All our findings described in the preceding paper and in the present paper have demonstrated that the sense of twist is determined by the chemical species and is, furthermore, dependent on the conformation of the molecule. Thus, the twisting should be explained by a mechanism which reflects the conformation of the molecule. Recently, in our laboratory, it has been found that the Na soap of a paraffin-chain fatty acid, for example, Na myristate, sometimes forms twisted fibers. In such a case, both right-handed and left-handed fibers are observed. Therefore, twisting is considered to be common for soap fibers and particularly likely in fibers with such asymmetric molecules as optically active 12-hydroxystearate.

Generally the crystal of a paraffin-chain compound is composed of alternating ionic and hydrocarbon layers. While the complete crystal structure determination has not yet been achieved for 12-hydroxystearic acid and its soaps, they may be regarded as being composed of such a layer structure, since these compounds also showed a long spacing, about 48 Å, in the X-ray powder patterns. Bird and Rooney[7] presented evidence of such a structure for Ca-soap fibers from a commercial fatty acid; they obtained that evidence by means of a high-resolution electron microscope. This structure must be responsible for the growth of the soap crystal in the form of a ribbon or a fiber.

If one of the surfaces of a thin ribbon is different from another surface in the structure, the distortion or twisting will tend to occur as a result of a surface stress which develops from the difference in the surface energy between the two surfaces. When the soap ribbon is produced from such a nonpolar solvent as Nujol, free-energy considerations require the development of the nonpolar surfaces in a manner that exposes the methyl groups to Nujol. Consequently, both surfaces of the ribbon would have the same structure, and would thus not cause any twisting. However, in the course of crystallization the two surfaces of a ribbon do not always have the same structure. In certain cases this may be caused by the adsorption of impurities on either surface. The case is the same with the ribbons deposited from any polar solvent. There could possibly also be a case in which one surface is polar, and the other, nonpolar. In these cases a surface stress would develop, leading to a twisting of the thin ribbon. Furthermore, when the molecules have an asymmetric conformation, the ribbon itself has an asymmetric structure and the surface stress acts to twist the ribbon favorably in a certain sense. Consequently, all the ribbons would twist in the same direction. In this view, twisting is considered to occur rather generally in thin ribbons. However, the surface stress decreases rapidly with an increase in the thickness, so the twisting becomes more difficult for too wide or too thick a ribbon. The analogy with a gross physical ribbon is useful in explaining the interesting electron-micrograph shown in Fig 3, which was obtained with a sample of the free D-acid from a nonanol solution. In this micrograph one can see many thin and twisted fibers split from an end of a straight and wide ribbon. Evidently twisting is likely in very thin ribbon-like fibers. However, there is a limitation in explaining the twisting phenomenon by this analogy alone. For instance, it is thereby difficult to explain why some soap fibers twist easily and others do not.

The fact that the sense of twist for the fibers of the free D(or L)-acid is opposite to that of the Li soap suggests that the sense of twist is associated with the structure of the ionic layers in crystal. The effect of the cation size was observed in a series of the alkali metal soaps. This fact suggests that the packing arrangement in the ionic layers plays an important role in determining the helical sense, but the nature of this role has yet to be determined. The solvent effect exhibited by particular alcohols is also suggestive in explaining the twisting phenomenon, since these alcohols may be involved in the formation of the soap-crystal structure and may affect the packing arrangement of molecules. Further studies are also in progress with bivalent-metal soaps, giving complicated results which will be presented in a subsequent paper.

These studies were supported by a Scientific Research Grant from the Ministry of Education.

Studies of the Liquid-Liquid Partition Systems. VII. The Solvent Extraction of Mercury(II) Chloride, Bromide, Iodide and Thiocyanate with Some Organic Solvents

Tatsuya SEKINE and Teruhiko ISHII

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received March 13, 1970)

The liquid-liquid distribution of mercury(II) has been determined when the organic phase was benzene, hexane containing tributylphosphate(TBP), methylisobutylketone(MIBK), or nitrobenzene, and when the aqueous phase was 0.5M sodium perchlorate containing chloride, bromide, iodide, or thiocyanate ions. The stability constants for the mercury(II) complexes in the aqueous phase and the distribution constants for the extractable complexes were determined by a graphic analysis of the distribution data, which were measured as a function of the ligand concentration. It was concluded that the stability constants determined from the present results agree almost entirely with the previous values and that the only extracted species into benzene and hexane containing TBP is the non-charged complex (HgX_2, where X^- is the ligand) in all cases, whereas those extracted into MIBK or nitrobenzene include not only the non-charged but also the charged species (HgX_3^- and sometimes HgX_4^{2-}) except in the case of the chloride system. The distribution ratio in the hexane-TBP system was further determined by changing the TBP concentration in the hexane phase, and the equilibrium constants for the adduct formation between the HgX_2 species and TBP molecules were determined. Finally, some discussion was made of the relation between the distribution behavior of the mercury(II) complexes and the natures of the ligands and the solvents.

It has been known for a long time that mercury(II) halides are somewhat soluble in organic solvents, while they are rather insoluble in water. This has been explained in terms of the formation of stable coordinate complexes which dissociate only slightly into mercuric ion and halide ions in aqueous solutions.

The stability constants of these complexes have been determined repeatedly by many authors by using various different experimental methods.[1] Of these, Sillén and his co-workers[2] determined these constants very comprehensively in a 0.5M sodium perchlorate constant ionic medium; their findings are listed in Table 1. Later, Marcus[3] published a series on the solvent extraction of mercuric halides or mixed halides with benzene. He concluded that the distribution ratio of mercury(II) between benzene and aqueous halide solutions can be explained in terms of the complex formation in the aqueous phase and the extraction of the non-charged dihalide mercury(II) complex into the benzene phase.

In the present investigation, the authors have studied the solvent extraction of mercury(II) in aqueous chloride, bromide, iodide, and thiocyanate solutions with four organic solvents, benzene, hexane containing tributylphosphate (TBP), methylisobutylketone (MIBK), and nitrobenzene. These solvents were chosen in order to examine how the nature of the organic solvent influences the distribution behavior of mercury(II) complexes. We determined that benzene has no lone-pair electrons, but can form π-complexes with an acceptor, that TBP coordinatedly solvates metal ions rather strongly in non-

polar solvents such as hexane, that MIBK also can solvate the metal ion, and the solvent itself is somewhat polar, and that nitrobenzene has one of the highest dielectric constants among the water immiscible organic solvents. The aqueous phase was kept as a 0.5M sodium perchlorate constant ionic medium in order to compare the present results with the previous results obtained in the same medium.

The changes in the distribution ratio, determined as a function of the ligand concentration, has been analyzed graphically, and the equilibrium constants in these systems were determined. There is some discussion of the distribution behavior of the complexes in these systems in connection with the chemical properties of the solvent and the ligand. The role of sodium ions in the organic phase for the extraction of the anionic complexes is also discussed.

Experimental

Reagents. About 0.2 g of mercuric dichloride was irradiated with thermal neutrons in the Triga III reactor at the Nuclear Research Laboratory of St. Paul's University, Kanagawa. It was dissolved in 5 m*l* of concentrated hydrochloric acid and then to the solution there was added an excess of zinc powder; the mixture was left standing overnight in order to reduce the mercury(II) to metallic mercury, and then the supernatant solution was decanted off. To the residue there was added a small amount of sulfuric acid in order to dissolve the excess of the zinc powder, and then the metallic mercury which remained was washed with water several times and finally dissolved in nitric acid. The solution was then evaporated in order to expel the excess acid, dissolved in 0.05M nitric acid, and stored for about one month in order to make the Hg-197 isotope decay out. The solution thus prepared was used as the stock tracer solution. The sodium-24 was obtained from the Japan Atomic Research Institute as a sodium chloride solution. It was diluted with a large amount of water and used as the stock solution. All of the reagents used were reagent-grade. The sodium perchlorate was recrystallized twice from water. The MIBK or TBP was washed with 0.1M perchloric acid, water, and 0.1M sodium hydroxide, and then several times with water. The other reagents were used without further purification. The concentration of the sodium thiocyanate solutions was determined by means of argentmetry, but the other concentrations were determined by means of gravimetry.

Procedures. All of the procedures were carried out in a thermostatted room at 25°C. Stoppered glass tubes (volume, 20 m*l*) were used to equilibrate the two phases. Five-milliliter portions of an aqueous solution containing mercury(II) labelled by the Hg-203 isotope, various amounts of ligand anions, and a 5-m*l* portion of one of the organic solvents were placed in the tubes. The initial concentration of the hydrogen ions in the aqueous phase was 1×10^{-3}M, and that of the mercury(II) ions was 1×10^{-5}M. The two phases were agitated mechanically for 30 min and then centrifuged off. A two-milliliter portion was pipetted from each phase and transferred into small test tubes. The γ-radioactivity in the sample solutions was measured with a well-type (NaI) scintillation counter, and the distribituion ratio of mercury(II) was calculated as follows:

$$D = [\mathrm{Hg(II)}]_{org,total}/[\mathrm{Hg(II)}]_{total} = \frac{\gamma\text{-count-rate per m}l\text{ of the org. phase}}{\gamma\text{-count-rate per m}l\text{ of aq. phase}}$$

Statistical

The complex formation of mercury(II) with these monovalent anions, X^-, can be described as follows:

$$\mathrm{Hg^{2+}} + n\mathrm{X^-} \rightleftarrows \mathrm{HgX}_n^{2-n} \quad (1)$$

$$\beta_n = [\mathrm{HgX}_n^{2-n}]/[\mathrm{Hg^{2+}}][\mathrm{X^-}]^n \quad (2)$$

or the stepwise formation constants can be described as follows:

$$\mathrm{HgX}_{n-1}^{3-n} + \mathrm{X^-} \rightleftarrows \mathrm{Hg}_n^{2-n} \quad (3)$$

$$K_n = [\mathrm{HgX}_n^{2-n}]/[\mathrm{HgX}_{n-1}^{3-n}][\mathrm{X^-}] \quad (4)$$

The solvent extraction of the neutral mercury(II) complexes may be described as follows;

$$\mathrm{HgX_2} \rightleftarrows \mathrm{HgX_2}(org) \quad (5)$$

$$K_{D2} = [\mathrm{HgX_2}]_{org}/[\mathrm{HgX_2}] \quad (6)$$

It would be also possible to extract the ion-pairs of the mercury(II) complex anion with sodium ions as:

$$\mathrm{HgX_3^-} + \mathrm{Na^+} \rightleftarrows \mathrm{NaHgX_3}(org) \quad (7)$$

$$\mathrm{HgX_4^{2-}} + 2\mathrm{Na^+} \rightleftarrows \mathrm{Na_2HgX_4}(org) \quad (8)$$

These ion-pairs could dissociate in the organic phase as:

$$\mathrm{NaHgX_3}(org) \rightleftarrows \mathrm{Na^+}(org) + \mathrm{HgX_3^-}(org) \quad (9)$$

$$\mathrm{Na_2HgX_4}(org) \rightleftarrows \mathrm{Na^+}(org) + \mathrm{NaHgX_4^-}(org) \quad (10)$$

$$\rightleftarrows 2\mathrm{Na^+}(org) + \mathrm{HgX_4^{2-}}(org) \quad (11)$$

The third complex in the organic phase may be treated as follows. The equilibrium constant for the ion-pair extraction in Eq. (7) is:

$$K_{ex3} = \frac{[\mathrm{NaHgX_3}]_{org}}{[\mathrm{HgX_3^-}][\mathrm{Na^+}]} \quad (12)$$

The dissociation constant for Eq. (9) is:

$$K_{diss3} = \frac{[\mathrm{HgX_3^-}]_{org}[\mathrm{Na^+}]_{org}}{[\mathrm{NaHgX_3}]_{org}} \quad (13)$$

The total concentration of the third complex in the organic phase can, then, be described from Eqs. (12) and (13) as follows;

$$[\mathrm{NaHgX_3}]_{org} + [\mathrm{HgX_3^-}]_{org} = [\mathrm{HgX_3^-}](K_{ex3}[\mathrm{Na^+}] + K_{ex3}K_{diss3}[\mathrm{Na^+}]/[\mathrm{Na^+}]_{org}) \quad (14)$$

From this, the distribution of the $\mathrm{HgX_3^-}$ species in the organic phase could be said to be dependent on the sodium concentration in the aqueous and the organic phases. However, it was concluded that both the aqueous and the organic sodium concen-

trations can be regarded as practically constant under the conditions employed in the present study, thus, the terms in parentheses in Eq. (14) can be regarded as constant. The terms in parentheses will be denoted in this study by a constant, "K_{D3}", as:

$$K_{D3} = ([NaHgX_3]_{org} + [HgX_3^-]_{org})/[HgX_3^-] \quad (15)$$

The same type of arguement, but a more complicated one, could be made for the fourth complex species in the organic phase, and for the same reason a "K_{D4}" constant can be defined as:

$$K_{D4} = ([Na_2HgX_4]_{org} + [NaHgX_4^-]_{org} + [HgX_4^{2-}]_{org})/[HgX_4^{2-}] \quad (16)$$

In the ligand-concentration range where the Hg^{2+} and HgX^+ species are negligible, the distribution ratio may be generally described as:

$$D = \frac{[HgX_2]_{org}+[HgX_3^-]_{org,total}+[HgX_4^{2-}]_{org,total}}{[HgX_2]+[HgX_3^-]+[HgX_4^{2-}]} \quad (17)$$

where $[HgX_3^-]_{org,total}$ and $[HgX_4^{2-}]_{org,total}$ stand for the total organic concentrations of the third complex species (HgX_3^- and $NaHgX_3$) and of the fourth complex species (HgX_4^{2-}, $NaHgX_4^-$ and Na_2HgX_4) respectively.

When the organic sodium-ion concentration is assumed to be constant, it can be described from Eqs. (4), (6), (15), and (16) as;

$$D = \frac{K_{D2}+K_{D3}K_3[X^-]+K_{D4}K_3K_4[X^-]^2}{1+K_3[X^-]+K_3K_4[X^-]^2} \quad (18)$$

When to the non-charged mercury(II) complex in an organic solvent there is added a non-charged organophilic ligand, L, the equilibrium constants can be described as:

$$HgX_2(org) + L(org) \rightleftarrows HgX_2L(org) \quad (19)$$

$$HgX_2(org) + 2L(org) \rightleftarrows HgX_2L_2(org) \quad (20)$$

$$\beta_1^\circ = [HgX_2L]_{org}/[HgX_2]_{org}[L]_{org} \quad (21)$$

$$\beta_2^\circ = [HgX_2L_2]_{org}/[HgX_2]_{org}[L]_{org}^2 \quad (22)$$

When the organic phase contains these adduct complexes as well as the HgX_2 species, but no charged complexes, the following holds;

$$[Hg(II)]_{org,total} = [HgX_2]_{org} + [HgX_2L]_{org} + [HgX_2L_2]_{org} = [HgX_2]_{org}(1 + \beta_1^\circ[L]_{org} + \beta_2^\circ[L]_{org}^2) \quad (23)$$

When the ligand-anion concentration in the aqueous phase, $[X^-]$, is kept at "a", the following equation may be introduced from Eqs. (18) and (23);

$$D = \frac{K_{D2}(1+\beta_1^\circ[L]_{org}+\beta_2^\circ[L]_{org}^2)}{1+K_3a+K_3K_4a^2} \quad (24)$$

When the distribution ratio at the same anionic-ligand concentration, but in the absence of the adduct-forming ligand, is denoted by D_0, the following equation is obtained;

$$\log D = \log D_0 + \log (1+\beta_1^\circ[L]_{org}+\beta_2^\circ[L]_{org}^2) \quad (25)$$

Results

Figures 1 to 4 give the changes in the distribution ratio as a function of the ligand concentration in the aqueous 0.5M perchlorate constant ionic medium when the organic phase was benzene, hexane containing 0.1M TBP, MIBK, and nitrobenzene, respectively.

It can be assumed that the concentration of the Hg^{2+} or HgX^+ species is very small in the ligand-concentration range studied[2]; when it is assumed that the extraction of the ion-pair species, $NaHgX_3$ and Na_2HgX_4, into benzene or into hexane containing a small amount of the extractant, TBP, is almost negligible, the follwing equation can be employed for the analysis of the data in Figs. 1 and 2;

$$D = \frac{K_{D2}}{1 + K_3[X^-] + K_3K_4[X]^{-2}} \qquad (18')$$

By using the following family of standard curves:

$$Y = -\log(1+pv+v^2),\quad X = \log v \qquad (26)$$

the equilibrium constants for the data in Figs. 1 and 2 were determiend by a curve-fitting method.[4-6] The stability constants and the distribution constants thus determined are listed in Tables 1 and 2. It was concluded that the stability constants for the HgX_3^- and HgX_4^{2-} complexes agree well with the values previously pointed by Sillén[2] within the limits of experimental error except for those for the bromide complexes. The equilibrium constants in the benzene system also agreed very well with the values reported by Marcus.[3] The stability constants for the thiocyanate complexes were also determined from Fig. 2; they are given in Table 1. They also agree with the constants in 0.2M nitrate media reported by Tanaka, Ebata, and Murayama[7] and with those in 1M perchlorate media reported by Nyman and Alberts.[8]

By introducing the constants, K_3 and K_4, determined from Figs. 1 and 2 into Eq. (18), the data in Figs. 3 and 4 were also analyzed graphically in order to obtain the distribution constants. After several attempts, it was found that the extraction constants for the charged complexes, K_{D3} and K_{D4}, should be taken into account as well as that for the non-charged complex, K_{D2}. However, the extraction curve of iodide in the MIBK system could be explained only in terms of the extraction of the charged complexes, HgI_3^- and HgI_4^{2-}, for a reason to be given below.

In order to ascertain the effect of the coexisting salt, some experiments were carried out in the absence of sodium perchlorate in the aqueous phase; that is, the aqueous phase contained only sodium halide, and the ionic concentration was not con-

$$K_{D_4} = \frac{[Na_2HgX_4]_{org} + [NaHgX_4^-]_{org} + [HgX_4^{2-}]_{org}}{[HgX_4^{2-}]}$$

* Taken from Ref. 3

** This value could not be determined but it was supposed that the extraction constant for the HgI_2 species with MIBK should be very large.

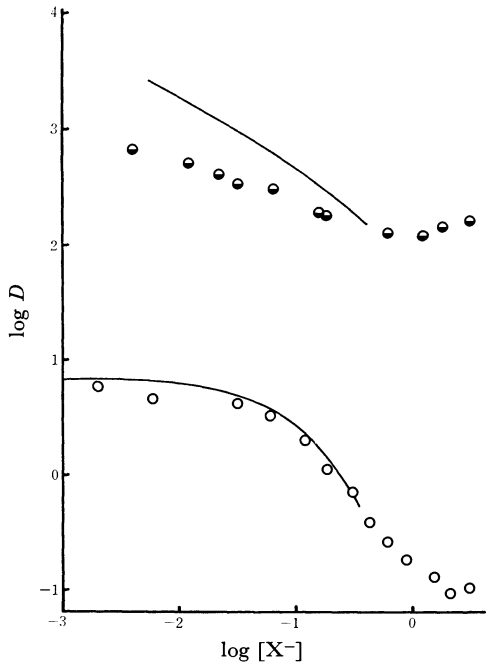

Fig. 5. Changes in the distribution of Hg(II) into MIBK when the aqueous phase containes sodium chloride(○) or sodium iodide(◒) but no sodium perchlorate (concentration of the ionic medium is not kept constant).

stant. Figure 5 gives some of the results of these experiments. In Fig. 5, the half-closed circles and the open circles show the extraction of mercury(II) with MIBK from aqueous sodium iodide and chloride solution respectively. The solid lines show the MIBK extraction curves from the 0.5M constant ionic media taken from Fig. 3. It can be seen that the extraction is not very different in the chloride system, but it is somewhat different in the iodide system.

The coextraction of sodium as ion-pairs with the anionic mercury(II) complex was also studied by using a sodium-24 radioactive tracer. An aqueous 0.1M sodium iodide solution containing no mercury-(II) was equilibrated with MIBK, and from the measurement of the γ-radioactivity of sodium-24 in the two phases, the organic sodium concentration was determined. Then, from 0.002M to 0.01M of mercury(II) nitrate, (which was not labelled) was added to this aqueous 0.1M sodium iodide solution, the aqueous phase was equilibrated with MIBK, and the organic sodium concentration was determined. In the absence of mercury, the sodium content in the organic phase was about 1×10^{-4}M; this is probably due to the extraction of sodium iodide. Upon the extraction of mercury, the organic sodium concentration increases; when the total organic mercury concentration was 0.002M, 0.003M, 0.005M, and 0.01M, the organic sodium concentration was 1.8×10^{-3}M, 3.4×10^{-3}M, 7.8×10^{-3}M, and 1.3×10^{-2}M. These results indicate that one molecule of the mercury iodide complex coextracts one or two sodium ions. As has been pointed out, the extracted mercury-iodide complexes in this iodide concentration are the HgI_3^- and HgI_4^{2-} species, and they should coextract one and two sodium ions respectively. The results of the above sodium coextraction, determined by means of radiometry, seem to be explained by this assumption regarding the complex species in the organic phase.

Figure 6 shows the dependence of the distribution ratio on the TBP concentration in hexane when the

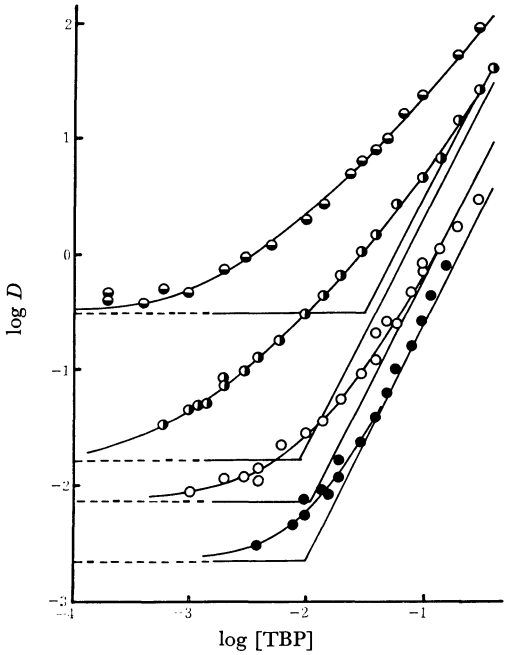

Fig. 6. The increase in the distribution of Hg(II) into hexane by the addition of TBP into the organic phase.

The aqueous phase is 0.5M $NaClO_4$ containing 1×10^{-3}M of the ligand. The broken lines represent the distribution ratio of the HgX_2 in the absence of TBP in hexane.

aqueous phase contains ligands at 1×10^{-3}M. It was found that some mercury(II) is extracted from these aqueous phases even into hexane containing no TBP. The distribution ratio into pure hexane is given in Table 3 as D_0. The distribution ratio increases as the TBP concentration increases. The plot was also analyzed by the curve-fitting method by using Eq.(24). The adduct-formation constants in Eqs. (21) and (22) thus determined are given in Table 3.

The distribution constant of the HgX_2 complex between pure hexane and the aqueous phases given by Eq. (6) was calculated by using the D_0 values and the stability constants in Table 1, for at this ligand concentration (1×10^{-3}M), the aqueous phases contain not only the HgX_2 but also the HgX_3^- and HgX_4^{2-} species except in the case of the chloride system. The K_{D2} values are also given in Table 3.

$$\beta_1^\circ=\frac{[HgX_2TBP]_{org}}{[HgX_2]_{org}[TBP]_{org}} \qquad \beta_2^\circ=\frac{[HgX_2 2TBP]_{org}}{[HgX_2]_{org}[TBP]_{org}^2}$$

Discussion

The results given in Figs. 1 to 6 and in Tables 1, 2 and 3 may be summarized as follows; i) In the benzene and 0.1M TBP-hexane systems, the only metal species in the organic phase is the HgX_2 species.

ii) In the MIBK and nitrobenzene systems, only the HgX_2 species is extracted from the chloride media, but anionic complexes, HgX_3^- and HgX_4^{2-} species, are also extracted as ion-pairs with sodium ions from other media.

iii) The extraction of the HgX_2 species into pure hexane grows larger in this order; $Hg(SCN)_2<HgCl_2<HgBr_2<HgI_2$. This extraction is increased by the addition of TBP. The increase can be explained in terms of the formation of TBP adduct complexes, HgX_2TBP and $HgX_2(TBP)_2$, in hexane. No systematic explanation has yet been made of the stability order of these adduct complexes of the different mercury(II) complexes.

iv) The stability constants for the HgX_3^- and HgX_4^{2-} species in the chloride and iodide systems agreed well with the data given by Sillén,[2] but those in the bromide system are slightly different. The same type of disagreement in the stability constants of the bromide complexes was also observed in the distribution work by Marcus[3] ($\log K_3$ and $\log K_4$ for the bromide complexes are 2.27 and 1.75), but the present results are closer to his values. Equilibrium constants in the benzene system agreed very well with the values reported by Marcus,[3] who also did his work in 0.5M sodium perchlorate constant ionic media.

The stability constants of the thiocyanate complexes obtained in the present study also agreed almost entirely with the previous data.[7,8]

As has been pointed out, the data in Figs. 3 and 4 were analyzed by using Eq. (18); that is, no effect of the organic sodium concentration on the distribution of the charged species was assumed. This is reasonable for the following reasons. According to the other studies, the sodium concentration in the organic phase equilibrated with 0.5M sodium perchlorate is about 5×10^{-5}M for nitrobenzene[9] and almost 1.5×10^{-3}M for MIBK (a small part of

9) T. Sekine and D. Dyrssen, *Anal. Chim. Acta*, **45**, 433 (1969).

these sodium ions could associate with perchlorate ions and form ion-pairs in MIBK).[10] The sodium concentration in the organic phases in the present systems can be described as follows:

$$[Na^+]_{org} = [ClO_4^-]_{org} + [X^-]_{org} + [HgX_3^-]_{org} + [NaHgX_4^-]_{org} + 2[HgX_4^{2-}]_{org} \quad (27)$$

In the ligand-concentration range studied, the aqueous sodium perchlorate concentration was kept pratically at 0.5M and the sums of the first and the second terms on the right side of Eq. (27) were 5×10^{-5}M and 1.5×10^{-3}M in nitrobenzene and MIBK respectively. On the other hand, as the total mercury concentration in the initial aqueous phase was 1×10^{-5}M, the maximum of the sum of the third, fourth and the fifth terms of Eq. (27) should be 2×10^{-5}M (when the HgX_4^{2-} species is dominant in the organic phase). However, as may be seen from Figs. 3 and 4 and Tables 1 and 2, this does not happen under the present experimental conditions. On the contrary, it is most probable that this sum is smaller than 1×10^{-5}M. From these points, it can be assumed that the sodium ions coextracted with the anionic mercury(II) complexes do not change the total organic sodium concentration seriously; in other words, the total sodium in the organic phase given by Eq. (27) is practically constant: 5×10^{-5}M in nitrobenzene and 1.5×10^{-3}M in MIBK.

Until now, not very much seems to have been discovered about the activity coefficient of ionic species in the organic phase in solvent extraction systems. The present results indicate that the activity coefficients of the ionic species in the organic phase can be controlled if the concentration of the metal complexes is very low. When the organic concentration of sodium perchlorate is much larger than that of the extracted metal ions in the organic phase, and when the aqueous phase is kept at a constant ionic medium by using sodium perchlorate, the concentration of the bulk sodium perchlorate in the organic phase is kept constant; in other words, this organic phase is a kind of constant ionic medium.

The distribution ratio of the complexes in these systems is probably influenced by many factors. When the interactions in the organic phase are not large as in hexane, the distribution ratio should be affected mainly by the interactions with the aqueous phase. Thus, the K_{D2} into pure hexane shown in Table 3 reflects the differences in the interactions with the aqueous phase. The order of the values of this K_{D2}, $HgCl_2 < HgBr_2 < HgI_2$, is the same as the order of the sizes of these complexes, which is in turn parallel with the difficulty of the dissolution into water with a hydrogen-bonded structure. The small distribution ratio of the thiocyanate complex could be due to another effect of the polyatomic nature of this ion.

The extraction of the dihalides into benzene becomes larger than that into hexane, but the difference is rather small with the dithiocyanate. This increase in the extraction can be explained in terms of the π-complex formation of the mercury dihalides, and the data seem to show a smaller tendency toward π-complex formation in the dithiocyanate.

The TBP adduct formation also increases the extraction, as may be seen from Fig. 6 and Table 3. Many neutral metal complexes have been known to be extracted into various solvents as TBP adducts, and the solvation number of TBP has been given to many of them on the basis of the TBP dependence of the extraction. As the neutral complex is usually extracted into an "inert diluent" only very poorly, not very much has been known about the adduct-formation constants, β°, except for the adduct metal chelate complexes which are known as "synergic complexes." Thus, although it is known to be a general tendency, for complexes of a certain metal with a series of similar ligands to be extracted better with a neutral extractant such as TBP when the size of the ligand is large, there has been little discussion as to whether this is due to the larger extraction into the diluent or whether it is due to the larger stability of the adduct complexes. The results shown in Table 3, however, indicate that the greater extraction into hexane, in other words, the larger "aquofobic" tendency, is more important in causing the larger extraction (the larger K_{D2} in Table 3) of the bis-mercury(II) complexes into hexane containing TBP.

It is remarkable that the extraction of the ion-pairs of the third complex anion and the sodium ion is larger in this order; chloride (no extraction) < thiocyanate < bromide < iodide, an order which is parallel to the order of K_{D2}. The extraction of the ion-pairs should be effected by the dissociation and the solvation in the organic phase, and when the extracted complexes dissociate more in the organic phase, the distribution ratio should be higher. As has been pointed out, no information about the dissociation of the ion-pairs in the organic phase has been obtained from the present distribution constant, not only for the neutral complex (K_{D2}), but also for the anionic complexes (K_{D3} and K_{D4}), probably indicates a larger contribution of the solvation than of the dielectric constant, because nitrobenzene has a higher dielectric constant ($\varepsilon=34.82$ at 25°C)[11] than MIBK ($\varepsilon=13.11$ at 20°C)[11]: However, the latter is obviously more favorable for the solvation than the former; this higher ability of solvation should make MIBK a better extractant of the charged complexes than nitrobenzene.

The distribution ratio of the iodide complexes in MIBK is too high to allow an accurate determina-

11) A. A. Maryott and E. A. Smith, Table of Dielectric Constant of Pure Liquids NBS Circular 514 Aug. 10 1951.

tion, especially in the lower-iodide-concentration region, where an extraction of the HgI_2 species could be expected ($[I^-] < 10^{-2}$M). Thus, the data used for the analysis were taken from the region where the iodide concentration was above 5×10^{-3}M when the concentration of the HgI_2 species was calculated to be lower than 1.8% of the mercury(II) content, neglecting the extraction of this species; the K_{D2} value for the iodide complex could not be determined. The K_{D2} for this species in the MIBK system, however, is probably very large because the K_{D2} can be assumed to be larger than the very large K_{D3}, $10^{3.68}$.

Due to the change in the ionic concentrations in the experiments in Fig. 5, no statistical analysis of the data has been carried out. However, the following qualitative discussion is possible. In the chloride system, the addition of the sodium perchlorate may change the activity coefficients of the species, but we observed a not very large effect in the experimental data. In the iodide system, however, the extraction of the ion-pairs is probably influenced by the change in the sodium concentration, as can be seen from Eq. (14) or from the discussion which has been given above. Therefore, the extraction of mercury(II) can be increased by an increase in the aqueous sodium concentration (*cf.* Eqs. (21) to (24)). Figure 6 shows the rather prominent independence of the iodide extraction on the sodium iodide concentration. This may be explained as follows; the increase in the sodium iodide concentration will increase the concentration of iodide ions, which in turn changes the metal species from the HgI_3^- species to the less extractable HgI_4^{2-} species. In consequence, this should decrease the extraction. At the same time, however, the increase in the salt concentration of the sodium ions may increase the extraction, as we can see from Eq. (14). By the combination of these two inverse effects, the increase or the sodium iodide concentration has a rather small effect on the net distribution ratio.

Part of this work has been carried out at the Laboratory of Nuclear Chemistry, Institute of Physical and Chemical Research. The authors are grateful to Professor Nobufusa Saito, the head of the laboratory. They are also grateful to Dr. Tadashi Nozaki of the same laboratory for his valuable discussions and continuous interest for this work. The authors wish to express their gratitude to Messrs. Hirokazu Fukuda, Masaaki Suzuki, and Michio Ohtsuki of the present laboratory for their experimental aid. This work has been financially supported by a research grant from the Ministry of Education.

Physical Chemistry of Binary Plastic Crystals. II. Dielectric Constant of the System, Carbon Tetrachloride and *t*-Butyl Chloride

Kayako KOTAKE,*1 Nobuo NAKAMURA and Hideaki CHIHARA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received March 19, 1970)

Careful measurements of the dielectric constant of a binary system of *t*-butyl chloride and carbon tetrachloride were made in the entire composition range and in three different phases, the liquid, the fcc solid, and the rhombohedral phases. The simple Debye theory applies to the liquid and the fcc solid, giving an effective dipole moment of *t*-butyl chloride of 2.11 ± 0.01 D whereas in the rhombohedral phase, it was 2.00 ± 0.03 D. Molecular polarization shows no discontinuity between the vapor, the liquid, and the fcc solid but there is a jump between the fcc and the rhombohedral solids. The molecular rotation in the plastic rhombohedral phase is more hindered by 450 cal/mol than in the liquid or the fcc phase. The 1 : 1 solid solution data were examined on the basis of the Onsager theory.

In the previous paper,[1] a dielectric and NMR study of *t*-butyl iodide dissolved in carbon tetrachloride in liquid and solid states was reported. It was then found that the solid solution formed a plastic crystal in which molecules not only reorient themselves but diffuse through the lattice with an

*1 Present address: Institute for Scientific and Industrial Research, Osaka University, Suita, Osaka.

1) H. Chihara, M. Otsuru and S. Seki, This Bulletin, **39**, 2145 (1966).

activation energy of 6.8 kcal/mol. The solid solution was dealt with by the theory of regular solutions. The stable solid phase I immediately below the melting point was then believed to be of the fcc structure, but as Post reported later[2] it was rhombohedral phase. The fcc phase of carbon tetrachloride and its solid solution does exist, however, as a metastable phase as our reexamination of the phase relations has shown.[3] The question now arises if there is any difference in the state of molecular motion in the two plastic phases, fcc and rhombohedral. The difference between the liquid and the solid phases, if any, is also of great interest in view of elucidating the nature of plastic crystals.

t-Butyl chloride forms two plastic solid solutions with carbon tetrachloride, having different structures, fcc and rhombohedral. The fcc phase becomes metastable where the concentration of *t*-butyl chloride is low. This binary system has been investigated by the dielectric[4] and the NMR[5] methods but the studies emphasized the similarity of the motional behavior between the liquid and the plastic phases. The present paper describes a careful dielectric measurements on the binary system in an attempt to learn about the motion of solute molecules in different matrix structures of carbon tetrachloride.

Experimental

Materials. Commercial special grade carbon tetrachloride and *t*-butyl chloride were distilled after drying over calcium chloride; carbon tetrachloride bp 76.7—76.8°C, n_D^{20} 1.45986, *t*-butyl chloride, bp 50.5—50.8°C, n_D^{20} 1.38550, literature values are as follows: *t*-butyl chloride bp 50.5,[6] 51.0°C,[7] n_D^{20} 1.38470,[8] 1.38786.[7]

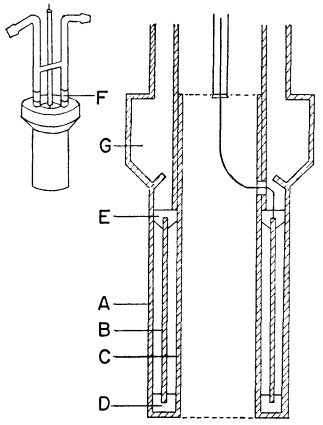

Fig. 1. The dielectric cell.

Equipments. The apparatus of the differential thermal analysis (DTA) is the same as the one reported earlier.[9]

The dielectric constant was measured by the heterodyne-beat method at the frequency of 1 MHz.

Two sample cells were used. One was the glass cell as described previously,[1] which often broke where the electrode leads were fused when the sample solution was remelted. A new cell, shown in Fig. 1 consists of three coaxial cylinders of nickel-plated copper A, B, and C that served as the electrodes: B is insulated from the cylinders A and C by the Teflon spacers D and F. To secure uniform temperature in the specimen, thermal conduction from the outside was reduced to a minimum by using thin-walled stainless steel pipes F through which the solution was charged or discharged. G is the space to allow for the thermal expansion of the specimen through the cutting of the spacer E. The new cell is sturdier than the previous one and also suffers smaller disturbances from environment. The air capacitance of either cell was about 18 pF. The cell was placed in a thick copper holder which was filled with toluene as the heat-exchange medium. The holder was cooled with Dry Ice in a Dewar vessel and the temperature of the cell, measured by a chromel-P-constantan thermocouple, was controlled manually with the heater wound around the holder.

Density was measured by a pycnometer[10] in the liquid state.

The dielectric constants and the densities of liquids were in good agreement with the literature values.[11]

Results and Discussion

1) Differential Thermal Analysis (DTA). Recent X-ray studies[2] of carbon tetrachloride showed that under certain conditions it exhibits monotropy immediately below the melting point; *i. e.*, the crystal formed upon solidification is of metastable cubic phase, which is transformed to a rhombohedral crystal on further cooling. Such phase relations were substantiated by our DTA work.[3] Figure 2 is a reproduction of the DTA result of pure carbon tetrachloride. The figure is self-explanatory but it is to be noted that the melting point of the cubic phase (peak G) is about 3.8°C lower than the melting point of the rhombohedral phase (peak E). Similar DTA curves were obtained, though the tem-

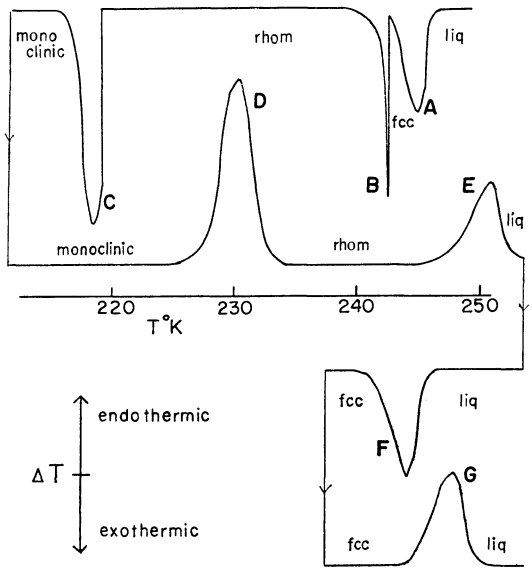

Fig. 2. DTA curves of carbon tetrachloride.

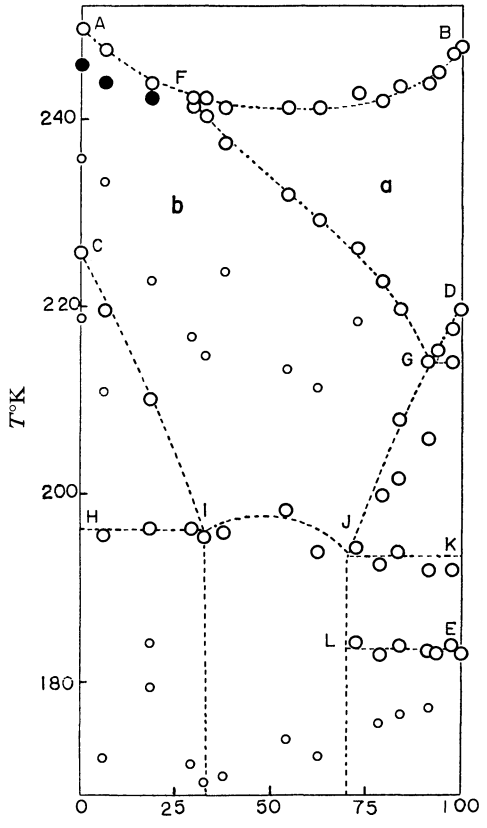

Fig. 3. The phase diagram of the system, CCl_4 - *t*-BuCl. Large and small circles represent the peaks on warming and on cooling, respectively. Closed circles represent the mp of metastable fcc phases. Dashed lines and capital letters refer to the work by Smyth *et al.*

peratures of transitions were displaced for binary mixtures of CCl_4 and *t*-BuCl where the concentration of the latter was less than 25 mol%. For more concentrated solutions, the melting and freezing points coincide and the second exotherm (B in Fig. 2) is replaced by a stable transformation corresponding to the curve FG in Fig. 3. The phase diagram determined by the DTA method (Fig. 3) confirms the dielectric result.[4]

Because the structure of the plastic phase of *t*-butyl chloride is fcc,[12] the area a of Fig. 3 must correspond to the fcc phase, the area b similarly corresponding to the rhombohedral phase.

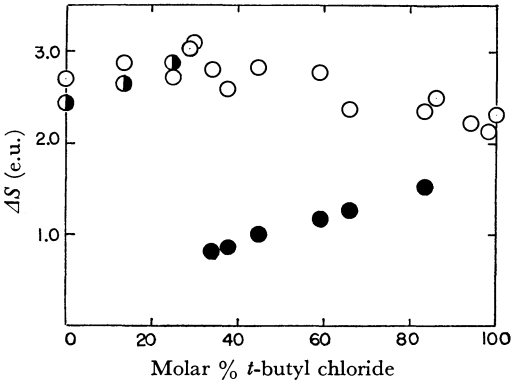

Fig. 4. Entropy of phase changes of CCl_4 - *t*-BuCl. ● rhombohedral → fcc, ◑ rhombohedral → liquid, ○ fcc → liquid.

The entropy changes of the phase transitions were estimated from the area under the peak in the DTA curves and are shown in Fig. 4. To obtain the internal consistency, the experimental conditions including the volume of the specimen in the measuring tube were fixed for all compositions. The literature values of the entropy of fusion is 2.401 cal/deg·mol[13] for carbon tetrachloride and 2.00 cal/deg·mol[14] for *t*-butyl chloride. It is interesting to note that the entropy of fusion of the fcc phase, either stable or metastable, changes almost linearly with the composition, *i. e.*, the solid solution is very close to the ideal solution. Also, the entropy change from the rhombohedral to the stable fcc phase increases linearly as the solution becomes more concentrated in *t*-butyl chloride. Extrapolation of the line back to the zero concentration gives about 0.3 cal/deg·mol to the entropy of transition from the rhombohedral to the metastable fcc phase of

pure carbon tetrachloride.

2) Dielectric Constants and Density. Uncertainty in the dielectric constant measurements was less than 0.1 pF, which arose from repeated assembly and disassembly. Samples were carefully frozen into plastic crystal phase to fill the space between the electrodes by slow cooling and annealing thereafter, and the dielectric constant values on warming and on cooling agreed well except in the region of the supercooled fcc phase, in contrast to the result of Smyth *et al.*,[4] who reported that the runs on two directions did not agree and that the dielectric constants were smaller on cooling. The values of the present work were reproducible to within 1%. The smoothed values for each temperature are listed in Tables 1—3. The values of the density are given in terms of the coefficients of the formula

$$\rho = a + bx + cx^2$$

where ρ is the density, x is mole% of *t*-butyl chloride and a, b and c are the coefficients.

3) Polarization at Infinite Dilution. The dielectric constant in both the cubic and the rhombohedral phases has negative temperature coefficients as is evident from Tables 2 and 3. The negative coefficient is commonly encountered in polar plastic crystals[1,15] and is generally interpreted as being due to the effect of thermal agitation opposing the orientation of molecules in the electric field. It is therefore interesting to see if the Debye theory for the liquid solution applies to the plastic solid solution. This is equivalent to seeing if the application of the Debye theory might lead to a reasonable value of the effective dipole moment of solute molecules in the solid state.

To obtain the specific polarization at infinite dilution, the Halverstadt-Kumler's method[16] was used. If linear relationships hold for the dielectric constant and the density,

$$\varepsilon_{12} = \varepsilon_1 + \alpha w_2$$

and

$$\rho_{12} = \rho_1 + \beta w_2 \qquad (1)$$

the specific polarization is given by the equation

$$p_\infty = p_1\left\{1 + \frac{3\alpha}{(\varepsilon_1-1)(\varepsilon_1+2)} - \frac{\beta}{\rho_1}\right\} \qquad (2)$$

where w_2 is the weight fraction of the solute, the suffix 1 referring to the solvent and the suffix 2 to the solute. The experimental results of Tables 1 to 3 were used to derive the values of α and β in the region of dilute solutions. In the absence of the density values of the solid solution, the ρ_1 values of pure carbon tetrachloride were taken from Ref. 17 and the β value was assumed to be equal to that in the liquid solution. This assumption would not lead to a serious error in p_∞ since a variation of 10% in the value of β changes the value of p_∞ by only 1%.*2 The values of moler polarization at

infinite dilution thus derived are plotted against $1/T$ in Fig. 5, which also shows the results of other investigations.[19-21] Our values for the liquid solution lie on a line extended from the values in the vapor phase, whereas there is a jump in the polarization between the liquid and solid (rhombohedral) phases and their slopes are also different.

Other conditions being equal, the difference in slope means a difference in the effective dipole moment between the liquid and the solid phases. By taking the electronic and atomic polarization to be 1.05 times the molar refraction, or 26.8 cc,[22] the magnitude of the dipole moment is estimated as 2.00 ± 0.03 D for the solid (rhombohedral) phase as compared with 2.11 ± 0.01 D for the liquid phase. The smaller effective dipole moment in the solid should be an indication of the effect of a stronger intermolecular interaction, which also accounts for the jump of the polarization at the melting point. After Debye,[23] we take

$$U = -\mu F\cos\theta' - V\cos\theta \tag{3}$$

as potential energy of a solute molecule in the solid solution, where the first term represents the part due to the external field and the second term represents the potential energy hindering the molecular rotation. The angle θ is measured from the direction of the minimum hindering potential that is determined by the structure of the solid solution. The orientation polarization is given by

$$P^{o} = \frac{4}{3}\pi N\frac{\mu^2}{3kT}\left\{1 - L^2(V/kT)\right\} \tag{4}$$

where $L(y)$ is the Langevin function. Since there is a smooth continuity in the polarization between the vapor and the liquid, we assume that $L(y)=0$ in the liquid and the jump at the melting point is entirely due to non-zero $L(y)$ in the solid solution. Inserting the numerical values into Eq. (4), we obtain $V=0.9kT=450$ cal/mol. That $L(y)$ is put to zero in the liquid should not be taken to imply that there is no potential barrier in the liquid but it should be interpreted as meaning that the apparent potential barrier vanishes after averaging over all possible values of θ' and θ because of the symmetry of the barrier,[24] its existence being expected from the structure of the liquid.[25]

4) More Concentrated Solutions. We shall consider a more concentrated solution. If we take a 51.03% solution, the cubic and rhombohedral phases may be compared on similar grounds. To make a comparison with the case of dilute solutions meaningful, we deduce a quantity which corresponds to the orientation polarization in the Debye theory by applying the Onsager formula[26] in the form

$$\frac{4\pi N\mu^2}{9kT} = \frac{1}{3}v_{12}\frac{100}{x}\left\{\frac{(\varepsilon-1)(2\varepsilon+1)}{3\varepsilon} - \frac{(2\varepsilon+1)(n_1^2-1)}{2\varepsilon+n_1^2}\frac{v_1}{v_{12}}\frac{100-x}{100} - \frac{2(\varepsilon+1)(n_2^2-1)}{2\varepsilon+n_2^2}\frac{v_2}{v_{12}}\frac{x}{100}\right\}\Big/ \left\{\frac{2\varepsilon+1}{2\varepsilon+n_2^2}\cdot\frac{n_2^2+2}{3}\right\}^2. \tag{5}$$

Here ε is the dielectric constant of the solution, n is the refractive index, and v is the molar volume. Rough estimate of the molar volume of solid solution may be made on the basis of the theory of Pople and karasz,[27] which relates the volume change to the entropy of fusion for the plastic crystals. Though

this theory was constructed for the pure substances, the extention to mixtures is possible on the assumption of perfectly random mixing in either phases. Precise application of this theory is not possible for rhombohedral phase of carbon tetrachloride, presumably due to the lower symmetry of the potential. Table 4 shows the parallelism of ΔS and $\Delta V/V_s$ among the fcc phases. V_s is estimated to be 92 cc, which is consistent with the density value, 1.349 g/cc, obtained from the equation $\rho=a+bx+cx^2$, where a is 1.760 g/cc for the fcc phase of carbon tetrachloride from the X-ray analysis[5] and b and c are mean values in liquid phase. The same value of molar volume is used for the rhombohedral phase of the mixture, though the actual value must be certainly less than it. The results

TABLE 4. THE RELATION OF THE ENTROPY CHANGES ΔS FROM DTA AND THE RELATIVE VOLUME CHANGES $\Delta V/V_s$ ON FUSION

V and V_s are molar volumes of liquid and solid phases at the melting point, respectively, and the former are obtained by extrapolation of density *vs.* temperature curves for each concentration.

	CCl_4 fcc	*t*-BuCl fcc	51% mixture fcc
ΔS	2.7	2.0	2.9
$\Delta V/V_s$	0.050	0.046	0.051*
V	91.8	103.4	96.3
V_s	87.4	98.9	92*

* estimated values

are shown in Fig. 6, compared with the value of the orientation polarization obtained in the preceding section. An inspection of the figure immediately reveals that:

1) the orientation polarization P^o derived from Onsager's equation are systematically larger than P^o at the infinite dilution, but the slopes are almost equal in the liquid phases.

2) P^o for the fcc and liquid phases lie on a straight line, whereas P^o for the rhombohedral phase falls short of the line.

These facts indicate that Onsager's treatment of dipole-dipole interaction is not adequate, mainly in the account of the short range interaction. However the defect of the theory is displayed in the liquid as well as in the solid phase in a similar fashion. The molecules are not as free in the rhombohedral phase as in the liquid or the cubic phases. The different behavior in the two solid phases is probably due to the different symmetry of the hindering potential of molecular rotation and is related to the factor $\overline{Z\cos\gamma}$ in the Kirkwood formula[28] which probably vanishes in the liquid and cubic phases.

Absorption Spectra of Gaseous Benzo[*g,h,i*]perylene and Coronene

Jun-ichi AIHARA*1, Koichi OHNO and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received March 30, 1970)

The gas-phase spectra of typical polycyclic aromatic hydrocarbons benzo[*g,h,i*]perylene and coronene, were measured. These data can be used as criteria for the solvent shifts and the molecular excitons.

One of the most refined analytical approaches to the molecule is to examine the gaseous behaviour of the isolated molecule. The conventional way of doing so is to make an experimental determination of the electronic transition energies. Further, the gas-phase spectra play an important role in the estimation of the energies in the crystalline phase and in solution.

For these purposes, several absorption spectra have been obtained for the vapours of various aromatic compounds.[1,2] However, in spite of many investigations, the absorption spectra have not been measured for benzo[*g,h,i*]perylene and coronene, which are typical higher polycyclic aromatic hydrocarbons. The latter is a famous example of the Shpolskii effect.[3]

We overcame the experimental difficulties resulting mainly from their lower volatility, and we succeeded in measuring their absorption spectra by the aid of a powerful electric furnace.[4]

This paper will report the optical absorption band positions of compounds, benzo[*g,h,i*]perylene and coronene, in the near-ultraviolet region, and will compare these results with the solution data.

Experimental

Benzo[*g,h,i*]perylene (Benzoperylene). The absorption spectra of benzo[*g,h,i*]perylene (Fig. 1) in the gas phase were observed as follows: Below 3.2×10^4 cm^{-1}, an Aminco 4-8401 monochromator was used. Above 3.2×10^4 cm^{-1}, a Cary recording spectrophotometer 14 was employed. The light sources were a 300-W tungsten lamp and a hydrogen discharge tube. Sodium and mercury lamps were employed to calibrate the spectral wavelengths.

The optical cell used was a Pyrex one, 30 cm in length, and also a silica cell, 2 cm long. A small quantity of benzoperylene crystals was placed in the cell, which was then evacuated to less than 10^{-5} mmHg pressure. The absorption coefficients of both compounds range from 10^2 to 10^4.[5] Therefore, the temperature must be varied widely in order to obtain the appropriate concentration of the gaseous specimen for observing their absorption spectra. In the case of coronene, the temperature ranges from 250 to 450°C.

When the absorption spectra of benzoperylene in the longer-wavelength region were observed, the Pyrex cell was maintained in a 50-KW electric furnace equipped with a temperature controller because the cell had to be kept at a fairly high temperature. To detect the spectra in the shorter-wavelength region, a small 80-W furnace for heating the cell was placed in the spectrophotometer. The spectra were taken after the specimen had been kept at the chosen temperature for at least 20 min. No condensation of the sample on the windows was detected during the measurement. The blank determination for the spectra was done by carefully cleaning and replacing the cell without changing the optical arrangement.

Benzo[*g,h,i*]perylene used was a synthetic one, prepared by Iwashima; it was purified by the chromatographic method.[6]

Coronene. For spectral measurements, a Spex spectrograph equipped with a 300-W tungsten lamp was used. The spectra were recorded photographic sheet films, Fuji Neopan SS. The spectral response on the films was determined by means of a Shimadzu microdensitometer. Iron lines were used for the wavelength calibration.

The cell used for coronene was a Pyrex one used to measure the absorption spectra of benzoperylene vapour; the 50-kW furnace was also employed. The third band could not be observed because of the limitation of the optical absorption of the Pyrex cell.

Coronene (Fig. 1) used was a commercial one; it had been purified by recrystallization from xylene and by sublimination *in vacuo*.

For a complete investigation of absorption spectra of coronene, thirty hours were needed, but measurements of such a long duration scarcely affected the sample at all.*2

Results

The gaseous absorption spectra of benzoperylene are shown in Figs. 2, 3, and 4, which correspond to the region of the first, second, and third electronic transitions respectively. The spectra in an *n*-hexane solution were added for the sake of comparison. Table 1 gives the absorption bands observed in the various phases.[7]

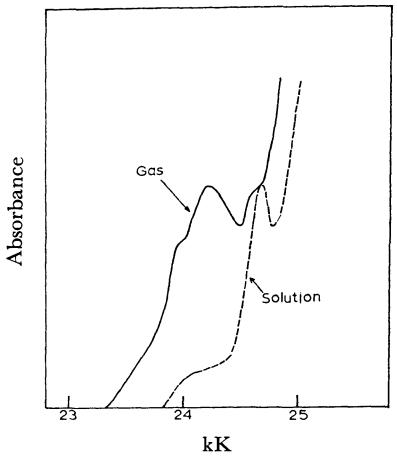

Fig. 2. Absorption spectrum of the α-band of benzo[*g*,*h*,*i*]perylene.

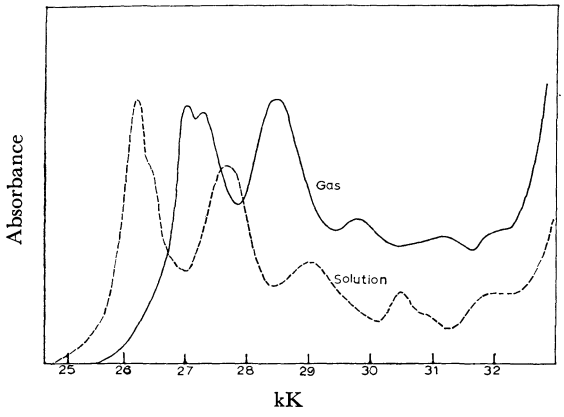

Fig. 3. Absorption spectrum of the *p*-band of benzo-[*g*,*h*,*i*]perylene.

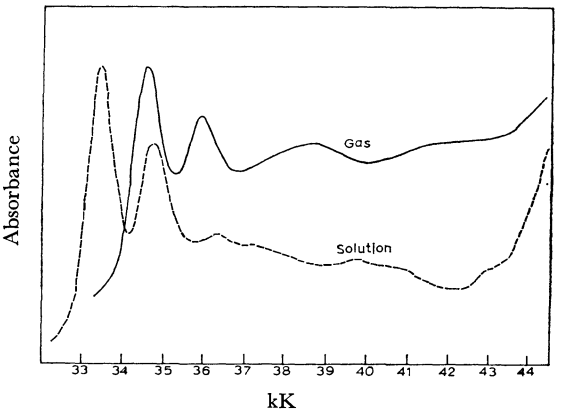

Fig. 4. Absorption spectrum of the β-band of benzo[*g*,*h*,*i*]perylene.

This compound has been subjected to scarcely experimental or theoretical treatments for the determination of its electronic transition energies, except for the case of the fluorescence spectra in the condensed phases.[8] As to benzoperylene, the best, and almost the only calculations, have been those of Hummel and Rüdenberg's, whose results are also listed in Table 1.[9]

Figures 5 and 6 show the spectra of gaseous coronene in the first two transition regions. The density on the films is plotted against the wave-numbers. Table 2 shows the bands of coronene which appeared in the various phases. The recent Pariser-Parr calculations for coronene are also listed.[10]

Discussion

The first transition bands of these compounds, *i. e.*, the α-bands according to Clar's notation, have very weak oscillator strengths, *f*. (f=0.008 for benzoperylene and f=0 for coronene.[9]) Especially, the first singlet-singlet transition of coronene is forbidden by symmetry, but it is slightly allowed by vibrational perturbations, as in the case of benzene.[10]

Accordingly, it is the vibronic bands coupled with asymmetric vibrations that appeared with the stronger intensities. The 0–0 band is very weak, and it completely disappears in the gas phase. In both cases, the extinction coefficients are of the order of 10^2 in the solution.[5]

To aid the analysis of these bands, the behaviour in various solvents was taken into consideration. According to McRae's theory of the solvent effect, the molecule is affected by the interaction between the induced dipoles in the following way:[11]

$$h\Delta\nu = A\frac{n^2-1}{2n^2+1} \quad (1)$$

where $h\Delta\nu$ is the spectral shift, where A is a constant characteristic of the transition of the solute, and where n is the refractive index of the solvent. The solvent-shifts are plotted for various kinds of solvents in Figs. 7 and 8.[12] As to benzoperylene, Eq. (1)

11) E. G. McRae, *J. Phys. Chem.*, **61**, 562 (1957).
12) H. Matsushita, *Nippon Kagaku Zasshi*, **84**, 110 (1963).

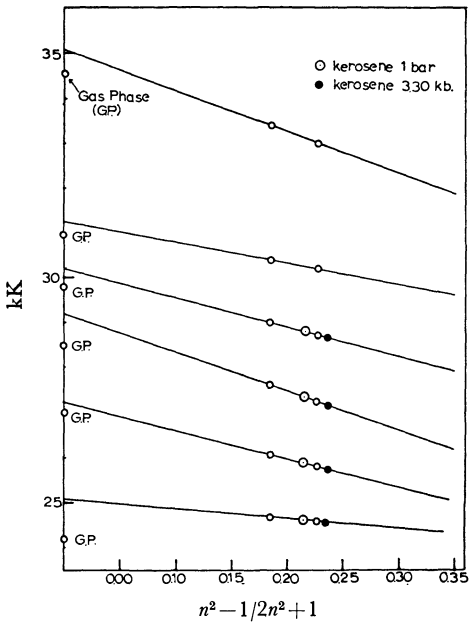

Fig. 7. Solvent effect for benzo[*g,h,i*]perylene.

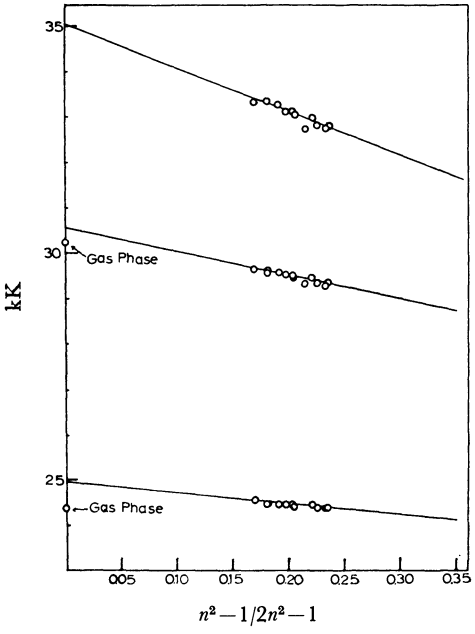

Fig. 8. Solvent effect for coronene.

is valid for the non-polar solvents, since it has a permanent dipole in the ground state.

The values extrapolated to the point of origin approximately indicate the positions of the spectra in the gaseous phase, but they generally exceed them to some extent. The discrepancies of the α-band are the greatest in both cases. The transitions with such small transition dipoles should not be expressed simply by Eq. (1), since the apparent amount becomes larger than the actual value, indicated by the abbreviation employed in the derivation of Eq. (1).[12,13]

The difference between the α-bands of benzoperylene in the gas phase and in solution is 460 cm^{-1}, while that of coronene is very little; the difference in f-values is thus reflected. This phenomenon is based on the fact that the solvent-shift is linearly correlated with the oscillator strength of the band to the second order of perturbation.[13]

However, the gaseous spectra became more diffuse than those in solution. This fact is the opposite of the general tendency, especially in the case of small molecules.

This line broadening can be explained if the following phenomenon is taken into consideration: in the first place, the thermal population can be considered in the vibrationally-excited states in the electronic ground state, which causes the hot bands in the excited states. The thermal energy kT amounts to 500 cm^{-1} when the α-band of coronene is measured. Considerable modes of fundamental vibration are obscured by this effect. This seems to have a very great effect on the line broadening. The relaxation process due to the intermolecular collisions may also be effective, thus reducing the lifetime of each vibronic band.

Coronene has many vibronic bands in the condensed phase, even at room temperature; this is rare among higher polycyclic aromatic hydrocarbons. These vibronic structures are reproduced in the gaseous spectrum. The redistribution of the oscillator strengths among the vibronic bands are not very distinguishable. The vibrational spacings are not changed. Several vibrational progressions, with fundamentals of 365, 650, 1440 cm^{-1}, *etc.*, are observed. These lines can be assigned by the aid of the studies in the rigid solution.[14,15]

From the two distinct lines, 4104 Å and 3887 Å, the location of the 0–0 band of coronene was deduced to be at 23390 cm^{-1}.

The second-transition bands of benzoperylene and coronene are called p-bands by Clar; they are theoretically-allowed transitions.[9,10] These two transitions have very similar red shifts in going from vapour to solution; the transitions amount to about 1000 cm^{-1}, corresponding to the fact that both transitions have nearly the same strong oscillator strengths (f= 2.08—2.20).

The spectrum of benzoperylene consists of four main peaks. The redistributions of the intensities were clearly observed in the passage from gas to solution. The shoulder on the band at 26075 cm^{-1} in solution grew into a distinct peak in the gas phase. The second vibronic peak augmented its intensity

13) Y. Ooshika, *J. Phys. Soc. Japan*, **9**, 591 (1954).

in comparison with the other bands. The solvent effect of this band is apparently twice as large as those of the others. The pressure effect on these bands is consistent with the behaviour mentioned above.[16]

It is likely, in view of only the intensities and the shifts of the absorption spectra, that the p-band of benzoperylene consists of two or more transitions. However, theoretical studies do not suggest that there exists another transition near the 27025 cm^{-1} band system.[9] Therefore, the most reasonable interpretation should be based on the assumption that there are two (or more) vibrational progressions, beginning at 27025 cm^{-1} and 27315 cm^{-1}. When these progressions are very similar to each other, the overlapped band shapes are probably directly dependent on the difference in the solvent effects of the two progressions. The apparent peaks even in the same transition will sometimes behave differently, as in the case of benzoperylene.

It may be remarked incidentally that the pressure shifts can be explained in terms of the change in the refractive index of the solvent due to the applied pressure. In Fig. 7, the spectral shifts induced by the pressure of 3.30 kb are also plotted, along with the linear relationship of the solvent effect expressed by Eq. (1); all the evidence points to the same n-value, 1.501. This interpretation is slightly different from the popular explanation based on the change in the density of the solvent.[17] Therefore, it must be further examined both experimentally and theoretically.

In the case of coronene's p-band, one main peak and two subsidiary shoulders were detected. No other vibrational structure was observed. The behaviour in this region seems unchanged, except for the shifts of the spectral lines.

The third-transition system of benzoperylene, which is ordinarily called the β-band, begins at 34565 cm^{-1} in the gas phase. This intense system shifts to an energy lower by as much as 1165 cm^{-1}. The β-band of coronene may be supposed, on the basis of the solvent-shifts, to be located at about 35000 cm^{-1}.

The comparison of the gaseous spectra with those in crystalline states will be made elsewhere.

It is a pleasure to acknowledge our helpful and stimulating discussion with Drs. Takashi Kajiwara, Ichimin Shirotani, and Tadayoshi Sakata of the Institute for Solid State Physics, The University of Tokyo, during the course of this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2439—2441 (1969)

Direct Determination of Charge Transfer Energy

Jun-ichi AIHARA,*1 Motoyuki TSUDA*1 and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received March 30, 1970)

The absorption spectrum of the gaseous anthracene - chloranil complex was measured. The Coulomb energy contributing to the charge-transfer transition was determined to be 3.03 eV. The polarization energy for the transition was 0.17 eV in an *n*-heptane solution.

Since the charge-transfer theory was advocated by Mulliken, various theoretical and experimental investigations have been made of the charge-transfer complexes.[1,2] By means of the theory, approximate linear relations between the energy of the charge-transfer transition and the ionization potential of the donor or the electron affinity of acceptor have been derived and experimentally confirmed.[3,4]

According to McConnell *et al.*, the energy of the charge-transfer transition, W, can often be expressed simply by the following relation:[5]

$$W = I - A - C - P \qquad (1)$$

*1 Present address: Department of Chemistry, Faculty of Science, Hokkaido University.

where I is the energy required to take an electron out of the highest occupied molecular orbital of a donor and where A is the energy gained as an electron is brought to the lowest vacant molecular orbial of an acceptor. C is a Coulomb-energy term, and P is a polarization-energy term.

If the geometrical configuration of the complex is known, the Coulomb term can be calculated by the following equation:[6]

$$C = \int \phi^2(1) \frac{e^2}{r_{12}} \theta^2(2) d\tau_1 d\tau_2 \qquad (2)$$

where ϕ is the molecular orbial of a donor and θ is that of an acceptor. However, the polarization energy is rather difficult to estimate theoretically, as it depends on the properties of the solvent as well as on the geometry of the complex. Moreover, the electron affinity of the acceptor can not be obtained accurately.

Because of these ambiguities, the estimation of Eq. (1) is very difficult as long as the available data are restricted to the optical absorption in condensed phases. Fortunately, the electron affinity of chloranil has recently been determined by the magnetron method to be 2.45 eV.[7] In order to make a rigorous analysis of each term in Eq. (1), we tried to observe the gaseous absorption spectrum of the anthracene-chloranil complex. The ionization potential of anthracene was determined to be 7.38 eV by the photoionization method.[8]

Experimental

Anthracene used in this work was a synthetic and zone-refined material prepared by Iwashima.[9] Chloranil was purified by recrystallization from benzene. The *n*-heptane solution of the anthracene - chloranil complex was prepared by mixing equimolecular components to an appropriate concentration.

The optical data for the complex in the gas phase were obtained by means of an Aminco 4-8401 monochromator. Anthracene and equimolecular chloranil were placed in a Pyrex-glass cell 30 cm long; the cell was sealed off after evacuation. The vapour pressure of chloranil is very low, so the cell was heated to around 250°C in a 50-kW electric furnance.[10] The absorption spectrum of the gaseuous complex was measured rapidly with a 200-W tungsten lamp.

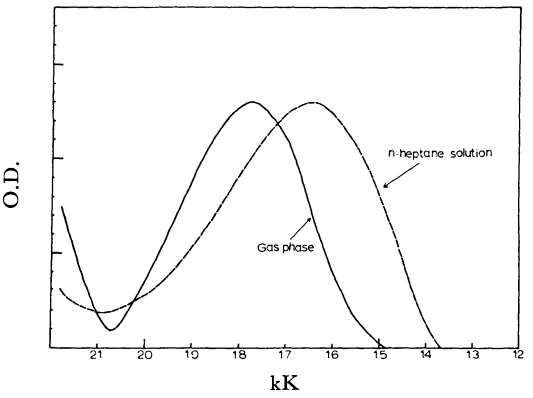

Fig. 1. Absorption spectra of the anthracene-chloranil complex.

Results and Discussion

Figure 1 shows the absorption spectrum of the anthracene - chloranil complex in the gas phase. The solution spectrum in *n*-heptane is added for the sake of comparison. Heptane was chosen as a common inert solvent in view of its solvent effect.[11]

The complex vapour gave evidence of a charge-transfer absorption maximum at 17800 cm^{-1} as compared with a value of 16400 cm^{-1} in an *n*-heptane solvent.

The shapes of the charge-transfer bands in the gaseous state and in solution are almost the same; the bands are all broad and diffuse. The asymmetry of bands is preserved in the vapour. However, the half-width, δ, in the gas phase is considerably smaller than that in solution (*e. g.*, $\delta = 3060$ cm^{-1} in gas and $\delta = 3930$ cm^{-1} in solution). The wave-number-shift from gas to solution amounts to 1400 cm^{-1} in this complex; this is considerably smaller than those in the complexes with TCNE.[11]

It has been shown that the width and diffuseness of the charge-transfer bands result from the difference in the form of the potential curves for the ground and excited states of the complex.[12] Therefore we tried to estimate the location of the 0–0 band with the aid of the fluorescence spectra, since the spectrum for the anthracene complex is deficient, but our efforts were in vain. Therefore, by analogy with the general behaviour of the mirror points of the fluorescent chloranil complexes, the 0–0 band of the anthracene - chloranil was estimated to be at 15400 ± 300 cm^{-1}, which is equivalent to 1.91 eV.[2]

As a considerable amount of the change in the molecular coordinate is caused by the augmentation of the Coulomb energy in the excited state,

the 0–0 position generally shifts to the band edge of the charge-transfer transition. Therefore, it is understandable that the band width of the absorption spectrum is often broader than that of the fluorescence.[2]

In 1964, Chakrabarti *et al.*,[13] using the relation concerning the solvent shifts, estimated the location of the band maximum of gaseous anthracene - chloranil at 21000 cm^{-1}. This overestimated value may be due to the misapplication of the solvent effect. They also failed to explain the dipole moment in the ground state.

In a previous paper,[11] we ourselves have reported the gaseous absorption spectra of aromatic-TCNE complexes. We concluded that the charge-transfer bands obey the McRae's formula of solvent effect, so the gas phase spectra can be regarded as the origin of that effect. This implies that the charge distribution of the complex is nearly preserved in normal solvents and in the gas phase.

Presupposing that this theory is valid for the anthracene - chloranil complex, we will proceed in our discussion. In the first place, the Coulombic-attraction term contributing to the charge-transfer transition can be directly deduced from Eq. (1), as the polarization energy vanishes in the gas phase. Therefore, the Coulomb term of the anthracene - chloranil amounts to 3.03 eV. It is a quite reasonable value compared with those calculated for a series of aromatics-TCNE complexes (*e. g.*, 3.34 eV for the naphthalene-TCNE, 3.10 eV for the pyrene-TCNE, and 2.91 eV for the perylene-TCNE).[14] These calculations have been made on every configuration, using Eq. (2) with the point-charge approximation. In view of their origin, the constancy of these attraction terms among various complexes is quite natural.

Employing the calculated Coulomb energy, we shall now determine the electron affinity of TCNE again. The ionization potential of naphthalene is 8.12 eV.[15] As the transition energy of the naphthalene-TCNE complex is considered to be around 2.23 ± 0.05 eV, its electron affinity can be estimated as 2.55 eV. This value is in good agreement with the 2.60 eV assumed in the previous paper.[11]

The smaller affinity was also estimated to be 2.10 eV from the SCFMO calculations performed by Flurry's laboratory.[16] The value derived by Briegleb from the spectroscopic data, 1.80 eV, seems too small.[17]

As to the polarization energy term, we define the spectral shift in the condensed phase as the polarization energy.

Table 1. The results of the charge transfer energies (eV)

	Anthracene-chloranil	Naphthalene-TCNE
Ionization potential of donor	7.38	8.12
Electron affinity of acceptor	2.45	2.55 ± 0.05
Coulomb energy	3.03 ± 0.05	3.34
Polarization energy		
in *n*-heptane	0.17	0.29
in carbon tetrachloride	0.22	0.38

So far, the physical meaning of the polarization energy has been very obscure, since the difference between the absorption maximum and the theoretically-calculated transition energy is considered to be the energy. This term often grows to 1 eV, depending on the MO adopted.[6] According to our definition, the transition energies of the anthracene - chloranil are 0.17 eV in *n*-heptane and 0.22 eV in carbon tetrachloride. Those of the naphthalene-TCNE are 0.29 eV in *n*-heptane and 0.38 eV in carbon tetrachloride.[11] (Summarized in Table 1) Consequently, the dipole-polarization force acting on the charge-transfer transition of the naphthalene-TCNE is stronger than that of the anthracene - chloranil by a factor of 1.7. This quantity can be explained by the usual McRae's formula.[18]

In the above treatment, we neglected an ionic character of several percent which stabilizes the complex in the ground state.[19] Probably, it influences each term in Eq. (1) within an accuracy of 0.20 eV. In the case of the TCNE complex, this effect may contribute to the increase in the electron affinity of TCNE, since its ionicity is considerably stronger than that of the chloranil complex.[19]

For further investigations of the charge-transfer complex, it is desirable to determine wavefunctions such as we obtained in this experiment wihch will accurately reproduce the energy diagram.

Giacometti *et al.*, who first treated the chloranil complex theoretically, adopted a complex with *p*-phenylenediamine in their MO calculations.[20] The SCFMO approach to the molecular complex system also seems fruitful.[21]

Ion-Solvent Interaction of Tetraalkylammonium and Some Common Ions in *N*-Methylformamide from Viscosity Data

Pushti Prakash RASTOGI

Chemistry Department, Lucknow University, Lucknow, India

(Received November 4, 1969)

Solute-solvent interaction of tetraalkylammonium iodides (R_4NI) and some common electrolytes has been studied in *N*-methylformamide (NMF) from the viscosity point of view. From the obtained results it has been concluded that common electrolytes like LiCl, KI, CsI are net structure promoters while R_4NI salts are net structure breakers in this solvent.

The interaction of the tetraalkylammonium (R_4N^+) ions with *N*-methylacetamide (NMA) molecules has already been reported from the point of view of conductance in a previous[1] communication. Another method commonly employed, for investigating ion-solvent interaction in solution, is to study the temperature dependence of the coefficient B of the viscosity equation of Jones and Dole,[2] namely,

$$\eta = \eta_0(1+A\sqrt{C}+BC)$$

or

$$(\eta/\eta_0-1)/\sqrt{C} = A + B\sqrt{C} \qquad \text{(i)}$$

This approach provides valuable information about the mode of solute-solvent interaction[3] on account of the fact that the coefficient B represents the interaction between the solvent molecules and the ions of the dissolved electrolyte. Ion-solvent interaction in aqueous solutions, from this point of view, has been studied by several workers.[4-6] According to Kaminsky[4] the coefficient B has a negative temperature coefficient for the highly hydrated ions like Li^+, Be^{2+}, Mg^{2+}, Ce^{3+}, *etc.*; on the other hand, B has a positive temperature coefficient for the less hydrated ions like Cs^+, Rb^+, I^-, NO_3^-, *etc.* These results led him to suggest that the former are net structure makers while the latter are net structure breakers in aqueous solutions. Nightingale[5] and Kay and coworkers[6] concluded that Pr_4N^+ and Bu_4N^+ ions are excellent structure promoters but Me_4N^+ ion is a net structure breaker, while the structure breaking and making effects almost balance one another for Et_4N^+ ion in aqueous solutions. In view of the current interest in the behaviour of R_4N^+ ions, on account of their "abnormal" properties in aqueous solutions and of their special structual features, one is tempted to investigate their behaviour in solvents other than water but similar to water in having high dielectric constant so that the complications arising out of ion-association may be avoided. Some interesting solvents of this type are monoalkyl-substituted amides, *e.g.*, NMF, NMA and *N*-methylpropionamide (NMP).

The present communication reports a study of the ion-solvent interaction of R_4NI salts in NMF from the viscosity data. Some common salts like LiCl, KI and CsI have also been included in the study for the sake of comparison.

Experimental

R_4NI salts were purified in the usual manner as described.[1] Merk's A. G. reagents LiCl, KI and CsI were twice recrystallized from conductivity dried in an electric oven and were kept in a vacuum desiccator until used.

NMF, obtained from M/s Distillation Products Industries, U.S.A., was left overnight on some freshly ignited quicklime and was then distilled under reduced pressure. The middle fraction of the distillate was collected and redistilled. The process of purification was continued until the specific electrical conductance of the middle fraction of the distillate was reduced to less than 10^{-6} ohm^{-1} cm^{-1}. The purified samples were collected in dark amber-coloured bottles which were kept in a dry box. A rapid variation in electrical conductance and viscosity of NMF with time was observed immediately after distillation. However, after several hours the changes were slow. Hence NMF was used after keeping it for about 24 hr.

Measurements of density and viscosity were carried out in a thermostat with maximum temperature fluctuation ± 0.01°C. Solutions were prepared on molar basis at 25°C and were corrected for the changes in volume at other temperatures.

Density was determined with a dilatometer which was provided with a graduated stem on which volume could be read upto 0.005 m*l* within an error of ±0.002 m*l*. A modified Ubbelohde viscometer with a flow time of about 500 sec, for NMF at 25°C, was employed for measuring the viscosity. The readings within the maximum deviation of ±0.1 sec were recorded and taken into account while the widely varying ones were discarded. A 40% sugar solution of known viscosity was used to determine the viscosity of NMF. The density and viscosity of NMF determined at different temperatures, were found to agree very closely to those reported in literature as is clear from the following table:

Temp. °C	Density and Viscosity of NMF			
	Density in g/ml		Viscosity in poise	
	Exptl.	Literature*	Exptl.	Literature*
25	0.9990	0.9988	0.0168	0.0165
30	0.9947	—	0.0155	—
35	0.9905	—	0.0144	—

* C.M. French and K.H. Glover, *Trans. Faraday Soc.*, **51**, 1418 (1955).

The viscosity of solution was calculated with help of the usual relation, namely,

$$\eta = \frac{d}{d_0} \times \frac{t}{t_0} \times \eta_0 \qquad \text{(ii)}$$

The viscosity data were subjected to the kinetic energy corrections which were usually negligible. From the corrected data, the factors $\eta_{sp}/\sqrt{C}$ ($\eta_{sp}=\eta/\eta_0-1$) were obtained for different solutions at various temperatures. The values of $\eta_{sp}/\sqrt{C}$ are given in Table 1. The factor $\eta_{sp}/\sqrt{C}$ was plotted against $\sqrt{C}$ for different salts at different temperatures. The plots are almost linear, the slopes of which give the values of B and are summarized in Table 2, whereas the ordinate intercepts give the coefficients A (which represent the contribution from interionic forces[7]).

Table 2. Viscosity B coefficients in *N*-methylformamide

Results and Discussion

It may be noted from Table 2 that B values increase with the increase in the radius of the ion, *i.e.*, dB/dr (r being the radius of the ion) is positive, which leads to the conclusion that R_4N^+ ions behave, more or less, like large spheres moving in a dielectric continuum as was postulated by Einstein. The value of B according to the Einstein theory[8] is given by:

$$B = 2.5(v/C) \qquad \text{(iii)}$$

where v is the total volume of the ions per ml of solution and C the molar concentration. So, for a particular solvent the value of B for different ions should be proportional to v. If the crystal radii of these ions as estimated by Robinson and Stokes[9] are used, it is found that $B \propto r^3$ as is clear from Fig. 1, in which the experimental values of B are plotted against r^3. Thus the ion-solvent interaction as shown by the dependence of B on radius of the R_4N^+ ions, shows that the larger the ion, the greater the resistance for its movement in the solvent medium and there is no other ion-solvent interaction. However, the variation of B with temperature does indicate some interaction.

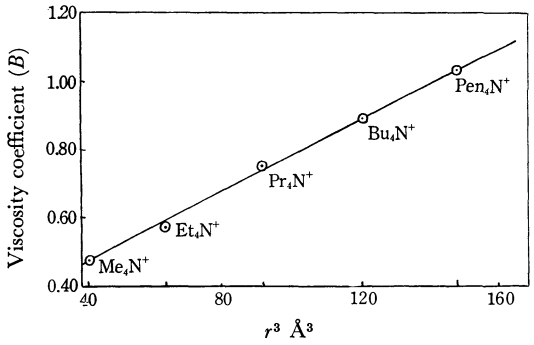

Fig. 1 *N*-Methylformamide temperature 35°C.

B values given in Table 2 indicate that dB/dt is positive for the R_4NI salts and negative for common electrolytes like LiCl, KI, CsI studied here in NMF. A positive dB/dt implies a net structure-breaking of the solvent at lower temperature in the presence of R_4NI salts so that the local viscosity around the ions does not decrease with temperature rise as rapidly as the viscosity η_0 of the pure solvent. The temperature coefficient (*i.e.*, dB/dt) is negative for common electrolytes containing cations like Li^+, K^+, Cs^+ *etc.*, because of the possible long range ordering (or secondary solvation) of the solvent molecules around them. As the temperature rises, long range ordering is disturbed by the thermal agitation and the local viscosity around the ions decreases faster than η_0 and this leads to a negative dB/dt. Although R_4NI salts appear to be structure breakers in these solvents, they do not give rise to long range ordering because of the low surface charge density, and hence dB/dt is positive. This is in contrast with their behaviour in aqueous solutions in which the temperature coefficient of B, *i.e.*, dB/dt, is negative[5,6] for the R_4N^+ (except Me_4N^+); this has been explained on the ground of the strong "hydrophobic solvation" of the R_4N^+ ions; strong hydrophobic solvation is equivalent to long range ordering of the water structure, similar to the electrostatic hydration of Li^+, Be^{2+}, Mg^{2+} and Ce^{3+} ions for which dB/dt is negative.[4-6,10] For larger common cations and for the halide ions, dB/dt is positive in aqueous solutions. In NMF, such hydrophobic ordering of the solvent by R_4NI salts does not occur, presumably because the solvents and R_4N^+ ions have methyl or similar organic groups, in both of them making the solvent and the solute similar in nature.

It appears that structure breaking effect goes on decreasing with the increase in the radius of the ion. This can be expected because the larger R_4N^+ ions have low surface change density; so the electrostatic ion-solvent interaction is not strong enough to break the hydrogen-bonded structure of the solvent.

It appears that R_4N^+ ions are net structure breakers (in the sense of breaking of hydrogen bonds) whereas the alkali metal ions are structure promoters (*i.e.*, the long range order makers) in NMF solutions.

The author thanks Dr. Ram Gopal for providing the laboratory facilities and valuable suggestions.

Oxidation of Substituted Glycollic Acids by Ce(IV) in Sulphuric Acid Solutions

V. K. GROVER and Y. K. GUPTA

Department of Chemistry, University of Rajasthan, Jaipur, India

(Received December 15, 1969)

A comparison of the rate constants, dissociation constants, tendency of complex formation and catalytic activity of Mn(II) in the oxidation of substituted glycollic acids (benzilic, DL-atrolactic, 2-hydroxyisobutyric, *p*-chloromandelic, *p*-bromomandelic, mandelic and lactic acids) by Ce(IV) in sulphuric acid solutions has been made. Hydrolyzed species of Ce(IV) are reactive and the kinetics conform to the empirical rate law

$$-\frac{d[Ce(IV)]}{dt} = \frac{kK[Ce(IV)][Org.\ Acid]}{[HSO_4^-]^2([H^+]+K[Org.\ Acid])}$$

The reactivity and the chelating tendency of the acids seem to follow the substituent order, $C_6H_5 > CH_3 > H$. The catalytic activity of Mn(II) appears to follow the same order as in the oxidation of these acids by Mn(III).

Oxidation of glycollic acid by Ce(IV) has been studied by McAuley,[1] and Bakore *et al.* and rupture of C–H bond is said[2] to be rate determining. In the oxidation of substituted acids also, *i.e.*, mandelic and lactic acids, Krishna and Tewari,[3] and Bhargava *et al.*[4] assume the same mechanism, while Kemp and Waters[5] from their experiments with deuterated mandelic acid showed that the slow step preferably involves C–C bond breaking. A detailed systematic study was, therefore, considered desirable and the present paper reports and compares the rate and other data of the phenyl and methyl substituted acids.

Experimental

Reagents. Ceric sulphate (E. Merck G. R.) was used without further purification. Benzilic, mandelic, *p*-chloromandelic and *p*-bromomandelic acids were Riedel products. DL-Atrolactic and 2-hydroxyisobutyric acids were obtained from Koch-Light Co. All other chemicals were either B.D.H. Analar and E. Merck G. R. quality.

Preparation of Solutions. Ce(IV) solutions in sulphuric acid were prepared as described[6] earlier. Ceric perchlorate was prepared in the following way. Ceric ammonium hydroxide was precipitated from a solution of ceric ammonium nitrate by ammonium hydroxide. The precipitate was allowed to settle (48 hr), leached several times with water, dissolved in perchloric acid and filtered. Ce(IV) solutions were standardized against ferrous ammonium sulphate using *N*-phenyl anthralinic acid indicator. Solution of benzilic, mandelic, *p*-chloromandelic and *p*-bromomandelic acids were prepared by dissolving them in equivalent amounts of caustic soda and adjusting the pH between 6—8. 2-Hydroxyisobutyric acid was dissolved in hot water. All other acids were soluble in cold eater.

Kinetic Procedure. Reactions were carried out at 35±0.05°C in a thermostat. They were initiated by adding a temperature equilibrated solution of the organic acid to the reaction vessel containing the desired amount of ceric solution, sulphuric acid and water at 35°C. The kinetics were followed by removing a 10 m*l* aliquot portion after suitable intervals and quenching the reaction by adding it to a known excess of ferrous ammonium sulphate solution. The excess was determined against standard ceric solution using *N*-phenylanthranilic acid indicator. The maximum error in the analysis of the aliquots was ±0.02 m*l* of Ce(IV). This introduced an error of ±1 to 6% in the rate constants depending on the volume of the titrant. In most cases duplicate rate measurements were reproducible to ±5%.

Spectrophotometric Work. Optical density measurements were made on Beckmann spectrophotometer (DU-G 2400) using 1 cm cell. Measurements were carried out to obtain information about the complex formation between Ce(IV) and the organic acid. All the measurements were done in perchloric acid solutions because in sulphuric acid solutions strong sulphate complexes of Ce(IV) are formed, and any complex with the organic substrate, even if formed, would not be indicated spectrophotometrically.

Ionization Constants. Ionization constants of the organic acids were determined in water-dioxane (1:4 v/v) potentiometrically.

5) T. J. Kemp and W. A. Waters, *J. Chem. Soc.*, **1964**, 1192.

Stoichiometry. The stoichiometry was determined as described[6] earlier. In each case two moles of Ce(IV) were used up by one mole of the organic acid. The products of oxidation, benzophenone, *p*-chlorobenzaldehyde, *p*-bromobenzaldehyde, methyl ethyl ketone and acetone were estimated either as such or as hydrazones. The yields were 70—80%. The volume of carbon-dioxide was measured in case of benzilic acid and was found to be about 90% of the expected amounts. Stoichiometry for lactic and glycollic acids was not determined, but it is reported[3] to be 5.75 and 4 mol of Ce(IV) for each mole of the acid respectively.

Products. The products of oxidation of the organic acids were as follows:

Benzilic acid - benzophenone; *p*-chloromandelic acid - *p*-chlorobenzaldehyde; *p*-bromomandelic acid - *p*-bromobenzaldehyde; DL-atrolactic acid - methyl phenyl ketone; 2-hydroxyisobutyric acid - acetone. Products of oxidation of lactic and glycollic acids have already been identified. Benzophenone and *p*-bromobenzaldehyde were obtained as white insoluble solid from concentrated solution. They were recrystallised from alcohol or benzene and were identified by melting points, IR spectra and other tests. In the case of *p*-chloromandelic acid, the white crude solid product responds to the tests of *p*-chlorobenzaldehyde, but it undergoes slow air oxidation yielding the acid. It is interesting to note, however, that experiments on stoichiometry indicate no oxidation of *p*-chlorobenzaldehyde by Ce(IV). Acetone was identified in the form of hydrazone. Methyl phenyl ketone was obtained as a solid at about 0°C and was identified by the melting point and its characteristic hydrazone.

Results and Discussion

The orders with respect to the various reactants conform to either of the following two empirical rate laws:

$$-\frac{d[Ce(IV)]}{dt} = \frac{k_{11}[Ce(IV)][Org.\ Acid]}{[HSO_4^-]^2[H^+]} \quad (1)$$

and

$$-\frac{d[Ce(IV)]}{dt} = \frac{kK[Ce(IV)][Org.\ Acid]}{[HSO_4^-]^2([H^+]+K[Org.\ Acid])} \quad (2)$$

The results are shown in Table 1 and Figs. 1 and 2. Although kinetic evidence for complex formation has been obtained[6] only in the case of benzilic acid, spectrophotometric results provide evidence in all the cases and hence in general, rate law (2) appears to be applicable in all the cases. The various equilibria,[6-9] involving the cerium(IV) species and the mechanism are given below:

$$Ce^{4+} + H_2O \overset{K_{h1}}{\rightleftharpoons} CeOH^{3+} + H^+ \quad (3)$$

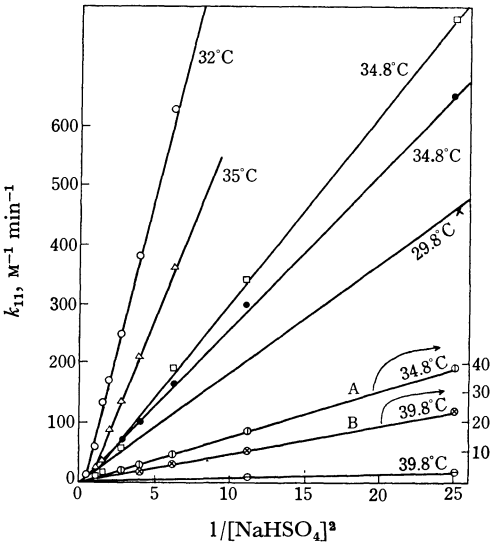

Fig. 1. Effect of bisulphate ion.
$[HClO_4]=0.5$M. ○, benzilic acid; △, atrolactic acid; ●, mandelic acid; □, *p*-chloromandelic acid; ×, *p*-bromomandelic acid; ⊕, 2-hydroxy isobutyric acid; ⊗, lactic acid; ⊖, glycollic acid. Straight lines A and B refer to the right scale.

$$CeOH^{3+} + H_2O \overset{K_{h2}}{\rightleftharpoons} Ce(OH)_2^{2+} + H^+ \quad (4)$$

$$Ce^{4+} + HSO_4^- \overset{K_5}{\rightleftharpoons} CeSO_4^{2+} + H^+ \quad (5)$$

$$CeSO_4^{2+} + HSO_4^- \overset{K_6}{\rightleftharpoons} Ce(SO_4)_2 + H^+ \quad (6)$$

$$Ce(SO_4)_2 + HSO_4^- \overset{K_7}{\rightleftharpoons} HCe(SO_4)_3^- \quad (7)$$

$$\text{Org. Acid} \overset{K_d}{\rightleftharpoons} \text{Anion} + H^+ \quad (8)$$

$$R_1\!\!\diagdown\!\!\overset{OH}{\underset{}{C}}\!\!\diagup\!\!R_2 \quad \diagdown\!\!COO^- + Ce(OH)_2^{2+} \overset{K_9}{\rightleftharpoons}$$

$$\left[R_1\!\!\diagdown\!\!\overset{H}{\underset{}{C}}\!\!\diagup\!\!R_2 \quad O\!\!\diagdown\!\!Ce(OH)_2 \quad \diagdown\!\!COO\!\!\diagup\right]^+ \quad (9)$$

(complex)

$$\text{Complex} \xrightarrow[\text{slow}]{k_{10}} R_1\!\!\diagdown\!\!\overset{H}{\underset{}{C}}\!\!\diagup\!\!R_2 \quad O + CO_2 + Ce(III) \quad (10)$$

$$R_1\!\!\diagdown\!\!\overset{H}{\underset{}{C}}\!\!\diagup\!\!R_2 \quad O + Ce(IV) \xrightarrow{\text{fast}}$$

$$R_1\!\!\diagdown\!\!C{=}O + Ce(III) + H^+ \quad (11)$$
$$R_2\!\!\diagup$$

The predominant species[8,9] of Ce(IV) is $Ce(SO_4)_2$ in bisulphate solutions employed in this work, but the reactive species as indicated by bisulphate and hydrogen ion effects, is $Ce(OH)_2^{2+}$. The rate law can be deduced only on such basis.

6) V. K. Grover and Y. K. Gupta, *J. Inorg. Nucl. Chem.*, **31**, 1403 (1969).
7) S. K. Mishra and Y. K. Gupta, *ibid.*, **29**, 1643 (1967).
8) T. J. Hardwick and E. Robertson, *Can. J. Chem.*, **29**, 828 (1951).
9) F. G. Soper, *J. Chem. Soc.*, **1935**, 802.

The above equations and equilibria lead to the rate law

$$-\frac{d[Ce(IV)]}{dt} = \frac{2k_{10}K_9K_{h1}K_{h2}K_d[Ce(IV)][Org.\ Acid]}{K_5K_6[HSO_4^-]^2([H^+]+K_9K_d[Org.\ Acid])} \quad (12)$$

which has the same form as (2). An alternative mechanism conforming to the rate law (1) is as follows.

$$Ce(OH)_2^{2+} + Anion \xrightarrow{k_{13}}$$
$$Org.\ free\ radical + CO_2 + Ce(III) + H^+ \quad (13)$$

$$Org.\ free\ radical + Ce(IV) \xrightarrow{fast}$$
$$product + Ce(III) \quad (14)$$

The complete rate law similar to (1) is:

$$-\frac{d[Ce(IV)]}{dt} = \frac{2k_{13}K_{h1}K_{h2}K_d[Ce(IV)][Org.\ Acid]}{K_5K_6[HSO_4^-]^2[H^+]} \quad (15)$$

These rate laws explain the observed order of the bisulphate ion. The rate decreases by the increase of hydrogen ion too, but a plot of k_{11} (observed second order rate constant) against $1/H^+$ does not yield a straight line as expected from (1) or (15). Thus these rate laws are not of the correct form so far as hydrogen ion dependence is concerned. On the other hand (2) or (12) conform to the observed hydrogen ion dependence (Fig. 2), but absence of kinetic evidence for complex formation does not justify their forms. Unfortunately the study with regard to hydrogen ion effect and complex formation could not be made under identical conditions. The effect of hydrogen ion was studied by varying perchloric acid concentration in a constant bisulphate medium. The reaction was fast in this medium. It could be made of measurable speed only by employing low concentrations of the reactants, particularly the organic acid, and consequently a study of complex formation could not be made.

Under such a situation, in view of the general characteristics of Ce(IV) oxidation of hydroxy acids, tendency of complex formation from optical density measurements and kinetic evidence for the complex formation in the oxidation of benzilic acid,[6] we are inclined to regard (12) as the correct form of the rate expression. However, since no kinetic evidence for complex formation has been obtained in other cases, it is better to retain it in the same form but with 'A' as unspecified constant in the denominator in place of K_9K_d[Org. Acid]. The second order rate constant, k_{11} which has no reference to Eq. (11) can be defined by

$$k_{11} = \frac{2k_{10}K_9K_dK_{h1}K_{h2}}{K_5K_6[HSO_4^-]^2([H^+]+A)} \quad (16)$$

Ce(IV) oxidation in general is without any isotopic effect as shown by Waters and coworkers in the oxidation of deuterated alcohols[10] and mandelic acid.[5] We have also carried out rate experiments with deuterated acids and the ratio k_H/k_D was in no case more than 1.1. Hence C–C fission is considered to be rate determining in the oxidation. The products of oxidation of the organic acids also support the involvement of C–C cleavage in the slow step. On the other hand Cr(VI) and V(V) oxidation is characterized by large isotopic effect suggesting C–H fission. Reactions in the presence of acrylamide further show that C–C fission occurs with the evolution of carbon dioxide. Acrylamide does not react[11] with Ce(IV), but it captures the free radical produced in step (10). This strongly suggests that carbon dioxide is produced in the slow step rather than in the fast step suggested by other workers.[2,3,12]

Mn (II) greatly catalyzes all these oxidations as is obvious from Fig. 3. These results can be expressed in the form

$$k_T = k_{11} + k_{Mn}[Mn(II)] \quad (16a)$$

where k_T and k_{11} are the rate constants in the presence and absence of Mn(II) and k_{Mn} is the specific rate constant for the catalyzed path. The catalytic activity of Mn(II) is ascribed to the rapid equilibrium[13]

$$Ce(IV) + Mn(II) \rightleftharpoons Ce(III) + Mn(III) \quad (17)$$

and the larger rate[5,14] for the oxidation of the organic acids by Mn(III). Table 1 shows the various data for all the acids. Mandelic acid is more readily oxidized than 2-hydroxyisobutyric acid[14] or lactic acid[15] by Mn(III) sulphate. Some visual observations have also indicated that the order of oxidation of different acids by Mn(III) is the same as given by the values of k_{Mn} of Table 2.

Spectrophotometric results indicate complex formation between Ce(IV) and the organic acid. Absorption curves typical of complex formation have

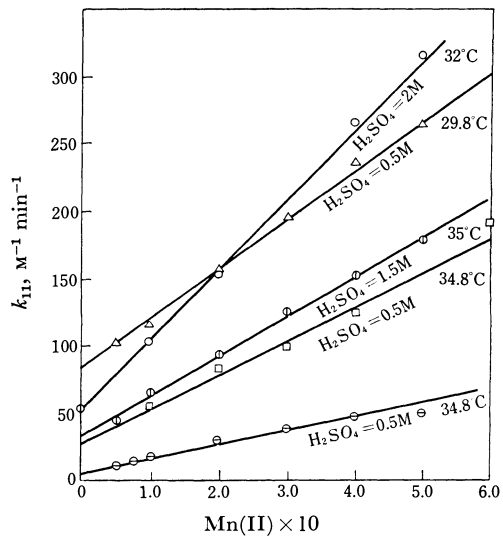

Fig. 3. Effect of Mn(II) on the oxidations of organic acids by Ce(IV).

been shown earlier[6] in the oxidation of benzilic acid. Similar curves were obtained for mandelic, *p*-chloromandelic, *p*-bromomandelic and DL-atrolactic acids. Flat bands with less absorption than that of Ce(IV) were obtained in case of 2-hydroxyisobutyric, lactic and glycollic acids. Complex formation seems to depend on two factors; the ionization constant of the organic acid and the substituted group C_6H_5 or CH_3 for H in CH_2. The ionization constants are in the sequence as expected from the $-I$ effect of C_6H_5 and $+I$ effect of CH_3 groups, it being largest for two C_6H_5 groups (benzilic acid) and lowest for two CH_3 groups (2-hydroxyisobutyric acid). The larger the ionization constant the greater is the tendency of complex formation as is obvious from Eq. (9). Another factor which seems to influence this tendency is the size of the group. A bulky group like C_6H_5 in benzilic acid facilitates complex formation. The larger value of the equilibrium constant[16] in case of *trans*-1,2-cyclohexanediol than that of *trans*-2-methoxycyclohexanol, has been explained on the basis of the steric hindrance. The same reason has been assigned to the failure for the complex formation by 2,3-butanediol as compared to ethylene glycol.[10] At first sight the formation of a complex in case of benzilic acid seems to violate the principle of steric hindrance, but closer examination would reveal that the steric hindrance of the phenyl groups brings the hydroxyl and the carboxyl groups closer facilitating the chelate formation with Ce(IV). On the other hand in case of *trans*-2-methoxy-cyclohexanol and 2,3-butanediol the substitution is in the hydroxyl group which may prevent the chelate formation. No maximum was obtained for lactic and 2-hydroxyisobutyric acids. On the other hand the corresponding absorption curves run below the curve of Ce(IV). A probable explanation for this may be the fact that the steric effect of the methyl group is less important than its inductive effect as suggested,[17] in the rare earth chelates of these organic acids. Kinetic evidence for the complex formation was obtained only in the case of benzilic acid obviously because both the factors, inductive and steric effects of the phenyl group act in the same direction.

The order of reactivity of different acids in general can be explained on the basis of free radical character developing in the activated complex at the carbon atom.[19] The formation of free radical is facilitated by the substituents of R in the order $C_6H_5 \gg CH_3 > H$.

k_{11} of Table 2 is a complex rate constant. It may be regarded as a product kK, where k and K are rate and equilibrium constants, respectively. It has not been possible to separate these two constants but it appears that the overall rate constant k_{11} follows the same order as that of the tendency of complex formation. Co(III) and V(V) oxidation of these acids also probably takes place *via* complex formation. The overall rate constants are in the same order, *i.e.*, atrolactic>mandelic>2-hydroxyisobutyric>lactic in 3.14M $[ClO_4^-]$ at 15°C in the case of Co(III)[20,21] and, mandelic>2-hydroxyisobutyric>lactic in 5M $[ClO_4^-]$ at 25°C in the case of V(V).[22]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2450—2457 (1970)

Polarographic Study of Metal Complexes. X.[1] The Disulfitotetracyanocobaltate(III) Complex[2]

Nobufumi MAKI and Kouei YAMAMOTO*1

Department of Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received December 25, 1969)

The sodium disulfitotetracyanocobaltate(III), $Na_5[Co^{III}(SO_3)_2(CN)_4]\cdot 3H_2O$, was found to be irreversibly reduced in one step to the cobalt(I) state in a 0.5M Na_2SO_3 aqueous solution at the dropping mercury electrode (DME). As for the resulting cobaltate(I) complex, neither further reduction to the metal nor oxidation was observed in the potential range of 0——2.0 V (*vs.* SCE). Above 40°C, a partial reduction to the metal was observed to take place at about −1.9 V (*vs.* SCE). The reduction was interpreted as being of the "*inert-inert*" type, as shown below:

$$trans\text{-}[Co^{III}(SO_3)_2(CN)_4]^{5-} \xrightarrow{2e} trans\text{-}[Co^{I}(SO_3)_2(CN)_4]^{7-}.$$

Here, the disulfito complex was presumed to take a *trans*-configuration rather than that of a *cis*-form on the evidence of its polarographic behavior and the absorption spectrum. That is, the tetracyano complexes with a *cis*-configuration are considered to be reduced to the metal, whereas those with a *trans*-configuration are reduced to the cobalt(I) state, and not to the metal polarographically, at the DME.

In earlier papers,[3] we reached some significant conclusions about the electrode reaction of the tetracyanocobaltate(III) complex, $K[Co^{III}(CN)_4en]\cdot H_2O$ (*cis*-form). Namely, the *cis*-$[Co(CN)_4en]^-$ ion gave rise to an apparent one-step wave of a three-electron reduction, representing a direct reduction from the cobalt(III) complex to the metal in aqueous solutions at the DME. In the presence of ethylenediamine (2M), however, the *cis*-$[Co(CN)_4en]^-$ ion was reduced to the metal *via* the cobaltate(I) complex. The hexa-coordinated cobalt(I) ion $[Co^{I}(CN)_4en]^{3-}$, was presumed to be able to exist under the conditions where aquation is prevented.

Recently, in examining the *cis*-dicyanobis(ethylenediamine)cobalt(III) complex polarographically, we ascertained the binuclear tetracyanocobaltate(II) ion,[4] $[Co^{II}(CN)_4\text{-}en\text{-}Co^{II}(CN)_4]^{4-}$, to be formed in the course of reductions by the rearrangement of cyanide ligands; the ion undergoes the step-by-step reduction of Co(II)→Co(I)→Co(0) at the DME.[5]

In connection with these results, several kinds of pentacyanocobaltate(III) complexes of the $[Co^{III}X(CN)_5]$-type have also been reported to be all reduced to the cobalt(I) state in aqueous solutions at the DME.[6-8] Neither further reduction of the pentacyanocobaltate(I) complex to the metal nor oxidation from the cobalt(I) state was observed in the potential range of 0——2.0 V (*vs.* SCE).

The present paper is concerned with the behavior of the disulfitotetracyanocobaltate(III) complex, $Na_5[Co(SO_3)_2(CN)_4]\cdot 3H_2O$, in aqueous solutions.

Experimental

Apparatus. A Yanagimoto Polarograph, Model P8-DP, was used for the measurements of the d.c. polarograms. The *iR* drop was corrected automatically with a compensator for the liquid resistances, Yanagimoto Model P8-PT. The other experimental set-up and the measurements were the same as those employed previously.[3,5] The characteristics of the capillary used were as follows: $m=1.38$ mg/sec, $t=4.50$ sec, both measured on an open circuit in a 0.5M Na_2SO_3 aqueous solution (25°C).

The absorption spectra in the visible and ultraviolet regions were determined manually with a Beckmann DU spectrophotometer.

Materials. The complex, $Na_5[Co(SO_3)_2(CN)_4]\cdot 3H_2O$,*2 was prepared by the method of Rây and Chackrabarty[9] and purified according to the directions of Chen *et al.*[10] The purifications were essential for obtaining the pure aimed-at complex and were carried out five times here. The complex thus obtained has this formula: $Na_5[Co(SO_3)_2(CN)_4]\cdot 12H_2O$ (orange-yellow); it is efflorescent in an open state and the crystallization water is lost partly in the air. The anhydrous salt, which had been dried *in vacuo* at 100—110°C (in an Abderhalden apparatus) for six hours, assumed a brown color and was very hygroscopic. Hence, the trihydrate salt used for the polarographic measurements was obtained by drying it *in vacuo* at 60°C overnight. Found: Co, 11.57; C, 10.03; N, 11.30; H, 1.35%. Calcd for $Na_5[Co(SO_3)_2(CN)_4]\cdot 3H_2O$: Co, 11.98; C, 9.76; N, 11.39; H, 1.23%.

The diaquotetracyanocobaltate(III) complex, $K[Co(OH_2)_2(CN)_4]\cdot \frac{3}{4}H_2O$, was also prepared by the method of Rây and Chackrabarty[9] according to the following reaction of scheme:

$$Na_5[Co(SO_3)_2(CN)_4]\cdot 3H_2O \xrightarrow{HNO_3} [Co(SO_4)_2(CN)_4]^{5-} \xrightarrow{H_2O} [Co(OH_2)_2(CN)_4]^- \xrightarrow{AgNO_3} Ag[Co(OH_2)_2(CN)_4]\ \text{ppt.} \xrightarrow{KI} K[Co(OH_2)_2(CN)_4]\cdot \tfrac{3}{4}H_2O.$$

The diaquo complex can not be stored for more than two weeks, because it decomposes gradually even in the solid state to yield an unknown product insoluble in water. The causes of this deterioration are not clear, but probably it is due to the polymerization of the complex. Therefore, the elementary analyses and the polarographic measurements were always carried out on a freshly-prepared complex. Found: Co, 24.09; C, 19.83; N, 22.97; H, 1.62%. Calcd for $K[Co(OH_2)_2(CN)_4]$: Co, 24.75; C, 20.18; N, 23.53; H, 1.69%.

The sulfitopentacyanocobaltate(III) complex, $K_4[Co(SO_3)(CN)_5]\cdot 3H_2O$, was prepared from the $K_3[CoBr(CN)_5]$ complex by the method of Fujita and Shimura.[11] Found: Co, 12.26; C, 12.38; N, 14.77; H, 1.32%. Calcd for $K_4[Co(SO_3)(CN)_5]\cdot 3H_2O$: Co, 12.29; C, 12.52; N, 14.61; H, 1.26%. The other complexes used in this work were lots prepared in our previous experiments.[3,5]

Results and Discussion

The disulfito complex, $Na_5[Co^{III}(SO_3)_2(CN)_4]\cdot 3H_2O$, gave rise to a well-defined wave of one step at the DME in a 0.5M sodium sulfite supporting electrolyte. This wave, corresponding to a gain of two electrons, represents the reduction from the cobalt(III) to the cobalt(I) state. No further reduction to the metal was found over the potential range of 0——2.0 V (*vs.* SCE). Figure 1 shows the dependence of the current-potential curves upon the concentration of the complex in the 10^{-2}—10^{-3}M range in a 0.5M Na_2SO_3 aqueous solution. In the figure, the current-scale is individually curtailed, lest it should change with the concentration of the complex. Scarcely no changes were found in the

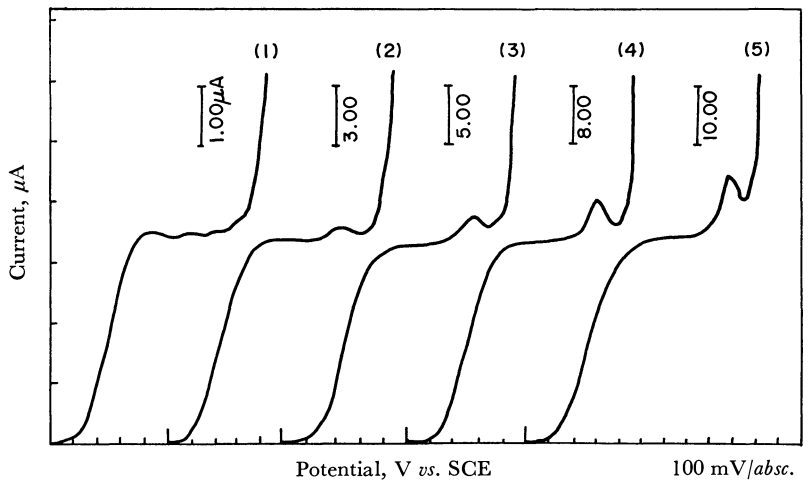

Fig. 1. The dependence of the current-potential curves upon the concentration of the complex, $Na_5[Co(SO_3)_2(CN)_4]\cdot 3H_2O$, in a 0.5M Na_2SO_3 aqueous solution (25°C). Concentration of the complex, (1) 10^{-3}; (2) $3\cdot 10^{-3}$; (3) $5\cdot 10^{-3}$; (4) $8\cdot 10^{-3}$; (5) 10^{-2}M; recorded from −1.00 V (*vs.* SCE).

*2 The sulfite ion, OSO_2^{2-}, can be bound to the cobalt either by the oxygen or by the sulfur atom; the former is named the sulfito complex, and the latter, the sulfono complex.

TABLE 1. THE RELATIONSHIP BETWEEN THE HEIGHT OF THE MERCURY RESERVOIR AND THE LIMITING CURRENT

$h_{corr.}$ (cm)	i_l (μA)	$i_l/\sqrt{h_{corr.}}$
92.0	18.5	1.93
82.0	17.3	1.92
72.0	16.5	1.93
62.0	15.1	1.92
52.0	13.7	1.90
42.0	12.3	1.89

Concentration of the complex: $5.0 \cdot 10^{-3}$M in a 0.5M Na_2SO_3 i_l=the limiting current at -1.50 V *vs.* SCE (25°C)

shape of the wave with the concentration. The limiting current and the concentration of the complex were ascertained to be strictly linearly related in the concentration range of 10^{-4}—10^{-2}M.

Table 1 shows that the limiting current is proportional to the root of the height of the mercury reservoir; the values $i_l/\sqrt{h_{corr.}}$ are almost constant, irrespective of the mercury pressure.

Figure 2 shows the temperature-dependence of the limiting current in the range of 0—60°C. Above 40°C, the current values were seen to deviate from the straight line of the plot; the current increases remarkedly with the temperature, indicating a kinetically-controlled feature. This seems to be due to the disruption of the cobaltate(I) complex in solution. Below 40°C, the current increases linearly with the temperature; its coefficient was 1.70%/degree at 25°C. Figure 3 shows the temperature-dependence of the current-potential curves in a 0.5M Na_2SO_3 supporting electrolyte. On the whole, scarcely no deformations of the wave with the temperature were observed, but the partial reduction to the metal could be discerned to appear at around -1.98 V (*vs.* SCE) above 50°C.

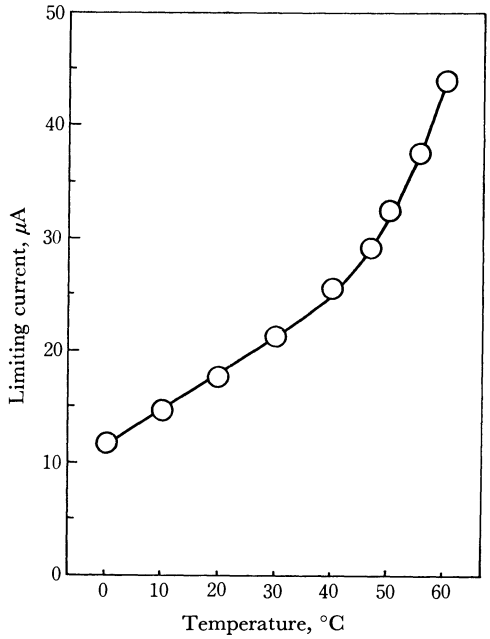

Fig. 2. The relationship between the limiting current and the temperature for the $Na_5[Co(SO_3)_2(CN)_4] \cdot 3H_2O$ complex in a 0.5M Na_2SO_3 solution (25°C).

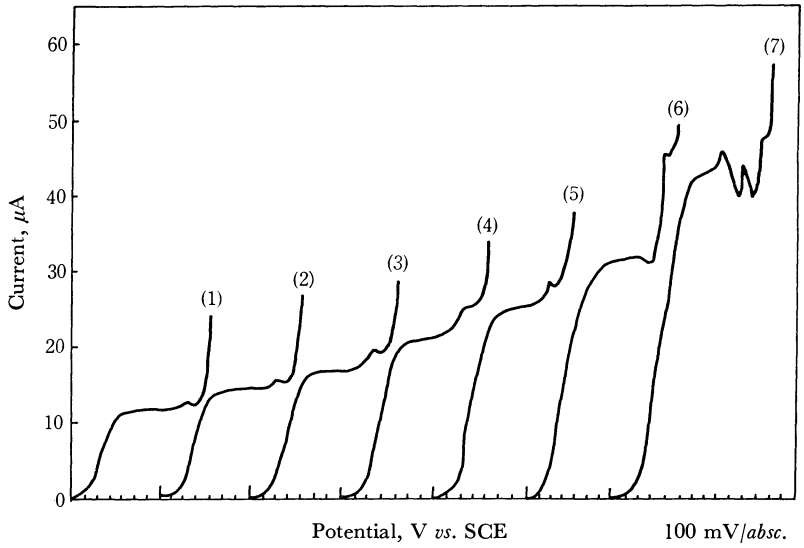

Fig. 3. The temperature-dependence of the current-potential curves for the $Na_5[Co(SO_3)_2(CN)_4] \cdot 3H_2O$ complex in a 0.5M Na_2SO_3 solution. The concentration of the comeplx, $5 \cdot 10^{-3}$M, the temperature, (1) 0; (2) 10; (3) 20; (4) 30; (5) 40; (6) 50; (7) 60°C. Recorded from -1.00 V (*vs.* SCE).

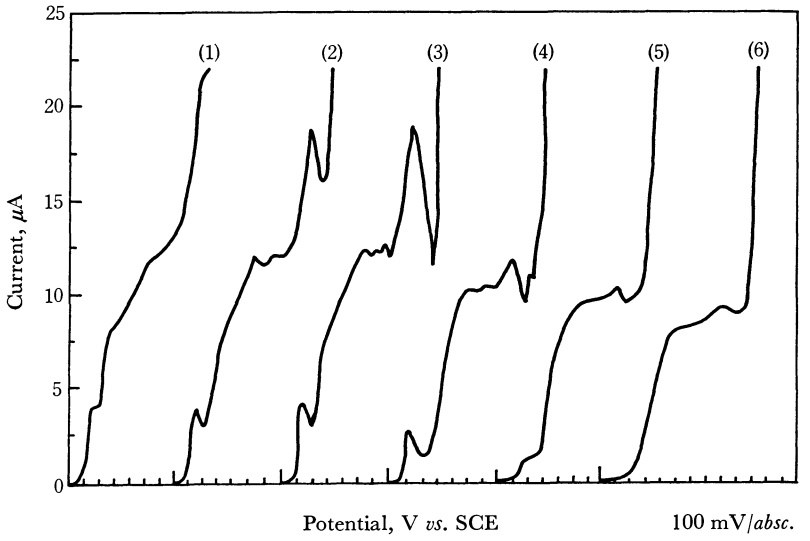

Fig. 4. The effect of sulfite ions upon the current-potential curves for the complex, $Na_5[Co(SO_3)_2(CN)_4]\cdot 3H_3O$, under a unit ionic strength ($Na_2SO_3+Na_2SO_4$). The concentration of SO_3^{2-} ions, (1) 0; (2) 0.005; (3) 0.01; (4) 0.05; (5) 0.1; (6) 0.5M. Recorded from −0.90 V (*vs.* SCE).

From these results, the limiting current may well be concluded to be diffusion-controlled below 40°C.

Figure 4 shows the effect of sulfite ions on the current-potential curves in solution under a unit ionic strength. The disulfitotetracyano complex has previously been described as not being able to exist stably in solution unless sulfite ions are present in excess. That is, the cobaltate(III) complex in solution decomposes with time to yield unknown yellow precipitates insoluble in water. Polarographic measurements were, however, practically possible on the freshly-prepared solution. The limiting current decreases with the increase in the concentration of the sulfite ions by about 15%.

Figure 5 shows oscillopolarograms of the Heyrovský-Forejt type photographed for the disulfito-, diaquo-tetracyanocobaltate(III), and sulfitopentacyanocobaltate(III) complexes in aqueous solutions. For the sulfito- and disulfito-complexes, only one incision was observed, at −1.26 or at −1.24 V (*vs.* Hg pool) respectively on the cathodic branch of the dE/dt - E curves, whereas no incision was found on the anodic branch; this is in agreement with the findings on the aquopentacyanocobaltate(I) ion by Kolthoff and Hume.[6] Moreover, in the solution not containing an excess of sulfite ions, the disulfitotetracyano complex also exhibited oscillopolarographic behavior quite similar to that in the presence of sulfite ions; neither further reduction to the metal nor oxidation from the tetracyanocobaltate(I) complex was found on the oscillopolarogram. On the other hand, for the diaquotetracyano complex, two incisions were recorded, at −0.59 and −1.39 V (*vs.* Hg pool) on the cathodic branch, while no incision was found on the anodic branch, just as above. The former two incisions correspond to the

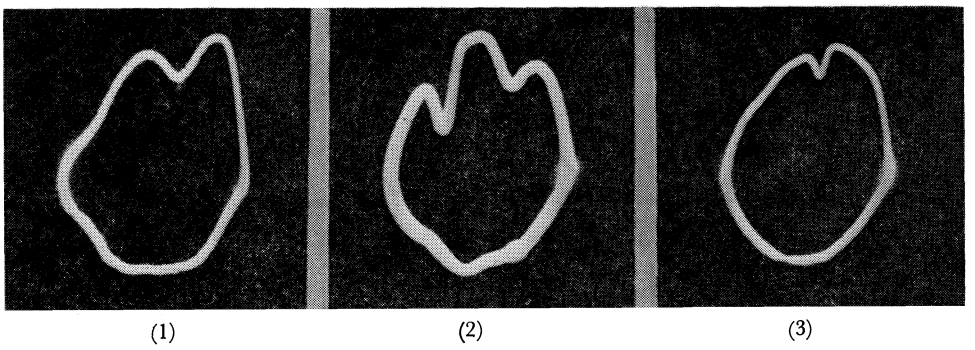

Fig. 5. The current-controlled oscillopolarograms of dE/dt-E curves measured at $5\cdot 10^{-3}$M complex ion (25°C). Voltage unit: V *vs.* Hg pool.

double wave in the conventional polarography, as will be described later. Therefore, we may conclude that the tetracyanocobaltate(I) complexes for these disulfito and diaquo complexes as well as for the sulfitopentacyano complex do not electrochemically take any oxidation at the DME.

From these results, it seems to be most likely that the following process of electrode reaction takes place at the DME:

$$\underset{inert}{trans\text{-}[Co^{III}(SO_3)_2(CN)_4]^{5-}} \xrightarrow{2e} \underset{inert}{trans\text{-}[Co^{I}(SO_3)_2(CN)_4]^{7-}}.$$

The cobaltate(III) and cobaltate(I) complexes may be considered to take a *trans*-configuration rather than that of a *cis*-form on the following evidence.

The diaquo complex, $K[Co^{III}(OH_2)_2(CN)_4]\cdot \frac{3}{4}H_2O$, which had been prepared from the disulfito complex was found to be reduced in two steps to the cobalt(I) state, but not to the metal at the DME, in a 0.5M Na_2SO_4 aqueous solution.

$$trans\text{-}[Co^{III}(OH_2)_2(CN)_4]^{-} \xrightarrow{e} trans\text{-}[Co^{II}(OH_2)_2(CN)_4]^{2-} \xrightarrow{e} trans\text{-}[Co^{I}(OH_2)_2(CN)_4]^{3-}.$$

On the other hand, the ethylenediaminetetracyano complex, $K[Co^{III}(CN)_4en]\cdot H_2O$ (*cis*-form), was found to be reduced directly to the metal in the same supporting electrolyte of a 0.5M Na_2SO_4 aqueous solution; no cobalt(II) and cobalt(I) states were detected by means of conventional polarography in the course of reductions.[3] The cobalt(I) state was detectable only in the presence of an excess of ethylenediamine, *i.e.*, under conditions where the aquation was prevented. In other words, the resulting cobaltate(I) ion, *cis*-$[Co^{I}(CN)_4en]^{3-}$, certainly aquates rapidly, unless an excess of ethylenediamines is present in the solution, to yield the *cis*-diaquo complex ion, *cis*-$[Co^{I}(OH_2)_2(CN)_4]^{3-}$. This diaquo-cobaltate(I) complex with a *cis*-form is immediately reduced to the metal at the DME.

Figure 6 shows the current-potential curves of the disulfitotetracyano and its related mixed cyanocobaltate(III) complexes measured in an aqueous solution under the same conditions, employing the same capillary, concentration, height of mercury head and temperature. Since the limiting currents to be investigated here are all diffusion-controlled, we can ascertain the number of electrons participating in the electrode process from the ratio of the wave-heights.

The electrode process for the tetracyano complex with a *cis*-form may be speculated to be as follows:

$$cis\text{-}[Co^{III}(CN)_4en]^{-} \xrightarrow{2e} cis\text{-}[Co^{I}(CN)_4en]^{3-} \xrightarrow{aquation} cis\text{-}[Co^{I}(CN)_4(OH_2)_2]^{3-} \xrightarrow{e} Co(metal).$$

in a 0.5M Na_2SO_4 aqueous solution.

In the dimethyl sulfoxide (DMSO), however,

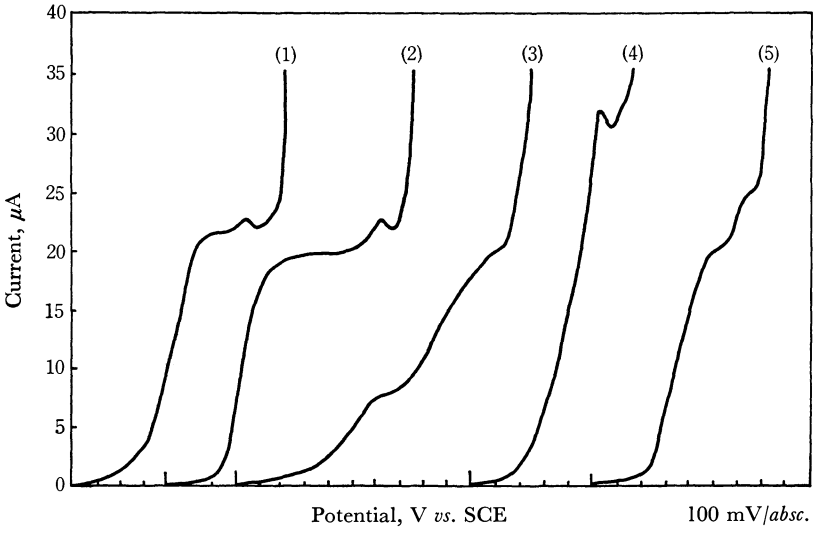

Fig. 6. The current-potential curves of the mixed cyano cobaltate(III) complexes at $5\cdot10^{-3}$ M complex ion measured under the same experimental conditions (25°C). The cobaltate(III) complexes are as follows: (1) $K_4[Co(SO_3)(CN)_5]\cdot 3H_2O$, recorded from −1.10 V; (2) $Na_5[Co(SO_3)_2(CN)_4]\cdot 3H_2O$ in 0.5M Na_2SO_3 solution, from −0.90 V; (3) $K[Co(OH_2)_2(CN)_4]\cdot \frac{3}{4}H_2O$, from −0.60 V; (4) $Na[Co(CN)_4en]\cdot 3.5H_2O$, recorded from −0.80 V; (5) $Na[Co(CN)_4en]\cdot 3.5H_2O$, in 0.5M Na_2SO_4 solution containing 1M ethylenediamine, recorded from −0.80 V (*vs.* SCE). The supporting electrolyte is an aqueous solution of 0.5M Na_2SO_4, except the cases (2) and (5).

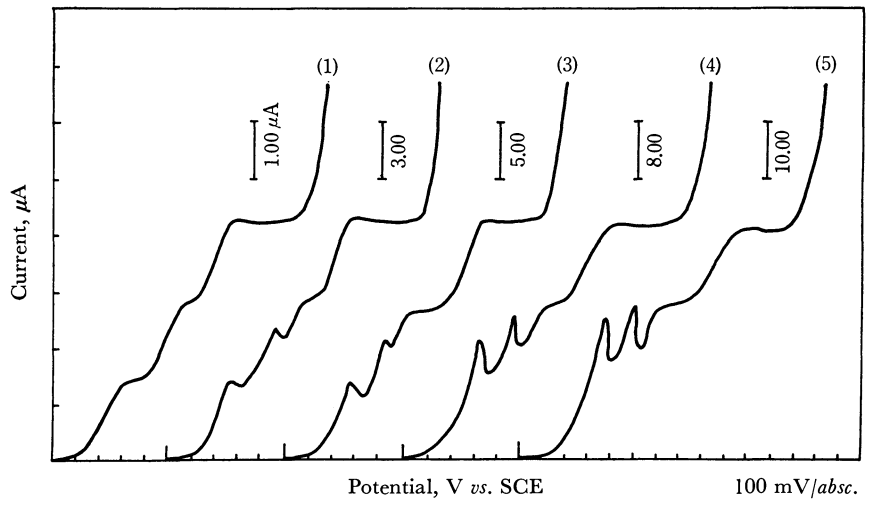

Fig. 7. The dependence of the current-potential curves upon the concentration of the complex, $Na[Co(CN)_4en]\cdot 3.5H_2O$, in the DMSO (100%) solution containing 0.1M $[(C_2H_5)_4N]ClO_4$(25°C). The concentration of the complex, (1) 10^{-3}; (2) $3\cdot10^{-3}$; (3) $5\cdot10^{-3}$; (4) $8\cdot10^{-3}$; (5) 10^{-2}M. Recorded from −1.40 V (*vs.* SCE).

the *cis*-tetracyano complex, $Na[Co^{III}(CN)_4en]\cdot 3.5H_2O$,*3 taking up three electrons, one by one, undergoes the step-by-step reduction of Co(III)→Co(II)→Co(I)→Co(*metal*) at the DME. In an aprotic non-aqueous solvent such as DMSO, it may be considered that all the cobalt complexes of the oxidized and reduced-forms are of the "*inert*" type for substitution, unlike those in aqueous solutions. Therefore, the cobaltate(III) complex may be presumed to be reduced, as it were, without any accompanying structural changes throughout the reduction; neither the aquation nor the rearrangements of ligands need be considered during reductions in DMSO. Hence, the *cis*-$[Co^{I}(CN)_4en]^{3-}$ ion of the "*inert*" type is interpreted as undergoing subsequent reduction to the metal in DMSO.

Figure 7 shows the dependence of the current-potential curves upon the concentration of the complex in the DMSO(100%) containing 0.1M $[(C_2H_5)_4N]ClO_4$. The following net processes of the electrode reaction are considered to be most reasonable:

$$\underset{inert}{cis\text{-}[Co^{III}(CN)_4en]^-} \xrightarrow{e} \underset{inert}{cis\text{-}[Co^{II}(CN)_4en]^{2-}} \xrightarrow{e}$$

$$\underset{inert}{cis\text{-}[Co^{I}(CN)_4en]^{3-}} \xrightarrow{e} Co(metal).$$

From the above-mentioned results, it would not be out of the way to assume that the tetracyanocobaltate(III) complexes with a *cis*-configuration are finally reduced to the metal *via* the cobalt(I) state, while those with a *trans*-configuration are reduced to the cobalt(I) state, but not to the metal at the DME. This difference in their polarographic behavior may be understood in terms of the configuration of four cyanides, which exerts a considerable effect on the stability of a cobalt(I) state, since the d^8-complexes of the univalent cobalt tend to get a coplanar structure with a *trans*-form rather than an octahedral configuration with a *cis*-form, a structure similar to that of nickel(II) complexes,

through a dsp^2-hybridization. Taking account of the Jahn-Teller effect, it might happen that, in solution, the coordinate bonds of the fifth and the sixth sulfite ligands became longer at the cobalt(I) state than those for the cobaltate(III) complex.

Figure 8 shows the absorption spectra of the tetracyano- and pentacyano-cobaltate(III) complexes in the visible and ultraviolet regions in water. Since the disulfito- and diaquo-complexes both gradually decompose even in a crystal state, the spectrum had to be measured in the solution of a freshly-prepared complex. The spectrum revealed that the disulfito complex can not be stored in the pure state for more than two weeks. In fact, the spectrum of the disulfito complex, $Na_5[Co(SO_3)_2(CN)_4]\cdot 3H_2O$, does not necessarily coincide in detail with that reported in 1941 by Kiss *et al.*[12]

Table 2 summarizes the absorption maxima and intensities of the cyano cobaltate(III) complexes measured in water. The first d–d transition band shifts towards a shorter wavelength in the following order of ligands: OH_2, SO_3, en. According to Shimura and Tsuchida,[13] however, the spectrochemical series for both the *cis*-tetrammine- and *cis*-bis(ethylenediamine)-cobalt(III) complexes of the $[CoX_2(NH_3)_4]$- and $[CoX_2en_2]$-types is in this order of ligands: OH_2, en, SO_3. Hence, the order for the *cis*-type complexes does not agree with that for the tetracyano complexes. This disagreement seems likely to be due to the *trans*-configuration of the disulfito complex. Since the diaquotetracyano complex was prepared from the disulfito complex, and since it exhibited quite different polarographic behavior from that of the aquated species of the *cis*-ethylenediaminetetracyano

complex, it may also be interpreted as getting a *trans*-configuration rather than a *cis*-form.

Table 3 summarizes the half-wave potentials and the corresponding electrode processes of the cyano cobaltate(III) complexes in various kinds of supporting electrolytes. Since the disulfito-, diaquotetracyano, and sulfitopentacyano complexes are quite insoluble in such organic solvent as DMSO, acetonitrile (AN), dimethylformamide (DMF), and ethanol, it was impossible for us to obtain the reduction waves of these complexes in such aprotic solvents.

Tables 4 and 5 show the apparent kinetic parameters for the irreversible electrode process of Co(III)→Co(I) in an aqueous solution, such parameter having been determined by a method described previously;[8] the terms have their usual significance. Here, the so-called "Frumkin's correction" was not taken into consideration in estimating these data. Since a plot of $\log k^a_f$ (apparent rate constant) against $1/T$ should be linear with a slope equal to $\Delta H^*/2.303\ R$, the activation energies at a constant pressure (ΔH^*) can be calculated; these values are shown below the respective tables. The ΔH^* value for the disulfito complex was found to be far smaller than that for the sulfitopentacyano complex, although it is noteworthy that these parameters have, ultimately, only a relative meaning.[14]

The authors wish to thank Professor Shukichi Sakuraba for his helpful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2457—2462 (1969)

Studies of the Ion-pairing of Hexylate and Picrate Ions with Alkali Metal Ions by Capillary Analysis

Kazuaki SANO, Michio SAKUMA,*1 Syoji MOTOMIZU, Tadashi IWACHIDO* and Kyoji TÔEI

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama
* *College of Liberal Arts, Okayama University, Tsushima, Okayama*

(Received December 30, 1969)

The hexyl (Dipicrylamine) anion, hexylate, and picrate form weak ion-pairs with alkali metal cations in an aqueous solution. The composition and the association constants of the ion-pairs are determined by capillary analysis based on the difference in the adsorbability of the anions and of the ion-pairs on a filter paper. A new constant temperature-humidity apparatus is devised, and by means of it the analysis is successfully carried out. The compositions of the cation and the anion in the ion-pairs formed are 1 : 1, in either case; the association constants of the ion-pairs for Li, Na, K, Rb, and Cs cations are about 10^2, and they tend gradually to decrease with the ionic radii.

Interactions in electrolyte solutions can largely be explained by assuming that electrolytes completely dissociate into rigid, spherically-symmetrical ions and that the resulting ions exert long-range

*1 Present address: Kohkoku Chemical Industry Co., Ltd., Nishimiya-cho, Ashikaga-shi.

electrostatic forces on the other ions through the medium of the dielectric constant, ε. The interaction increases with the decrease in the distance of charge separation; that is, a small cation and a small anion may have enough attractive force compared with the thermal energy. Bjerrum[1] calculated the critical distance to be 3.57 Å for 1 : 1 electrolytes in water at 25°C and regarded ions which can approach within the distance as a virtually new entity, an ion-pair, of a sufficient stability. The association equilibrium between free ions and ion-pairs is expressed by means of K, and the ion-pair species is treated as neutral molecules of unit activity, if the electrolyte is symmetrical. So long as only the Coulomb force is assumed between the adjacent ions, ion-pairing would be at minimum in the salts of alkali metals with large, univalent anions. However, the reverse is true in the present case, so some other forces must be considered.

Several methods have been adopted to determine the association constant, K,——for example, conductivity[2] and solubility[3] measurements, polarography,[4] and spectrometric methods.[5] In any case, it is important to find a suitable way to detect a certain difference in physical properties between free ions and an ion-pair. In the present case, the method of capillary analysis was found to be successful in ascertaining the significant difference between them.

The so-called "capillary analysis" is a kind of paper chromatography. One end of a paper strip is dipped into the solution to be tested (which is in striking contrast to the usual paper chromatography). When the system is saturated as much as possible by water vapor in order to avoid undesirable vaporization during the development, the ratio of the movements of the solute and the solvent can be related to the association constant with the aid of the following assumptions: 1) the paper is regarded as being divided into successive layers of such a thickness that the solution issuing from each layer is in equilibrium with the mean concentration of the solute in the stationary phase throughout the layer; 2) the diffusion from one plate to another is negligible, and 3) the partition coefficient of the solute between two phases is independent of its concentration.

The purpose of the present paper is to show that, contrary to our expectations judging from the Bjerrum theory, there is a considerable amount of ion-pairing between alkali metal cations and large organic anions, such as picrate or hexylate, in an aqueous solution, that the largest cation, Cs^+, forms the most stable ion-pair with such anions, and that the method of capillary analysis is useful in determining the association constant of such ion-pairs.

Theoretical

The theory of capillary analysis was first proposed by Hayama[6] based on analogy with the plate theory of liquid-partition chromatography; Hayama applied it to the complex formation between dyes and non-ionic surfactants.

Hexylate and picrate anions form precipitates with heavy alkali metal cations in an aqueous solution; hence, it may be assumed that hexylate and picrate associate with alkali metal ions to form ion-pairs even in a dilute solution and that each species has different adsorbabilities on cellulose. In such a solution, the associated ion-pairs are in equilibrium with the free ions; also, each species is equilibrate with those in the stationary phase, as is shown in Fig. 1. and Eqs. (1) to (4).

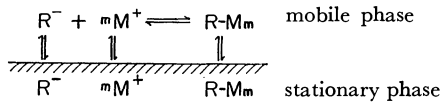

Fig. 1. Schematic representation of the behavior of hexylate and picrate, alkali metal ion and the ion-pair formed in an aqueous solution against a filter paper.

$$K = \frac{[\mathrm{R\text{-}M}_m]_a}{[\mathrm{R}^-]_a[\mathrm{M}^+]_a{}^m} \tag{1}$$

(K: Association constant)

$$K_1 = \frac{[\mathrm{R}^-]_s}{[\mathrm{R}^-]_a} \tag{2}$$

(K_1: Distribution coefficient of the reagent anion)

$$K_2 = \frac{[\mathrm{R\text{-}M}_m]_s}{[\mathrm{R\text{-}M}_m]_a} \tag{3}$$

(K_2: Distribution coefficient of the ion-pair)

$$K_3 = \frac{[\mathrm{R}^-]_s + [\mathrm{R\text{-}M}_m]_s}{[\mathrm{R}^-]_a + [\mathrm{R\text{-}M}_m]_a} \tag{4}$$

(K_3: Distribution coefficient of the total reagent)

where R^- denotes the reagent anions; M^+ and $R\text{-}M_m$, the alkali metal cations and ion-pairs; brackets, the concentration of each species, and the suffixes a and s, an aqueous and a stationary phase respectively.

From Eqs. (1), (2), (3), and (4), we obtain:

$$K_3 = \frac{K_1 + KK_2[\mathrm{M}^+]_a{}^m}{1 + K[\mathrm{M}^+]_a{}^m} \tag{5}$$

As the concentration of the reagent ions is much

lower than that of alkali metal ions, the equilibrium concentration of alkali metal cations, $[M^+]_a$, may be approximately replaced by the total concentration, neglecting the formation of the ion-pair.

On the other hand, according to the equation of capillary analysis, the distribution coefficient, K_3, is related to R_h by the following equation:

$$\alpha K_3 = \frac{1 - \ln 2}{R_h - \ln(1+R_h)} - 1 \quad (6)$$

where α is the ratio of volumes of the stationary phase (cellulose) and the mobile phase (solution), and R_h, the ratio of the movement of the solute and the solvent.

By combining Eq. (5) with Eq. (6), we obtain Eq. (7), in which R_h is related to the concentration of free alkali metal ions.

$$\alpha K_3 = \frac{\alpha K_1 + \alpha K K_2 [M^+]_a{}^m}{1 + K[M^+]_a{}^m} = \frac{1 - \ln 2}{R_h - \ln(1+R)} - 1 \quad (7)$$

When alkali metal cations are absent in the solution to be tested, $[M^+]_a = 0$, we denote the values of R_h by $R_h{}^0$:

$$\alpha K_1 = \frac{1 - \ln 2}{R_h{}^0 - \ln(1+R_h{}^0)} - 1 \quad (8)$$

On the contrary, when these cations are present in a large excess, and when most of the reagent anions associate completely to form ion-pairs, R_h is denoted by $R_h{}^\infty$. Then we obtain:

$$\alpha K_2 = \frac{1 - \ln 2}{R_h{}^\infty - \ln(1+R_h{}^\infty)} - 1 \quad (9)$$

By substituting Eqs. (8) and (9) into Eq. (7), we obtain the following expression:

$$\frac{[R\text{-}M_m]_a}{[R^-]_a} = K[M^+]_a{}^m = \frac{\dfrac{1}{R_h{}^0 - \ln(1+R_h{}^0)} - \dfrac{1}{R_h - \ln(1+R_h)}}{\dfrac{1}{R_h - \ln(1+R_h)} - \dfrac{1}{R_h{}^\infty - \ln(1+R_h{}^\infty)}} \quad (10)$$

Equation (10) shows that the logarithmic plot of $[M^+]_a$ against the right-hand side of the equation allows us to estimate the K and m values. For the first approximation, $[M^+]_a$ was made equal to the initial concentration of the alkali metal cations; then K was determined, and the $[M^+]_a$ value calculated from the K value was used to determine a more accurate K value, after which the procedure was continued until a constant K value was obtained. Only for the values of picrate, activity correction was made simultaneously.

Experimental

Reagents. Hexyl (2,2′,4,4′,6,6′-hexanitrodiphenylamine) was prepared by treating an aqueous solution of a commercial Hexyl calcium (Mitsubishi Chemical Industries, Ltd.) with dil. hydrochloric acid, by filtering the hexyl thus formed, and by then purifying it by recrystallization from acetic acid.

The hexyl was dissolved by warming it in a lithium carbonate solution (0.006%); reagent-grade picric acid was then dissolved in water to give 2.62×10^{-4}M and 2.000×10^{-3}M solutions respectively.

Apparatus and Procedures. The ordinary procedure of capillary analysis is not siutable for the present purpose because of the unavoidable vaporization of the solvent during the development, as has previous been described. To avoid such trouble, a vessel of a constant humidity and temperature was devised (Fig. 2). A

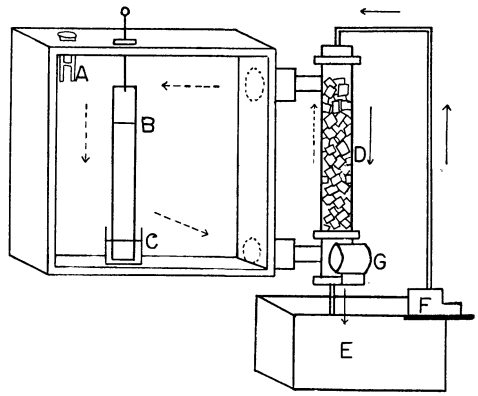

Fig. 2. Schematic representation of the apparatus. A: Assmann aspiration psychrometer, B: Filter paper (No. 50; 2×40 cm^2, Toyo Roshi Kaisha, Ltd.), C: Sample solution, D: Water vapor saturating tower, E: Water bath (25°C), F: Pump, G: Air blower

developing box was made of wood lined with a polyvinylchloride sheet and with a wet cloth on it. A gentle stream of water vapor introduced into the box from a saturation tower moistened the paper strips hung in it. The humidity was monitored by an Assmann aspiration psychrometer. A tower was filled with small pieces of polyvinylchloride pipes (2 cm in length and 1.5 cm in diameter). The water from a water bath was spreaded at the top of the tower, and the air in the box was blown upwards from the bottom through a column. Thus the humidity and the temperature in the box were kept at a constant values of 95 per cent and 25°C respectively. The room temperature was also controlled at 25°C.

Some paper strips previously moistened in another vessel for 24 hr were hung upon the hooks of the supporting rods at the upper wall of the box. Under each strip, 50 ml of 1.31×10^{-4}M hexyl or 1.00×10^{-3}M picric acid solutions containing alkali salts in various amounts (10^{-4} to 10^{-1} g-ion/l for hexyl solutions or 10^{-3} to 10^{-1} g-ion/l for picric acid solutions) were placed.

On dipping the paper strips into the test solution, it was always necessary to adjust exactly the solution level to the mark on the paper by handling the supporting rods. When the solvent fronts came near the upper ends of the strips, the front panel of the box made of double-walled transparent acrylate resin plate was removed and the detached strips were laid on a large sheet of filter paper and dried quickly by using a hot blower. Then the fronts of the solvent and of the solute

were marked. About two hours were requied for a single run.

Results and Discussion

The relationship between the R_h value and the free alkali metal ion concentration, $[M^+]_a$, is shown in Figs. 3a and 3b. The R_h^0 values are obtained by extrapolating the curves to an infinite dilution, $[M^+]_a=0$. To determine R_h^∞ values, R_h is plotted against the reciprocal of the alkali metal-ion concentration; the curves obtained are then extrapolated as in Figs. 4a and 4b.

The right-hand side of Eq. (10), evaluated in such a way, was plotted against the free alkali metal-ion concentration; these plots gave straight lines, as Figs. 5a and 5b show. The slopes of the five lines obtained are approximately unity; the $\log K$ values obtained by extrapolating these lines to $\log[M^+]_a=0$ are about 2 for hexylates, are slightly larger for picrates, and slightly increase in the order of Li, Na, K, Rb, and Cs in either case, as is shown in Table 1. The agreement between the results of the capillary analysis and the solvent

extraction previously reported[7] is fairly good.

The log K value for sodium hexylate was also obtained by using a pNa-meter (Horiba Instruments, Inc., Type N-5 Sodium Ion Indicator). The concentration of free sodium ions was determined with a pair of electrodes, *i. e.*, a glass electrode especially sensitive to sodium ions and a reference electrode of the double-junction type, with a sodium chloride solution as the liquid junction to prevent the direct contact of the potassium ions in the inner solution of the electrode with the hexylate anions, and thus precipitating potassium hexylate at the junction.

The instrument was calibrated with 0.1 and 0.001M standard sodium chloride solutions. Consequently, the pNa-meter directly measures the sodium-ion concentration in terms of moles per liter instead of activity.

Table 1. Combination ratio and association constant

	Alkali metal-ion	Li^+	Na^+	K^+	Rb^+	Cs^+
Hexylates	Combination ratio	0.95	0.95	0.98	1.0	1.0
	log K	1.7	1.9	1.9	2.0	2.1
Picrates*	Combination ratio	0.88	0.90	0.98	0.98	1.0
	log K	2.2	2.3	2.4	2.5	2.7

* Correcteed by activity coefficient.

7) S. Motomizu, K. Tôei and T. Iwachido, This Bulletin, **42**, 1006 (1969).

Two sodium solutions, one with and one without hexyl, were prepared (Table 2); a certain amount of sodium hydroxide was added equally in order to avoid the hydrolysis of the hexylate anion. A few pairs of such solutions, differing only in total sodium concentration, were also prepared, the concentration of sodium hydroxide being kept unchanged.

The free sodium ion in each pair was measured, and the two were then compared with each other. The solution with hexyl is less alkaline than that without hexyl because of the neutralization of the hydroxide ion with hexyl. In order to estimate the effect of the hydroxide ion on the glass electrode, the solution without hexyl was neutralized with acetic acid just as with hexyl, and then the free sodium ion was measured. The pNa values thus obtained are in good agreement with those calculated on the assumption that the acetate ion does not form an ion-pair with the sodium ion.

From these findings, it can be concluded that, in the solutions without hexyl, the differences in pNa between the measured and the calculated values, Δ, are attributable to the large amount of hydroxide ions present, and that, in the solutions with hexyl, the sodium ion is determined correctly and the increases in pNa can be considered as a measure of the extent of ion-pairing.

The equilibrium in the solution with hexyl can be written as follows:

$$\text{Hexyl}^- + \text{Na}^+ \rightleftarrows \text{Hexyl-Na}$$

$$K=\frac{[\text{Hexyl-Na}]}{[\text{Hexyl}^-][\text{Na}^+]} \qquad (11)$$

If the total concentrations of hexyl and the sodium ion are denoted by C_R and C_{Na} respectively, we obtain:

$$C_R = [\text{Hexyl-Na}] + [\text{Hexyl}^-]$$
$$C_{Na} = [\text{Hexyl-Na}] + [\text{Na}^+] \qquad (12)$$

Table 2. Determinination of $\log K_2$ by using pNa-meter

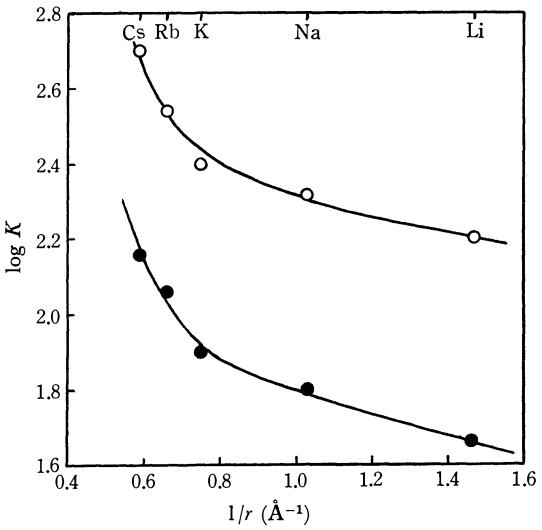

Fig. 6. log K's of alkali metal salts.
○ Picrate, ● Hexylate

By substituting Eq. (12) into Eq. (11), we obtain:

$$K = \frac{C_{Na} - [Na^+]}{(C_R - C_{Na} + [Na^+])[Na^+]} \qquad (13)$$

Thus, an association constant can be calculated from Eq. (13). The data necessary for the above calculation are given in Table 2, along with the log K values. The log K values thus obtained are very close to those obtained by capillary analysis.

Figure 6 shows the log K data for hexylates and picrates, plotted against the reciprocal of the radii of unhydrated cations. The curves thus obtained have negative slopes, unlike the common pattern of ion-pairing; that is, the cesium ion in the aqueous solution must be considered to be the smallest among the alkali metal cations as far as only the electrostatic force is concerned. In the ion-pairing of this type, it may be thought that the hydration of the cation is a predominant factor; *i. e.*, adjacent water dipoles rather than the hexylate or picrate ion are strongly affected by the field of the cation, and it is difficult for the hydration shell of the cation to be penetrated by such anions. The formation of the solvent-separated ion-pair is supported by the fact[7] that, with hexyl salts in dry nitrobenzene, lithium associates more firmly than cesium, while in nitrobenzene saturated with water the extent of ion-pairing decreases and by the fact that water is co-extracted with alkali metals into nitrobenzene.

The order among K values may be explained by the hydration, but it is difficult to explain these large values only in terms of the long-range, electrostatic force between adjacent ions; therefore, these large values lead us to suspect other forces, for example, the formation of a chemical bond, the contribution of the Van der Waals force, and the role of water-structure for the ion-pairing. It is of much interest to consider the last possibility, suggested by Diamond.[8] Considerations of these possibilities will, however, be described elsewhere; the present discussion will be confined to pointing out the similarity in ion-pairing between some oxy-acid anions and picrate or hexylate.

Some oxy-acid anions such as iodates[9] and thiosulfates[10] are known to associate with cations of the noble-gas configuration to form an ion-pair of this type; these anions have some common features with hexylate or picrate—for example, every ligand is large and has many ionic resonance forms, so that the negative charges on the ligands can be distributed over all the ligands.

The authors wish to thank Dr. Naomi Hayama for many helpful discussions and suggestions during this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2463—2469 (1970)

Ionic Equilibria in Mixed Solvents. V. Intermediates of Polymerization of Aluminum Ion in a 0.2 Mole Fraction Dioxane-Water Mixture

Hitoshi OHTAKI

The Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya

(Received January 7, 1970)

Formation of highly polymerized hydroxo-complexes of aluminum ions proceeded so slowly in a dioxane-water mixture that less polymerized intermediates were detected by means of the usual emf titration techniques. The titrations were performed at 25° in solutions of total aluminum concentrations of 0.00500, 0.0100, 0.0200, 0.0399, 0.0400 and 0.0798M in a 0.2 mol fraction (55.01 % w/w) dioxane-water mixture containing 3M $LiClO_4$ as an ionic medium. The emf data obtained can be explained in terms of the formation $Al_2(OH)_2^{4+}$ ($\log {}^*\beta_{2,2} = -6.95 \pm 0.07$) and $Al_2(OH)_3^{3+}$ ($\log {}^*\beta_{3,2} = -10.02 \pm 0.03$) assuming equilibrium conditions. It was observed that these complexes proceed further slowly to form highly polymerized complexes.

Several works have been made on the hydrolysis reaction of aluminum ion, and various conclusions have been reported on the formulae of the species formed. In dilute solutions a series of mononuclear complexes, $Al(OH)_n^{(3-n)+}$, may be formed. However, in more concentrated solutions formation of polynuclear complexes is certain. Treadwell and Zürcher[1] have found a dimerized species, $Al_2(OH)_5^+$, at room temperature. Formation of another dimer complex, $Al_2O(NO_3)_3^+$, and a highly polymerized complex, $(AlONO_3)_{\sim 8}$, has been reported by Jander and Jahr[2] by a diffusion method. Formation of a dimerized $Al_2(OH)_2^{4+}$ complex, which has recently been confirmed by some workers, was first suggested by Faucherre[3] in 1948 and he determined the formation constant of the species.[4] The same complex has been found by Jahr and Brechlin[5] at 0°C, Kenttämaa,[6] Kubota[7] and Aveston[8] at 25°C. In a crystalline state of a basic aluminum sulfate or selenate, a group of $Al_2(OH)_2(H_2O)_8^{4+}$ was found to construct a unit cell of the crystals.[9] For higher complexes several authors have described the formation of cationic trimers,[10,11] tetramers[5,6] and sometimes octamers.[12]

After X-ray analysis of another basic aluminum sulfate ($13Al_2O_3 \cdot 6SO_3 \cdot xH_2O$)[13] and the corresponding selenate ($Na[Al_{13}O_4 \cdot (OH)_{24} \cdot (H_2O)_{12}](SeO_4)_4 \cdot xH_2O$)[14] had been carried out by Johansson, Sillén[15] reexamined his results[16] in order to explain the data[16] in terms of the formation of the $Al_{13}(OH)_{34}^{5+}$ complex together with the $Al_7(OH)_{17}^{4+}$ complex. From the results obtained by ultracentrifugal methods and by emf measurements, Aveston[8] concluded that the highly polymerized cationic species has the formula $Al_{13}(OH)_{32}^{7+}$.

As has been pointed by Brosset[17] and Aveston,[8] diverse formulae of species hitherto reported may mainly be due to a slow reaction rate of the hydrolysis reaction of aluminum ions. Different conclusions may also have resulted from different accuracies of measurements by different authors. For such a complicated system of the complex formation, accuracy of measurements substantially affects the ratio of OH/Al in the complexes.

Schwarzenbach and Wenger[18] also reported that the hydrolysis reaction of aluminum ion proceeds rather slowly. Yotsuyanagi and Aoyama[19] reported that it reaches equilibrium after two to three years in aqueous solutions.

Although Brosset[17] pointed out that equilibrium potentials might be obtained on standing a solution tens of hours after the addition of an alkaline solution, no intermediate could be detected during the course of the formation of highly polymerized complexes of aluminum ion in aqueous solutions. However, in the aqueous dioxane solution the rate of polymerization reactions was so slow that some intermediates could be found and the data obtained could be treated assuming equilibrium conditions.

The present study deals with the hydrolysis reactions of aluminum ion in a 0.2 mol fraction dioxane-water (55.01% w/w dioxane) mixture containing 3M $LiClO_4$ as an ionic medium.

The hydrolysis reaction of aluminum ion may be written as

$$qAl^{3+} + pH_2O = Al_q(OH)_p^{(3q-p)+} + pH^+ \quad (1)$$

In Eq. (1) solvated dioxane and water molecules are omitted,[20] and ${}^*\beta_{p,q}$ was calculated, which is defined by

$${}^*\beta_{p,q} = [Al_q(OH)_p^{(3q-p)+}][H^+]^p/[Al^{3+}]^q = [Al_q(OH)_p^{(3q-p)+}]h^p/b^q \quad (2)$$

Here the brackets denote the concentration of the relevant species.

Symbols

h	Hydrogen ion concentration at equilibrium
H	Concentration of analytical excess of hydrogen ions $=[ClO_4^-]-3B-[Li^+]$
B	Total concentration of aluminum
b	Concentration of free aluminum ions
Z	Average number of hydrogen ion set free per aluminum atom $=(h-H)/B$
p	Number of OH groups bound to hydrolyzed species
q	Number of Al atoms present in hydrolyzed species
${}^*\beta_{p,q}$	Equilibrium constant of the formation of $Al_q(OH)_p^{(3q-p)+}$
E	Emf

Experimental

Reagents. Aluminum perchlorate was prepared from aluminum chloride and perchloric acid as follows. Reagent grade aluminum chloride was recrystallized three times from aqueous solution by bubbling dry hydrogen chloride, The aluminum chloride crystals were dissolved in a small amount of water and then an excess of perchloric acid was added. Hydrochloric acid thus liberated was evaporated repeatedly under an infrared lamp. Aluminum perchlorate crystals prepared were recrystallized from water. Neither chloride nor iron(III) was detected.

The concentration of aluminum ion in the stock solution was determined as Al_2O_3 by igniting aluminum hydroxide at about 1100°C.

The concentration of free acid in the aluminum perchlorate solution was determined in a similar way to that employed in the preceding works;[21-24] that is, aliquot of a dilute solution of aluminum perchlorate, which contained a known amount of the stock solution, was titrated with a standard perchloric acid, and then, the amount of free acid present was estimated from a plot of $V_{tot}.10^{E/59.15}$ *vs.* volume of the perchloric acid added (Gran plot[25]), where V_{tot} denotes the total volume of the solution in a titration vessel.

Lithium Perchlorate was prepared as described by Biedermann and Ciavatta.[26]

Dioxane was purified by the method described elsewhere.[21]

Apparatus. *Glass Electrodes and pH Meter.* Beckman Nos. 40498 and 41263 glass electrodes were used in combination with a Beckman 101900 Research pH Meter.

The Wilhelm-type Half-cell described by Forsling, Hietanen and Sillén[27] was used for emf measurements.

All emf measurements were performed at 25.00± 0.01°C in a paraffin oil thermostat in a room thermostated at 25±1°C. Air in a titration vessel was replaced by nitrogen gas free from carbon dioxide during the titration.

Methods of Investigation. The hydrolysis reactions were studied from the measurements of the hydrogen ion concentration of a series of aluminum perchlorate solutions at 25°C using a glass electrode. During the potentiometric titration B was kept constant. The values of B studied were 0.00500, 0.0100, 0.0200, 0.0399, 0.0400 and 0.0798M. All solutions were prepared with a 0.2 mol fraction dioxane-water mixture (55.01% w/w dioxane).

Emf Measurements. The general composition of a test solution may be described as: $B\,Al^{3+}$, $H\,H^+$, $(3-3B-H)\,Li^+$, 3M ClO_4^-, where H, the analytical excess of hydrogen ion, is either positive or negative depending on the degree of hydrolysis of aluminum ion. The original composition of the test solution, S_1, has a composition, $S_1 = B\,Al(ClO_4)_3$, $H_0\,HClO_4$, $(3-3B-H_0)$ $LiClO_4$. Values of H_0, the initial concentration of acid in the solution taken in a titration vessel, were controlled to fall in the range from 0.01 to 0.03M, where the acidity

of the solution is sufficiently high to prevent any appreciable hydrolysis of aluminium ion.

Compositions of titransts were as follows: $T_1=A$ LiOH, $(3-A)$ $LiClO_4$: and $T_1'=2B$ $Al(ClO_4)_3$, X $HClO_4$, $(3-6B-X)$ $LiClO_4$. Equal volumes of T_1 and T_1' were added to S_1 in order to keep B constant during the course of titration. Concentration of the added hydroxide ion was calculated from the difference of A and X.

The concentration of hydrogen ion was measured by means of the cell

$$(-)\text{GE}\,|\,\text{solution}\,|\,\text{Ref}\,(+) \qquad (3)$$

where GE denotes a glass electrode and Ref the reference half-cell,

3.00M $LiClO_4$ in 0.2 mol fraction aqueous dioxane	2.99M $LiClO_4$ and 0.01M $AgClO_4$ in aqueous solution	AgCl-Ag

The emf of the cell (3) at 25°C may be written as

$$E = E^\circ - 59.15 \log h - 59.15 \log f_H - E_J(h,B) \qquad (4)$$

where E° is a constant and f_H represents the activity coefficient of hydrogen ion. As described in the previous works,[21-23] the standard state is defined so that f_H, as well as the activity coefficients of the other reacting species, tends toward unity as the composition of the solution approaches 3M $LiClO_4$ in 0.2 mol fraction of aqueous dioxane. During the course of titration Z varied from zero to 0.3 at the lowest B and to 0.08 at the highest. Nevertheless, we assume that the activity coefficients of the reacting species to be constant as long as B is maintained constant and the ionic medium in the solution is sufficiently high.

The liquid-junction potential at the junction, test solution | 3M $LiClO_4$ in 0.2 mol fraction of aqueous dioxane, is described as $E_J(h,B)$ in Eq. (4). At $B=0$ it was found in a cell of similar design that $E_J(h,0)=-8.3h$ mV.[21] In the present study $E_J(h,B)$ can be assumed to be equal to $E_J(h,0)$ without causing any appreciable error in the evaluation of the hydrogen ion concentration from emf measurements.

A glass electrode is calibrated against a perchloric acid through a Gran plot.[25] The value, $E^0-59.15\cdot\log f_H$, in Eq. (4) thus obtained is assumed to be kept constant throughout titration.

At a sufficiently low pH range where no appreciable hydrolysis occurred, a stable potential was established within 5 to 10 min after addition of the titrants. However, in the range where the hydrolysis occurred, reactions seemed to progress rather slowly. At lower Z ($Z\lesssim 0.1$) and relatively low pH range, stable emf's were obtained only after two to three hours. When Z increased ($Z>0.1$), the reaction seemed to be so accelerated that the stable potential was established more rapidly (within half an hour or less). Finally the solution was distinctly turbid and the potential was nearly unchanged in systems of lower B. When the solution was clear and the emf remained unchanged for at least an hour, we recorded the emf value as the final one. In fact the emf was still maintained constant within an accuracy of ±0.1 mV for at least 5 hr thereafter.

Titration in the reverse way was demonstrated as follows: A test solution was prepared by the addition of LiOH solution into an aluminum perchlorate solution until precipitates formed. The solution was left for two months in a thermostated room at 25°C with occasional shaking. The precipitates were separated by centrifugation and a portion of the supernatant was subjected to gravimetric determination of the concentration of aluminum ion in the test solution. Another portion of the supernatant was used for emf measurements, in which the solution was gradually acidified by adding a titrant, whose composition was $T_2=B$ $Al(ClO_4)_3$, X' $HClO_4$ (back titration). In the present case $B=0.02913$M and $X'=0.1032$M.

All processes of preparation of the test solution and of transfer of solutions were performed in a glove box which was filled with air free from carbon dioxide.

The maximum Z value found was 0.6 which was almost three times as large as that expected from the ordinary forward titrations. At lower Z less than 0.3, reactions between the hydrogen ions added and the hydrolyzed aluminum species present in the solution progressed very slowly and no stable potential was obtained even after more than 24 hr. However, in a strong acid solution having pH lower than 1.9, all the hydrolysis products were decomposed and a stable emf was obtained within 5—10 min.

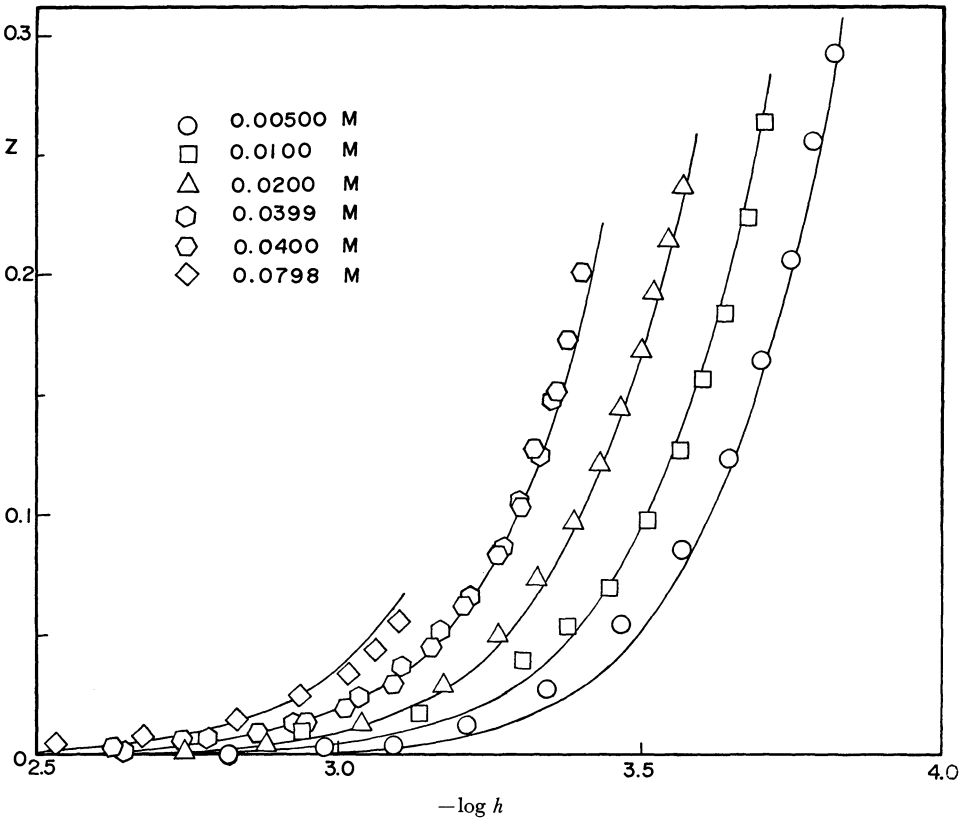

Fig. 1. Z as a function of $-\log h$. Curves were calculated with $^*\beta_{2,2}=1.16\times10^{-7}$ and $^*\beta_{3,2}=9.55\times10^{-11}$.

Results

Results obtained by means of forward titrations were treated with the assumption of the equilibrium condition. Values of $-\log h$ and Z at each series of B were calculated from the emf data obtained. They are shown in Table 1 and also represented graphically in Fig. 1.

The concentration of hydrogen ion set free by hydrolysis, BZ, is given by the general formula

$$BZ=\sum_p\sum_q p[\mathrm{Al}_q(\mathrm{OH})_p{}^{(3q-p)+}]=\sum_p\sum_q p{}^*\beta_{p,q}h^{-p}b^q \quad (5)$$

and B is given as

$$B=b+\sum_p\sum_q q[\mathrm{Al}_q(\mathrm{OH})_p{}^{(3q-p)+}]$$
$$=b+\sum_p\sum_q q{}^*\beta_{p,q}h^{-p}b^q \quad (6)$$

Plots of $\log B$ against $-\log h$ gave a set of straight lines with a slope of 2.7—3.0, which approximately corresponds to t in the formula $[\mathrm{Al}(\mathrm{Al}(\mathrm{OH})_t)_n]$ according to the core-link treatment.[28]

As a preliminary consideration, simple assumptions were made as follows: only a complex, $\mathrm{Al}_Q(\mathrm{OH})_P{}^{(3Q-P)+}$, is mainly formed and an approximation of $B\approx b$ is applied. Thus,

$$Z\approx P{}^*\beta_{P,Q}h^{-P}B^{Q-1} \quad (7)$$

or

$$\log Z\approx\log P{}^*\beta_{P,Q}B^{Q-1}-P\log h \quad (8)$$

An examination was made for the assumption of the formation of $\mathrm{Al}_{13}(\mathrm{OH})_{32}{}^{7+}$ which has been proposed by Aveston.[8] In the formula of this complex t is described as $32/12=2.667$ which is fairly close to that found in the present case. The following relations can be derived:

$$BZ=32{}^*\beta_{32,13}h^{-32}b^{13} \quad (9)$$

$$B=b+13{}^*\beta_{32,13}h^{-32}b^{13} \quad (10)$$

Then,

$$Z=32{}^*\beta_{32,13}\{B(1-0.406Z)^{13/12}\cdot h^{-32/12}\}^{12} \quad (11)$$

All points obtained in this work fell on a straight line of $\log Z$ plotted against $\log B+13/12\log(1-13/32.Z)-32/12\log h$. However, the slope of the line was not 12 but only 1. From this observation the main complex was not $\mathrm{Al}_{13}(\mathrm{OH})_{32}{}^{7+}$ but the formation of dimerized species ($q=2$) might be expected.

When we plotted $\log Z$ against $-\log h$ a set of straight lines with a slope of 2.4—2.6 was obtained, which corresponds to the value of P in Eq. (8).

28) L. G. Sillén, *Acta. Chem. Scand.*, **8**, 299 (1954).

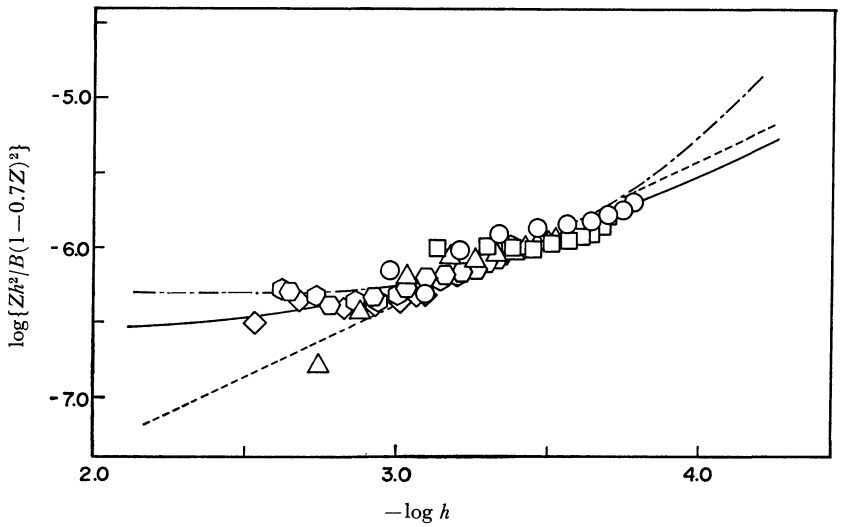

Fig. 2. log $(Zh^2/B(1-0.7Z)^2)$ as a function of $-\log h$.
————— , Assumption of the formation of both $Al_2(OH)_2^{4+}$ and $Al_2(OH)_3^{3+}$;
-·-·-·- , $Al_2(OH)_2^{4+}$ and $Al_2(OH)_4^{2+}$; ------ , $Al_2(OH)_3^{3+}$ only.
Symbols used are the same as those in Fig. 1.

Since P is given as nt in the $[Al(Al(OH)_t)_n]$ complex and t was found to be 2.7—3.0, the value of n should be unity and thus, the main species formed should contain two Al atoms.

The second step of the approximation was made for a nonstoichiometric complex such as $Al_2(OH)_{2.4}^{3.6+}$. A plot of Z against $\log B+2\log(1-0.833Z)-2.4\log h$ systematically deviated from a normalized curve, $y=x=f(\log x)$, which led to the conclusion that the average value of p ($\bar{p}$) of the complexes must be larger than 2.4. An examination with another assumption that $Al_2(OH)_3^{3+}$ is the unique complex formed led to the conclusion that $\bar{p}$ must be smaller than 3. Thus, the average value of p, *i.e.*, $\bar{p}$, must lie between 2.4 and 3.

It may be natural to assume the formation of two complexes both of which contain two aluminum atoms. An approach was tried for the formation of complexes of $Al_2(OH)_2^{4+}$ and $Al_2(OH)_3^{3+}$. The following approximation was made for calculation of b:

$$b = B(1-\alpha Z) \qquad (12)$$

For the value of α, we put $\alpha=0.7$ which is a number between 0.667 (for $\bar{p}=3$) and 0.833 ($\bar{p}=2.4$). The variation of α was insensitive to the present calculations. Inserting Eq. (12) into Eqs. (5) and (6), the following equation was readily derived:

$$BZ = 2{}^*\beta_{2,2}B^2(1-0.7Z)^2h^{-2} + 3{}^*\beta_{3,2}B^2(1-0.7Z)^2h^{-3} \qquad (13)$$

or

$$\frac{Zh^2}{B(1-0.7Z)^2} = 2{}^*\beta_{2,2} + 3{}^*\beta_{3,2}h^{-1} \qquad (14)$$

Plots of log $(Zh^2/B(1-0.7Z)^2)$ against log h^{-1} were compared with a normalized curve, $y=\log(1+x)$ plotted against log x. It is seen from Fig. 2 that all the points examined fall on a single curve which overlapped with the normalized curve. From the position of the best fit of curve we evaluated that log ${}^*\beta_{2,2}=-6.92$ and log ${}^*\beta_{3,2}=-10.02$. Another assumption that complexes formed were $Al_2(OH)_2^{4+}$ and $Al_2(OH)_4^{2+}$ gave a worse agreement. Evidently the assumption of the formation of $Al_2(OH)_3^{3+}$ complex only did not explain the experimental results.

Finally the data have been treated by a generalized least-squares method with the help of an electronic computer HITAC 5020E for various sets of complexes in order to find the best set of the complexes. Calculation of Z_{calc} ($Z_{calc}=\sum_p\sum_q \beta^*\beta_{p,q}\, h^{-p}b^q/B$ for a particular set of constants ${}^*\beta_{p,q}$) with a set of ${}^*\beta_{2,2}$ and ${}^*\beta_{3,2}$ resulted in a satisfactory agreement with the experimental data.

The other sets of ${}^*\beta_{p,q}$ gave more or less worse agreement *i.e.*, larger error square sums, U ($U=\sum(Z-Z_{calc})^2$) were obtained. Highly polymerized complexes such as $Al_7(OH)_{17}^{4+}$, $Al_{13}(OH)_{32}^{7+}$ or $Al_{13}(OH)_{34}^{5+}$ were thus excluded. Formation of any monomeric complexes was not conclusive in the present work. Various sets of complexes assumed and square sums obtained are listed in Table 2. The final values of the constants obtained by the computer calculation are $\log{}^*\beta_{2,2}=-6.95\pm0.07$ and $\log{}^*\beta_{3,2}=-10.02\pm0.03$. They are listed in Table 3 together with values reported by some workers in aqueous solutions.

Discussion

Although we could not estimate the composition of complexes formed after two months of aging, the following conclusions may be drawn from the results obtained by back titration: precipitates of aluminum hydroxide once formed dissolve slowly and, as a result, the value of the maximum Z increases to nearly threefold of that expected from the ordinary forward titration at the same B, and binuclear $Al_2(OH)_2^{4+}$ and $Al_2(OH)_3^{3+}$ complexes may coagulate, releasing some protons to form higher polynuclear complexes which result in the increase of the hydrogen ion concentration at equilibrium. Thus, the hydrolysis reactions of aluminum ion may be schematically described as follows:

$$2Al^{3+} + \begin{Bmatrix} 2H_2O \\ 3H_2O \end{Bmatrix} \overset{{}^*\beta_{p,q}}{\rightleftharpoons} \begin{Bmatrix} Al_2(OH)_2^{4+} + 2H^+ \\ Al_2(OH)_3^{3+} + 3H^+ \end{Bmatrix} \xrightarrow[k]{\text{slow}} \text{High polymers}$$

The rate constant k is so small that the formation

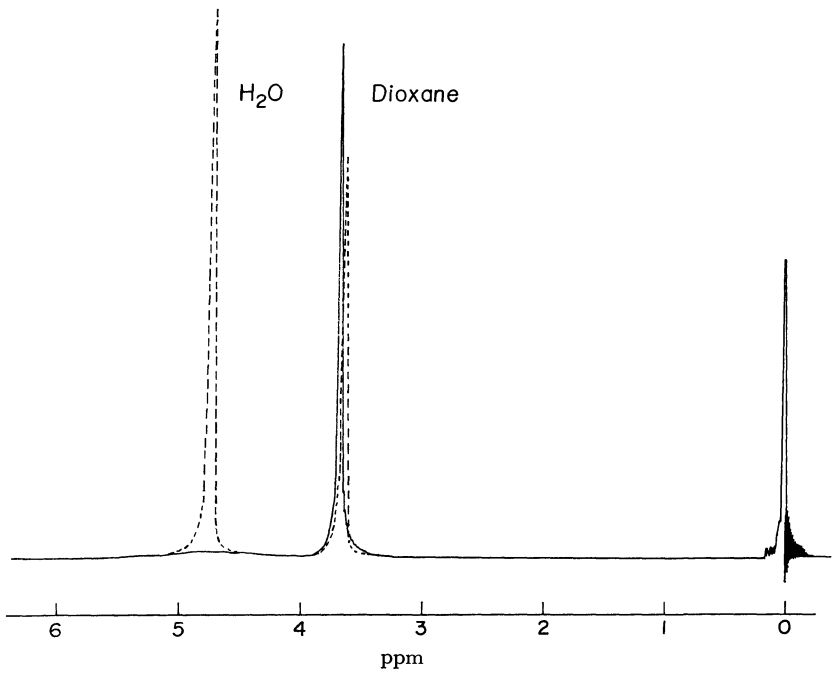

Fig. 3. Proton NMR spectra of water and dioxane in pure water (-----), pure dioxane (-----) and in 80% w/w dioxane-water mixture containing 0.35M $Al(ClO_4)_3$ (————).

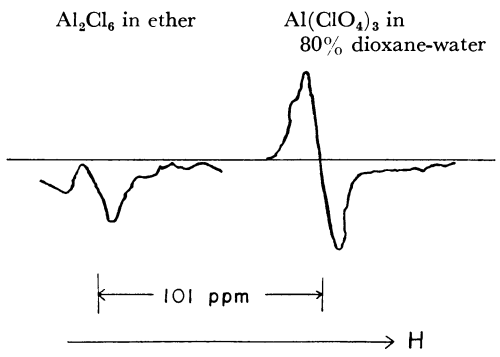

Fig. 4. NMR spectra of ^{27}Al of Al_2Cl_6 in ether and of $Al(ClO_4)_3$ in 80% w/w dioxane-water mixture.

reaction of higher polymers does not noticeably proceed during measurements. Thus, the formation constant obtained in the present work, $*\beta_{p,q}$ are for the intermediates on the way to higher polymers.

The solvent effect on the formation constants of hydrolysis reactions of aluminum ion may be seen from a comparison of $\log *\beta_{2,2}$ found in various media. In aqueous solutions at zero ionic strength the value of $\log *\beta_{2,2}$ spread from -7.55[6] to -6.27[7] at 25°C. In 1M sodium perchlorate solution $\log *\beta_{2,2}$ is evaluated to be -7.07,[8] which differs only slightly from that in 0.2 mol fraction (55.01% w/w) dioxane-water mixture.

NMR spectra of protons and aluminum ions (^{27}Al) in an acid aqueous dioxane (80% w/w dioxane) solution were measured and are shown in Fig. 3 and 4, respectively. In Fig. 3 a peak caused by protons in water becomes broad but no apparent shift in position compared with the peak in pure water (dotted line) was observed. On the other hand, a peak caused by hydrogen atoms in dioxane molecules remained almost unchanged both in shape and in position. Thus, it may be concluded that even in the aqueous dioxane solution with fairly high dioxane concentration, aluminum ions are surrounded only by water molecules.

The NMR spectra of ^{27}Al (Fig. 4) showed that a peak caused by the aluminum ion in the aqueous dioxane solution is located at about 101 ppm higher side of the magnetic field compared with that in Al_2Cl_6 in ether. We concluded that, at least in acid aqueous dioxane solution, aluminum ion has an octahedral configuration which is so in aqueous solutions. If we assume that the aluminum ions still keep the octahedral configuration even in hydrolyzed complexes, the structure of the $Al_2(OH)_2^{4+}$ complex may be similar to that depicted in Fig. 5,

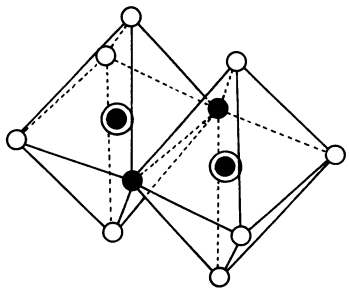

Fig. 5. A model proposed for the $Al_2(OH)_2^{4+}$ complex.

which has been determined by X-ray analysis of a basic aluminum sulfate crystal.[9] The $Al_2(OH)_3^{3+}$ complex may be formed by releasing another proton from one water molecule which occupies an apex of an octahedron of aluminum atom.

The author wishes to thank Professor M. Tanaka for his continued interest in this work. He is indebted to Prof. S. Fujiwara and Dr. H. Haraguchi of Tokyo University for their kind help in NMR measurements of ^{27}Al. The work has been financially supported by the Ministry of Education.

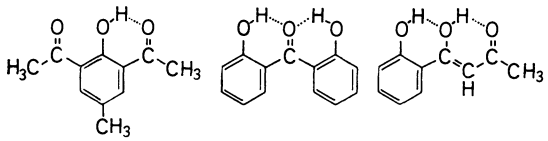
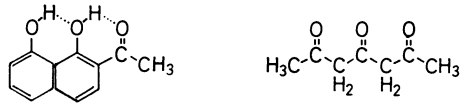
(Received January 30, 1970)

Copper(II) chelates of 2,6-diacetyl-4-methylphenol, 2,2′-dihydroxybenzophenone, 2-acetoacetylphenol and 2-acetyl-1,8-dihydroxynaphthalene were synthesized. The first and last ligands give only a mononuclear chelate of type CuL_2 respectively, whereas the second and third ones give a binuclear complex of type Cu_2L_2 in addition to the mononuclear complex. In the cases of the latter ligands two types of complexes are interconvertible and in a solution phase there exists an equilibrium between them. Higher temperature favors a binuclear form and lower temperature another form. Structures of the complexes are assigned with spectroscopic and thermogravimetric data.

In relation to our work on the metal chelates of 2,4,6-heptanetrione and related compounds,[1] the following four ligands have been synthesized and the properties of copper(II) chelates of the ligands have been investigated. The ligands synthesized are 2,6-diacetyl-4-methylphenol (Hdap), 2,2′-dihydroxybenzophenone (H_2dhb), 2-acetoacetylphenol (H_2aap) and 2-acetyl-1,8-dihydroxynaphthalene (H_2ahn), which are illustrated in Fig. 1. Although the compounds have been reported in literature, no systematic investigation concerning multidentate ligands was reported.



(Hdap) (H_2dhb) (H_2aap)



(H_2ahn) (H_2daa)

Fig. 1. Structure of the ligands.

The coordinating moiety of these ligands resembles that of 2,4,6-heptanetrione. However, features of the ligands are that the mono- or dienol tautomeric structures of the trione is fixed on certain oxygen atoms and that the free rotation of the coordinating site is partly restricted by fused aromatic rings. By analogy with 2,4,6-heptanetrione, the ligands are also expected to behave as bidentate as well as terdentate ligands. Thus, an investigation on the structures and properties of the metal chelates of the ligands may provide us with additional information for understanding 2,4,6-heptanetrione metal chelates.

In the cases of unsymmetrical ligands such as 2-acetoacetylphenol and 2-acetyl-1,8-dihydroxynaphthalene, it is also of interest to study which coordinating sites are preferred for metal chelation if they behave as bidentate ligands.

Experimental

Synthesis of the Ligands. All ligands were synthesized according to the methods given in literature, and were identified by means of their melting points, ultraviolet and infrared absorption spectra, nuclear magnetic resonance spectra and elemental analyses. Melting points and the appearence of the ligands are summarized in Table 1.

Synthesis of the Chelates. Lower temperature favors the mononuclear 1 : 2 chelate formation, while higher temperature favors the binuclear 2 : 2 chelate formation. Thus for preparation of 1 : 2 chelate, procedure A was followed. For preparation of 2 : 2 chelate, procedure B or C was followed.

Procedure A. To a methanolic solution of the ligand (2 mol), an aqueous solution of copper acetate (1 mol) was added with stirring below 15°C. Then pH of the solution was adjusted to 9 with aqueous ammonia. The resulting precipitates were recrystallized from ap-

propriate solvents whenever possible.

Procedure B. Equimolar amounts of the ligand and the metal salt were dissolved in methanol and pH of the solution was adjusted to 9 with aqueous ammonia. The solution was then refluxed for a few hours, until the precipitate of binuclear 2 : 2 chelate came out.

Procedure C. A solution of the mononuclear 1 : 2 chelate in ethanol, chloroform, benzene or pyridine, was refluxed for a few hours, until the precipitates of 2 : 2 chelate came out. If the 1 : 2 chelate was not soluble enough in these solvents, the 1 : 2 chelate was placed in an extraction thimble of a Soxhlet extraction apparatus, and was extracted with hot benzene. The 2 : 2 chelate was precipitated in a refluxing flask.

The results on synthesis of the copper(II) chelates are summarized in Table 2.

Apparatus and Procedure. All melting points are uncorrected. Ultraviolet and visible spectra were measured with a Hitachi 124 recording spectrophotometer. Solid reflectance spectra were measured with a Hitachi EPU-2A spectrophotometer. Infrared absorption spectra and nuclear magnetic resonance spectra were recorded with a JASCO DS-301 spectrophotometer and a Varian A-60 operating at 60 MHz, respectively. Molecular weights were determined with a Mechrolab vapour pressure osmometer. Thermogravimetric analyses on the pyridine adducts were conducted with a Shimadzu automatic recording thermobalance TB-10B. A weighed amount of a chelate (20—100 mg) was placed on a weighing pan of the thermobalance and a few drops of pyridine was added to it. After the sample was left at room temperature until its weight became constant, the temperature of the furnace was raised at a rate of 5°C per minute under atmospheric pressure, and the weight change was recorded automatically up to 150°C. The results are summarized in Table 3.

Results and Discussion

Copper(II) chelates of Hdap, H_2dhb, H_2aap and H_2ahn were prepared according to the procedure in Experimental. As in the case of 2,4,6-heptanetrione metal chelates,[2] the chelates of different ratio of metal to ligand were obtained according to the conditions of synthesis

The 1 : 2 chelates are obtained by procedure A, whereas the 2 : 2 chelates are obtained by either procedure B or C. In general, the 1 : 2 chelate is fairly soluble in various organic solvents such as ethanol, chloroform, benzene and pyridine. Thus, in most cases, they can be obtained as crystalline form by recrystallization from such solvents. On the other hand, the 2 : 2 chelates are hardly soluble in organic solvents except pyridine. The only exception is the 2 : 2 chelate of 2-acetoacetylphenol, which can be recrystallized from a mixture of tetrahydrofurane and ligroin. All chelates obtained do not show any definite melting points below 300°C.

As observed in the copper(II) chelates of 2,4,6-heptanetrione, the 1 : 2 chelate of the diprotonic ligands such as H_2dhb, H_2aap and H_2ahn can be converted into 2 : 2 chelates of the respective ligands, as described in the preparation of 2 : 2 chelates by procedure C. Reversely the 2 : 2 chelate can be converted into a 1 : 2 chelate when the solution of the 2 : 2 chelate in pyridine containing an excess of the ligand is kept at a lower temperature. Thus, the equilibrium seems to occur

$$2Cu(HL)_2 \rightleftarrows Cu_2L_2 + 2L \text{ (in pyridine)}$$

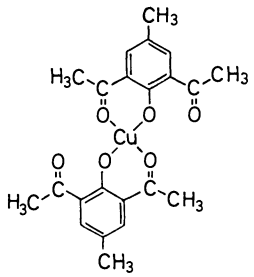
and the higher temperature favors the 2 : 2 chelate and lower temperature the 1 : 2 chelate.

Since the ligands chosen in this investigation are terdentate, there remains the possibility of their affording polymeric forms, especially in the case of the 2 : 2 chelates. The 1 : 2 chelates are, however, so soluble in various organic solvents that they are not likely to be of polymeric form. Moreover, the fairly fast rate of interconversion between the 1 : 2- and 2 : 2 chelates in pyridine suggests that the drastic rearrangement of the chelation is not likely to occur in the process of conversion in a solution phase. The results of the molecular weight determination of the 2 : 2 chelates in pyridine also support the monomeric form. Thus, there is no doubt that the 1 : 2- and 2 : 2 chelates are monomeric at least in a pyridine solution, and this may also be true in solid state. Although there is no positive reason to reject the possibility of affording the polynuclear chelates in solid state, a study with molecular models shows that the polymeric structures can be constructed only with heavy steric hinderance and strain, because free rotation of the coordinating sites is partly restricted by fused aromatic rings.

When the chelates are treated with pyridine, they easily form pyridine adducts, and the number of moles of pyridine per mole of the chelate varies from one to six depending upon the kind of ligand as summarized in Table 3. The reversible pyridine adduct formation is indicative of the vacancy of the coordinating sites of copper(II) on z axis. Two copper(II) ions in the chelate can accept at most four moles of pyridine. Thus, in the case of Cu_2-$(dhb)_2 \cdot 6Py$, two of the six moles of pyridine are not coordinated to copper ions. It is also noted that the last one mole of pyridine does not dissociate up to 150°C. The stepwise dissociation of pyridine with increasing temperature is clearly observed in the chelates of H_2aap, whereas the pyridine on the rest of the chelates dissociates gradually.

Chelate of 2,6-Diacetyl-4-methylphenol (Hdap). The chelate prepared by procedure A is found to have the formula of $Cu(dap)_2$. As this ligand has only one dissociable proton, the binuclear chelate of type Cu_2L_2 can not be obtained even under the condition of procedure B or C. $Cu(dap)_2$ is obtained as well defined green yellow needles after recrystallization from aqueous methanol, and its formula is confirmed by elemental analysis.

The infrared spectrum of the free ligand is characterized by a broad band of ν_{O-H} at 3000 cm^{-1} and a doublet band of free and hydrogen bonded carbonyl groups at 1669 and 1640 cm^{-1}, respectively. The infrared spectrum of the copper chelate, on the other hand, shows no ν_{O-H} band, but still shows $\nu_{C=O}$ bands at 1670 and 1619 cm^{-1} in addition to the new bands at 1530 and 1520 cm^{-1} which are related to the coordinated carbonyl group.

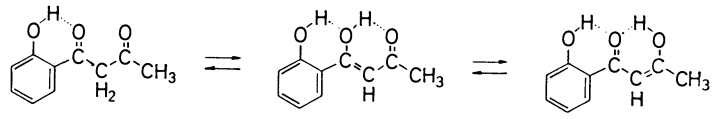


(I) Structure I

From the results, structure I is proposed for the chelate $Cu(dap)_2$. However, the question remains whether the two ligands take *cis* or *trans* arrangement as regards the central metal ion.

Chelates of 2-Acetoacetylphenol (H_2aap). The free ligand may possibly exist as three tautomeric forms A, B and C. The solid H_2aap, however, seems to exist as form B or C, since a free carbonyl band at 1730 cm^{-1} which is observed in chloroform

2) Ref. 1. More details will be published elsewhere.

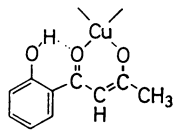


(A) (B) (C)

Scheme 1.

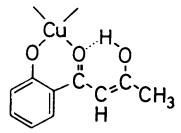
solution, can not be found in the spectrum of a solid sample. In the latter spectrum, absorption bands observed at 1680, 1615 and 1580 cm^{-1} can be assigned to those of the hydrogen bonded carbonyl and the conjugated olefinic groups.

The 1 : 2 chelate, which is obtained as yellow green needles by procedure A, is found to have the formula of $Cu(Haap)_2$. The infrared spectrum of the 1 : 2 chelate does not show a band due to the free carbonyl group, but shows new bands at 1570 and 1515 cm^{-1} which may be related to the coordinated carbonyl groups. From the above results, either of the following two structures, (II) and (III), can be proposed for the 1 : 2 chelate.



(II)

Structure II



(III)

Stucture III

Of the two structures, the chelating moiety of (II) resembles that of bis(benzoylacetonato)copper-(II), and structure (III) resembles that of bis(*o*-hydroxyacetophenonato)copper(II). Comparison of the electronic spectra of $Cu(Haap)_2$ with those of the above two model compounds suggests the probable chelate structure of this compound. The results of the visible absorption spectra of the pyridine solution and the reflectance spectra of solid samples are summarized in Table 4.

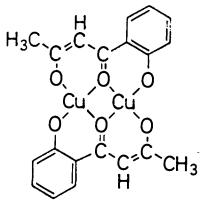
Table 4. Electronic spectra of the copper (II) chelates of 2-acetoacetylphenol, benzoylacetone and *o*-hydroxyacetophenone

Ligand of Cu (II) chelate	Visible absorption spectra in pyridine λ_{max} mμ, (log ε)	Solid reflectance spectra λ_{max} mμ
2-Acetoacetylphenol	680 (1.19), 353 (4.33)	640
Benzoylacetone	664 (1.92), 368 (4.48)	645
o-Hydroxyacetophenone	628 (2.01), 566 (2.14), 362 (3.90)	595

The bands in the range 500—600 mμ can be assigned to the ligand field *d–d* transition band, and the spectrum of $Cu(Haap)_2$ is more closely similar to that of bis(benzoylacetonato)copper(II) than that of bis(*o*-hydroxyacetophenonato)copper-(II) which has two peaks in this region. Thus, it is very likely that the structure of $Cu(Haap)_2$ is that shown in II.

As to the question of the two ligands taking either *cis* or *trans* arrangement, the *trans* structure is more probable because the *cis* structure may suffer from the steric hinderance of phenolic protons.

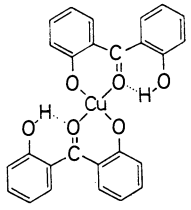
The binuclear chelate $Cu_2(aap)_2 \cdot H_2O$ can be obtained either by procedure B or C as green needles, the yield being higher by procedure B. Molecular weight determined in pyridine solution supports the above formula. No significant difference in infrared spectra is observed between 1 : 2- and 2 : 2 chelates. Thus, it is likely that the structure of $Cu_2(aap)_2$ is that shown in IV.



(IV)

Structure IV

Chelates of 2,2′-Dihydroxybenzophenone (H_2dhb). The 1 : 2 copper(II) chelate is obtained as a yellow brown powder by procedure A, and elemental analysis supports the formula $Cu(Hdhb)_2 \cdot 1/2H_2O$. The hydrogen bonded carbonyl band of the free ligand at 1630 cm^{-1} disappeared in the infrared spectra of the 1 : 2 chelate, and a new



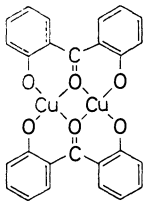
(V)

Structure V

band appearing at 1520 cm^{-1} is assigned to the coordinated carbonyl group. The results suggest structure V for the 1 : 2 chelate. The *trans* form is more probable than the *cis* form because of the steric hindrance of the phenolic protons.

The 2 : 2 copper chelate was obtained as yellow brown powder by procedure B or C, with a slightly higher yield by the latter procedure. The results of elemental analysis and molecular weight determination support the formula $Cu_2(dhb)_2$.

Infrared spectra of the 2 : 2 chelate in 1600—1500 cm^{-1} region differ from those of the 1 : 2 chelate, but structure VI is the most probable for this chelate. It has been reported that the hydrogen atoms at 6- and 6′-positions of the free ligand interfere with each other sterically.[3] Accordingly, the planer structure around copper atoms may be distorted to some extent.



(VI)

Structure VI

Chelates of 2-Acetyl-1,8-dihydroxynaphthalene (H_2ahn). As this ligand is found to be sensitive to atmospheric oxygen, all the procedure with this ligand is carried out in a nitrogen stream.

The 1 : 2 copper(II) chelate is obtained as yellow brown powder by procedure A, and elemental analysis as well as molecular weight determination supports the formula of $Cu(Hahn)_2$. Hydrogen bonded carbonyl band of the free ligand at 1640cm^{-1} disappears in the infrared spectrum of the 1 : 2 chelate, and a new band is observed at 1520 cm^{-1} which is assigned to the coordinated carbonyl groups. These results suggest structure VII for the 1 : 2 chelate. The *trans* form is more probable than *cis* form as discussed previously.

(VII)

Structure VII

An attempt to prepare a 2 : 2 chelate of 2-acetyl-1,8-dihydroxynaphthalene by procedure B, results in a chelate of 3 : 2 composition, whose empirical formula is found to be $C_{21}H_{20}O_9Cu_3$. In this procedure, when pH is adjusted to 9, a 3 : 2 chelate is obtained, whereas a 1 : 2 chelate is obtained when the reaction is carried out at pH 6—7. As the infrared spectrum does not show a sharp band at around 3600 cm^{-1}, it is not likely that the chelate contains copper hydroxide. In contrast to the chelates of 2,4,6-heptanetrione, 2-acetoacetylphenol and 2,2′-dihydroxybenzophenone where the interconversion of the 1 : 2- and 2 : 2 chelates is observed, the 3 : 2 chelate of 2-acetyl-1,8-dihydroxynaphthalene can not be converted into a 1 : 2 chelate. Furthermore, the 3 : 2 chelate is hardly soluble in pyridine, whereas 2 : 2 chelates of the other ligands are fairly soluble in pyridine. Thus, the 3 : 2 chelate may possibly be of an ionic complex or a highly polymeric form. One of the possible structures of this chelate may be something like that shown in VIII.

Titanium and Zirconium in Hydrothermally-altered Rocks from the Tateyama Jigokudani Hot Springs, Toyama, Japan

Masayuki IMAHASHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received February 3, 1970)

Hydrothermally-altered rocks and muds collected from the Tateyama Jigokudani hot springs were analysed for titanium and zirconium. In order to estimate the acidity of the thermal waters which contributed to these altered rocks, the concentration factor of the elements relative to SiO_2 was used for convenience. The titanium and zirconium contents of the alteration products are approximately equal to those of the fresh rocks. This seems to indicate that most of these elements remain in the rocks during the alteration under acidic conditions. The muds are characterized by high values of the concentration factors and the factors proved to be dependent on the acidity of the mud-suspending waters. From the relation between the concentration factors and the pH's of the waters, we could estimate the acidities of the thermal waters which attacked the altered rocks in the earlier stages.

The alteration of silicate rocks generally involves a change in their chemical composition. Under strongly acid conditions, all the chemical constituents except SiO_2 and TiO_2 are almost entirely leached out and the altered rocks are enriched in SiO_2 and H_2O.[1] Iwasaki *et al.* reported on the chemical compositions of alteration products in the Tamagawa hot springs.[2] According to their data, the TiO_2 and SiO_2 contents of these products are larger than those of the original rocks, and the concentration factors of TiO_2 relative to SiO_2 for these alteration products have values ranging from 0.77 to 1.07. The variation in the values of the factors may depend on the nature of the thermal waters which attack the rocks. Therefore, the factor may give some useful indications for use in estimating the environmental conditions of the alteration.

Zirconium can be expected to behave like titanium because of the similarity in chemical properties. Between titanium and zirconium, however, there may be some differences in leachability and in mobility in acid solutions. The differences may depend on the acidity of the thermal waters dominating during the alteration; the changes in the pH of the waters may, that is, reflect in some way the concentrations of these elements in hydrothermally-altered rocks.

There have been no detailed studies of the distribution of titanium and zirconium in altered rocks under acid conditions. The purpose of this investigation is to determine the titanium and zirconium contents of hydrothermally-altered rocks in an acid hot spring area and to estimate the acidity of the thermal waters using the concentration factor of these elements.

Experimental

Samples. The alteration products were collected from the Tateyama Jigokudani hot springs, Toyama Prefecture, where there is still volcanic actions and where there are many acid hot springs. The alteration products collected were divided into two groups according to where they occurred. The first group consisted of altered rocks; most of these are silicified and contain iron sulfide and free sulfur in small amounts. In general, the center part of the altered rocks is gray or a blackish gray, and the surface is white or a grayish white. Suffixes are used to distinguish the center part from the surface; "a" indicates a sample of the center part, "b" idicates the surface. These rocks are probably the alteration products of an earlier stage.

The second group consisted of the muds which were suspended in acid thermal waters. These samples are extremely fine-grained and contain considerable amounts of free sulfur and iron sulfide. These muds are denoted in the sample number by the prefix "s". They are presently undergoing active alteration. The fresh rocks were identified as augite hypersthene andesite by microscopic examination and by X-ray diffraction.*1

Chemical Analysis. Titanium and zirconium were determined colorimetrically using disodium 1,2-dihydroxy-benzene-3,5-disulfonate (Tiron) and 2,7-bis-(azo-2)-phenylarsono-1,8-dihydroxynaphthalene-3,6-disulfonic acid (Arsenazo-III) respectively. A 0.2 g—0.4 g portion of a powdered sample (under 100 mesh) was

*1 The identification was performed by Dr. J. Ossaka, to whom the author wishes to express his thanks.

decomposed with 10 m*l* of concentrated hydrofluoric acid on a hot plate. One milliliter of concentrated perchloric acid was then added, and the mixture was evaporated to dryness. The evaporated residue was fused sodium bisulfate, and the cooled melt was dissolved in dilute hydrochloric acid. The volume of the solution was made up to 50 m*l* with water.

An 1—2 m*l* aliquot of this solution was taken out and titanium was determined according to the method described by Rygg and Wagenbauer,[3] To determine the zirconium, a 5—10 m*l* aliquot of this solution was taken out and evaporated to white fumes with 1 m*l* of concentrated perchloric acid. The solution was then transferred to a 25 m*l* volumetric flask; 13 m*l* of concentrated nitric acid, 2 m*l* of a 10% urea solution, and 2 m*l* of a 0.1% Arsenazo-III solution were added, and the mixture was diluted with water to 25 m*l*. The zirconium content was determined from the absorbance at 660 mμ.[4] Elements commonly in rocks scarcely interfered with the determination at all. The experimental errors (relative) for the titanium and zirconium determinations were within $\pm 3\%$ and $\pm 5\%$ respectively.

Results and Discussion

Contents of Titanium and Zirconium. The titanium and zirconium contents of the alteration products and of fresh rocks are shown in Table 1, along with the percentage of SiO_2 and the ignition loss. Although the SiO_2 content of the altered rocks is larger than that of the fresh rocks, the titanium and zirconium contents are not necessary so; these, rather, have a tendency to scatter. This indicates that considerable portions of all the major constituents except SiO_2 were removed, while titanium and zirconium partly remained in the rocks or were leached out according to the environmental conditions. There is, at any rate, no considerable difference in the contents between the altered and the fresh rocks, so it may be considered that these elements in the rocks are generally resistant to alteration.

In the case of the muds, the SiO_2 content is apparently smaller than that of the altered rocks because considerable portions of these samples are ignition losses largely of free sulfur and water. On the other hand, the titanium and zirconium contents of the muds are approximately equal to those of the altered rocks; this leads to the conclusion that the concentration factors of the these elements in the muds are above unity, as will be discussed below.

Concentration Factors. In order to normalize the concentrations of these elements, relative to

SiO_2, for the alteration products, the concentration factor, denoted by r, is used. It is expressed by the following relation; $r(M)=(M/SiO_2)_a/(M/SiO_2)_f$, where M is the element to be considered and where the subscripts "f" and "a" stand for the fresh and the altered rocks respectively. In the case of discussion of the concentration factors, it must be assumed that the titanium and zirconium contents of the original rocks are essentially constant.

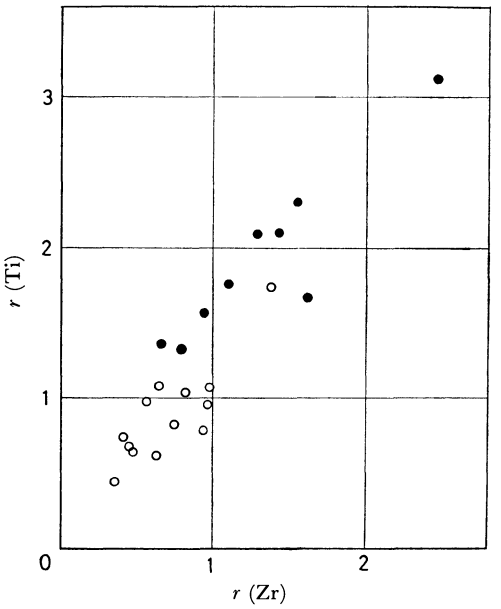

Fig. 1. Relationship between r(Ti) and r(Zr).
○: altered rock, ●: mud

The r values for titanium and zirconium and the ratio of r(Ti) to r(Zr) are shown in Table 1. Figure 1 represents the relationship between these values. These values fluctuate rather widely. However, it is certain that the values of the muds are above unity and that those of the altered rocks are below unity, with a few exceptions. As Fig. 1 shows, there is a linear relationship between these values, but the values of the muds are apparently different from those of the altered rocks. This suggests that there is no considerable difference in the rate of leaching between titanium and zirconium, but that the rates of these elements are different from those of silica. That is, the leaching rates of titanium and zirconium for the altered rocks were higher than those of silica, in contrast with the case of the muds. This may also suggest that the altered rocks were attacked by thermal waters with slightly lower pH values.

The large r values of the muds can be explained in terms of the difference in the leachabilities between these elements and silica and the occurrence of these elements in a resistant fraction in such an environment. Thus, the r values may be effectively used in estimating the conditions of the alteration.

Estimation of the Acidity of Thermal Waters. The variation in r values found for the muds and the altered rocks may be due to the environmental characteristics of the sample locality. The mobility and the leachability of a chemical element during alteration are known to be greatly affected by the acidity of the environment. Therefore, it can be assumed that the acidity is a factor governing the differences in leachability between titanium and zirconium. In Table 2, the acidity and the temperature of the mud-suspending waters are given. Because the disparity of temperature of the mud-suspending waters is not very large, as is shown in Table 2, and as the chemical compositions of the waters are nearly equal to each other, it may be possible to disregard the influences of other factors. In Fig. 2, the r(Ti)/r(Zr) ratio is plotted against the pH of the water in which the mud was suspended. The figure shows that the ratios tend to increase with an increase in the pH of the waters. Thus, these ratios prove to be affected by the pH of the mud-suspending waters; the ratios may provide some indications for use in estimating the acidity of the thermal waters dominating during the alterations.

As is shown in Table 1, the ratios of the altered rocks have values ranging from 0.83 to 1.8. From these values and from Fig. 2, it can be estimated

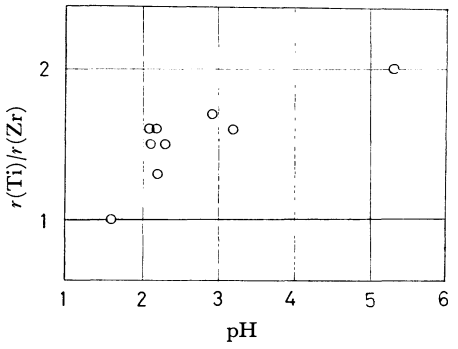

Fig. 2. Relationship between r(Ti)/r(Zr) ratio of muds and pH of the mud-suspending waters.

Table 2. Acidity and temperature of mud-suspending waters

No.	pH	T (°C)	SO_4^{2-} (g/l)	Cl^- (g/l)

that the pH values of the thermal waters which attack the altered rocks range from about 1 to 4, provided that none of the conditions except the acidity in the earlier stage change up to the final stage. It may be concluded that the pH values of the thermal waters are slightly lower than, or approximately equal to, those of the mud-suspending waters. This is consistent with the pH's of hot spring waters in the Tateyama Jigokudani area.[5]

In igneous rocks, most of titanium and zirconium may be incorporated in resistant minerals, such as ilmenite and zircon.[6] In a certain stage of the alteration, however, these elements gradually enter into solutions, but the titanium in an acid solution is slightly less mobile than is zirconium; the pH values of solutions which give rise to the precipitates of titanium and zirconium hydroxides are 1.4 and 2.0 respectively.[7] Moreover, titanium secondary minerals, such as rutile and anatase, are generally resistant to acid.[8] Consequently, during the alteration the Ti/Zr ratio in an alteration product may be changed and it may gradually increase in the later stage of the alteration. The higher the pH values of thermal waters, the larger will be the ratios.

It is necessary to make further leaching experiments on titanium and zirconium obtained from rocks with acid solutions and to study the occurrences of these elements in hydrothermally-altered rocks. These results will be reported in a future paper.

The author wishes to express his thanks to Prof. Masami Ichikuni for his valuable advice and for his critical reading of the manuscript.

Studies of Thin-layer Chromatography of Inorganic Salts. IV. Chromatographic Behavior of Square Planar Complexes in Comparison with that of Octahedral Complexes

Tetsuo BABA[1] and Hayami YONEDA

Department of Chemistry, Wakayama University, Masagocho, Wakayama

(Received February 4, 1970)

The chromatography of copper(II) and platinum(II) complexes on silica gel was investigated in comparison with that of cobalt(III) and nickel(II) complexes. Each complex showed various R_f values from zero to unity, when it was developed with aqueous solutions of various salts. This was interpreted to be due to different degrees of anionic association with the complex. The pattern of deversity of R_f values in copper(II) and platinum(II) complexes was found to be definitely different from that in cobalt(III) and nickel(II) complexes. Thus, different association mechanisms were proposed for both cases. In copper(II) and platinum(II) complexes, association occurs through the direct coordination of the anion to the metal ion, while, in cobalt(III) and nickel(II) complexes, association takes place at the outer-sphere of the complex.

We were interested in obtaining information concerning the behaviors and dissolved states of ions in solution through chromatographic studies. In a previous study[2] it was revealed that silica gel is charged negatively in contact with water and adsorbs cations so strongly that the R_f value of the complex cation is almost zero when developed with distilled water. Such strong adsorption is palliated and the increase of the R_f value is observed, when an aqueous solution of salts such as NaCl or Na_2SO_4 is used as a developer. The sample is eluted mainly through ionic association with anions contained in

1) On leave from the Minoshima High School, Arita-shi, Wakayama.

2) T. Baba, H, Yoneda and M. Muto, This Bulletin, **41**, 1965 (1968).

the developer. In other words, such association reduces the apparent positive charge of the complex cation, which results in the decrease of the electrostatic attraction by the adsorbent and in the increase of the R_f value of the sample. Thus, we undertook to study the feature of ionic association by means of thin-layer chromatography. In the preceding paper[3] the effect of hydration of anions upon association was investigated using the crystal violet cation. In the present paper, we should like to report the characteristic features of association involving square planar complexes in compariosn with those involving octahedral complexes.

Experimental

Thin-layer Chromatography. As an adsorbent, Merck's silica gel H was used without further purification. This was spread on a glass plate with length 25 cm and thickness 0.25 mm.

The complexes used in this investigation were [Co en$_3$]Cl$_3$ [Co gly$_3$], [Cu en$_2$] (NO$_3$)$_2$, [Cu gly$_2$], [Pt en$_2$]Cl$_2$, [Ni en$_3$] (NO$_3$)$_2$ and [Ni gly$_2$ (H$_2$O)$_2$]. Each complex was dissolved in water to 1/50M, and 2.5μl of the solution was spotted at a starting point 5 cm above the lower edge of the plate.

The salts used in development were sodium salts of Cl$^-$, Br$^-$, I$^-$, NO$_2^-$, NO$_3^-$, HCOO$^-$, CH$_3$COO$^-$, SO$_3^{2-}$, SO$_4^{2-}$ and S$_2$O$_3^{2-}$, and potassium salts of OCN$^-$, SCN$^-$ and SeCN$^-$. To obtain the best separation, different salt concentrations of developers were used, *viz.*, 0.2M for cobalt(III), 0.1M for nickel(II), 0.5M for copper(II) and platinum(II) complexes.

Development was carried out at room temperature (20—23°C). For detection of the developed spot an aqueous solution of potassium sulfide was sprayed on the cobalt(III) complex, while the alcoholic solution of rubeanic acid was sprayed on the other three complexes. For visualization of the platinum complex, a special procedure was necessary. Rubeanic acid must be acidified with a small amount of hydrochloric acid, and the sprayed plate must be heated to 100°C.

UV Spectral Measurement. The absorption spectra were recorded with a Hitachi Spectrophotometer Model 124.

Results and Discussion

The R_f values of the complexes are summarized in Table 1. In order to understand the characterisrics of the chromatography of square planar complexes, it is advantageous to discuss the chromatography of typical octahedral complexes first.

The tervalent complex cation is adsorbed so strongly on silica gel, that it can be eluted only through ionic association with anions contained in the developer. Thus, various R_f values of the [Co en$_3$]$^{3+}$ complex were obtained as shown in Table 1. This seems to reflect various degrees of anionic association. A marked feature of the chromatography of the [Co en$_3$]$^{3+}$ complex is that the difference in R_f values among univalent anions is not so marked, and that there is a definite difference in R_f values between univalent and bivalent anions. This seems to be the characteristics of octahedral complexes. In fact, the R_f value pattern of the

a) Development was not carried out, as no special difference of R_f values was expected.
b) The complex was reduced by the thiosulfate.
c) The developed spot was not identified, because red selenium appeared over the plate surface during the heating process for visualization of the spot.

3) T. Baba, K. Sakushima, and H. Yoneda, This Bulletin, **43**, 931 (1970).

$[Ni\ en_3]^{2+}$ complex is quite similar to that of the $[Co\ en_3]^{3+}$ complex as seen in Table 1.

In the neutral $[Co\ gly_3]^0$ complex, the R_f value is very large even with distilled water and is not affected much with salt solutions. This suggests that the octahedral neutral complex has little tendency towards association. A marked contrast to this can be seen in the R_f value pattern of the corresponding $[Cu\ gly_2]^0$ complex. As shown in Table 1, the $[Cu\ gly_2]^0$ complex is so strongly adsorbed on silica gel, it remains near the starting point when developed with distilled water. Such strong adsorption can not be explained by a simple electrostatic attraction between silica gel and the complex, because the complex as a whole is elecrically neutral. We must, therefore, assume that the adsorption of the complex takes place through the direct coordination of SiO_2 to the copper(II) ion. In other words, the oxygen atom of SiO_2 occupies the axial position of the square planar copper complex. Any kind of anion can make such direct coordination. Thus, a wide variety of R_f values were observed, when various salt solutions were used as a developer. This is considered to correspond to a wide variety of degree of coordination equilibrium between the complex and the anion. This makes a marked contrast to the case of the octahedral $[Co\ gly_3]^0$ complex which has no more reserved coordination seat to be occupied by the anion. It should be noted that the R_f value of the copper complex seems to depend not on the ionic charge of anions but on the kind of anion, especially on the kind of donor atoms. Thus, the R_f value is definitely larger in the case of I^- than in the cases of Br^- and Cl^-, and the large R_f values in the cases of $S_2O_3^{2-}$, SO_3^{2-}, NCS^- and $NCSe^-$ can be regarded to result from the coordination through sulfur and selenium atoms. On the other hand, the R_f value is relatively small in the case of SO_4^{2-}, which can be understood by considering that the coordination is made through the oxygen atom. A quite similar pattern of R_f value variation is observed in the $[Cu\ en_2]^{2+}$ complex too, as can be seen in Table 1. In this case the R_f value also depends not on the ionic charge of anions but on the kind of donor atoms. This is in contrast to the corresponding $[Co\ en_3]^{3+}$ complex.

The characteristics of the chromatography of the typical square planar $[Pten_2]^{2+}$ complex is quite similar to that of $[Cuen_2]^{2+}$ complex. The R_f value is definitely larger in the case of I^- than in the cases of Br^- and Cl^-, and definitely smaller in the case of SO_4^{2-} than in the cases of SO_3^{2-} and $S_2O_3^{2-}$. Therefore, in the platinum(II) complex also, association of anions is presumed to occur not in an equatorial direction but along the axial direction of the complex. In the case of $[Ni\ gly_2(H_2O)_2]^0$, though the complex has an octahedral configuration, the R_f value pattern appears to be similar to that of the square planar complex (R_f-value: 0.06 with H_2O, 0.82 with I^-, and 0.85 with SO_4^{2-}). Therefore, it is presumed that the water

molecules at the axial positions can be replaced by the anion.

The above-mentioned ionic association can be supported from the spectral data of the complex. As can be seen in Fig. 1, the UV spectra of the $[Coen_3]^{3+}$ and $[Cuen_2]^{2+}$ complexes dissolved in 1M Na_2SO_3 solution show a new band in the near ultraviolet region, which is not observed in water. Such a band can be regarded as a charge-transfer band due to ionic association. A similar charge-transfer band was also observed in the $[Cugly_2]^0$ complex (See Fig. 2). It should be noted that the intensity of the charge-transfer band in the $[Cu\,gly_2]^0$ complex is much larger than that in the $[Cu\,en_2]^{2+}$ complex. Thus a greater interaction is presumed between SO_3^{2-} and $[Cugly_2]^0$ than between SO_3^{2-} and $[Cuen_2]^{2+}$.[4] On the contrary, the absorption spectrum of $[Cogly_3]^0$ is almost the same both in water and in 1M Na_2SO_3 solution, which suggests no marked interaction between the complex and SO_3^{2-}.

4) The association constant for $[Cu\,alanin_2]^0$ and SO_3^{2-} is 240, while that for $[Cu\,en_2]^{2+}$ and SO_3^{2-} is only 25. H. Yoneda, This Bulletin, **29**, 68 (1956); *ibid.*, **29**, 319 (1956).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2482—2486 (1970)

Photon-Activation Analysis for Iodine by Using Cesium as the Internal-Reference Element*1

Hui-Tuh Tsai, Toyoaki Kato and Yoshinaga Oka

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received February 6, 1970)

The internal-reference method proposed previously has been applied to the determination of iodine by photon-activation analysis, using cesium as the internal-reference element. The present method is based on the measurement of the ^{126}I, ^{124}I and ^{123}I activities produced by the neutron-emitting reactions in iodine, and on the comparison of these activities with that of ^{130}I coming from cesium by the (γ, 2pn) reaction. A lithium-drifted germanium diode with a sensitive volume of 36 cm^3 was used as the detector. The yields of various photonuclear reactions in both elements have also been examined as a function of the bremsstrahlung maximum energies up to 65 MeV. A series of synthetic mixtures of iodine-cesium with known weight ratios has been used to check the sensitivity and the accuracy of this method. We found that we could determine amounts of iodine down to 0.2 μg under the present experimental conditions.

Recently, photon-activation analysis has been established as a useful analytical method for the determination of a number of elements in the periodic table. One of the advantages of photon-activation analysis, as compared with high-flux thermal neutron activation analysis, is that interferences due to ^{24}Na and ^{38}Cl encountered in the thermal neutron activation of various biological materials can be eliminated. Thus, Anderson *et al.*[1] and Wilkniss and Linnenbom[2] utilized the ^{19}F-(γ,n)^{18}F reaction in the determination of fluorine in biological samples and in sea water respectively. The bremsstrahlung-activation technique was also applied to the determination of iodine in biological materials,[3,4] in pharmaceuticals,[5] and in sodium chloride and sodium bromide media.[6]

On the other hand, the present authors have proposed the internal-reference method of activation analysis and have applied this method to the determination of silver in palladium[7] and to that of antimony in tin[8] by activation with thermal neutrons. By this method, the sources of errors associated with activation analysis, such as flux irregularities, can be avoided and no correction for the chemical yield is necessary. Another possible application of this method lies in photon-activation analysis. The residual activities from (γ,xn) reactions in an element to be determined can be compared with those from the (γ,p), the (γ,2pn), the (γ,α), or another charged particle emitting reactions in an internal-reference element. Recently, methods of photon-activation analyses for the determinations of arsenic and niobium have been reported; these methods use selenium and molybdenum respectively as the internal reference elements.[9,10]

The present work concerns a method for the determination of iodine by using cesium as the internal-reference element, along with bremsstrahlung from a linear electron accelerator. The present method depends on the much greater resolving power of a lithium-drifted germanium detector. A study is also included of the yields of photonuclear reactions at several different bremsstrahlung maximum energies up to 65 MeV.

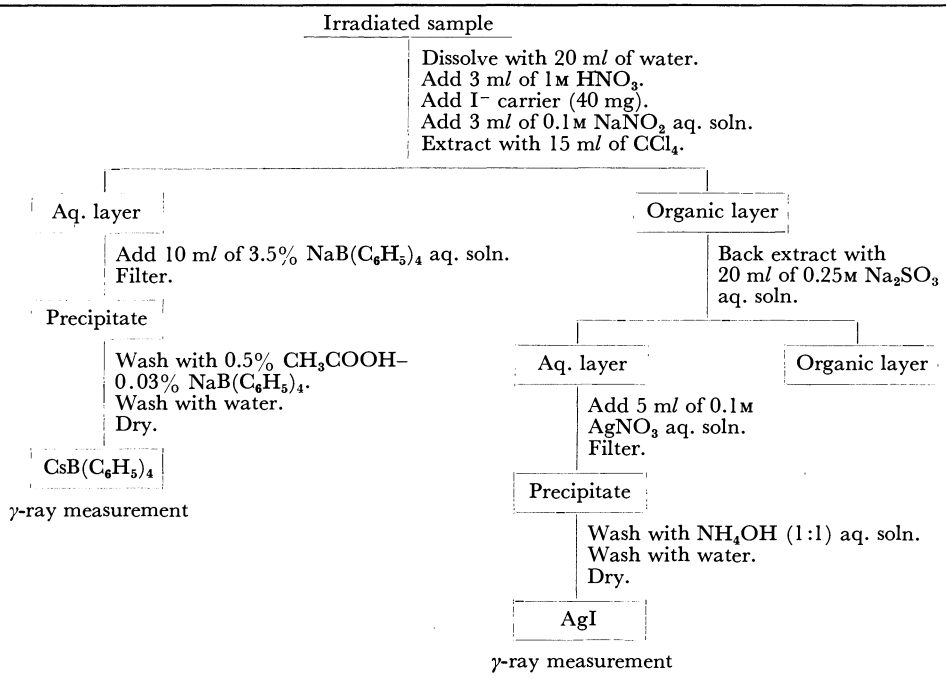
Table 1. Separation scheme



Experimental

Materials and Irradiation. Cesium chloride and potassium iodide of guaranteed reagent grades were used as the sample materials. A series of synthetic iodine-cesium mixtures with known weight ratios, ranging from 8.87×10^{-3} to 2.64×10^{-4}, were prepared by mixing these two kinds of compounds. Each sample, weighing about 500 mg, was placed in a quartz tube with an internal diameter of 6 mm, and was irradiated by bremsstrahlung with maximum energies up to 65 MeV. Irradiations were terminated after from 30 min to 2 hr. A linear electron accelerator of Tohoku University was used as the bremsstrahlung source. The electron beam was converted to bremsstrahlung photons by a platinum converter with a thickness of 3 mm. In the energy range from 40 to 65 MeV, the range used in this experiment, the average beam current was at least 100 μA, measured at the position of the converter using a current monitor. The pulse-repetition rate was 250 pps, with a pulse width of 3 μsec. During irradiation, the samples were located in a water-cooled sample holder on the bremsstrahlung-beam axis immediately behind the converter. To monitor the bremsstrahlung flux to which the samples were exposed, a thin sheet of gold was wrapped around each sample tube; this was irradiated together with the sample.

Radiochemical Separation. After irradiation, each sample was dissolved with water, and 40 mg of an iodine carrier were added; the sample was subjected to the radiochemical procedure diagrammed in Table 1.

After oxidation with sodium nitrite, the iodine was extracted with chloroform and then back-extracted with an aqueous solution of sodium sulfite. The iodide was precipitated as silver iodide, filtered, washed, and dried. After the removal of the radioiodine, cesium was precipitated as its tetraphenylborate from the aqueous layer, filtered, washed, and dried. The final precipitates were packed in thin aluminum foil for the determination of the chemical yield and for the measurement of the γ-ray spectra. The chemical yield of iodine was 70—75%.

Radioactivity Measurements. The γ-ray spectra were measured with a lithium-drifted germanium detector with a sensitive volume of 36 cm^3, coupled to a TMC 1024-channel pulse-height analyzer. A sample was measured at a fixed position, 9 mm from the active surface of the detector. The counting efficiencies of this detector had previously been determined as a function of the source distance and the γ-ray energy, by counting a series of calibrated sources of known activities. The counting system had a resolution of 4 keV for the 661.6 keV γ-line of ^{137}Cs.

Yield Determination. A photonuclear yield is defined as the rate of the production of a given radioactive nuclide per mole of the target nuclide when a standard amount of bremsstrahlung radiation with a given maximum energy has passed through the target during the irradiation period. In the present experiment, the initial decay rates of the various activities produced were determined from a decay curve analysis of the counting rate of the relevant photopeak area. The corresponding saturation rates were computed and normalized for the bremsstrahlung dose rate, which was measured in terms of the amount of ^{196}Au activity produced by the $^{197}Au(\gamma,n)^{196}Au$ reaction in gold foil irradiated together with the sample.

After correcting for chemical yields, counting efficiencies, branching ratios,[12] and the internal conversion

12) The decay schemes used were those listed in G. M. Lederer, J. M. Hollander and I. Perlman, "Table of Isotopes," Sixth Ed., John Wiley & Sons, New York (1967).

Table 2. Photonuclear reactions and nuclear characteristics of the product iodine nuclides[a)]

	(γ,6n)	51.3	^{121}I[b)]	2.1 hr	0.212(90)
	(γ,7n)	61.3	^{120}I[b)]	1.3 hr	0.562(100)

a) The data for ^{125}I and ^{122}I are not included because the former nuclide emites only very weak γ-ray (35 keV, 100%) and the latter has a short half-life (3.5 min).
b) Positron emitter.

electrons,[13] the yields were expressed relative to that of the ^{133}Cs(γ,n)^{132}Cs processes, which was measured by means of the amount of the 0.667 MeV γ-ray (95.6%) of 6.5d-^{132}Cs.

Results and Discussion

Photonuclear Reaction. Although the yield is strongly dependent on the photon energy, and, although, hence, higher sensitivities can be expected with higher maximum electron energies, it should be noted that interferences due to the competitive nuclear reactions would also increase in such circumstances. In order to determine the most suitable conditions for the determination of iodine in iodine-cesium mixtures, therefore, the induced photonuclear reactions and their production rates were investigated by irradiating the two elements individually by bremsstrahlung with several different maximum energies, 40, 45, 60, and 65 MeV. The possible reactions leading to the production of radionuclides of the present importance in this energy region, as well as their nuclear characteristics, are summarized in Table 2. The *Q*-values of the reactions were calculated on the basis of the difference in mass between the target and the product nuclei.

The threshold energy considerations show that the excitation of a nucleus by photons with energies up to 65 MeV produces excited states of the compound nucleus which can emit up to seven nuclei, leading to the production of several activities. Iodine and cesium are both elements with a single-isotopic composition. This makes the assignment of reaction paths for the (γ,xn) processes easy. On the other

Table 3. Photopeak activities of iodine nuclides formed by ^{127}I (γ,xn) reaction with 45 MeV bremsstrahlung

Nuclide	γ-ray energy (MeV)	Photopeak activity[a)] (cpm/mg)	Limit of determination (μg)
^{126}I	0.386	5.20×10^4	0.2
	0.48	2.73×10^3	3.7
	0.751	2.47×10^3	4.0
	0.870	4.92×10^2	20
^{124}I	0.603	2.69×10^3	3.7
	0.722	3.45×10^2	29
^{123}I	0.159	1.79×10^4	0.6

a) At the end of 2 hr-irradiation with a dose rate of bremsstrahlung with which 0.60 μCi^{196}Au is produced by the (γ,n) process in 1 mg Au.

13) The tables in M. E. Rose, "Internal Conversion Coefficients," North-Holland Publ. Co., Amsterdam (1958), were used.

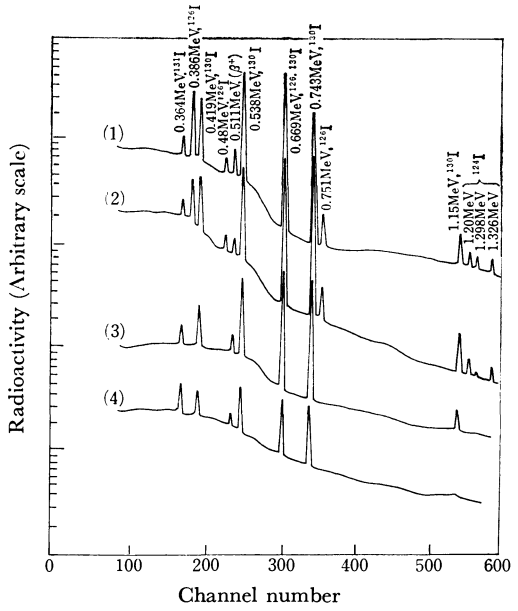

Fig. 1. γ-Ray spectra of iodine activities separated from cesium samples.
1) Irradiated with 65 MeV bremsstrahlung for 30 min; 13 hr after irradiation.
2) Irradiated with 60 MeV bremsstralung for 1 hr; 5.5 hr after irradiation.
3) Irradiated with 45 MeV bremsstrahlung for 1 hr; 9 hr after irradiation.
4) Irradiated with 40 MeV bremsstrahlung for 1 hr; 30 hr after irradiation.

hand, as Table 2 shows, all the iodine nuclides from ^{133}Cs except ^{131}I, can be formed through several different reaction paths.

When an iodine sample was irradiated by 45 MeV bremsstrahlung for a period of 2 hr, the production of ^{126}I, ^{124}I, and ^{123}I was recognized by means of their characteristic γ-rays in the γ-ray spectra. The areas under the photopeaks of the principal γ-rays from those nuclides are given in Table 3. The radioactivity strength of the 0.386 MeV γ-ray from ^{126}I produced by the (γ,n) reaction on ^{127}I was the highest over the energy range investigated; hence it provided the most sensitive method for the determination.

Figure 1 shows the γ-ray spectra of the iodine fractions separated from the cesium samples. It can be seen that ^{131}I, ^{130}I, and ^{126}I were produced at 60 MeV and at 65 MeV, but that the ^{126}I activities can not be detected in any appreciable amounts at excitation energies below 45 MeV. The data listed in Table 2 show that the only possible reaction leading to the production of ^{126}I from cesium at 45 MeV is the ^{133}Cs(γ,α3n)^{126}I reaction. The Coulomb barrier height for this reaction can be calculated as 14.5 MeV; this would restrict the emission of α-particles from an excited state of the cesium nucleus. The yields of the photonuclear reactions for the productions of those nuclides are shown in Table 4.

It should be noted that, with a maximum excitation energy of more than 60 MeV, the more deficient in neutron number the iodine nuclides are, the higher are their yields. This behavior has been emphasized in the previous photospallation work with bremsstrahlung photons up to 250 MeV.[14]

The Determination of Iodine. In the determination of iodine, irradiation were performed by

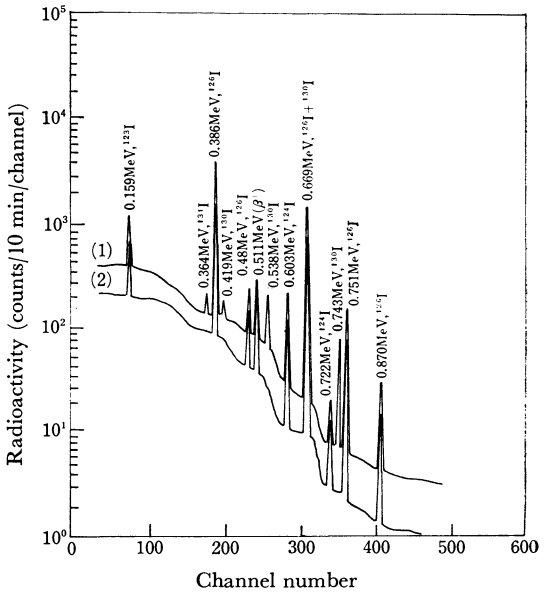

Fig. 2. γ-Ray spectra of radioiodine; (1) separated from an irradiated iodine-cesium mixture (I/Cs=2.64×10^{-4}), 7.5 hr after irradiation, and (2) of iodine sample.

Table 4. The yields of ^{133}Cs (γ, 2pxn) reactions as a function of bremsstrahlung maximum energy

Reaction	Yield relative to ^{133}Cs(γ,n))^{132}Cs			
	40 MeV	45 MeV	60 MeV	65 MeV
^{133}Cs(γ, 2p)^{131}I	7.20×10^{-7}	2.32×10^{-6}	1.27×10^{-5}	1.44×10^{-5}
^{133}Cs(γ,2pn)^{130}I	3.27×10^{-7}	1.87×10^{-6}	1.39×10^{-5}	1.61×10^{-5}
^{133}Cs(γ,2p5n)^{126}I	Not detected	Not detected	1.65×10^{-4}	2.48×10^{-4}

bremsstrahlung with a maximum energy of 45 MeV, and the photopeak activities due to ^{126}I, ^{124}I and ^{123}I were compared with the reference activity, ^{130}I, from cesium. The synthetic iodine-cesium mixtures were irradiated for a period of 2 hr. A typical γ-ray spectrum of the iodine fraction is shown in Fig. 2, together with that of the iodine sample. From the composite spectra obtained, the photopeak areas under the 0.386, 0.480, 0.751 and 0.870 MeV γ-rays from ^{126}I, the 0.603 and 0.772 MeV γ-rays from ^{124}I, and the 0.159 MeV γ-ray from ^{123}I were measured. Then the ratios of all of those activities to the photopeak area under the 0.538 MeV of ^{130}I were computed. All the activity data were corrected for decay to the end of irradiation. Table 5 shows the results, where the R_{A_0}'s represent the activity ratios and where the R_W's are the weight ratios, I/Cs. A good proportionality is given in each case between the R_{A_0}'s and the R_W's. A relative standard deviation of within ±4% was obtained in the weight-ratio range examined here. When the amount of iodine needed to give 100 cpm is defined as the limit of determination, the sensitivities of this method can be calculated to be as given in the last column of Table 3.

Under the present experimental conditions, amounts of iodine down to about 0.2 μg can be determined.

An increase in sensitivity may be expected with a higher bremsstrahlung dose rate and with a longer period of irradiation. A general applicability of this method will be found in the determination of the iodine content in samples to be analyzed when we add a proper amount of cesium as the internal-reference element.

Considerations were then given to the elements which would cause interferences in this method. The iodine nuclides can be produced by the (γ,pxn) reactions on xenon, *e. g.*, ^{129}Xe(γ,p2n)^{126}I, $-Q=$ 24.22 MeV. However, considering the abundance of xenon in samples ordinarily encountered, it may not appear to be a serious source of interference. The ^{130}Ba(γ,3pn)^{126}I ($-Q=29.36$ MeV) reaction is also a possible source of interference. However, the production rate of this reaction is low because of the small natural abundance of ^{130}Ba(0.101%) and because of the Coulomb barrier restriction inherent in this reaction. In the present case, the neutron reactions which arise from photoneutrons cause no serious problems.

In conclusion, the authors believe that the method presented here holds considerable promise for the accurate determination of iodine in samples of various origins.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2487—2491 (1970)

A New Method of Preparing θ-Alumina and the Interpretation of Its X-Ray-powder Diffraction Pattern and Electron Diffraction Pattern

Goro YAMAGUCHI, Itaru YASUI and Wen-Chau CHIU

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received February 12, 1970)

Highly crystallized θ-alumina was obtained by a two-step treatment, by hydrothermal and thermal treatment, of γ-alumina. Its X-ray-powder diffraction pattern was interpreted based on the structure of β-gallia, and least-squares refinements were carried out. The electron diffraction pattern of θ-alumina from boehmite was also interpreted, and the directional relations between the phases were established.

The preparation of θ-alumina has been studied since θ-alumina was recognized as a transient alumina by Stumph *et al.*[1-3] As to the structure of θ-alumina, an attempt has been made to index the X-ray-powder diffraction peaks using a hexagonal cell, but the proper indices have not yet been given.[4]

On the other hand, β-gallia, the high-temperature form of gallias, was revealed to have an isostructure with θ-alumina.[5-7] The single crystal of β-gallia was prepared, and its structure analysis was carried out by X-ray diffraction.[8-10] The X-ray powder diffraction pattern of θ-alumina has, however, not been interpreted so precisely that the identification of pure θ-alumina is unperfect, this makes the studies of the alumina polymorphs unsure.

In the present study, a new method of preparation will be described, the X-ray-powder diffraction and the electron diffraction pattern will be interpreted, and a least-squares refinement of the structure will be reported.

Experimental

Preparation of θ-Alumina from γ-Alumina (The New Method). The method of preparing the γ-alumina used as the starting material of θ-alumina was as follows.[11] Alumina gel was prepared by the procedure

through which an aluminum chloride of a 0.5-mol/*l* aqueous solution was neutralized with a 14% ammonia aqueous solution to pH 7.5; the gel thus precipitated was filtered out and rinsed. The gel was then aged in ethylenediamine, a 5% aqueous solution, for 3 days at 30—40°C, by which time it had crystallized into nordstrandite. This nordstrandite was then heated and dehydrated at 700°C in air for 1 hr; the η-alumina was thus obtained.

This η-alumina was treated hydrothermally at 500°C, under 150 atm, for 45 hr; quite well-crystallized θ-alumina was thus obtained. When this θ-alumina was heated again at 1000°C in air for 0.5 hr, it became highly well-crystallized θ-alumina.

Preparation of θ-Alumina from Boehmite. Well-crystallized boehmite was prepared from gibbsite by

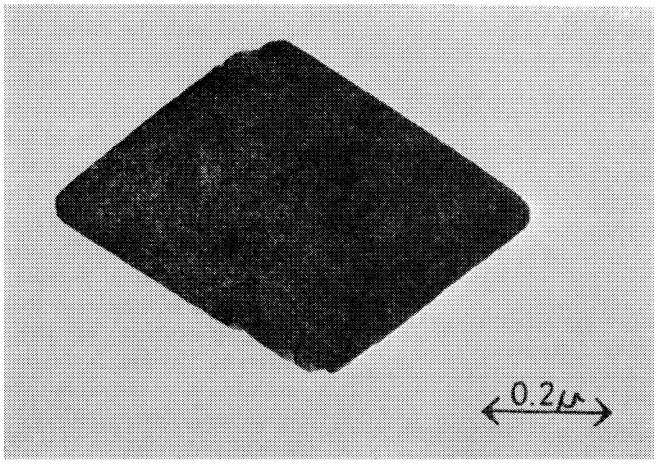

Fig. 2. Electron-micrograph of θ-alumina having the initial own shape of boehmite from well-crystallized boehmite.

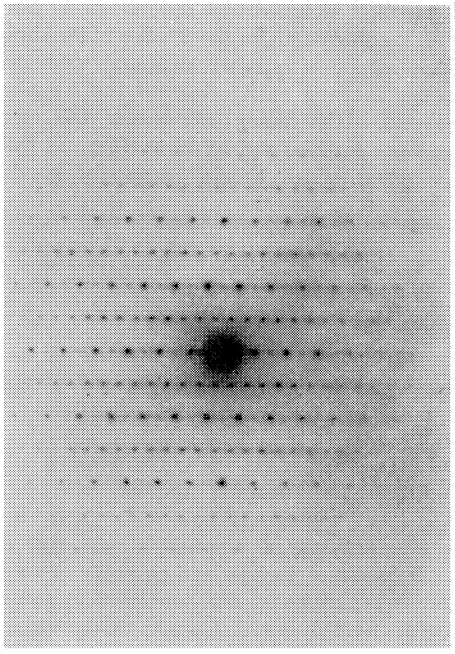

Fig. 3. Electron diffraction pattern of θ-alumina from well-crystallized boehmite.

hydrothermal treatment. This boehmite was heated at 1100°C in air for 2 hr, θ-alumina with the initial shape of boehmite was thus obtained.

X-Ray Powder Diffraction. The X-ray-powder diffraction pattern of θ-alumina from η-alumina was taken with a recording X-ray diffractometer, using Ni filtered Cu$K\alpha$ radiation, as is illustrated in Fig. 1. This pattern shows a fairly good crystallinity.

The numbers of the peaks and the relative intensities obtained from the areas of the peaks are given in the 1st and 3rd columns of Table 1 respectively.

Electron Diffraction. An electron-micrograph of θ-alumina with the shape of boehmite was taken, as is illustrated in Fig. 2. The electron-diffraction pattern of θ-alumina was also taken, as is illustrated in Fig. 3. In Fig. 2, the *a*-axis of boehmite lies in the direction of the short diagonal of the rhombus, the *b*-axis is parallel to the long diagonal, and the *c*-axis is parallel to the incident electron beam.

Results and Discussion

Analysis of the Lattice and Atomic Parameters and the Indexing of the Powder-diffraction Pattern. The programs for the calculation of the atomic and lattice parameters were written for the HITAC 5020E computer by the authors. On the basis of the structure of β-gallia,[10] the intensities were computed on the assumption that aluminum atoms occupy the positions of gallium atoms as substitutes. Moreover, the index of each peak and its overlapping state were confirmed, as is shown in Table 1.

The lattice parameters calculated by the least-squares method are given in Table 2.

Table 2. Lattice dimensions of θ-alumina

Monoclinic	$C_{2h}-C_{2/m}$
$a=$	11.813 ± 0.010Å
$b=$	2.906 ± 0.002Å
$c=$	5.625 ± 0.005Å
$\beta=$	$104.1\quad\pm0.1°$

The transformation matrix from the cubic lattice (*HKL*), that is, the lattice of spinel, to θ-alumina's monoclinic lattice (*hkl*) is given as follows:

$$\begin{pmatrix} h \\ k \\ l \end{pmatrix} = \begin{pmatrix} -1/4 & 1/4 & -3/2 \\ 1/4 & 1/4 & 0 \\ 1/2 & -1/2 & 0 \end{pmatrix} \begin{pmatrix} H \\ K \\ L \end{pmatrix}$$

The spinel indices corresponding to θ-alumina and their multiplicities are given in the 7th and 8th columns of Table 1.

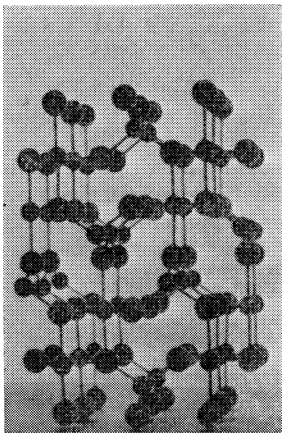

Fig. 4. Structure model of θ-alumina.
Large sphere: Oxygen
Small sphere: Aluminum

The least-squares refinement of the structure was executed with the initial value given in Table 3,[10] and the reliability factor was reduced from 0.17 to 0.08. The final coordinate, along with their estimated standard deviations, are given in Table 4, while the structure model is illustrated in Fig. 4.

This refinement reveals shifts of aluminum atoms from the ideal positions. The interatomic distances are given in Table 5. These interatomic distances show that the $Al(1)O_4$ tetrahedron is more distorted than that of β-gallia, but that the $Al(2)O_6$ octahedron is similar to that of β-gallia.

Interpretation of the Electron-diffraction Pattern. In Fig. 5, (a) is the shape of boehmite and (b) is a spinel lattice of the corresponding θ-alumina. Accordingly, in the electron-diffraction pattern of θ-alumina (Fig. 3), the horizontal direction corresponds to the c-axis of the spinel lattice of Fig. 5(b). This direction corresponds to one of the three diagonal directions of oxygen octahedrons in cubic closest packing of θ-alumina; it can thus be concluded that the horizontal direction in Fig. 2 corresponds to the a^*-axis of θ-alumina or to one of the two other diagonal axes perpendicularly crossing each other on the b-c plane of θ-alumina. Of these three cases, the electron-diffraction pattern clearly shows (Fig. 3) that the horizontal direction should correspond to the a^*-

axis of θ-alumina, in view of the possible reflections of $h0l$. This relation is shown in Fig. 5(c) and Fig. 6.

In this case, θ-alumina has a twinning structure or a twinning-like aggregate structure. The twinning phenomenon can be explained as follows: there are mirror planes parallel to the (110) planes in the spinel lattice, as is shown in Fig. 6, and two mirror planes, I and II, perpendicularly crossing each other are to be considered. The other (110) plane need not be considered, because it is not a mirror planes in γ-alumina through which θ-alumina is formed from boehmite. If one of the two mirror plane, plane II, is conserved as a mirror plane in the θ-alumina ($C_{2h}C_{2/m}$) lattice, the other, plane I, can not become a mirror plane, but it can possibly become a twinning plane. On the assumption of this twinning structure, the reciprocal lattice of θ-alumina is illustrated in Fig. 7(b). This figure is in good agreement with the observed electron-diffraction pattern. Figure 7(a) represents the indices of θ-alumina without a twinning structure. The reason why the two planes do not alternate must be investigated in the future.

In the electron-diffraction pattern, weak spots are observed; they are shown in Fig. 3 and are expressed by the smallest circles in Fig. 7(b). These spots show the distortion of the crystal structure from $C_{2/m}$, but the X-ray-powder diffraction does not show any evidence for this distortion. Therefore, it can be said that the true space group is distorted from $C_{2/m}$, but that the atomic arrangement of the structure analyzed above with $C_{2/m}$ is almost true.

All the calculations were performed with a computer of the Computation Center of Tokyo University.

Complexes Coordinated by 2,2′-Bipyridine Negative Ion. I. Synthesis of Sodium 2,2′-Bipyridinetetracarbonylchromium

Youkoh KAIZU and Hiroshi KOBAYASHI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 10, 1970)

Bipyridinetetracarbonylchromium was reduced by sodium metal in tetrahydrofuran. The first stage product of the reduction which showed a spectrum similar to that of sodium bipyridine (Na^+bipy^-) was isolated. The complex was identified as $Na[Cr(CO)_4bipy]$ by elementary analysis. On the basis of the electronic absorption spectrum and the electron spin resonance, the complex formed in the reduction was concluded to be complex coordinated by mononegative ion of bipyridine and should be named sodium 2,2′-bipyridine(1−)-tetracarbonylchromium(0).

An electronic configuration of the rare gas is required for the central metal atom in a stable compound of a transition metal in the lower oxidation state. Sidgwick's rule states that no open-shell exists in a stable compound. This rule has been found to be satisfied in various systems including organic and organometallic species. In the higher oxidation state, however, the transition metal ions with open *d* electron shell can exist in various stable coordination complexes. Even in an essentially ionic complex charge delocalization effect is crucial in coordination binding. However, the unpaired electron existing in the complex has been detected mainly on the central metal orbitals by physical measurements such as ESR.

For the past decade, tris-bipyridine complexes in the lower oxidation states have been prepared[1] and their electronic structures have been studied.[2-4] These compounds, even if in the lower oxidation states, can exist with open shell electronic configurations.[1] Monomeric tris-bipyridine complexes of the lower oxidation states are stabilized partly by chelate effect and partly by back-donation due to a higher π acceptability of the coordinating bipyridine. Migration of $d\pi$ electron into the antibonding π molecular orbital of the coordinating bipyridine makes the central metal more positive and therefore more σ-acceptable.

Some monomeric metal carbonyls of open shell electronic configuration have recently been succesfully prepared. An open shell metal carbonyl $[V(CO)_6]$ was obtained by oxidation of a closed shell metal carbonyl, $[V(CO)_6]^-$.[5] Oxidation or reduction of closed shell metal carbonyl is expected to give an open shell structure. However, in many cases it forms a dimer with carbonyl groups bridging or with metal-metal bonds.

In this paper, we present the synthesis of a new type of metal carbonyl with coordinating negative ion of 2,2′-bipyridine.

Experimental

Materials. 2,2′-Bipyridine (bipy) and its 4,4′-dimethyl (4dmbip) and 5,5′-dimethyl (5dmbip) derivatives were synthesized by the method of Sasse and Whittle.[6] Hexacarbonylchromium $Cr(CO)_6$ was of reagent grade (Strem Chemical Incorporated, Mass. U.S.A.) and was used without further purification. All other reagents and solvents were commercially available. Tetrahydrofuran (THF) used for solvent was purified by careful distillation over cuprous acetate, and a trace of water was removed by $LiAlH_4$.

Preparation of Compounds. $Cr(CO)_4bipy$ was prepared by the method of Stiddard.[7] Dimethyl substituted bipyridine complexes also were prepared by the same method. $Cr(CO)_4$4dmbip: Hexacarbonylchromium (1.1 g) and 4dmbip (0.95 g) were refluxed in toluene (50 ml) for 2 hr under oxygen-free, dry nitrogen atmosphere. Unreacted hexacarbonylchromium sublimed from the reaction vessel into the reflux condensers in the course of reaction. After cooling, deep reddish orange crystals (0.5 g) were collected, washed with light petroleum (60 ml) and dried *in vacuo*. The yields were not so high since hexacarbonylchromium sublimed during the reaction.

$Cr(CO)_4$5dmbip Found: Cr, 14.9%. Calcd for $Cr(CO)_4$5dmbip: Cr, 14.9%.

Reductions of $Cr(CO)_4L$. $Na[Cr(CO)_4L]$, where L is bipy, 4dmbip or 5dmbip, was prepared by reduction with sodium metal in the apparatus shown in Fig. 1 in a high vacuum using the method described in a previous paper.[8] $Na[Cr(CO)_4$4dmbip]: A mixture of $Cr(CO)_4$4dmbipy and a little excess amount of sodium metal in 15 m*l* of dried THF was shaken for 10 hr. After the solution was filtrated, the solvent was removed by distillation into a liquid-nitrogen cooling trap jointed to the vacuum system, the product was collected and dried *in vacuo*.

$Na[Cr(CO)_4$bipy] Found: Cr, 15.4%. Calcd for $Na[Cr(CO)_4$bipy]: Cr, 15.2%.

$Na[Cr(CO)_4$4dmbip] Found: Cr, 13.9%. Calcd for $Na[Cr(CO)_4$4dmbip]: Cr, 14.0%.

$Na[Cr(CO)_4$5dmbip] Found: Cr, 14.4%. Calcd for $Na[Cr(CO)_4$5dmbip]: Cr, 14.0%.

Electronic Absorption Spectra. Measurements of the electronic absorption spectra of air-sensitive compounds were described in a previous paper.[8] Spectra were measured using a Shimadzu automatic recording spectrophotometer Model MPS-50.

Electron Spin Resonance. ESR spectra were measured in THF solution at room temperature using a Japan Electron Optics Laboratory spectrometer Model JES-3BSX. The *g*-value was determined by the aid of the standard sample of Mn^{2+} ion.

Results and Discussion

Until quite recently no electronic absorption and electron spin resonance (ESR) studies had been carried out on complexes such as $[Al(bipy)_3]$, $[Mn(bipy)_3]$[4] or $Na[Fe(bipy)_3]$.[3] However, it has been recognized since a few years ago that the complexes, at least, $[Al(bipy)_3]$ should consist of a metal cation and bipyridine negative ions.[9] The low-valent tris-bipyridine complexes show a spectrum similar to that of bipyridine negative ion and an ESR spectrum of the free electron *g*-value (2.003).[4,10] The tris-bipyridine complexes are concluded to consist of bipyridine negative ions and a metal cation.

When zero-valent bipyridinetetracarbonylchromium was reduced by sodium metal in THF, the absorption spectrum of the solution changed stepwise and showed that there were two or more stages in the reduction. To obtain a complex coordinated by bipyridine negative ion, we tried to isolate a complex formed at the first stage of reduction.

The electronic absorption spectra of the bipyridine complexes isolated in this work are shown in Fig. 2. In such a low oxidation state, an extra electron donated by a reducing reagents in the preparation should be delocalized over the whole complex. However, partial localization of the trapped electron in some part of the complex has been reported.[4] The electronic absorption spectra, at least, of tris-bipyridine complexes have been reported to give a criterion on the major location of the trapped electron.[4] When the trapped electron is mainly localized on the coordinating bipyridine, it does not show charge transfer bands characteristic to the electron trapping by the central metal but a spectrum similar to that of the bipyridine negative ion. As shown in Fig. 2, the

10) Y. Torii, M. Murasato and Y. Kaizu, *Nippon Kagaku Zasshi*, **91**, 549 (1970).

complex reported here gave a spectrum similar to that of the mononegative ion of bipyridine in Na bipy. However, they did not coincide in details. The exact position of the absorption peak at about 19000 cm^{-1} of the complex was slightly shifted to the higher wavenumber. This tendency was observed for the other two complexes, $Na[Cr(CO)_4$-4dmbip] and $Na[Cr(CO)_4$5dmbip], and also in the case of zero-valent tris-bipyridine aluminum complex.[10] For such a small perturbation as introduced by two methyl groups, the absorption peak at about 19000 cm^{-1} of the bipyridine negative ion was blue-shifted in the order 5dmbip, 4dmbip and bipy.[8] When the extra electron was trapped by the central metal, the metal-ligand charge transfer bands found in the visible region showed a quite different behavior for the methyl substitutions. The absorption peaks at about 19000 cm^{-1} of $Na[Cr(CO)_4$-5dmbip], $Na[Cr(CO)_4$4dmbip] and $Na[Cr(CO)_4$-bipy] show the negative ion type of spectral shift. These findings on the electronic absorption spectra suggest that the bipyridine attached to the central chromium is not a neutral molecule but a negative ion. The ESR spectrum of $Na[Cr(CO)_4$bipy] in Fig. 3 gives a g-value close to that of a free electron

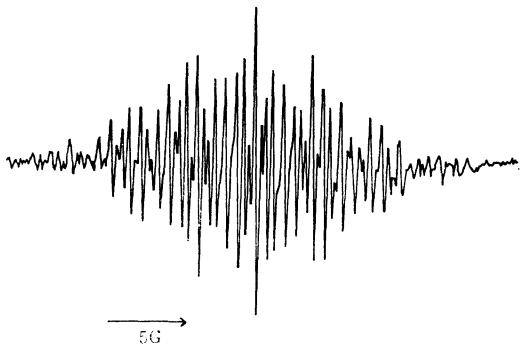

Fig. 3. The ESR spectrum of $Na[Cr(CO)_4$bipy] in THF at room temperature.

(g=2.0025) and a well-dispersed hyperfine structure. The hyperfine constants in the coordinating bipyridine negative ion were not so different from those of K bipy, even if the negative ion was strongly attached to the central chromium. In the case of K bipy, the binding between K^+ and $bipy^-$ is essentially ionic and the trapped electron in $bipy^-$ has a very poor population on K^+. As a matter of fact, the ESR spectrum of K bipy does not show the hyperfine structure due to the nuclear spin of potassium ion.[11] The ESR spectrum of Na bipy clearly shows the hyperfine structure due to the nuclear spin of sodium ion,[11] whereas in the case of $Na[Cr(CO)_4$bipy], it does not show any hyperfine structure due to either sodium or chromium. This is explained by the fact that an unpaired electron in an antibonding π orbital of bipyridine can not strongly interact with the closed shell $d\pi$ electron of the chromium and does not migrate over the outer sodium ion.

All of the complexes reported here are extremely soluble in polar organic solvents such as THF. They are very sensitive to oxygen and moisture in the air and are readily oxidized to the corresponding zero-valent complexes.

These observations and chemical analyses give sufficient evidence to conclude that the complexes synthesized in this work are the kind coordinated by bipyridine negative ion.

The sum of the numbers of the valence electrons in the central chromium and the σ electrons contributed by the ligands is the number of electrons in Kr atom. The paramagnetic character of the complex $Na[Cr(CO)_4$bipy] was identified by ESR, though, it still satisfies Sidgwick's rule as mentioned above. Since the complex is made of zero-valent chromium atom, four carbon monoxides and a bipyridine negative ion, the compound should be named sodium 2,2′-bipyridine(1−)tetracarbonyl-chromium(0).

The authors are indebted to Professor M. Nakahara, St. Paul's University for his advice concerning nomenclature.

Alkoxysilanes. V. The Preparation of Polyalkyl(aryl) Silicates

Yoshimoto ABE, Takeo TAKEUCHI and Ichiro KIJIMA

Department of Industrial Chemistry, Faculty of Engimeering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received March 18, 1969)

Silicon-containing novel polymers, polyalkyl(aryl) silicates $(-\overset{\overset{OR}{|}}{\underset{\underset{OR}{|}}{Si}}-O-R'-O-)_n$ (R=Bu^t and $(Bu^tO)_3Si$, R'=$-(CH_2)_{2 \text{ or } 4}-$, $-C_6H_4-$ or $-C_6H_4-\overset{\overset{Me}{|}}{\underset{\underset{Me}{|}}{C}}-C_6H_4-$), were prepared by the reaction of diaminosilanes with aliphatic or aromatic diols. The products were a white powder (fused at about 300°C), a highly viscous liquid, or a glassy solid; these products were soluble in common organic solvents, but insoluble in methanol. The results of the molecular-weight determination by the vapour-pressure method indicated that some of polymers had a molecular weight of 5000 or 6000. A study of the thermal stability of the polymers by means of TGA and DTA analysis made clear that the polymers with the aryloxy group in the molecular main chain were remarkably more stable than those with the alkoxy group. The former indicated a weight loss of about 50% at 350—400°C. An investigation of the TGA curve and thermal decomposition products allowed us to discuss the probable process for the degradation of the polymers. The reaction of the diaminosilanes with 1,4-butanediol afforded distillable products rather than the expected polymers; these products were identified as being cyclic alkoxysilanes.

In order to obtain thermally-stable polymers, many experiments[1] have been carried out concerning the preparation of polymers containing metal atoms. Although it is well-known that polyalkylsiloxanes have a superior thermal stability, they are also pyrolyzed at temperatures higher than 300°C to form ring compounds of a low molecular weight. Therefore, an attempt has been made to prevent the degradation and to increase the thermal stability by replacing the side[2] and main[3] chain of the polysiloxane by other groups or metals. Recently, Dunnavant[4] has synsesized polyaryloxysilanes with aryloxy groups in the main chain and the phenyl group in the side chain; his polyaryloxysilanes have excellent thermal and mechanical properties.

Polyalkyl(aryl) silicate $(-\overset{\overset{OR}{|}}{\underset{\underset{OR}{|}}{Si}}-O-R'-O-)_n$, however, has not been prepared; in it both the main and side chain are replaced by an alkoxy or aryloxy group. Probably, the reason is that the alkoxysilanes $(RO)_nSiX_{4-n}$ (n=2 and 1) have various functional groups and their reactivities have not yet been investigated. Since we have already reported on our study of the preparation and reaction of alkoxysilanes containing functional groups,[5,6] in this experiment we tried to prepare polyalkyl(aryl) silicates and to investigate their thermal stability.

Experimental

Material. The di-*t*-butoxydiaminosilane[7] and bis(tri-*t*-butoxysiloxy)diaminosilane[6] were prepared by the reaction of the corresponding dichlorosilanes with dry ammonia gas. The ethylene glycol and 1,4-butanediol were purified by distillation after having been dehydrated over anhydrous sodium sulfate. The hydroquinone and bisphenol A were recrystallized from methanol and benzene respectively.

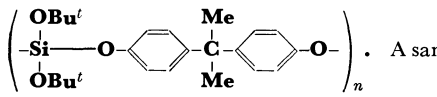
Polymerization and Measurement of the Reaction Rate. To a solution of diols dissolved into dry ethyl ether or benzene, diaminosilanes were added. After the solvent (ether) had been removed off along with stirring and the introduction of dry nitrogen gas, the residue was polymerized under the conditions shown in Tables 1 and 2. When the benzene was used as a solvent, the mixture was refluxed under the boiling point of the solvent. When the reaction was carried out without a solvent, the mixture was heated at the temperatures shown in Tables 1 and 2. The raw product (a highly viscous liquid or a glassy solid) thus formed was dissolved into benzene, and filtered off; the filtrate was then added, drop by drop, into vigorously stirred methanol. The precipitate was separated by decantation and dried *in vacuo*. When a white precipitate was produced from the reaction mixture, it was filtered off, extracted with benzene, and dried *in vacuo*.

The polymerization rate in the reaction of the diaminosilanes with hydroquinone or bisphenol A was determined by introducing ammonia evolved under the following conditions into a sulfuric acid solution: a mixed solution was heated up to 70°C for 30 min, and then the ether was removed. When the temperature rose to 70°C during the next 30 min, the residue was further heated for 170—180°C. The results are shown in Fig. 1.

The Reaction of Di-*t*-butoxydiaminosilane with 1,4-Butanediol. A mixture of 21.8 g (0.1055 mol) of the diaminosilane, 9.5 g (0.1055 mol) of 1,4-butanediol, and 50 m*l* of benzene was refluxed with stirring. After 3.5 hrs' heating (45%, ammonia evolved), the solvent was evaporated off; the residue was then further heated for 7.5 hr at 150—160°C (80.4%, ammonia evolved). The distillation of the residue *in vacuo* gave 11.0 g of a distillate (bp 115°C/21 mmHg) and 17.3 g of a brown, highly viscous liquid. The redistillation of the distillate yielded 7.5 g of a colorless, transparent liquid. The results of elemental analysis, the measurement of the NMR spectra, and the yield are shown in Table 3.

The Reaction of Bis(tri-*t*-butoxysiloxy)diaminosilane with 1,4-Butanediol. A mixture of 11.0 g (0.0188 mol) of the diaminosilane, 1.7 g (0.0188 mol) of 1,4-butanediol, and 30 m*l* of toluene was heated while being stirred. The mixture was refluxed for 6.5 hr (93%, ammonia evolved), and the solvent was removed off. Then the residue was distilled *in vacuo* to give 8.3 g of a solid; 160—161°C/1 mmHg. The solid was recrystallized with petroleum ether with a boilling point below 45°C, giving a needle crystal. The results are shown in Table 3.

Thermal Decomposition of the Polymer

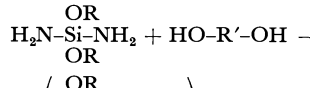


. A sample (9.1 g) was decomposed at 290—300°C *in vacuo* to form a gas, which was trapped into a vessel cooled by dry ice-acetone. The weight loss of the polymer was 2.1 g (23%). The residue (T-1), insoluble in solvents, was finely powdered, extracted with benzene, and subjected to elemental analysis (Found: C, 54.39; H, 5.08; Si, 9.48%) and IR-spectra measurements (Fig. 6). The gas, becaming a liquid under the cooling, was absorbed into a carbon tetrachloride-bromine solution. The solution was washed, dehydrated over anhydrous calcium chloride, and subjected to gas chromatography.

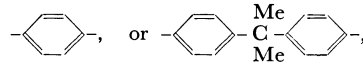
The T-1 (7.0 g) was further pyrolyzed at 480°C *in vacuo* to form a volatile liquid and a solid. To the mixture, carbon tetrachloride was added. Then the solid was filtered off and recrystallized with the solvent to give a crystal; mp 151—152°C (bisphenol A). The filtrate, having a phenolic odor and showing a positive color test for ferric chloride, was brominated to give a precipitate, which was then recrystallized with an aqueous alcohol, mp 91—93°C (tribromophenol). The weight loss of T-1 was 2.9 g (55%, total weight loss in relation to the initial polymer). The residue which remained was subjected to elemental analysis (Found: C, 41.60; H, 3.92; Si, 15.87%) and IR-spectra measurements (Fig. 6) after it had been treated as has been described above.

Results and Discussion

Preparation of Polyalkyl(aryl) Silicates. Polyalkyl(aryl) silicates were obtained by the following reactions:



where R=Bu^t and (Bu^t O)$_3$Si, R'=-(CH$_2$)$_2$-, -(CH$_2$)$_4$-,



At first, the reactivity of the diols to the diaminosilanes was investigated by measuring the ammonia evolved by the reaction of the diaminosilanes with hydroquinone or bisphenol A under definite conditions. The results are shown in Fig. 1. Figure 1 indicates that the reactions are completed within about 3 hr (90%, ammonia evolved); thus, it is clear that the polymerization proceeds easily. This figure also suggests that di-*t*-butoxydiaminosilane reacts more easily with hydroquinone or bisphenol

A than with bis(tri-*t*-butoxysiloxy)diaminosilane. This results from the smaller steric hindrance of the *t*-butoxy group than that of the tri-*t*-butoxysiloxy group. Further, in comparison with bisphenol A, hydroquinone is more reactive to di-*t*-butoxydiaminosilane (or bis(tri-*t*-butoxysiloxy)diaminosilane). This may be explained by the stronger acidity of hydroquinone than that of bisphenol A.

On the basis of the above results, polymerization was attempted; it gave the polymers shown in Tables 1 and 2. The products were a white powder (A-1, 2, 3; B-1; a-1; c-1), a highly viscous liquid (b-1,2; C-1), and a glassy solid (C-2; d-1; D-1); some of them (c, C, d, and D) form fiber when fused at elevated temperatures. The a-1, A-3, and B-2 polymers are soluble in hot benzene, but A-1 and 2 are insoluble in solvents. The others are soluble in all common organic solvents, such as benzene, *n*-hexane, ether, acetone, and carbon tetrachloride, but not methanol; hence, the polymers can be purified by adding them, dissolved in benzene, into vigorously-stirred methanol. The results of elemental analysis after the purification are shown in Tables 1 and 2. The tables indicate that the values, except for in the cases of a-1 and C-2, agree with those calculated for the linear structure $(-Si(OR)_2-O-R'-O-)_n$. It seems to support the above structure that the products are soluble in organic solvents and form fiber. The IR spectra are essentially identical and show absorption peaks at 2900 (Me), 1605 and 1505 (Ph), 1390 and 1365 (Bu^t), and 1100—1000 (Si–O–Si, Si–O–C) cm^{-1}. As Fig. 2 shows, the NMR spectra of the polymer (d) exhibit the proton signals at 2.87—3.27 (Ph), 8.38 (Me), and 8.66 (Bu^t) τ. These spectroscopic data also imply that the above

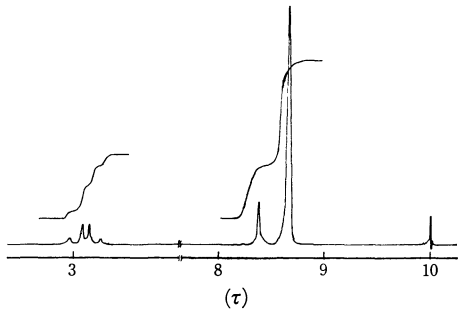

Fig. 2. NMR spectrum of polyaryloxy silicate d.

structure is reasonable. The polymer C and especially the polymer c are apt to discolor, probably due to the susceptibility of hydroquinone to oxidation. The results of the molecular-weight determination for D and d in benzene by the vapor-pressure method indicated the values of 6100 and 4800, which corresponded to the degrees of polymerization of 8 and 16 respectively. The X-ray powdery diffraction of D also showed no crystallinity. In general, it has been established that alkyl silicate are susceptible to hydrolysis and alcoholysis, but these polyalkyl(aryl) silicates have a remarkable stability.

The results of the elemental analysis for a-1 and C-2 are different from the values calculated for the structure. It is found that the deviation in the case of a-1 is due to a cross-linking of the polymer by ethylene glycol, which results from the alcohol-exchanging reaction between the *t*-butoxy and the hydroxy group of ethylene glycol, for *t*-butyl alcohol was detected in the gas chromatography of the solvent removed from the reaction mixture. Additional evidence of the cross-linking lies in the IR spectra of the product; a strong absorption peak appears at 3425 (OH) cm^{-1}, while the peaks at 1390 and 1360 cm^{-1} due to the *t*-butyl group almost disappear. Therefore, the product is a polymer partially crosslinked by ethylene glycol; however, the degree of the cross-linking seems to be low, for it is soluble in hot benzene. The deviation in c-2 may be ascribed to a partial decomposition during the course of polymerization at a high temperature (280°C).

On the other hand, distillable products rather than polymeric substances were obtained when the reaction of the diaminosilanes with 1,4-butanediol was carried out using toluene as the solvent. These products were found to be cyclic alkoxysilanes by elemental analysis, by molecular-weight determination (Table 3), and by means of examining the NMR spectra (Fig. 3). In the reaction of di-*t*-

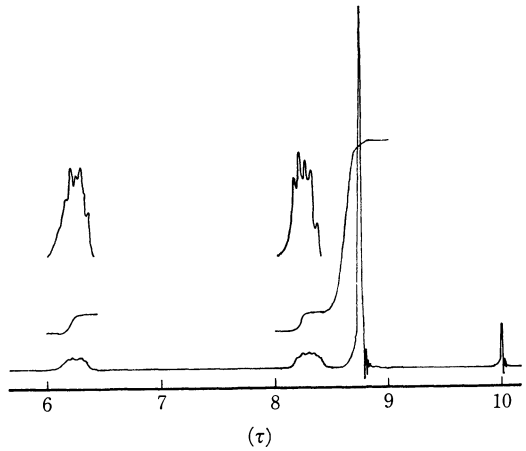

Fig. 3. NMR spectrum of cyclic alkoxysilane (R=Bu^t).

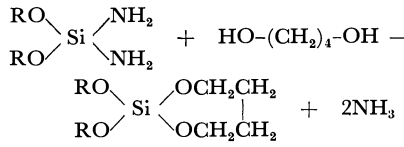
butoxydiaminosilane with the diol, a polymeric substance was formed in addition to the cyclic alkoxy silane; the ratio of the products was about 5 : 3 (by weight). On the other hand, in the reaction of bis(tri-*t*-butoxysiloxy)diaminosilane, only a distillable product was obtained.



where R=Bu^t and (Bu^{t}O)$_3$Si.

The tendency toward cyclization rather than the expected polymerization seems due to the length of the methylene linkage and the steric hindrance, since no distillable product was afforded by the reaction of the diaminosilanes with ethylene glycol

TABLE 3. PRODUCTS IN THE REACTION OF DIAMINOSILANES WITH 1,4-BUTANEDIOL

and only the cyclic alkoxysilane was formed in the case of bis(tri-*t*-butoxysiloxy)diaminosilane. These facts suggest that the seven-membered ring is more favorable to ring formation than the five-membered ring and that the steric hindrance of tri-*t*-butoxysiloxy group greatly contributes to the cyclization. Probably, the reactions proceed *via* the initial formation of the intermediate $(RO)_2Si(NH_2)(OCH_2CH_2CH_2CH_2OH)$, and at this stage it may undergo an intramolecular condensation, for the intermolecular condensation appears to be more difficult due to the steric hindrance of the RO groups. Indeed, the assumption that the intermediate is formed seems to be supported by the reports by Miner[7] and by our previous investigation.[6]

Thermal Properties of Polyalkyl(aryl) Silicates. The TGA curves of polyalkyl(aryl) silicates (Fig. 4) indicate that the weight loss of A-1 amounts to about 80% at 200—300°C, whereas those of c, C, d, and D amount to about 50—60% at 350—400°C and 70—80% at 900°C. Obviously the polymers with aromatic rings in the molecular main chain have a superior thermal stability to the A-1 with the methylene linkage. When c, C, or D is compared with d, no remarkable difference in thermal stability is observed, except that the weight loss of d is less than that of the others at 400—500°C. However, as Tables 1 and 2 show, there is a tendency for the fusing points of polymers with a butoxy group in the side chain are to be higher than those with a tri-*t*-butoxysiloxy group. This seems to be explained by considering that the flexibility of the molecule increased by the Si–O–Si linkage in the side chain of C and D results in a lowering their fusing points compared with those of c and d without the linkage.

The results of the differential thermal analysis of D and d are shown in Fig. 5. Figure 5 indicates that D and d have endo- or exothermic peaks at about 60 and 360°C. The endothermic peaks at about 60°C correspond to the fusing points, which are in good accordance with the results shown in Tables 1 and 2. The peaks at 360°C are due to decomposition, but the thermal behavior is

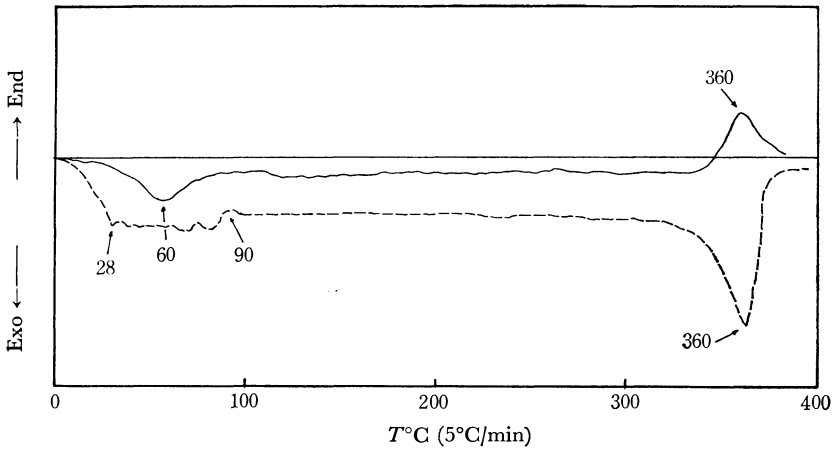

Fig. 5. DTA curve of D (----) and d (——).

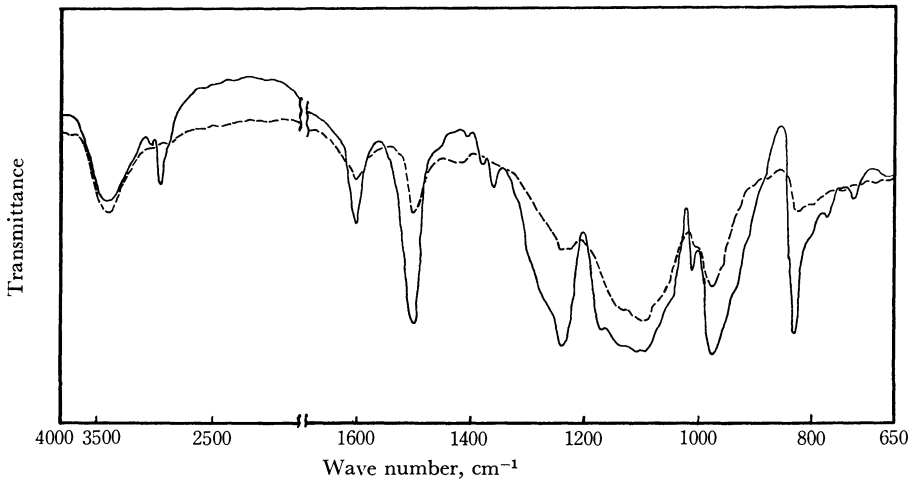

Fig. 6. IR spectra of $T-1$ (——) and $T-2$ (----).

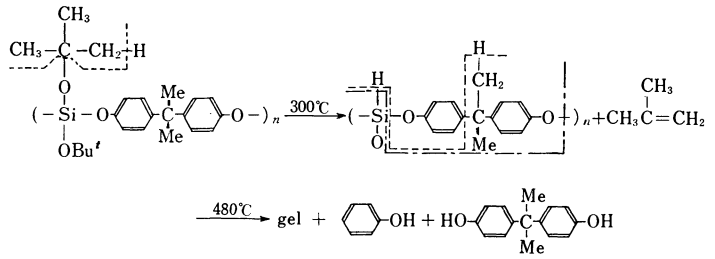
different, as may be seen when d is compared with D. This may be thought to be caused by the different side chains, the butoxy and butoxysiloxy groups.

During the investigation of the thermal stability by means of the TGA curves, it has been observed that the decomposition of all the polymers except A proceeds through two steps, as is shown by Fig. 4. This suggests that either step is caused by the degradation of the side or main chain; hence, the identification of thermal decomposition products would allow us to discuss the process of the degradation. With this in view, the d polymer was pyrolyzed at 300 and 480°C *in vacuo*; a gas evolved, and the residue was subjected to analysis. Consequently, the following facts were made clear: 1. The gas evolved at 300°C was confirmed to be 2-methyl propene by means of gas chromatography after it had been brominated. Moreover, as is shown in Fig. 6, the IR spectra of the residue (T-1) at this temperature exhibited absorption peaks at 1500 and 820 cm^{-1} due to the phenyl group, but lack the peaks at 1380 and 1360 cm^{-1} attributed to the branching of the alkyl group; therefore, the above facts seem to support the idea that the first step is the degradation of the side chain. 2. The volatile substances obtained at 480°C were identified as phenol and bisphenol A; besides, the IR spectra of the residue (T-1) at 480°C lack the peaks ascribed to not only the branching of the alkyl group, but to the phenyl group. These facts imply that the second step is the decomposition of the main chain. On the basis of the above results, it is thought that the probable decomposition process of the polymers proceeds step by step, as is shown by the following scheme:



The authors wish to thank Professor Yojiro Tsuzuki for his interest and helpful advice. Acknowledgement is also due to Mr. Takao Aoki of the Laboratory of the Physical Chemistry for his measurements of the molecular-weight determination, the Laboratory of the Chemical Engineering for the permission to employ its thermovalance, Assistant Professor Keizo Ogino for his suggestions regarding the differencial thermal analysis, and Mr. Tetsuo Kanamoto for his measurements of the X-ray powder diffraction for this work and for Part II.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2501—2506 (1970)

Synthese der Epiminozucker

Kunihiro ICHIMURA

Institut für Polymer- und Faserforschung, Yokohama, Kanagawa-ku, Sawatari, Yokohama

(Eingegangen am 20. September, 1969)

Two-step conversion of aldehydes to 2-monosubstituted aziridines has been extended to sugar derivatives. Treating *O,O'*-isopropylidene-D-glyceraldehyde with benzenesulfonyl chloride and sodium cyanide, 2-benzenesulfonyloxy-3,4-isopropylidenedioxybutyronitrile is obtained as a mixture of the diastereomers in a good yield, and is converted to the corresponding ketalaziridine, 2-(1,2-isopropylidenedioxyethyl)aziridine, by the reduction with lithium aluminum hydride. When the partially racemized isopropylideneglyceraldehyde is used, the diastereomers obtained are successfully separated by the fractional recrystallization. Each diastereomeric α-sulfonyloxynitrile is reduced by lithium aluminum hydride to afford the ketalaziridine, which is *p*-nitrobenzoylated and rearranged to the derivative of 1,3,4-trihydroxy-2-amino-butane by means of sodium iodide. Analogously, 3-*O*-benzyl-1,2-*O*-isopropylidene-α-D-glucopentodialdo-1,4-furanose was converted to two urononitriles, 3-*O*-benzyl-5-*O*-benzenesulfonyl-1,2-*O*-isopropylidene-α-D-glucofuranurononitrile and the epimeric β-L-idofuranurononitrile. The reduction of the former yielded 5,6-epimino-5,6-dideoxy-β-L-idofuranose.

Wegen ihrer reaktionsfreudigen Eigenschaften können Aziridine als Ausgangsmaterial zur Herstellung stickstoffhaltiger Verbindungen dienen. Vor kurzem wurde die stereospezifische Synthese von β-Aminoalkoholen[1] und von 1,2-Diaminen[2] mitgeteilt, indem zugängliche Verfahren zur Gewinnung der Aziridine von Olefinen aus beschrieben wurden.[3]

Wie in der voranstehenden Mitteilung erwähnt, haben wir eine zweistufige Umwandlung von Aldehyden in 2-monosubstituierte Aziridine aufgefunden, die vorteilhaft unter verhältnismäßig milderen Reaktionsbedingungen stattfinden kann.[4]

Ergebnisse

In dieser Arbeit haben wir diese Umwandlung an Zucker-Derivaten angewandt. Zuerst wird *O,O'*-Isopropylidenglycerinaldehyd gewählt. Um die unangenehme Nebenreaktion der Hydrolyse des Ketalrings oder der Aldolkondensation zu vermeiden, versetzt man zuerst ein Drittel des gebräuchlichen Natriumcyanids und anschließend Benzolsulfonylchlorid mit Aldehyd in Acetonitril und setzt dem Gemisch die wäßrige Lösung des übrigen Natriumcyanids zu. Dann entsteht α-Benzolsulfonyloxynitril vom Schmp 47—49°C (IIIa), dessen Struktur nach der Analysenwert und dem IR-Spektrum bestätigt wird.

Obwohl sich in dieser Reaktion zwei Diastereomere bilden könnten, ist es uns nicht gelungen, diese Diastereomere durch fraktionelle Kristallisation oder durch Dünnschichtchromatographie abzuteilen.

Bei dieser Umwandlung handelt es sich hauptsächlich um das Molverhältnis des Ausgangsmaterials, wie man in der Tabelle 1 sehen kann.

Im Versuch Nr. 2 entsteht vielmehr hydrolysiertes 2-Benzolsulfonyloxy-3,4-dihydroxybutyronitril (IVa), das durch die Dünnschichtchromatographie mit der bei der essigsauren Hydrolyse des Ketalnitrils (IIIa) erhaltenen Produkts vom Schmp 136—139°C identifiziert wurde. Im Gegensatz dazu färbt sich das Reaktionsgemisch nach der Umsetzung mit einer größeren Menge Natriumcyanid, und die Ausbeute des Ketalnitrils nimmt stark ab. Die besten Ergebnisse (85%-ige Ausbeute) erhält man bei der Benutzung des heterogenen Systems des Acetonitrils und der Na_2HPO_4-NaH_2PO_4-Pufferlösung von pH etwa 7.40 statt reinen Acetonitrils und bei einem Molverhältnis wie das des Ausgangsmaterials wie in Versuch Nr. 5.

Im Vergleich zum Hydrolysat (IVa) des Ketalnitrils (IIIa) mit Essigsäure entsteht bei der salzsauren Hydrolyse neben Ammoniumchlorid eine unreine Verbindung, die nach dem IR-Spektrum vermutlich γ-Lakton ist. Ferner fanden wir, daß D-Glycerinaldehyd selber bei der Einwirkung des Natriumcyanids und Benzolsulfonylchlorids in Dihydroxynitril (IVa) übergeführt wird.

Wenn man das so erhaltene Ketalnitril (IIIa)

mit Lithiumaluminiumhydrid reagieren läßt, entsteht Ketalaziridin (Va) in 55%-iger Ausbeute. Die Abtrennung der Diastereomere durch Gaschromatographie war auch hier erfolglos.

Bei der Oxydation des D-Mannitols durch Bleitetraacetat entsteht bei längerem Erhitzen ein sehr zähes Öl, das bei etwa 200°C in teilweise racemisiertes Isopropylidenglycerinaldehyd entpolymerisiert wird.

Bei der Einwirkung von Natriumcyanid und Benzolsulfonylchlorid auf diesen Isopropylidenglycerinaldehyd erhält man zwei verschiedene Produkte. Diese beiden können durch fraktionelle Kristallisation mit 2-Propanol in fast gleicher Ausbeute abgetrennt werden. Das eine (IIIb) schmilzt bei 100—102°C und das andere (IIIc) bei 52—56°C. Beide zeigen die gleichen Analysenwerte des Ketalnitrils vom Schmp 47—49°C, und die Anwesenheit des Ketalrings und des Sulfonsäureesters in den IR-Spektren. Die IR-Spektren dieser drei Isomere im festen Zustand sind aber im wesentlichen nicht identisch. Bei der essigsauren Hydrolyse liefern ferner die Kristalle (IIIb) vom Schmp 100—102°C das Dihydroxynitril (IVb) vom Schmp 89—90°C, und die Kristalle (IIIc) vom Schmp 53.5—56°C das entsprechende isomere Dihydroxynitril (IVc) vom Schmp 156—157°C.

Beim Vergleich der IR-Spektren dieser drei Ketalnitrile (IIIa, IIIb und IIIc) in Chloroform kann man vermuten, daß die Kristalle vom Schmp 47—49°C ein Gemisch von IIIb und IIIc sind. Diese Vermutung wird durch die NMR-Spektren bestätigt. Während die eine Methylgruppe der *gem*-Dimethylgruppe im Dioxolanring in beiden Kristallen (IIIb und IIIc) die gleichen chemische Schiebung bei τ 8.69 zeigt, tritt das andere Methylsignal von IIIb bei τ 8.60, und das von IIIc bei 8.57 auf. Die Protonen der Isopropyliden-Gruppe der Kristalle vom Schmp 47—49°C absorbieren doch bei τ 8.69, 8.57 und 8.60, im Stärkeverhältniss etwa 2 : 1 : 1. Auch die anderen Signale unterstützen die Vermutung, daß IIIa das Gemisch von IIIb und IIIc ist.

Diesen Tatsachen nach schließt man, daß die vom teilweise racemisierten Isopropylidenglycerinaldehyd aus stammenden beiden Verbindungen (IIIb und IIIc) die Diastereomere sind, und daß das vom optisch aktiven Aldehyd erhaltene Produkt (IIIa) ein Gemisch der beiden Diastereomere im Verhaltniss etwa 1 : 1 ist.

Diese beiden Diastereomere (IIIb und IIIc) liefern auch bei der Reduktion mit Lithiumaluminiumhydrid die entsprechenden Aziridine (Vb und Vc), deren IR-Spektra sehr verwandt sind.

Das aus IIIb erhaltene Aziridin (Vb) wird *p*-nitrobenzoyliert und anschließend mit Natriumjodid behandelt unter Bildung des Oxazolins vom Schmp 123—124.5°C (VIIb).

Indem 1-Acyl-2-alkylaziridin mittels Natriumjodids in 4-alkylsubstituiertes Oxazolin umgelagert wird,[5] ist das erhaltene Umlagerungsprodukt ein Derivat des 1,3,4-Trihydroxy-2-aminobutans.

Das andere Diastereomer des Trihydroxyaminobutan-Derivats (VIIc) vom Schmp 107—110°C wird nach gleicher Behandlung wie Vc dargestellt.

Als nächstens konnte Epiminozucker in analoger Weise hergestellt werden. 1,2:5,6-Diisopropylidenglucofuranose wird über partielle saure Hydrolyse durch Natriumperjodat oxydiert, und das rohe Prodkt wird wie unter den oben erwähnten Bedingungen mit Benzolsulfonylchlorid und Natriumcyanid behandelt.[4] Aus dem Reaktionsgemisch kann man keine einheitliche Substanz isolieren. Die Entstehung des erwarteten α-Sulfonyloxynitrils gelingt durch die Dimerisierung des Aldehyds und/oder durch die Bildung des Addukts mit Formaldehyds nicht, worüber vor kurzem Paulsen und Todt berichtet haben.[6]

Um diese unangenehmen Phänomene zu vermeiden, wird 1,2:5,6-Isopropyliden-α-D-glucofuranose nach Benzylierung partiell hydrolysiert, um 3-*O*-Benzyl-1,2-*O*-isopropyliden-α-D-glucofuranose zu gewinnen, das durch Natriumperjodat oxydiert wird.

Wenn man auf das rohe Aldehyd (IX) Benzolsulfonylchlorid und Natriumcyanid in gewöhnlicher Weise einwirken läßt, so erhält man α-Sulfonyloxynitril-Gruppe tragendes Produkt, in dessen IR-

5) H. W. Heine, *Angew. Chem.*, **74**, 772 (1962).

6) H. Paulsen und K. Todt, *Chem. Ber.*, **101**, 3358 (1968).

Spektrum die charakteristischen Absorptionen der Sulfonsäureester auftritt.[4] Sie zeigt auch keine deutlichen Bande der Nitril-Gruppe. Im NMR-Spektrum des rohen Produkts treten bei τ 5.50 und 5.65 zwei Dublette des Protons der 5-Stellung der Furanose im Stärkeverhältniss 19 : 10 auf, was zeigt, daß die rohe Verbindung ein Gemisch der zwei erwarteten Diastereomere ist. Wenn das rohe Produkt aus Tetrachlorkohlenstoff umgelöst wird, scheiden sich farblose Nadeln vom Schmp 137—139°C in 20%-iger Ausbeute in bezug auf 3-*O*-Benzyl-1,2-isopropyliden-α-D-glucofuranose. Im NMR-Spektrum dieser Verbindung tritt das anomere Proton bei τ 5.93 als eine Dublette (J=3 Hz) und das Proton in der 5-Stellung bei τ 5.46 (J=7.15 Hz) als eine Dublette auf, was zeigt, daß diese Verbindung das Hauptprodukt ist.

Aus dem vom kristallinen Hauptprodukt (X) freigesetzten Rückstand, der dem NMR-Spektrum nach ein Gemisch von X und dessen Epimer im Verhältniss 1 : 2 ist, fraktioniert man durch nochmalige Umkristallisationen das andere Epimer vom Schmp 106—108°C als farblose Blättchen. Im NMR-Spektrum tritt das anomere Proton bei τ 5.87 als Dublette (J=3 Hz) auf, das Proton in der 5-Stellung bei τ 5.29 als Dublette (J=8.2 Hz), was die Struktur und die Einheitlichkeit der Substanz stützt. Die beiden Epimere haben einen gleichen R_f-Wert bei der Dünnschichtchromatographie mit Silikagel oder Alumina, und die Abtrennung durch Säulenchromatographie gelingt dann nicht.*1

Wenn man als Sulfonylchlorid *p*-Toluolsulfonyl- und *p*-Brombenzolsulfonylchlorid benutzt, erhält man die entsprechenden α-Sulfonyloxynitrile, deren Strukturen durch IR- und NMR-Spektren festgestellt werden. Die beiden Rohprodukte enthalten zwei Epimere im Verhältniss von etwa 2 : 1 nach den NMR-Spektren, ganz analog wie im Fall vom 5-*O*-benzolsulfonylierten Uronsäurenitril. Es ist noch nicht gelungen, die Epimere in den beiden Fällen abzutrennen, außer dem Minorprodukt des *p*-Brombenzolsulfonyloxynitrils.

Der Cram-Karabatsos-Regel nach[8] wird vermutet, daß sich die Konfiguration des Kohlenstoffs der 5-Stellung des Benzolsulfonyloxygruppe tragenden Hauptprodukts (X) in der *R*-Chiralität befindet und daß es nämlich ein Derivat des D-Glucuronsäurenitrils ist, während das andere Epimer ein L-Idouronsäurenitril-Derivat (XI) ist, was durch die unten beschriebene Methode festgestellt wurde.

Wenn man X in THF mittels Lithiumaluminiumhydrids reduziert, ist ein Epiminozucker erhältlich, der im IR-Spektrum bei 3300 cm^{-1} absorbiert. Obwohl die Benzoyl-, Phenylcarbamoyl- und *p*-Nitrobenzoyl-Derivat alle nicht kristallin erhältlich sind, erhält man Kristalle vom Schmp 188—189°C nach der Behandlung des *N*-Nitrobenzoyl-Derivat mit Natriumjodid. Die Kristalle zeigen einen Oxazolinring bei 1650 cm^{-1} im IR-Spektrum,und der erhaltene Zucker ist also vermutlich ein Derivat des 5-Amino-5-desoxy-zuckers (XIII).

Wie in der voranstehenden Arbeit mitgeteilt, werden α-Chlor- und Bromnitrile stereospezifisch über *trans*-Eliminierung zum Ringschluß gebracht, und α-Sulfonyloxynitrile sind auch offenbar in gleicher Weise stereospezifisch umgewandelt.[4] Der durch LAH-Reduktion erhaltene Epiminozucker (XII) ist daher 5,6-Epimino-5,6-didesoxy-β-L-idofuranose. Gerade wie im Fall von VII erwähnt, ist der Oxazolinzucker (XIII) deswegen ein Derivat der 5-Amino-5-desoxy-β-L-idofuranose.

Um die Konfiguration von XII mehr ins klare zu bringen, synthetisiert man XII in der folgenden Weise, die vor kurzem Saeki und Ohki mitgeteilt haben.[9a] Nach der Tosylierung der 3-*O*-Benzyl-1,2-isopropyliden-α-D-glucose und der chromato-

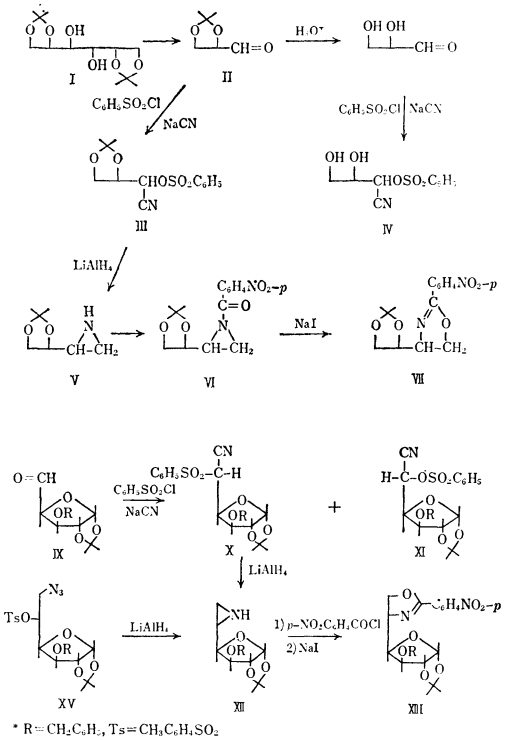

Fig. 1. Synthese der Epiminozucker.

*1 Von Saeki und Ohki wurde vor kurzem unabhängig mitgeteilt, daß das Cyanhydrin des 1,2:3,4-di-*O*-Isopropyliden-α-D-galactohexodialdo-1,5-pyranoses tosyliert und analog mit Lithiumaluminiumhydrid in Epiminozucker umgewandelt wird.[7]

graphischen Reinigung läßt man den ditosylierten Zucker mit Natriumazid in DMF reagieren. Wenn man das so erhaltene Azid-Derivat (XV) in THF durch LAH reduziert, entsteht der rohe Epiminozucker, dessen IR- und NMR-Spektrum mit denen von XII ähnlich sind. Für die Identifizierung des Produkts mit XII wird der Aziridinzucker über die *p*-Nitrobenzoylierung in das Oxazolin mittles Natriumjodids umgewandelt, das durch Mischprobe und IR-Spektrum mit XIII praktisch identisch ist. Der oben erhaltene Epiminozucker wird nach Destillieren kristallin erhalten und mit von Saeki und Ohki dargestelltem 5,6-Epimino-5,6-didesoxy-*β*-L-idose-Derivat identifiziert.*2 Die struktuelle Feststellung deutet nämlich daraufhin, daß die Konfiguration von X mit der nach der Cram-Karabatsos-Regel geschlossenen Konfiguration im Übereinstimmung steht.

Beschreibung der Versuche

IR-Spektra wurden mit Hitachi EPI und NMR-Spektra mit Japan Elektron Optik Laboratorium JNM C-60HL alle in $CDCl_3$ aufgenommen. Die Schmelzpunkte wurden nicht korrigiert.

***O,O'*-Isopropyliden-D-glycerinaldehyd.** Zu der Lösung des 22.2 g Bleitetraacetats in 60 m*l* wasserfreiem Benzol setzt man 13.1 g 1,2: 5,6-Diisopropyliden-D-mannitol in kleinen Portionen unterhalb 20°C unter Rühren zu und rührt eine Weile. Nach dem Freisetzen und Waschen des Unlöslichen mit Benzol versetzt man die vereinte benzolische Lösung mit wasserfreiem Kaliumcarbonat und rührt das Gemisch bis zum Ende der Entwicklung des Kohlendioxyds. Nach Filtrieren des Niederschlags destilliert man die Lösung im verminderten Druck ab, und erhält 7.8 g *O,O'*-Isopropyliden-D-glycerinaldehyd vom Kp 53°C/17 mmHg. (Ber Kp 27°C/2 mmHg).[10] $[\alpha]_D = +64.9°$. Das Aldehyd wird sofort nach dem Destillieren zur Umsetzung benutzt.

2-Benzolsulfonyloxy-3,4-isopropylidendioxybutyronitril aus Isopropylidenglycerinaldehyd von $[\alpha]_D = +64.9°$. Man versetzt 7.40 g *O,O'*-Isopropyliden-D-glycerinaldehyd und 8.75 g frisch destilliertes Benzolsulfonylchlorid mit M/20 30 m*l* Pufferlösung (NaH_2PO_4-Na_2HPO_4) von pH 7.40 und 20 m*l* Acetonitril unter Eis-Kochsalzkühlung. Unter gutem Rühren setzt man die wäßr. konz. Lösung des 3.01 g Natriumcyanids zu dem Gemisch unterhalb 7°C tropfenweise zu und rührt 30 Min bei Raumtemperatur. Nach Versetzen mit Wasser wird das Reaktionsgemisch mit Äther ausgezogen und mit Wasser gewaschen. Nach Trocknen über wasserfreiem Kaliumcarbonat und Entäthern der Lösung erhält man die Kristalle, die mit Aceton-Trockeneis abgekühltem 2-Propanol gewaschen werden. Ausbeute, 11.32 g (77% d. Th.). Schmp 40—47°C. Aus dem Filtrat werden 1.18 g (8.0% d. Th.) Kristalle vom Schmp 38—47°C zurückgewonnen. Sie werden aus abgekühltem 2-Propanol umkristallisiert und schmelzen bei 47—49.5°C. Ausbeute, 8.77 g $[\alpha]_D^{25} = -13.2°$ (*c* 0.5 $CHCl_3$). IR-Spektrum (KBr): 1380, 1220, 1190, 1180, 1095, 1070, 980, 730 cm^{-1}. Gef: C, 52.38; H, 4.91; N, 5.05%. Ber für $C_{15}H_{15}NO_5S$: C, 52.52; H, 5.09; N, 4.71%.

2-Benzolsulfonyloxy-3,4-dihydroxybutyronitril (IVa). *a) mit Essigsäure.* Das oben erhaltene Ketalnitril (IIIa) wird eine Weile in 50%-iger Essigsäure bei 60—70°C erwärmt, und anschießend dampft man die Lösung unter verm. Druck bei dieser Temperatur ein und erhält den kristallinen Rückstand, der aus Isobutylalkohol umkristallisiert wird. Schmp 136—139°C. Gef: C, 46.82; H, 4.19; N, 5.63%. Ber für $C_{10}H_{11}NO_5S$: C, 46.70; H, 4.31; N, 5.45%. IR-Spektrum (KBr): 3340, 3330, 1370, 1195, 1010, 731 cm^{-1}.

b) aus D-Glycerinaldehyde. 5.2 g *O,O'*-Isopropyliden-D-glycerinaldehyd wird in 10%-iger Essigsäure gelöst, über Nacht stehen gelassen und unter verm. Druck eingedampft. Den Rückstand löst man in 20 m*l* Wasser und versetzt dazu die Acetonitril (10 m*l*)-Lösung von 5.60 g Benzolsulfonylchlorid. Unter Rühren setzt man 1.88 g Natriumcyanid in 5 m*l* Wasser in die Lösung unterhalb 30°C zu. Beim anschließenden Versetzen mit Wasser scheiden sich die Kristalle aus, die aus Isobutylalkohol umkristallisiert werden, bei 136—138°C schmelzen und 0.85 g betragen. Sie werden mit dem oben erhaltenen Dihydroxynitril (IVa) durch Mischprobe identifiziert.

2-Benzolsulfonyloxy-3,4-isopropylidendioxybutyronitril (IIIb und IIIc) aus Isopropylidenglycerinaldehyd von $[\alpha]_D = +14.9°$. Diaceton-D-mannitol (15.2 g) wird in Benzol mittels Bleitetraacetat oxydiert und wie oben aufgearbeitet. Nach Behandlung mit Kaliumcarbonat destilliert man das Lösungsmittel unter gewöhnlichem Druck ab. Wenn man den öligen zähen Rückstand unter verm. Druck destilliert, so geht nach wenigem Vorlauf 8.2 g Isopropylidenglycerinaldehyd vom Kp 70°C/30 mmHg erst beim Erhitzen des Umsetzungsprodukts bei 160—200°C über. Nach einmaligem Destillieren zeigt das Aldehyde $[\alpha]_D^{25} = +14.6°$ (*c* 2.754 Bzl). Man läßt 2.38 g Natriumcyanid auf so erhaltenes 6.50 g Isopropylidenglycerinaldehyd und 7.75 g Benzolsulfonylchlorid in M/20 Pufferlösung und Acetonitril einwirken und arbeitet auf, genau so wie in der oben beschriebenen Weise. So erhält man die Kristalle vom Schmp 51—88°C, die aus Isobutylalkohol umkristallisiert werden und 4.02 g betragen. Schmp 90—100°C. Wenn man die Mutterlauge bei der Umkristallisation mit großer Menge Petroläther versetzt und sie im Eisschrank stehen läßt, so scheiden sich 6.95 g Kristalle vom Schmp 44—50°C ab. Nach nochmaligen Umkristallisationen der beiden Kristalle aus Isobutylalkohol schmelzen die einen bei 101.5—102.5°C, die anderen bei 52—54.5°C. 2-Benzolsulfonyloxy-3,4-isopropylidendioxybutyronitril vom Schmp 101.5—102.5°C (IIIb), Gef: C, 52.67; H, 5.36; N, 4.76%. Ber für $C_{13}H_{15}NO_5S$: C, 52.52; H, 5.09; N, 4.71%. $[\alpha]_D^{27} = \pm 0.0$ (*c* 0.5 $CHCl_3$). Das Diastereomer vom Schmp 52—54.5°C (IIIc), Gef: C, 52.65; H, 5.36; N, 4.82%. Ber für $C_{13}H_{15}NO_5S$: C, 52.52; H, 5.09; N, 4.71%. $[\alpha]_D^{27} = -4.0°$ (*c* 0.5 $CHCl_3$). IIIa, IIIb und IIIc haben alle die gleichen R_f-Werte bei der Dünnschichtchromatographie mittels Silikagels.

Essigsaure Hydrolyse von IIIb und IIIc. Genau so wie im Fall von IIIa hydrolysiert man IIIb vom Schmp 100—102°C und umkristallisiert aus Isobutylalkohol/Petroläther. Schmp 89—90°C. Gef: C, 46.89; H, 4.48; N, 5.41%. Ber für $C_{10}H_{11}NO_5S$: C, 46.70; H, 4.31; N, 5.45%. IR-Spektrum (KBr); 3450, 3250,

1370, 1190, 1180, 970 cm^{-1}.

Nach dem analogen Aufarbeiten erhält man das Hydrolysat (IVc) aus IIIc vom Schmp 50—52°C und umkristallisiert es aus Isobutylalkohol. Schmp 155—157°C. Gef: C, 46.72; H, 4.29; N, 5.77%. Ber für $C_{10}H_{11}NO_5S$: C, 46.70; H, 4.31; N, 5.45%. IR-Spektrum (KBr); 3450, 3300, 1375, 1195, 1180, 1000 cm^{-1}.

Reduktion von IIIa, IIIb und IIIc mit Lithiumaluminiumhydrid. Man löst 7.50 g Ketalnitril (IIIa) in 30 m*l* 1 : 1 Lösung von THF und Äther und tropft die Lösung in die Suspension von 1.82 g Lithiumaluminiumhydrid in 50 m*l* Äther unterhalb 0°C ein. Nach vierstündigem Rühren bei Raumtemperatur behandelt man das Reaktionsgemisch in gewöhnlicher Weise und erhält 2.00 g (55.4% d. Th.) 2-(1,2-Isopropylidendioxyäthyl)aziridin (Va) vom Kp 112°C/23 mmHg. n_D^{25} 1.4491. $[\alpha]_D^{25}=+7.51°$ (*c* 1.385 Bzl). In der Gaschromatographie mittels Carbowax 20 M-Säule beobachtet man nur eine einzige Spitze. Gef: C, 58.45; H, 9.05; N, 9.67%. Ber für $C_7H_{13}NO_2$; C, 58.72; H, 9.12; N, 9.78%. IR-Spektrum (Flüssigkeit); 3300, 3050, 1385, 1375, 1220, 1070 cm^{-1}.

IIIb liefert in analoger Weise das Aziridin (Vb) vom Kp 106—110°C/26 mmHg in 57%-iger Ausbeute. n_D^{25} 1.4450. $[\alpha]_D^{25}=+0.8°$ (*c* 0.5 Bzl). IIIc gibt das diastereomere Aziridin (Vc) vom Kp 107—109°C/28 mmHg in 60%-iger Ausbeute. n_D^{25} 1.4483, $[\alpha]_D^{25}=-4.2°$ (*c* 0.5 Bzl).

2-(*p*-Nitrophenyl)-4-(1,2-isopropylidendioxyäthyl)-2-Oxazolin (VIIb und VIIc). *VIIb vom Schmp 123—124.5°C.* Man setzt die ätherische Lösung des 1.10 g *p*-Nitrobenzoylchlorid in die Lösung des 0.80 g Ketalaziridins (Vb) und 1.13 g Triäthylamins in 30 m*l* wasserfreiem Äther unterhalb 7°C unter Rühren zu, und nach zweistündigem Rühren versetzt man das Reaktionsgemisch mit Wasser. Die ätherische Schicht wird abgetrennt, zweimal mit 2N Natronlauge und zweimal mit Wasser nachgewaschen und über wasserfreies Kaliumcarbonat getrocknet. Nach Entäthern erhält man 1.40 g (86% d. Th.) 1-(*p*-Nitrobenzoyl)-aziridin (VIb) als öligen Rückstand. Das IR-Spektrum zeigt die Amid-Bande bei 1680 cm^{-1}. Man löst den Rückstand in 60 m*l* wasserfreiem Aceton, versetzt die Lösung mit 7.0 g Natriumjodid und läßt sie 20 Std bei Raumtemperatur stehen. Bei Verdünnen mit Wasser erhält man das umgelagerte Produkt vom Schmp 115—121°C, das aus 2-Propanol umkristallisiert wird. Gelbliche Prismen vom Schmp 123—124.5°C. Gef: C, 57.29; H, 5.40; N, 9.61%. Ber für $C_{14}H_{16}N_2O_5$: C, 57.53; H, 5.52; N, 9.59%. IR-Spektrum (KBr): 1647, 1515, 1375, 1380, 1210, 1070 cm^{-1}.

VIIc vom Schmp 107—110°C. Von Ketalaziridin (Vc) ausgehend, erhält man nach der gleichen Aufarbeitung das diastereomere Oxazolin (VIIc), das aus wäßr. Äthanol umkristallisiert wird. Gelbliche Nadeln vom Schmp 107—110°C. Gef: C, 57.27; H, 5.50; N, 9.78%. Ber fur $C_{14}H_{16}N_2O_5$: C, 57.53; H, 5.52; N, 9.59%. IR-Spektrum (KBr); 1650, 1530, 1375, 1380, 1215, 1070 cm^{-1}.

3-*O*-Benzyl-5-*O*-benzolsulfonyl-1,2-isopropyliden-α-D-glucofuranuronsäurenitril (X) und 3-*O*-Benzyl-5-*O*-benzolsulfonyl-1,2-isopropyliden-β-L-idofuranuronsäurenitril (XI). 3-*O*-Benzyl-1,2:5,6-isopropyliden-α-D-glucofuranose (40 g) wird in 28 m*l* 5%-iger Schwefelsäure und 220 m*l* THF partiell hydrolysiert, und mittels Dünnschichtchromatographie geprüft. Danach wird das Gemisch mit Natriumbicarbonat neutralisiert. Man löst so erhaltene rohes 20.9 g 3-*O*-Benzyl-1,2-isopropyliden-α-D-glucofuranose in 100 m*l* Chloroform und versetzt mit 80 m*l* Wasser. 14.4 g Natriumperjodat wird anschließend in kleinen Portionen unter Eiskühlung zugesetzt, und man rührt das Gemisch 30 Min. Nach dem Filtrieren wäscht man die Chloroformschicht dreimal mit Wasser, trocknet mit Natriumsulfat, dampft sie ein und erhält Pentodialdose (IX) als Syrup. Man löst den Rückstand und 12.5 g Benzolsulfonylchlorid in 70 m*l* Acetonitril, versetzt 70 m*l* M/15 Pufferlösung von pH 7.40 (NaH_2PO_4-Na_2HPO_4) und setzt die konz. waßr. Lösung von 3.81 g Natriumcyanid tropfenweise unter Eiskühlung und gutem Rühren zu. Nach halbstündigem Rühren unter Eiskühlung versetzt man das Gemisch mit Wasser und zieht zweimal mit Äther aus. Die ätherische Lösung wird mit Wasser nachgewaschen, über Magnesiumsulfat getrocknet und eingedampft. Im NMR-Spektrum dieses Rückstands treten zwei Dublette bei τ 5.28 und 5.46 im Stärkeverhältniss 10 : 19 auf. Der Rückstand wird in 25 m*l* Tetrachlorkohlenstoff umgelöst und im Eisschrank stehen gelassen. Man nutscht 9.24 g (20% d. Th.) Kristalle vom Schmp 134—137°C ab, die mit kaltem Tetrachlorkohlenstoff gewaschen, aus Äthanol umkristallisiert werden und bei 137.5—139°C schmelzen. 3-*O*-Benzyl-5-*O*-benzolsulfonyl-1,2-isopropyliden-α-D-glucofuranuronsäurenitril (X) als farblose Nädeln. $[\alpha]_D^{25}=-29°$ (*c* 2.27 $CHCl_3$). Gef: C, 59.60; H, 5.21; N, 3.15%. Ber für $C_{22}H_{23}O_7NS$: C, 59.31; H, 5.20; N, 3.14%. IR (KBr); 1375, 1190, 1080, 990 cm^{-1}.

Man engt das von den Kristallen freigesetzte Filtrat unter verm. Druck ein, und im NMR-Spektrum des Rückstands treten zwei Dublette bei τ 5.28 und 5.46 im Stärkeverhältniss 31 : 13 auf. Die Dünnschichtchromatographie des Rückstands mittels Silikagels ergibt keine Abtrennung. Die Säulenchromatographie mittels Silikagels war auch zur Abtrennung der Diastereomere vergeblich: das Reaktionsgemisch jeder Fraktionen zeigt das gleiche NMR-Spektrum. Das kristalline Gemisch (6.27 g) wird dann mit Äthanol dreimal zur Fraktionierung umkristallisiert, und man erhält das Diastereomer (XI) vom Schmp 106—108°C als farblose Blättchen. $[\alpha]_D^{25}=-8.3°$ (*c* 2.06 $CHCl_3$). Die Kristallisation von XI ist langsamer als die von X in Äthanol. Gef: C, 59.36; H, 5.15; N, 3.04%. Ber für $C_{22}H_{23}O_7NS$: C, 59.31; H, 5.21; N, 3.14%.

5-Amino-5-desoxy-β-L-idose-Derivat (XIII). Man tropft 2.00 g X in 15 m*l* THF in die THF-Lösung von 0.34 g LAH unter Eiskühlung unterhalb 10°C ein und rührt bei Raumtemperatur 4 Std. Nach Stehenlassen über Nacht zersetzt man den Metallkomplex mit wenigem Wasser, nutscht den Niederschlag ab, dampft die Lösung unter verm. Druck ein, löst den Rückstand in Äther, wäscht die äther. Lösung mit Wasser zweimal und dampft sie nach Trocknen über Natriumhydroxyd ein. Der Rückstand zeigt die infraroten Banden bei 3300, 1385, 1375, 1210, 1165, 1070, 1020 cm^{-1}. Man löst oben erhaltenene rohen Aziridinylzucker und 2.00 g Triäthylamin in Benzol und setzt die benzolische Lösung von 1.08 g *p*-Nitrobenzoylchlorid unter Eiskühlung zu. Nach Filtrieren und Waschen mit Natriumbicarbonatlösung und Wasser dampft man die Lösung unter verm. Druck ein. Der Rückstand zeigt die Amid-Bande bei 1680 cm^{-1}. Man versetzt den Rückstand mit 5.10 g

Natriumjodid in 60 ml Aceton, läßt über Nacht stehen und verdünnt mit Wasser zur Bildung der kristallinen Substanz, die aus Äthylacetat umkristallisiert wird. 0.658 g (33% d. Th. in bezug auf X). Gelbliche Nädelchen vom Schmp 188—189°C. $[\alpha]_D^{25} = -48.3°$ (*c* 1.45 $CHCl_3$). Gef: C, 62.71; H, 5.49; N, 6.24%. Ber für $C_{23}H_{24}O_7N_2$: C, 62.72; H, 5.49; N, 6.36%. IR (KBr): 1650, 1515, 1375, 1350, 1080, 1015 cm^{-1}.

3-*O*-Benzyl-1,2-isopropyliden-5,6-*O*-ditosyl-α-D-glucofuranose (XIV). Man setzt 24 g *p*-Toluolsulfonylchlorid in Pyridin (20 ml)-Lösung der 8.46 g rohen 3-*O*-Benzyl-1,2-isopropyliden-α-D-glucofuranose und läßt das Gemisch 24 Std bei Raumtemperatur stehen. Nachdem man zur Lösung Wasser und Chloroform zusetzt und eine Weile stark rührt, trennt man die org. Schicht ab, die mit Wasser nachgewaschen, über Magnesiumsulfat abgetrocknet und eingeengt wird. Der Rückstand wird säulenchromatographisch mittels Silicagels gereinigt, und 12.7 g (64% d. Th.) ditosyliertes Produkt (XIV) wird erhalten. IR: 1370, 1190, 1180, 1095, 920 cm^{-1}. Dünnschichtchromatographisch einheitlich.

6-Azido-3-*O*-Benzyl-1,2-isopropyliden-5-*O*-*p*-toluolsulfonyl-6-desoxy-α-D-glucofuranose (XV). Man rhürt 1.51 g Natriumazid und 12.1 g oben erhaltene ditosylierte Glucofuranose (XIV) in 80 ml DMF eine Std bei Raumtemperatur und eine Std bei 120°C. Nach Stehenlassen über Nacht versetzt man die Lösung mit Xylol und nutscht den Niederschlag mit aktiver Kohle ab. Nach Einengen löst man den Rückstand in Äther und Petroläther (1 : 1), wäscht die Lösung dreimal mit Wasser, trocknet über Magnesiumsulfat ab und dampft sie ein. Man reinigt den Rückstand säulenchromatographisch mittels Silikagels. Ausbeute, 8.30 g (87% d. Th.). IR: 2100, 1375, 1190, 1180, 1095, 1080, 920 cm^{-1}.

5-Amino-5-desoxy-β-L-idose-Derivat (XIII) aus 6-Azido-3-*O*-benzyl-1,2-isopropyliden-5-*O*-*p*-toluolsulfonyl-6-desoxy-α-D-glucofuranose (XV). Man reduziert 2.34 g oben erhaltene Azidofuranose (XV) mit 0.40 g Lithiumaluminiumhydrid in THF und erhält 1.33 g öligen Rückstand, dessen infraroten Spektrum mit dem des oben dargestellten Epiminozuckers (XII) sehr verwandt ist. Wie oben beschrieben, *p*-nitrobenzoyliert man den Rückstand und versetzt das acylierte Produkt mit 5.1 g Natriumjodid in Aceton. Nach Eindampfen der Acetonlösung versetzt man das Reaktionsgemisch mit Wasser unter Bildung der Kristalle, die aus Äthylacetat umkristallisiert werden. Ausbeute, 0.608 g. Die erhaltene Nadeln vom Schmp 187—188°C sind durch Mischprobe und IR-Spektrum mit oben synthetisiertem Oxazolin (XIII) identisch.

In einem anderen Versuch erhält man kristalline 5,6-Epimino-5,6-didesoxy-3-benzyl-β-D-idofuranose (X) nach Destillieren (Kp 170—175°C/1 mmHg) und umkristallisiert aus Cyclohexan. Cyclic Diacylcarbene Generated from Iodonium Ylides and Diazodiketones

Yosio HAYASI, Taiiti OKADA and Mituyosi KAWANISI

Department of Industrial Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received December 12, 1969)

The preparative method of iodonium ylides, $Ph\text{–}\overset{\oplus}{I}\text{–}\overset{\ominus}{C}(COR)(COR')$, is improved by condensation of active methylene compounds, $H_2C(COR)(COR')$, with iodosobenzene in the presence of acetic anhydride. Thermal and Cu-catalyzed decomposition of iodonium ylides can be differentiated and both are explained in terms of diacylcarbene intermediate with different multiplicity. For the sake of comparison diazodimedone and related compounds are also decomposed by Cu-catalysis as well as by photochemical reaction. Carbene is also found to be a highly probable intermediate. Throughout these investigations the spin multiplicity of the carbene is discussed on the basis of product distributions. Notably in the presence of homogeneous Cu-catalyst in ethanol, diazodimedone gives an insertion product to O–H bond, 2-ethoxy-3-hydroxy-5,5-dimethyl-2-cyclohexenone (XVII), whereas the iodonium ylides do not give such a compound. The formation of XVII is explained by assuming a ketocarbene-Cu-chelate complex.

Ylides and carbenes are structurally related chemical species[1,2] and their reactions have often been interpreted in terms common to both.[3] Neilands *et al.* have carried out an extensive work on the

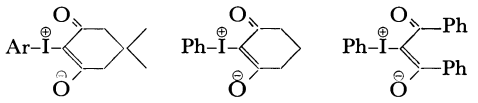
preparation of iodonium ylides,[4] but not much is known on the chemistry of an acylcarbene produced by the cleavage of the ylide bond $-\overset{\oplus}{I}-\overset{\ominus}{C}=$. We have been engaged in the iodonium ylide chemistry[5] and found some aspects of the reaction which suggests the carbene intermediacy. In order to gain further insight on the behavior of the cyclic diacylcarbene the reaction of cyclic diazodiketones was also investigated.

Results

Preparation of Iodonium Ylides. We were able to improve the Neilands method and prepared some compounds which could not be obtained by the original method.[4] A convenient method of preparation of sulfonium ylides previously reported[6] has now been extended to the reaction of iodosobenzene and active methylene compounds. Thus phenyl- (I, 74%), *p*-tolyl- (II, 70%), mesityl-iodonium dimedone betaine (III, 40%) and phenyl-iodonium cyclohexa-1,3-dione betaine (IV, 32%) were prepared by condensing respective active methylene compounds with iodosobenzene in the presence of acetic anhydride. An attempted synthesis of II and III according to the Neilands method which involves heating of iodosobenzene and active methylene compounds in chloroform resulted only in the formation of thermally rearranged products.

We were not successful in the preparation of the open chain ylide (V) from dibenzoylmethane presumably because of the instability of the ylide toward acetic acid generated in the reaction. Condensation of malononitrile or bisbenzenesulfonylmethane with iodosobenzene was also unsuccessful. Physical properties of iodonium ylides prepared by our method were reasonable as compared with those of the corresponding sulfonium ylides.[7]



I: Ar=Ph IV V
II: Ar=4-MeC_6H_4
III: Ar=2,4,6-$Me_3C_6H_2$

Thermal and Catalytic Decomposition of Iodonium Ylides. Thermolysis of I in pyridine, water, dioxane and toluene reported by Neilands[4] in which phenyl migration from iodine to oxygen was included has been discussed in detail in the previous paper.[5b] Heating of I in absolute ethanol for 2 hr under reflux afforded dimedone (VI, 10%), dimedone ethyl ether (VII, 32%) and iodobenzene in addition to the rearranged product (VIII, 15%). Analogous results were obtained with II and III.

In the presence of cuprous chloride an exceedingly facile decomposition of I took place at room temperature and a significant difference was observed in the product distribution between the simple thermal and copper-catalyzed decompositions. The major product was 2-iododimedone (IX, 56%) and the rearranged product (VIII) was obtained in only 2% yield. Additional products were phenethole (X, 6%),*1 ethyl 4,4-dimethyl-2-ketocyclopentanecarboxylate[8] (XI, 25%) and iodobenzene.

The thermal reaction of the open chain ylide (V) has never been reported. Heating of V in absolute ethanol under reflux for 2 hr yielded dibenzoylmethane (40%) as a major product along with ethyl benzoylphenylacetate (XII, 17%), ethyl benzoate (5%) and iodobenzene. In contrast to the reaction of I, no detectable amount of the thermally rearranged product (XIII) was obtained.

In the presence of cuprous chloride the spontaneous decomposition of V in ethanol took place at room temperature and afforded XII (46%), tetrabenzoylethylene (21%),[7] ethyl benzoate (5%) and iodobenzene. No detectable amount of dibenzoylmethane was produced.

Decomposition of Diazodimedone in the Presence of Homogeneous Copper Catalyst. When pyrolyzed in refluxing xylene diazodimedone (XIV)[9] was reported to give a dimeric product (XV).[8] Stetter and Kiehs obtained a similar product by an analogous treatment of 2-diazocyclohexane-1,3-dione.[10] The decomposition of XIV in aniline gave 4,4-dimethyl-2-ketocyclopentanecarboxanilide (XVI).[11] The results can be explained by assuming ketoketene intermediate. When XIV was decomposed in the presence of copper catalyst the reaction took a somewhat different course. Thus when XIV was heated in ethanol under reflux in the presence of homogeneous copper catalyst, bis-[*N*-α-phenethylsalicylaldiminato]copper(II),[12] three

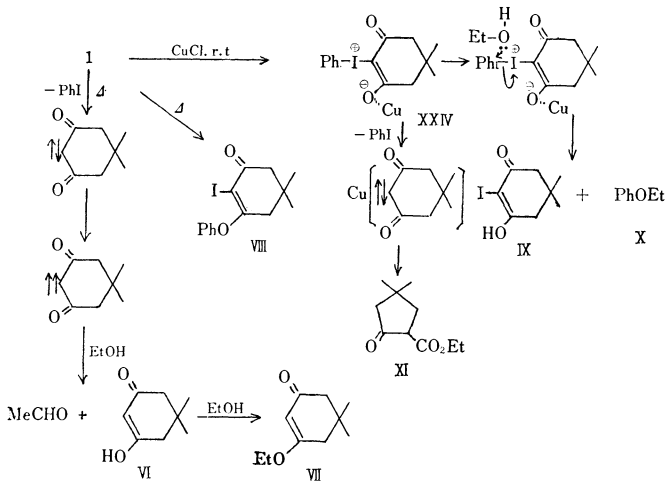
products, XI (39%), XVII (25%) and XVIII (14%) were obtained.*2 The product, XVII, mp 94.5°C showed IR absorption band at 1570 cm^{-1} which is ascribed to the monosubstituted dimedone derivative.*3 NMR signals due to the *gem*-methyl and ethyl groups were observed at δ 1.10 (singlet, 6H), 1.27 (triplet, 3H) and 4.04 (quartet, 2H), respectively. Ring methylene protons showed slightly broadened singlet at 2.35 and hydroxyl proton signal appeared at 6.61 as a very broad singlet which indicates the existence of five-membered enolic hydrogen-bonded hydroxyl group.[13] Analysis also supported the assigned structure, XVII. Another crystalline product (XVIII), mp 205°C, had molecular weight of 366 (by mass spectroscopy) corresponding to $C_{20}H_{30}O_6$. Its IR spectrum showed two kinds of carbonyl absorption band at 1732 and 1709 cm^{-1}, and NMR spectrum indicates the presence of both ethoxyl (1.35 and 3.34) and *gem*-methyl (0.83 and 1.72). Ring proton signals appeared as a quartet (geminal AB type; $J=15$ Hz) at 2.45 and 3.20 slightly broadened presumably due to the W-type long-range coupling. The stereochemistry of ring junction is undetermined, but the molecular model suggests that the *trans* configuration is highly probable. Thus we tentatively assigned structure XVIII to this compound. Compound XVII was considerably unstable and turned into XVIII when kept under atmospheric oxygen at room temperature. Thus XVIII can be considered as an oxidative coupling product of XVII.

Photolysis of Diazodimedone. When XIV was photolyzed directly in ethanol, Veschambre and Vocelle[8] observed the formation of VI, dimedone derivative of acetaldehyde (XIX) and 4,5-diketo-2,2,7,7,9-pentamethyloctahydroxanthene (XX) along with XI. We have also obtained the same results in the same reaction.[14] In addition we could confirm that photolysis of XIV in 2-propanol gave acetone which was not easily condensed with dimedone under the present conditions. However, when the reaction was carried out in the presence of an excess amount of benzophenone in ethanol, XIX was detected in the photolysate. Despite every effort we could not detect the presence of XI among the reaction products. It should be noted that benzopinacol was a minor product in this photoreaction with good recovery of benzophenone.

An attempted photolysis of diazomeldrum's acid (5-diazo-2,2-dimethyl-1,3-dioxane-4,6-dione) (XXI)[15] in ethanol resulted only in the formation of meldrum's acid (XXII, 67%)[16] after evolution of 76% of nitrogen.

Discussion

In thermolysis of I, the mechanism of phenyl migration has been discussed.[5b] The formation of other substances may be best rationalized by assuming the cleavage of I-C bond in the yildes to yield a diketocarbene (XXIII) and iodobenzene. The carbene abstracts hydrogen from ethanol to give dimedone (VI) and its ethyl ether (VII). From this chemical behavior the spin multiplicity



Scheme 1

*2 The reaction catalyzed by $Cu(acac)_2$ or CuCl was extremely complex and detailed analysis of the products was impossible.

*3 For example, 2-methyldimedone absorbs at 1570 cm^{-1}.

of the carbene (XXIII) which is responsible for the reaction is estimated to be triplet in view of the results obtained from the sensitized photolysis of diazodimedone described below. The reason for the facile intersystem crossing from singlet to triplet state is unknown at present, but it may be partly ascribed to the external heavy atom effect[17] due to the presence of iodobenzene.

The Cu-catalyzed reaction is clearly different from the purely thermal one. The formation of phenethole (X) and 2-iododimedone (IX) can be explained by assuming the Cu-coordinated intermediate (XXIV), and subsequent nucleophilic attack of ethanol as depicted in Scheme 1, whereas the formation of the ester (XI) is the result of the Wolff-rearrangement of XXIII in ethanol. The reactive species which is responsible for the Wolff-rearrangement has been claimed to be ketocarbene[18] whose multiplicity is considered to be singlet in view of the discussion by Padwa and Layton.[19] In the present case also the diketocarbene in singlet state should be produced. The presence of Cu salt may prohibit the intersystem crossing and the Wolff-rearrangement became predominant at the expense of hydrogen abstration reaction. This was also the case with V when decomposed by the action of Cu catalyst (Scheme 2). The yield of XII surprisingly increased while no dibenzoylmethane was detected. The absence of XIII among the products of purely thermal reaction may be attributed to the intrinsic lability of V. With respect to the formation of tetrabenzoylethylene the same rationalization as described for the sulfonium ylide should be taken into account.[7]

In conclusion the cleavage of phenyl-iodine bond occurs predominantly in the Cu-catalyzed decomposition of I, while the ylide bond is always broken in the case of V. The reason for this difference should be clarified by further investigation.

The decomposition of XIV in the presence of homogeneous copper catalyst presents a striking contrast to the non-catalyzed reaction as mentioned above. In this case the Wolff-rearrangement was a minor process and the insertion reaction to the solvent alcohol O–H bond became important. The insertion product (XVII) and its oxidation product (XVIII) were produced. Takebayashi and coworkers studied in detail the catalytic decomposition of diazoacetophenone in alcohol in the presence of copper chelates under heterogeneous conditions, and they obtained the insertion products at the expense of the rearranged product.[20] The observation was explained by assuming an intermediary ketocarbene-metal chelate complex. Our results can also be accomodated to this hypothesis except for the formation of the rearranged products (Scheme 3). This may be due to the difference existing in the intermediate carbene complexes or the reaction condition.

The photolysis of diazoacetophenones has been

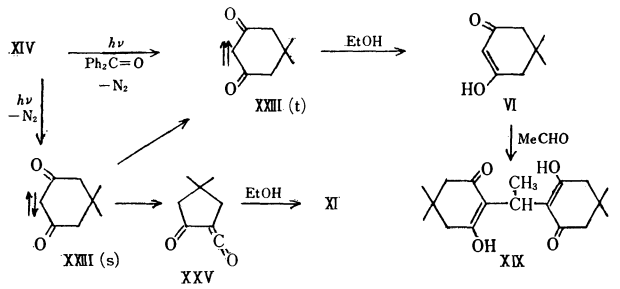

Scheme 4

investigated by several workers[19,21,22] and explained by assuming that triplet benzoylcarbene abstracts hydrogen to give acetophenones and the intersystem crossing of triplet ketocarbene to singlet species efficiently competes with the hydrogen abstraction. Although much has been done with respect to the photochemical generation of ketocarbene, little attention has been focused on the one of β-diketocarbenes.[8,23,24] Direct photolysis of XIV in ethanol gave VI, XIX, XX and XI.[8a] The sensitized photolysis of XIV in the presence of large excess of benzophenone has now clearly demonstrated that only VI was produced through XXIII in triplet state. VI then condensed with acetaldehyde generated in the reaction mixture (Scheme 4). Thus in the case of cyclic diketocarbene the intersystem crossing of triplet XXIII to singlet multiplicity is clearly ruled out, and ester (XI) must be derived from only XXIII in singlet state *via* ketoketene (XXV). It is still open to question as pointed out by Hammond[21] under the present circumstance whether the evolution of nitrogen takes place after or before the intersystem crossing of the excited diazodimedone.

Experimental

All melting points and boiling points are uncorrected. Microanalyses were performed at the Elemental Analyses Center of Kyoto University. The NMR spectra were obtained on a JEOL C-60-H spectrometer with $CDCl_3$ or CCl_4 as solvent and data are given in the order of multiplicity (s=singlet, d=doublet, t=triplet, q=quartet and m=unresolved multiplet), integration. Chemical shifts are reported in δ values relative to TMS as an internal standard. Mass spectra were obtained with a Hitachi RMU-6D mass spectrometer with a direct inlet (200°C) at 80 eV. Plates of Silicagel G were used for thin layer chromatography (TLC) and the spots were visualized with iodine vapor.

Preparation of Iodonium Ylides. A solution of PhIO (0.8 g, 3.6 mmol) and dimedone (0.5 g, 3.6 mmol) in Ac_2O (10 m*l*) was allowed to stand for 10 hr at room temp. The reaction mixture was made basic (pH *ca.* 10) with 20% NaOH aq. and then extracted with $CHCl_3$. Drying ($MgSO_4$) and concentration of the extract *in vacuo* gave an oil which solidified upon addition of ether. This solid substance was recrystallized from PhH to afford 0.9 g (74%) of I, mp 126—128°C(dec) (lit,[25] 132—133°C), IR (Nujol): 1530 cm^{-1}, λ_{max}^{EtOH}: 261 nm (log ε 4.0), NMR: δ 1.05 (s, 6H), 2.48 (s, 4H), 7.2—7.9 (m, 5H).

An analogous procedure was used for the preparation of III (40%), mp 133—135°C. Found: C, 52.60; H, 5.48. Calcd for $C_{17}H_{21}IO_2$: C, 53.14; H, 5.51%. IR (Nujol): 1560 cm^{-1}, λ_{max}^{EtOH} 266 nm (log ε 4.2), NMR: δ 1.02 (s, 6H) 2.30 (s, 3H), 2.43 (s, 4H), 2.75 (s, 6H), 6.9—7.1 (m, 2H), from iodosomesitylene and dimedone, and IV (32%), mp 109—110°C. Found: C, 46.00; H, 3.24. Calcd for $C_{12}H_{11}IO_2$: C, 45.88; H, 3.53%. IR (Nujol): 1530—1550 cm^{-1}, λ_{max}^{EtOH} 259 nm (logε 4.29), from iodosobenzene and dihydroresorcinol.

3-Mesityloxy-5,5-dimethyl-2-iodo-2-cyclohexenone. A $CHCl_3$ (20 m*l*) suspension of iodosomesitylene (1.32 g, 5 mmol) and dimedone (0.7 g, 5 mmol) was refluxed for 1 hr according to the Neilands method. Evaporation of the solvent afforded a crystalline solid, which was recrystallized from EtOH to give 1.2 g (60%) of 3-mesityloxy-5,5-dimethyl-2-iodo-2-cyclohexenone, mp 148—150°C, IR (nujol): 1660, 1583, 1130 cm^{-1}, NMR: δ 1.30 (s, 6H), 2.07 (s, 2H), 2.13 (s, 6H), 2.29 (s, 3H), 2.47 (s, 2H), 6.87 (s, 2H). Found: C, 53.01; H, 5.61. Calcd for $C_{17}H_{21}IO_2$: C, 53.14; H, 5.51%.

Thermolysis of I in EtOH. A solution of I (6 g, 17.5 mmol) in EtOH (100 m*l*) was refluxed for 10 hr under a slow stream of nitrogen. Removal of the solvent in a vacuum gave a mixture of products (4.1 g) from which a crystalline solid precipitated. Collection by filtration followed by recrystallization from EtOH afforded 0.9 g (15%) of VIII, mp 164—165°C (lit,[26] 165—166°C), IR(nujol): 1670, 1580, 1230 cm^{-1}, λ_{max}^{EtOH}: 275 nm (log ε 4.07), NMR: δ 1.05 (s, 6H), 2.30 (s, 2H), 2.50 (s, 2H), 6.9—7.5 (m, 5H). Distillation of the filtrate *in vacuo* afforded PhI and VII (0.95 g, 32%). bp 77—81°C/2 mmHg (lit,[27] 252°C), which solidified

to give white crystals on standing in a refrigerator, mp 58—59°C (lit,[27] 59.5—60°C), IR(Nujol): 1660, 1610, 1220, 1140 cm^{-1}, NMR: δ 1.10 (s, 6H,), 1.37 (t, 3H), 2.20 (s, 2H), 2.28 (s, 2H), 3.90 (q, 2H), 5.35 (s, 1H). (Found: C, 71.14; H, 9.51). The residue afforded VI (0.24 g, 10%) upon addition of ether. The evolved N_2 gas was passed into the 2,4-dinitrophenylhydrazine solution. The yellow precipitates obtained were identical with the authentic specimen of acetaldehyde 2,4-dinitrophenylhydrazone.

Copper-catalyzed Decomposition of I. Cuprous chloride (0.16 g, 1.6 mmol) was added in one portion to a solution of I (6 g, 17.5 mmol) in absolute EtOH (100 m*l*) under N_2 atm and stirred at room temp for 10 hr. Copper catalyst combined with iododimedone was removed by filtration and the filtrate was concentrated *in vacuo*. From the residual oil crystals were formed, collected by filtration and washed with PhH to yield IX (2.6 g, 56%), mp 150—152°C (lit,[28] 160—162°C), IR (Nujol): 1570 cm^{-1}. (Found: C, 36.18: H, 4.36.)

The filtrate was concentrated *in vacuo* and the residual oil (2.0 g) was subjected to chromatography (Silicagel), followed by preparative GLC giving VIII (0.1 g, 2%), phenethole (X) (0.12 g, 6%), PhI (0.3 g) and an oil XI (0.8 g, 25%). The compound XI showed IR (neat) absorptions at 3475, 1760, 1730 and 1190 cm^{-1}; NMR ($CDCl_3$) signals at δ 1.16 (s, 3H), 1.25 (s, 3H), 1.28 (t, 3H), 1.99 (d, 1H, J=14 Hz), 2.40 (s, 2H), 2.43 (d, 1H, J=14 Hz), 3.75 (broad s, 1H) and 4.23 (q, 2H), which were identical with those of authentic ethyl 4,4-dimethyl-2-oxocyclopentane-1-carboxylate.[8]

Thermolysis of V in EtOH. A solution of V (11 g, 25.8 mmol) in absolute EtOH (200 m*l*) was refluxed for 2 hr. After evaporation of the solvent, the residual oil (8.54 g) was chromatographed on a Silica gel column with PhH as an eluant to give PhI (3.2 g, 60%), dibenzoylmethane (2.3 g, 40%), ethyl benzoate (0.2 g, 5%) and XII (1.1 g, 17%), mp 89—90°C (from *i*-PrOH) (lit,[29] 90—91°C), IR (Nujol): 1750, 1685, 1260 cm^{-1}.

Copper-catalyzed Decomposition of V. Cuprous chloride (0.3 g, 3 mmol) was added to a solution of V (9 g, 21.2 mmol) in absolute EtOH (250 m*l*) under N_2 atm and stirred at room temp. for 12 hr. After filtration, the solvent was removed in a vacuum. The residual oil (6.3 g) was distilled *in vacuo* to yield an oily mixture, which was subjected to GLC analysis. Iodobenzene, ethyl benzoate (0.16 g, 5%) and XII (2.5 g, 44%) were identified by comparison of the retention times on GLC and IR spectra with those of authentic specimens. From the distillation residue, 2.0 g (21%) of tetrabenzoylethylene was obtained which melted at 183—185°C (lit,[30] 184°C) upon recrystallization from EtOH. (Found: C, 81.21; H, 4.80%. Calcd for $C_{30}H_{20}O_4$: C, 81.06; H, 4.54%.)

Thermal Decomposition of XIV in the Presence of the Homogeneous Catalyst. A solution of diazodimedone (XIV)[9] (3 g, 18 mmol) in EtOH (120 m*l*) in the presence of bis(*N*-α-phenethylsalicylaldiminate)copper(II)[12] (50 mg) was heated under reflux for 15 hr. Quantitative amount of nitrogen gas was evolved. After removal of the solvent, the resulting masses were collected by filtration and recrystallized from ethyl acetate to afford XVIII (0.47 g, 14%), mp 205—206°C IR(KBr): 1732, 1709, 1140 and 1098 cm^{-1}, NMR: δ 0.83 (s, 6H), 1.11 (s, 6H), 1.26 (t, 6H), 2.83 (q, (*gem*-AB), J=15 Hz, 8H), 3.35 (q, 4H). Found: C, 65.66; H, 8.30%. Calcd for $C_{20}H_{30}O_6$: C, 65.66; H, 8.25%. Mass spectra had parent peak at *m/e* 366. From these data XVIII was assigned to be bis-2,2'-(2-ethoxy-5,5-dimethyl-1,3-cyclohexanedione). The filtrate was concentrated and chromatographed on Silicagel column. The following compounds were isolated and identified: XI (1.29 g, 39%), bp 75—80°C/2 mmHg, 2-ethoxy-3-hydroxy-5,5-dimethyl-2-cyclohexenone (XVII), (0.83 g, 25%), mp 94.5°C (from cyclohexane), very hygroscopic, fairly unstable crystalline solid. IR (Nujol): 2600 (weak) 1570, 1250, 1120, 1035 cm^{-1}, NMR: δ 1.10 (s, 6H), 1.27 (t, 3H), 2.35 (s, 4H), 4.04 (q, 2H), 6.61 (s, 1H, enolic proton*4). Found: C, 65.19; H, 8.75%. Calcd for $C_{10}H_{16}O_3$: C, 65.32; H, 8.80%. Exposure of XVII to atmospheric oxygen resulted in the formation of XVIII almost quantitatively.

Photochemical Decomposition of Diazodimedone, a Sensitized Experiment. A solution of XIV (1.0 g, 6 mmol) in EtOH (20 m*l*) containing benzophenone (5 g, 28 mmol) was irradiated by means of 200 W high pressure mercury arc (Pyrex filter) for 12 hr. Under this condition almost all the incident light was absorbed by benzophenone.*5 After evolution of the theoretical amount of nitrogen gas the reaction mixture was concentrated *in vacuo* and the residue was chromatographed on Silicagel column. The following compounds were isolated: XIX (0.47 g, 51%), benzopinacol (0.16 g, 1.6%) and recovered benzophenone (4.28 g, 96%).

Photolysis of XIV in 2-Propanol. A solution of XIV (1 g, 6 mmol) in 2-propanol (20 m*l*) was irradiated by means of Pyrex-filtered Hg arc. The reaction mixture was subjected to distillation and the distillate was poured into a solution of 2,4-dinitrophenylhydrazine. 2,4-Dinitrophenylhydrazone of acetone precipitated. From the distillation residue VI (0.68 g, 80%) was isolated.

Photochemical Decomposition of 5-Diazo-2,2-dimethyl-1,3-dioxa-4,6-dione (Diazomeldrum's Acid). A solution of 2-diazomeldrum's acid[9] (2 g, 12 mmol) in EtOH (80 m*l*) was irradiated by means of a 200 W high pressure Hg arc (Pyrex filter) for 50 hr. Seventy per cent of theoretical amount of nitrogen gas was evolved. The reaction mixture was concentrated *in vacuo* and the residue was recrystallized from EtOH to afford meldrum's acid (1.12 g, 67%), mp 94°C (lit,[16] 94—95°C).

The authors are grateful to Professors Keiiti Sisido and Hitosi Nozaki for help and encouragement. They are also indebted to Messrs. Zyun-iti Morita, Tadasige Yamaguti and Koiti Kamogawa for valuable assistance.

The Codimerization of Styrene with Ethylene Catalyzed by Olefin-palladium(II) Chloride Complexes

Keiji KAWAMOTO, Toshinobu IMANAKA and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka

(Received December 12, 1969)

The codimerization of styrene with ethylene catalyzed by the olefin-palladium chloride complexes was investigated in a homogeneous system under mild conditions; di-μ-chloro-dichlorobis-(styrene)dipalladium(II), $(Pd(C_6H_5CH{=}CH_2)Cl_2)_2$, was found to be an effective catalyst. When ethylene was bubbled into a styrene solution containing the styrene-palladium complex at 50°C for 6 hr, codimers including *trans*-1-phenyl-1-butene, *cis*-1-phenyl-1-butene, and *trans*-1-phenyl-2-butene were obtained in 1278, 57 and 170% yields respectively, based on palladium(II) used. However, the absence of ethylene resulted in the formation of a 70% yield of the dimer of styrene, *trans*-1,3-diphenyl-1-butene. The order of the solvent effect on the rate of the codimerization was as follows: nitrobenzene>nitromethane>acetic acid, phenol>dioxane≫benzene≫acetonitrile. A possible mechanism for this reaction was discussed on the basis of the present results.

Many investigations have recently been reported into the cooligomerizations of conjugated dienes with mono-olefins catalyzed by transition-metal compounds.[1] Only little is known, however, about the codimerization of styrene with ethylene catalyzed by transition-metal compounds. Müller and his co-workers have reported that the cocatalyst consisting of nickel acetylacetonate, trialkylaluminum, and phosphite catalyzes the codimerization of styrene with ethylene to give cocyclic higher oligomers and a small amount of codimer.[2] Alderson and his co-workers described how rhodium chloride and ruthenium chloride also catalyze the codimerization of styrene with ethylene under a high pressure to give 2-phenyl-2-butene.[3]

As has been reported in a preliminary communication,[4] we have found that di-μ-chloro-dichlorobis-(styrene)dipalladium(II) is an effective catalyst for the codimerization of styrene with ethylene. In this paper detailed studies of the reaction catalyzed by olefin-palladium chloride complexes will be reported.

Experimental

Codimerization of Styrene with Ethylene by a Styrene-palladium Complex Catalyst. A reaction vessel was charged with 4.5 g of styrene-palladium chloride and 150 m*l* of styrene, and then ethylene was bubbled into the mixture at 50°C for 6 hr. This solution became a reddish-yellow. The color did not vary during the reaction, indicating that the complex functions as a stable catalyst, although only a slight precipitation of metallic palladium was observed in the final stage of the reaction. The resulting solution was diluted with petroleum ether after the unreacted styrene had been removed under reduced pressure at 50°C; then it was filtered in order to remove the palladium complex and palladium metal. The distillation of the filtrate gave 27.1 g of *trans*-1-phenyl-1-butene, 1.2 g of *cis*-1-phenyl-1-butene, 3.6 g of *trans*-1-phenyl-2-butene, and 0.4 g of acetophenone, all of which were identical with authentic samples.[5]

trans-1-Phenyl-1-butene: IR spectrum: *trans*-HC=CH- 960 cm^{-1}, phenyl 740 and 690 cm^{-1}. NMR spectrum: CH_3 τ 8.80 (triplet), CH_2 τ 7.70 (quintet), -HC=CH- τ 3.70 (multiplet), phenyl τ 2.38 (multiplet). Found: C, 90.92; H, 9.13%. Calcd for $C_{10}H_{12}$: C, 90.90; H, 9.12%.

cis-1-Phenyl-1-butene: NMR spectrum: CH_3 τ 8.95 (triplet), CH_2 τ 7.63 (quintet), -HC=CH- τ 3.67 and 4.40 (multiplet), phenyl τ 2.83 (multiplet).

trans-1-Phenyl-2-butene: IR spectrum: *trans*-HC=CH- 968 cm^{-1}, phenyl 745 and 695 cm^{-1}. NMR spectrum: CH_3 τ 8.31 (doublet), CH_2 τ 6.73 (doublet), -HC=CH- τ 4.50 (multiplet), phenyl τ 2.85 (multiplet).

Reaction Kinetics. The apparatus and procedure used to measure the reaction rates were similar to those employed before.[6] The reaction rates were determined

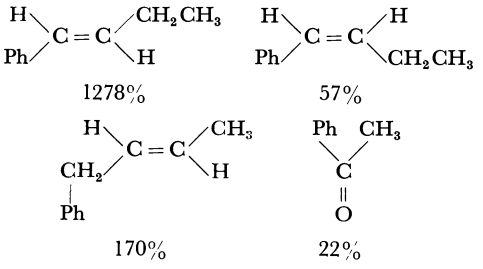
by measuring the amount of *trans*-1-phenyl-1-butene formed and that of ethylene absorbed.

Results and Discussion

Products. The codimerization reaction of styrene with ethylene catalyzed by the styrene - palladium chloride was carried out at 50°C for 6 hr, ethylene being bubbled into the styrene solution containing the catalyst.[4] The following products were obtained:



(based on palladium(II))

The total amount was more than 15 mol equivalents of the palladium complex, indicating that the styrene - palladium complex is an effective catalyst for the codimerization reaction under the mild conditions here adopted.

It is interesting that no dimers of styrene and ethylene were formed. In the absence of ethylene under the same conditions, the dimer of styrene, *trans*-1,3-diphenyl-1-butene, and acetophenone were formed in 70 and 30% yields respectively, on the basis of palladium(II). It has previously been reported[6] that the dimerization reaction of ethylene proceeded when ethylene was bubbled into a reaction mixture of dioxane and ethylene - palladium chloride. These facts indicate that the coexistence of styrene and ethylene inhibits the dimerization reactions.

The formation of acetophenone may be due to the reaction of styrene with the moisture, since a partial precipitation of metallic palladium in the course of the reaction was observed.[7]

Activity of Styrene-, Ethylene-palladium Complexes and Palladium Chloride. The codimerization reaction of styrene with ethylene was studied by using styrene- and ethylene-palladium complexes and palladium chloride. The results are shown in Fig. 1, where the amount of ethylene absorbed from the gas phase and that of the *trans*-1-phenyl-1-butene formed are plotted *vs.* the reaction time. From the gas-chromatographic analysis, it

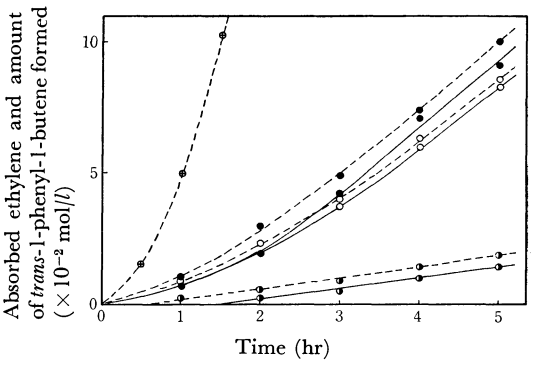


Fig. 1. The time dependences of the absorption of ethylene and the formation of *trans*-1-phenyl-1-butene.
——: amount of *trans*-1-phenyl-1-butene, ------: absorbed ethylene, ⊕: ethylene-palladium complex-dioxane system, ●: styrene-palladium complex, ○: ethylene-palladium complex, ◑: $PdCl_2$, neat(styrene at 8.72 mol/*l*), (Pd): 1.06×10^{-2} mol/*l*, concentration of ethylene: 6.36×10^{-2} mol/*l*, 50± 0.2°C.

was found that the amounts of the other codimers were proportional to that of *trans*-1-phenyl-1-butene, and that the absorbed ethylene was almost completely consumed in the codimerization. As is shown in Fig. 1, the reaction has an induction period (*ca.* 30 min) which was slightly different for various solvents.

The dimerization of ethylene, which was observed in the reaction system of dioxane and ethylene-palladium complex, is also shown in Fig. 1. It is necessary to point out that the dimerization reaction of ethylene is much faster than the codimerization reaction of styrene with ethylene. However, no dimer of ethylene has been formed in the present system.

The reactivities of palladium complexes decreased in the following order: styrene complex≳ethylene complex≫palladium chloride.

Solvent Effect. The solvent effect on the codimerization reaction of styrene with ethylene is summarized in Table 1. The dipole moments and the dielectric constants of the solvents are also shown in Table 1.

The reaction rate is subjected to restriction in both a nonpolar solvent such as benzene and a strongly polar solvent such as acetonitrile. In acetonitrile palladium complex is changed into an insoluble yellow complex. The reaction rate is particularly enhanced in a solvent containing oxygen atom. A similar effect was also observed in the dimerization reaction of ethylene.[9]

The rate decreases in the following sequence: nitrobenzene > nitromethane > acetic acid > phenol > dioxane. Table 1 shows that the sequence agrees

7) The formation of acetophenone from styrene and water by palladium salts is well known. For example, (i) J. Smidt, W. Hafner, R. Jira, J. Sedlmeiner, R. Sieber, R. Ruttinger and H. Kojer, *Angew. Chem.*, **71**, 176 (1959). (ii) J. Smidt, W. Hafner, R. Jira, R. Sieber, J. Sedlmeier and A. Sabel, *ibid.*, **74**, 93 (1962).

with the decreases in the dipole moment (μ) and dielectric constant (ε).

It should be noted here that; (i) the complex is partly reduced to metallic palladium in the early stage of the reaction in phenol, and (ii) the liquid-phase concentration of ethylene is much lower in phenol than in acetic acid. These facts indicate that the corrected rate of the codimerization in phenol is faster than that in acetic acid.

Effect of Ethylene Pressure. The codimerization was examined as the ethylene pressure increased from 1 to 15 atm. The results are shown in Fig. 2. The styrene - palladium complex was used as a catalyst. The amount of *trans*-1-phenyl-1-butene formed initially increases, reaches a maximum at an ethylene pressure of 4 atm, and then gradually decreases. At a high pressure of ethylene, the rate of the formation of butene increases with an increase in the ethylene pressure.

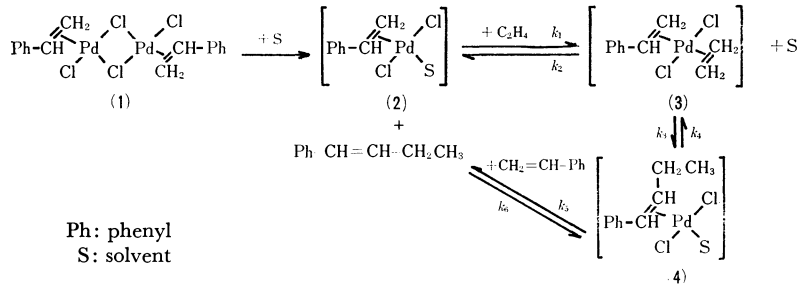
These results indicate that the codimerization reaction is favored at low pressures of ethylene and that the dimerization reaction of ethylene predominates above an ethylene pressure of 4 atm.

Effect of Styrene Concentration. The formation rate of *trans*-1-phenyl-1-butene was measured by diluting styrene with benzene. In benzene the codimerization and dimerization reactions did not occur. The results are shown in Fig. 3. The reaction rate increased with an increase in the styrene concentration, and the order of the reaction changed from one to zero.

Reaction Mechanism. In view of the above facts, we propose the reaction mechanism of the codimerization shown in Scheme 1.

The styrene-palladium complex (1) initially dissociates into the complex (2) in the presence of a solvent. The coordination of ethylene with the complex (2) results in the complex (3). In the complex (3) the insertion between the coordinated styrene and ethylene produces the complex (4). Finally styrene rapidly displaces the coordinated dimer in the complex (4), reforming the complex (2). In the stage of changing from the complex (4) to (2), the amount of coordinated ethylene instead of styrene can be ignored, since the liquid-

8) The Chem. Soc. Japan, "Kagaku Binran, Kisohen I," Maruzen, Tokyo (1966), pp. 1003, 1226.



Scheme 1

phase concentration of styrene is more than 100 mol equivalents of that of ethylene at a low pressure of ethylene. However, with an increase in the pressure of ethylene, this amount can not be ignored, and another complex coordinated by ethylene and the solvent must be formed. In this case, another circulation was previously proposed for the dimerization of ethylene by the present authors.[6]

In the stage of changing from the complex (2) to (3), it is natural that the complex coordinated by two molecules of styrene is formed, since the concentration of styrene is much higher than that of ethylene. Therefore, the fact that styrene does not undergo the dimerization suggests that the insertion reaction between coordinated styrene and ethylene is much faster than that between coordinated styrenes.

When the stage of changing from the complex (3) to (4) is the rate-determining step,[6] the rate of the codimerization is given by;

$$r_c = k(\mathrm{St})(\mathrm{S})/\{(k'+k''(\mathrm{St}))(\mathrm{S})+k'''(\mathrm{St})\}$$

where $k=k_1k_3k_5/(k_2+k_3)$, $k'=k_1k_3/(k_2+k_3)+k_6(\mathrm{C})$, $k''=k_5/(\mathrm{E})$, and $k'''=k_1k_5/(k_2+k_3)$, and where (C), (E), (St), (S) represent the liquid-phase concentration of the codimer, ethylene, styrene, and the solvent respectively.

The above equation shows that the reaction order changes from one to zero with an increase in the styrene concentrations. The experimental evidence in the reaction order can, therefore, be interpreted on the basis of Scheme 1.

The fact that solvents containing oxygen atom are effective in the codimerization reaction can be reasonably understood by considering that the oxygen atom tends to have a moderate ability of coordination. The ease of the solvents in both coordination to and dissociation from the complex leads to a promotion of the reactivity of the coordination site. The same argument was previously made by the present authors for the dimerization of ethylene.[9]

The Synthesis of Poly-L-arginine*1

Junzo NOGUCHI and Yukihiko FUJIWARA

Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo

(Received December 25, 1969)

N^{ω}-Tosyl-L-arginine-N^{α}-carboxylic acid anhydride hydrochloride was obtained as a crystal by the reaction of N^{α}-carbobenzyloxy-N^{ω}-tosyl-L-arginine and thionyl chloride. After treatment with silver oxide to remove the hydrochloride, N^{ω}-tosyl-L-arginine-N^{ω}-carboxylic acid anhydride (NCA) was prepared; it was then polymerized to poly-N^{α}-tosyl-L-arginine ($M \fallingdotseq 16200$, $n \fallingdotseq 52$), which was subsequently converted into poly-L-arginine hydrochloride by treating it with hydrogen fluoride and by passing it through a column of the hydrochloride form of the IRA-400 resin.

Poly-L-arginine is an interesting model of the natural basic proteins, such as curpeine or sarmine, containing large amount of arginine.

The preparation of the *N*-carboxylic acid anhydride (NCA) of the L-arginine derivative has been studied in order to synthesize poly-L-arginine,

*1 Presented at the Autumn Meeting of the Chemical Society and the related Societies of Japan, Nagoya, Oct. 14, 1969.

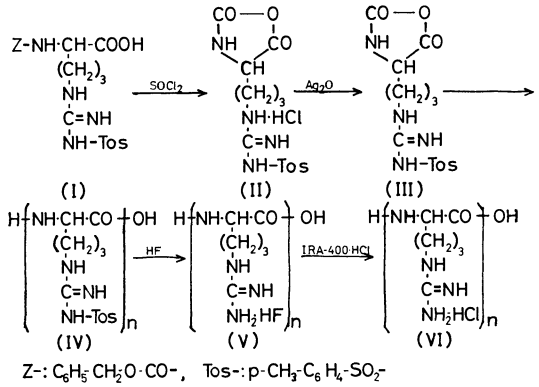
but the results were almost entirely unsuccessful with regard to the chemical specificity of the guanido group, although all of native amino acids except arginine have been converted into their NCA's. However, arginine NCA was recently prepared in the case of the arginine derivative whose N^{δ}-imino group was protected as the carbobenzyloxy group, because when the arginine derivative is treated by the Leuchs method[1] or the Fuchs-Farthing method,[2] the α-carboxyl group tends to form a closed ring with the N^{δ}-imino group of arginine. Poly-L-arginine has been prepared by the following three methods: **a**) poly-ornithine, which had itself been prepared from δ-protected ornithine NCA, was guanidized with 1-guanyl-3,5-dimethyl pyrazole[3] or with methyl isothiourea[4] into polyarginine; **b**) poly-L-nitroarginine, which had been prepared by the *N*-carbothiophenyl method,[5] was reduced in formic acid with stannous chloride into poly-L-arginine,[6] and **c**) $N^{\omega},N^{\omega'}$-dicarbobenzyloxy-L-arginine NCA hydrochloride,[7] which had been prepared from $N^{\alpha},N^{\omega},N^{\omega'}$-tricarbobenzyloxy-L-arginine and thionyl chloride, was polymerized, after treatment with silver oxide in order to remove its hydrochloride, into poly-$N^{\omega},N^{\omega'}$-dicarbobenzyloxy-L-arginine, which was then decarbobenzyloxylated with hydrogen bromide in acetic acid in order to convert it into poly-L-arginine.[7]

However, the quantitative guanidation of all the ornithine residues of poly-ornithine is not easy with the method a), poly-L-arginine is hard to get in a high polymer with the method b), and $N^{\alpha},N^{\omega},N^{\omega'}$-tricarbobenzyloxy-L-arginine can not easily be prepared in a good yield in the method c) and, for the complete decarbobenzyloxylation of poly-$N^{\omega},N^{\omega'}$-dicarbobenzyloxy-L-arginine, it is necessary to employ the drastic step of heating it at 50°C for 90 min in 6N HBr - glacial acetic scid. The chemical properties of the N^{ω}-carbobenzyloxy group are so different from those of an ordinary *N*-carbobenzyloxy group that such a drastic step to removing the protecting group is not generally applicable to the synthesis of an arginine copolymer without a cleavage of the peptide bond.

In this investigation, the synthesis of N^{ω}-tosyl-L-arginine NCA was studied, because the nature of N^{α}-carbobenzyloxy-N^{ω}-tosyl-L-arginine is such that it is hard to form a N^{δ}-closed ring with the α-carboxyl group in peptide syntheses and the tosyl of guanido group can easily be removed by hydrogen fluoride. N^{ω}-Tosyl-L-arginine NCA hydrochloride was obtained for the first time as a crystal without protecting an N^{δ}- or N^{ω}-imino group of L-arginine. After the removal of hydrogen chloride from the NCA hydrochloride with silver oxide, the resulting syrupy NCA was ploymerized into poly-N^{ω}-tosyl-L-arginine which was then converted to poly-L-arginine with hydrogen fluoride.[8]

Results and Discussion

The synthetic route of poly-L-arginine is summarized in Scheme 1.



Scheme 1. The synthetic route of poly-L-arginine hydrochloride.

A syrupy N^{ω}-tosyl-L-arginine NCA (III) was obtained from II by treating the dry acetone solution with silver oxide in order to remove the hydrogen chloride and by evaporating the solvent after the acetone solution had been passed through a column of dry active charcoal. This NCA was immediately dissolved in dimethylacetamide (DMA), dioxane, hexamethyl phosphoramide (HMPA), or dimethyl sulfoxide (DMSO), and polymerized at room temperature in a sealed flask with a mercury manometer. The highest molecular weight was obtained in DMA ($M\fallingdotseq16200$, $n\fallingdotseq52$, $[\alpha]_D^{30}$ +9.9°). The polymerization in dioxane and DMSO gave a lower polymer ($M\fallingdotseq8400$, $n\fallingdotseq27$, $[\alpha]_D^{30}$ +7°). The difference in $[\alpha]_D$ between the two polymers may be due to the difference in molecular weight, for their hydrolysates, when treated with 6N hydrochloric acid at 110°C for 22 hr, gave only L-arginine without any racemization. Poly-N^{ω}-tosyl-L-arginine (IV) was treated with hydrogen

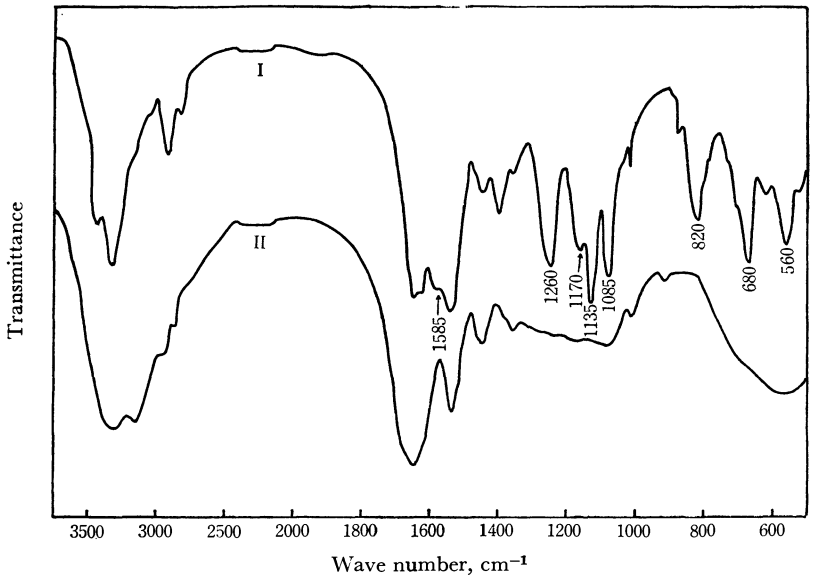

Fig. 1. Infrared absorption spectra of poly-N^{ω}-tosyl-L-arginine (I) and poly-L-arginine hydrochloride (II).

fluoride[8] at 0°C for 1 hr to remove the tosyl groups and then converted into poly-L-arginine hydrochloride by passing it through a column of the HCl type of resin (IRA-400). The infrared spectrum of poly-L-arginine (Fig. 1) shows the absence of the absorptions at 1585, 1265, 1085, 820, 680, 560, 1170, and 1135 cm^{-1} which are due to the benzene and SO_2 groups of the tosyl residue. The hydrolysate of poly-L-arginine gave only L-arginine (R_f 0.16)*2 and did not show any trace of ornithine (R_f 0.12)*2 or citruline (R_f 0.20)*2 on paper chromatography. Therefore, the complete detosylation proceeded by means of the HF method.[8]

Experimental

N^{α}-Carbobenzyloxy-N^{ω}-tosyl-L-arginine (I). N^{α}-Carbobenzyloxy-L-arginine,[9] which had been prepared from L-arginine hydrochloride and carbobenzyloxy chloride, was tosylated with tosyl chloride according to the procedure of Ramachandran and Li.[10]

N^{ω}-Tosyl-L-arginine NCA Hydrochloride (II). Five grams (10.8 mmol) of I were dissolved in 10 m*l* of thionyl chloride at room temperature for 5 hr, and then the excess thionyl chloride was evaporated *in vacuo* at room temperature. The residual syrup was crystallized with dry ether, and the crystal was centrifuged and washed with ether. It was then recrystallized from acetone and ether. Yield, 3.8 g (90%); mp 75°C (dec.); $[\alpha]_D^{23}$ −9.0° (*c* 2.6, acetone). The equivalent molecular weight, as determined by CH_3ONa titration, was 390 calcd 390).

Found: C, 43.4; H, 5.5; N, 13.8; Cl, 8.8%. Calcd for $C_{14}H_{19}O_5N_4SCl$: C, 43.1; H, 4.9; N, 14.3; Cl, 9.1%.

N^{α}-Tosyl-L-arginine NCA (III). Two grams (5.1 mmol) of II were dissolved in 20 m*l* of dry acetone, and then 2 g (8.0 mmol) of silver oxide were added. After the mixture had been stirred at room temperature until the chloride ion in the solution disappeared, it was filtered and the filtrate was passed through a column of dry active charcoal.[11] The colorless solution was evaporated *in vacuo*, and N^{ω}-tosyl-L-arginine NCA was obtained as a syrup. Yield, 1.6 g (89%). The NCA test with barium hydroxide was positive. The fresh syrup was used in the polymerization.

Poly-N^{ω}-tosyl-L-arginine (IV). a) N^{ω}-Tosyl-L-arginine NCA (III), 1.6 g (4.5 mmol), was dissolved in 4.2 m*l* of DMA and polymerized by the addition of triethylenediamine (TEDA) (0.045 mmol) as an initiator at room temperature over a 3-day period. After the mixture had been refluxed for 2 hr on a boiling water bath, it was cooled and poured into water to precipitate the polymer. The precipitate was then centrifuged and washed water. Yield, 0.7 g (50%). $[\alpha]_D^{30}$ +9.9° (*c* 2.0, DMF). The equivalent molecular weight was 16200 ($n \fallingdotseq 52$); it was measured by carboxyl-end titration with 0.02N CH_3ONa in methanol. b) 2 g (5.6 mmol) of IV were dissolved in 8 m*l* of dioxane and then polymerized with TEDA (0.028 mmol). The polymer which was separated out of the solution after it was stood for 16 hr was redissolved with the addition of DMSO (4 m*l*), and then the solution left to stand for a further 3 days. The reaction mixture was treated by the same procedure as that of a). Yield, 1.6 g (94%); $[\alpha]_D^{23}$ +7° (*c* 2.0, DMF). The equivalent molecular weight as determined by 0.02N CH_3ONa titration, was 8400 ($n \fallingdotseq 27$).

*2 Developed with an *n*-butanol-glacial acetic acid-water mixture (4 : 1 : 5).

Found: C, 47.8; H, 6.15; N, 16.8%. Calcd for $(C_{13}H_{18}O_3S \cdot H_2O)_n$: C, 47.8: H, 6.10; N, 17.2%.

Hydrolysis of Poly-N^{ω}-tosyl-L-arginine. IV was hydrolyzed with 6N hydrochloric acid at 110°C for 22 hr; when the hydrolysate was then analyzed by paper chromatography, it showed only one spot of arginine with ninhydrin. The quantity was determined by means of a colorimetric densitometer and compared with that of standard ariginine, it corresponded to the arginine content of the polymer. The optical rotation of hydrolysate was $[\alpha]_D^{19}$ +22.3° (*c* 0.7, 6N HCl); this is in good agreement with that of a standard arginine hydrochloride and shows no racemization.

Poly-L-arginine Hydrochloride (VI). Poly-N^{ω}-tosyl-L-arginine (IV) (1.4 g), containing 1.4 m*l* of anisole was treated with liquid hydrogen fluoride at 0°C for 1 hr by the procedure of Sakakibara *et al.*[8] After evaporating the hydrogen fluoride, the poly-L-arginine hydrofluoride (V) was taken out with ether and alcohol. It was dissolved in 10 m*l* of water and dialyzed against water. The solution was then treated with a HCl form of the IRA-400 resin in order to remove the fluoride ion and then evaporated *in vacuo*. The residue was washed with alcohol and dried. Yield, 0.6 g (62%); $[\alpha]_D^{17}$ −71.8° (*c* 1.9, water).

Found: C, 39.1; H, 7.52; N, 25.9; Cl, 16.7%. Calcd for $(C_6H_{13}ON_4Cl \cdot \frac{1}{2} \cdot C_2H_5OH)_n$: C, 39.3; H, 7.49; N, 26.0; Cl, 16.5%.

Hydrolysis of Poly-L-arginine Hydrochloride. A part of the VI was hydrolyzed with 6N hydrochloric acid at 110°C for 22 hr; when the hydrolysate was then analyzed by paper chromatography, it showed only one spot of arginine. The optical rotation of the hydrolysate was $[\alpha]_D^{22}$ +22.5° (*c* 1.0, 6N HCl); this is in good agreement with standard L-arginine hydrochloride and shows no racemization of the polymer.

The authors are very mcuh indebted to Dr. S. Sakakibara for his kind help and useful advice with the hydrogen fluoride; they wish also to thank Dr. S. Tokura for his kind support. This work was also supported by the Fuji Photofilm Co., Ltd., and by the Institute of Polymer Science.

Syntheses of Organic Phosphates. II. 3-Hydroxy-2-pyridylmethyl, 6-Methyl-2-pyridylmethyl, 3-Pyridyl and 8-Quinolyl Phosphate*1

Yukito MURAKAMI, Junzo SUNAMOTO, Hiromi SADAMORI, Hiroki KONDO and Makoto TAKAGI

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received October 11, 1969)

The phosphorylation of 3-hydroxy-2-pyridylmethanol and 6-methyl-2-pyridylmethanol was carried out with pyrophosphoric acid. 3-Pyridinol and 8-quinolinol were phosphorylated in pyridine by using five- to ten-fold molar amount of phosphoryl chloride at room temperature or below. The chromatographic elution of the reaction mixtures on a column of cation-exchange resin, with water as an eluent, was found to be effective for separation and purification of the products in most cases, while 8-quinolyl phosphate was obtained directly from the concentrated reaction mixture. These phosphates, with the exception of 3-hydroxy-2-pyridylmethyl phosphate, follow acid dissociation processes similar to the case of pyridylmethyl phosphates. The effect of the 3-hydroxy group in 3-hydroxy-2-pyridymethyl phosphate on its acid dissociation processes was discussed. A symmetric pyrophosphate ester was also isolated in the course of phosphorylation of 3-pyridinol.

In an earlier paper[1] from our laboratories, synthesis and purification of 2-, 3- and 4-pyridylmethyl phosphate were reported in connection with the studies of biochemically interesting model compounds, such as vitamin B_6 phosphate. Hydrolysis of these pyridylmethyl phosphates was also investigated in the absence and presence of metal ions.[2-4] As a result, it became desirable to investigate the participation of a neighboring functional group

in the hydrolysis of pyridylmethyl phosphate and the related compounds. The role of a hetero-aromatic nitrogen in such solvolysis reactions also needs to be clarified. In the present work, therefore, 3-hydroxy-2-pyridylmethyl phosphate (**1**), 6-methyl-2-pyridylmethyl phosphate (**2**), 3-pyridyl phosphate (**3**), and 8-quinolyl phosphate (**4**) have been synthesized. In addition, their ionization constants have been determined and discussed in terms of the structural effect.

Syntheses and Purification. The phosphorylation of 3-hydroxy-2-pyridylmethanol and 6-methyl-2-pyridylmethanol, by using pyrophosphoric acid, was carried out according to the previous method for the syntheses of the unsubstituted pyridylmethyl phosphates.[1] Figure 1 shows the eluting behavior

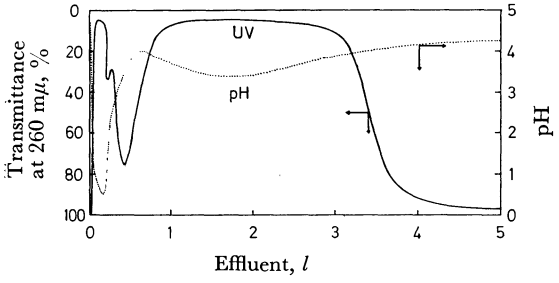

Fig. 1. Chromatographic separation of 3-hydroxy-2-pyridylmethyl phosphate from the phosphorylation mixture.
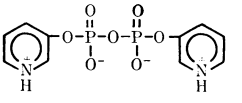
Mixture: 3.0 g of the alcohol underwent reaction with 23 g of pyrophosphoric acid
Column: Dowex 50W-X8 [H^+] (312 meq.), 3×34 cm
Eluent: mineral-free water
Elution rate: 300 ml/hr

of the phosphorylation mixture of 3-hydroxy-2-pyridylmethanol on a chromatographic column of cation-exchange resin, Dowex 50W-X8, with water as an eluent. The front effluent (about 100—150 ml) was strongly acidic (pH=1.0). The ultraviolet measurement of this effluent showed the presence of aromatic species (λ_{max}=294 mμ), and the paper chromatogram indicated the presence of some phosphate compounds. However, no organic phosphates could be isolated from this portion because of their low yield. 3-Hydroxy-2-pyridylmethyl phosphate was obtained in a comparatively good yield from the following fractions, as described in the experimental section.

Since 3-hydroxy-2-pyridylmethanol has two phosphorylation sites, it was necessary to confirm which group, the 2-hydroxymethyl or the 3-hydroxy, was predominantly phosphorylated. Nuclear magnetic resonance spectra directly provide an evidence for the phosphorylation of the former group. The singlet resonance signal of the methylene group in 3-hydroxy-2-pyridylmethanol, the original alcohol, was found to shift downfield and to become the doublet signal through coupling with ^{31}P upon phosphorylation.

6-Methyl-2-pyridylmethanol was phosphorylated nearly quantitatively by a method similar to that used for 3-hydroxy-2-pyridylmethanol. The phosphorylation mixture showed an eluting behavior similar to that case 3-hydroxy-2-pyridylmethanol.

Phosphorylation of 3-pyridinol and 8-quinolinol was carried out by using five- to ten-fold molar amount of phosphoryl chloride at room temperature or below in pyridine. The phosphorochloridate of 3-pyridinol thus produced was hydrolyzed with a sufficient amount of water. After the reaction mixture was neutralized with ammonia, the products were separated chromatographically. Figure 2 shows the eluting behavior of the phosphorylation mixture of 3-pyridinol on a column of cation-exchange resin, Dowex 50W-X8, with water as an eluent. Effluent I was found to contain the corresponding symmetric pyrophosphate ester, which was not isolated because of its low yield. 3-Pyridyl phosphate was obtained from effluent II. When the reaction mixture was treated with just enough amount of water to hydrolyze all the phosphorochloridate in the presence of pyridine, the major product was identified to be the symmetric pyrophosphate ester, P^1,P^2-di(3-pyridyl) pyrophosphate (**5**), and no detectable amount of 3-pyridyl



5

phosphate was found in the reaction mixture as the eluting profile in Fig. 3 indicates. Meanwhile, 8-quinolyl phosphate was obtained exclusively as precipitates from the concentrated phosphorylation mixture even though the phosphorochloridate was hydrolyzed with a just enough amount of water in the presence of pyridine.

Acid Dissociation Constants. 3-Hydroxy-2-pyridylmethyl phosphate was found to be a tetrabasic acid, while the remaining orthophos-

Elution rate: 2 ml/min
Effluent: I, the pyrophosphate ester; III, 3-pyridinol; IV, pyridine

phates were to be tribasic acids. Acid dissociation constants of these phosphates along with those of the related compounds are listed in Table 1.

Since pK_{H_2A} and pK_{HA} values for the tribasic phosphates are comparable in a qualitative sence with the corresponding values for pyridylmethyl

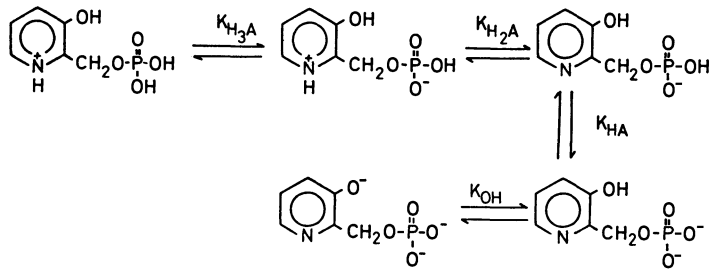

Chart 1. Acid dissociation processes for 3-hydroxy-2-pyridylmethyl phosphate.

Table 1. Acid dissociation constants

25.0±0.1°C, μ=0.10M (KNO_3)

Acid	pK_{H_2A}	pK_{HA}	pK_{OH}[a]
2-Pyridylmethyl phosphate[1]	4.42	6.29	—
3-Pyridylmethyl phosphate[1]	4.86	6.23	—
6-Methyl-2-pyridylmethyl phosphate	4.74	6.64	—
3-Hydroxy-2-pyridylmethyl phosphate	4.54	5.75	9.67
3-Pyridyl phosphate	3.86	5.64	—
8-Quinolyl phosphate	4.17	6.42	—
P^1,P^2-Di (3-pyridyl) pyrophosphate	3.58	4.51	—
3-Pyridinol	—	—	8.54
3-Hydroxy-2-pyridylmethanol	—	—	8.76

a) K_{OH} is the dissociation constant for the hydroxy proton.

phosphates, the present phosphates may undergo dissociation processes similar to those described previously.[1] Thus, K_{H_2A} is attributable to the dissociation constant of a pyridinium proton, while K_{HA} refers to that of the second phosphate proton. The most plausible proton-dissociation processes for 3-hydroxy-2-pyridylmethyl phosphate are shown in Chart 1 in the light of the acid dissociation steps for ordinary dibasic phosphates and hydroxypyridines.

3-Pyridyl phosphate demonstrated the lowest values of both pK_{H_2A} and pK_{HA} among the present six different phosphates listed in Table 1. This may be due to the phenolic character of the ester oxygen which may facilitate the electronic interaction between a pyridine ring and a phosphate group, while such an interaction would be minor in the remaining phosphates.

A comparatively low pK_{HA} value was observed for 3-hydroxy-2-pyridylmethyl phosphate. Through electron-withdrawing effect of the 3-hydroxy group and its participation in intramolecular hydrogen bonding with the phosphate group, the acidic nature of the phosphate proton seems to be greatly increased in this case. The above intramolecular hydrogen bonding is further confirmed by the fact that the dissociation of the 3-hydroxy proton is much suppressed as shown in Table 1.

The acid dissociation constants for pyrophosphoric acid have been evaluated at 20°C and the ionic strength of 0.1 in potassium chloride: pK_{H_3A} 2.22, pK_{H_2A} 6.08, pK_{HA} 8.45.[5] It is clear that the pK-values for P^1,P^2-di(3-pyridyl) pyrophosphate given in Table 1 are much higher than those of the first and the second protons of pyrophosphoric acid (pK_{H_4A} and pK_{H_3A}). Since these pK-values are comparable with those pK_{H_2A} values for other phosphate esters listed in Table 1, both K_{H_2A} and K_{HA} for the pyrophosphate ester may be attributed to the dissociation constants of pyridinium protons.

Experimental

3-Hydroxy-2-pyridylmethanol. To a mixture of sodium hydroxide (1.3 g), water (12.6 m*l*) and 3-pyridinol (3.0 g), 37% aqueous formaldehyde solution (2.5 m*l*) was added. After stirring for 3 hr at about 90°C, the mixture was neutralized with acetic acid, and evaporated to dryness. The yellow solid obtained was extracted with 200 m*l* of hot acetone. Through introduction of hydrogen chloride into the resulting extracts, the white hydrochloride was precipitated; yield 2.1 g (41%) upon recrystallization from ethanol; mp 213—216°C (dec.) (lit,[6] mp 209—211°C).

NMR (0.5M in D_2O, HOD as an internal standard): methylene, 0.31 ppm (singlet), ring protons, 3.22—3.57 ppm (multiplet).

This hydrochloride was converted to the corresponding free base with aqueous potassium hydroxide, and further purified by recrystallization from acetone followed by sublimation under reduced pressure; mp 145.4—146.5°C (lit,[6] mp 137—139°C) (Found: C, 57.62; H, 5.69; N, 11.12%).

3-Hydroxy-2-pyridylmethyl Phosphate. A mixture of 3-hydroxy-2-pyridylmethanol (3.0 g) and pyrophosphoric acid (23 g), which was freshly prepared by the brief heating of 85% orthophosphoric acid (13 g) and of phosphorus pentoxide (10 g), was placed in a 50 m*l* three-necked flask protected from moisture. This reaction mixture, after being heated at 80—85°C for

5 hr with sufficient stirring, was diluted with 16 ml of water and then reheated at 96°C for 30 min to hydrolyze any polyphosphates produced. After being cooled down to room temperature, an equal volume of water was added into the hydrolyzate. The resulting aqueous solution was applied to the top of a column (3×34 cm) of Dowex 50W-X8 [H^+] resin (312 meq.) and eluted with mineral-free water at 300 ml per hour. The ultraviolet absorption of the effluent was checked at 260 mμ with a ultraviolet detector, JEOL Model JLC-2B or Toyo UVICON-540, for the presence of aromatic species and the corresponding pH value was measured with a Hitachi-Horiba Model H-5 pH meter. After the front effluent (about 150 ml, pH=1.0) with absorption at 294 mμ came off, the acidity of the effluent gradually lowered, reaching pH 4.0 at a total effluent of 800 ml, in line with a decrease in the optical density. As the elution proceeded further, the effluent turned slightly acidic (pH=3.5), and the corresponding optical density at 295 mμ increased. After 3000 ml of the subsequent effluent was collected, the pH returned to 4.0 and the ultraviolet measurement did not show the presence of aromatic species. These fractions containing the phosphate ester (about 3000 ml, pH=3.5—4.0) were concentrated under reduced pressure below 30°C; white crystals precipitated; yield 2.53 g (66%) upon recrystallization from water, mp 201—203°C (dec.); neutralization equivalence 104.6 (calcd 102.5); $\lambda_{max}^{H_2O}$ (10^{-4}M) 252 mμ (ε 1270) and 288 mμ (ε 6910).

IR (KBr disc): 1250, 1175 cm^{-1} ($\nu_{P=O}$), and 1080 cm^{-1} ($\nu_{P-O-C(alk.)}$).

NMR (0.05M in D_2O, HOD as an internal standard): methylene, 0.64 ppm (doublet, J_{P-H}=7.40 Hz); ring protons, 3.33—3.62 ppm (multiplet); the accumulation (16 times) was carried out.

Found: C, 34.90; H, 4.02; N, 6.57; P*[2], 14.2%. Calcd for $C_6H_8NO_5P$: C, 35.14; H, 3.93; N, 6.83; P, 15.1%.

6-Methyl-2-pyridylmethanol. This was obtained from 2,6-lutidine *via* 2,6-lutidine *N*-oxide and 6-methyl-2-acetoxymethylpyridine in succession by a modification of the method in literature[7]; bp 86—92°C/0.2 mmHg; mp as the picrate 134.0—135.0°C (lit,[7] mp 129—132°C) (Found: C, 44.67; H, 3.38; N, 15.88%).

6-Methyl-2-pyridylmethyl Phosphate. A mixture of 44 g of phosphorus pentoxide and 56 g of 85% orthophosphoric acid were heated at 90—100°C with stirring. To the resulting viscous pyrophosphate, 5.4 g of 6-methyl-2-pyridylmethanol was added with caution at 67.5°C. Reaction temperature then immediately rose to about 110°C. After the exothermic reaction ceased, the reaction mixture was heated again up to 90—95°C and stirred for 9.5 hr. After being cooled down to room temperature, 100 ml of water was added and then reheated at 80—85°C for 1 hr in order to hydrolyze any polyphosphates produced. The hydrolyzate was subjected to the cation-exchange column chromatography by the use of Dowex 50W-X8 [H^+] resin (50—100 mesh, 425 meq.). Elution was carried out with mineral-free water at about 97 ml per hour. Eluting behavior was quite similar to that of 3-hydroxy-2-pyridylmethyl phosphate. From the later fractions of effluent (about 3840 ml), which were concentrated under reduced pressure at 40—45°C, white needle-like crystals were obtained; yield 7.5 g (92.7%) upon recrystallization from aqueous ethanol; neutralization equivalence 100.64 (calcd 101.57); $\lambda_{max}^{H_2O}$ (10^{-4}M) 269 mμ (ε 8350).

IR (KBr disc): ~3400 cm^{-1} (ν_{O-H}); 1268 cm^{-1} ($\nu_{P=O}$); 1182, 1164, 1102, and 1060 cm^{-1} ($\nu_{P-O-C(alk.)}$).

NMR (0.5M in D_2O, HOD as an internal standard): methyl, −1.87 ppm (singlet); methylene 0.44 ppm (doublet, J_{P-H}=8.29 Hz); 5H, 2.87 ppm (doublet); 3H, 2.93 ppm (doublet); 4H, 3.49 ppm (triplet, $J_{3-4} \simeq J_{4-5}$=7.80 Hz and J_{3-5}<1.0 Hz).

Found: C, 40.94; H, 5.04; N, 6.64; P, 14.6%. Calcd for $C_7H_{10}NO_4P$: C, 41.39; H, 4.96; N, 6.96; P, 15.3%.

3-Pyridyl Phosphate. A 2.00 g sample of 3-pyridinol dissolved in 25 ml of dry pyridine was added dropwise for 40 min into a mixture of 16.4 g of phosphoryl chloride and 25 ml of dry pyridine protected from moisture. The reaction flask was cooled with ice. The reaction mixture was then stirred for 3 hr at room temperature (10—15°C), followed by cooling with a freezing mixture (ice-sodium chloride). After the precipitated pyridine hydrochloride was removed immediately by filtration, pyridine and unreacted phosphoryl chloride were taken out by distillation *in vacuo* at 50°C from the filtrate. The residue was dissolved in 25 ml of acetonitrile, and then added in 80—90 ml of cold water in about 10 min with sufficient stirring. This aqueous mixture was neutralized with concd. ammonia, divided into two portions, each of which was concentrated to 10—15 ml *in vacuo* at 40°C and below. Each portion was then applied to the top of a column (2.8×48.5 cm) of Dowex 50W-X8 [H^+] resin (50—100 mesh, 430 meq.) and eluted with water at 2 ml per min until the front effluent (Fig. 2, I) came through; elution rate was doubled after then. The second part of eluted fractions (Fig. 2, II) was concentrated to about 10 ml *in vacuo* at 40°C and below; white needle-like crystals were precipitated by adding acetone; total yield 1.81 g (49%); mp 145.8—146.8°C (part. dec.); R_f 0.15—0.27 (Toyo filter paper No. 51A; developer, isopropanol : concd. ammonia : water=7 : 1 : 2 by volume); neutralization equivalence 87.4 (calcd 87.5); $\lambda_{max}^{H_2O}$ (2×10^{-4}M at pH 13) 268 mμ (ε 3340).

Found: C, 34.01; H, 3.62; N, 8.12; P, 17.5%. Calcd for $C_5H_6NO_4P$: C, 34.29; H, 3.46; N, 8.00; P, 17.7%.

***P*[1],*P*[2]-Di(3-pyridyl) Pyrophosphate.** The phosphorylation of 3-pyridinol (1.4 g) with phosphoryl chloride (11.4 g) was carried out in 80 ml of dry pyridine in a manner similar to that for 3-pyridyl phosphate. The unreacted phosphoryl chloride and pyridine were distilled off *in vacuo* from the reaction mixture without removing pyridine hydrochloride produced in the course of reaction. The mixture was stirred for 30 min at room temperature after addition of 40 ml of dry pyridine and 1 ml of water in succession, and was allowed to stand overnight. The solution was then concentrated to about 20 ml *in vacuo*, and charged to the top of a column (2.8×25 cm) of Dowex 50W-X8 [H^+] resin (50—100 mesh, 240 meq.). The elution was conducted with water at the flow rate of 2 ml per min, and with 1N hydrochloric acid subsequently as shown in Fig. 3.

*[2] A sample was decomposed by heating with concentrated nitric acid and 60% perchloric acid. The product was then analyzed for phosphorus by colorimetric method (R. J. L. Allen, *Biochem. J.*, **34**, 858 (1940)).

7) G. Kobayashi, S. Furukawa and Y. Kawada, *J. Pharm. Soc. Japan.*, **74**, 790 (1954).

The fractions of pH above 2 in the front effluent (Fig. 3, I) were collected, and concentrated *in vacuo* at 40°C and below; white precipitate (985 mg) was obtained upon addition of acetone. Repeated precipitation with water-acetone gave 100 mg of pure phosphate; mp 180—190°C (part. dec.); R_f 0.62; neutralization equivalence 165.3 (calcd 166.1)

Found: C, 35.74; H, 3.30; N, 8.84; P, 18.2%. Calcd for $C_{10}H_{10}N_2O_7P_2$: C, 36.16; H, 3.03; N, 8.43; P, 18.7%.

8-Quinolyl Phosphate. A 7.25 g sample of 8-quinolinol dissolved in 70 m*l* of dry pyridine was added dropwise in 2 hr into a mixture of 38.2 g of phosphoryl chloride and 70 m*l* of dry pyridine, while the reaction vessel was cooled with ice. Stirring was continued for another 5 hr. Pyridine hydrochloride formed was then recovered by filtration, and the filtrate was distilled *in vacuo* at 50°C to remove pyridine and the unreacted phosphoryl chloride. Into the residue, 100 m*l* of dry pyridine in one portion and subsequently 2.5 m*l* of water was added dropwise with shaking. Shaking was continued for another 30 min, and the reaction mixture was allowed to stand overnight at room temperature. The resulting yellowish brown mixture was concentrated *in vacuo* to 20—30 m*l*; filtered off to recover white precipitate (4.0 g). Repeated recrystallization from water-acetone (1 : 1) gave 1.95 g (17.5%) of needle-like crystals; mp 208—223°C (part. dec.); R_f 0.2—0.3 (developer, isopropanol : concd. ammonia : water=7 : 1 : 2), ~0.4 (developer, pyridine : concd. ammonia : water=6 : 3 : 1); neutralization equivalence 111.3 (calcd 112.6).

Found: C, 47.79; H, 3.66; N, 5.87; P, 13.0%. Calcd for $C_9H_8NO_4P$: C, 48.01; H, 3.58; N, 6.22; P, 13.8%.

The filtrate was applied to the top of column (3.0× 42.5 cm) of Dowex 50W-X8 [H^+] resin (50—100 mesh, 430 meq.) and eluted with water as described for 3-pyridyl phosphate; the eluting behavior was quite similar. Isolation of the pyrophosphate ester in its pure form from the front effluent was unsuccessful.

Acid Dissociation Constants. The acid dissociation constants of the phosphates prepared in this work were determined potentiometrically, with the use of a Hitachi-Horiba Model P pH meter with extension glass and calomel electrodes, at 25.0±0.1°C and the ionic strength of 0.10M in potassium nitrate.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2523—2526 (1970)

Ring-opening Reactions of Cyclic Ethers. VIII.*1 Acid-catalyzed Ring-opening Reactions of Isobutylene Oxide in Alcohols

Shizen SEKIGUCHI, Kohji MATSUI and Yoshihiro YASURAOKA

Department of Synthetic Chemistry, Faculty of Engineering, Gunma University, Tenjin-cho, Kiryu, Gunma

(Received January 20, 1970)

The rates of the ring-opening reaction of isobutylene oxide have been measured in methyl, ethyl, *n*-propyl and isopropyl alcohols in the range from 10 to 40°C under conditions where the molar ratio of an alcohol to the epoxide was kept at 10 and the range of the concentration of boron trifluoride etherate was *ca.* 1.0×10^{-3} to *ca.* 4.0×10^{-3} mol/*l*. The rate equation is expressed as follows: $-d[\text{epoxide}]/dt=k_2[C_0][\text{epoxide}]$, where $[C_0]$ is the initial concentration of the catalyst and [epoxide] is the instantaneous concentration of the epoxide at time *t*. The rate constants (k_2) decreased in the order, $CH_3OH>C_2H_5OH>n\text{-}C_3H_7OH>i\text{-}C_3H_7OH$. The entropies of activation decreased in the same order, while the energies of activation were not appreciably changed. A plot of $\log k_2$ against $1/D$ (D, the dielectric constant of the mixture of each alcohol and the epoxide) was found to be linear, its slope being -61.2. The results support the fact that the reaction is bimolecular.

Although the acid-catalyzed ring-opening reactions of epoxides in various solvents, such as water, alcohol, *etc.*, have recently received intensive attention,[1,2] there have still been controversies on their mechanisms. Long *et al.* reportrd that the acid-catalyzed hydrolyses of epichlorohydrin, propylene and isobutylene oxides were unimolecular (A-1).[3] On the other hand, that of epichlorohydrin was shown by le Noble and Muffy.[4] to proceed by

a bimolecular process(A-2)and Koskikallio *et al.* gave the same conclusion for those of propylene oxide and isobutylene oxide.[5]

An unsymmetrical epoxide reacts with excess alcohol to give the following products:

$$\begin{matrix}R\\R\end{matrix}\!\!>\!C\!-\!CH_2 + R'OH \rightarrow \underset{\underset{OH\ OR'}{|\quad|}}{\overset{R}{\underset{R}{>}}C\!-\!CH_2} + \underset{\underset{OR'\ OH}{|\quad|}}{\overset{R}{\underset{R}{>}}C\!-\!CH_2}$$

(I) (II)

(1)

In a previous paper*1 we determined the total amounts of I and II and the ratios (II/I) for the reaction of propylene oxide or isobutylene oxide with alcohols using boron trifluoride etherate as a catalyst. From the results obtained, we inferred that in the case of isobutylene oxide an A-1 reaction might perhaps take place. In the present investigation, kinetic measurements were carried out in excess alcohols using the same catalyst in order to obtain a closer insight into the reaction mechanism.

Results and Discussion

Reaction Products. In a previous investigation*1 the acid-catalyzed ring-opening reaction of isobutylene oxide was carried out in methyl, ethyl and isopropyl alcohols under conditions where the molar ratio of an alcohol to isobutylene oxide was kept at 10 and the concentration of boron trifluoride etherate was 1.2×10^{-3} mol/*l*. The values of II/I after three hours' reaction were found to be as follows:

Alcohol	Reaction temp. (°C)	II/I
CH_3OH	20	54.5
C_2H_5OH	20	42.4
	30	76.1
i-C_3H_7OH	20	II only
	30	II only

The figures indicate that II is the main product in the reactions.

Rate Constants. The rates of the reactions were followed by measuring a decrease in the concentration of isobutylene oxide under conditions where the molar ratio of an alcohol to the epoxide was kept at 10 and the range of the concentration of boron trifluoride etherate was *ca.* 1.0×10^{-3} to *ca.* 4.0×10^{-3} mol/*l*.

The data of a decrease in the concentration of the epoxide were found to obey the standard first-order kinetic equation:

$$k_1 = \frac{1}{t}\log\frac{a}{a-x} \qquad (2)$$

where a is the initial concentration and x is the instantaneous concentration at time t of the epoxide, respectively. When k_1 was plotted against the initial concentration of the catalyst for the reaction with ethyl alcohol, a straight line was obtained as shown in Fig. 1. Similar results were obtained for other alcohols.

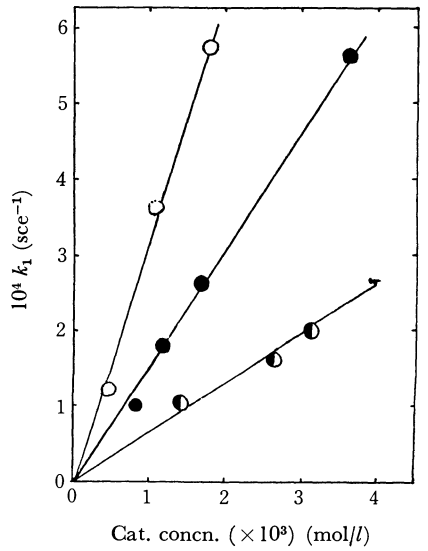

Fig. 1. Relation between rate constants and catalyst concentrations (EtOH).
○ 40°C, ● 30°C, ◐ 20°C

From the results the following equation was obtained.

$$k_1 = k_2[C_0] \qquad (3)$$

where $[C_0]$ is the initial concentration of the catalyst.

Therefore, the rate equation can be written as

$$\frac{-d[\text{epoxide}]}{dt} = k_2[C_0]\,[\text{epoxide}] \qquad (4)$$

The results of the rate measurements are tabulated in Table 1 together with the activation parameters.

It is evident from the results in Table 1 that the variations in the rates of the ring-opening reaction of isobutylene oxide are largely due to changes in the entropy of activation ($\Delta S^{\neq}$).

In their discussion of the acid-catalyzed hydration of olefins, Taft *et al.*[6,7] suggested that an A-1 reaction should be characterized by relatively more positive entropies of activation than an A-2 reaction.

Schaleger and Long[8] reported that the entropies of activation should be used as a criterion of mechanism for acid-catalyzed reactions in aqueous solution.

Whalley[9] further deduced that (i) if $\Delta S^{\neq}$ was less than zero then the reaction was probably A-2 and (ii) if $\Delta S^{\neq}$ was greater than zero the mechanism could be either A-1 or A-2. Stimson *et al.*[10,12] showed that the hydrolyses of *t*-butyl benzoate and *t*-butyl formate in acidified 60% acetone-water gave the $\Delta S^{\neq}$ values of +9.5 and −23.7 e.u., respectively, indicating that the former hydrolysis proceeds by an A-2 mechanism and the latter by an A-2 mechanism and that the hydrolysis of *t*-butyl 2,4,6-trimethylbenzoate in acidified 90% ethanol - water gave an $\Delta S^{\neq}$ of +8.1 by an A-1 mechanism.

Further examples that show the relation between $\Delta S^{\neq}$ and mechanism are listed in Table 2. The data in Table 2 show that the $\Delta S^{\neq}$ values fall into two groups, corresponding to the two types of mechanism. The $\Delta S^{\neq}$ values in Table 1 are closer to the value for the A-2 reactions rather than for the A-1 reactions. Therefore, we conclude that A-2 mechanism holds for the acid-catalyzed ring-opening reaction of isobutylene oxide.

Relationship between Rate Constants and Dielectric Constants of Media. The relationship between reaction rates and dielectric constants of media (D) have so far been studied by many investigators. Hiromi[12] further developed the theories of Kirkwood[13] and Laidler *et al.*[14] and concluded that the slope in a plot of logarithms of k_2 against reciprocals of dielectric constants of media was less than about −150 for A-1 reactions and greater than about −100 for A-2 ones. Hiromi's theory was applied by Parker *et al.*[15] to elucidate the mechanism of the reaction of benzylamine with 1,2-epoxyethylbenzene.

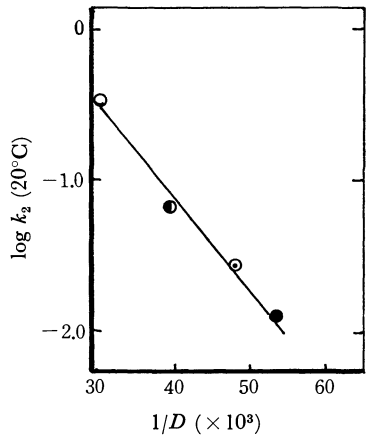

Fig. 2. Relation between rate constants and dielectric constants.
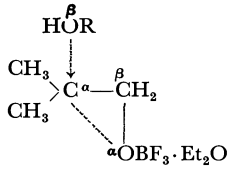
○ Methyl alcohol, ◐ Ethyl alcohol
⊙ *n*-Propyl alcohol ● Isopropyl alcohol

As shown in Fig. 2, the slope is −61.2, indicating that the reaction under investigation proceeds by a bimolecular process.

Our result is in agreement with the conclusion of Koskikallio *et al.*[5]

As shown in Table 1, the $\Delta S^{\neq}$ values for this ring-opening reaction are a little larger than those for the usual A-2 reactions and the rates increase in the increasing order of the polarity of alcohols.

As Parker *et al.*[1] proposed, we assume that the transition state for this ring-opening reaction is as follows:



where the extent to which bond breaking (C^{α}–O^{α}) has progressed is larger than the extent to which bond forming (C^{α}–O^{β}) has progressed. As the crowding in such a transition state should be less than the one in the usual bimolecular reaction, the lower $\Delta S^{\neq}$ values would be expected.

We conclude that this ring-opening reaction may be a borderline case between A-1 and A-2 reactions, but essentially is an A-2 reaction.

Experimental

Materials. *Alcohols.* Commercial reagents were purified by the usual procedures.

Boron Trifluoride Etherate. Commercial reagent of boron trifluoride etherate was distilled under a nitrogen atmosphere before use, bp 124.0—125.0°C.

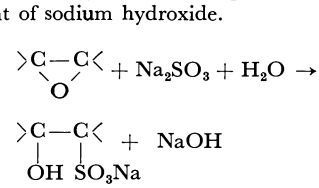
Isobutylene Oxide. Isobutylene chlorohydrin was prepared from isobutylene and hypochlorous acid according to the method of Michael *et al.*,[16] bp 63.0—65.0°C/74 mmHg (lit, 128—129°C[16]).

Found: C, 44.18; H, 8.20%. Calcd for C_6H_9OCl: C, 44.27; H, 8.31%.

The yield was 40% (based upon isobutylene).

Isobutylene oxide was prepared according to the method of Ishida,[17] bp 49.6—60.2°C (lit, bp 50°C[17]). The yield was 83% (based on isobutylene chlorohydrin). n_D^{20} 1.3732 (lit, 1.3730[17]).

Kinetic Measurements. The reaction was followed by the determination of isobutylene oxide according to the method of Swan.[18] About 1.0 g of a sample was pipetted out at different times from the reaction mixture and added to 30 m*l* of a saturated aqueous sodium sulfite solution. Sodium sulfite reacted smoothly and quantitatively with the epoxide, liberating an equivalent of sodium hydroxide.



The epoxide was determined by the titration of liberated sodium hydroxide with standard hydrochloric acid. A simple kinetic data for a representative run is shown in Table 3.

Table 3. Simple kinetic data for the ring-opening reaction of isobutylene oxide in ethyl alcohol[a]

Time min	Sample pipetted g	Titer[b] HCl cc	Epoxide %	$10^2 k_1$ min^{-1}
0	—	—	13.52	—
14.63	0.9643	6.08	8.23	3.43
20.84	1.0949	5.67	7.09	3.31
26.70	1.1812	5.30	6.40	3.11
32.39	1.0100	3.45	4.47	3.40
38.58	1.0543	3.00	3.72	3.33
44.42	1.3086	3.13	3.14	3.27
50.38	1.2392	2.68	2.83	3.08
			Average:	3.37

a) Concentration of $BF_3 \cdot Et_2O$ was 3.55×10^{-3} mol/*l*.
b) Concentration of HCl was 0.1792N.

Measurement of Dielectric Constants. Dielectric constants of the mixtures of isobutylene oxide and alcohols were measured by the phase difference compensation method with a Shibayama SS-207 type apparatus (Shibayama Scientific Co.).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2527—2530 (1970)

Reaction of P-N Compounds with Alkylating Reagents such as Alkyl Benzenesulfonates and Dialkyl Sulfates[1]

Jugo KOKETSU*1 and Yoshio ISHII

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Nagoya

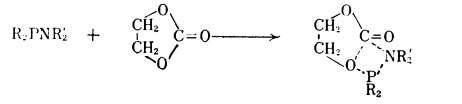
(Received January 24, 1970)

The reaction of *N,N*-dialkyl-diphenylphosphinous amides (I) with alkyl benzenesulfonates (III) or dialkyl sulfates (IV) took place exothermally, giving phosphonium salts (V). When phosphonium salts (V) were heated at 100°C for 5—10 hr, asymmetric phosphine oxide (VI) and *N,N*-dialkyl-benzenesulfonamides (VII) or polymeric materials were obtained. In the case of diphenyl dialkylphosphoramidites (II), no quaternization was observed at room temperature. However, diphenyl alkylphosphonates (VIII) and *N,N*-dialkylbenzenesulfonamides (VII) or the same polymeric materials were obtained through intermediate phosphonium salts when the mixture was heated.

The reaction of P–N compounds with phenyl cyanate[2] or cyclic carbonate esters[3] have been studied. In the reaction, the P–N compound behaved as an ambident reagent. When it was treated with an onium ion, the reaction took place at the phosphorus center, as exemplified by the reaction with phenyl cyanate:

$$R_2PNR_2' + PhOCN \rightarrow [R_2P^+(NR_2)(OPh)][CN^-] \rightarrow R_2POPh + R'_2NCN \quad (1)$$

In contrast, when the reaction partners were ester-carbonyl compounds, the P–N compound reacted as the N base and the phosphorus atom would attack ester oxygen or carbonyl oxygen synchronously:



$$\longrightarrow R_2POCH_2CH_2OC(O)NR'_2 \quad (2)$$

In reaction (2), predominancy of the nucleophilic attack of the nitrogen atom to the carbonyl carbon was confirmed by the kinetic study of the reaction of P–N compounds with acetic anhydride.[4]

The reaction between *N,N*-dialkyl-diphenylphosphinous amide (I) or diphenyl dialkylphosphoramidites (II) and alkyl benzenesulfonates (III) or dialkyl sulfates (IV), which would give phosphonium salts through a reaction similar to (1) are reported in this publication.

Results

A: Reaction of *N,N*-Dimethyl-diphenylphosphinous Amide (Ia) with Alkyl Benzenesulfonates (III) or Dialkyl Sulfates (IV). When Ia was added to equimoler amounts of III or IV at room temperature, an exothermic reaction took place with the formation of stable phosphonium salts (V), as shown in the following equations.

$$Ph_2PNMe_2 + PhSO_2OR''$$

Ia; IIIa: R″=Me, IIIb: R″=Et

$$\longrightarrow [Ph_2P^+(R'')NMe_2][PhSO_2O^-] \quad (3)$$

Va: R″=Me, Vb: R″=Et

$$Ph_2PNMe_2 + SO_2(OR'')_2$$

Ia; IVa: R″=Me, IVb: R″=Et

$$\longrightarrow [Ph_2P^+(R'')NMe_2][(R''O)SO_2O^-] \quad (4)$$

Vc: R″=Me, Vd: R″=Et

These phosphonium salts (Va—Vd) are insoluble to benzene, petroleum ether, dioxane, or carbon tetrachloride, but soluble to chloroform, acetone, or water. IR (KBr disk) and NMR (in $CDCl_3$) spectral data of Vb and Vd are shown in the Table 1.

When the phosphonium salts were heated at 100°C for 5 hr in a sealed tube under an atmosphere of nitrogen, the corresponding asymmetric phosphine oxides (VI) were obtained, along with

Table 1. IR and NMR spectra of phosphonium salts; Vb and Vd

Compounds	IR spectra ν (cm^{-1})	NMR spectra τ (TMS)
Vb	3060(w), 2980(w), 2940(w), 2910(w), 1585(w), 1480(m), 1438(m), 1352(s), 1220—1180(vs, br), 1118(s), 1165(m), 1033(m), 1019(m), 997(m), 915(w), 755(s), 730(s), 698(s), 611(s), 586(w), 562(s).	8.55—9.10(m); $PCH_2\mathbf{CH_3}$ 6.60—7.45(m); $\mathbf{PCH_2}CH_3$ 7.22(d); J=11 Hz; $PN\mathbf{Me_2}$ 2.30—2.80(m); $P\mathbf{Ph_2}$
Vd	3055(w), 2980(w), 2945(w), 2910(w), 1585(w), 1484(m), 1440(s), 1385(m), 1250—1190(vs, br), 1119(s), 1060(m), 1023(s), 996(m), 915(s), 759(s), 732(s), 698(s), 620(s), 578(s), 564(m).	8.40—9.00(m); $PCH_2\mathbf{CH_3}$ and $\mathbf{CH_3}CH_2OSO_2O$ 6.40—7.30(m); $\mathbf{PCH_2}CH_3$ 5.90(q); J=7Hz; $-\mathbf{CH_2}CH_3$ 2.30—2.80(m); $P\mathbf{Ph_2}$

N,N-dimethylbenzenesulfonamide (VIIa) in the case of two phosphonium salts Va and Vb (Eq. (5)). However, pyrolysis (100°C for 5 hr) products of Vc and Vd were phosphine oxides (VIa and VIb) and polymeric materials which showed a broad ν_{SO_2} band at 1220—1180 cm^{-1}.

$[Ph_2P^+(R'')NMe_2][PhSO_2O^-]$

Va: R″=Me
Vb: R″=Et

$\longrightarrow Ph_2P(O)R'' + PhSO_2NMe_2$ (5)

VIa: R″=Me VIIa
VIb: R″=Et

$[Ph_2P^+(R'')NMe_2][(R''O)SO_2O^-]$

Vc: R″=Me
Vd: R″=Et

$\longrightarrow Ph_2P(O)R''$ + Polymeric materials (6)

VIa: R″=Me
VIb: R″=Et

N,N-dimethylbenzenesulfonamide (VIIa) was identified by comparison of its IR and NMR spectra with those of an authentic sample.

B: Reaction of *N,N*-Diethyl-(Ib) and *N,N*-Di-*n*-propyl-diphenylphosphinous Amide (Ic) with Alkyl Benzenesulfonates (III) and Dialkyl Sulfates (IV). In the same manner as Ia, Ib and Ic reacted with III or IV, affording stable phosphonium salts. The phosphonium salts were subsequently heated to afford the corresponding phosphine oxide (VIa) and *N,N*-dialkylbenzenesulfonamides (VIIb and VIIc) or polymeric materials:

$Ph_2PNR'_2 + PhSO_2OR''$

Ib: R′=Et IIIa: R″=Me
Ic: R′=Pr^n

$\longrightarrow Ph_2P(O)R'' + PhSO_2NR_2'$ (7)

VIa: R″=Me VIIb: R′=Et
VIIc: R′=Pr^n

$Ph_2PNR'_2 + SO_2(OR'')_2 \rightarrow Ph_2P(O)R''$

Ib: R′=Et IVa: R″=Me VIa: R″=Me
+ Polymeric material (8)

C: Reaction of Diphenyl Dialkylphosphoramidites (II) with Alkyl Benzenesulfonates (III) or Dialkyl Sulfates (IV). Diphenyl dialkylphosphoramidite (II) did not react with III or IV at room temperature. However, when a mixture of equimolar amounts of II and III or IV was heated at 100°C under an atmosphere of nitrogen in a sealed tube for about 10 hr, a similar reaction took place with the formation of final deoxygenation products and counter products (probably through unstable phosphonium salts, Eqs. (9) and (10)). The results were supported by the appearance of the IR band characteristic of benzenesulfonamide at 1360 cm^{-1} ($\nu_{SO_2asym.}$) and 1160 cm^{-1} (ν_{SO_2sym}), and also by a sharp singlet at τ (in CCl_4) 7.40 for NMe_2 protons and complex ethyl protons at τ (in CCl_4) 7.9—9.2 for P(O)Et in the NMR spectra. After distillation and subsequent column chromatographic treatments of the reaction mixtures, diphenyl alkylphosphonates (VIII) and *N,N*-dialkylbenzenesulfonamides (VII) or polymeric materials were obtained:

$(PhO)_2PNR'_2 + PhSO_2OR''$

IIa: R′=Me IIIb: R″=Et
IIb: R′=Et IIIa: R″=Me

$\longrightarrow (PhO)_2P(O)R'' + PhSO_2NR'_2$ (9)

VIIIb: R″=Et VIIa: R′=Me
VIIIa: R″=Me VIIb: R′=Et

$(PhO)_2PNR_2' + SO_2(OR'')_2$

IIa: R′=Me IVb: R″=Et
IIb: R′=Et IVa: R″=Me

$\rightarrow (PhO)_2P(O)R''$ + Polymeric materials (10)

VIIIb: R″=Et
VIIIa: R″=Me

The structures of VIIIa and VIIIb were determined by IR and NMR spectra and elemental analyses, and those of VIIa and VIIb by comparison of their IR and NMR spectra with those of authentic samples.

Discussion

In the reaction with electrophilic reagents, the P–N compound exhibited an ambident property. When the reaction partners were typical soft acids such as carbonium ions and PhO^+, the P–N compound behaved as the P base. In this case, *N,N*-dialkyl-diphenylphosphinous amide (I) reacted more readily than diphenyl dialkylphosphoramidite (II). This can be ascribed to the fact that the phosphorus atom of I has higher electron density than II, because II has more electronegative oxygen atoms as substutients on the phosphorus atom. In addition, the phenyl group attached to the phosphorus atom donates an electron to the phosphorus center because of (p–d)π interaction between electrons of phenyl groups and an empty 3d orbital of the phosphorus atom.[5] On the other hand, when reaction partners were hard acids, *i.e.* ester-carbonyl compounds, the reverse reactivity order II$>$I was observed.[6] In this case the nucleophilic site of P–N compounds is considered as the nitrogen atom, and the phosphorus atom would attack ester or carbonyl oxygen synchronously as seen in Eq. (2). The different reactivity order between I and II (II$>$I) stems from the different affinity of the phosphorus atom to the oxygen atom. That is, II has more electronegative oxygen atom bonded to the phosphorus atom directly, hence, electron density on the phosphorus atom of II is reduced considerably. This electron attractive effect of oxygen gives large octet expansion ability,[7] *i.e.* an oxygen affinity to the phosphorus atom.

The structures of the phosphonium salts (V) resulting from the reaction between I and III or IV were confirmed by IR and NMR spectra (see Table 1) In the IR spectra, there were absorption bands characteristic of sulfonate ion at 1220—1180 cm^{-1} ($\nu_{SO_2asym.}$), 1120 cm^{-1} ($\nu_{SO_2sym.}$), and 610 cm^{-1} ($\nu_{SO_2-O^-}$). In the NMR spectra, NMe_2 protons showed doublet near τ (in $CDCl_3$) 7.1 (d, J=11 Hz) and PCH_2CH_3 protons showed complex multiplet signals at τ (in $CDCl_3$) 6.6—7.4 (PCH_2-CH_3) and 8.4—9.1 (PCH_2CH_3) as the result of large J_{PCCH} and J_{HCCH}[8]. The results indicate that quaternization occurred at the phosphorus center, being consistent with the results of Trippett[9] and Burg.[10] They suggested that the phosphorus atom has larger nucleophilicity than the nitrogen atom owing to (p–d)π conjugation between the phosphorus atom and the nitrogen atom. II could not be quaternized at room temperature. This phenomenon was already observed in the reaction of II with phenyl cyanate.[2] When the phosphonium salts (V) or the mixture of II with III or IV, were heated at 100°C, not only alkylation reaction of the phosphorus atom but also deoxygenation reaction from the sulfonate group took place, giving phosphine oxide (VI) or phosphonate (VIII). This reaction was assumed to proceed *via* a four centered mechanism as follows.

$$R_2PNR_2' + R'''SO_2(OR'') \rightarrow [R_2P^+(R'')NR_2'][R'''SO_2O^-] \xrightarrow{\text{heat}} \text{(cyclic intermediate)} \rightarrow R_2P(O)R'' + R'''SO_2NR_2' \quad (11)$$

The alkylation reactions of phosphorus by alkylbenzenesulfonate and dialkyl sulfate can be applied generally to P–N compounds as well as the alkylation reaction of P–N compounds by the Grignard reagent.[10]

Experimental

General Remarks. IR and NMR spectra were measured on a Nippon Bunko IR 403 G Spectrometer and a Japan Electron Minimer Spectrometer. By using benzene as solvent, thin layer chromatography (TLC) was carried out on 250μ thick WAKO Gel-5G (silica gel) layer. Column chromatography was performed in a column 50 cm long (ratio of column to diameter= 20 : 1). Into the column filled with 40 g of 100 mesh silica gel (Mallinckrodt Chemical Works) was put 1—2 g of the sample by the wet method (solvent benzene) which was then eluted by benzene.

Reagents. *N,N*-Dialkyl-diphenylphosphinous amides (I) and diphenyl dialkylphosphoramidites (II) were prepared by the same method as described previously.[2] Alkyl benzenesulfonates (III) and dialkyl sulfates (IV) were purified by distillation before use.

N,N-Dialkylbenzenesulfonamides (VII) were prepared from benzenesulfonyl chloride and the corresponding amine.

$PhSO_2NMe_2$(VIIa): bp 103—110°C/0.1 mmHg; mp 46—47°C; TLC, R_f=0.30; IR (KBr disk), 1324 (ν_{SO_2asym}), and 1158 cm^{-1} (ν_{SO_2sm}).

$PhSO_2NEt_2$(VIIb): bp 120—121°C/1.0 mmHg; n_D^{23} 1.5361; TLC, R_f=0.23; IR (KBr disk), 1332 (ν_{SO_2asym}), and 1158 cm^{-1} (ν_{SO_2sym}).

$PhSO_2NPr_2^n$(VIIc): bp 154—156°C/2.5 mmHg; n_D^{23} 1.5181; TLC, R_f=0.28; IR (KBr disk), 1338 (ν_{SO_2asym}), and 1170 cm^{-1} (ν_{SO_2sym}).

Reaction of *N,N*-Dimethyl-diphenylphosphinous Amide (Ia) with Methyl Benzenesulfonate (IIIa). An equimolar mixture of Ia and IIIa reacted exothermally, and the product became turbid and separated into two layers. Further stirring of the product for 5 hr gave a homogeneous and clear solution. This product was heated at 100°C for 5 hr in a sealed tube under a nitrogen atmosphere. When the reaction mixture was distilled, a distillate with boiling point range 104—140°C/mmHg was obtained *viz.*, two spots on TLC at R_f=0.0 and R_f=0.3. From the mixture, 1.17 g (82% yield) of diphenylmethylphosphine oxide (VIa) was separated as crystals from cyclohexane solution, and the filtrate gave 0.81 g (78% yield) of *N,N*-dimethylbenzenesulfonamide (VIIa).

VIa: bp 132—134°C/0.04 mmHg; mp 111.5—112.5°C (lit, 112.5—113°C,[11] 111°C[12]), IR (KBr disk) 1170 cm^{-1} ($\nu_{P=O}$); NMR (in $CDCl_3$) τ 7.79 (d, 3H, J=11Hz, P-CH_3), 2.20 and 1.86 (m, 10H, phenyl). Found: C, 71.99; H, 6.06; P, 14.35%. Calcd for $C_{13}H_{13}PO$: C, 72.22; H, 6.06; P, 14.33%.

VIIa was identified by a comparison of IR and NMR spectra with those of an authentic sample.

Reaction of *N,N*-Diethyl-diphenylphosphinous Amide (Ib) with Methyl Benzenesulfonate (IIIa). When the product from equimolar reaction (6.30 mmol) of Ib and IIIa was heated at 100°C for 5 hr, IVa and VIIb were obtained in 87% and 92% yield, respectively. The structure of VIIb was confirmed by comparison with the corresponding product by a standard procedure.

Reaction of *N,N*-Dimethyl-diphenylphosphinous Amide (Ia) with Ethyl Benzenesulfonate (IIIb). A mixture of 6.19 mmol of Ia and 6.25 mmol of IIIb reacted at room temperature to give the phosphonium salt (Vb) (see Table 1). The subsequent heating of Vb at 100°C for 6 hr in a sealed tube afforded 1.23 g (90% yield) of diphenylethylphosphine oxide (VIb) and 0.82 g (85% yield) of VIIa.

VIb: bp 145—147°C/0.2 mmHg; mp 120—122°C (lit, 124°C,[13] 121°C[12]); IR (KBr disk) 1178 cm^{-1} ($\nu_{P=O}$); NMR (in $CDCl_3$) τ 7.20—7.90 (m, 2H, P**C**H_2-CH_3), 8.45—9.10 (m, 3H, PCH_2**C**H_3), 2.18 and 1.86 (m, 10H, phenyl).

Reaction of *N,N*-Di-*n*-propyl-diphenylphosphinous Amide (Ic) with Methyl Benzenesulfonate (IIIa). From equimolar reaction of Ic and IIIa, 88% yield of VIa and 78% yield of VIIc were obtained.

Reaction of *N,N*-Dimethyl-diphenylphosphinous Amide (Ia) with Diethyl Sulfate (IVb). When 7.95 mmol of Ia was added to IVb (7.90 mmol), phosphonium salt (Vd) was formed exothermally (see Table 1). When Vd was heated in a sealed tube at 100°C for 7 hr, 82% yield of VIb was obtained, which was identified by comparison with the above products. The distillation residue was dark polymeric material, which showed a broad IR absorption band at 1220—1180 cm^{-1} attributable to ν_{SO_2} frequency, and was assumed to be the decomposition product of "$ROSO_2$-NR_2."

Reaction of *N,N*-Diethyl-diphenylphosphinous Amide (Ib) with Dimethyl Sulfate (IVa). In the same manner as in the above experiment, VIa was isolated in 50% yield by the reaction of equimolar mixture of Ib and IVa. The viscous distillation residue had the same IR spectrum as that obtained in the above experiment.

Reaction of Diphenyl Dimethylphosphoramidite (IIa) with Ethyl Benzenesulfonate (IIIb). When IIa was added to an equimolar amount of IIIb, heat evolution could not be observed. Even after standing for one week at room temperature, the IR and NMR spectrum of the mixture showed no change. When the mixture was heated in a sealed tube under a nitrogen atmosphere at 100°C for 10 hr, the mixture turned to yellowish brown. The reaction products showed IR and NMR spectra corresponding to the final alkylation-deoxygenation products as described (see Result). By distillation under reduced pressure, 2.70 g of the distillate with boiling point range 130—150°C/0.03 mmHg was obtained. The distillate gave two reaction products, which were separated on a chromatographic column. Thus, 73% yield of diphenyl ethylphosphonate(VIIIb) and 86% yield of *N,N*-dimethylbenzenesulfonamide (VIIa) were obtained.

VIIIb: bp 113.5—114.0°C/0.03 mmHg; n_D^{23} 1.5540; TLC, R_f=0.14; IR(KBr disk), 1265 cm^{-1} ($\nu_{P=O}$); NMR (in CCl_4), τ 7.80—9.00 (m, 5H, P**C**H_2**C**H_3), 2.85 (s, 10H, phenyl), (Found: P, 11.65% Calcd: P, 11.80%.)

Reaction of Diphenyl Diethylphosphoramidite (IIb) with Methyl Benzenesulfonate (IIIa). When an equimolar mixture of IIb and IIIa was heated at 100°C for 10 hr in a sealed tube under a nitrogen atmosphere, diphenyl methylphosphonate (VIIIa) and VIIb were isolated by distillation and subsequent column chromatography in 87% and 77% yields, respectively.

VIIIa: bp 110—112°C/0.01 mmHg; n_D^{23} 1.5480; TLC, R_f=0.17; IR (KBr), 1264 cm^{-1} ($\nu_{P=O}$); NMR (in CCl_4) τ 8.33 (d, 3H, J=18 Hz, PCH_3), 2.23 (S, 10H phenyl). Found: C, 62.69; H, 5.75; P, 12.20%. Calcd for $C_{13}H_{13}PO_3$: C, 62.91; H, 5.23; P, 12.43%.

Reaction of Diphenyl Dimethylphosphoramidite (IIa) with Diethyl Sulfate (IVb). No reaction took place between equimolar amounts (8.10 mmol) of IIa and IVb at room temperature. However when the mixture was heated at 100°C, VIIIb was isolated in 63% yield by distillation. The distillation residue was 2.0 g of dark polymeric material which showed the same IR spectrum as those of the above experiments.

Reaction of Diphenyl Diethylphosphoramidite (IIb) with Dimethyl Sulfate (IVa). By the same treatment as that mentioned above, VIIIa was obtained in 54% yield from an equimolar mixture (6.50 mmol) of IIb and IVa. In this case too, the counter product was dark polymeric material (1.80 g).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2531—2535 (1970)

Cyclizations of Thioureas with a Hydroxy Group at the β-Position of the *N*-Substituent. I. Reaction with Cupric Acetate

Yoshio IWAKURA, Tadahiro KAYA*1 and Keisuke KURITA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo

(Received January 27, 1970)

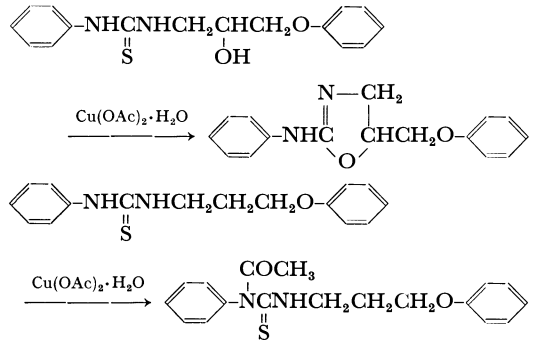
The reaction of 1-(3-phenoxy-2-hydroxypropyl)-3-phenyl-2-thiourea (thiourea I) with cupric acetate was investigated. The desulfurization reaction by the cupric ion proceeded in refluxing ethanol to yield 2-anilino-5-phenoxymethyl-2-oxazoline. At room temperature, thiourea I and cupric acetate gave a copper complex and the oxazoline. When the complex was heated in ethanol, the same oxazoline and thiourea I were obtained, along with inorganic copper compounds. On the basis of an investigation of the structure of the complex and the decomposition of the complex, the reaction mechanism involving copper-complex formation was discussed. On the other hand, the reaction of 1-(3-phenoxypropyl)-3-phenyl-2-thiourea with cupric acetate under the same conditions gave 1-(3-phenoxypropyl)-3-phenyl-3-acetylurea.

The desulfurization reaction of thiourea bearing a hydroxy group at the β-position of the *N*-substituent (hydroxythiourea) to give an oxazoline derivative was first reported by Söderbaum,[1] who used mercuric oxide to effect such a desulfurization-cyclization reaction. This method was later elaborated by Dains and his co-workers.[2,3] However, their version requires the use of a large excess of the metal oxide to complete the reaction. Adcock and his co-workers[4–6] used methyl iodide for such a desulfurization of hydroxythioureas.

In an earlier paper,[7] it was reported that 2-anilino-5-phenoxymethyl-2-oxazoline was obtained from 1-(3-phenoxy-2-hydroxypropyl)-3-phenyl-2-thiourea by treatment with *p*-toluenesulfonyl chloride. As part of a continuing investigation of the cyclization reaction of hydroxythiourea, the reaction of 1-(3-phenoxy-2-hydroxypropyl)-3-phenyl-2-thiourea with cupric acetate was attempted with the expectation that the oxazoline derivative would be formed by a homogeneous reaction.

Results and Discussion

The reaction of 1-(3-phenoxy-2-hydroxypropyl)-3-phenyl-2-thiourea (thiourea I) with an equimolar amount of cupric acetate proceeded readily in refluxing ethanol to give 2-anilino-5-phenoxymethyl-2-oxazoline in a 73% yield along with some blue-black inorganic precipitate. On the other hand, 1-(3-phenoxypropyl)-3-phenyl-2-thiourea (thiourea II), which has no hydroxy group, was found to afford 1-(3-phenoxypropyl)-3-phenyl-3-acetylurea in an 83% yield, along with a black, inorganic precipitate, under the same reaction conditions.



In order to obtain some clue to the reaction mechanism, the reaction of thiourea I and cupric acetate was examined at room temperature. When the solutions of thiourea I and cupric acetate in 70% aqueous dioxane were mixed at room temperature, a brown-black solution resulted and the color of the solution immediately turned yellow. From the yellow solution, yellow crystals containing copper (complex I) appeared gradually.

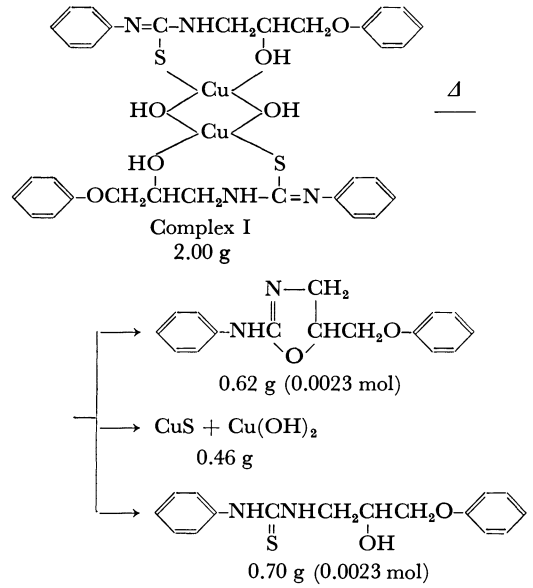
When the moler ratio of thiourea I to cupric acetate was exactly 2 : 1, only the oxazoline and acetic acid were found in the mother liquor obtained after the filtration of complex I from the reaction mixture mentioned above, while neither of the reactants remained unchanged. However, if the ratio was less than 2 : 1, the cupric acetate remained unchanged; on the contrary, if the ratio was larger than 2 : 1, thiourea I was recovered. These facts suggest that the formation of complex I and the oxazoline requires only a half mole of cupric acetate for each mole of thiourea I. Furthermore, a quantitative study of the reaction showed that two moles of thiourea I gave one mole of the oxazoline when the molar ratio of thiourea I to cupric acetate was just 2 : 1. This indicates that one of the two moles of thiourea I added was consumed in the formation of complex I. The elemental analysis of complex I indicated that it contained thiourea I and copper in a 1 : 1 ratio. These results are summarized in the following diagram, along with the quantitative relationship of the materials. Hydrogen sulfide was detected in the reaction mixture by gas chromatography.

Complex I is soluble in polar solvents, such as dimethylformamide and dimethyl sulfoxide, but insoluble in usual organic solvents, such as dioxane, toluene, benzene, methanol, and acetone. These facts suggest that the complex has a polymeric rather than a monomeric structure. From the elemental analysis, the empirical formula, $C_{16}H_{18}N_2SO_3Cu$, was obtained; this formula corresponded well with the composition, thiourea I·Cu·OH. On the basis of these facts, a dimeric olation structure was considered for complex I, since it is well known that a copper complex is apt to form a dimeric olation structure in an aqueous medium. The ESR measurement and particularly the thermoanalysis of the complex, to be described below, seemed to support the structure. Complex I showed a sharp signal in the ESR; this indicated that the copper was in the cupric rather than the cuprous state. The complex prepared from thiourea I and cuprous chloride showed no signal in the ESR.

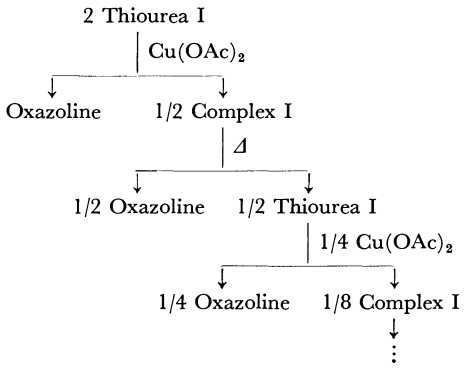
When complex I was heated while suspended in refluxing ethanol, it gradually decomposed, giving rise to a blue-black powdery material which was insoluble in ethanol. From the ethanolic solution, the oxazoline and thiourea I were obtained in equimolar amounts. The blue-black powder was considered to be a 1 : 1 mixture of cupric sulfide and cupric hydroxide on the basis of the following facts: (1) The sulfur content of the powder was found to be 17.00%, this value was in good agreement with the calculated value, 16.67%. (2) In a thermogravimetric analysis, the powder showed a 9.00% weight loss after being kept at 350°C for 4 hr in a nitrogen atmosphere. If the cupric hydroxide in the mixture loses water to give cupric oxide, the weight loss should be 9.30%. After heating, the color of the powder was black, suggesting a change from cupric hydroxide (blue) to the oxide (black). Complex I and its decomposition in boiling ethanol may be depicted thus:



Thus, on the basis of theses data, the reaction scheme between two moles of thiourea I and one mole of cupric acetate at room temperature was presumed to be as follows. Two molecules of thiourea I were co-ordinated to a cupric ion at the initial stage; then one molecule of thiourea I was removed to produce the oxazoline and hydrogen sulfide, and simultaneously the co-ordinated water

was changed to hydroxide to form the olation structure.

If it is assumed that the reaction of thiourea I with cupric acetate in refluxing ethanol also proceeds *via* the formation of complex I, the whole reaction sequence between equimolar amounts of thiourea I and cupric acetate at an elevated temperature would be as follows. Two moles of thiourea I and one mole of cupric acetate react to give one mole of the oxazoline and a half mole of complex I. Then complex I decomposes to give a half mole of the oxazoline and a half mole of thiourea I, along with inorganic materials. The half mole of thiourea I freed from complex I again reacts with a quarter mole of cupric acetate to repeat the sequence. Therefore, the minimum amount of cupric acetate required to convert one mole of thiourea I to the oxazoline completely should be 2/3 mol.



This sequence may be summarized as in the following equation.

$$2\ \text{Thiourea I} + 4/3\ \text{Cu(OAc)}_2 \longrightarrow 2\ \text{Oxazoline}$$

The experimental results showed that the reaction of one mole of thiourea I with 2/3 mol of cupric acetate in refluxing ethanol gave the oxazoline in a 67% yield, with no recovery of thiourea I or cupric acetate.

Figure 1 represents the infrared to far-infrared spectra of thiourea I, complex I, and the oxazoline.

The copper complex of thiourea II (complex II) was obtained by the procedure described for the preparation of complex I. The results of the elemental analysis of complex II agreed well with the calculated value for the 1 : 1 complex of thiourea II and copper. In contrast to complex I, complex II showed no signal in the ESR and was soluble even in a non-polar solvent such as benzene. From these facts, this complex may be considered to consist of thiourea II and copper in a cuprous state in a 1 : 1 ratio and to have no polymeric olation structure. Therefore, the mechanism of the reaction of cupric acetate with thiourea I and that with thiourea II are considered to be quite different; in the latter case, the cupric ion has been reduced to the cuprous ion during the formation of complex II. This problem is under investigation.

Figure 2 represents the infrared to far-infrared spectra of thiourea II, complex II, and the *N*-acylurea.

Experimental

1-(3-Phenoxy-2-hydroxypropyl)-3-phenyl-2-thiourea. This compound, prepared from 1-phenyl-3-amino-2-propanol and phenyl isothiocyanate, has been reported previously.[7]

3-Phenoxypropylamine. This compound was pre-

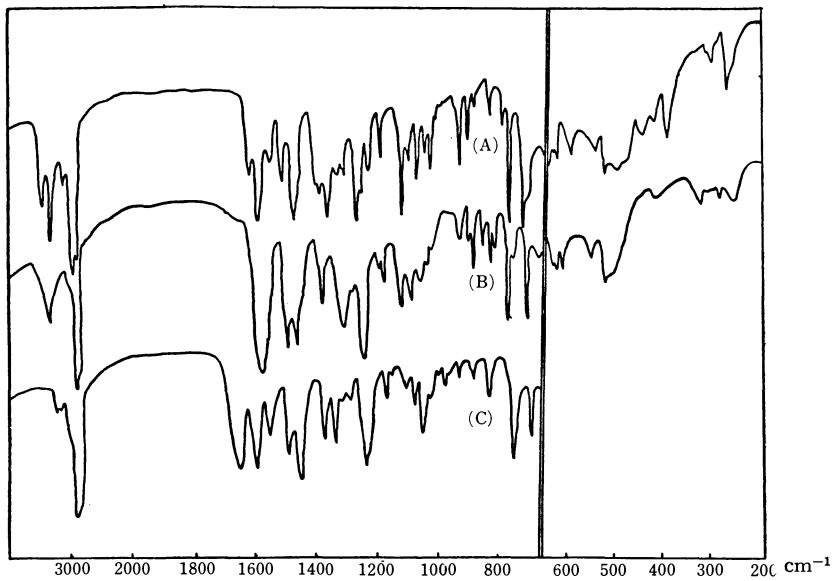


Fig. 1. Infrared to far-infrared spectra of thiourea I (A), complex I (B), and the oxazoline (C), (Nujol).

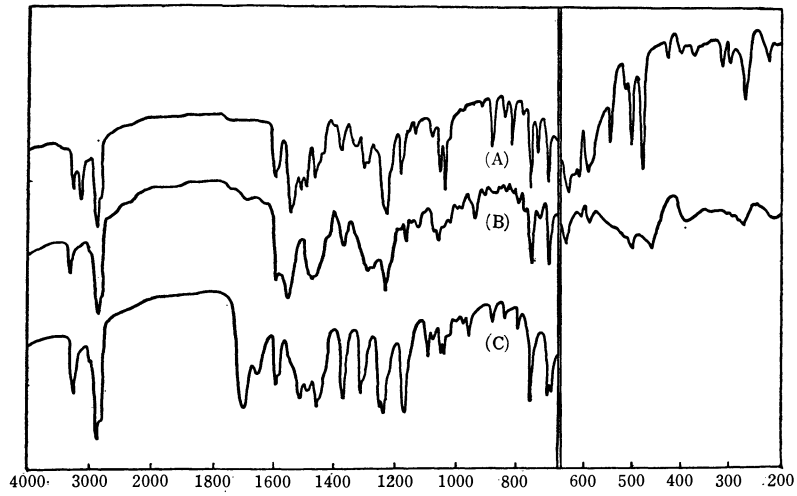

Fig. 2. Infrared to far-infrared spectra of thiourea II (A), complex II (B), and the *N*-acylurea (C), (Nujol).

pared from 3-phenoxypropyl bromide[8] and was synthesized from phenol, 1,3-dibromopropane, and potassium phthalimide according to the Gabriel synthesis. The yield was 64%, bp 138—139°C/23 mmHg.

1-(3-Phenoxypropyl)-3-phenyl-2-thiourea. Into a solution of 15.1 g (0.1 mol) of 3-phenoxypropylamine in 100 m*l* of methanol, we stirred 13.5 g (0.1 mol) of phenyl isothiocyanate, drop by drop, over a period of 30 min. The mixture was then stirred for 4 hr at room temperature; then the solvent was evaporated under reduced pressure. The residual white solid was recrystallized from toluene to give 25.4 g (89.0%) of the product; mp 89—90°C.

Found: C, 67.39; H, 6.42; N, 9.57%. Calcd for $C_{16}H_{18}N_2SO$: C, 67.10; H, 6.33; N, 9.78%.

2-Anilino-5-phenoxymethyl-2-oxazoline. 1-(3-Phenoxy-2-hydroxypropyl)-3-phenyl-2-thiourea (1 g; 0.0033 mol) was refluxed with 0.66 g (0.0033 mol) of cupric acetate monohydrate in 20 m*l* of ethanol. After 5 hr heating, the blue-black precipitate was filtered off and the filtrate was evaporated under reduced pressure. The residue was dissolved in 20 m*l* of toluene and extracted with dilute hydrochloric acid. On the basification of the aqueous extract with aqueous sodium hydroxide, 0.6 g (73%) of 2-anilino-5-phenoxymethyl-2-oxazoline was obtained; this was identical with the authentic sample prepared by the dehydration of 1-(3-phenoxy-2-hydroxypropyl)-3-phenylurea.[7]

1-(3-Phenoxypropyl)-3-phenyl-3-acetylurea. To a solution of 0.95 g (0.0033 mol) of 1-(3-phenoxypropyl)-3-phenyl-2-thiourea in 20 m*l* of ethanol, we added a solution of 0.66 g (0.0033 mol) of cupric acetate monohydrate in 30 m*l* of ethanol. After the mixture had been refluxed for 7 hr, the black precipitate which had formed was filtered off. The filtrate was evaporated under reduced pressure, and the residual solid was recrystallized from *n*-hexane to give 0.86 g (83%) of colorless needles, mp 84°C.

Found: C, 69.40; H, 6.53; N, 8.88% Calcd for $C_{18}H_{20}N_2O_3$: C, 69.21; H, 6.45; N, 8.97%

Reaction of 1-(3-Phenoxy-2-hydroxypropyl)-3-phenyl-2-thiourea with Cupric Acetate at Room Temperature. Cupric acetate monohydrate (1.99 g; 0.01 mol), dissolved in 120 m*l* of 70% aqueous dioxane, was added to a solution of 6.00 g (0.02 mol) of 1-(3-phenoxy-2-hydroxypropyl)-3-phenyl-2-thiourea in 120 m*l* of 70% aqueous dioxane. The mixture immediately became a brown-black solution, and then the solution turned yellow. When this yellow solution was allowed to stand yellow crystals began to appear. The mixture was allowed to stand at room temperature for 6 hr. The crystals were then collected by filtration and weighed 2.90 g; mp 115°C (decomposition).

Found: C, 49.71; H, 4.88; N, 7.51; Cu, 16.66%. Calcd for $C_{32}H_{36}N_4S_2O_6Cu_2$: C, 50.18; H, 5.00; N, 7.32; Cu, 16.59%.

The filtrate was evaporated under reduced pressure, and the residue was dissolved in toluene. The toluene solutions was extracted with dilute hydrochloric acid, and the aqueous extract was basified with aqueous sodium hydroxide to precipitate 2-anilino-5-phenoxymethyl-2-oxazoline in a yield of 2.34 g.

Copper Complex from Thiourea I and Cuprous Chloride. To a solution of 1.00 g (0.0033 mol) of 1-(3-phenoxy-2-hydroxypropyl)-3-phenyl-2-thiourea in 30 m*l* of 70% aqueous dioxane, we added a solution of 0.33 g (0.0033 mol) of cuprous chloride and 0.3 g of sodium chloride, which was added to dissolve the cuprous chloride, in 50 m*l* of 70% aqueous dioxane at room temperature. Aqueous sodium hydroxide was added to the reaction mixture to maintain the pH at 6.8, which was the value of the reaction mixture of the thiourea I and cupric acetate, since the complex was not formed in the low pH region. The precipitated yellow crystals weighed 0.95 g; mp 134°C (decomposition.

Reaction of 1-(3-Phenoxypropyl)-3-phenyl-2-thiourea with Cupric Acetate at Room Temperature. Cupric acetate monohydrate (0.697 g; 0.0033 mol) was dissolved in 40 m*l* of 70% aqueous dioxane, and then the solution was slowly added to a solution of 2.00 g

8) C. S. Marvel and A. L. Tanenbaum, "Organic Syntheses," Coll. Vol. I, p. 435 (1956).

(0.0067 mol) of 1-(3-phenoxypropyl)-3-phenyl-2-thiourea in 40 m*l* of 70% aqueous dioxane. The brown-black mixture changed to yellow, and yellow crystals gradually precipitated. The mixture was kept at room temperature for 6 hr. The crystals were then filtered off; they weighed 0.86 g; mp 104°C (decomposition).

Found: C, 55.31; H, 5.16; N, 8.38%. Calcd for $C_{16}H_{17}N_2SOCu$: C, 54.92; H, 5.18; N, 8.01%.

The filtrate was evaporated, and the residue was dissolved in toluene; the organic solution was washed with aqueous sodium hydroxide to remove the acetic acid, and then with water, and dried over sodium sulfate. The solvent was evaporated to give 0.80 g of 1-(3-phenoxypropyl)-3-phenyl-3-acetylurea.

Thermal Decomposition of Complex I. Complex I (2.00 g) was heated in 60 m*l* of refluxing ethanol for 7 hr heterogeneously. The yellow-orange complex decomposed, giving a blue-black powder. The blue-black powder was filtered, washed with ethanol and weighed; 0.46 g. The filtrate was evaporated under reduced pressure, and the residue was dissolved in toluene. The toluene solution was extracted with dilute hydrochloric acid. When the organic layer was evaporated, 0.70 g of thiourea I was obtained, while, from the aqueous extract, 0.62 g of 2-anilino-5-phenoxymethyl-2-oxazoline was obtained by basification.

Cyclizations of Thioureas with a Hydroxy Group at the β-Position of the *N*-Substituent. II. Oxidation with Thionyl Chloride to Benzothiazoles

Yoshio IWAKURA and Keisuke KURITA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received January 27, 1970)

The reaction of *N*-alkyl and *N'*-phenyl substituted thioureas with a hydroxyl group at the β-position of the *N*-substituent with thionyl chloride gave benzothiazole derivatives by an oxidative cyclization reaction; no other products, such as thiazolines or oxazolines, were formed. The structure was confirmed by the various spectral and chemical data.

The dehydration of *N*-acyl derivatives of β-hydroxyalkylamines with thionyl chloride has been one of the most useful methods for preparing oxazoline derivatives since Bergman and Brand[1,2] found in thionyl chloride a mild and effective cyclizing agent; in this manner, 2-phenyl-5-phenoxymethyl-2-oxazoline was obtained from 1-benzamido-3-phenoxy-2-propanol in a quantitative yield, as has been described in a previous paper.[3] Roggero and Metzger[4] investigated the cyclization reaction of 1-thiobenzamido-2-propanol by several reagents, such as thionyl chloride, *p*-toluenesulfonyl chloride, and phosphorus pentoxide, and reported that the cyclization by thionyl chloride led to a mixture of 2-phenyl-5-methyl-2-thiazoline and the corresponding oxazoline, and that the product composition varied with the reaction temperature.

In a preceding paper,[5] it was shown that the cyclization of 1-(3-phenoxy-2-hydroxypropyl)-3-phenyl-2-thiourea by various acids gave thiazoline, oxazoline, or a mixture of them, depending on the character of the acid used. The present investigation was undertaken in order to determine the cyclization products by thionyl chloride.

Results and Discussion

Reaction with Thionyl Chloride and Identification of the Products. The treatment of *N*-alkyl and *N'*-phenyl substituted thioureas with a hydroxyl group at the β-position of the *N*-substituent

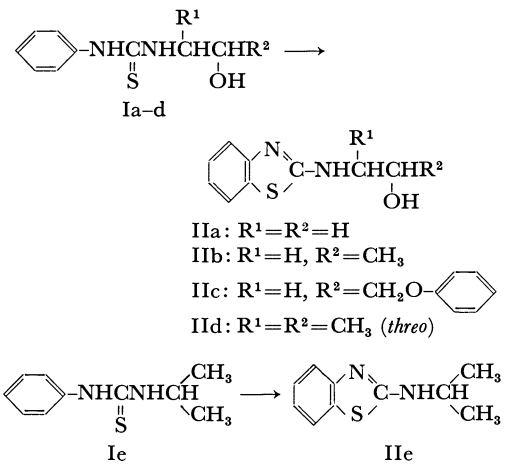
(hydroxythioureas) of such types as Ia—d with a large excess of thionyl chloride at room temperature resulted in the formation of the hydrochlorides of the basic materials, which were then converted to the free bases (IIa—d) with aqueous ammonia. The elemental analyses and the infrared spectra of these compounds showed, however, that they were identical with neither the thiazolines nor the oxazolines, nor were they identical with mixtures of the two, contrary to expectation. 1-Isopropyl-3-phenyl-2-thiourea (Ie), non-hydroxythiourea, gave a similar basic compound (IIe) by the same procedure, suggesting that this reaction proceeded independently of the existence of a hydroxyl group in the thioureas.

It is well known that thioureas are oxidized with bromine or thionyl chloride in chloroform to give the salts of bis(substituted formamidine)disulfides. However, the possibility that the above-obtained reaction products of thioureas Ia—e with thionyl chloride might be the bis(substituted formamidine)-disulfides can be ruled out, though the results of the elemental analysis were close to the calculated values. The salt of bis(substituted formamidine)-disulfide is known to be unstable to water or ethanol, and one of the two sulfur atoms is extruded on treatment with absolute ethanol or a mixture of absolute ethanol and benzene to give the monosulfide salt, followed by isomerization and cyclization to the so-called Hector's or Hugershoff's base.[6-14] Moreover, it has been reported that the disulfide base is too unstable to exist as a free base, and that it decomposes instantly, with the elimination of sulfur.

On the basis of the spectral and chemical data, as will be mentioned later, it is very likely that IIa—e has a benzothiazole structure. The oxidation of aryl thioureas with bromine[15] is a very convenient method for preparing benzothiazoles; other oxidizing reagents, such as sulfuryl chloride and sulfur monochloride, have also been reported



in several papers[16-18] and patents.[19-21]

The products obtained here were found to be resistive to such reducing agents as lithium aluminum hydride and zinc in acidic media. For instance, IIc was recovered quantitatively after being heated in refluxing tetrahydrofuran with a large excess of lithium aluminum hydride for 20 hr. Thermal analysis revealed that they were fairly stable to heat, that they decomposed thermally in a nitrogen atmosphere above 200°C, and that each compound showed only one DTA peak (endothermic) corresponding to its melting point. The molecular weight of IIc as determined by the Rast method (299), was very close to that of the starting thiourea, Ic (302). The mass spectra of IIa, IIb, IIc, IId, and IIe exhibited the molecular ion peak at *m/e*, 194, 208, 300, 222, and 192 respectively, as was to be expected from the benzothiazole structure. In the NMR spectra of IIc and IId, the ratio of the integration of aromatic protons to that of the aliphatic ones gave a better agreement with the benzothiazole than with the disulfide structure: 9/5 for IIc and 4/8 for IId. Figure 1 represents the NMR spectrum of IId. Beilstein's test was negative for all the compounds, IIa—e, showing that none of these was chlorinated under the conditions used.

Tables 1 and 2 summarize the properties of the benzothiazoles obtained. The melting point of IIe was practically the same as that of the reported 2-isopropylaminobenzothiazole, mp 95°C, prepared from 2-methylsulfonylbenzothiazole and isopropyl-

amine.[22] The elemental analyses of IIa—e and those of the picrates show good agreement with the calculated values for benzothiazoles and their picrates, as these tables show.

The ultraviolet spectra of IIa—e in 95% ethanol were very similar to each other and showed the λ_{max} at 223—226 and 268—269 mμ. The results (Table 3) correspond very well with the reported data that 2-aminobenzothiazole has the λ_{max} at 222 (log ε=4.52) and 264 mμ (log ε=4.09),[23] or 263 mμ (log ε=4.11)[24] in ethanol in the UV. A typical example of the ultraviolet spectrum is shown in Fig. 2.

The Acetylation of IIc and the Hydrolysis of IIc Diacetylate. Acetylation of IIc was carried out by treating IIc with a mixture of pyridine and acetic anhydride to give a diacetylated compound (IIIc).

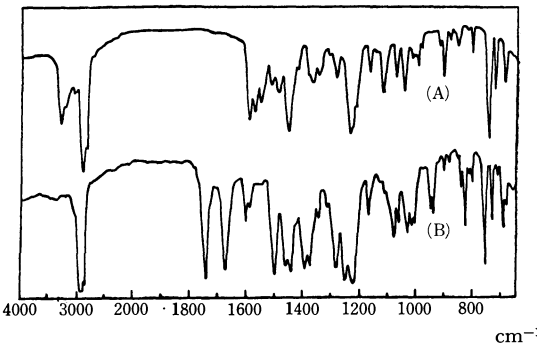

Fig. 3. Infrared spectra of IIc (A) and IIIc (B), (Nujol).

The infrared spectra of IIc and IIIc are shown in Fig. 3. The most characteristic absorption bands of IIIc are found at 1740 and 1670 cm^{-1}, assignable to the carbonyl groups of the *O*- and the *N*-acetyl group respectively. The NMR spectrum of IIIc in $CDCl_3$ showed two singlets at 8.00 τ and 7.46 τ (both 3 protons), indicating that acetylation had taken place at both OH and NH, and a peak due to the methine proton which appeared at 5.75 τ in IIc, was shifted downfield by the acetylation of hydroxyl group and appeared as a multiplet at 4.30 τ.

Diacetylated benzothiazole, IIIc, was subjected to alkaline hydrolysis to give the original benzothiazole, IIc, in a quantitative yield.

In view of the above facts, it can be concluded that the benzothiazoles were obtained quantitatively by the oxidation reaction of 1-aryl-3-alkyl-2-thioureas with thionyl chloride. Benzothiazoles are at a higher oxidation stage than disulfides, and Barnikow and Bödeker[13] have reported that the disulfides which were obtained by the oxidation of thioureas with bromine were further oxidized by bromine to give benzothiazoles. This reaction presumably proceeds also through the disulfides; then these disulfides are oxidized further by thionyl chloride to yield the benzothiazoles.

It is noteworthy that the hydroxythioureas, Ia—d, gave the benzothiazoles in preference to the thiazolines or the oxazolines, since a thioamide with a hydroxyl group at the β-position gave a mixture of a thiazoline and an oxazoline, as has already been mentioned in the introduction.

Experimental

Thioureas. The hydroxythioureas, Ia, Ib and Id, and the non-hydroxythiourea, Ie, were synthesized from the corresponding aminoalcohols or amine and phenyl isothiocyanate by the method previously used in the preparation of hydroxythiourea, Ic.[5] The results are listed in Table 4.

2-(3-Phenoxy-2-hydroxypropylamino)benzothiazole. To 20 ml of thionyl chloride we added 5 g (0.0165 mol) of 1-(3-phenoxy-2-hydroxypropyl)-3-

phenyl-2-thiourea at 0°C. After the vigorous evolution of gas had ceased, the reaction mixture was allowed to warm to room temperature and was then stirred for an additional hour. The solution was then poured into 300 m*l* of ether and allowed to stand in a refrigerator overnight. The precipitated salt was collected by filtration, washed with ether to remove the excess thionyl chloride, and dried. The benzothiazole hydrochloride was treated with aqueous ammonia to give the free base, which weighed 4.5 g (9.1%). Recrystallization from a mixture of benzene and *n*-hexane gave white crystals; mp 137—139°C.

The other benzothiazoles were prepared by virtually the same procedure.

Acetylation of Benzothiazole, IIc. A mixture of pyridine and acetic anhydride (15 m*l* each)was added to 1.7 g (0.0057 mol) of benzothiazole, IIc. The solution was allowed to stand at room temperature for 1 day and was then concentrated under reduced pressure. The residual solid was recrystallized from cyclohexane to give 1.8 g (83%) of diacetylated benzothiazole, IIIc; mp 149—150°C.

Found: C, 62.64; H, 5.36; N, 7.16; S, 8.29%. Calcd for $C_{20}H_{20}N_2SO_4$: C, 62.49; H, 5.24; N, 7.29; S, 8.33%.

Alkaline Hydrolysis of Diacetylated Benzothiazole, IIIc. To a solution of 0.7 g (0.0018 mol) of diacetylated benzothiazole, IIIc, in 50 m*l* of acetone, we added 20 m*l* of 0.2N sodium hydroxide. The mixture was stirred at 50°C for 5 hr, and then the solvent was evaporated under reduced pressure. The residual white solid was washed well with water and dried. The benzothiazole, IIc, was thus obtained; it weighed 0.53 g (97%).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2539—2543 (1970)

Bromodenitrogenation of N^2-Benzoylarginine Ethyl Ester with *N*-Bromosuccinimide

Kentaro ANZAI

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received February 3, 1970)

N^2-benzoylarginine ethyl ester (II) reacted with *N*-bromosuccinimide at pH's above 7 to yield, as the main product, N^2-benzoyl-N^5-cyanoornithine ethyl ester (VII), as well as N^3,N^6-bis(4-benzamido-4-ethoxycarbonylbutyl)*s*-tetrazine-3,6-diimine (VIII), *N*,*N*′-di(4-benzamido-4-ethoxycarbonylbutyl)urea (IX), and N^2-benzoylcitrulline ethyl ester (X) as minor products. On acid hydrolysis, VII afforded the following amino acids: ornithine (III), citrulline (IV), N^6-[(4-amino-4-carboxybutyl)-carbamoyl]arginine (V), and *N*,*N*′-di(4-amino-4-carboxybutyl)urea (VI). The mechanism of these reactions was also discussed.

Amino acids react with *N*-bromosuccinimide (NBS), with the evolution of carbon dioxide, to produce corresponding aldehydes.[1] According to Okuyama *et al.*,[2,3] arginine, acetyl arginine, and DNP-arginine as well as guanidine react with NBS, with the evolution of nearly equimolar amounts of nitrogen gas, at pH's above 7. Some proteins, *e. g.*, clupein, gelatin, and the crude urease extract, also suffer from NBS oxidation. On the basis of the above findings the chemical modification of a peptide antibiotic, triculamin,[4,5] which contains two arginine residues in a molecule, was attempted. However the product obtained was an intractable mixture which could hardly be separated chromatographically and this unfruitful result prompted

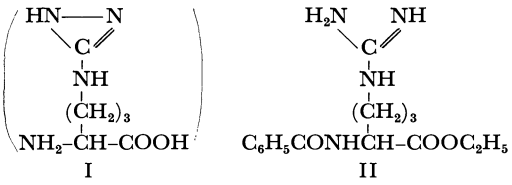
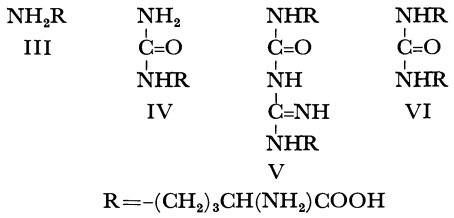
us to study the reaction path of NBS oxidation on arginine.

Okuyama *et al.*[3,6] postulated an intermediate, I, from which, on further oxidation, nitrogen could evolve, leaving N^2-formyl ornithine. However, an attempt to isolate the latter compound failed, though ornithine was obtained upon the hydrolysis of the oxidation product.



I II

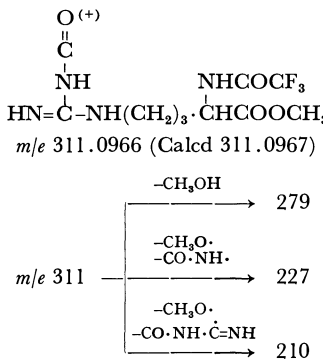
N^2-Benzoylarginine ethyl ester (II) was allowed to react with an excess amount of NBS under neutral conditions at room temperature. The product was extracted with ethyl acetate, and then hydrolysed with hydrochloric acid. CM Sephadex chromatography afforded the following five amino acids (yields): ornithine (III), 52%; citrulline (IV), 29%; N^6-[(4-amino-4-carboxybutyl) carbamoyl] arginine (V), 8%; N,N'-di(4-amino-4-carboxybutyl)urea (VI), 3%; arginine, 2%.



III IV V VI

R=$-(CH_2)_3CH(NH_2)COOH$

V is a strong base; it is eluted from CM Sephadex column closely after arginine, and it is obtained as an acetate. It showed a positive ferricyanide-nitropurside reaction (substituted guanidine). NMR shows the presence of two methylene and two methine groups: δ 3.24 (t, J=5 Hz, 2H), δ 3.35 (t, J=7 Hz, 2H), δ 3.71 (t, J=7 Hz, 1H), δ 3.75 (t, J=5 Hz, 1H). Though the trifluoroacetylated methyl ester of V does not give the parent peak, the

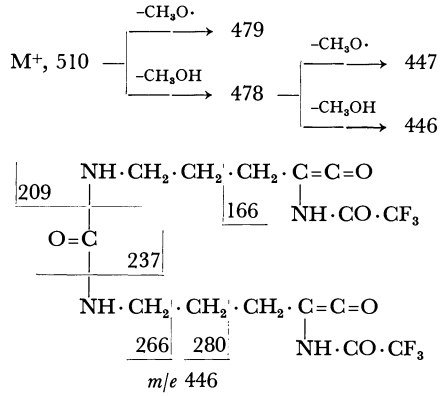


m/e 311.0966 (Calcd 311.0967)

Scheme 1

fragmentations, shown in Scheme 1, can be reasonably explained on the basis of the structure V.

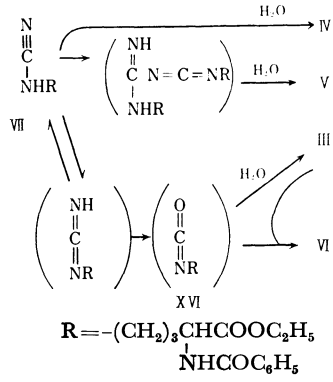
The NMR of VI shows one methylene (δ 3.15, t, J=6 Hz) and one methine (δ 3.75, t, J=6 Hz) proton signals, showing that it is a symmetrically-substituted compound. The trifluoroacetylated methyl ester of VI shows a very weak parent peak at *m/e* 510. However, the intense fragmentations shown in Scheme 2 can reasonably be explained on the basis of the structure VI.



Scheme 2

We attempted to isolate the NBS oxidation product of II using silicic acid chromatography. The main product was identified as N^2-benzoyl-N^5-cyanoornithine ethyl ester VII; three minor products were also obtained.

The IR of VII shows a strong band at 2210 cm^{-1} attributable to a cyano group. Though the analytical and NMR data support the structure VII, the mass spectrum shows some ambiguity. Though the operation conditions can be chosen so as to give the expected parent peak at *m/e* 289.1418 (calcd for $C_{15}H_{19}N_3O_3$ 289.1426), unexplicable peaks at higher mass are observed on an elevation of the temperature: These can possibly be ascribed to the polymerization of the sample. VII also afforded III, IV, V, and VI on acid hydrolysis; a reasonable reaction path from VII to the three amino acids is shown in Scheme 3:

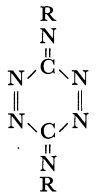


R=$-(CH_2)_3CHCOOC_2H_5$
$NHCOC_6H_5$

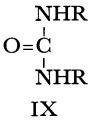
Scheme 3

6) K. Niijima and N. Okuyama, *Seikagaku*, **35**, 396 (1963).

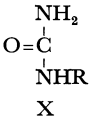
The three minor products were identified as N^3,N^6-bis(4-benzamido-4-ethoxycarbonylbutyl)-*s*-tetrazine-3,6-diimine (VIII), *N,N'*-di(4-benzamido-4-ethoxycarbonylbutyl)urea (IX), and N^2-benzoyl-citrulline ethyl ester (X).



VIII



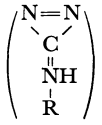
IX



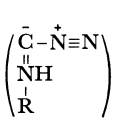
X

$R=-(CH_2)_3CHCOOC_2H_5$
$NHCOC_6H_5$

The intense UV absorption of VIII ($\lambda_{max}^{methanol}$ 222, ε 83000; 303 mμ, ε 7000), as well as the absence of IR absorption in the 1800—2900 cm^{-1} region, exclude other possible structures, XI and XII, which



XI



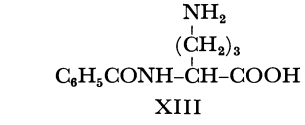
XII

$R=-(CH_2)_3CHCOOC_2H_5$
$NHCOC_6H_5$

could be expected to give the same analytical data and an NMR spectra similar to that of VIII. XI or XII was first postulated[7] as an intermediate through which N^2-benzoyl-N^5-formylornithine ethyl ester might be given, along with the evolution of nitrogen gas.

IX and X gave the corresponding amino acids, VI and IV, on acid hydrolysis; the analytical and spectral data are also consistent with the proposed structures.

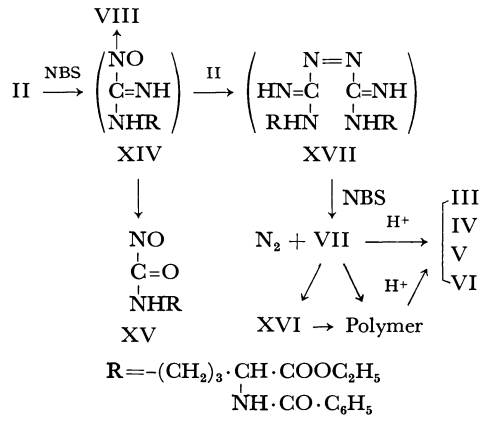
After VII, VIII, IX, and X had been extracted with ethyl acetate, the aqueous layer was heated with sodium hydroxide. Subsequent CM Sephadex chromatography afforded N^2-benzoylornithine (XIII).



XIII

The product analysis leads to the possible reaction path outlined in Scheme 4; by postulating an intermediate, XIV, all the products mentioned above can reasonably be situated there.

The compound XV was once obtained; though its poor reproducibility made satisfactory identification difficult, the analytical data and the MS



$R=-(CH_2)_3\cdot CH\cdot COOC_2H_5$
$NH\cdot CO\cdot C_6H_5$

Scheme 4

fragmentation pattern suggested it to be 2-benzamido-5-(2-nitrosoformamido)valeric acid ethyl ester (XV) (See Experimental section).

Possibly the main reaction proceeds *via* II, XIV, XVII, and VII, with the evolution of nitrogen from XVII. According to this process, 1.5 mol of NBS is needed for the oxidation of 1 mol of II. VII as well as its hydrolysed product, XVI, might have a tendency to polymerize easily under the present reaction conditions, resulting in an unexpectedly low yield of VII (20% after purification). A polymerized product, which was separated roughly by means of silicic acid chromatography, also gave four amino acids, *i. e.*, III, IV, V, and VI, on acid hydrolysis.

VII was still hydrolysed in a neutral solution, the reaction might proceed in a way similar to that shown in Scheme 3, giving IX, X, and the ethyl ester of XIII.

According to the reaction path proposed here, the two atoms of a nitrogen molecule do not originate from the same guanidine residue, as was first postulated.[7] Ammonia, liberated from VII by hydrolysis, may also be oxidized to a nitrogen molecule.

Experimental

Reaction Procedure. In 25 m*l* of a 0.1N phosphate buffer solution at pH 7, 171 mg (5×10^{-3}M) of the hydrochloride of N^2-benzoylarginine ethyl ester (II) were dissolved. A solution of 178 mg (10^{-2}M) of NBS in 25 m*l* of acetone was added dropwise with stirring and the reaction proceeded with an evolution of nitrogen gas accompanying the decrease in the pH. If the insoluble product separated, acetone was added until a homogenous solution was obtained; the pH of the solution was kept at 7—8 with sodium hydroxide throughout the reaction. The decrease in the pH ceased before the addition of NBS was completed. Five grams of ammonium sulfate were added to diminish the excess NBS.

Acid Hydrolysis of the Reaction Product Yielding Ornithine (III), Citrulline (IV), N^6-[(4-Amino-4-carboxybutyl)carbamoyl]-arginine (V), and *N,N'*-Di(4-amino-4-carboxybutyl)urea (VI). The reaction

7) In a letter to Dr. N. Okuyama the present author suggested the reaction path to be II→I→XI or XII $\xrightarrow{H_2O}$ N^2-benzoyl-N^5-formylornithine ethyl ester+N_2. This mechanism can be rejected on the basis of this paper.

mixture described in the preceding section was extracted with ethyl acetate; then, after the solvent had been evaporated, the residue, which weighed 1.15 g, was dissolved in a mixture of acetic acid and conc. HCl (1 : 1) and the solution was heated at 105°C for 14 hr. The acids were then evaporated, and the residue was dried over sodium hydroxide *in vacuo*. Water was added, and the water-insoluble part, from which 130 mg of benzoic acid was obtained after crystallization from ethanol and water, was excluded by filtration; we thus obtained a mixture of amino acids, which were separated chromatographically as will be described below.

The amino acid mixture was charged on a column (2×90 cm) of CM Sephadex and developed with a 0.4N pyridine solution buffered at pH 5.0 with acetic acid. Three fractions, all of which showed a positive ninhydrin reaction, were thus obtained. The first one (a fraction at 100—190 ml) consisted of two amino acids as the main components; they were separated further chromatographically on a cellulose column using a mixture of propanol, pyridine, acetic acid, and water (15, 10, 3, 10) as the developing solvent. The one which was eluted first was identified as citrulline (IV) by comparing it with an authentic sample; yield, 250 mg.

The latter one (yield, 20 mg) was crystallized from water and ethanol and was identified as *N,N'*-di(4-amino-4-carboxybutyl)urea (VI). It gradually decomposed above 240°C and did not show a definite mp; $[\alpha]_D$= +2.3 (20°C, *c* 1, H_2O).

Found: C, 44.62; H, 7.55; N, 20.05%. Calcd for $C_{11}H_{22}N_4O_5$: C, 45.50; H, 7.63; N, 19.30%. NMR (D_2O) δ 3.15 (t, J=6 Hz, $-NH\cdot C\underline{H}_2\cdot CH_2-$), δ 3.75 (t, J=6 Hz, $CH_2-C\underline{H}(NH_2)-COOH$): IR, ν_{max}^{KBr} 3350, 2940, 1625, 1583, 1417, 1347 cm^{-1}.

The second fraction (420—530 ml), which was eluted from the CM Sephadex column, consisted mainly of one amino acid; this amino acid was purified further chromatographically on a cellulose column and was identified as the acetate of ornithine (III) by comparing it with an authentic sample.

The third fraction (540—750 ml) consisted of two amino acids which were separated chromatographically on a cellulose column (2×90 cm; propanol, pyridine, acetic acid and water; 15, 10, 3, 10). The one which was eluted first was crystallized from water and ethanol and was identified as arginine acetate; yield, 29 mg.

The second one, which was eluted later, was identified as the acetate of N^6-[(4-amino-4-carboxybutyl)carbamoyl]arginine (V); yield, 78 mg, mp 178—183°C.

Found: C, 42.64; H, 7.03; N, 20.62%. Calcd for $C_{14}H_{28}N_6O_7$: C, 42.85; H, 7.19; N, 21.42%.

NMR (D_2O) δ 1.91 (s, $C\underline{H}_3COO^-$), δ 3.24 (t, J=5 Hz, $-NH\cdot C\underline{H}_2\cdot CH_2-$), δ 3.35 (t, J=7 Hz, $-NH\cdot C\underline{H}_2\cdot CH_2-$), δ 3.71 (t, J=7 Hz, $-CH_2\cdot C\underline{H}(NH_2)COOH$), δ 3.75 (t, J=5 Hz, $-CH_2\cdot C\underline{H}(NH_2)COOH$).

Isolation of N^2-Benzoyl-N^5-cyanoornithine Ethyl Ester (VII), N^3,N^6-Bis(4-benzamido-4-ethoxycarbonylbutyl)-*s*-tetrazine-3,6-diimne (VIII), *N,N'*-Di(4-benzamido-4-ethoxycarbonylbutyl)urea (IX), and N^2-Benzoylcitrulline Ethyl Ester (X). The ethyl acetate extract of the reaction mixture was dried *in vacuo*, and the residue was chromatographed on a silicic acid column (2×50 cm) using a mixting of ethyl acetate and benzene as the developing solvent, while the ratio of the former to the latter was gradually increased. The fractions, all of which showed single spots on TLC with a Greig-Leaback reagent, were then collected.

The main product, N^2-benzoyl-N^5-cyanoornithine ethyl ester (VII), was eluted with a mixture of benzene and ethyl acetate (2 : 3). After the solvent had been evaporated, the solidified residue was washed with benzene; yield, 290 mg; mp 85—85.5°C.

Found: C, 61.79; H, 6.59; N, 14.31%. Calcd for $C_{15}H_{19}N_3O_3$: C, 62.26; H, 6.62; N, 14.52%.

NMR ($CDCl_3$), δ 1.30 (t, J=7 Hz $-OCH_2C\underline{H}_3$), δ 1.85 (m, $-C\underline{H}_2\cdot C\underline{H}_2\cdot CH\swarrow$), δ 3.08 (m, $-NH\cdot C\underline{H}_2\cdot CH_2-$), δ 4.22 (q, J=7 Hz, $OC\underline{H}_2CH_3$), δ 4.70 (m, $-CH_2\cdot C\underline{H}\cdot NH-$), δ 5.30 (broad $N\equiv C\cdot N\underline{H}\cdot CH_2-$), δ 7.2—8.0 (complex, $-C_6\underline{H}_5$): ν_{max}^{KBr} 3300, 2930, 2210, 1735, 1640, 1535, 1490, 1215, 1030, 720, 700 cm^{-1}.

The molecular weight determination by the V.P.O. method gives much larger values (chloroform, 757; ethyl acetate, 839) than that calculated (289.33), suggesting that some molecules associate in the solvent.

After VII and two other minor products (one of which was identified as succinimide (yield, 90 mg), and the other of which was not yet been identified because of its low yield) had been eluted, the solvent for the development was changed to ethyl acetate. Two products were thus obtained.

The one which was eluted first was crystallized from ethyl acetate and ligroin and was identified as N^3,N^6-bis(4-benzamido-4-ethoxycarbonylbutyl)-*s*-tetrazine-3,6-diimine (VIII); yield, 31 mg; mp 157—158°C.

Found: C, 59.30; H, 6.10; N, 17.99%. Calcd for $C_{30}H_{36}N_8O_6$: C, 59.59; H, 6.00; N, 18.53%.

IR, ν_{max}^{KBr} 3280, 3050, 2920, 1740, 1633, 1604, 1580, 1540, 1210, 1193 cm^{-1}: $\lambda_{max}^{methanol}$ 222 (ε, 83000), 303 mμ (ε, 7000).

The other product, which was eluted later than VIII with ethyl acetate, was crystallized from ethanol and ligroin and was identified as *N,N'*-di(4-benzamido-4-ethoxycarbonylbutyl)urea (IX); yield, 32 mg; mp 196—197°C.

Found: C, 61.78; H, 7.06; N, 10.26%. Calcd for $C_{29}H_{28}N_4O_7\cdot\frac{1}{2}H_2O$: C, 61.78; H, 6.97; N, 9.94%.

M^+, 554 (weak): IR, ν_{max}^{KBr} 3360, 3260, 1740, 1648, 1605, 1570, 1540, 1490, 1470, 1340, 1260, 1035, 715 cm^{-1}: the acid hydrolysis (acetic acid-conc. HCl (1 : 1), 105°C, 16 hr) of IX gave VI, which was identified by comparison with a sample obtained as has been described in the second section.

When the developing solvent was changed to a mixture of ethyl acetate and methanol (9 : 1), a brownish-colored fraction was rapidly eluted; yield of the residue, 160 mg. No crystalline material was obtained from this dirty fraction. It exhibited a tailing aspect on TLC and may be a mixture of the polymerized products. As in the case of VII, it afforded four amino acids, *i. e.*, III, IV, V, and VI, on acid hydrolysis.

Another product was eluted with the same solvent mixture after the brownish fraction had been eluted and crystallized from ethanol and ligroin. The analytical and spectral data of the compound show that it is N^2-benzoylcitrulline ethyl ester (X), with one mole of succinimide as an adduct; yield, 90 mg; mp 196—197°C.

Found: C, 56.04; H, 6.27; N, 13.79%. Calcd for $C_{19}H_{26}N_4O_6$: C, 56.14; H, 6.45; N, 13.79%.

NMR (DMSO-d_6): δ 1.18 (t, J=7Hz, $-O\cdot CH_2\cdot C\underline{H}_3$), δ 1.7 (m, $NH\cdot C\underline{H}_2\cdot C\underline{H}_2\cdot CH\swarrow$), δ 2.4 (partially overlapped with the peak of DMSO, $2C\underline{H}_2$ of succinimide), δ 3.2 (m, $-NH\cdot C\underline{H}_2\cdot CH_2-$), δ 4.07 (q, J=7 Hz, $-OC\underline{H}_2$

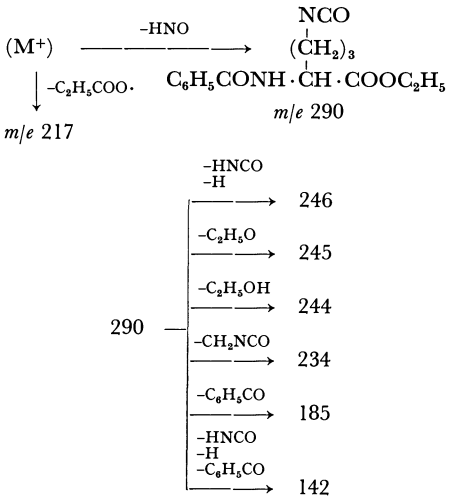
CH_3), δ 4.25 (m, $-CO\cdot NH\cdot C\underline{H}\cdot CH_2-$), δ 6.75 (s, $N\underline{H}$ of succinimide), 7.2—8.0 (complex, $C_6\underline{H}_5CO$), δ 8.30 (t, J=6 Hz, $-NH_2\cdot CO\cdot N\underline{H}\cdot CH_2-$), δ 8.70 (d, J=8 Hz, $C_6H_5\cdot CO\cdot N\underline{H}\cdot CH<$), δ 10.25 (s, $N\underline{H}_2\cdot CO\cdot NH-$): $\lambda_{max}^{methanol}$ 223 mμ (ε, 14200): IR, ν_{max}^{KBr} 3400, 3290, 3060, 2920, 1757, 1688, 1667, 1638, 1550, 1520, 1385, 1250, 1218, 1183, 1160 cm^{-1}: M^+, 307 (weak), M^+-NH_3, 290.1260 (Calcd for $C_{15}H_{18}N_2O_3$, 290.1267), M^+ of succinimide, 99 (intense). On acid hydrolysis (using a mixture of acetic acid and conc. HCl (1 : 1), 105°C, 20 hr) X afforded citrulline, which was identified by comparison with an authentic sample.

The Isolation of N^2-Benzoylornithine (XIII). After the reaction mixture described in the first section had been extracted with ethyl acetate, the volume of the aqueous layer was diluted to 100 m*l* and 4 g of sodium hydroxide were added. After the solution had been heated at 100°C for 2 hr, it was passed through an IR 120 (H-cycle) column (3×50 cm). With 1N aqueous ammonia a ninhydrin-positive fraction was eluted; it was shown to be almost homogeneous on TLC. Further purication was effective with chromatography on a CM Sephadex column (2×90 cm) using a 0.4N pyridine solution buffered at pH 5.0 with acetic acid. After the solvent had been evaporated, the residue was crystallized from water and ethanol; yield, 33 mg; mp 227—228°C.

Found: C, 60.48; H, 6.44; N, 11.76%. Calcd for $C_{12}H_{16}N_2O_3$: C, 61.00; H, 6.83; N, 11.86%. NMR (D_2O) δ 1.85 (complex, $-CH_2\cdot C\underline{H}_2\cdot C\underline{H}_2\cdot CH<$), δ 3.02 (t, J=6 Hz, $-NH\cdot C\underline{H}_2\cdot CH_2-$), δ 4.38 (t, J=6 Hz, $-CH_2\cdot C\underline{H}\cdot NH\cdot CO-$) δ 7.6 (complex, $-C_6\underline{H}_5$): IR, ν_{max}^{KBr} 3350, 2900, 1652, 1633, 1590, 1532, 1495, 1465, 1410, 1370, 1345, 1307, 1299 cm^{-1}. The methyl ester of XIII, prepared by the method of McLaffaty *et al.*[8], afforded the expected parent peak at 250. The acid hydrolysis of XIII (6N HCl, 105°C, 16 hr) afforded ornithine, which was identified by comparison with an authentic sample.

2-Benzamido-5-(2-nitrosoformamido)valeric Acid Ethyl Ester (XV). The reaction mixture described in the first section was extracted with ethyl acetate, the solvent was evaporated, and the residue, after dried *in vacuo*, was dissolved in hot benzene. Usually on standing in a refrigerator only an oily substance was separated. However, in a few cases a small amount of crystals was obtained; yield 10 mg; mp 183—184°C. The effort to create conditions which would give a good reproducibility in obtaining the compound was unfruitful. The attempt to separate the same compound by means of silicic acid chromatography was also unsuccessful. Though the sample obtained was too scanty to make a full identification, the analytical and spectral data suggested it to be 2-benzamido-5-(2-nitrosoformamido)valeric acid (XV).

Found: C, 53.23; H, 5.93; N, 12.53%. Calcd for $C_{15}H_{19}N_3O_5\cdot H_2O$: C, 53.09; H, 6.24; N, 12.39%. The parent peak was not observed: M^+-HNO, 290.1258 (calcd for $C_{15}H_{18}N_2O_4$ 290.1267). Other fragmentations, the compositions of which were confirmed by high-resolution MS, are shown in Scheme 5. IR, ν_{max}^{KBr} 3440, 3340, 3200, 3120, 3000, 1733, 1687, 1640, 1615, 1580, 1537, 1443, 1345, 1222, 1203, 1028, 710 cm^{-1}.



Scheme 5

The author wishes his hearty thanks to Dr. S. Suzuki, the chief of the Laboratory of Antibiotics, this institute, for his kindly giving him a chance to study on this subject and for his encouragement, and to Dr. S. Emoto, this institute, and Dr. N. Okuyama, Tokyo Metropolitan University, for their useful suggestions.

Lactone Carboxylic Acids. VII. Reaction of Lactone Pyrazolines with Acetic Anhydride. A Preparation of Lignans Skeleton by Thermal Decomposition of Pyrazoline

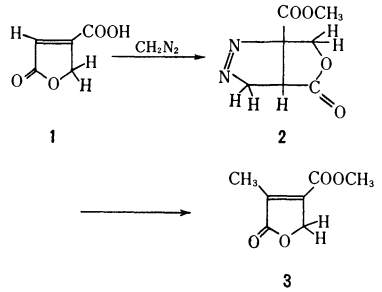
Sigeru Torii and Takuya Furuta

Department of Industrial Chemistry, Okayama University, Okayama

(Received February 9, 1970)

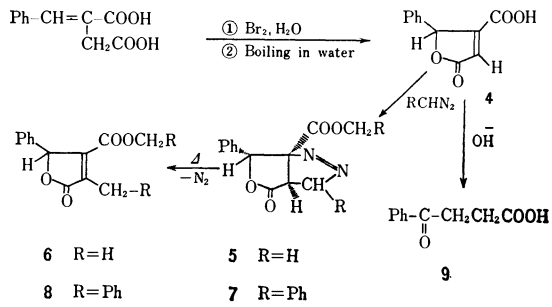
Cycloaddition of diazomethanes to aconic acids (**4** and **14**) gave 1-pyrazolines (**5**, **7** and **15**). Thermal decomposition of **7** afforded γ-phenyl-α-benzylaconic acid **8** having a lignans skeleton. By the action of phosphoric acid **5** was converted into 2-pyrazoline **12**. The chemical nature of pyrazolines (**5** and **12**) is discriminated by treatment with acetic anhydride in the presence of *p*-toluenesulfonic acid. Thus, 1-pyrazoline **5** gave the corresponding derivatives (**10**, **11** and **13**), and **12** gave **13**. The thermochemical stability of the pyrazolines (**15** and **16**) were also studied. A possible mechanism of the formation of **10** and **13** is described.

In the preceding paper of this series, the synthesis of γ-butyrolactones having lignans skeleton was reported.[1] The present paper describes an alternative route to ligans-like compounds and some new properties of pyrazoline derivatives[2] obtained by the addition of diazomethanes to aconic acid (**4** and **13**).



1 **2** **3**

The reaction of aconic acid **1** with diazomethane gives the corresponding pyrazoline **2** which undergoes thermal decomposition to afford **3**.[3] The applicable mode of cycloaddition of diazomethane to aconic acid has led to an extensive study on the preparation of lignans.[4] γ-Phenylaconic acid **4**, obtained in good yield by treatment of α-benzylidenesuccinic acid[5] with bromine in water followed by hot water, was characterized by the absorption spectrum: 1733 (carbonyl $\nu_{C=O}$) and 1645 cm^{-1} and by hydrolysis[6] with alkali to γ-keto acid **9**.[7]



6 R=H **5** R=H **9**

8 R=Ph **7** R=Ph

Scheme I

The adduct[8] of **4** with diazomethane gave **6** in a quantitative yield, when heated at 145°C for 30 min. Similarly, phenyldiazomethane[9] in the same reaction yielded crystalline pyrazoline **7** which was subjected to thermal decomposition to give **8**. The structural assignment of **8** was carried out by the infrared and NMR spectra which revealed the pres-

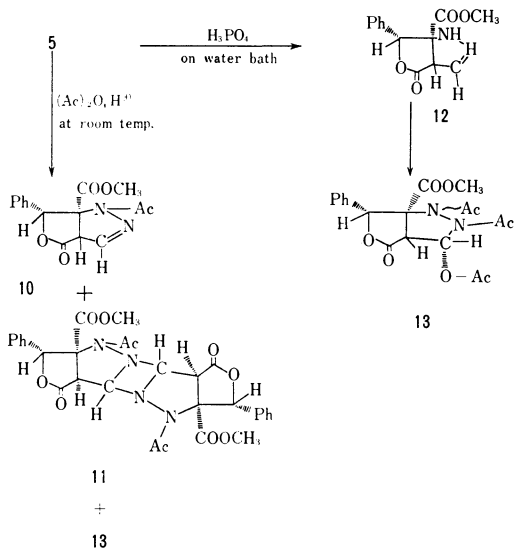

Scheme II

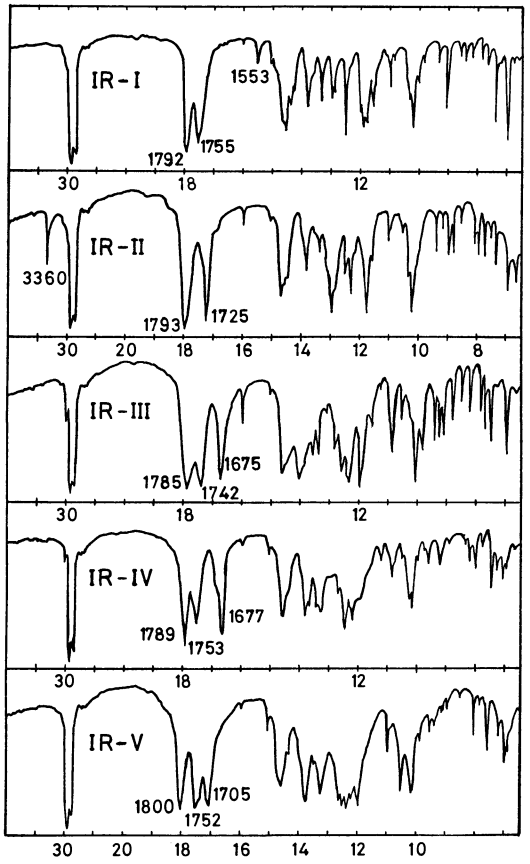

Fig. 1. IR spectra of the key compounds are as follows: IR-I, methyl γ-phenyl-α,β-(1-pyrazolino)-paraconate **5**; IR-II, methyl γ-phenyl-α,β-(2-pyrazolino)paraconate **12**; IR-III, *N*-Acetyl-2-pyrazoline **10**; IR-IV, Dimer of **10**; IR-V, the compound **13**.

ence of lactone, ester and double bond functions, 1785, 1725 and 1670 (shoulder) cm^{-1}, respectively, and also the presence of two kinds of methylene group (C=C-CH_2-Ph, τ 7.00, q, and -O-CH_2-Ph 5.03, q).

Many papers concerning cycloaddition of diazoalkanes to suitable unsaturated compounds have recently appeared.[2,10] However, concerning the isolation of the products, it was difficult to obtain the tautomers concurrently,[11] *i. e.*, 1-prazolines and 2-pyrazolines,[2] and the reactivities of these tautomers have not yet been examined. 2-Pyrazolines **12**, readily obtained by the treatment of **5** with phosphoric acid[12] at 70—80°C, can be distinguished by its infrared spectrum as shown in Fig. 1, since instead of the absorption band at 1553 cm^{-1} due

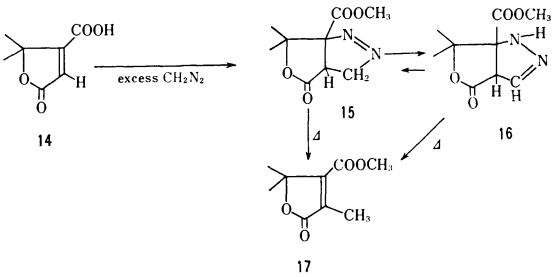
a) Purification was performed by column chromatography (see Experimental).
b) Separation and purification were carried out by preparative vpc.

to the diazo group[8a,13] of **5** a new band at 3360 cm^{-1} (ν_{NH}) was observed. Concerning the ester carbonyl of **12** the hydrogen bonding of the imino group may cause a shift of the absorption band from 1755 to 1725 cm^{-1}.

A mixture of 1-pyrazoline **5** and acetic anhydride in the presence of *p*-toluenesulfonic acid, on standing at room temperature for 24 hr, gave three compounds (**10**, **11**, and **13**) with a ratio of 90 : 7 : 3, respectively, whereas 2-pyrazoline **12** in the same treatment gave **13** exclusively. An attempt to prepare similar derivatives using acetic anhydride, upon standing for 2 days at room temperature, was unsuccessful.[13b,14]

The structural assignments of **10**, **11** and **13** were based on spectral and microanalytical data. The infrared spectrum of **10** shows a normal absorption band at 1742 cm^{-1} consistent with ester carbonyl owing to the loss of the hydrogen-bridge with the imino group observed on **12**. The NMR spectrum of **10** reveals that the proton at γ-position of the lactone ring is affected with the deshielding effect of acetyl carbonyl as shown in Fig. 2. Similarly, the NMR spectrum of **13** (Fig. 2) indicates that the deshielding effect of the neighbouring *N*-acetyl group is also expected to affect the hydrogen atom attached to the C_3 carbon atom and causes a pronounced shift to the lower field, while the shielding effect of the acetoxy group shifts the signal of the CH_α proton upfield. A structure of **11** for one of the minor products, mp 218—220°C, 7% of yield, consistent with the spectral and microanalytical evidences (See Table 1), is considered tentatively as a dimer of **5**. The infrared spectrum of **11** (Fig. 1) is subequal to that of **5**. The NMR spectrum of **5** shows a complex pattern, but number of the whole protons appearing in the chart of Fig. 2 coincides exactly with that of **11**.



Scheme III

The thermochemical stability about the tautomers (**15** and **16**) was found to be structure dependent when examined by vpc, since most of **15** was converted into **17** smoothly, whereas about 20% of change for **16** was noted as indicated in Table 2. It seems that the conversion of **16** into **17** may proceed *via* 1-pyrazoline **15**.[15] The partial change from **15** to **16** occurred spontaneously during storage.

As illustrated in Scheme IV, a mechanistic consideration of the formation of **10** and **13** involves the assumption that **12** is first protonated and then followed by combination with anionic acetoxy group to give **19**, which leads to **13** by further *N*-acetylation. On the other hand, the formation of **10** seems to result from a direct attack of cationic acetyl group on **5** owing to the weak polarization

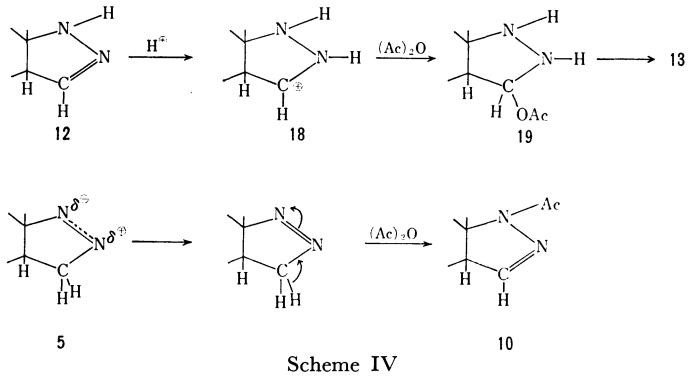

Scheme IV

of the azo bond. In the course of the reaction from **12** to **18** the dimer **11** may be obtained by addition of **12** with the cation intermediate **18**.

Table 2

Compound		Product, yield (%)		
		15	**16**	**17**
A	**15**	0	10	90
	16	0	80	20
B	**15**	40	60	0

A: Passing on vpc column, SE-30, 3 m long at 160°C;
B: Standing for 1 month at room temperature.

Experimental[16]

Preparation of γ-Phenylaconic Acid 4. To a suspension of α-benzylidenesuccinic acid[5] and 50 m*l* of water 6.3 m*l* of bromine was added with stirring for 2 hr at room temperature and then stirred for an additional 10 hr. After the precipitate was filtered the crude solid was allowed to react with boiling water. From the aqueous layer separated by decantation, after cooling to room temperature, the precipitates were collected and recrystallized from benzene giving 12.7 g (64% based on the dicarboxylic acid) of **4**, mp 142—143.5°C; IR (Nujol) 3300—2400 (COOH), 1733 (lactone C=O), 1700 (COOH, shoulder), 1645 (C=C), 1220, 990 and 690 cm^{-1}.

β-Benzoylpropionic Acid 9 from 4. A solution of **4** (1 g) in 50 m*l* of 0.1N ethanolic sodium hydroxide solution was allowed to stand for 0.5 hr. After acidification of the alkaline solution with dilute sulfuric acid, β-benzoylpropionic acid **9** was obtained in a quantitative yield. The IR spectrum of **9** was identical with that of the authentic sample;[7] IR 1710 (acid C=O), 1675 (ketone C=O) cm^{-1}.

Methyl γ-Phenyl-α,β-(1-pyrazolino)paraconate 5. To an ethereal solution of **4** (1 g) excess diazomethane solution was added. After standing for 10 min removal of the solvent gave **5** in a quantitative yield, which on crystallization from benzene-*n*-hexane melted at 141.8°C; IR (Nujol) 1792 (lactone C=O), 1755 (ester C=O), 1553 (-N=N-) cm^{-1}; UV λ_{max}^{EtOH} 324 mμ (ε_{max} 298) and 289 mμ (ε_{max} 270)[13c]; NMR ($CDCl_3$) τ 2.62 (5H s, C_6H_5), 3.58 (1H s, CH_γ), 4.64 and 5.61 (2H each q, $C-CH_aH_b-N=N$, J_{AB}=18.0, J_{AC}=8.7, J_{BC}=2.3 Hz), 6.19 (3H s, $-OCH_3$), 6.54 (1H q, $CH_c-C-N=N$).

Thermal Decomposition of 5. Pyrolytic decomposition of **5** was carried out by heating at 145—150°C for 30 min. Distillation of the residue afforded 1.6 g (*ca.* 90%) of methyl α-methyl-γ-phenylaconate **6**, bp 120°C/0.001 mmHg; IR 1766 (lactone C=O), 1725 (ester C=O), 1665 (C=C) cm^{-1}; UV λ_{max}^{EtOH} 217 mμ (ε_{max} 15000); NMR ($CDCl_3$) τ 7.77 (3H d, CH_3), 6.35 (3H s, $-OCH_3$), 4.05 (1H q, CH_γ), 2.78 (5H m, C_6H_5). A long range coupling (J=1.9—2.0 Hz) between methyl protons at α-position and a proton at γ-position was observed.

Benzyl γ-Phenyl-α,β-(3-phenyl-1-pyrazolino)paraconate 7. To an ethereal solution of **4** (1 g) excess phenyldiazomethane solution,[9] prepared from the oxidation of an ethereal solution of benzaldehydrazone with silver oxide, was added. After standing for 30 min the solid precipitated was filtered and recrystallized from benzene giving 1.7 g (88%) of **7**, mp 143°C (decomp); IR (Nujol) 1785 (lactone C=O), 1755 (ester C=O), 1553 (-N=N-) cm^{-1}; NMR ($CDCl_3$) τ 6.57 (1H d, CH_α), 4.78 (2H d, $O-CH_2-Ph$), 4.78 (1H d, CH-Ph), 3.67 (1H s, CH_γ), 2.70 (15H m, C_6H_5).

Thermal Decomposition of 7. Decomposition of **7** at 145—155°C for 30 min gave **8** in good yield. Purification of the crude product of **8** was performed on column chromatograph with Wako Gel-C200 using benzene-acetone-*n*-hexane (8 : 1 : 1.5) as an elute; IR 1785 (lactone C=O), 1725 (conjugated ester C=O), 1670 (C=C shoulder) cm^{-1}; UV λ_{max}^{EtOH} 225 mμ (ε 6600), NMR ($CDCl_3$) τ 6.97 and 7.20 (2H d, CH_AH_BPh J_{AB}=5.4 Hz), 5.10 and 5.21 (2H d, OCH_AH_BPh J_{AB}=7.8 Hz) 3.91 (1H s, CH_γ), 2.87 (15H m, C_6H_5).

Isomerization of 5. A mixture of **5** (0.5 g) and 20 m*l* of phosphoric acid was heated slowly with stirring for 10—15 min at 70—80°C. Upon cooling to room temperature, the reaction mixture was diluted with 50 m*l* of water and then the organic layer was taken up in ether. The extracts were washed with aqueous sodium chloride, next with saturated sodium bicarbonate solution and finally with sodium chloride solution, and

16) All melting and boiling points are uncorrected. Infrared spectra were determined with a Hitachi EPI-S2 and ultraviolet spectra on a Hitachi EPS-3T spectrophotometer. NMR spectra were obtained on a Japan Electron Optics Laboratory spectrometer (JNM-C-60) in deuteriochloroform with TMS as internal standard. Microanalyses were performed by Mr. E. Amano of the Department of Synthetics Chemistry in this Faculty and the results are listed in Table 1.

dried on Na_2SO_4. Removal of the solvent gave 0.4 g (80%) of 2-pyrazoline **12**, mp 106°C; IR (Nujol) 3360 (>NH), 1793 (lactone C=O), 1725 (ester C=O), 1600 (-C=N-) cm^{-1}; NMR ($CDCl_3$) τ 6.17 (3H s, $-OCH_3$), 5.52 (1H d, CH_α), 4.33 (1H broad, >NH), 4.09 (1H s, CH_γ), 3.27 (1H d, N=CH-), 2.68 (5H m, C_6H_5).

Acetylation of 1-Pyrazoline 5. A mixture of **5** (1 g) and 10 m*l* of acetic anhydride in the presence of a small amount of *p*-toluenesulfonic acid was kept for 24 hr at room temperature. After the reaction mixture was diluted with 20 m*l* of water and neutralized with solid sodium bicarbonate to pH 8, the organic layer was extracted with ether. The extracts were washed with saturated sodium chloride solution and dried on Na_2SO_4. Removal of the solvent gave 1 g of crude crystals which were allowed to dissolve in a hot solution of benzene-*n*-hexane (1 : 1), then standing for several hours, to give **10**. The filtrate, when allowed to stand for another day, gave **11**. After the filtrate was concentrated, 3 m*l* of hot benzene-*n*-hexane (2 : 3) was added. On cooling to room temperature, **13** was precipitated. Total yield of **10**, **11**, and **13** was in the ratio of 90 : 7 : 3. The ultraviolet spectrum of **11** showed two absorption bands at λ_{max}^{EtOH} 258 mμ (ε 5200) and 407 mμ (ε 240), whereas that of **10** showed an absorption at λ_{max}^{EtOH} 246 mμ (ε 7600). The infrared and NMR charts of these compounds (**10**, **11**, and **13**) are illustrated in Figs. 1 and 2. The physical constants together with microanalytical results are indicated in Table 1.

Acetylation of 12. Acetylation of **12** (0.2 g) was carried out in a similar manner as for **5**. After the usual treatment, 0.2 g of **13** was obtained.

Preparation of 15. To an ethereal solution of γ,γ-dimethylaconic acid **14**[17] excess diazomethane solution was added. After standing for 30 min, removal of the solvent gave **15** in a quantitative yield which melted at 50.5—51.5°C; IR (Nujol) 1775 (lactone C=O), 1735 (ester C=O) and 1558 (N=N) cm^{-1}; UV λ_{max}^{EtOH} 328 mμ (ε 210); NMR ($CDCl_3$) τ 4.72 and 5.24 (2H each q, C-CH_aH_b-N=N, J_{AB}=18.0, J_{AC}=8.0, J_{BC}=1.5 Hz), 6.12 (3H s, $-OCH_3$), 6.36 (1H q, CH_c-C-N=N), 8.40 and 8.09 (6H each s, gem CH_3).

Thermal Isomerization of 1-Pyrazoline 15 and 2-Pyrazoline 16 on VPC Column. When **15** was passed on 10% Diasolid-L Silicone (SE-30) coated column with a 3 m long, carrier gas H_2, 20 m*l*/min, operating at 160°C, two peaks of **17** and **16** were observed in a ratio of 9 : 1 (Rt: 5 and 17 min, respectively). Each component was isolated by VPC preparatively. On the other hand, the purified **16**, when passed on the same column in the similar condition, gave two peaks of **16** and **17** in a ratio of 4 : 1. These data are indicated in Table 2. The microanalyses of both **15** and **16** are recorded in Table 1. The spectral data are as follows: methyl γ,γ-dimethyl-α,β-(2-pyrazolino)-paraconate **16**, IR 3320 (NH), 1770 (lactone C=O), 1736 (ester C=O), 1588 (C=N-) cm^{-1}; NMR ($CDCl_3$) τ 8.57 and 8.40 (6H s, $-CH_3$), 6.16 (3H s, $-OCH_3$), 5.43 (1H d, CH_α J=2.6 Hz), 3.24 (1H, broad, CH=N), 2.5—4.0 (1H broad, NH); methyl γ,γ-dimethyl-α-methylaconate **17**, IR 1765 (lactone C=O), 1724 (conjugated ester C=O), 1661 (C=C) cm^{-1}; NMR ($CDCl_3$) τ 8.40 (6H s, $-CH_3$), 7.28 (3H s, α-CH_3), 6.07 (3H s, $-OCH_3$).

The authors wish to express their thanks to Professor Akira Takeda, Department of Synthetics Chemistry, for helpful discussions and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2549—2553 (1970)

The Condensation Reactions of Bivalent Sulfur Compounds-Copper(II) Complexes with Nucleophiles

Teruaki MUKAIYAMA, Koichi NARASAKA, Kazuo MAEKAWA and Hisao HOKONOKI

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 10, 1970)

It was found that the bivalent sulfur compounds such as benzaldehyde diethylmercaptal, benzophenone diethylmercaptole, ethyl orthotrithioformate and benzyl methylsulfide, react with copper(II) salts of 1,3-dicarbonyl compounds, active methylene compounds or anisole, in the presence of cupric chloride, to give condensation or substitution products in good yields accompanied with carbon-sulfur bond cleavage. On the other hand, in the absence of cupric chloride, the bivalent sulfur compounds underwent no reaction and the starting materials were recovered. These results can be explained by assuming initial formation of active complexes from the bivalent sulfur compounds and copper(II).

The condensation reactions of bivalent sulfur compounds, such as benzaldehyde diethylmercaptal [Ia], benzophenone diethylmercaptole [Ib] and ethyl orthotrithioformate [Ic], with active methylene compounds were reported briefly in a previous paper[1]. In the present report, these reactions are explained in detail with new results.

The new condensation reaction of carbon-carbon bond formation accompanied with carbon-sulfur bond cleavage was carried out on the assumption that the bivalent sulfur compound would be activated by coordination with the so-called soft acids,[2] such as Cu(II), Ag(I) and Hg(II), forming a reactive complex. Copper(II) was chosen as the acid because it has a soft character and is known to form mercaptide easily. The coordinated compounds of bivalent sulfur compounds and copper(II) would act as an electrophile and cleavage of the carbon-sulfer bond would occur without difficulty. Based on this assumption, the condensation reactions of the bivalent sulfur compounds [I] with nucleophilic reagents, such as copper(II) salts of 1,3-dicarbonyl compounds [II], active methylene compounds and anisole, were studied in the presence of cupric chloride.

Little work has been done on a synthetic study with the used of copper(II) salts of 1,3-dicarbonyl compounds [II] since they are very stable toward electrophiles.[3] For example, it is known that alkyl halide does not react with the copper(II) salts [II]. Instead, the condensation reaction occurs when 1,3-dicarbonyl compound is used as an alkali metal salt. In this reaction, *O*-substituted compound is always accompanied with *C*-substituted compound. On the other hand, when copper(II) salt is used for alkali metal salt, it is expected that the copper(II) atom would protect the *O*-position by chelation. Therefore, *C*-substituted products would result exclusively by treating copper(II) salts with bivalent sulfur compounds [I] under a nearly neutral condition.

At first, bis(acetylacetonato)copper(II) [IIa] and ethyl orthotrithioformate [Ic] were refluxed in dioxane, but the reaction did not occur and the starting materials were recovered quantitatively. However, when a half molar amount of cupric chloride was added to the tetrahydrofuran [THF] solution of Ic and IIa, the blue precipitate of IIa disappeared and a green precipitate appeared immediately. After being stirred for 8 hr and kept standing overnight, the green precipitate disappeared and a grey substance deposited. After filtration of the substance and purification by silica gel column chromatography and distillation, the condensation product, 3-(α-ethylthioethyl-

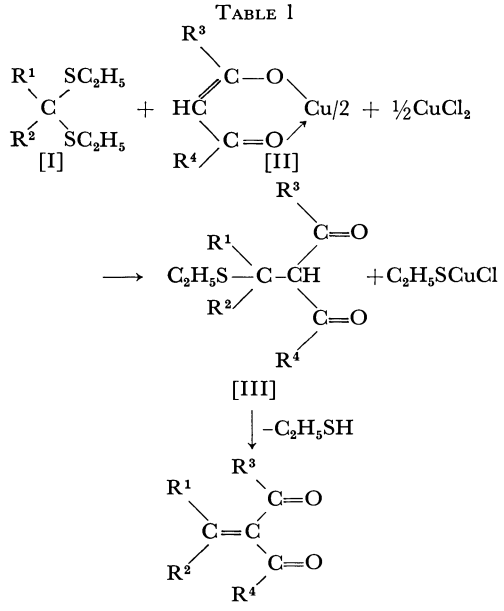
idene)-pentane-2,4-dione [IVca] was obtained in 65% yield.

Similarly, bivalent sulfur compounds [Ia,b,c] reacted with copper(II) salts of 1,3-dicarbonyl compounds such as acetylacetone [IIa], dibenzoylmethane [IIb] or ethyl acetoacetate [IIc] in the presence of cupric chloride at room temperature and the condensation products, [III] or [IV], were obtained. The results are shown in Table 1.

TABLE 1

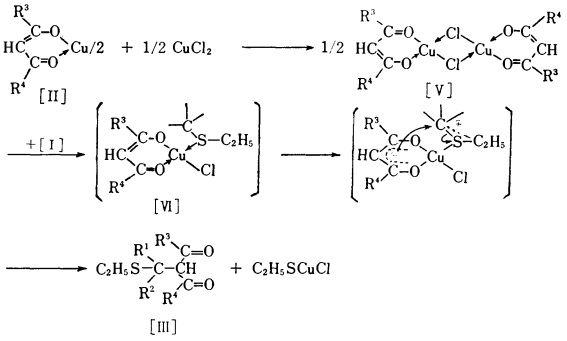


[I] R¹	[I] R²	[II] R³	[II] R⁴	Yield, % (III)	Yield, % (IV)
H	C_2H_5S	CH_3	CH_3		65
H	C_6H_5	CH_3	CH_3	92	
C_6H_5	C_6H_5	CH_3	CH_3	55	
H	C_2H_5S	C_6H_5	C_6H_5	73	
H	C_6H_5	C_6H_5	C_6H_5	82	
H	C_2H_5S	CH_3	OC_2H_5	58	
H	C_6H_5	CH_3	OC_2H_5		46

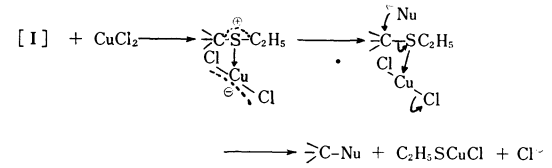
In all cases, *C*-substituted products were produced exclusively, as expected, and no detectable amount of *O*-substituted product was obtained.

In the absence of cupric chloride, the sulfur compounds [I] did not react with copper(II) salts [II] even at an elevated temperature, while, in the presence of cupric chloride the reaction proceeded smoothly under a mild condition.

This may be explained by assuming a double nuclear complex [V][4] of copper(II) salts [II] and cupric chloride. [V] readily affords chelate [VI] by coordination to a sulfur atom of bivalent sulfur compound [I]. Chelate [VI] thus formed decomposes into a condensation product [III] and ethylmercapto cupric chloride by way of an internal nucleophilic displacement as described in the following equation.



The result suggests that a complex of bivalent sulfur compounds [I] and cupric chloride would act as an electrophile and react with nucleophilic reagent [$Nu^{\ominus}$] giving a condensation product [$\geqslant$C–Nu] and ethylmercapto cupric chloride as shown below.



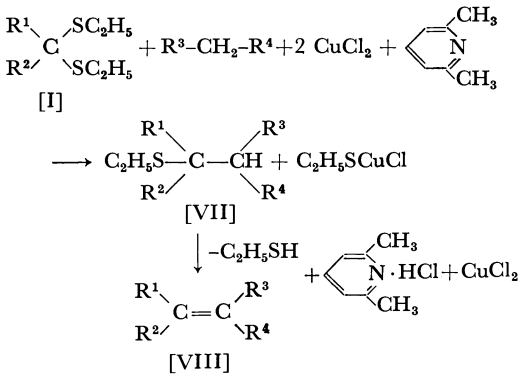
Based on this assumption, the reactions of sulfur compounds [I] and active methylene compounds in the presence of cupric chloride were investigated. Acetylacetone and benzaldehyde diethylmercaptal [Ia] were allowed to react for 12 hr at room temperature in the presence of 2 equimolar amounts of cupric chloride and an equimolar amounts of 2,6-lutidine, a hydrogen chloride catcher, in THF. After removal of the precipitate by filtration and purification by silica gel column chromatography, 3-(α-ethylthiobenzyl)pentane-2,4-dione was isolated in 79% yield as a white crystal. Similarly, 1,3-indandione, malononitrile or ethyl malonate reacted with sulfur compounds [Ia,b,c] to give condensation products, [VII] or [VIII]. The results are summarized in Table 2.

By this procedure, the condensation products can be directly prepared from 1,3-dicarbonyl compunds and sulfur compounds [I], without preparation of their copper(II) salts. It was confirmed that malononitrile and 1,3-indandione, which do not form their copper(II) salts, can react with sulfur compounds [I] in this way.

In the cases of cyclohexanone and benzaldehyde diethylmercaptal [Ia], a similar reaction did not occur and the starting materials were recovered. On the other hand, when they were refluxed in ether in the presence of 4 equimolar amounts of cupric chloride and a catalytic amount of Et_2O·

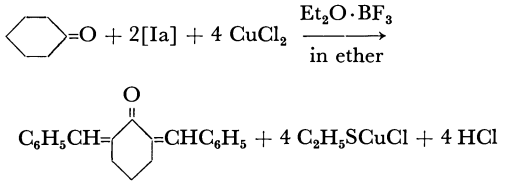
4) The double nuclear complex of IIa and cupric chloride, μ-dichloro-bis(acetylacetonato)dicopper(II), was isolated as a green precipitate by treating equimolar amounts of IIa and cupric chloride in THF under a dry nitrogen atmosphere. Elemental analysis gives $(C_5H_7O_2CuCl)_n$. It was found that the complex is readily hydrolyzed to give IIa and cupric chloride.

Table 2



[I]		Active methylene		Yield, %	
R^1	R^2	R^3	R^4	(VII)	(VIII)
C_6H_5	H	CH_3CO	CH_3CO	79	
C_6H_5	H	CN	CN		62
C_6H_5	H	$COOC_2H_5$	$COOC_2H_5$	63	
C_6H_5	H				53
C_2H_5S	H	CN	CN		45
C_2H_5S	H				62
C_6H_5	C_6H_5	CN	CN		64

BF_3, the condensation product, 2,6-dibenzylidenecyclohexanone [IX], was obtained in 62% yield.

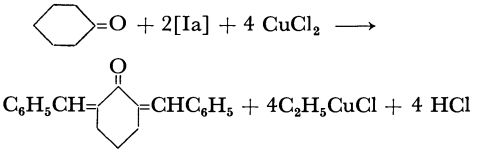


[IX]

The effects of the solvents on this type of reaction were studied by treating cyclohexanone and 2 equimolar amounts of Ia in the presence of 4 equimolar amounts of cupric chloride, in various solvents at room temperature. Among various solvents examined, ethyleneglycoldimethylether afforded the best result and the condensation product [IX] was obtained in 64% yield.

It was found that anisol also reacted with Ia,c and benzyl methylsulfide [XV] in the presence of cupric chloride to afford substituted products. When benzaldehyde diethylmercaptal [Ia] was

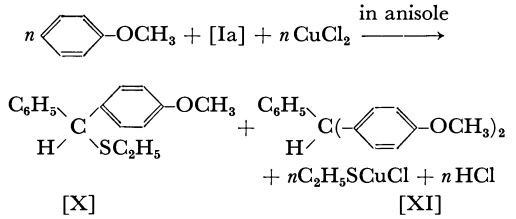
Table 3



[IX]

Solvent	[IX], Yield	Solvent	[IX], Yield
$C_2H_5OC_2H_5$	17%	CCl_4	45%
	15%	$CHCl_3$	28%
$(CH_3OCH_2)_2$	64%	CH_2Cl_2	41%
$(CH_3OCH_2CH_2)_2O$	50%	$(ClCH_2)_2$	35%
C_6H_{12}	24%	$CH_3COOC_2H_5$	53%
C_6H_6	58%	DMSO, DMF	0%

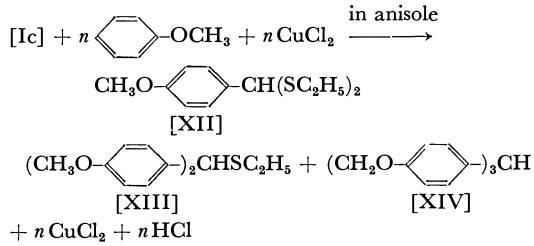
treated in the presence of an equimolar amount of cupric chloride in anisole, even at room temperature, hydrogen chloride evolved vigorously and after purification by silica gel column chromatography, a monosubstituted compound, anisylphenylmethyl ethylsulfide [X] and a disubstituted product, dianisylphenylmethane [XI] were obtained in 62% and 19% yields, respectively. When the molar ratio of cupric chloride to Ia was increased to 2 or 3, the disubstituted compound [XI] only was formed in a good yield according to the following equation.



[X] [XI]

	Yield, %	
	[X]	[XI]
$n=1$	62	19
$n=2$		83
$n=3$		100

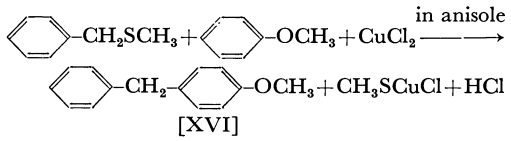
Similary, ethyl orthotrithioformate [Ic] reacted with anisole to give the following products.



[XII] [XIII] [XIV]

	Yield, %		
	[XII]	[XIII]	[XIV]
$n=1$	5	31	
$n=2$			32
$n=3$			38

It was also confirmed that anisylphenylmethane [XVI], was obtained in 51% yield by refluxing benzyl methylsulfide [XV] in anisole in the presence of an equimolar amount of cupric chloride.



[XVI]

Experimental

Material. Commercial cupric chloride was used. It was ground and dried over phosphorus pentoxide *in vacuo* at about 130°C before use. Bivalent sulfur compounds, [Ia,b,c] and [XV] were prepared according to the procedures in literature and purified by distillation.

[Ia][5] 135—136°C/8 mmHg; [Ib][5] 146—150°C/0.07 mmHg; [Ic][6] 129—132°C/14 mmHg; [XV][7] 97—101°C/27 mmHg.

Copper salts of 1,3-dicarbonyl compounds [IIa,b,c] were prepared from cupric acetate and 1,3-dicarbonyl compounds according to general procedure.[8]

Reaction of Bis(acetylacetonato)copper(II) [IIa] with Benzaldehyde Diethylmercaptal [Ia]. Into a suspension of 0.68 g (0.005 mol) of cupric chloride and 1.31 g (0.005 mol) of IIa in dry THF (35 m*l*) was added 2.12 g (0.001 mol) of Ia in one portion. The mixture was stirred for 8 hr and kept standing overnight at room temperature. After removal of 0.69 g of grey precipitate, the filtrate was concentrated under reduced pressure. The residue was then purified by silica gel column chromatography (silica gel column chromatography was used in order to remove ethylmercapto cupric chloride completely.), and a white crystal, 3-(α-ethylthiobenzyl)-pentane-2,4-dione was obtained; 2.20 g (92%), mp 71—72°C (recrystallized from ethanol, mp 71.5—73°C). Found: C, 67.25; H, 7.33; S, 12.88%. Calcd for $C_{14}H_{18}O_2S$: C, 67.18; H, 7.25; S, 12.79%. The infrared spectrum showed a strong absorption band at 1690 cm^{-1} assigned to the C=O group. The NMR spectrum showed absorption bands at τ 8.86 (triplet) 3H, 8.68 (singlet) 3H, 7.68 (singlet) 3H, 7.22 (quartet) 2H, 5.83 (doublet) H, 5.51 (doublet) H and aromatic protons 5H.

Similarly, the condensation products [III] or [IV] were obtained by the reaction of copper(II) salts of 1,3-dicarbonyl compounds [IIa,b,c] with sulfur compounds [Ia,b,c]. Physical properties and analytical data are summarized in Table 4.

Isolation of μ-Dichloro-bis(acetylacetonato)dicopper(II) by the Reaction of Bis(acetylacetonato)-copper(II) [IIa] with Cupric Chloride. When 2.62 g (0.01 mol) of [IIa] and 1.36 g (0.01 mol) of cupric chloride were allowed to react in 200 m*l* of dry THF stirred in a dry nitrogen atmosphere, the blue precipitate of IIa disappeared immediately and a green precipitate appeared soon. The green substance was collected by filtration in a dry nitrogen atmosphere and washed with THF. It was then dried *in vacuo* and analyzed. Found: C, 32.32; H, 4.44; Cl, 17.37%. Calcd for $C_{10}H_{14}O_4Cu_2Cl_2$: C, 33.29; H, 3.91; Cl, 17.90%.

Reaction of Acetylacetone with Benzaldehyde Diethylmercaptal [Ia]. Into a suspension of 2.68 g (0.02 mol) of cupric chloride and 1.07 g (0.01 mol) of 2,6-lutidine in THF (35 m*l*), 1.00 g (0.01 mol) of acetylacetone and 2.12 g (0.01 mol) of Ia were added in one portion. The solution was then stirred for 12 hr and kept standing overnight at room temperature. After filtering off a solid (3.76 g,) the filtrate was evaporated under reduced pressure. Purification of the residue by silica gel column chromatography gave 1.96 g (79%) of 3-(α-ethylthiobenzyl)pentane-2,4-dione (mp 68—72°C), which showed an infrared spectrum identical with that of the authentic sample obtained by the above mentioned reaction.

Similarly, the products [VII] or [VIII] were obtained by treating acetylacetone, malononitrile, ethyl malonate and 1,3-indandione with Ia,b,c. Their physical properties and analytical data are shown in Table 5.

Reaction of Cyclohexanone with Benzaldehyde Diethylmercaptal [Ia] in the Presence of a Catalytic Amount of $Et_2O \cdot BF_3$. 4.24 g (0.02 mol) of [Ia], 0.98 g of cyclohexanone and three drops of $Et_2O \cdot BF_3$ were added to a suspension of 5.44 g (0.04 mol) of cupric chloride in 40 ml of ether. The mixture was refluxed for 2 hr with stirring and kept standing overnight at room temperature. 2,6-Dibenzylidenecyclohexanone [IX] was obtained through the same procedure as described in the above reaction. 1.72 g (62%) (recrystallized from ligroin; mp 115—117°C). Found: C, 87.64; H, 6.40%. Calcd for $C_{20}H_{18}O$: C, 87.56; H, 6.61%.

Reaction of Cyclohexanone with Benzaldehyde Diethylmercaptal [Ia] in Various Solvents. Into a suspension of 2.68 g (0.02 mol) of cupric chloride in 50 m*l* of solvent were added 0.49 g of cyclohexanone and 2.12 g (0.01 mol) of Ia. The mixture was then stirred for 7 hr and kept standing 15 hr at room temperature. The reaction mixture was purified in a similar manner as mentioned above. The yields of IX in various solvents are summarized in Table 3.

Reaction of Anisole with Benzaldehyde Diethylmercaptal [Ia]. A mixture of 6.36 g (0.03 mol) of Ia and 4.08 g (0.03 mol) of cupric chloride in dry anisole (50 m*l*) was stirred at room temperature. Hydrogen chloride was evolved vigorously. A white precipitate (1.07 g) was filtered off and the filtrate was condensed in reduced pressure. Two substances, an oily substance and a white crystal, were separated by silica gel column chromatography. The oily substance was then fractionated, giving 4.73 g (62%) of anisylphenylmethyl ethylsulfide [X]. bp 147—155°C/0.05 mmHg. Found: C, 74.11; H, 6.79; S, 12.13%. Calcd for $C_{16}H_{18}OS$: C, 74.39; H, 7.02 ;S, 12.38%. The white crystal was dianisylphenylmethane [XI]. 1.71 g (19%) (recrystallized from ethanol. mp 96—97°C). Found: C, 82.81; H, 6.35%. Calcd for $C_{21}H_{20}O_2$: C, 82.86; H, 6.62%. The NMR spectrum of both X and XI has only one absorption band assigned to OCH_3 group at τ 6.45 and 6.33, respectively. The results show that *para*-substituted products were obtained exclusively.

Reaction of Ethyl Orthotrithioformate [Ic] with Anisole in the Presence of an Equimolar Amount of Cupric Chloride. A mixture of 3.92 g (0.02 mol) of Ic and 2.72 g (0.02 mol) of cupric chloride in dry anisole (40 m*l*) was stirred for 12 hr and kept standing overnight at room temperature. Through the same procedure as described above, an oily substance was obtained and distilled *in vacuo*. Ic was recovered in 21% and 0.24 g (5%) of methoxybenzaldehyde [XII] (bp 162—164°C/0.08 mmHg) was obtained. In addition to XII, 1.78 g (31%) of dianisylmethylethylsulfide [XIII] was fractionated at 192°C/0.08 mmHg. Found: C, 71.11; H, 7.20; S, 11.10%. Calcd for $C_{17}H_{20}SO_2$: C, 70.81; H, 6.99; S, 11.17%.

Reaction of [Ic] with Anisole in the Presence of Two Equimolar Amounts of Cupric Chloride. When 5.44 g (0.04 mol) of cupric chloride was used in the above experiment, 2.13 g (32%) of trianisylmethane [XIV] was isolated. (recrystallized from ethanol. mp 56—58°C). Found: C, 78.72; H, 6.50%. Calcd for $C_{22}H_{22}O_3$: C, 79.01; H, 6.63%.

Reaction of Benzyl Methylsulfide [XV] with Anisole. When a mixture of 4.14 g (0.03 mol) of XV and 6.00 g (0.044 mol) of cupric chloride in 60 m*l* of dry anisole was refluxed for 11 hr, the color of the solution turned black and a white precipitate was deposited. The precipitate was filtered off and the filtrate was concentrated *in vacuo* and purified by silica gel column chromatography. The eluate was concentrated and distilled, giving 3.02 g (51%) of anisylphenylmethane [XVI] (bp 112—114°C/1.5 mmHg). Found: C, 85.03; H, 7.31%. Calcd for $C_{14}H_{14}O$: C, 84.81; H, 7.12%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2554—2558 (1970)

The Resolution of *N*-Benzyloxycarbonyl-DL-amino Acids Using Ephedrine*1

Katsue Oki, Kuniyoshi Suzuki, Seiichi Tuchida, Tomoo Saito and Hiroshi Kotake

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received February 10, 1970)

The use of ephedrine has here been proposed to be of value in the direct resolution of racemic *N*-benzyloxycarbonylamino acids. By using a half equi-amount of natural (−)-ephedrine, *N*-benzyloxycarbonyl derivatives of β-methyl DL-aspartate, DL-leucine, DL-methionine, and *O*-benzyloxycarbonyl-DL-serine resulted, each in turn producing a salt of the respective D-isomer. On the other hand, DL-isoleucine, *erythro*-β-methyl-DL-leucine, *threo*-*N*,β-dimethyl-DL-leucine, DL-valine, and DL-phenylalanine each produced a salt of each L-isomer with the same base. It should be better to protect, if possible, the third functional groups of three functional amino acids before the resolution. Each antipode of the optically active *N*-benzyloxycarbonylamino acid obtained above was also conveniently produced, in a high optical purity, by using (+)-ephedrine alternately. However, a few limitations on the desirable method of resolution have also been observed.

Varieties of *N*-protecting groups for amino acids have recently been developed by splendid studies of peptide syntheses and have been used well. The *N*-benzyloxycarbonyl group, explored by Bergmann and Zervas in 1932[1], is, however, still one of the most favorable *N*-protecting groups for the sequential synthesis of peptides. The direct resolution of *N*-benzyloxycarbonyl derivatives of racemic amino acids would, therefore, be a much more convenient way of preparing optically active *N*-benzyloxycarbonylamino acids than the route of incorporating the protecting group onto optically active amino acids obtained *via* the appropriate resolution of temporary derivatives of racemic amino acids, *e.g.*, *N*-acetyl ones.

In this paper, the resolution of racemic *N*-benzyloxycarbonylamino acids by using (−)- and (+)-ephedrine alternately and a survey of the resolution will be described. In these experiments, a half equi-amount of ephedrine in relation to racemic *N*-benzyloxycarbonylamino acids was used principally. Although ethyl acetate could be employed as a predominant solvent in many cases, ethyl acetate-petroleum ether (2 : 3v/v) for *N*-benzyloxycarbonyl-DL-leucine and ether for *N*-benzyloxycarbonyl-DL-isoleucine and *N*-benzyloxycarbonyl-DL-phenylalanine were also effectively used in concentrations of *N*-benzyloxycarbonylamino acid and ephedrine of 0.45—4.68 and 0.25—2.58 M respectively. The selection of a suitable solvent for the aforementioned resolution is important, especially in the case of phenylalanine; usually only a racemate or a partially-resolved salt was deposited from a solution in a solvent such as ethyl acetate, benzene, or chloroform, though when ether was used the resolution was favored. The results obtained with salts with natural (−)-ephedrine are listed in Table 1. Of all the amino acids used, *N*-benzyloxycarbonyl derivatives of amino acids without a β-methyl side group—β-methyl DL-aspartate, DL-leucine, DL-methionine, and *O*-benzyloxycarbonyl-DL-serine—deposited to afford predominantly, if not exclusively, salts of the D-isomer of amino acids with natural (−)-ephedrine. Unlike the above cases, however, the same derivatives of amino acids with a β-methyl side group—DL-isoleucine, *erythro*-β-methyl-DL-leucine, *threo*-*N*, β-dimethyl-DL-leucine, and DL-valine—afforded salts bearing a reverse configuration, L, at the α-carbon atom of the amino acids. Entirely opposite results yielding each antipode were attained when (+)-ephedrine was used instead of (−)-base. Thus, it is possible to choose either antibode of ephedrine before the resolution, because it is possible, as a rule, to predict the configutarion of the amino acid to be obtained as an insoluble salt, depending on the presence of a β-methyl side group. This would be especially useful for the resolution of a new amino acid, as we have shown successfully in a preceding paper.[2] In consonance with this view, the preceding observation, made by

*1 Presented, in part, at the 22nd annual meetings of the Chemical Society of Japan, held at Tokyo, April 1969. Copies of the paper are available from T.S. or H.K. on request.

* Represented from our preceding paper.[2]
** All optical rotation values were measured in a solution of absolute alcohol, at 22—27°C.

Overby and Ingersoll,[3] that a salt of *N*-benzyloxycarbonyl-D-alanine with (−)-ephedrine was produced as a less soluble product when *N*-benzyloxycarbonyl-DL-alanine was allowed to react with natural ephedrine in ethyl acetate, also supports our above conclusion. An exception to the rule was, however, observed in the case of phenylalanine, which bears a β-aromatic group but no β-methyl group; thus, a salt of the L-isomer with natural (−)-ephedrine was deposited preferentially. In order to determine the effect of a β-aromatic side group on the resolution, further attempts have been made to resolve *N*-benzyloxycarbonyl-DL-tyrosine and -DL-tryptophan into their respective isomers, but these attempts have so far been unsuccessful. Even if the base was used in a half- or equi-molar amount ratio in various solvents, neither *N*-benzyloxycarbonyl-DL-aspartic acid nor *N*-benzyloxycarbonyl-DL-glutamic acid have provided favorable results. A successful resolution of DL-aspartic acid was, however, achieved by protecting β-carboxyl as its methyl ester. An additional attempt to resolve the γ-methyl DL-glutamate was unsuccessful, though. Similarly, the resolution of DL-serine was performed successfully only when its *N*,*O*-dibenzyloxycarbonyl derivative was employed. Thus, one recommendation, that the third functional groups of amino acids should be protected for the favorable resolution, can be made on the basis of our experiments involving aspartic acid and serine. Each antipode of *N*-benzyloxycarbonylamino acid with an entirely optical purity resulted, when (+)-ephedrine was used alternately, from a solution of the same solvent used in the corresponding case (Table 2), though it could also be produced in an optically active state from the mother liquor obtained after the removal of the

group using hydrogen bromide in glacial acetic acid,[15] followed by neutralization with triethylamine, with the exception of the deprotection of *N,O*-dibenzyloxycarbonyl serine. In the latter case, the protecting groups were removed by catalytic hydrogenation, using palladium-black as a catalyst in ethyl alcohol, in order to avoid any *O*-acylation, which is likely caused by the action of hydrogen bromide in glacial acetic acid.[16] The specific rotations of resolved *N*-benzyloxycarbonylamino acids and free amino acids are listed in Table 3, and their values are compared with those reported in the literature. The specific rotation value of β-methyl *N*-benzyloxycarbonyl-D-aspartate is comparable in magnitude to that of its L-antipode. The value of *N*-benzyloxycarbonyl-L-phenylalanine, along with that of the D-isomer, is relatively higher in magnitude than those reported. A striking difference is found to exist in the optical-rotation values of benzyloxycarbonyl valine reported in the literature; there are only a few values compatible with that of benzyloxycarbonyl valine obtained in this experiment. However, the two isomers of benzyloxycarbonyl valine afforded optically pure L- and D-valine respectively by debrocking.

Experimental

All the melting points are uncorrected. The optical rotation values were measured with a Jasco DIP-SL-type polarimeter.

Starting Materials. *A) (−)- and (+)-Ephedrine Hemihydrate Used Throughout This Work.* Commercially-available (−)-ephedrine hydrochloride, with a specific rotation value of −33.8° in water, was treated with a slight excess of N sodium hydroxide, and the organic base thus liberated was immediately taken up into ethyl acetate. The organic layer was dried over anhydrous sodium sulfate, filtered, and evaporated to dryness *in vacuo* to afford a crystalline material. This was then recrystallized from petroleum ether and dried spontaneously under an atmosphere to give (−)-ephedrine hemihydrate as needles; the melting point was 39—40°C, $[\alpha]_D = -5.8°$ in water. Found: C, 68.80; H, 9.14; N, 8.09%. Calcd for $C_{10}H_{15}ON \cdot 1/2H_2O$: C, 68.93; H, 9.26; N, 8.04%. Similarly, from (+)-ephedrine hydrochloride ($[\alpha]_D = +33.1°$ in water), (+)-ephedrine hemihydrate was obtained; mp 40°C, $[\alpha]_D = +5.9°$ in water. (Found: C, 69.29; H, 9.27; N, 8.21%).

B) N-Benzyloxycarbonyl Derivatives of Racemic Amino Acids. The compounds were prepared, in excellent yields, by the generally-applicable Schotten-Baumann method. Recrystallization from appropriate solvents afforded pure products as follows [name of *N*-benzyloxycarbonyl-DL-amino acid, mp°C, (lit, mp°C).]: β-methyl DL-aspartate, 110—112°C, (112°C).[17] DL-Isoleucine, 64—66°C, (48°C[18]). *erythro*-β-Methyl-DL-leucine, 62—64°C.[2] *threo-N,β*-Dimethyl-DL-leucine, 79°C.[2] DL-Leucine, 53—54°C, (52—55°C[4]). DL-Methionine, 112°C, (112°C[4]). DL-Phenylalanine, 102°C, (103°C[4]). *O*-Benzyloxycarbonyl-DL-serine, 93°C, (94°C[4]). DL-Valine, 74—75°C, (76—78°C[4]).

General Procedure for the Resolution of *N*-Benzyloxycarbonyl-DL-amino Acids. To a solution of 0.100 mol of *N*-benzyloxycarbonyl-DL-amino acid in ethyl acetate at a suitable concentration, depending on the amino acid employed, as will be shown below individually, 0.055 mol of (−)-ephedrine hemihydrate was added; then the solution was allowed to stand at room temperature (or stored in a refrigerator in some cases) until there was an adequate amount of a precipitate (this took from several hours to several days, depending on the materials employed.). The precipitate was collected by filtration and washed with ethyl acetate. An almost pure product was recrystallized from ethyl acetate to afford a fine salt of optically active *N*-benzyloxycarbonylamino acid with (−)-ephedrine (Table 1).

The suitable solvents and concentrations for *N*-benzyloxycarbonylamino acid favored for the resolution were as follows [name of *N*-benzyloxycarbonylamino acid, solvent (ethyl acetate was used unless stated otherwise), concentration in mole (M)]: β-methyl DL-aspartate, 0.45. DL-Isoleucine, ether, 2.49. *erythro*-β-Methyl-DL-leucine, ether, 2.00. *threo-N,β*-Dimethyl-DL-leucine, 1.00. DL-Leucine, ethyl acetate - petroleum ether (2 : 3 V/V), 2.62. DL-Methionine, 2.46. DL-Phenylalanine, ether, 0.17. *O*-Benzyloxycarbonyl-DL-serine, 1.00. DL-Valine, 4.68.

The above mother liquor was washed with a small amount of N hydrochloric acid and then water. The organic layer was dried over anhydrous sodium sulfate and evaporated to dryness *in vacuo*. The residue thus obtained was redissolved in a half volume of the same solvent as was used in the initial resolution stage, and 0.055 mol of (+)-ephedrine was added. The solution was then allowed to stand. The deposition of salt was usually much faster than in the initial case. The precipitate was filtered and washed with ethyl acetate. Recrystallization from ethyl acetate gave pure antipodal salt (Table 2).

Liberation of Optically Active *N*-Benzyloxycarbonylamino Acids from Salts. A suspension of the salt of optically active *N*-benzyloxycarbonylamino acid with ephedrine in ethyl acetate was treated with a slight excess of 2N hydrochloric acid, and the organic layer was washed with a small amount of water. The solution of ethyl acetate was then dried over anhydrous sodium sulfate. After filtration, the filtrate was evaporated to dryness *in vacuo* to give an almost optically pure material. Recrystallization from an appropriate solvent was performed to afford pure materials (Table 3).

Regeneration of Free Amino Acids Bearing Entirely Optical Activities. *A)* According to the usual way, optically active *N*-benzyloxycarbonylamino acid was dissolved in threefold equi-amounts of 30% hydrogen

bromide in glacial acetic acid. After about one hour, much anhydrous ether was added and deposition was collected by fitration. A solution of the resulting hydrobromide in ethyl alcohol was neutralized with triethylamine to deposit free amino acid. This was recrystallized from water or water–ethyl alcohol to give optically pure amino acids (Table 3).

B) In the case of serine, optically active *N,O*-dibenzyloxycarbonylserine was dissolved in ethyl alcohol and a palladium-black catalyst was added. Hydrogenolysis was carried out under slight pressure for 6 hr at room temperature with the aid of an efficient shaking machine. Then the catalyst, with the substance adhering to it, was filtered and the product was separated from the catalyst by extraction with hot water. To the aqueous solution, dioxane was added to complete the precipitation. Recrystallization from water and acetone afforded optically active serine (Table 3).

The authors wish to express their gratitude to Dr. Eishin Kyuno of this Department and to Fuji Pharmaceutical Industries Co., Ltd., for their kind donation of (+)-ephedrine.

Conformations of the Ester Group

Michinori Ōki and Hiroshi Nakanishi

Department of Chemistry, Faculty of Science, The Univercity of Tokyo, Hongo, Tokyo

(Received February 16, 1970)

In some esters of formic acid which carry bulky alkyl groups (*e .g*, *t*-butyl formate, 1,1-diethylpropyl formate, and triphenylmethyl formate), the presence of *s-cis* conformer has been confirmed by various spectroscopic techniques. The dipole-moment measurements also support the conclusion drawn from the spectroscopic data.

It has been reported that the *s-cis* conformer as well as the *s-trans* conformer is present in many carboxylic acids[1-3] and amides.[4,5] The presence of these isomers can be attributed to the partial double bond character of the C–O or C–N bond due to delocalization of the electrons. Although the ester is an analogous compound, its conformation has been reported to be *s-trans*, chiefly on the basis of the results of dipole moment measurements[6] and microwave spectroscopy.[7,8] The *s-cis* conformer has only rarely been found.[9,10]

the ester also has a partial double bond character due to the delocalization of electrons, as is exemplified by the resonance structures, (Ia, Ib). Therefore, *s-cis* conformers like carboxylic acid and amide may exist in some esters if either the *s-cis* conformer is stabilized or the *s-trans* is destabilized for some reason.

The purpose of this paper is to present the spectroscopic evidence, as well as the support from the dipole moment data, for the presence of *s-cis* conformers in some alkyl formates; it will also consider the effect of the bulkiness of the alkyl part of alkyl formates on the presence of the rotational isomers about the C–O bond of the esters.

Experimental

Materials. The simple esters were prepared by the standard methods. The *t*-butyl acetate was prepared from anhydrous acetic acid and *t*-butyl alcohol in the presence of zinc chloride. The *t*-butyl formate, *t*-amyl formate, 1-ethylpropyl formate, 1,1-diethylpropyl formate, phenyl formate, 2,6-dimethylphenyl formate, and geranyl formate were prepared from mixed anhydride of formic and acetic acid and the corresponding alcohol according to the Stevens method.[11] The triphenylmethyl formate was prepared from sodium formate and triphenylmethyl chloride.[12]

The γ-butyrolactone and cyclopentadecanolide were of commercial origin and were purified before the measurements.

The ε-caprolactone and cyclododecanolide were prepared from the corresponding ketone and perbenzoic acid. The physical constants of the compounds used in this study agree with those previously reported in the literature.

Apparatus. The IR spectra were measured by using a Perkin-Elmer 112G grating spectrometer, (1800—1700 cm^{-1}) (the precision of the instrument was believed to be 0.5 cm^{-1} at 1750 cm^{-1}), a JEOC-DS-402G infrared spectrophotometer (4000—400 cm^{-1}), a Hitachi EPI-G2 grating infrared spectrophotometer (1200—400 cm^{-1}), and a Hitachi EPI-L grating infrared spectrophotometer (700—200 cm^{-1}).

The UV spectra were measured on a Hitachi EPS-3 recording spectrophotometer.

The NMR spectra were measured on a JNM-C-60 spectrometer and on a JNM-4H-100 spectrometer.

The dipole moment was measured by the heterodine-beat method. (The estimated error was about 0.05D at 1.5D and about 0.02D at 2.5D).

Results and Discussion

The three chief factors governing the preference of the conformations of ester can be considered to be: the dipole-dipole interaction between C=O and O–R_2 bonds (Fig. 2a), the repulsion between lone-pair electrons of two oxygen atoms (Fig. 2b), and

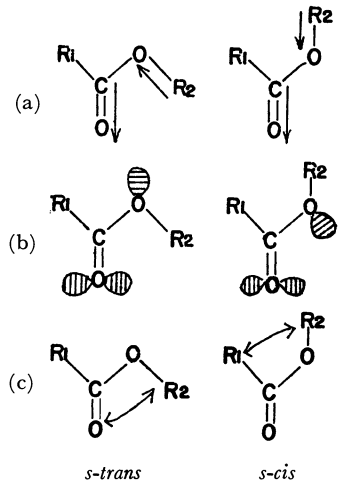

Fig. 2. The chief factors governing ester conformation.

the steric repulsion either between C=O and R_2 or between R_1 and R_2 (Fig. 2c).

The direction of the dipoles of the two bonds is roughly antiparallel in the *s-trans* conformer and roughly parallel in the *s-cis*. Therefore, the *s-trans* conformer is favored over the *s-cis* in less polar media as far as the first factor is concerned. In the second factor, the repulsion is considered to be very small in the *trans* conformer compared to that in the *s-cis*. Thus, the *s-trans* conformer is more stable than the *s-cis*. As to the third factor, when R_1 is bulky, the steric repulsion between C=O and R_2 in the *s-trans* conformer should be smaller than that between R_1 and R_2 found in the *s-cis*. Thus, the *s-trans* conformer is more stable in the ordinary esters. However, when R_1 is small, and R_2 bulky, the situation may be reversed; the *s-cis* conformer could be favored over the *s-trans* because of the increase in the interaction between R_2 and O relative to that between R_1 and R_2. These considerations lead to the conclusion that a *s-cis* conformer of the ester may exist when the ester has a small R_1 and a bulky R_2, which is possible in some formates which carry a large alkyl group.

Infrared Spectra

From the results obtained with carboxylic acids[13] and ketones,[14] it is natural to consider that the *s-cis* and *s-trans* conformations of the ester are reflected in the C=O stretching absorptions of these compounds. The results obtained with solutions in nonpolar solvents are shown in Table 1. It may be pointed out that some formates and acetates with

* geranyl formate

rather bulky alkyl groups show absorptions at the lower frequencies. However, this can not be taken as positive evidence for the presence of rotational isomers, because the absorption band is rather symmetrical except in the cases of isopropyl acetate and *t*-butyl acetate*[1] (see the discussions of the solvent effects). The present authors presume that the shift is the mere reflection of some effects of the electrical and bonding natures.

There are some lactones which are forced to take the *s-cis* conformation. Therefore, if the C=O absorption due to the lactones of the smaller ring and that due to the large lactone ring are compared, there will be a chance of finding the difference between the two conformers. Thus, the infrared C=O absorptions of various lactones were measured; the results are given in Table 2. The extraordinarily high frequency of γ-butyrolactone is, of course, attributable to the ring strain or the angle deviation, whereas ε-caprolactone is a compound which can take the *s-cis* conformation only. Judging from the knowledge of other esters, it may be assumed that cyclopentadecanolide exists in the *s-trans* conformation only. The data in Table 2 indicate that there

Table 2. Absorption maxima due to carbonyl stretching vibration of lactones (in CCl_4)

n	Compound	ν_{CO} (cm^{-1})	
5	γ-butyrolactone	1783	
7	ε-caprolactone	1740	13	cyclododecanolide	1736	
16	cyclopentadecanolide	1735	

is not much difference between these two compounds. Cyclododecanolide is expected to be a composite of *s-cis* and *s-trans* conformers, since the analogous C_{12} lactam is known to be so from NMR spectroscopy.[15] However, it shows only one sharp absorption in the carbonyl region. These results, although negative, may be interpreted as indicating that the *s-cis* and *s-trans* conformations of the ester can not be distinguished by the infrared C=O absorptions as measured in carbon tetrachloride or carbon disulfide.[16] Although the investigation of the infrared spectra in the C=O stretching region may not reveal the presence of the *s-cis* and *s-trans* conformers, the skeletal deformation region may be useful to this end, because the skeletal deformation is known to be sensitive to conformational change and because it has been shown recently that the spectra of amides in the 1200—200 cm^{-1} region reflect the presence of conformers superbly.[17]

The Effect of Temperature on the Absorptions in the 1200—200 cm^{-1} Region. The infrared spectra of *t*-butyl formate (II) were thus measured in various states and at various temperatures. The results are shown in Figs. 3 and 4.

Apparently, the intensities of absorptions bands change with a change in the temperature from 20°C (liquid) to <-100°C (solid), as is shown in Fig. 3;

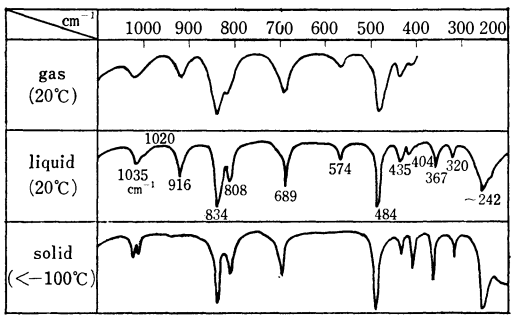

Fig. 3. IR spectra of *t*-butyl formate in three phases.

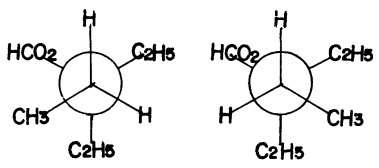
for example, the absorptions at 916 cm^{-1} and 574 cm^{-1}, which are present at 20°C, disappear in the spectrum of the solid. In the gas phase at a lower pressure, the absorptions become broader than those in the liquid phase, although all the absorptions which are present in the liquid phase also exist in the spectra of the gas.

A temperature dependence (Fig. 4) study of the spectra of liquid *t*-butyl formate has shown the interesting features of some bands; the intensities of the bands at 916, 574, and 435 cm^{-1} decrease as the temperature is lowered, whereas those at 1020, 484, 409, and 242 cm^{-1} increase at low temperatures. The temperature dependence study of the spectra of gaseous *t*-butyl formate at 20—70°C reveals the same tendency. These phenomena may be explained by asuming the presence of conformational isomers. These studies alone not establish how many conformers are present, but, from the considerations of structure, it may now be said that *t*-butyl formate has two conformers, *s-cis* and *s-trans*, and that the populations of these isomers change as the temperature varies, and that these changes are reflected in the far-infrared spectra. It is not easy to assign these bands at the present time; further sutdy will be necessary to clarify this point.[18]

A far-infrared spectral study of 1,1-diethylpropyl formate (III) and geranyl formate (IV) was also carried out, because the former compound has a bulkier alkyl group than *t*-butyl formate, while the latter has been reported, on the basis of dipole moment data, to exist as an *s-cis* conformer.[9]

The spectra of these compounds measured under various conditions (gas, liquid, solid, and temperature range 81.0°C to −100°C) show very complicated changes. However, these changes may not be directly related to the *s-cis* and *s-trans* conformers of the ester group, because there are many rotational isomers possible for the alkyl part also. *t*-Butyl formate is simple in this respect; the only rotational axis considered is C_{co}–O_{ether}; rotation about the other axes produces the same conformation because of the symmetry of the substituent. 1,1-Diethylpropyl formate, on the other hand, has two different conformations (Va, Vb), in addition to the *s-cis* and *s-trans* conformers, because of rotation about the C–C axis of the ethyl group. There is no doubt about the presence of more possible conformers in geranyl formate. Although desirable, it was even impossible to correlate these spectra with those of *t*-butyl formate, because the absorptions are seriously shifted by the mass effect.



Va Vb

Solvent Effect in the 1200—400 cm^{-1} Region. The *s-cis* conformer of ester is considered to be more polar than the *s-trans*, judging from the arrangement of bond dipoles, and the dipole moments are calculated to be 3.04 and 1.53 D for the *s-cis* and *s-trans* conformers respectively. This implies that the population of the *s-cis* conformer will become greater in a polar solvent relative to the nonpolar solvent. Thus, it may be possible to assign some bands to the respective conformations.

The infrared spectra of *t*-butyl formate and 1,1-diethylpropyl formate were thus measured in carbon disulfide (2.64),*2 acetone (20.7), acetonitrile (37.5), and *N*,*N*-dimethylformamide (DMF) (37.7). The results are shown in Fig. 5.

Apparently, the intensities of all the absorptions change. The outstanding feature of the change is

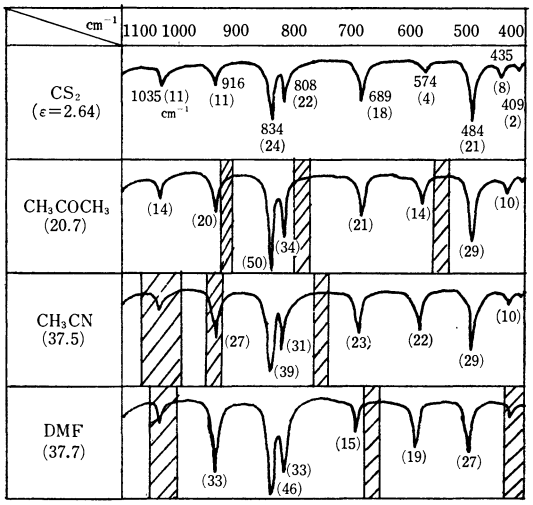


Fig. 5. Solvent effect of IR spectra of *t*-butyl formate.
The figures in parentheses are molar absorption coefficients.
The shaded range is a part of strong absorption of solvent itself.

18) In this skeletal deformation region, the assignment and calculation of each absorption of the ester were made only with methyl formate, methyl acetate, ethyl acetate, and methyl propionate. S. Ichikawa, Tokyo University, private communication.

*2 The numbers shown in parentheses are dielectric constants.

that the intensities of the absorptions at 916 and 574 cm^{-1} become larger in comparison with the band at 689 cm^{-1}, as the solvent polarity increases.*3 The results mean that the bands at 916 and 574 cm^{-1} can be assigned to some modes of vibration of the *s-cis* conformer. Since, as has been mentioned before, the intensities of these bands decrease on lowering of the temperature, it may now be said that the *s-cis* conformer of *t*-butyl formate is less stable than the *s-trans*. The solvent effect on the spectra of the 1,1-diethylpropyl formate is large, as is on *t*-butyl formate. This fact may be considered as a reflection of the presence of *s-cis* and *s-trans* isomers, since the population of the rotational isomers about the C–C axis of the ethyl groups is not affected to a great extent by the solvent polarity change; the dipole moment should not be affected too much by rotation about the bond in question.

Solvent Effect in the Region of the Carbonyl Stretching Vibration. The solvent effect on the far-infrared spectra of formates, as has been described above, naturally led the present authors to reinvestigate the carbonyl stretching region by means of the polar solvents. The results are given in Fig. 6.

It is apparent that *t*-butyl formate has at least two peaks in acetonitrile and dimethyl sulfoxide (DMSO) and that graphical seperation of these bands gives two peaks, the molecular extinction coefficients of which and the wave numbers of the absorption maxima of which, are also shown in Fig. 6. There are two possible reasons for the fact that *t*-butyl formate gives two absorption maxima in the polar solvents, whereas it gives only one peak in carbon disulfide. The first is the possibility that, although there is only one conformation, there are at least two species of solvation, the lower band representing the molecular species which are strongly solvated by the polar solvent. In this case, the exchange among these species is slow enough for resolution by infrared light. The second is the possibility that *s-cis* and *s-trans* conformers now give resolvable two bands. If the first possibility were really the case, however, other esters which exist in

*3 The wave numbers referred to are those observed in carbon disulfide.

one conformation should also give two bands in these polar solvents. Thus, the C=O stretching absorptions of various esters were determined and the results are shown in Table 3. It can immediately be pointed out that methyl formate, ethyl formate (whose conformations has been established to be *s-trans* by microwave spectroscopy),[7] and isopropyl formate have only one sharp symmetrical absorption in carbon disulfide, acetonitrile, and DMSO. The first possibility is, thus, not very likely. Therefore, the second becomes likely, since the existence of conformers has been proved for *t*-butyl formate from the far-infrared spectra (see below).

The reason why this compound gives only one band for C=O stretching in carbon disulfide may be that the wave number difference between the two conformers is so small that it cannot be resolved by the present optical instrument. As for the assignment of the two bands, the band at the higher wave number seems to correspond to the *s-cis* isomer. The reason for this assignment is two-fold. The first comes from a consideration of the population. The temperature dependence study has established that the *s-cis* isomer is the less stable one. Therefore, the weak band will correspond to less stable isomer. It may be argued that the absorption intensities per molecule for *s-cis* and *s-trans* are not known and that the reverse may be possible. However, consideration of bond dipole leads to the conclusion that, if the absorption intensity per molecule is different, it is the *s-cis* molecule which gives rise to a stronger absorption.*4 The second reason for the assignment comes from the location of maximum absorption. From the same consideration as the intensity, it is natural to expect the *s-cis* conformer to give absorption due to C=O stretching at a higher frequency than the *s-trans*, since a higher energy will be necessary to excite the molecule when the two dipoles are arranged roughly parallel.

Table 3 shows that formate esters with bulky alkyl groups give two C=O stretching absorptions in polar solvents, whereas isopropyl formate gives only one absorption in any of the solvents investigated. These results indicate that the alkyl group in formate esters should at least be tertiary in order to make the existence of the *s-cis* conformer possible.

The aryl esters in Table 3 are worthy of special mention. Phenyl formate has only one absorption due to C=O stretching in both carbon disulfide and acetonitrile. It is expected to exist as the *s-trans* isomer. On the other hand, 2,6-dimethylphenyl formate shows two bands due to C=O stretching even in carbon disulfide. It is believed that the resolution is now possible between the *s-cis* and *s-trans* conformers in carbon disulfide. The same is true of triphenylmethyl formate. This assignment may be explained as follows: The conformation of phenyl formate (VII) must, at least, be nearly planar because of the resonance stabilization. However, the planar conformation is not possible for 2,6-dimethylphenyl formate (VIII) because of the steric effect of the methyl groups. If the models of the latter compound are written schematically, the *s-trans* and *s-cis* conformers may be represented as in Fig. 7. (VIIIa, VIIIb). In the *s-trans* conformation, those which cause the repulsion are the *p*-electron pair of oxygen and the π-electrons of the benzene ring. On the other hand, in the *s-cis* conformation, the interaction takes place between hydrogen of the formyl group and the π-electrons of the benzene ring. The latter interaction, which could even be rather attractive, is at least expected to be less repulsive because the van der Waals radius of hydrogen is far less than that of oxygen. Thus the *s-cis* conformer becomes less unstable than that

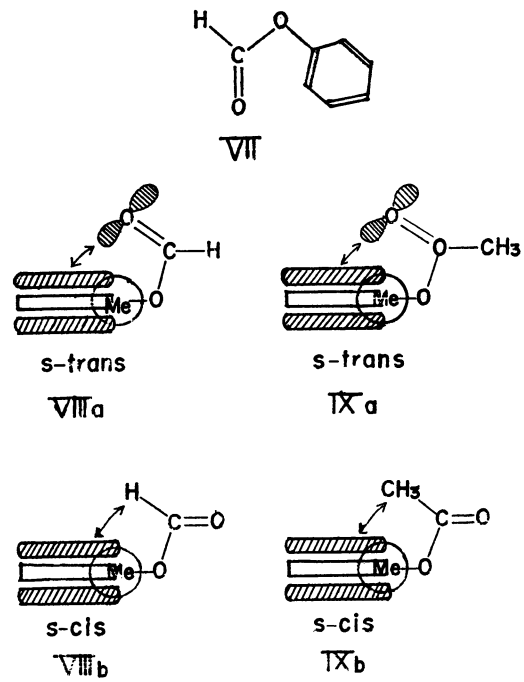

Fig. 7. Conformations of phenyl formate, 2,6-dimethylphenyl formate and 2,6-dimethylphenyl acetate.

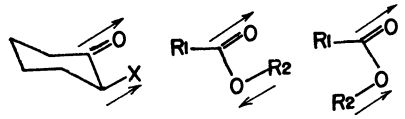
*4 It is well known that α-halocyclohexanone derivatives give stronger absorption due to C=O stretching per molecule when halogen is equatorial. This effect can be explained by considering the direction of the bond



VI *s-trans* *s-cis*

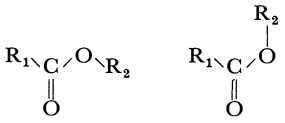
dipoles; the equatorial α-halocyclohexanone (VI) has dipoles as is shown above, which makes the change in dipole moment small on stretching the C=O bond. The situation is similar with the *s-cis* isomer of esters.

of the *s-trans*, although the interaction of the lone pair electrons of the two types of oxygen is still large in the *s-cis* conformation.

In this connection, the situation of 2,6-dimethylphenyl acetate (IX) is a different case. The repulsive interaction between the benzene ring and the methyl group of the acetyl seems to become large (Fig. 7, IXa and IXb), and this compound gives only one absorption due to C=O stretching in either carbon disulfide or acetonitrile.

Dipole Moment

It is known that the dipole moments of most esters are in the range from 1.4 to 2.0 D. Using the usual bond moments, the calculated values are 1.53 D and 3.40 D for the *s-trans* and *s-cis* isomers respectively. (The dipole moment of δ-valerolactone, which can take only the *s-cis* conformation, has been determined as 4.22 D[19]). Thus, the conformations of the ordinary esters are considered to be *s-trans*.

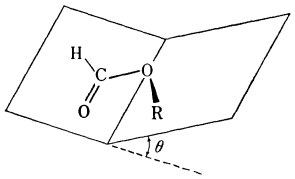


1.53 D 3.40 D

Calculated Dipole Moments.

In view of the above knowledge, it can be expected that the dipole moment data will provide another proof for the existence of the *s-cis* isomer. Krishna and his co-workers investigated along this line.[9] The results of the present work are tabulated in Table 4. Although the data are rather scattered, it may safely be said that methyl and ethyl formates and other acetates exist as *s-trans* conformers.

However, those of *t*-butyl formate, 1,1-diethylpropyl formate, and geranyl formate are a little too large to be attributed to the *s-trans* conformer only. Two reasons for the unusually high dipole moment may be considered. The first is the nonplanarity of the formate molecule ($\theta \neq 0$). Because of the steric requirement of the bulky alkyl group, the carbon atom attaching to the ether oxygen may not lie on the plane which is made by the formyloxy group. These conformations can be considered for both the *s-trans* and *s-cis* isomers. The second is the presence of both *s-trans* and *s-cis* conformers.



To clarify this point, the dipole moments of methyl formate, *t*-butyl formate, and 1,1-diethylpropyl formate were measured at various temperatures in benzene. The dipole moments of the compounds with bulky groups varied as the temperature changed, but that of methyl formate remained intact within the range of errors (Table 4). These results supported the idea that the second possibility is actually the case. The dipole moments of these compounds with bulky alkyl groups become large as the temperature becomes higher. This shows that the *s-cis* conformer is more unstable than the *s-trans* and agrees with the results obtained from the infrared spectra data.

Although it is now proved that the second possibility is actually the case, the first possibility cannot be ruled out. Indeed, the rather small excess of the dipole moment of *t*-butyl formate and 1,1-diethylpropyl formate over that of *s-trans* may reflect the nonplanarity of the molecule, since the nonplanar *s-cis* conformer may be expected to possess a smaller dipole moment as a result of the smaller contribution of the dipolar canonical structure. It is interesting to know in this connection that *t*-butyl acetate and ethyl acetate show larger dipole moments, in that order, than methyl acetate, whose structure has been shown by the microwave spectroscopic data to be planar.[7,8]

Ultraviolet Absorption Spectra.

The ultraviolet absorption spectra of esters and lactones were measured by Closson and Orenski,[22] who pointed out that the n–π^* absorption of the carbonyl oxygen appeared at a longer wavelength with the *s-cis* conformation than with the *s-trans*. Therefore, the UV spectral technique will give another clue in the reseach for the *s-cis* conformer.

The ultraviolet absorption spectra of various esters have been determined; the results are shown in Table 5. It is apparent that those which have been proved by the other techniques to exist as conformational mixtures have absorptions at wavelength longer than 216 mμ. The absorption maximum is still shifted bathochromically when the alkyl group becomes bulkier. The ultraviolet absorption may be used as supplementary evidence for the presence of the *s-cis* isomer in esters.

Nuclear Magnetic Resonance Spectra.

It is not possible to learn the population of the *s-cis* and *s-trans* conformers of the ester by means of infrared spectroscopy because of the nonidentical absorption intensity per molecule. Nor is it possible to do so by dipole moment measurements, because the absolute value for each isomer is not known. However, it is possible by means of NMR spectroscopy, provided the exchange of the isomers is sufficiently slow on the NMR time scale. Thus, it seemed that it would be interesting to measure the NMR spectra of several formates at various temperatures. Methyl, ether, isopropyl, and *t*-butyl formates show sharp singlets at 7.97, 7.87, 7.88, and 7.83 ppm respectively in carbon tetrachloride at room temperature. Although it might be hoped that the signal might be resolved into two singlets in a solvent which would give a specific solvent effect, *t*-butyl formate shows a sharp singlet at 7.68 ppm from tetramethylsilane (TMS) in benzene. Thus, it is necessary to lower the temperature in order to slow down the rate of exchange. DMF has been chosen as a solvent for this study because it has a rather low melting point (−61°C) and its proton signal may be used as a control. The concentration of this solution was *ca.* 50% to avoid freezing during the measurement at about −100°C. *t*-Butyl formate in DMF has a singlet peak at 8.04 ppm from TMS at 20°C. whereas the peak broadens at −64°C. The signals are resolved into two at −94°C, the chemical shifts beeing 8.88 and 8.03 ppm from TMS. The chemical shifts do not change at −99°C. The area under the peak at 8.88 ppm corresponds to 14% of the total signals of formyl proton. The peak at 8.88 ppm is assigned to the *s-cis* isomer, and that at 8.03 ppm, to the *s-trans* isomer, because it is established by the infrared study that the *s-cis* isomer is less stable.*[5]

The rough thermodynamic parameters for the *s-cis* and *s-trans* isomers are shown in Table 6; they

22) W. D. Closson and P. J. Orenski, *J. Org. Chem.*, **32**, 3160 (1967).
23) W. D. Closson and P. Haug, *J. Amer. Chem. Soc.*, **86**, 2384 (1964).

*[5] It may be argued that *t*-butyl formate and *N*,*N*-dimethylformamide (DMF) may form a complex and that there is an equilibrium between the complex and the monomer of the ester. In this case, the exchange between these species is slow enough to be detected on the NMR time scale at these low temperatures. In order to clarify this point, the NMR spectra of methyl formate were measured in DMF at a *ca.* 50% concentration at temperatures between 30°C and −95°C. The peak heights of formyl protons of methyl formate and DMF remained unchanged, although the chemical shift of the formyl proton of methyl formate shifted a little to a lower field (from 8.03 ppm to 8.06 ppm from TMS) as the temperature was lowered. These results support the idea that the splitting of the signal of *t*-butyl formate is due to the presence of rotational isomers and not to the presence of a complex molecule.

Table 6. The thermodynamic parameters for the *s-cis* and *s-trans* isomer equilibration of *t*-butyl formate

ΔH	-2.2 ± 0.7 kcal/mol
ΔS	-9 ± 2 e.u.

are obtained from the equilibrium constants at -94°C and -99°C. It is impossible at the present to obtain the kinetic parameters for the rotation about the $C-O_{ether}$ axis of *t*-butyl formate, for the intensities of the two peaks are not the same and, moreover, vary according to the temperature. However, judging from the large chemical shift, $\Delta\nu=0.85$ ppm (*cf*, the fact that *t*-butyl formamide has a $\Delta\nu$ value of 0.23 ppm and shows two peaks at room temperature[4]), it is apparent that the activation energy for the rotation of *t*-butyl formate is smaller than that of the corresponding amide.

Conclusion

It has been established, by various spectroscopic techniques and by dipole moment measurements, that *t*-butyl formate exists as a mixture of the *s-cis* and the *s-trans* conformers. The other formate, which has a rather bulky group, shows also the presence of two isomers. These may be attributed to the steric effect of the alkyl group, which interfers severely with carbonyl oxygen; the steric repulsion is relieved when the *s-cis* conformation is taken, because the hydrogen of the formyl group is less bulky than the carbonyl oxygen.

A rather striking example is geranyl formate. Every piece of evidence studied so far has indicated the presence of the *s-cis* isomer in this compound. Geranyl is the primary alkyl group, and we cannot expect a great steric bulkiness. A further surprising fact is that neryl formate, an isomer of geranyl formate, shows no evidence of the presence of the *s-cis* isomer. These puzzling facts must be studied further.

The Reactions of Sulfur Ylides with Cyclic Carboxyl Compounds and Isocyanates

Teruaki MUKAIYAMA, Moriaki HIGO and Hisashi TAKEI

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 19, 1970)

It was found that the reactions of dimethyloxosulfoniummethylide (II) with cyclic carboxyl compounds (I), such as lactones, carboxylic anhydrides and imides, gave the corresponding stable oxosulfonium ylides (III). In addition, the reaction of phenyl isocyanate dimer (IX) and dimethylsulfoniummethylide (X) afforded a 1 : 1 adduct (XI), which, on heating, decomposed to give a ring expansion product (XIV). Hydantoin derivatives (XVII) were also produced by treating dimethylsulfonium-α-methylacylmethylide (XVI) with two moles of isocyanates in dimethyl sulfoxide. On the other hand, when the same reactions were carried out in benzene, XVI reacted with an equimolar amount of isocyanates to give acrylamide derivatives (XVIII) in high yields by the rearrangement of the intermediate sulfoniummethylide (XX).

In the previous paper,[1] it was shown that 3-hydroxyfuran derivatives were synthesized in good yields from ketene dimer and stable sulfonium or oxosulfonium[2] ylides accompanied with ring expansion.

In the present paper, in connection with this methylene transfer reaction, the reactions of sul-

2) unpublished result.

fonium and oxosulfonium ylides with some cyclic carboxyl compounds (I) such as lactones, imides[3] or carboxylic anhydrides, and isocyanates[4] were studied. When I and dimethyloxosulfonium-methylide (II) were allowed to react in tetrahydrofuran (THF), stable oxosulfonium ylides (III)[5] were produced in high yields instead of the expected ring expansion compounds (IV). The reaction may proceed through an initial formation of a betaine intermediate (V), which in turn changed to III by an intramolecular proton transfer. The results are summarized in Table 1.

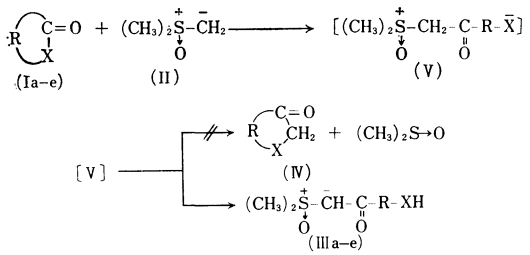

Table 1. Reactions of dimethyloxosulfonium-methylide (II) with cyclic carboxyl compounds (I)

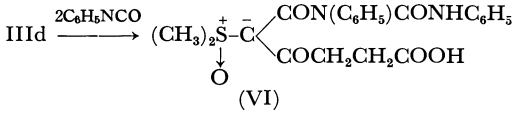
(I)	(III) -R-X-H	Yield, %
(Ia)	$-(CH_2)_2-OH$	93
(Ib)	$-(CH_2)_3-OH$	99
(Ic)	$-(CH_2)_2-C(=O)-NHC_6H_5$	94
(Id)	$-(CH_2)_2-COOH$	69
(Ie)	$-o-C_6H_4-COOH$	55*

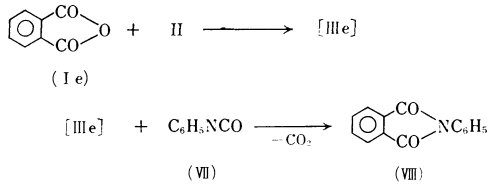
* IIIe was not isolated but subsequently treated with phenyl isocyanate to give *N*-phenylphthalimide (VIII) in a 55% yield.

In the case of succinic anhydride (Id), IIId was very hygroscopic and identified as its acylurea derivative (VI) by treating with phenyl isocyanate



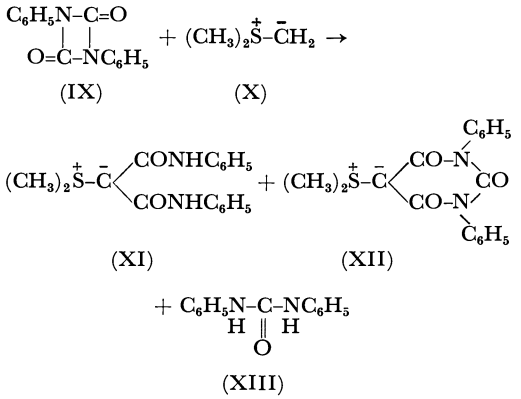
(VI)

(VII). On the other hand, when the mixture resulted from the reaction of Ie and II was treated with VII, *N*-phenylphthalimide (VIII) was produced with evolution of carbon dioxide.

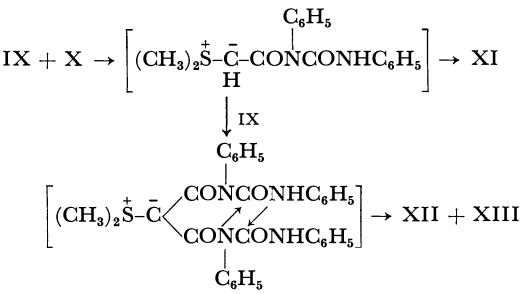


Several attempts to convert III into IV were unsuccessful (See Experimental).

The reaction of phenyl isocyanate dimer (IX) with dimethylsulfoniummethylide (X) was carried out at −15°C, and dimethylsulfonium-bis(phenylcarbamoyl)-methylide (XI), dimethylsulfonium-1,3-diphenylbarbiturylide (XII)[6] and 1,3-diphenylurea (XIII) were obtained in 15, 4 and 16% yields, respectively.



It seems reasonable to consider that the reaction proceeds *via* such two ylide intermediates as sketched below.



When XI was heated[7] at 160—170°C in a sealed tube, 1,3-diphenylhydantoin (XIV) was obtained with elimination of dimethyl sulfide probably

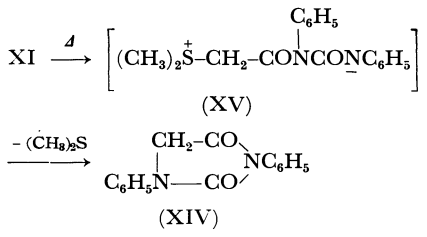
through a betain intermediate (XV), which decomposed to give XIV by an intramolecular nucleophilic displacement.

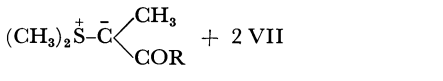


(XV)

(XIV)

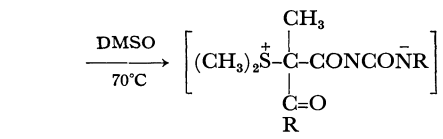
The result indicates that IX was transformed into XIV accompanied with ring expansion *via* XI. In addition, it was found that the intermediate XI was easily obtained from X and two moles of VII. Thus, it will be possible to obtain hydantoin derivatives directly from two moles of isocyanates and sulfur ylides through such intermediates as XV.

Based on the above assumption, the reactions of VII with stable sulfonium ylides having no proton on the ylide carbon atom, *e. g.*, dimethylsulfonium-α-methylphenacylide (XVIa), were investigated. When XVIa was treated in dimethyl sulfoxide (DMSO) with two moles of VII at 70°C, 1,3-diphenyl-5-benzoyl-5-methylhydantoin (XVIIa)[9] was obtained with evolution of dimethyl sulfide, as expected.

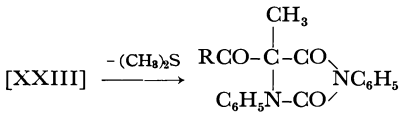


(XVI)

a, R=C_6H_5
b, R=CH_3



(XXIII)



(XVII)

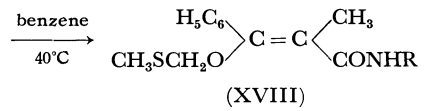
a, R=C_6H_5 52%
b, R=CH_3 49%

On the other hand, when the same reaction of XVIa with VII was carried out in benzene, evolution of dimethyl sulfide was not observed and α-methyl-β-methylthiomethoxy-β-phenylacrylanilide (XVIIIa) was obtained in a good yield along with the recovery of one mole of VII.

The structural assignment was made on the basis

XVIa + RNCO

R=C_6H_5 (VII)
R=C_2H_5
R=c-C_6H_{11}



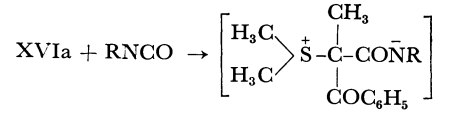
(XVIII)

a, R=C_6H_5 73%
b, R=C_2H_5 86%
c, R=c-C_6H_{11} 80%

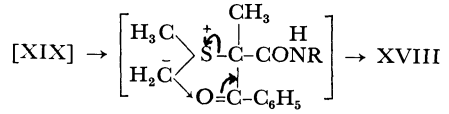
of elemental analyses and IR, NMR and mass spectra. The configuration about the carbon-carbon double bond is still not determined, but it is suggested that phenylcarbamoyl and phenyl groups have *trans* relationship because of bulkiness of these two groups.

In a similar manner, reactions of XVIa with ethyl and cyclohexyl isocyanates gave XVIIIb and XVIIIc, respectively.

The reaction is considered to proceed through a 1,4-betaine (XIX), which changed to an ylide intermediate (XX) by a proton transfer. The XX in turn undergoes the rearrangement reported by Ruiz[9] and by Ratts and Yao[10] to give XVIII.



(XIX)



(XX)

The difference in the reaction course between the two reactions mentioned above can be explained by considering that the intermediate XIX, formed from XVI and one mole of isocyanate, reacts rapidly with another mole of isocyanate in DMSO to give a 1,6-betaine (XXIII) (path a), and that, in benzene, the formation of XX from XIX by an intramolecular proton transfer proceeds more rapidly (path b) than that of XXIII.

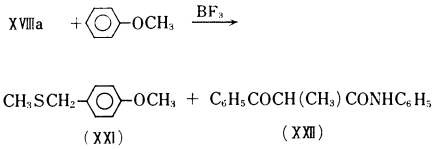
10) K. W. Ratts and A. N. Yao, *J. Org. Chem.*, **33**, 70 (1968).

It was found that XVIIIa obtained by the above reaction gave *p*-methylthiomethylanisole (XXI) in a 38% yield along with α-benzoylpropionanilide (XXII) by heating at 60°C with excess anisole in the presence of a catalytic amount of boron trifluoride etherate.



Experimental

Most of these reactions were carried out in the atmosphere of dry nitrogen. All melting and boiling points are uncorrected.

Reaction of β-Propiolactone (Ia) with Dimethyloxosulfoniummethylide (II). To a solution of II (25 mmol) in 40 m*l* of dry tetrahydrofuran (THF), a solution of Ia (1.80 g, 25 mmol) in 18 m*l* of dry THF was added over a period of 10 min with stirring at −15°C. An exothermic reaction soon took place to give a semi-crystalline mush, which, after warming at 50—60°C for 4 hr, afforded 3.80 g (in a 93% yield) of dimethyloxosulfonium-ω-hydroxypropionylmethylide (IIIa), mp 94.5—95.5°C (recrystallized from ethyl acetate). Found: C, 44.09; H, 7.70; S, 19.48%. Calcd for $C_6H_{12}O_3S$: C, 43,90; H, 7.37; S, 19.49%. IR (KBr): 3380, 1030 (OH); 1552 (C=O); 1172 cm^{-1} (S→O). NMR (DMSO-d_6): δ=2.20 (2H, t, CH_2–CO), 3.43 (6H, s, $2CH_3$), 3.62 (2H, t, CH_2–O), 4.40 (1H, s, OH), and 4.78 (1H, s, CH).

In a similar manner, dimethyloxosulfonium-ω-hydroxybutyrylmethylide (IIIb) was obtained from γ-butyrolactone (Ib) and II in a quantitative yield, mp 55—67°C (ethyl acetate). Found: C, 46.91; H, 8.28%. Calcd for $C_7H_{14}O_3S$: C, 47.18; H, 7.96%. IR (KBr): 3400, 1030 (OH); 1552 (C=O); 1172 cm^{-1} (S→O). IIIb was very hygroscopic and decomposed slowly even when stored in a desiccator over phosphorus pentoxide.

Attempts to Obtain IVa from IIIa. *1) Thermolysis of IIIa.* When 0.82 g (5.0 mmol) of IIIa was heated in a distilling flask under reduced pressure, decomposition started at 215°C and 0.27 g (70%) of dimethyl sulfoxide (DMSO) was distilled out. The resulting black tar prevented further purification.

2) Reaction of IIIa with Cupric Chloride.[11] A mixture of IIIa (1.00 g, 6.1 mmol) and anhydrous cupric chloride (0.82 g, 6.1 mmol) in 20 m*l* of dry dioxane was heated at 90°C for 1.5 hr to give dark brown resinous material which prevented further purification.

3) Reaction of IIIa with Triphenyl Phosphite.[12] When 1.64 g (10 mmol) of IIIa was heated in a distilling flask with 3.10 g (10 mmol) of triphenyl phosphite, a vigorous reaction took place at the bath temperature of 120°C. After cooling, 0.84 g (90%) of phenol was distilled from the reaction mixture. The expected IVa (lit. bp 137—138°C) was not obtained.

Reaction of *N*-Phenylsuccinimide (Ic) with II. To a solution of II (10 mmol) in 35 m*l* of dry THF, a solution of Ic (1.75 g, 10 mmol) in 30 m*l* of dry THF was added at room temperature with stirring. After stirring for 2 hr, followed by refluxing for 2 hr, the solvent was evaporated. The residue was recrystallized from benzene to give dimethyloxosulfonium-ω-phenylcarbamoylpropionylmethylide (IIIc), 2.52 g (94%), mp 131.5°C. Found: C, 58.27; H, 6.16; N, 5.17%. Calcd for $C_{13}H_{17}NO_3S$: C, 58.42; H, 6.41; N, 5.24%. IR (Nujol): 3320 (NH); 1660, 1534, 1294, 1254 (–CO–NH–); 1572 cm^{-1} (C=O).

Thermolysis of IIIc. When 0.82 g (3 mmol) of IIIc was heated in a distilling flask under reduced pressure, decomposition occurred at the bath temperature of 180°C and DMSO was distilled out, bp 75—76°C/11 mmHg, 0.23 g (quantitative yield). The resulting solid was recrystallized from ethanol to give Ic, 0.29 g (53%), mp and mmp 154°C.

Reaction of Succinic Anhydride (Id) with II. A solution of Id (1.00 g, 10 mmol) in 24 m*l* of dry THF was added to a solution of II (10 mmol) in 35 m*l* of dry THF over a period of 30 min with stirring at −15°C. The reaction started at once with evolution of heat to afford colorless precipitates. After stirring for 1.5 hr with the cooling bath removed, the precipitates were filtered and washed with dry THF. The resulting precipitates were very hygroscopic and prevented further purification. However, they were identified as dimethyloxosulfonium-ω-carboxypropionylmethylide (IIId), 1.30 g (69%), by the following manner. Thus, to a suspension of IIId in dry THF prepared from Id (10 mmol) and II (10 mmol) by the method described above, a solution of phenyl isocyanate (VII) (1.19 g, 10 mmol) in 30 m*l* of dry dioxane was added dropwise. The reaction mixture turned to a clear solution by warming at 30—60°C for 2 hr. After removal of the solvents, the resulting colorless solid was submitted to a silica gel column to afford 1,3-diphenylurea (XIII), 0.42 g (40%), and dimethyloxosulfonium-ω-carboxypropionyl-(2,4-diphenylallophanyl)-methylide (VI), 0.35 g (17%), mp 135—136°C (benzene). Found: C, 58.92; H, 5.13; N, 6.27%. Calcd for $C_{21}H_{22}N_2O_6S$: C, 58.60; H, 5.15; N, 6.51%. IR (KBr): 3320 (NH); 1700 (COOH); 1667 (C=O); 1614, 1545 cm^{-1} (C=O).

Reaction of Phthalic Anhydride (Ie) and II. When a solution of Ie (1.26 g, 8.5 mmol) in 25 m*l* of dry THF was added dropwise to a solution of I (8.5 mmol) in 32 m*l* of dry THF with stirring at −15°C, the reaction soon took place to give colorless precipitates, to which, after stirring for 2 hr with the cooling bath removed, VII (1.01 g, 8.5 mmol) in 20 m*l* of dry dioxane was added dropwise at room temperature. The mixture was stirred at 60—70°C for 3 hr and turned to a clear solution. During the time, 145 m*l* (15°C, 760 mmHg) of carbon dioxide (76%) was evolved. The solvents were evaporated and the residue was recrystallized from methanol to give *N*-phenylphthalimide (VIII), 1.05 g (55%), mp 205.5—206.5°C.

Reaction of Phenyl Isocyanate Dimer (IX) with Dimethylsulfoniummethylide (X). A solution of IX (2.14 g, 9.0 mmol) in 75 m*l* of dry THF was added to a solution of X (10 mmol) in dry DMSO with stirring at −15°C. Stirring was continued for 40 min, followed by an additional two hours' stirring with the cooling bath removed. The reaction mixture was poured into

200 ml of cold water, and the suspension was extracted with three 80 ml portions of ether, and then with three 100 ml portions of chloroform. The ethereal extract was dried over anhydrous sodium sulfate and the solvent was evaporated to give slight yellow crystals, to which a small amount of dichloromethane was added. The undissolved crystals were filtered, washed and recrystallized from ethanol to give XIII, 0.30 g (16%), mp 238°C (dec.). The filtrate was chromatographed over silica gel. Elution with dichloromethane gave dimethylsulfonium-bis(phenylcarbamoyl)-methylide (XI), 0.43 g (15%), mp 165°C (dec.) (benzene). IR (KBr): 3290, 1632, 1570, 1530, and 1510 cm^{-1}. NMR ($CDCl_3$): τ=6.95 (6H, s, $2CH_3$) and 2.45—3.00 (12H, m, $2C_6H_5$ and 2NH). The chloroform extract was dried over anhydrous sodium sulfate and the solvent was removed under reduced pressure. The resulting red-brown oil was chromatographed over silica gel. By elution with methylene chloride, dimethylsulfonium-1,3-diphenylbarbiturylide (XII) was obtained, 0.06 g (4%), mp 289°C (dec.) (methanol). Found: C, 63.50; H, 4.74; N, 8.49; S, 9.78%. Calcd for $C_{18}H_{16}N_2O_3S$: C, 63.52; H, 4.74; N, 8.23; S, 9.40%. IR (KBr): 3020, 1705, 1640, 1610, and 1595 cm^{-1}.

Thermolysis of XI. When XI (1.50 g) was heated in a sealed tube at 160—170°C for 2 hr, formation of dimethyl sulfide was observed by its characteristic odour. The resulting slight yellow solid was dissolved in a small amount of dichloromethane and chromatographed over silica gel to give 1,3-diphenylhydantoin (XIV), 0.15 g (13%), mp 137.0—137.5°C (ligroin). Found: C, 71.45; H, 4.99; N, 11.43%. Calcd for $C_{15}H_{12}N_2O_2$: C, 71.41; H, 4.80; N, 11.11%.

Reaction with VII and X. To a solution of X (30 mmol) in dry DMSO, a solution of VII (3.57 g, 30 mmol) in 10 ml of dry THF was added with stirring at −15°C. An exothermic reaction started at once. After stirring for 50 min with the cooling bath removed, the reaction mixture was treated in the same way as described for the reaction of IX and X to give XI (26%), XII (10%) and XIII (4%). From the water layer, kept standing after extraction with ether and chloroform, colorless precipitates were deposited, which were recrystallized from ligroin and identified as XIV, 0.17 g (5%).

In a similar way, the reaction of X with 2 mol of VII gave XI, XII and XIII in 32, 22 and 23% yields, respectively. The reaction of X with 4 mol of VII also gave XII (24%) and XIII (22%).

Reaction of Dimethylsulfonium-α-methylphenacylide (XVIa) with 2 mol of VII in DMSO. XVIa,b were newly prepared from the corresponding bromides by a method similar to that described for the preparation of dimethylsulfoniumcarbethoxymethylide.[13] To a suspension of XVIa (0.97 g, 5 mmol) in 18 ml of dry DMSO, VII (1.19 g, 10 mmol) was added portionwise. The mixture was stirred for a while, and then turned to a clear solution. When the solution was heated at 70°C, evolution of dimethyl sulfide was observed. After heating for 6 hr, the solvent was removed under reduced pressure at 50°C to give a slight yellow viscous oil, which was chromatographed over silica gel. Elution with benzene afforded XIII, 0.45 g (43%), and 1,3-diphenyl-5-benzoyl-5-methylhydantoin (XVIIa), 0.97 g (52%), mp 138.5—140°C (ligroin). Found: C, 74.84; H, 4.84; N, 7.72%. Calcd for $C_{23}H_{18}N_2O_3$: C, 74.58; H, 4.90; N, 7.56%. IR (KBr): 1775, 1716, and 1685 cm^{-1}. NMR ($CDCl_3$): τ=8.16 (3H, s, CH_3) and 2.15—2.90 (15H, m, $3C_6H_5$).

Similarly, 1,3-diphenyl-5-acetyl-5-methylhydantoin (XVIIb),[8] mp 135—137°C (ligroin), was obtained from XVIb and 2 mol of VII in a 49% yield along with XIII (24%). Found: C, 70.22; H, 4.90; N, 9.11%. Calcd for $C_{18}H_{16}N_2O_3$: C, 70.11; H, 5.23; N, 9.09%. IR (KBr): 1780 and 1720 cm^{-1}.

Reaction of XVIa with 1 mol of VII in Benzene. When 0.60 g (5.0 mmol) of VII was added portionwise to a suspension of XVIa (0.97 g, 5. 0mmol) in 20 ml of dry benzene, an exothermic reaction took place and the mixture turned into a clear solution. The solution was warmed at 40°C for 4 hr and the solvent was removed *in vacuo*. The residue was chromatographed over silica gel. Elution with benzene gave 1.13 g (73%) of α-methyl-β-methylthiomethoxy-β-phenylacrylanilide (XVIIIa), mp 118.5—119°C (ligroin). Found: C, 69.25; H, 5.85; N, 4.32; S, 10.11%. Calcd for $C_{18}H_{19}NSO_2$: C, 68.99; H, 6.11; N, 4.47; S, 10.22%. IR (KBr): 3300, 1640, 1535, 1340, and 1112 cm^{-1}. NMR ($CDCl_3$): τ=8.16 (3H, s, CH_3–C), 7.86 (3H, s, CH_3–S), 5.28 (2H, s, S–CH_2–O), 2.20—3.05 (10H, m, $2C_6H_5$), and 0.24 (1H, s, NH). Mass: *m/e* 251, 222, 146, 119, 105, and 77.

In a similar manner, *N*-ethyl- and *N*-cyclohexyl-α-methyl-β-methylthiomethoxy-β-phenylacrylamide, (XVIIIb) and (XVIIIc), were obtained by the reactions of XVIa with ethyl and cyclohexyl isocyanates, respectively. XVIIIb (in an 80% yield), mp 77—78°C (petroleum ether). Found: C, 67.50; H, 8.10; N, 4.35; S, 9.99%. Calcd for $C_{18}H_{25}NO_2S$: C, 67.69; H, 7.89; N, 4.39; S, 10.02%. XVIIIc (in an 86% yield), bp 141.0°C/0.073 mmHg. Found: C, 63.37; H, 7.13; N, 5.29; S, 11.83%. Calcd for $C_{14}H_{19}NO_2S$: C, 63.38; H, 7.22; N, 5.28; S, 12.06%.

Reaction of XVIIIa with Anisole. To a solution of XVIIIa (1.57 g, 5.0 mmol) in 25 ml of anisole, several drops of boron trifluoride etherate were added. Evolution of heat was observed and the color of the solution turned slightly yellow. After stirring for 1.5 hr at room temperature, followed by warming at 60°C for 6 hr, anisole was evaporated and dry ether was added to the residue to precipitate α-benzoylpropionanilide (XXII), 0.70 g (67%), mp 137.0—138.5°C (benzene). Found: N, 5.53%. Calcd for $C_{16}H_{15}NO_2$: N, 5.58%. From the filtrate, *p*-methylthiomethylanisole (XXI) was obtained, 0.31 g (38%), bp 80—81°C/1.6 mmHg. Found: C, 63.98; H, 7.43; S, 18.83%. Calcd for $C_9H_{12}OS$: C, 64.27; H, 7.19; S, 19.03%. NMR ($CDCl_3$): τ=8.08 (3H, s, CH_3–S), 6.43 (2H, s, $-CH_2-$), 6.28 (3H, s, CH_3–O), 3.22 and 2.85 (4H, a pair of doublets with a coupling constant of 8.5 Hz, $-C_6H_4-$).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2571—2574 (1970)

Studies on Pyrophosphates. I. A Selective Degradation of Pyrophosphates by Means of 2,6-Dichloroquinone *N*-Chloroimide

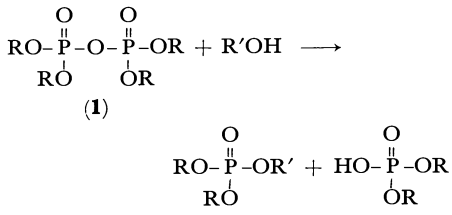
Kyu-Jang CHONG, Sheng-Shung PONG and Tsujiaki HATA

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 19, 1970)

Reaction of P^1,P^2-dialkyl pyrophosphate with alcohols or water in the presence of 2,6-dichloroquinone *N*-chloroimide (CQC) was studied. It was found that alkyl *p*-nitrophenyl phosphates are obtained in high yields by treating P^1,P^2-di-*p*-nitrophenyl pyrophosphate with alcohols in the presence of CQC. Similarly, alkyl phosphates are selectively produced by the reaction of P^1,P^2-dialkyl pyrophosphates with water in the presence of CQC. These reactions afford a new procedure for the selective degradation of P^1,P^2-dialkyl pyrophosphates, especially nucleoside pyrophosphates.

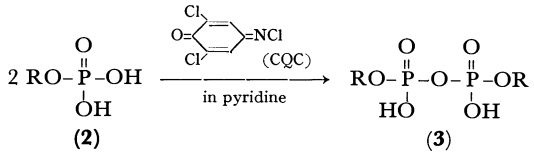
The method of phosphorylation with the use of tetraalkyl pyrophosphates (**1**) is a versatile one[1-3] that has been applied to nucleotide synthesis.[4]



However, only a few studies[5-7] have been reported on P^1,P^2-dialkyl pyrophosphates (**3**) as applied to the phosphorylation of alcohols, since pyrophosphates (**3**) are generally unreactive compared with tetraalkyl pyrophosphates (**1**).

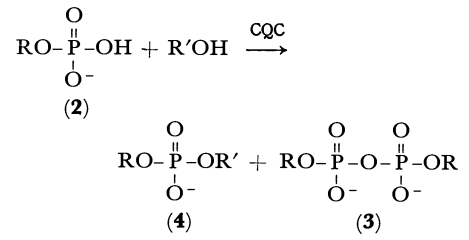
In the present study, phosphorylation of alcohols with P^1,P^2-dialkyl pyrophosphates (**3**) and 2,6-dichloroquinone *N*-chloroimide (CQC) was investigated.

It was found that P^1,P^2-di-*p*-nitrophenyl pyrophosphate (**3a**) was obtained in high yield by treating CQC with *p*-nitrophenyl phosphate (**2a**) in dry pyridine at room temperature for 5 hr.



2a and **3a**, R=*p*-nitrophenyl

This result suggests that CQC participates in the activation of *p*-nitrophenyl phosphate (**2a**), which leads us to surmise that it would be used as an active condensating reagent for the preparation of diesters of phosphoric acid (**4**) from **2a** and alcohols. When a mixture of 1 equiv. of **2a** and *n*-octanol in dry pyridine was treated with 3 equiv. of CQC at room temperature for 19 hr, *n*-octyl *p*-nitrophenyl phosphate (**4f**) and **3a** were produced in 15% and 77% yields, respectively.



After being kept standing for several days, **3a** decreased significantly and **4f** was obtained as the main product. This indicates that **3a**, initially formed, further reacts with CQC to yield an intermediate (**5**), which in turn reacts with alcohol to give a diester of phosphoric acid (**4**) and *p*-nitrophenyl 2,6-dichloroquinoneoxime phosphate (**6**). **6** thus formed also reacts with another alcohol to yield **4** and 2,6-dichloroquinone oxime (**7**).

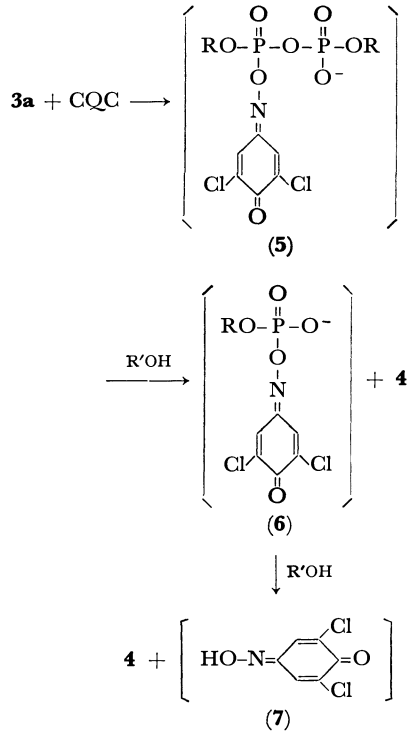
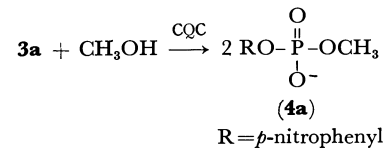
6) F. Cramer and K. H. Scheit, *Chem. Ber.*, **95**, 1657 (1962).
7) M. Smith, G. I. Drummond and H. G. Khorana, *J. Amer. Chem. Soc.*, **83**, 698 (1961).



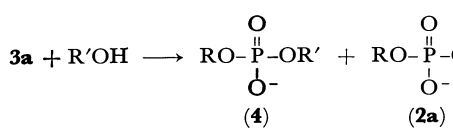
Based on the above mechanism, phosphorylation of alcohols with the use of CQC and P¹,P²-di-*p*-nitrophenyl pyrophosphate (**3a**), obtained from *p*-nitrophenyl phosphate (**2a**) and dicyclohexylcarbodiimide, was tried.

When a mixture of 3 equiv. of CQC and 1 equiv. of **3a** in methanol was heated at 100°C for 2 hr, methyl *p*-nitrophenyl phosphate (**4a**) was obtained in 91% yield, as expected.



R=*p*-nitrophenyl

This shows that the pyrophosphate can be effectively used as a phosphorylating reagent when it is treated with CQC. By this method, several alkyl *p*-nitrophenyl phosphates (**4**) were obtained in high yields from the corresponding alcohols as shown in Table 1. In the cases of *n*-octanol and *n*-hexadecanol, **2a** was produced as a by-product probably by way of a direct nucleophilic attack of alkoxide anion on phosphorus atom of **3a** to give **2a** and **4**.



R=*p*-nitrophenyl

Table 1. Preparation of alkyl *p*-nitrophenyl phosphate (**4**)

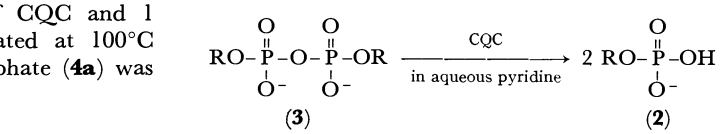
No.	alkyl (R)	yield (%)	R_f value
4a	methyl	91	0.75
4b	ethyl	85	0.76
4c	*n*-propyl	82	0.81
4d	*n*-butyl	93	0.82
4e	*n*-pentyl	72	0.85
4f	*n*-octyl	65	0.91
4g	*n*-hexadecyl	59	0.92

Solvent system: isopropyl alcohol : conc. ammonia : water=8 : 1 : 1 (v/v)

A nucleoside pyrophosphate, P¹,P²-di-thymidine 5′-pyrophosphate (**8a**) was also degradated in methanol to methyl thymidine 5′-phosphate and thymidine 5′-phosphate by treating with CQC.

A further study to extend the reaction for a selective hydrolysis of the pyrophosphates was carried out with the assumption that 2 mol of alkyl phosphate (**2**) is exclusively produced, when **3** is treated with water in place of alcohols in the above reaction.[8]

When a mixture of 1 equiv. of **3a** and 3 equiv. of CQC in aqueous pyridine was heated at 100°C for 2 hr, **2a** was exclusively obtained in 95% yield as expected. This non-enzymatic method can be applied to the hydrolysis of nucleoside pyrophosphates such as thymidine-, uridine-, adenosine-, guanosine-, and cytidine-pyrophosphate. These results are summarized in Table 2.



In the above reactions, six coloured substances were always detected by paper chromatography. All of the compounds contain no phosphate group and seem to be derivatives of CQC. Failure to isolate and identify the coloured substances makes the interpretation of the reaction mechanism more difficult.

Experimental

General Methods. Paper chromatography was carried out by the descending technique using Toyo Roshi No. 51 and No. 51A papers. The solvents used were isopropyl alcohol-concentrated ammonia - water (7 : 1 : 2 v/v) (Solvent A), or (8 : 1 : 1 v/v) (Solvent B) and isoamyl alcohol-5% disodium hydrogen phosphate (1 : 1 v/v) (Solvent C). The R_f values of different compounds are given in Tables 1 and 2. Except for

8) In general, on hydrolysis in aqueous alkali solution, P¹,P²-dialkyl pyrophosphate does not afford the single phosphate (**2**), but inorganic phosphate, pyrophosphoric acid and alcohol are always contaminated.

*** Mobility relative to the corresponding pyrophosphate.

the use of Solvent C, phosphorus compounds were made visible on paper chromatograms after spraying the chromatograms with the Isherwood Reagent[9] and exposing them to ultraviolet lamp. The ε_{max} value at 290 mμ used for alkyl *p*-nitrophenyl phosphates (**4**) was 10000 (pH : 7). Paper electrophoresis was carried out in an apparatus in which the paper was immersed in carbon tetrachloride. The buffers used were phosphate 0.05M KH_2PO_4 (pH 6, pH 7 and pH 8).

Materials. 2,6-Dichloroquinone *N*-chloroimide was a commercial sample (Tokyo Kasei Co., Tokyo, Japan). Alcohols and pyridine were purified and dried by ordinary procedures. *N*-Benzoyl guanosine 5′-phosphate,[7] *N*-benzoyl cytidine 5′-phosphate,[7] P^1,P^2-dithymidine 5′-pyrophospate (TppT),[11,12] P^1,P^2-di-adenosine 5′-pyrophosphate (AppA)[7] and P^1,P^2-di-uridine 5′-pyrophosphate (UppU)[10] were prepared by the procedures in literature. P^1,P^2-Di-*p*-nitrophenyl pyrophosphate (**3a**), P^1,P^2-di-*N*-benzoyl guanosine pyrophosphate ($G^{Bz}ppG^{Bz}$) and P^1,P^2-di-*N*-benzoyl cytidine pyrophosphate ($C^{Bz}ppC^{Bz}$) were prepared by a modification of Khorana's method[7,11] as described below.

P^1,P^2-Di-*p*-nitrophenyl Pyrophosphate. To a solution of *p*-nitrophenyl phosphate (**2a**) (0.438 g, 0.2 mM) in dry pyridine (5 ml) was added dicyclohexylcarbodiimide (0.247 g, 1.2 mM). To the mixture, after being stirred for 2 hr at room temperature, was added 1 ml of water. Stirring was continued for 1 hr at room temperature. A white precipitate, dicyclohexylurea, was filtered and washed with water. The filtrate and the washings were combined and concentrated under reduced pressure at a temperature below 40°C.

Evaporation was then repeated twice or three times with pyridine.

The flask was kept standing in a refrigerator overnight to afford P^1,P^2-di-*p*-nitrophenyl pyrophosphate (0.550 g, 95%) as a white powder: mp 166—167°C (di-pyridinium salt).

Found: C, 45.86; H, 3.59; N, 9.90. Calcd for $C_{22}H_{20}O_{11}N_4P_2$: C, 45.67; H, 3.46; N, 9.70%; mol wt, 578.

P^1,P^2-Di-*N*-benzoyl Guanosine 5′-Pyrophosphate ($G^{Bz}ppG^{Bz}$). *N*-Benzoyl guanosine 5′-phosphate (0.056 mM)[7] was rendered anhydrous by three repeated evaporations of 4 ml of dry pyridine. A gummy *N*-benzoyl quanosine 5′-phosphate was dissolved in 10 ml of dry pyridine and dicyclohexylcarbodiimide (35 mg) was then added. The reaction mixture was heated at 100° for 20 min and allowed to stand at room temperature overnight. The precipitate was filtered and washed with pyridine. The filtrate and the washings were combined and evaporated to dryness. White powder, thus obtained, was dissolved in 15 ml of water. The aqueous solution was washed with four portions of 20 ml of petroleum ether. The aqueous layer was treated with 2 ml of pyridine and evaporated to dryness. White powder was obtained and dry pyridine was added. The precipitate was filtered and washed with pyridine. The filtrate was evaporated to dryness. P^1,P^2-Di-*N*-benzoyl guanosine 5′-pyrophosphate (0.019 mM, 38%) was obtained as syrupy substance which was chromatographically pure. The yield was estimated spectrophotometrically. $\lambda_{max}^{H_2O}$ 292 mμ (ε : 16200), $\lambda_{max}^{H_2O}$ 259 mμ, $\lambda_{max}^{H_2O}$ 278 mμ.

P^1,P^2-Di-*N*-benzoyl Cytidine 5′-Pyrophosphate (CppC). *N*-Benzoyl cytidine 5′-phosphate[7] (0.046 mM) and 4-morpholine-*N*,*N*′-dicyclohexylcarboxamidine(13.5 mg) were dissolved in 10 ml of pyridine under anhydrous conditions at 100°C. After addition of dicyclohexylcarbodiimide (25 mg, 0.12 mM), the mixture was kept at 100°C for 10 min and was allowed to stand at room temperature for 1 day. After removal of pyridine, 10 ml of water was added. The gel was filtered and washed with three portions of petroleum ether. The aqueous layer was concentrated to dryness. The gummy residue was dissolved in 0.5 ml of ethanol and treated

12) M. W. Moon and H. G. Khorana, *ibid.*, **88**, 1798 (1966).

with 1 m*l* of concentrated ammonium hydroxide. The mixture was allowed to stand at room temperature for 3 days. A white precipitate appeared and the suspension was treated with 2 m*l* of pyridine. After removal of solvent, the residue was dissolved in 3 m*l* of water and neutralized with Dowex 50W-X8 (pyridinium form). The resin was filtered and washed thoroughly with water. The filtrate and the washings were concentrated to a small volume. Electrophoresis showed that the product contained almost pure P^1,P^2-di-cytidine 5′-pyrophosphate. The solution was passed through a column (45 cm × 2 cm dia.) of commercially available diethylaminoethyl cellulose (DEAE) (bicarbonate form), elution being carried out with a linear salt gradient, 1*l* of water and 1*l* of 0.05M triethylammonium bicarbonate in a reservoir. About 15 m*l* fractions were collected every 10 min. Fractions 47—56 contained P^1,P^2-di-cytidine 5′-pyrophosphate. The yield of this product, as estimated spectrophotometrically, was 69%. The product obtained as the triethylammonium salt was converted in to the pyridinium salt by treatment with Dowex 50W-X8 (pyridinium form) and the solution was lyophilized.

Alcoholysis of P^1,P^2-Di-*p*-nitrophenyl Pyrophosphate (3a) in the Presence of CQC. To a solution of **3a** (0.134 g, 0.2 mM) and an alcohol (2 mM) in 20 m*l* of dry pyridine was added CQC (0.132 g, 0.63 mM), and the mixture was heated at 100°C for 2 hr. The solution was concentrated to a syrup, which was washed thoroughly three times with chloroform. The chloroform was combined and evaporated to dryness. The residue was washed three times with benzene. The benzene was evaporated and the residual oil was dissolved in 30 m*l* of water and washed with two portions of 30 m*l* of ether. After removal of water under reduced pressure, chromatographically pure alkyl *p*-nitrophenyl phosphate (**4**) was obtained as shown in Table 1. Estimation of the yield of this product was carried out spectrophotometrically after elution of spot from paper chromatogram run in Solvent A.

Hydrolysis of P^1,P^2-Di-*p*-Nitrophenyl Pyrophosphate (3a) in the Presence of CQC. To a solution of **3a** (0.314 g, 0.2 mM) in aqueous pyridine was added CQC (0.132 g, 0.63 mM), and the mixture was heated at 100°C for 2 hr. *p*-Nitrophenyl phosphate (**2a**) was obtained in 93% yield which was estimated spectrophotometrically after elution of the spot from paper chromatogram run in Solvent A.

Hydrolysis of P^1,P^2-Di-nucleoside 5′-Pyrophosphate in the Presence of CQC. In Table 2 are summarized the reaction under various conditions. A typical procedure is described below.

Hydrolysis of P^1,P^2-Di-adenosine 5′-Pyrophosphate. To a solution of P^1,P^2-di-adenosine 5′-pyrophosphate in 2.5 m*l* of pyridine-dimethylformamide (1 : 1) was added water and then CQC. The mixture was heated on a boiling water bath for 2 hr. Adenosine 5′-phosphate was obtained (see Table 2) which was estimated spectrophotometrically after elution of the spot from Toyo Roshi No. 51A paper run in phosphate buffer (pH 6) by electrophoresis.

We heartily thanks Professor Teruaki Mukaiyama for his encouragement and discussion throughout the investigation. We also wish to thank Mr. Masaru Koezuka for his help with elemental analysis.

Thermal Demercuration Reactions of Organomercurials

Naoki INAMOTO and Masaaki YOSHIFUJI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received February 23, 1970)

Thermal demercuration reactions of organomercurials (RHgX) alone or with mercuric salts (HgY_2) were performed (where R=*n*-butyl, *s*-butyl, cyclohexyl, benzyl, phenyl, and *p*-tolyl; X,Y=Cl, Br, CN, SCN, and OAc). Alkyl chlorides were obtained in good yields in the cases of alkylmercuric chlorides. The results in the reactions of cyclohexylmercuric halides with mercuric salts suggested the exchange reaction between them. Thermal demercuration reactions of arylmercurials gave the corresponding aromatic hydrocarbons as main product, and their mechanisms which involve generation of aryl radicals were discussed. General mechanisms of demercuration reaction of organomercurials alone were also discussed, and the importance of intermolecular interaction between organic group and chlorine was suggested in the cases of aliphatic organomercuric chlorides.

French, Inamoto and Wright[1] found that mercurous salts are the most effective catalyst for redistribution reaction of the bis-organomercurials. As impure bis-organomercurials redistributed more readily than pure materials, the following mechanism

1) W. E. French, N. Inamoto and G. F Wright, *Can. J. Chem.*, **42**, 2228 (1964).

was postulated for the formation of mercurous salts as a catalyst.

$$RHgR \xrightarrow[\text{peroxide}]{\text{heat or}} R\text{-}R + Hg \quad (1)$$

$$RHgX \rightarrow RX + Hg \quad (2)$$

$$2\ RHgX \rightleftarrows R_2Hg + HgX_2 \quad (3)$$

$$HgX_2 + Hg \rightarrow Hg_2X_2 \quad (4)$$

The reaction (2) has not been reported except for some vinylmercuric salt,[2] although it is well known that organomercuric salts give mercurous salts by thermal decomposition,[3] photolysis,[4-6] or the action of peroxide.[1,7]

$$2\ RHgX \rightarrow 2R\cdot + 2\cdot HgX\ (\rightarrow Hg_2X_2)$$

According to the reactions (2) and (4), the following reaction would be expected to occur.

$$RHgX + HgX_2 \rightarrow RX + Hg_2X_2 \quad (5)$$

Inamoto and Wright[8] carried out the reactions of organomercurials with mercuric salts and obtained the following preliminary results. Reaction of cyclohexylmercuric or *n*-butylmercuric chloride with a slight excess of mercuric chloride at 150—240°C gave cyclohexyl chloride (isolated in 68% yield under reduced pressure) or *n*-butyl chloride (isolated in 40% yield), respectively, and mercurous chloride was produced in nearly quantitative yield in both cases. Therefore, it was proved that the reaction (5) occurs. On the other hand, phenylmercuric or *p*-tolylmercuric chloride gave benzene or toluene (isolated in 20—30% yield by distillation), respectively, instead of the corresponding aryl chloride, under similar conditions, and the yields of mercurous chloride were not quantitative. These results indicate that the reaction of arylmercuric chlorides does not follow the reaction (5). Furthermore, the similar reaction of cyclohexylmercuric bromide with mercuric chloride gave no cyclohexyl bromide but cyclohexyl chloride.

In order to clarify these reactions, we investigated the thermal decompositions of organomercurials alone or with mercuric salts in more detail.

Results and Discussion

Alkylmercuric Chloride, Bromide, and Cyanide. The thermal reaction of *s*-butylmercuric chloride with a slight excess of mercuric chloride at about 260°C for 2 hr gave *s*-butyl chloride in 64% yield after distillation.

Table 1 shows the results on the thermal reactions of the cyclohexylmercuric halide-mercuric halide system. The ratio of cyclohexyl bromide to the chloride increased with the bromine content in the system. The formation of the chloride, moreover, is apparently considered to be more favorable than that of the bromide. This result suggests that an exchange reaction occurs between cyclohexylmercuric halide and mercuric halide. Formation of considerable amount of cyclohexyl bromide in the thermal reaction of cyclohexylmercuric bromide with an insufficient amount of mercuric chloride is presumably attributed to a self-decomposition of an excess cyclohexylmercuric bromide.

Some attention should be given on the de-

mercuration reaction of cyclohexylmercuric chloride or bromide alone as in the following. First, the yield of mercury metal liberated in the latter was smaller than that in the former. Secondly, the yield of cyclohexane from the latter was much larger than that in the former, partly because of the formation of cyclohexyl radicals due to the weaker bond strength of C–Hg in the bromide than that in the chloride,*1 followed by hydrogen abstraction from the surrounding organomercurials. Partial formation of cyclohexyl radicals is evident from the detection of a trace of dicyclohexyl by means of vapor phase chromatography (VPC).

Another pathway of the formation of cyclohexane is a reaction of unchanged cyclohexylmercuric bromide with hydrogen bromide generated by mercuric bromide - catalyzed dehydrobromination of cyclohexyl bromide produced during the reaction,[10] because of facile dehydrobromination of organic bromide. This pathway is considered to be reasonable, because of the formation of a considerable amount of cyclohexene.

The demercuration reaction of cyclohexylmercuric cyanide alone at 240—265°C under reduced pressure gave cyclohexane (4%), cyclohexene (66%), cyclohexyl cyanide (9%), mercury metal (84%), and hydrogen cyanide.

Mechanisms of these demercuration reactions will be discussed later.

Phenylmercuric Chloride, Cyanide, and Thiocyanate. Table 2 shows the results on the thermal reactions of phenylmercuric chloride or cyanide*2 under various conditions. In every case, the main product was benzene (25—50% yields), and the yield of chlorobenzene or/and benzonitrile was very poor, but increased at higher temperatures. The benzene formation can be explained by assuming generation of phenyl radicals, followed by hydrogen abstraction from the surrounding organomercurials. It is confirmed by the presence of diphenyl among the products.

The reaction of phenylmercuric cyanide and mercuric cyanide at 350°C gave a large amount of mercury, which might be attributed to the

decomposition of mercuric cyanide at higher temperatures.[11]

Table 3 shows the results on the thermal reactions of phenylmercuric thiocyanate. The main product was also benzene, together with a considerable amount of mercury metal and mercuric sulfide. Phenyl isothiocyanate was not detected. In the demercuration reaction of phenylmercuric thiocyanate alone, no phenyl thiocyanate was obtained.

The demercuration reaction of *p*-tolylmercuric chloride alone gave toluene (47%) as a main product, together with a trace of *p*-tolyl chloride, dibenzyl, di-*p*-tolyl, phenyl-*p*-tolylmethane and mercury metal.

Bis-organomercuries. In order to test the possibility of the reaction (3), the reactions of diphenyl mercury with mercuric salts were carried out (Table 4). The thermal reaction of diphenylmercury with mercuric chloride (or cyanide) gave almost the same products as those of phenylmercuric chloride (or cyanide) with mercuric chloride (or cyanide).

The thermal reaction of bis-phenylethynylmercury with mercuric cyanide was similar to that of diphenylmercury with mercuric cyanide, but mercury liberated was almost quantitative.

Acetoxymercurials. The results of the thermal reactions of acetoxymercurials are summarized in Table 5.

n-Butylmercuric acetate gave metallic mercury in 72% yield, but only a small amount of *n*-butyl acetate (9.6%) was obtained together with a considerable amount of very volatile material, which is supposed to be butane or butene. Other products were acetic acid (24%), a considerable amount of acetic anhydride, and a trace of methyl acetate. In the presence of a slight excess of mercuric acetate, the yield of *n*-butyl acetate was rather small (5%). A considerable amount of very volatile material was also observed in this case.

Benzylmercuric acetate gave metallic mercury in 68% yield, but only a trace of benzyl acetate was formed, together with a considerable amount of dibenzyl and acetic acid and a trace of toluene, acetic anhydride and methyl acetate. In the presence of slight excess of mercuric acetate, the amount of benzyl acetate increased and the amount of dibenzyl decreased.

The demercuration reaction of phenylmercuric acetate alone or with mercuric acetate gave acetic acid, benzene (50%), and a trace of methyl acetate, together with mercury metal. Neither phenyl acetate nor toluene were detected.

In this connection, the thermal reaction of mercuric acetate alone was performed, and the products

were metallic mercury (90%), a large amount of acetic acid and a trace of methyl acetate. Thus the thermal reactions of organomercuric acetate proved to involve the self-decomposition of mercuric acetate itself.

The formations of acetic acid and methyl acetate are reasonably explained by radical mechanism including acetoxy radicals.*3

Mechanisms of Demercuration Reactions. The results on the thermal reactions of organomercuric halides alone are very interesting: although cyclohexylmercuric chloride liberated a large amount of mercury metal and gave cyclohexyl chloride, phenylmercuric and p-tolylmercuric chlorides gave the corresponding aromatic hydrocarbons and only a trace of mercury (Table 6). Moreover, cyclohexylmercuric and n-butylmercuric bromides gave smaller amount of mercury metal than cyclohexylmercuric chloride.

These results show that the appearance of the demercuration reaction depends upon both organic and inorganic groups, and that the demercuration reactions of alkylmercuric halides are different from those of arylmercuric halides.

Three mechanisms are possible for thermal demercuration of organomercuric salt alone.

Mechanism A

$$\text{R–Hg–X} \rightarrow \text{R}\cdot + \cdot\text{HgX} \quad (6)$$

$$\text{R}\cdot + \cdot\text{HgX} \rightarrow \text{RX} + \text{Hg} \quad (7)$$

$$2\cdot\text{HgX} \rightarrow \text{Hg}_2\text{X}_2$$

Mechanism B

$$2\ \text{R–Hg–X} \rightleftarrows \begin{bmatrix} \text{R–Hg–X} \\ \vdots \quad \vdots \\ \text{R—Hg–X} \end{bmatrix} \rightleftarrows \text{R}_2\text{Hg} + \text{HgX}_2 \quad (8)$$

$$\text{R–Hg–R} \rightarrow 2\text{R}\cdot + \text{Hg} \quad (1)$$

$$\text{R}\cdot + \text{HgX}_2 \rightarrow \text{RX} + \cdot\text{HgX} \quad (9)$$

$$\text{Hg} + \text{HgX}_2 \rightarrow \text{Hg}_2\text{X}_2 \quad (4)$$

$$2\cdot\text{HgX} \rightarrow \text{Hg}_2\text{X}_2$$

Mechanism C

$$\text{R–Hg–X} \rightleftarrows [\text{–X}\cdots\text{R–Hg–X}\cdots\text{R–Hg–}]$$

$$\text{or} \begin{bmatrix} \text{R–Hg–X} \\ \vdots \quad \vdots \\ \text{X–Hg–R} \end{bmatrix} \rightarrow \text{RX} + \text{Hg} \quad (10)$$

If the mechanism A is correct, organomercuric bromides would give larger amount of mercury metal than the corresponding chlorides, from a consideration of bond energy of R–HgX and ·Hg–X. However, as the results are opposite, the mechanism A seems to be unlikely.

In the mechanism B, the position of the equilibrium (reaction (8)) generally lies by far to the left-hand side, but, if at least one of the components in the right-hand side is unstable to heat, the equilibrium would shift to the right-hand side. Since bis-organomercurials are usually less stable to heat than organomercuric salts, organic free radicals would generate from bis-organomercurials thus produced, and would react according to the reaction (9), which would compete with the reaction (4). Thus the formation of mercury metal would be considerably supressed. Therefore, the formation of large amounts of mercury metal could not be explained by the mechanism B.

Kharasch *et al.*[12] and Shoolery *et al.*[13–15] have

*3 It is considered that the acetoxy radicals may be stabilized by some interaction with mercury metal, because completely free acetoxy radical would rapidly decompose into methyl radical and carbon dioxide.

14) J. R. Cavanaugh and B. P. Dailey, *J. Chem. Phys.*, **34**, 1099 (1961).

15) M. A. Davis, *J. Org. Chem.*, **32**, 1161 (1967).

established the relative electronegativities of organic and inorganic groups as follows:

$$p\text{-}CH_3C_6H_4 > C_6H_5 > CH_3 > n\text{-}C_4H_9 > C_6H_5CH_2 > cyclo\text{-}C_6H_{11};$$
$$OAc > Cl > Br > SCN > CN$$

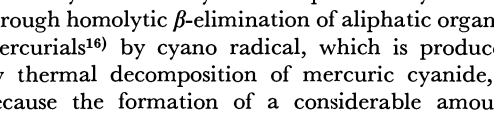
Since aryl groups are more electronegative than cyclohexyl, the intermolecular interaction between cyclohexyl and chlorine seems to be more strong than that between aryl and chlorine. From these considerations, the demercuration reactions of alkylmercuric chlorides are considered to proceed mainly through the mechanism C. Thus, the corresponding chlorides are obtained in good yields. Partial formation of alkyl radicals is attributed to the mechanisms A (may be less probable) and B.

In the cases of alkylmercuric bromides, intermolecular interaction between alkyl group and bromine is considered to be not so strong as in the alkylmercuric chlorides because of less electronegativity of bromine. Therefore, the contribution of the mechanism C decreases and both liberation of metallic mercury and the formation of organic bromide decrease.

Arylmercuric chlorides, on the contrary, might decompose on heating to generate aryl radicals mainly through mechanism B, because an intermediate complex in the reaction (8) seems favorable over that in the mechanism C from a consideration of the electronegativities of aryl group and chlorine. Formation of the corresponding aromatic hydrocarbon is presumably attributed to hydrogen abstraction from the surrounding organomercurials by aryl radicals. Thus the reaction (9), in which aryl radical is considered to be more favorable over alkyl radical, scarcely occurs.

In organomercuric cyanides, considerable amount of mercury metal was always liberated. These facts indicate that the demercuration reaction of organomercuric cyanides proceeds mainly through the mechanism B, because mercuric cyanide produced is also unstable to heat.[11]

A large amount of cyclohexene in the case of cyclohexylmercuric cyanide is presumably formed through homolytic β-elimination of aliphatic organomercurials[16] by cyano radical, which is produced by thermal decomposition of mercuric cyanide,[11] because the formation of a considerable amount of hydrogen cyanide was observed.



The demercuration reaction of phenylmercuric thiocyanate is considered to be very similar to that of the corresponding cyanide, excepting that no phenyl thiocyanate was obtained. This is explained by the following decomposition, because a large amount of mercuric sulfide was obtained and then liberated mercury metal decreased.

$$Hg(SCN)_2 \rightarrow HgS + \cdot CN + \cdot SCN$$
$$Hg + \cdot SCN \rightarrow HgS + \cdot CN$$

In the cases of organomercuric acetates, since mercuric acetate was almost decomposed to give metallic mercury under similar conditions, the demercuration reaction proceeds mainly through the mechanism B.

Phenylmercuric acetate gave neither phenyl acetate nor toluene. This fact shows that the mechanism C does not occur at all, because acetoxy group is more electronegative than chlorine. From the result, it is considered that the reaction (9) is also unlikely in other cases. Thus, the formation of a trace of RX is probably attributed to a small contribution of the mechanism C.

The following two mechanisms are possible for the demercuration reaction of organomercuric salt in the presence of mercuric salt.

Mechanism D

$$\begin{matrix} R\text{-}Hg\text{-}X \\ + \\ HgY_2 \end{matrix} \rightleftarrows \begin{bmatrix} R\text{—}Hg\text{-}X \\ \vdots \quad \vdots \\ Y\text{-}Hg\text{-}Y \end{bmatrix} \rightleftarrows RHgY + HgXY \quad (11)$$

$$RHgX(\text{or } RHgY) \xrightarrow[B,\ C \text{ or } E]{\text{Mechanism}}$$

Mechanism E

$$RHgX + HgY_2 \rightleftarrows [\cdots X\text{-}Hg\text{-}R\cdots Y\text{-}Hg\text{-}Y\cdots R\text{-}Hg\text{-}X\cdots] \rightarrow RY + Hg \quad (12)$$
$$Hg + HgY_2 \rightarrow Hg_2Y_2$$

In cyclohexylmercuric halide - mercuric halide systems, the ratio of cyclohexyl bromide to the chloride increased with the bromine content in the system, and the formation of the chloride was more favorable than that of the bromide (Table 1). These facts can be explained considering that the position of the equilibrium (11) lies to the side of cyclohexylmercuric chloride and that organomercuric salts thus produced decompose through the mechanism C or E depending on the amount of mercuric salts present.

Generally, it is concluded that alkylmercuric halides also decompose mainly through the mechanisms C and E in the presence of mercuric halides. In the cases of arylmercuric salts, the reactions presumably proceed through the mechanisms D and E. This conclusion is also supported from the facts that the results of the reactions of diphenylmercury with mercuric salts were very similar to those of phenylmercuric salts with mercuric salts.

In organomercuric acetate, the demercuration reaction proceeds through the mechanism B as described before. Thus, *n*-butylmercuric or benzylmercuric acetate gave the corresponding organic acetate only in a poor yield. In the case of *n*-butylmercuric acetate, the yield of *n*-butyl acetate

16) F. R. Jensen and H. E. Guard, *J. Amer. Chem. Soc.*, **90**, 3250 (1968).

decreased from 10% to 5% in the presence of mercuric acetate. This fact can be reasonably explained by a large contribution of homolytic β-elimination[16] similarly to that of cyclohexylmercuric cyanide.

On the other hand, in the case of benzylmercuric acetate, the yield of benzyl acetate increased considerably and the yield of dibenzyl decreased in the presence of mercuric acetate. Since benzyl group is much less electronegative and acetoxy group is much more electronegative, the observed results can be explained by the absence of homolytic β-elimination and by the contribution of the mechanism E in the presence of mercuric acetate.

Experimental*4

Materials. Organomercurials were prepared by usual methods: *n*-butylmercuric bromide, mp 129.5—131°C (lit,[17] 136°C); *n*-butylmercuric acetate, mp 54—55.5°C (lit,[17] 56°C); *s*-butylmercuric chloride, mp 26.5—29.5°C (lit,[18] 28°C); benzylmercuric acetate, mp 124—125°C (lit,[19] 128—128.8°C); cyclohexylmercuric bromide, mp 151—153°C (lit,[20] 153°C); cyclohexylmercuric chloride, mp 160—161.5°C (lit,[21] 163°C); cyclohexylmercuric cyanide, mp 147—148.5°C (lit,[21] 146°C); phenylmercuric acetate, mp 148.5—150°C (lit,[22] 149°C); phenylmercuric chloride, mp 249.4—249.7°C (lit,[21] 251°C); phenylmercuric cyanide, mp 203—205°C (lit,[21] 209°C); phenylmercuric thiocyanate, mp 230—231°C (decomp.) (lit,[23] 231—232.5°C (decomp.)); diphenylmercury, mp 125—127°C (lit,[24] 122—124°C); *p*-tolylmercuric chloride, mp 232.5—234.5°C (lit,[21] 233°C); bis-phenylethynylmercury, mp 123—124°C (lit,[25] 124.5—125°C).

Mercuric thiocyanate was prepared by the usual method.[26] Other inorganic mercuric salts were obtained commercially.

Authentic samples were prepared by the methods described in the literature: cyclohexyl cyanide,[27] bp 183—187°C (lit,[28] 184—185°C); dicyclohexyl, bp 110°C/15 mmHg, n_D^{19} 1.4800 (lit, bp 233°C/750 mmHg,[29] n_D^{20} 1.47954[26]); phenyl thiocyanate, bp 104—106°C/15.5 mmHg (lit,[23] 232—233°C), IR: 2150 cm^{-1} (-S-C≡N); *p*-tolyl chloride, bp 155—156.5°C, n_D^{16} 1.5231 (lit, bp 162—162.2°C,[30] $n_D^{18.20}$ 1.5199[31]); di-*p*-tolyl, mp 118—120°C (lit,[32] 121°C); phenyl-*p*-tolylmethane, bp 141°C/13 mmHg (lit,[33] 144°C/16 mmHg); phenylethynyl cyanide, bp 101°C/12 mmHg, mp 37.5—39°C (lit,[34] bp 105—106°C/13 mmHg, mp 41°C); benzyl acetate, bp 104°C/17 mmHg, n_D^{21} 1.5008 (lit,[35] bp 213°C, $n_D^{19.93}$ 1.50324).

Other samples were obtained commercially.

General Methods for Thermal Reactions. About 2 g of organomercurial or a mixture of about 2 g of organomercurial and an appropriate amount of mercuric salt, which was softly covered with glass wool to prevent from sublimation of mercurials, was placed without a solvent in a reaction tube equipped with a thermometer and a cold trap, and heated at 200—300°C for 1—2 hr under ordinary or/and reduced pressure. Volatile liquid was collected in the cold trap cooled with dry ice-ethanol, weighed, and submitted to VPC*5 or distilled. Nonvolatile material in the reaction tube was extracted with ether or petroleum ether, with ethanol, methanol or acetone, and with water, successively, and each extract after evaporation was submitted to determination of melting point and/or to thin layer chromatography for identification. Metallic mercury liberated was isolated from the residual material and weighed.

Some typical examples are described below, and the results are summarized in Tables 1—6.

s-Butylmercuric Chloride with Mercuric Chloride. A mixture of 4.917 g (16.7 mmol) of *s*-butylmercuric chloride and 6.091 g (22.4 mmol) of mercuric chloride was heated at 250—260°C under ordinary pressure for 2 hr. Generation of hydrogen chloride was observed. Volatile liquid (1.420 g) was distilled, and 0.977 g (10.6 mmol, 63.5%) of *s*-butyl chloride, bp 61—68°C, was obtained.

Cyclohexylmercuric Chloride with Mercuric Bromide. A mixture of 2.003 g (6.27 mmol) of cyclohexylmercuric chloride and 2.579 g (7.18 mmol) of mercuric bromide (mole ratio 1 : 1.14) was heated at 240—265°C under a pressure of 50 mmHg for 1.5 hr. Volatile liquid (0.683 g) was submitted to VPC, and cyclohexane (0.20 mmol), cyclohexene (1.87 mmol), cyclohexyl chloride (3.36 mmol) and cyclohexyl bromide (0.74 mmol) were determined. A trace of dicyclohexyl was also detected. From the ethanol extract of nonvolatile material 0.302 g (11.7%) of unchanged mercuric bromide was recovered. The residue consisted of 2.828 g of white insoluble material, and no metallic mercury was observed.

*5 Diisodecyl phthalate, Apiezon "L" grease, di-2-ethylhexyl sebacate and succinic polyester of diethylene glycol were used as liquid phase.

Phenylmercuric Thiocyanate with Mercuric Thiocyanate. A mixture of 2.003 g (5.96 mmol) of phenylmercuric thiocyanate and 2.013 g (6.34 mmol) of mercuric thiocyanate was heated at 220—290°C under atmospheric pressure for 1 hr and then under a pressure of 20 mmHg at 270°C for 45 min. The volatile liquid (0.327 g) was submitted to VPC, and benzene (1.92 mmol, 32.3%), benzonitrile (0.471 mmol), and phenyl thiocyanate (0.0232 mmol) were determined. No phenyl isothiocyanate was detected. From the petroleum ether extract of nonvolatile material, 6 mg (0.036 mmol) of diphenyl was obtained, and from the ethanol extract 20 mg (1%) of unchanged phenylmercuric thiocyanate was recovered. The residue consisted of a considerable amount of insoluble black material and 243 mg (1.21 mmol) of metallic mercury. The black material proved to contain mercuric sulfide by the usual analytical method.

The authors wish to express their thanks to Professor G. F Wright, The University of Toronto, Canada, for his valuable comments throughout this work.

Imidazole Catalyses in Aqueous Systems. IV. Bimolecular and Michaelis-Menten-Type Catalyses of a Phenyl Ester Hydrolysis by Some Hydrophobic Imidazole Derivatives*1

Toyoki KUNITAKE and Seiji SHINKAI

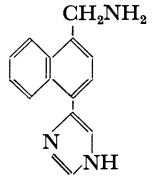
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka

(Received February 23, 1970)

Catalytic hydrolyses of *p*-acetoxybenzoic acid by several imidazole derivatives were conducted at 15—40°C in aqueous systems using a pH-stat. Imidazole compounds containing the naphthalene ring catalyzed the hydrolysis following the Michaelis-Menten kinetics as in enzymatic reactions, while catalysis by less hydrophobic imidazoles followed the second-order kinetics. Enhancement of the overall catalytic efficiency in the Michaelis-Menten pathway was estimated to be ten times at most as compared with the bimolecular pathway. The thermodynamic and activation parameters were obtained at 15—40°C for the Michaelis-Menten pathway. The binding of catalyst and substrate was characterized by small positive enthalpy changes ($\Delta H \cong +3.5$ kcal/ mol) and large positive entropy changes ($\Delta S_u \cong +28$ eu), indicating that the complex formation was ascribable to hydrophobic interactions. The intra-complex product formation was characterized by not unreasonable $\Delta H^{\neq}$ values and extraordinarily large negative $\Delta S^{\neq}$ ($\cong -50$ eu) values. The unexpectedly small rate enhancement in the Michaelis-Menten pathway was attributed to the unfavorable $\Delta S^{\neq}$ term, which suggested that the structure of the Michaelis complex was quite different from that of the transition state of the product formation.

In a previous publication of this series, we showed that a naphthylimidazole derivative (I) catalyzed the hydrolysis of a phenyl ester by the Michaelis-Menten kinetic as in enzymatic reactions.[1]

$$\text{catalyst} + \text{substrate} \underset{K_m}{\rightleftharpoons} \text{catalyst}\cdot\text{substrate} \xrightarrow{k_{cat}} \text{catalyst} + \text{product}$$



I

The substrate binding was attributed to hydrophobic interactions between catalyst and substrate. Apparently the naphthalene ring was hydrophobic enough to bind the substrate, *p*-acetoxybenzoic acid, under the hydrolytic conditions. In fact, naphthalenesulfonic acid and other water-soluble naphthalene derivatives were shown by NMR spectroscopy to associate with methanol or acetone in an aqueous system.[2] Occurrence of the substrate saturation in the hydrolysis of phenyl esters due to the hydrophobic interaction

have been observed increasingly in polymeric[3-6] and non-polymeric[7,8] systems. Interest in these studies arises from the fact that the active site of many hydrolytic enzymes comprises hydrophobic regions and the hydrophobic interaction with substrate is intrinsic in determining the specificity and efficiency of the active site.[9]

We showed that the catalytic efficiency was quite different in the neutral and monoprotonated spcies of I, indicating that the structural difference of the catalyst affected its catalytic activity appreciably. On the other hand, remarkable rate enhancement which might be expected from formation of the Michaelis complex was not observed because of rather small k_{cat} values.

Thus it was felt necessary to study in more detail the influence of hydrophobicity on the catalytic behavior of imidazoles. In the present investigation thermodynamic and activation parameters were estimated for the catalytic process in the hydrolysis of *p*-acetoxybenzoic acid (Eq. (2)) by several imidazole derivatives (Bz-Im, Ph-Im, N-oyl-Im, and N-yl-Im), in the hope that the results would be useful for designing more efficient catalytic systems.

Experimental

***N*-Benzoylhistamine (Bz-Im)** was prepared by reaction of histamine and benzoyl chloride in the presence of triethylamine,[10] mp 148.5—149.5°C (lit,[10] 148°C).

***N*-[4(5)-Imidazolylethyl]-phthalimide (Ph-Im).** *o*-Phthaloyl chloride was prepared from phthalic anhydride and phosphorus pentachloride in 90% yield, bp 142—146°C/15 mmHg (lit,[11] 131—133°C/9—10 mmHg). Histamine dihydrochloride (1.8 g, 0.01 mol) was dissolved in 60 m*l* of 4 N NaOH in a three-necked flask equipped with a mechanical stirrer. *o*-Phthaloyl chloride (1.0 g, 0.005 mol) in 30 m*l* of chloroform and 3.0 m*l* of 4 N NaOH were separately added dropwise over a 15 min period of ice cooling. The solution was confirmed to be alkaline and then stirred for 1 hr. Sodium chloride was added and the chloroform layer was separated. The aqueous layer was extracted with 30 m*l* of chloroform, and the combined chloroform solution was washed with dil. aqueous alkali and with a small amount of water. Chloroform was evaporated and the residue was recrystallized from water, colorless plates, mp 221—225°C (dec.), yield 45%. IR (KBr): $\nu_{C=O}$ 1700, 1772 cm^{-1}. Found: C, 64.59; H, 4.60; N, 15.99%; Calcd for $C_{13}H_{11}O_2N_3$: C, 64.72; H, 4.60; N, 17.43%; mol wt, 241.24. The equivalent weight determined from titration of the imidazole group was 244.

***N*-α-Naphthoylhistamine (N-oyl-Im).** Histamine dihydrochloride (1.8 g, 0.01 mol) was dissolved in a mixture of methanol (150 m*l*) and water (20 m*l*), containing 7.2 g (0.072 mol) of triethylamine. To this solution was added at 0—4°C 2.1 g (0.01 mol) of *N,N'*-dicyclohexylcarbodiimide in 40 m*l* of acetonitrile and 1.7 g (0.01 mol) of naphthalene-α-carboxylic acid in 20 m*l* of methanol in succession. The reaction mixture was kept with occasional shaking at 0—4°C for three days and at room temperature for four days. The unreacted carbodiimide was converted to *N,N'*-dicyclohexylurea by addition of 5 m*l* of glacial acetic acid. Upon addition of 3 m*l* of concentrated hydrochloric acid, the mixture was concentrated to about 20 m*l*, separated from dicyclohexylurea formed, added to saturated aqueous sodium carbonate and extracted with chloroform. Evaporation of chloroform and recrystallization of the residue from water yielded colorless needles

in 67% yield, mp 112—114°C (dec.). Found: C, 72.15; H, 5.85; N, 14.45%. Calcd for $C_{16}H_{15}ON_3$: C, 72.43; H, 5.70; N, 15.84%; mol wt, 265.32. The equivalent weight determined by titration of the imidazole group was 270.5.

1-Acetamidomethyl-4-[4(5)-imidazolyl]naphthalene (N-yl-Im). 265 mg of 1-aminomethyl-4-[4(5)-imidazolyl]naphthalene[1b] (10^{-3} mol) was reacted with 79 mg (10^{-3} mol) of acetyl chloride in a mixture of 10 m*l* of triethylamine and 100 m*l* of acetonitrile in an ice bath. Upon stirring for 1 hr solvents were evaporated, and the solid residue taken up in 0.1 N hydrochloric acid was reprecipitated by addition of saturated aqueous sodium carbonate. The precipitate was recrystallized from 3 : 2 water - ethanol, mp 144—150°C (dec.), 60% yield. IR (KBr): $\nu_{C=O}$, 1640 cm^{-1} (broad). Found: C, 72.04; H, 5.99; N, 15.35%. Calcd for $C_{16}H_{15}ON_3$: C, 72.43; H, 5.70; N, 15.84%; mol wt, 265.32. The equivalent weight determined by titration of the imidazole was 272.1.

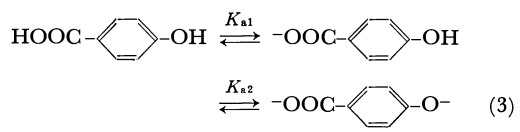
Substrate. *p*-Acetoxybenzoic acid was prepared as described before.[1b,12]

Titration and Hydrolysis Procedures. Titration and hydrolyses were carried out at several temperatures using a pH-stat connected with a recorder (TOA Electronics, Ltd., Models HS-1B and EPR-2T, respectively). The water-jacket holding the reaction vessel was maintained at given temperatures by circulating water from a constant temperature bath. The pH meter was calibrated at two pH values at the respective temperatures. Further details of the procedures have been described previously.[3b]

NMR Measurements. The imidazole derivative N-oyl-Im was saturated at room temperature in D_2O containing a trace of ethanol, and its NMR spectrum was obtained with a Varian A-60 spectrometer. Acetonitrile and contaminating water were used as internal standards. The imidazole protons at the 2 and 4(5) positions appeared at 7.56 and 6.80 ppm, respectively. Histamine dihydrochloride was dissolved in D_2O (30 mg/m*l*) and neutralized to pH 7—8. At this pH range, only the amino group is protonated. The imidazole protons at the 2 and 4(5) positions appeared at 8.11 and 7.39 ppm, respectively.

Results

Spontaneous Hydrolysis. Table 1 gives the rate of spontaneous hydrolysis of the substrate and pK_a of the resulting *p*-hydroxybenzoic acid at several temperatures. Spontaneous hydrolysis was undetectably slow at 15°C and increased with temperature. Dissociation of *p*-hydroxybenzoic acid is as follows.



That the phenol group was partially dissociated at pH 8 was taken into consideration in calculating the rate of hydrolysis from alkali consumption.

Table 1. Spontaneous hydrolysis of substrate and pK_a of *p*-hydroxybenzoic acid

Catalytic Hydrolysis by Bimolecular Mechanisms. The total rate of hydrolysis in the presence of the catalyst consists of the two terms—spontaneous and catalytic hydrolyses.

$$v = v_{cat} + v_{spont} \quad (4)$$

Throughout the present investigation v_{cat} represents the initial rate of catalytic hydrolysis. Spontaneous hydrolysis prior to the addition of catalyst was small and necessary corrections were made for substrate concentration. Figure 1 shows the relation between v_{cat} and substrate concentration with Bz-Im catalyst. In the temperature range from 15°C to 40°C, v_{cat} values are reasonably proportional to substrate concentration, and the catalytic hydrolysis with Bz-Im was concluded to proceed *via* the common second-order kinetics:

$$\text{catalyst} + \text{substrate} \xrightarrow{k'} \text{catalyst} + \text{product} \quad (5)$$

$$v_{cat} = k'[C][S] \quad (6)$$

where C and S denote catalyst and substrate, respectively. In Fig. 2 is given v_{cat} *vs.* [S] with Ph-Im as a catalyst. Similarly, a linear relationship was obtained. The second-order rate con-

stants k' were obtained from these data and are given in Table 2, together with the data with imidazole catalyst. When the catalyst concentration was varied ($(1—10) \times 10^{-3}$M) at a constant substrate concentration ([C]=0.020M, 30°C, 1.0M KCl), the relationships between v_{cat} and [S] were similarly linear, with the second-order rate constant of 0.49$M^{-1}min^{-1}$ and 0.39$M^{-1}min^{-1}$ for Bz-Im and Ph-Im, respectively. Since the imidazole groups are partially protonated at pH 8.0, the effective catalyst concentrations ($[C]_{eff}$) were calculated from the corresponding pK_a values

$$[C]_{eff} = [C]_{total} \cdot \frac{K_a}{K_a + a_H} \quad (7)$$

where K_a is the acid dissociation constant of the conjugate acid and a_H is the hydrogen ion activity. Bz-Im and imidazole show similar catalytic activities, whereas Ph-Im is somewhat more efficient.

Catalytic Hydrolysis by the Michaelis-Menten Mechanism. The relationships between v_{cat} and [S] at four temperatures are given for imidazole derivative N-oyl-Im in Fig. 3. Undoubtedly, v_{cat} showed substrate saturation which was particularly clear at high temperature. A similar catalytic behavior was previously observed for a related imidazole derivative[1] and some imidazole-containing polymers.[3] These kinetic patterns, typical of the enzyme-catalyzed reaction, can be described by Eq. (1) and the corresponding catalytic rate is expressed by

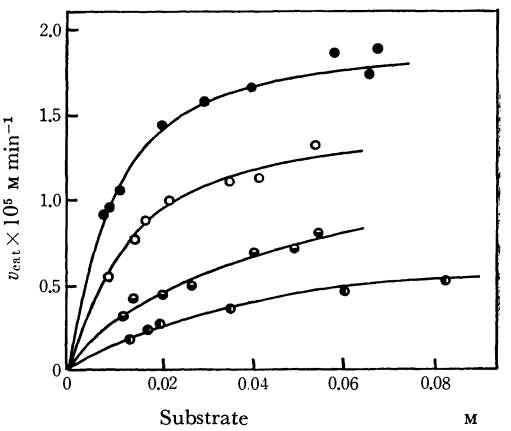

Fig. 3. Catalytic hydrolysis. catalyst, N-oyl-Im 0.82×10^{-3}M; pH 8.0; 1.0M KCl.
●, 40°C; ○, 30°C; ◒, 20°C; ◐, 15°C.

$$v_{cat} = \frac{k_{cat}[C][S]}{K_m + [S]} \quad (8)$$

Since k_{cat} values for the imidazole catalysts used are sufficiently small, the Michaelis constant K_m is considered to represent the true dissociation constant.[3b] The kinetic constants in the equation are determined from the Lineweaver-Burk plotting[13]

c) pH 7.0, 1M KCl.

of $1/v_{cat}$ *vs.* 1/[S]. The plots were sufficiently linear, showing the validity of the Michaelis-Menten expression of the rate data. Substrate saturation curves were similarly observed for the catalytic hydrolysis with N-yl-Im as a catalyst (Fig. 4). The corresponding Lineweaver-Burk plots were sufficiently linear. The kinetic constants for the enzyme-like catalysis are summarized in Table 3. Also included are kinetic constants obtained from hydrolysis at pH 7.0 with N-oyl-Im at 30°C.

The effect of ionic strength of the reaction medium was studied for the substrate-binding catalysts as shown in Fig. 5. v_{cat} increased with increase in ionic strength for both systems. Catalysis with N-oyl-Im was more sensitive to ionic strength as compared with N-yl-Im.

Thermodynamic and Activation Parameters of Catalytic Hydrolysis. From these kinetic data are obtained the activation parameter of the bimolecular catalysis by Bz–Im and the thermodynamic and activation parameters of the Michaelis-Menten-type catalysis by N-oyl-Im and N-yl-Im. The free energy of activation $\Delta G^{\neq}$ was calculated from k_{cat} or k' from the relationship $\Delta G^{\neq} = \boldsymbol{R}T\ln(\boldsymbol{k}T/\boldsymbol{h}k_r)$,[14] and plotted against T. Satisfactorily linear relationships were obtained as shown in

N-yl-Im[b)]	3.44	19.9	27.9	6.26	−52.0

a) Bimolecular pathway
b) Michaelis-Menten pathway

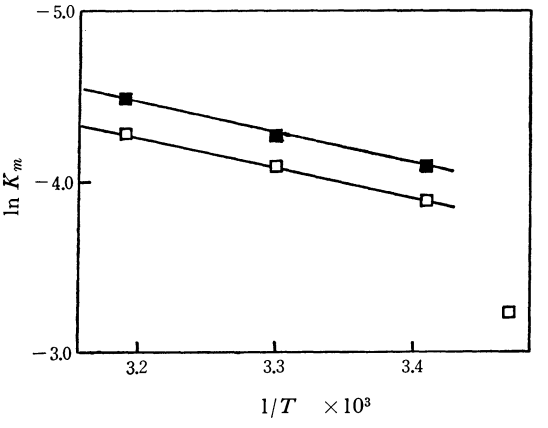

Fig. 7. Temperature dependence of the Michaelis constant. catalyst: □, N-oyl-Im; ■, N-yl-Im.

Fig. 6. $\Delta H^{\neq}$ and $\Delta S^{\neq}$ were obtained from intercept and slope, respectively, from the relationship $\Delta G^{\neq} = \Delta H^{\neq} - T\Delta S^{\neq}$, and are given in Table 4. Particularly noteworthy are exceptionally large negative entropies of activation obtained for the pseudo-intramolecular process.

The thermodynamic parameters of the dissociation process of the Michaelis complex were obtained from plots of $\ln K_m$ *vs.* $1/T$ (Fig. 7). Linear relationships are obtained for the respective catalysts except for a plot at 15°C for N-oyl-Im catalyst. The deviation may indicate that the bimolecular process is involved at this temperature. The enthalpy and entropy changes of the binding process are obtained from the relationship using the equation $\ln K_m = \Delta H/\boldsymbol{R}T - \Delta S/\boldsymbol{R}$. The thermodynamic parameters of binding are very similar for these two catalysts and characterized by small positive enthalpies and large positive entropies (see Table 4). The unitary entropy change was obtained from the relation $\Delta S_u = \Delta S + 7.98$.[15)]

Discussion

The results given above clearly demonstrate the different catalyst behavior between imidazole derivatives containing the naphthalene ring and less hydrophobic imidazole compounds. Thus, v_{cat} increased linearly with substrate concentration with the latter catalysts, whereas the Michaelis-Menten kinetics were observed for the former catalysts. The kinetic difference can be attributed to a large hydrophobicity of the naphthalene ring sufficient to bind a substrate molecule prior to the catalytic process. The benzene ring in Bz–Im or Ph–Im was not sufficiently hydrophobic to bind a substrate molecule under hydrolysis conditions and the formation of the Michaelis complex, if any, was not significant for these catalysts.

On the other hand, a bimolecular catalytic process by uncomplexed catalyst molecules might coexist in the overal Michaelis-Menten kinetics as long as the binding of catalyst and substrate occurs.[3b)] In this case the relative importance of the two processes is determined from a comparison of k_{cat}/K_m and k'. The second-order rate constants k' for three non-binding catalysts are 0.3—0.5 $min^{-1}M^{-1}$ at 30°C. Therefore, the hypothetical k' values for N-oyl-Im and N-yl-Im will certainly not be greater than 0.3—0.5 $min^{-1}M^{-1}$, considering their lower pk_a values. Since k_{cat}/K_m at 30°C is 1.3 and 3.9 for N-oyl-Im and N-yl-Im, respectively, the enzyme-like catalytic pathways are considered to be preferred to with these catalysts. At lower temperatures, however, the dissociation constant increases and the overall rate enhancement due to complexation is less pronounced. In fact, substrate saturation was not very clear for the catalytic hydrolysis at 15°C (Fig. 3). Deviation of the corresponding $\ln K_m$ plot from linearity in Fig. 7 and comparable k_{cat}/K_m and k' values (0.24 *vs.* 0.25 $min^{-1}M^{-1}$) obtained for closely related catalysts (Bz-Im and N-oyl-Im) suggest that the significance of the two catalytic processes becomes comparable at this temperature.

The tendency of non-polar groups to adhere to one another in aqueous environments has been referred to as hydrophobic bonding,[15)] and this process is usually accompanied by a large positive entropy change and a small enthalpy change. The thermodynamic parameters obtained (large positive ΔS_u and small ΔH for the binding process) clearly indicate that hydrophobic forces are responsible for substrate binding. Very close values obtained for both ΔH and ΔS_u with catalysts N-oyl-Im and N-yl-Im seemingly reflect the fact that the naphthalene

15) W. Kauzmann, *Advan. Protein Chem.*, **14**, 1 (1959).

ring is the major site of binding in these catalysts.

The pseudo-intramolecular rate constant k_{cat} was greater (about 2.5 times at 30°C) for imidazole N-yl-Im than for N-oyl-Im in spite of the lower pK_a value for the former. Since the nucleophilicity of simple imidazoles in the hydrolysis of *p*-nitrophenyl acetate was proportional to pK_a of the conjugate acid,[16] reversal in the intra-complex rate constant may be attributed to the structural difference of the Michaelis complexes. It was found that k_{cat} differed considerably between catalysts I and its protonated form (0.19 *vs.* 0.036 min^{-1}),[1b] and we anticipated a much greater difference in catalytic activity between N-oyl-Im and N-yl-Im, because k_{cat} was expected to be particularly sensitive to the spacial disposition of the imidazole group relative to the bound substrate. However, the difference in k_{cat} was rather small, although it would be greater if the difference in pK_a is to be corrected. Appearance of the imidazole proton peaks in N-oyl-Im at higher magnetic fields than the corresponding peaks in histamine by about 0.6 ppm can be ascribed to the paramagnetic shielding of the former proton by the naphthalene ring. Thus, the imidazole group in N-oyl-Im is conceivably located at a position fairly close to the plane of the naphthalene ring. The difference in pK_a between Bz-Im and N-oyl-Im also supports this supposition. Klotz and Lyndrup[17] noted that the charged state of an N-ethylimidazole residue placed in a polyvinylpyrrolidone matrix was destabilized relative to the uncharged state, because of changes in the local polymer or solvent environment, causing lowering of pK_a by about 1.15 pK units. Similarly we found that pK_a of the benzimidazole unit in polymers decreased with increasing hydrophobicity of the polymer in aqueous systems.[18] Thus the decreased pK_a of N-oyl-Im relative to that of Bz-Im can be considered to arise from destabilization of the charged state of the imidazole group due to the nearby hydrophobic naphthalene ring. The greater sensitivity to the ionic strength of the medium of the catalytic efficiency of N-oyl-Im as compared with that of N-yl-Im (Fig. 5) may be also ascribed to the conformational flexibility of N-oyl-Im molecules. Thus, a compact conformation of N-oyl-Im at $\mu=1.0$ will tend to lessen the difference in catalytic activity between N-oyl-Im and N-yl-Im, since the location of the imidazole group relative to the naphthalene ring will not be very different in these catalysts.

The overall enhancement in the catalytic efficiency due to substrate binding can be estimated from k_{cat}/K_m *vs.* k'. The rate enhancement observed in the present study was at most ten times (Table 2 *vs.* 3). A similar extent of rate enhancement was observed for related polymer catalysts, and some discussions were made concerning small k_{cat} values.[3b] These results are in a sharp contrast with much greater rate enhancement observed in imidazole-catalyzed hydrolyses of phenyl esters[8,19,20] and acylation of amines[21,22] where the hydrophobic interaction of long hydrocarbon chains significantly contributed to rate enhancement. The small rate enhancement in the present system is associated with a small k_{cat}. Bruice and Benkovic showed that intramolecular catalysis was characterized by favorable entropy terms (*ca.* 15 eu) compared with those of bimolecular catalyses.[23] The remarkable efficiency of enzyme-catalyzed reactions is commonly attributed to formation of the Michaelis complex and to the facile intra-complex reaction. However, the activation parameters shown in Table 4 indicate that the activation entropies are extremely unfavorable for the intra-complex process. The large negative $\Delta S^{\neq}$ observed betrays our expectation that the intra-complex product formation would be facilitated by the favorable entropy term. In fact $\Delta S^{\neq}$ for k_{cat} was more negative than that for k'.

The unfavorable entropy factor for k_{cat} may be explained by either or both of the following assumptions: (1) The relative disposition of catalyst and substrate in the Michaelis complex may be very different from the structure of the transition state, and extensive reorganization of the structure of the complex becomes necessary for the action of the imidazole group on the ester group to occur. In this case, k_{cat} will increase greatly if suitable combinations of catalyst and substrate are selected. Connors and coworkers[24] made extensive studies on the modification of reaction rates by complex formation in aqueous solutions. An analogous study may be necessary in order to establish the structure-reactivity relationship in the complex. Also interesting is the finding by Gitler and Ochoa-Solano that elongation of the hydrocarbon chain in substrate decreased the activation energy of the imidazole-catalyzed ester hydrolysis in micelles,[19]

since their results suggest that the disposition of substrate relative to catalyst possibly affects the activation energy.[25] (2) If it is assumed that acetylimidazoles are intermediates of the pseudo-intramolecular transformation, the transition state for the acyl transfer is considered to be rather polar. The polar transition state will not be favored on the surface of the hydrophobic naphthalene ring. Thus, the hydrophobic interaction between catalyst and substrate may have to be largely destroyed for the intra-complex reaction to occur, resulting in the large negative entropy of activation.

25) Recently this problem was discussed also by Cordes and Dunlop: E. H. Cordes and R. B. Dunlop, *Accounts Chem. Res.*, **2**, 329 (1969).

In conclusion, both of the bimolecular and Michaelis-Menten-type catalyses were observed for the imidazole-catalyzed hydrolysis of *p*-acetoxybenzoic acid in aqueous systems. Unfortunately, however, the rate acceleration expected from formation of the catalyst-substrate complex was not remarkable because of the highly unfavorable entropy of activation. We are now attempting syntheses of related catalytic systems which presumably possess different organizations of the catalytic site from those of the present one.

The authors are deeply grateful to Professor C. Aso of this department for his unfailing encouragement and advice.

Stereochemical Studies of Monoterpene Compounds. VIII.[1] The Stereochemistry of Dihydro-β-campholenolactone and 1,2-Campholide[2]

Toshifumi HIRATA, Takayuki SUGA[3] and Tamon MATSUURA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received February 25, 1970)

The stereochemistry of (+)-dihydro-β-campholenolactone (II) and (−)-1,2-campholide (III) was clarified to be IIa and IVc, respectively, by a combination of nuclear magnetic resonance, optical rotatory dispersion and circular dichroism measurements.

The reaction of α-campholenic acid (I) with sulfuric acid has been reported[4] to produce only dihydro-β-campholenolactone (II). However, no report has been given on that with organic acid. The stereochemistry of lactone II has been only presumed[5] by considering the reaction of pinonic acid with sulfuric acid. While the peracetic acid oxidation of camphor[5] has been reported to produce 1,2-campholide (III), its stereochemistry has not been reported yet. Our recent study of the stereochemistry and rearrangement of 2-hydroxypinocamphone necessitated our working on the reaction of α-campholenic acid (I) with anhydrous oxalic acid, and the stereochemistry of (+)-dihydro-β-campholenolactone (II) and (−)-1,2-campholide (III) produced.[6-8] The present paper deals with the stereochemistry of these lactones.

Results and Discussion

A mixture of (+)-α-campholenic acid (I) and anhydrous oxalic acid suspended in acetone was refluxed for 6 hr. The reaction gave not only

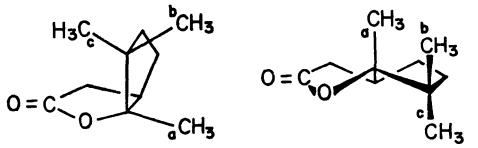
(+)-dihydro-β-campholenolactone (II) but also (−)-1,2-campholide (III) in 74% and 25% yield, respectively, in contrast to the reaction with mineral acid.[4] Lactones II and III were identified by a combination of infrared and nuclear magnetic resonance spectra measurements and the conversion to 1-(2-hydroxyethyl)-2,3,3-trimethyl-2-cyclopentanol and 1-(2-hydroxyethyl)-2,2,3-trimethyl-3-cyclopentanol respectively.

The Stereochemistry of (+)-Dihydro-β-campholenolactone (II). The spatial arrangement of the lactone ring of II was decided by the solvent effect of NMR spectra with benzene and pyridine. A reference plane was imagined through the carbonyl carbon atom at right angles to the carbon-oxygen bond of the carbonyl group as an aid in predicting the benzene-induced shift of methyl groups (*cf.* Fig. 1).[9] For the *cis*-form, a large upfield



cis-form *trans*-form

Fig. 1. *cis* and *trans*-Forms of dihydro-β-campholenolactone (II).

shift by the solvent is predicted to occur equally on the a- and b-methyl signals (*cf.* Fig. 1), and a smaller upfield shift for the c-methyl group. For the a-methyl group of the *trans*-form, a large upfield shift is predicted and a small one for the b- and c-methyl groups. The a-, b- and c-methyl resonances underwent an upfield shift by 0.43, 0.39 and 0.10 ppm, respectively, by changing a solvent from deuteriochloroform to benzene.

In order to predict the pyridine-induced shift, the reference plane was drawn through the α-position to the carbonyl group[10] (*cf.* Fig. 1). For the a- and b-methyl groups of the *cis*-form, a large upfield shift is expected, and a down field shift for the c-methyl group. The a-, b- and c-methyl signals of γ-lactone II exhibited shifts by +0.17, +0.27 and −0.08 ppm, respectively. It was thus found that the spatial arrangement of the lactone ring is *cis*. The stereochemistry of γ-lactone II is therefore assigned as either IIa or its optical antipode (IIb).

The octant and the sector projection diagrams of each conformer are shown in Fig. 2. According to the lactone sector rule,[11] the sign of the Cotton effect is predictable to be positive for IIa and negative for IIb. The ORD and CD curves of (+)-γ-lactone II exhibited the positive Cotton effect as shown in Fig. 3. The stereochemistry of (+)-dihydro-β-campholenolactone (II) was consequently found to be IIa.

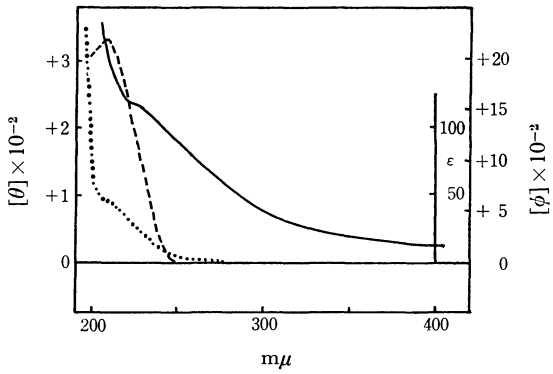


Fig. 3. Optical rotatory dispersion (the full line) and circular dichroism curves (the broken line) and ultraviolet spectrum (the dotted line) of (+)-dihydro-β-campholenolactone (II) in methanol.

The Stereochemistry of (−)-1,2-Campholide (III). Examination of the stereochemical structure of III by a molecular model[12] indicated that it was impossible for the lactone to take the *trans*-form. The stereochemistry of III is consequently

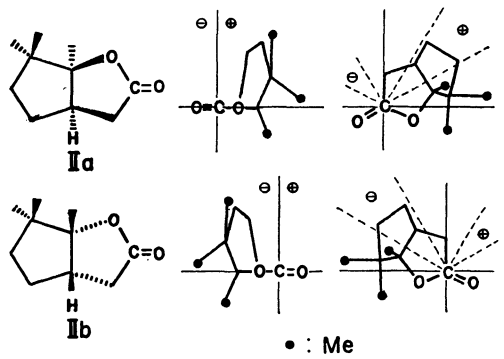

Fig. 2. Octant and sector projections of stereoisomers IIa and IIb.

assigned as either IV or its optical antipode (V). Conformers IVa, IVb and IVc are considered the possible preferred conformation for IV. Three conformers are also possible for V. A large upfield shift of the NMR spectrum by the solvent effect of benzene is expected equally for the a- and c-methyl groups of conformer IVa, and a smaller one for the b-methyl signal. The a- and b-methyl signals of conformer IVb may exhibit a large upfield shift, and the c-methyl signal a very small one. Three methyl signals of conformer IVc will show larger upfield shifts in the order of the b-, a- and c-methyl groups. The a-, b- and c-methyl signals of campholide III were observed to shift upfield by 0.37, 0.31 and 0.52 ppm, respectively.

Pyridine may induce the large upfield shift on a-, b- and c-methyl signals of IVa. On the other hand, a- and b-methyl groups of IVb may be shifted to a large upfield, and the c-methyl group to a down field shift. The a- and b-methyl signals of IVc may exhibit a large upfield shift, and the c-methyl signal a small one. The experimental data were +0.29, +0.13 and +0.08 ppm for a-, b- and c-methyl groups, respectively. The preferred conformation of III was thus found to be either IVc or its optical antipode (Vc).

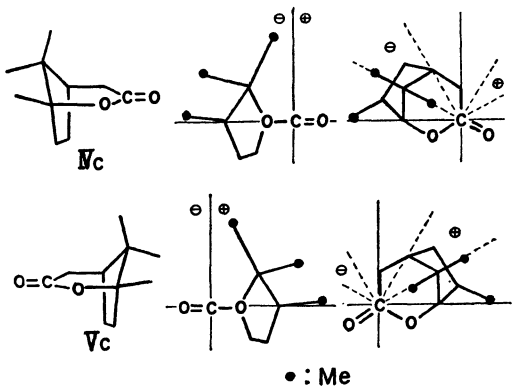

Fig. 4. Octant and sector projections of stereoisomers IVc and Vc.

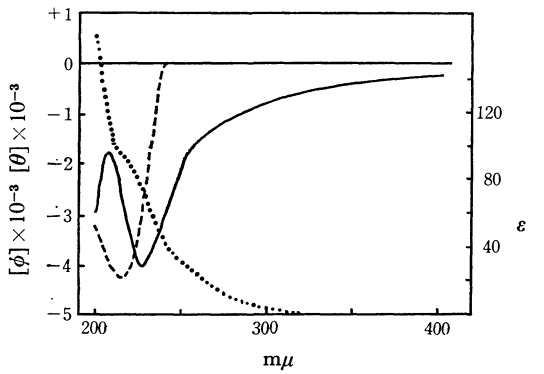

Fig. 5. Optical rotatory dispersion (the full line) and circular dichroism curves (the broken line) and ultraviolet spectrum (the dotted line) of (−)-1,2-campholide (III) in methanol.

The octant and the sector projection diagrams for IVc and Vc are shown in Fig. 4. According to the lactone sector rule,[11] a negative Cotton effect was predicted for IVc, and a positive one for Vc. The ORD and CD curves of (−)-1,2-campholide (III) showed a negative Cotton effect (Fig. 5). The stereochemical structure of III was thus concluded to be IVc.

The mechanism of the lactonization of α-campholenic acid (I) by anhydrous oxalic acid will be discussed in the near future.

Experimental

The NMR spectra were recorded with a Varian Associates A-60 spectrometer using tetramethylsilane as an internal standard. The ORD curves were obtained at 25°C with a Japan Spectroscopic Co. Ltd. automatically recording spectropolarimeter, Model ORD/UV-5, using the normally programmed slit width, and a cell 1 mm long. A monochromator and a cell compartment of the spectropolarimeter were kept in an atmosphere of dry nitrogen. The CD curves were also obtained by the same spectropolarimeter equipped with a circular dichroism attachment. Microanalyses were performed at the Microanalytical Center in the Faculty of Pharmacy of Kyoto University.

(+)-α-Campholenic Acid (I). A mixture of 25 g of (+)-10-camphorsulfonic acid, mp 192°C, $[\alpha]_D^{20}$ +37.5° (*c* 10.2, ethanol) and 25 g of potassium hydroxide was fused for 30 min in an iron crucible with stirring. After cooling, the mixture was dissolved in 200 m*l* of water. After the reaction mixture was washed with ether, then with dichloromethane, the mixture was acidified with 6N-hydrochloric acid solution and then extracted with ether. The usual treatment of the ether extract afforded 9.5 g of crude acid. The crude acid was rectified by distillation under reduced pressure to yield 6.6 g of pure (+)-α-campholenic acid (I): bp 138°C/8 mmHg (lit,[5] bp 95.5—97.5°C/0.54—0.65 mmHg), n_D^{25} 1.4675 (lit,[5] n_D^{25} 1.4695), d_4^{25} 0.9922, $[\alpha]_D^{25}$ +7.21° (*c* 10.1, ethanol).

(+)-Dihydro-β-campholenolactone (II) and (−)-1,2-Campholide (III). A mixture of 35 g of (+)-α-campholenic acid (I) and 140 g of anhydrous oxalic acid suspended in 112 m*l* of acetone was heated under reflux for 6 hr with stirring. After removal of acetone under reduced pressure, the reaction miture dissolved in water was extracted with ether to obtain 21.8 g of a reaction product. The product was subjected to column chromatography on silica gel with a mixture of ethyl acetate and *n*-hexane to separate into two kinds of lactone. The initial eluate gave 15.6 g of (+)-β-lactone II and the second eluate 5.9 g of (−)-δ-lactone III. The lactones were identified by a combination of physicochemical measurements and chemical treatment as follows.

(+)-Dihydro-β-campholenolactone (II) (15.6 g) was obtained from the initial eluate and showed following properties: mp 30—31°C (lit,[5] mp 32°C); $[\alpha]_D^{25}$ +49.9° (*c* 10.0, ethanol); $\nu_{C=O}$ 1774 cm^{-1} (lit,[4] 1786 cm^{-1}); $\lambda_{shoulder}^{MeOH}$ 210 mμ (ε 44.6); ORD (*c* 2.64, methanol),

$[\phi]_{400}$ +272, $[\phi]_{225}$ +1550, $[\phi]_{210}$ +2000; CD (*c* 2.64, methanol), $[\theta]_{250}$ 0, $[\theta]_{210}$ +328, $[\theta]_{200}$ +300.

Found: C, 71.45; H, 9.70%. Calcd for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59%.

The methyl proton signals of the NMR spectra appeared at δ 0.90 (a-CH_3), 1.29 (b-CH_3) and 1.08 ppm (c-CH_3) in 10% deuteriochloroform solution and δ 0.53 (a-CH_3), 0.90 (b-CH_3) and 0.98 ppm (c-CH_3) in 10% benzene solution and δ 0.73 (a-CH_3), 1.02 (b-CH_3) and 1.16 ppm (c-CH_3) in 10% pyridine solution.

The reduction of 0.30 g of γ-lactone II with 0.3 g of lithium aluminum hydride in 50 m*l* of dry ether gave 0.24 g of 1-(2-hydroxyethyl)-2,3,3-trimethyl-2-cyclopentanol: mp and mixed mp 147—148°C (lit,[5] mp 147°C); $[\alpha]_D^{25}$ +38.9° (*c* 1.49, ethanol) (lit,[5] $[\alpha]_D^{25}$ +15±2° (*c* 2, alcohol); $\nu_{OH(free)}^{CCl_4}$ 3626 cm^{-1}, $\nu_{OH(bonded)}^{CCl_4}$ 3462 cm^{-1}.

Found: C, 69.86; H, 11.93%. Calcd for $C_{10}H_{20}O_2$: C, 69.72; H, 11.70%.

(−)-1,2-Campholide (III) (5.9 g) was obtained from the second eluate and showed the following properties: mp 162—163°C (lit,[4] 168.5—171.5°C); $[\alpha]_D^{25}$ −43.0° (*c* 3.0, ethanol) (lit,[4] $[\alpha]_D^{25}$ −37°); $\nu_{C=O}$ 1729 cm^{-1} (lit,[4] 1745 cm^{-1}); $\lambda_{shoulder}^{MeOH}$ 215 mμ (ε 95.4); ORD (*c* 1.62, methanol), $[\phi]_{400}$ −250, $[\phi]_{227}$ −4010, $[\phi]_{208}$ −1770, $[\phi]_{200}$ −2970; CD (*c* 1.62, methanol), $[\theta]_{242}$ 0, $[\theta]_{215}$ −4270, $[\theta]_{200}$ −3200.

Found: C, 71.41; H, 9.73%. Calcd for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59%.

The methyl proton signals of the NMR spectra appeared at δ 1.07 (a-CH_3), 1.29 (b-CH_3) and 1.00 ppm (c-CH_3) in 5% deuteriochloroform solution and δ 0.70 (a-CH_3), 0.98 (b-CH_3) and 0.48 ppm (c-CH_3) in 5% benzene solution and δ 0.78 (a-CH_3), 1.16 (b-CH_3) and 0.91 ppm (c-CH_3) in 5% pyridine solution.

Reduction of 0.20 g of lactone III with 0.20 g of lithium aluminum hydride in 100 m*l* of dry ether afforded 0.09 g of 1-(2-hydroxyethyl)-2,2,3-trimethyl-3-cyclopentanol: mp and mixed mp 93—94°C (lit,[4] 91—93°C); $[\alpha]_D^{25}$ +72.4° (*c* 1.85, ethanol); $\nu_{OH(free)}^{CCl_4}$ 3624 cm^{-1}.

Found: C, 70.00; H, 11.76%. Calcd for $C_{10}H_{20}O_2$: C, 69.72; H, 11.70%.

The authors wish to express their thanks to Dr. Marcelle Harispe of College of Paris for a gift of 1-(2-hydroxyethyl)-2,3,3-trimethyl-2-cyclopentanol, to Dr. J. D. Connolly of the Glasgow University for a gift of 1-(2-hydroxyethyl)-2,2,3-trimethyl-3-cyclopentanol, and Dr. Shô Itô of Tohoku University for measuring the NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2591—2596 (1970)

Reactions of Aziridines with Acetyl Chloride and Related Compounds

Itaru OKADA, Toshio TAKAHAMA and Rokuro SUDO

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 25, 1970)

When aziridines (**1**) were treated with acetyl compounds, such as acetyl chloride, acetic acid, acetic anhydride, and thioacetic acid, the corresponding acetamide derivatives were obtained in good yields. In the case of acetyl chloride, some derivatives of *N*-(2-chloroethyl)acetamide (**5**) were found to be unstable in the face of moisture; they were easily hydrolyzed to give *N*-(2-hydroxyethyl)acetamide hydrochlorides (**3**). The NMR spectrum of *N*-(2-mercaptoethyl)-*N*-benzylacetamide (**12**) was discussed.

The reactions of aziridine with acid chlorides to give *N*-(2-chloroethyl)amide derivatives have been described.[1,2] On the other hand, at least two examples of the reactions of *N*-substituted aziridines with acid chlorides have been reported.[3,4] However, no systematic study of this type of reaction has yet been reported. In the present investigation, we studied the reactions of *N*-substituted aziridines with acetyl chloride and other acetyl compounds.

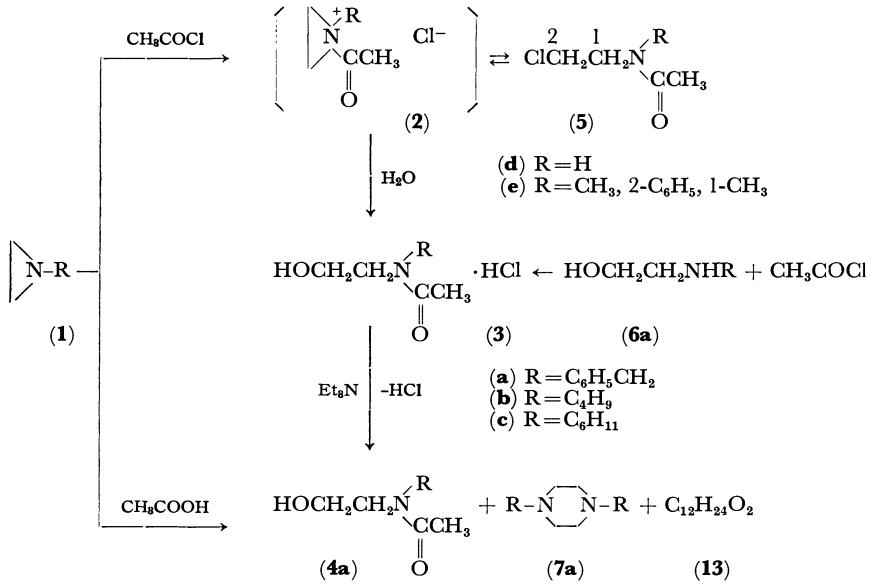
4) K. Tanaka, *Yakugaku Zasshi*, **70**, 220 (1950).

Results and Discussion

Reaction of Aziridines with Acetyl Chloride. When *N*-benzylaziridine (**1a**) was treated with acetyl chloride in dry benzene under ice cooling, a light yellow sirup was obtained. After being kept for 7 day at room temperature, the sirup crystallized. The crude product was recrystallized from ethanol. *N*-(2-Hydroxyethyl)-*N*-benzylacetamide hydrochloride (**3a**) was thus obtained in a 66% yield. **3a** was characterized by elemental analysis and by means of its IR and NMR spectra. The IR spectrum had absorptions at 2750—2350 cm^{-1} (ν_{NH^+}), 1735 cm^{-1} ($\nu_{C=O}$), and the NMR spectrum



Scheme 1

exhibited a broad peak at τ 0.1 (2H) due to -OH and $-NH^+$.

Furthermore, the fact that the reaction of **3a** with triethylamine in benzene yielded triethylamine hydrochloride and *N*-(2-hydroxyethyl)-*N*-benzylacetamide (**4a**) supported the idea of the structure of **3a**, while **4a** was also prepared by the reaction of *N*-benzylaziridine (**1a**) with acetic acid. On the other hand, the product prepared from *N*-benzylaminoethanol (**6a**) with acetyl chloride was identical with **3a** in its IR spectrum, and a mixed-melting-point determination showed no depression.

A probable pathway for this reaction involves an initial electrophilic attack of the acetyl group on the basic aziridine nitrogen, followed by the ring opening of the intermediate aziridinium salt (**2a**) to give *N*-(2-chloroethyl)-*N*-benzylacetamide (**5a**). This compound was unstable in the face of moisture and was easily hydrolyzed to **3a**. This fact was explained by the change in the IR bands from 1650 cm^{-1} ($\nu_{>N-C=O}$) to 1735 cm^{-1} ($\nu_{C=O}$).

Analogous reactions of *N*-butylaziridine (**1b**) and *N*-cyclohexylaziridine (**1c**) with acetyl chloride resulted in the formation of the corresponding *N*-(2-hydroxyethyl)amide hydrochloride derivatives (**3b**, **3c**). These results are summarized in Table 1.

On the contrary, when aziridine (**1d**) or 1,2-dimethyl-3-phenylaziridine (**1e**) was treated with acetyl chloride, a stable *N*-(2-chloroethyl) amide derivative (**5d** or **5e**) was obtained in a 95% or

a) The elemental analysis did not give a good agreement with the calculated values because of a very viscous oil.

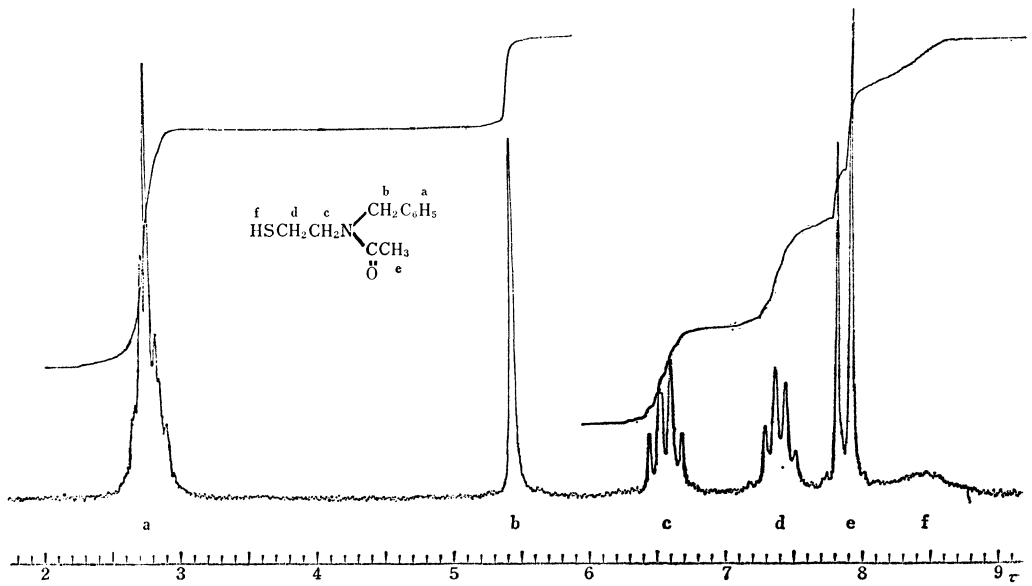

Fig. 1. NMR spectrum of *N*-(2-mercaptoethyl)-*N*-benzylacetamide (**12**) at 100 Mc in $CDCl_3$ using TMS as standard (23°C).

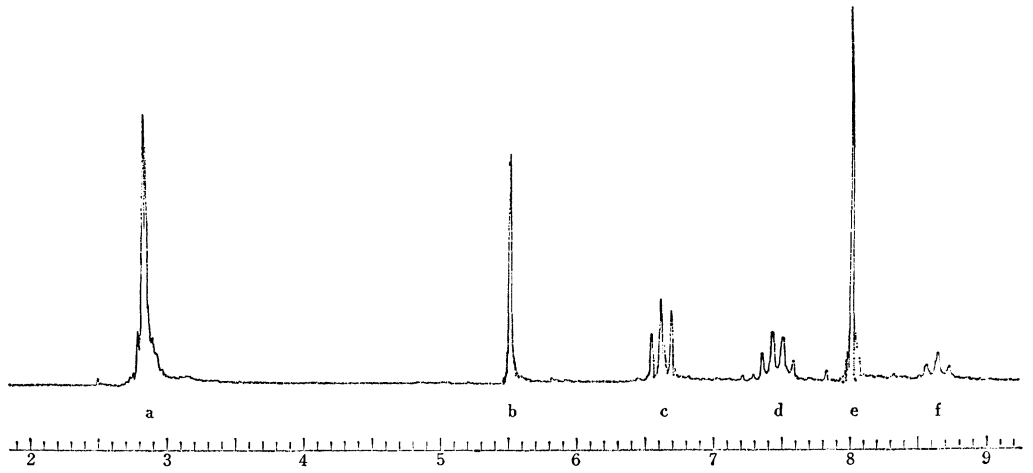

Fig. 2. NMR spectrum of **12** (100°C).

99% yield (Scheme 1).[5]

Two isomers (**8**,**9**) are possible through the ring opening of the aziridine moiety in the reaction of 1-benzyl-2-phenylaziridine (**1f**) with acetyl chloride. The product was found to be *N*-(2-phenyl-2-hydroxyethyl)-*N*-benzylacetamide hydrochloride (**8**). **8** was identified by a comparison of its IR spectrum with that of a sample prepared from 1-phenyl-2-benzylaminoethanol (**10**) with acetyl chloride; a mixed-melting-point determination supported this structure (Scheme 2).

Reaction of Aziridines with Other Acetyl Compounds. When 1-benzylaziridine (**1a**) was treated with other acetyl compounds, such as acetic acid,[6] acetic anhydride[7] or thioacetic acid,[6] the corresponding acetamide derivatives (**4a**, **11**, **12**) were obtained in good yields. When a reagent with a lower electrophilicity, such as acetamide, was used as an acetyl compound, the starting materials were recovered even after refluxing for 7 hr.

In the NMR spectra of these compounds (**4a**, **11**, **12**), acetyl protons exhibited a doublet at 23°C, and the doublet became a singlet at 100°C. This fact establishes that acetyl protons are nonequivalent due to the partial doublebond character of the >N–C-bond. As an example, the NMR spectrum of **12** is shown in Fig. 1 and Fig. 2.

(12)

In the cases of acetic acid or acetic anhydride, an unknown substance with the composition of $C_{12}H_{24}O_2$ (**13**) was obtained as a by-product; this substance's structure is now under investigation (Scheme 3).

Experimental

Benzene was dried over sodium. All the concentrations and evaporations were carried out under reduced pressure. All the melting points and boiling points are uncorrected.

Aziridines (**1**). These compounds were prepared by the methods in the literature. *N*-Benzyl-(**1a**), bp 77.5°C/7 mmHg;[8] *N*-butyl-(**1b**), bp 102—105°C;[9] *N*-cyclohexyl-(**1c**), bp 64.5—65.5°C/25 mmHg;[8] 1,2-dimethyl-3-phenyl-(**1e**), bp 82°C/14 mmHg;[10] 1-benzyl-2-phenylaziridine (**1f**), bp 138—139°C/1 mmHg[10] and aziridine (**1d**) 56—57°C, a commercial product.

Reaction of *N*-Benzylaziridine (1a) with Acetyl Chloride. A solution of acetyl chloride (2.36 g, 0.03 mol) in benzene (10 m*l*) was stirred, drop by drop, into a solution of **1a** (3.99 g, 0.03 mol) in benzene (30 m*l*) under ice cooling. The mixture was stirred at room temperature for 1 hr, and then refluxed for 3 hr. The mixture was concentrated to give a light yellow sirup, which was identified as *N*-(2-chloroethyl)-*N*-benzylacetamide (**5a**) by means of its IR spectrum. After standing for 7 day at room temperature, the sirup crystallized to give *N*-(2-hydroxyethyl)-*N*-benzylacetamide hydrochloride (**3a**). The crude product was collected by filtration, washed with benzene, and dried (4.55 g, 66% yield). Recrystallization from ethanol gave colorless needles; mp 152—153°C. IR (KBr): 2920, 2770, 2550, 2350, 1735, 1430, 1240, 1065, 980, 745 and 700 cm^{-1}; NMR (CD_3SOCD_3): τ 7.95 (3H, singlet) due to CH_3CO, τ 6.85 (2H, triplet) due to $>NCH_2-$, τ 5.83 (2H, singlet) due to $C_6H_5-CH_2-$, τ 5.65 (2H, triplet) due to $HOCH_2-$, τ 2.25—2.7 (5H, multiplet) due to aromatic protons, and τ 0.1 (2H, broad) due to –OH and $-NH^+$.

An attempt to obtain *N*-(2-chloroethyl)-*N*-benzylacetamide hydrochloride by the treatment of the sirup with hydrogen chloride failed, while **3a** was obtained through hydrolysis.

In a similar procedure, other aziridines (**1b**, **1c**, **1e**) were treated with acetyl chloride; the results are summarized in Table 1.

Reaction of 2-Benzylaminoethanol (6a) with Acetyl Chloride. A solution of acetyl chloride (7.85 g, 0.1 mol) in benzene (20 m*l*) was stirred, drop by drop, into a solution of **6a** (15.10 g, 0.1 mol) in benzene (100 m*l*) under cooling. The mixture was stirred for 5 hr at room temperature, and then refluxed for 1 hr. After cooling, the precipitated **3a** (16.70 g, 73%) was collected by filtration. Recrystallization from ethanol afforded colorless plates, mp 151—153°C; this was shown to be the same product as that prepared by the reaction of **1a** with acetyl chloride by a mixed-melting-point determination and by a study of its IR spectrum.

Reaction of Aziridine (1d) with Acetyl Chloride. A solution of acetyl chloride (7.85 g, 0.1 mol) in chloroform (10 m*l*) was stirred, drop by drop, into a solution of **1d** (4.31 g, 0.1 mol) in chloroform (50 m*l*) under ice cooling. The mixture was stirred at room temperature for 1 hr and then concentrated to give a light yellow oil; this oil was distilled to give *N*-(2-chloroethyl)-acetamide (**5d**) (7.30 g, 60%); bp 131°C/16 mmHg.

Reaction of 1-Phenyl-2-benzylaminoethanol (10)[10] with Acetyl Chloride. A solution of acetyl chloride (4.71 g, 0.06 mol) in benzene (15 m*l*) was stirred, drop by drop, into a solution of **10** (4.54 g, 0.02 mol) in benzene (100 m*l*) under ice cooling. The mixture was refluxed for 3 hr and then concentrated to give a light yellow oil. Ethanol containing hydrochloric acid (10 m*l*) was added to the oil, after which the mixture was concentrated to give *N*-(2-phenyl-2-hydroxyethyl)-*N*-benzylacetamide hydrochloride (**8**) (6.10 g, 99%); mp 178—181°C.

Found: C, 66.67; H, 6.42; N, 4.68%. Calcd for $C_{17}H_{20}NO_2Cl$: C, 66.78; H, 6.55; N, 4.58%.

Reaction of 1-Benzylaziridine (1a) with Acetic Acid. A solution of acetic acid (2.40 g, 0.04 mol) in benzene (12 m*l*) was added, drop by drop, to a solution of **1a** (5.30 g, 0.04 mol) in benzene (40 m*l*). The mixture was refluxed for 3 hr and then concentrated to give a light yellow oil; this oil was subsequently distilled at 53—65°C/2 mmHg (redistilled, 89°C/18 mmHg) to give **13** (1.00 g). IR (NaCl): 3300, 2900, 1705, 1460, 1375 and 1035 cm^{-1}. NMR ($CDCl_3$): τ 9.1, τ 8.7, τ 8.0, τ 7.15, τ 6.5 and τ 6.05.

Found: C, 71.39; H, 13.00%, MW 190—200 (VPM). After the mixture had stood for a day, the precipitated 1,4-dibenzylpiperazine (**7a**)[11] (0.53 g, 10%) was filtered off. The filtrate was redistilled to give *N*-(2-hydroxyethyl)-*N*-benzylacetamide (**4a**) (4.47 g, 58%); bp 174°C/1.5 mmHg.

Reaction of 1-Benzylaziridine (1a) with Acetic Anhydride. A solution of acetic anhydride (3.06 g, 0.03 mol) in benzene (9 m*l*) was added, drop by drop, to a solution of **1a** (3.99 g, 0.03 mol) in benzene (30 m*l*). The mixture was refluxed for 3 hr and then concentrated to give a light yellow oil; this oil was distilled at 50—54°C/4 mmHg to give **13** (0.90 g). This product was identified as **13** by a comparison of its IR spectrum with that of the product from the reaction of **1a** with acetic acid. Distillation at 155—159°C/1 mmHg gave *N*-(2-acetoxyethyl)-*N*-benzylacetamide (**11**) (5.40 g, 72%). An analytical pure sample was obtained by redistillation; bp 150—151°C/0.5 mmHg.

Reaction of 1-Benzylaziridine (1a) with Thioacetic Acid. A solution of thioacetic acid (1.52 g, 0.02 mol) in methanol (10 m*l*) was stirred, drop by drop, into a solution of **1a** (2.66 g, 0.02 mol) in methanol (10 m*l*) under ice cooling. The mixture was refluxed for 3 hr and then concentrated to give a red viscous

oil; this oil was distilled at 159—163°C/1.5 mmHg to give *N*-(2-mercaptoethyl)-*N*-benzylacetamide (**12**) (3.05, 73%). An analytical pure sample was obtained by redistillation; bp 158—160°C/1.2 mmHg.

Treatment of *N*-(Hydroxyethyl)-*N*-benzylacetamide Hydrochloride (3a) with Triethylamine. **3a** (4.60 g, 0.02 mol) and triethylamine (3.03 g, 0.03 mol) were dissolved in benzene (50 m*l*), after which the mixture was stirred. The triethylamine hydrochloride thus precipitated was filtered off. The filtrate was concentrated to give an oil which was subsequently distilled at 174—175°C/1 mmHg. Its IR spectrum was superimposed on that of **4a**.

Found: C, 67.91; H, 7.30; N, 7.12%. Calcd for $C_{11}H_{15}NO_2$: C, 68.37; H, 7.82; N, 7.25%.

Synthesis of [9]Heterophanes from 2-Cyclododecenone

Shinsaku FUJITA, Takeyuki KAWAGUTI and Hitosi NOZAKI

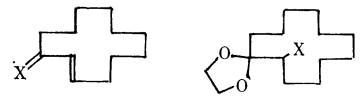
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto

(Received March 26, 1970)

[9](3,5)Pyrazolophane (V) and 11-methyl[9](2,4)furanophane (IX) were prepared from 2-cyclododecenone (I) and their spectral properties were discussed. A new route to I from cyclododecanone is described.

The unusual properties of cyclophanes have received considerable attention. In particular, NMR investigations of the conformational changes have been conducted extensively.[1] Interest has also been focused on their heteroaromatic analogs (heterophanes[2,3]), as two natural products, muscopyridine[4] and metacycloprodigiosin,[5] were shown to have [10](2,6)pyridinophane and [9](2,4)pyrrolophane structure, respectively. In continuation of studies on the heterophanes,[2,6] we carried out the synthesis of [9]heterophanes from 2-cyclododecenone (I).*1

cis- and *trans*-2-cyclododecenone (I) were prepared from cyclododecene oxide.[8] An alternative route to I has been explored in this study starting from commercially available cyclododecanone. Bromination of cyclododecanone ethylene acetal (II) followed by dehydrobromination of the resulting III with potassium *t*-butoxide in dimethyl sulfoxide afforded IV, which was in turn hydrolyzed to I (*cis* : *trans*=1 : 4). The stereoisomeric mixture of I was subjected to further reactions without separating the components. The spectral data of these compounds supported their assigned structures.



I: X=O II: X=H
IV: X=$-OCH_2CH_2O-$ III: X=Br

[9](3,5)Pyrazolophane (V) was synthesized as follows. Treatment of I with hydrazine hydrate in ethanol gave the corresponding pyrazoline (VI) which was a distillable but quite labile solid (MS, *m/e* 194 (M^+)). Freshly distilled VI was admixed with powdered sulfur and dehydrogenated at 200—220°C to afford pyrazolophane V. Compound V showed IR absorptions characteristic of the pyrazole ring (3200, 3025 and 1580 cm^{-1}). The NMR spectrum of V (Fig. 1) was consistent with the assigned structure (*vide infra*).

1,2-Addition of lithium acetylide to I gave 1-ethynyl-2-cyclododecen-1-ol (VII) whose spectral

data were consistent with the assigned structure. Acid catalyzed isomerization of VII yielded 3-ethynyl-2-cyclododecen-1-ol (VIII). Subsequent treatment of VIII with mercuric sulfate under acidic condition resulted in cycloaddition of hydroxyl on ethynyl group to afford 11-methyl [9](2,4)furanophane (IX) which displayed IR absorptions due to the furan ring (3100, 1579 and 798 cm^{-1}).

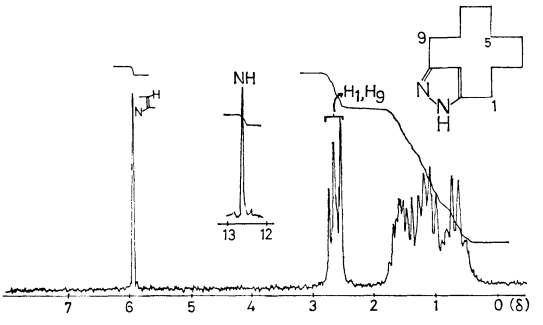

Fig. 1. The NMR spectrum of V (CCl_4, at 24°C, 60 MHz).

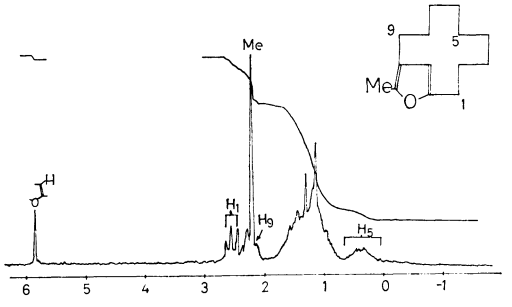

Fig. 2. The NMR spectrum of IX (CCl_4, at 60 MHz, 24°C).

The NMR spectra of the heterophanes prepared are shown in Figs. 1 and 2. Each nonamethylene chain should be flexible at room temperature, since the signal due to C_1 and C_9 protons can be approximately regarded as a triplet. Several methylene protons of chains were magnetically shielded as compared with the usual paraffinic methylene. The shielding effect may be ascribed to the diamagnetic ring current of pyrazole and furan ring. In particular, one of IX (*cf.* Fig. 2) made the signal of one methylene group separate from other peaks (δ 0.6—0.1 in CCl_4 and in CS_2). It is tentatively assigned to C_5 protons on the basis of conformational inspection by the Dreiding model. The position of the signal was dependent on temperature and shifted to a much higher field (δ 0.0——0.7, one proton) upon cooling to −72.5°C (Fig. 3). Probably, at this temperature the nonamethylene chain of IX is fixed to some extent and one of the C_5 methylene protons is forced close to the π-cloud of the furan ring. Since the UV spectrum of furanophane IX shows a considerable red shift as compared with 2,5-dimethylfuran (λ_{max} 218.5 nm), the furan ring of IX appears to suffer a distortion from coplanarity[9] similar to that of [8](2,5)furanophane.[2]

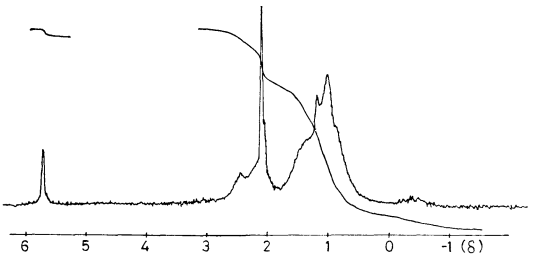

Fig. 3. The NMR spectrum of IX (CS_2, at 60 MHz, −72.5°C).

Experimental

All melting points are uncorrected. NMR data were obtained on a JEOL C-60-H spectrometer. Mass spectra were taken on a Hitachi RMS-4 spectrometer.

Cyclododecanone Ethylene Acetal (II). A solution of cyclododecanone (150 g, 0.82 mol), ethylene glycol (60 g, 0.97 mol) and *p*-toluenesulfonic acid (catalytic amount) in dry benzene (700 m*l*) was heated to reflux for 110 hr using a Dean-Stark condenser. The mixture was washed with water, dried over sodium sulfate and concentrated *in vacuo*. Distillation of the crude crystals through Vigreux column gave II (155 g, 84%) as pale yellow crystals, bp 104—105°C/0.2 mmHg, mp 68—71°C (ethyl acetate) (lit,[10] bp 125—130°C/3 mmHg, mp 70°C). IR (Nujol): 2948, 1480, 1390, 1231, 1124, 1064, 996, 957 and 875 cm^{-1}.

2-Bromocyclododecanone Ethylene Acetal (III). To a solution of II (22.6 g, 0.10 mol) in dry ether (70 m*l*) bromine (18.0 g, 0.11 mol) was added dropwise for 3 hr with vigorous stirring. The reaction mixture was neutralized with monosodium ethylene glycolate. After the ethereal layer was separated, the aqueous layer was thoroughly extracted with ether. The combined extracts were washed with water, dried over sodium sulfate and concentrated *in vacuo*. Fractional distillation of the residue yielded III (24.0 g, 79%), bp 120—124°C/0.08 mmHg, mp 72.9—73.6°C (ethyl acetate). IR

10) Haarmann and Reimer G. m. b. H., Fr. 1393647 (1965); *Chem. Abstr.*, 6886 (1965).

(Nujol): 2930, 2860, 1470, 1382, 1223, 1144, 1128, 1064, 984, 957 and 880 cm^{-1}. NMR (CCl_4): δ 4.4—4.7 (4H, m, $-OCH_2CH_2O-$) and 2.3—1.1 (21H, m).

Found: C, 55.0; H, 8.3%. Calcd for $C_{14}H_{25}O_2Br$: C, 55.1; H, 8.2%.

2-Cyclododecenone Ethylene Acetal (IV). A mixture of III (16.7 g, 55 mmol), potassium *t*-butoxide (12.3 g, 110 mmol) and dimethyl sulfoxide (70 m*l*) was mechanically stirred for 5 hr at 90°C under nitrogen atmosphere. The mixture was diluted with water and extracted with ether. The extracts were washed with water, dried (sodium sulfate) and concentrated *in vacuo*. Distillation of the residue gave IV (8.6 g, 70%), bp 150—153°C/5 mmHg. IR (neat): 3017, 2922, 1667, 1465, 1448, 1168, 1135, 1038, 983 and 946 cm^{-1}. NMR (CCl_4): δ 5.99—5.08 (2H, m, olefinic), 3.75 (4H, s, $-OCH_2CH_2O-$) and 2.5—1.2 (18H, m).

Found: C, 74.5; H, 10.6%. Calcd for $C_{14}H_{24}O_2$: C, 75.0; H, 10.8%.

2-Cyclododecenone (I). Hydrolysis of IV with dilute sulfuric acid gave a mixture of *cis*- and *trans*-2-cyclododecenone (*cis* : *trans*=1 : 4) in 74% yield, bp 127—134°C/7 mmHg (lit,[8] 95—105°C/3 mmHg).

3,5-Nonamethylene-2-pyrazoline (VI). A solution of I (1.85 g, 10.3 mmol) and hydrazine hydrate (80%, 1.37 g) in ethanol (30 m*l*) was heated to reflux for 1.5 hr. After concentration, the residue was distilled *in vacuo* to yield VI, as a white solid (1.10 g, 55%), bp 95—98°C/0.07 mmHg. The solid was so labile as to turn into a viscous yellow oil on exposure to air. The IR spectrum(neat) showed prominent peaks at 3302, 2902, 1624, 1471, 1293, 845 and 812 cm^{-1}, and MS exhibited a molecular ion peak at *m/e* 194.

[9](3,5)Pyrazolophane (V). Freshly distilled VI (1.10 g, 5.7 mmol) was admixed with powdered sulfur (0.18 g, 5.7 mmol) and heated at 200—220°C under nitrogen atmosphere for 2 hr. After the evolution of hydrogen sulfide had ceased, the crude product was subjected to separation on a silica gel column to afford crystalline V (0.77 g, 71%), mp 109—109.7°C (*n*-hexane). IR (Nujol): 3200, 3130, 3100, 3025, 2922, 2850, 1580, 1460, 1371, 1148 and 782 cm^{-1}. λ_{max} (EtOH): 207 nm (log ε 4.54). MS *m/e* (intensity): 192 (26), 177 (2), 163 (11), 149 (29), 135 (10), 124 (18), 110 (22), 109 (23) and 95 (100). The NMR is shown in Fig. 1.

Found: C, 75.1; H, 10.5%. Calcd for $C_{12}H_{20}N_2$: C, 75.0; H, 10.5%.

1-Ethynyl-2-cyclododecen-1-ol (VII). To a freshly prepared solution of lithium acetylide (from 0.13 g lithium) in liquid ammonia[11] a solution of I (2.41 g, 13 mmol) in dry ether (10 m*l*) was added dropwise in 10 min and mechanical stirring was continued for 2 hr at −35°C. The reaction mixture was treated with ammonium chloride (1.0 g) and allowed to stand overnight at room temperature. The residue was mixed with water and extracted with ether. The combined extracts were washed with water, dried over sodium sulfate, concentrated under reduced pressure and distilled to yield VII (1.41 g, 51%), bp 85—91°C/0.06 mmHg. IR (neat): 3425, 3332, 2120, 1625, 1464, 1448, 1111, 1015, and 978 cm^{-1}. NMR (CCl_4): δ 2.40 (1H, s, OH), 2.80 (1H, s, C≡CH), 5.75 (2H, m) and 2.45—0.77 (18H, m).

Found: C, 81.3; H, 10.7%. Calcd for $C_{14}H_{22}O$: C, 81.5; H, 10.8%.

3-Ethynyl-2-cyclododecen-1-ol (VIII). A solution of VII (1.27 g, 6.2 mmol) in tetrahydrofuran (15 m*l*) and 4% sulfuric acid (10 m*l*) was magnetically stirred at 100°C for 45 min under nitrogen atmosphere. After evaporation of tetrahydrofuran, the residual aqueous layer was extracted with ether, washed with water, dried over sodium sulfate and concentrated *in vacuo*. Distillation of the residue afforded VIII (1.10 g, 87%) as a highly viscous oil, bp 90—105°C/0.06 mmHg. IR (neat): 3372, 3325, 2079, 1621, 1464, 1447, 1111, 1034, 1009, 979 and 847 cm^{-1}. NMR (CCl_4): δ 5.73 (1H, d, J=9 Hz, C=CH), 3.94 (1H, s, OH), 3.26—2.88 (1H, m), 3.14 (1H, s, C≡CH) and 2.58—0.61 (18H, m).

Found: C, 81.3; H, 10.7%. Calcd for $C_{14}H_{22}O$: C, 81.5; H, 10.8%.

11-Methyl[9](2,4)furanophane (IX). A solution of VIII (0.25 g, 1.2 mmol), mercuric sulfate (92 mg) and 2% sulfuric acid (10 m*l*) in dioxane (15 m*l*) was heated to reflux at 100°C for 1.5 hr under nitrogen atmosphere. The mixture was neutralized with aqueous sodium hydrogen carbonate and extracted with ether. The ether extracts were washed with water, dried over sodium sulfate and concentrated *in vacuo*. The crude mixture was purified through a silica gel column and distilled under reduced pressure to give IX (0.045 g, 18%), bp 72—75°C/1.5 mmHg. IR (neat): 3100, 2927, 2862, 1637, 1579, 1467, 1346, 1217, 1191, 997, 929 and 798 cm^{-1}. λ_{max} (EtOH): 225 nm (log ε 2.68). MS *m/e* (intensity): 206 (49), 191 (16), 177 (11), 163 (35), 149 (34), 135 (48), 121 (60) and 108 (100).

Found: C, 81.7; H, 10.6%. Calcd for $C_{14}H_{22}O$: C, 81.5; H, 10.8%.

The NMR spectra at room temperature and at −72.5°C are shown in Figs. 2 and 3, respectively.

The authors are grateful to Professor Keiiti Sisido for his generous help and to Mr. Tamejiro Hiyama for his assistance. Financial support from Toray Science Foundation is acknowledged.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2599—2603 (1970)

Effect of Coexisting Minerals on the Graphitization of Carbon under Pressure. IV. Accelerating Effect of Calcium Oxide

Shin-ich HIRANO, Hajime SAITO and Michio INAGAKI

Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received January 22, 1970)

Heat treatments of polyvinylchloride coke in the presence of three kinds of calcium oxide calcined at different temperatures were carried out in order to study the effect of the reactivity of calcium oxide on the acceleration of graphitization of carbon under the quasihydrostatic pressure of 3.2 kbar. A remarkable difference in the accelerating effect on graphitization was confirmed. In the presence of the most reactive calcium oxide calcined at 920°C, the graphitization of the carbon began at about 1100°C and the content of the graphitic component became 100% by heat treatment at 1500°C for 60 min. While in the presence of the least reactive calcium oxide calcined at 1470°C, the graphitic component, an even hump on the corresponding diffraction angle, could not be detected in specimens heat-treated below 1500°C. The content of graphitic component and the distribution of calcium in heat-treated specimens were measured by an electron microprobe analyzer. It was found that the part having a larger content of calcium had a larger content of the graphitic component. A possible mechanism of the accelerating effect of calcium compound on graphitization is considered to be chemical concerning the intermediate formation of carbide or metal. The formation of the graphitic component seems to proceed by the reaction:

$$CaO+C\ (amorphous) \rightarrow Ca+CO \rightarrow CaO + C\ (graphite) \quad (1)$$

below 1300°C, and above 1300°C, mainly by the reaction:

$$CaO+3C(amorphous) \rightarrow CaC_2+CO \rightarrow CaO+3C\ (graphite) \quad (2)$$

and also by reaction (1). The driving force of the formation of the graphitic component through these reactions is the difference in the free energy between amorphous carbon and graphite, *viz.*, disordered and ordered graphite.

It was reported previously[1-3] that the graphitization of carbon was accelerated by the coexistence of calcium carbonate and hydroxide during heat treatment under the pressure of 3.2 kbar. A graphitic component began to appear in the carbon specimen at about 1100°C[1,2] in contact with calcium carbonate or limestone and at about 600°C[3] in contact with calcium hydroxide. The (002) diffraction line of these carbon specimens had a composite profile, *viz.*, graphitic component existed side by side with turbostratic component. The turbostratic component had transformed directly to the graphitic component without going through intermediate state. Though this heterogeneous process of graphitization seems to be similar to that observed on the same carbon heat-treated under pressure without any coexisting mineral,[2,4] the mechanisms of accelerating effects of these two processes were considered to be different from each other. The intermediate formation of unstable carbide seems to be formed by a chemical reaction of carbon and coexisting calcium compounds as one of the possible mechanism of the accelerating effect.

In the present work, calcium oxide specimens calcined at different temperatures were used as the coexisting mineral in the heat treatment of carbon under the pressure of 3.2 kbar. The object of the experiments was to study the effect of reactivity of calcium oxide on the acceleration of graphitization.

Experimental

The carbon sample used was the same polyvinyl chloride coke (PV-7) as that used in the previous works.[1-3] Three kinds of calcium oxide were prepared by the calcination of calcium carbonate at 920, 1050 and 1470°C for 60 min and were pressed into disks of 8.0 mm in diameter and 3.5 mm in thickness. It was confirmed by X-ray diffraction method whether calcium carbonate had decomposed completely or not. The disks were covered with calcium oxide powder and kept in an evacuated desiccator. The crystallite size

TABLE 1

Sample	Calcination °C	Calcination min	Crystallite size, Å	Bulk density g/cm	Prosity %
CaO-9	920	60	720	2.78	18
CaO-10	1050	60	950	2.88	15
CaO-11	1470	60	1000	2.95	13

and bulk density of the three kinds of calcium oxide (designated as CaO-9, CaO-10 and CaO-15) are given in Table 1. Calcium oxide calcined at lower temperature is known to be more reactive than that calcined at higher temperature.[5-7]

The heat treatment of the carbon sample in the presence of calcium oxide was carried out at various temperatures between 900 and 1500°C for 60 min under the quasi-hydrostatic pressure of 3.2 kbar in a simple piston-cylinder type pressure vessel. The cell arrangement and the procedure for the experiments were exactly the same as reported previously.[1-3] Temperature of heat treatment was estimated from the relation between temperature and input power. Pressure was calibrated by the transition points of KNO_3 and AgI.[8]

The diffraction profile of (002) line was measured for the central part of the heat-treated carbon specimen by using Ni-filtered Cu$K\alpha$ radiation and a recording goniometer. The composite profile observed was separated graphically into two component profiles corresponding to the graphitic component GM and turbostratic component AM.*1 The c_0-spacing and crystallite size L_c were measured from the (002) profile by the same method as reported previously.[1] The content of the graphitic component GM was obtained from the ratio of the area under the profile for the component GM to the total area under the composite profile. The area ratio was corrected for the preferred orientation of crystallite in the X-ray specimen by a conventional method.[2] The heat-treated specimens were also observed under an electron microscope. The specimen for electron microscopy was dispersed in trichloroethylene by ultrasonic vibration and then supported on an evaporated carbon film.

Results and Discussion

Each carbon specimen heat-treated above 1000°C was obtained as a caked tablet. In these caked specimens, calcium oxide was always detected by X-ray diffraction method. Its amount increased with the increase in heat treatment temperature (HTT). In the specimens heat-treated above 1300°C in the presence of CaO-9 and those heat-treated above 1400°C in the presence of CaO-10, calcium carbide was detected in the part where carbon and calcium oxide contacted each other. Recrystallization of calcium oxide was not observed

in the present experiment.

Changes of the profile of (002) diffraction line with HTT are shown in Fig. 1 a), b) and c). We see that there is a remarkable difference in the accelerating effect of the three kinds of calcium oxide on graphitization of carbon. In the presence of CaO-9, the graphitization of carbon began at about 1100°C and the profile for the graphitic component developed rapidly with the increase in HTT. The graphitization of the same carbon was found to begin at about the same HTT in the presence of limestone[1] and calcium carbonate.[2] In the presnece of CaO-10, the graphitic component G_M could be detected on (002) profile of the specimen heat-treated above 1400°C. In the presence of CaO-15, however, the graphitic component, an even hump at the corresponding diffraction angle, could not be detected in specimens heat-treated below 1500°C. From profiles of (004) line, the same results were deduced.

The variation of content of the graphitic component G_M is shown in Fig. 2 as a function of HTT. In the presence of the most reactive calcium oxide CaO-9, the graphitic component G_M increased very rapidly. The content of G_M turned out almost 100% at HTT of 1500°C. In the presence of less reactive CaO-10, however, only a small amount of the graphitic component G_M was found above 1400°C, and in the presence of CaO-15 no graphitic component G_M was observed at least up to 1500°C. The changes of c_0-spacing and crystallite size L_c with HTT are given in Figs. 3 a) and b), together with the results obtained in the presence of calcium

carbonate and without any coexisting mineral.[2] The c_0-spacing of the graphitic component G_M was almost constant at 6.72 Å as in the cases of coexistence of limestone or calcium carbonate and without any mineral.[2,3] The crystallite size L_c of G_M increased with the increase in HTT, and became larger than 1000 Å at 1500°C in the case of CaO-9. The c_0-spacing of the turbostratic component A_M decreased gradually and its crystallite size L_c increased only silghtly with the increase in HTT.

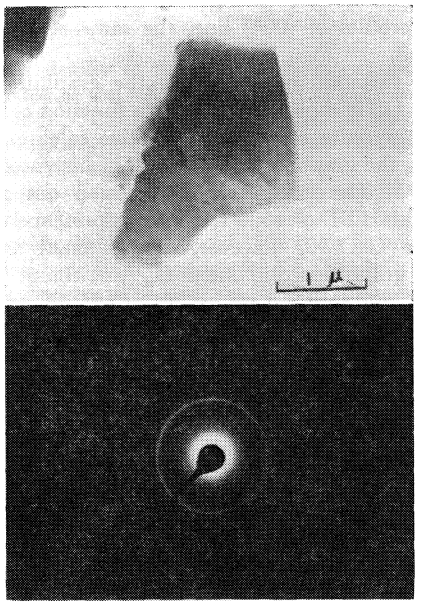

Fig. 4. Bright-field electron micrograph and selected area electron diffraction pattern of turbostratic particle under 3.2 kbar in the carbon specimen heat-treated at 1100°C for 60 min under 3.2 kbar in the presence of calcium oxide CaO-9.

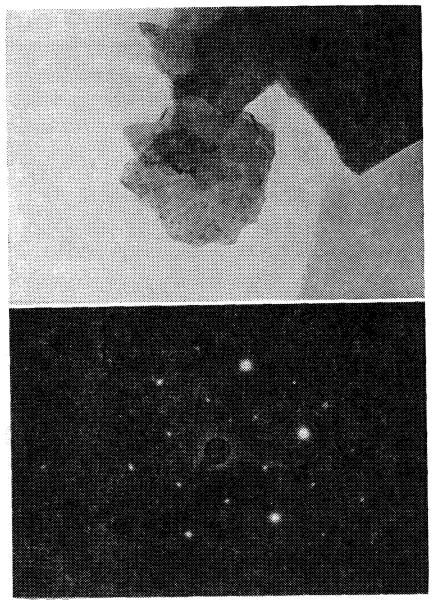

Fig. 5. Bright-field electron micrograph and selected area electron diffraction pattern of graphitic particle in the carbon specimen heat-treated at 1100°C for 60 min under 3.2 kbar in the presence of calcium oxice CaO-9.

In the specimens heat-treated above 1100°C in the presence of CaO-9 and those heat-treated above 1400°C in the presence of CaO-10, well-crystallized flaky particles having the same six-fold diffraction pattern as graphite single crystal were found under an electron microscope, besides the particles having continuous diffraction rings (Figs. 4 and 5).

The distribution of the graphitic component G_M in the caked specimens was examined by taking samples from different parts. The change of profiles and the distribution of the content of G_M in the specimen heat-treated at 1400°C in the presence of CaO-9 are shown in Fig. 6 as an example. The part closer to calcium oxide disk was found to have a larger content of G_M. The distribution of calcium element was measured by using an electron microprobe analyzer. In Fig. 7, the distribution of calcium across the thickness is shown on the specimen heat-treated at 1400°C in the presence of CaO-9. It is shown that the closer to calcium oxide disk, the larger the content of calcium.

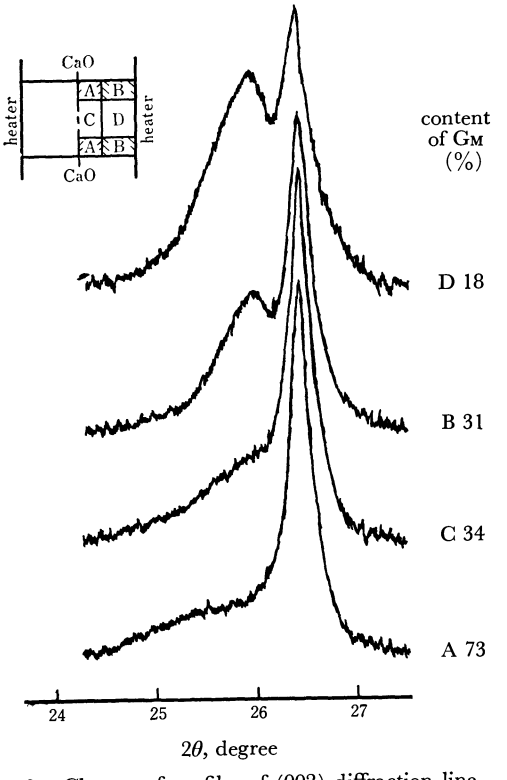

Fig. 6. Change of profiles of (002) diffraction line and distribution of content of graphitic component G_M in the specimen heat-treated at 1400°C for 60 min under 3.2 kbar in the presence of CaO-9.

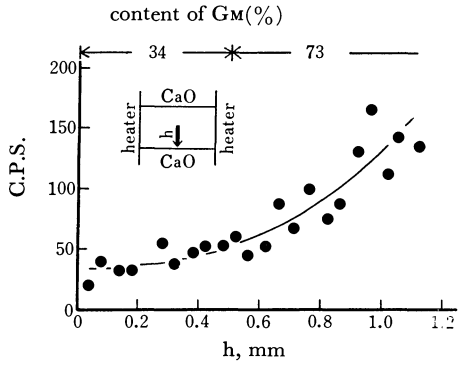

Fig. 7. Relation between distribution of calcium across the thickness and content of graphitic component G_M in the specimen heat-treated at 1400°C for 60 min under 3.2 kbar in the presence of CaO-9.

Generally, the part having the larger content of calcium has the larger content of the graphitic component G_M. The same relation between calcium content and content of G_M was observed in the specimens obtained by heat treatment in the presence of calcium carbonate under 3.2 kbar.[9]

It is suggested that the formation of the graphitic component in the presence of calcium compounds under pressure proceeds by the mechanisms explained below. The fact that calcium carbide was detected above around 1300°C, in the part where the carbon specimen contacted the calcium oxide disk, suggests that the intermediate formation and subsequent decomposition of calcium carbide may mainly lead to the formation of the graphitic component in the carbon specimen:

$$CaO+3C\ (\text{amorphous}) \rightarrow CaC_2+CO \quad (1)$$
$$CaC_2+CO \rightarrow CaO+3C\ (\text{graphite}). \quad (2)$$

Calcium oxide distributed in the carbon specimen must be the decomposition product of calcium carbide according to Eq. (2). The content of graphitic component should vary with the content of calcium oxide in the carbon specimen. This was in good accordance with experimental results.[9] On the other hand, the fact that calcium carbide was not detected below 1200°C in the specimen and the difficulty of the decomposition of calcium carbide under such condition make it impossible to explain the formation of the graphitic component at lower temperatures below 1300°C by the same mechanism as that above 1300°C. In this case, the formation of the graphitic component may proceed through the following reaction:

$$CaO+C\ (\text{amorphous}) \rightarrow Ca+CO \rightarrow CaO+C\ (\text{graphite}). \quad (3)$$

The results[11] concerning heat treatments of carbon in the presence of magnesia, alumina and silica under pressure also support this mechanism. The formation of the graphitic component by this mechanism is also possible for high temperature process. The driving force of the graphite formation through the intermediate formation of calcium carbide or calcium metal is the difference in the free energy between amorphous carbon and graphite, *viz.*, disordered and ordered graphite.[12]

The more reactive calcium oxide reacts with carbon more easily at lower temperature.[10] This was verified by the fact that carbide was detected in the carbon specimen heat-treated at 1300°C in the presence of CaO-9 and at 1400°C in the presence of CaO-10. This low reaction temperature of active oxide is closely related to the low temperture formation of the graphitic component in the presence of reactive oxide. When calcium carbonate (limestone) or calcium hydroxide was used as the coexisting mineral, nascent oxide formed during the heat treatment may have reacted with carbon to form calcium metal.

An apparent close association[1] of recrystallization and melting of coexisting calcium carbonate and hydroxide with the acceleration of graphitization is mainly due to the increased rate of reaction of the coexisting minerals with carbon at temperatures where recrystallization of minerals becomes vivid, or when the minerals melt.

The authors are indebted to Dr. T. Noda, President of Mie University, for many helpful suggestions and discussions on this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2604—2608 (1970)

The Adsorption of Polyvinyl Pyrrolidone on Silver Iodide Surfaces

Masaaki SUGIURA

7th Division, Government Chemical Industrial Research Institute, Tokyo, 85 Shinshuku, Hiratsuka-shi, Kanagawa

(Received March 7, 1970)

Adsorption isotherms for four kinds of polyvinyl pyrrolidone (PVP), having different molecular weights, on the sol particles and the powder of silver iodide at 25°C were obtained. Further, the adsorption of PVP on the sol particles was investigated by means of the electrophoresis method. All of the PVP materials give approximate adsorption isotherms of the Langmuir type, at least up to the PVP concentration of 0.4 g/*l*. At higher concentrations, the amounts of PVP adsorbed gradually increase with the increase in the PVP concentration. The effect of the molecular weight on the PVP adsorption is not observed except for the lowest-molecular-weight material, which displays a lower adsorption. The tendency for the ζ-potential of the sol particles to increase with an increase in the PVP concentration almost coincides with that of the amount of PVP adsorbed.

In previous works, the present author and co-worker have studied the adsorption of several lyophilic polymers (gelatin,[1] polyvinyl alcohol[2] and polyacrylamide[3]) on the sol particles of silver iodide as part of an investigation of the photographic emulsion of synthetic polymers. The adsorption isotherms of these polymer materials at low concentrations are roughly of the Langmuir type. However, considerable differences among the polymer materials in the limiting adsorption or in the ζ-potential for the sol particles are observed, as will be described later.

In this work, polyvinyl pyrrolidone (PVP), as a markedly water-soluble, nonionic polymer, was taken as the adsorbate to silver iodide. By measuring the amounts of PVP adsorbed on the sol particles and the powder of silver iodide and the ζ-potential of the sol particles, the adsorption behavior of PVP on the silver iodide surface could be discussed, and the values obtained were compared with those obtained for the polymers in previous works.[1-3]

Experimental

Materials. As PVP materials, PVP K-90, K-30 and K-15 obtained in the form of powder from the General Aniline & Film Co. and PVP K-60 obtained as a 45% aqueous solution from the Tokyo Kasei Kogyo Co. were used. The PVP materials were purified as follows: PVP was precipitated at room temperature (20—25°C) by the addition of freshly-distilled acetone to a concentrated solution obtained by dissolving PVP in water. The precipitate was again dissolved in small quantities of water, and then this procedure was repeated. The precipitate thus obtained was repeatedly washed with acetone and then vacuum-dried to free it from acetone and water at temperatures up to 100°C. The PVP solutions used for adsorption and electrophoretic experiments were prepared by dissolving the dry polymers in water. The concentrations of the PVP K-90 and K-60 solutions were determined by weighing the polymer films, prepared from 5-m*l* portions of the solutions cast on a stainless steel plate, after they had been vacuum-dried at 100°C for one hour. Those of the PVP K-30 and K-15 solutions were estimated from the weights of the dry polymers added to the water. The molecular weights of the PVP materials after purification were calculated from their intrinsic viscosities by the relationship;[4]

$$[\eta]=6.76\times10^{-2}M^{0.55},$$

where $[\eta]$ is the intrinsic viscosity in ml/g, and M, the viscosity-average molecular weight. The molecular weights of PVP K-90, K-60, K-30, and K-15 were 9.3×10^5, 3.0×10^5, 4.0×10^4, and 7.6×10^3 respectively.

Preparation of Silver Iodide Sol. Into the solution obtained by mixing 11 m*l* of a 0.1M potassium iodide solution and 69 m*l* of water, we vigorously stirred 10 m*l* of a 0.1M silver nitrate solution. This procedure was repeated six to ten times. All the silver iodide sols prepared in this manner were then combined and transferred into a flask with a 1-*l* capacity. After aging at room temperature for 18—24 hr, the silver iodide sol whose turbidity was in a range to be given below was used for the adsorption or electrophoretic experiments; when the sol was diluted by the addition of water to make the concentration of silver iodide 0.01 mol/*l*, the turbidity of the diluted sol was in the 0.89—1.02 cm^{-1} range. The surface area of the sol particles at a turbidity of 0.94 cm^{-1} was 1.7×10^5 cm^2/g, based on the adsorption of 1,1′-diethyl-2,2′-cyanine iodide with an assumed

molecular area of 43 Å².[5] On the basis of this particle size, assuming that the sol particles were spherical, the surface areas for other silver iodide sols were estimated from their turbidities by applying Rayleigh's law. The turbidity measurements were carried out using a Tokyo Koden nephelometer, and the dye-adsorption experiment was done by the method of Suzuki and Ishida.[6]

Preparation of Silver Iodide Powder. A silver iodide powder was prepared in the manner described by Mathai and Ottewill.[7] The surface area determined by the adsorption of the cyanine dye mentioned above was 6.7×10^3 cm²/g. This dye-adsorption experiment, considering that the dye adsorption was affected by cosolutes, was carried out by suspending the powder in a solution which had the same composition as the solvent of the sol described above. The particle size of this powder, obtained by the dye adsorption, roughly agreed with the results of observation using an electron micrograph.

Adsorption of PVP on Silver Iodide Sol Particles. 45 m*l* of the silver iodide sol were added to 5 m*l* of the PVP solution at 25±0.1°C. The mixture was maintained at this temperature for 1 hr, with occasionally shaking, and then centrifuged at room temperature for 30 min at 15000 g. The PVP concentration of the supernatant solution was determined interferometrically. For this we used a Zeiss interferometer with a 4- or 8-cm cell. The standard solutions used in constructing the calibration curves were prepared by mixing 5-m*l* portions of PVP solutions of known concentrations and a 45-m*l* portion of the supernatant solution obtained by centrifuging the silver iodide sol used for PVP adsorption.

The time dependence of the PVP adsorption was not recognized at times longer than 15 min, as is shown by the four examples in Fig. 1. The silver iodide particles dispersed in the sols were not precipitated in the presence of PVP during the adsorption process. However, since the particles were aggregated in the presence of PVP in the low concentration range, the aggregation was confirmed by the turbidity measurements.

Adsorption of PVP on Silver Iodide Powder. A 5-g portion of silver iodide powder was added to 50 m*l* of the PVP solution in a conical flask with a 100-m*l* capacity. After sealing, the contents were agitated with a magnetic stirrer for 1 hr in a thermostatted chamber at 25±1°C, and then centrifuged at room temperature for 15 min at 9000 g. The PVP concentration of the supernatant solution was determined interferometrically, as has been described above. In these measurements, since the adsorption equilibrium was almost established for 30 min, as is shown in Fig. 1, one hour was chosen as the time for the equilibration of PVP with the powder.

Electrophoretic Measurements. The electrophoretic measurements of the sol particles were carried out at 25±1°C using an ultramicroelectrophoresis apparatus described previously.[1] The sols used for these measurements were prepared as follows: a silver iodide sol having the same composition as the sol used for the adsorption experiment was diluted five-fold by a supernatant solution obtained by centrifuging the same sol, and then 45 m*l* of the diluted sol were added to 5 m*l* of the PVP solution. The ζ-potential of the sol particles was calculated using Henry's equation:[8]

$$\zeta=4\pi\eta u/Df(\kappa a), \qquad (2)$$

where η is the solvent viscosity; u, the mobility of the particle; D, the dielectric constant of the medium, and $f(\kappa a)$, the Henry factor, in which κ is the Debye-Hückel function, and a, the particle radius; the η values were obtained from the viscosity measurements of solutions with the same compositions as the solvents.

Results

Adsorption of PVP on Silver Iodide Sol Particles. The adsorption isotherms for PVP K-90, K-60, K-30, and K-15 on the sol particles are given in Fig. 2, plotted as mg PVP adsorbed per m^2 of the surface against the PVP concentration. There is no significant difference in the amounts adsorbed among PVP K-90, K-60, and K-30; PVP K-15, which has the lowest molecular weight, alone gives a lower adsorption.

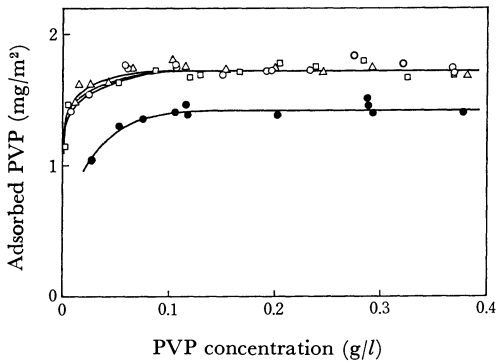

Fig. 2. Adsorption isotherms for PVP on silver iodide particles.
○ K-90, △ K-60, □ K-30, ● K-15

The turbidity-*versus*-PVP-concentration curves for silver iodide sols in the presence of PVP K-90, K-60, K-30, and K-15 are given in Fig. 3; the sols used for these measurements were prepared by adding the silver iodide sols, which gave a turbidity of 0.94 cm^{-1} in the absence of PVP, to various PVP solutions; then, after an hour, the turbidities were measured. The sol particles were aggregated in the presence of a PVP of a high molecular weight, such as PVP K-90 or K-60.

Adsorption of PVP on Silver Iodide Powder. The adsorption isotherms for PVP K-90, K-60, K-30, and K-15 on the silver iodide powder up to the PVP concentrations of 0.4 g/*l* and 4.5 g/*l* are given in Fig. 4 and Fig. 5 respectively. These isotherms in low PVP concentrations show tendencies similar to those shown in Fig. 2. At higher

PVP concentrations, the amounts of PVP adsorbed gradually increase with an increase in the PVP concentration.

ζ-potential of Sol Particles. The ζ-potential-*versus*-PVP-concentration curves for silver iodide sols in the presence of PVP K-90, K-60, K-30, and K-15 are given in Fig. 6; the free PVP concentrations were estimated from the relation between the added element and the equilibrium concentration of the PVP obtained from the measurements of the PVP adsorption on the sol particles, assuming that the amounts of PVP adsorbed per unit of the surface area of the particles in the diluted sols were equal to those in the concentrated sols. The ζ-potential of the sol particles in the absence of PVP was −75.6 mV. The tendency for the ζ-potentials to increase with an increase in the PVP concentration coincides with that of the amounts of PVP adsorbed.

Discussion

The adsorption isotherms and the turbidity curves for PVP in the low-concentration region are similar to those for polyvinyl alcohol and polyacrylamide, both nonionic, lyophilic polymers, obtained in previous works.[2,3] It can be considered that the plateaux of the isotherms in Fig. 2 or Fig. 4 are suitable for the monolayer saturation of PVP, since the ζ-potential curves, suggesting the coverages of the silver-iodide surfaces, approach constant values at the PVP concentrations reaching the plateaux. At higher concentrations of PVP, the increase in the isotherms, therefore, intimates that the adsorption extends to two or more molecular layers. In fact, in all cases considerable amounts of PVP were confirmed to be adsorbed at high PVP concentrations, up to about 30 g/*l*, though their exact values could not be obtained because of the difficulty of measuring the slight difference between the added element and the equilibrium concentration of PVP.

The difference in the amount of PVP adsorbed per unit of surface area between the sol particles and the powder, presented in Fig. 2 and Fig. 4, is mainly caused by a disagreement between the surface

** The values for PVP were calculated from the isotherms in Fig. 4 and for gelatin from those obtained for ten-fold diluted sols.

area required for PVP adsorption and that derived from the cyanine dye adsorption, except for the difference in the adsorption behaviour of PVP molecules at the surfaces; the low ionic strength in the solvent tends to decrease the adsorption. In this regard, further investigation is necessary.

The values of the limiting adsorption and the ζ-potential for PVP on the sol particles at monolayer saturation are listed in Table 1 and compared with those obtained for gelatin,[1] polyvinyl alcohol[2] and polyacrylamide[3] in previous works; the sols used all contained the same quantity of silver iodide per unit of volume, and the surface areas of the sol particles, to facilitate comparison, were recalculated from the turbidities of the sols in the absence of the polymers by applying Rayleigh's law on the basis of the particle size of the sols used for PVP. These values for PVP are smaller than those for the other polymers. This indicates that the surfaces of the silver iodide particles were more loosely covered with PVP molecules. On the other hand, as has been shown in previous paper, the power of PVP to protect gold sol against an electrolyte is stronger than that of polyvinyl alcohol and only slightly inferior to that of gelatin.[9,10] Therefore, it may be considered that PVP molecules, in consequence of their orientation, form a more stable hydration shell around silver iodide particles than those of polyvinyl alcohol.

Table 1 also includes the parameters, ν, estimated from the Frisch-Simha-Eirich[11] (FSE) equation:

$$\theta/\nu(1-\theta)^\nu = KC \qquad (3)$$

where θ is the surface converge; C, the equilibrium concentration of the polymer, and K, a constant; θ is replaced by a/a_∞ where a is the amount of polymer adsorbed at the concentration, C, and where a_∞ is the limiting adsorption. The ν parameter does not represent the number of anchor segments adsorbed per polymer chain, as has been described by Frisch *et al*, but only the deviation from the Langmuir form on the polymer adsorption, as has been pointed out by Curme and Natale.[12] From the values of ν, PVP also follows roughly the Langmuir-type adsorption in the low-concentration region, and the PVP molecules appear to be adsorbed from an aqueous solution on the silver-iodide surfaces without any remarkable transfiguration.

NOTES

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2609—2612 (1970)

A Spectrophotometric Study of the Formation and Thermochromism of the Nickel(II)-Piperidine Complexes in *N*,*N*-Dimethylformamide Solutions

Akira OUCHI, Toshio TAKEUCHI and Iwao TAMINAGA

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received November 14, 1969)

The transition energy between the pair of coordination states in a nickel(II) complex is sometimes low. In such a case, the state changes only upon a slight heating, so its solution shows a characteristic thermochromism. Such kinds of thermochromism of nickel(II) complexes have already been reported by several authors. Sone and Kato have studied the thermochromism of the ethylenediamine chelate of nickel(II),[1] Cotton and others studied the thermal change of bis(acetylacetonato)-nickel(II) in solution,[2] and several authors have reported about the formation of the $[NiCl_4]^{2-}$ ion at high temperatures.[3-5] Recently we have found that the nickel(II) chloride - piperidine complex formed in the *N*,*N*-dimethylformamide (DMF) solution containing a large excess (with a mole ratio of about 10 to 30 : 1) of piperidine is remarkably thermochromic. The solution which was yellow at room temperature became violet at high temperatures, and the color change was quite reversible. These observations led us to study the complex species formed in such solutions.

Experimental

The visible absorption spectra at 25°C were obtained with a Hitachi EPS-2 type automatic recording spectrophotometer. The spectra at high temperature were obtained with an Ito Model QU-3 spectrophotometer, with heated paraffin oil being circulated around the cell chamber. The reagents used were all GR grade, the $Ni(ClO_4)_2 \cdot 6DMF$ was made by the method reported by Gutmann.[6]

The Preparation of the Sample Solution. In general, a mixed solution of nickel(II) chloride and amine in DMF was stable for about 6 hours, and practically no spectral change could be observed in it. However, a gradual spectral change then appeared as a result of the aging of the solution. Consequently, the spectral measurements at 25°C were carried out within five hours after the preparation of the sample. The concentration of the nickel ion in the sample solutions was 0.04 M. The optical path length of the cell was 5.5 mm. The absorption coefficient of the solution showed a little deviation from Beer's law even at the concentration of 0.01 M. When the concentration of the nickel salt was higher, precipitation occurred when much amine was added.

Results and Discussion

The visible absorption spectra of the DMF solutions containing piperidine and nickel(II) chloride, where the mole ratio of the former to the latter was 0 to 101, were examined. Typical results are shown in Fig. 1. Many peaks which are considerably overlapping are observed, but no exact isosbestic points can be detected.

The relation between the absorption coefficients at various wave numbers and the mole ratio of amine to nickel are shown in Fig. 2. These curves seem to have a bending point at the mole ratio of 1 : 1, and probably another at about 2 : 1.

The DMF solution of nickel(II) chloride (curve a, Fig. 1) shows one low peak at 23800 cm^{-1}, a high peak at 16100 cm^{-1} with two shoulders at 17200 cm^{-1} and 15400—14300 cm^{-1} at its sides, and a small peak at 8050 cm^{-1}. The application of the band assignments proposed by Gutmann[6] for the DMF solution of the nickel(II) perchlorate-tetramethylammonium chloride system to our data

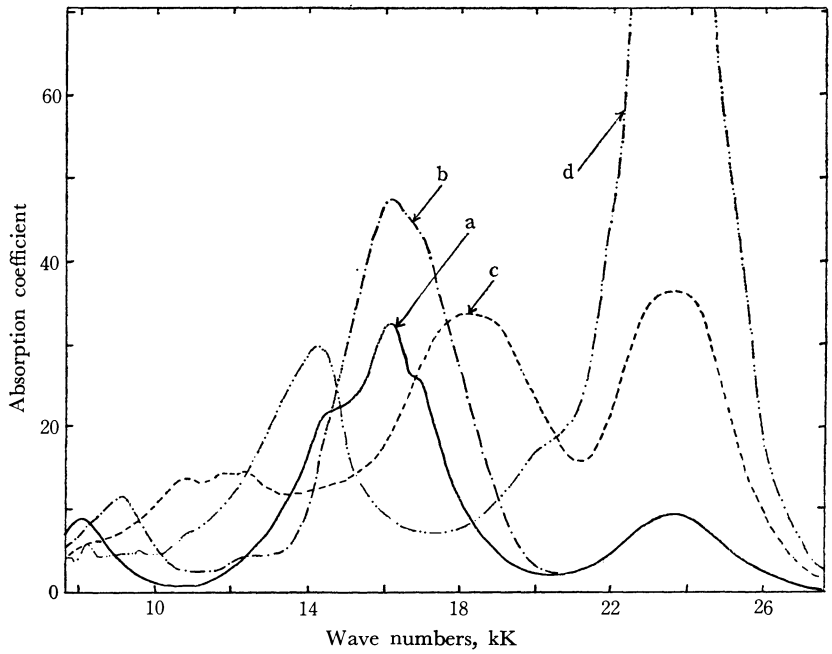

Fig. 1. Spectra of nickel(II) chloride - piperidine - DMF system. $Ni^{2+}=0.04$ M, at 25°C. Piperidine/Ni^{2+}(M/M) are a) —— 0, b) —·— 0.45, c) ---- 6.0, d) —··— 101.

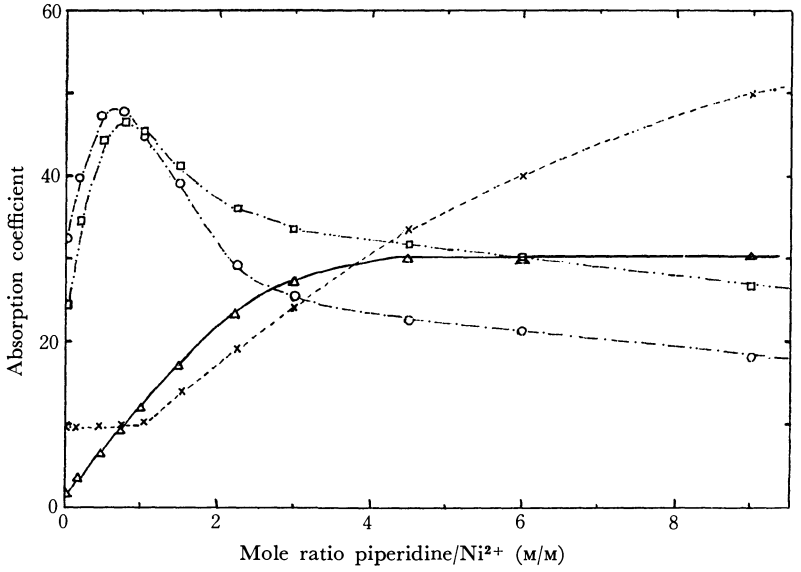

Fig. 2. The relation between the absorption coefficients at various wave numbers and the ratio of piperidine to nickel chloride in the DMF solutions. $Ni^{2+}=0.04$ M, at 25°C. a) --×-- 23800 cm^{-1}, b) —△— 19200 cm^{-1}, c) —··—□—··— 17200 cm^{-1} and d) —·—○—·— 16100 cm^{-1}

indicates that the main peak at 16100 cm^{-1} and the shoulder at 17200 cm^{-1} are the $^3T_1(F)\rightarrow{}^3T_1(P)$ absorptions of the tetrahedral $[Ni(DMF)Cl_3]^-$ and $[Ni(DMF)_3Cl]^+$, while the smaller peak at 23800 cm^{-1} is the $^3A_{2g}\rightarrow{}^3T_{1g}(P)$ absorption of such coexisting octahedral species as $[Ni(DMF)_4Cl_2]^0$ and $[Ni(DMF)_6]^{2+}$. Among these, the intensities of the peaks at about 16000—17000 cm^{-1} are far lower than the values to be expected from the $^3T_1(F)\rightarrow{}^3T_1(P)$ band of the pure tetrahedral species. This is probably due to the fact that a considerable amount of nickel is in the form of

octahedral species in the solution.[7-15]

When lithium chloride was added to the solution, the intensity of the shoulder at 15400—14300 cm^{-1} increased very rapidly and the other peaks disappeared. Consequently, it can be inferred that this peak corresponds to the $^3T_1(F) \rightarrow {}^3T_1(P)$ transition band of the tetrahedral $[NiCl_4]^{2-}$.

The results shown in Fig. 2 indicate that the dominant complex species in the solution containing a little amine have the amine : nickel composition of 1 : 1. They are probably such slightly distored tetrahedral species as $[Ni(DMF)_2(pip)Cl]^+$ and $[Ni(DMF)(pip)Cl_2]^0$. When the concentration of amine in the solution is increased, the species with the amine : nickel composition of 2 : 1 begins to appear, and in the concentrated amine solution, this diamine complex becomes predominant. Therefore the original tetrahedral species change into pentacoordinate species; probably they are such distorted square-pyramidal species as $[NiCl_2(DMF)(pip)_2]^0$ or $[NiCl(DMF)_2(pip)_2]^+$. This fact also seems to be proved by the spectral data. The spectra of the penta-coordinate bis(diethyldithiophosphate)diethylamine nickel(II) complex, for example, shows main peaks at about 6500 cm^{-1} (12), 9500 cm^{-1} (26), 12700 cm^{-1} (131), 17400 cm^{-1} (30) and 21500 cm^{-1} (250) (where the approximate ε's are shown in parentheses).[16] As is shown in Fig. 1, the spectra of the sample solutions in this study, especially those of the solutions containing a large excess of amine, show peaks at 14300, 19200 and 23800 cm^{-1} (curve d, Fig. 1.), and their general features resemble those of the penta-coordinate species.

The precipitate obtained from the concentrated DMF solution containing nickel(II) chloride and piperidine was always $NiCl_2(pip)_2 \cdot \frac{1}{2}DMF$, even if a large excess of amine was added. Moreover, the morpholine adduct of nickel sulfate was found to be $Ni(morph)_2SO_4$ (where morph means morpholine).[17] Therefore, it may be concluded that at most two molecules of amine can coordinate to one central nickel ion. The solid $NiCl_2(pip)_2 \cdot \frac{1}{2}DMF$ and the complex solutions always show their magnetic moments between 3.0 and 3.3 B.M. Therefore, the possibility of the presence of the square-planar complex species can be rejected.

It is expected that the equilibrium of the system under consideration is affected by the nature of the chloride ion, piperidine, and DMF. When the nickel perchlorate, $Ni(ClO_4)_2 \cdot 6DMF$, was used in place of nickel chloride, the intensities of

Table 1. The thermal change of the absorption spectra of nickel(II) chloride- piperidine-DMF solutions

The concentration of nickel(II) ion is 0.04 M.

The numbers in the table are apparent molar extinction coefficients (ε), and the wave numbers of the maxima of the respective peaks (kK) are given in parentheses.

the peaks were extensively lowered. The change in the spectra according to the variation of the amine concentration is small, and the thermochromism phenomenon was not observed. Probably it is due to the high stability of the $[Ni(DMF)_6]^{2+}$ ion.

Second, dimethylsulfoxide (DMSO) was used in place of DMF. The spectral change caused by the variation in the piperidine-nickel chloride mole ratio was examined. Although some spectral change according to the variation in the amine concentration was observed, it was not very remarkable, probably because of the high stability of the $[Ni(DMSO)_6]^{2+}$ ion which was dominant in the solution.

Third, various amines were added in place of piperidine to the DMF solution of nickel(II) chloride. When morpholine or pyrrolidine was used, the spectral change depending on the amine concentration was almost the same as when piperidine was used. On the other hand, in the case of using aniline, benzylamine or pyridine the change in the spectra depending on the amine concentration was not much. When diethylamine, di-*n*-butylamine, or isopropylamine was used, the spectral change and its dependence on the amine concentration were intermediate between these extremes. These results show that the amines which show the thermochromism are those which have a relatively high base dissociation constant, K_b, of about 10^{-3}. The K_b values of the amines which do not caused the thermochromism are much lower. The change in the spectra of nickel(II) chloride-DMF-piperidine solution with the variation in the temperature was then investigated; the results are shown in Fig. 3 and Table 1. The experimental results show that the spectra of a mixed sample at a high temperature resembles one which contains less amine, or one containing the same concentration of amine and an excess of chloride.

Therefore, the mechanism of the thermochromism of these complexes is explained the amine molecule in the complex species is replaced by a chloride ion or by a DMF molecule when the temperature is raised.

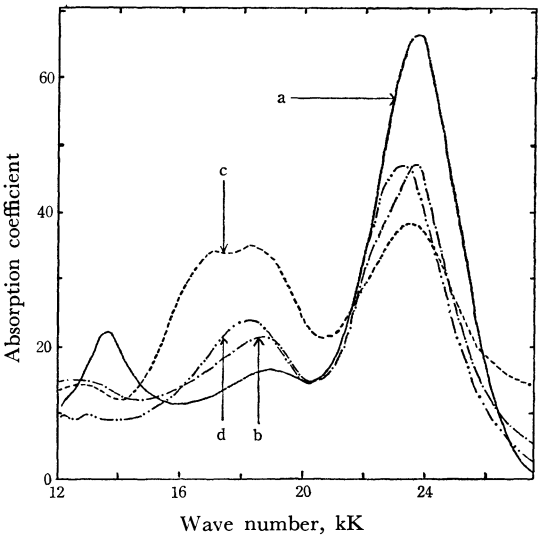

Fig. 3. The thermal change of the spectra of $NiCl_2$-piperidine-DMF system. The mole ratio of piperidine to nickel ion is 18.0, $Ni^{2+}=0.04$ M. a) —— 25°C, b) —·— 50°C, c) ---- 75°C and d) —···— 25°C, with 0.456 M LiCl.

The enthalpy change of the reaction obtained from the relation between the $1/T$ of the solution and the absorption coefficients of the main peaks of the spectra are about 3 kcal/M, far lower than those of the tetrahedral⇄octahedral or tetrahedral⇄square planar change described in the literature.[2,4]

The authors wish to thank Professors Y. Yoshino and K. Watanuki and the other colleagues of our laboratory for their helpful discussions.

The Preparation of 2-Chloroalkane-1-phosphonic Acid

Yoshiki OKAMOTO and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita-shi, Osaka

(Received November 18, 1969)

It is well known that 2-chloroalkane-1-phosphonic acid is a phosphorylation reagent[1,2] and a useful intermediate for the preparation of 1-alkane-1-phosphonic acid.[3]

The preparation of 2-chloroalkane-1-phosphonic acid or 1-alkene-1-phosphonic acid by the reaction of phosphorus pentachloride with a terminal olefin such as styrene derivatives has been reported by many investigators,[4] but in most cases the yields were unsatisfactory because of the side reaction. The yields of the desired products by this procedure usually ranged between 40—50%.

In the present experiments, it has been found that 2-chloroalkane-1-phosphonic acid can be prepared in a high yield by adding an adequate amount of phosphorus trichloride to the reaction medium. (see Table 1)

TABLE 1. THE RESULTS OF THE REACTION OF OCTENE-1 AND PHOSPHORUS PENTACHLORIDE[a]

Exp. No.	PCl_3/PCl_5	Time (hr)	Conversion[b] (%)	Yield (%) I	Yield (%) II
1	0	24	97	49	41
2	0.2	24	58	47	7
3	1	24	56	50	1
4	1	24	42	39	0
5	9	24	30	27	0
6	1	72	99	92	2
7	2	72	97	93	0

a) The PCl_5/octene-1 ratio was 2:1; benzene was used as the solvent, and the total volume of benzene+PCl_3 was maintained at 300 m*l*. The reaction temperature was 25°C.

b) The yields of 2-chlorooctane-1-phosphonic acid (I) and 1,2-dichlorooctane (II) were based upon the amount of octene-1 employed. The conversions of octene-1 were calculated from the amounts of them recovered.

When a larger amount of phosphorus trichloride was added to the reaction mixture, the rate of the reaction became much slower and the formation of 1,2-dichlorooctane was much suppressed. When the reaction time was lengthened to 72 hr, the conversion of the olefin increased to 97% and 2-chlorooctane-1-phosphonic acid was obtained in a 93% yield.

The reaction mechanism of the formation of 2-chloroalkane-1-phosphonic acid is considered to proceed *via* Eqs. (1) and (2):[5]

$$2PCl_5 \rightleftarrows PCl_4^+ + PCl_6^- \quad (1)$$

$$PCl_4^+ + CH_2{=}CHR \rightleftarrows PCl_4CH_2\overset{+}{C}HR \xrightarrow{Cl^-} PCl_4CH_2CHClR \quad (2)$$

1,2-Dichloroalkane may be produced by the addition of chlorine to the olefin by reactions (3) and (4).

$$PCl_5 \rightleftarrows PCl_3 + Cl_2 \quad (3)$$

$$Cl_2 + CH_2{=}CHR \longrightarrow ClCH_2CHClR \quad (4)$$

The equilibrium (3) may migrate to the left upon the addition of phosphorus trichloride, and the generation of chlorine may be suppressed; this latter may consequently decrease the formation of 1,2-dichlorooctane. When a large amount of phosphorus trichloride is present, the formation of the chloride is completely restrained and the side reaction (4) can be prevented. The slower rate of the reaction (2) may be due to the small concentration of PCl_4^+, caused by the nucleophilic attack of PCl_3 on PCl_4^+, as is shown in the reaction (5):

$$PCl_4^+ + PCl_3 \longrightarrow [PCl_4 \cdot PCl_3]^+ \quad (5)$$

Experimental

Preparation of 2-Chlorooctane-1-phosphonic Acid. Typical Procedure. Twenty-two grams (0.2 mol) of octene-1, 83.3 g (0.4 mol) of phosphorus pentachloride, 54.8 g (0.4 mol) of phosphorus trichloride, and 265 m*l* of absolute benzene were added to a 500 m*l*, three-necked flask fitted with a condenser protected by a drying tube. After the mixture had then been stirred for 24 hr, it was poured into ice water and stirred for 2 more hours. The oily layer was se-

The Liquidus Curve of the ZrO_2-Y_2O_3 System as Measured by a Solar Furnace

Tetsuo NOGUCHI, Masao MIZUNO and Toyoaki YAMADA

Government Industrial Research Institute, Nagoya

(Received November 19, 1969)

A subliquidus phase in the ZrO_2-Y_2O_3 system was studied by Duwez *et al.*,[1] who claimed an eutectic with 70 mol% Y_2O_3 at 2100°C and a peritectic at 2500°C, and by Otto[2] who claimed them at 2260°C and 2580°C respectively. More recently (1962) Fu-Kan *et al.*[3] have reported on a subliquidus-phase study of the system and demonstrated $Y_2Zr_2O_7$ compound at 2530±30° C. Liquidus curves in the ZrO_2-Ln_2O_3 systems[4] and the phase diagram of the ZrO_2-Y_2O_3 system[5] were also studied at the Ultra-Refractory Laboratory of Mont-Louis, France, using a heliostat-type solar furnace. The present authors have previously studied the high-temperature phases in ZrO_2–CaO[6] and ZrO_2–MgO[7] systems with a heliostat-type solar furnace; we found anomalies in the liquidus curves in the ZrO_2-rich side region. This note will be concerned with the liquidus curve measurement in the ZrO_2-Y_2O_3 system and with anomalies in the curve of the system.

Experimental

By the use of a brightness pyrometer the freezing points of a composition in the ZrO_2-Y_2O_3 system were measured by means of the specular reflection method.[8] The brightness temperature of the freezing point of the respective composition was obtained from the cooling curve. The spectral reflectivity of the specimen was also measured at 0.65 μm by the use of a shadowing plate, and the spectral emissivity was estimated from the reflectivity data. Thus, the true temperature of the freezing point was calculated. The materials used were ZrO_2 (99.8% pure, from the Yokozawa Chemicals Co.) and Y_2O_3 (99.9% pure, from the Johnson Matthey & Co., London). The carefully-mixed specimen was pressed into a $6\times6\times35$ mm bar under a pressure of 4000 kg/cm^2 and sintered at 1700°C for 3 hr with two heating and grinding cycles.

Results

The cooling-curve data are summarized in Fig. 1, while the mean values of from forty to fifty individual readings of the freezing point for each composition are indicated in Table 1. Anomalies in the liquidus curve not previously reported were found with compositions of 7.5, 15.0, and 20.0 mol% Y_2O_3.

In order to examine the stoichiometry of a composition quenched from the melt, the Y_2O_3 content of a specimen was analysed by chelate titration with an EDTA solution. The results obtained are shown in Table 2; the deviation from the stoichiometry was found to be almost negligible.

The findings on X-ray powder diffraction patterns of quenched specimens form the melt at the quenching rate of about 2000°C/sec are shown in Table 3. The Y_2O_3 solid solution was confirmed by means of diffraction lines from (332), (510), (541), and (631). The diffraction patterns of a 15 mol% Y_2O_3 composition quenched from the melt showed a broadening of peaks, though no extra reflection line was observed

parameters of the cubic zirconia solid solution were obtained at 2θ 1/8° from the diffraction lines with $2\theta > 90°$, and those of the yttria solid solution, with (332), (510), (541), and (631). The two-phase region containing a cubic zirconia solid solution and a yttria solid solution extended from 57—76 mol% Y_2O_3, as is shown in Fig. 2.

In a microscopic observation of the thin section of specimens quenched from the melt, the sample with a 15 mol% Y_2O_3 composition showed biaxial negative crystals with an optic angle of $2V = -80°$ unlike that of the monoclinic crystals ($-30°$), as in the cases of 7 mol% CaO and 12.5 mol% MgO compositions. The zirconia modification of this type is possibly of the rhombic form, though verification by X-ray diffraction data was not possible at present because of the difficulty in obtaining the single crystal.

These results suggest that the liquidus curve in the ZrO_2-rich side region of the ZrO_2-Y_2O_3 system is located at higher temperatures than those of ZrO_2-MgO and ZrO_2-CaO systems, as is shown in Fig. 3. An eutectic point on the yttria side was located at 76 mol% Y_2O_3 and at 2330°C. Further investigations should be focussed on the high-

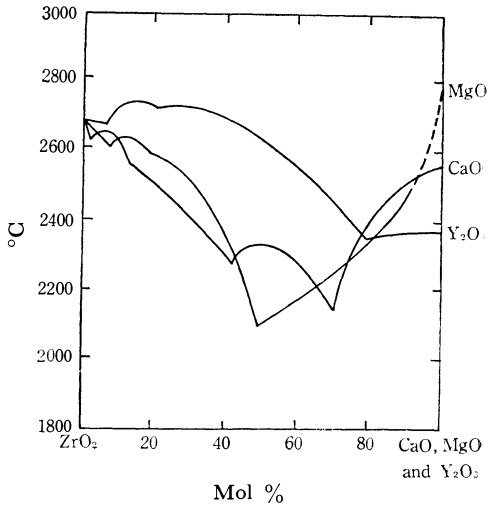

Fig. 3. Liquidus curves for binary oxide systems containing ZrO_2.

temperature phase study in the ZrO_2-rich side region in order to establish the complete phase diagram in the system.

Yttria showed its exothermic peak at about 2283°C in the solid state in the cooling curve; this might be ascribed to the cubic-hexagonal transition, as has been proposed by Rouanet.[5] However, the two phase-region of the cubic and hexagonal yttria solid solutions could not be clearly determined from the cooling-curve data.

The very narrow region for the monoclinic zirconia solid solution and the transformation of 15 mol% Y_2O_3 composition at a very high temperature might be assumed. The existence of the compound claimed by Fu-Kan *et al.* was not confirmed in this study.

The authors wish to express their appreciation to Dr. Hiroshi Hayashi for his help in the chemical analysis of the quenched specimen and in the microscopic work.

Solubility of Antimony Oxyhalides in Water

Toshiaki KISHIKAWA and Taizo YOSHIDA

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami-cho, Kumamoto

(Received December 8, 1969)

The hydrolytic behavior[2] of a neutron-irradiated antimony tribromide has indicated the presence of free bromine(^{82m}Br) at the end of the irradiation. Such a bromine atom must be the result of hydrolysis, of a solubility equilibrium of the hydrolyzed product, or of the Szilard-Chalmers process.[3] The present paper will deal with the hydrolytic behavior of antimony trihalides (chloride, bromide, and iodide), a study conducted by means of a radiotracer technique, X-ray diffractional identification, and X-ray spectrochemical analysis, and with the radiometric determination of the solubilities of the hydrolyzed products.

If water is added to antimony trihalides, various oxyhalides can be obtained, depending on the amount of water added and on the amount of free acid in the solution.[4] When 1 mol of antimony trihalide is treated with 8 mol of water, antimony monooxyhalide is formed (1). When 27 mol of water are used, the oxyhalide shown in Eq. (2) is formed:[4a]

$$SbX_3 + H_2O \rightarrow SbOX + 2HX \quad (1)$$

$$4SbX_3 + 5H_2O \rightarrow Sb_4O_5X_2 + 10HX \quad (2)$$

Experimental

Stoichiometric Determination of the Composition of Antimony Oxyhalides. Antimony oxybromide was chosen as a sample of the oxyhalides.

Materials. Radiobromine (^{82}Br) produced[5] from neutron-irradiated ammonium bromide, the radiochemical purity of which had been tested by measuring its gamma-spectrum and half-life, was introduced, after it has passed through a dehydrating agent ($CaCl_2$), into a cooled trap containing antimony powder suspended in carbon disulfide. After the reaction (performed at room temperature) had been completed, the excess antimony powder was filtered off, and then the solvent was evaporated. Antimony tribromide (^{82}Br) was thus obtained.

Procedure. About 36 mg of antimony tribromide (^{82}Br) were treated with 1 m*l* of water[6] in a small test tube. After thorough shaking for 3 min, the contents were centrifuged for 5 min (2000 rpm). Then the centrifugate was pipetted out and the residue was washed with water. The radioactivities of both the centrifugate plus washings and the residue were counted by using an NaI(Tl) well-crystal scintillation detector and a scaler.

X-Ray Diffraction. *Sample Preparation.* The antimony trihalides (Cl, Br, and I) were obtained commercially or were prepared by methods similar to that described above. Each of them was dissolved in carbon disulfide. Hydrolysis was done by thorough shaking from a two-phase mixture of the carbon disulfide solution and water in the same $SbBr_3/H_2O$ proportions as have been described above. After aging, the precipitate was filtered out and dried in a desiccator until use. The precipitate was finely powdered by means of a spatula.

Measurement. Powder X-ray diffraction patterns of the samples were recorded with a Tokyo Shibaura Electric, Model ADX-103, X-Ray Diffractometer. Mn-filtered Fe$K\alpha$ radiation at 35 kV and 7 mA was used. A G-M counter was used as an X-ray detector. The intensities reported are described in terms of peak heights above the background, so scaled that the most intense line is given a value of 100.

X-Ray Spectrochemical Analysis. *Sample Preparation.* An addition technique was carried out. As additives, Wako Pure Chemicals' antimony powder and ammonium halides (Br and I) were used. Each additive was homogeneously mixed in the oxyhalide by the use of a mortar and a pestle.

Measurement. The instrument used for the X-ray specter measurements was a Tokyo Shibaura Electric, Model AFX-103, Spectrometer. A Toshiba AF-50W-type tungsten target tube operated at 35 kV and 25 mA was used. A LiF plane-crystal and an NaI(Tl) crystal were used for diffracting the fluorescent spectrum and for the X-ray detection respectively. The peak measurements of the elements were corrected for the background near the peak to provide the net peak-intensity values. The position of each $K\alpha$ peak was located approximately by scanning the spectrum of the element and was then

more exactly located by point-set readings using mannual control.

Radiometric Determination of Solubilities. *Materials.* As a radiotracter, an ^{124}Sb isotope of a known radioactivity (*ca.* 10^5 cpm/mmol-oxyhalide) was precipitated according to the directions presented above. The radiochemical purity was also checked by the manner described above.

Procedure. A known amount of the antimony oxyhalide(^{124}Sb) was suspended in a reaction flask containing 50 m*l* of distilled water. After the suspension had been equilibriated for 20 hr (in a thermostat ± 0.2°C), an aliquot (*ca.* 2 m*l*) of the suspended solution was pipetted out and centrifuged for 5 min. A known amount of the centrifugate was then pipetted into a measuring tube and counted with an NaI(Tl) well cristal and a scaler. The comparison of the activity with that of a standard specific-activity solution indicated the solubility.

Results and Discussion

Hydrolytic Behavior of Antimony Tribromide. If the radioactivities of the residue and the centrifugate are *m* and *n* respectively, the following equation can be proposed:

$$\frac{m+n}{3}SbBr_3^* + \frac{n}{2}H_2O \rightarrow Sb_{(m+n)/3}O_{n/2}Br_m^* + nHBr^* \quad (3)$$

where an asterisk represents the ^{82}Br isotope. The *m* and *n* values thus obtained in cpm or in percentage of the total activity, are listed in Table 1.

Table 1. Radiometric determination of the hydrolytic behavior of antimony tribromide by using bromide-82 as a tracer

No.	Radioactivities of Residue (antimony oxybromide) *m*		Centrifugate (bromide ion) *n*	
	cpm	%	cpm	%
1	18361	19.7	74714	80.3
2	18963	20.4	74037	79.6
3	16040	17.4	76304	82.6
4	16160	17.7	74981	82.3
5	19430	19.4	79486	80.6
6	13932	15.7	74891	84.3
7	18044	19.6	74007	80.4
Av.		18.4±1.6		81.6±1.6

If the reaction (1) is predominant, the *m* value in percentage should be close to 33.3; if the reaction (2) is predominant, the *m* value in percentage should be close to 16.7. The average value of *m* in percentage in Table 1 is 18.4±1.6, which indicates that the composition of the obtained antimony oxybromide is $Sb_4O_5Br_2$.

Identification by X-Ray Diffraction. The X-ray diffraction patterns of the samples are shown in Fig. 1. The results of the diffraction of the oxychloride and the -bromide showed them to be $Sb_4O_5Cl_2$ and $Sb_4O_5Br_2$ respectively, according to the data of the ASTM cards.[7]

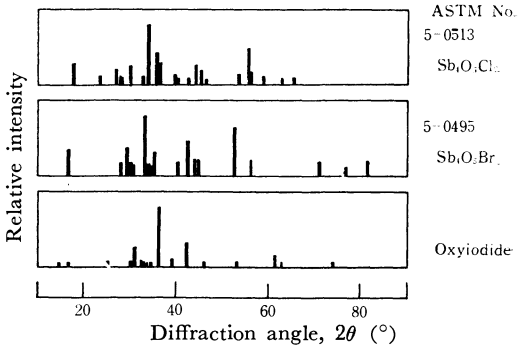

Fig. 1. X-Ray diffraction patterns of antimony oxyhalides.

X-Ray Spectrochemical Analysis. The $K\alpha$-line intensity of the relevant element was measured before and after the addition of a known amount of the element to the sample. After the determination of the intensity ratio of these two, the percentage of the element in the original sample could be calcurated from the following relationship:[8]

$$x = \frac{R \cdot w}{(1-R) \cdot W + w} \times 100(\%) \quad (4)$$

where x, R, W, and w are the percentage of the element in the original sample, the intensity ratio (intensity of the $K\alpha$ element before addition, I_x)/(intensity of the $K\alpha$ element after addition, I_s), the weight of the sample, and the weight of the standard element respectively.

The analyzed elements were Sb, Br, and I. The results of the X-ray spectrochemical analysis are listed in Table 2. The values of oxygen were calculated by subtracting the percentages of two atoms from 100%.

These results establish that the composition of the hydrolyzed product of antimony trihalides is $Sb_4O_5X_2$.

Table 2. Results of X-ray spectrochemical analysis

Element	Antimony oxibromide		Antimony oxyiodide

Table 3. Heat of solution

	Q, kcal/mol
$Sb_4O_5Cl_2$	21.0±0.1
$Sb_4O_5Br_2$	23.3±0.2
$Sb_4O_5I_2$	32.7±0.3

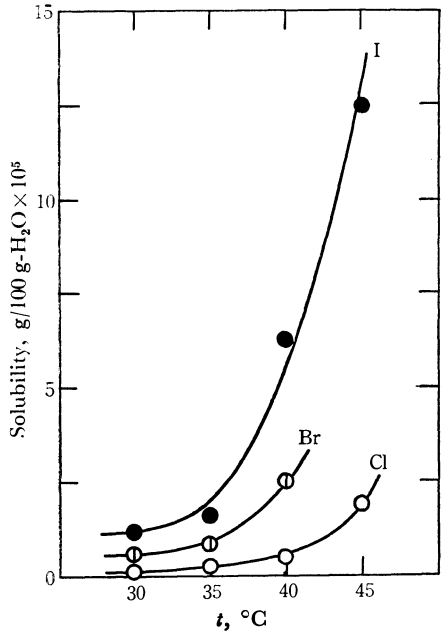

Fig. 2. Solubility curves of $Sb_4O_5X_2$ (X: Cl, Br, I). Thermostat±0.2°C

Radiometric Measurement of Solubilities. The data summarized in Table 3 and Fig. 2 indicate that the solubility increases in the following order: Cl<Br<I.

When the solubility, S, is expressed as mol/kg-solvent, the plots of log$S$ against $1/T$ gives a straight line, as is shown in Fig. 3. When a solid dissolves in a liquid, and when the state of equilibrium is reached, the van't Hoff equation holds between the equilibrium constant, K, and the absolute temperature, T:

$$\partial \ln K/\partial T = Q/RT^2 \qquad (5)$$

where Q is the heat of solution. If the heat of solution is taken as constant over the given range of temperature, the general integration of the van't Hoff equation gives, when the equilibrium constant, K, is replaced by the solubility, S:

$$\log S = -\frac{Q}{2.303R}\cdot\frac{1}{T} + \text{constant} \qquad (6)$$

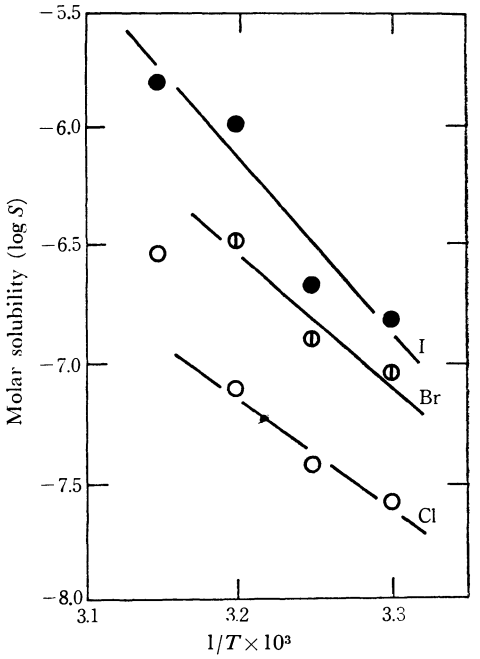

Fig. 3. Dissociation of $Sb_4O_5X_2$ (X: Cl, Br, I).

Equation (6) is shown in Fig. 3. From the slope, which is equal to $-Q/2.303R$, the heat of solution, which represents the heat of absorption when 1 mol of solution is dissolved afresh in a saturated solution, can be found in Table 3 over the given range of temperature.

The authors wish to thank Professor Chiro Shinomiya and Dr. Akira Oyoshi for their encouragement and valuable advice. Thanks are also due to Mr. Yoriyuki Ogawa of the Center for Engineering Research of this University for X-ray measurements. A part of the investigation was supported by the Joint Universities Facilities at the Tokai Establishment, the Japan Atomic Energy Research Institute, to the personnel of which thanks are also due.

The Reaction of 3,4-Dihydroxyphenylalanine with *p*-Benzoquinone under Physiological Conditions

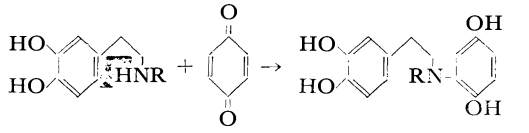
Aizo HIKOSAKA and Ju KUMANOTANI

Engineering Research Institute, Faculty of Engineering, University of Tokyo, Bunkyo-ku, Tokyo

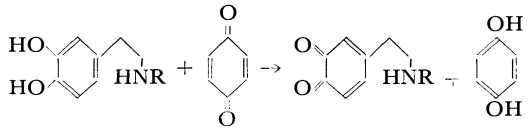
(Received December 23, 1969)

When 3,4-dihydroxyphenylalanine (dopa) is oxidized in the presence of tyrosinase, the oxidation is considerably enhanced by *p*-benzoquinone.[1] However, the stimulation by the quinone has not yet been elucidated.

This study was undertaken in order to examine the interaction of dopa and *p*-benzoquinone *in vitro* under physiological conditions. Two types of reactions were expected to occur; one of these was the ring amination of the quinone with dopa (Eq. (1)), and the other was the oxidation of dopa with the quinone (Eq. (2)).



(1)



(2)

In this study, the spectrum for the enzymic oxidation of dopa[2] was compared with that of the reaction of dopa with *p*-benzoquinone. It was found that these spectra were essentially identical.

The scheme for the enzymic oxidation of dopa by tyrosinase[3] has been confirmed polarographically.[4] The oxidation products of dopa give polarographic waves. In this study, by a comparison of the observed polarogram for the enzymic oxidation of dopa with that for the reaction of dopa with *p*-benzoquinone *in vitro* under physiological conditions (*i.e.*, in a buffer solution of pH 7.0 at ordinary temperatures), it was found that the polarograms (Fig. 2) were essentially identical, except that the anodic-cathodic wave for the hydroquinone and the quinone appeared in the dopa-*p*-benzoquinone reaction.

In view of the above facts, it appears that the reaction of dopa with *p*-benzoquinone *in vitro* under physiological conditions involves mainly the redox reaction.

The other expected course of the reaction was the amination of the quinone ring by the amino group of dopa. Polarographic investigation showed, however, that the rate of the reaction was much smaller than that of the redox reaction of dopa with *p*-benzoquinone. It is likely that the contribution of amination to the overall reaction was very small.

Experimental

Materials. Dopa (mp 271—272°C decomp. Found: C, 54.73; H, 5.59; N, 6.89%. Calcd for $C_9H_{11}O_4N$: C, 54.82; H, 5.62; N, 7.10%) was obtained commercially. No polarographic reduction wave was found in a solution of dopa. *p*-Benzoquinone (mp 116°C) was purified by the sublimation of commercially available chemicals. The buffers used were prepared according to the method of Sörensen in our laboratory. A tyrosinase preparation from a mushroom was kindly supplied by Prof. Y. Ogura.

Apparatus. The visible spectra were recorded on a Hitachi Recording Spectrophotometer, Model EPS-2U. The polarographic determinations were made with a Yanagimoto Pen Recording Polarograph, PA-102.

The Determination of 2,3-Dihydroindol-5,6-quinone (Red Quinone). 1) *Visible Spectroscopy. Enzymic Oxidation of Dopa*: To 3.0 m*l* of a solution buffered at pH 6.8 and containing 0.214 mg (1.09×10^{-6} mol) of dopa per m*l*, we added about 0.1 m*l*, of a tyrosinase solution. The absorption spectra were then immediately measured. The results are depicted in Fig. 1. The absorption spectra of intermediates between dopa and the pigment did not become evident. The experiment was conducted at room temperatures.

Reaction of Dopa with p-Benzoquinone: To 2.0 m*l* of a solution buffered at pH 6.8 and containing 0.106 mg (9.8×10^{-7} mol) of dopa per m*l*, we added 1.0 m*l* of a solution buffered at pH 6.8 and containing 0.229 mg (2.1×10^{-6} mol) of *p*-benzoquinone per m*l*. The experiment was conducted at room temperatures. The absorption spectrum of the pigment obtained in this manner was the same as that found in the enzymic oxidation.

2) *Polarography*. The experimental conditions were the same as those of the spectrophotometric studies.

A: Enzymically catalyzed oxidation of dopa. Three m*l* of a solution containing 0.624 mg of dopa buffered at pH 6.8 and 0.1 m*l* of enzyme solution.
B: Oxidation of dopa with *p*-benzoquinone. Two m*l* of a solution containing 0.212 mg of dopa buffered at pH 6.8 and 1.0 m*l* of a solution containing 0.229 mg of *p*-benzoquinone.

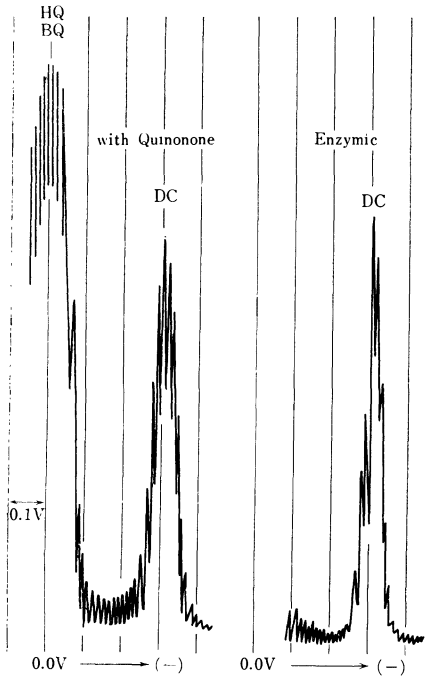

Fig. 2. Polarograms of dopachrome from tyrosinase catalyzed oxidation of dopa and from dopa-*p*-benzoquinone reaction.
DC; Dopachrome, BQ; *p*-Benzoquinone, HQ; Hydroquinone

Enzymic Oxidation of Dopa: The reaction mixtures showed a polarographic wave at −0.20 V.

Reaction of Dopa with p-Benzoquinone: The reaction mixtures showed two polarographic waves, at −0.20 and at 0.0 V. The polarograms are all essentially identical with the exception of the anodic-cathodic wave (at 0.0 V) for the hydroquinone and the quinone.

Reaction of Dopa with *p*-Benzoquinone. The buffered solution of dopa and that of the quinone were deoxygenated by passing nitrogen through, and then they were mixed in a polarographic cell in order to initiate the reaction. Nitrogen was bubbled through the reaction mixture in order to remove any oxygen and agitate the solution. The bubbling was stopped during the recording of the polarograms. Polarographic curves were registered at regular intervals, and the amounts of the unchanged quinone and its hydroquinone were determined by means of the polarograms.

To 3.0 m*l* of an oxygen-free solution buffered at pH 7.0 (phosphate buffer) and containing 0.091 mg (4.6×10^{-7} mol) of dopa per m*l*, we added 3.0 m*l* of an oxygen-free solution buffered at pH 7.0 (phosphate buffer) containing 0.15 mg (1.4×10^{-6} mol) of *p*-benzoquinone per m*l*. The rate of the reduction of the quinone was obtained at 28°C by polarography. The results are given in Fig. 3.

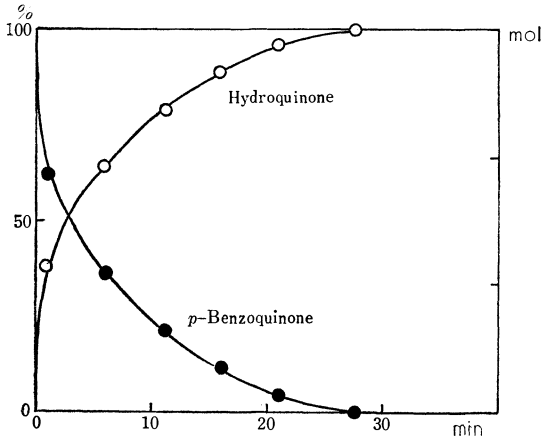

Fig. 3. Change of amount of *p*-benzoquinone and that of hydroquinone in dopa-*p*-benzoquinone reaction. The final reaction mixtures contained 4.6×10^{-7} mol of dopa and 1.4×10^{-6} mol of the quinone in a total volume 6.0 m*l* in 0.03 M phosphate buffer at pH 7.0. The experimental was run in a polarographic cell at 25°C.

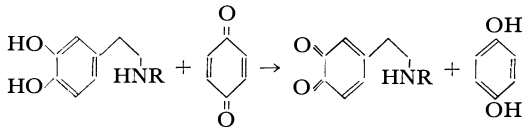
The experimental results show that, at any instant, the amount of hydroquinone formed was equal to the amount of quinone that had disappeared. Three moles of the quinone were quantitatively reduced to hydroquinone by one mole of dopa. Therefore, one might conclude that the redox reaction took place. When more than three moles of the quinone were used, hydroquinone was not quantitatively formed, although the amount of excess quinone decreased.

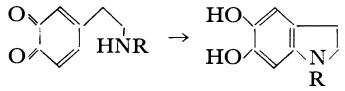
Results

The experimental results showed that dopa was oxidized to indol-5,6-quinone by *p*-benzoquinone. The oxidation was similar to the oxidation by phenoloxidase or that by inorganic oxidants.

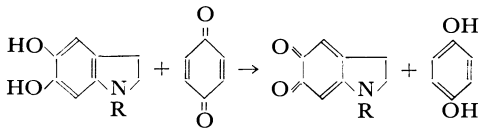
One molecule of dopa is capable of reducing 3 molecules of the quinone. The following scheme can be put forward to explain the reaction:



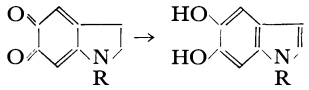
Next, the quinon undergoes an intramolecular change, with the production of 5,6-dihydroxy-2,3-dihydroindol derivatives:



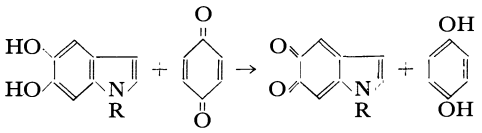
This is in turn oxidized to its quinone, which is the red pigment which appears in the first of the reaction stages:



This pigment undergoes further change on standing and yields 5,6-dihydroxyindole derivatives:



These are oxidizable in the air or by the quinone and yield indol-5,6-quinone derivatives:



The problem of the fate of indol-5,6-quinone derivatives is not discussed in the present paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2622—2623 (1970)

The Reaction Route of 2,4,6-Triphenyl-*s*-triazine to the C=N Conjugated Polymer

Eizo OIKAWA and Atsushi OHKUMA

Faculty of Engineering, Niigata University, Nagaoka, Niigata

(Received January 13, 1970)

The heating of 2,4,6-triphenyl-*s*-triazine (cyaphenin) with a metal halide afforded a black polymer. A similar polymer was obtained from the benzonitrile complex with a metal halide. In this note, the reaction route of cyaphenin to the polymer was investigated in order to determine whether or not the polymerization proceeds by the usual ring-opening, since Kabanov *et al.*[1] have reported the conversion of cyaphenin to the polymer as a ring-opening. Their meaning was, however, ambiguous.

The reaction of cyaphenin[2] with zinc chloride[3] was carried out in an about-20-m*l*, vacuum-sealed ampule by heating a mixture in the molar ratio of 2 : 3 (2 : 1 based on the benzonitrile unit) at 350—430°C in both the presence and absence of metaphosphoric acid (MPA) for from 1 to 13 hr. The black solid formed was dissolved in sulfuric acid and precipitated by pouring the solution into water. The weight difference between the initial cyaphenin and the precipitates gave the weight of the benzonitrile, which remained unchanged. The unreacted cyaphenin was recovered by sublimation. The polybenzonitrile from the zinc chloride complex was prepared by heating a mixture of benzonitrile and zinc chloride in a 2 : 1 molar ratio. The black product was extracted with hot toluene. The toluene was removed by distillation, and the residue was sublimed at about 200°C to give cyaphenin.

The relation between the polymer yields and the reaction time at different reaction temperatures in the presence of MPA is shown in Fig. 1. Similar curves were obtained in the absence of MPA. The apparent activation energy was calculated to be 14 kcal/mol in the presence of MPA and 16 kcal/mol in the absence of MPA, on the basis of the maximum slope in the yield-time curves.[4] The heating of cyaphenin without zinc chloride in either the presence or absence of MPA in an ampule at 430°C for 4 hr gave no appreciable amounts of benzo-

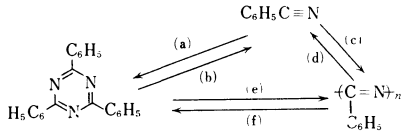
○ 430°C, □ 400°C, △ 370°C, ◐ 350°C

nitrile, although in the presence of MPA a little stronger smell of benzonitrile was perceived. In order to examine the influence of MPA on the trimerization, benzonitrile was heated with 5% MPA in an autoclave at 300°C for 24 hr. This gave only a 0.3% yield of cyaphenin. These facts indicate that MPA neither initiates the trimerization nor decomposes the trimer by itself.

Unreacted benzonitrile, as is shown in Figs. 2 (a) and (b), was formed by the decomposition of cyaphenin and was not changed to either the polymer or cyaphenin. The yields of benzonitrile decreased at higher temperatures and increased at lower temperatures with the reaction time. The decrease in the yields of the unreacted nitrile reveals that the decomposition of cyaphenin took place in the initial reaction period and in the subsequent reaction period the benzonitrile thus formed was converted to the polymer. In other words, the rate of the decomposition of cyaphenin is very rapid compared with the rate of the polymer formation at higher temperatures. On the other hand, the increase in the yields of the unreacted nitrile at lower temperatures corresponds to the accumulation of benzonitrile due to the difference between the decomposition and the polymer-formation rate of cyaphenin, since the decomposition of cyaphenin to benzonitrile proceeds at a higher rate than the conversion of benzonitrile to the polymer. Therefore, the activation energies noted above indicate those of the polymerization reaction of benzonitrile. The variations in the yields of the unreacted benzonitrile indicate that MPA acts as a promoter in the decomposition of the trimer to the monomer in the presence of zinc chloride. These results can be summarized as in the following diagram:



The once-produced polymer is thermally stable and remains unchanged except for a slight decomposition, accompanied by NH_3 formation.[5] The routes (d) and (f) can, therefore, be neglected compared with the other routes. The ring-opening path of cyaphenin *via* (b) to give benzonitrile is made possible by the preferential formation of benzonitrile in Figs. 2 (a) and (b). The route (c) from the benzonitrile complex with zinc chloride to the polymer is preferential to the route (a) back to cyaphenin, as is demonstrated by the higher yields of the polymer. Consequently, the route (e) should not be appreciable compared with (b) and (c). The presence of the equilibrium between (a) and (b) is demonstrated by the higher polymer yields from the complex than those from cyaphenin at 400°C, as is shown in Fig. 1, and by the simultaneous formation of cyaphenin from the complex.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2624—2625 (1970)

Effect of Coexisting Minerals on the Graphitization of Carbon under Pressure. V. Distribution of Calcium and Graphitic Components in Heat-Treated Carbon Specimens

Shin-ichi HIRANO, Michio INAGAKI and Hajime SAITO

Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received January 22, 1970)

The accelerating effect of coexisting calcium compounds on the graphitization of carbon under pressure has been reported.[1-4] The mechanism of the accelerating effect on the graphitization seems to consist of the formation and the successive decomposition of calcium carbide and/or the formation and the successive reaction of calcium metal and carbon monoxide.

In the present work, the distribution of calcium in carbon specimens heat-treated in the presence of calcium compounds under pressure was determined by using an electron microprobe analyser. The distribution was compared with that of the graphitic component G_M which was determined by the X-ray diffraction method.[1]

Specimens were prepared from a polyvinylchloride coke, carbonized at 680°C (PV-7) by heat treatment under 3.2 kbar for 60 min at 1090 and 1360°C in the presence of calcium carbonate, and at 1100, 1400 and 1500°C in the presence of calcium oxide precalcined at 920°C. All the five specimens were obtained as caked pieces.

Details on the apparatus and the procedure for the preparation of the caked specimens were reported previously.[2,4] The size of the caked specimens was about 7.6 mm in diameter and 2.5 mm in thickness.

The specimens were cut into halves (a) and (b) across their diameter, one half for the electron microprobe analysis and the other for the X-ray diffraction analysis.

Sample (a) was mounted in resin. The surface of the cross section was ground on an abrasive paper and finished to a very flat surface by polishing on a felt with very fine corundum powder dispersed in ethanol in order to avoid reactions between calcium compounds and water. Electron beam of 100μ width was scanned along the thickness (h-direction) and also along the radial direction (r-direction) on the polished section of the caked specimen (Fig. 1).

For X-ray diffraction analysis, sample (b) was cut down to pieces along the thickness and also

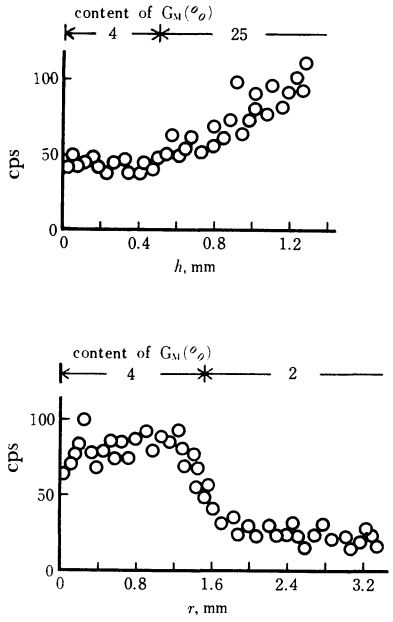

Fig. 3. Relation between distribution of calcium and content of graphitic component G_M in the specimen heat-treated at 1100°C under 3.2 kbar in the presence of calcium oxide.

along the radial direction, and the content of graphitic component G_M was measured for each piece.

Two examples of results are shown in Figs. 2 and 3. In the presence of calcium carbonate, the content of graphitic component G_M was found to be larger in the central part of the specimen than in the peripheral part which was close to carbonate layer. This distribution of graphitic component was attributed to a temperature gradient in the specimen.[2] In the presence of calcium oxide, however, the reverse distribution of graphitic component G_M was observed,[4] that is, the content of graphitic component was smaller in the central part than in the peripheral part. The reason for this difference in the distribution of graphitic component in the heat-treated carbon specimens is not clear. However, in both cases the part having a larger content of graphitic component G_M has larger calcium concentration. The same relation was observed for all the specimens.

X-ray fluorescence photographs of carbon and calcium in the central area (400 $\mu \times 400\ \mu$) of a specimen are shown in Figs. 4a and 4b. The concentration variation of calcium scanned with electron beam width of 10 μ from A to B (Fig. 4 b) across a carbon grain is shown in Fig. 4c. From the figures we see that calcium was accumulated in the boundaries of carbon grains. The concentration of calcium in the carbon grain decreased very steeply in the layer about 10 μ from the boundary and only a minute amount of calcium was detected in the inner part.

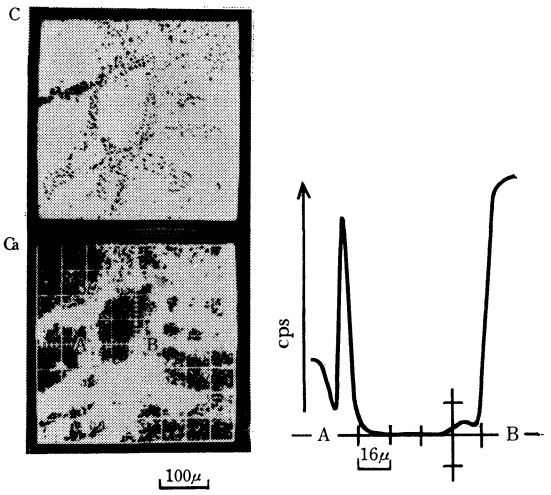

Fig. 4. a) X-ray fluorescence photograph of carbon in the central area of the specimen heat-treatd at 1360°C under 3.2 kbar in the presence of calcium carbonate.
b) X-ray fluorescence photograph of calcium in the same area as in Fig. 4a.
c) Concentration variation of calcium scanned from A to B in Fig. 4b.

The fact that the content of graphitic component G_M and the concentration of calcium were closely related to each other supports the proposed mechanism of the acceleration of graphitization in the presence of calcium compounds,[4] *viz.*, the intermediate formation of calcium carbide and/or calcium metal.

The authors wish to thank Dr. T. Noda, President of Mie University, for his helpful discussion and The Toyota Central Research Laboratory for kind arrangements for use of the Shimadzu-ARL electron microprobe analyser.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2626—2628 (1970)

Reactions of Recoil ^{35}S Atoms with Organic Compounds. I. The Distribution of ^{35}S Atoms on Mercaptobenzothiazole

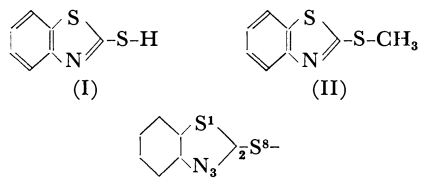
Ko Taki

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received January 28, 1970)

The reaction of ^{35}S atoms produced by neutron irradiation has been studied recently.[1,2] An appreciable proportion of the ^{35}S appears in oxidized forms,[3,4] especially as sulfate. Several investigations[5,6] have been reported regarding the chemical forms of ^{35}S, and extensive studies of the sulfur atom produced by the photolysis[7,8] of SCO have also been reported. However, few investigations[9] have been reported regarding the reaction of a sulfur atom produced by nuclear recoil reaction with organic compounds.

In this paper, the distribution of ^{35}S atoms in the molecules of mercaptobenzothiazole (I) and methylmercaptobenzothiazole (II) was studied; some differences in the reactions of the ^{35}S atoms formed by the $^{35}Cl(n,p)^{35}S$ and $^{34}S(n,\gamma)^{35}S$ processes were also investigated.



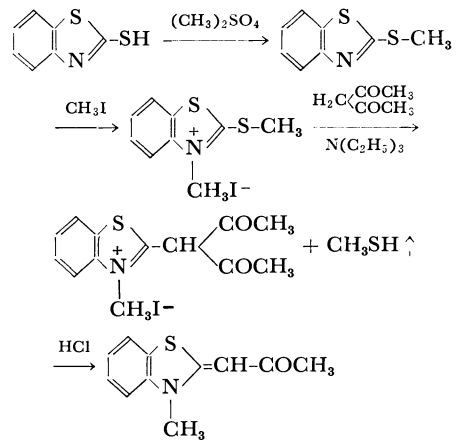
(I) (II)

Experimental

Mercaptobenzothiazole (I) and methylmercaptobenzothiazole(II) (Tokyo Kasei Co.) were irradiated with JRR-1,2 and 3 reactors of the Japan Atomic Energy Research Institute in the absence of and in the presence of trichlorobenzene as a chlorine source. The irradiations were performed in a quartz ampule (0.5×3.0 cm) containing the sample.*1

Separation and Purification of an Irradiated Sample. For the degradation of an activated compound, the starting material (I and II) was added as a carrier to the irradiated sample; the purification was performed by recrystalization, reprecipitation, and solvent extraction.

Measurement of Radioactivity. All the samples were oxidized by the Shöniger[10] method or by the method using a Pirie reagent,[11] and the sulfate thus produced was precipitated by barium chloride. The activity of the barium sulfate thus obtained was measured at an infinite thickness by an end-window-type Geiger Müller counter. The specific activity of each compound was calculated from the saturation value of the apparent activity. The measurement of the total activity was carried out by the simultaneous irradiation of $(NH_4)_2SO_4$, NH_4Cl, and the targets. At each step of degradation of the sulfur compounds, the relative activity was measured. The degradation was performed by the following processes:[12]



Results and Discussion

As is listed in Table 1, the reactions of the ^{35}S atoms in the presence and in the absence of ben-

*1 For the purpose of degassing, the sample was dissolved in pyridine or alcohol, and then the solvents were removed.

Table 1. Distribution (%) of ^{35}S produced by $^{35}Cl(n, p)^{35}S$ process in the presence and absence of benzoquinone

Benzoquinone %	 S_1-position	S_8-position
0	2.4	97.6
3.9	1.6	98.4

Mercaptobenzothiazole 0.2 g
1,2,4-Trichlorobenzene 0.1 g
Irradiation 2.5×10^{13} n/cm² sec, about 200 hr

Benzoquinone %	 S_1-position	S_8-position
0	2.2	97.8
3.5	5.7	94.3

Methylmercaptobenzothiazole 0.4 g
1,2,4-Trichlorobenzene 0.1 g
Irradiation 2.5×10^{13} n/cm² sec, about 200 hr

zoquinone and oxygen as a radical scavenger[13] gave almost the same ^{35}S distribution. This experimental fact suggests that all the reactions may be considered to be hot reactions and not thermal reactions. The radiochemical yield of the activated parent molecule (retention value) is about 2—5% for the $^{35}Cl(n,p)^{35}S$ process and about 30% for the $^{34}S(n, \gamma)^{35}S$ process. The distribution of the ^{35}S atoms in the molecule is much greater in the S_8-position than in the S_1-position in both mercaptobenzothiazole (I) and methylmercaptobenzothiazole (II). The experimental results can not be reasonably interpreted, but it may be considered that the collisional exchange (a knock on exchange in terms of a billiard-ball model) of the sulfur atom is easier in the S_8-position than in the S_1-position in the molecule. By the collision of a hot atom, C–S–C bond rupture may occur in a moment. A large number of bond-cleaved intermediates may decompose, and some of them may combine in a short duration with slow-downed ^{35}S atoms which are located near the molecule. Therefore, the distribution of the ^{35}S atoms may be dependent on the stability of the bond-cleaved intermediate. It may be considered that the intermediate which is bond-cleaved at the S_8-position  is more stable than that at the S_1-position  in the mercaptobenzothiazole molecule.

Table 2. Distribution (%) of ^{35}S produced by $^{34}S(n, \gamma)^{35}S$ and $^{35}Cl(n, p)^{35}S$ process

Process	 S_1-position	S_8-position	$\frac{S_8}{S_1}$	(Retention value) yield %
$^{34}S(n, \gamma)^{35}S$	12.6	87.4	6.9	27.5
$^{35}Cl(n, p)^{35}S$	5.4	94.6	17.5	4.8

Cl source: *p*-Dichlorobenzene (^{35}Cl atoms/^{34}S atoms=10)
Irradiation 3×10^{11} n/cm² sec, 240 hr
Targets were not degassed.

$^{34}S(n, \gamma)^{35}S$	6.4	93.6	14.6	
$^{35}Cl(n, p)^{35}S$	3.6	96.4	26.8	

Cl source: Trichlorobenzene (^{35}Cl atoms/^{34}S atoms=11
Irradiation 4×10^{13} n/cm² sec, 144 hr

Reaction of ^{35}S Atoms Formed by Two Nuclear Reactions. In the presence of trichlorobenzene, since the activation cross-section of ^{34}S and ^{35}Cl is almost the same (0.26 barn for ^{34}S and 0.17 barn for ^{35}Cl) and since the number of atoms of ^{35}Cl is much larger than that of ^{34}S, the $^{34}S(n, \gamma)^{35}S$ process can be disregarded. In this case the reactions are brought about by hot ^{35}S atoms produced by the $^{35}Cl(n, p)^{35}S$ process. On the other hand, in the absence of trichlorobenzene the reactions are brought about by hot ^{35}S atoms produced by the $^{34}S(n, \gamma)^{35}S$ process. The experimental results on hot ^{35}S atoms from the two formation processes are listed in Table 2. The ratio of ^{35}S atoms at the S_8-position to those at the S_1-position is smaller in the process of $^{34}S(n, \gamma)^{35}S$ than in that of the $^{35}Cl(n, p)^{35}S$ process in all the runs, as is shown in Table 2; the ^{35}S atoms formed from ^{34}S exchange with S_8-sulfur more easily than the ^{35}S atoms formed from ^{35}Cl.

The chemical reaction may occur when hot atoms have been slowed[14] sufficiently (25 eV—50 eV).

Process	 S_1-position	S_8-position	$\frac{S_8}{S_1}$	(Retention value) yield %
$^{34}S(n, \gamma)^{35}S$	12.5	87.5	7.0	
$^{35}Cl(n, p)^{35}S$	7.1	92.9	13.1	

Cl source; Trichlorobenzene (^{35}Cl atoms/^{34}S atoms=10)
Irradiation 4×10^{13} n/cm² sec, 200 hr

$^{34}S(n, \gamma)^{35}S$	17.1	82.9	4.8	29.7
$^{35}Cl(n, p)^{35}S$	10.5	89.5	8.5	2.1

Cl source: Trichlorobenzene (^{35}Cl atoms/^{34}S atoms=20)
Irradiation 1×10^{11} n/cm² sec, 288 hr

14) A. P. Wolf, C. S. Redvanly and R. C. Anderson, *J. Amer. Chem. Soc.*, **79**, 3717 (1957).

The reaction of sulfur atoms may not be affected by the initial recoil energy, about 17 keV for the $^{35}Cl(n, p)^{35}S$ process and about 1 keV for the $^{34}S(n, \gamma)^{35}S$ process, because the recoil energy is too high to react with an organic compound. Also, because of the simultaneous irradiation of the sample for two nuclear reactions, the effect of radiation damage may be disregarded.

It has been reported that, in the reaction of the ^{11}C formed from the $^{12}C(n, 2n)^{11}C$, $^{12}C(p, pn)^{11}C$,[15,16] and $^{12}C(\gamma, n)^{11}C$[17] processes, no essential differences are found among the processes.

The present author does not have any reasonable explanation for the experimental facts. It may, however, be presumably postulated that the distribution of ^{35}S atoms is affected by the original position of the nuclear-transformed atom in the molecule.

The author wishes to acknowledge the valuable assistance of Miss K. Motegi as well as to express his appreciation to Dr. T. Nozaki for his helpful discussions and suggestions. A part of this research was carried out with a Scientific Research Grant from the Ministry of Education, to which the author's thanks are due.

The Action of Boron Trifluoride Etherate on *l*-Menthol

Kimiko NAGAI

Fukuyama Women's Junior College, Fukuyama

(Received February 4, 1970)

The reaction of menthol with sulfuric acid has been reported by Wagner,[1] who detected *p*-menthane and alkane, bp 178.0—180.0°C/13 mmHg, in the reaction product. Aizawa *et al.*[2] have reported that the reaction of menthyl chloride with anhydrous aluminum chloride resulted in the formation of *p*-menthane, a dimer ($C_{20}H_{36}$), 1-*p*-menthene and 3-*p*-menthene via the menthyl cation. In this work, *l*-menthol was reacted with an equimolar amount of boron trifluoride etherate at 80°C for 45 min. A light-yellow oil separated as an upper layer; it consisted of a low-boiling part and a high-boiling part. Six components were isolated from the low-boiling part by preparative gas chromatography, and one component from the high-boiling part by column chromatography.

(a) Low-boiling Component. Component (1), 3-isobutyl-1-methylcyclopentane: The molecular formula is found to be $C_{10}H_{20}$ from the mass spectrum (parent peak M^+, *m/e* 140, Fig. 1). The IR and NMR spectra showed the bands at 1384, 1368, and 1169 cm^{-1} associated with a branched dimethyl group and the signals corresponding to three methyl groups (9H) between 0.80 and 1.00 ppm (Fig. 2). This component is a saturated mono-cyclic hydrocarbon which differs from *o*-, *m*- and *p*-menthane in its IR and NMR spectra. The main peaks of *m/e* 97, 83, 69, 55, and 41 in the mass spectrum can be well explained as those of 3-isobutyl-1-methylcyclopentane, which has not previously been reported.

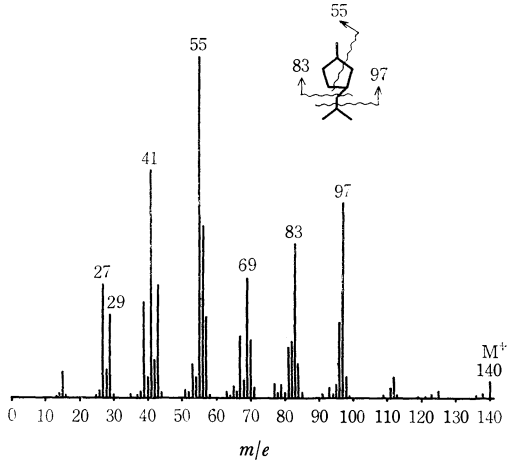

Fig. 1. Mass spectrum of 3-isobutyl-1-methylcyclopentane.

Component (2): The molecular formula is found to be $C_{10}H_{18}$ from the mass spectrum (parent peak M^+, *m/e* 138). The IR spectrum showed the bands at 1386, 1370, and 1167 cm^{-1} associated with a branched dimethyl group. The compo-

1) G. Wagner, *Ber.*, **27**, 1636 (1894).

2) F. Aizawa, M. Arai and M. Yamaguchi, *Nippon Kagaku Zasshi*, **90**, 497 (1969).

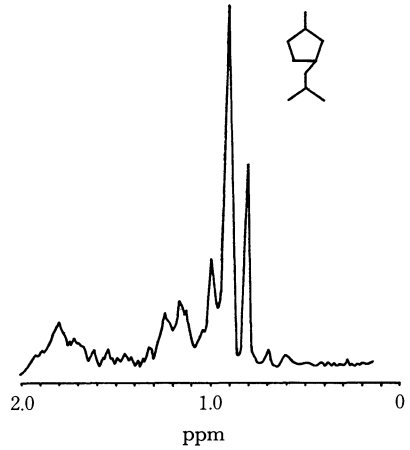

Fig. 2. NMR spectrum of 3-isobutyl-1-methylcyclopentane.

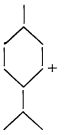
nent (2) seems to have been found to be a mixture of two compounds through careful gas chromatography using Carbowax 6000 as a stationary phase. When this component was hydrogenated in the presence of platinum oxide, it absorbed one mole of hydrogen and changed to 3-isobutyl-1-methylcyclopentane. Judging from the base peak of *m/e* 81 in the mass spectrum, this component seems to be an unsaturated five-membered ring compound having the same carbon skeleton as 3-isobutyl-1-methylcyclopentane.

Components (3), (4), (5) and (6) were identified as *trans-p*-menthane, *cis-p*-menthane, 3-*p*-menthene, and 1-*p*-menthene respectively by comparing them with authentic specimens by gas chromatography or by comparing their IR spectra and also by the preparation of nitrosochloride.

(b) High-boiling Component. A colorless and rather viscous oil was isolated from the high-boiling part by elution chromatography. The molecular formula is found to be $C_{20}H_{38}$ from the mass spectrum (parent peak M^+, *m/e* 278). Peaks at *m/e* 139 corresponding to a half of the molecular weight of this component and at *m/e* 235 ($M^+ - C_3H_7$) appeared in the mass spectrum. It was suggested that this compound was bis-menthyl.

The reaction of boron trifluoride etherate with *l*-menthol was carried out under various conditions (Experiment (1), temp. 25°C, reaction period 30 days; (2) temp. 60°C, reaction period 6.5 hr; (3) temp. 80°C, reaction period 45 min). The contents of C_{10}- and C_{20}-hydrocarbons identified in Experiment (3) were as follows: 3-isobutyl-1-methylcyclopentane 2%, 3-isobutyl-1-methylcyclopentene 1%, *trans-p*-menthane 9%, *cis-p*-menthane 2%, 3-*p*-menthene 10%, 1-*p*-menthene 2%, $C_{20}H_{38}$ 30%.

trans-p-Menthane was produced in a large quantity at room temperature (25°C), but the amount of 3-*p*-menthene increased with a rise in the reaction temperature. Also, C_{20}-hydrocarbon was



[I]

obtained in a large quantity in every experiment. It seems that 3-isobutyl-1-methylcyclopentane and 3-isobutyl-1-methylcyclopentene were formed through a ring contraction of the cation [I]. It is interesting that 3-isobutyl-1-methylcyclopentane and 3-isobutyl-1-methylcyclopentene were produced from *l*-menthol by ring contraction; these two compounds have not yet been reported.

Experimental

1. Sample. *l*-Menthol: mp 42.5—43.5°C, $[\alpha]_D^{25}$ —46.7° (in ether), phenylurethane, mp 111.0—111.5°C. The sample exhibited only one peak on gas chromatography with either Carbowax 6000 and Neopentyl glycol succinate. Neoiso-menthol which shows the same retention value at *l*-menthol, could not be detected on the basis of the IR spectrum (lack of bands, 795 and 629 cm^{-1} characteristic of the neoiso-isomer).

Boron trifluoride etherate: Commercially-available boron trifluoride ehterate (BF_3 47%) of the first grade was used.

2 Identification of the Reaction Product. Three hundred grams of *l*-menthol and 300 m*l* of boron trifluoride etherate were reacted at 80°C for 45 min; 260 g of the oil were thus obtained from the upper layer. The oil, washed with a saturated aqueous solution of sodium carbonate and water, was distilled under reduced pressure to 7 fractions. Six components were isolated from fractions (1) to (4) by preparative gas chromatography using Carbowax 6000 at 65°C.

Component (1), 3-isobutyl-1-methylcyclopentane: The component corresponding to the peak (1) on gas chromatography was a colorless oil with petroleum-like smell. The mass and NMR spectra are shown in in Figs. 1 and 2.

Component (2): This was a colorless oil with a petroleum-like smell; it corresponded to the peak (2). This oil was shown to be a mixture of two compounds by gas chromatography, but the two compounds could not be separated. When 0.5 g of the oil was hydrogenated on platinum oxide, it absorbed one molar equivalent of hydrogen and changed into 3-isobutyl-1-methylcyclopentane.

Components (3), (4), (5), and (6) were identified by the following measurements and by the preparation of derivatives. Their IR and GLC were compared with those of authentic specimens.

Component (3): *trans-p*-menthane, mol wt, 139 (Rast), Elementary analysis: $C_{10}H_{20}$, IR, GLC

Component (4): *cis-p*-menthane, IR, GLC

Component (5): 3-*p*-menthene, IR, GLC, nitrosochloride

Component (6): 1-*p*-menthene, IR, GLC, nitrosochloride

High-boiling component: The oil was isolated from the fraction (6) by passing *n*-hexane through a silica gel column. The component showed a spot of R_f 0.88

on thin-layer chromatography. Bp 145.0—145.5°C/5 mmHg, d_4^{25} 0.8829, n_D^{25} 1.4820, mol wt, 278 (mass spectrum); elementary analysis, $C_{20}H_{38}$. This component seemed, on the basis of the IR and NMR spectra, to be a saturated hydrocarbon with two separated C_6-rings and an isopropyl group.

Gas chromatography. A Shimadzu GC-2 apparatus equipped with a thermal conductivity detector was used. Carrier gas, helium; flow rate, 60 ml/min. For hydrocarbon analysis, Celite 545 (60—80 mesh) coated with Carbowax 6000 (30%) was used at 65°C.

The author wishes to express her sincere gratitude to Professor Tamon Matsuura and Professor Shuichi Hayashi, of Hiroshima University, for their kind guidance and discussions during this work.

Biogenesis of the Essential Oils in Camphor Trees. XXVI. On the Components of the Essential Oil of *Cinnamomum daphnoides* Sieb. et Zucc.*[1]

Yasuji FUJITA,* Shin-ichi FUJITA** and Hisashi YOSHIKAWA*

* *Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda-shi, Osaka*

** *Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto*

(Received February 4, 1970)

Cinnamomum daphnoides Sieb. et Zucc. (Japanese name, Marubanikkei) of Lauraceae is an endemic plant growing chiefly on the shores of the Osumi Peninsula and the Islands of Tane and Yaku in Kagoshima Prefecture, Japan.[1)]

This plant had been utilized as a linalool resource since a field survey of the senior author on Tane and Yaku Islands in 1947.[2)] Nakahara has reported that the plant obtained from Tane Island affords the essential oil in a 0.25% yield by the steam distillation of the twigs, and that the oil contains *l*-linalool (65—70%) and an unidentified high-boiling compound (15%) as the main components, besides α-pinene, *p*-cymene, cineole, and an ester.[3)]

The present investigation consists of the further study of this essential oil from the viewpoint of chemical systematics; in this paper, the authors will report on the results of their examination of the essential oil of the plant, bred from seeds collected on Tane Island in 1947.

The essential oil was obtained in a 0.15% yield by the steam distillation of fresh leaves and branchlets. The chemical composition of this oil is shown in Table 1. The characteristic of the oil is the abundant existence of *l*-linalool (69—75%) and elemicine (16—19%), the total amounting to 88.2—90.6%; the content of camphor is so small that it is not detected by the ordinary procedure.

A comparison with the essential oils of the relative species will be published later.

Experimental

Materials. Two plants in an experimental garden (Ikeda, Osaka), bred from seeds collected from a tree at Nishino-omote, Tane Island, Kagoshima Prefecture, on November 8, 1947.

Isolation of the Essential Oils. Sample I. On July 25, 1962, material gathered at the beginning of the flowering stage (21.7 kg) (the average length of a twig: 44 cm; its weight: 48 g, consisting of 69% leaves, plus a small amount of flowers, and 31% branchlets) was subjected to steam distillation. The distilled oil was extracted with ether, and then dried over anhydrous sodium sulfate. The oil (33.4 g) obtained in a 0.15% yield had the following properties: d_4^{30} 0.9208, n_D^{30} 1.4784, α_D^{10} −12.45°, A.V. 7.0, E.V. 3.1.

Sample II. On October 15, 1964, material gathered at fruiting stage (18.2 kg) (the average length of a twig: 44 cm; its weight: 42 g, consisting of 57% leaves, 42.6 % branchlets, and 0.4% fruits) was subjected to steam distillation; the oil (27.5 g) thus obtained in a 0.15% yield had the following properties: d_4^{30} 0.9077, n_D^{30} 1.4765, α_D^{10} −12.80°, A.V. 7.0, E.V. 2.4.

Gas-chromatographic Analysis. The gas chromatography was carried out by means of Shimadzu GC-1B Model equipment with a thermal conductivity detector. A 150×0.5-cm stainless steel column was packed with PEG 6000 (30%) on Celite 545 (100 mesh), and hydrogen was used as the carrier gas.

Separation and Identification of the Individual Components. The essential oil was fractionated by

b) This compound shows the bands at 3400, 1100, 885 cm^{-1}.

c) Bp 272°C/756 mmHg, d_4^{30} 1.0519, n_D^{30} 1.5228. Trimethylgallic acid (mp 169°C) was obtained by oxidation with potassium permanganate.

distillation under reduced pressure into nine fractions. Each fraction was further divided into hydrocarbons and oxygenated compounds by alumina-column chromatography.

The components were isolated by preparative gas chromatography using a PEG 6000 column (2 m × 10 mmϕ) and were identified by a comparison of the IR spectra and retention times (Rt.) with those of authentic samples. Some minor components were identified by Rt's. only using two kinds of columns (PEG 6000 and Silicone DC-550).

The results are shown in Table 1.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2632—2633 (1970)

A Convenient Method for the Preparation of Thiolesters

Tadashi ENDO, Shinichi IKENAGA and Teruaki MUKAIYAMA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 12, 1970)

In connection with a continuing investigation on the new synthetic reactions by the use of a disulfide as an oxidant, it was reported in the preceding paper that bis(diethylthiocarbamoyl) disulfide or benzenesulfenyl chloride reacts with mercuric carboxylates to give carboxylic acid anhydrides in high yields.[1] The present paper describes a convenient method for the preparation of thiolesters from free carboxylic acids by the use of triphenylphosphine and diphenyl disulfide.

It is known that dibenzoyl or bis(dimethylthiocarbamoyl) disulfide reacts with triphenylphosphine in refluxing benzene to give the corresponding sulfide and triphenylphosphine sulfide.[2]

$$(C_6H_5)_3P + RS\text{-}SR \rightarrow (C_6H_5)_3P{=}S + RSR$$
$$(R = C_6H_5\overset{\overset{\|}{O}}{C},\ Me_2N\overset{\overset{\|}{S}}{C})$$

Schönberg reported that 2 equiv. of benzenethiol and triphenylphosphine oxide resulted in low yields by treating diphenyl disulfide with triphenylphosphine in the presence of water in boiling benzene.[3]

$$(C_6H_5)_3P + (C_6H_5S)_2 + H_2O \rightarrow 2C_6H_5SH + (C_6H_5)_3P{=}O$$

This result suggests that the use of carboxylic acids in place of water as proton donors in the above reaction would lead to the formation of thiolesters, benzenethiol, and triphenylphosphine oxide. As expected, carboxylic acids reacted readily with diphenyl disulfide and triphenylphosphine in boiling acetonitrile to give thiolesters, benzenethiol, and triphenylphosphine oxide in high yields as shown in Table 1.

$$RCO_2H + (C_6H_5S)_2 + (C_6H_5)_3P \rightarrow RC(=O)SC_6H_5 + C_6H_5SH + (C_6H_5)_3P{=}O \quad (1)$$

Except for the case of crotonic acid, analytically pure thiolesters were easily isolated by chromatography over silica gel.[4] However, in the case of crotonic acid, phenyl *dl*-3-phenylthiothiolbutyrate (I) was obtained in 77% yield. The adduct (I)[5] resulted from the addition of benzenethiol to phenyl thiolcrotonate initially formed by the reaction (Eq. (1)).

$$CH_3CH{=}CHC(=O)SC_6H_5 + C_6H_5SH \rightarrow CH_3CH(SC_6H_5)CH_2C(=O)SC_6H_5 \quad (I)$$

The reaction can be explained by considering an initial formation of the first phosphonium salt (II) from diphenyl disulfide and triphenylphosphine. The intermediate (II) is in turn changed into the second phosphonium salt (III) by nucleophilic attack of a carboxylic acid on phosphorus of II with the elimination of benzenethiol. The intermediate (III) is further converted to the third phosphonium salt (IV) by the intramolecular oxidation-reduction reaction. In this process, the phenylthio moiety attached to phosphorus in the intermediate (III) accepts two electrons from phosphorus to be reduced to the benzenethiolate anion of the intermediate (IV). The intermediate (IV) undergoes decomposition to a thiolester and triphenylphosphine oxide.

TABLE 1. REACTIONS OF CARBOXYLIC ACIDS WITH DIPHENYL DISULFIDE AND TRIPHENYLPHOSPHINE

Carboxylic acid	Time hr	Yield, %		
		Thiol-ester	C_6H_5SH	$(C_6H_5)_3P{=}O$

Benzoic	3	89	73	90
Succinic	5	81	73	89
Crotonic	5	77[a]		90
Chloroacetic	3	81	64	92

a) The yield of the adduct (I)

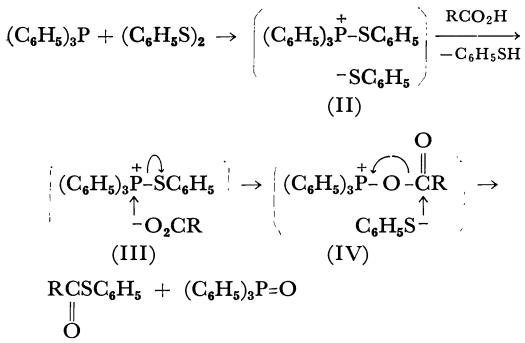
1) T. Mukaiyama, T. Endo, S. Ikenaga and K. Osonoi, *J. Org. Chem.*, **33**, 2242 (1968).

2) A. Schönberg and M. Z. Barakat, *J. Chem. Soc.*, **1949**, 892.

3) A. Schönberg, *Ber.*, **68**, 163 (1935).

4) With chloroacetic acid, phenyl chlorothiolacetate and benzenethiol were obtained in 81 and 64% yields, respectively, indicating that phenyl chlorothiolacetate is unreactive with benzenethiol.

5) A. A. Schleppnik and F. B. Ziently, *J. Org. Chem.*, **29**, 1910 (1964).



When diethyl disulfide was used as an oxidant, no reaction took place and the starting materials were recovered almost quantitatively. This result suggests that the reactivities of the disulfides in this reaction depend on the oxidizing power of the disulfides, which was found to decrease in the order of decreasing stabilities of the corresponding thiolate anions of the disulfides.[6]

Experimental

Materials. Various carboxylic acids, diphenyl disulfide, and triphenylphosphine were all commercial materials and purified by distillation or recrystallization before use. Acetonitrile was purified by the conventional procedure.

Preparation of Phenyl Thiolpropionate. Propionic acid (0.74 g, 0.01 mol), diphenyl disulfide (2.18 g, 0.01 mol), and triphenylphosphine (2.62 g, 0.01 mol) were refluxed in 30 m*l* of acetonitrile for 3 hr. After the reaction mixture was concentrated under reduced pressure, the residue was chromatographed on silica gel. Elution first with petroleum ether gave benzenethiol (0.88 g, 80%), bp 50—55°C/10 mmHg, and phenyl thiolpropionate (1.44 g, 94%), bp 112—113°C/10 mmHg. The infrared spectrum of this thiolester showed carbonyl absorption at 1710 cm^{-1}. Elution with ethyl acetate gave triphenylphosphine oxide (2.56 g, 92%), which was recrystallized from methylene chloride - petroleum ether, mp 154—156°C.

Preparation of Phenyl Thiolsuccinate. Succinic acid (0.60 g, 0.005 mol), diphenyl disulfide (2.18 g, 0.01 mol), and triphenylphosphine (2.62 g, 0.01 mol) were refluxed in 30 m*l* of acetonitrile for 5 hr. After the reaction mixture was concentrated *in vacuo*, the residual oil was chromatographed on silica gel to isolate three products. Elution first with petroleum ether gave benzenethiol (0.80 g, 73%), bp 50—53°C/10 mmHg. Elution next with methylene chloride - petroleum ether (1 : 1) gave first phenyl thiolsuccinate (1.23 g, 81%), mp 89—90°C, after recrystallization from isopropanol, then gave triphenylphosphine oxide (2.42 g, 89%).

Reaction of Crotonic Acid with Diphenyl Disulfide and Triphenylphosphine. Crotonic acid (0.86 g, 0.01 mol), diphenyl disulfide (2.18 g, 0.01 mol), and triphenylphosphine (2.62 g, 0.01 mol) were refluxed for 5 hr in 30 m*l* of acetonitrile. After removal of the solvent from the reaction mixture, the resulting oil was chromatographed on silica gel. Elution with petroleum ether gave phenyl *dl*-3-phenylthiothiolbutyrate (I) (2.31 g, 77%), bp 148—150°C/0.07 mmHg, n_D^{22} 1.6114 (lit,[5] bp 172—173°C/0.2 mmHg, n_D^{25} 1.6106). (Found: C, 66.50; H, 5.59; S, 21.94%). Elution next with methylene chloride gave triphenylphosphine oxide (2.54 g, 90%).

The Synthesis of 5,5′-Di-(2-methoxycarbonyl-vinyl)-2,2′-bifuryl by the Electrolysis of Methyl 3-(2-Furyl)acrylate[1]

Hajime SATONAKA, Zei SAITO and Toshio SHIMURA

Industrial Research Institute of Kanagawa Prefecture, Tomioka-machi, Kanazawa-ku, Yokohama

(Received February 23, 1970)

The present authors previously reported the synthesis of methyl 3-(2,5-dimethoxy-2,5-dihydrofuryl)acrylate (**2**) by the electrolysis of methyl 3-(2-furyl)acrylate (**1**) and the decomposition of **2**.[2-5]

4) T. Shimura, Z. Saito and H. Satonaka, *ibid.*, **90**, 716 (1969).

5) T. Shimura, Z. Saito and H. Satonaka, *ibid.*, **90**, 1173 (1969).

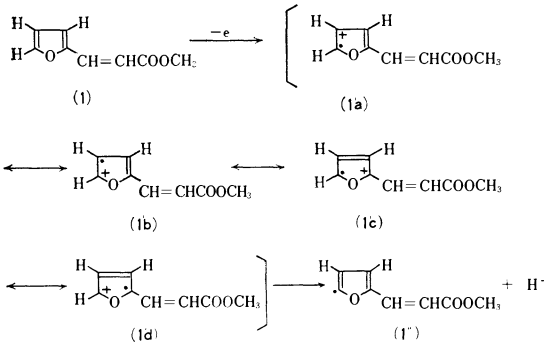
This paper will describe a new compound formed by the electrolysis of methyl 3-(2-furyl)acrylate (**1**) in methyl alcohol at low temperatures (−40—−50°C). When the electrolysis was carried out by use of the Clauson-Kaas method,[6] methyl 3-(2,5-dimethoxy-2,5-dihydrofuryl)acrylate (**2**) was mainly formed, a yellow precipitate was also obtained.

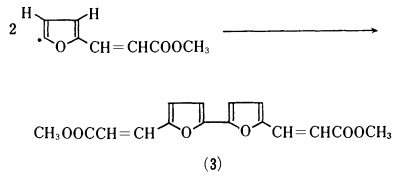
The IR spectrum of the yellow product showed an unsaturated ester carbonyl band at 1721 cm^{-1}, an olefinic band at 1638 cm^{-1}, and bands of the furan ring at 1023 and 881 cm^{-1}. The UV spectrum in methyl alcohol showed a maximum peak with a molecular extinction coefficient of 46000 at 392 mμ and a shoulder band at 410 mμ.

The NMR spectrum showed signals at τ 2.59 (2H, doublet, J=15 Hz), 3.27 (2H, doublet, J=5 Hz), 3.35 (2H, doublet, J=5 Hz), 3.62 (2H, doublet, J=15 Hz), and 6.21 (6H, singlet). The signals at τ 2.59 and 3.62 with the spin-spin coupling constant of 15 Hz were assigned to the methin protons of –CH=CH– in the acrylate group. The doublets at 3.27 and 3.35 with the J of 5 Hz were assigned to the protons of the furan ring. The signal at τ 6.21 was assigned to the methyl protons of the methyl ester. The elementary analysis data agreed with the formula of $C_{16}H_{14}O_6$.

On the basis of these results, the product was determined to be a dimer of methyl 3-(2-furyl)-acrylate, 5,5′-di(2-methoxycarbonyl-vinyl)-2,2′-bifuryl (**3**).

This dimer seems to be formed at the anode. The reactions may proceed as follows:





The anodic oxidation of furylacrylate (**1**) may give a radical cation which can be expressed in terms of the resonance hybrid of the four structures, **1′a**, **1′b**, **1′c**, and **1′d**, and this radical cation may then turn into a radical **1″** and a proton. At last, the coupling reaction of **1″** takes place to give **3**. The bifuryl thus formed seems to be deposited from the reaction mixture because of its small solubility.

This dimer is an interesting material which belongs to an unsaturated dibasic carboxylic acid and which contains two furan rings.

Experimental

Methyl 3-(2-Furyl)acrylate (1). This material was prepared by the condensation of furfural with methyl acetate by the method of Gilman *et al.*[7] Yellow crystals; mp 27°C.

5,5′-Di(2-methoxycarbonyl-vinyl)-2,2′-bifuryl (3). To a solution of 20 g of methyl 3-(2-furyl)acrylate in 250 m*l* of methyl alcohol, 1 m*l* of concentrated sulfuric acid was added; the mixture was then electrolyzed in a Clauson-Kaas electrolyser[6] for 6 hr with 10—12 V, 1.5 A at −40——50°C. A yellow product was obtained by the subsequent filtration of the electrolyzed solution. Recrystallization from methyl alcohol gave yellow needles with a melting point of 184°C; 2 g (10%).

Found: C, 63.40; H, 4.77%. Calcd for $C_{16}H_{14}O_6$: C, 63.57; H, 4.67%.

IR (cm^{-1}, KBr): 3130($\nu_{=C-H}$), 1721($\nu_{C=O}$), 1638 ($\nu_{C=C}$), 1023, 881(furan nucleus).

UV(λ_{max} mμ(ε), in CH_3OH): 392 (46000), 410 (39000), 228 (22000), 289 (9000).

NMR (τ, in $CDCl_3$): 6.21 (6H, s), 3.62 (2H, d, J=15 Hz), 2.59 (2H, d, J=15 Hz), 3.35 (2H, d, J=5 Hz), 3.27 (2H, d, J=5 Hz).

The authors wish to express their thanks to Dr. Minoru Hirota, Yokohama National University, for his kind suggestions and encouragement, and to Mr. Takayoshi Ozawa for his assistance in the elementary analysis.

Equilibria of the Isomerization of Xylene at 290°C under a Pressure of 300—6000 kg/cm²

Haruo TAKAYA,* Naoyuki TODO,* Tadasuke HOSOYA,* Toshio MINEGISHI* and Mikio YONEOKA**

* *The Government Chemical Industrial Research Institute, Tokyo, Mita, Meguro-ku, Tokyo*
** *Japan Gas-Chemical Company Inc., Niigata Laboratory, Enoki-cho, Niigata*

(Received February 23, 1970)

It is known that the isomeric forms of xylene, *i.e.*, *ortho*-xylene, *meta*-xylene and *para*-xylene, can be converted into one other by isomerization over acid catalysts under heterogeneous conditions. However, as has been reported by Taylor,[1] the *para*-xylene content in the mixture of xylene at equilibrium is 23—24% in the temperature range from 100°C to 600°C.

Recently a patent presented by Hepp[2] has reported an improved process for isomerizing xylenes; in this process the yield of the *para* isomer is about 58%, and that of the *ortho* isomer is almost twice that which can be obtained by a conventional operating process, when the reaction is conducted at 327°C and at a pressure of 5400 kg/cm². If such a process can be possible, both the economical and thermodynamical interests of the isomerization would be enhanced. However, it has been realized that the influence of the pressure on an equilibrium of a reaction is determined by the difference between the molar volumes of the product and the reactant.[3] The molar volumes of *ortho*-, *meta*- and *para*-xylene at 25°C are 121.2 ml/mol, 123.5 ml/mol, and 123.9 ml/mol respectively.[4] Hence, under a high pressure, the differences between the molar volumes of these isomers seem to be small even at a high temperature of 327°C, where the molar volumes of the xylenes are nearly equal to those at 25°C.

The present authors have previously developed high-pressure equipment for both the batch and the flow reactions and have investigated the rate of the isomerization of xylenes over acid catalysts under heterogeneous conditions.[5,6] This study was undertaken in order to examine the pressure dependency of the compositions of the mixtures of xylenes at equilibrium at 290°C and to confirm the improved process described above.

Experimental

The xylene isomerization was carried out by the contineous-flow method using the high-pressure equipment reported in the previous paper.[5] The catalyst used was powdered Nikki X633L silica-alumina. The feeds were prepared by mixing pure xylenes in the desired proportions; the compositions used are given in the column 2 of Table 1. The products were analyzed by gas chromatography in the same manner as has been described in a previous paper.[6]

Results and Discussion

The compositions of the xylene fraction in the reaction product at 290°C at pressures between 300 and 6000 kg/cm² are shown in column 3 of Table 1.

It has been proposed by Hanson that *para*-xylene and *ortho*-xylene do not directly interconvert,[7] that is, that the migrating methyl group moves around the benzene ring in steps of one ring position at a time. This can be represented schematically as;

$$ortho \rightleftharpoons meta \rightleftharpoons para$$

Hence, the results on the equilibrium composition of xylenes were treated with the following two reactions: *para*⇄*meta* and *meta*⇄*ortho*. The ratios of *para*-xylene and *ortho*-xylene to *meta*-xylene are also tabulated in column 2 (Reactant) and 3 (Product) of Table 1 and are shown in Fig. 1. The ratios of the products should approach closer to those at equilibrium than the ratios of the reactants. For example, the ratio of *p*/*m* at equilibrium under the pressure of 2000 kg/cm² can be obtained by the following procedure. The ratio of *p*/*m*

* A is the maximum value of the probable ratio at equilibrium.
** B is the minimum value of the probable ratio at equilibrium.

decreases from 1 to 0.45 upon the isomerization; thus, the ratio at equilibrium should be smaller than 0.45 (A in Fig. 1). The ratios of p/m increase from 0 to 0.37 and from 0.34 to 0.37; thus, the ratio at equilibrium should be larger than 0.37 (B in Fig. 1). Consequently, the ratio at equilibrium under 2000 kg/cm² should be 0.37(B)—0.45(A). The A and B values obtained from such a procedure, and also the corresponding compositions, are shown in Table 2 and in Fig. 2. Figure 2 clearly indicates that a mixture of xylenes at equilibrium, even under a pressure of 6000 kg/cm², consists of 20—21% *para*-xylene, 53—55% *meta*-xylene, and 25—27% *ortho*-xylene; these findings practically agree with those obtained under ordinary conditions, although the experiment in this study was carried out at 290°C, a temperature lower by 37°C than that in Hepp's work. However, it seems unlikely that the difference in the reaction temperature between the both cases greatly influences the equilibrium composition, for it is very difficult to suppose that by such a temperature difference discrete phenomena can occur.

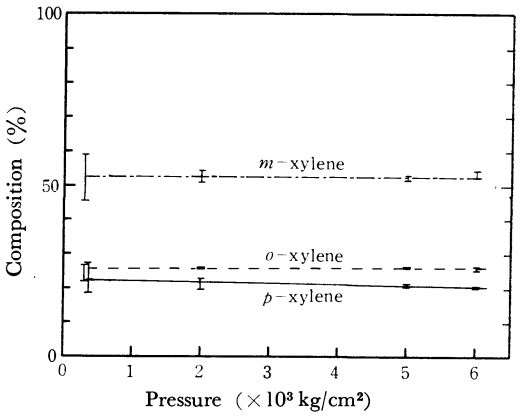

Fig. 2. Pressure dependency of the composition at equilibrium.

This conclusion is consistent with the thermodynamical consideration presented in the first paragraph.

trans-Shisool (*trans*-8-*p*-Menthen-7-ol) Isolated from the Essential Oils of *Perilla acuta* Nakai and *P. acuta* f. *viridis* Nakai*[1]

Yasuji FUJITA, Shin-ichi FUJITA and Yoshiko HAYAMA

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda-shi, Osaka

(Received March 4, 1970)

We have examined the essential oils of *Perilla acuta* (Thunb.) Nakai[1] (=*P. frutescens* Brit. var. *acuta* Kudo[2]) (Japanese name "Shiso") and *P. acuta* f. *viridis* (Makino) Nakai[1] (=*P. frutescens* var. *acuta* Kudo f. *viridis* Kudo[2]) (Japanese name "Aojiso") of the mint family, and have isolated a new monoterpene alcohol, amounting to 2.2—8.2% of the oil.

This alcohol was purified by preparative gas-liquid chromatography and was identified as *trans*-8-*p*-menthen-7-ol (I) by a comparison of its IR spectrum and of the retention time of its gas-liquid chromatography with those of the synthesized compound. The content of the *cis*-isomer (II) in the oils was very small.

We propose the name "Shisool" for these alcohols.

Ito[3] has reported the isolation of dihydroperillyl alcohol from *P. frutescens* Brit. var. *crispa* Decaisne f. *viridis* Makino (Japanese name "Chirimen-aojiso"); he showed the structure to be 8-*p*-menthen-7-ol, but did not mention anything about its configuration.

In a more recent report, Kayahara *et al.*[4] obtained these alcohols by the reduction of *l*-perillaldehyde (III) with sodium in aqueous ammonia; they proved the conformations of I and II clearly by means of NMR and IR spectra.

Many years ago, Semmler and Zaar[5] synthesized dihydroperillyl alcohol in the course of the determination of the structure of III; they showed its physical properties to be: bp 114—115°C/10 mmHg, d^{19} 0.9284, n_D 1.4819.

Experimental

Isolation. The essential oils were obtained by the steam distillation of fresh materials, while the monoterpene alcohols were separated from the bp 111—115 °C/20 mmHg fraction of the oil, by the following procedures.

The perillaldehyde of this fraction (90 g) was eliminated by shaking it with a saturated sodium sulfite solution; the residual oil (8.5 g) was then heated with phthalic anhydride at 80°C in a pyridine solution for one hour, and the esterified part was extracted by means of a sodium bicarbonate solution. The sodium salt of the phthalic acid ester was saponified by potassium hydroxide, and the regenerated alcohol was distilled with steam. The oil thus obtained (1.2 g) contained 85.5% of I.

The alcohol (I) was purified by preparative gas-liquid chromatography. This alcohol is a colorless oil: bp 225°C/760 mmHg (uncorrected), d_4^{30} 0.9212, n_D^{30} 1.4796, $\alpha_D \pm 0.00°$, and shows bands at 3350(s), 3080 (w), 2930(s), 2860(s), 1640(m), 1445(s), 1375(m), 1185 (w), 1090(m), 1035(s), 965(m), 885(s), and 530(w) cm^{-1} in its IR spectrum.

Synthesized I and II. These compounds were prepared by the method of Kayahara *et al.*[4] Namely, to a stirred mixture of III (0.5 g), benzene (2.5 m*l*), and 28% aqueous ammonia (2.0 m*l*), metallic sodium (0.2 g) was gradually added with cooling by ice water. The product was extracted with ether, the ether extract was washed with a dilute hydrochloric acid solution and water successively, and dried over anhydrous sodium sulfate, and the ether was distilled off. The oil thus obtained (0.3 g) consisted of 28.0% I and 57.5% II, besides other compounds.

The specific retention times of the gas-liquid chromatography relative to perillyl alcohol (PEG 6000, 175°C) are 0.70 and 0.78 for I and II respectively.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2638—2639 (1970)

Mutual and Acid Distribution in Methyl Isobutyl Ketone-Water System

Tatsuya SEKINE, Toshio FUKUSHIMA and Yuko HASEGAWA

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received March 4, 1970)

Many authors have reported on the mutual and acid distribution equilibria in extraction systems containing carbon-bonded oxygen-type solvents.[1] However, this kind of knowledge about the MIBK (methyl isobutyl ketone)-water system seems to be rather limited. In order to obtain further information on the system, the present authors have carried out the following measurements.

Experimental

Reagents. The MIBK was washed with 0.1 M perchloric acid, water, and 0.1 M sodium hydroxide respectively, and then several times with water. It was dried with anhydrous sodium sulfate and distilled. The distillate at 116°C was used for the experiments. All of the other reagents were of an analytical grade and were used without further purification.

Procedure. All of the procedures were carried out in a thermostatted room at 25°C. Stoppered glass tubes (volume, 20 ml) were used to equilibrate the two phases. Organic and aqueous solutions were placed in the tubes and agitated mechanically for one hour. They were then centrifuged at 1000 rpm for 3 min, with some portion being pipetted from each phase. The content of the material in these samples were determined as follows: the MIBK in an aqueous phase was determined by spectrophotometry at 273 mμ. The molar extinction coefficient of MIBK in water at this wavelength was 20, and the absorption obeyed Lambert-Beer's law, at least between 8.5×10^{-3} and 5.0×10^{-2} M. The concentration in the organic phase was calculated from the initial concentration and the aqueous concentration at the equilibrium. The water content was determined by Karl-Fischer titration. The acid concentrations in the organic and aqueous phases were determined by titration with standard barium hydroxide solutions.

Results

The distribution ratio of a material, M, is defined as;

$$D = [\mathrm{M}]_{\mathrm{org,total}}/[\mathrm{M}]_{\mathrm{total}}$$

The percentage concentration is given by the volume percentage. The density of water-saturated MIBK at 25°C is 0.793 g/ml; thus, the molar concentration is 7.8 M.

Mutual Distribution. The mutual solubility is 1.8×10^{-1} mol/l (18 g/l) for MIBK in water and 8.5×10^{-1} mol/l (15.3 g/l) for water in MIBK. The mutual distribution ratios of these materials have been calculated to be as is shown in Table 1.

Acid Distribution. The distribution ratios of five mineral acids are given in Fig. 1 as a function of the queous acid concentration. The results shown in Fig. 1 agree with the general tendency

1) Y. Marcus and A. S. Kertes, "Ion Exchange and Solvent Extraction of Metal Complexes," Wiley-Interscience, New York (1969), pp. 575, 617.

Table 1. Distribution of materials and effect of dilution with hexane

The figures show the distribution ratio of the materials ($D=[M]_{org}/[M]$).

Material	Organic phase		
	MIBK	50% MIBK*	Hexane
MIBK	4.3×10	3.3×10	1.0×10
Water	1.5×10^{-2}	3.1×10^{-3}	7×10^{-6}
$HClO_4$**	1.4×10^{-1}	5.2×10^{-4}	very low

* by the volume percent

** Values obtained when the aqueous concentration is 1.0 M.

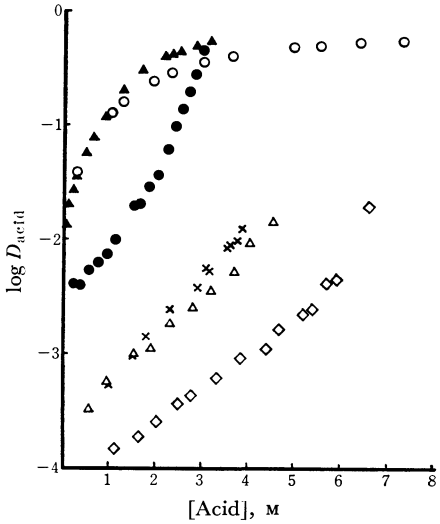

Fig. 1. Distribution of mineral acids as a function of the aqueous acid concentration. The organic phase is undiluted MIBK except the data given by ×.
▲: $HClO_4$, ○: HNO_3, ●: HI, △: HBr, ◇: HCl, ×: $HClO_4$ distributed between 50% MIBK (diluted with hexane) and water

of the distribution of mineral acids, that is, the extraction grows larger in this order; $HClO_4>HNO_3>HI>HBr>HCl$.[2)]

2) R. M. Diamond and D. G. Tuck, *Progress in Inorganic Chemistry*, **2**, 109 (1960).

It was observed that the mutual solubility of the organic and the aqueous phases increases with the increase in the acid concentration; the contact of the same volume of MIBK and the aqueous solution formed a single layer when the initial acid concentration was above 8 M (hydrochloric acid), 5 M (hydrobromic acid), or 3.5 M (perchloric acid and hydroiodic acid), but two immiscible layers were always observed in the nitric acid system, even when the initial acid concentration was 13 M.

Effect of Dilution with *n*-Hexane. The dilution of MIBK with an "inert diluent" changes the distribution of the materials. Figure 2 shows the effect of the dilution with *n*-hexane on the distribution of MIBK and water. The distribution of perchloric acid between 50% (*v*/*v*) MIBK and water is also shown in Fig. 1.

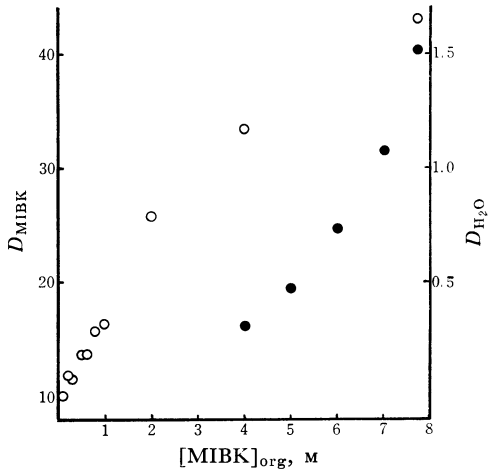

Fig. 2. Effect of the dilution with hexane on the distribution of MIBK (○) and water (●).

The effect of the dilution with *n*-hexane can be summarized as is shown in Table 1. It may be seen from Table 1 that the effect of the dilution can be quite different for different materials. MIBK has been used very often without any dilution. However, the results seem to indicate that dilution with an inert solvent could improve the efficiency of the separation of materials or that of back-extraction in MIBK-water systems.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2640—2641 (1970)

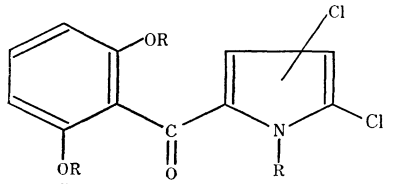
The Crystal and Molecular Structure of *O,O',N*-Trimethylpyoluteorin, $C_{14}H_{13}O_3NCl_2$

Yoshihisa UTSUMI,*1 Akio FURUSAKI and Yujiro Tomiie*2

Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received March 26, 1970)

Pyoluteorin, $C_{11}H_7O_3NCl_2$, mp 174—175°C (dec.), is an antibiotic produced by *Pseudomonas aeruginosa* it has been found to be efficacious against cholera germs, *etc.* For this antibiotic, the following structural formula (I) has been proposed on the basis of chemical evidence:[1]



I: R=H II: R=CH_3

However, the position of one of the chlorine atoms in the pyrrole ring has remained uncertain. Using single crystals of *O,O',N*-trimethylpyoluteorin (II) kindly supplied by Dr. Masao Nishikawa, Chemical Research Laboratories, Research and Development Division, Takeda Chemical Industries, Ltd., an X-ray-crystal structural analysis of the derivative has been undertaken in order to determine the chlorine position and in order to obtain more detailed information about the stereostructure of the molecule.

O,O',N-Trimethylpyoluteorin, $C_{14}H_{13}O_3NCl_2$, crystallizes in yellow needles and gives the crystal data shown in Table 1. The reflection intensities were visually measured from equi-inclination integrating Weissenberg photographs taken with Cu$K\alpha$ radiation for 0—5 layers around the *b* axis and for 0—10 layers around the *a* axis. To these intensities, the usual Lorentz and polarization corrections were applied. Thus, the structure factors of 1363 independent reflections were obtained.

TABLE 1. CRYSTAL DATA

Monoclinic	
	$a = 14.51 \pm 0.04$ Å
	$b = 7.71 \pm 0.03$
	$c = 14.60 \pm 0.04$
	$\beta = 116.5 \pm 0.3°$
Space group	$P2_1/a$
Z	4

The positions of the two independent chlorine atoms could be easily found from a three-dimensional Patterson function. These coordinates were refined by the diagonal-matrix least-squares method. As a result of five cycles of this refinement, the *R* factor dropped only a little from the initial value, 0.50, while the temperature factor converged into a value of about 6 Å^2 for either one of the chlorine atoms. The approximate coordinates of all the light atoms were obtained from the first Fourier map, calculated with the sign based on only the chlorine atoms. The coordinates of the two chlorine and eighteen light atoms thus obtained were refined at first by the diagonal-matrix least-squares method with individual isotropic temperature factors, and then by the block-diagonal-matrix least-squares method with anisotropic temperature factors. The final *R* factor thus obtained was 0.137. The atomic parameters obtained are given in Table 2, while the molecular framework is further shown in Fig. 1.

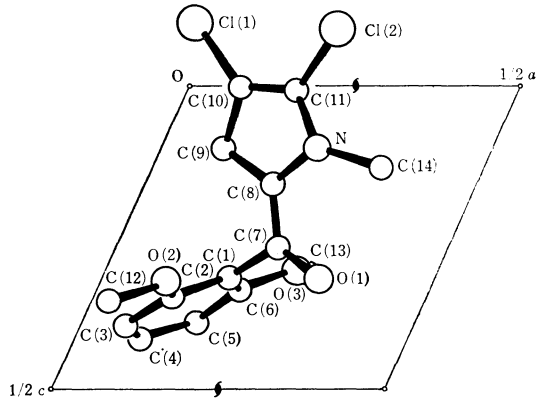


Fig. 1. The molecular framework viewed along the *b* axis.

As is shown in Fig. 2, the bond lengths and angles calculated with the final coordinates are all reasonable considering the mean standard deviations of the coordinates (0.007 Å for Cl, 0.014 Å for O, 0.016 Å for N, and 0.021 Å for C); for example, as to the benzene ring, they are 1.36—1.47 Å and 113—125° respectively. The molecular structure

The thermal parameters are given in values multiplied by 10^5.

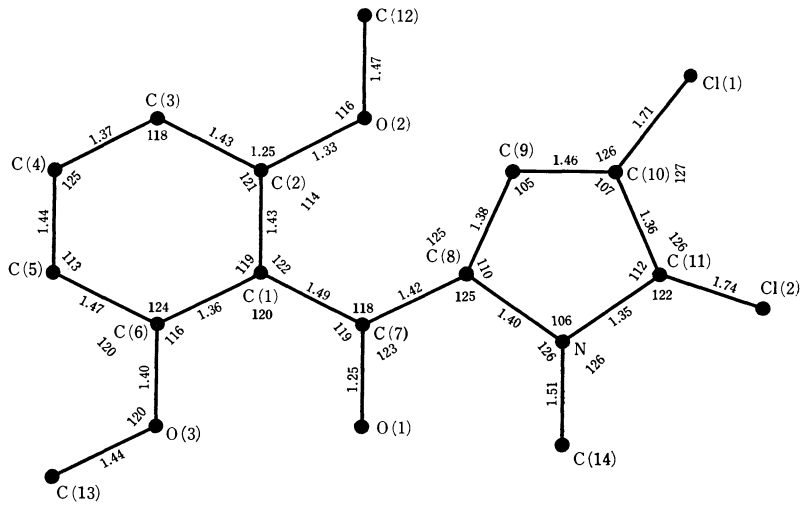

Fig. 2. The bond lengths (Å) and angles (°).

found in the present experiment corresponds exactly to Formula II, as may be seen from Fig. 1. One of the two chlorine atoms is situated at the 5′-position of the pyrrole ring, as was expected on the basis of chemical evidence, while the other is located at the 4′-position, the distance between them being about 3.41 Å. The pyrrole ring plane makes a dihedral angle of only about 7° with the carbonyl plane, while the benzene plane makes an angle of no less than 83° with it. This shows that the carbonyl group is considerably conjugated with the pyrrole ring, but is little conjugated with the benzene ring. Further, it is noteworthy that the *N*-methyl carbon atom, C(14), deviates to a considerable extent from the pyrrole ring plane, the distance being about 0.16 Å. Though one of the two methoxyl carbon atoms, C(12), lies almost on the benzene plane, the other, C(13), deviates from the plane by about 0.24 Å.

In conclusion, the authors would like to express their thanks to Professor Isamu Nitta of this university for his valuable discussions. The authors also wish to express their thanks to Dr. Masao Nishikawa, Chemical Research Laboratories, Research and Development Division, Takeda Chemical Industries, Ltd., for providing them with the sample.

X-Ray Diffraction Studies on *cis*- and *trans*-[Co $en_2(CH_3COO)_2$]ClO_4

Luigi CAMPANELLA

Institute of Analytical Chemistry, University of Rome, Italian National Researches Council, Rome, Italy

(Received February 23, 1970)

In a previous paper[1] X-ray crystallographic data of *cis*- and *trans*-[Co en_2Cl_2]ClO_4 and of *cis*- and *trans*-[Co $en_2(C_6H_{11}COO)_2$]ClO_4 were reported. Extending now the studies to another couple of *cis*- and *trans*-isomers of Co(III) complexes having formula $[Co\ en_2X_2]^+$, *cis*- and *trans*- [Co $en_2(CH_3COO)_2$]ClO_4 are examined and characterized by the X-ray powder patterns by means of a Debye-Scherrer camera of diameter 114.8 mm with monochromatized Cu$K\alpha_1$ and Fe$K\alpha_1$ radiations. The salts are prepared as described by Linhard and

Stirn.[2]

Ito's method[3] is successful in indexing powder patterns. The use of an IBM computer is helpful in applying this method.

The experimental data for d_{hkl}, I/I_0 and Q of the two compounds are listed in Tables 1 and 2 and compared with the Q values computed on the basis of the indexing. Studies so far perfomed lead to the following conclusions:

a) *cis*-$[Co\,en_2(CH_3COO)_2]ClO_4$: The unit cell is tetragonal with dimensions $a=b=(18.898\pm0.007)$ Å, $c=(14.908\pm0.005)$Å. The measured density is 1.48 g cm^{-3}; the cell content is 12 formula units, giving a calculated density of 1.48 g cm^{-3}.

b) *trans*-$[Co\,en_2(CH_3COO)_2]ClO_4$: The unit cell is tetragonal with dimensions $a=b=(17.953\pm0.007)$ Å, $c=(24.213\pm0.008)$Å. The measured density is 1.34 g cm^{-3}; the cell content is 16 formula units, giving a calculated density of 1.35 g cm^{-3}.

The Mechanism of the Oxidation of Acetaldehyde by Chromic Acid

C. GOSWAMI and K. K. BANERJI

Department of Chemistry, University of Jodhpur, Jodhpur, India

(Received March 16, 1970)

Aliphatic ketones are oxidized by chromic acid *via* their enol form.[1] There is a possibility that oxidation of aldehydes may also involve the enol intermediate. Chromic acid oxidation of aromatic aldehydes[2-4] and formaldehyde[5] has been studied in detail, but these aldehydes cannot enolize. Some preliminary studies have been carried out on the oxidation of acetaldehyde by Roček[6] and by Chat terji and Antony.[7] In the present investigation the role of enolization in the oxidation process has been studied.

Results

Product Study. Oxidation of acetaldehyde by aqueous chromic acid yielded acetic acid. The completely reduced reaction mixture gives a blue-brown colour with lanthanum nitrate and a drop of iodine solution in the presence of ammonia.[8]

Rate Laws. The rate of disappearance of Cr(VI) followed first order law, but the values of rate constants decreased with increase in the concentration of chromium(VI). The results show that the reaction is strictly of first order with respect to acid chromate ion, $HCrO_4^-$ (Table 1). The concentrations of $HCrO_4^-$ were calculated assuming a value 2.3×10^{-2} for association constant for dichromate formation ($K=[HCrO_4^-]^2/[Cr_2O_7^{2-}]$) at 25°C.[9]

The reaction is also of first order with respect to acetaldehyde (Table 2).

Under the conditions of constant ionic strength the rate is proportional to the square of hydrogen ion concentration (Table 3) and there is also a marked positive ionic salt effect.

Effect of Solvent Composition. Increase in proportion of acetic acid in the solvent mixture

Table 2. Substrate concentration dependence of the reaction

[Cr(VI)]: 1×10^{-3}M, [H$^+$]: 0.5M, Temp. 25°C

10^2[CH_3CHO] (mol/l)	1.00	2.00	3.00	4.00	5.00
10^2k_1 (min^{-1})	1.73	3.50	5.20	6.91	8.70
k_1/[CH_3CHO]	1.73	1.75	1.73	1.73	1.76

Table 3. Acidity dependence of the reaction velocity

[CH_3CHO]: 1×10^{-2}M, [Cr(VI)]: 1×10^{-3}M
Temp. −25°C, Ionic strength (μ)=2M

[H$^+$] (mol/l)	0.25	0.50	0.75	1.00	1.25	1.50
10^2k_1 (min^{-1})	0.691	2.53	6.15	10.1	16.1	23.0
k_1/[H$^+$]^2	11.0	11.2	10.9	10.1	10.3	10.2

increases the rate of oxidation (Table 4), probably because of the lowering of dielectric constant of the medium,[10] which favours reactions involving protonation. In acetic acid chromic acid exists as acetochromic acid, $CH_3COOCrO_3H$, which is assumed to be a stronger acid and a very powerful oxidizing agent[4,11] and hence the rate increases.

Table 4. Solvent composition dependence of the reaction rate

[CH_3CHO]: 1×10^{-2}M, [Cr(VI)]: 1×10^{-3}M
[H$^+$]: 0.5M, Temp. 25°C

Precentage acetic acid	20	40	50	60	70	80
10^2 k_1 min^{-1}	1.73	2.30	3.45	5.07	10.4	18.4

Effect of Manganese(II). Addition of manganese(II) did not affect the rate of oxidation. This prevents any conclusion as to whether chromium(IV) or chromium(V) is formed in the rate-determining step. A similar effect was noted in the oxidation of cyclohexanone[1] and has been attributed to the rapid oxidation of the organic substrate by Mn(III), formed by the reaction.

$$Cr(IV) + Mn(II) \longrightarrow Cr(III) + Mn(III) \quad (1)$$

Effect of Temperature. Data on the effect of temperature on the reaction rate are summarized in Table 5. A plot of $\log k_1$ against reciprocal of temperature gave a straight line. The specific rate constant, k, is defined by

$$k = \frac{k_1\ (\text{min}^{-1})}{60\cdot[CH_3CHO][H^+]^2}$$

The activation parameters were evaluated in the usual manner.

Table 5. Effect of temperature on the reaction rate

[CH_3CHO]: 1×10^{-2}M, [Cr(VI)]: 1×10^{-3}M
[H$^+$]: 1.0M

Temp. °K	10^2 k_1 min^{-1}	$k\times10^2$ $l^3\cdot$mol$^{-3}\cdot$ sec^{-1}	$\Delta H^{\ddagger}$ kcal/mol	$\Delta S^{\ddagger}$ e.u.
293	5.53	9.21	9.03	−33.2
298	7.14	11.90	$\Delta F^{\ddagger}$	
303	9.21	15.35	298°	
308	11.7	19.50	18.9 kcal/mol	

Rates of Enolization. The rates of enolization were measured by bromination method.

The rate of bromination of acetaldehyde is of first order with respect to acetaldehyde and hydrogen ions but of zero-order for bromine. Table 6 records the rate constants of bromination (k_2) at different temperatures and activation parameters.

Table 6. Effect of temperature on the bromination rate

Temp. °K	10^4 k_2 $l\cdot$mol$^{-1}\cdot$sec^{-1}	$\Delta H^{\ddagger}$ kcal/mol	$\Delta F^{\ddagger}$ 298° kcal/mol
293	1.08	15.3	
298	1.63	$\Delta S^{\ddagger}$	22.8
303	2.50	−25.3 e.u.	
308	3.83		

Discussion

A comparison of Tables 5 and 6 shows that oxidation is much faster than enolization. Moreover, the activation energy is much lower in the chromic acid oxidation than in enolization. On these grounds we are forced to conclude that enolization cannot be an essential step in the oxidation reaction.

The results obtained here are consistent with the following rate equation, which is very similar to that previously derived for the oxidation of isopropyl alcohol.[9]

$$-d[Cr(VI)]/dt = k[CH_3CHO][HCrO_4^-][H^+]^2$$

It has been proposed that aliphatic aldehydes are oxidized *via* their hydrates.[5,6] The kinetic solvent isotope effect demonstrated by acetaldehyde[12] is of the same order as that by formaldehyde[5] and hence either the acetaldehyde hydrate or its simple derivative is the most likely intermediate. Because the aldehyde hydrates so closely resemble alcohols both is structure as well as in practically all aspects of oxidation, it is reasonable

10) M. Cohen and F. H. Westheimer, *J. Amer. Chem. Soc.*, **74**, 4387 (1952).
11) K. B. Wiberg and H. Schäfer, *ibid.*, **91**, 927 (1969).

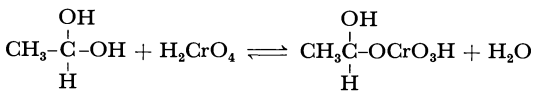
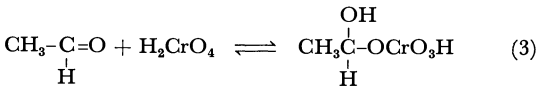
to expect a similarity in the mode of their oxidation as well.

Very recently Wiberg and Schäfer have established that oxidation of alcohols proceeds *via* chromate esters.[13] Analogously the oxidation of acetaldehyde can best be interpreted by assuming the reversible formation of a similar intermediate, which will then decompose in the rate-determining step. As long as the chromic acid ester is in rapid equilibrium with acetaldehyde and its hydrate, it is immaterial whether it is formed by the esterification to the hydrate or by a carbonyl addition reaction to the free aldehyde.

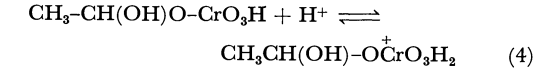


(2)



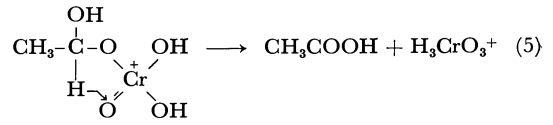
(3)

However, the second-order dependence on $[H^+]$ and magnitude of kinetic solvent isotope effect[12] ($k_{D_2O}/k_{H_2O}=6.29$), show that the rate-determining step must involve a protonated reaction complex. Thus formation of ester is followed by protonation of the chromic acid moiety of the ester.



(4)

The activation parameters suggest that C–H bond is ruptured in the rate-determining step[14,15] and this reasoning is made clear by the fact that both formaldehyde[5] and acetaldehyde[16] show a primary isotope effect. It is, however, far less clear whether hydrogen leaves as a proton, an atom or an anion. Westheimer[4] prefered the abstraction of proton in cyclic process by one of the chromate oxygen atoms. Roček,[6,17] however argued in favour of a hydride transfer. There are no data which permit one to distinguish conclusively between these two mechanisms. Recently, however, it has been shown that several two-electron oxidants oxidize alcohols by a hydride transfer mechanism[18,19] and it is likely that oxidation of acetaldehyde by chromic acid involves a hydride transfer as follows.



(5)

Experimental

Materials. Perchloric acid (60%, E. Merck) was used as a source of hydrogen ions; sodium perchlorate (Riedel) was used to adjust the ionic strength. Acetaldehyde (B.D.H.) was purified by the usual method. Acetic acid (99.5%, B.D.H.) was distilled over chromic acid before use. All other chemicals used were of "AR" grade.

Kinetic Measurements. The reactions were carried out at constant temperature (±0.05°C). Unless otherwise stated, the solvent was 20% acetic acid. The concentration of acetaldehyde was always kept in excess. Reactions were followed iodometrically.

Studies in Haloketones. I. Synthesis and Reactions of α-Bromo-β-chlorovinyl Aryl Ketones

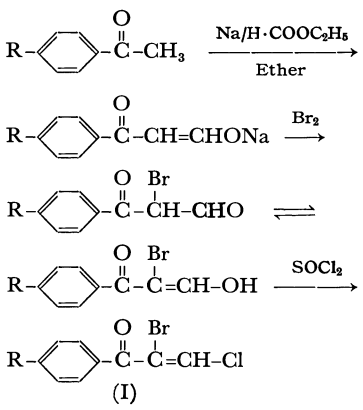
T. C. SHARMA, H. PATEL and M. M. BOKADIA

School of Studies in Chemistry, Vikram University, Ujjain, India

(Received May 20, 1969)

The reactivity of halogen atom in haloketones varies considerably depending upon the nature of the organic moiety and the position of the halogen atom with respect to the carbonyl group. The halogen atom of α-haloketones is activitated for S_N2 displacement reactions and is attributed with positive character. When these compounds are warmed with acidified potassium iodide solution, iodine is liberated.[1,2] Usually a vinylic halogen atom is very inert and cannot be replaced by direct substitution reactions. However, a keto group at the β-position of the vinyl moiety makes this halogen atom very susceptible to displacement reactions. For example, β-chlorovinyl aryl ketones react with ammonia[3,4] and amines[5,6] to eliminate hydrogen chloride and form corresponding amino compounds.

In the present work α-bromo-β-chlorovinyl ketones (I) have been synthesised by the following general route. These ketones are quite stable at room temperature.

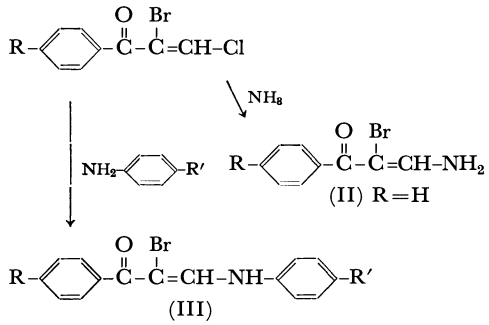


(I)

(a) R=H (b) R=CH_3 (c) R=Cl
(d) R=Br

The reactions of these compounds with ammonia and anilines have also been studied. It has been observed that it is only β-chlorine atom that undergoes substitution, whereas α-bromine atom remains intact in all the reactions.[7]

(The structures of the reaction products are as follows.)



(II) R=H

(III)

(III) (a) R=R'=H (b) R=H, R'=Cl
(c) R=H, R'=Br (d) R=CH_3, R'=H
(e) R=CH_3, R'=Cl (f) R=CH_3, R'=Br

Experimental

Synthesis of α-Bromo-β-chlorovinly *p*-Chlorophenyl Ketone (Ic). A mixture of equimolecular quantities of α-bromo-β-hydroxy vinyl *p*-chlorophenyl ketone (10 g), thionyl chloride (4.5 g) and dry benzene (40 m*l*) was refluxed on a water bath for eight hours. Benzene was removed by distillation and the residue, when distilled under reduced pressure (140°C/1 mmHg), yielded yellow coloured oil (4 g). IR spectrum (liquid film of the compound) showed a carbonyl frequency at 1667 cm^{-1}.

Found: C, 38.8; H, 1.9; (Cl+Br), 53.3%. Calcd for $C_9H_5OCl_2Br$: C, 38.6; H, 1.8; (Cl+Br), 53.9%.

The same procedure was adopted for the synthesis of other ketones. Data for these products are given in Table 1.

Action of Ammonia on α-Bromo-β-chlorovinyl Phenyl Ketone (II). α-Bromo-β-chlorovinyl phenyl ketone (1 g) was treated with aqueous ammonia (10 m*l*) (in the presence of air) at room temperature. The reaction mixture was kept for three days for the completion of the reaction when a brown coloured solid separated. It was filtered, washed with water and crystallised

from benzene to furnish light yellow needles (0.4 g, mp 136°C). The compound was characterised as α-bromo-β-aminovinyl phenyl ketone by elemental analysis and IR spectrum. Strong absorption bands in the spectrum are 3250, 1600, 1310, 1050 and 835 cm^{-1}. The lowering of keto frequency (1600 cm^{-1}) may be due to H-bonding in the molecule.

Found: C, 47.6; H, 3.6; N, 6.1; Br, 35.3%. Calcd for C_9H_8OBrN: C, 47.8; H, 3.5; N, 6.2; Br, 35.4%.

Similar treatment of the ketone with alcoholic ammonia also yielded the same product.

Action of Aniline on α-Bromo-β-chlorovinyl Phenyl Ketones (IIIa). A mixture of α-bromo-β-chlorovinyl phenyl ketone (2 g), sodium carbonate (2 g), aniline (1.6 g) and alcohol (10 m*l*) was shaken for eight hours and then refluxed for 15 min. It was cooled to room temperature and poured into cold water (150 m*l*). A yellow coloured solid separated. It was filtered, washed with water and crystallised from alcohol to provide yellow prisms (1 g, mp 127°C). The product was characterized as α-bromo-β-anilinovinyl phenyl ketone by chemical analysis and IR spectrum.

The presence of NH group is indicated by infrared absorption at 3100 cm^{-1}. A weak absorption peak at 1610 cm^{-1} and a strong broad band at 1570 cm^{-1} indicate carbonyl frequencies. This considerable shift in NH and carbonyl frequencies can be ascribed to hydrogen bonding in the molecule.

Found: C, 59.7; H, 4.2; N, 4.3; Br, 26.6%. Calcd for $C_{15}H_{12}OBrN$: C, 59.6; H, 4.0; N, 4.0; Br, 26.5%.

Data of other products of this series prepared by the same method are given in Table 2.

The authors are thankful to Professor W. V. Bhagwat for providing laboratory facilities and to the authorities of chemistry department I. I. T. Kanpur for providing analytical and spectral data.

Tautomerism of Phenols—A Theoretical Study

Z. MAJERSKI[1] and N. TRINAJSTIĆ[2]

Institute "Rudjer Bošković," Zagreb, Croatia, Yugoslavia

(Received February 27, 1970)

Keto-enol tautomerism in the polyacene series presents an interesting theroretical problem, since in the higher polyacene phenols the keto form is more stable, in contrast to the lower polyacene phenols where the enol form is more stable.[3] Although this displacement of equilibrium in the keto-enol tautomerism of phenols has been known for some time,[3] there are only a few theoretical studies, within the framework of the HMO theory, reported for these systems.[4]

Here we wish to report calculations of keto-enol tautomerism of the phenols based on Dewar's variant of the SCF π-MO method, which has been described in detail elsewhere.[5]

Theoretical Method

The location of a chemical equilibrium is determined by the variation of free energy (ΔF). Since free energy depends upon enthalpy and entropy, the equilibrium constant (K) can be expressed as a function of the variations of enthalpy (ΔH) and entropy (ΔS) of the compounds in the equilibrium:

$$-RT\ln K = \Delta F = \Delta H - T\Delta S \qquad (1)$$

The entropy variation for a given reaction occurring in a series of related compounds under the same experimental conditions remains essentially constant and thus can be neglected.[6] Making the usual assumption[6,7] that the difference in the keto and enol forms is due to changes in the heats of atomization rather than the enthalpy of reaction, the equilibrium can be expressed as follows:

$$-RT\ln K = \Delta H_a^A - \Delta H_b^B \qquad (2)$$

where ΔH_a^A and ΔH_a^B are the heats of atomization of the keto and enol form, respectively. Therefore, the position of equilibrium is determined essentially by the difference in the heats of atomization between the two tautomeric forms of phenols. The heats of stomization for the tautomeric forms in question can be calculated by Dewar's SCF π-MO (variable β)[4b] procedure.[4]

Results and Discussion

The systems studied are presented below.

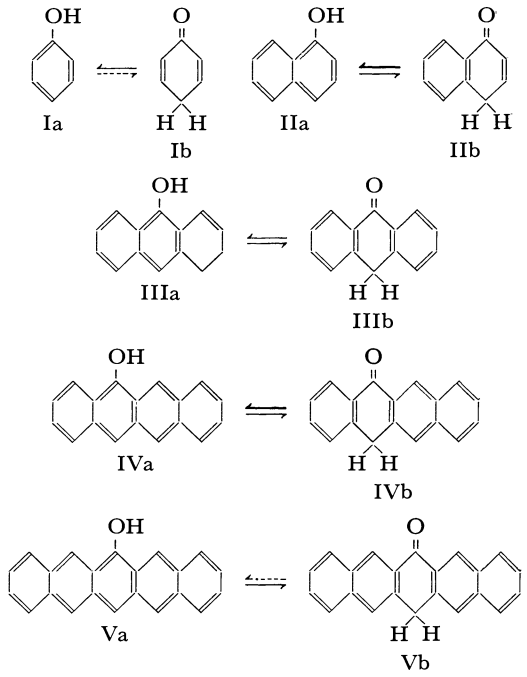

Table 1 lists the heats of atomization of tautomeric forms of phenols (A being phenol forms, B being

keto forms) and the differences in the heats of atomization between these forms. The obtained results appear to be in a good agreement with present experimental evidence.

The experimental evidence can be summarized as follows; there is no indication in literature that phenol (Ia) exists to any appreciable extent in the keto form (Ib), the equilibrium being heavily located on the phenol form. However, the keto form (Ib) is apparently quite stable when substituents are attached to the ring;[8] the substituents may stabilize this form considerably. Naphthol (IIa) shows some reactions which point to existence of keto form (IIb), but here again as in the case of phenol only the substituted keto form (IIb) is stable enough to be isolated.[9] In anthracene series the keto form (IIIb) is in a slightly more stable form in the equilibrium. The equilibrium anthranol (IIIa) $\rightleftharpoons$ anthranone (IIIb) has been fairly thoroughly investigated recently by Löber[10] and Baba and Takemura[11] using spectrometric methods (absorption and fluorescence spectrometry). The equilibrium was found[11] to be solvent dependent and the enthalpy change indicated a slight displacement of the equilibrium to the keto form (IIIb) in the less polar solvents ($_{293}\Delta H$=2.6 kcal/mol in benzene; $_{293}\Delta H$= 3.3 kcal/mol in isooctane).[11] The anthranol/anthranone equilibrium can be pushed on the anthranol side by adding basic substances.[13] This has been used for the preparation of anthranol from anthranone.[12,13] However, even pure anthranol is not stable and after some time a chemical equilibrium sets up between these two tautomers.[14] Tetracenone is a stable species and well known.[15] It can be transformed into hydroxytetracene (IVa) only in an alcoholic alkali solution.[15] There is no evidence, so far, that pentacenone (Vb) can be enolized to hydroxypentacene (Va),[3,16] although the pure keto form (Vb) has been isolated and studied.[16,17]

SHORT COMMUNICATIONS

The Photochemical Reactions of Several Mesoionic Compounds

Akiko CHINONE, Yoshiharu HUSEYA and Masaki OHTA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 30, 1970)

Since interest in the photochemistry of mesoionic compounds is increasing,[1-3] we wish now to report a part of the results of our studies of this subject, which are going on in our laboratory.

The irradiation of a dioxan solution of 3,4-diphenylsydnone (Ia) in a Pyrex vessel under nitrogen and with a high-pressure mercury lamp (100 W, 30 hr) gave white plates (yield, 15%; mp 119—120°C [UV λ_{max} (dioxan) 298 mμ (ε 7660); IR ν(KBr) 3050, 1595, 1493, 1455, 1439, 775, 756, 700, 693 cm^{-1}; NMR τ_{Me_4Si} ($CDCl_3$) 1.75—1.95(2H), 2.30—2.50(3H), 2.50—2.70 (5H); Mass spectra M$^+$, *m/e* 194 (11%)]) whose spectral characteristics are consistent with its formulation as 1,3-diphenyldiazirine (IIa). This reaction seems to proceed by a mechanism analogous to that of the photolysis of 3-phenylsydnone.[1] The irradiation of Ib and Ic gave seven and fourteen products respectively; those products were only detected with vpc and were not isolated.

The irradiation of an aqueous solution of IIIa and IIIb for 20—40 hr gave IVa (yield, 9%; white needles with a mp of 79—81°C [UV λ_{max} (EtOH) 253 and 357 mμ (ε 10500 and 1300); IR ν(KBr) 3440, 3300(w), 3210, 1695, 1660, 1240 cm^{-1}; NMR τ_{Me_4Si} ($CDCl_3$) 1.6—1.8(2H), 2.3—2.6(3H), 2.8—3.2(1H), 3.7—4.1(1H)]) and IVb (yield, 8%; white prisms with a mp of 120—123°C [IR ν(KBr) 3400, 3280(w), 3200, 1730, 1680, 1360 cm^{-1}]) respectively.

The irradiation of an aqueous solution of Va for 6 hr gave VIa (($C_{15}H_{11}N_2S)_2$, yield, 23%; yellow needles with a mp of 230—231°C [UV λ_{max} (EtOH) 265, 325 and 385 mμ (ε 23400, 18500 and 15300); IR ν(KBr) 3300, 3250, 2180, 1580, 1545 cm^{-1}; mol wt (in DMF) 444.7]), VII (yield, 70%; white needles with a mp of 165—166°C [UV λ_{max} (EtOH) 235 and 333 mμ (ε 12000 and 24600); IR ν(KBr) 3480, 3310, 3190, 1680, 1600 cm^{-1}; Mass spectra M$^+$, *m/e* 238 (63%)]), and H_2S, which was removed in a stream of N_2 and which was characterised by reaction with lead(II) acetate. The irradiation of an aqueous solution of Vb gave VIb (yield, 12%; mp 215—216.5°C [UV λ_{max} (EtOH) 275, 295 and 355 mμ (ε 15700, 12200 and 17800); IR ν(KBr) 3220, 2180, 1560, 1540 cm^{-1}]) and H_2S. These results show that the photolyses of thiazone imine derivatives most likely proceed *via* bicyclic intermediates (VIII). However, the irradiation of Vc in an aqueous solution gave no detectable products and resulted in the recovery of the starting material, while the irradiation of Vd gave only a resinous oil. No change was observed by the irradiation of Ve in an aqueous solution.

Synthesis of Succinonitrile by the Catalytic Reaction of Acrylonitrile in a Gaseous Phase

Michiaki OSHIO and Tadashi HARA

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto

(Received April 16, 1970)

During the course of an investigation of synthesizing adiponitrile by hydrodimerization of acrylonitrile in a gaseous phase, it has been found that succinonitrile is selectively produced from acrylonitrile by the catalytic reaction on a catalyst consisting of alkali and alkaline earth metal oxides. The conventional methods for the preparation of succinonitrile are based on, 1) the reaction between acrylonitrile and hydrogen cyanide in a liquid phase,[1] 2) the reaction between ethylene and hydrogen cyanide in a gaseous phase,[2] and 3) the irradiation of γ-rays onto acetonitrile molecule,[3] *etc.* The present work has an advantage in that succinonitrile can be prepared from acrylonitrile alone.

Acrylonitrile was made to react in a tubular flow reactor with fixed bed under the following conditions; fused silica tube 750×12 mm diam., catalyst 15 g (magnesium oxide: sodium oxide= 2 : 1 in moles, calcined at 500°C for 6 hr), reaction temp. 250—500°C, pressure 1 atm, W/F= 30—100 g-cat·hr/mol-feed, and hydrogen or nitrogen as a carrier gas. Gaseous components were trapped by ice-water, and analyzed by a gas chromatograph.

The liquid trapped weighed 90% of the acrylonitrile fed, and the succinonitrile content in the product was around 90 mol%. The results obtained are shown in Table 1 and Fig. 1. No acetylene was detected in the exhaust gas for 2 hr after initiation of the reaction, while it was confirmed in the sample prepared after 6 hr. This may be understood by taking the acetylide formation into consideration, that is, the reaction between alkali metal and acetylene. Hydrogen cyanide was more or less detected irrespective of the reaction time. It was further confirmed that acrylonitrile is not thermally decomposed if the reaction temperature is below 500°C and the catalyst is absent.

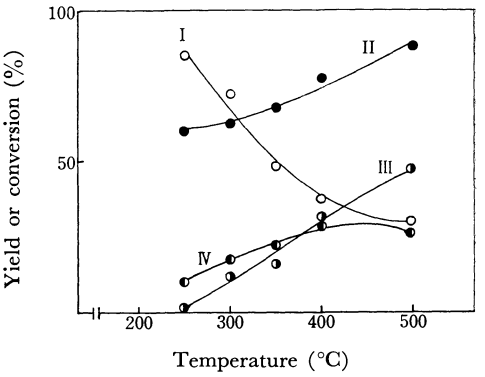

Fig. 1. Relationship between the yield or conversion and reaction temperature.
I: Succinonitrile, II: Conversion, III: Propionitrile, IV: Acetonitrile

From the results the reaction is supposed to proceed in accordance with the following in which acrylonitrile is decomposed into acetylene and hydrogen cyanide, followed by the Michael-type addition.

$$CH_2{=}CHCN \rightarrow CH{\equiv}CH + HCN \quad (1)$$

$$HCN + CH_2{=}CHCN \xrightarrow{\text{base catalyst}} NCCH_2CH_2CN \quad (2)$$

As seen in Fig.1, the yield of succinonitrile decreased with the rise of temperature while the yields of propionitrile and acetonitrile increased. In general, succinonitrile is synthesized favorably at 250°C or below.

A New Dynamic Approach for Elucidating the Mechanism of Catalytic Reactions. The Mechanism of the Decomposition Reaction of Methyl Alcohol on ZnO

Akifumi UENO, Takaharu ONISHI and Kenzi TAMARU

Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 2, 1970)

Many reports[1] have been published on the infrared spectra of the species on the catalyst surface, but most of them have dealt only with the kind or with the structure of the species when no catalytic reaction takes place. The importance of observing the amounts and the dynamic behavior of the chemisorbed species on the catalyst surface in the course of the reaction in order to elucidate the mechanism of the catalytic reaction was previously emphasized by one of the present authors.[2] Accordingly, the mechanism of the H_2-D_2 exchange reaction,[3] the decomposition of formic acid,[4] and the water-gas shift reactions[5] on zinc oxide have been elucidated by means of a new dynamic approach, measuring the infrared spectra of the surface species.

The mechanism of the decomposition reaction of methyl alcohol on ZnO was studied by means of a new dynamic treatment. When CD_3OD was introduced to ZnO at 200°C, the CD_3O(a), OD (a), and DCOO(a) chemisorbed were observed by means of infrared spectroscopy, but CD_3OD(a) was not. The behavior of these surface species as well as that of the ambient gas and the overall reaction rates were simultaneously examined under various reaction conditions, including non-stationary conditions.

D_2, CO_2 and CO were formed by the decomposition of CD_3OD on ZnO at 200°C, but when CD_3OD was trapped out of the system by a dry ice-methanol mixture or in the absence of an ambient methanol vapour, the evolution of D_2 and CO_2 stopped correspondingly, though that of CO from the surface species continued during the trapping. The amount of CD_3O(a) on the catalyst decreased, but that of DCOO(a) increased, during the trapping. The decrease in the CD_3O(a) was nearly equal to the total increase in DCOO(a) and CO(g). Most of the CD_3O(a) on the surface disappeared during the trapping at 240°C, though DCOO(a) still remained on the catalyst, whereas the evolution of CO(g) was uninfluenced and continued at a rate comparable to the overall rate. When the CD_3OD collected in the trap was released into the gas phase, the amounts of D_2 and CO_2 were increased rapidly, but that of CO continued to increase without any change. It was, consequently, concluded that the CO was produced mainly from the decomposition of DCOO(a) on ZnO, and that the D_2 and CO_2 resulted from the interaction between the CD_3OD in the ambient gas and the surface DCOO(a). The results are shown in Fig. 1.

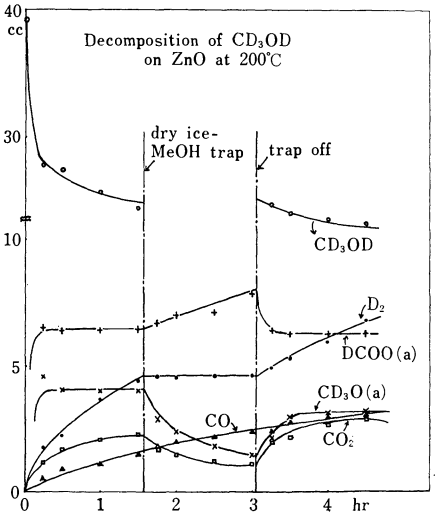

Fig. 1.

When CH_3OD was introduced onto the catalyst, the surface of which had been covered by OD(a), the hydrogen produced contained overwhelmingly more deuterium than protium. It was, accordingly, demonstrated that CH_3OD reacted not only with the surface formate, but also with the hydroxide on the surface of ZnO. It was, consequently, concluded that the mechanism of the decomposition of methyl alcohol on ZnO is shown as follows:

Single, Double and Triple Insertion of Cyclohexyl Isocyanide into Methyl-Palladium Sigma Bond

Yasuhiro YAMAMOTO and Hiroshi YAMAZAKI

The Institute of Physical and Chemical Research, Yamatomachi, Saitama

(Received May 20, 1970)

Recently Otsuka *et al.* reported that the reaction of tetrakis(*tert*-butyl isocyanide)nickel with methyl iodide or benzoyl chloride undergoes multiple successive insertions of isocyanide molecules.[1] They pointed out that the insertion reaction suggested a mechanism for the polymerization of isocyanides. During our studies on the interaction of isocyanide with alkyl transition metal complexes,[2] we found that a similar successive insertion occurred in the reaction of cyclohexyl isocyanide(I) with *trans*-iodo-bis(tertiary phosphine)-methylpalladium. We wish to report on this subject.

Addition of I to *trans*-iodo-bis(methyldiphenylphosphine)methylpalladium(IIa) in benzene at 0°C gave yellow orange crystals IIIa[3] (49%, mp 134—137°C dec.). The dimeric structure was confirmed by molecular weight determination, IR and NMR spectra. Treatment of IIIa with I in the presence of methyldiphenylphosphine produced yellow complex IVa[3] (57%, mp 126—130°C dec.). The IR spectrum showed two carbon - nitrogen double bonds at 1630 and 1585 cm^{-1}. The NMR spectrum*[1] showed a singlet peak at 8.47($C-CH_3$), three broad signals at 8.72, 8.43 and 2.35 (two cyclohexyl and four phenyl groups) and a triplet signal at 8.07 τ($P-CH_3$), indicating the *trans*-configuration for IVa. The complex IVa was also obtained from the reaction of IIa with I in 1 : 2 molar ratio.

When IVa was treated with I in benzene, stepwise-inserted reaction took place, affording a trisimino complex Va[3] (67%, mp 138—141°C dec.). Va was identified to be the five-membered chelate structure coordinated to palladium through the lone pair electrons of terminal imino nitrogen atom, based on its monomeric nature, electronic configuration of palladium atom and spectroscopic studies.[4] The IR spectrum showed carbon-nitrogen double bonds at 1636 and 1598 cm^{-1}. The NMR spectrum showed a sharp singlet peak at 7.68($C-CH_3$), a doublet resonance at 7.80($P-CH_3$, $J_{P,H}=9.0$Hz) and two broad signals at 8.50 and 2.60 τ(cyclohexyl and phenyl groups), in addition to two broad signals due to α-protons of two internal cyclohexyl groups (7.30 τ) and that of a terminal one(6.50 τ). Complex Va was also obtained from the reaction of IIa with I in 1 : 3 molar ratio. A series of reactions indicates the stepwise-inserted reaction of isocyanides.

The reaction of *trans*-iodo-bis(triphenylphosphine)methylpalladium (IIb) with I in 1 : 1 molar ratio gave an air-sensitive yellow complex VIb[3] (53%, mp 98—102°C dec.). Treatment of IIb with I in 1 : 2 molar ratio produced yellow crystals IVb[3] (51%, mp 117—119°C dec.). The IR and NMR spectra were in complete agreement with the suggested structure.

No reaction of I with VIb was observed, indicating that the reaction did not proceed stepwise as IIb→VIb→IVb.

It is interesting to note that the insertion proceeds stepwise or nonstepwise depending on the nature of tertiary phosphine ligand.

Detailed studies will be reported in the near future.

Optical Resolution of a Heteropolymolybdate Anion

Tomoharu AMA, Jinsai HIDAKA and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received May 22, 1970)

Shimura[1] studied the electronic absorption spectrum of a dark olive green heteropolymolybdate containing cobalt(III) in a ratio of Co : Mo= 1 : 5, and concluded that the heteropoly anion contains two or more central cobalt(III) atoms with a linkage of Co^{III}–O–Co^{III}. Recently, Evans and Showell[2] determined the crystal structure of the ammonium salt of this anion and proved the dimeric structure of the anion, $[H_4Co_2Mo_{10}O_{38}]^{6-}$ with the two CoO_6 octahedra sharing two oxygens. They showed that the dicobalt(III)-decamolybdate(VI) anion has a point group symmetry D_2, and that it might be possible to resolve the complex ion into the optical antipodes.

We have succeeded in the optical resolution as follows. To a solution of $(NH_4)_6[Co_2Mo_{10}O_{34}(OH)_4]\cdot 7H_2O$ (1.0 g, 0.5 mmol, in 1000 m*l* of water) was added a solution of $(+)_{589}$-[Co en_3]-$Br_3\cdot H_2O$ (0.25 g, 0.5 mmol, in 200 m*l* of water). After the solution had been kept at 55°C for 4 hr, the less soluble dark yellowish green diastereomer deposited was collected by filtration.

Found: C, 6.20; H, 3.03; N, 7.19%. Calcd for $(+)_{589}$-[Co $en_3]_2\cdot(+)_{589}$-$[Co_2Mo_{10}O_{34}(OH)_4]\cdot 9H_2O$: C, 6.18; H, 3.00; N, 7.21%. The diastereomer was stirred with the cation-exchange resin (Dowex 50 W×8, 200—400 mesh, NH_4^+ form) in water. After the resin had been filtered off, ammonium chloride was dissolved in the green filtrate. The solution was kept in a refrigerator overnight in order to complete the crystallization of the optically active isomer. $[\alpha]_{589}^{25}=+100°$.

Found: H, 1.99; N, 4.42%. Calcd for $(+)_{589}$-$(NH_4)_6[Co_2Mo_{10}O_{34}(OH)_4]\cdot 5H_2O$: H, 2.03; N, 4.45%.

The electronic absorption and circular dichroism (CD) spectra are shown in Fig. 1. Four CD bands, (−), (+), (−) and (−) listing from the longer wavelength side, are observed in the region of d-d absorption bands of the $(+)_{589}$ isomer. The isomer shows two rather strong CD bands in the region of near ultraviolet absorption band, which may be assigned to a charge-transfer band characteristic to the bridging oxygen ligands in the linkage of $Co^{III}\langle{}^{O}_{O}\rangle Co^{III}$. Similar CD bands have also been reported for some tetranuclear Co(III) complexes containing OH-bridges.[3]

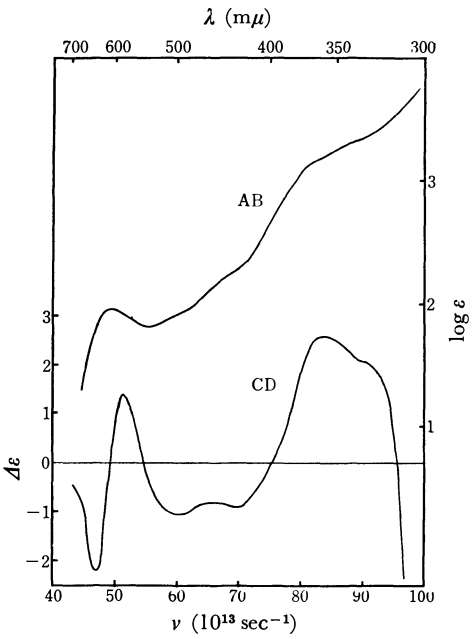

Fig. 1. Absorption AB and CD curves of $(+)_{589}$-$(NH_4)_6[Co_2Mo_{10}O_{34}(OH)_4]\cdot 5H_2O$.

This heteropolymolybdate anion appears to be the first heteropoly complex which has been optically resolved.

Preparation of Methyl 2,3-Anhydro-4,6-*O*-benzylidene-3-deoxy-3-nitro-β-D-allopyranoside and Some C^2-Branched-Chain Derivatives of Methyl 4,6-*O*-Benzylidene-2,3-dideoxy-3-nitro-β-D-glucopyranoside

Tohru SAKAKIBARA, Satoru KUMAZAWA and Toshio NAKAGAWA

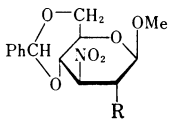
Department of Chemistry, Tokyo Institute of Technology, Ō-okayama, Meguro-ku, Tokyo

(Received May 29, 1970)

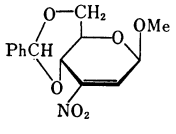
In a previous paper[1] we reported that new nucleosides (**3** and **4**) were easily formed on treatment of 3-nitroglucoside **1** with theophylline or 2,6-dichloropurine in the presence of sodium bicarbonate via a two-step mechanism, *i.e.* (i) elimination of acetic acid from 1 to yield α-nitroolefin **2** and (ii) nucleophilic addition of the purine bases to **2**. Recently Newman and Angier[2] described α-nitroepoxides, a new class of compounds, generated from α-nitroolefins with alkaline hydrogen peroxide.

We have found that on treatment with sodium hypochlorite in THF **2** also gives nitroepoxide **5** as the first member in the field of sugar chemistry. When the solvent was changed from THF to acetone, an unexpected addition of acetone, a very weak nucleophile(K_a[3] 10^{-20}), to **2** predominantly occurred[4] and a branched-chain compound **6** was obtained.

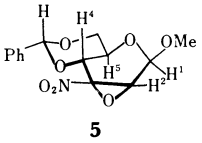
In THF (20 m*l*) **2**[5] (293 mg) was stirred with sodium hypochlorite (*ca.* 20% aq., 1.8 m*l*) for 2 hr at room temperature. It was then diluted with water (40 m*l*), condensed *in vacuo* to a half volume, extracted with chloroform, and on evaporation the remaining material was recrystallized from ethanol/water to give in 74% yield epoxide **5**, $C_{14}H_{15}NO_7$,[6] mp 184—185°C, $[\alpha]_D^{20}$ −96.2° (*c* 1, MeOH).



1 R=OAc
3 R=7-theophyllinyl
4 R=2,6-dichloro-9-purinyl
6 R=CH_2-C(=O)-CH_3
7 R=$CH(CN)_2$
8 R=$CH(CO_2Et)_2$
9 R= 



2



5

When stirred in acetone instead of THF overnight at room temperature, **2** gave in 91% yield adduct **6**, $C_{17}H_{21}NO_7$,[6] mp 176—177°C (from EtOH), $[\alpha]_D^{20}$ −66.9° (*c* 1, MeOH), IR(KBr) 1715 cm^{-1} (C=O), NMR($CDCl_3$) 7.89τ (3H-*s*, Ac).

Similarly, addition of malononitrile (K_a[3] 6.5×10^{-12}) and ethyl malonate (K_a[3] 5×10^{-14}) to **2** afforded the following, in an over 88% yield, respectively: *2-C-Dicyanomethyl derivative* **7**, $C_{17}H_{17}N_3O_6$,[6] mp 177—178°C (from EtOH), $[\alpha]_D^{20}$ −40.2° (*c* 1, MeOH); *2-C-(Diethoxycarbonyl)methyl derivative* **8**, $C_{21}H_{27}NO_{10}$,[6] mp 109—110°C (from EtOH), $[\alpha]_D^{20}$ −61.2°C (*c* 1, MeOH).

Under similar conditions cyclohexanone was shown to be inactive as a nucleophile, but its morpholino enamine was made to react with **2** without a catalyzer to afford adduct **9** in 76% yield, $C_{24}H_{32}N_2O_7$,[6] mp 145.5—146°C (from EtOH), $[\alpha]_D^{20}$ −135° (*c* 0.5, $CHCl_3$).

Structures of the products obtained were deduced from NMR-data: The fact that $J_{1,2}$=0(dihedral angle of H^1,H^2=100°) and $J_{4,5}$=9.5 Hz(diaxial of H^4,H^5) in **5** permits only a distorted β-*allo* structure, as shown in the figure. Large values of coupling constants (≳8 Hz) of H^1 - H^5 in **6**—**9** indicate their β-*gluco* configurations.

The Reactivity of Electron Donor-acceptor Complexes. The Effect of the Complex Formation on the Reduction of Methylene Blue in the Presence of Aromatic Hydrocarbons

Yasuhiro IWASAWA, Tamotsu KONDOW, Mitsuyuki SOMA, Takaharu ONISHI and Kenzi TAMARU

Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received January 27, 1970)

The hydrogen transfer from dihydro-aromatic hydrocarbons to methylene blue was chosen for study, with methylene blue being regarded as a model compound of flavin co-enzymes, and the effect of aromatic hydrocarbons added was studied.

Various aromatic hydrocarbons, such as naphthacene, perylene, anthracene, and pyrene, were purified by recrystallization and sublimation, while commercial methylene blue and dihydro-aromatic hydrocarbons, such as 9,10-dihydroanthracene, 9,10-dihydrophenanthrene, 4,5-dihydropyrene, and 5,12-dihydronaphthacene, were employed. The reaction was handled in the absence of air or oxygen at 0°C in 1,2-dichloroethane.

It was observed that the reduction of methylene blue, (Mb) (1.6×10^{-5} mol/l) by di-hydro-aromatic hydrocarbons, (ZH_2) (2.2×10^{-4} mol/l) was a Michaelis-Menten type with respect to the initial concentrations of aromatic hydrocarbons, $(Ar)_0$, in the concentration range from 5.45×10^{-7} to 5.45×10^{-4} mol/l.

The scheme and the rate of the overall reaction may be given as follows:

$$2Mb + Ar \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} (Mb_2\cdot Ar)$$

$$(Mb_2\cdot Ar) + ZH_2 \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} (Mb\cdot ZH_2) + Mb + Ar$$

$$(Mb\cdot ZH_2) \xrightarrow{k_3} MbH_2 + Z$$

for $d(Mb\cdot ZH_2)dt=0$ and $k_1,\ k_{-1}\gg k_2$,

$$-d(Mb)/dt = \frac{k_2k_3K(ZH_2)_0(Ar)_0(Mb)^2}{k_3+k_{-2}(Ar)_0(Mb)},$$

which is also equal to $k'(Mb)$, provided that $(Mb)_0\ll(ZH_2)_0$, where $(Mb_2\cdot Ar)$ and $(Mb\cdot ZH_2)$ represent the EDA complex of Mb with Ar and ZH_2 respectively, and where K is equal to k_1/k_{-1}.

Besides such kinetic investigations, new absorption bands were observed in the range between 500 and 600 mμ in the solution of Ar and Mb; for the absorption band of the EDA complex of pyrene and Mb, as a typical example, it was found at 530 mμ. The plots of $(Mb)_0/(O.D.)$ against $1/(Ar)_0^{1/2}(O.D.)^{1/2}$ gave a linear relation according to the Benesi-Hildebrand equation. It is of great interest to note that methylene blue formes EDA complexes with a molar ratio of 2 : 1 with various aromatic hydrocarbons. It was also observed that Mb forms EDA complexes with a molar ratio of 1 : 1 with ZH_2. When ZH_2 was 9,10-dihydroanthracene, the new absorption band was found at 618 mμ.

The reduction of methylene blue by various dihydro-aromatic hydrocarbons was accelerated by a factor of 50 by the formation of the EDA complexes with aromatic hydrocarbons. The rate constant, k', was determined in the initial stage of the reaction when the Z produced from ZH_2 is negligible. The k_1/k_{-1} and k_2/k_{-2} in the above scheme must have some relation with the stabilization energy of the EDA complex formation of Mb with Ar. In fact, the plots of the logarithms of both k_1/k_{-1} and k_2/k_{-2} against the reciprocal of the ionization potential of Ar, a measure of the stabilization energy of the EDA complex formation,

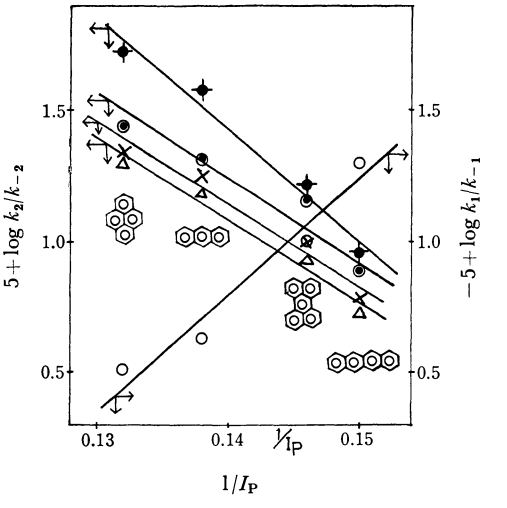

Fig. 1. The ionization potentials of aromatic hydrocarbons and the k_1/k_{-1} in the right scale and the k_2/k_{-2} in the left scale, respectively, in the concentration of aromatic hydrocarbons, 5.45×10^{-4} mol/l: for the k_2/k_{-2}, ●: 9,10-dihydroanthracene, ⊙: 9,10-dihydrophenanthrene, ×: 5,12-dihydronaphthacene, △: 4,5-dihydropyrene

gave a good linear relation, as is shown in Fig. 1. This shows that the EDA-complex formation plays a part in the redox reaction.

The Dehydration of Surface Silanol on Silica Gel

Seiichi KONDO* and Masa-aki MUROYA**

* *Osaka University of Education, Tennoji-ku, Osaka*

** *Osaka Electro-Communication University, Neyagawa, Osaka*

(Received February 23, 1970)

The thermal behavior of surface silanol groups on silica gel has been extensively studied.[1-3] Several authors have suggested various models, including the quasi-crystalline structure of the silica substrate, for the configuration and the dehydration reaction of free and hydrogen-bonded silanol groups. If the dehydration reaction occurs, the heat of reaction can be expected. In the present paper, some experimental findings derived by means of differential thermal analysis and thermogravimetric analysis are reported.

Silica gel was washed until the remaining sodium impurity became about 70 ppm of Na_2O. The presence of less than 100 ppm of the Na ion was shown to have a negligible effect on the thermal properties of silica gel.[4] The BET N_2 specific surface area of this material was 690 m^2/g.

The simultaneous measurements of DTA and TGA were carried out by means of two apparatuses, a Rigakudenki Co. Model 8001 CSL and a Shimadzu Model MTG-11. The sensitivities of the former instrument were ± 0.005°C and ± 0.02 °C using Chromel-Alumel and Pt-PtRh thermocouples respectively for DTA and ± 0.03 mg for TGA. About 30 mg of a powdered sample was heated in air in a shallow-dish-type platinum cell, using α-Al_2O_3 as the reference material, at a heating rate of 10°C and 20°C per minute.

Four endothermic DTA peaks, accompanied by four steps of weight decreases in the TGA curves and two exothermic DTA peaks, without any observable discontinuity in the TGA curves, were obtained in the range from room temperature to 1100°C, as shown in Fig. 1.

The largest DTA peaks at 150°C with the biggest weight decreases is obviously due to the desorption of adsorbed water. Three small peaks, 1, 2, and 3, at about 200, 400, and 500°C, and the corresponding small weight decreases are the facts newly found in this investigation. The pure sample which had preliminarily been heated at 570°C for six hours and then exposed to humid air with a 90% relative humidity for six hours showed

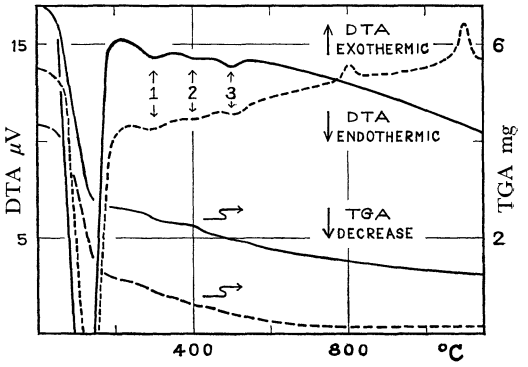

Fig. 1. DTA and TGA curves of silica gel. Full and dotted lines show pure and impure samples containing 70 and 800 p.p.m. Na_2O respectively. Sample weight was 30 mg and heating rate was 20°C/min in air.

smaller DTA and TGA changes at the same temperatures as that above. The ratio of these changes to each other was roughly equal to those obtained without preheating.

According to the preliminary test of the infrared spectroscopy in this laboratory, four absorption bands were observed in the O–H stretching vibration region, *i.e.*, at 3230, 3460, 3620, and 3750 cm^{-1}. These bands disappear, one after another, in the order from lower to higher wave numbers (except the 3750 cm^{-1} band assigned to the free silanol group) by successive heating at about the same temperatures where DTA peaks disappear. Therefore, it seems reasonable to relate the DTA peaks 1, 2, and 3 to the bands at 3230, 3460, and 3620 cm^{-1} respectively. These considerations suggest the existence of four species of silanol groups, one free and three hydrogen-bonded silanol species. According to the quasi-crystalline structure model,[2] the surface of the silica particle might have various kinds of planes, which may give rise to various types of silanol groups, similar to the crystal planes, such as (100), (110), (210) and (211), of cristobalite or similar planes of other silica crystals. The present results seem to support this theory.

No endothermic DTA peaks were found above 600°C. Two exothermic peaks, shown in Fig. 1 on samples impregnated with some metallic salts, were interpreted as the heats of crystallization to cristobalite at 800°C and to quartz or tridymite at 1000°C.[4]

The Reaction of Allene with Palladium(II) Acetate

Tadashi OKAMOTO, Yasumasa SAKAKIBARA* and Sango KUNICHIKA

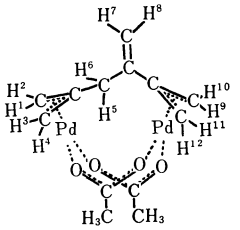
Institute for Chemical Research, Kyoto University, Gokasho, Uji

* *Chemical Laboratory of Textile Fibers, Kyoto University of Industrial Arts and Textile Fibers, Kyoto*

(Received March 17, 1970)

A recent note on the reaction of allene with π-allylpalladium(II) acetylacetonate to give 2,2'-bi-π-allyl complex of palladium[1] prompts us to report another bridged π-allyl complex obtained from allene and palladium acetate.

Palladium(II) acetate and allene were stirred in benzene at room temperature overnight; subsequent separation with a silica-gel column gave a yellow crystal, di-μ-acetato-[2,2'-(1-methyleneethylene)bis-π-allyl]dipalladium (I), in about a 20% yield. The structure of I was established by chemical and spectroscopic methods. Found: C, 34.63; H, 4.10%; mol wt (benzene, 37°C), 466. Calcd for $(C_3H_4)_3Pd_2(CH_3COO)_2$: C, 34.58; H, 4.11%; mol wt, 451. The hydrogenation of I gave 2,3,5-trimethylhexane and partially-hydrogenated products, 2,3,5-trimethyl-2-hexene and 2,4,5-trimethyl-2-hexene, which were determined by a study of



(I)

the mass and NMR spectra. The NMR spectrum of I shows singlet absorptions at 5.67 (1H, H^7), 5.21 (1H, H^8), 3.95 (2H, H^{10} and H^{12}), 3.77 (2H, H^2 and H^4), 3.26 (2H, H^5 and H^6), 2.90 (2H, H^1 and H^3), 2.80 (2H, H^9 and H^{11}), and 2.05 ppm [(6H), acetoxy protons] at 100°C in acetic acid-d_4, with TMS used as the internal reference. At −28°C in deuterochloroform, the absorptions at 3.95, 3.26, and 2.90 ppm each separated into two peaks (Fig. 1). The couplings of the AB-type by H^5 and H^6 protons at the low temperature are not clear because of the disturbance by neighboring absorptions. The IR spectrum of I shows two broad absorptions, at 1570 and 1410 cm^{-1}, which

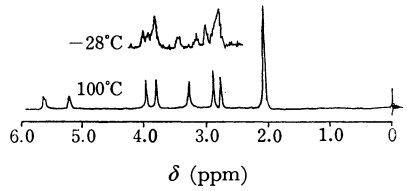


Fig. 1. NMR spectra of I.

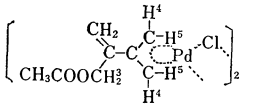
can be assigned to the carboxylate ion. Acetate ligands were replaced, resulting in an insoluble complex, when I was treated with an aqueous sodium chloride solution.

An iron complex of a ligand with the same carbon skeleton was also obtained by Otsuka *et al.*[2] from hexacarbonyl 2,2'-bi-π-allyldiiron and allene. A similar route may be supposed for the formation of complex I, but no absorption due to 2,2'-bi-π-allylpalladium acetate was observed on the NMR spectrum of our reaction mixture.

When an aqueous sodium chloride solution was added to the reaction mixture, di-μ-chloro-bis-[2-(1-(acetoxymethyl)vinyl)-π-allyl]dipalladium (II) and di-μ-chloro-bis(2-acetoxy-π-allyl)dipalladium (III) were isolated from the solution in a total yield of 52%. The NMR spectrum of II shows singlet absorptions at 5.68 (1H, $=CH_2$), 5.46 (1H, $=CH_2$), 4.86 (2H, H^3), 4.18 (2H, H^4), 2.90 (2H, H^5) and 2.20 ppm (3H, acetoxy protons) in deuterochloroform at room temperature, with TMS used as the internal reference.



(II)

Although the mechanisms of these reactions are not yet clear, the newly-obtained complexes are the first examples of a stable complex obtained from palladium acetate.

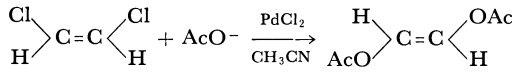
Catalytic Diacetoxylation of *cis*- and *trans*-Dichloroethylenes by Means of Palladium(II) Chloride

Masahiro YAMAJI, Yuzo FUJIWARA, Toshinobu IMANAKA and Shiichiro TERANISHI

Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka

(Received May 15, 1970)

It is well known that palladium(II) chloride and sodium acetate cause the displacement reaction of vinylic halides to give vinyl acetate derivatives.[1] However, examples are limited to only monohalides such as vinyl chloride or 2-chloropropylene. In order to study whether dihalides also undergo displacement reaction or not, we have carried out the reactions of *cis*- and *trans*-dichloroethylenes. Interestingly enough we have found that in the presence of catalytic amounts of palladium(II) chloride, *cis*-dichloroethylene reacts with acetate ions to produce *trans*-diacetoxyethylene[2] in high yield with a small amount of unidentified products. Similarly *trans*-dichloroethylene afforded *trans*-diacetoxyethylene in a 137% yield based on palladium(II) chloride used.



AcO: CH_3COO

This is the first example of direct diacetoxylation ethylene derivatives to give unsaturated diacetates by the nucleophilic substitution of halides with an acetate anion.

The following procedure is a representative one. A mixture of 0.09 mol of *cis*-dichloroethylene, 0.18 mol of sodium acetate, and 0.03 mol of $PdCl_2$ in 200 m*l* of acetonitrile under air was stirred at 80°C for 8 hr. The resulting mixture was filtered to remove $PdCl_2$ and Pd metal, and the filtrate was poured into water, and the organic layer was then separated. After drying over $MgSO_4$, the solvent was evaporated. The residual heavy oil crystallized on standing. The mixture was filtered and the crystals were washed with petroleum ether. From the mother liquor, a very small amount of two unidentified products was detected by glpc. The crude substance was recrystallized from ether-petroleum ether, then sublimed at 4 mmHg, to give 5.31 g (123% yield based on $PdCl_2$) of *trans*-diacetoxyethylene[3] as colorless crystals, mp 44—44.5°C, IR, 1720 (C=O), 1600 (C=C), 1188 (C-O-C) and 970 cm^{-1} (*trans*-C-H); NMR,[4] 3.29 (olefinic protons, s, 2H) and 7.80 τ (methyl protons, s, 6H).

The reaction provides an extremely convenient method for the synthesis of olefinic diacetate derivatives.

Further works on this reaction are now in progress together with mechanistic investigation, and details will be described in a full paper.

A New Synthesis of Organosilicon Azo Compounds

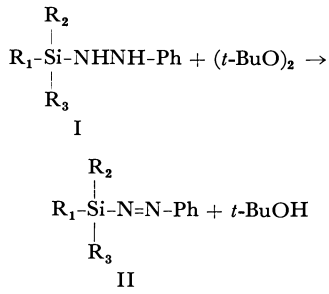
Hamao WATANABE, Kyoichi INOUE and Yoichiro NAGAI

Department of Applied Chemistry, Faculty of Technology, Gunma University, Tenjin-cho, Kiryu, Gunma

(Received May 16, 1970)

Although numerous methods have been proposed for synthesizing azo compounds, there are only a few reports on the formation of organometallic azo compounds with one or two silicon atoms substituted on nitrogen atoms. Mixed aryl azo organosilanes have been prepared in low yields by Krüger and Wannagat.[1] However, their method is circuitous and troublesome[2] and purity of the products was at best 90%.

We wish to report a new synthetic method for the preparation of organosilyl azo compounds in good yields by the reaction of organosilylhydrazines with radical generating agents such as di-*t*-butyl peroxide or azobisisobutyronitrile.



a) $R_1=Ph$, $R_2=R_3=Me$
b) $R_1=R_2=R_3=Et$

A mixture of Ia[3] (3.63 g, 15 mmol) and di-*t*-butyl peroxide (3.30 g, 22.5 mmol) was refluxed on a metal bath (210—230°C) for 3 hr under nitrogen and heated further at 180—200°C (metal bath temp.) for 1—1.5 hr, during which a mixture of low boiling materials (3.25 g; mainly *t*-butyl alcohol and the unreacted peroxide) was distilled off. Distillation of the resulting mixture gave 2.02 g (56%) of IIa, a deep blue liquid, bp 162—165°C/11 mmHg. Similarly, the reaction was effected employing Ib[4] and the peroxide to give a deep blue liquid of IIb. The analytical results are summarized in Table 1.

Compounds IIa and IIb are shown to be distillable, stable under nitrogen and considerably stable in dry air, and the solution in cyclohexane remains unchanged for a few months.

The present method is especially suitable for the preparation of such organometallic compounds sensitive to moisture or water in the reaction system. The results show that the isolation of the product from the reaction mixture is carried out with great ease due to the simplicity of the reaction system.

It is of interest to apply this method to the synthesis of other types of azo compounds. The usefulness is shown by the following example: hydrazobenzene (1.84 g, 10 mmol) was treated with the peroxide (2.02 g, 15 mmol) and worked up as described above to yield a dark-brown molten mass which was solidified on cooling. Purification of the solid by alumina column chromatography with benzene as an eluent afforded, after recrystallization from ethanol, 1.40 g, (77%) of orange-red fine crystals of azobenzene, mp 66.5—68.0°C.

The Substitution Reaction of Ligands in Copper(II) Acetylacetonate with Pyridine on a Molecular Sieve 13X

Yoshio YAMADA, Akinori HASEGAWA and Masaji MIURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received May 22, 1970)

It has been reported that well-resolved hyperfine structures of ESR spectra are obtained for copper(II) acetylacetonate ($Cu(acac)_2$) on silica gel.[1] The present authors found that the complex also presents a distinct ESR spectrum on a Molecular Sieve 13 X (MS). In this paper, it will be reported that the substitution of a part of the ligands in $Cu(acac)_2$ with pyridine is observed on the MS surface, but not in solutions containing pyridine.

The MS powder (Linde Lot No. 1380019) was treated in a vacuum for 5 hr at 500°C. The amount of $Cu(acac)_2$ used as the adsorbate was adjusted so as to be included in the cages of the MS in the ratio of one molecule to 20 cages. The solution of $Cu(acac)_2$ in chloroform was outgassed and introduced to the MS through a breakable seal. After the chloroform had been eliminated by means of a vacuum line, the complex adsorbed on the MS was exposed to pyridine vapor at room temperature and the ESR spectrum was measured at 77°K.

The spectral lines of perpendicular g components for the $Cu(acac)_2$ on MS were replaced upon the adsorption of pyridine by those consisting of about 11 lines, with a splitting of 16 gauss, as is shown in Fig. 1. The latter spectral lines can be explained by supposing that, in addition to the hyperfine splitting due to the copper nucleus, there exists a superhyperfine structure arising from ligand nitrogen atoms. On the other hand, none of the superhyperfine structure due to the ligand nitrogen atoms was observed in $Cu(acac)_2$ dissolved in 60% pyridine - 40% chloroform, 60% pyridine - 40% methanol, or 25% pyridine-25% water-50% methanol at 77°K.[2] Moreover, no ESR signal was obtained upon the adsorption of pyridine alone on MS. These results may imply that some of the ligands of the complex are substituted on the MS with pyridine molecules, but not in the solution containing pyridine. This conclusion is supported by the IR measurements; the absorption band at 1580 cm^{-1} of $Cu(acac)_2$ on MS, which has been assigned to the stretching of chelated carbonyl groups, disappears in $Cu(acac)_2$-pyridine on MS. The formation of $Cu(pyridine)_4^{2+}$ is not possible since the idea of a charge transfer during the substitution with pyridine is unreasonable. Consequently, the spectral lines exhibited in Fig. 1 seems to be due to the signal of a new complex in which two of four oxygen atoms originally coordinated with copper are replaced by two nitrogen atoms of pyridine. The observed spectral lines can be satisfactorily explained by the assumption that the ratio of the splitting constant of the copper nucleus to that of two ligand nitrogen atoms is 2 : 1 and that the separation of perpendicular g components can be disregarded.*1 A spectrum similar to that of $Cu(acac)_2$-pyridine on MS was observed when 4-methylpyridine was used instead of pyridine. It can be deduced from these results that such a characteristic substitution reaction is caused by the excitation of $Cu(acac)_2$ arising from the interaction of the complex with the active site on MS.

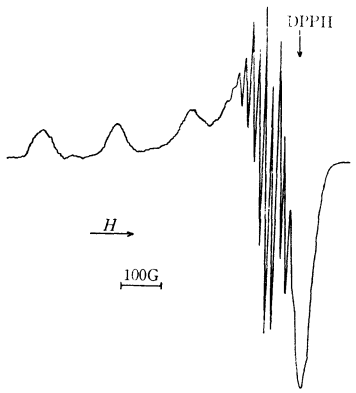

Fig. 1. ESR spectrum of $Cu(acac)_2$ on MS in the presence of pyridine at 77°K.

The Mechanism of the Formation of Tropolone from the Adduct of Cyclopentadiene and Dichloroketene*[1]

Toyonobu ASAO, Takahisa MACHIGUCHI*[2] and Yoshio KITAHARA

Department of Chemistry, Faculty of Science, Tohoku University, Katahiracho, Sendai

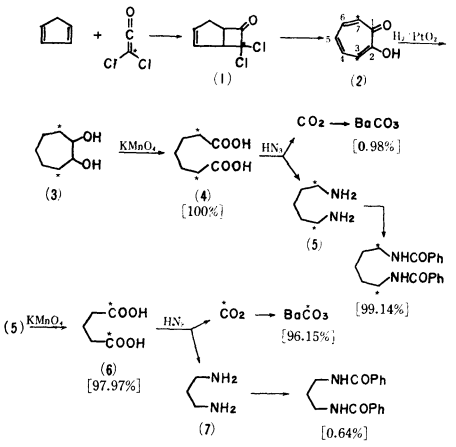
(Received May 29, 1970)

We have previously reported[1] the novel rearrangements of the adduct of 6,6-dimethylfulvene with dichloroketene, and have proposed a mechanism for the formation of tropone derivatives from the adduct involving a norcaradienone intermediate. We have also proposed a similar mechanism for the rearrangement[2] of the adduct of cyclopentadiene with dichloroketene to tropolone. This report will present evidence to support the proposed mechanism by a tracer experiment.

The reaction of cyclopentadiene with dichloroketene-2-^{14}C, produced by the reaction of the dichloroacetyl chloride-2-^{14}C and triethylamine, in boiling *n*-hexane afforded a 1 : 1 adduct (**1**).[2,3]

The adduct (**1**) was rearranged to ^{14}C containing tropolone (**2**) under solvolytic condition (potassium acetate in acetic acid and water) according to the method of Stevens *et al.*[2]

The tropolone was submitted to catalytic hydrogenation in the presence of the Adams catalyst to give ^{14}C containing cycloheptane-1,2-diol (**3**). The diol (**3**) was degraded to trimethylenediamine (**7**) and carbon dioxide via pimelic acid (**4**), pentamethylenediamine (**5**), and glutaric acid (**6**) by repeated oxidations and Schmidt reactions, as is shown in the following scheme.



Pimelic acid (**4**) shows a radioactivity*[3] of 152,883 dpm/mM; the activities of the consecutive degradation products or their derivatives are shown in parentheses in terms of a percentage of the activity based on the activity of pimelic acid.

It is clear from the above results that all the ^{14}C are located at the 3- or 7-carbon in the tropolone (**2**); this supports the previously-proposed mechanism for the formation of tropolone by way of the attack of the nucleophile at the 7-position of the norcaradienone intermediate (**8**). The details will be reported elsewhere.

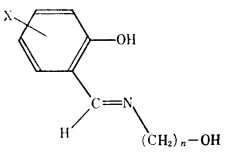
New Types of Copper(II) Complexes with Subnormal Magnetic Moments

Shoichiro YAMADA and Kuniko YAMANOUCHI

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received June 12, 1970)

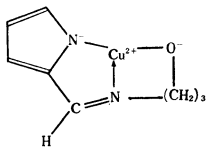
It is known that Schiff bases of a type represented by Formula I*[1] form copper(II) complexes of a Cu(X-SAL.$CH_2CH_2CH_2O$) type with subnormal magnetic moments, which are considered to be due



Formula I

to an interaction between two copper(II) ions within the binuclear molecule.[1,2] With Schiff bases of different series, we have recently succeeded in isolating crystals of new copper(II) complexes having subnormal magnetic moments.

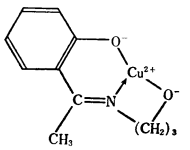
A copper(II) complex shown by Formula II*[2]



Formula II

was prepared as follows. An aqueous solution of copper(II) nitrate (0.005 mol) was added drop by drop to a solution of the Schiff base (0.01 mol) in ethanol, followed by addition of an aqueous solution of sodium carbonate (0.005 mol). After the solution was stirred at 60°C for one hour, it was allowed to cool to room temperature. A brown precipitate was collected and recrystallized from benzene or chloroform to yield brown crystals. Found: C, 44.87; H, 4.70; N, 12.43%. Calcd for Cu(Pra.$CH_2CH_2CH_2O$), $C_8H_{10}N_2OCu$: C, 44.96; H, 4.72; N, 13.11%.

By a similar method except that 2-hydroxyacetophenone was used instead of pyrrole-2-carboxyaldehyde, a copper(II) complex shown by Formula III*[3] was obtained as olive-colored crystals. This complex could also be obtained without sodium carbonate. Found: C, 52.04; H, 5.17; N, 5.53%. Calcd for Cu(Hap.$CH_2CH_2CH_2O$), $C_{11}H_{13}NO_2Cu$: C, 51.86; H, 5.14; N, 5.50%.



Formula III

The magnetic moments for Cu(Pra.CH_2CH_2-CH_2O) and Cu(Hap.$CH_2CH_2CH_2O$), which have been determined at room temperature to be 0.60 and 1.09 B.M., respectively, are significantly smaller than the spin-only moments expected for normal copper(II) complexes. The subnormal magnetic moments of these complexes are considered to be due to an antiferromagnetic interaction between copper(II) ions. One most probable structure may be a binuclear structure similar to that of the corresponding salicylideneiminato-complex.

It should be noted that similar methods using ethanol-amine instead of *n*-propanol-amine yielded compounds of a different type. Further study of copper(II) complexes with related ligands is now in progress.

Structure and Rotational Isomerism of Ethylenediamine by Gas Electron Diffraction—Evidence for a Dominant *gauche* Conformer

Akimichi YOKOZEKI and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received June 16, 1970)

Ethylenediamine is known as a typical chelating agent, and the structures of its complexes have been investigated extensively by X-ray crystallography.[1] However, only a little is known about the structure of free ethylenediamine. Neither the geometrical parameters nor the rotational isomerism have been studied in detail, while the spectroscopic data (IR and Raman) have been only tentatively assigned to a single (*cis*) conformer.[2] The present communication will report on the average structure of ethylenediamine and the rotational isomerism as studied by gas electron diffraction.

Anhydrous ethylenediamine (Guaranteed Reagent) was purchased from the Tokyo Chemical Industry Co., Ltd. Diffraction photographs (q= 7 to 130) were taken at various temperatures between 55°C and 118°C using 40 kV electrons with a high-temperature nozzle[3] and with camera lengths of 114 mm and 249 mm. The experimental and analytical procedures are analogous to those reported elsewhere.[4]

The average structure was determined by a least-squares analysis on the molecular intensity. The hydrogen positions were assumed to be similar to those for methylamine[5] and ethane.[6] The mean amplitudes of vibration were calculated by the use of a plausible force model.[7] The skeleton parameters and their limits of error were found to be: r_g(C–C)=1.55$_6$±0.01 Å, r_g(C–N)= 1.468±0.005 Å, and ∠C–C–N=110.2±0.8°. The C–C bond length was about 0.02 Å longer than those in ethane and other *n*-alkanes, whereas the C–N distance was similar to that in methylamine[5] within the limits of error.

The above analysis also gave the average N–C–C–N dihedral angle of 64.0±5.0°, as measured from the *cis* position. Thus, ethylenediamine is dominantly in the "*gauche*" conformation about the C–C axis at the above temperature range. This is also supported by the outstanding peak around 2.85 Å in Fig. 1 (essentially composed of the nonbonded N–N pair), where the experimental radial distribution curve with a damping factor, exp(−0.00062 q^2), is compared with the theoretical curves for different conformers. On the other hand, a small peak around 3.8 Å in the experimental curve indicates that a small fraction of the *trans* conformer may also be present.

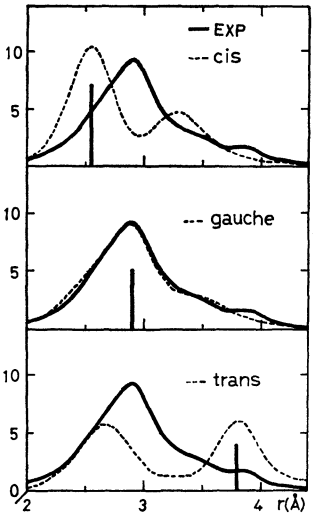

Fig. 1. Radial distribution curves. Solid line: experimental curve, from which the contribution from pairs independent of the internal rotation about the C–C and C–N axes are subtracted to accentuate the comparison. The subtracted peak, 16.4 at 2.5 Å and 1.0 at 2.8 Å, can be reproduced to within 0.2 by a theoretical curve based on the skeleton parameters given in the text with the index of resolution of 100%. The experimental error is estimated to be of the order of 0.4 in the whole region illustrated. Broken lines: corresponding theoretical curves for *cis*, *gauche* and *trans* conformers about the C–C axis with the index of resolution of 100%. Vertical line indicates the nonbonded N–N distance for each conformer.

In the above calculations, the NH_2 group was assumed to have a three-fold potential around the C–N axis with a barrier height of 1.6 kcal/mol, as in the case of ethylamine;[8] a classical average was taken to account for the effect of this motion.[4] The results presented in the preceding paragraphs are, however, found to be essentially independent of the assumptions as to the NH_2 conformation. A further analysis of the internal rotation about the C–C and C–N axes and the geometrical parameters is now being made.

The Behavior of Indium(III) Complexes in Several Liquid-Liquid Distribution System. I. A Solvent Extraction Study of Indium(III) Complexes in Aqueous Perchlorate Media Containing Several Anionic Ligands

Yuko HASEGAWA

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received April 2, 1969)

The stabilities of the indium(III) complexes in 4 M sodium perchlorate solutions with eight univalent anionic ligands have been studied at 25°C by using a TTA-chelate extraction method and a TBP adduct extraction method. The following conclusions have been reached. The stabilities of the indium(III) halide complexes are larger in this order; $Cl^- > Br^- > I^-$; on the other hand, those of indium(III) complexes with the halate anions increase in the order: $ClO_3^- < BrO_3^- < IO_3^-$. The former forms more stable complexes than the latter. Thiocyanate ions form the most stable indium(III) complexes (the first to the fifth complexes), while nitrate ions form the least stable one (only the first complex). The values obtained by the TTA method are almost identical with those obtained by the TBP method. It was also concluded that although the TTA method could be applied to all the systems studied, it is more suitable for the examination of the lower complexes; the TBP method, on the other hand, could be used only for the systems in which an extractable third complex is formed, but it could give more accurate constants for the higher complexes. Thus, only a combination of these two methods can give all the equilibria in a system where many complexes are formed.

Many kinds of indium(III) complexes in aqueous solutions have been reported. Among these, the halide complexes seem to have been most extensively studied and are known to be rather stable.[1)]

The present author grew interested in the differences in stability among the indium(III) complexes with halide ions and among those with the other univalent ions. In order to determine stabilities of these different complexes, measurements over a wide ligand-concentration range were necessary; thus an ionic medium, 4 M Na(ClO_4), has been employed throughout the study for this purpose. Two different solvent extraction methods, a TTA (thenoyltrifluoroacetone) chelate extraction method and a TBP (tributylphosphate) adduct extraction method, were used for the determination of the stability constants. Indium(III) in aqueous solutions containing different concentrations of the ligand was extracted by using these extracting agents, and the stability constants were determined by a graphic treatment. Some discussion was made regarding the stabilities of these complexes and regarding the solvent extraction method as a technique for the determination of the stability constants.

Statistical

The complex formation of indium(III) in aqueous solutions containing a univalent ligand, L^-, may be described as follows:

$$In^{3+} + nL^- \rightleftarrows InL_n^{3-n} \quad (1)$$

$$\beta_n = [InL_n^{3-n}]/[In^{3+}][L^-]^n \quad (2)$$

or:

$$K_n = [InL_n^{3-n}]/[InL_{n-1}^{4-n}][L^-] \quad (2')$$

The total indium(III) concentration in the aqueous phase may be described as:

$$[In(III)]_{total} = [In^{3+}] + [InL^{2+}] + \cdots + [InL_n^{3-n}] \quad (3)$$

The distribution ratio of indium(III) in a solvent extraction system is defined as follows (it can be measured radiometrically):

$$D = [In(III)]_{org,\ total}/[In(III)]_{total} = \frac{\gamma\text{-count-rate per m}l \text{ of the org. phase}}{\gamma\text{-count-rate per m}l \text{ of the aq. phase}}$$

(i) Extraction with an Organophilic Chelating Acid. The tripositive indium ion could be extracted with an organophilic chelating acid HA, in an immiscible organic solvent as follows:

$$In^{3+} + 3HA(org) \rightleftarrows InA_3(org) + 3H^+ \quad (4)$$

$$Kex_0 = [InA_3]_{org}[H^+]^3/[In^{3+}][HA]^3_{org} \quad (5)$$

When the aqueous phase contains only uncomplexed indium ions, the net distribution ratio may be described as follows:

$$D_0 = [InA_3]_{org}/[In^{3+}] \quad (6)$$

where the subscript "0" denotes no complex formation in the aqueous phase. The extraction constant can, then, be described as:

$$Kex_0 = D_0[H^+]^3[HA]_{org}^{-3} \quad (7)$$

When the indium ion undergoes complex formation with a uninegative ligand, L^-, and when only the InA_3 species is extractable, the net distribution ratio may be described as:

$$D = \frac{[InA_3]_{org}}{[In^{3+}] + [InL^{2+}] + \cdots + [InL_n^{3-n}]} = \frac{[InA_3]_{org}}{[In^{3+}](1 + \sum \beta_n[L^-]^n)} \quad (8)$$

From Eqs. (7) and (8), we obtain:

$$D[H^+]^3[HA]_{org}^{-3}/Kex_0 = (1 + \sum \beta_n[L^-]^n)^{-1} \quad (9)$$

(ii) Extraction as Adduct Neutral Complexes. The uncharged complex species in an aqueous phase, InL_3, could be extracted as an adduct with an organophilic neutral extractant, E, in the organic phase:

$$InL_3(org) + eE(org) \rightleftarrows InL_3E_e(org) \quad (10)$$

$$\beta_e^{\circ} = \frac{[InL_3E_e]_{org}}{[InL_3]_{org}[E]^e_{org}} \quad (11)$$

The net distribution ratio of indium(III) in such systems can be described as:

$$D = \frac{[InL_3]_{org} + [InL_3E]_{org} + [InL_3E_2]_{org} + \cdots + [InL_3E_e]_{org}}{[In^{3+}] + [InL^{2+}] + \cdots + [InL_n^{3-n}]} = \frac{[InL_3]_{org}(1 + \sum \beta_e^{\circ}[E]^e_{org})}{[In^{3+}](1 + \sum \beta_n[L^-]^n)} \quad (12)$$

When the concentration of the extractant is kept at a constant value, c_1, we can define the following partition coefficient for this complex:

$$K_{DM} = \frac{[InL_3]_{org}(1 + \sum \beta_e^{\circ}c_1^e,_{org})}{[InL_3]} \quad (\text{at } [E]_{org} = c_1) \quad (13)$$

From Eqs. (2), (12), and (13), the following equation is obtained:

$$D = \frac{K_{DM}\beta_3[L^-]^3}{1 + \sum \beta_n[L^-]^n} \quad (\text{at } [E]_{org} = c_1) \quad (14)$$

On the other hand, when the ligand concentration, $[L^-]$, is kept at a constant value, c_2, the distribution ratio is dependent on the $[E]_{org}$, and from Eq. (12) the following is obtained:

$$D = D_0(1 + \sum \beta_e^{\circ}[E]^e_{org}) \quad (15)$$

where D_0 stands for the $[InL_3]_{org}/[In^{3+}](1 + \sum \beta_n c_2^n)$ term, that is, the distribution ratio when the $[E]_{org}$ is zero.

If the "eth" adduct, InL_3E_e, is dominant in the organic phase, Eq. (15) can be described as:

$$\log D = \log D_0\beta_e^{\circ} + e \log [E]_{org} \quad (16)$$

Therefore, the plot $\log D$ *vs.* $\log[E]_{org}$ should be a straight line with the slope of $+e$, and from the value of $+e$, we can determine the number of the extractant molecules in the organic complex species.

Experimental

Reagents. The indium-114 m tracer was obtained from the Radiochemical Center, Amersham, England, as a hydrochloric acid solution. This was diluted with a large amount of 0.1 M perchloric acid and used as the stock tracer solution. All of the reagents used were of a reagent grade. The TTA was obtained from Dojindo & Co. The TBP was obtained from the Tokyo Kasei Co. and was washed with 0.1 M perchloric acid, water, and 0.1 M sodium hydroxide, and then several times with water. The chloroform was washed three times with water; The sodium perchlorate was recrystallized twice from water. The other reagents were used without further purification.

Procedures. All of the procedures were carried out in a thermostatted room at 25±0.5°C. Stoppered glass tubes (volume 20 m*l*) were used to equilibrate the organic and aqueous phases. The tracer and various amounts of ligand solutions and the sodium perchlorate solution were placed in the tubes, and then the organic solution was added. The hydrogen-ion concentration was adjusted by the addition of perchloric acid. A small amount (0.01 M at initial) of sodium acetate was added as a buffer for the iodate (pK_a, *ca.* 0.7) and thiocyanate (pK_a, *ca.* 0.8) systems in order to prevent the association of the ligand with the portion. The initial volume of each phase was 5.0 m*l*. The aqueous phase was kept at a constant ionic medium, 4 M $Na(ClO_4)$. The two phases in the tubes were agitated mechanically for one hour and then centrifuged. A two-milliliter portion was pipetted from each phase and transferred into a small test tube. The γ-radioactivity of these sample solutions was measured with a well-type(NaI) scintillation counter. A small portion was also pipetted from the aqueous phase and transferred into a small glass vessel, and the hydrogen-ion concentration was measured potentiometrically by using a standard solution containing 0.0100 M perchloric acid and 3.99 M sodium perchlorate as a standard of $-\log [H^+]$ 2.00.

Results

TTA-Extraction. Figure 1 shows the $-\log[H^+]$ dependence of the indium(III) extraction into the chloroform phase containing 0.02 M TTA from a 4 M sodium perchlorate medium containing no ligand. It may be seen from the figure that the slope of the plot is +3. The extraction constant, K_{ex_0} in Eq. (7), was obtained as $\log K_{ex_0} = -3.62$. Figures 2 to 5 give the $\log D[H^+]^3 \cdot [HA]_{org}^{-3}/K_{ex_0}$ *vs.* $\log[L^-]$ plot. The $-\log[H^+]$ for these experiments was kept at 2.0, but it was kept around 3 for the experiments with iodate and thiocyanate ions. The stability constants of the

(The extraction of the InI_3 complex is taken into account for the calculation, *cf.* Eqs. (13) and (14)). The dotted curve was drawn as

$$y = -\log(1+93[I^-]+190[I^-]^2+78[I^-]^3)$$

(A statistical curve assuming no InI_3 extraction, *cf.* Eq. (8))

complexes of indium(III) with these ligands were determined by a curve-fitting method.[2,3] They are summarized in Table 1-a.

As may be seen from Fig. 5, the slope for the plot obtained in the iodide system decreases in a manner to be expected from Eq. (9) in the lower ligand concentration region; however, the slope increases as the ligand concentration increases, and finally it becomes positive after a pronounced

* The values for the β_1 have not been determined accurately by this method.

minimum of D at about 0.7 M. From the statistical analysis of the data, it was concluded that the decrease in the distribution ratio in the lower iodide concentration region is caused by the iodide complex formation, but in the higher region the tris-iodide complex is assumed to be extracted into the chloroform phase. This may be the reason why the extraction curve deviates from that to be expected from Eq. (9).

The distribution ratio in this system may be described as:

$$D=\frac{[InA_3]_{org}+[InI_3]_{org}}{[In^{3+}]+[InI^{2+}]+[InI_2^+]+[InI_3]} \quad (13)$$

and from Eqs. (8) and (10), Eq. (13) can be described as:

$$D=\frac{K\varepsilon x_0[HA]^3_{org}\times[H^+]^{-3}+K_{DM}\beta_3[I^-]^3}{1+\beta_1[I^-]+\beta_2[I^-]^2+\beta_3[I^-]^3} \quad (14)$$

At first, the values β_1 and β_2 were determined, by the curve-fitting of the plot in the lower iodide concentration region in Fig. 5, to be $\log\beta_1=1.97$ and $\log\beta_2=2.28$. However, after several trials the data in Fig. 5 were concluded to be too errorneous to determine the β_3 and K_{DM} in Eq. (14). The equilibrium constants, β_2, β_3, and K_{DM}, only tentatively determined from the data in Fig. 5, are given in Table 1-a.

TBP Extraction. It was found that some of the tris-indium(III) complexes in the aqueous phase were extracted with TBP in hexane. Figure 6 shows the extraction of indium(III) from solutions containing 3 M sodium perchlorate and 1 M sodium bromide, iodide, or thiocyanate as a function of the TBP concentration in hexane. In Fig. 6 we can see that the slope of the log D *vs.* log $[TBP]_{org}$ plot ("e" in Eq. (16)) is +2 for the bromide and iodide systems, but +3 for the thiocyanate system. The dominant species in the organic phase may, then, be regarded as InL_3-

$(TBP)_2$ for the former two systems and $InL_3(TBP)_3$ for the latter system. Figure 7 shows the log D *vs.* log $[L^-]$ plot when the ligand anion, L^-, is a bromide ion ($[TBP]_{org}=0.1$ M), an iodide ion ($[TBP]_{org}=0.01$ M), and a thiocyanate ion ($[TBP]_{org}=0.01$ M). The plot in Fig. 7 was explained in terms of the extraction of the neutral complex

into the organic phase. The partition coefficient, K_{DM}, in Eq. (13) and the stability constants, β_n, were determined graphically by Eq. (14) as follows. In all cases, the slope of the log D *vs.* log [L^-] plot is smaller than +3 over the entire ligand concentration range studied; that is, even at the lowest concentration some of the indium ions are already complexed, and it is not possible to determine the β_1 accurately. For this reason, the values for β_1 determined by the TTA extraction method were introduced into Eq. (14); the rest of the stability constants and the partition coefficient, K_{DM}, were determined by a graphical method based on a successive approximation. The constants finally determined are listed in Table 1-b.

The extraction of indium(III) from 4 M Na(Cl, ClO_4) into hexane containing 0.1 M TBP was very poor over the entire chloride concentration range. When the TBP concentration was elevated, for example, to 1 M, a measurable extraction, one which was dependent on the chloride concentration, was observed. However, it was not possible to determine the stability constants of the chloride complexes from the analysis of these data by using Eq. (14), because those complexes which were extracted were assumed to be indium species containing perchlorate ions or both perchlorate and chloride ions.

Discussion

The Stabilities of the Complexes. It has previously reported[1] that indium(III) forms stable complexes with halide ions. The present results also indicate this. The stabilities of the halide complexes increase in the decreasing order of the ionic radii. Table 2 summarizes some of the earlier data on indium(III) complexes. The present values of log β_1 of chloride and bromide complexes seem to agree with the earlier data, but literature values of the stability constants of higher complexes are quite different from the present results. The literature constants for iodide complexes, especially, are not consistent.

It is remarkable that most of the earlier reports indicate the formation of such higher thiocyanate complexes as $In(SCN)_3$ and $In(SCN)_4^-$. The present results also indicate larger stabilities of the thiocyanate complexes.

The stabilities of indium(III) complexes with the halate and halide ions increase with the increase in the basicity of the ligands, as is usually to be expected. The nitrate ion, which has a

planar structure, forms the least stable indium complex among those studied; this may be explained in terms of the decrease in the polarity under steric conditions.

The Solvent Extractions for the Determination of the Stability Constants. As the distribution ratios in this study were always determined radiometrically, it was supposed that the distribution ratios would be accurate enough when they were between 10^{-2} and 10^{2}; thus, only the data in this range were used for the calculation and the discussion. The TTA extraction method may be applied to almost all complex formation systems, because it can determine the concentrations of the uncomplexed metal ion, which should decrease even upon the formation of a very weak complex. This method, however, is not appropriate for higher complexes with larger stability constants because, in such cases, the uncomplexed metal concentration is very low and, consequently, the distribution ratio is too low for an accurate determination ($D<10^{-2}$). Statistically, it would be possible to determine the distribution even under those conditions if the concentration of the chelating extractant is increased or if the hydration ion concentration is decreased ($[HA]_{org}/[H^+]$ is increased).

However, it is not always practically possible to carry out the above method practically because the aqueous chelate is very often formed in the higher $[HA]_{org}/[H^+]$ range, thus causing a systematic error in the stability constants.[4] Therefore, we should always confirm the constancy of K_{ex_0} value, $D_0[H^+]^3[HA]_{org}^{-3}$, in the absence of the ligand throughout the $[HA]_{org}/[H^+]$ region to be studied.

As may be seen from Fig. 1, the slope of the $\log D$ *vs.* $-\log [H^+]$ plot is $+3$ when the $\log D$ is smaller than $+1$. Thus, from Eq. (9) an accurate determination of the stability constants by the TTA method is possible when $10^3<(1+\sum\beta_n\cdot[L^-]^n)$. This fact and the results in Figs. 3 and 4 show that the TTA method can be applied only when the ligand concentration is lower than about 0.2 M.

When only the TTA method was used, no formation constants of the higher complexes could be determined, as may be seen in Table 1-a.

On the other hand, as may be seen from Fig. 7, the TBP method can cover the higher ligand-concentration region, where the TTA method can not be applied.

Statistically, it would be also possible to determine the complexes in the lower ligand-concentration range by the TBP method. Under such conditions, the distribution ratio should be very low if the TBP concentration is kept constant, as may be seen from Fig. 7. However, as may be seen in Fig. 6, the extraction of the TBP adduct increases when the TBP concentration is increased, and the distribution ratio becomes higher; consequently, a measurable distribution ratio should be obtained even in the ligand concentration range by the use of a high TBP concentration. However, when the TBP concentration is higher, the extraction of mixed complexes, such as $InX_n(ClO_4)_{3-n}$ or of such ion-pairs as $Na^+InX_4^-$ might be effected.

In the present paper, the ligand-concentration ranges studied have been too wide to allow for an accurate determination by using only one of these two methods. Only the combination of the two methods has made it possible to determine reasonable sets of stability constants for many such complexes. The agreement of the results obtained by these two different methods, shown in Tables 1-a and 1-b, is good.

The author is very grateful to Professor Tatsuya Sekine, of the Science University of Tokyo, for this invaluable discussions and helpful suggestions. She is also grateful to Mr. Akira Kaneko for his experimental aid.

Studies on Associated Solutions. II. Heat of Mixing of Methanol with Aliphatic Amines

Koichiro NAKANISHI, Hidekazu TOUHARA and Nobuatsu WATANABE

Department of Industrial Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received November 19, 1969)

The heat of mixing has been measured at 25.00°C and 45.00°C for binary mixtures of methanol with *n*-butylamine, diethylamine and triethylamine. A twin-type conduction calorimeter was used. All the systems exhibit large negative enthalpies of mixing, which become slightly less negative as the temperature increases. From the present results and vapor-liquid equilibrium data, the excess free energy and entropy of mixing at 25.00°C have been calculated for each system. The sign and magnitude of the excess functions were as follows: $H^M < TS^E < G^E < 0$ for methanol with *n*-butylamine and diethylamine, $G^E > 0$, $TS^E < H^M < 0$ for methanol with triethylamine. These facts were interpreted in terms of steric effects and specific solvation in the hydrogen bonding between hydroxyl group and amino bases.

Since Barker's theory based on a lattice model appeared,[1] theories of associated solutions have been developed by Prigogine and Defay,[2] Kehiaian and Sonkowaska-Kehiaian[3], and Renon and Prausnitz.[4] The theories interpreted with considerable success the behavior of excess functions of some types of associated solutions, such as those composed by an associated liquid (*e.g.*, aliphatic alcohol) and a nonpolar liquid (*e.g.*, hydrocarbon, CCl_4). Although there remains much ambiguity as to the species, role and behavior of the associated complex, we can visualize these solutions as being useful as a basis for more elaborate theoretical treatment.

However, for the solutions in which both components are associated, we have at present no satisfactory theory nor important experimental information. If the modes of association in both components are similar to each other, we may expect nearly ideal behavior for their mixtures. Mixtures of two aliphatic alcohols are such examples.[5] On the other hand, the mixtures with components each having a different mode of association exhibit peculiar anomalies in their thermodynamic properties. Aqueous solutions of alcohol are typical examples of those systems which show much complexity in their structural and thermodynamic properties.[6] We can expect many other combinations of associated liquids to show similar anomalies hitherto not yet fully understood.

Apart from general interest in associated solutions, we have paid attention in particular to the thermodynamic properties of aliphatic amine+alcohol solutions. It was found that a positive deviation from the ideal solution occurs with a methanol+triethylamine (Et_3N) solution, while binary solutions of methanol with *n*-butylamine (*n*-$BuNH_2$) and diethylamine(Et_2NH) have negative excess free energies.[7] On the other hand, the infrared spectra[8] indicate that the N–OH interactions in these solutions are always stronger than those for H–OH. Thus the question arises as to why G^E is positive, in other words, which of H^M and TS^E is responsible for the unexpected behavior of tertiary amine. For an answer, it is necessary to measure the heat of mixing and combine the results with G^E data in order to obtain the excess entropy value.

In this paper, we will report the data for the heat of mixing in binary mixtures of methanol with above mentioned three aliphatic amines. Based on these data and the values in literature, we will discuss the relationship between the thermodynamic properties and steric effects in hydrogen bond.

Experimental

Materials. All the samples were purified from the purest products commercially available according to the methods described in literature.[9] They were distilled twice before use under nitrogen with a 30 plate fractionating column. The purified samples showed no trace of impurity peaks on a gas chromatogram. Mercury was shaken with samples and then distilled.

Apparatus and Procedures. A twin-type conduction calorimeter based on the principle developed first by Tian and Calvet was used.[10] The apparatus, originally produced as model CM-502 by Oyodenki Kenkyusho Co., Japan, was modified for the purpose of detecting a very small amount of heat change. The calorimeter is surrounded by adiabatic materials and fixed in a submarine vessel. The submarine vessel is installed in a water thermostat, the temperature of which is kept within ±0.005°C. The temperature change due to the mixing is detected by the difference in thermal electromotive force of the thermoelement between the mixing vessel and the reference one. The electric potential is amplified by a dc-ac amplifier, the output signal of which is fed to an automatic pen recorder. With the present amplifying system we could detect the change $\pm 1 \times 10^{-6}$ V. The maximum sensitivity is about 1.5×10^{-4}°C under the present conditions. The experimental procedure was similar to that described previously.[11]

Calibration of Apparatus. In order to check the accuracy of the calorimeter, the heats of mixing were measured for the benzene + carbon tetrachloride system at 25.00°C. The results are given in Fig. 1, together with those obtained by Larkin and McGlashan,[12] and fitted by the method of least squares to an equation of the type

$$H^M = x_1x_2[A + B(x_1 - x_2) + C(x_1 - x_2)^2 + D(x_1 - x_2)^3] \quad (1)$$

where H^M is the enthalpy of mixing, x is the mole fraction and A, B, C and D are constants. The values of the constants are given in Table 1. The standard and maximum deviations of the experimental points from Eq. (1) are 0.58 and −1.1 cal/mol, respectively. Table 1 and Fig. 1 indicate that there is a reasonable agreement between our results and those of Larkin and McGlashan within 3 percent for x_1=0.1—0.9.

Results and Discussion

Heat of Mixing. The data for the heats of mixing of binary solutions of methanol with n-$BuNH_2$, Et_2NH, and Et_3N at 25.00°C and 45.00°C are given in Tables 2 to 4 and are plotted in Fig. 2. The values of constants in Eq. (1) are given in Table 5, together with their estimated uncertainties δ, where x_1 refers to the mole fraction of methanol.

The results obtained in the present study together with a brief qualitative interpretation may be summarized as follows. 1) All the systems exhibit large negative enthalpy of mixing with the sequence of triethylamine, n-butylamine and diethylamine. The curves of H^M *vs.* x_1 (the mole

fraction of methanol) are slightly asymmetric, each having a minimum at about $x_1=0.6$. This is consistent with the postulate that H^M results from the contributions of two effects,[13] a positive one, due to the breaking of hydrogen bonds between alcohol molecules, and large asymmetrical negative one, due to the formation of hydrogen bonds between free alcohol and amine molecules. The latter is approximately symmetrical with respect to mole fraction.

2) There is a slight tendency for H^M to become less negative as the temperature increases, that is, the excess heat capacity C_P^E is small and positive. The order of magnitude for C_P^E is less than 3 cal/deg. mole. This fact is in contrast to the system of alcohols[14] or aliphatic amines[15] with nonpolar liquids for which the temperature dependence of H^M is fairly large. This suggests that the hydrogen bonding OH–N is somewhat stronger than the OH–H hydrogen bonding in alcohols or NH–N in amines and that moderately stable complexes between alcohol and amine are formed. In fact,

Lambert and Zeegers-Huyskens[16] have shown calorimetrically that there is a considerably large association energy for some aliphatic alcohols with aliphatic amines.

Other Excess Functions. The excess free energy of mixing has been calculated from isobaric vapor-liquid equilibrium data[8] by means of equations

$$\mu_1^E = RT \ln (y_1P/x_1P_1) + (P_1 - P)(V_1 - B_{11}) + 2P\delta B_{12}y_2^2 \quad (2)$$

$$\mu_2^E = RT \ln (y_2P/x_2P_2) + (P_2 - P)(V_2 - B_{22}) + 2P\delta B_{12}y_1^2 \quad (3)$$

$$G^E = x_1\mu_1^E + x_2\mu_2^E \quad (4)$$

In the present case, the correction factors due to the vapor phase imperfection can be neglected.[8] The G^E values at 25.00°C can be evaluated from these data, since the heat of mixing has been measured as a function of temperature. For this purpose, the Gibbs-Helmholtz equation was used in the form

$$(G^E/T)_{T_2} - (G^E/T)_{T_1} = -\int_{T_1}^{T_2} H^M dT/T^2 \quad (6)$$

The excess entropies of mixing at 25.00°C have been calculated from the analytically smoothed values of H^M and G^E.*1

The results for each system are shown in Figs. 3—5. We see that the sign and magnitude of excess functions are as follows: $H^M < TS^E < G^E < 0$ for methanol with *n*-butylamine and diethylamine, $G^E > 0$, $TS^E < H^M < 0$ for methanol with triethylamine. For all the systems, both H^M and S^E exhibit large negative deviations, while the absolute value of G^E is relatively small owing to the counterbalance of two contributions, H^M and TS^E.

On the other hand, a large volume contraction has been observed in methanol solution with aliphatic amines. The absolute values of excess volumes of mixing were in the increasing order of *n*-$BuNH_2$, Et_3N and Et_2NH.[17] This sequence is not same as that for H^M.

Steric and Solvation Effects on H^M. The above results reveal that the thermodynamic properties of MeOH+Et_3N solution are somewhat anomalous, that is, G^E becomes positive because the absolute value of TS^E is larger than that of

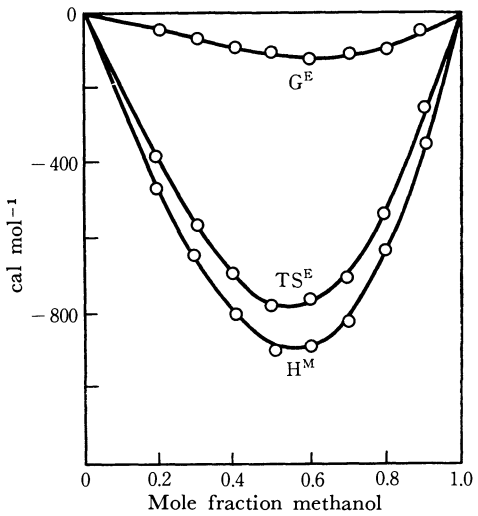

Fig. 3. Excess thermodynamic functions at 25.00°C: MeOH + *n*-$BuNH_2$.

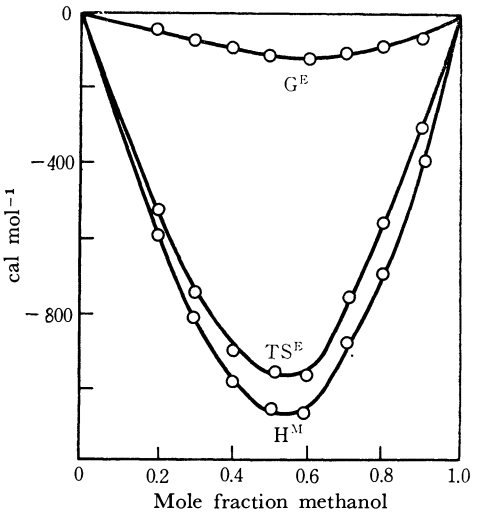

Fig. 4. Excess thermodynamic functions at 25.00°C: MeOH + Et_2NH.

H^M. In the following discussions, we will compare this with other evidences for the purpose of examining the effects of geometric characteristics on physical and chemical properties.

The specific interaction between alcohol and amine, which makes the values of H^M negative, is due to a strong hydrogen bond between hydroxyl and amino groups. This interaction can be considered as the reaction between alcohol as a Lewis acid and amine as a Lewis base. An absolute Lewis base strength of aliphatic amines may be measured by the ionization potential, I, and the acidic dissociation constant, p*Ka*. Kaufman and Koski[18] estimated the ionization potential of alipha-

16) L. Lambert and T. Zeegers-Huyskens, *J. Chim. Phys.*, **60**, 435 (1963).

*1 Strictly speaking, evaluation of S^E at 25.00°C should be made with the G^E values obtained at the same temperature. With lack of such data, we have used those at varying temperatures. However, for the present purpose of comparing the sign and the relative magnitude of excess functions, this may be justified since the excess heat capacity of the present system is very small as evident from Tables 2—4.

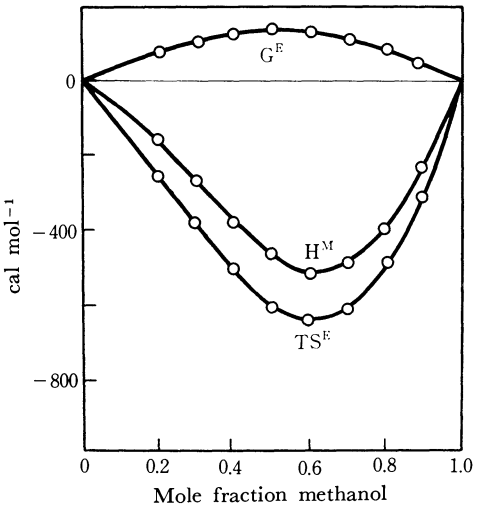

Fig. 5. Excess thermodynamic functions at 25.00°C: MeOH + Et_3N.

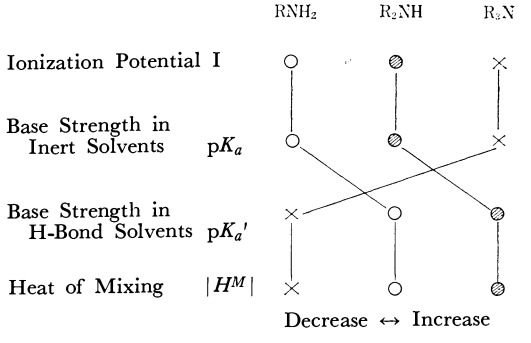
tic amines and defined the order as follows: $NH_3 < RNH_2 < R_2NH < R_3N$. The order is coincident with that for p*Ka* of aliphatic amines predicted by induced effect.

On the other hand, in hydrogen bonding solvents such as water or dioxane, the base strength or reactivity of amine with H^+ does not vary in the same manner.[19] We see that the order for this reactivity is in accordance with that for H^M obtained in the present work:



The phenomena, *viz.*, inversions of the sequence, have been ascribed to the steric strains and/or specific solvation effects.[20-22]

Brown *et al.*[23-25] have proposed that there should be two kinds of steric effect in determining the dissociation constant of amine. They defined them as B-strain and F-strain. The term, B-strain,[23] refers to the interference which is localized at the back of the molecule, and the term, F-strain,[24-25] refers to the repulsions due to the bulky alkyl groups in an ion pair. In the present case, rather bulky ethyl groups attached to the small nitrogen atom in Et_3N molecule tend to repel each other. This sets up the B-strain which reduces the stability of the hydrogen bonded complex, but co-ordination of an acidic proton of alcohol with the nitrogen atom of Et_3N does not cause an appreciable F-strain. Thus a certain amount of B-strain may be responsible for the relative decrease of alcohol-tertiary amine interaction, and the negative contribution to H^M will become smaller.

Another important factor which might influence H^M is the specific solvation. The amino hydrogen is considered to be a weak acidic proton, and co-ordinates to oxygen atom of alcohol. The interaction due to solvation is not as large compared with hydrogen bonding between hydroxyl group and amino bases, but it would affect the stability of hydrogen bonded complexes to some extent. Since tertiary amine has no acidic proton, its proton accepting ability is exceedingly small in comparison with that of primary or secondary amine. Thus, the two effects might be responsible for the smaller H^M of alcohol with tertiary amine system, though it is impossible to determine the dominant factor. Since no inversion in the order between R_2NH and RNH_2 is observed, steric and other effects for these two kinds of amine may be negligible.

The negative contribution discussed above is even larger than positive contributions due to the break-up of self-association of both components. In the present case, the contribution due to the break-up of alcohol structure is common to all the systems. A possible positive contribution due to the break-up of amine association should be proportional to the amino hydrogen contact number.[26] Since this contribution is negligible for Et_3N, the H^M value with Et_3N is expected to become more negative. The fact that this is not the case furnishes another support to the above interpretation.

There have been many works on the steric effects of hydrogen bonding in sterically hindered alcohols and phenols.[27-30] The low equilibrium constants of self-association have often been as-

cribed exclusively to entropy factors. In the present case where the alkyl groups attached to nitrogen atom are not too bulky, an enthalpy factor seems to be responsible for anomalous behavior of excess functions.

The authors thank Mr. Isao Matsumoto for his assistance in some of the experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2676—2679 (1970)

The Dipole Moments of α,ω-Alkanediols

Yoshio Toshiyasu,*1 Ko Kimura*2 and Ryoichi Fujishiro*2

Science Education Institute of Osaka Prefecture, Sumiyoshi-ku, Osaka

(Received January 24, 1970)

The electric dipole moments of α,ω-alkanediols such as HO-$(CH_2)_n$-OH (n being varied from 2 to 5) were measured both in dioxane and in a mixed solvent of dioxane with carbon tetrachloride at 25°C. The observed dipole moments increase with the increasing n until $n=4$, and then decrease for $n=5$, while the calculated dipole moments based on the vector addition of group moments on the assumption of the random coil model for alkane chains increase monotonously as n increases from 2 to 5. It is concluded that for both propanediol and butanediol the conformations forming the intramolecular hydrogen-bond which have the larger dipole moments contribute appreciably to the observed dipole moments. The dipole moment of pentanediol is close to the calculated one for the random coil model, whereas that of ethylene glycol suggests the existence of the intramolecular hydrogen-bond. Population analysis of the hydrogen-bonded species in solutions is also given.

The electric dipole moments of molecules with multiple degrees of freedom of internal rotation were already discussed.[1] Recently, the anomalous dipole moments of 1,4-dichlorobutane or 1,4-dibromobutane were reported by Thompson and Hanson,[2] and led to the conclusion that the steric hindrance between two halogen atoms attached at the end positions of the aliphatic chain excludes some of the conformations which have larger dipole moments. The dipole moments of these compounds are, therefore, anomalously small.

When the two halogen atoms in 1,4-dihalogenobutane are replaced by hydroxy groups, the intramolecular hydrogen-bond may be formed. Study of the intramolecular hydrogen-bonding in solutions is carried out extensively by help of the infrared absorption spectra, but α,ω-alkanediols dissolve scarcely in solvents commonly used in the infrared absorption study. Nevertheless, the formation of the intramolecular hydrogen-bond for some of α,ω-alkanediols in solutions is inferred from the infrared absorption[3] or from NMR spectra[4] by making suitable device. It is interesting and valuable to investigate the intramolecular hydrogen-bond in mixed solvents from the view point of dipole moments.

In this paper, the electric dipole moments of α,ω-alkanediols such as HO-$(CH_2)_n$-OH (n being varied from 2 to 5) are measured and discussed in connection with the intramolecular hydrogen-bonding.

Experimental

All the alkanediols used in this work were purified by the fractional distillation through a 100 cm column packed with stainless-steel helices, dried over molecular sieves and distilled in vacuum. Dioxane used as a solvent was refluxed over fresh sodium for a few days and distilled through the same column as that just mentioned. A mixed solvent of dioxane with carbon tetrachloride was also used, when necessary. Carbon tetrachloride was purified by shaking it with alcoholic sodium hydroxide, dried, and then distilled through

the same column.[5]

Measurements of the dielectric constants, ε's and the specific volumes, ρ's were carried out by the same apparatus and method as in the previous work.[6] All the data were obtained at 25±0.02°C. In the present investigation, the weight fractions, w's of solutes range over from zero to about 0.02.

Results

The observed values of ε's and of ρ's are fairly well expressed by the linear equations of w's. The molecular polarizations, p's were obtained from these experimental data according to Halverstadt-Kumler's method.[7] The molecular refractions, R_D's for the sodium D line were calculated on the assumption of the additivity of bond refractions, and distortion polarizations were assumed to be equal to $1.05\times R_D$. The polarization values and the observed dipole moments, μ's are tabulated in Table 1, together with the linear equations of ε's and ρ's to w's. Data for ethyl alcohol are also given in Table 1.

* A mixed solvent is composed of one volume of dioxane and two volumes of carbon tetrachloride.

** Measurements were carried out not in the mixed solvent but in both dioxane (the left column) and benzene (the right column).

Discussion

The mean square dipole moment, $\overline{\mu^2}$ of α,ω-disubstituted alkanes can be written on the assumption of the vector addition as

$$\overline{\mu^2}=\mu_1^2+\mu_n^2+2\overline{(\vec{\mu}_1\cdot\vec{\mu}_n)} \quad (1)$$

where $\vec{\mu}_1$ and $\vec{\mu}_n$ mean moment vecotrs of polar groups located at the both ends, and μ_1 and μ_n scalar quantities of $\vec{\mu}_1$ and of $\vec{\mu}_2$, respectively. The third term of Eq. (1) in the right hand side may be easily calculated by the use of transformation matrix.[8] The coordinate system is chosen as

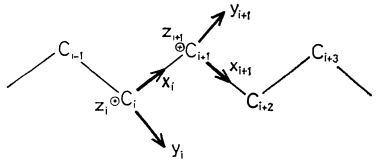

Fig. 1. The coordinate system.
⊕ Upwards from the plane
⊙ Downwards from the plane

follows, which is depicted in Fig. 1: the x_i axis of the origin C_i is taken in the direction of C_i-C_{i+1} bond of a chain, the z_i axis in the direction of the vector product of C_i-C_{i+1} and C_{i-1}-C_i, and the y_i axis in the direction to constitute the right-handed coordinate system. The coordinate system of the origin C_{i+1} is chosen in the same way as already mentioned. The transformation from the coordinate system$(x_{i+1}, y_{i+1}, z_{i+1})$ to (x_i, y_i, z_i) is carried out by help of the following transformation matrix:

$$T_{i,i+1}=\begin{pmatrix}\cos\chi & \sin\chi & 0\\ \sin\chi\cos\varphi_i & -\cos\chi\cos\varphi_i & -\sin\varphi_i\\ -\sin\chi\sin\varphi_i & \cos\chi\sin\varphi_i & -\cos\varphi_i\end{pmatrix} \quad (2)$$

where the valence angles$(\pi-\chi)$ are assumed to be tetrahedral, and φ_i is an angle of the internal rotation measured from the *trans*-form about C_i-C_{i+1} bond. The successive operation of this transformation on the third term of Eq. (1) gives

$$\overline{\mu^2}=\mu_1^2+\mu_n^2+2\overrightarrow{\mu_1(T_{1,2}\cdots\cdots T_{n-1,n})\mu_n}. \quad (3)$$

If all the internal rotations are free, the mean square dipole moment of α,ω-alkanediol becomes independent on φ_i's, and is given by[1]

$$\overline{\mu^2} = 2\mu_1^2(1-\cos^2\theta\cos^n\chi) \quad (4)$$

where μ_1 is the magnitude of the moment vector $\vec{\mu}_1$ for a HO-C group and is assigned to be 1.77D[1),9)] and θ is an angle between the moment vector $\vec{\mu}_1$ and the position vector, $\overrightarrow{C\text{-}O}$ bond and is equal to 62°. Dipole moments calculated by the use of Eq. (4) are summarized in Table 2, together with those obtained from Eq. (3) by assigning appropriate angles to φ_i's, which are determined by the intramolecular hydrogen-bonded conformations. Tables 1 and 2 show that the observed dipole moments increase with the increasing n until n=4, and then decrease for n=5, whereas the calculated moments on the assumption of the random coil model increase monotonously, as is expected from Eq. (4), when n increases from 2 to 5. This phenomenon is observed remarkably in the mixed solvent of dioxane with carbon tetrachloride, as is shown in Table 1. Agreement between the observed value and the calculated average one is good only for n=5 irrespective of solvents used in this research. If it is assumed that the vector addition of group moments is valid even for the hydrogen-bonded system, a pentanediol molecule forms no intramolecular hydrogen-bond at all in solutions. This result is supported by the infrared absorption spectra,[3)] and also by NMR spectra.[4)] On the contrary, the observed dipole moments for 1,3-propanediol and for 1,4-butanediol are larger than the calculated average moments. Difference between the calculated average moment and the calculated moment for the intramolecular hydrogen-bonded conformation amounts to about 1D for the former and to about 0.5D for the latter. Small but not negligible increase of the observed dipole moments over the calculated average moments is due to the appreciable contribution of the intramolecular hydrogen-bonded conformations to the observed dipole moments. The same kind of research as mentioned above was carried out recently by Toshiyasu and Fujishiro[10)] both for 1,3-dimethoxypropane or 1,4-dimethoxybutane and for monomethyl ether of 1,3-propanediol or 1,4-butanediol, although the former corresponds to the case of α, ω-dihalogenoalkane reported by Thompson *et al.*,[2)] and the latter to the present research. Hence, it is possible to infer the existence of the intramolecular hydrogen-bond in solutions from measurements of dipole moments together with the calculations of dipole moments based on the vector addition of group moments both for the random coil model and for the intramolecular hydrogen-bonded conformations. The intramolecular hydrogen-bond for ethylene glycol in solutions was confirmed by the infrared absorption spectra, but any information can not be obtained from dipole moment data, as is seen from Table 2.

Table 2. Calculated dipole moments

	The average moment μ_r (the random coil model)	The moment for the intramolecular hydrogen-bond conformations* μ_h	
$n=2$	2.47D	TGG' (TG'G)	2.51D

$n=4$	2.49	TGG'GG' (TG'GG'G)	3.06
		GGG'GG' (G'G'GG'G)	
$n=5$	2.50		

* T and G represent *trans*- and *gauche*-form, respectively.

Population analysis of rotational isomers in solutions is performed by the help of the theory of chemical equilibrium. According to the statistical thermodynamic treatment of associated solutions by Saroléa-Mathot,[11)] the partition function Ω is given by

$$\Omega = \phi_a^{N_a}\phi_d^{N_d}\phi_c^{N_c}\frac{(x-z-u+N_d+N_c)!}{x!y!z!u!v!(N_d-y-2\cdot z-v)!N_c!} \times \exp[-1/kT\{x_1f_1+x_2f_2+x_3f_3 + (y+2\cdot z+v)\Delta E_{\mathrm{I}} + (u+v)\Delta E_{\mathrm{II}}\}] \quad (5)$$

where ϕ_a, ϕ_d, and ϕ_c represent the internal partition functions of alkanediols, dioxane and carbon tetrachloride, respectively, and N_a, N_d, and N_c are the number of molecules corresponding to each suffix. The total number of molecules for alkanediols, N_a is divided into five molecular species, that is,

$$N_a = x + y + z + u + v$$

where x is the number of molecules with the free hydroxy groups without any hydrogen-bond, y the number of molecules with one free hydroxy group and the other hydrogen-bonded with dioxane, z the number of molecules with both hydrogen-bonded with dioxane, u the number of molecules with one free hydroxy group and the other forming the intramolecular hydrogen-bond, and v the number of molecules with one hydrogen-bonded with dioxane and the other forming the intramolecular hydrogen-bond. Interaction parameters f_1, f_2, and f_3 are defined as follows:

9) In order to confirm the value assigned by Smyth, the dipole moment measurement for ethyl alcohol was carried out in the same condition as that for α, ω-alkanediols. The observed value is fairly close to that given by Smyth, as is shown in Table 1.

10) Y. Toshiyasu and R. Fujishiro, to be published.

11) L. Saroléa-Mathot, *Trans. Faraday Soc.*, **49**, 8 (1953).

$$\left.\begin{aligned} f_1 &= f_{cd} - 1/2(f_{cc}+f_{dd}) \\ f_2 &= f_{ad} - 1/2(f_{dd}+f_{aa}) \\ f_3 &= f_{ac} - 1/2(f_{cc}+f_{aa}) \end{aligned}\right\} \quad (6)$$

where f_{ij} is the interaction energy due to dispersion force between two contact molecules i and j. The quantities x_1, x_2, and x_3 represent the number of contact pairs corresponding to each suffix. ΔE_{I} and ΔE_{II} are energies of the intermolecular hydrogen-bond and of the intramolecular hydrogen-bond, respectively. Equality of the chemical potentials of all species in the equilibrium state gives equilibrium concentrations of all species as functions of ΔE_{I}, ΔE_{II}, and $C=N_d/(N_d+N_c)$. On the assumption ($N_a \ll N_d$ or N_c) in dilute solutions, one obtains

$$\left.\begin{aligned} x &= N_d/[1+\exp(-\Delta E_{\mathrm{II}}/\boldsymbol{k}T) + C\cdot\exp(-\Delta E_{\mathrm{I}}/\boldsymbol{k}T) \\ &\quad \times \{1+\exp(-\Delta E_{\mathrm{II}}/\boldsymbol{k}T)\}+C^2\cdot\exp(-2\cdot\Delta E_{\mathrm{I}}/\boldsymbol{k}T)] \\ y &= N_d/[1+\exp(-\Delta E_{\mathrm{II}}/\boldsymbol{k}T) + 1/c\cdot\exp(\Delta E_{\mathrm{I}}/\boldsymbol{k}T) \\ &\quad \times \{1+\exp(-\Delta E_{\mathrm{II}}/\boldsymbol{k}T)\} + c\cdot\exp(-\Delta E_{\mathrm{I}}/\boldsymbol{k}T)] \\ z &= N_d/[1+1/c\cdot\exp(\Delta E_{\mathrm{I}}/\boldsymbol{k}T)\{1+\exp(-\Delta E_{\mathrm{II}}/\boldsymbol{k}T)\} \\ &\quad + 1/c^2\cdot\exp(2\cdot\Delta E_{\mathrm{II}}/\boldsymbol{k}T)\{1+\exp(-\Delta E_{\mathrm{II}}/\boldsymbol{k}T)\}] \\ u &= N_d/[1+\exp(\Delta E_{\mathrm{II}}/\boldsymbol{k}T)+c\cdot\exp(-\Delta E_{\mathrm{I}}/\boldsymbol{k}T) \\ &\quad \times \{1+\exp(\Delta E_{\mathrm{II}}/\boldsymbol{k}T)\} \\ &\quad + c^2\cdot\exp\{(\Delta E_{\mathrm{II}}-2\cdot\Delta E_{\mathrm{I}})/\boldsymbol{k}T\}] \\ v &= N_d/[1+\exp(\Delta E_{\mathrm{II}}/\boldsymbol{k}T) + 1/c\cdot\exp(\Delta E_{\mathrm{I}}/\boldsymbol{k}T) \\ &\quad \times \{1+\exp(\Delta E_{\mathrm{II}}/\boldsymbol{k}T)\} \\ &\quad + c\cdot\exp\{(\Delta E_{\mathrm{II}}-\Delta E_{\mathrm{I}})/\boldsymbol{k}T\}] \end{aligned}\right\} \quad (7)$$

Then, the observed dipole moments are approximately given by

$$\mu^2_{\mathrm{obs}} = (x+y+z)\mu_r^2 + (u+v)\mu_h^2 \quad (8)$$

where μ_r and μ_h represent the average dipole moment for the random coil model and that for the intramolecular hydrogen-bonded conformation, respectively, which are given in Table 2. When ΔE_{I} is assigned to be -4 kcal/mol,[12] a value of ΔE_{II} for $n=3$ and that for $n=4$ are -2.2 kcal/mol and -2.9 kcal/mol, respectively, each of which is close to already reported value[13], *i.e.*, -2.1 kcal/mol for $n=3$ and -2.7 kcal/mol for $n=4$. Population analysis in solutions was performed by using these energy values. Table 3 gives the equilibrium concentrations of all species present in solutions. This table is suggestive in giving information about what kind of molecular species is predominant in a solvent: for $n=3$, the species v is scarcely present in pure dioxane, but for $n=4$, it amounts to about 13% even in pure dioxane, and the amount of species v becomes significant in a mixed solvent(1 volume dioxane to 2 volumes carbon tetrachloride) both for $n=3$ and for $n=4$.

Table 3. Mole fractions of species present in solutions

		x	y	z	u	v
$n=3$	Dioxane	0	0.001	0.953	0	0.046
	A mixed solvent	0	0.003	0.880	0	0.117
$n=4$	Dioxane	0	0.001	0.865	0	0.134
	A mixed solvent	0	0.002	0.696	0.001	0.301

In conclusion, dipole moment study makes it possible in some cases of α,ω-alkanediols to confirm the existence of the intramolecular hydrogen-bonded species and to do population analysis of all species in solutions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2680—2689 (1970)

Kinetic Studies of Adsorbed Films of Tritium-labelled Sodium Stearate at the Air/Water Interface

Tsutomu SEIMIYA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received January 30, 1970)

The adsorption of tritium-labelled sodium stearate at the air/water interface was directly measured radiometrically using an ultra-thin-windowed Geiger-Müller tube for varying soap concentrations, pH values, and temperatures. The changes in the amount of adsorption and in the surface tension were simultaneously traced with the lapse of time. The pressure-area curve was then obtained by the successive plotting of the surface pressure against the area at the same aging; the curve at equilibrium was also obtained. Thus, the pressure-area relationship of the adsorbed monolayer was automatically measured during the course of adsorption approaching equilibrium. A close resemblance was observed between the monolayer of stearic acid on neutral water and the adsorbed films on the stearate solution of pH values from 8.85 to 9.30 at 30°C. The amount of adsorption measured for an alkaline solution often exceeds the value to be expected from the saturation value for a completely-ionized stearate monolayer. The pressure-area characteristics suggested a transition from the condensed state of the adsorbed film at a higher surface concentration to an expanded state at a lower concentration. It was also confirmed, by measuring the amount of adsorption in the atmospheres of both nitrogen and air containing carbon dioxide, that the atmospheric carbon dioxide acts to increase the adsorption of stearic acid on the aqueous surface. The diffusion coefficient of the adsorbing solute, calculated from the initial rate of adsorption, showed a smaller value than that obtained by conductometric measurements.

A number of investigations have been presented by many workers into the properties of adsorbed monolayers at both air/water and oil/water interfaces. Efforts have also been made to obtain the pressure-area relationship for the adsorbed monolayers of soluble, surface-active substances. In some of these studies, a monolayer was spread on an aqueous surface,[1,2] and from the observed surface pressure changes against the time, the surface pressure extrapolated to time zero was plotted against the area per molecule, assuming that no molecule was lost by desorption or evaporation.

In other studies the pressure-area relationships were obtained by spreading the film substances on aqueous substrates that contained excess salt, thus preventing the desorption of film molecules by decreasing the solubility of the film substance.[3-8] These methods may be convenient and easy to practise for the study of the soluble monolayer, but at the same time they involve several disadvantages. The major disadvantages exist in using a sufficiently concentrated solution of inorganic salt and/or a solution of a restricted pH as a substrate, especially for a monolayer of an ionizable nature. Another question is an uncertainty arising as to the amount of film substances remaining on the surface. For the theoretical treatment of the adsorbed film, it is also necessary to have exact knowledge regarding the dissolved state of the solute, which may suffer from hydrolysis or association.

In the present report, pressure-area studies were made for the soluble, adsorbed films of tritium-labelled sodium stearate, the amounts being determined directly by the radiotracer method. The pressure-area characteristics at the air/water interface have been investigated under various conditions of the substrate pH, solute concentration, and temperature. The results have then been discussed from both kinetic and equilibrium aspects.

Experimental

The Effect of Evaporation on the Surface Concentration. One of the major troubles encountered

in the study of the properties of the air/water interface is the evaporation of a solute or solvent from the solution surfaces. This evaporation affects the surface properties of liquid in a complicated manner by lowering surface temperature[9] and changing the surface concentration.[10] The first change subsequently changes other surface properties, such as the surface tension, and disturbs the system by promoting the convection current. The change in the concentration of a solute near the surface of the solution depends on a dynamic equilibrium between the rate of evaporation and the convection current occurring near the surface of the liquid. Preliminary radiotracer experiments have proven that only 60 seconds' exposure of the surface of an aqueous solution containing a 1.97×10^{-3} mol/l surface inactive sodium sulfate to an atmosphere of 40% relative humidity at 20°C without any air current produced the accumulation of a solute which is shown in Table 1. The accumulation was detected by the increase in the surface count rate of beta-rays from ^{35}S, with which Na_2SO_4 was labelled. The changed count rate was soon restored to its original value by suppressing the evaporation. Simple calculation shows that the amount of surface-concentration increase is about 50% of the amount of the maximum adsorption of such commonly-used surfactants as sodium dodecyl sulfate. Thus, it can be demonstrated that even a slight evaporation produces a serious error in the measurement of the properties concerning the liquid surface. Great care to prevent evaporation was taken in the present study by placing the trough containing the solution for study in a compact enclosure saturated with water vapor, as will be described later.

Table 1. Effect of evaporation of water on surface concentration of aqueous Na_2SO_4 solution

	Surface	Surface count rate (cpm)	Mean
1	Measured after 240 secs' stirring without evaporation	6460 6530 6530 6415 6510 6600	6518±81 ±1.24%
2	After 60 secs' exposure to open air	6760 6590 6600 6710 6740 6690 6860	6707±82 ±1.22%
3	After suppressing the evaporation of the above surface 2	6550 6510 6550 6460	6519±81 ±1.24%

$Na_2{}^{35}SO_4$: 1.97×10^{-3} mol/l
Specific activity: 1.09×10^{-12} mol/cpm. cm²
Room temperature: 20°C
Humidity of the atmosphere: 40% R.H.

Measurement of Tritium Radioactivity from an Aqueous Surface. The extremely soft beta-radiation is best suited for surface analyses, as has been mentioned above; unfortunately, however, the softness itself renders the detection of tritium very difficult.

Here, a windowless gas-flow 2π counter is generally used because of its high counting efficiency[11], as in the study of the adsorption of tritium-labelled sodium dodecyl sulfate[12] on an aqueous surface. In this case, however, the aqueous surface was inevitably exposed to hydrocarbon counting gas and to a high electrical field applied for the measurement of radioactivity.[13] To avoid such disturbances, we attempted to measure the tritium beta-radiation using an end-windowed Geiger-Müller counter tube equipped with a thin polycarbonate window. A thin film of polycarbonate was prepared by the following procedure,[14] The polycarbonate was dissolved in an equi-volume mixture of dioxane and ethylene dichloride up to 0.4 % and was then spread on a clean glass plate with an optically-flat surface, using a glass applicator composed of two glass rods tightly bound together with steel wire which determined the thickness of the liquid film. After slowly evaporating the solvent, the deposited film was removed and transferred on the water surface by immersing the plate in water. The thin film, floating on the aqueous surface was scooped up with a steel ring, treated with an aqueous polyvinyl alcohol solution in order to fill up the pinholes inevitably formed in the film, and dried at 100°C. After the vacuum deposition of gold on one side of the film, the film was fixed to an attachment grid with a 75% opening. The thin film thus prepared and attached to the end-windowed Geiger-Müller tube (type FC-16, Japan Radiation and Medical Electronics, Inc.) proved successful for the measurement of the soft beta-radiation of tritium from aqueous surfaces, a measurement which had hitherto been impossible with the ordinary Geiger-Muller tube with a thick window. The optimal thickness of the polycarbonate film used was 15—20 $\mu g/cm^2$. The overall counting efficiency attained for tritium was 9% of that obtained by using a windowless gas-flow 2π counter when polyvinyl alcohol-treated polycarbonate windows of 17.5 $\mu g/cm^2$ were used at a distance of 1 mm from an infinitely thin tritium sample in air. Further, th film proved to suffer no perceptible change in counting efficiency over several months. The details of the method of preparation and the properties of the film may be found in a former report.[14]

The Trough and Surface Balance. The surface tension of the aqueous sodium stearate solution was measured by a self-recording Wilhelmy-type surface balance[15]; the surface radioactivity was simultaneously measured. The apparatus is shown in Fig. 1. A Teflon trough ($120\times61\times5.6$ mm) was put in a jacket

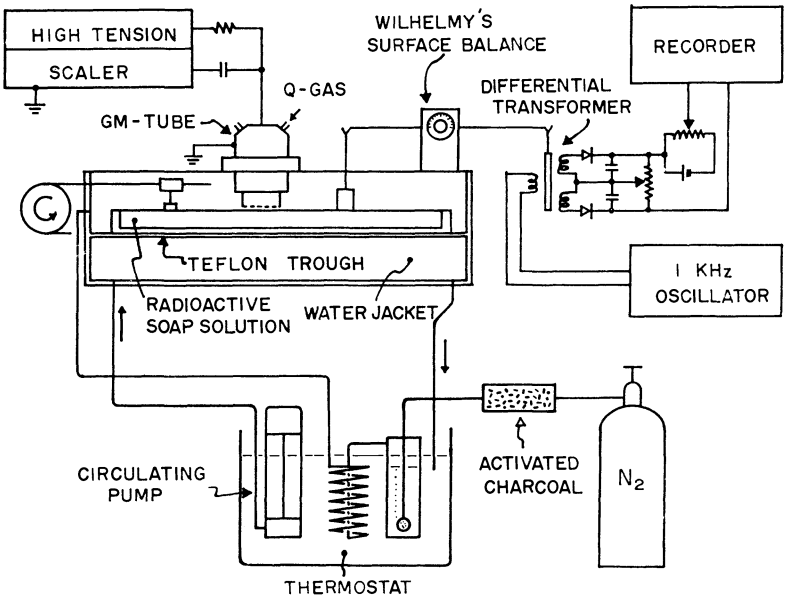

Fig. 1. Apparatus for simultaneous measurements of amount of adsorption and surface tension.

box, and the temperature of the solution in the trough was kept constant by the circulation of thermostatted water through the jacket surrounding the trough. The evaporation of water from the aqueous surface was prevented by slowly introducing nitrogen gas saturated with water vapor into the space above the trough. The radioactivity and surface-tension measurements were started just after the sweeping of the surface by a Teflon barrier which could be operated outside the lagged box. The Wilhelmy surface balance was equipped with a differential transformer (type DS-36-LM, Shinkoh Electric Works, Tokyo) which converted the minute displacement of the hanging plate to a proportional electrical output.[15] The primary input for the differeytial transformer was supplied by a 1-kHz oscillator. The output was then rectified and recorded by means of a Hitachi QPD 33 recorder after an appropriate application of bias voltage in order to put the desired part of the surface-tension change into the range of the recorder scale. Thus, the surface tension change could be recorded within an accuracy of ± 0.09 dyne/cm.

Materials. The tritium-labelled sodium stearate used was prepared[16] by dissolving tritium-labelled stearic acid[17] (specific activity, 7 Ci/mol) in absolute alcohol freshly distilled over sodium hydroxide; an amount of sodium hydroxide slightly less than that required for the neutralization of the acid was added as an alcoholic solution. The soap solution thus prepared was evaporated to dryness in vacuo, and the residue was washed with benzene to remove excess stearic acid by using a Soxhlet extractor. The water used in this experiment was obtained by first refluxing distilled water in an alkaline permanganate solution for 24 hours, and by then distilling it three times from a Hysil flask. The carbon-dioxide contamination from the air was removed by boiling the water for about ten minutes and then cooling it in a nitrogen atmosphere. The supernatant solution of saturated aqueous sodium hydroxide, after being centrifuged, was used to control the pH of the stearate solution.

Procedures. The conversion factor used for calculating the amount of adsorption from the observed counting rate was obtained by measuring the counting rate of a known amount of a radioactive stearic acid monolayer spread on the water surface. For this purpose, tritium-labelled sodium stearate was spread on distilled water from a 2.40×10^{-4} mol/l benzene solution by means of a microsyringe. At a low surface concentration, the heterogeneity of the monolayer and its time dependence were usually observed.[16] However, when left standing at 20°C for at least several hours, the film became homogeneous and the time dependence practically disappeared as far as the surface radioactivity was concerned. As the surface concentration increased, the surface film became more homogeneous and the time effects disappeared. The counting rate versus surface concentration curve was obtained from radioactivity measurements made at various surface concentrations by means of the compression and expansion of the monolayer. A linear relationship was confirmed within the limits of counting errors. For the measurement of the adsorption of sodium stearate at the air/water interface, a radioactive sodium stearate solution with a $1.0—5.0\times10^{-5}$ mol/l concentration was put in the Teflon trough used in the monolayer measurement, and the counting of the surface radioactivity was started immediately after the sweeping of the surface by the barrier. The bulk-count rate should be subtracted from the total count rate observed to give the surface radioactivity due to the adsorption of stearate at the air/water interface. In this experiment, the bulk-count rate was comparable to the background, so it was negligibly small compared with the total count rate. This

16) K. Sekine, T. Seimiya and T. Sasaki, This Bulletin, **43**, 629 (1970).

17) M. Muramatsu and T. Sasaki, *Radioisotope*, **10**, 100 (1961).

can reasonably be expected from the extremely low concentration of the solution used and the small range of beta-rays, about 1 micron in water. It is also confirmed by the fact that, for some solutions, the surface count rate at the initial stage of adsorption is comparable to that of the background. Therefore, the bulk-count rate can safely be neglected within the limits of counting error in the present experiment. The pH of these solutions was kept constant (within +0.1) throughout the experiment by keeping the trough in a humidified nitrogen atmosphere and by avoiding the dissolution of carbon dioxide from the air. The measurements were carried out at both 40°C and 30°C for the solutions with pH values from 8 to 11, and at concentrations from 1 to 5×10^{-5} mol/*l*.

Results and Discussion

Effect of Propane Gas. As for the measurement of tritium radioactivity using windowless gas-flow 2π counter mentioned above,[13] the aqueous surface must be exposed to the propane gas, and an appreciable change in the adsorption of the surface-active agent can subsequently be expected to occur. In this connection, the surface tension was measured for the aqueous sodium dodecyl sulfate solution in atmospheres of both nitrogen and propane gas. The results are shown in Fig. 2. In this figure, a remarkable drop in surface tension was observed upon the introduction

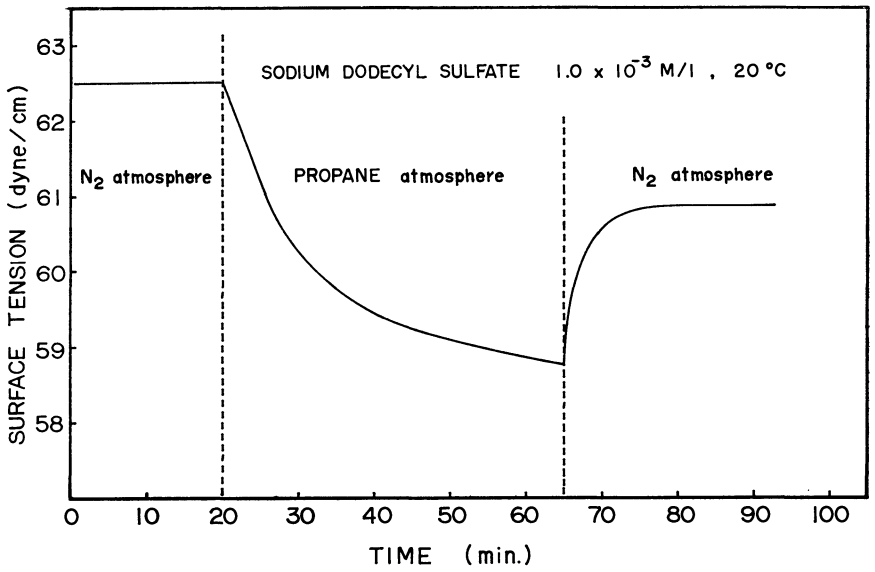

Fig. 2. Effect of propane gas on surface tension of aqueous sodium dodecylsulfate solution.

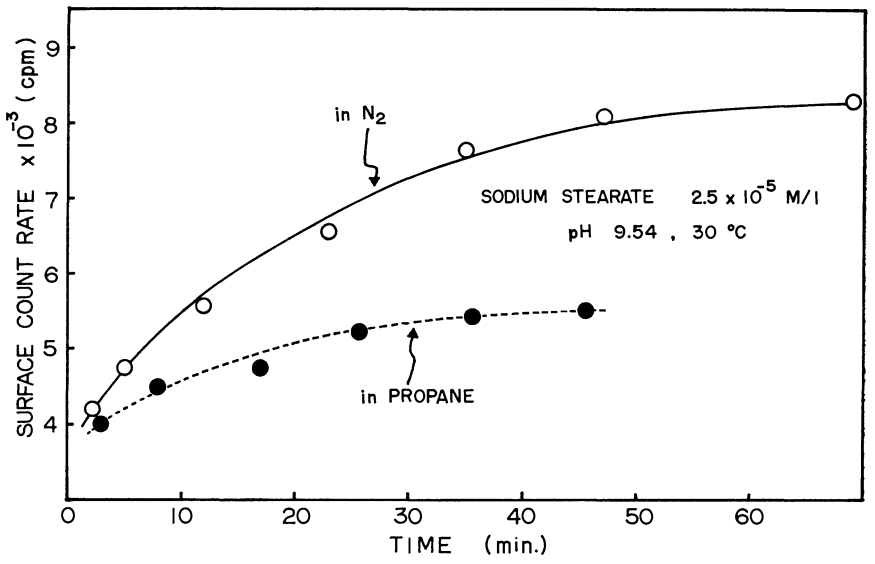

Fig. 3. Effect of propane gas on adsorption of sodium stearate at aqueous surface.

of propane gas to the aqueous surface of the sodium dodecylsulfate solution. The original value was only partially recovered by flushing the propane out with nitrogen. The effect of propane gas on the adsorption was further examined for the aqueous sodium stearate solution, as is shown in Fig. 3. An appreciable difference in the amount of the adsorption of stearate can be seen between the propane/water and nitrogen/water interfaces. The adsorption of stearate is lower for the propane/water interface than the nitrogen/water one, presumably because of the formation of a mixed film of stearate and propane at the aqueous surface, as was to be expected from the surface tension lowering shown in Fig. 2. The dissolution of propane into the aqueous stearate may also be expected to affect the stearate adsorption, although no tacit proof was found in this experiment. These experiments clearly show the considerable influence of atmospheric propane gas upon the adsorption of soap at the air/water interface.

Kinetic Aspects of Adsorpsion. Typical examples of the simultaneous measurement of the surface tension and the amount of adsorption at 30 and 49°C are presented in Fig. 4. The surface tension decreases and the amount of adsorption increases with the lapse of time. An amount of adsorption of about 8.5×10^{-10} mol/cm^2, nearly equal to that corresponding to the closely-packed monolayer of stearic acid, can be seen for the adsorption curve at 30°C. The surface tension curve in its early stage of aging, within 10 min, exhibits a gradual change which indicates the expanded nature of the adsorbed film at this stage. This tendency is more pronounced for the solution with a lower temperature (Fig. 4), pH (Fig. 5), and soap concentration (the third factor is not shown in the figure); the initial plateau appears in the surface tension, though a considerable increase in the amount of adsorption with time occurred during this stage. From the observed adsorption rate at an early period of aging, the diffusion coefficient of the solute can be calculated according to the equation of Ward and Tordai,[18] assuming the rate-determining process of adsorption to be the diffusion of the solute from the bulk to the sublayer of the surface, and assuming that the electrostatic potential barrier does not affect the diffusion practically in this early period of adsorption. The diffusion coefficient was calculated by the following equation;

$$\left(\frac{d\Gamma}{dt}\right)^2\cdot\frac{\pi t}{C_0^2}=D$$

where Γ denotes the amount of adsorption at time t, C_0 the bulk concentration of solute, and D, the diffusion coefficient. The observed D values for various C_0 and pH values at various temperatures are listed in Table 2, along with the values obtained by various other workers.[19-22] Although no comparison can be made between these data in a strict sense, it can at least be noted that the

results of the present experiment are comparatively direct and accurate as far as the diffusion to the surface is concerned. There is also a tendency for the D value for a stearate to decrease with an increase in the solute concentration C_0. This presumably due to the effect of the electrostatic barrier assuming some importance.

Concentration Dependence of the Adsorpsion and Surface Tension. From these time-dependent curves of the surface tension and adsorption for various concentrations of stearate at a constant temperature and pH, equilibrium values were obtained; they are plotted against the concentration in Fig. 6. The adsorption isotherm appears step-by-step, on the whole, and shows two plateaus. The amount of adsorption in the lower concentration region is about one-third of that in the higher concentration region. The former corresponds closely to the state of saturation of the ionized monolayer,[23] while the latter corresponds to that of stearic acid. Such a step-by-step adsorption may presumably be interpreted as the superposition of two isotherms for species differing in the area of surface occupation, such as a stearate ion and a stearic acid molecule, the latter being the hydrolysis product of a stearate in the solution. The stearate ion, requiring a larger area, is predominant in the low concentration region, while the stearic acid molecule, with a smaller molecular area, appears in the higher concentration region at constant pH. Although the amount of stearic acid adsorbed is not in agreement with that expected from the bulk hydrolysis calculated by using the ordinary pK of the stearate, the discrepancy may be explained by the difference in pK between the bulk and the surface, or by the adsorption of some surface active associates between stearate and the stearic acid molecule.[4] These explanations are further supported by the pressure-area characteristics of the film, which will be described below.

Pressure-area Curve. From the time-dependence curves of the amount of adsorption, $\Gamma(t)$, and the surface tension, $\sigma(t)$, shown in Figs. 4 and 5, a Γ-σ or F-A plot can be constructed by eliminating the parameter, t, where $F=\sigma_0-\sigma$ denotes the surface pressure, σ_0 being the surface tension of water, and $A=1/\Gamma$ the area occupied by a stearate ion or a stearic acid molecule in the monolayer. In Fig. 7 such plots are constructed for varying concentrations of stearate solutions. The plots for F and A values in equilibrium appear at the end of the series of plots for each solution concentration. F-A curve thus obtained for the non-equilibrium state runs closely to that in the equilibrium state. Namely, Γ and σ change with the time in such a manner as F-A plot moves along the equilibrium F-A curve, and the successive steps of the kinetic state closely resemble that of equilibrium. In this respect, we cannot distinguish between the compression of an insoluble monolayer by a barrier in the usual monolayer technique and the compression of the soluble film due to the increase in the amount of adsorption. Thus, an automatic scanning of the pressure-area curve is made for the soluble monolabers by the simultaneous measurement of the surface tension and the amount of adsorption. The slower compression is more desirable for the surface-pressure measurements from the viewpoint of the homogeneity of the monolayer.[16] Here, the time re-

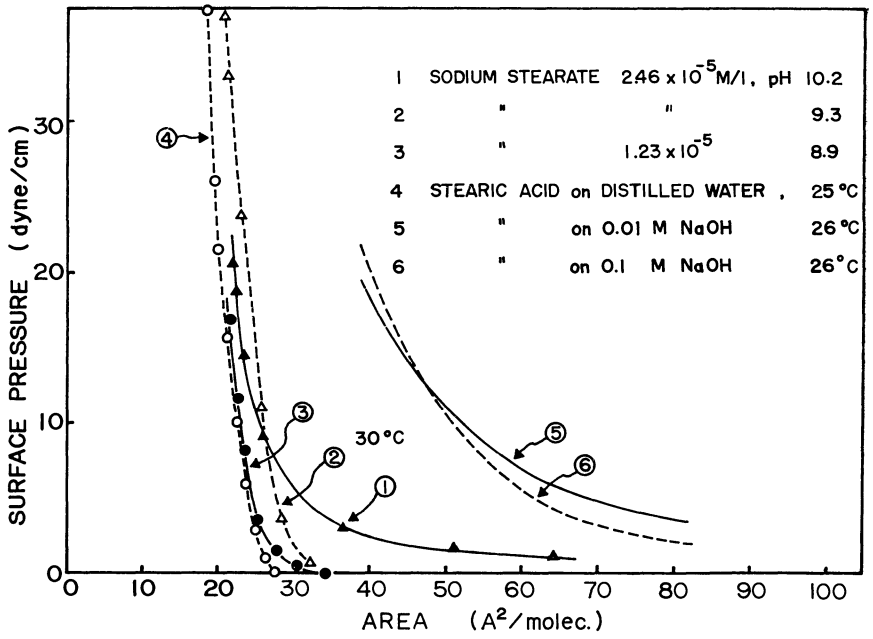

Fig. 9. Effect of pH on pressure-area relationship of adsorbed stearate films at 30°C.

quired for the establishment of the adsorption equilibrium is about 60 min, while in the usual monolayer technique about 10 min or so is required for complete compression.

The method of preparing a stearate solution markedly affects the pressure-area characteristics of the adsorbed monolayer (Fig. 8). The amount of adsorption increases, but the surface pressure decreases, with the increase in the age of the solution from 35 to 240 min before use. The effect of the pH of the stearate solution on the pressure-area relation is shown in Fig. 9, together with, for the sake of comparison, the curves for stearic acid on alkaline and neutral substrates at 30°C.[7] There is a close resemblance between the monolayer of stearic acid on neutral water and the adsorbed films on the stearate solution at pH values from 8.85 to 9.30. The difference in pH from 10 to 12 dose not produce any appreciable difference in the pressure-area relation, as is shown in Fig. 10.

The adsorption of stearic acid as a result of surface hydrolysis[24] is also expected to occur in these films. In the case of a stearate film adsorbed at

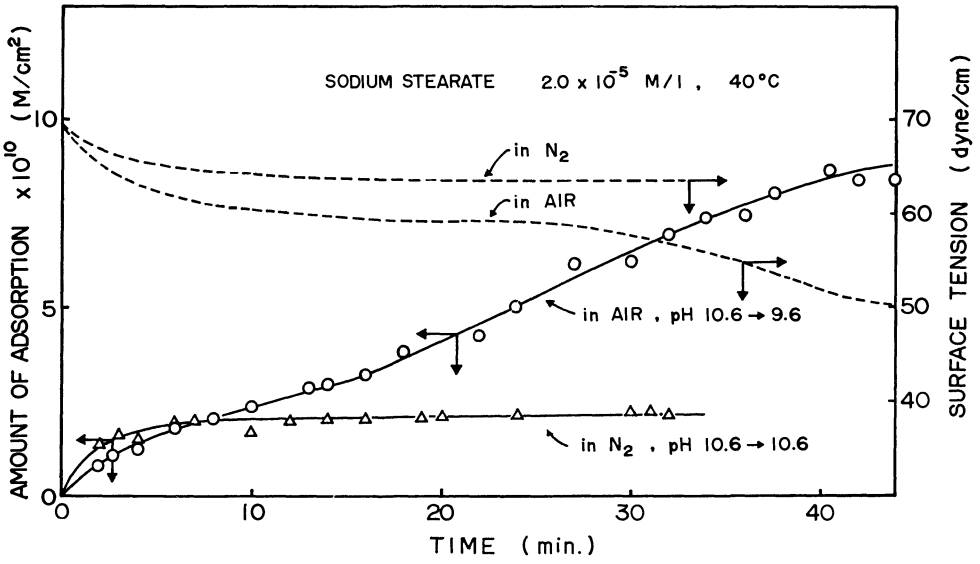

Fig. 11. Effect of atmospheric carbon dioxide on stearate adsorption.

pH 10.2, a transition from a condensed state at a higher surface concentration to an expanded state at a lower concentration can be observed. This behavior is in accord with the explanation of the step-by-step increase in Γ shown in Fig. 6, although the details are somewhat different because of the difference in temperature. The surface properties of soap are greatly affected by the presence of carbon dioxide either in solution or in atmosphere, as has been predicted by various workers.[3,5,25] In this experiment, extreme care was taken to avoid the contamination of either the surface or the bulk of the solutions by using carbonate free sodium hydroxide and sodium stearate, and by performing the experiments in a nitrogen atmosphere. In Fig. 11, the effects of carbon dioxide on the surface tension of stearate solution and on the amount of adsorption are shown by comparing the measurements in atmospheres of air (containing carbon dioxide) with those in carbon dioxide-free nitrogen. The exposure of an aqueous surface to air containing carbon dioxide increases the amount of adsorption and decreases the surface tension compared with the corresponding values obtained in nitrogen. From the observed change in the pH of the bulk solution, it is evident

25) J. Lucassen, *ibid.*, **70**, 1824 (1966).

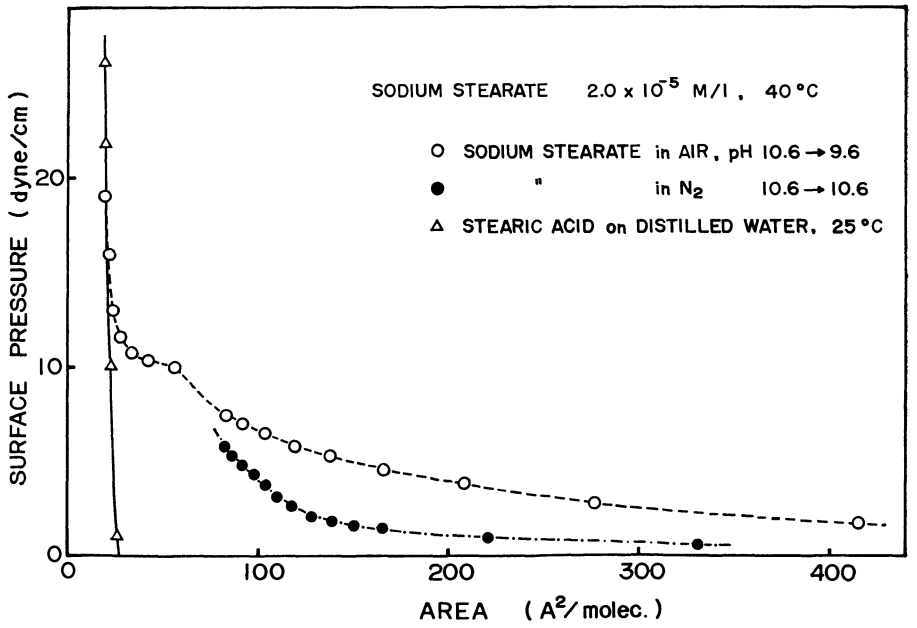

Fig. 12. Effect of atmospheric carbon dioxide on stearate adsorption.

that a considerable amount of carbon dioxide was absorbed by the solution from the air. This carbon dioxide distinctly lowers the pH of the surface layer of the solution and accelerates the hydrolysis to form free stearic acid or other surface-active associates[4,21,26] of a solute containing stearic acid, associates which preferentially adsorb at the surface and which often produce an abnormally large amount of adsorption. This tendency is also apparent in the pressure-area characteristic as shown in Fig. 12, which takes a form different from that obtained in an nitrogen atmosphere because of the dissolution of carbon dioxide into the solution. However, the curve coincides with that for stearic acid at a high surface pressure.

Author expresses his hearty thanks to Professors T. Sasaki and M. Muramatsu of Tokyo Metropolitan University for their kind discussions and suggestions. The cost of this research has been frayed by a Scientific Research Grant of the Ministry of Education given to Professor Sasaki.

Photoemission from Organic Crystal in Vacuum Ultraviolet Region. IV

Masakatsu KOCHI,*1 Yoshiya HARADA, Tomohiko HIROOKA and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received February 7, 1970)

The quantum yield and the energy distribution of photoelectrons were measured for organic crystals in the vacuum ultraviolet region. A model was presented for the photoemission from organic crystals with a narrow valence band, and a semiempirical power law was derived for the yield near the threshold. The ionization potentials found from the spectral distribution of the quantum yield using this model were as follows: anthracene—5.68 eV, naphthacene—5.43, pentacene—5.04, perylene—5.33, indanthrone—5.17, and tetrathionaphthacene—4.42. The effect of electrons which escape after one inelastic scattering was observed. It was shown how the contribution of once-scattered electrons can be separated in the energy distribution. The threshold for "pair production" was estimated to be nearly equal to the band gap for perylene and a little higher than the band gap for quaterrylene. The fine structures observed both in the yield spectra and in the energy distribution can be accounted for by assuming the existence of additional valence bands.

Photoemission from solids is considered to be a three-step process: first, electrons are optically excited into high energy states; second, the excited electrons move to the surface of solids, with or without inelastic scattering, and third, they escape over the surface barrier into a vacuum. We define the first process as an optical excitation process, and the latter two as transport processes. In order to study these processes in solids, measurements of the spectral distribution of the photoelectric yield and the energy distribution of photoemitted electrons at individual photon energies can be used. As a result, the analysis of photoemission from solids gives us information on the electronic states and the transport phenomena in the solids. Recently, ultraviolet photoemission has received increasing attention as an experimental method of probing the electronic structure in solid.[1-4]

Although the external photoelectric emission from organic cystals has been measured by several workers,[5-10] there have been no systematic studies about the total process mentioned above.

In this paper, the photoemission both at photon energy near the threshold and well above the threshold is investigated. The well-known fact that an intermolecular interaction in organic crystal is very weak as compared with that in metal or inorganic semiconductor is taken into account by considering the intramolecular vibrations. With regard to the transport process, inelastic scattering between electrons and the tunneling effect over the surface barrier is emphasized. By these means, general results are obtained which allow a considerably detailed interpretation of the photoemissive characters of the organic crystals.

Method of Analysis

1.1 A Model for the Photoemission from Organic Crystals. In the study of photoelectric phenomena in solids, the photoemission from metals has been investigated most extensively, and the work functions of metals have been obtained by using a method developed by Fowler.[11]

The photoemission from inorganic semiconductors is treated on the assumption of "density of state" considerations. Precise studies[12] of weak

photoelectric emission from silicon metal near the threshold on atomically-clean surfaces reveal direct and indirect thresholds. The plot of the quantum yield against the photon energy is linear when photoelectrons are generated by optical direct transition in the bulk. An indirect transition results in the cube-root of the quantum yield becoming proportional to the photon energy. These results are in agreement with Kane's theory.[13] Kane's power laws near the threshold mainly depend on the shape of the upper edge of the valence band. Therefore, his formula can not be applied to organic crystals with narrow valence bands.

Therefore, we wish now to propose a simple model for interpreting the general results of the photoemission from organic crystals. This model uses the following assumptions:

(a) the crystal is composed of vibrating molecules, and

(b) the wavefunction of an electron part may be described by Bloch representation inside the crystal, which joins smoothly through the surface barrier to a free electron state of equal energy.

Molecular vibrations in aromatic molecules typically have energies of approximately 0.4 eV (corresponding to C–H stretching), while the bandwidths for excess holes in molecular crystals of the naphthalene · anthracene type are very narrow—0.2 eV at the largest, and possibly smaller than that by an order of magnitude or more.[14] Thus, the effect of molecular vibrations is to split each hole band into many well-separated bands, all separated by the energy of a vibrational quantum. On the other hand, an excess electron band may not be separated by a vibrational quantum, because the ionized state with a wide electronic band is considered in the study of photoemission. Figure 1 illustrates a simplified case where there is only one vibrational frequency. A parabolic band is assumed for the conduction band. The energy difference, Δ, between the vacuum level and the bottom of the band will act as a surface barrier for slow photoelectrons. The valence bands are considered to be almost flat against the change in the k vector. The energy states which should exist below the conduction band for organic crystals are omitted in Fig. 1 for the sake of simplicity.

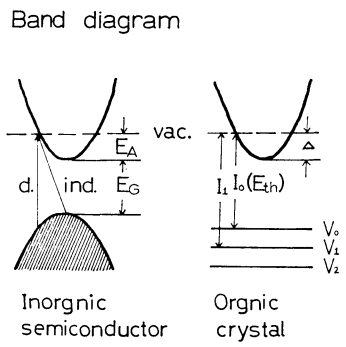

Fig. 1. Band diagram in photoemission from organic crystals including the vibronic bands. associated with hole bands.
The pure hold band is labeled V_0. Vibrationally excited bands are lebeled V_1, V_2, and so on.
(Band diagram for inorganic semiconductors is illustrated for reference; d. and ind. correspond to direct and indirect threshold, respectively.)

Assuming that no vibrational states are excited in the initial ground state, the electronic transition which puts a hole into V_0 requires only electronic excitation. The photon energy required for this pure electronic transition corresponds to the photoelectric threshold energy, E_{th}. It is denoted as I_0 in Fig. 1. Since the electronic transition which puts a hole into V_1 requires simultaneous electronic and vibrational excitation, it requires more energy than the excitation in V_0. For this reason, the vibrationally-excited hole bands are drawn downwards with increasing energy, as in Fig. 1.

1.2. The Form of the Spectral Distribution of the Quantum Yield near the Threshold. The quantum yield, $Y(h\nu)$, is designated by $Y(h\nu)$=number of electrons emitted/number of incident quanta. We assume that all the incident quanta are absorbed.*2 Then, using the first-order time-dependent perturbation theory, the quantum yield can be written as:

$$Y(h\nu) = \sum_i \int_0^\infty \int_{B.Z.} \delta(E_f - E_i - h\nu)|H_{if}|^2 \times \rho(E_f)D(E_f, x)I\mathrm{e}^{-\alpha x}\mathrm{d}x\mathrm{d}E_f \Big/ \int_0^\infty I\alpha \mathrm{e}^{-\alpha x}\mathrm{d}x$$

and

$$\alpha = \sum_i \int_{B.Z.} \delta(E_f - E_i - h\nu)|H_{if}|^2 \rho(E_f)\mathrm{d}E_f, \quad (1)$$

if all the photons of energy, $h\nu$, are absorbed in exciting electrons in the crystal. Here, I is the intensity of incident light; the absorption coefficient, $\alpha(h\nu)$, corresponds to the total absorption of the crystal at the photon energy, $h\nu$; H_{if} is the matrix element of the momentum; $\rho(E_f)$ is the state density, and $D(E_f,x)$ is the escape probability of an electron excited to a certain energy, E_f, at a certain distance, x, from the crystal surface. In Eq. (1) the state density of initial states is elimi-

13) E. O. Kane, *ibid.*, **127**, 131 (1962).

14) O. H. LeBlanc, *J. Chem. Phys.*, **40**, 2223 (1964); J. L. Katz, S. A. Rice, S. I. Choi, and J. Jortner, *ibid.*, **39**, 1683 (1963); R. Silbey, J. Jortner, S.A. Rice and M. Vala, *ibid.*, **42**, 733 (1965).

*2 This assumption was valid for the crystals several microns thick in the vacuum ultraviolet region. However, it may be necessary to take into account the optical reflectivity at the crystal surface for a more precise study.

nated because of the narrow band, the photoemissive crystal is assumed to be semiinfinite, and the integral with respect to E_f extends over the Brillouin zone (B.Z.).

The $D(E_f,x)$ term generally involves both the scattering probability and the surface transmission probability, $T(E_f)$. Near the threshold, $D(E_f,x)$ may be represented only by $T(E_f)$, because the scattering probability varies slowly near the threshold. The subsequent integration with respect to x gives the result:

$$Y(h\nu) = \frac{1}{\alpha(h\nu)} \sum_i \int_{\text{B.Z.}} \delta(E_f - E_i - h\nu) |H_{if}|^2 \times \rho(E_f) T(E_f) \mathrm{d}E_f. \quad (1')$$

With the adiabatic approximation, H_{if} is expressed as follows;

$$H_{if} = M_{if}(R_0) \cdot \langle n|0\rangle. \quad (2)$$

where $M_{if}(R_0)$ is the matrix element of the electronic part at the equilibrium atomic distance, R_0, and where $<n|0>$ is the "overlap integral" concerned with the vibrational part. By substituting Eq. (2) into Eq. (1'), we obtain:

$$Y(h\nu) = \frac{1}{\alpha(h\nu)} \sum_i \int_{\text{B.Z.}} \delta(E_f - E_i - h\nu) |\langle n|0\rangle|^2 \times |M_{if}|^2 T(E_f) \rho(E_f) \mathrm{d}E_f. \quad (3)$$

In Eq. (3) we assume that $\alpha(h\nu)$, M_{if}, and $\rho(E_f)$ are slowly varying in the vicinity of the threshold, because, in the absorption spectra, no drastic change is found near the photon energy corresponding to the threshold energy of photoemission.[5] Hence, Eq. (3) may take the following form near the threshold:

$$Y(h\nu) \propto \sum_i \int_{\text{B.Z.}} \delta(E_f - E_i - h\nu) |\langle n|0\rangle|^2 T(E_f) \mathrm{d}E_f. \quad (4)$$

The delta function in Eq. (4) gives the energy conservation relation:

$$E_f - E_i - h\nu = E + I_n - h\nu = 0 \quad (5)$$

In Eq. (5) the energy zero is taken to be a vacuum, E is the kinetic energy of a free electron, and I_n is the threshold energy corresponding to the n'th vibrational level:

$$I_n = I_0 + n\hbar\omega \quad (6)$$

I_0 corresponds to the ionization potential, I_c, of the crystal, and $\hbar\omega$ is the vibrational energy quanta, where the diversity of vibrational quanta due to many kinds of vibrational modes is neglected for the sake of simplicity. The critical escape condition:

$$\mathrm{E} \geq 0, \quad (7)$$

can be expected from the transmission probability, $T(E)$. From Eqs. (4), (5), (6), and (7), the following relation is obtained:

$$Y(h\nu) \propto \sum_n [|\langle n|0\rangle|^2 \cdot T(E)] \quad 0 \leq E = h\nu - I_0 - n\hbar\omega \leq h\nu - I_0. \quad (8)$$

Since it is difficult to calculate both factors, $T(E)$ and $|<n|0>|^2$, especially for polyatomic molecular crystals, we determine their forms empirically as follows.

The Form of $T(E)$. The surface transmission probability, $T(E)$, is difficult to determine exactly, for it depends on the shape of the surface barrier. However, it is evident that $T(E)$ must be zero for $E=0$ and that it must increase at higher values of E. In a first approximation we set:

$$T(E) \begin{cases} = 0 & \text{for } E < 0 \\ \propto E^l \left(\frac{1}{2} \leq l \leq 1\right) & \text{for } E \geq 0 \end{cases} \quad (9)$$

Note that it is for slow electrons that the shape of the surface potential barrier becomes important and that $T(E)$ usually becomes nearly constant for a large value of E. $T(E)$ is one of the main factors determining the energy distribution of slow electrons and the form of the quantum yield near the threshold.

The Form of $|<n|0>|^2$. Condon's "overlap integral," $<n|0>$, in Eq. (8) was considered in connection with diatomic molecules by Mannenback.[15] In general, if the change of equilibrium interatomic distances through the excitation process is large, a $<0|0>$ factor often becomes small and the overlap integral in the $<n|0>$ progressions will increase slowly with the increase in n. The energy distribution due to the $|<n|0>|^2$ factor is observed as a broadened band in the energy-loss curve, because there are many kinds of vibrational modes in polyatomic molecules, each having different vibrational quanta. It will be found in the energy-loss curves that the number of slower electrons increases almost linearly with the increase in the energy-loss, that is to say, with the increase in the vibrational quantum number, n, commencing at the electron energy corresponding to the $0\leftarrow0$ vibrational transition, and reaching the first maximum. Therefore, as a first approximation we replace the $|<n|0>|^2$ factor by a linear equation of n, setting $|<0|0>|^2 \simeq 0$.

Replacing $T(E)$ and $|<n|0>|^2$ in Eq. (8) by $E^l (1/2 \leq l \leq 1)$ and n respectively, and integrating over n in place of the summation in Eq. (8), we obtain the following relation:

$$Y \propto (h\nu - E_{th})^m, \left(\frac{5}{2} \leq m \leq 3\right) \quad (10)$$

This semi-empirical power law for the yield near the threshold will be compared with the experimental results in Section 4.1.

1.3. The Effect of Pair-production Scattering on the Energy Distribution. "Pair-production scattering" means the process by which the primary electron, with the energy of E', excites the second one, with the energy of E_0, to the

15) C. Mannenback, *Physica*, **17**, 1001 (1951); *ibid.*, **20**, 497 (1954).

conduction band and loses the minimum energy equal to the band gap energy, $\Delta\varepsilon$. In most organic crystals, the energy loss per collision is several eV for this process.

On the other hand, electron-phonon scattering involves a small energy loss per collision. Assuming that the phonon energy corresponds to the Debye temperature (for instance, it has been reported to be about 0.01 eV in naphthalene and anthracene.[16]), the average energy loss per collision at 300°K in organic crystals can be estimated to be about 0.003 eV. Note that it takes several hundred phonon-scattering events to produce as large an energy loss as one pair production event. Therefore, we consider pair-production scattering to be the main factor in the energy distribution of secondary electrons.

In their study of the energy distribution of photoelectrons from Cs_3Sb, Apker *et al.*[17] found evidence for the production of hole-electron pairs by energetic electrons. Spicer[18] determined the thresholds and the mean free path for pair production in semiconductors. Recently, pair-production scattering was investigated in detail by Spicer *et al.* for Cu and Ag[1] and by Kane for Si.[19]

In this work, we will consider only the escape probability of once scattered electrons in a way similar to that used for metal by Spicer *et al.*

Using a one-dimensional model, the total rate of the escape of electrons with energies between E and $E+dE$ after one scattering is*3:

$$N_s(E)dE \simeq AT(E)dE\int_{E+\varepsilon_{th}}^{h\nu-E_{th}} W(E')p(E,E')dE' \quad (11)$$

where $W(E')$ is the optical transition probability, where $p(E,E')$ is the probability that a primary electron with the energy of E' will be inelastically scattered to an energy between E and $E+dE$, where $T(E)$ is the surface transmission probability, where A is the function depending on the absorption coefficient and the scattering length, and where ε_{th} is the threshold energy for pair production.

Since we do not have enough information about the wavefunctions, particularly for excited states, the matrix element of electron-electron scattering is assumed to be constant. Under this approximation, and using the Fermi function at $T=0$, the following equation for $p(E,E')$ is obtained.[20]:

$$pdE = \frac{\rho(E)\left[\int \rho(E_0)\rho(E_0+E'-E)dE_0\right]dE}{\iint \rho(E)\rho(E_0)\rho(E_0+E'-E)dE_0dE} \quad (12)$$

Here, the scattering process by which an electron in the $(E,\vec{k'})$ state is scattered to the $(E,\vec{k})$ state and excites an electron in the $(E_0,\vec{k_0})$ state to the $(E_1,\ \vec{k_1})$ state is considered.

To ascertain the characteristic effects of a once-scatterd electron on the energy distribution, we assume a simple model. Assuming that $\rho(E)$, $\rho(E_0)$, and $\rho(E_0+E'-E)$ are constant, Eq. (12) reduces to:

$$pdE = dE\Big/\int_{-\Delta}^{E'-\varepsilon_{th}} dE = dE/(E'-\varepsilon_{th}+\Delta). \quad (13)$$

the lower limit of the integral means that we can neglect the interband transition for primary electrons. By substituting Eq. (13) into Eq. (11) and by assuming $AW(E')=W_0$ (const.) in Eq. (11), the following equation is derived:

$$N_s(E)dE \simeq W_0dET(E)\ln\frac{h\nu-E_{th}-\varepsilon_{th}+\Delta}{E+\Delta} \quad (14)$$

In Fig. 2 the energy distribution of secondary electrons, $N_s(E)$, is shown for several photon ener-

*3 Consider an electron excited to the energy of E' at a certain distance, x from the surface; the probability of this electron escaping with an energy between E and $E+dE$ after one scattering is the product of three probabilities: (1) the probability, p_1, that the primary electron will scatter after moving a certain distance, r, in the solids: (2) the probability, $p(E,E')$, that this electron will be scattered to an energy between E and $E+dE$, and (3) the probability, p_3, that it will escape without further scattering. Using a one-dimensional model, p_1 and p_3 are given as:

$$p_1 = \frac{1}{2}e^{-c'r}(c'dr),\ p_3 = \frac{1}{2}T(E)e^{-c(x\pm r)},$$

where c' is the reciprocal scattering length for an electron with the energy of E' and where, generally, $c'>c$. The distance of the electron from the surface is $x-r$ $(0\leq r\leq x)$ and $x+r(0\leq r\leq\infty)$. The factor, 1/2, reflects the fact that the electron can go either towards the surface or away from it.

In an optical absorption process, the rate per unit of length at which electrons are excited to energies between E' and $E'+dE'$, in a slab with a width of dx located at a certain distance, x, from the surface, has the form:

$$G(E',x) = W(E')dE'e^{-\alpha x}dx.$$

By integrating the product of p_1, $p(E,E')$, p_3 and $G(E',x)$ over r and x under the assumption that the photoemissive crystal is semi-infinite, we obtain the following equation:

$$N_s(E',E)dEdE' = \left(\frac{2c'}{c'+c}-\frac{\alpha+c}{\alpha+c'}\right) \times \frac{c'}{4(c'-c)(\alpha+c)}T(E)W(E')p(E,E')dEdE'.$$

By setting $A = \left(\frac{2c'}{c'+c}-\frac{\alpha+c}{\alpha+c'}\right) \times \frac{c'}{4(c'-c)(\alpha+c)}$ in the above equation, we obtain Eq. (11).

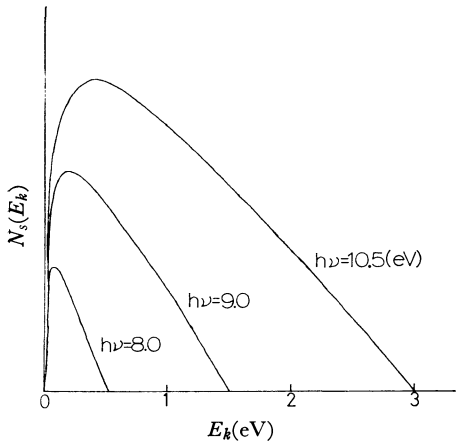

Fig. 2. Theoretical energy distribution of once-scattered electrons.

gies, setting $T(E) \propto E^{1/2}$, $E_{th}=5.5$ eV, $\varepsilon_{th}=2.0$ eV, and $\Delta \simeq 0$ in Eq. (14).

The most important feature of Fig. 2 is that pair-production scattering gives a low energy peak in the energy distribution of photoemitted electrons. The position of the peak remains almost constant in energy above the vacuum level and the height of the peak increases, as the photon energy increases. These results are in qualitative agreement with the results obtained for metal by Spicer:[1] Spicer used a three-dimensional model and introduced the "threshold function" in place of $T(E)$. Though the choice of Δ(defined in Fig. 1) has a slight influence on the curvature and the position of the peak, its behaviour described above does not change.

Experimental

The details of the purification of samples and the arrangement of the specimens in the photoemission measurement have been reported previously.[9,10],*4

2.1. Sample. Figure 3 shows the materials—anthracene, naphthacene, pentacene, perylene, quaterrylene, tetrathionaphthacene, and indanthrone—used in the present work. All the purified samples except anthracene were deposited on a copper disk, 10 mm in diameter, by means of a sublimation method *in vacuo* (10^{-6} Torr), the thickness of the film being a few microns. The single crystal of zone-refined anthracene[21] was attached to the copper disk by silver paste, its thickness being about 100 μ.

2.2. Experimental Technique. The photoemission was measured with a 0.5-metre Seya-Namioka-type vacuum ultraviolet monochromator. A concave grating coated by MgF_2, with 1200 grooves /mm, has a reciprocal linear dispersion at the exit slit of 16 Å/mm. A lithium fluoride window, which was attached with an O-ring to the exit slit, transmitted to a photon energy of about 11.5 eV. As a light source, a Hinteregger-type hydrogen discharge lamp was used. A collector was a glass sphere about 13 cm in diameter; on the inside it was coated with a conducting layer of colloidal graphite, Aguadag. An organic compound deposited onto a copper disk was fixed at the centre of the collector. Light was focussed on the sample in a spot with dimensions of about 6 mm×6 mm.

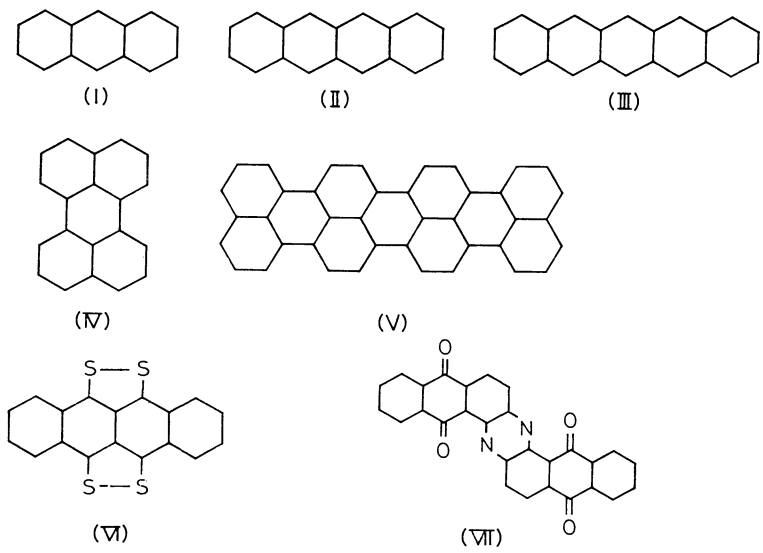

Fig. 3. Structural formula of materials.
(I) anthracene, (II) naphthacene, (III) pentacene, (IV) perylene, (V) quaterrylene, (VI) tetrathionaphthacene, and (VII) indanthrone.

*4 The method of purifying quaterrylene was reported by Y. Maruyama, H. Inokuchi and Y. Harada, This Bulletin, **36**, 1193 (1963).

21) S. Iwashima, K. Ogino and J. Aoki, *Nippon Kagaku Zasshi*, **89**, 338 (1968).

The photoemission current was amplified and observed by a Cary 31 vibrating-reed electrometer. Its spectral response was measured at intervals of 20 Å under an applied potential of 10 V, high enough to collect all the photoemitted electrons.[22]

One-mm slits were used in these experiments. The 16 Å/mm reciprocal dispersion at the exit slit gives, then, a photon-energy spread of 0.05 eV at 6.20 eV (2000 Å) and one of 0.13 eV at 10.33 eV (1200 Å).

The quantum yield, Y, was found from the ratio between the number of the photoemitted electrons and that of the incident photons. The absolute measurement of the incident photons was made by means of an Epply circular thermopile. The relative value of the light intensity was obtained by measuring the fluorescence intensity from a coronene film[23] evaporated onto a glass plate with a RCA 5819 photomultiplier tube.

The energy distribution curves (EDC) were obtained by differentiating graphically the current-voltage characteristics, which had been measured by the spherical retarding-potential method and recorded with a Yokogawa X-Y recorder, PRO-12. The estimated uncertainty in the location of structures in EDC was ±0.2 eV.

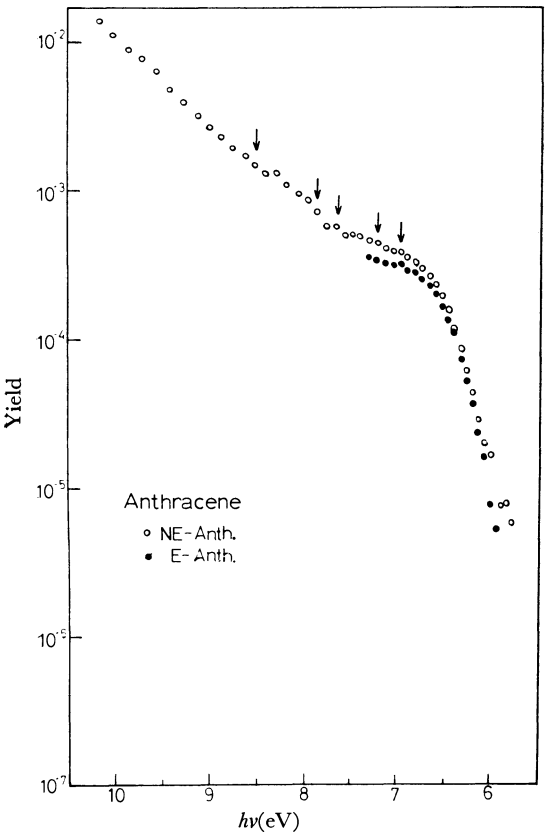

Fig. 4. Spectral distribution of the quantum yield for anthracene.

Results

3.1. Quantum Yield. Figure 4 shows the spectral distributions of the quantum yield for anthracene single crystal on the *a-b* plane under illumination. This single crystal was measured under a pressure of 10^{-3} Torr, because it evaporated easily in a high vacuum. One distribution was observed as soon as the photo-cell had been evacuated to a pressure of 10^{-3} Torr (this will be referred to as not-evaporated-anthracene, NE-Anth.). The other distribution was observed after more than five hours evacuation*5 (this will be referred to as evaporated-anthracene, *E*-Anth.). The most conspicuous difference between the two cases was that a tail appeared for NE-Anth. in the photon-energy region lower than 5.9 eV. This seems to indicate that NE-Anth. has two kinds of ionization potential, the larger value corresponding to that of anthracene itself, and the smaller one, to that of the impurity formed on the surface layer of the anthracene crystal. We will again discuss this problem in Section 4.4. The other features of the spectra were not so different in the two cases, though the magnitude of the yield for NE-Anth.

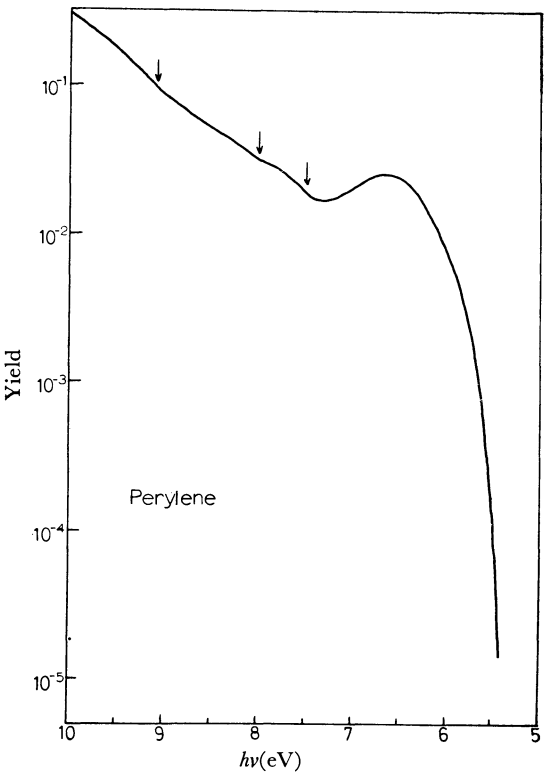

Fig. 5. Spectral distribution of the quantum yield for perylene.

*5 There was hardly any influence of evacuation when the photo-cell was evacuated for more than two hours.

was slightly higher than that for *E*-Anth.

Figure 5 shows the spectral response of the quantum yield for perylene. As can be seen in Fig. 5, a decrease in the yield was observed at photon energies between 6.8 and 7.3 eV. In Section 4.2, using the data of the energy distribution, it will be found that this decrease can be interpreted as the effect of pair-production scattering.

As may be seen from Figs. 4 and 5, the quantum yield of organic crystals rose with a considerable sharpness at the threshold and increased quickly with an increase in the photon energy. In the higher-energy region, the value of the yield increased gradually, reaching the order of 10^{-2}—10^{-1} electrons/photon at a photon energy of about 10 eV. Further, some inflection points were observed in the region more than 1 eV above the threshold.

3.2. Energy-distribution Curve and Energy-loss Curve. Figures 6, 7, and 8 show the energy distribution curves (EDC) for anthracene,*[6] perylene, and quaterrylene respectively, normalized

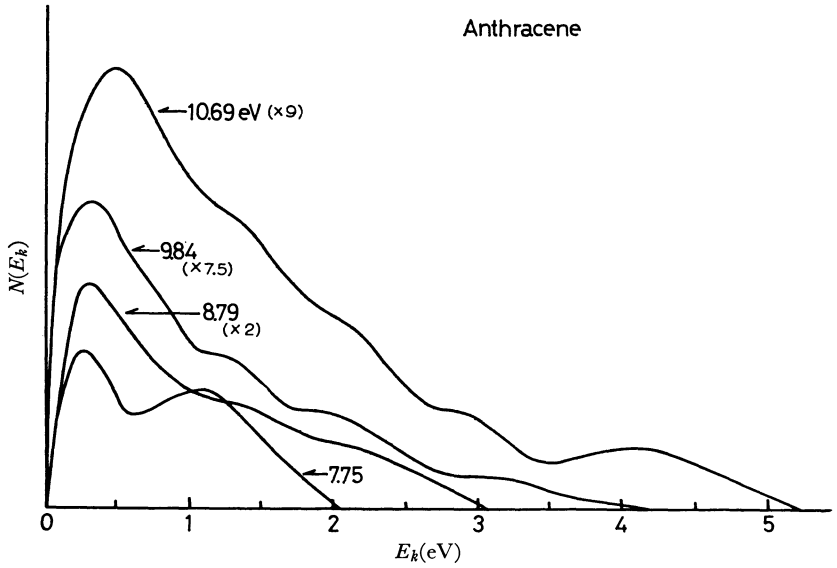

Fig. 6. Energy distribution curve for anthracene.

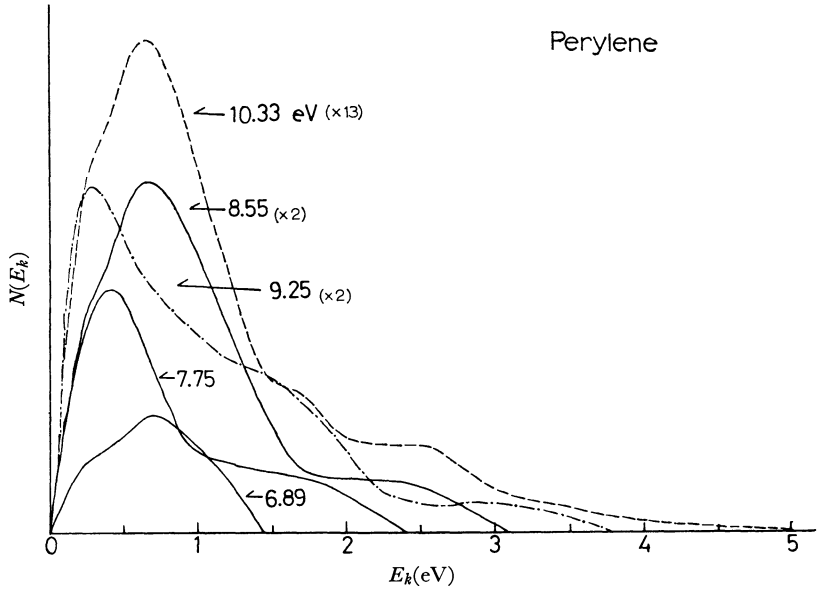

Fig. 7. Energy distribution curve for perylene.

*[6] A very slight increase in the current was observed above the saturation point in the current-voltage characteristics of the anthracene single crystal. Therefore, in the EDC for anthracene the tails due to an unsaturated current were cut off at the saturation voltage.

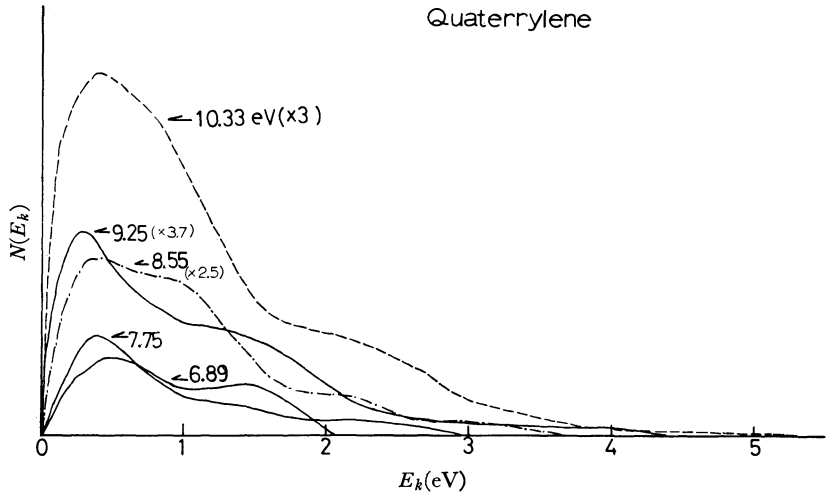

Fig. 8. Energy distribution curve for quaterrylene.

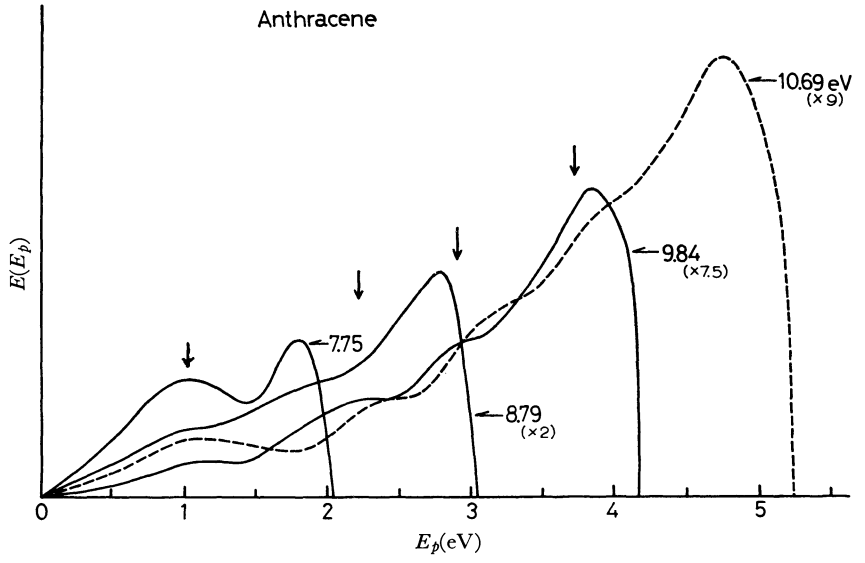

Fig. 9. Energy-loss curve for anthracene.

to the yield. On the ordinate axis, the relative numbers of the emitted electrons, $N(E)$, are plotted; on the abscissa axis, the electron energies, E_k, are stated relative to the vacuum level.

In Figs. 9, 10, and 11 the energy-loss curves (ELC) are shown; in them the difference, E_p, ($E_p = E_m - E_k$, E_m is the maximum kinetic energy) has been chosen on the abscissa axis instead of the electron kinetic energy, E_k. In this representation the $E_p=0$ point corresponds to electrons with a limiting maximum kinetic energy at any photon energy. The numerical values, increasing to the right, represent a deficiency in kinetic-energy losses.

As can be seen from EDC (Figs. 6, 7, and 8), two groups of photoelectrons were observed. The one formed by slow electrons was almost stationary in the same kinetic energy range (0.3—0.5 eV), independent of the increase in photon energy, while the height of their peaks increased as the photon energy increased. The group of fast electrons was regularly shifted to kinetic energies higher by the same amount as the photon energy increased.

The behaviour of the fast electrons can be described more pertinently in ELC. For the anthracene single crystal (see Fig. 9), at the photon energy of 7.75 eV ELC had a maximum at $E_p \simeq$ 1.0 eV. When the photon energy was increased to 8.79 eV, a shoulder appeared at $E_p \simeq 2.0$ eV. Subsequent shoulders appeared at $E_p \simeq 2.9$ and 3.7 eV at higher photon energies. The positions of the maxima and shoulders were independent

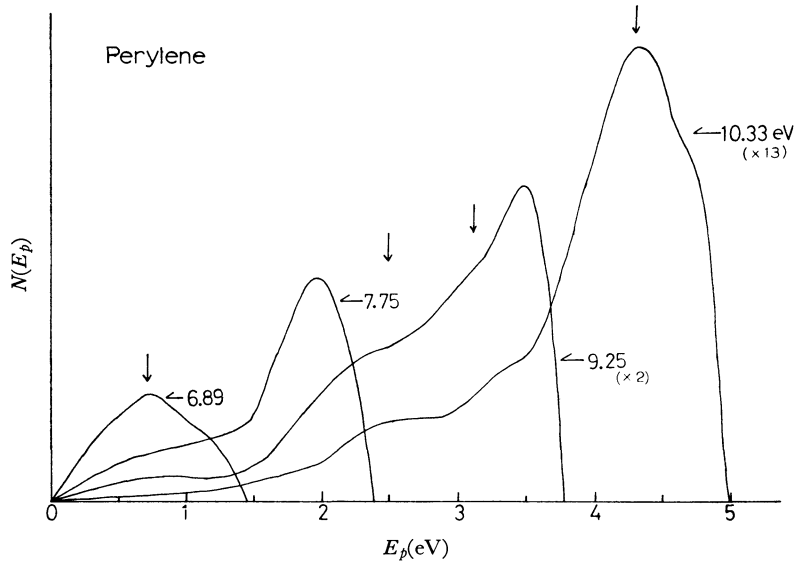

Fig. 10. Energy-loss curve for perylene.

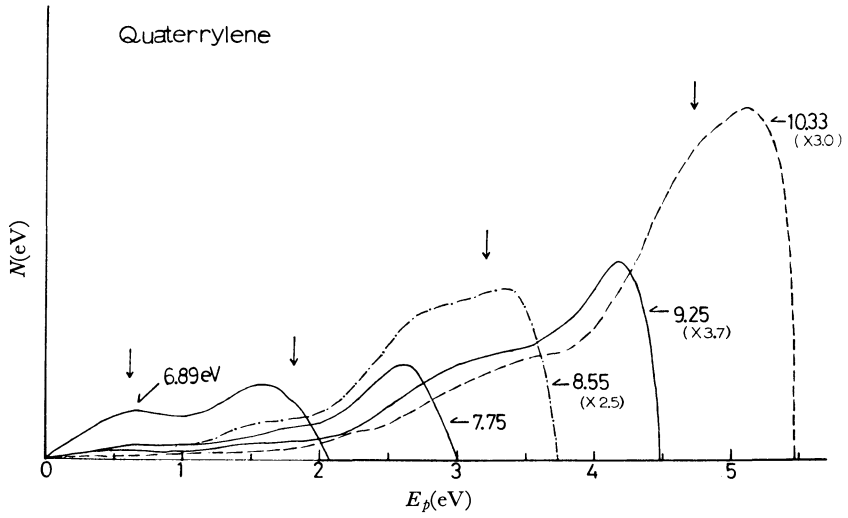

Fig. 11. Energy-loss curve for quaterrylene.

of the photon energy. The ELC of other compounds were qualitatively similar to that of anthracene.

For photon energies at which inelastic scatterings were not so frequent, broad energy-loss distributions due to vibrational excitation were clearly observed, with the maxima between $E_p=0.6$ eV and 1.0 eV (see Figs. 9, 10, and 11). Those distributions increased almost linearly with the increase in the energy-loss, commencing at $E_p=0$.

Discussion

4.1. Application of the Model to Organic Crystals. The quantum yield near the photoelectric threshold for all compounds was plotted on various power-law assumptions in order to establish the spectral characteristics. A typical example of such data is shown in Fig. 12, where the yield for the anthracene single crystal is plotted to the 1,1/2, and 1/3 power versus $h\nu$. These results, and those for other samples, indicate that the cubic power most closely represents the data and that the yield in this region obeys the relations:

$$Y \propto (h\nu - E_{th}^*)^3 \qquad (15)$$

where E_{th}^* is defined as the extraporated threshold value of the cube-root plots, such as are shown in the insets of Fig. 13. This empirical cube-law is in good agreement with the power-law predicted by Eq. (10), which may be considered to show that the form of the yield near the thresh-

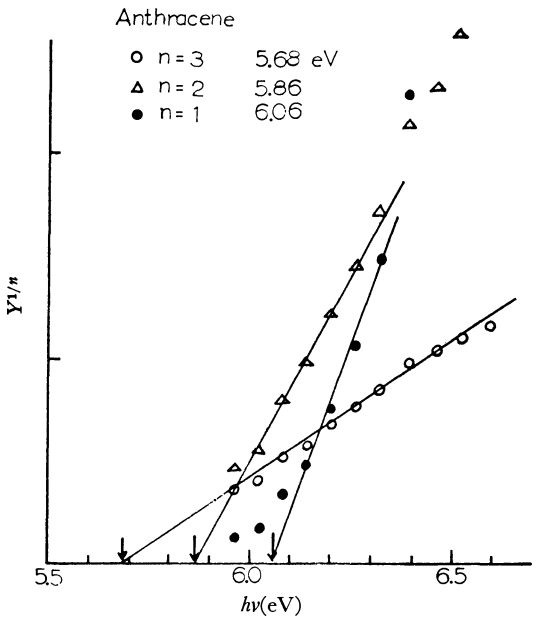

Fig. 12. Power-law fit for the photoelectric yield near the threshold for anthracene.

old for organic crystals can be effectively determined by the vibrational transition probability $|<n|0>|^2$ and the surface transmission probability $T(E)$. The importance of the $|<n|0>|^2$ factor in the photoemission of organic crystals and its linearity for n were implied by Williams and Dresner.[24]

The semi-empirical cube-power law expressed by Eq. (10) has certain limits for its validity, limits which come from the form of $T(E)$ assumed by Eq. (9). However, it is theoretically known that the $T(E) \propto E^{1/2}$ relation corresponds to the case of a rectangular potential wall.[25] Apker *et al.* used the $T(E) \propto E$ form in their analysis of the energy and spectral distribution of semiconductors.[26] Regarding the (b) assumption of our model, localized states are generally expected to exist in the continuum in molecular crystals. Although its influence was not observed in the present work, it is an important subject deserving future attention.

Figure 13 shows a cube-root-plot for each compound. In Table 1 the threshold values, E_{th}* and E_{th}, are listed and compared with those obtained by other workers. E_{th} was determined by extrapolation to a quantum yield of 10^{-7} electrons per incident photon. As can be seen from Table 1, the E_{th}* values show reasonable agreement with the E_{th} values and those of other workers.

In addition, the cube-law had been applied to determine the photoelectric threshold energy of charge-transfer complexes.[22] For those complexes the quantum yield near the threshold dropped so slowly that the threshold energy could not be determined by the extrapolation method.

4.2. Pair-production Scattering. As can be seen from EDC for perylene (Fig. 7), a remarkable low-energy peak appeared at $h\nu=7.75$ eV. Since an electron with the energy of E, less than ε_{th}, cannot escape after pair-production scattering, a low-energy peak due to pair production begins to appear in EDC at the photon energy of $h\nu \geq E_{th}+\varepsilon_{th}$. Note that perylene has a threshold energy of $E_{th} \simeq 5.40$ eV and a bandgap energy of $\Delta\varepsilon=1.95$—2.2 eV.[27] At photon energies of more than 7.75 eV, the low-energy peak was almost stationary at $E_k \simeq 0.5$ eV and grew rapidly in relative height with the increase in photon energy. Further, it was found that relatively few electrons escaped into a vacuum with kinetic energies larger than about 2 eV (see Fig. 7). These phenomena are expected from theoretical considerations for pair production (see Fig. 2). Now, we can attribute the behaviour of the low-energy peak and the scarcity of electrons with higher kinetic energies to pair-production scattering.

On the other hand, the decrease in the quantum yield is expected to occur in the $h\nu \leq E_{th}+\varepsilon_{th}$ region of the photon energy if the inelastic scattering takes place efficiently. The pair-production process is a kind of multiple process, and a decrease in quantum yield due to this process was observed in the photoemission of alkali halides.[28] For perylene, the decrease in the yield was observed in the $h\nu=6.8$—7.3 eV region (see Fig. 5). Therefore, we estimate that the threshold for the pair production of perylene is nearly equal to its band-gap energy.

For quaterrylene there are few electrons with energies larger than about 2 eV (see Fig. 8). Further, a decrease in the yield for quaterrylene had been observed between 2.2 and 2.7 eV above the photoelectric threshold by Harada.[29] The band-gap energy of quaterrylene has been reported to be 1.7 eV or more.[30] Therefore, the threshold for pair production is estimated to be a little more than its band gap.

For the anthracene single crystal, the threshold for pair production could not be estimated because the scarcity of energetic electrons in EDC and the decrease of the yield were not remarkable. It may be due to the inelastic scattering on the crystal surface.

4.3. Energy Structures of Organic Crystals. In ELC for anthracene (Fig. 9) the position of the first maximum was located at $E_p \simeq 1.0$ eV; the second shoulder, at $E_p \simeq 2.2$ eV; the third, at 2.9 eV, and the fourth at 3.7 eV, independent of the photon energy, meaning losses of 1.2, 1.9, and 2.7 eV respectively relative to the position of the first maximum. These results are in good agreement with that of Vilessov and Terenin.[31]

We reported[10] previously that the structures of this kind observed in ELC should be ascribed to those of valence bands. The structures which do not shift in ELC and which do shift in EDC linearly with the photon energy can be explained in terms of the so-called nondirect transition.[1,2] Schechtman and Spicer[32] found that these structures were observed very clearly for phthalocyanines under a high vacuum of 10^{-9} Torr.

At energies near the threshold for transitions from deeper bands, the yield may be expected to rise as a result of the larger density of possible initial states. In Figs. 4 and 5 the inflection points are illustrated by arrows. For anthracene they were situated at 6.93, 7.18, 7.61, 7.83, and 8.48 eV, thus meaning energies higher by 1.28, 1.53, 1.96, 2.18, and 2.83 eV respectively relative to the threshold energy, $E_{th} \simeq 5.65$ eV.

In Table 2, the discrete energy losses and the inflection points are given relative to the position of the first maximum and to the threshold value, respectively.*[7] In the table of anthracene, the two sets of values marked by(*) may show the lifting-up of the accidental degeneracies of the π-orbital energy, which are annexed to the LCAO method.[33] As may be seen from Table 2, the sequence of the descrete energy losses is well reproduced in the sequence of the inflection points in the yield, taking into consideration the resolution of ELC. This means that the discrete energy losses in ELC and the occurrence of inflection points in the yield spectra can be accounted for by assuming the existence of additional valence bands. It should also be noted that the fairly broad width of the first peak in ELC is due to the vibrational structure of the valence band. In order to ensure our observed valence band structure, a reliable method for the calculation for organic molecules is under consideration.

* Ref. 29.

4.4. Photoelectric Threshold Energy of Organic Crystals. The energy required to extract an electron from an organic crystal to a point in a vacuum outside its surface, *i.e.*, the photoelctric threshold energy, was obtained by measuring the quantum yield. The threshold energy, E_{th}*, corresponds to the ionization potential, I_C, of the crystal.

Table 1 summarizes the data for the threshold energies for the different organic crystal compounds studied in the present work. The table also includes data obtained by other workers and those for molecular ionization potentials, I_G. The values for I_C were obtained by extrapolation to $Y=0$ using the power-law of $Y \propto (h\nu - E_{th}^*)^3$. Regarding the column of "Other Work", Terenin and Vilessov[31] obtained their values from the measurement of the maximum kinetic energy. Kotani and Akamatu[34] determined the work function of organic crystals using a contact potential-difference method.

The table shows that the I_C values of the organic crystals under consideration are below I_G by 1—

2 eV. As has been suggested by Lyons,[35] this difference may be due to the polarization energy of the crystal by a positive centre.

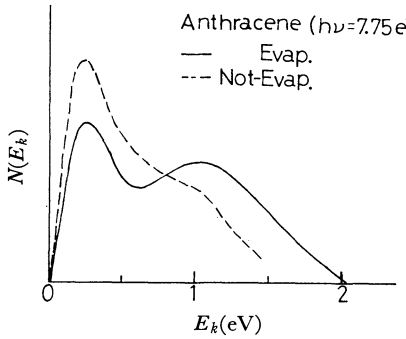

Fig. 14. Effect of oxygen on EDC for anthracene single crystal.

35) L. E. Lyons, *J. Chem. Soc.*, **1957**, 5001; L. E. Lyons and J. C. Mackie, *Proc. Chem. Soc.*, **1962**, 71.

For the I_C of the anthracene single crystal, we obtained two values for NE–Anth. One was 5.68 eV, which agreed with the I_C of E–Anth.; the other was about 5.2 eV. As Pope and Burgos[36] pointed out, the lower value for I_C seems to be caused by the oxygen-anthracene pair formed on the surface of the anthracene crystal. Figure 14 shows the energy distribution curves at $h\nu$= 7.75 eV for both E–Anth. and NE–Anth. It can be seen from the figure that the number of slow electrons for NE–Anth. is larger than that for E–Anth.; this may be attributed to an inelastic collision on the crystal surface between photoelectrons and the oxygen-anthracene pair.

Ionic Dissociation. II. An Extended Hückel Treatment of the Dissociation of Pseudo Acids

Hiroko YAMABE, Hiroshi KATO*1 and Teijiro YONEZAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received February 14, 1970)

The electronic structures of several pseudo acids are studied, in connection with their reactivity and stability, by the Extended Hückel method. The linear relationship between the observed pK_a value and the change in the calculated electronic energy, ΔE, in the course of the dissociation of the pseudo acids is also observed. The order of the stability of the carbanion, referred to its parent acid, as estimated from our calculations, is; $CH_2NO_2^- > CH_2COCH_3^- > CH_2CN^-$. Di- or tri- substituted carbanions should be more stable. This order is parallel with that of the electron-attracting abilities of the groups adjacent to the methylene group. The highest-occupied MO of the carbanion is remarkably unstable, resembling a lone-pair level, and the atomic orbital population of that MO is large at the P_z AO of the carbon. This reflects the high reactivities of the carbanion as a reaction intermediate; the electrophilic addition probably takes place at the carbon atom.

Carbanions are known as important intermediates in many organic and biological reactions,[1] especially in various condensations such as those of the aldol-type. The more easily the carbanion is generated, and the more stabilized it is, the more enhancement of the reaction may be expected. Therefore, it would be significant to ascertain what kinds of carbanions satisfy these conditions.

Studies of the carbanions have been carried out by many authors. Especially, there are many reports by Cram *et al.*[2] paying particular attention to their sterochemistry. However, as far as we know, there have been few discussions of the stabilities and the reactivities of the carbanions,

on the basis of the calculated electronic structures. Nagakura *et al.*[3] studied the dissociation of pseudo acids from the spectroscopic point of view and discussed their π electronic structures. However, they did not refer to the stability and reactivity of the carbanions.

In this paper, as one of a series of studies of the ionic dissociation,[4] we will report some findings on the electronic structures, including the π and σ electronic systems, of some pseudo acids which dissociate in water as in Eq. (1) and which give carbanions.

$$HA \rightleftarrows A^- + H^+ \qquad (1)^{*2}$$

Also the relationship between pK_a[5] and the change in the calculated electronic energy, ΔE, in the course of dissociation (Eq. (1)) will be presented.

Calculations

The electronic energy and the electronic structure of the molecule and its anion were calculated by using the Extended Hückel method proposed by Hoffmann,[6] in which all the valence atomic orbitals (AO) are taken into account. For the coulomb integrals, H_{rr}, the following valence-state ionization potentials (eV) for the hydrogen, carbon, oxygen, and nitrogen have been used:

H_{rr}(H1S) = −13.6 H_{rr}(C2S) = −21.43
H_{rr}(C2P) = −11.42 H_{rr}(O2S) = −35.30
H_{rr}(O2P) = −15.45 H_{rr}(N2S) = −27.50
H_{rr}(N2P) = −14.49

The resonance integrals, H_{rs}, have been calculated by means of $H_{rs}=(1/2)KS_{rs}(H_{rr}+H_{ss})$, where $K=1.75$[6] and where S_{rs} is the overlap integral between the rth and sth AO's. The electronic energy change, ΔE, in the dissociation process is estimated by means of the difference of the calculated total electronic energy as follows:

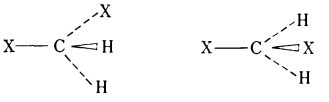
$$\Delta E = E(\text{final}) - E(\text{initial}) \qquad (2)$$

The bond lengths employed are given in Table 1. The bond angles are assumed to be as follows: ∠ONO in CH_3NO_2: 127°; for a sp^2 carbon, 120°, and for a sp^3 carbon, 109.5°. The Z axis is chosen in the direction of the π orbital. The calculation of the final state as an anion is made in the configuration of the sp^2 hybridization of the methylene carbon (abbreviated hereafter as the sp^2 configuration). For the anions of CH_3NO_2 and CH_4, two anionic forms, the sp^3 and sp^2 configurations, are calculated. As it is revealed that the sp^2 configuration is more stable for these molecules, the sp^2 configuration is adopted as the final anionic form of the other molecules.

Table 1. Interatomic distances (Å)

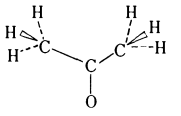
C-H	1.09
N-O (in CH_3NO_2)	1.21
C-N (in CH_3NO_2)	1.46
C-N (in CH_3CN)	1.16
C-C (in CH_3CN)	1.46
C-C (in CH_3COCH_3)	1.54
C-O (in CH_3COCH_3)	1.22

For $CH_2(NO_2)_2$, the cofiguration (1) is adopted; in our calculations it is slightly stable than the other configuration (2).



(1) (2)

In both (1) and (2), X denotes the NO_2 substituent and the central carbon has an sp^3 hybridization.*3 One of the reasons for this seems to be a rather large π-conjugation in the X–C bond of the configuration (1). For CH_3COCH_3, the following configuration is assumed, in which the central carbon has an sp^2 hybridization:



Results and Discussion

As many authors have pointed out, the charge distribution calculated by this method is unrealistic. Therefore, the absolute values of the electron densities and the energy levels have little meaning. However, the trend of their variation in a series of molecules may be discussed meaningfully. The calculated results are given in Table 2, together with the observed values of pK_a. The values of pK_a are plotted against ΔE (eV) for various pseudo acids as in Fig. 1. A linear

TABLE 2. CALCULATED ΔE AND OBSERVED pK_a VALUES

Compounds	Obsd.[5] pK_a	Calcd. ΔE (eV)
CH_4	40	6.783
CH_3NO_2	11	5.006
$CH_2(NO_2)_2$	4	4.576
$CH(NO_2)_3$	0	4.468
CH_3CN	25	5.876
$CH_2(CN)_2$	12	5.368
$CH(CN)_3$	0	5.011
CH_3COCH_3	20	5.791

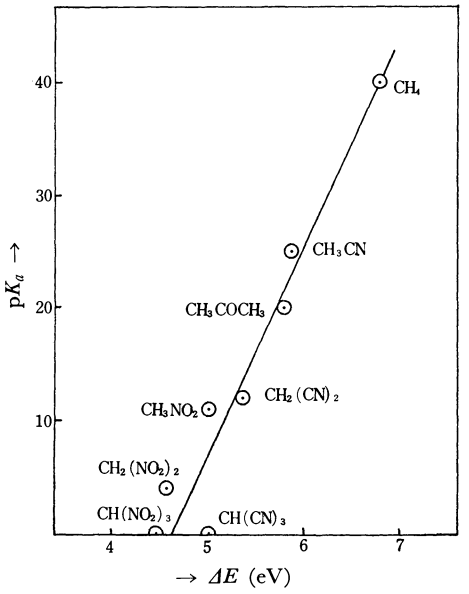

Fig. 1. The dissociation constant pK_a *vs* ΔE.

relationship between the pK_a's and the ΔE's is observed. That is the pseudo acid is ionized more easily as the ΔE is smaller. Therefore, the order of the stability of the carbanion referred to its parent acid, as estimated from our calculations, should be:

$$CH_2NO_2^- > CH_2COCH_3^- > CH_2CN^-$$

and di- or tri- substituted carbanion should be more stable still. On the other hand, the common order of the electron-attracting abilities of the groups adjacent to the methylene group is $NO_2 > CO > CN$. This order is also confirmed by the population analysis in our calculation to be $NO_2 > COCH_3 > CN$. Therefore, it can be said that the greater the ability of the substituent to bear a negative charge generated in the carbanion, the more stable is the carbanion to the parent acid and the smaller is the pK_a value of the parent acid.

Next we would like to give a detailed discussion of the electronic structure and energy levels of CH_3NO_2, picked as an example from the obtained results. In Fig. 2, atomic populations are given for the parent acid, CH_3NO_2 (I), and the anionic form, $CH_2NO_2^-$, in the sp^3 (II)*4 and sp^2 (III) configurations. The coordinate axes and the numbering of the three H atoms are also shown. The C atoms of CH_3NO_2 (I) and $CH_2NO_2^-$(II) have an sp^3 hybridization, and that of $CH_2NO_2^-$ (III) has an sp^2 hybridization. The NO_2 group is in the x–y plane, and $CH_2NO_2^-$(III) is planar. It may be seen that an electron released by the dissociation of the proton delocalizes on a whole molecule. The total electronic energy and the π atomic orbital population of the P_z AO in the highest occupied (HO) orbitals are shown in Table 3. In Table 3 and Fig. 2 it may be observed that, in spite of the delocalization of an electron released on a whole molecule, the π atomic orbital population of the p_z AO of the carbon atom C(Z) in the highest occupied orbital of the anion, which is a frontier orbital for the electrophilic attack,[7] becomes much larger than that of the parent acid. This means that the electrophilic addition must take place at the carbon atom; this is in agreement with the experimental suggestion.

Furthermore, the energy levels adjacent to the HO level and the lowest unoccupied (LU) level are illustrated in Fig. 3. The qualitative correlation between the energy levels of CH_3NO_2 (I) and its anion is studied. The third highest occupied MO (denoted by C–H in Fig. 3) of CH_3NO_2 (I) is considerably localized at the C–H_3 bond*5 to be dissociated*3). This C–H level corresponds to the HO level of the anion. (See the dotted line in Fig. 3.) These levels of the anions are remarkably unstable and seem to resemble a lone-pair level in which almost one electron localizes at the P_z AO of the carbon (See Table 3). This reflects the high reactivities of a carbanion as a reaction intermediate. The features of the elctronic structure and the energy levels of CH_3NO_2 and $CH_2NO_2^-$, which have been described above, are also seen in the cases of CH_4 and CH_3^- in the sp^3 and sp^2 configurations.

It is said that such carbanions as $CH_2NO_2^-$ and CH_2CN^- planar and π electron systems must develop a whole molecule. When the configuration of a carbanion, $CH_2NO_2^-$, is changed from an sp^3 to an sp^2, the following variations in

*4 In our calculations, the anionic form induced by the dissociation of the H_3 of CH_3NO_2 (I) becomes more stable than that induced by the dissociation of the H_1. The stable form is shown in Fig. 2 as CH_3NO_2 (II).

*5 The MO coefficients of the s, p_x, p_y and p_z AO's of the atoms C and H_3 in this level are as follows: C(s:−0.001, p_x:0.028, p_y: 0.000, p_z:−0.565), H_3 (s: −0.437)

	N(z)	0.000	0.369	0.446
	O(z)	0.000	0.264	0.294
Atomic orbital pop. of the P_z AO	C(z)	1.059	1.068	1.009
	N(z)	0.815	1.198	1.274
	O(z)	1.661	1.832	1.858

* $CH_2NO_2^-$(II), $CH_2NO_2^-$(III) denote the sp^3 and the sp^2 configuration, respectively.
** Highest occupied level

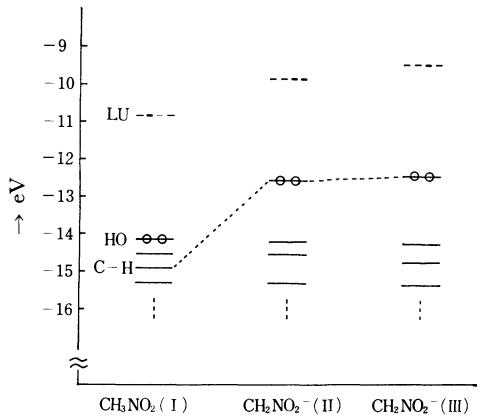

Fig. 3. Energy levels adjacents to the highest occupied level(HO) and the lowest unoccupied level(LU). C-H denotes the level, of which MO is considerably localized at the C-H bond to be dissociated. The dotted line shows the correspondence between the C-H level and HO of the anions.

the energy and the population are observed in our calculations:

1. An electron released is much delocalized over a whole molecule. That is the π conjugation strongly prevails.

2. The total electronic energy becomes lower in an sp^2 than in an sp^3. That is a carbanion treated here becomes more stable in the sp^2 configuration.

3. The highest occupied level becomes higher. That is, a carbanion becomes more reactive.

These results indicate that the configuration of the carbanion will be changed from the sp^3 to the sp^2 by the dissociation of the proton.

As for the electronic transition of the carbanion Nagakura *et al.*[3] observed that the ultraviolet absorption spectrum of the carbanion has a strong band at wavelengths longer than in the parent pseudo acid; they ascribed this to the intramolecular charge transfer band of the anion. In the present calculations, too, the π–π^* transition energy of the anion is certainly smaller than that of the neutral molecule. However, we can not discuss the electronic transition in more detail, for the approximation of our calculation is very rough.

The calculation was carried out on a HITAC 5020 computer at the computation center of the University of Tokyo.

Group Interactions in Polyelectrolytes. III. The Electrostatic Effect of Neighboring Groups on the Ionization of Polyelectrolytes

Hiroshi KAWABE and Masaya YANAGITA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received February 17, 1970)

The two parameters in the modified Henderson-Hasselbach equation, $pH=pK_a-n'\log[(1-\alpha)/\alpha]$, where pK_a and n' are empirical constants and where α is a degree of the ionization of a polymeric acid, were evaluated on the assumption that the ionization of polyelectrolytes is electrostatically affected in the main by a few neighboring ionized groups and that the overall ionization is composed of only a few elementary ionization. The titration curves of various polyelectrolytes in the absence of salt could be classified into two types: $\Delta pK' \geqq 2$ and $\Delta pK' < 2$, where $\Delta pK'$ is the difference between the succeeding ionization constants. The maleic acid-styrene copolymer and polyvinyl amine belong to the former type, while polyacrylic acid and pectinic acid belong to the latter. In the former, a plot of pH against $\log[(1-\alpha)/\alpha]$ nearly falls on a line in only a limited range and n' is substantially equal to the number of elementary ionizations. In the latter, both pK_a and n' are related to the distance between the groups. The titration curve of polyacrylic acid, drawn by means of the above equation with the parameters calculated on the basis of the kinetic data of the alkaline hydrolysis of polymethyl acrylate, was in good agreement with the observed titration curve. The titration data of other polyelectrolytes also fall nearly on their calculated titration curves.

The potentiometric titration curves of polymeric acids (or polymeric bases) do not obey the Henderson equation for monomeric acids (or bases), and their apparent dissociation constant, K_{app}, decreases with an increase in the degree of ionization in the case of polymeric acids and increases in the cases of polymeric bases depending on the electrostatic effect of the ionized groups fixed on the macromolecule. Although it is difficult to eliminate the electrical effect entirely by adding neutral salt, Katchalsky *et al.*[1] showed that the titration data of some polyelectrolytes could be expressed by a single dissociation constant of their monomeric unit when the correction for an electric field was properly made.

On the other hand, Marcus[2] presented a theory of the potentiometric titrations of polymeric acids taking into account only electrical interaction between neighboring groups; he suggested that the polymeric acids under the conditions given in his theory would behave much like dibasic acid. Katchalsky *et al.*[3] found that the electrostatic interaction between neighboring ionized groups of polyvinylamine could not be eliminated by the addition of salt in a very high concentration or even by making a correction for electrostatic field, and showed that its behavior in the titration with hydrobromic acid in the presence of sodium chloride was also similar to that of diamine. It was also reported that the titration curve of the maleic acid-styrene copolymer resembled that of dibasic acid.[4,5]

The titration curves of polymeric acids in the absence of salt are difficult to analyze theoretically because of the intense electrostatic effect of neighboring ionized groups, and the Henderson-Hasselbach-Katchalsky equation[6] is the only empirical relation to describe their titration data. In the present study, the empirical constants in the equation have been evaluated by assuming that the ionization of polyelectrolytes is electrically affected mainly by a few neighboring charged groups; the titration curves of several polymeric acids and bases have been interpreted on this basis.

Experimental

Commercial anhydrous ethylenediamine of a reagent grade was distilled before use; it was proved to be pure by its refractive index. Crystalline 1,3-propanediamine dihydrochloride was dissolved in water, and the solution was passed through a column of Dowex-2 X-8 in the hydroxide form to remove the hydrogen chlo-

ride. Aqueous solutions of the amines (0.01 M) were titrated with 0.1 N hydrochloric acid at 25°C, and the pH of the solution was measured with a Beckman Model G pH meter.

Evaluation of the Parameters in the Henderson-Hasselbach-Katchalsky Equation

Katchalsky and spitnik[6] found that the potentiometric titration curves of some polymeric acids could be described by the generalized Henderson-Hasselbach relation:

$$\mathrm{pH} = \mathrm{p}K_a - n' \log \frac{1-\alpha}{\alpha} \tag{1}$$

where $\mathrm{p}K_a$ and n' are empirical constants and where α is a degree of ionization of an acid. For a monobasic acid, n' is unity.

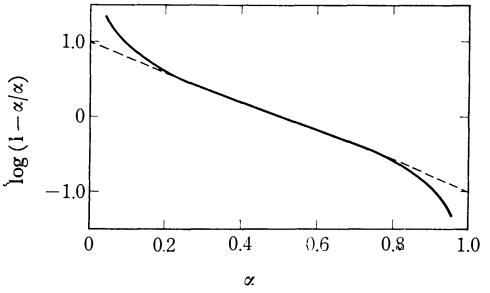

Fig. 1. Plot of $\log[(1-\alpha)/\alpha]$ against α.

As is shown in Fig. 1, $\log[(1-\alpha)/\alpha]$ is approximately proportiona to α over a wide range of α, 0.2—0.8:*1

$$\log \frac{1-\alpha}{\alpha} = 1 - 2\alpha \tag{2}$$

The introduction of Eq. (2) into Eq. (1) gives:

$$\mathrm{pH} = (\mathrm{p}K_a - n') + 2n'\alpha \tag{3}$$

Hence, n' may be estimated from the slope of a titration curve in its middle range at $(\Delta\mathrm{pH}/\Delta\alpha)/2$. Equation (3) also indicates that the main part of the titration curve of any monobasic acid ($n'=1$) is within 2 pH, and also suggests that in the titration curve of a dibasic acid or a mixture of two monobasic acids, two ionizable groups can be distinguished only when $\mathrm{p}K_2 - \mathrm{p}K_1 \gtrsim 2$.

In the titration of a polybasic acid with σ ionizable groups, the degree of ionization with respect to the nth ionized group, *i.e.*, the degree of the nth elementary ionization, α_n', is given by:

$$\mathrm{pH} = \mathrm{p}K_n' - \log \frac{1-\alpha_n'}{\alpha_n'} \tag{4}$$

or:

$$\alpha_n' = 1/[1+10^{(\mathrm{p}K_n'-\mathrm{pH})}] \tag{5}$$

where $\mathrm{p}K_n'$ is the negative logalithms of the nth elementary ionization constant.. If $\Delta\mathrm{p}K' \equiv \mathrm{p}K'_{n+1} - \mathrm{p}K'_n \geq 2$, α'_n can be estimated over a wide range of α'_n by the following relation:

$$\alpha_n' = \sigma\alpha - (n-1) \qquad \Delta\mathrm{p}K' \geq 2 \tag{6}$$

Since the α'_n of a polybasic acid is calculated by Eq. (5) when $\mathrm{p}K_n'$ is known, the over-all degree of ionization of an acid with σ groups is given by:

$$\alpha = (\sum_{n=1}^{\sigma} \alpha_n')/\sigma \tag{7}$$

The titration curves of several imaginary polybasic acids with various $\Delta\mathrm{p}K'$ values have been drawn in this manner. The titration curves calculated by arbitrarily taking $\mathrm{p}K'_1$ as unity in the case $\sigma=4$ are shown in Fig. 2, in which the circles indicate the points where $\alpha'_n=0.5$ and in which the four vertical lines correspond to $\alpha=1/8$, 3/8, 5/8, and 7/8. In the figure, the calculated plots of pH against $\log[(1-\alpha)/\alpha]$ are also shown. It may be seen that the plots can be represented by a line over a wide range. Upon the examination of the case when $\sigma=2$, the plot was also found to be substantially linear over a wide range of α provided that $\Delta\mathrm{p}K'<2$. The values of n' thus determined are listed in Table 1. It was also found that the value of n' is closely equal to

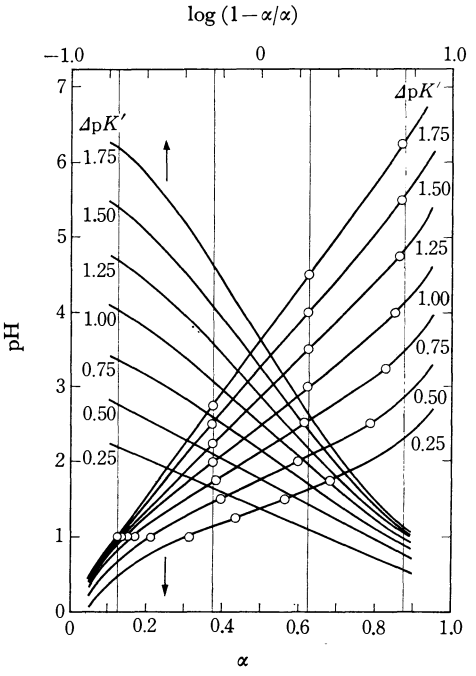

Fig. 2. Calculated titration curves of tetrabasic acids. ($\mathrm{p}K_1'=1$)

6) A. Katchalsky and P. Spitnik, *J. Polymer Sci.*, **2**, 432 (1947).

*1 Since the left term of Eq. (2) can be expanded as follows:

$$\log[(1-\alpha)/\alpha] = 2[(1-2\alpha) + (1-2\alpha)^3/3 + (1-2\alpha)^5/5 + \cdots]/2.303$$

this term is near to $(1-2\alpha)$.

TABLE 1. VALUES OF n' FOR SOME IMAGINARY POLYBASIC ACIDS

σ	$\Delta pK'$						
	0.25	0.50	0.75	1.00	1.25	1.50	1.75
2	1.02	1.12	1.16	1.28	1.45	1.66	1.87
4	1.09	1.32	1.69	2.10	2.58	3.06	3.58

the number of elementary ionization, σ, when $\Delta pK' \approx 2$. In the case when $\Delta pK' > 2$, it was found that the plots fall on σ parallel lines with the same slope, $n' = \sigma$, and that the distance between the lines is equal to $(\Delta pK' - 2)$ pH. Hence, when $\Delta pK' \geq 2$, n' is an integer which represents the total number of elementary ionizations. However, some difficulties are encountered when a plot of pH against $\log [(1-\alpha)/\alpha]$, based on the experimental titration data, is expressed by a single line with n' closely equal to an integer, since, for instance, $n' \approx 2$ will be realized not only when $\sigma = 2$ and $\Delta pK' = 2$, but also when $\sigma = 4$ and $\Delta pK' < 2$. The criterion is that if the titration curve is divided into two equal parts at the middle ionization point, the data of each part will fit Eq. (4) in the former case, but not in the latter case.

On the basis of the above-mentioned nature of the titration curve, the parameters in Eq. (1) will be evaluated in the following two cases: $\Delta pK' \geq 2$ and $\Delta pK' < 2$.

1) **$\Delta pK' \geq 2$.** On the basis of Eqs. (2) and (6), the following approximate relatoin is given for the case when $\Delta pK' \geq 2$:

$$\log \frac{1-\alpha_n'}{\alpha_n'} = \sigma \log \frac{1-\alpha}{\alpha} - (\sigma + 1 - 2n) \tag{8}$$

The introduction of the relation to Eq. (4) gives:

$$pH = [pK_n' + (\sigma + 1 - 2n)] - \sigma \log \frac{1-\alpha}{\alpha} \tag{9}$$

By comparing Eq. (9) with Eq. (1), we obtain:

$$\left.\begin{aligned} pK_a &= pK_n' + (\sigma + 1 - 2n) \\ n' &= \sigma \end{aligned}\right\} \tag{10}$$

Hence, the difference in pK_a between succeeding ionization steps, ΔpK_a, is:

$$\Delta pK_a = \Delta pK' - 2 \tag{11}$$

If $\Delta pK' = 2$, pK_a takes a single value. Therfore, the plot of pH against $\log [(1-\alpha)/\alpha]$ may be represented by a line with a slope of $n' = \sigma$. If $\Delta pK' > 2$, the plot may be represented by σ parallel lines separated by a distance of $(\Delta pK' - 2)$. It can thus be concluded that when $\Delta pK' \geq 2$ the constant n' does not correlate with the magnitude of the electrostatic effect, but is equal to the number of elementary ionizations. In this case, each ionization step is characterized substantially by a single ionizable group, and the electrostatic free energy of the nth elementary ionization, $(\Delta F^i{}_{el})_n$, is given by:

$$(\Delta F^i{}_{el})_n = 2.303 \boldsymbol{R}T [pK_n' + \log \frac{\sigma - n + 1}{n} - pK_0] \tag{12}$$

where pK_0 is the intrinsic ionization constant.

2) **$\Delta pK' < 2$.** When $\Delta pK' < 2$, each elementary ionization is no longer distinguishable in the titration curve, because the ionization of one kind of group is accompanied by that of certain number of other groups. When the ionizations of several kinds of groups overlap, the electrostatic free energy of ionization at a given α, $(\Delta F^i{}_{el})_\alpha$, may be given by:[*2]

$$\begin{aligned} (\Delta F^i{}_{el})_\alpha &= \sum_{n=1}^{\alpha} f_n (\Delta F^i{}_{el})_n \\ &= 2.303 \boldsymbol{R}T [\sum_{n=1}^{\sigma} f_n \left(pK_n' + \log \frac{\sigma - n + 1}{n} \right) \\ &\quad - pK_0 \sum_{n=1}^{\sigma} f_n] \end{aligned} \tag{13}$$

where f_n is the mole fraction of the nth ionizable group at a given α. Since a differential amount of the nth elementary ionization is given, from Eq. (4), by $d\alpha'_n / dpH = \alpha'_n (1 - \alpha'_n)$, f_n is defined as follows:

$$\left.\begin{aligned} f_n &= \alpha_n' (1 - \alpha_n') / \sum_{n=1}^{\sigma} \alpha_n' (1 - \alpha_n') \\ \sum_{n=1}^{\sigma} f_n &= 1 \end{aligned}\right\} \tag{14}$$

The second term of Eq. (13) is equal to pK_0 by the definition. The first term of Eq. (13) was computed for the imaginary acids given in Table 1 and then compared with the $pH + \log [(1-\alpha)/\alpha]$ term. In Fig. 3, the numerical difference between the two terms is plotted against α for various

*2 Since pK_n' is given by Eq. (4), the first term of Eq. (13) is transformed as follows:

$$\begin{aligned} &\sum_{n=1}^{\sigma} f_n \left(pH + \log \frac{(1-\alpha_n')(\sigma - n + 1)}{\alpha_n' \times n} \right) \\ &= \sum_{n=1}^{\sigma} f_n \left(pH + \log \frac{N_n (\sigma - n + 1)}{N_n' \times n} \right) \\ &= \log \prod_{n=1}^{\sigma} \frac{(m_n) f_n}{(m_n') f_n \times m_{H^+}} = -\log K_\alpha \end{aligned}$$

where N_n and N'_n are the numbers of the elements which concern the nth elementary ionization and which contain $(\sigma - n + 1)$ unionized groups and n ionized groups respectively, where m_n and m'_n are the molarities of unionized and ionized groups of the respective elements, and where K_α is the ionization constant defined in the equation. Hence,

$$(\Delta F^i{}_{el})_\alpha = 2.303 \boldsymbol{R}T (pK_\alpha - pK_0)$$

By comparing this equation with Eq. (16), pK_α can be estimated by:

$$pK_\alpha = pH + \log \frac{1-\alpha}{\alpha}$$

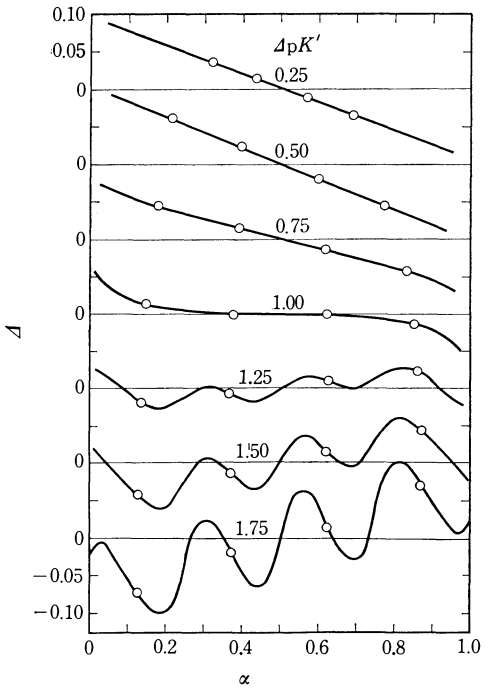

Fig. 3. Calculated difference $\Delta=\sum_{n=1}^{4}\left(pK_n'+\log\frac{5-n}{n}\right)-\left(pH+\log\frac{1-\alpha}{\alpha}\right)$ as a function of α.

$\Delta pK'$ values when $\sigma=4$. In the figure, the circles indicate the points where $\alpha'_n=0.5$. For the case when $\Delta pK'=2$, the difference amounts to about 0.2. Accordingly, the two terms may be equal within an error of ±0.1 when $\Delta pK'<2$; therefore:

$$\sum_{n=1}^{\sigma}f_n\left(pK_n'+\log\frac{\sigma-n+1}{n}\right)=pH+\log\frac{1-\alpha}{\alpha} \quad (15)$$

Hence, in the case when $2>\Delta pK'$, Eq. (13) may be transformed into the familiar equation:

$$pH=pK_0-\log\frac{1-\alpha}{\alpha}+\frac{(\Delta F^i{}_{el})_\alpha}{2.303\boldsymbol{R}T} \quad (16)$$

This equation was derived by Katchalsky and Gillis[7] for polymeric acid and transcribed, in the neighborhood of the half-ionization point, in the form of Eq. (1).[1,7]

The first term of Eq. (13) was also numerically compared with the term, $pK'+\log[(\sigma-n+1)/n]$, in Eq. (12) for the imaginary acids given in Figs. 2 and 3 ($\sigma=4$); the two terms were found to have almost the same value (within ±0.05) at $\alpha'_n=0.5$ when $n=2$ and 3. Hence, $(\Delta F^i{}_{el})_\alpha$ can be replaced by $(\Delta F^i{}_{el})_n$ at the points:

$$(\Delta F^i{}_{el})_\alpha=(\Delta F^i{}_{el})_n \qquad \alpha_n'=0.5\ (n=2 \text{ and } 3) \quad (17)$$

The fact that the titration curves of polyelectrolytes are independent of the chain length suggests that the electrical interaction between ionized groups which are situated close together compared with the over-all distance of the polyion contributes significantly to the electrostatic free energy of ionization.[8] Such an interaction was actually observed in the alkaline hydrolysis of polymethyl acrylate; the reaction in a 29% aqueous acetone solution proceeded in four distinct steps, and the rate constant of each step remained substantially unchanged.[9] This can be understood by assuming that the hydrolysis of an ester group is affected mainly by the electrical charges of the first and second neighboring groups. If the same assumption holds in the ionization of polyacrylic acid,*3 the ionization of the acid may be considered to be composed of four elementary ionizations ($\sigma=4$) and the electrostatic free energy of the nth ionization may be given by:

$$(\Delta F^i{}_{el})_n=(\boldsymbol{Ne}^2/D)\sum_i(z_i/\bar{r}_i) \quad (18)$$

where D is the effective dielectric constant, where z_i is the number of the electrical charge in the ith group apart from the ionizing group ($z_i=0,1$ or 2, and $i=1$ and 2), and where $\bar{r}_i$ is the average distance between the ionizing group and the ith group.

From Eqs. (12) and (18), it follows that:

$$pK_0=pK_n'+\log\frac{\sigma-n+1}{n}-\frac{\boldsymbol{Ne}^2}{2.303\boldsymbol{R}TD}\sum_i\frac{z_i}{\bar{r}_i} \quad (19)$$

Since $\sum_i(z_i/\bar{r}_i)$ is considered to be $2/\bar{r}_2$, $2/\bar{r}_1$, and $2(1/\bar{r}_1+1/\bar{r}_2)$ when $n=2$, 3, and 4 respectively, when $\sigma=4$, as has been illustrated in a previous paper,[9] this term can be represented by:

$$\sum_i(z_i/\bar{r}_i)=[2/k-1)\{(n-1)-2\}^2+(n-1)]/\bar{r}_1 \quad n\neq1 \quad (20)$$

where $k=\bar{r}_2/\bar{r}_1$.

Although Eq. (6) has been found to be correct for the case when $\Delta pK'\geqq2$, the relation still

7) A. Katchalsky and J. Gillis, *Rec. Trav. Chim. Pays-Bas*, **68**, 879 (1949).

8) H. Morawetz. "Macromolecules in solution," Interscience Publishers, New York (1965), p. 354; P. Doty and G. Ehrlich, *Ann. Rev. Phys. Chem.*, **3**, 81 (1952); See also Ref. 1.

9) H. Kawabe and M. Yanagita, This Bulletin, **42**, 3109, (1969).

*3 The reason why the four-step ionization does not appear in the titration curve of polyacrylic acid is that the $\Delta pK'$ is proportional to the increase in $(\Delta F^i{}_{el})_n$, whereas the rate constant of the alkaline hydrolysis of polymethyl acrylate, K_n, is an exponential function of $(\Delta F^{\neq}_{el})_n$, the electrostatic free energy of activation. The succeeding step of ionization is distinguishable if $\Delta pK'>2$, which corresponds to $\Delta(\Delta F^i{}_{el})_n>2.8$ kcal. On the other hand, the succeeding steps of the chemical reaction are distinguishable if the ratio of the succeeding rate constants is more than 2, which corresponds to $\Delta(\Delta F^{\neq}_{el})_n>0.5$ kcal.

holds at $\alpha' = 0.5$, at least when n=2 and 3 in the case when $\sigma=4$, even if $\Delta pK' < 2$.
Hence:

$$\alpha = (2n-1)/8 \qquad \alpha_n' = 0.5 \ (n=2 \text{ and } 3) \qquad (21)$$

It may be seen in Fig. 2 that the values of α at $\alpha'_n=0.5$ are almost equal to those given by Eq. (21) when $n=2$ and 3 (within an error of ± 0.05). It follows from Eqs. (2) and (21) that:

$$(n-1) = \frac{3}{2} - 2\log\frac{1-\alpha}{\alpha} \qquad (22)$$

The combination of Eqs. (16), (17), (18), (20), and (22) yields the relation:

$$\mathrm{pH} = \mathrm{p}K_0 + \frac{\Phi}{\bar{r}_1}\left[\frac{3}{2}+\frac{1}{4}\left(\frac{2}{k}-1\right)\right] - \left\{1+\frac{\Phi}{\bar{r}_1}\left[2-(6-8\alpha)\left(\frac{2}{k}-1\right)\right]\right\}\log\frac{1-\alpha}{\alpha} \qquad (23)$$

where $\Phi = Ne^2/2.303RTD$. This equation is derived under the conditions given by Eqs. (17) and (21). It has been shown that these conditions are well satisfied at the points where $\alpha'_n=0.5$ ($n=2$ and 3), whereas the equations yield larger errors if $n=1$ and 4. Additionally, Eqs. (2) and (15), which are also used in the derivation of Eq. (23), give a better approximation for the former points than the latter. Hence, the pH values at $\alpha'_n=0.5$ for $n=2$ and 3 are given, in good approximation, by Eq. (23). The values of α at the two points are estimated, according to Eq. (21), to be 3/8 and 5/8 respectively, and the corresponding pH values are given by Eq. (23). Provided that both the points are on a line represented by Eq. (1), $\mathrm{p}K_a$ and n' are given by:

$$\mathrm{p}K_a = \mathrm{p}K_0 + \frac{\Phi}{\bar{r}_1}\left[\frac{3}{2}+\left(\frac{1}{4}+\log\frac{5}{3}\right)\left(\frac{2}{k}-1\right)\right] = \mathrm{p}K_0 + \frac{Ne^2}{2.303RTD\bar{r}_1}\left(1.03+\frac{0.94}{k}\right) \qquad (24)$$

$$n' = 1 + \frac{\Phi}{\bar{r}_1}\left[2-2\left(\frac{2}{k}-1\right)\right] = 1 + \frac{4Ne^2}{2.303RTD\bar{r}_i}\left(1-\frac{1}{k}\right) \qquad (25)$$

From Eqs. (24) and (25) a parameter which is only a function of k is obtained:

$$\frac{\mathrm{p}K_a - \mathrm{p}K_0}{n'-1} = \frac{1}{4}\left(\frac{1.03k+0.94}{k-1}\right) \qquad (26)$$

Since k is the relative distance concerning the first and second neighboring groups, the left term of Eq. (26) will be more or less sensitive to the stereoisomerism of polyelectrolytes.

Discussion

1) **$\Delta pK' \geq 2$.** The plots of pH against log $[(1-\alpha)/\alpha]$ derived from some potentiometric titration data are shown in Fig. 4, where the solid lines are calculated on the basis of Eqs. (1) and (10) as below. Garret and Guile[4] and Ferry et al.[5] found that the titration curve of the maleic acid-styrene copolymer (MA–ST) was composed of two parts, which could be expressed by Eq. (1) with $n'=1$ and 2. If the second-half part ($n'=2$), which is plotted in Fig. 4 on the basis of Ferry's data,[4] is further divided into two parts, each of them can be represented by a line with a slope of unity. Hence, the corresponding dissociation constants can be determined on the basis of Eq. (4): $\mathrm{p}K'_2=9.4$ and $\mathrm{p}K'_3=11.4$. ($\mathrm{p}K'_1=4.4$ is given by Ferry for the first-half ionization). Upon substitution $\Delta \mathrm{p}K' = \mathrm{p}K'_3 - \mathrm{p}K'_2 = 2.0$ in Eq. (11), we obtain $\Delta \mathrm{p}K_a = 0$. Hence, the constants of Eq. (1) for the second-half ionization are given by Eq. (10). Since $\sigma=2$ in this case, the calculated values are $n'=2$ and $\mathrm{p}K_a=10.4$; these are close to the values observed by Ferry: $n'=2.2$ and $\mathrm{p}K_a=10.35$.

The behavior of MA–ST in the second-half ionization will be illustrated by the ionzation of 1,3-propanediamine (PDA), whose acidic dissociation constants are $\mathrm{p}K'_1=8.6$ and $\mathrm{p}K'_2=10.6$. The constants for PDA are calculated to be $n'=2$ and $\mathrm{p}K_a=9.6$. The line in Fig. 4, which is calculated by substituting these value in the parameters of Eq. (1), fits the titration data.

When $\Delta pK' > 2$, the plot of pH *vs.* log $[(1-\alpha)/\alpha]$ will be represented by σ parallel lines separated

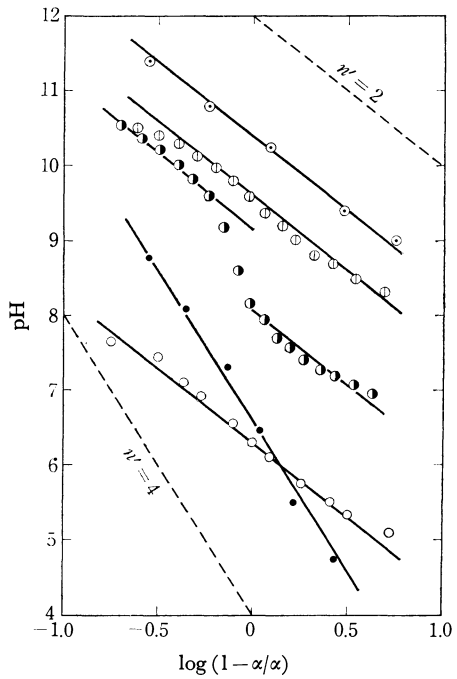

Fig. 4. Plot of pH *vs.* log $[(1-\alpha)/\alpha]$ from the potentiometric titration data in water.
⊙ MA-ST[5] (second-half ionization)

— calculated on the basis of Eqs. (1) and (10)

by a distance of ($\Delta pK'-2$), as was pointed out in the previous section. This situation will be illustrated by the ionization of ethylenediamine; $pK'_1=7.1$, $pK'_2=10.0$, and $\Delta pK'=3.0$. Actually, the titration data shown in Fig. 4 nearly all fall on two parallel lines with a slope of $n'=2$ and separated by a distance of 1.0 ($\Delta pK_a=3.0-2=1.0$).

It is interesting to note that polyvinylamine (PVAM) behaves similarly to MA-ST when it is titrated in the presence of salt. It is shown on the basis of the data in the 2N sodium chloride solution[3] that the titration curve can be divided into two parts. The plot of pH *vs.* $\log[(1-\alpha)/\alpha]$ for the first-half ionization is represented by a line of $n'=1$, and the corresponding acidic dissociation constant is $pK'_3=9.6$. The plot for the second-half ionization shown in Fig. 4 has a slope of $n'=2$, and the data of this part can be expressed by Eq. (4) if they are further divided into two parts. Thus, the acidic dissociation constants in the second part can also be determined; they are $pK'_2=7.3$ and $pK'_1=5.3$. Here, it is seen again that $\Delta pK'=pK'_2-pK'_1=2.0$ and $\Delta pK_a=0$; hence, the parameters of Eq. (1) are given by Eq. (10). The line in Fig. 4 drawn with the calculated values, $n'=2$ and $pK_a=6.3$, can well represent the plot for the second ionization.

On the other hand, polyvinyl amine behaves differently in the absence of salt. The data[3] can be expressed by Eq. (1), with $n'=4$ and $pK_a=6.6$ in the middle range of the titration curve, as is shown in Fig. 4. If the titration curve is divided into four even parts and if Eq. (4) is applied to the data of each part, the corresponding four acidic dissociation constants can be determined: $pK'_1=4.1$, $pK'_2=5.6$, $pK'_3=7.6$, and $pK'_4=9.3$. The linearity of the plot in the middle ionization range shown in Fig. 4 can be explained by $\Delta pK'=pK'_3-pK'_2=2$. Since $\sigma=4$ in this case, the parameters are determined on the basis of Eq. (10) to be $n'=4$ and $pK_a=6.6$.

Since the ionization of all the acids and bases shown in Fig. 4 satisfies the condition $\Delta pK'\geq 2$, their titration curves can be determined by the use of their pK'_n values on the basis of Eqs. (5) and (7). The observed values fall excellently on the calculated titration curves of MA–ST and PVAM, as is shown in Fig. 5, where β is the degree of the ionization of PVAM ($\beta=1-\alpha$).

2) **$\Delta pK'<2$.** polyacrylic acid was titrated with sodium hydroxide in the absence of salt;[9] the data are shown in Fig. 6, where the solid lines are calculated as below. The titration data are expressed by Eq. (1) with the parameters of $pK_a=6.9$ and $n'=2.4$; these values are in accordance with those given by Gregor and Frederic.[10]

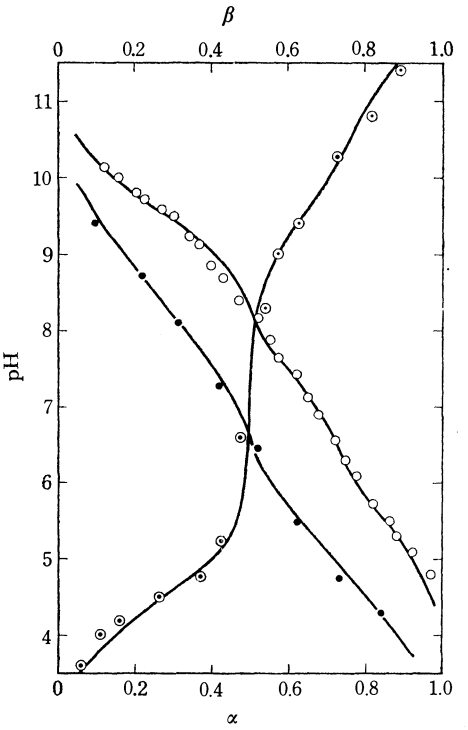

Fig. 5. Titration curves of the polyelectrolytes.
⊙ MA-ST[5] ● PVAM[3]
○ PVAM[3] (in 2N NaCl)
— calculated on the basis of Eqs. (5) and (7)

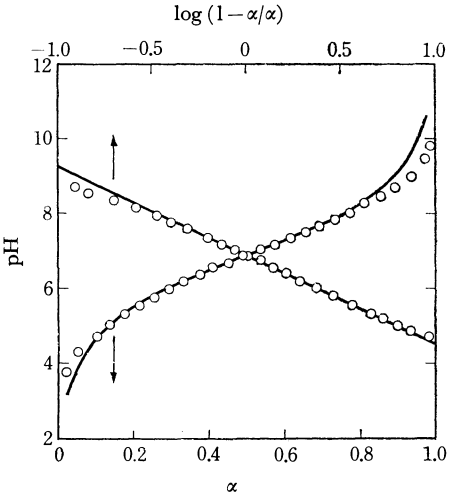

Fig. 6. Titration curve of polyacrylic acid.[9]
— calculated on the basis of Eq. (1) with $pK_a=6.89$ and $n'=2.35$.

The data do not fit Eq. (4) when they are divided into two equal parts. In the previous section, Eq. (23) was derived on the assumption that the ionization of polyacrylic acid is composed of four elementary ionizations, by analogy with the kinetic behavior in the alkaline hydrolysis of polymethyl acrylate. The distance between the groups

TABLE 2. INTRINSIC IONIZATION CONSTANT OF POLYACRYLIC ACID

n	$\alpha(\alpha_n'=0.5)$	pH	$\sum z_i/\bar{r}_i$	pK_0	
2	3/8	6.40	$2/\bar{r}_2$	5.38	5.36
3	5/8	7.39	$2/\bar{r}_1$	5.34	

determined on the basis of the kinetic data are $\bar{r}_1=3.25$ and $\bar{r}_2=5.07$ Å.[9] The parameters in Eq. (23) are $k=1.56$ and $\Phi=3.04$ ($T=298$ and $D=80$). The intrinsic ionization constant, pK_0, can be determined on the basis of Eq. (19), in which pK'_n is given by pH at $\alpha'_n=0.5$. An approximate value of α corresponding to $\alpha'_n=0.5$ is given by Eq. (21); a better approximation is obtained when $n=2$ and 3 than when $n=1$ and 4, as has been discussed in the previous section. The calculated values of pK_0 are shown in Table 2; the average value is 5.36. This value is slightly higher than the dissociation constant of isobutylic acid, 4.86, but it is comparable with the value determined from the pH value of an aqueous solution of polyacrylic acid on the basis of the approximate relation, $pK_0=2pH-\log$ [COOH], where [COOH] represents the concentration of polyacrylic acid expressed by monomole/l. The value estimated from the present experimental data is 5.4 ([COOH]=0.019 and pH=3.57); the value of 5.2 is obtained from Gregor's data.[10] The empirical constants in Eq. (1) are calculated on the basis of Eqs. (24) and (25): $n'=2.35$ and $pK=6.89$. These values are in good agreement with the observed values of the parameter. The titration curve determined on the basis of the equation, $pH=6.89-2.35\log[(1-\alpha)/\alpha]$, fits the titration data in the middle range of the curve, as is shown in Fig. 6.

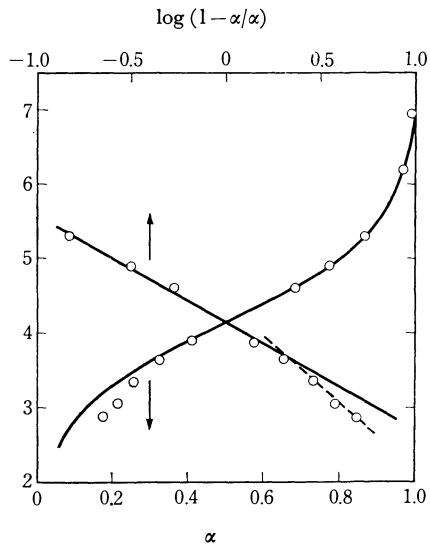

Fig. 7. Titration curve of pectinic acid.[11]
— calculated on the basis of Eq. (1) with $pK_a=4.15$ and $n'=1.44$.

Equation (23) is also applicable to the ionization of pectinic acid. The titration data of the acid[11] is shown in Fig. 7, in which the solid lines are drawn by means of Eq. (1) with the values of the parameter calculated as below. The plot of pH *vs.* $\log[(1-\alpha)/\alpha]$ is linear in the $\alpha>0.3$ range, and the empirical parameters determined from the titration data are $n'=1.5$ and $pK_a=4.1_5$. It may be presumed that pectinic acid has an elongated structure similar to cellulose when the ionization proceeds, for an intense repulsing force emerges among the charges formed on the macromolecule. It can thus be assumed that $r_2=10.3$ Å on the basis of the fiber period of cellulose.[12]*4 On the assumption of the elongated pectinic acid structure, $\bar{r}_1$ is estimated to be 7.5 Å on the basis of the length and angle of the bond. By assuming $\sigma=4$ for the ionization of pectinic acid, the pK_0 value is calculated on the basis of Eq. (19); the obtained values are shown in Table 3. The

TABLE 3. INTRINSIC IONIZATION CONSTANT OF PECTINIC ACID

n	$\alpha(\alpha_n'=0.5)$	pH	$\sum z_i/\bar{r}_i$	pK_0	
2	3/8	3.80	$2/\bar{r}_2$	3.45	3.45
3	5/8	4.45	$2/\bar{r}_1$	3.47	

mean value, $pK_0=3.45$, is in good agreement with the $pK=3.42$ of D-garacturonic acid,[12] the monomeric homologue of pectinic acid. The parameters of Eq. (1) can now be calculated on the basis of Eqs. (24) ayd (25) to be $n'=1.44$ and $pK_a=4.1_5$; those values are in accordance with the observed values. All the titration data except for the extent $\alpha<0.3$ fall excellently on the titration curve drawn by means of $pH=4.15-1.44\log[(1-\alpha)/\alpha]$, which is shown in Fig. 7. The structural transformation of pectinic acid presumably occurs in this range on account of an increase in the repulsion force among the fixed charges.

It has been pointed out in the previous section that the left term of Eq. (26) may correlate with the steric arrangement of the groups; this seems

13) A. Katchalsky and J. Feitelson, *J. Polymer Sci.* **13**, 385 (1945).

*4 By treating the kinetic data of the alkaline hydrolysis of pectin at 4°C in an aqueous solution[13] according to the procedure described in a previous paper,[9] the rate constans of $k_3=6.6$ and $k_4=1.7$ l/mol min are obtained; from them we obtain $\bar{r}_2=11$ Å.

really to be the case with polyacrylic acid and pectinic acid. The average distance from an ionizing group to the ith group, $\bar{r}_i$, is defined as follows:[9]

$$1/\bar{r}_i = \sum_j (X_{i,j}/r_{i,j})$$

where j is related to the steric configuration, where r is the distance between two groups, and where X is the mole fraction ($\sum_j X_{i,j}=1$). If the planar zig-zag structure is assumed in the vicinity of an ionizing group of polyacrylic acid, the value of $(pK_a-pK_0)/(n'-1)$ for an atactic isomer, whose structure is completely random, is estimated to be 1.0. The value obtained from the titration data is 1.1, close to the calculated one. If it is assumed that pectinic acid has an elongated structure like cellulose and that carboxylic acid groups are situated alternatively on the opposite sides of the plane consisting of piranose rings, $(pK_a-pK_0)/(n'-1)$ will be 1.5; this is close to the value obtained from the titration data, 1.4.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2713—2718 (1970)

A Theoretical Consideration of the Electron-scavenging Process in Liquid Hydrocarbons

Hideo YAMAZAKI and Kyoji SHINSAKA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received February 27, 1970)

The electron-scavenging process by a scavenger and the random recombination between ions and electrons in a spur in the radiolysis of nonpolar hydrocarbons have been investigated theoretically on the basis of the extended type of Smoluchowski equation. To obtain the approximate solutions, a model of the distribution of charged species in which a positive ion core is surrounded by electrons is assumed; several approximations are also made during the calculation. The reaction rate of the electron scavenging is expressed by the overlapping integral between the concentration of the electrons and that of the scavenger. The rate of the recombination reaction is approximately expressed as the total flux of the electrons flowing into the core of parent ions. The G value of electron scavenging shows a Langmuir-type dependence on the concentration of the electron scavenger. The values of the slope of the sigmoidal curve at the mid point and of the corresponding scavenger concentration almost agree with the experimental value.

In recent years a considerable number of experiments have been made on the ionic process in the radiation chemistry of liquid hydrocarbons; the quantitative interpretations of the experiments have become more important in ascertaining the various rates in the primary process. The theoretical treatments proposed hitherto for the reactions of the primary ionic process can be classified into the following four groups. The first method, utilized by Freeman[1,2] and by Sato *et al.*,[3,4] deals with the geminate recombination of ions, assuming an initial distribution of ion pairs. They evaluated the G value of free-electron formation as a function of the concentration of scavengers. The method seems to be successful in explaining the experimental results in nonpolar solvents. The second method, used by Monchick,[5] Mozumder,[6] and Hummel,[7] is based on the Smoluchowski equation of the distribution function of ion pairs in a static electric field. The third method, used by Schuler *et al.*,[8] investigates the reactions of ionic species by the scavenger technique and derives a simple formula from the nonhomogeneous kinetics of the recombination and scavenging processes. The last method, used by Schiller,[9,10] attempts to discuss the expansion and contraction of a spur or a track

using a thermodynamic consideration with Debye's linear response between electric field and electric displacement, and to compare the theoretical values. These theories have been tested by the following experiments: (1) scavenger method,[3,8] (2) decay of the solvated electrons in pulse radiolysis,[11] (3) luminescence intensity due to the recombination after pulse radiolysis.[12,13]

Even in the detailed calculations of the first and second methods, the random recombinations between ions and electrons in a spur or a track have been ignored. This corresponds to the assumption of a simplified spur involving an electron and an ion. However, this effect of random recombination in a spur is important, especially for a spur or a track with a high ionization density. This paper will present a theory using a distribution function of ionic species and considering random recombination in a spur or a track, as in the diffusion theory of radicals.[14] Since the effect of dielectric relaxation in nonpolar solvents can be ignored, it is necessary only to consider the movements of ionic species under a static electric field.

Theory

A) Basic Equation and Its Approximation. The basic equation of distribution functions for positive and negative species may be represented in the following form of the extended Smoluchowski equations:

$$\frac{\partial C^-}{\partial t} = u \text{ grad } C^- \cdot \text{grad}\phi + uC^- \nabla^2\phi + D_- \nabla^2 C^- - k_S^- S^- C^- - k_C C^+ C^- \quad (1)$$

$$\frac{\partial C^+}{\partial t} = -u \text{ grad } C^+ \cdot \text{grad}\phi - uC^+ \nabla^2\phi + D_+ \nabla^2 C^+ - k_S^+ S^+ C^+ - k_C C^+ C^- \quad (2)$$

where the plus and minus signs of the superscripts and the subscripts denote the quantities for positive ions and electrons; C is the distribution function, D is the diffusion constant, u is the mobility, ϕ is the static electric potential, S is the concentration of the scavenger, and k_S and k_C are the rate constants. ϕ and C are connected by the Poisson equation (3):

$$\nabla^2\phi = 4\pi e(C^+ - C^-) \quad (3)$$

where e is the electron charge.

The G value of the recombination reaction can be expressed as the overlapping of the concentrations of the species, as shown in Eqs. (4), (5) and (6), if the original equations can be solved:

$$S_\beta^\pm = k_S^\pm S^\pm \iint C^\pm \mathrm{d}v\mathrm{d}t \quad (4)$$

$$S_n = k_C \iint C^+ C^- \mathrm{d}v\mathrm{d}t \quad (5)$$

$$(G_\pm/G_\pm^0) = 1/\left\{1 + (k_S^\pm S^\pm \iint C^\pm \mathrm{d}v\mathrm{d}t/k_C \times \iint C^+ C^- \mathrm{d}v\mathrm{d}t)\right\} = 1/(1+S_\beta/S_n) \quad (6)$$

where $G_\pm^0$ is the G value of total ionization and where $G_\pm$ is the G value of the recombination reaction of positive ions and electrons.

The last terms in Eqs. (1) and (2) are important, especially for the track with a high ionic density. However, in a track or in a spur ions and electrons seem to be separated from each other as a central ion core surrounded by the electron cloud, so that the overlap of these species can be neglected in the initial distribution. The term of overlapping can be approximated as the total flux of electrons flowing into the central ion core, where the overlap of the distribution of the ions and electrons is quite appreciable in the course of reaction. However, due to the non-linearity of the equations it is generally difficult to solve these equations. Therefore, appropriate approximations are required to obtain the distribution of electrons. Equations (1), (2), and (3) may be expressed as a function of r and t in the cylindrical or spherical coordinate by ignoring the last term of the second-order reaction:

$$\frac{\partial C^-}{\partial t} = u\left(\frac{\partial \phi}{\partial r}\right)\frac{\partial C^-}{\partial r} + C^- u(1/r^n)\frac{\partial}{\partial r}\left(r^n \frac{\partial \phi}{\partial r}\right) + D_-(1/r^n)\frac{\partial}{\partial r}\left(r^n \frac{\partial C^-}{\partial r}\right) - k_S^- S^- C^- \quad (7)$$

$$\frac{\partial C^+}{\partial t} = -u\left(\frac{\partial \phi}{\partial r}\right)\frac{\partial C^+}{\partial r} - C^+ u(1/r^n)\frac{\partial}{\partial r}\left(r^n \frac{\partial \varphi}{\partial r}\right) + D_+(1/r^n)\frac{\partial}{\partial r}\left(r^n \frac{\partial C^-}{\partial r}\right) - k_S^- S^- C^- \quad (8)$$

($n=1$, cylindrical coordinate; $n=2$, spherical coordinate)

The potential function in the equation is given by Eq. (9) for the spherical coordinate:

$$\phi(r,t) = e(N^+)r,t(-N^-(r,t))/\varepsilon r \quad (9)$$

where ε is the dielectric constant and where

$$N^\pm(r,t) = \int_0^r C^\pm(r,t)\mathrm{d}v \quad (10)$$

One of the simplest models of the distribution of species is that the positive ion cluster is surrounded by the electrons ejected from the central ion cluster. If the ions are confined within the radius, r, the force from the central ion cluster is expressed by Eq. (11). In this approximation the motion of the electrons is much faster than that of ions, so that the spacial distribution of electrons is given by Eq. (12), which is reduced to the usual form of the Smoluchowski equation when $N^+(t)=1$ and $k_S^- S_S^- = 0$

$$\nabla^2\psi = 0 \quad r>R_0,$$

$$\mathrm{grad}\psi\cdot\mathrm{grad}\ C^- = \left(\frac{\partial C^-}{\partial r}\right)\left(\frac{N^+(t)e}{\varepsilon r^2}\right) \tag{11}$$

$$\frac{\partial C^-}{\partial t} = \left\{\frac{uN^+(t)e}{\varepsilon r^2}\right\}\frac{\partial C^-}{\partial r} + \frac{D_-}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial C^-}{\partial r}\right) - k_S^-S^-C^- \tag{12}$$

where R_0 means the radius of the central ion core. In the following discussion, the plus and minus signs of the superscripts and the subscripts are omitted for the sake of simplicity, because only the distribution of electrons is going to be discussed. The total amount of the recombination reaction can be approximated by the total flux of the electrons flowing into the core of the parent ions in place of Eq. (5). The flux consists of the terms of the diffusion and the electric potential:

$$S_n = u\int\int_{R_0}\left(C\,\mathrm{grad}\psi + \frac{D}{u}\mathrm{grad}C\right)\mathrm{d}s\mathrm{d}t \tag{13}$$

When G_- and G_-^0 are expressed by G_e and G_e^0 respectively, Eq. (6) gives Eq. (14). The two terms in Eq. (13) are going to equilibrate at the r_c distance.

$$(G_e/G_e^0) = 1/(1+S_\beta/S_n) \tag{14}$$

$$[u\ C\ \mathrm{grad}\psi + D\ \mathrm{grad}C]_{r_c} = 0 \tag{15}$$

The electrons separated by a longer distance than r_c become free electrons. In the case of a pair consisting of an ion and an electron, the scavenging probability is expressed by the function of r/r_c, and r_c is a constant. However, in the ion-cluster system it varies with the time. The next step is the actual calculation of the concentration distribution. Several models may be proposed for evaluating the distribution function.

B) Model I. The first model is derived by ignoring the diffusion term and by using $\bar{N}$, the mean number of ions for $N^+(t)$ in Eq. (11):

$$\frac{\partial C}{\partial t} = \frac{\alpha}{r^2}\frac{\partial C}{\partial r} - \beta C \tag{16}*1$$

where $\alpha=\bar{N}eu/\varepsilon$ and $\beta=k_sS$. When $C(r,t)$ is factorized by $T(t)\cdot R(r)$, the factorized functions are given by the following equations:

$$T(t) = c\ \exp\{(-\beta + m\alpha)t\},\quad R(r) = c\ \exp(mr^3/3) \tag{17}$$

where c and m are constants. The solution is obtained by the superposition of these solutions. One of the boundary condition is $C(\infty,\infty)=0$, so m should be negative.

By substituting n for $|m|$, the solution is given by Eq. (18):

$$C(r,t) = \sum_n c_n\ \exp\{-(\beta+n\alpha)t\}\cdot\exp(-nr^3/3) \tag{18}$$

where c_n are constants determined by the initial distribution. The distribution of electrons can be approximated by considering only one term in the summation of Eq. (18). The probability of the initial distribution, $\phi(r,0)=(1/N^-)C(r,0)\cdot$

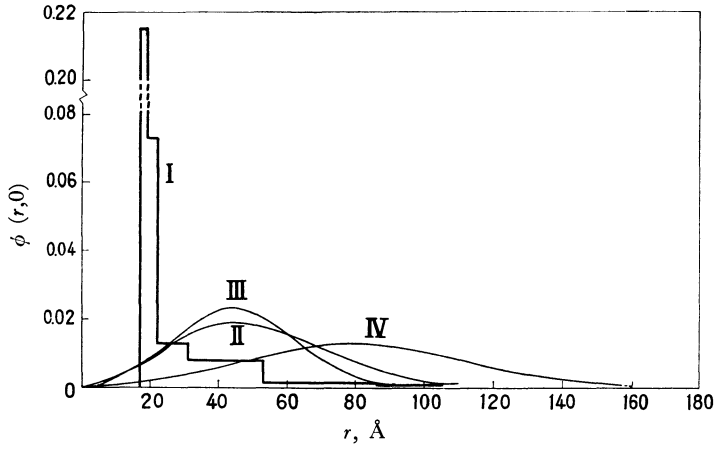

Fig. 1. The initial distribution of the separation distance between the positive-ion core and the surrounding negative electron cloud along with those estimated by Freeman and by Sato for ion pairs.

ϕ $(r, 0)$: the probability of initial distribution of the separation distance between the ion pairs in the cases of I and II and between the potitive-ion core and the surrounding negative electron cloud in the cases of III and IV; I: by Freeman, see Ref. 1 and Ref. 4; II: by Sato, see Ref. 4; III: this work, assuming that the distance, r_{max}, at a maximum initial distribution coincides with the distance where curve II reaches its maximum ($r_{max}\cong 45$ Å); IV: this work, assuming that $r_{max}=80$ Å.

*1 The general solution of Eq. (16) can be expressed by:

$$C(r,t) = \exp(-\beta t)\cdot f(t+r^3/3\alpha) \tag{18'}$$

where f is an arbitrary function.

$4\pi r^2$, obtained by means of Eq. (18) is shown in Fig. 1, along with the results of Freeman and of Sato. The value of r_{max} was chosen as 80 Å in the tentative calculations in view of the previous values,*2 but the curve corresponding to 45 Å is also shown in Fig. 1. The overlap between the electron and scavenger distribution may be evaluated as follows:

$$S_\beta = k_S S \int_{R_0}^{\infty} C(r,t)\ 4\pi r^2 \mathrm{d}r\mathrm{d}t = \frac{4\pi C k_S S\ \exp(-nR_0^3/3)}{n(\beta+n\alpha)} \tag{19}$$

In the vicinity of the ion cluster, the total current of electrons can be approximated by the electric potential term. The flux of electrons flowing into the central ion cluster is, then, obtained by means of Eq. (20):

$$S_n = \frac{4\pi \bar{N} e u C}{\varepsilon(\beta+n\alpha)} \exp(-nR_0^3/3) \tag{20}$$

The ratio of the G values, G_e/G_e^0, of the electron formation is given by Eq. (21). The G_e/G_e^0 is expressed as a sigmoidal curve of the first order of the concentration of the electron scavenger:

$$(G_e/G_e^0) = 1/(1+k_S S\varepsilon/\bar{N}eun) \tag{21}$$*3

C) Model II. In the second model the diffusion term is ignored. However, the change in the number of ions in the central cluster is considered to be a function of the time. The basic equation is, then, given by Eq. (22):

$$\frac{\partial C}{\partial t} = \frac{N(t)eu}{\varepsilon r^2}\frac{\partial C}{\partial r} - k_S S C \tag{22}$$

As in the previous model, the use of factorization, $C(r,t)=T(t)\cdot R(r)$, yields the following equation:

$$\frac{1}{\alpha(t)T(t)}\frac{\partial T(t)}{\partial t} + \frac{\beta}{\alpha(t)} = m \qquad \frac{1}{r^2 R(r)}\frac{\partial R(r)}{\partial r} = m \tag{23}$$

where $\alpha(t)$ and β are given by $\alpha(t)=N(t)eu/\varepsilon$ and $\beta=k_S S$. By the integration of these equations, $T(t)$ and $R(r)$ are obtained:

$$T(t) = c\ \exp(-\beta t)\cdot\exp\left\{m\int^t \alpha(t)\mathrm{d}t\right\} \tag{24}$$

$$R(r) = c\ \exp(mr^3/3)$$

Therefore, the general solution of Eq. (22) is given by the superposition of the product of $T(t)$ and $R(r)$ and by the substitution of n for $|m|$, since m should be negative.

$$C(r,t) = \sum_n c_n\ \exp(-\beta t) \times \exp\left\{-n\int^t \alpha(t)\mathrm{d}t\right\}\exp(-nr^3/3) \tag{25}$$

The overlapping, S_β, and the flux, S_n, can be evaluated as in the case of the first model.

$$S_\beta = 4\pi k_S S \sum_n c_n \int_0^{\infty} \exp\left\{-\beta t - n\int^t \alpha(t)\mathrm{d}t\right\} \times \frac{1}{n}\exp(-nR_0^3/3)\mathrm{d}t \tag{26}$$

$$S_n = 4\pi \sum_n c_n \int_0^{\infty} \alpha(t) \times \exp\left\{-\beta t - n\int^t \alpha(t)\mathrm{d}t\right\}\exp(-nR_0^3/3)\mathrm{d}t \tag{27}$$

Therefore, the S_β/S_n ratio is given by Eq. (28):

$$S_\beta/S_n = k_S S\varepsilon/eu\langle N(t)\cdot n\rangle \tag{28}$$

where $N(t)\cdot n$ is given by Eq. (29):

$$\langle N(t)\cdot n\rangle = \frac{\int \sum_n N(t)\cdot n\cdot\frac{c_n}{n}\exp\left\{-\beta t - n\int^t \alpha(t)\mathrm{d}t\right\}\exp(-nR_0^3/3)\mathrm{d}t}{\int \sum_n \frac{c_n}{n}\exp\left\{-\beta t - n\int^t \alpha(t)\mathrm{d}t\right\}\exp(-nR_0^3/3)\mathrm{d}t} \tag{29}$$

The final expression of the G value as a function of the scavenger concentration is given by Eq. (30):

$$(G_e/G_e^0) = 1/\{1+k_S S\varepsilon/eu\langle N(t)\cdot n\rangle\} \tag{30}$$

where the brackets express the average of the quantities. The average value can be written by the one-term approximation:

$$\langle N(t)\cdot n\rangle = \frac{n\int_0^{\infty} N(t)\exp\left\{-n\int_0^t \alpha(t)\mathrm{d}t - \beta t\right\}\mathrm{d}t}{\int_0^{\infty}\exp\left\{-n\int^t \alpha(t)\mathrm{d}t - \beta t\right\}\mathrm{d}t} \tag{31}$$

If $\alpha(t)$ is assumed to be a decreasing function expressed by a second-order reaction, $\alpha(t)=1/(1/\alpha(0)+bt)$, Eq. (31) is reduced to Eq. (32):

$$\langle N(t)\cdot n\rangle = \frac{n\varepsilon}{eu}\frac{\int_0^{\infty}(1/\alpha(0)+bt)^{-n/b-1}\exp(-\beta t)\mathrm{d}t}{\int_0^{\infty}(1/\alpha(0)+bt)^{-n/b}\exp(-\beta t)\mathrm{d}t} \tag{32}$$

where $\alpha(0)$ and b denote the initial value of $\alpha(t)$ at $t=0$ and a positive constant respectively. Therefore, after the integration of Eq. (32), and assuming $n/b\approx 1$ and $\alpha(0)/\alpha\approx 2$, (G_e/G_e^0) can be expressed as in Eq. (33):

$$(G_e/G_e^0) = 1/\{1+k_S S\varepsilon/1.4eu\bar{N}n\} \tag{33}$$

D) Model III. In the third model the effect of diffusion is taken into account, so that the

---

*2 For example, Sato,[4] r_{max} ($\cong$45 Å); Ludwig,[13] r_{max} (=80 Å, 112 Å).

*3 By using the general solution (18″),

$$C(r,t) = \exp(-\beta t)\int_0^{\infty} F(n)\exp\{-n(\alpha t + r^3/3)\}\mathrm{d}n \tag{18''}$$

where $F(n)$ is an arbitrary function of n, the G value is evaluated as a function of the scavenger concentration.

$$(G_e/G_e^0) = 1/\left\{1+(\beta\int_0^{\infty} F(n)e^{-nR_0^3/3}\frac{1}{n(\beta+n\alpha)}\mathrm{d}n \Big/ \alpha\int_0^{\infty} F(n)e^{-nR_0^3/3}\frac{1}{(\beta+n\alpha)}\mathrm{d}n\right\} \tag{21'}$$

basic equation of the distribution is as given by Eq. (34):

$$\frac{\partial C}{\partial t}=\left(\frac{u\bar{N}e}{\varepsilon r^2}\right)\frac{\partial C}{\partial r}+\frac{D}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial C}{\partial r}\right)-k_S SC \quad (34)$$

The following two equations are obtained by factorizing $C(r,t)$:

$$\frac{1}{T(t)}\frac{\mathrm{d}T(t)}{\mathrm{d}t}+\beta=-n\alpha$$

$$\frac{\mathrm{d}^2R(r)}{\mathrm{d}r^2}+\left(\frac{2}{r}+\frac{\alpha}{Dr^2}\right)\frac{\mathrm{d}R(r)}{\mathrm{d}r}+\frac{n\alpha}{D}R(r)=0 \quad (35)$$

By multiplying the appropriate coefficient M_n, the solution is expressed by an integral form:

$$C(r,t)=\sum_n M_n\cdot R_n(r)\cdot T_n(t) \quad (36)$$

S_β and S_n are then evaluated from $C(r,t)$ by:

$$S_\beta=k_S S\sum_n M_n\int R_n(r)\mathrm{d}v\cdot\int T_n(t)\mathrm{d}t \quad (37)$$

$$S_n=\frac{u\bar{N}e}{\varepsilon R_0^2}\sum_n M_n\int R_n(R_0)\mathrm{d}s\int T_n(t)\mathrm{d}t \quad (38)$$

(G_e/G_e^0) can be expressed by a formula of the Langmuir type:

$$(G_e/G_e^0)=1/\left[1+\left(\frac{k_S S\varepsilon R_0^2}{u\bar{N}e}\right)\frac{\sum_n M_n\left\{\int R_n(r)\mathrm{d}v\right\}\left\{\int T_n(t)\mathrm{d}t\right\}}{\sum_n M_n\left\{\int R_n(R_0)\mathrm{d}s\right\}\left\{\int T_n(t)\mathrm{d}t\right\}}\right] \quad (39)$$

Since S is involved in the integrals of $R_n(r)$ and $T_n(t)$, the actual result is generally quite a complicated function of S. However, a simplified approximation of the integrals gives a Langmuir formula of the first order of S:

$$(G_e/G_e^0)=\left\{1+\frac{k_S S\varepsilon}{ue\bar{N}}\cdot K\cdot\frac{1}{n}\right\} \quad (40)$$

and:

$$K=\frac{1+\{\Gamma(7/3)3^{4/3}-(1/7)\Gamma(10/3)3^{7/3}\}(D/\alpha n^{1/3})\exp(nR_0^3/3)}{[1+DnR_0^4/\alpha-Dn^2R_0^7/7\alpha]}$$

where n is a constant.

E) Results and Discussion. The result of the scavenger reaction is usually expressed by a plot of G_e/G_e^0 against the logarithm of the scavenger concentration, which shows a sigmoidal which is characterized by the concentration of the midpoint of the curve and the value of the slope at that point.

As the first step in comparing theory and experiment, let us examine the slope of the sigmoidal curve. In this theory the slope at the middle of the sigmoidal curve is given by Eq. (41):

$$\left(\frac{\mathrm{d}(G_e/G_e^0)}{\mathrm{d}\log[S]}\right)_{1/2}=-\frac{1}{4\log\mathrm{e}}[S]_{1/2}\left(\frac{\mathrm{d}(S_\beta/S_n)}{\mathrm{d}[S]}\right)_{1/2} \quad (41)$$

where the 1/2 suffix indicates the values corresponding to $G_e/G_e^0=1/2$.

Table 1. Comparison of theory and experiment of the slope at $G_e/G_e^0=1/2$

Theoretical	Experimental
First model: $-\frac{1}{4\log\mathrm{e}}=-0.58$[a]	-0.50[e]
	-0.47[f]
Second model: $-\frac{1}{4\log\mathrm{e}}=-0.58$[b]	-0.49[g]
	-0.57[h]
Third model: $-\frac{1}{4\log\mathrm{e}}=-0.58$[c]	-0.40[i]

(a), (b) and (c) are calculated according to Eqs. (21), (33) and (40), respectively.
(d) All the experimental values in Table 1 are obtained by assuming that $G_e^0=3.0$.

(h) Obtained from the curve of cyclohexane-D_2S system in Ref. 1.
(i) Obtained from the curve of cyclohexane-CH_3Cl system in Ref. 8.

Table 2. Comparison of theory and experiment of the scavenger concentration at $G_e/G_e^0=1/2$

Theoretical (mol/l)	Experimental (mol/l)
First model: $\frac{u\bar{N}en^{(a)}}{k_S\varepsilon}=0.17$—$0.017$	0.020[e]
	0.131[f]
Second model: $\frac{1.4\,u\bar{N}en^{(b)}}{k_S\varepsilon}=0.24$—$0.024$	0.019[g]
	0.131[h]
Third model: $\frac{u\bar{N}en^{(c)}}{k_S\varepsilon K}=0.17$—$0.017$	0.056[i]

* The superscripts in this table, (a)—(i), are the same with those in Table 1.

** In the calculation the following values are used: ε; the dielectric constant, 2, u; the mobility of electron for unit force, $6.0\times10^{-1\sim-2}$ esu cm sec^{-1} dyn^{-1} ($=2\times10^{-3\sim-4}$ cm^2 v^{-1} sec^{-1}), r_{max}; the radius where the distribution probability, $\frac{4\pi}{N^-}r^2C(r,t)\mathrm{d}r$ becomes maximum, 80 Å, $\bar{N}$; the average number of positive ions in cluster, 3, k_S; the reaction constant of electron with scavenger, 10^{10} M^{-1} sec^{-1}, e; the electron charge, 4.8×10^{-10} esu.

*** The following points are also taken into consideration. n can be replaced by $2/r_{max}^3$. D is the diffusion constant of electron calculated from the relation, $D=ukT/e$ where k is Boltzmann's constant, 1.38×10^{-16} erg·deg^{-1} and T is the absolute temperature taken as 300°K in this calculation and the evaluated value of D is $5.1\times10^{-5\sim-6}$ cm^2 sec^{-1}. K is the correction factor for diffusion process and the evaluated value of K is 1.

The values evaluated from the various models are shown in Table 1 along with the experimental values.

As the second measure, the value of the concentration at the mid-point of the sigmoidal curve is shown in Table 2. As is shown in Table 1 and Table 2, the theoretical values agree almost entirely with the experimental values. An even more plausible result can be obtained by changing N, *e.g.*, from four to zero, and by combining solutions with various values of N. The theory can be extended for the analysis of the effect of LET and the dependence of the density of the reactant on the electron-scavenging process.

The authors wish to thank Professor S. Shida and Dr. S. Sato of the Tokyo Institute of Technology and Dr. K. Fueki of Nagoya University for reading the preliminary manuscript of this paper and for many helpful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2718—2723 (1970)

Sound Velocity in Aqueous Non-Electrolyte Solutions in Relation to Water Structure

Otohiko NOMOTO*,** and Harumi ENDO*

* *Department of Applied Physics, Defense Academy, Yokosuka*
** *Kobayasi Institute of Physical Research, Kokubunzi, Tokyo*

(Received March 4, 1970)

An acoustic interferometer is employed to obtain the variation of sound velocity with concentration and temperature in hexamethylenetetramine (HMT), urea, thiourea, acetamide and *N*,*N*-dimethylformamide (DMF) and their aqueous solutions. The plot of velocity of aqueous solutions of these organic substances against temperature gives parabolic curves similar to one for pure water. In these curves, the maximum height of sound velocity is higher than that for pure water and the temperature at maximum point is lower than for water. The curves of sound velocity *vs.* concentration at various temperatures show values of maximum velocity at intermediate concentrations. The maximum value decreases with increasing temperature and finally disappears in some cases. Results show that the velocity dependency on temperature and concentration are qualitatively determined by the relative concentration of non-associated water to cluster. The sound velocity of acetamide and DMF is 1404.4 m/sec (65°C) and 1478.8 m/sec (20°C), respectively, and shows negative temperature coefficients of −2.68 m/sec/deg and −3.90 m/sec/deg, respectively.

All pure liquids, except water[1] and heavy water,[2] are found to have negative temperature coefficients of sound velocity V. Randall[1] found that water has a large positive coefficient of sound velocity at room temperature. The temperature coefficient (dV/dT) decreases to zero at 74°C and then becomes negative as for ordinary liquids. The origin of such an anomalous behaviour is sought in the structure of water.

According to the two-state model, liquid water consists of two species; a non-associated, close-packing-state water, and a bulky, associated state or cluster. According to the molecular view of the acoustic compression of water, compression of the former state is attributed to the compression of the free space among non-associated water molecules, while the compressibility of the latter part mainly results from the breaking of the hydrogen bonds and accordingly the partial destruction of the associated bulky structure. The structural sound absorption in pure water is explained along these lines by Hall.[3] The amount of the cluster part of water decreases with increasing temperature, resulting in a decrease of the structural part of the compressibility, while an increase in molecular distance with temperature rise accompanies an increase in ordinary compressibility. These opposing effects make the compressibility curve a minimum at an intermediate temperature, or the maximum of the sound velocity at a slightly different temperature.

Sound velocity in aqueous solutions is a function of both temperature T and concentration c, *i.e.*,

1) R. Randall, *Bur. Standards J. Res.*, **8**, 79 (1932).
2) M. Pancholy, *J. Acous. Soc. Amer.*, **25**, 1003 (1953).
3) L. Hall, *Phys. Rev.*, **73**, 775 (1948).

$V=V(T, c)$. Temperature dependence of sound velocity $V=V(T)$ at constant concentration and concentration dependence of sound velocity $V=V(c)$ at constant temperature are the two main aspects. An aqueous solution of any substance, either organic[4,5] or inorganic,[4,5] shows parabolic $V(T)$-curves similar to that of water. When the substance is dissolved in water, a part of the clusters in solution is decreased and the peak temperature T_m (temperature for velocity maximum V_m) is lowered, the peak velocity V_m becoming greater than that of pure water. The concentration dependence of sound velocity $V(c)$ in aqueous solutions, however, has hitherto been studied only in some primary alcohols, amines, amides, ketones, carboxylic acids and heterocyclic compounds.

In the present study, sound velocity in aqueous solutions of HMT, urea, thiourea, acetamide, and DMF is measured and the dependence on concentration and temperature is studied with the purpose of elucidating the molecular mechanism of the sound propagation in aqueous solutions.

Experimental

Materials. HMT, urea (mp 133.6°C), thiourea (mp 181.3°C) and acetamide (mp 83.1°C) were purified by recrystallization from absolute alcohol, from reagent grade products. The melting point of HMT was not measurable because of sublimation. DMF (bp 152.8—153.6°C) was purified from reagent grade product by drying with anhydride sodium sulfate and distillation.

Apparatus. A crystal-controlled ultrasonic interferometer with frequency of 5 MHz was used to measure the sound velocity. One hundred standing waves were counted. Solutions in the measuring cell were immersed in an oil bath. The temperature was kept constant within ±0.1°C.

Results and Discussions

The sound velocity in solutions of HMT, urea, thiourea, acetamide and DMF is plotted against temperature in Figs. 1—5. It should be noted that for dilute solutions the $V(T)$-curves change in a systematic manner with concentration keeping the parabolic form nearly the same as that for water. We see that the peak velocity V_m becomes higher than that of pure water with increasing concentration, and at the same time the temperature corresponding to peak velocity (T_m) becomes lower than that for pure water. In concentrated solutions, a small amount of remaining

water makes the sound velocity considerably higher than that of pure solute (acetamide or DMF), the $V(T)$-curves becoming linear as in pure liquids (Figs. 4 and 5).

It is to be expected that a small amount of water in high-concentration solutions is almost in non-associated state, so that structural compressibility is absent. This makes the sound velocity in "non-associated water" much higher than in ordinary water, accompanying the great rise in velocity in highly concentrated solutions.

By extrapolating the sound velocity for pure water from that in the high-concentration region we obtain $V_2=2140$ m/sec and 2160 m/sec respectively, from acetamide solutions and DMF-solutions at 20°C, if the thermodynamic Kudriavtsev equation[6] for the sound velocity in ideal mixtures

$$V^2 = \mu\frac{M_1}{\bar{M}}V_1^2 + (1-\mu)\frac{M_2}{\bar{M}}V_2^2$$

is used. Here V_1, M_1 and μ mean sound velocity, molecular weight, and molar fraction of the first component, respectively, and V_2,M_2 and $(1-\mu)$ are the corresponding quantities for the second component. $\bar{M}=\mu M_1+(1-\mu)M_2$ is the average molecular weight. This value of V_2 is appreciably higher than the usual sound velocity for pure water (1483 m/sec at 20°C) and represents the sound velocity of virtual non-associated water.

The sound velocity V_1 in pure acetamide and DMF is found to be 1404.4 m/sec (85°C) and 1478.8 m/sec (20°C), respectively. The temperature coefficients of sound velocity in these substances are found to be -2.68 m/sec/deg and -3.90 m/sec/deg, respectively. Reported values for DMF (20°C) are $V_1=1497$ m/sec, $dV_1/dT=-4.0$ m/sec/deg[7] and $V_1=1478$ m/sec, $dV_1/dT=-3.62$ m/sec.[8]

Parshad[9] found that when alcohol is added to water, the peak temperature (74°C in pure water) becomes lower with increasing concentration. Willard[10] studied the relation between velocity and concentration in the same system and found that the shapes of curves are parabolic as for water. He assumed that for $V(T)$-curves in aqueous solutions over a wide temperature range parabolas shifted in a systematic manner with concentration are obtained. Even when we cannot find an actual velocity peak, we can determine the height and temperature of the hypothetical peak outside the measured range, by assuming that the shape of the $V(T)$ curve for solution remains the same with that of pure water, and by shifting the latter curve along the both coordinate-axes T and V till the both curves do overlap. (The hypothetical velocity peak sometimes comes below melting point.)

We assumed that the shift of the peak temperature is determined by the increment of non-associated water molecules exclusively add that this increment depends on the total surface area of solute molecules in water, considering that larger the surface area, the larger the number of single water

molecules which might be oriented in the neighbourhood of the solute resulting in the breaking of clusters. Assuming the solute molecules to be hard spheres with surface area $S_0=k_0(M/\rho N)^{2/3}$, the total surface area of the solute in 100 g aqueous solution of p wt% becomes

$$S_t = k\frac{p}{(\rho^2 M)^{1/3}},$$

where k_0 and k are constants, and N, ρ, and M are the Avogadro number, density and the molecular weight of the solute, respectively. In Fig. 6, the peak temperatures in solutions are plotted against $p/(\rho^2\mathrm{M})^{1/3}$, a quantity proportional to the total surface area S_t. As can be seen, a simple linear relation exists between the peak temperature and surface area up to about 30 wt%. This shows, at least qualitatively, the validity of our assumption that the shift of the peak temperature is determined by the relative concentration of non-associated water molecules.

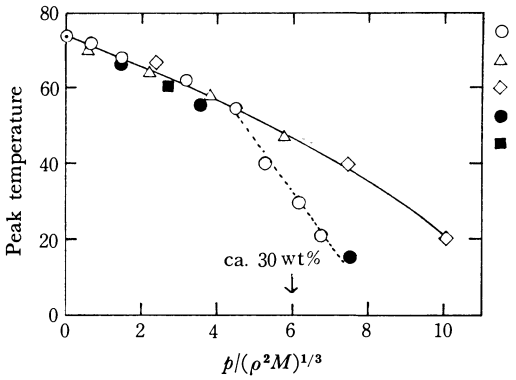

Fig. 6. Peak Temperature *vs.* $p/(\rho^2 M)^{1/3}$.
○ HMT, △ thiourea, ◇ urea, ● acetamide, ■ DMF

In Figs. 7—11 the sound velocity is plotted against molar fraction for aqueous solutions of HMT, urea, thiourea, acetamide and DMF over the whole range of concentration (up to the solubility limit in the case of HMT, urea and thiourea), and at temperatures 20—100°C. In case of sufficient solubility, these $V(c)$-curves exhibit maximum each at a fixed concentration, the maximum value gradually decreasing and shifting towards lower concentration with increasing temperature.

As seen in Figs. 10 and 11, the $V(c)$-curve at 100°C has no longer a maximum but exhibits a nearly linear relation. The aqueous solution hitherto investigated, which exhibit maximum in the $V(c)$-curve are those of primary alcohols, amines, amides, ketones, carboxylic acids and heterocyclic compounds. These compounds are known to be water-soluble non-electrolytes with radicals OH, NH_2, NH, CO, COOH and C_5H_5N, *etc.*, with tendency to form a hydrogen-bonded

structure with water. By addition of these substances to water, it is to be expected that the available number of single water molecules decreases, so that the clusters of associated water molecules may dissolve to some extent until a new equilibrium is established.

Figure 12 gives the viscosity curves in the system water-DMF at various temperatures. The viscosity curves of aqueous solutions, especially primary alcohols[11,12] and carboxylic acids,[12,13] when plotted as functions of concentration at various temperatures, also show the maximum each at a fixed concentration, the maximum becoming lower and slightly shifting towards higher concentration with increasing temperature. It should be noticed that the direction of the shift of the viscosity peak is opposite that of the velocity peak. Recent data by Kikuchi and Oikawa[14] show no shift of viscosity peak with temperature. At any rate, the shift of viscosity peak is smaller than that of the sound velocity-peak.

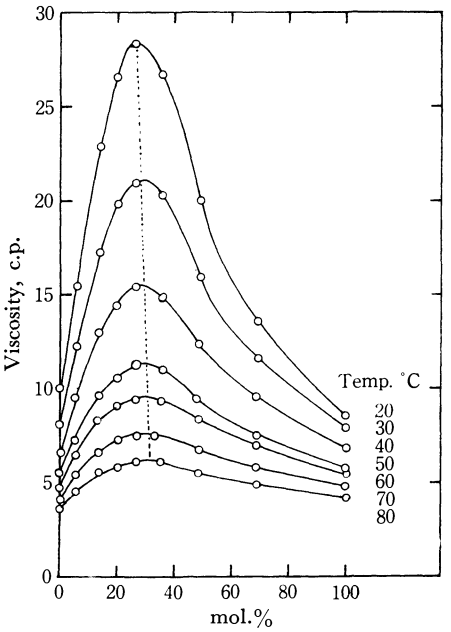

Fig. 12. Viscocity vs. concentration of aqueous DMF solutions at various temperatures. The dotted line shows the position of maximum viscocity (Larionov *et al.*[7]).

The maximum viscosity dependent on concentration is attributed to the molecular complex formation[12,15] among non-associated water molecules and the solute molecules. The viscosity maximum mighy shift towards higher concentration with temperature rise because of the increase in coordination number in the neighbourhood of the solute due to the increased fraction of the single water molecules, favouring complex formation at higher concentrations.

15) E. Hatschek, "The Viscosity of Liquids," Bell, London (1928), Chap. IX.

The solute-water-complex itself, however, does not influence sound velocity so much, because the complex is presumably of the same density and compressibility as the constituent parts before complex formation(solutes plus single-water molecules), approximately. The existence ratio of the single water molecules and clusters, however, changes with complex formation, and this gives rise on a shift towards lower concentration of the velocity peak with temperature rise.

We conclude that the maximum velocity observed for some aqueous solutions at a certain concentration at constant temperature does not correspond to the decrease in comressibility resulting from solute-water association, but is attributed to the balance between the relative magnitudes of the structural compressibility of the water-clusters and the ordinary compressibility of non-associated water molecules and solutes. Parshad[16] and Yasunaga *et al.*[17] attained analogous conclusions by adding small amounts of salt to ethanol-water system at constant temperature.

The Effect of Adsorbed Amines on the ESR of Copper Oxide

Hisashi UEDA and Naoyuki TODO

Government Chemical Industrial Research Institute, Tokyo, 2-19-19 Mita Meguro-ku, Tokyo

(Received March 6, 1970)

The effect of several additives on the ESR of copper oxide was studied. Among the additives studied, amines and NH_3 had peculiar effects on the ESR spectra. From the spectrum formed by NH_3, it is concluded that the $(Cu–NH_3)^{2+}$ complex cation is formed on the surface of a CuO particle. The formation of this complex cation obeyed a pseudo-first-order rate and can be interpreted in terms of the surface reaction between the exposed Cu^{2+} and NH_3. Among the amines studied, only primary amines gave ESR spectra which provide evidence for the existence of $(Cu\text{-amine})^{2+}$ complex cations. The foregoing fact and the results obtained on the three isomers of chloroaniline indicate that a strong *s*-character of the lone-pair orbital is needed if an amine molecule is to occupy a surface defect of the O^{2-}, by which the Cu^{2+} is exposed on the surface, thus forming a complex cation. By these facts, the *d*-orbital of Cu^{2+}, which can overlap with the nitrogen lone pair of the amine molecule, is concluded to be d_z^2. The three principal values of the *g*-tensor for the $(Cu–NH_3)^{2+}$ complex cation depend greatly on the temperature, indicating that this cation has some rotational and vibrational motions below 130°C, at which point Cu^{2+} and NH_3 dissociate.

The electron spin resonances of copper complex have been studied in both the liquid and solid states.[1] The paramagnetic species, which exist only on the surfaces of particles of copper compounds, have been studied little, however. The paramagnetic species formed on the surface of CuO particles by various solid additives have been observed by one of the present authors.[2] In that work, it was found that the effect of the aromatic amines on the surface of the oxides studied is different from those of the other types of aromatic compounds. In the present report, the effect of NH_3 and a few aromatic amines on the ESR of cupric oxide is studied in order to discuss the nature of the paramagnetic species thus formed.

Experimental

The cupric oxide used was prepared by the oxidation of cupric carbonate. The adsorption of an amine on CuO particles was carried out by adding a solution of it (0.2 mM amine in 2.0 m*l* of purified benzene per 1.000 g of CuO) to copper oxide powder. After the evaporation of the solvent, the CuO-amine mixture was placed in an ESR sample tube and evacuated to 10^{-4} mmHg or to the vapor pressure of the additive. NH_3 and five other additives, used for comparison, were added in the gas phase at the pressure of 405 mmHg (N_2O), 653 mmHg (H_2), 294 mmHg (NH_3), 107 mmHg (tetrahydrofuran), 63 mmHg (benzene), and 89 mmHg (1,2-dichloroethane), all at 28.0°C.

Results

In Table 1 the relative intensities and the δH_{msl} values obtained from the ESR spectra of CuO with several additives are shown. It may be seen

that only NH_3 affects the spectrum considerably and that only it yields the narrow ESR absorption in addition to the broad absorption which it yields in common with the other additives. This paper will descuss only the narrow component of the ESR spectra obtained from NH_3 and aromatic amines. In Fig. 1, a-d, the narrow components of the ESR spectra obtained from a CuO–NH_3 sample at various measurement temperatures are shown. The thermal change in the shape of the spectra is reversible in the temperature region below 140°C. When the sample is heated to as much as 300°C, the paramagnetic species (giving rise to the a–d spectra) receive some irreversible thermal damage; the resulting spectrum, measured at 20°C, is shown as e. If a CuO–NH_3 sample which is heated to 135°C (showing the *d* spectrum) is quickly cooled to 103°C, and if the spectra are repeatedly recorded, the intensity of the absorption spectrum, to be identified as I_t, begins to increase with the rate, as is shown in Fig. 2. As is shown in the figure, $\log(I_\infty - I_t)$ changes linearly with respect to time, t, indicating that the formation is a first- (or a pseudo-first-) order reaction. The spectrum (Fig. 1a) indicates three principal values of the g-factor, as has been observed with several cupric-ammonium complex salts.[3,4] The magnitude of the three principal

values of the g-tensor depend on the temperature of measurement, as is shown in Fig. 3. According to previous studies,[4] it seems reasonable to assign the g_1 to the $g_{\parallel}$, and the g_2 and g_3, to the $g_{\perp}$. When aromatic amines are used as additives, the ESR spectra shown in Fig. 4 are observed. Only primary amines, aniline, *o*- and *p*-chloroanilines but not *m*-chloroaniline, give spectra which are identical. In Fig. 5 the temperature dependence of the ESR intensities obtained by aniline and isomeric chloroanilines are shown.

Discussion

The ratio between the area covered by the narrow component of the spectrum obtained in the CuO–NH_3 sample at 29°C and the broad component of the same spectrum is approximately 0.0117, as may be seen in Table 1. If the surface Cu^{2+} is all converted to $(Cu–NH_3)^{2+}$-type complex ions, and if all the other Cu^{2+} (the second and the inner layers under the surface of a CuO particle) are not affected, the above-mentioned ratio can be shown to be a function of the dimensions of the particles. If the formation of $(Cu–NH_3)^{2+}$ is limited to some particular Cu^{2+} points on the surface, or if some of the Cu^{2+} are completely covered by O^{2-} ions, the ratio (the surface Cu^{2+} to combine with NH_3)/(the total surface and bulk Cu^{2+}) becomes smaller than expected. The observed ratio of the two spectral components is not unreasonable for considering the formation of $(Cu–NH_3)^{2+}$ exclusively at some or all of the surface Cu^{2+} points.

The reaction rate, $Cu^{2+}+NH_3 \rightarrow (Cu–NH_3)^{2+}$, also indicates that this is a surface process. The reaction rate is proportional to the product of the concentrations, $[Cu^{2+}][NH_3]$. If the reaction occurs under the surface, the $[NH_3]$ will be controlled by the velocity of the penetration of NH_3 into and through the CuO particles and will not depend much on the time, for the pressure of NH_3 is constant. $[Cu^{2+}]$ will also be constant, and the reaction rate will be zeroth order. However, if the reaction on the surface is assumed, $[NH_3]$ or p_{NH_3} is constant because of its excess amount, and $[Cu^{2+}]=[Cu^{2+}]_{total}-[(Cu–NH_3)^{2+}]$, where $[Cu^{2+}]_{total}$ signifies the amount of Cu^{2+} on the surface prior to the introduction of NH_3. The rate of the formation of $(Cu–NH_3)^{2+}$ is equal to the rate of the decay of the surface Cu^{2+}, therefore, it proceeds with a pseudo-first-order rate. Therefore, the surface reaction model agrees well with the observed rate.

The results in the previous paper indicated that, in the case of alumina, the chemisorption occured between the *p*-orbitals of the oxygen anions and the π-orbital of the aromatic additive, both having the same symmetry. In contrast with it, the chemisorption in the case of CuO was considered to occur between the 3d orbital of Cu^{2+} and the additive. Acturally, in some cases the unpaired electron was found on both Cu^{2+} and the nitrogen of the additive molecule.[2] If all the surface *d*-orbitals of Cu^{2+} are occupied or covered by O^{2-}

ligands, there will be no way for a NH_3 to occupy or overlap with one of them. Therefore, it can be concluded that the $(Cu\text{–}NH_3)^{2+}$ complex is formed when a NH_3 molecule fills the defect of a O^{2-} ligand on the surface. As NH_3 is a neutral molecule and so has no net negative charge on it, this chemisorption will partly consist of the formation of a covalent bond between the Cu^{2+} and NH_3, and partly of a polarization of the lone-pair orbital of the NH_3 toward the Cu^{2+}. In the case of aromatic amines, only primary amines gave ESR spectra with $g=2.03$—2.06. In the case of secondary and tertiary amines, the lone pair of the nitrogen will possess a considerably more *p*-character than that of aniline. Therefore, the stronger *s*-character of the lone pair bond is the better for a foreign ligand to occupy the O^{2-} defect on the surface. Since the H–N–H angle in NH_3 is 107.3°[5,6] and deviates somewhat from the pure sp^3 angle of 109°28′, the lone pair of NH_3 has a small *p*-character.

Though the *g*-factors observed in the CuO-aniline sample are closer to those of DPPH than those of the CuO–NH_3 sample, it is certain that the unpaired electron is on both Cu^{2+} and aniline; in other words, the $(Cu\text{-aniline})^{2+}$ complex is formed. The temperature dependence of the intensity of the line with $g=2.054$ is also similar to that of the $(Cu\text{–}NH_3)^{2+}$ complex (Fig. 5), and they both disappear above 130°C. In the cases of *o*- and *p*-chloroanilines, the double-bond character of C–Cl induces some negative electron density on the carbon atom to which the NH_2 group is attached. Probably because of the electrostatic repulsion, the configuration in which the nitrogen lone pair is out of the C_6H_4-plane is avoided and the *s*-character of the lone pair is strong. In the case of *m*-chloroaniline, the negative electron densities are distributed on the carbon atoms next to the $\rangle C\text{–}NH_2$ group; probably for this reason the nitrogen lone pair possesses some *p*-character of overlapping with the molecular π-bond.

As the O^{2-} ions are in the tetrahedral directions with respect to Cu^{2+},[7] the defect of one of the four O^{2-} ligands surrounding one Cu^{2+} ion leads to a electrostatic field of the C_{3v} symmetry. In the T_d symmetry, the unpaired electron occupies one of the ^2E_g orbitals, *i.e.*, $x^2\text{–}y^2$ and z^2. If the symmetry goes down to C_{3v}, it is uncertain which orbital accommodates the unpaired electron. The experimental evidence that the foreign or amine ligand orbital has a strong *s*-character suggests that the corresponding Cu^{2+} orbital has an A_1 symmetry or z^2. As the electronic state of a Cu^{2+} is considered to consist of a hole in a completely-filled 3d-shell, the energy eigenvalue of the z^2 orbital without an O^{2-} in the *z*-direction will be higher than that with an O^{2-}. Thus, it is possible that the energy level of the orbital with A_1 symmetry eventually becomes higher than those of the other orbitals with E symmetry when the crystal field symmetry goes down to C_{3v}. Therefore, for this reason too, it is likely that the unpaired electron occupies the z^2 orbital. The molecular orbitals formed may be written as $k\cdot z^2+l\cdot\phi_{\sigma N}$ where k and l are coefficients to be determined by the relative weights of the spin densities in each orbital.

The relatively smaller *g*-factor of $(Cu\text{-aniline})^{2+}$ absorption is due to the greater polarizability of the H–C_6H_4–NH_2 bonds toward Cu^{2+} than that of H–NH_2 bonds toward Cu^{2+}; as a result, the l for aniline is larger than that for NH_3. As the unpaired electron is in an antibonding molecular orbital with coefficients (k and $-l$), the larger l value for $(Cu\text{-aniline})^{2+}$ makes the complex less stable and the *g*-factor closer to that of DPPH.

The temperature dependence of the *g*-factor in Fig. 3 indicates that the three components of the *g*-factor at relatively low temperatures are reduced to two components at higher temperatures. This is due to the rotational and vibrational motion of the Cu^{2+}–NH_3 (partially covalent) bond. The anisotropy in the *g*-tensor is averaged out by thermal motions at elevated temperatures. Somewhere above 140°C, but below 300°C, the surface Cu^{2+} species decompose or react irreversibly with NH_3 and yield some paramagnetic species which give the ESR spectrum shown in Fig. 1e.

The active site of a solid catalyst may be described in two ways. One is in terms of the geometrical positions at which they are located on the surface of a particle, while the other is a description in molecular- or atomic-orbital language. The geometrical problems can be studied by means of an electron microscope and other optical techniques. The bulk symmetry of the orbitals and the crystal field in the solid state can be studied by X-ray and other methods. The symmetry of the atomic- or molecular-orbitals or crystal field on the surface, however, has not been investigated much. From such a point of view, the method employed in the present work would seem to have some significance even when the catalytic importance of CuO is considered to be rather meager.

The Electronic Nature of Paramagnetic Oxygen Species Combined with Metal Ions at Surface and in Solution

Morio SETAKA and Takao KWAN

Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo

(Received March 6, 1970)

ESR spectra of adsorbed oxygen species were investigated on cadmium, cerium and uranium oxides supported on alumina. The principal g values, g_x, g_y and g_z of the oxygen species were computed and compared with those on the other metal oxides. It was pointed out that the principal g values observed on cerium and uranium oxides are interpretable by a peroxy-like model rather than an O_2^- radical. ESR spectra due to radicals formed on mixing solutions of VO^{2+} or UO_2^{2+} (containing Ti^{3+}) with H_2O_2 were also investigated by a rapid-mixing flow technique. The g value of the radicals was very close to the isotropic one of the peroxy-like species adsorbed on the corresponding metal oxide. The electronic nature of the interaction of oxygen species with metal ions at surface and with those in solution was comparatively discussed.

ESR spectra of adsorbed oxygen species on various metal oxides[1-11] have been reported by many workers. These spectra were asymmetric and characterized generally with three different principal g values near 2.0, which varied from one metal oxide to the other. The observed shifts in the principal g values have been discussed in terms of an adsorbed O_2^- model; effect of the electric charge of the constituent metal ion of the oxides on the O_2^- radical was taken into consideration.[3,6] According to Kasai[12] who had studied ESR spectra of γ-irradiated zeolites in the presence of oxygen, the principal g values of the O_2^- radical were strongly dependent on the electric charge associated with the zeolite cation (Na^+ or Ba^{2+}).

The shift of the principal g values has been recognized also by us[8] with respect to the O_2^- radical adsorbed on ZnO, TiO_2 and ZrO_2. It was felt worthwhile, therefore, to extend this sort of study to metal oxides having different electric charges of the constituent metal ion. Thus, in the present paper, special interest will be placed on the ESR of oxygen species adsorbed on metal oxides of higher valencies *e.g.* CeO_2 and UO_3.

Literature shows that a mixture of metal ion and H_2O_2 produces an ESR signal near the g value of 2.0. We have already reported[13] that a mixture of $VOSO_4$ and H_2O_2 yields an ESR signal near $g=2.0$ characterized with eight hyperfine lines due to vanadium nucleus ($I=7/2$) and that the signal is attributable to a *complex* hydroperoxy radical. The observed resemblance in the g values between the complex peroxy-like species in solutions[13] and the oxygen species adsorbed on the surface of V_2O_5[9] is worthy of note. Since the nature of the hydroperoxy or peroxy-like species often observable in solutions of metal ion and H_2O_2 is still unknown, it would be pertinent to investigate ESR spectra of such solutions with particular interest in the valencies of metal ions and to compare the g value of generated radicals with that of adsorbed oxygen species on the corresponding metal oxide. Thus in the present work, solutions containing metal ions such as Ti^{3+}, VO^{2+} and UO_2^{2+} mixed with H_2O_2 were also subjected to ESR studies by using a rapid-mixing flow technique.

Experimental

Preliminary investigations indicated that the metal oxide such as CeO_2 or UO_3 gives only a weak ESR signal due to adsorbed oxygen species. Moreover the oxides became rather metallic, when outgassed at or above 500°C, leading to a decrease in the sensitivity of the cavity. Therefore, in the present work, we used Al_2O_3 as the support, and the supported Ce or U oxide sample (denoted as the Ce or U sample) was studied after appropriate pretreatment. The valency state of the cerium or uranium ion in the sample should therefore be regarded as indefinite. CdO was also investigated as an example of metal oxide having a lower valency.

A sample of Al_2O_3 powder (standardized, E. Merck AG) was impregnated with an aqueous solution of cadmium nitrate (guaranteed, Koso Chemical Co.), ceric ammonium nitrate (guaranteed, Wako Pure Chemical Co.) and uranyl nitrate (standardized, E. Merck AG), respectively. The samples were then dried at 100°C and calcined in a stream of oxygen (760 Torr) for four hours at 500°C except for the Cd sample which was pretreated below 400°C. The amount of added salts was so controlled that the metal ions were 5 wt% of the Al_2O_3. The calcined samples were white (Cd sample), pale yellow (Ce sample) and reddish brown (U sample).

A given amount of each sample was placed in individual quartz tubes (4 mm dia.). The Cd sample was evacuated for thirty minutes at 400°C and heated in a hydrogen atmosphere (50 Torr) for one hour at 300°C and then evacuated for another hour at the same temperature. When the sample was treated with hydrogen at temperatures higher than 300°C, cadmium sublimed and condensed in a metallic state on the wall of the sample tube. The Ce and U samples were evacuated for thirty minutes at 500°C and treated with 50 Torr of hydrogen for one hour and evacuated for another hour at the same temperature. The color was greyish white for the Cd sample and greyish brown for the Ce and U samples.

A capillary tube containing MgO powder dispersed thermally with Mn^{2+} ion was inserted into the center of the sample as a means of measuring relative ESR sensitivity. The g values were calculated on the basis of the g value ($g=2.0036$) of DPPH. Signal simulation of the sample was made with a computer (Hitachi, HITAC 5020) to confirm the obtained g-values. ESR measurements were carried out at room temperature with a JEOL P-10 spectrometer (X band, 100 kcps field modulation).

A rapid-mixing flow technique coupled with ESR was utilized to detect peroxy-like species formed on mixing solutions of Ti^{3+}, VO^{2+} or UO_2^{2+} with H_2O_2. The experimental procedures were nearly the same as those reported earlier.[13]

Results

1. Supported Oxides. So far we have observed ESR spectra of adsorbed oxygen species on a number of metal oxides with or without support.[8] For TiO_2 and SnO_2 supported on Al_2O_3, ESR spectra due to adsorbed oxygen species were essentially the same as those reported for the unsupported oxides.[7,8] On the metal oxide such as MoO_3, it was difficult to distinguish the signal of adsorbed oxygen species from that due to molybdenium ion. Thus we confined ourselves to investigating the Cd, Ce and U samples, which exhibited distinct ESR signals due to adsorbed oxygen species as will be shown later.

No ESR signal was detectable at least in the magnetic field investigated ($g=1.8$—2.2) with the Cd and U samples outgassed in a high vacuum at room temperature. Neither heat treatment in a high vacuum nor hydrogen pretreatment resulted in ESR signals. However, when 50 Torr of oxygen was introduced to the pretreated Cd and U samples at room temperature, followed by slight outgassing, ESR signals as shown in Figs. 1 and 2 were obtained. For the Ce sample, a very small signal consisting of six resonance lines was detected.

g_x' and g_y': g values for the minor signal

for both untreated and pretreated samples. It was attributed to manganese impurities. The Ce sample showed, after a similar oxygen pretreatment, a large signal which overlapped the signal of manganese impurities. The manganese signal was so small compared with the major signal due to adsorbed oxygen species (1/300) that it could be neglected as shown in Fig. 3. The Al_2O_3 support itself gave no ESR signal even after pretreatment.

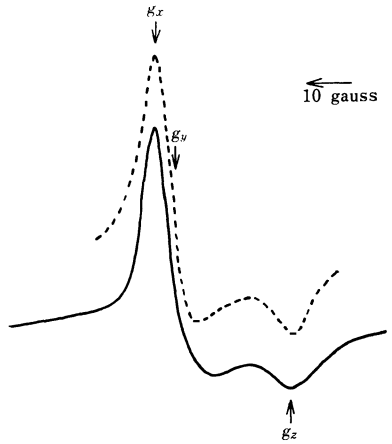

Fig. 3. ESR spectrum of adsorbed oxygen species on a pretreated $CdO-Al_2O_3$ sample.
Dotted curve: simulated

The ESR signals shown in Figs. 1, 2 and 3 were completely broadened by exposure to air. They were restored, however, by slight outgassing at room temperature. This phenomenon suggests that the signals are due to the surface paramagnetic species. When 50 Torr of NO was introduced onto the samples showing these signals, they disappeared in an irreversible manner. A chemical reaction probably had occurred between the paramagnetic species and NO. Although cerium and uranium ions of some lower valencies are indeed paramagnetic and hence may exhibit ESR signals, the observed g values are apparently different from those of the reported spectra.[14] Consequently, the ESR signals of Figs. 1, 2 and 3 should be regarded as due to adsorbed oxygen species.

In the case of the U sample, the major signal (g_x, g_y, g_z) appeared to overlap the minor one (g_x', g_y'). The two signals behaved quite similarly with respect to exposure to air or NO. It seems likely that there are two kinds of adsorped oxygen species on the surface.

It was rather difficult to obtain accurate ESR parameters directly from the maximum or the inflection point of the first derivative curve. The situation became more serious especially when the half width (ΔH) between the maximum slope of the derivative of the absorption line was large. Thus, signal simulation was carried out with a computer on the basis of the theoretical equation of the line shape given by Kneübuhl[15] for a polycrystalline sample having three principal g values.

The computed curves (dotted lines) are compared with the experimental curves (solid lines) in Figs. 1, 2 and 3. Agreement of both curves was rather poor with the U sample where two signals overlapped. The ESR spectrum of the O_2^- radical on ZrO_2[8] is reproduced in Fig. 4 where the signal simulation was similarly carried out and the g values were computed.

In Table 1, the principal g values reported for adsorbed oxygen species on various metal oxides

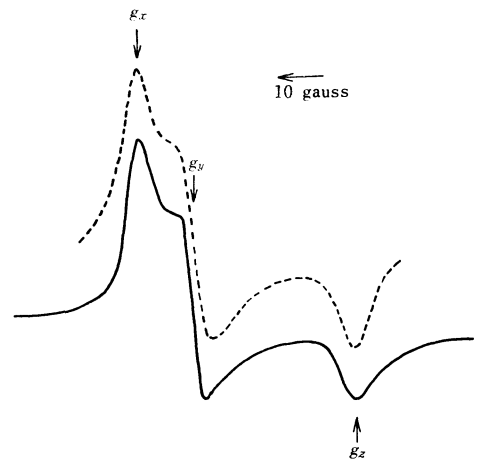

Fig. 4. ESR spectrum of adsorbed oxygen species on a pretreated ZrO_2 sample.

TABLE 1. THE PRINCIPAL g VALUES FOR PARAMAGNETIC OXYGEN SPECIES ADSORBED ON VARIOUS METAL OXIDES

Metal oxide	g_z	g_y	g_x	K[a]	Ref.

15) F. K. Kneübuhl, *J. Chem. Phys.*, **33**, 1074 (1960).

were listed in addition to those on the Cd, Ce and U samples determined in the present work.

2. Solutions. The rapid-mixing flow technique was applied to $UO_2(NO_3)_2$–H_2O_2 similarly as in the case of $VOSO_4$-H_2O_2 system.[13] Since UO_2^{2+} does not act as electron donor, a very small amount of Ti^{3+} we added to the mixing solution in advance. In other words, we expected that UO_2^{2+} would capture peroxy-like species produced by Ti^{3+}–H_2O_2. As a result, the Ti^{3+}–UO_2^{2+}–H_2O_2 system yielded a signal of the g value of 2.023 entirely different from that due to Ti^{3+}–H_2O_2. It is suggested that the $g=2.023$ signal is atrributed to a peroxy-like species combined with UO_2^{2+}.

ESR spectra of a mixture of Fe^{2+}–H_2O_2 or Ti^{3+}–H_2O_2 with organic additives have been the subject of many investigations. Nevertheless, the signal near $g=2.9$ observable for Ti^{3+}–H_2O_2 has not been well identified[16-18] while the nature of organic radicals produced was extensively worked out for both systems. We were able to show an ESR signal near $g=2.0$ for a $VOSO_4$-H_2O_2 system in sulfuric iacid by utilizing a rapid-mixing flow technique.[13] The g value of the signal was found to be 2.0016, and the signal was characterized with eight hyperfine resonance lines due to vanadium nucleus ($I=7/2$). On the basis of these findings, we have proposed that the signal is due to a HO_2 radical complexed with VO^{3+}. Ti^{3+} or Ce^{4+} is reported to give an ESR signal having g values of 2.01195, 2.1335 or 2.016[19] when mixed with H_2O_2 while no such signal is reported for Fe^{2+}–H_2O_2.[20] In the second column of Table 2, the reported g values of the signal observed for various metal ion-H_2O_2 systems are listed together with that of the Ti^{3+}–UO_2^{2+}–H_2O_2 system. In Table 2 are shown the isotropic g values for the oxygen radical adsorbed on the corresponding metal oxides for comparions. It is rather surprising to see that the g values of the peroxy-like species produced from a mixture of metal ions and H_2O_2 is nearly the same as that of the radical adsorbed on the corresponding metal oxide.

Discussion

It can be seen from Table 1 that g_z is, in general, larger than the g value of a free spin ($g_e=2.0023$), while g_x remains nearly constant around g_e. The principal g values of the O_2^- ion trapped in the lattice of alkali halide have been formulated by Kanzig and Cohen.[21] This approach was applied

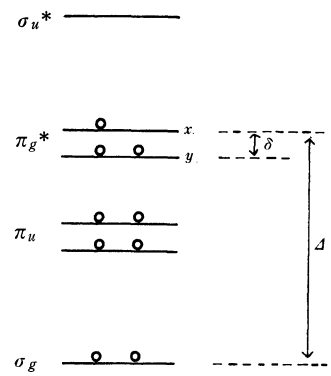

Fig. 5. Electronic energy levels of O_2^- after Kasai (Ref. 12).

here to the study of the adsorbed O_2^- radical. The ground-state electronic configurat on of O_2^- is $(\sigma_g\,2P)^2(\pi_u\,2P)^4(\pi_g^*\,2P)^3$. When O_2^- is adsorbed and exposed to the asymmetric surface field of the metal oxide, the originally degenerated π_g^* orbitals are expected to split into two orbitals, π_g^* $(2P_x)$ and π_g^* $(2P_y)$, as shown schematically in Fig. 5. The three principal g values are then given by

$$g_x = \frac{g_e\delta}{(\delta^2+\lambda^2)^{1/2}} + \frac{\lambda}{\Delta}\left[\frac{\delta+\lambda}{(\delta^2+\lambda^2)^{1/2}} - 1\right]$$
$$\simeq g_e - \frac{\lambda^2}{\delta^2} + \frac{\lambda^2}{\Delta\delta} \qquad (1)$$

TABLE 2. THE ISOTROPIC g VALUES FOR PARAMAGNETIC OXYGEN SPECIES COMBINED TO METAL IONS AT SURFACE AND IN SOLUTION

Metal ion-H_2O_2	g_{iso}	Metal oxide-O_2	g_{iso}	Ref.

$$g_y = \frac{g_e\delta}{(\delta^2+\lambda^2)^{1/2}} - \frac{\lambda}{\Delta}\left[\frac{\delta-\lambda}{(\delta^2+\lambda^2)^{1/2}} + 1\right]$$
$$\simeq g_e + \frac{2\lambda}{\Delta} - \frac{\lambda^2}{\delta^2} - \frac{\lambda^2}{\Delta\delta} \quad (2)$$

$$g_z = g_e + \frac{2\lambda}{(\delta^2+\lambda^2)^{1/2}} \simeq g_e + \frac{2\lambda}{\delta} \quad (3)$$

where, z is chosen along the internuclear axis of O_2^-, δ and Δ are the energy separations shown in Fig. 5. λ is the spin-orbit coupling constant for O_2^-. Approximate equations are useful when $\Delta > \delta \gg \lambda$.

As shown from the approximate equations, the principal g value, which deviates farthest from g_e, should be assigned to g_z, while g_x should be closest to and slightly below g_e. The obtained data except for the Ce and U samples are well explained by such an O_2^- radical model. The effect of a trapping site, which gives rise to the energy separation (δ) of the two π_g^* orbitals, is well reflected in the deviations in g_z values. The value, $K=2/(g_z-g_e)\simeq\delta/\lambda$ was calculated as a possible measure of the interaction of O_2^- with a cation. The results are shown also in Table 1 together with some results of K given by the other workers.[3,6] The K value is expected to increase when the interaction energy between the O_2^- radical and the trapping site increases.

The sequence of this effect, according to Table 1, is given by

$TiO_2 > V_2O_5/SiO_2 > SnO_2 >$ Vycor glass $>$
$ZrO_2 > CdO > ZnO > MgO$

It should be recognized, however, in view of the uncertainty in the g values and also in the approximation used in the theory that the sequence is only qualitative. Nevertheless, it may be inferred from the above sequence that the O_2^- radical is bound more strongly on oxides with cations of higher valencies.

The important role of metal cations for the adsorption of oxygen has already been pointed out by Schvets *et al.*[9] as well as by Kasai.[12] In this connection, mention should be made of the fact that the g_x values (2.011, 2.018) obtained for the Ce and U samples are considerably larger than that of a free spin. The fact suggests that the positive electric charge of Ce and U ions is large enough to interact with the O_2^- radical so that the O_2^- radical model is no longer applicable to these oxides. Probably, a peroxy-like model would be adequate.

Let us review the ESR spectra of hydroperoxy radical trapped in organic or inorganic matrices, since the principal g values of the spectra are known to be similar to those of the O_2^- radical adsorbed on the metal oxides. For example, $g_1=2.0495$, $g_2=2.0081$, $g_3=2.0018$ and $g_1=2.0353$, $g_2=2.0086$, $g_3=2.0042$ have been reported for HO_2 radicals generated in a γ-irradiated single crystal of H_2O_2–$CO(NH_2)_2$ and in a γ-irradiated H_2O_2-water matrix at 77°K, respectively.[22,23] Such O_2^--like spectra could be anticipated, if the unpaired electron, in the π * orbital, is affected by the field of the proton,[24] and moreover if the unpaired electron is located on the unprotonated oxygen.

The ESR of the organic peroxy radicals has been summarized by Bersohn and Thomas.[25] Accordingly, the g values differs slightly but significantly from one organic peroxy radical to another. For example, the principal g values ($g_1=2.0267$, $g_2=2.0193$, $g_3=2.102$) have been reported by Lontz[26] to an organic peroxy radical, $CF_3CF(\text{-}OO\cdot)CONH_2$, generated on a γ-irradiated single crystal of $CF_3CF_2CONH_2$. It is interesting to note that the observed g values are not much different from those of the oxygen species adsorbed on the supported Ce and U samples.

It can be seen from Table 2 that any metal ion that gives rise to an ESR signal of the complexed radical in a mixed solution with H_2O_2 also produce an ESR signal due to adsorbed oxygen on its oxide surface and that the g shifts are parallel at surfaces and in solutions. The phenomena led us to presume that the electronic nature of paramagnetic oxygen species combined with metal ion at surface is similar to that in solution.

Studies on Triplet Energy Transfer by Means of an Emission-Absorption Flash Technique. I. Reversible Energy Transfer between Xanthene Dyes and Anthracenes

Koichi KIKUCHI, Hiroshi KOKUBUN and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received March 24, 1970)

Choosing eosin and erythrosin as donor and anthracene and 9-methylanthracene as acceptor, we have kinetically investigated the triplet energy transfer process by flash technique involving emission measurement. In these systems the differences of T-levels of donor and acceptor are of the order of kT at most, and it was anticipated that a reversible energy transfer would occur. It has been established that it actually occurs in eosin-anthracene and erythrosin-anthracene, and very likely occurs in erythrosin-9-methylanthracene. Furthermore, it has been found that in the first two systems the energy transfer rate for the process, donor→acceptor is about half that for the process, acceptor→donor. This means that the rate in the present systems is determined by some other factor than the triplet level. Discussions have been given on the model for energy transfer.

According to Parker *et al.*,[1] triplet energy transfer between some dyes and aromatic hydrocarbons gives rise to various types of delayed fluorescence. Their observations, however, were qualitative in nature. By a flash apparatus modified so as to measure the emission as well as absorption,[2] the present authors made a quantitative study on the reversible energy transfer between eosin and anthracene.[3] We could demonstrate that an equilibrium, $D^T+A \rightleftarrows D+A^T$ practically holds between donor and acceptor.

The result of our studies will contribute to our knowledge concerning the efficiency of the triplet energy transfer. It is often assumed that when the transfer is highly exothermic its rate is diffusion-controlled.[4,5] But when the triplet levels of donor and acceptor are close to each other the rate becomes slower; Bäckström and Sandros proposed that in endothermic transfer the rate is governed by an exponential factor $\exp(-\Delta E)$, where ΔE is an endothermic energy.[5] Recent work has raised some criticism on the condition for diffusion controlled energy transfer.[6] It has been suggested that the energy transfer in less viscous solvents competes with the diffusion apart of donor and acceptor, which makes the energy transfer rate appreciably slower than the diffusion rate.[7] Such a suggestion has been made chiefly on the basis of the viscosity dependence of the bimolecular rate constant between quencher and triplet molecule. It may be expected that clearer understanding will be obtained by comparing the forward and backward energy transfer rates of a reversible system, for which the encounter rate is practically the same for forward and backward processes. Furthermore, such studies will enable us to examine experimentally whether and how the transfer efficiency is influenced by other factors than the triplet levels of donor and acceptor.

The object of the present paper is to describe the details on the reversible energy transfer be-

tween eosin and anthracene which has already been communicated briefly,[3] and to extend a similar study to the systems, erythrosin-anthracene eosin-9-methylanthracene and erythrosin-9-methylanthracene, all in ethanol.

The triplet levels of these substances are very close to each other[8] as shown in Fig. 1; in particular, the levels of erythrosin and anthracene are almost the same.

Experimental

Materials. 9-Methylanthracene of K & K Lab., Inc. was subjected to zone-melting and recrystallized from ethanol. G. R. grade ethanol of Wakojunyaku was used without further purification. Other substances were purified by standard methods.

Apparatus and Procedures. Essentially the same as has been described.[2]

Results

The elementary processes related with the energy transfer are those involved in the scheme

$$\begin{array}{ccccc} {}^3D + A & \underset{k_4}{\overset{k_2}{\rightleftharpoons}} & {}^3A + D & & \\ \downarrow k_1 \quad +A \quad k_3 \downarrow & & \downarrow k_6 \quad +D \quad k_5 \downarrow & & \\ D \qquad D + A & & A \qquad A + D & & \end{array}$$

in which D is a xanthene dye and A, anthracene. The differential equations to be solved are

$$-\frac{d[^3D]}{dt} = \{k_1+(k_2+k_3)[A]\}[^3D] - k_4[D][^3A] \quad (1)$$

$$-\frac{d[^3A]}{dt} = \{k_6+(k_4+k_5)[D]\}[^3A] - k_2[A][^3D] \quad (2)$$

When the dyes as donor are excited exclusively by means of a suitable filter, the initial condition is put as

$$[^3D] = [^3D]_0 \qquad [^3A] = 0$$

In the early stage of the decay, the above equations are written as follows with a good approximation, since most donor molecules are in the triplet state and the concentration of triplet acceptor is small.

$$-\frac{d[^3D]}{dt} = \{k_1 + (k_2 + k_3)[A]\}[^3D] \quad (3)$$

$$\frac{d[^3A]}{dt} = k_2[A][^3D]$$

Thus the rate constant of ^{3}D-decay is given by $k_1+(k_2+k_3)$ [A]. In order to keep such a situation for a long time, the concentrations of donor and acceptor should be made as low as possible. Of course the later stage under such a condition is not observable on account of very low concentrations of ^{3}D.

In order to study the later stage, higher concentrations of donor and acceptor must be used. In the later stage where the concentrations of donor and acceptor are approximately constant, the solution of (1) and (2) are expressed as the sum of two exponential terms in which the exponents of the two terms are given correctly as follows.

$$\beta_2^1 = \frac{1}{2}\{k_1 + (k_2 + k_3)[A] + k_6 + (k_4 + k_5)[D]\} \pm \frac{1}{2}[\{k_1 + (k_2 + k_3)[A] - k_6 - (k_4 + k_5)[D]\}^2 + 4k_2k_4[A][D]]^{1/2} \quad (4)$$

But one terms with an exponent β_1 can safely be neglected and the exponent β_2 ($=\beta$) for the remaining term is approximated as

$$\beta = \frac{k_2[A]\{k_6 + k_5[D]\} + k_4[D]\{k_1 + k_3[A]\}}{k_2[A] + k_4[D]} \quad (5)$$

if

$$k_2[A] > k_3[A] + k_1 \qquad k_4[D] > k_5[D] + k_6 \quad (6)$$

Furthermore the relation

$$[^3A]/[^3D] \simeq k_2[A]/k_4[D] \quad (7)$$

holds which shows the existence of equilibrium, $^3D+A \rightleftarrows D+{}^3A$. Although an attempt to give exact criterion for the above two extremes was not made, the two extremes could be distinguished by the linear relations in the log[^{3}D] *vs.* *t* plot and with quite different slopes.

It will be seen that relations (5) and (7) really hold in the case of eosin-anthracene and erythrosin-anthracene, and approximately in erythrosin-9-methylanthracene but not in eosin-9-methylanthracene.

Eosin-anthracene. The dependence of the decay curves of eosin at low concentrations (1.0×10^{-6}, 5×10^{-7} M) upon the concentration of anthracene was studied. The observed first order rate constants are plotted against the anthracene

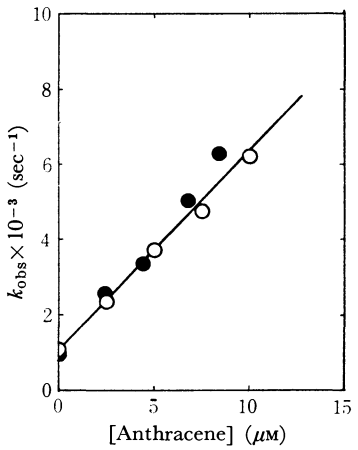

Fig. 2. Effect of anthracene concentration on the first-order rate constant of triplet eosin.

concentration in Fig. 2. From the plot one obtains

$$k_2 + k_3 = (5.1 \pm 0.5) \times 10^8\ \text{M}^{-1}\,\text{sec}^{-1} \quad (8)$$

In a similar way the dependence of the decay constant of triplet anthracene on [eosin] was studied. The result is shown in Fig. 3. As is expected, the slopes in the initial stage are linear but decrease remarkably in the later stage. The dependence of the observed first order rate constant on [eosin] is given in Fig. 4. From the slope we get

$$k_4 + k_5 = (1.2 \pm 0.2) \times 10^9\ \text{M}^{-1}\,\text{sec}^{-1}$$

Figure 5 gives the decay curves of triplet eosin*1 for 10^{-5} M eosin at various concentrations of anthracene. It is seen that the slopes are almost independent of the anthracene concentrations.

The decay of triplet anthracene in this case can be studied either by its triplet-triplet absorption or by the intensity of the delayed fluorescence. The latter is related to the former by the relation, $I_{DF}^A = \alpha\phi_F p k_{TT}^A [D_T^A/\varepsilon]^2$ (I_{DF}^A, intensity of the anthracene delayed fluorescence; α, experimental parameter; ϕ_F, fluorescence quantum yield; p, efficiency for the formation of singlet excited state. Other constants are the usual ones). In the present case, the latter method is more suitable because the anthracene T-T absorption is superposed by the absorption of eosin semiquinone[9] which is produced by a reaction between triplet eosin and alcohol. The relations between coexisting triplet eosin and triplet anthracene are

*1 Decay curves are shown by the log D_T^D *vs.* t plots, where D is the optical density and, suffixes D, T mean donor and triplet.

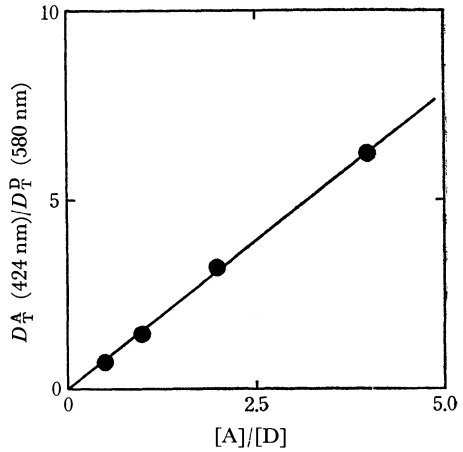

Fig. 7. Proof of the existence of equilibrium.
$^3D + A \rightleftarrows D + {}^3A$, [D] = 1×10^{-5} M

given in Figs. 6a, b and 7. It is clearly seen that a linear relation holds more satisfactorily between $\sqrt{I_{DF}^A}$ and D_T^D than between D_T^A and D_T^D. This, as stated above, is due to the superposition of the absorption from eosin semiquinone over the triplet anthracene absorption. Such situations are frequently encountered in the study of the behavior of the triplet state. Mixed T-T annihilation is another point to be noted. Although a mixed T-T annihilation $^3D+{}^3A\rightarrow A^*+D$ does not occur in the present system, another type, $^3D+{}^3A\rightarrow D^*+A$ does occur; this however does not prohibit the usage of delayed fluorescence intensity of anthracene as a measure of its triplet concentration. If the former were to occur, I_{DF}^A would not simply represent the concentration of triplet anthracene. The linear relation between D_T^A/D_T^D and [A]/[D] shown in Fig. 7 is nothing but the one expected from the existence of equilibrium, $^3D+A\rightleftarrows D+{}^3A$. Using the values of molecular extinction coefficient of ^3D and ^3A, the value of k_2/k_4 is evaluated to be 0.40*2±0.05.

The above result, however, is not enough to verify the existence of the equilibrium in question; it must be shown that the relation $k_2[A], k_4[D] \gg k_1+k_3[A], k_6+k_5[D]$ really holds. The values of k_3 and k_5 can be estimated as follows. Putting

$$k_2[A]/(k_2[A] + k_4[D]) = f \qquad (9)$$

one can transform eq. (5) as follows.

$$\beta = f(k_6 + k_5[D]) + (1 - f)(k_1 + k_3[A]) \qquad (10)$$

Hence

$$\beta - k_1 = f\{k_6 - k_1 + (k_5 + k_4k_3/k_2)[D]\} \qquad (11)$$

It was experimentally found that β is practically equal to k_1, independent of [A]. One can use this result to estimate the values of k_3 and k_5 as follows. The right side of eq. (11) should be less

*2 The value reported in Ref. 2 should be corrected.

than $0.1 \times k_1$, if one assumes the experimental error for the decay constant as *ca.* 10%. Thus

$$-2 \times 10^2 < f\{(k_6 - k_1) + (k_5 + k_3k_4/k_2)[\mathrm{D}]\} < 2 \times 10^2 \qquad (12)$$

Inserting the value of $k_2/k_4=0.40$ and the values of [A] and [D] into Eq. (9), f is found to change from zero to 0.54 and further from Eq. (12) one obtains the following relation.

$$1.2 \times 10^8 < k_5 + 2.5\,k_3 < 1.9 \times 10^8$$

From this, we get

$$k_5 < 1.9 \times 10^8 \qquad k_3 < 7.6 \times 10^7$$

In the case that $k_3=k_5$, we have $3.5 \times 10^7 < k_3 = k_5 < 5.5 \times 10^7$ Thus the values of k_3 and k_5 are estimated to be at most less than 10% of k_2 and k_4 respectively. The values of (k_2+k_3) and (k_4+k_5) then give $k_2/k_4 \approx 0.4$ which agrees satisfactorily with the one already described.

Erythrosin-anthracene. This system is particularly interesting because the triplet levels of donor and acceptor are almost the same. Similar experiments as in eosin-anthracene system were performed. Figure 8 shows the dependence of the decay constant of triplet erythrosin, k_{obs} upon [anthracene] at [erythrosin] $= 1.0 \times 10^{-6}$ M. From the slope we get,

$$k_2 + k_3 = (7.3 \pm 1.0) \times 10^8\ \mathrm{M^{-1}\,sec^{-1}}$$

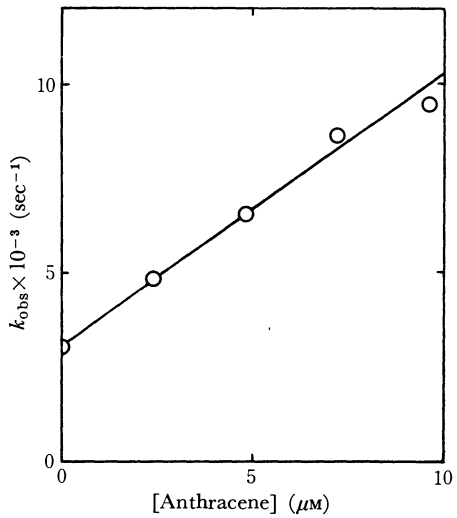

Fig. 8. Effect of anthracene concentration on the first-order rate constant of triplet erythrosin.
[Erythrosin] $= 1 \times 10^{-6}$ M

From the dependence of ^{3}A decay on [erythrosin] at low anthracene and erythrosin concentrations, we obtain $k_4+k_5=(1.7+0.2) \times 10^9\ \mathrm{M^{-1}\,sec^{-1}}$. Putting $k_2/k_4=0.45$ (see below) and $|\beta - k_1| = 0.1\,k_1$ we obtain the following relation by similar reasoning as performed for eosin

$$-5 \times 10^2 < 0.6\{-4.7 \times 10^3 + (k_5 + 5.5k_3)10^{-5}\} < 5 \times 10^2$$

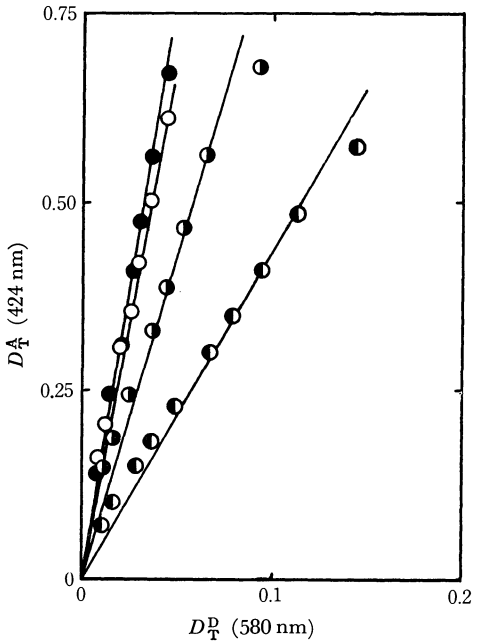

Fig. 9a. Relationship between triplet-triplet absorption of erythrosin and of anthracene.
[Erythrosin] $= 1 \times 10^{-5}$ M
[Anthracene]: ◐ 3×10^{-6} M ○ 9×10^{-6} M ◑ 6×10^{-6} M ● 1.2×10^{-5}

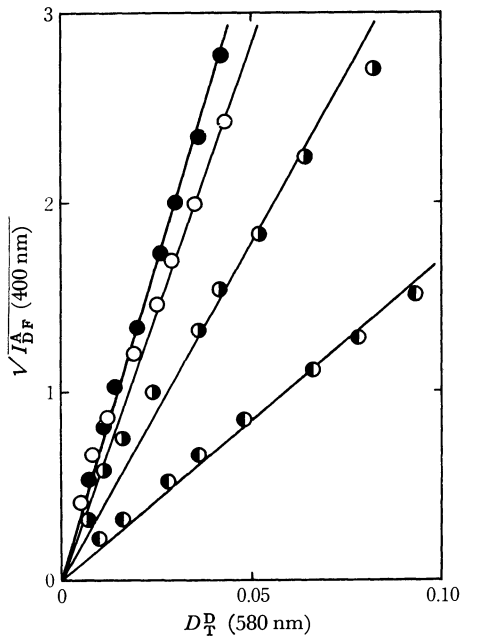

Fig. 9b. Relationship between triplet-triplet absorption of erythrosin and delayed flurescence of anthracene.
[Erythrosin] $= 1 \times 10^{-5}$ M
[Anthracene]: ◐ 3×10^{-6} M ○ 9×10^{-6} M ◑ 6×10^{-6} M ● 1.2×10^{-5} M

The results obtained are summarized as follows.

$$k_5 < 5.3 \times 10^8 \qquad k_3 < 2.5 \times 10^8$$

In the case $k_5 = k_3$, we have

$$1.2 \times 10^8 < k_5 = k_3 < 1.8 \times 10^8$$

In the system the values of k_3 and k_4 are 30% of the values of k_2 and k_4, respectively at most.

At 1.0×10^{-5} M of erythrosin, the $\log D_T^D$ *vs.* t plots in the later stage give almost the same slope from [anthracene]=0 to 12.0×10^{-5} M. The relation between the coexisting ^3D and ^3A in the later stage are given in Figs. 9 and 10.

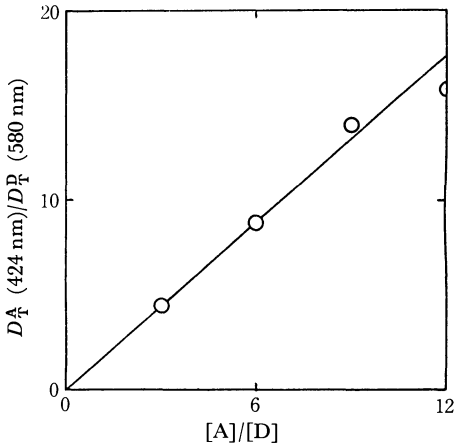

Fig. 10. Proof of the existence of equilibrium.
$^3D + A \rightleftarrows D + {}^3A$, [D]=$2.6 \times 10^{-5}$ M

It is seen that quite a similar relation to that in the case of eosin (Figs. 6 and 7) holds. It is to be noted that a good linear relation in Fig. 9a suggests that there is scarcely any absorption of intermediate such as semiquinone in the region of T-T absorption of anthracene. The value of k_2/k_3 was evaluated to be 0.45+0.05.

Erythrosin-9-methylanthracene. It is expected that the quasi-equilibrium $^3D+A \rightleftarrows D+{}^3A$ is more difficult to hold in this case than in the former two cases, because the difference of triplet levels of donor and acceptor is more than twice as large as that of eosin and anthracene and the decay constant of triplet erythrosin is also about two times larger than that of eosin. Figure 11 gives the plot of decay constant of triplet erythrosin, k_{obs} against [9-methylanthracene] at low [erythrosin]. From the slope, we get

$$k_2 + k_3 = 2.2 \pm 0.4 \times 10^9 \text{M}^{-1}\,\text{sec}^{-1} \qquad (12)$$

From a similar experiment for the triplet 9-methylanthracene, we have

$$k_4 + k_5 = (3.3 \pm 0.3) \times 10^8 \text{M}^{-1}\,\text{sec}^{-1} \qquad (13)$$

At higher concentrations of erythrosin (2.6×10^{-5} M), the plots of $\log D_T^D$ *vs.* t at various acceptor concentrations, give about the same slopes as in the previous two cases. Figure 12 gives the relation between the triplet absorbance of erythrosin

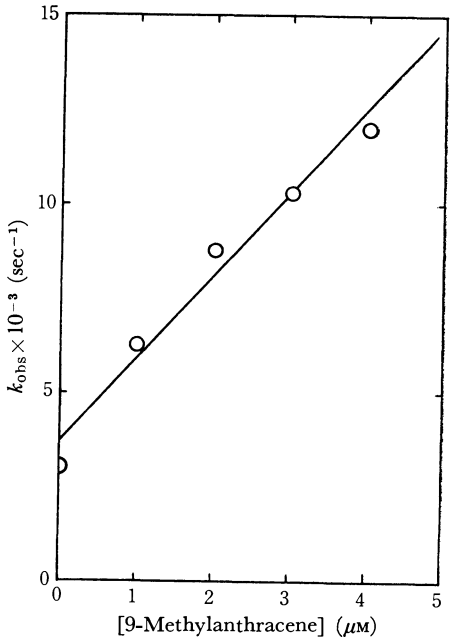

Fig. 11. Effect of 9-methylanthracene concentration on the first-order rate constant of triplet erythrosin.

[Erythrosin] $=2.6\times10^{-5}$ M
[9-Methylanthracene]: ◑ 4.7×10^{-6} M
◐ 9.5×10^{-6} M
○ 1.9×10^{-5} M
● 3.8×10^{-5} M

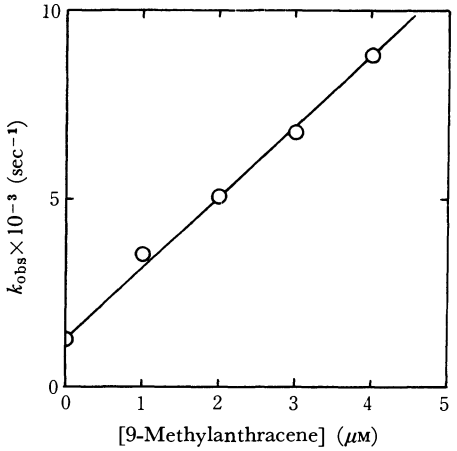

Fig. 14. Effect of 9-methylanthracene concentration on the first-order rate constant of triplet eosin.
[Eosin] $=2\times10^{-6}$ M

and 9-methylanthracene and Fig. 13, the relation between the delayed fluorescence of 9-methylanthracene and triplet erythrosin. It is seen that the linear relation holds approximately in both cases, suggesting the existence of quasi-equilibrium. However, the upper limits estimated for k_3 and k_5 are, respectively, 2.1×10^9 and 3.3×10^8 which are comparable with the values of (k_2+k_3) and (k_4+k_5). Hence it is somewhat doubtful that the approximate equilibrium in question really holds.

Eosin-9-methylanthracene. Since the difference in triplet levels of donor and acceptor is still larger than that for erythrosin-9-methylanthracene, it is expected that the quasi-equilibrium does not hold in this case. In fact, the existence of triplet eosin could not be observed at high concentration of donor and acceptor. From the plot of decay constant of triplet eosin, k_{obs} against [9-methylanthracene] at low [eosin] (2.0×10^{-6}), we obtain $k_2+k_3=(1.9+0.2)\times10^9$ M^{-1} sec^{-1} and from a similar experiment for the decay of 9-methylanthracene $k_4+k_5=(2.1+0.4)\times10^8$ M^{-1} sec^{-1}.

All the rate constants evaluated in the present paper are summarized in Table 1.

Discussion

In the present work it has been fully established that a quasi-equilibrium, $^3D+A\rightleftarrows D+{}^3A$ holds in eosin-anthracene and erythrosin-anthracene. It is well known that Bäckström and Sandros[5] found the reversible energy transfer between donor and acceptor with triplet levels close together. But they did not observe the establishment of a relation $[^3A]/[^3D]=\text{const}\cdot[A]/[D]$, as shown in the present paper. Besides, the present study demonstrates definitely that the rate constant for $^3D+A\rightarrow D+{}^3A$ (k_2) is smaller than that for the reverse transfer (k_4). Thus in erythrosin-anthracene where $\Delta E\sim0$, and in eosin-anthracene

Table 1. Rate constants for elementary reactions involved in energy transfer

	Eosin Anthracene	Erythrosin Anthracene	Erythrosin 9-Methylanthracene	Eosin 9-Methylanthracene
k_1 (sec^{-1})	$(2.4\pm0.3)\times10^3$	$(5.5\pm0.5)\times10^3$	$(5.5\pm0.5)\times10^3$	$(2.4\pm0.3)\times10^3$
k_2+k_3 (M^{-1} sec^{-1})	$(5.1\pm0.5)\times10^8$	$(7.3\pm1.0)\times10^8$	$(2.2\pm0.4)\times10^9$	$(1.9\pm0.2)\times10^9$
k_4+k_5 (M^{-1} sec^{-1})	$(1.2\pm0.2)\times10^9$	$(1.7\pm0.2)\times10^9$	$(3.3\pm0.3)\times10^8$	$(2.1\pm0.4)\times10^8$
k_6 (sec^{-1})	$(7.6\pm1.0)\times10^2$	$(7.6\pm1.0)\times10^2$	$(2.5\times0.5)\times10^2$	$(2.5\pm0.5)\times10^2$
k_3 (M^{-1} sec^{-1})	$<7.6\times10^7$	$<2.5\times10^8$	$<2.1\times10^9$	—
k_5 (M^{-1} sec^{-1})	$<1.9\times10^8$	$<5.3\times10^8$	$<3.3\times10^8$	—
k_2/k_4	0.40 ± 0.05	0.45 ± 0.05	6.4 ± 0.7	—
$(k_2+k_3)/(k_4+k_5)$	0.43 ± 0.10	0.43 ± 0.10	6.7 ± 1.0	—

where donor triplet level is 100 cm^{-1} higher than that of acceptor, the k_2-values are about twice as small as the k_4-values. This implies that for the system where $\Delta E \lesssim kT$, ΔE is not the only important factor for determining the transfer efficiency.

For interpreting the present results, it is helpful to refer to the results and the interpretations of other workers on the related phenomena. For the system in which the reversible energy transfer occurs, Sandros[5] proposed that the encounter complex is formed with a diffusion controlled rate and that the probability for the forward and backward energy transfer is determined only by the energy difference between ^{3}D and ^{3}A. Thus they inferred that the rate constant for endothermic transfer is essentially determined by a factor $e^{-\Delta E/RT}$ where $\Delta E = E(^3\mathrm{D}) - E(^3\mathrm{A})$. The same assertion was made also by Stevens and Walker.[10] Wagner,[7] on the other hand, studied the system in which energy transfer is irreversible and obtained results which lead to the conclusion that the transfer efficiency can be much smaller than the diffusion-controlled one, on account of the competition between the transfer process and the diffusion apart of ^{3}D and A. Richtol and Belorit[11] and also Borkman and Kearns[12] studied the irreversible energy transfer and found that the ^{3}D+A→D+A process occurs to some extent. Both groups proposed the following scheme where (^{3}D···A) is an encounter complex.

$$\begin{array}{ccccccc} {}^3\mathrm{D} + \mathrm{A} & \rightleftarrows & (^3\mathrm{D}\cdots\mathrm{A}) & \rightarrow & \mathrm{D} & + & {}^3\mathrm{A} \\ & & \downarrow & & & & \\ & & \mathrm{D} + \mathrm{A} & & & & \end{array}$$

Their conclusion is similar to Wagner's in that the overall rate constants for energy transfer and energy dissipation are small on account of the backward reaction (^{3}D···A)→^{3}D+A.

In view of all the previous results, it is quite reasonable to assume the following scheme for the present system.

$$\begin{array}{ccccc} {}^3\mathrm{D} + \mathrm{A} & \underset{k'_{\mathrm{ID}}}{\overset{k'_{\mathrm{DI}}}{\rightleftarrows}} & {}^3(\mathrm{D}\cdots\mathrm{A}) & \underset{k'_{\mathrm{AI}}}{\overset{k'_{\mathrm{IA}}}{\rightleftarrows}} & \mathrm{D} + {}^3\mathrm{A} \\ & & \downarrow k'_d & & \\ & & \mathrm{D} + \mathrm{A} & & \end{array}$$

In this scheme, ^{3}(D···A) is an intermediate (I) with perhaps a specific configuration by way of which the forward and backward energy transfer (^{3}D+A→D+^{3}A and D+^{3}A→^{3}D+A) and also the energy dissipation process (^{3}D+A→D+A, ^{3}A+D→A+D) can occur.*3

As to the interchange between I and the encounter complex, two typical models are to be discriminated. The first is a model in which the intermediate is very easy to reach from the encounter state, (^{3}D···A) and (D···^{3}A). In this case the forward and backward energy transfer is repeated and a certain equilibrium state is realized during the encounter state. If one assumes that the encounter rate k_e controlled by diffusion is the same for forward and backward reactions, k_2 and k_4 can be written as

$$k_2 = k_e k_{\mathrm{IA}}/(k_{\mathrm{IA}} + k_{\mathrm{ID}} + k_d)$$
$$k_4 = k_e k_{\mathrm{ID}}/(k_{\mathrm{IA}} + k_{\mathrm{ID}} + k_d)$$

where k_{IA} and k_{ID} is the rate constant for processes I→(D···^{3}A) and I→(^{3}D···A), respectively. Then the equilibrium constant $K=k_2/k_4$ is reduced to $k_{\mathrm{IA}}/k_{\mathrm{ID}}$ and this reflects the equilibrium state in the encounter complex. It should be added that this model requires $k_3 \approx k_5$.

The second is a model in which the intermediate is difficult to reach from the encounter state and only a small fraction α_f and α_r, respectively of (^{3}D···A) and of (D···^{3}A) goes to the ^{3}(A···D) state. In this case, k_2 and k_4 are written, respectively as follows.

$$k_2 = k_e \alpha_f k_{\mathrm{IA}}/(k_{\mathrm{IA}} + k_{\mathrm{ID}} + k_d)$$
$$k_4 = k_e \alpha_r k_{\mathrm{ID}}/(k_{\mathrm{IA}} + k_{\mathrm{ID}} + k_d)$$

Thus the equilibrium constant $K=k_2/k_4$ depends not only on $k_{\mathrm{IA}}/k_{\mathrm{ID}}$ but also on α_f/α_r. k_3/k_5 is then expected to be equal to α_f/α_r. If this model fits the truth, the result $k_2/k_4 < 1$ suggests that the intermediate has a configuration closely resembling that of an encounter compex (D···^{3}A) because the value of k_2/k_4 depends most likely on α_f/α_r much more than $k_{\mathrm{IA}}/k_{\mathrm{ID}}$.

Of the two models described above, the first appears to interpret the present results better than the second. Thus according to the first model, the sum of (k_2+k_3) and (k_4+k_5) should be the diffusion rate constants, and the experimental values are really very near them.

Apart from the argument as to which model is more suitable, it should be noted that the equilibrium state in the present system, contrary to Sandros' system,[5] is not determined only by an energy factor. As a possible factor, an overlap integral $\int^{\infty} f_{\mathrm{D}}(\nu)\varepsilon(\nu)\,d\nu$ involved in Dexter's theory[13] is conceivable. Since the longest absorption band of donor is located in the longer wavelength region than that of acceptor, this factor is expected to be favorable to k_{ID} than k_{IA}, resulting in a larger k_4 than k_2 according to the first model.

*3 It is possible that the forward and backward reaction occurs via a different intermediate state. Even in this case the conclusions for $K=k_2/k_4$ described below will be essentially the same.

Mercury-Photosensitized Reaction of Acetylene

Shoji SHIDA and Masao TSUKADA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 8, 1970)

The mercury-photosensitized reaction of acetylene has been studied with equimolar mixtures of C_2H_2 and C_2D_2 under various conditions of pressure, temperature, and additives. It is shown that the distribution of isotopically substituted benzenes can be explained by a modified excited state mechanism equally as well as, or more favourably than by the free radical mechanism. The results on deuterium-acetylene mixtures photosensitized by $Hg(^3P_1)$, however, suggest that benzene is also formed by the reaction of hydrogen atoms and acetylene molecules. The rates of benzene formation and of the polymer formation increased gradually with pressure in low pressure region to attain a maximum and then decreased. Argon very strongly inhibited the benzene formation and, to a less extent, the polymer formation. The primary process is explained by assuming the formation of a transient complex of a triplet mercury atom and an acetylene molecule.

Since the early work of Bates and Taylor,[1] photopolymerization of acetylene has been the subject of a number of studies. In spite of the simplicity of the over-all reaction, which produces mainly benzene and an involatile solid polymer, cuprene, no final agreement on the mechanism of the reaction has yet been attained, although the free radical mechanism appears to be predominant at the present stage. For the formation of benzene, an excited molecule mechanism was suggested for the mercury-photosensitized reaction,[2] though LeRoy and Steacie[3] proposed a free radical mechanism to explain the formation of polymer and volatile products from the fact that nitric oxide inhibited the polymerization. Mains, Niki and Wijnen[4] found that isotopic benzenes including an odd number of H or D atoms were produced in significant yields in mercury-photosensitization of C_2H_2-C_2D_2 mixtures, suggesting a free radical mechanism again. However, the observed distribution of isotopic benzenes can not necessarily support the free radical mechanism, which can also be explained by a modified excited molecule mechanism.[5]

Experimental

Acetylene (purity, 99.6%) supplied by Takachiho Trading Co. was passed through a silica gel column and further through a trap immersed in a carbon dioxide-acetone mixture followed by bulb-to-bulb distillation, and the middle third was used. No impurity was detected by gas chromatography or by mass spectrometry. Acetylene-d_2 was prepared by passing D_2O through high-purity carbide, purified with a dimethyl sulfolane column and degassed by bulb-to-bulb distillation. Less than 1.3% C_2HD was found as an impurity. Nitric oxide and argon (Takachiho Trading Co., purity, 98.5 and 99.999% respectively) were used without further purification.

The light source was a low-pressure mercury resonance lamp. Between the lamp and the quartz reaction vessel, a UV-25 filter (Toshiba Denki Co.) which eliminated a light shorter than 2300 Å was placed. The reactant was circulated through a closed loop system having a mercury vapor saturator and a glass pump circulator. Total pressure change was measured with a mercury manometer and a travelling microscope.

Benzene formed as a product was analyzed by gas chromatography under reduced pressure. The column used was packed with dioctyl phthalate at 80°C. The distribution of isotopically substituted benzenes was analyzed by means of a mass spectrometer using ionizing electrons of 10 eV which produce almost only the parent ions of benzenes.

Results and Discussion

Reaction Products. The products formed from C_2H_2 were hydrogen, diacetylene, vinylacetylene, benzene, cyclooctatetraene, polymer, and C_2HD in the case of C_2H_2-C_2D_2 mixtures. No attempt was made to measure quantitatively other products except for benzene, C_2HD, and polymer, since it was confirmed that they were formed only in very small amounts. These products are in general accord with those found by

earlier workers.[2,3,6]

Isotopic Studies. The mercury-photosensitized reaction of an approximately equimolar mixture of C_2H_2 and C_2D_2 resulted in the mixture of isotopically substituted benzenes shown in Table 1. The yields of C_6H_5D, $C_6H_3D_3$, and C_6HD_5 are too large to be accounted for by statistical inclusion of C_2HD, because the concentration of C_2HD formed is nearly less by a few per cent of the initial acetylene.[7] It can be seen that the yields of C_6H_6, $C_6H_4D_2$, $C_6H_2D_4$, and C_6D_6 are relatively larger than those of C_6H_5D, $C_6H_3D_3$, and C_6HD_5, and that the distribution of isotopic benzenes is almost constant at higher pressures.

As suggested by LeRoy,[8] this isotopic distribution may be explained by a free radical mechanism initiated by hydrogen atoms such as

$$\left.\begin{aligned} &C_2H_2 + H \rightarrow C_2H_3 \\ &C_2H_3 + C_2H_2 \rightarrow C_4H_5 \\ &C_4H_5 + C_2H_2 \rightarrow C_6H_7 \\ &C_6H_7 \rightarrow C_6H_6 + H \end{aligned}\right\} \quad (I)$$

The distribution of various benzenes predicted on the basis of the free radical mechanism (I) would be, in decreasing order of H atom content, 9.4%, 6.25%, 28.2%, 12.5%, 28.2%, 6.25%, 9.4%. The calculation is performed on the assumption that the quenching cross sections for the formation of H or D atoms from C_2H_2 and C_2D_2 are equal and that the probability of eliminating a D or H atom from a terminal =CHD group on cyclization is 0.5. The calculated percentages are nearly in agreement with the distributions except for those in the low pressure region.

As shown in Table 1, the observed distribution depends on the acetylene pressure in the low pressure region and the yields of benzenes containing an odd number of D atoms tend to increase as the acetylene pressure decreases.[9] The distribution of isotopic benzenes expected to be formed in the radical mechanism should be independent of the acetylene pressure. Thus, the free radical mechanism could not explain the change of the isotopic distribution at low pressures. The close agreement between the distribution observed in the higher pressure region and the calculated one can not necessarily support such a radical mechanism.

The observed distribution can be as well accounted for by a modified excited molecule mechanism as by the radical mechanism.[5] This mechanism which involves redissociation of a hot acetylene dimer molecule is shown as follows:

$$\left.\begin{aligned} &C_2H_2^* + C_2H_2 \rightarrow \begin{matrix} CH{=}CH^* \\ | \quad | \\ CH{=}CH \end{matrix} \\ &\begin{matrix} CH{=}CH^* \\ | \quad | \\ CH{=}CH \end{matrix} \rightleftarrows \begin{matrix} CH{-}CH^* \\ \| \quad \| \\ CH{-}CH \end{matrix} \\ &\begin{matrix} CH{-}CH^* \\ \| \quad \| \\ CH{-}CH \end{matrix} \rightarrow C_2H_2^{**} + C_2H_2 \\ &C_2H_2^{**} \xrightarrow[+C_2H_2]{} C_4H_4^{**} \xrightarrow[+C_2H_2]{} C_6H_6 \end{aligned}\right\} \quad (II)$$

where * denotes highly (electronically or vibronically) excited states and ** lower excited states. In this mechanism, $C_2H_2^*$ and $C_2D_2^*$ will be in the ratio 1 : 1 and no C_2HD^* exists, but $C_2H_2^{**}$, C_2HD^{**}, and $C_2D_2^{**}$ are produced in the ratio 3 : 2 : 3 in an equimolar C_2H_2-C_2D_2 mixture. Consequently, the benzene formed *via* the path including excited acetylene would again consist of the distribution, 9.4%, 6.25%, 28.2%, 12.5%,

6) J. K. Cashion and D. J. LeRoy, *Can. J. Chem.*, **32**, 906 (1954).

7) Recently, Fujisaki *et al.* studied the radiolysis of C_2H_2-C_6D_6 mixtures and found that benzene formed was only C_6H_6. N. Fujisaki and S. Shida, unpublished. From this, it can be confirmed that the isotopic exchange between acetylene and benzene formed does not occur in the mercury-photosensitized reaction of C_2H_2-C_2D_2 mixtures.

8) D. J. LeRoy, *J. Chem. Phys.*, **45**, 3482 (1966).

9) In the direct-photolysis of acetylene at 1849 Å, the distribution of isotopic benzenes and the change of it at lower pressures was just the same as in mercury-photosensitization. S. Shida and M. Tsukada, unpublished. In the radiolysis, the distribution was the same as in mercury-photosensitization at higher pressures and was constant in the higher pressure region than 20 mm. S. Shida and T. Oka, unpublished.

28.2%, 6.25%, 9.4%. However, the distribution would be independent of acetylene initial pressure also in this case.

In the reaction mechanism (II), it may be assumed that C_4H_4** is unstable and decomposes into two acetylene molecules or further reacts with an acetylene molecule. If this is the case, C_4H_4** might dissociate into no two ground state acetylene molecules but give C_2H_2** molecule as follows:

$$C_4H_4^{**} \rightarrow C_2H_2^{**} + C_2H_2 \qquad \text{(III)}$$

If the mechanism including reaction (III) is assumed as

$$\left.\begin{aligned} &C_2H_2^{*} + C_2H_2 \rightarrow C_4H_4^{*} \\ &C_4H_4^{*} \rightarrow C_2H_2^{**} + C_2H_2 \\ &C_2H_2^{**} + C_2H_2 \rightarrow C_4H_4^{**} \\ &C_4H_4^{**} \rightarrow C_2H_2^{**} + C_2H_2 \\ &\qquad\qquad \longrightarrow C_6H_6 \end{aligned}\right\} \qquad \text{(IV)}$$

the distribution of isotopic benzenes formed in C_2H_2-C_2D_2 mixture would be 8.6%, 7.8%, 25.8%, 15.6%, 25.8%, 7.8%, 8.6%.

If the reaction conforms to mechanism (II) at higher pressures and if the cyclobutadiene** molecules partially dissociate to give acetylene** molecules before coming into collision with acetylene at lower pressures, this mechanism would explain the result that the yields of isotopic benzenes containing an odd number of H or D atoms tend to increase at lower pressures. It seems that the modified excited state mechanism would be more favourable that the radical mechanism in this respect.

A fact which has been considered as a direct support for the radical mechanism is the benzene formation in the reaction of acetylene with hydrogen atom.[4,6] However, the formation of benzene in the Cd($^3P_1$)-photosensitized reaction of acetylene studied by Tsunashima and Sato[10] seems to strongly suggest that benzene is also formed by some excited molecule mechanism, because the dissociation energy of the C–H bond of acetylene molecule (114 kcal)[11] is larger than the energy of triplet cadmium (87.7 kcal) even when the heat of formation of cadmium hydride (15.5 kcal) is taken into account.

A single determination of isotopic cyclooctatetraene (COT) formed in the mercury-photosensitized reaction of C_2H_2-C_2D_2 mixture was also made (Table 2). If COT is formed from the reaction of free radicals as

$$H \xrightarrow[+4C_2H_2]{} C_8H_9$$

$$C_8H_9 \rightarrow C_8H_8 + H,$$

TABLE 2. DISTRIBUTION OF ISOTOPIC CYCLOOCTATETRAENES FORMED IN THE MERCURY-PHOTOSENSITIZED REACTION OF C_2H_2-C_2D_2 MIXTURES[a]

C_8H_8	6.3%
C_8H_7D	2.1
$C_8H_6D_2$	23.1
$C_8H_5D_3$	4.6
$C_8H_4D_4$	32.6
$C_8H_3D_5$	3.5
$C_8H_2D_6$	21.3
C_8HD_7	1.1
C_8D_8	5.4

a) Acetylene initial pressure 574 mm

the isotopic distribution predicted will be 4.7%, 3.1%, 18.8%, 9.4%, 28.1%, 9.4%, 18.8%, 3.1%, 4.7%. But if COT is assumed to be formed from the reaction of C_6H_6*, the precursor of benzene, with C_2H_2, just the same distribution as above is predicted. Consequently, it is impossible to determine from the isotopic distribution of COT whether the free radical or the excited state mechanism is more favourable.

Effect of Acetylene Pressure. Figures 1 and 2, respectively, show the pressure depend-

—●— C_2HD ($\times 10^{-7}$ mol/min)

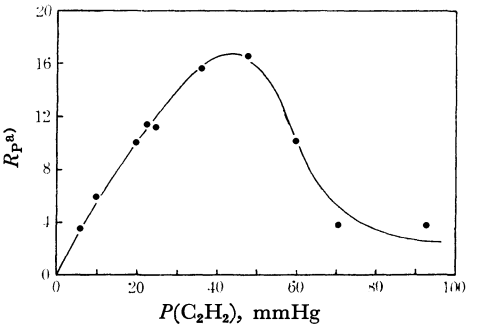

Fig. 2. Rate of polymer formation (acetylene consumed for cuprene).
a) $\times 10^{-7}$ mol/min

ence of the rate of benzene formation and of the rate of polymer formation. The shapes of both the curves are very similar. The rates increase gradually with pressure in the low pressure region to attain a maximum and then decrease. This fact has not been noted by previous investigators.[2,3] Although mercury vapor may be consumed by some reaction with actylene,[3,12] the decrease of the rates in the higher pressure region can not be ascribed to the deficiency of mercury vapor, because a mercury saturator is used in the present experiment. A similar pressure dependence has also been found in the cadmium-photosensitized reaction[10] and also in the radiolysis[13,14] of acetylene.

Effect of Argon. Figure 3 shows the effect of the addition of argon on the rates. Argon very strongly inhibits benzene formation and, to a less extent, polymer formation. It is considered that mechanisms of both benzene and polymer formation include a certain excited intermediate in some stage of reaction, because argon acts only as the deactivator under the experimental conditions. It should be noted here that argon does not quench the excited mercury atom, because the quenching cross section of argon for $Hg(^3P_1)$ is almost zero while that of acetylene is much larger.

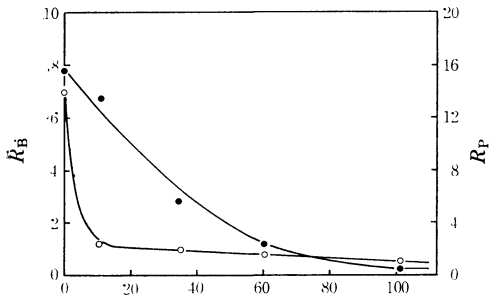

Fig. 3. Effect of argon on the rates of polymer formation and benzene formation.
—○— C_6H_6 ($\times 10^{-8}$ mol/min)
—●— Polymer Formation ($\times 10^{-7}$ mol/min)
Acetylene initial pressure 36.0 mmHg

Primary Process. If an initially excited acetylene decomposes to give an H atom and a C_2H as

$$\left.\begin{aligned} C_2H_2 + Hg^* &\rightarrow C_2H_2^* + Hg \\ C_2H_2^* &\rightarrow C_2H + H \end{aligned}\right\} \quad (V)$$

the formation of diacetylene C_4H_2 is to be expected. However, no significant amount of diacetylene was formed. It might be considered that C_2H radicals add to acetylene rather than recombine to give C_4H_2. But in the direct-photolysis of acetylene at 1849Å, diacetylene was formed as one of the major products as shown in Table 3. In the direct-photolysis, the initial absorption of light by acetylene leads to dissociation along with the formation of excited molecule, and C_4H_2 may be formed by the recombination of C_2H radicals.[15] Thus, the simple mechanism (V) is inadequate for the explanation of the initial stage of mercury-photosensitized reaction.

Table 3. Products in the direct-photolysis of acetylene at 1849 Å

C_2H_2 init. press. mmHg	C_6H_6[a]	C_4H_2[a]

36.0	3.5	4.5
64.5	3.7	4.1
92.0	4.8	3.8

a) $\times 10^{-8}$ mol/min

Sherwood and Gunning[16] showed that a stable mercury compound, probably a mercury carbide, is formed in the reaction and that enriched isotopic composition of ^{202}Hg was obtained in the solid reaction products under ^{202}Hg monoisotopic photosensitization. Furthermore, they studied the mercury-photosensitized decomposition of acetylene in the presence of nitric oxide using a fast-flow apparatus.[17] From the results they proposed the primary process

$$\left.\begin{aligned} Hg^* + C_2H_2 &\rightarrow HgH + C_2H \\ &\rightarrow HgC_2H + H \\ &\rightarrow Hg + C_2H_2^* \end{aligned}\right\} \quad (VI)$$

where $C_2H_2^*$ is not chemically reactive and only collisionally deactivated.

However, the deactivation effect of argon and the formation of only a small amount of diacetylene are probably not explained by a mechanism initially including the process (VI).

We suggest that the following primary sequence is in agreement with the observed data

$$\left.\begin{aligned} Hg^* + C_2H_2 &\rightarrow (HgC_2H_2)^* \\ (HgC_2H_2)^* &\rightarrow Hg + C_2H_2^* \\ &\rightarrow HgC_2H + H \\ (HgC_2H_2)^* + M &\rightarrow Hg + C_2H_2 + M \end{aligned}\right\} \quad (VII)$$

where $C_2H_2^*$ does not decompose to give an H atom any more.

a) Acetylene initial pressure 36.0 mmHg
b) Ref. 4

The primary process of photosensitization in which the photosensitizer interacts chemically or forms chemically reactive intermediates by bonding or complexing with the non-absorbing molecules can not always be distinguished from simple physical transfer of energy in collisions. However, it was suggested that a water molecule, for example, reacts with an excited mercury atom to give an excited complex, $(HgH_2O)^*$, which results in decomposition through a second collision with a third body.[18] In the cadmium($^3P_1$)-photosensitization, Tsushima and Sato[10] suggested the formation of the transient complex of a triplet cadmium atom and an acetylene molecule, $(CdC_2H_2)^*$.

As shown in Fig. 3, it seems that the deactivation effect of argon differs for polymer formation and benzene formation. From mechanism (VII), if excited species (some of $C_2H_2^*$, $C_2H_2^{**}$, $C_4H_4^*$, or $C_4H_4^{**}$) is deactivated in addition to the deactivation of $(HgC_2H_2)^*$, the rate of benzene formation will be much affected.

Using the method of the mercury-photosensitized decomposition of acetylene at very low pressure in the presence of excess amounts of helium, Kebarle[19] suggested that the primary decomposition of acetylene is very small which is about 7% of decomposition of ethylene having a similar quenching cross section. The deactivation of $(HgC_2H_2)^*$ based on analogous arguments as used above can interpret the fact.

Influence of Nitric Oxide. Effect of nitric oxide on the rates of pressure decrease and benzene formation is shown in Fig. 4. Nitric oxide largely suppresses the benzene formation. Nitric oxide usually behaves as a radical scavenger. But, at the same time, nitric oxide which is a paramagnetic molecule may quench the excited triplet species like oxygen.[20]

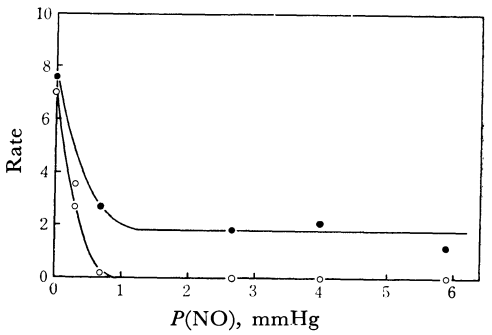

Fig. 4. Effect of nitric oxide on the rates of pressure decrease and of benzene formation.
—○— C_6H_6 ($\times 10^{-8}$ mol/min)
—●— Press. Decrease ($\times 10^{-2}$ mm/min)

Effect on Distribution of Isotopic Benzenes. Table 4 shows the effects of nitric oxide, argon, and temperature on the distribution of isotopic benzenes. Addition of nitric oxide or argon does not affect distribution so much, at least under the experimental conditions. It may be seen that the isotopic benzenes having an odd number of H or D atoms appreciably increase with the rise of temperature. On the basis of the modified excited state molecule mechanism shown above, the change of distribution can be understood on the assumption that the rate of decomposition of cyclobutadiene increases with the rise of temperature.

Effect of Hydrogen Atom. It is known that the hydrogen atom induces the polymerization of acetylene.[4,6,10] Table 5 shows the effect of addition of excess amount of D_2. Benzene formed from the reaction of C_2H_2-D_2 mixture photosensitized by Hg($^3P_1$) consists of a mixture of C_6H_6,

C_6H_5D and $C_6H_4D_2$. This suggests that a part of the benzene is actually formed by the reaction of hydrogen atoms.

Conclusion

The formation of benzene in the mercury-photosensitization of acetylene could be explained by a modified excited state mechanism equally as well as, or more favourably than, by the free radical mechanism on the basis of the distribution of isotopic benzenes. The effects of additives and of acetylene initial pressure suggest that the primary process is constituted including a transient complex of a triplet mercury atom and an acetylene molecule.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2745—2749 (1970)

Radiation Chemical Studies with Cyclotron Beams. II. The Radiolysis of an Aqueous Ferrous Ammonium Sulfate Solution with Carbon- and Nitrogen-Ion Radiations[1)]

Masashi IMAMURA, Masao MATSUI and Takashi KARASAWA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received April 13, 1970)

The yield of ferric ions in the radiolysis of an aqueous ferrous ammonium sulfate solution has been determined in the very high LET (linear energy transfer) range. The radiations used were ions of carbon-12 and nitrogen-14, which were accelerated by means of the IPCR cyclotron and which had energies (E_s) of 31—77 MeV for C-ions and of 17—78 MeV for N-ions; the LET ranges for water were 24—46 eV/Å and 26—85 eV/Å respectively. From the plot of $G(Fe^{3+})E_s$ *vs.* E_s, the value for $G(Fe^{3+})$ at an infinite LET was found to be in the vicinity of 2.9. It has also been shown that there is a substantial difference in the instantaneous yield (G_i) between the two ion radiations of the same LET; this may be ascribed to the differences in the track structures of the heavy-ion radiations.

In most of the experimental work on the LET (linear energy transfer) effect in radiolysis, protons, deuterons, or helium ions have usually been used as radiation sources with a high LET.[1-8)] The maximum LET available in water, however, is approximately 7 eV/Å for protons and 25 eV/Å for helium ions. It is expected that a much higher LET can be obtained from fission fragments of ^{235}U (several hundred eV/Å), but they are attended with some inevitable experimental difficulties.

Schuler[9)] has used ^{12}C-ions accelerated with a HILAC and has made measurements of the yields for aqueous ferrous ammonium sulfate solutions; the energy of the C-ions was in the range of 54—102 MeV. Other heavy ions, such as ^{14}N- and ^{20}Ne-ions, have been used by Burns and his colleague for the radiolysis of liquid cyclohexane and benzene.[10)]

We have initiated radiolysis studies using heavy-ion radiations made available by the IPCR 160 cm cyclotron, which can accelerate several heavy ions at variable energies. While the previous paper[1)] of this series has reported the radiolysis of aqueous ferrous ammonium sulfate solutions with protons and helium ions, the present paper

will concern the results with C- and N-ions, which had energies of 31—77 and 17—78 MeV respectively; a single result with 58 MeV ^{16}O-ions is also included.

By extrapolating the present results at very high LET's, one could obtain the value for $G(Fe^{3+})$ at an infinite LET and, therefore, the limiting yield of water decomposition, G_{-H_2O}. It has also been shown that there is a substantial difference in the instantaneous yield among C-, N-, and O-ions. This may be explained by the differences in the track structures of these heavy-ion radiations.

Experimental

The irradiation arrangement and experimental procedure were similar in outline to those described previously.[1] The ions accelerated in the cyclotron had a charge of +4.[11] The accelerated ions were withdrawn through a beam duct (10 m long) to a target. In the vicinity of the exit window of the duct, the ion beams were passed through a thin gold foil (2μ) and a small fraction of them were elastically scattered by it. The number of ions passing through the foil was thus monitored by counting the number of the scattered ions by a solid-state detector. Meanwhile, the beam currents of ions passing through the foil were determined with a Faraday cup. The number of ions collected in a Faraday cup was then calculated from the total charge, Q, and the average charge, $\langle z\rangle_f$, of ions collected in a Faraday cup after passing through the gold foil; the average charges of ions were obtained in a manner described below. As the number counted by the solid-state detector should be proportional to the number of ions collected in the Faraday cup, one can readily obtain the total number of ions deposited in the solution by assuming no loss of ions between the scattering foil and the solution. The ratio of the number of the scattered ions to that of the collected ions was determined before and after each run; the data were in agreement, within an error of 3%, for each run.

The incident energies of ions were obtained within an error of $\pm 2\%$ by $E_c(\mathrm{MeV}) = 0.107Af^2$, where A is the mass number of the ion and, f(MHz) the radio frequency of the cyclotron being operating. As the ion beams were passed through the scattering foil (2μ Au), the exit window (10μ Al), the air layer (10 mm), and the cell window (10μ mica), the incident energy, E_c, was reduced to E_s when the ions entered the solution. The initial energies of ions entering the solution, E_s, were estimated by the use of the range-energy relations given by Northcliffe.[12]

The principal difference between protons (or helium ions) and heavy ions is that the former can be regarded as charge-invariant over most of the energy region, while the latter can not. With an increase in the atomic number of the ion, there is an expansion of the velocity region in which charge variation is of importance. Northcliffe[13] summarized experimental equilibrium charge distribution data for several heavy ions. It seems that the data can be represented reasonably well by a single universal curve for each value of $z-z'$ (z: atomic number; z': net charge). In the present experiment, the total thickness of absorbers was sufficient to allow the heavy ions to be charge-equilibrated before entering the solution. We have calculated the average charge of ions entering the solution, $\langle z\rangle_s$, by taking weighted means of each fraction of ions having a charge, z', in a charge-equilibrated monoenergetic beam. Table 1 lists the values of z' and $\langle z\rangle_s$ for each ion used in this experiment.

distilled water was used under aerated conditions. The irradiation cells were the same as those used previously;[1] the aperture of the cell (10 mm in diameter) was glazed with mica (10 μ thick), the range of which was estimated to be 2.7 mg/cm^2. The solution was stirred during irradiation by means of a magnetic stirrer at a speed of 36 rps.

The oxidation yields of ferrous ions (the number of Fe^{3+} ions oxidized by 100 eV of energy deposited in the solution) were calculated by the equation:[1]

$$G(Fe^{3+}) = 0.96\times10^{7}\times\frac{DV}{\varepsilon d}\times\frac{\langle z\rangle_f}{E_sQ}$$

where: D: the optical density at 304 nm,
ε: the molar extinction coefficient of Fe^{3+} at 304 nm in $M^{-1}\,cm^{-1}$,
d: the optical path-length for D-measurement in cm,
V: the volume of the irradiated solution in ml,
E_s: the initial energy of ions entering the solution in Mev,
Q: the total charge collected in a Faraday cup in nanocoulomb, and
$\langle z\rangle_f$: the average charge of ions collected in a Faraday cup.

The initial LET values for ions with an energy of E_s and a net charge of z' were calculated by the reduced Bethe equations:

$$-\frac{dE}{dx} = \frac{22.2z'^2}{E_s}\log(2.75E_s) \quad \text{for } C^{+z'}\text{-ions}$$

$$-\frac{dE}{dx} = \frac{25.9z'^2}{E_s}\log(2.36E_s) \quad \text{for } N^{+z'}\text{-ions}$$

where the mean excitation potential (I) is assumed to be 66 eV for water and where $-dE/dx$ is expressed in eV/Å when E_s is in MeV. The effective values of $-dE/dx$ for ions with an average charge of $\langle z\rangle_s$ were obtained by taking the weighted means of the value for each z'-value; they are summarized in Table 1.[14]

Results and Discussion

The oxidation yield of ferrous ions was found to be linearly dependent on the dose. Some typical examples are given in Fig. 1; Figure 1 also shows that the yield is independent of the beam current in the range of 0.1—3 nA;[15] above 5 nA the yield decreases.

The radiation chemical yields ($G(Fe^{3+})$) were calculated from the slopes of these linear yield-dose plots and are summarized in Table 1. Figure 2 shows the dependence of the observed $G(Fe^{3+})$ value on the initial LET's of ions. The yields obtained by Schuler[9] with C-ions, also plotted in Fig. 2, indicate good agreement with the present C-ion data. It does not seem, however, that the data for the three ions are superimposable: the heavier the ion, the greater the yield. A similar discrepancy has also been observed between protons or deuterons and helium ions.[16] Furthermore, it seems that the yields at higher LET's can be extrapolated to a value lower than 3.6, which was assumed by Schuler and Allen[2b] to be a limiting yield at an infinite LET.

The $G(Fe^{3+})$-values have hitherto been determined by using accelerated protons, deuterons, and helium ions (LET as high as ~5 eV/Å) and

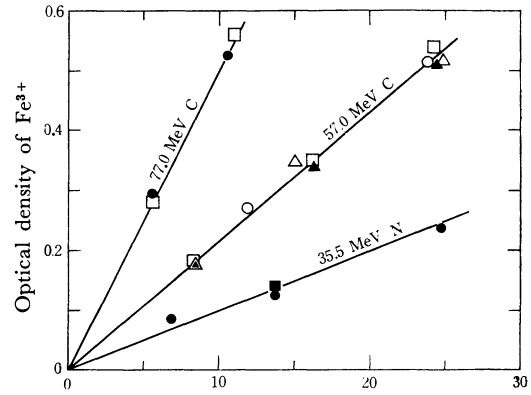

Fig. 1. Plots of Fe^{3+}-yield *vs.* number of ions scattered by a gold foil at various beam currents. The number of scattered ions is proportional to the total number of ions deposited in the solution. The optical densities (d= 10 mm) were determined at 304 nm.

14) Table 1 also contains a single result with O-ions; the experimental procedure was quite similar to that for C- or N-ions. The initial LET for O-ions is given by $(-dE/dx)=(29.6\,z'^2/E_s)\log(2.06\,E_s)$.

15) The beam currents determined by the use of a Faraday cup.

16) A. O. Allen, "The Radiation Chemistry of Water and Aqueous Solutions," Van Nostrand, Princeton, N. J. (1961), p. 54.

the recoil particles from (n,α) reactions of Li and B (~25 eV/Å).[17] These results indicate that the $G(Fe^{3+})$ decreases as the LET of the radiation is increased. No experimental value of $G(Fe^{3+})$ at the LET's higher than the above value has been reported except for those by Schuler with C-ions (LET's as high as ~30 eV/Å) shown in Fig. 2.[9] The present results indicate that the $G(Fe^{3+})$ still decreases at LET's above 30 eV/Å.

The integrated yield of ferric ions produced by an ion with E_s is given by:

$$G(Fe^{3+}) \times E_s = \int_0^{E_s} G_i dE \qquad (E_s \text{ in } 100\,eV)$$

where G_i represents an instantaneous yield at a a given energy. In Fig. 3 the values of $G(Fe^{3+}) \times E_s$ for C-, N-, and O-ions are plotted as a function of E_s; the data of Schuler with C-ions[9] are also included. It seems that, in unexpected contrast to Fig. 2, all the data fit a universal curve, as is shown in Fig. 3. The instantaneous yields, G_i, for given values of E_s are readily obtained from the slopes at the corressponding points on this curve, *i.e.*,

$$G_i(Fe^{3+}) = \frac{d[G(Fe^{3+})E_s]}{dE_s}$$

The values of $G_i(Fe^{3+})$ thus obtained are plotted as a function of the reciprocal LET in Fig. 4 for C-, N-, and O-ions. The dotted line in Fig. 3 represests the tangent at an infinite LET, which gives $G_i(Fe^{3+}) = 2.9$.

As may be seen in Fig. 3, the data for C- and N-ions and probably for O-ions apparently fit a single universal curve within the limits of experimental error. This is presumably adventitious; the curves may not coincide with each other at higher E_s's. Figure 4 clearly indicates the existence of substantial differences in $G_i(Fe^{3+})$ among these ions at the same LET. These differences may be explained by assuming the different contribution of high-energy secondary electrons; the heavier ion ejects the more energetic secondary electrons. The net yield is, therefore, a combination of the yields for the "core" of the track and for the emergent secondary electrons. The higher yields of heavier ions can thus be understood by assuming the effective expansion of the heavy-ion tracks; such a model has been proposed by Mozumder *et al.*[18] A similar effect observed with deuterons and helium ions has been discussed in terms of the kinetics of secondary electron production.[19] Further experimental study on this effect due to the quality of heavy ions is in progress by using C-, N-, and O-ion radiations.

The oxidation yield of ferrous ions in an aerated aqueous solution is given by the equations:

$$G(Fe^{3+}) = G_{OH} + 3G_H + 2G_{H_2O_2}$$
$$= G_{-H_2O} + 3G_H = 2G_{H_2} + 4G_H$$

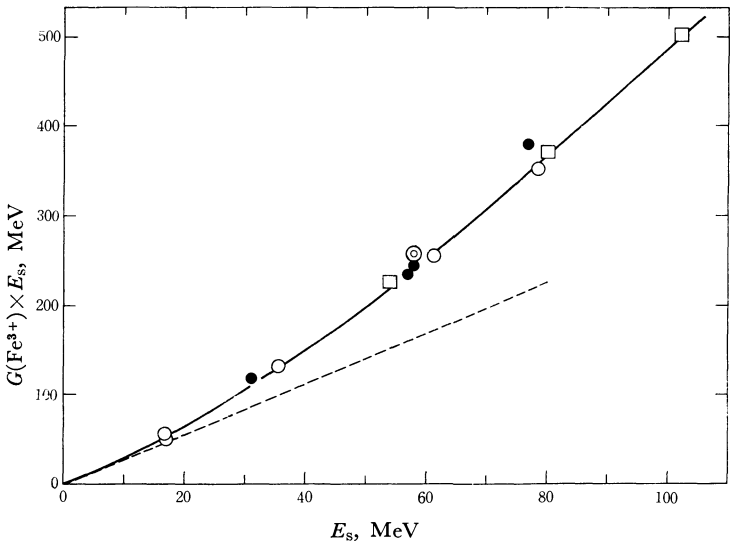

Fig. 3. A plot of the integrated yield of ferric ions *vs.* energy of the heavy ions entering the solution. The dotted line represents the limiting yield of $G(Fe^{3+}) = 2.9$ at an infinite LET.

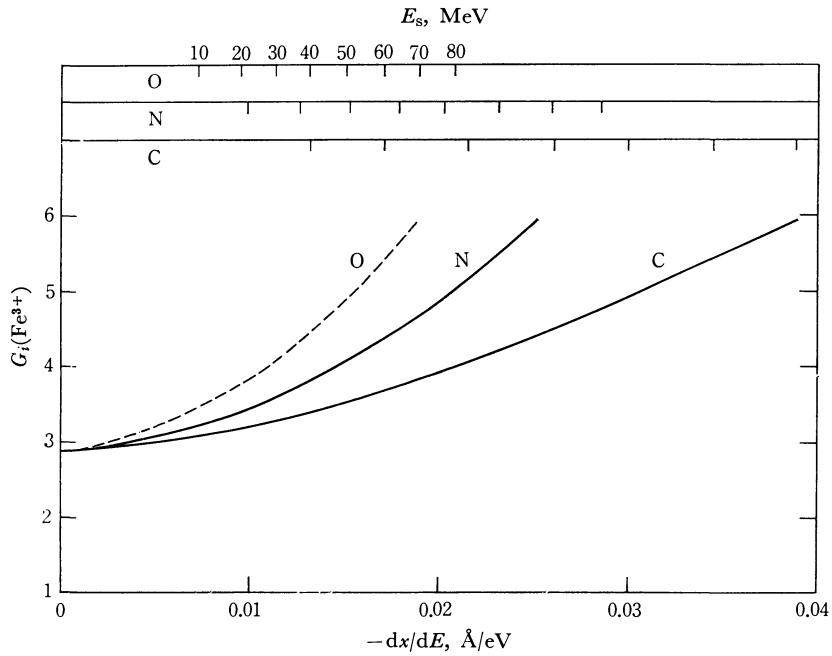

Fig. 4. Dependence on reciprocal LET of the instantaneous yields for C- and N-ions obtained from Fig. 3. Probable dependence for O-ions is also shown.

At an infinite LET, the free radical yields will vanish;[6,20] $G(Fe^{3+})$ will, therefore, approach G_{-H_2O} or $2G_{H_2}$. Schuler and Allen[2b] have assumed the limiting $G(Fe^{3+})=3.6$ from the values for G_{-H_2O} $(=3.6)$ or $2G_{H_2}(=3.4)$ in the radiolysis of an aqueous solution with $^{10}B(n,\alpha)^7Li$ recoil particles. As has been mentioned above, the present results gave the value of 2.9 for the limiting $G(Fe^{3+})$ at an infinite LET, which would mean $G_{-H_2O}\simeq 2.9$ according to the above argument.[21]

According to Allen,[22] the G_{-H_2O} for the 0.8 N H_2SO_4 solution decreases with an increase in the LET to about 3.6 at about 5 eV/Å; then it becomes constant in the higher LET range. In a neutral solution the G_{-H_2O} increases with an increase in LET above 5 eV/Å. However, Anderson and Hart,[6] who investigated the LET dependence of the initial yields from water using a formic acid solution saturated with oxygen, found that the value for G_{-H_2O} decreases with an increase in LET down to 2.4—2.6 for helium ions of about 10 MeV (LET ~5 eV/Å), and then increases slightly.

The present results indicate that the G_{-H_2O} in the 0.8 N H_2SO_4 solution seems substantially lower than the 3.6 estimated by Schuler and Allen.[2b] Although some discussions have been made concerning the value of G_{-H_2O} at very high LET's[21-24] and concerning the difference in that value between acid and neutral solutions,[6] more data should be accumulated in the higher LET region, and the variation in the value of G_{-H_2O} at LET's above 5 eV/Å is still open to question.

The authors wish to express their gratitude to the members of the cyclotron operation group, and also to Hiroshi Seki and Takahisa Imai for their experimental assistance.

21) In the high-LET tracks, some reactions between molecular products and free radicals may be taken into consideration. The most noteworthy reaction of them may be: $H_2O_2+OH\rightarrow H_2O+HO_2$ (*cf.* Ref. 16, p. 51). The formation of HO_2 in the α-ray tracks has been reported by Donaldson and Miller (*Trans. Faraday Soc.*, **52**, 652 (1956) and Appleby and Schwarz (Ref. 5). However, the rate constant of this reaction is not high (4.5×10^7 M^{-1} ses^{-1}, Schwarz, *J. Phys. Chem.*, **66**, 255 (1962)) and the yield has not been established. If this reaction is assumed to occur at all, the $G(Fe^{3+})$ is given, by assuming the material balance suggested by Allen (Ref. 16, p. 51(, by $G(Fe^{3+}(=G_{-H_2O}+G_{HO_2}$ at an infinite LET, yielding the value of G_{-H_2O} lower than 2.9.

Fluorescence Quenching Reactions due to the Intermolecular Electron Transfer Process in Solution

Tadashi OKADA, Hiroo OOHARI and Noboru MATAGA*[1]

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka

(Received April 13, 1970)

Mechanisms of the intermolecular electron transfer process in the electronically excited states of solute molecules have been studied in relation to the fluorescence quenching reactions in solution, employing pyrene as a fluorescer and some aromatic amine and cyano compounds as quenchers. The quenchers showed various strengths of the quenching actions which were classified and discussed on the basis of a new theoretical model of electron transfer process in excited state. Tetracyanoethylene showed a quite strong quenching action which was interpreted in terms of a long range electron transfer from excited pyrene to tetracyanoethylene. The relation between the exciplex formation, the electron transfer reaction due to the short range interaction and that due to the long range interaction have been discussed.

The mechanism of fluorescence quenching in solution has been studied for a long time.[1] Although there are diverse mechanisms of the luminescence quenching reactions, the intermolecular electron transfer or charge transfer processes in the excited state seem to be one of the most important mechanisms for fluorescence quenching reactions.[2] The mechanism may be connected with the fact that the electron affinity of a molecule is larger and its ionization potential is smaller in the electronically excited state than in the ground state and, the electron donor-acceptor interaction can arise in the excited state even though there is no interaction in the ground state. Recent studies[2] on exciplex (or heteroexcimer) luminescence are making important contributions to this fluorescence quenching mechanism.

The results of observations concerning exciplex fluorescence have indicated that the exciplex formed in a polar solvent by the encounter collision between the fluorescer (F*) and the quencher (L) molecule gradually shifts to the solvated ion-pair or to the dissociated ion-radicals during the lifetime of the excited state as follows:

$$F^* + L \underset{k_2}{\overset{k_1}{\rightleftarrows}} \text{exciplex} \xrightarrow{k_3} F_S^{\pm}\cdots L_S^{\mp} \rightarrow F_S^{\pm} + L_S^{\mp} \quad (1)$$

Although Eq. (1) seems to be important for fluorescence quenching due to the electron transfer, it might not be correct to say that the electron transfer in the fluorescence quenching reaction occurs always *via* the formation of a "complex" where the interaction between the electron donor and the acceptor is considerable. In principle, it may be possible for the electron transfer to occur by very weak interaction in a quite loose encounter complex, so weak that the states of the system before and after the electron transfer can be regarded as independent stationary states between which the quantum mechanical transition occurs.[3] Accordingly, it is necessary and important to examine various quenchers of different strengths in detail for the elucidation of the electron transfer processes.

In the following, we show the results of our measurements on the quenching of pyrene fluorescence by various quenchers in various solvents.

Experimental

Materials. Pyrene was chromatographed on activated alumina and silica gel, and extensively

zone-refined. *N,N*-Dimethylaniline (DMA) was refluxed with acetic anhydride, washed with water, dried over potassium hydroxide, and distilled in a vacuum several times. G. R. grade tetracyanoethylene (TCNE) was recrystallized from monochlorobenzene and sublimated several times in a vacuum. 1,2,4,5-tetracyanobenzene (TCNB) was synthesized and purified in this laboratory.[4] Isomeric dicyanobenzenes (DCNB) were recrystallized from ethanol and sublimated in a vacuum. *n*-hexane was passed through a column of activated silica gel and distilled. Pyridine was refluxed with 28% aqueous solution of sodium hydroxide, dried over sodium hydroxide and potassium hydroxide and after refluxing with potassium hydroxide distilled carefully. Ethanol was treated with sulfuric acid and silver nitrate, dried over aluminium amalgam and activated silica gel, distilled carefully. Acetonitrile was refluxed repeatedly over phosphorus pentoxide, distilled into potassium carbonate and distilled from it. Spectrograde *N,N*-dimethylformamide (DMF) was used without further purification.

All solutions for the measurement were carefully deaerated by freeze-pump-thaw cycles.

Apparatus and Measurements. Fluorescence spectra were measured with an Aminco-Bowman spectrophotofluorometer which was calibrated to obtain the correct fluorescence quantum spectrum. Absorption spectra were measured by a Cary 15 spectrophotometer.

In order to measure the fluorescence decay times, the specimens were excited by a pulse which was made monochromatic through a monochromator (335 mμ). The fluorescence pulses were received by a photomultiplier of 1P28 type. Responses from the photomultiplier were guided to a synchroscope(Tektronix 585A) and the decay curve was photographed, or they were led to a sampling oscilloscope(Tektronix 661) and the decay curves were recorded on a X-Y recorder.

The exciting pulsed lights were produced by discharging a specially designed capacitor (of a few hundreds pF and charged up to 2000—4000 V) through a gap of about 0.5 mm between small platinum electrodes in air. The half width of the pulsed light was about 15 ns.

The measurement of the temperature effect on the fluorescence was conducted by using a metal dewar with quartz windows (for the temperature range below −50°C) or by using a quartz dewar which contains purified ethanol as a refrigerant (for measurements above −50°C). In the case of the former, the temperature of a solution in a quartz cuvette placed in the dewar was controlled by a constant flow of cold nitrogen gas. The flow of the gas was controlled by heating liquid nitrogen, and the temperature of the solution was measured by a thermocouple. In the case of the latter, the temperature of the solution in the cuvette was controlled by dropping appropriate amounts of liquid nitrogen into the refrigerant.

The measurements of the absorption spectra of transiently produced ion radicals were made by means of an ordinary flash photolysis apparatus. Both the first and the second flash lights have a half-value width of 3 μsec. The spectra were photographed by using a Shimazu GE 100 type spectrograph.

Experimental Results and Discussion

In such polar solvents as ethanol, DMF and acetonitrile, the fluorescence of pyrene is quenched by DMA completely. As an example, the quenching curves in acetonitrile and DMF are shown in Fig. 1, where the simple Stern-Volmer equation (2) is well satisfied with respect to the fluorescence quantum yield as well as the fluorescence decay time.

$$\eta'_F/\eta_F = \tau'_F/\tau_F = 1/(1 + \gamma k_1 \tau_F[L]) \qquad (2)$$

where $\gamma = k_3/(k_2+k_3)$ according to Eq. (1).

●, ○: η'_F/η_F ▲, △: τ'_F/τ_F [Pyrene]: 1×10^{-5} mol/l

4) N. Mataga and Y. Murata, *J. Amer. Chem. Soc.*, **91**, 3144 (1969).

The quenching rate constants γk_1 at 300°K for the pyrene-DMA system were 1.3×10^{10} l/mol·sec in acetonitrile, 5.7×10^{9} l/mol·sec in DMF and 6.9×10^{9} l/mol·sec in ethanol, respectively. Similar results have been obtained also in the case of the quenching of pyrene fluorescence by TCNB and isomeric dicyanobenzenes in polar solvents. In the case of pyrene - TCNB system in acetonitrile, the quenching curve can be reporduced accurately by Eq. (2) and the γk_1 value at 300°K has been evaluated to be 1.6×10^{10} l/mol·sec.

When isomeric dicyanobenzenes are used as quenchers, the quenching curves are not exactly reproducible by Eq. (2), but η'_F/η_F value is a little smaller than τ'_F/τ_F value at the same [L] value, although $\tau'_F/\tau_F=(1+\gamma k_1\tau_F[L])^{-1}$.

It is well-known that a more detailed consideration based on the diffusion-controlled encounter process of Eq. (3), leads to Eqs. (4) and (5).[5]

$$F^* + L \underset{k_2}{\overset{k_1}{\rightleftarrows}} F^* \cdots L \xrightarrow{k_3} \text{intermediate} \longrightarrow \quad (3)$$

$$\eta'_F/\eta_F = \delta/(1 + \gamma k_1\tau_F[L]) \quad (4)$$

$$\delta = \exp\left[-4\pi(\gamma R_0)^2\{D\tau_F(\eta'_F/\eta_F)\}^{1/2}N'[L]\right] < 1$$

$$\tau'_F/\tau_F = 1/(1 + \gamma k_1\tau_F[L]) \quad (5)$$

where, $D=D_{F^*}+D_L$, the sum of the diffusion coefficients of F* and L, N' is the Avogadro number per 1 ml and γR_0 is the effective encounter distance. When the electron transfer interaction in the encounter complex is a sufficiently short range one, Eq. (4) is reduced to the simplest case of Eq. (1) because $\delta\simeq1$.

From the results, the mechanism of Eq. (1) seems to be correct at least for the pyrene-TCNB systems.

If the mechanism of Eq. (1) is correct and the ion radicals are formed, we should be able to observe the absorption spectra of transiently produced ion radicals by means of the flash photolysis method. Actually, we have observed such spectra for pyrene - DMA system in acetonitrile as well as in ethanol (Figs. 2 and 3).

In Fig. 2, we see clearly the absorption peaks due to pyrene anion radical at 20.3×10^3, 22.0×10^3 and 26.0×10^3 cm^{-1}. The peak at *ca.* 24×10^3 cm^{-1} may be ascribed to the T-T absorption, while shoulders around this peak can neither be ascribed to the absorption of radicals nor the T-T absorption. The small shoulder at *ca.* 21.3×10^3 cm^{-1} might be assigned to the absorption band of DMA cation radical.

In the case of Fig. 3, we can observe more clearly the absorption bands of both ion radicals. The spectrum in Fig. 3c where no added DMA is present is due to the T-T absorption. In the presence of DMA((a), (b)), the absorption bands at 22.0×10^3 and 20.3×10^3 cm^{-1} due to pyrene anion radical as well as those at 22.2×10^3 and 21.3×10^3 cm^{-1} which can be ascribable to DMA cation radical have been observed. From comparison of Fig. 3b and Fig. 3a, we see that in ethanol, pyrene anion is rather unstable and decays more

5) A. Weller, *Z. Phys. Chem. N. F.*, **13**, 335 (1957); *ibid.*, **15**, 438 (1958); *ibid.*, **18**, 163 (1958).

rapidly compared with DMA cation. Contrary to this, the spectrum DMA cation can hardly be observed in the case of acetonitrile solution. Presumably, the ion radicals will decay partly due to the reaction with solvent molecules or unknown impurities in the solvent in addition to the bimolecular recombination reaction between anion and cation radicals (electron transfer from anion to cation). At any rate, the ion radical formation according to the mechanism of Eq. (1) has been confirmed experimentally.

The fluorescence of pyrene is quenched completely even in a non-polar solvent by the strong quencher, TCNE. The quenching curve in *n*-hexane is shown in Fig. 4. This quenching curve of pyrene - TCNE - *n*-hexane system can be well reproduced by Eq. (2); $\gamma k_1 = 2.5 \times 10^{10}$ *l*/mol·sec at 300°K. However, the formation of ion radicals cannot be observed by means of flash photolysis studies on this system. Presumably, the ion radicals are extremely unstable in this non-polar solvent. Therefore, the encounter collision may lead to the formation of charge transfer type complex which is non-fluorescent.

$$F^* + L \xrightarrow{k_1} \text{Complex} \longrightarrow \text{Product} \qquad (6)$$

Because there is a large energy difference between the state (F^*+L) and the complex, the back reaction from the complex to the (F^*+L) state can be neglected. The energy difference is estimated to be *ca.* 13×10^3 cm^{-1} from the CT absorption band of pyrene-TCNE CT complex and the excitation energy of pyrene.

The fluorescence of pyrene is strongly quenched by TCNE in acetonitrile solution. In contradistinction to the case of *n*-hexane solution, there is a quite large difference between the quenching curve for the fluorescence quantum yield and that for the decay time as shown in Fig. 5. Namely, $\eta'_F/\eta_F < \tau_F'/\tau_F$ for the same [L] value in general. The quenching curves in acetonitrile can be reproduced by Eqs. (4) and (5). In this polar solvent, the electron transfer from excited pyrene to TCNE may occur and ion radicals may be produced. We have confirmed by flash photolysis the transient production of TCNE anion radical in addition to the formation of pyrene cation radical with absorption band at 22.2×10^3 cm^{-1}.

We obtain from Eqs. (4) and (5),

$$\ln \delta = \ln [(\eta'_F/\eta_F)(\tau_F/\tau'_F)] = -4\pi(\gamma R_0)^2(D\tau_F)^{1/2}N'(\eta'_F/\eta_F)^{1/2}[L] \qquad (7)$$

From the plot of $\ln[(\eta'_F/\eta_F)(\tau_F/\tau'_F)]$ against $(\eta_F'/\eta_F)^{1/2}[L]$, we can obtain the value of $4\pi(\gamma R_0)^2(D\tau_F)^{1/2}N'(=v)$. As we can evaluate γk_1 from the quenching curve of (τ'_F/τ_F) and $\gamma k_1 = 4\pi\gamma R_0 DN'$, the γR_0 value can be given by

$$\gamma R_0 = [v^2/4\pi\gamma k_1 \tau_F N']^{1/3} \qquad (8)$$

Thus, it is possible to evaluate (γR_0) experimentally without knowing the value of the diffusion coefficient which, in general, does not seem to be known accurately. The γR_0 value obtained in this way was 47±8Å irrespective of the temperature at which the measurement was made. This γR_0 value is so large that one cannot regard $R_0 \geqq \gamma R_0$ as physically meaningful for the actual encounter distance in the loose complex F*···L.

It might be argued that the pyrene - TCNE CT complex is formed in the ground state, which causes the large difference between η'_F/η_F and τ'_F/τ_F values. However, this possibility can be rejected

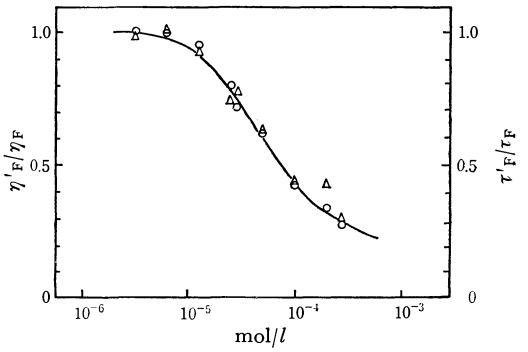

Fig. 4. Fluorescence quenching curve for pyrene - TCNE system in *n*-hexane at 300°K.
[Pyrene]: 1×10^{-5} mol/*l*, ○: η'_F/η_F, △: τ'_F/τ_F

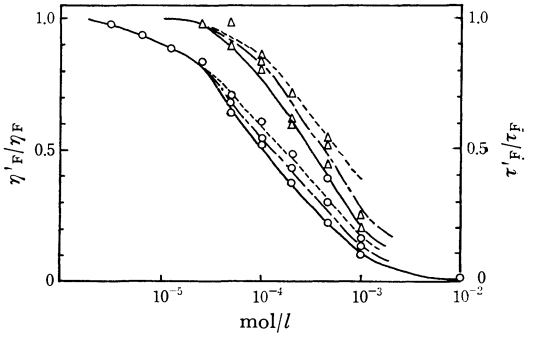

Fig. 5. Fluorescence quenching curve for pyrene - TCNE system in acetonitrile at various temperatures.
——: at 25°C, ———: at 0°C, ----: at −40°C
○: η'_F/η_F, △: τ'_F/τ_F [Pyrene]: 1×10^{-5} mol/*l*

because of the fact that the absorption spectrum does not show any change in the range of TCNE concentration used here, and because of the more important fact that the extent of the quenching with respect to both of the quantum yield and the decay time is greater at higher temperatures.

One should note that Eq. (4) and, accordingly, (7) and (8) contains rather drastic approximations. One should not regard R_0 as the actual intermolecular distance in the encounter complex, in general. These approximate equations may not be

valid for this quite strong quenching action of TCNE in acetonitrile. Nevertheless, the quite strong quenching and the anomalously large R_0 value seem to indicate a long range interaction between the fluorescer and the quencher.

The diffusion equation for the encounter and electron transfer process may be written as

$$-\frac{\partial\Phi(R,t)}{\partial t} = -D\nabla^2\Phi(R,t) + \frac{1}{\tau_F}\Phi(R,t) + \sum_i W(|R-R_i|)\Phi(R,t) \qquad (9)$$

where $\Phi(R,t)$ is the distribution function for F^* and $W(|R-R_i|)$ is the electron transfer probability.

In the case of the long range electron transfer caused by the very weak interaction, $W(|R-R_i|)$ represents the electronic transition probability which depends on the intermolecular distance $|R-R_i|$ between the fluorescer and the quencher. If W is hard core type, *i.e.*,

$$\begin{aligned} W &= 0 \quad \text{at } |R-Ri| > \gamma R_0 \\ W &= 1 \quad \text{at } |R-R_i| \leqq \gamma R_0 \end{aligned} \qquad (10)$$

then the bimolecular reaction rate constant should be proportional to the diffusion coefficient D. However, if W has a long range part, the bimolecular rate constant should be proportional to D^m, where $m<1$. Such a long range effect was actually observed in the case of the singlet excitation transfer from pyrene to perylene in fluid solution,[6] where W has been proved to be proportional to inverse sixth power of $|R-R_i|$.[7] Namely, it has been confirmed that the bimolecular rate constant for the quenching of pyrene fluorescence caused by the excitation transfer is proportional to D when the D value is relatively large, while it is proportional to $D^{3/4}$ at relatively small values of D in accordance with the theoretical consideration.[8]

From the viewpoint of the above consideration, we have examined the dependence of γk_1 value (which can be determined accurately by the measurement of the decay times) on the diffusion coefficient for the pyrene - TCNE - acetonitrile system.

The temperature dependences of $1/\tau_F$ and $1/\tau'_F$ values are shown in Fig. 6. These curves were obtained by repeating the measurement of the decay time many times at each temperature and averaging them. The accuracy of the measurement was not so good for curve (4) compared to the others, because of a little smaller number of measure-

ments. From these values of decay times, the γk_1 values have been obtained by means of the equation $\gamma k_1=(\tau_F/\tau_F'-1)/\tau_F[L]$.

In Fig. 7, log γk_1 values are plotted against log

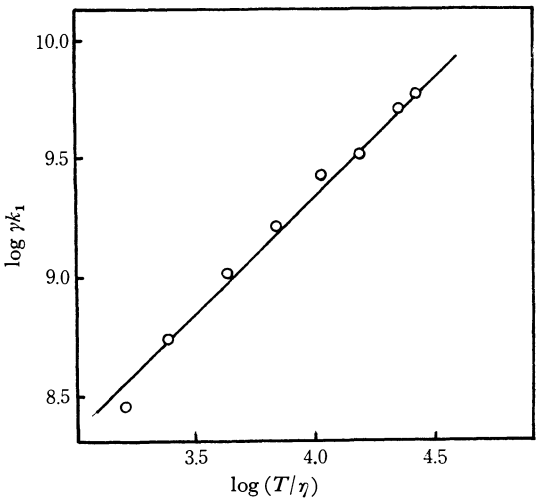

Fig. 10. Log γk_1 *vs.* log (T/η) relation for pyrene - *p*-DCNB system in ethanol.
[*p*-DCNB]: 1×10^{-3} mol/*l*, [Pyrene]: 1×10^{-5} mol/*l*

(T/η), where T is the absolute temperature and η is the viscosity of the solution. Although the absolute value of γk_1 for each [L] value is not very accurate, the shapes of the curves in Figs. 6 and 7 are certainly reliable. Of course, the correction for the change of the concentration of the quencher due to the change of the temperature of the solution has been taken into concideration. As (T/η) is proportional to the diffusion coefficient, this plot will provide the desired information as described above.

We see clearly from Fig. 7, that $m\simeq1$ in the range of relatively large (T/η) values, while $m<1$ at relatively small (T/η) values. Moreover, the long range effect appears to be more predominant in the case of higher concentrations of TCNE. Thus, the long range electron transfer process due to the very weak interaction seems to play an important role and the hard sphere model provides only a poor approximation for the pyrene - TCNE system in acetonitrile.

As the fluorescence quenching reaction of pyrene-DMA system in acetonitrile can be reproduced satisfactorily by Eq. (2) the long range effect may not be important in this system. Thus, one may expect a straight line with $m=1$ when log γk_1 is plotted against log (T/η). The relation is actually satisfied (Fig. 8).

Since quite an analogous result to the case of pyrene - DMA system has been observed for the quenching curve of pyrene-TCNB system in acetonitrile, we can expect that $m\simeq1$ also for this system. When *p*-DCNB and *o*-DCNB were used as quenchers for pyrene fluorescence in acetonitrile solution, there is a little tendency that $\eta'_F/\eta_F\lesssim\tau_F'/\tau_F$. By means of Eqs. (7) and (8), the γR_0 values have been evaluated to be 29Å for *p*-DCNB and 24Å

for *o*-DCNB in acetonitrile. These γR_0 values are much smaller than in the case of the fluorescence quenching due to TCNE. Therefore, it is possible that a similar result to the case of pyrene-TCNB system (*i.e.* $m \simeq 1$) can be obtained also for the pyrene - *o*-DCNB system, because the difference between the value of η'_F/η_F and that of τ'_F/τ_F is rather small.

As indicated in Fig. 9, log γk_1 is linear with log (T/η) and $m \simeq 1$ for both systems. In contrast to this, although log γk_1 is approximately linear with log (T/η), m is a little smaller than unity in the case of pyrene - *p*-DCNB system in acetonitrile. We have further examined pyrene - *p*-DCNB system in ethanol and also, in pyridine solution. Although η'_F/η_F is a little smaller than τ'_F/τ_F in ethanol solution, γk_1 is proportional to (T/η) and $m \simeq 1$ as shown in Fig. 10. In the case of pyridine solution, the quenching curve and the change of the fluorescence spectrum are shown in Figs. 11 and 12, respectively. The quenching curve can be well reproduced by the simple Stern-Volmer equation (2). However, as shown in Fig. 12, one can observe the fluorescence of pyrene - *p*-DCNB exciplex. Since the yield of this exciplex fluorescence is quite small, it is probable that the ion-pair formation process (k_3) as indicated in Eq. (1), is competing with the fluorescence transition, the probability of which may be rather small because of the very polar structure of the exciplex. In a more polar solvent such as ethanol, process k_3 is certainly much more dominant than the exciplex fluorescence transitions so that the exciplex fluorescence cannot be observed in ethanol solution.

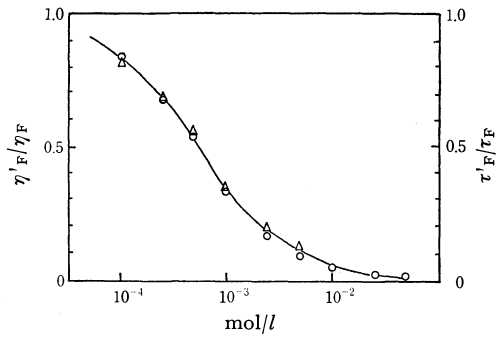

Fig. 11. η'_F/η_F or τ'_F/τ_F *vs.* [L] relation for pyrene - *p*-DCNB system in pyridine at 25°C.
○: η'_F/η_F, △: τ'_F/τ_F

We can summarize the results as follows. In non-polar and less polar solvents, the exciplex formation occurs between the fluorescer and the quencher molecules. The exciplex is either fluorescent or non-fluorescent. Furthermore, in a slightly polar solvent, there arises a solvated ion-pair via the exciplex. In the more polar solvents, there occurs an electron transfer from the fluorescer to the quencher and *vice versa* due to the short

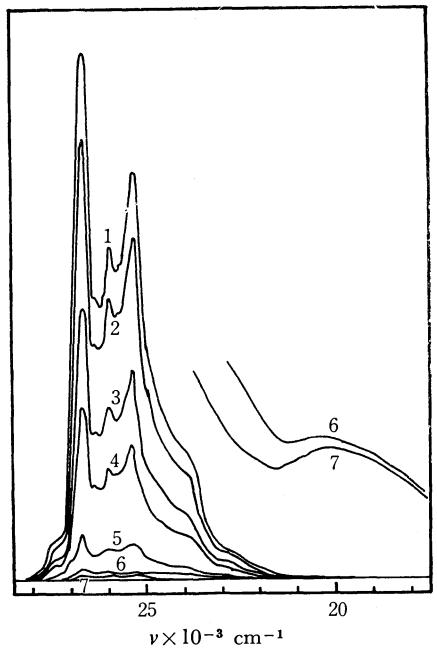

Fig. 12. Fluorescence spectra of pyrene - *p*-DCNB in pyridine at 25°C.
[*p*-DCNB]: (1) 0, (2) 1×10^{-4}, (3) 5×10^{-4}, (4) 1×10^{-3}, (5) 5×10^{-3}, (6) 2.5×10^{-2}, (7) 5×10 mol/l
[Pyrene]: 1×10^{-5} mol/l

range interaction or the long range very weak interaction depending on the strength of the quencher. The long range electron transfer process due to the very weak interaction may be a non-adiabatic quantum mechanical transition as will be described below.

Let us denote the energies of the various states in Eq. (1) as follows: $U_1 = U(F^* + L)$, $U_2 = U$ (exciplex), $U_3 = U(F_S^{\pm} \cdots L_S^{\mp})$ and $U_4 = U(F_S^{\pm} + L_S^{\mp})$ When $U_2^\circ > U_3^\circ$ or U_4°, the solvated complex will immediately shift to the solvated ion-pair or dissociate into the solvated ion radicals, where U_i°'s represent the values for the equilibrium state with respect to the solute-solvent interactions. If the interaction between the fluorescer and the quencher is not very weak, the reaction will proceed on the adiabatic potential energy surface and the probability W may be of a hard core type.

When the interaction between the partners in the exciplex is weak, its wavefunction may be written as

$$\Psi \sim c_1(s)\Phi_i^\circ(F^* \cdots L) + c_2(s)\Phi_f^\circ(F^+ \cdots L^-)$$
$$\text{or} \qquad (11)$$
$$\Psi \sim c_1(s)\Phi_i^\circ(F^* \cdots L) + c_2(s)\Phi_f^\circ(F^- \cdots L^+)$$

where s symbolizes the nuclear configurations including the surrounding solvent molecules. When the electronic interaction between F* and L in the loose encounter complex F*···L is very weak

in a sufficiently polar solvent, the isoenergetic electronic transition will occur from the state Φ_i° to Φ_f°. The electron transfer by this process may be given schematically by configuration coordinate diagrams as shown in Fig. 13. In this figure, the long range electron transfer is represented by the quantum mechanical tunnelling through the potential barrier as indicated by the horizontal wavy line. In the case of curve (a) for U_3, the barrier may be too high for the tunnelling to occur while it may be possible in the case of curve (b).

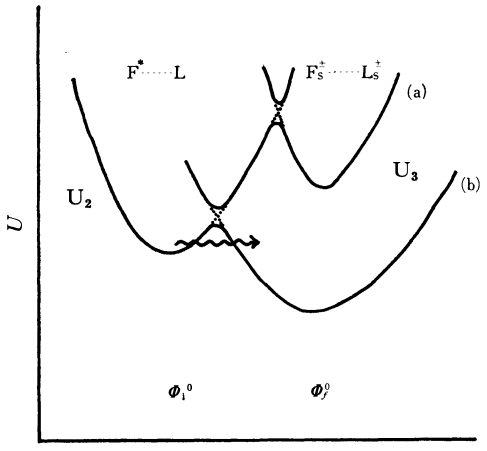

Fig. 13. Schematic diagrams of the electron transfer process by very weak interaction.

The energy of the curve U_3 depends upon the magnitudes of ionization potential of the donor and the electron affinity of the acceptor on the one hand and upon the solvation energies of the ion radicals on the other hand. Among the cyano compounds used in the present work, the electron affinity of TCNE is the largest. Moreover, the solvation energy of its anion in polar solvent may be the largest because its molecular radius is the smallest among others. Therefore, U_3 may be the lowest in the case of pyrene - TCNE - acetonitrile system.

The tunnelling efficiency depends also upon the magnitude of the matrix element of the perturbation Hamiltonian between Φ_i° and Φ_f°. As the spatial dimension of TCNE is the smallest among the quenchers employed, the overlap between the electron donating orbital of excited pyrene and the accepting orbital of TCNE may be large compared to those of the other systems, which results in a relatively large value of the perturbation matrix element.

We have discussed the long range electron transfer in analogy to the long range singlet-singlet excitation transfer. Let us examine the matrix elements responsible for the excitation transfer as well as the electron transfer transition. We assume both F and L are closed shell molecules and denote their MO's as ψ_m^F's and ψ_m^L's respectively, where the m-th MO's are the highest occupied ones in the ground state. The Hamiltonian $\mathscr{H}$ can be separated into the core part $\mathscr{H}_c=\sum f_c(i)$ and the electron interaction part $G=\sum g(ij)$. Then, the matrix elements for the following excitation transfer processes

$$F^*(^1L_a) + L \rightarrow F + L^*(^1L_a)$$
$$F^*(^1L_b) + L \rightarrow F + L^*(^1L_a)$$

can be written as

$$\langle\Phi_i^\circ(^1L_a)|\mathscr{H}|\Phi_f^\circ(^1L_a)\rangle = 2(\langle\psi_m^L\psi_{m+1}^F|g|\psi_{m+1}^L\psi_m^F\rangle - \langle\psi_m^L\psi_{m+1}^F|g|\psi_m^F\psi_{m+1}^L\rangle) \quad (12a)$$

$$\langle\Phi_i^\circ(^1L_b)|\mathscr{H}|\Phi_f^\circ(^1L_a)\rangle = \sqrt{2}(\langle\psi_m^L\psi_{m+2}^F|g|\psi_{m+1}^L\psi_m^F\rangle - \langle\psi_m^L\psi_{m+2}^F|g|\psi_m^F\psi_{m+1}^L\rangle - \langle\psi_m^L\psi_{m+1}^F|g|\psi_{m+1}^L\psi_{m-1}^F\rangle + \langle\psi_m^L\psi_{m+1}^F|g|\psi_{m-1}^F\psi_{m+1}^L\rangle) \quad (12b)$$

In contrast to this, the matrix elements for the electron transfer transitions

$$F^*(^1L_a)\cdots L \rightarrow F^+\cdots L^-$$
$$F^*(^1L_b)\cdots L \rightarrow F^+\cdots L^-$$

are given by[3]

$$\langle\Phi_i^\circ(^1L_a)|\mathscr{H}|\Phi_f^\circ(F^+\cdots L^-)\rangle = \langle\psi_{m+1}^F|f_c|\psi_{m+1}^L\rangle + \sum_{\lambda_k\neq\psi_{m+1}^F}\{\langle\psi_{m+1}^F\lambda_k|g|\psi_{m+1}^L\lambda_k\rangle - \langle\psi_{m+1}^F\lambda_k|g|\lambda_k\psi_{m+1}^L\rangle\} + \langle\psi_m^F\psi_{m+1}^F|g|\psi_{m+1}^L\psi_m^F\rangle \quad (13a)$$

$$\langle\Phi_i^\circ(^1L_a)|\mathscr{H}|\Phi_f^\circ(F^+\cdots L^-)\rangle = \frac{1}{\sqrt{2}}[\langle\psi_{m+1}^F|f_c|\psi_{m+1}^L\rangle + \sum_{\lambda_k\neq\psi_{m+2}^F}\{\langle\psi_{m+2}^F\lambda_k|g|\psi_{m+1}^L\lambda_k\rangle - \langle\psi_{m+2}^F\lambda_k|g|\lambda_k\psi_{m+1}^L\rangle\} + \langle\psi_{m+1}^F\psi_m^F|g|\psi_{m+1}^L\psi_{m-1}^F\rangle + \langle\psi_m^F\psi_{m+2}^F|g|\psi_{m+1}^L\psi_m^F\rangle - 2\langle\psi_{m+1}^F\psi_m^F|g|\psi_{m-1}^F\psi_{m+1}^L\rangle] \quad (13b)$$

For the excitation transfer, only the electron interaction integral plays an important role while both the core part and the electron interaction part may be important for the electron transfer. It is well-known that the Coulomb integral in $\langle\Phi_i^\circ|\mathscr{H}|\Phi_f^\circ\rangle$ plays the dominant role for the excitation transfer. Since the matrix elements in the r.h.s. of Eqs. (13a,b) are roughly proportional to the intermolecular overlap of MO's, the transition matrix elements for the electron transfer will be smaller than the Coulomb integrals (which do not depend on the intermolecular overlap) in Eq. (12), at a sufficiently large intermolecular distance. However, the matrix elements in Eq. (13) have a much longer range interaction than the corresponding matrix element for the triplet-triplet excitation transfer, where the electron exchange integral which is roughly proportional to the square of the intermolecular overlap plays the dominant role.

Although only the electronic part of the interaction is shown in Eqs. (12) and (13), Φ^0's are

also function of the nuclear coordinates of solute as well as the surrounding solvent molecules. As U's are adiabatic potential energies, the tunnelling may be caused essentially by the vibronic interactions between transferring electron and the nuclear motions. Presumably, the interaction process between the polarization motion (mainly orientational) of the solvent molecules and the transferring electron is the dominant mechanism for tunnelling. This sort of interaction may be large in a polar solvent such as acetonitrile, which is in accord with the observed results.

The intermolecular electron transfer by very weak interaction in the excited state, as demonstrated here, will be found out for other systems. Studies along this line are in progress.

Methane Formation in the Radiolysis of Neopentane and Isooctane

Shuichi IIDA, Rei YUGETA and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 21, 1970)

The formation of methane and hydrogen in the γ-radiolysis of neopentane and isooctane has been studied in the presence of an electron scavenger (N_2O) and/or a radical scavenger (styrene). The *G*-value of nitrogen from neopentane solutions of nitrous oxide was found to be about twice the sum of the decrease in the *G*-values of methane and hydrogen. From isooctane solutions, $G(N_2)$ was more than three times the sum of the decrease in $G(H_2)$ and $G(CH_4)$. This can be interpreted on the assumption that a significant part of the neutralization of isooctane ions with electrons induces the fragmentation into C_4-hydrocarbons. It was also found that a part of the methane formed (0.9 *G* in neopentane and 0.2 *G* in isooctane) was not produced by the reactions of ions or methyl radicals, but by a "molecular" process, probably the decomposition of the highly-excited states.

Because of its large *G*-value, the formation of hydrogen in the radiolysis of liquid hydrocarbons has been studied by many investigators in an attempt to clarify the primary process of the radiation-induced reactions.[1,2] In the case of branched hydrocarbons, it is well known that methane formation is important and that the *G*-value of methane increases with the increase in the number of the branched chain.[3] Several papers have reported on the effect of electron scavengers on the *G*-value of the formation of methane.[4,5] However, the mechanism of the formation of methane has not been discussed systematically in connection with the primary process.

Neopentane and isooctane are typical branched hydrocarbons, and their radiolyses have been studied by several groups.[6-9] Recently, Tanno and his collaborators investigated the fragmentation process of the radical ions produced in the radiolysis of branched hydrocarbons, including neopentane and isooctane.[10,11] In this paper, we will report on the effect of electron and radical scavengers on the *G*-values of methane and hydrogen, and will discuss the mechanism of the formation of these products.

Experimental

The neopentane (Matheson Co., pure grade) was used as supplied. The isooctane (Tokyo Kasei Co., spectro grade) was used after passing it through a 1-m silica gel column. Gaschromatographic analysis showed that both hydrocarbons contained impurities of less than 0.01%. The nitrous oxide and sulfur hexafluoride (Matheson Co., pure grade) were used after bulb-to-bulb distillations. The styrene monomer (Tokyo Kasei Co., pure grade) was distilled *in vacuo* before use.

Irradiation samples were prepared by repeated freeze-and-thaw cycles. The samples (2 or 10 m*l*), sealed in glass tubes, were irradiated by ^{60}Co-γ rays at a dose rate of 1.25×10^{6} R/hr. All the additives were assumed to be completely soluble, because the gas-phase volume above the irradiation liquid was less than a half of the liquid volume.

Non-condensable gas at 77°K was collected by a Toepler pump, and its amount measured by means of a gas buret. A cuprous oxide furnace at 240°C was used to combust hydrogen into water, which is condensable in a liquid nitrogen trap. The remainder (methane and nitrogen) was analyzed by gas-chromatography. The column used contained activated charcoal (2 m).

Results and Discussion

Neopentane. As is shown in Fig. 1, the *G*-value of nitrogen increased with an increase in the concentration of nitrous oxide and did not attain a limiting value even at 0.8 mol/*l*, the highest concentration examined. This is a typical trend observed in the charge scavenging. The *G*-values of methane and hydrogen decreased with an increase in the concentration of nitrous oxide and seemed to level off at 2.6 and 0.8 respectively.

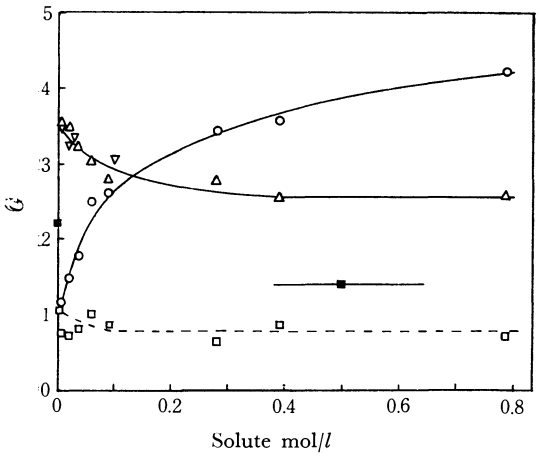

Fig. 1. *G*-Values of nitrgen (○), methane (△) and hydrogen (□) from neopentane solutions of nitrous oxide and the *G*-value of methane (▽) from SF_6 solutions. The irradiation dose is 2.0×10^{20} eV/m*l* except for (■) which is $G(H_2)$ obtained with the irradiation dose of 1.7×10^{18} eV/m*l*.

Table 1. Dose dependence of $G(H_2)$ from a neopentane solution

Additive	Irradiation dose 10^{18} eV/m*l*	$G(H_2)$
None	1.1	2.2
	1.7	2.2
	78	1.2
	115	1.1
0.4 mol/*l* N_2O	1.7	1.4

However, these values may be somewhat underestimated because the irradiation dose used for the data in Fig. 1 is not low enough to disregard the build-up of radical scavengers such as isobutene during the radiolysis.[7] The data shown in Table 1 were obtained with much lower irradiation doses. Obviously, the *G*-value of hydrogen is very much dependent upon the dose, as has already been reported by Holroyd.[7] The dose dependence of $G(CH_4)$ was, however, found to be small. This is consistent with the observation of Holroyd. Therefore, the decreases in the *G*-values of methane and hydrogen in the presence of 0.4-mol/*l* N_2O may be estimated to be 0.9 (=3.5−2.6) and 0.8 (=2.2−1.4) respectively. The sum of these values (0.9+0.8) is nearly equal to a half of the *G*-value of nitrogen (3.6/2) from a 0.4-mol/*l* N_2O solution.

The effect of sulfur hexafluoride was also examined. The results are plotted in Fig. 1. The effects of the two electron scavengers on the *G*-value of methane are almost the same. This observation is compatible with the conclusion that the electron scavenging process in the radiolysis of cyclohexane is diffusion-controlled.[12]

Table 2. The effect of styrene monomer on the *G*-values of products from neopfntane solutions of nitrous oxide

N_2O mol/*l*	Styrene mol/*l*	$G(H_2)$	$G(CH_4)$	$G(N_2)$
0	0.43	0.63	1.04	0
0.52	0.26	0.66	1.24	3.97
0.53	0.43	0.64	0.91	3.98
0	0.086	0.85	1.50	0

Use was made of the styrene monomer as a radical scavenger. As is shown in Table 2, the *G*-values of methane and hydrogen decreased rapidly with an increase in the concentration of styrene and leveled off at 0.9 and 0.6 respectively, while the *G*-value of nitrogen was not affected by the presence of styrene. These results suggest that the main precursor of methane is the methyl radical, whose *G*-value is estimated to be 2.6 (=3.5−0.9). Holroyd and Klein experimented with the radiolysis of neopnetane in the presence of iodine and found the *G*-value of methyl iodide to be 2.3.[13] The decrease in $G(H_2)$ from 2.2 to 0.6 due to the presence of styrene may be explained similarly. The difference, $\Delta G=1.6$, probably corresponds to the *G*-value of the thermal hydrogen atoms produced.

According to Tanno *et al.*,[10] primarily-produced

12) S. Sato, T. Terao, M. Kono and S. Shida, This Bulletin, **40**, 1818 (1967).

13) R. A. Holroyd and G. W. Klein, *J. Amer. Chem. Soc.*, **87**, 4983 (1965).

parent ions in the radiolysis of liquid neopentane can be classified into two types. One consists of highly-excited ions which decompose instantaneously into a methyl radical and a *t*-butyl ion, even in the liquid phase; the other consists of stable neopentane ions which are subject to charge neutralization. They estimated the *G*-value of the former process to be 1.0.

On the basis of the results presented above, we have tentatively constructed the following reaction mechanism for the formation of methane and hydrogen:

$$(CH_3)_3CCH_3 \rightsquigarrow (CH_3)_3C^+ + CH_3 + e^- \quad (1)\ G\sim 1.0$$

$$\rightsquigarrow (CH_3)_3CCH_3^+ + e^- \quad (2)\ \sim 2.2$$

$$\rightsquigarrow CH_4 + (CH_3)_2C{=}CH_2 \quad (3)\ \sim 0.9$$

$$\rightsquigarrow H_2 + \text{residue} \quad (4)\ \sim 0.6$$

$$(CH_3)_3CCH_3^+ + e^- \rightarrow (CH_3)_3C + CH_3 \quad (5)\ \sim 1.6$$

$$\rightarrow (CH_3)_3CCH_2 + H \quad (6)\ \sim 0.6$$

$$(CH_3)_3C^+ + e^- \rightarrow H + (CH_3)_2C{=}CH_2 \quad (7)\ \sim 1.0$$

$$CH_3 + (CH_3)_3CCH_3 \rightarrow CH_4 + (CH_3)_3CCH_2 \quad (8)$$

$$H + (CH_3)_3CCH_3 \rightarrow H_2 + (CH_3)_3CCH_2 \quad (9)$$

Here, the numbers shown after each reaction are the estimated *G*-values. When nitrous oxide is present in the system, nitrogen becomes an important product. As has been assumed in the radiolysis of the N_2O - cyclohexane solution, if $G(N_2)$ is twice the *G*-value of electrons scavenged by N_2O,[12] the $G(N_2)$ from the N_2O - neopentane solution should be equal to twice the sum of the decreases in $G(CH_4)$ and $G(H_2)$ for according to the above mechanism, each electron should produce a methyl radical or a hydrogen atom when they are neutralized. In fact, this relationship was observed, as has already been stated.

The reactions (3) and (4) are very tentative at present. In their studies of the radiolysis of olefins, Hatano and his collaborators discovered that hot-hydrogen-atom reactions play an important role in the formation of hydrogen and suggested that reactive species are formed from the superexcited state of the olefin.[14] In the radiolysis of neopentane, therefore, the corresponding reactive species might be hot methyl radicals and hot hydrogen atoms, which in turn give rise to the reactions (3) and (4).

Isooctane. Exactly the same experiments as those of neopentane were done with isooctane. The results are shown in Figs. 2 and 3 and in Table 3.

The isooctane molecule has two C–C bonds, whose splitting does not lead to the formation of a methyl radical. This is an essential difference from neopentane when considering the formation of methane. According to Tanno *et al.*,[10] highly-excited isooctane ions decompose into C_4-fragments, but the *G*-value is reported to be only 0.36. On the other hand, the *G*-values of isobutane and isobutene from isooctane have been reported to be about 3.0.[8] One of the possible origins is the following neutralization reaction:

$$iso\text{-}C_8H_{18}^+ + e^- \rightarrow t\text{-}C_4H_9 + iso\text{-}C_4H_9 \quad (10)$$

If so, the *G*-value of the electrons consumed for this reaction is estimated to be 1.1 (=3.0/2−0.36).

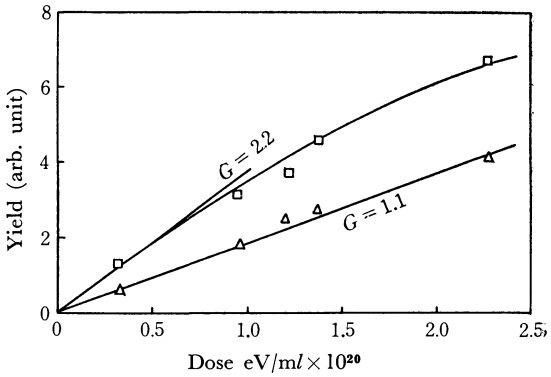

Fig. 2. Irradiation does dependence of *G*-values of hydrogen (□) and methane (△) from isooctane.

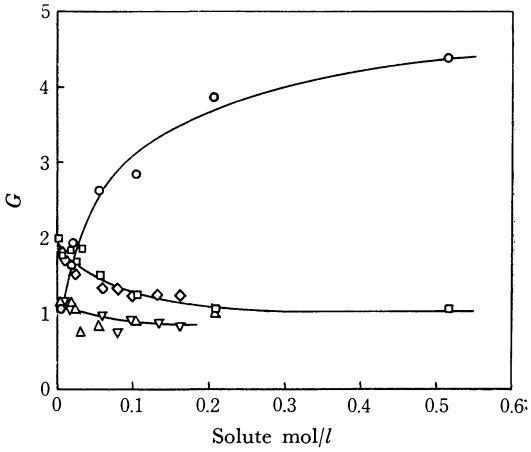

Fig. 3. *G*-Value of nitrogen (○), hydrogen (□) and methane (△) from isooctane solutions of nitrous oxide and *G*-values of hydrogen (◇) and methane (▽) from SF_6 solutions. The irradiation dose is 1.5×10^{20} eV/ml.

14) Y. Hatano, S. Shida and S. Sato, This Bulletin, **41**, 1120 (1968).

TABLE 3. THE EFFECT OF STYRENE MONOMER ON THE G-VALUES OF GASEOUS PRODUCTS FROM ISOOCTANE SOLUTIONS OF NITROUS OXIDE

N_2O mol/l	Styrene	$G(H_2)$	$G(CH_4)$	$G(N_2)$
0	0.43	0.83	0.38	0
0.52	0.43	0.70	0.23	4.6

As is shown in Fig. 3, the decrease in $G(H_2+CH_4)$ due to the presence of electron scavengers is about 1.2 and the corresponding G-value of nitrogen is more than 4.0. If $G(N_2)$ is equal to twice the G-value of the electrons scavenged by nitrous oxide, the following reaction mechanism may be constructed:

$$iso\text{-}C_8H_{18} \rightsquigarrow C_4H_9^+ + C_4H_9 + e^- \quad (11) \quad \sim 0.4$$
$$\rightsquigarrow C_8H_{18}^+ + e^- \quad (12) \quad \sim 3.1$$
$$\rightsquigarrow H_2 + \text{residue} \quad (13) \quad \sim 0.7$$
$$\rightsquigarrow CH_4 + \text{residue} \quad (14) \quad \sim 0.2$$
$$C_8H_{18} + e^- \rightarrow 2C_4H_9 \quad (10) \quad \sim 1.1$$
$$\rightarrow CH_3 + C_7H_{15} \quad (15) \quad \sim 0.9$$
$$\rightarrow H + C_8H_{17} \quad (16)$$
$$C_4H_9^+ + e^- \rightarrow H + C_4H_8 \quad (17) \quad \sim 1.5$$

Here, the G-value of the electrons was assumed to be 3.5 in order to make the G-values of the products self-consistent. The reactions (13) and (14) are tentative as the reactions (3) and (4) in the radiolysis of neopentane.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2761—2766 (1970)

Mechanism of Redox Surface Reaction between Wüstite and CO_2 or CO

Seiichi KURIHARA, Kazuo FUEKI, Takashi MUKAIBO and Yasuo WADA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received April 25, 1970)

The redox reaction between thin wüstite foil and CO_2 or CO was studied by means of a microbalance in a temperature range 900—1075°C. It was found that the reaction at the gas-wüstite interface is rate-controlling and that the reaction rate is expressed as

$$V_{ox} = k_O P_{CO_2} a_O^{-m/3} \quad \text{and} \quad V_{red} = k_O' P_{CO} a_O^{n/3},$$

where a_O is the oxygen activity of wüstite, and m and n are 2.1—2.2 and 0.8—1.2, respectively. On the basis of the theory by Kobayashi and Wagner, the most predominant mechanism is concluded to be

$$CO_2 + 2\ominus \rightleftarrows CO + O^{2-}$$

Actigation energies for k_O and k_O' were 35+3 and 32+3 kcal/mol, respectively.

In the redox reaction at the gas-solid interface, chemical species in the solid phase take part in the reaction as well as gaseous reactants. Therefore, in order to elucidate the reaction mechanism, it is necessary to determine the reaction rate as a function not only of the partial pressure of reactant gases but also of the activity of chemical species in the solid phase. Kobayashi and Wagner[1] constructed electrochemical cells, such as Ag|AgI|Ag_2S|Pt and Cu|CuI|Cu_2S|Pt, and measured the rate of reduction of the sulfides by hydrogen under the controlled metal activity by using the coulometric titration technique. They also proposed a new theory whereby the experimental results can be explained. Thereafter, new experimental techniques such as the isotopic exchange method[2,3] and the chemical relaxation method[4] have been developed in addition to the coulometric titration technique.

Grabke[2] has studied the exchange reaction between $^{14}CO_2$ and ^{12}CO on the wüstite surface at 800—985°C and found that the exchange rate is a function not only of the partial pressures of CO_2 and CO but also of the oxygen activity of wüstite. He has also discussed the reaction mechanism on the basis of the Kobayashi-Wagner theory.

In order to investigate the mechanism of the reaction at the gas-solid interface, we have devised

1) H. Kobayashi and C. Wagner, *J. Chem. Phys.*, **26**, 1609 (1957).

2) H. J. Grabke, *Ber. Bunsenges, Physik. Chem.*, **60**, 48, (1965).

3) K. Fueki, H. Inaba and T. Mukaibo, This Bulletin, **43**, 23 (1970).

4) S. Stotz, *Ber. Bunsenges, Physik. Chem.*, **70**, 37 (1966).

a new technique which uses a microbalance and studied the redox reaction between wüstite and CO_2 or CO. The purpose of the present paper is to report the result of the study.

Experimental

a) Principle of Microgravimetric Technique. Wüstite is a metal-deficit type nonstoichiometric compound and often expressed by the chemical formula $Fe_{1-\delta}O$. The equilibrium relation between δ and $a_O(\equiv P_{CO_2}/P_{CO})$ has been determined precisely by Darken and Gurry[5] and by other investigators.[6] According to the result of their thermodynamic investigations, the homogeneous nonstoichiometric range of wüstite is fairly wide, for instance, δ ranges from 0.05—0.15 at 1000°C. Thus, the change in δ within the stable region of wüstite can be followed gravimetrically.

According to a study of iron oxidation in CO_2–CO gas mixtures,[7] the oxidation is controlled by the gas-oxide interface reaction in the initial period of oxidation where the oxide scale is thin. Therefore in the case of oxidation and reduction of wüstite, the overall reaction is expected to be controlled by the reaction on the wüstite surface, if the wüstite specimen is sufficiently thin. In such a case, the surface reaction rate can be obtained by measuring the weight change of wüstite as a function of time. When the reaction is controlled by the surface reaction, δ is constant throughout the specimen. Thus, the value of δ of wüstite at every moment can be determined by following the weight change during the run. Since there is a close relationship between δ and a , we can determine the surface reaction rate as a function of a_O.

b) Apparatus. Figure 1 shows a schematic diagram of the apparatus. The reaction tube (A) was a mullite tube, 3.6 cm in inner diameter and 72 cm long, to which upper and lower glass tubes were connected by glass joints. The upper glass tube (B) was connected to a stainless steel inner tube (C). The outer tube (D) which was also made of stainless steel, can be raised or lowered together with the balance chamber (E) above it. In order to secure a vacuum seal, an O-ring (F) was inserted between the outer stainless steel tube and the inner one. Gas was passed upward through the reaction tube. The furnace (G) was wound with Kantal wire. The temperature gradient was less than 0.2 deg/cm over the region where the specimen (H) subjected to reaction. Temperature was controlled by means of an electronic controller within +1.5°C and measured by a calibrated Pt-Pt.Rh thermocouple (I). The weight change of wüstite specimen was followed continuously by means of Cahn RG electrobalance (J).

c) Purification of Gases. CO_2 was passed successively through a $Mg(ClO_4)_2$ column and an activated copper column to remove water vapor and oxygen. CO was passed through $Mg(ClO_4)_2$ to remove water vapor and then through an activated copper column to convert O_2 into CO_2, which was absorbed in a soda lime column.

d) Preparation of Wüstite Specimen. Wüstite specimens were prepared as follows. A rectangular coupon, approximately 1.2 cm long by 0.8 cm wide was taken from a sheet of electrolytic iron 0.14 mm thick. Results of spectroscopic analysis is shown in Table 1. A hole, 1 mm in diameter was drilled near one end of the coupon and the coupon was washed with soap and water, rinsed in alcohol, dried in a desiccator and weighed. A Pt hock was then attached through the hole. After the outer tube (D) was raised to position X so as to be detached from the inner one, the coupon was suspended from the balance with a silica fibre. The outer tube was then lowered to position Y and the reaction apparatus was evacuated. After evacuation CO_2 was admitted to the system and let to flow at a flow rate of 20 cc/min. The outer tube was then lowered to position Z in order to oxidize the iron specimen at 1050°C. When the weight reached the

value corresponding to the nearly stoichiometric ratio of iron to oxygen, the oxidized specimen was raised from the hot zone by raising the outer tube to position Y and the furnace temperature was changed to the desired reaction temperature. Then the reaction apparatus was evacuated and a CO_2–CO mixture whose CO_2/CO ratio was 2/3 was introduced to the system. The oxidized specimen was lowered to the furnace and equilibrated with the gas mixture at the reaction temperature. When the weight became constant, the metal deficit, δ, was calculated from the weight change the specimen before and after oxidation. Data of the present work agreed well with Darken's. The thickness of wüstite specimen was about 0.3 mm and the average grain size was about 100 μ.

e) Measurement of Surface Reaction Rate. After the reaction apparatus was evacuated, CO_2 gas desired partial pressure was introduced to the system to oxidize the wüstite. Since the length of time needed for the introduction of gas was less than 15 sec, weight change during the introduction was negligibly small. Thus, the value of log a of wüstite at the beginning of oxidation was thought to be equal to log 2/3. When the weight of the specimen reached the value corresponding to log a =0.6, CO_2 was removed from the system to stop the oxidation, and CO of desired partial pressure was introduced to initiate the reduction. In this way, the same wüstite specimen was used repeatedly for the kinetic measurement of oxidation in CO_2 and reduction in CO at desired partial pressures in a range of log a_O=−0.18—0.6. The wüstite specimen was kept in the furnace during the kinetic measurement to prevent the wüstite specimen from decomposing by quenching, since the wüstite phase is unstable below 570°C. After repetition of oxidation and reduction, a gas mixture of P_{CO}/P_{CO}=2/3 was introduced into the reaction apparatus to equilibrate the wüstite specimen with the gas mixture. A comparison of the equilibrium weight at the end of the run with that at the beginning showed the difference between the two weights to be less than 10% of the total weight change of the oxidation or reduction of wüstite.

The measurement was carried out in a temperature range 950—1075°C and at pressures of 70—300 mmHg.

Results

Typical oxidation curves of wüstite in CO_2 and reduction curves in CO are shown in Figs. 2 and 3. respectively. In these figures the scale of δ is also given. The wüstite specimen employed in this

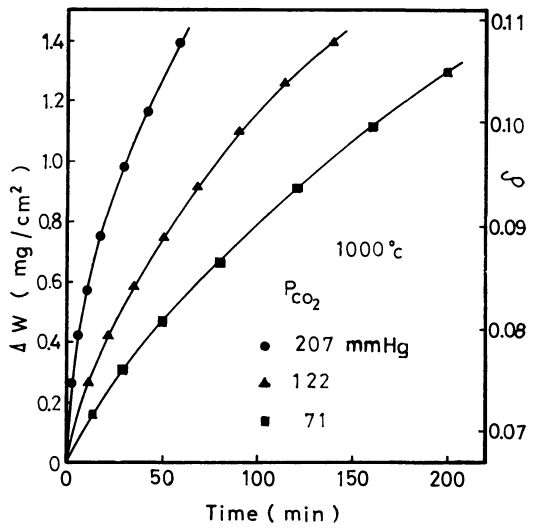

Fig. 2. Oxidation curves of wüstite by CO_2.

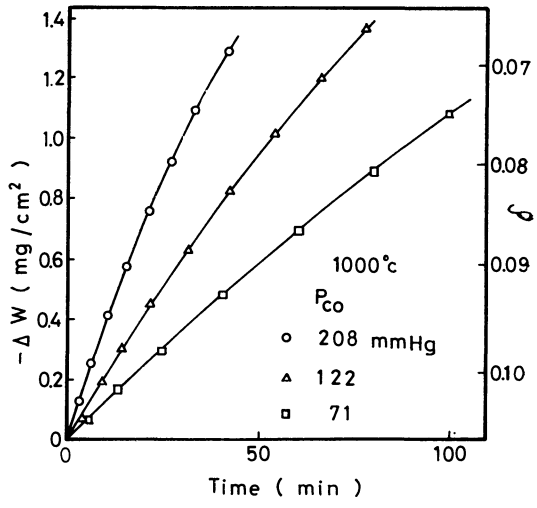

Fig. 3. Reduction curves of wüstite by CO.

experiment was so thin that the overall reaction is supposed to be controlled by the surface reaction. It is thought that the gradient of δ is not formed in the specimen, and the surface reaction rate, V, at a specified value of δ is determined from the slope of tangent drawn to the curve at the δ value. Since there is a relationship between the oxygen activity in wüstite (a_0) and δ, the relationship between V and a_0 is determined.

Figure 4 shows the plots of log V *vs.* log a_O. In the case of reduction, the plots of log V *vs.* log a_0 show a good linearity. In the case of oxidation, an abnormally high rate was observed in the initial period of oxidation, especially at high pressures of CO_2. However, even in such cases the reduction performed immediately after the oxidation showed no abnormality. At low CO_2 pressures,

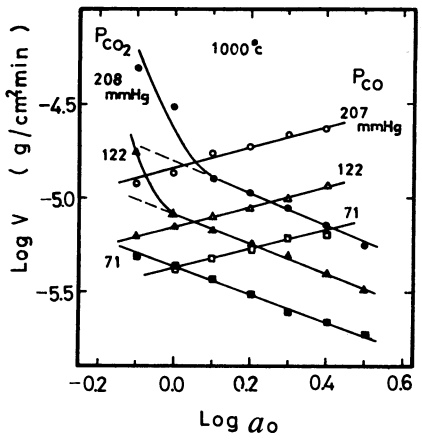

Fig. 4. Relationship between V and a_O.

the plots of log V *vs.* log a_0 give a good linearity. The cause of abnormally high rate of oxidation has not been elucidated yet.

Figures 5 and 6 show the dependence of V on partial pressures of CO_2 and CO at constant a_0, respectively. V linearly depends on gas pressures. This clearly shows that the overall reaction is controlled by the reaction at the surface.

Accordingly, the rate of oxidation, V_{red}, and the rate of reduction, V_{red}, are expressed in terms of P_{CO_2}, P_{CO} and a_O as follows:

$$V_{ox} = k_O P_{CO_2} a_O^{-m/3} \quad (1)$$

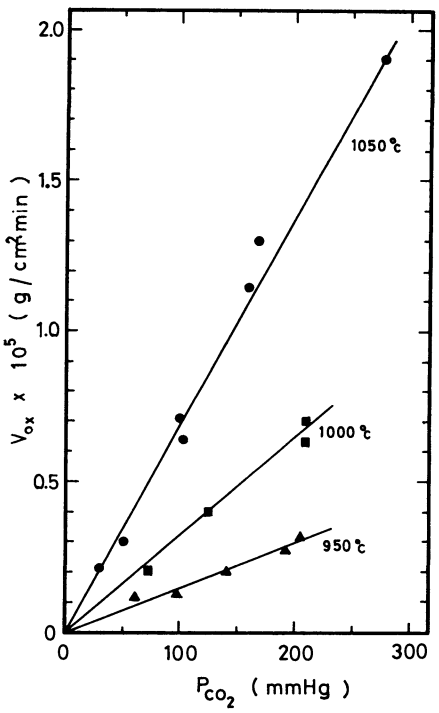

Fig. 5. Dependence of oxidation rate, V_{ox}, on partial pressure of CO_2, P_{CO_2} at $a_O=25$.

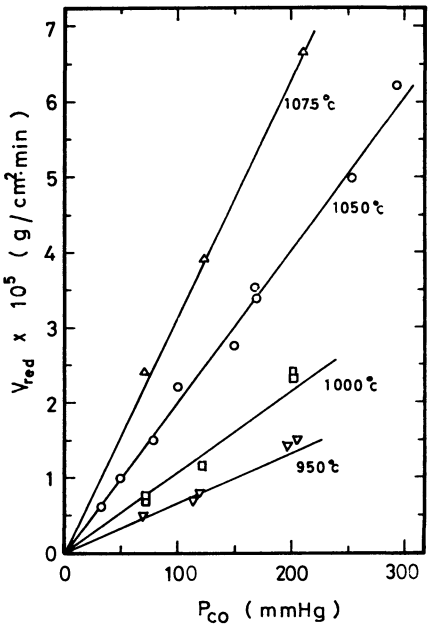

Fig. 6. Dependence of reduction rate, V_{red}, on partial pressure of CO, P_{CO} at $a_O=25$.

$$V_{red} = k_O' P_{CO} a_O^{n/3} \quad (2)$$

The values of m and n at various temperatures are listed in Table 2. It is noteworthy that m is approximately 2 and n is approximately 1. Rate constants k_O and k_O' defined in Eqs. (1) and (2) were obtained by extrapolating the linear relationship in Figs. 5 and 6 to the gas pressure of 1 atm. and substituting 2.5 for a_O. The Arrhenius plots of k_O and k_O' obtained in this way are shown in Fig. 7. From the definition of $a_O \equiv P_{CO_2}/P_{CO}$ and the equilibrium condition, $V_{ox}=V_{red}$, k_O and k_O' should be equal to each other. However, as seen in Fig. 7, a discrepancy of about 25% exists between k_O and k_O'. In the case of oxidation, experimental results showed a rather large deviation at high pressures of CO_2. Therefore, the value of k_O is thought to be less accurate than the value of k_O'. Activation energy for k_O and k_O' are 35.0+3 kcal/mol and 33.0±3 kcal/mol, respectively. Grabke[2] found 33.5±2 kcal/mol as the activation energy of of dissociative adsorption of CO_2 on wüstite in the kinetic study of isotopic exchange between $^{14}CO_2$ and ^{12}CO at temperatures from 800°C to 983°C.

The present activation energy is nearly the same as Grabke's.

Discussion

The reaction mechanism can be discussed on the basis of the Kobayashi-Wagner theory as follows. The reaction between CO_2 and CO on the wüstite surface proceeds by the parallel reactions

$$CO_2 \rightleftarrows CO + O \quad (3.A)$$

$$CO_2 + \ominus \rightleftarrows CO + O^- \quad (3.B)$$

$$CO_2 + 2\ominus \rightleftarrows CO + O^{2-} \quad (8.C)$$

where O, O^-, and O^{2-} represent adsorbed oxygen atoms, monovalent oxygen ions and divalent oxygen ions, respectively, and $\ominus$ electrons in wüstite.

Assuming that the adsorbed oxygen atoms and oxygen ions are in equilibrium with those in bulk of wüstite and that the adsorption of CO_2 and CO is weak, we can write the rate equations as

$$V_A = k_1 P_{CO_2} - k_1' P_{CO} a_O \quad (4.A)$$

$$V_B = k_2 P_{CO_2} a_\ominus - k_2' P_{CO} a_{O^-} \quad (4.B)$$

$$V_C = k_3 P_{CO_2} a_\ominus^2 - k_3' P_{CO} a_{O^{2-}} \quad (4.G)$$

where a_O, a_{O^-}, $a_{O^{2-}}$ and $a_\ominus$ denote the activities of respective species.

Assuming the equilibrium among positive holes ($\oplus$), cation vacancies ($Fe_{\square}''$) and oxygen atoms in wüstite, we obtain

$$O \rightleftarrows FeO + Fe_{\square}'' + 2\oplus$$

$$\frac{a_{Fe_{\square}''} a_\ominus^2}{a_O} = k_1 \quad (5)$$

Because of the low concentration of $Fe_{\square}''$ and $\oplus$, we have

$$x_{Fe_{\square}''} \approx a_{Fe} \quad (6)$$

$$x_\oplus \approx a_\oplus \quad (7)$$

where x denotes the concentration.

From the charge neutrality condition

$$2x_{Fe_{\square}''} = x_\oplus \quad (8)$$

it follows that

$$a_\oplus = K_2 a^{1/3} \quad (9)$$

Other equilibrium conditions and mass action laws are

$$\ominus + \oplus \rightleftarrows \text{Null}$$

$$a_\ominus \cdot a_\oplus = K_3 \quad (10)$$

$$O^- \rightleftarrows O + \ominus$$

$$a_O \cdot a_\ominus = K_4 a_{O^-} \quad (11)$$

$$O^{2-} \rightleftarrows O + 2\ominus$$

$$a_O \cdot a_{\ominus^2} = = K_5 a_{O^{2-}} \quad (12)$$

Combination of Eqs. (9), (10), (11) and (12) yields

$$a_\ominus = K_6 a_O^{-1/3}$$

$$a_{O^-} = K_7 a_O^{2/3} \quad (14)$$

$$a_{O^{2-}} = K_8 a_O^{1/3} \quad (15)$$

Inserting these equations into Eqs. (4.A)—(4.C), we obtain

$$V_A = k_1 P_{CO_2} - k_1' P_{CO} \quad (16.A)$$

$$V_B = k_2 K_6 P_{CO_2} a_O^{-1/3} - k_2' K_7 P_{CO} a_O^{2/3} \quad (16.B)$$

$$V_C = k_3 K_6^2 P_{CO_2} a^{-2/3} - k_3' K_8 P_{CO} a_O^{1/3} \quad (16.C)$$

The generalized rate equation is

$$V = k_O P_{CO_2} a_O^{-m/3} - k_O' P_{CO} a_O^{3/n} \quad (17)$$

where m and n are integers characteristic of reaction mechanism as listed in Table 3. The first term

Table 3. Predominant reaction mechanism and values of m and n

Mechanism	m	n
(A) $CO_2(ads) \rightleftarrows CO(ads) + O(ads)$	0	3
(B) $CO_2(ads) + \ominus \rightleftarrows CO(ads) + O^-(ads)$	1	2
(C) $CO_2(ads) + 2\ominus \rightleftarrows CO(ads) + O^{2-}(ads)$	2	1

on the right side represents the oxidation rate of wüstite by CO_2 and the second term represents the reduction rate of wüstite by CO, namely,

$$V_{ox} = k_O P_{CO_2} a^{-m/3} \quad (18)$$

$$V_{red} = k_O' P_{CO} a_O^{n/3} \quad (19)$$

In the present work, values of m and n were determined experimentally, so we can conclude the predominant mechanism of the three. From a comparison of Tables 2 and 3 it is concluded that the most predominant mechanism of the surface reaction is

$$CO_2 + 2\ominus \rightleftarrows CO + O^{2-}$$

Summary

(1) Oxidation of wüstite by CO_2 and reduction by CO in a homogeneous range of wüstite were

studied kinetically by the microgravimetric method. The reactions were found to be countrolled by gas-oxide interface reaction.

(2) The surface reaction rate was determined as a function of gas pressure and oxygen activity in wüstite, a_O, in a temperature range 950—1075°C at pressures of 70—300 mmHg.

(3) The oxidation rate in CO_2 and reduction rate in CO were expressed respectively as

$$V_{ox} = k_O P_{CO_2} a^{-m/3} \qquad (m = 2.1—2.2)$$

$$V_{red} = k_O' P_{CO} a_O^{n/3} \qquad (n = 0.8—1.2)$$

(4) Activation energies for rate constants k_O and k_O' were 35±3 kcal/mol and 32±3 kcal/mol respectively and coincided with those obtained by Grabke.

(5) From Wagner's theory the predominant mechanism was determined as the two electron transfer mechanism:

$$CO_2 + 2\ominus \rightleftarrows CO + O^{2-}$$

Ionic Processes in the Radiolysis of Nitrous Oxide. The Effect of Electron Scavenger and Rare Gas Sensitization

Satoshi TAKAO and Shoji SHIDA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received April 28, 1970)

The effect of electron scavenger (SF_6) on the radiolysis products of N_2O was examined. The sensitization of N_2O by various rare gases was also measured. In the presence of an electron scavenger we got 3.0 for the value of $-\Delta G(-N_2O)$ in good agreement with the value of $G(e^-)$ for N_2O. In the experiments of Xe or Kr containing small amounts of N_2O, the $G(-N_2O)$ values were nearly equal to the respective $G(e^-)$ values for the rare gases, and the addition of SF_6 to the Xe-N_2O system almost completely inhibited nitrogen formation. The results show that one electron decomposes just one molecule of N_2O. This fact can not be accounted for by the hitherto assumed mechanism, and a new mechanism involving N_2O^- is proposed for ionic processes in the radiolysis of N_2O. In the N_2O-rare gas mixtures of various compositions, the sensitized yields of N_2O decomposition per 100 eV energy absorbed by rare gases were divided into two groups, *e.g.*, the yields from He, Ne mixtures were about twice as large as those from Ar, Kr and Xe mixtures. This result is discussed in terms of charge transfer and the Penning ionization.

Nitrous oxide has been currently used as an effective electron scavenger in the study of liquid[1] and gaseous[2] hydrocarbon radiolysis. In these systems, the nitrogen yields which are considerably in excess of the estimated yields of electrons have been found, and many discussions are raised on the mechanism of the radiolytic formation of nitrogen from nitrous oxide in hydrocarbons.[3]

The study of the radiolysis of nitrous oxide in the gas phase has long received considerable attention in relation to the gas dosimeter, and a number of determinations of the radiolysis products have been reported,[4] but nothing definite has yet been established about the reaction mechanism.

The present study was undertaken in order to obtain a better insight of the mechanism for ionic processes in the radiolysis of N_2O by using SF_6 as an electron scavenger and various rare gases, especially Xe, as electron supplier.

Experimental

Nitrous oxide from a cylinder supplied by the Takachiho-Shoji Co. was freed from nitrogen and oxygen by careful degassing.

The gases SF_6 and CO_2 were used after the usual degassing. The rare gases were of high purity and used as obtained, the stated purities being 99.99%, 99.99%, 99.999%, 99.9% and 99.9% for He, Ne, Ar,

Kr and Xe, respectively.

Irradiations were done in a cylindrical vessel of about 50 cc with ^{60}Co γ-rays at 25°C at a dose rate of 3.0×10^{19} eV/g/hr and the highest dose used was 7.2×10^{20} eV/g.

The initial products of radiolysis of nitrous oxide are N_2, O_2 and NO, but NO and O_2 were known to react to form NO_2 in a cold trap[5] and so the products, N_2 and O_2, after the cold trap reaction were measured by gas chromatography (a 5 m column of Molecular Sieve-5 A at room temperature). The initial amounts of NO formed were calculated stoichiometrically from the measured amounts of N_2 and O_2 and the initial amount of nitrous oxide.

The total energy absorbed in pure N_2O or mixtures was measured by the Fricke dosimeter making appropriate corrections for electron density. In the calculation of the total energy absorbed in these systems and the energy partition in mixtures, especially in the rare gas sensitization experiments, it would be better to use the relative stopping powers and the so-called effective atomic numbers suggested by Klots.[6] The results brought about slightly larger G-values (about 15% for all G_{sens}-values described below), but this does not change our conclusion. We advance discussions using the G-values obtained by the usual electron density corrections.

Results

The initial products, N_2, O_2 and NO from pure nitrous oxide of 50 to 400 mmHg pressures at room temperature have been determined. The observed G-values at 200 mmHg were $G(N_2)=10.1$, $G(O_2)=3.8$ and $G(NO)=5.1$ which were almost independent of pressure within experimental error. From these values we get 12.6 for the value of $G(-N_2O)$ in good agreement with those of Sworski[4] and other earlier investigators.

Although nitrous oxide is known to be an effective electron scavenger, SF_6 is much more effective in the gas phase,[7] and we could estimate the role of electrons in the radiolysis of N_2O by the addition of SF_6 to N_2O. The effect of adding SF_6 to N_2O of a constant pressure of 200 mmHg is shown in Fig. 1. The addition of very small amounts of SF_6 rapidly reduced the yields of N_2, O_2 and NO, which then remained constant on further addition of SF_6. The observed decreases were $-\Delta G(N_2)=2.1$, $-\Delta G(O_2)=0.6$ and $-\Delta G(NO)=1.8$, and thus the value of $-\Delta G(-N_2O)$ is calculated to be 3.0.

In Fig. 2 are shown the results with CO_2[8] which

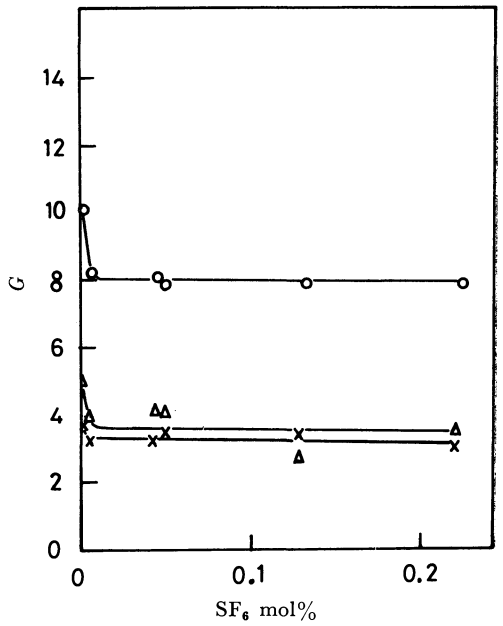

Fig. 1. The effect of adding SF_6 to N_2O on the yields of the products: ○, N_2; ×, O_2; △, NO.

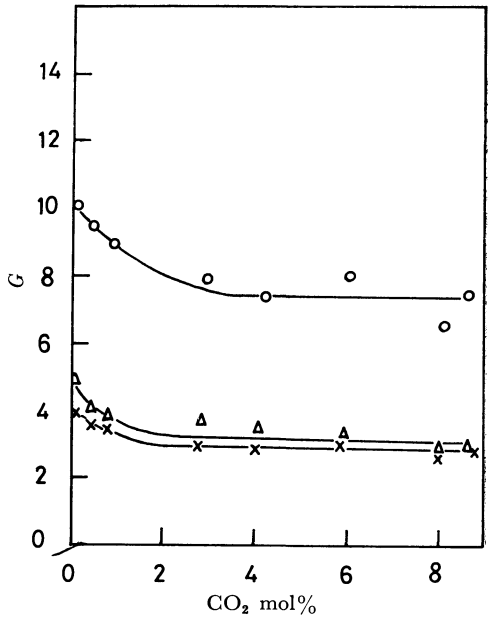

Fig. 2. The effect of adding CO_2 to N_2O: ○, N_2; ×, O_2; △, NO.

are similar to the above except for much slower levelling off of the G-values.

Figures 3 and 4 show, respectively, the results of the addition of N_2O to Xe and Kr of a constant pressure of 600 mmHg. All these values are corrected for the products formed by the direct radiolysis of N_2O.

Next, the effect of adding SF_6 to Xe including 5 mol% of N_2O was examined. Addition of

7) G. R. A. Johnson and J. M. Warman, *Trans. Faraday Soc.*, **61**, 1709 (1965).
8) There are few reports in which CO_2 is used as an electron scavenger in the gas phase and no evidence in the electron attachment experiments that CO_2 is an electron scavenger (L. C. Christophorou and J. A. D. Stockdale, *J. Chem. Phys.*, **48**, 1956 (1968)). The results in Fig. 2 show nearly the same G-values as those in Fig. 1. In the present system, CO_2 may act as an electron scavenger.

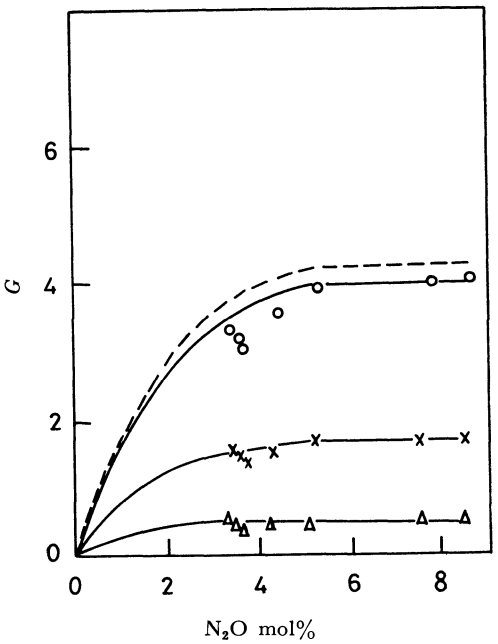

Fig. 3. The effect of adding N_2O to Xe: ○, N_2; ×, O_2; △, NO; ----, yields for $-N_2O$. In this figure and Fig. 4, corrections were made for the products arising from the direct radiolysis of N_2O.

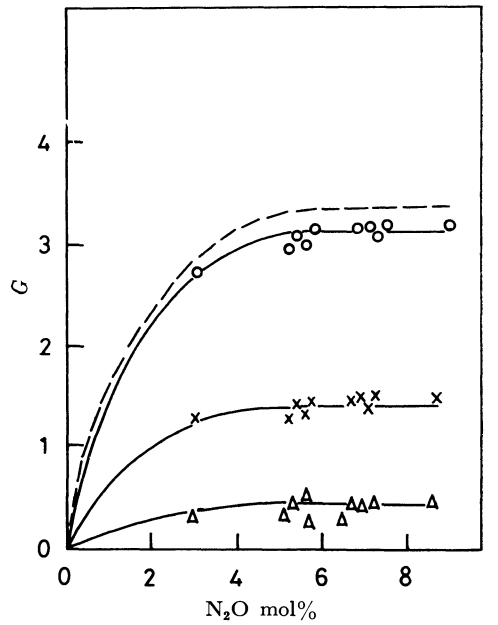

Fig. 4. The effect of adding N_2O to Kr: ○, N_2; ×, O_2; △, NO; ----, yields for $-N_2O$.

SF_6 of only 0.1% with respect to Xe completely inhibits nitrogen formation, indicating the electrons to be the primary precursor of products (Fig. 5).

We further studied the radiolysis of N_2O with

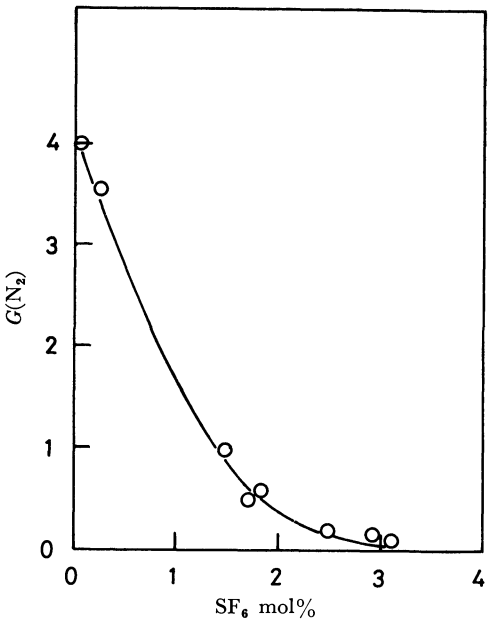

Fig. 5. The effect of adding SF_6 to Xe including 5 mol.% of N_2O. In this figure, SF_6 mol% shows the value with respect to N_2O.

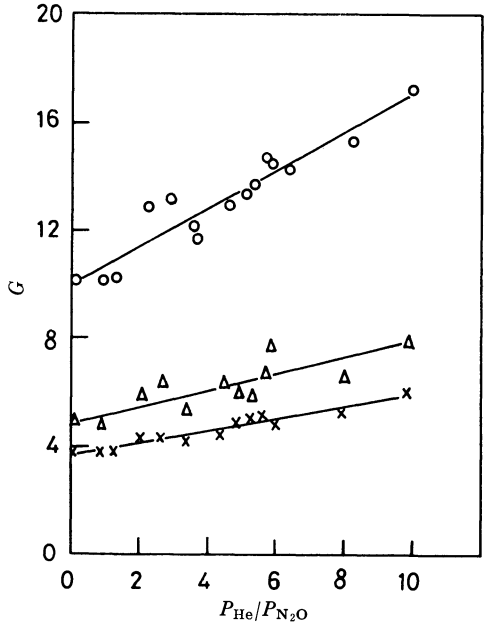

Fig. 6. Sensitization by He: ○, N_2; ×, O_2; △, NO. $P_{N_2O}=50$ mmHg.

various rare gases including those of higher ionization energies and metastable excitation energies. In Figs. 6—10, the results are shown with various ratios of rare gas to N_2O; the G-values are expressed as the number of molecules of products formed per 100 eV absorbed directly by N_2O. The amounts of N_2, O_2 and NO all increased linearly in the system of He and Ne, while in the

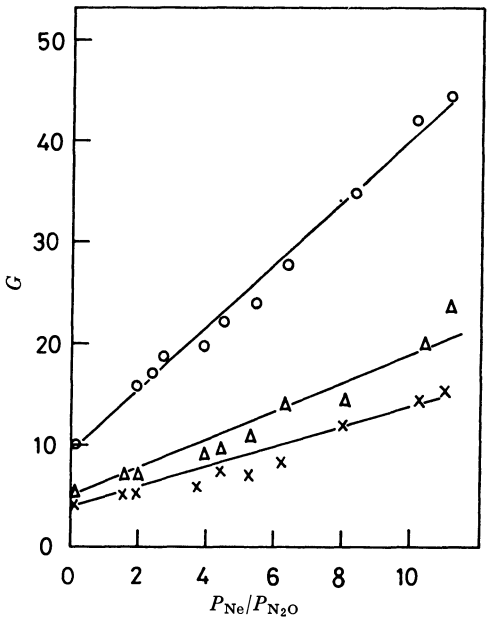

Fig. 7. Sensitization by Ne: ○, N_2; ×, O_2; △, NO. P_{N_2O} = 50 mmHg.

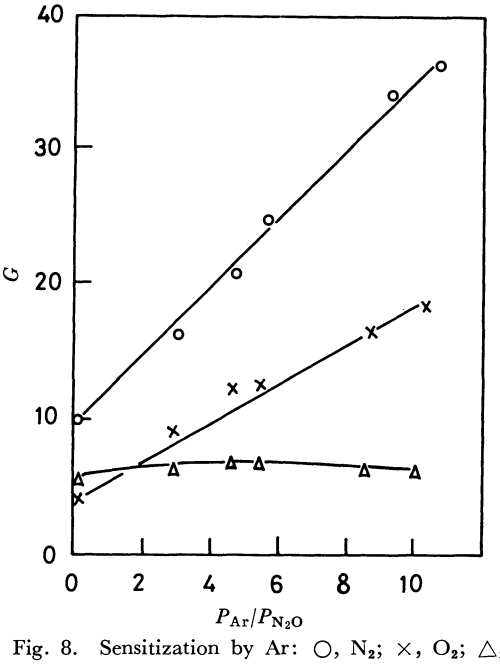

Fig. 8. Sensitization by Ar: ○, N_2; ×, O_2; △, NO. P_{N_2O} = 50 mmHg.

system of Ar, Kr and Xe, N_2 and O_2 increased linearly but the amounts of NO did not increase at all.

In order to investigate the effects of rare gas sensitization more quantitatively, we calculate the value represented as G_{sens}, that is, the increase in the G-value of a product by sensitization based on the energy absorbed by the rare gas as defined by the equation

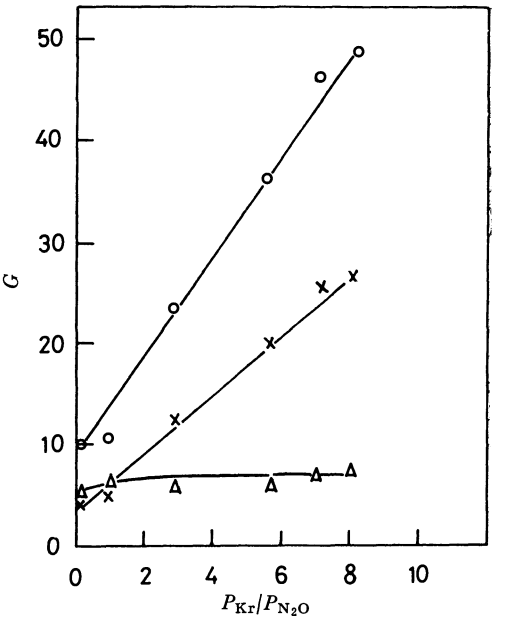

Fig. 9. Sensitization by Kr: ○, N_2; ×, O_2; △, NO. P_{N_2O} = 50 mmHg.

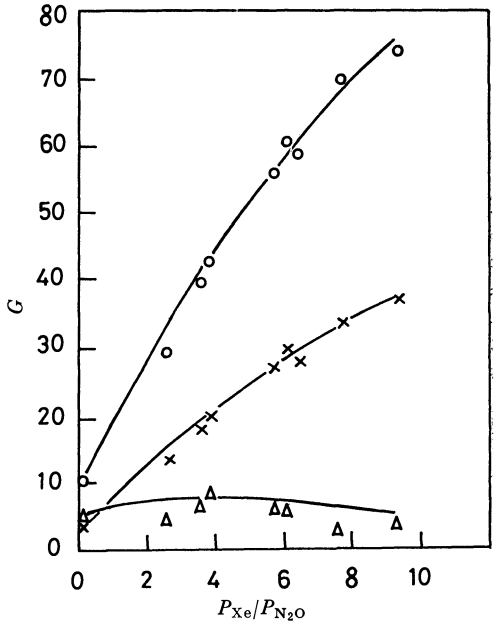

Fig. 10. Sensitization by Xe: ○, N_2; ×, O_2; △, NO. P_{N_2O} = 50 mmHg.

$$G_{sens} = (G_N R_N - G^\circ_N R_N)/R_r$$

where G°_N and G_N represent the values of the particular product based on the energy absorbed by N_2O in the N_2O pure system and in the sensitization experiment, respectively, and R_N and R_r the energy absorbed by N_2O and rare gas, respectively. The values obtained from the above equation are shown in Table 1.[9]

TABLE 1. G_{sens} VALUES FOR VARIOUS RARE GASES (The W-values and $G(e^-)$ values are also presented.)

G_{sens}	He	Ne	Ar	Kr	Xe
N_2	7.3	6.3	3.0	2.9	3.8
O_2	2.8	2.4	1.5	1.6	1.8
NO	3.0	3.2	0.0	0.5	0.5
$-N_2O$	8.8	7.9	3.0	3.2	4.1
W(eV)	42	37	26	24	22
$G(e^-)$	2.5	2.8	3.9	4.1	4.4

Discussion

From the experiments shown in Fig. 1, we get 3.0 for the value of $-\Delta G(-N_2O)$. This is in good agreement with the value of $G(e^-)=3.0$ calculated from $W(N_2O)=33$ eV.[10] If we assume that all electrons are scavenged by SF_6 and that the resulting SF_6^- does not contribute in any way to the decomposition of N_2O, it seems that one electron produced by the ionization of N_2O decomposes just one molecule of N_2O. If this is correct, the addition of small amounts of N_2O to Xe may result in the decomposition of N_2O close to the value of $G(e^-)$ expected from the W-value of Xe. This is the case for Xe and approximately for Kr (Figs. 3 and 4).

It is noted here that Xe has lower ionization energy than N_2O, while Kr has a higher one. However, experimental results showed that there was no appreciable difference between the Xe and the Kr systems and the product distributions were nearly the same in both cases. Thus in spite of the higher ionization potential of Kr, the charge transfer from Kr^+ to N_2O does not seem to occur effectively.

In the Xe-N_2O system as well as in other rare gas-N_2O systems, there is the possibility of excitation energy transfer from rare gas to N_2O besides that from the ionic processes:

$$Xe^* + N_2O \rightarrow N_2O^* + Xe$$

$$N_2O^* \rightarrow N_2 \text{ or other products}$$

Many photolysis data of nitrous oxide (λ: 1470, 1830 or 1849 A)[11-13] show that the ratio of NO to O_2 is greater than unity, but in the present Xe-N_2O system the ratio of NO to O_2 is less than 0.3. In the Xe-N_2O-SF_6 system, the formation of nitrogen was almost completely inhibited by SF_6, and we consider that there is no appreciable contribution from the excitation transfer processes.

Quite recently after the present work had been completed, Sears[14] reported the effect of addition of a small amount of SF_6 on the radiolysis of N_2O. His results and conclusion are not inconsistent with ours. Hummel[15] also reported experiments to determine the effect of small amounts of SF_6 on $G(N_2)$ at temperatures from 30 to 200°C. His results, however, were different from ours. We thought this discrepancy might lie mainly in the experimental conditions (he used a very large vessel of 1.9 l). Therefore we also examined the same system by using a larger vessel of about 400 cc, but the results obtained did not differ much from our earlier results obtained with a small vessel.

Thus we conclude that one electron decomposes one molecule of N_2O and yields one or less molecule of N_2 (0.7 and 0.9 molecules in pure N_2O and in Xe, respectively).

The results obtained here for ionic processes can not be accounted for by the hitherto assumed mechanism:[16]

$$e^- + N_2O \rightarrow N_2 + O^-$$

$$O^- + N_2O \rightarrow N_2 + O_2^- \text{ and } NO + NO^-$$

According to this mechanism, more than one molecule of N_2 should be produced per electron, instead of the observed values of 0.7 and 0.9.

In order to explain the observed facts, we assumed a long-lived N_2O^- molecule resulting from the electron capture by N_2O, and proposed the following mechanism for the ionic processes in the radiolysis of pure N_2O.[17]

$$e^- + N_2O \rightarrow N_2O^-$$

$$N_2O^- + N_2O^+ \rightarrow N_2 + O + N_2O \text{ and } N + NO + N_2O.$$

Consideration of the possible reaction schemes and reaction rate constants[18] led us to the assumption that the resulting O and N atoms react to form O_2 and NO through NO_2. Of course, the presence of other positive ions (NO^+, N^+, *etc.*) other than N_2O^+ could be considered as possible participants. There is the possibility that the difference of positive ions changes the decomposition mode and product formation. However, from the mass spectra of N_2O[19] it can be seen that only 36% of the parent ions decomposes. A number of studies have been reported of the mass spectra of N_2O, but ion-molecule reactions

9) Ausloos *et al.* (R. Gordon and P. Ausloos, *J. Res. Natl. Bur. Std.*, **69A**, 79 (1965)) studied the rare gas sensitization of $^{15}N^{14}NO$ by Kr and Xe and reported rather qualitative ion pair yields for nitrogen. Their results were consistent with ours qualitatively but not quantitatively. Their ion pair yields are approximate calculated values.

between positive fragment ions from N_2O^+ and N_2O molecules and their rate constants are not known in detail.[20] Charge transfer reaction is a likely one among many possible reactions. We assume then that some of these ions transfer their positive charge to N_2O to produce N_2O^+, eventually resulting in the neutralization of N_2O^+ with N_2O^-.

Recently, Warman and Fessenden[21] and Phelps and Voshall[22] reported the experimental facts showing that the electron capture of N_2O proceeds by a three-body process and suggested that N_2O^- ion is initially formed. Their results are consistent with our ionic processes in the radiolysis of N_2O.

In Table 1, we can classify the rare gases into two groups, *viz.*, He, Ne group and Ar, Kr, Xe group. The He, Ne group has much higher $G_{sens}(-N_2O)$ values than the Ar, Kr, Xe group. In the case of He and Ne the product distributions were nearly the same as in the direct radiolysis of N_2O, but in the case of Ar, Kr and Xe the yields of oxygen amount to about one-half of the nitrogen yields, NO being a minor product.

As mentioned before, the energy transfer from excited rare gas atom (X*) or ion (X^+) to N_2O molecule and the resulting decomposition of N_2O is possible in the rare gas sensitization such as

$$X^* \text{ or } X^+ + N_2O \rightarrow N_2 \text{ or other products.}$$

In the experiments with Ar, Kr and Xe, however, the $G_{sens}(-N_2O)$ values are nearly equal to the values of $G(e^-)$, and we believe that the energy transfer (charge or excitation) from Ar or Kr to N_2O does not occur in spite of the higher ionization potentials of Ar and Kr.

In the experiments with He and Ne, we observed nearly the same product distributions as in the direct radiolysis of N_2O and large $G_{sens}(-N_2O)$ values. We think that N_2O^+ ion produced by charge transfer in these systems could have considerable energy in excess of the ionization energy and that this might cause NO formation and large $G_{sens}(-N_2O)$ values in the rare gas sensitization by He and Ne. Of course, there is no saying that the difference in the object of neutralization of N_2O^- plays some part in the overall decomposition mechanism. In the case of He and Ne, the neutralization occurs between N_2O^+ resulting from charge transfer from He^+ or Ne^+ and N_2O^-, while in the case of Ar, Kr and Xe, the neutralization occurs between Ar^+, Kr^+ or Xe^+ and N_2O^-.

In the case of He and Ne, we must further take into account the formation of products from excitation energy transfer processes besides those from electron capture by N_2O and charge transfer to N_2O. We mentioned above that the results shown in Table 1 can be classified into two groups. From the discontinuity lying between Ne and Ar with respect to the product distributions and $G_{sens}(-N_2O)$ values, we remarked that the ionization potential of N_2O lies between the metastable energies of Ne and Ar. These conditions are shown in Table 2. It seems true that the product formation initiated from the Penning ionization of N_2O by metastable He or Ne atoms takes considerable part in the sensitization experiments with He and Ne, though we can not say to what extent.

Table 2. Ionization potentials and metastable excitation energies of rare gases[a]

	I.P. (eV)	E_m^* (eV)
He	24.6	19.8
Ne	21.7	16.1
Ar	15.9	11.6
Kr	14.5	9.9
Xe	12.1	8.8
N_2O	12.9	—

a) G. R. A. Johnson and G. Scholes, "The Chemistry of Ionization and Excitation," Taylor and Francis Ltd., London (1967), p. 145.

The total processes in the rare gas sensitization are described as follows.

$$X \rightsquigarrow X^+ + e^- \quad (1)$$

$$\rightsquigarrow X_m^* \quad (2)$$

$$X^+ + N_2O \rightarrow N_2O^+ + X \quad (3)$$

$$X_m^* + N_2O \rightarrow N_2O^+ + X + e^- \quad (4)$$

$$e^- + N_2O \rightarrow N_2O^- \quad (5)$$

$$N_2O^- + N_2O^+ \rightarrow N_2 \text{ and other products} \quad (6)$$

$$N_2O^- + X^+ \rightarrow N_2 \text{ and other products} \quad (7)$$

where X_m^* represents the metastable rare gas atom. Reactions (3), (4) and (6) do not occur in the case of Ar, Kr and Xe. Reaction (7) does not occur in the case of He and Ne. For overall radiolytic decomposition of N_2O in rare gases, the contribution from the neutral excited molecule decomposition by excitation transfer must be added except for the case of Ar, Kr and Xe. In the latter case, neither the excitation transfer from rare gas to N_2O nor the charge transfer takes place.

The authors wish to thank Dr. Y. Hatano and Dr. H. Yamazaki for many valuable suggestions throughout the course of this work. The authors gratefully acknowledge discussions with Professor G. R. Freeman, University of Alberta.

The Electronic Spectra of the Anion Radical Salts Derived from Halogen-substituted *p*-Benzoquinones*[1]

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received April 30, 1970)

The anion-radical salts derived from *p*-chloranil, 2,5-dibromo-3,6-dichloro-1,4-benzoquinone, and *p*-bromanil were prepared. The absorption spectra in an acetone solution and the diffuse reflection spectra of the solid salts were examined. These solid salts were then classified into three groups, namely, those showing the spectrum of the anion-radical monomer, those showing a strong charge-transfer band characteristic of the solid salts, and, finally, those showing not only the spectrum of the anion-radical monomer but also an intermolecular charge-transfer band. The mode of intermolecular interaction in these anion-radical salts was discussed according to this classification. Their magnetic behaviour was also speculated upon on the basis of the charge-transfer interaction.

Solid ion-radical salts are particularly interesting because, in crystals of such ion-radical salts, the ion-radical molecules form, in themselves, a plane-to-plane stacking into columns so as to make a large overlap between their half-filled molecular orbitals.[1] Since, in this case, any individual radical molecule interacts through charge transfer most strongly with one or two other radicals, the electronic spectrum of the solid salt is expected to be different from the monomer spectrum in solution and to show an intermolecular charge-transfer band. In this respect, it was interesting to examine the solid-state spectra, particularly of Würster cation-radical salts and of 7,7,8,8-tetracyanoquinodimethane (TCNQ) anion-radical salts.[2-4]

The present paper will describe the solid-state spectra, as well as the absorption spectra in solution, of some stable anion-radical (*i.e.*, semiquinone ion) salts derived from halogen-substituted *p*-benzoquinones (see Fig. 1). The purpose of this paper is to report the results of our electronic-spectrum measurements and to show that a charge-transfer interaction similar to those in Würster cation-radical salts and in TCNQ anion-radical salts takes place in these anion-radical salts. It is also interesting to discuss their magnetic properties on the basis of the charge-transfer interaction.

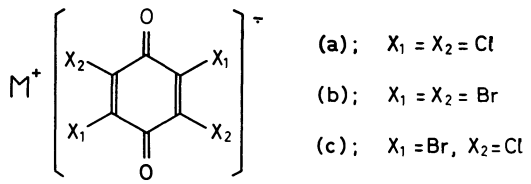

Fig. 1. The anion-radical salts of (a) *p*-chloranil, (b) *p*-bromanil, and (c) 2,5-dibromo-3,6-dichloro-1,4-benzoquinone. M^+ represents a diamagnetic counter cation.

Experimental

Materials. The *p*-chloranil and *p*-bromanil were commercially available. The 2,5-dibromo-3,6-dichloro-1,4-benzoquinone (*p*-QBr_2Cl_2) was synthesized by the bromination of 2,5-dichloro-1,4-benzoquinone. These compounds were purified by recrystallization from benzene or acetic acid.

The following six anion-radical salts were prepared according to the method of Torrey and Hunter[5]: Na^+ *p*-Chloranil$^-$, K^+ *p*-Chloranil$^-$, Na^+ *p*-$QBr_2Cl_2^-$, K^+ *p*-$QBr_2Cl_2^-$, Na^+ *p*-Bromanil$^-$, and K^+ *p*-Bromanil$^-$. In this method, the anion-radical salts were made by the one-electron reduction of the corresponding quinones with alkali metal iodides in a cold acetone solution.

Measurements. The absorption spectra in an acetone solution were measured at room temperature, using a Beckman DK-2A spectrophotometer at concentrations of the order of 10^{-4} mol/*l*.

The diffuse reflection spectra of the solid salts were

recorded on a Beckman DK-2A spectroreflectometer in the range from 4.0 to 30.8 kK at room temperature. In order to avoid cation exchange between the salt and the diluent, the sodium salts were ground with sodium chloride, and the potassium salts, with potassium bromide. The solid-state spectra were then obtained by plotting the diffuse reflection spectra using the Kubelka-Munk equation, $f(R)=(1-R)^2/2R$, in which R is the reflectance. The experimental details were the same as those in previous papers.[2-4]

The Absorption Spectra in Solution

Some of the absorption spectra of these anion-radical salts in an acetone solution are given in Fig. 2. The spectra are not changed when the counter cation of the salt is replaced. Since the concentrations are so dilute, the salts seem to be completely dissociated. The obtained spectra are those of the anion-radical monomer, because the counter cations of the salts are simple alkali metal cations.

The *p*-Chloranil Anion Radical (Fig. 2, Curve a). The absorption spectrum of this anion was found to be very similar to that of the *p*-benzoquinone anion-radical reported by Harada and Inokuchi.[6] The spectrum of the *p*-chloranil anion-radical consists of bands at 22.2 kK, 26.7 kK, and 30.3 kK, while that of the *p*-benzoquinone anion-radical has bands at 22.7 kK, 27.0 kK, and 31.3 kK. We can see that the introduction of the chlorine substituents into the *p*-benzoquinone anion-radical causes slight shifts in their corresponding bands. Therefore, it may be assumed that the π-conjugated system for the *p*-chloranil anion-radical may be approximated by that for the *p*-benzoquinone anion-radical. According to Harada's calculations,[7] the ground configuration of the *p*-benzoquinone anion-radical belongs to the $^2B_{3g}$ representation. He assigned the bands at 22.7 kK, 27.0 kK, and 31.3 kK to the transitions of $^2B_{3g}\rightarrow{}^2B_{1u}$, $^2B_{3g}\rightarrow{}^2A_u$, and $^2B_{3g}\rightarrow{}^2B_{1u}$ respectively. Therefore, the same assignments seem to be applicable to the bands at 22.2 kK, 26.7 kK, and 30.3 kK for the *p*-chloranil anion-radical.

On the other hand, Shirotani *et al.* have found the monomer-dimer equilibrium for the *p*-chloranil anion-radicals in an ethanolic solution at low temperatures.[8] At this time, the charge-transfer band of the dimer*2 appears around 14.9 kK; this value is smaller than that of 17.1 kK for the dimer of the *p*-benzoquinone anion-radical reported by Kimura *et al.*[9]

The *p*-Bromanil Anion Radical (Fig. 2, Curve b). Because both were similar to those for the *p*-chloranil anion-radical, the bands at both 22.2 kK and 30.2 kK for the *p*-bromanil anion-

*2 According to the Hausser and Murrell's theory, the ion-radicals in a dimer may lie in parallel planes, one above the other, and the spin-exchange interaction leads to a singlet ground state and an excited triplet state. Therefore, we must take into consideration the fact that intermolecular charge-transfer may make a significant contribution to stabilizing the ground singlet state of the dimer. The low-energy charge-transfer absorption characteristic of the dimer arises from a transition from the thus-stabilized ground state to an excited singlet state expressed by an antisymmetric combination of the wave-functions for charge-transfer structures, $R\text{-}R^{2-}$. See K. H. Hausser and J. N. Murrell, *J. Chem. Phys.*, **27**, 500 (1957).

9) K. Kimura, H. Yamada and H. Tsubomura, *J. Chem. Phys.*, **48**, 440 (1968).

radical were assigned to the transitions of $^2B_{3g} \rightarrow {}^2B_{1u}$. However, it was noted that, unlike the *p*-chloranil anion-radical, the transition due to $^2B_{3g} \rightarrow {}^2A_u$ was not detected, while a shoulder appeared around 20.5 kK.

The *p*-QBr_2Cl_2 Anion Radical (Fig. 2, Curve c). The point group for this molecule belongs to the C_{2h} symmetry, which is degraded from the D_{2h} symmetry for the above two molecules. Therefore the bands at both 22.1 kK and 30.2 kK must belong to the $^2B_g \rightarrow {}^2A_u$ transitions. Except for this difference, the electronic structures of the *p*-QBr_2Cl_2 and *p*-bromanil anion-radicals seem to be much alike.

The Solid-State Spectra

K^+ *p*-Chloranil$^-$ (Fig. 3, Curve a). The solid-state spectrum of this salt shows a low-energy band at 11.8 kK, a strong high-energy band at 23.3 kK, and a shoulder around 30 kK. Except for the appearance of the low-energy band, the bands seem to be similar to those for the *p*-chloranil anion-radical monomer in an acetone solution. Therefore, the high-energy band at 23.3 kK and the shoulder around 30 kK can be assigned to the $^2B_{3g} \rightarrow {}^2B_{1u}$ transitions at 22.2 kK and at 30.3 kK respectively for the monomer. Unfortunately, in the present investigation, the band due to the $^2B_{3g} \rightarrow {}^2A_u$ transition for the monomer spectrum was not observed for the solid-state spectrum. Although the value of the low-energy band, 11.8 kK, of the solid-state spectrum is a little bit lower than that of 14.9 kK of the charge-transfer band of the *p*-chloranil anion-radical dimer in solution, we assigned this band to the charge-transfer transition in the solid state. However, the intensity of this band is rather weaker than that of Na^+ *p*-Chloranil$^-$ (see below).

Na^+ *p*-Chloranil$^-$ (Fig. 3, Curve b). Unlike K^+ *p*-Chloranil$^-$, the solid-state spectrum of this salt shows a high-energy band at 26.5 kK and a shoulder beyond 30 kK. The charge-transfer band is located at 11.6 kK. Although this value is coincident with that of K^+ *p*-Chloranil$^-$, the charge-transfer band for Na^+ *p*-Chloranil$^-$ was found to be very much intensified. In accordance with this view, the high-energy band at 23.3 kK for K^+ *p*-Chloranil$^-$ is shifted to the band at 26.5 kK for Na^+ *p*-Chloranil$^-$, which is, therefore, assigned to the shifted band of the $^2B_{3g} \rightarrow {}^2B_{1u}$ transition for the anion-radical monomer. The π-π transitions of the monomer will be perturbed in the field of the other anion-radicals when the anion-radicals come close enough together for the π orbitals to overlap.

K^+ *p*-$QBr_2Cl_2^-$ (Fig. 4, Curve a). Obviously, in spite of weak low-energy absorptions at 11.5 kK and at 17.4 kK, the solid-state spectrum of this salt is almost identical with that of the anion-radical monomer in an acetone solution. The strong band at 23.3 kK of the solid-state spectrum corresponds well to the $^2B_g \rightarrow {}^2A_u$ transition at 22.1 kK of the monomer spectrum. The shoulder around 30 kK of the solid salt corresponds to the place where the band at 30.2 kK appears in the monomer spectrum. The intensity of the charge-transfer band of this salt located at 11.5 kK is very much decreased in comparison with that at 11.8 kK of K^+ *p*-Chloranil$^-$. The origin of the other weak absorption, at 17.4 kK, of K^+ *p*-$QBr_2Cl_2^-$ remains in question. From the above-mentioned results, the anion-radicals in this salt appear to interact more weakly than those in K^+ *p*-Chloranil$^-$. It seems that the *p*-QBr_2Cl_2 anion-radicals exist almost as monomers in the solid state.

Na^+ *p*-$QBr_2Cl_2^-$ (Fig. 4, Curve b). Unlike K^+ *p*-$QBr_2Cl_2^-$, this salt shows strong absorptions at 12.2 kK and at 26.3 kK, and a slight shoulder around 22 kK. These features seem to be similar to those of Na^+ *p*-Chloranil$^-$. Figure 4 shows that the intensity of the charge-transfer band for Na^+ *p*-$QBr_2Cl_2^-$ is very much increased compared

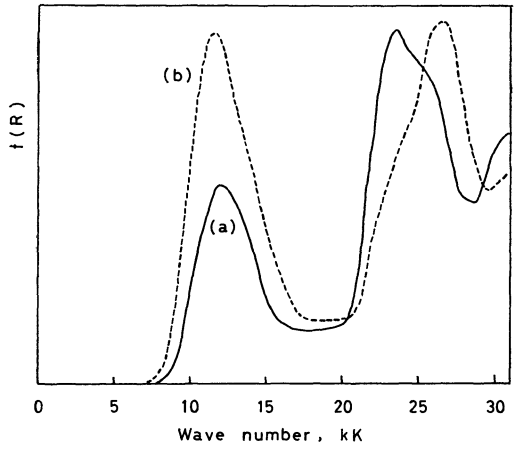

Fig. 3. The solid-state spectra of (a) K^+ *p*-Chloranil$^-$ and (b) Na^+ *p*-Chloranil$^-$.

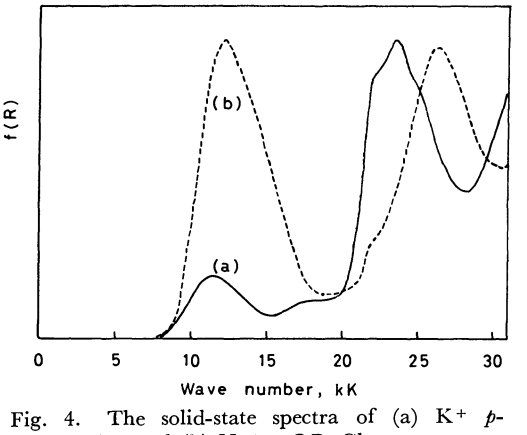

Fig. 4. The solid-state spectra of (a) K^+ *p*-$QBr_2Cl_2^-$ and (b) Na^+ *p*-$QBr_2Cl_2^-$.

to that for K^+ p-$QBr_2Cl_2^-$. In accordance with this view, the band at 23.3 kK due to the $^2B_g \rightarrow {}^2A_u$ transition for K^+ p-$QBr_2Cl_2^-$ is appreciably shifted to 26.3 kK for Na^+ p-$QBr_2Cl_2^-$. Judging from these results, the situation of the solid state of this salt seems to be very analogous to that of Na^+ p-Chloranil$^-$.

K^+ p-Bromanil$^-$ (Fig. 5, Curve a). The solid-state spectrum of this salt shows weak low-energy bands at 10.9 kK and at 17.5 kK, and a strong high-energy band at 23.0 kK. The locations of the band peaks for this salt coincide with those of K^+ p-$QBr_2Cl_2^-$. The high-energy band at 23.0 kK corresponds well with the band due to the $^2B_{3g} \rightarrow {}^2B_{1u}$ transition at 22.2 kK for the p-bromanil anion-radical monomer. The intensity of the low-energy band is as weak as that of K^+ p-$QBr_2Cl_2^-$. These spectroscopic features clearly indicate that the situations in these two substances are very much alike.

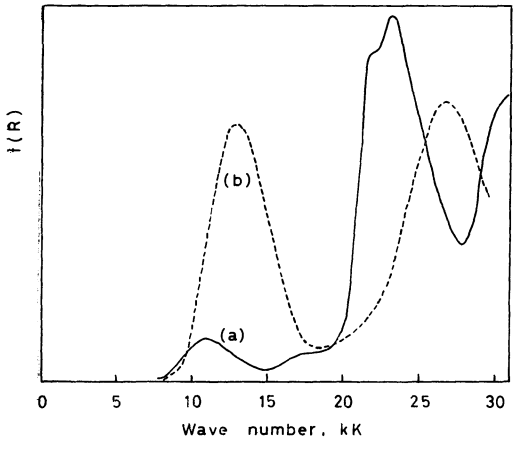

Fig. 5. The solid-state spectra of (a) K^+ p-Bromanil$^-$ and (b) Na^+ p-Bromanil$^-$.

Na^+ p-Bromanil$^-$ (Fig. 5, Curve b). Unlike K^+ p-Bromanil$^-$, this salt shows a solid-state spectrum comprising a strong band at 13.0 kK and a strong high-energy band at 26.8 kK. It is interesting to see that these spectral differences between Na^+ p-Bromanil$^-$ and K^+ p-Bromanil$^-$ are very analogous to those between Na^+ p-$QBr_2Cl_2^-$ and K^+ p-$QBr_2Cl_2^-$. Therefore, the mode of the charge-transfer interaction in Na^+ p-Bromanil$^-$ seems to be very similar to that in Na^+ p-$QBr_2Cl_2^-$.

Discussion

The experimental results of the solid-state spectra clearly indicate that these anion-radical salts can be classified into the following three groups (this classification is based on the mode of the charge-transfer interaction between the anion-radical molecules):

(I) K^+ p-$QBr_2Cl_2^-$ and K^+ p-Bromanil$^-$ belong to this group, in which the solid-state spectra are almost identical with the spectrum of the anion-radical monomer. This means that the anion-radical molecules exist as monomers in the solid state. Hence, the magnetic properties of these salts may be expected to exhibit nearly the behaviour due to free-spin paramagnetism. In this case, the temperature variation of the paramagnetic susceptibility may be approximated by the Curie law.

(II) Na^+ p-Chloranil$^-$, Na^+ p-$QBr_2Cl_2^-$, and Na^+ p-Bromanil$^-$ belong to this group. In these cases, the intensity of the low-energy charge-transfer band is remarkably strong, and the high-energy band, originating from the monomer band, is blue-shifted. A strong charge-transfer interaction between the anion-radicals is expected to cause such behaviour. Therefore, the intermolecular overlap between the molecular orbitals of the anion-radicals is quite large in the crystal of these salts. For this reason, the anion-radicals seem to be stacked in the solid salts one flat upon another to form parallel chains. On the other hand, such a crystal system is considered to be a linear-chain antiferromagnet, since the charge-transfer interaction leads to a considerable stabilization of the state where the spins are antiparallel.[2-4] It can, therefore, be expected that the salts in this group may be diamagnetic or, at most, weakly paramagnetic at room temperature.

(III) Only K^+ p-Chloranil$^-$ belongs to this group. The spectrum of this salt shows a low-energy charge-transfer band. However, the high-energy band is similar to the monomer band. Therefore, the charge-transfer interaction for this group is intermediate between those for the (I) and (II) groups. Such an intermediate case may be observed only when the temperature of the measurement is comparable with the interaction. McConnell and Lynden-Bell have discussed the electronic structures for such systems composed of the linear chains of $S=1/2$ ion-radical molecules.[10] According to their discussion, at temperatures which are large compared to the exchange interaction, the spin of any one individual radical interacts equally strongly with two others, while at temperatures comparable to or less than the exchange interaction the linear chains are unstable with respect to the distortions that produce an alternation in the distances between the interacting units. At this time, since this effect is cooperative, a sharp decrease in the magnetic susceptibility may be expected. In accordance with this view, Andre *et al.* have found a sharp decrease in the paramagnetic susceptibility for K^+ p-Chloranil$^-$ around 250°K when the temperature is

10) H. M. McConnell and R. Lynden-Bell, *J. Chem. Phys.*, **36**, 2393 (1962).

lowered.[11] We consider that this "magnetic" anomaly may be attributed to the phase-transition that has been discussed by McConnell and Lynden-Bell.*3

Summarizing the above-mentioned results, we have to note that the charge-transfer interaction in these anion-radical salts is largely affected not only by the kinds of the halogen substituents in the anion-radical molecules, but also by the species of the counter cations. In the case of the potassium cation, the interaction of the salt is markedly decreased compared to that of the sodium salt. In this respect, the crystal structure of the potassium salt is expected to be quite different from that of the sodium salt. This difference may be related to the difference in the ion radii between these two cations. It is obvious that the charge-transfer interaction is decreased when the substituted chlorine for the anion-radical molecule is replaced by bromine.

In conclusion, the existence of charge-transfer interaction between ion-radical molecules is not limited to Würster cation-radical salts or TCNQ anion-radical salts, but is regarded as of the nature of ion (cation and anion) radical salts in general.

BULLETIN OF THE CHEMICAL SOCEITY OF JAPAN VOL. 43 2776—2785 (1970)

Molecular Structure and the Effect of Large-Amplitude Vibration of Carbon Suboxide as Studied by Gas Electron Diffraction

Mitsutoshi TANIMOTO,*1 Kozo KUCHITSU and Yonezo MORINO*1

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 4, 1970)

The molecular structure of carbon suboxide, C_3O_2, has been studied by the sector-microphotometer method of gas electron diffraction. The C=O and C=C distances (r_g) have been determined to be $1.163_2 \pm 0.001_3$ Å and $1.289_4 \pm 0.002_2$ Å, respectively, where the uncertainties represent estimated limits of error. The observed mean amplitudes for three nonbonded atom pairs and their shrinkages are found to be much larger than those expected for ordinary molecules with linear framework. A usual harmonic approximation up to the quadratic terms of displacements cannot account for the observed values in this molecule. This indicates that the π_u bending vibration ν_7 has a very low frequency (an *effective* frequency being about 68 cm^{-1}) and that this vibration is essentially a bending motion of the valence angle of the central carbon atom, in agreement with recent spectroscopic studies. The effect of the large-amplitude vibration on mean amplitudes and shrinkages has been studied in detail by using a model, which assumes that atomic motions take curvilinear paths in the ν_7 vibration with the valley in the potential surface running along the loci of fixed bond lengths. The potential function for this bending motion has been estimated by a least-squares analysis on the observed structural parameters. The potential function is given by $V(Q_7) = (23 \pm 5)Q_7^4 - (100 \pm 31)Q_7^2$ (cm^{-1}), where the uncertainties representing random standard errors take the upper and lower signs in the same order and $Q_7 = \sin\alpha/0.145$ ($amu^{1/2}$ Å). The potential rises steeply with increasing angle of bending, $\alpha = 1/2[180° - \angle(C=C=C)]$, and appears to have a small hump at $\alpha = 0$. This "quasi-linear" potential function is consistent with the recent experimental estimates by Seip *et al.* within experimental errors, but the double-minimum nature of the potential is subject to a further critical examination by other experimental methods.

Carbon suboxide has presented a number of problems with regard to its structure and spectra. From a naive valence consideration, this molecule should have a linear equilibrium structure. However, no definite conclusion about its structure has been drawn in spite of various spectroscopic in-

*1 Present address: Sagami Chemical Research Center, 3100 Ohnuma, Sagamihara, Kanagawa.

vestigations.[1-5] The infrared and Raman spectra of this molecule were so complex that they were once regarded as evidence for a nonlinear structure.[1-3] Lafferty *et al.*[5] reported that their high-resolution vibration-rotation spectrum in the 3170 cm^{-1} region could be assigned satisfactorily as a linear symmetric structure. Their analysis also indicated that the lowest bending fundamental mode was very low, probably between 25—70 cm^{-1}. This was consistent with the entropy measurements by McDougall and Kilpatrick;[6] they estimated ν_7 to be 61.6 ± 2.6 cm^{-1} on the assumption of a rigid rotor and harmonic vibrations. The first successful detection of ν_7 was reported in 1965 by Miller *et al.*,[7] who observed a very weak and broad absorption band with a maximum around 63 ± 2 cm^{-1}.

The finding of the ν_7 band, however, by no means answered all the problems in the infrared spectrum of carbon suboxide. In order to explain a number of anomalous features in the spectra, Pitzer and Strickler[8] and later Miller *et al.*[7] suggested that this CCC bending vibration may be highly anharmonic like the low-frequency bending mode in diazomethane. On the other hand, Bell *et al.*[9] claimed that the anharmonicity constant x_{77} must be small, although the interaction with other fundamental vibrations may be large. With regard to the details of the CCC bending potential function, controversial remarks have been made. Redington[10] fitted a two-term potential function for this bending motion to the spectra observed by Miller *et al.*[4,7] using the theory of Thorson and Nakagawa[11] and suggested that the potential was relatively flat-bottomed, being characteritic of a quasi-linear molecule. Almenningen *et al.*[12] favored a potential with a barrier at a linear structure on the basis of their analysis of electron-diffraction data.

The interatomic distances in carbon suboxide were determined by the Norwegian group by electron diffraction at three different temperatures (237°K, 290°K, 508°K).[12] Their results at room temperature were $r(C=C)=1.2898\pm0.0036$ Å and $r(C=O)=1.1655\pm0.0021$ Å, which are consistent with the earlier results of Livingston and Rao,[13] and of Mackle and Sutton,[14] both by the visual method. These earlier results were used by Lafferty *et al.*[5] to prefer one of their assignments on the π-π transitions in a vibration-rotation band.

The presence of a low-frequency vibration should have a significant influence on some of the structural parameters observed by gas electron diffraction. The study of such anomalous vibrational effects by a diffraction method should supply useful information, which is hard to obtain by other methods, on the potential function. Accordingly, the present study aims to make a precise analysis of the mean amplitudes and shrinkages so as to shed light on this problem.

Experimental

The sample of carbon suboxide was prepared by the dehydration of malonic acid in vacuum[15] using glass tubes and stopcocks with KEL-F stopcock grease. Twenty grams of malonic acid, 200 g of fresh powdered phosphorus pentoxide and 40 g of roasted sand were mixed in a 1*l* flask, which was attached to a vacuum system with a sample holder and a U-tube of 20 mm diameter. Towers packed with glass-wool and with calcium oxide were inserted between the U-tube and the sample holder. The flask was heated for two hours on an oil-bath at 140 to 150°C under about 10^{-2} mmHg, and volatile products (carbon suboxide, carbon dioxide, and acetic acid) were condensed in a U-tube cooled to liquid-nitrogen temperature. The U-tube was then put in a dry ice-acetone bath, and the gaseous mixture of carbon dioxide and carbon suboxide was allowed to pass into a sample holder cooled at liquid-nitrogen temperature. Carbon dioxide was then distilled off at dry ice-acetone temperature until the vapor pressure decreased to about 6 mmHg, the pressure of carbon suboxide measured by Stock and Stolzenberg.[15] A gas-chromatographic analysis of the product showed that the sample was more than 99% pure. It was possible to store the sample at liquid-nitrogen temperature for over a month without decomposition.

Diffraction photographs were taken on Fuji Process Hard plates at 20°C with an apparatus equipped with an r^3-sector.[16] The sample stored in a 2*l* flask with a pressure of about 40 mmHg at 20°C was introduced into the diffraction chamber through a nozzle of 0.2 mm diamter. The camera lengths used were measured

to be 107.78±0.02 mm and 243.22±0.02 mm. The beam current was about 0.16 μA. The exposure times were about 1 and 3 minutes for the longer and shorter camera lengths, respectively. The accelerating voltage was stabilized within 0.1% during the experiment and was measured by the method of Rymer and Wright[17] to be about 39.4 kV. The wavelength of the electron beam was calibrated to within 0.07% with reference to the r_a(C=O) bond length of carbon dioxide, 1.1646 Å.

The photographic densities were measured using an integrating digital voltmeter along the diameter of the diffraction pattern at integral q values.[18] Several readings on both sides for 4 sec each were averaged. The optical densities were regulated below 0.6, where a linear relation for the conversion of optical density into electron intensity is applicable. The electron intensity was divided by a theoretical background function in order to make the background nearly flat. A slight uniform fogging observed in the region of larger scattering angles was ascribed to the reflection of scattered electrons by the sector race[16] and was subtracted from the observed total intensity.*2 No significant systematic deviations were observed among the intensities taken from different photographic plates nor from different camera lengths.

Analysis

The molecular intensity curve was obtained by drawing a smooth background through the intensity curve corrected for the imperfection in the sector opening and for the effect of non-nuclear scattering.[19] The background was revised with the aid of Karles' criterion of minimum ghosts in the radial distribution curve.[20] The atomic scattering factors, F, of carbon and oxygen were calculated from the Hartree-Fock potential expressed analytically by Strand and Bonham.[21] The inelastic scattering factors, S, and the phase shift, $\Delta\eta_{CO}=\eta_C-\eta_O$, were taken from the tables of Pohler and Hanson[22] and those of Ukaji and Bonham,[23] respectively.

The molecular parameters were determined by a least-squares fit of the observed molecular intensity (Fig. 1) to the following theoretical expression with a preestimated weight function:[24]

$$qM(q) = k\sum_{i\neq j} A_{ij}\mu_{ij}\cos\Delta\eta_{ij}\sin\frac{\pi}{10}q \times\left[r_{aij}-\left(\frac{\pi}{10}q\right)^2\kappa_{ij}\right]\exp\left[-\frac{1}{2}\left(\frac{\pi}{10}ql_{ij}\right)^2\right], \quad (1)$$

where the symbols have their usual significance. The parameters representing asymmetry, κ, for the bonded C=O and C=C atom pairs were fixed in the analysis to the values estimated by assuming the Morse potential functions.[25] The anharmonicity parameters, a_3, were assumed to be 2.39 $Å^{-1}$ and 2.13 $Å^{-1}$, respectively.[26] The κ parameters for all the nonbonded pairs were ignored. Despite the presence of a low-frequency bending vibration, the present assumption for the O_1–C_4

and O_1–O_5 pairs is justified by the approximate symmetry of their radial distribution peaks (Fig. 2), which are found to fit to Gaussian functions within experimental error. It is hard to make analogous tests for the C_2–C_4 and C_3–O_1 distributions, since they overlap each other. Nevertheless, their κ parameters are possibly within the range of $\pm 10^{-6}$ Å[3,25] and hence, the systematic errors in their distances and shrinkages due to the neglect of their κ are certainly within their quoted uncertainties.

Six atomic distances r_a, six mean amplitudes l, and the index of resolution k were determined in the analysis as variable parameters. The most probable values of the parameters with their limits of error are given in Tables 1 and 2.*3 The mean value of an internuclear distance averaged over the probability distribution function, $\langle r \rangle$ or r_g, is related to r_a as[25] $r_g = r_a + l^2/r_a$. The shrinkages, δ_g,[27] for nonbonded atom pairs are given in Table 3. The observed mean amplitudes and the shrinkages for the C_2–C_4, O_1–C_4, and O_1–O_5 atom pairs are much larger than for the other atom pairs, as expected from the low frequency of the ν_7 vibration. This effect is discussed in detail in the following section.

Table 1. Observed values of bond lengths in carbon suboxide at room temperature (in Å units)

	r_a	r_g	ε[a]
$O_1=C_2$	1.162_0	1.163_2	0.001_3

Vibrational Effects

Conventional Calculations. *Mean Amplitudes.* If a linear equilibrium structure and small amplitudes of bending vibrations are presupposed for this molecule, the mean-square amplitudes for bonded and nonbonded atom pairs are related in the first approximation to the stretching vibrations only, namely Q_1 through Q_4. Provided the force constants representing the interactions between non-adjacent bonds are ignored and the normal frequencies are approximated by the fundamental frequencies, the force constants for the stretching vibrations can be determined uniquely, and the mean amplitudes can be calculated by a conventional method.[28] Table 2 lists the values derived in this way; they agree with those calculated by Brunvoll *et al.*[29] In striking contrast to the ex-

28) Y. Morino, K. Kuchitsu and T. Shimanouchi, *ibid.*, **20**, 726 (1952).

29) J. Brunvoll, S. J. Cyvin, I. Elvebredd and G. Hagen, *Chem. Phys. Lett.*, **1**, 566 (1968).

perience for ordinary molecules, where the present approximation is known to be valid,[30] the calculated values for the atom pairs C_2–C_4, O_1–C_4, and O_1–O_5 cannot account for the observed values. This implies that a higher-order effect due to the bending vibrations is important for the above-mentioned atom pairs.

Shrinkage Effects. The linear shrinkage effect is given by:[27]

$$\delta_g = \boldsymbol{D}[r_g], \tag{2}$$

where $\boldsymbol{D}$ stands for the operation of taking a difference of the quantity in brackets for a nonbonded atom pair and a sum of those for the component bonded pairs. If one assumes that the vibrations are *harmonic*, then the shrinkage may be approximated by the following expression:[27]

$$\delta_g = \boldsymbol{D}[(1/2r_e)\langle\Delta\rho^2\rangle], \tag{3}$$

where r_e is the corresponding bonded or nonbonded equilibrium distances and $\Delta\rho^2=\Delta x^2+\Delta y^2$ is linearly related to the squares of bending coordinates, Q_5^2, Q_6^2 and Q_7^2. The perpendicular amplitudes $\Delta\rho^2$ were calculated by the usual *GF* method,[31] with the quadratic force constant for the CCO bending transferred from the out-of-plane CCO bending constant of ketene.[32] Since the calculated shrinkages are insensitive to the differences of several wave numbers in ν_5 and ν_6, the observed fundamental frequencies ν_5 and ν_6 were used in place of the normal frequencies ω_5 and ω_6, respectively. On the other hand, the position of the maximum absorption (63 cm^{-1})[7] was tentatively substituted for the effective ω_7 frequency in order to estimate the shrinkages. Table 3 shows that the above harmonic approximation roughly accounts for the observed shrinkages.

The above conventional procedure thus fails to predict the observed mean amplitudes, although the agreement is fair for the shrinkages. The principal origin of the discrepancies in the mean amplitudes lies in the ν_7 bending vibration; the instantaneous displacements of certain nonbonded distances caused by this vibration should be much larger than those caused by the parallel vibrations ν_1 through ν_4 as a result of the large amplitude of the ν_7 vibration.

If the average values of the mass-adjusted bending coordinate ($\langle Q_7^2\rangle$ and $\langle Q_7^4\rangle$) and the ratio of the perpendicular amplitudes, $\Delta\rho_{CC}/\Delta\rho_{CO}$, are taken as parameters, one can analyze the observed mean amplitudes and shrinkages without assuming any explicit form of the potential function for the ν_7 vibration. According to a preliminary analysis of this kind,[33] the average value $\langle Q_7^2\rangle$ turns out to be about 3.0 amu Å^2, which corresponds to an effective normal frequency of *ca.* 68 cm^{-1}, being compatible with the thermodynamic and infrared results. Furthermore, the ratio $\langle Q_7^4\rangle/\langle Q_7^2\rangle^2$, which should be equal to 2 if the potential were harmonic,[*4] is estimated to be about 1.36. Thus the problem is to find a potential function that satisfies the above average values.

Large-amplitude Analysis for the ν_7 Vibration. *Hamiltonian Operator.* For ordinary triatomic molecules the potential function is expanded in terms of the normal coordinates, and the average values of interatomic displacements are calculated by a perturbation method.[34,35] However, this method is not suitable for the present problem because the large vibrational amplitude deteriorates the convergence. Thus it is simpler to use a curvilinear coordinates for this vibration at the expense of a more complicated expression for the kinetic energy. The mean amplitudes and shrinkages were calculated by the following model: The ν_7 mode is regarded as a set of doubly-degenerate slowly-varying coordinates, since this vibration has much lower frequency than the other vibrations. The atoms take curvilinear paths holding the bond distances (averaged over the vibrations ν_1 through ν_6) constant. This is equivalent to assuming that the effective force field characterizing the small-amplitude vibrations (ν_1 through ν_6) is independent of the ν_7 displacement.

Being analogous to the case of puckering motions in ring compounds[36] and that of quasi-linear molecules,[11] the reduced mass for this vibration depends on the ν_7 displacement coordinate. This was taken into account when the kinetic energy was set up in classical dynamics and converted into an operator representing the quantum-mechanical kinetic energy.

After the separation of translational motions, the ν_7 motion is described by a molecule-fixed coordinate system xyz, where the z axis corresponds to the equilibrium molecular axis, and the bending motion takes place in the xz plane, because the coupling between the ν_7 vibration and other bending modes has been ignored.

According to the above assumptions the in-

stantaneous coordinates of the atoms, $x(=\rho)$ and z, are given to a good approximation in terms of a mass-adjusted bending coordinate Q_7.

$$\left.\begin{array}{ll} O_1\ (d_1Q_7,\ -D_{12}-D_{23}) & C_2\ (d_2Q_7,\ -D_{23}) \\ C_3\ (d_3Q_7,\ 0) & C_4\ (d_2Q_7,\ D_{23}) \\ O_5\ (d_1Q_7,\ D_{12}+D_{23}) & \end{array}\right\} \quad (4)$$

where the constants d_i are equal to the $(i, 7)$ elements of the L_x matrix, usually defined for infinitesimal displacements around the linear position, and D_{ij} is defined as

$$D_{ij} = [r_{ij}^2 - (d_i - d_j)^2Q_7^2]^{1/2}. \quad (5)$$

The constants r_{12} and r_{23} represent the C=O and C=C distances, respectively, averaged over the normal modes ν_1–ν_6. Equation (4) shows that the ratio of the relative displacements of the C=C and C=O bonds in the direction of the ρ axis, $\Delta\rho_{CC}/\Delta\rho_{CO}$, assumes a constant value for the ν_7 vibration.

The kinetic energy for this motion is given by

$$2T = \sum m_i\boldsymbol{v}_i^2 + \sum m_i(\omega\times\boldsymbol{r}_i)^2 + 2\omega\cdot\sum m_i(\boldsymbol{r}_i\times\boldsymbol{v}_i), \quad (6)$$

where $\boldsymbol{v}_i$ and ω are the velocity of the atom i and the angular momentum of the molecule-fixed frame, respectively. Substitution of the coordinates $\boldsymbol{r}_i$ in Eq. (4) and their derivatives into (6) leads to

$$2T = M_7\dot{Q}_7^2 + I_{xx}\omega_x^2 + I_{yy}\omega_y^2 + I_{zz}\omega_z^2, \quad (7)$$

where M_7 is the reduced mass for the ν_7 vibration and I_{xx}, I_{yy} and I_{zz} are instantaneous moments of inertia. They are expressed in terms of Q_7 in the following way

$$\left.\begin{array}{l} M_7 = 1 + [2m_O\{(d_1-d_2)^2/D_{12} + (d_2-d_3)^2/D_{23}\}^2 + 2m_C(d_2-d_3)^4/D_{23}^2]Q_7^2 \\ I_{xx} = 2[m_O(D_{12}+D_{23})^2 + m_CD_{23}^2] \\ I_{yy} = 2[m_O(D_{12}+D_{23})^2 + m_CD_{23}^2] + Q_7^2 \end{array}\right\} \quad (8)$$

and

$$I_{zz} = Q_7^2.$$

In terms of the momenta P_m the kinetic energy takes the following form,

$$2T = \sum G^{mn}P_mP_n \qquad (P_m = P_x, P_y, P_z, P_7) \quad (9)$$

The coefficient G^{mn} is given by a diagonal matrix with elements I_{xx}^{-1}, I_{yy}^{-1}, I_{zz}^{-1} and M_7^{-1}.

The corresponding quantum-mechanical operator is given by the relation[37]

$$2T'_{QM} = G^{1/2}\sum P_mG^{mn}G^{-1/2}P_n, \quad (10)$$

where G is the determinant of G^{mn} and the wavefunction is normalized in the Cartesian coordinate system as in the case of a degenerate bending motion in a linear triatomic molecule.[38] Since the reduced mass depends on Q_7, the density factor defined in Ref. 37 contains contributions from higher powers of Q_7, whereas the resulting differential equation is equal to that for a two-fold degenerate vibration[39] as far as the zeroth-order terms are concerned.

In order to make the density factor proportional to Q_7, the following substitution is made

$$G^{-1/2} = I_0Q_7g^{-1/2}, \quad (11)$$

where I_0 is the moment of inertia about the x-axis in the equilibrium structure and

$$g^{-1/2} = 1 + FQ_7^2 \quad (12)$$

where the coefficient F is a function of the constants A, B, and C given in Appendix 1. When the factor $g^{-1/2}$ is taken into the kinetic energy operator, the resulting operator is given by

$$\left.\begin{array}{l} T_{QM} = g^{-1/4}T'_{QM}g^{1/4} \\ \quad = \dfrac{1}{2}g^{-1/4}G^{1/2}\sum P_mG^{mn}G^{-1/2}P_ng^{1/4} \\ \quad = T_{rot} + T_{vib}, \end{array}\right\} \quad (13)$$

where the rotational energy is

$$2T_{rot} = P_x^2/I_{xx} + P_y^2/I_{yy}. \quad (14)$$

The vibrational part

$$2T_{vib} = P_7^2 - \frac{i\hbar P_7}{Q_7} + \frac{P_z^2}{I_{zz}} + 6i\hbar AQ_7P_7 - 2AQ_7^2P_7^2 - F(8A-3F)\hbar^2Q_7^2 + F^2(2A+F)\hbar^2Q_7^4 \quad (15)$$

can be expanded in terms of a dimensionless coordinate $q_7=(2\pi c\nu/\hbar)^{1/2}Q_7$, where a constant ν, which has a dimension of frequency, can be chosen arbitrarily since it does not appear in the result of the analysis. Thus $2T_{vib}$ is divided into two parts,

$$2T_{vib} = 2T^0_{vib} + 2T'_{vib}, \quad (16)$$

where

$$2T^0_{vib} = -hc\nu\left[\frac{\partial^2}{\partial q_7^2} + \frac{1}{q_7}\frac{\partial}{\partial q_7} + \frac{1}{q_7^2}\frac{\partial^2}{\partial\chi^2}\right]$$

and

$$2T'_{vib} = 6\hbar^2Aq_7\frac{\partial}{\partial q_7} + 2\hbar^2Aq_7^2\frac{\partial^2}{\partial q_7^2} - F(8A-3F)\hbar^3q_7^2/2\pi c\nu + F^2(2A+F)\hbar^4q_7^4/(2\pi c\nu)^2$$

The operator T^0_{vib} leads to a differential equation for a two-fold degenerate vibration, where χ represents the angular coordinate. Following the treatment of puckering motions in a number of ring compounds,[40] the potential function is assumed to have the following form

$$V(Q_7) = aQ_7^4 + bQ_7^2 \quad (17)$$

Thermal Average Values of Normal Coordinates. With the approximate Hamiltonian operator obtained above, the thermal average values of even powers of the normal coordinate q_7 can be calculated in a straightforward way. The Hamiltonian matrix is set up with the orthonormal set of functions which diagonalize the Hamiltonian for the two-dimensional harmonic oscillator, and the matrix is diagonalized by Jacobi's method.*5 The anharmonic mean values of q_7 are calculated by a weighted sum,

$$\langle q_7^{2m}\rangle = \sum_{n,l}\langle n,l|q_7^{2m}|n,l\rangle \times \exp(-E_{n,l}/\boldsymbol{k}T)/\sum_{n,l}\exp(-E_{n,l}/\boldsymbol{k}T) \quad (18)$$

where $\langle n,l|q_7^{2m}|n,l\rangle$ denotes the expectation values for a transformed function numbered with n and l.

The harmonic mean values for q_1 through q_6 are calculated by[28]

$$\left.\begin{aligned}\langle q_i^{2m}\rangle &= \frac{(2m)!}{4m!}\left(\coth\frac{\boldsymbol{hc}\omega_i}{2\boldsymbol{k}T}\right)^m \quad (i=1-4)\\ \text{and}\\ \langle q_i^{2m}\rangle &= m!\left(\coth\frac{\boldsymbol{hc}\omega_i}{2\boldsymbol{k}T}\right)^m \quad (i=5,6)\end{aligned}\right\} \quad (19)$$

Mean Amplitudes and Shrinkage Effects. An instantaneous distance of an atom pair is expressed in terms of its Cartesian displacements up to the sixth power as

$$r = r_e + \Delta z + \frac{\Delta\rho^2}{2r_e} - \frac{\Delta z\Delta\rho^2}{2r_e^2} + \frac{\Delta z^2\Delta\rho^2}{2r_e^3} - \frac{\Delta\rho^4}{8r_e^3} - \frac{\Delta\rho^2\Delta z^3}{2r_e^4} + \frac{3\Delta z\Delta\rho^4}{8r_e^4} - \frac{\Delta\rho^6}{16r_e^5} - \frac{3\Delta\rho^4\Delta z^2}{4r_e^5} + \frac{\Delta\rho^2\Delta z^4}{2r_e^5} \quad (20)$$

The parallel displacement, Δz, may essentially be divided into two parts, $\Delta z_{\mathrm{I}}+\Delta z_{\mathrm{II}}$, where the first and second terms represent the changes in the projected bond length due to stretching and bending vibrations, respectively.[26] The Δz_{I} term may be expanded in terms of q_1 through q_4, while the Δz_{II} term may be expanded in terms of the perpendicular amplitudes $\Delta\rho$; by assumption the average values of the bond lengths are unchanged in the bending vibrations, so that the constraint, $\langle r\rangle = r_g$, exists for the bending vibrations. It therefore follows that

$$\Delta z_{\mathrm{II}} = (r_g^2 - \Delta\rho^2)^{1/2} - r_g = -\frac{\Delta\rho^2}{2r_g} - \frac{\Delta\rho^4}{8r_g^3} - \frac{\Delta\rho^6}{16r_g^5} + \cdots \quad (21)$$

for bonded atom pairs, and

$$\Delta z_{\mathrm{II}}(ij) = \Delta z_{\mathrm{II}}(ik) + \Delta z_{\mathrm{II}}(kl) + \cdots + \Delta z_{\mathrm{II}}(nj) \quad (22)$$

for nonbonded atom pairs i-k-$l\cdots j$. Thus, it is possible to express an instantaneous distance in terms of q_1 through q_7, and its thermal average value can be calculated by Eqs. (18) and (19).

The mean amplitudes l_g^2 may be calculated by the relation:[25]

$$l_g^2 = \langle r^2\rangle - \langle r\rangle^2 \quad (23)$$

and the shrinkages, δ_g, are calculated by the use of Eqs. (2) and (20).

Least-squares Analysis on Mean Amplitudes and Shrinkages. Two parameters a and b in the potential function, Eq. (17), and the ratio $\Delta\rho_{\mathrm{CC}}/\Delta\rho_{\mathrm{CO}}$, by which the shape of the ν_7 mode is specified, were used to adjust the calculated values of mean amplitudes and shrinkages. A least-squares method was applied with statistical weights estimated from the errors of their observed values. The HITAC 5020E in the Computer Centre of the University of Tokyo was used for this analysis. Thermal averages of the q_7 coordinate were calculated by solving a matrix of 30×30. The parameters a, b, and $\Delta\rho_{\mathrm{CC}}/\Delta\rho_{\mathrm{CO}}$ were refined until the deviations of the calculated values for the mean amplitudes and shrinkages were in the limits of their experimental errors. The final values of the determined parameters are listed in Table 4 with their estimated standard errors[41] and the parameters representing the vibrational coordinate.*6 The mean amplitudes and shrinkages calculated from the parameters are listed in the last columns of Tables 2 and 3, respectively. The $\Delta\rho$ ratio is estimated to be 1.30 ± 0.10. If the C=O and C=C bonds stay colinear in the ν_7 mode, the ratio should be equal to $r_{23}/r_{12}=1.10$. Thus the CCO angle does not deviate far from 180° in the ν_7 mode. The half bending angle,[19] $\alpha=1/2[180°-\angle(\mathrm{C{=}C{=}C})]$, is related to Q_7 as $\sin\alpha=\Delta\rho_{\mathrm{CC}}/r_{\mathrm{CC}}=0.145\ Q_7$.

*5 Perturbing terms involved in T'_{vib} do not mix states with different values of l, and hence, a separate matrix can be set up for each l value. Since v and l have the same parity, the rows and columns of a matrix for a given l are labeled by a series of either even or odd v numbers according to whether the l is even or odd.

41) Y. Morino and T. Nakagawa, *J. Mol. Spectry.*, **26**, 496 (1968).

*6 In our preliminary analysis, where the perturbing terms in the kinetic energy operator, T'_{vib}, were ignored and a first-order perturbation method was used, the potential function was estimated to be $V=1.35Q_7^4+43.6Q_7^2$ (cm^{-1}). This potential function was cited by Pickett and Strauss[42] in their calculation of the statistical entropy (61.94 cal/deg·mol). However, a subsequent, more rigorous procedure described in this article has shown that the first-order treatment is not accurate enough and the T'_{vib} terms make a significant contribution to $\langle Q_7^2\rangle$ and $\langle Q_7^4\rangle$. The values listed in Table 4 replace the above estimates. The presented study still ignores stretching-bending interactions, by which the C=O and C=C stretching force constants may change slightly with angle deformation.

TABLE 4. POTENTIAL CONSTANTS AND DYNAMICAL PARAMETERS CHARACTERIZING THE ν_7 BENDING MODE[a)]

a	b	$\Delta\rho_{CO}/\Delta\rho_{CO}$	V_0[c)]	
23 ± 5[b)] $cm^{-1}\,amu^{-2}Å^{-4}$	-100 ± 31[b)] $cm^{-1}\,amu^{-1}Å^{-2}$	1.30 ± 0.10	110 ± 47[d)] cm^{-1}	
$\langle Q_7^2\rangle$	$\langle Q_7^4\rangle$	d_1	d_2	d_3
2.98 ± 0.10[d)] $amuÅ^2$	$12.0_9\pm0.7_7$[d)] $amu^2Å^4$	-0.110[e)] $amu^{-1/2}$	0.035[e)] $amu^{-1/2}$	0.222[e)] $amu^{-1/2}$

a) Derived from a least-squares analysis on the observed mean amplitudes and shrinkages. The potential function is expressed as: $V(Q_7)=aQ_7^4+bQ_7^2$ cm^{-1}, where $\sin\alpha=0.145Q_7$.
b) Random standard errors. The upper and lower signs should be taken in the same order because of the correlation of the parameters a and b.
c) Potential hump. See Fig. 3.
d) Evaluated from the standard deviations with allowance for the correlation among the parameters (Ref. 41). The uncertainties represent standard deviations. No systematic error due to the assumption made in the analysis is included.
e) Coefficients of the atomic ρ coordinates. Eq. (4).

Discussion

Bond Length. The r_a distances for the C=O and C=C atom pairs agree with the distances reported in earlier investigations within their limits of error.[12-14] The C=O bond length (r_g=(C=O)=1.163_2 Å) is shorter than that in carbon dioxide ($r_g=1.165_1$ Å) and is nearly the same as that in ketene ($r=1.16_1$ Å).[43] The distance between adjacent carbon atoms linked with a double bond, r_g(C=C)$=1.289_4$ Å, is appreciably shorter than 1.311_6 Å in allene[44] and nearly equal to 1.283 Å of the central C=C bond in butatriene.[45] A general rule, suggested by Stoicheff *et al.*[46] for the estimation of CC bond lengths from the number of adjacent atoms, leads to 1.282 Å in this case, in good agreement with the experimental r_g value.

Potential Function. The potential function for the bending mode ν_7, calculated with the values of a and b obtained above, is illustrated in Fig. 3. The potential energy rises steeply with increasing angle of bending, and possibly a small potential hump of the order of 100 cm^{-1} exists at the linear position. The potential nimimum appears at the α angle of about 12°. The random standard errors in the parameters listed in Table 4, not including systematic errors originating from the assumptions on which the present analysis is based, result in the uncertainties indicated as vertical bars in the figure. There is little doubt as to the quasi-linearity of the potential function for the ν_7 mode in spite of the above assumptions, whereas the double-minimum nature of the function, which is obscured appreciably by random and systematic uncertainties, is subject to a further critical examination by other experimental methods.

This potential function is consistent with those reported by Almenningen *et al.*,[12] who first suggested a double-minimum potential with humps ranging from 40 to 255 cm^{-1}. The mean amplitudes and shrinkages for 237°K and 508°K, calculated from the potential function given in Table 4, are found to be consistent with their observed values within their experimental uncer-

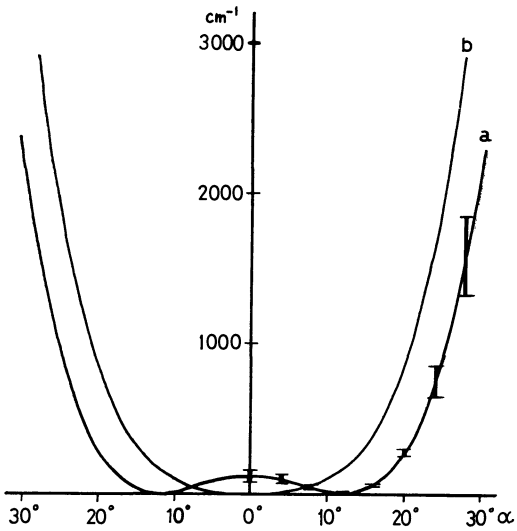

Fig. 3. Potential function for the ν_7 bending vibration in terms of the half bending angle $\alpha=(1/2)[180°-\angle(C=C=C)]$.

tainties.*7

On the other hand, Redington[10] calculated the low-lying energy levels by the WKB method and determined the force constants on the assumption that $\nu_7(n,\ l=0,1\leftarrow 0,0)=63\ cm^{-1}$ and $\nu_7\ (1,1\leftarrow 0,0)=214\ cm^{-1}$. The frequencies of these transitions have not been established, however, because the observed absorption bands are evidently composed of many hot bands ($\Delta l=1$). His potential function shown in Fig. 3, $V(\alpha)=1500\alpha^2+45000\alpha^4$ (cm^{-1}) (the half bending angle α in radians), has no hump and rises moer steeply than the potential determined in the present study.

Centrifugal Effect. A comment should be made on the recent work of Smith.[47] He suggested that the excess in the O_1–O_5 vibrational amplitude observed by Almenningen *et al.*[12] over that calculated by an ordinary method was due to an oscillatory displacement of the nuclei as a result of the centrifugal force generated by the large-amplitude bending motion. If this were the case, the effective force balancing the centrifugal stretching should correspond to the force constants for the C=C and C=O bond stretching, because the centrifugal force acts in the bond direction and is most effective near the zero bending displacement, where the atoms have the largest angular velocities. The effect of the centrifugal force on the O_1–O_5 amplitude, calculated with a set of stretching force constants, turns out to be an order of magnitude smaller than that needed to account for the observed anomaly. Thus the centrifugal force cannot be the essential source of the anomaly. It is not permissible to estimate the centrifugal effect with a much smaller force constant representing "effective stretch-bend interactions" as he assumed in his calculation, because the physical significance of the equation is then lost. As the present analysis has shown, the observed O_1–O_5, O_1–C_4 and C_2–C_4 amplitudes can be explained by a large-amplitude model for the ν_7 vibration.

Statistical Entropy. The entropy due to the ν_7 vibration has been calculated using the potential function determined in the present study. In order to take account of the anharmonicity, the partition function is calculated by a direct summation over all the vibrational levels. The statistical entropy for 230°K and 1 atm is found to be 61.87 cal/deg·mol. This compares with the experimental values,[8] 62.12 ± 0.15 and 61.37 ± 0.11 cal/deg·mol; the ambiguity arises from alternative measurements of the heat of vaporization. According to the recent calculations of Pickett and Strauss,[42] the entropy is insensitive to the various bending potentials which have been suggested to fit the electron-diffraction data.

Infrared Spectra. A series of sharp band heads were observed by Milionis[48] in a high-resolution spectrum in the far-infrared region (20 to 300 cm^{-1}). The spectrum was interpreted in terms of a linear equilibrium structure and a strongly anharmonic vibration with a large increase in the rotational constant B with increasing values of the vibrational quantum number. Since the spectrum was analyzed parametrically, the shape of the potential function for the ν_7 vibration was not determined.

The shape of the ν_7 band has been estimated by the use of the potential function given in Table 4. According to Thorson and Nakagawa,[11] who discussed the characteristic features of the infrared spectrum of a quasi-linear molecule, the band intensities for the bending mode resemble those for a linear molecule, whereas the frequencies approach those for a bent molecule. As the potential hump at the linear position, if present, is estimated to be less than the thermal energy at room temperature, levels above the hump are densely populated. Therefore, the band intensities are calculated by using the band strength S corresponding to the transition in a linear molecule. The band strength is given for a molecule with no nuclear spins by the relation[49]

$$S = K\nu_0[1 - \exp(-\boldsymbol{h}\nu_0/\boldsymbol{k}T)]\,|R|^2 G \exp(-E/\boldsymbol{k}T) \tag{24}$$

where K is a constant, E is the energy of the lower state, R is the transition moment, ν_0 is the transition frequency, and G is a weight factor dependent on the transition (1 for transitions between a $\sum$-state and any other state, and 2 for all other transitions). The transition moment was calculated by the use of perturbed wavefunctions. The intensities of a series of the transitions $\Delta l=1$, $\Delta n=0$, which are analogous to the "pure rotational spectrum" of a bent molecule, are found to be much stronger than the other transitions. The calculated band contour has its absorption maximum at about 70 cm^{-1}, in contrast to the observed peak around 63 cm^{-1}.[7,48] Both observed and calculated bands have absorption peaks well below 63 cm^{-1}, but the calculated band has much fewer absorption maxima than the observed spectrum. The reason for this discrepancy is unknown. Should the present calculation be responsible for this discrepancy, possible sources are that the n dependence of B has been ignored and that the intensities of the

*7 After the present manuscript had been submitted to this Bulletin, the authors received a preprint from Dr. H. M. Seip (A. Clark and H. M. Seip, *Chem. Phys. Lett.*, **6**, in press (1970)). Their estimate of the potential is in good agreement with that of the present study.

P and R branches have been calculated jointly with those of the Q branches using Eq. (24).

Rotational Constant. The rotational constant B_0 has been determined to be 0.073206 ± 0.00002 cm^{-1} by Lafferty *et al.*[5] from the analysis of a $\Sigma_g^+ - \Sigma_g^+$ transition around 3170 cm^{-1}. This constant should be contrasted with the molecular geometry determined in the present study. For a system having a large-amplitude vibration, no theory is available by which one can calculate the "average" rotational constant B_z from B_0*8. If one assumes that the conventional second-order theory is applicable, the B_z constant is calculated from the above B_0 to be 0.07330 cm^{-1}. On the other hand, the average rotational constant can also be estimated from the observed r_g distances provided the approximate procedure of the r_g to r_α^0 conversion[50] is permissible. The B_α^0 constant estimated in this way is 0.0738 ± 0.0002 cm^{-1}. The two constants, B_z and B_α^0, which agree with each other for most nonlinear molecules,[51] thus seem to differ significantly. The origin of this discrepancy is left for a future study.

The authors wish to thank Professors O. Bastiansen, R. C. Lord, F. A. Miller, H. M. Seip and H. L. Strauss for their helpful comments and discussions. They are also indebted to Dr. T. Itoh of the Department of Physics for his valuable advice in deriving the quantum-mechanical Hamiltonian operator.

Appendix 1

The constants F and A in Eqs. (12) and (15) are given by the following relations:

$$F = A - B - C + 1/2I_0$$

$$A = m_O[(d_1 - d_2)^2/r_{12} + (d_2 - d_3)^2/r_{23}]^2 + m_C(d_2 - d_3)^4/r_{23}^2$$

where

$$B = 2m_O(r_{12} + r_{23})(d_1 - d_2)^2/r_{12}I_0$$

$$C = 2(d_2 - d_3)^2[m_O(r_{12} + r_{23}) + m_C r_{23}]/r_{23}I_0$$

and other parameters are defined in the text.

Appendix 2

The nonvanishing matrix elements of $q\frac{d}{dq}$ and $q^2\frac{d^2}{dq^2}$ are:

$$\left(\sigma, s \left| q\frac{d}{dq} \right| \sigma + 1, s\right) = -[(\sigma + 1)(\sigma - s + 1)]^{1/2}$$

$$\left(\sigma, s \left| q\frac{d}{dq} \right| \sigma, s\right) = -1$$

$$\left(\sigma, s \left| q\frac{d}{dq} \right| \sigma - 1, s\right) = [\sigma(\sigma - s)]^{1/2}$$

$$\left(\sigma, s \left| q^2\frac{d^2}{dq^2} \right| \sigma + 2, s\right) = [(\sigma + 1)(\sigma + 2)(\sigma - s + 1)(\sigma - s + 2)]^{1/2}$$

$$\left(\sigma, s \left| q^2\frac{d^2}{dq^2} \right| \sigma + 1, s\right) = 3[(\sigma + 1)(\sigma - s + 1)]^{1/2}$$

$$\left(\sigma, s \left| q^2\frac{d^2}{dq^2} \right| \sigma, s\right) = 1 - [(\sigma - s)(2\sigma + 1) + \sigma]$$

$$\left(\sigma, s \left| q^2\frac{d^2}{dq^2} \right| \sigma - 1, s\right) = -3[\sigma(\sigma - s)]^{1/2}$$

$$\left(\sigma, s \left| q^2\frac{d^2}{dq^2} \right| \sigma - 2, s\right) = [\sigma(\sigma - 1)(\sigma - s)(\sigma - s - 1)]^{1/2}$$

Photoreduction of Phenazine in Alcohols and by EDTA in the Aqueous Solution

Teiki IWAOKA, Shigeya NIIZUMA and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received May 4, 1970)

By the combined use of the steady-light experiment and a flash technique, photoreduction of phenazine in methanol, ethanol, isopropanol and by EDTA in the aqueous solution and also the related elementary processes have been studied. The photoproduct has been identified as dihydrophenazine of which the absorption spectrum has been measured for the first time. It has been concluded that the lowest triplet, $T(\pi-\pi^*)$ is not a reactive state. Most probably the reactive state is a higher $T(n-\pi^*)$. The quantum yields of photoreduction in methanol, ethanol, and isopropanol are respectively 0.023, 0.037 and 0.050. Singlet-Triplet transition probability (Φ_{ST}) has been found to be >0.33 in the aqueous solution. Semiquinone produced in alcohols disappears by disproportionation reaction with almost the diffusion controlled rate constant while in the aqueous solution the disproportionation is much slower and at high EDTA concentrations, semiquinone is further reduced by EDTA. The absorption due to a molecular compound consisting of phenazine and dihydrophenazine has been detected in the visible region. It has been suggested that a certain equilibrium exists between three compounds and that a rather stable radical species, the existence of which has been proved by an ESR spectroscopy, participates in this equilibrium.

This paper is an extension of our photochemical investigation of acridine[1-5] and reports the general feature of the photoreduction of phenazine in alcohols and by EDTA in the aqueous solution all dearated which was elucidated by the steady light experiment and by flash photolysis.[6] At the time when we commenced this work, there was no work on the photoreduction of phenazine other than that of Toromanoff.[7] He reported that the deaerated 2-propanol solutions of phenazine (ϕ), when exposed to sunlight, yield two types of molecular compound, 3 phenazine-1 dihydrophenazine (violet) and 1 phenazine-1 dihydrophenazine (blue) but the final product obtained by the prolonged irradiation is dihydrophenazine (ϕH_2) (colourless). The interrelation of the molecular compound with the eventual photoreduction was unknown and even the electronic spectrum of dihydrophenazine was not found in literature.

A little later after we have finished the present work, a report by Bailey *et al.*[8] appeared. They studied mainly in acidic methanol and concluded that the photoproduct in weakly acidic solutions is dihydrophenazine while in strong acidic solutions the final product is a radical cation, ϕH_2^+. They also proposed that a reactive state is the excited singlet (n-π^*) state. But unambigous evidence for the formation of molecular complex was not given and the product in the weakly acidic solution, *i.e.* dihydrophenazine was not identified in any way.

We have investigated the photoreduction in pure methanol, ethanol and isopropanol and by EDTA in the aqueous solution. The results obtained agree with Bailey's in some points but not in others. This is natural partially because the experimental conditions are different. Firstly, we have demonstrated unequivocally, that the photoproduct is dihydrophenazine by comparing its absorption spectrum with that of chemically prepared dihydrophenazine. Secondly, strong evidence has been obtained for the view that a molecular complex consisting of ϕ and ϕH_2 is produced in solution in equilibrium with ϕ and

ϕH_2. A radical cation reported by Bailey *et al.* has also been detected by ESR in pure methanol but in a very small quantity. Thirdly, it has been concluded that our kinetic results cannot be consistently interpreted unless a higher $T(n\text{-}\pi^*)$ is a reactive state.

Before entering the experimental part, it will be convenient to write down the reaction scheme in alcohol (RH_2) which we would like to propose. The processes underlined are the main ones.

$$\underline{\phi \xrightarrow{h\nu} {}^1\phi^*} \quad (1)$$

$$\underline{{}^1\phi^* \longrightarrow {}^3\phi(n\text{-}\pi^*)} \quad (2)$$

$${}^3\phi(n\text{-}\pi^*) \longrightarrow {}^3\phi(\pi\text{-}\pi^*) \quad (3)$$

$$\underline{{}^3\phi(n\text{-}\pi^*) + RH_2 \longrightarrow \phi H\cdot + RH\cdot} \quad (4)$$

$${}^3\phi(n\text{-}\pi^*) + O_2 \longrightarrow \phi + O_2 \quad (5)$$

$${}^3\phi(n\text{-}\pi^*) + \phi \longrightarrow 2\phi \quad (6)$$

$${}^3\phi(\pi\text{-}\pi^*) + \phi \longrightarrow 2\phi \quad (7)$$

$${}^3\phi(\pi\text{-}\pi^*) + RH_2 \not\longrightarrow \quad (8)$$

$$\underline{2\phi H\cdot \longrightarrow \phi H_2 + \phi} \quad (9)$$

$$\phi H_2 + \phi \longrightarrow (\phi H_2 \cdots \phi) \quad (10)$$

In the case of the aqueous solution, (4) and (9) are replaced by

$${}^3\phi(n\text{-}\pi^*) + EDTA \longrightarrow \phi H\cdot + EDTA' \quad (4)$$

$$2\phi H\cdot \longrightarrow \phi H_2 + \phi \quad (9)$$

$$\phi H\cdot + EDTA \longrightarrow \phi H_2 + EDTA' \quad (9')$$

Experimental

Materials and Procedures. Phenazine rom Tokyo Kasei was purified by recrystallization from ethanol two times. Methanol, ethanol, isopropanol and tetrahydrofuran used as solvents were of Wako Junyaku and were distilled before use. Disodium ethylenediaminetetraacetate (EDTA) of Wako Junyaku G. R. grade was used without further purification. Palladium charcoal was kindly supplied by Professor Nakanishi.

An apparatus for the steady-light illumination and a flash apparatus are the ordinary ones used in our laboratory. The exciting light for the steady-light experiments was 365 nm from a Toshiba SHL-100UV mercury lamp monochromatized with suitable filters. The reaction temperature was always 25°C.

Results from the Steady-light Experiments

Photoreduction in Alcohols. Figures 1a, b, c, d give the spectral changes when the solutions of phenazine in methanol, ethanol, isopropanol and tetrahydrofuran were irradiated by 365 nm. Broadly speaking, they are similar in that the 362 nm peaks of phenazine decline monotonously with more or less shift to shorter wavelengths and with isosbestic points around 340 nm. The ultimate absorption spectra obtained by prolonged illumination are different from solvent to solvent; the peak positions are 345 nm (methanol), 358 nm (ethanol), 360 nm (isopropanol) and 320 nm (tetrahydrofuran). At first sight, these results led us to suspect that the photoproduct might not be dihydrophenazine, because dihydro compounds with the similar type of structure such as acridan in general, have no absorption in this wavelength region. Hence the hydrogenation of phenazine by two other methods were attempted. One is the reduction by treating the ethanol solution of

phenazine with amalgamated sodium *in vacuo*, and the other is the catalytic hydrogenation using palladium charcoal as a catalyst. As seen from Figs. 2a, and 2b, the absorption spectra of both products dissolved in ethanol agree with that of the photoproduct except for the lack of a slight absorption around ~280 nm. The difference may be due to the presence of aldehyde or some other photoproduct resulting from alcohol in the irradiated sample. Upon introduction of air, the chemically prepared dihydrophenazine was oxidized quantitatively to phenazine as shown in Fig. 2a, while the photoproduct gave some unknown substance in addition to phenazine, as judged from a slight shift of the absorption peak to the longer wavelength. Apart from these minor points, the agreement between the photoproduct and chemically prepared dihydrophenazine verifies that the photoproduct is dihydrophenazine and that it gives the absorption band near 340 nm. This may be due to the participation of lone pairs on nitrogen atoms in the π-electron system of the molecule.

Quantum Yields of Photoreduction in Alcohols. Figure 3 gives a typical example for photobleaching curves, which indicates that the photoreduction rate is simply proportional to the absorption of light. But in order to get the correct values of quantum yield, a certain correction should be made because the photoproduct absorbs the exciting 365 nm light to some extent. By assuming that the photoproduct merely acts as an inner filter, the following relation can easily be derived,

$$\ln(e^{2.303A}-1)-\ln(e^{2.303A_0}-1) = 2.303\Phi I_0\varepsilon\left\{t-\varepsilon' C_0\int_0^t (1/A)dt\right\}\times 10^3 \qquad (1)$$

where I_0, ε and ε' are respectively the incident light intensity (mol/cm^2 sec), molar extinction coefficients of phenazine and of the photoproduct

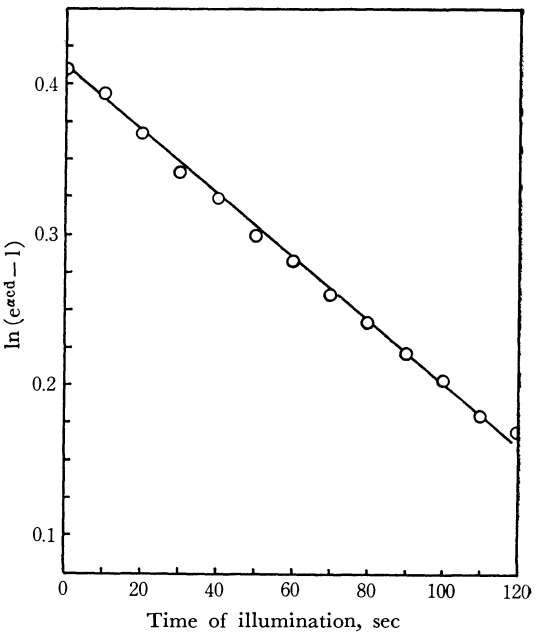

Fig. 3. Photobleaching curve of phenazine in the deaerated methanol solution.

d, optical path length.

(both at 365 nm). The evaluation of the correction terms $\varepsilon' C_0\int_0^t (1/A)dt$ is a simple matter, and these corrections made on the time axis for the similar plots as in Fig. 3 give the corrected values of quantum yield. The quantum yields for the four solvents, corrected and uncorrected are given in Table 1. The quantum yield increases in the order, methanol<ethanol<isopropanol; this is the same as the order of easiness with which α-hydrogen is detached from alcohols.

TABLE 1. QUANTUM YIELD (Φ) OF PHOTOREDUCTION

	Concn. of phenazine (M)	Φ, uncorrected	Φ, corrected

Tetrahydrofuran	3.7×10^{-5}	0.031	0.062

Retarding Effect of Oxygen on the Photoreduction of Phenazine in Methanol and Ethanol. Since dihydrophenazine is sensitive to oxygen, the photoreduction does not occur in the aerated solutions. This is in sharp contrast to acridine which is reduced to acridan by a molecular mechanism even in the presence of oxygen. When the aerated solutions of phenazine in methanol or in ethanol are irradiated by 365 nm for a long time, the original peak of phenazine at 362 nm gradually shifts to red and attains to 370 nm and 375 nm in the case of methanol and ethanol respectively. These shifts may perhaps be due to some oxidation reaction which yields, for instance, phenazine oxide. Along with these shifts, a new small band appeared at about 510 nm, the assignment of which is still unknown. The above spectral changes, however, proceed at very slow rates and no appreciable spectral change was observed by several minutes' irradiation. In such a short time illumination, oxygen is considered as a mere quencher on the photoreduction and the retarding effect of a small quantity of oxygen is expected to afford the information about the intermediate which is attacked by oxygen. From such a viewpoint, the photoreduction of phenazine in methanol and ethanol containing oxygen in the order of 10^{-5} M were investigated. It was really found that the spectral change is not essentially different from that of the completely deaerated solution. Some typical photobeaching curves are shown in Fig. 4. The plots are somewhat similar to those obtained in the case of acridine[3] in the point that the bleaching occurs at much slow rate in the initial stage and after a certain time interval the rate increases rather rapidly to the final value which is 70—90% of the rate in the deaerated solution. These results imply that in the initial stage oxygen prevents the photoreduction by attacking some intermediate, and that the final rate is attained after oxygen is consumed by the reaction, for instance, with semiquinone. Figure 5 shows the dependence of Φ (obtained from the initial slopes in Fig. 4) on the oxygen concentration. Presuming tentatively that oxygen*1 attacks $^3\phi$-

$[\phi]=3—6\times10^{-5}$ M

(n-π^*), the data can be treated simply by the following equation,

$$1/\Phi = (1/\Phi_0)\times(1+k_5[O_2]/k_3) \quad (2)$$

where Φ_0 and Φ are the quantum yields in the absence and in the presence of oxygen respectively. Assuming that the quenching process is diffusion controlled, and putting $k_5=10^{10}$ M^{-1} sec^{-1}, the estimated lifetime of the intermediate in methanol and ethanol was 8×10^{-6} and 5×10^{-6} sec respectively.

*1 It will be demonstrated later that this intermediate is neither semiquinone nor the excited singlet state. (See Discussion.)

Time of illumination,
—— before illumination, - - - 40 sec, —·— 80 sec, —··— 270 sec,
—···— 165 min

Photoreduction of Phenazine by EDTA in the Aqueous Solution. To get a better insight into the mechanism of the photoreduction in question, the reaction with a reducing agent (EDTA) dissolved as a solute in an inert solvent (H_2O) was investigated. pH of the solution containing EDTA is *ca.* 6. A typical example of the spectral change caused by 365 nm irradiation is shown in Fig. 6. It is seen that the reaction proceeds in a simple way with a higher rate than in organic solvents. The spectrum for 165 min irradiation shows a slight deviation from the isosbestic point, perhaps due to the decomposition of dihydrophenazine. In contrast to alcoholic solutions, there is no sign of the superposition of the absorption band due to some other photoproduct. Upon introduction of air, phenazine was recovered almost quantitatively unless the illumination period was not so long.

Dependence of the Quantum Yield on the Concentration of Phenazine and of EDTA in the Aqueous Solution. The phenazine concentration effect was investigated because it is well known that the triplet states of some substances are often quenched by the same substances in the ground state. Fixing the concentration of EDTA at 7.9×10^{-3} M, the concentration of phenazine was changed from 3×10^{-5} to 1×10^{-4} M. The results are shown in Fig. 7. It is to be added that a small absorption becomes observable at 450 nm at higher concentrations of phenazine; this may be

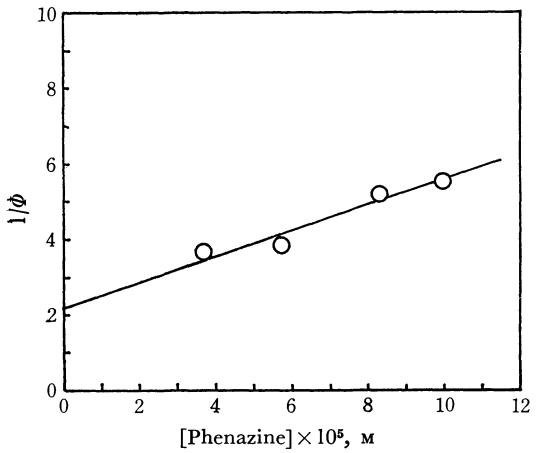

Fig. 7. Dependence of the quantum yield on the phenazine concentration in the aqueous solution involving EDTA as a reducing agent.
$[EDTA]=7.9\times10^{-3}$ M

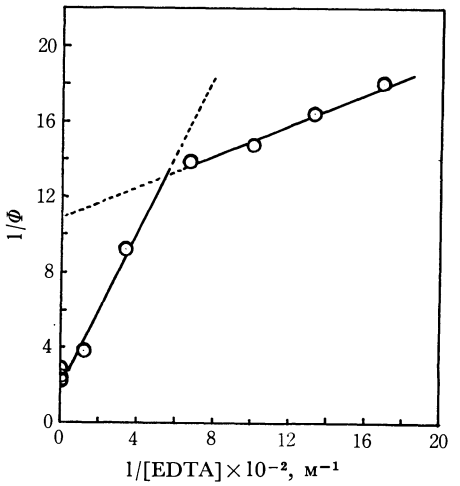

Fig. 8. Dependence of the quantum yield on the concentration of EDTA in the aqueous solution.
$[\phi]=5.0\times10^{-5}$ M

attributed to the formation of a certain molecular complex as will be described later. Since the absorption spectrum is not essentially affected by the above change in the phenazine concentration, decrease in the quantum yield with increasing phenazine concentrations is due to deactivation of a certain reactive state by phenazine in the ground state.

The quantum yield increases with the increase of EDTA concentration but becomes practically constant above 3×10^{-2} M. Figure 8 gives the plot of $1/\Phi$ against 1/[EDTA]. It is apparent that the plot consists of two linear portions. This is due to the processes (9) and (9′) as will be more fully established later. Assuming that the entire reaction consists of (1), (2), (3), (4), (6), (9) and (9′), the lower limit of the intersystem crossing probability, Φ_{ST} was evaluated from the intercept of the plot in Fig. 8 as 0.33. If this is a true value for Φ_{ST}, the values of k_6/k_4 and k_3/k_4 are calculated from the slope of the plot in Fig. 7 and the slope/intercept of the plot in Fig. 8 as follows,

$$k_4/k_3 = 2.7\times10^{2}\ \text{M}^{-1}$$
$$k_4/k_6 = 1.3\times10^{-2}$$

Investigation by a Flash Technique

Transient Spectra in Various Media. Figure 9 shows the transient spectra in various media and at various time points after flashing. Since

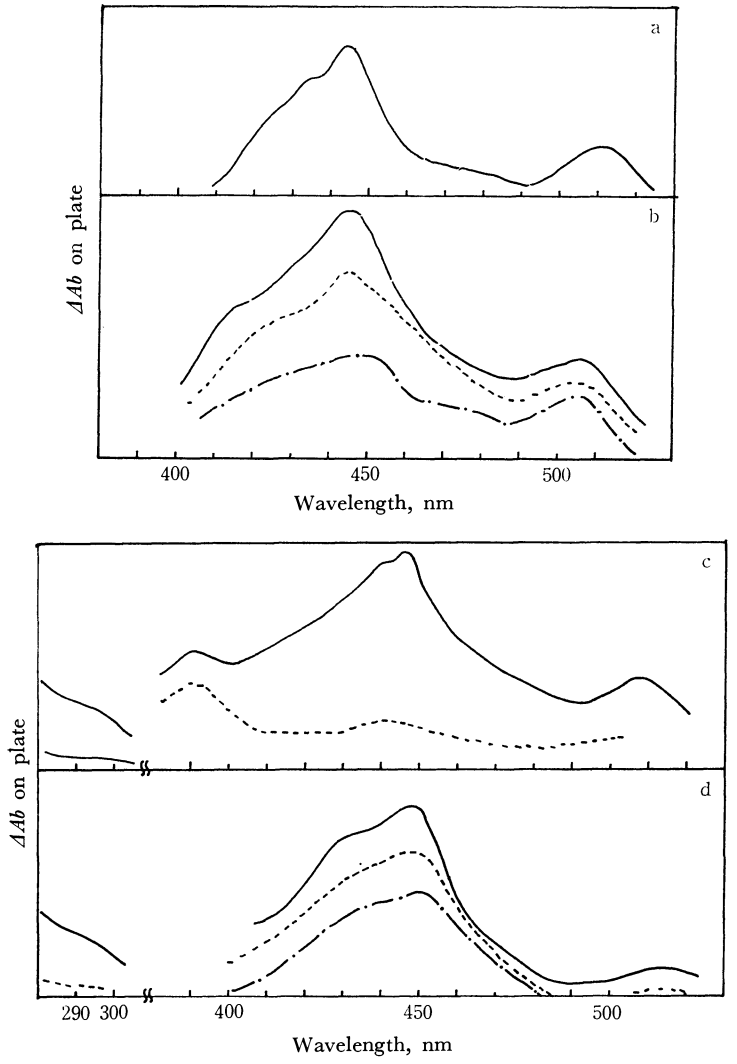

Fig. 9. Transient absorption spectra in the deaerated various solutions of phenazine.
a: Cyclohexane, —— 30 μsec after flashing.
b: Water, —— during photolysis; - - - after 17 μsec; —·— 30 μsec.
c: Methanol, —— 65 μsec after flashing; - - - 365 μsec.
d: Water involving EDTA, [EDTA]=3.2×10^{-2} M; —— during photolysis; - - - 17 μsec after flashing; —·— 1200 μsec

photoreduction does not occur in the plain aqueous solution, the transient spectra observed in these cases are safely assigned as $T(\pi-\pi^*)$. In the case of the reactive media on the other hand, two transient species can be discriminated, short lived and relatively long lived ones. The comparison with the results for inert media leads to the assignment that the former is $T(\pi-\pi^*)$ and the latter is most likely semiquinone. These assignments will be further substantiated by the findings described later. The characteristic bands for $T(\pi-\pi^*)$ are

490—525 nm (510), 410—470 nm (~445), <300 nm

and are essentially the same in different solvents. The numbers in parentheses are for the peak positions. The results are consistent with those of Bailey *et al.*[8]

The absorption of semiquinone in the aqueous solution was investigated in some details. From Fig. 9d it is evident that there is a prominent absorption in the 400—480 nm (~450 nm) region in agreement with the spectrum given by Bailey *et al.*[8] The assignment of this band to semiquinone is supported by the fact that the absorbance at 320 nm due to dihydrophenazine increases in a parallel way with the decrease in absorbance at 445 nm. The transient increase in absorbance occurs in the neighborhood of 360 nm and this means that the gain in absorption by semiquinone supersedes the loss due to the disappearance of phenazine. At 340 nm *i.e.* at the isosbestic point of the steady light reaction, the opposite phenomenon is observable. Although the exact measurement of the absorption spectrum of semiquinone was not attempted, the tentative values of extinction coefficient at some selected wavelengths were determined in the following way. Assuming that dihydrophenazine is exclusively produced by disproportionation of semiquinone in methanol and that in the aqueous solution, semiquinone is further reduced by EDTA (when its concentration is high) (see below), the yield of the semiquinone was estimated from the decrease in the phenazine concentration by one flash. The ε-values thus obtained are given in Table 2. Although these values are not very reliable but may be used for the semiquantitative discussion on the kinetic data.

Table 2. ε-Values of semiquinone

	390 nm	400 nm	430 nm	450 nm
in methanol	2.1×10^4	1.2×10^4	1.4×10^4	1.7×10^4
in water	$(6.0\pm1)\times10^3$ at 445 nm			

Kinetics for the Elementary Reactions. The decay of semiquinone in methanol was measured at 390 nm where the absorption of other species does not exist. As shown in Fig. 10, the

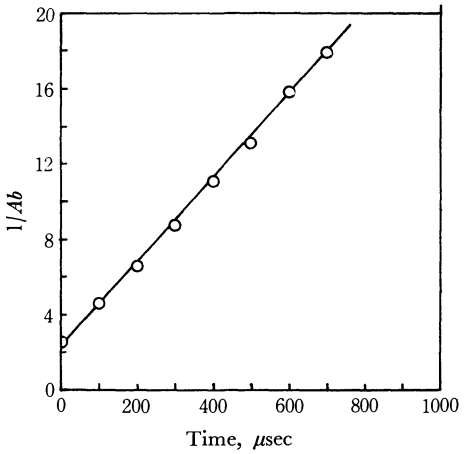

Fig. 10. Second order decay of phenazine semiquinone in the deaerated methanol solution observed at 390 nm.

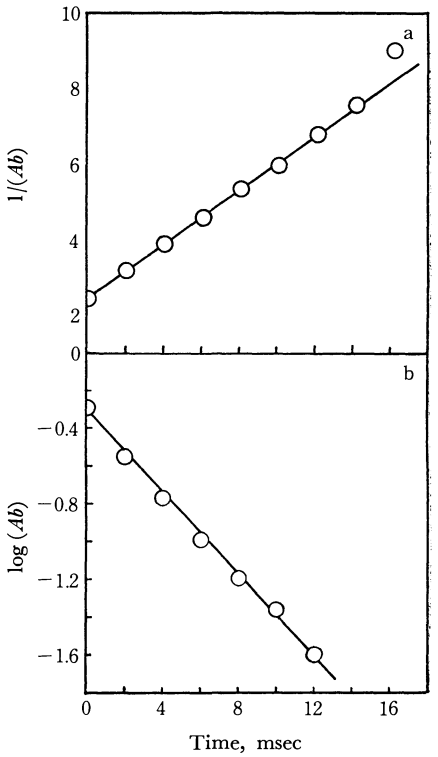

Fig. 11. Decays of phenazine semiquinone in the aqueous solutions involving EDTA as a reducing agent, observed at 445 nm.
a: Second order decay at low EDTA concentration, [EDTA]$=7.9\times10^{-3}$ M
b: First order decay at high EDTA concentration, [EDTA]$=7.7\times10^{-2}$ M

decay was found to be satisfactorily reproduced by the second order plot throughout the entire stage beginning from the end of flashing. This is one of the strongest evidences that $T(\pi-\pi^*)$ still surviving after flashing, does not participate in

the reaction. It can also be concluded that the semiquinone does not react with alcohol nor with alcoholic radical produced in the preceeding process. The analysis was also made at 445 nm where the triplet absorption superposes, by making use of the data in the later stage. The results obtained are moderately satisfactory and the ultimate value for the disproportionation rate constant is $(3.0\pm 0.5)\times 10^9$ M^{-1} sec^{-1}. The semiquinone in the aqueous solution survives a longer time than in alcohol. This made it possible to measure the decay rate at 445 nm. It has been found that the decay consists of two processes, disproportionation reaction and the reaction with EDTA. Of course the former prevails in low concentrations of EDTA while the latter is predominant in the opposite condition. This is shown in Fig. 11. In general the decay can be treated by the following equation which takes into account the above two processes.

$$-\mathrm{d}[\phi\mathrm{H}]/\mathrm{d}t = 2k_9[\phi\mathrm{H}]^2 + k_{9'}[\phi\mathrm{H}][\mathrm{EDTA}] \quad (3)$$

From this equation the following relation can easily be derived.

$$\log A - \log (A + k_{9'}[\mathrm{EDTA}]\varepsilon \cdot d/2k_9) = -k_{9'}[\mathrm{EDTA}]t/2.303 \quad (4)$$

This relation fits the decay curve quite satisfactorily. By making experiments at various EDTA concentrations, the ultimate values of k_9 and $k_{9'}$ were evaluated as follows.

$$k_9/\varepsilon d = (1.8\pm 0.2)\times 10^2, \quad k_9 = 1.1\times 10^7 \text{ M}^{-1}\text{ sec}^{-1},$$
$$k_{9'} = \sim 3\times 10^3 \text{ M}^{-1}\text{ sec}^{-1}$$

These values are not so much reliable, particularly so for the disproportionation reaction because of the uncertainty of the ε-value.

The decay of $T(\pi\text{-}\pi^*)$ in methanol was measured at 280 nm, where the absorption of semiquinone is small, though not negligible. The decay is neither first order nor second order. Assuming that $T(\pi\text{-}\pi^*)$ is not a reactive state, the analysis was made by the following formula

$$\ln (A - A(\phi\mathrm{H})) = -kt + \text{const} \quad (5)$$

where $A(\phi\mathrm{H})$ is the absorbance of semiquinone and can be evaluated from the extrapolation of the later stage of the $1/A$ - t plot in case of methanol. In the aqueous media the similar procedure was allowed for low EDTA concentrations but the log A - t plot must be used for high EDTA concentrations. The first order rate constant obtained for methanol is $\sim 10^4$ sec^{-1}. Figure 12 gives the dependence of the decay rate on the concentration of EDTA in the aqueous solution. Figure 12 definitely shows that the addition of EDTA does never increase the decay constant of $T(\pi\text{-}\pi^*)$. The effect is rather opposite and may be due to the difference in physical properties of the solutions such as pH or ionic strength. The dependence of the decay rate on the phenazine concentration was similarly investigated, in order to know whether the triplet state $T(\pi\text{-}\pi^*)$ is deactivated by the ground state molecule or not. The result as shown in Fig. 3, clearly demonstrates the occurrence of such a process. The k_7-value was estimated to be $\sim 4\times 10^7$ M^{-1} sec^{-1}.

[EDTA]=7.9×10^{-3} M

The Formation of Molecular Complex and a Radical Species related with it

In the course of the steady light experiment, a remarkable fact was found that in the illuminated solutions of rather high phenazine concentrations (from 10^{-4} to 10^{-2} M), a new small absorption band appears in the $\sim$450 nm region, as shown in

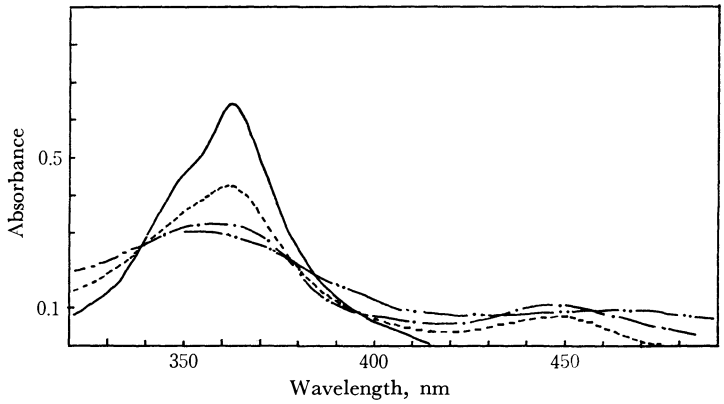

Fig. 14. Spectral change of the deaerated methanol solution in the high phenazine concentration. $[\phi]=1.7\times10^{-4}$ M. —— 0 min, - - - 6 min, —·— 12 min, —··— 199 min

Fig. 14. This band with a peak at 450 nm gradually grows with the time of illumination and in about 30 minutes attains its maximum and then declines slowly accompanied with a shift to the longer wavelength. The ultimate position of the peak is usually about 500 nm. The quantum yields of the photoreduction in the case that the above band was observed, were not essentially different and the spectral changes from 300 to 400 nm region was the same as that in other cases. All these facts are understandable if one assumes that the visible absorption is due to the complex formation occuring between phenazine and dihydrophenazine and the equilibrium exists between them with a rather small equilibrium constant for the complex formation.

Since the complex consisting of 3 phenazine-1 dihydrophenazine and 1 phenazine-1 dihydrophenazine has been reported by Toromanoff *et al.*,[7] the molecular weight of the photoproduct was examined by mass spectrometry. Thus the deaerated ethanol solution of phenazine was illuminated for about three hours, and then the solid mixture obtained by distilling off the solvent, was submitted to mass spectrometry. A fragment with a molecular weight about two times that of phenazine was really detected but most of the fragments are of the molecular weight near that of phenazine. No fragment of larger molecular weight was not detected. The solid mixture consisting of the complex, phenazine and dihydrophenazine was found to display the ESR signal. When the degassed methanol solution of phenazine 1×10^{-3} M was illuminated in a capillary cell for ESR with a light of 365 nm, the signal was clearly detected and it increased in intensity with the time of irradiation. The signal intensity was found to remain constant for a long time after the irradiation was stopped. Hence the signal is due to a certain stable paramagnetic species different from neutral semiquinone radical which is not so stable. The complex itself may be paramagnetic, but some other radical species might be formed in the equilibrium system $\phi+\phi H_2 \rightleftarrows (\phi\cdots\phi H_2)$ in solutions. In the former case a molecular complex may be of a charge transfer type or the dimer of the semiquinone radical. However, we have some evidence for identifying the paramagnetic species as the radical cation reported by Bailey *et al.*,[8] though it is not clear how it is formed. Further studies are now in progress.

General Discussion

As to the reactive state of phenazine, the results obtained exclude definitely the possibility of the lowest $T(\pi\text{-}\pi^*)$ being a reactive state. Evidence in addition to the one already described are as follows. Firstly, in alcohols the decay constant of $T(\pi\text{-}\pi^*)$, $k\lesssim10^4$ sec^{-1} is too small for considering it as a reactive state because this value cannot compete with the quenching action of $\sim10^{-5}$ M oxygen. If the reactive state were $T(\pi\text{-}\pi^*)$, the reaction would have to be retarded by oxygen far more efficiently than was observed. Secondly, in the aqueous solution, the decay rate of $T(\pi\text{-}\pi^*)$ does not increase by the addition of EDTA in the amount which is enough to make the steady reaction to occur.*2 Thus the remaining possible states are certain higher $T(n\text{-}\pi^*)$ or the singlet excited state. But the latter is not likely in view of the result that the quantum yield becomes constant at and above the EDTA concentration of $\sim3\times10^{-2}$ M. Furthermore, the inhibiting action of oxygen of 10^{-5} M in methanol cannot be understandable if the reactive state is the excited singlet.

The view that a $T(n\text{-}\pi^*)$ is a reactive state is

*2 Baiely *et al.* concluded from somewhat similar argument as above, that the lowest $T(\pi\text{-}\pi^*)$ is not a reactive state. But their argument does not seem to be strong enough to support the excited singlet mechanism and to reject the $T(n\text{-}\pi^*)$ state.

further supported by the following consideration about the intermediates attacked by oxygen. At first sight it seems reasonable to consider that oxygen attacks only semiquinone in addition to the final product, ϕH_2. But this is highly improbable because semiquinone would have a much longer lifetime than $5—8\times10^{-6}$ sec (the value of lifetime estimated for the intermediate attacked by oxygen). One must therefore consider another shorter-lived intermediate attacked by oxygen and there is no other state conceivable than a certain higher $T(n–\pi^*)$. The exact lifetime of $T(n–\pi^*)$ however, cannot be evaluated, since the deactivation process of $T(n–\pi^*)$ by oxygen is superposed by the reaction between semiquinone and oxygen. Hence the above value $5—8\times10^{-6}$ sec is an overestimation. The real value may be $\lesssim1\times10^{-6}$ sec.

The result that the quantum yield is much less in alcohols than the Φ_{ST} value obtained for the aqueous solution, 0.33 (lower limit) can be attributed to the difference of reactivity of alcohol molecules and EDTA. The exact value of Φ_{ST} will be determined in near future.

As for the semiquinone, it disappears in methanol only by disproportionation and its rate constant approximates the diffusion controlled value. This differs from Bailey's result in acidic medium where the disproportionation is rather slow. In the aqueous solution on the other hand, the reaction with EDTA occurs in addition to the disproportionation. The rate constant for the former is $\sim3\times10^3$ M^{-1} sec^{-1} and for the latter $\sim1\times10^7$ M^{-1} sec^{-1}. The result that the $1/\Phi$ - 1/[EDTA] plot consists of two linear portions is related with these two reactions. Thus the overall quantum yield when the semiquinone disappears by disproportionation is expected to be half that when it is reduced to dihydrophenazine by EDTA. The result in Fig. 8 is qualitatively consistent with this expectation. Much smaller rate constant of disproportionation in the aqueous solution may be due to the liquid state.*3 If one assumes that the lifetime of $T(n–\pi^*)$ in the aqueous solution, is the same as that in alcohol, then the rate constants k_4 and k_6 in the aqueous solutions are evaluated as $k_4=3\times10^8$ M^{-1} sec^{-1}, $k_6=2\times10^{10}$ M^{-1} sec^{-1}, from the values of $k_4/k_3=2.7\times10^2$ M^{-1} and $k_4/k_6=1.3\times10^{-2}$ obtained by the steady light experiments. The value of k_6 is compared with the rate constant, 4×10^7 M^{-1} sec^{-1} for the reaction $T(\pi–\pi^*)+\phi\rightarrow2\phi$.

The determination of the exact Φ_{ST} value, the dependence of the stability of semiquinone on the solvent property, especially the dependence on pH, and more decisive evidence for $T(n–\pi^*)$ as a reactive state by means of the triplet energy transfer await further studies. In particular, further investigations on the molecular complex and the radical species related with it will be most interesting.

*3 It is well comprehended that Bailey's result in acidic media is rather similar to the present one in the aqueous solutions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2796—2800 (1970)

Photochromic Reaction of *N*-Nitroso-*N*-alkylaniline in the Aqueous Solution—A Contribution to the Photochemistry of Nitrosamine

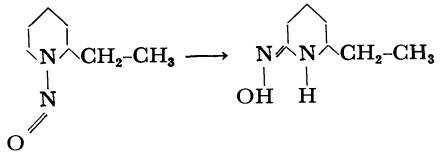
Mikio Hoshino, Hiroshi Kokubun and Masao Koizumi

Department of Chmistry, Faculty of Science, Tohoku University, Katahira, Sendai

(Received May 8, 1970)

It has been found that the aqueous solution of *N*-nitroso-*N*-methylaniline when irradiated by 253.7 nm shows photochromism. The unstable photoproduct reconverts to the original compound photochemically as well as thermally. The quantum yields for the forward and backward reaction are respectively 0.23 and 0.58. *N*-Nitroso-*N*-ethylaniline also reacts in the similar way. In the alcoholic solutions, different types of reaction occurred; in the absence of oxygen the reaction is mainly the formation of *N*-methylaniline. It has been suggested that the present photochromism is due to the *cis-trans* isomerization.

Photochemical reactions of nitrosamines have attracted much attention in recent years because of various and interesting types of reaction. One type is a splitting of nitrous oxide, an example of which is $(CH_3)_2N-NO \rightarrow (CH_3)_2N\cdot + NO$ studied by Banford in the gaseous state.[1] Another type of reaction is a photoaddition of *N*-nitrosodialkylamine to olefines followed by the C–C double bond cleavage.[2] The third is an intramolecular rearrangement of the following type studied extensively by Chow,[3-5] and by others,[6,7] from the organic viewpoint,



Chow in one of his papers, mentioned the non-reactivity of *N*-nitroso-*N*-methylaniline (NMA) even in the acidic mixture of water and alcohol. We have found, however, that this compound shows an interesting type of photochromism in the aqueous solution although the eventual reaction does not occur. The present paper reports on this newly discovered photochromism and some observations related with it.

Experimental

Materials. NMA was prepared by a usual method from *N*-methylaniline and nitrous acid and purified by vacuum distillation.

Procedures. A light source is a 6 W germicidal mercurs lamp. The absorption spectrum was measured by a Hitachi EPS-3T spectrophotometer. The gradual change of the optical density with time was followed at several fixed wavelengths on the same instrument.

Results

Photochromism and the UV Spectrum of the Product. When the aqueous solution of 1.32×10^{-4} M NMA was irradiated by 253.7 nm for about five minutes, the UV spectrum displayed a change as shown in Fig. 1. Further it was found

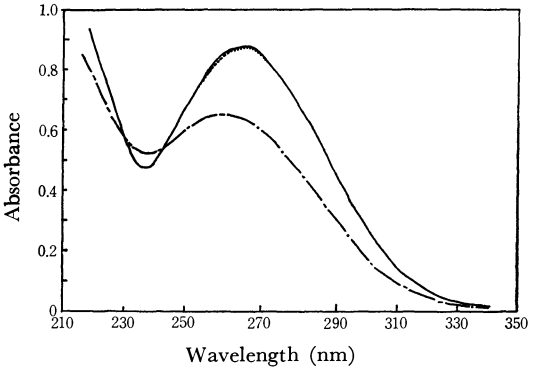


Fig. 1. Spectral change.
—— Spectrum of NMA in the aqueous solution(a)
—·— after irradiation at 253.7 nm for 5 min(b)
····· after being kept in dark for 30 min

that the original spectrum was almost completely recovered by keeping the irradiated solution in dark for thirty minutes. This photochromism was observed in quite the same way in the degassed solution indicating the non-participation of oxygen in the reaction. When one plots the decrease

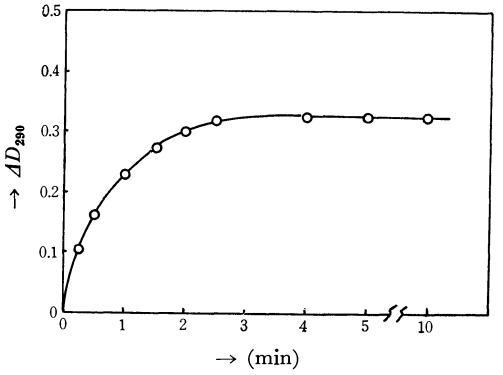

Fig. 2. Change of D (at 253.7nm) with time of irradiation.

in the optical density, ΔD at 290 nm against the time of irradiation, ΔD reaches a certain limiting value in about four minutes as shown in Fig. 2. This indicates that the photoproduct which absorbs the exciting light (see below) is not transformed photochemically to any other compound than NMA and that the photostationary state holds between the forward and backward reaction.

The absorption spectrum of the photoproduct was obtained in the following way. The ratios of the optical density of the absorption spectrum a and b in Fig. 1 were evaluated at various wavelengths and were found to be constant beyond 290 nm. This means that the photoproduct has no absorption in this region. On the basis of this assumption, the absorption of the photoproduct can easily be obtained. The result is shown in Fig. 3.

—···— kept in dark for 4 min
····· kept in dark for 10 min

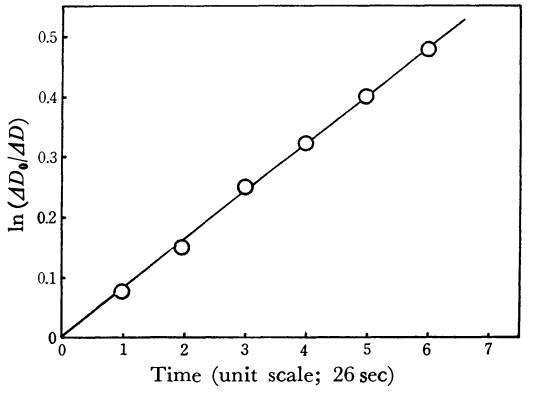

Fig. 5. Plot of $\ln(\Delta D_0/\Delta D)$ (at 290 nm) against time of irradiation.

$$\mathrm{B} \longrightarrow \mathrm{A}$$

where B is the photoproduct and A is the original compound. From the above scheme the following equations hold,

$$D = \varepsilon_A C_A + \varepsilon_B C_B$$

$$\Delta D = \varepsilon_A C_A^0 - (\varepsilon_A C_A + \varepsilon_B C_B) = (\varepsilon_A - \varepsilon_B) C_B$$

$$-\frac{d\Delta D}{dt} = k\Delta D$$

where D is the optical density of the sample at time t, $\Delta D = D_0 - D$ and C_A^0 is the original concentration of NMA. The other notations are the usual ones. Figure 5 gives the plot of $\ln(\Delta D_0/\Delta D)$ against time. From the slope of the plot one obtains the value of the rate constant at 17°C as 3.08×10^{-3} sec^{-1}. Thus the lifetime of the photoproduct at this temperature is about 5.5 min.

The Effect of Light Intensity on the Steady State and the Evaluation of the Quantum Yields for the Two Opposed Reactions. Since the backward reaction in photochromism often proceeds photochemically, the dependence of the steady state on the light intensity was examined.

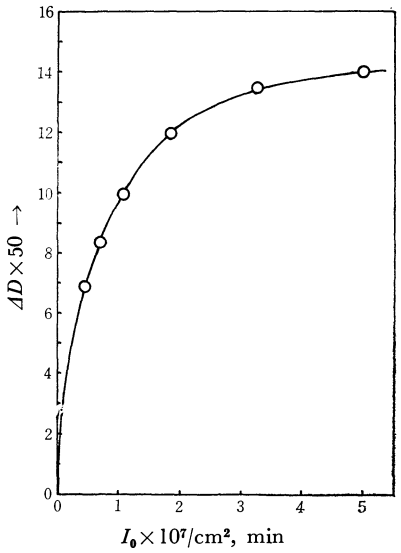

Fig. 6. Dependence of ΔD_∞ (at 290 nm) on light intensity.

As seen from Fig. 6, the limiting value of ΔD_∞ at 290 nm increases appreciably with the increase in light intensity when it is low but gradually tends to a constant value which is only a fraction of the original optical density. This indicates that the backward reaction involves the photochemical reaction in addition to the thermal one.

On the basis of the following scheme,

$$A \underset{k}{\overset{h\nu}{\rightleftarrows}} B \quad (h\nu)$$

the result given in Fig. 6 was analysed in the following way. The rate of the forward reaction is

$$\frac{dC_B}{dt} = \Phi_{AB} I_0 (1 - e^{-2.303D}) \left(\frac{D_A - \alpha D_B}{D} \right) - kC_B$$

where D, D_A and D_B are the optical densities of the sample, A- and B- species at time t and Φ_{AB} and $\alpha\Phi_{AB}=\Phi_{BA}$ are respectively the quantum yields for the forward and backward reactions. In the photostationary state, the relation

$$\Phi_{AB} I_0 (1 - e^{-2.303D}) \frac{D_A - \alpha D_B}{D} = kC_B$$

holds, and this equation can be rewritten as follows.

$$\Phi_{AB}(1 - (D_B/D_A)\alpha) = (1/I_0)(1/1 - e^{-2.303D})(D/D_A)kC_B \quad (= \Gamma)$$

Since all the quantities involved on the right hand term are known experimentally, the values of Γ at various light intensities can easily be obtained. Then the Γ *vs.* (D_B/D_A) plot should be linear with an intercept Φ_{AB} and the slope $\Phi_{AB}\alpha=\Phi_{BA}$. Figure 7 shows the result obtained when the light intensities were changed at the constant concentration

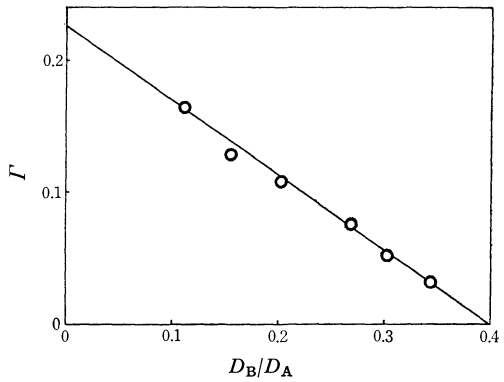

Fig. 7. Plots of Γ *vs.* D_B/D_A.
$\Gamma=(1/I_0)(1/1-e^{-2.303D})(D/D_A)kC_B$

of NMA, 1.56×10^{-4} M, at 17°C. It was checked that the rate of the thermal backward reaction always remained constant. The values of quantum yield for the forward and backward reactions thus obtained are

$$\Phi_{AB} = 0.23, \qquad \Phi_{BA} = 0.58$$

The intercept of the abscissa which corresponds to the infinite light intensity gaves the values of Φ_{AB}/Φ_{BA}, because the relation $\Phi_{AB}D_A=\Phi_{BA}D_B$ holds under this condition. The value of Φ_{AB}/Φ_{BA} evaluated by this method is 0.4 in complete agreement with 0.39_4 calculated from the values of Φ_{AB} and Φ_{BA} obtained above.

Photoreaction of Other Related Nitrosamines in the Aqueous Solution. Some other nitroso-compounds were investigated in order to know whether they show the similar photochromism or not. It was found that *N*-nitroso-*N*-ethylaniline (NEA) displays quite the same photochromism as shown in Fig. 8. On the other hand, *N*-nitrosodiethylamine 10^{-3} M in the aqueous solution decomposed photochemically without any sign of pnotochromism. *N*-nitrosodiphenylamine 5.3×10^{-5} M in the aqueous solution also did not

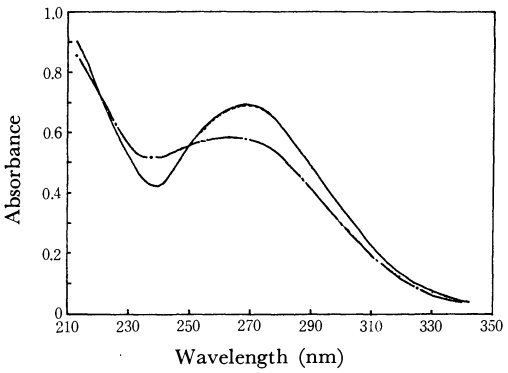

Fig. 8. Spectral change of NEA in the aqueous solution.
—— Spectrum of NEA
—·— after 5 min irradiation (at 253.7 nm).

show photochromism and only the formation of carbazole was observed.

Reaction in Ethanol. In order to know whether the similar photochromism occurs in other solvents, the reaction of NMA and NEA in alcohols were investigated preliminarily. When the degassed ethanol solution of 1.08×10^{-4} M of NMA was irradiated by 253.7 nm, the absorption spectrum changed quite rapidly with two distinct isosbestic points, as shown in Fig. 9. But in this case the final product was found to be stable. It was identified as *N*-methylaniline for the following reason. Firstly, NMA in ethanol gives no emission, while the sample irradiated for 25 minutes gives the fluorescence spectrum with two peaks at 345 nm and 430 nm, and the measurement of the excitation spectra clearly showed that these two peaks belong to the two different emitting species. The excitation spectrum for the 345 nm peak agrees with that of *N*-methylaniline, and moreover, the fluorescence spectrum of this compound coincides almost exactly with the shorter wavelength part of the spectrum of the irradiated sample (Fig. 10). The absorption spectrum also supports this identification.

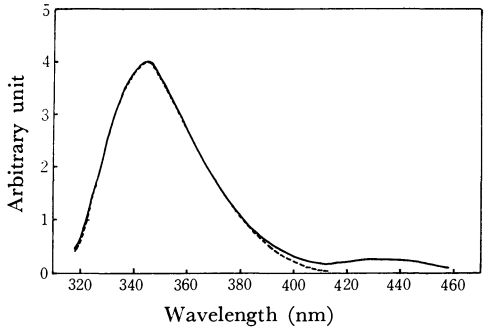

Fig. 10. Fluorescence spectrum of the photoproduct when the degassed ethanol solution of NMA was irradiated at 253.7 nm for 12 min.
——— solid line
– – – *N*-Methylaniline in ethanol

On the other hand, the aerated ethanol solution when irradiated, gave a quite different absorption spectrum, which is shown in Fig. 11. The photoproduct in this case has not yet been identified although there is no doubt that it is not *p*-nitroso-*N*-methylaniline. Somewhat similar spectral change was also observed upon irradiation of the aerated ethanol and cyclohexane solutions of *N*-nitroso-*N*-ethylaniline.

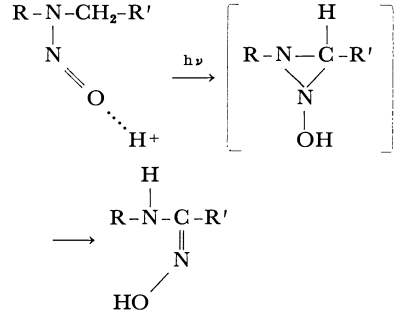
Discussion

The unstable photoproduct produced in the present photochromism has not yet been fully identified. Here, a plausible interpretation will be given by taking into consideration the results reported in literature. Chow in his study on photochemical isomerization reaction of nitrosamines, presumes the formation of a ring of the –N–C– type, as follows,



If one considers as a possible interpretation, that the present photoproduct has such an annular structure, then the C–N bond instead of the N–N bond should be broken for the present photochromism to occur. This, however, is not reasonable in view of the bond strength of C–N and N–N. As another possibility, *cis-trans* isomerization is conceivable and this is very plausible. Karabatsos

et al.[8] in their studies on the structure of *N*-nitroso-*N*-alkylamines by means of NMR, proposed the existence of the following *cis-trans* isomerization in *N*-nitroso-*N*-alkylamines,

8) G. J. Karabatsos and R. A. Taller, *J. Amer. Chem. Soc.*, **86**, 4373 (1964).

According to them, only the *cis*-form exists in case that *R* is methyl, while in ethyl and isopropyl, *trans-form* can also be existent in equilibrium with the *cis-form*. They proposed that the absorption of the *trans-form* is located in the shorter wavelength than that of the *cis-form*. In view of these results it is very likely that the present photochromism is the *cis* to *trans* isomerization. The non-occurrence of photochromism in alcoholic solution may be due to the preponderance of other types of reaction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2800—2804 (1970)

The Precise Coulometric Titration of the Acidic Primary Standard using Amperometric End-point Detection

Takayoshi Yoshimori and Ikuko Matsubara

Faculty of Engineering, Science University of Tokyo, Shinjuku-ku, Tokyo

(Received November 5, 1969)

The sensitive amperometric end-point procedure (*Anal. Chem.*, **23**, 1662 (1951)) with an antimony electrode is used in the titrations of acids. The cyclic voltammetric curves of the electrode indicate the possibility of the use of the above method for the titration of acids. The purities of potassium biphthalates (primary standard substances) are determined directly by precise coulometric titration with this end-point location. The standard deviations of the results (99.999%) are 0.007 or 0.008%. The purity of the benzoic acid prepared as the standard material for the calorimeter is also determined by this method. The standard deviation of these results (99.993%) is 0.009%.

Many investigations have indicated that coulometric titration is the most precise and accurate method in analytical chemistry. The purities of several primary standard substances have been directly determined by this method.[1-5]

Although the relative standard deviation by this method has been 0.003% in the most accurate studies, there are several problems in obtaining this value in ordinary laboratories without atmospheric control. Among these problems, the location of the end-point of the titration is the most important, especially in the titration of an acid or a base.[6] A pH meter with a glass electrode has been preferably used in locating the end-point of the titration. This potentiometric method has, however, several disadvantages because of the very high impedance of the electrode.

In the direct determination of the bulk material in a sample, a large amount of the sample should be taken in order to decrease the error in weighing. This causes the need to use a correspondingly large electrolytic current; otherwise, the electrolysis cannot be finished within a reasonable time interval. The electric field in the titrating cell caused by such a large electrolytic current then interferes with the high impedance circuit, that is say, the indication of the pH meter for end-point detection. After the current is cut off, it is necessary to wait several minutes in order to measure the pH value of the titrating solution. Furthermore, it is also necessary to measure many pH values in order to draw the titration curve clearly.

On the other hand, the circuit for the amperometric end-point location has a low impedance. Therefore, the disturbance caused by the electrolytic current disappears; also, only a few measurements are enough to locate the end-point. Chris-

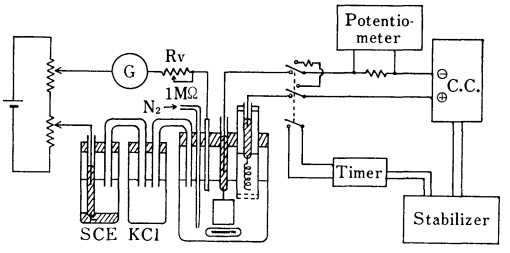
tian[7] has already recommended the use of the amperometric method in locating the end-point of a coulometric titration, and the present authors have had the same experience. However, only a few amperometric methods have yet been used in the case of the titration of an acid or a base.

The present authors have now tried to use an antimony electrode with the aid of a sensitive amperometric end-point procedure,[8] they have obtained fairly satisfactory results.

Experimental

Apparatus and Reagents. The apparatus used for the amperometric titration with an antimony electrode and that used for the coulometric generation of hydroxyl ions are shown in Fig. 1. The generating



G: Galvanometer (2×10^{-9} A) C.C.: Constant current source

Fig. 1. Apparatus.

current was measured with a standard resistor and a potentiometer. The error in the measurement of the current had a standard deviation of less than 0.005%. As the Faraday constant, 96487.2 coulomb was used. The generating current was kept constant by the following method; the fine adjuster of the constant-current source was regulated so as to keep as small as possible the deflection of the galvanometer (Sens. 10^{-6} V) connected to the potentiometer in the electrolytic circuit.

The 50-Hz oscillator of a quartz crystal and a cycle counter were used to measure the time interval of the electrolysis.[9]

The potential between the antimony electrode and a saturated calomel electrode was 0.50 volt for the titration of potassium biphthalate and 0.58 volt for benzoic acid. According to the character of the electrode, and also according to the pH value at the end-point, this potential should be chosen from the titration curve obtained by a preliminary potentiometric titration of the sample.

All the weights were corrected to standard weights. A weighing bottle of nearly the same weight as that containing the sample was used as a counterpoise. A lipless beaker made from polystyrene (about 200 m*l*) was used as the cell. An auxiliary electrode compartment, made from a polyethylene tube with an agar-agar diaphragm,[6] was installed through a silicone rubber stopper. About a 100-mg portion of barium carbonate was added into the compartment in order to neutralize the acid produced by the anodic reaction.

All the reagents were of an analytical grade, and all were used without further purification. For the purity determination of potassium biphthalate, a 0.5 M potassium chloride solution was used as the electrolyte, while for benzoic acid a 30% v/v ethanolic solution of 0.7 M potassium chloride was used.

Procedure. *Drying of the Sample.* Potassium biphthalate was heated at 120°C for 4 hr and then cooled in a desiccator containing concentrated sulfuric acid for 1.5 hr.

Benzoic acid was dried by the following two methods. First, the acid was dried in the desiccator containing concentrated sulfuric acid for 72 hr. Secondly, it was melted in a platinum crucible at 135°C,[10] cooled under the same conditions as above for 1.5 hr, and then weighed and introduced into the cell.

Coulometric titration. Place an electrolytic cell containing 100 m*l* of a potassium chloride solution (0.5 M) in a thermostat. Introduce nitrogen (free from carbon dioxide) for more than 40 min; then neutralize the solution with electrolytically-generated hydroxyl ions until the galvanometer in the indicator circuit shows zero. At this point, the potential of the antimony electrode (*vs.* SCE) coincides with the voltage of the potentiometer in the indicator circuit.

A weighed sample is introduced into the solution, and nitrogen is allowed to flow through for about 10 min. The solution is then electrolyzed with a constant current until it is neutralized to the previous pH value. The end-point of the electrolysis can be located by the point at which the galvanometer in the indicator circuit reaches zero. During the electrolysis, nitrogen must be allowed to flow over the electrolyte (not through the solution). Early in the titration, the indicator current through the galvanometer must be regulated with a variable resistor (1 MΩ).

Results and Discussion

Before the practical use of the antimony electrode, the cyclic voltammetric curves of the electrode were recorded with the instrument named Electroscan 30 (Beckman Instrument Co.). Typical cyclic voltammetric curves thus obtained at pH 4.0, 7.0, and 9.0 are shown in Fig. 2 (a).

Figure 2 (b) is an example of the curve obtained at pH 4.0. Identical curves were obtained at pH 7.0 and 9.0. This figure shows that the potentials of the zero-current point in cathodic curves (from the positive to the negative direction) coincide with one another. Since the pH of the electrolyte changes from acidic to basic near the end of the titration, the good reproducibility of the zero-current potential of the electrode from the positive to the negative direction demonstrates

that the electrolyte has the same pH value when the indicator current becomes zero (galvanometer zero). Thus, the titration of acid with electrolytically-generated hydroxyl ions will be possible with the antimony electrode and a sensitive amperometric end-point procedure.

Determination of the Purities of Potassium Biphthalates. The results obtained for the analyses of potassium biphthalates are shown in Table 1. In this case, the samples were weighed with a semimicrobalance; the error in the measurement of the electricity was less than 0.01% as a standard deviation. These accuracies are the same as those of the potentiometric method reported previously.[6]

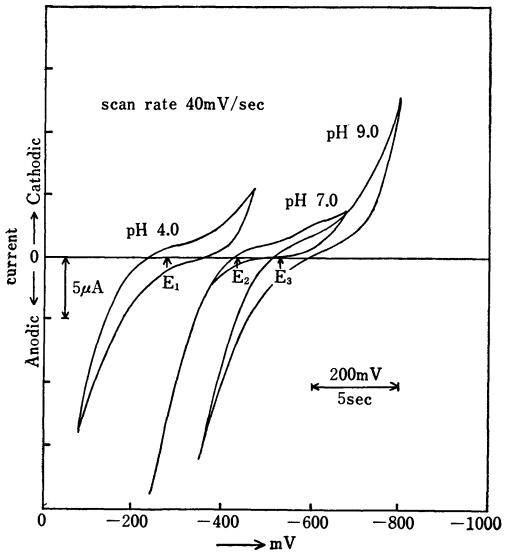

Fig. 2(a). Current-voltage curves of antimony electrode
$E_1 \sim E_3$: equilibrium potentials of the electrode measured by the very high impedance circuit.

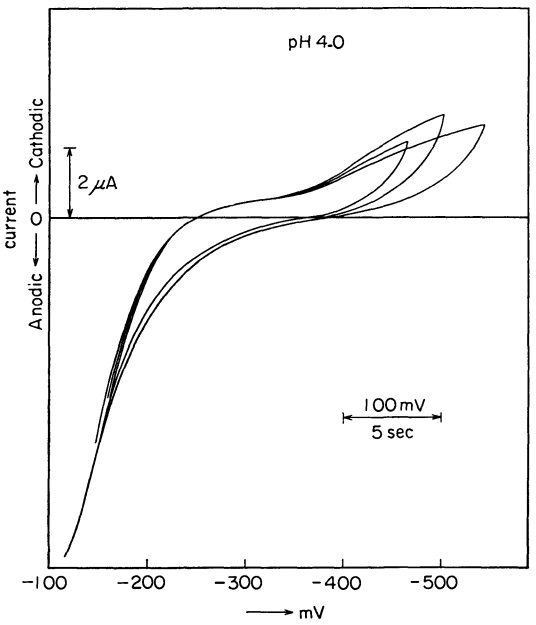

Fig. 2(b). Cyclic voltammetric curves of antimony electrode.

When the relative standard deviation in Table 1 is compared to that of the previous potentiometric method,[6] it is seen to be considerably decreased (nearly one-half). In this case, the time necessary for a single determination does not exceed

1 hr. By the potentiometric method, more than 3 hr are needed.

Next, the error due to the measurements of the electricity decreased to about 0.005% as the standard deviation, and the samples were weighed with a microbalance. In order to verify the error in the weighing of the sample, the following experiment was carried out. The potassium biphthalate in a weighing bottle (0.5 g) was dried at 110°C for 4 hr, cooled in the desiccator for 1.5 hr, and then weighed with the microbalance. This procedure was repeated 6 times.

				$\hat{\sigma}=0.009\%$

The results thus obtained are shown in Table 2; there may be some problems in the above method for drying, because it seems that the weight of the sample decreased gradually. The decrease is, however, very small, and may be considered at a later time. When the overall difference is regarded as the error of drying and weighing of the sample, the standard deviation of the error does not exceed 0.003%.

The results obtained by the procedure described previously are shown in Table 3. The standard deviation of these results was 0.007%, somewhat larger than the value to be expected from the errors in samplings and in coulometric titration. The difference may be based on the errors connected with the location of the end point. Material transference through the diaphragm used should also be considered. Taylor's method[1] is very time-consuming, and the diaphragm proposed by Eckfeldt and Shaffer[3] is not suitable either because the condition of the electrolyte at the end-point does not coincide with that at the beginning of the electrolysis. Although the diaphragm used here does not have as many advantages as the above two types, it is simple and useful when the electrolysis is finished within one hour.

Determination of the Purity of Benzoic Acid. The purity of the benzoic acid was determined by the proposed method. The acid was prepared as a standard material for a calorimeter and could be obtained from the Resources Research Institute (Japan). Two drying methods shown previously were used here.

The results obtained are shown in Table 4. These results indicate that there are not much difference between the above methods for drying; the purity of the acid was somewhat lower than 100% when the acid was evaluated as the "acidic" standard.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2805—2807 (1970)

Dielectric Relaxation of Esters in Benzene Solutions

KRISHNAJI, S. C. SRIVASTAVA and DINA NATH

Physics Department, Allahabad University, Allahabad-2, India

(Received January 5, 1970)

Dielectric relaxation times and distribution parameters of three esters in benzene solutions have been evaluated using three methods, *viz.*, Cole-Cole arc plot method, Higasi's single frequency method and the Gopal Krishna method. Three microwave frequencies have been used to determine a' and a'' apart from the static and optical frequencies for a_0 and a_∞. The distribution parameters obtained from Cole-Cole arc plot and Higasi's method are in good agreement showing that the sploes a' and a'' have been determined accurately. In these esters the values of the distribution parameter are high. Since the dipole-dipole interactions are negligible in dilute solutions, the higher values of the distribution parameter suggests the existence of multiple relaxation processes.

Earlier[1] measurements on a few esters have been carried out in the pure liquid. In order to reduce the effect of dipolar fields we have studied the esters in solutions. In this paper three esters *viz.*, ethyl capronate, ethyl α-bromobutyrate and ethyl α-bromoisobutyrate have been studied in benzene solutions at three microwave frequencies apart from the static and optical frequencies. Because of the interesting results obtained by other workers on different esters it seemed desirable to determine their dielectric relaxation.

Method of Measurement and Analysis of Data. Static permittivity was measured at the frequency 1 MHz by means of a dipolemeter based on the principle of heterodyne beat method. The cell used for the purpose was calibrated with standard liquids. Refractive indices of all the solutions were measured with the help of an Abbe's refractometer and the square of the refractive index gave the values of optical permittivity ($\varepsilon_\infty = n_D^2$).

The permittivity and dielectric loss at microwave frequencies were determined using Smyth's method[2] and the shorted standing wave technique.

The compounds were obtained from M/s Fluka AG, Switzerland. Benzene, Analar Grade (B.D.H.), was used for making the solutions and was distilled twice before use.

It has been observed by earlier workers[3] that permittivity and dielectric loss in solutions are linear functions of the concentration. Thus one can represent the permittivity and dielectric loss by the equations,

$$\begin{aligned} \varepsilon_0 &= \varepsilon_{10} + a_0 c_2 \\ \varepsilon' &= \varepsilon_1 + a' c_2 \\ \varepsilon'' &= a'' c_2 \\ \varepsilon_\infty &= \varepsilon_{1\infty} + a_\infty c_2 \end{aligned} \qquad (1)$$

where ε_0 is static permittivity and $\varepsilon_\infty = n_D^2$ is optical permittivity. Subscript 1 refers to the pure solvent, c_2 is the molar concentration of polar solute and a's are the slopes of the straight lines obtained by plotting the dielectric quantity against concentration. These graphs have been plotted and the slopes determined from these plots are given in Table 1.

Cole-Cole[4] semi-empirical relation for the complex permittivity, $\varepsilon^* = \varepsilon' - j\varepsilon''$ is given by

$$\varepsilon^* = \varepsilon_\infty + \frac{\varepsilon_0 - \varepsilon_\infty}{1 + (j\omega\tau)^{1-\alpha}} \qquad (2)$$

where τ and α are the relaxation time and the distribution parameter respectively and ω is the angular frequency. Substituting equations (1) into (2) we obtain

$$a^* = a' - ja'' = a_\infty + \frac{a_0 - a_\infty}{1 + (j\omega\tau)^{1-\alpha}} \tag{3}$$

The plot of a' *vs.* a'' is an arc of a circle with its centre below the abscissa. The angle which the line joining the centre with the a_∞ point makes with the abscissa is equal to $\alpha\pi/2$. The values of τ and α can thus be determined from the Cole-Cole are plot of a' *vs.* a''.

Higasi[5] has proposed that the values of relaxation time and the distribution parameter may be determined from a measurement of a' and a'' at a single frequency in the dispersion region. The equations for τ and α are

$$\tau = \frac{1}{\omega}\left(\frac{A^2+B^2}{C^2}\right)^{1/2(1-\alpha)} \tag{4}$$

$$1 - \alpha = (2/\pi)\tan^{-1}(A/B) \tag{5}$$

where

$$\begin{aligned} A &= a''(a_0 - a_\infty) \\ B &= (a_0 - a')(a' - a_\infty) - a''^2 \\ C &= (a' - a_\infty)^2 + a''^2 \end{aligned} \tag{6}$$

For the three esters studied here, we have calculated τ and α from Eqs. (4) and (5) using the data at 9.9 GHz.

Relaxation times have also been determined by the Gopal Krishna method.[6] In this method ε' and ε'' of a solution are determined at a single frequency at many concentrations. A graph is then plotted between X and Y. The parameters X and Y are related to the observed quantities as follows:

$$X = \frac{\varepsilon' + \varepsilon''^2 + \varepsilon'' - 2}{\varepsilon''^2 + (\varepsilon'+2)^2} \tag{7}$$

$$Y = \frac{3\varepsilon''}{\varepsilon''^2 + (\varepsilon'+2)^2} \tag{8}$$

and $$X = P + \frac{1}{\omega\tau}Y, \quad \text{where } P = \frac{\varepsilon_\infty - 1}{\varepsilon_\infty + 2}.$$

The slope of the straight line plot is equal to $(1/\omega\tau)$ and thus the relaxation time τ can be determined. The distribution parameter α cannot be determined by this method.

The values of τ and α determined by the above three methods are compared in Table 2.

Discussion

The values of the distribution parameter α obtained from Cole-Cole and Higasi's method are in good agreement. In the Cole-Cole method α is evaluated from the semi-circular plot of a' *vs.* a'' (Figs. 1, 2 and 3) at different frequencies and then the most probable value of the relaxation time is calculated over the whole frequency region used, while in the Higasi method α is calculated from the slopes a', a'', a_0 and a_∞ and the value of the relaxation time is calculated at the single frequency of measurement. Since the values of the distribution parameter α calculated from both the methods are in good agreement, we can say that the values of the slopes obtained at the single frequency of observation in Higasi's method are quite accurate and hence the value of τ will also be accurate.

We have obtained, invariably, low values of relaxation time from the Gopal Krishna method. In this method, it has been assumed that the Debye equation of a single relaxation time holds good and the value of α is nearly zero. It means that this method is not applicable to the systems showing large distribution of relaxation times. It will give correct values of τ only in the case where α is zero or nearly zero, and smaller values of τ where α is large. The Gopal Krishna method does not give correct values also because the parameter P is not a constant as the concentration is changed.

The distribution of relaxation times obtained for these esters is large. It has been observed by some workers[8,9] that the distribution parameter in solution are larger than in pure liquid. In any liquid the distribution in the relaxation time is due to two basic causes. One factor is the variation in the local field about the individual molecule due to random field fluctuations; and the other is due to possible multiple relaxation processes in the molecule. The latter phenomenon depends on how the internal energy is distributed in the various possible ways of the motion of the molecule. In an actual case both these factors are significant in determining the value of the distribution parameter. In dilute solutions the distribution due to field fluctuations is small, and so if the distribution parameter in solution is large it indicates the existence of multiple relaxation processes.

The values of relaxation times are, however, not very high presumably due to the fact that the dipole-dipole interactions are reduced to a greater extent in dilute solutions. The value of the relaxation time of ethyl α-bromoisobutyrate is less than that of ethyl α-bromobutyrate, though both the compounds have nearly the same molar volume. Ethyl α-bromobutyrate has larger free volume of rotation than ethyl α-bromoisobutyrate, hence the volume swept away by ethyl α-bromobutyrate in the dipole rotation will be larger than the volume swept away by ethyl α-bromoisobutyrate. This explains the larger value of τ in ethyl α-bromobutyrate than in ethyl α-bromoisobutyrate.

One of us (Dina Nath) is thankful to the Atomic Energy Commission for financial support in the form of a Senior Research Fellowship.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2808—2811 (1970)

Radiolysis of Aqueous Solution of Potassium Periodate

S. N. BHATTACHARYYA and D. K. BARDHAN

Saha Institute of Nuclear Physics, Nuclear Chemistry Division, Acharya Prafulla Chandra Road, Calcutta-9, India

(Received March 16, 1970)

Aqueous solutions of potassium periodate in neutral medium were irradiated with X-rays and with Cobalt-60 gamma rays. It was observed that the periodate on radiolysis is reduced only to iodate and no other reduction product was detected. A mechanism for the radiation induced reduction of periodate in aqueous solution is proposed and discussed. Effect of methanol on the course of radiolysis has also been studied.

Radiation induced reduction has been studied[1] in a number of cases of oxidizing agents. It is difficult, however, to make any definite correlation between such studies. Moreover, there are systems where the effect of radiation is little understood or has not been studied at all. Iodate and periodate, though well known as classical oxidizing agents, comprise such systems where not enough studies have been made to get a clear understanding of the mechanism of the radiation induced reduction. Radiolysis of iodate in acid or alkaline solution has been studied by earlier workers.[2-4] However, no study has yet appeared on the radiolysis of periodate. Radiation induced reduction of potassium periodate in aqueous solution in neutral medium forms the subject matter of the present investigation.

Experimental

Materials. Reagents such as potassium periodate, methanol, sodium bicarbonate, potassium iodide, *etc.* used in the investigation were all of analytical grade. Triply distilled water was used for preparing solutions for irradiation.

Irradiation. Irradiation with ^{60}Co γ-rays was carried out at 29°C at the Bhabha Atomic Research Centre, Trombay. The dose rate was determined with the Fricke dosimeter taking $G(Fe^{3+})=15.5$ and measuring absorbances due to Fe^{3+} at 305 mμ. The dose rate was also determined by using ceric sulphate-sulphuric acid solutions. The Ce^{3+} yield was computed by measuring the depletion in absorbances due to Ce^{4+} at 315 mμ. The temperature dependence[5] of Ce^{3+} yield was taken into consideration and $G(Ce^{3+})$ was accordingly taken as 2.34.

Exposures to X-rays were done at the Biophysics Division of the Institute by using unfiltered X-rays in a Mullard MG 150 tube operated at 80 KV and 9 mA. Average energy of the X-ray beam at the irradiation position as determined through aluminium absorption curves was found to be 27 keV. The dose rate was again measured with the help of the Fricke dosimeter. $G(Fe^{3+})$ was, however, taken from Allen's mean curve[6] as 14.5 molecules per 100 eV. Deaeration of solutions was carried out by means of nitrogen gas containing less than 10 ppm of oxygen. The nitrogen gas, which was procured from Messrs. Indian Oxygen Limited, was washed with alkaline pyrogallol and then passed through the solutions for about half an hour.

Analytical Procedures. Periodate was determined[7] iodometrically in $NaHCO_3$ solutions. When periodate is added to iodide solution which is 1 M in $NaHCO_3$, the following reaction takes place:

$$IO_4^- + 2I^- + 2H^+ = IO_3^- + H_2O + I_2$$

Iodate was also determined iodometrically by using the usual reaction in acid medium:

$$IO_3^- + 5I^- + 6H^+ = 3I_2 + 3H_2O$$

Iodine liberated in both cases was extracted with benzene and the optical density of the benzene layer was measured spectrophotometrically at the absorption maxima, 297 mμ.

H_2O_2 was determined with the help of titanium sulfate reagent.[8] All spectrophotometric measurements were carried out in a Hilger Uvispek photoelectric spectrophotometer.

Results and Discussion

Figure 1 shows the amount of decomposition of periodate as a function of absorbed dose due to γ- or X-irradiation. It is thus observed that the amount of decomposition is linear with dose up

to an absorbed dose of about 10^{19} eV/m*l* and the radiolytic reduction yield, $G(-IO_4^-)$ was accordingly calculated from the slope. Both aerated and N_2-saturated solutions were irradiated and the decomposition yields in both cases were determined and $G(-IO_4^-)$ value was found to remain constant either in the presence or absence of dissolved oxygen.

It should be pointed out here that the radiolytic yield of the decomposition of periodate was ascertained by determining the concentration of periodate iodometrically both before and after radiolysis. In the iodometric procedure, as has already been mentioned, periodate is reduced only to iodate state, and if it is assumed that radiation induced degradation of periodate also leads to the formation of iodate only, then the molar concentration of iodate, as determined after reduction of periodate by iodide in $NaHCO_3$ medium and the removal of the liberated iodine from the system, should be equivalent to the molar concentration of periodate as taken initially before radiolysis. It is evident from Fig. 2, where the observed concentration of iodate is plotted as a function of absorbed dose, that the concentration of iodate is identical with that of initial periodate and that it remains fairly constant in the initial stages of radiolysis. When the absorbed dose, however, exceeds 60×10^{18} eV/m*l*, the observed iodate concentration is characterized by its linear decrease, which indicates that iodate is possibly undergoing radiolysis. It should also be pointed out that no periodate could be detected at such high doses, *i.e.*, all periodate ions that were present have been radiolysed. Moreover, the reduced states, such as I^- and I_2, which happen to be the characteristic products in the radiolysis of iodate, appear only at such high doses. But prior to such a limiting high dose no such reduction product could be detected. Therefore, the aforesaid linear decrease of iodate concentration with absorbed dose may in all probability be due to the radiolysis of iodate only, and if the dose corresponding to the point at which the straight line showing the linear decrease in observed iodate concentration meets on extrapolation the straight line showing its constant behavior, is taken as the point initiation of the process, then the iodate decomposition yield, $G(-IO_3^-)$, is found to have a value of 0.34 molecules per 100 eV which agrees well with our observed value in the case of radiolysis of iodate in neutral medium. However, this study on the radiolysis of iodate will, form the subject matter of a separate investigation. From what has been discussed above it can be concluded that periodate on radiolysis is reduced to iodate only.

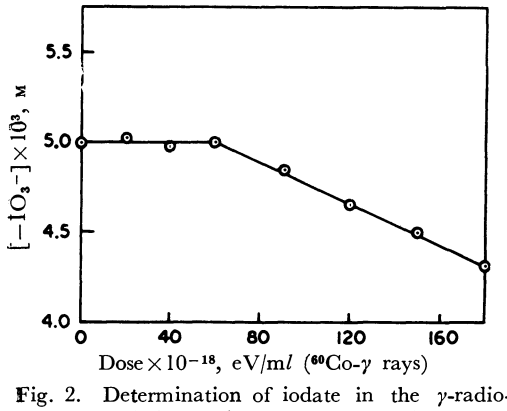

Fig. 2. Determination of iodate in the γ-radiolysed periodate solution after reduction of the periodate with KI in $NaHCO_3$ medium and removal of the liberated iodine through extraction with benzene. 5 mM KIO_4 solution was always initially taken before radiolysis.

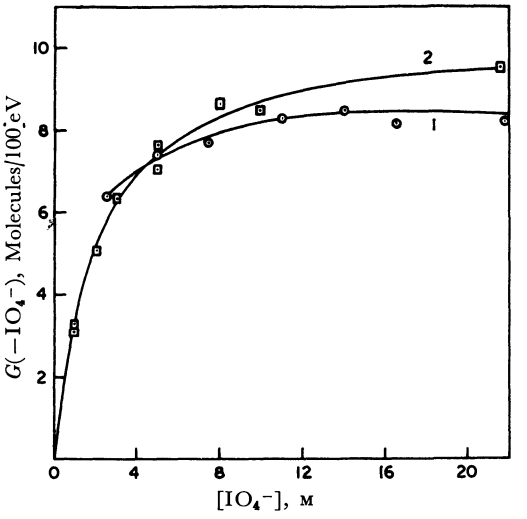

Fig. 3. Effect of initial concentration of periodate on $G(-IO_4^-)$. 1: irradiation with X-rays; 2: irradiation with ^{60}Co γ-rays.

Figure 3 shows the decomposition yield values as a function of solute concentration in cases where radiolysis is initiated by γ- or X-rays. It is evident from the figure that in the case of X-irradiation the decomposition yield, $G(-IO_4^-)$, initially increases but easily attains a steady value of 8.30 molecules per 100 eV. In the case of γ-radiolysis, however, the yields are strongly dependent on the initial concentration of periodate, and they have a tendency to attain a limiting value with increase of the solute concentration. It is therefore necessary to find the limiting G value where all the radicals generated in the solution are supposed to be swept away by the scavenger so that the stoichiometric explanation of the decomposition yields may be made easier. The limiting G value can be evaluated[9] by plotting reciprocals of G value against reciprocals of solute concentration and by extrapolating the straight line to zero reciprocal concentration. The results are shown in Fig. 4 and the limiting $G(-IO_4^-)$ value for γ-irradiation has thus been found to be 11.11 molecules per 100 eV.

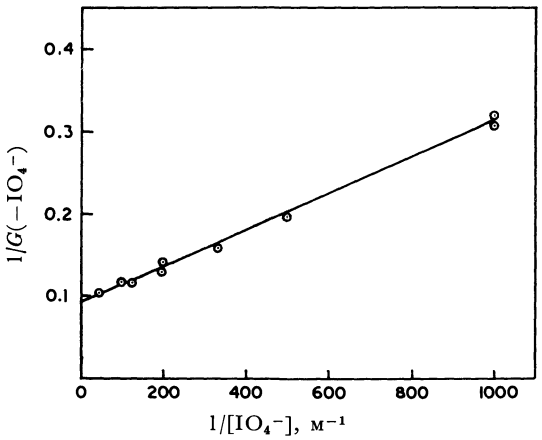

Fig. 4. Plot of the reciprocals of $G(-IO_4^-)$ against the reciprocals of $[IO_4^-]$ in case of γ-radiolysis.

It is well known [10] that water on absorption of γ-radiation gives rise to radical and molecular products as:

$$H_2O \text{ -}\!\!\wwave\!\!\rightarrow H, OH, e_{aq}^-, H_2, H_2O_2 \qquad (1)$$

and the radiolysis of a dilute aqueous solution is initiated by an attack of the solute by these radical and molecular products.

It should be pointed out that no hydrogen peroxide could be detected in the solutions after irradiation. It can therefore be presumed that hydrogen peroxide takes part in some form of reaction during radiolysis. In fact, it is known[11] that hydrogen peroxide in neutral medium reacts with periodate. Although gaseous hydrogen was not determined in the solutions after irradiation, it is assumed that such a small amount of molecular hydrogen that is formed as a result of absorption of radiation by water, will not play any important role in affecting the course of radiolytic reduction taken under consideration.

Amongst the water radiolysis products, H or e_{aq}^- has a reducing action. If it takes part in one electron reduction process in the radiolysis of periodate, unstable IO_3 will be produced and this will immediately disproportionate itself into IO_3^- and IO_4^-. In that case the observed high reduction yield cannot be accounted for. Periodate is, however, known to be reduced to iodate very easily. If, on the other hand, it is assumed that H atom reduces IO_4^- to IO_3^-, then an equivalent amount of OH radicals will be produced in the system.

Now, as regards the mode of reaction of OH radicals in the system, one is naturally immediately inclined to treat them as oxidizing entities. But since a very high reduction yield has been observed in the system, one is tempted to think that OH radicals also take part in some sort of reduction processes. If the reduction of IO_4^- by OH comprises a two-electron process, as has been assumed for H atom reaction, then IO_3^- and an equivalent amount of HO_2 radical will be produced. It has already been stated that the reduction yield is not affected by the presence or absence of dissolved oxygen, which is clearly indicative of the fact that both H and HO_2 are equally effective in reducing periodate. If HO_2 is produced in the reaction of OH with IO_4^-, it will give rise to the development of a chain reaction. But a study of the dose rate dependence on the reduction yield does not, however, conform to such a view. Another possibility is that OH may reduce by an one-electron process. Then IO_3 and an equivalent amount of HO_2^- will be produced which in turn will reduce more periodate.

In the light of the observed results the following reaction sequences together with reaction (1) may be proposed for the radiolytic mechanism, e_{aq}^- for simplicity being represented by H:

$$IO_4^- + H \rightarrow IO_3^- + OH \qquad (2)$$

$$IO_4^- + H_2O_2 \rightarrow IO_3^- + H_2O + O_2 \qquad (3)$$

$$IO_4^- + OH \rightarrow IO_3 + HO_2^- \qquad (4)$$

$$2IO_3 + H_2O \rightarrow IO_3^- + IO_4^- + 2H^+ \qquad (5)$$

$$IO_4^- + HO_2^- \rightarrow IO_3^- + OH^- + O_2 \qquad (6)$$

From the proposed mechanism it follows that the reduction yield, $G(-IO_4^-)$, at the steady state will be expressed by the relation:

9) N. Matsuura, N. Shinohara and M. Takigawa, *Sci. Papers Coll. Gen. Educ., Univ. Tokyo*, **13**, 179 (1963).
10) H. A. Schwarz, "Advances in Radiation Biology," Vol. 1, Academic Press, New York (1964), p. 1.
11) I. M. Kolthoff and P. J. Elving, "Treatise on Analytical Chemistry," Part II, Vol. 7, Interscience Publishers, New York (1961), p. 375.

$$G(-IO_4^-) = \frac{5}{2}G_H + \frac{3}{2}G_{OH} + G_{H_2O_2}$$

Taking[12] $G_H=2.80$, $G_{OH}=2.22$ and $G_{H_2O_2}=0.71$ for γ-rays, the yield is calculated to be 11.04. Taking[13] again $G_H=2.09$, $G_{OH}=1.42$ and $G_{H_2O_2}=0.98$ for X-ray induced radiolysis in neutral solution, the decomposition yield, according to the above relation, comes out to be 8.33. The observed limiting yield values in cases of γ- and X-irradiation have, however, been found to be as 11.11 and 8.30 respectively. Thus it is evident that the observed decomposition yields are in good agreement with the values calculated in terms of the yields of the primary radical and molecular products.

If radiolysis of periodate is carried out in the presence of small amounts of methanol, the periodate decomposition yield is found to be significantly large. When methanol is present during radiolysis, the OH radicals will naturally compete for both CH_3OH and IO_4^- ions. By the reaction of OH with CH_3OH another reducing radical, CH_2OH, will be produced which in turn may reduce more periodate.

$$CH_3OH + OH \rightarrow CH_2OH + H_2O \quad (7)$$

$$IO_4^- + CH_2OH \rightarrow IO_3^- + CH_2O + OH \quad (8)$$

Any possibility that formaldehyde that is produced in reaction (8) may react with undecomposed periodate in neutral medium has been tested separately, but no such reaction within the concentration limits of the present investigation could be detected. Radiolysis of periodate in the presence of methanol will then comprise the reactions (1) through (8) and the reduction yield will accordingly be expressed by the relation:

$$G(-IO_4^-) = \frac{5}{2}G_H + \frac{3}{2}G_{OH} + G_{H_2O_2} \div (G_H \div G_{OH})\frac{K_7[CH_3OH]}{K_4[IO_4^-]}$$

13) Ref. 1, p. 58.

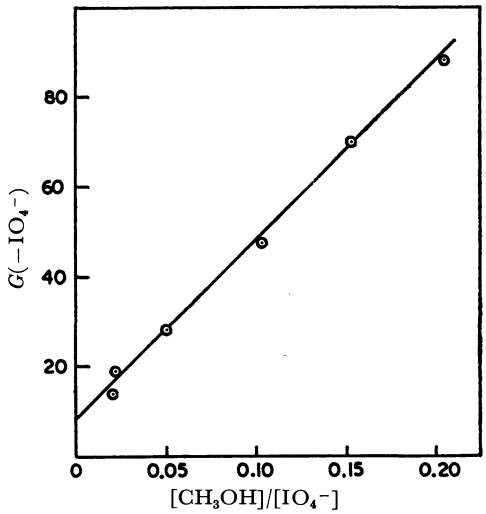

Fig. 5. Effect of methanol on X-ray induced radiolysis of potassium periodate in deaerated neutral solution.

A plot of $G(-IO_4^-)$ against $[CH_3OH]/[IO_4^-]$ will therefore yield a straight line. As has been stated previously, the intercept in case of the X-ray induced radiolysis will be equal to 8.33. Figure 5 shows the variation in the radiolytic decomposition yields with the ratios of the concentrations of methanol and periodate in the medium. A smooth straight line is thus obtained with an intercept of 8.3 which agrees well with the calculated value. This confirms the assumed kinetic behaviour in the proposed radiolytic mechanism. From the slope, the ratio of the rate constants K_7/K_4 is found to be 1.12×10^2.

The authors are grateful to Professor B. C. Purkayastha of this Division for discussion and encouragement and to Dr. S. B. Bhattacharjee of the Biophysics Division for the facilities of irradiation with X-rays. For the irradiation facilities with cobalt-60 gamma rays the authors are highly indebted to the Bhabha Atomic Research Centre, Trombay.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2812—2815 (1970)

Spectrophotometric Determination of Mercury(II) by Solvent Extraction with Variamine Blue B*[1]

Masahiro TSUBOUCHI

Faculty of Education, Tottori University, Tottori

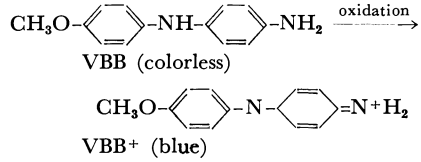
(Received February 5, 1970)

A new rapid, sensitive and selective method is proposed for the spectrophotometric determination of a trace of mercury(II) by solvent extraction. The method is based on the formation of an ion-pair complex between the tribromo-mercury(II) complex anion and the dyestuff cation obtained by oxidation of variamine blue B. The optimum pH range for the color reaction is 2.5—4. The blue complex can be extracted into nitrobenzene and has a maximum absorption at 605 mμ in the organic solvent. Beer's law holds in the range $3.2\times10^{-6}-2.2\times10^{-5}$ M of mercury(II) in the aqueous layer before the extraction, with a molar absorptivity of 4.03×10^{4} $mol^{-1}cm^{-1}$ l at 605 mμ. The color reaction is instantaneous and the complex remains stable 15 mintes in the nitrobenzene layer. Of the 22 cations and 11 anions examined, tin(II), tin(IV), antimony(III), iodide, cyanide, and thiocyanate showed serious interferences.

Many investigations[1] have been made on the spectrophotometric determination of mercury(II). The standard method based on the reaction with dithizone has been considered unsatisfactory because of its extreme sensitivity to variations in laboratory conditions, while the diphenylcarbazone method has serious drawbacks because of its extreme sensitivity to changes in acidity. A spectrophotometric method using thiocyanate has also been reported.[2] The method is limited by interference of halide and pseudohalide ions as well as such as silver.

Recently, rhodamine B,[3] phthalein complexone[4] and xylenol orange[5] were described as spectrophotometric reagents for mercury(II). The methods are sensitive, but suffer from a number of interferences. Another method based on the complex formation between mercury(II) ions and iodide ions has been described by Pappas and Powell.[6] A molar absorptivity of about 2.34×10^{4} is claimed. 2,2′-dipyridyl-iron(II) chelate[7,8] was proposed for the spectrophotometric determination of mercury(II) by solvent extraction. Although this method is more reliable than the dithizone method, it is not sufficiently sensitive. The method proposed here has even greater sensitivity than the above techniques which have employed iodide ions or 2,2′-dipyridyl-iron(II) chelate.

Variamine blue B[9,10] (VBB) is known to be oxidized to form the blue dyestuff cation (VBB^+) as follows:



The tribromo-mercury(II) complex anion can be extracted into nitrobenzene with the VBB^+. This system was studied in detail to establish a method for the determination of mercury(II).

Experimental

Apparatus. Absorbance measurements were made using a Shimadzu Beckman Model QR-50 spectrophotometer with matched 1 cm quartz cells. A Toa Denpa Model HM-5A pH meter was used for pH measurements. An Iwaki Model KM shaker was used for the

extraction.

Reagents. Guaranteed grade of mercuric chloride was dissolved in dilute sulfuric acid and diluted with deionized water to a concentration of 1.0×10^{-3} M of mercury(II). This standard solution was then diluted to the concentration required for the experiments.

Variamine blue B (VBB) solution, 10^{-3} M, was prepared by dissolving variamine blue B hydrochloride in deionized water.

A buffer solution was made 0.2 M from reagent grade sodium citrate and dilute sulfuric acid.

All the other reagents of a reagent grade were used without further purification.

Recommended Procedure. A solution was prepared by pipetting 2 m*l* of 0.1 M potassium bromide solution, 7 m*l* or less of a sample solution containing less than 0.016 g of mercury(II) per liter, 5 m*l* of 0.2 M citrate buffer solution (pH 2.9), 2 m*l* of 10^{-3} M VBB solution, and 2 m*l* of 0.1 M ammonium persulfate solution into 100-m*l* separatory funnel. This solution was brought to 25 m*l* with water. After adding 10 m*l* of nitrobenzene to the separating funnel, the contents were mixed thoroughly by a shaker for about one minute. After standing for five minutes, the nitrobenzene layer was drawn off into a glass tube with a glass stopper containing about 1 g of anhydrous sodium sulfate, and shaken to remove droplets of water. The absorbance of the extract is measured immediately at 605 mμ against a reagent blank or nitrobenzene.

Results and Discussion

Absorption Spectra. The absorption spectra shown in Fig. 1 were obtained for 0 and 1.6×10^{-5} M of mercury(II) solution through the recommended procedure. The presence of mercury(II) leads to a considerable increase in the absorbance (curve 1). The curve has a maximum value at 600 mμ. The absorbance maximum of the reagent blank (curve 2) in the nitrobenzene was at 500 mμ. The shift in the organic layer may be attributed to the effect of the association between the dyestuff cation and the complex anion. The maximum difference in the absorbance between curves 1 and 2 is found at 605 mμ. The absorbance is propotional the mercury(II) concentration at this wavelength.

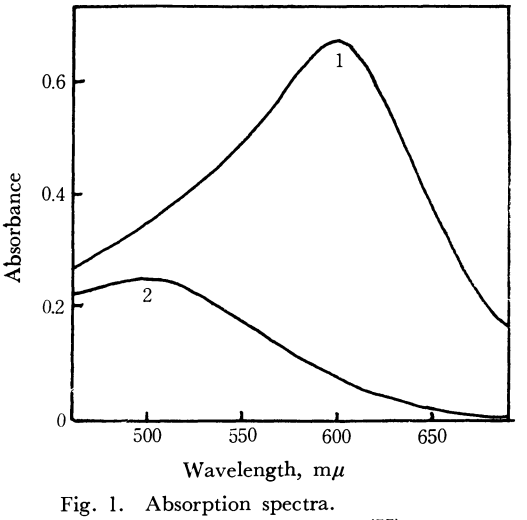

Fig. 1. Absorption spectra.
1: 1.6×10^{-5} M of Mercury(II)
2: Reagent blank
Reference: Nitrobenzene

Effect of pH. Figure 2 shows the typical pH dependence of the extraction system. The study was made by extracting 1.6×10^{-5} M of mercury(II) through the recommended procedure. The optimum pH was from 2.5 to 4.0. The pH of the solution was adjusted to 2.9 in this work.

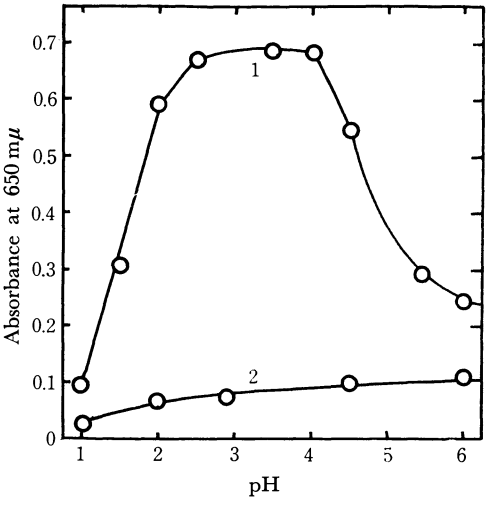

Fig. 2. Effect of pH.
1: 1.6×10^{-5} M of mercury(II)
2: Reagent blank
Reference: Nitrobenzene

A sodium citrate buffer was effective in keeping the solution at pH 2.9 as well as in masking metal ions. When the citrate concentration was less than 0.01 M in the aqueous layer, it took too long to separate the two layers. 0.01—0.08 M of citrate had no influence on the absorbance of the extract. At pH 2.9 no citrate-mercury(II) complex formation was apparent from this experiment.

Solvent for Extraction. Several organic solvents have been examined for their ability to extract the bromo-mercury(II)-dyestuff ternary complex. The solvents investigated were benzene, butyl acetate, carbon tetrachloride, chloroform, cyclohexane, 1,2-dichloroethane, ether, ethyl acetate, *n*-hexane, isoamylalcohol, methyl isobutyl ketone, monochlorobenzene, nitrobenzene, and toluene. Among the solvents tested, only nitrobenzene was capable of extracting the complex while in the other cases a blue precipitate was slightly observed at the interface.

Effect of Reagents. In aqueous solution the tribromo-mercury(II) complex anion is in equilibrium with the mercury bromide and tetrabromo-

mercury(II) complex anion. The distribution of the tribromo-mercury(II) concentration in the 8×10^{-3} M of potassium bromide is about 60%, from the formation constant ($\log\beta_1$: 9.05, $\log\beta_2$: 17.3, $\log\beta_3$: 19.7, $\log\beta_4$: 21.0). The absorbance in the nitrobenzene layer of a series of 1.6×10^{-5} M mercury(II) solution remained unchanged when the potassium bromide concentration was varied from 1.0×10^{-3} to 1.6×10^{-2} M. Mercury(II) seemed to be extracted as tribromo-mercury(II) through the equilibrium shift against the changes of bromide concentration.

Several kinds of oxidizing agents were tested to obtain the colored dyestuff cation. They were ferric sulfate, hydrogen peroxide, ammonium persulfate, potassium permanganate, ceric sulfate, potassium dichromate, manganic sulfate, potassium bromate, potassium iodate, calcium hypochlorite, chloramine T, and iodine. Of these, ammonium persulfate was chosen for the present work because it is the most effective in oxidizing the VBB and gives a lower absorbancy of the reagent blank. Maximum and constant color development required about a 5-fold molar excess of the ammonium persulfate to the VBB concentration. 2 m*l* of 0.1 M ammonium persulfate solution used in this work supplies the oxidizing reagent in a ratio of 100 to 1 against the 8×10^{-5} M of VBB.

Samples containing 1.6×10^{-5} M of mercury(II) were treated by the recommended procedure, except that the concentration of VBB was varied. Maximum color development in the nitrobenzene layer required more than about a 3-fold molar excess of VBB to mercury(II). 2 m*l* of 10^{-3} M VBB solution used in the procedure supplies a ratio of 5 to 1 if the sample contains 1.6×10^{-5} M of mercury(II).

Other Variable. In order to confirm complete extraction with nitrobenzene, a sample containing 1.6×10^{-5} M of mercury(II) was treated according to the procedure. The first extraction yielded an absorbance of 0.605 using a reagent blank as a reference. The aqueous solution was then extracted with another 10 m*l* portion of nitrobenzene. The measured absorbance of this organic layer was 0.003 against a reagent blank. From this experiment, it seems that the extraction rate using 10 m*l* of nitrobenzene is not less than 95%.

The stability of the color of the extracted organic layer was studied. Little or no error will be introduced if the absorbance is measured within fifteen minutes after extraction. After an hour, the absorbance decreased by 6.3%.

Color development in the nitrobenzene layer varied with the shaking time. For the condition in the present work, full color development took about thirty seconds. Continued shaking up to five minutes produced no further change in absorbance.

Calibration and Reproducibility. The system followed Beer's law in the range 3.2×10^{-6}—2.2×10^{-5} M of mercury(II). The molar absorptivity can be calculated to be 4.03×10^{4} $mol^{-1}\,cm^{-1}l$.

Ten identical samples, each with a final mercury(II) concentration of 1.6×10^{-5} M, were treated and their absorbance were measured at 605 mμ using a reagent blank as a reference. The mean absorbance was 0.605, with a standard deviation of 0.007 absorbance unit.

Method of Continuous Variations. In order to investigate the structure of this colored complex, continuous variations plots were employed. The total concentration of mercury(II) plus VBB was 4×10^{-5} M. The continuous variations plots at 605 mμ and 560 mμ have a maximum 0.5 mole fraction of mercury(II), indicating a 1 to 1 mercury(II)-VBB ratio. The overall molar ratio of the mercury(II) : bromide : VBB is 1 : 3 : 1, and its formula can be suggested as $VBB^{+}\cdot[HgBr_3]^{-}$.

Effect of Diverse Ions. The effect of diverse ions was studied for a sample containing 1.6×10^{-5} M of mercury(II). The tolerance to a given ion was defined as the maximum concentration which could be present without causing a deviation of 0.025 for the absorbance of the sample. Tolerances for diverse ions tested are listed in Table 1. Anions were added as solutions of their sodium, potassium or ammonium salts. Cations were added as solutions of their chlorides or sulfates. The citrate used as a buffering agent is also useful.

Table 1. Effect of diverse ions

Ion	Tolerance (M)	Ion	Tolerance (M)
Ag^{+}	1×10^{-3}	Sn^{2+}	5×10^{-7}
Al^{3+}	2×10^{-3}	Sn^{4+}	1×10^{-6}
Ba^{2+}	5×10^{-3}	Th^{4+}	1×10^{-4}
Be^{2+}	5×10^{-3}	Tl^{+}	1×10^{-4}
Bi^{3+}	2×10^{-4}	Zn^{2+}	5×10^{-3}
Ca^{2+}	5×10^{-3}	CH_3COO^{-}	2×10^{-3}
Cd^{2+}	5×10^{-4}	SO_4^{2-}	5×10^{-3}
Co^{2+}	1×10^{-3}	F^{-}	5×10^{-3}

Nickel(II) Complexes of Ethylenediaminemonoacetic Acid (EDMA). The Preparation and Thermal Decomposition of Nickel(II)-EDMA Complexes

Yuki FUJII

Department of Chemistry, Ibaraki University, Bunkyo-cho, Mito, Ibaraki

(Received March 4, 1970)

The following nickel(II) complexes containing ethylenediaminemonoacetate anion(s) (edma) were newly prepared from an aqueous solution containing nickel(II) ion and edma: $[Ni(edma)(H_2O)_3]X$ (X=Cl and Br), $[Ni(edma)I]_4$, and $[Ni(edma)_2]\cdot 2H_2O$. By the thermal decomposition of $[Ni(edma)(H_2O)_3]X$, $[Ni(edma)X]_4$-type complexes (X=Cl and Br) were also prepared. By absorbing three molecules of water in an atmosphere, two new, mixed complexes containing a halogen anion and water molecule(s), $[Ni(edma)Cl(H_2O)_2]\cdot H_2O$ and $[Ni(edma)Br(H_2O)]_2\cdot 4H_2O$ (dimer), were prepared from $[Ni(edma)X]_4$. By the measurements of the absorption spectra, the magnetic moments, and the dehydrations, their structures were all assigned to octahedral. The $[Ni(edma)X]_4$ complexes (X=Cl, Br and I) were presumed to have the tetramer structure, where four halogen anions are triply bridged to the nickel(II) ion. The difference between the $[Ni(edma)(H_2O)_3]X$, $[Ni(edma)Cl(H_2O)_2]\cdot H_2O$, and $[Ni(edma)Br(H_2O)]_2\cdot 4H_2O$ complexes were clearly observed on the basis of their derivatographic behavior. The mechanisms of the dehydrations were also discussed.

In the previous paper, the stability constants of nickel(II)-EDMA complexes with 1-to-1 and 1-to-2 compositions were reported.[1] From the spectrophotometric evidence, it was concluded that the formation of a mixed complex containing chloride ions could be ruled out in an aqueous solution. This conclusion is reasonable because it is known that the formation constant of a nickel(II)-hexaquo complex with chloride ions is very small.[2] However, it can not always be said that the information obtained by the solution equilibrium study safely holds for solid-state chemistry. Therefore, in order to obtain much information concerning the complex formation reaction, it would be necessary to prepare the complexes and characterize them.

In these circumstances, in order to obtain information on mixed nickel(II)-EDMA complexes containing halogen anions and in order to compare the properties in the solution state and those in the solid state, the preparation and thermal decomposition of nickel(II)-EDMA complexes were examined.

Experimental

Preparation of the Complexes. *1) Ethylenediaminemonoacetatotriaquonickel(II) Chloride,* [Ni(edma)-

1) M. Kodama, Y. Fujii and T. Ueda, This Bulletin, **43**, 2085 (1970).

2) L. G. Sillén and A. E. Martell, "Stability Constants of Metal-Ion Complexes," The Chemical Society, London (1964), p. 282.

$(H_2O)_3]Cl$ (I). To an aqueous solution containing 2.4 g (0.01 mol) of nickel(II) chloride hexahydrate, 2.5 g (0.012 mol) of ethylenediaminemonoacetic acid dihydrochloride monohydrate (EDMA·2HCl·H_2O)[3] were added, and the solution was warmed at 70—80°C. After adjusting the solution's pH to 6—7 by adding sodium bicarbonate, the resulting solution was concentrated to about 15 m*l*. Three or four volumes of alcohol were then added to the solution, and the resulting solution was cooled to 0°C for a day. Light blue crystals were separated out. They were recrystallized from water-alcohol. Yield, about 2.0 g (75%). Found: C, 18.81; H, 5.93; N, 10.97; H_2O, 20.6%. Calcd for $C_4H_{15}NiN_2O_5Cl$: C, 18.55; H, 5.62; N, 10.67; H_2O, 20.37%.

2) Tetramer of Ethylenediaminemonoacetatochloronickel(II), $[Ni(edma)Cl]_4$ (II). The complex I was heated at about 180°C for half an hour. A light green powder was thus obtained. This complex was cooled and preserved in a desiccator with silica gel. Found: C, 22.41; H, 4.26; N, 12.58%. Calcd for $C_4H_9NiN_2O_2Cl$: C, 22.11; H, 4.18; N, 12.89%.

3) Ethylenediaminemonoacetatochlorodiaquonickel(II) Monohydrate, $[Ni(edma)Cl(H_2O)_2]\cdot H_2O$ (III). The complex II was allowed to stand in an atmosphere for two or three days at room temperature. The color thus changed gradually from light green to light blue. Found: C, 18.40; H, 5.92; N, 10.44; H_2O, 20.2%. Calcd for $C_4H_{13}NiN_2O_4Cl\cdot H_2O$: C, 18.55; H, 5.62; N, 10.67; H_2O, 20.37%.

4) Ethylenediaminemonoacetatotriaquonickel(II) Bromide, $[Ni(edma)(H_2O)_3]Br$ (IV). To an aqueous solution of the complex I (7 g, 0.0264 mol), an aqueous solution of silver nitrate (5.1 g, 0.03 mol) was added. The silver chloride which resulted was filtered off, and then potassium bromide (9.4 g, 0.07 mol) was added to the filtrate. The precipitate of silver bromide was filtered off, and the resulting solution was concentrated to about 15 m*l*. Three or four volumes of alcohol were added to the solution, which was then cooled to 0°C for a day. After filtering off the potassium bromide thus precipitated, the filtrate was concentrated to a volume of about 25 m*l*. When it was cooled to 0°C, light blue crystals were separated out. They were recrystallized from water-alcohol. Yield, about 5 g (61%). Found: C, 15.75; H, 4.78; N, 9.27; H_2O, 17.7%. Calcd for $C_4H_{15}NiN_2O_5Br$: C, 15.51; H, 4.89; N, 9.04; H_2O, 17.45%.

5) Tetramer of Ethylenediaminemonoacetatobromonickel(II), $[Ni(edma)Br]_4$ (V). This compound was prepared from the complex IV by the same way as was employed for the complex II. Found: C, 18.58; H, 3.77; N, 10.49%. Calcd for $C_4H_9NiN_2O_2Br$: C, 18.35; H, 3.47; N, 10.70%.

6) Bis(ethylenediaminemonoacetato)diaquo-μ-dibromodinickel(II) Tetrahydrate, $[Ni(edma)Br(H_2O)]_2\cdot 4H_2O$ (VI). This compound was prepared from the complex V in the same manner as has been described for the complex III. Found: C, 15.92; H, 4.44; N, 9.45; H_2O, 17.1%. Calcd for $C_4H_{11}NiN_2O_3Br\cdot 2H_2O$: C, 15.51; H, 4.89; N, 9.04; H_2O, 17.45%.

7) Tetramer of Ethylenediaminemonoacetatoiodonickel(II), $[Ni(edma)I]_4$ (VII). An aqueous solution of the complex I (7 g, 0.0264 mol) was treated with a silver nitrate solution. After filtering off the silver chloride thus precipitated, potassium iodide was added to the filtrate. The resulting solution was treated in the same manner as in the case of the complex IV. When the alcoholic solution was then concentrated to about 30 m*l* and allowed to stand for a day, light green crystals were separated out. They were washed with 50% alcohol. Yield, about 2 g (24%). Found: C, 15.76; H, 2.92; N, 9.47%. Calcd for $C_4H_9NiN_2O_2I$: C, 15.56; H, 2.94; N, 9.08%.

8) Bis(ethylenediaminemonoacetato)nickel(II) Dihydrate, $[Ni(edma)_2]\cdot 2H_2O$ (VIII). To an aqueous solution of nickel(II) chloride hexahydrate (2.4 g, 0.01 mol), 8.4 g (0.08 mol) of ethylenediaminemonoacetic acid dihydrochloride monohydrate were added. The solution was warmed to about 80°C, and the solution's pH was adjusted to 10—11 by adding a 6 N sodium hydroxide solution. The resulting solution was concentrated to about 10 m*l*. The sodium chloride thus precipitated was filtered off. About 60—70 m*l* of alcohol were added to the filtrate, and the resulting solution was allowed to stand in a refrigerator for 2—3 weeks. Blue crystals could thus be separated out. They were washed with 80% alcohol. Yield, about 1.0 g (34%). Found: C, 29.39; H, 6.91; N, 16.94%. Calcd for $C_8H_{18}NiN_4O_4\cdot 2H_2O$: C, 29.20; H, 6.75; N, 17.03%.

Measurements. The visible and far-infrared absorption spectra of aqueous solutions were recorded on a Hitachi EPS-3 pen-recording spectrophotometer. The reflection spectra were measured with a Hitachi Perkin-Elmer 139 spectrophotometer with a standard Hitachi reflection attachment. The infrared absorption spectra were taken on Nujol mulls between sodium chloride or on potassium bromide disks using a Hitachi EPI-S2 spectrometer. The TGA, DTA, and DTG curves were automatic-photographically recorded with a single sample by means of a Metrimpex Derivatograph, type-OD-102. The magnetic susceptibility was determined with a Gouy balance at room temperature. The elemental analyses were performed by the conventional combustion method, using a Yanagimoto C.H.N. Corder, MT-1.

Results and Discussion

IR Spectra. The infrared absorption spectra were measured in order to confirm whether or not the carboxylate group was coordinated to the nickel(II) ion. All the spectra of the complexes showed the νCOO-Ni band in the range from 1585 to 1660 cm^{-1} (Table 1). Therefore, it is clear

Table 1. Infrared absorption spectra (in cm^{-1}) and mangetic moments

Complex	νCOO-Ni asym. str.	νN-H def.	μ (B.M.)
I	1645	1575	3.26
II		1585 (overlapped)	3.26
III	1650	1570	3.27
IV	1645	1570	3.08
V		1585 (overlapped)	3.15
VI		1585 (overlapped)	3.06
VII		1605 (overlapped)	3.10
VIII	1660	1575	3.06

3) Y. Fujii, E. Kyuno and R. Tsuchiya, This Bulletin, **43**, 786 (1970).

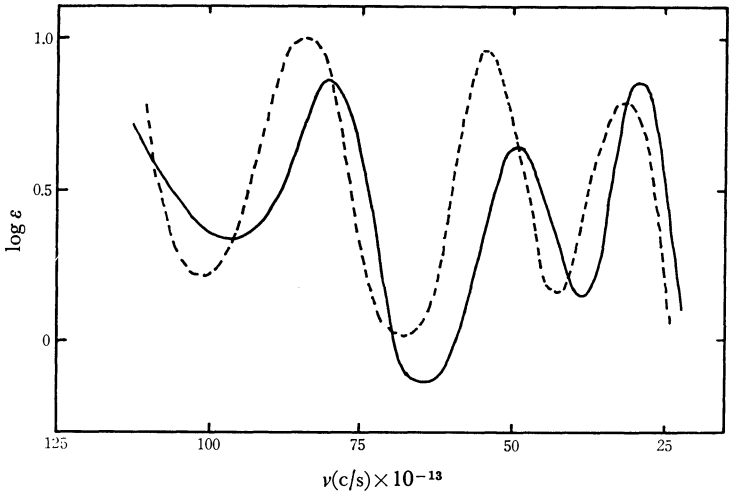

Fig. 1. Absorption spectra: complexes I and IV (——), VIII (----).

that the carboxylate group is coordinated to the nickel(II) ion.[4] In the cases of the complexes II, V, VI, and VII, the νCOO–Ni band is shifted to lower energy sites than those of the other complexes. This fact may indicate that the COO–Ni bonds of the complexes II, V, VI, and VII are slightly weakened as compared with those of the other complexes because of the distortion of their structures. On the other hand, the complexes I, III, IV, and VIII, in which they take the monomer structure, showed the νCOO-Ni band at higher energy sites than those of the complexes II, V, VI, and VII. Therefore, though it is difficult to distinguish the difference in the structure between the complexes III and VI on the basis of their absorption spectra (shown in the next paragraph), it can be suggested from their clearly different νCOO–Ni bands that the complex VI has a different structure than the complex III.

Electronic Spectra. The absorption spectra in an aqueous solution and those obtained by the diffuse-reflectance method are shown in Figs. 1, 2, and 3. The numerical values are summarized in Table 2, together with those of the related compounds.

The spectra of the complexes I and IV in an aqueous solution are similar to those which are characteristic for the octahedral Ni–N_2O_4-type complexes.[5] The aqueous solutions of the complexes I and IV were adsorbed by a cation exchanger, but not by an anion exchanger. Therefore, in an aqueous solution, the complexes I and IV must be cationic and the coordination of the halogen anion to the nickel(II) ion can be ruled out. This result agrees well with the finding obtained in the previous study.[1] In the solid state,

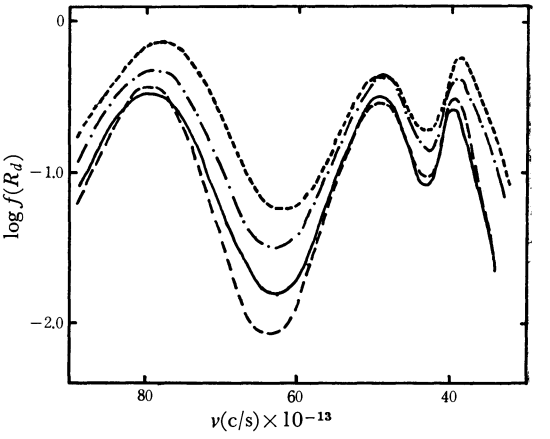

Fig. 2. Absorption spectra by the diffuse-reflectance method: I (——), III (—·—·—), IV (— — —), VI (----).

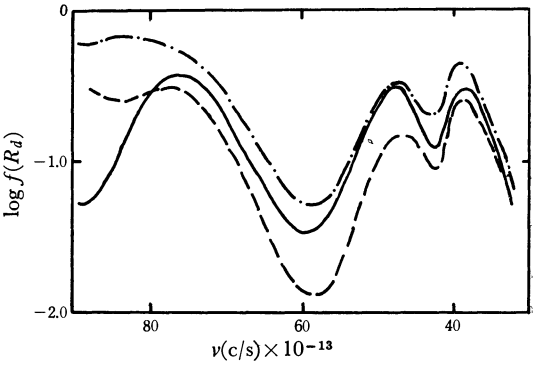

Fig. 3. Absorption spectra by the diffuse-reflectance method: II (——), V (—·—·—), VII (———).

the diffuse-reflectance spectra of the complexes I and IV also show spectra similar to those in an aqueous solution, although the peak near 30×

$[Ni(gly)_2(H_2O)_2]$[5]	80.8 (0.90)	48.8 (0.68)	29.3 (0.85)
$[Ni(en)_2(H_2O)_2](ClO_4)_2$[5]	84.0 (1.02)	54.8 (0.81)	33.4 (0.85)

The frequency is given in 10^{13} sec^{-1}.
* Data by the diffused-reflectance method, ( ) is the value of $\log f(R_d)$.

10^{13} c/s observed in an aqueous solution shifts to a shorter wavelength. Though there is a possibility that the halogen anion coordinates to the nickel(II) ion in the case of the solid state, this can be safely ruled out on the basis of the facts that the complexes in which the halogen anion is coordinated to the nickel(II) ion can be isolated by another method (the complexes III and VI) and that the behavior of the dehydration, as measured by the derivatograph, is clearly different between the complexes I, IV and III, VI. Therefore, the complexes I and IV can be concluded to have an octahedral structure, $[Ni(edma)(H_2O)_3]X$ (X= Cl and Br), where three molecules of water are all coordinated to the nickel(II) ion, in both an aqueous solution and a solid crystal.

The reflectance spectra of the complexes II, V, and VII show three peaks with nearly the same intensities in the visible and far-infrared regions. Their magnetic-moment data indicate that their structures are octahedral or tetrahedral (Table 1). If these complexes have a tetrahedral structure, only one peak would be expected in this absorption region.[6-8] The existence of three peaks with nearly identical intensities can, then, be thought to be characteristic of the octahedral nickel(II) complexes.[5] Therefore, on the basis of absorption spectra, the structures of the complexes II, V, and VII can be identified as octahedral.

The reflectance spectra of the complexes III and VI are nearly identical with those of the complexes I and IV, except that all the peaks of the complexes III and VI are shifted to slightly lower energy sites than the peaks of the complexes I and IV. This is thought to be due to the coordination of the halogen anion. Therefore, an octahedral structure can be assigned to them. These explanations were confirmed by the behavior of their dehydrations. The details will be discussed in the next paragraph. Here, it is enough to note that the difference in the coordination between one molecule of water and one molecule of the halogen anion (Cl^- and Br^-) do not show any considerable difference in their absorption spectra.

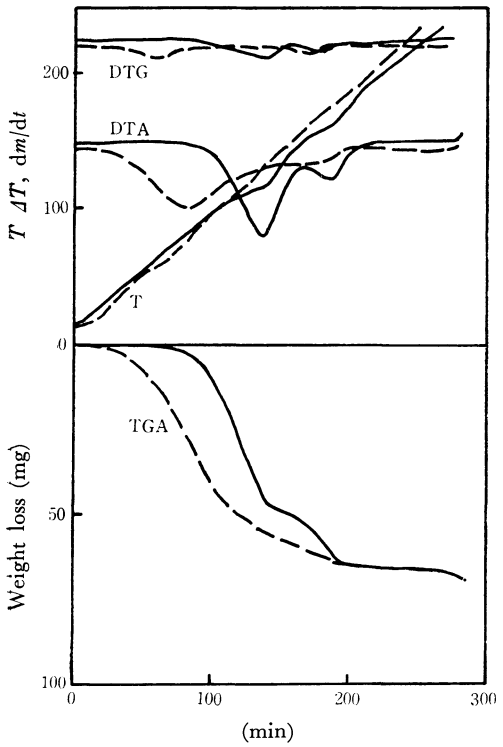

Fig. 5. Derivatogram of IV (——) and VI (— — —). The starting weight of sample is 400 mg.

The 1-to-2-ratio complex, VIII, shows a spectrum similar to those of Ni–N_4O_2-type complexes.[5] Therefore, an octahedral structure can be assigned to the complex VIII, although the configuration of the coordinated edma is not clear in detail.

Derivatogram and Magnetic Moments. From the TGA, DTA, and DTG curves[9] (Figs. 4 and 5), it was observed that two molecules of water dehydrated from 110°C to 140°C, and another molecule of water, from 140°C to 175°C, for the complex I. On the other hand, in the case of the complex III, one molecule of water dehydrated from a very low temperature (from about 50°C to 110°C), and other two molecules of water, from 110°C to 175°C. These facts indicate that the structure of the complex I is clearly different from that of the complex III. The low temperature of the dehydration of one molecule of water for the complex III can be ascribed to the dehydration of crystalline water. Therefore, the structure of the complex III can be presumed to be $[Ni(edma)Cl(H_2O)_2]\cdot H_2O$, where the chloride ion is coordinated to the nickel(II) ion, and the structure of the complex I to $[Ni(edma)(H_2O)_3]Cl$, where the three molecules of water are all coordinated to the nickel(II) ion. The high temperature of the dehydration of one molecule of water for the complexes I and III may suggest that the dehydration proceeds through the intermediate of the dimer structure in which two molecules of the chloride ion are bridged to the nickel(II) ion as is shown in Fig. 6 (A). Further information which gives strong support to the explanation presented above was obtained by the dehydration of the complex IV. The difference in the dehydration between two molecules of water (from 80°C to 125°C) and one molecule of water (from 125°C to 175°C) is clearly distinguished in the case of the complex IV. The high temperature of the dehydration of the last molecule of water clearly indicates that the dehydrations proceed through the intermediate of the dimer structure in which two bromide ions are bridged and in which the two molecules of water are coordinated to the nickel(II) ions, as is shown in Fig. 6 (A).

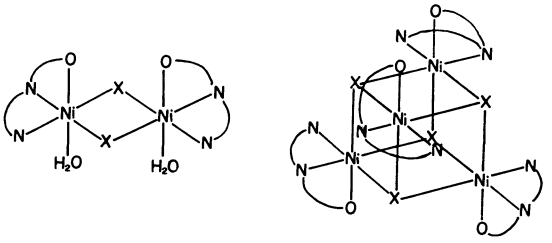

Fig. 6. The probable structure of the dimer and tetramer structures.
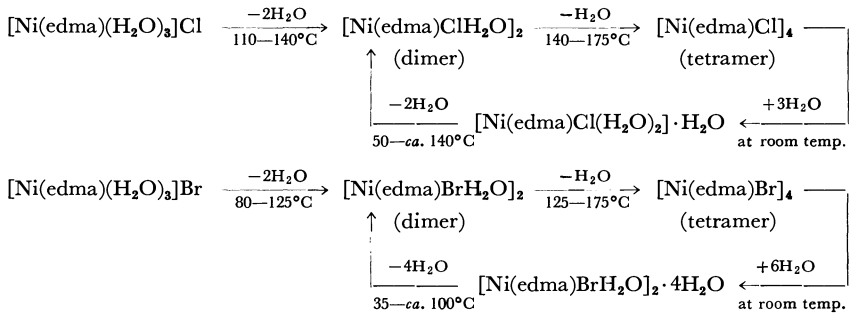
A: $[Ni(edma)X(H_2O)]_2$ (X=Cl and Br)
B: $[Ni(edma)X]_4$ (X=Cl, Br and I)

On the other hand, in the case of the complex VI, the dehydration of two molecules of water takes place from a very low temperature (from 35°C to about 100°C) compared with the case of the complex IV, and the last molecule of water dehydrates from about 100°C to 175°C. The low temperature of the dehydration of the two molecules of water is ascribed to two molecules of crystalline water. Therefore, the structure of the complex VI is assigned to the dimer of $[Ni(edma)Br(H_2O)]\cdot 2H_2O$, where the bromide ion is bridged. This assignment agrees well with the suggestion of the IR spectra that the complex VI may take a different structure from that of the complex III.

The values of the effective magnetic moment of the complexes are listed in Table 1. All the complexes show values near 3.10 B.M. These values suggest that all the complexes have an octahedral structure, for the nickel(II) complexes with a tetrahedral structure have been established generally to have the effective magnetic moments from 3.50 to 4.00 B.M.[10]

9) R. Tsuchiya, Y. Kaji, A. Uehara and E. Kyuno, This Bulletin, **42**, 1881, 1886 (1969).

10) D. M. L. Goodgame, M. Goodgame and F. A. Cotton, *J. Amer. Chem. Soc.*, **83**, 4161 (1961).



Scheme 1. The mechanism of dehydrations.

On the basis of these results and discussions, as the structure of the complexes II, V, and VII, tetramer in which the four halogen anions are triply bridged to the four nickel(II) ions may be considered reasonable (Fig. 6 (B)). Here, it is established that two nitrogen atoms and one oxygen atom of edma coordinate to the nickel(II) ion, making a facial form.

As the mechanism of the dehydration process, the above scheme can be proposed (Scheme 1).

The author wishes to express his deep thanks to Professor R. Tsuchiya and his co-workers of Kanazawa University for their kind help in measurements using the Derivatograph. He also wishes to thank Professor K. Yamamoto and Dr. M. Kodama of Ibaraki University for their encouragement.

Anodic Process of Thiosulfate at a Dropping Mercury Electrode

Teisuke MURAYAMA, Toshiko SAWAKI and Shukichi SAKURABA

Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu

(Received March 13, 1970)

In the anodic process of thiosulfate at a dropping mercury electrode, the formation of a species $Hg(S_2O_3)_3^{4-}$ is considerable even in dilute solution. An equation of current-potential curve is derived with proper consideration for the formation of the species. The successive stability constant of $Hg(S_2O_3)_3^{4-}$ was calculated to be 3×10^2 (at 25°C and an ionic strength of 0.2) by comparing the equation with experimental results.

A few decades ago, Kolthoff and Miller showed that the anodic wave of thiosulfate at a dropping mercury electrode (DME) corresponds to the formation of a complex ion $Hg(S_2O_3)_2^{2-}$.[1] More recently Nyman and Salazar investigated the same process.[2] They found that although a plot of $\log i/(i_d-i)^2$ *vs.* E gave a straight line its reciprocal slope did not remain constant. The slope increased from 30 to 41 mV when the concentration of thiosulfate increased from 2×10^{-4} to 5×10^{-3} M. They attributed the slope increase to the formation of a species $Hg(S_2O_3)_3^{4-}$, which invalidated Eq. (9) in the paper by Kolthoff and Miller. Nyman and Salazar applied DeFord-Hume's method to evaluate stability constants of $Hg(S_2O_3)_2^{2-}$ and $Hg(S_2O_3)_3^{4-}$ from the observed shift in half-wave potential. However, they did not mention whether calculated values of constants were consistent with the behavior of the slope of the plot or not. In the following we have examined the relationship between the reciprocal slope of log plot and stability constants of the complex ions.

Results and Discussion

The potential of the dropping mercury electrode, E, may be written as

$$E = E^0 + \frac{RT}{2F}\ln\gamma_1 + \frac{RT}{2F}\ln[Hg^{2+}] \qquad (1)$$

where E^0 is the standard potential of mercuric-mercury electrode, γ_1 is the activity coefficient of mercuric ion, and R, T, and F are molar gas constant, absolute temperature, and Faraday, respectively. Square brackets indicate the concentration at the surface of DME. Mercuric ions are produced by an electrode process

$$Hg = Hg^{2+} + 2e \tag{2}$$

and consumed by chemical reactions

$$Hg^{2+} + 2S_2O_3^{2-} = Hg(S_2O_3)_2^{2-} \tag{3}$$

$$Hg^{2+} + 3S_2O_3^{2-} = Hg(S_2O_3)_3^{4-} \tag{4}$$

which follow the electrode process. Formation of $Hg(S_2O_3)_4^{6-}$ is not considered here, because its high negative charge forbids it. In the following we assume that reactions (2), (3), and (4) are reversible.

The average anodic current, i, may be written as

$$i = i_2 + i_3 \tag{5}$$

where i_2 and i_3 are the current parts relating to concentration of $Hg(S_2O_3)_2^{2-}$ and $Hg(S_2O_3)_3^{4-}$ at the electrode surface through

$$i_2 = \kappa_2[Hg(S_2O_3)_2^{2-}]$$

$$i_3 = \kappa_3[Hg(S_2O_3)_3^{4-}]$$

where κ_2 and κ_3 are the Ilkovic constants for $Hg(S_2O_3)_2^{2-}$ and $Hg(S_2O_3)_3^{4-}$, respectively. Because $[Hg^{2+}]$ is too small compared with $[Hg(S_2O_3)_2^{2-}]$ and $[Hg(S_2O_3)_3^{4-}]$ at the potential of thiosulfate wave, the current part relating to $[Hg^{2+}]$ is neglected in Eq. (5).

Equation (5) may be rewritten as

$$i = (\beta_2\kappa_2 + \beta_3\kappa_3 x)x^2[Hg^{2+}] \tag{6}$$

where β_2 and β_3 are stability constants of $Hg(S_2O_3)_2^{2-}$ and $Hg(S_2O_3)_3^{4-}$, respectively, and x is the concentration of thiosulfate ions at the surface of DME. After rearrangement, we obtain the equation for $[Hg^{2+}]$:

$$[Hg^{2+}] = \frac{2\kappa_4 y}{\beta_2\kappa_2(1 + rx)x^2} \tag{7}$$

In the above κ_4 is the Ilkovic constant for thiosulfate ion, and

$$r = \frac{\beta_3\kappa_3}{\beta_2\kappa_2} \tag{8}$$

$$y = \frac{i}{2\kappa_4} \tag{9}$$

Combination of Eqs. (1) and (7) gives

$$E = E^0 + \frac{2.303RT}{2F}\log\frac{2\gamma_1\kappa_4}{\beta_2\kappa_2} + \frac{2.303RT}{2F}\log\frac{10^{-3}y}{(1 + rx)x^2} + \frac{6.909RT}{2F} \tag{10}$$

The last term of the right-hand side is added in order to compensate the factor 10^{-3} in the third term, which is introduced to displace the zero point of ordinate of the log plot for convenience. The third term represents the contribution by the current. For construction of a log plot according to Eq. (10) it is necessary to know numerical values of x at given potentials. This can be done as follows.

Fluxes of out-going species, $Hg(S_2O_3)_2^{2-}$ and $Hg(S_2O_3)_3^{4-}$, at electrode surface are given by

$$f_2 = \frac{i_2}{2F} = \frac{\kappa_2[Hg(S_2O_3)_2^{2-}]}{2F} \tag{11}$$

$$f_3 = \frac{i_3}{2F} = \frac{\kappa_3[Hg(S_2O_3)_3^{4-}]}{2F} \tag{12}$$

The flux of in-coming species $S_2O_3^{2-}$ is given by

$$f_4 = \frac{i_d - \kappa_4 x}{F} \tag{13}$$

where i_d is the diffusion current. There is no accumulation of S_2O_3 group at the surface of DME. Hence

$$f_4 = 2f_2 + 3f_3 \tag{14}$$

Substituting Eqs. (11), (12), and (13) into Eq. (14) we obtain

$$i_d - \kappa_4 x = \kappa_2[Hg(S_2O_3)_2^{2-}] + \frac{3}{2}\kappa_3[Hg(S_2O_3)_3^{4-}]$$

$$= \frac{1}{2}\beta_2\kappa_2(2 + 3rx)x^2[Hg^{2+}] \tag{15}$$

Combining this with Eq. (7), we get

$$x_0 - x = \frac{2 + 3rx}{1 + rx}y \tag{16}$$

where $x_0 = i_d/\kappa_4$.

Equation (16) is solved for x.

$$x = \frac{(x_0 - 3y)r - 1 + \sqrt{(x_0 - 3y)^2r^2 + 2r(x_0 - y) + 1}}{2r} \tag{17}$$

Numerical values of x can be calculated by this equation if r is known. However, it is not and we adopted the following procedure as we did previously.[3] First, values of x are calculated by Eq. (17) with a value of r arbitrarily chosen, and $\log 10^{-3}y/(1+rx)x^2$ is plotted against E. With an

arbitrary value of r, the plot does not necessarily produce a straight line. Then the whole process is repeated with a slightly different value of r which is chosen to lessen deviation of the plot from a straight line. The process is repeated until the plot yields a straight line. It was found that the plot constructed from polarograms obtained at 25°C gave a straight line when a value of 3×10^2 was substituted for r. The accompanying table shows the reciprocal slope of plots constructed with this value of r and the potential at which log $10^{-3}\cdot y/(1+rx)x^2$ becomes zero. Fair agreement may be considered as an evidence in support of Eq. (10) and underlying assumptions.

The value of r is related to a stability constant ratio β_3/β_2, which is the successive stability constant of the tris complex, through Eq. (8). Evaluation of a ratio κ_3/κ_2 is necessary for calculation of the successive constant. It seems possible to determine the ratio by observing the change of diffusion current of mercuric ion with increasing concentration of thiosulfate ions in supporting electrolyte. However, this is not possible because mercuric ions react with thiosulfate ions to precipitate mercuric sulfide. The difficulty was overcome by substituting mercuric ions by mercuric cyanide in a buffer solution of an appropriate pH. Although the stability constant of mercuric cyanide, having a value of $10^{35.2}$ (activity constant),[4] is much larger than that of bis(thiosulfato)mercurate-(II), it is still possible to convert the most part of mercuric cyanide to the bis complex, without precipitation of mercuric sulfide, by selecting pH of the buffer.

Measurement of diffusion current was carried out for 1 mM mercuric cyanide in the buffer of pH 5.26 with varying thiosulfate concentrations. Results are shown in Fig. 1 as the ratio of the diffusion current to that in the absence of thiosulfate. With a value of $10^{29.27}$ for the stability constant (activity constant) of bis(thiosulfato) complex,[2] the mole ratio of $Hg(S_2O_3)_2^{2-}$ to $Hg(CN)_2$ was calculated to be not less than 100 when the concentration of thiosulfate was 4.5 times as much as that of mercuric cyanide. Accordingly, the decrease of diffusion current beyond this point is due to the formation of tris(thiosulfato) complex. The formation of the tris complex seems incomplete even in the presence of thiosulfate of the highest concentration employed in this experiment (see Fig. 1). Although it is impossible to determine exactly the ratio κ_3/κ_2 from this experiment, it does not seem to deviate much from unity. If it is assumed to be equal to unity, the successive stability constant of tris(thiosulfato)mercurate(II) is calculated to be 3×10^2 (concentration constant). The activity constant was calculated to be $3._4\times10$ from this and activity coefficients estimated by the Debye and Hückel equation without the extended term.[5]

$$\log\gamma_i = -\frac{0.358z_i^2(2\mu)^{1/2}}{1+10^8a_i0.2325(2\mu)^{1/2}}$$

In this equation γ_i, z_i, and a_i are the activity coefficient, the electrovalency, and the ionic parameter, respectively, of the ion i, and μ is the ionic strength of the solution. Values of a_i assumed for thiosulfate ion, and bis- and tris(thiosulfato)mercurate-(II) ions are 4, and 4 and 5 Å, respectively. These values were chosen for respective ions to be in accord with ions listed in Kielland's table with respect to charge type.[5,6]

A value of 3×10 was calculated for the successive stability constant (activity constant) from β's at zero ionic strength given by Nyman and Salazar.[2] This is in good agreement with the value derived from the slope of the log plot in the present study.

Concentration of mercuric cyanide, 0.983 mM.

Experimental

A manual polarograph was used for the measurement of the current-potential curve. The cell used was of a beaker type with a Hume and Harris type salt bridge.[7] To avoid contamination of chloride ion, the intermediate agar plug saturated with potassium chloride was replaced by one prepared with 1 M potassium nitrate. The dropping mercury electrode used had an m value of 1.865 mg/sec and a drop time of 4.28 sec, being measured in a deaerated 0.2 M sodium nitrate solution at the potential of the saturated calomel electrode with a head of mercury of 90.0 cm.

Stock solutions were prepared from redistilled water with chemicals of guaranteed grade. The sodium thiosulfate stock solutions were standardized against potassium iodate.[8] The mercuric cyanide stock solution

was prepared by dissolving a weighed amount of solid salt in known volume of the solution. As supporting electrolyte, 0.2 M sodium nitrate solution was used for anodic wave, and an acetate buffer of pH 5.26, of which ionic strength was controlled to 0.2 with sodium nitrate, for cathodic wave. To the latter 0.005% gelatin was added as a maximum suppressor. The pH of the buffer was measured by a Hitachi-Horiba Model P pH meter.

All measurement were carried out in a thermostat kept at 25.0 ± 0.1°C. All potentials were corrected for the internal resistance (iR drop) across the cell.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2823—2827 (1970)

An Internal-Reference Method for the Determination of Rubidium by Photon-Activation Analysis with Strontium Used as the Reference Element*[1]

Hui-Tuh TSAI, Toyoaki KATO and Yoshinaga OKA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received March 17, 1970)

We have studied a method for the determination of rubidium by activation analysis with bremsstrahlung photons, with strontium used as the internal-reference element. This method is based on the γ-ray spectrometric measurement of the ^{84}Rb activities produced by the ^{85}Rb(γ,n) reaction and on the comparisons of those activities with that of ^{83}Rb arising from strontium as a result of the (γ,p) reaction. The yields of various photonuclear reactions in rubidium and in strontium have also been examined as a function of bremsstrahlung maximum energies up to 60 MeV, and the best conditions for the determination of rubidium are proposed. When the maximum energy was set at 18 to 20 MeV, no interfering reactions occurred; a rubidium content down to about 2 μg can be determined accurately. A comparison of solid-state and scintillation γ-ray spectrometry in this method has also been included with respect to the sensitivity and the selectivity.

A minute amount of rubidium can be determined by a thermal neutron activation method by inducing ^{86}Rb activity in an irradiated sample; this technique has been applied to the determination of rubidium in a number of materials of geochemical interest[1-3] The contents of rubidium and strontium in terms of the rubidium-to-strontium ratios have been utilized for the age-determination of these materials.[4] An accurate and precise analytical method was required in this work.

The work described here was undertaken for the purpose of establishing an accurate method for the determination of rubidium by photon-activation analysis, using strontium as the internal-reference element. In order to determine the best conditions for the determination of rubidium by this method, some work has also been carried out on the yields of photonuclear reactions over the energy range of bremsstrahlung photons up to 60 MeV. When a maximum energy was set at 18 to 20 MeV, no interfering reactions occurred, and traces of rubidium down to about 2 μg could be determined accurately. A comparison of the solid-state detection by means of the scintillation-detection method is also included with respect to the sensitivity and the selectivity.

Experimental

Materials and Irradiation. The rubidium chloride was a guaranteed reagent grade. Strontium carbonate of a guaranteed reagent grade was further purified by repeated reprecipitations. Synthetic mixtures of these two compounds, with known weight ratios of rubidium to strontium ranging from 1.3×10^{-1} to 5.4×10^{-3}, were prepared in order to examine the sensitivity and the accuracy of the method. Each sample (weight, about 100 mg) was placed in a quartz tube with an internal diameter of 4 mm for bremsstrah-

lung irradiation. All the irradiations were terminated in 1 hr. The linear electron accelerators of Tohoku University and of the Japan Atomic Energy Research Institute were used as the bremsstrahlung sources. The experimental method involving bremsstrahlung-flux monitoring and the details of the irradiation were essentially the same as have been described in detail in a previous paper.[5]

Separation Procedure. The irradiated sample was dissolved in a small amount of 0.1 N hydrochloric acid, along with 20 mg of a rubidium carrier. The solution was evaporated to dryness, and the residue was dissolved with dilute aqueous ammonia (pH 8) and then subjected to cation-exchange separation. The resin used was Dowex 50W×8, 100 to 200 mesh size. This was fed into a column 25 cm long and with an internal diameter of 8 mm. The rubidium was eluted with a 0.5 M ammonium acetate solution and was precipitated by the addition of 0.1 N perchloric acid with ice-cooling. The rubidium perchlorate was filtered and dried in a vacuum.

After the elution of the rubidium, the strontium was eluted from the column with 1 N nitric acid and precipitated as strontium carbonate by means of an aqueous ammonium carbonate solution. The precipitate was filtered and dried at 500°C. Either rubidium perchlorate or strontium carbonate was wrapped with a thin sheet of aluminum in order to determine the chemical yield, if needed, and for γ-counting.

Counting Equipment. A lithium-drifted germanium detector with an active volume of 36 cm^3, ORTEC 8101-30P, was coupled to a TMC 1024-channel pulse-height analyzer. The counting system had a resolution of 4 keV for the 661.6 keV γ-line of ^{137}Cs. The counting efficiency of this detector has been determined as a function of the source distance and the γ-ray energy by counting a series of calibrated sources of known activities. A sample was measured at a fixed position, 9 mm from the active surface of the detector.

A 3″ dia.×3″ NaI(Tl) crystal was also used as the detector. This was coupled to an 800-channel pulse-height analyzer made by the Tokyo Shibaura Electric Co., Ltd. For the determination of the photonuclear yields where a much greater resolving power was required, the Ge(Li) detector was used exclusively; for analytical purposes, both counting systems were employed.

Yield Determination. A yield was defined as the production rate of nuclide due to a certain photonuclear reaction in dps at the end of the irradiation of one mole of a parent nucleous when a standard amount of bremsstrahlung radiation with a given maximum energy has passed through the target during the irradiation period. The initial decay rates of the various activities produced were determined from a decay-curve analysis of the counting rate of the relevant photopeak area. The corresponding saturation rates were computed and normalized for the bremsstrahlung intensity, which was measured by means of the amount of of ^{196}Au activity produced by the $^{197}Au(\gamma,n)^{196}Au$ reaction in a gold foil irradiated together with the sample. After correcting for chemical yields, counting efficiencies, branching ratios,[6] and the internal conversion electrons,[7] the yields were expressed relative to that of the $^{87}Rb(\gamma,n)^{86}Rb$ process or of the $^{84}Sr(\gamma,n)^{83}Sr$ process.

Results and Discussion

Photonuclear Reaction. Rubidium has two naturally-occurring isotopes, ^{85}Rb(72.15%) and ^{87}Rb(27.85%), while strontium has four isotopes, ^{84}Sr(0.56%), ^{86}Sr(9.86%), ^{87}Sr(7.02%), and ^{88}Sr-(82.56%). The experimental results showed that the rubidium nuclides formed in the irradiations of the two elements by bremsstrahlung with maximum energies up to 60 MeV were ^{82m}Rb ($T_{1/2}$= 6.3 hr), ^{83}Rb ($T_{1/2}$=83d), ^{84}Rb ($T_{1/2}$=33.0 d), ^{84m}Rb ($T_{1/2}$=20 min), and ^{86}Rb ($T_{1/2}$=18.66 d). In addition, the production of ^{81}Rb($T_{1/2}$=4.7 hr) was also observed in an irradiated strontium sample. In this experiment, γ-rays from ^{81m}Rb could not be measured because of its lower energies (0.085 MeV with IT) and its relatively short half-life (31 min). The ^{84m}Rb activity could not be detected from strontium since it has decayed away during the separation processes.

From the threshold-energy considerations, the main reactions which can occur in both elements with bremsstrahlung and with maximum energies below 20 MeV are the (γ,n) and (γ,p) reactions. Thus, when irradiated with 17.6 MeV bremsstrahlung, ^{84}Rb, ^{84m}Rb, and ^{86}Rb, the (γ,n) reaction products, were measured. No nuclides other than the above were produced at 20 MeV. Since the ^{84}Rb activity was used in the determination of rubidium, the irradiation conditions leading to the production of ^{84}Rb from strontium had to be avoided. The only possible reaction producing ^{84}Rb in the irradiation with bremsstrahlung below 20 MeV is the $^{86}Sr(\gamma,d)^{84}Rb$ reaction ($-Q$=17.84 MeV). The experimental results showed that the production of ^{84}Rb from strontium with 20 MeV bremsstrahlung could not be observed in any appreciable amount.

The yields of various reactions are given as a function of the bremsstrahlung maximum energy in Figs. 1 and 2. Since an excitation energy beyond 30 MeV covers the giant resonance region well for most nuclei, and since the main nuclear event in this energy region is the emission of one neutron,[8] the yield value of the (γ,n) reaction remains almost unchanged throughout this energy region. The yield of the reaction with the emission of more than one nucleon appeared to be strongly

energy-dependent. In the energy region higher than 45 MeV, the $^{85}Rb(\gamma,3n)^{82m}Rb$ and $^{85}Rb(\gamma,4n)^{81m,81}Rb$ reactions occurred; the ^{81}Rb and ^{82m}Rb activities were also measured from an irradiated strontium sample. An increase in the yields of the (γ,pn) reactions can be seen beyond 45 MeV. The $^{84}Sr(\gamma,pn)^{81}Rb$ reaction contributes mainly to the production of ^{81}Rb from strontium. At 60 MeV, however, the additional contribution to the total production rate comes from the $^{86}Sr(\gamma,p4n)^{81}Rb$ reaction. The main reaction leading to the production of ^{82m}Rb in this energy region is the $^{84}Sr(\gamma,pn)$ reaction.

For analytical purposes, the ^{84}Rb activity as a result of the (γ,n) reaction can be used effectively with respect to the sensitivity at a given maximum energy investigated here. Table 1 shows the photopeak activities of ^{84}Rb, together with those of ^{83}Rb from strontium, as a function of the bremsstrahlung maximum energy. In the determination of rubidium by the use of strontium as a reference, however, it is necessary to avoid interferences due to the production of ^{84}Rb from strontium through the (γ,d) and (γ,pn) reactions. As has been stated earlier, the irradiation by bremsstrahlung with maximum energies below 20 MeV gives no such trouble.

Determination of Rubidium. The 0.880 MeV γ-ray photopeak of ^{84}Rb can be utilized for the determination of rubidium, while the ^{83}Rb activity arising from strontium can be used as a reference. A comparison of the scintillation detection by the solid-state detection method can be discussed in terms of the sensitivity and the selectivity by processing the synthetic mixtures.

When a 3″ dia. × 3″ NaI(Tl) detector was used, we obtained the typical γ-ray spectrum shown in Fig. 3. The sample was irradiated with 20 MeV bremsstrahlung in this case. It can be seen that the photopeak appearing at 0.525 MeV is the compound peak of the 0.511 MeV γ-ray from ^{84}Rb and the 0.521, 0.530, and 0.553 MeV γ-rays of ^{83}Rb. The area under the latter three different γ-rays of ^{83}Rb were determined from these spectra by the following sequences:

1) from the spectrum in Fig. 3, the background activity due to the 1.078 MeV γ-ray of ^{86}Rb was subtracted by the graphical subtraction method;[9]

2) the area under the 0.880 MeV photopeak, A_{detn}(cpm), was obtained;

3) the 0.511 MeV photopeak area due to ^{84}Rb,

(III): Photopeak due to the 0.880 MeV γ-ray of ^{84}Rb.
(IV): The area under the 0.880 MeV photopeak.

Fig. 3. γ-Ray spectra of radiorubidium separated from a mixed sample (Rb 7.21 mg+Sr 55.5 mg), 29 days after irradiation with 20 MeV bremsstrahlung with a NaI(Tl) detector.

A(0.511 MeV), was calculated by:

$$A(0.511\ \mathrm{MeV}) = R\,A_{\mathrm{detn}}$$

where R is the activity ratio, $A_{^{84}\mathrm{Rb}}$(0.511 MeV)/$A_{^{84}\mathrm{Rb}}$(0.880 MeV), which has been determined with the aid of ^{84}Rb, and

4) the area under the composite peak of ^{83}Rb used as reference, A_{ref}, was then calculated by:

$$A_{\mathrm{ref}} = A_{\mathrm{m}} - A(0.511\ \mathrm{MeV}) = A_{\mathrm{m}} - R\,A_{\mathrm{detn}}$$

where A_{m} is the observed area under the compound peak at 0.525 MeV. From the spectra obtained from irradiated mixtures, the A_{detn}'s and the A_{ref}'s were determined, and those activity data were corrected for decay to the end of the irradiation through the use of the half-lives of ^{84}Rb and ^{83}Rb respectively. In the present experiment, all separations were performed 12 days after irradiation; all of the 20 min-^{84m}Rb had decayed away to ^{84}Rb.

Table 2 shows the relation between the photopeak activity ratios, $R_{A_0}=(A_{\mathrm{detn}}/A_{\mathrm{ref}})_{t=0}$, and the ratios of the weights, R_W=Rb/Sr. A good

Table 2. R_W *versus* R_{A_0} for rubidium-strontium mixtures with a NaI(Tl) detector

R_W	R_{A_0}	R_W/R_{A_0}
1.30×10^{-1}	21.6	5.99×10^{-3}
6.23×10^{-2}	10.1	6.16×10^{-3}
1.55×10^{-2}	2.61	5.82×10^{-3}
6.87×10^{-3}	1.14	6.04×10^{-3}
2.40×10^{-4}	3.90×10^{-2}	6.16×10^{-3}

Mean: $6.0_3\times10^{-3}$
Std. dev.: $\pm0.1_3\times10^{-3}$

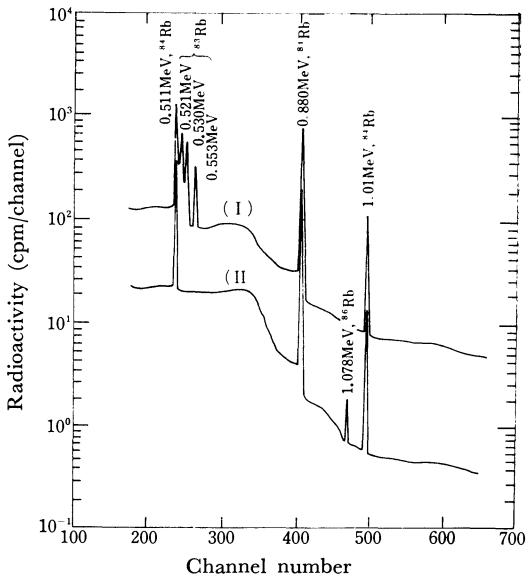

Fig. 4. γ-Ray spectra of radiorubidium with a Ge(Li) detector; (I) separated from a mixed sample (Rb 0.84 mg+Sr 419 mg), 11.9 days after irradiation with 17.6 MeV bremsstrahlung, and (II) of the rubidium sample.

proportionality was held between them, and a relative standard deviation of ±2.1% was obtained under the present experimental conditions:

$$R_W = (6.0_3 \pm 0.1_3) \times 10^{-3} R_{A_0}$$

When the amount of rubidium needed to give a photopeak activity of 10 cpm is selected as the limit of determination, it can be set at 2 μg.

When a 36 cm^3 Ge(Li) detector was used, we obtained the typical γ-ray spectrum shown in Fig. 4, together with that of the rubidium sample. The much greater resolving power of this detector made it feasible to distinguish clearly three different γ-ray photopeaks of ^{83}Rb. The photopeak area under the 0.553 MeV γ-ray was selected as the reference. The ratios of the area under the 0.880 MeV γ-ray to that under the 0.553 MeV γ-ray were computed and corrected for decay to the end of the irradiation. The relation between the R_{A_0}'s and the R_W's was again discussed from these activity data. Table 3 shows the results. The following relationship was obtained:

$$R_W = (1.1_3 \pm 0.0_5) \times 10^{-3} R_{A_0}$$

The relative standard deviation was ±4.8%. A sensitivity of 23 μg for rubidium was obtained in accordance with the definition described earlier.

With a Ge(Li) detector, the method is less sensitive by one order, but the determination of the photopeak areas is quite feasible as compared with scintillation spectrometry. An increase in sensitivity would be expected with a higher bremsstrahlung dose rate and with a longer period of irradiation.

Table 3. R_W *versus* R_{A_0} for rubidium-strontium mixtures with a Ge(Li) detector

R_W	R_{A_0}	R_W/R_{A_0}
5.30×10^{-2}	5.01×10^{1}	1.06×10^{-3}
4.28×10^{-2}	3.86×10^{1}	1.11×10^{-3}
2.95×10^{-2}	2.52×10^{1}	1.17×10^{-3}
1.20×10^{-2}	9.90×10^{0}	1.21×10^{-3}
5.41×10^{-3}	4.90×10^{0}	1.11×10^{-3}

Mean: $1.1_3\times10^{-3}$
Std. dev.: $\pm0.0_5\times10^{-3}$

The general applicability of this method lies in the determination of rubidium in samples of geochemical interest, in biological materials, and in various chemicals. A sample is ready for bremsstrahlung irradiation when it is ground to a powder along with a known amount of strontium carbonate, 100 mg in most cases. Rubidium often accompanies cesium in such samples, and the mutual separation of them can not be performed by the procedure described earlier. Considering the nuclear characteristics of ^{132}Cs ($T_{1/2}$=6.5 d, β^+ 0.6%, γ's), the (γ,n) reaction product, however, does not appear to be a serious source of interference. The γ-ray energies are 0.6678 MeV (96.7%), 0.6303 MeV(0.85%), 0.508 MeV(0.5%), and others (very weak). When a sample contains a large amount of cesium, a lithium-drifted germanium detector may be considered to be superior to a scintillation detector.

Polarography of Halides in Dimethylformamide. V. Bromine and the Tribromide Ion

Yoshihisa MATSUI and Yoshio DATE

Department of Agricultural Chemistry, Shimane University, Nishikawazu-cho, Matsue

(Received March 30, 1970)

The polarographic behavior of bromine and the tribromide ion at the dropping mercury electrode was investigated in dimethylformamide. A freshly-prepared solution of bromine gives two cathodic waves. When the solution is allowed to stand at 25°C in the dark, however, the first wave gradually becomes anodic, independently of the electrolysis. When the first wave is completely anodic, an equilibrium is established. The resulting polarogram coincides with that of hydrogen tribromide. The formation of hydrogen tribromide was ascribed to the chemical reduction of bromine by dimethylformamide. Diffuse sunlight accelerates the decomposition of bromine, which in turn yields hydrogen bromide. It was also suggested that, when the dropping mercury is used as an indicator electrode, bromine and the tribromide ion may react with the dropping mercury prior to being electrolyzed, forming mercuric bromide and the tribromomercurate ion respectively, which may in turn depolarize the indicator electrode.

The halogen-halide systems in non-aqueous solutions have been the subjects of a number of voltammetric studies. The solvents so far used include acetic acid,[1] acetic anhydride,[1] acetonitrile,[2-6] dimethylformamide (DMF),[7-11] dimethyl sulfoxide,[12,13] sulfolane,[14] and tetrahydrofuran.[15] In these solvents the trihalide ion (X_3^-) is so stable that the halogen species give two voltammetric waves, corresponding to the two redox reactions as follows:

$$3X_2 + 2e \rightleftarrows 2X_3^- \quad (1)$$

$$2X_3^- + 4e \rightleftarrows 6X^- \quad (2)$$

On the other hand, X_3^- is unstable in an aqueous solution, and X_2 gives only one reduction wave due to the reaction, as follows:[16]

$$X_2 + 2e \rightleftarrows 2X^- \quad (3)$$

Among the halogen-halide systems, the iodine-iodide system has been studied most extensively.[1-3,5-7,10-15] Fewer studies have been reported about the bromine-bromide[2,4,5,8,13,14] and the chlorine-chloride[2,9,13,14] systems, and none about the fluorine-fluoride system. The electrodes used in these investigations are made of platinum or pyrolytic graphite, each of which is inert to the halogen species. The dropping mercury electrode, which is reactive to the halogen species, has never been used for these studies.

In the present paper, the bromine-bromide system in DMF was investigated as part of a series of polarographic studies of halides in this medium.[17] The dropping mercury electrode was used as the indicator electrode. Sinicki and Bréant[8] have already studied the voltammetric behavior of bromine in DMF, using the platinum electrode. They have reported that a freshly-prepared solution of bromine gives two cathodic waves due to the reactions expressed by Eqs. (1) and (2). Using the dropping mercury electrode,

however, we found that the two cathodic waves given by a freshly-prepared solution of bromine may be explained in terms of the electrolytic reduction of the mercuric bromide formed by the reaction between the bromine and the mercury of the electrode prior to the electrolysis. Sinicki and Bréant[8] have also reported that bromine in DMF quantitatively converts to the tribromide ion on standing for a few hours, irrespective of the electrode process:

$$3Br_2 \text{ (in DMF)} \rightarrow 2Br_3^- \quad (4)$$

This reaction is rather unusual in view of the fact that halogens or interhalogen compounds generally undergo disproportionation reactions in electron-donating solvents to yield the trihalide ions and the uni-positive halogen ions:[18-20]

$$2X_2 \rightleftharpoons X_3^- + X^+ \quad (5)$$

They ascribed it to the reduction of bromine by formic acid, which was formed by the hydrolysis of DMF, but no experimental proof was presented. In the present paper, we also will examine the mechanism of the chemical reduction of bromine to the tribromide ion, and will suggest that the reductant may be not formic acid, but DMF.

Experimental

The DMF was purified as has been described previously.[21] The tetraethylammonium perchlorate (TEP) used as a supporting electrolyte was prepared and purified as has been described by Fujinaga *et al.*[22] Polyvinyl chloride (PVC) obtained commercially was used as a maximum suppressor. The bromine was dried over phosphorus pentoxide and was purified by distillation. Bp 57.8—58.1°C. Hydrogen bromide which had been generated from aqueous hydrobromic acid and concentrated sulfuric acid was passed through a glass tube packed with red phosphorus and was then bubbled through concentrated sulfuric acid. The dry hydrogen bromide thus obtained was dissolved in DMF. The resulting solution was standardized by titration against an aqueous sodium hydroxide solution, using phenolphthalein as the indicator. The solution of hydrogen tribromide in DMF was prepared by an equimolar addition of the hydrogen bromide solution to bromine. The solution of hydrogen tribromomercurate in DMF was similarly prepared from the hydrogen bromide and mercuric bromide.

D. c. polarography and conductivity measurements were carried out at 25°C as has been described previously.[23] All the potential measurements were done with reference to the aqueous saturated calomel electrode connected with the cell solution by a DMF-agar salt bridge.[22] The dropping mercury electrode used had the following characteristics in a 0.10 M solution of TEP in DMF (open circuit): m=1.245 mg/sec, t=4.97 sec for h=66.0 cm. The oxygen dissolved in the solution was expelled by passing a stream of dry nitrogen through the cell solution for about 20 min prior to each electrolysis.

Results

Variation in the Polarographic Characteristics of Bromine with the Time. The polarographic characteristics of bromine varied with the time. Figure 1 shows the polarograms recorded at several intervals after the addition of

bromine to DMF containing 0.10 M TEP and 0.005% PVC. Since it was found that diffuse sunlight accelerates the change, as will be discussed later, the cell solution was placed in the dark. When the recording of the polarogram was started as soon as possible (45 sec) after the addition of bromine to a DMF solution, most of the two waves obtained were cathodic, although the first wave had already turned anodic in part. The anodic part of the first wave increased with the time at the expense of its cathodic part. When the first wave was completely anodic, an equilibrium was established. Parallel to this change, a new cathodic wave and a maximum arose and grew at about −1.33 and −2.15 V *vs.* SCE respectively (Fig. 6).

Figures 2 and 3 show the plots of the limiting currents and the half-wave potentials respectively *vs.* the time. The height of the second wave was approximately double that of the first wave, and both of them slightly decreased with the time. The height of the third wave increased with an increase in the anodic part of the first wave. An equilibrium was attained about two hours after the addition of bromine to DMF. Throughout these changes, however, the half-wave potential of each wave remained practically constant. The increase in the anodic part of the first wave obeyed good first-order kinetics (Fig. 4). The rate constant was determined to be 0.030 min^{-1} at 25°C.

The conductance of the bromine solution also increased with the time. The mode of increase in the conductance was analogous to that in the anodic current (Fig. 2). If bromine was added to DMF containing excess tetraethylammonium bromide, the conductance of the solution scarecely varied with the time (Fig. 5). No increase in the conductance with the time was observed until the molar concentration of the bromine added was higher than that of the bromide ion. This indicates that bromine rapidly reacts with the bromide ion, forming the tribromide ion, which is stable in DMF in the dark.

Polarographic Behavior of Bromine, the Tribromide Ion, and Related Compounds. The polarogram of 1.0 mM bromine, which was recorded in the dark about two hours after it had been added to DMF, is shown in Fig. 6. The effects of the bromine concentration and of the height of the mercury reservoir on the polarographic characteristics are summarized in Tables 1 and 2 respectively. The heights of both the first and second waves were virtually proportional to the concentrations of the depolarizer and to the square roots of the heights of the mercury reservoir; this indicates that these waves are diffusion-controlled. The ratio between the diffusion-current constants (I_d's) of these waves is about 1.0 : 2.3. The characteristics of the third wave are somewhat more complicated. The height of this wave was practically proportional to the square root of the height of the mercury reservoir, but not to the con-

centration of bromine. As will be described later, however, the wave is due to the reduction of the hydrogen ion which is formed by the reaction between bromine and DMF. Therefore, the decrease in the diffusion-current constant may be due to the consumption of the hydrogen ion for the neutralization of such bases as dimethylamine present in solution as impurities.

With an increase in the concentration of bromine, the half-wave potential of the first wave shifted to a more positive direction, and that of the second wave, to a more negative direction, while that of the third wave remained virtually constant. Figure 7 shows the relation between the half-wave potentials of the waves ($E_{1/2}$) and the common logarithms of the concentrations of bromine (log C). Approximately linear relations were obtained between them with slopes of 0.030 V for the first wave, −0.060 V for the second wave, and 0.000 V for the third wave.

Figure 6 also shows the polarograms of hydrogen bromide, hydrogen tribromide, and formic acid in DMF. It is notable that hydrogen tribromide gives three polarographic waves closely similar to those of bromine recorded about two hours after it had been added to DMF. Hydrogen tribromomercurate also gave three waves similar to those of hydrogen tribromide. These data indicate that bromine converts to hydrogen tribromide in DMF and that the tribromide ion may react with mercury at the electrode surface, yielding the tribromomercurate ion, which may in turn depolarize the electrode. Formic acid gives no wave at the potential where the hydrogen ion is electrolytically reduced.

The polarographic characteristics of these depolarizers at various concentrations and at various heights of the mercury reservoir are summarized in Tables 3 and 4 respectively. All the heights of the first and second waves given by these depolarizers were practically proportional to the concentrations and to the square roots of the mercury heads; this indicates that they are diffusion-controlled. The height of the third wave of hydrogen bromide or of hydrogen tribromide was also proportional to the square root of the height of the mercury reservoir, but not to the concentration of the depolarizer, as had been observed for bromine. Hydrogen tribromomercurate gave no third wave until the concentration was as high as 2.1 mM. The relation between the half-wave potentials and the common logarithms of the concentration is plotted for hydrogen tribromide in Fig. 7. Approximately linear relations were obtained be-

part of the polarographic wave, as well as the increase in the electric conductivity, of the bromine solution is accelerated by diffuse sunlight. The rate of the current increase abruptly slows down about 15 min after the addition of bromine to DMF. The resulting polarogram coincides with that of hydrogen tribromide. However, the tribromide ion is not so stable in diffuse sunlight as in the dark, and it slowly decomposed hereafter. Equilibrium was not established until both the first and second waves were completely anodic. The polarogram recorded after equilibrium was attained agreed with that of hydrogen bromide, as is shown in Fig. 6.

Discussion

Mechanism of the Formation of Hydrogen Tribromide from Bromine in DMF in the Dark.

The conversion of the first wave of bromine from cathodic to anodic (Fig. 1) and the excellent agreement of the resulting polarogram with that of hydrogen tribromide (Fig. 6) indicate that bromine in DMF gradually forms hydrogen tribromide. This is supported by the fact that the conductance of the solution increases with an inrecase in the anodic part of the first wave (Fig. 2). The stoichiometry of this reaction is interesting. The height of each wave of 1.0 mM bromine measured about two hours after it is added to DMF is approximately equal to two-thirds of that of the corresponding wave of 1.0 mM hydrogen tribromide, which indicates that three moles of bromine quantitatively yield two moles of hydrogen tribromide in DMF:

$$3Br_2 + 2H\cdot(DMF) \rightarrow 2H^+ + 2Br_3^- \quad (6)$$

This reaction is rather unusual, since it is well known that a disproportionation reaction occurs between two moles of halogen in electron-donating solvents, yielding one mole of the trihalide ion and one mole of the uni-positive halogen ion (Eq. (5)).[18-20] However, Reid and Muliken[18] have also reported that iodine in pyridine (Pr) forms the trihalide ion, together with the uni-positive iodine ion solvated by pyridine (PrI^+), which may in turn decompose to the iodide ion and the cation radical of pyridine ($Pr\cdot^+$) as follows:

$$Pr + PrI^+ \rightarrow I^- + 2Pr\cdot^+ \quad (7)$$

Similar reactions have also been proposed by Zingaro *et al.*[24] Recently, Bist and Person[25] reported that a rapid reaction occurs between iodine and excess triethylamine in dioxane, yielding the iodide ion quantitatively as the end product. The reaction was ascribed to the reduction of the uni-positive iodine ion to the iodide ion by the amine. Thus, it can be considered that the following reaction may occur between bromine and DMF:

$$Br_2 \rightleftharpoons Br^+ + Br^- \quad (8)$$

$$Br^+ + 2DMF \rightarrow Br^- + 2DMF\cdot^+ \quad (9)$$

$$2DMF\cdot^+ \rightarrow 2H^+ + 2R \quad (10)$$

$$2Br_2 + 2Br^- \rightleftharpoons 2Br_3^- \quad (11)$$

The net result would be:

$$3Br_2 + 2DMF \rightarrow 2H^+ + 2Br_3^- + 2R \quad (12)$$

In this reaction mechanism, Br_2 and Br^+ may be strongly solvated by DMF. The electron-transfer reaction from DMF to Br^+ has never been reported, but it is well known that DMF forms charge-transfer complexes with a number of Lewis acids. We have also found that DMF can reduce the simple mercuric ion, yielding metalic mercury.[17] The cation radical ($DMF\cdot^+$) thus formed may

24) R. Zingaro, C. A. VanderWerf and J. Kleinberg, *J. Amer. Chem. Soc.*, **73**, 88 (1951).

25) H. D. Bist and W. B. Person, *J. Phys. Chem.*, **73**, 482 (1969).

rapidly decompose to the hydrogen ion and an unknown radical (R). Among the elemental reactions demonstrated above, either the disproportionation reaction (Eq. (8)) or, more probably, the electron-transfer reaction (Eq. (9)) may be the rate-determining step, for the kinetics of the total reaction is of the first-order (Fig. 4).

Sinicki and Bréant[8] have attributed the quantitative formation of the tribromide ion to the reduction of bromine by formic acid, which had been formed by the hydrolysis of DMF. However, none of the polarograms of the DMF solutions in either the presence or absence of bromine gave any appreciable wave at −2.25 V *vs.* SCE, where formic acid gives a cathodic wave. Accordingly, it is unlikely that the formic acid plays a major role in the reduction of the uni-positive bromine ion. Michlmayr and Sawyer[13] have reported that halogen may react with dimethyl sulfoxide and acetonitrile, yielding hydrogen halide, as follows:

$$X_2 + (CH_3)_2SO \rightarrow CH_2X(CH_3)SO + HX \quad (13)$$

$$X_2 + CH_3CN \rightarrow CH_2XCN + HX \quad (14)$$

However, according to these mechanisms, halogen does not quantitatively form the trihalide ion, but a part of it enters into combination with the carbon atoms of the solvents. Therefore, this is not the present case.

Effect of Diffuse Sunlight on the Reaction of Bromine in DMF. Diffuse sunlight accelerates the increase in the anodic part of the polarographic waves given by bromine. This rapid increase accompanies the rapid increase of the conductance of the solution (Fig. 9). The polarogram obtained after equilibrium is established is in accord with that of hydrogen bromide; this indicates that bromide is quantitatively reduced to the bromide ion in DMF. This behavior may be explained in terms of the following mechanism:

$$Br_2 \rightleftarrows 2Br\cdot \quad (15)$$

$$Br\cdot + DMF \rightarrow H^+ + Br^- + R \quad (16)$$

$$Br^- + Br_2 \rightleftarrows Br_3^- \quad (17)$$

$$Br_3^- \rightleftarrows 2Br\cdot + Br^- \quad (18)$$

The net result would be:

$$Br_2 + 2DMF \rightarrow 2H^+ + 2Br^- + 2R \quad (19)$$

Mechanism of the Electrode Reaction of Bromine and the Tribromide Ion in DMF. The following electrode reaction mechanism has been proposed by Sinicki and Bréant[8] for the reduction of bromine in DMF at the platinum electrode:

$$3Br_2 + 2e \rightleftarrows 2Br_3^- \quad (20)$$

$$2Br_3^- + 4e \rightleftarrows 6\,Br^- \quad (21)$$

A similar mechanism has also been offered by Michlmayr and Sawyer[13] for the oxidation of hydrogen bromide in dimethyl sulfoxide at the platinum electrode. However, in the present study the dropping mercury electrode was used as the indicator electrode, and it is reactive to both bromine and the tribromide ion. If the heterogeneous reactions between mercury and bromine, and between mercury and the tribromide ion, are very rapid, the formation of mercuric bromide and of the tribromomercurate ion may precede the electrode reactions. Thus, the following mechanisms can be considered for bromine:

(Chemical process)

$$Br_2 + Hg \rightarrow HgBr_2 \quad (22)$$

(Electrode process)

$$3HgBr_2 + 2e \rightleftarrows Hg + 2HgBr_3^- \quad (23)$$

$$2HgBr_3^- + 4e \rightleftarrows 2Hg + 6Br^- \quad (24)$$

and for the tribromide ion:

(Chemical process)

$$Br_3^- + Hg \rightarrow HgBr_3^- \quad (25)$$

(Electrode process)

$$2HgBr_3^- + Hg \rightleftarrows 3HgBr_2 + 2e \quad (26)$$

$$2HgBr_3^- + 4e \rightleftarrows 2Hg + 6Br^- \quad (27)$$

These mechanisms are supported by the fact that the polarographic characteristics of bromine and the tribromide ion are closely similar to those of mercuric bromide and the tribromomercurate ion respectively. The electrocapillary curve of the solution of bromine in DMF was also very similar to that of mercuric bromide. Sinicki and Bréant[8] have reported that the tribromide ion in DMF gives two waves, anodic and cathodic, at +0.57 and −0.46 V *vs.* Hg/Hg(II) at the platinum electrode. The difference (1.03 V) in the half-wave potential between these two waves is much greater than that observed at the dropping mercury electrode (0.40 V). This may be caused either by the irreversibility of the electrode reaction at the platinum electrode or, more probably, by the difference between the depolarizers in the two cases.

In any case, however, the relations between the current (i) and the potential of the dropping mercury electrode (E) should be expressed for the first wave of the tribromide ion or of bromine measured after equilibrium is attained as:[23]

$$E_p = C_p + (\boldsymbol{RT}/2\boldsymbol{F}) \ln i^3/(i_d - i)^2 \quad (28)$$

and for the second wave as:

$$E_n = C_n - (\boldsymbol{RT}/2\boldsymbol{F}) \ln i^3/(i_d - i) \quad (29)$$

where i_d is the limiting current and where C_p and C_n are constants. The results of the logarithmic plot for the waves of the tribromide ion, as well as those for bromine (Fig. 10), show that Eqs. (28) and (29) hold for these depolarizers. The reciprocal slopes of the logarithmic plots are equal to 0.032—0.035 V for the first wave and to −0.040 ——0.041 V for the second wave. Both of the values are somewhat larger than the theoretical

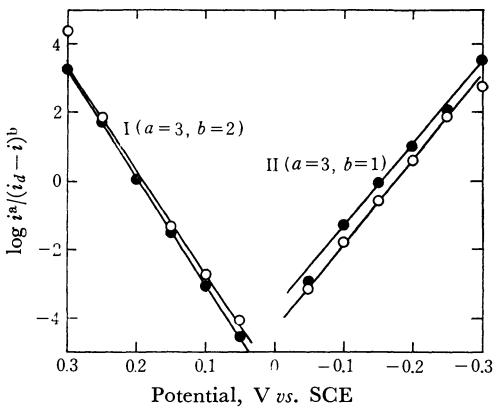

Fig. 10. Analysis of the polarograms of 1.0 mM Br_3^- (●) or of 1.0 mM Br_2 measured *ca.* 2 hr after it was added to DMF (○).

reciprocal slopes; I(●), 0.032 V; II(●), −0.041 V; I(○), 0.035 V; II(○), −0.040 V

value (0.030 V), but virtually agree with those obtained for the waves of the tribromomercurate ion (0.032 and −0.038 V respectively[23]).

From Eqs. (28) and (29), the following relations between the half-wave potentials ($E_{1/2}$) and the limiting currents (i_d), or between $E_{1/2}$ and the concentrations (C) of the tribromide ion or of bromine, can easily be derived for the first wave:

$$E_{p,\,1/2} = C_p' + (\boldsymbol{RT}/2\boldsymbol{F}) \ln C \qquad (30)$$

and for the second wave:

$$E_{n,\,1/2} = C_n' - (\boldsymbol{RT}/\boldsymbol{F}) \ln C \qquad (31)$$

Fig. 5 shows that these relations also hold for the depolarizers.

No close examination was made of the maximum which appeared at −2.15 V *vs.* SCE on the polarograms of hydrogen tribromide and hydrogen bromide. However, it was found that no maximum arose on the polarograms with tetraethylammonium tribromide, but that a maximum appeared on the polarogram with hydrogen perchlorate. This clearly indicates that the hydrogen ion is responsible for the maximum.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2835—2839 (1970)

The Thermal Annealing Behavior of ^{80}Br Recoils Produced by the Nuclear Isomeric Transitions in Alkali Metal Bromates*[1]

Teikichi SASAKI*[2] and Takanobu SHIOKAWA

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received April 8, 1970)

The transient annealing behavior of bromine recoils produced by isomeric transition was studied in five alkali metal bromates. In the case of ^{80m}Br-labelled potassium bromate, the isothermal annealing curves were characterized by maximum and minimum points. A numerical treatment of them indicated that, at the earlier stage of the thermal treatment, the annealing processes proceeded very fast, which was ascribed to the characteristics of the isomeric transition recoils. A remarkable effect of the cationic components on the thermal annealing was observed and interpreted in terms of their ionization potentials.

Several investigations have been reported into the thermal annealing behavior of bromine recoils produced by the radiative neutron capture.[1-5] However, no detailed work has been made on the thermal annealing effect of isomeric transitions.

Jones[6] found that the retention for ^{80}Br recoils in the ^{80m}Br-labelled sodium bromate increased rapidly for a few minutes and then decreased over a longer period on thermal annealing. Shiokawa and his co-workers[7] have also studied the transient

annealing of the recoils in the ^{80m}Br-labelled potassium bromate. They observed that the annealing curves had maximum and minimum points and that the increase in the retention continued even after the radioactive equilibrium had been reached. The thermal annealing behavior of the recoils produced by isomeric transition depends only on the annealing temperature, while that of the recoils produced by neutron capture is complicated with the secondary effects of gamma radiation during a pile irradiation, for this radiation inevitably produces vacancies, color centers, various defects, etc. Therefore, the transient annealing of ^{80}Br recoils seems to provide us with direct information about the effects of the inherent crystal defects on the thermal annealing.

This paper will describe the annealing behaviors of ^{80}Br recoils produced by the nuclear isomeric transition. A numerical treatment will be given to explain the role of the inherent crystal defects. The effects of the cations, which supports the previous assumptions regarding the thermal annealing of manganese recoils[8], will also be described.

Experimental

Samples. The potassium bromate labelled with ^{80m}Br atoms was prepared by a previously-described method.[7] The other labelled alkali metal bromates were prepared from the potassium bromate by usnig cationic exchange resin. All the samples except for lithium salt were dried at 160°C for 1 hr, while the latter was dried at 110°C for 1 hr.

Thermal Annealing Procedure. After drying, all the samples were stored at the temperature of liquid nitrogen until the radioactive equilibrium was attained. The thermal annealing procedure in the temperature region above 100°C was usually carried out by using an oil bath whose temperature was controlled within ±1°C.

Chemical Separation and Radioactivity Measurements. Although most of the samples were dissolved in redistilled water, in some cases aqueous solutions of methanol or solutions whose pH had been adjusted with nitric acid or sodium hydroxide were used as the solvents. The chemical separations were performed by the extraction method described by Saito *et al.*[9] The radioactive measurements were carried out by means of a multi-channel pulse-height analyser connected with a well-type NaI(Tl) scintillation detector. The 0.62 MeV gamma rays of ^{80}Br were counted for aliquots of the organic and the inorganic fractions. The retention—the yield of the inorganic fraction—was calculated in a manner reported before.[7]

Results and Discussion

Thermal Annealing Processes. The recoil species detected were the bromide and bromate ions, but no evidence for the presence of $^{80}BrO_2^+$ ions found in the ^{80m}Br-labelled bromate solution by Campbell[10,11] was obtained.

The transient annealing curves of ^{80}Br recoils in the labelled potassium bromate are shown in Fig. 1. In these experiments, samples were stored for 3 hr at −196°C to ensure the radioactive equilibrium and were then quickly heated to 184 or 264°C. While the annealing curves have maximum and minimum points in the early stage of the heating, the retentions increase slowly even after the radioactive equilibrium has been attained. In Fig. 2, the retentions for the samples annealed for 3—4 hr are plotted against the annealing temperatures. The retentions are constant for all the bromates in the temperature region below room temperature, while they increase slowly at higher temperatures. All the alkali bromates show different rates of thermal annealing.

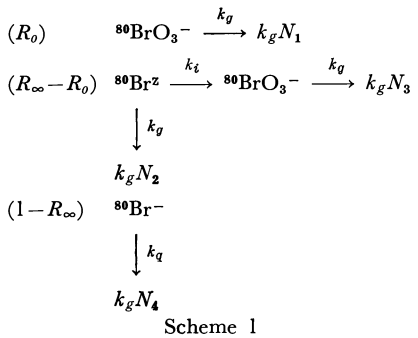
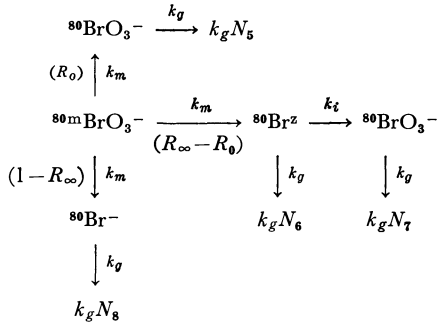
In order to discuss quantitatively the mechanism of the thermal annealing of ^{80}Br recoils, corrections must be made for the radioactive growth and decay of ^{80}Br atoms during the thermal annealing. Their schematic processes and the thermal annealing of ^{80}Br recoils are shown in Fig. 3.



Scheme 1



Scheme 2

Fig. 3. Schemes for the radioactive growth and decay of ^{80}Br and for the thermal annealing processes.

In these schemes, k_m and k_g are the decay constants of the metastable and ground states, while k_gN_{2i-1} and $k_gN_{2i}(i=1, 2, 3, 4)$ are the radioactive intensities corresponding to the bromate ions and the bromide ions respectively. R_0 is the initial yield of the recoil species which become precursors of the bromate ion in consequence of the isomeric transition at −196°C, while R_∞ is the plateau or the asymptotic value of the retention in the annealing curve.

Scheme I shows the changes in the initial yield of the recoil species; these species are, respectively, R_0, $(R_\infty - R_0)$, and $(1-R_\infty)$ at the beginning of the thermal treatment. An intermediate species, Br^z, which may be converted by the thermal annealing to a precursor of the bromate ion with a rate constant, k_i, is assumed. Scheme 2 shows the annealing and the decay processes of the recoils which are produced during the thermal treatment of the sample. Thus, considering the radioactive growth and decay of ^{80}Br, the retention, R, is related to the annealing time, t, as follows (see also the Appendix):

$$R = R_0 + [k_i(R_\infty - R_0)\{1 - \exp(-kt)\}]/k$$

where $k = k_g + k_i - k_m$. Since the values of R and R_0 are determined experimentally k_i can be calculated by varying the value of R_∞ as a parameter.

Some of the calculated results are shown in Fig. 4. The constant values of k_i are obtained after the initial rapid decrease in both the annealing temperatures. The changes in k_i show similar trends regardless of the changes in R_∞ at the same annealing temperature.

The results from the transient annealing seem to offer direct information about the role of the inherent crystal defects in the thermal annealing processes of bromine recoils. Campbell[3] has found that the thermal annealing of the ^{82}Br recoils produced by the (n, γ) reaction in the sodium bromate could be prevented by heating the samples prior to the neutron irradiation. This phenomenon was ascribed to the removal of the crystal defects, which might otherwise participate in the annealing processes of the recoils in the non-heated sample. The observations about k_i may, then, be interpreted as follows. The concentration of crystal defects is higher in the early stage of the thermal treatment, and the thermal annealing proceeds very fast. Since it becomes lower after a few hours' heating, the processes of the ^{80}Br recoils produced during the thermal treatment are

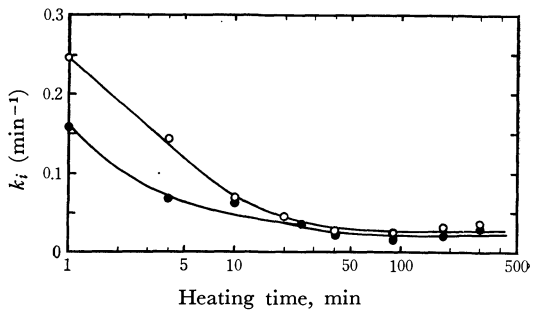


Fig. 4. Variations of k_i calculated from the results in Fig. 1.

●: 184°C, $R_\infty = 0.60$ ○: 264°C, $R_\infty = 0.65$

Table 1. The annealed fractions in the alkali metal bromates

Compound	R (%)		ΔY(%)	ΔR(%)*
	−196°C	184°C		
$LiBrO_3$	25.7±1.3	40.5±1.1	14.8	24.0
$NaBrO_3$	31.4±1.0	47.2±0.8	15.8	—
$KBrO_3$	32.5±1.2	43.6±1.3	11.1	19.5
$RbBrO_3$	25.3±1.2	34.2±1.0	8.9	—
$CsBrO_3$	32.2±1.0	35.5±0.8	3.3	17.8

* The values of ΔR were estimated from the work by Boyd and Larson[4] as follows:
$\Delta R = R$(200°C, 1 hr) − R(room temperature)

suppressed; this corresponds to the rapid decrease in the value of k_t with the lapse of the annealing time.

Effect of the Cations. A remarkable effect of the cations was observed in the thermal annealing behavior of the recoils. Table 1 shows the retentions for the samples stored at −196 and 184°C for 5 hr and the values of ΔY, which are the fractions annealed between these two temperatures. The tabulated values are the means of three determinations. The values of ΔR are the annealed fractions of ^{82g}Br recoils estimated from the work by Boyd and Larson.[4] The values become smaller in the order of the atomic number of the cation, and the tendencies are independent of the type of nuclear transformation.

In a study of the radiolytic decomposition of the alkali metal bromates, Boyd and his co-workers[12] found the relationship between the G-value and the crystal free space. The latter term was introduced by Saito and his co-workers[9] in order to interpret the amount of the retention for bromine recoils produced by the (n,γ) reactions. However, the electrostatic factor seems to influence the annealing behaviors of the recoils more strongly. The relationship between ΔY and the first ionization potential of the alkali metal is shown in Fig. 5.

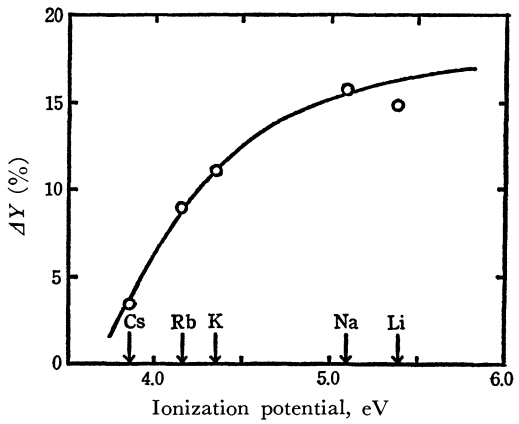

Fig. 5. Relationship between the retention and the ionization potential of alkali metals.

Although the trend is similar to that observed for the annealing behavior of bromine recoils in alkaline earth metal bromates,[13] it is entirely the reverse of the results for the permanganates salts.[8] These observations suggest that the thermal annealing is the more promoted as the polarization of the lattice constituents is larger, or as the electron density of the inactive bromate ion is higher, and that it proceeds through a direct interaction between the bromate ion and the reduced species of bromine recoil. The present conclusions also support the previous considerations regarding the annealing behavior of manganese recoils.[8]

Comparison with the Results for Other Nuclear Transformations. The thermal annealing of bromine recoils produced by the isomeric transition proceeds more rapidly than that of those produced by the (n,γ) reactions.[1-5] Furthermore, the retention for the former nuclear process is higher than those for the other nuclear transformations at room temperature, as Table 2 shows.

Table 2. Retentions for the various nuclear transformations in potassium bromate crystals

Nuclear transformation	Retention (%)	Reference
$^{80m}Br \xrightarrow{IT} {}^{80}Br$	35.5±1.2	present work
$^{79}Br(n,2n)^{78}Br$	12.4±0.4	14)
$^{79}Br(n,\gamma)^{80m}Br$	12±1	9)
$^{81}Br(n,\gamma)^{82m}Br \xrightarrow{IT} {}^{82}Br$	14.6±0.2	9)

A similar effect of the different nuclear processes on the retention was also observed in the case of aqueous solutions of labelled potassium bromate; the retention was 24.6±2.3% for the $^{80m}Br \xrightarrow{IT} {}^{80}Br$ process, whereas it was lower than 5% for the

$^{79}Br(n,\gamma)^{80m}Br$ reaction. By an approximate calculation, the initial kinetic energy is estimated to be less than 50 eV for the isomeric transition, while it is 220 eV for the (n,γ) reaction and 260 keV for the $(n,2n)$ reaction. Therefore, the disordered region of the ^{80}Br recoil sites may be smaller than those of the recoils produced by the (n,γ) and $(n,2n)$ reactions, and the recovery process for the former may proceed faster than those for the latter in the condensed phase. These properties caused by the isomeric transition account for the characteristic annealing curves shown in Fig. 1.

The authors wish to thank Dr. K. Yoshihara and Dr. T. Omori for their useful discussions. They are also indebted to Dr. K. Kondo for arranging the bremsstrahlung irradiation in the Laboratory of Nuclear Science of Tohoku University.

Appendix

In order to obtain information about the processes of the thermal annealing of ^{80}Br recoils, corrections of the measured radioactivities must be made for the growth and the decay of ^{80}Br atoms. According to the schemes shown in Fig. 3, $^{80m}BrO_3^-$ ions are converted to $^{80}BrO_3^-$, ^{80}BrZ, and $^{80}Br^-$ ions in consequence of the isometic transition at the ratio of R_0, $(R_\infty - R_0)$, and $(1-R_\infty)$ respectively. If these values are taken to be constant regardless of the annealing time, Scheme I under the state of radioactive equilibrium may be expressed as follows:

$$\frac{dN_2}{dt} = -k_g N_2 - k_i N_2 \tag{1}$$

$$\frac{dN_4}{dt} = -k_g N_4 \tag{2}$$

where N_2 and N_4 are, respectively, the numbers of Br^z and bromide ions after the lapse of annealing time, t. Thus, the values of N_2 and N_4 are given by the following equations:

$$\ln N_2 = -(k_g+k_i)t + \ln(R_\infty - R_0)N_g^\circ \tag{3a}$$

or:

$$k_g N_2 = k_g(R_\infty - R_0)N_g^\circ \exp\{-(k_g+k_i)t\} \tag{3b}$$

and:

$$\ln N_4 = -k_g t + \ln(1-R_\infty)N_g^\circ \tag{4a}$$

or:

$$k_g N_4 = k_g(1-R_\infty)N_g^\circ \exp(-k_g t) \tag{4b}$$

Equations for Scheme II are given with the same considerations as for Scheme I:

$$\frac{dN_6}{dt} = k_m N_m - k_i N_6 - k_g N_6 \tag{5}$$

$$\frac{dN_8}{dt} = k_m N_m - k_g N_8 \tag{6}$$

The values of N_6 and N_8 are evaluated from the equations for a transient equilibrium:[15]

$$k_g N_6 = \frac{k_g k_m (R_\infty - R_0)N_m^\circ}{k_g + k_i - k_m} \times [\exp(-k_m t) - \exp\{-(k_g+k_i)t\}] \tag{7}$$

$$k_g N_8 = \frac{k_g k_m (1-R_\infty)N_m^\circ}{k_g - k_m} \times \{\exp(-k_m t) - \exp(-k_g t)\} \tag{8}$$

and:

$$N_g^\circ = \frac{k_m}{k_g - k_m} N_m^\circ \tag{9}$$

In the above equations, N_m° and N_g° denote the total numbers of ^{80}Br and ^{80m}Br atoms at $t=0$. The sum of Eqs. (3b), (4b), (7), and (8) gives the radioactive intensity of the bromide fraction. Therefore, the retention can be related with the annealing time as follows:

$$\begin{aligned} R &= 1 - \frac{\sum_{i=1}^{4}(k_g N_{2i})}{k_g N_g} \\ &= 1 - \frac{(k_g-k_m)(N_2+N_4+N_6+N_8)}{k_m N_m^\circ \exp(-k_m t)} \\ &= R_0 + \frac{k_i(R_\infty - R_0)}{k_g+k_i-k_m}[1-\exp\{-(k_g+k_i-k_m)t\}] \end{aligned} \tag{10}$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2840—2844 (1970)

The Syntheses and Properties of the Benzothiazole or Benzimidazole Derivative Adducts of Tin(II, IV) and Antimony(III) Halides

Akira Ouchi, Toshio Takeuchi and Iwao Taminaga

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received April 9, 1970)

The benzothiazole, 2-amino-benzothiazole, benzimidazole-2-thiol, and benzothiazole-2-thiol adducts of tin(II, IV) chlorides, antimony(III) chloride, and antimony(III) bromide with the formulae of $M^{n+}L_mX_n^-$ (where L is the ligand and where X is Cl or Br) were synthesized. From their electronic and infrared spectra, it can be seen that the 2-amino-benzothiazole adducts are more stable than those of other ligands and that the metal–ligand bonds in the former remain even in the ethanolic solution.

Benzothiazole(BT), benzimidazole(BI), and their 2-derivatives (2-amino-benzothiazole (ABT), benzimidazole-2-thiol(BIT), and benzothiazole-2-thiol(BTT), for example) are interesting ligands, and many transition metal complexes have already been synthesized and investigated.[1-8] All of these studies, however, have been confined to the transition metal complexes; the tin(II, IV) and antimony(III) adducts have not yet been reported on. Since we expected that tin and antimony halides could also form adducts with such ligands, we attempted syntheses and thus obtained a series of adducts.

Experimental

Starting Materials. The ligands used were all Tokyo Kasei G. R. grade reagents. The tin(II) chloride, tin(IV) chloride, antimony(III) chloride, and antimony(III) bromide used were all G. R. or E. P. grade reagents of the Wako Chemical Co.; they were all used without any further purification.

The organic solvents used, such as isopropyl ether, acetone, and ethyl alcohol, were all of the E. P. grade and were used after distillation.

The Syntheses of the Adducts. *The synthesis of the Benzothiazole-2-thiol Adduct of Tin(IV) Chloride.* Anhydrous tin(IV) chloride and benzothiazole-2-thiol were dissolved in anhydrous ethyl alcohol in the mole ratio of 1 to 2. (The mole ratio of the starting materials varied between 1 : 2 to 2 : 1, but the same product was always obtained, though in different yields.) The solution was concentrated on a water bath to a syrupy liquid; then it was cooled and kept at room temperature several hours with stirring. The powder product thus obtained was washed well first with an isopropyl ether–acetone mixture, next by pure isopropyl ether, and finally by petroleum ether, washing being done several times with each material. The other adducts were synthesized in the same way. Some of them could be recrystallized by acetone, but the others could not. The products thus obtained were dried in a vacuum desiccator overnight.

Instruments. The magnetic moments were measured using a Gouy balance at room tempetature. The reflectance spectra were obtained with an Ito Model QU-3 spectrophotometer, using the reflectance attachment and a magnesium oxide standard. The electronic absorption spectra were obtained with a Hitachi EPS-2-type automatic recording spectrophotometer, using ethanolic-solution samples as well as nujol-mull samples. The infrared spectra were obtained by means of the nujol or hexachloro-1,3-butadiene mull procedure, using a Japan Spectroscopic Co. 403 G grating infrared spectrophotometer.

Results and Discussion

The analyses of the adducts and their expected chemical formulae are shown in Table 1. They are all diamagnetic at room temperature, and no abnormal valency of the central metal was expected. Therefore, the benzothiazole or benzimidazole derivatives in these adducts seem to be neutral, and the positive charge of the central metal ion is neutralized by halogen ions. The analytical data as well as the results of alkalimetric titration show that the 2-amino-benzothiazole adducts of tin(II, IV) chlorides contain two moles

of hydrogen chloride per mole of the adduct. It is not the adsorbed one, since the content is always constant, but it is not yet known how these molecules are bound in the adducts.

In order to study why the colors of these adducts are sometimes more intense than those of the free ligands (white or light yellow), the absorption spectra of the nujol mulls of the solid adducts were examined. The wave numbers of the maxima of the spectra coincide approximately with those of the surface diffuse-reflectance spectra, although the latter were obtained only in the visible region; moreover, it was difficult to obtain precise data in both measurements because of the experimental difficulties. The results are shown in Table 2. The absorption maximum or a shoulder appears in about the 24—26 kK region in the cases of benzothiazole-2-thiol adducts and at about 28 kK in the cases of benzimidazole-2-thiol adducts. These peaks or shoulders disappear when the substances are dissolved in ethyl alcohol. The electronic absorption spectral data of the adducts and the ligands in ethanolic solutions shown in Table 3 show that the absorption maxima appear only in the ultraviolet region. All the metal complexes of the same ligand show nearly the same spectra; even the ABT adducts of Sn(II, IV) containing hydrogen chloride show almost the same spectra as the Sb(III) adducts which do not contain it. (Therefore, in Table 3 their average values are

shown).

In the cases of BT, BIT, and BTT complexes, each free ligand also shows the same spectra as the respective metal adduct. However, in the case of ABT complexes the absorption peaks of the free ligand is somewhat different from those of the metal adducts.

Duff has reported[8] that, in the cases of nickel, copper, and cobalt complexes of benzothiazole and all its derivatives except 2-amino-benzothiazole, the ligand bonds to the central metal ion by means of the nitrogen hetero-atom of the ring just like pyridine in its complexes and not by means of the sulfur atom of the thiol or the thion group on the 2-carbon, while the 2-amino-benzothiazole shows a different behavior toward metal ions and the amino nitrogen atom seems to act as a donor atom. Probably this is also true in these tin and antimony adducts, since the spectral data indicate that 2-amino-benzothiazole adducts are more stable than the others and that their metal–ligand bonds are kept even in an ethanolic solution. On the other hand, in the cases of benzothizaole, benzimidazole-2-thiol, and benzothiazole-2-thiol adducts, the spectra show that the adducts are perfectly dissociated in the solution. However, the existence of metal-ligand bonds in the solid adducts of these ligands is quite probable (*cf.* the specific colors of the solid products and the characteristic bands in the near-ultraviolet region in the nujol mull of reflectance spectra). Among the bands of the solid adducts observed, the band at 30.5 kK of benzothiazole-2-thiol and that at 32.5 kK of benzimidazole-2-thiol are probably due to the transition of conjugated p_π electrons of the thiazole or imidazole ring. When the ligand coordinates to the metal ion by means of the hetero-atom of the ring, the electronic structure of the conjugated ring π-system changes and there should be a shift of the band. The phenomenon was observed in the cases of several BIT or BTT adducts.

The main peaks of the infrared spectra (1700—400 cm^{-1}) of the ligands and the tin(IV) chloride adducts are shown in Table 4. The general fea-

tures of the spectra of the adducts resemble those of the respective free ligand. As these peaks seem to be mainly caused by the ligands, their tentative assignments are obtained with reference to those of the benzothiazole or benzimidazole derivatives.[9-12]

In the cases of 2-amino-benzothiazole adducts, the bands of the free ligand at 1641, 1523, and 1444 cm^{-1} shift to 1629—1638, 1562—1568, and 1467—1470 cm^{-1} respectively. These bands all correspond to the stretching modes of particular bonds or to conjugated modes of the thiazole ring. Therefore, the shifts seem to be due to the bonding of of the metal, which causes the change in the bonding states in the ring system, such as the prohibition of the tautomeric transition of the ring system. The adducts of the other ligands show only far smaller shifts of the corresponding bands.

The metal-halogen and the metal-ligand stretching bands appear in the 400—200 cm^{-1} region. The metal-halogen stretching bands (Sn(II)-Cl,[13] Sn(IV)-Cl,[14-16] Sb(III)-Cl,[17] and Sb(III)-Br,[17]) have already been reported; they appear as an almost pure group vibration, and do not mix with other modes. Consequently, the bands have been assigned according to the references mentioned above.

On the other hand, the metal-ligand group frequencies are not clear. Only a very few references have yet been published for the pure group-stretching vibration between tin or antimony and nitrogen or sulfur. Duff[8] shows that the metal-nitrogen stretching mode of benzothiazole complexes is apt to mix with some ring-vibrations, as in the cases of pyridine complexes. Therefore, the bands in this region, which appear only in the spectra of the adducts and are not identified as metal-halogen stretching bands, may be assigned tentatively to the metal-ligand vibrations. The results are summarized in Table 5.

Thus, the exact structures of the adducts are not yet clear; the ligand may bond not only by means of -N but, in some cases, also by means of -S, forming a multi-layer polymer structure, as in the cases of some benzothiazole complexes reported by Duff,[8] although all the metal-ligand bonds are certainly not very strong.

The authors wish to express their thanks for the helpful discussions by Professor Yukichi Yoshino and our other colleagues of this laboratory.

The Hydrated and Anhydrous Copper(II) Complexes with Thioglycolic Acid Derivatives

Yayoi OHASHI, Toshio TAKEUCHI, Akira OUCHI and Yukichi YOSHINO

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received April 10, 1970)

The dihydrates and anhydrous copper(II) complexes with methyl, ethyl, *n*-propyl, isopropyl, *n*-butyl, and benzyl thioglycolic acids were synthesized, and their properties were investigated. The magnetic data show that the copper in the complexes is divalent and that the complexes do not have a copper(II) acetate structure. The spectroscopic data show that these ligands bond to the central metal ion as strongly as does amino acid or water. In the case of isopropyl thioglycolato copper(II) dihydrate, the blue and the violet isomers were obtained. The structures of the complexes in the solid state as well as in the solution were discussed.

In a previous paper,[1] solid metal complexes with ETTA(ethanediylidenetetrathiotetraacetic acid) and some alkyl di- or mono-thioglycolic acid derivatives were reported. The copper(II) complex of benzylthioglycolic acid was obtained in the dihydrate form as well as in the anhydrous form; their colors are quite different, the former being light blue, and the latter, dark green. On the other hand, McAuliffe recently studied the structural difference between hydrated and anhydrous nickel complexes of amino acids.[2] Therefore, in order to study the structural difference, hydrated and anhydrous copper complexes of methyl, ethyl, *n*-propyl, isopropyl, *n*-butyl and benzyl thioglycolic acids were synthesized and investigated magnetically as well as spectroscopically. In the course of this study, two isomers of isopropyl thioglycolato copper(II) dihydrate were isolated.

Experimental

Instruments. The magnetic moments of the samples were measured with a Gouy balance at room temperature (15°C). The electronic absorption spectra were obtained by the use of a Hitachi EPS-2 automatic recording spectrophotometer. The reflectance spectra were measured with an Ito QU-3 spectrophotometer, using a reflectance spectra attachment. The infrared spectra were obtained by means of a nujol or hexachloro-1,3-butadiene mull procedure, using a Japan Spectroscopic Co. DS 403 G grating automatic recording infrared spectrophotometer.

The Syntheses of the Metal Complexes. The ligands were obtained by Larsson's method[3] from thioglycolic acid and alkyl halides. The metal complexes were synthesized from the ligands and copper(II) hydroxide. A typical pattern of the process is shown below.

The Synthesis of the Isopropyl Thioglycolato Copper(II). Copper(II) hydroxide, itself produced from one gram of copper(II) chloride dihydrate and sodium hydroxide, was mixed with 2 grams of isopropyl thioglycolic acid, and the mixture was stirred. After the copper(II) hydroxide had been dissolved, the residue was filtered off; the filtrate was kept overnight in a refrigerator. A pale blue dihydrate complex was thus precipitated. The product was filtered off and repeatedly washed with diethyl ether. It could be recrystallized with acetone, but the recrystallized product was found to be an anhydrous green complex and not the dihydrate. After the pale blue dihydrate had been filtered off and the filtrate had been kept several days more in a refrigerator, the violet dihydrate was deposited as black, needle-like crystals. The complex was filtered off and washed with diethyl ether. The yield of the blue complex was 0.6 g (26%), and that of violet one, 0.7 g (31%). The yield was calculated on the basis of copper chloride.

The other complexes in the dihydrate form were synthesized by almost the same procedure, but only those in the pale blue form have thus for been obtained. The isopropyl and the benzyl thioglycolato copper(II) dihydrate were dehydrated by refluxing them with acetone or benzene respectively (the violet and blue isomers of the former gave the same green anhydrous product). However, the anhydrous methyl, ethyl, *n*-propyl, and *n*-butyl complexes could not be obtained by refluxing their dihydrates with any organic solvents; some of them were decomposed. Therefore, their anhydrous complexes were obtained by heated their dihydrate to 40°C on phosphorus pentoxide in a vacuum for about 10 hours.

Results and Discussion

The elemental analysis, the expected chemical formulae, and the magnetic moments of the com-

plexes obtained are shown in Table 1. The sulfur analyses sometimes gave values which were a little low, probably because of the experimental difficulties. However, as the contents of other elements coincided with calculated values well enough, the proposed chemical formulae seem to be supported.

The magnetic moments of these complexes are about 1.75—1.85 B.M. Although many copper(II) compounds show the magnetic moment of 1.9—2.1 B.M., some amine or amino acid complexes give values in the range of 1.8—1.88 B.M.[4-6]. Therefore, Cotton stated that usual copper(II) complexes show magnetic moments of 1.75—2.20 B.M.[7] Some copper(II) complexes show a subnormal magnetic moment (<1.74 B.M.).[8] Copper(II) acetate containing three atom bridges of the carboxyl group has a magnetic moment value of 1.43 B.M., while copper(II) bromide containing monoatomic bridges of halogen atom has a

$2H_2O$: dihydrate, $0H_2O$: anhydrous complex.

value of 1.31 B.M. These phenomena are caused by the spin-spin interaction between copper(II) ions. However, the subnormally low magnetic moment is not found in all carboxyl group bridged polymers. Copper(II) benzoate trihydrate, for example, shows a magnetic moment of 1.87 B.M. in spite of its linear polymer structure.[9] These alkyl thioglycolato complexes surely do not have a strong spin-spin interaction between copper(II) ions. It is not probable that they have a structure like copper(II) acetate, but the possibility of some weakly-bonding linear polymer structure of the copper(II)-benzoate type, for example, can not be denied.

The reflectance spectra of the solid dihydrate and anhydrous complexes as well as the absorption spectra of ethanolic or aqueous solutions of the anhydrous complexes are shown in Table 2.*1

All of the complexes studied show one band in the visible region. It has been identified as the *d-d* band ($^2E_g \rightarrow {}^2T_{2g}$) of the octahedral copper(II) ion.[10] As all octahedral copper(II) complexes are apt to be deformed by the Jahn-Teller effect, the band is broadened. These alkyl thioglycolates, do not seem to be in the pure square-planar form. The square-planar copper(II) complexes, bis-(acetylacetonato) copper(II), for example, show two bands of nearly equal intensities in the visible region, at about 15.0 and 18.0 kK; they are identified as the $^2B_{1g} \rightarrow {}^2A_{1g}$ and $^2B_{1g} \rightarrow {}^2E_g$ bands respectively.[11-13] Almost all of these alkyl thioglycolato copper(II) complexes show only one absorption maximum with a relatively low ν_{max} value, although in some cases they are broad or have a shoulder.

Two other bands in the ultraviolet region are probably charge-transfer or ligand-transition bands. By comparing the wave numbers of the *d-d* bands given in Table 2, it can be seen that, for

9) M. Inoue, T. Kishita and S. Kubo, *Nippon Kagaku Zasshi*, **84**, 759 (1963).

*1 The absorption spectra of aqueous solutions of dihydrates are the same as those of the respective anhydrous salts. However, those of ethanolic solutions of both forms are slightly different from each other, although the general features of the spectra are the same and the difference in their maximum wave numbers (ν_{max}) is small. Probably a part of the coordinated water of the solid dihydrate is not removed completely even in the ethanolic solution.

each complex, the ν_{max} of the aqueous solution is the lowest, and that of the reflectance spectra of the solid dihydrate, which is a little higher, is next. The *d-d* band of the complex in the ethanolic solution always has higher ν_{max} and ε values than those of an aqueous solution. The *d-d* band of the reflectance spectra of the dihydrates shifts to the higher-wave number side in the cases of *n*-butyl and benzyl thioglycolato complexes when they are dehydrated. However, in the cases of methyl, ethyl and propyl thioglycolates, the band shifts to the opposite side.

It seems that these facts can be explained as follows. The alkyl thioglycolic acids generally have a little stronger ligand field effect than water, and the smaller the alkyl group is, the higher the affinity of the ligand is. In the aqueous solution, however, as the concentration of water is predominant, the complex species have four molecules of water and two molecules of ligand working as a monodentate and bonding with the copper ion by means of its carboxyl oxygen only. Therefore, the wave number as well as the intensity of the *d-d* band of the aqueous solution is low, although it is higher than that of $[Cu(H_2O)_6]^{2+}$.

In the cases of solid dihydrates, the complex is also in an octahedral form, but the ligand serves as a bidentate and bond with the central metal ion not only by means of the carboxyl group but also by means of the sulfur atom, although the metal-sulfur bond is probably not strong. The other two bonds of the octahedral copper ion may be linked with each other by means of the bridge of a water molecule, thus forming a linear polymer. The species in an ethanolic solution also seems to be in an octahedral form. Probably only two alcohol molecules bond weakly to the metal ion, and the ligand molecules work as the bidentate. In the case of a solid anhydrous complex, not a simple monomeric square-planar structure, where two molecules of the ligand coordinate to the metal, but a polymeric, distorted octahedral structure bridged with the carboxyl group of the ligand, as with the amino acid complexes of nickel proposed by McAulliffe,[2] is probable.

The violet isomer of isopropyl thioglycolato copper(II) dihydrate gives a different reflectance spectra as well as a different X-ray powder pattern of the solid from those of the blue isomer. Moreover, the violet color is very deep, although the exact measurement of the intensity of the bands is impossible. However, when the violet isomer is dissolved into solvents, its absorption spectra are just the same as those of the pale blue isomer, and when the violet or blue dihydrates were dehydrated by refluxing them with acetone, the same anhydrous complex was obtained. Therefore, the structural difference between them is probably caused only by the bond type of the ligand and the water in the complex. Probably the sulfur atom of the ligand bonds more tightly to the copper ion in the violet dihydrate than in the blue one.

s: strong, m: medium, w: weak, sh: shoulder. Refer the other abbrevations in Table 1.

A nearly square planar form with two bidentate ligand molecules is probable in the former. The water molecules are only loosely bonded or are held in crystalline interstices.

The infrared spectra (1700—200 cm^{-1}) of the complexes were studied; their tentative assignments, obtained with reference to those of oxalato, acetylacetonato, and amino acid complexes,[2,6,7,14-16] are shown in Table 3.

The antisymmetric COO stretching bands of the complexes appear at about 1580—1590 cm^{-1}. These values correspond to those of glycinato and other amino-acid complexes. The bridging carboxyl groups of metal carboxylato complexes also show the band in this region. Therefore, the low wave number of the band is not necessarily a proof of the ionized carboxyl group. The symmetric COO stretching bands appear at about 1440—1460 cm^{-1}. In the far infrared region, the ν(Cu–O) bands of pyridine-1-oxide complexes are found at about 400 and 450 cm^{-1};[17] that of acetylacetonate, at about 480 cm^{-1},[14] and those of oxalato complexes, at about 420 cm^{-1}. Therefore, the ν(Cu–O) bands of these alkyl thioglycolato complexes should appear near the 400—450 cm^{-1} region. The bands in 360—410 cm^{-1}, which appear only in the spectra of these metal complexes, not in those of the free ligands, are tentatively assigned as ν(Cu–O) bands, although their wave numbers are a little low.

The metal-sulfur stretching band of the first transition metals have been reported to occur over a wide range of wave numbers,[7] the bands of monothio- or dithio-β-diketonates occur at about 350 cm^{-1}, while the bands occur in the range of 205—298 cm^{-1} in the cases of thiourea adducts.[18] A broad band at 205 cm^{-1} was identified as the ν(Cu–S) one in the case of the ethylenethiourea complex of copper(I). Consequently, the bands at about 250 cm^{-1} can be tentatively assigned.

A strong band at about 450—470 cm^{-1} is also observed in the spectra of all metal complexes. However, the free ligands also have the band. Therefore, it is probable that this band is the δ(O-CO) one. As the alkyl thioglycolato complexes are less stable than β-diketonates and such complexes, the bond between the Cu–O and Cu–S of the former are probably weaker and, consequently, their stretching bands appear in the lower-wave number region.

18) D. M. Adams and J. B. Cornell, *ibid.*, **1967**, 884.

The characteristic difference in the infrared spectra between the blue and violet dihydrate isomers appears only in about the 200—400 cm^{-1} region. In the spectra of the violet isomer, the 368 cm^{-1} band of the blue isomer shifts to 401 and 410 cm^{-1} and the band near 242 cm^{-1}, to 250 cm^{-1}. In the case of the blue isomer, it is supposed that the sulfur atom of the ligand bonds to the central copper ion more weakly, and the water coordinates more strongly. On the other hand, in the violet form, the ligand works as a bidentate and water molecules bond weakly. Therefore, the shifts of the ν(Cu–O) as well as ν(Cu–S) of the violet isomer to the higher-wave number side are reasonable, and these results are consistent with those from the electronic spectra.

The wave numbers of several infrared bands, and the tentative assignments of other alkyl thioglycolic acids and their copper(II) complexes are summarized in Table 4.

The authors wish to express their gratitude for the helpful discussions of Professor Kunihiko Watanuki, Mr. Iwao Taminaga, Mr. Bokuichiro Takano, Mr. Mitsuhisa Nakatani, and Mr. Yoshiaki Takahashi.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2850—2858 (1970)

Ion-exchange Chromatographic Analysis on the Chain Length of Polyphosphate Products

Niro MATSUURA, Tsin-ko LIN and Yoshimitsu KOBAYASHI

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received April 22, 1970)

The ion-exchange chromatographic technique was used in order to find the average chain number of a polyphosphate product. For the assignment of the *n*th polymer in the obtained chromatogram, the dependence of the distribution coefficient, K_d, on the eluent concentration examined by the use of both 20-cm and 60-cm resin columns. A lower series of polyphosphate was included in a relatively large amount in order that the average chain number based on the chromatographic analysis could be duly appreciated only for the case of basic polymers with lower molecular weights. For a product "Graham Salt" with a number of phosphate links, the higher series of polyphosphate could not be desorbed entirely from the resin column; the accurate estimation of the average number was, then, improbable. The viscosity method is also not advisable to use the computation of a mean polymerization number in the polyphosphate with a low molecular weight. An attempt was made to improve the data on the average chain number by the viscosity measurements together with the chromatographic analysis of the polymer constituent.

Among the wide range of industrial applications of the condensed polyphosphate[1,2] its use as an inorganic high polymer, soluble in water and inert to redox chemical reagents, is of great interest for promise and it holds of a possible improvement in the natural products in both the solid and dispersion phases. In order to have a correct understanding of its polymer structure, the knowledge of the chemical composition of a polyphosphate product is indispensable for physical and chemical research into the characteristic properties of this material. Paper chromatographic analysis is a convenient tool for the detection of the constituent members in a polyphosphate product;[3-5] nevertheless, the obtained result offers only a perspective on qualitative or semi-quantitative analysis. In this work, a microamount of an ingredient in the polyphosphate was examined in the presence of an excess of a major component by the ion-exchange chromatographic technique, which makes it possible to treat several hundred milligrams of the sample in order to obtain more detailed information on the chemical composition.[6] A large number

of works have been published on the analytical procedure, studying the conditions to be used in separating the constituent members of polyphosphate by means of ion-exchange chromatography;[5-10] however, few of them have dealt with the distribution of the constituent species. The conventional degree of polymerization in a polyphosphate product is evaluated as a mean value on the basis of the molar ratio in a mixture of the monobasic salt of $M^{I}H_2PO_4$ and the dibasic salt of $M^{I}_2HPO_4$ taken as starting materials, although the true degree of polymerization is far different, depending on the conditions of the synthesis, particularly on the temperature and the time of dehydration.

In the course of our studies of the hot atom and the radiation chemistry of polyphosphate in the aqueous phase and in the solid glassy state,[11] a hundred various samples were dealt with. The data resulting from the analysis of the phosphates, detected as resolved constituent members, will be summarized; they subtantiate, from the analytical point of view, the polymer structure of the condensed phosphate, using its molecular weight and polymerization number as an average.

Experimental

Reagent and Materials. For the purification of sodium triphosphate, a commercial anhydrate product which was 80% pure was used as the starting material. Purification by recrystallization[2] was carried out from an aqueous solution consisting of 20% ethyl alcohol; the procedure was repeated five times. The anhydrate polyphosphates were prepared from a mixture of monophosphates, dibasic sodium dihydrate salt, and monobasic sodium decahydrate salt by pyrosynthesis with a temperature-controlled electric-muffle furnace. A chelate triphosphate of the divalent metallic cation was obtained by the precipitation method. A hot clear solution containing one equivalent of the metallic ion and two equivalents of the triphosphate ion separates out when a chelate salt with the composition of $Na_6M^{II}(H_2P_3O_{10})_2$ is cooled. The ammonium triphosphate was obtained by the cation-exchange method through a column of ammonium-form resin, while the ammonium salt was precipitated by the addition of alcohol, as was in the precipitation of sodium salt. All the other chemical reagents used were of an analytical grade.

Chemical Analysis. For the chemical analysis, from 20 to 1000 mg of the sample were dissolved in 5 to 25 m*l* of distilled water, out of which 1 or 2 m*l* was adsorbed on a Dowex 1×8 anion-exchange resin column. The gradient elution technique described in a published paper[6] was used in the chromatographic development of polyphosphate species. Each 5- or 10-m*l* fraction of the eluates from the resin column was subjected to the colorimetry of the phosphate by the molybdenum blue method using a red filter (Madzuda VR-1 filter). A fractionated aliquot sample should be diluted for color development when the fraction is too concentrated with phosphate.

Viscosity Measurements. An Ubellohde-type viscosimeter of 1 to 5 centi-Stokes was used for the viscosity measurements. The temperature was controlled by a thermostat at 25.00±0.05°C for all the measurements. In order to obtain reproducible data, the hydrolysis of the unstable branch-points in the polyphosphate glass should be completed before the measurements by keeping the sample solution for 12 hr. According to our preliminary examination,[12] the anion species of a supporting electrolyte little affected the reduced viscosity of a sample solution. In the present work, 0.035 N sodium chloride was, therefore, employed in place of bromide. In the medium containing 0.035 N NaCl or NaBr, the reduced viscosity is regarded as constant no matter what the concentration of the phosphate is, and the intrinsic viscosity was determined by the standard of 1 g/100 m*l* phosphate solution according to this equation:

$$[\eta] = K \cdot M$$

where K is a constant based on the light scattering data given by 1.76×10^{-5} M^{-1},[13] and where M is the average molecular weight to be computed.

Results

1. Analysis of Short-chain Members. The chromatographic development of orthophosphate, pyrophosphate, and triphosphate can be effcted in an excellent resolution by using as the eluent a potassium chloride solution whose concentration is raised in an exponential-gradient form. At a certain stage of elution the effluent has a concentration of KCl, C being given by (1).[14]

$$C = C_0 + (C_r - C_0)(1 - \exp[-V_f/V_0]) \quad (1)$$

In Eq. (1) C_0 is the starting concentration of KCl in the mixing bottle of V_0 m*l* and C_r is the concentration of KCl in the reservoir joined to the mixing bottle for the supply of a concentrated eluent solution. For the purpose of the impurity analysis of a purified triphosphate hexahydrate sample, the parameters in Eq. (1) were 2×10^{-3}M HCl for C_0 and 0.6 M KCl for C_r; 500 m*l* was the volume for V_0,[6] and as the sample as much as 100 mg of $NaPO_3$ was taken for the adsorption on

a 20-cm resin column. The developed pattern, as is illustrated in Fig. 1, demonstrates that three peaks are located about equidistantly apart, even though the highest peak of the major component (triphosphate) is present thousand times in excess. In the analysis of a commercial product of triphosphate, a very small amount of the sample is required; for example, two mg or less is sufficient for an accurate analysis. However, for assaying the impurities of polyphosphate present in an orthophosphate sample, the tailing of the precedent peak interferes with the accurate computation of the nearest neighbor, as is shown in Fig. 2. The results of the impurity analysis of

triphosphate products are summarized in Table 1. A considerable amount of monophosphate is included as an impurity in a variety of triphosphate products, probably because the chemical treatment of repeated dissolutions and precipitations brings about a partial degradation of the triphosphate products.

2. Standardization of Polyphosphate Analysis. The separation of polyphosphates into their components can be achieved by anion-exchange chromatography according to their step-by-step rising negative charge on the $H_2P_nO_{3n+1}^{n-}$ ion. The resolution among them depends on the partition of polyphosphate between the resin and liquid phases, and its distribution coefficient, K_d, is defined by Eq. (2):[15]

$$K_d = (V_f - V_m)/(V_b - V_m) \quad (2)$$

The effluent volume, V_f, at a break-through point was determined from the appearance of a concentration peak, while the holding-up volume, V_m, in the column was measured by pouring 2 N hydrochloric acid through the column until the indicator added to the recipient changed color. Since the total resin-bed volume, V_b, is given by our experimental conditions, the net volume of the charged resin is, then found to be $(V_b - V_m)$ by measuring the difference. In our routine work, both 20 cm- and 60-cm columns were employed in comparing the results in detail, assuming $V_m =$ 10 m*l* for the first and 30 m*l* for the second.

As Beukenkampf *et al*,[16] have pointed out, the K_d value of a polyphosphate ion species, $H_2P_nO_{3n+1}^{n-}$, obeys the rule of *n*-power inverse proportionality with regard to the chloride concentration, [Cl$^-$], in the exchange reaction (3):

$$R_n(H_2P_nO_{3n+1}) + Cl^- = n \cdot RCl + H_2P_nO_{3n+1}^{n-} \quad (3)$$

This rule is a valuable guide for determining the polymerization number, $\bar{n}$ of the species found in a chromatogram, particularly in the analysis of a polyphosphate sample lacking several members of an unknown $\bar{n}$. To the first approximation, the activity of the chloride in the resin, [RCl], can be regarded as unity, because a greater part of the resin phase is in the form of RCl; therefore:

$$K_d = [R_n(H_2P_nO_{3n+1})]/[H_2P_nO_{3n+1}^{n-}]$$
$$= [RCl]^n/K \cdot [Cl^-]^n = 1/K \cdot [Cl^-]^n$$

or

$$\log K_d = -\log K - n \cdot \log [Cl^-] \quad (4)$$

where K denotes the ion-exchange selectivity coefficient. In accord with this rule, K_d values were obtained from the data on the gradient elution of a polyphosphate sample with the mean-chain number of ten, as is shown in Table 2. The agreement is surprisingly good; a constant value of 0.15 ± 0.03 was obtained for the sum $(\log K_d + n \cdot \log[Cl^-])$ if a non-integer number of polymerization is allowed to serve for the assignment of the *n*th polymer of a suspicious peak, very close to a distinct maximum, as is shown in Fig. 3.

However, a negative deviation of the calculated *n* in Eq. (4) was observed in the data by the use of a 60-cm column charged with Dowex 1×4, especially for higher members of polyphosphate, even though the agreement is quite excellent for the first three members, ortho-, pyro-, and triphosphates. A picture of the chromatogram pattern of the same sample developed through the use of a 60-cm resin column is shown in Fig. 4. In so far as we have observed, it is likely that the unfavored conditions are related to the incomplete attainment of the exchange equilibrium, involving a shift of the K_d value to the negative side by the use of the 60-cm column.

By taking the polyphosphate sample with a mean chain number of ten as the standard reference, two products of polyphosphate with six and twenty links of phosphate were tested in order to find if the mean chain number coincides with the average composition of polyphosphate obtained from the chromatographic data. As is shown in Figs. 5—7, the largest peak lies at nearly the effluent volume corresponding to its mean chain number, while the distribution of the members is

Sample prepared under heat at 650°C for 12 hr

not of a Gaussian type. They contained, on the one hand, a considerable amount of low polymers with three to six links and, on the other hand, very high polymers. It should be emphasized here that preparing a polyphosphate with a normalized distribution of polymer components around its mean chain number is very hard, even for a lower polyphosphate product with six to twenty chains which has a melting point lower than long-chain Graham salt.

3. Calculation of the Mean Chain Number from the Chemical Composition. The mean chain number of a polyphosphate product is determined by end-group titration or by the viscosity measurement of its solution as a function of the molecular weight. More directly, the mean $\bar{n}$ can be calculated from the data of chemical analysis. The amount of the constituent members present in a given mean $\bar{n}$ product is evaluated by the colorimetry of Molybdenum-blue in optical-

density units, denoted here by x_n, which is proportional to the phosphorus content in the resolved nth polymer. The molar abundunce is, then, (x_n/n) for each nth polymer, while the mean value of n for a polyphosphate mixture is described by (5):

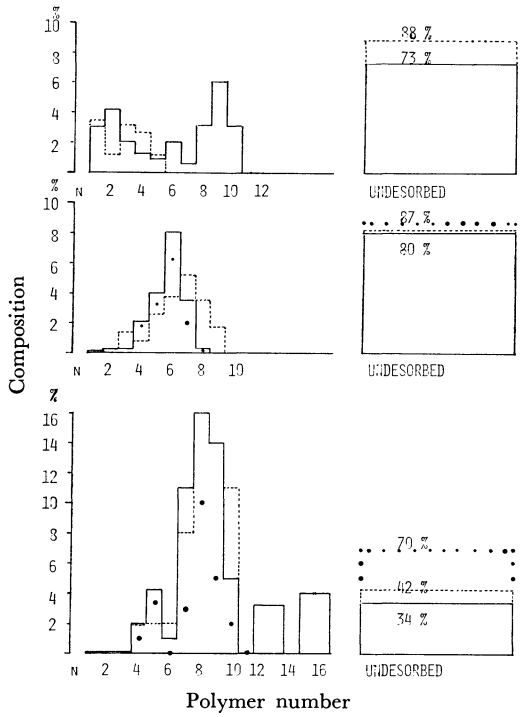

Fig. 7. Composition of polymers in Graham salt, prepared at (A) 800°C 3 hr (B) 850°C 12 hr (C) the sample as (B) irradiated in 2 MW reactor for 20 to 40 min.

Chromatographic analysis under the same condition as Fig. 5 and Fig. 6.

$$\bar{n} = \sum_1^\infty x_n / \sum_1^\infty (x_n/n) = 1/\sum_1^\infty (x_n/n) \qquad (5)$$

In practice, the greater the number of n in (5), the smaller the (x_n/n) value, and the latter value can be ignored in the calculation of the mean $\bar{n}$ value from (5) for uneluted fractions of a very high polymer. This approximation is valid in our case so long as the polyphosphate product has a mean chain length not greater than twenty. However, more than half of the higher members are left uneluted in the analysis of Graham salt. Accordingly, the mean $\bar{n}$ computed from the analysis of a developed chromatogram is surely underestimated, although a lower limit for $\bar{n}$ can be decided by means of the equation expressed in (6), where the suffix below $\bar{n}_l$ indicates the last number of n so far eluted throughout the resin column:

$$\bar{n}_l = \sum_1^l x_n / \sum_1^l (x_n/n) \qquad (6)$$

The calculated $\bar{n}$ values are displayed in Table 3, along with the lower limit, $\bar{n}_l$, as determined by (6), which must serve as a reference for the validity of the estimated $\bar{n}$ values. The difference between the values of $\bar{n}$ estimated under the above assumption and the lower limit, $\bar{n}_l$, is of no problem for a polyphosphate of a small $\bar{n}$, but the disagree-

ment is conceivable for the Graham salt. For the sake of comparison, the mean chain number, $\bar{n}$, of polyphosphate was computed by means of viscosity measurements; the results are represented in the middle column of Table 3. These data indicate that the viscosity measurements are liable to evaluate too highly the mean $\bar{n}$ number for the lower homologue of polyphosphate. This is probably because the viscosity method is based on the interaction between long-chain polymer molecules and because the contribution of lower polymers to the viscosity is disregarded.

4. Analysis of Oxyphosphorus Acid in a Lower Oxidation State. By the use of a Molybdenum(V)+(VI) reagent[17] incorporated with acid sulfite[18] to facilitate the colorimetry of phosphorus, many oxyphosphorus acids with low oxidation numbers can be observed in a chromatogram developed by the usual method described above. The elution order of the lower oxidation species is: hypophosphite($\overset{1}{P}$), phosphite($\overset{3}{P}$), hypophosphate (P_2) and diphosphite($\overset{2\ 4}{P\text{-}P}$), and other polymerized oxyphosphorus acids with low oxidation numbers. all these non-polymerized species without bridged oxygen (P–O–P) behave like a monomer species in the chromatography, as is evidenced by the effluent volumes of hypophosphate and diphosphite, which are located very close to that of orthophosphate in the developed chromatographic pattern.

The distribution coefficients, K_d, of this series are shown in Table 4; they have been obtained from the data obtained both on the 20-cm resin column in the chloride form and on the 10-cm column in the acetate form. As may be seen in Table 4, the K_d values on the acetate resin are found to be several times larger than those on the chloride resin. A favorable condition is anticipated by the use of a resin bed in the acetate form from the point of view of mutual separation; however, the ammonium acetate reagent used for elution proved to cause an unadvisable contamination of phosphorus, which increased the reagent blank in our chromatogram. The radiometric technique used as this occasion has, though, caused no trouble, and has provided good results for computing the phosphorus content by means of the radioactivity of ^{32}P. The difference in K_d values between the ammonium acetate and potassium chloride methods can be interpreted in terms of their selectivity coefficients. The results of the comparison of these two methods, shown in Table 4, indicate that the two K_d values differ by the factor, of 13, which is in good agreement with the selectivity coefficient of the acetate ion to the chloride-form resin of Dowex 1×8.[19]

Discussion

As may be seen in Table 1, the commercial products named metaphosphate and metaphosphoric acid and formulated as MPO_3 and HPO_3 respectively, contain polyphosphate in a diverse composition. No PO_3^- ion is substantiated as a stable anion, taking part in the hydrolysis and condensation reactions, although such an ion is frequently assumed to be a transient intermediate in interpreting the kinetic behavior of phosphate derivatives. In general, the polyphosphate anion, $H_2P_nO_{3n+1}^-$, is characterized as a PO_3^- donor in an aqueous medium, while orthophosphate and lower members of polyphosphate behave like PO_3^- acceptors under limited conditions of a strongly dehydrated and acid medium. The identity of the lower polymers of phosphate with three to six links, appearing in considerable yields throughout the hydrolysis process of Graham salt, has been established by several authors.[11,12] It appears likely that there exists a polymer unit with chain or ring numbers of three to six in the intermediate stage of the alkaline hydrolysis of a long-chain polymer, and that a similarity exists in the dehydration of a single phosphate into a polymer. The quite high yields of the lower members in contrast to the low yields of the middle members of polyphosphate, as established in this work, reflect the important role played by the lower polymer in the condensation process. This means that the growth of the chain length needs a certain amount of phosphates with a low polymerization, one of them three to six. This coincides with the fact that the eutectic mixture has a composition corresponding to hexapolyphosphate, with a (NaH_2PO_4/Na_2HPO_4) ratio around two and with a melting point of 550°C. The contribution of the low-members of polyphosphate to the chemical composition was, thus, emphasized in correctly com puting the average number of links in polyphosphate in relation to the structure and the kinetic behavior of polyphosphate. The viscosity data, on the other hand, underestimate this contribution, since the viscosity is mostly decided by the long-chain polymers alone and is little affected by the presence of a solute with a low molecular weight. In view of the above points, and by a combination of two complimentary contributions, a more accurate evaluation of the mean chain number, $\bar{n}$, is possible on the basis of the data of

the chromatographic analysis as well as those of the viscosity measurement, by the following relation (7):

$$1/\bar{n} = (1-x_f)/\bar{n}_c + x_f/\bar{n}_v \quad (7)$$

Equation (7) can be interpreted in terms of $\bar{n}_c$, the mean chain number as computed by chromatographic analysis, and $\bar{n}_v$, that based on the visocity data, where x_f is the fraction of phosphorus content belonging to the high-polymer group that could not be desorbed by our chromatographic technique. The assumption previously introduced for computing a mean $\bar{n}$ from the chromatographic data was that x_f, the high-polymer fraction, was considered to be. On this assumption, the $\bar{n}$ in (7) is exactly equal to $\bar{n}_c$. The results of the computation of $\bar{n}$, represented in the last column of Table 3, provide a reasonable way to correct the discrepancy in the data between those obtained by chromatographic analysis and those obtained by viscosity measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2858—2862 (1970)

The Copolymerization of Dimethallylidenepentaerythritol and Dicrotylidenepentaerythritol with Maleic Anhydride*[1]

Tatsuro OUCHI and Masayoshi OIWA*

* *Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita-shi, Osaka*

(Received October 14, 1969)

Dimethallylidenepentaerythritol (DMAPE) and dicrotylidenepentaerythritol (DCPE) have been copolymerized with maleic anhydride (Manh), using benzoyl peroxide as an initiator. From the results of the UV spectrum concerning the rate of copolymerization, it was found that the copolymerization might proceed on the *pseudo*-terpolymerization of the charge transfer complex-allylidene group-Manh. The following functional group reactivity ratios were calculated at 60°C in these systems:

DMAPE(M_1)-Manh(M_2)
$r_{1c}K=0.77$, $r_{2c}K=0.058$
$r_1=0.05$, $r_2=0.025$
DCPE(M_1)-Manh(M_2)
$r_{1c}K=0.89$, $r_{2c}K=0.057$
$r_1=0.02$, $r_2=0.020$

It has already been pointed out that maleic anhydride (Manh) is copolymerized alternately with various vinyl monomers.[1-10]

In a previous experiment paper,[11] the copolymerization of diallylidenepentaerythritol (DAPE) and Manh was carried out as one of a series of studies of the copolymerization of DAPE; then the behavior of the radical copolymerization was investigated by means of kinetic equations derived by assuming a *pseudo*-tersystem.

On the other hand, 2-vinyl-1,3-dioxolane (VDOL) has been further copolymerized with Manh, and the difference in the copolymerizations between mono- and di-allylidene cyclic acetal compounds with Manh has been studied.[12]

In this paper, the copolymerizations of dimethallylidenepentaerythritol (DMAPE) and dicrotylidenepentaerythritol (DCPE), which are α,α'- and β,β'-substitution products of DAPE respectively, with Manh will be reported; the functional reactivity ratios will be estimated, and the in-

fluence of substituents on the reactivity of copolymerization will be discussed.

Experimental

Materials. The DMAPE and DCPE were synthesized by a previously-reported method.[13] The Manh was purified by the recrystallization and vacuum distillation of a commercial product.

The benzoyl peroxide (BPO) used as an initiator and the solvents were purified by the conventional method.

Copolymerization Procedure. A glass ampoule was charged with prescribed amounts of each monomer, BPO, and benzene in such a way that the concentration of DMAPE or DCPE was kept constant. The ampoule was then sealed off under a vacuum and set in a thermostated water bath at 60±0.1°C, without stirring, for the time necessary to give less than 10% of conversion. A hydroquinone/benzene solution was added to the reaction solution to inhibit further polymerization, and the polymer was precipitated from an excess of dehydrated ether. The polymer thus obtained was washed repeatedly with ether in the Soxhlet extractor and dried under reduced pressure to a constant weight.

Analysis of the Copolymer. The composition of the resulting copolymer was determined by C and H elementary analysis. The residual unsaturation was calculated by the determination of the bromine value of the resulting copolymer according to a previously-described method.[14]

The UV spectrum was measured by means of an Ito Chodenpa apparatus, Model QU-3, in chloroform with a quartz cell over the range of 352—358 mμ and at room temperature.

Results and Discussion

The Ratio of "Charged" to "Reacted" Vinyl Groups. The copolymerizations were carried out at 60°C under various concentrations and ratios of the functional groups in the monomer feed. The relations among the residual unsaturation and the monomer and copolymer compositions are plotted in Figs. 1 and 2. From Figs. 1 and 2, it can be found that the DMAPE or DCPE mole fraction in copolymer increases with an increase in that in the monomer over the range of 0.3—0.4, and also with an increase in the feed concentration of DMAPE or DCPE. On the other hand, the residual unsaturation of the polymer tends to decrease with a decrease in the DMAPE or DCPE mole fraction and in the concentration in the monomer feed.

When all the allylidene-compound units in a copolymer have unreacted pendant double bonds without any cyclization or crosslinking, the ideal bromine values of the copolymer are indicated by BV_{id}; the ratio of the experimental bromine

value (BV_{ex}) to BV_{id}, that is, BV_{ex}/BV_{id}, indicates the residual unsaturation.

When the concentrations of the allylidene compounds and the Manh in the copolymer are $d(M_1)$ and $d(M_2)$, and when those of the allylidene group and the Manh in it are $d(m_1)$ and $d(m_2)$ respectively, the following relation may be obtained:

$$d(m_1)/d(m_2) = (2-BV_{ex}/BV_{id})d(M_1)/d(M_2)$$

The relations between charged and reacted vinyl

groups are plotted in Figs. 3 and 4. The reacted methallylidene- or crotylidene-group fraction tends to increase with an increase in the charged methallylidene- or crotylidene-group fraction, and also with a decrease in its concentration. It may be expected that the formation of the CT complex is related to the propagation reaction.

The Relation between the Charged Composition and the Rate of Copolymerization. The dependence of the monomer composition and concentration upon the rate of copolymerization is shown in Fig. 5. The rate of copolymerization reaches a maximum at the feed ratio of 1 : 2, regardless of the monomer concentration.

A similar tendency was also recognized in the DCPE-Manh system.

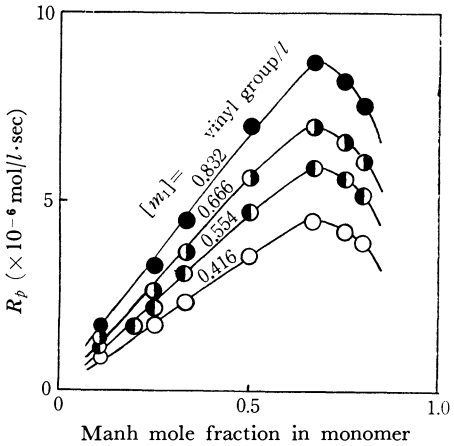

Fig. 5. Plots of the rate of copolymerization against the monomer composition in benzene at 60°C.
DMAPE-Manh

The Continuous-variation Method. The Q and e values for the functional group of DMAPE have already been calculated as 0.05 and −0.48, while those of DCPE have been obtained as 0.01

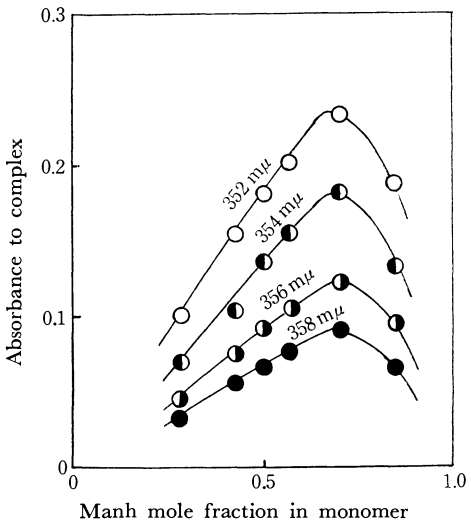

Fig. 6. The continuous variation method.
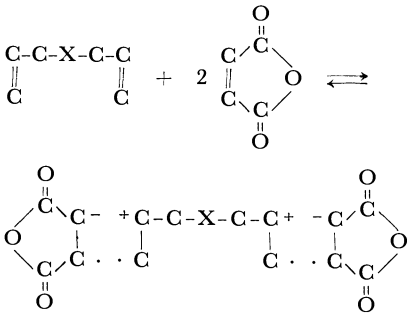
DMAPE-Manh
Solvent: chloroform, room temp.

and −0.32, respectively.[15] As the Q and e values of Manh are also 0.23 and 2.25,[16] the complex formation between such monomer pairs may be expected. Further, when DMAPE and Manh were mixed, no color appeared, but it was found according to the optical analysis, that is, according to the continuous-variation method, that a 1 : 2 complex formation occurred between the monomer[17] (Fig. 6).

A similar tendency was observed in the DCPE-Manh system.

These molecular complexes are probably CT complexes with the following structure, if we can make an analogy with the results of *p*-dioxen and Manh:[9-10]



CT Complex

The Kinetic Analysis. The copolymerizations of DMAPE and DCPE with Manh were kinetically investigated by a previously-reported method.[1]

The *pseudo*-terpolymerization of the CT complex-allylidene group-Manh is dealt with assuming that the complex is attacked on the side of Manh, assuming that the active growing chain ends become allylidene radicals. Here, m_1 denotes an allylidene group; m_2, Manh; C or m_1m_2, the complex; $m_1\cdot$, an allylidene radical, and $m_2\cdot$, a Manh radical. The following elementary reactions can then be presumed to hold in the copolymerization of these allylidene compounds and Manh:

		Rate Const.
Complex Formation	$m_1 + m_2 \rightleftarrows m_1m_2(C)$	k_1, k_{-1}
Propagation	$m_1\cdot + C \rightarrow m_1\cdot$	k_{1c}
	$m_1\cdot + m_1 \rightarrow m_1\cdot$	k_{11}
	$m_1\cdot + m_2 \rightarrow m_2\cdot$	k_{12}
	$m_2\cdot + C \rightarrow m_1\cdot$	k_{2c}
	$m_2\cdot + m_1 \rightarrow m_1\cdot$	k_{21}
	$m_2\cdot + m_2 \rightarrow m_2\cdot$	k_{22}

If a steady state is assumed for the radicals and the complex, Eq. (1) can be derived:

$$\frac{F}{1-f} = A\left(\frac{1}{B+F}\right)\left(\frac{f}{1-f}\right) - C \qquad (1)$$

where $r_1=k_{11}/k_{12}$, $r_2=k_{22}/k_{21}$, $r_{1c}=k_{1c}/k_{12}$, $r_{2c}=k_{2c}/k_{21}$, $K=k_1/k_{-1}$, $F=(m_1)/(m_2)$, $f=d(m_1)/d(m_2)$, and

$$A = \frac{r_{2c}K(m_1)+r_2}{r_1},\quad B = r_{2c}K(m_1),\quad C = \frac{r_{1c}K(m_1)+1}{r_1} \qquad (2)$$

The values of A, B, and C can be obtained by the trial-and-error method according to Eq. (1). The relation of $F/(1-f)$ *vs.* $f/(1-f)(B+F)$ is plotted in Fig. 7, when (m_1) is the 0.666 vinyl group/l on the DMAPE-Manh system. It is found that a straight line is obtained when B is 0.04. Therefore, A and C are estimated to be 1.30 and 31.3 respectively from this slope and intercept. A similar example of the DCPE-Manh system is shown in Fig. 8.

17) P. Job, *Ann. Chim.*, **9**, 113 (1928).

By varying the m_1 concentration, the *A*, *B*, and *C* values are obtained by the same procedure; the relations among *A*, *B*, and *C* *vs.* (m_1) are plotted in Figs. 9—11. Straight lines are obtained in every case, as was expected on the basis of Eq. (2).

From these slopes and intercepts, the parameters of copolymerization can be estimated to be as in Table 1.

From Table 1, it can be found that $r_{1c}K$ values became DAPE < DMAPE < DCPE, and that r_1 and r_2 values decreased unlike as in the case of $r_{1c}K$ in the order of DCPE < DMAPE < DAPE.

The values of r_{1c}, r_{2c} were much larger than those of r_1 and r_2 in allylidene compounds-Manh systems because the *K* values were presumed to be very small; therefore, it seemed that the propagation radicals reacted preferentially with the functional groups of the complex rather than with the monomer. If the *K* values are taken to be equal in these systems, such a tendency was observed in the order of DAPE < DMAPE < DCPE; the influence of an α- or β-methyl group on the reactivity of the functional group was thus recognized. Since the $r_{1c}K$ values were larger than $r_{2c}K$, $K_{1c} > K_{2c}$; this suggests that the addition rate of allylidene radicals to the complex is larger than that of Manh radicals, as had been expected.

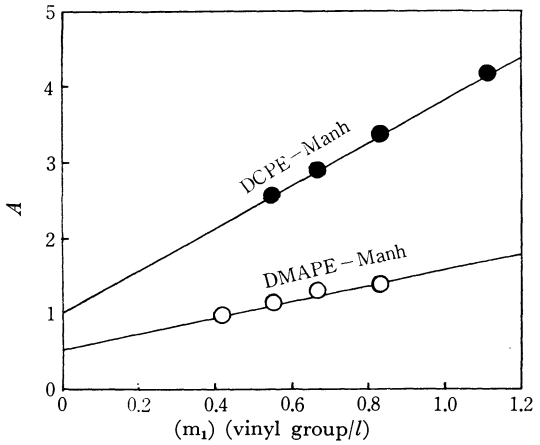

Fig. 9. Plots of *A* *vs.* (m_1).

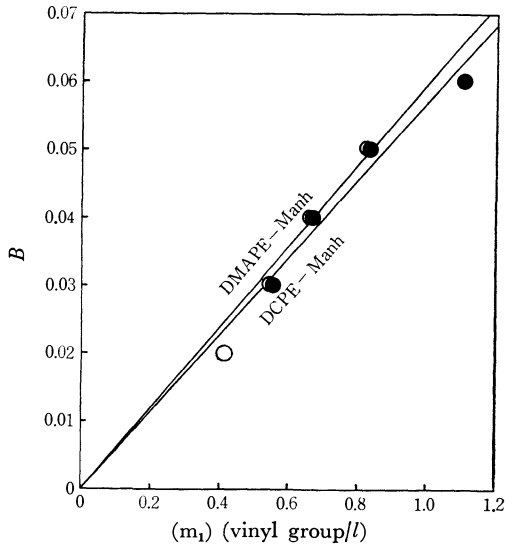

Fig. 10. Plots of *B* *vs.* (m_1).

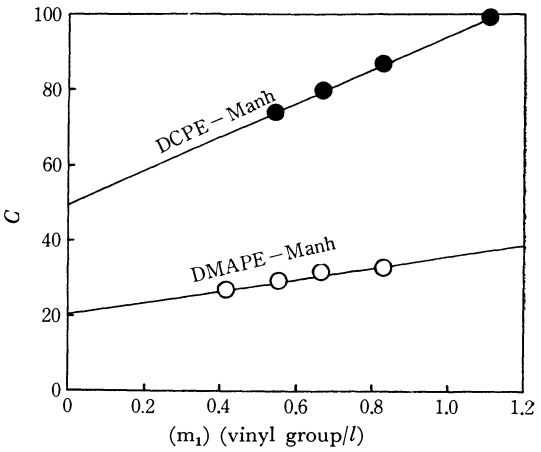

Fig. 11. Plots of *C* *vs.* (m_1).

Table 1. The parameters of copolymerization

M_2	$r_{1c}K$	$r_{2c}K$	r_1	r_2
DMAPE	0.77	0.058	0.05	0.025
DCPE	0.89	0.057	0.02	0.020
DAPE	0.76	0.055	0.08	0.030

The curves of the relation between charged and reacted vinyl group fractions agreed well with the experimental results shown in Figs. 3 and 4.

Summarizing the above results, three significant facts can be pointed out:

1) DMAPE or DCPE and Manh are copolymerized easily with a radical initiator to give the alternating copolymer, whereas neither one can be polymerized with a radical initiator. 2) The rate of copolymerization reaches a maximum at the feed ratio of 1 : 2. 3) The formation of the 1 : 2 CT complex between DMAPE or DCPE and Manh may proceed by way of a *pseudo*-terpolymerization of the allylidene group - Manh - the CT complex.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2863—2870 (1970)

The Polymerization of Di-(β-methacrylyloxypropionaldehyde)-pentaerythritolacetal*[1]

Tatsuro OUCHI, Yorihiro IMASE and Masayoshi OIWA*

** Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita-shi, Osaka*

(Received October 18, 1969)

The polymerization of di-(β-methacrylyloxypropionaldehyde)-pentaerythritolacetal (DβMPP) and the copolymerizations of DβMPP with styrene (St) and acrylonitrile (AN) have been carried out at 60°C, using benzoyl peroxide as an initiator. They have then been discussed kinetically from the point of view of cyclopolymerization. The results can be summarized as follows:

1) The relation among the rate of polymerization, R_p, the initiator concentration, (I), and the monomer concentration, (M), can be expressed by the following equations;

$$R_p/(\mathrm{I})^{1/2} = A(\mathrm{I})^{1/2} + B$$
$$R_p/(\mathrm{M}) = C(\mathrm{M}) + D$$

where A, B, C, and D are constant.

2) The ratio of the rate constant of the unimolecular cyclization reaction to that of the bimolecular propagation reaction of the uncyclized radical, k_c/k_p, was 22.0 mol/l.

3) The copolymerization of DβMPP proceeded primarily by means of cyclocopolymerization, and the ratio of the cyclization rate to the vinyl propagation also decreased with an increase in the comonomer fraction in the copolymer.

4) The following reactivity ratios were estimated on the basis of the Smets-Roovers equation:

System	$K_c=k_c/k_{11}$	$K_c'=k_c/k_{12}$	$r_1=k_{11}/k_{12}$	$r_2=k_{22}/k_{21}$	$r_c=k_{c1}/k_{c2}$
DβMPP(M_1)-St(M_2)	12.7	2.54	0.20	0.35	0.32
DβMPP(M_1)-AN(M_2)	12.7	5.08	0.40	0.35	0.61

As one of a series of studies of the polymerization of diallylidenepentaerythritol (DAPE), di-(β-methacrylyloxypropionaldehyde)-pentaerythritol (DβMPP) was prepared from DAPE and methacrylic acid; it was then confirmed to be a pure product. Although a patent has been previously published regarding the synthesis of DβMPP, its method is still far from clear.[1] On the present paper, it is well known that divinyl-compounds undergo cyclopolymerization.[2-4]

In the present paper, the polymerization of DβMPP will be discussed kinetically from the point of view of cyclopolymerization by modifying the Minoura and Mitoh method,[3] and the correlation with the rate constants will be investigated.

The copolymerizations of DβMPP with styrene (St) and acrylonitrile (AN) will also be carried out, and then the reactivity ratios will be estimated according to the Roovers and Smets procedure.[5]

Experimental

Materials. DβMPP was prepared as follows. A mixture of 310 g (1.46 mol) of DAPE, 372 m*l* (4.38 mol) of methacrylic acid, and 0.3 g of *p*-toluenesulfonic acid as an initiator was heated in a flask fitted with a reflux condenser at 55—60°C for 8—10 hr, the mixture was then washed with water to remove any unreacted methacrylic acid. Benzene was added, whereupon two layers formed; the product remaining in the benzene layer was separated and treated with sodium hydrosulfite to remove the dark color. After the benzene had been distilled under reduced pressure, the residual solution was filtered through an activated silica-charcoal layer to remove any haziness and foreign particles. The final product gave 90% of a light brown liquid and was confirmed to be DβMPP by the determination of the infrared spectrum, the molecular weight (MW), the saponification value (SV), and the bromine value (BV). $d_D^{20}=1.1353$, $n_D^{20}=1.4735$.

Found: C, 59.29; H, 7.41%; MW, 382.3; BV, 84.99; SV, 289.9. Calcd for $C_{19}H_{28}O_8$: C, 59.36; H, 7.34%; MW, 384.4; BV, 83.14; SV, 291.9.

DβMPP

oxide (BPO), and the solvents were purified by the conventional method.

Polymerization Procedure. A glass ampoule was charged with the prescribed amount of each monomer, a solvent, and BPO; it was then degassed, sealed off under a vacuum, and set, without stirring, in a thermostated water bath at 60±0.1°C. The reaction solution was poured into a large amount of petroleum ether, and the polymer which was thus precipitated was centrifuged, filtered, and then dried *in vacuo* until a constant weight was attained. The conversion was less than 10%. The homopolymer was then purified from benzene-petroleum ether. The copolymers obtained on DβMPP-St and DβMPP-AN systems were also reprecipitated from benzene-petroleum ether and acetone-petroleum ether respectively.

Analyses of the Polymer and Copolymer. The polymer was dissolved in benzene, saponified in excess alcoholic potassium hydroxide, and neutralized with hydrochloric acid; then the residual unsaturation of the polymer was determined by the method of Siggia.[6] The molecular weight of the polymer was determined by means of a vapor-pressure osmometer (Hewlett Packard Model-302) at 37°C, using benzene as the solvent.

The composition of the resulting copolymer was determined by C, H, and N elementary analysis. The residual unsaturation of the copolymer was also calculated according to the Siggia method.[6]

The infrared spectra were measured by applying the potassium bromide-pellet technique to the polymer and the salt-plate method to the monomer on a Shimadzu infared spectrophotometer, Model IR-27.

The Kinetics of Polymerization

The preliminary experiment showed that the rate of the cyclization reaction was larger than that of the propagation reaction of the uncyclized radical on the polymerization of DβMPP. Therefore, the kinetics of the polymerization of DβMPP was discussed according to a modification of the Minoura *et al.* procedure.

The kinetic equations on the following reaction scheme were derived by assuming a steady-state condition:

		Rate const.	
Decomposition of initiator	$I \rightarrow 2R\cdot$	k_d	(1)
Initiation	$R\cdot + M \rightarrow M\cdot$	k_i	
Cyclization	$M\cdot \rightarrow M_c\cdot$	k_c	
Propagation	$M\cdot + M \rightarrow M\cdot$	k_p	
	$M_c\cdot + M \rightarrow M\cdot$	k_{cp}	
Termination	$M_c\cdot + M_c\cdot \rightarrow P_c$	$\alpha^2 k_t$	
	$M_c\cdot + M\cdot \rightarrow P_c'$	$\alpha\beta k_t$	
	$M\cdot + M\cdot \rightarrow P$	$\beta^2 k_t$	

where I denotes an initiator; M, a monomer; P_c, P_c', and P, the polymers; R·, the initiator radical; M·, the uncyclized radical, and M_c·, the cyclized radical. α and β are certain constants introduced to simplify the following algebraic treatment; the rate constants of the three termination reactions are, of course, determined by the values of α and β.

Here the crosslinking may be neglected as having been treated with the initial state.

If a steady state is assumed for the different types of radicals, Eqs. (2)—(4) can be obtained:

$$(R\cdot) = fk_d(I)/k_i(M) \tag{2}$$

$$(M\cdot) = \frac{(2/\alpha)(2fk_d/k_t)^{1/2}(I)^{1/2}\{k_{cp}(M)+(\alpha/2)(2fk_dk_t)^{1/2}(I)^{1/2}\}}{k_c+(2\beta/\alpha)\{k_{cp}(M)+(\alpha/2)(2fk_dk_t)^{1/2}(I)^{1/2}\}} \tag{3}$$

$$(M_c\cdot) = \frac{(k_c/\alpha)(2fk_d/k_t)^{1/2}(I)^{1/2}}{k_c+(2\beta/\alpha)\{k_{cp}(M)+(\alpha/2)(2fk_dk_t)^{1/2}(I)^{1/2}\}} \tag{4}$$

or $$\alpha(M_c\cdot) + \beta(M\cdot) = (2fk_d/k_t)^{1/2}(I)^{1/2} \tag{5}$$

Here, f denotes the efficiency of the initiator.

The Rate Polymerization. Consequently, the rate of polymerization is given in Eq. (6);

$$\begin{aligned} R_p &= -\mathrm{d}(M)/\mathrm{d}t \\ &= 2k_p(M\cdot)(M) + 2k_{cp}(M_c\cdot)(M) \qquad (6) \\ &= (2k_{cp}/\alpha)(2fk_d/k_t)^{1/2}(I)^{1/2}(M) \\ &\quad \times \frac{1+(2k_p/k_{cp})\{(k_{cp}/k_c)(M)+(\alpha/2k_c)(2fk_dk_t)^{1/2}(I)^{1/2}\}}{1+(2\beta/\alpha)\{(k_{cp}/k_c)(M)+(\alpha/2k_c)(2fk_dk_t)^{1/2}(I)^{1/2}\}} \qquad (7) \end{aligned}$$

Eqaution (7) can be developed as:

$$R_p = R_o\{1+(a-b)x-b(a-b)x^2+\cdots\cdots\} \tag{8}$$

where:

$$R_o = (2k_{cp}/\alpha)(2fk_d/k_t)^{1/2}(I)^{1/2}(M)$$

$$a = 2k_p/k_{cp},\ b = 2\beta/\alpha$$

and:

$$x = (k_{cp}/k_c)(M) + (\alpha/2k_c)(2fk_dk_t)^{1/2}(I)^{1/2} \tag{9}$$

From the results of the investigation of residual unsaturation, it was found that the rate of cyclization was far faster than that of propagation, namely,

$$k_c(M\cdot) \gg k_p(M\cdot)(M) \tag{10}$$

Therefore,

6) S. Siggia, "Quantitative Organic Analysis *via* Functional Groups," 3rd ed., J. Wiley & Sons, New York and London (1963), p. 301.

$$k_c \gg k_p(\mathrm{M}) \tag{11}$$

Both k_p and k_{cp} may be assumed to be almost of the same order. Equation (11) is, then given by:

$$k_c \gg k_{cp}(\mathrm{M}) \tag{12}$$

The second term of x in Eq. (9) is rewritten as:

$$(\alpha/2k_c)(2fk_dk_t)^{1/2}(\mathrm{I})^{1/2} = (\alpha/2k_c)k_t^{1/2}R_i^{1/2} \tag{13}$$

where R_i is the rate of initiation.

Generally, R_i is of an order of about 10^{-8}, and k_t is about 10^8—10^6; then, $\alpha \leq 1$ in the case of a radical polymerization such as is described in this experiment. Therefore, the second term of x in Eq. (9) is influenced only by $1/k_c$.

As will be described later, the value of k_p/k_c is 0.046 l/mol. The rate constant of the propagation reaction in radical polymerization is in the range of 10—10^3; therefore, the value of $1/k_c$ is very small.

In view of these considerations, x is very small, and x^2, x^3 and other higher terms in Eq. (8) may be neglected.

Considering this approximation, R_p may be indicated as in the following equation:

$$\begin{aligned} R_p &= R_0\{1+(a-b)x\} \\ &= (2k_{cp}/\alpha)(2fk_d/k_t)^{1/2}(\mathrm{M}) \\ &\quad \times [1+\{2k_p/k_{cp}-(2\beta/\alpha)\}\{(k_{cp}/k_c)(\mathrm{M}) \\ &\quad + (\alpha/2k_c)(2fk_dk_t)^{1/2}(\mathrm{I})^{1/2}\}] \end{aligned} \tag{14}$$

Accordingly, if the monomer concentration is kept constant and the initiator concentration is varied, Eq. (14) can be written as follows:

$$R_p/(\mathrm{I})^{1/2} = A(\mathrm{I})^{1/2} + B \tag{15}$$

where:

$$\begin{aligned} A &= (k_{cp}/k_c)(2fk_d)(2k_p/k_{cp}-2\beta/\alpha)(\mathrm{M}) = \text{const.} \\ B &= (2k_{cp}/\alpha)(2fk_d/k_t)^{1/2}(\mathrm{M}) \\ &\quad \times \{(2k_p/k_{cp}-2\beta/\alpha)(k_{cp}/k_c)(\mathrm{M})+1\} = \text{const.} \end{aligned} \tag{16}$$

Similarly, when the initiator concentration is kept constant and the monomer concentration is varied, Eq. (14) can be written as follows:

$$R_p/(\mathrm{M}) = C(\mathrm{M}) + D \tag{17}$$

where:

$$\left.\begin{aligned} C &= (2k_{cp}/\alpha)(2fk_d/k_t)^{1/2}(2k_p/k_{cp}-2\beta/\alpha)(k_{cp}/k_c)(\mathrm{I})^{1/2} \\ &= \text{const.} \\ D &= (k_{cp}/k_c)(2fk_d)(2k_p/k_{cp}-2\beta/\alpha)(\mathrm{I}) \\ &\quad + (2k_{cp}/\alpha)(2fk_d/k_t)^{1/2}(\mathrm{I})^{1/2} = \text{const.} \end{aligned}\right\} \tag{18}$$

The Residual Unsaturation of the Polymer. On the other hand, the rate of the formation of the pendant double bonds in the polymer is given by:

$$\mathrm{d(m)/d}t = 2k_p(\mathrm{M}\cdot)(\mathrm{M}) + 2k_{cp}(\mathrm{M}_c\cdot)(\mathrm{M}) - k_c(\mathrm{M}\cdot) \tag{19}$$

From Eqs. (6) and (19), we obtain:

$$\mathrm{d(m)/d(M)} = 1 - \frac{k_c(\mathrm{M}\cdot)}{2(\mathrm{M})(k_p(\mathrm{M}\cdot)+k_{cp}(\mathrm{M}_c\cdot))} \tag{20}$$

The combination of Eqs. (3), (4), and (20) gives:

$$\frac{1}{(\mathrm{M})(1-\mathrm{d(m)/d(M)})} - \frac{k_p}{k_c} = \frac{k_{cp}}{2k_{cp}(\mathrm{M})+\alpha(2fk_dk_t)^{1/2}(\mathrm{I})^{1/2}}$$

which, on rearrangement, gives:

$$\frac{1}{1-2R_{us}} - \frac{1}{1+E(\mathrm{I})^{1/2}/2(\mathrm{M})} = (2k_p/k_c)(\mathrm{M}) \tag{21}$$

where:

$$2R_{us} = \mathrm{d(m)/d(M)},\quad E = \alpha(2fk_dk_t)^{1/2}k_{cp}$$

Results and Discussion

Polymerization of DβMPP. The conditions and the results of polymerization are summarized in Tables 1 and 2. From these tables, it is obvious that the rate of polymerization is not proportional to the square root nor to the first power of the initiator concentration, nor is it proportional to either the first or the second power of the monomer concentration, as was to be expected from Eqs. (15) and (17).

Table 1. Results of polymerization of DβMPP in benzene at 60°C, (M)=1.48 mol/l

(M) (mol/l)	R_p ($\times 10^{-6}$ mol/l·sec)	BV*	$2R_{us}$*	$\bar{P}_n$*
2.95	19.1	7.98	0.192	342
2.22	14.0	6.82	0.164	243
1.48	9.05	4.32	0.104	155
1.03	6.18	2.62	0.063	105
0.738	4.31	2.04	0.049	71

* The value were obtained by extrapolating to zero for the conversion.

Since the value of residual unsaturation, $2R_{us}$, was very small, the rate of the cyclization reaction might be far faster than that of the propagation reaction. That is, the residual unsaturation decreased with a decrease in the monomer concentration.

Influence of the Initiator and Monomer Concentrations on the Rate of Polymerization. When the monomer concentration is varied, it may

be kinetically expected from Eq. (15) that the plots of $R_p/(\mathrm{I})^{1/2}$ *vs.* (I) will be a straight line.

Similarly, if the initiator concentration is kept constant and the monomer concentration is varied, a linear relationship between $R_p/(\mathrm{M})$ and (M) may be expected on the basis of Eq. (17).

The results are plotted in Fig. 1, in which the fit of the experimental data to the linear relationship is fairly good. From the slopes and intercepts of the straight line shown in Fig. 1, *A*, *B*, *C*, and *D* were estimated to be 7.00×10^{-6}, 1.27×10^{-4}, 2.65×10^{-7}, and 5.68×10^{-6} respectively. Thus, the following ratios of the rate constant were calculated from the above values:

$$2fk_d = 6.95\times10^{-5}\ \mathrm{sec}^{-1}$$

$$2k_{cp}/\alpha\sqrt{k_t} = 1.14\times10^{-2}\ l^{1/2}/\mathrm{mol}^{1/2}\cdot\mathrm{sec}^{1/2}$$

$$(2k_p/k_{cp}-2\beta/\alpha)(k_{cp}/k_c) = 4.52\times10^{-2}\ l/\mathrm{mol}$$

Here, $2fk_d$ of the order of 10^{-5} seems to be pertinent when BPO is used as an initiator.

On the other hand, $2k_{cp}/\alpha\sqrt{k_t}$ of the order of 10^{-2} suggests that the termination between two $\mathrm{M}_c\cdot$ may be very fast. Therefore, $(2k_p/k_{cp}-2\beta/\alpha)(k_{cp}/k_c)$ of the order of 10^{-2} may be presumed to be much cyclized by this polymerization.

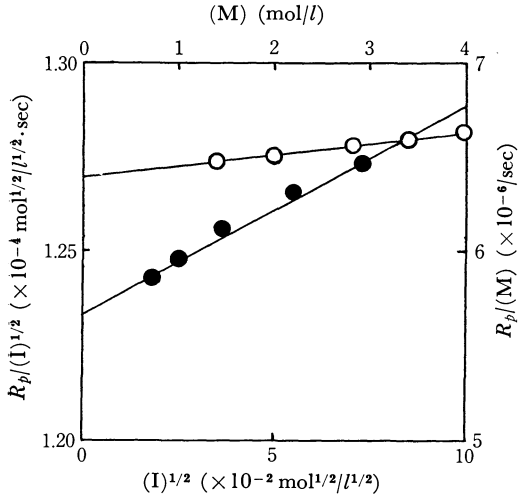

Fig. 1. Plots of $R_p/(\mathrm{I})^{1/2}$ *vs.* (I)$^{1/2}$ and $R_p/(\mathrm{M})$ *vs.* (M).

The Residual Unsaturation. If the monomer concentration is kept constant, the residual unsaturation is almost independent of the initiator concentration; the ratio of cyclization is almost never related to the initiator concentration, as is shown in Table 1. The ratio of the rate constant of the unimolecular cyclization reaction to that of the bimolecular propagation of the uncyclized radical, k_c/k_p, was evaluated by means of Eq. (21). E was then calculated to be 1.46 mol$^{1/2}/l^{1/2}$ on the basis of the previous rate constants. Accordingly, the plots of $\{1/(1-2R_{us})-(1+\mathrm{E(I)}^{1/2}/2(\mathrm{M}))\}$ *vs.* (M) are shown in Fig. 2; there is a good

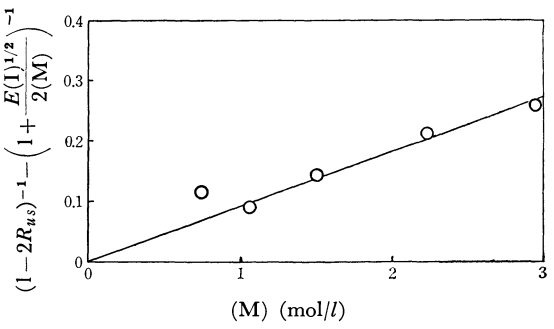

Fig. 2. Plots of $\left\{(1-2R_{us})^{-1}-\left(1+\frac{E(\mathrm{I})^{1/2}}{2(\mathrm{M})}\right)^{-1}\right\}^{-1}$ *vs.* (M).

linear relationship, as was predicted by Eq. (21). The k_c/k_p value was estimated to be 22.0 mol/l from the slope of the straight line.

As the rate of cyclization was larger than the propagation of uncyclized radicals, the previous kinetic equations may be suitable for the polymerization of DβMPP. By combining k_c/k_p and $(2k_p/k_{cp}-2\beta/\alpha)(k_{cp}/k_c)$, the following rate constant could be obtained;

$$(k_{cp}/k_c)(2\beta/\alpha) = 4.58\times10^{-2}\ l/\mathrm{mol}$$

Accordingly, it was presumed that the propagation of the cyclized radical was almost equal to that of uncyclized radicals.

The degree of polymerization, $\bar{P}_n$, is small, and it then decreases with a decrease in the monomer concentration and with an increase in the initiator concentration, as is shown in Tables 1 and 2.

Copolymerization Results. The curves of the monomer and copolymer compositions are shown in Fig. 3. It was found that the azeotropic copolymers were prepared in both systems; Dβ-MPP was copolymerized with St and AN. On the other hand, it might be seen that the rate of copolymerization had a minimum, but was almost

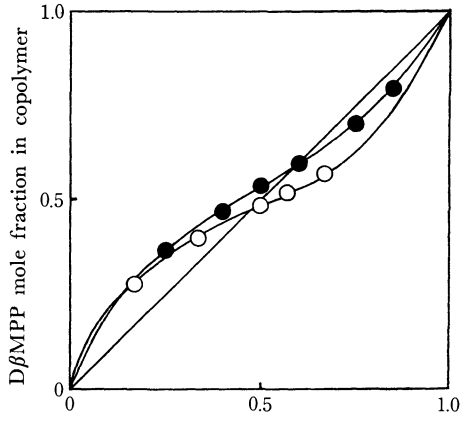

Fig. 3. Monomer - copolymer composition curves.
○: DβMPP-St, ●: DβMPP-AN,
—: calculated curve

independent of the monomer composition.

The Residual Unsaturation of the Copolymer. The ideal bromine value of the copolymer denotes BV_{id} when all the DβMPP units in polymer have pendant double bonds without any cyclization or crosslinking reaction, and the ratio of the experimental bromine value (BV_{ex}) to BV_{id} defines the residual unsaturation. Accordingly, the value of BV_{ex}/BV_{id} becomes 1.0 without any cyclization or crosslinking reaction, and it then decreases with an increase in those reactions.

The relation between the copolymer composition and the residual unsaturation is shown in Fig. 4. It was found that the residual unsaturation decreased with an increase in the DβMPP mole fraction in the copolymer, while the degree of cyclization increased. Such a tendency was more obvious in DβMPP-AN than in DβMPP-St because St was polymerized more easily than AN.

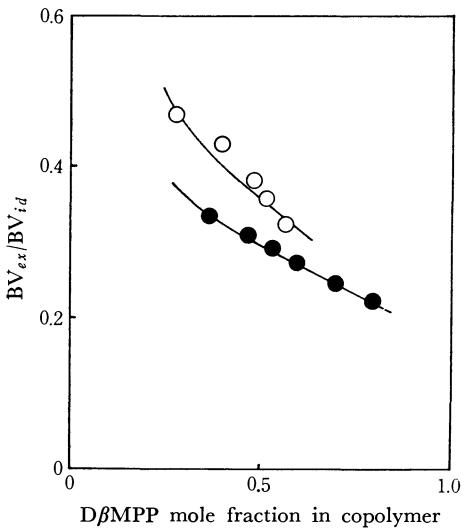

Fig. 4. Correlation of the copolymer composition to the residual unsaturation.

The Determination of the Reactivity Ratio. The degree of cyclization to propagation was very large in those copolymerizations, as has been described previously.

Although the apparent monomer reactivity ratios could be calculated by the well-known Fineman-Ross method, the true monomer reactivity ratios could not be obtained.

In this experiment, the Smets-Roovers equation was applied to these copolymerizations, and then the reactivity ratios were calculated.

That is, the following reaction scheme was based on these copolymerizations:

$$M_1\cdot + M_1 \rightarrow M_1\cdot \qquad k_{11}(M_1\cdot)(M_1)$$
$$M_1\cdot + M_2 \rightarrow M_2\cdot \qquad k_{12}(M_1\cdot)(M_2)$$

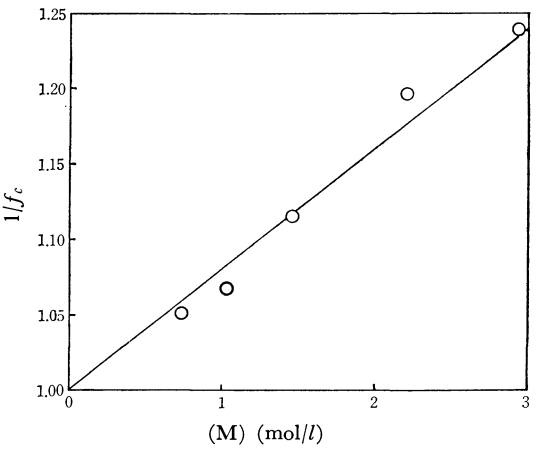

Fig. 5. Plots of $1/f_c$ *vs.* (M) on polymerization of DβMPP at 60°C; $[BPO]=5.00\times10^{-3}$ mol/l.

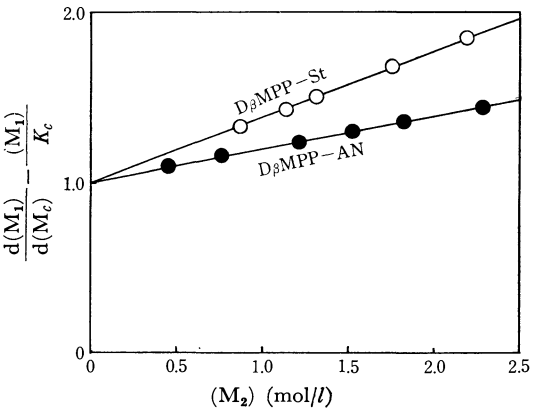

Fig. 6. Plots of $\left(\frac{d(M_1)}{d(M_c)}-\frac{(M_1)}{K_c}\right)$ *vs.* (M_2).

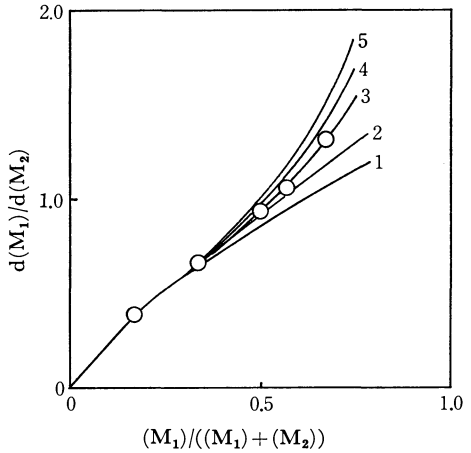

Fig. 7. Plots of $(M_1)/((M_1)+(M_2))$ *vs.* $d(M_1)/d(M_2)$.

$r_2=0.35$ 1: $r_c=0.10$, 2: $r_c=0.20$, 3: $r_c=0.30$
4: $r_c=0.40$, 5: $r_c=0.50$,
○: experimental value

$$M_1\cdot \rightarrow M_c\cdot \qquad k_c(M_1\cdot)$$
$$M_c\cdot + M_1 \rightarrow M_1\cdot \qquad k_{c1}(M_c\cdot)(M_1)$$
$$M_c\cdot + M_2 \rightarrow M_2\cdot \qquad k_{c2}(M_c\cdot)(M_2)$$
$$M_2\cdot + M_1 \rightarrow M_1\cdot \qquad k_{21}(M_2\cdot)(M_1)$$
$$M_2\cdot + M_2 \rightarrow M_2\cdot \qquad k_{22}(M_2\cdot)(M_2)$$

Here M_1 denotes a divinyl monomer; M_2, a comonomer; $M_1\cdot$ and $M_2\cdot$, the uncyclized radical, and $M_c\cdot$, the cyclized radical.

If a stationary state is assumed for the different types of radicals, Eqs. (22)—(24) can be derived:

$$\frac{d(M_1)}{d(M_2)} = \frac{(M_1)}{(M_2)} \times \frac{r_1(M_1)+(M_2)+K_c'}{\left\{r_2(M_2)+(M_1)+K_c'\left[\frac{r_2(M_2)+(M_1)}{r_c(M_1)+(M_2)}\right]\right\}} \quad (22)$$

$$\frac{d(M_1)}{d(M_c)} = 1 + \frac{(M_1)}{K_c} + \frac{(M_2)}{K_c'} \quad (23)$$

$$\frac{d(M_2)}{d(M_c)} = (M_2)\left\{1+r_2\frac{(M_2)}{(M_1)}\right\}\left\{\frac{1}{K_c'}+\frac{1}{r_c(M_1)+(M_2)}\right\} \quad (24)$$

where $r_1=k_{11}/k_{12}$, $r_2=k_{22}/k_{21}$, $r_c=k_{c1}/k_{c2}$, $K_c=k_c/k_{11}$, and $K_c'=k_c/k_{12}$; d(M_1), d(M_2), and d(M_c) then denote M_1, M_2, and M_c respectively in the copolymer.

On the other hand, the relation between the fraction of cyclized units, f_c, and the monomer concentration is given in Eq. (25):

$$1/f_c = 1 + (M)/K_c \qquad (25)$$

The plots of $1/f_c$ *vs.* (M) are shown in Fig. 5 by using the data of the previously-reported homopolymerization of DβMPP; they have a good linear relationship, as was predicted from Eq. (25). K_c was estimated to be 12.7 mol/*l* from the slope of the straight line.

The correlations of $\{d(M_1)/d(M_c)-(M_1)/K_c\}$ to (M_2) are plotted in Fig. 6; they have a good linear relationship, and the K_c' values were calculated to be 2.54 on DβMPP-St and 5.08 on DβMPP-AN from these slopes.

From the values of K_c and K_c', the r_1 values were estimated to be 0.20 on DβMPP(M_1)-St(M_2) and 0.40 on DβMPP(M_1)-AN(M_2).

Then r_2 and r_c were determined from Eqs. (22) and (24) according to the trial-and-error method. The theoretical curves are compared with the experimental results in Figs. 7 and 8 (DβMPP-St) and Figs. 9 and 10 (DβMPP-AN). A good agreement between them is seen at $r_2=0.35$ and $r_c=0.30$ on DβMPP-St and $r_2=0.35$ and $r_c=0.60$ on DβMPP-AN.

By using these values, the relations between $(M_1)/((M_1)+(M_2))$ and $d(M_2)/d(M_c)$ are plotted in Fig. 11. The values calculated from Eq. (24) agreed very closely with the experimental values. Accordingly, the monomer reactivity ratios obtained might be proper for the copolymerizations.

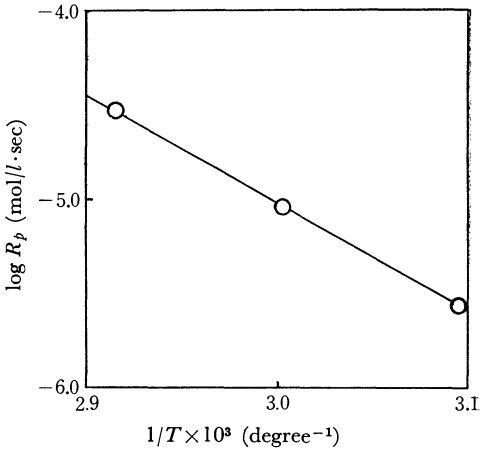

Fig. 13. Arrhenius plots.
(M)=1.48 mol/*l*, (I)=5.00×10⁻³ mol/*l*

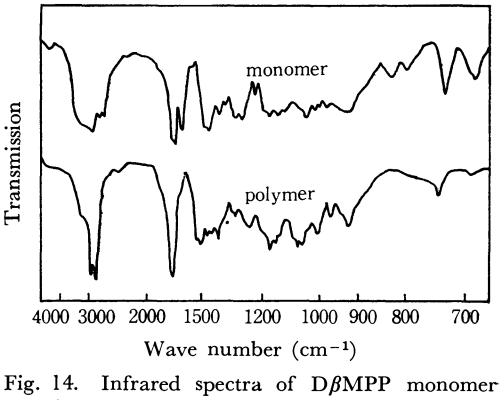

Fig. 14. Infrared spectra of DβMPP monomer and polymer.

If the cyclization and crosslinking reaction are neglected, the apparent monomer reactivity ratios can be obtained by the well-known Fineman-Ross method. The following results were estimated from the slopes and the intercepts of the straight line shown in Fig. 12:

$D\beta MPP(M_1)$-$St(M_2)$ $r_1'=0.27$, $r_2'=0.35$

$D\beta MPP(M_1)$-$AN(M_2)$ $r_1'=0.55$, $r_2'=0.35$

Activation Energy. To determine the overall activation energy, the polymerization of DβMPP was carried out at 50, 60, and 70°C. The plots of the logarithm of R_p *vs.* $1/T$ are shown in Fig. 13. The apparent activation energy was calculated to 26.5 kcal/mol from the slope of the obtained straight line. The value was almost equal to those of the normal vinyl polymerizations.

IR Spectrum. The infrared spectra of the resulting monomer and polymer are shown in Fig. 14. The absorption peaks at 1625, 1740, and 2930 cm^{-1} are assigned to C=C, >C=O, and CH_3 respectively. The absorptions of the cyclic acetal compound are also presented in the range of 1200—1040 cm^{-1}. In spite of the initial state, the C=C band at 1625 cm^{-1} on the polymer almost disappears; therefore, it was found that the cyclization reaction was preferential upon the polymerization of DβMPP.

On the other hand, DβMPP was gelated with a high conversion; we will later report on such crosslinking.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2870—2873 (1970)

The Reactions of Phosphonium Ylides and Oxosulfonium Methylide with Sulfenamide Derivatives

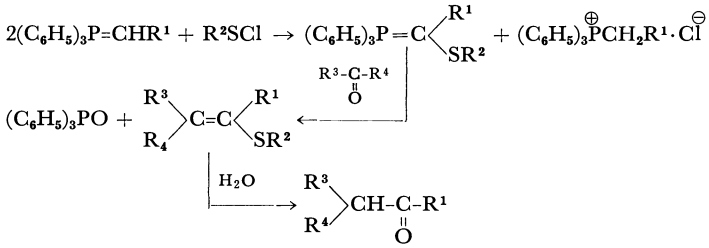
Teruaki MUKAIYAMA, Takanobu KUMAMOTO, Shinichi FUKUYAMA and Takeo TAGUCHI

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 19, 1969)

It was found that vinyl sulfide derivatives were obtained in good yields by the reactions of carbonyl compounds with α-phenylthioalkylidenetriphenylphosphorane. Phosphorane was prepared by the equimolar reaction of alkylidenetriphenylphosphorane and *N*-phenylthio-*N*-methylacetamide. It was established that, differing from the case of alkylidenetriphenylphosphorane, dimethyloxosulfonium methylide reacted with *N*-phenylthiophthalimide and *N*-phenylthiosuccinimide to give *N*-bis(phenylthio)methylphthalimide and *N*-bis(phenylthio)methylsuccinimide, respecitively.

It was recently reported that unsymmetrical ketones are synthesized in good yields *via* vinyl sulfide derivatives obtained from α-thioalkylidenetriphenylphosphorane and carbonyl compounds.[1] The phosphorane is successfully derived from 2 mol of alkylidenetriphenylphosphorane and 1 mol of sulfenyl chloride as shown in the following equation (1).



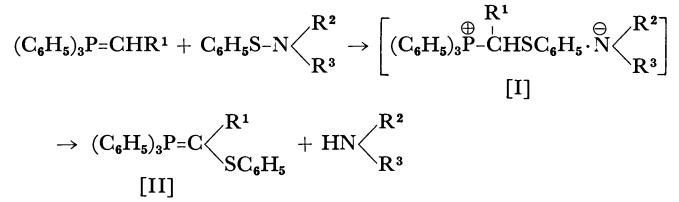
(1)

In this reaction, one mole of alkylidenetriphenylphosphorane is consumed as hydrogen chloride scavenger to form phosphonium chloride.

We studied the reactions of alkylidenetriphenylphosphorane with sulfenamide derivatives with the

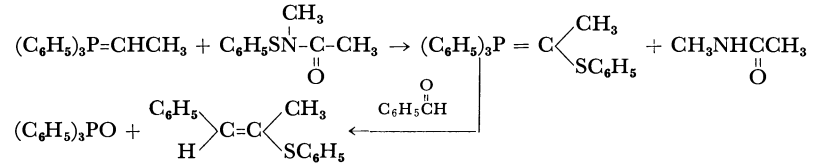
1) T. Mukaiyama, S. Fukuyama and T. Kumamoto, *Tetrahedron Lett.*, **1968**, 3787.

expectation that the equimolar reactions may proceed to give α-phenylthioalkylidenetriphenylphosphorane and amine, since the amido anion of initially formed phosphonium salt [I] may carry out the deprotonation from [I] to form corresponding phosphorane [II] (Eq. 2).

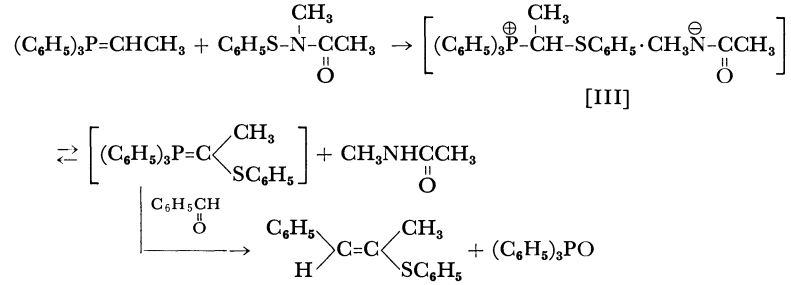


(2)

Benzenesulfenyl diethylamide did not react with ethylidenetriphenylphosphorane even after refluxing them in tetrahydrofuran, and benzenesulfenyl diethylamide was recovered quantitatively. On the other hand, it was established that when *N*-phenylthio-*N*-methylacetamide was treated with ethylidenetriphenylphosphorane at room temperature under nitrogen, a white precipitate deposited soon and β-methyl-β-phenylthiostyrene and triphenylphosphine oxide were obtained in 75% and 82% yields, respectively, by the subsequent reaction with benzaldehyde in refluxing tetrahydrofuran for 3 hr.



The white precipitate did not disappear in the absence of benzaldehyde even when it was refluxed for 5 hr in tetrahydrofuran. This suggests that the addition of benzaldehyde may shift equilibrium from the initially formed phosphonium salt [III] to the side of the α-phenylthioethylidenetriphenylphosphorane.



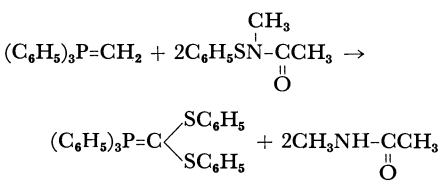
The reactions of α-phenylthioethylidenetriphenylphosphorane with *n*-butyraldehyde and acetophenone were also studied (see Table 1).

Table 1. The reactions of α-phenylthioethylidenetriphenylphosphorane with carbonyl compounds

Carbonyl compound	Thiovinyl ether Yield (%)	Thiovinyl ether Bp (°C/mmHg)	$OP(C_6H_5)_3$ Yield (%)
C_6H_5CHO	75	132/3	82
n-C_3H_7CHO	83	121/11	77
$C_6H_5COCH_3$	22	—*	57

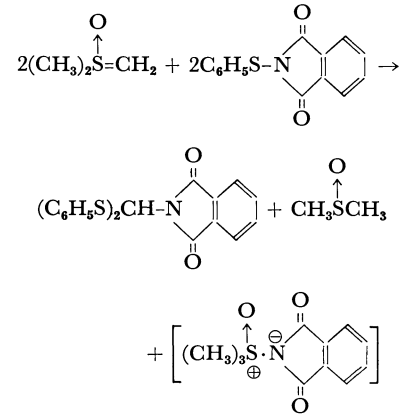
* This compound was isolated by column chromatography.

It was found that bis(phenylthio)methylenetriphenylphosphorane was obtained in 98% yield by treating 1 mole of methylenetriphenylphosphorane with 2 moles of *N*-phenylthio-*N*-methylacetamide in tetrahydrofuran at room temperature under nitrogen.

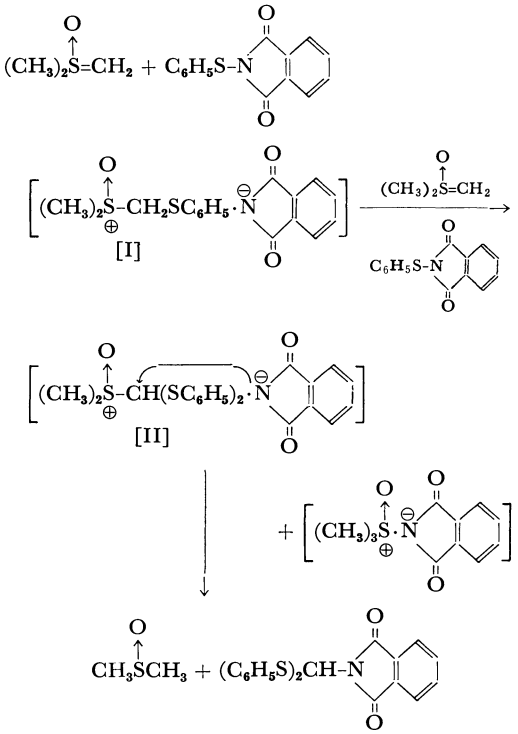


Sulfenamide derivatives were treated with dimethyloxosulfonium methylide in place of alkylidenetriphenylphosphorane. When dimethyloxosulfonium methylide was treated with *N*-phenylthiophthalimide[2] in boiling tetrahydrofuran for 6 hr under nitrogen, *N*-bis(phenylthio)methylphthalimide was obtained in 41% yield instead of dimethyloxosulfonium phenylthiomethylide expected from the reaction of the alkylidenetriphenylphosphorane with sulfenamide mentioned above.

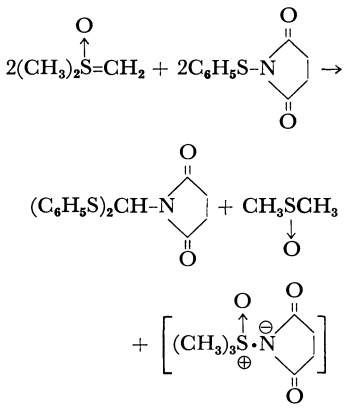
2) M. Behforouz and J. E. Kerwood, *J. Org. Chem.*, **34**, 51 (1969).



The unexpected formation of *N*-bis(phenylthio)-methylphthalimide may be explained by considering an initial formation of oxosulfonium salt [I] from equimolar amounts of dimethyloxosulfonium methylide and *N*-phenylthiophthalimide. Salt [I] rapidly reacts with one mole of dimethyloxosulfonium methylide and one mole of *N*-phenylthiophthalimide to give oxosulfonium salt [II]. Salt [II] thus formed affords *N*-bis(phenylthio)methylphthalimide and dimethyl sulfoxide by the nucleophilic attack of the phthalimide anion to the α-carbon atom of the salt [II] as sketched below.

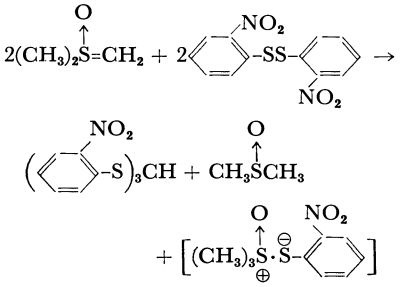


Similarly, *N*-bis(phenylthio)methylsuccinimide was obtained in 42% yield by the reaction of *N*-phenylthiosuccinimide[2] with dimethyloxosulfonium methylide in boiling tetrahydrofuran.

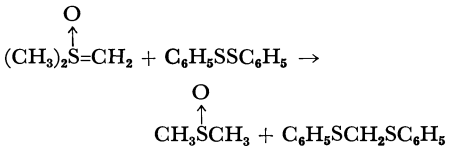


Benzenesulfenyl diethylamide did not react with dimethyloxosulfonium methylide even after refluxing them in tetrahydrofuran for 10 hr and the starting materials were recovered quantitatively.

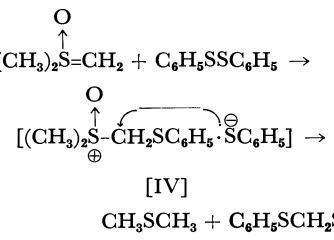
It was found that the reaction of dimethyloxosulfonium methylide with bis(2-nitrophenyl) disulfide in tetrahydrofuran at room temperature gave tris(2-nitrophenylthio)methane in 77% yield.



In the reaction of diphenyl disulfide with dimethyloxosulfonium methylide in boiling tetrahydrofuran, bis(phenylthio)methane was obtained in 51% yield.



This suggests that the nucleophilic attack of phenylthio anion on the α-carbon atom of the oxosulfonium salt [IV] to form bis(phenylthio)methane is much faster than the reaction of [IV] with the oxosulfonium methylide to form tris(phenylthio)-methane through dimethyloxosulfonium phenylthiomethylide.



Experimental

Synthesis of *N*-Phenylthio-*N*-methylacetamide. Into a solution of sodium salt of *N*-methylacetamide, formed from *N*-methylacetamide (7.30 g, 0.10 mol) and sodium ethoxide, in tetrahydrofuran, benzenesulfenyl chloride (14.45 g, 0.10 mol) was added dropwise under stirring at room temperature. After stirring for 1 hr at room temperature, the solvent was evaporated under reduced pressure. The residue was added into 100 m*l* of water and the mixture was extracted with ether. After removal of ether, *N*-phenylthio-*N*-methylacetamide was obtained by distillation under reduced pressure, 11.13 g (62%) bp 96°C/2 mmHg.

Reaction of *N*-Phenylthio-*N*-methylacetamide with Ethylidenetriphenylphosphorane. *N*-Phenylthio-*N*-methylacetamide (1.10 g, 0.0065 mol) was added into a solution of ethylidenetriphenylphosphorane, formed from triphenylethylphosphonium bromide (2.41 g, 0.0065 mol) and *n*-butyl lithium (0.0065 mol), in tetrahydrofuran under stirring. Following the addition of *N*-phenylthio-*N*-methylacetamide, a white precipitate was obtained. Into the reaction mixture, benzaldehyde (0.69 g, 0.0065 mol) was added under stirring. The white precipitate disappeared by refluxing for 2 hr. After removal of the solvent, the residue was chromatographed on silica gel with benzene and ether, *β*-phenylthio-*β*-methylstyrene, 1.10 g (75%), bp 130—132°C/3 mmHg and triphenylphosphine oxide, 1.48 g (53%), mp 153—155°C, were obtained from the elute with benzene and ether, respectively.

Similarly, 2-phenylthio-2-hexene and 2-phenylthio-3-phenyl-2-butene were obtained by the reaction of *α*-phenylthioethylidenetriphenylphosphorane with *n*-butyraldehyde and acetophenone, respectively. The results are listed in Table 1.

Reaction of Methylenetriphenylphosphorane (1 mol) with *N*-Phenylthio-*N*-methylacetamide (2 mol). A solution of *N*-phenylthio-*N*-methylacetamide (1.81 g, 0.01 mol) in tetrahydrofuran was added into the solution of methylenetriphenylphosphorane (0.005 mol) in tetrahydrofuran under stirring. The reaction mixture was stirred for 1 hr at room temperature. After removal of the solvent, a crystalline solid precipitate was obtained by the addition of ethanol to the residue. Recrystallization from a mixture of benzene and ethanol gave bis(phenylthio)methylenetriphenylphosphorane, 2.40 g (98%), mp 165°C.

Reaction of Dimethyloxosulfonium Methylide with *N*-Phenylthiophthalimide. Into a solution of *N*-phenylthiophthalimide (2.55 g, 0.01 mol) in tetrahydrofuran, dimethyloxosulfonium methylide[3] (0.01 mol) was added under nitrogen. The reaction mixture was refluxed for 6 hr under stirring. After removal of the solvent, phthalimide (0.84 g, quantitatively) was obtained as white crystalline solid by the addition of a mixture of benzene and ether. The residue was chromatographed on silica gel with benzene. From the elute of benzene, *N*-bis(phenylthio)methylphthalimide was obtained by recrystallization from ethanol, 0.77 g (41%), mp 164—165°C. Found: C, 67.07; H, 3.89; N, 3.82; S, 16.76%. Calcd for $C_{21}H_{15}NO_2S_2$: C, 66.84; H, 4.01; N, 3.71; S, 16.96%.

Similarly, *N*-bis(phenylthio)methylsuccinimide was obtained by the reaction of dimethyloxosulfonium methylide with *N*-phenylthiosuccinimide, 42%, mp 94—95°C.

Found: C, 62.64; H, 4.36; N, 4.17; S, 19.70%. Calcd for $C_{17}H_{15}NS_2O_2$: C, 62.00; H, 4.59; N, 4.25; S, 19.43%.

Reaction of Dimethyloxosulfonium Methylide with Bis(2-nitrophenyl) Disulfide. Dimethyloxosulfonium methylide (0.01 mol) was added to a solution of bis(2-nitrophnyl) disulfide (3.08 g, 0.01 mol) in tetrahydrofuran under stirring. After stirring for 3 hr at room temperature, the solvent was evaporated under reduced pressure. A yellow crystalline was obtained by the addition of a small amount of ether to the residue. Recrystallization of the crystalline solid from ethanol gave tris(2-nitrophenylthio)methane 1.82 g (77%) mp 198—199°C.

Reaction of Dimethyloxosulfonium Methylide with Diphenyl Disulfide. Into a solution of diphenyl disulfide (2.18 g, 0.01 mol) in tetrahydrofuran, dimethyloxosulfonium methylide (0.01 mol) was added under stirring. The reaction mixture was refluxed for 2 hr. After removal of the solvent, the residue was chromatographed on silica gel with benzene. From the elute with benzene, bis(phenylthio)methane was obtained by distillation under reduced pressure, 1.19 g (51%), bp 170—175°C/0.7 mmHg.

Studies of Unnatural Amino Acids and Their Peptides. IV. The Syntheses of DL-β-(5-Cytosinyl)-α-alanine Peptides

Mitsuhisa SHIMADA, Kōji TAKEUCHI,*1 Yoshiya ASAI,*2 Shigeru KUWATA and Hiroshi WATANABE

Laboratory of Chemistry, Faculty of Science, Kōnan University, Okamoto, Higashinada, Kobe

(Received December 22, 1969)

DL-β-(5-Cytosinyl)-α-alanine and its dipeptides with glycine were synthesized. The benzyloxycarbonylation of this amino acid afforded the α-*N*-substituted derivative, but all attempts to obtain the diacylated derivative were unsuccessful. The condensation of the benzyloxycarbonyl derivative with glycine ethyl ester by the carbodiimide method afforded the expected dipeptide, though the yield was low (18%); it was accompanied by a large amount of a bicyclic compound, a lactam produced by an intramolecular acylation. The ethyl ester hydrochloride of this amino acid could not be obtained in a pure state, probably because of its ready cyclization to the same lactam structure under weakly acidic conditions. This complication could be avoided by using the tertiary butyl in place of the ethyl ester. Benzyloxycarbonylglycine *p*-nitrophenyl ester was condensed smoothly with this ester, affording the expected dipeptide in a 53% yield. The carbodiimide method could also be used, but it was less effective.

As a part of a series of studies of unnatural amino acids and their peptides, DL-β-(5-cytosinyl)-α-alanine derivatives were investigated. The present authors were interested in this amino acid not only biologically, because cytosine is one of the constituents of nucleic acid, but also chemically, because it had become clear that the usual method a synthesizing peptides was not always applicable to phenylalanine analogs containing such a heterocyclic ring as furan,[1] thiazole,[2] or pyridine.[3]

This amino acid has already been prepared by Blank and Caldwell.[4] The present authors followed substantially the same scheme, with only a few modifications; in place of 4-amino-5-bromomethyl-2-methylthiopyrimidine, the corresponding chloride was used. The starting material, 4-amino-5-ethoxycarbonyl-2-mercaptopyrimidine, was prepared according to the method described by Ulbricht and Price.[5]

In order to synthesize *N*-benzyloxycarbonyl-DL-β-(5-cytosinyl)-α-alanyl-glycine ethyl ester, *N*-benzyloxycarbonyl-DL-β-(5-cytosinyl)-α-alanine (VII) was prepared from DL-β-(5-cytosinyl)-α-alanine (VI) and an equivalent amount of benzyloxycarbonyl chloride by the usual method. The analytical data of this substance showed that it contains only one benzyloxycarbonyl group introduced into the α-amino group, for this compound showed no ninhydrin reaction. The benzyloxycarbonyl derivative VII was coupled with glycine ethyl ester hydrochloride in dry pyridine in the presence of dicyclohexylcarbodiimide. The oily material thus obtained was then solidified by trituration with ethyl acetate, which was separated by extraction with a large amount of water into two components, *i.e.*, a water-insoluble, colorless, amorphous powder, IX, decomposing at 310—312°C, and a water-soluble, colorless, amorphous powder, VIII, decomposing at 254—258°C. When the compound VIII was hydrolyzed with concentrated hydrochloric acid, the hydrolysate gave two spots of cytosinylalanine and glycine on a paper chromatogram. This result, as well as that of its elementary analysis, supports that the compound VIII is a dipeptide derivative : *N*-benzyloxycarbonyl-cytosinylalanyl-glycine ethyl ester.

The molecular formula, $C_{15}H_{14}N_4O_4$, was assigned to the compound IX on the basis of the results of an elementary analysis (C, 57.23; H, 4.88; N, 17.58%) and the molecular weight, 329, determined by the method of Schwyzer and his coworkers.[6] When hydrolyzed with hydrochloric

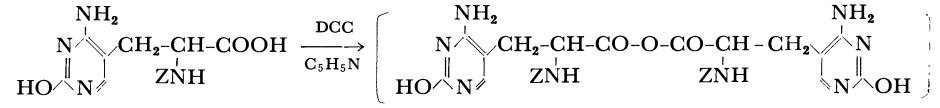
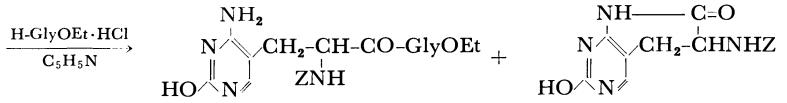
acid, IX gave only one ninhydrin-positive material, one which was identical with cytosinylalanine. On the basis of these facts, the structure of the compound IX was assumed to be 2-hydroxy-6-benzyloxycarbonylamino-5,6,7,8-tetrahydro-7-oxopyrido-[2,3-*d*]pyrimidine; it is probably produced by lactam-formation between the 6-amino group of the pyrimidine and the carboxyl group activated by the carbodiimide. In order to confirm this, the benzyloxycarbonylated amino acid, VII, was treated with the carbodiimide under the same conditions as above except that ethyl glycinate hydrochloride was omitted. The substance thus obtained was found to be identical with IX by elementary analysis and by a comparison of the infrared spectra. Thus, the reactions producing these two compounds may be represented by the following equation:



(VII)



(VIII) (IX)

(Z = benzyloxycarbonyl; DCC = dicyclohexylcarbodiimide; Gly = glycine)

To prevent the lactam formation of the 6-amino group, we attempted to provide protection by the benzyloxycarbonyl group; unfortunately, all the attempts to acylate it with a large excess of benzyloxycarbonyl chloride ended in failure. When, for instance, the further benzyloxycarbonylation of the monobenzyloxycarbonyl derivative was attempted in pyridine at 40°C, the compound IX was obtained in place of the expected one.

In order to esterify cytosinylalanine, hydrogen chloride gas was bubbled into a suspension of the amino acid in ethanol; the reaction was pursued by paper chromatography. When the spot of the free amino acid disappeared and a new spot (R_f = 0.31*[3]) (probably of the desired ester) appeared, the reaction mixture was concentrated to dryness *in vacuo*; the colorless, hygroscopic crystalline residue was then left to stand over sodium hydroxide in a desiccator in order to remove the excess hydrogen chloride. In this step, paper chromatography gave only one spot. When the dried material was dissolved in hot ethanol for recrystallization, however, it gave another spot (R_f = 0.41*[3]). This new spot can probably be attributed to 2-hydroxy-6-amino-5,6,7,8-tetrahydro-7-oxopyrido[2,3-*d*]pyrimidine produced by the cyclization of cytosinylalanine ethyl ester under weakly acidic conditions. This complication was avoided by using the tertiary butyl ester in place of the ethyl ester. It was found that *t*-butyl β-(5-cytosinyl)-α-alaninate could be prepared without any trouble by treating the acid with a large amount of *t*-butyl acetate in the presence of perchloric acid, according to the method of Taschner.[7] When we used five times as much catalyst as in the literature, the transesterification proceeded smoothly; after the raw product has been treated with sodium hydrogen carbonate, the ester was obtained in a 71% yield as perchlorate-monohydrate. The free ester was obtained as a colorless, amorphous powder by treating it with aqueous ammonia or triethylamine. Benzyloxycarbonylglycine *p*-nitrophenyl ester was condensed with *t*-butyl cytosinylalaninate in hexamethylphosphoramide. From

the reaction mixture, a colorless, amorphous powder decomposing at about 320°C was obtained in a 53% yield. Upon hydrolysis with concentrated hydrochloric acid, it gave cytosinylalanine and glycine. This result and the analytical data support that the substance obtained here is the desired product: benzyloxycarbonylglycyl-DL-β-(5-cytosinyl)-α-alanine *t*-butyl ester. The same compound was also obtained in a lower yield by the use of the carbodiimide method in a mixture of dimethylformamide and dimethyl sulfoxide.

Experimental

4-Amino-5-ethoxycarbonyl-2-mercaptopyrimidine (I). This was prepared in a 79% yield, according to the literature,[5] by condensing ethyl ethoxymethylenecyanoacetate and thiourea in the presence of sodium ethoxide.

4-Amino-5-ethoxycarbonyl-2-methylthiopyrimidine (II). The procedure described in the literature[5] was somewhat modified; into a suspension of I (100 g) in methanol (50—100 m*l*) was stirred aqueous potassium hydroxide (37 g/500 m*l*), and then dimethyl sulfate (67 g) over a 10—15-min period; the mixture was then stirred for 1 hr at room temperature. The pH of the reaction mixture was adjusted to 9.4—9.6 with aqueous potassium hydroxide; the separated crystals were collected by filtration, washed with dilute aqueous potassium hydroxide and then with water, and dried *in vacuo* on a water bath to give 89.5 g (84%) of II; mp 125—129°C. Recrystallization from 50% acetic acid gave tiny, glistening plates. The yield was 69 g (65%); mp 130—131.5°C (lit,[5] mp 130—131°C).

4-Amino-5-Hydroxymethyl-2-methylthiopyrimidine (III). Prepared, according to the literature,[4] in a 73% yield; mp 125—126°C (lit,[4] mp 126—127°C).

4-Amino-5-chloromethyl-2-methylthiopyrimidine Hydrochloride (IV). To a cooled and stirred suspension of III (24 g) in dry ether (600 m*l*), there was added thionyl chloride (40 m*l*) drop by drop. The mixture was refluxed for 3 hr with stirring and then evaporated to dryness. After this procedure had been repeated twice more, the residue was used for the next reaction without purification.

Ethyl 6-Acetamido-5,6,7,8-tetrahydro-2-methylthio-7-oxopyrido[2,3-*d*]pyrimidine-6-carboxylate (V). Prepared by condensing IV with diethyl acetamidomalonate in the presence of sodium ethoxide by a method similar to that in the literature.[4] The reaction period was, however, elongated to 6 hr. The yield was 57% (calculated from the alcohol (III)); mp 186—189°C (lit,[4] mp 187—188°C).

DL-β-(5-Cytosinyl)-α-alanine (VI). Prepared by the method in the literature.[4] The yield was 85%. Crude amino acid was purified by dissolving it in aqueous ammonia, decolorizing it, and acidifying it to pH *ca.* 6 with acetic acid. The yield was 65%; mp above 360°C (decomp.) (turned brown from about 220°C and darkened at 290°C) (lit,[4] mp above 300°C); R_f = 0.23*[3]; $\lambda_{max}^{0.1\ N\ HCl}$ 283 mμ (lit,[4] $\lambda_{max}^{0.1\ N\ HCl}$ 283 mμ).

***N*-Benzyloxycarbonyl-DL-β-(5-cytosinyl)-α-alanine (VII).** Benzyloxycarbonyl chloride (1.10 g) and 2 N sodium hydroxide (3.5 m*l*) were stirred, drop by drop, into a solution of VI (1.08 g) in 0.5 N sodium hydroxide (20 m*l*) over about a 1-hr period under ice-cooling. The solution was kept alkaline throughout the reaction. Stirring was continued further at room temperature until the solution became negative to the ninhydrin test (4—5 hr). After washing with ether, the solution was then acidified to Congo Red with glacial acetic acid. The white crystals thus formed were collected and washed thoroughly with water. The yield was 0.96 g (55%); mp about 310°C (decomp.). Recrystallization from a large amount of methanol gave a white, amorphous powder melting at about 315°C (decomp.). This compound dissolves sparingly in ethyl acetate, acetone, dioxane, methanol, ethanol, acetonitrile, tetrahydrofuran, or chloroform, and forms a viscous emulsion in dimethylformamide and pyridine.

Found: C, 51.32; H, 5.15; N, 15.57%. Calcd for $C_{15}H_{16}N_4O_5 \cdot H_2O$: C, 51.43; H, 5.18; N, 15.99%.

The Reaction of *N*-Benzyloxycarbonyl-DL-β-(5-cytosinyl)-α-alanine with Ethyl Glycinate.

***N*-Benzyloxycarbonyl-DL-β-(5-cytosinyl)-α-alanylglycine Ethyl Ester (VIII).** Glycine ethyl ester hydrochloride (0.35 g) was added to an emulsion of VII (0.84 g) in dry pyridine (20 m*l*). Into the mixture was then stirred a solution of dicyclohexylcarbodiimide (0.57 g) in dry pyridine (5 m*l*) over about a 15-min period under strong cooling (about −10°C). After an additional 2 hrs' stirring in the cold, the mixture was allowed to stand for three days at room temperature. The dicyclohexylurea which was thus separated was filtered off, and the filtrate was concentrated under reduced pressure. To the resulting oil was added ethyl acetate, and the mixture was allowed to stand at room temperature. Meanwhile, the oil solidified; this solid was thoroughly extracted with water. From the extracts the dipeptide derivative, VIII, was separated as an amorphous powder. The yield was 0.18 g (18%); mp 253—262°C (decomp.). Recrystallization from methanol gave a colorless, amorphous powder decomposing at 254—258°C.

Found: C, 54.40; H, 5.42; N, 16.55%. Calcd for $C_{19}H_{23}N_5O_6$: C, 54.67; H, 5.55; N, 16.78%.

2-Hydroxy-6-benzyloxycarbonylamino-5,6,7,8-tetrahydro-7-oxopyrido[2,3-*d*]pyrimidine (IX). The solid material, the residue of the extraction described above, melted at 308—314°C (decomp.). The yield of IX was 0.5 g (66%). Recrystallization from dimethylformamide-methanol gave an amorphous powder; mp 310—312°C (decomp.).

Found: C, 57.23; H, 4.88; N, 17.58%. Calcd for $C_{15}H_{14}N_4O_4$: C, 57.32; H, 4.49; N, 17.83%.

The Reaction of *N*-Benzyloxycarbonyl-DL-β-(5-cytosinyl)-α-alanine with Dicyclohexylcarbodiimide in Pyridine. Into an emulsion of VII (1.05 g) in dry pyridine (35 m*l*) was stirred a solution of dicyclohexylcarbodiimide (0.71 g) in the same solvent (6 m*l*) over about a 20-min period under cooling (about −5°C). The stirring was continued for 2 hr under the same conditions, and then the mixture was allowed to stand for 5 days at room temperature. The crystals which were thus separated were collected by filtration and washed with a large amount of boiling ethyl acetate. The yield of IX was 0.50 g. From the mother liquor some crystals were obtained by adding glacial acetic acid; this also gave an additional 0.21 g of IX. The

total yield was 0.71 g (75%); mp about 316°C. For analysis, it was recrystallized from dimethylformamide.

Found: C, 57.64; H, 4.56; N, 17.46%. Calcd for $C_{15}H_{14}N_4O_4$: C, 57.32; H, 4.49; N, 17.83%.

The same compound was obtained by the action of 3 equivalents of benzyloxycarbonyl chloride on *N*-benzyloxycarbonyl-cytosinylalanine in dry pyridine at 40°C. The yield here was 0.60 g (56%).

DL-β-(5-Cytosinyl)-α-alanine *t*-Butyl Ester Perchlorate Monohydrate (X). Into a suspension of the amino acid, VI (1.08 g), in *t*-butyl acetate (116 m*l*), was stirred, drop by drop, 70% perchloric acid (3.66 g) at about 5°C; the mixture was then stirred at room temperature. After about 3 hr, the amino acid was almost dissolved into the solution and crystals began to separate. After the mixture had stood at room temperature overnight, the crystals were collected, dissolved in chilled water (10 m*l*), and kept in the cold after the pH had been adjusted to 7.6 with sodium hydrogencarbonate. Thus the crude crystalline *t*-butyl ester perchlorate was obtained. The yield was 1.42 g (71%); mp 175—180°C (decomp.). For further purification, it was dissolved in a mixture of acetone and chloroform (2 : 1) and freed from insoluble materials, while the solvent was removed under reduced pressure. To the residue was added a mixture of *t*-butyl alcohol and water (2 : 1), and the separated solid was recrystallized from the same mixture. The purified compound melted at 216—219°C (decomp.); R_f=0.57*[3].

Found: C, 36.04; H, 5.71; N, 15.25%. Calcd for $C_{11}H_{18}N_4O_3 \cdot HClO_4 \cdot H_2O$: C, 35.44; H, 5.68; N, 15.03%.

DL-β-(5-Cytosinyl)-α-alanine *t*-Butyl Ester (XI). Into a solution of the perchlorate, X (1.00 g), in dimethylformamide (5 m*l*), was stirred triethylamine (0.3 g) at −10°C. After the solution had been stirred for 30 min at this temperature, a colorless solid separated; this was filtered, washed with cold water, and dried in a desiccator. The yield was 0.62 g (91%); mp above 320°C (decomp.). (It turned yellow from about 180°C and darkened from about 280°C.) Recrystallization from a mixture of dimethylformamide and dimethyl sulfoxide gave a colorless powder; mp above 320°C (it turned yellow from about 190°C and darkened from about 305°C).

***N*-Benzyloxycarbonyl-glycyl-DL-β-(5-cytosinyl)-α-alanine *t*-Butyl Ester (XII).** To a suspension of XI (0.25 g) in hexamethylphosphoramide (20 m*l*), there was added benzyloxycarbonylglycine *p*-nitrophenyl ester (0.33 g) and triethylamine (0.1 g); the mixture was then stirred at room temperature overnight. To the almost clear solution was added a large quantity of water, and then the solution was left to stand in a refrigerator overnight. The crystals which were thus separated were collected, washed with cold 0.1 N citric acid, water, 0.5 N aqueous sodium hydrogencarbonate, and then with water, and dried in a desiccator. The yield was 0.24 g (53%); mp above 320°C (decomp.). Recrystallization from a mixture of dimethyl sulfoxide and methyl ethyl ketone gave a colorless, amorphous substance; mp above 320°C (decomp.) (sintered at about 93°C). When hydrolyzed with hydrochloric acid, this compound gave glycine and cytosinylalanine, the presence of which was confirmed by paper chromatography.

Found: C, 55.01; H, 6.15; N, 14.93%. Calcd for $C_{21}H_{27}N_5O_6 \cdot H_2O$: C, 54.42; H, 6.31; N, 15.11%.

From XI (355 mg), benzyloxycarbonylglycine (881 mg), and dicyclohexylcarbodiimide (640 mg) in a mixture of dimethylformamide and dimethyl sulfoxide (1 : 1), the same dipeptide was obtained in a lower yield (58 mg; 9%).

Transformation of Progesterone by *Rhizopus nigricans* REF 129 as Influenced by Modification of the Fermentation Medium

Abdel-Monem EL-REFAI, Lotfy SALLAM and Ismail EL-KADY

Microbiological Chemistry Research Lab., National Research Centre, Dokki, Cairo, U.A.R.

(Received January 14, 1970)

Hydroxylation of progesterone with *Rhizopus nigricans* REF 129 at C-11, C-6, C-17, C-21 as well as formation of 11α-hydroxy-5α-pregnane-3,20-dione was investigated when the fermentation medium was modified in a different manner. The various transformation products of progesterone were found to be affected qualitatively and quantitatively by the composition of the medium employed. Mg^{2+}, PO_4^{3-} proved to be indispensable for the transformation processes. Mn^{2+} and Fe^{2+} stimulated the reactions. Similarly, acetate, malate and riboflavin enhanced the transformation processes. Formation of the various derivatives of progesterone, except for 11α-hydroxy-5α-pregnane-3,20-dione and 6β,11α-dihydroxyprogesterone, was also favoured by the addition of adenine, adenosine, uracil and guanine to the fermentation medium.

The very important discovery of the microbiological 11α-hydroxylation of progesterone and other steroids by Peterson and Murray[1] served as a new and vigorous stimulus for studies on microbiological transformation of steroids. By using common industrial microbiological methods, chemical transformation of steroids have now been effected in many different ways.[2] However, the studies made for the elucidation of various physiological and biochemical aspects of the microbiological hydroxylation of steroids are still of fragmentary nature. O'Connell *et al*[3] had studied the effect of the composition of the fermentation media on the conversion of substance S (17α,21-dihydroxy-4-pregene-3,20-dione) to cortisone (17α,21-dihydroxy-4-pregnene-3,11,20-trione) and cortisol (11β,17α,21-trihydroxy-4-pregnene-3,20-dione) by *Cunninghamella blakesleeana*. Zetsche[4] also showed that the enzyme system of *Curvularia lunata*, responsible for the introduction of 6β;7α;11β; 14 α hydroxyl groups to progesterone, was affected by the conditions of the culture.

In a previous communication the authors[5] reported the role of some redox agents and trace elements on the transformation of progesterone with *Rhizopus nigricans* REF 129. It was found that the addition of potassium ferricyanide or cadmium ions to the fermentation medium inhibited the formation of 11α-hydroxy-5α-pregnane-3,20-dione and 6β,11α-dihydroxyprogesterone with the subsequent increase of the yields of 11α-hydroxyprogesterone and 11α,17α,21-trihydroxy derivative. However, the formation of the other transformation products, namely, 17α-hydroxyprogesterone; 21-hydroxyprogesterone and 11α, 17α-dihydroxyprogesterone were unaffected. Identity of the different transformation products of progesterone with this local strain of *R. nigricans* were previously confirmed by the authors.[6]

In this paper, we should like to report our studies on the role of some factors that influence the hydroxylation of progesterone with *R. nigricans* REF 129, in a trial to throw some light on the identification of the required cofactors for hydroxylases systems of microbiological origin.

Experimental

Cultivation. The local strain of *R. nigricans* REF 129 was selected from the centre of culture of the Microbiological Chemistry Research Lab., National Research Centre, Cairo. Cultivation was performed in 250-m*l* Erlenmeyer flasks each containing 75 m*l* of the following medium:[5] glucose, 40.0; KH_2PO_4, 0.74; $MgSO_4 \cdot 7H_2O$, 1.0; asparagine, 1.825 g/*l*. The pH was adjusted to 5.5. The flasks were sterilized at 1 atm for 20 min and inoculated with 2-m*l* spore suspension of 48 hr old culture of the pure organism. The culture flasks were agitated on reciprocal shaker (110 strokes/min, amplitude 7 cm) at 30°C±2 for 48 hr; 100 mg of progesterone dissolved in 2 m*l* ethanol was then added to each flask and fermentation was continued for another 72 hr. Throughout the course of this study, grading of the amount of growth by visual estimation

has been a routine observation.

Extraction and Analysis of the Mixture of Transformation Products. At the end of the fermentation period, the contents of each flask (medium+fungus) were homogenized in a blender (16000 rpm) with twice its volume of chloroform(150 m*l*). Extraction was repeated 3 times in order to assure that all the transformation products were extracted. The combined chloroform extracts were washed with half its volume 5% sodium bicarbonate followed by an equal volume distilled water, dried over anhydrous sodium sulphate, filtered, then distilled to give a semi-solid residue which was then dissolved in a measured volume of chloroform: methanol (1 : 1, v/v) mixture. The mixture was referred to as "tested material".

Qualitative analysis of the different transformation products encountered during this work was carried out as previously described.[7] The preparative thin-layer chromatographic analysis using silica gel G and standard equipments were used for quantitative determination of the different components of the transformation mixture. A measured volume of the tested material was applied as a streak across the bottom of the glass plate (20×20 cm) covered with a layer of silica gel G (1 mm thickness). The plates were developed with cyclohexane : acetone : chloroform (75 : 25 : 20, v/v). After development, the bands of the individual steroids were marked, scraped off from the plate and quantitatively eluted with spectroscopic ethanol. The concentration of each compound was determined by UV spectrophotometric measurement. The band corresponding to 11α-hydroxy-5α-pregnane-3,20-dione was eluted and the eluate was evaporated in a tared beaker whereby its exact weight was determined.

Results

Inorganic Constituents. In considering the inorganic ions affecting the transformation of progesterone when *R. nigricans* was grown on the basal medium, certain ones seemed to be indispensable. In order to test this idea and investigate the need for other inorganic ions, the basal medium was modified by the omission of the ion under investigation and the addition of various levels of this ion in different experimental series. The data were compared with yields obtained from incubation in the basal medium from which the compound under investigation was omitted.

Effect of $MgSO_4 \cdot 7H_2O$. Study of the effect of the addition of various levels of $MgSO_4 \cdot 7H_2O$ to the fermentation medium(Table 1) showed that the formation of the different transformation products of progesterone was markedly stimulated by the addition of the magnesium salt. Addition of 1.5 g/*l* $MgSO_4 \cdot 7H_2O$ seemed to be optimal for the formation of 11α-, 17α- and 21-monohydroxyprogesterones, as well as 6β,11α- and 11α,17α-dihydroxy derivatives. Although the concentration of 6β, 11α-dihydroxyprogesterone did not appear to be affected by the addition of higher levels of $MgSO_4 \cdot 7H_2O$, the concentrations of the other products were gradually decreased under these conditions. However, the concentration of 11α,17α,21-trihydroxyprogesterone was markedly increased with the increase of the magnesium salt level.

Effect of KH_2PO_4. Omission of KH_2PO_4 from the medium markedly reduced the amounts of progesterone transformed (Table 2). Thus, about 23% and 82% of the added progesterone was transformed when the experimental organism was grown on the medium without added phosphate and on the medium supplemented with 1.5 g/*l* KH_2PO_4, respectively. Similarly, the formation of the different derivatives of progesterone was enhanced with phosphate addition. Maximal yields of 11α-, 17α- and 21-monohydroxyprogesterones, as well as 11α,17α,21-trihydroxy derivative were obtained with 1.5 g/*l* KH_2PO_4 treatment. However, the optimal level for the formation of 6β,11α- and 11α, 17α-dihydroxyprogesterones seemed to lie at 0.5 g/*l*. On the other hand, the addition of lower concentrations of phosphate exerted no noticeable effect on the formation of 11α-hydroxy-5α-pregnane-3,20-dione. However, inhibition of the formation of this product was observed with higher

levels of phosphate.

Effect of $MnSO_4$. The data presented in Table 3 show that the addition of $MnSO_4$ to the basal medium stimulated the transformation processes. However, 11α-hydroxylation does not appear to be affected by such addition. The yield of 11α-hydroxyprogesterone was appreciably decreased upon the addition of 0.1—0.2 g/*l* of $MnSO_4$. 17α, 21-Dihydroxyprogesterone, a compound not detected when the experimental organism was grown on the basal medium (control treatment), was detected on the addition of manganous salt. The concentration of this product increased with the increase of the level of the manganous salt.

Effect of $FeSO_4 \cdot 7H_2O$. Addition of the ferrous salt exhibited different effects on the various transformation reactions (Table 4). Hydroxylation at C-17 or C-21 was appreciably enhanced on the addition of the different levels of ferrous salt. On the other hand, the concentration of 11α-hydroxy-5α-pregnane-3,20-dione decreased at the higher levels of $FeSO_4$. The transformation of progesterone to 6β,11α-; 11α,17α- as well as to 11α,17α,21-trihydroxy derivatives did not seem to be appreciably influenced by the addition of ferrous salt to the medium. Hydroxylation into both 17α- and 21-positions was observed when the experimental organism was grown on the basal medium to which ferrous salt was added. Under the experimental conditions employed, the concentration of this product increased with the increase of the level of the ferrous salt.

Organic Acids. The effect of the addition of some organic acids, mostly the intermediates of TCA cycle, to the fermentation medium, on the transformation of progesterone with the experimental organism is presented in Table 5. It was found that the addition of these acids exerted different effects on the transformation reactions. Thus, although the addition of citrate, *cis*-aconitate, fumarate, pyruvate and α-ketoglutarate showed no noticeable effect on the transformation processes, yet malate, succinate, acetate, and oxalate affected the reactions in a different manner. The concentrations of the residual progesterone obtained in the case of malate and acetate were about 46% and

** The same composition as in Table 4.

27% of that recorded with basal medium (control treatment). The addition of malate favoured the formation of both 6β,11α- and 11α,17α-dihydroxyprogesterones as well as 11α,17α,21-trihydroxy derivative, rather than the transformation of progesterone to the monohydroxy derivatives. Similar results were recorded in the case of succinate treatment, however, in contrast to malate, the formation of 6β,11α-dihydroxyprogesterone was not stimulated in the case of succinate. On the other hand, the yields of the various transformation products except for 6β,11α-dihydroxyprogesterone and 11α-hydroxy-5α-pregnane-3,20-dione were markedly increased when acetate was added to the basal medium. Oxalic acid appeared to exert an inhibitory effect on the transformation processes.

Biological Bases and Nucleoside. The effect of adding some purine, pyrimidine bases as well as a nucleoside (adenosine) on the different transformation processes of progesterone was also investigated. As shown in Table 6, the addition of xanthin and uracil to the fermentation medium increased the concentrations of the transformed progesterone (compare with control treatment). Addition of adenine, adenosine, guanine and uracil stimulated the formation of 17α- and 21-hydroxyprogesterones. The yields of these two products greatly increased as compared with those recorded with the control treatment. Moreover, a noticeable increase in the concentrations of 11α-hydroxyprogesterone; 11α,17α-dihydroxyprogesterone and 11α,17α,21-trihydroxy derivative was observed. In contrast, the formation of 11α-hydroxy-5α-pregnane-3,20-dione and 6β,11α-dihydroxyprogesterone were greatly reduced in the cases of uracil, guanine and adenosine treatments. The addition of xanthine increased also the concentrations of various transformation products except 11α-hydroxy-5α-pregnane-3,20-dione and 6β,11α-dihydroxyprogesterone.

Vitamins. Addition of some individuals of the vitamin B group, namely, nicotinic acid, thiamine and riboflavin to the fermentation medium proved to enhance the transformation reactions (Table 7). The concentration of the residual progesterone greatly decreased with nicotinic acid and thiamine. Moreover, progesterone was almost completely consumed in the case of riboflavin treatment. An appreciable increase in the yields of the various transformation products was generally observed under these experimental conditions, maximal yields being obtained with riboflavin.

Discussion

The nature of the fermentation medium employed is a decisive factor influencing the microbiological transformation of steroids. We have shown that the transformation of progesterone with a local strain of *Rhizopus nigricans* REF 129 was greatly affected by the composition of the fermentation medium. Various transformation products were found to be affected quantitatively as well as qualitatively by the nature of the fermentation medium. In considering the inorganic ions required for an adequate transformation of progesterone with the experimental organism, certain ions seemed to be indispensable. Only Mg^{2+} and PO_4^{3-} were considered as possibly superfluous constituents of the medium. Omission of either one of these two ions proved to inhibit the transformation processes. The activities assayed when the organism was grown on medium without added Mg^{2+} or PO_4^{3-} might be due to the presence of traces of these two ions as impurities already present in the analytical reagent grade chemical ingradient used in the preparation of the medium. Under these conditions the growth of the fungus was greatly inhibited. Similarly, the addition of Fe^{2+} or Mn^{2+} stimulated the hydroxylation process especially at C-17 and C-21. On the other hand, formation of 11α-hydroxy-5α-

*** Control medium: The same composition as in Table 4.

pregnane-3,20-dione decreased on the addition of Fe^{2+} to the medium. A peculiar finding is the presence of 17α,21-dihydroxyprogesterone, in addition to the other derivatives of progesterone, when the experimental organism was grown on the basa lmedium supplemented with Fe^{2+} or Mn^{2+} ions. This product which was not detected on cultivation of the organism on other medium modifications was proposed by the authors[8] to be formed momentarily, by the introduction of 17α-hydroxyl group into 21-hydroxyprogesterone, during the course of transformation to 11α,17α,21-trihydroxyprogesterone. Addition of Fe^{2+} or Mn^{2+} ions to the medium was accompanied with the formation of comparatively lower yields of 11α-hydroxyprogesterone, although the yields of both 17α- and 21-hydroxy derivatives were appreciably increased. It seems, therefore, that the presence of Fe^{2+} or Mn^{2+} stimulated hydroxylation at C-17 and C-21. As a result of the comparatively lower activities of 11α-hydroxylase system, catalyzing the transformation of 17α,21-dihydroxyprogesterone to 11α,17α,21-trihydroxy derivative, the dihydroxylated product was accumulated.

Formation of 17α,21-dihydroxyprogesterone from 21-hydroxyprogesterone was confirmed, however, when 21-hydroxyprogesterone was charged as substrate to fermentation medium supplemented with Fe^{2+} or Mn^{2+} (Table 8). Under these conditions, 21-hydroxyprogesterone was transformed after 24 hr into 11α,21-dihydroxyprogesterone and 17α,21-dihydroxy derivative. After 48 hours of fermentation, 11α,17α,21-trihydroxyprogesterone was detected.

The importance of Mg^{2+}, PO_4^{3-} and Fe^{2+} ions for the microbial hydroxylation of steroids had been reported by some workers.[3,4] Sweat and Bryson,[9] also showed that 11β-hydroxylase of mammalian system is markedly enhanced by the addition of Mn^{2+} and to a lesser extent by Mg^{2+}. Evidence from studies carried out by many workers[10-13] clearly confirms the hydroxylation reaction to be an aerobic reaction requiring conditions for oxidative phosphorylation, and that reduced triphosphopyridine nucleotide (TPNH) is an important cofactor. Diphosphopyridine nucleotide (DPN^+), adenosine triphosphate (ATP), triphosphopyridine nucleotide (TPN^+), nicotinamide, magnesium ions, and intermediates of the Kreb's citric acid cycle were needed as cofactors in the formation and maintenance of TPNH in its reduced state.

In a trial to identify the required cofactors for the hydroxylation processes, the role of intermediates of TCA cycle, some purine and pyrimidine bases and nucleoside as well as some vitamins, on the transformation of progesterone by the experimental organism was investigated. Among the different organic acids tested, acetate, malate and succinate appeared to stimulate the hydroxylation reactions. Similarly, riboflavin, thiamine and nicotinic acids increased the capacity of the organism to transform progesterone. Maximal yields of the various progesterone derivatives were obtained with riboflavin whereby progesterone was practically quantitatively transformed after 3 days of fermentation. Ryan and Engel[14] noted that nicotinic acid amide stimulated the hydroxylation of steroids in mammals presumably because nicotinic acid amide participate in the synthesis of DPNH or TPNH. Zetsche[4] also showed

that malate and riboflavin the favour hydroxylation of progesterone at 7α,11β and 14α by *Curvularia lunata*.

Addition of adenine, adenosine, xanthin, uracil or guanine to the fermentation medium seemed to enhance the transformation reactions. However, in the cases of adenine, adenosine, uracil and guanine, formation of 11α-hydroxy-5α-pregnane-3, 20-dione as well as 6β,11α-dihydroxyprogesterone was noticeably restricted. Such results are encouraging because the latter two compounds were considered to be undesired products.

We are grateful to Professor Dr. M. Abdel-Aziz, Faculty of Science, Cairo University, Professor Dr. H. G. Osman, and Professor Dr. M.B.E. Fayez, National Research Centre, Cairo, for their encouragement and interest.

Thanks are also due to Dr. D. H. Peterson UpJohn Company, U.S.A., Dr. H. Azfasadour, Organon, Oss. Holland and the Schring group for the in gifts of the steroid compounds.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2884—2890 (1970)

The Friedel-Crafts Reaction of 2,3-Dimethylbenzofuranyl Ketones and the Corresponding Carboxylic Esters[1]*

Yoshiyuki KAWASE, Tomoko OKADA and Toshio MIWA*

Department of Chemistry, Faculty of Literature and Science, Toyama University, Gofuku, Toyama
** Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka*

(Received January 21, 1970)

The acetylation of methyl 2,3-dimethyl-4- and -7-benzofurancarboxylates was carried out by the action of acetyl chloride and aluminum chloride in carbon disulfide at room temperature to afford the 6-acetyl compounds; these compounds were converted to keto-acids by hydrolysis, and then to the known dicarboxylic acid or to the known 6-acetylbenzofuran. The alkylation of acetyl and methoxycarbonyl derivatives of 2,3-dimethylbenzofuran was carried out by the action of *n*- or iso-propyl bromide and aluminum chloride in carbon disulfide at reflux temperature, both the bromides furnishing the same isopropylated product. The crude products from the 4-acetyl- and 4-methoxycarbonyl-benzofurans could not be purified, but 2,3-dimethyl-6-isopropyl-4-benzofurancarboxylic acid was obtained by the hydrolysis of the product from the latter. In the cases of 5-acetyl- and 5-methoxycarbonyl-benzofurans, the isopropylation occurred at the 7-position and the products were converted to the same carboxylic acids, while the isopropylation occurred at the 4-position in the cases of 6-acetyl- and 6-methoxycarbonylbenzofurans, and diisopropylation occurred in the case of 7-methoxycarbonylbenzofuran.

In previous papers, one of the present authors and others reported that acetylation by the Fridel-Crafts reaction of acetyl-[1-4] and methoxycarbonyl-2,3-dimethylbenzofurans[4] afforded the acetylated compounds, generally in the *m*-position to the acetyl or methoxycarbonyl group except that methyl 2,3-dimethyl-5-benzofurancarboxylate (**9b**) afforded the 6-acetylated compound; they also reported that the isopropylation of the 2,3-dimethyl-6-benzofuranyl methyl ketone (**5**) furnished the 4-isopropyl compound[1,2] (**18**).

In connection with this, the acetylation of other isomeric methyl benzofurancarboxylates (**8b** and **23b**) and the alkylation of benzofuranyl methyl ketones (**3**, **4** and **5**) by the Friedel-Crafts reaction have been studied further; also, extended studies of the alkylation of methyl benzofurancarboxylates (**8b**, **9b**, **10b** and **23b**) have been carried out.

At first, some examinations of the preparation of starting compounds were carried out[5] (Chart 1);

3-(*m*- and *p*-acetylphenoxy)butanones[4,6] (**1** and **2**) were treated with concentrated sulfuric acid at 45 or 60°C for 30 min to give 2,3-dimethyl-4- and -5-benzofuranyl methyl ketones (**3** and **4**) respectively, while **1** and **2** afforded 2,3-dimethyl-6- and -5-benzofuranyl methyl ketones (**5** and **4**) by means of the action of polyphosphoric acid.[4,5] Therefore, the almost pure ketone **3** could be prepared much more easily than by the reported method;[4] however, the product was found by the NMR spectroscopy to contain only a small amount (*ca.* 1%) of the isomeric ketone (**5**). On the other hand, 3-(*m*- and *p*-methoxycarbonylphenoxy)-butanones[4] (**6** and **7**) were treated with polyphosphoric acid at 100°C for 1 hr to give a mixture of 2,3-dimethyl-4- and -6-benzofurancarboxylic acids (**8a** and **10a**) and 2,3-dimethyl-5-benzofurancarboxylic acid (**9a**) respectively, the ester group having been hydrolyzed, while **6** and **7** afforded 4-benzofurancarboxylic acid (**8a**) and methyl 5-benzofurancarboxylate (**9b**) respectively, by the action of concentrated sulfuric acid.[4]

The mixture of 4- and 6-carboxylic acids (**8a** and **10a**) described above could not be separated by crystallization or chromatography, but the ratio of the components was determined by estimating the areas of the peaks corresponding to the 3-methyl protons of **8a** and **10a** (δ=2.22 and 2.17 ppm respectively) in the NMR spectrum of the mixture. The ring closure of **1** and **6** occurred at the ortho position of the acetyl or methoxy-

6) E. Bisagni, J. -P. Marquet, A. Cheutin, R. Royer and M. L. Desvoye, *Bull. Soc. Chim. Fr.*, **1965**, 1466.

carbonyl group by means of sulfuric acid and mainly at the para position by means of polyphosphoric acid. 2,3-Dimethyl-7-benzofurancarboxylic acid (**23b**) was prepared by the action of carbon dioxide on the Grignard reagent prepared from 7-bromobenzofuran[7] (**21**) or by the bromoform reaction of the 7-benzofuranyl methyl ketone[7] (**22**), and methyl 4- and 7-benzofurancarboxylates (**8b** and **23b**) were prepared by the esterification of the corresponding carboxylic acids (**8a** and **23a**).

Therefore, the actylation of the esters **8b** and **23b** was carried out much as has been reported before[4] by the action of acetyl chloride and aluminum chloride in carbon disulfide at room temperature; this gave the acetylated compounds (**11b** and **24b**) (Charts 2 and 5). The position of the acetyl group was determined by NMR spectroscopy and also by converting the keto-esters to known compounds; the keto-esters (**11b** and **24b**) were converted to the corresponding keto-acids (**11a** and **24a**). The keto-acid **11a** was oxidized by the bromoform reaction to the known 2,3-dimethyl 4,6-dicarboxylic acid[4] (**12**); this indicated that the acetylation occurred at the 6-position of the ester **8b**, similarly to the case of the 4-benzofuranyl methyl ketone[4] (**4**). The keto-acid **24a** was decarboxylated to the ketone **5**;[6] this indicated that the acetylation occurred at the 6-position of the ester, **23b**, as in the case of methyl 2,3-dimethyl-5-benzofurancarboxylate[4] (**9b**). The analogous acetylation of 6-carboxylic acid (**10b**) furnished the 4-acetyl compound (**20**), which was identical with the authentic sample prepared by the acetylation of the 6-carboxylic ester (**10b**), followed by hydrolysis[4] (Chart 4).

Next, the alkylation of the ketones (**3**, **4** and **5**) and the esters (**8b**, **9b**, **10b** and **23b**) was carried out by the use of *n*- or iso-propyl bromide and alminum chloride in carbon disulfide at the reflux temperature, whereas the alkylation occurred at room temperature in the cases of the 6-substituted compounds (**5** and **10b**). Normal- and iso-propyl bromide gave the same isopropylated products, probably through the isomerization of the *n*-propyl group, while ethyl bromide or iodide and aluminum chloride or bromide gave no alkylation products.

In the cases of the ketone **3** and the ester **8b** (Chart 2), the crude products could not be purified by usual methods; it was confirmed by gas chromatography that they contained some recovery compounds and two other compounds in each case. The crude product from the ester **8b** was hydrolyzed and then crystallized to give pure 2,3-dimethyl-6-isopropyl-4-benzofurancarboxylic acid (**13b**). The position of the isopropyl group was determined from the fact that the compound was not identical with 2,3-dimethyl-7-isopropyl-4-benzofurancarboxylic acid (**15**), which had itself been prepared by the bromoform reaction of the corresponding ketone[2] (**14**), and from the pattern of the NMR spectrum.

The alkylation of the ketone **4** and the ester **9b** was carried out similarly to give the isopropylated ketone (**16**) and ester (**17b**) (Chart 3); these products were then both converted to the same 2,3-dimethyl-7-isopropyl-5-benzofurancarboxylic acid (**17a**) by the bromoform reaction or by hydrolysis respectively. The ketone **16** was identical with an authentic sample[2] prepared from the 4-hydroxy-3-isopropylphenyl methyl ketone, and the NMR spectra of **16** and **17b** had two doublets (J= 2 Hz) corresponding to the aromatic protons, indicating that the two aromatic hydrogens were at positions meta to each other.

The alkylation of the ketone **5** and the ester **10b** afforded the known 4-isopropyl compounds (**18** and **19b**)[2,8] (Chart 4).

The alkylation of the ester **23b** by a similar procedure afforded a mixture which was proved by gas chromatography to contain the recovery compound and four other compounds. The crude product was hydrolyzed and then crystallized from ethanol to give an acid, the structure of which was confirmed to be 2,3-dimethyl-5,6-diisopropyl-7-benzofurancarboxylic acid (**25a**) from the data of microanalysis and the NMR spectrum (Chart 5). The NMR spectrum of **25a** had a peak corresponding to one aromatic proton and two doublets corresponding to two isopropyl methyl protons, plus a peak corresponding to 3-methyl protons which was in a higher field than in the cases of 4-substituted compounds,[5,8] indicating that **25a** had no substituent in the 4-position.

In conclusion, we can say that in the electrophilic substitution of *bz*-acetyl or *bz*-methoxycarbonyl derivatives of 2,3-dimethylbenzofuran, all position, but especially the 6- and 4-positions, are activated by the effect of the furan ring,[1-4] and that the *m*-position relative to the acetyl or methoxycarbonyl group is less deactivated than the *o*- or *p*-position by the effect of the group. In the cases of the acetylation of **8b** and the alkylation of **5** and **10b**, the reaction occurred at the 6- and 4-positions, favored by both effects, and the effect of the furan ring predominated in the acetylation of **23b**, while the substituent effect dominated in the alkylation of **4** and **9b** and the polyalkylation occurred in the alkylation of **3**, **8b** and **23b**.

Experimental

All the melting points and boiling points are uncorrected, and IR spectra were measured in the form

7) C. Pène, P. Demerseman, A. Cheutin and R. Royer, *Bull. Soc. Chim. Fr.*, **1966**, 586.

8) Y. Kawase, S. Takata and T. Miwa, This Bulletin, **43**, 1796 (1970).

of KBr disks in the case of solid samples, and the gas chromatography was carried out on a Hitachi K23 apparatus, with Silicone DC-11 on Chamelite as a stationary phase, a flow rate, He, of 46 ml/min (0.7 kg/cm^3), and a temperature rise of 5°C/min from 180°C. The NMR spectra were measured on a Nihon Denshi 60 MHz spectrometer in carbon tetrachloride (*ca.* 5% solution), unless otherwise noted, with TMS as the internal standard. The detailed data are summarized in the tables.

Materials. *a) Aryloxybutanones.* The 3-(*m*- and *p*-acetyphenoxy)butanones[4,6] (**1** and **2**) and 3-(*m*- and *p*-methoxycarbonylphenoxy)butanones[4] (**6** and **7**) were prepared following the methods in the references.

b) Benzofuranyl Methyl Ketones. 2,3-Dimethyl-6-[9] and -7-benzofuranyl methyl ketones[7] (**5** and **22**) and 2,3-dimethyl-7-isopropyl-4-benzofuranyl methyl ketone[2] (**14**) were prepared following the methods in the references. 2,3-Dimethyl-4- and -5-benzofuranyl methyl ketones (**3** and **4**) were prepared as follows:

Table 1. Reactions other than alkylation

c) This consists of 77% of **8** and 23% of **10**.
d) The crude compound.

9) E. Bisagni and R. Royer, *Bull. Soc. Chim. Fr.*, **1962**, 925.

2,3-Dimethyl-5-benzofuranyl Methyl Ketone (4). Concentrated sulfuric acid (5 g) was stirred, drop by drop, into the 3-aryloxybutanone **2** (3 g) with cooling below 60°C, after which the mixture was stirred at 60°C for 30 min. The cooled mixture was then poured into ice water and extracted with ether. The ethereal solution was washed with an aqueous sodium hydroxide solution, and the ether was distilled off. The residual product was distilled, bp 175—183°C/23 mmHg, 1.2 g (44%), and then crystallized to give the pure ketone **4**, mp 78°C, 0.9 g (33%), which was identical with an authentic sample.[6]

2,3-Dimethyl-4-benzofuranyl Methyl Ketone (3). This was also prepared by the same procedure with a reaction temperature of 45°C; the product, bp 157—160°C/20 mmHg, 1.7 g (62%), was confirmed to be identical with an authentic sample[4] by a study of the IR and NMR spectra, by gas chromatography, and preparing 2,4-dinitrophenylhydrazone. However, it was found to contain a small amount (*ca.* 1%) of the isomeric ketone **5** on the basis of the NMR spectrum, in which a low peak corresponding to the 3-methyl protons of **5** appeared at $\delta=2.14$ in addition to high peak corresponding to those of **3** at $\delta=2.11$.[5,8]

c) Benzofurancarboxylic Acids. 2,3-Dimethyl-4- and -6-benzofurancarboxylic acids[4] (**8a** and **10a**) were prepared following the method in the reference, while 2,3-dimethyl-5- and -7-benzofurancarboxylic acid (**9a** and **23a**) were prepared as follows:

2,3-Dimethyl-5-benzofurancarboxylic Acid (9a). A mixture of 3-aryloxybutanone (**7**) (3 g) and polyphosphoric acid ($n=2.5$, 60 g) was heated at 100°C for 1 hr with stirring, after which the cooled mixture was poured into ice water. The crystalline product thus formed was collected and recrystallized from ethanol to give **9a**, mp 239—240°C, 2.2 g (86%), which was identical with an authentic sample.[4]

The 3-aryloxybutanone (**6**) (1.5 g) was also treated similarly to give a crude crystalline product, mp 151—155°C, 0.55 g (43%), which could not be purified by crystallization; the product was found to be a mixture of **8a** (77%) and **10a** (23%) by estimating the area of the peaks, $\delta=2.22$ and 2.17 ppm (in trifluoroacetic acid), corresponding to the 3-methyl protons of **8a** and **10a** respectively.[5,8]

2,3-Dimethyl-7-benzofurancarboxylic Acid (23a). *i) By the Grignard Reaction of the Bromo Compound **21**.* A solution of 2,3-dimethyl-7-bromobenzofuran[7] (**21**) (30 g) in tetrahydrofuran (80 ml) was gradually added to a suspension of magnesium (3.3 g) in tetrahydrofuran (30 ml), with the addition of a small amount of iodine at first. After all of the magnesium had been dissolved (about 40 min), the solution was cooled to −10°C; then a stream of carbon dioxide from dry ice was passed into it with stirring and cooling. Dilute sulfuric acid was added, and the mixture was extracted with ether. The ether was distilled off, and the residue was crystallized from ethanol to give **23a**; mp 192—193.5°C, 14.6 g (58%). The UV[8] and NMR[5,8] spectra were reported previously.

*ii) By the Bromoform Reaction of the Ketone **22**.* A solution of **22** (0.7 g) in dioxane (30 ml) was added with cooling to an aqueous sodium hypobromite solution; this solution had been prepared by adding bromine (0.8 g, 3.8 mol equivalents) to a mixture of sodium hydroxide (1.5 g, 9 mol equivalents), water (5 ml),

and ice (5 g). The mixture was stirred for 30 min with cooling and then for 1.5 hr at 45°C. The cooled mixture was diluted with water, washed with ether, and then acidified after the addition of a small amount of sodium bisulfite. The crystalline product thus formed was collected and recrystallized from ethanol to give **23a**, mp 189—191°C, 0.1 g (14%), which was identical with the other sample.

d) Methyl Benzofurancarboxylates. Methyl 2,3-dimethyl-5- and -6-benzofurancarboxylates[4] (**9b** and **10b**) were prepared following the method of the reference, while the 4- and 7-isomers (**8b** and **23b**) were prepared as follows:

Methyl 2,3-Dimethyl-4- and -7-Benzofurancarboxylates (8b and 23b). *i) By the Action of Dimethyl Sulfate and Potassium Carbonate.* Potassium carbonate (8.5 g, 3 mol equivalents) was added to a solution of the acid **8a** (4 g) and dimethyl sulfate (3.9 g, 1.4 mol equivalents) in acetone (150 m*l*), and the mixture was refluxed for 8 hr. Most of the acetone was distilled off, and the residue was treated with water and then extracted with ether. The ethereal solution was washed with an aqueous sodium hydroxide solution, and the ether was distilled off. The residual product was distilled to give **8b**, bp 162—165°C/16 mmHg, n=1.5660 (21.5°C), 3.2 g (74.5%). The UV[8] and NMR[5,8] spectra of which have been reported previously. The ester **23b** was prepared by the same procedure; mp 58—59°C (from cyclohexane); yield, 76%; its UV[8] and NMR[5,8] spectra have also been reported previously.

ii) By the Action of Methanol and Sulfuric Acid. A mixture of the acid **8a** (7 g), methanol (40 m*l*), and concentrated sulfuric acid (2 g) was refluxed for 4 hr. A half of the methanol was then distilled off, and the mixture was treated with water and then extracted with ether. The ethereal solution was washed with a 5% aqueous sodium hydroxide solution, and the ether was distilled off. The residual product was distilled to give **8b**, bp 163—164°C/20 mmHg, 7 g (93%).

Acetylation of the Esters (8b and 23b) and the Acid (10a). Powdered aluminum chloride (4.5 g, 2.2 mol equivalents) was gradually added, with cooling, to a solution of the ester **8b** (3.1 g) and acetyl chloride (1.5 g, 1.7 mol equivalents) in carbon disulfide (50 m*l*); the mixture was stirred for 4 hr at room temperature and then allowed to stand overnight. The next day, the mixture was poured into ice water and extracted with chloroform. The organic layer was washed with an aqueous sodium hydroxide solution and the solvent was distilled off. The residual product was crystallized from petroleum ether to give methyl 2,3-dimethyl-6-acetyl-4-benzofurancarboxylate (**11b**), mp 106—107°C, 1.4 g (37.5%).

Methyl 2,3-dimethyl-6-acetyl-7-benzofurancarboxylate (**24b**) was obtained by the same procedure from the ester **23b**, and 2,3-dimethyl-4-acetyl-6-benzofurancarboxylic acid (**20**), mp 211—212°C, which was identical with an authentic sample,[4] was also obtained by the same procedure from the acid **10a** by means of the action of acetyl chloride (1.2 mol equivalents) and aluminum chloride (3 mol equivalents) in carbon di-

sulfide.

Alkylation of the Ketones (3, 4, and 5) and the Esters (8b, 9b, 10b and 23b) (Table 2). Powdered aluminum chloride (2.8 g, 2 mol equivalents) was added, with stirring and cooling, to a solution of the ketone **4** (2 g) and *n*-propyl bromide (1.6 g, 1.2 mol equivalents) in carbon disulfide (50 m*l*); the mixture was then refluxed for 3 hr. The cooled mixture was poured into ice water containing some dilute hydrochloride acid and subsequently extracted with chloroform. The organic layer was washed with a dilute aqueous sodium hydroxide solution, and the solvent was distilled off. The residual product was distilled to give a crude product, bp 185—195°C/20 mmHg, 1.8 g; this crude product was crystallized from petroleum ether to give a pure 2,3-dimethyl-7-isopropyl-5-benzofuranyl methyl ketone (**16**), mp 107—108°C, 0.9 g (37%), which was identical with an authentic sample.[2]

The alkylation was carried out much as in the cases of the ketones (**3** and **5**) and the esters (**8b**, **9b**, **10b**, and **23b**) as is shown in Table 2, but the products could not be purified by distillation, crystallization, or chromatography on alumina in the cases of **3**, **8b**, and **23b**; the crude products from the latter two were directly hydrolyzed to the carboxylic acids. In the cases of the ketone **5** and the ester **10b**, some of the alkylated products were obtained by a reaction at room temperature.

Hydrolysis of the Keto-esters (11b and 24b) and the Esters (13b, 17b and 25b). A mixture of the keto-ester **11b** (1.3 g), methanol (2 m*l*), and a 50% aqueous potassium hydroxide solution (2 m*l*) was refluxed for 3 hr. The cooled mixture was diluted with water and washed with ether. The alkaline solution was then acidified to give a crystalline product; this product was subsequently recrystallized from ethanol to give 2,3-dimethyl-6-acetyl-4-benzofurancarboxylic acid (**11a**), mp 178—180°C, 1 g (81%).

Similarly, 2,3-dimethyl-6-acetyl-7-benzofurancarboxylic acid (**24a**) and 2,3-dimethyl-7-isopropyl-6-benzofurancarboxylic acid (**17a**) were obtained from **24b** and **17b** respectively, and 2,3-dimethyl-6-isopropyl-4-benzofurancarboxylic acid (**13a**) and 2,3-dimethyl-5,6-diisopropyl-7-benzofurancarboxylic acid (**25a**) were obtained from two crude esters, **13b** and **25b** respectively.

The Bromoform Reaction of the Ketones (14 and 16) and of the Keto-acid (11a). In the cases of **14** and **16**, the reaction was carried out to give 2,3-dimethyl-7-isopropyl-4-benzofurancarboxylic acid (**15**) and **17a** respectively, much as has been described for **23a** from **22**. The keto-acid **11a** was treated with an excess of sodium hydroxide to give 2,3-dimethyl-4,6-benzofurandicarboxylic acid (**12**), mp 324°C, which was identical with an authentic sample.[4]

Decarboxylation of the Keto-acid 24a. A mixture of the keto-acid **24a** (0.29 g), copper powder (0.18 g), and quinoline (5 m*l*) was refluxed under a stream of nitrogen until the evolution of carbon dioxide had ceased. The cooled solution was then acidified by the addition of dilute hydrochloric acid, and the mixture was extracted with ether. The ethereal solution was washed with a 5% auqueous sodium hydroxide solution, and the ether was distilled off. The residual product was crystallized from cyclohexane to give the ketone **5**, mp 79—80°C, 0.034 g (42.5%), which was identical with an authentic sample.[9]

The authors are grateful to the members of the Laboratory of Analysis, Faculty of Pharmacology of Toyama University, for their microanalyses.

Photoinduced Reactions. XLI.[1] Stereochemical Course in the Photochemistry of a 2,5-Cyclohexadienone

Katsuyuki OGURA and Teruo MATSUURA

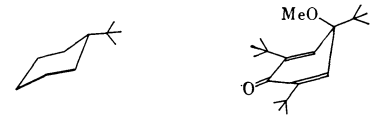
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto

(Received January 24, 1970)

Mechanism for the photochemical transformation of a 2,5-cyclohexadienone into a bicyclo[3.1.0]hex-3-en-2-one (so-called lumiketone) was discussed. Photolysis of 2,4,6-tri-*t*-butyl-4-methoxy-2,5-cyclohexadienone (VII) gave only one stereoisomer (VIIIa) of the corresponding lumiketones. This fact and the prediction by the Woodward-Hoffmann rule indicate that a biradical-like excited state XI with 3,5-bonding gives rise to a direct rearrangement to lumiketone VIIIa as shown in Path B (Scheme II).

The transformation of 2,5-cyclohexadienone into bicyclo[3.1.0]hex-3-en-2-one, the so-called lumiketone, is a most intriguing photochemical reaction. It was originally postulated[2] that the course of this transformation involves the sequence of events shown in Scheme I (Path A), namely, rebonding of the triplet excited state II to give the bridged excited state III, followed by electron demotion to the ground-state zwitterion IV which finally undergoes rearrangement to the product V. That the immediate precursor to the lumiketone is the zwitterion is generally accepted in recent discussions.[3] However, Schuster and Patel[4] suggested that an alternative pathway, by which rearrangement and electron demotion occur simultaneously without involvement of the zwitterion intermediate (Path B in Scheme I), is favorable in the photochemical transformation of 4-trichloromethyl-4-methyl-2,5-cyclohexadienone (VI) into the corresponding lumiketone (XVII). The latter possibility (Path B) was also supported by Swenton *et al.*[5] We now wish to discuss these possibilities from the stereochemical viewpoint of this photochemical reaction.

In a previous paper,[6] we reported that photolysis of 2,4,6-tri-*t*-butyl-4-methoxy-2,5-cyclohexadienone (VII) underwent the same transformation as mentioned above to yield a lumiketone (VIII), which on further irradiation gave photoketone(IX) and photophenol(X). For the transformation of VII into VIII, two routes, Path A and Path B shown in Scheme II, are also possible. It can be expected that intermediates of steric formulas, XIa for a biradical-like species and XIIa for a zwitterion species, are preferred to the isomeric forms, XIb and XIIb, respectively. It is well known that the preferred conformation of *t*-butylcyclohexane is i. The methoxyl of VII showed its NMR signal at τ 6.88. This value is relatively large compared with that of dimethyl ether (τ 6.76), and may indicate that this methoxyl is located on a shielding area of π-clouds. Therefore, it is reasonable that the preferred conformation of VII is depicted as ii, and that XIa is more easily formed from VII than XIb is formed.



i ii

Zimmerman and Crumrine,[7] and Brennan and Hill[8] have shown that the isomerization of the zwitterions, which were produced by treatment of XIIIa and XIIIb with potassium *t*-butoxide and of XIIIc with zinc, to the corresponding lumiketones follows the "slither" mechanism, involving two 1,2-shifts with C-6 migrating from C-5 to C-4 and then from C-1 to C-5 (Scheme III). fore, if the zwitterion XI is involved in the photochemical reaction of VII, VIIIb should be the preferred structure for the lumiketone. The conjugated system, over which 1,4-sigmatropic migration occurs, may be considered as a 2-oxobutadiene skeleton. Calculation of the symmetry properties of the Hückel molecular orbitals of XIV shows that the highest occupied molecular orbital (ψ_2 of butadiene or ψ_3 of 2-oxobutadiene) is antisymmetric irrespective of the effect of the oxygen. Thus it is supported that the transformation of IV to V follows the slither mechanism.[7,8] However, the lowest vacant molecular orbital (ψ_3 of butadiene or ψ_4 of 2-oxobutadiene) is symmetric, and consequently a concerted suprafacial rearrangement in an excited state requires inversion of configuration of the migrating group (the "pivot" mechanism, the orbital at C-6 detaching itself from C-1, then bonding to C-4 as shown in Scheme

IV).[9] If the photochemical isomerization of VII to VIII follows Path B (Scheme II), the lumiketone with structure VIIIa should be formed predominantly.

Photolysis of VII in petroleum ether with a visible light gave only an isomer of VIII. Furthermore, careful chromatographic analyses of the reaction mixture at various stages of irradiation showed that only one isomer of VIII was formed in addition to recovered VII. The configuration of this lumiketone was deduced by comparing its NMR spectrum with that of 1,3-di-*t*-butyl-6-methyl-6-methoxybicyclo[3.1.0]hex - 3 - en - 2 - one (XV), which was formed on photolysis of 2,6-di-*t*-butyl - 4 - methyl - 4 - methoxy - 2,5 - cyclohexadienone.[10],*1 The resonance of the methoxyl of VIII appeared at τ 6.73, similar to that of dimethyl ether (τ 6.76), while the methoxyl singlet of XV was observed at an unusually high field (τ 6.97). The high-field shift should result from diamagnetic shielding by the enone system of XV. The analogous unusual shifts were also observed in a methoxyl of α-lumicolchicine[11] and C-6 methyl of 1,3-di-*t*-butyl-6-allyl (or *n*-propyl)-6-methylbicyclo[3.1.0]-hex-3-en-2-one (XVI),[12] and it was suggested that the shifts were ascribed to the location of these groups over the π-electron clouds. In the NMR spectra of VII and XV measured in benzene, the methoxyl signal of VIII appeared at a field (τ 6.70) similar to that in $CDCl_3$, while the methoxyl of XV was shifted to a higher field (τ 7.17). This might indicate that the methoxyl group of XV is located over the cyclopentenone ring but not that of VIII.[13]

Both of the *t*-butyl groups of XV at C-1 and C-3 positions were shifted to lower fields by using benzene as a solvent instead of $CDCl_3$. Although two *t*-butyl signals of VIII appeared at lower fields

in benzene than in $CDCl_3$, other *t*-butyl signal shifted to a higher field. This suggests that the *t*-butyl of VIII at C-6 position may have an endo-configuration. The aliphatic methyl signal of XV appears at τ 8.45, characteristic of an exo-geometry.*2.

Accordingly, formulas VIIIa and XV were given as the stereochemical structures of the "lumi" compounds VIII and XV, respectively. It seems reasonable from the stereochemical structure of VIIIa and the above prediction by the Woodward-Hoffmann rule that Path B (Scheme II) is favorable in the photochemical reaction of VII. It should be also noted that the same stereochemistry is held in the photochemical transformation of VI into its lumiketone XVII.*3 Of course, our conclusion does not necessarily deny the zwitterion intermediate (Path A) in the photochemical transformation of 2,5-cyclohexadienones. It can be expected that the formation of lumiketones predominantly follows Path A (the "slither" mechanism), if electron demotion occurs faster than direct isomerization of III to V (Path B) or if Path B (the "pivot" mechanism) is stereochemically excluded (for example, the photochemical formation of lumisantonine from santonin[2]).

One of the authors (K. O.) is indebted to Fuji Film Co. for a financial support.

*2 Miller and Margulies[12] reported that an exo-methyl at C-6 position of XVI shows its NMR signal at a lowet field (τ 8.60 or 8.65) than an endo-methyl (τ 9.05 or 9.08).

*3 Schuster and Patel[14] reported that this transformation is stereospecific and formula XVII is assigned as the stereochemical structure of this lumiketone. This stereochemical assignment is supported by the fact that the methyl of XVII shows its NMR signal at a field analogous to that of XV.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2893—2899 (1970)

Formation and Cycloaddition Reactions of Substituted *N*-Ethoxycarbonyl-1(1*H*)-azepine Derivatives[1]

Tadashi SASAKI, Ken KANEMATSU and Akikazu KAKEHI

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa, Nagoya

(Received February 25, 1970)

The formation of substituted *N*-ethoxycarbonyl-1(1*H*)-azepine derivatives is reinvestigated in the thermal reactions of benzene derivatives with ethyl azidoformate. The rate-determining step in these reactions is determined by kinetic experiments to be the decomposition of the azide. The (4+2) π cycloadducts of these azepine derivatives are obtained by thermal reactions with tetracyanoethylene (TCNE) as a dienophile. The formation of compounds **22**, **23**, **24**, **25**, **26**, and **27** is confirmed by the spectral evidence.

Previously, we reported on the photosynthesis of substituted 1(1*H*),2-diazepines and their reactivities in the cycloaddition reactions.[2] In view of the interest in the theoretical aspects of the cycloaddition reactions of seven-membered cyclic non-benzenoid heteroaromatic hydrocarbons, the above-mentioned new 1(1*H*),2-diazepines would seem to be of timely interest. At the same time, substituted 1(1*H*)-azepines are also considered to comparable with the diazepines in the cycloaddition reactions. Furthermore, recent works[3,4] along these lines have prompted us to report our different preliminary observations concerning the

cycloaddition reactions of 1(1*H*)-azepine derivatives.

This paper will deal with the thermal formation of azepine derivatives from benzene derivatives and ethyl azidoformate under various conditions in both open and sealed-tube systems. To obtain further information concerning the mechanisms for these reactions, we carried out kinetic experiments in the formation of azepines from *p*-xylene and ethyl azidoformate. Subsequently, we investigated the isomeric structures of the reaction adducts between ethyl azidoformate and benzene derivatives in the presence of TCNE.

Results and Discussion

Thermal Reaction of Benzene Derivatives and Ethyl Azidoformate. Although substituted *N*-ethoxycarbonyl-1(1*H*)-azepines have been prepared by the photolysis or pyrolysis of ethyl azidoformate in aromatic substrates such as toluene, anisole, and halobenzenes,[5] we reinvestigated the thermal reaction under various conditions.

When ethyl azidoformate was decomposed in *o*-, *m*- and *p*-xylene in an open flask or in a sealed-tube at 120°C, the corresponding azepines were obtained, together with aromatic urethans. However, when ethyl azidoformate was refluxed in benzene (at 80°C) and toluene (at 110°C) or in a sealed-tube at 120°C, only the corresponding azepines were obtained. On the other hand, when ethyl azidoformate was decomposed in mesitylene at 120°C in an open flask, the corresponding azepines and aromatic urethans were produced in 25 and 30% yields respectively, but at 120°C in a sealed-tube, only the aromatic urethan was produced in about a 60% yield. These results are summarized in Table 1.

These results indicate that ethyl azidoformate was not thermolyzed appreciably at the reflux temperatures of benzene and toluene, as has been reported by Baldwin and Smith.[6]

Substituted aromatic urethans were obtained conveniently by the thermal isomerization of dimethyl and trimethyl-substituted azepines under more drastic conditions. Especially, because of the thermal instability of the tri-substituted azepine skeleton, 1-ethoxycarbonyl-2,4,6-trimethylazepine was readily converted to the aromatic urethans and no seven-membered ring compounds could

Table 2. The number and the ratio of 1(1*H*)-azepines produced

Azepine precusor	Number of azepines	Ratio of azepines* (Comp. No.)
Toluene	3	40 (**9**) : 35 (**8**) : 25 (**10**)
o-Xylene	4	50** : 30** : 15** : 5**
m-Xylene	3	15 (**15**) : 50** : 35**
p-Xylene	2	20 (**18**) : 80 (**19**)

* These ratios were determined by glpc and NMR spectra.
** Structures of isomeric azepines were difficult to determine.

Zinser and K. L. Moritz, *Tetrahedron Lett.*, **1964**, 1733. d) R. A. Smith, J. E. Baldwin and I. C. Paul, *J. Chem. Soc., B*, **1967**, 112.

6) Ethoxycarbonylnitrene and ethoxycarbonylcarbene have been generated by the thermal decomposition of ethyl azidoformate and ethyl diazoacetate at 129.6°C in a solution of benzene and anisole, toluene, chlorobenzene or of fluorobenzene in an unreactive perfluorinated polyether: see J. E. Baldwin and R. A. Smith, *J. Amer. Chem. Soc.*, **89**, 1886 (1967).

be detected. The relative ratio of the yielded isomeric ethoxycarbonylazepine derivatives was determined by gas-chromatographic and spectroscopic means. However, the reaction mixture was difficult to separate by means of column chromatography and molecular distillation. These results[7] are shown in Table 2.

In order to obtain kinetic information concerning the above-mentioned reactions, we investigated the reaction of *p*-xylene with ethyl azidoformate in an open flask. The thermolysis of ethyl azidoformate was done at 100, 120, and about 140°C in pure *p*-xylene, and the reactants were then analyzed by glpc. The products were identified as di-substituted *N*-ethoxycarbonylazepines by their retention times and IR and NMR spectra, given in Table 3. The amounts of unchanged ethyl azidoformate at different reaction times were measured by glpc in the reactions of the heating of the mixture of *p*-xylene and ethyl azidoformate at 120°C. These results are shown in Fig. 1. Thus, the following zeroth-order rate constants were determined: $k_{100°}=1.7\times10^{-3}$ min^{-1}; $k_{120°}=6.3\times10^{-3}$ min^{-1}; $k_{138°}=1.7\times10^{-2}$ min^{-1}. On the other hand, the rate of the decomposition of ethyl azidoformate was calculated to be -6.3×10^{-3} min^{-1} at 120°C. These results can be explained in terms of a ethoxycarbonylnitrene which

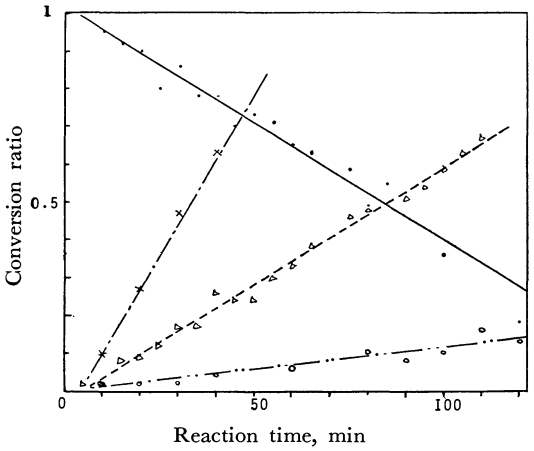

Fig. 1. Kinetic experiments in the reactions of ethyl azidoformate with *p*-xylene.

——— Decomposition curve of ethyl azidoformate at 120°C.

—··— Formation curve of azepines at 100°C.

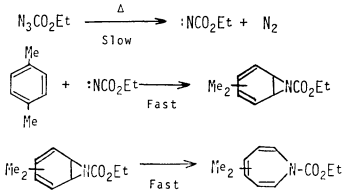

Chart 1.

is generated by the thermal decomposition of ethyl azidoformate in the rate-determing step (slow); it is added to *p*-xylene to form the bicyclic aziridine intermediate, and they converted to the valence-bond isomerization products rapidly (Fig. 1 and Chart 1).

On the basis of the above facts, in summary it can be said that 1*H*-azepines are formed by the kinetically-controlled and aromatic urethans by the thermodynamically-favored reaction pathway shown in Chart 2.

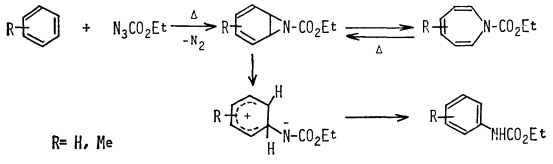

Chart 2.

The structures of a representative number of 1(1*H*)-azepines thus formed from the corresponding benzene substrates are illustrated in Table 3.

The structural assignments for the produced azepines and aromatic urethans were determined by means of their spectral characteristics. In the infrared spectra, the azepines (**7**—**20**) show two strong absorptions due to the carbonyl ester in the ranges of 1700—1720 cm^{-1} and 1320—1340 cm^{-1}, and medium absorptions due to the carbon-carbon double bond in the range of 1610—1660 cm^{-1}. On the other hand, the aromatic urethans exhibit absorptions at 3240—3320 cm^{-1} (NH) and at 1600 cm^{-1} (C_6H_5). More significantly, the isomeric azepine mixture was confirmed by NMR inspection.[8]

From their NMR assignments for substituted 1*H*-azepines, the structures of the isomeric mixture of methyl-substituted 1*H*-azepine derivatives were confirmed. In the 2- and 7-methyl isomers, methyl protons appeared at the lowest field, while in the 3- and 6-methyl isomers, methyl protons appeared at the highest field. The spectrum of a mixture of **18** and **19** showed signals at τ 7.93 (C_2-Me, almost singlet), 8.09 (C_5-Me, almost

7) These results were different from the preliminary observations in the reactions of the ethoxycarbonylnitrene and methoxycarbonylcarbene with substituted benzene derivatives; a) K. Hafner, D. Zinter and K. L. Moritz, *Tetrahedron Lett.*, **1964**, 1733. b) K. Alder, R. Munders and P. Wirtz, *Ann. Chem.*, **627**, 59 (1959).

8) Coincidentally, a general synthetic entry to 1*H*-azepine derivatives has been reported in which structures of substituted 1*H*-azepines have been elucidated by their NMR and Mass spectra: L. A. Paquette, D. E. Kuhla, J. H. Barrette and R. J. Haluska, *J. Org. Chem.*, **34**, 2866 (1969).

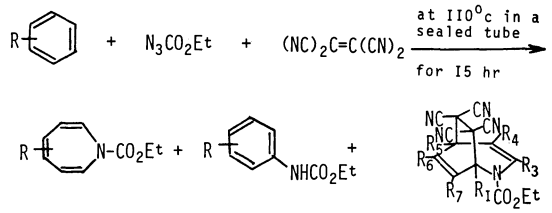
singlet), and 8.34 (C_3- and C_6-Me, doublet $J=1.5$ Hz) with relative intensities of 2 : 2 : 1. However, the chemical shifts of the C_3- and C_4-Me of the mixture (**8**—**17**) showed approximate values in the range of τ 8.05—8.30, and the signals often overlap. Aromatic urethans, of course, showed a broad signal at about τ 3.60 due to the amino group and at τ 7.65—7.85 attributable to methyl protons attached to the benzene ring.

Thermal Reaction of Ethyl Amidoformate and Aromatic Substrates in the Presence of TCNE. The adducts from tetracyanoethylene and 1-ethoxycarbonylazepines[9] have already been reported to arise from (4+2) π Diels-Alder cyclo addition reactions.[3]

We investigated a series of cycloaddition reactions of ethyl azidoformate and aromatic substrates in the presence of TCNE under thermal conditions (in a sealed-tube at 110°C for 15 hr.).

A dark solution of the reaction mixture was carefully chromatographed in order to obtain the adducts. Thus, four 1 : 1 adducts, **21**,[3] **22**, **26**, and **27**, were isolated. These adducts were structurally elucidated through a consideration of their NMR



Adduct Comd. No.	R_1	R_3	R_4	R_5	R_6	R_7

* In this case, urethan was not detected.
** In this case, azepine was not detected.

9) The (4+2) π cycloadditions of *N*-substituted azepines to various dienophiles such as tetracyanoethylene,[3] 4-phenyl-1,2,4-triazoline-3,5-dione,[1] *N*-phenylmaleimide,[4] and isobenzofurans,[4] have already been studied. In addition, *N*-carbethoxyhomoazepine and a TCNE adduct were obtained in a similar fashion: T. Sasaki, K. Kanematsu and A. Kakehi, *Chem. Commun.*, in press.

(in $CDCl_3$) and mass spectral menas. The NMR spectrum of the adduct from *m*-xylene shows signals at τ 3.30 (bs, 1H, H_3), 4.03 (bd, 1H, H_7 overlapped with H_1), 4.11 (bs, 1H, H_1 overlapped with H_7), 5.66 (q, 2H, J=7.0 Hz, $COC\underline{H}_2$-), 6.93 (d, 1H, J=7.5 Hz, H_5), 7.90 (d, 3H, J=1.5 Hz, C_6-Me), 8.07 (d, 3H, J=1.5 Hz, C_4-Me), and 8.66 (t, 3H, J=7.0 Hz, $COCH_2C\underline{H}_3$), which was assigned as **26**. Similarly, the spectrum of the adduct from *p*-xylene shows characteristic signals at τ 3.30 (bs, 1H, H_3), 3.59 (bd, 1H, J=7.5 Hz, H_6), 4.30 (bs, 1H, H_1), 5.61 (q, 2H, J=7.0 Hz, $COC\underline{H}_2$-), 6.71 (d, 1H, J=7.5 Hz, H_5), 7.89 (d, 3H, J=1.5 Hz, C_7-Me), 8.06 (d, 3H, J=1.5 Hz, C_4-Me), and 8.62 (t, 3H, J=7.0 Hz, $COCH_2C\underline{H}_3$). The cycloaddition product in this case was then concluded to be **27**. On the other hand, the adduct fraction from toluene afforded a 61% yield of a mixture of **22** and **23**[10] in a 4 : 6 ratio (NMR). The mixture was then recrystallized from chloroform - *n*-hexane to give a 1 : 1 adduct with a mp of 131—133°C (**22**) and which shows signals at τ 3.12 (bd, 1H, J=9.0 Hz, H_3), 3.95 (bd, 1H, J=8.0 Hz, H_7), 4.02 (be, 1H, J=8.0 Hz, H_1), 4.99 (t, 1H, J=9.0 Hz, H_4), 5.66 (q, 2H, J=7.0 Hz, $COC\underline{H}_2$), 6.75 (bd, 1H, J=9.0 Hz, H_5), 7.88 (d, 3H, J=1.5 Hz, C_6-Me), and 8.66 (t, 3H, J=7.0 Hz, $COCH_2C\underline{H}_3$). From the mother liquor, however, **23** was obtained by further recrystallization, but it was still mixed with **22**. The spectrum of the crude adduct, **23**, shows weak signal at τ 3.95, but it exhibited characteristic signals at 3.62 (bd, 1H, J=7.5 Hz, H_6), 4.02 (bs, 1H, H_1), and τ 6.75 (bt, J=7.5 and 8.0 Hz, H_5). For the adducts from *o*-xylene, a mixture of **24** and **25** was produced in a 3 : 7 ratio, but it could not be separated by column chromatography. However, the NMR spectrum of the mixture showed C-methyl groups at τ 8.00 and 8.33 with relative intensities of 17 : 3. Because of the abnormality of the chemical shift

27	7	5	100	57	28	71	27	10	30

of methyl protons at τ 8.33, the structure of the adduct **24** was tentatively identified as that of a 5,6-dimethyl isomer. The chemical shifts of these compounds are shown in Table 5.

These results suggest the importance of both steric and inductive effects on the 1*H*-azepine reactivity and that it is difficult for the methyl substitution of the adduct to proceed at a bridgehead position excepting that of **24** and at an α-position adjacent to nitrogen.[11] Furthermore, the mass spectra of **21**, **22**, **26**, and **27** show molecular ion peaks, and strong at M′-128 (=M) by the loss of a C_6N_4-molecule from the molecular ion; this fragment may arise from a retro-Diels-Alder fragmentation. Further fragmentations are pararelled to those of substituted azepinium ions,[4] as is shown in Chart 4 and Table 6.

On the basis of the above facts, we could determine the positions of the substituted 1(1*H*)-azepine derivatives (**7**, **8**, **9**, **11**, **12**, **15**, and **18**) by confirming the structures of their adducts (**21**—**27**) with TCNE. Other azepine derivatives (**10**, **13**, **14**, **16**, **17**, **19** and **20**) had been confirmed only partially by spectral and glpc data because of the difficulty of forming their adducts.

Experimental[12]

Preparation of Azepine Derivatives. Method A. A solution of ethyl azidoformate (2.3 g) and an excess of the respective benzene derivatives (10 g) was heated in an oil bath for 3 hr. The solution was then evaporated *in vacuo*, and the residue was separated by chromatography (silica gel), using chloroform as the eluent. The resulting crude red or orange azepine derivatives were purified by fractional distillation.

Method B. Ethyl azidoformate (4.0 g) and an aromatic compound (20 g) were mixed in a 100 m*l* stainless tube. The reaction was carried out in a sealed system at 120°C for 2 hr, after which the reaction mixture was treated much as with method A. These results are summarized in Tables 1 and 2.

These azepine derivatives were isomerized to the aromatic urethans under thermal conditions at 150—200°C in an oil bath for 4—5 hr.[13]

The relative ratio of the produced isomeric *N*-ethoxycarbonylazepine derivatives was determined by glpc and spectroscopic means. Especially, the structures of the mixture of azepine derivatives were determined by the NMR data in the following regions: 3.70—4.65 (olefinic-ring protons), τ 7.90—8.00 (C_2- and C_7-methyl protons), 8.10—8.30 (C_3-, C_4-, C_5- and C_6-methyl protons), and 5.60—6.00 and 8.60—8.90 (ethyl protons of the carbethoxyl group).

2,5-Dimethyl-*N*-ethoxycarbonylaniline. This compound was obtained by the reaction described above when *p*-xylene was employed; mp 95—96°C; NMR τ 2.47 (bs, 1H, H_6), 3.30 and 3.25 (each bd, 2H, J=7.0 Hz, H_3- and H_4), 3.60 (bd, 1H, NH), and 7.69 and 7.81 (each broad singlet, 6H, C_2- and C_5-Me).

Found: C, 68.30; H, 7.95; N, 7.00%. Calcd for $C_{11}H_{15}NO_2$: C, 68.37; H, 7.82; N, 7.25%.

2,4,6-Trimethyl-*N*-ethoxycarbonylaniline. This compound was obtained by the reaction described above when mesitylene was employed; mp 90—92°C (lit,[5c] 90°C); mass *m/e* 207: NMR 3.23 (bs, 2H, H_3 and H_5), 3.63 (bs, 1H, NH), and 7.77—7.83 τ (two singlets, 9H, C_2-, C_4- and C_6-Me).

Kinetics in the Reaction of *p*-Xylene and Ethyl Azidoformate. Solutions for the "nitrene" runs were prepared by adding *p*-xylene (10 g, 0.094 mol) an ethyl azidoformate (2.3 g, 0.02 mol) from a 10-μ*l* syringe to a 20-m*l* volumetric flask at 100, 120, and 138°C (in oil baths). The contents of the reaction solution were then analyzed by glpc. Each analysis was carried out at least three times. The relative rate ratios thus determined are given in Fig 1. The peaks of azepine derivatives were calculated by the half-width method, but the amounts of the side-formed aromatic urethan were not calculated because the yields were low

11) Recently, the adduct of 2-methyl-*N*-methoxycarbonylazepine has been reported to give the 3-methyl compound, but only in a 2.5% yield.[4]

12) The melting points were measured with a Yanagimoto micro-melting-point apparatus and are uncorrected. The microanalyses were performed on a Yanagimoto C.H.N.-Corder, Model MT-1. The NMR spectra were taken with a Japan Electric Optics Lab. Co., Ltd, Model JNN-MH-60 NMR spectrometer and with a Varian A-60 recording spectrometer, with tetramethylsilane as the internal standard. The chemical shifts are expressed in τ values. The mass spectra were obtained on a Hitachi RMU-D double-focussing mass spectrometer operating at an ionization potential of 70 eV. The IR spectra were taken with a JASCO Model IR-S spectrophotometer. The glpc was done isothermally with a Hitachi K-23 Gas Chromatograph on a 3-ft, 5 wt% SE 30 (Chromosorb G NAW) column (flame-ionization detector).

(below 3%).

Reaction of Benzene and Ethyl Azidoformate in the Presence of TCNE. In a stainless steel tube benzene (10 g), ethyl azidoformate (1.15 g, 0.01 mol) and TCNE (0.005 mol) were mixed. The closed tube was heated at 100—110°C in an oil bath for 15 hr and then cooled. After the reaction mixture had been concentrated *in vacuo*, the residue was purified by column chromatography (silica gel) using *n*-hexane, benzene, and chloroform successively as eluents. A red oil (0.51 g, 24%) was obtained from the first fraction; it was identical in all respects with *N*-ethoxycarbonyl-1-(1*H*)-azepine (**7**).[5c] Subsequently, white crystals **21** (0.54 g, 24%) were obtained from the second fraction, mp 156—158°C; they were identical with a specimen prepared by the method of Kende *et al.*[3b]

Reaction of Toluene and Ethyl Azidoformate in the Presence of TCNE. In a closed tube toluene (10 g), ethyl azidoformate (1.15 g), and TCNE (1.28 g, 0.01 mol) were mixed. The reaction was then carried out under the conditions described above. The reaction mixture was concentrated *in vacuo*, and the tarry residue was purified by column chromatography (silica gel). Red, oily compounds (0.35 g, 20%) were obtained from the first fraction, but they were found to consist of azepine derivatives and aromatic urethans (by IR and NMR). On the other hand, a yellow, oily adduct (1.88 g,61%) was obtained from the second fraction; its NMR spectra showed that it consisted of **22** and **23** in a 40 : 60 ratio, together with the 4-methyl isomer as a minor product. However, the mixture was recrystallized from *n*-hexane - chloroform to give colorless crystals, **22**; mp 131—133°C; IR ν_{max}^{KBr} 1645 (C=C), 1710 (C=O), 2280 cm^{-1} (w, C≡N); mass *m/e* 307.

Found: C, 62.60; H, 4.26; N, 22.70%. Calcd for $C_{16}H_{13}N_5O_2$: C, 62.53; H, 4.26; N, 22.79%.

The mother liquor afforded crude **23**, which was still mixed with **22** and the 4-methyl isomer (τ 8.06, d, J=1.5 Hz, 3H, C_4-Me distinguish between C_6- and C_7-methyl protons) even after further purification by recrystallization from benzene.

Reaction of *o*-Xylene and Ethyl Azidoformate in the Presence of TCNE. In a closed tube *o*-xylene (10 g), ethyl azidoformate (0.75 g), and TCNE (0.83 g, 0.065 mol) were mixed. The reaction was then carried out under the conditions described above. After the reaction mixture had been concentrated *in vacuo*, the residue was separated by column chromatography (silica gel), using *n*-hexane and benzene successively as eluents. Red, oily compounds (0.20 g, 16%) were obtained from the first fraction; they were determined by NMR and IR inspections to be mixtures of aromatic urethans (major products) and azepine derivatives (minor products).

The second fraction afforded colorless crystals (0.78 g, 39%) of **24** and **25** in a 30 : 70 ratio, but no further purification was undertaken. On the other hand, when two equimolar portions of ethyl azidoformate were employed in the reaction, a mixture of **24** and **25** was obtained in a 22% yield, while the aromatic urethans were given in a 22% yield.

Reaction of *m*-Xylene and Ethyl Azidoformate in the Presence of TCNE. In a closed tube *m*-xylene (10 g), ethyl azidoformate (2.3 g, 0.02 mol), and TCNE (1.28 g, 0.01 mol) were mixed. The reaction was then carried out under the conditions described above. From the reaction mixture, aromatic urethans and **26** were obtained in 10 and 11% yields respectively. The adduct was recrystallized from benzene; mp 200—201°C; IR ν_{max}^{KBr} 1660 (C=C), 1705 (C=O), 2280 cm^{-1} (w, C≡N); mass *m/e* 321.

Found: C, 63.60; H, 4.75; N, 21.90%. Calcd for $C_{17}H_{15}N_5O_2$: C, 63.54; H, 4.70; N, 21.80%.

Reaction of *p*-Xylene and Ethyl Azidoformate in the Presence of TCNE. In a closed tube *p*-xylene (10 g), ethyl azidoformate (2.3 g, 0.02 mol) and TCNE (1.28 g, 0.01 mol) were mixed, and the reaction was carried out under the conditions described above. From the reaction mixture, 2,5-dimethylethoxycarbonylaniline and **27** were obtained in 22 and 11% yields respectively. **22** was recrystallized from ether - *n*-hexane, mp 147—149°C; ν_{max}^{KBr} 1668 (C=C), 1716 (C=O), 2280 cm^{-1} (w, C≡N); mass *m/e* 221.

Found: C, 63.64; H, 4.56; N, 21.99%. Calcd for $C_{17}H_{15}N_5O_2$: C, 63.52; H, 4.70; N, 21.80%.

Reaction of Mesitylene and Ethyl Azidoformate in the Presence of TCNE. In a closed tube mesitylene (10 g), ethyl azidoformate (2.3 g), and TCNE (0.25 g, 0.002 mol) were mixed, and the reaction was carried out under the conditions described above. After the reaction mixture had been under concentrated *in vacuo*, the residue was recrystallized from benzene to give 2,4,6-trimethyl-ethoxycarbonylaniline (3.04 g, 73%), mp 90—92°C (lit,[5] 90°C), while TCNE (0.25 g) was recovered from the mother liquor.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2900—2907 (1970)

The Synthesis of Benzoyl-L-arginine-*p*-nitroanilide*[1]

Norio NISHI, Seiichi TOKURA and Junzo NOGUCHI

Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo

(Recieved February 27, 1970)

Benzoyl-arginine-*p*-nitroanilide (BAPA) is a synthetic substrate for trypsin, papain, and other enzymes, but it has not yet been prepared in the active L-form, although the preparations of DL-form and D-form by the trypsin digestion of the DL-form have been reported. The optically active L-BAPA was prepared by the following route; N^{α}-carbobenzyloxy-N^{ω}-nitro-L-arginine-*p*-nitroanilide was prepared from N^{α}-carbobenzyloxy-N^{ω}-nitro-L-arginine and *p*-nitrophenyl isocyanate, and the subsequent decarbobenzyloxylation and the benzoylation of this compound gave N^{α}-benzoyl-N^{ω}-nitro-L-arginine-*p*-nitroanilide. The removal of the nitro group was followed by Sakakibara's method using hydrogen fluoride. The L-BAPA shows the same melting point and the same reversal optical rotation as those of D-BAPA. When N^{α}-benzoyl derivatives of L-arginine were used as starting materials in the preparation of BAPA, DL-BAPA was always obtained with complete racemization; when N^{α},N^{ω},$N^{\omega'}$-tricarbobenzyloxy-L-arginine as the starting material reacted on *p*-nitrophenyl isocyanate, the product had no racemization, but the desired L-BAPA was not obtained because one of the carbobenzyloxy groups on the guanido group was extraordinally stable to reagents and could not be removed completely.

Benzoyl-arginine-*p*-nitroanilide (BAPA) is a interesting material for use as a synthetic chromogenic substrate of trypsin and papain; DL-BAPA has been used as a substrate because the L-form has not yet been prepared. The synthesis of the L-form is important in order to see whether enzymic activity to the L-form is inhibited by the D-form or not. BAPA has thus far been synthesized from benzoyl-arginine and *p*-nitroaniline using the polyphosphoric ester[1] or phosphorous pentoxide in diethylphosphite[2] as a condensation reagent, but only the racemic compound was obtained in these methods. The optically-active D-form was prepared by the tryptic digestion of the DL-form.[2] The optically-active L-BAPA was prepared after we had examined the several synthetic routes shown in Scheme 1.

The obtained L-BAPA shows the same melting point, the same reversal optical rotation, and the same solubility to water and ethanol as D-BAPA.[2] The carboxyl group of arginine tends to form a six-membered lactam by cyclization with the δ-imino group, and the reactivity of the amino group of *p*-nitroaniline is less than that of amino acid because of its low basicity.

In this paper, *p*-nitrophenyl isocyanate was used to form an amide bond with the carboxyl group of arginine.[3] Generally, it is hard to prepare *p*-nitroanilide of amino acids by other methods, such as the use of dicyclohexyl carbodiimide[4] or Woodward's reagent.[5] When a carbobenzyloxy derivative is used on the coupling step of the carboxyl and isocyanate group, as is shown in Scheme 1-A, no racemization occurs, but when a benzoyl derivative, like N^{α}-benzoyl-N^{ω}-nitro-L-arginine (Scheme 1-B) or N^{α}-benzoyl-N^{δ}-carbobenzyloxy-L-ornithine (Scheme 1-C),[6] is used, the reaction always proceeds with racemization. When N^{α},N^{ω},$N^{\omega'}$-tricarbobenzyloxy-L-arginine is used as the starting material and is coupled with *p*-nitrophenyl isocyanate, the reaction proceeds, producing a high yield without any racemization (Scheme 1-D), but one of the carbobenzyloxy group on the guanido group is not removed by the usual method without a breakdown of the amide bond because of the extraordinally stability.[7]

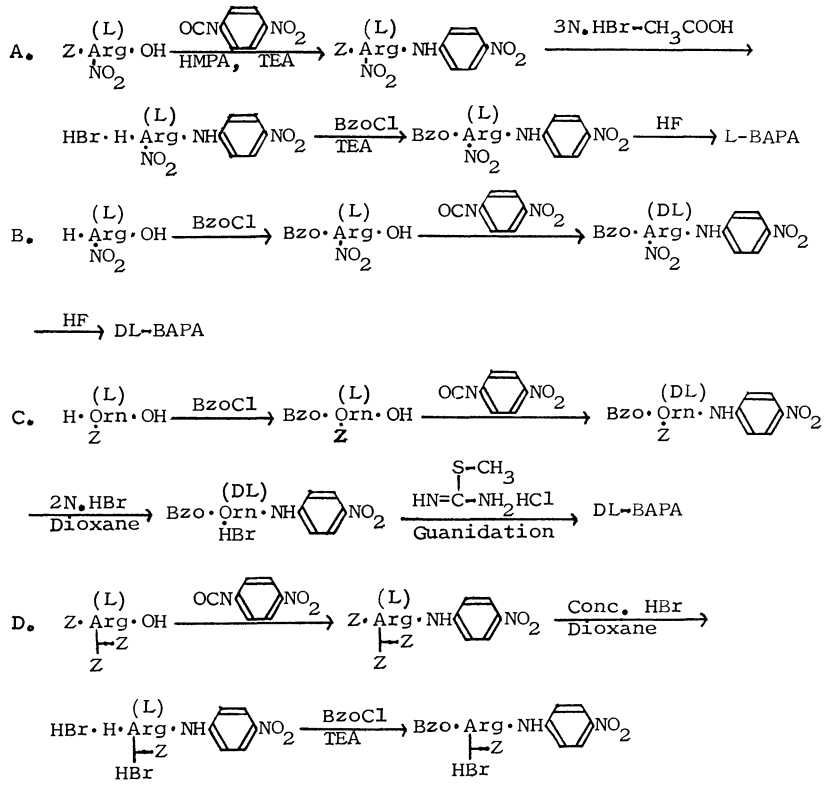

Scheme 1

HMPA: Hexamethyl Phosphoramide; TEA: Triethylamine; Z: Carbobenzyloxy; Bzo: Benzoyl.

Experimental

The melting points for the sample over 220°C were determined with a Mitamura Hot-stage Apparatus. The ultraviolet and visible absorption spectra were measured with a Hitachi 124 Spectrophotometer, while the infrared absorption spectra were measured with a Hitachi Grating Infrared Spectrophotometer, EPI-G2. The optical rotations were measured with a Yanagimoto Direct Reading Polarimeter, Model OR-10, and an Automatic Recording Polarimeter, Model OR-1. Toyo Densitorol #2 was used for the measurement of the concentration after development by ninhydrin. The elemental analysis was carried out by means of a Yanagimoto C.H.N. Corder, Model MT-2, and a Coleman Nitrogen Analyser, Model 29.

N^{ω}-Nitro-L-arginine. N^{ω}-Nitro-L-arginine was prepared according to Hayakawa *et al.*[8]

N^{α}-Carbobenzyloxy-N^{ω}-nitro-L-arginine. This material was prepared by the carbobenzyloxylation of N^{ω}-nitro-L-arginine essentially as has been described by Hofmann *et al.*[9]

***p*-Nitrophenyl Isocyanate.**[10] Hydrogen chloride was introduced into *p*-nitroaniline (20 g, 145 mmol) in dry dioxane (200 ml) until saturation at room temperature, and then phosgene was bubbled into the reaction mixture for 1 hr at 50°C until a clear solution was obtained. After expelling the excess phosgene at room temperature by bubbling with nitrogen for 30 min, the solution was evaporated to dryness below 40°C and the residue was refluxed with dry carbon tetrachloride (120 ml) for 2.5 hr. The insoluble part was removed by filtration at room temperature, the filtrate was concentrated to dryness, and the crystalline *p*-nitrophenyl isocyanate was recrystallized from carbon tetrachloride. Yield, 21.8 g (92.4%). mp 56°C.

Found: C, 51.1; H, 2.23; N, 17.3%. Calcd for $C_7H_4N_2O_3$: C, 51.2; H, 2.44; N, 17.1%.

N^{α}-Carbobenzyloxy-N^{ω}-nitro-L-arginine-*p*-nitroanilide. Into the solution of N^{α}-carbobenzyloxy-N^{ω}-nitro-L-arginine (20.0 g, 56.7 mmol) in dry hexamethylphosphoramide (HMPA) (120 ml), triethylamine (7.92 ml, 56.7 mmol) and *p*-nitrophenyl isocyanate (18.7 g, 114 mmol) were stirred successively at 20°C. The mixture was stirred for 20 hr at room temperature, diluted with 1000 ml of 2% sodium bicarbonate to separate the product, and then cooled. The resulting precipitate was filtered and washed successively with 2% sodium bicarbonate, water, 0.5 N hy-

drochloric acid and water. The product was extracted twice with 300-ml and 100-ml portions of hot dioxane, and the extract was concentrated to dryness. The residue was washed several times with ether and recrystallized from *n*-butanol (300 ml). The crystal was washed with ether and dried. Yield, 20.4 g (76.2%); mp 178°C, $[\alpha]_D^{29}$ +52.8° (*c* 1.05, HMPA), −1.4° (*c* 1.02, glacial acetic acid).

Found: C, 50.7; H, 4.75; N, 20.4%. Calcd for $C_{20}H_{23}N_7O_7$: C, 50.8; H, 4.87; N, 20.7%.

N^{ω}-Nitro-L-arginine-*p*-nitroanilide Hydrobromide. N^{α}-Carbobenzyloxy-N^{ω}-nitro-L-arginine-*p*-nitroanilide (20.0 g, 42.3 mmol) was treated with 3 N hydrogen bromide in glacial acetic acid (200 ml) for 7 hr at 20—23°C while being stirred. The product was precipitated by the addition of dry ether (1000 ml); after the mixture had stood for 1 hr at 0°C, the precipitate was collected by decantation and washed with dry ether. This precipitate was easily crystallized with water, cooled, filtered, washed with a small amount of cold water, and dried. From the concentration of the mother liquor of acetic acid and ether containing HBr, an additional product was obtained. The combined product was refluxed with dioxane (40 ml) for a few minutes to remove the impurity; then it was cooled, filtered and dried. Yield, 15.8 g (88.8%); mp 174—175°C.

Found: Br, 18.7%. Calcd for $C_{12}H_{18}N_7O_5Br$: Br, 19.0%.

N^{α}-Benzoyl-N^{ω}-nitro-L-arginine-*p*-nitroanilide. N^{ω}-Nitro-L-arginine-*p*-nitroanilide hydrobromide (19.5 g, 46.4 mmol) was dissolved in a mixture of tetrahydrofuran and water (9 : 1, 195 ml) and then cooled to −5—−7°C. After the addition of triethylamine (13.5 ml, 97.5 mmol) to the solution, benzoyl chloride (6.05 ml, 51.1 mmol) was stirred in, drop by drop, over a five-minute period. After standing for 1 hr, it was kept for 1 hr at 0°C and for another 1 hr at room temperature; then the solution was evaporated to dryness at room temperature. The residue was washed with water, dried, and crystallized by refluxing with ethanol. It was recrystallized from dimethyl formamide (DMF) and water. Yield, 15.4 g (75.2%); mp 246°C; $[\alpha]_D^{26}$ +60.7° (*c* 1.12, HMPA).

Found: C, 51.5; H, 4.41; N, 21.9%. Calcd for $C_{19}H_{21}N_7O_6$: C, 51.5; H, 4.73; N, 22.1%.

N^{α}-Benzoyl-L-arginine-*p*-nitroanilide Hydrochloride. N^{α}-Benzoyl-N^{ω}-nitro-L-arginine-*p*-nitroanilide (13 g, 29.4 mmol) was placed in a HF-reaction cylinder containing anisole (13 ml, 120 mmol). Forty milliliters of hydrogen fluoride dried with CoF_3 were collected under cooling with dry ice in the cylinder;[11] the mixture was then allowed to react at 0°C for 40 min while being stirred. The excess HF was removed under reduced pressure, and the residue was kept *in vacuo* for a further 2 hr. The residue was washed with ether, and then hydrofluoride was converted into the hydrochloride by successive treatment with 3 N HCl. It was crystallized with ethanol (100 ml) and ether (300 ml), and then left for 1 hr at 0°C. The crystal was collected by filtration and dried. The yield was 11.0 g. This crude product was extracted four times with hot ethanol (200 ml, 100 ml, 50 ml and 50 ml), and the combined extract was concentrated to dryness and recrystallized from absolute ethanol. Yield, 5.6 g (44.1%); mp 225°C; $[\alpha]_D^{25}$ +14.2° (*c* 1.0, water).

Found: C, 52.4; H, 5.23; N, 19.2; Cl, 8.1%. Calcd for $C_{19}H_{23}N_6O_4Cl$: C, 52.5; H, 5.29; N, 19.3; Cl, 8.2%.

N^{α}-Benzoyl-N^{ω}-nitro-L-arginine. A solution of N^{ω}-nitro-L-arginine (20 g, 91.5 mmol) in 1 N sodium hydroxide (91.5 ml, 91.5 mmol) was cooled to −3—−5°C. 1 N sodium hydroxide (109 ml, 109 mmol) and benzoyl chloride (12.8 ml, 109 mmol) were stirred in alternatively over a 30-min period. After stirring for an additional 90 min, the reaction mixture was extracted three times with ether in order to remove the excess benzoyl chloride. The solution was acidified to pH 1—2 with concentrated hydrochloric acid, and the precipitate was crystallized by trituration. The crystal was collected by filtration, and then washed with diluted hydrochloric acid, water, and ether. It was recrystallized from water. Yield, 27.8 g (94.5%); mp 158—159°C; $[\alpha]_D^{24}$ +1.4° (*c* 1.0, methanol).

Found C, 48.5; H, 5.47; N, 21.3%. Calcd for $C_{13}H_{17}N_5O_5$: C, 48.3; H, 5.26; N, 21.6%.

N^{α}-Benzoyl-N^{ω}-nitro-DL-arginine-*p*-nitroanilide. Into a solution of N^{α}-benzoyl-N^{ω}-nitro-L-arginine (3.2 g, 10 mmol) in 30 ml of dry dioxane, *p*-nitrophenyl isocyanate (1.64 g, 10 mmol) was stirred at 20°C. After the dissolution of *p*-nitrophenyl isocyante in the solution, the mixture was kept for a further 2 hr at 50°C. The crystal which separated out from the solution was filtered and refluxed with methanol (15 ml). It was recrystallized from nitrobenzene and washed with methanol and ether. Yield, 2.5 g (56.4%); mp 236°C; $[\alpha]_D^{25} \fallingdotseq 0$ (*c* 0.5, glacial acetic acid).

Found: C, 51.6; H, 4.78; N, 22.0%. Calcd for $C_{19}H_{21}N_7O_6$: C, 51.5; H, 4.73; N, 22.1%.

N^{α}-Benzoyl-DL-arginine-*p*-nitroanilide Hydrochloride. N^{α}-Benzoyl-N^{ω}-nitro-DL-arginine-*p*-nitroanilide (2.0 g, 4.5 mmol) was treated with hydrogen fluoride in order to remove the nitro group by the same procedure as was used for N^{α}-benzoyl-N^{ω}-nitro-L-arginine-*p*-nitroanilide. The product was recrystallized from 20% acetic acid. Yield, 1.5 g (76.6%); mp 262°C; $[\alpha]_D^{25}=0$ (*c* 0.4, glacial acetic acid).

Found: C, 52.4; H, 5.16; N, 19.2; Cl, 8.1%. Calcd for $C_{19}H_{23}N_6O_4Cl$: C, 52.5; H, 5.29; N, 19.3; Cl, 8.2%.

N^{δ}-Carbobenzyloxy-L-ornithine. N^{δ}-Carbobenzyloxy-L-ornithine was prepared according to the method of Synge.[12]

N^{α}-Benzoyl-N^{δ}-carbobenzyloxy-L-ornithine. Into a cold solution (−1—−2°C) of N^{δ}-carbobenzyloxy-L-ornithine (20.0 g, 75 mmol) in 1 N sodium hydroxide (75 ml, 75 mmol), 4 N sodium hydroxide (22.5 ml, 90 mmol) and benzoyl chloride (10.6 ml, 90 mmol) were stirred alternately over a 20-min period. After the addition of ether (5 ml), the reaction proceeded for a further 3 hr at the same temperature. Then the reaction mixture was extracted three times with ether in order to remove the excess benzoyl chloride. The

solution was acidified to pH 1—2 with concentrated hydrochloric acid, and the precipitate was crystallized by trituration. The crystals were collected by filtration and washed with diluted hydrochloric acid, water and ether. They were then recrystallized from ethyl acetate. Yield, 26.7 g (96.2%); mp 145°C; $[\alpha]_D^{20}$ −1.4° (*c* 1.0 and 3.0, methanol); $[\alpha]_{508}^{20}$ −1.7° (*c* 3.0, methanol).

Found: C, 64.7; H, 5.60; N, 7.40%. Calcd for $C_{20}H_{22}N_2O_5$: C, 64.8; H, 5.95; N, 7.57%.

N^{α}-Benzoyl-N^{δ}-carbobenzyloxy-DL-ornithine-*p*-nitroanilide. Into a solution of N^{α}-benzoyl-N^{ω}-carbobenzyloxy-L-ornithine (24.0 g, 65 mmol) in dry dioxane (240 m*l*), *p*-nitrophenyl isocyanate (18.0 g, 110 mmol) was stirred at 20°C. After 2 days at 20—23°C, the product which precipitated from the solution was filtered and dried. It was then recrystallized from ethanol. Yield, 25.8 g (81.5%); mp 174°C; $[\alpha]_D^{20} \fallingdotseq 0°$ (*c* 1.3, dioxane).

Found: C, 63.3; H, 5.02; N, 11.5%. Calcd for $C_{26}H_{26}N_4O_6$: C, 63.7; H, 5.31; N, 11.4%.

Dinitrodiphenyl Urea.[6,10] The above-mentioned part which was insoluble in hot ethanol was confirmed to be dinitrodiphenyl urea by the elemental analysis after recrystallization from dimethyl formamide. Yield, 4.8 g; mp 340°C (lit,[10] 360°C).

Found: C, 51.7; H, 3.14; N, 18.3%. Calcd for $C_{13}H_{10}N_4O_5$: C, 51.7; H, 3.31; N, 18.5%.

N^{α}-Benzoyl-DL-ornithine-*p*-nitroanilide Hydrobromide. N^{α}-Benzoyl-N^{δ}-carbobenzyloxy-DL-ornithine-*p*-nitroanilide (10.0 g, 20.4 mmol) was treated with 2 N hydrogen bromide in dioxane (300 m*l*) for 30 min at 20°C, and the N^{δ}-carbobenzyloxy group was removed. The product was then recrystallized from methanol-ethylacetate. Yield, 6.4 g (71.5%); mp 207°C.

Found: C, 49.0; H, 4.55; N, 12.8; Br, 18.5%. Calcd for $C_{18}H_{21}N_4O_4Br$: C, 49.2; H, 4.78; N, 12.8; Br, 18.2%.

The Guanidation of Benzoyl-ornithine-*p*-nitroanilide Hydrobromide. To a methanol solution (500 m*l*) of benzoyl-ornithine-*p*-nitroanilide hydrobromide (8.4 g, 19.1 mmol), 1.08 N sodium methylate in methanol (17.64 m*l*, 19.1 mmol) was added, and the sodium bromide was centrifuged. *S*-Methyl isothiourea hydrochloride (3.9 g, 28.8 mmol) in methanol (10 m*l*) was then added to the solution, and the solution was refluxed for 5 hr. After treatment with charcoal, the reaction mixture was concentrated to dryness and washed with water. The product was recrystallized from 20% acetic acid, washed with hot ethyl acetate (50 m*l*), and recrystallized again with 10% aqueous DMF. Yield, 4.8 g (57.6%); mp 225°C; $[\alpha]_D^{25}=0°$ (*c* 1.0, DMF). The Sakaguchi reaction was positive, and the ninhydrin reaction was negative. $R_f=0.84$ (*n*-butanol: glacial acetic acid : water=4 : 1 : 5). *Cf.* Standard DL-BAPA's R_f is 0.84.

Found: Cl, 8.0%. Calcd for $C_{19}H_{23}N_6O_4Cl$: Cl, 8.2%.

N^{α},N^{ω},$N^{\omega'}$-Tricarbobenzyloxy-L-arginine. This material was prepared according to the method of Zervas *et al.*[13]

N^{α},N^{ω},$N^{\omega'}$-Tricarbobenzyloxy-L-arginine-*p*-nitroanilide. Into a dry dioxane solution (68 m*l*) of N^{α},N^{ω},$N^{\omega'}$-tricarbobenzyloxy-L-arginine (11.3 g, 19.6 mmol), *p*-nitrophenyl isocyanate (4.4 g, 26.8 mmol) was stirred at 20°C. After the mixture had then stood for 20 hr at 20°C, a small excess of water corresponding to the excess isocyanate was added. 150 m*l* of ether were added to the reaction mixture, it was stirred for 1 hr, and the insoluble part was filtered off. The clear filtrate was concentrated to dryness *in vacuo* and the residue was washed with 0.1 N hydrochloric acid and water. The crude product was dissolved in methanol and reprecipitated with water. The precipitate was crystallized with cold water, and the crystals were filtered out, washed with water, and dried. Yield, 13.4 g (97.8%); mp 64°C; $[\alpha]_D^{25}$ +4.1° (*c* 1.0, chloroform). Found: C, 61.8; H, 5.31; N, 12.0%. Calcd for $C_{36}H_{36}N_6O_9$: C, 62.1; H, 5.18; N, 12.1%.

Decarbobenzyloxylation of N^{α},N^{ω},$N^{\omega'}$-Tricarbobenzyloxy-L-arginine-*p*-nitroanilide by Hydrogen Bromide and its Benzoylation. A solution of N^{α},N^{ω},$N^{\omega'}$-tricarbobenzyloxy-L-arginine-*p*-nitroanilide (5 g, 8.7 mmol) in dioxane was saturated with dry HBr and then heated at 50°C for 6 hr. The progress of the reaction was followed by paper chromatography every hour. A spot of the reaction mixture was applied to paper in performing ascending chromatography in a *n*-butanol : glacial acetic acid : water (4 : 1 : 5), and the quantity of the color developed with ninhydrin was measured by means of Densitorol at 563 mμ. The ratio of each spot to the total color is plotted against the time in Fig. 4. After six hr, the reaction mixture was concentrated, treated with dry ether (150 m*l*), washed with water saturated with NaCl, and dried. The product was dissolved in ethanol and precipitated with ether. The precipitate was crystallized from ether. The crystals were centrifuged, washed with ether, and dried. Yield, 2.7 g (63.7%); mp 75—78°C (hygroscopic). Found: Br, 27.4%. Calcd for $C_{20}H_{26}N_6O_5Br_2$ ($N^{\omega'}$-carbobenzyloxy-L-arginine-*p*-nitroanilide dihydrobromide): Br, 27.1%.

The hydrobromide (1 g, 1.7 mmol) was dissolved in 10 m*l* of tetrahydrofuran-water (9 : 1), and the mixture was cooled at −8°C. Triethylamine (0.71 m*l*, 5.1 mmol) and benzoyl chloride (0.20 m*l*, 1.7 mmol) were then stirred in. The solution was allowed to stand for 30 min at −8°C, and then for another hour at room temperature. The reaction mixture was concentrated to dryness, washed with 1 N hydrochloric acid and water, and then dried. The product was recrystallized twice from 20% acetic acid. Yield, 330 mg; mp 157°C. Found: C, 52.2; H, 4.92; N, 13.4; Br, 13.1%. Calcd for $C_{27}H_{29}N_6O_6Br$ (N^{α}-benzoyl-$N^{\omega'}$-carbobenzyloxy-L-arginine-*p*-nitroanilide hydrobromide): C, 52.8; H, 4.73; N, 13.7; Br, 13.0%.

After the hydrolysis of a sample (6.14 mg) with 4 m*l* of 6 N HCl at 110°C for 15 hr, the quantity of arginine was determined by studying ninhydrin color on a paper chromatogram, while that of *p*-nitroaniline was measured by means of the absorption at 380 mμ; Found: Arg. 1.67 mg (27.2%); Calcd for $C_{27}H_{29}N_6O_6Br$: Arg. 1.74 mg (28.4%), Found: *p*-nitroaniline, 1.33 mg (21.7%); Calcd: 1.38 mg (22.5%).

Results and Discussion

North and Young[14] have reported that in acyl

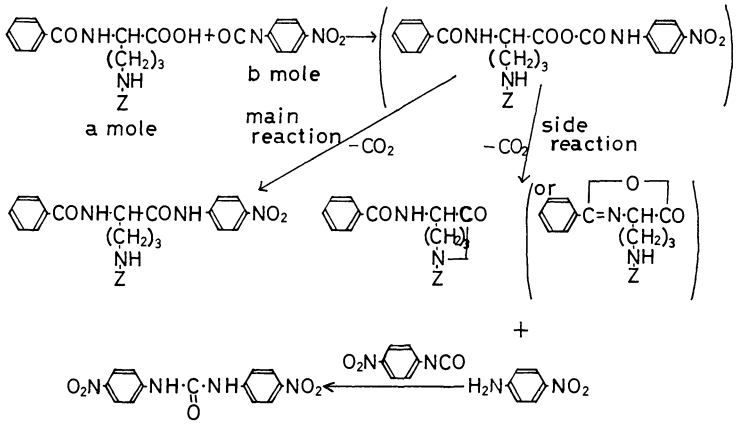

Scheme 2. The main and side reaction during the coupling reaction of N^{α}-benzoyl-N^{ω}-carbobenzyloxy-L-ornithine with *p*-nitrophenyl isocyanate.

amino acids of the urethane type, such as carbobenzyloxy amino acid, no racemization occurs on the coupling of the carboxyl group with an other amino group because the carbobenzyloxy derivative can not form the oxazolone as an intermediate. Recently optically-active acetyl-L-phenylalanine-*p*-nitroanilide[15] and acetyl-D-phenylalanine-*p*-nitroanilide[16] were prepared by Ramenskii and Botovinik *et al.* They used carbobenzyloxy-L- or D-phenylalnine as the starting material, and coupled it with *p*-nitroaniline before the decarbobenzyloxylation and the acetylation. This is consistent with our method. Optically-active L-BAPA could not be prepared by the benzoyl derivatives, but it was successfully prepared by carbobenzyloxylation at the first step and by the displacement of the carbobenzyloxy group with the benzoyl group at the last step.

Formation of *p*-nitroanilide by a Reaction between Carboxyl and Isocyanate Groups. N^{α}-Carbobenzyloxy-N^{ω}-nitro-L-arginine-*p*-nitroanilide was prepared by the reaction of N^{α}-carbobenzyloxy-N^{ω}-nitro-L-arginine and *p*-nitrophenyl isocyanate in hexamethyl phosphoramide (HMPA). When dioxane, pyridine, and *N*-methyl pyrolidone but not HMPA were used as solvents, this reaction did not proceed at all, even upon the addition of triethylamine or acids as a catalyst; only HMPA gave a good result in spite of the fact that N^{α}-benzoyl-N^{ω}-nitroarginine, N^{α}-benzoyl-N^{ω}-carbobenzyloxy-ornithine, and N^{α},N^{ω},$N^{\omega'}$-tricarbobenzyloxy-L-arginine reacted with *p*-nitrophenyl isocyanate in dioxane. By another route, one *via* such benzoyl derivatives as N^{α}-benzoyl-N^{ω}-nitro-L-arginine and N^{α}-benzoyl-N^{δ}-carbobenzyloxy-L-ornithine, as is shown in Scheme 1, DL-BAPA was always prepared with racemization. In the reaction of N^{α}-benzoyl-N^{δ}-carbobenzyloxy-L-ornithine with *p*-nitrophenyl isocyanate, dinitrodiphenyl urea was obtained as its by-product in addition to the main product, N^{α}-benzoyl-N^{δ}-carbobenzyloxy-L-ornithine-*p*-nitroanilide. This dinitrodiphenyl urea seems to be formed through a side reaction, as is shown in scheme 2. Since the *p*-nitroaniline produced by the side reaction reacts with *p*-nitrophenyl isocyanate, the yield of the main product was only 43 percent when equivalent moles (a : b= 1 : 1) of isocyanate were used, but if the reaction was carried out with 1.7 equivalent moles (a : b= 1 : 1.7) of isocyanate, the amount of *p*-nitrophenyl isocyantate was sufficient and the main product was obtained in an 82 percent yield. N^{α},N^{ω},$N^{\omega'}$-

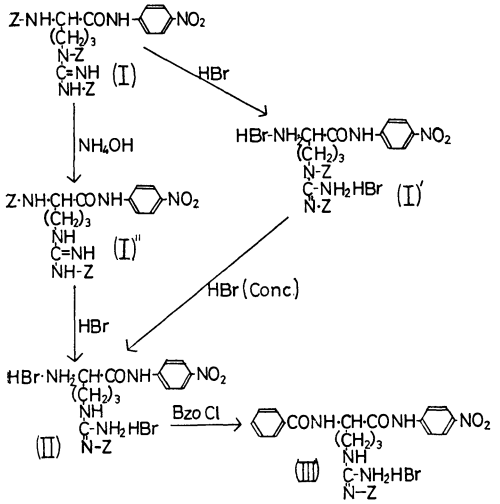
tricarbobenzyloxy-L-arginine gave N^{α},N^{ω},$N^{\omega'}$-tri carbobenzyloxy-L-arginine-*p*-nitroanilide in a good yield of 98 percent through a coupling reaction with *p*-nitrophenyl isocyanate. The absorption spectrum in dioxane shows its maximum at 320 mμ, as is shown in Fig. 1.

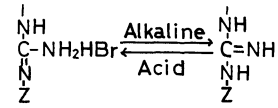
Removal of the Protected Groups in L-Arginine-*p*-nitroanilide Derivatises. The removal of the carbobenzyloxy group in N^{α}-carbobenzyloxy-N^{ω}-nitro-L-arginine-*p*-nitroanilide was more difficult than that of the usual N^{α}-carbobenzyloxy group; upon standard treatment with 2 N HBr-glacial acetic acid at room temperature for 30 min, the decarbobenzyloxylation of the N^{α}-position did not proceed completely. The treatment of 3 N HBr-glacial acetic acid at 20—23°C for 7 hr was necessary in order to remove it. This is likely to be related to the difficult decarbobenzyloxylation of N^{α},N^{ω},$N^{\omega'}$-tricarbobenzyloxy-L-arginine-*p*-nitroanilide which will be described below. After the benzoylation of nitro-L-arginine-*p*-nitroanilide, benzoyl-L-arginine-*p*-nitroanilide hydrochloride was obtained by the removal of the nitro group through the HF method of Sakakibara *et al.*[11] However, the yield of L-BAPA was about 44 percent on the removal of the nitro group.

It was very much harder to remove two of the three carbobenzyloxy groups of N^{α},N^{ω},$N^{\omega'}$-tricarbobenzyloxy-L-arginine-*p*-nitroanilide in Scheme 3 completely than it was to remove the ordinary N^{α}-carbobenzyloxy group ((I)′ in Scheme 3).



Scheme 3. Decarbobenzyloxylation of N^{α},N^{ω},$N^{\omega'}$-tricarbobenzyloxy-L-arginine-*p*-nitroanilide and its benzoylation.

This might be due to the transfer of a double bond in the guanido group (–N(Z)–C(=NH)–NH–Z→ –N(Z)–C(NH_2HBr)=N–Z) in HBr-dioxane, which stabilises the guanido group to acid, because the carbobenzyloxylated nitrogens are accompanied by no proton. Under even more drastic conditions, one N^{ω}-carbobenzyloxy group was removed ((II) in Scheme 3). The third carbobenzyloxy group was removed in concentrated HBr-glacial acetic acid at a high temperature, the process being accompanied by the cleavage of the amide bond and by the decomposition of the guanido group. When I in Scheme 3 was treated with aqueous ammonia, $>N^{\omega}$–Z, without a proton, was split into I″ without any cleavage of the –NH–Z groups, which were stable in alkaline. By the treatment of I″ in Scheme 3 with HBr, the transfer of the double bond in the guanido group was induced, as is shown in I′ of Scheme 3, and only the N^{α}-carbobenzyloxy group was removed (II). As is shown in Scheme 4, one of the carbobenzyloxy group on the guanido group was made very stable to acid or alkaline by the transformation of guanido group, and the final product was N^{ω}-monocarbobenzyloxy-L-arginine-*p*-nitroanilide. The course of the decarbobenzyloxylation of N^{α},N^{ω},$N^{\omega'}$-tricarbobenzyloxy-L-arginine-*p*-nitroanilide with hydrogen bromide at 50°C is shown in Fig. 2.



Scheme 4. The transfer reaction of carbobenzyloxylated guanide group with acid and alkaline.

An aliquot of the reaction mixture was spotted on paper (Toyo Roshi No. 51) every hour, used in ascending chromatography in a mixture of *n*-butanol : glacial acetic acid : water (4 : 1 : 5) and developed with ninhydrin. The ratios of the color intensities of the spots, (A) (R_f=0.65), (C) (R_f=0.51) and (B) (several spots in the closed R_f values) to the total spots were then plotted against the reaction time. The (A) spot corresponding to I′ in Scheme 3, disappeared after 4—5 hr. The (C) spot corresponded to II in Scheme 3; it increased with time and reached a constant value after 6 hr. The (B) spot was the side product of the cleavage of the amide bond and the decomposition of the guanido group. At the end of the reaction, the (C) and (B) spots were given instead of the (A) spot and the density of the (C) spot to the total density was 64 percent. From the reaction mixture, a product corresponding to the (C) spot was isolated, it was then benzoylated into compound III. The infrared absorption spectrum III showed a sharp absorption at 1740 cm^{-1} corresponding to the *N*-carbobenzyloxy group, as is shown in Fig. 3.

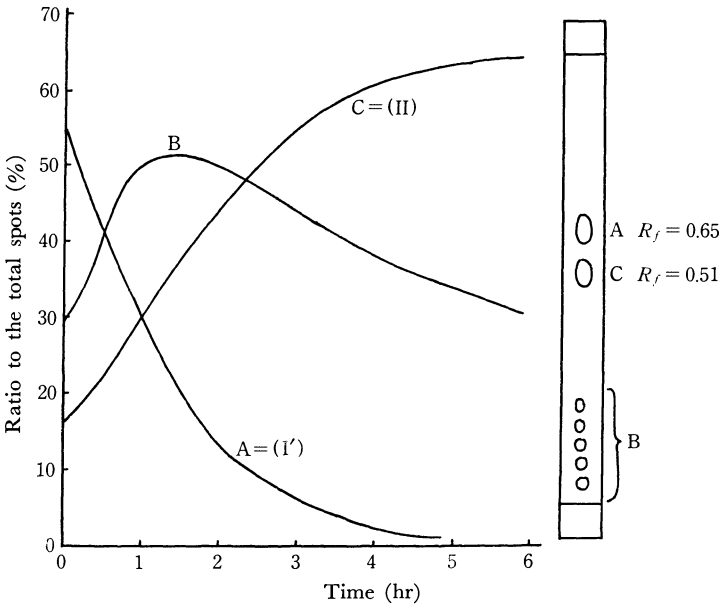


Fig. 2. The time course of decarbobenzyloxy reaction of $N^{\alpha},N^{\omega},N^{\omega'}$-tricarbobenzyloxy-L-arginine-*p*-nitroanilide with HBr saturated dioxane at 50°C.

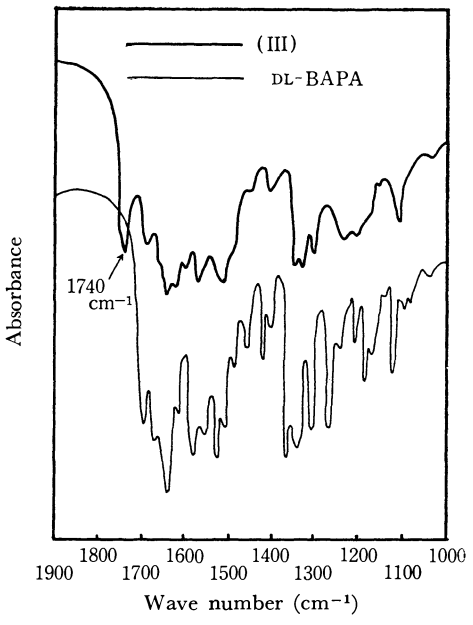

Fig. 3. The infrared absorption spectrum of III and DL-BAPA.

$N^{\alpha},N^{\omega},N^{\omega'}$-tricarbobenzyloxy or N^{α},N^{ω}-dicarbobenzyloxy-L-arginine-*p*-nitroanilide was treated with hydrogen fluoride instead of hydrogen bromide, and the reaction was followed by thin-layer chromatography or by paper electrophoresis. However, one carbobenzyloxy group on the guanido group was too stable to be removed by hydrogen fluoride as it had been by hydrogen bromide. Hayakawa *et al.*[17] succeeded in removing two carbobenzyloxy groups on the guanido group of poly-$N^{\omega},N^{\omega'}$-dicarbobenzyloxy-L-arginine by the treatment of 6 N HBr-glacial acetic acid at 50°C for 90 min, and Sakakibara *et al.*[11] have reported that carbobenzyloxy groups are easily removed from $N^{\alpha},N^{\omega},N^{\omega'}$-tricarbobenzyloxy-L-arginyl-peptide by means of treatment with hydrogen fluoride at 0°C for 30 min. In the case of $N^{\alpha},N^{\omega},N^{\omega'}$-tricarbobenzyloxy-L-arginine-*p*-nitroanilide, the difficulty in completely removing the three carbobenzyloxy groups is due to the steric hindrance of *p*-nitroanilide.

Properties of L-BAPA. The melting point of L-BAPA, 225°C, is the same as that of D-BAPA reported by Cohen *et al.*[2] and is considerably lower than the melting point of 262°C for DL-BAPA. The specific optical rotation of the L-form is +14.2° (*c* 1.0, water, 25°), while that of the D-form is −14.2° under the same conditions.

The absorption spectrum of L-BAPA in water is the same as that of DL-BAPA; it shows its maximum absorption at 312 mμ, as is shown in Fig. 4.

The infrared absorption spectra of the DL-form and the L-form in the solid state (KBr pellet) give almost the same pattern, except for the absorptions of amide I at 1630 cm^{-1} and of the guanido group at 1660 cm^{-1} in DL-BAPA, which shift to the shorter wavelengths of 1640 cm^{-1} and 1680 cm^{-1} respectively in L-BAPA.

These results seem to indicate that DL-BAPA forms a stable racemic compound by means of the

guanido group; L-BAPA is more easily soluble in water and ethanol than is DL-BAPA.

Conclusions

Optically-active N^{α}-benzoyl-L-arginine-*p*-nitroanilide hydrochloride was synthesized through N^{α}-carbobenzyloxy-N^{ω}-nitro-L-arginine-*p*-nitroanilide, which had been prepared from N^{α}-carbobenzyloxy-N^{ω}-nitro-L-arginine and *p*-nitrophenyl isocyanate in hexamethyl phosphoramide. The N^{α}-carbobenzyloxy group was removed with HBr-glacial acetic acid and converted to the N^{α}-benzoyl derivative, and then the nitro group was removed with hydrogen fluoride. If the benzoyl derivative is used as the starting material, racemization is unavoidable, and so the urethane type of N^{α}-protecting group should be used in order to prevent racemization upon the coupling between carboxyl and isocyanate groups. The coupling reaction proceeded smoothly only in hexamethyl phosphoramide. $N^{\alpha},N^{\omega},N^{\omega'}$-tricarbobenzyloxy-L-arginine-*p*-nitroanilide was prepared from $N^{\alpha},N^{\omega},N^{\omega'}$-tricarbobenzyloxy-L-arginine, but the complete removal of the carbobenzyloxy group into L-arginine-*p*-nitroanilide was unsuccessful. The enzymatic study of trypsin or papain to L-BAPA or DL-BAPA is still in progress.

The authors wish to thank for Dr. Shumpei Sakakibara and Mr. Yasuo Kishida of the Peptide Center, the Protein Research Institute, Osaka University, for permission to use the HF-reaction apparatus and for much useful advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2908—2911 (1970)

Photochemistry of Non-enolizable β-Diketones Containing Cyclopropane Ring in Conjugation

Taiiti OKADA, Koiti KAMOGAWA, Mituyosi KAWANISI and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received March 11, 1970)

Irradiation of bicyclo[3.1.0]hexane-2,4-diones affords isomeric enol lactones retaining the cyclopropane ring. In contrast, photoreaction of 6,6-dimethylspiro[2.5]octane-4,8-dione in ethanol results in the formation of an isomeric benzofuran derivative and dimedone-acetaldehyde condensation product. Cleavage of the cyclopropane ring is characteristic of the behavior of the latter β-diketone.

A compound with a cyclopropane ring in close proximity to a carbonyl group is expected to be photoreactive on account of the unsaturated nature of the three-membered ring. In fact, the photochemical reactions of conjugated cyclopropyl ketones are well-known.[1] In continuation of photochemical studies on non-enolizable β-diketones,[2] we have examined the behavior of two types of this class of compound containing a cyclopropane ring in conjugation of both ketone chromophores, in which the cyclopropane ring is in a different environment with respect to carbonyl groups. One is bicyclo[3.1.0]hexane-2,4-diones (I and II) and the other spiro[2.5]octane-4,8-dione (X). A remarkable difference in the stability of cyclopropane ring has been observed.

Irradiation of I*1 in a benzene solution by means of a Pyrex-filtered mercury arc lamp afforded a single volatile product V in a 98% isolation yield. The structure assigned to V was consistent with spectral data and analyses. Alkaline hydrolysis of V gave a known keto-acid VIII,[3],*2 which was transformed into the known keto-ester IX[3] by means of diazomethane. Epimerization of the *cis*-isomer VII into a thermodynamically stable *trans*-isomer VIII must have occurred during the alkali treatment.*3 UV irradiation of the diketone II[4] also induced the same

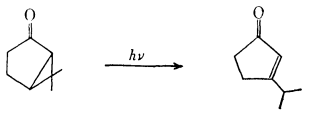
type of rearrangement to afford lactone VI in an 85% isolation yield. This kind of transformation reminds us of the photochemical rearrangement of 2,2-dimethyl-1,3-cyclohexanediones.[2] The intermediacy of the diradicals III and IV is to be considered.

Irradiation of X[5] was conducted in an ethanolic solution by means of a high pressure mercury arc (quartz vessel). Chromatographic separation on a silica gel column afforded two products, which were found to be 4-oxo-6,6-dimethyl-2,3,4,5,6,7-hexahydrobenzofuran (XIII, 31%) and a dimedone-acetaldehyde condensation product (XV, 5%). Both products were identified by comparison with authentic samples.

Conjugated cyclopropyl ketones such as XVI gives the primary photoproduct XVII under cleavage of the cyclopropane ring.[1a] If the cyclopropane ring is held in a rigid conformation with



XVI XVII

respect to the carbonyl π system so as to construct optimum geometry for an overlap with the π electrons of the carbonyl group, excitation of an electron into π^* orbital appears to lead to rupture of the cyclopropane bond. Absence of cyclopropane ring cleavage is rather unexpected in the reaction of I and II. Inspection of the molecular model shows the existence of considerable conjugation between cyclopropane ring and carbonyl group. *Gem*-dimethyl groups in the cyclopropane ring should be expected to contribute to the conjugation. However, α-fission is preferred to cyclopropane ring cleavage in the case of I and II. This is because the diradical(s) III and/or IV are stabilized on account of allylic conjugation.

Cleavage at C_1–C_2 position of X affords the diradical XI (path a), which isomerizes to the O-radical XII followed by cyclization to form the furan XIII. As the conversion of X to XIII was also observed thermally (>120°), the precursor of XIII would be either the electronically excited state of X or the vibronically excited one. The formation of XV is rationalized by assuming the intermediacy of cyclic diketocarbene XIV.*4 Carbene XIV abstracts hydrogen from the solvent ethanol to afford dimedone and acetaldehyde, which subsequently condense to form XV. It is not certain whether XIV is derived from X in one step in a concerted manner (path b) or from X by a stepwise mechanism *via* XI (path c). Thus, α-fission is not observed in the case of X. This can be accounted for by the fact that the bond order of C_1–C_4 or C_1–C_8 increases on account of conjugation between the cyclopropane ring and both the carbonyl groups. Cyclopropane ring cleavage is the only observed process, although the result differs greatly from that obtained in the case of XVI.

Experimental

All melting points and boiling points were uncorrected. The IR spectra were obtained in a neat liquid film or in Nujol mull on a Shimadzu IR-27-G spectrophotometer. The NMR spectra were taken with a JEOL C-60-H spectrometer with CCl_4 as a solvent, and chemical shifts are reported in δ values relative to TMS as an internal standard. The NMR data are given in the order of multiplicity (s=singlet, d=doublet, t=triplet, q=quartet and m=unresolved multiplet), integration and assignment. The UV spectra were taken in EtOH on Hitachi EPS-2 recording spectrophotometer. The mass spectra were obtained with a Hitachi RMU-6D spectrometer with a direct inlet (200°) and at 80 eV. Plates of Silica gel G were used for TLC and the spots were visualized with iodine vapor.

Preparation of 4-Bromo-2,2,5,5-tetramethyl-1,3-cyclohexanedione. The method was essentially based on the bromination procedure.[4] A solution of 2,2,5,5-tetramethyl-1,3-cyclohexanedione[7] (40.0 g, 240 mmol) in carbon tetrachloride (150 m*l*) was treated with *N*-bromosuccinimide (50.0 g, 280 mmol), which afforded a bromide (43.0 g, 73%), mp 91°C (from ether). IR (Nujol): 1710 (C=O) and 1685 cm^{-1} (C=O). NMR: δ 1.05 (s, 3, CH_3), 1.20 (s, 3, CH_3), 1.37 (s, 3, CH_3), 1.46 (s, 3, CH_3), 2.77 (s, 1, CH_2), 2.85 (s, 1, CH_2) and 4.75 ppm (s, 1, CH).

Preparation of 3,3,6,6-Tetramethylbicyclo[3.1.0]-hexane-2,4-dione (I). The method was essentially based on the one reported by Stetter in the preparation of 3,3-dimethylbicyclo[3.1.0]hexane-2,4-dione (II).[4] A solution of bromide (15.0 g, 61 mmol) in dry dioxane (150 m*l*) was dropwise added with a solution of potassium *t*-butoxide (f=1.3) (20.0 g, 178 mmol) in *t*-butyl alcohol (50 m*l*) with stirring at reflux. Evaporation

*4 We have independently found that diketocarbene XIV in triplet state, generated by the benzophenone-sensitized photolysis of 2-diazo-5,5-dimethyl-1,3-cyclohexanedione, abstracts hydrogen from the medium to form dimedone.[6] When ethanol was used as a solvent, dimedone-acetaldehyde condensation product XV was obtained, but in 2-propanol dimedone and acetone were isolated, which do not condense under that condition. In view of these behaviors of diketocarbene XIV, the formation of XV in the photolysis of X reminds us of the intermediacy of XIV.

*5 The sample of II was kindly supplied by Professor H. Stetter, Technische Hochschule Aachen. The measurement of NMR spectrum was performed in our laboratory (Fig. 2).

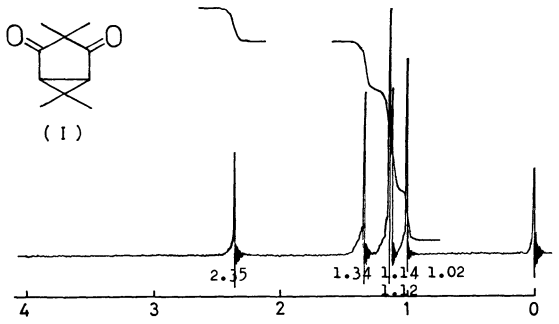

Fig. 1. NMR spectrum of I.

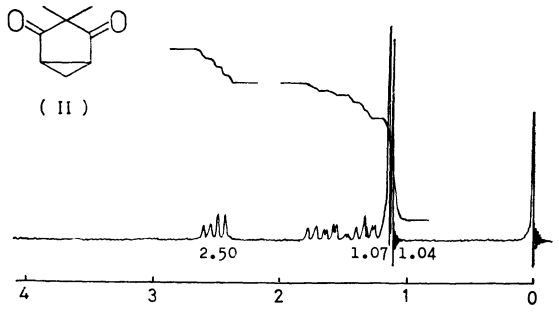

Fig. 2. NMR spectrum of II.

of the solvent, ether extraction, drying ($MgSO_4$), concentration *in vacuo* followed by distillation afforded I (4.50 g, 44%), bp 75°C/5 mmHg, n_D^{20} 1.4681. IR (neat): 3060 (C-H stretching in cyclopropane ring),[8] 1710 (C=O) and 1040 cm^{-1} (cyclopropane ring).[8] NMR: δ 1.02 (s, 3, CH_3), 1.12 (s, 3, CH_3), 1.14 (s, 3, CH_3), 1.34 (s, 3, CH_3) and 2.35 ppm (s, 2, CH). The NMR spectrum of I is shown in Fig. 1. Each methyl signal can be assigned by comparing the spectrum of I with II.*5 UV: λ_{max} (EtOH) 281 nm (log ε 2.01). Mass spectrum consisted of parent peak at *m/e* 166.

Found: C, 72.1; H, 8.2%. Calcd for $C_{10}H_{14}O_2$: C, 72,3; H, 8.5%.

Acid-catalyzed Isomerization of I. A solution of I (4.5 g, 27 mmol) in 18 N hydrochloric acid (120 m*l*) was heated under reflux for 3 hr. After cooling the reaction mixture was extracted twice with ether, and the combined extracts were washed with aqueous sodium carbonate solution and subsequently with water and dried ($MgSO_4$). Removal of the solvent *in vacuo* followed by distillation at 90—92°C/20 mmHg afforded a greenish yellow oil (2.7 g, 60%), which was established to be 1,1-dimethyl-3-isopropyl-3-cyclopentene-2,5-dione, n_D^{20} 1.4667. NMR: δ 0.90 (s, 6, CH_3), 1.04 (d, 6, CH_3), 2.67 (septet, 1, CH) and 6.55 ppm (s, 1, -CH). UV: λ_{max}(EtOH) 232 nm (log ε 4.12).

Found: C, 72.5; H, 8.6%. Calcd for $C_{10}H_{14}O_2$: C, 72.3; H, 8.5%.

Irradiation of 3,3,6,6-Tetramethylbicyclo[3.1.0]-hexane-2,4-dione (I). A solution of I (1.40 g, 8.4 mmol) in benzene (43 m*l*) was irradiated by means of 200 W high pressure mercury arc (Pyrex filter) for 9 hr under nitrogen at room temperature. The progress of the reaction was followed by vpc analysis of the aliquots. Evaporation of the solvent and single distillation afforded 2,2-dimethyl-3-*cis*-(1′-hydroxy-2′-methyl-1′-propenyl)cyclopropanecarboxylic acid γ-lactone (V) (1.37 g, 98%), bp 115—117°C/20 mmHg, n_D^{20} 1.4793. IR (neat): 3050 (C-H stretching in cyclopropane),[8] 1785, 1720 (enol lactone) and 995 cm^{-1}. NMR: δ 1.10 (s, 3, CH_3), 1.23 (s, 3, CH_3), 1.70 (broad s, 6, olefinic CH_3), 2.05 (d, 1, J=6 Hz, CH) and 2.47 ppm (d, 1, J=6 Hz, CH). The NMR spectrum of V is shown in Fig. 3. UV: λ(EtOH) 220 nm (log ε 3.66) and λ(EtOH) 280 nm (log ε 2.42). The mass spectrum consisted of parent peak at *m/e* 166.

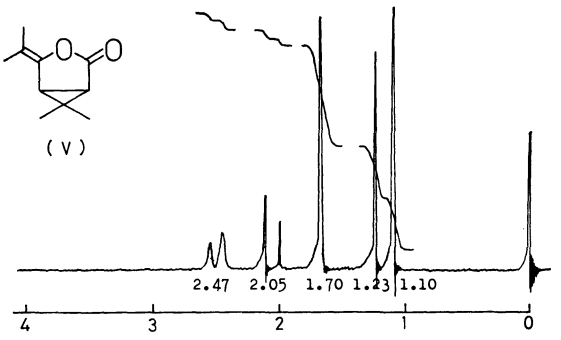

Fig. 3. NMR spectrum of V.

Found: C, 72.2; H, 8.3%. Calcd for $C_{10}H_{14}O_2$: C, 72.3; H, 8.5%.

Hydrolysis of the Enol Lactone V. A solution of V (332 mg, 2 mmol) in alcoholic aqueous potassium hydroxide solution (20 m*l*) was heated under reflux for 2 hr. Work-up afforded 2,2-dimethyl-3-*trans*-isobutyrylcyclopropanecarboxylic acid (VIII) (250 mg, 68%), mp 88—89°C (from *n*-hexane) (lit,[3] mp 86—87.5°C). The IR spectrum was superimposable with that of the authentic spectrum.*6 (Found: C, 65.0; H, 8.6%). 2,4-Dinitrophenylhydrazone of VIII melted at 186—187°C (lit,[3] mp 184—186°C).

Esterification of VIII by means of excess ethereal diazomethane afforded methyl 2,2-dimethyl-3-*trans*-isobutyrylcyclopropanecarboxylate (IX), bp 118—120°C/22 mmHg (lit,[3] bp 126—131°C/38 mmHg). The IR spectrum was superimposable with that of the authentic sample.*6 (Found: C, 65.9; H, 9.0%).

Irradiation of 3,3-Dimethylbicyclo[3.1.0]hexane-2,4-dione (II). A solution of II (100 mg, 0.72 mmol) in benzene (15 m*l*) was irradiated by means of 200 W high pressure mercury arc (Pyrex filter) for 1 hr

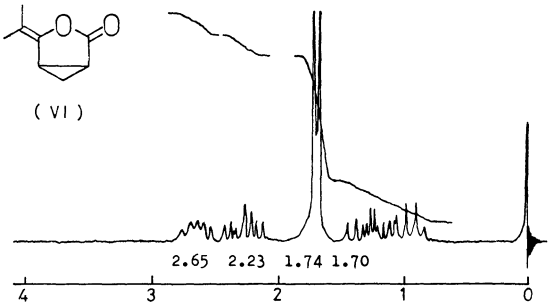

Fig. 4. NMR spectrum of VI.

*6 The IR spectra of VIII and IX were kindly supplied by Professor M. Matsui, The University of Tokyo.

at room temperature. The progress of the reaction was followed by vpc analysis of the aliquots. After the complete disappearance of II, the reaction mixture was concentrated *in vacuo* and the single distillation at 123—125°C/25 mmHg afforded 2-*cis*-(1′-hydroxy-2′-methyl-1′-propenyl)-cyclopropanecarboxylic acid γ-lactone (VI) (85 mg, 85%), n_D^{24} 1.4958. IR (neat): 3100 (C–H stretching in cyclopropane ring),[8] 1795, 1720 cm^{-1} (enol lactone). NMR: δ 0.80—1.50 (m, 2, CH_2), 1.70 (s, 3, CH_3), 1.74 (s, 3, CH_3), 2.23 (m, 1, CH) and 2.65 ppm (m, 1, CH). The NMR spectrum is shown in Fig. 4. UV: λ(EtOH) 220 nm (log ε 3.62) and λ(EtOH) 280 nm (log ε 2.12). The mass spectrum consisted of parent peak at *m/e* 138.

Found: C, 69.5; H, 7.4%. Calcd for $C_8H_{10}O_2$: C, 69.5; H, 7.3%.

Irradiation of 6,6-Dimethylspiro[2.5]octane-4,8-dione (X). A solution of X[5] (1.3 g, 8.2 mmol) in EtOH (20 m*l*) was irradiated by means of 200 W high pressure mercury arc (quartz vessel) for 16 hr under nitrogen at room temperature. The reaction mixture was concentrated *in vacuo* and taken up in benzene (5 m*l*). Polymeric amorphous material undissolved in benzene was removed by filtration and the filtrate was chromatographed on silica gel. The following compounds were isolated: 4-oxo-6,6-dimethyl-2,3,4,5,6,7-hexahydrobenzofuran (XIII) (210 mg, 31%), bp 125—128°C/15 mmHg (lit,[5] bp 109—113°C/4 mmHg). IR (neat): 1630 (broad), 1407, 1223 and 1035 cm^{-1}. The IR spectrum was superimposable with that of the authentic specimen.*[7] The NMR spectrum of XIII was quite similar to the one given in literature.[5] Mass spectrum consisted of parent peak at *m/e* 166. 2,2′-Ethylidenebis(5,5-dimethyl-1,3-cyclohexanedione) (XV) (33 mg, 5%), mp 139—140°C (from H_2O) (lit,[9] mp 140°C). The IR spectrum was superimposable with that of the authentic specimen, which was prepared from dimedone and acetaldehyde.[9] NMR: δ 1.06 (s, 12, CH_3), 1.50 (d, 3, J=7.5 Hz, CH_3), 2.30 (s, 8, CH_2), 4.15 (q, 1, J=7.5 Hz, CH) and 11.45 ppm (broad s, 2, enolic protons). X (638 mg, 50%) was recovered in addition.

Thermal Reaction of X. Neat X (50 mg) was heated at 120°C in a sealed tube for 1 hr. Vpc analysis indicated the formation of XIII (60%) accompanied with the recovered X and unidentified products.

The authors are grateful to Professor K. Sisido for help and encouragement. They are also grateful to Prof. K. Ichikawa for valuable suggestions concerning the preparation of X. They are indebted to the staff of Kao Soap Co., to the sttaff of the Central Research Institute of Toray Industries, and to Dr. M. Nishikawa, Chemical Research Laboratories of Takeda Chemical Industries, Ltd., for determining the mass spectra.

*[7] The IR spectrum of XIII was kindly supplied by Professor K. Ichikawa, Kyoto University.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2912—2919 (1970)

Synthesis of *N*-Terminal Nonapeptide of Trypsinogen and Its Hydrolysis by Trypsin[1)]

Norio YOSHIDA, Tetsuo KATO and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received March 13, 1970)

An *N*-terminal nonapeptide fragment of bovine trypsinogen, H-L-Val-L-Asp-L-Asp-L-Asp-L-Asp-L-Lys-L-Ile-L-Val-Gly-OH, was synthesized *via* two routes and its susceptibility with trypsin was investigated. Protected derivatives, *t*-butyloxycarbonyl protected nonapeptide *t*-butyl ester and benzyloxycarbonyl protected nonapeptide benzyl ester, were prepared by stepwise elongation. Removal of the protecting groups was carried out by treatment with trifluoroacetic acid and hydrogenation respectively. The naked peptide was purified with chromatography on ECTEOLA cellulose column using dilute acetic acid as a solvent. Upon lyophilization the desired nonapeptide was obtained as colorless powder, a portion of the product being digested with trypsin. Rate of tryptic hydrolysis of the peptide was found to be unexpectedly low in the absence of calcium ion, while considerable acceleration of the hydrolysis by calcium ion was noted.

Bovine trypsinogen is activated to trypsin upon cleavage with trypsin. An *N*-terminal hexapeptide of trypsinogen, H-Val-Asp-Asp-Asp-Asp-Lys-OH,[2)] is isolated on the cleavage and a tripeptide sequence of Ile-Val-Gly is found to be a newly generated *N*-terminal protion of trypsin.[3)] A similar tryptic cleavage of chymotrypsinogen furnishes the same Ile-Val-Gly sequence as a new *N*-terminal.[4)] Calcium ions seem to take part in this specific cleavage,[5)] but the mode of action of calcium has not yet been made clear. Savrda and Bricas[6)] prepared a related heptapeptide, H-Val-Asp-Asp-Lys-Ile-Val-Gly-OH, but the rate of tryptic digestion of this peptide was found to be rather low.[7)] As a cluster of four β-carboxylates in a tetra-aspartyl sequence adjacent to the cleaved bond was suggested to be the site of interaction of calcium ions with trypsinogen,[8)] a synthesis of *N*-terminal nonapeptide of trypsinogen, H-Val-$(Asp)_4$-Lys-Ile-Val-Gly-OH (I) was undertaken in order to clarify the role of the tetra-aspartyl carboxyl cluster in tryptic cleavage of the Lys-Ile bond.

Savrda and Bricas[9)] reported recently the synthesis of I and Abita *et al.*[10)] discussed the mode of tryptic digestion of I and related peptides. The rate of tryptic hydrolysis of I was found to be much lower than that of the previous heptapeptide,[7)] but it was raised three to four times by the addition of calcium ion. Radhakrishnan *et al.*[11)] reported that the role of calcium ion is in chelation to the tetra-aspartyl residues. These publications prompt us to disclose the present status of our study which includes synthesis of the nonapeptide I *via* two routes and tryptic digestion of synthesized I.

Reaction sequences employed for synthesis of I are shown in Figs. 1 and 2. In both routes, each protected amino acid was coupled with amino acid ester or peptide esters from *C*-terminus.

In the route of Fig. 1, *Z* group was used as α-amino protecting group of each amino acid other than *N*-terminal valine, and the Z group was selectively hydrogenolyzed in the presence of pal-
