikoff adduct from the following data and from the dehydrochlorination to be described below. Bp 97°C/3 mmHg, n_D^{25} 1.5597 (lit,[15] bp 59—60°/3 mmHg, n_D^{28} 1.5661). NMR (τ); 8.45 (6H, s), 6.78 (2H, s), 2.7—3.1 (5H, m). IR (cm^{-1}); 1579, 1107, 1090, 740, 693, 615, 568. Found: C, 60.03; H, 6.24%. Calcd for

$C_{10}H_{13}ClS$: C, 59.84; H, 6.53%.

The other product which disappeared on distillation had NMR signals at τ 8.62 (6H, s) and 6.48 (2H, s), the lower chemical shift of CH_2 supporting the assigned structure.

The distillate (9 g) was heated under reflux for 30 min with a solution prepared from 2 g potassium and 80 ml of *t*-butyl alcohol. After the usual work-up, the distillation of the product gave 5.1 g of 2-methyl-1-phenylthiopropene; bp 88°C/4 mmHg, n_D^{20} 1.5791 (lit,[16] n_D^{25} 1.5782). NMR (τ): 8.22 (3H, s), 8.20 (3H, d), 4.32 (1H, m), 3.05 (5H, m). IR (cm^{-1}): 1580, 803, 738, 690.

Benzyl Phenyl Disulfide. The crude mixture obtained from the reaction of benzyl *t*-butyl sulfide and benzenesulfenyl chloride was chromatographed on alumina to give the pure disulfide; $n_D^{28.5}$ 1.6409. NMR (τ): 6.32 (2H, s), 2.8—3.2 (10H, m). IR (cm^{-1}): 1070, 1027, 689, 567. Found: C, 67.19; H, 5.04%. Calcd for $C_{13}H_{12}S_2$: C, 67.17; H, 5.21%.

Methyl Phenyl Disulfide. The product from methyl α-phenethyl sulfide and benzenesulfenyl chloride was chromatographed on alumina. The disulfide was eluted as a yellow oil with petroleum ether; $n_D^{26.5}$ 1.6125. NMR (τ): 7.72 (3H, s), 2.7—3.2 (5H, m). IR (cm^{-1}): 1027, 955, 742, 693. Found: C, 53.75; H, 5.31%. Calcd for $C_7H_8S_2$: C, 53.80; H, 5.16%.

***cis*-and *trans*-α-Methylthio-β-phenylthiostyrenes.** This olefin was eluted with petroleum ether in a later fraction on the alumina chromatography of the product from the above-mentioned reaction. NMR (τ): 8.08 (3H, s), 3.53 (1H, s), 2.6—3.3 (10H, m) and 8.02 (3H, s), 3.83 (1H, s), 2.6—3.3 (10H, m). IR (cm^{-1}): 806, 758, 740, 698, 690. Found: C, 69.36; H, 5.33%. Calcd for $C_{15}H_{14}S_2$: C, 69.70; H, 5.46%.

***cis*-and *trans*-α-Methylthio-α′-phenylthiostilbenes.** An isomeric mixture of the olefin was isolated by alumina chromatography from the reaction mixture obtained from 1,2-diphenylethyl methyl sulfide and benzenesulfenyl chloride. NMR (τ): 8.17 (3H, s), 2.5—3.3 (15H, m) and 8.31 (3H, s), 2.5—3.3 (15H, m). IR (cm^{-1}): 1075, 1027, 738, 699, 582. Found: C, 75.41; H, 5.50%. Calcd for $C_{21}H_{18}S_2$: C, 75.41; H, 5.42%.

α-Chlorobenzyl Methyl Sulfide. Although this sulfide was not isolated, the NMR spectrum of the reaction mixture from benzyl methyl sulfide and benzenesulfenyl chloride showed the existence of the sulfide by the signals at τ 7.75 (3H, s) and 4.03 (1H, s); these signals were situated at the same positions as those of the chlorinated products of benzyl methyl sulfide with chlorine[6] or methanesulfenyl chloride.[10] When methanesulfenyl chloride was used, the reaction products were directly treated with 2,4-dinitrophenylhydrazine in acetic acid; the product was identified with the 2,4-dinitrophenylhydrazone of benzaldehyde (mp 237°C).

2-Methylthio-2-cyclohexen-1-one. The product from the reaction of α-methylthiocyclohexanone and benzenesulfenyl chloride was eluted with benzene through an alumina column to give crude 2-methylthio-2-cyclohexen-1-one, which showed an olefinic proton signal at τ 3.49 (triplet, J=4.5 Hz) in NMR and an absorption at 1679 cm^{-1} in IR.

When the crude product was treated with 2,4-dinitrophenylhydrazine, pure 2,4-dinitrophenylhydrazone of 2-methylthio-2-cyclohexen-1-one was obtained as dark red crystals; mp 222—224°C. NMR (τ): 7.66 (3H, s), 7.2—8.1 (6H, m), 3.78 (1H, t, J=4.5 Hz), aromatic protons (3H, m). IR (cm^{-1}): 3310, 848, 745. Found: C, 48.69; H, 4.65; N, 17.63%. Calcd for $C_{13}H_{14}O_4N_4S$: C, 48.44; H, 4.38; N, 17.38%.

α-Chloro-α-methylthiopropionitrile and α-Methylthioacrylonitrile. The NMR spectrum of the product from the reaction of α-methylthiopropionitrile showed two 1 : 1 singlets at τ 7.78 and 7.47 as the major component (90% yield). The formation of an olefinic compound in a small quantity (*ca.* 5%) was observed from the NMR signals at τ 3.99 (1H, d), 4.23 (1H, d), and 7.68 (3H, s); this compound was identified as α-methylthioacrylonitrile by comparing its NMR with that of an authentic sample prepared as described in the literature.[17] The major product was distilled under reduced pressure (29°C/4 mmHg); it was identified as α-chloro-α-methylthiopropionitrile from the spectroscopic data. IR (cm^{-1}): 2250, 720, 690. Treating this compound with 2,4-dinitrophenylhydrazine in ethanol and a small amount of sulfuric acid gave red crystalline hydrazone of pyruvonitrile; mp 185—186°C. NMR (τ): 7.61 (3H, s), aromatic proton (3H, m). IR (cm^{-1}): 3305, 2235, 850, 840, 745, 723, 600. Found: C, 43.41; H, 2.59; N, 28.35%. Calcd for $C_9H_7N_5O_4$: C, 43.38; H, 2.83; N, 28.10%.

Ethyl α-Chloro-α-methylthiopropionate and Ethyl α-Methylthioacrylate. The major component (40%) of the products was found to be ethyl α-chloro-α-methylthiopropionate by a study of the NMR spectrum of the crude reaction mixture (τ 8.02, τ 7.76, and ethyl protons). The ester was easily hydrolyzed to give ethyl pyruvate. The distillate (bp 28—43°C/5 mmHg), which contained the above product as the major component, was directly treated with 2,4-dinitrophenylhydrazine; the 2,4-dinitrophenylhydrazone of ethyl pyruvate was thus obtained; mp 155°C (lit,[18] mp 153°C). The structure of the olefinic product, which was obtained in a 15% yield, was assigned on the basis of a study of the NMR spectrum and from analogy with a previous example:[19] when the addition products of methanesulfenyl chloride to ethyl acrylate were dehydrochlorinated with an excess of triethylamine in carbon tetrachloride at 0°C, only the anti-Markownikoff adduct gave off hydrogen chloride to form ethyl α-methylthioacrylate, and the Markownikoff adduct was left intact. The NMR spectrum of the resulting products showed the signal of an olefinic compound at the same position as that of the product from the reaction of ethyl α-methylthiopropionate: τ 4.85 (s) and τ 3.75 (s).

α-Chloro-α-methylthioacetophenone. The NMR signals (τ 7.94, τ 3.65, and phenyl protons) of the product obtained from the reaction between α-methylthioacetophenone and benzenesulfenyl chloride agreed with those of the reaction product from α-methylsulfinylacetophenone and thionyl chloride,[20] and also with those

of the product of the reaction between α-methylthioacetophenone and methanesulfenyl chloride.[21] The latter reaction was reported to give α-chloro-α-methylthioacetophenone.

Stereochemical Study of the Substitution Reaction. Optically active methyl 1-phenylpropyl sulfide was prepared from (−)-1-phenylpropyl chloride and methyl mercaptide. The stereochemical outcome must be inversion in this reaction. The treatment of the resulting (+)-sulfide with methanesulfenyl chloride afforded (−)-1-phenylpropyl chloride. Thus, the inversion of configuration must have taken place in this reaction, although racemization was observed to some extent.

$$C_6H_5\underset{\displaystyle Cl}{\underset{|}{C}}HC_2H_5 \xrightarrow{CH_3S^{\ominus}} C_6H_5\underset{\displaystyle SCH_3}{\underset{|}{C}}HC_2H_5 \xrightarrow{CH_3SCl} C_6H_5\underset{\displaystyle Cl}{\underset{|}{C}}HC_2H_5$$

(−)-1-Phenylpropyl Chloride. The racemic 1-phenylpropyl alcohol was resolved by the fractional crystallization of the strychnine salt of its hydrogen phthalate, $[\alpha]_{578}^{25}$ −25.53 (neat) (lit,[22] $[\alpha]_{578}^{25}$ −23.413 (neat)), and was treated with thionyl chloride as in the literature.[23] $[\alpha]_{365}^{25}$ −69.84, $[\alpha]_{436}^{25}$ −41.47 (ethanol) (lit,[23] $[\alpha]_{D}^{25}$ −28.9 (neat)).

(+)-Methyl 1-Phenylpropyl Sulfide. An ethanolic solution from 11.5 g of (−)-1-phenylpropyl chloride was treated with sodium methyl mercaptide from 0.075 mol of sodium in 130 m*l* of ethanol at 45°C for 20 min. The reaction mixture was then poured into an aqueous solution (200 m*l*) of sodium chloride and extracted with ether. The distillation of the extract after drying gave 9.3 g of (+)-methyl 1-phenylpropyl sulfide, bp 82°C/5 mmHg, $[\alpha]_{365}^{25}$ +108.49, $[\alpha]_{436}^{25}$ +64.70 (ethanol).

(−)-1-Phenylpropyl Chloride from (+)-Methyl 1-Phenylpropyl Sulfide and Methanesulfenyl Chloride. Methanesulfenyl chloride (3.8 g) was added to a solution of 7.5 g of (+)-methyl 1-phenylpropyl sulfide in 150 m*l* of carbon tetrachloride. After standing for 1 hr at 0°C, the mixture was decomposed with ice water. The organic part was then extracted with ether, dried over sodium sulfate, and distilled under reduced pressure to give 5.2 g of (−)-1-phenylpropyl chloride; $[\alpha]_{365}^{25}$ −47.97, $[\alpha]_{436}^{25}$ −27.61 (ethanol).

The Reaction of Sulfenyl Chlorides with Thioethers. II. Kinetic Studies

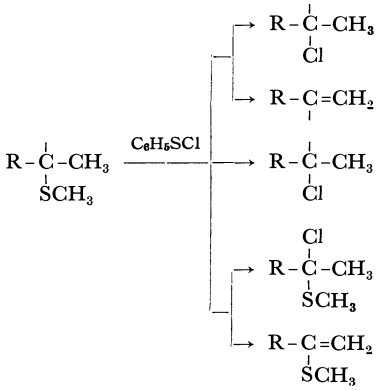
Michinori Ōki and Keiji Kobayashi

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received November 17, 1969)

The rates of the reaction of methyl α-phenethyl sulfide with benzenesulfenyl chloride were measured by means of product analyses. It was found that the reaction was general-acid-catalyzed and autocatalyzed. The rate-determining step was suggested to be the formation of a sulfonium ion derived from the reactants. Mechanisms for the formations of the products are suggested.

In the preceding paper,[1] a general survey of the reactions of thioethers with sulfenyl chlorides has been presented. It has been established that three types of reactions occur, depending upon the structure of the thioethers: 1) the sulfur-carbon bond is cleaved to form a carbonium ion, which then undergoes nucleophilic substitution by chloride-ion and El-type elimination; 2) there is a cleavage of the C–S bond, with the simultaneous formation of a C–Cl bond, *i. e.*, an S_N2-type reaction takes place, and/or 3) there is oxidative chlorination at the alpha position, together with dehydrogenation, to form vinyl sulfide derivatives, probably *via* a common intermediate.



The purpose of this paper is to present kinetic data on the reaction between the thioether and the

1) M. Ōki and K. Kobayashi, This Bulletin, **43**, 1223 (1970).

sulfenyl chloride, and also to propose reaction mechanisms for the formation of products.

Results and Discussion

For the kinetic measurements, methyl α-phenethyl sulfide has been chosen as the sample because this compound has been shown to undergo two kinds of reactions of the possible three: the products are α-phenethyl chloride and a *cis-trans* mixture of α-methylthio-β-phenylthiostyrene. The stoichiometries of the formations of these compounds can be described as follows:[1]

$$C_6H_5\underset{\displaystyle SCH_3}{\underset{|}{C}}HCH_3 + C_6H_5SCl \rightarrow C_6H_5\underset{\displaystyle Cl}{\underset{|}{C}}HCH_3 + CH_3SSC_6H_5 \quad (1)$$

$$C_6H_5\underset{\displaystyle SCH_3}{\underset{|}{C}}HCH_3 + 3C_6H_5SCl \rightarrow C_6H_5\underset{\displaystyle SCH_3}{\underset{|}{C}}=CHSC_6H_5 + 3HCl + C_6H_5SSC_6H_5 \quad (2)$$

The rates of the reaction of 0.199M methyl α-phenethyl sulfide with 0.525M benzenesulfenyl chloride in carbon tetrachloride at 25°C were followed by analyzing the starting thioether and the products by means of the NMR spectra, after quenching a fraction of the reaction mixture by dilute alkali, at various time intervals. It was not hard to find signals which were suitable for analytical purposes; the product distribution was then computed from the relative intensities of the signals.

Characteristic kinetic curves are shown in Fig. 1, where the yields of the respective products are calculated on the basis of the starting methyl α-phenethyl sulfide. The olefinic isomer which is predominant at the completion of the reaction is named A, while the less populated isomer as B. The configuration of A is *cis*, as will be shown in a subsequent paper.[2]

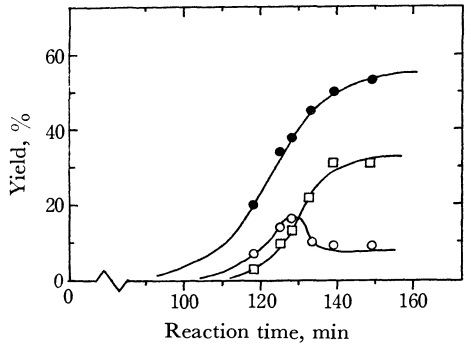


Fig. 1. Rate of the reaction of benzenesulfenyl chloride with methyl α-phenethyl sulfide at 25±0.1°C in carbon tetrachloride.
Initial concentration: benzenesulfenyl chloride 0.525M; methyl α-phenethyl sulfide 0.199M.

● : Yield of α-phenethyl chloride
□ : Yield of (A) ○ : Yield of (B)

The most remarkable feature of the kinetic curves is that each curve, not only of the olefin-forming reaction but of the chlorine-substitution reaction, shows the formation of the products with a definite induction period.

The addition of a small amount of trichloroacetic acid to the reaction mixture caused an increase in the rate of the formation of the products, whereas no decrease in the rate was observed upon the addition of a radical scavenger, 2,4,6-tri-*t*-butylphenol or *p*-benzoquinone, ruling out the possibility that these are radical reactions.

The appearance of the induction period, together with the rapid rise of the curve, suggests that some of the reaction products may be acting as catalysts; that is, these may be autocatalyzed reactions. None of the reaction products, except for the hydrogen chloride which was released by the reaction shown by Eq. (2), seemed to catalyze the reaction. Accordingly, a definite amount of trichloroacetic acid was added to the mixture, since, if this is a general acid-catalyzed reaction, the rate must be increased on the addition of this compound. The results, shown in Fig. 2, clearly indicate that the induction

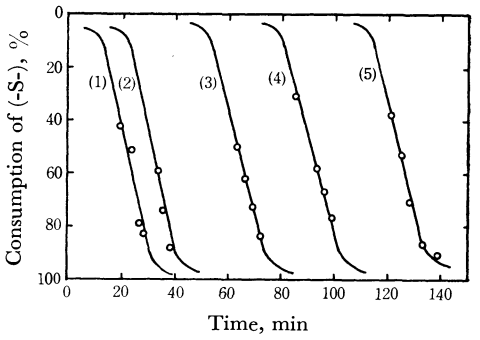

Fig. 2. The effect of added trichloroacetic acid on the rate of disappearance of methyl α-phenethyl sulfide.

Initial concentration of trichloroacetic acid:
(1) 4.11×10^{-3}M (2) 2.74×10^{-3}M
(3) 1.37×10^{-3}M (4) 0.69×10^{-3}M
(5) without trichloroacetic acid

period, characterized by the half-life period of the starting material, decreases with the increase in the concentration of added trichloracetic acid, providing a firm basis for the idea that the reaction is general-acid-catalyzed. Further support is obtained from the facts that Lewis acids such as alu-

2) M. Ōki and K. Kobayashi, This Bulletin **43**, 1234 (1970).

minum chloride and boron trifluoride also have the ability to catalyze the reaction.

Evidence that this reaction is autocatalyzed is obtained by plotting the logarithm of the initial concentration of acid *versus* the half-life period of methyl α-phenethyl sulfide. A good linear relation is obtained between these quantities, as is shown in Fig. 3. Since this behavior is characteristic

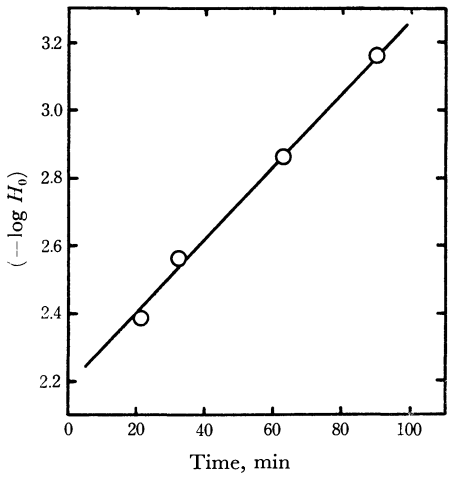

Fig. 3. Plot of the half-life period of methyl α-phenethyl sulfide *vs.* the logarithm of the concentration of added trichloroacetic acid (H_0).

of the autocatalyzed reactions, as will be discussed later, it is now established that the reaction between methyl α-phenethyl sulfide and benzenesulfenyl chloride is general-acid-catalyzed and autocatalyzed.

Under the conditions of a pseudo-first order, *i. e.*, high concentrations of acid and one of the reactants, the reaction was too fast to follow by conventional methods. Therefore, the following discussion has to rely upon the results of the product analyses.

The rates of the disappearance of the sulfide are affected by the initial concentrations of itself and of benzenesulfenyl chloride. As is shown in Fig. 4, the change in the initial concentration of benzenesulfenyl chloride, with the concentration of the sulfide kept constant, modified both the shape of the kinetic curves and the half-life period of methyl α-phenethyl sulfide. A similar dependence of the features of the curves on the initial concentration of methyl α-phenethyl sulfide was also observed, using the constant concentration of the sulfenyl chloride.

These results suggest that at least three molecules participate in the rate-determining step of the reaction: one molecule each of the sulfide, the sulfenyl chloride, and acid.* The existence of the induction period, not only in the formation of the olefins but also in the substitution reaction, suggests that there is a common intermediate from which two pathways are initiated to give chloride on the one hand and to give olefins on the other, and that the formation of the intermediate is the rate-determining step. Accordingly, the rates may be expressed by the following equation:

$$\text{rate} = k(\text{acid})(\text{sulfide})(\text{sulfenyl chloride})$$

A detailed observation of the rates of disappearance of *t*-butyl phenyl sulfide, on treatment with benzenesulfenyl chloride, shows the presence of the induction period here also. The same is true for the reactions of other sulfides, reported in the preceding paper, with benzenesulfenyl chloride. Thus, it is common for there to exist an induction period when sulfides are treated with sulfenyl chlorides.

The rates of the autocatalyzed three-molecular reaction can be expressed by,

$$\frac{dP}{dt} = k(R_0-P)(S_0-yP)(H_0+xP) \qquad (3)$$

where R, S, and P are the concentrations of methyl α-phenethyl sulfide, benzenesulfenyl chloride, and the products respectively, after t minutes. R_0, S_0, and H_0 denote the initial concentrations of the reactants, whereas x and y are the constants as determined by stoichiometry and represent the amount of hydrogen chloride formed by the reaction and the sulfenyl chloride consumed per mole of the consumed sulfide. Here it is assumed that, during the reaction, the ratio of the products from the two reactions is constant throughout. This assumption seems fair judging from the experimental results: a 55 : 45 ratio is observed at all times during the reaction. It is also assumed that the efficiency of hydrogen chloride as the catalyst is the same as that of trichloroacetic acid. Thus, H_0 is null when no trichloroacetic acid is added.

By integrating Eq. (3) when H_0 is negligible compared with R_0, S_0, and $P_{1/2}$, which is the concentration of products at the half-life period of the sulfide ($t_{1/2}$), the following relation between H_0 and $t_{1/2}$ is obtained:

$$t_{1/2} = -\frac{\ln H_0}{kxR_0S_0} + \text{"constant"} \qquad (4)$$

The term "constant" contains neither H_0 nor $t_{1/2}$. The observed relationship shown in Fig. 3 is in harmony with Eq. (4), since this equation shows that $t_{1/2}$ and (−log H_0) are related linearly. Equation (4) also implies that half-life period decreases with the increase in concentrations of either the sulfide or the sulfenyl chloride; it was found that this implication was really the case (for example, see Fig. 4).

Furthermore, it can be expected from Eq. (4) that kxR_0S_0 can be obtained as the slope in Fig. 3,

*1 It is not possible from these results to know how many molecules of the acid are participating. The authors assume that only one molecule of the acid is taking part in the reaction for the sake of convenience and simplicity of the analyses.

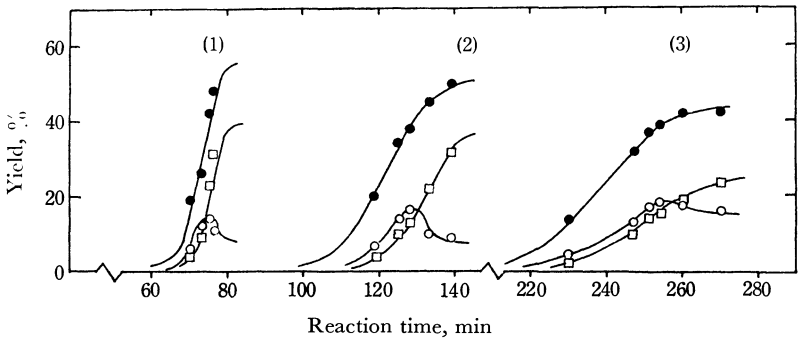

Fig. 4. The dependence of kinetic curves on the initial concentration of benzenesulfenyl chloride.
● : Yield of α-phenethyl chloride ○ : Yield of olefin (B)
□ : Yield of olefin (A)
Initial concentration; (1) (-S-): 0.199M, (PhSCl): 0.683M
(2) (-S-): 0.199M, (PhSCl): 0.525M
(3) (-S-): 0.199M, (PhSCl): 0.420M

since $t_{1/2}$ is now the abscissa and $(-\log H_0)$, the ordinate. Thus, various inclinations of the relationship between $(-\log H_0)$ and $t_{1/2}$ were obtained with various initial concentrations and plotted against R_0S_0. The good linear relation of these quantities implies that above treatment is fair (Fig. 5). These results also support the idea that

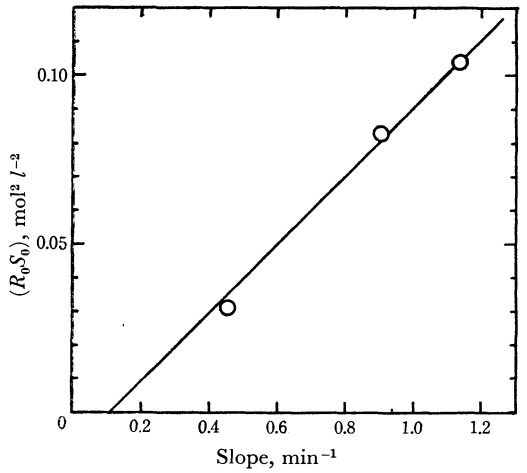

Fig. 5. Plot of the slope *vs.* R_0S_0.

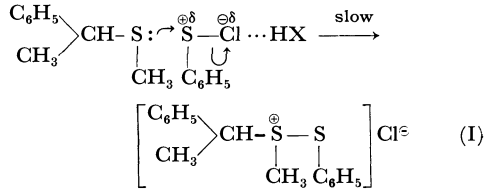
the reaction is first-order in both the thioether and the sulfenyl chloride, since, if this were not the case, the linear relation would have been found between the slope and $(R_0S_0)^n$ instead of between the slope and R_0S_0.

From the discussions presented above, it appears that acid is necessary in order to promote the reaction of the thioether with the sulfenyl chloride, and that the formation of an intermediate from thioether, sulfenyl chloride, and acid is the rate-determining step. After the rate-determining step, there are several rapid reaction paths which could result in the formation of the products. A sulfonium ion resulting from the electrophilic attack by benzenesulfenyl chloride on the sulfur atom of the thioether is the most likely such intermediate, since the rate is proportional to the concentrations of both the thioether and the sulfenyl chloride.

Although there are many points to be clarified before we have a full understanding of the catalytic action of the acid, at present the authors choose to attribute it to the aid of acids in polarizing the sulfenyl chloride in an activated complex. That is, it is assumed that, although sulfenyl chlorides are polar enough to add to the olefinic bonds by second-order kinetics, they are too poorly electrophilic to attack the sulfur atom directly and that, subsequently, acids are necessary to assist the polarization. Thus, a kind of concerted mechanism can now be postulated:



An analogy for this concerted reaction mechanism may be found in the electrophilic addition of hydrogen halide to olefins, which has been suggested[3] to proceed *via* an activated complex which involves a few extra molecules of hydrogen halide in addition to the actually-adding molecule of HX. The paticipation of the extra molecule has been attributed to assistance in the polarization of the attacking hydrogen halide, thus facilitating the ionic cleavage of the molecule.

The reactions involving the electrophilic attack

3) F. R. Mayo and J. J. Katz, *J. Amer. Chem. Soc.*, **69**, 1339 (1947).

by sulfenyl chloride are known to be accelerated by an acidic catalyst: the addition of sulfenyl chloride to the acetylenic bond[4] and electrophilic aromatic substitution[5] with arenesulfenyl chloride are catalyzed by Lewis acids. These examples, together with the results presented here, suggest that the sulfenium cation, RS^+, plays an important role in the electrophilic attack by the sulfenyl chlorides. Moreover, this idea is in conformity with the fact[6] that the solution of methanesulfenium 2,4,6-trinitrobenzenesulfonate generates dimethyl(methylthio)sulfonium salts in the presence of dimethyl sulfide.

It may be argued that the sulfonium ion (I) would be formed rather rapidly from the sulfenyl chloride and the sulfide, and that the decomposition of the sulfonium ion, I, would be the rate-determining step, because the data presented here are confined to product analyses and to the measurement of the half-life period, and because various S_N2 reactions of sulfonium ions are known. This argument can be worthwhile if it is assumed that the sulfonium ion from the disulfide gives back the starting sulfide upon the subsequent work-up. However, it is rather unlikely, since the measurements of the ultraviolet spectra ($\lambda_{max}=390$ mμ, $\varepsilon=470$) of benzenesulfenyl chloride, when mixed with the thioether, show an induction period in the decrease in the absorption coefficient, indicating that the sulfenyl chloride is not used until some time later, even in the presence of the thioether. The decrease in intensity might have been observed immediately after mixing if I were formed rapidly. Furthermore, this induction period corresponds to that of the decrease in the thioether.

After the unstable sulfonium ion intermediate is formed, the reaction may now take three different courses, according to the structure of the intermediate. One reaction path is the loss of the disulfide molecule to form a carbonium ion, which then undergoes nucleophilic substitution or the elimination of a proton to form the olefin. This occurs when a stable carbonium ion is to be formed; *t*-butyl phenyl sulfide[1] is an example. The second path is the S_N2 reaction by the chloride ion, which is evident from the inversion of the configuration in the reaction of methyl 1-phenylpropyl sulfide.[1] The third path is the elimination of α-hydrogen and the alkylthio (or arylthio) group. The mechanism of this last case has not been studied well enough to present the details here, but, by analogy from other Pummerer-type reactions, it can tentatively be postulated that a sulfur ylide is formed first by the elimination of α-hydrogen as the proton, followed by the elimination of the phenylthio group. In the latter step, probably another molecule of benzenesulfenyl chloride assists the removal by forming diphenyl disulfide. The carbonium ion thus formed will give α-chloro sulfide if it is not too stable, whereas it will give α,β-unsaturated sulfide if it can survive long enough to eliminate a proton from the β-carbon.

Although α,β-unsaturated sulfide is sometimes obtained[7] in the original Pummerer reaction, *i.e.*, the reaction of sulfoxide and acetic anhydride,

its formation can be explained if the thermal decomposition of an intermediate α-acetoxy sulfide is assumed. Therefore, there can be disagreement concerning the mechanism of the formation of α,β-unsaturated sulfide in the Pummerer reaction. The present authors feel that the discussions given above may throw light on the possibility of the presence of a carbonium ion intermediate in the formation of α,β-unsaturated sulfide.

Experimental

Starting Materials. Methyl α-phenethyl sulfide was prepared from α-phenethyl chloride and methyl mercaptan and was freshly distilled immediately before making the solution for experiments in every case; bp 67°C/3 mmHg, $n_D^{20.5}$ 1.5491 (lit,[8] n_D^{20} 1.5497).

Benzenesulfenyl chloride was prepared from diphenyl disulfide and chlorine, as in the literature,[9] and was always distilled prior to its use; bp 79°C/10 mmHg.

Carbon tetrachloride of a commercial source was purified by distillation.

Commercial trichloroacetic acid was distilled under reduced pressure in a dry atmosphere. Contact with moisture was carefully avoided.

Rate Measurements. Stock solutions of the sulfenyl chloride, methyl α-phenethyl sulfide, and trichloroacetic acid were prepared by weighing the proper amounts of the freshly-purified materials and by then making the solution up to the desired volume with dry carbon tetrachloride at 25°C. The solutions were then brought to a desired temperature (25±0.1°C) in a constant-temperature bath. The desired volume of each solution was pipeted and mixed. Although some change in volume may result from the mixing of three kinds of solutions, this effect was neglected in the calculation.

The reaction mixture was taken out with a pipet, *ca.* 20 m*l* at a time, and drained into a separately funnel containing 30 m*l* of aqueous sodium carbonate. The lower layer was dried over anhydrous sodium sulfate and then submitted to NMR analysis after filtration. In the NMR spectra of the reaction mixture, the signal of the methylthio protons of methyl α-phenethyl sulfide and the lower one of the doublet signal of methyl protons of α-phenethyl chloride coincided. However, the yields based on methyl α-phenethyl sulfide could be calculated by the integration of the other, non-overlapping signals.

The Reaction of Sulfenyl Chlorides with Thioethers. III. The Configuration and the Isomerization of *cis*- and *trans*-α-Methylthio-β-phenylthiostyrenes

Michinori Ōki and Keiji Kobayashi

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received November 17, 1969)

Various α-methylthio-β-arylthiostyrenes were prepared by the action of arenesulfenyl chloride on α-methylthiostyrene. The configuration of the stereoisomers of the styrene derivatives was determined by studying the nuclear Overhauser effect in the proton magnetic resonance. The relative stabilities of α-methylthio-β-phenylthiostyrene isomers were determined by equilibrating with the aid of hydrogen chloride at various temperatures.

It has been found that the treatment of methyl α-phenethyl sulfide with benzenesulfenyl chloride in carbon tetrachloride gives an isomeric mixture of *cis*- and *trans*-α-methylthio-β-phenylthiostyrenes in a 45% yield according to the following stoichiometry:

$$C_6H_5\underset{\displaystyle SCH_3}{\underset{|}{C}}HCH_3 + 3C_6H_5SCl \rightarrow C_6H_5\underset{\displaystyle SCH_3}{\underset{|}{C}}=CHSC_6H_5 + 3HCl + C_6H_5SSC_6H_5 \quad (I)$$

As has been shown in our previous papers,[1,2] one isomer which was predominant in the earlier stage of the reaction gradually decreased in quantity and another isomer became predominant in the later stage. That is, the formation of the olefins is kinetically-controlled, but these isomers are equilibrated even at room temperature under the present reaction conditions.

1) M. Ōki and K. Kobayashi, This Bulletin, **43**, 1223 (1970).
2) M. Ōki and K. Kobayashi, *ibid.*, **43**, 1229 (1970).

Since this phenomenon seemed interesting from the standpoints of stereochemistry and the reaction mechanism, an extensive study was made of the stereochemistry of the olefins. The purpose of this paper is to report the assignment of the configuration and some pertinent data on the geometrical isomers of α-methylthio-β-phenylthiostyrene.

Results and Discussion

Separation of Isomers. The NMR spectrum of the isomeric mixture of α-methylthio-β-phenylthiostyrene shows two sharp singlets for CH_3S protons at τ 8.08 and 8.02 and two singlets for olefinic protons at τ 3.53 and 3.85. From the integration of the peaks, the signals at τ 8.08 and 3.53 are assigned to one isomer and those at τ 8.02 and 3.85 to another. Hereafter, the isomer which is obtained in a higher yield at the equilibrium will be called the isomer A, and the other, the isomer B, for the sake of simplicity in discussion. The ratio of the formation of IA and IB is calculated from the NMR integration to be approximately 3 : 1 under the present reaction conditions.

All attempts at separating isomer IA and IB ended in failure. Therefore, we aimed to separate the corresponding isomers with a substituent at the *p*-position of the phenylthio group, since it seemed that the introduction of a substituent might help the separation owing to the change in intermolecular forces. Thus, α-methylthiostyrene was treated with *p*-nitrobenzene-, *p*-bromobenzene-, *p*-chlorobenzene-, *p*-methylbenzene-, and *p*-methoxybenzene-sulfenyl chlorides; the corresponding α-methylthio-β-arylthiostyrenes (II—VI) were thus obtained:

$$C_6H_5C(SCH_3)=CH_2 + ArSCl \rightarrow C_6H_5C(SCH_3)=CHSAr + HCl$$

II: Ar=*p*-$NO_2C_6H_4$ V: Ar=*p*-$CH_3C_6H_4$
III: Ar=*p*-BrC_6H_4 VI: Ar=*p*-$CH_3OC_6H_4$
IV: Ar=*p*-ClC_6H_4

The *p*-nitrophenylthio derivatives (IIA and IIB) could be separated by fractional recrystallization from ethanol. The less soluble isomer was found from its NMR spectrum to be the isomer IIA; the isomer which was richer at the equilibrium was found to be less soluble. Therefore the more soluble isomer was IIB. The less soluble isomers of the *p*-bromo derivative (IIIA) and the *p*-chloro derivative (IVA) were also isolated by recrystallization.

Assignment of the Configuration. Since we will not attempt to assign all the configurations of the olefins, but to use analogy in making assignments, it will be necessary to establish the general tendency of the physical and/or chemical characteristics of the A or B series and to confirm that the analogy holds in this series. The relative stabilities have already been established from the equilibration, and it will be safe to say that the introduction of a substituent at the *p*-position of the phenylthio group will not affect the stability to such an extent that the relative stability will be reversed, since this is rather a minor change in the whole molecule.

The second criterion is the chemical shifts of the olefinic and methylthio protons of the series. As is shown in Fig. 1, the more stable isomers, the series

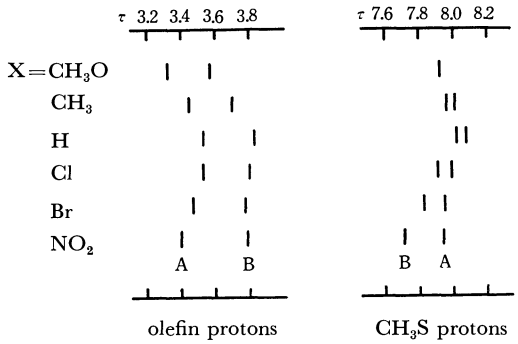

Fig. 1. Chemical shift data of the protons of α-methylthio-β-arylthiostyrenes in carbon tetrachloride solution (*ca.* 10%) except for the nitro derivative ($CDCl_3$).

A, always exhibit the methylthio signals at a higher field, and the olefinic proton signals, at a lower field, than the series B, except that the *p*-methoxy derivative (VI) happens to give signals of the methylthio protons of A and B at the same chemical shift. Here again, it may be assumed that the series A has the same configuration, since it is not usual to postulate that the introduction of a substituent may cause an abrupt anomaly in the chemical shifts of a series of compounds.

In spite of various attempts, we found it impossible to assign the configurations for the isolated isomers, IIA and IIB, on the basis of these chemical behavior: for example, attempted cyclization with ethylene iodide by heating ended only in the recovery of the starting material. The UV and the

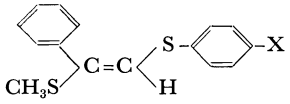
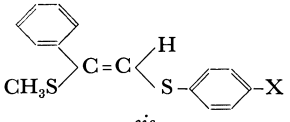
	761, 742, 700	761, 735, 700

IR spectra of these isomers, shown in Table 1, do not help much in assigning the stereochemistry. Although the former does show some difference in the absorption maxima, the coplanarity of the molecule can not be assumed because of the steric effect of the other groups; this assumption is, however, essential to establishing the configuration from the UV spectra.

However, the NMR spectral data in Table 1 do give some clue for elucidating the structure of the isomers. If it is assumed that the additivity rule of the chemical shifts in substituted ethylenes holds in these cases, as has been reported by Pascual and his co-workers,[3] the chemical shift of the olefinic protons in the *cis* isomer will be at a lower field than in the corresponding *trans* isomer, since it is expected that a proton *cis* to the phenyl ring and *trans* to the methylthio group will give a signal at a lower field than the counterpart, which is *trans* to the phenyl and *cis* to the methylthio group. Thus, from the additivity rule, the compounds of the series A should be assigned to the *cis* isomers:



trans



cis

It will not be safe, however, to rely too heavily on the additivity rule in the assignment, because the coplanarity of the molecule will not necessarily hold in these compounds. In order to confirm this tentative assignment, it will be necessary to use another technique in assigning the structure; the measurement of the intramolecular nuclear Overhauser effect (NOE) was chosen for this purpose.

The NOE has been increasingly used in assigning the stereochemistry of the organic compounds by identifying those protons which are in close proximity and which are coupled by dipole-dipole interaction. The transient method[4] was utilized for the NOE measurement with degassed solutions of IIA and IIB in deuteriochloroform. The magnetization of the methylthio protons was saturated by irradiating them at τ 7.94 for IIA and at τ 7.71 for IIB. After the irradiation, a transient recovery of the enhanced signal intensity of the olefinic proton to the thermal equilibrium was observed; IIB showed a definite enhancement in this process, while no change in signal intensity took place upon

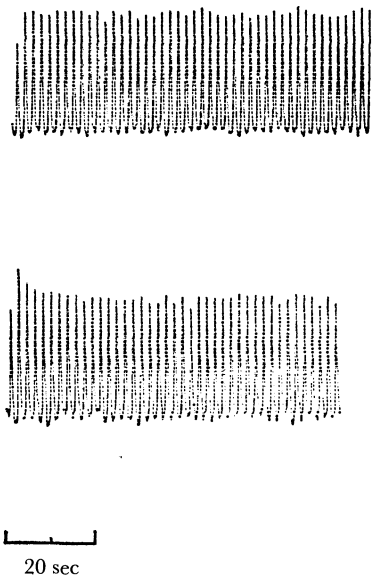


Fig. 2. Nuclear Overhauser enhancement and recovery to the thermal equilibrium of the olefinic proton.

this treatment in IIA. From Fig. 2, it can be estimated that a 25% Overhauser enhancement is associated with IIB, whereas IIA does not show any intramolecular NOE.

The spin-lattice relaxation time (T_1) of the olefin proton was also measured. The estimation of T_1 is necessary because the following correlation[4,5] should be used in comparing the internuclear distance between two protons in a pair of configurational or conformational isomers:

$$d \propto \left[\frac{T_1}{\eta}\right]^{1/6}$$

where η is the nuclear Overhauser enhancement parameter; d is, in this case, the internuclear distance between the methylthio and the olefinic protons. Namely, if the T_1 of one proton is much larger than the other, it may affect the observed enhancement.

T_1 was found to be 4.7 sec for the olefinic proton of the isomer IIB, which showed a 25% enhancement of the signal intensity, whereas that for IIA was 5.8 sec. These results establish that the distance between two kinds of protons in IIB is shorter than that in IIA, since the T_1 for the olefinic proton of IIB is the smaller; if it were T_1 that was affecting the enhancement, IIA would show more enhancement than IIB.

The distance between the olefinic proton and a closest proton in the methylthio group in the *trans* isomer is estimated to be 1.5 Å from the Dreiding model, if the molecule assumes a conformation which possesses these protons at the

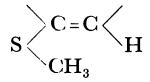
5) F. A. L. Anet and A. J. R. Bourn, *J. Amer. Chem. Soc.*, **87**, 5250 (1965).

closest approach, whereas the protons in the *cis* isomer are far apart. Thus, IIA is assigned to the *cis* isomer, and IIB, to the *trans*, confirming the results obtained by the use of the additivity rule.

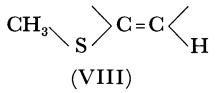
The NOE of the *p*-methoxyphenylthio derivative (VI) was also examined by the usual stationary state method. Although the isomers could not be separated, and although they happened to give methylthio signals at the same chemical shift, τ 7.92, the situation was rather auspicious for the NOE measurements: simple irradiation at τ 7.92 and observation of the intensities at the olefinic proton region sufficed in comparing the isomers. A degassed sample of VI, which contained *ca.* 2 : 1 isomers of A and B, was irradiated. The olefinic signal due to VIB showed 21% NOE, the amount of which was estimated from the relative change in the intensities of the two singlets at τ 3.57 (VIB) and τ 3.32 (VIA). Thus, VIB can be assigned to the *trans* isomer, and VIA, to the *cis*.

At this stage, it has been established that the isomers of the A series, which are the more stable, have the *cis* configuration, while those of the series B have the *trans* configuration.

The observation of NOE enhancement for IIB and VIB indicates that the olefinic and methylthio protons are in close proximity, which would require that the carbon-sulfur bond in the methylthio group eclipse the carbon-carbon double bond (VII). If it were taking the S-*trans* conformation (VIII), the enhancement would be expected to be very small, since the distance between the two kinds of protons is estimated to be more than 4.6 Å from the Dreiding model, in contrast to 1.5 Å in the S-*cis* conformation.



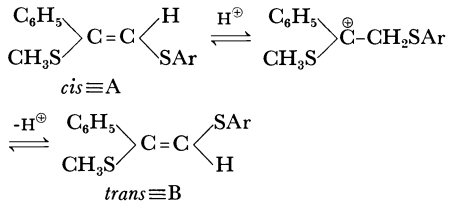
(VII)



(VIII)

This conformation is supported by the analogy of the situation in methyl vinyl ether, which has been shown by microwave spectroscopy to possess the S-*cis* conformation.[6] There is also an example of NOE measurement with methyl vinyl ether derivatives in which NOE is observed between the *O*-methyl protons and the vinyl proton *cis* to each other.[7]

Relative Stabilities of the *cis-trans* Isomers. The *cis-trans* isomerization of the olefiins can be effected by the action of hydrogen chloride in carbon tetrachloride. The mechanism of the isomerization is assumed to proceed *via* a carbonium ion intermediate which is formed by addition of a proton and which forms olefins by the elimination of the proton. Incidentally, the intermediate is the same as that assumed in the addition of sulfenyl chloride to α-methylthiostyrene.



To estimate the thermodynamic parameters for the pair of *cis* and *trans* isomers, II was equilibrated with hydrogen chloride in carbon tetrachloride at four temperatures. The isomer distribution was calculated from the integration of the signal areas of the NMR spectra. The Arrhenius plot is shown in Fig. 3, while the parameters obtained therefrom are summarized in Table 2.

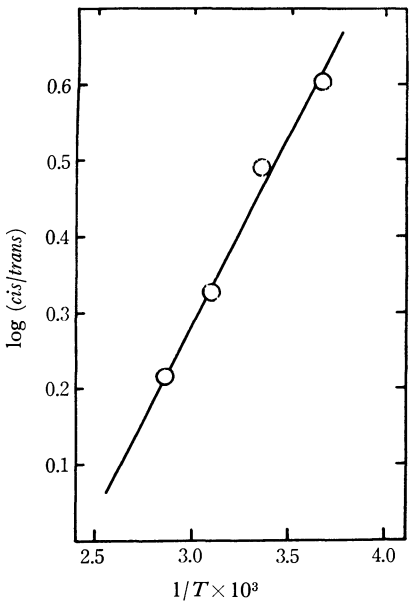


Fig. 3. Arrhenius plot for the *cis-trans* equilibration of α-methylthio-β-phenylthiostyrene.

Table 2. The thermodynamic parameters for the *cis-trans* equilibration of α-methylthio-β-phenylthiostyrene

ΔH	-2.2 ± 0.7 kcal/mol
ΔS	-5 ± 2 e.u.

Although the reasons for the stability of the *cis* isomer relative to the *trans* are not completely understood at the present time, two factors may be considered. The first factor may be of the steric origin. If it is assumed (and it is common to assume) that the steric effect in the olefinic compound is determined by the first atom which directly

attaches to the double bond, when there is freedom of rotation for the other part, sulfur must play the main role in determining the steric effect in the methylthio and arylthio groups; by appropriate rotation, methyl and aryl groups can take conformations in which these groups have little steric effect. Therefore, it is the van der Waals radius of the sulfur atom that should be taken into account; it is usually taken as 1.85 Å. The half-thickness of the benzene ring is also estimated to be 1.85 Å. Therefore, if the benzene ring is perpendicular with respect to the olefinic bond, the steric effect on the conformational energy will be almost the same in both isomers. However, due to the delocalization energy to be gained at the coplanar conformation, the benzene ring will come as close by as possible to the planar conformation. This, of course, increases the apparent van der Waals radius of the benzene ring; the steric interaction between the phenyl and the arylthio groups is then larger than that between the methylthio ant the arylthio groups. The steric factor, therefore, may favor the *cis* configuration.

There is another factor to be considered; it may be called the electrostatic interaction. It has been well known that the *cis* isomer is more stable than the *trans* in 1,2-dihaloethylenes,[8-10] although halogens are much larger than hydrogen. The cause for this phenomenon may be the dispersion force, and the same effect may be operating in the series of compounds discussed in this paper.

The separation of these factors is not at all possible at the present time and awaits further studies.

Experimental

The General Method for the Preparation of α-Methylthio-β-arylthiostyrenes. To a solution of 6 g (0.04 mol) of α-methylthiostyrene[2] in 50 m*l* of dry carbon tetrachloride, equimolar arenesulfenyl chloride in 25 m*l* of carbon tetrachloride was slowly added at 0°C; hydrogen chloride was then evolved. The solution was allowed to stand for another hour after the color of the sulfenyl chloride had essentially faded, and then poured into 100 m*l* of aqueous sodium carbonate. The organic layer was separated, and the aqueous layer was extracted with ether. The combined extracts were dried over anhydrous sodium sulfate and concentrated *in vacuo*. The residue was chromatographed on alumina to give 75—95% yields of α-methylthio-β-arylthiostyrene.

Isolation of Isomers. In the case of α-methylthio-β-*p*-nitrophenylthiostyrene, the remaining yellow solid was fractionally recrystallized from ethanol to give the *cis* isomer, mp 134—135°C, as a less soluble part and the *trans*, mp 88—89°C, as a more soluble part.

In the cases of α-methylthio-β-*p*-chlorophenylthiostyrene and α-methylthio-β-*p*-bromophenylthiostyrene, on long standing they gave crystals which were then separated from the oil and recrystallized from petroleum ether to give the *cis* isomers. The mp's of the chloro and bromo derivatives were 91°C and 92—93°C respectively.

Equilibration of *cis*- and *trans*-α-Methylthio-β-phenylthiostyrenes. The title isomers were equilibrated by maintaining a carbon tetrachloride solution, into which hydrogen chloride was introduced, at the specific temperature for 30 min. The temperatures at which the equilibration was carried out were 0, 25, 50, and 77°C. The products were analyzed by means of the NMR spectra of the reaction mixture after washing the solution with aqueous alkali and then drying it.

NOE Measurements. The NOE measurements were carried out with a Japan Electron Optics 4H-100 spectrometer operating at 100 MHz. The transient NOE was observed in the "HR mode," employing the usual double-resonance technique. In measuring the spin-lattice relaxation time, the magnetization of the olefin proton was inverted adiabatically and the recovery of the magnetization was observed by scanning through the resonance with a weak rf field.

The samples were dissolved in deuteriochloroform (in the case of II) or in carbon tetrachloride (in the case of VI) to make a *ca.* 15% solution, which was then degassed and sealed.

The authors are indebted to Mr. T. Fukumi for the NOE measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1239—1242 (1970)

Transformation of Progesterone by *Aspergillus niger* 100 and *Rhizopus nigricans* REF, 129

Lotfy SALLAM, Abdel-Monem EL-REFAI and Ismail EL-KADY

Microbiological Chemistry Research Lab., National Research Centre, Cairo, U.A.R.

(Received July 3, 1969)

The microbiological transformation of progesterone by the local moulds *Aspergillus niger* and *Rhizopus nigricans* was studied. To a 48 hr old culture, progesterone (0.4 g/*l* medium) dissolved in ethanol was added and the transformation was left to proceed for 72 hr. Thereafter, the different transformation products were resolved chromatographically. The identity of each product was established through the determination of mp, mixed mp, optical rotation and ultraviolet as well as infrared absorption spectra. A comparison of the R_f values of each product with that of the corresponding reference using different solvent systems as well as their colours with two spray reagents was used as a further proof for the identity of the isolated products. In case of *A. niger*, progesterone was converted to 17α-hydroxyprogesterone; 21-hydroxyprogesterone (cortexone); 11α-hydroxyprogesterone; 11α,17α-dihydroxyprogesterone; 6β,11α-dihydroxyprogesterone and 11α,17α, 21-trihydroxyprogesterone (epicortisol). These products together with 11α-hydroxy-5α-pregnane-3,20-dione were also identified in case of *R. nigricans*.

The microbiological oxidation of progesterone at one or more of the strategic carbon atoms 11, 17, and 21 was applied to the preparation of the cortical hormones. The introduction of a hydroxyl group at carbon 11 of progesterone was performed by many fungi, mostly Rhizopi and Aspergilli.[1,2] The 17α-hydroxyl group was introduced into steroids by *Trichothecium roseum*.[3,4] However, Meister *et al.*[5] announced that *Cephalothecium roseum* could accomplish this interesting tertiary hydroxylation along with simultaneous introduction of the biologically important oxygen at C-11. Meyster *et al.*[3] also found that *Ophiobolus herpotrichus* introduced a hydroxyl group at C-21. The microbial 21-hydroxylation of several susbtrates by *Aspergillus niger* was also reported.[6] Moreover, a strain of *A. niger* was able to introduce both 11α- and 21-hydroxyl groups simultaneously into progesterone.[7,8] Epicortisol (11α-,17α,21-trihydroxyprogesterone) was isolated by CIBA group[9] together with other transformation products when *R. nigricans* and *Cunninghamella blakesleeana* were acted on progesterone.

Many works have been carried out on hydroxylation for progesterone by *A. niger*, but in most work the strain ATCC 9142 was used, and hydroxylation occurred at C-6, 11 or 21. Screening of the ability of some microorganisms for the transformation of progesterone was carried out by the authors,[10] and some active moulds were found. Using the local strain *A. niger* 100, we observed that the hydroxylation of progesterone occurs at C-6, 11, 17 and 21. A similar hydroxylation was observed using the strain *R. nigricans* REF, 129. Qualitative as well as quantitative analyses were carried out on the different products which were obtained when these two active moulds were acted upon progesterone.

Experimental

and *Rhizopus nigricans* REF, 129 were collected from the Centre of culture of the Microbiological Chemistry Research Lab., National Research Centre, Cairo. The cultivation was performed in 250 m*l* Erlenmeyer flasks each containing 75 m*l* of the medium formulated by Capek *et al.*[11] The flasks were sterilized at 1 atm. for 20 min and inoculated with 2 m*l* inocula of a 48 hr culture of the pure organsim. The culture flasks were agitated on a reciprocal shaker (110 strokes/min, amplitude 7 cm) at 30±2°C for 48 hr. Thereafter, 30 mg of progesterone dissolved in 1 m*l* ethanol was added to each flask and fermentation was continued for another 72 hr.

Extraction. At the end of the fermentation periods, the contents of each flask (medium+mycelium) were homogenized in a blender (16000 rpm) with two volumes of chloroform (150 m*l*). The extraction was repeated 3 times in order to make sure that all the transformation products were extracted. The combined chloroform extracts were washed with half its volume 5% sodium bicarbonate, followed by an equal volume distilled water, dried over anhydrous sodium sulphate, filtered, then distilled to give a semi-solid residue.

Analysis of the Mixture of the Transformation Products. The semi-solid residue was dissolved in the minimal volume of benzene and then fractionated on standard activated alumina column (100 g). The following sequence of solvents was used: *n*-hexane : benzene (1 : 1); benzene containing different concentrations of chloroform and benzene containing different concentration of methanol. The fractions containing similar products were collected and crystallization from a suitable solvent was carried out whereby determination of mp; mixed mp; $[\alpha]_D$; IR and UV absorption spectra were made.

Further proof of the identity of each product was gained by the application of the thin-layer chromatographic technique.[12] The solvent systems used are: I: Cyclohexane : acetone : chloroform (75 : 25 : 20), II: Ethylene chloride : acetone (80 : 20), III: Benzene : ethyl acetate : acetone (60 : 20 : 20) and IV: Chloroform : cyclohexane : isopropanol (50 : 100 : 20).

The plates were then sprayed with two different colour reagents namely: I_2/KI,[13] and chlorosulphonic acid : acetic acid (3 : 1).[14]

Results and Discussion

Progesterone Bioconversion by *A. niger* 100. The chromatographic resolution of the mixture (1.3 g) containing the different transformation products obtained when *A. niger* was acted on progesterone (1 g) revealed the presence of unchanged progesterone (11%);*1 17α-hydroxyprogesterone (11.9%); 21-hydroxyprogesterone (cortexone) (13.3%); 11α-hydroxyprogesterone (22.4%); 11α,17α-dihydroxyprogesterone (13.1%); 6β,11α-dihydroxyprogesterone (10.8%) and 11α, 17α,21-trihydroxyprogesterone (epicortisol) (7.5%), respectively.

The fractions eluted with *n*-hexane : benzene (1 : 1) were evaporated and crystallized from methanol : chloroform to give crystals (110 mg), mp 128—129°C, $[\alpha]_D$+195°. This substance was found to be unchanged progesterone. The fraction eluted with 5% chloroform in benzene gave after repeated crystallization from chloroform: methanol crystals (119 mg), mp 218—220°C, $[\alpha]_D$ +120.3°, λ_{max}^{EtOH} 239 mμ (ε=12920). The material did not depress the mp of an authentic sample of 17α-hydroxyprogesterone. Reported[15] mp 210—214°C, identical IR spectra.

The solid residue eluted with 10% chloroform in benzene was repeatedly crystallized from methanol: chloroform to afford crystals (133 mg), mp 139—141°C, $[\alpha]_D$ +183°, λ_{max}^{EtOH} 241 mμ (ε=12700). This material was found to be 21-hydroxyprogesterone. Reported[6] mp 142—143°C, $[\alpha]_D$ +185°, identical IR spectra.

The combined fractions eluted with 20% chloroform in benzene on cyrstallization from chloroform: methanol gave crystals (224 mg), mp 165—168°C, $[\alpha]_D$ +177°, λ_{max}^{EtOH} 242 mμ (ε=12960). The material did not depress the mp of an authentic sample of 11α-hydroxyprogesterone. Reported[16] mp 166—168°C, $[\alpha]_D$ +176°, identical IR spectra.

The fifth product eluted with 5% methanol in benzene afforded after crystallization from methanol crystals (131 mg) mp 217—220°C, $[\alpha]_D$ +72°, λ_{max}^{EtOH} 242 mμ (ε=16100). This material was found to be 11α,17α-dihydroxyprogesterone. Reported[17] mp 220—222°C, $[\alpha]_D$ +76°, identical IR spectra.

The substance eluted with 10% methanol in benzene gave upon crystallization from methanol: water, crystals (180 mg), mp 244—246°C, $[\alpha]_D$ +140°, λ_{max}^{EtOH} 239 mμ (ε=13480). The material did not depress the mp of the authentic sample of 6β,11α-dihydroxyprogesterone. Reproted[16] mp 245—248°C, $[\alpha]_D$ +144°, identical IR spectra.

Final strip of the column with 25% methanol in benzene gave a solid material which yielded on repeated crystallization from methanol: water,

* 11α-Hydroxy-5α-pregnane-3,20-dione was detected in case of *R. nigricans* only.

crystals (75 mg) mp 208—210°C, $[\alpha]_D$ 109°, λ_{max}^{EtOH} 241 mμ ($\varepsilon = 14700$). This substance did not depress the mp of an authentic sample of 11α, 17α,21-trihydroxyprogesterone (epicortisol). Reported,[18] mp 210—212°C, $[\alpha]_D$ +113°, identical IR spectra.

Futher proof of the identity of the different compounds produced from the bioconversion of progesterone by *A. niger* was made by application of thin-layer chromatographic analysis. The results of this study are presented in Table 1.

Progesterone Bioconversion by *R. nigricans* REF, 129. Inspection of the mixture (1.4 g) resulting from the bioconversion of progesterone (1 g) by *R. nigricans* revealed the presence of unchanged progesterone (6%), 17α-hydroxyprogesterone (8.2%), 21-hydroxyprogesterone (7.9%), 11α-hydroxy-5α-pregnane-3,20-dione (7.4%), 11α-hydroxyprogesterone (24.4%), 11α,17α-dihydroxyprogesterone (16.7%), 6β,11α-dihydroxyprogesterone (9.5%) and finally 11α,17α,21-trihydroxyprogesterone (epicortisol) (10.5%).

The first fraction eluted with *n*-hexane : benzene (1 : 1) gave upon crystallization from chloroform: methanol, crystals (60 mg) mp 126—128°C, $[\alpha]_D$ +194°. This was found to be unchanged progesterone. Evaporation of the fractions eluted with 5% chloroform in benzene followed by crystallization from chloroform : methanol gave crystals (82 mg), mp 209—212°C, $[\alpha]_D$ +120—123°, λ_{max}^{EtOH} 239 mμ ($\varepsilon = 12960$). This material did not depress the mp of an authentic sample of 17α-hydroxyprogesterone. Reported[15] mp 210—214°C, identical IR spectra.

The solid substance removed with 10% chloroform in benzene gave crystals (79 mg) mp 140—142°C, $[\alpha]_D$ +180°, λ_{max}^{EtOH} 241 mμ ($\varepsilon = 12700$). This substance was found to be 21-hydroxyprogesterone as no depression in the mp was observed upon admixture with an authentic sample of cortexone. Reported[14] mp 142—143°C, $[\alpha]_D$ +185°, identical IR spectra. The compound eluted with 15% chloroform in benzene gave on crystallization from chloroform : methanol crystals (74 mg) mp 194—196°C, $[\alpha]_D$ +81°. No depression in the mp of an authentic sample of 11α-hydroxy-5α-pregnane-3,20-dione with the isolated crystals. Reported[16] mp 198—200°C, $[\alpha]_D$ +84°, identical IR spectra. The fractions collected with 20% chloroform in benzene yield upon crystallization from methanol crystals (244 mg), mp 165—167°C, $[\alpha]_D$ +175°. This substance did not depress the mp of an authentic sample of 11αhydroxyprogesterone. Reported[16] mp 166—168°C, $[\alpha]_D$ +176°, identical IR spectra.

Elution with 5% methanol in benzene gave a compound which upon crystallization from methanol gave crystals (167 mg), mp 216—218°C, $[\alpha]_D$ +75°, λ_{max}^{EtOH} 243 mμ ($\varepsilon = 16200$). This compound is 11α,17α-dihydroxyprogesterone. Reported[17] mp 220—222°C, $[\alpha]_D$ +76°, identical IR spectra.

The fractions eluted with 10% methanol in benzene gave on crystallization from methanol : water crystal (95 mg), mp 242—245°C, $[\alpha]_D$ +139°, λ_{max}^{EtOH} 239 mμ ($\varepsilon = 13480$). This material was found to be 6β,11α-dihydroxyprogesterone. Reported[16] mp 245—248°C, $[\alpha]_D$ +144°, identical IR spectra.

The fractions collected with 25—50% methanol in benzene was crystallized from methanol: water to give crystals (105 mg), mp 208—210°C, $[\alpha]_D$ +105°, λ_{max}^{EtOH} 241 mμ ($\varepsilon = 14700$). This product did not depress the mp of an authentic sample of epicortisol. Reported[18] mp 210—212°C, $[\alpha]_D$ +113°, identical IR spectra.

Further establishment of these different products was made through thin-layer chromatographic analysis as presented in Table 1.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1243—1244 (1970)

Formation of Acetals from Vinyl Chloride and Alcohols Catalyzed by Transition Metal Chlorides

Akira MISONO, Yasuzo UCHIDA and Ken-ichi FURUHATA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo Bunkyo-ku, Tokyo

(Received March 31, 1969)

Recently, the formation of acetaldehyde dialkyl acetal from vinyl chloride and alcohol catalyzed by palladium chloride and a base was reported.[1,2]

In an attempt to oligomerize vinyl chloride by transition metal chlorides in alcohol, we have observed the formation of acetaldehyde dialkyl acetals instead of the oligomerization by ruthenium, rhodium and palladium chlorides. This reaction did not take place by iron, cobalt, chromium, zirconium and hafnium chlorides.

Results and Discussion

In a preliminary experiment, vinyl chloride and rhodium trichloride trihydrate (molar ratio; 150) were dissolved in methanol and the mixture was kept at 50°C for 48 hr. The only product isolated was acetaldehyde dimethyl acetal, no product corresponding to a dimer of vinyl chloride being detected on gaschromatography.

More detailed studies on the acetal formation reaction by rhodium trichloride trihydrate were carried out using ethanol. The time dependence of the formation of acetaldehyde diethyl acetal at 60°C is shown in Fig. 1. The selectivity for acetaldehyde diethyl acetal was about 70% and it decreased when the reaction time exceeded 25 hr. In the reaction at 80°C, vinyl chloride was consumed completely in 24 hr but the selectivity for acetaldehyde diethyl acetal was only 20.3%. Small amounts of vinyl ethyl ether and acetaldehyde were detected on gas chromatography (identified by comparing retention times with those of authentic samples), and the rest was higher boiling products. The formation of acetaldehyde is likely to be due to the reaction of vinyl chloride with water[3] and/or the oxidation of ethanol by rhodium(III). Higher boiling products were not studied further.

Ruthenium and palladium chlorides also catalyzed the formation of acetaldehyde diethyl acetal but iron, cobalt, chromium, zirconium and hafnium chlorides did not (Table 1). In the reaction using palladium dichloride as a catalyst, partial reduction to palladium metal was observed.

Recently, the formation of acetal from vinyl chloride and alcohol catalyzed by palladium chloride was reported, but those reactions require the presence of a strong base[1] or an alkoxide anion.[2]

Reaction conditions: Vinyl chloride, 43 mmol; Catalyst, 0.2—0.4 mmol; Ethanol, 160 mmol

* Conversion of vinyl chloride, %

** Yield of acetaldehyde diethyl acetal based on vinyl chloride supplied, %

The reaction intermediate was considered to be vinyl ether which is formed by the nucleophilic attack of an alkoxide anion onto vinyl chloride coordinating to a palladium ion.

We believe that the coordination of vinyl chloride to ruthenium, rhodium or palladium is significant in the acetal formation reaction.

Experimental

Reagents. Vinyl chloride was passed through columns packed with calcium chloride and phosphorus pentoxide and then condensed into a pressure glass tube held at −78°C.

Methanol and ethanol were purified by conventional methods, and were distilled under a nitrogen stream.

Tris(triphenylphosphine)chlororhodium(I) was synthesized according to the reported method.[4]

Commercial metal chlorides were used without further purification.

Reaction Procedure. In a typical reaction, vinyl chloride (43 mmol) was charged into a glass ampule (20 m*l*) containing rhodium trichloride trihydrate (0.22 mmol) by a trap-to-trap distillation and then ethanol (160 mmol) was charged with a syringe under nitrogen stream. Then the solution was freezed with liquid nitrogen, and the ampoule was evacuated and was sealed. It was then kept at 60°C for 20 hr.

Analysis. The gas chromatography was carried out for the detection and the quantitative analysis of products using a 2 m stainless steel column, 4 mm in diameter, packed with bis(2-cyanoethyl) ether on Diasolid M. Operation conditions: column temperature, 68°C; flash evaporator, 200°C; carrier gas (helium) speed, 40 m*l*/min. Ethyl formate was used as the internal standard.

Tantalum(V)-Schiff Base Complexes

Pramila PRASHAR and J. P. TANDON

Department of Chemistry, University of Rajasthan, Jaipur-4, India

(Received January 30, 1969)

Considerable amount of work has been reported on the stereochemically important and useful chelates of Schiff bases with bivalent metals[1-4] but only a few scattered references are available for similar complexes of tetravalent and pentavalent metals.[5,6] In earlier publications from this laboratory, a few titanium[7] and zirconium[8] compounds have been reported. In the present paper, the reactions of tantalum(V) alkoxides with Schiff bases have been studied and some of their important properties described.

Tantalum isopropoxides, prepared by the ammonia method[9] and Schiff bases, prepared by azeotropic condensation and vacuum distillation, are the starting materials for these reactions. The technique consists of the addition of stoichiometric quantity of the Schiff base to the anhydrous benzene solution of tantalum isopropoxide and refluxing the reac-

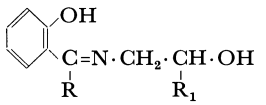
a=analysis of the compound, b=calcd for the formula

tion mixture on a fractionation column. The reaction is completed by the removal of the isopropanol produced azeotropically and drying the reaction mixture in a vacuum. These reactions in different molar ratios can be presented as

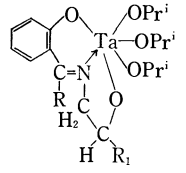
$$Ta(OPr^i)_5 + SBH_2 \longrightarrow Ta(OPr^i)_3(SB) + 2Pr^iOH,$$
$$Ta(OPr^i)_5 + 2SBH_2 \longrightarrow Ta(OPr^i)(SB)_2 + 4Pr^iOH,$$
$$Ta(OPr^i)_5 + 3SBH_2 \longrightarrow Ta(SB)_2(SBH) + 5Pr^iOH,$$

where SBH_2 represents the Schiff base and -SB- the corresponding anion of the Schiff base. The bases used in these reactions may be represented by the general formulae:

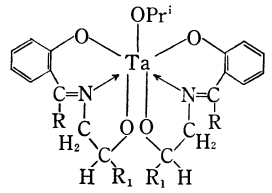


where in (I) R=H, R_1=H
(II) R=H, R_1=CH_3
(III) R=CH_3, R_1=H
and (IV) R=CH_3, R_1=CH_3.

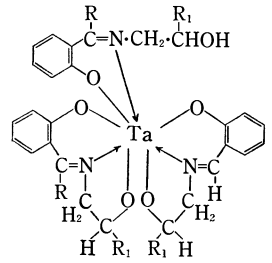
These reactions take place quite easily and the resulting compounds could be isolated in quantitative yields. Tantalum (V) - Schiff-base chelates are pale-yellow to dark-yellow foamy solids (Table 1), soluble in benzene, parent alcohol and chloroform and are non-volatile. Their molecular weights have been determined ebullioscopically in benzene and they are almost monomers. Their probable structures may be indicated as follows:



1:1 derivative



1:2 derivative



1:3 derivative

Analytical results and molecular weights of these derivatives are listed in the table.

One of us (P.P.) is grateful to the C. S. I. R., New Delhi for the award of a Research Fellowship. The authors are also grateful to Dr. R. C. Mehrotra, Professor and Head of the Chemistry Department, Rajasthan University, Jaipur, for providing research facilities.

Intramolecular Cyclization of *N*-(Phenylcarbamoyl)anthranilic Acid Derivatives

Shunroku TOHYAMA,*1 Masaru KURIHARA† and Naoya YODA†

Basic Research Laboratories, Toray Industries, Ltd., Tebiro, Kamakura

(Received May 16, 1969)

The thermal dissociation of urea derivatives under various conditions has been reported.[1,2] Iwakura and Nagakubo described the thermal decomposition of 1,3-di-*p*-phenetylurea in aliphatic alcohol solution to give *p*-phenetidine and phenyl isocyanate.[3] So far, no studies have been reported on the thermal dissociation of *ortho*-substituted *N*-(phenylcarbamoyl)aniline derivatives in polar organic solvents.

In connection with the study of cyclopolycondensation reactions[4] of aromatic diamino dicarboxylic acids with various active carbonyl compounds, we noted that several open-chain precursors of aromatic heterocyclic polymers such as polyurea acids[5] were sensitive to elevated temperatures in usual cyclodehydration. By the cyclodehydration reactions of *ortho*-substituted *N*-(phenylcarbamoyl)aniline derivatives, two condensation products, isatoic anhydride and 3-phenyl-2,4(1*H*,3*H*)-quinazoline-dione were isolated.

In this paper, we wish to report the new intramolecular cyclization reactions and the mechanism of the formation of isatoic anhydride (II) and 3-phenyl-2,4(1*H*,3*H*)-quinazolinedione (IV) from *N*-(phenylcarbamoyl)anthranilic acid derivatives (I). When *N*-(phenylcarbamoyl)anthranilic acid (Ia), its ammonium salts (Ib,c) and methyl ester (Ia) were treated either (A) in organic solvent such as *N*-methylpyrrolidone at 100°C or (B) in an inert gas at 220°C, the following two types of reactions were found to occur depending upon the reaction conditions.

The results of the cyclization reaction in *N*-methylpyrrolidone are summarized in Table 1.

The reaction product obtained in nitrogen was found to be solely 3-phenyl-2,4(1*H*,3*H*)-quinazoline-dione (IV). The yields of IV are shown in Table 2.

The formation of isatoic anhydride by the elimination of aniline is a new intramolecular cyclization reaction which has not been reported. For this cyclization reaction, two types of reaction mechanism are considered: (a) an intramolecular cyclization takes place directly by nucleophilic attack of carboxyl group on carbonyl group of ureido linkage to eliminate aniline as shown in Eq. (3),

or (b) the dissociation of ureido group forms isocyanate as a reaction intermediate (Eq. (4)).

When *N*-methyl-*N*-(phenylcarbamoyl)anthranilic acid was treated in *N*-methylpyrrolidone under the same reaction conditions, *N*-methylisatoic anhydride was obtained. In this case the formation of isocyanate as an intermediate (Eq. (4)) is impossible, and it should inevitably involve the participation of carobxyl group in the reaction process. Furthermore, reaction path (a) is favored by the fact that *N*-(phenylcarbamoyl)anthranilic acid (Ia) and its ammonium salts (Ib,c) afforded isatoic anhydride, whereas methyl ester (Id) did not give isatoic anhydride in organic solvent as shown in Table 1. The fact suggests that only the species which easily dissociate to give carboxylate anion respond to path (a).

When methyl *N*-(phenylcarbamoyl)anthranilate was fused in nitrogen atmosphere, it affords quinazolinedione as a sole product by intramolecular cyclization.

Experimental

***N*-(phenylcarbamoyl)anthranilic Acid.** Phenyl isocyanate (4.0 g, 1/300 mol) dissolved in benzene (20 m*l*) was added slowly at 30°C into a solution of anthranilic acid (4.6 g, 1/300 mol) in benzene (40 m*l*). After stirring for 3 hr, the precipitate was collected and recrystallized from ethanol: mp 185—186°C. Found: C, 65.51; H, 4.65; N, 10.65%. Calcd for $C_{14}H_{12}O_3N_2$: C, 65.62; H, 4.72; N, 10.93%.

***N*-Methyl-*N*-(phenylcarbamoyl)anthranilic Acid.** A 3.02 g (0.02 mol) portion of *N*-methylanthranilic acid (mp 186—187°C, recrystallized from aqueous ethanol) was dissolved in 100 m*l* of benzene at 60°C. To this solution was added 2.38 g (0.02 mol) of phenyl isocyanate (bp 46—47°C/7 mmHg) in 10 m*l* of benzene, and the mixture was refluxed at 80°C for 2.5 hr. After the mixture had been allowed to cool to room temperature, the precipitate was filtered, washed several times with distilled water, and dried. It was then recrystallized twice from ethyl acetate to obtain colorless needles in a 43% yield. Mp 252—253°C. It was identified to be *N*-methyl-*N*-(phenylcarbamoyl)anthranilic acid on the basis of infrared spectrum and elemental analysis.

The infrared spectrum (KBr) shows absorption bands at 3300 cm^{-1} (N–H), and 1650 cm^{-1} (ureido carbonyl). Ultraviolet spectrum: λ_{max}=210 mμ (ε, 29200), 257 mμ (ε, 33600). Found: C, 66.87; H, 5.35; N, 10.41%. Calcd for $C_{15}H_{14}O_3N_2$: C, 66.81; H, 5.08; N, 10.58%.

Methyl *N*-(Phenylcarbamoyl)anthranilate. To a solution of methyl anthranilate (5.0 g, 1/300 mol) in 30 m*l* of benzene was added phenyl isocyanate (4.0 g, 1/300 mol) dissolved in 20 m*l* of benzene. After stirring for 3 hr at 30°C, benzene was removed and the residue was recrystallized from ethanol: mp 138—139°C. Found: C, 66.65; H, 5.22; N, 10.32%. Calcd for $C_{15}H_{14}O_3N_2$: C, 66.81; H, 5.08; N, 10.58%.

Cyclization Reaction in *N*-Methylpyrrolidone. A solution of *N*-(phenylcarbamoyl)anthranilic acid or its derivatives (1/300 mol) in 20 m*l* of *N*-methylpyrrolidone was kept at 100°C for 3 hr with stirring. After removal of the solvent under reduced pressure, the residue was separated by fractional recrystallization from ethanol.

Cyclization Reaction in Nitrogen Gas. *N*-(Phenylcarbamoyl) anthranilic acid derivative (0.1 g) was introduced into a test tube in a nitrogen atmosphere. The test tube was sealed and placed in an oven and heated at 220°C for 2 hr. In every case, the product was identified to be 3-phenyl-2,4(1*H*,3*H*)-quinazolinedione (IV) from its IR spectrum and melting point (282°C).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1248—1249 (1970)

The Coupling Mode of Propargyl Undecynoate in a Cupric Acetate Monohydrate-Pyridine System

Ichiro WATANABE, Kunio KOGAMI, Shinichi ISAOKA and Ju KUMANOTANI

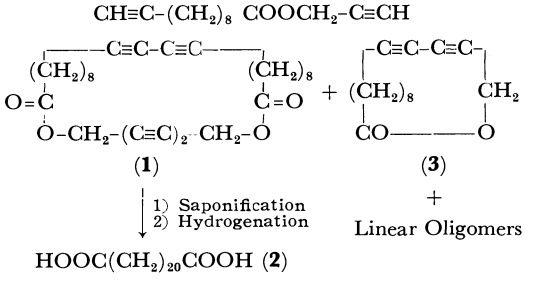
The Engineering Research Institute, The University of Tokyo, Yayoi-cho, Tokyo

(Received August 20, 1969)

It is well known that α,ω-diyne compounds are oxidatively coupled and that cyclic compounds containing α,γ-diyne units are formed in cupurous chloride-ammonia water[1] and cupric acetate-pyridine systems.[2]

However, the coupling mode of diyne esters into cyclic oligomers—whether diynes undergo the coupling in a head-to-head or in a tail-to-head manner—has not yet been established.

In the oxidative coupling reaction of propargyl undecynoate in a cupric acetate monohydrate-pyridine system,[3] we have found that, among the possible cyclic oligomers, the dimer results only from a head-to-head coupling reaction, and that linear oligomers are given in a head-to-tail coupling reaction. The structure of the dimer was identified according to the following scheme:



The yields of the dimer and monomer increased up to 20% (of the theoretical yield) with an increase in the dilution up to a pyridine : ester volume ratio of 200.

The linear oligomers were identified by the Ilosvay method[4] and they were derived into 14-hydroxy-tetradecanoic acid quantitatively.

The fact that the dimer (**1**) is formed in a head-to-head coupling manner, and not in a head-to-tail manner, can be explained by considering that, according to the Dale rule[5] concerning the conformational stability of macrocyclic compounds, the dimer (**1**), which has a strain-free conformation, can exist more stably than the other possible dimer, formed in a head-to-tail coupling manner.

The different formation modes of the cyclic dimer and the linear oligomer still remain to be elucidated.

Experimental*1

Propargyl Undecynoate. This was prepared by the esterification method of Black and Weedon[6]; bp 128—130°C/2 mmHg: d_{20}^{20} 0.9442; n_D^{20} 1.4624.

Oxidative Coupling of Propargyl Undecynoate. Into a mixture of cupric acetate monohydrate (30 g, 0.15 mol) and pyridine (1.4 *l*), a solution of the propargyl undecynoate (5 g, 0.023 mol) in 100 m*l* of pyridine was stirred, drop by drop, at 55—60°C over a 3-hr period. The reaction mixture was concentrated to *ca.* 300 m*l* at 55—60°C under a pressure of 20—30 mmHg and then cooled. Seven hundred m*l* of an aqueous solution of 15% hydrochloric acid previously cooled with ice were then added to the concentrated solution. The resulting solution was extracted with ether (100 m*l*×5). The ethereal solution was washed with 200 m*l* of an aqueous solution of 5% sodium carbonate and dried over Na_2SO_4. By the removal of the ether from the solution, an oily product (4.8 g) was obtained.

Separation of Products. The product showed three spots, with R_f values of 0.0, 0.47, and 0.77, by t.l.c. on a silica-gel layer (thickness, 0.25 mm) with a mixed

*1 The infrared (IR) spectra were obtained with a Nihon-Bunko IR-spectrometer, Model IR-S. The ultraviolet (UV) spectra were taken in ethanol with a Hitachi spectrometer, EPS-2. The nuclear magnetic resonance (NMR) spectra were determined in carbon tetrachloride and acetone at 60 Mc with a Nihon-Denshi. NMR spectrometer, JMN C-60. The chemical shifts are described in values relative to tetramethylsilane as the internal standard. The multiplicity of signals is indicated in abbreviated form; *s* for singlet, and *m* for multiplet. The molecular weight was measured in methyl ethyl ketone with a vapor-pressure osomometer, Model 301-A (Mechrolab, Inc.). The silica-gel layers used for the thin-layer chromatography(t.l.c.) were made from Silica Rider (silica-gel with 12—14% calcium sulfate, purchased from Daiichi Pure Chemicals) and were activated at 105°C for 1.5 hr.

solvent of *n*-hexane and ether (7 : 3 v/v).

A suspension of silica-gel (100—200 mesh, 250 g) in *n*-hexane was poured in a tube (2.4 cm in diameter and 1200 cm long). Then, a solution of the product (4.8 g) in *n*-hexane was passed through the column and subsequently eluted with *n*-hexane-ether (7 : 3 v/v, 1.5 *l*). The effluent was divided into 25 m*l*×60 fractions using an auto-fraction collector. The elution speed was 100 m*l* per hour. Products with R_f value of 0.77 and 0.47 appeared in the fractions of Nos. 20—25 and Nos. 36—40 respectively; each of them gave 0.95 or 0.99 g of a white solid after the evaporation of the solvent *in vacuo*. A product with an R_f value of 0.0 remained in the column. After the elution, the silica-gel column was extracted with ether and then with acetone in a Soxhlet apparatus. Thus, by the removal of the solvent from the extract, ether- and acetone-soluble portions were obtained in yields of 2.4 g and 0.3 g respectively.

Identification. In order to collect a sufficient amount of aliquot for analysis, the above-described procedures were repeated twice within the limits of experimental error.

Cyclic Compounds Dimer (1). The dimer crystals had a melting point of 94.5—95.5°C. The IR spectrum, ν_{max} (KBr); 2190, 2280(–C≡C–C≡C–), and 1745 (>C=O) cm^{-1}. The UV spectrum, λ_{max} (CH_3OH) mμ (ε): 214(1272), 222(868), 233(1047), 245(1058), 258 (628), 267(185), 284(115). The NMR spectrum, τ (CCl_4): 5.25 (s, –C≡C–C≡C–CH_2–O–), 7.65 (m, –CH_2–C–O), 8.51 (m, –CH_2–). The saponification value was 256.9 (Calcd 256.8). Found: C, 76.94; H, 8.26%. Calcd for $C_{28}H_{36}O_4$: C, 77.03; H, 8.31%. The dimer (**1**) (a 1-g portion of the dimer separated by column chromatography) was saponified with 10 m*l* of an ethanolic 0.5N potassium hydroxide solution. The resultant solution was acidified with an aqueous solution of 10% hydrochloric acid, and then extracted with ether (20 m*l*×5). The ethereal solution was dried over Na_2SO_4 and then evaporated to give white crystals (1.2 g) as a residue. The crystals were hydrogenated in ethyl acetate (50 m*l*) at room temperature over 5% Pd-on-charcoal (100 mg) to give docosanedioic acid (**2**) (mp 126°C; acid value, 302.8 (theoretical value 302.7)), the identity of which was confirmed by observing no depression of the melting point when it was mixed with an authentic sample prepared from methyl undecynoate by the McCrae method,[7] further, the crystals were examined by t.l.c. (thickness of silica-gel layer, 0.25 mm; developing solvent, a mixture of *n*-hexane, ether and acetic acid (50 : 40 : 1 v/v); the chromatogram, after being sprayed with an aqueous sulfuric acid solution (1 : 1), was heated at 150°C for 30 min); they exhibited only one spot with the R_f value of 0.42 of docosanedioic acid, and not the spot with the R_f value of 0.24 of 14-hydroxytetradecanoic acid.

Monomer (3). The lactone (**3**) (1.0 g, 0.0045 mol) was recrystallized twice from *n*-hexane (5 m*l*) to give white crystals (500 mg); mp 41°C. The IR spectrum, ν_{max} (KBr): 2140, 2240(–C≡C–C≡C–), and 1750 (>C=O) cm^{-1}; the UV spectrum, λ_{max} (CH_3OH) mμ (ε): 219(897), 232(684), 245(624), 258(659), 273(601): the NMR spectrum, τ(CCl_4): 5.25(s, –C≡C–C≡C–CH_2–O–), 7.65(m, –CH_2–C=O), 8.51(m, –CH_2–). The saponification value was 257.0 (Calcd 256.8). Found: C, 76.76: H, 8.36%. Calcd for $C_{14}H_{18}O_2$: C, 77.03; H, 8.31%.

The crystals (200 mg) were hydrogenated over a 5% Pd-on-charcoal catalyst (50 mg) in ethyl acetate (50 m*l*) to yield cyclo-tetradecanolide (mp 28°C), the identity of which was confirmed by comparison with the IR spectrum and gaschromatogram of an authentic, commercially-available sample.

Linear Oligomer. A solution of a 0.3-g portion of the combined ether and acetone-soluble fraction in 40 m*l* of a mixed solvent of acetone-ether was shaken with a solution of the Ilosvay reagent,[4] consisting of cuprous chloride (1 g), ammonium carbonate (5 g), 28% ammonia water (5 m*l*), and water (20 m*l*). The precipitates thus formed were filtered off. The evaporation of the oily layer separated from the filtrate gave no product, indicating no contamination of cyclic oligomers in the products.

Upon the t.l.c. of the product obtained by the hydrolysis, followed by hydrogenation over the Pd-on-charcoal of the linear oligomer, only one spot, with a R_f value of 0.24, appeared; we may thus conclude that the linear oligomer is formed by a coupling of the esters only in a head-to-tail manner.

Moreover, the ether-soluble portion (2.3 g) was saponified with 50 m*l* of an ethanolic 1N potassium hydroxide solution. The resulting solution was acidified with an aqueous solution of 10% hydrochloric acid, and then extracted with ether (20 m*l*×4). The product (2.3 g) obtained by the removal of the solvent from the ether solution dried over Na_2SO_4 was hydrogenated at 10 kg/cm^2 of hydrogen over Pd-on-charcoal; 14-hydroxytetradecanoic acid, mp 95°C, was thus obtained in a 95% yield.

The IR spectrum, ν_{max} (KBr): 3300(HC≡C–), 2280 and 2150(–C≡C–C≡C–) and 1745(>C=O) cm^{-1}. The NMR spectrum, τ(acetone): 5.05(s, –C≡C–C≡C–CH_2–O–), 7.65(m, –CH_2–C=O) and 8.65(m, –$(CH_2)_8$–).

These spectral data were in good agreement with those of the linear oligomer prepared by the Sondheimer method.[8]

Effects of Ditertiary Phosphine Ligands in Co-dimerization of Butadiene and Ethylene Catalyzed by Cobaltous Chloride —Ditertiary Phosphine— Triethylaluminum*1

Teruhiko KAGAWA, Yoshio INOUE and Harukichi HASHIMOTO

Department of Synthetic Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received September 8, 1969)

There are some reactions catalyzed by the transition metal catalyst in which the coordinated ligand plays an important role. This investigation has been carried out in order to find out the role of the ligand. The co-dimerization of butadiene and ethylene catalyzed by $CoCl_2$-ditertiary phosphine-$AlEt_3$[1a-e] was chosen for the study. Using ditertiary phosphine, $Ph_2P(CH_2)_nPPh_2$ ($n=1,2,3,4,5,10$) and $Ph_2P(CH_2)_mO(CH_2)_mPPh_2$ ($m=1,2$) as the ligand, the effects of the length of methylene chain between two phosphorus atoms and the ether bond have been investigated.

Experimental

Reagents. Toluene was purified by the usual method and distilled under an atmosphere of nitrogen. Triethylaluminum (Ethyl Corp., U.S.A.) was used without further purification. Butadiene was dried by passing through a column of anhydrous calcium chloride and condensed in a measuring vessel in a dry ice-methanol bath in order to measure its volume. Anhydrous cobaltous chloride and triphenylphosphine were obtained commercially. The preparation of ditertiary phosphines ($Ph_2P(CH_2)_nPPh_2$ and $Ph_2P(CH_2)_mO(CH_2)_mPPh_2$) were performed by the method described by Hewertson and Watson.[2] The purity was confirmed by elementary analysis and melting point. The cobalt complexes of ditertiary phosphine were obtained by the reaction of anhydrous cobaltous chloride with ditertiary phosphines in appropriate solvents, and used for experiments after recrystallization.[3]

Procedure. A 100 m*l* stainless steel autoclave equipped with a magnetic stirrer was charged with calculated amounts of cobalt complex, toluene, butadiene and triethylaluminum in this order under a nitrogen atmosphere. Temperature was then raised to 80—90°C, and ethylene was injected to a pressure of approximately 50 kg/cm² and the reaction was carried out with agitation under a constant ethylene pressure. After 2 or 3 hr, the autoclave was cooled to room temperature and the catalyst was quenched by adding a small amount of methanol. The reaction mixture was washed with water and dried with anhydrous sodium sulfate. The products were analyzed by gaschromatography.

Result snd Discussion

The co-dimerization products of butadiene and ethylene catalyzed by the cobalt catalyst are mainly 1,4-*cis*-hexadiene and a small amount of 1,3-hexadiene and 2,4-hexadiene. Among these products 2,4-hexadiene is formed by the isomerization of 1,4-hexadiene at higher temperature.[1f]

The effects of the length of methylene chain between two phosphorus atoms in the ditertiary phosphine are shown in Fig. 1. Complexes $CoCl_2$-($Ph_2P(CH_2)_nPPh_2$) ($n=3,4$) were found to show the most selective catalytic action for the formation of 1,4-*cis*-hexadiene. In the case of $n=1,5,10$,

the amount of 1,4-hexadiene decreased and that of 1,3-hexadiene increased and the products distribution became similar to that of $CoCl_2$-$AlEt_3$ catalyst. It seems that the above selectivity is partly due to the adequate stabilization of the active intermediate by the formation of six or seven membered chelate ring which consists of metal and ditertiary phosphine. However, the bulkiness of the ligand may also influence the selectivity of the products.

$CoCl_2$(DPE)*2 and $CoCl_2(DPE)_2$ had the same activity at a low concentration of triethylaluminum, but at the molar ratio of Al/Co=11, $CoCl_2$(DPE) lost the selectivity of 1,4-hexadiene as is given in Table 1. From a structural point of view, the complex $CoCl_2$(DPE) has a tetrahedral structure, and $CoCl_2(DPE)_2$ is considered to be five coordinated complex.[3a)] However, $CoCl_2$(DPP)*3 which has the same structure as $CoCl_2$(DPE)[3b)] was a good catalyst for 1,4-hexadiene formation in a wide range of the molar ratio of Al/Co.*4 It may be shown that the activity does not depend on the initial structure of the complex. The structure of reaction intermediates seems to be different. Further addition of DPE to $CoCl_2$DPE with molar ratio of DPE/$CoCl_2$(DPE)=1.0, did not change the yield of 1,4-hexadiene appreciably. When DPE was added to the $CoCl_2(DPE)_2$, the result was similar to that of $CoCl_2(DPE)_2$ alone. Thus the additional DPE may not disturb 1,4-hexadiene formation by occupying the active site of the metal

When $Ph_2P(CH_2)_mO(CH_2)_mPPh_2$ was used as a ligand, the selectivity of 1,4-hexadiene was small and the high boiling point products were produced. The product distribution depended on the reaction temperature; at lower temperatures 1,3-hexadiene and butadiene dimerization product *i. e.* 3-methyl-1,4,6-heptatriene were mainly formed, and at higher temperatures 1,4-hexadiene and 2,4-hexadiene. The catalyst $CoCl_2$DPMO*5 was active at 50°C. However, in the case of $CoCl_2$DPEO*6 the activity appeared over 120°C. If we compare the number of atoms between two phosphorus atoms of DPMO with that of DPP, the length of the ligand is of the same order, but the catalytic activity and the selectivity are extremely different. Thus the electronic effect of the oxygen atom in the ether bond can not be neglected.

Studies on Reactions of Isoprenoids. XI.[1] Stereochemistry of the Ritter Reaction Products of Camphene with Unsaturated Nitriles

Tadashi SASAKI, Shoji EGUCHI and Takeshi OYOBE

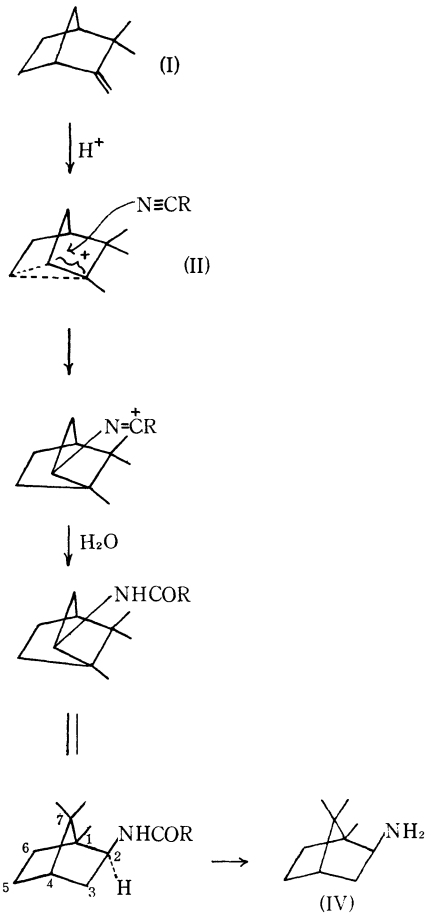
Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received September 24, 1969)

The Ritter reactions of camphene (I) with various nitriles except unsaturated nitriles have been studied mainly from the interest in the pharmacological activities of the products.[2] We have recently reported the Ritter reactions of I with cyanoacetylene and chlorocyanoacetylene as the first examples of the Ritter reactions with acetylenic nitriles.[3] However, the stereochemistry of the corresponding products was not described in detail. This note describes the structural elucidation of the Ritter reaction products of I with cyanoacetylene and chlorocyanoacetylene as well as that with acrylonitrile on the basis of their analytical, IR and NMR data in comparison with the NMR data of *N*-acetylisobornylamine (IIId),[2a] and of their hydrolysis produdts.

The Ritter reactions were carried out with the ratio, I : nitrile : sulfuric acid = 1 : 2 : 4. The yields of IIIa from I and cyanoacetylene, and IIIb from I and chlorocyanoacetylene were both improved to 41 and 61% as compared with the previous values 15 and 40%. The Ritter reaction of I with acrylonitrile proceeded similarly to afford an unsaturated amide (IIIc) in 49% yield. The yields, mps and analyses of these products are summarized in Table 1.

In the NMR spectra (Table 2) of these products (IIIa—c), a common characteristic double triplet signal for one proton appeared in the range τ 6.00—6.08. A similar pattern signal was also observed at τ 6.07 in the spectrum of IIId,[2a] suggesting that IIIa—c have the same configuration as IIId at C-2 position. Thus, the structures of IIIa—c were assigned as *N*-propioloylisobornylamine, *N*-chloropropioloylisobornylamine, and *N*-acryloylisobornylamine respectively. These assignments were supported by hydrolyses of IIIa—c to afford the same isobornylamine (IV) in the yields



(IIIa) R = -C≡CH
(IIIb) R = -C≡CCl
(IIIc) R = -CH=CH$_2$

* This signal was overlapped with the signals of vinyl protons.

46, 10,[4] and 50%, respectively. This was identified as a phenylurea derivative with an authentic specimen[5] by means of mixed melting point determination and IR spectral comparison.

From the results it was concluded that the Ritter reactions of I with unsaturated nitriles at *ca.* 30°C afford the corresponding unsaturated amide derivatives after the Wagner-Meerwein rearrangement of I as observed in these reactions with certain saturated nitriles, though this type of rearrangement is known to be dependent on the reaction temperature as well as on nitriles (Scheme 1).[2d]

Experimental[6]

General Procedure for the Ritter Reactions. A mixture of 0.01 mol of I and 0.02 mol of nitrile was added to an ice-cooled mixture of 0.04 mol of concentrated sulfuric acid (sp. gr., *ca.* 1.84) and 30 m*l* of glacial acetic acid with stirring. Stirring was continued for 20 hr at room temperature (*ca.* 30°C) and the mixture was poured onto ice-water (200 g). The product was taken in chloroform and recrystallized from *n*-hexane or *n*-hexane-dichloromethane to give the corresponding amide derivatives (see Table 1).

General Procedure for the Hydrolyses of IIIa—c. *Ca.* 0.2 g of IIIa (or IIIb, and or IIIc) was heated in a mixture of 10 m*l* of ethanol and 20 m*l* of 6N hydrochloric acid under refluxing for 2 days.[4] After removal of ethanol under reduced pressure, the reaction mixture was washed with ether (30 m*l*×3). The water layer was made alkaline with 10% aqueous solution of sodium hydroxide and extracted several times with ether (30 m*l*×5). The combined ether extracts were dried over

4) IIIb was very stable to acidic hydrolysis; only 10% conversion to IV was observed together with an 80% recovery of IIIb after refluxing for 10 days under the conditions given in Experimental.

5) L. S. Luskin, A. J. McFaul and G. E. Geutest, *J. Org. Chem.*, **21**, 1430 (1956).

6) All melting points were determined on a Yanagimoto micromelting point apparatus and are uncorrected. Microanalyses were carried out on a Yanagimoto C. H. N. Corder Model MT-1. The IR spectra were recorded on a JASCO Model IR-S IR spectrophotometer and NMR spectra were obtained with a Varian A-60 spectrometer at 60 MHz using TMS as an internal reference.

sodium sulfate and the solvent was removed under reeduced pressure to give clorless solids of IV which were directly treated with phenyl isocyanate in dry benzene (10 m*l*) to afford a phenylurea derivative of IV, mp 255.5—258°C (dec.) (from aqueous ethanol, lit,[5] mp 252—255°C (dec.)).

Studies on Heteroaromaticity. XXXVII.[1] 1,3-Dipolar Cycloaddition of a Nitrilimine Possessing a Nitrofuran Ring

Tadashi SASAKI and Toshiyuki YOSHIOKA

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received September 24, 1969)

In continuation of our previous reports concerning the 1,3-dipolar cycloaddition of nitril oxides,[2] nitrones,[3] and diazoalkanes[4] possessing a nitrofuran ring, this note deals with similar reactions of a nitrilimine also possessing a nitrofuran ring. Such a nitrilimine has not been reported yet.

Many procedures have been reported for the preparation of reactive nitrilimines.[5] Among them, the most probable access to nitrilimines is by the action of tertiary bases on hydrazidoyl halides as reported by Huisgen.[6] We treated 5-nitro-2-furoylhydrazide (I) with phosphorus pentachloride according to his procedure. However, the expected hydrazidoyl chloride (II) could not be isolated and intractable polymers were produced instead. Recently Gladstone[7] demonstrated the intermediate formation of nitrilimines in lead tetraacetate-oxidation of benzaldehyde arylhydrazones by the 1,3-dipolar cycloaddition to acrylonitrile.

We treated readily available 5-nitro-2-furfural phenylhydrazone (III) with lead tetraacetate in a tetrahydrofuran(THF)-benzene mixture in the presence of dipolarophilic acrylonitrile at room temperature. The crude product was purified on column chromatography to afford pale yellow crystals; the structure was assigned as 5-cyano-3-(5-nitro-2-furyl)-1-phenylpyrazole (IV) on the basis of analytical and spectral data. The structure was further confirmed by the treatment of III with cyanoacetylene under similar reaction conditions affording the same product IV. This indicates the initial formation of a pyrazoline (V) by the 1,3-dipolar cycloaddition of a nitrilimine (VI) to acrylonitrile followed by heteroaromatization[1] to afford IV. When acetic acid was used as the solvent in the above reactions, the yield was lowered to 10%. Attempts to isolate a sideproduced hydrazidic acetate were unsuccessful, though this type of compound is generally believed to be produced from nitrilimine and acetic acid.[6] Treatment with styrene instead of acrylonitrile in the above reactions afforded 3-(5-nitro-2-furyl)-1,5-diphenylpyrazole (VII), which could not be obtained, however, from phenylacetylene and III in the presence of lead tetraacetate; the reaction afforded intractable oils. Similar reactions with acrylic and methacrylic acid afforded 3-(5-nitro-2-furyl)-1-phenylpyrazole (VIII) and 5-methyl-3-(5-nitro-2-furyl)-1-phenylpyrazole (IX) respectively, in good yields. Their analytical and spectral data were compatible with the above structures. The results indicate that the above reactions involve decarboxylation of the initial 1 : 1 adducts (X) by radical mechanism of lead tetraacetate and its oxidative heteroaromatization.[1]

Contrary to this, when methyl acrylate, methacrylate and allyl bromide were used as dipolarophiles, deep-red colored products, XI, XII and XIII, respectively, were produced. Their analytical and spectral data supported their pyrazoline structures; especially in the UV spectra strong bathochromic shifts were observed in the pyrazoline derivatives compared with the corresponding pyrazole derivatives.

The direction of addition of nitrilimine VI in the formation of IV and VIII was concluded to be the same irrespective of the polarization of used dipolarophiles, and in good accordance with the results obtained from nitril oxides[2,8] and other

nitrilimines.[8] The same holds in the reactions with α,β-unsaturated acids, esters and olefins.

We reported the thermal 1,3-dipolar cycloaddition of aromatic hydroxamoyl chloride with indene and acenaphthylene affording the corresponding isoxazolidines.[9] Treatment of III with indene and acenaphthylene in the presence of lead tetraacetate at room temperature afforded indenopyrazole (XIV or XIV′) and acenaphthopyrazole (XV) after oxidative heteroaromatization of the expected pyrazolines. The pyrazole structure present in XIV or XIV′ and XV was demonstrated by their UV spectra and by the absence of C-4 and C-5 methine proton in the NMR spectra.[9] There are two possible structures for the indenopyrazole, either 3-(5-nitro-2-furyl)-1-phenylindeno[2,3-*d*]pyrazole (XIV) or its [3,2-*d*]pyrazole (XIV′). Assuming a similar trend in the direction of addition of nitrilimines to nitrile oxides,[9] we tentatively assigned XIV preferentially to XIV′.

However, no cycloaddition of VI to acetonitrile, benzonitrile, benzaldehyde and *m*-nitrobenzaldehyde was observed.

Experimental[10]

5-Cyano-3-(5-nitro-2-furyl)-1-phenylpyrazole (IV). *From Acrylonitrile.* To a solution of 1 g (4.5 mmol) of 5-nitrofurfural phenylhydrazone III[11] and 1.1 g (25 mmol) of acrylonitrile in 60 m*l* of a THF-benzene (1 : 5) mixture was added 4 g (9 mmol) of lead tetraacetate at room temperature with stirring. The reaction mixture was further stirred at room temperature for 3 days. After filtering off undissolved parts, the solvents were removed under reduced pressure. The residual crude product was purified on a silica-gel (Mallinckrodt, 100 mesh) column using chloroform as the eluent to afford 0.58 g (55%) of pale yellow crystals IV, mp 165—167°C (from ethanol). IR (KBr) cm^{-1}: 2260 (CN). UV λ_{max}^{EtOH} mμ (ε): 290 (shoulder, 8650) and 344 (18400). NMR ($CDCl_3$) τ: 2.59 (s, C-4-H of pyrazole ring).[12]

Found: C, 60.03; H, 2.53; N, 19.63%. Calcd for $C_{11}H_8N_4O_3$: C, 60.00; H, 2.88; N, 19.99%.

From Cyanoacetylene. Similar treatment of 1.6 g (25 mmol) of cyanoacetylene[13] instead of 1.1 g (25 mmol) of acrylonitrile in the above reaction afforded 0.57 g (55%) of IV.

3-(5-Nitro-2-furyl)-1,5-diphenylpyrazole (VII). Similar treatment of 2.0 g (25 mmol) of styrene instead of 1.1 g of acrylonitrile afforded 0.33 g (20%) of pale yellow crystals VII, mp 155—157°C (ethanol). UV λ_{max}^{EtOH} mμ (ε): 236(23600) and 358(18400). NMR ($CDCl_3$) τ: 3.01 (s, C-4-H of pyrazole ring).[12] Found: C, 69.19; H, 3.59; N, 12.67%. Calcd for $C_{19}H_{13}N_3O_3$: C, 68.87; H, 3.96; N, 12.68%.

3-(5-Nitro-2-furyl)-1-phenylpyrazole (VIII). Acrylic acid (2.0 g, 27 mmol) was dissolved in a mixture of 20 m*l* of THF and 30 m*l* of benzene. To this solution was added 1.0 g (4.5 mmol) of III and then a solution of 3.1 g (8.5 mmol) of lead tetraacetate in 30 m*l* of benzene with stirring at room temperature. Work up as above afforded 0.65 g (90%) of pale yellow crystals VIII, mp 124—126°C (ethanol). UV λ_{max}^{EtOH} mμ (ε): 264(13200) and 364(20600). NMR ($CDCl_3$) τ: 2.13 (d, 1H, J=3.0 Hz, C-5-H of pyrazole ring) and 3.20 (d, 1H, J=3.0 Hz, C-4-H of pyrazole ring).[12]

Found: C, 60.99; H, 3.41; N, 16.48%. Calcd for $C_{13}H_9N_3O_3$: C, 61.17; H, 3.55; N, 16.47%.

5-Methyl-3-(5-nitro-2-furyl)-1-phenylpyrazole. (IX). Similar treatment of 0.8 g of III, 1.5 g of methacrylic acid and 3.2 g of lead tetraacetate in 15 m*l* of THF and 60 m*l* of benzene afforded 0.62 g (88%) of pale yellow crystals IX, mp 121—123°C (ethanol). UV λ_{max}^{EtOH} mμ (ε): 252(17400) and 358(18200). NMR ($CDCl_3$) τ: 3.46 (s, C-4-H of pyrazole ring) and 7.65 (s, C–CH_3).

Found: C, 62.25; H, 3.99; N, 15.48%. Calcd for $C_{14}H_{11}N_3O_3$: C, 62.45; H, 4.12; N, 15.61%.

5-Methoxycarbonyl-3-(5-nitro-2-furyl)-1-phenyl-2-pyrazoline (XI). When 2 g of methyl acrylate was used instead of methacrylic acid in the above reaction, 40% yield of deep red colored crystals XI, mp 138—140°C (ethanol) was obtained. UV λ_{max}^{EtOH} mμ (ε): 245 (8700), 296(11700) and 452(19500). NMR ($CDCl_3$) τ: 5.18 (double d, J=8.0 and 10.0 Hz, C-5-H of pyrazoline ring),[14] 6.30 (s, $-COOCH_3$) and 6.45 (m, $-CH_2-$).[14]

Found: C, 57.51; H, 4.15; N, 13.28%. Calcd for $C_{15}H_{13}N_3O_5$: C, 57.14; H, 4.16; N, 13.33%.

5-Methyl-5-methoxycarbonyl-3-(5-nitro-2-furyl)-1-phenyl-2-pyrazoline (XII). Deep red colored crystals, mp 165—167°C (ethanol). Yield was 50%. UV λ_{max}^{EtOH} mμ (ε): 304(10000) and 450(19500). NMR ($CDCl_3$) τ: 6.35 (s, $-CH_2-$), 6.38 (s, $-COOCH_3$) and 8.18 (s, C-5-CH_3 of pyrazoline ring).[14]

Found: C, 58.23; H, 4.64; N, 12.70%. Calcd for $C_{16}H_{15}N_3O_5$: C, 58.35; H, 4.59; N, 12.76%.

5-Bromomethyl-3-(5-nitro-2-furyl)-1-phenyl-2-pyrazoline (XIII). Deep red colored crystals, mp 121—122°C (ethanol). Yield: 60%. UV λ_{max}^{EtOH} mμ (ε): 250(8800), 300(10800) and 460(20000). NMR ($CDCl_3$) τ: 5.15 (m, C-5-H of pyrazoline ring)[14] and 6.5 (m, $-CH_2-$ of pyrazoline ring and CH_2Br).

Found: C, 47.69; H, 3.12; N, 11.64%. Calcd for $C_{14}H_{12}N_3O_3Br$: C, 48.01; H, 3.45; N, 12.00%.

3-(5-Nitro-2-furyl)-1-phenyl-indeno[2,3-d]pyrazole (XIV). Pale yellow crystals, mp 238—240°C (ethanol). Yield: 15%. UV λ_{max}^{EtOH} mμ (ε): 270(23000) and 365 (21000). NMR (DMSO-d_6) τ: no signal due to methine

9) T. Sasaki, T. Yoshioka and Y. Suzuki, *Yuki Gosei Kagaku Kyokai Shi*, **27**, 998 (1969).

10) Melting points are uncorrected. Microanalyses were carried out with a Yanagimoto C.H.N. Corder MT-1 type. The ultraviolet absorption spectra (UV) were recorded on a Nippon Bunko optical rotary dispersion recorder, Model ORD/UV-5. The infrared spectra (IR) were obtained with a Nippon Bunko IR-S spectrophotometer. The NMR spectra were determined with a Varian A-60 spectrometer, using tetramethylsilane as the internal standard. The chemical shifts are recorded in τ-values.

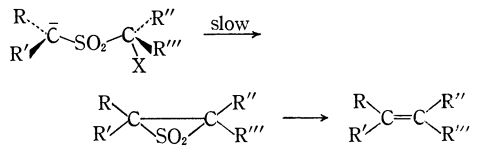
The Reaction of α,α-Dichlorobenzyl Methyl Sulfone with Phenyllithium

Seiichi ASADA and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita-shi, Osaka

(Received September 24, 1969)

Few studies have been published on the intramolecular nucleophilic substitution of 1-halosulfones. Ramberg and Bäcklund[1] reported on how they formed *cis*-2-butene by reacting 1-bromoethyl ethyl sulfone with potassium hydroxide. Recently, Bordwell and Cooper[2] have elucidated the reaction mechanism as the formation of an episulfone, followed by decomposition to yield an olefin. It is worth noting here the predominant formation of *cis*-olefin:[3]



A similar reaction of 1,1-dihalosulfone with a base has been reported to yield an acetylenic compound and an olefinsulfonic acid, suggesting the

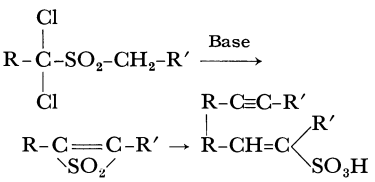
formation of thiirene dioxide as the intermediate:[4,5]



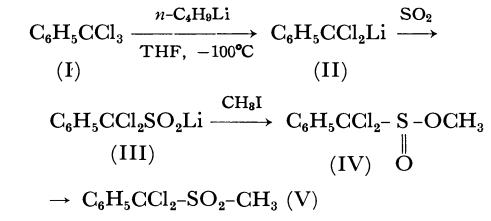
(2)

In the present communication, the results of the reaction of α,α-dichlorobenzyl methyl sulfone with phenylithium in tetrahydrofuran will be reported.

Results and Discussion

α,α-Dichlorobenzyl methyl sulfone (V) has been prepared from benzotrichloride (I). I was treated with *n*-butyllithium in tetrahydrofuran at −100°C to obtain a lithium compound (II). The insertion of sulfur dioxide into II has been found to be very easy, as is the carbon dioxide insertion into a similar compound,[6] which yields the α,α-dichlorobenzylsulfonyl lithium (III).

The reaction of III with methyl iodide resulted in the formation of α,α-dichlorobenzyl methyl sulfone (V) through the rearrangement of IV:



(3)

The reaction of the sulfone (V) with phenyllithium has been carried out in diethyl ether at 0°C for 3.5 hr. The products were then separated by alumina column chromatography. Several of the water-soluble products were treated with methyl iodide to convert the lithium salt to the methyl sulfone, and the products were eluted through a silica column in order to separate the methyl sulfones. The identified substances are listed in Table 1.

The following chart will account for the reaction paths for the various products from dichlorobenzyl methyl sulfone (V). (Chart 1).

The formation of *cis*- and *trans*-stilbenes (VI and VII), and the predominance of the *trans* compound over the *cis*, can be well reconciled with the fact that the addition of phenyllithium to 1-chloro-1-phenyl episulfone was followed by the elimination of sulfur dioxide. 1,1-Diphenyl episulfone was not found in the product. The difficulty of adding phenyl to the 1-position can be adequately explained by the steric reason and by the chlorine-lithium interaction.

The cleavage of 1-chloro-1-phenyl episulfone by phenyllithium leads to 1-chloro-1,2-diphenylethylsulfonyllithium, which then gives compound VIII by OLi-phenyl exchange and compound IX by the reaction with methyl iodide.

Experimental

α,α-Dichlorobenzyl Methyl Sulfone (V). To a solution of 58.7 g (0.3 mol) of benzotrichloride (I) in 600 m*l* of dehydrated tetrahydrofuran cooled at −100°C, freshly-prepared *n*-butyllithium (0.3 mol) in 150 m*l* of ether was slowly added under a nitrogen atmosphere for one hour, after which the mixture was stirred further at the same temperature for an additional half hour.

Sulfur dioxide (20 g) gas was streamed into the mixture at −100°C for 30 min, and then the solution was stirred for an additional hour and 50 m*l* of methyl iodide were added. The mixture was then slowly warmed and refluxed for fourteen hours.

After the mixture had been condensed to 1/3 its volume, water was added to the mixture and then it was extracted with ether. The ethereal solution was dried with sodium sulfate, condensed, and treated with 50 m*l* of petroleum ether to yield white crystals, which were then filtered and washed with chilled ether. Yield, 11.6 g (16.2%); mp 134.5—135.0°C. ν_{max}^{Nujol} 1155 and 1335 cm^{-1} (SO_2); 635 cm^{-1} (C–Cl). $\tau_{TMS}^{CCl_4}$, 6.80 (3H simple peak, SO_2CH_3), 2.4—2.7 (5H multiplet, phenyl).

Found: C, 39.96; H, 3.52%. Calcd for $C_8H_8Cl_2O_2S$: C, 40.18; H, 3.37%.

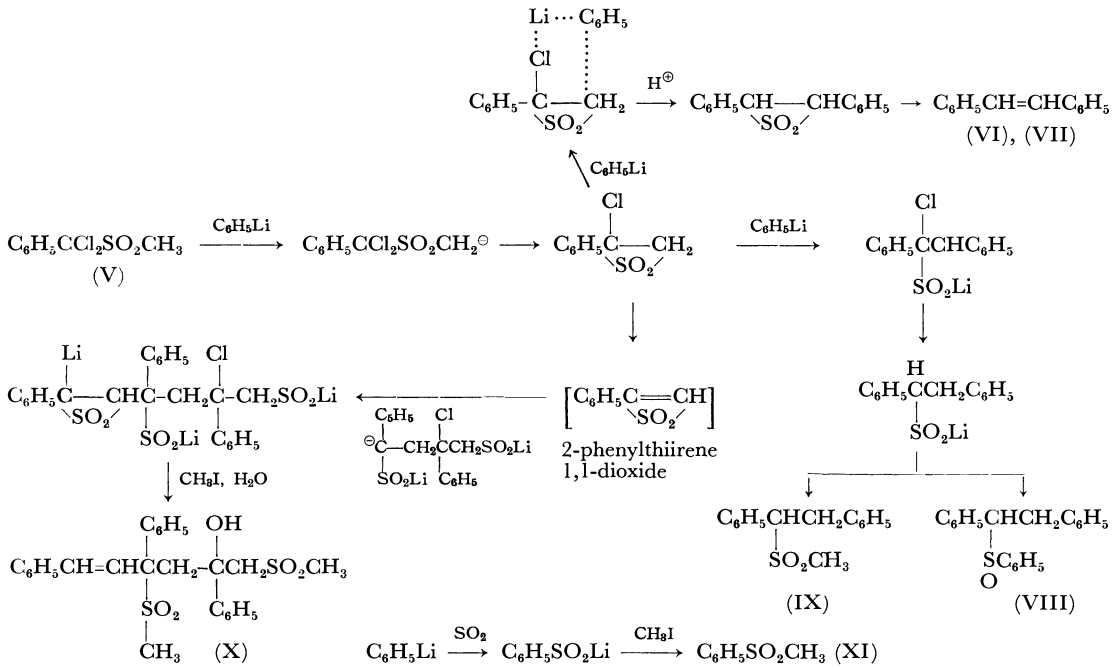

Chart 1

a capacity of 500 m*l*, 0.03 mol of phenyllithium in 70 m*l* of ether was cooled at 0°C; the mixture was stirred and then 2.0 g of α,α-dichlorobenzyl methyl sulfone dissolved in 250 m*l* of ether were added over a 1.5-hr period under a nitrogen atmosphere, with the temperature of the mixture kept at 0°C. The mixture was then stirred for an additional 3.5 hr at the same temperature.

After the reaction was over, the mixture was poured into ice water and the whole mixture was extracted with ether; the ether solution was then dried with sodium sulfate and condensed. The condensate was dissolved in petroleum ether and separated chromatographically using an alumina column. The solvents used as the eluants were in the following order: petroleum ether-benzene-ether-methanol. The aqueous layer was refluxed with 6.0 g of methyl iodide for 15 hr. The reaction mixture was then extracted with ether, and the extract was dried with sodium sulfate and evaporated. The residue was dissolved in benzene and eluted on a silica column.

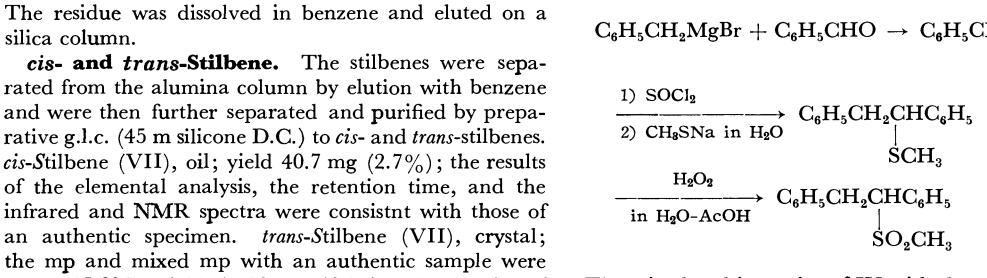
***cis*- and *trans*-Stilbene.** The stilbenes were separated from the alumina column by elution with benzene and were then further separated and purified by preparative g.l.c. (45 m silicone D.C.) to *cis*- and *trans*-stilbenes. *cis*-Stilbene (VII), oil; yield 40.7 mg (2.7%); the results of the elemental analysis, the retention time, and the infrared and NMR spectra were consistnt with those of an authentic specimen. *trans*-Stilbene (VII), crystal; the mp and mixed mp with an authentic sample were 214—125.0°C; yield 11.28 mg (6.2%); the results of the elemental analysis, the retention time, and the IR and NMR spectra all supported the above identification.

1,2-Diphenylethyl Phenyl Sulfoxide (VIII). Elution by methanol gave the sulfoxide (VIII); yield, 122 mg (4.7%); mp 126.0—126.5°C. ν_{max}^{Nujol} 1050 cm^{-1} (SO), $\tau_{max}^{CCl_4}$, 2.5—3.4 (15H multiplet), 5.9—7.0 (3H ABC type multiplet). Found: C, 77.92; H, 5.75%. Calcd for $C_{20}H_{18}OS$: C, 78.39; H, 5.92%.

1,2-Diphenylethyl Methyl Sulfone (IX). An aqueous layer refluxed with methyl iodide was extracted with ether and then separated on a silica column. The fraction eluted with an ether-benzene mixture gave 1,2-diphenylethyl methyl sulfone (IX); yield 269 mg (12.2%); mp 124.5—125°C (from ethanol). ν_{max}^{KBr}, 1295 and 1130 cm^{-1} (SO_2). Mass., parent peak, 260 *m/e*, (Calcd 260). $\tau_{TMS}^{CDCl_3}$, 7.39 (3H, singlet, SO_2-$C\underline{H}_3$), 6.72 (1H quartet), 6.18 (1H quartet, C_6H_5-$C\underline{H}_A\underline{H}_B$), 5.72 (1H quartet, CH_2 - $C\underline{H}_X$), J_{BA}=13.8 Hz, J_{AX}=3.9 Hz, J_{AX}=10.6 Hz.

Found: C, 69.22; H, 6.24%. Calcd for $C_{15}H_{16}O_2S$: C, 69.21; H, 6.20%.

An authentic sample was prepared from benzylmagnesium bromide and benzaldehyde by the following route:



The mixed melting point of IX with the above specimen was not depressed: 124.5—125.0°C.

Disulfone (X). A fraction obtained from the silica column above mentioned (ether-benzene eluant) was condensed. Recrystallization of the residual substance from ethanol gave crystals of X; mp 182.0—182.5°C; yield 114 mg (8.3%). ν_{max}^{Nujol} 1290 and 1110 cm^{-1},

(=SO_2), 1645 cm^{-1}, (olefin). Mol. Wt. 480 (vapor) pressure osmometry) (calcd 484.5).

Found: C, 64.58; H, 5.97%. Calcd for $C_{26}H_{28}O_5S_2$: C, 64.43; H, 5.82%. $\tau_{max}^{CCl_4}$, 7.32 (3H singlet, SO_2CH_3), 7.41 (3H SO_2CH_3), 8.24 (1H singlet, OH), 5.80—7.00 (4H octet, $=CH_2$), 4.60 (1H doublet), 3.88 (1H doublet), 2.10—3.50 (15H multiplet).

Phenyl Methyl Sulfone (XI). This substance was obtained from a fraction eluted by benzene on the silica column; after the evaporation of the solvent this substance gave crystals. Yield, 251 mg (24.6%); mp 88.0—89.0°C (from ethanol); mixed mp with an authentic specimen, 88.0—89.0°C; Mass. parent peak, 156 *m/e*, (calcd 156). ν_{max}^{Nujol}, 1295 and 1150 cm^{-1}, (=SO_2). $\tau_{max}^{CCl_4}$, 6.92 (3H singlet, SO_2CH_3), 1.85—2.50 (5H multiplet, phenyl protons).

Molecular Orientation and Absorption Spectra of Quaterrylene Evaporated Film

Yusei MARUYAMA, Tohru IWAKI,*1 Takashi KAJIWARA, Ichimin SHIROTANI and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received October 4, 1969)

When, in 1963, experimental studies of the electrical and optical properties of quaterrylene evaporated films were carried out, interesting results were obtained.[1] In the optical absorption spectrum of the evaporated film, the large absorption peak in about the 540 mμ region, as is shown in Fig. 1, seems to be an anomalous one with respect to its position and absorbance in comparison with the spectrum of the crystalline state and also with the solution spectrum. It seems to be true that this peak appears only in the spectrum of the evaporated film, but not in that of the single crystal.

Therefore, the relation between the molecular orientation and the absorption spectra must be persued in order to analyze the structure of thin organic film.[2] The orientation of the molecules in the film was observed by the X-ray diffraction method, and its change was examined as a function of the deposited temperature, which was controlled by heating a glass plate substrate during the evaporation. The temperature dependence and pressure dependence of this absorption spectral peak were also measured.

Experimental

Quaterrylene evaporated films were prepared by the following method.[3] During the evaporation, the substrate was heated by a proper heater and a temperature gradient was set up along the substrate surface; the substrate temperature thus changed from 90°C to 300°C. The X-ray diffraction patterns and the optical absorption spectra of each part were observed. The structure of the highest-temperature part of the film was rather crystallized, and microcrystallites were deposited on the film. The absorption spectra produced by polarized light to the proper axis of the single crystal were measured by microscope-spectroscopy employing the micro-crystal thus obtained.

In order to ascertain the origin of the optical absorption bands, especially that of the 540 mμ band, of the evaporated film, the temperature dependence and pressure dependence of the optical absorption bands were observed. The former, the temperature dependence of the absorption bands, was observed down to 4.2°K using a liquid helium cryostat, while the latter, the pressure dependence, was measured up to 6.6 kbar using a high-pressure optical cell.[4]

Results and Discussion

Figure 1 shows the absorption spectra of quaterrylene evaporated film, of its trichlorobenzene solution, and of the single crystal. The last is a polarized spectrum of a typical crystal axis. The absorption peaks in the 550—700 mμ region observed in the trichlorobenzene solution spectrum may be due to the lowest singlet excitation of the quaterrylene molecule. The 710 mμ and 780 mμ peaks in the film spectrum may correspond to an exciton band arising from this lowest molecular excitation. They are shifted in the direction of wavelengths longer than those of the solution spectrum because of intermolecular interaction in the solid state. These peaks also appear in the single crystal spectrum.

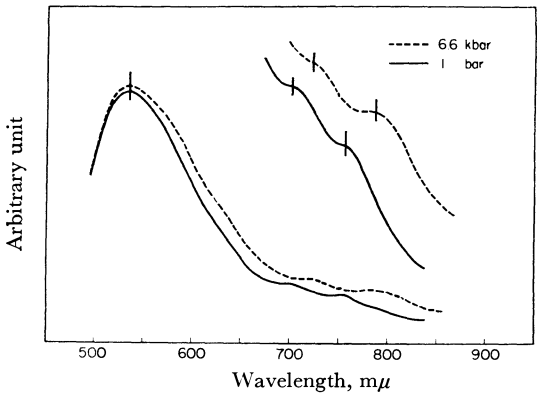

Fig. 2. The pressure induced red-shift of absorption spectral bands of quaterrylene.

This assignment is also supported by the fact that the pressure-induced red shift of these bands is about $-69\ cm^{-1}/kb$, as is illustrated in Fig. 2; this is a reasonable value for an exciton band.[5] These bands became rather sharper when the film was cooled to 4.2°K. This fact also suggests their exciton nature.

However, the 540-mμ band, found in the film spectrum, showed almost no change in its position and sharpness when it was cooled to 4.2°K or pressed to 6.6 kbar. This behavior is the most peculiar aspect of the band.

The relation between the spectra of the film and of the crystal was also strange, as is shown in Fig. 1. The effect of the molecular orientation on the absorption spectrum was studied next. The high temperature (~300°C)*2 part (1) appeared to be crystallized and micro-crystallites were deposited on the thin film. Part (2) (~150°C)*2 was bluish grey, Part (3) (~100°C)*2 was green, and the part (4) (room temperature),*2 violet.

Figure 3 shows the absorption spectra for the film specimens prepared at different substrate temperatures. The 540 mμ band in the spectrum deposited at room temperature seems to split to ~490 and ~630—680 mμ bands in the high-temperature specimens. The spectra of the (1)—(2)*3 and (2)—(3)*3 parts described above are rather similar to that of the single crystal (see Fig. 1).

The X-ray diffraction patterns of these different specimens deposited at various temperatures are shown in Fig. 4. The main diffraction lines of the high-temperature-part specimen (1) correspond to those from the (00n) planes, that is, the ab plane: The quaterrylene molecules are well oriented in

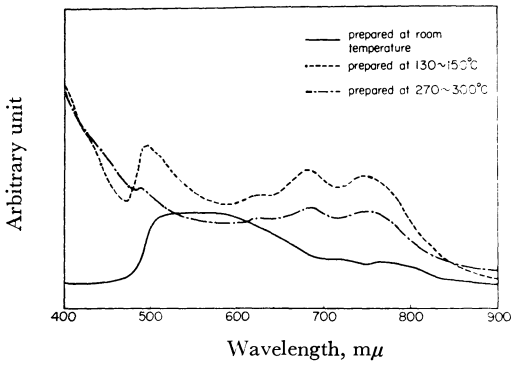

Fig. 3. The absorption spectral response curve of quaterrylene as a function of deposited temperature.

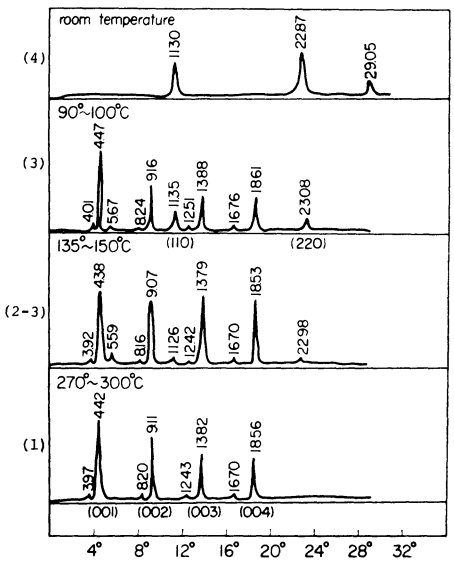

Fig. 4. The X-ray diffraction patterns of quaterrylene films deposited at various temperature: (1) is 270—300°C, (2—3) 135—150°C, (3) 90—100°C and (4) is room temperature.

5) I. Shirotani, H. Inokuchi and S. Akimoto, *ibid.*, **40**, 2277 (1967).

*2 The temperatures given in parentheses illustrate the substrate temperature.

*3 The (1)—(2) spectrum corresponds to the —·— line in Fig. 3, and (2)—(3), to the ------ line of Fig. 3.

this region.[2] In the patterns of (2)—(3) and (3), several diffraction lines other than (00n) appear. Among them, 11.30°, 22.87°, and 29.05° lines survive and grow in the region (4), as is the case with the substrate at room temperature.

The last three lines in (4) are not so sharp and large as the (00n) lines of (1) or (2)—(3), and no reasonable assignment of the crystal plane indices seems feasible. The possibility of crystal polymorphy cannot be perfectly denied, but the three lines in (4) may be, rather, due to an amorphous state judging from the appearance of these lines; that is, there is less sharpness and more weakness. Therefore, we assume that the existence of the 540 mμ band of the quaterrylene film is due to the plane ordering which is observable in the case of amorphous carbon.

The Copper(II) Complexes Distorted from a Planar Configuration

Takahiko INAZU and Takako INAZU

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received October 11, 1969)

In the course of studies of the effects of bulky groups on the formation of dimeric copper(II) complexes with bridged alkoxy groups,[1] copper(II) complexes distorted from a planar configuration were synthesized.

With few exceptions, all X-ray analyses of the four coordinate copper(II) complexes have shown them to have a square planar arrangement of the donor atoms about the metal atom. We do not know of a purely tetrahedral copper(II) complex, but some distorted tetrahedral copper(II) complexes of Schiff bases from the substituted salicylaldehydes and the branched alkyl amines have been synthesized by Yamada and Nishikawa[2] and by Sacconi and Ciampolini.[3]

We synthesized the copper(II) complexes, I, II, and III, in which the bulky cyclohexyl or *t*-butyl groups are introduced not only in the amine component but also in the aldehyde portion. In these complexes, there must exist steric interactions between the bulky cyclohexyl or *t*-butyl group on the 3-position of the aldehyde portion and the bulky *t*-butyl group in the amine component. Two copper(II) complexes, I and III,[4] in chloroform showed a ligand-field band at 12200 cm^{-1}, while the complex II showed one at 12650 cm^{-1}. The square-planar copper(II) complexes of the Cu-$(N)_2(O)_2$ type show absorption in the 17700 cm^{-1}

	R	R′

2) S. Yamada and H. Nishikawa, *ibid.*, **36**, 755 (1963).

3) L. Sacconi and M. Ciampolini, *J. Chem. Soc.*, **1964**, 276.

4) The complex, III, was not isolated in a pure crystalline state.

region,[5] and it is known that a ligand-field band shifts to a lower-wave-number region as distortion from a planar configuration increases.[2] Bis(*N*-*t*-butylsalicylideneiminato)copper(II), IV, which was considered to have a distorted tetrahedral configuration,[6] shows absorption in the 13000 cm^{-1} region.[2]

From these facts, the copper(II) complexes obtained here can be though to have a configuration much more distorted from the square-plane than the complex IV.

Experimental

The melting point is uncorrected. The visible and near-infrared spectra in a chloroform solution were measured on a Hitachi EPS-3T spectrophotometer.

***N*-*t*-Butyl-3-*t*-butyl-5-nitrosalicylideneimine.** To 500 mg of 3-*t*-butylsalicylaldehyde[1] in 1 m*l* of acetic acid, we added 0.5 m*l* of nitric acid (sp gr 1.38) at room temperature. After standing for a few minutes, the mixture was poured into water. To the yellow crystals thus obtained we added excess *t*-butylamine in methanol and refluxed the mixture for a few minutes. The yellow crystals thus obtained were recrystallized from methanol. Yield, 180 mg, mp 150—151°C.

Intermolecular Interaction in Mixed Monolayers of *isotactic* and *syndiotactic* Poly(Methyl Methacrylate) at the Air-Water Interface

Akira TAKAHASHI, Shinji OHWAKI and Ikumi KAGAWA

Department of Applied Chemistry, Nagoya University, Chikusa-ku, Nagoya

(Received November 1, 1969)

Attention has recently been focussed on stereochemical interaction between *isotactic* and *syndiotactic* poly(methyl methacrylate)(PMMA). Various experimental methods have been utilized to clarify the nature of interaction. Beredjick *et al.*,[1,2] were the first not only to show that the film balance technique can differentiate two stereoisomers of PMMA but also that the pressure-area isotherm of 1 : 1 mixture of *synd*- and *iso*- PMMA was closer to that of stereoblock PMMA, thereby indicating strong cohesion between two isomers at the air-water interface. Watanabe *et al.*,[3] found that the mixing of dilute dimethylformamide solutions of two isomers resulted in instantaneous gelation. Liquori *et al.*,[4] reported that stereocomplex is formed between two isomers from their dimethylformamide solution, and the stoichiometry of the complex was 2/1 for the ratio of *synd*/*iso*. They proposed a structure of the complex in which extended *synd*-PMMA molecules are fitted between the grooves of 5_2 helix of *iso*-PMMA. Subsequent studies[5,6] also concluded the 2/1 complex formation. However, Chiang *et al.*,[7] concluded that the stoichio-

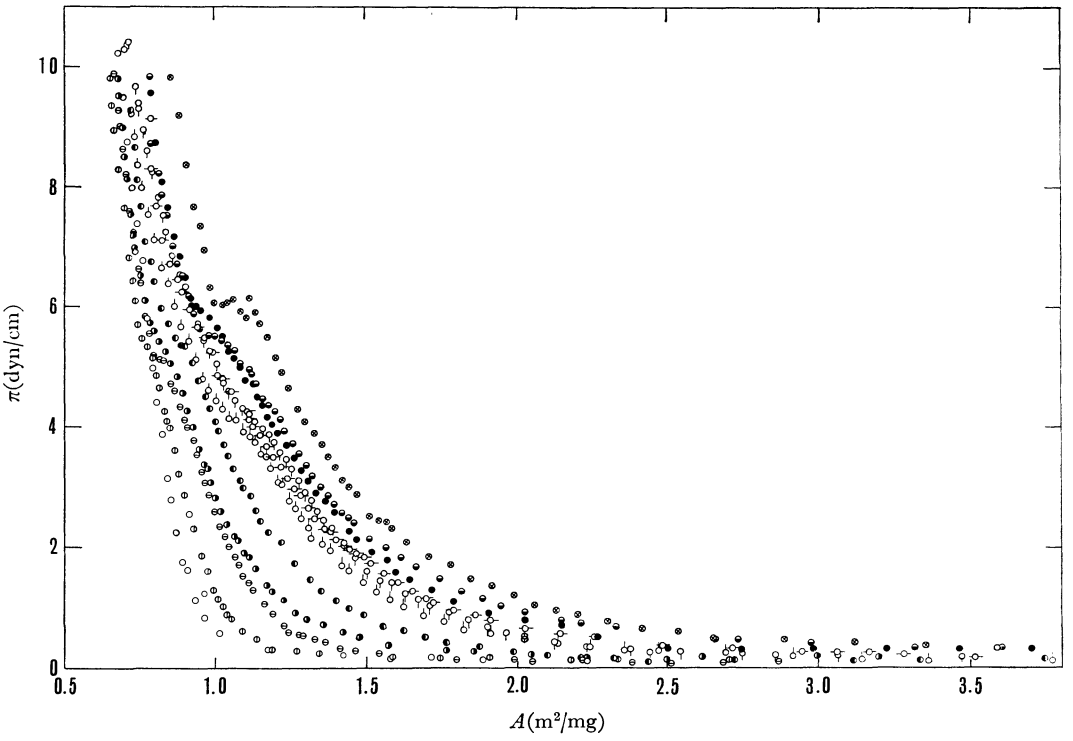

Fig. 1. Pressure-area isotherms for mixtures of *isotactic* and *syndiotactic* poly (methyl methacrylate) at the air-water interface at 25°C.
The ratio of *synd/iso*: ⊗ 0/1; ◒ 0.104/0.896; ● 0.178/0.822;-◯-0.286/0.714; ♀ 0.418/0.582; ♂ 0.468/0.532; ◐ 0.571/0.429; ◑ 0.717/0.289; ⊖ 0.783/0.217; ⓘ 0.915/0.085; ○ 1/0

metric ratio of *synd/iso* in the comlex formation was not as critical as reported by Liquori. Recently, Dayantis *et al.*,[8] determined an equilibrium curve of the concentration of the complex for each composition of *iso*- and *synd*-PMMA mixture in dimethylformamide-benzene solution. The curve has the maximum at the ratio 2/1 of *synd/iso*.

The measurement of the free energy of complex formation has not yet been reported, since its determination in bulk is cumbersome. In order to investigate the nature of interaction, we have carried out the measurements of pressure-area isotherms of mixtures of two stereoisomers of PMMA as a function of the ratio of *synd/iso*, and determined the molar excess free energy of mixing of monolayers of two stereoisomers at the air-water interface.

Experimental

Materials. The *isotactic* form was prepared by anionic polymerization, and purified by precipitation from a benzene solution into *n*-hexane and by freeze-drying from benzene. The *syndiotactic* form was synthesized by γ-irradiated polymerization at −70°C. Purification and drying were carried out in the same way as in the case of *isotactic* form. Viscosity average molecular weights were 1×10^6 for the *iso*-PMMA and 1×10^5 for the *synd*-PMMA, respectively. Tacticities were determined according to the NMR method of Bovey and Tiers.[9] The tacticity of *iso*-PMMA was *iso*=83.3%, *hetero*=8.2% and *synd*=10.5%; that of *synd*-PMMA was *iso*=0%, *hetero*=13.8% and *synd*=86.2%.

Film Balance. Teflon trough (20 cm × 120 cm) was used and surface pressures were measured at 25°C by a film balance similar in design to that of Inokuchi.[10] The spreading solvent was three times distilled benzene, and the substrate was three times distilled water. Benzene solutions of specified mixtures of two isomers were spread from an Agla microsyringe.

Results and Discussion

Pressure-area isotherms for specified mixtures are shown in Fig. 1. In the low pressure region, reproducibility was excellent. The isotherms obtained for both *iso*-PMMA and *synd*-PMMA are quite similar to that reported by Bereddjick *et al.*,[1,2] the *iso*-PMMA is more expanded, while the *synd*-PMMA is clearly condensed. The isotherm of *iso*-PMMA has distinct segments, and has a transition point at 6 dyn/cm; the extra-

10) K. Inokuchi, This Bulletin, **26**, 471 (1953).

polated area is 18 and 15.5 Å²/monomer unit, respectively. The transition point at 6 dyn/cm could be attributed to conformational transformation involving 5_2 helices from extended form.[1] The monolayer of *synd*-PMMA is more tightly packed than that of *iso*-PMMA. The extrapolated area is 14 Å²/monomer unit.

Below surface pressure, $\pi=6$ dyn/cm, the isotherms for all mixtures fall in the region limited by that of two isomers, however, above $\pi=6$ dyn/cm, the isotherms shift to lower area with the increase of the composition of *synd*-PMMA. In particular, when the ratio of *synd/iso* exceeds 2/1, the isotherms lie on the left hand side as compared to that of *synd*-PMMA alone.

The molar excess free energy of mixing, $\Delta G^{\pi}_{xs,m}$, of two pure monolayers to forms as mixed monolayer at constant temperature and surface pressure was derived by Goodrich[11] and Gaines[12] and is given by

$$\Delta G^{\pi}_{xs,m} = \Delta G^{\pi}_{m} - \Delta G^{\circ}_{m} = \int_0^{\pi} (A_m - N_i A_i - N_s A_s) d\pi \quad (1)$$

where ΔG^{π}_{m} is the molar free enrgy of mixing at surface pressure π, and ΔG°_{m} is that at zero sufrace pressure. A_m is the molecular area measured in the mixed monolayer, N_i and N_s are the segment mol fractions of the *iso*- and *synd*-PMMA and A_i and A_s are the segment molar areas in the *iso*- and *synd*-PMMA monolayers at the same sufrace pressure. In evaluating the integral, we neglected the surface pressure of the polymer monoleyer in equilibrium with its surface vapor. If the mixed monolaryer behaves ideally, $\Delta G^{\pi}_{xs,m}$ vanishes so that the area of the mixed monolayer is the average of two isomer monolayers, thus

$$A_m = A_i N_i + A_s N_s \quad (2)$$

If A_m shows negative deviation from the average value, $\Delta G^{\pi}_{xs,m}$ will become negative. This indicates attractive interaction and compatibility. However, it is important to note that the linear additivity of areas holds also in the case of incompatibility.

The $\Delta G^{\pi}_{xs,m}$ values were calculated by Eq. (1) from the results shown in Fig. 1 using graphical integration. The results are shown in Fig. 2. In Fig. 3, areas of mixtures A_m at the specified surface pressures are plotted against isomer composition. Below 5 dyn/cm, $\Delta G^{\pi}_{xs,m}$ is almost zero and the additivity of areas holds as expected. Above 6 dyn/cm, $\Delta G^{\pi}_{sx,m}$ becomes negative, and at 10 dyn/cm it becomes minimum for the ratio 2/1 of *synd/iso*. At the same time, A_m shows negative deviation from the ideal behavior and has an inflexion point for the same ratio of *synd/iso*. These results indicate that, at the composition, *i. e.*, *synd/iso* is 2/1, the attractive interaction between two isomers is the strongest, and their efficient packing resulted under the surface pressure exceeding 6 dyn/cm.

12) G. L. Gaines, Jr., "Insoluble Monolayers at Liquid Gas Interface," Interscience, New York, N.Y. (1966).

According to Crisp,[13] and Defay and Prigogine,[14] the surface phase rule is expressed as

$$F = C^B + C^S - P^B - q + 3 \quad (3)$$

where T, P and π are variables, F is the number of freedom, C^B is the number of components in the bulk phases, C^S is the number of componetns confined to the surface phase, P^B is the number of bulk phases, and q is the number of surface phases in equilibrium with one another. As is clear from Fig. 1, the transition point of surface pressures of mixtures, π_t, varies with the composition of monolayers; *viz.*, starting at $\pi_t=6$ dyn/cm for *synd/iso*=0/1, gradulally decreases with the increase of the ratio, reaches a minimum at 4 dyn/cm where the ratio is 0.468/0.532, and then increases with the increase of *synd.* content. Thus, we have one degree of freedom at T and P constant. We may consider four possible cases at the transition point with one degree of freedom.[15] (1) Compatible monolayer with phase transition ($C^B=2$, $C^S=2$, $P^B=2$ and $q=2$); (2) compatible monolayer with squeezing out of one component ($C^B=3$, $C^S=1$, $P^B=3$ and $q=1$); (3) compatible monolayer which becomes incompatible at π_t ($C^B=2$, $C^S=2$, $P^B=2$ and $q=2$); (4) incompatible monolayer which becomes compatible at π_t ($C^B=2^2$ $C^S=2$, $P^B=2$ and $q=2$). Of these four possibilities, case (3) may be discarded since the attractive interaction is shown to be above above π_t. Beredjick, *et al.*,[1] concluded that *iso*-PMMA is transformed to helical form from extended conformation at $\pi_t=6$ dyn/cm. Moreover, the isotherms of mixed monolayer with the ratio of *synd/iso* higher than 2/1 are almost superposed on those of the pure *synd*-PMMA monolayer above 5 dyn/cm. Thus, it is likely that an overlayer is formed. If we adopt a tentative layer model of the stereocomplex where *synd*-PMMA are snugly fitted between grooves of *iso*-PMMA helix as proposed by Liquori *et al.*,[4] case (1) is most likely, though no structural evidence such as an electron diffraction of built-up film of the mixed monolayer is present. It appears that the stereocomplementary molecular packing between two isomers at the air-water interface is promoted under pressure.

We are grateful to Dr. Tatsuo Matsuda, Government Industrial Research Institute, Nagoya and Dr. Masao Ishii for the supply of samples.

Photoionization of Naphthalene

Jun-ichi AIHARA and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received November 12, 1969)

Studies of the photoionization of aromatic hydrocarbons in the vapour phase play an important role in obtaining the direct information on the highly-excited states of these molecules. These results can also be used in the estimation of the exciton states in the molecular aggregates.

Recently, several articles concerning the ionization phenomena of naphthalene have been published. Various experimental values of the ionization potential have been obtained by an electron-impact method, by the spectroscopic method, and by photoelectron spectroscopy.[1-5] During the last decade, the theory of the ionization has also been improved.[6-9]

In this paper, we wish to report the ionization potentials of some aromatic hydrocarbons involving naphthalene and to compare the photoionization efficiency curve of naphthalene with the photoelectron spectrum obtained by Turner, and Dewar and Worley.[4,5]

Experimental

The photoionization efficiency curve obtained in this study was made by the method developed by Watanabe.[10] The experimental arrangements and the procedure were nearly the same as those described in Kitagawa's article.[3]

The apparatus employed consisted of a Seya-Namioka-type, 0.5-m vacuum ultraviolet monochromator. A spectral resolution of about 2 Å was obtained with the two slits set about 100 μ in width. The high-voltage discharge of hydrogen was used as the light source.

The photoionization cell was made of Pyrex glass, and LiF windows were attached. Non-magnetic stainless-steel electrodes were set in a cylindrical form 2 mm apart from each other.

The applied voltage of 10 V was sufficient to collect the electrons produced. The collected ionization current was measured on a Cary 31 vibrating-reed electrometer.

All the photoionization-yield measurements were made with a static pressure and at room temperature.

The naphthalene used was a zone-refined material; it was subjected to over 50 passes of the zone heater. Durene, acenaphthene, and indene were purified according to the usual procedures.

The ionization efficiency, Y, was obtained from the equation:

$$Y = \frac{Ki}{I - I_0} \qquad (1)$$

where K is an apparatus constant, i is the photocurrent, I is the intensity of the incident light, and I_0 is the intensity of the transmitted light through the gaseous specimen.

Results and Discussion

The photoionization efficiency of naphthalene is plotted as a function of the energy in electron volts in Fig. 1. The wavelength scale is also given. The lowest adiabatic ionization energy is denoted by I.P. The photoelectron spectrum of naphthalene is also shown in Fig. 1.[4]

In the region observed, the products caused by photolysis are considered to be small in amount. Therefore the ionization yield is mainly that of the naphthalene cation, $C_{10}H_8^+$.[11]

The photocurrent rapidly increased as the photon energy increased. Various structures exist in the ionization efficiency curve. In the first, this curve is a gradually varying-step function of the energy. The threshold is the first step: it corresponds to the first ionization potential, 8.12 eV. This value agrees well with that obtained by Watanabe *et al.*[2] The literature values of the ionization potential of naphthalene are summarized in Table 1.

In the region below the threshold energy, the yield exponentially increases forward the threshold energy. This exponential rise can be explained by the population of thermally-activated molecules in the ground state.

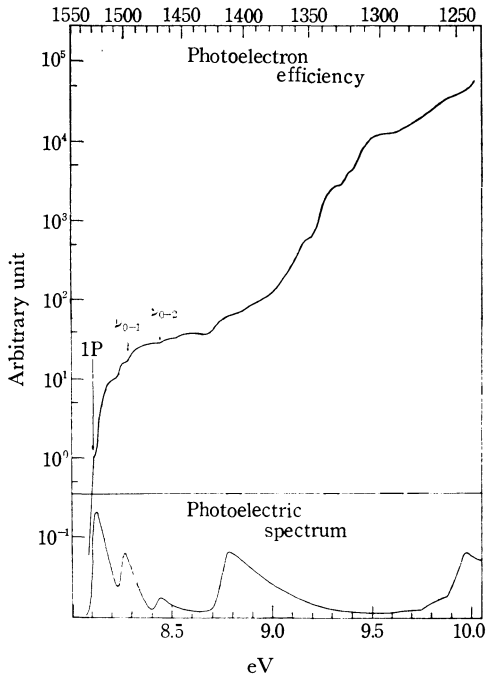

Fig. 1. Photoionization efficiency curve and photoelectron spectrum of naphthalene.*

Table 1. First ionization potential of naphthalene

Experimental	This work	8.12 eV
	Photoionization[2]	8.12
	The convergence limit of Rydberg series[3]	8.13
	Electron impact[1]	8.26
Theoretical	*Ab initio*[8]	9.20 eV
	Modified Koopman's theorem[6]	8.61
	Half-electron method[7]	8.30

In the first ionization region, three vibrational structures were observed. They were located at 1506, 1497, and 1466 Å. The origin of the first band is unknown. The second and the third bands correspond very well to the vibronic bands in the photoelectron spectrum.[4] Accordingly, these are interpreted as 0-1 and 0-2 bands. The vibrational spacings are around 0.17_5 eV.

The ratio of the contributions of the 0-0, 0-1, and 0-2 bands to the ionization yield is approximately 5 : 3 : 1. This trend is comparable to that of the integrated strengths of the vibrational structures in the photoelectron spectrum.

The ionization potential value, 8.26 eV, is that obtained by the electron-impact method.[1] It

10) K. Watanabe, *J. Chem. Phys.* **22**, 1564 (1954).
11) A. Terenin and F. Vilessov, "Advances in Photochemistry," Vol. 2, Interscience, New York (1964), p. 391.

was considered to be the vertical ionization potential. However, the strongest vibronic transition to the first ionization state is the 0-0 band, as is shown in Fig. 1. From this point of view, the vertical ionization potential should coincide with the adiabatic one; that is, the vertical ionization also takes place without any change in the molecular geometry. The observed difference in the measured ionization potentials, 0.14 eV, should be attributed not to the Franck-Condon factors, but to the experimental difficulties latent in the electron impact.

The higher ionization potentials have been reported to be located at 8.79, 9.96, and 10.90 eV.[5]

The electronic binding energies have also been calculated by the MINDO method in the energy range covering all the valence orbitals.[5] However, if we assume that the reorganization energy of an ion is the same in all the states, the higher ionization potentials can be estimated by means of the π-electron approximation by applying a constant correction. 1.15 was subtracted from the binding energies cited in the article of Baird and Dewar.[12] The results are entered in Table 2.

Table 2. Higher Ionization potentials of naphthalene

Experimental*	Theoretical	From the efficiency curve
8.11 eV	8.12 eV	8.12 eV
8.79	8.92	8.6—8.9
9.96	9.96	>9.6
10.90	10.89	
12.26	12.48	

* cited from Ref. 5.

When a radiation shorter than 1430 Å was used, there was a marked enhancement of the yield, mainly due to the second ionization by the resemblance to the photoelectron spectrum.

However, in the region concerned, the structure could not be observed distinctly. These phenomena are perhaps caused by the overlapping of possible vibrational modes. The Franck-Condon envelopes are smoothed. Consequently, the total ionization yield may become apparently continuous, or at least diffuse. These broad peaks, as well as the sub-step at 1506 Å, do not reflect on the photoelectron spectrum. In view of this the significance of such experiments is clear.

The efficiency curve shows a gradual rise again in the region shorter than 1250 Å; this is interpreted as the beginning of the third ionization region.

The approximate values of the ionization potentials estimated from the efficiency curve are also listed in Table 2. However, the exact potentials can not be obtained in this manner, since the efficiency in the higher-energy regions is closely related to the change in the molecular geometry and to such other effects as autoionization and predissociation.[13]

In spite of this, the spectral efficiency is well correlated with the photoelectron spectrum, as has been mentioned above. Further measurements in the higher-energy region are desirable: we are also preparing an apparatus for photoelectron spectroscopy.

In order to analyse the amount of the ionization yield, it is necessary to calculate the photoionization probability. Some theoretical formalisms have been reported using the hydrogenic continuum-wave function.[14,15] The probability of each ionization state depends on the wavelength of the exciting light, so no detailed analysis can be made between the efficiency curve and the photoelectron spectrum.

The behaviour of the experimental ionization cross-section is quite similar to the efficiency curve. The cross section in the first ionization region is of the order of 10^{-19} cm^2. It seems rather a reasonable value, judging from the calculated value of benzene, 10^{-19}—10^{-18} cm^2.[16]

We also measured the first ionization potentials of three compounds, durence, acenaphthene, and indene; they are 8.03 ± 0.02, 7.66 ± 0.03, and 8.08 ± 0.02 eV respectively.

The authors are very much indebted to Professor Taiji Kitagawa of Toyama University for giving them valuable advice and guidance throughout this work.

SHORT COMMUNICATIONS

Synthesis of Cinnamolide

Takeshi SUZUKI,*1 Mitsuru TANEMURA,*2 Tadahiro KATO and Yoshio KITAHARA*3

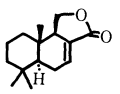
Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received February 2, 1970)

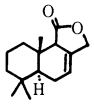
Cinnamolide (I), a driman type sesquiterpene lactone isolated from *Cinnamosma fragrans*,[1] was reported to exhibit antifungal activity, which prompted us to synthesize I from drimenin II.

Reduction of II with lithium aluminum hydride afforded the corresponding diol (III), mp 75.5—77°C, which was subjected to oxidation with active manganese dioxide to give a mixture. Addition of *n*-hexane to the mixture afforded the crystalline (IVa), mp 95—97°C, IR (KBr) spectrum of IVa shows a strong band at 3300 cm^{-1} but no carbonyl absorption. In carbon tetrachloride IVa becomes an equilibrium mixture with IVb, the IR and NMR spectra of which show the presence of conjugated formyl group (1675 and 1628 cm^{-1} in IR (CCl_4) and 9.5 ppm in NMR).

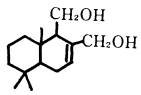
The mixture of IVa and IVb was oxidized with chromic anhydride-pyridine complex in dichloromethane 2 to obtain a crystalline lactone (I), mp 88°C. Direct comparison of its IR and NMR spectra with those of natural cinnamolide, as well as conversion of I to diol (III) with lithium aluminum hydride indicate that the γ-lactone, thus obtained, is identical with (±)-cinnamolide.[3]



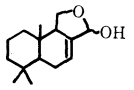
(I)



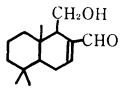
(II)



(III)



(IVa)



(IVb)

Since we have already carried out the synthesis of (±)-drimenin II based on biogenetic consideration,[4] the conversion of II to I demonstrates the synthesis of (±)-cinnamolide.

The Absolute Configuration of the $(-)_{589}$-$[Co(NCS)_2tn_2]$-$[Sb((+)\text{-tart})]\cdot 2H_2O$ Diastereoisomer

Keiji MATSUMOTO, Michitaka YONEZAWA, Hisao KUROYA
Hiroshi KAWAGUCHI and Shinichi KAWAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received November 17, 1969)

It has been shown by X-ray studies that the absolute configurations of $(+)_{589}$-$[Co(CN)_2en_2]^+$ [1] and $(-)_{589}$-$[Co\ ox\ en_2]^+$ [2] are of the *Λ*- and *Δ*- types respectively.[3] These results are consistent with the empirical predictions derived from CD or ORD measurements. Few investigations have, though, been made of the cobalt(III) complexes involving trimethylenediamine (=tn); with regard to the absolute configuration particularly, only that of $(-)_{589}$-$[Co\ tn_3]^{3+}$ [4] has been reported. We have now determined the crystal structure of $(-)_{589}$-$[Co(NCS)_2tn_2][Sb((+)\text{-tart})]\cdot 2H_2O$ as well as the absolute configuration of the complex cation.

Crystal data: orthorhombic, space group $P2_12_12$; $a=12.14$, $b=19.51$, $c=9.13$ Å; $Z=4$. Three-dimensional Fourier methods were used, the absolute configuration of the (+)-tartrate ion being referred to. The R value is 0.149 for 870 observed reflections.

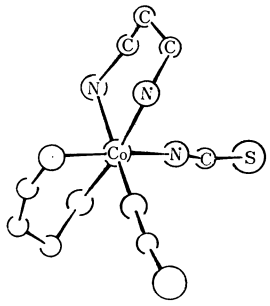

Fig. 1

Figure 1 is a perspective drawing of the complex cation, which has an approximately two-fold axis passing through the cobalt atom and bisecting the N(NCS)–Co–N(NCS) angle. Both of the two six-membered Co-tn rings are of the chair form. The absolute configuration of $(-)_{589}$-$[Co(NCS)_2tn_2]^+$ can be denoted as *Λ*, as is the case with $(-)_{589}$-$[Co\ tn_3]^{3+}$.

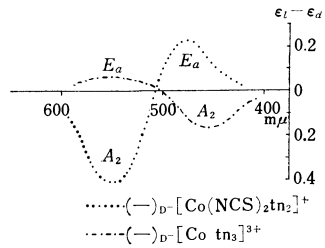

Fig. 2

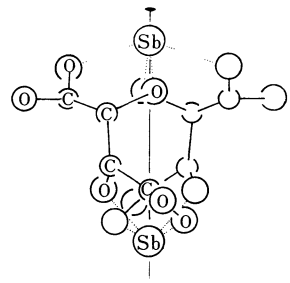

Fig. 3

The sign of the E_a component of the CD peaks in the first absorption-band region is regarded as diagnostic of the absolute configuration of the trigonal cobalt(III) complex ion.[5] The CD curve of $(-)_{589}$-$[Co\ tn_3]^{3+}$ [6,7] in this region shows a weak positive E_a peak in the longer-wavelength region and a strong negative A_2 peak on the shorter-wavelength side (Fig. 2). Therefore, the assignments indicated in Fig. 2 were made for the two components in the CD diagram of $(-)_{589}$-$[Co(NCS)_2tn_2]^+$ obtained in the present work.

In Fig. 3 the geometry of the (+)-tartrato-antimonate(III) ion is presented. A symmetric "dimerized" structure is built up of the two tetradentate tartrate ions bridging the two metal atoms lying on the two-fold axis of rotation.

The Ring-size Effect in the Photoreaction of Phenylcycloalkenes

Masaru TADA and Hiraku SHINOZAKI

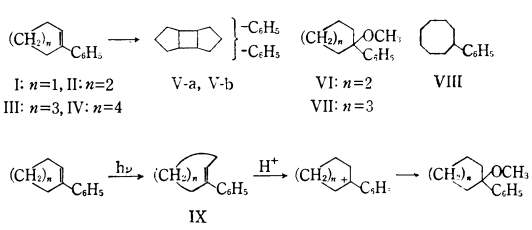
School of Science and Engineering, Waseda University, Shinjuku, Tokyo

(Received November 25, 1969)

We have been studying the ring-size effect in the photoreaction of phenylcycloalkenes, in which the double bonds are a part of the chromophore. A recent publication by Nozaki *et al.*[1] reporting the photo-induced addition of acetic acid to phenylcyclohexene and phenylcycloheptene has now prompted us to report the results from our independent work.*1

Methanolic solutions (0.1 M) of phenylcycloalkenes (I, II, III, and IV) containing a small amount (0.05% to methanol) of sulfuric acid were irradiated with a 100 W high pressure mercury lamp placed in a quartz cooling jacket for 6—24 hr (I, 10 hr; II, 6 hr; III, 7 hr: and IX, 24 hr). The reference solution was kept in the dark, and no change of phenylcycloalkenes was observed.

Phenylcyclopentene (I) gave a crystalline dimer, V-a (25%), mp 186°C, and an oily dimer V-b (12%) besides polymeric products. These two isomers were purified successively by alumina chromatography and preparative vapor-phase chromatography. The dimers have only phenyl-hydrogens and cycloparaffin-hydrogens in their NMR spectra. The mass spectrum of the V-a dimer has a strong peak at $m/e=144$ ($C_{11}H_{12}$) due to phenylcyclopentene, formed by the cleavage of the cyclobutane ring of the dimer upon electron impact, and no distinct peak over $m/e=144$. The V-b dimer has a molecular peak at $m/e=288$ ($C_{22}H_{24}$). Phenylcyclohexene (II) and phenylcycloheptene (III) gave methoxy-phenylcycloalkanes (VI, 54% and VII, 64%, after distillation) as the only isolable products besides the polymer. The structures of these adducts were characterized by a study of their mass spectra (M^+, $m/e=190$ for VI and 204 for VII) and by their NMR spectra, which have characteristic signals due to methoxy groups ($\delta=2.95$ for VI and 2.92 for VII in CCl_4). The irradiation of phenylcyclooctene (IV) gave phenylcyclooctane (VIII) (7%) and recovered phenylcyclooctene (15%) besides the polymer. The formation of the adduct between IV and methanol could be observed from the NMR spectrum of the crude product, but it was not present in an isolable amount.



Cyclohexene and cycloheptene give adducts with alcohol upon irradiation in the presence of benzene, but no photo-addition of alcohol to cyclopentene and cyclooctene occurs.[2] This difference in the reactivity of cycloalkenes with a variation in the ring-size is also seen in our experimental results on phenylcycloalkenes. This similarity in the reactivity between cycloalkenes and phenylcycloalkenes indicates that the addition of methanol to phenylcycloalkenes (II and III) may be the thermal addition of methanol to the *trans*-phenylcycloalkenes (IX, $n=2,3$) formed through the orthogonal excited states of II and III.

The protonation to these *trans*-phenylcycloalknes with high energy contents is obviously the rate-determining step of the addition reaction, since the reaction without an acid catalyst is much slower. The steric requirements do not allow the formation of *trans*-phenylcyclopentene (IX, $n=1$) from the excited state, and the dimerization of phenylcyclopentene (I) takes place preferentially on irradiation. The formation of *trans*-phenylcyclooctene (IX, $n=4$) can be expected without difficulty. The *trans*-isomer, however, does not suffer much ring strain and the enrgy content is not high enough for the facile addition of methanol. Phenylcyclooctene (IV) gives no dimer, but abstracts hydrogen radicals from the solvent to give phenylcyclooctane (VIII).*2

Peptide Synthesis *via* Oxidation-Reduction Condensation by the Use of Non-metallic Compound as a Mercaptan Scavenger

Teruaki MUKAIYAMA, Rei MATSUEDA and Hiroshi MARUYAMA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received January 16, 1970)

We have recently shown[1] that peptides with a high optical purity are produced in excellent yields (as determined by the Young test[2]) by the use of di-*p*-anisylmercury as a mercaptan scavenger *via* the following oxidation-reduction condensation reaction:

$$\text{Bz-L-Leu-OH} + \text{H-Gly-OEt} + \text{Ph}_3\text{P} + (o\text{-O}_2\text{NC}_6\text{H}_4\text{S})_2 + (p\text{-CH}_3\text{OC}_6\text{H}_4)_2\text{Hg} \longrightarrow \text{Bz-L-Leu-Gly-OEt} + \text{Ph}_3\text{P=O} + (o\text{-O}_2\text{NC}_6\text{H}_4\text{S})_2\text{Hg} + 2\,p\text{-CH}_3\text{OC}_6\text{H}_5 \quad (1)$$

In recent years, the potential utility of the solid phase method in peptide synthesis has been extended. With respect to this problem, various non-metallic mercaptan scavengers were investigated in an attempt to purge the insoluble metal mercaptide in the above equation.

First, the reaction was tried by the use of olefins as mercaptan scavengers; they yielded soluble sulfides instead of metal compounds (Eq. (1)), and good results were obtained. When the above reaction was carried out by using 2,3-dihydropyran and zinc chloride, the *N*-benzoyl-L-leucylglycine ethyl ester (Bz-L-Leu-Gly-OEt) was obtained in a 92% yield; mp 147—152°C $[\alpha]_D^{20}$ −32.9° (*c* 3.1, EtOH), L isomer 97%.[2] Another olefin, *n*-butyl vinyl ether, also gave a good result (90% yield, L isomer 95%).

Then, the reaction was carried out by using the sulfenate ester, which yields disulfide; a good result was obtained here also. When equimolar amounts of *N*-benzoyl-L-leucine, the *N*-*o*-nitrophenylsulfenylglycine ethyl ester, and triphenylphosphine were allowed to react in the presence of methyl 2,4-dinitrobenzenesulfenate in methylene chloride for 3 hr, Bz-L-Leu-Gly-OEt was obtained in a 92% yield; L isomer 92%.

Next, the reaction was tried in the absence of a mercaptan scavenger by using dipyridyl-2,2′-disulfide as a disulfide component, on the assumption that the 2-mercaptopyridine produced along with the peptide would isomerize to the stable thione form.[3] In a typical experiment, ethyl glycinate (5 mmol) and triphenylphosphine (5 mmol) in methylene chloride were added at room temperature to a stirred mixture of equimolar amounts of *N*-benzoyl-L-leucine and dipyridyl-2,2′-disulfide in methylene chloride. After stirring for 30 min, Bz-L-Leu-Gly-OEt was isolated by an ordinary procedure;[1] 1.46 g (91%); mp 148—152°C, $[\alpha]_D^{20}$ −32.6° (*c* 3.1, EtOH), L isomer 96%.

Finally, it was found that the third process could be successfully applied to the solid phase method and the dipeptide thus prepared in a high yield. For example, 0.644 mmol of *t*-amyloxycarbonylglycine estrified to 2 g of the supporting cross-linked polystyrene resin[4] was deprotected by 2N hydrogen chloride in acetic acid, and the general procedure[4] of the solid phase method was followed. Coupling was carried out using a threefold excess of *t*-butyloxycarbonyl-L-leucine monohydrate, triphenylphosphine, and dipyridyl-2,2′-disulfide in methylene chloride for 6 hr. The peptide was liberated from the resin by bubbling in hydrogen bromide in trifluoroacetic acid; after it had been evaporated to dryness and water had been added, the resin was filtered off. The amount of the peptide in the filtrate was determined by the aminoacid analyser to be 0.64 mmol of Leu-Gly (99% yield) (calculated from the authentic sample) and the glycine peak was not observed. This solution was desalted by DEAE cellulose, and the peptide was precipitated by adding ethanol after the water had been evaporated *in vacuo* to a very small amount. Ninety-one milligrams of H-L-Leu-Gly-OH (76% yield) were isolated after drying over phosphorus pentoxide at 100°C for 2 hr, mp 235—240°C (dec.), $[\alpha]_D^{20}$ 86.5 (*c* 2, H_2O). Found: C, 51.07; H, 8.48; N, 15.11%. Calcd for $C_8H_{16}N_2O_3$: C, 51.05; H, 8.57; N, 14.88%. [lit,[5] mp 235—242°C (dec.), $[\alpha]_D^{20}$ 85.99 (*c* 2, H_2O)]. The amino-acid analysis of a 24-hr 6N HCl hydrolysate gave: Leu, 0.92; Gly, 0.95.

A New Route to Free Radical Aromatic Substitution

Atsuyoshi OHNO and Noboru KITO

Sagami Chemical Research Center, 3100 Onuma, Sagamihara-shi, Kanagawa

(Received February 2, 1970)

The mechanism of free radical aromatic substitution has been studied extensively[1-5] and shown to follow the scheme

$$\mathrm{ArH} + \mathrm{R}\cdot \longrightarrow \underset{\mathbf{1}}{\mathrm{RArH}\cdot} \xrightarrow{\mathrm{R'}\cdot} \mathrm{ArR} + \mathrm{R'H}$$

where R'· may be **1** or other radicals. The reactions of this type involve intermolecular hydrogen-transfer. We could expect a reaction involving intramolecular hydrogen-transfer if the composite radical **1** has an appropriate leaving group.

In this communication we wish to report a new example for free radical aromatic alkylation. A mixture of phenyl isopropyl ether (**2**) and di-*t*-butylperoxide (DTBP) (2 : 1 in mole ratio) was irradiated in a pyrex flask for 20 hr at 25°C with a high-pressure mercury lamp (Riko-kagakusangyo 400 W, principal wavelength 3150 and 3660 Å). Product analyses[6] showed the presence of a mixture of *o*- (predominant), *m*- and *p*-isomers of isopropoxycumene (**3**) (51.5%)[7] and phenol (**4**) (42.5%)[7] along with other minor products. Photolysis of a solution of azobis(2-phenoxy)-2-propane in **2** (0.25M) also resulted in the formation of **3** (21.3%) and **4** (15.3%).

The fact that neither dimer nor trimer of phenols could be detected from the reaction mixture, together with the absence of Pummerer's ketone in the products of photolysis of azobis(2-*p*-methylphenoxy)-2-propane, reveals that phenol is not produced from free phenoxy radical.[8,9] Furthermore, it is difficult to attribute the formation of **3** to carbene reaction because no information is obtained for the presence of propylene and 2-phenoxy-2,3-dimethylbutane that are expected from the reaction:[10]

$$(\mathrm{CH_3})_2\dot{\mathrm{C}}\mathrm{OPh} \longrightarrow \mathrm{PhO}\cdot$$
$$+ (\mathrm{CH_3})_2\mathrm{C}: \begin{cases} \nearrow \mathrm{CH_3{-}CH{=}CH_2} \\ \searrow (\mathrm{CH_3})_2\mathrm{C(OPh)CH(CH_3)_2} \end{cases}$$

Thus, the most probable mechanism for the formation of **3** is

$$(\mathrm{CH_3})_2\dot{\mathrm{C}}\mathrm{OPh} + \mathbf{2} \longrightarrow \mathrm{PhO{-}C(CH_3)_2{-}}\underset{\mathrm{H}}{\overset{\mathrm{OCH(CH_3)_2}}{\langle\bigcirc\rangle}} \xrightarrow{-\mathrm{PhOH}}$$
$$\left[(\mathrm{CH_3})_2\mathrm{C}{-}\langle\bigcirc\rangle{-}\mathrm{OCH(CH_3)_2} \longleftrightarrow (\mathrm{CH_3})_2\dot{\mathrm{C}}{-}\langle\bigcirc\rangle{-}\mathrm{OCH(CH_3)_2}\right] \xrightarrow{+\mathrm{H}\cdot} \mathbf{3}$$

where the driving force of the reaction may be the stability of phenol and aromatization of the composite radical.

Henbest and co-workers[11] obtained methylanisoles, phenoxymethylanisoles and phenol as products of the reaction of anisole with DTBP at 140°C. This clearly supports the first step of the above mechanism. Although they interpret the formation of methylanisoles as aromatic substitution with methyl radical, a part of it could be another example of intramolecular hydrogen abstraction.

Determination of Magnetic Moments of Copper Ions in Water by the Viscometer Method

Toshio IKEDA

Department of Chemistry, Shizuoka University, Shizuoka

and Kazuo SUEOKA

Department of Chemistry, Johsai University, Sakado, Saitama

(Received May 10, 1969)

The viscometer method was applied to determine the magnetic susceptibilities of aqueous solutions of cupric salts. The effective magnetic moments of the cupric ions obtained were in agreement with values in literature, except for cupric nitrate and acetate. The former showed a relatively high value and the latter gave variable values, which suggest some dimerization effect occuring in aqueous solution with increasing concentration.

Recently, one of the authors reported the viscometer method[1] to determine the magnetic susceptibility of liquids by measuring the time of flow of liquids through the capillary of a viscometer in an external magnetic field. This method was applied to determine the magnetic moments of copper ions in aqueous solutions.

General Scheme

A capillary viscometer of the Ostwald type is placed in a magnetic field so that its bulb part is in the homogeneous part near the center of the pole gap of an electromagnet, while its capillary part extends vertically, through the inhomogeneous part, outside the field. In this case, the Hagen-Poiseuille expression for the time, t, of flow of a liquid of volume v through the capillary of the viscometer is reduced as follows ignoring the magnetostrictive effect.[1]

$$1/t_0 - 1/t = \kappa H^2/2\rho g h t_0 \qquad (1)$$

where t_0 is the time of flow in the absence of an external magnetic field; H denotes the local magnetic field in the liquid medium in the homogeneous magnetic field near the center of the pole gap of the magnet. This can be replaced by the intensity of an externally applied magnetic field; κ and ρ are the volume magnetic susceptibility and the density of the liquid, respectively; g is the gravity constant; h is the vertical height of the capillary part of the viscometer. We see from Eq. (1) that the liquid is identified as diamagnetic or paramagnetic according to whether time t is shorter or longer than t_0. A similar equation can be written also for water. Adopting water as a reference substance for calibration, we can calculate the mass magnetic susceptibility χ ($\kappa=\rho\chi$) of the solution in terms of the mass magnetic susceptibility of water χ_w as follows.

$$\chi = \frac{t_w(t-t_0)}{t(t_w-t_{w0})}\chi_w \qquad (2)$$

where t_w and t_{w0} are respectively the time of flow of water through the viscometer in the presence and absence of the magnetic field under the same field strength as applied in the solution.

Experimental

Materials. Aqueous solutions of cupric chloride, cupric nitrate, cupric sulfate, and cupric acetate were prepared by using Guaranteed Reagent grade chemicals obtained from Wakō Pure Chemicals and distilled oxygen-free water. Iron was found to be the only paramagnetic impurity involved in cupric chloride, cupric nitrate, and cupric sulfate in quantities below 0.0002, 0.02, and 0.005%, respectively. The content of copper in solutions was determined by electroanalysis.

Apparatus and Measurements. A Bitter type 500 kg electromagnet of Tokyo Denki Seiki Co. was used to produce a magnetic field of strength up to 20 kG with a relative fluctuation of 10^{-4} using a well stabilized d.c. source, where the pole pieces of the magnet were set at a distance 21 mm apart. A capillary viscometer of the Ostwald type, equipped with a thermostat water jacket, was inserted vertically between the pole gap of the magnet so as to have its upper reservoir (18 mm diameter) come within the homogeneous magnetic field formed in the central circular region (about 30 mm diameter) inside the 60 mm diameter pole pieces. The details of the apparatus were described previously.[1] The time of flow of liquids was measured with a stopwatch of 0.1 sec division, down to 0.01 sec by visual estimation, at 25°±0.05°C.

1) T. Ikeda and H. Yoshioka, *J. Phys. Chem.*, **72**, 4392 (1968).

Calculation. The mass magnetic susceptibility, χ_s, of cupric salts was calculated from the data of χ of the solution by means of the Wiedemann additivity law, $\chi = p\chi_s + (1-p)\chi_w$, where p is the weight fraction of cupric salt in aqueous solution. The value -0.722×10^{-6} emu/g was adopted for χ_w in the present work.[2] The molar magnetic susceptibility χ_+ of the cupric ion was obtained from the molar susceptibility of cupric salt, making correction for the diamagnetic contribution from the anion constituent in aqueous solution: *i.e.*, -28 for Cl^-, -23.5 for NO_3^-, -38 for SO_4^{2-} and $CH_3CO_2^-$ (in 10^{-6} emu/mol).[3] The effective Bohr magneton number, μ_{eff}, of copper(II) ion was calculated by using the Langevin equation as follows.

$$\mu_{eff} = 2.828\sqrt{\chi_+ T} \text{ B.M.}$$

where B.M. is the Bohr magneton unit, 0.9273×10^{-20} erg/G, and T is the absolute temperature. The diamagnetic correction for the cupric ion was not made.

15	12.27	219.86
20	16.05	219.06
25	19.05	218.27
28	20.15	217.95

a) Measured with a TOSHIBA HM-3 Hall element magnetic field meter at the center of the pole gap of electromagnet.
b) Mean of seven measurements.

Results and Discussion

The results are shown in Tables 1, 2, and 3. When measurements are carried out with solutions of low concentration in a low magnetic field, the resulting magnetic moments might suffer an appreciable error, because a small difference between two large figures, t and t_0, and t_w and t_{w0}, seriously influences the value of magnetic susceptibility. This

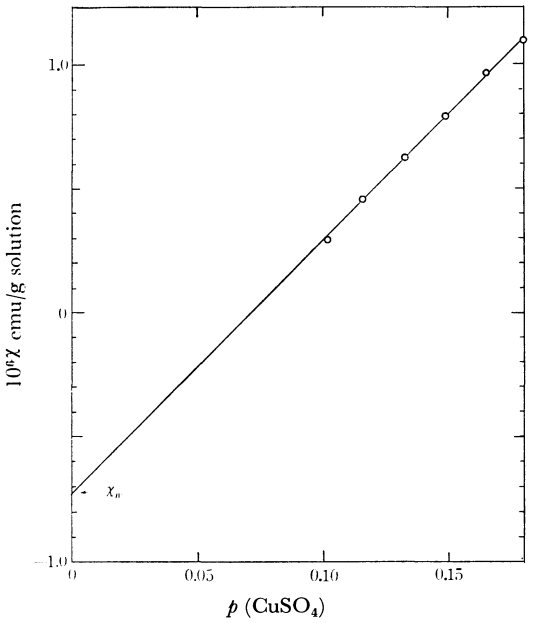

Fig. 1. The Wiedemann relation for aqueous solution of $CuSO_4$ at 25°C, representing the values measured at the magnetic field strength of 20.15 kG.

effect is actually seen in the Tables. Thus, in order to get reliable results, measurements should be carried out with solutions of higher concentration in as high a magnetic field as possible, particularly in the case of a solution involving a weak paramagnetic ion species such as Cu^{2+}: In the present method, a magnetic field of a strength higher than 12 kG gives results with tolerable accuracy.

Magnetic susceptibilities of aqueous solutions of cupric salts, except for cupric acetate, were found to obey the Wiedemann law. The Wiedemann relation for cupric sulfate was found to be perfectly linear, intersecting, on extrapolation to concentration zero, the ordinate at -0.725×10^{-6} emu/g. This is in close agreement with the susceptibility of water (Fig. 1). From the slope of the line in Fig. 1 we obtain the effective magnetic moment 1.92 B.M. for Cu^{2+}. The magnetic moments of copper(II) ion were found in good agreement with literature values,[4] except for cupric nitrate and cupric acetate (Tables 2 and 3). Cupric nitrate exhibited a value, about 15% higher than the

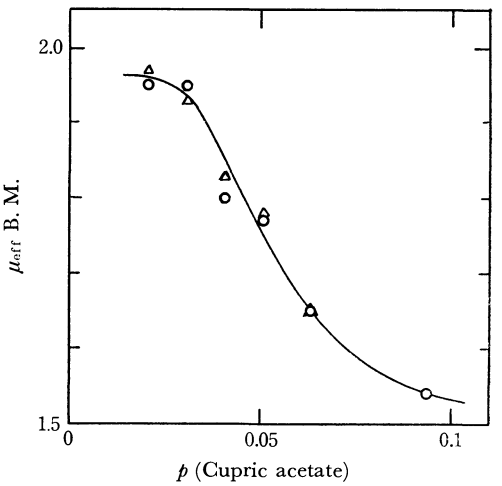

Fig. 2. Relation between the apparent magnetic moments of Cu^{2+} and the weight fraction, p, of cupric acetate in aqueous solutions at 25°C, Δ, measured at 19.05 kG; ○, measured at 20.15 kG.

literature values 1.92—1.96 B.M.[4] The magnetic moment we obtained seems to involve an error of 2—3%. The paramagnetic cation found as impurity in cupric nitrate was exclusively iron contained in such a minute quantity below 0.02% which can cause a deviation 0.15% at most from the accepted value of the magnetic moment of cupric ion. There might be some reason to cause such a large deviation of 15% in the case of cupric nitrate.

The apparent magnetic moments of Cu^{2+} observed in aqueous solutions of cupric acetate appeared to depend on the concentration (Table 3 and Fig. 2): A value of 1.95 B.M. found at lower concentration is in agreement with the literature value.[4] However, it decreased with increasing concentration towards a value 1.42 B.M. found in the crystalline state where the dimerization of cupric acetate through a weak copper-copper bond formation was concluded.[5] This fact suggests a similar association of cupric acetate occuring also in aqueous solution with increasing concentration.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1276—1282 (1970)

Hot-Atom Chemistry of Bromine. IV. Chemical Effects of $^{81}Br(n,\gamma)^{82g}Br$, $^{81}Br(n,\gamma)^{82m}Br$ and $^{82m}Br(I.T.)^{82}Br$ Excitation in Antimony Tribromide and Benzene System[1,2]

Toshiaki KISHIKAWA, Yasuyuki ARATONO and Chiro SHINOMIYA

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto

(Received July 19, 1969)

Antimony tribromide and a molecular compound between antimony tribromide and benzene (2 : 1) have been irradiated to provide ^{82m}Br sources. The results obtained by the dissolution of the irradiated molecular compound, by means of which technique the chemical effects of $^{81}Br(n,\gamma)^{82g}Br$ and $^{82m}Br(I.T.)^{82}Br$ were determined separately, had shown very low organic yields from either (n,γ) or (I.T.) excitation. The reaction of $^{82m}Br(I.T.)^{82}Br$ in benzene showed a growth in the organic yields. Moreover, the organic yield of ^{82}Br was lower when the system was frozen than when it was stored as a liquid. These results are explained by assuming that, in the frozen system, the antimony tribromide (^{82m}Br) forms a molecular compound with the benzene. The higher organic yields in the frozen systems than those in the molecular compound itself must be due to the formation of free bromine (^{82m}Br), which turns out to be an organic radiobromide. The hydrolytic behavior of the irradiated antimony tribromide and the molecular compound supports the idea of the presence of free bromine (^{82m}Br) at the end of the irradiation.

Since the discovery of the meta-stable-state bromine-82,[3] much work has been done on the chemical effects of the $^{82m}Br(I.T.)^{82}Br$ excitation in various liquid or solid organic media. The vertue of the subject transformation is that the experiment can be conducted in the absence of those transformations due to (n,γ) reactions and also of any possible influence of the accompanying gamma-radiation from a reactor. The major portion of the activity produced from the (n,γ) activation by ^{81}Br is the ^{82m}Br-activity, which undergoes the (I.T.) process (activation cross sections,[3a] $\sigma_m=3.0$ and $\sigma_g=0.3$ barns). The bromine-82m decays with a highly-converted transition[3a] of 46 keV (internal conversion coefficient, $\alpha_k=268$). This means that a large fraction of the ^{82}Br is produced with a positive charge. The ^{82m}Br source has thus far been prepared by two methods for the sake of experimental convenience: by irradiating molecular bromine,[4] and by irradiating an organic bromide.[5] A third method, to be proposed here, proceeds by irradiating an inorganic bromide.

The present work will deal with the chemical effects of radiative neutron capture by bromine-81 and of isomeric transition by bromine-82m in mixtures of antimony tribromide and benzene.

Experimental

Materials. Wako Pure Chemicals' JIS special-grade benzene was purified by the usual method. Tokyo Kasei JIS 1st-grade antimony tribromide was used after it has been purified by recrystallization (mp 96.6°C) from carbon disulfide. The other reagents used were all of a JIS special-grade, but were also further purified if necessary. The $2SbBr_3 \cdot C_6H_6$ molecular compound

($2SbBr_3Bz$) (mp 92.6°C, lit,[6] 92.5°C) was prepared[7] by adding antimony tribromide to hot benzene, followed by cooling and evaporating the excess benzene.

Neutron Irradiation. Samples sealed in a quartz ampule were irradiated in a pneumatic tube of KUR[8] at the temperature of dry ice or at the reactor temperature (*ca.* 40°C). The thermal neutron flux was 5×10^{12} n/cm²/sec, and the accompanying gamma-radiation flux was 2.7×10^{7} R/hr.

Procedure. *Dissolution Technique.* The ampule of the irradiated $2SbBr_3Bz$ molecular compound at the temperature of dry ice was immersed in a boiling-water bath immediately after it has been irradiated for 60 min; during the immersion almost all the ^{82m}Br isotopes produced by the radiative neutron capture decayed to the ^{82}Br ground state. The ampule was then cooled in a bath of dry ice and ethanol. The sample was extracted directly from the frozen state into a two-phase mixture of benzene containing a bromine carrier plus 0.5M aqueous sodium sulfite, after which hydrochloric acid (1 : 1) was added to the mixture.[9] The organic layer was then dried over calcium chloride.

Antimony Tribromide - Benzene System. The irradiated molecular compound or antimony tribromide was dissolved in benzene immediately after irradiation; it was then stored at room temperature (liquid) or at the temperature of dry ice (frozen). Aliquot portions were extracted after varying periods of time.

Counting and Analysis. A NaI(Tl) scintillation crystal and a multi-channel pulse height analyzer were used. By radiative neutron capture the activities of ^{122}Sb (half-life 2.75 day), ^{122m}Sb (4.2 min), ^{124}Sb (60 day), ^{124m}Sb (21 and 1.3 min), ^{80}Br (18.5 min), and ^{80m}Br (4.5 hr) as well as of ^{82}Br (36 hr) and ^{82m}Br (6.2 min[3]) were produced. Only the ^{82}Br activities were studied. After all, since the ^{82m}Br had dceayed to the ^{82}Br ground state, a 0.78 MeV gamma-ray photo peak was measured and used for the calculation.

Results and Discussion

Effects of the Time and Temperature of Irradiation and Those of Standing on the Organic Yields of the $2SbBr_3Bz$ Molecular Compound. To determine the effects of the accompanying gamma-ray and the temperature in the reactor, the molecular compound was irradiated for varying periods at different temperatures. Table 1 lists the overall organic yields (experimental error range, ±1%); these yields mean that it is not necessary to take the accompanying gamma dose in the reactor into consideration. Little dependency of the temperature of irradiation and standing was observed, as is shown in Fig. 1.

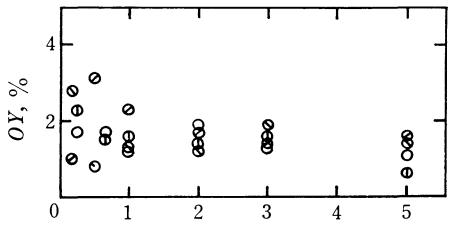

Fig. 1. Organic yields induced by $^{81}Br(n,\gamma)^{82}Br$, $^{81}Br(n,\gamma)^{82m}Br$ and $^{82m}Br(I.T.)^{82}Br$ processes at the molecular-compound $2SBr_3Bz$. Effects of temperature at time of these nuclear events.

EM1: Eutectic mixture ($C_6H_6+2SbBr_3\cdot C_6H_6$)
EM2: Eutectic mixture ($2SbBr_3\cdot C_6H_6+SbBr_3$)
MC: Molecular compound ($2SbBr_3\cdot C_6H_6$)

Dissolution of the Irradiated $2SbBr_3Bz$ Molecular Compound. The following experiments were performed in order to obtain information on the effects of the isomeric transition-induced process. Immediately after the irradiation, quartz ampules containing $2SbBr_3Bz$ were immersed in the boiling-water bath; the molecular compound in the ampule were thus decomposed into a two-phase mixture of its components - benzene (gas, bp 80.1°C) and antimony tribromide (liquid, mp 92.6°C), as may be seen in the phase diagram of the $SbBr_3$-C_6H_6 system[6] in Fig. 2.

After the completion of the (I.T.) process, the sample was resolidified in the bath of dry ice and ethanol and then extracted. The observed overall organic yields at the various irradiation periods are listed in Table 2. The results of standing at the temperature of dry ice are also listed in the table. If there were an organic radiobromide-(^{82m}Br) which had been produced by the (n,γ) activation and subsequent recoil bond-forming processes, the following (I.T.) process might cause the organic radiobromide to dissociate the ^{82}Br atom resulting from Coulombic repulsion. The overall organic yield value on the first line in each irradiation-time column in Table 2 may then be attributed, for the most part, to the organic radiobromides-(^{82g}Br) produced directly by the (n,γ) activation.

A slight increase in the organic yield with an increase in the standing time was observed (the values on the second and the third lines). The values on the last line, which are attributed to the fraction of the (I.T.)-excited reaction, are obtained by subtracting the value on the first line from that on the third line in each column.

Reaction of Bromine-82m Prepared by Irradiating Antimony Tribromide or the $2SbBr_3$-Bz Molecular Compound in Liquid and Solid Benzene. To ascertain whether or not the increase in the organic yield is affected by the (I.T.) depending process, the following rate determinations in liquid and solid benzene were carried out. As soon as the end of the irradiation of $SbBr_3$ or

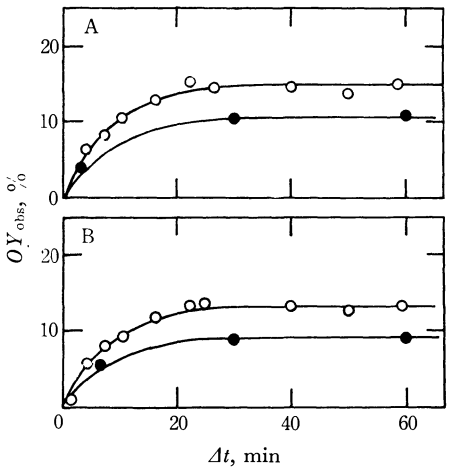

Fig. 3. Growths of ^{82}Br organic yields in benzene.

○: Liquid, ●: Frozen

$2SbBr_3Bz$, the sample-benzene system (1.64×10^{-4} mol fraction of $SbBr_3$) was produced as is described in the Experimental section. The inorganic radiobromine in a portion of the system was separated by extraction at different time intervals. Figure 3 shows plots of the activities of the overall organic yield obtained from systems left to stand for various length of time, Δt, after the preparation of the systems. The curves increase with an increase in the standing time.

If the observed increase in the ^{82}Br organic yield is a result of chemical excitation by the (I.T.) alone, the rate of growth should be dependent only on the decay of the ^{82}Br and should be related to the half-life of the ^{82m}Br. Therefore, when OY^{∞}_{obs} represents the overall organic yield attained after all the ^{82m}Br has decayed to the ^{82}Br ground state, when OY^{0}_{obs} represents the organic yield present at the time the system is prepared (*viz.*, for the irradiated $SbBr_3$, $OY^{0}_{obs}=0$; for the irradiated $2SbBr_3Bz$, $OY^{0}_{obs}=$[the values listed on the first line of the irradiation-time column in Table 2 which are due to $^{81}Br(n,\gamma)^{82g}Br$]), and when $OY^{\Delta t}_{obs}$ represents the organic yield at any time before the ^{82m}Br has completely decayed, the growth of the ^{82}Br organic yield will be given[4d,4j] by:

$$(OY^{\Delta t}_{obs}-OY^{0}_{obs}) = (OY^{\infty}_{obs}-OY^{0}_{obs})(1-e^{-\lambda\Delta t}),$$

where λ is the decay constant of ^{82m}Br. By rearranging the equation, $\log(OY^{\infty}_{obs}-OY^{0}_{obs})-(OY^{\Delta t}_{obs}-OY^{0}_{obs})/(OY^{\infty}_{obs}-OY^{0}_{obs})$ *versus* Δt should yield a straight line (Fig. 4) with a slope of $-0.693/-2.303T_{1/2}$. The half-life of ^{82m}Br was determined to be 6.00 and 5.87 min from the yields of the liquid systems of the irradiated-$SbBr_3$ - C_6H_6 and of the irradiated-$2SbBr_3Bz$ - C_6H_6 respectively. The close relative rates of increase in the overall organic yields[10] in the different systems can be attributed to the ^{82m}Br(I.T.)-excited reaction. Similar phenomena have been reported in liquid and solid systems of irradiated-Br_2 - C_6H_6 by two of the present authors (C.S. and T.K.) in a previous paper.[4j]

Behavior of the ^{82}Br Produced by (n,γ)- and (I.T.)-activation at $SbBr_3$ and $2SbBr_3Bz$. If water is added to antimony tribromide, various antimony oxybromides are formed. An appropriate amount of water hydrolyzes it to form $Sb_4O_5Br_2$, the solubility of which in water is very low.[12]

$$4SbBr_3 + 5H_2O \longrightarrow Sb_4O_5Br_2 + 10HBr$$

Stoichiometrically speaking, five-sixths of all the bromine atoms are present in the aqueous solution,

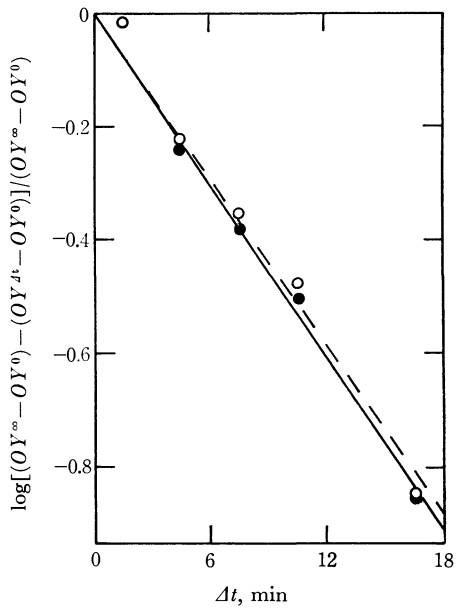

Fig. 4. Bromine-82 organic yields as a result of isomeric transition in benzene.
○: Irrad. $SbBr_3$, ●: Irrad. $2SbBr_3Bz$

and the rest in the precipitate. The hydrolysis of the compound provides a means to study the Szilard-Chalmers reaction,[13] in which a portion of the radiobromides produced by the (n,γ) reaction is found in an un-recombined form and thus can be extracted with water. The results of the hydrolysis are listed in Table 3. The higher bromide yield which was obtained by hydrolysis a short time after the irradiation can be attributed to the presence of the ^{82m}Br activities. When the irradiated sample was left standing for 90 min at the temperature of dry ice, the hydrolyzed yield of bromide was reduced nearly to the calculated value. The results of the hydrolysis coincide with those of dissolution.

b) $SbBr_3$ concentration was 1.64×10^{-4} mol fraction.

Determination of the ^{82}Br Organic Yield Resulting from the ^{82m}Br(I.T.)^{82}Br Process in the Liquid and Solid Systems. Correcting for the contributions of the activities of the ground-state ^{82}Br produced directly from the (n,γ) reaction and for those of the activities decayed from the ^{82m}Br before preparing the reaction systems, one can obtain the net organic yield values (OY^{∞}_{net}); these values are presented in Table 4.

As has been pointed out in the introduction, the decay of the ^{82m}Br goes through a 46 keV highly-converted transition; this suggests that a large fraction of the ^{82}Br is produced with a positive charge. It would appear that the chemical stabilization of the daughter ^{82}Br in the present liquid systems is due either to ion-molecule reactions of these charged atoms with the surrounding organic medium or to reaction of the neutralized hot atoms with the medium.

It is well known that molecular bromine is stable in benzene, forming a charge-transfer complex[14] (the charge-transfer energy is 4.25 eV[15]), and that aromatic bromination with molecular bromine proceeds quite gently in a non-polar organic medium such as benzene.[16] The electron acceptability of bromine in the charge-transfer complex depends on the state of bromine in the following order: $Br^+ > Br^0 > Br_2$. Also, the positively-charged ^{82}Br ion produced by the (I.T.) and the accompanying internal conversion processes is a much better electron-acceptor; the chance of its staying alive to form a charge-transfer complex with benzene may be small, since its electron affinity is high (the ionization potential of benzene is 9.25 eV,[17] lower than that of bromine by 2.59 eV). The fact that not all the bromines formed *via* the (I.T.) are found in the organic combination suggests that the ion-molecule reaction is less significant in the present systems. The ^{82}Br may, therefore, react by means of the energetic reaction. Some recent data[11] on the ^{82m}Br(I.T.)-induced reaction in alkyl benzenes indicate that the values of the overall organic yield follow the same order as the ionization potential of the benzenes. The charge-transfer complex may, then, act as a reaction intermediate. The small growth in the observed organic yield after 25 min (plateaus in Fig. 3) indicates that the simple free-radical reactions of the bromine atoms after complete thermalization are negligible.

On the other hand, in the resolidified systems, which are composed of polycrystalline mixtures[18] (eutectic mixture) of benzene plus the $2SbBr_3Bz$ molecular compound, the free bromine produced by the (n,γ) or (I.T.) reaction and remaining before resolidification may also be composed of a molecular compound ($^{82m}Br\cdot C_6H_6$ or $Br_2(^{82m}Br)\cdot C_6H_6$[4j,19]). Lambrecht and Rack,[4h] after a consideration[4d,20,21] of the clustering of bromine in an organic medium, put forward a scheme attempting to provide a better understanding of solid-state organic yields in polycrystalline systems. Their scheme can be rather satisfactorily applied to the present systems by replacing $(Br_2)_n$ by $(2SbBr_3Bz)_n$, because a very low organic yield has been observed in the irradiated molecular compound (the benzene in the molecular compound may be comparatively inert, since the ionization potential of antimony is 8.46 eV,[17] lower than that of benzene by 0.79 eV): That is, the ^{82}Br atoms formed by the (I.T.) process in the molecular-compound clusters mostly remained inorganically in the clusters, while those formed in the polycrystalline benzene reacted within the benzene, and while those formed on the surface of the molecular-compound clusters remained either organically or inorganically.

Distribution of Organic Radiobromides in the Irradiated Molecular Compound. The fractional distillation of the benzene layer of the

irradiated $2SbBr_3Bz$ after all the ^{82m}Br has decayed indicates the formation of low- and high-boiling products as well as of bromobenzene. Recrystallization with the addition of inactive *p*-dibromobenzene indicated its formation. The distributions (%) of (low bp fraction, bromobenzene and dibromobenzenes) in the benzene layers at the irradiation times of 1, 3, and 20 min were (24, 64, and 34), (21, 37, and 42) and (15, 46, and 39) respectively.

Contribution of Thermal Exchange and Substitution Reactions. To determine whether the organic yield built up after 60 min is due only to the (I.T.) process or whether a part of it is due to the thermal exchange and/or thermal substitution reactions of antimony tribromide(^{82}Br) with bromobenzene or with benzene, the following experiment was performed by synthesizing antimony tribromide-(^{82}Br).[12] It was dissolved in an organic medium (12.5×10^{-3} g-atom/*l* of $SbBr_3$(^{82}Br) and 3.54×10^{-3} g-atom/*l* of C_6H_5Br in benzene, or 20.0×10^{-3} g-atom/*l* of $SbBr_3$(^{82}Br) in bromobenzene). The reaction mixture was then stored at 25 or 19.5°C (±0.5°C reguration) and portions were extracted at regular intervals in the manner described above. The activities of both the organic and aqueous layers were then measured. After the conventional treatment of the isotopic exchange,[22] the apparent half-time values and the fractional exchange values at 60 min, after the preparation of the reaction mixture in all cases, were found to be 10^4 hr and 0.001 respectively; these value indicate no prominent role of either isotopic exchange or substitution reactions.

From these findings, the probable paths of the organic-radiobromide formation in the irradiated-$SbBr_3$ - benzene or the irradiated-S2bBr_3Bz - benzene systems due to the (I.T.) process by the ^{82m}Br may be assumed to be as is illustrated schemati-

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1282—1286 (1970)

Kinetics of Alkaline Hydrolysis of Esters. III. Acyl Acetals

R. C. SHARMA and M. M. SHARMA

Department of Chemical Technology, University of Bombay, Matunga Road, Bombay-19, India

(Received July 14, 1969)

The kinetics of the alkaline hydrolysis of some acyl acetals (liquid and solid) was studied in 90 parts (wt/wt) aqueous ethanol medium. Steric and inductive effects were found to play an important role. A straight line relationship was observed between the rate constants for the alkaline hydrolysis of benzylidene-, and *m*- and *p*-nitrobenzylidene diacetates and Hammett's substitution constant, σ. In the case of *n*-butylidene and benzylidene diacetates the theory of mass transfer accompanied by fast pseudo first-order reaction was employed for the determination of rate constants in an aqueous medium.

There is a limited information available in the literature on the kinetics of the alkaline hydrolysis of acyl acetals. The reaction can be written as:

$$R'CH(OAC)_2 + OH^- \xrightarrow[\text{slow}]{k_2} R'\underset{\displaystyle OH}{\underset{|}{C}}H(OAC) + CH_3COO^- \quad (1)$$

$$R'\underset{\displaystyle OH}{\underset{|}{C}}H(OAC) + OH^- \xrightarrow{\text{fast}} RCHO + H_2O + CH_3COO^- \quad (2)$$

The first step of the hydrolysis has been reported to be first order with respect to the ester and first order with respect to hydroxyl ions.[1,2] The second step is very fast.[3] There are some discrepancies in the data reported in the literature concerning the rate constants of the alkaline hydrolysis of acyl acetals. Skrabal and Schiffrer[1] and Skrabal and Belavic[2] have reported the value of the rate constant for the alkaline hydrolysis of methylene diacetate to be 18 and 16 $l/g \cdot mol \cdot sec$ at 25°C, respectively. Salmi and Kantola[3] have, however, reported a value of 5.3 $l/g \cdot mol \cdot sec$ for methylene diacetate and 2.33 $l/g \cdot mol \cdot sec$ for ethylidene diacetate. Most recently Euranto and Moisio[4] reported the rate constant for methylene diacetate as 5.85 $l/g \cdot mol \cdot sec$. It was thought desirable to study a series of typical acyl acetals like ethylidene-, *n*-butylidene- and benzylidene diacetates. The effect of an electronegative group, $-NO_2$, in the benzene ring of benzylidene diacetate was also studied in this work.

Mechanism

An acyl acetal is an acetic ester with the group $-OCOCH_3$ at the α-carbon atom of the alkyl part.

$$CH_3COO\underset{\displaystyle OCOCH_3}{\underset{|}{C}}H-R'$$

The alkaline hydrolysis of an acyl acetal probably involves acyl-oxygen fission ($B_{AC}2$)[5] and the following mechanism is likely to hold:

$$HO^- + \underset{\displaystyle CH_3}{\underset{|}{\overset{\displaystyle O}{\overset{\|}{C}}}}-O-\underset{\displaystyle R'}{\underset{|}{C}}-OCOCH_3 \underset{\text{I}}{\overset{\text{Slow}}{\rightleftharpoons}} \left[HO-\underset{\displaystyle CH_3}{\underset{|}{\overset{\displaystyle O}{\overset{|}{C}}}}-O-\underset{\displaystyle R'}{\underset{|}{C}}-OCOCH_3\right]^- \quad (3)$$

$$\left[\quad\right]^- \overset{\text{fast}}{\underset{\text{II}}{\uparrow\downarrow}}$$

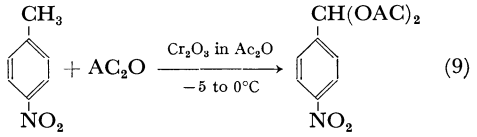
Materials

Ethylidene-, *n*-butylidene- and benzylidene diacetates were prepared by the reaction of the relevant aldehyde with acetic anhydride at a temperature of about 0 to 5°C in the presence of 0.5 per cent *ortho*-phosphoric acid as a catalyst.[6]

(8)

o-, *m*- and *p*-Nitrobenzylidene diacetates were synthesized by the method reported in the literature.[7]



(9)

Ethylidene-, *n*-butylidene-, and benzylidene diacetates were purified by fractional distillation at a reduced pressure (10 to 50 mmHg). *o*-, *m*-, and *p*-Nitrobenzylidene diacetates were purified by recrystallization using 95 per cent ethanol as a solvent. For all the esters, studied in this work, except *n*-butylidene diacetate, the physical properties are reported in the literature. The boiling point of *n*-butylidene diacetate was 106°C at 25 mmHg.

Commercial ethanol was purified by the standard method. The amount of alcohol was estimated by the dichromate method.[8]

Kinetic Measurements

The kinetics of alkaline hydrolysis of acyl acetals was studied in 90 per cent (wt/wt) aqueous ethanol as some of the esters have very low solubility in water. Further, the rate constant of some of fast reacting acyl acetals can be conveniently studied in the alcoholic medium as rate constants in 90 per cent (wt/wt) aqueous ethanol medium are substantially lower than in water. In addition, experiments were carried out at lower temperatures so that the homogeneous method could be used.

Appropriate amounts of sodium hydroxide and ester solutions were taken separately in two conical flasks and brought to the experimental temperature in the thermostatic bath where temperature could be controlled to within ±0.05°C of the desired temperature. The reactants were mixed at a noted time and aliquots were withdrawn periodically into flasks containing a known excess of standard hydrochloric acid solution to arrest the reaction. The excess acid was back titrated with standard sodium hydroxide solution to a phenolphthalein end point. The following equation was used to calculate the rate constant:

$$k_2 = \frac{2.303}{t(2a-b)} \log_{10} \frac{b(a-x)}{a(b-2x)} \cdot \frac{V}{N} \qquad (10)$$

where, a and b are the initial concentrations of the ester and alkali, in terms of m*l* of sodium hydroxide of N normality used as titrant, respectively; $(a-x)$ and $(b-2x)$ are the concentrations of these reactants at time t. V is the volume of sample withdrawn from the reaction mixture, m*l*. A plot of $\log_{10}(a-x)/(b-2x)$ against t, should give a straight line with a slope of $k_2(2a-b)/2.303 \cdot N/V$ from which the value of the rate constant, k_2, can be calculated.

For fast reacting esters which are sparingly soluble in water, the theory of diffusion accompanied by fast pseudo first order reaction was employed for studying the kinetics. The details of this method have been reported in the previous paper.[9]

Results and Discussion

In Table 1 are reported the second order rate constants for the alkaline hydrolysis of some acyl acetals. The values are very much higher than that for simple acetic esters. The higher values are due to the presence of a highly electron attracting group, –O–C–CH_3, at the α-carbon atom of the alkyl part of the ester. The nature of R′ of an acyl acetal would also influence the rate of the reaction as it is also attached to the α-carbon atom of the alkyl part. The rate would increase with an increase in the electronegativity of R′ and decrease when R′ is a bulky group.

The most recent value of rate constant for alkaline hydrolysis of methylene diacetate, reported by Euranto and Moisio[4] is 5.85 *l*/g mol sec in water at 25°C. It would be expected that the rate constant for ethylidene diacetate would be about 4.0 *l*/g·mol·sec in water at 25°C as the rate constant decreases

* Extrapolated

by a factor of about 1.5 when ethyl group is substituted at the alkyl portion instead of methyl group.[10] The value of the rate constant obtained in this work is 1.08 l/g·mol·sec in 90 per cent (wt/wt) aqueous ethanol at 25°C (extrapolated). It is likely that the rate constant increases by a factor of about 4 when water is used instead of 90 per cent (wt/wt) aqueous ethanol. Thus the estimated rate constant would be about 4.3 l/g·mol·sec.

n-Butylidene diacetate reacts at a rate lower than that of ethylidene diacetate because of the steric effect. The extrapolated value of the rate constant in 90 per cent (wt/wt) aqueous ethanol is 0.75 l/g·mol·sec at 25°C. The value of the ratio of the rate constants for ethyl and butyl acetates of about 1.35[11] may be compared with the ratio of rate constants for ethylidene and butylidene diacetates of about 1.4. Apparently the effect of steric factors for the alkaline hydrolysis of acetic esters and the corresponding acyl acetals is comparable.

The rate constant for the alkaline hydrolysis of benzylidene diacetate is nearly twice that of ethylidene diacetate. The higher rate is due to the electronegative nature of the phenyl group. The inductive effect is of the same order of magnitude as observed in the case of benzyl acetate.[12] The values of the rate constant for ethyl and benzyl acetates are 0.11 and 0.2 l/g·mol·sec, respectively, in water at 25°C.

It is obvious that substitution on the benzene ring of benzylidene diacetate would affect the value of the rate constant. Tommila and Hinshelwood[13] have studied the influence of substitution on the alkaline hydrolysis of benzoic, phenyl and benzyl esters.

The values of the rate constants for the alkaline hydrolysis of benzylidene diacetates were obtained at −5.5°C as these esters are relatively fast reacting. These values are 1.153 and 0.953 l/g·mol·sec

TABLE 2. RELATIVE INFLUENCE OF *m*- AND *p*-NITRO SUBSTITUENTS ON THE ALKALINE HYDROLYSIS OF ESTERS

No.	Ester	Solvent	Temperature °C	k_2, l/g·mol·sec			Ratio (m/p)	References
				Unsubstituted	*m*-Nitro substituted	*p*-Nitro substituted		
1	Ethyl benzoate	60% (wt/wt) aq. acetone	25	0.00289	0.1365	0.2465	0.554	13
2	Phenyl acetate	60% (wt/wt) aq. acetone	25	0.537	5.49	8.05	0.7	13
3	Benzyl acetate	60% (wt/wt) aq. acetone	25	0.0697	2.13	2.685	0.682	13
4	Benzylidene diacetate	90% (wt/wt) aq. ethanol	−5.5	0.275	0.953	1.15	0.828	This work

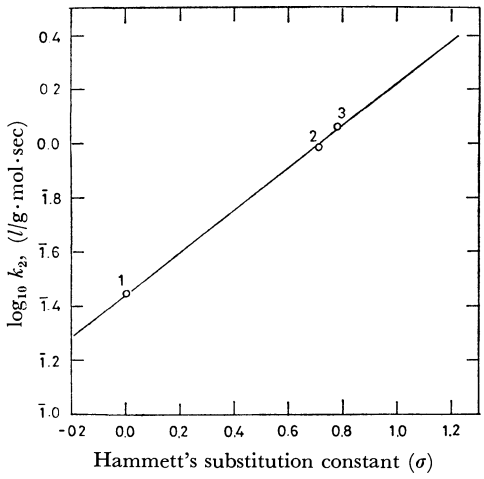

Fig. 1. Hammett's plot.
○(1) Benzylidene diacetate
○(2) *m*-Nitrobenzylidene diacetate
○(3) *p*-Nitrobenzylidene diacetate

for *p*- and *m*-nitrobenzylidene diacetates, respectively. The ratios of *m*- and *p*-substituted esters of different types are compared in Table 2.

A straight line relationship is obtained when the logarithms of the rate constants for the alkaline hydrolysis of benzylidene and *m*- and *p*-nitrobenzylidene diacetates in 90 per cent (wt/wt) aqueous ethanol at −5.5°C are plotted against the Hammett's substitution constant,[14] σ (Fig. 1). It would be necessary to investigate the kinetics of alkaline hydrolysis of some more related substituents, notably chloro- and bromo-, before it can be said that the Hammett's correlation is really applicable. Fife and Jao[15] have studied the acid catalyzed hydrolysis of acetals containing substituted benzene ring and found a straight line correlation between the logarithms of the rate cnstants and the substitution constant, σ.

Ortho Effect

It was thought desirable to investigate the effect of *ortho*-substitution on the kinetics of the alkaline hydrolysis of benzylidene diacetate. For this purpose, *o*-nitrobenzylidene diacetate was considered. *Ortho* effects arising from the proximity of the substituents to the reaction center vary with the reaction as well as with the substituents and this makes it almost impossible to represent the effect of *ortho*-substituents in the same manner as those of *m*- and *p*-substituents. The rate constant for the alkaline hydrolysis of *o*-nitro-benzylidene diacetate was found to be 0.23 *l*/g·mol·sec in 90 per cent (wt/wt) aqueous ethanol at −5.5°C which is lower than the value of 0.275 *l*/g·mol·sec for benzylidene diacetate.

Watkinson *et al.*[16] have investigated the *Ortho* effect in the alkaline hydrolysis of *Ortho* substituted ethyl phenyl acetate. The ratio of the rate constants of the unsubstituted and *o*-substituted benzylidene diacetates of 1.18, may be compared with that reported by Watkinson *et al.*[16] for unsubstituted and *o*-substituted ethyl phenyl acetates of 1.28.

Some of the acyl acetals satisfy the conditions for the applicability of the theory of mass transfer accompanied by fast pseudo first-order reaction for the determination of the rate constant for the alkaline hydrolysis of esters.[9] Solubilities of esters in water and aqueous solution of sodium chloride were determined experimentally in this work as such data are not available in literature. The results were correlated by the methods reported in the literature,[17-19] and are given in Table 3. Diffusivities of esters were estimated by the method of Wilke and Chang[20] and are reported in Table 4. The rate constants determined by the diffusion method are also reported in Table 4.

The rate constant for the alkaline hydrolysis of *n*-butylidene diacetate was found to be 2.58 *l*/g·mol·sec in the aqueous medium at 30°C (2M NaCl+1N NaOH). The value of the rate constant in alkaline solution at vanishing concentration of OH^- would be higher because of the negative salt effect. The value of the rate constant for the alkaline hydro-

TABLE 4. SPECIFIC RATES OF EXTRACTION, DIFFUSIVITIES AND RATE CONSTANTS FOR ALKALINE HYDROLYSIS OF ACYL ACETALS IN AQUEOUS SOLUTIONS

No.	Acyl acetal	Concentration of electrolytes, g·mol/l		Temp. °C	Specific rate of extraction, g·mol/cm²·sec ×10⁸	Diffusivity ×10⁶, cm²/sec	k_2 l/g·mol·sec
		NaCl	NaOH				
1	*n*-Butylidene diacetate	2	1	30	2.97	5.15	2.58
2	Benzylidene diacetate	0	0.5	30	2.94	6.46	11.5
		0	0.5	50	7.65	10.0	51.3
		0	0.5	60	14	12.1	93.6

lysis of *n*-butylidene diacetate at 30°C in 90% (wt/wt) aqueous ethanol is 0.87 *l*/g·mol·sec (Table 1). It would be expected that the rate constant in the aqueous medium would be about four times that in the aqueous medium containing 90% (wt/wt) alcohol. Thus the value of the rate constant in the aqueous medium would be expected to be about 3.5 *l*/g·mol·sec.

As the melting point of benzylidene diacetate is 46°C, the kinetics of alkaline hydrolysis was studied by the extraction of molten ester in the stirred cell at 50 and 60°C. Benzaldehyde, the hydrolysis product of benzylidene diacetate, may further react with sodium hydroxide (Cannizzaro's reaction).

$$2R'CHO + NaOH \rightarrow R'COONa + R'CH_2OH \quad (11)$$

Therefore, it was necessary to study the specific rate of extraction in aqueous sodium hydroxide for a short period (say 5 min) so that the possibility of the Cannizzaro's reaction was minimised. The rate constant was also determined at the room temperature (30°C) by the solid dissolution technique. The value of the rate constant for the alkaline hydrolysis of benzylidene diacetate was found to be 11.4 *l*/g·mol·sec at 30°C in water (Table 4). This value is about four times greater than the extrapolated value obtained by the conventional method in 90 per cent (wt/wt) aqueous ethanol at 30°C (3.16 *l*/g·mol·sec, Table 1). The energy of activation was found to be 13 kcal/g·mol.

Ethylidene diacetate did not satisfy the necessary conditions for the validity of the diffusion method as its solubility is relatively high. *o*-, *m*- and *p*-Nitrobenzylidene diacetates, on the other hand have too low a solubility to be determined accurately. In view of the above the diffusion method could not be used for these esters and conventional method was used employing 90 per cent (wt/wt) aqueous ethanol as the medium.

Studies of the Chemiluminescence of Several Xanthene Dyes. V. Blue Emission from an Excited State of a Reaction Product

Isao KAMIYA and Sadao KATO*1

Department of General Education, Nagoya University, Chikusa-ku, Nagoya

(Received July 26, 1969)

We have found that the chemiluminescence emission of several xanthene dyes with hydrogen peroxide is comprised of two emission components; one is a greenish-yellow emission whose spectral distribution is similar to that of the fluorescence of the dye, and the other is a blue emission similar to the fluorescence band which appears during the course of the reaction. Summarizing the results, we can conclude that the chemical formation of an excited species from the oxidation of a dye, and an energy-transfer process from the species to an unoxidized dye, are likely to be the mechanism for the luminescent reaction. Certain dyes, uranin, eosin Y, eosin R, erythrosin B, 2′,7′-dichlorofluorescein, mercurochrome, rhodamine B, rhodamine 6G, and rhodamine S, showed similar characteristic chemiluminescence emissions, whereas phloxine, rose bengale, 4-nitrofluorescein, 4,5,6,7-tetrachlorofluorescein, sulfonfluorescein, and pyronine G did not chemiluminesce under comparable conditions.

In the present study, we have found that the chemiluminescence emission from the reaction of several xanthene dyes with hydrogen peroxide in an alkaline solution is comprised of two emission components; one is a greenish-yellow emission whose spectral distribution is similar to that of the fluorescence of the dye, and the other is a blue emission similar to the fluorescence band which appears during the course of the reaction.

In our previous papers, though only the greenish-yellow emission component could be detected in a concentrated uranin or eosin Y system where appreciable self-absorption occurred,[1] the possibility of such a component as the blue emission from an excited product was considered[2] because the behavior of the emission (the kinetic data[3] and the enhancement effect with a foreign dye[4]) gave support to a reaction scheme; an excited species is produced by the reaction of a dye with a radical produced by the decomposition of hydrogen peroxide, and energy is transferred from the species to an unoxidized dye, thereby exciting the dye to emit fluorescence.

Eosin R, erythrosin B, 2′,7′-dichlorofluorescein, mercurochrome, rhodamine B, rhodamine 6G, and rhodamine S showed a similar characteristic chemiluminescence, whereas such dyes as phloxine, rose bengale, 4-nitrofluorescein, 4,5,6,7-tetrachlorofluorescein, sulfonfluorescein, and pyronine G did not chemiluminesce under comparable conditions.

This paper will describe our experimental results in detail and will present a discussion based on these results.

Experimental

The luminescent systems were prepared by a method essentially identical with that described previously.[3] The reaction was performed by adding 0.5 m*l* of a 20% aqueous solution of hydrogen peroxide to a mixture of 3 m*l* of an aqueous solution or a 50% dimethylsulfoxide solution of a dye (about 1.3×10^{-3} mol/*l*) and 1 m*l* of a 2N or 1/2N aqueous sodium hydroxide in a quartz cell ($10\times10\times45$ mm). The chemiluminescence spectra were measured with a Hitachi MPF-2A type fluorescence spectrophotometer (using a R-104 photomutiplier tube) equipped with a thermostatic cell assembly with water circulating at a constant temperature (40°C). The fluorescence spectra of the reaction systems were also measured by lowering the voltage of the photomultiplier, with the same apparatus with the exciting done at 380 mμ. The slit width for the chemiluminescence measurements was about 40 mμ, whereas that for the fluorescence measurements was about 10 mμ. The scan speed was 5 sec per 10 mμ, the recorded spectral curves were corrected if necessary by means of decay curves measured under the same experimental conditions.

Results

Figure 1 shows the chemiluminescence spectrum in an eosin Y system measured at several different reaction times. The results indicate that the spectrum varies during the course of the reaction. At

the initial stage, the apparent emission is composed of one intense peak at about 580 mμ, as has been reported previously.[1] During the course of the reaction, however, the intensity of the peak gradually decreases with the blue shift, and simultaneously a new peak appears at about 480 mμ until only the blue emission is observed at the final stage.

The change in the fluoresence spectrum of the chemiluminescent eosin Y system after oxidation was measured*[2] with exciting at 380 mμ. The results are illustrated in Fig. 2. It is demonstrated that the fluorescence of the system shows the same spectral change with the reaction time as does the chemiluminescence emission. When we compare

the spectral change in the chemiluminescence with that of the fluorescence, it is apparent that the greenish-yellow emission component is to be attributed to the fluorescence emission from an excited dye, and the blue-emission component to the emission from an excited species produced in the reaction.

The peak at 480 mμ of the blue-fluorescence emission was further blue-shifted to 430 mμ by successive oxidation, as is shown by the dashed line in Fig. 2, but no chemiluminescence emission appeared at this oxidation stage. Hence, it can be said that the primary excited species is an intermediate product.

The changes in both the chemiluminescence and the fluorescence spectra with the reaction time in a uranin system are shown in Figs. 3 and 4 respectively. In the system, the blue emission com-

ponent was not very appreciable. However, with regard to the intense fluorescence of unoxidized uranin at the final stage, we may say that the self-absorption of the dye prevents any blue emission from the excited product.

Eosin R, erythrosin B, 2′,7′-dichlorofluorescein, mercurochrome, rhodamine B, rhodamine 6G, and rhodamine S chemiluminesced with the same two emission peaks as were observed in the eosin Y system. Typical examples of the results are illustrated in Fig. 5-a, where they are compared with the changes in the fluorescence spectra with the reaction time (Fig. 5-b). In each case, we can clearly find a spectral correspondence between the chemiluminescence and the fluorescence emissions.

On the other hand, such fluorescent dyes as phloxine, rose bengale, 4-nitrofluorescein, 4,5,6,7-tetrachlorofluorescein, sulfonfluorescein, and pyronine G did not actually chemiluminesce under comparable conditions. However, when one of

these dyes, such as sulfonfluorescein, was added to eosin Y, the emission corresponding to the fluorescence of the added dye appeared in place of the blue emission at the final stage, as is shown in Fig. 6. This experimental evidence can best be explained in terms of an energy-transfer process from an excited product to the added dye.

Discussion

All the findings presented above give support to the following reaction scheme, suggested in the previous paper; an excited species is produced from the reaction of the dye with a radical which is itself produced by the decomposition of hydrogen peroxide, and the energy is transferred from the species to the unoxidized dye, thereby exciting the dye to emit fluorescence.

An analogous mechanism has been proposed for the chemiluminescence of lucigenin.[5] The *N*-methylacridon produced is primary the emitting species because a blue emission corresponding to the fluorescence of *N*-methylacridon was observed in a hot dilute system, whereas a greenish-yellow emission whose major component was similar to that of the lucigenin fluorescence was observed in a cold, concentrated system.[6]

On the other hand, two different types of the chemiluminescence of several dyes have been reported. The first type is the induced-chemiluminescence of anthracene, acridine, eosin Y, fluorescein, quinoline sulfate, and aesculin, which is observed when these dyes are present in the reaction of alkaline hydrogen peroxide with chlorine gas or the hypochlorite ion.[7] The suggested mechanism involves the formation of excited (singlet) molecular oxygen, which then forms an excited dimer through collision, and an energy-transfer from the dimer to these added fluorescers.[8] The second type is the visible light emission, which builds up and decays over a period of microseconds, this emission is induced when deaerated solutions of certain dyes, rhodamine B, acriflavin, fluorescein, and eosin are electron-pulse radiolysed.[9] The emission corresponds to the fluorescence of each dye. The proposed mechanism involves the processes by which the OH-adduct, DOH, reacts with the hydrated electron, e^-, to give the excited dye, D*:[10]

$$DOH + e^- \longrightarrow D^* + OH^-$$

Neither of these two mechanism is likely, for if the excited dimer of oxygen and the blue-fluorescent product were involved, as a donor and an acceptor respectively, in an energy-transfer process, the intensity of the peak at 480 mμ would increase with the increase in the concentration of the fluorescent product.[11] (We can see from Figs. 1 and 2 that the intensity of the peak of the blue component of the chemiluminescence is kept almost constant, whereas that of the fluorescence increases with the increase in the concentration of the reaction product). Moreover, a significant emission would also be observed in the systems of such fluorescent dyes as 4-nitrofluorescein, 4,5,6,7-tetrachlorofluorescein, and sulfonfluorescein. Furthermore, if the dye were primarily excited, we would not observe a blue-emission component which changes to greenish-yellow emission when sulfonfluorescein or 4-nitrofluorescein is added.

In summarizing the above results, we can conclude that the chemical formation of an excited species from the oxidation of dye, and an energy-transfer process from the species to an unoxidized dye, are most likely to compose the mechanism for the chemiluminescent reaction. Reconsidering the present experimental findings, we can develop the previously-proposed reaction scheme:[2]

Radical ($R^\cdot$) formation:

$$H_2O_2 \longrightarrow R^\cdot (O_2H^\cdot \text{ or } OH^\cdot)$$

The production of an excited species (M_E^*) by the reaction of $R^\cdot$ with a dye, for example, eosin Y (E):

$$E + R^\cdot \longrightarrow M_E^* \quad \text{(reaction rate, } k_1\text{)}$$

An energy-transfer process:

$$M_E^* + E \longrightarrow M_E + E^* \qquad (k_2)$$

Blue fluorescence emission from M_E^*:

$$M_E^* \longrightarrow M_E + h\nu_1 \qquad (k_3)$$

Greenish-yellow fluorescence emission from E*:

$$E^* \longrightarrow E + h\nu_2 \qquad (k_4)$$

Self-quenching:

$$E^* + E \longrightarrow E + E \qquad (k_5)$$

According to the above scheme, the intensity of the chemiluminescence, I_E, is given by:

$$I_E = k_3[M_E^*] + k_4[E^*] \qquad (1)$$

Using the steady-state approximation, $d[M_E^*]/dt = 0$ and $d[E^*]/dt = 0$, I_E can be written as:

$$I_E = k_1k_3[E][R^\cdot]/(k_2[E]+k_3) + k_1k_2k_4[E]^2[R^\cdot]/(k_2[E]+k_3)(k_4+k_5[E]) \qquad (2)$$

The experimental results indicate that the intensity of blue emission is almost constant. This

11) E. A. Ogryzlo and A. E. Pearson, *ibid.*, **72**, 2913 (1968).

means that the first term of Eq. (2) can be reduced to (k_1k_3/k_2) [R·] by assuming that $k_2[E]>k_3$, since [E] decreases with the reaction time. On such an assumption, I_E is finally given by:

$$I_E = (k_1k_3/k_2)[R^\cdot] + k_1[E][R^\cdot]\phi_E \quad (3)$$

where ϕ_E is the fluorescence efficiency of E and is given by:

$$\phi_E = k_4/(k_4+k_5[E])$$

As has been shown, the greenish-yellow emission is so intense, compared to the blue emission, except for the final stage, that the I_E in the decay stage can be given as approximately:

$$I_E = k_1[E][R^\cdot]\phi_E \quad (4)$$

When a foreign dye such as sulfonfluorescein (S) is added to the eosin Y system, the following steps are also present: An energy-transfer process from M_E^* to S:

$$M_E^* + S \longrightarrow M_E + S^* \quad (k_6)$$

Fluorescence emission from S*:

$$S^* \longrightarrow S + h\nu_3 \quad (k_7)$$

Quenchings:

$$S^* + S \longrightarrow S + S \quad (k_8)$$

$$E^* + S \longrightarrow E + S \quad (k_9)$$

$$S^* + E \longrightarrow S + E \quad (k_{10})$$

Taking all of the steps into account, we can write the intensity of the emission in the eosin Y-sulfonfluorescein system as follows, since no blue emission appears:

$$I_{ES} = k_4[E]^* + k_7[S^*]$$

Under stationary conditions, we can write:

$$[E^*] = k_2[M_E^*][E]/(k_4+k_5[E]+k_9[S])$$

$$[S^*] = k_6[M_E^*][S]/(k_7+k_8[S]+k_{10}[S])$$

$$[M_E^*] = k_1[E][R^\cdot]/(k_2[E+k_6[S])$$

Assuming that the quenching with a foreign dye is not appreciable compared to the self-quenching, we can write that:

$$\phi_E = k_4/(k_4+k_5[E]) \fallingdotseq k_4/(k_4+k_5[E]+k_6[S])$$

Hence,

$$I_{ES} = k_1[E][R^\cdot](k_2[E]\phi_E+k_6[S]\phi_S)/(k_2[E]+k_6[S]) \quad (5)$$

where

$$\phi_S = k_7/(k_7+k_8[S]+k_{10}[E]).$$

From Eqs. (4) and (5), we obtain:

$$\Delta = \int (I_{ES}-I_E)dt$$

$$= k_1 \int \{[R^\cdot](k_2[E]^2\phi_E-k_6[E][S])\phi_S/$$

$$(k_2[E]+k_6[S])-[E]\phi_S\}dt \quad (6)$$

Since an intense fluorescence of the dye is observed in the reaction system, we prefer the approximations that $k_4 \gg k_5[E]+k_9[S]$ and that $k_7 \gg k_8[S]+k_{10}[E]$ to the approximation used previously. Using these approximations, and recalling the results that [R·] is independent of the reaction time and that $[E]=[E]_0 \exp(-K_E t)$, we can write:

$$I_E = k_1[R^\cdot][E]_0 \exp(-K_E t) \quad (7)$$

$$\Delta = (k_1k_6[R^\cdot](\phi_S-\phi_E)[S]/k_2K_E)$$

$$\times \ln(1+k_6[S]/k_2[E]_0) \quad (8)$$

We have already shown in the previous paper that the experimental results of I_E and Δ can be reasonably explained by Eqs. (7) and (8) respectively.

However, neither the exact nature of the emitting product nor the reason why some dyes produce chemiluminescence emission, whereas others do not, is at present known. Much further work, including the chemical identification of the blue-fluorescent product, is required.

The Reactions of ^{80}Br Activated by Isomeric Transition in the Gaseous Phase. The Isotopic Variation between CH_4 and CD_4

Enzo TACHIKAWA and Toshiki KAHARA*1

Japan Atomic Energy Research Institute, Tokai-Mura, Ibaraki

(Received September 13, 1969)

The roles of the excess kinetic energy and the thermal ionic processes in the reaction of the ^{80}Br from the isomeric transition of ^{80m}Br in gaseous CH_4 and CD_4 were investigated using a rare gas additive. A possible isotope effect has appeared on the substitution reaction of the energetic Br atom to form $CH_3{}^{80}Br$ or $CD_3{}^{80}Br$, but not on the thermal processes to form $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ or their isotopic alternatives. At a zero mole fraction of moderator, the $CH_3{}^{80}Br/CD_3{}^{80}Br$ ratio for the energetic process was found to be 2.7 ± 0.3. This is consistent with the moderator and/or probability integral isotope effects. However, in a highly moderated system the results indicated that the former effect is more important than the latter. Furthermore it can be inferred from the total pressure effects on the energetic reaction products that the excited primary products are able to decompose unimolecularly due to internal excitation.

Many investigations concerning the target isotope effect on the reactions of recoil atoms have been performed using the recoil tritium atom.[1,2] However, only a few papers have appeared on the recoil Br atom. Spicer and Gordus[3] observed the isotopic variations in the total organic yield between CH_4 and CD_4 in the reaction of ^{80}Br activated by the (I.T.) process. A different attitude was taken by Nicholas and Rack,[4] who concluded that there was same dependence in kinetic energy for (I.T.)-induced ^{82}Br reactions with CH_4 and CD_4.

Experimental evidence shows that both ^{80}Br and ^{82}Br react with CH_4 *via* the energetic process to form CH_3Br and *via* the thermal ionic process to form CH_3Br and CH_2Br_2.[5] These findings, along with the results on the target isotope effect between CH_4 and CD_4 using ^{82}Br reported in a previous paper,[6] have led to these tentative conclusions: a) a target isotope effect appears in the energetic process, but not in the thermal process. b) the yield from the energetic process is higher for ^{82}Br than for ^{80}Br, while the thermal ionic reaction yield is similar for the two species.

In this paper we will deal with the target isotope effect between CH_4 and CD_4 as well as with the pressure effect using ^{80}Br activated by the (I.T.) process, since a comparative study of ^{80}Br and ^{82}Br can provide further knowledge concerning the chemical consequences of the recoil Br atom.

Experimental

The general experimental procedure is the standard one for recoil Br atom reactions, involving the formation of the ^{80}Br atom from the ^{80m}Br(I.T.)^{80}Br and the analysis of the radioactive products by radio gaschromatography.[5] The neutron irradiations were carried out in the JRR-4 in JAERI under a neutron flux of $10^{13}n/cm^2/sec$. The total pressure was always kept at 51 ± 1 cmHg throughout the series of moderator experiments. The ratio of Br_2 as a scavenger, relative to CH_4 or CD_4 was 0.11 ± 0.01.

Materials. The CH_4 was supplied by the Takachiho Chemical Co., and CD_4, by the Merck Sharp and Dohm Co. Their nominal purities were 99.995 and 99.8% respectively, and they were used without further purification. The rare gas, xenon, was obtained from the Takachiho Chemical Co., its nominal purity was 99.995%.

Sample Processing. The inorganic bromides were isolated from the organic bromides by the insertion of a short glass column packed with potassium ferrocyanide into the gas stream ahead of the organic separation column. The gas-chromatographic separations were carried out in a column containing the celite and coated with dioctyl sebacate (15% by weight).

Correction and Experimental Error. All of the data obtained have been corrected using the half-lives 4.38 hr and 17.6 min for ^{80m}Br and ^{80}Br respectively. In most cases, the activity of the products was large enough to reduce the standard deviation of counting to

a small percentage. The most serious error results from the correction of the results to the percentage yield, relative to the total activity. The product activities were measured in the flow system on radio gas chromatography. However, the total activities were measured under stationary conditions. The 17.6-min half-life is too short to obtain the correction factor between the different counting methods with a precision better than ±5%. Thus, the accuarcy of the present data is usually limited to ±5%. Moreover, in some cases where the total organic yield is relatively small, as in the case of the highly-moderated systems, the standard deviation of counting amounts to 15—20%.

Results and Discussion

Moderator Effect. The organic products observed in the reaction of gaseous CH_4 or CD_4 with the (I.T.)-activated ^{80}Br were $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ or their isotopic products. The moderator effects of Xe on these are graphically displayed in Fig. 1. The following things can be noticed in the figure. Firstly, both $CH_3{}^{80}Br$ and $CD_3{}^{80}Br$ are moderatorsensitive, although the effect of the additive is not the same, the former decreasing from 3.5±0.3% to 0.5±0.3%, and the latter, from 1.6±0.2% to 0.5±0.3%, with an increase in the mole fraction of Xe. Secondly, both $CH_2{}^{80}BrBr$ and $CD_2{}^{80}BrBr$ show a constant yield of 1.1±0.2% over the whole range of the mole fractions of the moderator. Under the present experimental conditions, the yield is 3.5−0.5=3.0% for $CH_3{}^{80}Br$ and 1.6−0.5=1.1% for $CD_3{}^{80}Br$ as formed *via* the energetic Br for H and Br for D processes respectively. Thus, the isotopic variation between them is obtained as 2.7±0.3, a value which is very consistent with the value, 2.8±0.2, found using ^{82}Br instead of ^{80}Br.[6] These results imply that the overall isotope effect between CH_4 and CD_4 is 2.7±0.3 for the energetic reaction of both ^{80}Br and ^{82}Br, although the absolute yield is always higher for ^{82}Br than for ^{80}Br by a factor of 1.5±0.2.[5]

In a previous paper[5] we attempted to ascribe the difference in the absolute yields between ^{82}Br and ^{80}Br to the difference in kinetic energies between them. The γ-transition of ^{82m}Br to the ground state is attained in a single transition, whereas ^{80m}Br is converted by two successive transitions. If the excited ^{80}Br resulting from the first transition enters into a chemical combination with the surrounding molecules within its lifetime, a kinetic energy achieved on ^{80}Br in the successive transition of the excited ^{80}Br is very much dependent upon the remainder of the molecule.[7,8]

From the results, the thermal yields are found to be 0.5±0.3% for $CH_3{}^{80}Br$ or $CD_3{}^{80}Br$ and 1.1±0.2% for $CH_2{}^{80}BrBr$ or $CD_2{}^{80}BrBr$. The ratio between them is 0.45±0.08. Again, these results are in good agreement with those found using ^{82}Br,[5] suggesting that the relative ionization potential of the reactant is the main factor controlling the thermal ionic reactions. Thus, as long as the difference in the ionization potentials between CH_4 (13.12 eV) and CD_4 (13.26 eV)[9] or between ^{80}Br and ^{82}Br is small enough to be ignored, compared to that between CH_4 and Br, it seems that no isotope effect appears as either a target or as a reacting one in the thermal ionic process.

Spicer snd Gordus[3] observed the isotopic variations of the total organic yields between CH_4 and CD_4 as 1.4 ± 0.2. This value is not directly compared with the present value of $(3.5+1.1)/(1.6+1.1)=1.7\pm0.2$, since the amounts of Br_2 added as a scavenger are greatly different between their system and ours. However, the qualitative conclusion that the target isotope effect exists between CH_4 and CD_4 in the reaction of Br activated by the (I.T.) process can be drawn from both experiments. Contrarily, Nicholas and Rack observed no difference in the total organic yields from CH_4 and CD_4 using ^{82}Br, within the range of experimental uncertainty.[4] Unfortunately, it is not immediately possible to explain this contradiction.

Origin for the Isotope Effects. Extensive research into the isotope effects on the energetic reactions has been made using the recoil tritium atom. Several possible sources have been suggested for the variations in the yields measured for isotopic molecules.[10-12] If the energy losses in non-reacting collisions are not same for the two molecules, the isotopic variation can be observed. These differences are called "moderator isotope effects." On the other hand, the isotopic variation may still be expected if the reactivity integrals are not identical for the isotopic molecules. They can be grouped as "probability integral isotope effects." Another possible source is the "average-energy effect" resulting from the differences in the average energy for the reactions. All three effects may influence the energetic reaction of the Br atom and produce the observed differences in the yields from CH_4 and CD_4 molecules. However, the similar CH_3Br/CD_3Br ratios in the energetic processes for both ^{80}Br and ^{82}Br imply that the observed isotopic variations result from the same origins.

The "average-energy isotope effect" may be excluded, since it is only considered when the energetic *Br for H* and *Br for D* reactions compete with each other in the same reaction system. In such a system, the flux of the recoil Br atom surviving to lower energies can be noticeably diminished by a higher-energy reaction. Therefore, fewer energetic reaction may be observed with the lower-energy process than with the higher one.

Thus, the present results are consistent only with the "moderator isotope effect" and/or the "probability" one. One of the experimental approaches for distinguishing the "moderator isotope effect" from the "probability integral effect" is to use a single molecule containing both protium and deuterium. In this way, the same energy spectrum of the energetic Br atom can be used for both reactions; therefore, the "moderator isotope effect" is excluded. The second approach is to control the Br spectrum experimentally by the addition of a large excess of the third molecule.[13] In the limiting case of this type of approach, the reactant represents a negligible fraction of each sample. Therefore, the energetic reaction with a reactant would represent a negligible fraction of the total reaction and the non-reacting energetic Br collisions with the molecule would be completely unimportant. In such an ideal system, the reactant molecules would introduce only infinitely small perturbations to the total Br flux at each energy level, the total energetic yiels would, then, be a direct measure of the ease of the reactions.

Table 1. Yields of products from the reaction of ^{80}Br with CH_4 or CD_4 at high moderation with Xe

Br_2 (cmHg)	CH_4 (cmHg)	Xe (cmHg)	$CH_3{}^{80}Br$ (%)	$CH_2{}^{80}BrBr$ (%)
5.0	5.4	41.1	0.53 ± 0.03	0.71 ± 0.04
5.0	5.3	40.7	0.46 ± 0.02	0.65 ± 0.03
			av. 0.50 ± 0.04	0.68 ± 0.03
Br_2	CD_4	Xe	$CD_3{}^{80}Br$	$CD_2{}^{80}BrBr$
5.0	5.2	40.0	0.39 ± 0.02	0.71 ± 0.04
5.0	5.2	39.9	0.34 ± 0.02	0.68 ± 0.03
			av. 0.37 ± 0.03	0.70 ± 0.03

Table 1 shows the yields from the systems consisting of 0.8 m.f. of Xe, 0.1 m.f. of Br_2, and 0.1 m.f. of CH_4 or CD_4. The experiments are quite far from the ideal because the total reaction with a reactant is not negligible and the flux perturbation cannot be ignored. However, these conditions are the closest that we could attain experimentally. Thus, if the calculations are carried out as though the samples were actually of this ideal limiting type, a difference has been noticed between $CH_3{}^{80}Br$ and $CD_3{}^{80}Br$, but not between $CH_2{}^{80}BrBr$ and $CD_2{}^{80}BrBr$. By assuming that the $CH_3{}^{80}Br$ or $CD_3{}^{80}Br$ formed *via* the thermal ionic process is 45% of the total $CH_2{}^{80}BrBr$ or $CD_2{}^{80}BrBr$ (see Fig. 1), the thermal yield of the mono-substituted products can be extimated to be $0.69\times0.45=0.31$ (%). Thus, the yields of $0.50\%-0.31\%=0.19\%$ for $CH_3{}^{80}Br$ and of $0.37\%-0.31\%=0.06\%$ for $CD_3{}^{80}Br$ are assigned to the energetic process. The ratio between them is 3.2 ± 0.3; this is in the range of the value (2.7 ± 0.3) found in the system containing no moderator. Thus, it can be concluded that the isotope effect observed in the energetic reaction results mostly from the "probability integral isotope effect."

Reaction Mechanisms Resulting in Isotopic Variations. The "probability integral isotope effect" observed in the replacement of the H or D atom by the Br atom could be either the result of the isotopic difference between the atoms replaced (the primary isotope effect) or between the CH_3 and CD_3 residues with which the Br atom then combines (the secondary isotope effect). The bond strength of C–H and C–D have been reported to be 4.45+0.02 eV and 4.56+0.03 eV respectively.[14] The C–H bond-dissociation energy has been shown to be correlated with the abstraction reaction of the recoil tritium atom,[13,15] but no definite correlation of it with the substitution reaction has yet been reported.[16] Instead, Rowland *et al.*[1] have suggested that the more rapid relaxation of the H atoms than D atoms into positions favorable for the successful bonding of the T atom is responsible for the observed isotopic variation in the recoil tritium substitution reactions. Moreover, the tendency in hot halogen reactions with alkanes for the reactivity of halogen atoms to decrease as the size of the halogen increases[17] has been ascribed to the ease with which the atoms can change direction in response to a newly-available chemical composition.[18] Thus, by analogy with this concept, it is possible that the fact the relaxation time for a new chemical bond is a controlling factor is also responsible for the present results. However, more work is required to clarify the reaction mechanisms of the substitution reaction of the energetic Br atom in detail.

Pressure Dependency of Products. The substitution of an energetic atom into a molecule is usually accompanied by a high excitation of the products. The excited molecule is able to undergo a secondary decomposition or isomerization, as detected by a pressure-dependent competition between the collisional stabilization and the secondary reaction, as in recoil tritium and other halogen experiments.[18-20] Recently, Spicer and Wolfgang[17]

obtained negative evidence for a unimolecular decomposition of the $CH_3{}^{39}Cl$ and $CH_2{}^{39}Cl\cdot$ formed by the reaction of recoil ^{39}Cl with CH_4 and suggested that a collisional decomposition of hot molecules was involved.

Thus, it seemed that it would be very interesting to examine the pressure effects of the products from the present system. If a unimolecular decomposition of the excited $CH_3{}^{80}Br$ or $CD_3{}^{80}Br$ occurs, the splitting of the C–Br bond is most probable, since it is the weakest bond in the molecule (2.93 eV). However, in our radiochemical method of approach, a decomposition reaction is traced only through the fragment containing the radioactive atom. Under these conditions, no experimental procedures are available to trace the decomposition reaction of $CH_3{}^{80}Br$ or $CD_3{}^{80}Br$.

The results of a series of measurements of the yields *vs.* the total pressure is shown in Fig. 2. The results provide evidence for the pressure dependency of both $CH_3{}^{80}Br$ and $CD_3{}^{80}Br$. Pressure effects are also noticed on both $CH_2{}^{80}BrBr$ and $CD_2{}^{80}BrBr$. This suggests that the observed pressure dependency of $CH_3{}^{80}Br$ and $CD_3{}^{80}Br$ is partly due to the increase in the thermal ionic yields with an increase in the pressure. As an approximation, by assuming that the thermal ionic yields of these mono-substituted methanes are 45% of the $CH_2{}^{80}BrBr$ or $CD_2{}^{80}BrBr$ throughout the pressure range, $CH_3{}^{80}Br$ and $CD_3{}^{80}Br$ from the energetic process are estimated to be as is shown in Table 2. The yields increase with the pressure at the beginning and then tend to flatten out, suggesting that the excited $CH_3{}^{80}Br$ and $CD_3{}^{80}Br$ are stabilized through the collisional removal of the excitation energy. At low pressures, a considerable fraction of the energetic substitution products seems to decompose. The observed pressure dependency indicates the life-time of these species in the 10^{-8}—10^{-9} sec range. Furthermore, from the smaller significance of the pressure effect on the higher pressure side, it can be inferred that, at pressures of more than 50 cmHg, the excited $CH_3{}^{80}Br$ or $CD_3{}^{80}Br$ can be stabilized well. However, no highly-excited molecules having a life-time much shorter than 10^{-9} sec will be subjected to the present pressure effects.

On the other hand, the behavior of the thermal products in response to the pressure are consistent with either the increase in the collisional frequency of $CH_4Br^{+1}*$ and $CD_4Br^{+1}*$[21] the plausible primary reaction products ($Br^{+1}+CH_4$ or $CD_4=CH_4Br^{+1}*$ or $CD_4Br^{+1}*$), with their surroundings or the collisional stabilization of the products. Unfortunately, on the basis of the present experiments alone it is impossible to distinguish which process is involved here.

The authors are very grateful to Dr. K. Motojima and Dr. M. Koike for their encouragement during the course of the work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1298—1302 (1970)

The Anodic Oxidation of a Propionate-Propionic Acid Solution in the Presence of Several Organic Compounds

Akira KUNUGI, Toshiyuki SHIMIZU and Shigeo NAGAURA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received September 26, 1969)

The anodic oxidation of the propionate anion in aqueous solutions of propionic acid at a platinum electrode has been studied in the presence of several organic compounds in order to demonstrate the formation of both propionoxy and ethyl radicals as the reaction intermediates. One of the following organic compounds was added to each solution: two vinyl monomers (acrylic acid and acrylamide), two alkylbenzenes (toluene and cumene), and two aliphatic alcohols (methanol and isopropanol). The electrooxidation of sodium propionate in the presence of acrylamide resulted in polymerization, which was confirmed to be initiated by the ethyl radical. Acrylic acid, unlike acrylamide, gave no polymers. In this case, both the current efficiency for the formation of carbon dioxide and the yield ratio of ethylene to carbon dioxide were always less than those observed in the absence of acrylic acid. While the addition of alcohols gave no definite results, the addition of toluene or cumene resulted in an appreciable decrease in the yield ratio of ethylene to carbon dioxide, but affecting neither the ratio of ethane to carbon dioxide nor the current efficiency for the carbon-dioxide evolution. These results indicate that the anodic oxidation of the propionate anion proceeds through the consecutive formation of propionoxy and ethyl radicals as the reaction intermediates.

Although many studies have been made of the electrolytic Kolbe reaction, work has mainly been restricted to the acetic acid-acetate system. A few papers have been published on the propionate system.[1-4] The acetate system seems, however, somewhat exceptional in the series of straight-chain fatty acids, because, for instance, the yield efficiency of ethane is exceptionally high (90%) and no olefinic compound is found in the products. Putting aside the acetate system, the relative yield of alkenes increases and that of alkenes generally decreases with an increase in the carbon numbers in the series of straight-chain fatty acids.[5] Accordingly, it might be expected that the propionate system is more adequate for the Kolbe reaction than the acetate system.

The purpose of the present paper is to elucidate in detail the mechanism of the anodic oxidation of the propionate anion in aqueous solutions containing propionic acid. The effects of the presence of several organic compounds on the anodic oxidation of the propionate anion have been studied. Particular attention was paid to the current efficiency for the evolution of carbon dioxide and to the relative yield of ethane and ethylene to carbon dioxide.

Experimental

Reagents. Reagent-grade sodium propionate, methanol, toluene, and sodium hydroxide were used without further purification. Propionic acid, acrylic acid, cumene, and isopropanol were distilled under reduced pressure. The acrylic acid distilled was stocked in an ice box. Reagent-grade acrylamide was recrystallized from benzene and dride at about 60°C.

Solutions. An aqueous solution containing 2M propionic acid and 2M sodium propionate was used as the base solution (pH 4.8) for the experiments using acrylic compounds or alcohols. Each solution was made up to 1 or 0.5M. In the case of acrylic acid, sodium hydroxide was added to maintain the same pH as that of the base solution. Toluene and cumene were dissolved in 95% aqueous solutions of propionic acid containing 1M sodium propionate.

Apparatus. The electrolytic cell used in the present experiment was an H-shaped glass vessel having anode and cathode compartments separated by a sintered glass disk. The temperatures were 25 ± 0.3°C for the voltammetric experiments and 5—10°C for the macroscale electrolysis. The electrode used for the voltammetric measurements was a smooth platinum wire, 1.1 cm in

length and 0.03 cm in diameter, sealed at one end of a soft glass tube. The other end of the electrode was fused into a small glass bead to avoid any edge effect. The electrode was then subjected to repeated anodic and cathodic polarizations in a 10% sulfuric acid solution. The electrodes used for the macroscale electrolysis were cut from a sheet of platinum foil and spot-welded to a platinum wire.

Procedures. Cyclic voltammograms were obtained with a Nichia Keiki-type HE-Potentiostat in conjunction with a triangular sweep function generator and with an X–Y recorder, Model XYR–IA, of Toa Denpa, Ltd. Macroscale electrolysis were mainly using a Yanagimoto Model VE-3 controlled potential electrolyser. The current was recorded with a potentiometer-type recorder. The total quantity of electricity passed through was graphically determined.

In the polymerization experiment, the solution was agitated by bubbling in oxygen-free nitrogen gas before and during the electrolysis. The polymerization products were precipitated by adding a large amount of methanol. The precipitate was purified by repeated dissolution and precipitation, and was finally dried for weighing.

Gases evolved from the anodic chamber were collected in a gas buret. The first 60 cc portion of the gas was thrown away in order to avoid any error caused by air in the dead space. The composition of the sample gas was analysed by means of a Yanagimoto GCG-220 gas chromatograph equipped with an active charcoal column. The current efficiency for the formation of carbon dioxide was calculated by assuming that one mole of the gas corresponds to two faradays.

All the potential measurements are referred to the SCE with a salt bridge.

Results and Discussion

Cyclic Voltammetry. Shukla[3] reported that the current-potential curves for the propionate oxidation were monotonous and that the anode potential increased with an increase in the current density applied. This is in contrast with the curves observed with acetate, which exhibit a shoulder prior to the final rise of the current. The current-potential curve for the propionate oxidation has, therefore, been re-examined using the potential sweep method. When the anode potential was swept from 0.4 to 2.5 V (*vs.* SCE), the curve in the first sweep was monotonous, but a shoulder appeared at about 2.0 V in the succeeding sweeps. The critical potential*1 was dependent on both the sweep rate and propionate concentration, as in the case of the acetate oxidation.[6]

In Fig. 1, similar curves obtained with acrylic acid and acrylamide are shown by curves B and C respectively. It should be noted that the curve B, which was obtained in the presence of acrylic acid, exhibits a shoulder at a higher potential region than the curve A. Such a shoulder is not seen, however, in the curve C for the acrylamide solution. Similar behavior in acrylic compounds was observed in the acetic acid-acetate system,[7] although the reason why the critical potential shifted was uncertain.

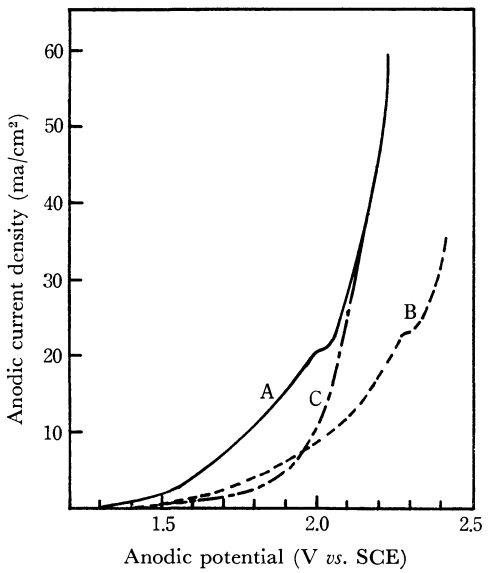

Fig. 1. Current-potential characteristics of aqueous propionate solutions with and without vinyl monomers.

Electroinitiated Polymerization. In order to examine whether or not the anodic oxidation of propionate proceeds through the radical intermediate, a series of experiments on the electropolymerization of acrylic acid in aqueous propionate solutions has been carried out. The electrolysis of solutions containing 1M sodium propionate, 1M propionic acid, and 1.9M acrylic acid under constant-current conditions gave polymers in the cathodic chamber. No polymerization was observed in the anodic chamber, even when the anode potential was as high as 2.5 V (*vs.* SCE). When acetate was used in place of propionate, olygomers were obtained in the anodic chamber under similar conditions.[8] The reason why no polymer was obtained with propionate could be attributed to the fact that neither radical species was included in the anodic process of propionate, or to the fact

that the products formed were of a very low molecular weight, such as the dimer or the trimer.*2

In order to make this point clear, gases evolved from the anodic chamber were analysed. Table 1 summarizes the experimental results on the propionate solution with and without acrylic acid. It is evident from the table that there is a marked decrease in the current efficiency for the formation of carbon dioxide when acrylic acid is present. The yield ratio of ethylene to carbon dioxide also decreases in the presence of acrylic acid. This probably indicates that both propionoxy and ethyl radicals attack the acrylic acid molecule to form its dimers or trimers. It seems, therefore, probable to assume that acrylic acid itself does not participate in the charge-transfer reaction and that the propionate ion is the only species which is electroactive. Exploratory experiments showed that the anodic oxidation of acrylic acid (1.0M) at 2.6 V in a 0.5M sodium hydroxide solution at 25±3°C resulted in a minor formation of carbonaceous compounds, while gases consisting mainly of oxygen (more than 95%), plus minor portions of carbon dioxide, ethylene, acetylene, and carbon monoxide, were detected.

A series of studies of the electroinitiated polymerization was undertaken, using acrylamide as a monomer. With this substance, polymers were obtained in both the anodic and the cathodic chambers. The polymer yields at the anode electrode were found to increase linearly with increases in the concentrations of both propionate and acrylamide. When sodium sulfate and sulfuric acid were used in place of sodium propionate and propionic acid as electrolytes, the polymerization of acrylamide did not occur, suggesting that the presence of the propionate anion is essential for the polymerization. In addition, the presence of *p*-benzoquinone was found to inhibit the polymerization totally. This indicates that the polymerization of acrylamide under the present conditions was initiated by radicals originating from the propionate oxidation, while, on the other hand, *p*-benzoquinone trapped radicals to inhibit the polymerization.

The analysis of gases evolved from the propionate-acrylamide system showed that the addition of acrylamide resulted in a decrease in the yield ratio of ethylene to carbon dioxide. No appreciable change was observed in the current efficiency for the formation of carbon dioxide (see Table 1). On the basis of these findings, it can be concluded that the polymerization of acrylamide is initiated by the ethyl, not by propionoxy, radicals.

Effect of Aromatic Hydrocarbons. The base solution used in the experiment described here was composed of propionic acid containing 1M sodium propionate and 5% water. A desired quantity of the aromatic compounds was dissolved in this solution. Upon the electrolysis of the base solution, the anodic gases produced were almost entirely carbon dioxide and ethylene in a mole ratio of approximately 1 to 0.35. The formation of carbon dioxide required 2 F per mole. Other gaseous products (oxygen, ethane, and carbon monoxide) were also found (see Table 2). The addition of two aromatic hydrocarbons, toluene and cumene, to

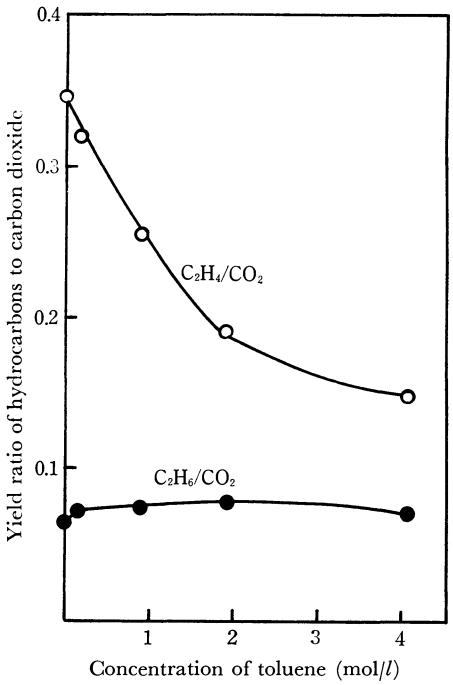

Fig. 2. The effect of the concentration of toluene added on the composition of gases evolved. Solution: 1.0M sodium propionate in propionic acid containing 5% water.

the solution resulted in profound changes in the composition of the gases produced during the electrolysis (see Table 2). The following discussion is based on the assumption that either the aromatic substrates examined in the present study are totally inactive to the electrooxidation or, even if they were oxidized, the oxidation is incomplete and no carbon dioxide is formed. If this assumption is acceptable, the determinations of the relative yields of the gases evolved, namely, ethane to carbon dioxide and ethylene to carbon dioxide, will serve as a sensitive means for the discussion of the mechanism of the reaction concerned. If the ethyl radical originating from propionate abstracts the hydrogen atom in the aromatic substrate, the ethane to carbon dioxide ratio will increase and the ethylene-to-carbon dioxide ratio will decrease. On the other hand, if the radical species effective in the hydrogen abstraction is propionoxy instead of the ethyl radical, the yield ratio of ethane to carbon dioxide will remain constant and the ratio of ethylene to carbon dioxide will vary with the type of termination reaction.

The experimental results are summarized in Table 2 and also in Fig. 2. It is evident from the table that the ethylene-to-carbon dioxide ratio is significantly decreased, while the ethane-to-carbon dioxide ratio was unchanged, when toluene or cumene was present. It should be noted that the ethan formation was not affected by changing the aromatic substrate from toluene to cumene, since it is accepted[9] that the rate of hydrogen abstraction is much greater in cumene than toluene. The current efficiency for the carbon dioxide evolution was found unaffected by the presence of the aromatic substrates. The results in Fig. 2 indicate that the ethylene-to-carbon dioxide ratio decreases and the ethane-to-carbon dioxide ratio increases, though slightly, with an increase in the concentration of toluene. Accordingly, two possibilities can be considered: (1) the hydrogen atom is abstracted from the side chain of aromatic substrates by the propionoxy radical, and the resultant benzyl radical combines with the ethyl radical, and (2) hydrogen abstraction occurs at the aromatic ring by means of the propionoxy radical and the aromatic radical so generated combines with the ethyl radical.

Ross and his co-workers[10] have reported that, when the acetic acid-acetate system was electrolyzed in the presence of ethylbenzene, the methylation occurred to both the side chain and the aromatic ring with greater ease than with the side-chain methylation. This indicates that the possibility (1) is the preferred reaction mode. The anodic oxidation of the propionate ion in the presence of an aromatic substrate, *e.g.*, toluene, can thus be considered to proceed in the following manner:

$$2C_2H_5CO_2^- \longrightarrow 2C_2H_5CO_2\cdot + 2e$$

$$C_2H_5CO_2\cdot \longrightarrow C_2H_5\cdot + CO_2$$

$$C_6H_5CH_3 + C_2H_5CO_2\cdot \longrightarrow C_6H_5CH_2\cdot + C_2H_5CO_2H$$

$$C_6H_5CH_2\cdot + C_2H_5\cdot \longrightarrow C_6H_5CH_2C_2H_5$$

Effect of Alcohols Added. Fioshin *et al.*,[11] have reported the effect of alcohol addititives on Kolbe's electrosynthesis. The addition of aliphatic alcohols up to hexanol to aqueous solutions of acetate or mono-methyl adipate increased the yields of ethane or di-methyl sebacate. In the present experiment, however, no such definite effects nor any others of alcohols were observed, as is shown in Table 3.

Mechanisms of the Anodic Oxidation of Propionate. The foregoing discussion revealed that both the propionoxy and ethyl radicals are involved in the anodic oxidation of the propionate anion. It was also confirmed that the yield ratio of ethylene to carbon dioxide was approximately unity, that the ratio of ethane to ethylene was very small (*ca.* 10^{-2}), and that a charge of 2 F was required for the formation of 1 mol of carbon

Isopropanol (1.0M)	6.6	trace	51.4	41.4	0.5	70.2	0.81

dioxide. Therefore, two mechanisms can be considered for the formation of ethylene, *i.e.*:

I) Disproportionation reaction;

a) $2C_2H_5CO_2^- \longrightarrow 2C_2H_5CO_2\cdot + 2e$

b) $C_2H_5CO_2\cdot \longrightarrow C_2H_5\cdot + CO_2$

b′) $C_2H_5CO_2\cdot + C_2H_5\cdot \longrightarrow C_2H_4 + C_2H_5CO_2H$

II) Decomposition reaction;

$$C_2H_5CO_2^- \longrightarrow C_2H_5CO_2 + e$$
$$C_2H_5CO_2\cdot \longrightarrow C_2H_5\cdot + CO_2$$
$$C_2H_5\cdot \longrightarrow C_2H_4 + H$$
$$H \longrightarrow H^+ + e$$

or

$$C_2H_5\cdot \longrightarrow C_2H_4 + H^+ + e$$

At the present stage, it is impossible to differentiate the two mechanisms without ambiguity. Wilson and Lippincott[2] have suggested, though, that the anodic formation of ethylene proceeds through a second-order reaction with respect to the reaction intermediate. If this is the case, and if the intermediate with which they are concerned is the propionoxy radical, the mechanism I seems more likely.

On the other hand, the formation of ethane can be accounted for by the radical reactions shown below, where RH is the solvent or solute molecules:

III) $C_2H_5\cdot + C_2H_5\cdot \longrightarrow C_2H_6 + C_2H_4$

IV) $C_2H_5\cdot + RH \longrightarrow C_2H_6 + R\cdot$

Considering the fact that, in the electrolytic oxidation of anions of saturated aliphatic acids, the yield ratio of paraffins to olefines increases with an increase in the carbon numbers in the series of acids, the reaction III seems more favourable for the formation of ethane.

Although ethylene is formed in two ways, *i.e.*, disproportionation between two ethyl radicals (III) and disproportionation between propionoxy and ethyl radicals (I-b′), Reaction I-b′ might be concluded to be the dominant one because of the one-sided formation of ethylene *vs.* ethane.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1303—1306 (1970)

The Solution Properties of Poly-*o*-methylstyrene

Kimiyoshi MATSUMURA

Department of Chemistry, Aichi Kyoiku University, Nagoya

(Received October 11, 1969)

The solution properties of poly-*o*-methylstyrene in toluene were measured by the light-scattering and viscosity methods, and the results were compared with those obtained from poly-*o*-chlorostyrene and other polystyrene derivatives. The dependencies of the intrinsic viscosity, the second virial coefficient, and the end-to-end distance of the polymer chain on the molecular weight are as follows:

$$[\eta] = 9.22 \times 10^{-5} \cdot M_w^{0.72} \text{ (dl/g)}, \quad A_2 = 3.89 \times 10^{-2} \cdot M_w^{-0.38} \text{ (mol·cc/g}^2\text{)}$$

and $\langle L^2 \rangle^{1/2} = 0.197 \times M_w^{0.62}$ (Å).

It was made clear that the unperturbed dimension of poly-*o*-methylstyrene was larger than that of poly-*p*-methylstyrene, and that the cause of this difference is the large steric repulsion between the side groups of the former. Moreover, the unperturbed dimension of poly-*o*-methylstyrene was smaller than that of poly-*o*-chlorostyrene. From these results, it is considered that the large extension of poly-*o*-chlorostyrene was affected by the electrostatic repulsion between the side groups.

Many authors have reported on the solution properties of polystyrene and its derivatives. These polystyrene derivatives are mainly *p*-substituted polymers, and the results of the experiments show that the unperturbed dimension of the polymer-chain skeleton is affected not by the electrostatic interaction between the substituents placed on the *p*-position of polystyrene, but by the volume of the side group, the *p*-substituted phenyl group, of the polymer.

In a preceeding paper[1] the present author reported his experimental results on poly-*o*-chlorostyrene, which showed that the unperturbed dimension is larger than that of poly-*p*-chlorostyrene. However, the reason for the difference between these two polymers was not made clear.

In this report, by means of light-scattering and viscosity measurements of the poly-*o*-methylstyrene solution, the effect of the substituent on the polymer-chain dimensions are compared with the findings for poly-*o*-chlorostyrene.

Experimental

Sample. The poly-*o*-methylstyrene was prepared from *o*-tolylmethylcarbinol, which had itself been obtained by the Grignard reaction of *o*-bromotoluene and acetaldehyde, by dehydration with potassium bisulfate; bp 34—36°C/4 mmHg.

The monomer was polymerized by heating it in a sealed tube at 90°C for 150 hr without any initiator. The conversion rate was about 60%. The polymer was a jelly-like substance. The polymer was dissolved in hot benzene (*ca.* 20 g/*l*), and the solution was fractionated at 30°C by subsequent precipitation with methanol. Twenty fractions were obtained. They were redissolved in benzene, reprecipitated with methanol, and dried under reduced pressure.

The toluene, used as the solvent, was purified by the method described in a previous paper.[1]

It seemed that poly-*o*-methylstyrene would dissolve in toluene at room temperature. However, the flow time of the solution in the viscometer decreased with the time of heating at 30°C, showing a constant value only after about 18 hr, as is shown in Fig. 1, in which the sample used for the test of the flow time was the fraction 1-1 and the concentration of the solution was about 0.5 g/dl. Therefore, the toluene solution used for the measurements were prepared by heating it at 35—40°C for about 20 hr.

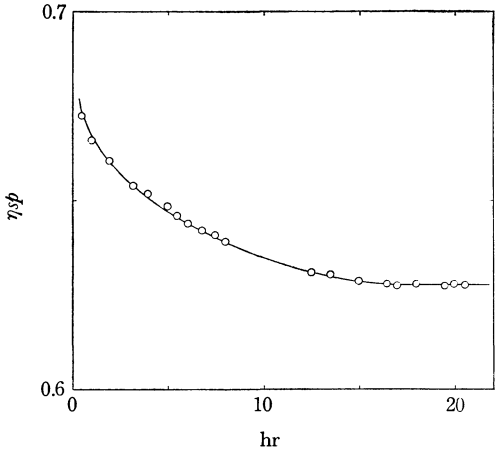

Fig. 1. Relation between the specific viscosity and time of heating at 30°C, for poly-*o*-methylstyrene (Frac. 1-1) in toluene (0.5 g/dl).

TABLE 1. THE EXPERIMENTAL RESULTS OF THE LIGHT-SCATTERING AND VISCOSITY MEASUREMENTS FOR POLY-*o*-METHYLSTYRENE IN TOLUENE AT 30°C

Fraction	$M_w \times 10^{-4}$	$A_2 \times 10^{-4}$ $(\frac{\text{mol ml}}{g^2})$	$\langle L^2 \rangle^{1/2}$ (Å)	$[\eta]$ $(\frac{dl}{g})$	k'	$\phi \times 10^{-21}$
1-2	43.0	2.64	616	1.047	0.31	1.9
1-3	42.2	2.90	613	1.023	0.32	1.9
2-1	32.0	3.17	494	0.867	0.34	2.3
2-2	22.2	3.85	416	0.651	0.31	2.0
3-2	17.6	3.86	355	0.564	0.36	2.2
4	14.6	4.25	311	0.476	0.38	2.3
5	10.2	4.80	251	0.368	0.38	2.4

Measurements. A Shimadzu photometer was used for the measurement of the light-scattering of the solutions. The measurements were carried out at 30°C by the use of the 436 mμ and 546 mμ of wavelengths and covering the angular range 40—140°. The increments of the refractive index of the solution with the concentration, dn/dc, were measured at 30°C with the wavelengths of 436 mμ and 546 mμ.

For the viscosity measurements of the solutions at 30°C, a modified Ubbelohde viscometer was used. At 30°C the flow time of toluene was 270.1 sec in this viscometer.

Results and Discussion

Results. By means of the light-scattering measurements, the weight-average molecular weight, M_w, the second virial coefficient, A_2, and the root-mean-square end-to-end distance of the polymer chain, $\langle L^2 \rangle^{1/2}$, were obtained according to the ordinary method by means of a Zimm plot for each fraction. The observed values of dn/dc were 0.120 ml/g for the 436 mμ wavelength and 0.116 ml/g for 546 mμ. An example of the Zimm plot, that for the fraction 1—3 of poly-*o*-methylstyrene in toluene at 30°C for 436 mμ, is shown in Fig. 2.

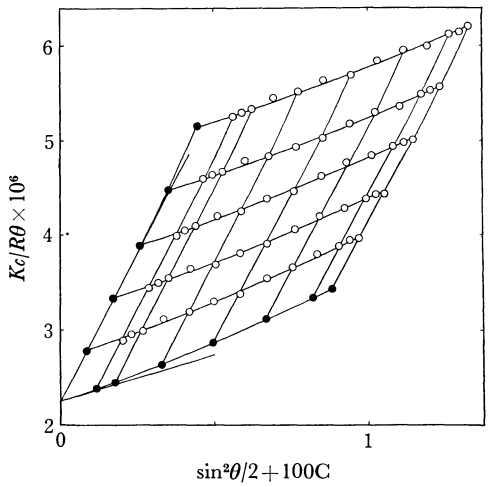

Fig. 2. Zimm plot for poly-*o*-methylstyrene 1—3 in toluene at 30°C for 436 mμ.

Through the viscosity measurements, the intrinsic viscosity, $[\eta]$, and the Huggins constant, k', shown in Fig. 3 are obtained.

These results are shown in Table 1.

The molecular-weight dependencies of $[\eta]$, A_2, and $\langle L^2 \rangle^{1/2}$ are obtained by means of the log–log relations between M_w and these values; they are shown in Figs. 4, 5, and 6 respectively. By the least-squares method, these relations are found to be as follows:

$$[\eta] = 9.22 \times 10^{-5} \cdot M_w^{0.72} \text{ (dl/g)},$$
$$A_2 = 3.89 \times 10^{-2} \cdot M_w^{-0.38} \text{ (mol·cc/g}^2\text{)},$$
$$\langle L^2 \rangle^{1/2} = 0.197 \times M_w^{0.62} \text{ (Å)}.$$

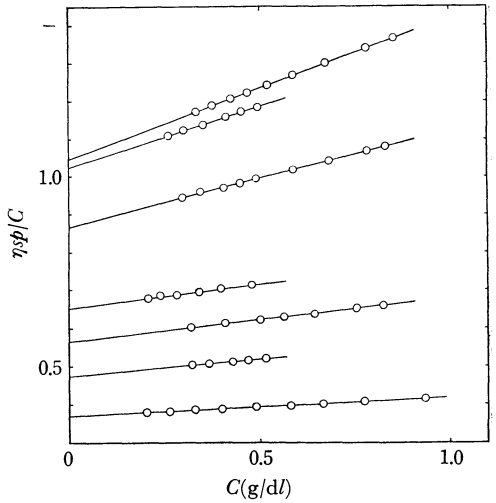

Fig. 3. Relation between reduced viscosity and concentration of poly-*o*-methylstyrene in toluene at 30°C.

TABLE 2. THE EFFECT OF TOLUENE ON THE EXPANSION OF POLY-*o*-METHYLSTYRENE AND POLYCHLOROSTYRENES P_w =4240

Polymer	Temp(°C)	$\{\langle L^2 \rangle / \langle L^2 \rangle_0\}^{1/2}$
Poly-*o*-methylstyrene	30	1.47
Poly-*o*-chlorostyrene	35	1.41
Poly-*m*-chlorostyrene	35	1.57
Poly-*p*-chlorostyrene	room temp.	1.48

Discussion. The dotted lines in Figs. 4—6 show the relations between M_w and $[\eta]$, A_2, and $\langle L^2\rangle^{1/2}$ of poly-*o*-chlorostyrene, in toluene at 30°C.[1] For the same molecular weight, these poly-*o*-methylstyrene values are larger than those of poly-*o*-chlorostyrene, as the figures show.

To ascertain the effect of the side group of poly-*o*-methylstyrene on the unperturbed dimension of the polymer-chain skeleton, the K_θ value was calculated by the Stockmayer-Fixman relation,[2] where $K_\theta=[\eta]_\theta/M^{1/2}=\Phi_0(\langle L^2\rangle_0/M)^{3/2}$, where $[\eta]_\theta$ is the intrinsic viscosity at the theta state, where $\langle L^2\rangle_0$ is the unperturbed dimension, and

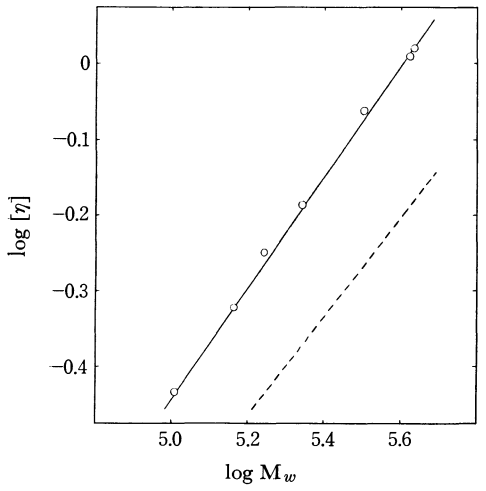

Fig. 4. Molecular weight dependencies of the intrinsic viscosities for poly-*o*-methylstyrene in toluene at 30°C. A dotted line is corresponding to poly-*o*-chlorostyrene.

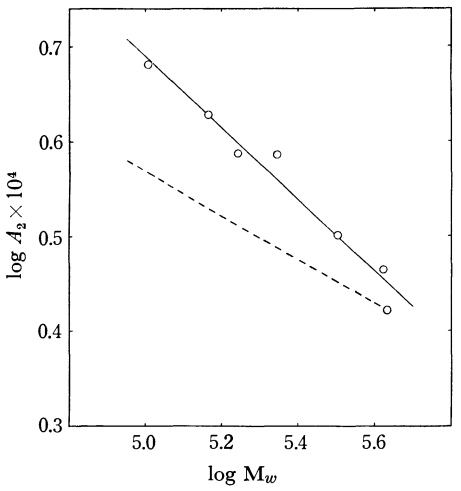

Fig. 5. Molecular weight dependencies of the second virial coefficients for poly-*o*-methylstyrene in toluene at 30°C.

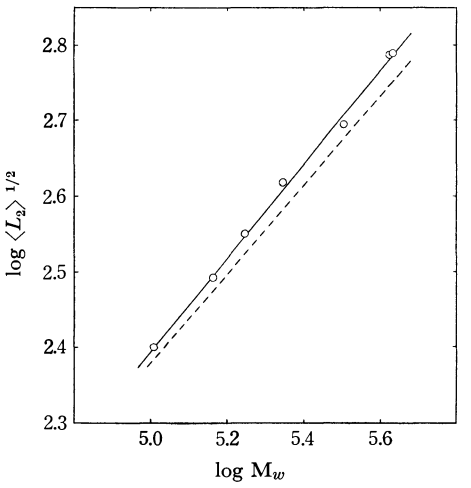

Fig. 6. Molecular weight dependencies of the end-to-end distances for poly-*o*-methylstyrene in toluene at 30°C.

where Φ_0 is the Flory parameter at the theta state, for which the value of 2.87×10^{21} is assumed in this paper.

As is shown in Fig. 7, K_θ was found as 7.75×10^{-4} by the least-squares method. By the use of this K_θ value, the value of $\{\langle L^2\rangle_0/M\}^{1/2}$ was calculated as 0.646 (Å), and the value of σ, $\{\langle L^2\rangle_0/\langle L^2\rangle_{0f}\}^{1/2}$, was obtained as 2.27, where $\langle L^2\rangle_{0f}$ is the mean-square end-to-end distance with the fixed valence angle of 109.5° for the carbon atom, but where there is a completely free internal rotation of the polymer-chain skeleton.

This σ value, 2.27, is slightly larger than that of poly-*p*-methylstyrene obtained by osmotic-pressure measurements at 30°C, 2.17.[3] It can, therefore,

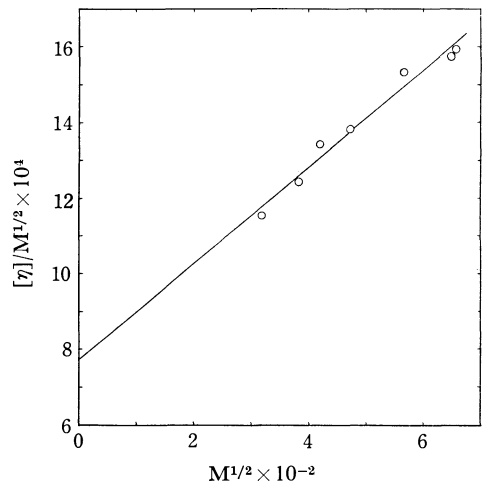

Fig. 7. Viscosity plots for poly-*o*-methylstyrene in toluene at 30°C.

2) W. H. Stockmayer and M. Fixman, *J. Polym. Sci., Part C*, **1**, 137 (1963).

3) N. Kuwahara, K. Ogino, A. Kasai, S. Ueno and M. Kaneko, *J. Polym. Sci., Part A*, **3**, 985 (1965).

be considered that the chain of poly-*o*-methylstyrene extends further than that of poly-*p*-methylstyrene. The difference between the σ values of these two polymers is caused by the steric repulsion between the neighboring side groups resulting from the difference in the substituted position of the methyl group on the phenyl group, as the strong electrostatic repulsions between the side groups for these polymers can not be considered.

The σ value, 2.27, for poly-*o*-methylstyrene is smaller than that for poly-*o*-chlorostyrene, 2.42.[1] Therefore, it can be considered that the extension of the poly-*o*-methylstyrene chain is smaller than that of the poly-*o*-chlorostyrene chain.

Kuwahara *et al.* concluded, from a comparison with the σ values for *p*-substituted polystyrene ($\sigma=$ 2.15 for poly-*p*-chlorostyrene, $\sigma=2.17$ for poly-*p*-methylstyrene, *etc.*) found by osmotic-pressure and viscosity measurements, that the chain conformations of these polymers are not so much affected by the electrostatic interaction between the polar side groups as by the molar volumes of the side groups, the effect of these on the polymer chain being the steric one.[3]

The molar volume of the side group of poly-*p*-methylstyrene and that of the side group of poly-*o*-methylstyrene are equal to that of toluene, 107.3 cc, and the molar volume of the side group of poly-*p*-chlorostyrene and that of the side group of poly-*o*-chlorostyrene are the same as that of chlorobenzene, 102.7 cc. Therefore, according to the findings for poly-*p*-substituted styrene, it can be considered that the difference between the σ value of poly-*o*-methylstyrene and that of poly-*o*-chlorostyrene must be a fairly small one as long as the steric effect of the side group on the chain conformation of these polymers is preferred to the electrostatic repulsion between the side groups. However, when we compare the findings for these polymers the difference between the σ values is fairly large.

From these considerations, it can be considered that the contribution of the electrostatic repulsion between the polar side groups, *o*-$Cl \cdot C_6H_4$, to the extension of the poly-*o*-chlorostyrene chain is fairly large.

The author wishes to thank Professor Akira Kotera for his kindly advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1306—1312 (1970)

The Crystal Structure of 1-Ethyl-2-methylquinolinium Iodide, $[(C_{12}H_{14}N)^+ \cdot I^-]$

Seiki SAKANOUE,*1 Yasushi KAI, Noritake YASUOKA, Nobutami KASAI*2 and Masao KAKUDO

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received November 11, 1969)

The crystal structure of an organic charge-transfer complex, 1-ethyl-2-methylquinolinium iodide, $[(C_{12}H_{14}N)^+ \cdot I^-]$, has been determined by means of three-dimensional X-ray data (Mo$K\alpha$). The crystals are monoclinic, space group $P2_1/c$, and have four formula units in a unit cell with the dimensions of $a=7.187\pm0.002$, $b=15.914\pm0.002$, $c=10.331\pm0.002$ Å, and $\beta=94.67\pm0.01°$. The structure is built up from an iodide anion and a planar 1-ethyl-2-methylquinolinium cation, which lie roughly on a plane. The cations are stacked approximately parallel to the a-plane, forming an endless column along the a axis; the interplanar spacings of these cations are alternately 3.4 and 3.6 Å. The iodide anions are located in the spaces between these columns and the ethyl groups of the cations. The closest distance between an iodide anion and the carbon atoms of a 1-ethyl-2-methylquinolinium ring is 3.93 Å.

The charge-transfer interaction of *N*-heteroaromatic iodide complexes in solution, in particular, the solvent effect and the effect of different cations on the transition energies, has been studied by Kosower[1] and by Mason.[2] The characteristic coloration of these complexes in the solid state seems to be due to the interaction between the *N*-heteroaromatic cation and the iodide anion.

It seemed that it would be interesting to obtain

*1 Present address: Research Laboratories, Ashigara, Fuji Photo Film Co. & Ltd., Minami-Ashigara, Kanagawa, 250-01.

information on the crystal structure by which to elucidate the charge-transfer interaction. A series of crystal structure analyses of several organic charge-transfer complexes has thus been carried out, and some preliminary results have already been reported.[3,4] This paper will deal with the crystal structure determination of 1-ethyl-2-methylquinolinium iodide, $[(C_{12}H_{14}N)^+\cdot I^-]$.

Experimental

Yellowish-green crystals of 1-ethyl-2-methylquinolinium iodide, $[(C_{12}H_{14}N)^+\cdot I^-]$, were supplied by Professor Hiroshi Mikawa of this university. A small, regular-shaped crystal was selected for investigation. Although the approximate cell dimensions had previously been determined by Neuhaus,[5] they were redetermined accurately on a Rigaku on-line controlled four-circle diffractometer with Mo$K\alpha_1$ radiation (λ=0.70926 Å).

The crystals obtained by the recrystallization from an ethanol solution are monoclinic with unit cell dimensions of $a=7.187\pm0.002$, $b=15.914\pm0.002$, $c=10.331\pm0.002$ Å, and $\beta=94.67°\pm0.01$. The density, 1.689 g·cm^{-3}, was determined at 14°C by flotation in a carbon tetrachloride-methyl iodide mixture, while the calculated value is 1.687 g·cm^{-3}, assuming four formula units per unit cell.

The space group, $P2_1/c$, was uniquely determined from the systematic absences of reflections ($h0l$ with $l\neq2n$, $0k0$ with $k\neq2n$).

The intensity data were collected at room temperature on the diffractometer by the ω-2θ scan technique:

Range of ω-scan$=1.0°+0.35\tan\theta_c$ and

Starting angle of the scan$=\theta_s-0.5°$,

where θ_c is the calculated value of the Bragg angle of the reflection to be measured. At the end of each scan the background scattering was measured for 10 sec by the stationary-crystal stationary-counter technique. The intensity was then corrected for the background scattering and for the Lorentz-polarization effects on an Aicom-C2 computer attached to the diffractometer. All the reflections within a range of $(\sin\theta)/\lambda=0.57$ were measured; in all, 1841 independent non-zero reflections were obtained.

Determination of the Structure

The position of the iodide anion was readily deduced from a three-dimensional Patterson map; the positions of the remaining atoms were found on successive three-dimensional electron density maps based on the phases determined by the iodide anion. The calculation of the structure factors with an isotropic temperature factor, B, of 3.0 Å^2 for all non-hydrogen atoms gave a discrepancy factor, $R=\sum||F_o|-|F_c||/\sum|F_o|$, of 0.25.

The parameters of the I, N, and C atoms were then refined by the block-diagonal least-squares

Table 1. (a) The final atomic co-ordinates along with their estimated standard deviations within parentheses each multiplied by 10^2 (Å)

Atom	X	Y	Z
I	0.1650 (0.1)	0.1850 (0.1)	0.0238 (0.1)
N	0.7494 (1)	0.0861 (1)	0.3353 (1)

procedure, and anisotropic thermal parameters were considered. In the refinement, the function minimized was $\sum w(|F_o|-|F_c|)^2$, and the weight, w was taken as unity for all reflections. Using the HBLS IV (UNICS) program,[6] the calculation was done on a HITAC 5020E computer at the University of Tokyo. After 7 cycles of refinement, the R factor was reduced to 0.073 for non-zero reflections (R=0.082 for all reflections). The final atomic co-ordinates and thermal parameters, along with their estimated standard deviations, are listed in Table 1. The observed and calculated structure factors are listed in Table 2. In the calculation the neutral atomic scattering factors used were taken from those of Hanson and his co-workers.[7]

A composite diagram of the final electron density distributions along the a axis is shown in Fig. 1.

Description and Discussion of the Structure

The skeleton of the 1-ethyl-2-methylquinolinium cation, together with the bond distances and angles, is illustrated in Fig. 2. The estimated standard deviations of the bond distances and angles are about 0.028 Å and 1.6° respectively.

The quinoline ring is planar within the limit of experimental error. The mean plane of the ring is expressed by:

$$-0.9680X + 0.2188Y + 0.1228Z + 4.2243 = 0,$$

where

$$X = ax + cz \cdot \cos\beta,\ Y = by, \text{ and } Z = cz \cdot \sin\beta.$$

The views along the a and c axes of the crystal structure are both shown in Fig. 3. The main feature is that the iodide anions and the planar 1-ethyl-2-methylquinolinium cations lie roughly on a plane. Each iodide anion is surrounded by three cations. The planar cations are stacked approximately parallel to the a-plane, forming an endless column along the a axis. The interplanar spacings of these cations along the column are alternately 3.4 and 3.6 Å; there thus seem to be the usual van der Waals contacts. The iodide ions are located in the spaces between these columns and the ethyl groups of the cations. The closest contact between an iodide ion and the carbon atoms of

an 1-ethyl-2-methylquinolinium ring is 3.93 A (Fig. 3). Some close inter-ionic atomic contacts are shown in Table 3.

In the study of the solvent effects on the charge-transfer absorption band of 1-alkylpyridinium iodide complexes, Kosower[1] assumed that the complexes exist in the form of ion-pairs in non-polar solvents, and to explain the effects he proposed a model in which an iodide ion is in contact with a 1-alkylpyridinium ion, with the line joining the centers of charge perpendicular to the plane of the ring.

In the structure of the tropylium iodide crystal, it was found that the iodide ion is located on the center of the tropylium ring.[8] This finding gives evidence for a weak charge-transfer bond between the iodide ion and the tropylium ion, such a bond as might be expected to persist in an ion-pair.[9] In the *N*-methylacridinium iodide[10] and the quinolinium salt of 2-dicyanomethylene-1,1,3,3-tetracyanopropanediide,[4] it was again found that the crystal structures of these salts persist in having ion-pairs.

Unlike these, the obtained crystal structure of the present crystal (Fig. 3) seems not to be so useful in explaining the charge-transfer absorption band, although the yellowish-green color of the crystal may be due to weak interionic interaction. The differences in structure between the 1-ethyl-2-methylquinolinium iodide and the tropylium iodide may be due to the facts that the electron affinity of the tropylium ion is larger than that of the 1-ethyl-2-methylquinolinium ion and that the bulky ethyl and methyl groups of the 1-ethyl-2-methylquinolinium ion affect the packing of ions in the crystal.

The authors wish to express their deep thanks to Professor Hiroshi Mikawa of this University for supplying materials and for his continued interest.

Lattice Vibrations of Potassium Oxalate Monohydrate and the Bound State of Water of Crystallization

Kunio FUKUSHIMA

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka

(Received November 19, 1969)

A normal coordinate treatment of the potassium oxalate monohydrate crystal as a whole was carried out. On the basis of the results of the calculation, the nature of the lattice vibrations and the bound state of the water of crystallization were discussed.

Recent investigations of the crystal structure of potassium oxalate monohydrate by Pedersen[1] and by Chidambaram *et al.*[2] have concluded that it is a monoclinic structure belonging to the $C2/c$ space group. The IR spectra of the substance have also been measured by Collman and Holtzclaw,[3] Schmelz *et al.*,[4] Pedersen,[5] and the present author.[6] In the region of 300—4000 cm^{-1}, no remarkable differences are not found among the spectra obtained by the various investigators except for the differences ascribed to the different resolving powers of the spectrometers. Pedersen measured a powder X-ray diagram for the sample used for the measurement of the IR spectra, and identified it with the sample which he had used for structural determination.[1] From these facts, it may be concluded that the samples used for the IR measurements by the other investigators have the same crystal structure as that of Pedersen's sample or that differences in IR spectra due to differences in crystal structure do not appear in the 300—4000 cm^{-1} region even if these are differences in crystal structure due to crystal modification among the samples. Therefore, in the present investigation, I calculated the lattice vibrations for the crystal structure obtained by Pedersen[1] and Chidambaram *et al.*,[2] using the observed frequencies,[6] in order to make clear the bound state of the water of crystallization and also to elucidate the nature of the lattice vibrations.

Normal Coordinate Treatment

A normal coordinate treatment was carried out for the crystal structure obtained by Chidambaram *et al.*;[2] the lattice parameters were $a=9.236$ Å, $b=6.190$ Å, $c=10.694$ Å, and $\beta=110°47'$. The Bravais unit lattice, which has a cell containig $2K_2C_2O_4\cdot H_2O$ and belonging to each lattice point, is the monoclinic lattice (C), and the cell-repeating vectors are $(\boldsymbol{a}+\boldsymbol{b})/2$, $(\boldsymbol{a}-\boldsymbol{b})/2$, and $(\boldsymbol{a}-\boldsymbol{c})$. The numbering of the atoms and ions in the chemical units and a part of the crystal lattice is shown in Fig. 1.

Optically-active lattice vibrations were calculated according to the $\boldsymbol{G}\boldsymbol{F}$ matrix method developed by

$x_{s14} = \Delta(y_4+y_{11}-y_{15}-y_{22})/2$
$x_{s15} = \Delta(z_4+z_{11}+z_{15}+z_{22})/2$
$x_{s16} = \Delta(x_2+x_{13})/\sqrt{2}$
$x_{s17} = \Delta(z_2+z_{13})/\sqrt{2}$

* Underscripts in the left side of the equations represent coordinate numbers, while those in the right side represent atom (or ion) numbers.

Shimanouchi *et al.*[7] The optically-active cartesian symmetry coordinate vector, X_{op}, and the optically-active internal symmetry coordinate vector, R_{op}, are expressed as follows.

$$X_{op} = \lim_{n_1, n_2, n_3 \to \infty} (n_1 n_2 n_3)^{1/2} \sum_{i=0}^{n_1} \sum_{j=0}^{n_2} \sum_{k=0}^{n_3} (X_s)^{i,j,k}_{\text{Bravais}}$$

$$R_{op} = \lim_{n_1, n_2, n_3 \to \infty} (n_1 n_2 n_3)^{1/2} \sum_{i=0}^{n_1} \sum_{j=0}^{n_2} \sum_{k=0}^{n_3} (R_s)^{i,j,k}_{\text{Bravais}}$$

In these equations, $(X_s)^{ijk}_{\text{Bravais}}$ and $(R_s)^{ijk}_{\text{Bravais}}$, respectively, are the cartesian and internal symmetry coordinate vectors associated with the three-dimensional Bravais cell, (i,j,k). The components of the vectors are shown in Tables 1 and 2. The optically-active B matrix, B_{op}, is defined as: $R_{op}=B_{op}X_{op}$.

The optically-active F matrix, F_{op}, constructed from the diagonal matrix with respect to each Bravais cell, F_{000}, and the interaction matrices, F_{100}, F_{010}, F_{001}, *etc.*, are as follows.

$$F_{op} = F_{000} + F_{100} + \tilde{F}_{100} + F_{010} + \tilde{F}_{010} + F_{001} + \tilde{F}_{001} + \cdots$$

The lattice vibration frequencies were calculated by the secular equation, $|M^{-1}F_{xs}-\lambda E|=0$. In this equation, M is the diagonal matrix constructed from the masses of the atoms and ions, and $F_{xs}=\tilde{B}_{op}F_{op}B_{op}$.

The following potential was assumed:

$$V = V^{2-}_{C_2O_4} + V_{H_2O} + V_{inter}$$

$V_{C_2O_4^{2-}}$ and V_{H_2O} represent the Urey-Bradley force fields associated with $C_2O_4^{2-}$ and H_2O respectively, and V_{inter} is the interaction potential of H_2O, $C_2O_4^{2-}$, and K^+. In the case of deuterated potassium oxalate monohydrate, the same potential function

Table 2. Internal symmetry coordinates (element of the vector, $(R_S)^{i,j,k}_{Bravais}$) *

A_g $\Delta R_{si} = \Delta(R_i^{I}+R_i^{II}+R_i^{III}+R_i^{IV})/2$
i = 1 to 36 excluding 5, 28, 34, 35
$\Delta(R_i^{I}+R_i^{III})/\sqrt{2}$
i = 5, 28, 34

A_u $\Delta R_{si} = \Delta(R_i^{I}-R_i^{II}-R_i^{III}+R_i^{IV})/2$
i = 1 to 36 excluding 5, 28, 34, 35
$\Delta(R_i^{I}-R_i^{III})/\sqrt{2}$
i = 28, 34, 35

B_g $\Delta R_{si} = \Delta(R_i^{I}+R_i^{II}-R_i^{III}-R_i^{IV})/2$
i = 1 to 36 excluding 5, 28, 34, 35
$\Delta(R_i^{I}-R_i^{III})/\sqrt{2}$
i = 5, 28, 34

B_u $\Delta R_{si} = \Delta(R_i^{I}-R_i^{II}+R_i^{III}-R_i^{IV})/2$
i = 1 to 36 excluding 5, 28, 34, 35
$\Delta(R_i^{I}+R_i^{III})/\sqrt{2}$
i = 28, 34, 35

$\Delta R_{28}^{I} = \Delta\alpha_{1\,(i,j,k)\,2\,(i,j,k)\,3\,(i,j,k)}$
$\Delta R_{29}^{I} = \Delta\alpha_{5\,(i,j,k)\,7\,(i,j,k)\,6\,(i,j,k)}$
$\Delta R_{30}^{I} = \Delta\alpha_{5\,(i,j,k)\,7\,(i,j,k)\,8\,(i,j,k)}$
$\Delta R_{31}^{I} = \Delta\alpha_{6\,(i,j,k)\,7\,(i,j,k)\,8\,(i,j,k)}$
$\Delta R_{32}^{I} = \Delta\alpha_{1\,(i,j,k)\,2\,(i,j,k)\,4\,(i,j,k)}$
$\Delta R_{33}^{I} = \Delta\alpha_{1\,(i,j,k)\,2\,(i,j,k)\,22\,(i,j,k+1)}$
$\Delta R_{34}^{I} = \Delta\alpha_{4\,(i,j,k)\,2\,(i,j,k)\,22\,(i,j,k+1)}$
$\Delta R_{35}^{I} = \Delta t$ (7–8) (internal rotation angle coordinate around the bond, 7–8)
$\Delta R_{36}^{I} = \Delta\pi$(7–568) (out- of -plane bending coordinate regarding the plane formed by atoms, 5,6,7 and 8)
$\Delta R_i^{II} = \mathbf{i}\,(\Delta R_i^{I})$, $\Delta R_i^{III} = \boldsymbol{\sigma}\,(\Delta R_i^{I})$, $\Delta R_i^{IV} = \mathbf{C}_2\,(\Delta R_i^{I})$

* In this table, ΔR_i^{I}'s for i=1 through 27 correspond to R_i's in Table 3. The symbols, **i**, $\boldsymbol{\sigma}$ and $\mathbf{C}_2$ represent symmetry operations associated with inversion, glide plane and 2-fold axis, respectively.

was assumed:

$$
\begin{aligned}
2V_{\text{inter}} = & \sum_i f_i(\text{O}\cdots\text{H})(\Delta q_i(\text{O}\cdots\text{H}))^2 \\
& + \sum_i f_i(\text{O}\cdots\text{K}^+)(\Delta q_i(\text{O}\cdots\text{K}^+))^2 \\
& + \sum_i f_i(\text{O}\cdots\text{O})(\Delta q_i(\text{O}\cdots\text{O}))^2 \\
& + \sum_i H_i(\text{H-O}\cdots\text{K}^+) r^i_{\text{O-H}} r^i_{\text{O}\cdots\text{K}^+} (\Delta\alpha^i_{\text{H-O}\cdots\text{K}^+})^2 \\
& + \sum_{(i,j)} 2a(\Delta\alpha^i_{\text{H-O}\cdots\text{K}^+})(\Delta\alpha^j_{\text{H-O}\cdots\text{K}^+}) \\
& + \sum_{(k,l)} 2b(\Delta\alpha^k_{\text{H-O}\cdots\text{K}^+})(\Delta\alpha^l_{\text{H-O}\cdots\text{K}^+})
\end{aligned}
$$

In the above potential, only those interactions between atoms and ions with an atom-ion or atom–atom distance of less than 4.5 Å were taken into account. The atom-ion and atom–atom distances are shown in Table 3. The force constant, a, is the interaction force constant between two bond angles, $\alpha^i_{\text{H-O}\cdots\text{K}^+}$ and $\alpha^j_{\text{H-O}\cdots\text{K}^+}$, which share a H–O bond, and the force constant, b, is the interaction force constant between two bond angles, $\alpha^k_{\text{H-O}\cdots\text{K}^+}$ and $\alpha^l_{\text{H-O}\cdots\text{K}^+}$, which share a O···K+ bond.

Table 3. atom-atom and atom-ion interactions *

	Atom or ion number		Atom-atom (atom-ion) distance (Å)

with * in Table 5 were adjusted by the method of least squares.[8] The numerical computations were carried out by making use of the Computation Center, Tokyo University, and the programs, BGLZ and LSMB, set up at the Shimanouchi Laboratory, Department of Chemistry, Faculty of Science, University of Tokyo, and also a program made by the author. The force constants, Set I, in Table 5 were obtained by the following equations. The O···O force constant, f_i (O···O), was assumed to be $f_i=A\cdot\exp(-Br)$, and the parameters, A and B, were determined by the method of least squares, using seven values of the O···O force constant (5.14 mdyn/Å, 3.02 mdyn/Å, 3.03 mdyn/Å, 1.74 mdyn/Å, 1.05 mdyn/Å, 0.76 mdyn/Å, and 0.555 mdyn/Å, corresponding to the interatomic distances of 2.09 Å, 2.20 Å, 2.21 Å, 2.27 Å, 2.36 Å, 2.47 Å, and 2.48 Å),[9] while the K$^+$···O force constant, f_i(K$^+$—O), was assumed to be $f_i=C\cdot\exp(-Dr)$ $(D-(2/r))$ and the C and D parameters were determined using two values of the K$^+$···O force constant (0.11 mdyn/Å and 0.14 mdyn/Å, corresponding to the atom-ion distances of 3.05 Å and 2.83 Å).[10] In the above equations, represents the atom-atom or atom-ion distance.

Here, the expressions of the force constants, f_i(O···O) and f_i(K$^+$···O), were obtained from the second derivatives of an assumed repulsive potential, $a\cdot\exp(-br)$, and an electrostatic attractive potential, c/r. The potential for K$^+$···O was assumed to be $a\cdot\exp(-br)+(c/r)$, and the first derivative of the potential was set at zero, while the potential for O···O was assumed to be $a\cdot\exp(-br)$. The other force constants were transfered from related compounds. In Table 5, the force constants, Set II, are the force constants obtained by the method of least squares,[8] which gives the calculated frequencies shown in Tables 6, 7, 8 and 9.

energy distributions. From the terms, it is clear that the calculated frequencies, 691 cm^{-1} and 601 cm^{-1} (B_u species), are related to the R_{32} and R_{33} coordinates. Therefore, they are due to the rotational lattice vibrations of the water of crystallization and correspond to the bands at 718 cm^{-1} and 614 cm^{-1}. The vibration having the calculated frequency 520 cm^{-1} (A_u species) is also due to another lattice vibration associated with the water of crystallization, as the significant terms of the potential energy distributions show.

In the region below 250 cm^{-1}, it is interesting that the calculated frequencies correspond well with the observed frequencies despite the fact that the assumed potentials of $a\cdot\exp(-br)$ and $a\cdot\exp(-br)+(c/r)$ were used for the O···O and K^+···O interactions respectively.

II. Bound State of the Water of Crystallization. The potassium oxalate monohydrate crystal contains one kind of water of crystallization molecule. Each oxygen atom in the water of crystallization molecule is on the symmetry element, the 2-fold axis, of the Bravais cell of the crystal, and it is accompanied by two nearest neighbor potassium ions at a distance of 2.93 Å. Each water of crystallization molecule is bound to the oxygen atoms of $C_2O_4^{2-}$'s by hydrogen bonds. If we assume sp^3 orbitals for the oxygen atom of the water of crystallization molecule, as in the case of ice, the orbitals of the lone-pairs do not point to the potassium ions; therefore, we can not expect a simple σ-bond for O···K^+. In order to obtain information about the bound state of the water of crystallization molecule, the force constants of rotation about the principal axes of the moment of inertia, A, B and

C, of the molecule were calculated.

Expressing the angle of rotation around the principal axis, m, and the force constant by $\Delta\theta_m$ and k_m respectively, we obtain the following equation:

$$k_m(\Delta\theta_m)^2 = \sum_n \tilde{\rho}_{mn}\tilde{B}FB\rho_{mn}$$

Here, ρ_{mn} represents the displacement of the atom, n, caused by the rotation around the axis, m, having an angle of rotation, $\Delta\theta_m$. B is the matrix transforming the displacements of the atoms in the water of crystallization molecule to the coordinates which change by the displacements, and F is the potential energy matrix having the coordinates as its bases. ρ_{mn} is expressed by the equation: $\rho_{mn}=e_m\times r_n\cdot\Delta\theta_m$. The vector, e_m, is a unit vector parallel to the principal axis, m, and r_n is a vector from the center of gravity of water molecule to the atom, n. The values of the k_m's obtained by the use of the force constants in Table 5 are as follows:

$$k_A=0.081 \text{ mdyn}\cdot\text{Å},\ k_B=0.237 \text{ mdyn}\cdot\text{Å},$$
$$k_C=1.886 \text{ mdyn}\cdot\text{Å}$$

From these values, it can be concluded that the water of crystallization molecule is more strongly bound around the C axis than around the A and B axes. The contributions of the hydrogen bonds to k_A, k_B, and k_C were calculated to be 0.001 mdyn·Å, 0.002 mdyn·Å, and 0.002 mdyn·Å respectively. As the $O\cdots K^+$ interactions make as little contributions to the k_m's as the $H\cdots O$ interactions, most contributions to the k_m's are considered to arise from the interaction between the nearest neighbor potassium ions and the lone-pair electrons of the water of crystallization molecule. Each of the potassium ions is on the side of the plane passing the oxygen atom of the water of crystallization molecule and perpendicular to H–O–H plane at the same distance, 2.02 Å, from the plane. The relatively small values of k_A suggest that the rotation around the axis, A, does not seriously change the degree of the interaction between the potassium ions and the lone-pair electrons; the small change in the degree of the interaction may be realized when we note that the lone-pair orbitals extend along the above-mentioned plane separating the two potassium ions. The large values of k_B and k_C also suggest this type of extension of the orbitals.

The author's thanks are due to Professor T. Shimanouchi of the University of Tokyo for allowing him to use the BGLZ and LSMB programs, and to Dr. I. Suzuki of Professor Shimanouchi's labolatory for his kind instruction on how to use the programs. He also wishes to express his gratitude to Professor S. Shibata of our Department for allowing him to use the IBM key-punch.

The Cadmium-photosensitized Decomposition of Acetone

Shin SATO, Chiharu TAKAHASHI and Shigeru TSUNASHIMA

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 22, 1969)

The cadmium-photosensitized decomposition of acetone has been studied and compared with the 3261 Å direct photolysis at 270±1°C. The data could be consistently explained by the following reaction mechanism:

$$Cd(^3P_1) + CH_3COCH_3 \longrightarrow Cd + {}^3A^* \quad (1)$$
$${}^3A^* \longrightarrow 2CH_3 + CO \quad (2)$$
$$CH_3 + CH_3COCH_3 \longrightarrow CH_4 + CH_3COCH_2 \quad (3)$$
$$2CH_3 \longrightarrow C_2H_6 \quad (4)$$
$$CH_3 + CH_3COCH_2 \longrightarrow C_2H_5COCH_3 \quad (5)$$
$$2CH_3COCH_3 \longrightarrow (CH_3COCH_2)_2 \quad (6)$$

The mechanism from (2) to (6) is exactly the same as that proposed for the 3130 Å direct photolysis at temperatures higher than 100°C. By using the *cis-trans* isomerization of 2-butene as the actinometer, the quantum yield of the photosensitized decomposition of acetone was estimated to be 0.3. Kinetic analysis showed that the energy-rich ethane produced by the recombination reaction (4) has the lifetime of 2×10^{-8} sec at 270°C.

In a previous series of papers,[1] we have reported the reactions of various hydrocarbons photosensitized by cadmium ($^3P_1$). Since the electronic energy tranferred in the cadmium photosensitization is only 87.7 kcal/mol, most of the hydrocarbons investigated did not decompose appreciably. The chemical changes observed thus far have been the *cis-trans* isomerizations of 2-butene and 2-pentene, the hydrogen-atom scrambling of dideuteroethylene, and the formations of vinylacetylene and benzene from acetylene.

In this paper, we have experimented with acetone as the reactant in the expectation that its decomposition may take place because of the low dissociation energy of the C–C bond attached to the carbonyl. The photochemistry of acetone has extensively been studied, and its reaction mechanism has almost been completely established.[2] Therefore, acetone was thought to be a suitable subject for the first application of the cadmium photosensitization of compounds containing oxygen atoms.

Experimental

Acetone (Koso Chemical Co.) was distilled bulb-to-bulb, with the middle third retained. Gas-chromatographic analysis showed no measurable impurities. Pure-grade *cis*-2-butene (Matheson Ltd.) was used as supplied.

The quartz reaction cell mounted in a furnace was 9.0 cm long and 4.8 cm in diameter, with a total volume, including acess tubing, of 175 m*l*. The cell was attached to the vacuum line through a greaseless stopcock equipped with a Viton diaphragm.

A home-made cadmium discharge lamp, with argon (2 mmHg) as the buffer gas, was used. The lamp was heated in another furnace which was kept at 270°C (within ±2°C) by an electric controller. The 2288 Å resonance line was filtered out by a UV-29 Toshiba glass filter, so that the emitting light was mainly the 3261 Å resonance line.

Products from the photolyses were analyzed by gas chromatography after removing the noncondensable gases at 77°K (carbon monoxide and methane) with a Toepler pump. The amounts of carbon monoxide and methane were measured using a gas buret attached to a cuprous oxide furnace at 280°C. In this furnace carbon monoxide is selectively oxidized to carbon dioxide, which is condensable at 77°K.

Since the extinction coefficient of acetone is strongly dependent on the temperature, it was measured using a combination of a set of slits, a photomultiplier (Toshiba MS-9SY), and a micro-ammeter. In the cadmium photosensitization, the light intensity absorbed by cadmium atoms was measured by using the *cis-trans* isomerization of 2-butene as the actinometer. The quantum yield was assumed to be 0.5.[1,3]

Results

Extinction Coefficients of Acetone. Since a monochromator was not used, the impinging light

was not only the 3261 Å resonance line, but was contaminated by the lights which were not absorbed by acetone. To estimate the molar extinction coefficient, therefore, the following equation was used:

$$I^{obs}-I=(I_0^{obs}-I)10^{-\varepsilon[A]l}$$

Here, I^{obs} and I_0^{obs} are the light intensities obtained in the presence and in the absence of acetone respectively. I is the intensity in the presence of a large amount of acetone. ε is the molar extinction coefficient, [A] is the concentration of acetone, and l is the length of the cell. Table 1 summarizes the obtained values. Although the 3261 Å resonance line is contaminated by weak lines at 3466 and 3613 Å,[4] which are in the absorption band of acetone, the extinction coefficients obtained are in fair agreement with the reported value[5] (about 0.6 $l\,mol^{-1}\,cm^{-1}$ at 3261 Å at 25°C).

* The light is from a Cd resonance lamp through a Toshiba UV-D25 glass filter.

Direct Photolysis. The results are summarized in Table 2. The products observed were carbon monoxide, methane, ethane, methyl ethyl ketone, and a compound with a high melting point which was not identified. The formations of ethylene, hydrogen, ketene, and biacetyl were not observed. Since the quantum yield of carbon monoxide is believed to be unity above 100°C,[5] the light intensity at 3261 Å of this lamp was estimated using the data of Table 1 and those of Runs No. 2, 13, 12, 11 and 10 in Table 2, their acetone concentrations being almost constant in the cell ($3.02\pm0.02\times10^{-3}$ moll^{-1}). The estimated value was 0.55 ± 0.03 μEinstein min^{-1}.

Cadmium-sensitized Photolysis. In order to check the thermal reaction, a few mmHg of acetone were kept in the cell at 270°C for several hours in the presence of cadmium, but no decomposition was detected. The photolysis results are summarized in Table 3. The products observed were the same as those obtained in the direct photolysis. The light intensity absorbed by cadmium atoms was estimated to be 0.21 ± 0.01 μEinstein min^{-1}. Figure 1 shows the quantum yield of carbon monoxide as a function of the acetone pressure. The curve A was obtained from the data shown in Table 3. Obviously the quantum yield above 10 mmHg increases linearly with the increase in the pressure of acetone. The curve B shows the results of another series of experiments using a different lamp, the light intensity absorbed by cadmium being 0.12 μ-Einstein min^{-1}. In the latter case, the increase in the quantum yield of carbon monoxide was not appreciable. This discrepancy will be discussed in the next section.

Discussion

The first absorption band of acetone extends from 3500 Å to 2200 Å. Therefore, if the broadening of the 3261 Å resonance line is large, direct photolysis will take place even in the presence of a large amount of cadmium vapor. The broadening of the resonance line is known to be very sensitive to the pressure of the buffer gas, the shape of the lamp, and the condition of discharge. In this experiment, we prepared two cadmium resonance lamps. The data presented here were obtained with the one of the higher intensity except for the curve B in Fig. 1. As has been stated in the Results section, the light intensity absorbed by acetone was 0.55 μEinstein min^{-1}, while that used for the cadmium photosensitization was 0.21 μEinstein min^{-1}. This difference may be attributed mainly to the broadening of the resonance line from the lamp. Thus, the increase in the quantum yield of carbon monoxide with the increase in the pressure of acetone can be interpreted in terms of the direct photolysis by the light which is not absorbed by cadmium. The difference in the slope between the curves A and B is explained by the difference in the broadening of the resonance line from the two lamps. The true quantum yield of carbon monoxide formed by the cadmium photosensitization is, therefore, obtained by extrapolating the curve obtained at higher pressures of acetone to zero pressure. Obviously the two curves point to the same value, 0.3.

The 3130 Å direct photolysis of acetone at temperatures higher than 100°C has been established to occur through the following reaction mechanism:[2]

$$CH_3COCH_3 + h\nu \longrightarrow {}^1A^* \quad (1)$$

$$^1A^* \longrightarrow {}^3A^* \quad (2)$$

$$^3A^* \longrightarrow 2CH_3 + CO \quad (3)$$

$$CH_3 + CH_3COCH_3 \longrightarrow CH_4 + CH_3COCH_2 \quad (4)$$

$$2CH_3 \longrightarrow C_2H_6 \quad (5)$$

$$CH_3 + CH_3COCH_2 \longrightarrow C_2H_5COCH_3 \quad (6)$$

$$2CH_3COCH_2 \longrightarrow (CH_3COCH_2)_2 \quad (7)$$

The quantum yield of the decomposition through the excited singlet state is known to be small.[5] The fluorescence and the phosphorescence, which are not shown in the above mechanism, are also known to be very small compared with the decomposition.[5] The quantum yield of carbon monoxide, therefore, is believed to be nearly unity. Although, in the present study of the 3261 Å direct photolysis, the quantum yields have not been measured, the products observed correspond well with the mechanism described above. In the cadmium photosensitization, the formation of the excited state of acetone may be written as follows:

$$CH_3COCH_3 + Cd(^3P_1) \longrightarrow {}^3A^* + Cd \quad (8)$$

The successive reactions will, then, be the same as has been described above from the reactions (3) to (7). We will show below that the data presented in the previous section can be consistently explained by this mechanism.

Since the quantum yields calculated from the data have some ambiguities, the relative yields will now be discussed. Figure 2 shows the relative rates of the formation of methane, ethane, and methyl ethyl ketone against that of carbon monoxide as a function of the pressure of acetone. The curves obtained in the two photolyses, direct and cadmium-photosensitized, are obviously different from each other. However, the material balance:

○, ● for CH_4
△, ▲ for C_2H_6
□, ■ for $C_2H_5COCH_3$
◇, ◆ for $[CH_4]+2[C_2H_6]+[C_2H_5COCH_3]$

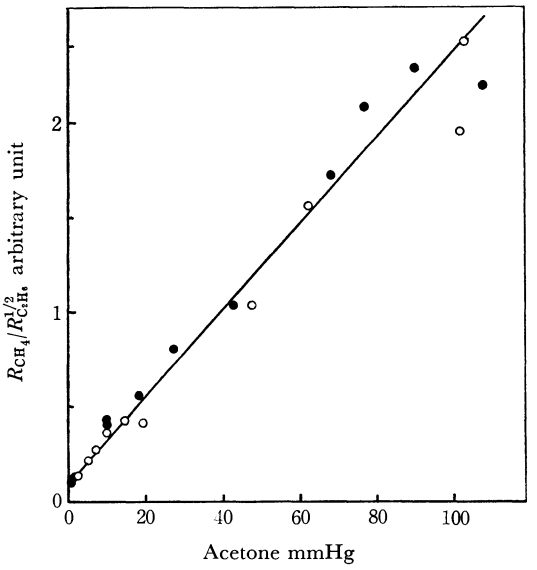

Fig. 3. The plots for $R_{CH_4}/R_{C_2H_6}^{1/2}$ against the pressure of acetone.
○ for the direct photolysis
● for the cadmium photosensitization

$$2[CO] = [CH_4] + 2[C_2H_6] + [C_6H_5COCH_3]$$

which is derived from the reaction mechanism proposed, holds rather nicely. This is also shown in Fig. 2. Moreover, the plots of the $[CH_4]/[C_2H_6]^{1/2}$ ratio against the pressure of acetone coincide with each other on a single straight line. This is shown in Fig. 3. The following equation is obtained by the steady-state treatment of the reaction mechanism proposed:

$$R_{CH_4}/R_{C_2H_6}^{1/2} = (k_4/k_5^{1/2})[A] \qquad [I]$$

Here, R_{CH_4} and $R_{C_2H_6}$ are the rates of the formation of methane and ethane, and k_4 and k_5 are the rate constants of the reactions (4) and (5). From the slope of the linear relationship in Fig. 3, the value for $(k_4/k_5^{1/2})$ is calculated to be 0.25 $l^{1/2}$ (mol sec)$^{-1/2}$. The literature values for k_4 and k_5 are $10^{8.88}\exp(-10.0/RT)$ and $10^{10.5}$ l (mol sec)$^{-1}$.[6] Therefore, the value for $(k_4/k_5^{1/2})$ at 270°C 0.58 $l^{1/2}$ (mol sec)$^{-1/2}$, a value which is in reasonable agreement with the value obtained in the present experiment. From the above discussion, it can be concluded that the apparent discrepancy between the two types of photolysis in the relative rate of the formation of the products is not essential, but is due to the difference in the concentrations of radicals in the steady states of the two photolyses. The light intensity used for the decomposition in the cadmium photosensitization is constant, while in the direct photolysis the intensity depends upon the pressure of acetone.

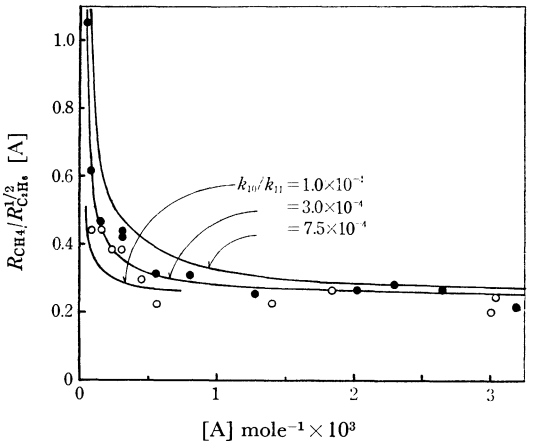

Fig. 4. The plots for the estimation of the lifetime of the energy-rich ethane molecule.
○ for the direct photolysis
● for the cadmium photosensitization

According to Eq. [I], the linear relationship in Fig. 3 should not have a definite intercept at the zero pressure of acetone. However, if the following mechanism:

$$2CH_3 \longrightarrow C_2H_6^* \qquad (9)$$

$$C_2H_6^* \longrightarrow 2CH_3 \qquad (10)$$

$$C_2H_6^* + CH_3COCH_3 \longrightarrow C_2H_6 + CH_3COCH_3 \qquad (11)$$

is assumed in place of the reaction (5), the existence of the intercept can be understood. Moreover, the lifetime of the energy-rich ethane formed in the reaction (9) can be estimated. If the reactions (9), (10) and (11) are included, the steady-state treatment gives Eq. [II] instead of [I]:

$$\frac{R_{CH_4}}{R_{C_2H_6}^{1/2}[A]} = \frac{k_4}{k_9^{1/2}}\left(1 + \frac{k_{10}}{k_{11}[A]}\right)^{1/2} \qquad [II]$$

In Fig. 4, the left-hand side of Eq. [II] is plotted against the concentration of acetone, [A]. Obviously at higher concentrations, the value of Eq. [II] remains around 0.25, but as the concentration of acetone decreases the value is rapidly increased. As is shown in Fig. 4, the best fit-curve is obtained by assuming the k_{10}/k_{11} ratio to be 3×10^{-4}. If every collision between energy-rich ethane and acetone is effective for the stabilization, then, by assuming the collision frequency to be $10^{11.3}$ $l$mol^{-1} sec^{-1},[6] the lifetime of energy-rich ethane molecules at 270°C can be calculated to be 2×10^{-8} sec.

(Received December 1, 1969)

The PMR spectra of 22 amino acids and peptides were measured in a D_2O solution. From the change in the NMR parameters in amino acids and their di- and tripeptides, it has been concluded that a tripeptide is a good model for polypeptides. The chemical shift of the α-proton of an amino-acid residue in tripeptide can be obtained from those of amino acid and dipeptide. The spin-spin coupling constant of an amino acid grows larger, and the population of a *trans* rotamer becomes larger, as its amino (or carboxyl) group forms a peptide bond. The PMR spectra of two diasteroisomers of valyl-valyl-valine were also measured, and the influences of the configuration of an amino-acid residue on the NMR parameters of its peptides were investigated.

The high-resolution NMR technique has been applied to the studies of oligopeptides and proteins. The PMR spectra of simple amino acids and dipeptides have been measured in an aqueous medium by Takeda and Jardetzky,[1] while Bovey and Tiers,[2] employing trifluoroacetic acid as the solvent, have investigated the relations between the NMR parameters and the peptide structures.

Several works[3-5] have also appeared trying to investigate the structures of proteins on the basis of the PMR spectra of amino acids and peptides. Spectrometers operating at 220 MHz have recently become available and have been used for this purpose.[4-5]

Sheinblatt[6] proposed a method for determing the sequence of amino acid residues in di- and tripeptides; he also measured[7] the rate of the exchange of the peptide hydrogen of glycylglycine. Morlino and Martin[8] reported glycylmethylene splitting due to a chemical-shift nonequivalence in amino acid-glycyl dipeptides. Kim and Martell[9] studied glycine dipeptides and their complexes with copper and nickel in an aqueous solution. Systematic analyses of the chemical shifts of the oligopeptides have also been reported by some workers. Gorkom[10] tried to distinguish a long-range shielding effect on the chemical shifts. For the chemical-shift calculation of an amino acid in a given polypeptide, a simple additive law has been found to hold by Nakamura and Jardetzky.[11-12] Beecham and Ham[13] reported the chemical-shift change of glycine and L-leucine residues in seversl peptides.

In this investigation, we have systematically investigated the changes in the NMR parameters (chemical shifts and spin-spin coupling constants) in amino acids and their di- and tri-peptides; we will here report a rather large difference in the vicinal coupling constants of amino-acid residues. From these changes, we deduced the structures of the peptides (the conformations of the side chains); we found that a tripeptide is a good model for polypeptides from the point of view of NMR parameters.

Experimental

The common amino acids and peptides were purchased

from Wako Pure Chemical Ind., Ltd. (Special Grade), or Tokyo Kasei Ind., Ltd. (GR). The L-valyl-L-valine, L-valyl-glycyl-glycine, L-valyl-L-valyl-D-valine, L-valyl-L-glutamic acid, L-valyl-L-valyl-L-glutamic acid, L-alanyl-glycine, and L-alanyl-glycyl-glycine were from the Ajinomoto Co., Ltd., while the glycyl-L-valyl-glycine, L-valyl-glycine, and L-valyl-L-valyl-L-valine were from the Institute for Protein Research, Osaka University; the D_2O was from E. Merck A.G. Darmstadt, "Solvent for NMR Spectroscopy" (99.75D%).

All the chemicals employed were PMR spectroscopically pure and were used without further purification.

The NMR spectra were obtained with samples prepared by dissolving 25 mg of the amino acids or peptides in 0.5 m*l* of D_2O, with 5 mg of sodium 2,2-dimethyl-2-silapentane 5-sulfonate(DSS) as a reference substance.

However, L-valyl-L-valine, L-valyl-L-valyl-L-valine, L-valyl-L-valyl-D-valine, L-valyl-L-valyl-L-glutamic acid, glycyl-glycine, and glycyl-glycyl-glycine were not soluble to that extent, and so about 2% D_2O solutions were prepared with these peptides. All the peptides are considered to have zwitter-ion forms in these solutions.

The NMR spectra were measured with a 60 MHz or a 100 MHz NMR spectrometer (JNM 3H-60 and JNM 4H-100) at a probe temperature of 29 ± 1°C. The chemical shift values were read from the frequency counter (Universal Counter MF-47 A, Anritsu Electric Co., Ltd.); the accuracy of the measurements is estimated to be within ± 0.05 Hz. All the chemical shifts were

Results and Discussion

The results obtained for a series of peptides are presented in Table 1. For a given amino-acid residue in the peptides, the spin-spin coupling constants of the α-proton (H) with the β-H, and its chemical shifts, are designated as J_{vic} and δ_{CH_α} respectively. The chemical shifts of methyl groups for the valine and alanine residues, and the methylene group of glycine (δ_{CH_3} and δ_{CH_2}), are also presented when precise measurements were possible.

In this report, the amino-acid residues are numbered in the following way:

NH_2—A—COOH
(1, 3)

NH_2-A—A-COOH
(1) (3)

NH_2-A—A—A-COOH
(1) (2) (3)

where A denotes the amino-acid residue. Therefore, L-val(1,3) indicates L-valine. L-valyl-L-valine consists of two valine residues, L-val(1) and L-val(3).

1) Chemical Shifts. Generally speaking, the chemical shifts of amino-acid protons go to a lower field when peptide bonds are formed. Because an amino acid has both an amino and a carboxyl group, two types of dipeptides can exist; a rather distinct difference in NMR parameters is observable between them.

Let us now summarize the chemical shifts changes of the α-H of L-valine, paying special attention to the δ_{CH_α} of L-val(2) in tripeptides, in Fig. 1. The δ_{CH_α}'s of the amino-acid(1)(L-valine, L-leucine and L-alanine) residues in di- and tripeptides are shown in Fig. 2. Figure 3 shows the δ_{CH_2}'s of glycine peptides. From these figures, the δ_{CH_α} (or δ_{CH_2})'s of a given amino-acid residue in a certain position of the oligopeptides can be seen to have a tendency to cluster within a small range of chemical shift values. The mean values obtained for δ_{CH_α} and δ_{CH_2} are shown in Table 2. The difference, $\Delta\delta$, between the δ_{CH_α} of an amino acid residue in the peptide and that of the free amino acid is also presented in Table 2.

The δ_{CH_2}'s of glycine dipeptides have been reported to be 228.8, and 227.2 Hz from the DSS values for gly(1) and gly(3) respectively.[11] Our results agree fairly well.

A rather large discrepancy is found between

3	L-val (2)	253.5	37.7	4
	L-val (3)	242.6	27.6	1

δ_{CH_2} of glycine peptides

n-Peptides	Amino acid residue	δ_{CH_2} (Hz from DSS)	$\Delta\delta$ (Hz)	Number of cases
1	Gly (1,3)	213.6	0	1
2	Gly (1)	231.4	17.8	3
	Gly (3)	228.1	14.5	3
3	Gly (1)	234.8	21.2	2
	Gly (2)	242.6	29.0	3
	Gly (3)	227.1	13.5	4

δ_{CH_α} and δ_{CH_2}. That is, the δ_{CH_α} of L-val(3) does not agree with the δ_{CH_2} of gly(3), while the δ_{CH_α} of L-val(1,3) and the δ_{CH_2} of gly(1,3), and those of L-val(1) and gly(1), of dipeptides coincide. This discrepancy can not be explained in terms of the difference in electronegativity; this suggests that the electric field and the magnetic anisotropy effect play an important role in determining the chemical shifts of the peptides.

A rough correlation is found to exist between these chemical shift values; the δ_{CH_α} (or δ_{CH_2}) of the A(1) and A(3) of a given amino acid is almost unchanged through di- and tripeptide, and the δ_{CH_α} (or δ_{CH_2}) of A(2) can easily be estimated by adding the sum of the $\Delta\delta$'s of A(1) and A(3) to the δ_{CH_α} (or δ_{CH_2}) of A(1,3). From this observation, it may be concluded that a tripeptide can be a good model for polypeptides. This conclusion is supported by a comparison of the δ_{CH_2} of the central methylene group of triglycine (243.7 Hz) with the reported[12] δ_{CH_2} value of that of the pentaglycine (240.0 Hz).

2) Spin-spin Coupling Constants. The spin-spin coupling constants of L-valine change when it forms a peptide bond. Figures 4 and 5 show

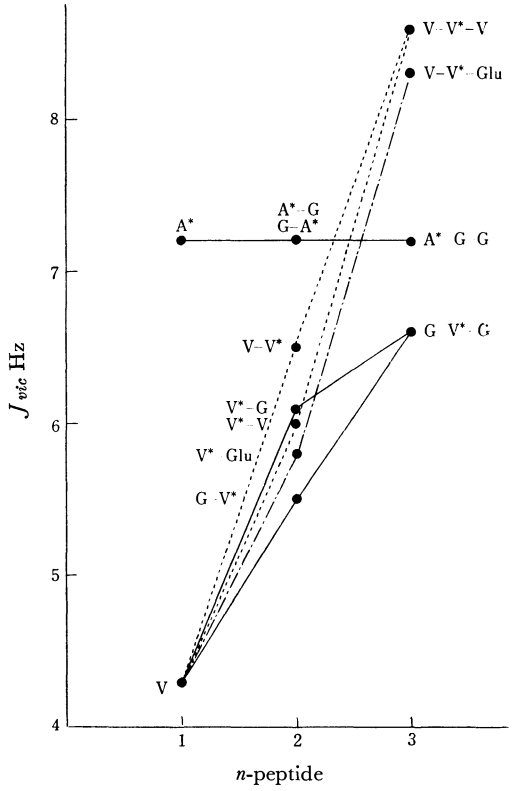

Fig. 4. The change of spin-spin coupling constants (J_{vic}) of L-valine and alanine residues.
(J_{vic} of amino acid residue with an asterisk is shown. A; Alanine, G; Glycine, Glu; Glutamic acid, V; Valine)

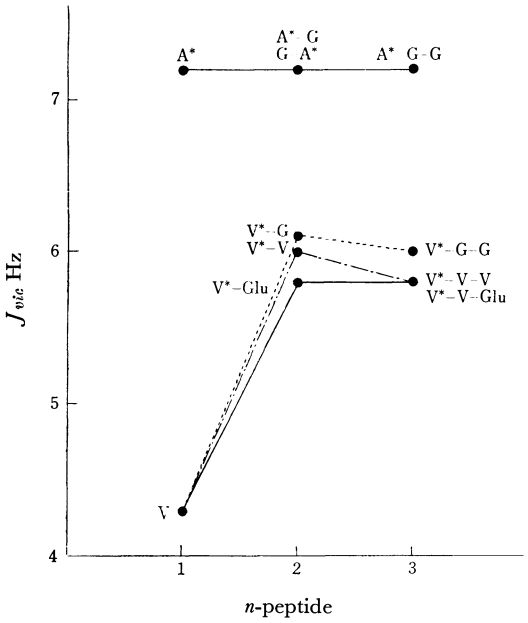

Fig. 5. The change of spin-spin coupling constants (J_{vic}) of L-valine and alanine residues.
(J_{vic} of amino acid residue with an asterisk is shown. A; Alanine, G; Glycine, Glu; Glutamic acid, V; Valine)

the J_{vic}'s of L-valine residues. From these figures, rather clear trends are observable; the J_{vic} for L-val(1,3) is 4.3 Hz. The averages of J_{vic} for L-val(1) and L-val(3) in dipeptides are 6.0 and 6.0 Hz respectively, while that for L-val(2) in tripeptides is 7.8 Hz. However, the J_{vic}'s for L-val(1) and L-val(3) hardly change from dipeptide to tripeptide; they are all about 6.0 Hz. That is, the J_{vic} for L-val(1,3) grows larger as its amino and carboxyl groups form peptide bonds. The difference in electronegativity between a free amino (or carboxyl) group and that which formed a peptide bond can not be considered[14] to have such a large effect on the J_{vic} of L-valine. Moreover, the J_{vic} of L-alanine is considered to be influenced by the difference in electronegativity alone and not by the population change in the rotamers,[15-16] because the three rotamers are equivalent. The observed J_{vic} of L-alanine is 7.2 Hz, and it does not change at all when it forms a peptide bond with glycine. From these considerations, it can be concluded that the difference in electronegativity between a free amino (or carboxyl) group and that which formed a peptide bond does not influence the J_{vic} of a given amino-acid residue. Therefore, the J_{vic} of L-valine residues in oligopeptides is mainly affected by the population change of the rotamers. Employing 13.6 and 2.6 Hz as the J_{vic} values of the *trans* and *gauche* rotamer (J_t and J_g)[17], we calculated the populations of the *trans* and *gauche* rotamers (P_t and P_g).

Table 3-1. The populations and the relative energies of the rotational isomers for L-valine derivatives

	J_{vic} (Hz)	P_t	P_g	ΔE (kcal/mol)
L-Val*	4.3	0.15	0.85	−0.63
L-Val*-Gly	6.1	0.31	0.69	−0.06
L-Val*-L-Val	6.0	0.31	0.69	−0.07
L-Val*-L-Glu	5.8	0.29	0.71	−0.11
L-Val*-Gly-Gly	6.0	0.31	0.69	−0.07
L-Val*-L-Val-L-Val	5.8	0.29	0.71	−0.11
L-Val*-L-Val-L-Glu	5.8	0.29	0.71	−0.11

Results for the valine residue with an asterisk are shown.

Table 3-2. The populations and the relative energies of the rotational isomers for L-valine derivatives

	J_{vic} (Hz)	P_t	P_g	ΔE (kcal/mol)
L-Val*	4.3	0.15	0.85	−0.63
Gly-L-Val*	5.5	0.26	0.74	−0.21
L-Val*-L-Val	6.0	0.31	0.69	−0.07
L-Val-L-Val*	6.5	0.36	0.64	0.07
Gly-L-Val*-Gly	6.6	0.36	0.64	0.07
L-Val-L-Val*-L-Val	8.6	0.55	0.45	0.53
L-Val-L-Val*-L-Glu	8.3	0.52	0.48	0.47

Results for the valine residue with an asterisk are shown.

The relative energies of *gauche* rotamers with respect to the *trans* rotamer (ΔE) were obtained, assuming that the two *gauche* rotamers have equal populations. The results are shown in Table 3. It can clearly be seen that the successive formations of peptide bonds to both ends of a valine (amino and carboxyl group) cause the population of the *trans* rotamer to grow larger, thus enlarging the dihedral angle. This phenomenon accords with the one observed hitherto[14] and may be explained in terms of the steric hindrance of the functional groups.

In conclusion, the J_{vic} of a given amino acid residue is found to be influenced by the one with which it is combined directly; therefore, tripeptide is a good model for polypeptides.

3) The Influence of the Configuration of an Amino Acid Residue on the NMR Parameters of Peptides. Out of the eight diastereoisomers of valyl-valyl-valine, we have chosen two isomers, L-val-L-val-L-val [I] and L-val-L-val-D-val [II], and have studied the influence of optically active residues on the NMR parameters of these diastereoisomers. Figure 6 shows the NMR spectra of I and II at 100 MHz. The results, together with *Pt*, *Pg*, and the ΔE values calculated on the assumptions described above, are shown in Table 4. The influence of the configuration of val(3) is observable in the large differences between the NMR parameters of the val(2)'s of the two isomers.

With I, L-val(2) appears at a higher field and have a larger J_{vic} than L-val(2) of II. However, the NMR parameters of the L-val(1)'s of the two isomers agree very well. These facts show that the configuration of a given amino-acid residue influences its vicinal amino acid residues' NMR parameters and their conformations. However, the influence is very localized and change only the NMR parameters of the amino acid residues combined directly. Therefore, it can be concluded that tripeptide can be a good model compound for polypeptides, even when one considers the influence of the optical isomerism.

The authors are grateful to Professor Shizuo Fujiwara and to Dr's. Yoji Arata and Takeo Yamamoto of the University of Tokyo for stimulating and helpful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1329—1336 (1970)

The Radiolysis and Photolysis of Methanolic Solutions of Eosin. I. The γ-Radiolysis of Neutral and Alkaline Solutions

Kazuie KIMURA, Takuji MIWA*1 and Masashi IMAMURA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received December 1, 1969)

The γ-radiolysis of eosin has been studied in deaerated neutral and alkaline methanolic solutions. Eosin is reduced principally with CH_2OH radicals in dilute solutions. In neutral solutions, $G(-\text{eosin})$ is about 2 at the eosin concentration of 10^{-5}M and increases as the concentration of eosin is increased. The final products are leuco-eosin and an unidentified substance which has an absorption peak at 455 nm. In an alkaline solution (10^{-5}M), $G(-\text{eosin})$ is about 4 and the product is semireduced eosin, which is stable in the dark and which undergoes photo-debromination. The ESR spectrum of semireduced eosin has also been recorded. Comparative studies have also been made on uranin solutions.

The photochemistry of several xanthene dyes, eosin, erythrosin, and uranin in aqueous and alcoholic solutions was investigated by Imamura and Koizumi during the 1955—1958 period.[1-6] Thereafter, Koizumi and his co-workers have worked on the flash photolysis of these systems and have elucidated the primary processes in detail; the outlines have recently been reviewed by Koizumi.[7] The flash-photolysis technique has also been applied by Lindqvist[8,9] and by Grossweiner and Zwicker[10,11]

to aqueous solutions of these dyes. The photochemical oxidation or reduction of these dyes is initiated by the reaction between the dye in the triplet state and the oxidizing or reducing substance or the dye in the ground state, depending upon the concentration of dye.

In the radiolysis of dilute solutions, however, dyes in the ground state are attacked by intermediates produced from the radiolyzed solvent. For aqueous solutions, the attacking species are principally hydrated electrons and hydroxyl radicals, and the products are semireduced and semioxidized dyes respectively.[12-14] Subsequent reactions seem similar to those in the photochemical systems. These intermediate products for uranin and eosin in aqueous solutions have been investigated by the pulse-radiolysis technique,[12,13] and the overall yields for the bleaching of eosin by γ-rays have been reported.[14] No corresponding studies have yet been reported on alcoholic solutions, however. As the radiolysis of alcohols has been investigated to a considerable extent,[15] it seemed that it would be interesting and worthwhile to compare the results for aqueous and alcoholic solutions. It seemed that it would be interesting also to observe if the dehalogenation of halogenated dyes occurred in the radiolysis; it has been observed but not fully explained in the photolysis of aqueous alcoholic solutions containing alkali.[3] The photochemical dehalogenation reaction will be described at length in the succeeding paper. In this paper the results obtained for the ^{60}Co-γ radiolysis of neutral and alkaline methanolic solutions of eosin, along with the ESR spectra of semireduced eosin and uranin produced in alkaline solutions, will be presented.

Experimental

Eosin (disodium salt of 2′,4′,5′,7′-tetrabromofluorescein) of Merck was recrystallized four times from a slightly alkaline methanol solution. Uranin (disodium salt of fluorescein) of Merck was also purified similarly. The molar extinction coefficient of the purified eosin was 1.17×10^{5}M^{-1}cm^{-1} in methanol at 521 nm, while that of uranin was 8.7×10^{4}M^{-1}cm^{-1} at 495 nm.

Methanol of a spectral quality (Dotite Spectrosol) was refluxed with sodium borohydride (1 g/400 m*l*) before distillation on a 40-theoretical-plate column. A middle fraction of the distillate was taken and was dried by refluxing it on magnesium methoxide prepared by dissolving 2—3 g of magnesium turnings in 150 m*l*. Purified methanol was kept *in vacuo*.

Nitrous oxide (standard gas of Takachiho Chem. Ind.; purity stated >99.9%) was further purified by distillation *in vacuo*. Extra-pure sodium and potassium hydroxides were used without further purification.

A concentrated eosin solution in methanol (stored in the dark) was diluted with purified methanol by distillation *in vacuo* and then degassed thoroughly by the microstill reflux method.[16] Nitrous oxide was added to the degassed solution manometrically; the concentration was calculated from the solubility data.[17]

Solutions were irradiated in the dark with 1.2 kCi ^{60}Co-γ rays at a dose rate in the vicinity of 1×10^{16} eV ml^{-1}min^{-1}. An irradiation ampoule made of Pyrex glass was provided with a quartz optical cell (10 or 1 mm thick). The optical cell was shielded from γ-rays with lead blocks during γ-irradiation. Dye solutions were kept in the dark throughout the experiment because some irradiation products were found to be particularly sensitive to light. The dose rate was determined by Fricke dosimetry on the basis of $G(Fe^{3+})=15.5$, with a correction for the electron density of the solvent used. The absorption spectra were recorded on a Shimadzu SV-50A spectrophotometer at room temperature.

The ESR spectra were recorded at room temperature with a JEOL 3B-X spectrometer with a 100 kHz-field modulation. A capillary cell (1 mm *i.d.*) attached to the irradiation ampoule was heated before use to remove any paramagnetism induced by γ-irradiation.

Results

Neutral Solutions. Upon the γ-irradiation of neutral eosin solutions in methanol in the concentration range of 9.38×10^{-6}—1.64×10^{-4}M, the absorption peak of eosin at the longest wavelength (521 nm) decreases with a slight shift (2—3 nm) to the shorter wavelength. Isosbestic points are observed in the vicinities of 242, 355, and 460 nm. A typical spectral change induced by γ-irradiation for the 7.64×10^{-5}M solution is shown in Fig. 1.

Close examination revealed that a small absorption band which was very sensitive to light appears between 360 and 450 nm. This absorption spectrum is shown more clearly in Fig. 2, which was obtained with the eosin solution (9.29×10^{-5}M) subjected to prolonged irradiation. Other product absorptions are observed at 289 and <260 nm.

The absorption spectra of irradiated eosin solutions did not change for at least one day so long as the solutions were kept in the dark. However, upon the absorption of light the 455 nm absorption band decreased, finally disappearing as the 521 nm band increased. The saturation by air or bubbling oxygen gas into the irradiated eosin solution caused a slight depression of both 455 and 521 nm absorption bands, but they were restored by bubbling nitrogen gas.

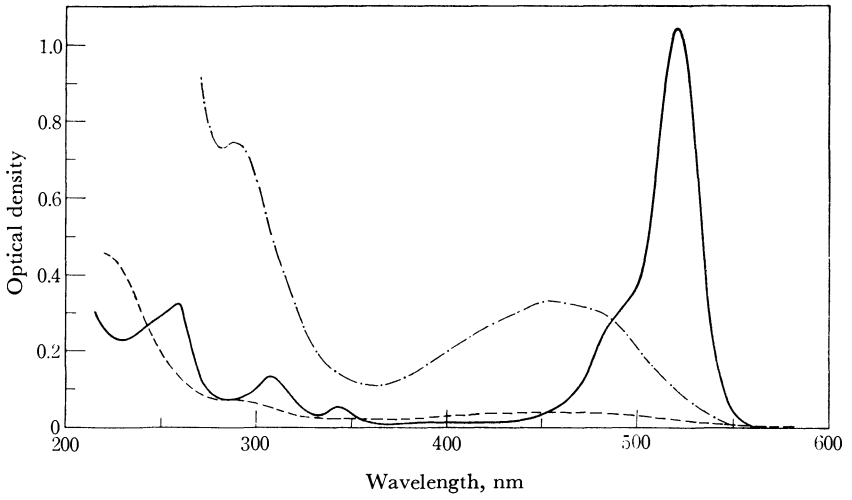

Fig. 2. Absorption spectra of 9.29×10^{-5}M eosin solution in MeOH before and after γ-irradiation.
—— before irradiation (l=1 mm), ------ afterirradiation 4.8×10^{18} eV/ml (l=1 mm), -·-·- (l=10 mm).

Similar absorption spectra were obtained with uranin solutions containing 2×10^{-3}M NaOH. Absorption peaks appear at 395, 280, 255, and $<$ 230 nm. The absorption at 395 nm probably corresponds to that for eosin at 455 nm; the latter was scarcely affected by light, however.

The radiation chemical yields for the disappearance of eosin can be obtained from the decrease in the optical density at 521 nm. The decrease in the optical density at 521 nm showed a good linear relationship with the radiation does. A typical example is shown in Fig. 3. The yields (G, the number of eosin molecules disappearing per 100 eV of energy absorbed) are plotted in Fig. 4 as a function of the initial concentration of eosin. The G(−eosin) rapidly increases to about 2 with an increase in the concentration from the initial 0 through 10^{-5}M; then it increases rather slowly. The scattered plots in the higher concentration range may be partly due to the effect of stray light, despite the meticulous care, and partly to some contamination in the eosin.

In Fig. 4 are also shown the yields for the solutions containing N_2O ($\sim10^{-2}$M), which is a solvated-electron scavenger. No substantial effect of N_2O on the G-value is observed within the range of

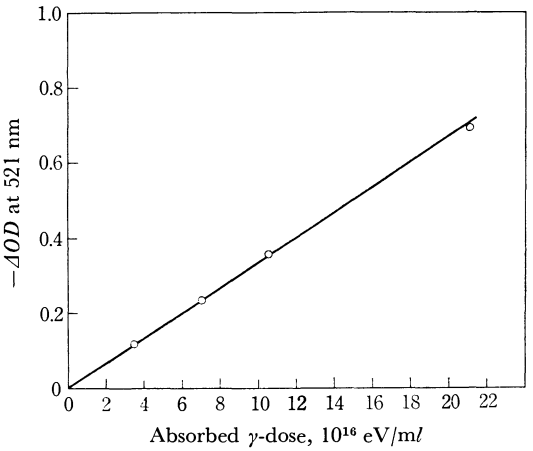

Fig. 3. A plot of $-\Delta OD$ at 521 nm *vs.* absorbed dose. Eosin 8.88×10^{-6}M in MeOH.

experimental error. The absorption spectra and the effects of light and oxygen on them were quite the same as in the case without N_2O.

Alkaline Solutions. Eosin disappears in an alkaline solution with $G(-\text{eosin})=4.0\pm0.3$ at 1.3×10^{-5}M eosin and 0.1—0.2M NaOH; this $G(-\text{eosin})$ is twice as large as in a neutral solution at the same concentration.

The absorption spectra of the irradiated eosin (10^{-5}—10^{-3}M) solutions in methanol containing 2 vol% H_2O and alkali hydroxide (NaOH or KOH 0.1—0.3M) were quite different from those of neutral solutions. The absorption spectrum obtained with a 1.29×10^{-5}M eosin solution containing about 0.2M NaOH is shown in Fig. 5. Figure 5 shows that a product with its absorption maximum at 408 nm forms as the eosin disappears. A similar absorption spectrum was obtained with uranin under the same conditions, the peak wavelength being 394 nm.

This product is considerably stable *in vacuo* and in the dark, but upon the addition of oxygen it converts rapidly and almost completely into the original eosin or uranin. Assuming a full conversion of the product into eosin or uranin by the addition of oxygen, which is reasonable when the amount of bleached dye is small, one can obtain the molar extinction coefficients for the products as $\varepsilon(408\text{ nm})=(6.28\pm0.05)\times10^4\text{M}^{-1}\text{cm}^{-1}$ for eosin and $\varepsilon(394\text{ nm})=(3.95\pm0.03)\times10^4\text{M}^{-1}\text{cm}^{-1}$ for uranin both in 98 vol% methanol containing 0.1M NaOH.

By comparing these results with the previous photochemical results,[6,9,11,18,19] one can assign this product to the basic form of the semireduced eosin or uranin. The absorption spectra of semireduced eosin and uranin produced by the prolonged γ-irradiation of eosin and uranin solutions containing NaOH are shown in Figs. 6 and 7 respectively. The ESR spectra could in fact be obtained as shown in Figs. 8 and 9 for semireduced eosin and uranin respectively.

Interestingly, upon excitation with 408 nm light, the absorption at 408 nm of the irradiated eosin solution showed a hypsochromic shift as its intensity was decreased. Consequently, the ESR spectrum grew more complex, until ultimately it was superimposable on the corresponding spectrum obtained with an irradiated uranin solution. This result has

been briefly communicated elsewhere;[20] a full account will be reported in the succeeding paper.

Discussion

Reactive Species in Aqueous and Methanolic Solutions. The radiolysis of methanol yields several primary free radicals:

$$CH_3OH \rightsquigarrow e^-_{solv}, \cdot H, \cdot CH_3O, \cdot CH_2OH, \cdot CH_3, \cdot OH, \text{ and molecular products} \quad (1)$$

In the radiolysis of a methanolic solution of eosin in the absence of oxygen, eosin will be reduced with some of these radicals. In an aqueous solution eosin is assumed to react with radicals by the following fast processes:[12,14]

$$D + e^-_{aq}(H) \rightarrow \cdot S \quad (2)$$

$$D + \cdot OH \rightarrow \cdot X + OH^- \quad (3)$$

$$D + \cdot OH \rightarrow \cdot DOH \quad (4)$$

where D, S, X, and DOH are eosin, semireduced eosin, semioxidized eosin, and OH adduct respectively. The rate constants of Reactions (2) and (3) have been determined by the pulse-radiolysis technique to be $k_2 \geq 5\times10^9 M^{-1}$ sec^{-1} and $k_3=(1.4\pm0.4)\times10^{10} M^{-1}$ sec^{-1}.[12]

In the γ-radiolysis of methanol, solvated electrons (G=2.0[21]) decay with a rate constant of the order of 10^5 sec^{-1}:[22,23]

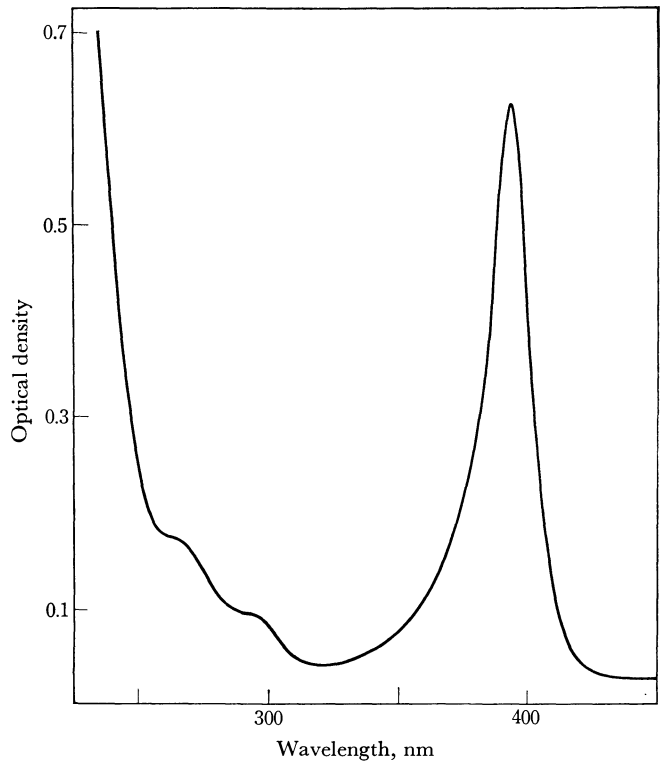

Fig. 7. Absorption spectrum of semireduced uranin prepared by prolonged γ-irradiation (1.4×10^{16} eV/ml) of 1.47×10^{-5}M uranin solution in 98% MeOH cantaining 0.1M KOH.

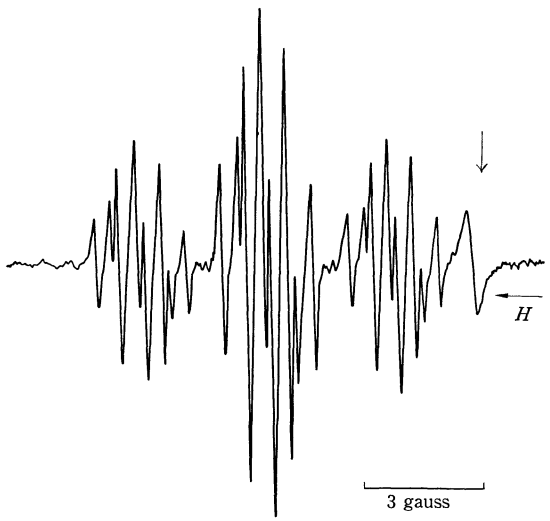

Fig. 8. ESR spectrum of semireduced eosin prepared by γ-irradiation (10^{18} eV/ml) of 1×10^{-4}M eosin solution in 70% MeOH cantaining 0.3M NaOH. The arrow indicates the standard signal of $K_2(SO_3)_2NO$.

$$e^-_{solv} \rightarrow CH_3O^- + \cdot H \qquad (5)$$

and H atoms ($G=1.7$[21]) react with methanol with $k_6=1.6\times10^6$M^{-1} sec^{-1} [24] to produce hydrogen and CH_2OH radicals:

$$\cdot H + CH_3OH \rightarrow H_2 + \cdot CH_2OH \qquad (6)$$

The other radicals produced by Reaction (1) also yield CH_2OH radicals by reactions with methanol, the total radical yield in the γ-radiolysis of methanol being determined to be 6.2.[25,26]

Reduction of Eosin in Methanolic Solutions. If the rate constant between the solvated electron and eosin in methanol is assumed to be the same as that in the aqueous solution,[27] $k_2[D]<k_5$ for the solution of 10^{-5}—10^{-4}M eosin. Figure 4 shows that $G(-\text{eosin})$ is about 2 at eosin concentrations as low as 10^{-5}M; above this point the rate of the increase in $G(-\text{eosin})$ is lower. This fact may indicate that eosin undergoes reduction principally by Reaction (7) to form semireduced eosin:

$$D + \cdot CH_2OH \rightarrow \cdot S + CH_2O \qquad (7)$$

26) H. Seki, R. Nagai and M. Imamura, This Bulletin, **41**, 2877 (1968).
27) This assumption will be correct if reactions are diffusion-controlled.

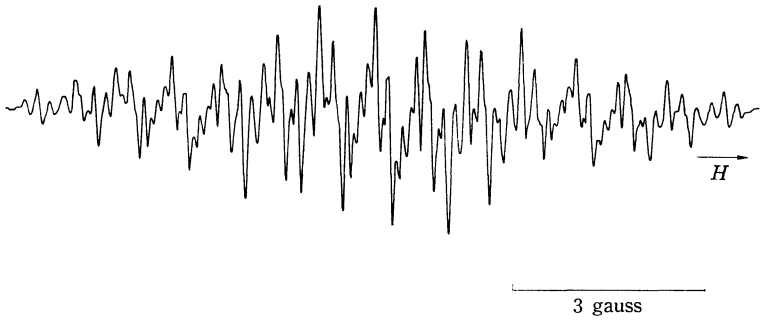

Fig. 9. ESR spectrum of semireduced uranin prepared by γ-irradiation (10^{18} eV/ml) of 1.4×10^{-4}M uranin solution in 80% MeOH containing 0.4M NaOH.

A similar reaction between eosin and C_2H_4OH radicals has been proved by Grossweiner *et al.* for aqueous eosin solutions containing 1 mM H_2O_2 and 10 mM C_2H_5OH; the rate constant of this reaction is $(1.1\pm0.2)\times10^{9}$M^{-1} sec^{-1}.[12]

Hydroxymethyl radicals combine with each other to form ethylene glycol:

$$\cdot CH_2OH + \cdot CH_2OH \rightarrow C_2H_6O_2 \qquad (8)$$

Reaction (8) is the principal reaction pathway of CH_2OH radicals in the radiolysis of methanol[26] and competes with Reaction (7) in the present systems. The rate constant of Reaction (8) has not been determined, but $2k=(1.4\pm0.4)\times10^{9}$M^{-1} sec^{-1} (23°) has been reported for C_2H_4OH radicals.[28]

Effect of Nitrous Oxide. The argument for Reaction (7) is obtained from the results with eosin solutions containing N_2O. Nitrous oxide scavenges solvated electrons in methanol completely at less than 5×10^{-3}M to form equivalent amounts of N_2 and OH radicals:[21,23c]

$$e^-_{solv} + N_2O \rightarrow N_2 + O^- (\rightarrow \cdot OH) \qquad (9)$$

The hydroxyl radicals produced by Reaction (9) react rapidly with the neighboring methanol to form CH_2OH radicals. If eosin is reduced with CH_2OH radicals, as has been mentioned above, the addition of N_2O to an eosin solution should not have any appreciable effect on $G(-\text{eosin})$; that is indeed the case, as may be seen from Fig. 4. As the concentration of eosin is increased, however, the reduction with solvated electrons may be of increasing importance.

Leuco-Dye Formation in Neutral Solutions. In deaerated aqueous solutions the reaction intermediates of eosin were assumed to decay predominantly by the back reaction:

$$\cdot S + \cdot X \rightarrow 2D \qquad (10)$$

accompanied by slower processes:

$$2X\cdot \rightarrow \text{products} \qquad (11)$$

$$2S\cdot \rightarrow D + L \qquad (12)$$

where L is the leuco-eosin.[14]

In dilute methanolic solutions, however, a principal intermediate is semireduced eosin, for the oxdizing radicals, CH_3O and OH, will rapidly disappear to form CH_2OH radicals by reactions with methanol. Thus, the semireduced eosin in methanol decays according solely to Reaction (12) to form leuco-eosin.

The absorption spectrum of the prolonged γ-irradiated eosin solution, Fig. 2, has three absorption peaks, at wavelengths of $<$230, 290 and 455 nm. For an irradiated uranin solution, four absorption peaks due to stable products were observed at $<$230, 255, 280, and 395 nm. The absorption spectrum of leuco-eosin has not been determined. However, Uchida *et al.*[29] have reported the absorption spectrum of leuco-uranin, which has two peaks at 210 and 280 nm ($\varepsilon=5\times10^{3}$M^{-1}cm^{-1}). We re-determined the absorption spectrum with leuco-uranin prepared chemically by a method similar to that employed by Uchida *et al.* and confirmed the existence of three absorption peaks, at $<$230, 255, and 280 nm. (We did not succeed in preparing leuco-eosin). Comparing the absorption spectra for the irradiated eosin and uranin with that for the chemically-prepared leuco-uranin, one may reasonably ascribe two of the three absorption peaks for eosin and three of the four for uranin to the formation of leuco-eosin and leuco-uranin by γ-irradiation.

Absorption at 455 nm Produced by γ-Irradiation. An absorption band at 455 nm produced in the γ-irradiated neutral eosin solution is sensitive to light, but is not affected by oxygen. A similar absorption appears in the uranin solution at 395 nm, but it is not sensitive at all to either light or oxygen. A free-radical nature can, therefore, be ruled out. The resumption of a complex between leuco-dye and one of the radiolysis products of methanol (say, formaldehyde) can also be ruled out, for no such absorption was observed for the leuco-dye solution containing formaldehyde. The experi-

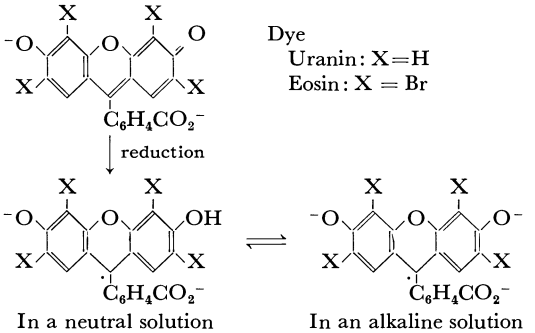
28) L. M. Dorfman and I. A. Taub, *J. Amer. Chem. Soc.*, **85**, 2370 (1963).

29) K. Uchida, S. Kato and M. Koizumi, This Bulletin, **35**, 16 (1962).

mental facts that, upon light absorption, a simultaneous decrease in the 455 nm band and increase in the 521 nm band, with slight shifts to shorter wavelengths, were observed, and that no similar change was observed for uranin solutions, may indicate that the 455 nm absorption is due to an unidentified product which undergoes photo-debromination (see below).

Intermediate in Alkaline Solutions. The reaction intermediate produced in alkaline eosin solutions ($\lambda_{max}=408$ nm) can be identified with semireduced eosin. The semireduced eosin formation in aqueous media has been confirmed by the flash-photolysis technique;[9,11,18,19] the molar extinction coefficient at the peak wavelength has been reported as $\varepsilon=4\times10^4$ (405 nm),[9] 3.8×10^4 (405 nm),[11] and 2.5×10^4 M^{-1} cm^{-1} (408 nm).[19] For uranin $\varepsilon=5\times10^4$ M^{-1} cm^{-1} (394 nm) in an aqueous medium has been reported as well.[8] Imamura found that the semireduced uranin is produced photochemically in alcoholic solutions and that it is stable in the dark in the absence of oxygen.[6] Several semireduced quinones have been known to be stable in alkaline solutions as a result of the formation of symmetrical anions. In alkaline solutions $G(-\text{eosin})$ is about twice that for neutral solutions; this indicates that the semireduced eosin is stable and does not undergo Reaction (11).

Semireduced xanthene dyes may be represented as follows:



Semireduced forms

ESR Spectra of Simireduced Eosin and Uranin. The ESR spectrum for an irradiated eosin solution, Fig. 8, consists of three groups of lines with the intensity ratio of 1 : 2 : 1 and with the coupling constant of 3.16 gauss. Each group has hfs with the ratio of 1 : 1 : 3 : 3 : 3 : 1 : 1. The fact that the ESR spectrum for the uranin solution (Fig. 9) is more complex than for the eosin solution is apparent from the fact that four bromine atoms are replaced by hydrogen atoms for uranin. This result is in agreement with, and is evidence for, the conclusion that the product is the semireduced eosin. An ESR study of the semireduced uranin has been carried out by Okuda *et al.*;[30] the analysis of the ESR spectra for semireduced forms of xanthene dyes will be described in detail elsewhere.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1337—1342 (1970)

The Radiolysis and Photolysis of Methanolic Solutions of Eosin. II. The Photo-Debromination of Eosin in an Alkaline Solution

Kazuie KIMURA, Takuji MIWA*1 and Masashi IMAMURA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received December 1, 1969)

Semireduced eosin was found to undergo photo-debromination and was identified with a precursor in the photo-debromination of eosin in alkaline methanolic solutions. Semireduced eosin was prepared by the γ-irradiation of an eosin solution. The photolysis of semireduced eosin was investigated by the use of continuous and flash light. From the absorption spectral change and a study of the decay, the mechanism of the photo-debromination was proposed. The debromination process of the photo-excited semireduced eosin was explained satisfactorily by assuming the transient formation of the debrominated-eosin σ-radical as an intermediate. In addition, we found an electron-transfer reaction from semireduced debrominated eosin to eosin, which results in the formation of semireduced eosin and debrominated eosin in the dark. A general conclusion as to the photo-dehalogenation of xanthene dyes is also given.

The photochemical debromination of eosin was found by Imamura and Koizumi in alkaline alcoholic solutions.[1] Upon irradiation by light, the absorption peak of eosin shifts gradually to shorter wavelengths; this shift proceeds until it attains the wavelength corresponding to the peak wavelength of uranin. Other halogenated xanthene dyes, such as eosin-blue (dinitro-dibromo-fluorescein) and erythrosin (tetraiodofluorescein), have also been observed to undergo similar photochemical dehalogenation.[2]

The debromination of eosin has also been reported for aqueous solutions containing phenol[3] and tertiary amines.[4] Zwicker and Grossweiner[3] assumed that the debromination takes place from the semireduced eosin on the basis of the marked dependence on the acidity. Oster *et al.*[4] postulated the same intermediate, which decomposes spontaneously to yield the partially-dehalogenated species as well. No concrete evidence has, however, yet been presented for the precursor of the dehalogenation or for its reaction mechanism.

In the photochemical system of eosin solutions, there appear several reactive intermediates, either one of which might be the precursor of debromination. These are the triplet state and semioxidized and leuco-eosin as well as the semireduced eosin. In fact, leuco-anthraquinonoid dyes in alkaline aqueous ethanolic solutions have been reported to undergo photo-dehalogenation.[5] In the preceding paper of this series,[6] we have reported on the γ-radiolysis of the neutral and alkaline methanolic solutions of eosin. In both solutions, eosin is reduced with the CH_2OH radical to form semireduced eosin. The semireduced eosin becomes leuco-eosin by means of the disproportionation reaction in the neutral solution, whereas it is stable in the dark in the alkaline solution.

No debromination has been observed in the radiolysis in the dark. The stable semireduced eosin has, however, been found to undergo photo-debromination. We have, therefore, investigated in detail the photo-debromination of the semireduced eosin which had been prepared by γ-irradiation in alkaline methanolic solutions of eosin. The results having been briefly communicated,[7] the accounts will be presented in detail in this paper.

Experimental

The materials and the experimental procedures, except for the photolysis, were largely the same as those reported previously.[6]

Irradiation was carried out with a projector lamp (300 W) with the aid of a lense and several filters.

Toshiba glass filters, VG-1, VY-450, and VV-40, and Bausch and Lomb filters, 7-3269-2, C, and C-1, were used independently or in combination. The absorption spectra were recorded on a Shimadzu SV-50A or a Cary 14R spectrophotometer.

Flash photolysis was carried out with semireduced eosin solutions by using an apparatus which has been described elsewhere.[8] Briefly, the photolysis flash consisted of two Ushio xenon lamps. The operating characteristics of the lamps were: energy per flash: 100 joule; flash duration, to 50% peak: 10 μsec. The reaction vessel was a quartz cylinder, 10 mm in *i.d.* and 10 cm in length, with flat plates sealed on either end. The apparatus had facilities for both flash spectroscopic and kinetic spectrophotometric measurements.

Results

Photo-Debromination of Eosin in Alkaline Solutions. The absorption spectral shift for eosin solutions in deaerated aqueous methanol containing alkali was observed when they were irradiated with white light or with light which had passed through a Toshiba glass filter VG-1[9] (Fig. 1). The spectral shift induced by light absorption is identical with that reported previously; it has been proved to be due to the debromination of eosin.[1] The absorption peak finall attains a wavelength corresponding to the peak wavelength (495 nm) of uranin (disodium salt of fluorescein), which has no bromine substitution. The absorption bands appearing between 521 and 495 nm are due to the formation of dyes in which there is a replacement of bromine by hydrogen; 4′,5′-dibromouranin has its absorption peak at 506 nm.[4]

substantial spectral shift, as is shown in Fig. 2. These facts caused us promptly to carry out experiments to determine if the debromination would occur upon the photo-excitation of semireduced eosin. In fact, it took place, as is also shown in Fig. 2.

The photo-debromination of semireduced eosin was more clearly shown to take place for the solution of semireduced eosin which had been prepared by the γ-irradiation of an alkaline methanolic solution of eosin. In this solution, semireduced eosin is produced as quite a stable product, as has been reported previously.[6] Using an interference filter which transmits the light (402 nm) to be absorbed solely by semireduced eosin, we could observe the spectral change shown in Fig. 3; the change indicates that the photo-debromination of semireduced eosin is taking place.

As may be seen in Figs. 1, 2, and 3, the absorption bands developing in the course of the debromination process are as sharp as those for eosin or uranin, indicating that each intermediate absorption band may be due largely to a single compound and that, therefore, debromination may proceed in a step-by-step fashion. The above experimental results also indicate that the precursor of the photo-debromination of eosin is semireduced eosin.

ESR Spectrum Change Upon Light Irradiation. Figure 3 shows that the absorption peak of semireduced eosin also shifts to a shorter wavelength as its intensity is decreased. In a previous paper ESR spectra have been reported for semireduced eosin and uranin, prepared by the γ-irradiation of alkaline methanolic solutions of eosin

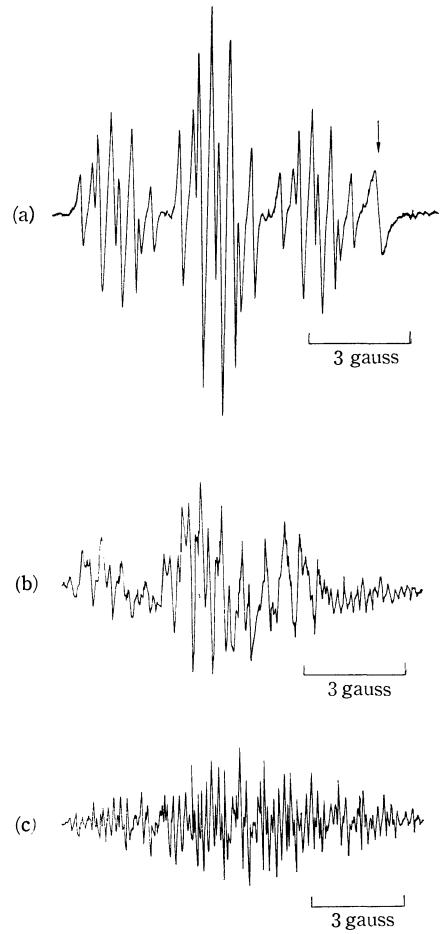

Fig. 4. Change of ESR spectrum of semireduced eosin caused by light-irradiation.
a: for semireduced eosin prepared by γ-irradiation of alkaline methanolic solution of eosin.
b and c: after irradiation by 402 nm light. ESR spectrum c is almost superimposable on that of semireduced uranin (see Ref. 6). The arrow indicates the standard signal of $K_2(SO_3)_2$-NO.

and uranin respectively.[6] Figure 4 shows the successive change in the ESR spectra for the semireduced-eosin solution which was subjected to light-irradiation for different periods. The ESR spectrum of semireduced eosin grows more complex until ultimately it is superimposable on that of semireduced uranin. These results indicate that semireduced forms of debrominated eosins are also produced as intermediate products.

Reaction of Eosin with Semireduced Uranin. Figure 3 implies another interesting feature. Upon the excitation of semireduced eosin (408 nm of the Absorption Spectrum 2), the absorption band of debrominated dye (505 nm of 3) developed and the original absorption band due to eosin (521 nm of 2) vanished. This result may be explained in terms of electron transfer from the semireduced

form of dehalogenated dye to eosin, the latter having an electron affinity higher than the former. By this electron-transfer reaction, semireduced debrominated-eosin is oxidized to debrominated eosin and the remaining eosin is reduced to semireduced eosin.

This reaction was demonstrated to take place by following experiment shown in Fig. 5. When semireduced uranin (2 in Fig. 5) prepared by the γ-irradiation of uranin (1) in an alkaline methanolic solution was mixed with eosin *in vacuo* and in the dark, the absorption peak of semireduced uranin (394 nm) shifted to a longer wavelength, the absorption band of eosin (521 nm) disappeared, and that of uranin (495 nm) increased (3). The results clearly show that uranin and semireduced eosin (408 nm) were produced by the electron-transfer reaction between semireduced uranin and eosin; this is in agreement with the assumption mentioned above.

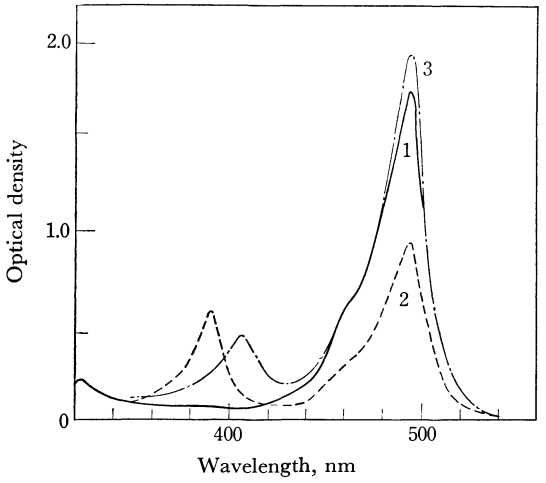

Fig. 5. Absorption spectra for (1) uranin, (2) semireduced uranin and (3) the mixed solution of semireduced uranin and eosin. All the solutions were in alkaline MeOH *in vacuo*. Note that the absorption of added eosin (521 nm) vanished.

Flash Photolysis of Semireduced Eosin. The primary processes of the photo-debromination of semireduced eosin were studied by flash photolysis. Semireduced eosin which had been prepared by the prolonged γ-irradiation of an alkaline methanolic solution of eosin, and which contained a negligible amount of unreacted eosin, was photolyzed by flash light through a VV-40 glass filter. The absorption spectra recorded 20 μsec and several minutes after the flash are given in Fig. 6. Upon the excitation of the semireduced eosin, a rapid development of the absorption band at 514 nm was observed; this development is due to the formation of partially-debrominated eosin. A decrease in the absorption intensity of the original semireduced eosin was observed at the same time. The absorption band at 514 nm then showed a decrease in intensity in the dark, along with a recovery of the absorption band at a shorter wavelength to an extent equivalent to the decrease in the intensity of the former band. The decay characteristics of semireduced eosin are given in Fig. 7, in which the oscillographic trace of the transmittance at 514 nm is also shown. These traces were recorded separately with semireduced eosin solutions which had been prepared in the same way by γ-irradiating solutions of equal eosin concentrations. Figure 7 shows that, upon flash-excitation, semireduced eosin rapidly converts during the duration of the flash to partially-debrominated eosin having its absorption peak at $\sim$514 nm.

The rapid processes are followed in the dark by

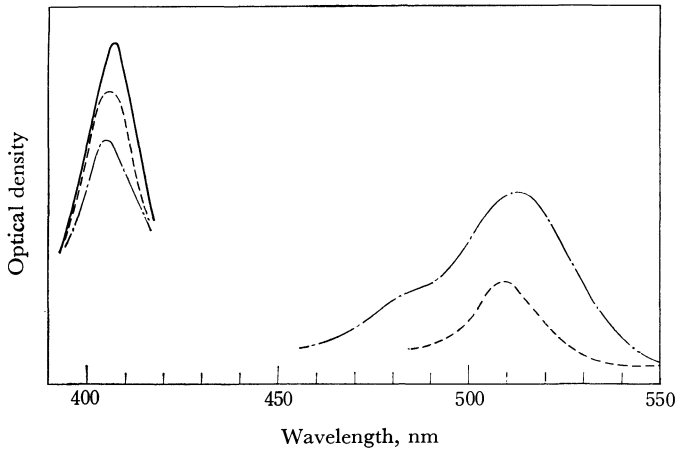

Fig. 6. Absorption spectra of semireduced eisoin solution after flash-irradiation.
—— before flash, practically no absorption of eosin (521 nm) is observed. -·-·- 20 μsec after flash, ------ several min after flash.

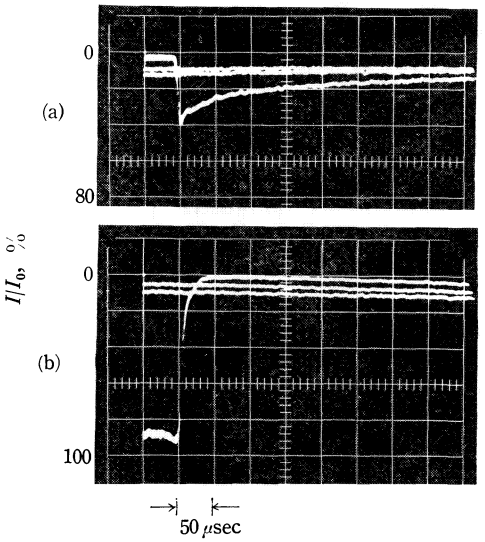

Fig. 7. Oscillographic traces of (a) semireduced eosin at 408 nm and (b) debrominated eosin at 514 nm.

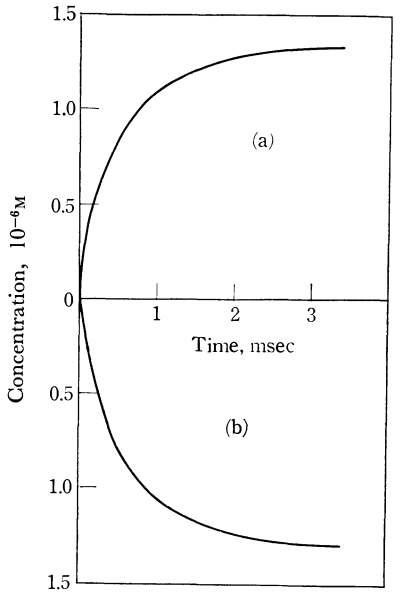

Fig. 8. Slow processes in the dark followed by flash photolysis of semireduced eosin.
(a) Increase in [semireduced eosin] at 408 nm.
(b) Decrease in [debrominated eosin] at 514 nm.

the slow processes. Figure 8 shows the slow processes more clearly by plotting the concentrations of semireduced and partially-debrominated eosin as a function of the time from 0.1 msec after the flash. The concentrations of both species were calculated by taking ε (514 nm) $= 1.08 \times 10^5 \text{M}^{-1}\,\text{cm}^{-1}$ and ε (408 nm) $= 5.67 \times 10^4 \text{M}^{-1}\,\text{cm}^{-1}$.[10] The two curves are apparently mirror images of each other, indicating that partially-debrominated eosin is reduced solely to its semireduced form in the dark.

Discussion

From the experimental results presented above, the following conclusions can be immediately drawn:

(1) The precursor of the photo-debromination is semireduced eosin, which is quite stable in deaerated alkaline methanolic solutions.

(2) Semireduced eosin is debrominated and oxidized, upon photo-excitation, to debrominated eosin.

(3) The photo-debromination of semireduced eosin takes place in a step-by-step fashion.

(4) Semireduced forms of debrominated eosin are successively produced as intermediates in the debromination process.

(5) The electron transfer from semireduced debrominated-eosin to eosin occurs in the dark.

Semireduced Eosin as a Precursor. The present results show clearly that the photo-debromination of eosin is actually initiated by the photo-excitation of semireduced eosin. Semireduced eosin is stable in alkaline media because of the symmetrical structure of its basic form.[6] In a neutral solution, however, semireduced eosin undergoes a disproportionation reaction to produce leuco-eosin and eosin.[6] These results provide an explanation of the fact that the photo-debromination of eosin is observed only in alkaline media in the presence of such reducing agents as alcohols and amines. This conclusion is in agreement with previous suggestions by other authors.[3,4]

All other reaction intermediates can be ruled out as the precursor of the photo-debromination. The experiment in which only eosin was photo-excited showed no debrominations, indicating that the excited eosin is not the precursor of the debromination. Semioxidized eosin, which has been proved to form in the radiolysis of aqueous solutions,[11-13] is not produced in alcoholic solutions.[6] Leuco-eosin, if any is present, might undergo debromina-

10) The molar extinction coefficients of debrominated eosins were estimated by assuming the linear relationship between the maximum ε's and the peak wavelengths of these dyes, those for eosin, dibromoeosin and uranin being known. The ε's for semireduced forms with different numbers of bromine were determined from the estimated ε's for their corresponding oxidized forms as mentioned above, where each semireduced form is assumed to be oxidized quantitatively by oxygen.

tion when it is oxidized, as has been observed for anthraquinonoid dyes,[5] because it probably produces semireduced eosin as a reaction intermediate. In the present system, however, no leuco-eosin was produced and no experiment has been carried out with leuco-eosin.

Debromination of Semireduced Eosin. The spectral change recorded in the flash photolysis of semireduced eosin (Fig. 6) seems to indicate that the replacement of bromine atoms by hydrogen atoms takes place one by one. Upon the flash irradiation of semireduced eosin, a new absorption band appeared with a peak at 514 nm. This absorption band is apparently due to the formation of debrominated eosin. The absorption peaks of eosin and uranin are at 521 and 495 nm respectively, while that of dibromouranin is between them (506 nm).[4] Insofar as the absorption band at 514 nm can be ascribed to any single debrominated product, this product (514 nm) may be assigned to the debrominated eosin, in which one bromine is replaced by one hydrogen. We have concluded in the "Results" section that each absorption band appearing in the course of the photo-debromination is due largely to a single debrominated product. The shape of the absorption spectra in Fig. 6 also supports this conclusion.

Figure 7 indicates that semireduced eosin is debrominated and simultaneously oxidized to debrominated eosin. The reaction is completed within the duration of the flash (10 μsec). Since no oxidizing species can be considered to be present in a concentration as to react rapidly with semireduced eosin, the reaction may reasonably be assumed to proceed by a first-order kinetics. No experimental evidence has been obtained for the reaction of excited semireduced eosin producing semireduced debrominated-eosin directly.

Proposed Mechanism of Debromination. The rapid formation of debrominated eosin caused by the photo-excitation of semireduced eosin and the ensuing slow process can be explained by assuming the following reactions:

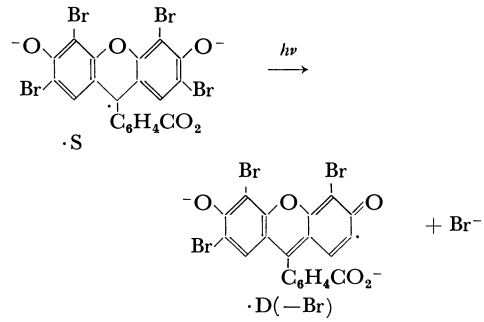
$$\cdot S \xrightarrow{h\nu} \cdot S^* \longrightarrow \cdot D(-Br) + Br^- \quad (1)$$

$$\cdot D(-Br) + CH_3OH \longrightarrow D(-Br) + \cdot CH_2OH \quad (2)$$

$$D(-Br) + \cdot CH_2OH \longrightarrow \cdot S(-Br) + CH_2O \quad (3)$$

where D and S stand for eosin and semireduced eosin respectively.

Semireduced eosin exists in an alkaline solution in the basic symmetrical form.[6] The electron-rich semireduced eosin may easily release a bromide ion upon photo-excitation, thus forming the debrominated-eosin σ-radical, $\cdot D(-Br)$, Reaction (1). The exact position where the first bromine atom is released has not yet been established; $\cdot D(-Br)$ is, in any case, a free radical and will rapidly abstract hydrogen from the neighboring methanol to form debrominated eosin, $D(-Br)$, and the CH_2OH radical (Reaction (2)). The rapid process



shown in Fig. 7 can thus be explained by the sequence of Reactions (1) and (2).

The ensuing slow process can be explained by Reaction (3), where debrominated eosin $D(-Br)$ is reduced with the CH_2OH radical produced by Reaction (2). The semireduced form of $D(-Br)$, $\cdot S(-Br)$, then replaces its bromine with hydrogen by a sequence similar to that of Reactions (1) and (2), and so on. Thus photo-debromination will continue until all the bromines are replaced with hydrogens, final product being nothing but uranin.

This mechanism can also explain the fact that semireduced forms of various debrominated eosins are successively produced in the course of the debromination process. It may be speculated that such an electron-transfer reaction as that observed between eosin and semireduced debrominated-eosin plays a role in making the intermediate products a single component.

Photo-debromination of Eosin. The overall mechanism of the photo-debromination of eosin can be understood on the basis of the results presented above. The photo-debromination does not take place unless semireduced eosin is photo-excited. In previous experiments,[1-4] solutions were exposed to the light, which is absorbed not only by eosin, but also by its semireduced form. Furthermore, the debromination is observable only in deaerated alkaline media containing appropriate reducing agents; every role of those agents is also clear from the present investigation. The dehalogenation of other xanthene dyes can be explained largely in the same manner.

Recently Sherman[14] has found another type of radiation-induced dehalogenation for some halogenated benzenes as well as for alkyl halides. Alkaline alcoholic solutions of these compounds have been reported to show chain dehalogenation. The reaction, however, is initiated by dissociative electron attachment to the halogens of these compounds; no indication of such a reaction has been observed with eosin solutions in the present study.

The authors wish to thank Dr. Akira Kira for his helpful advice in the flash-photolysis experiments.

Thermodynamic and X-Ray Studies of Solid Solutions of Silver Bromide and Lithium Bromide

Toshihide Tsuji,* Shunichi Murakoshi,** Kazuo Fueki and Takashi Mukaibo

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received December 2, 1969)

A miscibility gap in AgBr-LiBr solid solutions has been found by the high temperature X-ray diffraction method, and a new phase diagram is presented. Activity, partial molar free energy, enthalpy and entropy of AgBr in AgBr-LiBr solid solutions have been obtained at 350 and 400°C from the e.m.f. data of galvanic cells of the type Ag/AgBr-LiBr/Br_2. It has been found that the solid solution forms a regular solution difined by Hildebrand.

It was shown by Kiukkola and Wagner[1] that e.m.f. measurements on galvanic cells involving solid electrolytes can be used for the determination of standard free energies of formation of halides, oxides, sulfides and other compounds at elevated temperatures, and many e.m.f. studies have been carried out ever since.

The authors have determined the miscibility gap in AgBr-NaBr solid solutions by means of a high temperature X-ray diffraction method.[2] The authors have also measured the e.m.f. of solid electrolyte cells of the type Ag/AgBr-NaBr/Br_2 and calculated activities and partial molar quantities of AgBr in the AgBr-NaBr solid solution. It was found that the AgBr-NaBr system forms a regular solution above the critical temperature. This paper reports the results of similar studies on the AgBr-LiBr system.

Experimental

High purity lithium bromide and silver bromide, prepared by Yoneyama Chemical Industries Ltd. and Kojima Chemical Co., Ltd., respectively, were used.

Lithium bromide was dried *in vacuo* at about 300°C until the weight of the salt became constant. Lithium bromide and silver bromide were then mixed in a desired proportion, melted in a quartz tube in bromine atmosphere, and heated until the solution became clear. Subsequently, the solution was frozen, kept at about 400°C for several hours and quenched. After cooling, the sample was taken out from the quartz tube and ground in an agate mortar in a dry box.

The apparatus and the experimental procedures for the present work were the same as described in detail previously.[2]

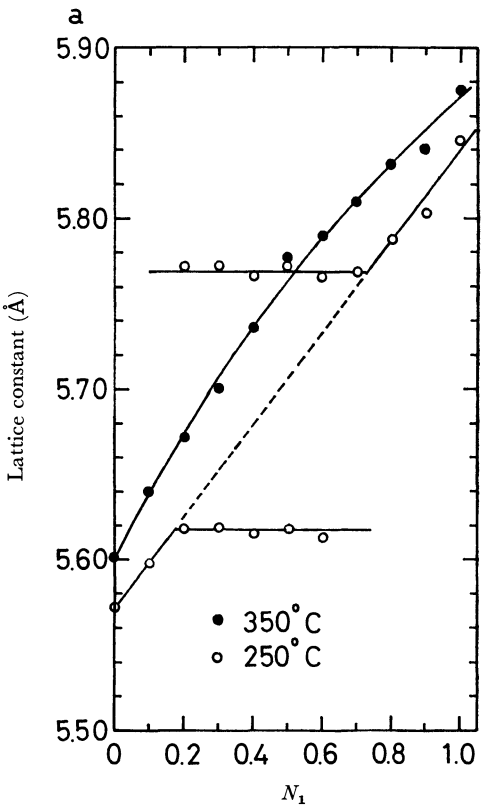

Fig. 1. Plot of lattice constant against the mole fraction of AgBr.

Results and Discussion

High Temperature X-Ray Diffraction Study. As reported previously, a miscibility gap exists in the AgBr-NaBr system.[2] Although Sandonnini and Scarpa[3] have reported that the AgBr-LiBr system forms a complete solid solution, a miscibility gap may exist in the system in view of the similarity between AgBr-NaBr and AgBr-LiBr systems.

In order to determine whether or not the solubility limit exists, a study by the high temperature X-ray diffraction method was carried out at temperatures between 50 to 350°C at an interval of 50°C. Lattice constants obtained from the reflections of (200), (220), (222), (422) and (600) planes are shown in Fig. 1 as plots against the mole fraction of silver bromide, N_1. We see that the lattice constant at 350°C increases continuously with the increase in mole fraction of silver bromide, but at lower temperatures such as 250°C, the discontinuities in lattice parameter exist.

0.900	−19.28	−0.02	0.05	0.01	0.985	0.287
1.000	−19.26	0	0	0	1.000	0

The slope of the plot of E *vs.* $\log P_{Br_2}$ of AgBr-LiBr solid solutions with various compositions is the same as that of pure silver bromide. A similar relationship is found at 350°C. Since it was shown previously[2] that pure silver bromide is entirely ionic above 300°C, AgBr-LiBr solid solutions also seem to be an ionic conductor at 350 and 400°C.

Table 1 lists the value of E_0, the e.m.f. at a bromine pressure of 1 Torr., which was obtained by extrapolating the plot of E *vs.* $\log P_{Br_2}$.

If ΔG_1 and ΔG^0 denote the free energy changes of the reaction $Ag+\frac{1}{2}Br_2=(AgBr)$ in solid solution and in pure state, respectively, the partial molar free energy of silver bromide in solid solutions, $\bar{G}_1$, is obtained by the equation

$$\bar{G}_1 = \Delta G_i - \Delta G^\circ. \quad (1)$$

From the temperature dependenc of $\bar{G}_1$, the partial molar entropy and enthalpy of silver bromide in solid solutions are calculated. If pure silver bromide is chosen as the standard state, the activity of silver bromide in its solution is calculated by the relation

$$\bar{G}_1 = 2.303\,RT\log a_1. \quad (2)$$

The activity of lithium bromide, a_2, is obtained by the Gibbs-Duhem equation in the integrated form

$$\log(a_2/N_2) = -\int_0^{N_1}(N_1/N_2)\,d\log(a_1/N_1). \quad (3)$$

Thermodynamic data of the AgBr-LiBr system at 350 and 400°C are summarized in Table 2.

As seen in Fig. 4, the AgBr-LiBr system shows positive deviations from Raoult's law.

Figure 5 gives the plot of $(\bar{G}_1-\bar{G}_1^i)$ *vs.* N_2^2, where $\bar{G}_1^i$ is the partial molar free energy of component 1 in the ideal solution. Linearity holds between $(\bar{G}_1-\bar{G}_1^i)$ and N_2^2, and the two sets of points for 350 and 400°C lie on a single straight line. The result clearly shows that the AgBr-LiBr system above the critical temperature forms a regular solution defined by Hildebrand.[4] It is concluded from this result that the partial molar entropy is the same as it would be in the ideal solution, *i.e.*, $S_1=S_1^i=R\ln N_1$, and that two kinds of positive ions are distributed at random in the solid solution.

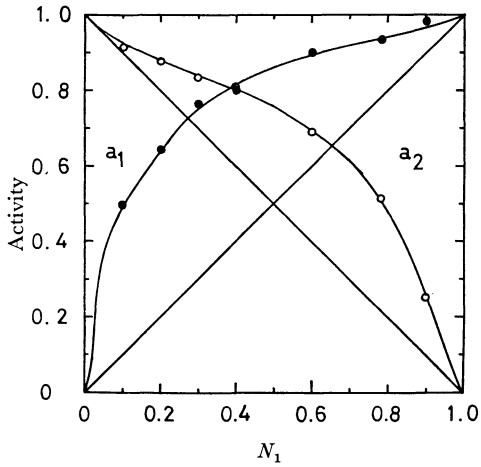

Fig. 4. Activity curves for AgBr-LiBr solid solutions at 400°C.

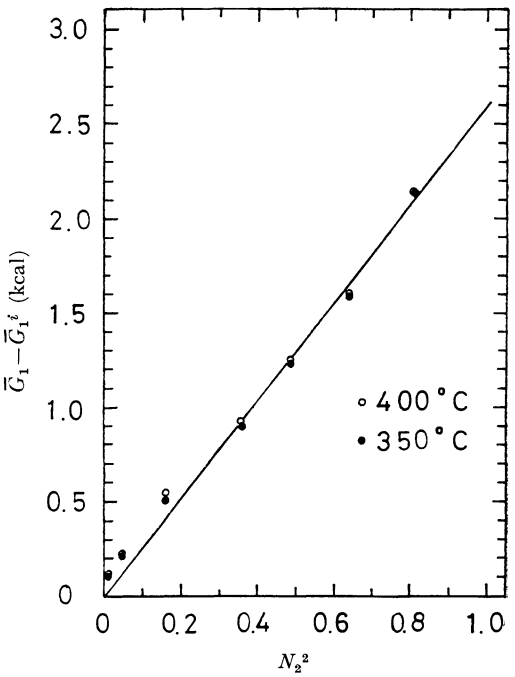

Fig. 5. Plot of $(\bar{G}_1-\bar{G}_1^i)$ against N_2^2.

Summary

1) The solubility limit in the AgBr-LiBr system was determined by means of the high temperature X-ray diffraction method and a new phase diagram of the system was presented.

2) The partial molar free energy of AgBr in the system was determined by the e.m.f. measurement for the galvanic cell, $Ag/AgBr\text{-}LiBr/Br_2$ at 350 and 400°C.

3) The partial molar entropy and the partial molar enthalpy of AgBr in the system were calculated.

4) The system was found to form a regular solution defined by Hildebrand.

4) J. H. Hildebrand, *J. Amer. Chem. Soc.*, **51**, 66 (1929).

(Received December 6, 1969)

The charge-transfer interaction is investigated theoretically for linear chain systems in molecular crystals. The charge-transfer excitation energy is shown to diverge in crystals by the usual configuration interaction method considering only one-molecule excitation. In order to overcome this difficulty, the second quantized Hamiltonian is solved with the Bose approximation for the charge-transfer exciton. Consequently, reasonable results are obtained for the stabilization of the ground state due to the contribution of many virtual excitons, for the electric dipole moment of the ground state, and for the transition moment of a charge-transfer excitation. The results correspond well to those by Mulliken's theory for an electron donor-acceptor pair. The second quantization model is also applied in the extended form to crystals of charge-transfer complexes and ionic radicals of complex stoichiometry. The lower excited states in these crystals are understood as the coupled ones of the one-site and two-site charge-transfer configurations.

Concerning the crystals of charge-transfer (abbreviated hereafter to CT) complexes and radical ion salts, the geometrical structures and also the electrical, magnetic and optical properties have been studied by many authors from the experimental point of view.[1-5] Consequently, some interesting phenomena have been found in relation with their electronic structures. For example, radical salt crystals such as (Quinolinium)$^+$(Tetracyano-*p*-quinodimethan)$_2^-$ and (*N*-Methylphenazinium)$^+$(Tetracyano-*p*-quinodimethan)$^-$ exhibit a large electrical conductivity up to $10^2\,\Omega^{-1}\mathrm{cm}^{-1}$.[3a,3c] Furthermore, some of radical salt crystals are known to show in the infrared region strong absorption bands characteristic of the interaction between electron donor and acceptor.[6-9] In contrast to a plenty of experimental studies, there are only a few literatures[10] about the theory of electronic structures of these crystals.

Concerning usual molecular crystals[11-15] as well as CT complex crystals, the CT interaction plays an important role in their electronic processes. For example, the absorption bands ascribed to no intramolecular excitations were found for the α-form crystals of perylene and 9,10-dichloroanthracene and were assigned reasonably to the CT band.[14,15]

Under these circumstances, we undertake to develop the theory in the second quantization form on the electronic structures of molecular crystals and also of crystals of CT complexes and radical ion salts. We propose a model Hamiltonian appropriate to the case where the Coulomb energy

is larger than the transfer energy and discuss the CT electronic state. At first, the basic theory of the CT interaction in molecular crystals is presented. Thereafter the problem of some CT complexes and ionic radical crystals of complex stoichiometry, for example Et_3NH^+(Tetracyano-*p*-quinodimethan)$_2^-$ crystals, is treated by applying the basic theory in the extended form.

Theoretical

Wave Functions and Energy Levels. We consider a linear chain system consisting of N identical radicals or molecules and also that consisting of alternatively located N electron donors and N electron acceptors. In the former case, each component acts as both donor and acceptor. In the latter case, however, the electron donor and acceptor can be distinguished explicitly from each other. Furthermore, in these crystals the component molecules and radicals are assumed to be equally spaced. In actuality, the X-ray crystal analysis data show that there exists one-dimensional equivalent interaction along a chain in most of these crystals.[2a-d]

We can represent the ground configuration as $\psi(0,0)$ and one site CT configuration as $\psi(\pm 1,j)$ in which an electron on the jth site component transfers to the nearest neighbors.*1 Here + and − show the direction of electron migration. The numbering of j is made for identical molecules or radicals in the case of molecular or radical crystals, and for electron donors and for electron acceptors separately in the case of CT complexes.

Keeping the above-mentioned facts in mind, we construct the wave functions of crystals. In the case of usual molecular crystals and of weak CT complex crystals, the ground configurations $\psi(0,0)$ is singlet, and there are possibilities of singlet and triplet for the CT configurations. By considering only the highest occupied and lowest vacant orbitals, the wave functions of the ground and CT configurations can be represented by the following equations for usual molecular crystals:

$$\psi(0,0) = |\phi_1^0(1)\bar{\phi}_1^0(2)\cdots\phi_j^0(2j-1)\bar{\phi}_j^0(2j)\cdots \phi_N^0(2N-1)\bar{\phi}_N^0(2N)| \text{ (singlet)} \quad (1)$$

$$\psi(m,j) = \frac{1}{\sqrt{2}}\{|\phi_1^0(1)\bar{\phi}_1^0(2)\cdots\phi_j^0(2j-1)\bar{\phi}_{j+m}^v(2j)\cdots \phi_N^0(2N-1)\bar{\phi}_N^0(2N)| \pm |\phi_1^0(1)\bar{\phi}_1^0(2)\cdots \bar{\phi}_{j+m}^v(2j-1)\bar{\phi}_j^0(2j)\cdots\phi_N^0(2N-1)\bar{\phi}_N^0(2N)|\} \quad (2)$$

where $m=\pm 1$ (+ and − correspond to the singlet and triplet states, respectively), ϕ_j^0 is the highest occupied molecular orbital of the jth site component, and suffix v signifies the lowest vacant molecular orbital. They are orthonormalized like Wannier orbitals. The wave function for the CT configuration which satisfies the translational symmetry of crystals can be written as follows:

$$\Psi(m,k) = \frac{1}{\sqrt{N}}\sum_j e^{ikj}\psi(m,j),\ m = 1, -1 \quad (3)$$

where $k=2\pi/Nj$ ($j=1, 2, \cdots, N$) from the cyclic boundary condition and the unit length is taken to be equal to the distance between the neighbouring molecules for usual molecular crystals and that between the neighbouring donor (acceptor) molecules for CT complexes.

The above-mentioned two CT configurations $\Psi(1,k)$ and $\Psi(-1,k)$ mix with each other, and consequently the following two energy levels can be obtained.

$$\omega_{k+} = \omega + \sum_{l\neq 0} e^{-ikl}U_1(|l|) + |\sum_l e^{-ikl}U_2(l)|\cdot\tau$$
$$\omega_{k-} = \omega + \sum_{l\neq 0} e^{-ikl}U_1(|l|) - |\sum_l e^{-ikl}U_2(l)|\cdot\tau \quad (4)$$

where

$$U_1(|j-j'|) = \langle\psi(m,j)|H|\psi(m,j')\rangle$$
$$U_2(j-j') = \langle\psi(1,j)|H|\psi(-1,j')\rangle$$
$$\omega = \langle\psi(m,j)|H|\psi(m,j)\rangle;\ m=1,-1 \quad (5)$$
$$U_2(l)\neq U_2(-l)$$

and

$$\tau = \frac{\sum_l U_2(l)}{|\sum_l U_2(l)|}$$

The corresponding wave functions are

$$\Psi(1,k,\nu) = \frac{1}{\sqrt{2N}}\sum_j e^{ikj}\{\psi(1,j) + \nu e^{i\theta_k}\times\psi(-1,j)\} \quad (6)$$

where

$$e^{i\theta_k} = \frac{\sum_l e^{ikl}U_2(l)}{|\sum_l e^{ikl}U_2(l)|}\cdot\tau \quad (7)$$

and $\nu=\pm$.

The interaction between the ground configuration and the one site CT configuration with the spin multiplicity of singlet is rather large and can not be disregarded. For the evaluation of the matrix element necessary for the calculation of the interaction, the following two cases can be considered, when there is a center of symmetry of the point group between the neighbouring two molecules (or radicals).

Case A) When

$$\langle\psi(1,j)|H|\psi(0,0)\rangle = \langle\psi(-1,j)|H|\psi(0,0)\rangle$$

the matrix element is

$$\langle\Psi(1,k,\nu)|H|\psi(0,0)\rangle = \sqrt{2N}\,\beta\delta_{k0}\delta_{\nu+} \quad (8)$$

Case B) When

*1 In the case of CT complexes, $\psi(\pm 1,j)$ represents the configuration in which an electron on the jth donor molecule transfers to the nearest neighbouring acceptor molecule.

$$<\Psi(1,j)|\boldsymbol{H}|\psi(0,0)> = -<\psi(-1,j)|\boldsymbol{H}|\psi(0,0)>,$$

the matrix element is

$$<\Psi(1,k,\nu)|\boldsymbol{H}|\psi(0,0)> = \sqrt{2N}\,\beta\delta_{k0}\delta_{\nu-} \qquad (9)$$

where

$$\beta = <\phi(1,j)|\boldsymbol{H}|\psi(0,0)>$$

The quantity β corresponds to the transfer energy which determines the band width in the band model. As is seen in Eqs. (8) and (9), the only CT configurations of $k=0$, $\nu=+$ and $k=0$, $\nu=-$ mix with the ground configuration for cases A and B, respectively. Hereafter we consider only case A, since the similar discussion can be applied to case B. By taking the configuration interaction between the ground and CT configurations into account on the assumption of neglecting the contribution from the excited configurations in which many molecules are excited simultaneously in a crystal, the energy eigen values for the system can be obtained as follows:

$$E = \frac{\varepsilon_{0+}}{2} \pm \frac{1}{2}\sqrt{\varepsilon_{0+}{}^2+8N\beta^2} \qquad (10)$$

where

$$\varepsilon_{k\nu} = \omega_{k\nu} - <\psi(0,0)|\boldsymbol{H}|\psi(0,0)>$$

Therefore the excitation energy between these states is

$$E_{\text{exc.}} = \sqrt{\varepsilon_{0+}{}^2+8N\beta^2}$$

The obtained excitation energy depends on N and diverges with its increase.

$$E_{\text{exc.}} \to \infty \quad (N \to \infty)$$

This divergence arises from disregarding the configurations in which two or more than two molecules are excited simultaneously in a crystal. In the present paper, we undertake to overcome this difficulty by adopting second quantization formalism.

In the case of radical crystals and of strong CT complex crystals, each component has open shell structure and $S=1/2$. Since it is difficult to handle explicity the spin multiplicity of each electronic state of the crystal, we neglect the electron spin for simplicitly in these cases and represent the wave functions of the ground and CT configurations by the simple product of appropriate orbitals ϕ_j's. Then we can obtain the conclusion that the transition energy diverges with the increasing N also for this case.

Hamiltonian and the Bose Approximation. From the above discussion we can write a model Hamiltonian in the following second quantization form.[16]

$$\boldsymbol{H} = \boldsymbol{H}_1 + \boldsymbol{H}_2 + \boldsymbol{H}_3 \qquad (12)$$

$$\boldsymbol{H}_1 = \sum_{j,\sigma}\varepsilon\, a^+_{j\sigma}a_{j\sigma} \qquad (13)$$

$$\boldsymbol{H}_2 = \frac{1}{2}\sum_{\substack{j,j'\\ \sigma,\sigma'\\ (j\sigma)\neq(j'\sigma')}} U(j'\sigma',0;0,j\sigma)(a^+_{j'\sigma'}a_{j\sigma}+a^+_{j\sigma}a_{j'\sigma'}) + \frac{1}{2}\sum_{\substack{j,j'\\ \sigma,\sigma'\\ (j\sigma)\neq(j'\sigma')}} U(j'\sigma',j\sigma;0,0)(a^+_{j'\sigma'}a^+_{j\sigma}+a_{j\sigma}a_{j'\sigma'}) \qquad (14)$$

$$\boldsymbol{H}_3 = \sum_{j,\sigma}\beta(a^+_{j\sigma}+a_{j\sigma}) \qquad (15)$$

Here $a^+_{j\sigma}$ and $a_{j\sigma}$ are the creation and annihilation operators for an excitation which transfers an electron on the jth site, by one site, to $\sigma(\sigma=+,-)$ direction.

Hamiltonian $\boldsymbol{H}_1$ corresponds to the diagonal matrix element of $(j\sigma)$ excitation and $\varepsilon=<\psi(m,j)\cdot|\boldsymbol{H}|\psi(m,j)>-<\psi(0,0)|\boldsymbol{H}|\psi(0,0)>$; $m=1,-1$.

The first term of $\boldsymbol{H}_2$ signifies the process of the excitation transfer in which an excitation $(j\sigma)$ transfers to that of $(j'\sigma')$ and its inverse process. The coefficient $U(j'\sigma', 0;0, j\sigma)$ is the corresponding matrix element, satisfying the relations $U(j'\sigma, 0;0, j\sigma)=U_1(|\boldsymbol{j}-\boldsymbol{j}'|)$ and $U(j'-, 0;0, j+)=U_2(\boldsymbol{j}-\boldsymbol{j}')$. The second term of H_2 signifies the pair creation and the pair annihilation of two excitations $(j\sigma)$ and $(j'\sigma')$, $U(j'\sigma', j\sigma; 0,0)$ being its matrix element. The matrix elements $U(j'\sigma', 0;0, j\sigma)$ and $U(j'\sigma', j\sigma; 0,0)$ are considered to be small compared with the diagonal matrix element ε, since these quantities are proportional to the square of the intermolecular overlap integral.

Hamiltonian $\boldsymbol{H}_3$ represents the interaction between configurations which differ in the excitation number by one from each other and the interaction energy corresponds to the transfer (or resonance) energy β. This term represents the CT interaction.

Considering the diagonalization of the Hamiltonian $\boldsymbol{H}$, we disregard the second term of $\boldsymbol{H}_2$ for simplicity, since this term may give negligibly small influence when ε is large compared with $U(j'\sigma', j\sigma; 0,0)$.

We difine new operators which create and annihilate a one site CT exciton corresponding to Eq. (6).

$$b_{k+} = \frac{1}{\sqrt{2N}}\sum_j e^{-i\boldsymbol{kj}}(a_{j+}+e^{-i\theta_k}a_{j-})$$

$$b_{k-} = \frac{1}{\sqrt{2N}}\sum_j e^{-i\boldsymbol{kj}}(a_{j+}-e^{-i\theta_k}a_{j-}) \qquad (16)$$

The inverse transformation is,

$$a_{j+} = \frac{1}{\sqrt{2N}}\sum_k e^{i\boldsymbol{kj}}(b_{k+}+b_{k-})$$

$$a_{j-} = \frac{1}{\sqrt{2N}}\sum_k e^{i\boldsymbol{kj}+i\theta_k}(b_{k+}-b_{k-}) \qquad (17)$$

Operators $a^+_{j\sigma}$ and $a_{j\sigma}$ are essentially the Pauli operators.[10,16] However, we assume both $a^+_{j\sigma}$ and $a_{j\sigma}$ to be the Bose operators as usually done. Then $b^+_{k\nu}$ and $b_{k\nu}$ $(\nu=+,-)$ are also the Bose operators as can be shown easily. In this approximation the Hamiltonian can be diagonalized by the fol-

16) V. M. Agranovich, *J. Exptl. Theoret. Phys.* (U.S.S.R.), **37,** 430 (1959).

lowing procedures. From Eq. (16),

$$\sum_{j,\sigma} \varepsilon\, a^+_{j\sigma} a_{j\sigma} = \sum_{k,\nu} \varepsilon\, b^+_{k\nu} b_{k\nu}$$

$$\frac{1}{2}\sum_{\substack{j,j'\\ \sigma,\sigma}} U(j'\sigma', 0; 0, j\sigma)(a^+_{j'\sigma'} a_{j\sigma} + a^+_{j\sigma} a_{j'\sigma'}) \quad (j\sigma)\neq(j'\sigma')$$

$$= \sum_k \sum_l e^{-ikl} U_1(|l|)(b^+_{k+} b_{k+} + b^+_{k-} b_{k-}) + \sum_k \left|\sum_l e^{-ikl} U_2(l)\right| (b^+_{k+} b_{k+} - b^+_{k-} b_{k-})$$

$$\sum_{j,\sigma} \beta(a^+_{j\sigma} + a_{j\sigma}) = \sqrt{2N}\,\beta(b^+_{0+} + b_{0+}) \tag{18}$$

Therefore,

$$\boldsymbol{H} = \sum_{k,\nu} \varepsilon_{k\nu} b^+_{k\nu} b_{k\nu} + \sqrt{2N}\,\beta(b^+_{0+} + b_{0+}) \tag{19}$$

Furthermore, by introducing new Bose operators[17]

$$c_{0+} = b_{0+} + \frac{\sqrt{2N}\beta}{\varepsilon_{0+}} \tag{20}$$

$$c_{k\nu} = b_{k\nu} \qquad \text{expcept for } (k=0, \nu=+)$$

the Hamiltonian can be diagonalized as follows:

$$\boldsymbol{H} = \sum \varepsilon_{k\nu} c^+_{k\nu} c_{k\nu} - 2N\frac{\beta^2}{\varepsilon_{0+}} \tag{21}$$

Next we construct wave functions represented by the original representations which are applied prior to the diagonalization. For the ground state $|0\rangle$

$$|0\rangle = \sum_{n=0}^{\infty} \alpha_n |n\rangle_o \tag{22}$$

where $|n\rangle_o$ is the wave function of the original representation in which the number of virtual excitations of $(k=0, \nu=+)$ is n and no other excitation exists and suffix o means the original representation. Coefficient α_n can be obtained from

$$c_{0+}|0\rangle = 0 \tag{23}$$

$$\sum_n \alpha_n^2 = 1 \text{ (normalization condition)} \tag{24}$$

The final result is

$$\alpha_n = \frac{(-\gamma)^n}{\sqrt{n!}} e^{-\frac{1}{2}\gamma^2} \qquad (N\to\infty) \tag{25}$$

where

$$\gamma = \sqrt{2N}\frac{\beta}{\varepsilon_{0+}}$$

Extention of the Theory to Complex Radical Salt Crystals. As a model for complex radical salt, we take a closed linear chain of $2N$ acceptors (A) in which N excess electrons exist. The crystals of tetracyano-*p*-quinodimethan with various donor cations fit into this model. We take the above-mentioned localized model and neglect electron spin for simplicity. There are two ground configurations with excess electrons at odd and even number sites. They are represented by $\psi^o(0,0)$ and $\psi^e(0,0)$, respectively. The off diagonal matrix element between them is zero. Therefore the ground state is doubly degenerate unless there is an asymmetry concerning the locations of the cations. Hereafter we assume that N excess electrons locate at odd-number molecular sites even when the degeneracy is not removed. Then we can take $\psi^o(0,0)$ as the ground configuration of the system.

The CT configuration in which an electron on $(2j-1)$-th site migrates by m sites in the + (or −) direction is represented by $\psi^o(m, 2j-1)$ (or $\psi^o(-m, 2j-1)$), $m=1$ and 2 being assumed in the present paper. The excitation process corresponding to $m=1$ and 2 can be represented schematically by $\cdots$AA$^-$AA$^-\cdots \rightarrow \cdots$AAA$^-A^-\cdots$ and by $\cdots$ A$^-$AA$^-$A$\cdots \rightarrow \cdots$AAA$^=$A $\cdots$, respectively. Therefore these two kinds of excitations are different from each other in their characters.

By replacing $\phi(m,j)$ in Eq. (3) by $\psi^o(m, 2j-1)$, we can construct the wave function $\Psi^o(m,k)$ for the m site CT configuration which satisfies the translational symmetry of the crystal.*2 Furthermore, combining $\Psi^o(m,k)$'s corresponding to charge transfer in the + and − directions, we can obtain

$$\Psi^o(m,k,\nu) = \frac{1}{\sqrt{2N}} \sum_j e^{ikj}\{\psi^o(m,2j-1) + \nu\psi^o(-m,2j-1)\} \tag{26}$$

where $\nu=+,-$. We neglected for simplicity the small terms which correspond to $U_1(|l|)$ and $U_2(l)$ of Eq. (7). As in the case of usual molecular crystals and of crystals of CT complexes mentioned in the preceding chapter, the excitation energy calculated for complex radical salt crystals by this single excitation model diverges for $k=0$ and $\nu=+$.

The second quantization Hamiltonian may be written as

$$\boldsymbol{H} = \sum_{j,\sigma} \varepsilon a^+_{j\sigma} a_{j\sigma} + \sum_{j,\sigma} (\varepsilon+\Delta)\, b^+_{j\sigma} b_{j\sigma} + \sum_{j,\sigma} \beta\,(b^+_{j\sigma} a_{j\sigma} + a^+_{j\sigma} b_{j\sigma}) + \sum_{j,\sigma} \beta\,(a^+_{j\sigma} + a_{j\sigma}) \tag{27}$$

where ε, $\varepsilon+\Delta$ and β are defined as

$$\varepsilon = \langle\psi^o(m,2j-1)|\boldsymbol{H}|\psi^o(m,2j-1)\rangle - \langle\psi^o(0,0)|\boldsymbol{H}|\psi^o(0,0)\rangle \quad \text{for } m = \pm 1,$$

$$\varepsilon + \Delta = \langle\psi^o(m,2j-1)|\boldsymbol{H}|\psi^o(m,2j-1)\rangle - \langle\psi^o(0,0)|\boldsymbol{H}|\psi^o(0,0)\rangle \quad \text{for } \boldsymbol{m} = \pm 2$$

$$\beta = \langle\psi^o(2,2j-1)|\boldsymbol{H}|\psi^o(1,2j-1)\rangle = \langle\psi^o(1,2j-1)|\boldsymbol{H}|\psi^o(0,0)\rangle$$

$$\langle\psi^o(2,2j-1)|\boldsymbol{H}|\psi^o(0,0)\rangle = 0 \text{ (assumed)}$$

Operators $a^+_{j\sigma}$ and $a_{j\sigma}$ are the creation and the annihilation ones for an excitation which transfers an electron at $(2j-1)$th site, by one site, in the $\sigma(\sigma=+,-)$ direction. Operators $b^+_{j\sigma}$ and $b_{j\sigma}$ are the creation and the annihilation operators for an excitation which transfers an electron at the $(2j-1)$-

17) D. B. Chesnut, *Mol. Cryst.*, **1**, 351 (1966).

*2 By electron-phonon interaction the unit spacing of the crystal is twice that of the crystal without N excess electrons even if the chain is regular.

th site, by two sites, in the σ direction. The first and the second terms of Eq. (27) correspond to the diagonal matrix elements. The third terms represent the interactions between the one site CT configurations and the two site ones. The fourth terms represent the interaction between the ground configuration and the one site CT configurations. The usual Pauli commutation relations hold for the one-site and two-site CT operators. The one-site CT operators $a^+_{j\sigma}$ and $a_{j\sigma}$ commute with the two-sites ones $b^+_{j\sigma}$ and $b_{j\sigma}$, since the wave functions of the former are orthogonal to those of the latter when molecular orbitals in a crystal are orthonormalized.

The symmetry of translation is brought into the theory by transforming $a^+_{j\sigma}$, $a_{j\sigma}$, $b^+_{j\sigma}$ and $b_{j\sigma}$ to the wave operators $A_{k\nu}$ and $B_{k\nu}$;

$$A_{k+} = \frac{1}{\sqrt{2N}} \sum_{j=1}^{N} e^{-ikj}(a_{j+} + a_{j-})$$

$$A_{k-} = \frac{1}{\sqrt{2N}} \sum_{j=1}^{N} e^{-ikj}(a_{j+} - a_{j-}) \tag{28}$$

The operators $B_{k\nu}$ are defined in the same form as $A_{k\nu}$.

By the aid of the inverse transformation of Eq. (28), Eq. (27) is transformed as follows:

$$\boldsymbol{H} = \sum_{k,\nu} \varepsilon A^+_{k\nu} A_{k\nu} + \sum_{k,\nu} (\varepsilon + \Delta) B^+_{k\nu} B_{k\nu} + \sum_{k,\nu} \beta (A^+_{k\nu} B_{k\nu} + B^+_{k\nu} A_{k\nu}) + \sqrt{2N}\beta (A_{0+} + A_{0+}) \tag{29}$$

By assuming $a^+_{j\sigma}$, $a_{j\sigma}$, $b^+_{j\sigma}$ and $b_{j\sigma}$ to be the Bose operators as in the preceding section, the Hamiltonian can be diagonalized by the following transformation to new boson operators $C^+_{k\nu}$, $C_{k\nu}$, $D^+_{k\nu}$ and $D_{k\nu}$. The new operators are

$$C_{k\nu} = u_{k\nu} A_{k\nu} + v_{k\nu} B_{k\nu}$$
$$D_{k\nu} = u'_{k\nu} A_{k\nu} + v'_{k\nu} B_{k\nu} \tag{30}$$

for the k, ν states except for the $k=0$, $\nu=+$ state. For the $k=0$, $\nu=+$ state they are

$$C_{0+} = u_{0+} A_{0+} + v_{0+} B_{0+} + w$$
$$D_{0+} = u'_{0+} A_{0+} + v'_{0+} B_{0+} + w' \tag{31}$$

Here it may be assumed in general that coefficients $u_{k\nu}$, $v_{k\nu}$ $u'_{k\nu}$ and $v'_{k\nu}$ to be real.

The transformation is canonical when

$$u^2_{k\nu} + v^2_{k\nu} = 1,$$
$$u'^2_{k\nu} + v'^2_{k\nu} = 1, \quad u_{k\nu}u'_{k\nu} + v_{k\nu}v'_{k\nu} = 0 \tag{32}$$
$$\text{for all } k,\nu$$

Eq. (32) can be solved and the coefficients are represented by parameter $\chi_{k\nu}$ as follows:

$$u_{k\nu} = -\sin\chi_{k\nu}, \quad v_k = \cos\chi_{k\nu}$$
$$u'_{k\nu} = \cos\chi_{k\nu}, \quad v'_{k\nu} = \sin\chi_{k\nu}; \tag{33}$$
$$-\frac{\pi}{2} \leqq \chi_{k\nu} < \frac{\pi}{2}$$

where we neglect the trivial phase factor.

The parameter $\chi_{k\nu}$ is determined by the diagonalization of Hamiltonian. The Hamiltonian of Eq. (29) is reduced to the following diagonal forms:

$$[\boldsymbol{H}, C_{k\nu}] = -E_{k\nu} C_{k\nu}$$
$$[\boldsymbol{H}, D_{k\nu}] = -E'_{k\nu} D_{k\nu} \tag{34}$$

From Eqs. (30), (31) and (34)

$$(\varepsilon - E_{k\nu})u_{k\nu} + \beta v_{k\nu} = 0$$
$$\beta u_{k\nu} + (\varepsilon + \Delta - E_{k\nu})v_{k\nu} = 0$$
$$(\varepsilon - E'_{k\nu})u'_{k\nu} + \beta v'_{k\nu} = 0 \tag{35}$$
$$\beta u'_{k\nu} + (\varepsilon + \Delta - E'_{k\nu})v'_{k\nu} = 0$$

for all the k, ν. In particular, for the case of $k=0$, $\nu=+$

$$\sqrt{2N}\beta u_{0+} = E_{0+} w, \quad \sqrt{2N}\beta u'_{0+} = E'_{0+} w' \tag{36}$$

The solutions of Eq. (35) are

$$E_{k\nu} = \varepsilon + \frac{\Delta}{2} - \frac{1}{2}\sqrt{\Delta^2 + 4\beta^2}$$

$$E'_{k\nu} = \varepsilon + \frac{\Delta}{2} + \frac{1}{2}\sqrt{\Delta^2 + 4\beta^2} \tag{37}$$

where we tentatively assume $E_{k\nu} < E'_{k\nu}$. The energies $E_{k\nu}$ and $E'_{k\nu}$ and therefore also $u_{k\nu}$, $v_{k\nu}$, $u'_{k\nu}$ and $v'_{k\nu}$ are independent of k,ν. Therefore we remove the suffixes k,ν from these quantities.

The inverse transformation of Eq. (30) is

$$A_{k\nu} = u C_{k\nu} + v D_{k\nu}$$
$$B_{k\nu} = v C_{k\nu} - u D_{k\nu} \tag{38}$$

except for the case of $k=0$, $\nu=+$. For $k=+$, $\nu=+$

$$A_{0+} = u C_{0+} + v D_{0+} + (-uw - vw')$$
$$B_{0+} = v C_{0+} - u D_{0+} + (uw' - vw) \tag{39}$$

The transformation coefficients are

$$u = -v' = -\frac{|\beta|}{\beta}\left(\frac{1}{2} + \frac{\Delta}{2\sqrt{\Delta^2 + 4\beta^2}}\right)^{\frac{1}{2}}$$

$$v = u' = \left(\frac{1}{2} - \frac{\Delta}{2\sqrt{\Delta^2 + 4\beta^2}}\right)^{\frac{1}{2}} \tag{40}$$

where we assume Δ to be positive as reasonably expected. By this transformation, the Hamiltonian is diagonalized as,

$$\boldsymbol{H} = \sum_{k,\nu} E C^+_{k\nu} C_{k\nu} + \sum_{k,\nu} E' D^+_{k\nu} D_{k\nu} - (Ew^2 + E'w'^2) \tag{41}$$

The zero point energy is calculated from Eqs. (36), (37) and (40),

$$Ew^2 + E'w'^2 = 2N\beta^2 \frac{\varepsilon + \Delta}{\varepsilon^2 + \varepsilon\Delta - \beta^2} \tag{42}$$

The ground wave function $|0\rangle$ can be expanded by the original representations as

$$|0\rangle = \sum_{m,n} \alpha_{mn} |m,n\rangle_0 \tag{43}$$

Here $|m,n\rangle_0$ is the state function which contains

m one-site CT excitations of $k=0$, $v=+$ and n two-sites CT excitations of $k=0$, $v=+$. The suffix o signifies the original representations. The coefficient α_{mn} is determined from the following conditions.

$$\begin{aligned} &C_{0+}|0\rangle = 0 \\ &D_{0+}|0\rangle = 0 \\ &\sum_{m,n} \alpha_{mn}^2 = 1 \quad \text{(normalization condition)} \end{aligned} \tag{44}$$

The final result is

$$\alpha_{mn} = \frac{x^m y^n}{\sqrt{m!n!}} e^{-\frac{1}{2}(x^2+y^2)} \quad (N\to\infty) \tag{45}$$

and

$$x = -\frac{\varepsilon+\Delta}{EE'}\sqrt{2N}\beta \quad y = \frac{\beta}{EE'}\sqrt{2N}\beta \tag{46}$$

Discussion

First we consider the effect of the Bose approximation. The occupation number of $a_{j\sigma}^+ a_{j\sigma}$ is essentially 0 or 1. But the Bose approximation adopted in the present study takes off this restriction and consequently many excitations turn out to occupy the same crystals site. Therefore this approximation may be applicable only when the mean value $\langle a_{j\sigma}^+ a_{j\sigma}\rangle_{\text{av.}}$ for the concerned state is[16]

$$\langle a_{j\sigma}^+ a_{j\sigma}\rangle_{\text{av.}} \ll 1. \tag{47}$$

For the ground state represented by Eq. (21), the mean value is

$$\langle 0|a_{j\sigma}^+ a_{j\sigma}|0\rangle = \frac{\beta^2}{\varepsilon_{0+}^2} \tag{48}$$

Therefore under the restriction of $\beta^2/\varepsilon_{0+}^2 \ll 1$, the number of the virtual excitations in the ground state is small compared with N and the Bose approximation may not cause a large error. For most of the crystals which are treated here, this restriction seems to be satisfied.

The zero point energy $2N\beta^2/\varepsilon_{0+}$ in Eq. (20) represents the stabilization energy of the crystal due to the contribution of the CT configurations ($k=0$, $v=+$) to the ground state. This is twice as large as the simple sum of the CT stabilization energies of component pairs. The factor 2 comes from the fact that the charge transfer occurs in the two directions ($\sigma=+,-$).

From Eq. (21) the n-molecule excitation configuration is known to contribute to the ground state by α_n^2. As is seen in Eq. (25), the coefficient α_n^2 follows the Poisson distribution function. In Fig. 1 the relation between α_n^2 and n is shown for the case of $\gamma^2=10^6$. The number of virtual excitation $n_{\max}$ for the greatest α_n^2 and the average number of virtural excitations $\bar{n}$ are equal to each other, and they are evaluated form Eq. (24) as follows:

$$n_{\max} = \bar{n} = 2N\frac{\beta^2}{\varepsilon_{0+}^2} \tag{49}$$

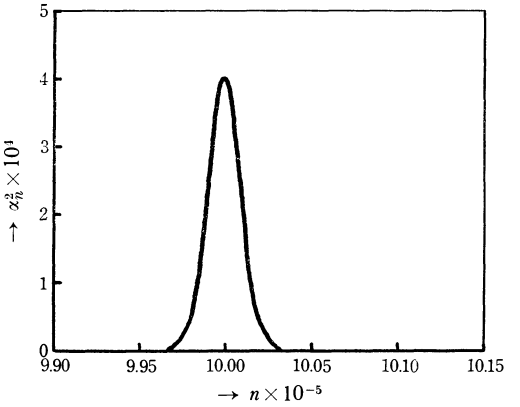

Fig. 1. The dependency of α_n^2 upon n for $\gamma^2=10^6$.

The $n_{\max}$ value is equal to N and $2N$ times the weight of the CT configuration in the corresponding component pairs for radical or molecular crystals and for CT complex crystals, respectively. The excitation density of the jth molecular site in the ground state is

$$\langle 0|\sum_\sigma a_{j\sigma}^+ a_{j\sigma}|0\rangle = 2\frac{\beta^2}{\varepsilon_{0+}^2} \tag{50}$$

Therefore weak CT complexes may be written schematically as $\cdots D^{+\delta}A^{-\delta}D^{+\delta}A^{-\delta}\cdots$ ($\delta=2\beta^2/\varepsilon_{0+}^2$).

According to the second quantization method combined with the Bose approximation the excitation energy between the ground and CT states is equal to ε_{kv} in Eq. (20). In this method, the transfer energy β does not affect the excitation energy.

One may calculate the matrix of operator $\hat{\boldsymbol{\mu}}=\sum_i e\boldsymbol{r}_i$. The operator $\hat{\boldsymbol{\mu}}$ can be expanded in the second quantization form for the following two cases.

Case 1, for usual molecular crystals, radical crystals and weak CT complexes;

$$\begin{aligned} \hat{\boldsymbol{\mu}} = \sum_i e\boldsymbol{r}_i &= \sum_j \{\boldsymbol{\mu}_{1+}(a_{j+}^+ + a_{j+}) + \boldsymbol{\mu}_{1-}(a_{j-}^+ + a_{j-})\} \\ &+ \sum_j \{\boldsymbol{\mu}_d(1)\, a_{j+}^+ a_{j+} + \boldsymbol{\mu}_d(-1) a_{j-}^+ a_{j-}\} \end{aligned} \tag{51}$$

Case 2, for strong CT complexes;

$$\begin{aligned} \hat{\boldsymbol{\mu}} = \sum_i e\boldsymbol{r}_i &= \sum_j \{\boldsymbol{\mu}_{1+}(a_{j+}^+ + a_{j+}) + \boldsymbol{\mu}_{1-}(a_{j-}^+ + a_{j-})\} \\ &- \sum_j \{\boldsymbol{\mu}_d(1)(1-a_{j+}^+ a_{j+}) + \boldsymbol{\mu}_d(-1)(1-a_{j-}^+ a_{j-})\} \end{aligned} \tag{52}$$

where

$$\boldsymbol{\mu}_{1+} = \langle \psi(1,j)|\sum_i e\boldsymbol{r}_i|\psi(0,0)\rangle$$

$$\boldsymbol{\mu}_{1-} = \langle \psi(-1,j)|\sum_i e\boldsymbol{r}_i|\psi(0,0)\rangle$$

$$\mu_{d(m)} = \langle(m,j,)|\sum_i e\boldsymbol{r}_i|\psi(m,j)\rangle - \langle\psi(0,0)|\sum_i e\boldsymbol{r}_i|\psi(0,0)\rangle \;;\; m=1,-1$$

$$\mu_{1//} = \frac{1}{2}(\mu_{1+}-\mu_{1-}), \quad \mu_{1\perp} = \frac{1}{2}(\mu_{1+}+\mu_{1-})$$

$$\mu_{d//} = \frac{1}{2}(\mu_d(1) - \mu_d(-1)),$$

$$\mu_{d\perp} = \frac{1}{2}(\mu_d(1) + \mu_d(-1)) \tag{53}$$

For case 1 every component molecule is assumed to have no dipole moment and $\langle\psi(0,0)|\sum_i e\boldsymbol{r}_i|\psi(0,0)\rangle=0$. The first term in Eqs. (51) and (52) comes from the off-diagonal matrix elements between the CT and ground configurations. The second terms signify the appearance and disappearance of the dipole with a CT excitation, respectively.

Equations (51) and (52) are transformed by the use of Eqs. (16) and (19) as follows:

Case 1,

$$\hat{\boldsymbol{\mu}} = \sqrt{2N}\left(\mu_{1\perp} - \frac{\beta}{\varepsilon_{0+}}\mu_{d\perp}\right)(c^+_{0+}+c_{0+}) + \sqrt{2N}\left(\mu_{1//} - \frac{\beta}{\varepsilon_{0+}}\mu_{d//}\right)(c^+_{0-}+c_{0-}) + \sum_k\{\mu_{d\perp}(c^+_{k+}c_{k+}+c^+_{k-}c_{k-}) + \mu_{d//}(c^+_{k-}c_{k+}+c^+_{k+}c_{k-})\} + 2N\left(-2\mu_{1\perp}\frac{\beta}{\varepsilon_{0+}} + \mu_{d\perp}\left(\frac{\beta}{\varepsilon_{0+}}\right)^2\right) \tag{54}$$

Case 2,

$$\hat{\boldsymbol{\mu}} = \sqrt{2N}\left(\mu_{1\perp} - \frac{\beta}{\varepsilon_{0+}}\mu_{d\perp}\right)(c^+_{0+}+c_{0+}) + \sqrt{2N}\left(\mu_{1//} - \frac{\beta}{\varepsilon_{0+}}\mu_{d//}\right)(c^+_{0-}+c_{0+}) + \sum_k\{\mu_{d\perp}(c^+_{k+}c_{k+}+c^+_{k-}c_{k-}) + \mu_{d//}(c^+_{k-}c_{k+}+c^+_{k-}c_{k-})\} + 2N\left(-2\,\mu_{1\perp}\frac{\beta}{\varepsilon_{0+}} - \mu_{d\perp}\left(1-\frac{\beta^2}{\varepsilon^2_{0+}}\right)\right) \tag{55}$$

As can be seen in the first and second terms of Eqs. (54) and (55), the optical transition from the ground state is allowed for the two kinds of states c_{0+} and c_{0-} within the approximation of electric dipole transition. Hereafter the corresponding state is abbreviatedly represented by the operator $c_{k\nu}$. Their transition moments are

$$\langle 0|c_{0+}\hat{\boldsymbol{\mu}}|0\rangle = \sqrt{2N}\left(\mu_{1\perp} - \frac{\beta}{\varepsilon_{0+}}\mu_{d\perp}\right)$$

$$\langle 0|c_{0-}\hat{\boldsymbol{\mu}}|0\rangle = \sqrt{2N}\left(\mu_{1//} - \frac{\beta}{\varepsilon_{0+}}\mu_{d//}\right) \tag{56}$$

for the both cases. According to Eq. (56), the absorption intensity of the transition to the $c_{0-}(c_{0+})$ state is $2N$ or N times larger in the component parallel (perpendicular) to the chain direction than that for a DA pair of the CT complex or that for a dimer of radicals and usual molecules, respectively.

Usually the second term on the right hand side of Eq. (56) is larger than the first term in their absolute values. Therefore the CT configurations mixing in the ground state contribute mainly to the intensity of optical absorption. In the one molecule excitation method where $\Psi(1,k,\nu)$ of Eq. (6) is taken as an excited state wave function and $\psi(0,0)$ as the ground state one, the optical transition is allowed for the two excited states of $(k=0, \nu=+)$ and $(k=0, \nu=-)$ and their transition moments are only the first term of Eq. (56). Therefore, the Hamiltonian $\boldsymbol{H}_3$ plays an essential role in the mechanism of optical transition.

The dipole moment of the ground state can be evaluated for cases 1 and 2.

Case 1,

$$\boldsymbol{\mu} = \langle 0|\hat{\boldsymbol{\mu}}|0\rangle = 2N\left(-2\mu_{1\perp}\frac{\beta}{\varepsilon_{0+}} + \mu_{d\perp}\frac{\beta^2}{\varepsilon^2_{0+}}\right)$$

Case 2,

$$\boldsymbol{\mu} = \langle 0|\hat{\boldsymbol{\mu}}|0\rangle = 2N\left(-2\mu_{1\perp}\frac{\beta}{\varepsilon_{0+}} - \mu_{d\perp}\left(1-\frac{\beta^2}{\varepsilon^2_{0+}}\right)\right) \tag{57}$$

Since in our model the CT complex has the translational symmetry, the CT complex of a zigzag chain has a dipole moment in the direction perpendicular to the chain. Its magnitude is $2N$ times larger than the component perpendicular to the chain direction of the dipole moment of a DA pair. Thus the zigzag chain of the CT complex is expected to have a large dipole moment, and therefore ferroelectricity is expected for crystals in which the component chain dipoles do not negate each other.

Next we discuss the results obtained in the case of complex radical crystals. The zero point energy $2N\beta^2(\varepsilon+\Delta)/(\varepsilon^2+\varepsilon\Delta-\beta^2)$ can be explained as the stabilization energy due to the mixing of the one-site and two-site CT configurations into the ground state. The main contribution to the zero point energy comes from the fourth term of Eq. (29) which is quite similar to the second terms of Eq. (18). The energy is larger than $2N\beta^2/\varepsilon$ which is the limiting value for $\beta/\varepsilon\to 0$.

The excitation energy E and E' are different from the respective diagonal matrix elements of the one-site and two-site CT states. As is seen in Eqs. (30) and (31), the excited state of the crystal can be understood as a coupled excited state of the one-site and two-site CT excitations. According to Eq. (40), the coupling strength between them becomes larger with the increase in β/Δ.

The configuration which contains m one-site and n two-site CT excitations contributes to the ground state by α^2_{mn}. The $m_{\max}$ and m values which are the m value for the greatest α^2_{mn} and the average number of m for a fixed n, respectively, are obtained from Eq. (45),

$$m_{\max} = \bar{m} = x^2 \tag{58}$$

In the similar way, for a fixed m,

$$n_{\max} = \bar{n} = y^2 \tag{59}$$

Then

$$\frac{n_{\max}}{m_{\max}} = \frac{\bar{n}}{\bar{m}} = \left(\frac{\beta}{\varepsilon+\Delta}\right)^2 \tag{60a}$$

$$\frac{m_{\max}}{N} = \frac{\bar{m}}{N} = 2\left\{\frac{(\varepsilon+\Delta)\beta}{\varepsilon^2+\varepsilon\Delta-\beta^2}\right\}^2 \tag{60b}$$

When $\beta/\varepsilon \to 0$, these quantities are

$$m_{\max} = \bar{m} \xrightarrow[\beta/\varepsilon\to 0]{} 2N\left(\frac{\beta}{\varepsilon}\right)^2 \tag{61a}$$

$$n_{\max} = \bar{n} \to 2N\left(\frac{\beta^2}{\varepsilon^2+\varepsilon\Delta}\right)^2 < 2N\left(\frac{\beta}{\varepsilon}\right)^4 \tag{61b}$$

$$\frac{m_{\max}}{N} = \frac{\bar{m}}{N} \to 2\left(\frac{\beta}{\varepsilon}\right)^2 \tag{61c}$$

Eq. (61a) corresponds to Eq. (49). The results shown by Eqs. (61a), (61b) and (61c) are reasonable.

The transition moment and the dipole moment of the system are obtained by using the equation similar to Eq. (51) except for the contribution from the two-sites CT excitation. The matrix element of transition moment is not zero only for C_{0+}, D_{0+}, C_{0-} and D_{0-}. The transition moments finally obtained are as follows:

$$\begin{aligned}\langle 0|C_{0+}\hat{\boldsymbol{\mu}}|0\rangle &= \boldsymbol{\mu}_{d\perp}(-uw-vw')u \\ &= -\sqrt{2N}\,\beta\,\frac{\varepsilon+\Delta}{E\,E'}\,u\,\boldsymbol{\mu}_{d\perp}\end{aligned}$$

$$\begin{aligned}\langle 0|D_{0+}\hat{\boldsymbol{\mu}}|0\rangle &= \boldsymbol{\mu}_{d\perp}(-uw-vw')v \\ &= -\sqrt{2N}\,\beta\,\frac{\varepsilon+\Delta}{E\,E'}\,v\,\boldsymbol{\mu}_{d\perp}\end{aligned}$$

$$\begin{aligned}\langle 0|C_{0-}\hat{\boldsymbol{\mu}}|0\rangle &= \boldsymbol{\mu}_{d//}(-u^2w+uvw'-2v^2w) \\ &= -\sqrt{2N}\,\beta\,\frac{\varepsilon+\sqrt{\Delta^2+4\beta^2}}{E\,E'}\,u\,\boldsymbol{\mu}_{d//}\end{aligned}$$

$$\begin{aligned}\langle 0|D_{0-}\hat{\boldsymbol{\mu}}|0\rangle &= \boldsymbol{\mu}_{d//}(-v^2w'+uvw-2u^2w') \\ &= -\sqrt{2N}\,\beta\,\frac{\varepsilon-\sqrt{\Delta^2+4\beta^2}}{E\,E'}\,v\,\boldsymbol{\mu}_{d//}\end{aligned} \tag{62}$$

The dipole moment of the ground state is

$$\begin{aligned}\langle 0|\hat{\boldsymbol{\mu}}|0\rangle &= \boldsymbol{\mu}_{d\perp}(-uw-vw')^2 = 2N\,\boldsymbol{\mu}_{d\perp} \\ &\times\left(\beta\,\frac{\varepsilon+\beta}{\varepsilon^2+\varepsilon\Delta-\beta^2}\right)^2\end{aligned} \tag{63}$$

where

$$\boldsymbol{\mu}_d(n) = \langle\psi^0(n,2j-1)|\sum_i e\boldsymbol{r}_i|\psi^0(n,2j-1)\rangle \;;$$

$$n = \pm 1, \pm 2.$$

$$\boldsymbol{\mu}_{d\perp} = \frac{1}{2}(\boldsymbol{\mu}_d(1)+\boldsymbol{\mu}_d(-1)),\quad \boldsymbol{\mu}_{d//} = \frac{1}{2}(\boldsymbol{\mu}_d(1)-\boldsymbol{\mu}_d(-1))$$

$$\langle\psi^0(n,2j-1)|\sum_i e\boldsymbol{r}_i|\psi^0(0,0)\rangle = 0 \quad \text{(assumed)};$$

$$n = \pm 1,\ \pm 2$$

As is seen in Eqs. (62) and (63), the regular chain has no transition dipole for C_{0+} and D_{0+} states and no dipole moment, because of $\mu_{d\perp}=0$ for the regular chain.

For $\beta/\varepsilon \to 0$, C_{0+} and C_{0-} states are mainly composed of the one-site CT state in which an electron transfers from an anion radical A^- to the nearest neighboring neutral molecule A, whereas D_{0+} and D_{0-} states are of the two-site CT state corresponding to an electron transfer between the two neighboring A^- ions. In this case the transition probability to D_{0+} and D_{0-} states become negligibly small, since $|u|\to 1$ and $v\to 0$. On the other hand, for the case where $|\beta|/\Delta$ is large, the transitions to D_{0+} and D_{0-} states turn out to have significant intensity and their excitation energies become lower, as is seen in Eqs. (37) and (40). These CT states become the strongly coupled ones of the one-site and two-sites CT configurations.

(Received December 15, 1969)

The crystal structure of *trans*-$[Co(NO_3)_2(tn)_2]NO_3$ (tn: $H_2N-CH_2-CH_2-CH_2-NH_2$) has been determined from three-dimensional X-ray diffraction data. The dimensions of the monoclinic unit cell are: $a=8.62$ Å, $b=10.04$ Å, $c=9.61$ Å, $\beta=114.0°$, and $Z=2$. The space group is $P2_1/c$. The structure has been refined by the least-squares method to $R=0.114$. The complex ion has a slightly distorted octahedral coordination, with four N atoms of trimethylenediamine molecules at 1.990 ± 0.009 Å and two O atoms of nitrate ions at 1.898 ± 0.007 Å. The two six-membered cobalt-trimethylenediamine rings are identical, as is required by the center of symmetry, and take the chair form. The complex ions and nitrate ions are tightly bound together by N-H···O hydrogen bonds in the layers parallel to the (100) plane, but there exists no evidence for hydrogen bonding between the layers.

Only one investigation[1] has been made into the structure of a complex with trimethylenediamine chelate rings. It is, though, obviously important to obtain more information about the shape and size of the six-membered chelate ring. Several crystals of cobalt complexes of the type $[CoXY(tn)_2]Z$, where X, Y, and Z are Cl, NO_2, NO_3, and NCS, were previously prepared by two of the present authors.[2] We have now initiated a structure investigation of these complexes. This paper will report on the crystal structure of *trans*-$[Co(NO_3)_2(tn)_2]NO_3$.

Another point of interest in this work is how nitrate ions coordinate to the cobalt atom. The crystal structure of the α-form of $Cu(NO_3)_2$ has been studied by Wallwork and Addison,[3] that of $Cu(NO_3)_2\cdot CH_3NO_2$, by Duffin and Wallwork,[4] and that of $Cu(NO_3)_2\cdot 2CH_3CN$, by Duffin.[5] However, the nitrate ion coordinated to the cobalt atom has not yet been reported on. It seemed that it would be of interest to compare the results in our work with those of Cu(II) complexes.[3-5]

Experimental

The *trans*-$[Co(NO_3)_2(tn)_2]NO_3$ was prepared and purified according to the method described in a previous paper.[2] The final pure product appears as thin red-violet needles elongated along the *c*-axis. The unit-cell dimensions were determined from higher-order reflections of Weissenberg photographs (Ni$K\alpha$, $\lambda=1.6591$ Å). The systematic absences were: $h0l$ for l odd and $0k0$ for k odd. Hence, the space group was unequivocally determined. The crystal data are listed in Table 1. Sets of multiple-film, equi-inclination Weissenberg photographs were taken about the *c*-axis (0 to 7th layers), and the *a*- and *b*-axes (0th layer).

Ni$K\alpha$ radiation was used throughout. The intensities were estimated visually with a standard film strip and were converted to $|F_0(hkl)|^2$ and $|F_0(hkl)|$ by applying the usual Lorentz, polarization, and spot-shape corrections. No correction was made for absorption and extinction. The range of relative intensities was from 1 to 17000. 916 independent reflections fell within this range, whereas 207 others were too weak to be observed.

Structure Analysis

The presence of two formula units in a unit cell of the space group $P2_1/c$ requires the cobalt atoms to occupy one of the sets of two-fold positions. Without loss of generality they can be placed at 000 and $0\frac{1}{2}\frac{1}{2}$. On the other hand, nitrate ions have to take statistical configurations because they do not possess a center of symmetry.

At first, a three-dimensional Patterson synthesis was calculated. From the Patterson maps, the approximate positions of the lighter atoms of the complex ions were deduced, but those of the nitrate anion could not be fixed. Attempts were made to deduce the atomic parameters of the nitrate ions from two-dimensional Fourier and difference syntheses of electron density projected along the *b*- and *c*-axes, the signs of which were calculated from the parameter values of the atoms of the complex ion. From these maps, only two oxygens of the nitrate ion could be easily fixed; the others could not be fixed because of the overlapping of the electron density due to its particular statistical arrangement. Finally, the atomic parameters of the other atoms were assigned by assuming the nitrate ions to be triangular. After the inclusion of these parameters in the structure-factor calculation, these was a considerable improvement in the agreement between the observed and calculated structure factors. At this stage, the discrepancy factor, R, became 0.24 for all the observed reflections. The structure thus obtained was refined by three-dimensional Fourier and difference syntheses to $R=0.18$, and later by a block-diagonal least-squares method using a HBLS-4 program written by T. Ashida. In this least-squares method, anisotropic temperature factors were introduced and six cycles of refinement were carried out.

The weighting scheme employed was:

$w = 0.2$ if $F_0 \leqq F_{min.}$ $(=3.0)$

$w = 1.0$ if $F_{min.} < F_0 \leqq F_{max.}$ $(=90.0)$

$w = F_{max.}/F_0$ if $F_0 > F_{max.}$

The final discrepancy factor, $R=\sum||F_0|-|F_c||/\sum|F_0|$, was 0.114 for all the reflections. The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[6] The final atomic parameters and their estimated standard deviations are summarized in Table 2. The observed and calculated structure factors are listed in Table 3.

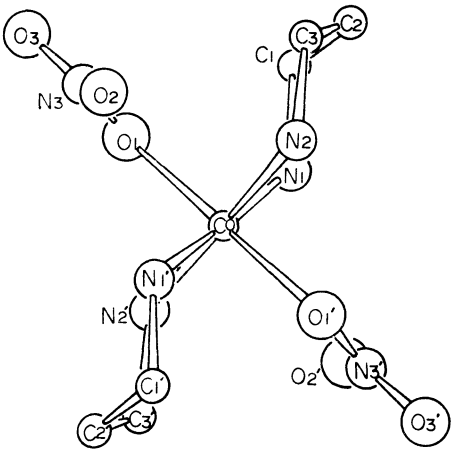

Fig. 1. A perspective drawing of the complex ion, *trans*-$[Co(NO_3)_2(tn)_2]^+$.

6) "International Tables for X-Ray Crystallography," Vol. III, Kynoch Press, Birmingham (1962), p. 202.

Table 2, are listed in Table 4, while the other important interatomic distances in the complex ion are listed in Table 5. The structure projected upon a plane normal to the *a*-axis is shown in Fig. 2. The important intermolecular contacts (*i.e.*, those less than 3.5 Å) are listed in Table 6. The interatomic distances and bond angles were calculated using a DAPH program written by T. Ashida.

The cobalt atoms are surrounded by two oxygen atoms of nitrate ions and four nitrogen atoms of trimethylenediamine molecules, which form a slightly distorted octahedron. Two nitrate ions are coordinated to a cobalt atom in *trans*-positions. The distortion of the coordinated octahedron is more marked than those in the nitroamminecobalt(III) complexes studied recently.[7,8] For example, the N(1)–Co–N(2), O(1)–Co–N(1), and O(1)–Co–N(2) angles are 87.7, 86.7, and 96.2° respectively. The N(1)–Co–N(2) angle of 87.7° in the Co–tn ring is less than those found in $[Co(tn)_3]Br_3 \cdot H_2O$[1] (96, 92, and 95°). Short contacts were found between O(2) and N(1′), and between O(2) and N(2), the distances being 2.898 and 2.784 Å respectively. A check on the angles (Co–N–O) at N(1′) and N(2) indicates that such short distances are not a intramolecular hydrogen bond: the angles are 75.4 and 78.0° respectively.

The Co–O (NO_3) distance of 1.897 Å agrees well with the corresponding values of 1.900 Å in ammonium ethylenediaminetetraacetatocobaltate(III) dihydrate.[9] The Co–N (tn) distances of 1.997 and 1.983 Å agree well with the values, 1.954—2.006 Å, in $[Co(tn)_3]Br_3 \cdot H_2O$ and nitroamminecobalt(III) complexes.[1,7,8]

The N–O (coordinated to the Co atom) distance in the nitrate ions of 1.336 Å is significantly longer than the other N–O distances of 1.223 and 1.190 Å. These values generally agree well with those found in the related compounds,[3,5] but the Co–O–N angle of 125.0° is larger than those of 110 and 113° in $Cu(NO_3)_2$,[3] and of 110 and 114° in $Cu(NO_3)_2 \cdot 2CH_3CN$.[5] This seems to be partly due to the short contacts described above. The plane of the nitrate ion coordinated to the cobalt atom is listed in Table 7. This plane makes an angle of 91.6° with the coordination plane and is approximately parallel to the direction of the N(1)—N(2) vector.

The shape and size of the trimethylenediamine chelate ring is illustrated in Fig. 3. Some least-squares and other important planes are listed in

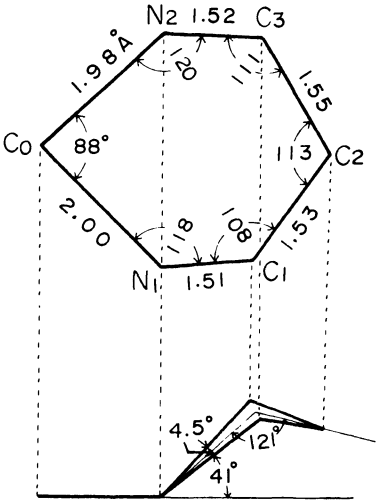

Fig. 3. The shape and size of the chelate ring.

Table 7. The two six-membered Co-tn rings are identical, as is required by centrosymmetry, and take the chair form. They are nearly identical to those in $[Co(tn)_3]Br_3\cdot H_2O$[1] except for the bond lengths of N–C. The N–C distances of 1.522 and 1.507 Å are longer than the mean values of 1.47 Å in $[Co(tn)_3]Br_3\cdot H_2O$,[1] but not significantly so. The angle between the coordination plane (α) and the plane of N(1), N(2), C(3), and C(1) (β) is 43°, significantly larger than the values of 31°, 34°, and 38° in $[Co(tn)_3]Br_3\cdot H_2O$.[1] From these values it appears that the chelate rings in $[Co(tn)_3]Br_3\cdot H_2O$ are, as a result of non-bonded hydrogen interactions, rather more flattened out than those in *trans*-$[Co(NO_3)_2(tn)_2]NO_3$, where there exists no such repulsion, as the two chelate rings are in *trans*-positions. The angle between the β plane and the plane of C(1), C(2), and C(3) is 122°, which value agrees well with those in $[Co(tn)_3]Br_3\cdot H_2O$ (122°, 118°, and 122°). The Co–N–C bond angles of 117.9° and 120.1° are larger than the normal tetrahedral angle, but the mean value of the N–C–C and C–C–C angles is 111.0°, which is closer to the normal tetrahedral angle. The distortions of the chelate ring and of the octahedral coordination described above appear to make the complex less stable than that with five-membered chelate rings,[10] as in the case of $[Co(tn)_3]Br\cdot H_2O$.[1] The bond lengths and angles in the nitrate ion are different from those in *trans*-$[Co(NO_2)_2(NH_3)_4]NO_3\cdot H_2O$[7] and *cis*-$[Co(NO_2)_2(NH_3)_4]NO_3$.[8] The difference seems to be due to the presence of disorder in the arrangement of nitrate ions; at any rate, it is insignificant. The structure is built up of complex cations $[Co(NO_3)_2(tn)_2]^+$ and nitrate ions; thus, it is essentially ionic. A complex ion is surrounded by four nitrate ions in the layers parallel to the (100) plane. In these layers there are hydrogen bonds between complex ions and nitrate ions. They are indicated by dotted lines in Fig. 2. There exists no hydrogen bond between the layers.

The numerical calculations were carried out on the FACOM231 computer at this University and the HITAC5020E computer at the Computer Center, The Tokyo University.

Part of the cost of this investigation has been defrayed by a Scientific Research Grant of the Ministry of Education, to which the authors' thanks are due.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1360—1364 (1970)

The Chemical Behavior of Low Valence Sulfur Compounds. II.[*1] Thin-layer Chromatographic Separation and Photometric Determination of Low Valence Sulfur Compounds

Kunishige NAITO, Shinsuke TAKEI[*2] and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai

(Received May 21, 1969)

The quantitative determination of some low valence sulfur compounds, especially low polythionates, which appeared as intermediate products in the oxidation of elemental sulfur with compressed oxygen in aqueous ammonia was investigated by means of thin-layer chromatography and colorimetry with methylene blue to establish the mechanism of the oxidation of elemental sulfur. Thiosulfate and some low polythionates could be resolved clearly by thin-layer chromatography using silica gel as an absorbent. A suitable solvent for the development was a mixed solution of ethyl alcohol, *n*-butyl alcohol, aqueous ammonia, ammonium acetate and distilled water. The amount of sulfur in the developed spot of the thin-layer chromatogram was determined photometrically with precision of 10 to 20% using methylene blue as a color reagent. Sulfate, sulfite and thiosulfate could not be developed effectively by this method.

In a previous paper,[1] it was reported that ammonium sulfamate and ammonium sulfate were finally produced in the oxidation of elemental sulfur with compressed oxygen in aqueous ammonia solution. The reaction mechanism of the oxidation was not completely established, but its main course through some low polythionates has been disclosed. For the development of these serial studies, it is necessary to establish a rapid, reliable and simple analytical method for the mixture of polythionates in the presence of sulfite, sulfate and thiosulfate. Analytical methods have been proposed by many investigators. 1. A chemical method developed by Kurtenacker and Goldbach,[2] and Goehring[3] has generally been accepted for the detection and quantitative determination of polythionates. So far, this is the most reliable method. However, the skill and delicate operation required make it difficult to achieve reliable results. 2. A fractional precipitation method with benzidine was taken up by Spohn and Weitz[4] for the isolation of low polythionates, but the troublesome procedure prevents it from becoming popular. 3. A photometric method with ferric thiocyanate was proposed by Urban[5] and improved by Koh and Iwasaki.[6] As only a mean value of polythionate content is obtained, its application for the quantitative determination of polythionates is limited. 4. Recently, excellent works on the detection of polythionates using paper chromatography have been reported by Bighi and Trabanelli,[7] Scoffone and Carini,[8] and Pollard.[9] Two improved methods, in which radio-paper chromatography or thin-layer chromatography was used, were carried out by Blasius and his co-workers[10] and Seiler and Erlenmeyer,[11] respectively. These methods are superior in the effectiveness of qualitative separation of polythionates to any other

method proposed previously.

In the present study, chromatographic separation and photometric determination of polythionates and some sulfur-oxy acids are examined by thin-layer chromatography and the colorimetric technique with methylene blue as a color reagent.

Experimental

Sample Compounds of Sulfur. Compounds of sulfur used in the present study were potassium salts of thiosulfate, sulfate, sulfite and tri-, tetra-, penta- and hexathionates. Potassium salts of thiosulfate, sulfate and sulfite were of E.C.P. grade from Kanto Chemical Co., Inc. Potassium tri- and tetrathoinates were prepared from potassium thiosulfate and sulfur dioxide gas and from potassium thiosulfate and ethyl alcoholic solution of iodine by Martin's method,[12] respectively. Potassium penta- and hexathionates were prepared from sodium thiosulfate, sulfur dichloride and alcoholic potassium hydroxide solution and from sodium thiosulfate, sulfur monochloride and alcoholic potassium hydroxide solution by Goehring's method,[13] respectively. Each polythionate was recrystallized from aqueous solution. Its purity is as follows: trithionate 98%, tetrathionate 99%, pentathionate 80% and hexathionate 96%.

Preparation of Thin-layer Plate. Before the application on a glass plate, silica gel, Wako gel B-O of Wako Pure Chemical Industries, Ltd., was washed with distilled water to be free from chloride ion, and soluble starch was also washed with ethyl alcohol for several hours. Washing soluble starch with ethyl alcohol prevents the back-ground of the thin-layer from being colored, and clearly colored spots were visualized when silver nitrate solution was sprayed. Developing time is shortened to one-half or one-third by adding a small quantity of aqueous ammonia to the paste before spreading it on a glass plate. Development takes more than five hours on the thin-layer without adding aqueous ammonia. Thin-layer plates were prepared as follows: Two grams of soluble starch was kneaded with 20 m*l* of about 1.6 mol/*l* solution of aqueous ammonia in a mortar. Twenty grams of silica gel and 20 m*l* of distilled water were added little by little to the mortar to obtain a uniform paste. The paste was spread in about 330 μ thickness on a $200\times200\times3$ mm of glass plate with an applicator. The plate was dried for 12 hr in air, and then activated by heating at 110 to 120°C for 2 to 3 hr and stored in a desiccator.

Development and Visualization. Two to five μ*l* of the sample solution was taken accurately with a 0.05 m*l* micro-pipet and applied along one side of the thin-layer plate at intervals of 2 cm. Then the plate was developed in a closed vessel under saturated vapor of the solvent by the ascending technique. After development, the plate was taken out, dried and sprayed with 0.1 mol/*l* solution of silver nitrate. By this operation, polythionates and thiosulfate were visualized as dark-brown spots of silver sulfide formed by the following reactions:

$$S_2O_3^{2-} + 2Ag^+ + H_2O = Ag_2S + H_2SO_4 \quad (1)$$

$$S_xO_6^{2-} + 2Ag^+ + 2H_2O = Ag_2S + 2H_2SO_4 + (x-3)S \quad (2)$$

Though sulfate and sulfite generally appear in the reaction of sulfur compounds, they cannot be detected with silver nitrate differing from thiosulfate and polythionates. In this case, before the detection of polythionates and thiosulfate, the thin-layer plate was first sprayed with barium chloride solution acidified with acetic acid and with sodium rhodizonate solution. Sulfate and sulfite appeared then as pale-yellow spots on a pink colored background. Visualization of polythionates and thiosulfate was attained by spraying the spots with a silver nitrate solution.

Procedure of Colorimetric Determination. Sulfur amounts in the visualized spot was determined colorimetrically by the technique proposed by Kiba and his co-workers[14] as follows: The visualized spot was scratched as completely as possible and removed into a reduction quartz tube. Two or three m*l* of barium solution and bromine water were added to oxidize sulfur compounds, such as sulfide and elemental sulfur, to barium sulfate.

After evaporation to dryness, 5 to 10 m*l* of strong phosphoric acid solution of stannous chloride was poured into the tube and nitrogen gas was passed through the tube vigorously for first 5 min and then reduced to the flow rate of one bubble per second. After heating the quartz tube at 300 to 320°C for 30 to 60 min to reduce barium sulfate to hydrogen sulfide, nitrogen gas was passed again through the tube vigorously for 5 min. The absorption tube of hydrogen sulfide was taken off from the quartz tube and 1.5 m*l* of 1 : 1 sulfuric acid solution of *p*-amino dimethyl aniline and 0.5 m*l* of ferric ammonium sulfate solution were added under vigorous shaking to form methylene blue coloration. The colored solution of methylene blue was removed into a measuring flask and was diluted to 50 m*l* with distilled water. After standing for 20 to 30 min at room temperature, the absorbance was measured at 662.5 mμ through 0.03 mm width of slit in a glass cell of 10 mm thickness.

Results and Discussion

Selection of Developing Solvent. As developing solvents for sulfur-oxy acids, the following mixtures were used.

Bighi and Trabanelli:[7] isopropyl alcohol, pyridine and water (5 : 3 : 5)

Scoffone and Carini:[8] *n*-butyl alcohol, aceto-acetic ester, acetic acid and water (10 : 2 : 1 : 7)

Pollard:[9] isopropyl alcohol, acetone and water (5 : 2 : 3)

Seiler and Erlenmeyer:[11] methyl alcohol, dioxane, aqueous ammonia and water (3 : 6 : 1 : 1)

The suitablity of mixed solvents of various alcohols given in literature was tested. From the results, it can be stated that no effective resolution of polythionates was obtained except for a case in

which a mixture of ethyl alcohol, *n*-butyl alcohol, aqueous ammonia and water or ethyl alcohol, methyl isobutyl ketone, aqueous ammonia and water was used. Therefore, the solvent system consisting of ethyl alcohol, *n*-butyl alcohol, aqueous ammonia and water was studied by varying the amounts

of aqueous ammonia. The results are shown in Fig. 1. The resolution of polythionates was almost independent of the amounts of aqueous ammonia.

Generally the addition of neutral salts affects activities of polythionates. It is expected that the resolution of polythionates might be improved. The addition of ammonium acetate to the solvent actually improved the resolution of the spots as shown in Fig. 2.

It is concluded that the following composition may be the most suitable as the developing solvent in the thin-layer chromatography of these sulfur compounds, *viz.* ethyl alcohol 75 m*l*, *n*-butyl alchol 75 m*l*, concentrated aqueous ammonia 8 to 10 m*l*, 1 mol/*l* solution of ammonium acetate 20 to 40 m*l* and distilled water 10 to 30 m*l*. Under these conditions, the R_s values of thiosulfate and some low polythionates obtained are shown in Table 1.

Table 1. The R_s values

Species	Present study	Pollard's results*
$S_2O_3^{2-}$	0.18—0.20	0.11
$S_3O_6^{2-}$	0.63—0.64	0.67
$S_4O_6^{2-}$	1.00	1.00
$S_5O_6^{2-}$	1.34—1.38	1.25

* Pollard's results were obtained by paper chromatography. R_s values: R_f values are normalized to that of tetrathionate.

The chromatographic separation of sulfate, sulfite and thiosulfate was studied by the same method using various mixed solvents, but a suitable solvent system for the resolution of these compounds was not found.

Colorimetric Determination of Sulfur in the Developed Spot. In the developed spot which was visualized by spraying silver nitrate solution, sulfur is contained as silver sulfide, sulfate and elemental sulfur. The amounts of sulfur can be roughly determined by comparing the color intensity of these spots with the standard color, but the accuracy is not satisfactory for quantitative determination of sulfur. Thus, the colorimetric technique proposed by Kiba and his co-workers[14] was chosen.

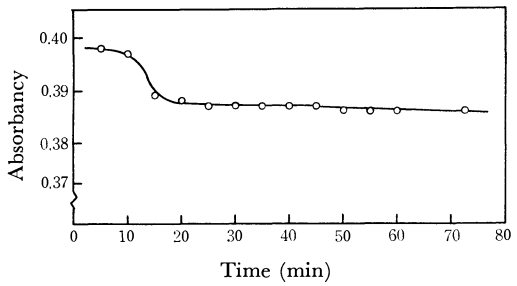

Fig. 4. The change of the absorbancy in the colored solution of methylene blue.

Reduction Time in Strong Phosphoric Acid. At the beginning, the detected amounts of sulfur fluctuated a great deal. The reduction time in strong phosphoric acid, one of the causes of fluctuation, was examined. The results are shown in Fig. 3. It was found that the sample should be heated for 20 to 30 min at 300°C to reduce sulfate to hydrogen sulfide completely.

Stability of the Color of Methylene Blue Solution. The stability of the color of methylene blue solution under room light, which has not been given in literature, was examined to simplify the analytical procedure. From the result, it is obvious that the absorbance has a constant value from 25 to 45 min after the color development. Thus the measurement should be carried out within 30 min after the solution was stood in room light at room temperature.

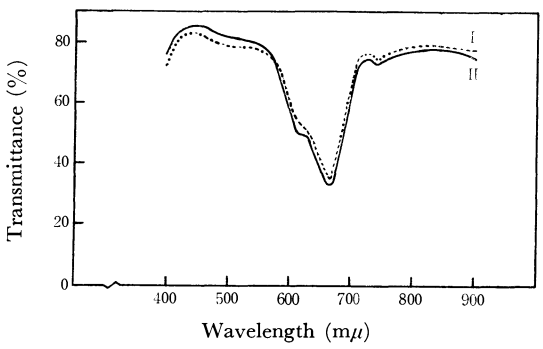

Fig. 5. The absorption spectrum curve of methylene blue solution.
I methylene blue solution prepared from a standard solution of sodium sulfide
II methylene blue solution prepared from a standard solution of sodium sulfate

Absorption Curve. Kiba and his co-workers[14] proposed that the absorbance of methylene blue solution should be measured at 655 mμ. Others[15] recommend 740 or 640 mμ as a proper wave length. Because of this uncertainty the absorption curve of methylene blue was reexamined with a Hitachi EPU-2A type spectrophotometer. The results are shown in Fig. 5. From the figure, it may be stated that the maximum absorption exists at 662.5 mμ rather than 655 mμ. Accordingly, the absorbance of methylene blue should be measured at 662.5 mμ.

Calibration curves were obtained by using sodium sulfide and sodium sulfate. These curves give linear relationship in the concentration range from 0 to 40 μg/50 ml. The molar absorptivity calculated from the slope of these calibration curves agreed well with the value reported by Johnson and Nishita.[16]

TABLE 2. THE MOLAR ABSORPTIVITY

Sulfur compounds	Molar absorptivity	
	present study	Johnson and Nishita
Sodium sulfide	34100	34000
Sodium sulfate	33800	—

Interference of nitrate on the absorbance was pointed out by Kiba and his co-workers.[14] Accordingly, the interference of silver nitrate used on the visualization of spots was examined by using potassium tetrathionate as a sample. No influence was found on the determination of sulfur. The sulfur derived from silica gel can be disregarded, because only 0.4 μg of sulfur is contained in about 20 mg of silica gel.

The Determination of Sulfur. The results obtained for the developed spots by the above procedure are shown in Table 3. Since the measured values are obtained 10 to 30% lower than the theoretical values, it is impossible to determine directly a minute amount of sulfur. Therefore, an internal standard method, in which the amount of polythionate sulfur is compared with that of thiosulfate sulfur determined iodimetrically, was examined by using a mixed solution containing

TABLE 3. RESULTS BY THE DIRECT METHOD

S_2, S_3 and S_5 represent thiosulfate, trithionate and tetrathionate, respectively.

an equal amount of potassium trithionate and tetrathionate. The results are shown in Table 4.

The measured values fluctuate within 10 to 20%. The cause of the fluctuation may be mainly due to the imperfect collection of visualized spots and could be diminished by careful technique. Thus this method may be applied to semi-quantitative determination of low valence sulfur compounds such as polythionates.

The authors wish to thank Professor Tsugio Sawaya of the Laboratory of Industrial Analytical Chemistry for very valuable advice and help.

The Chemical Behavior of Low Valence Sulfur Compounds. III.*1 Production of Ammonium Sulfamate by the Oxidation of Ammonium Thiosulfate

Kunishige NAITO, Masahiro YOSHIDA,*2 Mu-Chang SHIEH and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai

(Received August 1, 1969)

The oxidation of ammonium thiosulfate with compressed oxygen in aqueous ammonia solution was examined. It was found that ammonium sulfamate and ammonium sulfate are mainly produced and a small amount of nitrite and imidodisulfonate obtained in the final solution. The most suitable conditions to produce ammonium sulfamate from ammonium thiosulfate industrially are as follows: reaction temperature 100°C, oxygen pressure 50 kg/cm^2, concentration of ammonia 16 mol/*l*, concentration of cupric ion 0.1—0.2 mol/*l*. The electrolytic oxidation, hydrogen peroxide oxidation and ozone oxidation of ammonium thiosulfate were also examined.

The authors, in their studies on the chemical behavior of low valence sulfur compounds, have investigated the oxidation of elemental sulfur with compressed oxygen in aqueous ammonia solution.[1] It was found that oxidation proceeds through thiosulfate and some low polythionates as intermediates, and under a suitable condition, a large amount of ammonium sulfamate is formed by the oxidation. The oxidation of thiosulfate may be said to be the rate determining step of the overall reaction and has an important effect upon the yield of sulfamate.

The air-oxidation of thiosulfate is a very slow reaction under normal pressure. Under atmospheric pressure and normal temperature, a trace of sodium tetrathionate was detected in the air-oxidation of sodium thiosulfate by Schulek and Koros,[2] and ammonium thiosulfate was observed to be oxidized very little in a neutral or alkaline solution by Koseki.[3]

The oxidation of thiosulfate with compressed air or oxygen has been rarely investigated. In Gluud's work,[4] elemental sulfur and sodium sulfate were detected in a neutral solution, but only sodium sulfate in an alkaline solution at 100°C under an air-pressure of 10 kg/cm^2. The formation of ammonium trithionate was confirmed by Forward[5] in the oxidation of ammonium thiosulfate with compressed air. The oxidation of ammonium thiosulfate with compressed oxygen in aqueous ammonia solution has been investigated in the author's laboratory, and Kanematsu[6] found that the oxidation is almost a zero order reaction and that metal ions such as copper, nickel and cobalt extremely accelerate the oxidation reaction, although the products were not sufficiently confirmed.

In the present study, effort was made to clarify the chemical behavior of thiosulfate in oxidation and to obtain the most suitable conditions for industrial production of ammonium sulfamate from ammonium thiosulfate.

Experimental

Apparatus and Procedure. In the oxidation with oxygen, two autoclaves, one the same as shown in a previous paper,[1] and the other a Shin-Sakashita Seisakusho Model SR-100 with 1 *l* capacity lined with Hastelloy-F, were used for the reaction.

On addition of crystalline ammonium thiosulfate, aqueous ammonia and cupric sulfate as a catalyst, the autoclave was kept in a heated glycerine bath at temperatures regurated within 0.5°C. When the autoclave was heated to fixed temperature, oxygen was introduced and kept at a constant pressure. After the introduced oxygen showed the fixed pressure, 15 m*l* of the solution was withdrawn every few hours and was analyzed.

Electrolytic oxidation was carried out by keeping the anode potential constant with Yanagimoto Controlled Potential Electrolyser Model VE-3. The cell was a 300 m*l* closed glass vessel with platinum plates as electrodes and with a Soxlay filter paper (Toyo No. 84) as a diaphragm. A saturated calomel electrode (SCE) was used as a reference electrode, and concentrated aqueous ammonia was used as an intermediate solution and they were coupled with a salt bridge. The cell and electrode were kept at 0°C in an ice bath. Ammo-

nium thiosulfate and aqueous ammonia were added into the cell and electrolyzed. The quantity of electricity was roughly calculated from the current and time.

Hydrogen peroxide oxidation was carried out by adding C.P. grade hydrogen peroxide solution to thiosulfate solution drop by drop from a buret at a constant temperature with constant stirring.

Analysis. The final solution contained sulfamate, sulfate, cupric ion, sometimes traces of nitrite and imidodisulfonate. When nitrite is present in the solution, it is necessary to determine these ions by avoiding the interference of nitrite, because nitrite decomposes sulfamate and imidodisulfonate to sulfate. The determination of sulfur compounds such as sulfamate, sulfate and imidodisulfonate was successfully carried out by the method proposed by Sisler and Audrieth,[7] and the determination of nitrite and cupric ion was performed by an improved iodimetric method proposed originally by Kolthoff and Abeledo.[8]

The sample solution was diluted to a suitable concentration and then analyzed.

SO_4^{2-}: After the addition of an equal volume of 4 mol/*l* aqueous ammonia to one portion of the sample solution, it was heated on a water bath. Barium salts of sulfate, imidodisulfonate and carbonate were precipitated by the addition of 0.5 mol/*l* solution of barium chlorid in excess. The precipitate was filtered and washed with 4 mol/*l* aqueous ammonia making the filtrate within 200 m*l*. It was washed with 4 mol/*l* acetic acid and a small amount of 0.1 mol/*l* hydrochloric acid to decompose and remove barium imidodisulfonate and barium carbonate making the filtrate within 200 m*l*, and was determined as barium sulfate by the usual method.

$SO_3NH_2^-$: The filtrate obtained by washing with aqueous ammonia was evaporated to 100 m*l*, and acidified with concentrated hydrochloric acid. Sulfamate was decomposed with sodium nitrite. The precipitate of barium sulfate was determined by the usual method.

$HN(SO_3)_2^{2-}$: The filtrate obtained by washing with acetic acid and hydrochloric acid was evaporated and acidified with 4 mol/*l* hydrochloric acid. Imidodisulfonate was decomposed with sodium nitrite as follows.

Imidodisulfonate was determined as barium sulfate

$$HN(SO_3)_2^{2-}+NaNO_2+HCl = 2HSO_4^-+N_2+NaCl$$

by the gravimetric method.

Total Amount of Sulfur: One portion of the sample solution was evaporated nearly to dryness. Potassium chlorate and concentrated hydrochloric acid were added in order to oxidize all sulfur compounds to sulfate. After evaporation to near dryness again, the sulfate in the solid was extracted with 4 mol/*l* hydrochloric acid and determined as barium sulfate.

Cu^{2+}: After the addition of potassium carbonate and urea, one portion of the sample solution was acidified with concentrated hydrochloric acid. When the generation of carbon dioxide ceased, potassium iodide was added and the iodine liberated was titrated with a standard solution of sodium thiosulfate.

NO_2^-: After addition of potassium carbonate and urea to one portion of the sample solution, nitrogen gas was passed through it for 15—20 min, and for additional 5—10 min after the addition of potassium iodide. It was acidified with hydrochloric acid and iodine liberated was titrated with a standard solution of sodium thiosulfate. The nitrite was obtained by subtraction of cupric ion from the total.

The solution taken out during the course of the reaction contains thiosulfate and traces of polythionates in addition to the above-mentioned compounds. For determination of thiosulfate by the iodimetric method, it is necessary to remove cupric ion previously added as a catalyst. When the concentration of cupric ion is low, it can be easily removed by passing the solution through ion-exchange resin column, but when the cupric ion concentration is higher than 0.1 mol/*l*, it is difficult to be removed with the resin because of the complex formation of cupric ion with thiosulfate. In this case, therefore, sulfate and sulfamate are determined as follows:

SO_4^{2-}: One portion of the sample solution was controlled at pH=5 with 4 mol/*l* acetic acid by using bromocresol purple. By adding iodine solution, thiosulfate in the sample solution was oxidized to tetrathionate. Sulfate was precipitated as barium sulfate by adding 0.02 mol/*l* solution of barium chloride and determined.

$SO_3NH_2^-$: By adding 1 mol/*l* solution of silver nitrate to one portion of the sample solution heated on a water bath, thiosulfate and some low polythionates in the solution were decomposed and converted into silver sulfide, sulfate and elemental sulfur. After the addition of barium chloride solution, insoluble matters such as silver sulfide, barium sulfate and silver chloride were removed by filtration. Sulfamate remained in the filtrate and was determined by the above method.

Results and Discussion

Oxidation of Ammonium Thiosulfate with Compressed Oxygen in Aqueous Ammonia Solution. In the present study, the formation of nitrite and imidodisulfonate were observed for the first time. Nitrite was ascertained by the Peter-Griess reaction, and imidodisulfonate was identified by X-ray diffraction of barium salt. During the cource of preliminary experiments, the composition of the products seemed to differ somewhat with autoclave made of SUS 32 stainless steel and that lined with Hastelloy-F alloy. In order to clarify the effect of reactor materials, several materials were tested for the reaction. However, no remarkable results were obtained as shown in Table 1.

The Effect of the Concentration of Cupric Ion. It has been found that cupric ion is the most suitable catalyst to increase the reaction rate and the yield of sulfamate in the oxidation of elemental sulfur. Although a similar effect was expected in the present study, the reaction was examined in the presence of 10^{-3} to 1.0 mol/*l* cupric ion.

The results obtained are shown in Table 2 and Figs. 1, 2 and 3. It is obvious that the reaction time is shortened with the increase of the concentration of cupric ion, but the yield of sulfamate has its maximum at 0.1—0.2 mol/l of cupric ion. The formation of sulfamate shows a zero order reaction in the concentration higher than 0.1 mol/l of cupric ion. The catlytic oxidation of thiosulfate has been explained by Abel[9] as

$$2Cu^{2+} + 2S_2O_3^{2-} = 2Cu^{+} + S_4O_6^{2-} \quad \text{(fast)}$$
$$2Cu^{+} + \tfrac{1}{2}O_2 = 2Cu^{2+} + O^{2-} \quad \text{(slow)}$$
$$O^{2-} + 2H^{+} = H_2O \quad \text{(fast)}$$

But it is supposed that cupric ion exists as an ammine complex in aqueous ammonia solution and in the presence of thiosulfate, forms further a thio-

sulfate complex. Abel's mechanism, therefore, can not be easily accepted. The formation of complexes between cobalt ammine[10] or cupric ethylenediamine[11] and thiosulfate has been actually known to take place.

The Effect of Oxygen Pressure. The effect of oxygen pressure, in which the vapor pressure of the solution was included, was examined in the range of 25—75 kg/cm^2. As shown in Figs. 4, 5 and 6, the reaction time is shortened with the increase of presure. The yield of sulfamate has its maximum at 50 kg/cm^2, while in the presence of 0.1 to 0.5 mol/l of cupric ion, it decreases with the increase of the pressure.

The Effect of the Ammonia Concentration. The ammonia concentration was varied from 4 to 16 mol/l. The results are shown in Fig. 7. An increase in the ammonia concentration improves the yield of sulfamate, and accelerates the reaction slightly. This tendency for the yield of sulfamate to increase in a high concentration of ammonia is quite similar to that of the oxidation of elemental sulfur and the decomposition of potassium trithionate in aqueous ammonia solution.

Reaction temperature: 0°C
Ammonia concn.: 12.25 mol/*l*
Amounts of ammonium thiosulfate: 0.145 mol
Anode potential: 1.5 V (*vs.* SCE at 30°C)

The Effect of Reaction Temperature. The reaction temperature was varied from 80 to 120°C. The results are shown in Fig. 8. The reaction time is shortened with the rise in reaction temperature, while the yield of sulfamate has its maximum at 100°C. It seems that an induction period appears at 80°C in the beginning of the reaction.

From the above results, the suitable conditions to prepare ammonium sulfamate by the oxidation of ammonium thiosulfate with compressed oxygen in aqueous ammonia solution are as follows: the concentration of cupric ion 0.1—0.2 mol/*l*, the ammonia concentration 16 mol/*l*, oxygen pressure 50 kg/cm^2 and reaction temperature 100°C.

The Electrolytic Oxidation of Ammonium Thiosulfate in Aqueous Ammonia Solution. Ammonium thiosulfate was dissolved in 12.25 mol/*l* aqueous ammonia to make 0.145 mol/*l* solution, and oxidized by means of anodic oxidation at 0°C and 1.5 V of the anode potential (*vs.* SCE at 30°C). The results are shown in Table 3.

The oxidation was carried out in a high concentration solution of ammonia at a low temperature, because the yield of sulfamate increases with the increase of the concentration of ammonia and with the lowering of temperature. As the oxidation was carried out at a high potential to improve the reactivity, some known reactions took place simultaneously. From the results, it may be said that thiosulfate is oxidized to tetrathionate or trithionate and converted finally to sulfate, sulfamate and dithionate.

The electrolytic oxidation of sodium thiosulfate has been studied by several investigators.[12-14] It has found that the electrolytic oxidation of sodium thiosulfate proceeds as follows:

$$S_2O_3^{2-} = S_2O_3^{-} + e$$
$$2S_2O_3^{-} = S_4O_6^{2-}$$
$$S_2O_3^{2-} + H_2O = SO_4^{2-} + S + 2H^+ + 2e$$

The first reaction takes place mainly at the low voltage in a neutral solution. From the present results, it is not clear whether tetrathionate or trithionate is first formed from thiosulfate. However, it might be certain that the final products such as sulfamate and sulfate are formed from the low polythionates. The formation of sulfamate in the electrolytic oxidation of ammonium thiosulfate seems to be new.

The Oxidation of Ammonium Thiosulfate with Hydrogen Peroxide and Ozone in Aqueous Ammonia Solution. Hydrogen peroxide and ozone were tested as stronger oxidants than oxygen for the production of sulfamate. The results are shown in Tables 4 and 5. The oxidation of thiosulfate with hydrogen peroxide, an exothermic reaction, is one which accompanies simultaneous decomposition of hydrogen peroxide because of the alkalinity. Kurtenacker and Benson reported that thiosulfate is completely oxidized to sulfate with hydrogen peroxide in an alkaline solution and the oxidation is useful for the determination of thiosulfate.[15] The formation of sulfamate in this reaction is new information. As the presence of trithionate in the reaction solution was confirmed by thinlayer chromatography, the formation of sulfamate should proceed through the course of trithionate decomposition in an aqueous ammonia solution.

flow rate of ozone:	5.02 g/hr

The ozone oxidation differes extremely from the above-mentioned oxidation in which the yield of sulfamate is very low, and, traces of sulfite and low polythionates appear. In a previous work by B. C. Brodie,[16] it was found that sodium thiosulfate is oxidized to dithionate, sulfate and sulfur

dioxide with ozone in a weak alkaline solution according to the following schema.

$$Na_2S_2O_3 + O_3 = Na_2S_2O_3 \cdot O_3 \begin{cases} \nearrow Na_2S_2O_6 \\ \searrow Na_2SO_4 + SO_2 \end{cases}$$

Because of the presence of sulfite, which is not detected in the oxidation with oxygen, thiosulfate must be oxidized with ozone through a different mechanism from those of other oxidations.

Consequently, by the oxidation of ammonium thiosulfate with compressed oxygen in aqueous ammonia solution, 55—65 mol% of thiosulfate-sulfur is converted to sulfamate and the remainder to sulfate. The oxidation proceeds forming some low polythionates as intermediates.

Sulfamate and sulfate are formed by electrolytic oxidation or hydrogen peroxide oxidation, but the yield of sulfamate is lower than that by oxidation with compressed oxygen. By ozone oxidtaion, a large amount of sulfate is finally formed with sulfite as an intermediate, but the yield of sulfamate is extremely small.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1372—1376 (1970)

The Chemical Behavior of Low Valence Sulfur Compounds. V. Decomposition and Oxidation of Tetrathionate in Aqueous Ammonia Solution

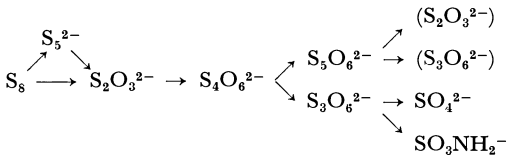
Kunishige NAITO, Mu-Chang SHIEH and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai

(Received August 1, 1969)

The decomposition and oxygen oxidation of tetrathionate in aqueous ammonia solution have been investigated. In the decomposition, thiosulfate, sulfate and sulfamate were formed through penta- and trithionate as intermediate compounds. The molar ratio of the products $(SO_4^{2-}+SO_3NH_2^-)/S_2O_3^{2-}$ was roughly equal to 2/7, where 0.1N ammonia solution was used. The deficient use of ammonia made the solution neutral or weakly acidic and the precipitation of sulfur and the formation of higher polythionates were observed. The polythionate was detected by means of TLC (Thin Layer Chromatography). In the oxidation, tetrathionate was supposed to go through the following three sequent steps. 1) Decomposition of tetrathionate to form thiosulfate, tri- and pentathionate, and further decomposition of pentathionate to thiosulfate. 2) Oxidation of thiosulfate to tetrathionate and partly to sulfate. 3) Decomposition of trithionate to form sulfate, sulfamate and thiosulfate.

During the course of an investigation of the chemical behavior of low valence sulfur compounds, the oxidation of sulfur in aqueous ammonia was studied and the main process of the reaction was briefly proposed in the preceding paper.[1] It seemed reasonable to assume that tetrathionate is first formed as an intermediate in the oxidation of thiosulfate and disintergrates into pentathionate and trithionate as follows:



Kurtenacker and Goehring[2] have already reported that the decomposition of tetrathionate proceeds diversely, depending on the alkalinity of the solution as follows:[3-6]

pH = 8.9

$$2S_4O_6^{2-} = S_3O_6^{2-} + S_5O_6^{2-} \quad (1)$$

pH = 11.5

$$4S_4O_6^{2-} + 6OH^- = 2S_3O_6^{2-} + 5S_2O_3^{2-} + 3H_2O \quad (2)$$

pH = 12

$$S_3O_6^{2-} + 2OH^- = S_2O_3^{2-} + SO_4^{2-} + H_2O \quad (3)$$

pH = 13

$$2S_3O_6^{2-} + 6OH^- = S_2O_3^{2-} + 4SO_3^{2-} + 3H_2O \quad (4)$$

$$2S_5O_6^{2-} + 6OH^- = 5S_2O_3^{2-} + 3H_2O \quad (5)$$

When tetrathionate is stood for a long time in a strong alkaline solution, sulfite and thiosulfate are finally formed by the following reaction[7]

$$2S_4O_6^{2-} + 6OH^- = 3S_2O_3^{2-} + 2SO_3^{2-} + 3H_2O \quad (6)$$

In this reaction, sulfamate is not formed, but a great deal of sulfite is observed. The discrepancy of the products in each case is not due to the presence of compressed oxygen, but might dependent on the reaction medium which controls the first step of the decomposition of tetrathionate. In the present investigation, the decomposition and the oxidation of tetrathionate were studied to clarify the chemical behavior of sulfur compounds in aqueous ammonia solution.

Experimental

Materials. Potassium tetrathionate was prepared according to the method of Martin.[8] An alcoholic solution of iodine was added drop by drop into a potassium thiosulfate solution with stirring. The crude crystals of potassium tetrathionate obtained were then recrystallized from an alcoholic solution. Its purity was 99%, and was free from thiosulfate and sulfur.

Methods. The oxidation and decomposition reactions were carried out in the same autoclave and by the same procedure described in a previous paper.[1] The decomposition reaction in a diluted ammonia solution at low temperature was carried out in a 50 m*l* flask, which contained 20 m*l* of reactant. A portion of the solution in the flask was withdrawn at regular intervals and analyzed in the same manner as described previously, and chromatograph in ethanol-*n*-butanol-1 mol/*l* solution of NH_4Ac-conc. NH_4OH=75 : 75 : 40 : 10. The concentration of potassium tetrathionate in the decomposition and in the oxidation reaction were 0.02 and 0.25 mol/*l*, respectively.

Results

Decomposition of Tetrathionate. The decomposition of potassium tetrathionate was carried out in ammonia solution of various concentrations at 50—80°C. The results obtained are shown in Figs. 1—7. Under these conditions tetrathionate decomposed rapidly, and trithionate and thiosulfate were formed unless ammonia was deficiently used. Since trithionate also decomposed, thiosulfate remained in the final solution with small amounts of sulfate and sulfamate. The general view of the whole reaction is shown in Fig. 1.

The behavior of these sulfur compounds may be qualitatively supported from TLC as shown in Fig. 2. That is, the spots of tetrathionate, trithionate and thiosulfate appeared on the TLC plate at the beginning, but the first two faded away successively, the spot of thiosulfate remaining till the last.

The decomposition of tetrathionate was largely influenced by concentration of ammonia as shown in Figs. 3 and 4. The increase of ammonia concentration accelerated the decomposition. The largest amount of thiosulfate was produced in around 0.4N solution of ammonia. When an

extremely dilute ammonia such as 0.017N was used, the pH of the solution gradually decreased from 11.2 to 7.9, where elemental sulfur, pentathionate and hexathionate appeared as indicated by Figs. 5 and 6. The rise of temperature also accelerated the rate of decomposition as shown in Fig. 7.

Oxidation of Tetrathionate. The oxidation of potassium tetrathionate was carried out in 12N solution of ammonia at 90°C with compressed oxygen of 75 kg/cm². The results obtained are shown in Figs. 8 and 9. The difference of introduction time of oxygen made the reaction rate somewhat vary, but no remarkable change in the composition of the final solution was observed.

Discussion

It is apparent from this study that the mechanism of the decomposition of tetrathionate in aqueous ammonia solution is partly in conformity with Eqs. (1) and (2) suggested by the previous investigators. Therefore, the first products which depend on ammonia concentration are trithionate, pentathionate and thiosulfate. Then pentathionate and trithionate decompose as:

$$2S_5O_6^{2-} + 6OH^- = 5S_2O_3^{2-} + 3H_2O \quad (7)$$

$$S_3O_6^{2-} + 2OH^- = SO_4^{2-} + S_2O_3^{2-} + H_2O \quad (8)$$

$$S_3O_6^{2-} + NH_3 + OH^- = SO_3NH_2^- + S_2O_3^{2-} + H_2O \quad (9)$$

Equations (8) and (9) are in competition with each other. Sulfamate is formed through Eq. (9), which is different from tetrathionate decomposition in caustic soda solution.

It is obvious from the experiments that the yield of sulfamate depends on the ammonia concentration.

When the ammonia concentration is below 2N, sulfamate is hardly formed. If ammonia is deficiently used, the solution will become neutral or weakly acidic leading to the precipitation of sulfur and the formation of higher polythionates. In this case sulfite is also produced because trithionate and tetrathionate should react with excess thiosulfate to form higher polythionates, *viz*:

$$S_3O_6^{2-} + H^+ + S_2O_3^{2-} = S_4O_6^{2-} + HSO_3^- \quad (10)$$

$$S_4O_6^{2-} + H^+ + S_2O_3^{2-} = S_5O_6^{2-} + HSO_3^- \quad (11)$$

$$S_5O_6^{2-} = S_4O_6^{2-} + S \quad (12)$$

In the presence of excess free ammonia, the details of the reaction are not clear, but the overall reaction may be expressed as follows:

$$4S_4O_6^{2-} + 10OH^- = 7S_2O_3^{2-} + 2SO_4^{2-} + 5H_2O \quad (13)$$

$$4S_4O_6^{2-} + 2NH_3 + 8OH^- = 7S_2O_3^{2-} + 2SO_3NH_2^- + 5H_2O \quad (14)$$

The above equations indicate that the molar ratio of $(SO_4^{2-}+SO_3NH_2^-)/S_2O_3^{2-}$ should be equal to 2/7, even if the ammonia concentration or the temperature may change. When the ammonia concentration is about 0.1N, the experimental results obtained agree with the theoretical values within about 10% error. However, the molar ratio of $(SO_4^{2-}+SO_3NH_2^-)/S_2O_3^{2-}$ becomes about 1.01—1.10 in the ammonia concentration 2N or higher than 2N as shown in Table 1. This large discrepancy may be explained by the fact that tetrathionate is easily oxidized to sulfate in alkaline solution. That is, tetrathionate is easily oxidized to sulfate and sulfamate by air remaining in the flask. The overall equation may be considered as follows:

$$3S_4O_6^{2-} + 10OH^- + 2\tfrac{1}{2}O_2 = 4S_2O_3^{2-} + 4SO_4^{2-} + 5H_2O \quad (15)$$

$$3S_4O_6^{2-} + 4NH_3 + 6OH^- + 2\tfrac{1}{2}O_2 = 4S_2O_3^{2-} + 4SO_3NH_2^- + 5H_2O \quad (16)$$

Consequently, the oxidation of tetrathionate in the presence of excess free ammonia may be represented by the following three sequent steps.

1) At first, tetrathionate is decomposed to trithionate and pentathionate, or trithionate and thiosulfate according to Eq. (1) or (2), respectively. Pentathionate is further decomposed to thiosulfate.

2) Oxidation of thiosulfate occurs as:

$$2S_2O_3^{2-} + \tfrac{1}{2}O_2 + H_2O = S_4O_6^{2-} + 2OH^- \quad (17)$$

Decomposition of tetrathionate is repeated until all thiosulfate is consumed and, in these consecutive steps, this oxidation step of thiosulfate seems to be rate-determining. However, a small part of thiosulfate is considered to be oxidized to sulfate as:

$$S_2O_3^{2-} + 2O_2 + 2OH^- = 2SO_4^{2-} + H_2O \quad (18)$$

3) The final step is the decomposition of trithionate as shown in Eqs. (8) and (9).

From the above results, the oxidation of potassium tetrathionate in ammonia solution may be considered to proceed *via* the following course:

$$S_4O_6^{2-} \begin{cases} \nearrow (S_3O_6^{2-}) \\ \rightarrow S_5O_6^{2-} \rightarrow (S_2O_3^{2-}) \rightarrow (S_1O_6^{2-}) \\ \rightarrow S_3O_6^{2-} \rightarrow SO_4^{2-} \\ \searrow SO_3NH_2^- \end{cases}$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1377—1379 (1970)

Measurement of the Lyonium Ion Concentration in a H_2O-D_2O Mixed Solvent by Means of a Glass Electrode*1, *2

Hidetake KAKIHANA, Masunobu MAEDA and Toshihiko AMAYA

Research Laboratory of Nuclear Reactor, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received August 20, 1969)

In the present work, experiments were carried out for the systems of 20, 80 and 99.8% heavy water. It has turned out that the relationship between the emf and the lyonium ion concentration in a H_2O–D_2O mixed solvent can be expressed at 25°C by the so-called Nernst equation within the limits of experimental accuracy of ± 0.1 mV. This means that the lyonium ion concentration in a H_2O–D_2O mixed solvent can be measured with the same experimental accuracy (uncertainty of ± 0.1 mV) as that in light water by the use of a glass electrode.

The measurement of the lyonium ion concentration is of great importance to the studies of solution chemistry in a H_2O–D_2O mixed solvent. Thus far, the concentration of the lyonium ions has been measured with a H_2O–D_2O mixed gas electrode, a quinhydrone electrode, a glass electrode, and several other techniques.

It would, though, be very convenient for the studies of solution chemistry if the lyonium ion concentration in a H_2O–D_2O mixed solvent could be determined accurately with a glass electrode, which is rather cheap and easy to handle. The acidity in a H_2O–D_2O mixed solvent has been measured by several investigators.[1,2] They have standardized the pH meters with light water buffers and determined the values for pL by the addition of some experimental values to the readings of the pH meter. On the other hand, few determinations have been made by the direct measurement of emf with a glass electrode.[3] The determination of the lyonium ion concentration by the direct measurement of emf is of considerable importance to the investigation of complex ionic equilibria in a H_2O–D_2O mixed solvent containing background salt of a high concentration.[4-7]

This work has been undertaken to determine whether the electromotive-force-lyonium-ion dependence is the same as for the hydrogen ion and whether the lyonium-ion concentration can be determined with the same accuracy as the hydrogen-ion concentration by electromotive-force measurements employing a glass electrode.

Symbols

$[L_3O^+]$	concentration of free lyonium ions M (mol/l)
E, E_0, E_0', E_{og}	emf's (mV)
E_j	liquid junction potential
n	deuterium atom fraction
m	equilibrium constant of the following reaction: $1/3H_3O^+ + 1/2D_2O = 1/3D_3O^+ + 1/2H_2O$
$f_{L_3O^+}$	activity coefficient of the lyonium ion in a test solution
$f^g_{L_3O^+}$	activity coefficient of the lyonium ion in a gel layer of a glass electrode
C^g_0	total ion-exchange capacity of a gel layer of a glass electrode
$K_{L_3O^+}$	equilibrium constant of the following reaction: $H_2O(\text{glass}) + L_3O^+(\text{soln.}) = H_3O^+(\text{soln.}) + L_3O^+(\text{glass})$
V	volume of a test solution added (ml)
V_0	initial volume of a test solution (ml)
v	number of μF passed through a test solution
ω, C	constants

L will be used to mean H and D.

Experimental

Reagents and Apparatus. *All the reagents used* were prepared and analyzed by procedures similar to those described in Refs. 4 and 5.

A Wilhelm-type half cell[8] was used for the emf measurement, and a modified one for constant-current coulometry.

Glass electrodes of the Beckman type No. 40498 were employed.

Emf was measured with *a Radiometer PHM-4C(Copenhagen)*. The reading accuracy of this instrument is ± 0.1 mV.

Silver-silver chloride electrodes were used as references.

A coulometric analyzer(Leeds & Northrup Co., Philadelphia) was employed as a constant-current power source. In the present work, 6.43 mA was used as a constant current.

Procedures. All the measurements were carried out in a paraffin-oil thermostat kept at 25.00 ± 0.01°C and placed in a room thermostated at 25 ± 1°C. All the test solutions were made so as to contain 3M ClO_4^- as an ionic medium by the addition of $NaClO_4$.

The lyonium-ion concentration in a H_2O–D_2O mixed solvent was measured by means of the cell:

$$\text{Ref}|L\text{M } L^+, (3-L)\text{M } Na^+, 3\text{M } ClO_4^-|\text{GE} \qquad \text{(A)}$$

where GE denotes a glass electrode, and Ref, the reference half cell:

|3M $NaClO_4$ in a H_2O–D_2O mixed solvent|2.99M $NaClO_4$ and 0.01M $AgClO_4$ in light water|AgCl-Ag

The lyonium-ion concentration in the cell (A) was varied by two procedures; one was the technique of constant-current coulometry, whose experimental details are similar to those presented in Ref. 9, and the other was the technique of titration by the use of a buret.

A steady emf was usually attained within ten minutes. This means that the time required to reach equilibrium is the same as that for the system of light water. During the measurements, a test solution was stirred by a vigorous stream of nitrogen gas which had been purified by leading through a H_2O–D_2O mixed solvent and 3M $NaClO_4$ in a H_2O–D_2O mixed solvent.

Results

1) Relationship between the emf and the Lyonium-ion Concentration. The emf-lyonium-ion dependence was derived on the basis of the assumptions that a gel layer of a glass surface acts as a cation exchanger,[10,11] which adsorbs exclusively the ions of hydrogen isotopes when a glass electrode is brought into equilibrium with a H_2O–D_2O mixed solvent, that H^+ and D^+ ions are present in the forms of H_3O^+, H_2DO^+, HD_2O^+, and D_3O^+ in a H_2O–D_2O mixed solvent,[12,13] and that the rule of the geometric mean[14] is applicable as a first approximation to acid-base equilibria in a H_2O–D_2O mixed solvent. On the basis of the above assumptions, it was found that the emf of a glass electrode could be represented approximately by Eq. (1a):

$$E = E_0' - \boldsymbol{R}T/F(\ln C_0^g) + \boldsymbol{R}T/F\left(\ln\left(\frac{f_{H_2O^+}(1-n)^3}{f^g_{H_3O^+}(1-n+nm)^3} + \frac{f_{D_3O^+}K_{D_3O^+}n^3m^3}{f^g_{D_3O^+}(1-n+nm)^3} + \frac{3f_{HD_2O^+}K_{HD_2O^+}(1-n)n^2m^2}{f^g_{HD_2O^+}(1-n+nm)^3} + \frac{3f_{H_2DO^+}K_{H_2DO^+}(1-n)^2nm}{f^g_{H_2DO^+}(1-n+nm)^3}\right)\right) + \boldsymbol{R}T/F(\ln[L_3O^+]) \qquad \text{(1a)}$$

Since the first, second, and third terms on the right-hand side are constant provided that the temperature of the cell, the activity coefficients of the lyonium ions, and the deuterium atom fraction in a H_2O–D_2O mixed solvent are held constant, Eq. (1a) can be restated in this form:

$$E = E_0 + \boldsymbol{R}T/F(\ln[L_3O^+]) \qquad \text{(1b)}$$

On the other hand, the emf of a cell with a liquid-junction that corresponds to cell(A) is given by:

$$E = E_0 + \boldsymbol{R}T/F(\ln[L_3O^+]) + E_j \qquad \text{(2a)}$$

On the basis of the assumption that Henderson's equation for a continuous-mixture boundary and the rule of the geometric mean[14] are applicable as a first approximation to equilibria in which the ions of hydrogen isotopes take part, it was proved that the liquid-junction potential for the system of a 3M $NaClO_4$ solution of a H_2O–D_2O mixed solvent was approximated by a linear function of the lyonium-ion concentration. Therefore, the emf of a cell with a liquid-junction is given by:

$$E = E_0 + \boldsymbol{R}T/F(\ln[L_3O^+]) + \omega[L_3O^+] \qquad \text{(2b)}$$

Eq. (2b) is expressed at 25°C as follows:

$$E = E_0 + 59.15 \log [L_3O^+] + \omega[L_3O^+] \qquad \text{(3)}$$

2) Experimental Proof of the Reliability of Eq. (3). In this section, we will examine experimentally whether Eq.(3), which holds as a first approximation, is true within the limits of experimental error. 20, 80, and 99.8% heavy-water systems were used as the solvents. Since the liquid-junction potential for the system of light water containing 3M $NaClO_4$ has been found to be negligible in the acid region less than 0.01M[15] it was examined experimentally whether the $E = E_0 + 59.15 \log[L_3O^+]$ term in Eq.(3) held within the limits of experimental accuracy. It was then examined, at an acidity of more than 0.01M, whether the liquid-junction potential in the cell (A) had a linear dependence on the lyonium-ion concentration.

When the liquid-junction potential is negligible, Eq.(3) is transformed as follows:[16]

$$(V_0+V) \times 10^{E/59.15} = C(V_0(L)_0 - V(OL)) \qquad \text{(4)}$$

when an alkaline solution is added from a buret to a test solution, and

$$V_0 \times 10^{E/59.15} = C(V_0(L)_0 - \nu \times 10^{-3}) \qquad \text{(5)}$$

when an alkali is generated by constant-current coulometry.

A glass-electrode function in the higher acid region was investigated by the titration method, and one in the lower acid region was investigated by constant-current coulometry capable of generating a very small amount of acid or alkali.

If Eq. (3) is valid, plots of $(V_0+V)\times 10^{E/59.15}$ as a function of V, or of $V_0\times 10^{E/59.15}$ as a function of γ, should show straight lines.

The results obtained by means of constant-current coulometry for the systems of 20, 80 and 99.8% heavy water are visualized in Fig. 1.

From this figure, it is obvious that the experimental plots show straight lines. In addition, the values for E_0 calculated at each point were kept constant within the exprimental error of ± 0.1 mV, and there was no systematic error in the value of E_0. These things were also true for the results obtained by the titration method.

Next, it was examined experimentally, by plotting $(E-59.15\times\log [L_3O^+])$ as a function of $[L_3O^+]$, whether the liquid-junction potential could be approximated as a linear function of the lyonium-ion concentration. The experiments were carried out by the titration method. The results obtained thereby are pictured in Fig. 2. This figure shows that the liquid-junction potential for the system of a H_2O-D_2O mixed solvent is expressed approxi-

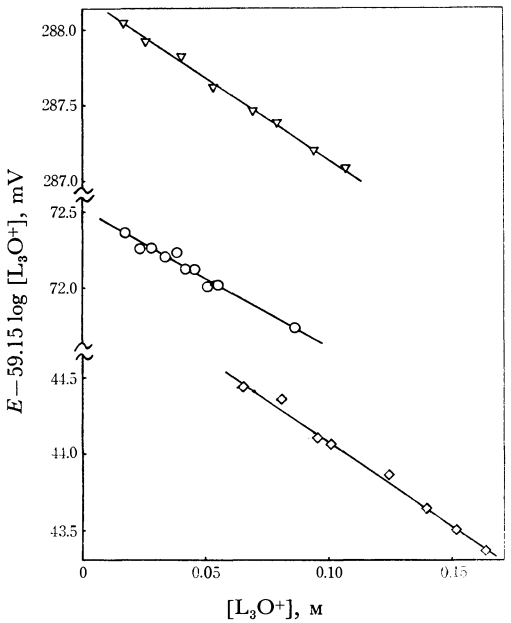

Fig. 2. $(E-59.15\log [L_3O^+])$ as a function of $[L_3O^+]$;
▽, for the system of 99.8% heavy water;
○, 80% heavy water; ◇, 20% heavy water

mately as a linear function of the lyonium-ion concentration.

From the slopes of the straight lines, the liquid-junction potentials for the systems of 20, 80 and 99.8% heavy water were found to be approximated by $-13._2\times[L_3O^+]$, $-8._4\times[L_3O^+]$, and $-10._9\times[L_3O^+]$mV respectively.

From the results described above, it has been found that Eq.(3) is valid within the experimental error of ± 0.1 mV.

Conclusion

In this work, it has been verified that the relationship between the emf of a glass electrode and the lyonium-ion concentration in a H_2O-D_2O mixed solvent is given at 25°C by the so-called Nernst equation with an experimental accuracy of ± 0.1 mV. This means that the lyonium-ion concentration in a H_2O-D_2O mixed solvent can be measured with the same experimental accuracy (an uncertainty of ± 0.1 mV) as that in light water by the use of a glass electrode.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1380—1382 (1970)

Studies of the Behavior of Trivalent Uranium in an Aqueous Solution. III. Extraction from a Hydrochloric Acid Solution by Bis(*n*-butyl) Orthophosphoric Acid and by Bis-(2-ethylhexyl) Orthophosphoric Acid

Akiko Satō and Shin Suzuki

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira-cho, Sendai

(Received August 25, 1969)

The distribution of U(III) between hydrochloric acid solutions and benzene solutions of bis-(*n*-butyl) orthophosphoric acid or cyclohexane solutions of bis(2-ethylhexyl) orthophosphoric acid has been investigated by using the uranium-237 isotope as a tracer. It has been found that the log-log plot of the distribution ratio *vs.* the concentration of dimeric organophosphoric acids, and that of the distribution ratio *vs.* the hydrogen ion concentration, always show a good linearity, with a slope of 3. This indicates that the complex-forming reaction is as follows:

$$U^{3+} + 3(HA)_2 \rightleftarrows U(HA_2)_3 + 3H^+$$

where $(HA)_2$ represents the dimeric solvent, $(HDBP)_2$ or $(HDEHP)_2$. The above results are in agreement with the conclusions reached in the cases of other trivalent actinide and lanthanide elements by other investigators.

Several papers have been reported on U(III) because of its instability in aqueous solutions.[1-4] The present authors found that U(III) is fairly stable in aqueous solutions at low acid concentrations in the absence of atmospheric oxygen.[5] They studied the preparation, stability, absorption spectra, and ion-exchange behavior of U(III) in various acid solutions.[5,6] The reduction of U(VI) to U(III) with liquid zinc amalgam gives a high yield within a short period of time and with a good reproducibility. Particularly in a hydrochloric acid solution, the reduction is more complete than in other media, and the stability of U(III) is also high. Its stability increases with the decrease in the acid concentration.

In this paper, the solvent-extraction behavior of U(III) in hydrochloric acid solutions will be reported on; the investigations were done by using bis(*n*-butyl) orthophosphoric acid-benzene and bis-(2-ethylhexyl) orthophosphoric acid-cyclohexane.

Experimental

Reagents and Apparatus. *Uranium-237 and Hydrochloric Acid Solutions of U(VI).* The uranium-237 tracer was prepared by the conventional method[6,7] after natural uranium dioxide had been irradiated for about 2 hr with 20 or 50 MeV Bremsstrahlung from the Liniac, JAERI, or the Laboratory of Nuclear Science, Tohoku University.

Bis(2-ethylhexyl) Orthophosphoric Acid (HDEHP) and Bis(n-butyl) Orthophosphoric Acid (HDBP). The HDEHP and HDBP were purified by the method reported by Peppard *et al.*[8] The purified organophosphoric acids were dissolved with a purified solvent such as benzene or cyclohexane. The concentration of organophosphoric acid was determined by titrating it with a standard sodium hydroxide solution.

The liquid zinc amalgam was prepared by a method reported previously.[5] The benzene and the other solvents were purified before use in the usual manner. All the other chemicals, such as hydrochloric acid and lithium chloride, were of an analytical grade.

The reductor and radiation measurement instruments were those described in a previous report.[6]

Procedures. All the experiments were carried out in a plastic globe-box with an argon, nitrogen, or carbon dioxide atmosphere at 25±2°C.

Five milliliters of a uranyl chloride solution tagged with a uranium-237 tracer were taken into the reductor. A calculated quantity of lithium chloride solution was added to this to maintain the ionic strength of the total aqueous phase at 0.2, and then the total volume was adjusted to 10 m*l*. After about 10 m*l* of the liquid zinc amalgam had been added to the reductor, the U(VI) was reduced as has been described in a previous report.[5] After the liquid zinc amalgam had then been

carefully removed from the reductor, 10 m*l* of a HDBP or HDEHP solution was added to it. Both phases were shaken with a mechanical shaker.

Pre-equilibration. Two portions of barren HDBP or HDEHP were, successively, placed in contact with two equal-volume portions of barren aqueous acid. The second portions of the solvent and aqueous phases were then used in the study.

Care was taken to ascertain the material balance in each case; the concentration of uranium in the aqueous phase was about 2×10^{-3}M.

After the separation of the two phases, a 1 m*l* aliquot of each phase was taken into a polyethylene tube. The γ-radioactivity was measured with a well-type scintillation counter, and the distribution ratio, D, was calculated.

Here, D is defined as:

$$D = \frac{\gamma\text{-activity per ml of the org. phase}}{\gamma\text{-activity per ml of the aq. phase}}$$

The hydrogen-ion concentration of the aqueous phase in equilibrium was determined by titration with a standard sodium hydroxide solution.

To an extent depending on the kind of mineral acid and its concentration, the reduction of U(VI) to U(III) does not proceed completely[5] and U(IV) is also present in the sample solution. Although an insoluble U(IV) compound forms between the two phases in the extraction with $(HDBP)_2$ below 0.10M, it can be easily separated by the centrifugal method. The solubility of this compound increases with an increase in the HDBP concentration; about 30% of the U(IV) is extracted with a 0.25M $(HDBP)_2$ - benzene solution. On the other hand, U(IV) is completely extracted into the HDEHP phase over a wide range of hydrochloric acid concentrations. Consequently, it was necessary to correct for this by the method reported previously.[6]

Results

Experimental Conditions. The equilibrium of the solvent extraction with HDBP or with HDEHP was reached within about 30 sec. Therefore, a shaking time of 60 sec is recommended.

Diluent. As is shown in Table 1, the relative extractability of U(III) increases in the following sequence: cyclohexane>xylene>isopropyl ether>toluene>benzene. Uranium(III) is extracted to a moderate extent with HDBP, while it is very poorly extracted with HDEHP from a weak hydrochloric acid solution. On the basis of these results, we used benzene as the diluent for the HDBP extraction and cyclohexane for the HDEHP extraction.

Table 1. Influence of the diluent for the U^{3+}-HDEHP and - HDBP system

Diluent	Distribution ratio*	
	U^{3+}-HDEHP	U^{3+}-HDBP
Cyclohexane	2.6	450
Xylene	0.8	36
Isopropyl ether	0.4	16
Toluene	0.03	9.8
Benzene	0	6.5

* HCl, 0.05M; $(HDEHP)_2$ or $(HDBP)_2$, 0.1M; U, 2×10^{-3}M

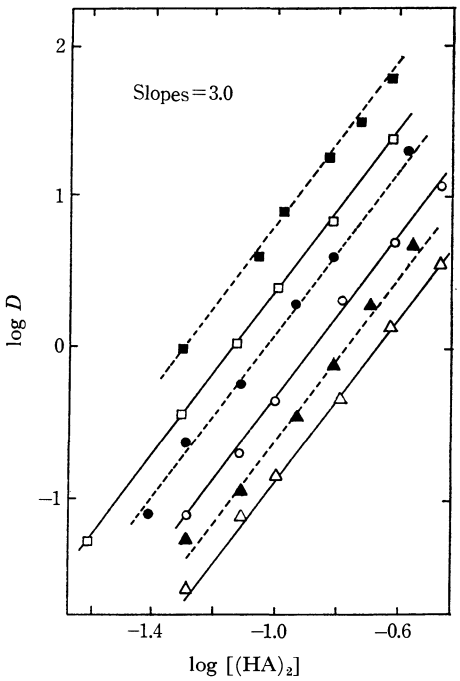

Fig. 1. Extractant dependency of the extraction o the U(III) into HDBP or HDEHP.
HDBP extraction;
---■---■---: 0.06M HCl ---●---●---: 0.1M HCl
---▲---▲---: 0.15M HCl
HDEHP extraction;
—□—□—: 0.06M HCl —○—○—: 0.1M HCl
—△—△—: 0.14M HCl

The extraction of U(IV) with HDEHP is practically complete over a wide range of hydrochloric acid concentrations. The back extraction into the aqueous phase is difficult even with high concentrations of hydrochloric acid. However, the back extraction of U(III) is complete in a hydrochloric acid solution of >2M. The above results are in good agreement with those of Peppard *et al.*,[9,10] who were concerned with the distribution coefficients of other actinide elements between HDEHP and hydrochloric acid.

Solvent Dependence of the Distribution Ratio. As is shown in Fig. 1, a good linear solvent dependency is seen to be directly third power over a wide range of HDBP and HDEHP concentrations for 0.06, 0.1, and 0.14M hydrochloric acid con-

centrations. Each point is the mean of six experiments, having the standard deviations of 2.3—3.8% for the HDEHP extraction and 1.7—4.2% for the HDBP extraction.

Acid Dependence of the Distribution Ratio in a Constant-ionic-strength Medium. The effect of the acidity of the aqueous phase was studied at the constant ionic strength of 0.2. Benzene solutions of 0.05 and 0.14M $(HDBP)_2$ and cyclohexane solutions of 0.05 and 0.15M $(HDEHP)_2$ were used for the extraction. It is clear from Fig. 2 that the log-log plot of the distribution ratio and the hydrogen ion concentration in the aqueous phase shows a linear relationship with a slope of an inversive third power. Each point is the mean of six experiments, having the standard deviations of 1.3—3.9% for the HDEHP extraction and 2.2—4.7% for the HDBP extraction.

Discussion

It should be noted that, in the present discussion, HA is a dimer.[8,11-15] Consequently, for HDBP or HDEHP, the ionization of the extractant and the composite equilibrium are written as:

$$(HA)_2(org) \rightleftarrows H^+(aq) + H(A)_2^-(org)$$

where the subscripts (aq) and (org) refer to the aqueous and the organic phase respectively and where HA represents the organophosphoric acid solvent, HDBP or HDEHP.

Thus, the above equation becomes:

$$M^{m+}(aq) + m(HA)_2(org) \rightleftarrows M[H(A)_2]_m(org) + mH^+(aq)$$

The expression for the distribution ratio, D, is written as:

$$D = K_E[(HA)_2]^m(org)/[H^+]^m(aq)$$

If the temperature and the concentration of HDBP or HDEHP, or the pH, are constant in the extraction, the following equations can be obtained from the above equation:

$$\log D = \log K_E[H^+]^{-m}(aq) + m \log [(HA)_2](org)$$

and:

$$\log D = \log K_E[(HA)_2]^m(org) + m \log [H^+]^{-1}(aq)$$

From the experimental results shown in Figs. 1 and 2, the plots of log D *vs.* the log of the HDBP or HDEHP concentration and the plots of log D *vs.* the pH show straight lines, with a slope of 3, so it can be considered that the species extracted into the organic phase have the form of $U[H(DBP)_2]_3$ or $U[H(DEHP)_2]_3$. This indicates that the complex-forming reaction is as follows:

$$U^{3+} + 3(HDBP)_2 \rightleftarrows U[H(DBP)_2]_3 + 3H^+$$

or:

$$U^{3+} + 3(HDEHP)_2 \rightleftarrows U[H(DEHP)_2]_3 + 3H^+$$

Here, a good agreement is seen with the conclusions reached in the cases of other trivalent actinide and lanthanide elements by other investigators.[15-21]

The authors wish to express their thanks to Mr. Mitsuyuki Takahashi for his technical assistance in the present experiments. Thanks are also due to the members of the Liniac laboratory of both JAERI and Tohoku University for their helpful operation of Liniac. Support by the Scientific Research Fund of the Ministry of Education is gratefully acknowledged.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1383—1387 (1970)

Derivatographic Studies on Transition Metal Complexes. III.*1 The Thermal *trans-cis* Isomerization of $[CoCl_2pn_2](H_5O_2)Cl_2$ in Solid-Phase*2

Ryokichi Tsuchiya, Kiyoko Murai, Akira Uehara and Eishin Kyuno

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received August 27, 1969)

The thermal decomposition of *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$ in solid-phase was measured by derivatography and the isothermal method with a thermobalance. It was found by the latter that dehydration and dehydrochlorination took place with partial isomerization below 170°C. The rate of isomerization gradually increased with temperature until it became equal to the rate of dehydration and dehydrochlorination above 170°C. The activation energies for dehydration and dehydrochlorination and for isomerization were calculated from the isothermal measurement below 170°C to be 10 kcal/mol and 23 kcal/mol, respectively. The activation energy obtained from DTA curve analysis at about 144°C in the derivatogram was 33 kcal/mol. The reaction was explained in terms of "aquation-anation" mechanism. Since the *trans-cis* isomerization in anhydrous state at 180°C gave a larger activation energy in DTA analysis, the "twisting" mechanism might be preferable to "aquation-anation" for the reaction.

Several examples of *cis* ↔ *trans* isomerization on transition metal complexes in solution[1] are known. However, the situation is different in solid-phase.[2] The complex, *trans*-$[CoCl_2(NH_3)_4]IO_3 \cdot 2H_2O$, undergoes a distinct color change on being heated in solid state.[3] A detailed study was reported.[4]

A complicated *trans-cis* isomerization involving both the thermal dehydration and the dehydrochlorination was also found for the complex, *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$.[5,6] It has been proposed that the *trans-cis* isomerization in the two complexes, *trans*-$[CoCl_2(NH_3)_4]IO_3 \cdot 2H_2O$ and *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$, occurred *via* an "aquation-anation" pathway on crystal surface when the water molecules are set free from the crystalline hydrates.[4,6]

It is of interest to note that the dehydration and dehydrochlorination of *trans*-$[CoCl_2en_2](H_5O_2)Cl_2$ are accompanied by no isomerization as in the corresponding pn-complex.[7]

A recent study on the dehydration and dehydrochlorination of *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$ and of the corresponding en-complex indicates that both chlorides exhibit the closely equal activation energies of 16.1 kcal/mol *in vacuo* regardless of the occurrence of *trans-cis* isomerization.[6,7] The activation energies in the thermal reaction of analogous bromo-complex bromides, *trans*-$[CoBr_2(A\text{–}A)_2](H_5O_2)Br_2$ (A–A: en or pn), were 24—29 kcal/mol. Only the corresponding pn-complex was found to undergo *trans-cis* isomerization such as the chloride.[8] The above difference of activation energies between the chloro- and the bromo-complexes is understood to be due to a somewhat more difficult diffusion of HBr and H_2O in the latter complex. In the present work, thermochemical and kinetic analysis of *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$ was carried out from derivatograms. They were also done by means of isothermal measurements. The mechanism is discussed in detail.

Experimental

Preparation of Complexes. Both *trans*-$[CoCl_2pn_2]$-

$(H_5O_2)Cl_2$[9] and *cis*-$[CoCl_2pn_2]Cl$[10] were prepared by the known method partly modified.*3 The corresponding *trans*-en-complex was prepared by the method in literature.[7] These compounds were confirmed by elemental analysis and spectrophotometric measurements.

Derivatographic Measurements. The derivatograms (the chart involves TGA, DTA and DTG curves) for these complexes were obtained with a MOM Derivatograph Typ-OD-102.[11,12] The activation energies (E^*) in the desired reaction steps were calculated by analysis of DTA curves in the derivatograms.[12,13] The enthalpy changes (ΔH) in the corresponding steps were estimated from the same DTA curves.[12,14] 0.5 g finely powdered samples were used in each run (100—200 mesh/inch) under a constant flow of nitrogen stream with the heating rate of 1°C min^{-1}.

Isothermal Measurements using a Thermobalance. Direct and isothermal determination of the dehydration and dehydrochlorination accompanied by isomerization were made by using a Shimadzu TM-1A Thermanobalance. Samples of 0.5 g in each run placed in a small platinum basket hung from one arm of the balance were heated at desired temperatures. The mass loss of each sample in a constant time interval at each temperature was recorded as a TGA curve, and the rates of dehydration and dehydrochlorination were determined. In the same experiment, a part of the products in the basket was dissolved in methanol and the *trans-cis* ratio was determined spectrophotometrically as follows. The visible and UV absorption spectra of the starting complex, *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$, and the final product, *cis*-$[CoCl_2pn_2]Cl$, were measured in methanol with a Hitachi R-3 Spectrophotometer, because the complexes are fairly soluble in methanol and the solutions do not undergo further isomerization within 20 min at room temperature. Their spectra are shown in Fig. 1. Since the pure *trans*- and *cis*-compounds have the absorption coefficients, 6.8 and 62.7, at 530 mμ, and, 40.8 and 51.6, at 600 mμ in methanol, respectively, the *trans/cis* ratios in the product in each step can be determined spectrophotometrically by means of the equations:

$$6.8X + 62.7Y = D_{530}$$

$$40.8X + 51.6Y = D_{600}$$

where X and Y are the concentrations (in mol^{-1}) of *trans*- and *cis*-compounds, and D_{530} and D_{600} are the absorbancies at 530 and 600 mμ with 1.0 cm cell, respectively. Thus, *trans/cis* ratios are given by X/Y.

Results and Discussion

The derivatogram obtained for the thermal decomposition of *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$ is shown in Fig. 2, together with that of the corresponding en-complex.

In the case of the former pn-complex, as seen in Fig. 2, one molecule of hydrogen chloride and two molecules of water are simultaneously lost with partial isomerization at 144°C, where both DTA and DTG curves show a single peak. An apparently analogous decomposition reaction was observed for the corresponding en-complex by the appearance of a single endothermic peak in DTA due to the dehydration and dehydrochlorination as in the above pn-complex, but no isomerization occurred.

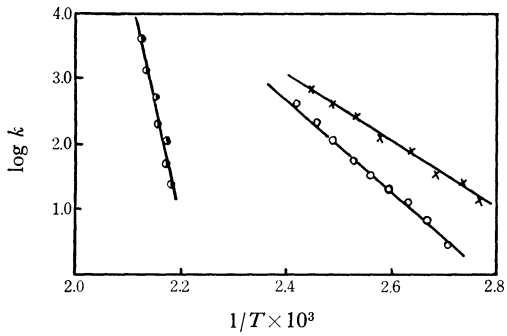

Fig. 3. The "Arrhenius plots" of the rate constants of the dehydration and dehydrochlorination and of the exothermic reaction without mass loss on *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$.
◑—◑: isomerization $E_i^* = 120 \pm 3$ kcal·M^{-1}
○—○: $-HCl \cdot 2H_2O$ reaction $E_{d(i)}^* = 33 \pm 2$ kcal·M^{-1} (DTA)
×—×: $-HCl \cdot 2H_2O$ reaction $E_{d(i)}^* = 31 \pm 2$ kcal·M^{-1} (DTG)

Dehydration and dehydrochlorination of the pn-complex begin to take place at a lower temperature than that of the corresponding en-complex as shown in Fig. 2.

Analysis of DTA curve for *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$ gave 36.5 kcal/mol as ΔH. The Arrhenius plots for the pn-complex, *viz.*, the relationships between the rate constants derived from the analysis of DTA and DTG curves and reciprocal absolute temperatures are shown in Fig. 3. The activation energies, E^*, are obtained to be 33 ± 2 and 31 ± 2 kcal/mol, respectively.

The values are larger than that for the dehydration and dehydrochlorination of the complex, *i. e.*, 16.1 kcal/mol given in literature.[6]

The second peak in DTA curve was found only for the pn-complex without any mass change in TGA, probably due to the occurrence of a small exothermic reaction at 180°C before complete decomposition. Since the corresponding en-complex did not show a similar peak, appearance of such a peak in the former complex is believed to be due to a certain constitutional change; *i e.*, *trans-cis* isomerization *trans*-$[CoCl_2pn_2]Cl$ in an anhydrous state partly remained after complete dehydration and dehydrochlorination. From the analysis of DTA curve, the enthalpy change was estimated to be -4.6 kcal/mol, and the activation energy in this step was calculated to be about 120 kcal/mol.

The relationship between mass losses and *trans/cis* ratios at various heating temperatures, obtained from the isothermal measurements with a thermobalance, are shown in Fig. 4.

From this figure, the *trans/cis* ratio at 140°C corresponding to the temperature of the first peak in the derivatogram of *trans*-complex is found to be 70 : 30. With stepwise elevation of temperature, the *trans/cis* ratio gradually increased. It should

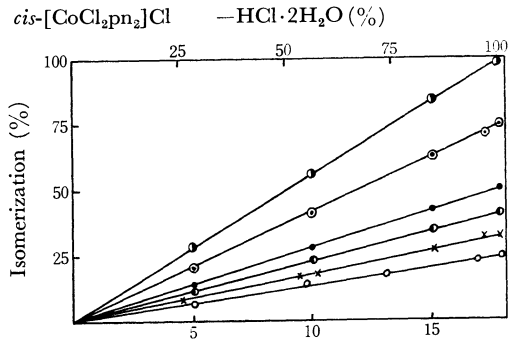

Fig. 4. The relationships between mass loss and *trans-cis* mixture ratio of various constant temperatures on *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$.
○—○: 110°C, ×—×: 130°C, ◐—◐: 140°C,
●—●: 150°C, ⊙—⊙: 160°C, ◑—◑: 170°C

be emphasized that, in other words, isomerization proceeds more slowly than dehydration and dehydrochlorination below 170°C, but it is completed as soon as dehydration and dehydrochlorination are finished above 170°C.

From the results, the rate constants for the mass loss (dehydration and dehydrochlorination), k_d, and those for the *trans-cis* isomerization, k_i, of the *trans* complex were calculated. They are listed in Table 1. At 110°C, the rate constant, k_d, is almost six times larger than that of isomerization, k_i. However, with the rise of temperature, the value of k_d gradually increases and approaches the value of k_i above 170°C.

The Arrhenius plots of the rate constants are shown in Fig. 5. The activation energies were obtained from these plots as 10 ± 2 and 23 ± 3 kcal/mol for the mass loss reaction and for isomerization, respectively. The activation energies for thermal dehydration and dehydrochlorination in this case may be considerably smaller than those in literature.[6] However, it can be accepted that the sum of the values of the activation energies for the mass loss reaction and isomerization is equal to the value 33 kcal/mol obtained from TDA analysis of the derivatogram.

Table 1. Rate constants for the mass loss k_d and isomerization k_i of *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$

Temp., °C	k_d, sec^{-1}	k_i, sec^{-1}
110	$(2.6 \pm 0.4) \times 10^{-4}$	$(4.4 \pm 0.4) \times 10^{-5}$
120	$(4.3 \pm 0.4) \times 10^{-4}$	$(1.2 \pm 0.4) \times 10^{-4}$
130	$(8.2 \pm 0.4) \times 10^{-4}$	$(1.8 \pm 0.4) \times 10^{-4}$
140	$(1.2 \pm 0.2) \times 10^{-3}$	$(3.8 \pm 0.4) \times 10^{-4}$
150	$(1.6 \pm 0.2) \times 10^{-3}$	$(7.3 \pm 0.2) \times 10^{-4}$
160	$(1.9 \pm 0.2) \times 10^{-3}$	$(1.3 \pm 0.2) \times 10^{-3}$
170	$(2.4 \pm 0.2) \times 10^{-3}$	$(2.4 \pm 0.2) \times 10^{-3}$
180	$(3.3 \pm 0.2) \times 10^{-3}$	$(3.3 \pm 0.2) \times 10^{-3}$
190	$(4.1 \pm 0.2) \times 10^{-3}$	$(4.1 \pm 0.2) \times 10^{-3}$

The mechanism in the *trans*↔*cis* isomerization of the complex, $[CoCl_2en_2]Cl$, in polar solvents has been interpreted by solvation-anation reaction.[15,16] In a neutral solution, *trans*-isomer clearly changes to *cis*-isomer upon heating.[17] However, in an acidic solution, the inversed reaction occurs even at room temperature.[18] A similr isomerization has also been found with $[CoCl_2pn_2]^+$ in aqueous solution,[10] but the *trans*-complex undergoes more rapid acid hydrolysis than the corresponding en-complex under similar conditions.[8]

Isomerization with dehydration and dehydrochlorination in *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$ in the solid-phase is believed to occur by aquation-anation mechanism like that in aqueous solutions as follows:

LeMay, Jr., has found that the pn-complex shows a greater resistance to the loss of hydrogen chloride and water from the prominent (100) faces of the crystals than the corresponding en-complex.[6] Radioactive chloride-exchange studies[8] have indicated that the dehydration and dehydrochlorination of the pn-complex are accompanied by the almost complete scrambling of chloride ions in both inner and outer coordination spheres, but this is not the case for the corresponding en-complex under the same conditions. Considerable amounts of chloride ion were exchanged when the pn-complex was heated in solid phase at 120°C for 90 min in air.[8] However, in the corresponding en-complex only 1% exchange could be found upon heating at 125°C for 90 min.

Although the lack of examples for isomerization in solid-phase makes clarification of mechanism difficult, isomerization of *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$ to the *cis*-complex below 170°C might proceed through the aquation-anation pathway accelerated by the dehydration and dehydrochlorination on the faces except for (100).

All the pathways in the thermal decomposition of *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$ and the values of the thermochemical functions, ΔH and $E^{\neq}$, in each process are schematically summarized in Fig. 6.

The derivatogram for *trans*-$[CoCl_2pn_2](H_5O_2)Cl_2$ in Fig. 2 shows that the anhydrous *trans*-pn-complex remaining after dehydration and dehydrochlorination still undergoes *trans-cis* isomerization over 180°C. This indicates that the anhydrous *trans*-

complex is unstable and is changed to *cis*-complex. The mechanism may be explained by means of intramolecular isomerization, *e. g.*, "twisting"[17,19] or "chelate ring opening-closing"[20] because of a relatively large activation energy such as 120 kcal/mol. Although examples of activation energies calculated derivatographically on thermal *trans*↔*cis* isomerization are rare, the large value described above might be accepted as reasonable.

It should be noted that the activation energies calculated in a similar way by authors were 51.4 and 87 kcal/mol for the complexes, *cis*,*trans*-$[CoCl_2(NH_3)_2en]ClO_4$ and *trans*-$[CrBr(H_2O)(NH_3)_4]Br_2$, respectively. The details will be published elsewhere.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1387—1389 (1970)

Studies on the Separation of Rare Earths. Determination of the Optimum Concentration of Ligand Ion Used in Electromigration

Emiko OHYOSHI

Department of Chemistry, Faculty of Science, Kumamoto University, Kumamoto

(Received September 20, 1969)

An attempt to determine the optimum concentration of ligand ion for the separation of adjacent pairs of rare earth elements by electromigration was made using the method employed for the determination of the stability constant of complex. To examine the theory, separation of lanthanum and cerium, and cerium and praseodymium was carried out using α-hydroxyisobutyric acid as a complexing agent. From the results, factors necessary for the separation of all kinds of rare earth elements were discussed.

Studies on the separation of rate earth elements by electromigration have been carried out. Successful results are obtained when α-hydroxyisobutyric acid[1-3] is used as a complexing agent. In most cases, however, the conditions for the separation are arbitrary.

In recent years, the theory of electromigration of metal and complex ions derived by Kiso[4] was applied to the separation of rare earth elements and justified experimentally.[5] Shvedov and Stepanov[6] proposed the method of determination of the stability constant of complex by electromigration. The results obtained were in good agreement with those by potentiometry.

In order to find the optimum condition for the separation based on the difference in the stability of complex of two elements, it is most important to choose a suitable concentration of ligand ion depending on the stability of complexes to be formed. In the present investigation, it is intended to determine the optimum concentration of ligand ion for the separation of rare earth elements using the method proposed by Shvedov and Stepanov which is simpler than that by Kiso. Factors affecting the separation are also discussed.

Determination of the Optimum Concentration of Ligand Ion. When a metal, M, forms a complex, ML, in solution the following equilibrium may be established (the charges are omitted for simplicity):

$$M + L = ML \quad (1)$$

The equilibrium constant of process (1), *i.e.*, stability constant, is expressed by

$$K = \frac{[ML]}{[M][L]} \quad (2)$$

According to Shvedov and Stepanov, when an electric field is applied to such solution, the over all migration of a metal can be expressed as the sum of two components one of which governs the

transfer in the form of metal ions and the other the transfer in the complex form.

$$u([M]+[ML]) = u_M[M] + u_{ML}[ML] \quad (3)$$

where u, u_M and u_{ML} are the mobilities of zone, of metal ion and of complex ion, respectively. Equation (3) can be brought into the form

$$[ML]/[M] = (u-u_M)/(u_{ML}-u) = K[L] \quad (4)$$

From Eq. (4), Shvedov and Stepanov determined the stability constant of the complex ML with measurements of u_M, u_{ML} and u. By rearrangement of Eq. (4), the zone mobility u is given as follows.

$$u = \frac{u_{ML}K[L] + u_M}{1 + K[L]} \quad (5)$$

To separate M_1 from M_2, in the first case where $u_{ML}>0$, *e.g.*, α-hydroxyisobutyric acid, lactic acid, *etc.*, the ratio of zone mobility of each metal u_1/u_2 can be taken as the separation factor S. Hence, it is important to find the condition under which S takes the maximum value. In the case of rare earth elements, the difference in mobility of metal or complex ions of two kinds of element is neglected. Thus we have

$$S = \frac{u_1}{u_2} = \frac{(1+K_2[L])(K_1[L]+u_M/u_{ML})}{(1+K_1[L])(K_2[L]+u_M/u_{ML})} \quad (6)$$

Differentiating with respect to [L], we get

$$\frac{dS}{d[L]} = \frac{(1-u_{ML}/u_M)(K_2-K_1)(1-u_{ML}/u_MK_1K_2[L]^2)}{\{(u_{ML}/u_MK_2[L]+1)(1+K_1[L])\}^2} \quad (7)$$

In the case of $K_2>K_1$, with an increase in [L], S increases and reaches maximum at $dS/d[L]=0$, and then decreases. At $dS/d[L]=0$, we have

$$[L] = \left(\frac{u_M/u_{ML}}{K_1K_2}\right)^{1/2} \quad (8)$$

S takes the maximum value. It can be seen that this concentration of ligand ion is the optimum one for separating M_1 from M_2.

In the second case, $u_{ML}\leqq 0$, *e.g.*, EDTA, NTA, *etc.*, S should be taken as the difference in the zone mobility of two metals. Thus we get

$$S = u_1-u_2 = \frac{u_{ML}K_1[L] + u_M}{1 + K_1[L]} - \frac{u_{ML}K_2[L] + u_M}{1 + K_2[L]} \quad (9)$$

Differentiation of this equation with respect to [L] leads to the expression

$$\frac{dS}{d[L]} = \frac{(u_M-u_{ML})(K_2-K_1)(1-K_1K_2[L]^2)}{\{(1+K_1[L])(1+K_2[L])\}^2} \quad (10)$$

At $dS/d[L]=0$, we obtain

$$[L] = \{1/(K_1K_2)\}^{1/2} \quad (11)$$

S becomes the maximum.

Comparing the two cases, $u_{ML}>0$ and $u_{ML}\leqq 0$, the optimum concentration of ligand ion in the former case is larger than that in the latter (since $u_M/u_{ML}>1$).

Experimental

Materials. Oxides of lanthanum (Mitsuwa Chemical Co. 99.99%) and praseodymium (Katayama Chemical Industries Co., Ltd. 99.9%) were dissolved in nitric acid. The solution of cerium was prepared by heating $Ce(NO_3)_3\cdot 6H_2O$ (Katayama Chemical Industries Co., Ltd. G. R. grade) with hydrogen peroxide in hydrochloric acid. Mixtures of lanthanum and cerium, and cerium and praseodymium at the same concentration of 10^{-3}M were used as samples. α-Hydroxyisobutyric acid (Tokyo Chemical Industry Co., Ltd. G. R. grade) in varying concentration at the constant ionic strength of 0.1 was used as electrolyte solution.

Procedures. A paper strip (Toyo Roshi No. 50 1×20 cm) was uniformly soaked in the electrolyte solution, and excess solution was removed by pressing between sheets of filter paper. The sample (0.005 m*l*) was then spotted at a point 6.5 cm from the end of the anodic side. The paper was set into a migration cell containing carbon tetrachloride as coolant. A potential gradient of 500 V(D.C.)/16 cm was applied for 15—25 min. After the current was switched off, the paper was dried rapidly under an infrared lamp. The migrating zone was detected by color reaction with Arsenazo III.

Results and Discussion

Measurements of u_M and u_{ML}. Equation (5) can be brought into the form

$$u = \frac{1}{K[L] + 1}(u_M-u_{ML}) + u_{ML} \quad (12)$$

Hence, the values of u_M and u_{ML} are obtained from the intercept and the slope of a plot of u *vs.* $1/(K[L]+1)$. Figure 1 gives the linear relationship of u to $1/(K[L]+1)$ for lanthanum and cerium using α-hydroxyisobutyric acid, where K[7] is the stability constant of complex LaL or CeL. The concentration of α-hydroxyisobutyrate ion [L] was

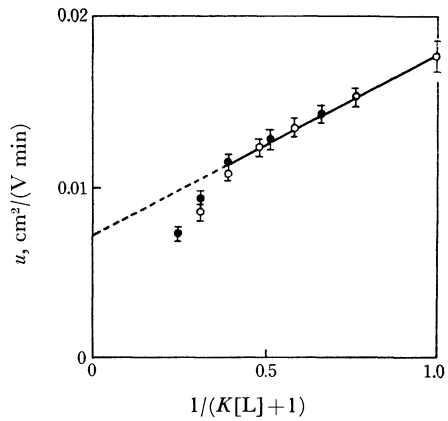

Fig. 1. A plot of u *vs.* $1/(K[L]+1)$ for La ○ and Ce ●.
L=α-hydroxyisobutyrate

7) W. R. Stagg and J. E. Powell, *Inorg. Chem.*, **3**, 242 (1964).

calculated from the equation $[L^-]=k_a([HL]_t-[L^-])/[H^+]$, where k_a is the dissociation constant of α-hydroxyisobutyric acid[8] and $[HL]_t$ is the total concentration of α-hydroxyisobutyrate. The deviation of the points from the linearity at high concentration of ligand suggests that the complexes formed are not only ML but also ML_2, ML_3,$\cdots ML_n$ with the increase of concentration of ligand ion. This also accounts for the fact that the zone mobilities of lanthanum are smaller than those of cerium at the same value of $1/(K[L]+1)$ in the range of high concentration of ligand ion (since the value of $k_{1(Ce)}/k_{1(La)}$ is larger than that of $k_{2(Ce)}/k_{2(La)}$, where k_1 and k_2 are the consecutive constants of complexes ML and ML_2). By extrapolation of the straight line in Fig. 1, u_M and u_{ML} are given as 0.0175 and 0.0070 cm^2/V min, respectively.

Separation of Lanthanum and Cerium, and Cerium and Praseodymium. From the values of u_M and u_{ML}, the optimum concentration of ligand ion for the separation of two kinds of rare earth elements can be calculated by Eq. (8). For example, the values for separation of lanthanum and cerium, and cerium and praseodymium are given as $(u_M/(u_{ML}k_{1(La)}k_{1(Ce)}))^{1/2}=8.04\times10^{-3}$M and $(u_M/(u_{ML}k_{1(Ce)}k_{1(Pr)}))^{1/2}=5.95\times10^{-3}$M. In the vicinity of these values of ligand concentration, the separation of lanthanum and cerium, and cerium and praseodynium was carried out to examine the theory. Figure 2 gives the separation factor S, the ratio of the zone mobility for two elements observed and calculated from Eq. (6) as a function of the concentration of ligand ion. It is found that the separation factor for the La–Ce pair is larger than that for the Ce–Pr pair at any concentration of ligand ion, indicating that the greater the difference of stability of the complex of two kinds of elements, the greater the effect on their separation. It is noted that at low concentration of ligand ion, both observed and calculated S values are close while with the increase of ligand concentration, a discrepancy between them becomes apparent, that is, the observed values do not decrease even after passing beyond the optimum concentration of ligand ion. The consecutive formation of complexes ML_2, ML_3,$\cdots ML_n$, might proceed with the increase of ligand concentration, though the calculated value from Eq. (6) is assumed to form only one complex ML. Thus, it can be seen that the formation of various complexes by the consecutive reaction makes the range of optimum concentration of ligand wider than cases in which only one kind of complex is possible. From this, the factor affecting the separation is not only the difference in the stability of complex but also the possibility to proceed a consecutive formation of complexes.

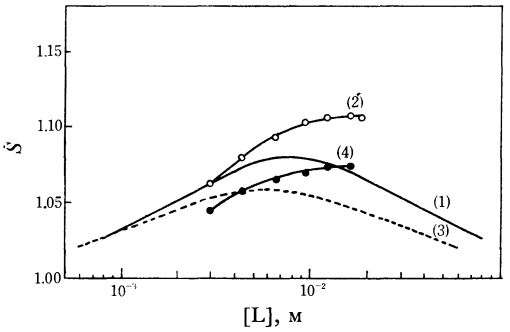

Fig. 2. The separation factor S calculated and observed for La–Ce and Ce–Pr as a function of ligand concentration. (1) calculated, (2) observed for La–Ce; (3) calculated, (4) observed for Ce–Pr.
L=α-hydroxyisobutyrate

In particular, in order to separate all kinds of rare earth elements, it is important to know whether consecutive formation of complexes is taking place or not. If only one complex ML can be formed, the ligand concentration optimum for a pair of light rare earths may greatly differ from that for a pair of heavy rare earths. For example, using the concentration of ligand ion suitable to separate light rare earths, heavy members can not be separated because of the complete formation of complex ML. On the other hand, the concentration suitable to separate the heavy members is so low that the light members remain almost as metal ions. In the case of the consecutive formation of complexes ML, ML_2, $\cdots$ ML_n, as illustrated in Fig. 2, the range of the ligand concentration suitable to separate an adjacent pair is extended toward the higher side because further transformation of ML to ML_2 or of ML_2 to ML_3 gives a different zone mobility to the respective element. Since this extension of the range is observed for any pair of adjacent elements it is probably that a higher part of the range for the last pair of the series (Yb–Lu) and a lower part of that for the first pair (La–Ce) overlap each other. Hence, choosing the ligand concentration at the position of overlapping, it is possible to separate all kinds of rare earths.

Thus, it seems reasonable that the use of α-hydroxyisobutyric acid for the separation of all rare earths gives more successful results as compared with EDTA.

Activity Measurements in Orthosilicate and Metasilicate Solid Solutions. II. $MgSiO_3$-$FeSiO_3$ at 1154, 1204, and 1250°C

Kenzo KITAYAMA

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 18, 1969)

The activity-composition relation in the pyroxene solid solution, $MgSiO_3$–$FeSiO_3$, is determined by the quenching method in the atmosphere of a gas mixture of CO_2 and H_2 at 1154, 1204, and 1250°C. A non-ideality is found in the solution at these temperatures, and it increases with a decrease in the temperature. The standard free energy values of the formation of ferrosilite, $FeSiO_3$, from metallic iron, silica, and oxygen are -42.5 ± 0.3, -41.7 ± 0.2, and -41.3 ± 0.2 kcal per mole of $FeSiO_3$ at 1154, 1204, and 1250°C respectively. Using the data by Darken and Gurry, the standard free energies of the formation of ferrosilite from wüstite and silica are obtained as -1.8 ± 0.3, -1.5 ± 0.2, and -1.8 ± 0.2 kcal per mole of $FeSiO_3$ at 1154, 1204, 1250°C respectively.

In the previous paper[1] it was concluded that both olivine, Mg_2SiO_4–Fe_2SiO_4, and pyroxene, $MgSiO_3$–$FeSiO_3$, solid solutions showed significant deviations from ideality at 1204°C. The non-ideality in the olivine solid solution was also recognized by Nafziger and Muan,[2] but their results on the pyroxene solid solution are very different from ours; they found the pyroxene solid solution to be practically ideal in its activity-composition relation, though their data were from an experiment at 1250°C and the difference in temperature may have caused the difference in the deviations from ideality. The objectives of the present paper are to find the activity-composition relation in the pyroxene solid solution, to determine the standard free energy change in the formation of ferrosilite, and to confirm whether or not the deviations from ideality in the activity of $FeSiO_3$ in the pyroxene solid solution depend on the temperature. As has been described above, we have already reported data at 1204°C but the samples used in the present experiment are newly prepared by adding some silicon oxide to the previous samples in order to position, in the two-phase region, the silica+pyroxene solid solution. Therefore, the same experiment was repeated in order to check the first results.

Method of the Calculation of the Activity. The method of the calculation of the activity of the pyroxene solid solution has been described in the previous paper.[1] The activity of the $FeSiO_3$ in the pyroxene solid solution is represented by Eq. (1):

$$a_{(FeSiO_3)_{ss}} = (P_{O_2}/P_{O_2}^*)^{1/2} \quad (1)$$

The subscript ss means a solid solution. The P_{O_2} in Eq. (1) represents the oxygen partial pressures of the decomposition of pyroxene solid-solution samples with various compositions, and the equation:

$$(FeSiO_3)_{ss} = Fe + SiO_2 + \tfrac{1}{2}O_2 \quad (2)$$

indicates the corresponding chemical reaction. The $P_{O_2}^*$, which is used as the standard oxygen partial pressure, is the oxygen partial pressure corresponding to the reaction (2) of a pure ferrosilite that does not exist at ordinary temperatures and pressures but which is obtained at each temperature by extrapolating, by means of the α-function method, to $(1-N_{FeSiO_3})^2=0$ (Fig. 1).

Experimental

Preparation of Samples. The pyroxene solid solutions were prepared by the method of the previous paper.[1] It is very difficult to prepare one-phase samples with the desined composition. If the samples prepared had a lower silica content than that of the expected one-phase composition, the total composition of the samples would lie in the two-phase area of pyroxene and olivine solid solutions. Therefore, such samples must give a large oxygen partial pressure corresponding to the olivine solid solution. To avoid problems like this, the samples which contained excess silica were prepared.[3] The samples thus prepared were confirmed to be in the two-phase area, to be, that is, silica and pyroxene solid solution, by a chemical analysis of the iron and magnesium contents and by the use of an X-ray diffractometer. Excess silica does not participate the reaction (2), as can be seen from the phase diagram in the previous paper.[1] Table 1 shows the analytical values of the samples used in the present experiment in

	0.206	12.94±0.02	0.26±0.01	5.78±0.01
	0.301	12.66±0.02	0.35±0.02	5.81±0.01
	0.401	12.42±0.03	0.47±0.03	5.81±0.02

* These values are determined assuming total composition were in the two-phases area as in the case of other samples.

Procedure. Mixed gases with various ratios of CO_2 and H_2 are introduced from the bottom to the top of the furnace tube. Then the samples are suspended by thin platinum wires at a definite position in the furnace controlled at the expected temperature. After 24 hr the suspended sample is quenched and a formation of iron metal corresponding to the reaction (2) is confirmed by dipping the sample into dilute hydrochloric acid. The details of the procedure are the same as those of the previous paper.[1] After determining the hydrogen-to-carbon dioxide ratio corresponding to that of the (2) reaction, the oxygen partial pressure is immediately measured by means of a solid electrolyte cell.[5]

Results and Discussion

The experimental results are listed in Table 2. In the second column, the compositions of the pyroxene solid solution are shown. It is found that the chemical compositions (Table 1) of the samples are in the two-phase area (SiO_2+pyroxene solid solution) of the phase diagram of the previous paper (Fig. 1).[1] Tie lines can then be drawn so as to pass through points of the sample composition in the two-phase area to the SiO_2 apex. The intersections of the tie lines and the pyroxene solid-solution line show the composition of the pyroxene solid solution. In the third column, the oxygen partial pressures corresponding to that of the reaction (2) are listed. The activities calculated with Eq. (1) are shown in the fourth column. The

5) T. Katsura and M. Hasegawa, *ibid.*, **40**, 561 (1967).

oxygen partial pressures of 0.599 Fs and 0.497 Fs samples at 1154°C have the same value. This fact suggests that the total compositions of both the samples may be situated within the three-phase area (SiO_2+pyroxene solid solution+olivine solid solution) at 1154°C. The data at 1204 and 1250°C are also shown in Table 2. At 1204°C the oxygen partial pressure of 0.599 Fs is different from that of 0.497 Fs. Therefore, the 0.497 Fs sample seems to be positioned in the two-phase area, while the 0.599 Fs sample in the three-phase area. Judging from the experimental results, the composition of 0.497 Fs seems to be near the boundary between the two- and three-phase areas. Moreover, the results presented above show that the boundary line between two- and three-phase areas must move toward the iron-rich side in the present subsolidus condition with an increase in the temperature. This result is in great contrast to those of Nafziger and Muan[2] and of Bowen and Schairer.[6]

In Fig. 1 the relationship between ($\log N_{FeSiO_3} - 1/2 \log P_{O_2}$) and $(1-N_{FeSiO_3})^2$ is shown at 1154, 1204, and 1250°C. Errors are given as the deviates of the results of three experiments. It may be concluded from Fig. 1 that α[1] is not zero, but 0.28, at 1154°C, that is, the pyroxene solid solution deviatives slightly from ideality. Extrapolating graphically to $(1-N_{FeSiO_3})^2=0$, $\log P_{O_2}=-13.03\pm 0.08$ atm is obtained as the value of the oxygen partial pressure of pure ferrosilite, corresponding to Eq. (2) at 1154°C. By substituting this value into the equation:

$$\Delta G^0 = 1/2RT \ln P_{O_2} \qquad (3)$$

-42.5 ± 0.3 kcal per mole is obtained as the standard free energy change of the formation of ferrosilite at 1154°C. The same relationships are shown at both 1204 and 1250°C. The values of 0.22 at 1204°C and 0.17 at 1250°C are obtained as the α values. They are smaller than that at 1154°C. That is, the higher the temperature becomes, the more ideal is the activity-composition relation. Nafziger and Muan's data show that α is nearly parallel to the abscissa at 1250°C. The present results show non-ideality even at 1250°C. The extrapolated values of $\log P_{O_2}$ for pure ferrosilite are determined to be -12.35 ± 0.04 and -11.76 ± 0.02 atm at 1204 and 1250°C respectively.

The $\log P_{O_2}$ value at 1204°C is in good agreement with the our previous result, -12.35 ± 0.03.[1]

It gives the standard free energy changes of the formation as -41.7 ± 0.2 and -41.3 ± 0.2 kcal/mol respectively. Those values are shown in Table 3 together with a previously determined value. At 1250°C Nafziger and Muan[2] reported -40.6 kcal/mol as the standard free energy change of the formation of ferrosilite. By combining the standard free energy change of the formation of ferrosilite corresponding to Eq. (2) with the value of that of wüstite obtained by Darken and Gurry,[7] the free energy changes of the formation of ferrosilite from wüstite and silica, followed by the reaction:

$$\text{"FeO"} + SiO_2 = FeSiO_3 \qquad (4)$$

are determined to be -1.8 ± 0.3, -1.5 ± 0.2, and -1.8 ± 0.2 kcal per mole at 1154, 1204, and 1250°C respectively. In the calculation of P_{CO_2}/P_{CO} ratios in Darken and Gurry's data to the oxygen partial pressure, the thermochemical data of Elliot and Gleiser[8] are used. The previous values relating to Eq. (4) are summarized in Table 4, together with the above present values. As may be seen from Table 4, the present values agree very well with the values of Akimoto *et al.*,[9] but they are smaller than those of the others. The relationship between the activity and the mole fraction of $FeSiO_3$ are represented in Fig. 2. As is shown in Fig. 2, and as can be expected from Fig. 1, the non-ideality is the largest at 1154°C, but the differences in the other values are small. It is also shown in Fig. 2 that nonideality increases with

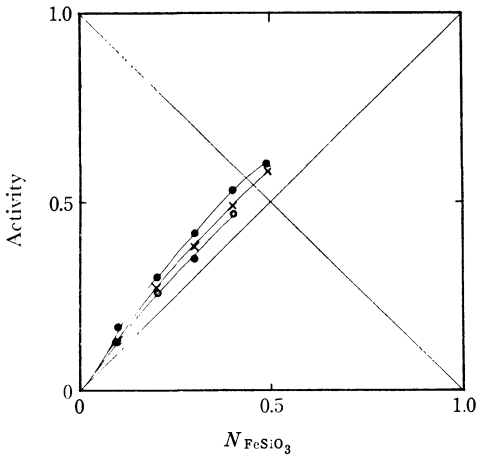

Fig. 2. Activity-composition relations in pyroxene solid solution at 1154, 1204, and 1250°C.
○ 1250°C × 1204°C ● 1154°C

a decrease in the temperature.

The variations in the activity with the temperature in other system have been reported by many investigator. In the MgO - FeO system[10] no apparent difference in activity between at 1100 and 1300°C is found. Aukrust and Muan[11] studied the activity-composition relations in the Co_3O_4-Mn_3O_4 system and did not find any differences in the activity in the 1100—1400°C temperature range.

Three metasilicate solid solutions, the Ca - Fe system[12] at 1080°C, the Mn - Co system[13] at from 1200 to 1250°C, and the Fe - Mn system[14] at 1154°C, are all ideal in their activity-composition relation, differing from the results obtained in the present experiment. In Fig. 3 the relation between the oxygen partial pressures of the formation of ferrosilite and the temperatures are shown. The abscissa represents a reciprocal of the absolute temperature. The log P_{O_2} is related to the standard free-energy change in the formation by the equation:

$$\Delta G^0 = 1/2RT \ln P_{O_2} = \Delta H^0 - T\Delta S^0 \quad (5)$$

Therefore, the gradient of the line in Fig. 3 indicates the $2\ \Delta H^0/R$ of the ferrosilite formation in the present experimental temperature ranges. The data for the fayalite formation:

$$2Fe + SiO_2 + O_2 = Fe_2SiO_4 \quad (6)$$

have already been reported.[3] The values are plotted in Fig. 3, as open circles, together with

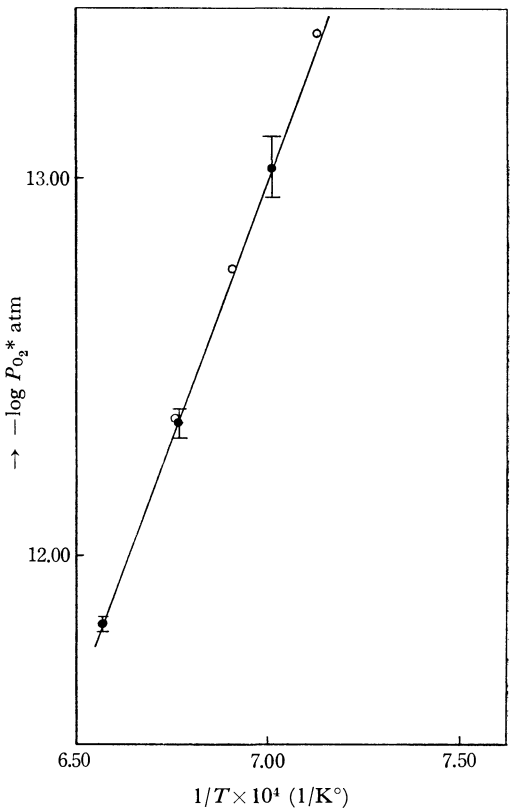

Fig. 3. Relationship between log P_{O_2}* and $1/T$ (K°)
○ $2Fe+SiO_2+O_2=Fe_2SiO_4$
● $Fe+SiO_2+\frac{1}{2}O_2=FeSiO_3$

the present ferrosilite results. The data for fayalite are plotted on just the present temperature-oxygen partial pressure line. That is, oxygen partial pressures of Eq. (2) for pure ferrosilite and Eq. (6) for fayalite are nearly equal. Strictly speaking, the oxygen partial pressure of the ferrosilite decomposition, shown in Eq. (2), should be lower than that of fayalite. The correspondence of the oxygen partial pressures in the two reaction may be due to the experimental technique. The difference is, however, so small that it can not be detected, and it may be due to the extrapolation done with the present, insufficient data. As has been described above, the difference in the changes in the free energy of formation is merely that of the factors of oxygen in the two equations. Therefore, the standard free-energy change in the formation of the ferrosilite must be one-half of that of fayalite.

The author wishes to express his hearty thanks to Dr. Takashi Katsura for encouraging him throughout the study, to Mr. Hiroshi Haramura to his kind chemical analysis of the samples, and to Dr. Yoshito Matsui to his kind discussion of the previous paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1394—1397 (1970)

Bis-Type Cobalt(III) and Chromium(III) Complexes with Related Compounds of Iminodiacetic Acid*1

Akira UEHARA, Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received November 11, 1969)

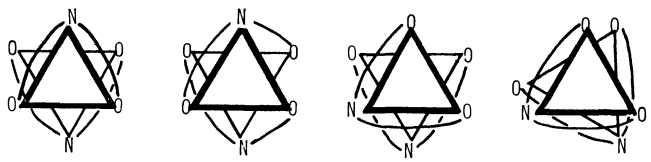
The geometrical structures and some properties of the following complexes were investigated: $K[Co(ida)_2]\cdot H_2O$ (I), $K[Co(ida)_2]\cdot 2H_2O$ (II), $K[Cr(ida)_2]\cdot 3H_2O$ (III), $Ba[Cr(ida)_2]_2\cdot 6H_2O$ (IV), $K[Co(mda)_2]$ (V), $K[Cr(mda)_2]$ (VI), $K[Co(eda)_2]\cdot H_2O$ (VII) and $K[Cr(eda)_2]\cdot H_2O$ (VIII), where ida, mda and eda are the abbreviations of iminodiacetate, methyliminodiacetate and ethyliminodiacetate ions, respectively. IV, VII and VIII are new compounds. On the basis of electronic spectra, it was found that VII and VIII have the *trans* form with respect to nitrogen atoms in the ligands, and IV, the *cis* form. Comparison of the properties and structures of the cobalt(III) complexes with those of the corresponding chromium(III) complexes were also made.

Although the stability constants[1,2] of the metal complexes with iminodiacetic acid(IDA) have been reported, no fundamental discussion on the coordinating structures, especially on geometrical isomerism, has been given, except for a few recent, preliminary works on the analysis of the isomerism of cobalt(III) and chromium(III) complexes with IDA or its derivative as methyliminodiacetic acid (MDA).[3-6]

There are three, geometrically possible isomers in the bis-type complexes with these ligands, their structures being depicted as (A), (B) and (C) in Fig. 1. So far as cobalt(III)-IDA complexes are concerned, the so-called "brown complex" was expected to have either (A) (*trans-fac*) or (B) (*trans-mer*),[4] whereas the "violet complex" was obviously assigned to have (C) structure (*cis-fac*).[3,4] On the other hand, a structural analysis of the complex species such as $[Co(ida)(dien)]^+$ (dien: diethylenetriamine) indicated that IDA prefers the *facial* to the *meridional* configuration.[5] The other works with respect to such configuration also supported the finding that (A) is more stable than (B) because of the more favorable angle ∠C–N–C in (A) than that in (B).[4,6]

Among chromium(III) complexes, $K[Cr(ida)_2]$ has been synthesized,[7,8] and is presumed to have the *cis* configuration (C) on the basis of its spectroscopic results.[9] The bis-type complexes of cobalt(III) and chromium(III) with MDA have also been reported,[5,6,9] where only the *trans-fac* configuration (A in Fig. 1) was assumed. The results that IDA can coordinate either in *cis* or *trans* form, but MDA can not coordinate in *cis* form suggest the presence of some steric hindrance between two methyl groups attached to nitorgen atoms in *cis* isomer.[5,6]

The present work was undertaken (1) to prepare



(A) *trans-fac* (B) *trans-mer* (C) *cis* (D) distorted *cis*

the bis-type complexes of cobalt(III) and chromium (III) with IDA, MDA or the alternative derivative as ethyliminodiacetic acid (EDA), and (2) to investigate systematically the coordinating structures and the properties of the complexes with the above three ligands.

Experimental

Preparation of Chelating Agents. *Methyliminodiacetic Acid.* $CH_3N(CH_2COOH)_2$. 190 g of monochloroacetic acid was dissolved in 300 m*l* of water, and the solution was neutralized by adding slowly 200 g of potassium hydrogen carbonate little by little. To this solution, 75 g of 40% methylamine solution was added, and the resulting solution was heated up to 50°C on a water bath. 200 m*l* of aqueous solution containing 110 g of potassium hydroxide was poured into the warm solution, and a violent reaction took place. Heating was continued for one hour to complete the reaction. After the solution was stood for a while at room temperature, 100 m*l* of concentrated hydrochloric acid was gradually added. At pH 3.5, the wall of the reaction vessel was scrubbed with a glass rod, and white powdered crystals were obtained. Recrystallization was carried out from water. Yield 67 g.

Found: N, 9.83; C, 40.63; H, 6.18%. Calcd for $C_5H_9O_4N$: N, 9.52; C, 40.81; H, 6.21%.

Ethyliminodiacetic Acid. $C_2H_5N(CH_2COOH)_2$. To 300 m*l* of aqueous solution containing 190 g of monochloroacetic acid, 200 g of potassium hydrogen carbonate was gradually added. 65 g of 70% ethylamine solution was added, and then the solution was heated up to 50°C on a water bath. As 200 m*l* of 50% potassium hydroxide solution was dropped little by little, the reaction gradually proceeded. After the solution was stood at room temperature, 100 m*l* of concentrated hydrochloric acid was added. The solution was gradually concentrated by evaporating on a water bath, and then the deposited potassium chloride was filtered off. The filtrate was concentrated to about 300 m*l*. From the solution stored in a refrigerator, white powdered crystals were obtained. Recrystallization was achieved from water. Yield about 60 g.

Found: N, 8.53; C, 44.36; H, 6.21%. Calcd for $C_6H_{11}O_4N$: N, 8.69; C, 44.63; H, 6.38%.

Iminodiacetic Acid. Special grade reagent of Wako Pure Chemical Co. was used.

Preparation of Complexes. 1) *trans-Potassium Bis-(iminodiacetato)cobaltate(III) Monohydrate, trans*-$K[Co(ida)_2]\cdot H_2O$ (I). The compound was prepared by the method as described in literature.[4]

2) *cis-Potassium Bis-(iminodiacetato)cobaltate(III) Dihydrate, cis*-$K[Co(ida)_2]\cdot 2H_2O$ (II). The preparation was carried out following the procedure given in literature.[3,4]

3) *Potassium Bis-(iminodiacetato)chromate(III) Trihydrate*, $K[Cr(ida)_2]\cdot 3H_2O$ (III). This was prepared by a method similar to that outlined in literature.[7,8]

4) *Barium Bis-(iminodiacetato)chromate(III) Hexahydrate*, $Ba[Cr(ida)_2]_2\cdot 6H_2O$ (IV). To 200 ml of aqueous solution containing 5 g of chromium(III) chloride hexahydrate, 5 g of iminodiacetic acid was added, and then 6.8 g of barium hydroxide octahydrate was added little by little under stirring. The mixed solution was evaporated on a water bath for one hour (to approximately 100 m*l*). After cooling, red needle-like crystals were obtained. The products were recrystallized from water.

Found: N, 6.32; C, 21.38; H, 3.49%. Calcd for $Ba[Cr(ida)_2]_2\cdot 6H_2O$: N, 6.41; C, 21.99; H, 3.66%.

5) *Potassium Bis-(methyliminodiacetato)cobaltate(III)*, $K[Co(mda)_2]$ (V). The preparation was carried out by the method in literature.[6]

6) *Potassium Bis-(methyliminodiacetato)chromate(III)*, $K[Cr(mda)_2]$ (VI). The crystals were prepared by the method already known.[9]

7) *Potassium Bis-(ethyliminodiacetato)cobaltate(III) Monohydrate*, $K[Co(eda)_2]\cdot H_2O$ (VII). To 200 m*l* of aqueous solution containing 5 g of cobalt(II) chloride hexahydrate, 6 g of EDA was added, and then 3 g of potassium hydrogen carbonate was gradually added. The mixed solution was heated on a water bath for one hour. After the pH of the solution was adjusted to 6—7, a few m*l* of hydrogen peroxide was added, and pink orange crystals were then obtained under cooling. Recrystallization was carried out from water. Yield about 2 g.

Found: N, 6.50; C, 32.98; H, 4.58%. Calcd for $K[Co(eda)_2]\cdot H_2O$: N, 6.45; C, 33.21; H, 4.61%.

8) *Potassium Bis-(ethyliminodiacetato)chromate(III) Monohydrate*, $K[Cr(eda)_2]\cdot H_2O$ (VIII). To 250 m*l* of aqueous solution containing 5 g of chromium(III) chloride hexahydrate, 6 g of EDA was added. The solution was heated on a water bath for one hour, and then 3 g of potassium hydrogen carbonate was added little by little to the solution. Heating was continued for one hour. After cooling, orange crystals were separated out. The crystals were recrystallized from water. Yield about 2.5 g.

Found: N, 6.57; C, 33.54; H, 4.52%. Calcd for $K[Cr(eda)_2]\cdot H_2O$: N, 6.55; C, 33.69; H, 4.68%.

Apparatus. Electronic and IR spectra, and molar conductivities were measured with a Hitachi EPS Spectrophotometer and a Nippon Bunko DS-301 Infrared Spectrophotometer and with a Yokogawa Universal Bridge BV-Z-13A, respectively.

Results and Discussion

IR Spectra. Infrared absorption spectra of the complexes were measured to confirm whether or not the carboxylate groups were coordinated.

It is well known that the characteristic band for the free carboxylic acid and that for the coordinated one in aminopolycarboxylic acid complexes appear at $\sim$1750 and $\sim$1640 cm^{-1}, respectively.[10]

Since all the complexes showed the bands near $\sim$1640 cm^{-1}, it is obvious that the carboxylate groups are all coordinated.

Molar Conductivities. The molar conductivities of the complexes in 10^{-3} mol/*l* aqueous solution were measured at 25°C in order to ascertain the valency-type of the complexes. All the complexes except for IV showed the values of 92—98 mho·cm^{-1}, indicating that they are 1 : 1 type electrolyte. The value of 183.1 mho·cm^{-1} for complex IV is fairly

10) D. H. Busch and J. C. Bailar, Jr., *J. Amer. Chem. Soc.*, **75**, 4574 (1953).

reasonable for 1 : 2 type electrolyte.

Electronic Spectra and Possible Structures. The electronic spectra of all the complexes were measured in aqueous solutions. The spectra for the cobalt(III) complexes are depicted in Fig. 2, and those for the chromium(III) complexes in Fig. 3. The absorption maxima are also listed up in Table 1, together with those of reference substances.

It has been discussed from MO treatments that, in the cobalt(III) complexes of N_2-O_4 type, the *trans* form with respect to the nitrogen atoms shows the splitting in the first band at the longer wavelength side.[11] The assignments of *trans*- or *cis*-K[Co(ida)$_2$] have been made from the above viewpoint.[4] The spectra for complexes V and VII show such a splitting in the first band as in the case of complex I, differing from that of II which shows no splitting. This indicates that the former two complexes are considered to have the *trans*-form. The frequencies of absorption maxima of the above three complexes in *trans*-form are seen from Fig. 2 and Table 1 to be raised in the order VII$<$V$<$I, suggesting that spectrochemical series of these ligands is concluded to follow the order, EDA$<$MDA$<$IDA. This is also in agreement with the fact that the stability of the complexes is lowered by *N*-alkyl substitution in the ligands.

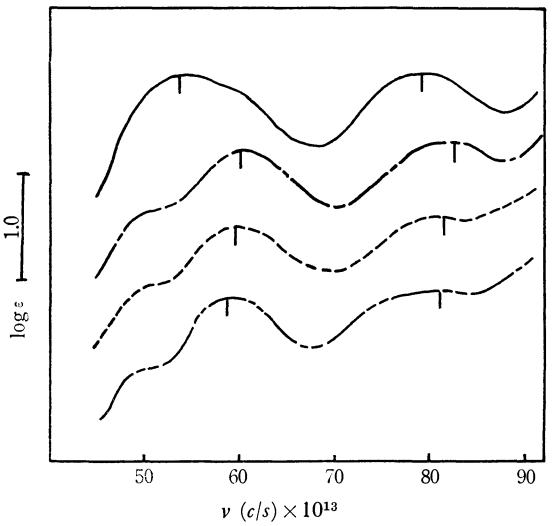

Fig. 2. Electronic spectra for *cis*-K[Co(ida)$_2$]·2H$_2$O (II) (———) *trans*-K[Co(ida)$_2$]·H$_2$O (I) (—·—), K[Co(mda)$_2$] (V) (– – – –) and K[Co(eda)$_2$]·H$_2$O (VII) (—··—).

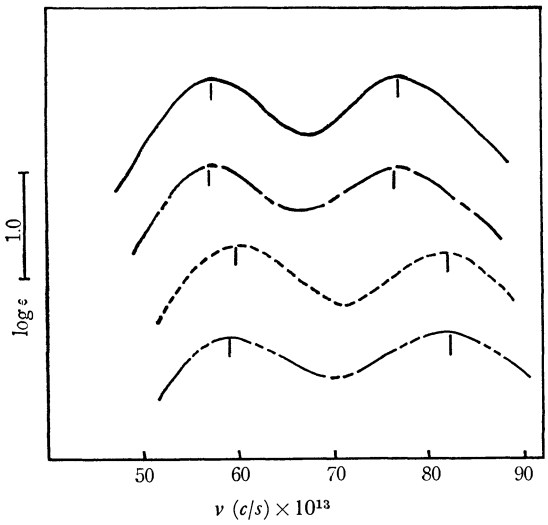

Fig. 3. Electronic spectra for K[Cr(ida)$_2$]·3H$_2$O (III) (———), Ba[Cr(ida)$_2$]$_2$·6H$_2$O (IV) (—·—), K[Cr(mda)$_2$] (VI) (– – – –) and K[Cr(eda)$_2$]·H$_2$O (VIII) (—··—).

TABLE 1. ABSORPTION MAXIMA

Complex	$m\mu_1(\nu_1 10^{-13}$/sec) log ε_1	$m\mu_2(\nu_2 10^{-13}$/sec) log ε_2
A. for the cobalt complexes		
I	500(60.00)1.70	365(82.19)1.74
II	566(53.00)2.03	380(78.95)2.04
V	509(58.94)1.74	367(81.74)1.84
VII	516(58.14)1.78	369(81.30)1.84
B. for the chromium complexes		
III	523(57.36)1.87	392(76.53)1.91
IV	524(57.25)1.85	393(76.34)1.92
VI	500(60.00)1.58	364(82.42)1.42
VIII	504(59.52)1.56	363(82.64)1.38
[Cr(edta)]$^-$ [12]	543	394
[Cr(tmta)]$^-$ [9,13]	509	385

Concerning *trans* configuration, two possible forms may be assumed; one is *trans-fac* (Fig. 1-A) and the other, *trans-mer* (Fig. 1-B). However, the former configuration seems to be reasonable in EDA complex of *trans* type, because the observation of the favorable angle of ∠C–N–C in the *trans* IDA and MDA complexes[4,6] suggested only the *trans-fac* configuration.

Preparation of the *cis*-isomer of the MDA or EDA complexes has not been successful probably because of the steric hindrance of methyl or ethyl groups, as reported by Weyh and Hamm.[9]

Although complexes VI and VIII do not show distinct splitting in the first band unlike cobalt complexes, it should be considered from the discussion of the corresponding cobalt complexes that they have also the same *trans-fac* configuration. As seen from Fig. 3, complex VIII has the absorption maxima at the longerwave length region than VI, as in the case of cobalt complexes.

Concerning the structures of complexes III and IV, if it is assumed that they have the *trans* configuration, their absorption maxima should be

11) H. Yamatera, This Bulletin, **31**, 95 (1958).

detected at ~500 and ~365 mμ, and their log ε_1 are expected to be 1.5—1.6. As can be seen from Table 1, however, the experimental results seem to be inconsistent with the above expectation. On the other hand, $[Cr(edta)]^-$ ion prepared by the method given in literature[12] shows the bands at 543 and 394 mμ. If III and IV are expected to have the same *cis*-form as $[Cr(edta)]^-$, the complexes should show the absorption maxima at 540—550 and 390—395 mμ.

The trimethylenediaminetetraacetatochromate (III) ion ($[Cr(tmta)]^-$),[13] which has six-membered chelate ring through two nitrogen atoms, shows the maxima at 509 and 385 mμ. These values are shorter than those of $[Cr(edta)]^-$ in spite of the fact that they have the same *cis*-configuration.

Studies of the metal chelate with diaminetetracarboxylic acids of the type $(HO_2CCH_2)_2N(CH_2)_n$-$N(CH_2CO_2H)_2$ indicated that the conformational strain becomes larger with the increase of n over 2,[14] when the octahedral coordination structure is assumed to be kept without any distortion. We thus consider that, in TMTA complex (TMTA: trimethylenediaminetetraacetic acid), the normal octahedral coordination form is somewhat distorted so as to diminish the strain due to the chelate ring through nitrogen atoms. It may be understood that complexes III and IV, like the chromium TMTA complex, take the *cis* configuration without much strain in the chelate ring structure as imagined by the sketch (D) in Fig. 1.

The authors wish to thank the Ministry of Education for the financial support granted for this research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1397—1402 (1970)

Bis-Type Cobalt(III) and Chromium(III) Complexes with Related Compounds of Nitrilotriacetic Acid*1

Akira UEHARA, Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received November 17, 1969)

β-Amino-*n*-butyric-*N*,*N*-diacetic acid (β-ABDA) and γ-amino-*n*-butyric-*N*,*N*-diacetic acid (γ-ABDA) were prepared as compounds related to nitrilotriacetic acid (NTA). Bis-type cobalt (III) and chromium(III) complexes with these ligands, *viz.*, $K_3[Co(\beta\text{-abda})_2]$ (I), $K[Co(H\text{-}\gamma\text{-abda})_2]\cdot 2H_2O$ (II) and $K[Cr(H\text{-}\gamma\text{-abda})_2]\cdot 2H_2O$ (III), and the same type cobalt(III) complex with β-aminoethylsulfonic-*N*,*N*-diacetic acid (AEDA), *viz.*, $K_3[Co(aeda)_2]\cdot 4H_2O$ (IV), were also synthesized. Chemical properties of the above complexes were compared with those of the chromium (III) complex corresponding to IV and of the cobalt(III) and chromium(III) complexes with NTA and NPDA. From the analysis of electronic spectra, it was found that the new complexes, I, II, III and IV have the *trans* form with respect to the nitrogn atoms in the ligands. A spectrochemical series of these ligands, containing iminodiacetic acid (IDA), methyliminodiacetic acid (MDA) and ethyliminodiacetic acid (EDA), was determined to be:

IDA>MDA>NPDA>β-ABDA>EDA>AEDA>NTA>γ-ABDA.

Most active works on the aminetricarboxylic acid complexes may be classified into four categories. The first deals with the formation constants of the bivalent metal complex species, *e*,*g*., those with NTA[1,2] and nitrilopropionicdiacetic acid (NPDA).[3] The second deals with the reaction kinetics of

*1 Presented at 19th Symposium on Coordination Chemistry, Sendai, September, 1969.

Table 1. Chelating agents and their abbreviations

A. Iminodiacetic Acid and Related Compounds

Rational formula	R	Name	Abbreviation
R–N(CH$_2$COOH)(CH$_2$COOH)	H	Iminodiacetic acid	IDA
	CH_3	Methyliminodiacetic acid	MDA
	C_2H_5	Ethyliminodiacetic acid	EDA

B. Nitrilotriacetic Acid and Related Compounds

Rational formula	R	R′	Name	Abbreviation
N(R′CH–R)(CH$_2$COOH)(CH$_2$COOH)	COOH	H	Nitrilotriacetic acid	NTA
	CH_2COOH	H	Nitrilopropionicdiacetic acid	NPDA
	CH_2SO_3H	H	β-Aminoethylsulfonic-*N*,*N*-diacetic acid	AEDA
	CH_2COOH	CH_3	β-Amino-*n*-butyric-*N*,*N*-diacetic acid	β-ABDA
	CH_2CH_2COOH	H	γ-Amino-*n*-butyric-*N*,*N*-diacetic acid	γ-ABDA

bivalent metals with NTA.[4,5] The third deals with the preparation of cobalt(III) and chromium(III) complexes containing NTA[6-8] or its related compounds, *e.g.*, NPDA,[9,10] AEDA,[11] nitriloisopropionicdiacetic acid (NIPDA),[12] and *l*-leucine-*N*,*N*-diacetic acid (LDA).[13] The fourth deals with the thermal reaction in the solid-state.[14] Study on the geometrical isomerism of the mixed cobalt(III) complexes with NTA and natural amino acids[15] might also be included.

In the previous paper,[16] the bis-type cobalt(III) and chromium(III) complexes with iminodiacetic acid (IDA) and its related compounds were reported from the viewpoint of geometrical isomerism. As a continuation of the work, investigations were carried out (1) to prepare bis-type cobalt(III) and chromium(III) complexes with nitrilotriacetic acid (NTA) or its related compounds, β-amino-*n*-butyric-*N*,*N*-diacetic acid (β-ABDA) and γ-amino-*n*-butyric-*N*,*N*-diacetic acid (γ-ABDA), the structures of these ligands being shown in Table 1, where those of IDA and its related compounds are also included, (2) to assign the geometrical structures of the complexes; *i. e.*, *cis* or *trans* with respect to the nitrogen atoms in ligands, (3) to inspect the difference in coordinating behaviors of these ligands, (4) to determine the spectrochemical series of all the ligands shown in Table 1, and (5) to compare the properties of cobalt(III) complexes with those of the corresponding chromium(III) ones.

Experimental

Preparation of Ligands. *β-Amino-n-butyric-N,N-diacetic Acid (β-ABDA)*, N(CH(CH$_3$)CH$_2$COOH)(CH$_2$COOH)$_2$. Five grams of β-amino-*n*-butyric acid was neutralized with 30 m*l* of water containing 3 g of potassium hydroxide. Fifty milliliters of water containing 10 g of monochloroacetic acid was gradually neutralized with 10 g of potassium hydrogen carbonate. The two solutions were mixed and heated on a water bath. When the temperature of solution was raised to *ca.* 70°C, 30 m*l* of water containing 6 g of potassium hydroxide was added, and heating was continued for 1—2 hr. The solution was cooled at room temperature. After potassium chloride deposited was filtered off, the pH of the solution was adjusted to *ca.* 5 by adding concentrated hydrochloric acid. The solution was then concentrated to about half its volume. After potassium chloride deposited was filtered off, the pH of the solution was adjusted to about 3. By scrubbing the wall of the reaction vessel with a glass rod, white powdered crystals were obtained. The crude products were recrystallized from water. Yield about 4 g.

Found: N, 6.31; C, 43.56; H, 5.82%. Calcd for $C_8H_{13}O_6N$: N, 6.39; C, 43.83; H, 5.98%.

γ-Amino-n-butyric-N,N-diacetic Acid (γ-ABDA), N(CH$_2$CH$_2$CH$_2$COOH)(CH$_2$COOH)$_2$. The preparative method closely resembles to that of β-ABDA; *i. e.*, in the preparation, γ-amino-*n*-butyric acid was used as a starting material in place of β-amino-*n*-butyric acid. Yield about 2 g.

Preparation of Complexes. *Potassium Bis-(β-amino-n-butyric-N,N-diacetato)cobaltate(III)*, $K_3[Co(\beta\text{-abda})_2]$ (I). Five grams of β-ABDA was added to 100 m*l* of aqueous solution containing 3 g of cobalt(II) chloride hexahydrate and the solution was then gradually neutralized with about 5 g of potassium hydrogen carbonate. After a few m*l* of 28% hydrogen peroxide solution was added, the solution was heated on a water bath and concentrated to about half its volume. After cooling pink crystals were obtained and recrystallized from water. Yield about 2 g.

Found: N, 4.74; C, 31.92; H, 3.31%. Calcd for $K_3[Co(\beta\text{-abda})_2]$: N, 4.60; C, 31.57; H, 3.29%.

Potassium Bis-(hydrogen-γ-amino-n-butyric-N, N-diacetato)-cobaltate(III) Dihydrate, $K[Co(H\text{-}\gamma\text{-abda})_2]\cdot 2H_2O$ (II). Five grams of γ-ABDA was added to 100 m*l* of aqueous solution containing 3 g of cobalt(II) chloride hexahydrate, and then about 3 g of potassium hydrogen carbonate was gradually added. A few m*l* of 28% hydrogen peroxide solution was dropped to oxidize the solution which was concentrated to half its volume on a water bath. After cooling pink crystals were obtained. The crude products were recrystallized from water. Yield about 1.5 g.

Found: N, 4.87; C, 33.42; H, 4.60%. Calcd for $K[Co(H\text{-}\gamma\text{-abda})_2]\cdot 2H_2O$: N, 4.93; C, 33.80; H, 4.61%.

Potassium Bis-(hydrogen-γ-amino-n-butyric-N, N-diacetato)-chromate(III) Dihydrate, $K[Cr(H\text{-}\gamma\text{-abda})_2]\cdot 2H_2O$ (III). To 100 m*l* of water containing 3 g of chromium(III) chloride hexahydrate, 5 g of γ-ABDA was added and 5 g of potassium hydrogen carbonate was then gradually added. The solution was heated on a water bath until the color of solution turned to pink from violet. From the solution pink crystals were obtained. Recrystallization was carried out from water. Yield about 3 g.

Found: N, 4.99; C, 33.85; H, 4.56%. Calcd for $K[Cr(H\text{-}\gamma\text{-abda})_2]\cdot 2H_2O$: N, 4.99; C, 34.22; H, 4.63%.

Potassium Bis-(β-aminoethylsulfonic-N,N-diacetato)cobaltate(III) Tetrahydrate, $K_3[Co(aeda)_2]\cdot 4H_2O$ (IV). 12 g of cobalt(II) chloride hexahydrate was dissolved in 200 m*l* of water and then 24 g of AEDA was added. 25 g of potassium hydrogen carbonate was gradually added to the mixture, which was then heated on a water bath until the solution turned from pink to red. After the solution was cooled to room temperature, about 5 m*l* of 28% hydrogen peroxide solution was added for oxidation. Reddish violet crystals were obtained from the cold solution. Recrystallization was carried out from water. Yield about 8 g.

Found: N, 3.83; C, 20.07; H, 3.27%. Calcd for $K_3[Co(aeda)_2]\cdot 4H_2O$: N, 3.86; C, 19.89; H. 3.31%.

Potassium Bis-(β-aminoethylsulfonic-N,N-diacetato) chromate(III) Tetrahydrate, $K_3[Cr(aeda)_2]\cdot 4H_2O$ (V),[11] *Potassium Bis(nitrilotriacetato)cobaltate(III) Trihydrate*, $K_3[Co(nta)_2]\cdot 3H_2O$ (VI),[10] *Potassium Bis-(hydrogennitrilotriacetato)cobaltate(III) Dihydrate*, $K[Co(Hnta)_2]\cdot 2H_2O$ (VII),[10] *Potassium Bis-(nitrilotriacetato)chromate(III) Tetrahydrate*, $K_3[Cr(nta)_2]\cdot 4H_2O$ (VIII),[7] *Potassium Bis-(hydrogennitrilotriacetato)chromate(III) Dihydrate*, $K[Cr(Hnta)_2]\cdot 2H_2O$ (IX),[7] *Potassium Bis(nitrilopropionic-diacetato)cobaltate(III) Dihydrate*, $K_3[Co(npda)_2]\cdot 2H_2O$ (X).[10] and *Potassium Bis-(nitrilopropionicdiacetato)chromate (III) Dihydrate*, $K_3[Cr(npda)_2]\cdot 2H_2O$ (XI)[9] were prepared by the similar method as in the corresponding ammonium salts given in literature and were identified by elemental analysis in order to compare their properties with those of complexes I, II, III and IV.

Apparatus. The same instruments as described previously were used.[16]

Results and Discussion

IR Spectra. Infrared absorption spectra were measured in Nujol mull state in order to see how carboxylate groups behave toward central metals. The band assignments with respect to carboxylate groups were carried out by the method of Busch and Bailar.[17] Numerical data of spectra arising from the free carboxylic acid (–COOH), the coordinated carboxylate (–COO–M) and the ionic carboxylate groups ($-COO^-$) are given in Table 2.

Complex IV shows the bands due to the coordinated carboxylate and the free sulfonate groups ($-SO_3^-$). The shoulder originating from the ionic carboxylate groups ($-COO^-$), besides the band assigned to a coordinated group, is also detected in the case of complex I. Complexes II and III give the bands assigned to the free carboxylate groups in addition to the coordinated groups.

Molar Conductivities. In order to examine to what kind of valency-type the new complexes belong, the molar conductivities were measured at 25°C in a 10^{-3} mol/*l* aqueous solution. The numerical values are given in Table 3.

The values of complexes I and IV fairly show that they are 1 : 3 type electrolytes. Complexes II and III show considerably high values which suggest partial dissociation of hydrogen ions in

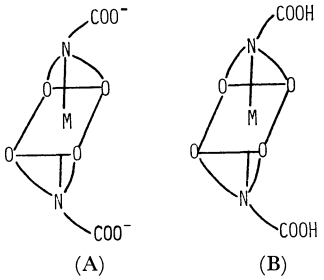
the complex species.

Electronic Spectra and Coordinating Structures. The electronic absorption spectra for the complexes were measured in aqueous solutions. Those for complexes VIII and XI were measured in a buffer solution of pH 6—7 in order to prevent aquation. Figure 1 shows the spectra for complexes I, II, IV and *trans*-K[Co(ida)$_2$]·H_2O, and Fig. 2, those for complexes III, *trans*-K[Cr(mda)$_2$] and *cis*-K[Cr(ida)$_2$]·3H_2O. For the sake of comparison, the values of absorption maxima due to *d–d* transition for cobalt(III) and chromium(III) complexes are summarized in Tables 4 and 5 respectively, together with those for related complexes.

Appearance of splitting in the first band at longer wavelength in [Co N_2O_4] type complexes has been assigned to *trans* form from MO theory.[18] We see from Fig. 1 that complexes I, II and IV show the splitting in the first band at longer wavelength side which suggests that all the complexes have the *trans* configuration with respect to nitrogen atoms as in the case of *trans*-K[Co(ida)$_2$]·H_2O.[19]

It can be seen from Fig. 2 and Table 5 that complex III shows a spectrum similar to that of *trans*-K[Cr(mda)$_2$][16] rather than to that of *cis*-K[Cr(ida)$_2$]·3H_2O.[16] This suggests that complex III has a *trans* structure rather than *cis*. The possibility of the presence of *cis*-configuration in the bis complexes with aminetricarboxylic acids seems to be slight because the steric hindrance due to the methyl or ethyl groups prevents the formation of *cis* complexes even in the case of the MDA[20,21] and EDA[16] complexes.

With the *trans* isomer, two types of configuration can be assumed, one is *trans facial* and the other *trans meridional*. It has been mentioned that the former may be preferred because of the relevant bond angles of these ligands coordinated[22] as in the case of the bis-type complexes with IDA and the related compounds.[16] Thus the structures of complexes I, II, III and IV might belong to *trans-fac* type. In Fig. 3, two types of *trans-fac* are depicted, one of which has noncoordinating –COO$^-$ (A) and the other, –COOH (B). From IR and molar conductivity data, complexes I and IV may have (A) structure, and II and III (B) structure.



(A) (B)

Fig. 3. Possible structures. M: Co(III) or Cr(III).

From a comparison of the spectra in Figs. 1 and 2, it can be seen that the first and second bands clearly appear in the case of the chromium(III) complexes, while the second band of the cobalt(III) complexes is not so distinct owing to the overlap of CT bands. Such a difference has been detected in the case of acidopentaammine complexes of cobalt(III) and chromium(III).[23,24]

Spectrochemical Series of the Ligands. Although all the complexes obtained show a band pattern very similar to each other, a careful inspection of data in Tables 4 and 5 reveals a small but distinct difference in the wavelength of absorption bands. The differences in a series of cobalt(III) complexes are much remarkable in contrast with those in the chromium(III) ones. A spectrochemical series in the cobalt(III) complexes will be settled as follows according to the sequences of weavelength of the first band in Table 4;

IDA>MDA>NPDA>β-ABDA>EDA>AEDA>NTA>γ-ABDA

TABLE 6. COORDINATING BEHAVIORS OF LIGANDS HAVING (5,5,5)-, (5,5,6)- OR (5,5,7)-MEMBERED CHELATE RINGS

Ligand	Chelate ring	Coordinating type	Coordination number	Cr(III)	Co(III)
NTA	5.5,5	N_1-O_3	4	○	○
		N_1-O_2	3	○	○
		O_3	3	○	×
NPDA	5,5,6	N_1-O_3	4	○	○
		N_1-O_2	3	○	○
		O_3	3	×	×
γ-ABDA	5,5,7	N_1-O_3	4	×	×
		N_1-O_2	3	○	○
		O_3	3	×	×

Difference in the Coordinating Behaviors of the Ligands. The relations between the coordinating behaviors in NTA, NPDA and γ-ABDA complexes which have three chelate rings consisting of (5,5,5)-, (5,5,6)-, (5,5,7)-members respectively are summarized in Table 6. Each complex is respectively classified into three groups owing to the possible coordinating types, N_1-O_3, N_1-O_2 and O_3, which represent the coordinating nitrogen and oxygen atoms and their number per one molecule of these ligands. The complexes which we succeeded in preparing are denoted by ○, and those in which we did not succeed by × in Table 6.

NTA could act as N_1-O_3, N_1-O_2 and O_3 types toward chromium(III), but not as O_3 type toward cobalt(III). This might be due to the smaller affinity of cobalt(III) to oxygen as compared with that of chromium(III).[10] NPDA could not behave as O_3 type to both metals.[9,10] It may be understood by empirical facts that the complexes with a ligand forming two five-membered and one six-membered chelate rings are more stable than those forming three five-membered rings.

γ-ABDA acted only as an N_1-O_2 type. In this case the butyric acid group may be uncoordinated, because the formation of a seven membered ring is difficult.

The Kinetics of the Aminolysis of Phenyl Phenoxyacetates with Benzylamine in Dioxane

Yoshiaki FURUYA* and Kazuo ITOHO**

*Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto
**Daiichi College of Pharmaceutical Sciences, Fukuoka

(Received May 30, 1969)

The rates of the reactions of *p*- and *m*-substituted phenyl phenoxyacetates with benzylamine in dioxane, thus forming *N*-benzylphenoxyacetamide and the corresponding phenols, were followed by the non-aqueous titration of benzylamine. The reaction satisfied the following general equation:

$$v = \{k_2' + k_3'[\text{Amine}]\}[\text{Amine}][\text{Ester}] + \{k_3'' + k_4[\text{Amine}]\}[\text{Amine}][\text{Ester}]^2.$$

The reaction was a neucleophilic substitution, and the Hammett plots gave straight lines with positive ρ values. A marked enhancement in the conductivity of the reaction mixtures in 50% dioxane was observed, it increasing with the reaction time. A probable mechanism was presented which involves an ion pair of the quaternary ammonium salt type somewhat similar to that discussed in a previous paper (Y. Furuya, S. Goto, K. Itoho, I. Urasaki and A. Morita, *Tetrahedron*, **24**, 2367 (1968)).

The mechanism for the aminolysis of carboxylates has been studied by many investigators.[1a-e] In our previous paper, we suggested that a probable mechanism of the triethylenediamine-catalyzed aminolysis of phenyl *N*-phenylcarbamates with aniline in dioxane involves an ion pair of quarternary ammonium salt as an incipient intermediate. Generally, a specific catalyst is not required for usual aminolyses because the reactant amine itself acts as a catalyst.

In the present paper, it will be shown that the non-catalyzed aminolysis also involves an ion pair of the ammonium salt type.

Experimental

Materials. The phenyl phenoxyacetates were prepared by the reaction of phenoxyacetyl chloride and the corresponding phenols in the presence of a catalytic amount of tertiary amine in dry benzene, and then the reaction mixtures were recrystallized from aqueous methanol. Phenyl phenoxyacetate, mp 54—55°C (lit,[2] 56—57°C). *p*-Tolyl phenoxyacetate, mp 86—86.5°C. Found: C, 74.55; H, 6.03%. Calcd for $C_{15}H_{14}O_3$: C, 74.36; H, 5.83%. *p*-Chlorophenyl phenoxyacetate, mp 101.5—102°C. Found: C, 64.35; H, 4.46%. Calcd for $C_{14}H_{11}O_3Cl$: C, 64.01; H, 4.22%. *m*-Nitrophenyl phenoxyacetate, mp 97°C. Found: C, 61.28; H, 3.94; N, 5.21%. Calcd for $C_{14}H_{11}O_5N$: C, 61.54; H, 4.06; N, 5.13%. The *N*-benzylphenoxyacetamide used as an authentic sample was obtained by the reaction of phenoxyacetyl chloride with benzylamine; mp 82—83°C (lit,[3] 85—86°C). The benzylamine was dried over anhydrous sodium sulfate and then distilled; bp 183°C. The dioxane was purified as has been described in a previous report;[4] bp 102°C. The N/100 glacial acetic acid solution of perchloric acid was prepared with glacial acetic acid and 70% perchloric acid (special grade), and then standardized with a N/100 sym.-diphenylguanidin benzene-monochlorobenzene solution, using a tetrahydrofuran (THF) solution saturated with methyl violet as the indicator. The benzene was distilled from metal sodium; bp 80.1°C.

Reaction Product Criterion. The crystal obtained in an almost quantitative yield by the reaction of phenyl phenoxyacetate with benzylamine in dioxane did not show any melting-point depression when the product was mixed with the authentic sample of *N*-benzylphenoxyacetamide; mp and mmp 82—83°C.

The Reaction Products in 50% Aqueous Dioxane. A mixture of phenyl phenoxyacetate (0.02 mol) and benzylamine (0.02 mol) in 200 m*l* of 50% aqueous dioxane was stirred for a few hours at room temperature (*ca.* 30°C) and then allowed to stand overnight. The reaction mixture was diluted with a 200 m*l* of cold water and subsequently extracted several times with a total of 200 m*l* of ether. The ether layer was dried on anhydrous sodium sulfate overnight and then was washed with cold water. The oily matter obtained by removing the ether was recrystallized from aqueous methanol.

3) S. Kushner, R. I. Cassell, J. Morton, II, and J. H. Williams, *J. Org. Chem.*, **16**, 1283 (1951).

4) Y. Furuya, S. Goto, K. Itoho, I. Urasaki and A. Morita, *Tetrahedron*, **24**, 2367 (1968).

The crystal of *N*-benzylphenoxyacetamide was thus obtained; mp and mmp, 82°C; yield, 64.2%. The aqueous layer was acidified with aqueous hydrogen chloride together with the washings, and then extracted several times with a total of 250 m*l* of ether. The extract was dried on anhydrous sodium sulfate overnight. When the ether was then removed, an acidic crystalline matter, phenoxyacetic acid, was obtained; mp and mmp, 96°C; yield, 33.5%.

The Calibration Curve in the Chemical Analysis of Benzylamine. The calibration curve gave a straight line in solutions with benzylamine concentrations ranging from 1×10^{-2} to 3×10^{-1}M. It was, moreover, not influenced at all by the presence of ester, amide, and phenol.

A Typical Run for the Rate Measurement. A 7.5-m*l* portion of a 0.2M dioxane solution of benzylamine was poured into a solution of 7.5 m*l* of 0.2M phenyl phenoxyacetate in dioxane to start the reaction after both solutions had attained temperature equilibrium. Aliquots (each 1.0 m*l*) were pipetted out at appropriate time intervals, and each one was diluted with cold benzene (50 m*l*). The solution was then titrated by a N/100 perchloric acid - glacial acetic acid solution, using a solution saturated with methyl violet (0.5—1.0 m*l*) as the indicator. The values of the second-order rate constants, k_{2obs}, were calculated from the conversions thus obtained.

A Typical Procedure for the Conductivity Measurement. A 25-m*l* portion of a 50% aqueous dioxane solution of 1×10^{-2}M benzylamine aged at 30 ± 0.2°C was added to a 25-m*l* portion of a 50% aqueous dioxane solution of 1×10^{-2}M phenyl phenoxyacetate; then the conductivity at 30 ± 0.2°C was measured by means of a Yokogawa-Hewlett-Packard universal bridge 4255A (BV-Z-13C) at appropriate intervals of time.

Results and Discussion

Typical rate data of the aminolysis at 20°C are shown in Fig. 1. Here, *a*, *b*, and *x* are the initial concentrations of the amine and the ester and the consumed concentration of the amine at time *t* respectively. The kinetics follows the second-order equation. The plots of the apparent second-order rate constant *vs.* the concentration of the ester gave a straight line which does not pass through the point of origin, as is illustrated in Fig. 2. Therefore, the k_{2obs} rate constant is given by the following equation:

$$k_{2obs} = k_2 + k_3[\text{Ester}] \quad (1)$$

The values of k_2 and k_3 varied with the concentration of benzylamine (Figs. 3 and 4). Hence, k_2 and k_3, the rate constants, should be expressed as follows:

$$k_2 = k_2' + k_3'[\text{Amine}] \quad (2)$$

$$k_3 = k_3'' + k_4[\text{Amine}] \quad (3)$$

The total kinetics is, therefore, given by the following equation:

$$v = \{k_2' + k_3'[\text{Amine}]\}[\text{Amine}][\text{Ester}] + \{k_3''+k_4[\text{Amine}]\}[\text{Amine}][\text{Ester}]^2 \quad (4)$$

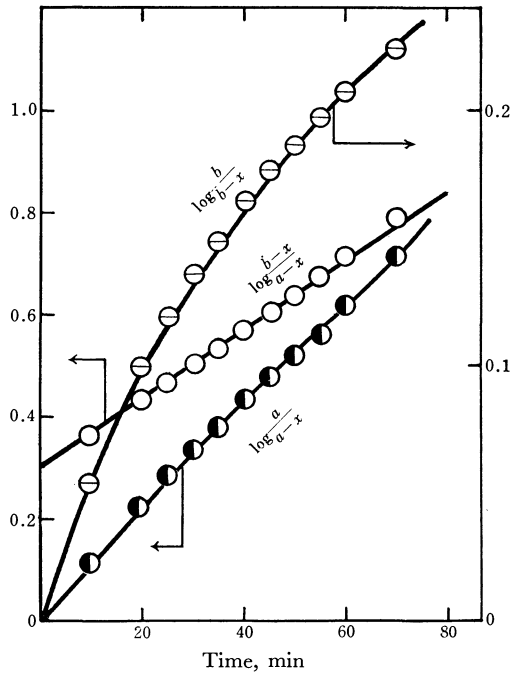

Fig. 1. Determination of reaction order of the aminolysis in dioxane at 20°C.
Concn. of phenyl phenoxyacetate: 0.20M
Concn. of benzylamine: 0.10M

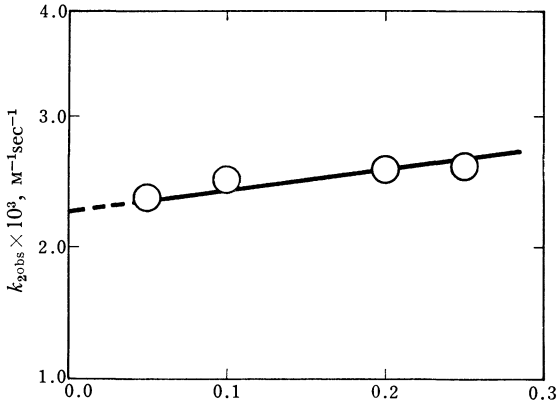

Fig. 2. The plots of k_{2obs} *vs.* the concentration of the ester for the aminolysis in dioxane at 20°C.
Concn. of benzylamine: 0.10M

The values of k_2', k_3', k_3'', and k_4 are tabulated in Table 1.

The reaction was retarded by the introduction of an electron-releasing group into the phenyl group of the ester. Thus, the plots of the logarithm of k_2', k_3', k_3'', and k_4 *vs.* Hammett's σ gave straight lines with slopes of $+1.13$, $+2.38$, $+2.42$, and $+2.45$ respectively. The reaction course represented by the first term of Eq. (4) is considered to be as follows:

$$PhOCH_2CO_2Ph + PhCH_2NH_2 \overset{k_2'}{\rightleftharpoons} \left[PhOCH_2\overset{\overset{O}{\|}}{C}\cdots OPh \;\; NH_2CH_2Ph \right]$$

[I]

As the ρ values of the reaction steps expressed by the second, third, and fourth terms all have plus signs and are nearly equal to each other, the rates must be controlled by similar steps. It is apparent from the calculation of the reaction order in the rate equation, however, that the rates of the two courses expressed by the second and third terms are not controlled by Step (7), but by Steps (5) and (6) respectively.

$$PhCH_2NH_2 + B \rightleftharpoons \left[PhCH_2\overset{\overset{H}{|}}{N}\cdots NHCH_2Ph \right]$$

[II]

$$\text{and/or} \left[PhOCH_2\overset{\overset{O}{\|}}{C}\cdots\overset{\overset{H}{|}}{N}\cdots NHCH_2Ph \right]$$

[III]

(B: Benzylamine or phenyl phenoxyacetate)

$$PhOCH_2CO_2Ph + II \overset{k_3', -\text{Amine}}{\rightleftharpoons} I \qquad (5)$$

$$PhOCH_2CO_2Ph + III \overset{k_3'', -\text{Ester}}{\rightleftharpoons} I \qquad (6)$$

$$I \longrightarrow \text{Prod.} + PhOH \qquad (7)$$

As the reaction indicated by the fourth term is very small under these concentration conditions, it might be negligible in the reaction of the non-substituted ester. However, if we make bold to suggest a probable mechanism for the reaction expressed by the fourth term, it can be written as follows:

$$PhCH_2NH_2 + PhOCH_2CO_2Ph \rightleftharpoons \left[PhOCH_2\overset{\overset{O}{\|}}{C}\cdots\overset{\overset{H}{|}}{N}\cdots NHCH_2Ph \right] \qquad (8)$$

[IV]

$$2\,IV \overset{k_4}{\rightleftharpoons} \left[PhCH_2\overset{\overset{H}{|}}{N}\cdots\overset{\overset{O}{\|}}{C}CH_2OPh \;\; \overset{\overset{H}{|}}{N}\cdots\overset{\overset{OPh}{|}}{C}\cdots NHCH_2Ph \right] \qquad (9)$$

[V]

$$V \longrightarrow \text{Prod.} + PhOH \qquad (10)$$

$$V \longrightarrow \text{Ester} + \text{Amine} \qquad (11)$$

Considering the reaction order obtained by the calculation, the rate-determining step is probably Step (9). When the phenoxy group has an electron-releasing group, phenol may be easily able to leave the ring complex, V. On the other hand, each bond in the carbophenoxy group, especially the bond between the carbonyl C-atom and the phenoxy O-atom, may be strengthened by the resonance effect in the carbophenoxy group when an electron-attracting group is introduced into the phenoxy group. This may be the reason why the Hammett plot of the k_4 rate constant has a positive ρ value.

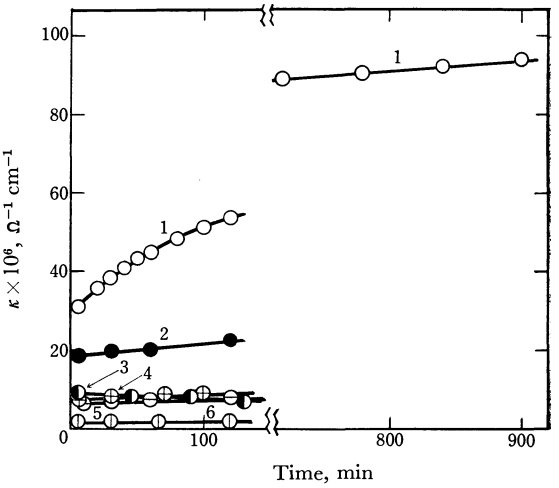

Fig. 6. Conductivity change with time for the each member and the couple of the aminolysis of phenyl phenoxyacetate with benzylamine in 50% aqueous dioxane at 30°C.
1, Concn. of the mixture of the ester and amine: each 5×10^{-3}M; 2, concn. of the mixture of the amine and phenol: each 5×10^{-3}M; 3, concn. of the mixture of the ester and amide: each 5×10^{-3}M; 4, concn. of the mixture of the amide and phenol: each 5×10^{-3}M; 5, concn. of the amine: 5×10^{-3}M; 6, concn. of the ester, amide and/or phenol: 5×10^{-3}M, respectively.

The conductivities of the [Ester+Amine], [Amine+PhOH] and [Amide+PhOH] couples are larger than the sums of the conductivities of the components, as is shown in Fig. 6 and Table 2. No initial large increase such as that in the conductivity of the [Ester+Amine] couple is observed in the conbinations of [Amine+PhOH] and [Amide+PhOH], as is shown in Fig. 6. The value of the conductivity on the heel of starting the actual reaction ($30\times10^{-6}\Omega^{-1}$cm^{-1}) is larger than the value of the sum of the ester and the amine ($10.4\times10^{-6}\Omega^{-1}$ cm^{-1}). It corresponds to the value in a 10% conversion of hydrolysis. Moreover, in the reaction in 50% aqueous dioxane at 30°C for 30 hr, the conversions of hydrolysis and aminolysis were 30 and 60% respectively. The conductivity of the model mixture, which has 30 and 60% conversions

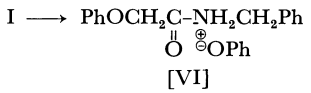
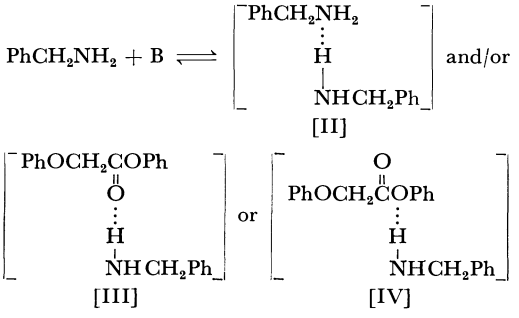
b) The values in parentheses are the sums of an actual value of each component constituting each couple.

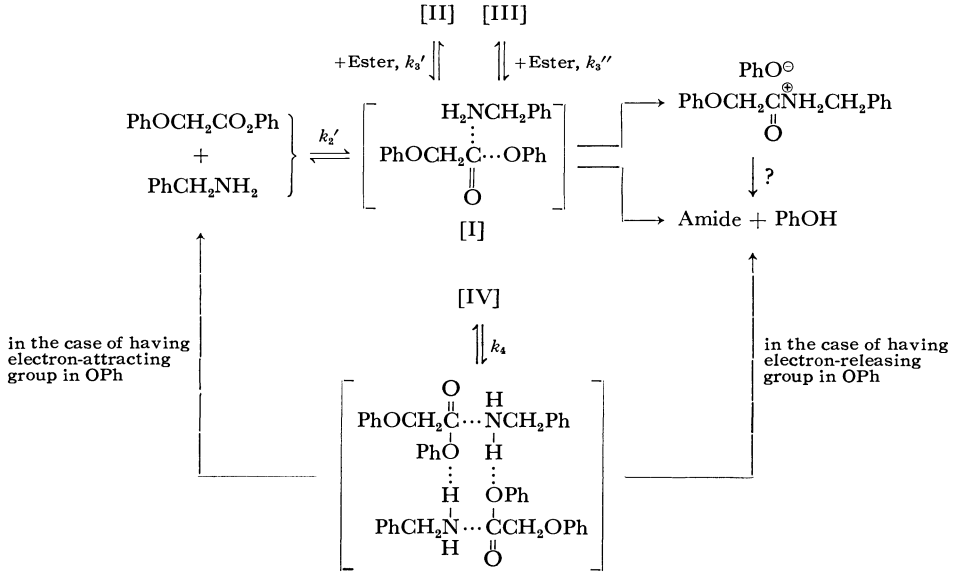
of hydrolysis and aminolysis respectively, was observed to be $69\times10^{-6}\Omega^{-1}$ cm^{-1}. This value is considerably smaller than the conductivity value ($94\times10^{-6}\Omega^{-1}$ cm^{-1}) obtained in the actual reaction at 30°C for 900 min. This suggests that another conductive matter is formed in addition to the formation of benzylammonium phenoxyacetate. It would be a quarternary ammonium salt like VI. Though the ion pair is perhaps formed, we can't



[VI]

decided that the salt is either an intermediate or a side reaction product. The amide formed by the reaction did not give benzylamine in either the presence or absence of phenol in dioxane at 70°C for 2 hr. From these findings, the following probable mechanism which involves I formed by the nucleophilic attack of the lone pair of the N-atom of amine on the carbonyl C-atom of the ester may be suggested:





(B: Benzylamine, Phenyl Phenoxyacetate)

Mass Spectra of Phenyl *p*-Toluenesulfonates. Substituent Effect in Fragmentation

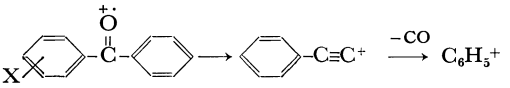
Seizi KOZUKA, Hideo TAKAHASHI, Seizo TAMAGAKI and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received June 30, 1969)

Mass spectra of substituted phenyl *p*-toluenesulfonates were analyzed with the aid of metastable peaks. Three steps in fragmentation were suggested as the main processes for these compounds *i.e.*, the initial S–O bond cleavage giving sulfonylcation, the second desulfonylation and the final loss of acetylene. Effect of substituent on the rate of the decomposition was observed in these three steps. The results are discussed in terms of various internal energies of the initial fragment ions. Apparently, the rates of the initial decomposition depend on the nature of the substituents.

Examination of mass-peak shifts by substituents is the usual method for clarifying the nature of electron impact decomposition. However, the effect of substituent on the rate of fragmentation has not been paid much attention till recently.[1] The substituent effects on the mass spectra hitherto being examined are those of acetophenones, benzophenones,[2–5] phenyl carbonates,[6,8] azobenzenes,[7] benzyl phenyl ethers,[9] dibenzyls,[10] methyl-4-phenyl butylate[11] and butyrophenones.[12] With most of these compounds, the relative peak heights (*Z*-values) of the first step of fragmentation, *i.e.*, the processes leading to the first fragment ions from the molecular ions, were nicely correlated with Hammett σ-values. In the case of substituted benzophenones, the effect of substituents was observed not only in the first step of fragmentation, *i.e.*, the formation of the benzoyl ions from the molecular ions, but also in the subsequent step, namely the decarboxylation of the benzoyl ions.[2]



Recently we have reported the mass spectra of aromatic sulfur compounds having three different S–S bonds *i. e.*, disulfides, thiol sulfinates and thiol sulfonates.[13] As an extention of our previous work, we have examined the mass spectra of the following five diaryl sulfonates (I)

and found that the effects of substituents are clearly observed not only in the first step of the decomposition of the molecular ion but also in the second and third steps of fragmentation. In this paper, we wish to report the fragmentation scheme of diaryl sulfonates, the correlation of the decomposition rate with substituents and the energy states of the particular fragment ions.

Fragmentation. Five *p*-substituted phenyl *p*-toluenesulfonates were analyzed. An example of the mass spectrum is shown in Fig. 1. The intense peaks and metastable peaks of these compounds observed in their mass spectra are listed in Table 1.

All the compounds gave distinct molecular ions, and the subsequent fragment ions were formed by the loss of the phenoxy radicals from the molecular ions. Base peaks of most of these compounds appeared at the mass number of 91 which corresponds to tropylium ion.[9,10,14-17] However, in the case of *p*-methoxyphenyl toluenesulfonate, phenoxy cation was the base peak. This difference may be ascribed to the strong electron-releasing nature of the substituent, *i. e.*, methoxy group. Thus, the cleavage of the S–O bond of the molecular ion leaving a cationic center on the sulfur atom is less favored in the methoxy substituted compound and the heterolytic decomposition giving phenoxy cation would become the predominant process. This observation is in good accord with the previous observation of the mass fragmentation patterns of mono-substituted benzophenones in which similar two competing processes were suggested.[5]

All the patterns shown in Table 1 are similar to those of the thiol sulfonates.[13] A noticeable but minor difference may be the absence of oxygen migration which was presumed to occur from the sulfonyl sulfur to the sulfenyl sulfur atom at the initial stage of fragmentation of the thiol analogues.[13] The major fragmentation scheme suggested for the thiol sulfonates is applicable to the present compounds.

in mass spectra seem to be related to the rate of the decomposition.[1-5,18,19] The Hammett plots of the relative intensities of the peak heights corresponding to steps 1, 2 and 3 against σ^+ values are shown in Fig. 2. The ρ value of the individual steps calculated by the least square method is also given in Scheme 1.

The substituent effects hitherto reported in mass spectra have been correlated with σ values. However, in this particular case, a better correlation was attained with σ^+ values.

The low electron voltage mass spectroscopic determination was usually employed for obtaining a good Hammett plot in order to avoid various decompositions.[4] In this study, we have also examined the mass spectra of the compounds at 20 eV. The results are shown in Fig 3.

In this case, the decomposition of step 3 disappeared completely in all the compounds. The formation of the phenoxy cation in the methoxy compounds was observed more markedly since the formation of ions A and B was too small to be observed. Thus, the data obtained by 80 eV mass spectrometry will be discussed.

The effect of substituents observed at the first step of the decomposition is in good accord with electrostatic consideration. The electron-withdrawing substituent is expected to accelerate step 1 decomposition while the electron-donating substituent such as methoxy group retards the reaction accompanied by the fragmentation through the heterolysis of opposite orientation. The following considerations might help to explain the effect observed at the processes (steps 2 and 3) which do not actually deal with the fragment ions bearing substituents of the precursor ions.

One explanation is to assume the direct process leading to the fragment B from the molecular ion by the C–S bond fission or the concerted two bond fission. The stepwise reaction shown in Scheme 1 could not be neglected because of the existence of the metastable peaks. Thus the two competing processes must be included. The ρ-value obtained from the relative peak heights of the molecular ions and the ion B in the presumed direct process of step 1′ ($\rho=+0.72$) is identical with that of the sum of the ρ-values of steps 1 and 2. ($+0.72$). The hypothesis involving two competing processes is not in conflict with the additivity of the ρ-values. Therefore, the direct process from M to B is ruled out.

The only plausible explanation is to apply the statistical theory of mass spectra to the present system as was applied to the spectra of substituted benzophenones by Gross and McLafferty.[5] The two competing processes of the decomposition of the molecular ion in the series of substituted phenyl *p*-toluenesulfonates are the formation of *m/e* 155 $R\text{-}SO_2^+$ ion and substituted phenoxy cation. The pathway requiring less activation energy is the formation of the $R\text{-}SO_2^+$ ion when the substituent is electron-withdrawing group. The $R\text{-}SO_2^+$ ion thus formed would be recoiled with a less excess internal energy to accelerate the subsequent decomposition. When the substituent is an electron-donating group, the favored path gives rise to the formation of phenoxy cation. In this case, the

$R-SO_2^+$ ion formed in the minor path would be endowed with a larger internal energy, and the rate of the subsequent step (step 2) would be more accelerated than that of aryl *p*-toluenesulfonates having electron-withdrawing groups.

The positive and negative ρ-values of the first and the second steps of the decompositions are now rationalized. It is interesting to note that the absolute ρ-values decrease gradually ($1.05 \rightarrow 0.33 \rightarrow 0.27$). The deviation of the rate of the second step with the variation of substituents is ascribed to the various rates of the first step of decomposition. The negative ρ-value may result from the consumption of the excess energy of the $R-SO_2^+$ ion formed in the first step of fragmentation. If the consumption of the excess energy is enough, the ρ-value of the second step may have a magnitude similar to that of the first step but with opposite sign. If the excess internal energy of the $R-SO_2^+$ ion is retained even after the second step, the energy would be consumed by further decomposition processes. The magnitude of the absolute ρ-value of the second step would be smaller than that of the first step, and the ρ-value of the third and forth steps, if any, must have the same sign as that of the second step. The size of the ρ-values of these succeeding steps is considered to decrease to zero until any excess energy formed by the initial step completely disappears. The rates of the decomposition of the fragment ions A and B are influenced by the difference of the activation energies of the first step which depends on the substituent of the molecular ion.

In this connection, the result observed would suggest that the difference of the recoiled energy with the variation of the substituents is retained in the fragment ion even after step 3. The retained energy would be consumed by the succeeding fragmentation. Unfortunately, no clear fragmentation of ion C was observed except for a very small amount of loss of acetylene. However, the peak corresponding to $C_3H_3^+$ was too small to make any sensible plot of the fourth step.

The effect of substituent at the second and third steps of ion-fragmentations in mass spectroscopy is now being tested with other systems.

Experimental

The spectra were recorded with a Hitachi RMU-6E single focus mass spectrometer using 80 eV at the emission current 110 μA. Samples were introduced through an all glass inlet system kept at about 200°C.

The authors are grateful to Dr. K. Takeda of Shionogi Research Laboratory who enabled us to purchase a mass spectrometer.

Chlorinative Coupling of Thiophene by the Action of Sulfuryl Chloride and Iron Powder*1

Tyo SONE, Koji SAKAI and Kimio KURODA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa

(Received July 14, 1969)

In the presence of iron powder, thiophene reacted with sulfuryl chloride at room temperature to give a mixture of chlorinated 2,2′-dithienyls as the main product in yields of up to 42%, while the reaction without a catalyst gave chlorothiophenes. The yield of the coupling product and the chlorine content in the product increase with an increase in the molar ratio of sulfuryl chloride to thiophene. 5,5′-Dichloro-, 3,5,5′-trichloro-, and 3,3′,5,5′-tetrachloro-2,2′-dithienyls were isolated from the reaction products. The reaction was also catalysed by Friedel-Crafts-type catalysts, the efficiency of the catalysts decreasing in the order: $AlCl_3 > FeCl_3 > SnCl_4 > ZnCl_2$.

There have been several papers concerning the coupling of aromatic[1] and heteroaromatic compounds[2,3] with halogenating agents. In one of these papers, Töhl and Eberhard briefly and without structural elucidation described the forma-

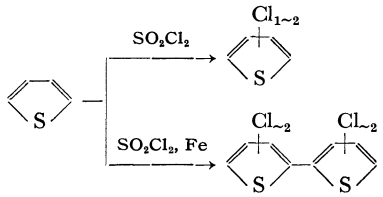
tion of chlorinated 2,2′-dithienyls by the reaction of thiophene with sulfuryl chloride and aluminum chloride.[2]

In the presence of iron powder as well as Friedel-Crafts-type catalysts, thiophene was found to react with sulfuryl chloride at room temperature to afford chlorinated 2,2′-dithienyls as the main product, while the reaction without a catalyst has been known to give 2-chloro- and 2,5-dichlorothiophene.[4] These facts are of interest not only from mechanistic but also from preparative points of view. Certain 2,2′-dithienyl derivatives, including 5,5′-dichloro-2,2′-dithienyl (II), have been shown to have a

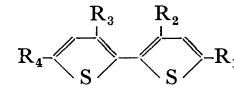


strong nematicidal activity.[5] Previous procedures of preparing 2,2′-dithienyls are based on the coupling of 2-halothiophene by the Ullmann or Grignard method. On the other hand, the present method may provide a convenient, one-step synthesis of those compounds.

The object of the present work is to ascertain the reaction conditions which favor the formation of the coupled products, to isolate the products, and to identify their structures.

Results and Discussion

The reaction of thiophene with sulfuryl chloride and iron powder afforded a crystalline product along with a small amount of liquid chlorothiophenes (less than 10%) and a polymeric material. The crystalline product melted over a rather wide temperature range (60—100°C); it has been suggested that it has a dithienyl structure on the basis of UV spectral and molecular-weight determination. In addition, the product gave a positive test for the Beilstein test. These facts indicate that the product is mainly a mixture of chlorine-substituted dithienyls, presumably chlorinated 2,2′-dithienyls. Although the separation of a pure chlorinated 2,2′-dithienyl from the others is not easy, as has been pointed out in connection with the preparation of 5-chloro-2,2′-dithienyl by the direct chlorination of 2,2′-dithienyl,[5,6] three chlorinated 2,2′-dithienyls, *i. e.*, II, 3,5,5′-trichloro-2,2′-dithienyl (III) and 3,3′,5,5′-tetrachloro-2,2′-dithienyl (IV), could be isolated by the fractional recrystallization of the reaction mixtures.



(I): $R_1=Cl$, $R_2=R_3=R_4=H$
(II): $R_1=R_4=Cl$, $R_2=R_3=H$
(III): $R_1=R_2=R_4=Cl$, $R_3=H$
(IV): $R_1=R_2=R_3=R_4=Cl$
(V): $R_1=R_2=R_3=Cl$, $R_4=H$

The product obtained from the reaction of thiophene with a large excess of sulfuryl chloride consisted principally of tetrachloro-2,2′-dithienyl. The positional assignment of chlorine atoms was based on the NMR spectrum of the dechlorination product of the tetrachloro-2,2′-dithienyl with zinc powder in an acetic acid solution. The spectrum of the trichloro-2,2′-dithienyl thus obtained shows a singlet and two doublets with a relative intensity of 1 : 1 : 1, as is shown in Table 1. The singlet at 6.84 ppm is due to the hydrogen at the β-position of one thiophen ring, and the doublets at 7.32 ppm and 6.95 ppm correspond to two hydrogens of the other ring in the trichloro-2,2′-dithienyl, coupling constant ($J=5.5$ Hz) being indicative of 2,3-disubstituted thiophene.[7] These results are in agreement with those to be expected for 3,3′,5-trichloro-2,2′-dithienyl (V), which in turn indicate that the original tetrachloro-2,2′-dithienyl is IV.

II and III were isolated from the products obtained by the reactions of thiophene with a one-half molar equivalent of sulfuryl chloride (Table 2, No. 3) and with an equimolar amount of sulfuryl chloride (Table 2, No. 4) respectively, but in low yields. II was identified by comparison with the authentic sample prepared from 2-chloro-5-iodothiophene by the Ullmann reaction. The structure of III was confirmed by means of NMR spectroscopy, as in the case of V.[7] The UV and NMR spectral data of the chlorinated 2,2′-dithienyls are summarized in Table 1.

The effects of the molar ratio of sulfuryl chloride to thiophene and catalysts on the composition of the product were studied in some detail. The crystalline products[8] obtained under various condi-

8) The IR spectra of the crystalline products exhibit a moderate band other than those of the chlorinated 2,2′-dithienyls at about 710 cm^{-1}. It was also shown by vpc that the crystalline products usually consisted of 10—20% of unidentified materials in which one component predominated; when zinc chloride was used as the catalyst, the crystalline product, exceptionally, consisted of about 30% unidentified materials.

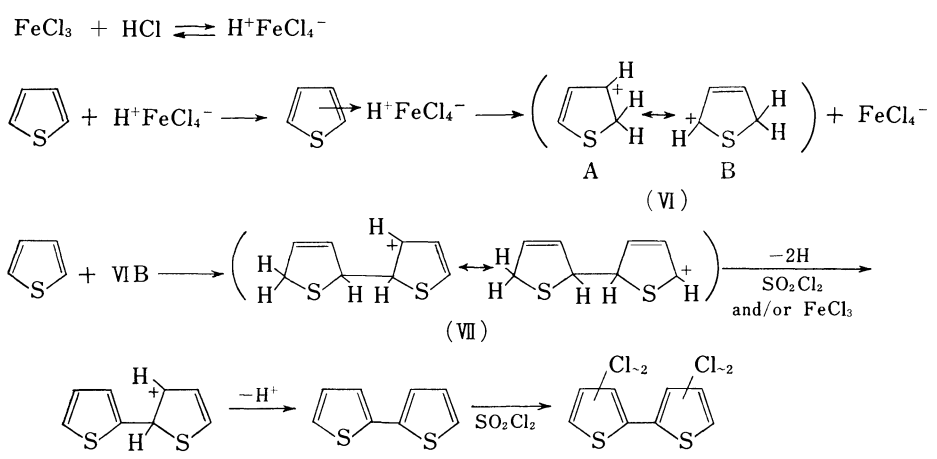
tions were shown by vapor-phase chromatography (vpc) to consist mainly of a mixture of chlorinated 2,2′-dithienyls, the composition depending on the conditions employed. Table 2 shows the results. The yield of the coupling product, and at the same time the chlorine content in the product, increase with an increase in the molar ratio of sulfuryl chloride to thiophene. An increase in the amount of iron powder tends to increase the formation of the polymeric material. The presence of sulfur or nitrobenzene, which is known to retard free-radical reactions, did not essentially influence the composition of the product. The reaction was also catalyzed by Friedel-Crafts-type catalysts, the efficiency of the catalysts in the coupling reaction then decreasing in the order: $AlCl_3 > FeCl_3 > SnCl_4 > ZnCl_2$.[9] This

9) The use of zinc chloride as a catalyst particularly tends to increase the chlorine content in the product; the reason for this is not clear.



Scheme 1

order is substantially in agreement with that observed in the Friedel-Crafts reaction.[10] These results suggest that the chlorinative coupling of thiophene proceeds *via* an ionic mechanism.

Attempts to isolate 5-chloro-2,2′-dithienyl (I),[11] the presence of which was revealed by vpc, and the crystalline products other than I, II, III, and IV from the reaction mixtures were unsuccessful.

When another chlorinating agent, such as thionyl chloride or sulfur chloride, was used in place of sulfuryl chloride, not coupling but polymerization occurred.[13] The reaction of thiophene with bromine in the presence of iron powder gave only bromothiophenes. 2-Chlorothiophene and 2-methylthiophene, on the other hand, were merely chlorinated at the 5-position in the reaction with sulfuryl chloride and iron powder.

From the facts mentioned above, the following reaction path seems to be most probable for the chlorinative coupling of thiophene with sulfuryl chloride and iron powder (Scheme 1): The first step in the process is the protonation of thiophene by the hydrogen chloride and ferric chloride which were produced during the reaction, thus forming an ionic complex (VI) analogous to the Friedel-Crafts complex. The second step is the attack of the more stable cation, VIB, on the 2-position of a thiophene molecule, followed by the dehydrogenation of the so-formed carbonium ion intermediate (VII) with sulfuryl chloride and/or ferric chloride and then by the loss of a proton to yield 2,2′-dithienyl, although the stage at which dehydrogenation takes place is not yet clear. The chlorination of the resulting dithienyl produces chlorinated dithienyls. The repetition of the process will give polythienyls. In fact, a small amount of a polymeric material was formed in every run. The possibility of the formation of 2,3′-dithienyl derivatives (VIII) can not be ruled out, but VIII could not be isolated from the reaction mixtures. The reason why coupling does not take place with 2-chlorothiophene and with 2-methylthiophene may be expalined as follows. 2-Chlorothiophene is not basic enough to be protonated in the system, and even if it were, it is not susceptible to the attack of the so-formed cation analogous to VI in the next step. On the other hand, 2-methylthiophene is so reactive that chlorination occurs in preference to coupling.

Experimental[14]

Reaction of Thiophene with Sulfuryl Chloride in the Presence of Iron Powder. General Procedure. Sulfuryl chloride (34 g, 0.25 mol) was added to a stirred mixture of thiophene (21 g, 0.25 mol) and commercially-obtained reduced iron powder (0.5 g) at room temperature. Within several minutes the mixture darkened and sulfur dioxide and hydrogen chloride

13) Recently, Fujisawa *et al.* found that some aromatic compounds such as anisole reacted with sulfur chloride or sulfur dichloride in the presence of iron powder to give the corresponding diaryl sulfides in fair yields. T. Fujisawa, N. Kikuchi and G. Tsuchihashi, Preprints for the 21st Annual Meeting of the Chemical Society of Japan (April, 1968), pp. 1572, 1573.

14) All the melting points and boiling points are uncorrected. The infrared spectra were obtained on a Hitachi EPI-S2 spectrophotometer, and the ultraviolet spectra, on a Hitachi EPU-2A spectrophotometer. The NMR spectra were recorded with a Varian Associates A-60 spectrometer in carbon tetrachloride at 60 MHz, using tetramethylsilane as the internal reference. The vpc analyses were carried out on a Hitachi K23F instrument.

were evolved, but the temperature remained almost unchanged. After three hours chloroform (60 ml) and then water (100 ml) were stirred into the deep purple reaction mixture; when the mixture was stirred for an additional 10 min, the mixture turned brown. A small amount of the brown precipitate (0.5 g) was filtered and washed with chloroform. The chloroform layer was washed with water, a 5% sodium bicarbonate solution, and again with water, and then dried (Na_2SO_4). After the solvent and the unreacted thiophene (4.5 g, analyzed by vpc) had been removed, the residue was distilled under reduced pressure to give chlorothiophenes (2.4 g, bp 25—55°C/56 mmHg). The residual mass (12.2 g) was sublimed twice under reduced pressure (2—4 mmHg) at about 140°C; pale yellow crystals (8.7 g, mp 54—87°C) were thus separated from the tarry material.

The data for the various run are given in Table 2.

5,5′-Dichloro-2,2′-dithienyl (II). *a) Isolation of II from the Coupling Products.* II was isolated from the reaction mixture which had been obtained by the reaction of thiophene with a one-half molar equivalent of sulfuryl chloride (Table 2, No. 3) by fractional recrystallization from methanol; colorless leaflets; mp 107.5—109°C (lit, 109—110°C,[2] 109°C[5]).

Found: C, 41.16; H, 2.03%. Calcd for $C_8H_4Cl_2S_2$: C, 40.85; H, 1.71%.

b) Ullmann Reaction of 2-Chloro-5-iodothiophene (IX). The procedure was a modification of the method used for the preparation of 2-iodothiophene from thiophene.[15] Nitric acid (*d* 1.42; 20.6 g) was added to a stirred mixture of 2-chlorothiophene (20 g) and pulverized iodine (19.6 g) over a period of about 2 hr. During the addition, the temperature of the reaction mixture remained at 25—30°C and brown nitrogen oxides were evolved. After the addition was complete, the mixture was heated at 40—45°C for 1 hr and then at 80°C for 1 hr, after which it was treated as has been described for 2-iodothiophene. The yield was 35.5 g (86.6%); bp 94—97 °C/14 mmHg (lit, 95—96°C/14 mmHg[16]).

A mixture of IX (20 g) and copper-bronze (Cu 80%, 20 g) was heated with stirring at 210—215°C for 2 hr. The reaction mixture was then cooled and carefully extracted with chloroform (100 ml). The solvent was removed from the extract to leave a solid material, the recrystallization of which from methanol (300 ml) afforded almost pure II (4.8 g, mp 108—108.5°C). The concentration of the filtrate gave an additional crop (1.0 g, mp 106—107°C) and an oily material which was assumed to be recovered IX. The total yield of II was 5.8 g (60.3%). The sublimation of the crude product under reduced pressure raised the melting point to 108—109°C. This compound was proved to be identical with the II isolated from the coupling product by a comparison of their IR and NMR spectra and by a mixed-melting-point determination.

3,5,5′-Trichloro-2,2′-dithienyl (III). III was isolated from the product which had been obtained by the reaction of thiophene with an equimolar amount of sulfuryl chloride (Table 2, No. 4) by the repeated recrystallization from methanol: mp 102—103°C (lit, 103°C[2]).

Found: C, 35.36; H, 1.11%. Calcd for $C_8H_3Cl_3S_2$: C, 35.63; H, 1.12%.

3,3′,5,5′-Tetrachloro-2,2′-dithienyl (IV). The product obtained by the reaction of thiophene (10.5 g, 0.125 mol) with five molar equivalents of sulfuryl chloride (84.5 g, 0.625 mol) was sublimed at 2—4 mmHg and at 140°C; the sublimate (9.2 g, mp 118—126°C) was then recrystallized from chloroform (160 ml) to give almost pure IV (5.7 g) as colorless needles; mp 127—128°C (lit, 126.5—127°C[17]) (Table 2, No. 6).

Found: C, 31.21; H, 0.83%. Calcd for $C_8H_2Cl_4S_2$: C, 30.99; H, 0.65%.

The further chlorination of a mixture of the chlorodithienyls with excess sulfuryl chloride in carbon tetrachloride at the boiling temperature of the solvent also gave IV, along with a small amount of a resinous material.

Dechlorination of IV. A mixture of IV (0.62 g), zinc dust (2.5 g), acetic acid (20 ml), and water (10 ml) was gently refluxed for 30 hr. The reaction mixture was filtered while hot, and the solid material was washed with hot acetic acid (10 ml). The combined filtrates were cooled to room temperature, and the resultant crystals, which consisted of zinc acetate and recovered IV (0.25 g, mp 124—127°C), were filtered off. To this filtrate, water (100 ml) was added to give crystals (0.19 g, mp 52—56°C); the recrystallization of these crystals from methanol yielded 3,3′,5-trichloro-2,2′-dithienyl (V) as colorless needles; mp 56—57°C.

Found: C, 35.48; H, 0.71%. Calcd for $C_8H_3Cl_3S_2$: C, 35.63; H, 1.12%.

Vapor-phase Chromatographic Analysis. Vpc analyses were performed on a stainless steel column packed with 10% Silicone DC 44M on Chromosorb WAW (Gasukuro Kogyo Co., Ltd.; 60—80 mesh; 3 mmϕ × 1 m). The column temperature was programmed from 150° to 200°C at 5°C/min; the flow rate of nitrogen gas was 8 ml/min. Biphenyl was used as the internal standard.

The authors wish to express their gratitude to Professor Emeritus Yasuo Matsuki of Tohoku University for his continued interest in and support of this work. Thanks are also due to Mr. Fusaji Shoji for his help in many respects.

Reaction of Sulfoxides with Acylating Reagents. I. Mechanism of Oxygen Exchange Reaction of Diaryl Sulfoxides with Acetic Anhydride[1)]

Shigeru OAE and Masahiro KISE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received July 21, 1969)

Racemization and oxygen exchange reactions were carried out by heating both optically active and ^{18}O-labeled diaryl sulfoxides in a large excess of acetic anhydride. The rate of racemization of *p*-tolyl phenyl sulfoxide was found to be twice the rate of oxygen exchange, suggesting the reaction to involve a Walden inversion at the rate-determining step. When the reaction was carried out in a mixture of acetic anhydride and chlorobenzene, the rate of racemization was found to be first order with respect to both the sulfoxide and acetic anhydride. The remarkably small substituent effect is also in keeping with the S_N2 type mechanism. The marked retardation of the rate of racemization by the addition of common salt is similar to well-known cases in the S_N2 reaction of alkyl halides, and the remarkably large acceleration of the rates of both racemization and oxygen exchange reactions by the addition of sodium perchlorate seems to be caused by a special salt effect.

The sulfur-oxygen linkage in sulfoxides has been considered to possess a semi-polar character,[2)] and unlike those in sulfone groups, the sulfur-oxygen links in sulfoxides are weak and readily cleaved. Another important feature is that optical isomerism can exist in sulfoxide compounds,[3)] and the stereochemical stability of sulfoxides is known greatly to exceed those of similar sulfonium compounds.[4)] Thus sulfoxides are utilizable for studying the nature of nucleophilic substitutions on sulfur atom.

Sulfoxides have been known to undergo concurrent oxygen exchange and racemization reactions in various acidic media, such as concentrated sulfuric acid,[5,6)] hydrochloric acid in aqueous dioxane,[7)] hydrobromic acid in acetic acid,[8)] dinitrogen tetraoxide[9)] and acetic anhydride.[10)] In a previous paper,[11)] we showed that sulfoxides undergo concurrent oxygen exchange and racemization reactions through an acid catalyzed S_N1-type process in weak carboxylic acids. In this paper we would like to report a detailed account of another oxygen exchange reaction of aromatic sulfoxides in acetic anhydride, which appears to proceed through an S_N2-type route.

We suggested[12)] on the basis of ^{18}O tracer experiments with ^{18}O-labeled acetic anhydride that the Pummerer reaction of dimethyl sulfoxide with acetic anhydride proceeds through an intermolecular nucleophilic attack of an acetate group on the methylene carbon of the ylide-ylene intermediate II.

$$CH_3SCH_3 + (CH_3CO)_2O \rightleftarrows CH_3-\overset{+}{S}(\overset{\downarrow}{O})-CH_3 + {}^-OAc \rightarrow CH_3-\overset{+}{S}(OAc)-CH_2OAc$$

significance of our ^{18}O tracer experiments, since a facile acetoxy interchange could also take place within salt I.

$$^{14}CH_3O\text{-}\overset{+}{S}(CH_2Ph)(CH_2Ph) + CH_3O^- \rightleftharpoons$$

$$^{14}CH_3O^- + \overset{+}{S}(CH_2Ph)(CH_2Ph)\text{-}OCH_3$$

In fact, when an optically active diaryl sulfoxide labeled with ^{18}O was heated in acetic anhydride and the sulfoxide was quantitatively recovered by quenching the reaction mixture with cold water, the recovered sulfoxide was found to have lost its optical activity as well as the excess of ^{18}O. Thus the acetoxy interchange appears to take place readily. We have investigated this oxygen exchange reaction of diaryl sulfoxides extensively in order to understand the nature of the reaction, focusing our attention only on the acetoxy interchange, since with these sulfoxides other competing reactions such as Pummerer rearrangement and the heterolysis of carbon-sulfur linkage which will be discussed in a succeeding paper[14] can be avoided.

Results and Discussion

The oxygen exchange reaction was carried out by heating both optically active and ^{18}O-labeled diaryl sulfoxides in a large excess of acetic anhydride. The sulfoxides employed in this study were *p*-tolyl phenyl, *p*-chlorophenyl phenyl and diphenyl sulfoxides.

When the reaction of *p*-tolyl phenyl sulfoxide with acetic anhydride was carried out in an inert solvent, chlorobenzene, the rate was found to be correlated nicely with a second order kinetic equation, *i. e.* $v=k_2[p\text{-}CH_3C_6H_4SOC_6H_5][Ac_2O]$. (Table 1, Fig. 1). The rate of the reaction of *p*-tolyl benzyl sulfoxide with acetic anhydride was found to be correlated similarly with a second order equation in the same solvent.[14] However, when the reaction was carried out in dioxane, the rate was found not to be correlated by a second order equation. A similar anomaly was observed in the case of *p*-substituted phenyl benzyl sulfoxides with acetic anhydride. The plot of the second order rate constants against the concentration does not give a straight line of slope one in Fig. 2. In fact, the rate is apparently correlated by a 3rd order kinetic equation, namely second order with respect to the concentration of acetic anhydride and first order with the sulfoxide ($v=k_3[>S\rightarrow O][Ac_2O]^2$).

Probably this is due mainly to a special interaction between dioxane and acetic anhydride. Since dioxane is a nucleophilic solvent, it would interact with acetic anhydride to form a loose complex and this interaction may compete with the acetylation of the sulfoxide oxygen of low basicity ($pK_a=-4.40$),[15] thus reducing the rate of the reaction. Incidentally, the reaction between more basic α- or γ-alkylpyridine- or alkylquinoline *N*-oxide with

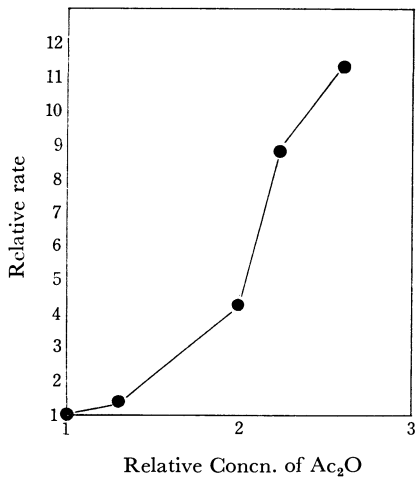

Fig. 2. Determination of the kinetic order of the racemization reaction in dioxane. Plot of relative rate of racemization against concentration of acetic anhydride.

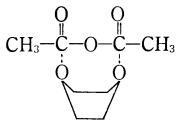
acetic anhydride in dioxane is known to be correlated with the normal second order kinetic equation.[16] The oxygen exchange reaction is undoubtedly of ionic character and hence expected to be facilitated in a more polar solvent, acetic anhydride. A similar oxygen exchange reaction of aryl benzyl sulfoxides is accelerated markedly in a still more polar solvent, acetonitrile.[17]



The rates of ^{18}O exchange and racemization in acetic anhydride, together with other pertinent data, are shown in Table 3.

Inspection of the kinetic data reveals that the rate of racemization, k(rac), of *p*-tolyl phenyl sulfoxides was twice that of oxygen exchange. This means that the reaction involves a Walden inversion at the rate determining step. The energy and the entropy (at 120°C) of activation for the reaction were found to be 19.2 kcal/mol and −28.6 e.u., respectively. The small value of the entropy of activation is also in keeping with the suggested mechanism. In the ^{18}O exchange reactions in both dinitrogen tetraoxide and highly concentrated sulfuric acid, k_{exch}/k_{rac} is unity, while the entropies of activation of both reactions are substantially large and positive. The oxygen exchange reaction in less concentraetd sulfuric acid (for example 75.4% H_2SO_4) is considered to be an S_N2-type process and gives a k_{exch}/k_{rac} value of roughly 1/2.[18] In this case the entropy of activation is quite small ($\Delta S^{\neq} = -18.9$ at 30°C).

The small substituent effects are also in accordance with the S_N2-type mechanism, since the reaction is expected to pass through an ideal transition state in which both the entering and the leaving group are identical. The polar effect of substituents should be considerably cancelled and reduced in many typical S_N2 reactions at the saturated carbon atom.[19] Thus, the over-all process of the reaction can be illustrated as shown in Fig. 3.

It is known that the acetate ion, once formed, undergoes a rapid interconversion with acetic anhydride as represented by the following equation.[20]

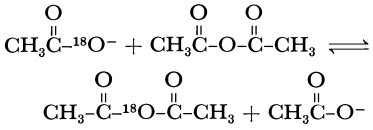


Table 3. Kinetic data on oxygen exchange and racemization reactions in acetic anhydride[a] at 120°C

Run No.	R in R-C$_6$H$_4$-S(=O)-C$_6$H$_5$	Added salt	k(rac) $\times 10^5$ (sec^{-1})	k(exch) $\times 10^5$ (sec^{-1})

Thus ^{18}O-containing acetate ion will be quickly diluted by rapid interchange with the bulk unlabeled acetic anhydride.

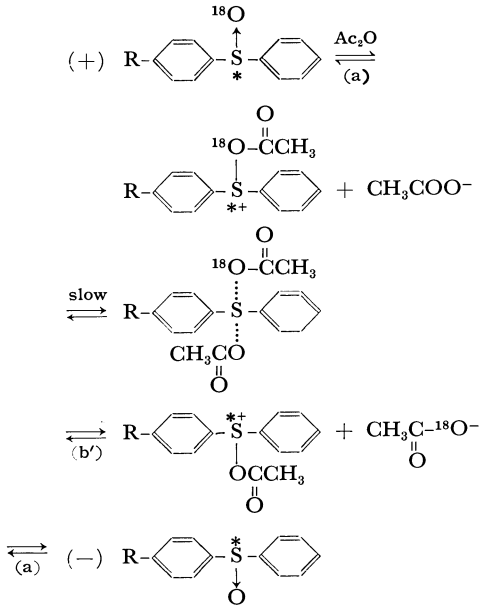

Fig. 3

The marked retardation of the rate of racemization by the addition of common salt is considered to be due to a similar retardation found in the S_N2 reactions of alkyl halides and related compounds.[21] A similar, though small, negative common salt effect was known in a few rearrangement reactions of heteroaromatic *N*-oxides and acetic anhydride.[22] The remarkably large acceleration of the rates of both racemization and oxygen exchange reactions by the addition of sodium perchlorate also seems to be caused by a special salt effect as in the well-known cases found by Winstein and his coworkers.[23] A similar rate acceleration by the addition of perchlorate ion was also observed in the reaction of quinaldine *N*-oxide and acetic anhydride.[24]

The addition of acetic acid also increases the rate of both the racemization[25] and the oxygen exchange. Racemization of sulfoxides in acetic anhydride is also known to be catalyzed markedly by a small amount of Lewis acid.[26]

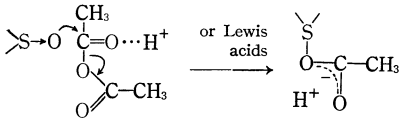
a) The reaction was carried out at 120°C in a sealed tube. Sulfoxide, 10^{-3} mol, was treated with acetic anhydride. No solvent was used.

A question arises whether the acid catalyzed reactions would proceed through an S_N1-like path involving rate-determining S–O bond cleavage, as in the oxygen exchange reactions in carboxylic acids and concentrated sulfuric acid. When the reaction was carried out in the presence of a small amount of acetic acid, the ratio of the rate constants, k_{exch}/k_{rac} became unity. This may mean than the presence of Brönsted acid facilitates the cleavage of S–O bond by the easy protonation on the sulfoxide oxygen and the assistance of the nucleophilic attack by acetate becomes less important in the reaction.

The catalytic effect of both the Brönsted and Lewis acid is considered to be due to the acceleration of both the first acetylation step (a) and also the second slow step of S_N2 type process, since in both steps the leaving of acetate group will be facilitated by either protonation or co-ordination with a Lewis acid as shown below.



Phenol, albeit a weak Brönsted acid, was found to accelerate the rate of racemization of sulfoxides.

Experimental

Materials. *Optically Active p-Tolyl Phenyl Sulfoxide.* This sulfoxide was prepared by the method of Anderson[3] whereby (—)- menthyl (—)-*p*-toluenesulfinate was allowed to react with phenylmagnesium bromide in ether (mp 91—93°C $[\alpha]_D = +26.9°$ in ethanol).

^{18}O-Labeled p-Substituted Aryl Phenyl Sulfoxide. The corresponding sulfide was oxidized with bromine in the presence of pyridine in acetic acid and $H_2{}^{18}O$, according to the usual procedure.[27] All the sulfoxides had >S→O stretching bands in their infrared spectra at about 1050 cm^{-1}. Their melting points and ^{18}O-contents are shown below.

Dioxane, obtained commercially, was purified according to the usual procedure, thoroughly dried with sodium and distilled (bp 101.5°C).

Acetic Acid, obtained commercially, was treated with chromic oxide. After refluxing for several hours it was distilled (bp 117.5—118°C).

Acetic Anhydride, obtained commercially, was treated with anhydrous sodium acetate. After refluxing for several hours, it was distilled (bp 139.5—140°C).

Kinetic Procedure (I). Concurrent oxygen exchange and racemization reactions were carried out at 120±0.05°C (paraffin bath) while the molar ratio of sulfoxide to acid anhydride was kept at 1 : 100. Thus, a mixture of sulfoxide (5×10^{-3}) and acetic anhydride (5×10^{-1} mol) was allowed to react. From time to time, 5 m*l* of the reaction mixture was pippetted out and poured into an excess of water. The sulfoxide separated out, was then extracted with carbon tetrachloride, and dried with anhydrous magnesium sulfate. Carbon tetrachloride was distilled off and the resulting sulfoxide was recovered. The recovered sulfoxide was dried thoroughly and subjected to measurements of both specific rotation and ^{18}O-analysis. The specific rotation was measured in ethanol at c : 3.00, and ^{18}O-analysis of sulfoxide-oxygen was carried out as usual according to the modified Rittenberg-Porticorvo method.[5] The k values in Table 3 and the activation parameters were determined by this procedure. All the rate constants quoted were determined from the equations for racemization.

$$\log [\alpha]_{D0} - \log [\alpha]_{Dt} = \frac{kt}{2.303},$$

where $[\alpha]_{D0}$ and $[\alpha]_{Dt}$ are the rotatory powers at times 0 and t, respectively, and for oxygen exchange,

$$\log [\beta_0-\beta] - \log [\beta_t-\beta] = \frac{kt}{2.303},$$

where β_0 and β_t are the atom % ^{18}O at times 0 and t, respectively, and β is the atom % ^{18}O of natural CO_2. A typical kinetic run is shown below.

Kinetic Procedure II. The racemization reaction was carried out at 120±0.05°C in sealed tubes in which *p*-tolyl phenyl sulfoxide (10^{-3} mol) was dissolved in 10 m*l* of acetic anhydride containing no other solvent or solute. From time to time a sealed tube was taken out from the paraffin bath and placed in an ice bath in order to stop the reaction. Then the acetic anhydride solution containing the sulfoxide was immediately subjected to the measurement of specific rotation.

Determination of the Kinetic Order of Racemization Reaction in Dioxane. The reaction was carried out at 120°C in sealed tubes, each containing 10 m*l* of the reaction mixture, which was prepared from dioxane and acetic anhydride containing optically active *p*-tolyl phenyl sulfoxide (10^{-3} mol). From time to time, a sealed tube was taken out from the paraffin bath. Each kinetic run was carried out as in the above procedure.

Influence of Acetic Acid on Racemization. The reaction was carried out at 120°C in sealed tubes. A mixture af acetic anhydride and acetic acid containing an optically active sulfoxide (10^{-3} mol) was prepared and 10 m*l* of the reaction mixture was sealed in each tube and subjected to the usual kinetic measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1421—1426 (1970)

Reaction of Sulfoxides with Acylating Reagents. II. Mechanism of the Reactions of Aryl Benzyl Sulfoxides with Acetic Anhydride[1)]

Masahiro KISE and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received July 24, 1969)

Aryl benzyl sulfoxides undergo oxygen exchange and racemization reaction with acetic anhydride, and the rate is dependent on the concentration of both the sulfoxide and acetic anhydride. The reaction proceeds faster in a more polar solvent. Addition of sodium perchlorate or acetic acid accelerates the reaction. In this case, the rate of oxygen exchange is not exactly half of that of racemization. As an example, the ratio, k_{ex}/k_{rac}, is 0.36 when the reaction was carried out at 100°C. Under the same condition, both the Pummerer reaction and thermal racemization are negligible. Similar to diaryl sulfoxides the effects of phenyl group are small. Implication of the ratio is discussed.

In previous papers,[2)] dealing with the reaction of diaryl sulfoxides with acetic anhydride, we focused our attention only on the oxygen exchange. In this reaction with an optically active diaryl sulfoxide, the rate of racemization k_{rac}, was found to be twice that of oxygen exchange and the effect of polar substituents was rather small. Based on these and related observations, we suggested that the reaction proceeds through an S_N2 type Walden inversion at the rate determing step. As an extension of this oxygen exchange reaction with acetic anhydride, we have chosen aryl benzyl sulfoxides, with the intention of comparing the rate of the oxygen exchange with that of possible Pummerer rearrangement, since the rate-determining removal of proton from benzylic carbon in the Pummerer reaction is considered to be easier with these sulfoxides. Thus we have prepared a few *p*-substituted phenyl benzyl sulfoxides and subjected them to the reaction with acetic anhydride. This paper will describe detailed accounts of our kinetic experiments and the mechanistic implications of the data obtained.

Results and Discussion

When optically active *p*-tolyl benzyl sulfoxide was heated with a large excess of acetic anhydride at 100°C, the sulfoxide recovered from time to time was found to have lost its activity. The ^{18}O-labeled *p*-tolyl benzyl sulfoxide, under the same reaction condition, was found to undergo oxygen exchange reaction. The rate of the Pummerer rearrangement was quite small under the same reaction condition as compared to the rates of both oxygen exchange and racemization. The kinetic order of the racemization of *p*-tolyl benzyl sulfoxide was examined. When the reaction was carried out in chlorobenzene, the rate was found to be first order in each component *i. e.*, $v=k_2[>S\rightarrow O][Ac_2O]$ (Table 1, Fig. 1).

However, as in the case of diaryl sulfoxides, the kinetics of racemization did not follow the second order equation but satisfied the third order equation, $v=k_3[>S\rightarrow O][Ac_2O]^2$ when the reaction was

performed in dioxane (Table 2, Fig. 2). Since dioxane is a nucleophilic solvent, it would interact with acetic anhydride and the interaction might reduce the rate of the reaction notwithstanding the fact that the reaction is expected to be faster in a more polar solvent, acetic anhydride, than in nonpolar dioxane.

The effect of substituents on phenyl group in the oxygen exchange reaction of *p*-substituted phenyl benzyl sulfoxide was examined in acetic

anhydride at 100°C and the results are tabulated in Table 3. (Table 3). As in the case of *p*-substituted diphenyl sulfoxides, the substituent effect is rather small, suggesting that the main path of the reaction is S_N2 type oxygen exchange process in which the effect of substituent is largely cancelled. We see, however, that the rate constant of racemization is more than two-fold that of oxygen exchange, *viz.*, the ratio, k_{ex}/k_{rac} was 0.36 when the reaction was carried out at 100°C. Apparently other processes cause additional racemization in addition to the main reaction of the oxygen exchange process of S_N2 type nucleophilic substitution which is the only path observed in the case of diaryl sulfoxides. Other processes responsible for the racemization may include thermal racemization of sulfoxide itself, nucleophilically assisted heterolysis of S–C bond of either non-acetylated or acetylated sulfoxide by acetate ion and Pummerer rearrangements. All these processes are illustrated as shown below (Fig. 3).

The first possibility, namely, the thermal racemization (path a), by either the direct inversion of the pyramidal structure of the sulfoxide[3,4)] or the double rearrangements involving the incipient formation of benzyl arylsulfenate as the intermediate, is quite unlikely, since these aryl benzyl sulfoxides undergo very little thermal racemization at this temperature (at 100°C) in any of the common solvents, chlorobenzene, acetonitrile, dioxane, and dimethyl sulfoxide without acetic anhydride.

The second possible path for racemization (path b) which does not necessarily accompany oxygen exchange, namely, the acetic acid-catalyzed racemization appears plausible but is not likely, since the

$$k_{rac} = k_1 + k_2 + k_3 + k_4 + k_5$$

Fig. 3

rate of racemization of any of aryl benzyl sulfoxides in acetic acid alone is negligible as compared to that in acetic anhydride ($k_{Ac_2O}/k_{AcOH} \gg 100$). Acetic anhydride undoubtedly takes part in facilitating the racemization.

The third possible path (path c) that takes the role of acetic anhydride into consideration is plausible. It involves the heterolysis of S–C bond following the prior acetylation of the sulfoxide function. Since benzylic sulfoxide compounds are known to undergo homolytic C–S bond cleavage in solvents of low polarities,[4] the heterolysis of benzyl acetoxysulfonium acetate would be more facile because of the substitution of more electronegative acetoxy group at the sulfur atom.

This path is very likely to contribute in the excess racemization during oxygen exchange. If the heterolysis always leads to a complete racemization, the contribution of path (c) in the racemization is calculated to be 29% from the value of 0.36 for k_{ex}/k_{rac}, and the rest of the racemization is ascribed to the S_N2 type process as illustrated by path (d).

Undoubtedly path (d) is the main reaction pathway for racemization, since the racemization is accompanied by a substantial oxygen exchange though not as completely as in the case of diaryl sulfoxides.

Another path which is responsible for reducing optical rotation of the original solution of the sulfoxide is the Pummerer rearrangement (path e) which eventually results in the conversion of the sulfoxide to α-acetoxybenzyl aryl sulfides. However, this reaction is negligible. Thus, the first two paths (a and b) can be ruled out and path (c) also appears to be negligible. The pathways (c) and (d) are the remaining possible paths for racemization and responsible for the apparent anomaly of the ratio of the rates of oxygen exchange and racemization, *i. e.* $k_{ex}/k_{rac}=0.36$. These reactions are interwoven to make the overall kinetic rates of the racemization complicated.

In order to clarify the relative importance of three different pathways at different temperatures, kinetic experiments were carried out in the range of temperatures between 60 and 120°C and the results are shown in Table 4. The Arrhenius plot of the kinetic data is shown in Fig. 4. The data

in Table 4 and Fig. 4 reveal that the Arrhenius plot of the rate gives a curve instead of a straight line.

At 90°C the energy and entropy of activation of the overall racemization of the sulfoxide was estimated to be 21.8 kcal/mol and −17.24 e.u., while those at 110°C were calculated as 28.5 kcal/mol and 0.0 e.u. respectively. Apparently, there in a gradual change of mechanistic pathways around 100°C, where the curve of the Arrhenius plot makes a turn. We expected that the S_N2 type process would be the predominant path at a low temperature and the value of k_{ex}/k_{rac} would approach 0.5 while at a higher temperature other paths would participate giving rise to the reduction of the k_{ex}/k_{rac} value.

At a low temperature, *e. g.* 80°C, the Pummerer rearrangement is negligible. However, the value of k_{ex}/k_{rac} was found to be 0.35 suggesting that the S_N2 type oxygen-exchange process (path d) is not the only route but another path, very likely path (c), is participating in the racemization. The small activation energy and entropy factor suggest that the main reaction for the racemization is the nucleophilic substitution process (path d).

7	961.7	0.1309	29.3 ±0.4	45.1
8	987.7	0.1344	31.3 ±1.2	48.2

a) The reaction was carried out at 55°C. The sulfoxide, 3×10^{-4} mol, was reacted in acetic anhydride of 6 ml soln. containing sodium perchlorate.

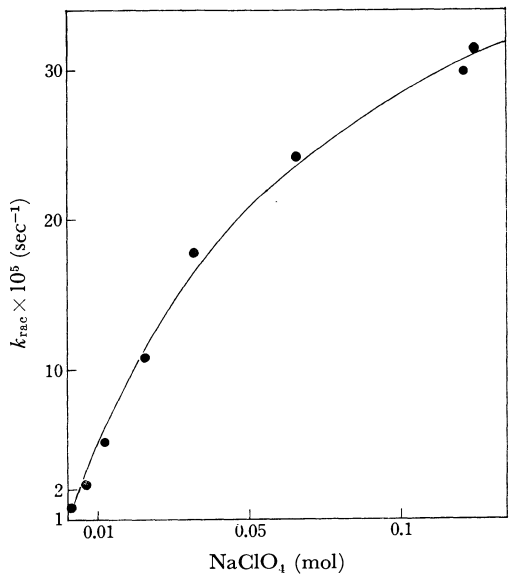

Fig. 6. The influences of sodium perchlorate to the racemization reaction of sulfoxides.

The racemization of the sulfoxide in this reaction was catalyzed markedly in the presence of acetic acid (Table 5, Fig. 5).

The rate of racemization increases remarkably with the increase of the concentration of acetic acid up to the concentration of acetic anhydride. It falls off gradually with further increase of the concentration. In a low concentration acetic acid it would solvate effectively only at the carbonyl groups of both acetic anhydride and the acetoxysulfonium intermediate, thus increasing the rate. Excess acetic acid would solvate sulfoxide oxygen either by hydrogen bonding or protonation and the initial acetylation would be retarded, though both the heterolysis of O–S and C–S bonds will be facilitated.

As in the case of diaryl sulfoxides, the addition of mercuric chloride or Lewis acid increases the rate of racemization remarkably (Table 6) as also is the case with sodium perchlorate (Table 7, Fig. 6).

Addition of the Lewis acid facilitates both the acetylation and heterolysis of both S–O and C–S bonds substantially while the addition of sodium perchlorate would increase the ionic strength of the medium and also shift the equilibrium of acetylation step to the right to increase the rate of racemization.

Table 8. Kinetic data of the racemization of *p*-tolyl benzyl sulfoxide with acetic anhydride in several solvents at 100°C[a)]

Run	Used solvent	$k_{rac} \times 10^5$ (sec^{-1}) at 100°C	Ac_2O (g)
1	C_6H_5Cl	7.20	10.7797
2	CH_3CN	17.2	10.7936
3		2.30	10.8228
4	$(CH_3)_2NCHO$	2.16	10.7573

a) Sulfoxide, 10^{-3} mol, was reacted with acetic anhydride in 20 ml reaction soln.

Solvent effect was examined with four different solvents and the results are summarized in Table 8. Apparently the reaction is slow in two nucleophilic solvents, dioxane and dimethyl formamide (DMF) but is faster in less nucleophilic and polar solvents, chlorobenzene and acetonitrile. Undoubtedly nucleophilic solvents interact with acetic anhydride to retard the initial acetylation of the sulfoxide group while both acetylation and the succeeding hetero lysis would be facilitated in less nucleophilic but polar media to result in the increase of the over-all rate of the racemization.

We might conclude that the apparent over-all racemization of aryl benzyl sulfoxides in acetic anhydride or acetic anhydride containing media is caused by two participating reactions, *i. e.*, pathways (c) and (d) in which (d) is the predominant route. At low temperatures below 100°C, the contribution of S–C bond cleavage pathway (c) is small but becomes substantial as the reaction temperature is raised.

Experimental

Material. *Optically Active p-Tolyl Benzyl Sulfoxide.* The sulfoxide was prepared by the method of Anderson[5)] in which (−)-menthyl (−)-*p*-toluenesulfinate was treated with benzylmagnesium chloride in ether. Mp 167°C $[\alpha]_D$ +250° (in ethanol), lit,[6)] mp 169—170°C $[\alpha]_D$ +252°.

p-Substituted Phenyl Benzyl Sulfoxides ^{18}O-Labeled.[7)] Each of the corresponding sulfide was oxidized with bromine in the presence of pyridine in acetic acid and $H_2{}^{18}O$, according to the usual procedure. All the sulfoxides had S–O stretching bonds in their infrared spectra at about 1050 cm^{-1}. Their melting points, ^{18}O-concentration (atom %) and chemical shift of methylene are summarized in Table 9.

Dioxane, obtained commercially, was purified according to the usual procedure, finally dried with sodium and distilled (bp 101.5°C).

Acetic Acid, obtained commercially was treated with chromic anhydride and after refluxing for several hours, was distilled (bp 117.5—118°C).

Acetic Anhydride, obtained commercially, was treated with anhydrous sodium acetate and after refluxing for several hours, was distilled (bp 139.5—140°C).

Kinetic Procedure I (Oxygen Exchange Reaction). The oxygen exchange reaction was carried out at 100±0.05°C in sealed tubes into which aliquotes of a solution containing *p*-substituted phenyl benzyl sulfoxide (10^{-3} mol) in 20 m*l* of acetic anhydride were placed. From time to time a sealed tube containing 5 m*l* of the solution of the reaction mixture was withdrawn and placed in an ice bath in order to stop the reaction. The sulfoxide separated out was extracted with carbon tetrachloride, then carbon tetrachloride was distilled off and the resulting sulfoxide was recovered. The recovered sulfoxide was dried throughly and subjected to ^{18}O-analysis.[11]

Kinetic Procedure II (Racemization Reaction). The racemization reaction was carried out at a set temperature ranging from 60 to 120°C in sealed tubes in each of which a portion of the reaction mixture containing optically active *p*-tolyl benzyl sulfoxide (10^{-3} mol) in 20 m*l* of acetic anhydride was placed without using other solvents. At suitable time intervals sealed tubes each containing 3 m*l* of reaction mixture were drawn out and placed into an ice bath to stop the reaction. 3 m*l* of dioxane was then added into the tube and the whole solution was subjected to the determination of specific rotation. The constants obtained are usually in good agreement with those obtained by isolating the product under kinetic procedure I.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1426—1430 (1970)

Reaction of Sulfoxides with Acylating Reagents. III. Mechanism of the Reactions of Phenyl Methyl Sulfoxide with Acetic Anhydride[1]

Masahiro KISE and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received July 29, 1969)

The Pummerer reaction, *viz.*, the reaction of sulfoxides having at least one methyl or methylene group with carboxylic acid anhydride gives α-acyloxy derivatives of the corresponding sulfide. Earlier, we suggested on the basis of ^{18}O tracer experiments with ^{18}O-labeled acetic anhydride that the Pummerer reaction of dimethyl sulfoxide with acetic anhydride proceeds through an intermolecular nucleophilic attack of acetoxy group on the methylene carbon of the ylide-ylene intermediate. Noticeable acetoxy interchange has been found to take place during a similar Pummerer reaction of aryl methyl sulfoxide. However, the Pummerer reaction is the main path when the reaction with acetic anhydride is performed at around 120°C. In the Pummerer reaction of aryl methyl sulfoxides, the substituent effect is large ($\rho = -1.6$) and the kinetic isotope effect (k_H/k_D) is also substantial, *i.e.*, 2.9. The reaction is assumed to involve the initial acetylation and the subsequent slow proton removal steps. Addition of sodium perchlorate or acetic acid accelerates the acetoxy exchange reaction rather than the Pummerer reaction.

The Pummerer Reaction[2] has been known for many years. When an alkyl (or aryl) methyl sulfoxide is treated with acetic anhydride, there is formed a rearranged ester (III) *i. e.* acetoxymethyl alkyl (or aryl) sulfide which upon hydrolysis results in the formation of alkyl (or aryl) mercaptan, formaldehyde and acetic acid. Among the mechanisms suggested for the Pummerer reaction[2-4]

$$\mathrm{R\text{-}S\text{-}CH_3} + (\mathrm{CH_3CO})_2\mathrm{O} \rightleftharpoons \underset{\mathrm{O}}{\mathrm{R\text{-}S\text{-}CH_3}} \rightarrow \underset{\text{(III)}}{\mathrm{R\text{-}S\text{-}CH_2O\overset{\overset{\mathrm{O}}{\|}}{C}CH_3}} + \mathrm{CH_3COOH} \xrightarrow{\mathrm{H_2O}} \mathrm{R\text{-}SH} + \mathrm{CH_2O} + \mathrm{CH_3COOH}$$

only the one by Bordwell and Pitt,[3] involving the

3) F. G. Bordwell and B. M. Pitt, *J. Amer. Chem. Soc.*, **77**, 572 (1955).

4) W. J. Kenney, J. A. Walsh and D. A. Davenport, *ibid.*, **83**, 4019 (1961).

ylide-ylene intermediate (II), appears reasonable. We suggested on the basis of ^{18}O tracer experiments with ^{18}O-labeled acetic anhydride that the Pummerer reaction of dimethyl sulfoxide with acetic anhydride proceeds through an intermolecular nucleophilic attack of acetoxy group on the methylene carbon of the ylide-ylene intermediate (II).[5]

$$CH_3SCH_3 + (CH_3CO)_2O \rightleftarrows CH_3-\overset{+}{S}(OAc)-CH_3 + \overset{+}{O}Ac \quad (I)$$

$$CH_3-\overset{+}{S}(OAc)-CH_2^- \longleftrightarrow CH_3-S(OAc)=CH_2 \xrightarrow{HOAc} CH_3SCH_2OAc$$

(II) (III)

However, the fast interchange of alkoxy group in the following reactions found by Johnson and Phillips[6] made the significance of our ^{18}O tracer experiments doubtful,

$$^{14}CH_3O-\overset{+}{S}(CH_2Ph)(CH_2Ph) + CH_3O^- \rightleftarrows$$

$$^{14}CH_3O^- + \overset{+}{S}(PhCH_2)(PhCH_2)-OCH_3$$

since a facile interchange could also take place within the salt (I) and the possible acetoxy interchange would also scramble the ^{18}O completely in the whole reaction system. We found that acetoxy interchange which causes both the oxygen exchange and the racemization does take place with diaryl sulfoxides in warm acetic anhydride. The rate of the racemization of *p*-tolyl phenyl sulfoxide was found to be twice that of the oxygen exchange suggesting that the reaction involves a Walden inversion at the rate-determining step.[7]

In the case of aryl methyl sulfoxides both concurrent oxygen exchange with racemization reactions and Pummerer reaction take place. As in the case of diaryl sulfoxides[8] racemization of aryl methyl sulfoxides with acetic anhydride is also catalyzed markedly by a small amount of Lewis acid. In order to clarify the over-all feature of the reaction, the kinetic investigation of the reaction is desirable. This paper describes a detailed account of the kinetic study of the Pummerer reaction and the concurrent oxygen exchange and racemization reactions of *p*-substituted phenyl methyl sulfoxide with acetic anhydrides.

Results and Discussion

A few *p*-substituted phenyl methyl sulfoxides and two α-trideuterated derivatives were synthesized and subjected to both the Pummerer reaction and the concurrent oxygen exchange and racemization reactions. The rate of the Pummerer reaction can be readily followed spectrophotometrically, taking an advantage of the difference of UV spectra of the starting sulfoxide and the final compounds, *i. e.*, aryl mercaptan obtained by quenching the reaction mixture with water.

The rate of racemization reaction of optically active *p*-tolyl methyl sulfoxide was determined by the usual procedure, measuring the optical rotation of the reaction solution. In this case, the rate constant of the racemization consisted of two rate constants, the one due to the oxygen exchange and the other caused by the Pummerer reaction. When the reaction was carried out in dioxane, the rate of the Pummerer rearrangement of *p*-tolyl methyl sulfoxide with acetic anhydride was found to be correlated by the second order equation, *i. e.*,

$$v = k_2[p\text{-}CH_3C_6H_4SOCH_3][Ac_2O]$$

Similarly, the rate of the racemization reaction was also found to be correlated by the second order

equation.

However, in dioxane solutions containing acetic anhydride in high concentration, the plots of relative rates of both the Pummerer rearrangement and the racemization against the concentration give convex upward curves probably due to the solvent effect.[9)] Tables 1 and 2, reveal that the rate of racemization was the sum of the rates of the Pummerer and twice that of the oxygen exchange reaction, *i. e.*, $k_{rac}=k_P+2k_{ex}$

The over-all rates of the Pummerer reactions of a few *p*-substituted phenyl methyl sulfoxides were determined and the results are listed together with those of trideuterated compounds in Table 3.

The rates are in line with the Hammett equation, and a negative ρ value (for σ), -1.60, was obtained.

When only the rate variation of *p*-substituted phenyl methyl sulfoxides is considered as if the first step of the reaction, *i e.*, acetylation, is the rate-determining step. A large positive ρ-value obtained[10)] in the reaction of dimethyl sulfoxide and *p*-substituted benzoic anhydride seems to support this.

However, the kinetic isotope effect, $k_H/k_D=2.85$ indicates that the rate-determining step is the succeeding step of the reaction, namely the proton removal by acetate anion. Recently Johnson reported that acetoxy group migrates to the least substituted α-carbon in the Pummerer reaction of a few unsymmetrical dialkyl sulfoxide with acetic anhydride. The result is also undoubtedly a reflection of the difference in the acidities of α-protons of the two alkyl groups of the intermediate acetoxysulfonium salts, and the removal of the proton is the rate-determining step of the reaction.[11)] The relatively small value of kinetic isotope effect is due mainly to the fact that the first step of the reaction requires also a substantial energy of activation, as in the reaction between quinaldine *N*-oxide and acetic anhydride.[12)] The addition of sodium perchlorate or acetic acid[13)] was found to accelerate the over-all rates by 3 or 4 fold. Apparently the

b) The relation, $k_{racemization}=k_{pummerer}+2\ k_{exchange}$ is assumed. The rates of the oxygen exchange reaction were calculated from this equation.

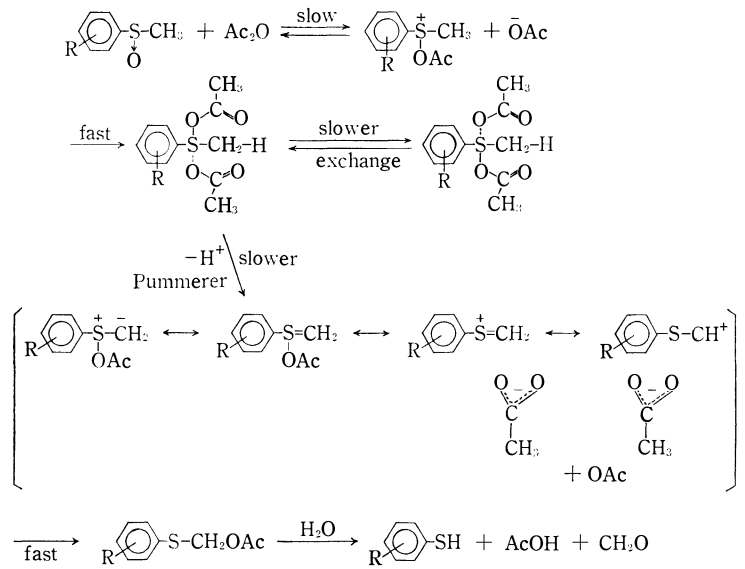
addition of perchlorate tends to shift the equilibrium to the right to increase the concentration of the acetoxysulfonium salts, increasing the rate of the Pummerer reaction. The addition of both sodium perchlorate and acetic acid was found to increase the rate of the reaction of the acyloxy exchange markedly.

Racemization of sulfoxides in acetic anhydride is known to be catalyzed markedly by a small amount of Lewis acid.[8)]

In the oxygen exchange and racemization reactions, both Brönsted and Lewis acids will catalyze the first acetylation step and also the second slow step of S_N2 type process because the leaving of acetate group will be facilitated by either protonation or coordination of Lewis acids.[14)] But in the Pummerer reaction, the effect of the rate acceleration by the addition of acetic acid or sodium perchlorate was considerably smaller than that in oxygen exchange and racemization reaction. The over-all picture of the reaction can be depicted as follows. A mechanism similar to that of this reaction was recently suggested by Johnson.[11)] We have measured the rate of racemization of an optically active *p*-tolyl methyl sulfoxide in acetic anhydride in order to estimate the rate of concurrent oxygen exchange during the reaction. The results are listed together with the rates of the Pummerer reaction in Table 7.

Apparently, the rate of the Pummerer reaction increases markedly with the rise of reaction temperature. This can be seen from a comparison of the enthalpies and entropies of activation of the two reactions, *i. e.*, for O-exchange: E_a, 13.1 kcal/mol; $\Delta S^{\neq}$, −45.1 e. u., for the Pummerer reaction: E_a 21.2 kcal/mol; $\Delta S^{\neq}$, −20.7 e.u., respectively. Below 65°C, under which the Pummerer reaction is negligible, only the oxygen exchange proceeds slowly.

The Pummerer reaction involves the rate-determining proton removal and is accelerated slightly. However, the oxygen-exchange and racemization reactions are markedly accelerated by the addition of acid or sodium perchlorate as in the case of



14) S. Oae and M. Kise, following paper in these series.

diaryl and aryl benzyl sulfoxides. The Pummerer reaction becomes significant and takes place faster than the possible oxygen exchange reaction at a high temperature. Our ^{18}O experiments may be still valid in the interpretation of the mechanism especially in connection with the rearrangement steps of the reaction. However, both the S–O bond cleavage and the succeeding formation of the ester are considered to be so fast that these steps cannot be significant in the energy profile of the over-all reaction.

Experimental

Materials. *Optically Active p-Tolyl Methyl Sulfoxide.* The sulfoxide was prepared by the method of Mislow[15] in which(−)-menthyl(−)-*p*-toluenesulfinate was allowed to react with methylmagnesium iodide in ether, (mp 75°C $[\alpha]_D$ +151° in ethanol), lit,[15] mp 73—74°C $[\alpha]_D$ +145.5° (*c* 2.0, acetone).

p-Substituted Phenyl Methyl Sulfoxides. The corresponding sulfide was oxidized with bromine in the presence of pyridine in acetic acid and water, according to the usual procedure.[16] All the sulfoxides has S–O stretching bands in the infrared region at about 1050 cm^{-1}. Thier melting points (boiling points where pressures are given) were *p*-CH_3: 42—43°C, lit,[16] 42—43°C. H: 110°C (1—2 mmHg), lit,[16] 84°C (0.25 mmHg). *p*-Cl: 46—47°C, lit,[16] 47—48°C. *p*-NO_2: 148—149°C, lit,[16] 148—147°C.

p-Substituted Phenyl Tridueterated Methyl Sulfoxide. Phenyl methyl sulfoxide (10^{-2} mol) was heated with deuterium oxide (5×10^{-1} mol) containing triethylamine (10^{-1} mol) for 20 hr at 100°C. After heating, triethylamine and deuterium oxide were distilled off and the residue was distilled *in vacuo* (105°C/1.5 mmHg, lit[16] 84°C/0.25 mmHg). From NMR spectrum the resulting phenyl methyl sulfoxide was found to contain only 85% deuterium at the methyl group. The above procedure was repeated until the resulting sulfoxide showed no methyl proton signal in the NMR spectrum. *p*-Nitro compound was also synthesized by the same procedure. (mp 149°C, lit,[17] 148—149°C).

Dioxane obtained commercially was purified according to the usual procedure and dried with sodium and distilled (bp 101.5°C).

Acetic Acid obtained commercially was treated with chromium trioxide, and was distilled (bp 117.5—118°C), after refluxing for several hours.

Acetic Anhydride obtained commercially was treated with anhydrous sodium acetate and was distilled (bp 139.5—140°C) after refluxing for several hours.

Kinetic Procedure I (The Rate of the Pummerer Reaction). The Pummerer reaction was carried out at 120±0.5°C in sealed tubes in which *p*-substituted phenyl methyl sulfoxide (5×10^{-5} mol) was dissolved without solvent in 10 m*l* of acetic anhydride. From time to time a sealed tube containing 1 m*l* solution of the above mixture was drawn out form the paraffin bath and cooled in an ice-bath to stop the reaction. The mixture was then hydrolyzed with 50 m*l* of alkaline solution (3%). The rates of the Pummerer reaction were readily followed spectrophotometrically, taking advantage of the difference of UV spectra of the starting and the final hydrolyzed compounds (*p*-substituted phenyl mercaptans). All the rate constants quoted in Table 2 were determined from the equation for the Pummerer reaction.

$$\log\frac{a-a_0}{a-a_t}=\frac{k\cdot t}{2.303},$$

where a = the intensity of the absorption due to resulting mercaptide.

Kinetic Procedure II (Racemization Reaction). Recemization reaction was carried out at 120±0.5°C in sealed tubes in which optically active *p*-tolyl phenyl sulfoxide (10^{-3} mol) was dissolved without any solvent in 20 m*l* acetic anhydride. From time to time a sealed tube containing 3 m*l* of the reaction mixture was drawn out from the paraffin bath and cooled in an ice bath to stop the reaction. After the reaction, 3 m*l* of dioxane was added into the sealed tube, and the acetic anhydride solution was subjected to measurement of specific rotation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 1431—1434 (1970)

The Photochromism, Thermochromism, and Piezochromism of Dimers of Tetraphenylpyrryl

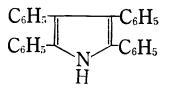
Koko MAEDA, Akiko CHINONE*1 and Taro HAYASHI*2

Department of Chemistry, Faculty of Science, Ochanomizu University, Bunkyo-ku, Tokyo

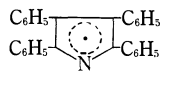
(Received July 25, 1969)

By the oxidation of tetraphenylpyrrole, two types of dimers of tetraphenylpyrryl were obtained. One dimer showed piezochromism and thermochromism, while the other showed photochromism and thermochromism. These phenomena were found to correspond to those of the piezochromic and photochromic dimers of triphenylimidazolyl obtained from triphenylimidazole. The photochromism, thermochromism, and piezochromism of the dimers of tetraphenylpyrryl are determined to be due to the radical dissociation caused by irradiation, heating, and grinding, the same machanism as that in the case of the dimers of triphenylimidazolyl.

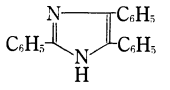
Kuhn and Kainer reported[1] that 2,3,4,5-tetraphenylpyrrole (I) was partially oxidized to the tetraphenylpyrryl radical (II) (about 4%). From spectroscopic and ESR studies Blinder *et al.* reported[2] that the oxidation product of I exhibits



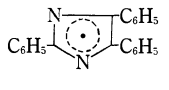
(I)



(II)



(III)



(IV)

photochromism and thermochromism in solutions and that the phenomena are due to the dissociation of the oxidation product into the radical II caused by irradiation and heating. These results corresponded to the photochromism and thermochromism of the photochromic dimer of triphenylimidazolyl (IV) obtained by the oxidation of triphenylimidazole (III).[3] The existence of the photochromic and piezochromic dimers for IV suggests the presence of similar dimers for II. This paper will deal with the preparation of two isomeric dimers of II and with the radical mechanism of photochromism, thermochromism, and piezochromism exhibited by these dimers.

Experimental

Materials. *Oxidation with Lead Dioxide.* A photochromic compound was obtained according to the method Kuhn and Kainer.[1] A solution of I (1 g) in benzene (50 m*l*) was refluxed with lead dioxide (10 g) for about 7 hr in a nitrogen atmosphere. The solution gradually turned pink. By the evaporation of the solvent in a dimmed room under reduced pressure in a nitrogen atmosphere, 0.7 g of a light pink powder (PH), mp 197—204°C, was obtained. PH was slightly soluble in benzene, ethanol, and *n*-hexane.

Found: C, 90.26; H, 5.62; N, 3.70%. Calcd for $C_{56}H_{40}N_2$ (dimer of II): C, 90.77; H, 5.44; N, 3.79%.

PH showed an infrared absorption spectrum similar to that of I. An almost colorless ethanolic solution of PH which was prepared in dim light at room temperature showed absorption maxima at 264 and 317 mμ, maxima which agreed with those of I. The solution turned pink on irradiation at room temperature. The pink solution showed new absorption maxima at 365, 525, and 563 mμ and an ESR signal (g=2.003). From these experimental results, PH was determined to be a mixture of I and a dimer of II. The dimer is called the photochromic dimer (photo-dimer). The concentration of the photo-dimer in PH was determined to be 13% by means of a hydroquinone titration according to the following reaction (1):

$$\underset{\text{(hydroquinone)}}{C_6H_4(OH)_2} + 2\underset{\text{(II)}}{C_{28}H_{20}N} \longrightarrow \underset{\text{(benzoquinone)}}{C_6H_4O_2} + 2\underset{\text{(I)}}{C_{28}H_{21}N} \qquad (1)$$

Oxidation with Potassium Ferricyanide. A piezochromic compound was obtained from I by means of a modification of the oxidation method of III.[3b] To a solution of I (1.5 g) in ethanol (280 m*l*), a 2% aqueous solution of potassium ferricyanide (400 m*l*) and a 5% ethanolic solution of potassium hydroxide (15 m*l*) were added[4] over about a 30-min period at about 50°C in a nitrogen atmosphere. The pink color of II first appeared, and then a light pink precipitate was formed. After the reaction mixture was cooled to room temperature, the precipitate was filtered in a nitrogen atmosphere, washed repeatedly with water, and dried at room temperature under reduced pressure. A light pink powder (PI) (1.3 g), mp 160—165°C, was thus obtained. PI is soluble in ethanol, benzene, and *n*-hexane.

Found: C, 90.16; H, 5.20; N, 3.67%. Calcd for $C_{56}H_{40}N_2$ (dimer of II): C, 90.77; H, 5.44; N, 3.79%.

The infrared absorption spectrum of PI was rather different from that of I, although it showed a weak N–H band at 3420 cm^{-1}, thus indicating the presence of I. PI showed a weak ESR absorption (g=2.00) and exhibited piezochromism which showed a pink color. A pink solution which was prepared by dissolving PI in ethanol at room temperature showed absorption maxima at 365, 525, and 563 mμ. From these experimental results, PI was determined to be a mixture of I, a dimer of the radical II, and a small amount of II. The dimer is called the piezochromic dimer (piezo-dimer). The concentration of the piezo-dimer in PI was determined to be 23% by means of hydroquinone titration according to Reaction (1).

PH and PI were used for the present study because I itself did not exhibit photochromism, thermochromism, and piezochromism and caused no disturbance in studies of these phenomena.

Spectroscopic Measurements. The absorption spectra were measured with a Hitachi EPS 2 recording spectrophotometer. The absorption spectra at temperatures from −196°C to room temperature were measured by the method described in a previous paper.[3d] The absorption spectrum in the solid state was measured by means of an opal-glass transmission method.

Electron Spin Resonance Absorption. The ESR measurements were carried out in a deaerated state with a Japan Electron Optics Laboratory JES-P-10-type ESR spectrometer (100 kc modulation) which had, as attachments, a 1D-2 integrator and a VT-2 variable temperature controller. The ESR spectra of the triplet state at −196°C were measured with a Japan Electron Optics Laboratory 3B-type ESR spectrometer (100 kc modulation).

Irradiation. The 365-mμ light of a high-pressure mercury lamp (Toshiba SHL-100 UV), filtered through a Toshiba UV-D1B glass filter, was used.

Results and Discussion

Structures of Photo-dimer and Piezo-dimer. The structures of the dimers of IV[5,6] suggest that two tetraphenylpyrryl radicals in the photo-dimer and the piezo-dimer combine at N, C2, or C3 of the pyrryl rings. The HMO calculation of the spin density of II (given in Fig. 1) shows a high probability of the dimerization of II to the piezo-dimer at C2.

The fact that 2,3,4,4-tetrachloro-1,4-dihydronaphthalene-1-one,[7] tetraphenylhydrazine,[8] and the photochromic dimer of IV exhibit photochromism due to a radical dissociation of C–Cl, N–N, and C–N respectively suggests a high probability of linking between the N of one pyrryl ring and the C of another ring in the photo-dimer.

Photochromism of PH in Solutions. An almost colorless solution of PH in benzene, ethanol,

or another solvent, prepared in dim light and at room temperature, showed no ESR absorption. On irradiation at temperatures between room temperature and about −20°C, the benzene solution rapidly turned pink and showed a strong ESR signal (shown in Fig. 2) (g=2.003). The color and ESR hardly faded at all[9] over several days in the dark at room temperature. However, in solutions of PH in decaline and naphthalene, which turned pink on irradiation at 80—90°C, the color faded after the irradiation was cut off. This fact shows that PH exhibits photochromism at 80—90°C, above which exhibits thermochromism.

At temperatures between about −20°C and −100°C, the benzene solution showed no color change on irradiation. At temperatures lower than about −100°C, a purple color appeared on irradiation. The color became deeper with a decrease in the temperature. Such changes in the color were investigated by means of the absorption and the ESR spectra.

An EPA solution of PH, which turned purple on irradiation at −196°C, showed the absorption bands shown in Fig. 3. The bands corresponded to those of the pink solution obtained by irradiation at room temperature. The absorption maxima at −196°C showed a red shift of about 10 mμ compared with those of the pink solution. The change in the absorption spectra was measured at temperatures from −196°C to room temperature. The change corresponded to the dependence of the color change on the temperature.

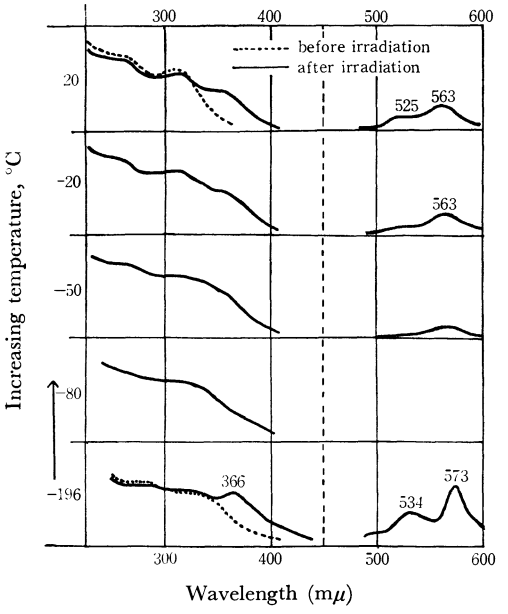

Fig. 3. Absorption spectra of PH in EPA at temperatures from −196°C to room temperature.

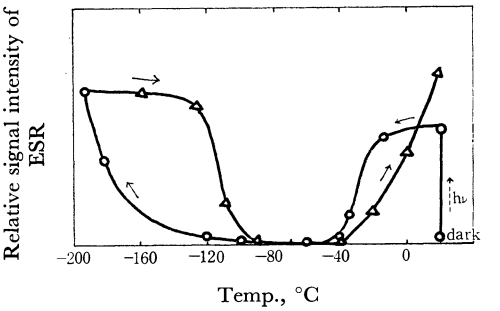

Fig. 4. Dependence of the ESR signal intensity on the temperature under irradiation in benzene.

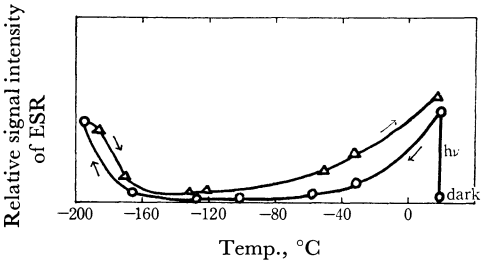

Fig. 5. Dependence of the ESR signal intensity on the temperature under irradiation in EPA.

The dependence of the relative signal intensity of ESR on the temperature under irradiation is shown in Figs. 4 and 5.

These experimental results can be interpreted by a mechanism similar to that used in the case of the dimer IV.[3,5,10]

$$R_2 \overset{h\nu}{\rightleftharpoons} R_2^* \underset{(a)}{\rightleftharpoons} 2R\cdot \underset{(b)}{\rightleftharpoons} R'_2$$

(photo-dimer) (radical II) (piezo-dimer)

The equilibrium (a) is likely to lie far to the side of R_2 at temperatures near room temperature. However, because the dimerization of R· produced by the photo-dissociation of R_2 is very slow, the photochromic color faded hardly at all at temperatures, near room temperature. With the elevation of the temperature, dimerization was accelerated and photochromism was exhibited at 80—90°C. At temperatures between about −20°C and −100°C the photochromic color does not appear, for the equilibrium (b) lies far to the side of R'_2 and the dimerization of R· is rapid. The purple color observed at temperatures lower than about −100°C is due to a tetraphenylpyrryl radical, which has more coplanarity than the pink radical. At low temperatures the equilibrium (b) lies far to the side

9) Blinder *et al.* reported[2] that a reversible, rapid color change was observed at room temperature in a benzene solution of the oxidation product of I. We could not observed such a reversible phenomenon at room temperature.

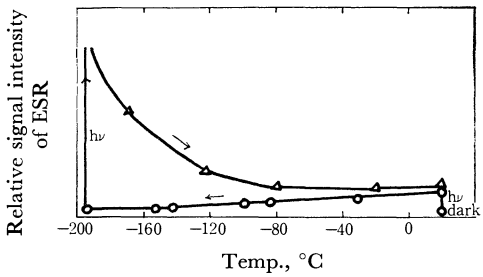

Fig. 6. Dependence of the ESR signal intensity of PH on the temperature in the solid state.
–○– in the dark

of R′$_2$. However, because the dimerization of the purple radical is slow at such low temperatures, the purple color was observed.

The ESR spectrum observed at −196°C showed a strong signal at 3296 gauss, three pairs of weak signals at 3358—3231 gauss, and a weak signal at 1762 gauss. These signals suggest the formation of a radical pair similar to that of the photochromic dimer of IV.[3d,10]

Photochromism of PH in the Solid State. PH exhibits photochromism in the solid state at temperatures near room temperature and near −196°C. With intense irradiation at room temperature, a pink color and a weak ESR signal were observed. On heating to about 50°C after irradiation was cut off, the color and ESR faded very slowly. On irradiation at −196°C, a deep bluish-purple color and a strong ESR signal were immediately observed. The color and ESR signal hardly faded at all at −196°C in the dark, but they rapidly faded on slight warming from −196°C, even under irradiation. The dependence of the signal intensity on the temperature was measured under irradiation, as is shown in Fig. 6.

These phenomena, which correspond to those shown by the photochromic dimer of IV in the solid state,[3g] suggest a radical mechanism similar to that of the photochromism of the latter. The ESR absorption at −196°C showed a strong signal at 3127 gauss and a weak signal at 1762 gauss which is likely to be due to the formation of a radical pair, as in solutions.

Thermochromism of PH and PI. PH and PI showed thermochromism in solutions and in the solid state. In solutions PH showed a thermochromic pink color and an ESR signal ($g=2.00$) when heated above 90°C without irradiation. In the solid state PH showed a pink color and an ESR signal ($g=2.00$) when heated to temperatures higher than about 180°C, and the deep pink melt formed on melting showed a strong ESR signal. When PH which had been heated to about 190°C in the solid state without irradiation was rapidly cooled to room temperature in the dark, the thermochromic color rapidly faded.

A benzene solution of PI prepared at room temperature showed a deep pink color due to the radical II (λ_{max} 365, 525 and 563 mμ) produced by the dissociation of the piezo-dimer present in PI. The color did not change with irradiation. When the pink solution was cooled, the color gradually faded until it disappeared at temperatures lower than about −20°C. The absorption and ESR spectra showed variations corresponding to the change in the color. In the solid state PI showed a thermochromic pink color on heating to about 130°C. PI heated in the solid state *in vacuo* at about 100°C for 1 hr showed photochromism both in solutions and in the solid state. This fact shows that the piezo-dimer isomerizes to the photodimer upon heating, probably through the radical II.

Piezochromism of PI. PI showed piezochromism in the solid state. PI, which turned pink with grinding, showed absorption maxima at 535 (sh) and 570 mμ; these maxima can be attributed to the radical II. The piezochromis of PI is due to a radical dissociation similar to that of the piezochromic dimer of IV.[3g] The change in the spin concentration caused by piezochromism was measured by means of ESR. The spin concentration increased from 7.8×10^{18} spin/g to 7.6×10^{19} spin/g when grinding was continued for about 1 min. The spin concentration of the PI ground gradually decreased at room temperature. It became about one third after 1 week.

The authors wish to express their hearty thanks to Dr. Hiroshi Midorikawa and Dr. Tadamasa Shida of the Institute of Physical and Chemical Research, and Professor Takeshi Nakajima of Tohoku University for their kind help, and to the Ministry of Education for the financial support granted this research.

β-Ferrocenyl-α,β-unsaturated Ketones. III.[1] The Conformational Study of β-Ferrocenyl-α,β-unsaturated Ketones by Means of IR Spectroscopy

Hiromichi KONO, Mikio SHIGA, Izumi MOTOYAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received July 26, 1969)

The geometrical and conformational isomerism of various β-ferrocenyl-α,β-unsaturated ketones, most of which had been reported in a previous paper, was discussed on the basis of their IR spectra in the 1700—1600 cm^{-1} range and their NMR spectra. An unusually strong IR absorption of the olefinic double bond was observed in comparison with that of the carbonyl group. Considering the IR and NMR data, it was concluded that 3-ferrocenyl-1-(*p*-substituted phenyl)-2-propen-1-ones may mostly exist in a *s-cis* conformation.

Generally, α,β-unsaturated ketones may exist in *s-cis* and *s-trans* forms. For the conformational study of such unsaturated ketones, UV and IR spectroscopic methods are very useful and a number of spectroscopic data concerning α,β-unsaturated carbonyl compounds have been reported.[2-5] Recently, Dimmock and his co-workers reported on their observation of carbonyl absorption bands due to *s-cis* and *s-trans* isomerism in the IR spectra of substituted 1-phenyl-1-hepten-3-ones and related compounds.[6] However, in such aryl-substituted α,β-unsaturated carbonyl compounds, the absorption bands near 1600 cm^{-1} due to the conjugated C=C stretching vibrations overlap unfavorably with the bands due to the C=C skeletal in-plane vibrations of the aromatic ring. On the other hand, the IR spectra of β-ferrocenyl-α,β-unsaturated ketones show a distinct absorption band due to the C=C bond conjugated with the ferrocenyl group, since the ferrocenyl group has no appreciable absorption in this region. Hence, they seem to be compounds favorable for such conformational study.

In this investigation, the IR spectra of five β-ferrocenyl-α,β-unsaturated ketones (**1**), which had been reported in a preceding paper,[7] and those of five 3-ferrocenyl-1-(*p*-substituted phenyl)-2-propen-1-ones (**2**) were measured in carbon tetrachloride and the assignment of bands near 1600 cm^{-1} to *s-cis* and *s-trans* isomers was discussed.

Results

The IR spectrum of 4-ferrocenyl-3-buten-2-one (**1a**) in a KBr disk shows two strong bands, at 1655 and 1619 cm^{-1}, due to the carbonyl and ethylenic stretching vibrations respectively. When it was observed in solution, a new band appeared near these bands, although its position and intensity varied with the nature of the solvent employed, as is shown in Fig. 1. These phenomena, also observed in all the other compounds studied here except **1e**, may be attributed to the presence of two rotational isomers, *s-cis* and *s-trans*, in the solution.

Table 1 summarizes the absorption maxima, ν_{max} and the extinction coefficients, ε' (for the definition of ε', see the Experimental part), of these bands, measured in CCl_4. According to the conformational study by Erskine and Waight[2] using α,β-unsaturated ketones which maintain their rigid conformations, the carbonyl stretching bands appear in the 1704—1684 cm^{-1} range (ε 250—333) for *s-cis* and the 1679—1669 cm^{-1} (ε 454—670) for *s-trans* isomers, while the ethylenic stretching bands

are in the 1633—1613 cm^{-1} range for the *s-cis* and the 1639—1615 cm^{-1} range for the *s-trans* isomers. Following their observation, the carbonyl band with the higher frequency and the olefinic band with the lower frequency were identified as being due to *s-cis*, and the another pair were identified as being due to the *s-trans* isomer. Table 1 shows that the carbonyl bands for *s-cis* isomers are generally 19—25 cm^{-1} higher than those for *s-trans*, while the olefinic bands for *s-cis* isomers are 17—18 cm^{-1} lower than those for *s-trans*. The differences between the absorption maxima of the carbonyl and the olefinic bands were found to be 84—87 cm^{-1} and 34—50 cm^{-1} for *s-cis* and *s-trans* isomers respectively. These values are in accord with the observations of Braude and his co-workers.[8]

In the IR spectrum of 2-(ferrocenylmethylene)-cyclohexanone (**1e**), four bands were also observed in this region, in spite of its exclusive *s-cis* structure. This can, however, be explained by the presence of the geometric isomers with respect to the olefinic double bond. The bands at 1676 and 1584 cm^{-1} were assigned to the isomer in which ferrocenyl group lies *trans* to the carbonyl group, while those at 1684 and 1600 cm^{-1}, with lower intensities, were assigned to the *cis* isomer.

3-Ferrocenyl-1-(*p*-substituted phenyl)-2-propen-1-ones (**2**) were prepared by the base-catalyzed condensation[9] of formylferrocene with *p*-substituted acetophenones. It was proved, by means of their NMR spectra (Table 2), that their olefinic double bonds had *trans* configurations, as had previously been shown in the case of 4-ferrocenyl-3-buten-2-one and related compounds.[7]

In the IR spectra of the aryl ketones (**2**), the strong absorptions due to the carbonyl group of sterically-favored *s-cis* isomers appeared at about 1660 cm^{-1}, about 20 cm^{-1} lower than those of the corresponding alkyl ketones (**1**). In addition to the strong bands, weak bands were observed in the 1640—1635 cm^{-1} range in the spectra of **2a**, **2b**, and **2d**, the corresponding bands being absent in those of **2c** and **2e**. These bands are considered to be due to the carbonyl group of *s-trans* isomers. On the other hand, the band with several shoulders at about 1600 cm^{-1} could not be assigned because of the heavy overlapping of the olefinic band with the aromatic band.

Discussion

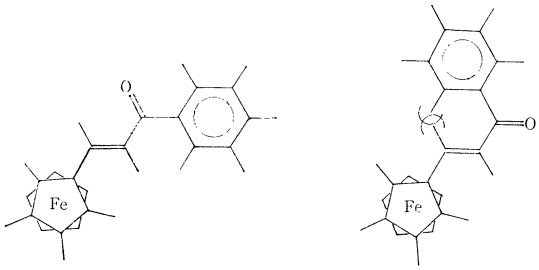
The main factors influencing the conformation of α,β-unsaturated ketones are the steric environment around the carbonyl group, especially the steric requirements of the substituent, and the nature of the solvent. It can be seen in Table 1 that the alteration of an alkyl group on the carbonyl group has a great influence on the extinction coefficients of both carbonyl and ethylenic absorption bands, whereas it does not very much affect the frequencies of these bands. The ratios of the extinction coefficient, $\varepsilon'_{C=O}/\varepsilon'_{C=C}$, were calculated to be 0.30—2.89 for *s-cis* isomers and 0.68—1.72 for *s-trans* isomers. These values are unusually small compared with those of the ordinary α,β-unsaturated ketones previously reported: $\varepsilon_{C=O}/\varepsilon_{C=C}$ for *s-cis*: 0.7—2.5; $\varepsilon_{C=O}/\varepsilon_{C=C}$ for *s-trans*: 6—9.[2] It is thus noticeable that the olefinic double bond in β-ferrocenyl-α,β-unsaturated ketones has an unusually strong absorption in this region. The enhanced olefinic absorption may be due to the conjugation of the double bond with the ferrocenyl group, a conjugation originating in the great electron-releasing ability of the ferrocenyl nucleus. In this connection, it must be mentioned that the ethylenic band of 1,5-diferrocenyl-1,4-pentadien-3-one (**3**) at

8) E. A. Braude and C. J. Timmons, *J. Chem. Soc.*, **1955**, 3766.

9) C. R. Hauser and J. K. Lindsay, *J. Org. Chem.*, **22**, 906 (1957).

1614 cm^{-1} was observed to be unusually stronger ($\varepsilon'=1740/2$) than the carbonyl band at 1649 cm^{-1} ($\varepsilon'=416$).[1]

The examination of the molecular structure of the *s-trans* conformation suggests that a bulky group on the carbonyl group may force the conjugated system of the unsaturated ketone out of coplanarity or force it to take the *s-cis* conformation. Although the estimation of the isomer ratio is impossible from the spectra data shown in Table 1, it is clear that the concentration of the *s-trans* isomer qualitatively decreases with an increase in the bulkiness of the alkyl group on the carbonyl group. The steric situation is especially emphasized in aryl ketones (**2**). An aryl substituent on the carbonyl group brings about a great decrease in the concentration of the *s-trans* isomer. If the whole conjugated system of the aryl-substituted unsaturated ketone with an *s-trans* conformation takes a coplanar arrangement, the ortho hydrogen atom of the phenyl group may overlap heavily with the β-vinyl hydrogen, as is shown in Fig. 2. Thus, the *s-cis* isomer,



s-cis *s-trans*

Fig. 2.

which is free from this strain and which may be somewhat stabilized by holding the whole conjugated system of the molecule in a coplanar conformation, will be predominant in solution. This consideration is consistent with the observations that the $\varepsilon'_{s\text{-}cis}/\varepsilon'_{s\text{-}trans}$ ratios of carbonyl bands in the IR spectra of the aryl ketones (**2**) exhibited considerably larger values than those of the alkyl ketones (**1**), and that the chemical shift of the β-vinyl proton of the aryl ketones (**2**) appeared in a low field, as is shown in Table 2, probably due to the anisotropic effect of the carbonyl group.
