Nitration of Mixed Penta-alkylbenzenes. A syrup obtained from nitration of 1-methyl-2,3,4,5-tetraethylbenzene showed prominent infrared peaks at 856, 1060, 1273, 1377, 1451, 1525, and 1634 cm^{-1}; PMR peaks at 8.7—9.0 (CH_3, m), 8.41 (CH_3, d, J=6.7 Hz), 7.72 (CH_3), 7.1—7.5 (CH_2, m), 4.57 (CH_2, s), 3.78 (CH, q, J=6.7 Hz), 3.14 and 2.97 τ (ArH). The methylene signal was readily attributed to 2,3,4,5-tetraethylbenzyl nitrate by comparison with the reference compound. The methine quartet probably arose from 5,α-dimethyl-2,3,4-triethylbenzyl nitrate since its PMR pattern closely resembled that of α-methyl-2,3,4,5-tetraethylbenzyl nitrate.

The nitration product from 3-methyl-1,2,4,5-tetraethylbenzene had strong infrared bands at 854, 1053, 1271, 1376, 1451, and 1632 cm^{-1}; PMR peaks at 8.7—9.0 (CH_3, m), 8.39 (CH_3, d, J=6.8 Hz), 7.77 (CH_3, s), 7.2—7.6 (CH_2, m), 4.43 (CH_2, s), 3.78 (CH, q, J=6.7 Hz), 3.12 and 2.91 τ (ArH).

A light brown syrup from the nitration of 1,3,4-trimethyl-2,5-diisopropylbenzene showed infrared peaks at 857, 1270, 1370, 1461, 1527, 1573, and 1633 cm^{-1}; PMR peaks at 8.6—8.9 (CH_3, m), 7.66 (CH_3, m), 6.2—7.1 (CH, m), 4.47 (CH_2, s), 2.93 and 2.87 τ (ArH). Chromatography on alumina using light petroleum as eluant gave a mixture of nitro compounds as the major product, and from the ether eluates a small amount of white needles was obtained, mp 140—142°C, identified as 3,4-dimethyl-2,5-diisopropylbenzyl alcohol by analysis; infrared spectra, 884, 1008, 1027, 1045, 1108, 1137, 1299, 1548, and 3290 cm^{-1}; PMR spectra, 8.82 (2 CH_3, d, J=6.8 Hz), 8.67 (2 CH_3, d, J=7.5 Hz), 7.83 (CH_3, s), 7.72 (CH_3, s), 6.4—7.2 (CH, m), 5.39 (CH_2, s), and 2.96 τ (ArH).

Found: C, 81.7; H, 11.3%. Calcd for $C_{15}H_{24}O$: C, 81.8; H, 11.0%.

When the crude syrupy product was dissolved in a small amount of carbon tetrachloride and stood in a refrigerator, some white powder (mp 131—133°C) was precipitated. It was poorly soluble in ether and had the composition, C, 45.6, H, 5.3, N, 13.2%.

Orientation of the Products from the Nitration of Halopentamethylbenzenes[1)]

Hitomi SUZUKI

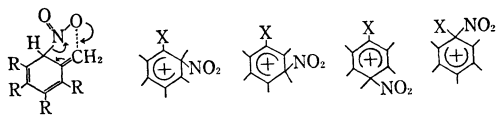
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received July 9, 1969)

The action of fuming nitric acid upon chloropentamethylbenzene, bromopentamethylbenzene, and iodopentamethylbenzene has been investigated. 5-Halo-2,3,4,6-tetramethyl- and 6-halo-2,3,4,5-tetramethylbenzyl nitrate were the principal products. 4-Halo-2,3,5,6-tetramethylbenzyl nitrate was never formed in any significant amount. The orientation was consistent with the previously suggested mechanistic scheme. PMR spectral data for nine halotetramethylbenzyl chlorides and nitrates have been presented.

Nitration of polyalkylbenzenes by fuming nitric acid often yields unusual products in which a hydrogen atom in one of the alkyl groups has been replaced by $-ONO_2$ group. The formation of such benzyl nitrates was first observed in 1915 by Huender in the nitration of bromopseudocumene.[2)] Smith and coworkers established that the nitrate formation is a property of the highly alkylated benzenes.[3-7)] But the mode of peculiar substitution has remained undiscussed for long. Our interest in the side-chain substitution of alkyl aromatics under ionic conditions led us to reinvestigate the nitration of penta-alkylbenzenes. The preferred formation of 2,3,4,5-tetra-alkylbenzyl nitrate was explained by a process similar to that postulated for the unconventional chlorination of hexamethylbenzene[8)]; *i.e.*, a process involving the electrophilic attack of the nitronium ion on the ring, followed by the hyperconjugative release of a proton from the neighboring methyl group and the rearrangement of the unstable intermediate (I) to the benzyl nitrite, which will then be transformed into the nitrate.[9)]

In this connection, the nitration of halopentamethylbenzenes seems to be of special interest. According to the suggested mechanism, four intermediate carbonium ion (II—V) are produced by electrophilic attack of nitronium ion on halopentamethylbenzene.



I II III IV V

Except for the case where X is the good leaving group, iodine atom, the fourth ion V, is considered to be less important since the electron-attracting halogen atom is bonded direct to the reaction site. Ion III, in which three methyl groups can contribute to the stabilization of the ion by interaction with the positively polarized centers to which they are adjacent, would be more preferable to II and IV, where there are two such methyl groups. Of the other two ions, II is more favorable than IV not only for statistical reason, but also for more effective stabilization by one methyl group in an ortho position and one in para position than two methyl groups in ortho, as IV. Positive charge distribution in the cyclohexadienyl cation system (VI) has been found to be concentrated in the order para > ortho > meta position.[10)] When the nitronium ion replaces a proton in VI, it follows that an electron-attracting halogen atom should have a more favorable effect on the stability of VII when it is ortho (VII, R_1 = halogen) to the entering

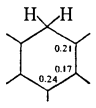
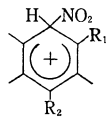
reagent (NO_2^+) than when it is para (VII, R_2= halogen). Thus it is understandable that the intermediate cation II will be energetically more preferred than IV.

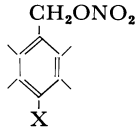


VI*1

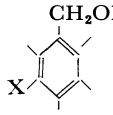


VII

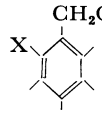
Rearrangement of the ions II and IV according to the suggested sequence will lead to the same nitrate, 5-halo-2,3,4,6-tetramethylbenzyl nitrate (IX). Migration of the nitro group in ion III, however, can occur in two directions, to yield either 4-halo-2,3,5,6-tetramethylbenzyl nitrate (VIII), or 6-halo-2,3,4,5-tetramethylbenzyl nitrate (X). Simple electronic consideration suggests that the hyperconjugative proton release from the methyl group in ortho to the halogen atom would be more preferable than that from the methyl group in a para position, since the former is bonded to the more positively polarized carbon. It follows that the ion III should give rise to X rather than VIII, and if the decomposition of the intermediate benzenonium ion into the side-chain products is quite a slow step, IX and X will be the major products derived from the ordinary nitration of halopentamethylbenzene. The amount of the latter is somewhat greater than that of the former.



VIII



IX



X

Nitration of halopentamethylbenzene has been investigated only by Smith and Horner.[6] They converted the nitration product from bromopentamethylbenzene into a mixture of the amines and separated them by fractional sublimation, and concluded that the action of fuming nitric acid upon bromopentamethylbenzene produced an inseparable mixture of two benzyl nitrates, 5-bromo-2,3,4,6-tetramethylbenzyl nitrate (IX, X= Br) and 6-bromo-2,3,4,5-tetramethylbenzyl nitrate (X, X=Br) in an approximate ratio 3 : 2. No derivative of durene could be obtained from the mixture. Their result seems to be quite consistent with the above discussion, although their conclusion based on the classical method of separation leaves some uncertainty as to the claimed absence of 4-bromo-2,3,5,6-tetramethylbenzyl nitrate (VIII, X=Br) in the reaction mixture. We have carried out nitration of three halopentamethylbenzenes and investigated the product by means of infrared and PMR spectroscopy. Identity of the product has been confirmed by comparison with the authentic specimen, prepared from the corresponding halotetramethylbenzenes by chloromethylation and subsequent treatment of the chlorides with silver nitrate in acetonitrile. PMR spectral data for the chlorides and nitrates derived from each of the three halotetramethylbenzenes are summarized in Table 1.

Chloropentamethylbenzene was nitrated with fuming nitric acid at −5—0°C in methylene chloride to give pale yellow, half-crystalline solid, the PMR spectrum of which showed two prominent peaks due to $-CH_2ONO_2$ at 4.31 and 4.45 τ with average relative areas of 58 : 42. By comparison with the reference compound, a signal at lower field was readily attributed to 6-chloro-2,3,4,5-tetramethylbenzyl nitrate (X, X=Cl). A signal at higher field may be due to either 4-chloro-2,3,5,6-tetramethylbenzyl nitrate (VIII, X=Cl), or 5-chloro-2,3,4,6-tetramethylbenzyl nitrate (IX, X= Cl), since both nitrates absorb at the same position in this region. On the basis of infrared spectra, the absorption at 4.45 τ was assigned to the 5-chloro isomer. Some minor peaks observed at 5.16, 5.36 and 6.60 τ were not investigated further.

A pale yellow oily solid obtained from the nitration of bromopentamethylbenzene showed two methylene peaks at 4.25 and 4.43 τ, to which 6-bromo-2,3,4,5-tetramethyl- and 5-bromo-2,3,4,6-tetramethylbenzyl nitrates respectively, were readily assigned. Of three isomeric nitrates, 4-bromo-2,3,5,6-tetramethylbenzyl nitrate absorb at the highest field, 4.46 τ, and the lack of observable peak at this position excludes the possibility of the formation of this isomer in any significant amount, in line with the previous findings.[6] The ratio of the two nitrates was 56 : 44, which was just opposite to the reported value of 2 : 3, but can be rationalized in terms of the difference in the contribution of the benzenonium intermediates, II and III. Several minor peaks at 5.31, 5.54, an 6.61 τ were not assigned.

Nitration of iodopentamethylbenzene proceeded somewhat differently from that of the other two halopentamethylbenzenes. The reaction was always accompanied by nitrodeiodination. PMR spectra of an oily solid, dark-brown with liberated iodine, showed two sharp methylene signals at 4.19 and 4.37 τ, each attributable to 6-iodo-2,3,4,5-tetramethylbenzyl nitrate (X, X=I) and 5-iodo-2,3,4,6-tetramethylbenzyl nitrate (IX, X=I). The relative intensity of two signals was 53 : 47 on an average. A very weak signal which might arise from 4-iodo-2,3,5,6-tetramethylbenzyl nitrate (VIII, X=I) was also observed at 4.42 τ, but its amount was insignificant as compared with that of the other two isomers. Minor peaks observed below 7 τ were at 4.61, 5.28, 5.50, 6.58, and 6.61 τ.

The orientation of the products is in good agree-

*1 Figures refer to π-electron deficiencies in benzenonium ion calculated from PMR proton shift.

ment with the suggested mechanism, involving the migration of the nitro group from the nucleus to the neighboring side-chain.[9] The nitro to nitrite rearrangement is quite reasonable in an activated complex, and may be expressed in a fashion similar to those observed in mass spectrometer or photochemistry.[11] It resembles to some extent the base-catalysed oxidation-reduction mechanism and the photochemical oxygen transfer processes widely observed in ortho nitro compounds.[12] In the benzenonium intermediate, proton release from the adjacent alkyl group and the subsequent redistribution of electrons to give nitrite would proceed in a single continuous process, and it does not seem necessary to postulate a discrete intermediate as I in the reaction sequence. The increasing amount of meta substitution as the atomic number of the halogen increases is explained by the steady growth of the contribution of ion II and IV relative to that of III, and is rationalized on the basis of the change in the inductive effect of the substituent.[13] The radical character of the reaction is ruled out by the high selectivity in orientation and the absence of phenylnitromethane or dibenzyl in the reaction product.

Experimental

IR spectra were measured in Nujol with a DS-402G spectrophotometer, and PMR spectra were obtained with a Varian A-60A spectrometer at 60 Mc/sec. with tetramethylsilane as internal standards.

Materials. *Chloropentamethylbenzene* (mp 155—156°C)[14] and *bromopentamethylbenzene* (mp 159—161°C)[15] were prepared as described in literature. *Iodopentamethylbenzene* was prepared by stirring a mixture of pentamethylbenzene (22.2 g), iodine (15.3 g), and periodic acid dihydrate (6.9 g) in 80% acetic acid (60 ml) containing a small amount of sulfuric acid as catalyst, at 70—80°C for about 1 hr until the color of iodine disappeared.[16] The mixture was poured into water, and the solid was removed and recrystallized from ethanol. It weighed 30.4 g (75%) and melted at 140—141°C.[17]

Preparation of Halotetramethylbenzyl Chlorides. A mixture of halotetramethylbenzene, concen-

trated hydrochloric acid, and an excess of 37%-formalin was stirred vigorously and heated on a water-bath, while a stream of hydrogen chloride was passed through. In due course, the benzyl chloride gradually separated as crystalline solid which was removed, washed with water and crystallized from ligroin. The iodotetramethylbenzenes underwent extensive chloromethyldeiodonation at elevated temperature and the product was usually accompanied by an appreciable amount of bis-chloromethyltetramethylbenzenes. Satisfactory results were obtained by stirring the mixture at low temperature for prolonged hours, although under these mild conditions iodoisodurene yielded some bis-chloromethyl compound.

Conversion of Benzyl Chlorides into Nitrates. A warm solution of silver nitrate in acetonitrile was added all at once to a magnetically stirred solution of halotetramethylbenzyl chloride in acetonitrile. The mixture was stirred for several hours, and the silver chloride was filtered. After removal of the solvent the residue was crystallized from light petroleum. Physical properties and spectral data of halotetramethylbenzyl chlorides and nitrates are given in Table 1.

Nitration of Halopentamethylbenzenes. Fuming nitric acid (d=1.50, 31.5 g) was added over a period of thirty minutes to a vigorously stirred solution of halotetramethylbenzene (0.1 mol) in methylene chloride (120 ml). During the reaction the temperature was kept at −5—0°C. The mixture was poured into water and the organic layer was washed with water and dilute sodium bicarbonate. Removal of the solvent left an oily solid which was identified as a mixture of halotetramethylbenzyl nitrates by infrared and PMR spectroscopy.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 484—487 (1970)

A Comparative Study of the Constituents of Volatile Oils of *Zanthoxylum*

Tsutomu SAKAI, Kazuo YOSHIHARA and Yoshio HIROSE

The Institute of Food Chemistry, Dojimanaka, Kita-ku, Osaka

(Received July 18, 1969)

The constituents of the volatile oils of three *Zanthoxylum* species were studied on the basis of the preceding exhaustive analysis of fruit oil from the Japanese pepper. It seems that the fragrance quality among the genera *Zanthoxylum* depends on the content of citronellal in the essential oil. That is, the unripe fruit oil of Japanese pepper with the strongest characteristic aroma contained the largest amount of citronellal. Ripe fruit oil of *Z. simulans* containing a trace amount of citronellal had a poor flavor.

According to Engler,[1] the genus *Zanthoxylum* (15 species) is distributed in the temperate regions of Asia and North America, and the genus *Fagara* (200 species), in the tropics. However, there has been much confusion in the nomenclature because of meager morphological distinction between these genera. A number of *Faraga* species are alternatively named *Zanthoxylum*, and *vice versa*. Since the differences of distribution and chemical constituents have been recognized, these two genera may be differentiated from the chemotaxonomic point of view. In our country, there are two endemic species, *i.e.*, *Z. piperitum* (Linn.) DC and *Z. planispinum* Sieb. et Zucc., and one horticultural species, *i.e.*, *Z. piperitum f. inerme* (Makino) Makino. Generally, the essential oils of *Zanthoxylum* constitute a complex mixture of terpenic compounds and are superior in fragrance. On the other hand, the essential oils of *Fagara* consist of aliphatic ketones and phenolic ethers and are inferior in aroma.

In previous communications, we reported on the compositions of volatile oils obtained from the fruits[2] and the young leaves[3] of *Zanthoxylum piperitum f. inerme*. This paper will present the results of our comparative study of the constituents of volatile oils from the ripe fruits of *Z. planispinium* (Fuyu-sanshoo in Japanese) and from the ripe fruits of *Z. simulans* (Hana-sanshoo, of Red Chinese origin), on the basis of the preceding exhaustive analysis of *Z. piperitum f. inerme* (Asakura-sanshoo).[2]

Experimental

Apparatus. *Gas Chromatography.* Preparative gas chromatography was carried out in a Varian 90-P gas chromatograph, fitted with a 10 ft-by-3/8 inch aluminum column packed with 20% Carbowax 20M or SF-96 on Chromosorb W. The flow rate of the helium carrier gas was 30—60 ml/min. The separated components were trapped in thin-walled glass capillaries. Analytical gas chromatography was performed in a Hitachi K-53 gas chromatograph, wherein two 45 m-by-0.25

mm stainless steel capillary columns coated with HB-2000 and SF-96 were used.

Infrared Spectroscopy. The infrared spectra were taken as thin films between sodium chloride plates on a Hitachi EPI-G2 spectrometer equipped with a beam condenser.

Nuclear Magnetic Resonance Spectrometry. The NMR spectra were measured on a JEOL Model C-60 spectrometer at 60 MHz in carbon tetrachloride, using tetramethylsilane as the internal reference. The microcell technique was used.

Mass Spectrometry. The mass spectra were obtained on a Hitachi RMU-6 mass spectrometer. The operating conditions were as follows: ionization voltage, 80 eV; ion-accelerating voltage, 2000 V; temperatures of ionization chamber and sample injection block, 250 and 150°C respectively.

Preparation and Separation of the Volatile Oils. The volatile oil of the ripe fruits of Asakura-sanshoo which was used was the same as in a previous study.[2] The volatile oils of the ripe fruits of Hana-sanshoo imported from Szechwan, Red China, and the ripe fruits of Fuyu-sanshoo cultivated at the Botanical Gardens of Osaka City University, Kisaichi, Osaka-fu,[*1] were obtained by steam distillation.

The volatile oil of Hana-sanshoo was fractionated by means of distillation and column chromatography. The volatile oil of Fuyu-sanshoo was divided into two fractions, hydrocarbons and oxygenated compounds, by silicagel column chromatography. Each fraction was further fractionated by preparative gas chromatography utilizing various columns.

Results and Discussion

Figure 1 shows the comparative capillary chromatograms of the ripe fruit oil of Asakura-sanshoo (top of Fig. 1), the ripe fruit oil of Hana-sanshoo (middle), and the ripe fruit oil of Fuyu-sanshoo (bottom). Each chromatogram was obtained by injecting 0.5—1.0 μl of the raw volatile oil into a HB-2000 capillary column. The column temperature was held initially at 80°C for 4 min; then it was programmed at 2°C per minute to 150°C, and run isothermally at 150°C until all the components had emerged. The nitrogen-carrier gas inlet pressure was 1.0 kg/cm^2. Attenuation was kept at 1 except otherwise indicated. The location of each component was determined by a manner reported previously.[2]

The gas chromatogram of the Fuyu-sanshoo oil fairly well resembles that of the unripe fruit oil of the Asakura-sanshoo. Monoterpene hydrocarbon fractions of both oils contain almost the same components. A serious difference was, however, noted in that there were large amounts of citronellal and methyl cinnamate in the Asakura-sanshoo oil, while, on the contrary, there was only a small amount of citronellal and no methyl cinnamate in the Fuyu-sanshoo oil. A considerable amount of nerolidol was found in the Fuyu-sanshoo oil.

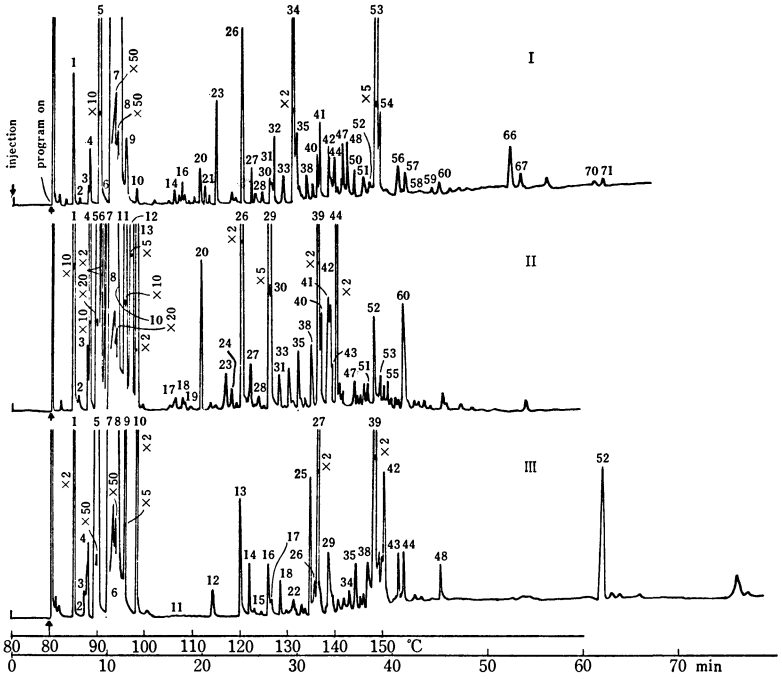

Fig. 1. Gas chromatograms of the genus *Zanthoxylum* I. Asakura-sanshoo oil, II. Hana-sanshoo oil, III. Fuyu-sanshoo oil 45 m×0.25 mm HB-2000 column; temperature isothermal at 80°C for 4 min then programmed at 2°C per minute to 150°C and run isothermal thereafter; sample 0.5—1.0 μl; range 1×1 except as indiated.

*1 The authors thank Botanical Garden of Osaka City University for supplying ripe fruits of Fuyu-sanshoo.

Nerolidol	1842	1597	71		52

The gas chromatograms show that the Hana-sanshoo oil is very rich in monoterpene hydrocarbons, we noticed several compounds, such as γ-terpinene, α-terpinene, ocimene, alloocimene, and perillene, which were not found in the oils of the other two species. A large amount of linalool oxide was also found in the Hana-sanshoo oil. It is a remarkable difference that citronellal, methyl cinnamate, and nerolidol were not found in this oil.

Table 1 lists the components, which were confirmed by a comparison of their Kovats' indices and their infrared, nuclear magnetic resonance, and mass spectra with those of authentic samples and the literature data. Kovats' indices were determined under isothermal conditions on 45-m capillary columns (α-pinene through perillene, HB-2000 column at 80°C, 1.0 kg/cm² N_2 : SF-96 column at 100°C, 0.5 kg/cm² N_2; β-terpinen-3,4-oxide through nerolidol, HB-2000, 130°C, 1.0 kg/cm² : SF-96, 130°C, 0.5 kg/cm²).

Obviously, the young leaves and the unripe fruits of Asakura-sanshoo are most fragrant, and their essential oils contained the largest amount of citronellal. A parallelism is observed between the fragrance and the content of citronellal in a downward order from the ripe fruit of the Asakura-sanshoo through the ripe fruit of the Fuyu-sanshoo and Hana-sanshoo oils. The latter had a rather disagreeable odor because of the large amounts of myrcene and ocimene which replaced the citronellal.

As far as was tested, no identified component has been estimated to be essential to the characteristic flavor of the Sanshoo oil. The essential oil of Sanshoo loses its characteristic odor when stored for a week at room temperature in a tightly-sealed tube. The gas chromatogram of this deteriorated oil shows the disappearance of the peak of β-phellandrene and a decrease in the amounts of citronellal, myrcene, and terpinolene. On the other hand, the amounts of isopulegol, *cis*-2,8-*p*-menthadien-1-ol, dihydrocarvone, limonen-4-ol, carvone and piperiton, geranyl acetate, *trans*- and *cis*-carveols, cuminalcohol, β-caryophyllene alcohol, and, especially, cryptone increased.

Therefore, it may be concluded that the fragrance of the genus *Zanthoxylum* consists mainly in the characteristic odor of citronellal and depends on its content.

The Double Cycloaddition of Disulfene and Its Related Reactions

Koji HIRAI and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita-shi, Osaka

(Received July 14, 1969)

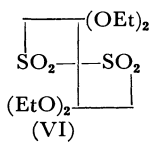
The reactions of methanedisulfonyl chloride (II) with ketene diethylacetal (III), 1-morpholinocyclohexene (IV), and 1-piperidinopropene (V) in the presence of triethylamine were studied. The products obtained were the double cycloadduct, spiro bithietane tetroxide (VI), and the substitution products (X and XV). These findings suggest that triethylamine dehydrochlorinates methanedisulfonyl chloride to produce disulfene. However, as yet we cannot say whether the formation of disulfene is the one-step dechydrochlorination mechanism ($ClSO_2CH_2SO_2Cl \rightarrow SO_2{=}C{=}OS_2$) or the two-step one ($ClSO_2CH_2SO_2Cl \rightarrow ClSO_2CH{=}SO_2 \rightarrow SO_2{=}\underset{|}{C}{-}\underset{|}{SO_2}$).

In the presence of triethylamine, various alkanesulfonyl chlorides react with compounds containing electron-rich and polarizable double bonds, such as enamines and ketene acetals, to afford four-membered cyclic sulfones (thietane dioxide) or isomeric acyclic compounds, depending on the nature of reactants and the reaction media. These reactions have been formulated as involving the reactive intermediacy of sulfene ($RCH{=}SO_2$).[1-3] However, it has only recently been reported that 1,3-propanedisulfonyl chloride reacts with 1-morpholinocyclohexene or ketene diethylacetal in the presence of triethylamine to yield the corresponding bithietane tetroxide (Fig. 1).[4] These reactions are regarded as proceeding through the intermediacy of disulfene.

In view of these facts, we were prompted to study the possibility of preparing a new disulfene $O_2S{=}C{=}SO_2$ (I) as an analogy to carbon suboxide $OC{=}C{=}CO$. In this paper we now wish to report some of the information obtained from the reactions of methanedisulfonyl chloride (II) with ketene diethylacetal (III), 1-morpholinocyclohexene (IV), and 1-piperidinopropene (V) in the presence of triethylamine. The reaction of II with III and

$$ClSO_2CH_2SO_2Cl + 2\,CH_2{=}C(OEt)_2 \xrightarrow[\text{benzene}\ -5°C\ 10\text{ hr}]{4\text{ or }2\ Et_3N}$$

(II) (III)



(VI)

triethylamine in benzene at −5°C for 10 hr gave a crystalline substance, which was formulated as spiro bithietane tetroxide (VI), in a 45% yield. The formation of VI is conceived of as proceeding through the intermediacy of disulfene, which then undergoes a double cycloaddition reaction with III.

When VI was dissolved in cold ethanol and set aside at −10——50°C for more than 30 hr, a ring cleavage and proton transfer occurred to give the product, VII, quantitatively. This reaction is

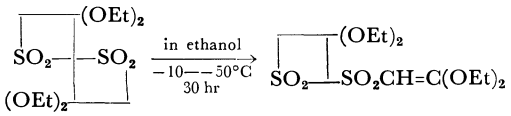
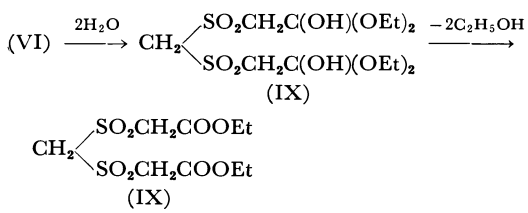
considered to be due to the strain inherent in VI.



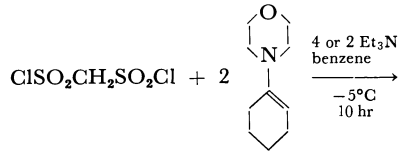
(VI) (VII)

On the other hand, when pure VI was dissolved in ether or ethanol containing a trace of water at 30°C, the diester (IX) was immediately formed quantitatively. Presumably, IX may have arisen from the β-elimination of ethanols from the intermediate diol (VIII), which was produced by the two ring cleavages of VI and the addition of water. The compound VII is found to be stable and does not change to IX under similar or even more vigorous (reflux in ethanol) conditions.

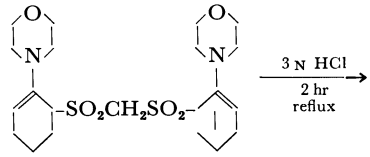


Although the IR and NMR spectra of VI have not yet been obtained because of its instability, the structure VI is adequate judging from elemental analysis and the conversion to VII and IX. The IR spectrum of VII shows strong bands at 1340 and 1130 ($-SO_2-$) and at 1585 cm^{-1}, the latter being attributed to the olefinic double bond; it also shows weak band at 3100 cm^{-1} (CH=). The NMR spectrum is also in harmony with the structure VII. The appearance of the ring methine proton at τ 4.5 as a quartet leads us to attribute the splitting to a 1,3-transannular interaction with the two nonequivalent ring methylene protons (ABX system). A singlet at τ 5.21 was assigned to an olefinic proton, and the abnormal up-field shift of the olefinic proton is considered to be due to the polarization of the double bond by the two electron-donating ethoxyl groups. A double triplet at τ 8.75 accounts for the methyl protons of the ketal moiety. This is regarded as a result of the fact that the two ethoxyl groups of the ketal moiety become unequivalent. Similarly, the methyl protons of the vinyl ether moiety appeared as a double triplet at τ 8.63. The IR spectrum of IX had absorptions at 1740 cm^{-1} (C=O of the ester).

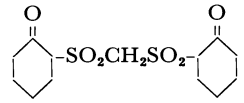
A similar reaction of II with IV in the presence of triethylamine led to the formation of sulfonylenamine (X) in a 34% yield. The acid-catalyzed hydrolysis of X gave the expected corresponding ketosulfone (XI) almost quantitatively. The IR spectrum of X shows an olefin band at 1658 cm^{-1}. A broad triplet at τ 4.55 was assigned to the two olefinic protons, and a multiplet at τ 5.4 was attributed to the two methine protons. This reaction has the possibility of generating different products, for example, the less substituted sulfonylenamine (X) and the more substituted one (XIII) by proton transfer from the 2 and 6 positions of the ring respectively, or a compound like XIV by a double cycloaddition. In this reaction several factors may contribute to the preferred formation of one of the possible isomers. The determining factors may be the particular structure and conformation of the zwitterionic intermediate (XIIa, XIIb) and the nature of the reactants (II, IV, base). For instance, when the intermediate (XIIa, XIIb) bears bulky groups at the electrophilic center, only the less substituted sulfonylenamine (X) is formed.



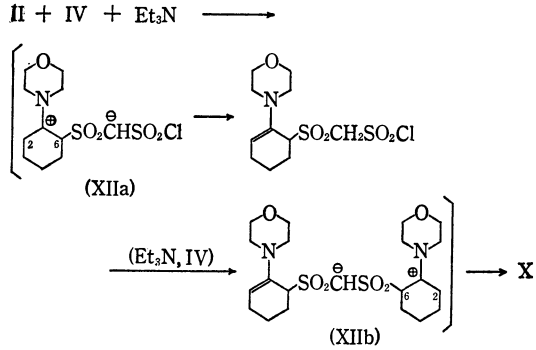
(II) (IV)



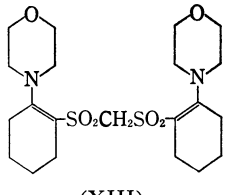
(X)



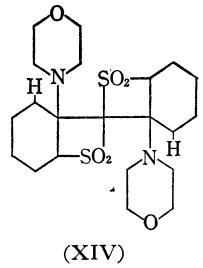
(XI)



Although the two-step dehydrochlorination mechanism seems to be preferable to the one-step one, more definitive experiments are needed.



(XIII)



(XIV)

When the reaction time was 1—2 hr, the yields of VI and X were lowered to 2—4% and a white precipitate formed during the reaction immediately decomposed to methanedisulfonic acid, triethylamine hydrochloride, and an intractable dark brown oil on exposure to air. After 10 hr, however, the products obtained did not include this precipitate, but VI (45%) or X (34%) and triethylamine hydrochloride. From these results, it is apparent that these reactions are not complete within 1—2 hr and that this precipitate is the unstable intermediate, from which VI and X result. Methanedisulfonic acid was characterized by its conversion to the dianilide.

In like fashion, the interaction of II, triethylamine, and V under the same conditions led to the formation of XV in a 16% yield. The IR spectrum of XV shows the presence of the olefinic double bond at 1638 cm^{-1}.

The path of this reaction cannot be stated with certainty, but a postulated mechanism is shown below. In this case again, if the steric interference exists, the compound XV would arise from substitution instead of cyclization *via* a zwitterionic intermediate such as XVI (path b), but presumably XV may have arisen from ring cleavages of the intermediacy of spirane (XVII), as is shown in path a, in view of recent articles[5,6] about the reactions of sulfenes and such enamines as V and our own finding regarding ketene diethylacetal, which is not greatly different with regard to its steric circumstances.

Experimental

Materials. The methanedisulfonyl chloride,[7] ketene diethylacetal,[8] 1-morpholinocyclohexene,[9] and 1-piperidinopropene[10] were prepared by methods described in the literature.

Reaction of Methanedisulfonyl Chloride with Ketene Diethylacetal. A solution of 5.3 g (0.025 mol) of methanedisulfonyl chloride in 50 m*l* of benzene was stirred, drop by drop, into a solution of 5.8 g (0.05 mol) of ketene diethylacetal and 11.0 g (0.1 mol) of triethylamine in 200 m*l* of benzene at −5°C over a 10-hr period. The amine hydrochloride was then removed by filtration, and the benzene solution was evaporated under reduced pressure to afford 4.15 g (45%) of crude VI, which was then washed with cold petroleum ether - ether and recrystallized from cold ethanol, the temperature being kept below 0°C.

Found: C, 41.70; H, 6.20; S, 17.25%. Calcd for $C_{13}H_{24}O_8S_2$: C, 41.92; H, 6.49; S, 17.21%.

Compound VI (2.0 g) was dissolved in cold ethanol (20 m*l*) and then set aside at −10——50°C for more than 30 hr. The subsequent removal of the ethanol under reduced pressure and recrystallization from ethanol gave 2.0 g of VII. Colorless needles, mp 135.5—136.5°C. IR: 3100 (ν CH=), 1585 (ν C=C), 1340, 1130 cm^{-1} (ν SO_2). NMR ($CDCl_3$): τ 4.5(1H, quartet, SO_2CHSO_2), 5.21 (1H, singlet, $=CHSO_2$), 5.6—6.1 (2H, octet, CH_2SO_2), 5.76 (4H, quartet, $CH_2O-C=$), 6.35 (4H, quartet, CH_2O-C-), 8.63 (6H, double triplet, $CH_3CH_2O-C=$), 8.75 (6H, double triplet, CH_3CH_2O-C-).

Found: C, 41.75; H, 6.55; S, 17.02%. Calcd for $C_{13}H_{24}O_8S_2$: C, 41.92; H, 6.49; S, 17.21%.

The mass spectrum gave a parent peak at 372 *m/e* and other major peaks at 357, 317, 271, 179, 151, 123, 116, 105, 79, 78, 77, 73, 60, 55, 46, 44, and 43 *m/e*.

When VI (2.0 g) was dissolved in ether or ethanol containing a trace of water at 30°C, 1.7 g of IX were immediately formed; the IX was then recrystallized form ethanol. Colorless needles; mp 73.5°C.

IR: 1740 (ν C=O), 1320, 1100 cm^{-1} (ν SO_2). NMR ($CDCl_3$): τ 4.7 (2H, singlet, $SO_2CH_2SO_2$), 5.6 (4H, singlet, SO_2CH_2CO), 5.7 (4H, quartet, OCH_2CH_3), 8.67 (6H, triplet, OCH_2CH_3).

Found: C, 34.14; H, 5.03%. Calcd for $C_9H_{16}O_8S_2$: C, 34.18; H, 5.09%.

The mass spectrum gave a parent peak at 316 *m/e* and other major peaks at 289, 271, 243, 225, 166, 137, 88, 45, 43, and 42 *m/e*.

Reaction of Methanedisulfonyl Chloride with 1-Morpholinocyclohexene. A solution of 5.3 g (0.025 mol) of methanedisulfonyl chloride in 50 m*l* of benzene was stirred, drop by drop, into a solution of 8.4 g (0.05 mol) of 1-morpholinocyclohexene and 11.0 g (0.1 mol) of triethylamine in 200 m*l* of benzene at −5°C over a 10-hr period. The amine hydrochloride was removed by filtration, and the benzene solution was evaporated under reduced pressure to afford 4.0 g

(34%) of crude X, which was then washed with ether and recrystallized from methanol. Colorless needles, mp 202°C (dec). IR: 1658 (ν C=C), 1310, 1120 cm^{-1} (νSO_2). NMR($CDCl_3$): τ4.0 (2H, singlet, $SO_2CH_2SO_2$), 4.55 (2H, broad triplet, =CH), 5.4 (2H, multiplet, $CHSO_2$), 6.2 (8H, triplet, O-CH_2), 6.6—7.1 (4H, multiplet, allylic proton), 7.1—8.5 (16H, multiplet, N-CH_2 and other CH_2 groups of the cyclohexene ring).

Found: C, 53.30; H, 7.26; N, 5.74%; mol wt, 474. Calcd for $C_{21}H_{34}N_2O_6S_2$: C, 53.14; H, 7.22; N, 5.90%; mol wt, 474.

Hydrolysis of Sulfonylenamine (X). Compound X was suspended in 200 m*l* of 3 N hydrochloric acid and heated at a gentle reflux for 2 hr, during which time dissolution was completed. The solution was then extracted with benzene, and the bezene layer was washed with water, dried, and concentrated. The solid residue was washed with petroleum ether and recrystallized from ethanol to give 1.35 g (95%) of XI. Colorless plates; mp 158.5°C. IR: 1720 (νC=O), 1320, 1120 cm^{-1} (νSO_2). NMR ($CDCl_3$): τ 4.67 (2H, singlet, $SO_2CH_2SO_2$), 5.5 (2H, multiplet, $CHSO_2$), 7.28—8.4 (16H, multiplet, CH_2 groups of the cyclohexane ring).

Found: C, 46.18; H, 6.21%. Calcd for $C_{13}H_{20}O_6S_2$: C, 46.31; H, 6.00%.

The mass spectrum gave a parent peak at 336 *m/e* and other major peaks at 241, 223, 176, 175, 174, 98, 97, 96, 81, 69, 68, 67, 55, and 41 *m/e*.

Reaction of Methanedisulfonyl Chloride with 1-Piperidinopropene. A solution of 5.3 g (0.025 mol) of methanedisulfonyl cholride in 50 m*l* of benzene was stirred, drop by drop, into a solution of 6.2 g (0.05 mol) of 1-piperidinopropene and 11.0 g (0.1 mol) of triethylamine in 200 m*l* of benzene at −5°C over a 10-hr period. The amine hydrochloride was then removed by filtration, and the benzene solution was evaporated under reduced pressure. The residue was chromatographed on activated alumina. Elution with chloroform gave 1.45 g (16%) of XV, which was then washed with ether and recrystallized from ether. Colorless needles; mp 99—100°C. IR: 1638 (ν C=C), 1300, 1150 cm^{-1} (νSO_2). NMR ($CDCl_3$): τ 3.0 (2H, singlet, =CH), 5.7 (2H, singlet, $SO_2CH_2SO_2$), 6.6 (8H, broad singlet, N-CH_2), 7.9 (6H, singlet, CH_3), 8.35 (12H, broad singlet, other CH_2 groups of the piperidine ring).

Found: C, 52.21; H, 7.76; N, 7.28%. Calcd for $C_{17}H_{30}O_4S_2N_2$: C, 52.27; H, 7.74; N, 7.17%.

The mass spectrum gave a parent peak at 390 *m/e* and other major peaks at 248, 188, 150, 138, 125, 124, 123, 122, 110, 96, 81, 68, 55, and 41 *m/e*.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 491—495 (1970)

A-Substituted 5β-Steroids. III. Synthesis of 2-Oxo-5β-steroids and Their Derivatives

Yasuo SATOH, Akira HORIUCHI and Akira HAGITANI

Department of Chemistry, College of Science, St. Paul's University (Rikkyo Daigaku), Nishi-Ikebukuro, Toshima-ku, Tokyo

(Received July 25, 1969)

The synthesis of 2-oxo-5β-steroids (5β-cholestan-2-one and methyl 2-oxocholanate) and their derivatives have been described. Both oxo-steroids were prepared from 2β-acetoxy-3-oxo-5β-steroids according to the following synthetic pathways: (a) condensation with ethylmercaptan to diethylmercaptol, desulfurization, hydrolysis and oxidation, (b) condensation with ethylmercaptan to diethylmercaptol, hydrolysis to hydroxy-ethylmercaptol, desulfurization and oxidation, and (c) isomerisation to 3α-acetoxy-2-oxo derivative and deacetylation with zinc powder to 2-oxo derivative. In these pathways, it was found that method (b) gave the best yield. On the other hand, desulfurization of the hydroxy-mercaptols with one-half the weight of Raney nickel used for that of method (b) gave 2β-hydroxy-3β-ethylthio derivatives as intermediates. Reductive cleavage of these hydroxy-ethylthio derivatives with Raney nickel produced 2β-hydroxy-5β-steroids in good yields. In the halogenation of these 2-oxo derivatives, the products were 1β-halo-2-oxo-5β-sterodis, not 1α- or 3-halo isomers.

Although most 5α-steroids which possess subtituents on each position in ring A have been thoroughly investigated,[1] only very little information is found in literature concerning the synthesis of 1- and 2-substituted 5β-steroids.[2] On the synthesis of 2-substituted 5β-steroid, Tomoeda and Koga[3] recently repoted that 2α-hydroxy-5β-chloestane was obtained from 4β,5β-epoxycholestan-3-one through

the epoxy ring opening, condensation with ethanedithiol to an ethylene thioketal, desulfurization, and hydrogenation.

During the course of our studies of A-substituted 5β-steroids, we have found that the substitution reaction of 4β-bromo-3-oxo-5β-steroids (1) with potassium acetate and acetic acid is accompanied with a new rearrangement of a substituent from C_4 to C_2 resulting in the 2β-acetoxy-3-oxo derivative (2) in good yield.[4] In our previous communication, we also reported that the bromination of 2-oxo-5β-steroids affords the 1β-bromo-2-oxo-5β-steroids.[5] In the present paper, we wish to describe in full the details for the synthesis of 1-haloketones from 2β-acetoxy-3-oxo-5β-steroids (2).

Condensation with ethyl mercaptan to diethylmercaptols (3) of the acetoxyketones (2) and hydrogenation of the mercaptols with Raney nickel (W-2) gave acetoxy compounds corresponding in spectroscopic properties to 2β-acetoxy-5β-steroids (4).

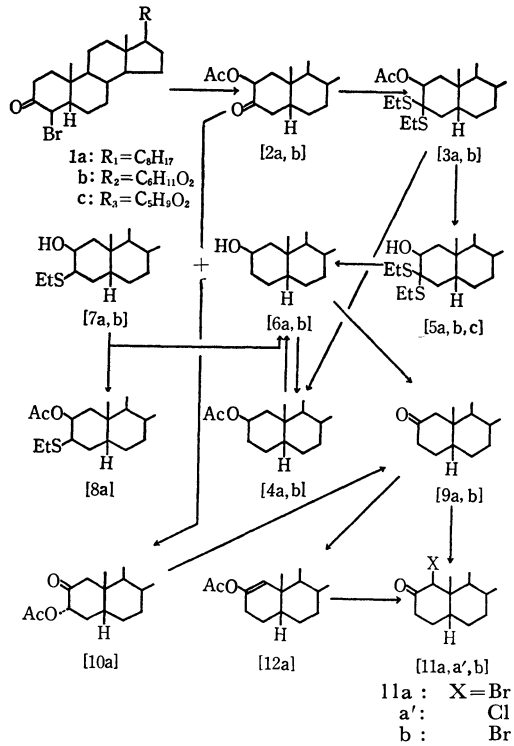
In the desulfurization method, considerable amounts of saturated 5β-steroids were formed, and so we attempted another route for the deketonisation; that is, the derivatives (3) were converted to 2β-hydroxy-3-oxo diethylmercaptols (5) by alkaline hydrolysis. In the case of (3b), however, the carbomethoxy group in the side chain was hydrolyzed to carboxylic acid (5c) and then the acid was converted to its methyl ester (5b) with diazomethane. By desulfurization of these 2β-hydroxy-3-oxo-5β-steroid diethylmercaptols with Raney nickel according to the same method for (3), 2β-hydroxy-5β-steroids were formed in good yield. The configuration of these products has been determined by IR spectra and the patterns of NMR spectra. The total yields of 2β-hydroxy-5β-steroids from the 2β-acetoxy-3-oxo-5β-steroids were 80 and 44% (cholestane and 3-bile acid series, respectively).

Acetylation of the 2β-hydroxy-5β-steroids with acetic anhydride and pyridine produced 2β-acetoxy derivatives (4), identical with the specimens described above. In the NMR spectra of 2β-hydroxy- and 2β-acetoxy-5β-cholestanes, it was found that the signals due to C_2-αH were shifted more to the the upper field than those of 2α-isomers.[3] This agreed with the relation of the chemical shifts between *a*- and *e*-H due to the anisotropy of C–C linkage in cyclohexane ring.[6]

When the desulfurization of the hydroxy diethylmercaptols (5) was carried out with one-half the weight of Raney nickel used for that of (3), 2-hydroxy-3-ethylthio derivatives (7) were obtained as intermediates. Small amounts of 2-oxo- and 2β-hydroxy-5β-steroids were also formed. One of the products (7b) could be isolated as needles, but it was so difficult to crystallize the other product (7a) that it was converted to its acetate (8) by treatment with acetic anhydride and pyridine. In the NMR spectra of both crystalline products, (8) has a multiplet at τ 6.60 (Hw=8 Hz, 1H) and a sextet at τ 4.97 (J=4.5, and 10.5 Hz, 1H) and (7b) has multiplets at τ 6.88 (Hw=8 Hz, 1H) and near τ 4.2.*1 From these data, it was found that the intermediates obtained from the desulfurization were 2β-hydroxy-3β-ethylthio-5β-steroids. The reductive cleavages of these hydroxy-ethylthio derivatives with Raney nickel produced 2β-hydroxy-5β-steroids in good yields.

Oxidation of the 2β-hydroxy-5β-steroids with chromic acid and acetic acid gave 2-oxo-5β-steroids (9) showing a double Cotton curve near 310 mμ. One of the products was identical with 5β-cholestan-2-one prepared by Tomoeda and Koga.[3]

In a previous paper, it was reported that the isomerisation of 2β-acetoxy-5β-cholestan-3-one with hydrogen bromide and acetic acid gave 3α-acetoxy-5β-cholestan-2-one (10).[7] In general, α-ketols and their acetates are reduced to the ketone with zinc



*1 This signal owing to C_2-αH could not be clarified, because it was overlapped by the CH_3-signal of the C_{24}-carbomethoxy group.

and acetic acid.[8] Therefore, the synthesis of 5β-cholestan-2-one from the 3α-acetoxy-2-oxo derivative (10) has been studied according to this method. In a small scale experiment, satisfactory result was obtained, but in a large scale experiment, zinc in great bulk prevented stirring, so that this method was not practical for the synthesis of 5β-cholestan-2-one.

In the bromination of the 2-oxo derivatives, the products were 1β-bromo-2-oxo-5β-steroids, not 1α- or 3-bromo isomers. This was determined by signs of the Cotton effect, Δ[A] (+233 for 5β-cholestan-2-one and +164 for methyl 2-oxocholanate) and $\Delta\lambda_1$-values (+20 and +18 mμ, respectively) in ORD, the shifts of C=O stretching bands (+4 and +2 cm^{-1}, respectively) in IR spectra and the patterns of the NMR spectra.

In connection with the above investigation, we carried out the enol acetylation of 5β-cholestan-2-one according to the directions of Djerassi *et al.* described for the 5α-series.[9] On chromatographical separation of the reaction product, 5β-cholest-1-en-2-ol acetate was obtained. It was found, moreover, that bromination of this enol acetate with bromine in acetic acid gave the same product as described above for that of 5β-cholestan-2-one. From these results, we may conclude that the enolization of the 2-oxo-5β-steroids occurs in the direction of C_1, not C_3, and that the bromination of these ketones forms the 1β-bromo-2-oxo derivatives. The configuration of these bromoketones is consistent with Corey's prediction for the 2-oxo-5β-steroid.[10]

Chlorination of 5β-cholestan-2-one also produced 1β-substituted derivative as in the case of bromination. In the NMR spectra of both 1β-haloketones, it was found that the signal due to C_1-αH in the chloroketone was shifted more to the upper field than that of the bromoketone.

Experimental

Instrumentation. IR and ORD spectra were measured on a Shimadzu model IR-27B infrared spectrometer and a JASCO model ORD/UV-5 spectrometer, respectively. NMR spectra were recorded in deuterochloroform, with TMS as the internal standard with a JEOL model JNM-4H-100 high resolution nuclear spectrometer.

2β-Acetoxy-5β-cholestan-3-one Diethylmercaptol (3a). A current of dry hydrogen chloride was passed into a mixture of (2a) (19.0 g) and ethyl mercaptan (24 m*l*) under cooling with an ice-bath for 10 min. After the reaction mixture had stood for 15.5 hr in a refrigerator, the excess of ethyl mercaptan was removed in a vacuum desiccator on sodium hydroxide. The resulting oil was then extracted with ether. The ether extracts were washed with sodium hydrogencarbonate solution and water, dried, and evaporated under reduced pressure. A slightly brownish oil (21.7 g) was obtained. Attempts to crystallize the diethylmercaptol were unsuccessful, and so it was used in the next step without purification. ν_{max}^{Film} cm^{-1}: 1745 (C=O), 1234 (C–O), 770 (C–S).

Methyl 2β-Acetoxy-3-oxocholanate Diethylmercaptol (3b). The method used here was identical with that described for (3a). No crystalline diethylmercaptol (22.0 g) was obtained from methyl 2β-acetoxy-3-oxocholanate (16.5 g). ν_{max}^{Film} cm^{-1}: 1733 (C=O), 1230, 1165 (C–O), 771 (C–S).

2β-Acetoxy-5β-cholestane (4a). A solution of diethylmercaptol (3a) (9 g) in methanol-acetone (1 : 1, 400 m*l*) was refluxed with Raney nickel (W-2, 90 g) under effecient stirring for 2.5 hr. The hot reaction mixture was filtered and the clear filtrate was evaporated under reduced pressure. The resulting oil (7 g) was chromatographed on silica gel; 5β-cholestane was first eluted by petroleum ether, and the next fraction eluted with benzene - petroleum ether (2 : 1), on crystallization from ethanol gave plates of 2β-acetoxy-5β-cholestane (1.7 g), mp 59—61.5°C, $[\alpha]_D^{24}$ +19.7°C (*c* 1.26, $CHCl_3$), NMR ($CDCl_3$) τ: 5.23 (septet, *J*=5.5 and 11 Hz, 1H), ν_{max}^{KBr} cm^{-1}: 1732 (C=O), 1240 (C–O).

Found: C, 80.55; H, 11.62%. Calcd for $C_{29}H_{50}O_2$: C, 80.87; H, 11.71%.

Methyl 2β-Acetoxycholanate (4b). The desulfurization of the diethylmercaptol (3b) (7.1 g) was carried out using the technique described for the synthesis of (4a). The resulting oil (5.4 g) from the reaction mixture was chromatographed on silica gel; benzene eluted a yellow oil which on crystallization from methanol gave needles of methyl cholanate (3.6 g), mp 85—87°C. The next fraction, eluted by the same solvent, on crystallization from methanol gave plates of methyl 2β-acetoxycholanate (0.3 g), mp 75.5—77°C, $[\alpha]_D^{24}$ +17.9° (*c* 1.12, $CHCl_3$), ν_{max}^{KBr} cm^{-1}: 1739, 1725 (C=O), 1255, 1173 (C–O), NMR ($CDCl_3$) τ: 5.21 (septet, *J*=6.5 and 13 Hz, 1H), 6.36 (s., 3H), 8.01 (s., 3H).

Found: C, 75.33; H, 10.39%. Calcd for $C_{27}H_{44}O_4$; C, 74.96; H, 10.25%.

2β-Hydroxy-5β-cholestan-3-one Diethylmercaptol (5a). A mixture consisting of (4a) (21.7 g), sodium hydroxide (2.4 g), water (2 m*l*), and methanol (800 m*l*) was refluxed for 4.5 hr. After evaporation of the reaction mixture, the residue was dissolved in ether. The ethereal solution was washed with water, dried, and evaporated. Crystallization of the resulting oil from ethanol gave 2β-hydroxy-5β-cholestan-3-one diethylmercaptol as needles (16 g), mp 79—80.5°C, $[\alpha]_D^{24}$ +15.0° (*c* 1.00, $CHCl_3$), ν_{max}^{KBr} cm^{-1}: 3420 (O–H), 770 (C–S), NMR ($CDCl_3$) τ: 6.44 (t., *J*=5 and 10 Hz, 1H), 7.28 (m., 4H).

Found: C, 73.47; H, 11.06; S, 12.49%. Calcd for $C_{31}H_{56}OS_2$: C, 73,16; H, 11.09; S, 12.60%.

Methyl 2β-Hydroxy-3-oxocholanate Diethylmercaptol (5b). A solution of (3b) (6.09 g) in methanol (200 m*l*) was refluxed with potassium hydroxide (2 g) in water (15 m*l*) for 6 hr. After cooling, the reaction mixture was poured into ice-water and acidified with dilute hydrochloric acid. The resulting precipitate

was taken up in ether and the ether extracts were washed with water, dilute sodium hydrogencarbonate solution, then water, dried, and concentrated. Crystallization of the residue from methanol gave needles of 2β-hydroxy-3-oxocholanic acid diethylmercaptol (5c) (4.77 g), mp 152—154°C, $[\alpha]_D^{26}$+12.4° (*c* 0.97, $CHCl_3$).

The acid (5c) (4 g) was converted to its methyl ester with diazomethane. After evaporation of the solvent, crystallization of the residue from methanol gave methyl ester (5b) (2.98 g), mp 89—90.5°C, $[\alpha]_D^{24}$+13.5° (*c* 1.13, $CHCl_3$), ν_{max}^{KBr} cm^{-1}: 3450 (O–H), 1735 (C=O), 1166 (C–O), 765 (C–S).

Found: C, 68.32; H, 9.70; S, 12.51%. Calcd for $C_{29}H_{50}O_3S_2$: C, 68.19; H, 9.87; S, 12.55%.

From the mother liquor, a second crop (0.79 g), mp 81.5—85°C, was also obtained.

2β-Hydroxy-5β-cholestane (6a). (i) A solution of 2β-acetoxy-5β-cholestane (4a) (1.4 g) in methanol (5.6 m*l*) and ether (10 m*l*) was refluxed with sodium hydroxide (0.36 g) in water (1.4 m*l*) for 3 hr. After evaporation of the reaction mixture, the residue was dissolved in ether. The ethereal solution was washed with water, dried, and evaporated. Crystallization of the residue from ethanol gave needles of (6a) (0.91 g), mp 100—104°C, $[\alpha]_D^{24.5}$+14.9° (*c* 0.93, $CHCl_3$), ν_{max}^{KBr} cm^{-1}: 3300 (O–H), NMR ($CDCl_3$) τ: 6.28 (septet, *J*=5 and 10 Hz, 1H).

Found: C, 83.10; H, 12.41%. Calcd for $C_{27}H_{48}O$: C, 83.43; H, 12.45%.

(ii) 2β-Hydroxy-5β-cholestan-3-one diethylmercaptol (5a) (12.2 g) was treated with Raney nickel according to the method for the synthesis of (4a) from (3a). Attempts to crystallize the residue were unsuccessful, but this product was identical with 2β-hydroxy-5β-cholestane prepared by the method (i) in t.l.c., g.l.c., and IR spectrum. Acetylation of a part of the product gave 2β-acetoxy-5β-cholestane as plates, which was identical with the specimen prepared from 2β-acetoxy-5β-cholestan-3-one diethylmercaptol with Raney nickel. Thus the oily product was used for the synthesis of 5β-cholestan-2-one (9a) without further purification.

Methyl 2β-Hydroxycholanate (6b). A mixture of (5b) (6.15 g), methanol-acetone, and Raney nickel was treated by the same method as for (6a) (method ii). The resulting oil (4.75 g) was chromatographed on silica gel. A small amount of methyl 2-oxocholanate was first eluted with benzene-ether (20 : 1), and a second fraction, eluted with the same solvent, on crystallization from methanol gave plates of methyl 2β-hydroxycholanate (2.5 g), mp 80—81°C, $[\alpha]_D^{24}$+10.5° (*c* 0.96, $CHCl_3$), ν_{max}^{KBr} cm^{-1}: 3420 (O–H), 1737 (C=O), 1166 (C–O).

Found: C, 76.84; H, 10.76%. Calcd for $C_{25}H_{42}O_3$: C, 76.87; H, 10.84%.

Acetylation of the product (6b) in the usual method produced methyl 2β-acetoxycholanate, which was identical with the product prepared from the mercaptol (3b) by desulfurization.

2β-Acetoxy-3β-ethylthio-5β-cholestane (8a). A solution of (5a) (19.5 g) in methanol-acetone (1 : 1, 300 m*l*) was refluxed with one-half the weight of Raney nickel used for the synthesis of 2β-hydroxy-5β-steroid from diethylmercaptol (5). After 30 min, the reaction mixture was filtered and evaporated. On chromatography of the residue with silica gel, benzene - petroleum ether eluted an oil (5.38 g), which consisted of 2β-hydroxy-3β-ethylthio-5β-cholestane (7a) and 5β-cholestan-2-one (9a). Isolation of (7a) from the mixture was so difficult that the compound was converted to its acetate with acetic anhydride and pyridine. Recrystallization of the acetylation product from ethanol gave needles of 2β-acetoxy-3β-ethylthio-5β-cholestane (8a) (3.6 g), mp 66—68.5C°, $[\alpha]_D^{24}$+2.5°C (*c* 1.22, $CHCl_3$), ν_{max}^{KBr} cm^{-1}: 1744 (C=O), 1238 (C–O), 731 (C–S), NMR ($CDCl_3$) τ: 4.97 (sextet, *J*=4.5 and 10.5 Hz, 1H), 6.60 (m., Hw=8 Hz, 1H), 7.23—7.67 (q., –S– CH_2–), 7.93 (s., 3H).

Found: C, 76.23; H, 11.20; S, 6.45%. Calcd for $C_{31}H_{54}O_2S$: C, 75.86; H, 11.09; S, 6.53%.

Further desulfurization of the mixture consisting of (7a) and (9a) with Raney nickel produced needles of 2β-hydroxy-5β-cholestane.

Benzene eluted a yellow oil which on crystallization from ethanol gave 2α-hydroxy-5β-cholestane (3.7 g).

Methyl 2β-Hydroxy-3β-ethylthiocholanate (7b). A solution of the diethylmercaptol (5b) (1g) in methanol-acetone (1 : 1, 30 m*l*) was treated with Raney nickel according to the procedure described for the synthesis of (7a) except that the reaction was carried out for 1 hr. On chromatography of the residue with silica gel, crystallization of benzene eluates gave needles of methyl 2β-hydroxy-3β-ethylthiocholanate (201 mg), mp 105.5—106.5°C, from methanol. $[\alpha]_D^{24}$ −27.3° (*c* 1.06, $CHCl_3$), ν_{max}^{KBr} cm^{-1}: 3473 (O–H), 1746 (C=O), 1153 (C–O), 766 (C–S).

Found: C, 71.63; H, 10.32; S, 7.09%. Calcd for $C_{27}H_{46}O_3S$: C, 71.95; H, 10.29; S, 7.11%.

Desulfurization of the hydroxy-ethylthio derivative by the method used for (8a) gave methyl 2β-hydroxycholanate.

Further elution with benzene afforded a mixture consisting of a trace of methyl 2-oxo- (9b) and 2β-hydroxycholanate (6b).

5β-Cholestan-2-one (9a). (i) From 2β-Hydroxy-5β-cholestane (6a). A solution of (6a) (8.4 g) in acetic acid (160 m*l*) was treated with chromium trioxide (2.4 g) in 80% acetic acid (14 m*l*) at 10—15°C. After standing for 2 hr, a small amount of methanol was added to the reaction mixture. The solution was slightly warmed on a water bath, cooled, and poured into water, and the resulting precipitate was extracted with ether. The ether extracts were washed with sodium hydrogencarbonate solution and water, dried, and evaporated. Crystallization of the residue from ethanol gave plates of (9a) (5.9 g), mp 86—88°C, ν_{max}^{KBr} cm^{-1}: 1712 (C=O), ORD (*c* 0.49, Di) at 26°C: $[\alpha]_{589}$+16.3°, $[\alpha]_{400}$+24.5°, $[\alpha]_{370}$ 0°, $[\alpha]_{316}$ −321.5° (trough), $[\alpha]_{306}$ −244.9° (sh.), $[\alpha]_{302}$ 0°, $[\alpha]_{275}$+263.3° (peak).

Found: C, 83.29; H, 11.81%. Calcd for $C_{27}H_{46}O$: C, 83.86; H, 11.99%.

(ii) From 3α-Acetoxy-5β-cholestan-2-one (10a). A mixture of (10a) (377 mg), zinc powder (37.7 g), and acetic acid (198 m*l*) was refluxed with stirring for 14 hr. After evaporation of the solvent, the residue was taken up into ether and the ether extracts were washed with sodium hydrogencarbonate solution and water, dried, and concentrated. Crystallization from ethanol gave plates of 5β-cholestan-2-one (50 mg), mp 85—87°C. This product was identical with a sample prepared by method (i) in IR and ORD spectra.

Methyl 2-Oxocholanate (9b). This substance was prepared according to method (i) described above for

the synthesis of (9a). The crystallization of the resulting oil from methanol gave needles of methyl 2-oxocholanate (819 mg), mp 88—89.5°C, from (6b) (1 g). ν_{max}^{KBr} cm^{-1}: 1733, 1708 (C=O), 1162 (C–O), ORD (*c* 0.59, Di) at 26°C: $[\alpha]_{589}$+20.3°, $[\alpha]_{400}$+31.6°, $[\alpha]_{357}$ 0°, $[\alpha]_{317}$ −273° (trough), $[\alpha]_{307}$ −166° (sh.), $[\alpha]_{302}$ 0°, $[\alpha]_{275}$ +509° (peak).

Found: C, 77.27; H, 10.38%. Calcd for $C_{25}H_{40}O_3$: C, 77.58; H, 10.49%.

1β-Bromo-5β-cholestan-2-one (11a). 5β-Cholestan-2-one (4.24 g) was dissolved in acetic acid (100 m*l*) and a few drops of 47% hydrogen bromide were added, followed by addition of bromine (1.75 g) in acetic acid (10 m*l*) with stirring for 25 min at 18°C. The reaction mixture was cooled, and the crystals formed were collected. The crystals were dissolved in ether and the ethereal solution was washed, dried, and evaporated. Crystallization of the residue from methanol-ether gave needles (3.82 g), mp 128—130°C, ν_{max}^{KBr} cm^{-1}: 1714 (C=O), 668 (C-Br), ORD (*c* 0.52, Di) at 26°C: $[\alpha]_{589}$ +9.6°, $[\alpha]_{400}$+421°, $[\alpha]_{336}$+2187° (peak), $[\alpha]_{314}$ 0°, $[\alpha]_{288}$ −2369° (trough), NMR ($CDCl_3$) τ: 5.68 (s., 1H).

Found: C, 69.78; H, 9.80%. Calcd for $C_{27}H_{45}OBr$: C, 69.65; H, 9.74%.

Methyl 1β-Bromo-2-oxocholanate (11b). Bromination of methyl 2-oxocholanate (834 mg) was carried out using the technique for the synthesis of (11a). The reaction mixture was taken up in ether and the ether extracts were washed, dried, and evaporated. On chromatography of the residue with silica gel, elution with benzene gave an oily product (650 mg). Crystallization of this product from methanol afforded needles (81 mg) of (11b), mp 138—140°C, ν_{max}^{KBr} cm^{-1}: 1735, 1710 (C=O), 1171 (C–O), 673 (C–Br), ORD (*c* 0.62, Di) at 25°C: $[\alpha]_{589}$+67.7°, $[\alpha]_{400}$+271°, $[\alpha]_{335}$+1394° (peak), $[\alpha]_{313}$ 0°, $[\alpha]_{289}$−1468° (trough), NMR ($CDCl_3$) τ: 5.66 (s., 1H), 6.35 (s., 3H).

Found: C, 63.33; H, 8.00%. Calcd for $C_{25}H_{39}O_3Br$: C, 64.24; H, 8.41%.

1β-Chloro-5β-cholestan-2-one (11a′). A solution of chlorine (79 mg) in chloroform (3 m*l*) was added to a mixture consisting of 5β-cholestan-2-one (9a) (386 mg), concd. hydrochloric acid (2 drops) and acetic acid (15 m*l*) with stirring at 20°C. After 15 min, the reaction mixture was poured into water, and the chloroform layer was washed, dried, and evaporated. Crystallization of the residue from methanol-acetone gave needles (247 mg), mp 116—118°C, ν_{max}^{KBr} cm^{-1}: 1721 (C=O), ORD (*c* 0.59, Di) at 25°C: $[\alpha]_{589}$+50.8°, $[\alpha]_{400}$+131.4°, $[\alpha]_{327}$+645.8° (peak), $[\alpha]_{321}$+557.6° (trough), $[\alpha]_{316}$+627.1° (peak), $[\alpha]_{298}$ 0°, $[\alpha]_{281}$−314.4° (trough), NMR ($CDCl_3$) τ: 5.83 (s., 1H).

Found: C, 76.49; H, 11.22%. Calcd for $C_{27}H_{45}OCl$: C, 77.01; H, 10.77%.

2-Acetoxy-5β-cholest-1-ene (12a). This substance was prepared according to the directions of Djerassi *et al.* described for 5α-isomer.[9] The reaction product was chromatographed in petroleum ether on silica gel. Elution with benzene gave needles of (12a) from ethanol, mp 103—105°C, $[\alpha]_D^{26}$+52.0°C (*c* 0.997, in $CHCl_3$), ν_{max}^{KBr} cm^{-1}: 1750 (C=O), 1687 (C=C), 1215 (C–O), NMR ($CDCl_3$) τ: 4.66 (s., 1H), 7.93 (s., 3H).

Found: C, 80.52; H, 11.01%. Calcd for $C_{29}H_{48}O_2$: C, 81.25; H, 11.29%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 496—500 (1970)

Addition of Tellurium Tetrachloride to Olefins and Pyrolysis of the Adduct

Masao OGAWA and Ryoji ISHIOKA

Central Research Laboratory, Showa Denko K. K., Tamagawa, Ohta-ku, Tokyo

(Received July 28, 1969)

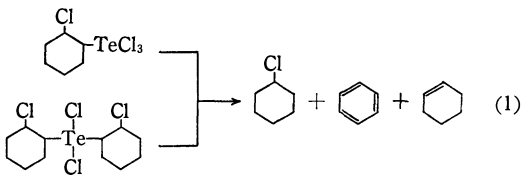
The tellurium tetrachloride-cyclohexene adduct, 2-chlorocyclohexyltellurium trichloride (I) and bis(2-chlorocyclohexyl)tellurium dichloride (II), both gave, on pyrolysis, chlorocyclohexane as the chlorinated compound. An intermolecular hydrogen transfer is required for the formation of chlorocyclohexane from I. Chloro-*n*-propyltellurium trichloride (III) and bis(chloro-*n*-propyl)-tellurium dichloride (IV) were formed by the addition of tellurium tetrachloride to propylene. The pyrolysis of III afforded allyl chloride, 1,2-dichloropropane, and hydrogen chloride, while tellurium was simultaneously reduced. Besides these products, isopropyl chloride was also obtained from IV. Some properties of the adduct and the effect of the temperature on the thermal decomposition were studied.

In an earlier communication[1] the formation of bis(chloroalkyl)tellurium dichloride by the addition of tellurium tetrachloride (TTC) to olefins and the pyrolysis of the adducts affording organic chlorides were briefly reported. The lower-valent tellurium compounds produced in the pyrolysis are reoxidized by oxygen and hydrogen chloride. Thus, the oxychlorination of olefins for the production of allylic chloride is thought to be possible; the process is now being investigated.[2]

The present paper will deal with the behavior of the TTC-propylene adducts, including the hydrogen transfer observed in the pyrolysis of the TTC-cyclohexene adducts. The results will give a clue to the catalysis of the tellurium compound in the chlorination reaction.

Results and Discussion

Pyrolysis of the TTC-cyclohexene Adducts. In the addition of TTC to cyclohexene,[1] 2-chlorocyclohexyltellurium trichloride (I) was obtained when TTC was allowed to react with less than an equivalent amount of cyclohexene, while bis-(2-chlorocyclohexyl)tellurium dichloride (II) was obtained from the reaction with excess cyclohexene. Both I and II gave, on pyrolysis, chlorocyclohexane, benzene, and cyclohexene, as well as hydrogen chloride and inorganic tellurium compound.



(1)

A certain amount of 3-chlorocyclohexene was expected to be found in the pyrolysate. In fact, it was assumed by gas chromatography. However, its amount was very small; if it was present at all, it was estimated at less than 1% of the products. In contrast to the pyrolysis of the TTC-propylene adducts (Table 3), the yield of allylic chloride was very low, probably because the concurrent dehydrogenation to benzene predominated over the allylic chlorination. The product distribution in the pyrolysis of I is shown in Table 1, along with the corresponding data for II.

TABLE 1. PRODUCTS FROM THE PYROLYSIS OF I AND II

Compound	Organic product (g/g)	Product distribution (%)		
		Chloro-cyclohexane	Ben-zene	Cyclo-hexene
I[a]	0.18	51	28	21
I[b]	0.17	55	28	17
II[a]	0.27	38	13	49

a) Decomposed at 150°C. b) At 200°C.

It seems natural that a tellurium-catalyzed intramolecular hydrogen transfer should be involved in the pyrolysis of II, which has hydrogens available within the molecule, while the intermolecular hydrogen transfer is bound to occur in the pyrolysis of I.

During the thermal decomposition of I and II, an intermediate formation of the tellurium-hydrogen

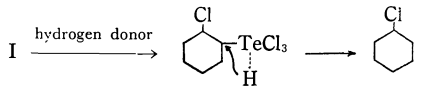
bond, a probable representation of which is shown in Eq. (2), may be implied before the complete cleavage of the tellurium-carbon bond.



and other products (2)

It is known that the atomic valency of the VIb-group element, particularly that of covalent tellurium,[3] increases to 6 and more upon the participation of vacant *d* orbitals; this character of the element is thought to be related to the hydrogen transfer (perhaps the hydride transfer) observed in the experiment.

Addition of TTC to Propylene. The reaction of propylene with TTC in an organic solvent, after the solvent had been evaporated, afforded the adduct as an faint yellow viscous oil. The IR spectrum showed that the adduct had no double bond in it. The NMR spectrum coincided with the structure of addition compound.

When TTC in acetonitrile was allowed to react, in a sealed tube, with an equivalent amount of propylene, one type of product (named III) was exclusively obtained. On the other hand, another product (named IV) was formed together with III in the reaction with excess propylene. (See Figs. 2 and 3 in the "Experimental" section.) The same results were observed when nitromethane instead of acetonitrile was used as the solvent. Accordingly, compared with the case of cyclohexene, III and IV are thought to be 2-chloropropyltellurium trichloride and bis(2-chloropropyl)tellurium dichloride respectively.

CH_3-CHCl-CH_2-$TeCl_3$ (III)

$(CH_3$-CHCl-$CH_2)_2TeCl_2$ (IV)

Neither the NMR spectrum nor the chemical reaction was conclusive as to the orientation of the addition, but Markownikoff addition was tentatively estimated from the product of the pyrolysis. The Markownikoff additions of aryltellurium trichloride[4] and I[5] to 2,2-disubstituted-penten-4-oic acid, and of selenium tetrachloride[6] to the simple olefins, have been reported, while the random orientation has been manifested in the addition of sulfenyl chloride[7] and sulfur dichloride[8,9] to olefins.

It was suggested in the previous paper[1] that the TTC-butene-1 adduct was a mixture of isomers of bis(chloro-*n*-butyl)tellurium dichloride; this suggestion was based on the analytical method which is now found to involve considerable uncertainties in the determination of tellurium. The estimation must, then, be in error and must be corrected in view of the present results. The TTC-butene-1 adduct can now be thought to be a mixture of bis(2-chlorobutyl)tellurium dichloride and a minor amount of 2-chlorobutyltellurium trichloride.

The effects of the solvent on the addition were investigated, though the number of usable solvents was limited because of the reaction with TTC[10] and the solubility requirements. Gaseous propylene was introduced into a solution of TTC in an organic solvent at room temperature for a sufficiently long period.

Table 2. Solvent effect in addition reaction
TTC 2 g; solvent, 20 m*l*; reaction time, 1 hr

Solvent	Dielectric constant	Time (min)[a]	III (%)[b]	IV
Ethyl acetate[c]	6.03	60	98	2
Acetic acid	6.19	45	83	17
Methylene dichloride[d]	8.9	14	81	19
Acetonitrile	37.5	13	56	44
Nitromethane	39.0	11	32	68

a) The approximate time required for the disappearance of the yellow color of TTC in solution.
b) The ratio of III and IV was calculated approximately from the relative intensity of the NMR signals.
c) The reaction was not completed within an hour.
d) TTC was not fully dissolved in this solvent.

The reaction is generally faster, and IV is more preferentially formed, with increases in the dielectronic constant and in the solvating power of the solvent used. In such a polar solvent, the ionization and the subsequent addition of III to the olefin is accelerated; consequently, the formation of IV, at the expense of III, is favored.

Properties of the TTC-propylene Adduct. The adduct (III or IV) was relatively stable at room temperature, but it began to decompose at approximately 80°C. Sensitive to water, it was hydrolyzed to a white, insoluble mass,[11] losing the chlorine atoms attached to tellurium. With

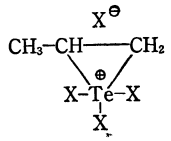
reducing agents such as sodium sulfite and hydrazine hydrochloride, propylene and elemental tellurium were recovered. When the adduct was dissolved in an acidic solution of potassium perchromate, 1,2-dichloropropane was obtained in a low yield, besides several unidentified compounds.

The tellurium-carbon bond of the adduct was cleaved by the action of bromine. III yielded a mixture of dihalopropanes.

$$\text{III} \xrightarrow{Br_2} CH_2Br\text{-}CHBr\text{-}CH_3 + CH_2Cl\text{-}CHBr\text{-}CH_3 + CH_2Br\text{-}CHCl\text{-}CH_3 + CH_2Cl\text{-}CHCl\text{-}CH_3 \quad (3)$$

Under the same conditions, the chlorine atom in 1,2-dichloropropane or bromochloropropane was not replaced by bromine. This indicates that the chlorine atom in the alkyl remainder of the adduct was activated toward substitution by a neighboring tellurium atom. The activation of the chlorine and the products in Eq. (3) were interpreted in terms of the cyclic tellurium-ion intermediate (V), which had previously been postulated by De Moura Campos and Petragnani[5] in analogy to the episulfonium ion considered in the behavior of the sulfenyl chloride-olefin adduct.[7,12]



(V) X: Cl or Br

Pyrolysis of the TTC-Propylene Adduct. The pyrolysis of the adducts afforded allyl chloride, isopropyl chloride, 1,2-dichloropropane, and hydrogen chloride as well as inorganic telluride and propylene. It is likely that the adduct was of the Markownikoff type, for if it were of the anti-Markownikoff type *n*-propyl chloride, instead of isopropyl chloride, would be produced by hydrogen transfer at the pyrolysis.

The effect of the temperature on the yield of organic chloride (based on tellurium, mol/atom $\times 100$) was studied by using the adduct obtained from the reaction in an acetonitrile solvent (III 56%, IV 44%).

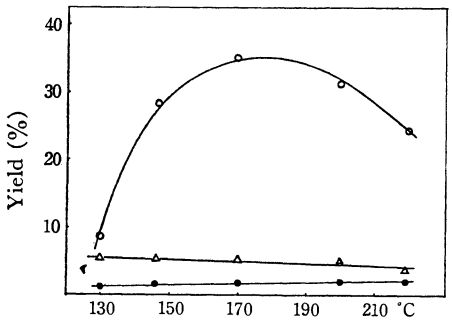


Fig. 1. Effect of temperature on the pyrolysis.
○: Allyl chloride, △: Isopropyl chloride,
●: 1,2-dichloropropane

At a low temperature, the decomposition was incomplete and the residue contained organic tellurides. At a higher temperature, the dissociation (Eq. (8)) predominated over the chlorination. Therefore, the optimum temperature appears in Fig. 1.

The relation between the yield of organic chlorides and the ratio of III and IV in the adduct is shown in Table 3.

Table 3. Pyrolysis of III and IV
170°C, 5 mmHg

III (%)	IV	Isopropyl chloride (%)	Allyl chloride (%)	1,2-dichloropropane (%)
98	2	<1	11	1.2
83	17	1.6	19.9	2.7
81	19	6.0	25.3	2.4
56	44	5.0	34.9	1.7
32	68	9.9	49.0	3.0

Table 3 shows that isopropyl chloride was mainly produced from IV, indicating that intramolecular hydrogen transfer was operating and that intermolecular hydrogen transfer was not important in this case.

$$\begin{array}{l} CH_2\text{-}CHCl\text{-}CH_3 \\ | \\ Cl\text{-}Te\text{-}Cl \\ | \\ CH_2\text{-}CHCl\text{-}CH_3 \end{array} \longrightarrow$$

$$CH_3\text{-}CHCl\text{-}CH_3 + CH_2{=}CH\text{-}CH_2Cl + TeCl_2 \quad (4)$$

The formation of allyl chloride from III and IV is thought to require some type of allylic intermediate, which may be stabilized by the tellurium atom.

$$\text{III, IV} \xrightarrow{-HCl} \text{allylic intermediate} \xrightarrow{-Te} CH_2{=}CH\text{-}CH_2Cl \quad (5)$$

The allylic intermediate illustrates how 3-chloro-1-butene and 1-chloro-2-butene were formed, along with isomeric butenes, from the TTC-butene-1 adduct,[1] and also from the TTC-butene-2[13] adduct.

In this thermal decomposition, the elimination of hydrogen from the carbon bearing both hydrogen and chlorine or the preliminary development of the carbonium ion at the α to tellurium carbon is excluded, because no vinylic chlorides were found in the pyrolysate.

The adduct would give 1,2-dichloropropane by either Eq. (6) or (7), though it is uncertain which process prevails:

12) N. Kharasch, "Organic Sulfur Compounds," Vol. 1, Pergamon Press, New York (1961), p. 382.

13) Unpublished work.

$$\text{III, IV} \longrightarrow \begin{cases} \rightarrow CH_2Cl\text{-}CHCl\text{-}CH_3 + Te & (6) \\ \rightarrow CH_2Cl\text{-}CHCl\text{-}CH_3 + CH_2{=}CH\text{-}CH_3 + TeCl_2 & (7) \end{cases}$$

All these reaction, Eqs. (4)—(7), compete in the rather fast dissociation of the adduct to regenerate TTC and propylene.

$$\text{III, IV} \rightarrow CH_2{=}CH\text{-}CH_3 + TeCl_4 \quad (8)$$

This reaction may be partly responsible for the absence of vinylic chlorides in the pyrolysate.

The results with propylene, described here, can be applied to the study of the behavior of other linear olefins.

Experimental

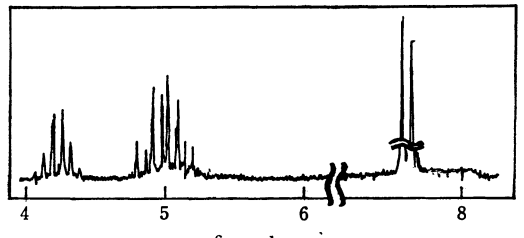
The IR spectrum was measured using a Nippon Bunko DS-401G-type spectrophotometer. The NMR spectra were recorded on a Japan Electron Optics H-100 spectrometer (100MHz), with benzene as the internal standard. TMS was not used, because it caused precipitation with the organic tellurium compounds described in this report. As has been shown previously,[14] the isotopes of tellurium (^{123}Te and ^{125}Te; nuclear spin, 1/2; natural abundance, *ca.* 25%) hardly affected the NMR spectrum.

The chlorinated organic compounds were analyzed by gas chromatography, using a Carbowax column (at 60°C and 110°C) or a tricresylphosphate column (at 60°C).

2-Chlorocyclohexyl Trichloride (I).[15] Mp 112—113°C (decomp.), Found: C, 20.5; H, 3.8; Cl, 40.0%, mol. wt (cryoscopic), 360.

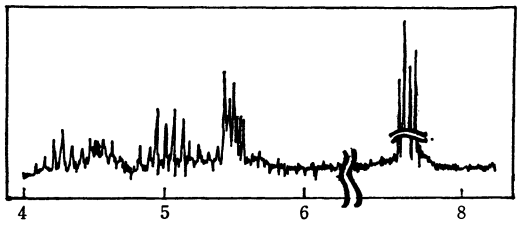
Addition of TTC to Propylene. Two grams (7.4 mmol) of TTC in 20 m*l* of acetonitrile were mixed with 0.45 m*l* (*ca.* 7.4 mmol) of liquid propylene in a sealed tube. The mixture was then left standing for 2 hr at at room temperature. On removing the solvent *in vacuo*, chloro-*n*-propyltellurium trichloride (III) was obtained as a viscous oil. The characteristics in the NMR spectrum of III (Fig. 2) in deuteriochloroform were similar to those of the sulfenyl chloride-propylene adduct.[7] The terminal methylene and the methine protons form an ABX-type spin system: a double quartet for the methylene protons ($J_{gem} \simeq 12$Hz, $\Delta\nu \simeq 22$Hz) and six symmetrical lines for the methine protons.

The same procedure was repeated using 3.7 mmol of TTC and 77 mmol of propylene. The NMR spectrum of the resulting oil (Fig. 3) suggested that bis(chloro-*n*-propyl)tellurium dichloride (IV) was formed in addition to III. The absorptions that represent the methylene and methine protons also show the features of an ABX-type spin system, though the band for the former protons is distorted and that for the latter is broadened.



ppm from benzene

Fig. 2. NMR spectrum of III.



ppm from benzene

Fig. 3. NMR spectrum of III and IV.

Small percentages of impurities, depending on the solvent used in the addition reaction, were also observed in the higher field of the NMR spectra, but they are omitted in the figures cited above.

Attempt to distill or recrystallize the adduct resulted in failure.

The experiments for Table 2 were carried out as follows: two grams of TTC in 20 m*l* of a solvent were transferred to a three-necked flask fitted with a magnetic stirrer, a gas inlet, and an ice-water cooled condenser. After replacing the air with a stream of nitrogen, propylene was bubbled in under vigorous stirring at room temperature for an hour. The solvent was then removed under reduced pressure and a part of the adduct was dissolved in deuteriochloroform in order to measure the NMR spectrum.

The Reaction of the TTC-propylene Adduct with Bromine. One gram of III was dissolved in 10 m*l* of methanol containing 7.0 g of bromine and 1.5 g of potassium bromide. The mixture was warmed at 50°C for 4hr, washed with aqueous potassium hydroxide to remove the excess bromine, and filtered from inorganic tellurium compounds. A mixture of dihalopropanes and unreacted organotellurium compound separated as an oily layer. The dihalopropanes obtained by the distillation of the oil under reduced pressure gave three peaks on gas chromatography; each of them was then separated. By comparing the IR spectra with Sadtler's standard ones, the first and the third fraction, in order of elution, were found to be 1,2-dichloropropane and 1,2-dibromopropane respectively. The second fraction was a mixture of 1-bromo-2-chloropropane and 1-chloro-2-bromopropane, the ratio of which was determined from the NMR spectra. The authentic sample of the bromochloropropanes, in which 1-chloro-2-bromopropane predominates, was prepared from propylene oxide by ring closure with hydrogen chloride, followed by bromination with phosphorus pentabromide. In the NMR spectrum, the doublets for the methyl protons of 1-chloro-2-bromopropane and 1-bromo-2-chloropropane appeared at δ 1.79 (from TMS) and at δ 1.65 respectively. These signals were used to calculate the ratio of the isomers. The composition of the dihalopropanes formed by the reaction of III with bromine was approximately as follows: $CH_3CHCl\text{-}CH_2Cl$ 5%, $CH_3\text{-}CHCl\text{-}CH_2Br$ 6%, $CH_3\text{-}CHBr\text{-}CH_2Cl$ 18%, and $CH_3\text{-}CHBr\text{-}CH_2Br$ 71%. When one gram of III

was refluxed with 2 g of bromine in methylene dichloride for 10 hr and then worked up as has been described above, the following product distribution was observed: CH_3–CHCl–CH_2Cl 11%, CH_3–CHCl–CH_2Br 20%, CH_3–CHBr–CH_2Cl 38%, and CH_3–CHBr–CH_2Br 31%.

Pyrolysis of the Adducts. Pyrolysis was conducted under a pressure of 1—5 mmHg. About one gram of the adduct in a 25-m*l* flask was immersed into an oil bath maintained at a desired temperature. The decomposition occurred immediately. The products were inorganic tellurium compounds (residue), hydrogen chloride, and organic compounds, the last of which were collected in a dry ice-methanol trap. When necessary, the trap contained a weighed amount of chloroform as an internal standard for gaschromatography. It was ascertained that the simple addition of hydrogen chloride to the olefins did not occur in the cold trap. Each of the organic products from the pyrolysis was separated by distillation or by gas chromatography and was identified by comparing the IR spectrum with that of the authentic sample or with Sadler's standard spectrum.

The authors wish to thank Dr. M. Kitabatake and C. Inoue for their discussions and Mr. N. Tanaka for his measurement of the NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 500—505 (1970)

Polymerization of Vinyl Chloride and Copolymerization of Vinyl Chloride with Styrene by Alkylmagnesium Chlorides

Hiroshi MINATO,* Masayoshi OKU and Nobuyuki HIGOSAKI

Department of Chemistry, International Christian University, Mitaka-shi, Tokyo

(Received July 29, 1969)

t-Butylmagnesium chloride was found to initiate the polymerization of vinyl chloride efficiently at −22—30°C. The best solvent was diethyl ether, but the degree of polymerization was the highest when no solvent was used ($\bar{P}_n = 1940$ at 20°C). The apparent activation energy for the rate of polymerization was 13.2 kcal/mol and the frequency factor was 9.06×10^4. The rate of polymerization, R_p, was equal to const. $\times [VC]^{3.90} \times [t\text{-BuMgCl}]^{1.98}$. Isopropylmagnesium bromide initiated the polymerization with less efficiency, and phenylmagnesium bromide was completely ineffective. Vinyl chloride and styrene were copolymerized in ether by *t*-butylmagnesium chloride at 30°C. The mole % styrene included in the copolymer was considerably different from those obtained by benzoyl peroxide at 48°C or by di-*t*-butylperoxy oxalate at 30°C.

Guyot and Tho investigated the polymerization of vinyl chloride in tetrahydrofuran with *t*-butylmagnesium chlorde, and suggested that the polymerization was anionic.[1-3] Their study was of great interest, since there have been no other papers on the anionic polymerization of vinyl chloride. However, their evidence did not seem convincing, and there was a paper reporting that the polymerization of vinyl chloride with Grignard reagents was of free radical nature.[4] Thus a more detailed study seemed to be desirable. This paper will describe the results of the investigation.

Experimental

Materials. Diethyl ether was shaken with one-tenth volume of a 10% sodium hydrogen sulfite solution for one hour, washed with a saturated sodium chloride solution containing 10% sodium hydroxide, then with a saturated sodium chloride solution containing some sulfuric acid, and twice with a saturated sodium chloride solution, dried over calcium chloride and then over sodium wire, and finally distilled over sodium under a nitrogen atmosphere at 34.5°C.

A *t*-butylmagnesium chloride solution was prepared in a 300 m*l* three-necked, round-bottomed flask from 1.46 g of magnesium turnings, 6.5 m*l* of *t*-butyl chloride and 150 m*l* of absolute ether under a nitrogen atmosphere. The supernatant solution was titrated and then used. The concentration was usually $1.5—2.0 \times 10^{-4}$ mol/*l*. Other Grignard solutions were prepared in a similar manner from halides and magnesium in absolute ether under a nitrogen atmosphere.

Styrene was distilled under reduced pressure before use. Vinyl chloride was passed through a silver nitrate solution and a calcium chloride tube, and then collected

in a pressure-tube cooled with a dry ice-methanol bath in a vacuum system.

Polymerization of Vinyl Chloride by *t*-Butylmagnesium Chloride. A pressure tube containing *t*-butylmagnesium chloride dissolved in ether was connected to a vacuum system under a nitrogen atmosphere, and cooled with a dry ice-methanol bath. A measured amount of deaerated vinyl chloride was distilled into the pressure tube, which was then sealed under a nitrogen atmosphere. Tubes were placed in a constant temperature bath and shaken by hand occasionally. After the polymerization was over, the ampoule was opened, and the polymer was washed with 6 N hydrochloric acid, water and methanol, and then dried under reduced pressure.

For the runs containing no ether, the ethereal solution of a Grignard reagent was evaporated to dryness in a vacuum, and then vinyl chloride was added to the residue. The mixture was then polymerized by the same procedure as described above.

Copolymerization of Vinyl Chloride with Styrene or Methyl Methacrylate by *t*-Butylmagnesium Chloride. A measured amount of deaerated vinyl chloride was distilled into the pressure tube containing *t*-butylmagnesium chloride and styrene or methyl methacrylate. The tubes were sealed under a nitrogen atmosphere, and placed in a constant temperature bath at 30.0°C. After appropriate intervals, the tubes were removed from the bath, cooled to −20°C, opened, and the content was poured into methanol. The polymer precipitated was filtered and washed with methanol until the filtrate formed no precipitates with a silver nitrate solution. The copolymer was dried and was burned in platinum wire within a flask, and chloride ions produced were titrated with 0.02 N mercuric nitrate solution.[5]

Copolymerization of Vinyl Chloride with Styrene by *t*-Butylperoxy Oxalate. *t*-Butylperoxy oxalate was prepared according to the method of Bartlett, Benzing and Pincock.[6] Procedures of polymerization and the work-up were the same as described above.

Results and Discussion

At first, the polymerization of vinyl chloride was attempted in tetrahydrofuran, but both the extent of conversion and the degree of polymerization were always smaller than those reported by Guyot and Tho.[3] After various solvents were investigated, diethyl ether was found to be an excellent medium for the polymerization. The degrees of polymerization reported by Guyot and Tho were 66—73, but those of polyvinyl chloride produced in diethyl ether were as large as 1455.[7] It was further found that in the absence of diethyl ether,

6) P. D. Bartlett, E. R. Benzing and R. E. Pincock, *J. Amer. Chem. Soc.*, **82**, 1762 (1960).

7) Recently a detailed investigation on the composition of Grignard compounds has been published, which has established that RMgX (X=Cl, Br, or I) exists as monomeric form in tetrahydrofuran, whereas in diethyl ether RMgCl exists as a dimer in both dilute and concentrated solutions and RMgBr and RMgI are monomeric at low concentrations (0.1 mol/*l*) and polymeric at higher concentrations. (F. W. Walker and E. C. Ashby, *J. Amer. Chem. Soc.*, **91**, 3845 (1969)).

i.e., with a solid Grignard reagent in liquid vinyl chloride, the degree of polymerization was as large as 1940. The results of polymerization are summarized in Table 1.

Run 1 shows that this polymerization proceeds even at −22°C though the rate is small. Runs 2—6 show that the degree of polymerisation increases with the extent of conversion; this behavior is not what is expected for free-radical polymerization. Runs 7—10 indicate that in the absence of ether the degree of polymerization is larger though the rate of polymerization is somewhat

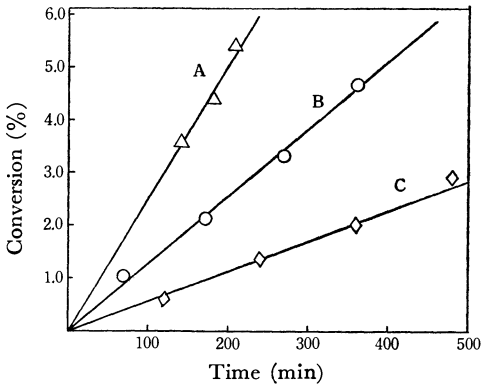

Fig. 1. Rates of polymerization of vinyl chloride at different temperatures.
A, 40.0°C; B, 30.5°C; C, 20.1°C; $[VC]_0=12.64$ mol/l, $[t\text{-BuMgCl}]_0=2.50\times10^{-2}$ mol/l

smaller. Runs 11—16 show that the larger the catalyst concentration the smaller the degree of polymerization. Runs 17—22 indicate that upon dilution of a mixture with ether the extent of conversion is unaltered, but the degree of polymerization decreases.

Figure 1 shows the rates of polymerization at different temperatures with solutions of the same composition. R_p was 1.25, 2.73, and 5.33×10^{-5} mol/l sec at 20.1, 30.5, and 40.0°C, respectively. Plots of log R_p *versus* $1/T$ yielded a straight line, and R_p was expressed as follows.

$$R_p = 9.06\times10^4\, e^{-\frac{13200}{RT}} \qquad (1)$$

The relationship between R_p and the initial concentration of *t*-butylmagnesium chloride is shown in Fig. 2. With $[VC]_0=11.23$ mol/l and at 30.1°C, R_p was 0.333, 3.85 and 9.76×10^{-5} mol/l sec when $[t\text{-BuMgCl}]_0$ was 0.0128, 0.0428 and 0.0711 mol/l, respectively. From the slope of the straight line, R_p was expressed as follows.

$$R_p = \text{const.}\times[t\text{-BuMgCl}]^{1.98} \qquad (2)$$

Figure 3 shows the relationship between the rates of polymerization and the concentration of vinyl chloride. From the slope of the straight line, R_p was expressed as follows.

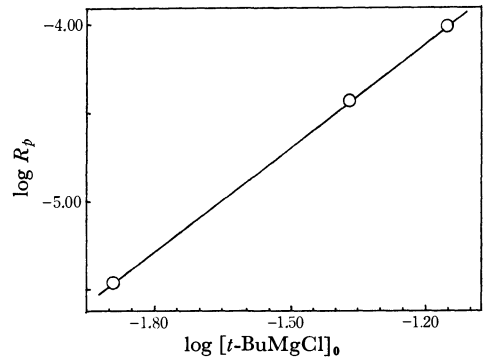

Fig. 2. Rates of polymerization of vinyl chloride with different catalyst concentration at 30.1°C.
($[VC]_0=11.23$ mol/l)

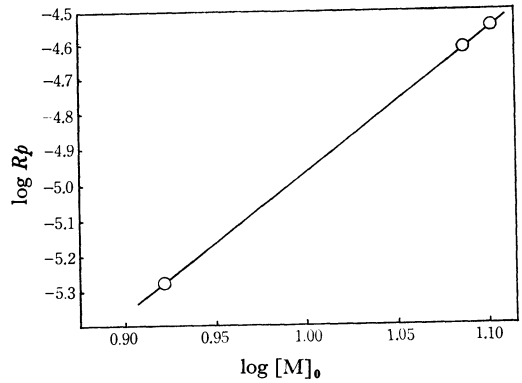

Fig. 3. Rates of polymerization of vinyl chloride with different monomer concentrations at 30.1°C.
($[t\text{-BuMgCl}]_0=2.50\times10^{-2}$ mol/l)

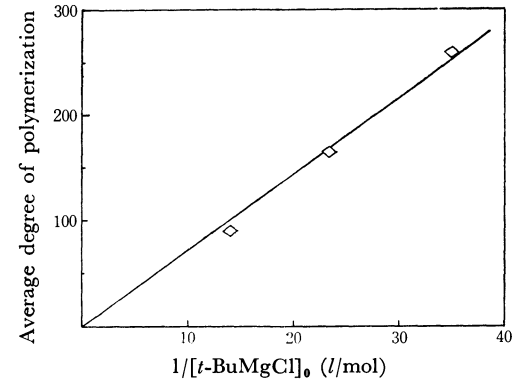

Fig. 4. Relationship between average degree of polymerization and catalyst concentration.
$[VC]_0=11.23$ mol/l, Conversion=3.0%, 30.1°C

$$R_p = \text{const.}\times[VC]^{3.90}[t\text{-BuMgCl}]^{1.98} \qquad (3)$$
(const. = 2.08×10^{-6} at 30°C)

The relationship between the average degree of polymerization and $1/[t\text{-BuMgCl}]_0$ is shown in Fig. 4.

As for other Grignard reagents, isopropylmagnesium bromide was found to initiate the polymerization with less efficiency and phenylmagnesium bromide initiated no polymerization. With $[i\text{-PrMgBr}]_0=0.058$ mol/l and $[VC]_0=12.51$ mol/l at 25.0°C, a polymer with $\bar{P}=625$ was obtained with 13% yield after 16 hr of polymerization. With $[PhMgBr]_0=0.288$ mol/l and $[VC]_0=7.30$ mol/l, no polymer was formed after 20 hr at 20.0°C or after 3 hr at 60°C.

The possible mechanisms of the initiation of the polymerization are (1) monomolecular homolytic decomposition of RMgX, (2) production of free radicals by the reaction between RMgX and vinyl chloride, (3) anionic polymerization, (4) polymerization by an anion-radical, and (5) polymerization by a complex involving magnesium.

The possibility of (1) was definitely excluded from the observation that an ethereal solution of *t*-butylmagnesium chloride underwent no decomposition when it was kept under a nitrogen atmosphere at room temperature for 25 days.

The frequency factor obtained from the Arrhenius plots was 9.06×10^4 which was smaller than the values found for ordinary radical polymerizations (10^6—10^8). Equation (3) is quite different from the equation applicable to ordinary radical polymerizations ($R_p=\text{const.}\times[VC]\times[\text{Initiator}]^{0.5}$).

In an attempt to clarify the mechanism of the initiation of polymerization by *t*-butylmagnesium chloride, copolymerization of vinyl chloride and styrene was investigated. The results are summarized in Table 2, and are compared with the results of a free radical polymerization in acetone by benzoyl peroxide at 48°C in Fig. 5. The mol % styrene included in the copolymer obtained by use of *t*-butylmagnesium chloride is considerably different from that obtained by use of benzoyl peroxide.[8] Since the difference in temperatures and solvents might be the cause for such discrepancy,

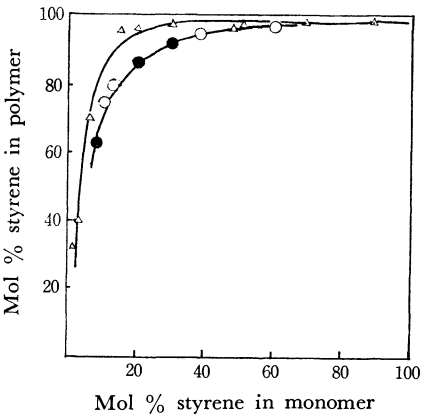

Fig. 5. Copolymerization of vinyl chloride and styrene.
△ with *t*-butylmagnesium chloride in ether at 30°C
○ with benzoyl peroxide in acetone at 48°C
● with di-*t*-butylperoxy oxalate in ether at 30°C

styrene and vinyl chloride were copolymerized in ether at 30°C by use of di-*t*-butylperoxy oxalate. Results are summarized in Table 3 and Fig. 5. These findings indicate that the polymerization initiated by *t*-butylmagnesium chloride is different from ordinary radical polymerization.

Copolymerization of vinyl chloride and methyl methacrylate by *t*-butylmagnesium chloride was attempted, and the results are shown in Table 4. The rates of polymerization were much greater than those of vinyl chloride and styrene, and the polymer obtained was the homopolymer of methyl methacrylate. Apparently the anionic polymerization of only methyl methacrylate took place. It is reasonable that vinyl chloride could not compete with methyl methacrylate, since methoxycarbonylcarbanion is far more stable than chlorocarbanion.

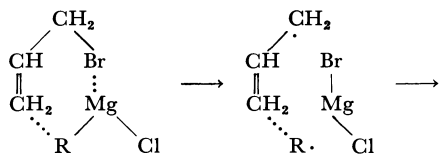
4.87	0.44	5	4.13	0	100
1.97	0.4	20	1.49	1.82	95.0

From the data on the copolymerization of styrene and vinyl chloride shown in Table 2, the monomer reactivity ratios r_1 and r_2 were calculated by means of Fineman and Ross' plots. The values obtained were r_1(styrene)=56 and r_2(vinyl chloride)=0. The values reported for the copolymerization with benzoyl peroxide were $r_1=35$ and $r_2=0.067$.[8]

Since the rate of conversion in the styrene-vinyl chloride was very low, the rate of polymerization of styrene alone by *t*-butylmagnesium chloride was determined. The initial rate of polymerization of styrene alone was 4.86×10^{-7} mol/*l* sec at 30.0°C when $[t\text{-BuMgCl}]_0$ was 0.57 mol/*l* and $[\text{styrene}]_0$ was 5.46 mol/*l*. The initial rate of polymerization of vinyl chloride alone was 9.76×10^{-5} mol/*l* sec at 30.0°C when $[t\text{-BuMgCl}]_0$ was 0.63 mol/*l* and $[\text{VC}]_0$ was 10.2 mol/*l*.

Gough and Dixon studied the reaction between allyl bromide and *t*-butylmagnesium chloride, and proposed that a radical mechanism is operative. They formulated the reaction as follows.[9]



$RCH_2\text{–}CH{=}CH_2$, *etc.*

They found that relative rates of reaction of alkylmagnesium halides with allyl bromide were *t*-BuMgCl 107, *s*-BuMgCl 22.6, *n*-BuMgCl 2.77 and PhMgCl 1.00. This variation in rates is somewhat in parallel with the variation in the efficiency of initiation by *t*-tubyl-, isopropyl-, and phenylmagnesium halides in this investigation. However, as a possible intermediate of the polymerization by *t*-butylmagnesium chloride a free radical is excluded on the basis of the findings that (1) the rate of polymerization was proportional to $[\text{VC}]^4\cdot[\text{Cat}]^2$ instead of $[\text{VC}][\text{Cat}]^{0.5}$, (2) the results of copolymerization by *t*-butylmagnesium chloride were different from those by benzoyl peroxide or *t*-butylperoxy oxalate, and (3) the frequency factor obtained from the Arrhenius plots of rates of polymerization was 9.06×10^4 which was smaller than the values found for ordinary radical polymerizations (10^6—10^8).

Another possible intermediate of this polymerization is an anion, but this possibility can be rejected on the basis of the finding that phenylmagnesium bromide failed to initiate the polymerization of vinyl chloride. It is not reasonable that *t*-butylmagnesium chloride initiates an anionic polymerization whereas phenylmagnesium bromide does not.

Other possible propagating species in this polymerization are an anion-radical or a complex involving magnesium.

Russel, Jansen and Strom have shown that butylmagnesium bromide in a tetrahydrofuran solution forms an anion-radical with a variety of nonbenzenoid aromatic compounds of aromatic ketones such as benzophenone of fluorenone.[10]

9) R. G. Gough and J. A. Dixon, *J. Org. Chem.*, **33**, 2148 (1968).

10) G. A. Russell, E. G. Jansen and E. T. Strom, *J. Amer. Chem. Soc.*, **86**, 1807 (1964).

$$[Bu:]^- + A \rightarrow [Bu\cdot + A^{\overline{\cdot}}] \rightarrow BuA^-$$

Maruyama has found that Grignard reagents react with ketones to form an anion-radical.[11]

$$RMgX + \overset{|}{\underset{|}{C}}{=}O \rightarrow [\overset{|}{\underset{|}{C}}\cdot{-}O^-] \rightarrow R\overset{|}{\underset{|}{C}}OMgX$$

Thus it is probable that an anion-radical is the propagating species in the polymerization by *t*-butylmagnesium chloride. Findings in this investigation excluded three other possible initiation mechanisms, namely (1) radical polymerization by monomolecular decomposition of *t*-butylmagnesium chloride, (2) radical polymerization by a reaction between *t*-butylmagnesium chloride and some other substances, and (3) anionic polymerization. At this stage it is not possible to determine whether the propagating species is an anion-radical or a complex involving magnesium.

Though the mechanism of initiation was not completely clarified, the investigation demonstrated that polymerization of vinyl chloride proceeded efficiently in the presence of *t*-butylmagnesium chloride in diethyl ether or in the absence of solvent at −22°—30°C, and the degree of polymerization of polyvinyl chloride thus obtained was as high as 1940.

Grateful acknowledgement is made to the donors of the Petroleum Research Fund, administered by the American Chemical Society, for support of this research.

Asymmetric Reactions. IV. An Attempted Asymmetric Reduction by a Solution of $[Co(CN)_5]^{3-}$ and Optically Active α-Amino Acid, and Its Reactive Species[1)]

Yoshiaki OHGO, Seiji TAKEUCHI and Juji YOSHIMURA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received August 1, 1969)

Reduction of various olefines by a solution of pentacyanocobaltate and glycine or optically active α-amino acid was studied. There is no essential difference between the reactivity of $[Co(CN)_5H]^{3-}$ to olefines and that of the solution of pentacyanocobaltate and α-amino acid. Atropic acid was reduced with the solution containing optically active α-amino acid (L-isoleucine) to give slightly optically active hydratropic acid. It was found that the main reactive species in the solution of $[Co(CN)_5]^{3-}$ and α-amino acid was $[Co(CN)_5H]^{3-}$ (this might be the reason for the asymmetric reduction not taking place effectively), and the reversible change between $[Co(CN)_5]^{3-}$ and $[Co(CN)_5H]^{3-}$ was observed depending on the pH of the solution.

It has been reported by Kwiatek *et al.* that many olefines are hydrogenated catalytically by $[Co(CN)_5]^{3-}$,[2)] and recently by Suzuki and Kwan that an aqueous equimolar solution of $[Co(CN)_5]^{3-}$ and α-amino acids or other acids reduces dienes to monoenes by the following mechanism.[3)]

$$[Co(CN)_5]^{3-} + R\text{-}\underset{\displaystyle NH_2}{\underset{|}{CH}}\text{-}COOH$$

$$\xrightarrow{-CN} \left[(CN)_4Co\begin{array}{l}NH_2\text{-}CH\text{-}R\\ |\\ O\text{-}C{=}O\\ /\\ H\end{array}\right]^{2-} \quad \text{(I)}$$

$$\xrightarrow{\text{electron transfer}} \left[(CN)_4Co\begin{array}{l}NH_2\text{-}CH\text{-}R\\ |\\ O - C{=}O\end{array}\right]^{2-} \quad \text{(II)}$$

$$+ 1/2\,H_2$$

$$2\left[(CN)_4Co\begin{array}{l}NH_2\text{-}CH\text{-}R\\ |\\ O\text{-}C{=}O\\ /\\ H\end{array}\right]^{2-} + CH_2{=}CH\text{-}CH{=}CH_2 \longrightarrow CH_3\text{-}CH{=}CH\text{-}CH_3 + II$$

Table 1. Hydrogenation of monoenes

Substrate	Solvent	Complex	Product and yield
	Pyridine and water	$[Co(CN)_5H]^{3-}$ (a)	(c)
		Co-Gly (b)	(d)
	Water	$[Co(CN)_5H]^{3-}$ Co-Gly	(e)
	Pyridine and water	$[Co(CN)_5H]^{3-}$ Co-Gly	(e)
	Ethanol and water	$[Co(CN)_5H]^{3-}$ Co-Gly	(e)
	Water	$[Co(CN)_5H]^{3-}$ Co-Gly	(e)
	Water	Co-Gly	 (f)	Water	Co-Gly	 (f)	Water	Co-Gly	 Quantitatively
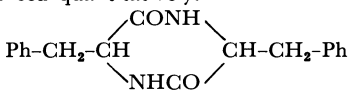
		Co-L-Isol (b)	(g)

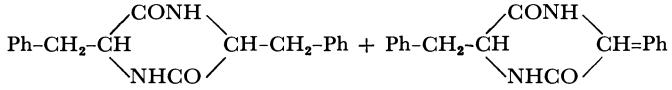
(a) Reaction time of catalytic hydrogenation by $[Co(CN)_5]^{3-}$ was 4 to 5 days at room temperature.

(b) Co-Gly or Co-L-Isol represents the solution of $[Co(CN)_5]^{3-}$ and glycine or L-isoleucine. Reaction time was 1 day at room temperature.

(c) Both double bonds were reduced quantitatively.



(d) Mixture of fully and partially hydrogenated products was obtained.



(e) The starting material was recorded quantitatively.

(f) These material were known to be reduced by $[Co(CN)_5H]^{3-}$.[2]

(g) Raw product had $[\alpha]_D$ +0.2° but distillate had slightly negative rotation which was converted to acylthiourea derivative ($[\alpha]_{436}$ −0.2°).

They suggested that dienes are reduced to monoenes *via* coordination to the cobalt (Co^{II}) of the intermediate complex (I).

If monoenes which form asymmetric carbon after reduction can be reduced with the solution of $[Co(CN)_5]^{3-}$ and optically active α-amino acid by the similar mechanism, the coordination of monoenes to the intermediate complex (I) will be affected stereospecifically by the optically active α-amino acid, and an asymmetric reduction will take place.

This paper gives a comparison of the reactivity of a solution of $[Co(CN)_5]^{3-}$ and α-amino acid with that of $[Co(CN)_5H]^{3-}$ to monoenes, and a discussion on whether asymmetric reduction takes place.

Results and Discussion

The results of hydrogenation with a solution of $[Co(CN)_5]^{3-}$ and glycine are summarized in Table 1 in comparison with that of $[Co(CN)_5H]^{3-}$.

As shown in Table 1, the reactivities of $[Co(CN)_5H]^{3-}$ and Co-Gly are similar to each other, and atropic acid is reduced to hydratropic acid quantitatively.

Experiments were carried out to see whether an asymmetric reduction would occur, using atropic acid as substrate and L-isoleucine as an optically active α-amino acid (in an aqueous solution of $[Co(CN)_5^{3-}]$). Atropic acid was reduced by this solution quantitatively to give crude hydratropic acid having slightly positive rotation ($[\alpha]_D+0.2°$), but the optical acivity of hydratropic acid purified by distillation changed to a very small negative value. The acylthiourea derivative of the hydratropic acid was synthesized and the ORD spectrum[4] was measured in order to identify the substance having slightly negative rotation with hydratropic acid. However, because of the very low optical activity ($[\alpha]_{436}-0.2°$) of the purified acylthiourea derivative ($\begin{matrix}Ph\\CH_3\end{matrix}\!\!>\!CH_3\text{-}CH\text{-}CONH\text{-}\overset{\overset{S}{\|}}{C}\text{-}S\text{-}N(C_2H_5)_2$), identification of the optically active material by ORD spectrum failed. Nevertheless, we could not consider it due to contaminant, because the sample was extremely pure. If this optical activity is that of acylthiourea derivative of hydratropic acid, the optical yield is 0.1% (acylthiourea derivative of optically pure hydratropic acid has $[\alpha]_{436}-200°$).

The fact that the reactivities of $[Co(CN)_5H]^{3-}$ and Co-Gly are similar to each other and the optical yield is very small lets us deduce that the intermediate complex such as I to which α-amino acid coordinates directly may not play an essential role in this hydrogenation reaction. On the other hand, it is known that dienes are reduced to monoenes by a solution of $[Co(CN)_5]^{3-}$ and organic or inorganic acids[3] instead of α-amino acids, and the formation of $[Co(CN)_5H]^{3-}$ by aging of an aqueous solution of $[Co(CN)_5]^{3-}$ is promoted by cesium chloride and other salts.[5] Thus, it was deduced that α-amino acid might promote the aging reaction as cesium chloride. As metal hydride signal of $[Co(CN)_5H]^{3-}$ was known to be observed at high magnetic field of the nuclear magnetic resonance spectrum,[6] the NMR spectrum of Co-Gly was measured. The results are shown in Table 2 and Fig. 1.

Fig. 1. NMR spectrum.

Metal hydride signal was observed at high magnetic field and the chemical shift of the hydride formed in Co-Gly was almost the same as that of $[Co(CN)_5H]^{3-}$, and the amount of the hydride did not depend on the amount of α-amino acid (glycine). Thus, this hydride is considered to be $[Co(CN)_5H]^{3-}$ and the main reactive species in the hydrogenation with the aqueous solution of $[Co(CN)_5]^{3-}$ and glycine, *i.e.* α-amino acid. It was also found that the pH of the solution was an important factor in the formation of $[Co(CN)_5H]^{3-}$ from the following experiment. The color of the solution of $[Co(CN)_5]^{3-}$ changes from green to yellow and *vice versa* depnending on the pH:[7]

$$\underset{\text{green}}{[Co(CN)_5]^{3-}} \underset{\text{pH increase on addition of NaOH}}{\overset{\text{pH decrease on addition of glycine}}{\rightleftharpoons}} \text{yellow}$$

The spectrophotometric change of an aqueous solution of $[Co(CN)_5]^{3-}$ and glycine is shown in Fig. 2. Absorption of $[Co(CN)_5]^{3-}$ at 970 mμ[8] decreased gradually on standing for 16 hr at room temperature, and increased on addition of an

6) W. P. Griffith and G. Wilkinson, *J. Chem. Soc.*, **1959**, 2757.

7) The pH of a solution of $Co(CN)_5^{-3}$ prepared by dissolving $CoCl_2\cdot 6H_2O$ (3.18 g) and KCN (4.5 g) in H_2O (26 m*l*) was about 13. On addition of molar equivalent glycine the pH decreased to 9.5.

6 3 hr
7 19 hr

aqueous sodium hydroxide. From this it is apparent that there is an equillibrium $[Co(CN)_5]^{3-} \rightleftharpoons [Co(CN)_5H]^{3-}$ in the solution of $[Co(CN)_5]^{3-}$ and glycine, and the equillibrium shifts to the right with decrease of pH and to the left by the addition of alkali.[9] Consequently, the following reactions are considered to occur mainly in the hydrogenation with the solution of $[Co(CN)_5]^{3-}$ and α-amino acid.

(A) $2[Co(CN)_5]^{3-} + H_2O \rightleftharpoons [Co(CN)_5H]^{3-} + [Co(CN)_5OH]^{3-}$

(B) $[Co(CN)_5H]^{3-} +$  $\xrightarrow{H_2O}$  $+ [Co(CN)_5OH]^{3-}$

(C) $[Co(CN)_5OH]^{3-} + R\text{-}CH(NH_2)\text{-}COOH \longrightarrow$  (II) $+ H_2O$

The reactive species $[Co(CN)_5H]^{3-}$ formed in the reaction (A) which is promoted by α-amino acid reduces olefine to saturated compound in the reaction (B). $[Co(CN)_5OH]^{3-}$ formed incidentally with $[Co(CN)_5H]^{3-}$ reacts with α-amino acid to give the complex(II) isolated by Suzuki and Kwan.[3]

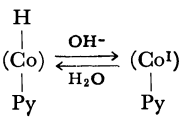
Thus, the asymmetric grouping of the optically active amino acid can not effectively control the coordination of olefines to the metal of the reactive species.

Experimental

Reduction of Monoenes by a Solution of $[Co(CN)_5]^{3-}$ and Glycine, or $[Co(CN)_5H]^{3-}$. The solution of $[Co(CN)_5]^{3-}$ and glycine was prepared by Kwan's method.[3] In the case of $[Co(CN)_5H]^{3-}$, 1/2 mole of the substrate was used to 1 mole of cobalt chloride, and 1/3 mole in the case of the solution of $[Co(CN)_5]^{3-}$ and glycine. Water-insoluble substrates were reacted in the mixture of water and organic solvents (see Table 1), and recovered by the addition of a large amount of water. Carboxylic acids were used as sodium salts, and the products were extracted with ether after acidification with hydrochloric acid.

Reduction of Atropic Acid by a Solution of $[Co(CN)_5]^{3-}$ and L-Isoleucine. To a solution of 9.4 g of cobalt chloride (0.04 mol) in 100 ml water, 13.0 g of potassium cyanide (0.20 mol) in 40 ml of water was added. When the solution became homogeneous and dark green, 5.2 g of L-isoleucine (0.04 mol) dissolved in 200 ml of water was added. The color of the solution turned to yellow within 10 min and 2.0 g of sodium atropate (0.013 mol) in 40 ml of water was then added. All the procedure was carried out under nitrogen atmosphere. After 1 day the solution was acidified with

9) An analogous phenomenon was observed in formation of alkylcobaloximes. Near neutral medium only α-substitutedcobaloximes was formed and alkaline solution addition in the β-position took place. In order to explain the differences Schranzer and Windgassen postulated an pH-dependent equilibrium. G. N. Schrauzer and R. J. Windgassen, *J. Amer. Chem. Soc.*, **89**, 1999 (1967).



hydrochloric acid and extracted with ether and dried with calcium chloride. The ether solution was evaporated and 1.7 g of residual oil was obtained. This was found to be identical with the authentic hydratropic acid in IR spectrum. The optical activity of the product was slightly positive ($[\alpha]_D+0.2°$, *c* 10, ethanol), and no contamination of L-isoleucine in the product was detected by paper chromatography, using *n*-butanol saturated with water as a developing solvent and ninhydrin or BTB as coloring reagents (R_f: L-isoleucine 0.31, hydratropic acid 0.89, product 0.88). However, the optical activity of the material which was obtained by distillation of the product showed a slightly negative rotation. The main fraction was distilled at 82—83°C/0.05 mmHg and 1.45 g of purified material was obtained. The acylthiourea derivative of the purified hydratropic acid was synthesized[4] and the crude crystals obtained was recrystallized twice from *n*-hexane and about 0.5 g of crystals was obtained, mp 106—7°C. The silica-gel TLC showed one spot (developing solvent; ethyl acetate: pyridine= 1 : 1). Elemental analysis was as follows, Found: C, 63.94; H, 7.54; N, 10.25; S, 12.28%. Calcd for $C_{14}H_{20}N_2OS$: C, 63.61; H, 7.63; N, 10.60; S, 12.13%. The specific rotation was $[\alpha]_{436}$ −0.2° (*c* 12, benzene) and the optical yield was only 0.1%.

Measurement of NMR Spectra. The NMR spectrum was measured with a JNM-4H-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.) at 100 Mc/sec. The concentration of the solution of $[Co(CN)_5]^{3-}$ and glycine was 0.5 M (0.18 g) of $CoCl_2 \cdot 6H_2O$ in 25 m*l* of water). As internal standard sodium acetate was used and the quantity of the hydride formed in the solution was estimated from the ratio of the integration of the hydride signal to that of sodium acetate. The average value taken from integration repeated a few times was used.

The authors are grateful to Ajinomoto Co., Inc., for the gift of amino acids, to Dr. Khoko Tanabe for the measurement of ORD spectra and to Mr. Kiyoshi Fukukawa for the measurement of NMR spectra.

The Thermal Reaction of 3-Acetylguaiazulene with Sulfur

Shinji KUROKAWA

Department of Chemistry, Faculty of Education, Saga University, Honjyô-machi, Saga

(Received August 9, 1969)

When 3-acetylguaiazulene was heated with sulfur at 200°C, three new azulenoids were obtained, in addition to the S-guaiazulene formed by the loss of the acetyl group; the structures were established as 2-acetylguaiazulene, 6-acetyl-, and 7-acetyl-3,5,8-trimethylazuleno[6,5-*b*]thiophenes. From the experimental results it became obvious that a sulfur atom linked one methyl carbon atom of the isopropyl group with the C_6-azulene-ring carbon atom in 3-acetylguaiazulene, resulting in the formation of a thiophene ring, and also that the loss and the migration of the acetyl group took place in 3-acetylguaiazulene as well. The acetyl migration in this compound was ascertained to be a simple thermal reaction and to occur in one direction, from C_3 to C_2.

In the previous works on the thermal reaction of S-guaiazulene or vetivazulene with sulfur, the formations of 3,5,8-trimethylazuleno[6,5-*b*]thiophene[1,2] and 3,5,9-trimethylazuleno[1,2-*b*]thiophene[3] have been reported. The present investigation will be concerned with the thermal reaction between sulfur and 3-acetylguaiazulene (I), which contains both alkyl and acetyl substituents.

Results and Discussion

Structural Elucidation of the Reaction Products. 3-Acetylguaiazulene (I) was heated with sulfur powder at 200°C. When the reaction mixture was subjected to step-by-step elution chromatography, three new compounds were isolated in addition to a small amount of S-guaiazulene (II), as is shown in Table 1. On these compounds, structural elucidation was carried out as follows.

a) 2-Acetylguaiazulene (III). The green crystalline substance, mp 80—81°C, which was isolated as the major product in this reaction had the same molecular formula, $C_{17}H_{20}O$, as the 3-acetylguaiazulene used as the starting material, but it was different in that is easily formed 2,4-dinitrophenylhydrazone, mp 246—247°C. The carbonyl group of this compound was an acetyl group from a methyl singlet (2.72 ppm) which can be assigned to an acetyl group in the NMR spectrum (Fig. 1-B), and from prominent peaks at *m/e* 43 and 197 (m^*= 161.7) in the mass spectrum which may, respec-

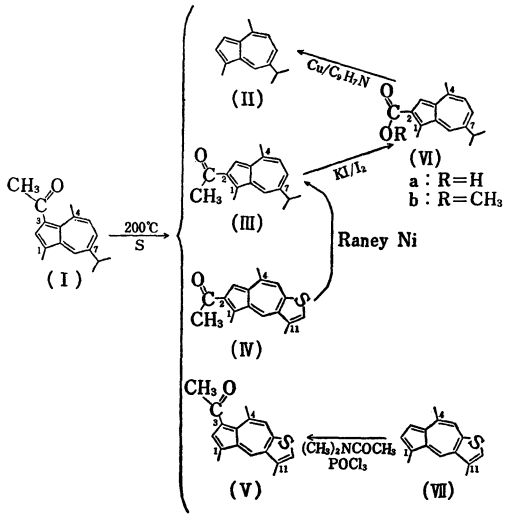

Chart 1*1

tively, be ascribed to CH_3CO^+ and $(M-CH_3CO)^+$ ions.[4]

When the compound was oxidized by hypoiodite and the resulting acid (VIa) of green plates, mp 150—161°C, was subsequently decarboxylated by heating it with copper powder in quinoline, S-guaiazulene (II) was obtained in a good yield. Thus, the compound is thought to be a monoacetyl derivative of S-guaiazulene, which differs from 3-acetylguaiazulene in the position of the acetyl group. This deduction was, furthermore, supported by the fact that the signals of an isopropyl group (1.33 and 3.08 ppm) and a signal of two methyl groups attached to an aromatic ring system (2.83 ppm) were seen in the NMR spectrum of the compound.

The compound exhibited two visible absorption maxima of nearly equal intensities at 637 and 692 mμ. When those hypsochromic shifts from the maximum of S-guaiazulene (607 mμ) are analyzed according to the Plattner rule,[5] three positions of the azulene nucleus, C_2, C_6, and C_8, are possible for the acetyl group.

On the other hand, the aromatic-proton region

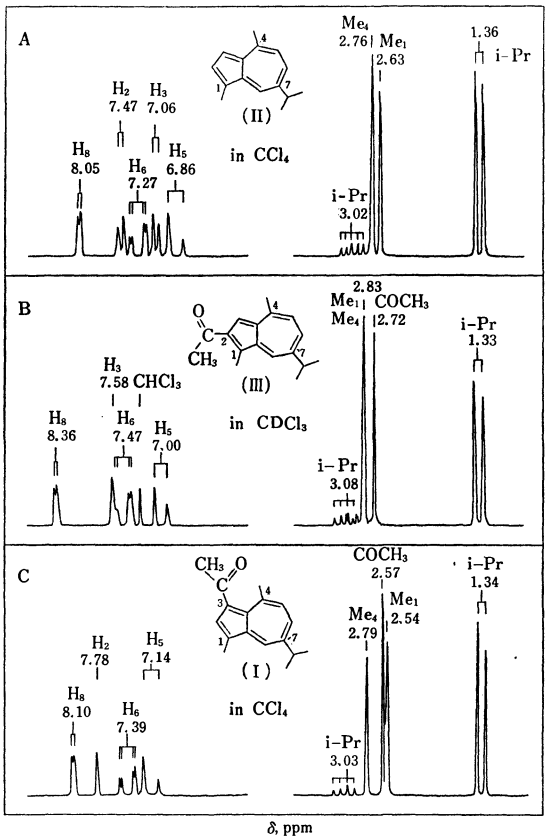

Fig. 1. NMR spectra of S-guaiazulene (A), 2-acetylguaiazulene (B) and 3-acetylguaiazulene (C).

of the NMR spectrum (Fig. 1-B) held four-proton signals. In comparison with the spectra of S-guaiazulene (Fig. 1-A)[6] and 3-acetylguaiazulene (Fig. 1-C), two doublets (2H) at 7.00 and 8.36 ppm can reasonably be assigned to H_5 and H_8, and the remaining signals (2H) from 7.31 to 7.58 ppm, to H_6 and H_3. As for the latter signals, it is thought that a part of a double doublet*2 (J=11.0, 2.0 Hz, 1H) centered at 7.47 ppm, to which H_6 is assigned, overlaps on the foot of the singlet of 7.58 ppm attributed to H_3. By such assignments, the coupling constants, $J_{5,6}$=11.0 Hz and $J_{6,8}$=2.0 Hz, are found to be in good agreement with those of 7-substituted azulene.

From the three positions, C_2, C_6, and C_8, shown to be possible by the visible absorption spectrum, C_6 and C_8 were thus excluded, and the structure of this compound was determined to be 2-acetylguaiazulene (III).

*1 The skeleton numbering of the azulenothiophenes according to the IUPAC nomenclature, used only for the name of the compound, is as follows:

For convenience in comparing these substances with the acetylguaiazulenes in terms of the NMR data, the numbering system in the azulene compounds was generally adopted for the azulenothiophenes in this paper.

6) D. Meuche, B. B. Molloy, D. H. Reid and E. Heilbronner, *Helv. Chim. Acta*, **46**, 2483 (1963).

*2 The appearance of the double doublet due to H_6 can be expected from the signals of H_5 and H_8 observed as doublets.

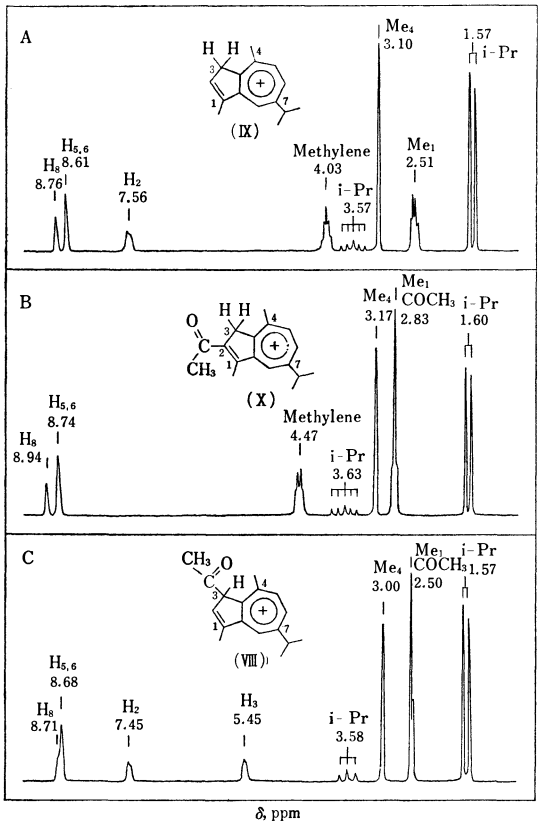

Fig. 2. NMR spectra of conjugate acids of S-guaiazulene (A), 2-acetylguaiazulene (B) and 3-acetylguaiazulene (C) (in CF_3COOH).

In addition, the NMR spectrum (Fig. 2-B) taken in a trifluoroacetic acid solution had no signal to be assigned to an olefinic proton, H_2 (*cf.* Fig. 2-A and 2-C). This fact can be well explained by the structure of the conjugate acid of 2-acetylguaiazulene (III).

b) 6-Acetyl-3,5,8-trimethylazuleno[6,5-b]thiophene (IV). Dark brown needles (mp 162—163°C) with a molecular formula of $C_{17}H_{16}OS$ were isolated from a benzene-eluted fraction in the elution chromatography of the reaction products. This compound gave a green oxime, mp 223—224°C, and exhibited prominent fragment ions of *m/e* 225 (base peak, $m^*=188.8$, $(M-CH_3CO)^+$) and *m/e* 43 (CH_3CO^+) in the mass spectrum. Thus, it is certain that the compound also contains an acetyl group.

When the compound was subjected to reductive desulfurization by heating it with a Raney nickel catalyst, the 2-acetylguaiazulene (III) described in the preceding section was obtained. In the NMR spectrum of this sulfur-containing compound (Fig. 3-B), moreover, there is a singlet (8.34 ppm, 1H) corresponding to the H_8 of 2-acetylguaiazulene, but there are no signals which can be attributed to the isopropyl group or to H_6, which are both present in the spectrum of the original compound. The result of the reductive desulfurization and the NMR evidence lead to the conclusion that the compound is 6-acetyl-3,5,8-trimethylazuleno[6,5-*b*] thiophene (IV), which may be derived from 2-acetylguaiazulene through the formation of a sulfur bond between one methyl carbon atom of the isopropyl group and the C_6 of the azulene nucleus.

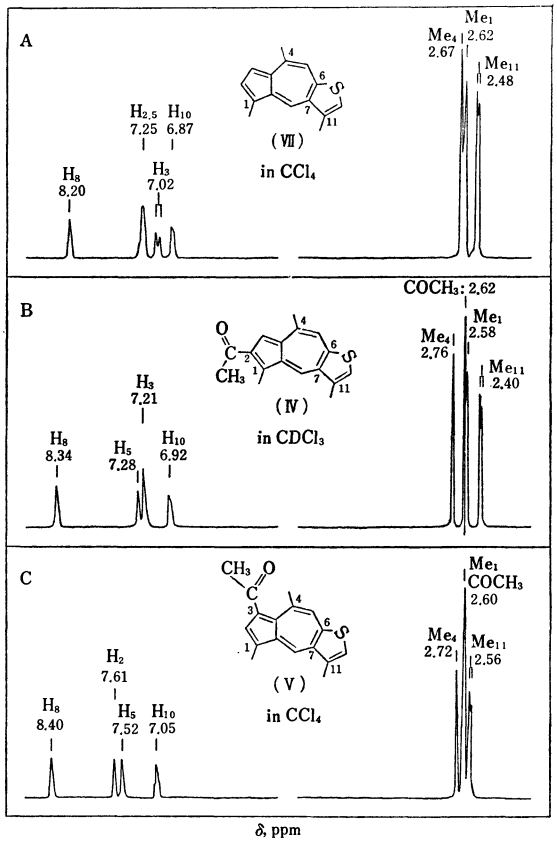

Fig. 3. NMR spectra of 3,5,8-trimethylazuleno-[6,5-*b*]thiophene (A), and its 6-acetyl- (B) and 7-acetyl derivatives (C).

This structure is further supported by the facts that the UV (λ_{max} 324 mμ) and visible absorption spectra (λ_{max} 625 mμ and 668 mμ) show hypsochromic shifts*3 as compared with those of azulenothiophene,[1,2] and that the NMR spectrum (Fig. 4-B) taken in a trifluoroacetic acid solution exhibits the signals assigned to Me_1 (2.95 ppm, 3H) and C_3-methylene (4.49 ppm, quartet, 2H), but has no peak corresponding to H_2 (*cf.* Fig. 4-A).

c) 7-Acetyl-3,5,8-trimethylazuleno[6,5-b]thiophene (V). The third product was brown needles (mp 141—142°C) whose molecular formula,

*3 According to the Plattner rule,[5] this hypsochromic shift of the visible absorption maximum indicates that the acetyl group exists on the C_2 or C_6 of the azulenothiophene nucleus.

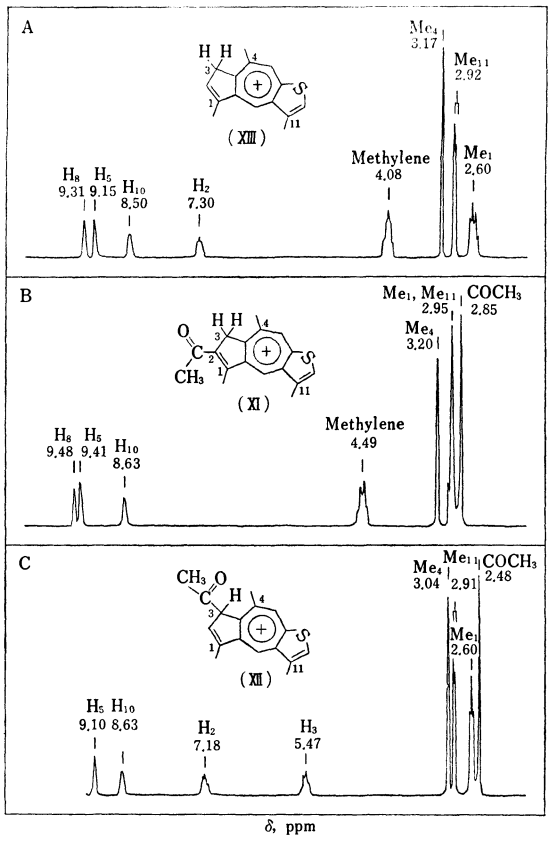

Fig. 4. NMR spectra of conjugate acids of 3,5,8-trimethylazuleno[6,5-*b*]thiophene (A), 6-acetyl-3,5,8-trimethylazuleno[6,5-*b*]thiophene (B) and 7-acetyl-3,5,8-trimethylazuleno[6,5-*b*]thiophene (C)*4 (in CF_3COOH).

$C_{17}H_{16}OS$, was the same as that of the foregoing compound, 6-acetyl-3,5,8-trimethylazuleno[6,5-*b*]-thiophene. This compound also had an acetyl group, as was indicated by the strong carbonyl band at 1650 cm^{-1} and by the fragment ions at *m/e* 253 (base peak, $m^*=238.8$) and at *m/e* 225 ($m^*=200.0$), which were correlated with, respectively, $(M-CH_3)^+$ and $(M-CH_3-CO)^+$. Besides, the NMR spectrum of the compound has a remarkable resemblance to that of 6-acetyl-3,5,8-trimethylazuleno[6,5-*b*]thiophene, as is shown in Fig. 3-C and 3-B. The evidence presented above suggests that the compound has a structure closely related to that of the 6-acetyl derivative.

However, the NMR spectrum (Fig. 4-C) taken in trifluoroacetic acid is extremely different from that of the 6-acetyl derivative (Fig. 4-B); two multiplets similar to those of the 3-acetylguaiazulenium cation (Fig. 2-C) and which can be assigned to H_3 and H_2 appear at 5.47 (1H) and 7.18 ppm (1H) respectively, but a methylene signal seen in the spectra of conjugate acids of azulenothiophene and 6-acetylazulenothiophene (Fig. 4-A and 4-B) is absent. This evidence indicates that this compound is 7-acetyl-3,5,8-trimethylazuleno[6,5-*b*]-thiophene (V).

Furthermore, this structure was proved by its synthesis through the Vilsmeier acetylation[7] of 3,5,8-trimethylazuleno[6,5-*b*]thiophene.

Sequence of the Reaction. As is shown in Table 1, the main product of this reaction was 2-acetylguaiazulene, formed through the migration of the acetyl group in the starting material; the second product was 6-acetyl-3,5,8-trimethylazuleno-[6,5-*b*]thiophene, formed by the reaction of the 2-acetylguaiazulene with sulfur. S-Guaiazulene and 7-acetyl-3,5,8-trimethylazuleno[6,5-*b*]thiophene were obtained as minor products.

In order to clarify the effect of sulfur on the migration and the loss of the acetyl group, 3-acetylguaiazulene was heated at 200°C for 2 hr without sulfur. In this reaction, 2-acetylguaiazulene (16.4%) and S-guaiazulene (1.4%) (*cf.* Experimental section) were obtained in yields similar to those of the thermal reaction of 3-acetylguaiazulene with sulfur. Hence, the migration and the loss of the acetyl group in 3-acetylguaiazulene seem to depend upon the reaction temperature and to be hardly affected at all by sulfur.

On the other hand, when 2-acetylguaiazulene was heated at 200°C in a nitrogen atmosphere or at 300°C in a sealed tube, no appreciable isomerized product was obtained; only the original material was recovered.

Thus, the migration of the acetyl group in the thermal reaction of 3-acetylguaiazulene is not such a reversible reaction as that observed between 1-phenyl and 2-phenylazulenes,[8] but an irreversible reaction proceeding from 3-acetylguaiazulene to 2-acetylguaiazulene. This difference between acetylguaiazulenes and phenylazulenes may result from the fact that the difference in the potential energy between 2-acetyl- and 3-acetylguaiazulenes is much greater than that between phenylazulenes. Further investigation into this point is presently in progress in this laboratory.

Experimental

All the melting points in this paper are uncorrected. The IR spectra were measured using KBr disks. The NMR spectra were obtained at 60 M Hz. The mass spectra were taken at 70 eV. Thin-layer chromatography (TLC) was conducted by the use of silica gel G (Merck), while vapor-phase chromatography (VPC) was carried out by using a stainless steel column (1 m×

*4 The concentration of this sample was so small that the H_8 signal, being covered with the peaks originating from CF_3COOH (spin side band, impurities, *etc.*), could not be identified.

3 mm) packed with 10% NGS on Diasolid L.

3-Acetylguaiazulene (I). This compound was synthesized from S-guaiazulene (II) and acetyl bromide according to the method of Reid *et al.*[9] It was obtained as purple plates (mp 88.2—88.8°C) after being recrystallized from a mixed solvent of petroleum ether and methanol, which showed a single brown spot (R_f, 0.17) in TLC using benzene.

Thermal Reaction of 3-Acetylguaiazulene (I) with Sulfur. 3-Acetylguaiazulene (1.00 g) was heated with half as much powdered sulfur at 200°C on an oil bath for 4 hr under a nitrogen atmosphere. The reaction mixture, which solidified at room temperature, was crushed into small fragments in the reaction vessel; then it was taken out, ground to powder in a mortar, and extracted with benzene. A black oil (320 mg) thus obtained was chromatographed on activated alumina (Merck II—III); after the non-azulenic components had been eluted out with *n*-hexane, the solvents being changed step by step, the four fractions shown in Table 1 were separated depending upon the color.

2-Acetylguaiazulene (III). Green crystals of Fr. 2 (170 mg), which had been collected by repeating the thermal reaction, were developed on a silica-gel column with a mixed solvent of ether and *n*-hexane (1 : 19). The part of a blue-colored main adsorption band was cut off and extracted with the same mixed solvent to yield green crystals (130 mg), which gave green needles (mp 80.0—81.0°C) after being recrystallized twice from methanol. This compound showed a single green spot (R_f, 0.36) in TLC with an ether-*n*-hexane (1 : 19) mixture. IR: 1666 cm^{-1} (C=O). UV: $\lambda_{max}^{cyclohexane}$ mμ (log ε) 250 (4.40), 301.5 (4.63), 345 (3.74), 360 (3.76), 370 sh (3.30). Visible absorption spectrum: $\lambda_{max}^{cyclohexane}$ mμ (ε) 637 (656), 692 (650).

Found: C, 84.83; H, 8.15%. Calcd for $C_{17}H_{20}O$: C, 84.96; H, 8.39%.

The 2,4-dinitrophenylhydrazone of this compound was obtained by using a mixed solvent of ethanol and phosphoric acid[10] as a reddish-brown powder. After being recrystallized twice from benzene, it showed a mp of 246.0—247.0°C. IR: 1526, 1328 cm^{-1} (NO_2).

Hypoiodite Oxidation of 2-Acetylguaiazulene (III). A solution of 2-acetylguaiazulene (III) (170 mg) in dioxane (22 m*l*) was gradually mixed with a 10% aqueous sodium hydroxide solution (23 m*l*). To this mixture, kept at 60°C, an aqueous solution (8.2 m*l*) containing iodine (820 mg) and potassium iodide (1.64 g) was stirred in, drop by drop, over a 10-min period; the stirring was then continued for an additional 20 min at 60°C. At the end of this period, the excess iodine was reduced with a saturated aqueous solution of sodium hydrogen sulfite. The reaction mixture was chilled to 0°C and filtered to remove the precipitate of the iodoform. When the filtrate, from which unchanged 2-acetylguaiazulene was removed by dilution with water (30 m*l*) and subsequent extraction with chloroform, was acidified with 2 N hydrochloric acid, S-guaiazulene-2-carboxylic acid (VIa) (120 mg) was obtained as a green crystalline substance, mp *ca.* 145°C. This crude substance was further purified by sublimation at 220—250°C and 1.5 mmHg to give green prisms, mp 150—161°C. These crystals showed a dispersed blue spot (R_f, 0—0.18) in TLC with benzene; the spot turned yellow when sprayed with a solution of bromocresol green. IR: 1670 (C=O), 1260 (coupled C–O and O–H), 952 cm^{-1} (O–H, out-of-plane deformation). NMR: $\delta_{TMS}^{CDCl_3}$ 2.82 (s, 3H; Me_1), 7.78 (s, 1H; H_3), 2.90 (s, 3H; M_4), 7.03 (d, 1H; H_5), 7.47 (q, 1H; H_6), 1.36/3.08 (d, 6H/m, 1H; *i*-Pr), 8.38 (d, 1H; H_8). $\delta_{TMS}^{CF_3COOH}$ 2.68 (t, 3H; Me_1), 4.23 (q, 1H; H_3), 2.97 (s, 3H; Me_4), 8.66 (s, 2H; $H_{5,6}$), 1.41/3.43 (d, 6H/m, 1H; *i*-Pr), 8.85 (s, 1H; H_8). MS: *m/e* 242 (M^+, $C_{16}H_{18}O_2$), 39.3%; *m/e* 227 $(M-CH_3)^+$ (m*=212.9), 42.3%; *m/e* 197 $(M-COOH)^+$, 11.0%; *m/e* 28 (CO^+), base peak.

Preparation of the Methyl Ester of S-Guaiazulene-2-carboxylic Acid (VIb). Crude S-guaiazulene-2-carboxylic acid (VIa) (70 mg) was dissolved into an ethereal solution of diazomethane prepared from nitrosomethylurea (4 g) in the usual manner; the solution was then allowed to stand at room temperature for 8 hr. After the excess diazomethane had been decomposed by adding a few drops of acetic acid, the solvent was distilled off under reduced pressure to give an oily residue (250 mg). The residue was then eluted through a silica-gel column with a mixed solvent of benzene and ether (1 : 1); the methyl ester of S-guaiazulene-2-carboxylic acid (VIb) (60 mg) was thus isolated as a blue oil. It showed a single blue spot (R_f, 0.47) in TLC using benzene - ether (1 : 1) mixture. IR: 1710 (C=O), 1230 and 1068 cm^{-1} (C–O). UV: $\lambda_{max}^{cyclohexane}$ mμ (log ε) 248.5 (4.29), 290 sh (4.47), 298.2 (4.52), 310 sh (4.33), 340 (3.59), 355.8 (3.69). Visible absorption spectrum: $\lambda_{max}^{cyclohexane}$ mμ (ε) 631 (484), 680 (468). NMR: $\delta_{TMS}^{CCl_4}$ 2.75 (s, 3H; Me_1), 3.88 (s, 3H; COOMe),

9) D. H. Reid, W. H. Stafford and W. L. Stafford, *J. Chem. Soc.*, **1958**, 1118.

10) G. D. Johnson, *J. Amer. Chem. Soc.*, **73**, 5888 (1951).

7.52 (s, 1H; H_3), 2.80 (s, 1H; H_4), 6.86 (d, 1H; H_5), 7.29 (q, 1H; H_6), 1.33/3.02 (d, 6H/m, 1H; i-Pr), 8.22 (d, 1H; H_8). $\delta_{TMS}^{CF_3COOH}$ 2.85 (t, 3H; Me_1), 4.16 (s, 3H; COOMe), 4.41 (q, 1H; H_3), 3.16 (s, 3H; Me_4), 8.75 (s, 2H; $H_{5,6}$), 1.60/3.63 (d, 6H/m, 1H; *i*-Pr), 8.94 (s, 1H; H_8). MS: *m/e* 256 (M^+, $C_{17}H_{20}O_2$), 87.5%; *m/e* 241 $(M-CH_3)^+$(m^*=226.9), base peak; *m/e* 225 $(M-OCH_3)^+$, 17.7%.

Decarboxylation of S-Guaiazulene-2-carboxylic Acid (VIa). A solution of crude S-guaiazulene-2-carboxylic acid (VIa) (30 mg) in quinoline (2 m*l*) was refluxed with copper powder (30 mg) for 1 hr on a sand bath. The reaction mixture was then diluted with *n*-hexane and subsequently filtered. The filtrate, after being washed with 1N hydrochloric acid and then with a 2N aqueous sodium carbonate solution to take quinoline and the unchanged acid away, was concentrated under reduced pressure to give a crude blue oil (30 mg). This oil was subsequently chromatographed on a silica-gel column with *n*-hexane; a blue oil (8.3 mg) was thus isolated in a pure state. The oil thus obtained was identical with an authentic specimen of S-guaiazulene (II) in TLC, VPC, and IR spectrometry.

6-Acetyl-3,5,8-trimethylazuleno[6,5-*b*]thiophene (IV). The purple oil (150 mg) of Fr. 3 (Table 1) was rechromatographed on a silica-gel column with a mixed solvent of ether and benzene (1 : 19), and then with an ether-*n*-hexane (1 : 3) mixed solvent. A green crystalline substance thus isolated was collected by repeating the above process. The substance (40 mg), after recrystallization from a mixed solvent of *n*-hexane and methanol (1 : 1) and again from methanol, gave dark brown needles (10.6 mg), mp 162.0—163.0°C, which exhibited a single blue spot (R_f, 0.37) in TLC with an ether-*n*-hexane (1 : 3) mixture. IR: 1655 cm^{-1} (C=O). UV: $\lambda_{max}^{cyclohexane}$ mμ (log ε) 240.5 (4.10), 290 (4.41), 302 sh (4.60), 324 (4.80), 370 (3.77), 386 (3.82). Visible absorption spectrum: $\lambda_{max}^{cyclohexane}$ mμ (ε) 624.6 (595), 668 (578).

Found: S, 12.38%. Calcd for $C_{17}H_{16}OS$: S, 11.95%.

The oxime of this compound was prepared from a pyridine solution and was obtained as green needles, mp 223.0—224.0°C, after recrystallization from methanol. IR: *ca.* 3400 (O-H), 1638, 1620 and 1592 (C=C and/or C=N), 992 or 910 cm^{-1} (N-O).

Desulfurization of 6-Acetyl-3,5,8-trimethylazuleno[6,5-*b*]thiophene (IV). A solution of 6-acetyl-3,5,8-trimethylazuleno[6,5-*b*]thiophene (IV) (11.3 mg) in methanol (10 m*l*) was stirred with a freshly-activated W-2 Raney nickel catalyst (500 mg) at 50—60°C for 30 min. The reaction mixture was filtered, and the filtrate was concentrated under reduced pressure to give a blue oil (10 mg). The oil was then submitted to elution chromatography using benzene; we separated a green crystalline substance (0.4 mg) which was found to be identical with 2-acetylguaiazulene (III) by TLC and UV spectrometry.

7-Acetyl-3,5,8-trimethylazuleno[6,5-*b*]thiophene (V). Brown crystals of Fr. 4 (15 mg), obtained from several repetitions of the reaction, were recrystallized from ethanol to give brown needles (10 mg; mp 141.0—142.0°C), which showed a single yellow spot (R_f, 0.37) in TLC with benzene. IR: 1650 cm^{-1} (C=O). UV: $\lambda_{max}^{cyclohexane}$ mμ (log ε) 235.5 (4.19), 287 sh (4.28), 300 sh (4.43), 327.4 (4.62). Visible abosorption spectrum: $\lambda_{max}^{cyclohexane}$ mμ (ε) 518 sh (442), 554 (492), 600 sh (370), 660 sh (119).

Acetylation of 3,5,8-Trimethylazuleno[6,5-*b*]thiophene (VII). 3,5,8-Trimethylazuleno[6,5-*b*]thiophene (VII) (80 mg; mp 116.0—116.5°C), prepared by the reaction of S-guaiazulene (II) with sulfur,[1,2] was dissolved in absolute tetrahydrofuran (1 m*l*) together with *N*,*N*-dimethylacetamide (90 mg). To the solution there was then added, drop by drop, another absolute terahydrofuran solution (1 m*l*) of phosphorus oxychloride (150 mg); the mixture was then refluxed on a water bath for 4 hr. The reaction mixture, after being diluted with water (100 m*l*), was made alkaline by adding ammonia water, and a dark brown oil separated was taken up into chloroform. The dark brown oil (140 mg) thus obtained was chromatographed on activated alumina (Merck II—III) with chloroform to afford brown crystals (20 mg). The recrystallization of these crystals from ethanol gave brown needles (12.5 mg; mp 141.5—142.5°C), which were identified as 7-acetyl-3,5,8-trimethylazuleno[6,5-*b*]thiophene by a mixed-melting-point determination and by TLC and IR spectrometry.

Thermal Rearrangement of 3-Acetylguaiazulene (I). In a slow stream of nitrogen, 3-acetylguaiazulene (1.0 g) was heated at 200°C for 2 hr. The reaction mixture was chromatographed on silica gel with benzene to separate it into the following three fractions.

Fr. 1: S-Guaiazulene (II), 10 mg (1.4%). Fr. 2: 2-Acetylguaiazulene (III), 120 mg (16.4%). Fr. 3: 3-Acetylguaiazulene (I), 600 mg (82.2%).

Thermal Reaction of 2-Acetylguaiazulene (III). 2-Acetylguaiazulene (III) (400 mg), which had been isolated from the reaction products of the above thermal isomerization of 3-acetylguaiazulene, was heated at 200°C for 2 hr in the same manner as has been described in the case of 3-acetylguaiazulene. The spots corresponding to 3-acetylguaiazulene and S-guaiazulene (II) were not observed in the TLC of the reaction mixture with benzene, and only the starting material (220 mg) was recovered when the reaction mixture was chromatographed on silica gel with benzene.

Next, 2-acetylguaiazulene (94 mg) was heated in a sealed glass tube at 300°C for 1 hr. In this case also, no spot corresponding to S-guaiazulene or 3-acetylguaiazulene was observed; only the starting material (48 mg) was recovered from the reaction mixture.

The author wishes to thank Professor Tamon Matsuura and Professor Shûichi Hayashi of Hiroshima University for their helpful guidance and advice on this work. Thanks are also due to Professor Shô Itô of Tohoku University for his kind measurement of the NMR and mass spectra and to Dr. Hitoshi Minato of Shionogi Research Laboratory of Shionogi & Co., Ltd., for his kind measurement of the NMR spectra.

Conformations of Sequential Polypeptides Containing L-Alanyl and Glycyl Residues

Takayoshi Iio and Sho Takahashi

Department of Physics, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received August 11, 1969)

The conformations of four polypeptides containing ordered sequences of L-alanyl(A) and glycyl (G) residues, $(A)_n$, $(A_3G)_n$, $(A_2G)_n$, and $(AG_2)_n$, are investigated in solution. The optical rotatory dispersion and infrared spectra showed that all the polymers assume both an α-helical conformation and a β-conformation in solution. The stability of the α-helix decreases in the oder: $(A)_n$, $(A_2G)_n$, $(A_3G)_n$, and $(AG_2)_n$; this may be explained in terms of the interaction between methyl groups of L-alanyl residues regularly arranged on the surface of the α-helix.

The study of sequential polypeptides (regular copolymers) is very useful in clarifying the role of the residue sequence in determining the conformations of polypeptides and proteins. For instance, poly-glycyl-L-prolyl-L-alanine was synthesized as an analog of collagen.[1] Recently, three series of sequential polypeptides containing L-valyl and γ-methyl-L-glutamyl residues, S-benzyl-L-cysteinyl and γ-ethyl-L-glutamyl residues, and glycyl and γ-ethyl-L-glutamyl residues have been synthesized and influence of the residues sequence on conformation was reported by Fraser *et al.*[2-4]

Poly-L-alanine takes an α-helical conformation in an organic solvent[5] and in water as a part of a block copolymer with D,L-glutamic acid or D,L-lysine.[6-8] In the solid state, however, poly-L-alanine can take both a β-conformation and an α-helical conformation.[9,10] On the other hand, poly-glycine forms a β-conformation in the solid state.[11] Poly-L-alanylglycine was shown to form a β-conformation similar to that found in *Bombyx mori* silk fibroin in an oriented film.[12]

In this paper we intend to investigate the effect of the residue sequence on the conformation of various sequential polypeptides containing L-alanyl and glycyl residues, because these polymers may reveal simpler types of side chain-side chain interactions and side chain-main chain interactions than do the polymers containing other amino acids.

Experimental

Preparation of Polymers. The several sequential polypeptides, poly-(L-alanyl)$_3$-glycine, poly-(L-alanyl)$_2$-glycine, and poly-L-analyl-glycyl-glycine, were obtained from the corresponding tri- and tetrapeptide-*p*-nitrophenyl esters by treatment with triethylamine. The optical purity of each sequential polypeptide was checked by comparing the specific rotation of the acid hydrolyzate of each polymer with that of L-alanine. The racemization of each polymer was less than 5%. The syntheses of these polymers have previously been reported by one of the present authors (S.T).[13]

The poly-L-alanine was prepared by the polymerization of L-alanyl-N-carboxyanhydride in dioxane, using triethylamine as the initiator. The intrinsic viscosity of each polymer in dichloroacetic acid was 1.80 for poly-L-Ala, 0.15 for poly-(L-Ala$_3$-Gly), 0.26 for poly-(L-Ala$_2$-Gly), and 0.22 for poly-(L-Ala-Gly$_2$). These polymers are abbreviated as $(A)_n$, $(A_3G)_n$, $(A_2G)_n$, and $(AG_2)_n$.

Solution Studies. The polymers can dissolve only in dichloroacetic acid (DCA) or in trifluoroacetic acid (TFA), so the solutions were prepared by dissolving the vacuum-dried polymer in DCA and by then adding

DCA and chloroform($CHCl_3$) or TFA and DCA to give a solution of the required solvent ratio. All these solvents except TFA (Nakarai Chemicals, Analytical Grade) were redistilled before use.

The optical rotatory dispersions over the 260—450 mμ wavelength range were measured with a JASCO ORD/UV 5 apparatus made by the Japan Spectroscopic Co., Ltd., using a 0.2 cm, 1 cm, or 5 cm cell set in a water-jacketed cell holder. The temperature in the cell was controlled with flowing water from a Haake constant-temperature bath. The concentrations of solutions were in the range of 0.2—0.7 g/100 cc. Absorption due to the solvents precluded measurements at shorter wavelength below 260 mμ.

To compute $[m']_\lambda$, the reduced mean residue rotation (in degrees·cm^2/dmol) at the λ wavelength from the observed rotation, χ_λ, the following equation was used:

$$[m']_\lambda = \frac{3}{n^2+2} \cdot \frac{\overline{M}}{c} \cdot \frac{\chi_\lambda}{l}$$

Here, n is the refractive index of the solvent calculated by means of Lorentz-Lorenz's equation from the value of the refractive index of each pure solvent; c is the concentration of the polymer in grams per 100 cc; l is the path length in decimeters, and $\overline{M}$ is the mean residue molecular weight of the polymers, that is, 71.08 for $(A)_n$, 67.57 for $(A_3G)_n$, 66.40 for $(A_2G)_n$, and 61.72 for $(AG_2)_n$. We adopted the above values for $\overline{M}$ because it is difficult to estimate the contribution of the glycyl residues to the optical rotations of the sequential polypeptides. The optical rotatory dispersion parameters, a_0 and b_0 were obtained by plotting the original value of the optical rotation in terms of the equation given by Moffitt and Yang:[14]

$$[m']_\lambda = \frac{a_0\lambda_0^2}{\lambda^2-\lambda_0^2} + \frac{b_0\lambda_0^4}{(\lambda^2-\lambda_0^2)^2}$$

Linear relations were obtained between $[m']_\lambda \cdot (\lambda^2-\lambda_0^2)/\lambda_0^2$ and $\lambda_0^2/(\lambda^2-\lambda_0^2)$ using a value of λ_0=212 mμ.

The infrared spectra were measured with a model DS 402 G apparatus made by the Japan Spectroscopic Co., Ltd., using a cell with NaCl windows. The concentrations of the solutions ranged from 2 to 3 g/100 cc. The infrared spectrum of the solution and that of the solvent mixture with the same solvent composition were measured separately, the difference in the spectra was obtained by subtracting the optical density of the latter from that of the former.

Results

Optical Rotatory Dispersion. The dispersion curves of four kinds of polymers in various solvent compositions at 24.5°C are shown in Fig. 1. In the TFA-DCA system, all the polymers exhibit negative rotations; the negative rotation of each polymer decreases as the solvent composition is changed from a high TFA content to 100% DCA, and then to a high $CHCl_3$ content. In 66.7% $CHCl_3$—33.3% DCA, the polymers $(A)_n$ and $(A_2G)_n$ exhibit positive rotations above 355 and 340 mμ respectively.

The parameter, b_0, for the polymers is plotted in Fig. 2 as a function of the solvent composition.

It will be seen that the magnitude of $-b_0$ for each polypeptide is not zero in a DCA solution, and that it decreases as the proportion of TFA increases in the TFA-DCA system; on the other hand, in the DCA-$CHCl_3$ system, the magnitude of $-b_0$ increases as the proportion of $CHCl_3$ increases. Thus, all the polymers assume an α-helical conformation to some extent, although the maximum magnitudes of $-b_0$ and the stabilities of the helices towards DCA and TFA differ markedly from polymer to polymer.

(1); 66.7% $CHCl_3$ - 33.3% DCA, (2); 100% DCA.

The value of b_0 of the homopolymer $(A)_n$ increases from −200 in 66.7% TFA - 33.3% DCA to −327 in 33.3% TFA - 66.7% DCA; thereafter it increases very slowly to the value of −411 in 66.7% $CHCl_3$ - 33.3% DCA. This behaviour is almost the same as that found by Fasman.[15] Other polymers, having smaller magnitudes of b_0 than $(A)_n$ over the whole range of the solvent composition, exhibit gradual increases in the b_0 values as the solvent composition is changed from a high TFA content to 100% DCA, and then to a high $CHCl_3$ content. However, the magnitude

of the value b_0 of each polymer decreases in the order of $(A_2G)_n$, $(A_3G)_n$, and $(AG_2)_n$ over the whole range of the solvent composition.

Each parameter of the polymers in 66.7% $CHCl_3$—33.3% DCA showed only a small change when the temperature of the solution was raised to 57°C, and the values of the parameters returned to the original values when the temperature was

lowered to 24.5°C. In the same solvent proportion, the $[m']_\lambda$ values of all the polymers were independent of the concentration in the range of 0.1—1.0 g/100 cc.

Infrared Spectra. The infrared spectra over the frequency range from 1500 cm^{-1} to 1700 cm^{-1} are shown in Fig. 3. In the 25% DCA - 75% $CHCl_3$ solution, it was found that all the polymers exhibited an amide I band at about 1630 cm^{-1}, which may be attributed to a β-conformation,[16] and another band at about 1655 cm^{-1} due to an α-helical conformation.[16] This 1655 cm^{-1} component reveals a strong absorption band in the polymers $(A)_n$ and $(A_2G)_n$, but only a weak band in $(A_3G)_n$ and $(AG_2)_n$. The 1655 cm^{-1} component, however, may also contain a contribution from a random-coiled conformation of the polypeptides. Thus, all the polymers assume the β-conformation in addition to the α-helical conformation.

Discussion

Judging from the infrared spectra of the polymers, there is a possibility that all the polymers assume not only the α-helix but also a β-conformation in solution. The behaviour of the β-conformation of these polymers in solution can be investigated on the basis of an analysis of the parameters a_0 and b_0. These parameters can be written in the following forms:[17]

$$a_0 = a_0^R + a_0^H f_H + a_0^\beta f_\beta$$
$$b_0 = b_0^H f_H + b_0^\beta f_\beta$$

Here, a_0^R, a_0^H, and a_0^β are the contributions to a_0 from the random, α-helical, and β-conformations; b_0^H and b_0^β have the usual meanings, and f_H and f_β are the fractions of the α-helical conformation and the β-conformation respectively. For the parameters corresponding to the α-helical conformation, we adopt the values of $a_0^H = 680$ and $b_0^H = -630$.[17]

On the other hand, for the β-conformation various values of the parameters have been reported.[18–23] It, therefore, might be quite difficult to estimate the values of the parameters for the polymers containing L-alanyl and glycyl residues. In this paper we assume tentatively the values of $a_0^\beta = 700$ and $b_0^\beta = 0$. We measured the ORD curve of each polymer in 100% TFA, and we adopted the a_0 value obtained from the curve as the a_0^R of each polymer.

We can now calculate the fraction of the β-conformation from the observed values of a_0 and b_0 according to the above equations. However, it should be emphasized that, because of the ambiguity of the numerical values of the parameters assumed above, the content of the β-conformation thus calculated does not represent the absolute values, but, rather, relative values.

The fraction of the β-conformation, f_β, thus obtained is plotted in Fig. 4 as a function of the solvent composition. In the polymer $(AG_2)_n$, f_β is nearly constant over the whole range of the solvent compositions, while in the polymer $(A_3G)_n$, f_β increases as the proportion of $CHCl_3$ increases. In the polymer $(A_2G)_n$, f_β changes greatly, and in $(A)_n$ f_β has a maximum at 100% DCA and decreases as the proportions of both $CHCl_3$ and TFA increase.

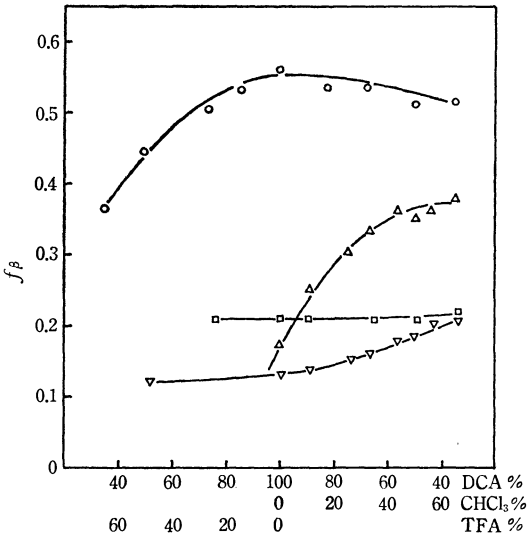

Fig. 4. Variation of the fraction of β-conformation with solvent composition.
-○-; $(A)_n$, -▽-; $(A_3G)_n$, -△-; $(A_2G)_n$, -□-; $(AG_2)_n$.

On the other hand, because of $b_0^\beta = 0$, we can see directly the behaviour of the α-helix of each polymer from the b_0 value in Fig. 2.

The contents of the α-helix conformation and the β-conformation in the highest $CHCl_3$ composition for each of the polymers are shown in Table 1. The ratio of f_H to f_β decreases in the order of $(A)_n$, $(A_2G)_n$, $(A_3G)_n$, and $(AG_2)_n$. This order coincides with the observation of the infrared measurements. In the infrared spectra, the optical density of the 1655 cm^{-1} component

also decreases in the order of $(A)_n$, $(A_2G)_n$, $(A_3G)_n$, and $(AG_2)_n$ compared to that of the 1630 cm^{-1} component (Fig. 3).

As has been mentioned above, the values of the β-contents of the polymers depend largely on the choice of the values of the parameters, so that further quantitative discussions can not be made concerning the behaviour of the β-conformation of the polymers. In the following discussions, we will discuss the behaviour of the α-helix in solution independently of the β-conformation, on the basis of the observation of the paramter b_0.

It is known that the L-alanyl residue stabilizes the α-helical conformation of polypeptide[5-8,24] and that the glycyl residue markedly reduces the α-helical stability.[4,25] In the γ-benzyl-L-glutamateglycine random copolymers[25] and in the sequential polypeptides containing γ-ethyl-L-glutamyl and glycyl residues,[4] the helical stabilities of the polypeptides are reduced as the content of the glycyl residue increases. In this experiment, however, the stability of the α-helix is reduced in the order of $(A)_n$, $(A_2G)_n$, $(A_3G)_n$, and $(AG_2)_n$, as may be seen in Fig. 2. This order does not coincide with the order of the increment of the glycine content. Therefore, the instabilities of the α-helices of these polymers can not be explained merely by the main-chain flexibility at the position of the glycyl residues.[4] It is necessary to consider also the regularity of the residue sequence and the contribution of the side chain of the L-alanyl residue to the α-helical stability.

The distribution of the glycyl (G) and L-alanyl (A) residues on the surface of a 3.6 residue right-handed-turn α-helix is illustrated schematically in Fig. 5 for each of the four polymers. If the residue in the center of each diagram is referred to as the 0 residue, it is convenient to number successive residues +1, +2, *etc.* in the $-CO-C_\alpha-NH-$ direction and −1, −2, *etc.* in the opposite direction. As may be seen in Fig. 5, in the polymer $(A_2G)_n$, if one G is located at the position 0, the 0, ±3, ±6, *etc.* positions are all occupied by G's. In the polymer $(A_3G)_n$, the positions 0, ±4, ±8, *etc.* are all occupied by G's. If the values of b_0 reflect the stabilities of the α-helices, then it should be concluded from the experiments that the introduction of G's decreases the stability of an α-helix, especially in the case of two G's at 0 and 4 as compared with two G's at 0 and 3. The polymer $(AG_2)_n$, where both types of relative arrangements of G's exist, is most unstable.

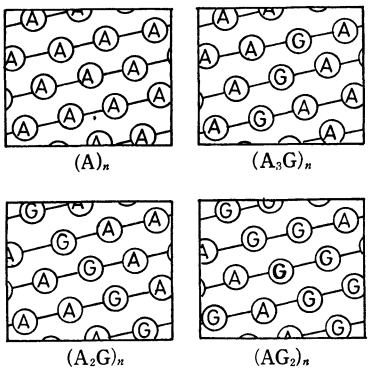

Fig. 5. Radial projection showing the distribution of the residues on an α-helix for each of the polymers.

The α-helix of poly-L-alanine in water is considered to be more stabilized by the hydrophobic bond between the methyl group of the residue A(O) and the $C_\alpha H$ group of the residue A(3).[7,24] This interaction should operate on the poly-L-alanine in the polar organic solvents as the lyophobic bond. This interaction may exist to some extent between A(0) and G(3), but not between G(0) and A(3). Although we do not have accurate knowledge of the magnitudes of these lyophobic interaction energies, we can understand the variation in the α-helical stabilities of the polymers if the energy of this interaction between A(0) and G(3) is assumed to be a half or less than that between A(0) and A(3). We can calculate, based on the above assumption, the total energy of the lyophobic interaction between the residues at 0 and 3 for each repeating unit of the polymers. Of course, the energy between G(0) and G(3) is zero. In the polymer $(A_3G)_n$, where the repeating unit is G(0)-A(1)-A(2)-A(3), the total energy is a sum of the energies of the interactions between G(0) and A(3), between A(1) and G(4). between A(2) and A(5), and between A(3) and A(6); their relative magnitudes are 0, 0.5, 1, and 1 respectively. Therefore, the sum is given by 2.5, and the energy per residue is 0.62. The interaction energy per residue for the other polymers is calculated by the same procedure, resulting in an energy of 1 for $(A)_n$, of 0.67 for $(A_2G)_n$, and of

24) M. Bixon, H. A. Scheraga and S. Lifson, *ibid.*, **1**, 419, (1963).
25) H. Block and J. A. Kay, *ibid.*, **5**, 243, (1967).

0.33 for $(AG_2)_n$. Thus, the average lyophobic interaction energies per residue of the polymer decrease in the order of $(A)_n$, $(A_2G)_n$, $(A_3G)_n$, and $(AG_2)_n$; this order coincides with that of the instabilities of the α-helices observed in the optical rotatory measurements.

The glycyl residue does not have a methyl group, so the polar hydrogen-bond breakers (DCA or TFA) are more easily accessible to the α-helical backbone at the position of the glycyl residue than at that of the L-alanyl residue. It is, therefore plausible that the interaction between A(0) and G(3) is weaker than that between A(0) and A(3).

The authors wish to thank Professor F. Oosawa, Dr. A. Ikegami, and Dr. A. Minakata for their helpful advices and discussions. Professors K. Yamazaki and S. Kubo of the Department of Chemistry, Nagoya University, kindly made available their apparatus for the experiments.

Aromatic Sulfonylation. II. Attacking Species under Various Conditions.*1

Yoshio KOHARA, Michio KOBAYASHI and Hiroshi MINATO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo

(Received August 27, 1969)

p-Toluenesulfonylation of toluene and anisole in the presence of $AlCl_3$, $SbCl_5$ or $TiCl_4$ was investigated in methylene chloride, nitromethane and nitrobenzene. Substitution took place at 8.6—13.4% and 86.6—91.4% *para* positions for toluene in methylene chloride, but 42.0—45.7% *ortho* and 54.2—58.0% *para* isomers were obtained in nitromethane and nitrobenzene. Sulfonylation of toluene with p-$CH_3C_6H_4SO_2^+$ ClO_4^- afforded 44.8—46.3% *ortho* and 53.7—55.2% *para* isomers. Partial rate factors for toluene were $p_f=52.5$ in methylene chloride, $o_f=12.6\pm0.9$, $p_f=31.4\pm2.0$ in nitromethane, and $o_f=16.0\pm1.7$, $p_f=38.3\pm4.2$ with p-$CH_3C_4H_4SO_2^+ClO_4^-$. A plausible mechanism is proposed, in which the attacking species is TsCl-MCl_n complex in methylene chloride, but it is an ion pair, $ArSO_2^+MCl^-_{n+1}$, in nitromethane and nitrobenzene.

In part I of this series we have described the results of kinetic studies on the aluminum chloride-catalyzed *p*-toluenesulfonylation of aromatics in methylene chloride.[1] On the basis of the kinetic data, existence of the kinetic isotope effect and spectroscopic observations, it was concluded that the attacking species of aromatics was TsCl-$AlCl_3$ complex. Jensen and Brown made a kinetic study of Friedel-Crafts sulfonylation of aromatics with aluminum chloride by using nitrobenzene or benzenesulfonyl chloride as solvent, and concluded that either sulfonyl cation or ion pair $ArSO_2^+$ $AlCl_4^-$ was the species which attacked aromatics.[2] Klages and Hoheisel made a study of sulfonyl cations, but did not report the kinetic data of aromatic sulfonylation.[3] In order to clarify the mechanism of sulfonylation, we have investigated the sulfonylation of aromatics with Ts^+ ClO_4^- and with *p*-toluenesulfonyl chloride, using aluminum chloride, antimony pentachloride and titanium chloride as catalysts, and methylene chloride, nitromethane and nitrobenzene as solvents.

Experimental

Materials. The purification of *p*-toluenesulfonyl chloride, toluene, methylene chloride and aluminum chloride was described in a previous paper.[1] Anisole was shaken with sodium carbonate, dried over calcium chloride, and then distilled. Antimony pentachloride and titanium chloride were distilled. Ferric chloride was sublimed. Nitromethane and nitrobenzene were dried over calcium chloride, and then distilled. Silver perchlorate of first grade(Kojima Chemical Co., Ltd.) was used without further prification.

Syntheses of Authentic Samples. *o,p*-Ditolyl sulfone: Reaction between ethyl *p*-toluenesulfinate and *o*-tolylmagnesium bromide, prepared from *o*-bromotoluene and magnesium in ether, gave *o,p*-di-tolyl sulfoxide. Oxidation of sulfoxide, with hydrogen peroxide in acetic acid as solvent, afforded the *o,p*-ditolyl sulfone, mp 55—56°C from methanol(lit, 60°C[4]).

m,p-Di-tolyl sulfone was prepared in a similar way from *m*-bromotoluene and ethyl *p*-toluenesulfinate, mp 112.5—113.0°C from methanol (lit, 116°C[4]). Di-(*p*-tolyl) sulfone was prepared by aluminum chloride-catalyzed *p*-toluenesulfonylation of toluene in methylene chloride, mp 155°C from methanol(lit, 157—158°C[5]). *p*-Tolyl *o*-methoxyphenyl sulfone: Reaction between sodium *p*-toluenesulfinate and *o*-nitrochlorobenzene in DMSO gave *p*-tolyl *o*-nitrophenyl sulfone. Reduction of the nitro-compound, with hydrochloric acid and stannous chloride, afforded the amino-compound, and hydrolysis of the diazonium chloride in sulfuric acid, prepared from amino-compound, afforded the *p*-tolyl *o*-hydroxyphenyl sulfone. Methylation of hydroxy-compound with dimethyl sulfate gave *p*-tolyl *o*-methoxyphenyl sulfone, mp 118.5—119.0°C from ethanol (lit, 119—120°C[6]). *p*-Tolyl *m*-methoxyphenyl sulfone: A Grignard reagent prepared from 12.5 g of *m*-iodoanisole and 1.3 g of magnesium in 50 m*l* of ether was added drop by drop to 5.0 g of ethyl *p*-toluenesulfinate in 50 m*l* of ether. An excess of dilute hydrochloric acid was then added to the reaction mixture to dissolve the oil. The organic layer was separated, washed with alkali and water, and dried over magnesium sulfate. When the solvent was evaporated, an oily residue was obtained. The oily sulfoxide was purified by elution chromatography over alumina with benzene, and 5.0 g of crystals of *p*-tolyl *m*-methoxyphenyl sulfoxide was obtained (I.R. S-O stretching at 1035 cm^{-1}). To 5.0 g of the sulfoxide in 100 m*l* of acetic acid, 20 g of 30% hydrogen peroxide was added at room temperature, and the reaction mixture was allowed to stand overnight. The solution was warmed to and kept at 50—60°C for about one hour, and the sulfone was extracted with methylene chloride. The solution was evaporated, and the red crystals were purified by elution chromatography over alumina with benzene and ether, and 2.0 g of *p*-tolyl *m*-methoxyphenyl sulfone was obtained, which was recrystallized from methanol, mp 80°C; IR. 1145 cm^{-1}($\nu_s SO_2$), 1285 and 1310 cm^{-1} ($\nu_{as} SO_2$) KBr disc;

Found: C, 63.79; H, 5.55%. Calcd for $C_{14}H_{14}O_3S$: *D*, 64.09; H, 5.39%. *p*-Tolyl *p*-methoxyphenyl sulfone was prepared by aluminum chloride-catalyzed-*p*-toluenesulfonylation of anisole in methylene chloride, mp 103.5—104.0°C from ethanol (lit, 103—104.5°C[7]).

Sulfonylation of Toluene. Two grams of *p*-toluenesulfonyl chloride and 3.0 g of aluminum chloride in 25 m*l* of nitromethane were added to 5.0 g of toluene in 25 m*l* of nitromethane at 10°C. After about 37 hr, a dilute hydrochloric acid was added to the reaction mixture. The residual *p*-toluenesulfonyl chloride was decomposed by steam distillation of organic layer, and then the sulfone which crystallized was extracted with methylene chloride. The isomer ratio of a sulfone obtained was determined by gas-chromatographic analysis on a 2 m column packed with 10% SE-30 on Chromosorb using H_2 as a carrier gas (30 m*l*/min) at 230°C; retention time: *p*-tolyl *o*-tolyl sulfone, 19.9 min, *p*-tolyl *m*-tolyl sulfone, 23.5 min, di-(*p*-tolyl) sulfone, 24.5 min.

Sulfonylation of Anisole. Sulfonylation of anisole was carried out in a manner similar to that used for toluene. Absence of 860 cm^{-1} band showed the absence of *p*-tolyl *m*-methoxyphenyl sulfone in the products. The isomer ratio of a sulfone produced was determined by gas-chromatographic analysis on a 2 m column packed with 10% SE-30 on Chromosorb using H_2 as a carrier gas (30 m*l*/min.) at 250°C; retention time, *p*-tolyl *o*-methoxyphenyl sulfone, 15.8 min, *p*-tolyl *m*-methoxyphenyl sulfone, 16.0 min, *p*-tolyl *p*-methoxyphenyl sulfone, 20.4 min, *p*-tolyl phenyl sulfone, 9.0 min.

Sulfonyation with Sulfonyl Cation. *p*-Toluenesulfonyl perchlorate was prepared from *p*-toluenesulfonyl chloride and silver perchlorate by Klages' method.[3b] The solution of the *p*-toluenesulfonyl perchlorate was added to the solution of an aromatic substrate. The reaction mixture was kept at 10°C overnight, then the sulfone produced was separated by extraction with methylene chloride and analyzed by gas chromatography.

Measurement of Relative Rates by Competitive Sulfonylation. The relative rates were determined by a method similar to that used for measurements of isomer ratios. Gas-chromatographic conditions; 10% SE-30 on Chromosorb, 3 m, H_2 as carrier gas (40 m*l*/min) at 240°C, retention time; *p*-tolyl phenyl sulfone, 15.5 min., *p*-tolyl *o*-tolyl sulfone 19.2 min, *p*-tolyl *m*-tolyl sulfone, 21.0 min, di-(*p*-tolyl) sulfone, 22.5 min.

Results and Discussion

Results concerning the orientation for the *p*-toluenesulfonylation of toluene are summarized in Table 1. The orientation for sulfonylation of toluene with antimony pentachloride and titanium chloride in methylene chloride agreed with the data for aluminum chloride in methylene chloride within the limit of error of gas-chlomatographic analysis. The agreement among the values of orientation for the reactions catalyzed by aluminum chloride, antimony pentachloride or titanium chloride in nitromethane or nitrobenzene is also satisfactory. These values were not in accord with the values obtained in methylene chloride.

Klages and Malecki reported on the formation of sulfonyl cation;[3b] *i.e.* *p*-toluenesulfonyl cation was prepared from *p*-toluenesulfonyl bromide and silver perchlorate in nitromethane. Measurement of electroconductivity indicated that not a free sulfonyl cation but an equilibrium mixture of covalent-bonded(I) and ionized(II) was present in the medium as shown below.

$$\underset{(I)}{Ts\text{-}OClO_3} \rightleftarrows \underset{(II)}{Ts^+ClO_4^-} \xrightarrow{ArH} TsAr + HClO_4 \qquad (1)$$

Sulfonylation of an aromatic substrate with sulfonyl cation (II) took place when the aromatics

was added to this solution.[3b,8]

The orientation for the Lewis acid-catalyzed sulfonylation in nitromethane or nitrobenzene agrees fairly well with the orientation for sulfonylation with tosyl perchlorate solution as seen in Table 1. This fact suggests that the attacking species in the sulfonylation with tosyl perchlorate system was the same as that of the Lewis acid-catalyzed sulfonylation in nitromethane or nitrobenzene, namely sulfonyl cation (II)-like species for both reactions.

Partial rate factors for sulfonylation of toluene are determined by competitive experiments and shown in Tables 2 and 3.

Those values at *para* position were 31.4±2.0 for aluminum chloride-catalyzed sulfonylation in nitromethane and 38.3±4.2 for sulfonylation with sulfonyl cation in nitromethane. The value for the aluminum chloride-catalyzed sulfonylation in methylene chloride was 52.5.[1] Both orientation and partial rate factors clearly indicate that the attacking species in methylene chloride was different from those in nitromethane or nitrobenzene.

Sulfonylation with a sulfonyl perchlorate in nitromethane and nitrobenzene is less selective than that in methylene chloride and toluene. This finding suggests that the attacking species in the sulfonylation with sulfonyl perchlorate in nitromethane and nitrobenzene were in a relatively free states, whereas the attacking species in methylene chloride or toluene was bulky, less reactive. In order to explain the results of *p*-toluenesulfonylation under various conditions, a plausible mechanism is proposed, which involves several attacking species with various degrees of charge separation. The results of orientation and partial rate factors indicate that; sulfonylations catalyzed by aluminum chloride, antimony pentachloride and titanium chloride in methylene chloride proceed through (2), but sulfonylation in nitromethane and nitrobenzene proceeds through (2), (3) and (4); the

antimony pentachloride-catalyzed sulfonylation in toluene proceeds through (2) and (3); the aluminum chloride-catalyzed benzenesulfonylation of chlorobenzene in benzenesulfonyl chloride as solvent[2b] proceed through (2), (3), (4) and (5). The energy relationship among these attacking species may be represented by a free energy diagram shown in Fig. 1. The formation of various attacking species could be partially attributed to the difference in solvating power of the solvents. Four attacking species expressed in this diagram, namely the complex, contact ion pair, solvent-separated ion pair and free cation should not be considered to be distinctly differentiated from each other as shown in Fig. 1

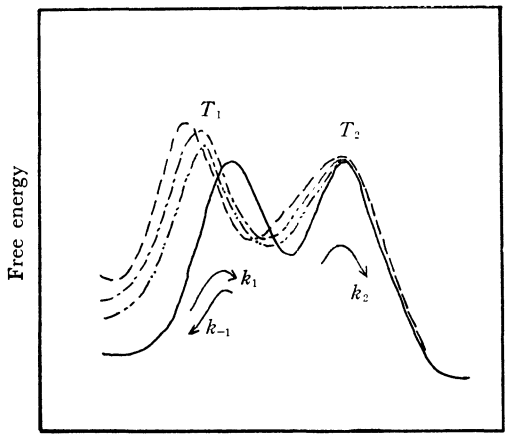

Fig. 1. Free energy diagram for the possible intermediates in the sulfonylation.
——— free cation
——— solvent-separated ion pair
——— contact ion pair
——— complex

and (1)—(5), and the bond strength between sulfonyl group and counter ion varies continuously with the solvents and counter ions. If the aromatic substrate is highly reactive, it can be attacked by sulfonyl chloride-metal chloride complex. Since the reactivity of the complex is low, both its substrate and positional selectivity are high. On the other hand, attacking species similar to free sulfonyl cation is highly reactive and therefore, should have low selectivity. In fact, kinetic evidence supported these suggestions. Kinetic hydrogen isotope effects were observed in sulfonylation with TsCl-$AlCl_3$ complex in methylene chloride,[1] but was not detected in benzenesulfonylation in benzenesulfonyl chloride,[2b] where the sulfonylation was considered to be effected with solvent separated ion pair or free cation. These findings may be explained by the energy diagram in Fig. 1. The difference of energy between reactant and transition states T_1 is small for free cation or ion pair, and considerably large for complex. Transition states T_1 for the complex may be reached in the later stage along the reaction coordinate, where C–H bond length may be stretched much longer than that in T_1 for free sulfonyl cation. On the other hand, the energy difference among transition states T_2 for all attacking species will be very small. Forward rate constant k_2 should be smaller than k_{-1} or at least in comparable order of magnitude with k_{-1} for complex, resulting in kinetic hydrogen isotope effects. For the free cation or solvent-separated ion pair, k_2 should be larger than k_{-1}, and no kinetic isotope effects should be present.

The reaction between arenesulfonyl chloride and such highly reactive aromatics as *m*-dimethoxybenzene in the presence of zinc chloride in aromatic solvent was found to afford a sulfone and attributed to the intermediate formation of the sulfonyl cation.[9] Considering the fact that zinc chloride is a weak Lewis acid and *m*-dimethoxybenzene is a less polar solvent, it seems that a true attacking species was complex or contact ion pair under these reaction conditions.

Orientation for the sulfonylation of anisole is shown in Table 4.

Table 4. Orientation for the sulfonylation of anisole

9) H. Burton and E. Hoggarth, *ibid.*, **1945**, 14.

The difference in the orientation is less clear than in the cases of other aromatics. It is reasonable that the difference in the reactivity is less clear since anisole is very reactive and reacts with various attacking species of different reactivity more evenly. Partial rate factors for the sulfonylation of anisole catalyzed with aluminum chloride in nitromethane at 10°C were found to be $o_f=50.7$, $m_f \fallingdotseq 0$, $p_f=150$ ($k_{PhOCH_3}/k_{PhH}=41.9$) by competitive experiments. These values are extremely small compared with those of ordinary electrophilic aromatic substitutions ($p_f=1.8\times10^6$ for acetylation[10] and $p_f=1.1\times10^{10}$ for bromination[11]). Plausible explanations for this anomaly is that the reactivity of anisole was depressed by formation of $PhOCH_3$–$AlCl_3$ complex and the concentration of the remaining free anisole was very low for the same reasons.

On the basis of orientation, partial rate factors and other kinetic data, it is concluded that the attacking species varies with the conditions and is a complex, a contact ion pair, a solvent-separated ion pair or a free cation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 524—530 (1970)

The Non-enzymatic Cleavage of Peptide Bonds. II. The Chemical Cleavage of the Tryptophyl Bond in Several Synthetic Peptides[1,2]

Michiyo MORISHITA and Fumio SAKIYAMA

Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received September 5, 1969)

Several synthetic peptide derivatives containing tryptophan were examined for the selective cleavage at the tryptophyl residue, according to a new scheme involving ozonization and subsequent treatment with hydrazine. The ozonization reaction of the tryptophyl residue was carried out in the presence and in the absence of resorcinol in formic acid. Then the reaction of the ozonized product with hydrazine was performed at pH 3.6 to bring about the tryptophyl bond cleavage. The yield of the present cleavage reaction ranged from 35 to 68% on the basis of the starting peptide derivative used. The cleavage reaction could be followed spectroscopically in parallel with the exposure of the amino group acylated by the tryptophyl residue. The 2,3,4,5-tetrahydropyridazone derivative derived from the parental tryptophyl residue was identified by a comparison of both its chromatographic behavior and its ultraviolet spectrum with those of the standard sample. Thus it was confirmed that the present cleavage proceeded through the proposed reaction sequence.

In a previous paper, a new approach to effect the selective cleavage of tryptophyl bonds was proposed.[1] The cleavage reaction consists of two reactions; one is the oxidative conversion of the tryptophyl residue into a *N'*-formylkynurenyl residue (the first reaction), and the other is the selective cleavage of the tryptophyl bond by the reaction of the kynurenyl residue with hydrazine. The second step in the cleavage reaction was previously studied by using model compounds.[1] The reaction scheme is thought to be useful not only for the fragmentation of the peptide chain in the structural analysis of the protein molecule, but also for the study of the structure-function relationship of the biologically-active protein by the chemical modification of the particular tryptophyl residue, since the oxidized tryptophan in the protein can be easily characterized by identifying any newly-formed amino terminal amino acid after hydrazine treatment. In the present paper the authors will describe the cleavage reaction of the tryptophyl bond in several synthetic peptide derivatives according to the scheme depicted in Fig. 1.

Results and Discussion

Conversion of the Tryptophyl Residue into a *N'*-Formylkynurenyl Residue by Ozone. Among the oxidation reactions of indoles previously studied, such oxidants as ozone,[3,4] peracids,[5]

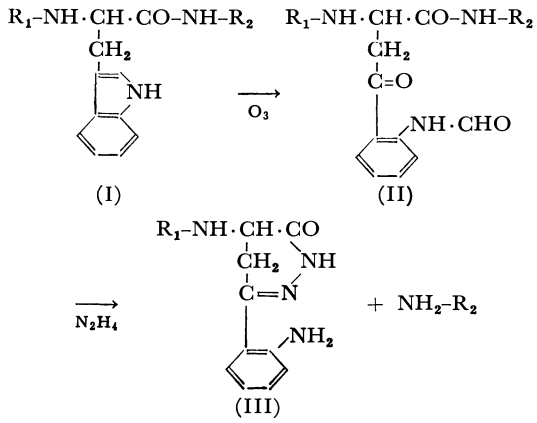

Fig. 1. The reaction sequence for the chemical cleavage of the tryptophyl bond.

and periodate ions[6] have been shown to effect the oxidative scission of the α,β-unsaturated bond of the pyrrole part in the indole nucleus. Molecular oxygen can also act as an oxidizing agent in either physiological[7] or photochemical[8] reactions. For the present purpose, the complete and selective oxidation of the tryptophyl residue in a peptide chain is desirable, and ozone was considered as one of the most favorable oxidants among the above agents. It has previously been reported that, on the controlled ozonization of protein amino acids, tryptophan could be selectively converted into *N'*-formylkynurenine with a side reaction, the oxidation of the sulfur atom of methionine.[9]

The reaction conditions for the quantitative conversion of tryptophan into *N'*-formylkynurenine was first examined since, in the experiment reported by Previero and Bordignon,[9] the amount of ozone to be used for the oxidation of tryptophan was not specified. The oxidation was followed by an increase in the absorption at 322 mμ which was characteristic of the chromophore of *N'*-formylkynurenine. Another determination of the oxidation product was simultaneously achieved by the ninhydrin assay of kynurenine after mild acid hydrolysis and subsequent chromatographic separation on filter paper.

The ozonization of tryptophan was very rapid, and the indole nucleus was oxidized almost completely within one minute either with or without resorcinol. As is shown in Fig. 2, the quantitative formation of kynurenine was observed by the ninhydrin assay when ozonization was carried out in

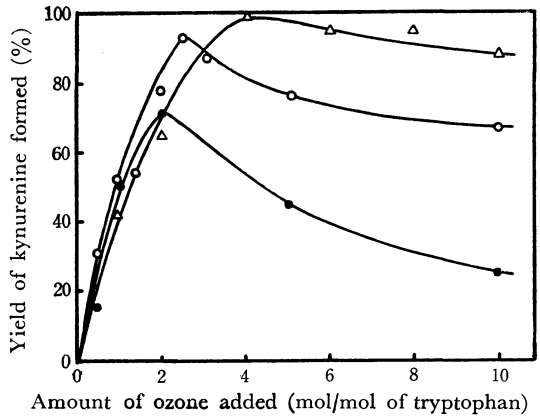

Fig. 2. Ozonization of tryptophan by various amounts of ozone (Formation of kynurenine after acid hydrolysis).
Reaction conditions: concentration of tryptophan was 5 mM in formic acid and ozone was added for a minute. Ozonization in the absence (-●-) or the presence (a molar equivalent (-○-) and twice equivalents (-△-) to the amino acid) of resorcinol was presented.

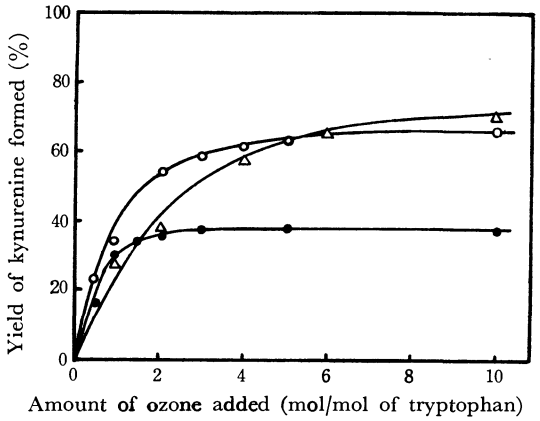

Fig. 3. Ozonization of tryptophan by various amounts of ozone (Formation of *N'*-formylkynurenine).
Reaction conditions and notations are similar with those described in Fig. 2. The amount of *N'*-formylkynurenine was estimated by absorbancy at 322 mμ.

a formic acid containing resorcinol (molar ratio of O_3 : resorcinol : tryptophan = 4 : 2 : 1). However, different features were observed when the same oxidation was monitored by the ultraviolet absorption (322 mμ, Fig. 3). In the presence of resorcinol, the ninhydrin method afforded more kynurenine than did the spectrometric method. It should be noted that no maximal formation of *N'*-formylanthranyl grouping was detected when kynurenine was quantitatively obtained. The same phenomenon was also observed on ozonization without resorcinol. This discrepancy can be explained by the formation of a certain

stable intermediate carrying no *N'*-formylanthranyl group; this intermediate was then transformed into kynurenine on acid hydrolysis. Resorcinol was obviously effective in enhancing the ozonization yield of tryptophan and in reducing the over-oxidation of the ozonization products. Phloroglucinol was also effective, but tyrosine was not.

When the carbobenzoxy derivative of tryptophan was ozonized under the best conditions described above, no quantitative formation of kynurenine was observed. In accounting for this phenomenon it was postulated that the bulky aromatic group attached to the tryptophan residue might interfere with the access of ozone to the indole nucleus when the oxidant was added to the reaction media over a short period. Thus, the ozonization of *N*-α-carbobenzoxytryptophylleucine was examined from time to time by both the ninhydrin and spectrometric methods (Fig. 4). The increase in the absorption at 322 mμ reached a plateau after one minute, but the amount of kynurenine estimated by the ninhydrin reaction gradually increased and an almost quantitative formation was observed after half an hour. Such a slow addition of ozone was also recommended by Previero *et al.*[4,9] for the effective conversion of tryptophan to *N'*-formylkynurenine.

Under the same conditions, the ozonization of the tryptophyl residue in several synthetic oligopeptides was undertaken. As is shown in Table 1, on the ozonization of the peptide in the presence of resorcinol the tryptophyl residue could be oxidized to the *N'*-formylkynurenyl residue in a 51—100% yield and, on acid treatment, the formation of kynurenine was estimated to be 80—99%. As long as ozonization is utilized for the first step in the cleavage reaction, it is not relevant to estimate the oxidation of the tryptophyl residue only by absorption at 322 mμ since the *N'*-formylkynurenine would not be a single ozonization product. However, since the second step in the cleavage reaction was performed in weakly acid media, the intermediate ozonization product of the tryptophyl residue can be expected to be readily hydrolyzed to kynurenine during heating in the aqueous media. For the present chemical cleavage of the tryptophyl bond, the carbonyl function at the γ-position is indispensable and the kynurenyl

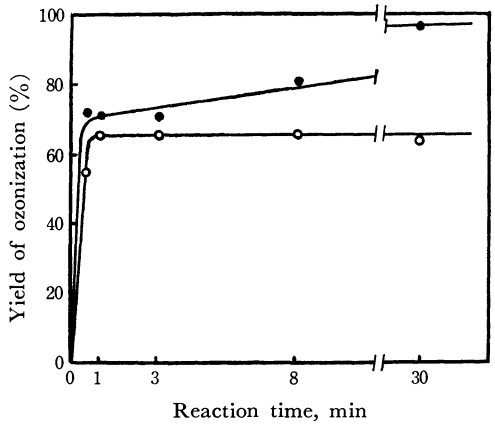

Fig. 4. Ozonization of carbobenzoxytryptophylleucine.
Reaction conditions: concentrations of tryptophan and resorcinol were 5 mM and 10 mM, respectively. Ozone (1—2% in oxygen, total amount was four-fold molar equivalents to tryptophan) was bubbled for half an hour. The extent of ozonization was estimated by both absorbancy at 322 mμ (-○-) and determination of kynurenine after acid hydrolysis (-●-).

residue is a potent candidate as well as its *N'*-formyl derivative in the second step.[10] Therefore, photooxidation would be another promising reaction for the quantitative, selective conversion of tryptophan into a kynurenine derivative.[11]

Reaction of the Ozonized Product of the Tryptophyl Peptide with Hydrazine (the Second Step). *N*-α-Carbobenzoxytryptophylleucine oxidized by ozone was reacted with hydrazine under the conditions described previously.[1] The formation of the *N'*-formylkynurenyl residue was moderately achieved (66% yield), and about a half of the *N'*-formylkynurenyl bond could be cleaved. The leucine was released in a 31% yield, which was calculated on the basis of the parental tryptophyl peptide. In order to establish more effective conditions for the release of leucine, the reaction of the ozonized tryptophyl peptide with hydrazine was investigated further. The modification of certain parameters usually favorable for the present type of chemical reaction, that is, an increase in the reaction temperature and the reaction period, was not preferable for the selective cleavage reaction of the peptide bond. The effect of the concentration of hydrazine on the release of leucine was first examined. As is shown in Fig. 5, a five-fold molar excess of hydrazine was insufficient for the efficient cleavage reaction of the *N'*-formylkynurenyl bond and the maximal liberation of the amino acid (quantitative from the *N'*-formylkynurenyl residue formed) attained when twenty or more equivalent of the binucleophile were used. Thus, several of the tryptophyl peptides oxidized were submitted to the cleavage reaction: the amino group linked originally with the carboxyl group of the tryptophyl residue could thus obtained in a 35—68% yield (Table 2). The cleavage yield apparently depended on the amount of *N'*-formylkynurenine formed. As the last column in Table 2 shows, the tryptophyl peptide bond was partly hydrolyzed in certain cases when the parental derivative was reacted with hydrazine without ozonization.

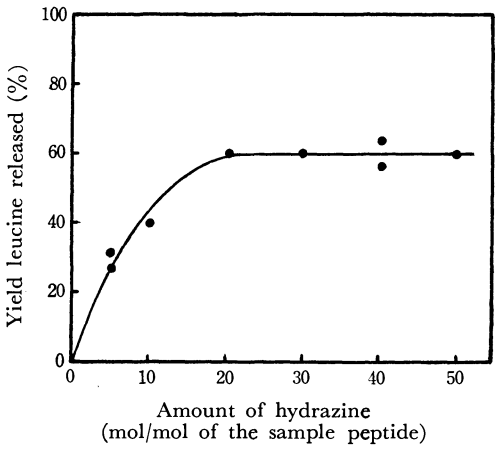

Fig. 5. Effect of concentration of hydrazine on release of leucine from the oxidized product of carbobenzoxytryptophylleucine.

Then the pH-dependence of the cleavage reaction of the *N'*-formylkynurenyl bond was again examined in order to minimize such undesirable non-specific hydrolysis. The release of the amino group was not significantly affected by the concentration of hydrogen ions between pH 3.6 and pH 5.85 (Fig. 6). Furthermore, no remarkable difference in the rate of the cleavage reaction was observed at the more extreme pH's. Therefore, it is expected that the hydrazine treatment at pH 5.85 would give a fruitful result since the non-specific hydrolysis of the peptide bond may occur to a lesser extent at this pH.

Table 2. Yield of the specific cleavage at the tryptophyl bond*

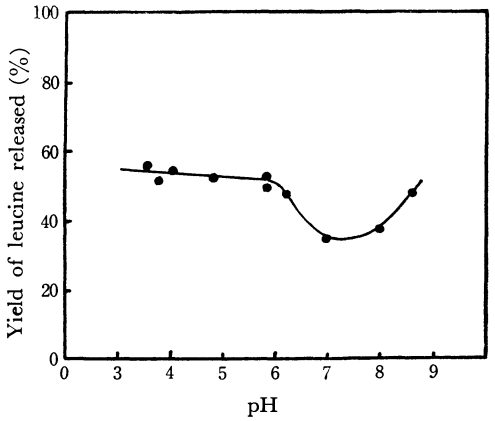

Fig. 6. pH-Profile of release of leucine from the oxidized product of carbobenzoxyalanyltryptophylleucine.

It should be possible to identify the counterpart of the newly-exposed amino group by a conventional technique. The other reaction product which was derived from the tryptophyl residue is probably 4-peptidylamino-6-(*o*-aminophenyl)-2,3,4,5-tetrahydropyridaz-3-one (III). However, little has been known about the chemical properties of the 4-amino-6-(*o*-aminophenyl)-2,3,4,5-tetrahydropyridaz-3-one (IV) derivative. Therefore, two 4-acylamino derivatives of IV, the 4-carbobenzoxy (V) and 4-*N*-carbobenzoxy-L-alanyl (VI) derivatives, were prepared by the reaction of the corresponding α-acylamino-γ-oxo acid ester with hydrazine. Both pyridazones developed an orange color with the Ehrlich reagent, emitted a yellow-orange fluorescence when excited at 260 mμ and showed a characteristic absorption near 350 mμ; this absorption was attributed to a conjugated system composed of the *o*-aminophenyl group and the ketimino function in the tetrahydropyridazone ring.

Then the cleavage reaction of the *N'*-formylkynurenyl bond was spectrophotometrically monitored (Fig. 7). The absorption at 322 mμ due to *N'*-formylkynurenine decreased rapidly in the early stage of the reaction and a new absorption maximum emerged near 350 mμ. This new absorption maximum, however, was gradually shifted to a shorter wavelength after about two hours. In this case the substrate was the carbobenzoxy derivative of tryptophylleucine, and the release of leucine, as expected, was observed in parallel with the increase in the absorption at 350 mμ until the amount of leucine reached a plateau (Fig. 8). However, it has to be noted that the formation of the tetrahydropyridazone derivative was estimated to be less than the concomitant release of leucine throughout the reaction period. For this reason, it was supposed, from the instability of III, that the compound (III), once formed, tended to decompose during the cleavage reaction.

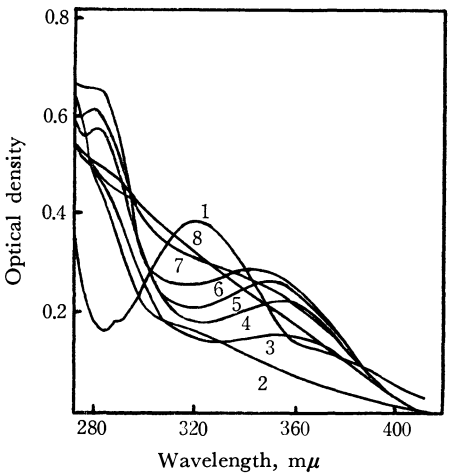

Fig. 7. Change of absorption spectrum during the reaction of the oxidized carbobenzoxytryptophylleucine with hydrazine in a 50% ethanol solution.

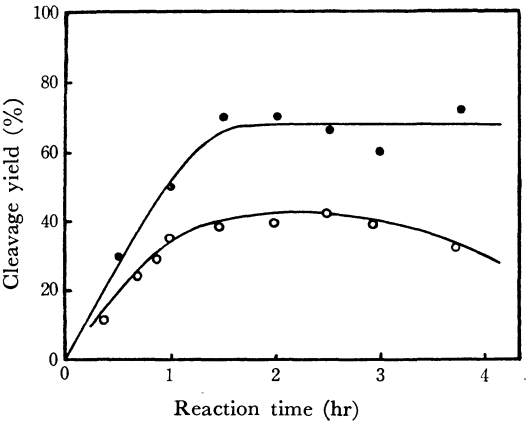

Fig. 8. Relationship between the change of absorbancy at 350 mμ (-○-) and release of leucine (-●-) during the reaction of the oxidized carbobenzoxytryptophylleucine with hydrazine.

By the thin-layer chromatography of the reaction mixture after the reaction of the ozonized carbobenzoxyalanyltryptophylleucine for two hours, two new yellow substances were detected. The major one, slowly moving, was identified as VI, and the other, a minor component, was assumed to be one of decomposition products since this substance showed a spectrum quite different from that of VI. This product was neither alanine nor leucine, and it gave no ninhydrin reaction even after acid hydrolysis.[12] Though no details on the decomposition reaction of VI are available at the present time, it may be concluded that the cleavage reaction of the tryptophyl bond occurred through the series of chemical reactions presented in Fig. 1.

Experimental

Methods and Materials. Paper chromatography on Toyo No. 51 filter paper was carried out using a solvent system, A (*n*-butanol-water-acetic acid, 4 : 1 : 1 by volume) or B (pyridine-*n*-butanol-water-acetic acid, 10 : 15 : 12 : 3 by volume). Thin-layer chromatography (silica gel G, Merck AG) was also performed with either solvent system. The amino acid was determined by Cd-ninhydrin reaction after chromatography on filter paper.[13] The absorption spectra were measured by a Beckmann spectrometer, type DB. Ozone (1—2%) was generated from oxygen by a generator manufactured by the Nippon Ozone Co., Ltd., type 0—3—2, and the ozone concentration was determined by the KI–$Na_2S_2O_3$ method. The formic acid (99—100%) was purchased from Merck AG and was used without purification. Carbobenzoxy-DL-tryptophyl-L-alanine, -L-leucine, -L-phenylalanine, and -L-aspartic acid were prepared by a conventional method. Four tryptophyl peptides related to the adrenocorticotropic hormone were courteously supplied by Dr. H. Yajima of Kyoto University, Kyoto. All the melting points were uncorrected.

Ozonization of Tryptophan with or without Resorcinol. Into 1.0 m*l* of a formic acid solution containing 5 μmol of tryptophan and resorcinol (0, 5 or 10 μmol), the desired amount of ozone was bubbled within one minute at room temperature. Aliquots (0.1 m*l*) of the reaction mixture were then transferred into 3 m*l* of ethanol, and the absorbancies at 322 and 280 mμ were measured. The yield of *N'*-formylkynurenine formed was estimated by the absorbance at 322 mμ on the basis of the molar extinction of *N*-acetyl-*N'*-formylkynurenine ($\varepsilon = 4.25 \times 10^3$ in the mixture of formic acid and ehtanol, 1 : 10 by volume). Another aliquot (0.1 m*l*) was dried up under reduced pressure and incubated in 0.05 m*l* of 1 N hydrochloric acid for one hour at room temperature in order to remove the *N'*-formyl group. Then 10 μ*l* of the above solution was submitted to paper chromatography with either the A solvent or with water in order to determine kynurenine.

Ozonization of Several Synthetic Peptide with Ozone. One milliliter of a formic acid solution containing 5 μmol of the tryptophyl peptide or its derivative was treated by a stream of ozone (20 μmol with, or 10 μmol without, 10 μmol of resorcinol) for half an hour at room temperature. The amount of *N'*-formylkynurenine and kynurenine were estimated much as has been described above except for the procedure of the hydrolysis of kynurenine determination: that is, the hydrolysis of the ozonized peptide derivative was carried out under more drastic conditions (105°C for 20 hr with 6 N hydrochloric acid).

Effect of the Concentration of Hydrazine and the pH on the Release of Leucine from the Oxidized Product of *N*-α-Carbobenzoxytryptophyl Peptide. Into 10 m*l* of formic acid containing *N*-α-carbobenzoxy-DL-tryptophyl-L-leucine (45.1 mg, 100 μmol), 200 μmol of ozone were bubbled at room temperature within one minute. Aliquots (0.1 m*l*) were taken out and the formic acid was removed under reduced pressure. Into the residue, 0.5 m*l* of the hydrazine-acetate buffer listed in Table 3 was added. The solution or suspension was then heated to boil for two hours. When ten microliters of the reaction mixture were chromatographed on filter paper with the A solvent, the leucine was identified and determined.

For the study of the pH dependence of the hydrazine treatment, the oxidized *N*-α-carbobenzoxy-L-alanyl-L-tryptophyl-L-leucine was similarly treated with a hydrazine-acetate buffer at various pH values (molar ratio of the peptide derivative to hydrazine=1 : 20 in all experiments). (*Cf.* Table 4).

Cleavage Reaction of the Tryptophyl Bond by a Standard Procedure. One milliliter of a formic acid solution containing 5 μmol of the sample peptide derivative was treated with 20 or 10 μmol of ozone for half an hour with or without resorcinol (10 μmol). An aliquot (0.1 m*l*) taken out was evaporated to dryness and treated with a hydrazine(0.1 M)-acetate buffer (pH 3.6) at 105°C for 2 hr in a sealed tube. Then the sample was transferred quantitatively onto filter paper for chromatographic identification, and the amount of amino acid released was determined. A duplicate

experiment was made for the cleavage reaction of each tryptophyl peptide derivative.

The non-specific hydrolysis of *N*-α-carbobenzoxy-tryptophyl amino acids was studied by the same procedure except for the ozonization.

N-α-Acetyl-N'-formyl-DL-kynurenine. *N*-α-Acetyl-DL-tryptophan (2.46 g) dissolved in 100 m*l* of formic acid was oxidized with a stream of ozone at room temperature until the absorption at 280 mμ disappeared almost completely. On the evaporation of the formic acid, the resulting oily product was treated with methanol, and the slightly yellow powder (1.25 g) thus obtained was crystallized from methanol. Mp 194°C. λ_{max} 322 mμ ($\varepsilon=4.25\times10^3$ in ethanol and 4.05×10^3 in ethanol-formic acid (30 : 1 by volume)). ν(Nujol) 3395, 3300, 1729, 1710, 1590 and 1559 cm^{-1}. R_f(A) 0.81 (orange with an Ehrlich reagent).

Found: C, 56.16; H, 5,13; N, 9.74%. Calcd for $C_{13}H_{14}O_5N_2$: C, 56.11; H, 5.07; N, 10.07%.

4-L-(N-carbobenzoxy-L-alanylamino)-6-(o-aminophenyl)-2,3,4,5-tetrahydropyridaz-3-one (VI). By a similar procedure, the *N*-α-carbobenzoxy-L-alanyl-tryptophan methyl ester (400 mg) was oxidized by ozone. After the removal of the formic acid, the oily residue was dissolved in 10 m*l* of ethanol. To the ethanol solution 0.125 m*l* of 80% hydrazine hydrate was added, after which the solution was allowed to stand overnight at room temperature. The slightly yellow crystals thus separated were collected and recrystallized from ethanol (377 mg, 92%). Mp 197.5—198.5°C. R_f(B) 0.87 (orange with an Ehrlich reagent and a yellowish-orange fluorescence under ultraviolet light). λ_{max} 350 mμ ($\varepsilon=8.13\times10^3$), 285 mμ ($\varepsilon=10.5\times10^3$) and 250 mμ ($\varepsilon=16.5\times10^3$) in ethanol. ν(Nujol) 3420, 3270, 1660, 1609, 1558, 1540, 1530 and 1488 cm^{-1}.

Found: C, 61.19; H, 5.46; N, 16.61%. Calcd for $C_{21}H_{23}O_4N_5$: C, 61.60; H, 5.66; N, 17.11%.

4-L-Carbobenzoxyamino-6-(o-aminophenyl)-2,3,4,5-tetrahydropyridaz-3-one (V). By a similar procedure, V was prepared from the *N*-α-carbobenzoxy-L-tryptophan methyl ester. The crude product was recrystallized from methanol. Yield, 37%. Mp 199—200°C. R_f(B) 0.95 and (A) 0.81 (orange with an Ehrlich reagent and a yellowish-orange fluorescence under ultraviolet light). λ_{max} 350 mμ ($\varepsilon=8.10\times10^3$), 285 mμ ($\varepsilon=11.4\times10^3$) and 250 mμ ($\varepsilon=16.0\times10^3$) in ethanol. ν(Nujol) 3450, 3285, 3200, 1609, 1600, 1588, 1544, 1527 and 1488 cm^{-1}.

Found: C, 63.39; H, 5.25; N, 16.10%. Calcd for $C_{18}H_{18}O_3N_4$: C, 63.89; H, 5.36; N, 16.56%.

6-(o-Aminophenyl)-2,3,4,5-tetrahydropyridaz-3-one. This compound was prepared from β-indolepropionic acid in a 15% yield by ozonization and subsequent hydrazine treatment. λ_{max} 350 mμ ($\varepsilon=7.0\times10^3$), 285 mμ ($\varepsilon=10.6\times10^3$) and 250 mμ ($\varepsilon=15.9\times10^3$) in ethanol.

Found: C, 63.26; H, 5.84; N, 21.74%. Calcd for $C_{12}H_{11}ON_3$: C, 63.47; H, 5.84; N, 22.21%.

N-α-Carbobenzoxy-L-alanyl-L-tryptophyl-L-leucine Methyl Ester. *N*-α-Carbobenzoxy-L-alanine was coupled with the L-tryptophyl-L-leucine methyl ester by dicyclohexylcarbodiimide, and the pure, protected tripeptide ester was then obtained by recrystallization from ethyl acetate-petroleum ether. Mp 169.5—170°C. $[\alpha]_D^{26}=-34.5$ (*c* 1.0, glacial acetic acid).

Found: C, 64.74; H, 6.70; N, 10.32%. Calcd for $C_{29}H_{36}O_6N_4$: C, 64.91; H, 6.76; N, 10.44%.

N-α-Carbobenzoxy-L-alanyl-L-tryptophyl-L-leucine. The *N*-α-carbobenzoxy-L-alanyl-L-tryptophyl-L-leucine methyl ester (1.07 g) was suspended in methanol (30 m*l*), and the 2 N sodium hydroxide (2.2 m*l*) was added. The alkaline solution was stirred for an hour under cooling with ice water and then for four hours at room temperature. After the evaporation of the methanol, the aqueous solution was acidified with 1 N hydrochloric acid, and the white precipitates thus separated was collected. Yield, 1.01 g (96.2%). The crude protected tripeptide was dissolved in ethyl acetate (30 m*l*); by the addition of dicyclohexylamine (0.48 m*l*), the dicyclohexylammonium salt (1.30 g, 92.2%) was obtained. Mp 183—185°C.

Found: C, 66.81; H, 8.36; N, 9.95%. Calcd for $C_{40}H_{57}O_6N_5\cdot H_2O$: C, 66.55; H, 8.24; N, 9.70%.

The dicyclohexylammonium salt (1.30 g) suspended in water (50 m*l*) was acidified with 1N hydrochloric acid (2 m*l*), and the white precipitates were extracted into ethyl acetate, which was then dried over anhydrous sodium sulfate and evaporated. Since the protected tripeptide was not crystallized, it was again dissolved in a 5% sodium hydrogencarbonate solution. The pure tripeptide was then separated by acidification with 1N hydrochloric acid. Yield, 0.98 g (96.9%). Mp 156—157°C. $[\alpha]_D^{26}=-29.5$ (*c* 1.0, glacial acetic acid).

Found: C, 64.29; H, 6.52; N, 10.46%. Calcd for $C_{28}H_{34}O_6N_4$: C, 64.35; H, 6.56; N, 10.72%.

The authors wish to express their thanks to Professor Kozo Narita for his discussions throughout this investigation. We also wish to thank Mr. Minoru Kuroda for his technical assistance.

Studies on Aminosugars. XXIV. The Facile Elimination of the Derivatives of a Pyranosid-4-ulose*1

Tsutomu TSUCHIYA, Kiyohiko SUO and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received September 13, 1969)

Methyl 3-azido-3-deoxy-α and β-D-xylopyranoside are prepared. The oxidation of the 2-*O*-benzoylated derivative of the above-mentioned α-anomer with the Pfitzner-Moffatt reagent leads to the facile elimination of the elements of benzoic acid and the formation of the 4-azido derivative of 5,6-dihydro-α-pyran-5-one. The 3-ethoxycarbonylamido derivative obtained from the above-mentioned 3-azido derivative is oxidized similarly to afford the 4-ethoxycarbonylamido derivative of 5,6-dihydro-α-pyran-5-one. The mechanisms of these elimination reactions are discussed.

In recent years, it has been shown that the oxidation of suitably-protected carbohydrates with dimethyl sulfoxide in the presence of dicyclohexylcarbodiimide and a proton source,[1] phosphorous pentoxide[2] or acid anhydride[3] is a unique and mild method of general application. The reagents oxidize either primary or secondary sugar hydroxyl groups into aldehydes or ketones which are versatile and which are, especially, of potential importance in the synthesis of branched-chain sugars. On the other hand, the oxidation of a secondary hydroxyl group of sugars into a ketone group sometimes results in the elimination of an acyloxyl group and proton in addition to oxidation affording such enones as pyranoid derivatives. Elimination of this kind is useful for introducing a double bond into the pyranoside ring.

In this paper we will present a study of the oxidation of several protected 3-azido-3-deoxy and 3-ethoxycarbonylamido pyranosides with the above-mentioned reagents; this oxidation resulted in the formation of 4-azido and 4-ethoxycarbonylamido derivatives of 5,6-dihydro-2*H*-pyran-5-one.

The first objective of the synthesis was methyl 3-azido-3-deoxy-α-D-xylopyranoside (VIII). 1,2-*O*-Isopropylidene-α-D-xylopyranose (II) was prepared from D-xylose through 1,2 : 3,5-di-*O*-isopropylidene-α-D-xylofuranose (I) by the method of Levene and Raymond[4] and was tritylated to give the 5-*O*-trityl derivative (III). The oxidation of III with the Pfitzner-Moffatt reagent[1] gave a 3-keto derivative (IV) which, on reduction with sodium borohydride, afforded 1,2-*O*-isopropylidene-5-*O*-trityl-D-ribose (V).[5] It should be noted that, when the oxidation of III was effected with dimethyl sulfoxide-acetic anhydride, 1,2-*O*-isopropylidene-3-*O*-methylthiomethyl-5-*O*-trityl-α-D-xylofuranose (IV′) was obtained in addition to IV. A mesyl derivative (VI) prepared from V was treated with sodium azide in dimethyl formamide to afford 3-azido-3-deoxy-1,2-*O*-isopropylidene-5-*O*-trityl-D-xylose (VII). The inversion at C-3 of VI was confirmed by a comparison of the NMR spectra of VI, VII, and the 3-*O*-mesyl derivative (VI′) of III.

The treatment of VII with acidic methanol afforded the desired methyl 3-azido-3-deoxy-D-xylopyranoside in the form of an anomeric mixture. The separation of anomers was effected by column chromatography with Dowex 1×2 (OH form) resin; the α-form (VIII) and β-form (VIII′) were thus obtained in approximately equal amounts. Catalytic hydrogenation over platinum oxide gave the α-form(IX) and β-form (IX′) of methyl 3-amino-3-deoxy-D-xyloside respectively. The melting points and optical rotations of IX and IX′ agreed well with those reported for the corresponding substances prepared by entirely different methods;[6,7] this confirmed the pyranoside structure of the azido compounds. The overall yield of

the total of IX and IX′ from xylose was about 25%.

The selective benzoylation of the α-anomer (VIII) with benzoyl chloride in pyridine gave 2-*O*-benzoyl derivative (X) in a 70% yield. It is of interest to note that the β-anomer yielded 2 and 4-*O*-benzoylated products in low yields, suggesting that the selectivity is peculiar to the α-anomer.

When the 2-*O*-benzoyl derivative was oxidized with dimethyl sulfoxide-dicyclohexylcarbodiimide-trifluoroacetic acid - pyridine, the product was found to be an azido-ketonic derivative of dihydropyran (XII) which showed a characteristic absorption maximum at 273 mμ (ε 7500). The structural proofs were obtained by infrared and NMR spectroscopy; the patterns, shown in Fig. 1, indicated the structure of XII to be (2S)-4-azido-5,6-dihydro-2-methoxy-α-pyran-5-one. The absence of the expected oxidative product (XI) in the crude product was shown by thin-layer chromatography.

On the other hand, the 2-*O*-benzoyl derivative (X) was hydrogenated over platinum oxide to give an amino derivative (XIII), which was then caused to react with ethyl chloroformate in the presence of sodium bicarbonate to give an ethoxycarbonylamido derivative (XIV). The oxidation

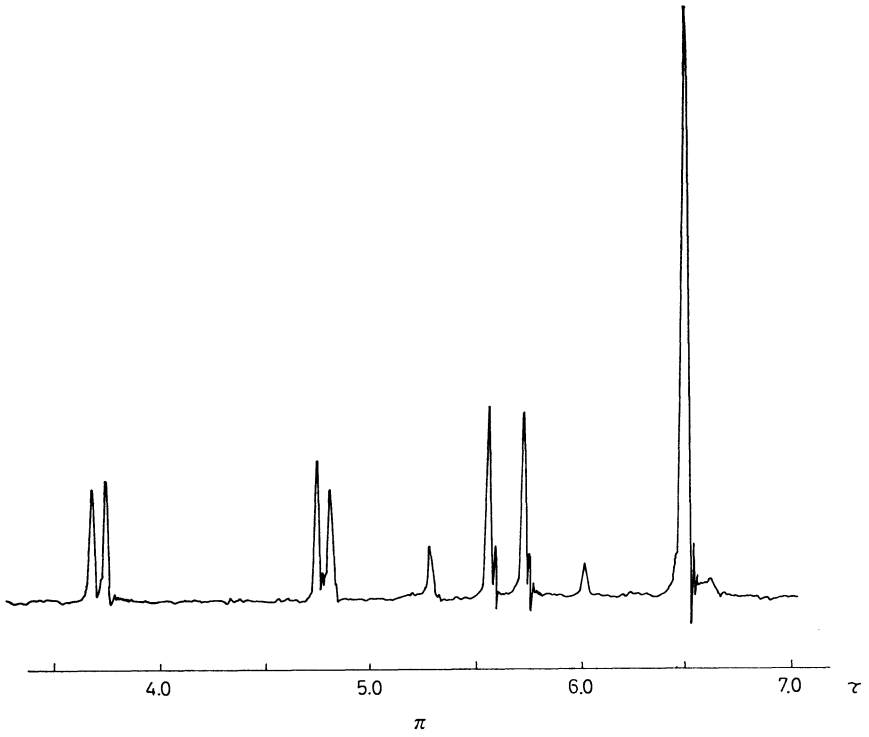

Fig. 1. The NMR spectrum of (2S)-4-azido-5,6-dihydro-2-methoxy-α-pyran-5-one (XII) at 60 MHz in chloroform-*d*.

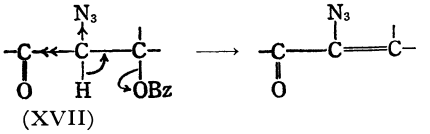
of XIV with dimethyl sulfoxide-acetic anhydride again afforded a dihydropyran derivative, namely, (2S)-5,6-dihydro-4-ethoxycarbonylamido-2-methoxy-α-pyran-5-one (XVI).

Discussion

Though such an elimination reaction as has been described above appears to be rarely encountered, several definite examples have recently been described. Beynon *et al.*[8] reported that the methyl-3,4,6-tri-*O*-benzoyl-α-D-*arabino*-hexopyranosidulose obtained from methyl 3,4,6-tri-*O*-benzoyl-α-D-glucoside by oxidation with ruthenium tetroxide underwent facile elimination to give an enone, 2-D-*glycero*-benzoyloxymethyl-4-benzoyloxy-6-D-*glycero*-methoxy-5,6-dihydro-α-pyran-5-one. Shibata *et al.*[9] reported that the oxidation of methy 3-acetamido-4,6-di-*O*-acetyl-3-deoxy-α-D-mannopyranoside with the Pfitzner-Moffatt reagent resulted in the formation of 2-D-*glycero*-acetyloxymethyl-4-acetylamido-6-D-*glycero*-methoxy-5,6-dihydro-α-pyran-5-one. Cree *at al.*[10] also found that the oxidation of some partially-acetylated monosaccharides with dimethyl sulfoxide-sulfur trioxide-pyridine-triethyl amine led to the elimination of acetic acid and the formation of 6-aldehydo-4-hexenopyranosides.

Whichever detailed mechanism is involved, these reactions are β-eliminations; the driving force of the elimination is the energy released in forming the double bond, while a potent influence is exerted by the carbonyl and azide group (in the case of XI) in facilitating elimination, as is depicted



(XVII)

by XVII. The substrates (XI and XV) are favorable for carbanion formation, and, in the elimination, the H and OBz removed are *cis*; those findings support an ElcB mechanism, but not an E2 mechanism, as in the case of the elimination of acetic acid from 2-phenyl-2-acetoxy-1-nitrocyclohexane, in which the H and OAc are *cis*.[11]

A possible alternative mechanism may proceed through such an enol-form as is shown by XI′.

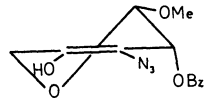
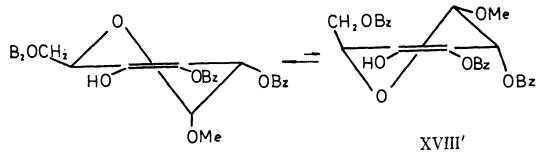
The electron-withdrawing benzoyloxy group may be oriented pseudoaxially, because a pseudoaxial group at an allylic position is better disposed for a π-orbital overlap than a pseudoequatorial one; thus, carbonium ion formation at the allylic position proceeds more readily upon the departure of a pseudoaxial group than upon the departure of a pseudoequatorial one,[12] and the resulting carbonium ion is stabilized by the allylic delocalization of the positive charge.



XI′



XVIII XVIII′

In connection with the mechanism, we should like to cite the finding by Gabriel,[13] who prepared methyl 2,3,6-tri-*O*-benzoyl-α-D-*xylo*-hexopyranosid-4-ulose by the oxidation of methyl 2,3,6-tri-*O*-benzoyl-α-D-galactopyranoside with dimethyl sulfoxide-acetic anhydride and found it unstable, although he made no study of the decomposition product. This 4-keto-derivative is closely related to our XI and XV; both are derivatives of α-D-xylopyranosid-4-ulose. However, XI and XV differ from the 4-keto-derivative in having no benzoyloxymethyl group (equatorial) at C-5 and in having an azido or ethoxycarbonylamido group at C-3 instead of a benzoyloxy group. When elimination occurs, the 4-keto-derivative may be transformed into a half-chair conformation, XVIII′, which has an axial benzoyloxy group at C-2 (allylic position). As compared with the stability of the conformation XI′, the stability of the conformation XVIII′ differs in having an instability factor caused by a pseudodiaxial interaction between the 5-benzoyloxymethyl group and the anomeric hydrogen atom, the same anomeric effects and $\Delta 2$ effects being involved in both conformations. Consequently, the 4-keto-derivative may have more of a tendency to take a stable conformation such as that of XVIII rather than one such as XI′. This may be the reason why XI and XV are more labile than the 4-keto-derivative.

Experimental

The NMR spectra were measured with a Varian A-60D spectrometer. Tetramethylsilane (τ 10.00; for the solutions of deuteriochloroform) and sodium 4,4-dimethyl-4-silapentane-1-sulfonate (τ 10.00; for the solutions of deuterium oxide) were used as the internal standards. The abbreviations used were as follows: p: proton, s: singlet, d: doublet, t: triplet, q: quartet, m: multiplet, d.d: doublet of doublets. Thin-layer chromatograms were visualized by spraying them with sulfuric acid at room temperature or by heating them at 110°C.

1,2-*O*-Isopropylidene-5-*O*-trityl-α-D-erythro-pentofuranos-3-ulose (IV). *a)* To a solution of 1,2-*O*-isopropylidene-5-*O*-trityl-α-D-xylofuranose (III) (8.77 g) in anhydrous benzene (60 m*l*) containing dry dimethyl sulfoxide (DMSO) (10 g), pyridine (3.2 m*l*), and trifluoroacetic acid (1.6 m*l*) was added dicyclohexylcarbodiimide (3.5 g×2, at an interval of 0.5 hr); the suspension was then stirred for 2 hr at room temperature. Ether (300 m*l*) and a solution of oxalic acid (2.6 g) in methanol (20 m*l*) were added in turns. After the evolution of gas had ceased, water (150 m*l*) was added, and an insoluble material was filtered off. The ether-layer was washed with a sodium bicarbonate solution and with water successively. After having been dried over sodium sulfate, the ether solution was evaporated to give a syrup which, on trituration with ether or ethanol, gave crystals. The addition of petroleum ether completed the crystallization; 6.97 g (80%), recrystallized from isopropanol; mp 131—132°C, $[\alpha]_D^{25}$ +132° (*c* 1, chloroform). (Sowa[5] reported mp 132°C and $[\alpha]_D$ +132°). Found: C, 75.83; H, 6.42%. Calcd for $C_{27}H_{28}O_5$: C, 75.33; H, 6.09%. R_f 0.60 (benzene-ethyl acetate 30 : 1).

IR (KBr): 1775 (C=O), 1388, 1375 (isopropyl), 703 cm^{-1} (phenyl).

NMR ($CDCl_3$): τ: 8.53 (6-p. s., isopropylidene), 6.67, 6.52 (each 1-p. q., H-5, 5′), 5.60 (1-p. m., H-4), 5.45 (1-p. d.d., H-2), 3.68 (1-p. d., H-1), 2.5—2.85 (15-p. m., phenyl); $J_{1,2}$ 4.5 Hz, $J_{2,4}$ 1 Hz, $J_{5,5'}$ 10.2 Hz, $J_{4,5}$ 2.7 Hz, $J_{4,5'}$ 2.6 Hz.

b) With DMSO-Ac_2O. To an ice-cold solution of III (37.05 g) in DMSO (120 m*l*), acetic anhydride (80 m*l*) was added; the mixture was set aside for 2 hr at that temperature and then for 3 days at room temperature. On thin-layer chromatography (TLC) (silica gel, benzene-ethyl acetate 30 : 1), three spots (R_f 0.67 (IV′), 0.60 (IV), and 0.22 (III)) were detected. Evaporation *in vacuo* gave a syrup, which was then dissolved in chloroform (200 m*l*). The solution was washed with a sodium bicarbonate solution and water successively. After having been dried over sodium sulfate, the solution was evaporated to give a syrup. As the separation of IV and IV′ by column chromatography was unsuccessful, the syrup was reduced with sodium borohydride. To a suspension of the syrup in aqueous ethanol (1 : 3, 750 m*l*), sodium borohydride (3.35 g) was added; the mixture was then agitated for 5 hr. The syrup obtained by evaporation was dissolved in ethyl acetate (900 m*l*) and washed thoroughly with water. Drying over sodium sulfate, followed by evaporation, gave a syrup which was subjected to column chromatography (silica gel, 450 g) with benzene-ethyl acetate (15 : 1). Fractionation gave IV′ between 930

and 1250 m*l* (yield 17.6 g), V between 1330 and 1590 m*l* (12.3 g), III+V between 1590 and 2100 m*l* (11 g), and III between 1200 and 3000 m*l* (4 g). V was recrystallized from benzene-*n*-hexane (1 : 25); 9.39 g; mp 99—100°C. IV′ was recrystallized from ethanol and proved to be 1,2-*O*-isopropylidene-3-*O*-methylthiomethyl-5-*O*-trityl-α-D-xylofuranose (14.6 g); mp 102—103°C, $[\alpha]_D^{15}$ −59.0° (*c* 1, chloroform).

Found: C, 70.94; H, 6.54; S, 6.57%. Calcd for $C_{29}H_{32}SO_5$: C, 70.70; H, 6.55; S, 6.51%.

IR (KBr); 1383, 1375 (isopropyl), 705 cm^{-1} (phenyl).

NMR ($CDCl_3$): τ: 8.68 (3-p. s., isopropylidene), 8.46 (3-p. s., isopropylidene), 8.10 (3-p, s., SCH_3), 6.80 (1-p. q., H-5), 6.48 (1-p. q.. H-5′), 5.75 (1-p. d., H-2 or H-3), 5.3—5.7 (4-p. m., H-3 or H-2, H-4, OCH_2-SCH_3), 4.12 (1-p. d., H-1), 2.35—2.90 (15-p. m., trityl); $J_{1,2}$ 3.9 Hz, $J_{2,3}$ ~0 Hz, $J_{4,5}$ 6.2 Hz, $J_{4,5'}$ 5.8 Hz, $J_{5,5'}$ 9.7 Hz.

1,2-*O*-Isopropylidene-5-*O*-trityl-D-ribofuranose (V). To a suspension of IV (6.97 g) in aqueous ethanol (1 : 3, 80 m*l*), sodium borohydride (0.37 g) was added; the mixture was then shaken gently for a while, a clear solution soon resulted, and then crystals were gradually deposited. After 1 hr's standing, the whole mixture was concentrated to a small volume, and the resultant precipitate was dissolved in ethyl acetate. The solution was washed with water, dried over sodium sulfate, and evaporated to give a solid. To a solution of the solid in benzene (10 m*l*), a 75-m*l* portion of petroleum ether was added all at once; the mixture was then stimulated with a glass rod to give needles (6.1 g); mp 99—100°C, $[\alpha]_D^{18}$ +25.0° (*c* 1, chloroform) (reported[5] mp 117°C, $[\alpha]_D$ +25.8°), R_f 0.53 (silica gel, benzene-ethyl acetate 6 : 1).

Found: C, 75.07; H, 6.45%. Calcd for $C_{27}H_{28}O_5$: C, 74.98; H, 6.52%.

The product was chromatographically homogeneous, and no contamination of the xylo-isomer (III, R_f 0.40) was shown.

IR (KBr): 3460 (OH), 1385, 1377 (isopropyl), 700 cm^{-1} (phenyl).

NMR ($CDCl_3$): τ: 8.64 (3-p. s., isopropylidene), 8.45 (3-p. s., isopropylidene), 7.7 (1-p. d., disappeared on deuteration, OH). 6.63 (2-p. m., H-5, 5′), 6.2—5.95 (2-p. m., H-3, H-4; irradiation at τ 5.49 changed the pattern of this area), 5.49 (1-p. triplet-like pattern, H-2), 4.16 (1-p. d., H-1; collapsed to a singlet on irradiation at τ 5.49), 2.35—2.95 (15-p. m., trityl); $J_{1,2}$ 4.0 Hz.

1,2-*O*-Isopropylidene-3-*O*-mesyl-5-*O*-trityl-D-ribofuranose (VI). To an ice-cold solution of V (6.55 g) in pyridine (60 m*l*), methanesulfonyl chloride (1.77 m*l*) was added drop by drop; the mixture was then allowed to stand for 1 hr under ice-cooling, and then for 24 hr at room temperature. The evaporation of the solution gave a syrup which was then dissolved in chloroform and washed successively with water, a sodium bicarbonate solution, and water. After having been dried over sodium sulfate, the solution was treated with charcoal and coevaporated with toluene to give a thick syrup (7.70 g). The product was chromatographically homogeneous (R_f 0.49 with silica gel, benzene-ethyl acetate 30 : 1) and sufficiently pure for the subsequent reaction. The syrup was crystallized from aqueous 50% ethanol; mp 123—125°C, $[\alpha]_D^{15}$ +64.6° (*c* 0.8, chloroform).

Found: C, 66.11; H, 5.97; S, 6.30%. Calcd for $C_{28}H_{30}O_7S$: C, 65.86; H, 5.92; S, 6.28%.

IR (KBr): ~1365 (broad, isopropylidene), 1180, 835 (mesyl), 703 cm^{-1} (phenyl).

NMR ($CDCl_3$): τ: 8.64 (3-p. s., isopropylidene), 8.45 (3-p. s., isopropylidene), 7.13 (3-p. s., SO_2CH_3), 6.83 (H-5) and 6.47 (H-5′)(eight-line signals, with the inner four being most intense, typical for the AB part of an ABX system), 5.79 (1-p., doublet of triplets in appearance, H-4), 5.17 (1-p. q., H-2), 5.04 (1-p. q., H-3), 4.08 (1-p. d., H-1), 2.9—2.4 (15-p. m., trityl); $J_{1,2}$ 3.5 Hz, $J_{2,3}$ 4.6 Hz, $J_{3,4}$ 8.5 Hz, $J_{4,5}$ 3.5 Hz, $J_{4,5'}$ 2.5 Hz, $J_{5,5'}$ 11.2 Hz. The irradiation at the frequency of H-5 causes H-5′ to become a doublet ($J_{4,5'}$ 2.5 Hz) and H-4 to become a doublet of doublets; the irradiation at the frequency of H-5′ causes H-5 to become a doublet ($J_{4'5}$ 3.5 Hz) and H-4 to become a doublet of doublets; the irradiation at the frequency of H-1 causes H-2 to become a doublet ($J_{2,3}$ 4.6 Hz); the irradiation at the frequency of H-4 causes H-5 and H-5′ to become an AB quartet ($J_{5,5'}$ 11.2 Hz) and H-3 to become a doublet ($J_{2,3}$ 4.6 Hz).

1,2-*O*-Isopropylidene-3-*O*-methyl-5-*O*-trityl-D-xylofuranose (VI′). This compound was prepared from III as has been described in the procedure for the D-ribo isomer (VI); mp 116—117°C, $[\alpha]_D^{15}$ −55.0° (*c* 1, chloroform).

Found: C, 65.69; H, 6.16; S, 5.95%. Calcd for $C_{28}H_{30}O_7S$: C, 65.86; H, 5.92; S, 6.28%.

IR (KBr): 1370 (isopropylidene), 1175, 837 (mesyl), 700 cm^{-1} (phenyl).

NMR ($CDCl_3$): τ: 8.70 (3-p, s., isopropylidene), 8.49 (3-p. s., isopropylidene), 7.28 (3-p. s., SO_2CH_3), 6.72 (H-5) and 6.40 (H-5′)(eight-line signals typical for the AB part of an ABX system), 5.56 (1-p. clear-cut octet, H-4), 5.20 (1-p. d., H-2), 4.90 (1-p. d., H-3). 4.10 (1-p. d., H-1), 2.84—2.4 (15-p. m., trityl); $J_{1,2}$ 3.8 Hz, $J_{2,3}$ 0 Hz, $J_{3,4}$ 3.0 Hz, $J_{4,5}$ 7.6 Hz, $J_{5,5'}$ 9.7 Hz.

3-Azido-3-deoxy-1,2-*O*-isopropylidene-5-*O*-trityl-D-xylofuranose (VII). To a solution of VI (6.38 g) in anhydrous dimethyl formamide (60 m*l*, dried over CaH_2) was added sodium azide (2.1 g). The suspension was heated at 150°C under stirring, and the reaction was pursued by TLC (silica gel, developed with benzene). After 24 hr, the reaction was completed. The organic layer was evaporated *in vacuo*. The resultant brown syrup was dissolved in benzene and passed through a column of silica gel (100 g) with the aid of benzene; after the initial benzene solution had thus been absorbed in the column, the column was set aside for several hours and then treated with benzene as usual. This procedure gave a completely decolorized eluate. The fraction containing the substance with an R_f value of 0.51 was collected and evaporated to give a clear thick syrup: 4.48 g (78%), $[\alpha]_D^{15}$ −42.5° (*c* 0.9, chloroform), IR (KBr): 2108 (N_3), 1385, 1375 (isopropylidene), 703, 697 cm^{-1} (phenyl).

NMR ($CDCl_3$): τ: 8.72 (3-p. s., isopropylidene), 8.50 (3-p. s., isopropylidene), 6.70 (H-5) and 6.46 (H-5′) (eight-line signals typical for the AB part of an ABX system), 6.00 (1-p. d., H-3), 5.67 (1-p. octet, H-4), 5.43 (1-p. d., H-2), 4.20 (1-p. d., H-1), 2.45—2.85 (15-p. m., trityl); $J_{1,2}$ 3.8 Hz, $J_{2,3}$ 0 Hz, $J_{3,4}$ 3.2 Hz, $J_{4,5}$ 7.3 Hz, $J_{4,5'}$ 5.6 Hz, $J_{5,5'}$ 9.7 Hz.

Methyl 3-Azido-3-deoxy-α and β-D-xylopyranoside (VIII, VIII′). A solution of VII (15.26 g) in 1.5% hydrochloric acid in methanol (200 m*l*) was ref-

luxed for 20 hr. Powdered sodium bicarbonate was then gradually stirred in until all gas evolution had ceased. After filtration, the solution was evaporated to give a solid; this solid was boiled with water (30 ml) for a while and then cooled, and the solution was filtered from an insoluble material. The filtrate was evaporated to give a solid, and the procedure was repeated twice more. The resultant solid (6.83 g), which contained a trace amount of tritylcarbinol, was dissolved in a small amount of water and slowly chromatographed on a column of Dowex 1×2 (OH form) resin (220 ml, 20×700 mm) with water. After the removal of the early eluate of 350 ml of water, the fractions were cut into 13-ml portions. An unknown substance (R_f 0.24 with silica gel and benzene - methyl ethyl ketone 3 : 1) appeared between Nos. 6—9 (170 mg after dried), and next the α-anomer (VIII, R_f 0.39) appeared between Nos. 11—37. The β-anomer (VIII′, R_f 0.36) appeared between Nos. 42—80. The second and the third fractions were collected and evaporated to give the α-anomer (2.28 g) and the β-anomer (2.73 g) respectively.

The α-anomer was dissolved in chloroform (30 ml), and filtered, and the filtrate was evaporated to about 5 ml. Gradual cooling at 5°C gave cubic crystals (2.22 g); mp 93—93.5°C, $[\alpha]_D^{20}$ +147° (*c* 0.6, water).

Found: C, 38.29; H, 5.89; N, 22.18%. Calcd for $C_6H_{11}O_4N_3$: C, 38.10; H, 5.86; N, 22.21%.

The β-anomer was crystallized by a similar procedure; cubic crystals (2.48 g), mp 88—89°C, $[\alpha]_D^{20}$ −65.7° (*c* 0.6, water).

Found: C, 38.27; H, 5.89; N, 22.11%.

IR (KBr): α and β-Anomers: 3300—3500 (broad, OH), 2100 (N_3) cm^{-1}. NMR (D_2O) α-Anomer (VIII): τ: 5.31 (1-p. d., H-1), 6.53 (3-p. s., OCH_3); $J_{1,2}$ 2.3 Hz. β-Anomer (VIII′): τ: 5.64 (1-p. d., H-1), 6.45 (3-p. s., OCH_3); $J_{1,2}$ 7.5 Hz.

Methyl 3-Amino-3-deoxy-α- and β-D-xylopyranoside (IX, IX′). Compound VIII (107 mg), dissolved in 50% aqueous ethanol (2 ml), was hydrogenated with hydrogen (50 lb/sq. inch) and preactivated platinum oxide (47 mg) for 2 hr at room temperature. After filtration, the solution was then evaporated to give a solid; this solid was subsequently recrystallized from ethanol to give needles (70 mg); mp 193—195°C (decomp.), $[\alpha]_D^{20}$ +158° (*c* 0.4, water) (lit,[6] mp 195—196°C, $[\alpha]_D$ +155° (*c* 1, pyridine)).

Found: C, 44.54; H, 8.31; N, 8.31%. Calcd for $C_6H_{13}O_4N$: C, 44.16; H, 8.03; N, 8.58%.

β-Anomer (IX′) was obtained by a procedure similar to that used for VIII′; needles, mp 196—199°C (decomp.), $[\alpha]_D^{20}$ −63.2° (*c* 0.5, water) (lit,[7] mp 196—197°C, $[\alpha]_D$ −65° (*c* 1, water)).

The α and β-anomers showed the same R_f values (0.6) on paper chromatography (Toyo Roshi No. 50, sprayed with ninhydrin) with *n*-butanol-pyridine-water-acetic acid (6 : 4 : 3 : 1).

Methyl 3-Azido-2-*O*-benzoyl-3-deoxy-α-D-xylopyranoside (X). Into an ice-cold solution of VIII (6.45 g) in anhydrous pyridine (100 ml), benzoyl chloride (6.78 g) was gradually stirred in; the solution was then set aside for 0.5 hr under ice-cooling, and subsequently for one day at room temperature. TLC (silica gel, benzene-ethyl acetate 6 : 1) showed that the reaction mixture contained three components, with R_f values of 0.82 (dibenzoate), 0.37 (X, main), and 0.09 (VIII). Evaporation *in vacuo* gave a syrup; this syrup was dissolved in chloroform, and the solution was washed successively with a potassium bisulfate solution, water, a sodium bicarbonate solution, and with water again. After drying over sodium sulfate, followed by evaporation, the resultant syrup was chromatographed on silica gel (100 g) with benzene - ethyl acetate (6 : 1). After the removal of the early eluate (120 ml), the fractions were cut into 15-ml portions. Dibenzoate appeared between Nos. 1—5, and X appeared between Nos. 6—20. The latter fractions were collected and evaporated to give a syrup. A solution of the syrup in chloroform was washed with water, dried over sodium sulfate, and concentrated. The addition of petroleum ether gave a syrup. This syrup did not crystallize; 7.02 g (70%), $[\alpha]_D^{16}$ +202.0° (*c* 0.5, chloroform).

Found: C, 53.53; H, 5.49; N, 13.81%. Calcd for $C_{13}H_{15}O_5N_3$: C, 53.24; H, 5.16; N, 14.33%.

IR (KBr): 3450 (OH), 2100 (N_3), 1725 (ester), 710 cm^{-1} (phenyl).

NMR ($CDCl_3$): τ: 6.9 (OH, disappeared on deuteration), 6.62 (3-p. s., OCH_3), 5.88—6.44 (4-p. m., H-3, 4, 5, 5′), 5.10 (1-p. q., H-2), 4.97 (1-p. d., H-1), 1.86—1.97 (2-p.) and 2.3—2.75 (3-p.)(benzoyl); $J_{1,2}$ 3.2 Hz, $J_{2,3}$ 10.0 Hz.

The NMR pattern indicated X to be 2-*O*-benzoate, not 4-*O*-benzozte.

(2S) - 4 - Azido -5,6-dihydro-2-methoxy-α-pyran-5-one (XII). To a solution of X (569 mg) in a mixture of anhydrous benzene (6 ml), dimethyl sulfoxide (6 ml), pyridine (0.32 ml), and trifluoroacetic acid (0.16 ml) was added dicyclohexylcarbodiimide (2.0 g); the suspension was then stirred for 2 hr at room temperature. Ether (50 ml) and a solution of oxalic acid (1.1 g) in methanol (10 ml) were then added in turn. After the evoluation of gas had ceased, water (50 ml) was added; an insoluble material was subsequenty filtered off. The ethereal layer was washed several times with a sodium bicarbonate solution and with water. After having been dried over sodium sulfate, the ethereal solution was evaporated. The resultant syrup was dissolved in a mixture of benzene-ethyl acetate (30 : 1) and chromatographed on a column of silica gel (45 g) with the above-described solvent system. The fractions containing XII were collected and evaporated to give a pale yellow solid; 246 mg (76.3%); mp 58—58.5°C, $[\alpha]_D^{16}$ −23.1° (*c* 0.4, chloroform), λ_{max}^{MeOH} 273 mμ (ε 7500), R_f 0.63 (silica gel, benzene-ethyl acetate 30 : 1).

Found: C, 42.53; H, 4.15; N, 24.40%. Calcd for $C_6H_7O_3N_3$: C, 42.60; H, 4.17; N, 24.85%.

IR (KBr): 2120 (N_3), 1705 (C=O), 1630 (C=C) cm^{-1}.

NMR ($CDCl_3$): τ: 6.49 (3-p. s., OCH_3), 5.80, 5.52 (2-proton AB quartet, H-6, 6′), 4.80 (1-p. d., H-2), 3.71 (1-p. d., H-3); $J_{2,3}$ 3.8 Hz, $J_{6,6'}$ 17.3 Hz.

This substance gradually changes during storage.

(2S) - 4 - Carboethoxyamido-5,6-dihydro-2-methoxy-α-pyran-5-one (XVI). A solution of X (194 mg) in a mixture (2 ml) of equal volumes of 1 N hydrochloric acid and ethanol was hydrogenated with preactivated platinum oxide (30 mg) and hydrogen under pressure (50 lb/sq. inch) for 2 hr. After filtration, the solution was evaporated and an aqueous solution of the residue was treated with charcoal. The aqueous solution was evaporated to give a solid (184 mg), which showed no absorption of the azide group (~2100 cm^{-1}) in the infrared spectrum: it was positive for ninhydrin

coloration.

To an aqueous-acetone (1 : 1) solution (3 ml) of the solid (179 mg) was added ethyl chloroformate (73.2 mg) in the presence of sodium bicarbonate (107 mg); the mixture was then stirred for 1 hr. Evaporation of the solution to about a half volume deposited an oily precipitate; this precipitate was extracted with ether, and the ethereal solution was washed with water, dried over sodium sulfate, and evaporated. The resultant solid (151 mg) was homogeneous on TLC, showing an R_f value of 0.62 with silica gel and ether.

A solution of the solid (104 mg) in DMSO (1.5 ml) and acetic anhydride (0.3 ml) was allowed to stand overnight at room temperature. On TLC (silica gel and chloroform), three sports, with R_f values of 0.05 (starting material), 0.20, and 0.30 (XV), were discerned. After the addition of a saturated sodium bicarbonate solution (15 ml), the reaction mixture was extracted with ether; the ethereal layer was washed thoroughly with water, dried over sodium sulfate, and concentrated. The residue was chromatographed on a silica-gel column with chloroform. The fraction containing XV was evaporated to give a solid; this solid was then recrystallized from ethanol to afford needles (38 mg); mp 64—65°C, $[\alpha]_D^{15}$ +73.8° (*c* 0.4, chloroform), λ_{max}^{MeOH} 271 mμ (ε 8500).

Found: C, 50.50; H, 6.32; N, 6.51%. Calcd for $C_9H_{13}O_5N$: C, 50.23; H, 6.09; N, 6.51%.

IR (KBr): 1745, 1705 (C=O), 1660 (C=O) cm^{-1}.

NMR ($CDCl_3$): τ: 8.72 (3-p. t., CH_2CH_3, J=7.1 Hz), 6.49 (3-p. s., OCH_3), 5.80 (2-p. q., CH_2CH_3), 5.77, 5.47 (2-proton AB quartet, H-6, 6′), 4.71 (1-p. d., H-2), 2.77 (1-p. d., H-3); $J_{2,3}$ 3.8 Hz, $J_{6,6'}$ 17.3 Hz.

The authors wish to thank Mr. Saburo Nakada for his elementary analysis and Mr. Yukio Horiuchi for his technical assistance. This work was supported in part by a grant-in-aid from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 537—542 (1970)

Color Reactions of Polyvinyl Acetate and Its Derivatives with Iodine*[1]

Sadao HAYASHI, Chozo KAWAMURA and Masanari TAKAYAMA

Faculty of Fiber Science and Technology, Shinshu University, Tokiiri, Ueda

(Received July 29, 1969)

It has been found that the addition of a methanol solution containing polyvinyl acetate (PVAc) and iodine to an aqueous solution of potassium iodide results in a red-violet color without precipitating any polymer. The absorption maximum was located at 510 mμ. The absorbance of the PVAc-iodine complex decreased only slightly with an increase in the degree of the polymerization of PVAc. A linear relationship was obtained between the abosrbance and the PVAc concentration. It was found from these results that the color reaction of PVAc with iodine can be used in a colorimetric determination of PVAc, which is insoluble in water. Further, an attempt was made to investigate the complex formation of the vinyl acetate-vinyl propionate copolymer (PVAc-PVPr) and the vinyl acetate-vinyl formacetal copolymer (PVAc-PVFA) with iodine. Although the absorption maximum of the color complex of PVAc-PVPr with iodine appeared at 510 mμ, independent of the copolymer composition, the absorbance decreased with an increase in the number of vinyl propionate units in the copolymer. The absorption maximum of the complex of PVAc-PVFA with iodine was observed to lie at 620 mμ for highly-acetalyzed polyvinyl alcohol and at 520 mμ for polyvinyl alcohol of a low degree of acetalyzation, while a new absorption maximum appeared in the range from 520 to 620 mμ in the intermediate case. The absorbances at the absorption maxima of the complexes of PVAc-PVFA with iodine were approximately the same as those of PVAc. The effect of an elevated temperature on the absorbance was smaller for PVAc-PVFA than for PVAc-PVPr. From these experiments, it became clear that the glass-transition temperature and the color intensity of the polymer-iodine complex have a simple relation.

It is well known that PVAc yields a red-violet-colored complex with iodine; this reaction has previously been applied to the detection of PVAc.[1)] This color development has been carried out in a heterogeneous system which sprays an iodine-potassium iodide solution on the polymer, or immerses the polymer in an iodine-iodide solution. Schweepe[2)] has already reported, regarding the detection of PVAc, that when a few drops of iodine in a potassium iodide solution are added to a sample

*[1] Polyvinyl Acetate and Its Derivatives. VI. Part V: S. Hayashi, M. Takayama and C. Kawamura, *Kogyo Kagaku Zasshi*, **73**, 412 (1970).

1) F. D. Hartley, *J. Polym. Sci.*, **34**, 397 (1959).

2) H. Schweepe, *Paint Technol.*, **27**, 14 (1963).

dissolved in some glacial acetic acid and the solution is diluted with water, the solution develops an intensive red-violet color. We[3] have also found that when both PVAc and iodine are dissolved in a solvent which is easy to mix with water such as methanol or acetone, and the solution is poured into an aqueous solution containing potassium iodide, then, immediately after mixing, the solution exhibits a red-violet color. If the color reaction of PVAc with iodine takes place in a homogeneous system, its reaction might be expected to be applicable to the determination of PVAc and the investigation of the properties of PVAc.

The present work was undertaken in order to examine the optimum conditions of the complex formation of PVAc with iodine in an aqueous phase, and to determine PVAc colorimetrically under the optimum conditions thus obtained. The invessigations of the complex formation of the PVAc copolymers, PVAc-PVPr and PVAc-PVFA, with iodine were also made, and the relationships between the absorbances of the complexes of the copolymers with iodine and the temperature at various temperatures were discussed.

Experimental

Preparations of PVAc and Its Derivatives. It may be expected that the color reaction depends on the degree of polymerization and on the branches in the polymer, as in the cases of amylose and amylopectin.[4] Therefore, two kinds of PVAc samples prepared by different processes were investigated.

PVAc samples made from vinyl acetate: Vinyl acetate was purified by distillation under a reduced pressure in a stream of nitrogen. The polymerization of vinyl acetate was carried out at 60—62°C by using benzoyl peroxide as an initiator. After polymerization for a given time, the contents were poured into a large amount of water in order to precipitate the polymer. The resultant polymer was washed five times with boiling water and then dried in a vacuum.

PVAc samples derived from polyvinyl alcohol (PVA): The various fractionated PVA samples listed in Table 2 were acetylated with acetic anhydride in pyridine. The pyridine solution was then poured into water to obtain the acetylated polymer. The resultant polymer was washed in boiling water until the odor of pyridine completely disappeared; then it was dried in a vacuum. The degree of acetylation of all the samples obtained was over 98 mol %, judging from the saponification values.

The degree of polymerization of PVAc was measured in a Ubbelohde Viscosimeter at 30°C in acetone by using the following equation:[5]

$$[\eta] = 7.94\times10^{-4}P^{0.62}$$

The PVAc samples are summarized in Tables 1 and 2.

PVAc-PVPr was prepared by the acetylation of partially-propionated PVA, which had been propionated in a homogeneous system of water and propionic acid by using hydrochloric acid as a catalyst. These samples are listed in Table 3. PVAc-PVFA was also prepared by the acetylation of partially-formacetalyzed PVA, which had been acetalyzed in a homogeneous system of water and formaldehyde by using sulfuric acid as a catalyst. These samples are presented in Table 4.

Reagents. All the chemicals were of a guaranteed grade and were used without further purification. An iodine stock solution was prepared by dissolving iodine (3.2g) in methanol (250 m*l*). The resultant solution was standardized by sodium thiosulfate and was used by diluting it with methanol to the desired concentration just before its use. A 0.1 N solution of potassium iodide was accurately prepared by dissolving potassium iodide (8.3005 g) in distilled water (500 m*l*); it was used by diluting it with distilled water to the desired concentration before use.

Absorbance Measurements. A Shimadzu spectrometer, Model Spectronic 20, was used for the measurement of the absorption spectra. The color development of PVAc-iodine was done as will be described in the following section. The absorption spectra of the PVAc copolymer-iodine complex were recorded under the optimum conditions established by the use of the PVAc-iodine complex. After 1 m*l* of a methanol solution of the polymer (0.1g/d*l*) had been added to 1 m*l* of a methanol solution of iodine (2.5×10^{-3} mol/*l*), 1 m*l* of the mixture was added to 25 m*l* of an aqueous iodide solution (2×10^{-3} mol/*l*) and the mixture was allowed to stand for an hour at 20°C. The absorbance of the color complex was then measured at the absorption maximum by using the iodine-iodide solution as the reference.

The effect of the temperature on the color development of the polymer-iodine complex was discussed under the above-mentioned conditions. After the color solution had been cooled at 3°C for 24 hr, the solution was permitted to stand for an hour at a definite temperature; then the absorbance was measured at the absorption maximum.

Results and Discussion

The Color Reaction of PVAc with Iodine. A methanol solution containing PVAc and iodine was poured into an aqueous solution of potassium iodide. Immediately after the addition, the solution developed an intensive red-violet color without precipitating any polymer. The spectra of the color complex are indicated in Fig. 1, together with those obtained under different color conditions. The absorption maximum was located at 510 mμ. The absorbance of an iodine-potassium iodide solution at 510 mμ was very small. Even if the contents of PVAc, iodine, and iodide were the same, the order in which iodine was added had a significant effect on the absorbance, as is illustrated in Fig. 1. This is considered to be due to the fact that the penetration of iodine into the polymer was insufficient since molecules of both PVAc and iodine are separately

dispersed in an aqueous solution. Considering the fact that the PVAc-iodine color reaction did not occur in the absence of potassium iodide, it may be concluded that iodide ions are indispensable to the formation of the complex with PVAc, as in the case of amylose.[6]

The standing time for the color development of the PVAc-iodine complex was investigated at 20°C, while the other components were kept constant. The color of the complex reached its maximum within half an hour after mixing; thereafter the absorbance remained almost constant for three days.

In order to study the effects of the concentrations of iodine and potassium iodide, a series of absorbances was measured under various concentrations of iodine and iodide. It was found from these experiments that the absorbance of the complex at 510 mμ, when the concentration of PVAc was kept at (5×10^{-4} g), reached a higher maximum more than iodine (2.5×10^{-6} mol) and potassium iodide (5×10^{-5} mol).

Figure 2 shows the effect of the amount of methanol on the color development, while the other compoments were kept constant. As is shown by the curve in Fig. 2, the absorbance decreased with an increase in the amount of methanol, but the decrease was only slight in the range of small amounts of methanol.

From the experimental results obtained above, the following procedures were selected as the optimum conditions for the measurement of the PVAc-iodine complex. One volume of a methanol solution of iodine (2.5×10^{-3} mol/*l*) is added to an equal volume of a methanol solution of PVAc, and then 1 m*l* of the mixture is stirred into 25 m*l* of an aqueous solution of iodide (2×10^{-3} mol/*l*). The color solutions are at once transferred into the test tube cells, which are covered with parafilm. The test tube cells are stored for an hour at 20°C, after which the absorbance at 510 mμ is measured with a spectrometer by using an iodine-iodide solution as a reference.

A calibration curve was made under the above-mentioned conditions. A linear relationship was obtained between the absorbance and the PVAc concentration over the range investigated.

The effect of the degree of the polymerization of PVAc on the color development was studied by using the samples shown in Tables 1 and 2. The results are shown in Fig. 3. In both the PVAc obtained from the acetylation of PVA and the PVAc formed by the polymerization of vinyl acetate in methanol, it was found that all the absorption maxima appear at 510 mμ, regardless of the degree of polymerization, while the absorbances of the PVAc-iodine complexes decrease only slightly with an increase in the degree of polymerization.

From the above results, it was found that, if the degree of polymerization of PVAc is known, the color reaction of PVAc with iodine can be used in the colorimetric determination of PVAc, which is itself insoluble in water.

In free-radical polymerization, it is well known that long-chain branches are present in the PVAc molecules.[7] These branches are released during the hydrolysis of PVAc to PVA. Thus, such long-chain branches do not exist in PVA molecules.[8] To ascertain the effect of a branch on the color

○: PVAc derived from acetylation of PVA

reaction, the color reaction was attempted, but the color intensity of the PVAc samples obtained from vinyl acetate was almost identical with that of the PVAc samples derived from PVA, as is indicated in Fig. 3. The long-chain branches in the PVAc molecules may be so small as to be negligible at the low conversion[9] shown in Table 1. However, the effects of nonhydrolyzable long-chain branches formed by the abstration of an α-proton and those of the short-chain branches made by an intramolecular-chain transfer mechanism,[10] as in the case of the free-radical polymerization of ethylene,[11] can not be considered on the basis of the experimental results obtained here. Such discussion must await a detailed investigation of many samples synthesized under various conditions.

The Color Reactions of PVAc Copolymers with Iodine. On the basis of the results obtained above, we then proceeded to examine the absorption spectrum and the temperature dependence of the PVAc copolymer-iodine complex.

Although the color complex of PVAc-PVPr with iodine had its absorption maximum at 510 mμ, as in PVAc, regardless of the copolymer composition, the absorbance decreased with an increase in the number of vinyl propionate units in the copolymer, as is summarized in Table 3.

Table 3. Dependence of degree of propionylation on absorbance of PVAc-PVPr-iodine complex

Degree of propionylation (mol%)	Absorption maximum (mμ)	Absorbance (at 20°C)	T_g (°C)
0	510	0.475	28
5.72	510	0.460	25
11.04	510	0.450	23
16.28	510	0.430	21
22.18	510	0.360	19
27.97	510	0.320	16
30.46	510	0.295	15
32.04	510	0.284	15
33.93	510	0.239	14

Degree of polymerization of PVA used: 1090.

The absorption spectra of the color complex of PVAc-PVFA with iodine are illustrated in Fig. 4. A change in the color from red-violet to green-blue was observed with an increase in the number of vinyl formacetal units in the copolymer. The absorption maximum was observed at 620 mμ for highly-acetalyzed PVA and at 520 mμ for PVA of a low degree of acetalyzation, while a new absorption maximum appeared in the region

between 520 and 620 mμ in the intermediate case. These results are tabulated in Table 4.

Although the PVA used in our experiments did not give the color reaction in a dilute aqueous solution with iodine, partially-formacetalyzed PVA, which had been prepared by the acetalyzation of PVA in a homogeneous system of water and formaldehyde in the presence of sulfuric acid, developed a green-blue color with an increase in the degree of acetalyzation.[12] Since partially-formacetalyzed PVA was insoluble in methanol, the color reaction of the PVA derivatives with iodine was carried out in the aqueous phase, in which methanol as the polymer solvent was replaced by water. The results for formacetalyzed PVA, which had about a 30 mol% degree of acetalyzation, as a representative example are indicated in Fig. 4, together with those of the other PVAc copolymer. The absorption maximum was located at the longer wavelength of 670 mμ, and the absorbance was remarkably lower compared with that of PVAc-PVFA, but with the same degree of acetalyzation. These results clearly suggest that the higher green-blue color development of the copolymer-iodine complex depends not only on the acetal units, but on the vinyl acetate units, and that the red-violet color reaction of PVAc-iodine is based on the long sequence lenght of the vinyl acetate unit in the polymer chain.

Figures 5 and 6 show the results of the temperature dependence of the absorbance at the absorption maximum for the PVAc homopolymer and the PVAc copolymer. In the case of the PVAc homopolymer, it was found that the color intensity is slightly decreased up to about 30°C as the temperature is raised, and that color-fading takes

place in the vicinity of 30°C. This temperature agrees with the glass-transition temperature (T_g) of PVAc. In order to examine this phenomenon more exactly, the effects of the various PVAc concentrations were investigated. These results are given by the broken lines in Figs. 5 and 6, which show that all the color-fadings of PVAc-iodine complexes are in the vicinity of 30°C, independent of the PVAc concentration. For the temperature dependence of the copolymer-iodine complexes, it is of interest to compare these data with the results of PVAc. The difference between the type of curve obtained with the PVAc copolymer and that obtained with the PVAc homopolymer is striking, as Figs. 5 and 6 show. For the copolymer with vinyl propionate, the magnitude of the decrease in the color intensity with the temperature increased with an increase in the number of vinyl propionate units. On the other hand, the absorbances of the complexes of PVAc-PVFA with iodine at the absorption maximum were approximately the same as that of PVAc, and the effect of the elevated temperature on the absorbance appeared to be smaller for PVAc-PVFA than the PVAc, as the vinyl formacetal units as comonomer are introduced into the PVAc chain.

The polymer-iodine complexes generally lose their color intensities at elevated temperatures. The extent of the loss depends on the kind of polymer[12] and on the degree of steric regularity.[13] However, these differences have been difficult to explain satifactorily in the absence of mechanistic studies of polymer-iodine complexes. If it is assumed that the source of the color reaction of polymer with iodine is based on the formation of polyiodine chains in the polymer,[14] the degree of mobility of the polymer molecule at a given temperature at which the color intensity is measured seems to be one of the important causes of the color development. For example, the color-fading temperature of PVAc agreed with the T_g of PVAc. This probably means that the molecular motion of the PVAc polymer over the T_g is so vigorous that the iodine molecules can not be oriented in polyiodine chains in the PVAc polymer. The reason that the effect of the temperature on the color intensity was greater for PVAc-PVPr than for PVAc-PVFA may be also attributed to the T_g of the copolymer. The T_g values of copolymers tabulated in Tables 3 and 4 were calculated by means of the following equation:[15]

$$\frac{1}{T_g} = \frac{W_1}{T_{g1}} + \frac{W_1}{T_{g2}}$$

where T_g, T_{g1}, and T_{g2} are the glass-transition temperatures of the copolymer, the homopolymer 1, and the homopolymer 2, and where W_1 and W_2 are the weight fractions of the homopolymer 1 and the homopolymer 2 respectively.

On comparing these values with the results of the temperature dependence of the absorbance, it is evident that the T_g and the absorbance have a simple relation, that is, the higher the T_g value, the lower the temperature dependence of the absorbance. Therefore, the curves in Figs. 5 and 6 can be explained as follows. As the temperature rises, the color intensity is gradually lowered up to the extent of the T_g of the polymer; then the rate of lowering becames rapid in the vicinity of the T_g. This can be taken as indicating that the polymer in which iodine molecules form the polyiodine chains can not be held in a definite conformation at elevated temperatures.

The authors are grateful to Professor Nobumasa Hojo of Shinshu University for his valuable discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 543—545 (1970)

Studies on Reactions of Isoprenoids. VIII.[1] Reactions of Sulfur Dichloride with Certain Cyclic-Acyclic 1,5-Dienes

Tadashi SASAKI, Shoji EGUCHI and Teruhiko ISHII

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received May 10, 1969)

Although the reactions of sulfur dichloride (SD) with various olefins have been well investigated,[2-7] there seems to have been no study on the reactions of SD with cyclic-acyclic polyolefins. This paper deals with the reactions of SD with 1,5-cyclic-acyclic dienes I-III.[8]

The product from 4-cyano-1-(4-methyl-3-pentenyl)-1,4-cyclohexadiene (I) and SD is a viscous oil, the structure of which was assigned as 3-(1-*p*-cyanophenyl-4-methylene)pentyl sulfide IV on the basis of analytical and spectral data: IV gave a negative Beilstein- and a positive sulfur test[9] and analysis showed a composition of $C_{26}H_{28}N_2S$. IR spectrum (liquid film) exhibited strong bands at 2265 (C≡N), 1605 and 830 (1,4-disubstituted phenyl), and 1650 and 895 (C=CH_2) cm^{-1}. UV spectrum had a λ_{max}^{MeOH} 231 mμ (log ε 4.37) which is very similar to that of *p*-tolunitrile, $\lambda_{max}^{H_2O}$ 234 mμ (log ε 4.2),[10] suggesting the presence of a *p*-alkylcyanobenzene moiety. NMR spectrum had signals at τ 2.38 and 2.68 (*ca.* 8 H, AB-q, J=9.0 Hz, phenyl protons), 4.92 and 5.03 (*ca.* 4H, each broad s, C=CH_2), 6.80—8.25 (6H, broad complex m allylic methylene protons and S–CH), and 8.33 and 8.49 (*ca.* 10H, each s, allylic methyl- and saturated methylene protons). In the mass spectrum at 70 eV, shown in Fig. la, the molecular ion peak could not be observed, as was also the case in the spectrum at 15 eV. However, appearance of ion peaks at *m/e* 269 (0.1%, $C_{17}H_{20}NS^+$) and 268 (0.08%, $C_{17}H_{19}NS^+$) excluded the possibility of a monomeric cyclic sulfide structure in accordance with analytical data. These ions could be formed by the characteristic α-cleavage of a dialkyl sulfide molecule.[11] The dimeric unsaturated sulfide structure was supported by ion peaks at *m/e* 154 (10%, CH_2=$C(CH_3)$–$CH(\dot{C}H_2)$–$\overset{+}{S}$=CH–$C(CH_3)$=CH_2), 153 (8.5%, CH_2=$C(CH_3)$–$C(=CH_2)$–$\overset{+}{S}$=CH–$C(CH_3)$=CH_2), and 141 (10.5%, CH_2=$C(CH_3)$–CH_2–$\overset{+}{S}$=CH–$C(CH_3)$=CH_2). The other main fragmentation resulted from the cleavage of a sulfur-carbon bond to give ion peaks at *m/e* 217 (10%, $C_{13}H_{15}\dot{\overset{+}{N}}S$), 215 (12%, $C_{13}H_{13}\dot{\overset{+}{N}}S$), 213 (24%, $C_{13}H_{11}\dot{\overset{+}{N}}S$), 186 (14%, $C_{13}H_{16}N^+$), 185 (48%, $C_{13}H_{15}N^{+\cdot}$). Sulfur-carbon bond rupture after isomerization of the side-chain double bond and loss of methyl and isopropyl group afforded ion peaks at *m/e* 200 (14%), 168 (22%), 174 (13%), 172 (24%), 142 (10%), and 140 (12%).[12] Appearance of ion peaks at *m/e* 117 (100%) and 116 (43%) in abundance supported structure IV involving a benzene ring but not a cyclic sulfide structure, since these fragmentations are typical for alkyl-

benzene derivatives.[13] All these analytical and spectral data led us to conclude that the product has the unsaturated symmetrical dialkyl sulfide sturcture IV.

The product from 4-cyano-1-(4-methyl-3-pentenyl)cyclohexene II and SD was also an oil, and its structure was assigned as 3-[1-(6'-chloro-4'-cyanocyclohex-1'-enyl)-4-mehylene]pentyl sulfide (V) from analytical and spectral data. V had a composition of $C_{26}H_{34}N_2SCl_2$ from analysis and gave a positive Beilstein- and sulfur test.[9] IR spectrum (liquid film) exhibited strong bands at 2275 (saturated alkyl nitrile), 1645 (C=C), and 892 (C=CH_2) cm^{-1}. NMR spectrum showed signals at τ 4.55 (2 H, broad s, cyclohexenyl vinyl proton),[14] 5.08 (4H, broad s, C=CH_2), 5.45—7.10 (*ca.* 4H, broad complex m, -CHCl- and -CH-S-), 7.30—8.50 (*ca.* 24H, complex m, allylic methyl-, methylene- and methine protons). The mass spectrum at 70 eV is shown in Fig. 1b. The ion peak at *m/e* 255 ($C_{13}H_{17}\overset{+\cdot}{N}SCl$) corresponds to a fragmentation involving a sulfur-carbon bond fission, followed by a hydrogen abstraction.[11] In the other fragmentations, the most characteristic feature is the loss of hydrogen chloride to give ion peaks at *m/e* 219 (18%, $C_{13}H_{16}\overset{+\cdot}{N}S$) and 218 (100%, $C_{13}H_{15}\overset{+}{N}S$). Appearance of ion peaks at *m/e* 154 (2%), 153 (6%), 141 (2%), as well as at 117 (62.5%, $C_7H_7\overset{+\cdot}{N}$) as in the spectrum of IV, supported the unsaturated symmetrical dialkyl sulfide structure V. The spectrum at 15 eV was very simple, having ion peaks originating from a sulfur-carbon bond fission, at *m/e* 219, 218, 204, 186 and 185.

The reaction of 1,2-diethoxycarbonyl-4-(4-methyl-3-pentenyl)-3,6-dihydropyridazine III with SD also gave dimeric sulfide VI. A composition of $C_{32}H_{48}N_4O_8SCl_2$ was indicated by analysis, and by the positive Beilstein and sulfur tests.[9] IR spectrum (liquid film) showed bands at 1710 (C=O), 1650 (C=C) and 898 (C=CH_2) cm^{-1}, and NMR spectrum showed signals at τ 5.08

14) This chemical shift is very similar to that of a cyclohexenyl vinyl proton of II: see Ref. 8.

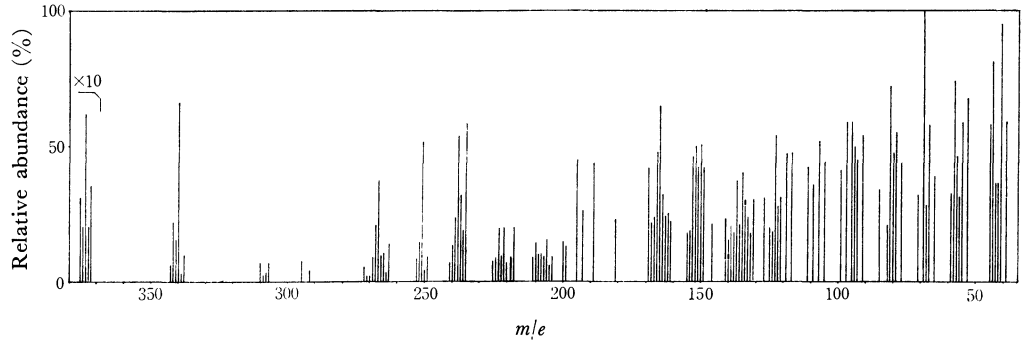

Fig. 2. Mass spectrum of VI at 70 eV.

(4H, broad and unsymmetrical s, C=CH_2), 5.50—7.20 (*ca.* 18H, m, N–CH_2–C=C, –CH–S–, and $COOCH_2C\underline{H}_3$*[1]), 7.45—8.45 (14H, m, allylic methylene-, methyl- and methylene protons of the side-chain), and 8.70 (12H, t, J=6.5 Hz, $COOCH_2C\underline{H}_3$). The mass spectrum (Fig. 2) showed an ion peak at m/e 376 (3.1%, $C_{16}H_{25}N_2\overset{+}{S}Cl$) which originated in a sulfur-carbon bond rupture.[11] The spectrum in the lower *m/e* regions was very complex compared to those of IV and V. Loss of hydrogen chloride from the ion peak at *m/e* 376 affords an abundant ion peak at *m/e* 340 ($C_{16}H_{24}N_2\overset{+}{S}$). Further loss of an ethoxylcarbonyl group from this ion yields an ion peak at *m/e* 267 ($C_{13}H_{19}N_2\overset{+}{S}$), whichcan afford an ion peak at *m/e* 193 ($C_7H_5N_2\overset{+}{S}$) by the loss of another ethoxycarbonyl group. Cleavage of carbon-carbon bond of the side-chain between the positions α and β to a pyridazine ring and the loss of hydrogen chloride afford an ion peak at *m/e* 239 ($C_{11}H_{15}N_2^+$), which can give rise to ion peaks at *m/e* 166, 165, 95, and 93 on the loss of an ethoxycarbonyl group. The base ion peak appeared at *m/e* 69 ($C_5H_9^+$), apparently arising from the side-chain. Ion peaks at *m/e* 154, 153 and 141 *etc.* were observed, supporting the dimeric sulfide structure VI.

All the reactions of SD with I-III occurred between two molecules of the dienes at their side-chain double bond and one molecule of SD to give IV-VI respectively,[15] though these reactions were carried out at high dilutions (2—4 wt% of olefins and 1.5 wt% of SD). The formation of these products can be explained by a facile attack of SD on a side-chain double bond and by chlorinations of cyclohexenyl or cyclohexadienyl moieties with SD.[16]

*[1] The methylene protons of the ethoxycarbonyl group appeared at τ 5.75 in a q, J=6.5 Hz in these overlapped signals.

15) The products seem to be diastereoisomeric mixture since these compounds have two or more asymmetric carbons.

Experimental[17]

Addition Reaction of SD with I. To a mixture of 1.87 g (0.01 mol) of I[8] and 50 m*l* of reagent-grade dichloromethane at *ca.* −50°C under a nitrogen atmosphere in a 200-m*l* three-necked flask fitted with stirrer, addition funnel and nitrogen inlet-outlet, was added with stirring a solution of 0.64 m*l* (0.01 mol) of SD in 50 m*l* of reagent-grade dichloromethane.[7] Addition was carried out for 1 hr and the resulting red solution was allowed to stand at *ca.* 15°C for 5 hr, shaken several times with cold brine and dried over sodium sulfate. After removal of the solvent, the residue was distilled *in vacuo* to give 0.86 g (43%) of IV: bp 117—119°C/0.1 mmHg, $n_D^{22.5}$ 1.5550. Found: C, 77.79; H, 7.50; N, 6.96%. Calcd for $C_{26}H_{28}N_2S$: C, 77.97; H, 7.05; N, 7.00%.

Addition Reaction of SD with II. Similarly 1.89 g (0.01 mol) of II[8] was treated with 0.64 m*l* (0.01 mol) of SD as above, and the product obtained was distilled to give 1.26 g (53%) of V: bp 145—149°C/0.5 mmHg, $n_D^{22.5}$ 1.5544. Found: C, 65.73; H, 7.34; N, 5.63%. Calcd for $C_{26}H_{34}N_2SCl_2$: C, 65.38; H, 7.14; N, 5.87%.

Addition Reaction of SD with III. Similarly 3.10 g (0.01 mol) of III[8] was treated with 0.64 m*l* (0.01 mol) of SD as above. The work-up and distillation afforded 0.97 g (27%) of VI: bp 165—175°C/0.5 mmHg, $n_D^{22.5}$ 1.5227. Found: C, 53.61; H, 7.31; N, 8.33%. Calcd for $C_{32}H_{48}N_4O_8SCl_2$: C, 53.41; H, 6.81; N, 7.79%.

16) a) Ref. 3: b) Chevron Res. Co., Brit. 1084670; *Chem. Abstr.*, **68**, 21528x (1968).

17) Microanalyses were carried out using a Yanagimoto C.H.N. Corder, Model MT-1. IR spectra were recorded on a JASCO Model IR-S IR spectrophotometer and UV spectra, on a JASCO Model ORD/UV-5 spectrophotometer. NMR spectra were obtained with a Hitachi H-60 spectrometer in deuterochloroform and are reported in τ values relative to TMS as an internal standard. Mass spectra were determined with a JEOL Model JMS-OlSG mass spectrometer at 70 and 15 eV of electron energy.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 546—547 (1970)

2,4-Dinitrophenylhydrazones of Benzoin

Yoshie KURIHARA and Rumiko HOSHI*1

Laboratory of Chemistry, Faculty of Education, Yokohama National University, Minami-ku, Yokohama

(Received May 23, 1969)

It is well known that the melting point of the 2,4-dinitrophenylhydrazone (DNP) of benzoin is 234°C.[1] Braude and Jones reported another DNP obtained from benzoin which melted at 174°C.[2] However, they stated nothing about the difference between the two.

Benzoin reacted with 2,4-dinitrophenylhydrazine (DNPH) prepared according to the procedure of Shriner and Fuson[3] at room temperature to give the DNP (I) (mp 236°C). On the other hand, when the reaction was carried out at 80°C for 45 min, the DNP (II) (mp 175°C), which is probably identical with that reported by Braude[2], was isolated as the main product. When the reaction was carried out at a temperature under 80°C, both I and II were formed. The I hydrazone was much more soluble in alcohol than II. The R_f values of I and II on the thin-layer chromatography using benzene-ether (17 : 3) were 0.74 and 0.94 respectively. When the reaction of benzoin and DNPH prepared according to Shriner's method was carried out under refluxing for 2 hr, di-DNP (osazone) of benzoin III, mp 314°C,[4] was obtained. III was also obtained when I or II was treated with Shriner's reagent at the boiling point. Further, I was converted to II when I was warmed at 80°C in ethanolic sulfuric acid.

The structure of II was confirmed as that of the DNP of benzoin ethyl ether on the basis of its elemental and spectral evidence; an absorption band as 1060 cm^{-1} in the infrared spectrum and signals at 8.60 (triplet, 3H, CH_3) and 6.15 τ (quartet, 2H, CH_2) in the NMR spectrum indicate the presence of an ethoxy group in II. Thus, it may reasonably be concluded that the hydroxy group of benzoin may be replaced by the ethoxy group in the reaction with DNPH in a hot alcoholic sulfuric acid solution. As acetoin and propionoin reacted with DNPH to form only sole DNP, even at 80°C, such behavior of benzoin seems somewhat peculiar.

Experimental[5]

Reaction of Benzoin with DNPH. *i) At Room Temperature.* Benzoin (3.5 g, 0.0165 mol) in 10 m*l* of ethanol was stirred into a solution of 18.5 g (0.09 mol) of DNPH in 150 m*l* of ethanol, 140 m*l* of water, and 92.5 m*l* of concentrated sulfuric acid. A nitrogen stream was then bubbled through the mixture. The precipitated product was filtered, washed with alcohol, and recrystallized from ethanol-ethyl acetate (3 : 1).

4) Mp 317°C in Ref. 1, p. 334.

5) All the melting points were determined on a Mettler electric micromelting-point apparatus and are uncorrected. The infrared spectra (KBr) were recorded on a Hitachi Model EPI-S2 spectrophotometer. The NMR spectra were determined in $(CD_3)_2CO$ on a JEOL NMR spectrometer at 60 MHz, with tetramethylsilane as the internal standard.

Mp 236°C.

Found: C, 61.90; H, 4.35; N, 13.29%. Calcd for $C_{20}H_{16}O_5N_4$: C, 61.22; H, 4.11; N, 14.28%.

ii) At 80°C. After the reaction mixture (the molar ratios were the same as those in the case of i) was heated at 80°C for 45 min, the solution was cooled. The precipitated product was filtered and then washed with ethanol. Recrystallization from ethanol-ethyl acetate (3 : 1) gave red-yellow crystals; mp 175°C.

Found: C, 63.13; H, 5.03; N, 12.72%. Calcd for $C_{22}H_{20}O_5N_4$: C, 62.85; H, 4.79; N, 13.33%.

Conversion of I to II. A few drops of conc. sulfuric acid were added to a solution of I (0.3 g) in 50 m*l* of ethanol. This solution was heated at 80°C for 2 hr. After cooling, the ethanol was evaporated under reduced pressure and the crude product was washed with ethanol. This reaction product indicated two spots on thin-layer chromatography; its R_f values were 0.72 and 0.94, identical with those of I and II.

The authors wish to thank Miss Keiko Inoue for her assistance during this work.

Polymerization of β-Ethoxypropionaldehyde

Hiroshi SUMITOMO and Junji FUJII

Faculty of Agriculture, Nagoya University, Chikusa-ku, Nagoya

(Received June 18, 1969)

Vogl[1] reported that 3-methoxypropionaldehyde was anionically polymerized with potassium triphenylmethoxide in propylene at −75°C. Takida and Noro[2] attempted the cationic polymerization of methoxybutyraldehyde with use of a magnesium sulfate-sulfuric acid complex at −78°C to give a sticky elastomeric product with a low yield.

The purpose of the present work is to obtain a high molecular weight crystalline polymer from β-alkoxypropionaldehyde.

β-Ethoxypropionaldehyde was prepared by refluxing the mixture of acrolein and ethyl alcohol in the presence of triethylamine and formic acid as catalyst at 65—75°C. Bp 66.0—66.5°C/67 mmHg.

Tetrahydrofuran (THF), methylene chloride, toluene and *n*-hexane used as solvents were purified in the usual way prior to use. Purification of triethylaluminum, diethylaluminum chloride, ethylaluminum dichloride (all of them, from Ethyl Corp.), aluminum trichloride, and titanium tetrachloride was previously described.[3,4] *n*-Butyllithium was prepared by the reaction of *n*-butyl chloride and lithium in a stream of nitrogen.

Polymerization was conducted by the same method as previously described.[3,4] Resulting polymer was isolated by precipitation by pouring the reaction mixture into a large amount of water after adding a mixture of acetic anhydride and pyridine. Waring Blendor was used, when necessary, for crushing and washing the product in water.

In Table 1 are shown the results of polymerization of β-ethoxypropionaldehyde initiated by triethylaluminum at −78°C. It should be noticed that the viscosity numbers, η_{sp}/c, of resulting polymers

measured at the concentration of 0.2g/100 m*l* in *o*-cresol at 25°C are all extremely high.

The results of polymerization with diethylaluminum chloride are given in Table 2. The rate of polymerization is found to decrease in the order, toluene>*n*-hexane>methylene chloride. No polymer was obtained in THF at −78°C and even in toluene at −21 and 0°C.

Ethylalminum dichloride gave no polymer in all these solvents at −78°C.

Table 3 summarizes the effects of aluminum compounds with different acid strength on the polymerization of β-ethoxypropionaldehyde at −78°C. It was found that diethylaluminum chloride with a moderate acid strength is the most active, whereas aluminum chloride and ethylaluminum dichloride with a high acid strength are inactive in the present system.

Besides these cationic initiators, *n*-butyllithium also induces the polymerization of β-ethoxypropionaldehyde in toluene at −78°C (for example: 1 day; 10.8% convn.; η_{sp}/c, 8.6).

In Fig. 1 are shown the IR spectra of β-ethoxypropionaldehyde and its polymer. The fact that

Table 3. Polymerization with various aluminum compounds*

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 549—550 (1970)

Mechanism and Rate of the Intramolecular Energy Transfer in Rare Earth Chelates

Minoru TANAKA, Gentaro YAMAGUCHI, Jiro SHIOKAWA and Chiyoe YAMANAKA

Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received July 1, 1969)

The intramolecular energy transfer in rare earth (RE) chelates under excitation by near-ultraviolet light has been the subject of several recent investigations. Three mechanisms by which the excitation energy is transferred from the ligand to the RE ion in RE chelates have been proposed.

As no luminescence is observed from the RE levels higher than T_1,*1 Crosby *et al.* proposed the mechanism I: the energy transfer from S_1 to the *RE* ion *via* T_1 ($S_1 \rightsquigarrow T_1 \rightsquigarrow$ *RE* level$\rightarrow$ emission),[1] while Kleinerman proposed the mechanism II: the direct transfer of energy from S_1 to the *RE* ion ($S_1 \rightsquigarrow$ *RE* level$\rightarrow$emission).[2] Later, Bhaumik *et al.* proposed the mechanism III: the energy is transferred from S_1 to an upper intermediate *RE* level and then is transferred back to T_1 and returns to a lower *RE* level ($S_1 \rightsquigarrow$ *RE* level higher than $T_1 \rightsquigarrow T_1 \rightsquigarrow$ *RE* level lower than $T_1 \rightarrow$emission).[3] Though many other investigators supported the mechanism I on the basis of studies such as that of the intermolecular triplet-triplet energy transfer phenomenon,[4] the possibility of the mechanism II or III has not yet been fully denied. This is mainly due to the fact that the energy-transfer process from the lowest ligand triplet state to the RE ion was too fast to be observed. Bhaumik and El-sayed estimated this time to be $\sim 10^{-10}$ sec.

In this note, we will show some experimental confirmation that the time for this $T_1 \rightsquigarrow$ *RE* level transfer is about $\sim 10^{-8}$ sec and that the intramolecular energy transfer occurs by means of the mechanism I.

Experimental

Synthesis of β-Diketones. Naphthoyltrifluoroacetone (NFA) and benzylidenetrifluoroacetylacetone (BZDTF) were prepared by the condensation of ethyltrifluoroacetate with naphthoyltrifluoroacetone and benzylideneacetone respectively in a manner similar to that described by Reid and Calvin.[5] Some other β-diketones, benzoyltrifluoroacetone (BFA), and thenoyltrifluoroacetone (TTA) were obtained from Tokyo Kasei and were used without further purification.

Synthesis of RE Chelates. The RE chelates used in this study were prepared by the methods described in the literatures.[6-8] Tris and tetrakis chelates of europium, gadolinium, and terbium were prepared.

Luminescence Studies. All the chelates were studied at 300 and 77°K at a concentration of 10^{-3} mol/*l* in the following solvents; (1) EPA: mixed solvent of ether, isopentane, and ethanol (8 : 3 : 5 by volume ratio), (2) ethanol, and (3) acetonitrile. The details of the stroboscopic studies and the numerical calculations undertaken in order to obtain the luminescence rise times are given in Ref. 9.

Results and Discussion

The ligand triplet-state energies were obtained from the phosphorescence spectra of the Gd chelates. These data are presented in Fig. 1, along with several electronic states of Eu^{3+} and Tb^{3+}.

The triplet states of all the Eu chelates except $Eu(BZDTF)_4 \cdot HP$ lie above the $^5D_1$ state of Eu^{3+}. In these cases the time-resolved emission spectra can be accounted for as follows: the population of the $^5D_1$ state occurs in a time of the order of $\sim 10^{-8}$ sec; then the depopulation of the $^5D_1$ sate occurs in about 2 μsec through radiative and nonradiative transitions to the ^7F manifold as well as through simultaneous nonradiative transition to the $^5D_0$ state; On the other hand, the population of $^5D_0$ occurs in about 2 μsec, which is nearly the same as the decay time of $^5D_1$; finally, radiative and nonradiative transitions from $^5D_0$ to the ^7F manifold occur in about 500 μsec. However, in the

*1 Here we used the following abreviations:
S_1: the lowest excited singlet state of the organic ligand.
T_1: the lowest triplet state of the ligand.

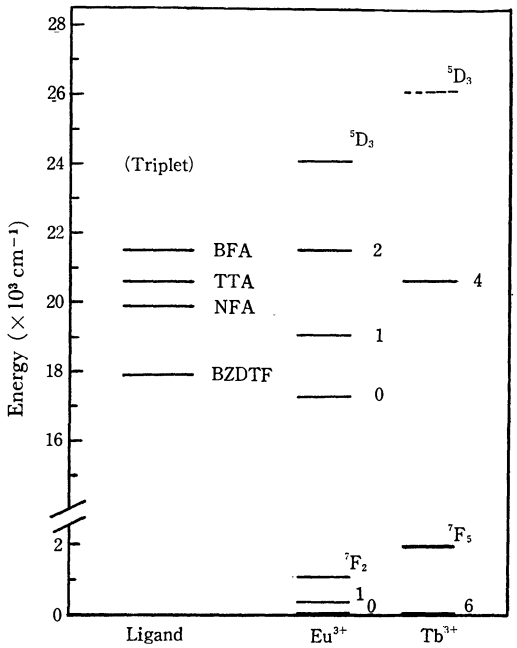

Fig. 1. The triplet states of organic ligands and the f-electronic states Eu^{3+} and Tb^{3+} ion.

case of $Eu(BZDTF)_4 \cdot HP$, where the lowest ligand triplet is situated between $^5D_1$ and $^5D_0$, no emission from the $^5D_1$ level is observed. The population of $^5D_0$ occurs in a time of the order of $\sim10^{-8}$ sec, and this is followed by radiative and nonradiative transitions to the ^7F manifold in about 500 μsec. In the cases of the Tb chelates, $Tb(BFA)_4 \cdot HP$, $Tb(BFA)_3 \cdot 2H_2O$, and $Tb(TTA)_3 \cdot 2H_2O$, the population of $^5D_4$ occurs in a time of the order of $\sim10^{-8}$ sec and decays in about 500 μsec.

The luminescence-rise curve of the $^5D_0 \rightarrow {}^7F_2$ transition (613 mμ) of $Eu(BZDTF)_4HP$ is shown

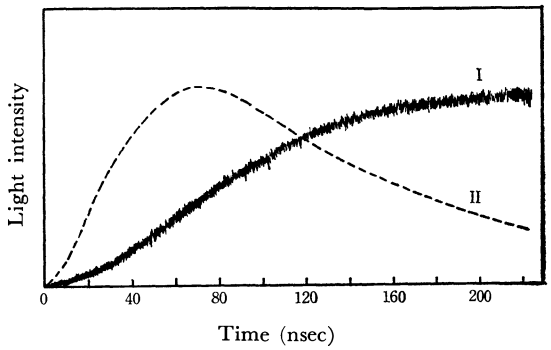

Fig. 2. (I) The typical rise curve of the ion luminescence of Eu, Tb chelates. (II) The rise curve of the excitation flash light.

in Fig. 2. The rise curves of the $^5D_1 \rightarrow {}^7F_1$ transition (538 mμ) in other Eu chelates and of the $^5D_4 \rightarrow {}^7F_5$ transition (545 mμ) in Tb chelates have almost the same behavior as is shown in Fig. 2. These rise times can be estimated to be about 10^{-8} sec. The time-resolved spectroscopic data on several RE chelates are given in Table 1.

From the results stated above, the following conclusions can be reached: First, since the luminescence from RE levels which are higher than T_1 is not observed, as Crosby[1] reported, and since the time for energy transfer is too long to account for the direct transfer from S_1, there is no possibility of the mechanism II. Second, the mechanism III can also be rejected, because the rise times of the RE-ion luminescence in several RE chelates investigated are nearly the same, *i.e.* 10^{-8} sec, in spite of the fact that the energy differences between the intermediate RE level and T_1 are not similar. Therefore, we can conclude that the energy transfer occurs by means of the mechanism I.

Studies of Aliphatic Hydroxycarboxylic Acids as Antioxidants. III. The Preparation of Two Isomers of Hydroxycitric Acid Lactone (*erythro*- and *threo*-3,4-dicarboxy-3-hydroxy-γ-butyrolactone)

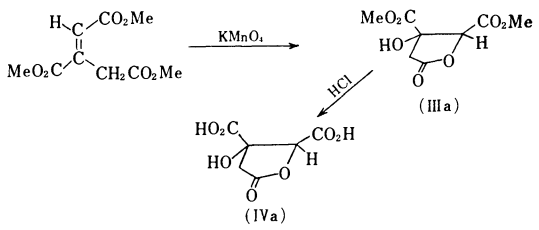
Kazuo HORIKAWA and Shinroku MASUYAMA

The Osaka Municipal Technical Research Institute, Kita-ku, Osaka

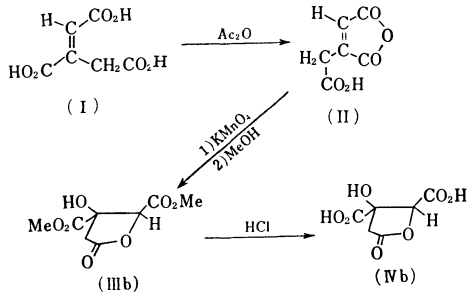
(Received July 4, 1969)

In 1883, Lippmann[1] found a hydroxycarboxylic acid in a by-product of beet sugar. He reported that the formula of this compound corresponded to that of hydroxycitric acid, which had already been synthesized by Pawollek.[2] On the other hand, Martius and Maué[3] prepared the hydroxycitric acid lactone by the addition of hypochlorous acid to calcium aconitate. Two isomers were obtained in this reaction; the one with the lower melting point of 152°C was hydroxycitric acid lactone, while the other, with the higher melting point of 182°C was allohydroxycitric acid lactone. The configurations of these two racemic acids have, however, never been described. Therefore, it seemed worthwhile to confirm the configurations of these lactones, since the configuration might be related to the stabilizing effect on the vegetable oil as an antioxidant.

As has been reported previously from our laboratory,[*1,4] erythro lactonic acid (IVa) was synthesized by the oxidation of *trans*-trimethylaconitate with permanganate and by subsequent hydrolysis (Scheme I).



Scheme I



Scheme II

In this paper, another isomer, *threo* lactonic acid (IVb), was similarly prepared from *cis*-aconitic anhydride (II).[5] The oxidation mixture was separated after methylation, and the obtained dimethyl ester (IIIb) was hydrolysed (Scheme II). As for the relative configurations of these two lactonic acids, it was inferred, on the basis of the *cis*-hydroxylation mechanism of permanganate, that IVa was *erythro* and that IVb was *threo*.[*1] These assignments were supported by the reaction of both lactonic acids with acetic anhydride. Thus, when they were treated with this reagent at 60°C for 1.5 hr, the former gave a lactonic anhydride, which exhibited characteristic bands due to the 5-membered anhydride group at 5.31 and 5.75μ, while the latter did not. The NMR spectra of IIIa and IIIb are of interest in connection with the above assignment. The NMR spectra of IIIa and IIIb in chloroform exhibited signals at τ 6.18, 6.22 (each 3 H, $-OCH_3$) and 6.10, 6.23 (each 3 H, $-OCH_3$), 5.04 (1 H, methin proton) and 4.88 (1 H, methin proton), respectively. The methin proton signal of IIIb appeared in a field lower than that of IIIa. The methin proton of IIIb may be more deshielded by the β methoxycarbonyl group, which is situated closer than in IIIa. The IIIb compound has a larger difference in chemical shifts about the *O*-methyl proton (τ 6.10, 6.23) of the two methoxycarbonyl groups than those in IIIa (τ 6.18, 6.22)

*1 In the preceding paper, the lactonic acid obtained was prefixed with *threo* according to a Fischer projection on the basis of the tartaric acid moiety, but in this paper the lactonic acid obtained was prefixed with *threo* on the basis of the citric acid moiety. Therefore, in order to eliminate this confusion, the authors wish to correct the prefix of the previously-obtained lactonic acid to *erythro*.

Experimental

All the melting points are uncorrected. The infrared spectra were measured in Nujol mull using a Shimadzu IR-27 spectrometer in the 2—15 μ region, while the NMR spectra were determined at 100 Mc with a Japan Electron Optics JNM-4H-100 NMR spectrometer, using TMS as the internal reference. The elemental analyses were done at the Microanalytical Laboratory, Faculty of Science, Osaka City University.

The Preparation of *cis*-Aconitic Anhydride (III). To 240 m*l* of acetic anhydride 240 g of *trans*-aconitic acid (I) were added, after which the reaction mixture was maintained at 60°C for 1.5 hr. The reaction solution was then concentrated *in vacuo* to a syrup, which was crystallized upon the addition of dry benzene. Recrystallization from dry benzene gave pure II. Yield, 125 g; mp 76°C. Found: C, 46.20; H, 2.77%. Calcd for $C_6H_4O_5$: C, 46.17; H, 2.58%.

The Oxidation of *cis*-Aconitic Anhydride (II). A solution of II (30 g) dissolved in 300 m*l* of methanol was neutralized by the addition of sodium bicarbonate and was oxidized with 2% aqueous potassium permanganate for 3 hr at 0—5°C. The reaction solution was then allowed to stand at room temperature overnight. The precipitated inorganic salt was removed by filtration; the filtrate was acidified with hydrochloric acid and then evaporated to a syrup, which was esterified by refluxing for 7 hr with 300 m*l* of methanol and 5 m*l* of concentrated hydrochloric acid. After the methanol had been evaporated *in vacuo*, the syrupy residue was treated as will be described below.

Separation of The Lactonic Ester (IIIb). Five grams of the syrup obtained above were chromatographed on a silica-gel column (140 g). Elution with a large amount of chloroform gave 330 mg of IIIb. Recrystallization from chloroform gave pure IIIb as crystals. Yield, 267 mg; mp 97—98°C.

IR: 2.85, 2.95, 5.55, 5.75 μ. NMR($CHCl_3$): τ 4.88 (1H, singlet, methin), 6.10, 6.23 (2 OCH_3, each 3H, singlet), 7.04 (2H, quartet, methylene). Found: C, 43.99; H, 4.81%. Calcd for $C_8H_{10}O_7$: C, 44.03; H, 4.58%.

Hydrolysis of IIIb. A mixture of 9% hydrochloric acid (10 m*l*) and IIIb (125 mg) was maintained at 80°C for 5 hr. The hydrolysate was then evaporated to dryness under a vacuum. The residue was dissolved in ethyl acetate and crystallized by the addition of small amount of carbon tetrachloride. Mp 180—181°C. IR: 2.92, 5.61, 5.75 μ. Found: C, 37.70; H, 3.11%. Calcd for $C_6H_6O_7$: C, 37.89; H, 3.14%.

The Reaction of IVa and IVb with Acetic Anhydride. A mixture of acetic anhydride (0.5 m*l*) and IVa (81 mg) was maintained at 60°C for 1.5 hr. The reaction solution was then evaporated under a vacuum in order to remove the acetic acid and the acetic anhydride. The residue was treated with dry benzene, after which the benzene was removed *in vacuo*. The infrared spectrum of the product showed the characteristic bands due to the 5-membered anhydride group at 5.31 and 5.75 μ. On the other hand, in the case of IVb the characteristic bands were not observed.

The authors are grateful to Professor T. Kubota and Dr. T. Tokoroyama, Osaka City University, for their valuable discussions and suggestions, and to Professor Y. Izumi, Osaka University, for his NMR spectral measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 553—555 (1970)

A Polarographic Study of Metal Dithio-β-diketonates*1

Akiko FURUHASHI, Shigeyuki KAWAI, Yasumasa HAYAKAWA and Akira OUCHI*2

Department of Chemistry, College of Engineering and Science, Aoyama Gakuin University, Megurisawa, Setagaya-ku, Tokyo

(Received May 10, 1969)

The synthesis and the infrared or visible spectroscopic properties of metal dithio-β-diketonates have been potentially sutided very recently.[1-6] Concerning the abnormal valency states of the central metal ion of the five-membered-ring dithiolate chelates, nickel dithiolate complexes have been extensively studied polarographically,[7-8] and it has been shown that the half-wave potentials of the dithiolates correlate linearly with Taft's substituent constants.[8] However, the polarographic behavior of the six-membered-ring dithio-β-diketonates has not yet been reported on. In our last paper[4] we reported that the dithioacetylacetonate was more stable than the other dithio-β-diketonates, which contain a phenyl or trifluoromethyl group rather than the one or two methyl groups of the former. The correlation between the polarographic and spectroscopic behavior of these chelates will be discussed in this paper.

Experimental

Reagents. All the metal chelates were synthesized by a method reported in previous papers.[3-4] The lithium chloride and the sodium perchlorate were of a guaranteed reagent grade and were used without further purification. The organic solvents were purified by a standard technique.[9]

Apparatuses and Experimental Procedure. A model PA-101 pen-recording d. c. polarograph of the Yanagimoto Mfg. Co., Ltd., and a dropping mercury electrode were employed. The reference electrode was a saturated calomel electrode (SCE); it was connected to the cell by means of a salt bridge (aqueous potassium chloride-agar gel). The liquid junction potential was not measured in this experiment.

Results and Discussion

In a dimethylformamide (DMF) solution, these chelates show three waves. The polarogram of nickel dithioacetylacetonate is shown in Fig. 1. The diffusion-controlled current, i_d, of the sum of the first and the second waves was proportional to the concentration of the chelate in the region of 2×10^{-4}—2×10^{-3}M, and the $i_d/\sqrt{h_{eff}}$ ratio (h_{eff}: the mercury head corrected for the back pressure) of the first wave was almost constant. A plot of $\log i/(i_d-i)$ *versus* the potential, E, of the first wave is shown in Fig. 2. The linear portion of

Concentration of lithium chloride=1 M

the plot gave a slope of approximately 100 mV. From these results it seems that the wave is somewhat irreversible. The other dithio-β-diketonates give similar polarograms, though they seem to be more irreversible.

The color of the solution of trifluoromethyl derivatives changes from green to red several minutes after dissolution, perhaps because of the fast solvolysis reaction of the chelate. The polarogram of the species was obtained by using the red solution 1 to 5 hr after dissolution. The half-wave potentials of the dithio-β-diketonates and related compounds in various solvents are summarized in Table 1.

The acetonitrile solutions of nickel dithio-β-diketonates show a wave of $E_{1/2}=-1.0$——1.1 V *vs.* SCE. On the other hand, those of nickel(II) chloride show a wave of $E_{1/2}=1.05$ or 1.03 V in a 1 M $NaClO_4$ and a 1 M LiCl aqueous solution respectively, while nickel(II) acetate shows a wave of $E_{1/2}=1.06$ V in 1 M $NaClO_4$. Accordingly, the waves of $E_{1/2}$ = *ca.* -1.0 V *vs.* SCE are probably due to Ni(II)→Ni(0).

In DMF solutions, the first of the three waves seems to be that of the reduction of chelated nickel: Ni(II)→Ni(0). The second wave is lower than the first one and it overlaps with the first one a little. The third wave is unclear because of the superposed wave of the electrolyte; it is probably the reduction wave of the organic part of the ligand.

Since the half-wave potential of the wave of nickel chloride in DMF is close to that of the second wave, the second wave may correspond to the reduction of the nickel chelate, partly solvolysed by the DMF in the solution. In fact, the chelates such as trifluoromethyl derivatives, which are solvolyzed easily by DMF, give larger wave heights. The sum of the heights of the first and the second waves is always approximately the same at any given concentration of the dissolved metal chelate,

** Not well-defined owing to the overlapping of the waves.

even if the ligands of the chelates are not the same. This fact also seems to show that both the first and second waves are Ni(II)→Ni(0) reduction waves.

The ratio between the heights of the first and the second waves seems to be related to the ratio between the chelated and solvolyzed species in the solution. However, the evaluation of the stability constants attempted in the present work was not successful because of various unknown factors.

Dithioacetylacetonatomonothioacetylacetonato-nickel(II) and bis(monothioacetylacetonato)nickel-(II) show a small maximum wave between the first and the second wave. The ratio of the second wave height to the first one increases depending on the number of oxygen atoms introduced into the ligands, though the half-wave potentials of both waves do not show any appreciable change.

It is very interesting that the half-wave potential of the first wave of nickel chelates is more positive than that of simple nickel salt in a DMF solution. Perhaps because of the special coordinate bond

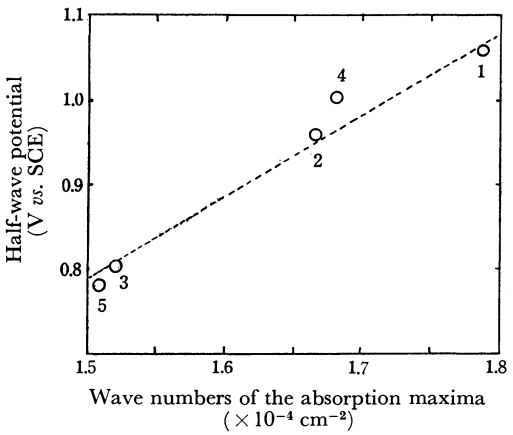

Fig. 3. Relation between the half-wave potential of the first wave and the wave numbers of the absorption maxima.
1. $Ni(sacsac)_2$ 2. $Ni(sbzsac)_2$ 3. $Ni(sbzsbz)_2$
4. $Ni(sfasac)_2$ 5. $Ni(sfasbz)_2$

character between sulfur and the central metal, as well as because of the pseudo-aromaticity of the dithio-β-diketonate chelate ring, electrons are more easily supplied to the central ion than usual complexes; this should cause a positive shift of the wave. On the other hand, the more stable a complex is, the more the wave shifts toward negative potentials. In this case, the former effect is predominant, and the first wave shows a positive shift. The first wave of bis(dithioacetylacetonato)cobalt(II) also shows the same tendency.

The relation between the wave number of the maxima of the electronic spectral band in the 500-to-600 mμ region of the chelates and the half-wave potentials of their first waves is shown in Fig. 3. According to Schrauzer *et al.*,[8] the half-wave potential of the polarograms of five-membered-ring dithiolate chelates shifts toward more positive potentials when Taft's inductive coefficients of ligands are higher. Although this phenomenon is also to be expected for the dithio-β-diketonates, the Taft constants for the six-membered-ring chelates containing a trifluoromethyl group, as calculated by the method of Schrauzer *et al.*,[8] are too high and are not in any linear relation with the $E_{1/2}$ and $\sum\sigma^*$.

In the case of five-membered-ring dithiolate complexes, the waves near −1.0 V and +0.1 V *vs.* Ag/AgCl were assigned to Ni(I)→Ni(0) and Ni(II)→Ni(I) respectively. However, the six-membered-ring dithio-β-diketonato chelates do not give the latter wave; moreover, it is not probable to identify any of the waves as an Ni(I)→Ni(0) one; consequently, it can be said that dianionic or monoanionic species are not stable in the case of six-membered-ring chelates. This is probably because of the weaker aromaticity of the latter chelate ring.

Helpful discussions by Professors Niro Matsuura, Yukichi Yoshino, and Kunihiko Watanuki and by Drs. Kisaburo Umemoto and Toshio Takeuchi are hereby gratefully acknowledged.

Formation and Absorption Spectra of Mixed Copper(II) Chelates Containing Acetylacetone and 2,2′-Bipyridine or 1,10-Phenanthroline

Yutaka FUKUDA* and Kozo SONE**

* *Department of Chemistry, Faculty of Science, Shizuoka University, Ôya, Shizuoka*

** *Department of Chemistry, Faculty of Science, Ochanomizu University, Ôtsuka, Bunkyo-ku, Tokyo*

(Received July 9, 1969)

The formation and absorption spectra of a number of mixed copper(II) chelates of the general type [CuAB], where A is bip or phen and B is en, gly or ox, were studied by Sone, Utsuno and Ogura.[1] The extension of this study to the systems

(1) $[Cu\ bip_2]^{2+} + [Cu\ aca_2] \rightleftarrows 2[Cu\ bip\ aca]^+$

(2) $[Cu\ phen_2]^{2+} + [Cu\ aca_2] \rightleftarrows 2[Cu\ phen\ aca]^+$

is reported here[2].

Figure 1 shows the visible absorption spectra of the solutions containing $[Cu\ bip_2](NO_3)_2 \cdot H_2O$ and $[Cu\ aca_2]$ in various proportions. The solvent used is 80% (v/v) dioxane, and the total concentration of the two chelates is 10^{-2} M in every case. Existence of two isosbestic points is evident; one at 704 mμ is observed in solutions in which the ratio $[Cu\ bip_2]^{2+}$: $[Cu\ aca_2]$ is 0 : 10 to 5 : 5, and another at 628 mμ is found in solutions where the ratio is 5 : 5 to 10 : 0. In Fig. 1, the curves for the solutions of the ratios 3 : 7, 4 : 6, 6 : 4 and 7 : 3 are not shwon. However, each of them passes the corresponding isosbestic point. The absorption bands of $[Cu\ bip_2]^{2+}$ at 740 and 950 mμ (ε=88 and 78, respectively) disappear almost completely in the solution where the ratio is 5 : 5, and a new band appears, the λ_{max} of which (610 mμ; ε=62) is smaller than those of $[Cu\ bip_2]^{2+}$ and even than that of $[Cu\ aca_2]$ (620 mμ; ε=39). Essentially similar data are obtained with $[Cu\ phen_2](NO_3)_2 \cdot H_2O$ and $[Cu\ aca_2]$ in 72% dioxane, where the

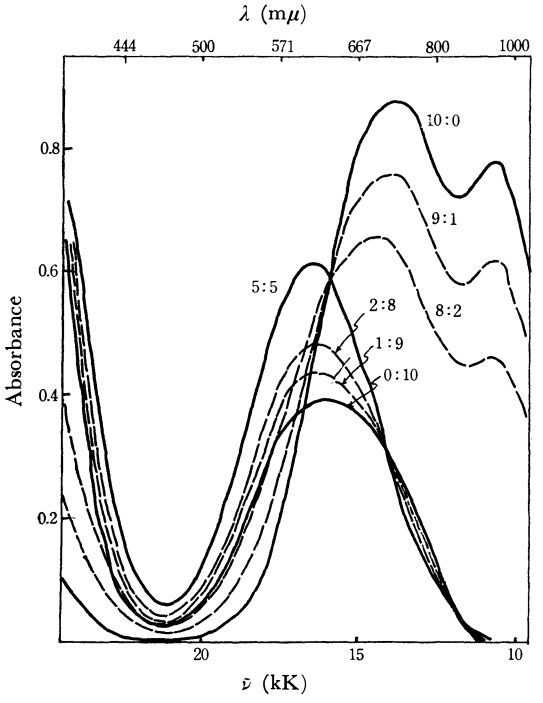

Fig. 1. Absorption spectra of $[Cu\ bip_2]^{2+}$ - $[Cu\ aca_2]$ mixed solutions in 80% dioxane. The molar ratio of the component chelates ($[Cu\ bip_2]^{2+}$: $[Cu\ aca_2]$) is shown for each curve.

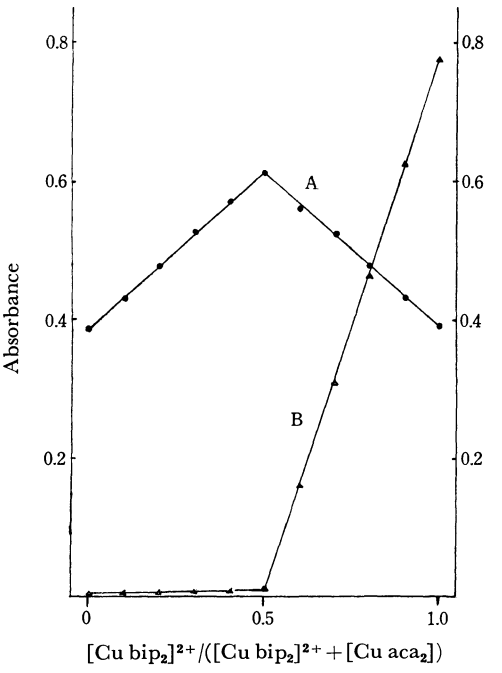

Fig. 2. Application of continuous variation method to the data of Fig. 1. The wavelength used: (A) 600 mμ; (B) 940 mμ.

1) K. Sone, S. Utsuno and T. Ogura, *J. Inorg. Nucl. Chem.*, **31**. 117 (1969).

2) Abbreviations used in this paper are: bip=2,2′-bipyridine; phen=1,10-phenanthroline; en=ethylenediamine; gly=glycinate anion; ox=oxalate anion; aca=acetylacetonate anion.

total concentration of the two chelates is 0.8×10^{-2} M; here the band of $[Cu\ phen_2]^{2+}$ at 720 and 980 mμ ($\varepsilon=46$ and 41, respectively) practically disappears in the 5 : 5 mixture, and a new band appears instead at 615 mμ ($\varepsilon=48$). These facts, and especially the application of continuous variation method to these data (*cf.* Fig. 2), clearly indicate that the mixed chelates $[Cu\ bip\ aca]^+$ and $[Cu\ phen\ aca]^+$ are formed nearly quantitatively in the respective mixed solutions. Estimation from these spectral data indicates that the equilibrium constants (K) of the two systems (1) and (2) are both very large ($K\geqq 10^4$), showing the remarkably high stability of these mixed species. It was also found that dark-green crystalline chelates [Cu bip aca]X and [Cu phen aca]X (X=NO_3 or ClO_4) can be readily obtained by evaporating equimolar mixtures of $[Cu\ aca_2]$ and $[Cu\ bip_2]X_2$ or $[Cu\ phen_2]X_2$ dissolved in aqueous ethanol. The results of elemental analyses are as follows; Found: C, 47.21; H, 3.99; N, 10.96%. Calcd for [Cu bip aca](NO_3): C, 47.29; H, 3.97; N, 11.03%. Found: C, 41.47; H, 4.00; N, 6.50%. Calcd for [Cu bip aca](ClO_4)·H_2O: C, 41.29; H, 3.94; N, 6.42%. Found: C, 47.39; H, 4.23; N, 9.84%. Calcd for [Cu phen aca](NO_3)·1.5 H_2O: C, 47.27; H, 4.21; N, 9.73%. Found: C, 44.37; H, 3.80; N, 6.17%. Calcd for [Cu phen aca](ClO_4)·H_2O: C, 44.35; H, 3.73; N, 6.09%.

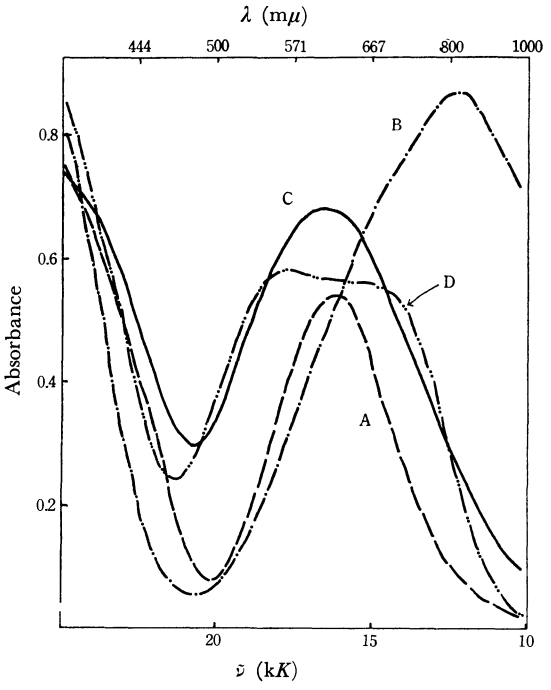

Fig. 3. Spectral data of the chelates in the system $[Cu\ bip_2]^{2+}-[Cu\ aca_2]$. Curve A: absorption spectrum of [Cu bip aca]$^+$ in 80% dioxane; curves B, C and D: reflectance spectra of [Cu bip$_2$](NO_3)$_2$·H_2O, [Cu bip aca](NO_3) and [Cu aca$_2$], respectively.

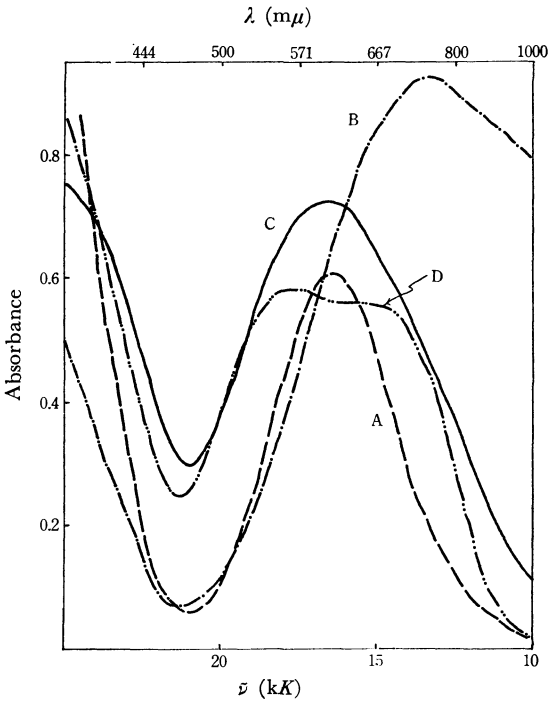

Fig. 4. Spectral data of the chelates in the system $[Cu\ phen_2]^{2+}$-$[Cu\ aca_2]$. Curve A: absorption spectrum of [Cu phen aca]$^+$ in 80% dioxane; curves B, C and D: reflectance spectra of [Cu phen$_2$](NO_3)$_2$·H_2O, [Cu phen aca](NO_3)·1.5H_2O and [Cu aca$_2$], respectively.

Figures 3 and 4 show that the λ_{max} values of the reflectance spectra of these newly obtained chelates agree fairly well with those in the absorption spectra of their 80% dioxane solutions; the latter spectra, on the other hand agree nearly exactly with the spectra of the corresponding 5 : 5 mixtures described above. These facts show that these crystalline chelates are true mixed chelates, and not the mere mixtures of the component chelates.

It is of interest to compare these data with the earlier data of Kida[3] on the formation of [Cu en aca]$^+$ from $[Cu\ en_2]^{2+}$ and $[Cu\ aca_2]$ in water-dioxane. Although his experimental conditions are not exactly the same as ours, it is apparent that the stability of [Cu en aca]$^+$ with respect to its component chelates is very much lower than that of [Cu bip aca]$^+$ and [Cu phen aca]$^+$. The value of K calculated by Kida was only 2.6, and did not differ so much from the statistical value 4. He also found that the absorption band of [Cu en aca]$^+$ was nearly at the middle between those of $[Cu\ en_2]^{2+}$ and $[Cu\ aca_2]$. Thus the behavior of this mixed chelate seems to be quite normal in every respect.

The remarkably greater stability and apparently anomalous spectra of the mixed chelates can now

3) S. Kida, This Bulletin, **29**, 805 (1956).

be ascribed, as in the case of other bip- or phen-containing mixed chelates,[1] to the removal of the steric hindrance existing in $[Cu\ bip_2]^{2+}$ and $[Cu\text{-}phen_2]^{2+}$ by mixed chelate formation. As described in a previous paper,[1] scale model studies show that these chelates are considerably deformed from the square-planar structure normally favored by Cu^{2+}. On the other hand, the same studies show that the mixed chelates $[Cu\ bip\ aca]^+$ and $[Cu\ phen\ aca]^+$ are perfectly square-planar. Therefore, we can expect that they will be very readily formed in solution containing the component chelates, and the value of K will be very much higher than the statistical value. We can also expect that their λ_{max} values will be much smaller than those of $[Cu\ bip_2]^{2+}$ or $[Cu\ phen_2]^{2+}$, and even than that of $[Cu\ aca_2]$ as they are both $[Cu\text{-}N_2O_2]$-type chelates.[1),4] It is apparent that these expectations agree quite well with our observations.

It is of some interest to note that the band of $[Cu\ aca_2]$ in Figs. 3 and 4 is notably split. This can probably be related to its crystal structure in which the chelate molecules are highly planar and each copper atom is practically 4-coordinate.[5]

4) It is noteworthy that the λ_{max} of $[Cu\ aca_2]$, which is a $[Cu\ O_4]$-type chelate, is quite small, and even somewhat smaller than that of $[Cu\ gly_2]$ (635 mμ) which is a $[Cu\ N_2O_2]$-type chelate. However, since the ligand field strength of bip or phen will be more or less comparable with that of en ($[Cu\ en_2]^{2+}$: λ_{max}= 550 mμ), we can anticipate what is stated in the text.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 558—560 (1970)

Removability of Oils from Cotton Cloths

Maresuke KASHIWAGI and Tomoko TAMURA

School of Home Economics, Kyoritsu Womens University, Chiyoda-ku, Tokyo

(Received July 22, 1969)

It is well-known that oily substances attached to soiled cloths play an important role in the process of detergency. It seems, however, that the mechanism operating underneath the detergency process has not yet been firmly established.

According to a direct observation of the detergency process, the particulate constituent might give little trouble if the oily constituent could be removed first.[1] However, exactly the opposite may be true, that is, it may be held that it is rather particulate dirt that has become firmly attached to the textile itself, instead of adhering by means of a fatty film.[2] In fact, it seems most likely that the solid and liquid soils are under certain conditions, often removed independently.[3]

Yet it appears that no direct demonstration of the influence of oil on a quantitative basis has ever been made. The present authors, using the gas-chromatographic technique, tried to determine the removability of oily substances from cotton cloths, paying particular attention to the type of oil used. The present report will be concerned with the desorption of three different types of oils with the same carbon chain and with the correlation of the desorption with the detergency.

Experimental

Oils. The three types of oils used were dodecane $C_{12}H_{26}$, dodecyl alcohol $C_{12}H_{25}OH$, and lauric acid $C_{12}H_{24}O_2$, each with a twelve carbon chain. We attempted to use oils with a shorter carbon chain, but we found that alkanes of less than 12 carbons evaporated rather quickly upon gas-chromatographic analysis and upon weight-loss measurement as well. The dodecane and lauric acid were both extremely pure, showing the presence of only one peak on a gaschromatogram. The dodecyl alcohol was purified from commercial lauryl alcohol by repeated distillation under reduced pressure, but it still showed about 7% content of homologous alcohols.

Cloths, Carbon Black, and Carbon Tetrachloride. These were used as assigned by a standard detergency test method.*1

Detergents. The sodium dodecyl sulfate (SDS), which had been purchased from Wako Junyaku Co., Ltd., was purified once by recrystallization from ethanol. The polyoxyethylene condensate of nonyl phenol ($\bar{p}=7.5$ NPE) was used as obtained from the Toho Chemical Co., Ltd. The household detergent mixture

*1 JIS-C9606 (1968).

was a recently-purchased one. The gaschromatograph used was a Hitachi K-53 type apparatus, equipped with a rising temperature programer. The sensitivity was $10-2\times10^2$. Its column was packed with chromosorb W with phosphoric acid plus polyethyleneglycol.

Procedure. An oil-impregnated cotton cloth was prepared by applying 0.5 cc of an equimolar mixture (2.4×10^{-4} mol of each/cc) of dodecane, dodecyl alcohol, and lauric acid in CCl_4 to a piece of cloth (10×5 cm) by means of a micropipet. After the evaporation of the solvent, the oiled cloths were aged for 3 days before use. The oiled cloth was washed with a scrub-*o*-meter in the usual manner at 30°C for 10 min, and then rinsed for 3 min. Ion-free water was used throughout. Washed cloths from 12 runs were collected and air-dried, and the residual oils were extracted in ether with soxlet for 12 hr. After the removal of the ether, 1 cc of CCl_4 was added to this remaining oil in order to analyze it by gas chromatography. The relative contents of the three oils were calculated by the ordinary triangle method.

By a separate detergency test, we made three types of artificially soiled cotton cloth, in each test using the same amount of a different oil instead of using hardened tallow and paraffin. The cloth was impregnated with carbon black and oil in CCl_4.

The washing time was made 20 min, while keeping the other conditions the same as above.

The detergency may be expressed as; $D=\dfrac{R_w-R_s}{R_o-R_s}$

where R_w: reflectance of the washed cloth
R_s: reflectance of the soiled cloth
R_o: reflectance of the original cloth before soiling.

All the detergency data are averages of four runs made under the same conditions and examined by means of statistical calculations.

Results and Discussion

Table 1 shows the residual oil contents of washed cotton cloths. These are calculated from the gaschromatograms, a sample of which is shown in Fig. 1. As is clearly indicated here, overwhelmingly more dodecyl alcohol remained than the corresponding alkane and acid. In other words, the alcohol was most difficult to remove by any detergent solution including SDS and NPE. Table 2 shows the detergency of water alone, SDS, NPE, and a commercial detergent mixture on cloths artificially soiled with carbon blacks and with one of the three oils. For any of the detergent systems listed in Table 2 except for the commercial detergent, which alone contains alkaline builders, it was found that detergency is strongly dependent on the soiling oil. The influence of oil on the removal of carbon particles from cloths is very clear. In almost all cases, except for the commercial detergent formulation, the detergency for soiled cloths increases in the order of: without oil>alkane>alcohol>acid.

Table 1. Unremovable oils in cotton cloths after washing

Detergent system	Residual oil (ratio against alkane)		
	Alkane	Alcohol	Acid
Water	1	715	10
NPE 0.25%	1	71	44
SDS 0.25%	1	240	34

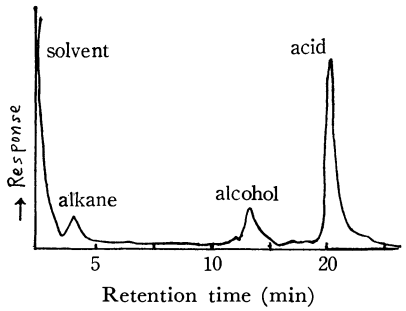

Fig. 1. A GL Chromatogram of residual oil (SDS 0.25%; sensitivity $10-2\times10^2$).

These two results may be summarized by saying that the removability of oil out of cotton cloth by these detergents is definitely: alkane>acid>alcohol in the order of ease, while the removability of carbon soil with regard to the presence of oil is in the order of: without oil>alkane>alcohol>acid. This, in turn, should be interpreted as meaning that the removability of oil is not parallel with that of soiled soil, *i.e.*, carbon black.

The soiled cloth without oil exhibits the highest detergency, and the presence of lauric acid, which should behave like solid, (mp 44°C) interferes with the removal of carbon soil most strongly. The exception of the commercial detergent regarding

Table 2. Detergency on artificially-soiled cloths

Soiling Composition	Detergency %			
	Water	SDS	NPE	Commercial detergent
Carbon black	27.6	51.0	59.2	52.3
Carbon black plus alkane	25.3	54.1	54.2	57.7
Carbon black plus alcohol	19.4	45.8	41.5	48.7
Carbon black plus acid	14.8	30.2	30.0	59.3

(Concentration of detergents: 0.25%)

the order of detergency with respect to acid appears to be very reasonable, because the acid soil may be removed more easily by alkaline builders like sodium tripolyphosphate in detergent formulation. As for the removal of oily dirt, emulsification may be considered to be of importance.[3]

However, it may also be interesting to add that alkane is much more difficult to emulsify than alcohol by these detergent solutions at concentrations of 2.5% or less when emulsification test are carried out by an ordinary method.[4] We have found that alcohol was most easily emulsified, even to a thixotropic gel, while acid, being a solid, never went into emulsion at 30°C.

The author wish to express their appreciation to Mr. H. Uchiki of Hitachi for carrying out the gas-chromatographic analysis and to Mr. H. Akabayashi of the Nissan Co., Ltd., for supplying the samples of alkane and dodecyl alcohol.

A Simple HMO Treatment of the Acidity of Substituted Tropolones

Kimiaki IMAFUKU and Hisashi MATSUMURA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

(Received August 4, 1969)

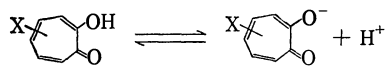
It is known that the dissociation constants of tropolone derivatives which have the phenolic hydroxyl group are linearly correlated with Hammett's substituent constants obtained in benzenoid compounds.[1] In an application of the Hammett equation to tropolone derivatives, we found that the π-electron densities of oxygen atoms and neighboring carbon atoms are correlated with substituent constants.[2]

As a molecular orbital treatment, we examined the energy changes in dissociation of some tropolone derivatives in terms of localization energies. This was on the assumption that the dissociation constants of this type of derivatives are directly proportional to the π-electron energy differences between the unionized and the ionized tropolones.

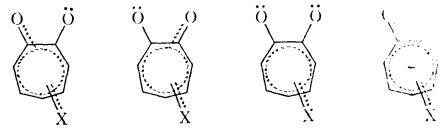
Calculation Method

The simple Hückel molecular orbital method was used for all calculations as in previously reported.[2]

In the molecular orbital treatment of the energy changes in dissociation equilibrium of tropolones (see below),



the following localized and delocalized models are assumed. In the dissociation of phenols, the degree of delocalization by the interaction of phenyl group with OH group is smaller than that of phenyl group with O^- group.[3] Similarly, in tropolone derivatives, it is thought that tropolonate anions



[A] [B] [C] [D]

Fig. 1. The localized models for tropolones and the delocalized model for tropolonate anions.

are more delocalized than tropolones themselves. The localized tropolones can be represented by states [A] or [B] in Fig. 1. However, state [C] was chosen as the model for calculations, since the two oxygen atoms are nearly equivalent in reactivity and the calculation might be simplified. Model [D] was used as the delocalized tropolonate anions. On these assumptions, the energies for the unionized tropolones $(E_\pi)_{AH_I}$ and for the ionized tropolonate anions $(E_\pi)_{A^-_I}$ are calculated, and the energy changes $(\Delta E_\pi)_I$ for dissociation are given by the equation[4]

$$(\Delta E_\pi)_I = (E_\pi)_{A^-_I} - (E_\pi)_{AH_I} = 2\alpha + (\Delta M_I)\beta \quad (1)$$

As the integral parameters for the oxygen atoms and the adjacent carbon atoms, the parameters we obtained previously are used,[2] and Fueno's parameters[3] are applied to all substituents.

3) T. Fueno, T. Okuyama and J. Furukawa, *ibid.*, **39**, 569 (1966).

Results and Discussion

The ΔM_i terms in the energy changes in dissociation of tropolone derivatives are listed in Table 1, together with their dissociation constants. When the values of ΔM_i are plotted against pK_i (Fig. 2), irrespective of many assumptions, an approximately linear relation holds according to the electron-releasing and the electron-attracting forces of substituents. The relationship between pK_i and ΔM_i is represented by the equation

$$pK_i = 7.77 - 2.87\Delta M_i \quad (2)$$

The calculated pK_i values obtained by this equation are shown with the observed values in Table 1. The correlation coefficient between the observed and the calculated values is 0.98. Thus, the dissociation constants of other tropolone derivatives with substituents in the 4- and 5-positions can be estimated by molecular orbital calculation and equation (2).

Table 1. Energy changes in dissociation and pK values

No.	Substituent	ΔM_i	pK_i	
			calcd	obsd
1	5-OCH_3	0.0610	7.59	7.75
2	5-CH_3	0.1550	7.33	7.32
3	4-CH_3	0.1658	7.29	7.26
4	H	0.2530	7.04	6.92
5	5-Cl	0.5232	6.24	—
6	5-Br	0.5486	6.20	6.32
7	5-NO_2	0.8160	5.43	—

No. of substituents are related to those in Fig. 2.

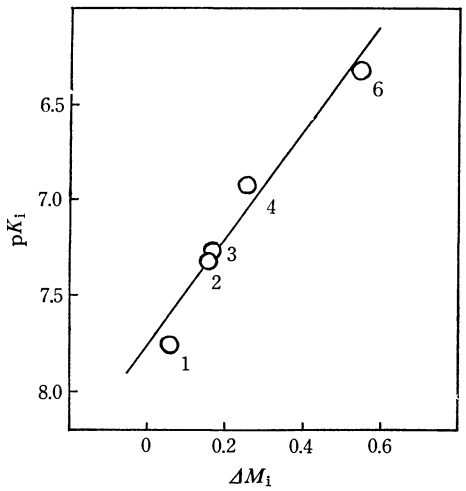

Fig. 2. Correlation of pK_i with ΔM_i.

ΔM_i is correlated with Hammett's substituent constants. This shows that the Hammett relationship is applicable to tropolone derivatives, together with the linearity of the static π-electron densities of oxygen atoms and the neighboring carbon atoms with σ-constants.[2)]

Nuclidic Mass Measurement by Ion Cyclotron Resonance

Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

Katsuyuki AOYAGI and Teruo MIYAMAE

Japan Electron Optics Laboratory, Akishima-shi, Tokyo

(Received August 8, 1969)

Recently Baldeschwieler and his co-workers[1] have applied the double-resonance technique of magnetic resonance to ion cyclotron-resonance spectroscopy (ICRS) and proved it useful for the investigation of the kinetics of organic reactions. Besides the use of ICRS along this line, it is also assumed to be useful for the measurement of the nuclidic masses. This sort of application is important because the atomic masses are, at present, determined by mass spectroscopy[2] as well as by microwave spectroscopy;[3] the effort to build a new and independent method for the determination of nuclidic masses is to be encouraged.[4]

1) L. R. Anders and J. L. Beachamp, R. C. Dunbar and J. D. Baldeschwieler, *J. Chem. Phys.*, **45**, 1062 (1966).

2) H. E. Duckworth "Mass Spectroscopy," Cambridge University Press, Cambridge (1960), p. 97.

3) C. H. Townes and A. L. Schawlow, "Microwave Spectroscopy," McGraw-Hill, New York (1955), p. 42.

4) A. E. Cameron and E. Wichers, Comprehensive Review, Report of the Commission on Atomic Weights, Comptes rendus of IUPAC XXI (1961), p. 20.

The ICRS is based on the motion of charged particles in magnetic and electric fields. The cyclotron frequency, ω_c, is given by Eq. (1), where e is the charge of the particle; H, the magnetic field strength in Gaussian

$$\omega_c = eH/mc \qquad (1)$$

cgs units; m, the particle mass, and, c, the velocity of light. When an alternating electric field, $E_1(t)$, at a certain frequency ω_1, is applied normaly to H with $\omega_1=\omega_c$, an absorption of energy by the ions occurs; this absorption can easily be observed by a bridge-type detector. With a fixed observing frequency, the mass of the ion can be obtained by measuring the intensity of H by the proton magnetic resonance technique.

With this consideration, an experimental set-up has been built according to the descriptions which have been published in the literature.[5)]

The experimental conditions and some results concerning argon 40 will be described below.

Experimental

Since most of the construction of the apparatus is the same as in the literature,[5)] its details will not be given in this paper. A schematic diagram of the apparatus is shown in Fig. 1, where the observing frequency is calibrated as 99.986 kHz; the magnetic field strength is measured by the proton magnetic resonance technique.

Beauchamp *et al.* have shown the dependence of ω_c on the instrumental factors, especially on the trap voltage, V_T, and have shown a relation of:

$$\Delta H_c = (2\times 10^8/\omega_c d^2)V_T \qquad (2)$$

In Eq. (2), ΔH_c is the deviation of the resonant field from the theoretical value of Eq. (1), and d, the distance between the electrodes. Equation (2) has been derived by the consideration that an additional magnetic field, ΔH_c, is produced by V_T in the probe; it implies that the theoretical resonant field will be obtained by extrapolating V_T to 0. However, we assume this condition is not sufficient to produce the state of $\Delta H_c=0$, and it is assumed to be necessary to take the effect of the drift voltage, V_D, into consideration also. Namely, we assume that this condition is realized in the central region of the probe, when V_T is taken as one half of V_D.*1 In other words, Eq. (2) is replaced by Eq. (3):

$$\Delta H_c = (K/d^2\omega_c)(V_T - V_D/2) \qquad (3)$$

where K is an experimental constant.

Measurements have been carried out with respect to Ar 40 under the conditions shown in Table 1.

The values of V_D and V_T have been measured with an experimental error of ± 0.001 V. The resonant field has been measured by the proton resonance technique, it is expressed in terms of the frequency scale shown in Fig. 2. Each point of the observed values in Fig. 2 refers to the average of 5 runs and is assumed to be accurate within 1 Hz.

The observed points present a linear relation with V_T as may be seen in Fig. 2. According to the results of the aforementioned consideration, the real resonant field is determined to be 11.081 MHz in frequency units by the point which refers to the condition of $V_T=-0.1$ V on the extrapolated line of Fig. 2. Hence, the atomic weight of Ar 40, M, is calculated either by

5) J. L. Beauchamp, L. R. Anders and J. D. Baldeschwieler, *J. Amer. Chem. Soc.*, **89**, 4569 (1967).

*1 Dr. Beauchamp has written the present author that he also noticed the same phenomenon. The author's thanks are due to Dr. Beauchamp for sending preprint of his work.

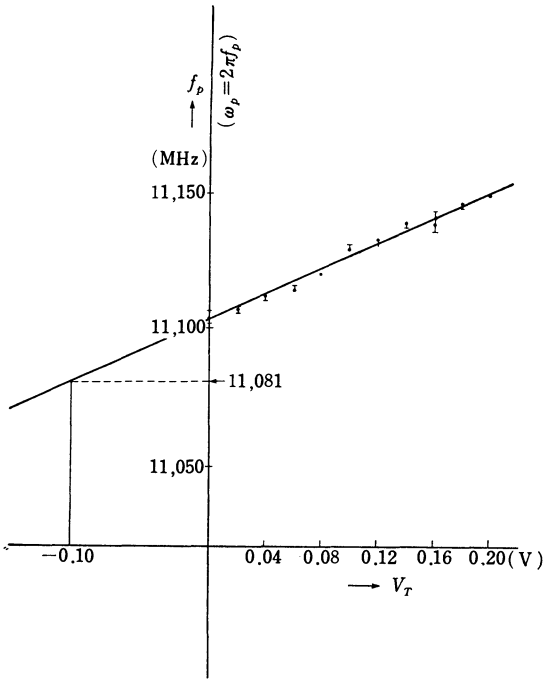

Fig. 2

Eq. (4) or Eq. (5), depending on the choice of the physical constants:

$$M = \frac{e}{c}\frac{N}{\gamma_p}\frac{\omega_p}{\omega_c} \tag{4}$$

$$M = N\frac{m_p}{\mu_p}\frac{\omega_p}{\omega_c} \tag{5}$$

In the sense that the atomic weight thus obtained is still dependent on the mass of the proton, which is determined on the basis of $C=12$ standard, the atomic weight of Ar 40 which has been determined in this experiment still depends on the latter. Calculations after Eqs. (4) and (5) both give a value of 39.970 ± 0.001, which is comparable to that of 39.961324 given in the literature.[6] Agreement between the two values is fairly good, and this agreement gives a sound basis for the assumption involved in Eq. (3) and also for the experimental techniques adopted in this experiment. The latter statement, in turn, implies that the present technique can be utilized for the precise measurement either of the gyromagnetic ratio or the magnetic dipole moment of the proton with the use of the established data on the mass.*2 Further investigation along this line is now in progress.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 564—565 (1970)

Absolute Configurations of 2-Methyl-2-phenylaziridine, 2-Phenylpropylamine, and Their Derivatives

Yoshihiro SUGI and Sekio MITSUI

Department of Applied Science, Faculty of Engineering, Tohoku University, Aoba Aramaki, Sendai

(Received August 11, 1969)

In previous publications,[1,2] we reported the stereoselectivity[1] and the effects of solvent and additive on the stereochemistry[2] of the catalytic hydrogenolysis of optically active 2-methyl-2-phenylaziridine derivatives. We now wish to describe the syntheses and the absolute configurations of 2-methyl-2-phenylaziridine, 2-phenylpropylamine, and their derivatives.

(+)-Ethyl 2-amino-2-phenylpropionate (I) was obtained by the resolution of (±)-I as its tartrate. The subsequent reduction of (+)-I with lithium aluminum hydride gave (+)-2-amino-2-phenylpropanol (II).[1] (+)-II was converted to (+)-2-methyl-2-phenylaziridine (III) *via* its sulfonate.[1] (−)-1-Acetyl-2-methyl-2-phenylaziridine (IV) was obtained by the acetylation of (−)-III. (+)-Ethyl 2-formylamino-2-phenylpropionate (V) was prepared by the formylation of (+)-I. The subsequent reduction of (+)-V with lithium aluminum hydride gave (+)-2-methylamino-2-phenylpropanol (VI). The cyclization of (+)-VI afforded (+)-1,2-dimethyl-2-phenylaziridine (VII). (+)-I has the S configuration.[3] Therefore, (+)-III, (+)-IV, and (+)-VII all have S configurations.

The formylation of (+)-2-phenylpropylamine (VIII) afforded (+)-*N*-2-phenylpropylformamide (IX). (+)-IX was reduced to (+)-*N*-methy-2-phenylpropylamine (X) with lithium aluminum hydride. (−)-*N*-2-Phenylpropylacetoamide (XI) was obtained by the acetylation of (−)-VIII. (+)-VIII has the R configuration.[4,5] Therefore, (+)-IX, (+)-X, and (+)-XI all have R configurations.

Experimental

S(+)- and R(−)-Ethyl 2-Amino-2-phenylpropionates (I), S(+)- and R(−)-2-Methyl-2-phenylaziridines (III), and S(+)- and R(−)-2-phenylpropylamines (VIII). These substances were prepared by the procedure previously described.[1] The NMR spectrum of III had signals at 0.40 (broad singlet, >NH); 1.53 (singlet, $-CH_3$); 1.73 (singlet) and 1.78 (singlet), ($-CH_2-$); 7.25 (multiplet, aromatic protons).*1

R(−)-Acetyl-2-methyl-2-phenylaziridine (IV). Acetyl chloride (8.2 g) in ether (25 ml) was added at 0°C to a solution of R(−)-III (13.3 g, α_D^{22} −18.86 (neat), 37.3% optically pure) and triethylamine (15.0 g) in ether (75 ml). The reaction mixture was allowed to proceed to completion by being stirred for 1 hr at this temperature. The triethylamine hydrochloride thus precipitated was filtered off and washed well with ether. After the ether had been removed at room temperature *in vacuo*, the oily residue was distilled to give R(−)-IV; bp 45—47°C/0.01 mmHg, $[\alpha]_D^{24.5}$ −36.2 (*c* 8.98, ethanol), 7.5 g.

Found: C, 75.68; H, 7.67; N, 8.27%. Calcd for $C_{11}H_{13}ON$: C, 75.40; H, 7.48; N, 7.99%.

The NMR spectrum had signals at 1.59 (singlet, $-\overset{|}{C}-CH_3$); 1.94 (triplet, J=0.4 Hz, $-COCH_3$); 3.75 (quartet, J=0.4 Hz, $-CH_2-$); 7.25 (multiplet, aromatic protons).*1

S(+)-Ethyl 2-Formylamino-2-phenylpropionate (V). The procedure described by Tsuboyama[6] was used with slight modifications. To a solution of S(+)-I (39.6 g, $[\alpha]_D^{22}$ +26,6 (*c* 9.70, ethanol), 90.3% optically pure) in 88% formic acid (720 g), acetic anhydride (244 g) was added with stirring at 95°C. The reaction mixture was then allowed to stand at this temperature for 30 min. The excess of the reagents was removed *in vacuo*, and then water (500 ml) was added to the oily residue. The resulting precipitates were filtered and then recrystallized from benzene-*n*-hexane to give S(+)-V; mp 94—95°C, $[\alpha]_D^{23}$ +19.50 (*c* 5.18, ethanol), 25.3 g.

Found: C, 65.20; H, 6.88; N, 6.25%. Calcd for $C_{13}H_{15}O_3N$: C, 65.14; H, 6.83; N, 6.33%.

The filtrate was treated with aqueous ammonia. S(+)-I (17.5 g, $[\alpha]_D^{20.5}$ +26.4 (*c* 9.88, ethanol)) was thus recovered.

For the check of the optical purity, S(+)-V (1.1 g, $[\alpha]_D^{23}$ +19.50 (*c* 5.18, ethanol)) was heated with hydrochloric acid in ethanol for 3 hr. S(+)-I was then isolated in the usual manner; $[\alpha]_D^{20.5}$ +27.8 (*c* 9.25, ethanol), 91.0% optically pure.

S(+)-2-Methylamino-2-phenylpropanol (VI). S(+)-V (24.2 g, $[\alpha]_D^{23}$ +19.50 (*c* 5.18, ethanol), 91.0% optically pure) in tetrahydrofuran (100 ml) was added to lithium aluminum hydride (8.0 g) in tetrahydrofuran (100 ml); the reaction mixture was then heated under reflux for 64 hr. After cooling, water (30 ml) was added with vigorous stirring; the organic layer was then decanted from the precipitates. The resulting precipitates were dissolved with aqueous sodium hydroxide, and the aqueous solution was extracted with ether. The combined extracts were dried over anhydrous sodium sulfate. After the evaporation of the solvents, the oily residue was distilled under a nitrogen stream to give S(+)-VI: bp 94—102°C/0.4 mmHg, $[\alpha]_D^{22.5}$ +21.2 (*c* 4.58, benzene), 16.0 g.

Found: C, 73.00; H, 9.15; N, 8.44%. Calcd for $C_{10}H_{15}ON$: C, 72.69; H, 9.15; N, 8.48%.

S(+)-1,2-Dimethyl-2-phenylaziridine (VII). S(+)-VII was obtained from S(+)-VI by a method similar to that used for the preparation of III.[1] S(+)-VI (16.0 g, $[\alpha]_D^{22.5}$ +21.2 (*c* 4.58, benzene), 91.0% optically pure) afforded S(+)-VII: bp 88—91°C/14 mmHg, $[\alpha]_D^{22}$ +45.0 (*c* 8.95, ethanol), 9.3 g.

Found: N, 9.41%. Calcd for $C_{10}H_{13}N$: N, 9.82%.

R(+)-*N*-2-Phenylpropylformamide (IX). R(+)-IX was prepared by a method similar to that used for the preparation of V. R(+)-VIII (4.0 g, $[\alpha]_D^{19.0}$ +9.84 (*c* 9.71, ethanol), 33.4% optically pure) gave R(+)-IX; bp 130—132°C/0.6 mmHg. $[\alpha]_D^{18.4}$ +8.26 (*c* 10.04, ethanol), 2.2 g.

Found: N, 8.37%. Calcd for $C_{10}H_{13}ON$: N, 8.58%.

R(+)-*N*-Methyl-2-phenylpropylamine (X). R(+)-X was obtained from R(+)-IX by refluxing it with lithium aluminum hydride in ether for 24 hr. R(+)-IX (2.0 g, $[\alpha]_D^{18.4}$ +8.26 (*c* 10.04, ethanol), 33.4% optically pure) afforded R(+)-X; bp 100—103°C/15 mmHg, $[\alpha]_D^{22}$ +8.45 (*c* 9.45, ethanol), 0.3 g (this substance was purified by preparative gas chromatography (10% PEG-10% KOH on fire-brick, 180°C, using helium-carrier gas), for two impurities were present in the crude product).

Found: N, 9.17%. Calcd for $C_{10}H_{15}N$: N, 9.39%.

S(−)-*N*-2-Phenylpropylacetoamide (XI). Acetic anhydride (3.50 g) was added at 0°C to a well-stirred suspension of S(−)-VIII (2.70 g, $[\alpha]_D^{20}$ −8.65 (*c* 9.37, ethanol), 29.3% optically pure) and sodium carbonate (4.2 g) in water (30 ml). The reaction mixture was then stirred for 1 hr at this temperature. The resulting suspension was extracted with ether. The etheral solution was washed with dilute hydrochloric acid, water, and saturated sodium bicarbonate, and was dried over anhydrous sodium sulfate. The evaporation of the ether and the subsequent distillation afforded S(−)-XI: bp 130—132°C/0.6 mmHg, $[\alpha]_D^{19.5}$ −13.83 (*c* 9.55, ethanol), 2.4 g.

Found: N, 7.81%. Calcd for $C_{11}H_{15}ON$: N, 7.90%.

The authors wish to thank Dr. Kaoru Hanaya of Yamagata University for his NMR spectra measurements.

*1 The NMR spectra were determined with a Hitachi model H-6013 spectrometer for the carbon tetrachloride solution, using tetramethylsilane as the internal standard. The chemical shifts are expressed in δ-values.

Asymmetric Hydrogenation of C=O Double Bond with Modified Raney Nickel. XIII.*1 Modification with Peptides

Yoshiharu IZUMI, Susumu TATSUMI,*2 Masami IMAIDA*3 and Kazuo OKUBO

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received August 14, 1969)

Previous papers of this series have reported that Raney nickel catalysts (R-Ni) modified with optically-active α-amino acids or α-hydroxy acids asymmetrically catalyze the hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate. The relationship between the asymmetric hydrogenation activity of a modified R-Ni catalyst and the structure of its modifying reagent has also been studied in previous papers.[1)]

On the other hand, the silk-palladium asymmetric catalyst prepared as an enzyme model was studied prior to the modified R-Ni catalyst by one of the present authors.[2)] Investigations of R-Ni catalysts modified with peptides have a great importance in elucidating the mechanisms for the substrate specificity of the enzyme action and for the asymmetric hydrogenation of a silk-palladium catalyst. However, no modifications with peptides have been attempted. The influence of the peptide structure used as a modifying reagent on the asymmetric activity of the catalyst was studied, with focussed attention on several leucyl-peptides in the present work. In additionl the asymmetric activity of the catalyst modified with glycyl-L-aspartic acid was tested. The results of the present work are listed in Table 1.

TABLE 1. THE OPTICAL ROTATION OF THE PRODUCTS ON THE MODIFICATIONS WITH DIPEPTIDES

Modifying reagent	Modifying conditions		$[\alpha]_D^{20}$ of methyl 3-hydroxybutyrate

* Y. Izumi, M. Imaida, H. Fukawa and S. Akabori, This Bulletin, **36**, 155 (1963).

L-Leucyl-glycine (L-Leu-Gly) gives the catalyst a higher asymmetric yield*4 than glycyl-L-leucine (Gly-L-Leu) and the reverse asymmetric direction to Gly-L-Leu or L-leucine as a asymmetric modifying reagent. The asymmetric direction of the catalyst modified with Gly-L-Leu is the same as that with L-leucine, and the asymmetric yield of the former

*4 The "asymmetric activity" of a catalyst involves two factors. One is the direction of the asymmetric activity, which is expressed as the direction of the specific rotation, (+) or (−), of the hydrogenated product. The other is the degree of asymmetric activity, which is usually presented as the asymmetric yield.

is considerably weaker than that of the latter. It can be expected from the results that the peptide bond existing at the carboxy group of amino acid residue reverses the effect of the asymmetric center of the amino acid itself on the asymmetric direction of the catalyst, and that the peptide bond existing at the amino group of amino acid reduces the effect of the asymmetric center of amino acid on the asymmetric yield of the catalyst.

Since glycine has no asymmetric center, the deviation of the asymmetric activity of the catalyst modified with L-Leu-Gly or Gly-L-Leu from that with L-leucine is considered to occur mainly as a result of the peptide structure.

If the simple additional regulality in the structure of the peptide can be found in the asymmetric activity of the catalyst, it should be possible to calculate the asymmetric activity of the catalyst modified with L-leucyl-L-leucine (L-Leu-L-Leu) or L-leucyl-D-leucine (L-Leu-D-Leu) from those with L-Leu-Gly and Gly-L-Leu. The asymmetric activities of the catalysts modified with L-Leu-L-Leu and L-Leu-D-Leu at 0°C are calculated as follows, respectively;

$$(+1.12) + (-0.41) = +0.71$$

and

$$(+1.12) - (-0.41) = +1.53$$

However, our results, shown in Table 1, are quite far from the above expectations.

Within the limited number of experiments of the present work, the effect of the structure of the peptides as the asymmetric modifying reagent are not simple; there are two possible reasons, either there are two types of adsorption states of peptide on the catalyst surface, as is shown in Fig. 1, or the effect of the structure of the leucine residue is different from that of the glycine residue in the peptide structure as a modifying reagent.

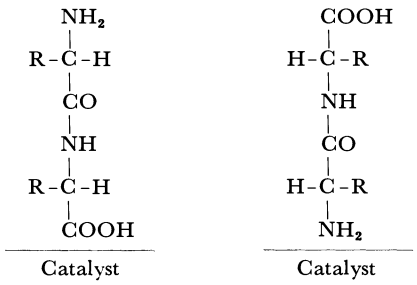

Fig. 1. Adsorption formulas of dipeptide on the catalyst surface.

Although the relationship between the structure of the dipeptide used as a modifying reagent and the asymmetric activity of the catalyst seems to be rather complicated, the following experimental regularity can be presented as the conclusion of the present work. The asymmetric direction of the catalyst modified with dipeptide is ruled by asymmetric center in C-terminal amino acid and has the same sign as the asymmetric direction of the catalyst modified with C-terminal amino acid itself. The glycine residue at the C-terminal reverses the effect of the asymmetric center of N-terminal amino acid itself on the asymmetric direction of the catalyst.

Initiation of Vinyl Polymerization with Tertiary Amines/Alkylating Agents

Takayuki OTSU and Yasuhiko TAKEMURA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received August 18, 1969)

It has been reported that the binary system of such tertiary amines as dimethylaniline and such organic halides as benzyl chloride initiates the radical polymerization of methyl methacrylate.[1,2] In this case, a quaternary salt is formed, and then it decomposes at the N^+–C bond into radicals which react with the monomer to initiate the polymerization.[1,3]

On the other hand, several workers[4–6] have found that vinyl pyridine is polymerized in the presence of some alkylating agents, such as methyl iodide and dimethyl sulfate, through a quaternary pyridinium salt. The present paper will describe

DMS	C_2H_5OH	7	12.8	30	1.6	20	0.4
MTS	C_6H_6	7	5.0	30	3.7	—	—
MTS	C_2H_5OH	7	11.5	30	6.1	20	3.0

the results of the polymerization of vinyl monomers with the binary system and the quaternary salt of several dialkylanilines, especially dimethylaniline (DMA), and dimethyl sulfate (DMS) or methyl *p*-toluenesulfonate (MTS).

Experimental

The tertiary amines and vinyl monomers were purified in the usual manner from the reagent-grade materials. The commercial DMS and MTS were distilled prior to use.

The quaternary salts of DMA with DMS and MTS were prepared by reacting an equimolar mixture of the two materials in water, followed by recrystallization from water: mp 126 and 167—168°C respectively.

Polymerizations were carried out in a sealed tube in the absence of light with shaking at 60°C.

Results and Discussion

Table 1 shows the results of the polymerizations of methyl methacrylate (MMA), styrene (St), and vinyl acetate (VAc) with the binary initiator system of DMA and DMS or MTS at 60°C.

From Table 1, these binary systems may be seen to have been effective as the initiator of the MMA polymerization in the presence of ethanol, but they showed rather weak activity for the St and VAc ploymerizations. A similar tendency was found in the polymerization with the DMA-benzyl chloride system.[1] From Table 1, these binary systems may be seen to show a lower activity in benzene than in ethanol, for the quaternary salts, which were formed concurrently, were insoluble in benzene and were precipitated in the polymerizing mixture.

Table 2. Polymerization of MMA with quaternary salts of DMA-DMS and of DMS-TMS at 60°C for 22 hr

Quaternary salts	Solvent	Yield %
DMA-DMS	none	1.1
DMA-DMS	C_2H_5OH**	2.3
DMA-MTS	none	1.5
DMA-MTS	C_2H_5OH**	2.1

* The concentration was kept at 2×10^{-2} mol/l.
** MMA (5 ml) and C_2H_5OH (5 ml) were used.

However, the quaternary salts of DMA with DMS and MTS showed very weak activity for the MMA polymerization in ethanol, as is shown in Table 2. This result might indicate that the initiating radical was produced from the unstable intermediate formed through the quaternary reaction.

Table 3 shows the effects of the tertiary amines on the MMA polymerization with these binary initiator systems. From this table, it can be seen

Table 3. Polymerization of MMA with a system of various amines and alkylating agents at 60°C*

[MMA]=[C_2H_5OH]=5 ml.

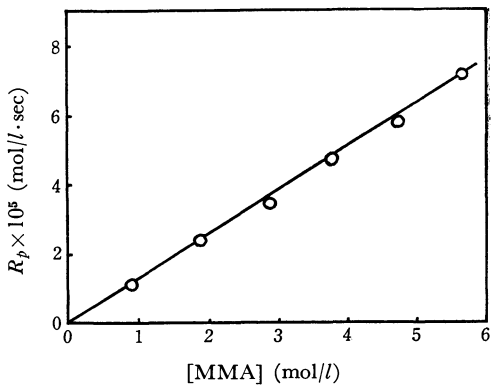

Fig. 1. Relationship between R_p and [MMA] in the polymerization of MMA with DMA/DMS at 60°C: [DMA]=[DMS]=0.2 mol/l, [C_2H_5OH]=6.87 mol/l in benzene.

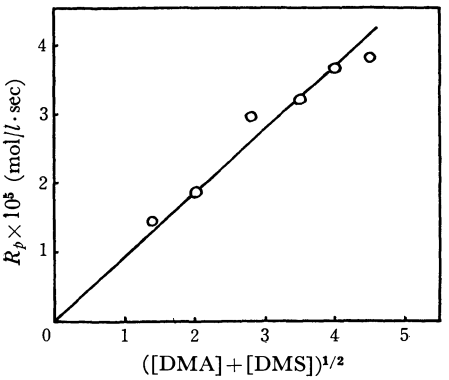

Fig. 2. Relationship between R_p and initiator concentration in the polymerization of MMA with DMA/DMS at 60°C: [MMA]=4.7 mol/l, [C_2H_5OH]=8.58 mol/l in benzene.

that, when the methyl group in DMA was replaced with the benzyl group, the initiator activity of the binary system decreased. The aliphatic tertiary amine, benzyldimethylamine, formed a very weak initiator system with DMS and MTS. This result was the same as that reported in a previous paper.[6]

The polymerization of MMA with an equimolar mixture of DMA and DMS was then investigated kinetically at 60°C. The effects of the monomer and the total initiator concentrations on the rate of polymerization (R_p) are shown in Figs. 1 and 2. From these figures, the following rate equation was obtained:

$$R_p = k([\text{DMA}] + [\text{DMA}])^{1/2}[\text{MMA}]$$

A similar rate equation was observed with the binary system of DMA and MTS at 60°C. It was also found that the copolymers obtained from the copolymerization of an equimolar mixture of MMA and St with DMA-DMS and DMA-TMS contained 49.7 and 47.7 mol% of the St unit respectively; this finding agrees with those reported with azobisisobutyronitrile as the initiator. These findings might suggest that the polymerization proceeded *via* a radical mechanism.

Kinetics of the Reaction of α-Bromonaphthalene with Carbon Monoxide Catalyzed by Nickel Carbonyl

Mikitake NAKAYAMA and Tsutomu MIZOROKI*1

Government Chemical Industrial Research Institute, Tokyo, Mita, Meguro-ku, Tokyo

(Received August 27, 1969)

In a previous paper,[1] it has been reported that the reaction rate of an aryl halide with carbon monoxide catalyzed by nickel tetracarbonyl to form the corresponding aromatic carboxylic acid is much increased by adding a sufficient amount of potassium acetate; its kinetics showed that the course of the reaction could be represented by the scheme similar to that of an oxo reaction when nickel tetracarbonyl was regenerated rapidly under high temperatures and pressures. On the other hand, nickel carbonyl complexes are more reactive than cobalt carbonyl complexes, and their stoichiometrical reactions with aryl iodides take place under a *ca.* 1 atmosphere of nitrogen and at low temperatures (<100°C), resulting in the formation of aromatic carboxylic compounds.[2] Accordingly, their catalytic carbonylation reactions must take place under milder reaction conditions as long as nickel carbonyls are regenerated smoothly from carbon monoxide. This work was undertaken in order to study the carbonylation reaction of α-bromonaphthalene under milder conditions and to discuss its kinetics.

Experimental

α-Bromonaphthalene obtained from commercial sources was purified by distillation under a vacuum. The other materials used were the same as those in the previous work.[1] The reaction was carried out under a constant temperature and at a constant pressure for a given period by using the same apparatus as that described in the previous paper.[1] The absorption rate of carbon monoxide was also determined. The autoclave used was made of titanium-molybdenum alloy (300 m*l* in vol).

The products were taken out of the autoclave by using sufficient amounts of diethyl ether and water. An aqueous sodium bicarbonate solution was added to the ether phase to separate α-naphthoic acid form α-naphthol and the other organic compunds. α-Naphthoic acid was then precipitated again by adding

a sufficient amount of an aqueous hydrochloric acid solution to the sodium α-naphthoate solution. The α-naphthoic acid had been washed well with cold water before its amount was determined by titration with an aqueous potassium hydroxide solution. The amounts of nickel(II) ion and bromide ion were determined according to the EDTA method and the Volhard method respectively.

Results

The absorption rate of carbon monoxide in the reaction of α-bromonaphthalene (0.30—0.55 mol) with carbon monoxide in the presence of water (1.60—4.00 mol), potassium acetate (0.75 mol), and nickel(II) acetate (0.0040 mol) under 100 kg/cm² at 200°C is plotted in Fig. 1. The figure shows that the absorption rate depends neither on the amount of α-bromonaphthalene nor on that of water. The effects of the amounts of nickel(II) acetate and potassium acetate on the absorption rate are shown in Figs. 2 and 3. The rate increases nearly proportionally with the increase in the amount of nickel(II) acetate, which is converted almost quantitatively into nickel tetracarbonyl under these reaction conditions, and also with the increase in potassium acetate. The effect of the

b) Obtained from the amount of Ni(II) ion present in the product.

pressure of carbon monoxide is represented in Table 1, where the other results already shown in Figs. 1, 2, and 3 are also summarized. The absorption rate is almost independent of the pressure of carbon monoxide over the range from 80 to 150 kg/cm². Its decrease under pressures lower than 60 kg/cm² is caused by the fact that these pressures are not high enough to convert nickel(II) acetate into nickel tetracarbonyl quantitatively; the decrease under pressures higher than 200 kg/cm² is probably because these high pressures of carbon monoxide prevent α-bromonaphthalene from coordination to nickel tetracarbonyl, as was discussed in the previous paper.

In summary, the reaction rate of α-bromonaphthalene with carbon monoxide to form α-naphthoic acid increases with an increase in the amounts of nickel tetracarbonyl or potassium acetate, while it depends on neither the amount of α-bromonaphthalene nor on that of water, nor on the partial pressure of carbon monoxide.

Discussion

The course of the reaction with α-bromonaphthalene can be explained by the scheme proposed for the reaction with bromobenzene:[1]

$$\text{Ary-Br} + Ni(CO)_4 \rightleftarrows (\text{Ary-Br})Ni(CO)_3 + CO \quad (1)$$

$$(\text{Ary-Br})Ni(CO)_3 + H_2O \rightarrow \text{Ary-COOH} + (HBr)Ni(CO)_2 \quad (2)$$

$$(HBr)Ni(CO)_2 + \text{AcOK} \rightarrow Ni(CO)_2 + \text{AcOH} + \text{KBr} \quad (3)$$

$$Ni(CO)_2 + 2CO \rightarrow Ni(CO)_4 \quad (4)$$

(Ary-Br=aryl bromide)

Under pressures of carbon monoxide high enough to regenerate nickel tetracarbonyl quickly, Eq. (2) became the rate-determining step of the carbonylation of bromobenzene and its kinetics could be expressed by Eq. (5), where k and K are the rate constant of Eq. (2) and the equilibrium constant of Eq. (1) respectively. Preliminary experiments showed that the carbonylation rate of α-bromonaphthalene could also be expressed by the same equation under pressures higher than 200 kg/cm², while its kinetics under lower pressures of cabon monoxide is very different from Eq. (5) and is, rather, given by Eq. (6):

$$r = \frac{d[C_6H_5COOH]}{dt} = k \cdot K \frac{[Ni(CO)_4][C_6H_5Br][H_2O]}{p_{CO}} \quad (5)$$

$$r = d[\alpha\text{-}C_{10}H_7COOH]/dt \propto [Ni(CO)_4][AcOK] \quad (6)$$

This finding can, however, be understood on the basis of the scheme described above. Lower pressures of carbon monoxide should be favorable for the equilibrium of Eq. (1) to incline much toward the right, and the rate of Eq. (2) must be large enough because α-bromonaphthalene is usually more reactive than bromobenzene, as has been reported in the cases of other organic reactions. The rate of the carbonylation is, accordingly, determined by that of regeneration of nickel tetracarbonyl by Eqs. (3) and (4); we thus find that the rate of the carbonylation is independent of the amounts of α-bromonaphthalene and water. The fact that the rate of carbonylation is also independent of the partial pressure of carbon monoxide, as described in Table 1, suggests that the rate of Eq. (4) is much faster than Eq. (3) and that the true nickel catalyst is nickel tricarbonyl rather than nickel tetracarbonyl.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 572—573 (1970)

ESR Spectra of Irradiated Nitroethane and Polynitroethylene

Kozo TSUJI,*1 Koichiro HAYASHI*2 and Seizo OKAMURA

Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received September 9, 1969)

In a previous paper[1] we have reported that the NO_2·, $CH_2{=}\dot{C}NO_2$, nitroethylene anion radical and some other species showing a very broad ESR spectrum were observed after the γ irradiation of nitroethylene at −196°C. It has also been reported[2] that the ESR spectra of NO_2· and ·CH_3 were observed when nitromethane was irradiated with γ rays at −196°C and that ·CH_2NO_2 was produced after warming the sample to −143°C. Nitrogen dioxide-free radicals seem to be obtained after the radiolysis of every organic compound containing NO_2 groups, while counter radicals are not always detected by ESR spectroscopy.

In this investigation, nitroethane and polynitroethylene were irradiated with electron beams from a Van de Graaff accelerator and the ESR spectra were recorded in order to identify the free radicals produced from these compounds. The change in the ESR spectra with the increase in the temperature was also examined.

Experimental

Polynitroethylene was obtained by radiation-induced polymerization.[3] For nitroethane, we used a commercial sample from the Nakarai Chemical Co., Ltd., without further purification. The experimental techniques have already been described.[1]

Results and Discussion

Nitroethane gave the ESR spectrum shown in Fig. 1a after irradiation at −196°C. This spectrum did not change with the subsequent visible light irradiation. The asymmetric spectrum characteristic of the NO_2· radical can easily be distinguished. Some shoulders of the spectrum may indicate the presence of ethyl radicals.[4] The hyperfine coupling constants and g values of the NO_2· radical are tabulated in Table 1. These values are almost identical with those previously reported.[2,5-9] NO_2· radicals decayed out at about

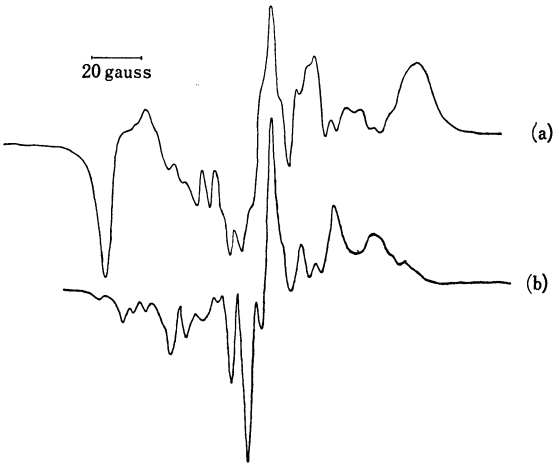

Fig. 1. ESR Spectra of irradiated nitroethane.
a) immediately after irradiation at −196°C 5×10^5 rad $G=100$
b) at −123°C $G=200$

−123°C, and there remained the spectrum shown in Fig. 1b, which may be identified as due to the $CH_3\dot{C}HNO_2$ radical. The coupling constant of the four protons is about 25 gauss, and that of nitrogen is about 7 gauss. These values should be compared with the corresponding values $a_H=20\pm1$ gauss and $a_H=6\pm1$ gauss, for the $\cdot CH_2NO_2$ radical.[2] $CH_3\dot{C}HNO_2$ radicals seem to be produced through hydrogen abstraction by ethyl radicals, since the ESR spectrum due to the $CH_3\dot{C}HNO_2$ radical, which was not observed at −196°C, appeared after the ethyl radicals had decayed out. The same mechanism has been suggested for $\cdot CH_2NO_2$ formation.[2] The spectrum due to $CH_3\dot{C}HNO_2$ radicals decayed out at about −103°C.

From irradiated polynitroethylene, the ESR spectrum shown in Fig. 2a was obtained at −196°C. A spectrum due to the $NO_2\cdot$ radical was clearly observed. The hyperfine coupling constants and g values are shown in Table 1. The $NO_2\cdot$ radical in polynitroethylene was relatively stable at −78°C, but it decayed out after treatment at 0°C for

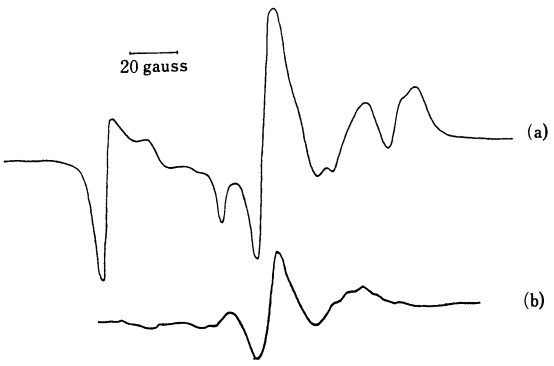

Fig. 2. ESR spectra of irradiated polynitroethylene at −196°C.
a) immediately after irradiation 5×10^5 rad $G=100$
b) after treatment at 0°C for 30 min. $G=630$

30 min. There remained the ESR spectrum shown in Fig. 2(b), which seems to be a slightly asymmetric, five-line spectrum, and this spectrum tentatively attributed to free radicals, $-CH_2-\dot{C}(NO_2)-CH_2-$. For this sample, however, no definite indication of the presence of the $-CH_2-\dot{C}H-CH_2-$ radicals was obtained at −196°C. Therefore, hydrogen abstraction by the $-CH_2-\dot{C}H-CH_2-$ radical at −196°C may possibly cause the formation of $-CH_2-\dot{C}(NO_2)-CH_2-$ radicals. The observation of some shoulders which can be attributed to the later free radicals supports this mechanism.

The authors would like to express their thanks to Professor I. Sakurada for providing us with the opportunity to carry out this investigation at the Osaka Laboratories of the Japanese Association for Radiation Research on Polymers, which is now known as the Osaka Laboratories for Radiation Chemistry, Japan Atomic Energy Research Institute, and to Mr. H. Yamaoka for his kindness in giving us polynitroethylene.

SHORT COMMUNICATIONS

Complete Resolution of the Racemic Trisethylenediaminecobalt(III) Complex into Its Optical Antipodes by Means of Electrophoresis

Hayami YONEDA and Takao MIURA

Department of Chemistry, Wakayama University, Masago-cho, Wakayama

(Received December 4, 1969)

The racemic $[Co\ en_3]^{3+}$ complex can be resolved into its optical antipodes by way of the diastereomers, *d*-$[Co\ en_3]Cl(d\text{-tartrate})\cdot 5H_2O$, separated as crystals, and *l*-$[Co\ en_3]Cl(d\text{-tartrate})$, remaining in solution. This suggests that the tendency of the *d* and *l* forms of the $[Co\ en_3]^{3+}$ complex cation towards ion-pair formation with *d*-tartrate anion is different. In fact, Ogino and Saito[1] showed that the association constant of the *d*-$[Co\ en_3]^{3+}$-*d*-tartrate system differs from that of the *l*-$[Co\ en_3]^{3+}$-*d*-tartrate system by analyzing the increase in the optical density of the charge-transfer band. On the other hand, Yamatera and Fujita[2] measured the rates of amino-hydrogen deuterium exchange for the *d*- and *l*-$[Co\ en_3]^{3+}$ complex in the presence of *d*-tartrate and found that the rate constant was appreciably smaller for *d*-$[Co\ en_3]^{3+}$ than for the *l*-isomer. This also implies that there is some stereoselective interaction in the solution between the isomers of the $[Co\ en_3]^{3+}$ complex cation and the *d*-tartrate anion. Thus, we can expect the complete resolution of the racemic $[Co\ en_3]^{3+}$ complex into its optical antipodes under appropriate conditions by means of electrophoresis.

We would like to report a successful result obtained by paper electrophoresis. Samples tested were *d,l*-$[Co\ en_3]Cl_3\cdot 3H_2O$, *d*-$[Co\ en_3]Cl(d\text{-tratrate})\cdot 5H_2O$ and *l*-$[Co\ en_3]Cl(l\text{-tartrate})\cdot 5H_2O$. Sodium *d*-tartrate was used as a main component of a background electrolyte solution. For electrophoresis a migration apparatus with multicompartment cells was used so that ten samples could be run at one time. Samples were run for 2.5 hr under a potential gradient 250 V/34 cm, keeping the temperature of the migrating box at 25°C. The spot of the sample was easily identified by the orange yellow color of the complex. By spraying a sodium sulfide solution we could visualize the spot more clearly.

When only sodium *d*-tartrate was used in a background electrolyte, the racemic form of the complex appeared always in one spot, irrespective of the concentration of the background solution. This means that resolution by electrophoresis was not successful. However, when aluminum chloride was added to the sodium *d*-tartrate solution, the racemic form was completely separated into two spots, as can be seen in Table 1. This should be taken as a resolution, because the sample of the *d* form showed only one spot just at the same position as the upper spot of the racemic form, and the *l* form showed only one spot corresponding to the lower spot of the racemic form.

TABLE 1. MIGRATION DISTANCE OF THE $[Co\ en_3]^{3+}$ COMPLEX IN VARIOUS BACKGROUND ELECTROLYTE SOLUTIONS

Sample	Background electrolytes		
	0.18M Na_2-*d*-tartrate	0.18M Na_2-*d*-tartrate 0.12M $AlCl_3$	
d,l-$[Co\ en_3]Cl_3$	41 mm	12 mm	59 mm
d-$[Co\ en_3]Cl$-(*d*-tartrate)	41 mm		59 mm
l-$[Co\ en_3]Cl$-(*l*-tartrate)	41 mm	12 mm	

Migration time, 2.5 hr
Potential gradient, 250 V/34 cm

A detailed discussion of the separation mechanism will be reported elswhere. Extension of our new method of resolution to a variety of racemic compounds is in progress.

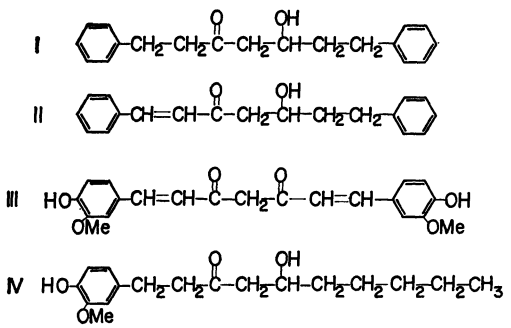
A New Ketol, 1,7-Diphenyl-5-hydroxy-3-heptanone, and *trans*-Stilbene from *Alnus firma* Sieb. et Zucc. (BETULACEAE)

Yoshinori ASAKAWA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received October 23, 1969)

I wish to report at this time the occurrence in *A. firma* Sieb. et Zucc. of a new ketol and of *trans*-stilbene, and to outline the biosynthetic pathway of closely-related compounds, such as cinnamic acid, β-phenylethyl cinnamate, pinostrobin (5-hydroxy-7-methoxy-flavanone), and alpinetin (5-methoxy-7-hydroxy-flavanone), which exist together with II and the new ketol (I).



Dihydroyashabushiketol (I). 1,7-Diphenyl-5-hydroxy-3-heptanone. The high-resolution mass-spectral measurement of I isolated from the benzene extract clearly established its molecular formula as $C_{19}H_{22}O_2$. The constituent (I), M^+ 282, mp 36.0—37.0°C, gives positive coloration with 2,4-DNP and with alkali-alkyl xanthate, and is shown by its spectral properties to possess a simple ketone group ($\lambda\lambda_{max}^{EtOH}$: 285 mμ; 1706 cm^{-1}), a monosubstituted benzene ring (3060, 3020, 1600, 1490, 1450, 745 and 698 cm^{-1}), a non-conjugated benzene ring (248 mμ, 254, 261 and 268), active methylene (1409 cm^{-1}), and a hydroxyl group (3440 cm^{-1}). The NMR spectrum (60 MHz) of I in $CDCl_3$ indicates signals at 7.22 ppm (s, 10H, two monosubstituted benzene-ring protons), 4.07 ppm (quintet, 1H, J=7 Hz, $-CH_2-\underline{C}HOH-CH_2-$), 3.10 ppm (s, 1H, O$\underline{H}$), 2.80 ppm (m, 4H, $-\underline{C}H_2-CO-\underline{C}H_2-CHOH-$), 2.55 ppm (t, 4H, J=7 Hz, two $Ar-\underline{C}H_2-CH_2-$), and 1.66 ppm (m, 2H, $-CHOH-\underline{C}H_2-CH_2-$). The mass spectrum shows the parent ion at *m/e* 282, the base peak at *m/e* 91 $(C_7H_7)^+$, and other strong fragment ions at *m/e* 264 (M-18, m*=247.1), *m/e* 177 $(Ar-CH_2-CH_2-CO-CH_2-CH=\overset{+}{O}H)$, *m/e* 159 $(Ar-CH_2-CH_2-CO-CH=CH)^+$, *m/e* 148 $(Ar-CH_2-CH_2-CO-CH_3)^+$, *m/e* 133 $(Ar-CH_2-CH_2-CO)^+$, *m/e* 105 $(Ar-CH_2-CH_2)^+$, *m/e* 104 $(Ar-CH=CH_2)^+$, and *m/e* 43 $(CH_3-CO)^+$. The presence of *m/e* 39, 51, 65, and 77 suggests that I is a benzene derivative. These results have shown the structure of this ketol to be 1,7-diphenyl-5-hydroxy-3-heptanone. Furthermore, this was confirmed by the fact that the TLC R_f value, the mp, and the IR spectrum of I were all completely indentical with those of the hydrogenated product of yashabushiketol (II). In connection with a previous report,[1] I wish to propose the name "dihydroyashabushiketol" for this compound. It is very interesting, from the standpoint of biochemistry, that the ketols (I) and (II) possess the same skeleton as the curcumin (III) isolated from *Curcuma longa* (ZINGIBERACEAE)[2] and are partially similar to the structure of gingeron (IV) isolated from *Zingiber officinalis* Rosc. (ZINGIBERACEAE).[3]

***trans*-Stilbene (V).** The colorless, leaflet crystals (M^+ 180, mp 120.0—121.0°C, R_f=0.75) isolated from the hydrocarbon portion was confirmed to be *trans*-stilbene by a study of the spectral data (UV,[4] IR, NMR, and mass spectra[5]).

It has been reported that oxygen-containing stilbene derivatives are widely distributed and coexist with flavones and flavanones in the family of Pinaceae.[6] According to the shikimate-acetate biosynthesis pathway, dihydroyashabushiketol (I) and yashabushiketol (II) would be formed by the condensation of two molecules of cinnamic acid and a molecule of acetic acid. *trans*-Stilbene, flavanones (pinostrobin and alpinetin), and β-phenylethyl cinnamate would also result from a combination of acetic acid and shikimic acid pathways. It is very interesting, from the biochemical viewpoint, that free *trans*-stilbene and ketol I, ketol II, flavanones (pinostrobin and alpinetin), β-phenylethyl cinnamate, and cinnamic acid have been found to occur together in *A. firma* Sieb. et Zucc.

The Yields of $^{133}Cs(\gamma, xn)$ and $^{133}Cs(\gamma, 2pxn)$ Reactions with 150, 200 and 250 MeV Bremsstrahlung

Toyoaki KATO, Hui-Tuh TSAI and Yoshinaga OKA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received November 11, 1969)

The yields of the reactions (γ, n), $(\gamma, 4n)$, $(\gamma, 6n)$, $(\gamma, 2p)$, $(\gamma, 2pn)$, $(\gamma, 2p5n)$, $(\gamma, 2p7n)$, $(\gamma, 2p8n)$, $(\gamma, 2p10n)$ and $(\gamma, 2p11n)$ in ^{133}Cs have been determined by the residual activity method in order to investigate the reactivity of high-energy bremsstrahlung photons with nuclei in heavy mass region.

Cesium chloride targets were irradiated by bremsstrahlung with maximum energies of 150, 200 and 250 MeV generated by the linear electron accelerator of Tohoku University. The radioactivity measurements were carried out on both the cesium and iodine fractions after radiochemical separation by using a lithium-drifted germanium detector with a sensitive volume of 36 cc coupled to a TMC 1024-channel pulse-height analyzer.

Of the iodine nuclides measured, ^{123}I, ^{121}I and ^{120}I can be formed through decays of the corresponding xenon nuclides generated by $^{133}Cs(\gamma, pxn)$ reactions. In order to reduce such contributions, all irradiations were terminated in 1 hr, and separation was performed very rapidly.

The yield was calculated as the initial disintegration rate of a given radioactive cesium or iodine product. A corresponding saturation rate was computed and expressed relative to that of the $^{133}Cs(\gamma, n)^{132}Cs$ processes. The yield thus obtained are plotted against the difference in mass between the target and product nuclei at each excitation energy in Fig. 1. It can be seen that (1) the yield of cesium nuclides decreases almost exponentially with the number of emitted neutrons, and (2) the more deficient the iodine nuclides in neutron number, the higher their yields, and a yield maximum is found around mass number 123.

The mass number of the center of the stable valley of the nuclear energy surface for iodine ($Z=53$) can be estimated to be 125.[1] Thus the maximum obtained stays at 2 mass unit to the neutron-deficient side. The yield distribution curve shifts 1.5 mass units more towards the neutron-deficient side of the stability line than the photonuclear yield surface in the copper-to-arsenic mass region characterized by Halpern *et al.*[2] The high-energy nuclear reaction mechanism including the initial nucleon cascades and subsequent evaporation steps will be responsible for this behavior. The longer evaporation path will displace the products towards the neutron-deficient side of stability, and thus the fractional yield of heavier iodine nuclides will decrease.

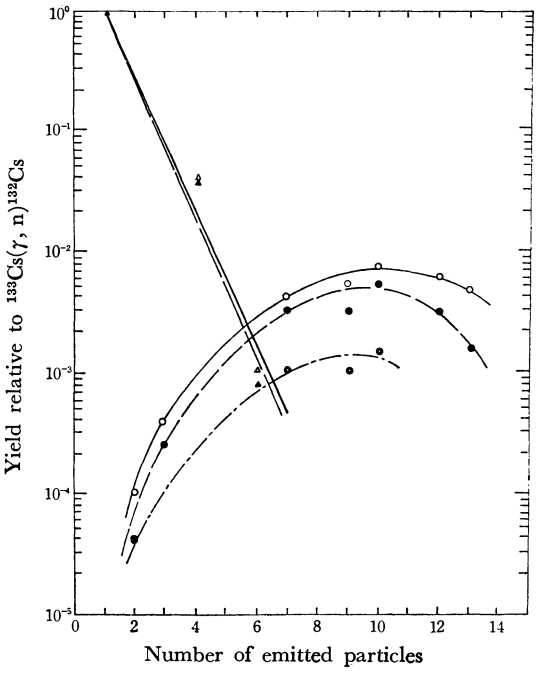

Fig. 1. The relation between yields and the number of emitted particles
△: (γ,xn), 250 MeV ○: $(\gamma,2pxn)$, 250 MeV
▲: (γ,xn), 200 MeV ●: $(\gamma,2pxn)$, 200 MeV
⊙: $(\gamma,2pxn)$, 150 MeV

The exponential decrease in the (γ, xn) reaction yield *versus* the difference in mass between the target and product nuclei has been shown experimentally by photospallation work.[3-5] The yield for the (γ, n) reaction of ^{133}Cs is much greater than that expected from yield surface considerations. This arises from the large contribution of photons in the giant resonance energy region to the production rate of ^{132}Cs.

The Crystal Structure of Nitrato-bis(2,2′-bipyridine)copper(II) Nitrate Monohydrate $[Cu(NO_3)(bipy)_2]NO_3 \cdot H_2O$

Hisayoshi NAKAI, Shun'ichiro OOI and Hisao KUROYA

Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received November 27, 1969)

It is well known that the reaction of Cu(II) with bipyridine gives three different products — the 1 : 1-, 1 : 2-, and 1 : 3-complexes — depending on the molar ratio of metal to ligand. Of these three, the structure of the 1 : 2-complex can be guessed to be *trans*-planar, as is shown in Fig. 1.

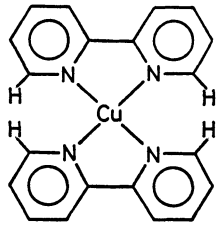

Fig. 1

However, the molecular model indicates that there must be a remarkable steric interference between the hydrogen atoms linked to the 3- and 3′-carbon atoms of the two bipyridine molecules. On the basis of his spectroscopic study, Jørgensen suggested that the complex has the *cis* configuration.[1] In order to elucidate the structure of the complex in detail, a single-crystal X-ray analysis has been carried out on $Cu(bipy)_2(NO_3)_2 \cdot H_2O$.

The blue crystals were prepared by Jaeger's method.[2] The unit cell has these dimensions:

$a=7.53$ $b=10.05$ $c=15.65$ Å
$\alpha=111.8°$ $\beta=91.0°$ $\gamma=90.5°$

The space group is $P\bar{1}$, with $Z=2$. The intensity data of $0kl$—$4kl$, $h0l$, $hk0$ were recorded on Weissenberg photographs ($CuK\alpha$ radiation) and were measured visually, the usual corrections being applied. The structure was solved by Patterson and Fourier techniques and refined by the block-diagonal least-squares method with isopropic temperature factors. The *R*-factor was 0.13 for 3087 independent reflections.

The crystal is essentially ionic and is composed of $[Cu(NO_3)(bipy)_2]^+$, NO_3^-, and H_2O. A schematic drawing of the complex ion is shown in Fig. 2. Four nitrogen atoms of the two bipyridine molecules and one of the oxygen atom of the coordinated nitrate ion form a distorted trigonal bipyramid around the copper atom. Cu, O_1, N_1,

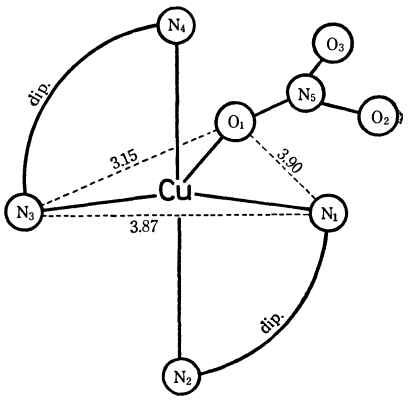

Fig. 2.

and N_3 are equatorially coplanar within the maximum deviation of 0.003 Å, making a dihedral angle of $\sim 10°$ with the O_1—$N_5\langle^{O_3}_{O_2}$ plane; N_5 and O_2 are distant by 0.20 Å, and O_3, by 0.39 Å, from the equatorial plane. The bipyridine molecules are necessarily in the *cis*-planar configuration, and their molecular dimensions are in good agreement with those found in the crystal of bipyridine.[3] The bond lengths and angles are listed in Table 1.

TABLE 1.

Bond length (Å)	Bond angle (degree)
$Cu-N_1=2.04$	$\angle N_4-Cu-N_1=99.3$
	$\angle N_2-Cu-O_1=85.9$
$Cu-N_2=2.01$	$\angle N_4-Cu-N_3=81.8$
	$\angle N_1-Cu-O_1=127.7$
$Cu-N_3=2.07$	$\angle N_4-Cu-O_1=85.4$
	$\angle N_3-Cu-O_1=91.9$
$Cu-N_4=1.99$	$\angle N_2-Cu-N_1=82.4$
	$\angle N_3-Cu-N_1=140.4$
$Cu-O_1=2.30$	$\angle N_2-Cu-N_3=103.3$

In the three-dimensional Fourier synthesis phased on the atomic coordinates of the complex ion, the electron density of the uncoordinated nitrate ion is rather more diffuse than that of the coordinated nitrate ion. The average temperature factor of the four atoms is 15 Å^2 in the former and 4.5 Å^2 in the latter. This fact suggests that the uncoordinated nitrate ion must be loosely bound in the crystal lattice.

The Phase Transitions of the Anion-radical Salts Containing Mixed Cations; $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$, $(0 \leq x \leq 1)$

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo, Hokkaido

(Recieved December 6, 1969)

Much attention has been paid to the solid anion-radical salts of 7,7,8,8-tetracyanoquinodimethane (TCNQ) because of their prominent electrical, magnetic, and optical properties.[1-3] In the course of our study of these salts, we found that the ESR absorption intensity of the salt of methyltriphenylphosphonium, $[(C_6H_5)_3PCH_3]^+(TCNQ)_2^-$, increased abruptly at 40°C when the temperature was raised.[4] The discontinuity was also found in the electrical conductivity at that temperature.[4] This anomaly was ascribed to the phase transition of the crystal, as evidenced by the differential thermal analysis.[5] The methyltriphenylarsonium salt, $[(C_6H_5)_3AsCH_3]^+(TCNQ)_2^-$, exhibits electronic properties almost identical with those of the phosphonium salt; on the other hand, the arsonium salt is known to have no such anomaly. It was suggested that one could prepare the salts containing mixed cations, which may be expressed as $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$, $(0 \leq x \leq 1)$.[6] Therefore, it seemed that it would be interesting to investigate the effect of the composition upon the phase-transition phenomenon. The present investigation was performed by means of a differential scanning calorimeter (DSC).

The six salts with $x=0.00$, 0.20, 0.40, 0.60. 0.80, and 1.00 were prepared according to the method of Melby *et al.*[6] The DSC measurements were made by using powdered α-alumina as a standard substance, with the temperature raised at the rate of 3.0°C/min.

All the salts except for that with $x=1.00$ showed endothermic phase transitions when the temperature was raised. These phase transitions were found to be reversible. The relation of the transition temperature, T_c, to the composition parameter, x, is given in Fig. 1. In DSC measurements, the

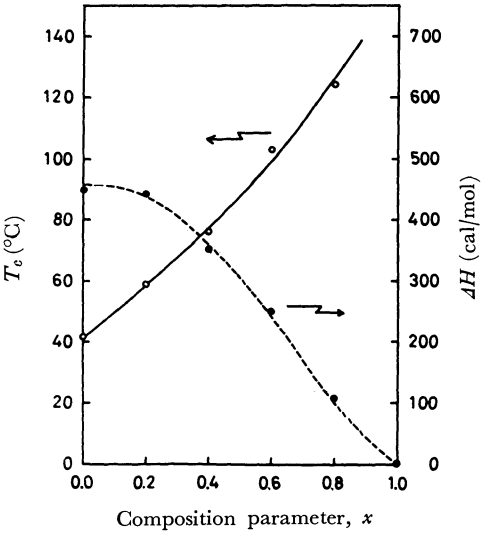

Fig. 1. The relations of the transition temperature, T_c, and of the magnitude of the heat, ΔH, associated with the phase transition, to the composition parameter, x, in $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$, $(0 \leq x \leq 1)$.

peak area of the signal line should be proportional to the magnitude of the heat, ΔH, associated with the phase transition. Therefore, in order to determine the heats associated with the phase transitions of these salts, the area of the signal line of $[(C_6H_5)_3PCH_3]_{1-x}^+[(C_6H_5)_3AsCH_3]_x^+(TCNQ)_2^-$ was compared with that of hexachloroethane or hexamethylbenzene. The phase transition of hexachloroethane is known to take place at 318.1°K with $\Delta H=0.613$ kcal/mol and at 344.4°K with $\Delta H=1.965$ kcal/mol, and that of hexamethylbenzene, at 384.1°K with $\Delta H=0.42$ kcal/mol.[7] The magnitudes of ΔH *versus* x obtained with the above six TCNQ salts are also illustrated in Fig. 1.

It is noteworthy that T_c increases, and the value of ΔH decreases, monotonously with an increase in the value of x, and that the phase transition disappears with $x=1.00$.

Asymmetric Hydrogenation of C=O Double Bond with Modified Raney Nickel. XIV

Yoshiharu IZUMI and Toshio NINOMIYA

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received December 8, 1969)

In the course of the studies of the asymmetric hydrogenation reaction, many kinds of optically-active amino and hydroxy acids have been used as the modifying reagents of Raney nickel catalysts.[1] It has been found that two functional groups, carboxyl and amino or hydroxy groups, are essential in a modifying reagent in order to produce a strong asymmetric activity of the catalyst; that is, the derivative formation of these functional groups of modifying reagents, for example, the acylation of the amino and hydroxy groups or the esterification of carboxyl groups, gives a catalyst which has a lower asymmetric activity than the catalyst modified with the original amino or hydroxy acids.[2] This fact and the physical and physicochemical evidence suggest that the carboxyl and amino or hydroxy groups of the modifiying reagents take part in the binding to the catalyst by chelation, so it seems that these functional groups are indispensable to the adsorption of the modifying reagents on the catalyst surface.

When the metal amino acid chelates are used as the modifiying reagents, all the amino acid molecules on the catalyst surface can adsorb as nickel chelates, so the metal amino acid chelates are expected to have special properties as modifying reagents.

In the present experiment the abilities of the metal chelates of several optically-active amino acids used as modifying reagents were tested. These investigations were carried out with catalysts modified with aqueous or methanolic solutions; the results are summarized in Table 1.

Three points are noticeable in Table 1. The first is the fact that the asymmetric activities of the catalysts modified with the metal chelates of the optically-active amino acids are rather higher than those modified with their original amino acids. The second is the fact that the asymmetric activity depends on the solvent used in the modification of the catalyst; that is, the aqueous solution and the methanolic solution of $[Ni(L\text{-}Ala)_2]\cdot 4H_2O$ give an opposite asymmetric direction to the catalyst. The third is the finding that the modification with the aqueous solution of $[Cu(L\text{-}Ala)_2]$ gives the catalyst with an asymmetric direction opposite to that of the catalyst modified with the aqueous solution of $[Ni(L\text{-}Ala)_2]\cdot 4H_2O$.

The detalis of this investigation will be published after the descriptions of our physical and physicochemical investigations of the adsorption of amino acids on the nickel surface.

TABLE 1. ASYMMETRIC ACTIVITIES OF THE CATALYSTS MODIFIED WITH METAL CHELATES

Modifying solution	$[\alpha]_D^{20}$ of methyl 3-hydroxybutyrate
$[Ni(L\text{-}Val)_2]\cdot 2H_2O$ in MeOH (1% soln.)	−4.21
$[Ni(L\text{-}Ala)_2]\cdot 4H_2O$ in MeOH (1% soln.)	−0.18
$[Ni(L\text{-}Ala)_2]\cdot 4H_2O$ in H_2O (1% soln.)	+0.86
$[Cu(L\text{-}Ala)_2]$ in H_2O (1% soln.)	−0.50
$[Ni(L\text{-}Glu)]\cdot 2H_2O$ in H_2O (1% soln.)	−4.00
L-Val in H_2O (2% soln.)	−2.31*1
L-Ala in H_2O (2% soln.)	+1.08*1
L-Glu in H_2O (2% soln.)	−3.46*2,*3

Substrate: methyl acetoacetate 0.15 mol
Hydrogenation temperature: 60°C
Modifying temperature: 0°C

A Novel Type of Methyl Radical Trapped in Porous Vycor Glass at 77°K

Norio SHIMAMOTO, Yuzaburo FUJITA and Takao KWAN

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received December 11, 1969)

There has been interest in the study of methyl radicals trapped in various matrices.[1] As has been reported previously, the CH_3 radical photoproduced from methyl iodide in the porous Vycor glass (V. G.) (Corning, # 7930) was very stable even at room temperature.[1a] According to its extraordinary stability over a wide range of temperature, Fujimoto *et al.*[1c] have been able to study the temperature dependence of the hyperfine coupling (hfc) constant of the methyl radical stabilized on the porous V. G. surface.

Recently, in the course of our studies of the photolysis of adsorbed species on the porous V. G. surface at 77°K, we observed a novel type of methyl radical produced by the photolysis of methane; this radical was stable at 77°K and has an abnormally small hfc constant.

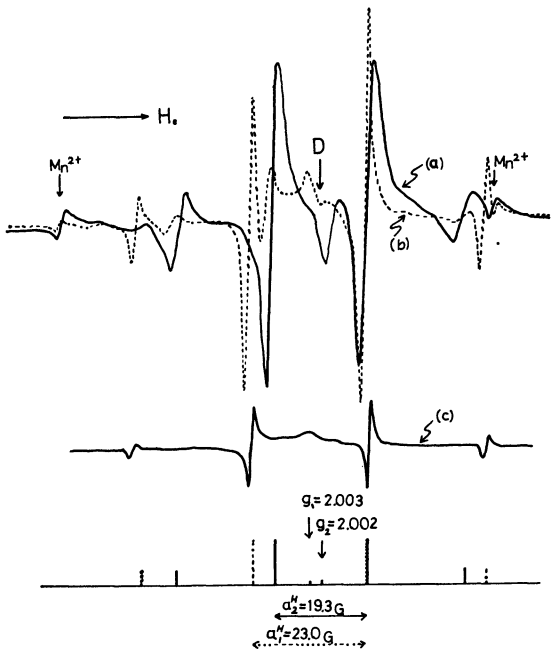

Fig. 1. ESR signals from methane photolysis at 77°K.
(a), Pure methane; (b), In the presence of iodine; (c), After slight warming of (b); Mn^{2+}, hfs of the standard; D, Defect signal

A porous V. G. rod (4 mmϕ, 20 mm in length) was preheated in an oxygen atomosphere at 600°C to remove any adsorbed organic substances. After repeating the pretreatment of the V. G. rod in a quartz sample tube, less than a monolayer amount of purified methane (usually 1/10 of a monolayer) was introduced into the evacuated sample tube at room temperature. Then the sample tube was cooled gradually from room temperature to the temperature of liquid nitrogen in order to secure a homogeneous adsorption of methane on the surface of the porous glass. Irradiation was then carried out at 77°K with the light of a low-pressure mercury lamp (Ushio Electric Co., Ltd., UL 200W). About five minutes' irradiation was enough to observe a methyl-radical signal with a good S/N ratio.

The observed ESR constants of the methyl radical were as follows:

$$|a^H| = 19.3 \pm 0.3 \text{ G}, \quad g = 2.002_3 \pm 0.0003.$$

A linewidth alternation in the proton hf lines was observed, as in the case of the CH_3 obtained from methyl iodide. However, unlike the normal radical from methyl iodide, this methyl radical showed an inverse linewidth alternation; *i. e.*, the higher field lines were broader (Figs. 1a and 1b). The thermal stability was also different, and the abnormal CH_3 decayed rapidly on slight warming, indicating a reactive character. However, this radical was efficiently trapped on the surface and did not decay, at least at 77°K.

When iodine was present during the photolysis of methane, the main signal was a normal one (Fig. 1b). This shows that iodine plays an important role in the stabilization of the normal methyl radical.

The fact that the new type of the methyl radical has a *g*-value close to that of the free electron and an extraordinary small hfc constant compared to that of the planar methyl radical ($a^H = -23$ G, $g = 2.003$) probably indicates a nonplanar (pyramidal) structure, in which an unpaired electron is in an orbital with a larger *s*-character.

The nonplanar structure may be stabilized by the strong interaction between methyl radical and the surface of porous V. G., resulting in the large linewidth. The order of the rotational correlation time of this radical was estimated to be $\tau_c = 10^{-7}$ sec. This value can be compared with that of $\tau_c = 10^{-8}$ sec of the normal methyl radical obtained from methyl iodide.

A detailed analysis is now in progress.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 581—589 (1970)

A Chemical Study on Some Archaeological Samples from Iran and Afghanistan[1)]

Teruko MUROGA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received September 28, 1968)

From archaeological interest, chemical analyses were performed on samples which had been collected from Iran and Afghanistan by the Kyoto University Scientific Mission to the Iranian Plateau and Hindukush. As samples were used more than one hundred pieces of glass and glazed material, and two slag-like objects. By analyzing the glass and glazes for major components, it was found that all were made of soda-lime glass except for a fragment of a glaze of tri-colored pottery collected at Kerman, Iran. It is noteworthy that this fragment of tri-colored pottery had a lead content similar to that of Chinese glazes, while Western glasses are rarely found to contain so much lead. Among the minor components detected, detailed consideration was given to the color origins. Although iron and copper were commonly found in blue-colored samples, the origin of the color of the tile from a mosque at Tabriz was confirmed to be cobalt. Investigations of slag-like objects collected from Tepe Sialk have revealed the possibility that these objects are slags from copper smelting. Studies of the silvery effect or of the weathering observed on the surface of glass and glazes of archaeological importance were carried out by semi-quantitative spectrochemical analysis.

Introduction

Until recently, most studies which have been made by historians and archaeologists upon archaeological samples have concentrated on the objects themselves and not on their chemical compositions. It has been and should be recognized, however, that detailed examinations of archaeological materials by physical and chemical methods can bring quite fruitful results in the field of archaeology. Indeed, in discussing age and in estimating the degree of technological accomplishment, furthermore, as part of understanding cultural exchange between the East and the West, archaeology must not neglect the data from the probes of natural science.

In a previous paper,[2)] some results of studies on Chinese and Japanese samples were reported. The author's intention in these works is to contribute to the histories of science and technology through chemical analyses of archaeological samples. The present paper will deal with the results of the chemical analyses of more than one hundred samples of glass, glazes, and slag-like objects, all of which were brought from Iran, Afghanistan, and Pakistan by the Kyoto University Scientific Mission to the Iranian Plateau and Hindukush.

Western Asia is located in a historically-important position through which the interchange of two cultures, the Eastern and the Western, has taken place since most ancient times. Nevertheless, few scientific investigations have been undertaken in that area. Therefore, the project of the Mission was to make a composite study of Western Asia which could serve as one preliminary step to a really thorough plunge into the archaeology of that area. As usual, the collection of these kinds of samples can be neither as systematic nor as complete as one would wish, because the chances of getting samples by excavation can not be foreseen. Moreover, a sample itself is sometimes too valuable for even a part of it to be destroyed; it just has to be kept untouched.

Although the present work was made under these restrictions, care has been taken in choosing samples so that characteristic features of samples from era to era and from area to area may be obtained. The samples chosen here were more than one hundred pieces of glass and glazes and two slag-like objects. For most of the glass and glazes, the major and minor components were qualitatively identified spectrochemically, though for several samples they were determined quantitatively. The main interest in the major components was in finding out whether they were soda-lime glass or lead glass; most Western glass belongs to the former group, while the latter has been manufactured in

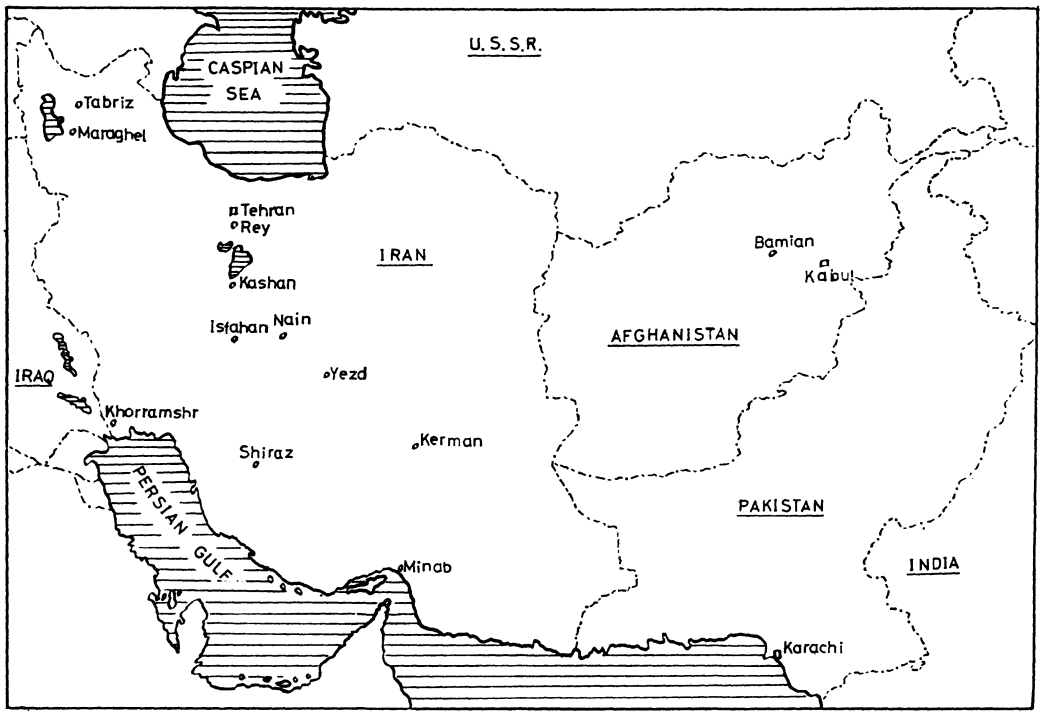

Fig. 1. A map of sampling stations.

China since the ancient period.[3] For the minor components, attention was paid to color origins, which may offer clues to the origin and to the exchange of the techniques of glassmaking. The two slag-like samples, which were picked up at the ruins of a smelting furnace, were subjected to the quantitative determination of their major components. If they were indeed slags of copper smelting, the quality of the techniques of extracting copper from the ore could be estimated from them. The last subject was the silvery effect or weathering which is frequently observed on the surface of glass or glazes of archaeological importance. Semi-quantitative analysis showed a continuous change in composition from the surface to the inner part of the sample.

Experimental

Semi-quantitative spectrochemical analyses were performed on the archaeological samples by using the internal standard (Ge, Pt) method.

The quantitative analytical methods used especially for the glass and glazes were described in the previous report.[4] In brief, the glass and glazes were brought into solution by carbonate fusion and then treated with hydrochloric acid. The analytical methods used subsequently are given in Table 1. In some cases, X-ray micro-probe analysis was performed in order to examine the distribution of elements in a non-destructive way.

expectation, specimens containing tin were quite rare in these samples. Only four samples contained tin; the results on these sample, all glass bracelets from Minab and Share-Bonn, were shown in Table 2. It should be emphasized here that the other glass samples from the same area, Minab, were found to be soda-lime glass. This fact is in clear contrast with the case in China, where most of the glass manufactured in ancient periods was lead glass. As Minab was a famous port in old Hormus, a trading center between East and West, much Chinese porcelain was imported there.[5,6] Hormus is said to have prospered between the thirteenth and the fifteenth centuries, and to have declined with the collapse of the Kerman Kingdom; now it is only ruins. It can be thought that the porcelain in Minab was produced under the influence of China. From the results of the chemical analyses of glass samples of many colors and sorts, it can be said that all soda-lime glass; none of these samples was of the lead-glass type. This fact suggests that the glassmaking in Minab was, unlike the porcelain-making, not influenced by Chinese glassmaking. It is very interesting that the glassmaking technique is thus in striking contrast to that of porcelain.

The only sample which contained a large amount of lead was a fragment of tri-colored pottery found at Kare-dokhtal, Kerman. The tri-colored glaze was found to be very similar to that in China, not only in the external appearance but also in the lead content.

The other samples which were found to contain small amounts of lead were beads. Beads which were made in China before the fourth century B.C.[7] have also been found in Iran, but, like the glass from China, the Chinese beads show greater

amounts of lead. The beads of Western Asia are usually larger in size, more colorful, and more complicated in design than those from China, Figure 2 presents an example with the eye pattern and also a bead with cord-design. They were obtained in Tehran and are estimated to have been manufactured in about the fifteenth century A.D. The No. 4 bead has a very complicated structure. The results of the analyses are shown in Tables 4, 5, and 6. The details, shown in Fig. 3, reveal a black cylindrical body upon which white lines have been placed, with a yellow knob at the corners and with larger varicolored knobs imbedded within the square formed by the white line. Lead is detected in all parts of all the beads examined. However, lead might have been put in the glass not for the purpose of making lead glass, as was done in China, but for the purpose of lowering the melting point of glass in order to make it more

malleable. At any rate, as their specific gravities were less than 3.3 and contained much silicon and sodium, those pieces of glass, on the whole, are of the soda-lime-glass type.

Coloring Materials. As for the color origins of the bead No. 1, the blue color comes from iron, and the yellow, from lead and iron. In the bead No. 2 the purple color is due to the combination of manganese and nickel, and the blue color is due to copper. In No. 3 the blue color may be due to nickel, and the crimson, and the blue, to copper. In the yellow parts of the beads No. 3 and No. 4, more lead was detected than in the other colored parts. A similar fact has been also described by another researcher.[8] Since these beads are unknown provenance, no definitive conclusion can be reached here.

In Iran and Afghanistan there are many mosques decorated with tiles of a blue called "cobalt blue." One fragment of a blue tile was collected from the blue Mosque at Tabriz in Iran, and the other, from Balkh in Northern Afghanistan. The results of chemical analyses, presented in Tables 7 and 8, demonstrate that cobalt was the origin of the color in both cases.

The coloring materials used on the pottery (*ca.* 3000 B.C.) from Tepe Sialk were also investigated. Although a similar pottery in pattern has been found in prehistoric China,[9] the coloring materials have not as yet been closely investigated. A fragment of pottery about 5×5 cm, which appeared to be a part of the base and side of a vessel, was examined. The body was light gray, and upon one surface there

was a curved painted line. On this line there appeared a node of paint. A part of the body and a part of the node were removed and subjected to chemical analysis. As can be seen in Table 9, approximately 6.3 times as much iron and manganese were found in the sepia-colored part as in the body itself. It is thus obvious that iron was used as the coloring agent. However, it is difficult to state definitely whether manganese was also purposely used as an additive. The ratio of iron to manganese is about the same for both the paint used for the design and the body itself. If the manganese was purposely added to produce this sepia color, it seems to be a highly-advanced technique. The possibility exists, however, that the color was produced by an accidental discovery. Further studies will be necessary to clarify this problem.

Bronze (Slag-like Objects). In 1956 Mitsukuni Yoshida, a member of the Kyoto University Scientific Mission to the Iranian Plateau and Hindukush, discovered rock-like objects in a site at Tepe Sialk, in Iran, which is considered to be the ruins of a refinery (*ca.* 2000 B.C.). From the archaeological point of view, these pieces were obviously pieces of the slag of smelting. Although

they were collected from the same site and layer, however, they were of different colors, one being greenish and the other black. It was believed that this was an important find because it sheds more light upon the actual processes used in the smelting of copper.

Both lumps of slags were about 1.5×1.5 cm in size. Qualitative examinations showed that the chemical compositions of the two were approximately the same. The results of the quantitative determination of the major components are given in Table 10, together with the ratios of the contents of each component in the two samples. As is obvious in the table, the greatest difference between the two samples is in their copper contents. The contents of the other components change to a lesser extent. If, however, one takes the ratios of the contents of the major components, silica, ferric oxide, and calcium oxide, in the two samples, one obtains strikingly constant values, which are shown in the third column of the table.

Another way of comparing the two samples is as follows. The contents of the major components in the green sample are recomputed on the assumption that the black sample is a slag of the green one from which the copper has been almost completely extracted out. In this calculation, the copper content of the green sample was excluded and the contents of the rest of the components were assumed to amount to one hundred percent. The values in the last column of Table 10 were thus obtained; they are in good agreement with the experimental results for the black sample. According to the literature, the ore used in that era (2000 B.C.) was mainly malachite consisting approximately seventy percent of copper,[10] and it was quite precious. Although we could not determine the original ore in the present investigation, the following conclusion may be drawn. It is very probable that there were successive smelting processes; that the green sample is the slag from the first smelting processes of the

ore, thus retaining 15.52% copper oxides, and that the black sample is the slag from the second process, in which the residue of the first processes was treated, with only 0.13% copper (II) oxide remaining. Thus, it is obvious that these ancient people had achieved a high level of technique in the process of extracting copper, the major component of bronze.

Weathering. Efflorescence caused by weathering is frequently observed on the surface of glass or glaze samples. A typical example is a fragment of a glass bowl, about 4×4 cm, collected at the ruins of Rey. A schematic picture of the sample is

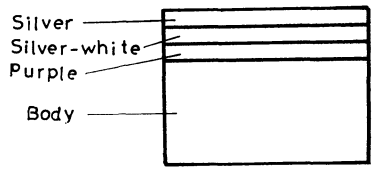

Fig. 4. Schematic diagram of weathering glass.

presented in Fig. 4. The surface of the glass shows the effects of considerable weathering. However, a silvery powder still remained on the surface. Under the weathered surface, there were silvery-white and purple layers beneath which the glass body itself could be seen.

Spectrochemical analysis was performed on each layer of the sample as well as on the sample itself. According to the results, which are shown in Table 11, the contents of such elements as magnesium, sodium, and calcium were found to decrease in proportion to the distance from the inside of the glass to the surface. Potassium was found in substantial amounts only in the glass body; in all the other layers only traces of it were found. The results of other glasses and glazes are also shown in Table 11.

It is very probable, from the chemical point of view, that the ions have partly moved out from the surface to the soil; that is, an ion exchange between the sample and the surrounding materials has taken place, thus forming the outer layers of the sample.

It should be pointed out that the excavation of not only glass objects but also any object should be done carefully, and with the extraction of as much of the surrounding soil as possible, if chemical analyses are desired. It is possible that such ion exchange as occurred with glass objects may occur with other objects. The chemical analyses of surrounding or imbedded soils may yield important clues about this.

The author wishes to express her deep gratitude to Professor Taitiro Fujinaga of the Faculty of Science, Professor Mitsukuni Yoshida of the Research Institute for Humanistic Studies, and Mr. Takenori Sonoda of the Faculty of Engineering of Kyoto University, for their kind guidance and encouragement in the course of this work.

The Kinetics of the Chromic Acid Oxidation of Phenylphosphonous Acid

Kalyan K. Sen Gupta

Department of Physical Chemistry, Jadavpur University, Calcuta-32, India

(Received December 9, 1968)

The kinetics of the oxidation of phenylphosphonous acid by chromic acid has been investigated. The rate at which gross concentration of chromium(VI) disappears follows a first order law. The rate increased with the increase of hydrogen ion concentration. The activation energy of the reaction was found to be 7.4 kcal. The effect of pyridine on the reaction rate confirmed the findings of Westheimer who showed that pyridine catalyzes the oxidation of isopropyl alcohol. It is suggested that the oxidation appears to proceed through the initial formation of an intermediate compound between the active form of phenylphosphonous acid with chromic acid which finally decomposes slowly by the rate determining step. The inactive form is finally oxidized by chromium(V) by very fast step.

Chromic acid oxidizes several inorganic and organic compounds. Westheimer[1] has reviewed works on this subject. Although chromic acid oxidation of some phosphorus compounds was not studied in detail, the oxidation of phosphorous acid has been studied by Dhar.[2] In the present investigation, the kinetics of the oxidation of phenylphosphonous acid by chromic acid has been reported.

Experimental

Reagents. The materials employed were of the highest purity available. Chromic acid was prepared from 'Anala R' potassium dichromate (E. Merck), and 60% perchloric acid (E. Merck) was used without any further purification. Manganous sulfate used was of 'Anala R' grade. Pyridine (B.D.H.) was purified by redistillation. Sodium perchlorate (Riedel) of analytical grade was also used without any further purification. All other reagents were chemically pure.

Synthesis of Phenylphosphonous Acid.[3] Benzene (205 g) was treated with phosphorous trichloride (109 g) under reflux for 30 hr with stirring in the presence of anhydrous aluminium trichloride (43 g). A stream of nitrogen was passed through the reaction mixture throughout the course of the reaction and 86% H_3PO_4 (15 m*l*) was added with vigorous shaking of the mixture. The precipitate was then removed by filtration using glass wool and excess benzene was removed by distillation. Finally the compound was vacuum-distilled and purified by redistillation to give dichlorophenylphosphine (bp 130°C/18 mmHg).

Found: Cl, 39.8%. Calcd for $C_6H_5Cl_2P$: Cl, 39.6%.

Dichlorophenylphosphine (1 vol) was then added to absolute alcohol (5 vol) with stirring, subsequently diluted with water (2 vol) and boiled for about 10 min. After benzene (2 vol) was added, the excess water and benzene were removed by distillation. The solution was then concentrated and the compound after isolation was purified by recrystallization from benzene. The compound after successive recrystallizations showed 99.6% purity which was checked by cerimetric oxidation[3] method (mp 85—86°C).

Found: C, 50.8; H, 5.1%. Calcd for $C_6H_7O_2P$: C, 50.7; H, 5.0%.

Kinetic Measurements. Rate studies were carried out at constant temperature (±0.1°C). The reactants were brought to thermostat temperature. The reaction was then started by the rapid addition of dichromate solution to phenylphosphonous acid and mixing was achieved by stirring. At definite time intervals, 10 m*l* portions of the reaction mixture were withdrawn and quickly transferred to a flask containing freshly prepared potassium iodide solution (2 g in 20 m*l* water). The liberated iodine was then estimated by standard sodium thiosulphate solution and finally gross concentration of chromium was estimated.

Effect of Light. The hydroxy acids are oxidized by chromic acid in the presence of light.[4] Experiments showed that the reactions in the dark as well as in diffuse daylight proceeded at the same rate and hence the reactions were performed in diffuse daylight.

Results

Rate. The rate at which gross concentration of chromium(VI) disappears follows a first order rate law. It is known[5] that when $[Cr(VI)] \leq 4.0 \times 10^{-3}$M, the concentration of $HCrO_4^-$ ions is the same as the gross concentration of chromium(VI)

Temp.=40°C; μ=0.607

Fig. 1. Variation of rate with hydrogen ion concentration.

and the results indicate that $HCrO_4^-$ ions affect the rate of oxidation.

Stoichiometry. The stoichiometry was determined by allowing reaction mixtures containing a large excess of dichromate ion to stand for 48 hr at 30°C. The unreacted oxidant was then estimated by the usual procedure. The reaction may be represented by the following equation:

$$3PhPO_2H_2 + Cr_2O_7^{2-} + 8H^+ \longrightarrow 3PhPO_3H_2 + 2Cr(III) + 4H_2O$$

(Found: 0.31 mol of oxidant per mol of the substrate)

Effect of Hydrogen Ion on the Rate. The experiments were performed at constant ionic strength and temperature. Hydrogen ion concentration was varied by the addition of perchloric acid. The ionic strength was maintained constant with sodium perchlorate. The rate increased with the increase of hydrogen ion concentration. Figure 1 represent the plot of rate constant against [H$^+$].

Effect of Substrate Concentration on the Rate. The rates were investigated at different phenylphosphonous acid concentrations. The experiments were carried out at constant chromium(VI) concentration and temperature. The kinetic evidence indicates that an intermediate ester is formed during oxidation. The plot $1/k$ against 1/ (Substrate) labels the corresponding $1/k$ axis, indicating the formation of an intermediate compound[6] (Fig. 2). Waters and Jones[7] have shown that oxalic acid forms complexes with vanadium (V) and these complexes undergo decomposition. Since vanadium has several chemical similarities to chromium(VI), our assumption regarding the intermediate formation of an ester is quite plausible. In a more recent study, Rao and Ayyar[8] have also shown that the oxidation of oxalic acid by chromic acid proceeded through the initial formation of a metal complex. Similar is the case with glycerol[9] when it is oxidized by chromic acid. The formation of a complex species by interaction of chromium(VI) with several oxyacids has been reported by Lee and Stewart.[10]

Table 1. Variation of rate with oxidant

$[PhPO_2H_2]=1.032\times10^{-2}$M, Temp.=40°C, $[H^+]=0.325$M

No.	$[Cr(VI)]\times10^{-3}$M	$k\times10^3$ (min^{-1})
1	1.666	5.527
2	3.332	3.070
3	4.998	2.303

dielectric constants of acetic acid-water mixtures are not known. Therefore, if it is assumed that the reciprocal of the dielectric constant of the mixture is proportional to the percentage of acetic acid in the solvent mixture, it has been noticed that the rate increases with the decrease in dielectric constant indicating ion dipole interaction. The increased rate of oxidation of isopropyl alcohol by chromic acid in 86.5% acetic acid has been explained[11,12] on the basis of increased protonation of $HCrO_4^-$ before the reaction in a solvent of low dielectric constant. Figure 3 shows that logarithm of the rate constant increases with the increase in the proportion of acetic acid in the mixture.

Effect of Oxidant. The reaction was also studied at different chromium(VI) concentrations, but the concentrations of phenylphosphonous acid and hydrogen ions were kept constant. Table 1 summarizes the results of the oxidation, which shows that the rate constant decreases with the increase of chromium(VI) concentration. A complication concerning chromic acid oxidation may arise due to the fact that different ionic species of chromium(VI) can exist in solution.[13] The neutral chromate ion, CrO_4^{2-}, has no oxidizing ability and in aqueous solution the dichromate ion, $Cr_2O_7^{2-}$, is formed by the rapid equilibrium

$$2HCrO_4^- \rightleftharpoons (Cr_2O_7)^{2-} + H_2O$$

Thus with the increase of the concentration of chromium(VI), a progressively smaller portion of the total amount of chromium appears in the form of an acid chromate ion, and we observe that the rate constants decrease with increasing chromium(VI) concentration.

Retarding Influence of Added Oxidizable Ions. It has been observed that commonest oxidations involve only a one-electron transfer though instances are not rare where the change involves a two-electron transfer. In the present work, the starting material is chromic acid or the acid chromate ion and the end product is trivalent chromium in a solvated condition. In the present study the rate of oxidation is diminished to one third of that in the absence of manganous ions, when the concentration of manganese(II) is 5.0×10^{-2}M. (Table 2) This is possibly due to the fact that manganous ions catalyze the disproportionation of intermediate valence states of chromium and also indicates that chromium(IV) is probably an intermediate. Since manganese dioxide does not accumulate in the reaction mixture, it may be reasonable to propose the following reaction in the presence of manganous ions.

$$3Cr(IV) + Mn(II) \longrightarrow HCrO_4^- + 2Cr(III) + (Mn(II))$$

and not the reactions

$$Cr(IV) + Mn(II) \longrightarrow Cr(III) + Mn(III)$$

$$2Mn(III) \longrightarrow Mn(II) + MnO_2$$

as suggested by Westheimer[1] for the oxidation of arsenious acid by chromic acid.

Variation of Rate with Temperature. The plot of log k against $1/T$ has been represented in Fig. 5. The experiments were carried out at constant ionic strength and hydrogen ion concentrations. From the slope of log k *vs.* $1/T$ plot, the activation energy has been calculated to be 7.4 kcal/mol. It is interesting that the activation energy calculated in the cases of the oxidation of some hydroxy acids by chromic acid are of the same orders.[5] Such closeness of value suggests that same mechanism may be operative for the rate controlling step of the reaction.

Effect of Pyridine on the Reaction Rate. The rate studies have been carried out in different pyridine concentrations. The results have been recorded in the Table 3. If pyridine catalyzes the oxidation, the value $k/\{[H^+]-[Py]\}$ is expected to increase with the increase in the concentration of pyridine which is in agreement with the experimental finding. It is also known[5] that pyridine effectively removes hydrogen ions and the effective hydrogen ion concentration would correspond to $\{[H^+]-[Py]\}$. The result confirmed the findings of Westheimer who showed that pyridine catalyze the oxidation of isopropyl alcohol.

Discussion

Oxidation of a variety of organic compounds by chromic acid has been investigated. As result of the pioneering work of Westheimer and his co-workers, the details of the mechanism of some reactions have been well elucidated. In connection with the oxidation of isopropyl alcohol by chromic acid, Westheimer[1] considers that the oxidation involves the rapid formation of a chromate ester, followed by the interaction with a base, and water plays the role of base in the slow rate determining step. In our case, we have also evidence for ester formation between phenylphosphonous acid and the acid chromate ion. It is well known that at very low concentration of dichromate solution[5,9] ($\sim4.0\times10^{-3}$M) the hexavalent chromium exists wholly as $HCrO_4^-$. This anion possibly reacts with phenylphosphonous acid to give an ester. But phenylphosphonous acid is said to exist in two forms, normal and active form which are tautomers[14] of the structures:

(I) active (II) normal

Other phosphorous compounds[15] also exhibit the same sort of behaviour. Griffith and McKeown[15] have postulated the interconversion between normal and active forms of phosphorous acid and also dialkyl phosphites to explain their respective results on the oxidation of phosphorous acid and dialkyl phosphites by iodine. The existence of tautomeric equilibrium of phosphorous acid has also been discussed by Finch *et al.*[16] who concluded that both forms of phosphorous acid exist. Carrol and Thomas[17] and recently Gupta and Mishra[18] studied the oxidation of hypophosphorous acid by cerium(IV) ion and showed that the following equilibrium exists in solution.

$$H_3PO_2(\text{normal}) + H^+ \underset{k'_{H^+}}{\overset{k_{H^+}}{\rightleftharpoons}} H_3PO_2(\text{active}) + H^+ \quad (1)$$

followed by the reaction of the active form with the oxidizing agent:

$$H_3PO_2 + OX \xrightarrow{k_{OX}} H_3PO_3 + \text{reaction product} \quad (2)$$

The presence of active form in the case of hypophosphorous acid has also been indicated by Jenkins and Yost[19] who proved that $H-\ddot{P}\begin{smallmatrix}OH\\OH\end{smallmatrix}$ is a better electron donor than the normal form of the structure $\begin{smallmatrix}HO\\H\end{smallmatrix}\!\!>\!P\!<\!\begin{smallmatrix}O\\H\end{smallmatrix}$. Therefore it is quite likely that at high acid concentration, the active form of phenylphosphonous acid is predominating although we cannot totally exclude the presence of normal form in solutions, since the monobasic

19) W. A. Jenkins and D. M. Yost, *ibid.*, **11**, 297 (1959).

character of phenylphosphonous acid can only be explained assuming the normal form of the acid. However, the oxidation of phenylphosphonous acid may proceed in two different ways. Phenylphosphonous acid on initial oxidation may give phenol and phosphorous acid with the consumption of one oxygen atom, followed by the oxidation of the latter to H_3PO_4 with the consumption of another oxygen atom according to the equation

$$PhPO_2H_2 + 2O + H_2O \longrightarrow PhOH + H_3PO_4 \quad (3)$$

Some phosphonous acids also undergo scission[9] of the carbon-phosphorous bond at temperature below the disproportionation temperature. The consumption of one oxygen atom and the absence of phenol in the reaction mixture rule out the possibility of reaction (3). Consequently, phenyl phosphonous acid is oxidized to give phenyl phosphonic acid according to the equation

$$PhPO_2H_2 + O \longrightarrow PhPO_3H_2 \quad (4)$$

It is, therefore, reasonable to suppose that the oxidation of phenylphosphonous acid proceeds in the following manner. The rapid reversible formation of a chromate ester can best be explained by assuming the active form of the acid in the following way:

$$Ph-\ddot{P}\begin{matrix}OH\\OH\end{matrix} + HCrO_4^- + H^+ \overset{\text{fast}}{\rightleftharpoons} Ph-\ddot{P}(OH)-O-\overset{\overset{O}{\|}}{Cr}(=O)-OH + H_2O \quad (5)$$

followed by the decomposition of the ester to give a cation of the type $Ph-\overset{+}{P}(OH)=O$ and chromium(IV) by a slow rate determining step

$$Ph-\ddot{P}(OH)-O-\overset{\overset{O}{\|}}{Cr}(=O)-OH \xrightarrow[\text{slow}]{k} Ph-\overset{+}{P}(OH)=O + Cr(IV) \quad (6)$$

The cation which has been obtained in step (6) reacts with water and by fast step gives phenylphosphonic acid:

$$Ph-\overset{+}{P}(OH)=O + H_2O \overset{\text{fast}}{\longrightarrow} Ph-P(OH)(OH)=O + H^+ \quad (7)$$

Chromium(IV) produced in process (6) is then converted to chromium(V) either by reacting rapidly with chromium(VI) or chromium(IV) itself, undergoes rapid disproportionation in the following manner:

$$Cr(IV) + Cr(VI) \overset{\text{fast}}{\longrightarrow} 2Cr(V) \quad (8)$$

$$2Cr(IV) \overset{\text{fast}}{\longrightarrow} Cr(III) + Cr(V) \quad (9)$$

Similar steps have been considered in many reactions.[8,20] Finally chromium(V) formed oxidizes the inactive form of the phenylphosphonous acid rapidly abstracting two electrons, and is reduced to Cr(III) by fast step as

$$Cr(V) + Ph-\overset{\overset{O}{\|}}{P}(OH)-H + H_2O \overset{\text{fast}}{\longrightarrow} Cr(III) + Ph-\overset{\overset{O}{\|}}{P}\begin{matrix}OH\\OH\end{matrix} + 2H^+ \quad (10)$$

The standard oxidation potential of chromium(V) - chromium(III) couple exceeds 1.75 V whereas the same for chromium(VI)-chromium(III) couple is 1.36 V. This suggests that chromium(V) is a much more active oxidant than chromium(VI) which is possibly responsible for the oxidation of inactive form of phenylphosphonous acid.

Thanks are due to Dr. M. N. Das, Head of the Physical Chemistry Section for laboratory facilities. Part of the investvation was carried out during the tenure of Scientists' Pool.

Studies of Ion Exchange Membranes. XXXI. The Hydrogen Peroxide Treatment of the Cation Exchange Membrane of Ferric Ion Form

Yukio MIZUTANI

Tokuyama Soda Co., Ltd., Tokuyama, Yamaguchi

(Received February 3, 1969)

Neosepta CL-2.5T, the cation-exchange membrane prepared by the "Paste Method," of the ferric-ion form was treated with hydrogen peroxide, and the changes in the membrane properties (the thickness, the water content, and the ion-exchange capacity) were measured. The porous membrane, having no ion-exchange capacity, was obtained by the treatment with hydrogen peroxide and the water permeation through the membrane was measured. Assuming the capillary model, the water-permeability data of this membrane suggested that the apparent pore radius of this membrane was 15—17 mμ and that the apparent pore distance was about 40 mμ. This suggests that Neosepta CL-2.5T contains a minute and continuous heterogeneity; *i.e.*, there is a localized distribution of the ion-exchange resin component within the membrane.

The present author has previously proposed the "Paste Method"[1-4] as a practical procedure for the preparation of an ion-exchange membrane. In this procedure, a fine powder of polyvinyl chloride (PVC) and a monomer mixture, mainly consisting of styrene (St) and divinylbenzene (DVB), were mixed to prepare a paste, and then this paste was coated onto Teviron cloth (a reinforcing material). The resultant polymer composite was heated to polymerize the monomers and to convert the PVC powder to a PVC gel. Then, an ion-exchange group was introduced to the base membrane by sulfonation or chloromethylation and amination with trimethylamine. The ion-exchange membrane thus prepared (commercial name, Neosepta) has been used in electrodialytic concentration[5-7] or in the desalination of sea water.[8] One of the characteristic properties of this ion-exchange membrane is its excellent flexibility, which makes it easy to handle the membrane in practical use; this fact also suggests that the structure of the membrane may be different from a rigid gel-structure such as, for example, that of amberlite IR-120.

In a preceding paper,[9] the chemical structure of the ion-exchange membrane prepared by the "Paste Method" was studied by means of extraction with tetrahydrofuran and it was concluded that the fine powdery ion-exchange resin component, extractable through a filter paper with tetrahydrofuran, was present, while the matrix of the ion-exchange resin component was complicatedly entwined with the PVC chain and there was a graft copolymer of the former onto the latter. In this study, the chemical structure of the ion-exchange membrane prepared by the "Paste Method" was investigated by making use of the treatment with hydrogen peroxide.

Experimental

The Sample. Prior to the experiment, Neosepta CL-2.5T was treated alternately with 0.1N aqueous solutions of sodium chloride and hydrochloric acid; thus the membrane properties were made stationary. The ion-exchange capacity, the thickness, and the water content were measured at 21°C by ordinary methods.

The Treatment with Hydrogen Peroxide. After Neosepta CL-2.5T of the hydrogen-ion form had been soaked in an aqueous solution of ferric chloride (0.15 mol/*l*), the surface of the membrane was wiped with a filter paper and the membrane was soaked in an aqueous solution of hydrogen peroxide (5—6%) at room temperature with intermittent stirring.

The Measurement of the Water Permeability. The apparatus is shown in Fig. 1. The pressure difference (Δp) between the both sides of the membrane

was measured by means of the mercury differential manometer (E). While the Δp value was kept constant, the water permeating in a given period was collected in a weighing bottle (G) and weighed. The temperature of the thermostat (F) was 21°C. The effective area of the membrane was 20 cm².

Characterization of the Water Permeability Through the Membrane. The size and the number of pores of a porous diaphragm can be calculated by applying D'Arcy's law and Poiseuille's law, as has been done for a porcelain diaphragm by Sanada.[10] The following equation is well-known as D'Arcy's law, relating to water permeability through a porous membrane:

$$K_p = \frac{Q\eta L}{A\Delta p} \tag{1}$$

where K_p is the specific permeability (cm²); Q, the permeation rate (cm³/sec); A, the effective area of the membrane (cm²); η, the viscosity of water (poise); Δp, the pressure difference (dyne/cm²), and L, the thickness of the membrane (cm).

Assuming that a pore is cylindrical and that it is vertical to the membrane plane and does not intercross with it, Poiseuille's law (Eq. (2)) can be applied to the water permeation through the pore:

$$V = \frac{\pi r^4 \Delta p}{8\eta L} \tag{2}$$

where r is the pore radius (cm) and V, the permeation rate through a pore (cm³/sec). Therefore, the permeation rate through the porous membrane can be expressed as follows:

$$Q = \frac{nA\pi r^4 \Delta p}{8\eta L} \tag{3}$$

where n is the pore number/cm².

On the other hand, the porosity of the membrane (ε) is given by Eq. (4):

$$\varepsilon = \frac{W_e - W_d}{AL\rho_w} = \pi r^2 n \tag{4}$$

where W_e is the wet weight of the membrane (g); W_d, the dry weight of the membrane (g), and ρ_w, the specific gravity of water. By comparing Eqs. (1), (3), and (4), Eqs. (5) and (6) can be derived:

$$r = \sqrt{\frac{8\pi LQ}{\varepsilon A\Delta p}} = \sqrt{\frac{8}{\varepsilon}K_p} \tag{5}$$

$$n = \frac{\varepsilon^2}{8\pi K_p} \tag{6}$$

Assuming the square array of the pores, the apparent pore distance (δ, cm) can be given by Eq. (7).

$$\delta = \frac{1}{\sqrt{n}} \tag{7}$$

Results and Discussion

As a preliminary, it was confirmed that Amberlite IR-120 was completely decomposed by the treatment with hydrogen peroxide, while PVC was essentially stable under the same treatment.

Figure 2 shows the change in the membrane

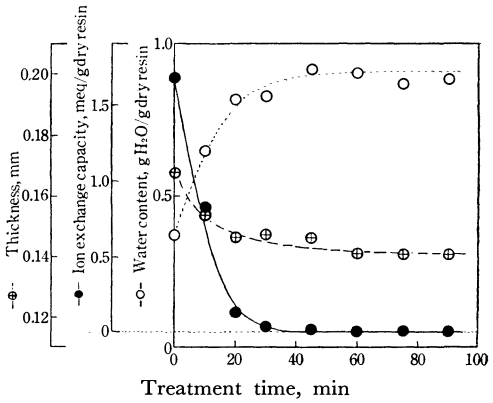

Fig. 2. The membrane properties *vs.* the treatment time with hydrogen peroxide.

properties *vs.* the treatment time with hydrogen peroxide. After 40 min, the thickness and the water content became constant, and the ion-exchange capacity was completely lost. The decrease in the thickness can be attributed to the decrease in the swelling pressure due to lack of the ion-exchange group. Contrary to the decrease in the thickness, the water content increased. This can be explained by the increase in the membrane porosity caused by the decomposition of the ion-exchange resin component within the membrane.

Figure 3 shows the dry weight of the membrane against the treatment time with hydrogen peroxide. After more than 40 min, constant values were observed. Table 1 shows the change in the chlorine content of the membrane *vs.* the treatment time with hydrogen peroxide. The chlorine content gradually decreased with the increase in the treatment time, approaching a constant value after 75—90 min. However, the decreased chlorine contents

are less than that of polyvinyl chloride itself (56.4%). This indicates the treatment with hydrogen peroxide caused not only the decomposition of the ion-exchange resin component but also a slight decomposition of the polyvinyl chloride.

Thus, Neosepta CL-2.5T was transformed to a pale yellowish brown membrane after the complete decomposition of the ion-exchange resin component, and the resultant membrane showed definite properties and an appreciable water permeability, indicating that the membrane was porous. Figure 4

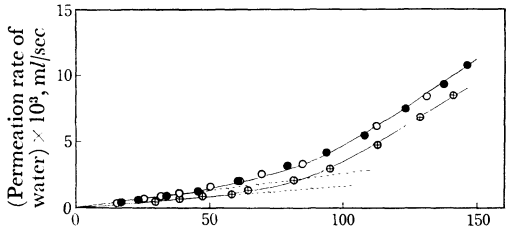

Fig. 4. The permeation rate of water *vs.* the pressure difference between both sides of the membrane.
Treatment time
⊕: 45 min ●: 75 min ○: 90 min

shows the experimental results on the water permeation. When Δp is small, a linear relation was observed between the permeation rate of water and Δp. From the slopes of this straight line, the specific permeation rate was calculated according to Eq. (1). The calculated values are cited in Table 2. As is shown in Table 2, the apparent pore radius is 15—17 mμ, and the apparent pore distance, about 40 mμ.

$\delta\times 10^6$, cm	3.6	4.2	4.2

η: 0.981 centipoise at 21°C

These values are in good agreement with the results of the previous paper,[9] in which there was a fine powdery cation-exchange resin component of 50 mμ or less in the cation-exchange membrane prepared by the "Paste Method." Furthermore, the obtained result suggests that the structure of Neosepta CL-2.5T is different from that of both Amberlite IR-120 having a rigid gel-structure and that of a mosaic-type membrane[11,12] having a discontinuous heterogeneity of the ion-exchange resin component.

A membrane structure such as that described above may be comprehended by considering the mechanism of the process of preparing the base membrane. Since St and DVB were polymerized in a gel phase of PVC, the St-DVB matrix should be complicatedly entwined with the PVC chain and the former should be grafted onto the latter. This may be supported by the fact that a graft copolymer is formed when St is polymerized in a PVC film.[13] These facts should be effective in improving the homogeneity of the membrane. However, while a gel phase of PVC is comiscible with both St and DVB, it is immiscible with polystyrene; thus, the resultant polymer should be separated in a fine powdery form. This may be deduced from the fact that a fine powdery polymer is obtained when *n*-heptane, which is comiscible with both monomers but immiscible with polystyrene, is used in place of PVC.[14,15] This should engender the heterogeneity of the membrane and, in fact, is probably the reason why Neosepta CL-2.5T was transformed into the microporous membrane with no ion-exchange capacity upon treatment with hydrogen peroxide.

In conclusion, Neosepta CL-2.5T contains a minute and continuous heterogeneity; *i.e.*, there is a localized distribution of the ion-exchange resin component. Furthermore, the excellent flexibility of Neosepta CL-2.5T may be attributed to the heterogeneity described above. Further details will be investigated in the future.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 598—600 (1970)

Kinetics and Mechanism of the Silver Catalysed Oxidation of Malic Acid by Potassium Peroxydisulphate

G. L. AGRAWAL[*1] and Arun K. BHATTACHARYA[*2]

Department of Chemistry, University of Saugor, India

(Received January 29, 1969)

Preliminary experiments showed that the reaction between malic acid and potassium peroxydisulphate is very slow. The reaction rate becomes a measurable value at 25°C by introducing the Ag^+ ion as a catalyst. The total order of the reaction has been found to be nearly unity. The effect of the concentration of catalyst and malic acid has been studied. The temperature coefficient of the reaction between the temperature range of 30 and 45°C is 1.76 and the mean value of the energy of activation is 10.9 kcal. The frequency factor and entropy of activation are 16.8×10^5 sec^{-1} and −41.1 e.u. respectively. The probable mechanism for the reaction has been suggested.

The reaction between potassium peroxydisulphate and several reducing ions such as oxalate, formate, *etc.*, has been studied by a number of workers and various mechanisms have been suggested to explain the reactions in each case. Ghosh and co-workers[1] following the work of King[2] and Howell[3] studied the catalysed and uncatalysed reaction between oxalic acid and potassium peroxydisulphate. Allen[4] studied the copper catalysed reaction between potassium formate and potassium peroxydisulphate. The kinetics of the reaction between potassium formate and potassium peroxydisulphate also formed a topic of study of Ghosh *et al.*[5] Saxena and Singhal[6] have studied the reduction of peroxydisulphate with tartaric acid.

A study of literature (*loc. cit.*) showed that the reaction between malic acid and potassium peroxydisulphate has not been studied so far. The authors have therefore taken up the study of this in order to arrive at the general mechanism of the reaction.

Preliminary experiments showed that the reaction in the absence of any catalyst is very slow. However, the rate is enhanced by the introduction of Ag^+ ion as a catalyst.

Experimental

All the chemicals used were that of purest quality available. Solutions were prepared in redistilled water. Calculated amounts of malic acid and silver nitrate solutions were taken in a reaction vessel kept in a Townson and Mercer, Croydan Thermostat (adjustable upto ±0.1°C). The flask containing potassium peroxydisulphate was also kept in the thermostat to attain the temperature of the bath. After attaining the required temperature in the bath, the two solutions were mixed in order to initiate the reaction. At suitable intervals of time, 10 m*l* of the reaction mixture were withdrawn and added to 10 m*l* of an ice cold solution of 10% potassium iodide in order to estimate the unreacted potassium peroxydisulphate. The flask was allowed to remain for five minutes in order to liberate the iodine. The liberated iodine was titrated by a standard solution of sodium thiosulphate using starch as an indicator.

Results

Order of Reaction. The total order of the reaction was calculated employing the isolation method. The data of experiments are recorded in Tables 1 and 2. Column 1 gives the time in minutes, colum 2 volume of sodium thiosulphate used to titrate the liberated iodine at various time intervals and column 3 the values of k. "a" is the volume of sodium thiosulphate at the start of the reaction and $a-x$ is the volume of sodium thiosulphate at different time. Since k exhibits satisfactory consistency, the order with respect to potassium peroxydisulphate must be unity.

By making a run at each of two different initial concentrations of any one component, the other concentrations remaining constant, the data will enable the determination of the order of the reac-

tion with respect to that component.[7] Using the data given in Tables 1, 2 and 3, the order of reaction with respect to malic acid was determined by means of the equation

$$n=\frac{\log\frac{k_1'}{k_2''}}{\log\frac{C_2'}{C_2''}}$$

where k_1' and k_2'' are the first order rate constants obtained at two different concentrations of malic acid C_2' and C_2''. The value of n is -0.3 which suggests that the rates of reaction are slightly

7) A. A. Frost and R. G. Pearson, "Kinetics and Mechanism," John Wiley, New York (1961), p. 45.

Table 3

$[K_2S_2O_8]=0.0066M$, $[AgNO_3]=0.00066M$

Temperature	[Malic acid]	$k\times10^{-2}$ (min^{-1})	
25°C	0.0330M	1.93	$n=-0.27$
25°C	0.0660M	1.59	
30°C	0.1330M	1.57	
35°C	0.1638M	1.50	$n=-0.32$
35°C	0.3276M	1.21	

dependent on the concentration of reducing ions. Thus the total order of the reaction is 0.7 which may be taken as unity *i. e.* the velocity at any instant is dependent on the peroxydisulphate concentration only.

Effect of Malic Acid. Different sets of experiments were carried out at different concentrations of malic acid in order to study is behaviour on the reaction rates. The results are tabulated in Table 3.

A perusal of the above table shows that the value of the first order rate constant decreases with simultaneous increase in malic acid concentration and temperature. The effect can be seen clearly that even increase in temperature has little effect on the rate indicating the important role of malic acid concentration on the reaction mechanism.

Effect of Silver Nitrate Concentration. In order to decide the role of silver nitrate as catalyst on the kinetics of the reaction, the study was carried out using different concentration of $AgNO_3$. The observations are given below:

Table 4

(Temperature 25°C)

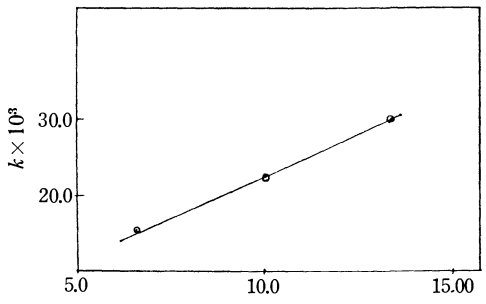
$[K_2S_2O_8]=0.0066M$, [Malic acid]$=0.0660M$

[Silver nitrate]	$k\times10^{-2}$ (unimolecular)
0.00066M	1.57
0.00100M	2.28
0.00133M	3.16

The above data indicates that the rate is dependent on the catalyst concentration. When a graph is plotted between $AgNO_3$ concentration and the rate constant, a linear curve is obtained indicating that the rate is linearly related to $AgNO_3$ concentration *i. e.* $dx/dt\propto[Ag^+]$ (Fig. 1)

Temperature Coefficient. The reaction velocities were measured at four different temperatures. All the four experiments were performed at the identical concentration of the reactants. The values of temperature coefficient calculated are given in Table 5.

Energy and Entropy of Activation. The average value of energy of activation (E) was found to be 10.9 kcal. The value of E is also calculated graphically by plotting $1/T$ *vs.* log k and is found



$[AgNO_3]\times10^4$M

Fig. 1. Concentration of $AgNO_3$ *vs.* *K*.

TABLE 5

$[K_2S_2O_8]$=0.0066M, [Malic acid]=0.0660M
$[AgNO_3]$=0.00066M

Temperature	$k\times10^{-2}$ (in units)	Temperature coefficient
30°C	2.28	$k(t+10)/k(t)$
40°C	4.12	1.81 (30—40°C)

45°C	6.12	
	Average value 1.76	

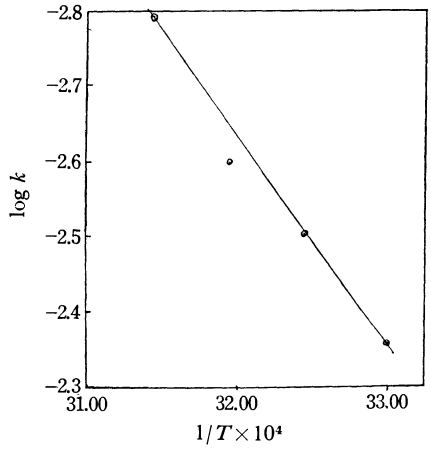

Fig. 2. Plot of log *k* *vs.* $1/T$.

to be 11.4 kcal (Fig. 2). The value of frequency factor with E=10.9 kcal at 40°C is 16.8×10^5 sec^{-1} and entropy of activation at 40°C is −41.1 e. u.

Discussion

The total order of the reaction between potassium peroxydisulphate and malic acid in presence of Ag^+ ion as a catalyst comes out near unity. Then the observed rate equation is

$$-\frac{d(S_2O_8^{2-})}{dt} = k(S_2O_8^{2-})\ (\text{malic acid})^{-0.3}\ (Ag^+)$$

which represents that velocity at any instant is largely proportional to the peroxydisulphate concentration.

Since the rate of reactions catalysed by silver ions are very much independent of the reductant concentrations, it has been suggested[8] that these reactions have a common rate determining step

$$Ag^+ + S_2O_8^{2-} \longrightarrow Ag^{3+} + 2SO_4^{2-} \quad (1)$$

If we take this reaction as a rate determining step, then Ag^{3+} formed reacts with malic acid:

$$\begin{matrix}CH(OH)\cdot COOH\\ |\\ CH_2COOH\end{matrix} + Ag^{3+} + H_2O \longrightarrow \begin{matrix}CH_3CH\begin{matrix}OH\\ \diagdown OH\end{matrix}\end{matrix} + 2CO_2 + Ag^+ + 2H^+ \quad (2)$$

$$\begin{matrix}CH_2CH\begin{matrix}OH\\ \diagdown OH\end{matrix}\end{matrix} \longrightarrow CH_3CHO + H_2O \quad (3)$$

The presence of acetaldehyde in the reaction mixture after completion of the reaction has been confirmed by the spot test method.[9]

It has also been observed that the rate of reaction decreases with an increase in the concentration of malic acid. Decrease in the rate might be due to the complex formation between Ag^{3+} ion and malic acid. If this is the case, part of the trivalent silver will be used to form complex compound and thus the concentration of silver will be reduced in the reaction mixture. Since the rate is linearly related to the catalyst concentration, a decrease in the rate constant is observed with increasing concentration of malic acid

Kinetic Investigations of the Reaction of Brilliant Green with Alkalies. Influence of Ionic Strength

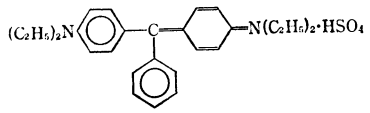
Sarvagya S. KATIYAR

Department of Chemistry, Indian Institute of Technology, Kanpur, India

(Received February 19, 1969)

Kinetic studies of the reaction of brilliant green with alkalies have been made by following the reaction spectrophotometrically at 625 mμ. The reaction has been found to be bimolecular but under experimental condition of excess alkali, it obeyed a first order law. The rate constants was independent of the concentration of brilliant green but it varied linearly with the hydroxyl ion concentration. Effect of neutral salt on the rate of reaction was investigated in aqueous and in 40% acetone-water media. The rate was found to decrease progressively with increasing ionic strength in both media. Analysis of the data by Brønsted-Christiansen-Scatchard equation yielded a value of -1 for $Z_A Z_B$ indicating thereby that the rate-determining step involves oppositely charged species possessing unit charge. The value of inoic interaction parameter, a_i, corresponded to 1.5 and 4.75 Å in aqueous and 40% acetone-water medium respectively. Without attaching too precise a meaning to a_i it is suggested that B.G. ion is presumably solvated to a greater extent in 40% acetone-water than pure water.

Brilliant green (B.G.), chemically known as 4,4'-bisdiethylaminotriphenyl methyl sulfate belongs to a group of dyes known as triphenylmethane



dyes. The physico-chemical[1,2] biological[3,4] and pharmaceutical[5,6] studies of these dyes have attracted the attention of a number of workers. Besides being a compound of biological interest, its major use is in the dye industry where it is used for dyeing and printing all types of fibers, *viz.* cotton, wool, silk, *etc.* Furthermore, it has also been suggested that B.G. can be employed for the colorimetric estimation[7] of Au^{+3}, *etc.*, quantitatively. In biological uses the dye is employed in the biological important pH range 6—7. However, at higher pH the characteristic green color of the dye fades away with time. The kinetic data existing on the instability of B.G. in alkaline solutions are rather scanty[8] while for many other dyes of the series the kinetic data are non-existent. The significance of the stability of these dyes in acidic and alkaline medium, in the course of their biological analytical and dyeing applications, led the author to undertake a systematic kinetic investigation of their reactions. This communication reports the influence of ionic strength, hydroxyl ion concentration and the dye concentration on the reaction responsible for the fading of color of B.G. in alkaline medium, and the data have been employed to detect the species involved in the rate determining step.

Experimental

Materials Used. Brilliant green used was of medicinial quality from British Drug House and was purified by the partition methods[9] described by Lewis, Magel and Lipkin.

Sodium hydroxide employed was a British Drug House 'Anala R' sample.

Potassium nitrate, used for varying the ionic strength of the medium, was a British Drug House 'Anala R' grade reagent which was recrystallized twice from double distilled water.

Acetone employed was a British Drug House 'Anala R' grade reagent and it was further purified[10] before use.

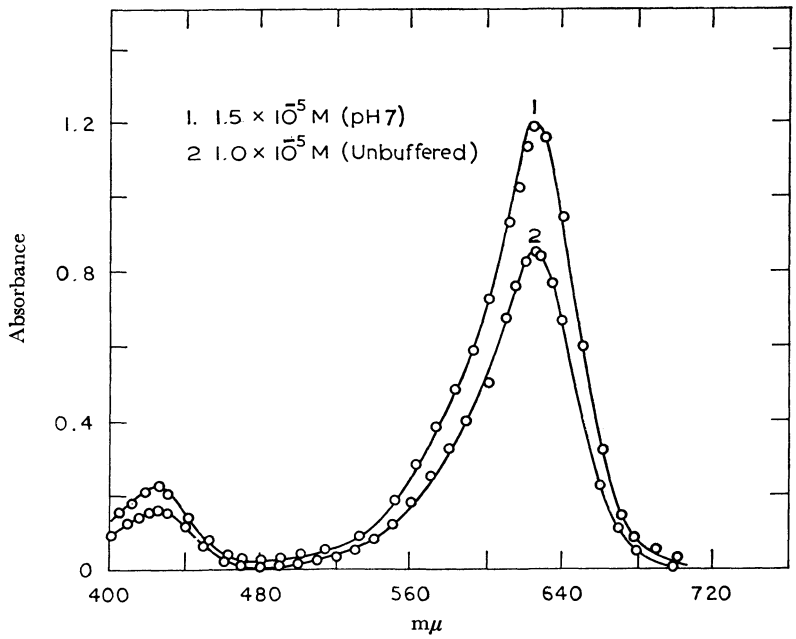

Fig. 1. Absorption spectrum of B.G. in water.

Pre Treatment of Reaction Vessels. B.G. gets adsorbed[11] strongly on the glass surfaces due to which there is a decrease in the effective concentration of the dye. In order to avoid this loss all the vessels used for keeping the solutions of B.G. were coated with a thin layer of purified paraffin wax, which checked the adsorption for sufficiently long durations. The glass cells used for absorbance measurements were rinsed periodically with purified ethanol to remove the adsorbed dye.

Procedure for Following the Reaction. The rate of the chemical change undergone by B.G. in the alkaline medium was studied spectrophotometrically by a Beckman DU spectrophotometer fitted with a dual thermospacer set. The temperature in the cell compartment was regulated by circulating water in the thermospacer set from an external thermostat maintained at 25 ± 0.5°C. The kinetic experiments were carried out in the paraffined flasks kept in the external thermostat and the samples from these flasks were drawn out into 10 mm corex glass cells and their absorbances were noted with time. The absorption measurements were made at λ_{max} of the dye.

Results and Discussion

Absorption Spectrum of Brilliant Green. The absorption spectrum of B.G. in water at two different concentrations in the visible region of the spectrum is given in Fig. 1. It is seen that B.G. exhibits λ_{max} at 625 and 426 mμ. Beer's law held at both these wavelengths as shown by the linear plots of absorbance *vs.* millimicrons in Fig. 2. The value of absorptivity (ε) at 625 mμ corresponded to 8.00×10^4 l mol^{-1}cm^{-1}, which is very high as compared to the absorptivity at 426 mμ. Hence the absorbance measurements during kinetic runs were made at 625 mμ in aqueous solutions. The wavelengths of maximum absorption were unaffected by the buffered or unbuffered nature of the solutions. But in acetone-water mixtures λ_{max} was shifted to 627.5 mμ and therefore the measurements were made at this wavelength in acetone-water mixtures.

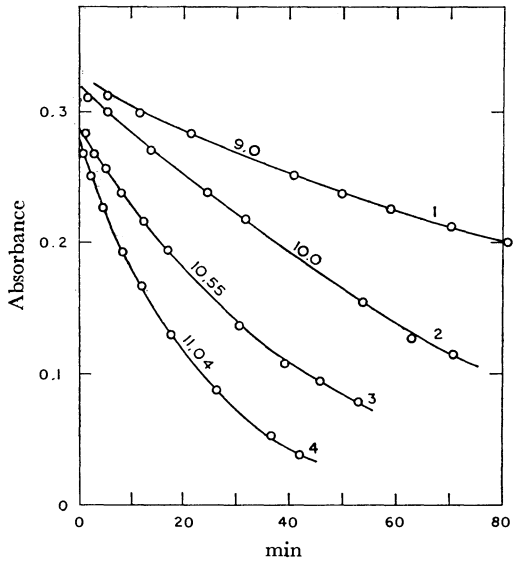

Fig. 3. Typical kinetic runs for the reaction of B.G. in different buffers.

Kinetic studies for the reaction of B.G. and sodium hydroxide could not be carried out at concentrations greater than 5×10^{-5}M of the dye and also at $\lambda=426$ mμ for the following reasons. At concentrations greater than 5×10^{-5}M, turbidity appeared. This was due to the low solubility of the reaction product. At concentrations below 5×10^{-6}M, the absorbance at $\lambda=426$ mμ was so small that spectrophotometric measurements were not feasible.

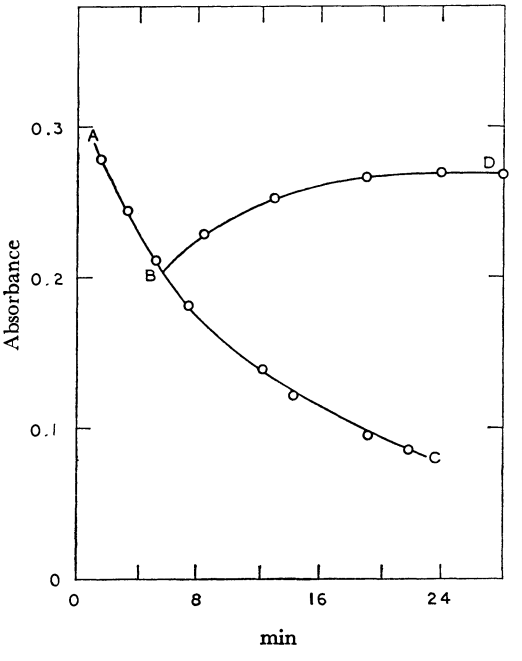

Fig. 4. Reversible nature of the reaction.

Nature of the Reaction. A typical set of kinetic data for the reaction of B.G. in alkaline medium is given in Fig. 3. Here curves 1, 2, 3 and 4 refer to the kinetic runs obtained at pH 9.0, 10.0, 10.35 and 11.04 respectively, the concentration of B.G. being 4×10^{-6}M in all the experiments. In the presence of sufficient hydroxyl ions, the absorbance of the solutions progressively decreased to zero and the solutions became colorless; the color however reappeared gradually with time when the alkali was neutralized by addition of acid. This suggests that the reaction of B.G. with the alkali is reversible in nature, an observation in conformity with that made by Sidgwick and Moore.[8] The reversibility of the reaction was further confirmed by the data presented in Fig. 4. In this figure the portion AB represents the process of fading of color of 4.5×10^{-6}M B.G. solution containing 1.0×10^{-3}M sodium hydroxide. This reaction would have normally proceeded along the curve BC, but as a result of addition of pre-determined quantity of the acid (HCl), which exactly neutralized the alkali present without causing any significant change in volume, the reaction followed the course shown by BD. This portion represents a process in which there is a gradual formation of B.G. This experiment, besides proving the reversibility of the reaction also exposes the complete dependence of the reaction on hydroxyl ion concentration.

In order to make the reaction kinetically simple, sufficient alkali was employed to make the back reaction negligible. Under this condition the equilibrium point of the reaction was shifted to the

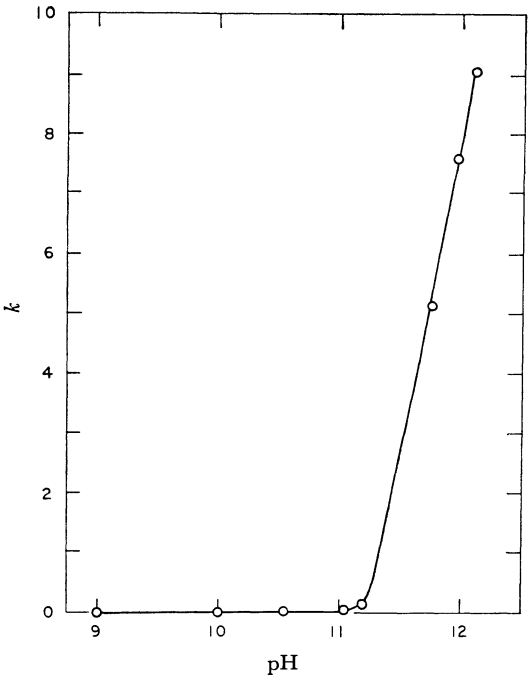

Fig. 5. Variation of velocity constant with pH.

side of the products. Further, less alkali could not be used since spurious rate constants were obtained when the reaction proceeded slowly ($t_{2/1}>1$ hr). The order of the reaction (n) was determined by various methods,[12] *viz.* integration method, graphical method, equifractional parts method, differential method and Guggenheim's method.[13] A typical set of values of n calculated from the data of Fig. 3 by equifractional parts method are given in Table 1. The last column of this table shows that the order of reaction responsible for the decolorization of B.G. corresponds to 1.04 ± 0.14, which indicates that the reaction is first order with respect to B.G. concentration. The values of velocity constant (k) were determined in a number of alkaline buffers in the pH range 9—12. The variation of k with pH is shown in Fig. 5. It is of interest to note from this figure that the value of velocity constant increases slowly up to pH 10.5 but the increase becomes very steep at pH values greater than 10.5. This confirms the marked dependence of the reaction on the OH^- ion concentration.

Dependence of Rate on Hydroxyl Ion Concentration. The dependence of the rate of reaction on the hydroxyl ion concentration was investigated by running the reaction at different concentrations of sodium hydroxide. The data obtained are reported in Fig. 6. In all these experiments the initial concentration of B.G. was 4×10^{-6}M while that of sodium hydroxide was varied in the range $1.0—4.5\times10^{-3}$M. The linear variation of logarithm of absorbance of B.G. with time indicates the applicability of the first order law. The values of the apparent velocity constant (k) obtained from the data of Fig. 6 at different concentrations of hydroxyl ion are given in Fig. 7. It is of interest to note that a linear plot is obtained, which shows that the experimental condition employed in the experiments, *viz.* the excess of OH^- ion concentration, is an important factor responsible for the above observations. This is not an uncommon observation and similar behavior was noticed by Turgeon

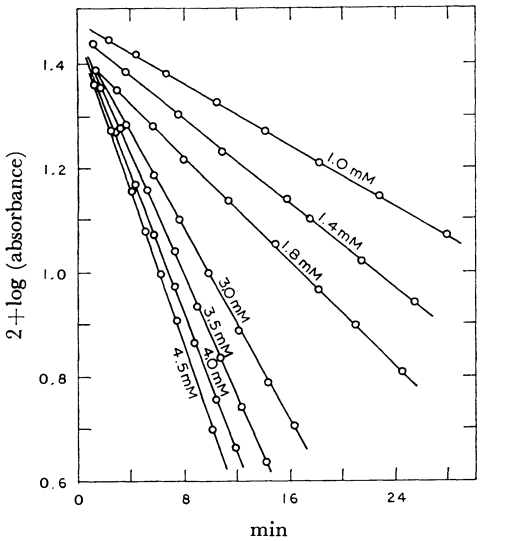

Fig. 6. Kinetic runs at varying sodium hydroxide concentration.

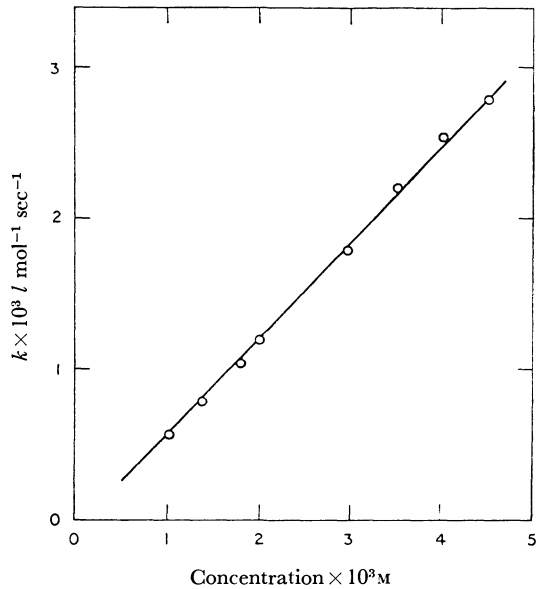

Fig. 7. Dependence of k on sodium hydroxide concentration.

and LaMer[14] and Amis and Lamer.[15] The reaction under study is in fact bimolecular but since OH^- present is in much excess, change in its concentration is negligible. The real or true velocity constant was therefore computed by dividing the apparent velocity constant k by the hydroxyl ion concentrations:

$$k' = \frac{2.303(\Delta \log C_{B.G.})\, l}{(\Delta t)(C_{OH^-})\ \text{mol}\cdot\text{sec}} \qquad \text{(i)}$$

Dependence of Rate Constant on B.G. Concentration. The effect of concentration of B.G. on the rate constant of the reaction was examined by carrying out the reaction at varying concentrations of B.G. and fixed concentration of hydroxyl ions. The data obtained are given in Fig. 8. It is noted that k is independent of the conecntration of B.G. in the range $(1.0—5.0) \times 10^{-6}$M, as the values of k obtained from Fig. 8 and shown in Table 2 are constant. Similar observations were made earlier for the reaction of murexide[16] and crystal violet[14] with alkali where the value of k' was independent of the initial concentration of murexide and crystal violet. Studies at higher concentrations of B.G. could not be carried out due to low solubility of the reaction product and inapplicability of Beer's Law.

concentrations of B.G. and NaOH were kept constant, while the ionic strength was varied in the range 0.002—1.2. In the calculation of μ of the reaction system, the concentration of B.G. (4×10^{-6}M) was not taken into account due to its extreme low value as compared to the added neutral electrolyte. Prior to carrying out investigations on the influence of μ on k', it appeared necessary to examine the effect of the neutral salt, potassium nitrate, on the absorption spectrum of B.G. Experiments indicated that potassium nitrate exerts no influence on the absorption spectrum of B.G. which shows the same characteristic absoprtion maxima at λ=625 and 426 mμ. It may be seen from the data of Fig. 9 that increase in ionic strength of the system decreases the rate of reaction of B.G. The value of k' at different ionic strengths are summarized in Table 3. These data were analyzed by the Brønsted equation, which gives the following relation between k' and μ at 25°C.

$$\log k' = \log k_0' + 1.02 Z_A Z_B \sqrt{\mu} \qquad \text{(ii)}$$

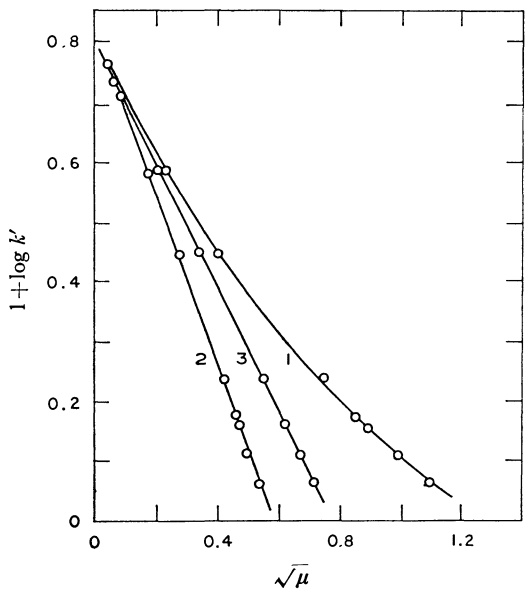

Fig. 10. Variation of velocity constant with ionic strength in water.

where Z_A and Z_B are the charges on the reacting species. According to this equation a plot of log k' *vs.* $\sqrt{\mu}$ should be a straight line with a slope equal to 1.02 $Z_A Z_B$. The variation of log k' *vs.* $\sqrt{\mu}$ is shown in Fig. 10 (curve 1). It may be noted from this plot that at higher values of μ, the points do not lie on a straight line suggesting thereby the non-applicability of Brønsted's equation at higher values of μ. However, if a straight line is drawn by taking into consideration the data below 0.09 μ, the slope of it gives a value of -0.82 for $Z_A Z_B$. The non-applicability of the above equation at higher ionic strengths has been attributed to the inaccurate values of activity coefficients computed from the Debye-Hückel equation, and has been observed by numerous workers. Guntelberg suggested the use of modified form of the Debye-Hückel equation which is as follows:

$$\log k' = \log k_0' + \frac{1.02 Z_A Z_B \sqrt{\mu}}{1+\sqrt{\mu}} \qquad \text{(iii)}$$

Plot 2 of Fig. 10 represents the variation of log k' *vs.* $\sqrt{\mu}/(1+\sqrt{\mu})$. It is instructive to find that the plot is linear over a wide range of μ and the $Z_A Z_B$ as computed from the slope of this plot is -1.36 which is higher than unity. Scatchard[17] made a further modification of the Debye-Hückel equation and this modification when introduced into the Brønsted-Christiansen equation gave the relation

$$\log k' = \log k_0' + \frac{2AZ_A Z_B \sqrt{\mu}}{1+\beta a_i \sqrt{\mu}} \qquad \text{(iv)}$$

A and β are Debye-Hückel constants and a_i is an ionic interaction parameter.[18] The computation of a_i was done by observing the influence of different values of a_i on the constancy of Eq. (iv). The value of a_i which gives a constant value of log k_0' for all the observed values of k' at different μ, over the whole range of ionic strength investigated, was calculated by the method of successive trials. The effect of varying ionic parameter on the constancy of Eq. (iv) is shown in Fig. 11. The calculations were made by taking the values of $2A$ and β as 1.02 and 0.329×10^8 in water at 25°C respectively. According to Eq. (iv) for a correct value of a_i the plot of log k_0' and $\sqrt{\mu}$ will be a straight line parallel to $\sqrt{\mu}$ axis. Interesting enough is to note that curves 1 and 3 of Fig. 11, which give the variation of log k_0' with $\sqrt{\mu}$ at ionic parameter values equal to 0.5 and 4 Å respectively, are not straight lines parallel to x-axis, but are rather diverging lines. This suggests that the correct value for a_i for B.G. in water lies between 0.5 and 4 Å. Plot 2 in Fig. 11 which represents a linear variation of log k_0' *vs.* $\sqrt{\mu}$ was obtained by putting a_i equal to 1.5 Å, suggesting thereby that 1.5 Å is the correct value of interionic attraction parameter for B.G. in water.

Now putting this value of a_i in Eq. (iv) the variation of log k' *vs.* $\sqrt{\mu}/(1+\beta a_i\sqrt{\mu})$ was examined. The plot thus obtained is shown in Fig. 10 (plot 2). From the slope of this plot the value of $Z_A Z_B$ corresponds to -1.01. It is instructive to compare this value with other values of $Z_A Z_B$ computed earlier which corresponded to -0.82 and -1.36. It may, therefore, be concluded that the Brønsted-Christiansen-Scatchard equation gives a value of $Z_A Z_B$ which is nearest to unity. This value suggests that the reaction is taking place between oppositely

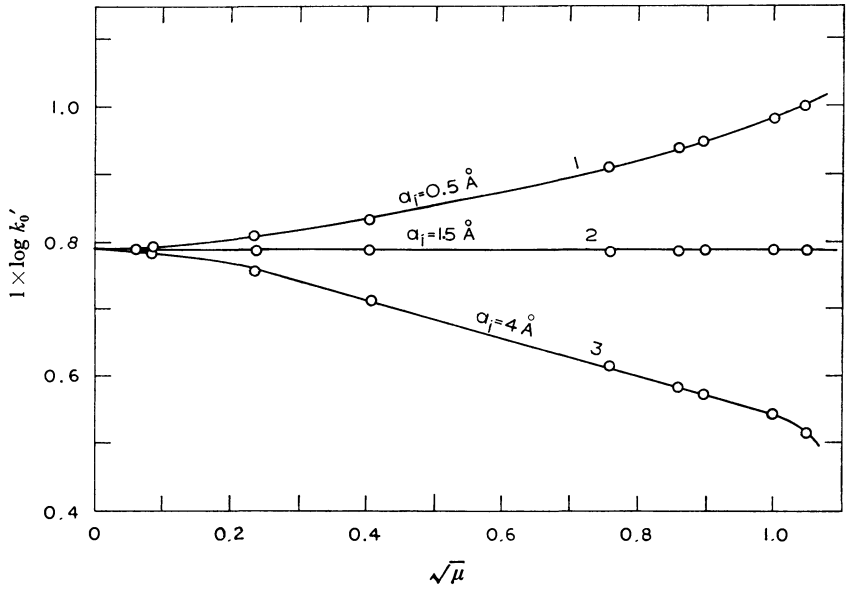

Fig. 11. Effect of varying ionic parameter on the constancy of Eq. (iv) in water.

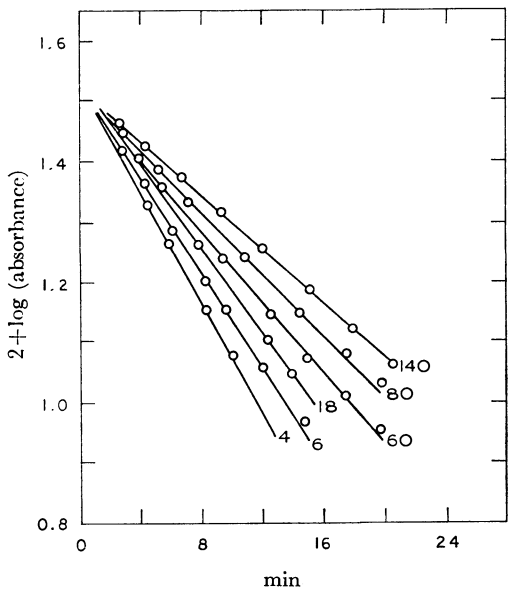

Fig. 12. Kinetic runs at varying ionic strength in 40% acetone-water medium.

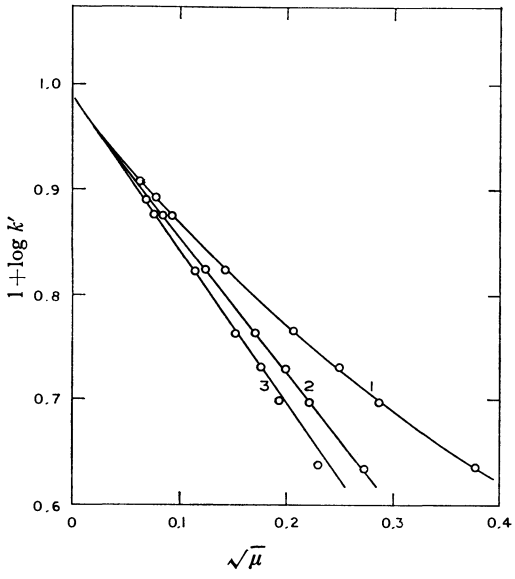

Fig. 13. Variation of k' with ionic strength in 40% acetone-water.

charged species of unit charges.

Salt Effect in 40% Acetone-Water Mixtures. The studies of salt effects were extended to 40% acetone-water mixtures, to determine the value of interionic attraction parameter and hence indirectly the extent of solvation of B.G. in mixed media. To investigate this, kinetic runs were made in 40% acetone-water at varying ionic strength but with fixed concentration of B.G. (4×10^{-6}M) and NaOH (2×10^{-3}M). A typical set of data obtained are given in Fig. 12. The linearity of plots indicates the first order nature of the reaction in this medium. The velocity constant k' was found to decrease with increase in the ionic strength, an observation similar to that obtained in aqueous medium. Analysis of the data for Eqs. (ii) and (iii) yielded the results shown in Fig. 13. Curves 1 and 2 of this figure give the variation of log k' *vs.* $\sqrt{\mu}$ and $\sqrt{\mu}/1+\sqrt{\mu}$ respectively. It is quite evident that plot 1 is a

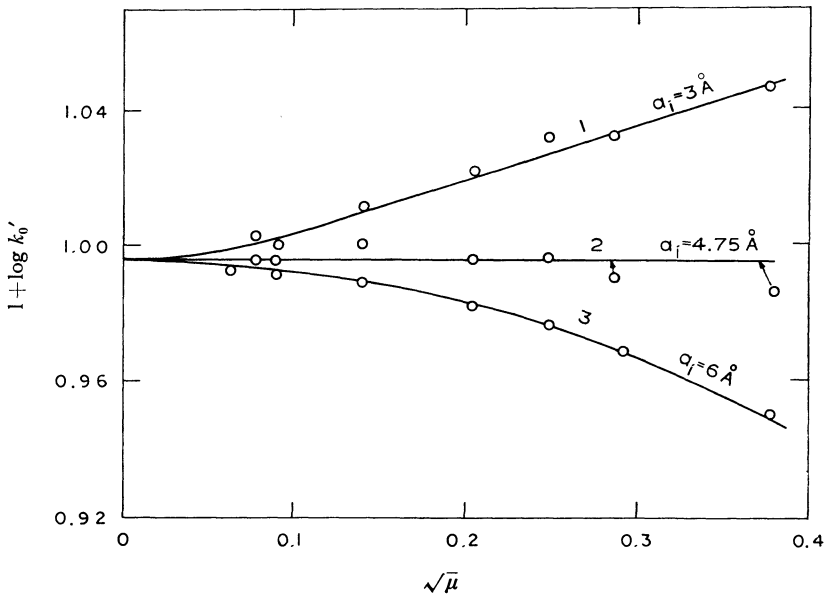

Fig. 14. Effect of varying ionic parameter on the constancy of Eq. (iv) in 40% acetone-water.

curved line and not a straight line, which indicates the non-applicability of Eq. (ii) at higher μ, while plot 2 is linear over a wide range of μ. The slopes of plots 1 and 2 gave a value of Z_AZ_B equal to -0.89 and -1.25 respectively.

For the application of Eq. (iii) the value of a_i of B.G. in acetone-water medium was determined as described earlier. The results obtained are summarized in Fig. 14, which gives the effect of varying ionic parameter on the constancy of Eq. (iv) in 40% acetone-water medium. For the calculations β was taken to be equal to 0.38×10^8 at 25°C. It is of interest to note from Fig. 14 that plots 1 and 3 obtained by putting a_i equal to 3 and 6 Å are non-linear, while plot 2 obtained by putting a_i equal to 4.75 Å is linear. Thus the value of ionic attraction parameter corresponds to 4.75 Å in 40% acetone-water, which is substantially larger than its value in aqueous medium (1.5 Å). Utilizing the value of a_i=4.75 Å in 40% acetone-water, the plot of log k' *vs.* $\sqrt{\mu}/(1+\beta a_i\sqrt{\mu})$ (Fig. 13, plot 3) gave a value of -1.30 for Z_AZ_B, which indicates that the reaction is taking place between oppositely charged species of unit charge. In a ternary system a too precise physical meaning cannot be attached to the parameter a_i. Hence from its larger value in the acetone-water mixture it can be presumed that B.G. ion is solvated to a greater extent in this solvent than in water. In agreement with Sheppard and Geddes[19] it can be suggested that in the B.G. ion the hydrophilic groups at the end of benzene ring are preferentially surrounded by water molecules whereas acetone molecules are probably bound to the hydrophobic parts. These bound acetone molecules will make the B.G. ion appear larger during its reaction in alkaline medium with OH^- ion, as indicated by the larger value of a_i. It appears therefore that it approaches the central carbon atom from a direction perpendicular to the plane of B.G. ion. A similar type of behavior was observed by Turgeon and LaMer[14] in the reaction of crystal violet.

The author is indebted to Professor N. A. Ramaiah of National Sugar Institute, Kanpur for valuable and helpful discussions during the progress of this work.

Molecular Vibrations and Force Fields of Alkyl Sulfides. I. Dimethyl Sulfide and Its Deuterated Compounds

Yuji SHIRO,*1 Masaru OHSAKU, Michiro HAYASHI and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received April 7, 1969)

Dimethyl sulfide and dimethyl sulfide-d_1 were prepared, and their infrared spectra were measured in the gaseous and liquid states. The Raman spectra were measured in the liquid state. The assignments of their spectra were made. On these assigned frequencies, two sets of modified Urey-Bradley force constants and a set of local symmetry force constants were determined by a least-squares technique. The obtained force constants were then transferred to the treatment of the vibrational frequencies of dimethyl sulfide-d_3. The centrifugal distortion constants obtained from the vibrational data were compared with those from the data of the microwave spectra in order to confirm the reasonableness of the obtained force constants.

It would be useful to find a reasonable force field which could reproduce the observed vibrational frequencies and to acertain the assignments of the frequencies of a group of molecules of alkyl sulfides. The present paper, the first of a series of reports on alkyl sulfides, will deal with the molecular vibrations and several force fields of dimethyl sulfide, dimethyl sulfide-d_1, and dimethyl sulfide-d_3.

Although many papers[1-6] on the infrared and Raman spectra of dimethyl sulfide have been reported, the assignments for the methyl group have not consistent with each other. For this reason we have attempted to study the vibrational spectra of dimethyl sulfide in detail. Dimethyl sulfide and dimethyl sulfide-d_1 were prepared, and the observed infrared and Raman bands were newly assigned. Their assigned frequencies were then used to determine the force constants of the modified Urey-Bradley force fields and of the local symmetry force field. When each final set of those force constants was then used in the normal coordinate treatment of dimethyl sulfide-d_3, the calculated frequencies agreed well with the observed frequencies.[4] In order to confirm the reasonableness of the obtained force constants, the centrifugal distortion constants were further calculated from the force constants; their values were found to be consistent with those determined by the microwave study.[7]

Experimental

The dimethyl sulfide was prepared by the reaction of dimethyl sulfate with sodium sulfide.[8] The dimethyl sulfide-d_1 was prepared by the reduction of monochloromethyl methyl sulfide with lithium aluminum deuteride in *n*-buthyl ether, and the monochloro-methyl methyl sulfide was prepared by the reaction of dimethyl sulfide with thionyl chloride.[9]

The infrared spectra of dimethyl sulfide and dimethyl sulfide-d_1 were recorded in the region from 600 to 4000 cm^{-1} in the gaseous and liquid states with Perkin-Elmer Model 112-G and Hitachi Model EPI-S2 Spectrometers. The Raman spectra were measured in the liquid state by the use of a Cary 81 Raman Spectrometer.

Vibrational Assignments

Dimethyl Sulfide. Table 1 shows the observed infrared and Raman data. As the molecule has a C_{2v} symmetry, the fundamental vibrations can be subdivided into these four groups: A_1, A_2, B_1, and B_2. The vibrations belonging to the A_1, B_1, and B_2 species are active in infrared, and all of the A_1, A_2, B_1, and B_2 vibrations are active in Raman. In the gaseous-state absorption spectra, A_1, B_1, and B_2 vibrations have *b*-type, *a*-type, and *c*-type band contours respectively.

a) The *a*-type or *c*-type band contours, b) the *b*-type band contour, c) from Ref. 6; s. strong, m. medium, w. weak, v. very, sh. shoulder, br. broad. Values in parentheses of Raman data indicate relative intensities.

The CH_3 rocking vibrations of this molecule may be expected in the region from 900 to 1050 cm^{-1}. In Fig. 1-a, the spectrum of the 900—1050 cm^{-1} region observed in dimethyl sulfide is illustrated. The infrared band at 1028 cm^{-1} is obviously a *b*-type band; therefore, it is assigned to the CH_3 rocking vibration belonging to the A_1 species. The infrared band at 972 cm^{-1} is an *a*-type band; this band is assigned to the CH_3 rocking vibration belonging to the B_1 species. As the B_2 rocking band is expected around the region of 1000 cm^{-1} on the basis of the normal coordinate treatment, as will be discussed later, the weak band at 1005 cm^{-1} can perhaps be assigned to the B_2 vibration. Although the band belonging to the A_2 species of the CH_3 rocking vibration should appear in Raman, the corresponding band is not observed in the Raman spectra. The band at 907 cm^{-1} might be an impurity band, since the absorption intensity is much reduced by the fractional distillation. The infrared band at 1317 cm^{-1} is assigned to the symmetrical deformation vibration. In the gaseous state, as is shown in Fig. 1-b, the band at 1317 cm^{-1} splits into three components, at 1329, 1317, and 1303 cm^{-1}, and is considered to be an *a*-type band belonging to the B_1 species overlapped by a *b*-type band belonging to the A_1 species. Therefore, the bands of the A_1 and B_1 species are considered to have nearly the same frequencies. This was also shown by the results of the normal coordinate treatment. Four CH_3 degenerate deformation vibrations may be expected in the region from 1500 to 1400 cm^{-1}. In this region the infrared bands are made up of three components in the liquid state; these are assigned to the vibrational modes as is shown in Table 1 on the basis of the normal coordinate treatment.

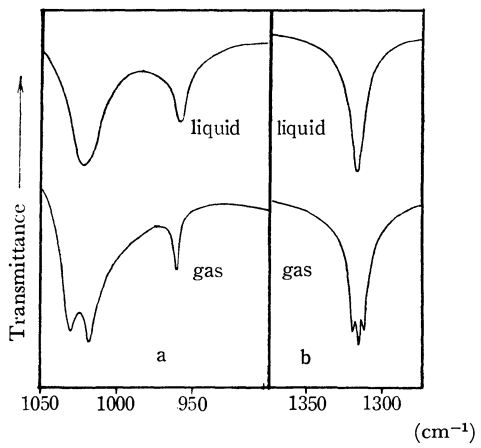

Fig. 1. Infrared spectra of dimethyl sulfide in the gaseous and liquid states in the region of the CH_3 rocking (a) and the CH_3 symmetrical deformation (b) vibrations.

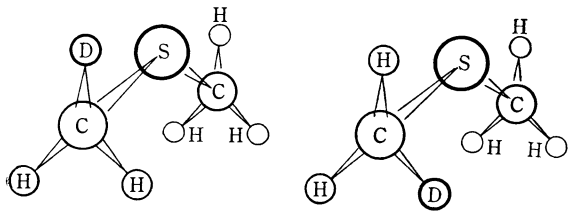
Notations are the same to Table 1.

Dimethyl Sulfide-d_1. Table 2 shows the obtained data. The observed infrared spectra of dimethyl sulfide-d_1 are more complicated than those of dimethyl sulfide. For this isotopic species, two rotational isomers, in one of which the deuterium atom is in the plane of the CSC skeleton (sym-dimethyl sulfide-d_1), while in the other it is out of the plane (asym-dimethyl sulfide-d_1), can be expected, as is presented in Fig. 2. Moreover, Pierce and Hayashi[10] have confirmed the existence of the two molecular forms by their analysis of the microwave spectra. The deuterated species has a structure similar to that of monochloro-methyl methyl sulfide, although their atomic masses are different. The CH_2 deformation frequencies of monochloromethyl methyl sulfide have been reported as 1404, 1230, 1149, and 835 cm^{-1}.[11] In the deuterated species, new bands are observed, at 1420, 1260, 1230, and 960 cm^{-1}, which are not observed in the normal species. These frequencies correspond well with those of monochloromethyl methyl sulfide. In view of these aspects of the observed bands, it would be much better to consider the CH_2D group in this isotopic species as two separate groups, one, the CH_2 group and the other, the CD group, much as is the case of monochloromethyl methyl sulfide, rather than to consider the CH_2D group as one group. The experimental result is also confirmed in the $\boldsymbol{L}$ matrix obtained from the normal coordinate treatment. A part of the $\boldsymbol{L}$ matrix of sym-dimethyl sulfide-d_1 is shown in Table 3. Table 3 shows that each normal coordinate has a main contribu-



sym-dimethyl sulfide-d_1 asym-dimethyl sulfide-d_1

a) This coordinate is the sum of six coordinates of bond angles in the CH_3 group or the CH_2 group.

tion from each underlined symmetry coordinate; these coordinates are constructed for the CH_3, CH_2, and CD groups, respectively. The new bands at 1420, 1260, 1230, and 960 cm^{-1} are assigned to the CH_2 bending, wagging, twisting, and rocking vibrations respectively, though these CH_2 group vibrations contain other, slight contributions. This is also the case with asym-dimethyl sulfide-d_1.

Two infrared bands are observed close to each other, at 806 and 789 cm^{-1}, in the liquid state. They could not be assigned to the C–S stretching vibrations or to the CH_3 and the CH_2 deformation vibrations by comparing them with those of dimethyl sulfide. From the results of the normal coordinate treatment, the SCD deformation vibrations can be expected to be observed around 800 cm^{-1} and the splitting due to the rotational isomerism can be expected to be 5—10 cm^{-1}. This spacing of the calculated frequencies explains well the observed frequency (17 cm^{-1}). Therefore, the two bands at 789 and 806 cm^{-1} are assigned to the SCD deformation bands of sym-dimethyl sulfide-d_1 and asym-dimethyl sulfide-d_1 respectively. In the region from 750 to 600 cm^{-1}, four bands can be expected, since each rotational isomer has two C–S stretching modes. In the experiment three bands, at 738, 696, and 660 cm^{-1}, are observed in the liquid state. Two modes among the four might be overlapped. From the normal coordinate treatment, the bands at 738 and 660 cm^{-1} are assigned to the C–S stretching vibrations of sym-dimethyl sulfide-d_1, and the bands at 738 and 696 cm^{-1} are assigned to the C–S stretching vibrations of asym-dimethyl sulfide-d_1.

The complicated infrared absorption bands in the region from 1050 to 950 cm^{-1} are assigned to the overlapped CH_3 and CH_2 rocking vibrations. On the basis of the assignments of the CH_3 rocking vibrations for dimethyl sulfide and the normal coordinate treatment, these bands in the liquid state are assigned as follows: the band at 963 cm^{-1} is assigned to the CH_2 rocking vibration, the band at 981 cm^{-1} is assigned to the CH_3 out-of-plane rocking vibration, and the band at 1007 cm^{-1}, to the CH_3 in-plane rocking vibration. These assignments are summarized in the 5th and 6th columns of Table 2.

The CH_2 wagging and twisting vibrations for the CH_2 group could be observed around 1250 cm^{-1}. The frequency differences between sym-dimethyl sulfide-d_1 and asym-dimethyl sulfide-d_1 can be expected from the calculations to be about 10—20 cm^{-1}. Consequently, the bands at 1250 and 1259 cm^{-1} are assigned to the CH_2 wagging vibrations of sym- and asym-dimethyl sulfides respectively, and the bands at 1223 and 1236 cm^{-1} are assigned to the CH_2 twisting vibrations of sym- and asym- sulfides respectively. The band at 1327 cm^{-1} is so close to the band at 1317 cm^{-1} of normal dimethyl sulfide that it can easily be assigned to the CH_3 symmetrical deformation vibration.

The absorption bands in the region from 1500 to 1400 cm^{-1} are much shifted to frequencies lower than those of normal dimethyl sulfide. The CH_2 bending vibrations of the CH_2D group may be expected to appear at slightly lower frequencies than the CH_3 degenerate deformation vibrations. This is also confirmed by the normal coordinate treatment. Since the band at 1424 cm^{-1} is assigned to the CH_2 bending, the bands at 1451 and 1436 cm^{-1} are assigned to the CH_3 degenerate deformation vibrations.

The sum rule and the product rule are used to check the above assignments, assuming that the potential energy is common to dimethyl sulfide, sym-dimethyl sulfide-d_1, and asym-dimethyl sulfide-d_1. The total sums of the squared frequencies are calculated to be 6.470×10^7 for sym-dimethyl sulfide-d_1 and 6.475×10^7 for asym-dimethyl sulfide-d_1. The difference is 0.1%; the assignments of the

observed frequencies are thus confirmed to be correct. The ratio of the squares of the product of the observed frequencies to the values of the determinants of the G matrices are found to be 0.8650, 0.8594, and 0.8600 for dimethyl sulfide, sym-dimethyl sulfide-d_1, and asym-dimethyl sulfide-d_1 respectively; the differences are 0.5%. Therefore, all of our assignments are acceptable.

Normal Coordinate Treatment

The Urey-Bradley force field has been applied to various molecules by many authors, and several modifications have been found to be necessary for complicated molecules. We assumed two following kinds of potential functions of dimethyl sulfide: 1) a modified Urey-Bradley force field, and 2) a local symmetry force field. It has been also supposed that the potential constants of sym- and asym-dimethyl sulfide-d_1 are the same as those of normal species. The force constants were determined by a least-squares technique. In the treatment, the observed frequencies of dimethyl sulfide-d_1 were used together with those of normal species since the investigation of the CH_2D-group vibrations, which have different vibrational modes from those of normal species, as well as of the CH_3 group vibrations could lead to reliable findings on the force constants of the methyl group. The obtained force constants were then transferred to dimethyl sulfide-d_3. The molecular parameters used in the computation were those reported by Pierce and Hayashi.[10]

1) Modified Urey-Bradley Force Field (MUBFF). At first the normal coordinate treatment was carried out in the simple Urey-Bradley force field. For the CH_3 rocking, CH_3 degenerate deformation, and C–S stretching vibrations, however, we could not reduce the deviation between the calculated and the observed frequencies to less than 5%. In order to get better agreements of their frequencies, the following modifications of the simple Urey-Bradley force field were attempted: the bond interaction constant of C–H bonds (p), the angle interaction constant between ∠HCS and ∠HCH (n), the *trans* and *gauche* coupling constants between ∠HCS and ∠CSC (t and g), and the bond interaction constant of C–S bonds (p'). This is the force field designated as "MUBFF-I" in the present paper.

The force constants obtained by a least-squares technique and the calculated frequencies are shown in Tables 4 and 5. An effect of anharmonicity was seen with the C–H and C–D stretching frequencies. On the SCD deformation vibration, the effect of anharmonicity was not so clear, since the CH_2 deformation coordinate is coupled with it. For the CH_3 rocking vibrations of dimethyl sulfide, the observed frequencies were 1028 (A_1), 972 (B_1), and 1005 cm^{-1} (B_2), and the calculated frequencies in this force field were 1019 (A_1), 971 (B_1), and 979 cm^{-1} (B_2), although the frequencies in the simple Urey-Bradley force field were 962 (A_1) and 949 cm^{-1} (B_1). The calculated frequencies and difference between the A_1 and B_1 vibrations in MUBFF-I satisfactorily agree with the observed values of the A_1 and B_1 frequencies. The B_2 vibration could not be discussed since the observed frequency was ambiguous. The observed spectra could reasonably be explained by MUBFF-I using the five modification terms.

The set of the force constants of MUBFF-I was then transferred to dimethyl sulfide-d_3. The calculated frequencies are shown in Table 6 together with the reported experimental values.[4] These force constants of MUBFF-I are confirm to reproduce the observed frequencies well except for the CD_3 rocking A' vibration on dimethyl sulfide-d_3. Since the band assigned by Perchard *et al.*[4] to the CD_3 rocking mode is so weak, we can not discuss the disagreement between the calculated and observed frequencies at present. In the calculated results the anharmonicity mentioned above is also seen in the case of the C–H and C–D stretching vibrations.

In MUBFF-I we treated the interactions in methyl groups as modification terms, n, t, and g. However, the nearest atomic distance between two hydrogens

a) From Ref. 4.

situated at the ends of methyl groups is 2.6 Å, and the second nearest is 3.2 Å (see Fig. 3.). Therefore,

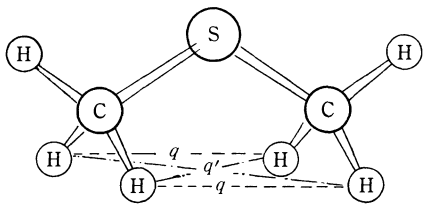

Fig. 3. Repulsion potentials (q and q') between hydrogen atoms.

we could expect the other kind of interaction between methyl groups, namely a direct interaction between two methyl groups. Let us denote the repulsion potentials between the two hydrogen atoms in the case of the nearest and the second nearest atomic distances as q and q' respectively. We then assumed the second modified Urey-Bradley force field (MUBFF-II), in which the modification terms are the bond interaction potential, p, besides the repulsion potentials between two methyl groups, q and q'. The obtained force constants and the calculated frequencies are shown in Tables 4 and 5. This force field reproduces the observed frequencies well. Moreover, the deviation was only about 1%. The determined values of q and q' were 0.009 and 0.043 respectively; these however do not satisfy the relation expected from the van der Waals function ($q \fallingdotseq 2q'$). This suggests that same other weak interactions contribute to the force field of the sulfides.

2) Local Symmetry Force Field (LSFF). In the second place the normal coordinate treatment was carried out using the local symmetry force field reported by Shimanouchi *et al.*[12] All of the diagonal elements and a part of the off-diagonal elements of the $\boldsymbol{F}$ matrix, expressed in terms of local symmetry coordinates, were treated as independent force constants, while the other off-diagonal elements were calculated from the relation of the Urey-Bradley force field. The results thus obtained are shown in Tables 4 and 5. The calculated frequencies agreed well with the observed frequencies. The set of force constants was transferred to the calculation of dimethyl sulfide-d_3. In this force field the calculated frequencies of the CD_3 rocking vibrations agreed fairly well with the observed frequencies. The values of the $\boldsymbol{F}$ matrix elements of LSFF resemble those of MUBFF-I. From these facts it can be said that the off-diagonal elements of the potential energy matrix are, greatly, related to the repulsion force constants.

Discussion

The normal coordinate treatments presented above lead to the conclusion that the interaction terms of the methyl group with the other group are indispensable in the force fields of dimethyl sulfides. If the interaction terms of the methyl group with the other group, t, and g in MUBFF-I, q and q' in MUBFF-II, and f(cs, sd) and f(dr, dr) in LSFF, were not introduced, the observed frequencies could not be reproduced satisfactorily by their force fields. In Table 4 the values in brackets beside the force constants represent the dispersion[13] (Calcd 1) of the force constants around the convergence values. It may be seen that none of the force constants for diagonal and off-diagonal elements relating to the skeletal coordinate are tightly adjusted. At first stage of the calculation by the least-squares technique, some of the force constants for diagonal and off-diagonal elements of the CSC skeletal and C–S stretching vibrational coordinates were reasonablely fixed in several cases. In the final stage, all of the fixed force constants were released from the fixed values. The value of dispersion in this case is shown as Calcd 2 in Table 4. After all, it seems that the force constants relating to the skeleton, especially the off-diagonal elements, can not be exactly determined. Their precise determinations may, however, be accomplished by studies of the isotopic effect of the skeleton or by a completely different approach.

It is well known that the centrifugal distortion constants are closely related to the force constant.[14] We have attempted to compare the centrifugal distortion constants determined on the basis of the force constants with those determined on the basis of the microwave data.[7]

The centrifugal distrotion constants of dimethyl sulfide as determined by microwave measurements have been reported by Rudolph *et al.*,[15] these values were later corrected by Sørensen.[7] He found that none of the six constants could be determined independently when the determinant of the centrifugal distortion matrix (6×6) was almost zero. Therefore, five new linear combinations were selected in such a way that the direct influence of the fixed constant on the observed values was entirely negligible. The determined constants are shown in the 2nd column of Table 7.

The centrifugal distortion constants, $\tau_{\alpha\beta\gamma\delta}$, are defined thus:

$$\tau_{\alpha\beta\delta\gamma} = -\sum_{ij}[J^0_{\alpha\beta}]_i[J^0_{\gamma\delta}]_j[F^{-1}]_{ij}/2\ I^0_{\alpha\alpha}I^0_{\beta\beta}I^0_{\gamma\gamma}I^0_{\delta\delta} \quad (1)$$

b) Fixed constant which contributes with less than 1.6×10^{-5} MHz to the centrifugal distortion correction.

c) $T_1 = \tau_{aaaa}$, $T_2 = \tau_{bbbb}$, $T_3 = \tau_{cccc}$,

$$T_4 = \tau_{abab} + \frac{1}{2}\left[\tau_{aabb} - \left(\tau_{cccc} - \left(\frac{C}{A}\right)^4\tau_{aaaa} - \left(\frac{C}{B}\right)^4\tau_{bbbb}\right)\frac{A^2B^2}{2C^4}\right],$$

$$T_5 = \tau_{bcbc} + \frac{1}{2}\left[\tau_{bbcc} - \left(\tau_{cccc} - \left(\frac{C}{A}\right)^4\tau_{aaaa} + \left(\frac{C}{B}\right)^4\tau_{bbbb}\right)\frac{B^2}{2C^2}\right],$$

$$T_6 = \tau_{caca} + \frac{1}{2}\left[\tau_{ccaa} - \left(\tau_{cccc} + \left(\frac{C}{A}\right)^4\tau_{aaaa} - \left(\frac{C}{B}\right)^4\tau_{bbbb}\right)\frac{A^2}{2C^2}\right],$$

$T_4' = T_4 + 0.8426T_6$, $T_5' = T_5 + 0.1574T_6$, $A = 17809.7$, $B = 7621.1$ and $C = 5717.8$ MHz

where $I_{\alpha\alpha}$ denotes the moment of inertia and where $\boldsymbol{F}$ is the potential energy matrix expressed in terms of displacement coordinates, and $[J_{\alpha\beta}{}^0]_i$ is defined by:

$$[J^0_{\alpha\beta}]_i = (\partial I_{\alpha\beta}/\partial q_i) \quad (2)$$

where $I_{\alpha\beta}$ is the inertia tensor and where q_i is the ith displacement coordinate. Using Eq. (2) the centrifugal distortion constants were calculated from the above-mentioned three sets of force constants; the six constants were then recalculated in the same form as the constants obtained by Sørensen. They are shown in the last three columns of Table 7. The calculated centrifugal distortion constants were in good agreement with the observed values in the cases of MUBFF-I and LSFF, while in the case of MUBFF-II the agreement was not sufficient.

Then we examined the change in the centrifugal distortion constants due to the change in the force constants. From Eq. (1) the following equations were deduced:[16]

$$(\partial\tau_{\alpha\beta\gamma\delta}/\partial f_{ij}) = -\sum_{kl}[J^0_{\alpha\beta}]_k[F^{-1}]_{ik}[F^{-1}]_{jl}[J^0_{\gamma\delta}]_l/ I^0_{\alpha\alpha}I^0_{\beta\beta}I^0_{\gamma\gamma}I^0_{\delta\delta} \quad (\text{if } i \neq j)$$

a) The matrices are expressed with the local symmetry coordinates. The i and j denote the ith and jth coordinates, respectively.

or $$= -\frac{1}{2}\sum[J^0_{\alpha\beta}]_{ik}[F^{-1}]_{ik}[F^{-1}]_{jl}[J^0_{\gamma\delta}]_{lj}/ I^0_{\alpha\alpha}I^0_{\beta\beta}I^0_{\gamma\gamma}I^0_{\delta\delta} \quad (\text{if } i=j)$$

where the i and j denote ith and jth local symmetry coordinates respectively. Therefore, f_{ij} denotes the element of the F matrix represented by the local symmetry coordinates. Normal dimethyl sulfide has a C_{2v} symmetry. Therefore, τ_{aaaa}, τ_{bbbb}, τ_{cccc}, τ_{bbcc}, τ_{ccaa}, and τ_{aabb} are related to the vibrations belonging to the A_1 species; τ_{abab} is related to the B_1 species; τ_{caca}, to the A_2 species, and τ_{bcbc}, to the B_2 species. Table 8 shows the calculated values of $(\delta\tau_{\alpha\beta\gamma\delta}/\delta f_{ij})$ in each symmetry species. The larger values show the more relations between $\tau_{\alpha\beta\gamma\delta}$ and f_{ij}. If $\tau_{\alpha\beta\gamma\delta}$ is completely determined by the microwave analysis, the force constants with a large value of $(\delta\tau_{\alpha\beta\gamma\delta}/\delta f_{ij})$ can be correctly obtained. Such force constants are f(cs), f(cs, csc), f(csc), f(to), and so on. On the other hand, f(ts), f(dd), f(sd), *etc.* can not be correctly determined from the centrifugal distortion constants. In general, the $(\delta\tau_{\alpha\beta\gamma\delta}/\delta f_{ij})$ values related to the vibrational coordinates on hydrogen atoms, *i.e.*, small-mass atoms, are small. Those related to skeletal vibrational coordinates (skeletal stretching, skeletal deformation, and torsional) are large. Therefore, their off-diagonal values are rather larger than the diagonal values. Thus, the force constants related to the hydrogen stretching and deformation vibrations can be determined only with difficulty from the centrifugal distortion constants, whereas those for diagonal and off-diagonal elements related to the skeletal stretching, skeletal deformation, and torsional vibrations can be determined more easily. This fact may be valuable for studies of molecular force fields, since usually it is too hard to determine the force constants related to the skeleton, especially their off-diagonal elements with sufficient accuracy. The determination of the force constants on the basis of the centrifugal distortion constants may be expected to be valuable. In this study, however, we did not calculate the force constants from the centrifugal distortion constants. The comparison of the two sets of centrifugal distortion constants obtained from the vibrational spectra and the microwave spectra reveals that the force field of MUBFF-I and LSFF would be preferable. The application of the force constants we have obtained will be discussed in the near future.

The authors wish to express their gratitude to Professor T. Shimanouchi of the University of Tokyo, for the permission to use the Perkin-Elmer 112-G spectrometer and to Dr. Shinnosuke Saeki of the Tokyo Government Industrial Research Institute for his measurements of the Raman spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 619—622 (1970)

Molecular Vibrations and Force Fields of Dimethyl Selenide and Dimethyl Selenide-d_6

Yuji SHIRO,*1 Masaru OHSAKU, Michiro HAYASHI and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received May 6, 1969)

A set of the modified Urey-Bradley force constants and of the local symmetry force constants of dimethyl selenide have been calculated by a least-squares technique, using the vibrational frequencies of the two isotopic species, $(CH_3)_2Se$ and $(CD_3)_2Se$. The calculated frequencies thus obtained are in good agreement with the observed values. Comparison has been made for the force constants among dimethyl ether, dimethyl sulfide, and dimethyl selenide. This has shown the reasonable relation to be expected among the force constant, the bond length, the bond angle, and the atomic number of the central atom. The centrifugal distortion constants, which were calculated from the two sets of force constants, were then compared with those obtained from the microwave spectra; their values are found to be consistent with those obtained from a microwave study in a three-body approximation.

The force fields of dimethyl ether[1-3] and dimethyl sulfide[4] have been extensively investigated. For dimethyl selenide, the vibrational data have been reported by Allkins and Hendra,[5,6] who made a treatment of the simple valence force field for the skeleton. Although Fritz and Keller[7] made a simple computation of the vibrational frequencies of dimethyl ether, dimethyl sulfide, dimethyl selenide, and dimethyl telluride, no study has been made of the Urey-Bradley and the local symmetry force fields. In our paper[4] on the most probable force fields of dimethyl sulfide, we determined two sets of force constants. One of them was a set of modified Urey-Bradley force constants which contained such modification constants as C–H bond interaction, p(C–H); C–S bond interaction, p(C–S); *trans* coupling, t; *gauche* coupling, g, between ∠HCS and ∠CSC, and angle interaction, n, between ∠HCS and ∠HCH. The other set was the local symmetry potential constants. For dimethyl selenide, we have attempted to estimate, by a least-squares technique, a set of the force constants of the modified Urey-Bradley force field (MUBFF) and of the local symmetry force field (LSFF) from the reported vibrational frequencies of the normal[5] and fully-deuterated[6] species. To make sure of the propriety of the two sets of the force constants thus obtained, the centrifugal distortion constants were calculated and compared with those reported by Beecher[8] on the basis of his microwave study.

Calulated Vibrational Frequencies

Assuming that dimethyl selenide and dimethyl selenide-d_6 belong to the same symmetry class as a C_{2v} symmetry, 21 fundamental modes of vibrations can be subdivided by symmetry properties into four species, $7A_1$, $4A_2$, $6B_1$, and $4B_2$. Two types of potential function were treated as in the case of dimethyl sulfide. One is the modified Urey-Bradley force field. This contains the C–H bond interaction term, p(C–H); the C–Se bond interaction term, p(C–Se); the *trans* and *gauche* coupling terms, t, and g, between ∠HCSe and ∠CSeC, and the angle interaction term, n, between ∠HCSe and ∠HCH. The other is the local symmetry force field. Normal coordinate treatments were carried out by a least-squares technique on the basis of the observed frequencies of the normal[5] and fully deuterated[6] species by Allkins and Hendra. Computation has been carried out assuming that the

potentials of dimethyl selenide and dimethyl selenide-d_6 are common. The molecular parameters used on the computation were those reported by Beecher.[8] Table 1 shows the observed frequencies and two cases of the calculated frequencies with the deviation between the observed and calculated frequencies.

For normal dimethyl selenide in the modified Urey-Bradley force field, the calculated frequencies of the CH_3 rocking region, $\nu_{16}(B_1)$ and $\nu_{20}(B_2)$, and of CH_3 symmetric deformation, $\nu_{15}(B_1)$, are fairly different from each observed frequency. However, the other vibrations are in good agreement within a deviation of about 1%. In the local symmetry force field the CH_3 rocking vibrations, $\nu_{10}(A_2)$ and $\nu_{20}(B_2)$, also have fairly large deviations.

For dimethyl selenide-d_6 in the modified Urey-Bradley force field, the vibrations of the CD_3 rocking region, $\nu_{10}(A_2)$ and $\nu_{20}(B_2)$, and those in the local symmetry force field, $\nu_5(A_1)$ and $\nu_{16}(B_1)$, of the CD_3 rocking vibrations have also fairly large deviations. That is, CH_3 or the CD_3 rocking vibrations were not reproduced in good agreement either in the modified Urey-Bradley or in the local symmetry force fields. This tendency was also shown in our work on dimethyl sulfides.[4] The calculated mean deviation (m.d.) and the root mean squared deviation (r.m.s.d.) are as follows: MUBFF; m.d. 1.1%, r.m.s.d. 1.4%, LSFF; m.d. 0.9%, r.m.s.d. 1.1%. Thus the modified Urey-Bradley force field and the local symmetry force field are appropriate as the force fields of dimethyl selenide.

Force Constants

Table 2 shows the two final sets of the force constants and their dispersion, together with the sets obtained from dimethyl ether[1] and dimethyl sulfide.[4] Although some modification constants taken into consideration differ from each other, the force constants among the listed molecules will be made compared in order to establish a definite tendency.

The C–X bond length in these compounds with the formula $(CH_3)_2X$ increases and, on the other hand, the CXC angle decreases towards 90°, with an increase in the atomic number of the atom X (X: O, S, and Se). The data provided by the microwave studies are as follows:

Table 2. Calculated force constants with their dispersion

∠COC 111°43′, r(C–O) 1.410 Å Ref. 9;
∠CSC 98°52′, r(C–S) 1.802 Å Ref. 10;
∠CSeC 96°11′, r(C–Se) 1.943 Å Ref. 8.

K; Stretching Force Constants. The stretching force constant of K(C–H) does not show any clear tendency. The results due to the simple computation of Fritz and Keller[7] show that the C–X stretching force constants with the general formula of $(CH_3)_2X$ decrease with an increase in the atomic number (X; O, S, Se, and Te). Such a phenomenon is also shown in this work. The force constants of K(C–O) and K(C–S) were found to be 3.366 and 1.691 respectively, and the force constant of K(C–Se) was found to be 1.288, both decreasing with an increase in the atomic number.

H: Bending Force Constants. As the C–X bond length increases and the CXC angle decreases, the bending force constant, H(HCX), decreases, but H(CXC) shows no definite tendency.

F: Repulsion Force Constants. This kind of force constant decreases with an increase in the atomic number of central atom. This shows that the repulsive force in each case decreases with an increase in the C–X bond length.

κ: Internal Tension. These constants also decrease in the order O<S<Se.

Y: Torsional Force Constants. These constants can be calculated from the barrier height (V_3) of each molecule; the barrier heights of the normal species with the formula $(CH_3)_2X$ (X; O, S, and Se) were found to be 2720, 2132, and 1500 cal/mol.[8,10,11] Therefore, the constants also decrease in the order O<S<Se.

Modification Constants. Generally, the modification constants are in the same order, as have been mentioned above. However, most of the modification constants have a fairly large dispersion. This suggests that these potentials bear at the same time the effect of other interactions which are not taken into consideration, and also that these constants are not tightly adjusted. Therefore, the modification constants are fairly arbitrary and a regular comparison could not be made.

In the case of the local symmetry force constants, our results were nearly the same as the modified Urey-Bradley force constants. That is, the constants decrease in the order O<S<Se. However, the physical meanings of the local symmetry force constants are not obvious enough for us to discuss the local symmetry force constants.

Centrifugal Distortion Constants

In order to confirm the reasonableness of the

11) P. H. Kasai and R. J. Myers, *ibid.*, **30**, 1096 (1959).

obtained force constants, we calculated the centrifugal distortion constants. Table 3 shows the centrifugal distortion constants calculated from the two final sets of the force constants and those from the microwave study by Beecher,[8] who determined the centrifugal distortion constants in the three-body approximation. The two cases of the modified Urey-Bradley force field and the local symmetry force field are in good agreement with those from the microwave study. In comparing Beecher's results and the present results we noticed the following two results; (1) the four observed values of constants, τ_{aaaa}, τ_{bbbb}, τ_{aabb}, and τ_{abab} agreed well with the calculated values, and (2) three constants, τ_{cccc}, τ_{bbcc}, and τ_{ccaa}, which are ignored by Beecher are found in this work to have small values.

Therefore, it is confirmed that the obtained force constants are reasonable in the light of the first finding, while, on the other hand, Beecher's assumption is reasonable as the first approximation in the light of the second finding.

n–π^* Electronic Emission Spectrum of *o*-Methoxybenzaldehyde Vapour

M. P. SRIVASTAVA, O. N. SINGH and I. S. SINGH

Department of Spectroscopy, Banaras Hindu University, Varanasi-5, India

(Received March 27, 1969)

The n–π^* vapour emission spectrum of *o*-methoxybenzaldehyde has been excited in transformer discharge in flowing vapours of benzene and the substance. In the spectrum the C=O stretching frequency is the most prominent and its found to form progression of bands. The entire spectrum has been analyzed in terms of several ground state frequencies.

In recent years there has been a growing interest in the study of non-bonding electron transition specially in benzaldehyde derivatives. The n–π^* electronic emission and absorption spectra of benzaldehyde[1–3] and halobenzaldehydes[4–9] have been investigated in detail by many workers. The electronic absorption spectrum due to n–π^* system of *o*-methoxybenzaldehyde in vapour state was recorded by Dwivedi.[10] However, the emission spectrum of *o*-methoxybenzaldehyde was not studied by any earlier worker. The present paper deals with the detailed study of the emission spectrum of the compound in vapour state obtained for the first time in transformer discharge. To make the electronic study more comprehensive the infrared spectrum was also recorded.

Experimental

The emission spectrum has been obtained in transformer discharge through the flowing mixture of benzene and *o*-methoxybenzaldehyde vapour. The discharge tube was of π type 35 cm in length, narrower in the middle (14 mm diam.) and broader at the two ends.

Two separate containers joined to each other in series to hold the substance and benzene, were attached to one end of the discharge tube facing the slit. The benzene container was provided with a fine capillary tube to control the flow of the benzene vapour whereas the substance container was externally heated to a desired temperature to give requisite vapour pressure in the discharge tube. The use of benzene in this experiment is to prevent dissociation of the molecules to a great extent. The stablized discharge condition was obtained at 4500—5000V and the discharge was bright blue in colour.

The spectrum was recorded on a Fuess glass spectrograph and a Q-24 Zeiss medium quartz spectrograph. Ilford HP-3 and ORWO blue rapid plates were used to photograph the spectra. With a slit-width of 40 μ, exposures of 6—10 hr were found sufficient on both the instruments. The wavelength and wave number of the bands, their relative intensities, separation from the 0-0 band and proposed assignments are given in Table 1.

Results

The emission spectrum lies in the region 3750—5447 Å and consists of about 75 bands. The spectrum consists of a long progression of bands. These bands form the head of the groups. The first group is observed with weak intensity but the intensity of the second group abruptly increases and is maximum for the third and then decreases gradually. Between each pair of successive bands in each group there is a recurring pattern of bands. A typical spectrogram of the emission spectrum is shown in Fig. 1.

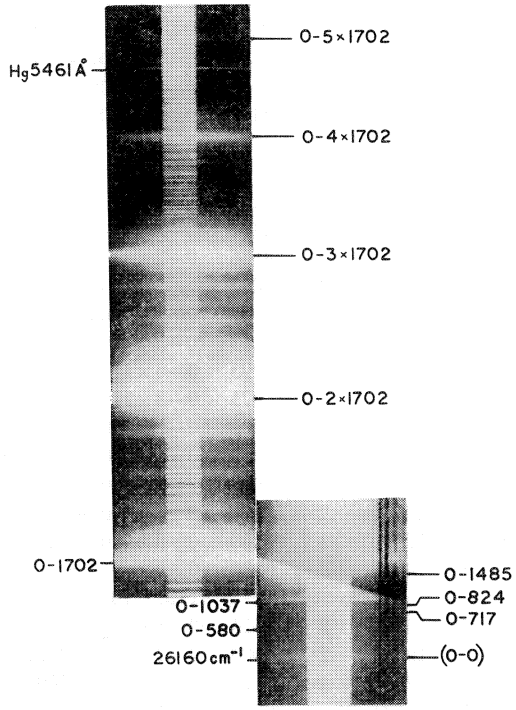

Fig. 1. Emission spectrum of *o*-methoxybenzaldehyde.

Analysis and Discussion

It is well established that the longest wavelength electronic transition of compounds containing carbonyl groups arises from the excitation of a non-bonding (n) electron localized on the oxygen atom to the anti-bonding π^* orbital. The eletronic transition is supposed to be confined to a large extent to the C=O part of the molecule and has been interpreted by McMurry[11] as corresponding to a transition in which a loosely bound electron occupying a non-bonding orbital lying in the molecular plane and across the C=O direction is excited to an anti-bonding π^* orbital with a mode in the plane. Padhye[12] and Sidman[13] have also reviewed the nature and characteristics of such non-bonding electron transition. The electronic transition responsible for the present system is similar to 3714 Å system in benzaldehyde and corresponds to the forbidden transition $^1A_2$–$^1A_1$ of formaldehyde. However, in *o*-methoxy benzaldehyde with lower symmetry C_s (considering the OCH_3 group to behave as a single mass point and CHO group to lie in the plane of the ring), the above forbidden transition becomes allowed and is ascribed to $^1A''$–$^1A'$.

The band 26160 cm^{-1} observed with medium weak intensity in the emission spectrum has been identified as the 0–0 band of the system. In the absorption spectrum of vapour, Dwivedi[10] has assigned the band at 26136 cm^{-1} as the 0–0 band of the system. The choice of the 0–0 band is supported by the smooth vibrational analysis as well as the good agreement of the ground state freqencies observed in the emission spectrum with those recorded in infrared spectrum.

The frequency 1702 cm^{-1} is the most prominent one which dominates the spectrum. Four quanta of it have been observed forming a progression of bands. This frequency with its overtones combines with most of the ground state frequencies giving thereby a recurring pattern of bands. It has been assigned as the C=O stretching frequency in the ground state. Its magnitude in both Raman and infrared spectrum in liquid phase is 1684 cm^{-1}. The difference in the C=O stretching frequency in liquid and vapour phase is probably due to hydrogen bonding resulting from the intermolecular interaction in the liquid phase. The molecules in the liquid phase are very close to each other and due to partial linking of the hydrogen atom of the CHO group of one molecule with the oxygen atom of the CHO group of another molecule, the C–O bond strength is slightly lowered and consequently the magnitude of the C=O stretching frequency is slightly lowered in liquid phase. Such shifts have also been observed in benzaldehyde,[3] fluoro and chlorobenzaldehydes.[5,8]

Another ground state frequency 1037 cm^{-1} is involved in the band at 25123 cm^{-1} occurring with weak intensity. The frequency is correlated with the totally symmetric 1039 cm^{-1} Raman and 1040 cm^{-1} infrared frequency and is assigned to the ring breathing mode corresponding to 992 cm^{-1} (a_{1g}) vibration of benzene.

Other ground state frequencies observed in the emission spectrum are: 130, 192, 270, 475, 580, 717, 824, 1016, 1155, 1231, 1450, 1485 and 1597 cm^{-1}. All these are observed to combine with the 1702 cm^{-1} C=O stretching frequency and its overtones. A correlation of ground state frequencies

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 625—628 (1970)

Theory of Solvent Effects on Oscillator Strengths for Molecular Electronic Transitions

Takehiro ABE

College of General Education, Tohoku University, Kawauchi, Sendai

(Received April 30, 1969)

A theoretical expression has been presented for an oscillator strength of an electronic transition in a solute molecule immersed in an isotropic dielectric continuum of solvent. It is assumed that a charged particle in the solute is subjected to a force due to a cavity field. The approximate expression derived on the basis of a quantum-mechanical perturbation theory has been successfully tested for nitrobenzene and acetone.

Many theoretical expressions have recently been presented for solvent effects on frequency shifts in electronic absorption spectra. There are, however, few theoretical expressions relating to solvent effects on intensities of electronic transitions in solute molecules. The only explicit expression

relating an oscillator strength of solution to that of vapor was given by Chako[1] who used the classical dispersion theory. Schuyer[2] gave a classical extension relating a molar extinction coefficient of solution to that of vapor. Weigang[3] and Liptay[4] independently presented expressions of an integrated intensity.

In the present work, attempts are made to present a new expression for the oscillator strength of solution on the basis of a quantum-mechanical theory, and to compare the result with previous theories. The approximate expression is applied to the data for nitrobenzene and acetone.

Theoretical

Spectra of solutions are usually measured at very low concentrations. Let us consider a solution containing numerous solvent molecules and one neutral solute molecule, and assume that the solute molecule is contained within a spherical cavity in an isotropic continuous medium of the solvent. According to the Franck-Condon principle the same molecular configurations are assumed for the ground and excited states of the solute. The present theory does not include specific effects like hydrogen bonding and complexing.

Solution spectra are commonly measured by using transparent solvents. Thus we can assume that the electronic absorption region of the solvent is at shorter wavelengths than that of the solute.

We consider an electromagnetic radiation field of frequency ν with an electric field $\vec{E}$. The change of field $\vec{E}$ with time t may be written as

$$\vec{E}(\nu) = -\frac{1}{\sqrt{\varepsilon(\nu)}\,\{c/n(\nu)\}} \times \frac{\partial}{\partial t}\vec{A} \tag{1}$$

where $\vec{A}$ is a vector potential, c is the velocity of light in a vacuum, and $n(\nu)$ and $\varepsilon(\nu)$ are the refractive index and dielectric constant of the solvent at ν, respectively. In Eq. (1) a scalar potential is neglected, since the wavelength of the radiation is much longer than the diameter of the cavity. In electromagnetic theory a radiation density $\rho(\nu)$ is given by:

$$\rho(\nu) = \frac{\varepsilon(\nu)}{4\pi} \times \overline{E^2(\nu)} \tag{2}$$

Applying the Onsager cavity field, the author assumes that a particle of charge e_j in the solute molecule immersed in the solvent in the presence of the electromagnetic field is subjected to the force

$$\vec{F} = e_j \times \frac{3n^2(\nu)}{2n^2(\nu)+1} \times \vec{E}(\nu) \tag{3}$$

Reaction field is neglected herewith, assuming that the effect of the reaction field is much smaller than that of the cavity field. The effect of magnetic intensity of light is also neglected, since the velocity of electrons in the solute is small compared to that of light.

Starting from Eq. (3) and calculating in the same way as Eyring, Walter and Kimball,[5] we can approximately write the Einstein transition probability coefficient $B_{0\to i}$ for an electronic transition from the ground state to the ith-excited state in the solute molecule as

$$B_{0\to i} = \frac{8\pi^3}{3h^2} \times \frac{9n_D^2}{(2n_D^2+1)^2} \times |\vec{\mu}_{0i}^{\,0}|^2 \tag{4}$$

where h is the Planck constant, n_D is the refractive index of the solvent at the frequency of sodium-D line, and $\vec{\mu}_{0i}^{\,0}$ is the transition moment from the ground state to the ith-excited state for the free solute molecule. In Eq. (4) $n(\nu)$ is replaced approximately by n_D.

By the definition of oscillator strength, we find the theoretical expression for the oscillator strength of the transition of the solute molecule in solution from Eq. (4) as

$$f_{0\to i}^{\text{theor}}(\text{soln}) = \frac{mhc\bar{\nu}_{0i}}{\pi e^2} \times B_{0\to i} = \frac{8\pi^2 cm}{3he^2} \times \frac{9n_D^2}{(2n_D^2+1)^2} \times \bar{\nu}_{0i}|\vec{\mu}_{0i}^{\,0}|^2 \tag{5}$$

where e and m are the charge and mass of an electron, respectively, and $\bar{\nu}_{0i}$ is the transition energy of the solute in solution in unit of cm^{-1}. From Eq. (5), we find the relation

$$f_{0\to i}^{\text{theor}}(\text{soln})/f_{0\to i}^{\text{theor}}(\text{vap}) = \frac{9n_D^2}{(2n_D^2+1)^2} \times \frac{\bar{\nu}_{0i}^0}{\bar{\nu}_{0i}^0} \tag{6}$$

where $\bar{\nu}_{0i}^0$ is the transition energy of the free solute.

When the traditional Lorentz field is used instead of the Onsager cavity field, we can derive the following approximate expression by the same method as described above.

$$B_{0\to i} = \frac{8\pi^3}{3h^2} \times \frac{1}{n_D^2} \times \left(\frac{n_D^2+2}{3}\right)^2 \times |\vec{\mu}_{0i}^{\,0}|^2 \tag{7}$$

Thus we have

$$f_{0\to i}^{\text{theor}}(\text{soln}) = \frac{8\pi^2 cm}{3he^2} \times \frac{(n_D^2+2)^2}{9n_D^2} \times \bar{\nu}_{0i}|\vec{\mu}_{0i}^{\,0}|^2 \tag{8}$$

Accordingly, we have the relation

$$f_{0\to i}^{\text{theor}}(\text{soln})/f_{0\to i}^{\text{theor}}(\text{vap}) = \frac{(n_D^2+2)^2}{9n_D^2} \times \frac{\bar{\nu}_{0i}}{\bar{\nu}_{0i}^0} \tag{9}$$

Experimental Expression for Solution Oscillator Strength. The experimental oscillator strength for the solute molecule in solution has been customarily determined by

1) N. Q. Chako, *J. Chem. Phys.*, **2**, 644 (1934).
2) J. Schuyer, *Rec. Trav. Chim. Pays-Bas*, **72**, 933 (1953).
3) O. E. Weigang, Jr., *J. Chem. Phys.*, **41**, 1435 (1964).
4) W. Liptay, *Z. Naturforsch.*, **21A**, 1605 (1966).
5) H. Eyring, J. Walter and G. E. Kimball, "Quantum Chemistry," John Wiley & Sons, Inc., New York (1949), p. 107.

$$\bar{f}^{\exp}_{0\to i}(\text{soln}) = \frac{10^3 \ln 10 \cdot mc^2}{\pi e^2 N}\int \kappa(\tilde{\nu})\mathrm{d}\tilde{\nu} \qquad (10)$$

where N is the Avogadro number, and $k(\tilde{\nu})$ is a molar extinction coefficient. Equation (10) has been derived on the assumption that the velocity of light in the solution is equal to that in a vacuum. When the velocity of light in the solution is considered by replacing c by $c/n(\nu)$, as pointed out by Baba,[6] we can approximately write

$$f^{\exp}_{0\to i}(\text{soln}) = \frac{10^3 \ln 10 \cdot mc^2}{\pi e^2 N} \times \frac{1}{n_D^2}\int \kappa(\tilde{\nu})\mathrm{d}\tilde{\nu} \qquad (11)$$

Thus we can relate $\bar{f}^{\exp}_{0\to i}(\text{soln})$ to $f^{\exp}_{0\to i}(\text{soln})$ as

$$f^{\exp}_{0\to i}(\text{soln}) = (1/n_D^2) \times \bar{f}^{\exp}_{0\to i}(\text{soln}) \qquad (12)$$

Discussion

The Onsager cavity model is adopted in the present theory. Any deviation of the cavity from spherical symmetry would result in a great difference between the observed and theoretical ratios of the oscillator strength of solution to that of vapor. It is, however, probable that a thermal motion makes the cavity nearly spherical.

If the Onsager reaction field is considered in Eq. (3), the expression for the oscillator strength will differ from Eq. (5), but the difference will not be great.

Equations (5) and (8) show that the effective microscopic fields and the dielectric constant of the solvent at ν_{0i} have important roles for the solvent effects on the oscillator strength. It is, of course, better to use the refractive index measured at the frequency of ν_{0i}, although n_D was used herewith for the sake of convenience.

Previous Theories. *(1) Chako's Formula.* Chako's formula[1] based on the classical dispersion theory is usually written as

$$f^{\text{theor}}_{0\to i}(\text{soln})/f^{\text{theor}}_{0\to i}(\text{vap}) = (n_D^2+2)^2/9n_D \qquad (13)$$

(2) Schuyer's Theory. An original formula (Eq. (29) in Ref. 2) derived by Schuyer[2] from the theory of Onsager-Böttcher may be approximately written as

$$\frac{(2n_D^2+1)(n_D^2+1)}{6n_D^3} \times \kappa(\tilde{\nu}_{0i}) = \text{constant} \qquad (14)$$

Combining Eq. (14) with $k^0(\tilde{\nu}_{0i})$=constant for n_D=1, we have

$$\kappa(\tilde{\nu}_{0i}) = \frac{6n_D^3}{(2n_D^2+1)(n_D^2+1)} \times \kappa^0(\tilde{\nu}_{0i}) \qquad (15)$$

Putting Eq. (15) into Eq. (11), we obtain after some calculation

$$f_{0\to i}(\text{soln})/f_{0\to i}(\text{vap}) = 6n_D/(2n_D^2+1)(n_D^2+1) \qquad (16)$$

Assuming the simple relation $f_{0\to i}(\text{soln})/f_{0\to i}(\text{vap}) = k(\tilde{\nu}_{0i})/k^0(\tilde{\nu}_{0i})$ on the basis of Schuyer's theory, Bayliss and Wills-Johnson[7] presented a formula different from Eq. (16).

(3) Weigang's Theory. Applying Moffitt and Moscowitz's formula[8] for dispersion, Weigang[3] presented the expression

$$\int \frac{\kappa(\nu)}{\nu}\mathrm{d}\nu = \frac{8\pi^3 N}{3\times 10^3 \ln 10 \cdot hc} \times \frac{\{n^2(\nu)+2\}^2}{9n(\nu)} \times \frac{|\vec{\mu}_{0i}|^2}{k} \qquad (17)$$

where k is the number of the solute molecules contained in a small cavity, and $\vec{\mu}_{0i}$ is the transition moment for the solute molecule in solution. The Lorentz condition is included in Eq. (17). Using Weigang's expression[3] for $\vec{\mu}_{0i}$, we may write $B_{0\to i}$ as follows

$$\begin{aligned} B_{0\to i} &= \frac{10^3 \ln 10 \cdot (c/n_D)}{hN}\int \frac{\kappa(\nu)}{\nu}\mathrm{d}\nu \\ &= \frac{8\pi^3}{3h^2} \times \frac{(n_D^2+2)^2}{9n_D^2} \times |\vec{\mu}^0_{0i}|^2 \times \left\{1 + A \times \frac{n_D^2-1}{2n_D^2+1} \right. \\ &\quad \left. + B \times \frac{n_D^2-1}{2n_D^2+1} - C\left(\frac{\varepsilon_0-1}{\varepsilon_0+2} - \frac{n_D^2-1}{n_D^2+2}\right)\right\}^2 \end{aligned} \qquad (18)$$

where the coefficients of A, B and C are characteristic of the solute, the cavity radius and the absolute temperature. Equation (18) may be approximated to Eq. (7). Thus we obtain the relation identical to Eq. (9) from Weigang's theory.

(4) Liptay's Theory. Liptay[4] presented the following formula.

$$\begin{aligned} \int \frac{\kappa(\tilde{\nu})}{\tilde{\nu}}\mathrm{d}\tilde{\nu} &= \frac{8\pi^3 N}{2.303\times 10^3 \times 3h(c/n_D)} \times |\vec{\mu}^0_{0i}|^2 \\ &= \frac{8\pi^3 N}{2.303\times 10^3 \times 3h(c/n_D)} \times [|\vec{\mu}^0_{0i}|^2 + \tilde{R}\vec{F}_{RW} \\ &\quad + \tilde{F}_{RW}(\vec{P}+\vec{Q})\vec{F}_{RW} + 2Re\{\tilde{\mu}^0_{0i}\vec{W}_{0i}\}f'] \end{aligned} \qquad (19)$$

Here the notations refer to Liptay's original paper. In Eq. (19), c in the original formula of Liptay is replaced by c/n_D. Carrying out the same calculation as in the case of Weigang's theory, we obtain approximately

$$f_{0\to i}(\text{soln})/f_{0\to i}(\text{vap}) = \tilde{\nu}_{0i}/\tilde{\nu}^0_{0i} \qquad (20)$$

It is obvious from Eq. (19) that Liptay did not consider any effective microscopic field such as the Onsager cavity or Lorentz field.

Application

Equations (6), (9), (13), (16) and (20) were applied to the 240 mμ band of nitrobenzene and to the 280 mμ band of acetone. The results are summarized in Tables 1 and 2.

TABLE 3. RATIOS OF CUSTOMARY OSCILLATOR STRENGTHS OF NITROBENZENE

Solvent	n[10] 2800 Å	$\frac{\bar{f}^{exp}(soln)}{\bar{f}^{exp}(vap)}$ (from Refs. 9 and 10)	$\frac{n^2 f^{theor}(soln)}{f^{theor}(vap)}$ (Eq. (6) $\times n^2$)
Vapor	—	1	1
n-Heptane	1.42	1.3_5	1.38
Cyclohexane	1.47	1.5_3	1.41
Chlororoform	1.50	1.4_7	1.38

The ratio of the customary experimental oscillator strength of solution to that of vapor can be directly compared with the theoretical value. Using Eq. (6) and values of refractive indexes for 2800 Å, the values of $\bar{f}^{exp}(soln)/\bar{f}^{exp}(vap)$ were compared with those of $n^2 f^{theor}(soln)/f^{theor}(vap)$, as indicated in Table 3.

The values of $\bar{f}^{exp}$ by Bayliss and Wills-Johnson were computed by assuming the spectra to be symmetric about absorption maxima.[7] As Bayliss and Wills-Johnson[7] mentioned, the determination of oscillator strength is complicated by the fact that the transitions under investigation are overlapped by other transitions. In view of the above discussion, Tables 1—3 seem to show that Eq. (6) best reproduces the experimental results among the five theoretical formulas.

The author is particularly indebted to Professor Yoshito Amako for discussion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 629—632 (1970)

Measurement of the Adsorption of Tritium Labelled Sodium Stearate at Air/Water Interface using Thin Windowed Geiger-Müller Counter Tube

Keiichi SEKINE, Tsutomu SEIMIYA and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received May 29, 1969)

The adsorption of tritium labelled sodium stearate at various pH values and temperatures was directly measured by using a thin end-windowed Geiger-Müller counter. The disturbances due to the application of high electrical potential and the introduction of counting gas were avoided, which are inevitably encountered in an ordinary windowless 2π counter. Precautions were taken to avoid both surface evaporation effect and contamination of solution due to the absorption of carbon dioxide from the air. The results show that free stearic acid is considered to be the main surface active species in an aqueous sodium stearate.

The radiotracer technique using tritium is particularly suited for the accurate measurement of adsorption because of extreme softness of its beta radiation. But for this same reason the counting of tritium radiation suffers from errors which should not be overlooked. For tritium beta-counting, a windowless gas flow 2π counter is often used because of its high detection efficiency,[1] and the adsorption of tritium labelled detergent at air-water interface has been measured by this method.[2] However, this counter introduces several difficulties in the measurement of the radioactivity from aqueous surface. They arise chiefly from the high electrical potential applied between the solution surface and the anode placed over it for the counting of radioactivity, and from the contamination of the aqueous surface by a counting gas such as propane, though a good counting stability is shown against moisture. These disturbances can be shown by the following.

In the first experiment, the surface tension of water and that of aqueous solution of sodium dodecyl sulfate (SDS) were measured at 20°C by the Wilhelmy method in atmosphere with and without propane gas. No surface tension depression was observed when the water surface was brought to contact with propane gas, whereas for 5×10^{-3} mol/l aqueous SDS solution the surface tension depression of about 2.3 dyne/cm was produced by contact of propane gas with the aqueous surface. This evidently shows the influence of propane gas, presumably producing a change in adsorption of SDS and/or propane due to its contact. Such a change was demonstrated in a separate experiment.

In the second experiment, the effect of applied electric field upon the surface tension of aqueous solution was checked at the same temperature. Using the electrode assemblies which simulate the conditions of the counting chamber of a windowless 2π counter usually employed in such a measurement, the surface tension of aqueous SDS solution was measured with and without an applied electric field of 4000 V in the propane gas atmosphere. In this experiment precaution was taken to avoid the influence of direct electrical interaction, if any, between the anode and the glass plate for the surface tension measurement. The results show a surface tension drop of 3.1 dyne/cm for an aqueous surface of SDS solution (5×10^{-3} mol/l) in propane gas by the application of 4000 V external field, while in the case of water surface only 0.1 dyne/cm drop was observed for the surface tension under the same condition. We can observe the streaming of the solution at the surface caused by applied electrical potential from the motion of talc scattered over the surface. These experiments also show the possibility of undesirable effect of high electrical potential upon the establishment of the true adsorption equilibrium. Therefore measurements free from such disturbances are desired.

In our preceding paper,[4] we stated that soft tritium radioactivity could be measured effectively by using a thin polycarbonate end-windowed Geiger-Müller counter tube without the difficulties which an ordinary windowless flow-counter encounters. It also enables measurements free from the above electrical and surface chemical disturbances. In the present investigation, we employed this method for the measurement of the adsorption of tritium labelled sodium stearate on aqueous surface. Here, precautions were further taken to avoid both

the surface evaporation affecting the surface concentration of the solute,[5] and the absorption of carbon dioxide into the solution from atmosphere, which proved to have great effect on the results.[6]

It may be mentioned in this connection that Flengas and Rideal also studied the adsorption of ^{14}C-labelled sodium stearate solutions[7] and obtained results somewhat different from ours as will be described later. Their results, however, involve some uncertainty as to the solubilities of soap,[8] evaporation effect, the constancy of pH and the effect of carbon dioxide[3,6] since no distinct statements concerning them could be found. The present paper described the apparatus and measurement of adsorption of sodium stearate, free of these uncertainties and the errors due to the applied electrical field and contact with gas.

Experimental

Apparatus. The surface concentration was measured by a gas flow GM-counter (FC-16, Japan Radiation and Medical Electronics Inc.), the counter tube being equipped with an end-window of a thin polycarbonate film[4] of 34 mm effective aperture. The tritium-labelled sodium stearate was dissolved in distilled water and the solution was contained in a 120×61 mm rectangular Teflon trough of 5.6 mm depth. The distance between the window of the counting tube and the aqueous surface was kept to 0.5 mm by means of a platinum needle fixed to the window. A movable barrier was placed on the trough and was operated from outside the thermostatted box to sweep the aqueous surface.

Special care was taken to avoid a change of geometry due to the difference in pressure across the thin window, by supporting the film with a perforated thin brass sheet (0.15 mm thick and 50% perforation in area). In order to avoid surface evaporation and absorption of carbon dioxide from the surrounding atmosphere, nitrogen gas which was passed through charcoal and saturated with water, was let to flow gently over the liquid surface. The whole apparatus was put in an air thermostat of 30, 40 and 50°C during the experiment.

Materials. Sodium stearate was prepared by dissolving tritium-labelled stearic acid (specific activity 7 Ci/mol)[9] in absolute alcohol freshly distilled over sodium hydroxide, and a smaller amount of sodium hydroxide than that required for neutralization of the acid was added. The soap solution thus prepared was evaporated to dryness *in vacuo*, and the residue was washed with benzene to remove excess stearic acid using a Soxhlet extractor. The water used in this experiment was obtained by refluxing ordinary distilled water in an acid permanganate solution for 24 hr, then adding excess alkali and distilling. Water thus obtained was further distilled twice from Hysil flasks connected in series.

Procedures. The calibration curve used for calculating the amount of adsorption from the observed counting rate was made by measuring the counting rate of a known amount of radioactive stearic acid monolayer spread on water surface. For this purpose the trough was filled with water of pH controlled to 5.5 by adding distilled hydrochloric acid, and tritium-

labelled stearic acid having the same sprecific activity as that of the tritium-labelled sodium stearate was spread on water surface from 2.40×10^{-4} mol/l benzene solution by means of a microsyringe. The plots of the counting rate *versus* surface concentration were obtained from the radioactivity measurements made at various surface concentrations by compressing and expanding the monolayer. The result is shown in Fig. 1.

At low surface concentration, surface heterogeneity and its time dependence were observed for this monolayer by the radioactivity measurement (Fig. 2a). Usually, however, by standing the surface film at 20°C for at least several hours the film became homogeneous and the time dependence practically vanished when detected by means of radioactivity. As the surface concentration increased, the surface film became more homogeneous and time effect also disappeared (Fig. 2b).

To measure the adsorption of sodium stearate at solution-air interface the radioactive sodium stearate solution of 2.5×10^{-5} mol/l concentration was put in the same Teflon trough as used in the monolayer measurement, and the counting of surface radioactivity was started immediately after the sweeping of surface by the barrier. The geometry of the whole arrangement including the GM-tube was kept constant.

The counting rate obtained by subtracting the one due to the bulk of the solution[2] from the observed surface counting rate gives the amount of sodium stearate adsorbed at the solution/air interface. In this experiment, the bulk counting rate turns out to be a very small fraction of the total counting rate, being comparable to the back ground counting rate when the monolayer adsorption is established. This fact may be expected from an extremely low concentration of the solution (2.5×10^{-5} mol/l) and the softness of beta-ray. This can also be confirmed by the fact that for some solutions the surface counting rate at the initial stage of measurement is comparable to that of the back ground. Therefore the bulk counting rate can be neglected within the limit of the counting error. The pH of the solution was controlled by hydrochloric acid and sodium hydroxide free from carbon dioxide, and was kept constant throughout the experiment within ±0.1 by keeping the trough in a humidified nitrogen atomsphere. Measurements were made at 30, 40 and 50°C, and the concentration of sodium stearate was kept at 2.5×10^{-5} mol/l throughout the experiment.

Results and Discussion

The equilibrium amount of adsorption Γ was measured and plotted against the pH of the solution at each temperature as shown in Fig. 3. The curves for 30 and 40°C show plateaux in the pH region proper for each system and the Γ values of these plateaux nearly agree with that of monolayer

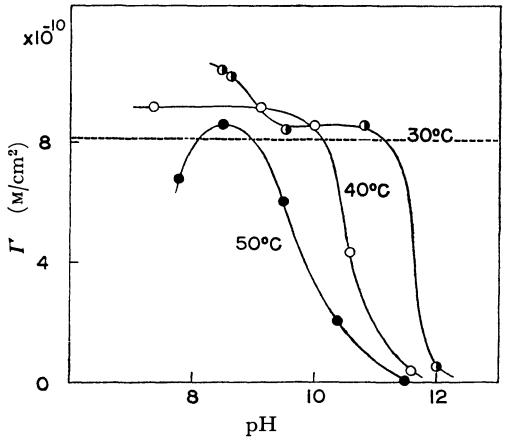

Fig. 3. pH dependence of stearate adsorption at air/solution interface.
Concentration of sodium stearate : 2.5×10^{-5} mol/l

adsorption (dotted line in Fig. 3) calculated by using the value of 20.5 A^2/mol known as the area occupied by a stearic acid molecule on water. In a less alkaline region Γ exceeds the monolayer value at 30°C, while Γ is smaller than the monolayer value at 50°C.

Apart from some irregularities, the agreement of Γ value of the plateaux with that of monomolecular area of stearic acid suggests the possibility that the adsorption layer actually consists of stearic acid instead of stearate ion. We have some evidence to support this view. Lucassen[10] pointed out that the major species of the aqueous solution prepared by dissolving sodium stearate in distilled water is changed to free stearic acid. Harkins[11] also observed a relatively high surface tension for an aqueous sodium laurate solution in an alkaline region, and low surface tension for a neutral solution and gave a similar explanation. Our study on the surface pressure-area curve for sodium stearate by means of the simultaneous measurements of the amount of adsorption and surface tension of the solution suggests that the adsorbed species is stearic acid.[3] Figure 3 shows that at pH higher than 12, the amount of adsorption of the solution is almost reduced to zero. This sudden decrease of adsorption is ascribed to salting out of the soap due to the high concentration of sodium hydroxide added, causing decrease of concentration of stearate ion. To assure the concentration decrease of soap solution at high pH, soap solutions at pH 10.7 and 12.3 were centrifuged, and the concentration of the supernatant solution was determined by radioactivity measurement. The results show a marked decrease of soap concentration in the solution for pH 12.3 while no tendency of decrease is observed for 10.7. Flengas and Rideal[7] reported a higher value of stearate adsorption than ours in this pH region. However, their results do not seem to confirm the presence of carbon dioxide in an atmosphere which influence the amount of adsorption (possibly resulting in an overestimation), since it can be confirmed[6] that the amount of adsorption is quite sensitive to the presence of carbonate ions in solution even in the pH of the solution is kept unchanged.

We note the decrease of adsorption below pH 8 at 50°C. This may be explained by the formation of free stearic acid precipitate[10] as recognized by the turbidity of the solution. However, the increase of adsorption beyond the monolayer at 30°C remains unexplained at present.

An overall trend of decrease of adsorption with temperature is also seen. The adsorption may be affected by temperature in two ways. One, by enhanced degree of bulk hydrolysis at high temperatures, and the other, by the increased solubility of stearic acid at higher temperature. Adsorption is expected to increase in the former case and decrease in the latter case. The result suggests that the latter tendency is dominant as far as the present experimental conditions of temperature and time ranges are concerned.

We are of the opinion that in an aqueous sodium stearate solution the surface active species is exclusively free stearic acid, while stearate ion is less surface active. The adsorption of stearic acid is unexpected although suggestions have been made as to the hydrolysis in bulk of the solution by other investigators. It should be emphasized that the present conclusion is mainly based upon the results of direct adsorption measurements in comparison with the conclusions or predictions obtained more or less theoretically and indirectly.

Thinning of Nonionic Detergent Films

Teruko YAMANAKA*1

Department of Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama

(Received June 21, 1969)

The effect of added electrolytes on the thinning of single vertical film formed from nonionic detergent solution has been studied. Addition of the electrolytes did not show an appreciable effect on the thinning of the film in the region of interference fringes. Specific effects of anions upon the "blackening time" (the time necessary for turning the total film area completely into a black film) were observed similarly to those on the cloud point. The order of magnitude of these effects followed the lyotropic series, which may be explained qualitatively by the effects on the dehydration of detergent molecules and on the electrical double layer of the film. The effect of the electrolytes on aqueous ionic detergent film was also examined. It was mainly explained by their influence on the electrical double layer.

Single liquid film is considered to be a very simple colloid system, and is useful in elucidating various colloidal and interfacial phenomena. Interest has been shown by many investigators,[1-4] particularly the kinetic study of single liquid film stabilized by ionic detergent for its influence on the drainage of the film. However, there are few reports on nonionic detergent films.[5,6]

It has been confirmed that the effects of the addition of electrolytes on the foam stability and on the cloud point of aqueous solutions of nonionic detergent are similar.[7] They are both specific for anion and follow the lyotropic series.

The purpose of this work is to study the effect of the addition of electrolytes upon the thinning of single liquid film formed from aqueous nonionic detergent solutions, in connection with the investigation of foaming. In observing the thinning process of liquid film, special attention was paid to the rate of formation of an ultra-thin film, the so called "black film", which always appears in the last stage of the draining process of the liquid film.

Experimental

Materials. Polyoxyethylene nonylphenyl ether (PNP) was obtained from commercially available PNP by molecular distillation. The average chain length of the ethylene oxide adducts obtained by distillation was determined from their hydroxyl values to be 11.4 in ethylene oxide units. The aqueous solutions of this compound exhibited a sharp break in the plots of surface tension against logarithm of concentration, so it is considered to be sufficiently homogeneous. Sodium dodecylsulphate (SDS) was prepared by the reaction of $C_{12}H_{25}OH$ with $ClSO_3H$ and purified by the ordinary procedure. Inorganic electrolytes were of analytical reagent grade and were purified by using a soxhlet extractor with ether as a solvent, except for HCl and NaOH which were used without further purification. Water was distilled first in a hard glass apparatus from potassium permanganate solution to remove organic impurities and then was redistilled in a quartz glass apparatus. All solutions were freshly prepared before use.

Apparatus and Procedure. The method used for these measurements is similar to that discribed by Miles and co-workers[8] and by Lyklema and co-workers.[9] The apparatus consists essentially of a square cell 4×4 cm containing the solution and a rectangular frame supported from above. The rectangular frame is made from a glass rod of about 1 mm in diameter, and is 2.3 cm wide for PNP solutions and 1.4 cm wide for SDS solutions.

After standing the solution in the closed cell for about 17 hr, the frame was vertically withdrawn in about 5 sec

Time: time elapsed after formation of liquid film.
Aqueous solutions: 0.1% PNP (a), 0.1% PNP+Na_2CO_3 [0.1N (b) 0.5N (c) 0.8N (d) 1N (e)], 0.1% PNP+NaCl [0.1N (b') 0.5N (c') 1N (d') 2N (e')]

from the solution by manual opperation so that the top of the frame was 3 cm above the solution surface (2.5 cm in the case of SDS solutions). Xenon lamp was used for illuminating the film. By using optical filters, wave length was limited to 400—450 mμ with the maximum at about 417.5 mμ. The positions of interference fringes and boundary between black and silver film were measured and expressed as the distance from the solution surface on the photograph properly enlarged. All the measurements were carried out in a thermostated room of 30±1°C.

Results

The effect of the addition of electrolytes on the thinning process of single liquid film was measured for 0.1% PNP aqueous solutions. For comparison, the observation was made with 1×10^{-2}M SDS solutions in the presence of NaCl and Na_2SO_4.

Freshly formed films quickly drain and the horizontal interference fringes are produced. The film drains further and a silver film appears at the top of the film and spreads downward. Finally a black film develops and its area gradually increases at the expense of silver film. The boundary between black and silver films is very sharp and horizontal except for the place near the frame. Black films so formed are fairly stable, with the exception of those formed from pure SDS solution. Their average life is more than 2 hr.

Aqueous PNP Solutions. Figure 1 shows typical effects of concentration of some electrolytes upon the rate of descent of the black-silver boundary. The positions of the black-silver boundary are plotted against time elapsed after complete formation of the liquid film. The time necessary for turning the whole film area into a black film, which is taken as the standard of the rate of formation of a black film, was also measured in all solutions. For brevity, this is called "blackening time" in this paper.

Curves of the descent of black-silver boundary in liquid films formed from aqueous solutions of PNP with and without added electrolytes can be classified into three types. Type 1 curve shows that the rate of descent of the black-silver boundary is faster in the early period and slower in the later stage, except for the first stage. This type appears in the case of relatively long blackening time. Type 2 curve shows a nearly constant rate of descent. Each instance is shown by (a) and (c) in Fig. 1. In the same electrolytes, curves of the descent tend to change into type 2 from type 1 with increasing concentrations, and the tendency is marked in the case of shorter blackening time. Type 3 curve, which shows a slow rate of descent in the early stage and a fast one in the final stage, only appears in the case of addition of 1N NaOH.

Contrary to these behaviors, the drainage of the film in the region of interference fringes is not affected by the addition of electrolytes.

Figure 2 shows the effect of added electrolytes and their concentrations upon the blackening time. Evidently, blackening time of liquid films formed from PNP solutions is greatly affected by the nature and concentration of the added electrolytes. The effect is classified into two types; namely electrolytes which decrease and those which increase blackening time with increasing concentration. The electrolytes can be arranged in the following series according to the order of magnitude of blackening time. $Na_3PO_4<Na_2CO_3\simeq Na_2SO_4<NaF\simeq NaOH\ll NaCl\simeq KCl\simeq LiCl\simeq NaSCN\simeq HCl$.

Ions such as SCN^- and Cl^- act as an inhibitor whereas PO_4^{3-}, SO_4^{2-}, CO_3^{2-}, F^- and OH^- ions act as a promoter for the black film formation. It is evident that the effect is not so sensitive to the

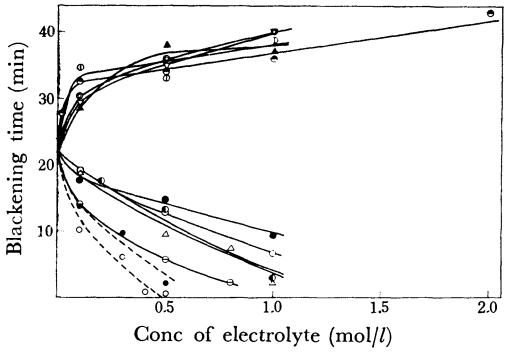

Fig. 2. Effect of added electrolytes on the blackening time of liquid films at 30°C. (average of five films)
Aqueous solutions: 0.1% PNP+electrolyte (◎ NaSCN, ▲ HCl, ▽ LiCl, ⓘ KCl, ◓ NaCl, ● NaOH, ○ NaF, ◐ $1/2Na_2SO_4$, △ $1/2Na_2CO_3$, ⊖ $1/3Na_3PO_4$), 1×10^{-2} mol/l SDS+electrolyte (---●--- $1/2Na_2SO_4$, ---○--- NaCl)

nature of cation, but is specific to the nature of anion, and the series is similar as a whole to the lyotropic series of anions.

With regard to the region of the interference fringes, the change of the film thickness with time at its center is almost independent of the nature and concentration of the electrolytes added as shown in Fig. 3. The film thickness is calculated from the order of interference fringes.

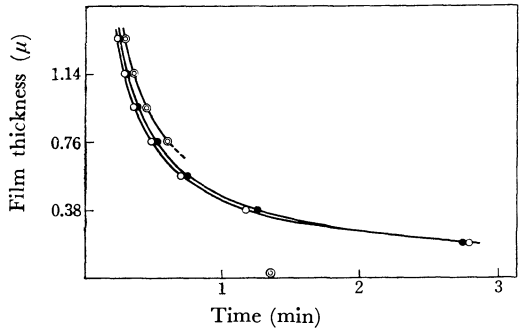

Fig. 3. Time dependence of film thickness at center of films at 30°C.
Aqueous solutions: 0.1% PNP+electrolyte (○ 0, ● 0.5N Na_2CO_3, ◎ 0.8N Na_3PO_4)

Aqueous SDS Solutions. Measurements of the SDS solutions were performed for a smaller film area (width 1.4 cm, height 2.5 cm), because the instability of the liquid film of pure SDS solution prevented the use of a larger frame employed in the measurement of PNP solutions.

The broken lines in Fig. 2 show the effect of added electrolyte upon the blackening time of films formed from 1×10^{-2}M SDS solutions. It is evident that the effect of electrolytes is quite different for the films formed from SDS and PNP solutions. Addition of NaCl prolongs blackening time in the case of PNP solutions, whereas in the case of SDS solutions blackening time is shortened.

Discussion

Thinning of vertical thin film is caused mainly by gravity and the border suction when the film is thick. However, the van der Waals force and electrostatic repulsion become important as the thinning advances by drainage to such an extent that the formation of a black film begins.[10]

Overbeek explained the mechanism of the formation of balck film as follows.[2] The welt at the boundary between black and colored films is a kind of border and sucks the colored film (a thicker film) by border suction to form more black film (a thinner film). An excess liquid accumulates at the welt and later flows down as a two-dimensional droplet. The rate of formation of a black film depends upon the electrostatic repulsion between detergent ions adsorbed on both surfaces of the film, the van der Waals force acting among all the molecules in the film and the viscous resistance in the film.[2] However, a precise interpretation of this kinetic process is not clear.

On the other hand, it has been proved experimentally that the thin film has a sandwich structure, consisting of two surface layers and inner core of solutions.[11] Of the forces acting on the thin film, the force between water molecules gathered around the polar heads of the detergent molecules assumes considerable importance in films of an aqueous nonionic detergent. However, in the case of aqueous ionic detergent film, the electrostatic repulsion between the charged surface layers on both sides of the film becomes important as well.

Thus the influence of electrolyte on black films may be explained as follows.

For nonionic detergent, added electrolytes affect the stability and so the rate of drainage of the film through their influence on the amount of hydration and on the formation of the diffuse double layer.

It is recognized that the solubility of polyoxyethylated detergents is closely related to the hydration of ethylene oxide. The effect of added electrolyte on black film is considered to cause dehydration of the ethylene oxide chains and this results in the decrease of steric repulsion against the thinning of the film. Thus, small or polyvalent and strongly hydrated ions are expected to be more effective in decreasing stability and increasing the rate of drainage than large and weakly hydrated ions. However, to elucidate the increase in stability and the retardation of film drainage produced by some electrolytes the possibility of electrostatic repulsion of surface film should be also taken into account,

10) A. Scheludko, "Colloid Chemistry," Elsevier Pub. Co., Amsterdam, London, N. Y. (1966), p. 173.
11) J. M. Corkill, J. F. Goodman, D. R. Haisman and S. P. Harrold, *Trans. Faraday Soc.*, **57**, 821 (1961).

since the added electrolytes are expected to be adsorbed at the film surface to form a diffuse electrical double layer. This effect would be stronger for weakly hydrated large ions than strongly hydrated small ions.

It may be expected that large ions such as SCN^- and Cl^- increase while small or polyvalent ions such as OH^-, F^-, CO_3^{2-}, SO_4^{2-} and PO_4^{3-} decrease the stability of the film. The results shown in Fig. 2 are in line with this explanation. It should be inferred that such an explanation is in accord with the lyotropic effect of anions. A similar effect of electrolytes on the cloud point of nonionic detergent could be observed.[7]

As regards the effect of electrolyte on the ionic detergent, increase in the rate of black film formation with increasing concentration of electrolyte may be explained by the contraction of the diffuse electrical double layer and the resulting decrease of the repulsion between two surface layers. The minor difference observed in the effect between Na_2SO_4 and NaCl requires further study. It should be noted that the mutually opposite effect of NaCl for ionic and nonionic detergent films can also be understood from the opposite effect of ions on the electrical double layer of the film.

The author expresses her gratitude to Professor K. Kinoshita and to Professor T. Sasaki for their encouragement throughout this study. The study was supported in part by a grant from the Asahi Glass Foundation for the Contribution to Industrial Technology given to Professor Kinoshita.

Ultrasonic Study of Dilute Aqueous Solutions of Urea, Guanidine Hydrochloride and Dioxane

Kiyoshi ARAKAWA, Nobuo TAKENAKA and Katsutaka SASAKI

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received July 21, 1969)

An ultrasonic study on dilute aqueous solutions of urea, guanidine hydrochloride and dioxane was made by means of a pulse method, with the intention of investigating the influence of these solutes upon the structure of water. Ultrasonic absorption coefficient was measured in the range of frequency from 15 to 45 Mc/sec, and ultrasonic velocity was measured at 5 Mc/sec. Temperature was varied from 10 to 40°C. In urea solutions, the magnitude of α/f^2 (α=absorption coefficient, f=frequency) decreases first very slowly with concentration, then rapidly in the range from about 0.5 to 3M and at about 4—6M reaches a nearly constant value. In guanidine hydrochloride solutions a similar change in the relation α/f^2 *vs.* concentration takes place with a smaller amount than in urea solution. This shows that guanidine hydrochloride has greater ability as a structure breaker in liquid water than urea. In the dioxane-water system, absorption increases with the concentration of dioxane. A nearly flat region in the absorption *vs.* concentration curve is found for a small concentration of dioxane.

This feature in the α/f^2 *vs.* concentration curve, which is found in the small concentration region, is ascribed to the "cooperative breaking effect" upon the "open-packed structure" in water.

In preceding papers[1-3] we have reported results of ultrasonic investigation on aqueous solutions of urea, alkyl-substituted urea and dioxane by means of an ultrasonic pulse technique. These materials are known as denaturing agents for proteins. The main purpose of these studies was the investigation of the influence of solutes upon the structure of water. Along this line, we have further made a detailed investigation and have chosen urea, guanidine hydrochloride and dioxane as solutes in the present study.

Experimental

Apparatus and Procedures for Measurements. The ultrasonic velocity and absorption were measured according to the pulse method developed by Pinkerton.[4] The detailed procedures for the measurements were

1) K. Arakawa and N. Takenaka, This Bulletin, **40**, 2739 (1967).
2) K. Sasaki and K. Arakawa, *ibid.*, **42**, 2485 (1969).
3) K. Arakawa and N. Takenaka, *ibid.*, **42**, 5 (1969).
4) J. M. M. Pinkerton, *Proc. Phys. Soc.*, **B62**, 86, 129, 286 (1949).

described in the preceding paper.[5] The sound velocity was measured at a fixed frequency of 5 Mc/sec. The absorption was measured in the frequency range of 15—45 Mc/sec.

Materials. Urea, guanidine hydrochloride and dioxane were obtained from Wako Pure Chemical Industry Co., Ltd. The melting points of the former two materials were 132.5±0.5°C and 175.9±0.5°C, respectively. The urea was the same as that used in the preceding study.[1] The dioxane was used after being treated according to the purification procedure described previously.[3] Its boiling point was 101.1—101.3°C.

Results

Sound Velocity. The ultrasonic velocity at 5 Mc/sec obtained for dilute aqueous solutions of urea and guanidine hydrochloride is plotted against temperature in Figs. 1 (a) and (b). The velocity *vs.* concentration curves obtained for the dilute solutions of dioxane are given in Fig. 2, and those for the entire range composition, including earlier results,[3] are given in Fig. 3.

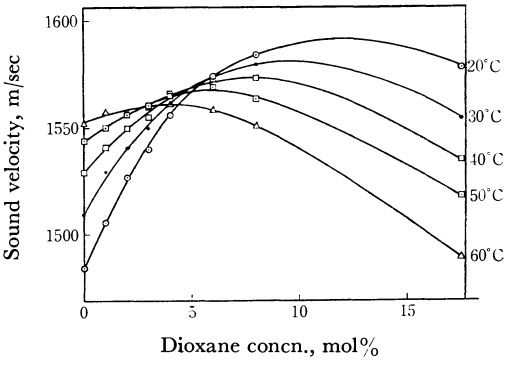

Fig. 2. Ultrasonic velocity of dioxane-water system.

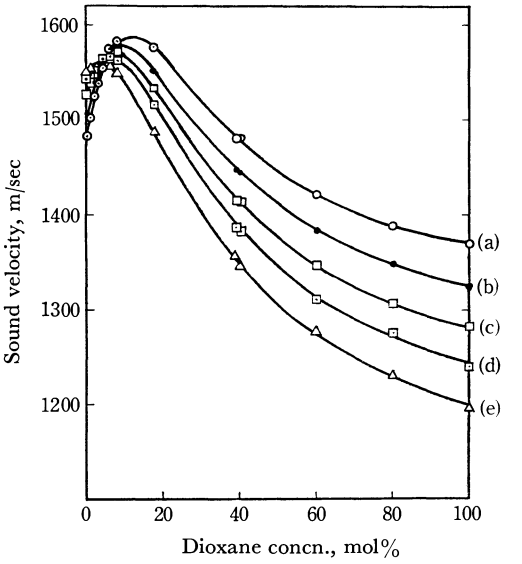

Fig. 3. Concentration dependence of ultrasonic velocity for dioxane-water system.
Temp.: (a) 20°C, (b) 30°C, (c) 40°C, (d) 50°C, (e) 60°C

We see from Fig. 2, that all curves cross at about 4 mol% of dioxane (about 2M of dioxane), but not at one point. The velocity *vs.* temperature curves for urea and guanidine hydrochloride solutions resemble each other. The accuracy of the data of sound velocity was within 2 m/sec.

Ultrasonic Absorption. The absorption coefficient, α, was measured for solutions of urea, guanidine hydrochloride and dioxane. The accuracy of α is within $\pm 2\%$. No relaxation frequency is observed for urea and guanidine hydrochloride solutions, as seen in Fig. 4(a) and (b). For the dioxane-water system, the α/f^2 *vs.* $\log f$ curves given in Fig. 4(c) decrease gradually, but a relaxation frequency can not be determined.[3]

Temp.: (a)20°C, (b) 30°C, (c) 40°C, (d) 50°C, (e) 60°C

Concentration Dependence of Ultrasonic Absorption. For urea and guanidine hydrochloride solutions, values of α/f^2 obtained are plotted against concentration by vol% in Figs. 5(a) and (b). In Fig. 6(a) the α/f^2 *vs.* concentration curves for urea solutions are plotted, including the previous data obtained for concentrated solutions,[1] those by Hammes and Schimmel[6] and those by Beauregard and Barrett.[7] In the range of concentration greater than 2M urea (about 9 vol%), the agreement of these data is very good. However, for a smaller concentration a noticeable difference is

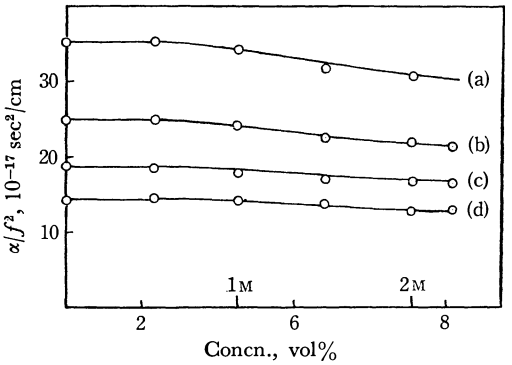

Fig. 5(a). Concentration dependence of ultrasonic absorption for urea solutions.

observed between our present data and those of Hammes and Schimmel.

As seen in Fig. 6(a), the value of α/f^2 decreases first very slowly with concentration. At a concentration greater than 0.5M urea (about 2—3 vol%), it decreases more rapidly, and at about 4—6M becomes nearly constant again.

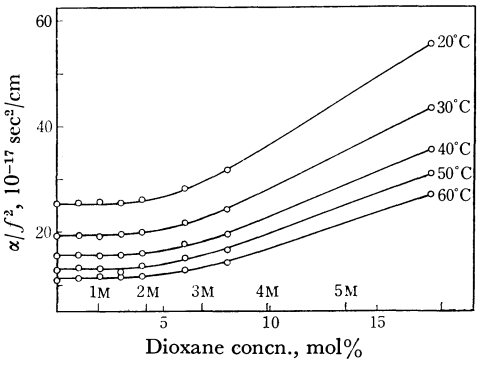

Fig. 7. Concentration dependence of ultrasonic absorption for dioxane-water system at 35 Mc.

In Fig. 6(b) the α/f^2 *vs.* concentration curve of guanidine hydrochloride solution at 10°C is given, including the data reported by Hammes and Swann.[8] In the curve, a tendency similar to that of urea solution is observed, though the decreasing rate of α/f^2 is greater than in urea solution.

For the dioxane-water system concentration dependence of α/f^2 is given in Fig. 7 for a smaller concentration than 17.5 mol% of dioxane. The results for the entire range of composition is given in Fig. 8, including earlier results.[3] As seen in

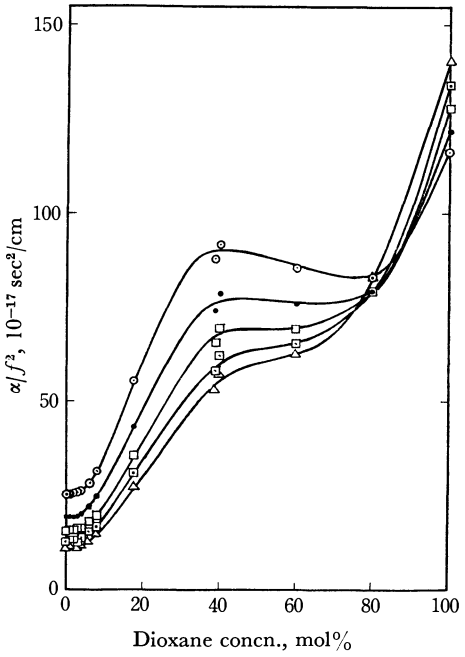

Fig. 8. Concentration dependence of ultrasonic absorption for dioxane-water system at 35 Mc.
Temp.: ⊙ 20°C, ● 30°C, □ 40°C, ⊡ 50°C, △ 60°C

Figs. 7 and 8, the α/f^2 *vs.* concentration curve is nearly flat in the concentration range smaller than about 4 mol% (about 17 vol%; about 2M in molarity). The magnitude of α/f^2 begins to increase rapidly at about 6 mol% of dioxane.

Discussion

The Structure-Breaking Effect of Urea and Guanidine Hydrochloride. Studies have been made on the effect of denaturing agents of urea-guanidium class[9-16] upon the conformation of

8) G. G. Hammes and J. C. Swann, *Biochemistry*, **6**, 1591 (1967).

protein molecules, and also on the effect of organic solvents such as dioxane,[13,17] ethanol. The effect of denaturing agents seems to be due to two factors: direct interaction between the agent and protein molecules,[10,11] and influence on conformation of protein molecules resulting from the change of the structure of water caused by the agent.[1,6,9,18]

Studies on the effect of denaturing agents upon the structure of water have been made recently by the authors,[1,2,18] Hammes *et al.*[6,8] and Beauregard and Barrett.[7] Concerning the behavior of urea in water, there are ambiguities.[19,20] However, from the results of ultrasonic studies, it has been concluded that urea behaves as a structure breaker for the clusters in water. Recently a statistical mechanical explanation of the behavior of urea as a breaker has been given by Frank and Franks.[21]

The data agree in the range of concentration greater than about 2M,[6,7] as seen in Fig. 6(a). However, for a concentration smaller than 2M, our data are greater than those of Hammes and Schimmel, and the curves by the authors are found to be nearly flat in the range of concentration smaller than about 0.5M. This tendency is seen at temperatures from 10°C to 40°C,*1 as seen in Fig. 6(a). A similar tendency is observed in guanidine hydrochloride solution.

The α/f^2 *vs.* concentration curves for solutions of urea and guanidine hydrochloride are compared in Fig. 9. The magnitude of α/f^2 for guanidine hydrochloride solutions decreases more rapidly than for urea solutions. This supports the idea that guanidine has a greater ability as a structure breaker than urea. It is also seen in Fig. 9 that the constant value of α/f^2 at about 20—30 vol% (4—6M urea) for the urea solution is nearly equal to that for the guanidine solution at about the same volume concentration (3—4M guanidine). This suggests that the "open-packed structure" in water is nearly completely disrupted with addition of 4—6M urea, and nearly the same situation occurs with addition of 3—4M of guanidine hydrochloride.

Cooperative Breaking[22] of Open-Packed Structure in Water through Addition of Solutes. Frank and Wen[22] have proposed the cooperative formation and breaking of clusters in water. A statistical theory based on the flickering cluster model has been developed by Némethy and Scheraga.[23] We have presented recently a two state theory based on the model proposed by Hall.[24,25]

The source of ultrasonic absorption is attributed to the presence of the "open-packed structure" or "flickering clusters" in water.*2 This "structure" is in equilibrium with a high density region in water as represented by:

open-packed structure $\rightleftarrows$ close-packed structure,
or
flickering clusters $\rightleftarrows$ unbonded monomers. (1)

The lifetime of clusters is believed to be of the order of 10^{-11}—10^{-10} sec,[22,23] and the formation

and breaking of them is supposed to proceed "cooperatively," as proposed first by Frank and Wen. As seen in Fig. 10, the magnitude of α/f^2 for urea solutions is greater than that given by the dotted line in an extremely small concentration. The dotted line represents calculated magnitude of absorption attributed to only water as a solvent under the assumption that no structural change takes place in water.[1,2] The α/f^2 *vs.* concentration curve at 10°C is seen to cross the line at about 1M, and the magnitude of α/f^2 decreases further with concentration. It is concluded, therefore, that the effect of urea as a structure breaker is not appreciable in an extremely dilute solution, and that the effect becomes appreciable with the increase of urea concentration (about 0.5—1M urea). This trend in the concentration dependence of α/f^2 for a small concentration seems to be ascribed to the cooperative nature of cluster formation and breaking.

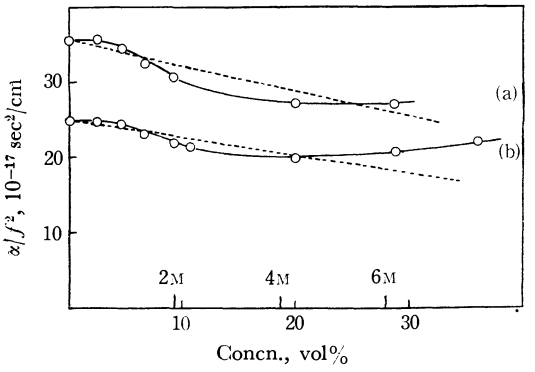

Fig. 10. Concentration dependence of ultrasonic absorption for urea solutions.
Temp. (a) 10°C, (b) 20°C
Dotted line; absorption due to water as solvent.

When a very small amount of urea is added to water, the influence of urea molecules upon the structure of water is isolating, and does not affect the cooperative formation of clusters. Phenomenologically, urea molecules enter the empty space among water molecules with no appreciable influence upon the structure. When the amount of urea becomes greater, the influence becomes appreciable, and urea affects the clusters cooperatively to disrupt them into unbonded monomers. Therefore, for a greater concentration, ultrasonic absorption decreases rapidly with concentration.

The situation is similar in guanidine hydrochloride solutions, the influence being greater than that of urea.

As for the dioxane-water system, the over-all increasing trend of α/f^2 *vs.* concentration curves becomes pronounced because of a large absorption of pure dioxane,[3] but a similar flat region appears for a small concentration. As seen in Figs. 7 and 8, α/f^2 *vs.* concentration curves are nearly flat for a concentration of dioxane less than 4 mol%. This behavior is also attributed to the cooperative nature of cluster formation and breaking. However, the concentration range of nearly flat region is clearly broader than that in urea and guanidine solutions. This is ascribed to the fact that in a dioxane molecule the structure-breaking ability owing to two ether oxygens is diminished in part by the structure-forming ability[27,28] owing to two ($-C_2H_4-$) groups.

Summary and Conclusion

An ultrasonic study on dilute aqueous solutions of urea, guanidine hydrochloride and dioxane has been made by means of a pulse technique in order to investigate the influence of solutes upon the structure of water.

The following conclusions have been obtained.

1) Urea behaves as a structure breaker in water.

2) Guanidine hydrochloride has a greater ability as a breaker than urea.

3) For a small concentration, the structure-breaking effect is not appreciable. This is ascribed to the cooperative nature of cluster formation and breaking in aqueous solutions.

4) In the case of the dioxane-water system, the ability of dioxane as a breaker is diminished in part by the structure-forming effect owing to two ($-C_2H_4-$) groups within a dioxane molecule.

The authors wish to thank Miss Yuko Endo for her cooperation in carrying out this study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 642—645 (1970)

Kinetics of Alkaline Hydrolysis of Esters. II.*1 Unsaturated Esters and Oxalic Esters

R. C. SHARMA and M. M. SHARMA

Department of Chemical Technology, University of Bombay, Matunga Road, Bombay-19, India

(Received July 14, 1969)

The kinetics of alkaline hydrolysis of some typical esters, with unsaturation in the alkyl and the acyl portions, was studied. It was found that, in general, unsaturation results in enhancing the rate as compared to that of the corresponding saturated esters, provided that there is no conjugation between the double bond and the carboxyl carbonyl group. Oxalic esters hydrolyze relatively very fast due to the close proximity of the two ester groups. Rate constants for the alkaline hydrolysis of di-*n*-propyl-, di-isopropyl-, di-*n*-butyl-, di-*s*-butyl-, dicyclohexyl- and di-*β*-chloroethyl oxalates were obtained by using the theory of mass transfer accompanied by fast pseudo first-order reaction (diffusion method).

There is limited information in literature concerning the effect of unsaturation, present either on the alkyl or the acyl portion of the ester, on the kinetics of alkaline hydrolysis of esters.[2,3] It was therefore thought desirable to study some typical esters.

In the case of oxalic esters also only limited information is available. The first step of the alkaline hydrolysis of these esters is known to be an extremely fast reaction. Skrabal and coworkers[4-6] have studied the kinetics of this reaction using a phosphate buffer ($HPO_4^{2-}/H_2PO_4^-$) solution. The values of rate constant for the first step of the alkaline hydrolysis of dimethyl and diethyl oxalates obtained by them at 25°C were approximately 20000 and 6300 *l*/g mol sec. Tommila and Stenberg[7] studied the kinetics of alkaline hydrolysis of diethyl oxalate in a flow reactor similar to that used by Hartridge and Roughton.[8] The value of the rate constant was 3900 *l*/g mol sec in water at 30°C. Homan[9] found the value of the rate constant for the alkaline hydrolysis of di-*t*-butyl oxalate in 66.7 per cent (v/v) aqueous dioxane at 25°C to be 21.7 *l*/g mol sec. Sharma and Sharma[1] employed the theory of mass transfer with chemical reaction to obtain the value of the rate constant for the alkaline hydrolysis of di-*n*-butyl oxalate. They reported a value of 1780 *l*/g mol sec in water at 30°C. It was thought desirable to cover a more representative range of oxalic esters.

Experimental

Materials. Vinyl and isopropenyl acetates, methyl-, ethyl- and *n*-butyl acrylates and methyl methacrylate were purified by distillation at reduced pressure. Allyl acetate was synthesized by the reaction of allyl alcohol and acetic anhydride in the presence of one per cent sulphuric acid, and subsequently purified by distillation.

Oxalic diesters of *n*-propyl-, isopropyl-, *n*-butyl-, *s*-butyl, cyclohexyl and *β*-chloroethyl alcohols were synthesized by refluxing anhydrous oxalic acid with appropriate alcohol, taken as two to three times the stoichiometric requirement, in the presence of about three per cent sulphuric acid. The esters were purified by distillation at reduced pressure (10 to 50 mmHg). The physical properties for all the esters are reported in literature. The properties of purified esters agreed with those reported in literature.

Kinetic Measurements. The kinetics of alkaline hydrolysis of esters was studied in the aqueous medium. The rate constants for unsaturated esters were determined by the conventional method. The experimental procedure for this method was reported in a previous paper.[1] In some cases studies were made at lower temperatures (0.2 to 15°C). A constant temperature bath was used, where the temperature could be controlled to within ±0.05°C.

The theory of mass transfer accompanied by fast pseudo first-order reaction was used to study the kinetics of alkaline hydrolysis of oxalic esters. Details of the

method for the determination of rate constants have already been reported.[1,10-12]

Analysis. Methods of analysis have already been reported[1] except in the case of solid oxalic esters (dicyclohexyl and di-β-chloroethyl). In these cases about 20 ml of 8 N H_2SO_4 solution was added to 25 ml of an aqueous solution containing disodium oxalate. The solution was heated to about 70°C and titrated against standard $KMnO_4$ solution. Under these conditions disodium oxalate is oxidized quantitatively.[13]

Results and Discussion

1) Unsaturated Esters. An unsaturated carbon to carbon linkage near the carbonyl carbon in a carboxylic ester should speed up the rate of alkaline hydrolysis compared to that of the corresponding saturated ester due to the electronegative nature of unsaturation.[14,15] However, if there is conjugation of the unsaturation with the carboxyl (–C(=O)–O–) group then this retards the rate of the alkaline hydrolysis of the ester. Esters considered in this work could be divided in two groups: (i) unsaturation present in the alkyl group, (ii) unsaturation present in the acyl part.

(i) Unsaturation in the Alkyl Group. The presence of unsaturation on the alkyl portion of an ester accelerates the rate of alkaline hydrolysis. The effect decreases when the unsaturation moves away from the reaction centre. The results are given in Table 1.

Table 1. Rate constants for the alkaline hydrolysis of unsaturated esters in aqueous medium

Ester	Temperature °C	k_2 l/g mol sec
Vinyl acetate	0.3	0.392
	5	0.594
	10	0.854
	15	1.17
Isopropenyl acetate	10	0.145
	20	0.285
	30	0.512
Allyl acetate	30	0.23
Ethyl propionate	30	0.119
Methyl acrylate	30	0.198
Ethyl acrylate	30	0.102
n-Butyl acrylate	30	0.074
Methyl methacrylate	30	0.083

Only a limited amount of information is available in literature concerning the kinetics of alkaline hydrolysis of vinyl acetate.

$$CH_3COOCH{=}CH_2 + OH^- \xrightarrow{k_2} CH_3COO^- + H_2C{=}CHOH \quad (1)$$

$$H_2C{=}CHOH \xrightarrow{\text{fast}} CH_3CHO \quad (2)$$

The value of the rate constant for alkaline hydrolysis of vinyl acetate has been reported as 10.3 l/g mol sec by Skrabal and Zahorke.[16] They used a borate buffer solution for kinetic studies. The accuracy of the rate constant will be dependent on a precise knowledge of the hydroxyl ion concentration in the borate buffer solution. The value reported in this work is very different from that given by Skrabal and Zahorke.[16] The kinetics of alkaline hydrolysis of vinyl acetate was studied in the homogeneous phase by the conventional method[17] at lower temperatures (0.2 to 15°C) and data were extrapolated to room temperature. The extrapolated value of 2.6 l/g mol sec at 27°C is in good agreement with that obtained by the "diffusion method" (2.34 l/g mol sec at 27°C).

In the case of isopropenyl acetate, it would be expected that the steric hindrance due to the methyl group at the α-carbon atom of the alkyl portion would considerably decrease the rate of alkaline hydrolysis:

$$CH_3COOC(CH_3){=}CH_2 + OH^- \xrightarrow{k_2} CH_3COO^- + H_2C{=}C(CH_3)OH \quad (3)$$

$$H_2C{=}C(CH_3)OH \xrightarrow{\text{fast}} CH_3COCH_3 \quad (4)$$

The rate constant for this ester is about one sixth of that for vinyl acetate. The ratio of the rate constants for vinyl and isopropenyl acetates may be compared with the ratio for ethyl and isopropyl acetates (0.145 and 0.032 l/g mol sec at 30°C, respectively).

The value of the rate constant for the alkaline hydrolysis of phenyl acetate is about 12 times that of ethyl acetate.[18] The value of the rate constant for phenyl acetate should be obviously higher than that of isopropenyl acetate as there are two more unsaturation linkages present between 2,3- and 4,5-carbon atoms in the phenyl group. Further-

more, the rate constant for phenyl acetate should be expected to be less than that of vinyl acetate as the latter is sterically less hindered.

The rate constant for allyl acetate was found to be 0.23 *l*/g mol sec in water at 30°C, which is about one twelfth of that for vinyl acetate. In the case of allyl acetate the double bond is further away from the reaction center. Moreover it is well known that when an electronegative group or atom moves away from the reaction center the rate decreases. For instance, the value of the rate constant for the alkaline hydrolysis of chloromethyl acetate is about twenty times higher than that for β-chloroethyl acetate.[19,20]

(ii) Unsaturation in the Acyl Part. Unsaturation between α-, β-carbon atoms of the acyl portion results in conjugation with the carboxyl carbonyl group (–C(=O)–) of the ester. The effect of conjugation is not very marked in acrylic acid.[21] (The dissociation constants (K_a) of propionic and acrylic acids are 1.33×10^{-5} and 5.56×10^{-5}, respectively). However, the effect is much greater in acrylates, since here the conjugation energy of carbonyl group is approximately 4000 cal lower than that of carbonyl group in the acid.[22]

The values of the rate constant for the alkaline hydrolysis of ethyl propionate, methyl-, ethyl- and *n*-butyl acrylates and methyl methacrylate were obtained in water at 30°C by the conventional method and are given in Table 1.

The value of the rate constant decreases with the increase in the size of the alkyl group of acrylates. The relative decrease was found to be of the same magnitude as that in the case of acetic ester.

The effect of methyl substitution on the acyl portion, near the reaction center, was also investigated. The retardation of the alkaline hydrolysis of methyl methacrylate as compared to that of methyl acrylate was observed. The decrease in the rate constant when a hydrogen atom of the α-carbon atom of the acyl portion is replaced by a methyl group is comparable in the case of methyl acrylate and methyl methacrylate, and ethyl propionate and ethyl isobutyrate.[2] The ratio of the rate constants in these two cases is about 2.5 to 3.

2. Oxalic Esters. In order to obtain the values of the rate constant by the diffusion method, it is necessary to know the values of solubility and diffusivity of the ester in water. Solubilities of oxalic esters in water and aqueous solutions of sodium chloride were determined. The results were correlated by the methods reported in literature[23-25] and are given in Table 2. Diffusivities of esters were estimated by the method of Wilke and Chang[26] and are given in Table 3. The rate constants determined by the diffusion method are also given in Table 3.

In oxalic esters, the two ester groups are in close proximity to each other. The ester group (–COOR′) is a strong electron-attracting group and it is well known that such groups enhance the rate of alkaline hydrolysis. Hence the values of rate constants for alkaline hydrolysis of oxalic esters are relatively very high.

The kinetics of alkaline hydrolysis of dimethyl- and diethyl oxalates could not be studied in this work because of their higher solubilities. However, in the case of di-*n*-propyl oxalate the necessary conditions were satisfied. Extraction of this ester in the stirred cell was carried out only for five minutes to avoid the formation of disodium oxalate in excess of its saturation concentration. However, in the case of di-*n*-butyl oxalate, because of its very low solubility, experiments could be conducted even upto 30 min.

The values of the rate constant for di-*n*-propyl- and di-*n*-butyl oxalates are 2020 and 1780 *l*/g mol·sec, respectively. The ratio of rate constants of diethyl to di-*n*-propyl, and di-*n*-propyl to

6	Dicyclohexyl oxalate	0	0.25	30	8.35×10^{-9}	6.43	1080

di-*n*-butyl oxalates are approximately 2 and 1.2, respectively. For the acetates of the corresponding alcohols the ratio of rate constants for alkaline hydrolysis are about 1.23 and 1.2, respectively. (The values of the rate constant for ethyl, *n*-propyl and *n*-butyl acetates are 0.41, 0.12 and 0.1 l/g mol·sec in water at 30°C, respectively). Oxalic esters, other than dimethyl and diethyl oxalates, seem to follow the normal trend of change in the rate constant due to inductive and steric factors.

The rate constant for di-β-chloroethyl oxalate would be expected to be higher than that of diethyl oxalate due to the electronegative nature of the chlorine atoms present at the β-carbon atoms of the alkyl portions.

It was observed that the solubility of di-β-chloroethyl oxalate (mp 45°C) in water increases with an increase in the temperature. It is so high at 30°C that the necessary conditions for the validity of pseudo first-order reaction mechanism are not satisfied. However, all the conditions were satisfied when the experiments were carried out at 5°C in a bubble column where the temperature was kept constant by circulating water at the desired temperature through the outer jacket. The rate constant was found to be 2160 l/g mol sec at 5°C. If the energy of activation for the alkaline hydrolysis of di-*n*-propyl ester is assumed to be the same as that for other related oxalic esters of about 7 kcal/mol,[7] then the rate constant for di-*n*-propyl oxalate at 5°C works out to be about 700 l/g mol sec. This value is about one-third of that of di-β-chloroethyl oxalate. The rate constant of β-chloroethyl acetate is about 3.5 times higher than that of *n*-propyl acetate.

The steric effect was investigated by studying the kinetics of alkaline hydrolysis of di-isopropyl, di-*s*-butyl and dicyclohexyl oxalates. The value of the rate constant for the alkaline hydrolysis of di-isopropyl oxalate was found to be 890 l/g mol sec and that of di-*s*-butyl oxalate 810 l/g mol sec. These values are very close to each other, probably because of a similar steric effect offered by the isopropyl and *s*-butyl groups. The rate constants for isopropyl and *s*-butyl acetates and the corresponding formates are practically the same. However, the rate constant for dicyclohexyl oxalate is higher than the expected value. The discrepancy might be caused by the error involved in the determination of the solubility of this ester which is relatively very low. A 10 per cent error in the solubility results in about 20 per cent error in the rate constant.[1]

One of the authors (R.C.S.) wishes to thank the University Grants Commission for an award of a scholarship which enabled this work to be carried out.

Electronic Structures and Electronic Absorption Spectra of Cyclohexadienyl and Related Radicals Produced by γ-Irradiation

Tadamasa SHIDA and Ichiro HANAZAKI

The Institute of Physical and Chemical Research, Yamatomachi, Kitaadachi-gun, Saitama

(Received July 26, 1969)

The electronic absorption spectrum for the cyclohexadienyl radical produced upon γ-irradiation of pure benzene and benzene-alcohol solutions both at 77°K was investigated. In addition to the absorption band at 3.9 eV, a weak band with a prominent vibrational structure was observed at 2.2 eV. An SCF-CI molecular orbital calculation was carried out for the radical taking into account explicitly the hyperconjugation effect of methylene group. The theory predicts the two observed bands with satisfactory accuracy. The calculated spin densities are also in good agreement with the existing ESR data of the radical. Vibrational analysis was carried out for the band system at about 2 eV as well as for the corresponding bands of isotopically mixed radicals, C_6H_6D, C_6D_6H, and C_6D_7. Parallel calculations for hydronaphthyl radicals are also in harmony with the available experimental data of optical and ESR measurements.

Cyclohexadienyl-type radicals are assumed as the reaction intermediates in radical substitution reactions at the benzene ring.[1] They are also known to be important intermediates in the radiolysis of benzene and its derivatives. Both the liquid benzene at room temperature[2] and the solid at 77°K,[3] produce the radical upon γ-irradiation which has been identified by its characteristic absorption band in the near UV and the triplet ESR spectrum. In the irradiated solid benzene the radical is assumed to be formed by the reactions,[3]

$$C_6H_6 \xrightarrow{\gamma} \cdot C_6H_5 + H \quad (1)$$

$$C_6H_6 + H \longrightarrow \cdot C_6H_7 \quad (2)$$

The same radical can also be produced in dilute benzene solutions in alcoholic solvents γ-irradiated at 77°K,[4,5]

$$CH_3OH \xrightarrow{\gamma} CH_3OH^+ + e^- \quad (3)$$

$$C_6H_6 + e^- \longrightarrow C_6H_6^- \quad (4)$$

$$C_6H_6^- + CH_3OH \longrightarrow \cdot C_6H_7 + CH_3O^- \quad (5)$$

Similarly γ-irradiation of naphthalene single crystal or naphthalene in methanol glass at 77°K produces α-hydronaphthyl radical which has been confirmed by ESR and optical absorption measurements.[6,7]

The characteristic feature common to these radicals is the participation of ring methylene group in the π electron system through hyperconjugation. In the present work we have undertaken an open-shell SCF-CI calculation for electronic states of these radicals taking into account explicitly the effect of hyperconjugation. A method previously developed for the benzenium ion and related cations[8] was applied to the neutral radicals.

The results for cyclohexadienyl radical predicts a new electronic absorption band in the visible region in addition to the band in the near UV region.[5] Hence the absorption spectrum of the radical was carefully reexamined for irradiated solid benzene and benzene in alcoholic solvents. We have found the corresponding weak absorption band in the visible region with a marked vibrational structure which can be analyzed directly on the basis of fundamental vibrational frequencies close to those of the benzene molecule.

Experimental

Pure benzene and benzene in alcohols both degassed thoroughly were frozen at 77°K to a polycrystalline and a glassy solid. The samples were kept at the same temperature throughout the measurements of absorption

spectrum before and after irradiation with γ-rays from a 12 kCi (kilocurie) ^{60}Co source. Optical cells of the thicknesses of 2.0 and 1.5 mm were made of Suprasil quartz. A quartz Dewar with flat quartz windows was placed in the sample compartment of a Cary spectrophotometer Model 14RI which was equipped with a high-intensity source attachment 1417200 operated at 110 V. The accessory was indispensable for the optical measurements because pure benzene solidifies at 77°K to an opaque polycrystalline and transmits light only to a small extent. Since the absorption induced by irradiation appears at wavelengths longer than 280 mμ where neither benzene nor methanol absorbs, the difference in the optical density before and after irradiation was taken to be due to the absorption of products formed upon irradiation.

Thiophene-free benzene was purified by distillation with a theoretical plate number of about 40 followed by repeated crystallization. Perdeuterobenzene of a stated atomic purity (>99%) from E. Merck AG was used. Methanol was purified by the standard method.[9] CH_3OD and C_2H_5OD were supplied from CIBA AG. Methanol and methanol-d_1 were added with 4% of water and D_2O respectively which formed clear glass with cracks at 77°K, while the ethanols vitrified without water. The cracks did not interfere with the optical measurement in the thin absorption cells. The aqueous methanols used as a solvent for benzene will be designated simply "methanol" hereafter.

Theoretical

In a previous paper[8] the electronic structures of benzenium ion and some related compounds were studied in the framework of the Pariser-Parr-Pople SCF-CI theory.[10] The hyperconjugation effect of the methylene group was treated explicitly in the following manner. The H_2 unit of CH_2 in the ion is regarded as a pseudo atom which provides a σ- and a π-type valence electrons to the ring system. The ionization potential and electron affinity of the pseudo π atomic orbital (AO) of the H_2 "atom" is calculated non-empirically to be 9.4219 and -0.7007 eV, respectively, by reducing the integrals over the pseudo AO into those over the hydrogen 1s AO's. The two-center Coulomb repulsion and core resonance integrals are also evaluated by the standard method by reducing them into the intergrals over the hydrogen 1s AO's. Satisfactory agreement with the experimental results for the benzenium ion and its derivatives encouraged us to use the same method of calculation for the corresponding neutral radicals. The method developed by Longuet-Higgins and Pople[11] for the open-shell electron system was applied to the radical in combination with the above method of evaluating the molecular integrals.

Results and Discussion

The Cyclohexadienyl Radical. One mol/l of benzene in methanol irradiated at 77°K to the dose of 1.1×10^{19} eV/g produced absorption spectra shown in Fig. 1. In accordance with the previous

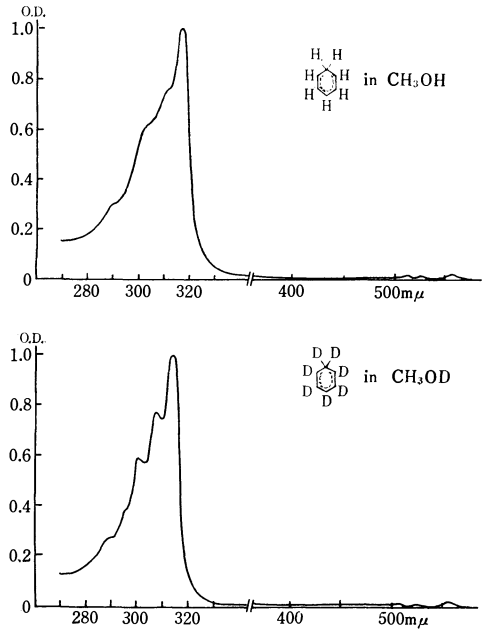

Fig. 1. Absorption spectra of cyclohexadienyl radicals in benzene-methanol solutions γ-irradiated at 77°K.

conclusion[5] they are associated with cyclohexadienyl radicals, C_6H_7 and C_6D_7 produced by reactions (3)—(5). The band at 3.9 eV was observed for a sample treated similarly, while the band system in the visible region was not detected apparently because of a high level of noise in the previous experiment.[5] By irradiating for a longer period the band system at about 2 eV became intense enough to reveal the structure as shown in Fig. 2 for the two isomeric radicals. The molar extinction coefficient of the most intense peak in the visible band system can be estimated knowing that of the band at 3.9 eV as 1.21×10^4 $l$mol^{-1} cm^{-1}.[12]

TABLE 1. ELECTRONIC TRANSITIONS OF CYCLOHEXADIENYL RADICAL, C_6H_7.

Sym-metry[a]	Theroretical Energy (eV)	Theroretical Oscillator strength	Experimental Energy (eV)	Experimental Oscillator strength
A_2	2.030	4.07×10^{-4}	2.22	4.3×10^{-4}
B_1	3.626	3.20×10^{-4}		
A_2	3.950	1.35×10^{-1}	3.92	1.27×10^{-1}
B_1	5.649	4.20×10^{-2}		

a) The molecule has the C_{2v} symmetry.

Table 1 summarizes the theoretical results for the cyclohexadienyl radical together with the experimental results obtained. The prediction that a weak absorption should be observed at 2.03 eV is well substantiated. The first A_2 transition can be correlated to the benzene B_{2u} transition strongly mixed with the charge transfer transitions between the methylene pseudo AO and the π electron system of the aromatic ring. Similarly, the second A_2 transition comes from the benzene E_{1u} transition strongly affected by the charge transfer interactions.

The first B_1 transition predicted at 3.6 eV was not observed. We consider that either the intensity of the band is too small or the band is over-shadowed by the strong absorption at 3.9 eV.*1

The ESR spectrum of the radical has been studied by previous workers[3,4] who attributed the observed splittings of 47.5, 10.4, and 2.5 gauss to the methylene protons, three ring protons at ortho and para positions and two protons at meta position, respectively. The calculated spin densities are given in Fig. 3. The splitting due to the ring protons

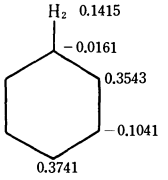

Fig. 3. Calculated spin densities of cyclohexadienyl radical.

are calculated by means of McConnell's relation with the proportionality constant of 30 gauss. The values of 10.6, 11.2, and 3.1 gauss for the ortho, para, and meta protons, respectively, are in fairly good agreement with the observed values. The splitting due to the methylene protons is derived to be 49.9 gauss by the following procedure. The pseudo AO χ is written as

$$\chi = [2(1-S)]^{-1/2}(\chi_1-\chi_2) \quad (6)$$

where χ_1 and χ_2 are the hydrogen $1s$ AO's and S is the overlap integral between them. Assuming the geometrical conformation of methane S is estimated as 0.282 from the table given by Mulliken *et al.*[13] The net atomic spin density ρ^{net} on each $1s$ AO is

$$\rho^{net} = [2(1-S)]^{-1}\rho \quad (7)$$

where ρ stands for the spin density on χ. With this relation and the calculated value of $\rho=0.1415$, we obtain $\rho^{net}=0.09854$. Using the hyperfine splitting of 506.8 gauss for the hydrogen atom the splitting due to the methylene protons is obtained as 49.9 gauss.*2

The general agreement between the theoretical and experimental results on the optical and ESR

*1 We have not succeeded in observing this weak band for radicals of lower symmetry (*e.g.*, the radical derived from ortho xylene),[5] where the intensity of the band might be enhanced a little by the removal of symmetry of the radical.

13) R. S. Mulliken, C. A. Rieke, D. Orloff and H. Orloff, *J. Chem. Phys.*, **17**, 1248 (1949).

*2 The contribution from the "overlap" spin density has been neglected. This gives an error of about 7% for the splitting. The odd electron on the $2p\pi$ AO of methylene carbon may induce an additional spin density on the methylene protons by the mechanism of spin polarization. This effect, however, can also be neglected since the $2p\pi$ spin density on the methylene carbon is minute.

properties of the radical indicates the adequacy of the present theoretical treatment. It must be emphasized that the effect of hyperconjugation is crucial in the electronic behavior of the radical. The striking resemblance of the electronic absorption spectrum of the cyclohexadienyl radical to that of the benzyl[14] may be an indication that the pseudo π electron in the former radical is as important as the $2p\pi$ electron of the methylene group in the latter radical.

The α-Hydronaphthyl Radical. Theoretical results for the electronic transition energies and intensities of α-hydronaphthyl radical are summarized in Table 2. Upon γ-irradiation an H atom

Table 2. Electronic transitions of α-hydronaphthyl radical

Theoretical			Experimental[a]

may be added to naphthalene at α- and/or β position. The calculation for the total π electron energy predicts a lower value for the α radical by the amount of 4.2 eV. Thus the experimentally observed absorption bands are regarded as predominantly due to the α radical*3

In Table 2 the experimental transition energies obtained for the γ-irradiated naphthalene single crystal are also included.[7] Agreement between the theoretical and observed values is satisfactory. Because of the overlapping of absorption bands due to several species produced in the irradiated crystal, it is difficult to determine the intensity of each band accurately. However, the intensity ratio of the observed three bands seems to be consistent with the calculated oscillator strengths.[7]

The spin densities calculated for the α-hydronaphthyl radical are shown in Fig. 4. By a similar

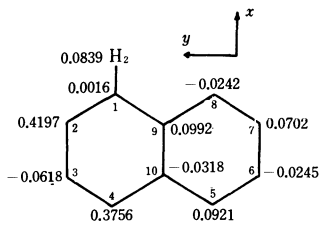

Fig. 4. Calculated spin densities of α-hydronaphthyl radical.

procedure to that for the cyclohexadienyl radical the triplet splitting due to the methylene protons was found to be 29.3 gauss in comparison with the observed 37 gauss.[6] We assign, in conformity with the previous workers,[6] the observed minor triplet of splitting of 12.8 gauss to the ring protons at the 2 and 4 positions whose theoretical splittings are 12.6 and 11.3 gauss, respectively. The calculated spin densities for the β-radical cannot explain the ESR spectrum even qualitatively.

The Vibrational Analysis of the Visible Band System of Cyclohexadienyl Radical. γ-Irradiation of pure solid benzene produced sharp peaks in the region of 400—560 mμ as shown in Fig. 5.

was required to obtain the optical density of 0.5 to 1.0. In irradiated benzene concomitant reactions could yield species other than the cyclohexadienyl radical,[16] while in the methanol solution reactions (3)—(5) are predominant processes and no other species is expected which absorbs in the visible region.[5] Since Fig. 5 for the irradiated benzene is strikingly corresponding to Fig. 2 for the methanol solution, it can be concluded that in irradiated benzene also cyclohexadienyl radical is the main species responsible for the absorption in the visible region. It is fortunate that only a few minor bands are foreign. The other product of reactions (1) and (2), that is, the phenyl radical, is known to absorb in the region of 432—530 mμ.[17] However, the radical is so reactive that it may not exist as such in the irradiated solid but transform itself to other species transparent in the visible region. Even if the radical survives, it may have eluded our observation because the extinction coefficients of the radical may be extremely small as Porter and Ward implied.[17]

The appearance of the spectrum in Figs. 2 and 5 indicates clearly that the strongest peak is the 0–0 band. This is in accord with the theoretical prediction that the visible band is symmetry-allowed. All other peaks in Figs. 2 and 5 can be readily analyzed in terms of six and five fundamentals for

the light and the heavy radicals, respectively. Tables 3 and 4 list the assignment for the two radicals. The deduced fundamentals bear close resemblance to those of $^1A_{1g}$ benzene.[18] Because of the wavelength accuracy of the monochromator the reproducibility of the measured wave number is roughly $\pm 10\ cm^{-1}$ for the sharp peaks in solid benzene and $\pm 20\ cm^{-1}$ for the blunt peaks in alcohol solutions.

The 0–0 band of C_6H_7 in CH_3OH is blue-shifted by about 45 cm^{-1} compared with that of the same radical in C_6H_6 (Tables 3 and 5). Similarly C_6D_7 in CH_3OD and C_6D_6 has a difference of about 40 cm^{-1} (Tables 4 and 8). Since the inherent error of the wave number is about 10 cm^{-1}, this amount of difference is quite significant. The wave number difference $\Delta\tilde{\nu}$, however, is more or less similar in the methanol and the benzene matrices. This implies that both C_6H_7 and C_6D_7 are stabilized in their ground electronic state by the dielectric alcohol matrix but that the vibrational levels of the electronically excited radicals are little affected by the environment. Parallel experiments using ethanol instead of methanol show that the stabilization effect is roughly equal for both alcohols (Tables 5 through 8).

The difference in 0–0 band of C_6H_7 in C_6H_6 and C_6D_7 in C_6D_6 amounts to 138 cm^{-1}. Likewise C_6H_7 in CH_3OH and C_6D_7 in CH_3OD has a difference of 130 cm^{-1} (Tables 5 and 8). Similar isotopic shift of about 190 cm^{-1} is observed for another 0–0 band at 3.9 eV as shown in Fig. 1. The shifts between the light and the heavy radicals are attributed to the smaller zero point energies of the heavy radical in the two electronic states concerned.

According to the mechanism of reactions (3)—(5) it is possible to produce two other isotopically different cyclohexadienyl radicals; light benzene in methanol-d_1 and heavy benzene in the normal methanol will yield C_6H_6D and C_6D_6H respectively. Leone and Koski[4] have shown by ESR that both are actually produced, although they did not clarify the reaction mechanism of radical formation.[4,5] We found that both C_6H_6D and C_6D_6H give rise to very similar spectra to those of C_6H_7 and C_6D_7, respectively. Barely significant differences (in the 0–0 band between C_6H_7 and C_6H_6D (Tables 5 and 6), and between C_6D_6H and C_6D_7 (Tables 7 and 8) are again atrributed to the slight difference in the mass of the radicals.

The authors wish to thank Dr. N. Itoh of Nagoya University for informing them of the experimental results on the hydronaphthyl radical prior to publication. They are also indebted to Dr. S. Iwata and Mr. H. Katsumata for writing the computer program and to Dr. M. Imamura for his helpful discussion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 652—657 (1970)

Optical and ESR Studies on Triphenylimidazolyl Radicals Produced by Photolysis and Radiolysis at Low Temperature*1

Tadamasa SHIDA,* Koko MAEDA** and Taro HAYASHI

* *The Institute of Physical and Chemical Research Yamato-machi, Kitaadachi-gun, Saitama*

** *Department of Chemistry, Faculty of Science, Ochanomizu University, Bunkyo-ku, Tokyo*

(Received July 29, 1969)

The characteristic temperature-dependent behavior exhibited by the solution of the photochromic dimer of triphenylimidazolyl (photo-dimer) has been reinvestigated by means of optical and ESR spectroscopy. Assuming two conformations for triphenylimidazolyl radical, the spectral change at low temperatures has been elucidated in terms of a conformational isomerization of the radical and dimerization of the radical to a colorless dimer. Photo-dimer in γ-irradiated glassy solutions undergoes a dissociative electron attachment to produce triphenylimidazolyl radical and its anion.

UV-illumination of the photochromic dimer of triphenylimidazolyl in benzene at room temperature produced triphenylimidazolyl radical which was characterized by the absorption spectrum having absorption maxima of 347 and 554 mμ.[1] Upon lowering the temperature of the solution under illumination the intensity of the absorption band diminished gradually, and at sbout -20——150°C the absorption in the visible region disappeared. The phenomenon first studied by Hayashi and Maeda[2] was later interpreted by White and Sonnenberg on the basis of a thermochemical equilibrium between the radical and the colorless piezochromic dimer.[3],*2 It was found that illumination at still lower temperatures gave a color slightly different from that observed at higher temperatures.[4] We attributed the absorption observed at -196°C to the radical cation of photo-dimer produced by photoionization.[4] Later work revealed, however, that the absorption should be associated with triphenylimidazolyl radical produced by the same mechanism as that in solutions at room temperature.[5] Assuming two conformations for the radical, one stable at higher temperatures ($>$*ca.* -20°C), the other at lower temperatures ($<$*ca.* -150°C), we are able to explain the temperature dependence of photochemical reactions of the lophine system.

Experimental

Photo-dimer was dissolved in deaerated solvents in a dimmed room. Methyltetrahydrofuran (MTHF) was mainly used as a solvent, because it forms a clear glass at -196°C. For the optical measurement the solution was transferred in a vacuum to a thin quartz absorption cell. The absorption spectrum of the solution was measured at -196°C in a quartz Dewar with quartz windows using a Cary 14 RI spectrophotometer. Polymer films containing photo-dimer was prepared by dissolving the dimer in polystyrene-benzene gel and solidifying it by evaporation of benzene in nitrogen stream. A 500 W high-pressure mercury lamp in combination with a glass filter passing light of 240 mμ $<\lambda<$ 400 mμ and a 12000 Ci Co 60 γ-ray source were for photolysis and radiolysis. ESR spectra were recorded on a JEOL 3B spectrometer with a 100 kc modulation.

Results and Discussion

Photolysis. When a colorless solution of photo-dimer in MTHF glass at -196°C was exposed to UV light, the glass colored immediately to reddish-

phenylimidazolyl radical in solutions at room temperature (*e.g.*, the absorption maximum of the visible band at −196° was 556 mμ which corresponded to 552 mμ at room temperature). Apparently photo-dimer dissociates also in the rigid matrix at −196°C. Reaction (1) formulates the process with R· standing for triphenylimidazolyl radical.

$$R_2 \xrightarrow{h\nu} 2R\cdot \qquad (1)$$

In the rigid glass the bulky radicals must be confined in a cage. Strong evidence for the formation

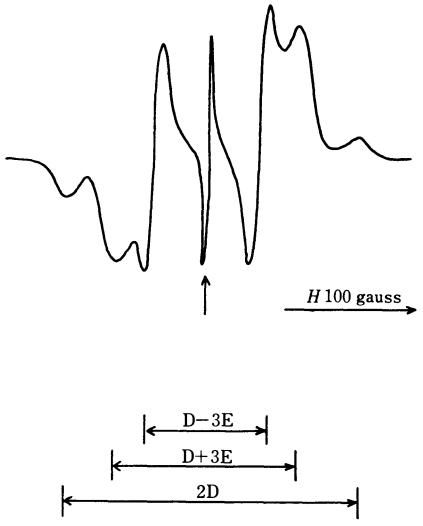

Fig. 2. ESR spectrum of photo-dimer in MTHF UV-illuminated at −196°C.

of radical pair is a broad ESR spectrum shown in Fig. 2. Since the monomeric triphenylimidazolyl radical in solutions at room temperature gives a singlet ESR spectrum of a line width of $\Delta H_{msl}=9.1$ gauss,[6] the spectrum of the width of about 200 gauss must be attributed to the fine structure of the two-spin system. The three pairs of bands connected by leading lines in Fig. 2 were also observed for solutions in several other solvents. The intensity of the central singlet (arrowed) varied with the solvent, illumination time and wavelengths of the exciting light, and was more easily saturated with the microwave power. Following Kommandeur's discussion on the photolyzed tetraphenylhydrazine[7] we identified the outermost pair of a small intensity with the separation of $2D$ and the inner two sets with $D\pm3E$. In view of complexity of the molecules we used a simple relation, $D=3g\beta r^{-3}/2$ to estimate the approximate distance between the two radicals.[8] From the observed $D=112.6$ gauss we obtain $r=6.3$ Å. As in the case of an EPA solution[4] a weak half-field absorption was detected also for the MTHF solution which confirms the triplet state of the two-spin system. The central singlet in Fig. 2, on the other hand, may be due to unknown species produced as byproducts of photolysis.

When the solution photolyzed at −196°C was taken out of the liquid nitrogen, the color of the sample faded with the rise of temperature. Before the rapid fading started, a very subtle color change from reddish-purple to purple took place. The purple solution, quickly dipped again in liquid nitrogen to quench the fading, exhibited the absorption spectrum shown in curve 2 of Fig. 1 which differs from the spectrum in curve 1: (1) the absorption maxima shifted towards red, (2) the bands became narrower with the increase of absorbance at λ_{max}, (3) the band structure manifested slightly. Hereafter we will denote the spectra before and after the heat treatment by R and S bands, respectively. A change from R to S bands was also observed invariably in other glass-forming solvents such as 3-methylpentane, decalin-cyclohexane 3 : 1 mixture, isobutyl chloride. In all cases tested only R and S bands appeared and no intermediate spectrum was observed as long as the temperature was controlled to ensure the color change from reddish-purple to purple. In alcoholic glasses such as EPA and ethanol the absorption maxima of both R and S bands shifted further to red probably because of the general dielectric solvent effect (*e.g.*, the absorption maximum of S bands in EPA was

575 mμ compared with 566 mμ of the corresponding band in MTHF).

Since a simple heat treatment transforms the radical R· at −196°C to a species giving rise to the S bands which resemble the R bands in general appearance, we presume that the species responsible for the S bands is a similar radical to R· with the conformation slightly modified, and will designate the species S· radical. The features of S bands enumerated above in relation to the R bands may be associated with the enhancement of planarity in the radical; as the radical becomes more planar, the extent of conjugation would increase to result in a red shift of the absorption band. The variance in the twist angle between the planes of phenyl groups and of imidazole ring would produce a number of potential energy curves for both the ground and the excited electronic states of the radical, and the electronic absorption band would be broadened on account of the Franck-Condon principle.[9] Thus the observed sharpening of the absorption band may be an indication of the enhancement of planarity.

The phenyl groups in the crowded photo-dimer must be twisted considerably from the plane of imidazole ring. The phenyl groups in a monomeric R· radical at room temperature are also considered to be twisted by analogy with orthoterphenyl and hexaphenylbenzene.[10] The rotatory displacement of the phenyl group, however, must have been attained at the sacrifice of conjugation, and at low temperatures a planar conformation might be favored. On the basis of this inference we account for the R· to S· transition in the following way; the radical produced by reaction (1) in a rigid cage is forced to retain the same conformation of twisted phenyl groups as in photo-dimer. However, as soon as the original cage is relaxed by softening the matrix, the radical assumes a more or less planar conformation presumed to be stable at −196°C.

Upon warming the solution the S bands disappeared at about −100——150°C. This can be explained by dimerization of S· radicals to a colorless dimer S_2. When the temperature was further raised to room temperature, the solution regained a reddish-purple color attributable to the regeneration of R· radical.

The R bands also appeared when the MTHF solution containing photo-dimer was illuminated first at room temperature. Upon lowering the temperature, however, the bands diminished and disappeared at temperatures below about −20°C. This phenomenon is essentially the same as reported before for benzene and EPA solutions.[5,11] For the latter systems White *et al.* constructed an energy diagram reproduced in the solid curve of Fig. 3.[3]

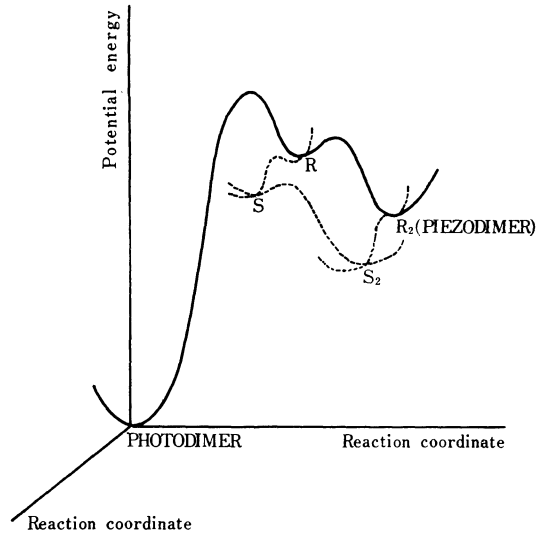

Fig. 3. Possible potential surface of the system of triphenylimidazolyl radicals and dimers.

To incorporate the newly proposed S· and S_2 we modify the diagram as shown in Fig. 3 and account for the processes throughout the whole temperatures; photo-dimer in the matrix at −196°C is "pumped up" by photons to dissociate into R· radicals in a cage. By raising the temperature slightly above −196°C radical R· overcomes a small barrier to become radical S· which successively dimerizes to piezo-dimer R_2 *via* S_2. Dimer S_2 assumed here may be less substantive than S·, because dimerization of S· radicals could lead directly to piezo-dimer, in which case the paths of S· to S_2 and S_2 to R_2 should be replaced by a single path of S· to R_2. Since piezo-dimer is thermochemically unstable in relation to photo-dimer, the former eventually isomerizes to the latter through the thermal dissociation to R· radicals.[3]

The polymer film illuminated at room temperature also exhibited the R bands. In contrast with the MTHF solution the color of the polymer did not fade on cooling, and the bands measured at −196°C showed a spectral change indicative of the transition from R to S. The change is not due to a mere temperature shift of the R bands, because the polymer film illuminated at −196°C produced the same R bands as those obtained by the illumination at room temperature. These results of film samples are also consistent with the diagram of Fig. 3; R· radical produced in the film at room temperature may be prevented from dimerization in the rigid polymer network, and on lowering the temperature the radical may undergo the isomerization to S· radical without the intervention of the formation of piezo-dimer.

Radiolysis. When γ-irradiated at -196°C, pure MTHF glass yields an absorption band in the near IR region ($\lambda_{max} \cong 1.2\ \mu$) which is known as due to the electron trapped by the matrix and is designated $(e^-)_t$.[12] In the presence of photo-dimer (0.67 mM) the $(e^-)_t$ band was suppressed to about 70% and new absorption bands identifiable with the R bands appeared (curve 1 of Fig. 4). The

Concentration $= 6.7 \times 10^{-4}$ M. Cell thickness = 0.5 mm. Dose $= 6.3 \times 10^{19}$ eV/g.

remaining $(e^-)_t$ band was easily photobleached with light of λ—620 mμ. The bleaching enhanced the R bands as shown in curve 2 of Fig. 4. The decrease of the $(e^-)_t$ band with the concomitant enhancement of R bands indicates that the formation of R· radical in the radiolysis is related with electron and not with photon as in the photolysis.

In a study of tetraphenylhydrazine in MTHF we have found that UV-illumination induces the homolysis,

$$(C_6H_5)_2NH(C_6H_5)_2 \xrightarrow{h\nu} 2(C_6H_5)_2N\cdot \qquad (2)$$

while γ-irradiation leads to the heterolytic dissociation,[13]

$$(C_6H_5)_2NN(C_6H_5)_2 + e^- \longrightarrow (C_6H_5)_2N\cdot + (C_6H_5)_2N^- \qquad (3)$$

By analogy with reaction (3) we may assume that the γ-irradiated photo-dimer induces the following reaction.

$$R_2(\text{photo-dimer}) + e^- \longrightarrow R\cdot + R^- \qquad (4)$$

A criterion for this type of reaction is the exothermicity of the reaction; if the electron affinity of the radical exceeds the dissociation energy of the central bond of the dimer, reaction (4) is possible.[14] Although the electron affinity of triphenylimidazolyl radical is not known, reaction (4) may be exothermic owing to the extremely small dissociation energy of photo-dimer($\sim$1 eV[1,5]). If the excess energy is utilized to excite R· or R^- to a luminescent state, reaction (4) should accompany the emission of light which was, in fact, observed; when γ-irradiated solutions corresponding to curve 1 of Fig. 4 was thawed in the dark, a bright yellow light was emitted. However, if, prior to thawing, the $(e^-)_t$ band was photobleached (see curve 2 of Fig. 4), the solution did not luminesce on thawing. Thus electrons released from the trap by thawing seem to produce excited R· or R^-.

Addition of 10 vol% of carbon tetrachloride to the solution of photo-dimer in MTHF prevented the formation of R· radical in the radiolysis, whereas in the photolysis the chloride caused no effect on the production of R· radicals. This can

be accounted for by the competition for electron between photo-dimer and the chloride which is known to react with electron as follows.[15]

$$CCl_4 + e^- \longrightarrow \cdot CCl_3 + Cl^- \qquad (5)$$

ESR measurements also support reaction (4): Fig. 5 shows the ESR spectra of γ-irradiated pure MTHF and a solution of photo-dimer (5 mM) in MTHF. The singlet in pure MTHF having $\Delta H_{msl}=4.6$ gauss disappears on photobleaching and is attributed to the $(e^-)_t$.[12] The spectrum remaining after the bleaching is due to the MTHF radical.[12] On the other hand, the singlet in the photo-dimer solution, though similar to the $(e^-)_t$ singlet, has a width of $\Delta H_{msl}=8.1$ gauss and did not disappear on the same optical bleaching. It was more resistive against the microwave power saturation than the $(e^-)_t$ singlet. Contrary to the photolysis, the spectrum of the radiolyzed photo-dimer solution showed no sign of radical pairs. These results indicate that the singlet of photo-dimer solution is due to the singlet R· radical produced by reaction (4). The line width of the singlet, $\Delta H_{msl}=$ 8.1 gauss, is comparable with that of the R· radical in solutions at room temperature.[6]

Closer examination of the absorption spectra of photolyzed (curve 1, Fig. 1) and radiolyzed (curve 2, Fig. 4) rigid solutions reveals that the absorption maxima of R bands in the γ-irradiated solution are slightly blue-shifted, compared with the photolyzed solution (347 and 552 mμ for the former and 350 and 556 mμ for the latter). Although the shift is admittedly small, it was reproducible. This shift may reflect the weak interaction between the paired radicals in the photolyzed solution as manifested by the ESR fine structure. The R bands of the radiolyzed solution at -196°C coincide with those of the R· radical in MTHF at room temperature ($\lambda_{max}=552$ mμ). This coincidence may be attributed to the fact that in both media R· radicals are not paired as in the photolyzed rigid solution.

The R bands of the radiolyzed solution also changed to S bands with the heat treatment (Fig. 6). Since the change occurring in the softened matrix was transient, the signal of S bands was liable to disappear by the successive dimerization. However, the disappearance was less rapid in the radiolyzed solution than in the photolyzed and the spectral change is seen more distinctly in Fig. 6 than in Fig. 1 (curve 2). This may be because in the photolyzed solution the radical pairs are ready to recombine geminately whereas in the radiolyzed solution the R· radical from reaction (4) has more chances for the isomerization to S·. Contrary to the R bands which show a slight shift between the radiolyzed and photolyzed rigid solutions, the

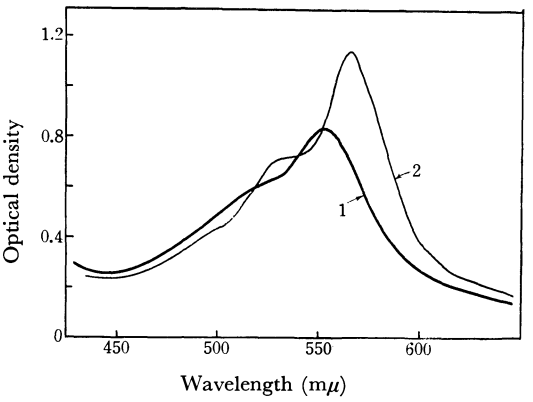

Fig. 6. Absorption spectra of photo-dimer in MTHF γ-irradiated at -196°C. Curve 1: corresponding to curve 2 of Fig. 4. Concentration=5 mM. Cell thickness=1.5 mm. Dose=3.1×10^{19} eV/g. Curve 2: the preceding solution after limited warming.

S bands derived from both photolysis and radiolysis were identical with $\lambda_{max}=566$ mμ. This indicates that the R· radicals in a cage in photolyzed solutions separate from each other upon softening the matrix and the resulting S· radicals are no longer paired to exhibit any spectral shift due to the pairing.

The absorption at 300—400 mμ of the R· radical in the radiolyzed solution (curve 2, Fig. 4) is disproportionately high compared with the spectrum of the photolyzed solution (curve 1, Fig. 1). Since the lophine anion, R^-, produced by reaction (4) is known to have $\lambda_{max}=326$ mμ with $\varepsilon_{326}=2.48\times$

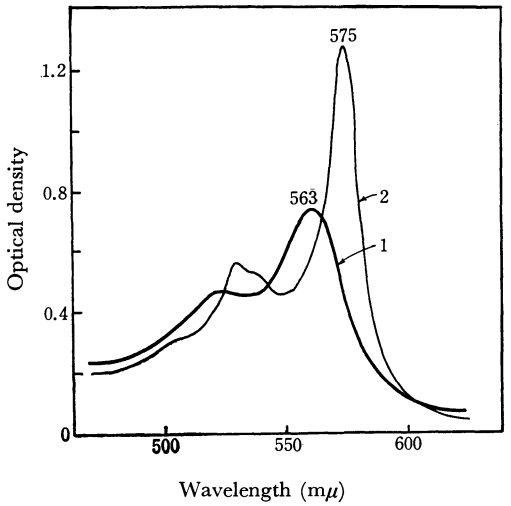

Fig. 7. Absorption spectra of photo-dimer of 2,3,4,5-tetraphenylpyrryl in MTHF UV-illuminated at -196°C. Curve 1: immediately after illumination. Curve 2: the same solution after limited warming. Concentration=1 mM. Cell thickness=1.5 mm.

15) T. Shida and W. H. Hamill, *J. Chem. Phys.*, **44**, 2369 (1966).

10^4,[5] the anion should contribute to the absorption in the near UV region. This contribution can be subtracted by using the known molar extinction coefficients of R bands at 552 mμ (8.4×10^3) and 347 mμ (4.8×10^4).[5] Even after the subtraction, however, the absorption at 300—400 mμ is still high compared with the spectrum of the photolyzed solution. The reason for this discrepancy is not clear at present.

Additional Remark

As in the case of triphenylimidazole, 2,3,4,5-tetraphenylpyrrole produces two isomeric dimers on oxidation, one photochromic and the other piezochromic.[5,16] We have carried out parallel studies on these dimers also and obtained quite analogous results. One example is shown in Fig. 7 where the spectrum in curve 1 was observed immediately after UV-illumination at -196°C, and that in curve 2 was obtained after the limited warming. The two spectra are regarded as corresponding to the R and S bands in the case of lophine dimer.

The authors wish to thank Dr. Masashi Imamura and Dr. Hiroshi Midorikawa of The Institute of Physical and Chemical Research for their helpful discussion.

ESR Spectra of γ-irradiated Linear Aliphatic Polyesters*1

Yasuo NOZAWA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received July 28, 1969)

The ESR spectra of γ-irradiated linear aliphatic polyesters (2.2, 2.4, 2.6, 2.7, 2.8 and 6.8 polymer) have been measured at various temperatures ranging from 77°K to room temperature. Two types of spectra are obtained in these polyesters except for 2.2 polymer. The first, the six-line spectrum obtained at low temperatures was relatively short-lived and increased in signal intensity with increasing methylene groups of these polyesters. The well-resolved, second, five-line spectrum is stable even at room temperature in comparison with the former. The possible structures of two radicals were discussed.

Recently a number of ESR studies on the radical produced by γ-irradiation of low molecular weight organic and polymeric substances have been carried out. Correlations between the radical species and chemical structures of various polymers have been extensively found.[1-7] Configurations of the free radical in irradiated polyethlene and polypropylene in particular were discussed with respect to the relation of the radical decay reaction to a molecular motion in the matrices.[8,9]

In the linear aliphatic polyesters, however, no studies on the radical species produced by γ-irradiation or the behaviour of radical decay have been reported except for an anisotropic study on irradiated poly(β-propiolactone).[10] From the data obtained by the observation of ESR spectra of irradiated polyesters, the species and the site of the radical are discussed.

The crystal structures of the polyesters have been

extensively studied by many investigators.[11-14] From the results, it is apparent that the crystal structure is similar to that of polyethylene and the molecular chain conformations are planar zigzag except for poly(ethylene adipate) and the glycol parts of the polyesters with ethlene glycols. The chemical structure of the polyesters studied is expressed as $-\left[(CH_2)_n-O-\overset{\overset{O}{\|}}{C}-(CH_2)_m-\overset{\overset{O}{\|}}{C}-O\right]-$, and the polyesters are denoted as *n.m* polymer hereafter. In the present paper the results deduced from ESR spectra of 2.2, 2.4, 2.6, 2.7, 2.8 and 6.8 polymer are mainly discussed.

Experimental

Samples (the 2.2, 2.4, 2.6, 2.7, 2.8 and 6.8 polymer) were prepared by polycondensation between the corresponding diol and dibasic acid using the $ZnCl_2$ as a catalyst. To obtain high molecular weight polymers, the later stage of the reaction was carried out in a vacuum keeping the pressure below 1 mmHg and bubbling argon gas through the reacting mass. The polyesters prepared as above were purified by repeated precipitation from benzene solution with methylalcohol and dried in a high vacuum at room temperature.

The samples used for ESR measurements were prepared in a 5 mmϕ glass tube with dried nitrogen atmosphere, and subjected to irradiation at 77°K. Irradiation dose was about 4 Mrad.

The ESR spectrometer used in the present study was a JES-3BSX type apparatus (Japan Electron Optics Laboratory Co., Ltd.) with 100 kHz field modulation and TE_{011} mode cavity. The ESR measurements were carried out at different temperatures from liquid nitrogen to room temperature using variable attachments for the spectrometer.

The drawn samples of 6.8 polymer were also prepared from the film obtained by means of hot pressing at melting point. Drawing was carried out at room temperature, up to 500% in draw ratio. The ESR spectra were measured on various orientations of the specimen in the applied magnetic field.

Results and Discussion

The ESR spectra of the irradiated 2.4 polymer measured at various temperatures are shown in Fig. 1. At low temperature, a single line spectrum is overlapped on a weak six-line spectrum. By raising the temperature, the signal intensity decreases gradually and the spectrum begins to split at around −140°C. At room temperature, it splits into a five-line spectrum with a hyperfine (hf) constant of about 25 gauss.

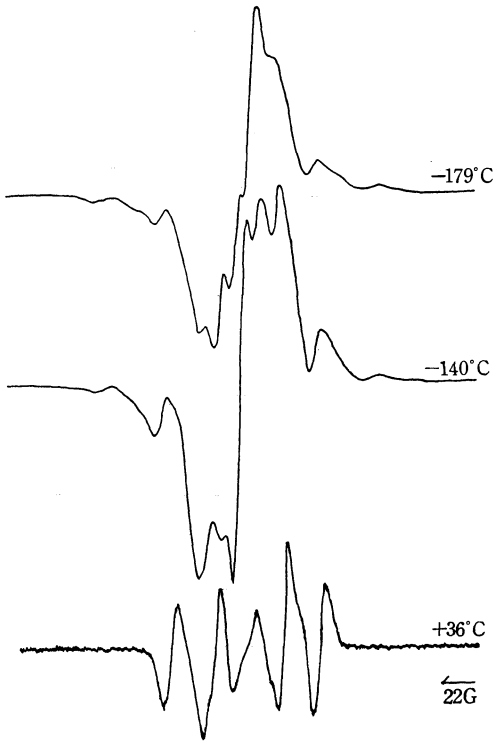

Fig. 1. The ESR spectra of γ-irradiated 2.4 polymer.

As possible species of the radical produced in these polyesters, three kinds of species are expected which are produced by abstraction of hydrogen atom from the acid or the glycol part of the main chain.*2 The three types are those which could be produced by extracting α-hydrogen from the acid

(A) $-\left[(CH_2)_n-O-\overset{\overset{O}{\|}}{C}-\dot{C}H-(CH_2)_{m-1}-\overset{\overset{O}{\|}}{C}-O\right]-$

(B) $-\left[(CH_2)_{n-1}-\dot{C}H-O-\overset{\overset{O}{\|}}{C}-(CH_2)_m-\overset{\overset{O}{\|}}{C}-O\right]-$

(C) $-\left[CH_2-\dot{C}H(CH_2)_{n-2}-O-\overset{\overset{O}{\|}}{C}-(CH_2)_m-\overset{\overset{O}{\|}}{C}-O\right]-$ or

*2 At the first stage of the analysis we examined the possibility of radical production by chain scission, but the possibility was excluded on the basis of ESR spectra.

part (A), α-hydrogen from glycol part (B) and the other hydrogen from both the acid or glycol parts (C).

Type C is expected to give the same spectrum as that of the alkyl radical which has often been observed in irradiated polyethylene at low temperatures. From the experimental results, the weak six-line spectrum detected at low temperature might be assigned to type C radical, because the hf constant of the signal is about 33 gauss which equals that of polyethylene.

The spectral changes caused by the rise of temperature in the irradiated 2.6, 2.7 and 2.8 polymer are shown in Fig. 2. This behavior is similar to that of 2.4 polymer. At low temperature the weak six-line spectrum with the hf constant of 33 gauss is also observed more strongly than in that of 2.4 polymer. At room temperature the same type of five-line spectrum as detected in 2.4 polymer is also observed in each polymer. The spectrum may be attributed to either type A or type B radical.

The crystal structures of the linear aliphatic polyesters have been extensively studied by Fuller and Frosh,[11] Turner-Johns and Bunn,[12] Chatani *et al.*,[13] and Kanamoto.[14] According to their

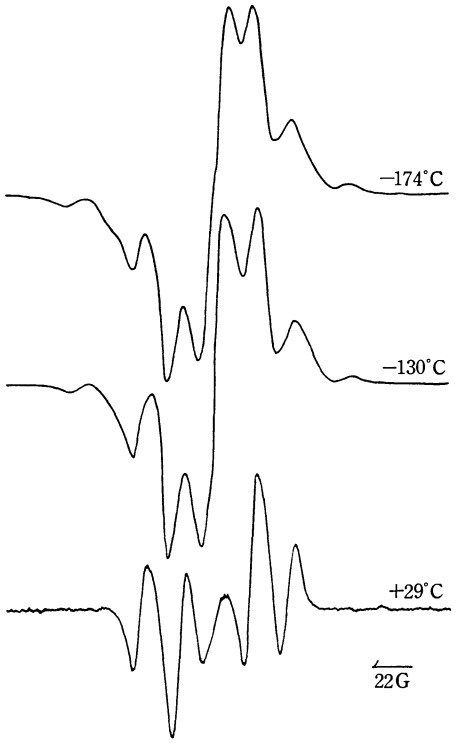

Fig. 2-b. The ESR spectra of γ-irradiated 2.7 polymer.

studies, the crystal structure of these polyesters are very similar to each other and a molecular packing in planes perpendicular to the chain axis is very similar to that of polyethylene. From these results, the chain conformation of the polyesters is found to be nearly planar zigzag except for 2.2 polymer which has helical chain conformations, and for 2.4, 2.6, 2.7 and 2.8 polymers which are slightly distorted around the chain axis in glycol parts. The 6.8 polymer has a substantially planar zigzag chain conformation throughout the chain.

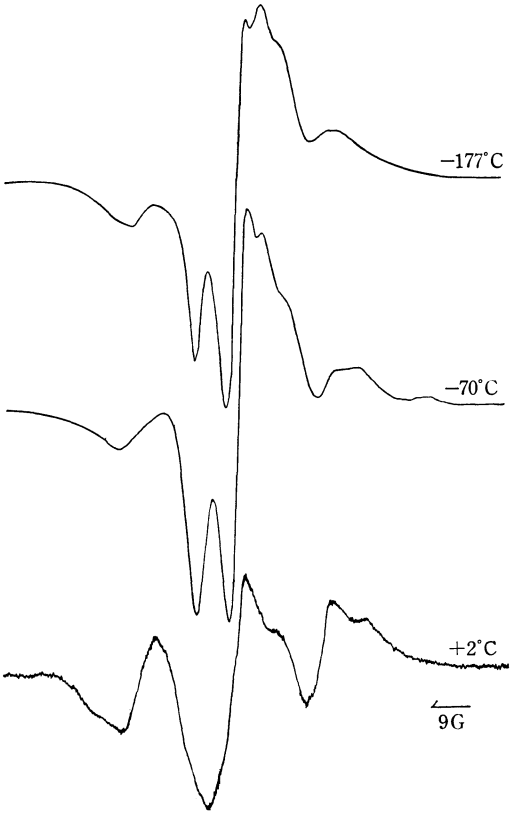

Fig. 3. The ESR spectra of γ-irradiated 2.2 polymer.

In order to obtain further information, the same experiment was performed on 2.2 polymer. As shown in Fig. 3, the spectrum at low temperature is complicated, and is not well resolved even at room temperature. On the other hand, the same type of spectrum has been observed on both irradiated poly(ethylene terephthalate)[15] and powdered succinic acid,[16] and the spectrum has been interpreted as the result of the interaction between an odd electron and three nonequivalent hydrogen atoms (*i.e.*, α and two β-hydrogen atoms). The nonequivalency of these hydrogen atoms in the hf interaction may be caused by distrotions of the methylene groups from the planar zigzag conformation. Considering the chemical structure of 2.2 polymer, the radical produced by irradiations is probably situated on α-carbons of diacid or diol parts. According to the crystal structure of the polymer,[13] methylene groups in both parts are distorted from the planar zigzag chain conformation. From the distortion in the methylene group we can see the coincidence of the ESR spectrum of the 2.2 polymer with that of poly(ethylene terephthalate). In 2.4, 2.6, 2.7 and 2.8 polymer, as mentioned above, it is known that the ethylene glycol part of the polymers have also a slight departure from the planar chain conformation. If type B radical was produced in the polymers, unresolved signals similar to that obtained in 2.2 polymer should be expected. However, only the five-line spectrum is observed in the polyesters. This suggests that the five-line spectrum observed at room temperature could be assigned to the type A radical on the acid parts having planar zigzag chain conformation.

The effect of temperature on the ESR spectra of the 6.8 polymer was studied by raising the tem-

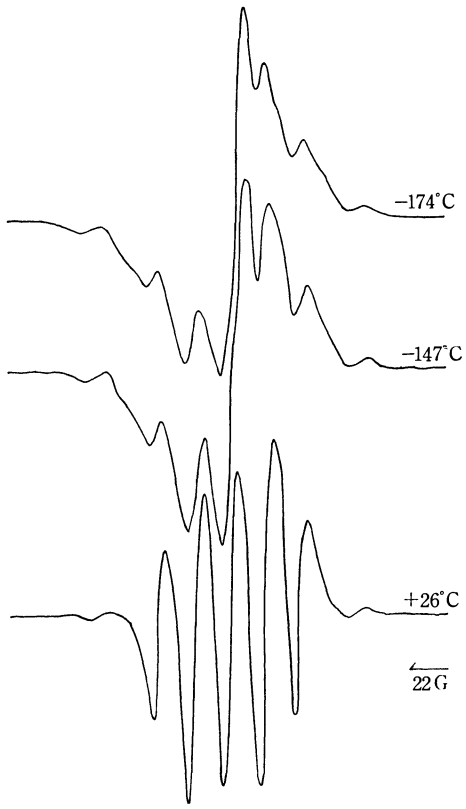

Fig. 4. The ESR spectra of γ-irradiated 6.8 polymer.

16) C. Heller and H. M. McConnell, *J. Chem. Phys.*, **32**, No. 5, 1535 (1960).

perature (Fig. 4). At low temperature the six-line spectrum is larger than that of the 2.4, 2.6, 2.7 and 2.8 polymers, and decreases with rising temperature. At room temperature the five-line spectrum was also observed with a trace of type C, and the spectral pattern and the hf splitting are very similar to those of polymers described above.

The chain conformation of the polymer, as reported by Kanamoto,[14] is planar zigzag in both dibasic acid and the diol parts. If type B radical was produced in the polymer, the spectral pattern and the hf constant of the signal might be different from that of the five-line spectrum. However, the spectrum is in good agreement with that of the polyester with ethylene glycol. This indicates that type A radical is more probable than type B because of the resonance stabilization

As shown in Fig. 5, the integrated intensity ratio of the five-line spectrum is nearly 1 : 2 : 2 : 2 : 1. The intensity distribution is interpreted as the result of the interaction between an odd electron and one α-hydrogen and two equivalent β-hydrogen atoms. To obtain the anisotropic behaviour of α-hydrogen, experiments are carried out in drawn 6.8 polymer. The spectra were measured in orientation axes parallel and perpendicular to the external magnetic field. The radicals trapped in the specimen quickly disappear by the reaction with oxygen, since experiments are carried out in air without sealing the sample tube. The spectra obtained at −80°C are shown in Fig. 6-a, where type C radical remains.

Salovy and Yager[17] have reported the anisotropy in the ESR spectrum of oriented mats of solution-grown polyethylene single crystal.

In the present case, the signal intensity of type C radical will be similar to the alkyl radicals of the polyethylene studied by Salovy and Yager.

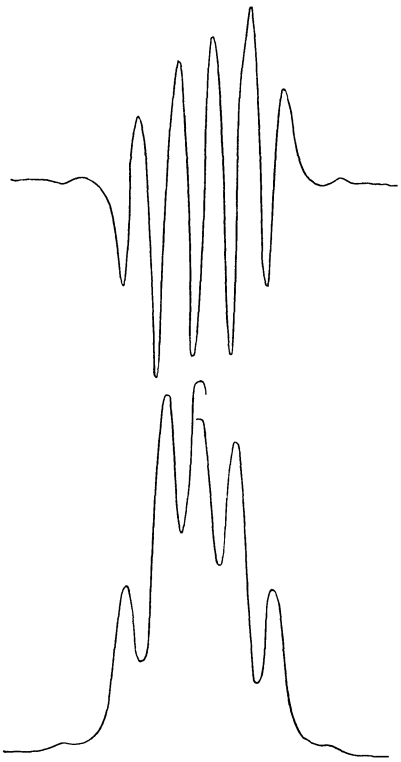

Fig. 5. The ESR spectrum of γ-irradiated 6.8 polymer at 26°C: (top) observed first derivative curve; (bottom) its integrated absorption curve.

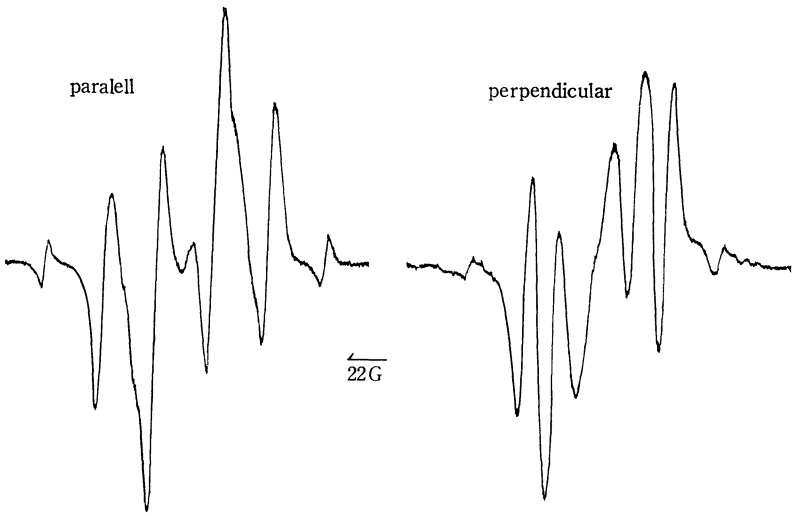

Fig. 6-a. The ESR spectra of γ-irradiated 6.8 polymer measured at −80°C. Magnetic field parallel (left) and perpendicular (right) to chain.

17) R. Salovy and W. A. Yager, *J. Polym. Sci.*, **A-2**, 219 (1964).

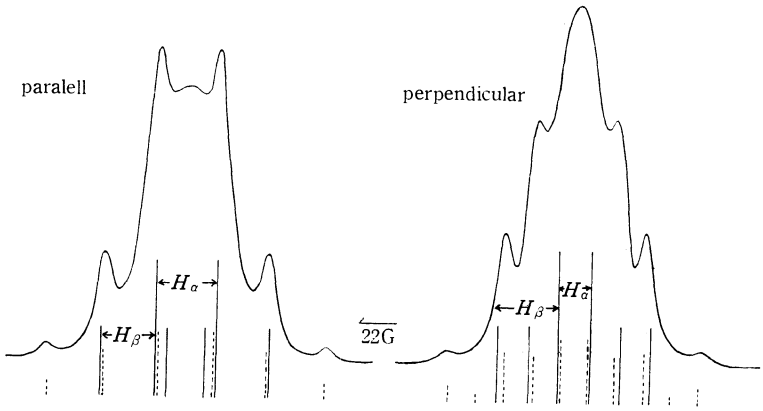

Fig. 6-b. The integrated absorption curves of γ-irradiated 6.8 polymer. Vertical dotted lines show hyperfine pattern obtained by Salovey[17] and solid lines show predicted hyperfine pattern of type A radical.

Thus, by substracting the signal intensity of polyethylene from the integrated absorption curves of our spectrum, the intensity due to type A is obtained in both orientations parallel and perpendicular to the external magnetic field, as shown in Fig. 6-b. The anisotropy of the hf constant of α-hydrogen was estimated as $A^{\alpha}_{//}=34.6$ gauss and $A^{\alpha}_{\perp}=17.3$ gauss. In oriented polymeric substances the molecular chain is aligned to the orientation axis (Y). Thus the hf constant of α-hydrogen to direction (X and Z) normal to the molecular chain is obtained as the average in hf interactions, so that $A^{\alpha}_{//}$ and $A^{\alpha}_{\perp}$ are to be A_y and $(A_x+A_z)/2$, respectively. Consequently, $A_y=34.6$ and $A_x+A_z=34.6$ are evaluated. A values are in close agreement with those of low molecular weight organic compounds.[16,18-20] The fact also permits the five-line spectrum to be attributed to type A radical.

Existence of two kinds of species is concluded. The one is relatively short-lived and gives a six-line spectrum which is attributed to type C. The other gives the five line spectrum which is stable even at room temperature. Based on the chain conformation of the polymer, it is assigned to type A radical in the acid parts.

The author wishes to thank Professor M. Takeda and Dr T. Kanamoto, Department of Chemistry, Science University of Tokyo, for their valuable advice and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 663—669 (1970)

Measurement of the Hydrogen Ion Concentration in the Vicinity of the Anode during Electrodeposition of Water-Soluble Resin*1

Yoshio NAKAMURA, Kimio KOMATA and Hiroshi NOZAKI

Institute of Industrial Science, The University of Tokyo Roppongi, Minato-ku, Tokyo

(Received August 4, 1969)

In order to make clear the mechanism of the electrodeposition of water-soluble resin, the hydrogen ion concentration in the vicinity of the anode during electrodeposition was measured using a quinhydrone reaction on platinum wire. The measured concentration of hydrogen ions in the vicinity of the anode was then compared with that of hydrogen ions which had been calculated according to the diffusion theory. The results show that the most of the hydrogen ions produced at the anode during electodeposition are consumed in the vicinity of the anode. This shows that there is apparently ionic combination of hydrogen ions with organic anions on the anode; this may lead to the deposition of organic anions.

Many reports related to the mechanism of the electrodeposition of water-soluble resin have been published. For example, the results of the analyses of the gas generated at the anode during electrodeposition,[1-3] chemical analyses of the components of the deposited film,[4-6] and electrochemical interpretations of electrode phenomena[2,5,7] have been reported. These reports have supported the idea that the film formation of water-soluble resin is made by coagulation caused by the ionic combination of anionic resin with hydrogen ions according to the following reaction:

$$R(COO^-)_n + nH^+ = R(COOH)n \qquad (1)$$

where $R(COO^-)_n$ represents the organic anion.

Moreover, a current-time relation was observed at a constant voltage deposition, and results which may support the coagulation theory were obtained.[8]

These reports show that the principal electrode reaction at the anode during the electrodeposition of water-soluble resin is the electrolysis of water, which gives hydrogen ions at the anode; these ions then cause the coagulation of organic anions. Therefore, one of the best means to make clear the mechanism of the film formation is the measurement of the concentration of hydrogen ions on the anode surface. However, this measurement is very difficult because the diameter of the glass electrode is not small enough to measure the concentration gradient of hydrogen ions on the anode. Nevertheless, even the results were not rigorous, at first, the concentration gradient of hydrogen ions on the anode was measured using indicating reagents.

In order to obtain detailed results, the concentration of hydrogen ions in the vicinity of the anode was measured using a quinhydrone reaction on the platinum wire; some appreciable results were thus obtained.

Experimental

Sample. Maleic methyleleostearate was used as a water-soluble resin. Methyleleostearate was obtained by the methyl-inter-esterification of china wood oil. A mixture of 150 g of methyleleostearate and 50 g of maleic anhydride was heated for two hours at 180°C and then for additional three hours at 230°C. During the reaction, the mixture was kept in a nitrogen atomosphere. The method of purifying the reaction product was the same as that reported in a previous report.[8] The purified maleic methyleleostearate was dissolved into potassium hydroxide solution, after which this solution was used as a sample. The pH of the solution was adjusted by means only of the potassium hydroxide solution and maleic methyleleostearate. We name this solution simply the MME solution.

The potassium chloride, quinhydrone, and hydroquinone used in this experiment were of a special grade.

Apparatus. The measurement of the pH in the vicinity of the anode was made by means of measuring the potential of the hydroquinone-quinone reaction on platinum wire, as is shown in Fig. 1 (A).

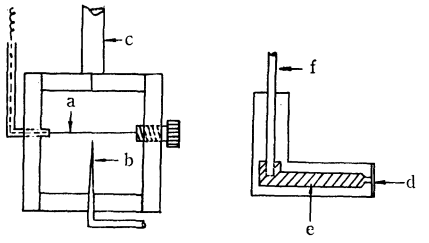

Fig. 1. Platinum wire electrode (A) and electrolysis electrode (B).
a: platinum wire, b: capillary electrolyte bridge, c: arm, d: platinum plate electrode, e: mercury, f: copper rod.

The platinum wire had a diameter of 0.05 mm, all its surface except for a length of 5 mm was insulated by organic resin. The arm of the frame which supported the platinum wire electrode was supported by the arm of the cathetometer. The platinum electrolysis electrode is shown in Fig. 1(B). A polished platinum plate was stuck on the even frame and connected to the copper rod through the mercury pool. The frames of both (A) and (B) were made of acrylic resin. As is shown in Fig. 2, a microscope was arranged above the electrolysis electrode and the wire electrode, so the wire electrode was set at will in the vicinity of the electrolysis electrode.

The circuits of the electrolysis and the measurement of the quinhydrone electrode potential are shown in Fig. 2.

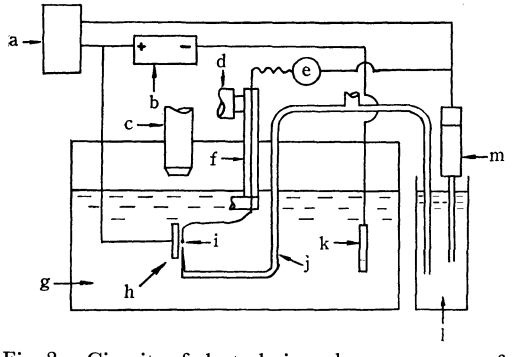

Fig. 2. Circuits of electrolysis and measurement of Q.H. potential.
a: XY recorder, b: current supply, c: microscope, d: arm of cathetometer, e: electrometer, f: arm of wire electrode, g: electrolyte solution, h: platinum plate, i: platinum wire electrode, j: electrolyte bridge, k: cathode, l: saturated KCl solution, m: saturated calomel electrode.

During electrolysis, the electrolysis electrode potential (=anode potential) was recorded by means of a Riken Denshi XY recorder, model F-42. The quinhydrone potential was measured by means of a Keysley electrometer, model 610B. This measurement was made when the electrolysis circuit was open in order to escape the $i \cdot R$ effects, where i and R are the current and the resistance of the electrolyte solution respectively. The quinhydrone potential was measured within 2 sec. However, when the electrolyte solution was a 1N KCl solution saturated with quinhydrone, the quinhydrone potential was measured without cutting the current. We will abbreviate hydroquinone, quinone and quinhydrone H.Q., Q., and Q.H. respectively.

When Q.H. was added to the electrolyte solution, H.Q. was oxidized at the anode as follows:

$$C_6H_4(OH)_2 \rightleftarrows C_6H_4O_2 + 2H^+ + 2e \qquad (2)$$

Then the anode reaction of the electrolyte solution saturated with Q.H. was observed. The pH of the anode part of the cell, which is shown in Fig. 3, was measured.

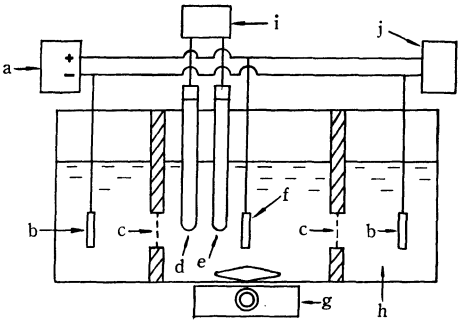

Fig. 3. Apparatus for pH measurement of anode part.
a: current supply, b: cathode, c: milipore filter, d: calomel electrode, e: glass electrode, f: anode, g: stirrer, h: electrolyte solution, i: pH meter, j: XY recorder.

The anode part and the cathode parts of the cell were separated by milipore filters. When a electrolyte solution including a supporting electrolyte is used, most hydrogen ions produced at the anode remain within the anode part because the migration and diffusion of the hydrogen ions into the cathode parts are negligible compared with their production rate. The cells shown in Figs. 2 and 3 were kept 25±0.5°C.

Results

Hydrogen Ion Production at the Anode. The mechanism of the deposition of water-soluble resin is considered to be a coagulation of organic anions occuring by means of ionic combination with hydrogen ions, so the anode reaction of the aqueous electrolyte solution saturated with Q.H. must also be investigated.

Using the cell shown in Fig. 3, the pHs of the anode part during the constant-current electrolysis of a 1N KCl solution and a 1N KCl solution saturated with Q.H.*2 were measured. The results are shown in Fig. 4, which shows that the rate of the production of hydrogen ions is nearly the same whether the electrolyte solution includes Q.H. or

*2 An oversaturated solid substance of Q.H. was filtered out at 25°C.

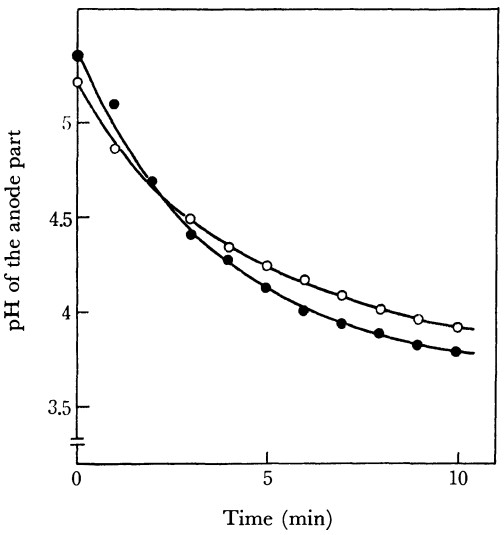

Fig. 4. pH of the anode part against time.
●: 1N KCl solution saturated with Q.H., ○: 1N KCl solution, current density 2.5 mA/cm².

not.

However, the anode potentials during electrolysis were about 0.45 and 1.1 V (*vs.* SCE) in the cases of a 1N KCl solution saturated with Q.H. and a 1N KCl solution respectively. These results can naturally be expected according to Reactions (2), (3), and (4):

$$4OH^- = 2H_2O + O_2 + 4e \quad (3)$$

$$2H_2O = 4H^+ + O_2 + 4e \quad (4)$$

Moreover, the effects on the deposition of the addition of Q.H. to the deposition bath (5% in-weight MME solution) were observed; the results are shown in Table 1, where τ_2 is the transition time as shown in Fig. 9. It is known that after $t=\tau_2$ an organic film is formed on the anode.

Table 1. Effects of the concentration of Q.H. on transition time τ_2 (sec)

Current density (mA/cm²)	Concentration of Q.H. (mol/l)·10²		
	0	0.9	2.0
2.5	86	80	75
5.0	21	20.5	20

The results show that τ_2 decreased as the weight of the addition of Q.H. increased, but the effect was minor.

pH and Q.H. Electrode Potential. The equilibrium potential of Q.H. solution is given by Eq. (5) according to Reaction (2):

$$E = E_0 + (RT/2F)\ln(a_{Q.}/a_{H.Q.}) + (RT/F)\ln a_{H^+} \quad (5)$$

where E, E_0, and a_i are measured potential, the standard potential, and the activity of the i species respectively. As the concentration of Q. equals that of H.Q. in the bulk solution, according to Eq. (6), the second term on the right-hand side of Eq. (5) is zero.

$$C_6H_4(OH)_2 \cdot C_6H_4O_2 = C_6H_4(OH)_2 + C_6H_4O_2 \quad (6)$$

Here we name the second term E_1. However, when the Q.H. electrode potential was measured in the vicinity of the anode where the current flows, the second term (E_1) is not zero but a function of x, t, and I, where x, t, and I are the distance from the anode surface, the time after switch-on, and the current density respectively.

The relations between the pH and the Q.H. equilibrium potential are shown in Fig. 5.

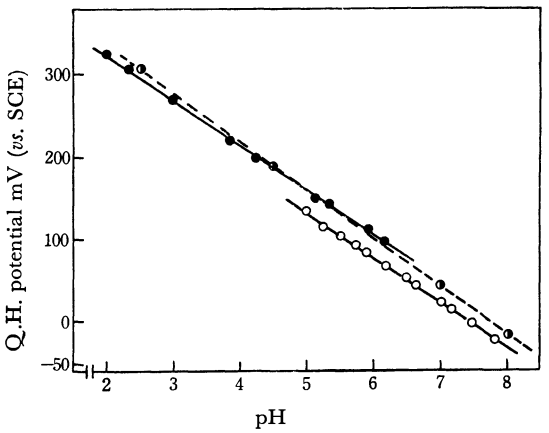

Fig. 5. Q.H. potential against pH.
●: 1N KCl solution, ○: MME solution, ◑: theoretical curve.

The potential was measured at 25°C using a saturated calomel electrode as the reference electrode. The pH was measured by means of a Hitachi-Horiba pH meter, model 5. The pH of the solution was adjusted by means of the addition of hydrogen chloride solution. The same figure also shows theoretical curve given by Eq. (5). The potential-pH curve of a 1N KCl solution differs from that of the 5% (in weight) MME solution.

However, the linear relation between the potential and the pH is satisfied in both solutions, and the values of the slopes of the curves are nearly equal. In the MME solution, a plot of the potential against the same value of pH gradually decreased with time, but the linearity between potential and pH was satisfied at all times and the value of the slope of the line was kept constant. Therefore, by measuring a potential against a value of pH, the relation between potential and pH was obtained as a function of the time.

Electrolysis of KCl Solution and pH Measurements. In order to test the method, the pH in the vicinity of the anode was measured by means of Q.H. potential measurement and was

compared with the results of theoretical calculation. The electrolyte solution was a 1N KCl solution saturated with Q.H.

In Fig. 6, the measured potential at $x=0.1$ mm is shown; the anode potential is also shown in Fig. 6.

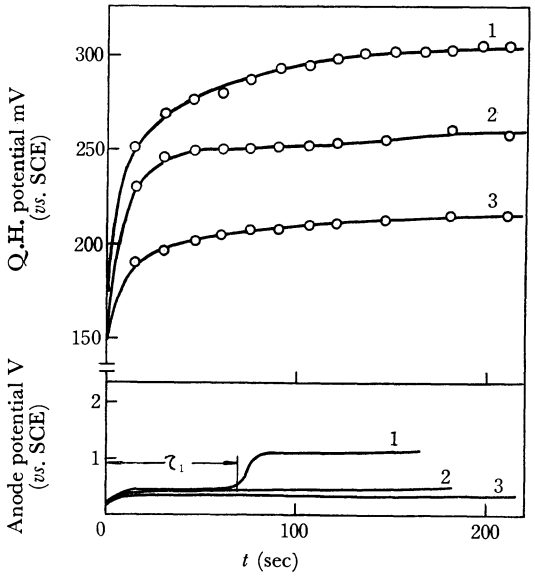

Fig. 6. Q.H. potential at $x=0.1$ mm and anode potential against time in 1N KCl solution saturated with Q.H. current density, 1 : 1.0, 2 : 0.1, 3 : 0.01 mA/cm².

In the range of current density from 0.01 to 0.1 mA/cm², the anode potential during electrolysis was kept about 0.4—0.6 V (*vs.* SCE). However, when the current density was 1 mA/cm², the transition to a more noble potential was observed; we term this transition time τ_1.

The values of the Q.H. potential shown in Fig. 6 were converted to the pH value using the results shown in Fig. 5, and the pH-time curves are shown in Fig. 7. In a solution containing a supporting electrolyte, hydrogen ions produced at the anode will diffuse to the bulk solution from the anode surface. Therefore, it is possible to calculate the hydrogen ion concentration or pH as a function of x, t, and I.[9]

Assuming that the diffusion is one dimension and that the reaction shown in Eq. (2) or (4) occurs at the anode, the values of pH in the vicinity of the anode were calculated; the results are also shown in Fig. 7. The chemical reaction of hydrogen ions and hydroxide ions is negligible when the pH of the electrolyte solution is smaller than 6. Figure 7

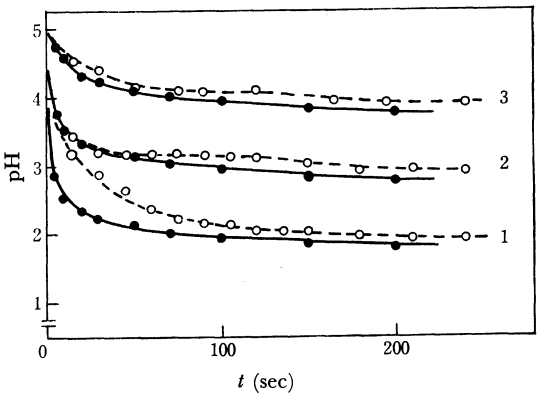

Fig. 7. pH at $x=0.1$ mm against time in 1N KCl solution saturated with Q.H. current density, 1 : 1.0, 2 : 0.1, 3 : 0.01 mA/cm², the dotted lines are experimental curves and the solid lines are theoretical curves.

shows that this method of pH measurement is reproducible, though it is not highly accurate.

Electrodeposition and pH Measurement. Electrodeposition was made at a constant current density. The concentration of MME was 5% (in weight), and the pH of the MME solution was 7.9. The Q.H. potential during deposition was measured, after which the values were converted to the pH values. In Fig. 8, the pH values at $x=0.1$, 0.2, and 0.5 mm are shown against the time after the current has been put on. The dotted line drawn in Fig. 8 shows that film formation begins at that time, that is, $t=\tau_2$.

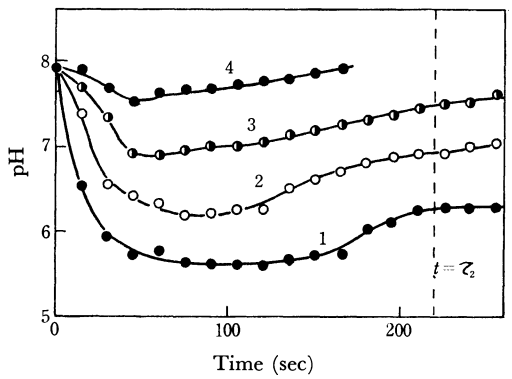

Fig. 8. pH against time.
Current density 2 mA/cm², MME concentration 2.5% (in weight), x, 1 : 0.1, 2 : 0.2, 3 : 0.3, 4 : 0.5 mm.

Deposition was made at several concentration of MME but at a constant current density, 3 mA/cm², and the potential of Q.H. at $x=0.3$ mm was measured. The pHs of the solution were adjusted to 7.9. The results, converted to the pH values are shown in Fig. 9. The anode potentials are also shown in Fig. 9.

9) P. Delahay, "New Instrumental Method in Eelctrochemistry," Interscience Pub. (1954), p. 47; H. S. Carslaw and J. C. Jaeger, "Conduction of Heat in Solids," Clarendon Press (1950), p. 216.

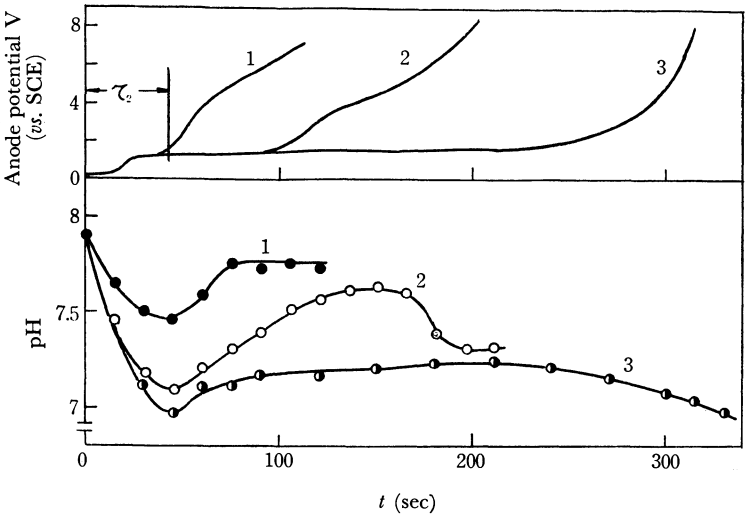

Fig. 9. Anode potential and pH at $x=0.3$ mm against time.
MME concentration, 1 : 5, 2 : 2.5, 3 : 1.25% (in weight), current density 3 mA/cm^2.

τ_2 increases with a decrease in the concentration of MME. On the other hand, the values of pH decrease with an increase in the concentration of MME, and the curves of pH and time have a peak.

The Q.H. potential at several concentrations of MME was measured as a function of x, and t; the values of the potential were then converted to the pH values by using the results shown in Fig. 5. The values of pH at $t=20$ and 75 sec are shown against x in Figs. 10 and 11 respectively. The theoretical values of the pH calculated as before are also plotted in these figures. They show that the concentration of hydrogen ions in the vicinity of the anode is smaller than that of the hydrogen ions which were calculated theoretically.

Discussion

When the potential of the reaction shown in Eq. (2) in the vicinity of the anode, where the current flow is measured, the concentration of H.Q. decreases and that of Q. increases in the solution. This causes the E_1 potential. By means of chronopotentiometry, the saturated concentration of Q.H. was measured. $I\cdot\tau_1^{1/2}$ was plotted against the concentration of Q.H. in 1N KCl solution and 5% (in weight) MME solution. Moreover, $I\cdot\tau_1^{1/2}$ was plotted against the concentration of H.Q. in a 1N KCl solution. The results, shown in Fig. 12, show that the concentration of H.Q. is nearly equal to that of Q.H. when Q.H. is dissolved in the solution.

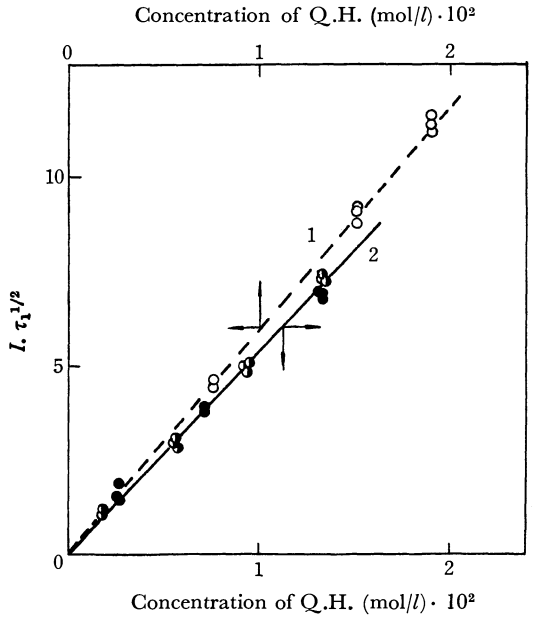

Fig. 12. $I\cdot\tau_1^{1/2}$ against concentration of Q.H. or H.Q.
1: when H.Q. was dissolved into 1N KCl solution,
2: when Q.H. was dissolved into, ●: 5% MME solutionl ◑: 1N KCl solution.

That is, most of the dissolved Q.H. dissociates to H.Q. and Q. From the $I\cdot\tau_1^{1/2}$ values of the saturated solution and the results shown in Fig. 12, the saturated concentrations of Q.H. were found to be about 1.5×10^{-2} and 2.1×10^{-2} mol/l in the 1N KCl solution and in the 5% (in weight) MME solution respectively.

Assuming that the reaction shown in Eq. (2) occurs at a constant current density, I, and that H.Q. and Q. are transported only by diffusion with one dimension, their concentrations can be calculated as functions of x, t, and I. Then, if $C_i(x,t)=a_i(x,t)$, E_1 can be calculated according to Eq. (5), where $C_i(x,t)$ means the concentration at x and t of the i species. In Table 2, the values of E_1 are shown as functions of x, t, and I. The values of E_1 were calculated assuming that $D_{Q.}=D_{H.Q.}$*3 and $(dC_{Q.}(x,t)/dX)_{x=0}+(dC_{H.Q.}(x,t)/dX)_{x=0}=0$.

$I\cdot\tau_1^{1/2}$ in a 1N KCl solution saturated with Q.H. is about 8.5. Therefore, when the current densities are from 0.01 to 0.1 mA/cm², the transition from the oxidation of H.Q. to that of water does not occur within 200 sec, and the value of E_1 is negligibly small compared with the values of the other term in Eq. (5). When the current density is larger than 0.5 mA/cm², E_1 becomes appreciable with the time, as is shown in Table 2, and the transition occurs as is shown in Figs. 6 and 9. In Table 2, the values of E_1 at $I=1.0$ mA/cm² and $t=100$ sec are not obvious because the transition occurs at 75 sec.

However, as is shown in Figs. 8 and 9, the Q.H. potential does not increase so much with the time. After the transition has occurred, the anode reaction will be the reaction shown in Eqs. (3) and (4), so Reaction (2) may be retrained by Reaction (3) and (4).

In the case of high current densities, the approximate concentrations of H.Q. and Q. will be given as follows. When the current density is high, τ_1 becomes very short, so it may be assumed that at $t=0$, the initial concentration of H.Q. at $x=0$ is zero and that the initial concentration of Q. equal to that of H.Q. at $x\neq0$. According to the diffusion theory, the concentrations of H.Q. and Q. were calculated as functions of x and t, and the values of E_1 were calculated. The results are shown in Table 3.

Table 3 shows that, within $t=200$ sec, the value of E_1 is 30 mV at most; this value corresponds the pH value of 0.5, according to Fig. 5. It is considered that the peak of the pH-time curve in Fig. 9 is caused by E_1 and the transition from the oxidation of H.Q. to that of water, for the pH-time curves in Figs. 7—11 were obtained from the value of the

*3 $D_{H.Q.}$ is the diffusion constant of H.Q.; it has value of 7.6×10^{-6} cm²/sec at 25°C.[10]

10) International Critical Table, Vol. 70 (1933); M. Kolthoff and E. F. Lingane, *J. Amer. Chem. Soc.*, **63**, 664 (1941).

TABLE 3. CALCULATED E_1 (mV) AT HIGH CURRENT DENSITY

x (mm)	t (sec)									
	5	10	15	20	30	50	70	100	150	200
0.1	4.0	13	16	18	21	24	28	30	32	34
0.2	1.4	3.6	5.9	7.6	11	14	17	21	23	24
0.3	—	1.0	1.8	4.9	5.2	8.5	12	15	17	18
0.5	—	—	—	—	0.8	2.5	4.5	7.5	10	11

measured Q.H. potential without any correction for E_1. However, the transition time, τ_1, does not correspond to the time at which a peak appears. At present, it is not obvious why a peak appears on the pH-time curve.

As is shown in Figs. 8 and 9, the hydrogen ion concentration in the vicinity of the anode does not increase with the time, but remains lower than the concentration to be expected from only the diffusion process. That is, most hydrogen ions produced at the anode are consumed on the anode surface. This shows that there is an ionic combination of hydrogen ions with MME anions. In Fig. 9, some anode potential-time curves are shown, and the transition time, τ_2, is observed on the curves. As has been noted previously, τ_2 shows that film formation begins. Compared with the pH-time curve, it is found that the rate of the ionic combination of hydrogen ions on the anode does not change at all at $t=\tau_2$.

These results show that the ionic combination of hydrogen ions begins at switch-on.

In this experiment, the pH on the anode surface was not measured. Though the pH-x curves are shown in Figs. 10 and 11, it is not impossible to ascertain the value of pH on the anode surface. In the experiment of the bulk solution without an electric field, the value of pH which the MME solution begins to coagulate was about 5.

The Dye-sensitized Photolysis of Hexamethyleneammonium Hexamethylenedithiocarbamate by Thiazine Dyes

Toshihiro YAMASE, Hiroshi KOKADO and Eiichi INOUE

Imaging Science and Engineering Laboratory, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received August 4, 1969)

Hexamethyleneammonium hexamethylenedithiocarbamate (HMTC) was photolyzed by UV light to yield carbon disulfide as the decomposition product. This photolysis could be sensitized by thiazine dyes, such as methylene blue and thionine. New methylene blue was the most effective among the sensitizers of this type examined. Bewteen the reciprocal concentration of HMTC and the reciprocal quantum yield, a linear relation was observed. The presence of oxygen was essential for the sensitization. Systems containing methylene blue appear to be more sensitive to oxygen than those containing thionine or new methylene blue. In the presence of an appropriate reducing agent such as allylthiourea, the quantum yield was decreased. The sensitization mechanism by thiazine dyes was probably different from that by benzophenone previously reported. It seems that the sensitization by thiazine dyes takes place by means of the interaction of the triplet state of the sensitizer with dissolved oxygen.

In previous papers,[1,2] the photochemical reaction of sodium *N,N*-dimethyldithiocarbamate (SMTC) was reported. Carbon disulfide was found in the decomposition products. This photolytic reaction could be sensitized by benzophenone under the light (365 nm wavelength) which was absorbed by benzophenone. The photo-sensitization was observed regardless of whether or not the solution contained dissolved oxygen. It seemed that the sensitization took place by means of energy transfer

2) T. Yamase, H. Kokado and E. Inoue, *ibid.*, **72**, 162 (1969).

from the triplet state of the sensitizer to SMTC molecules.[2)]

We have found that SMTC could be efficiently sensitized by thiazine dyes such as methylene blue if the solution contained dissolved oxygen. However, we encountered difficulty in studying the sensitizing effect of these dyes for the photolysis of SMTC; for their stability is greatly reduced in the alkaline ethanol, while SMTC is stable only under alkaline conditions. This difficulty could be avoided by using HMTC as the photolyzable dithiocarbamate, because this substance is stable in neutral ethanol. This paper will describe the effects of the concentration and the reducing agent on the sensitized-photolysis by thiazine dyes. The effect of oxygen will also be discussed in connection with them.

Experimental

HMTC was prepared by adding carbon disulfide slowly to a petroleum ether solution of hexamethyleneimine cooled to about 5°C. The resultant white precipitate was then filtered off, washed with fresh petroleum ether, and dried in the air. The crystallized HMTC was a pale cream-colored powder. It was recrystallized three times from ethanol to form white needles melting at 147°C. Methylene blue, thionine, and new methylene blue (G. R. grade, Tokyo Kasei Corp.) were purified by three recrystallizations from water. Allylthiourea, triethanolamine, and ethanol were G.R. grade reagents (Tokyo Kasei Corp.). The experimental procedure used in this study was almost the same as that described previously.[1,2)] Oxygen was removed from the solution by a standard freeze-thaw cycle procedure under a vacuum of 10^{-4} mmHg. A 1 kW-tungsten lamp was used as a source of actinic light for the dye-sensitization. Transmitting glass filters which cut off light shorter than 580 and 620 nm were used for thionine or methylene blue, and for new methylene blue, respectively. In most of the experiment a filter absorbing heat (HR 1-69) was also employed. Unfortunately, convenient chemical actinometers for measuring red light are not available. We assumed, therefore, that the quantum yield under the incident red light is the same as that under a 546 nm light. The latter was easily measured using Reinecke's salt as a chemical actinometer. In this case, the concentration of dye has to be increased for it to have enough absorption at 546 nm. The dye concentration was then high enough to absorb 100% of the incident red light. The quantum yields under various dye concentrations were calculated from the dye concentration against decomposed HMTC quantity relationship at a constant illumination time.

Results and Discussion

Photolysis Rate. Typical examples of the degree of photolysis *versus* time relationships under different experimental conditions are shown in Fig. 1. The logarithm of the surviving HMTC concentration changed linearly with the time. Sensitization showed no induction period and proceeded at a considerable speed. Almost no fading of dye was observed, even if the initial HMTC concentration was changed ($2-6\times10^{-4}$M). The slope in Fig. 1 was unchanged within the range of experimental uncertainty, as long as all the other factors were held constant.

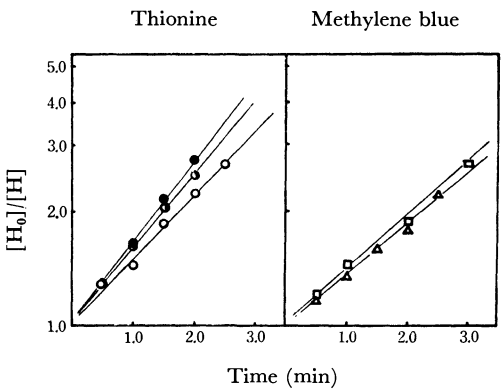

Fig. 1. Photolysis of HMTC as a function of illumination time.
Thionine conc.$=8.0\times10^{-5}$M; methylene blue conc.$=4.0\times10^{-5}$M; initial HMTC conc. ($[H_0]\times10^4=3.69$. (○), 7.51 (●), 2.64 (◑), 3.75 (△), 2.64 (□)

Effect of Dye Concentration. The effects of the concentrations of thiazine dyes are shown in Fig. 2. The reciprocal of the quantum yield changed linearly with the dye concentration.

	Thionine	Methylenene blue	New methylene blue
Intercept	4.3	6.0	3.4
$(\text{Slope})^{-1}$	3.9×10^4	3.4×10^4	1.9×10^4

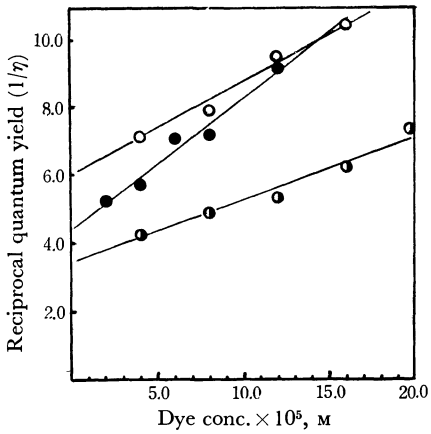

Fig. 2. Dependence of the quantum yield on the dye concentration.
HMTC conc.$=3.7$—3.8×10^{-4}M; methylene blue (○), thionine (●), new methylene blue (◑)

Effect of HMTC Concentration. The results of photolysis at different HMTC concentrations are

	Thionine	Methylene blue	New methylene blue
$(\text{Slope})^{-1}$	5.9×10^{2}	4.5×10^{2}	7.0×10^{2}

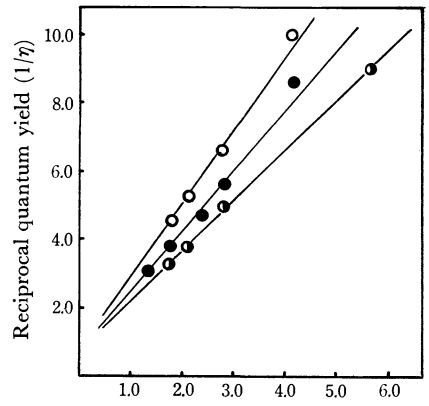

Fig. 3. Dependence of the quantum yield on the HMTC concentration.
Dye conc.$=4.0\times10^{-5}$M; methylene blue (○), thionine (●), new methylene blue (◑)

represented in Fig. 3. Figure 3 shows that a linear relation between the reciprocal of the quantum yield and that of the HMTC concentration holds for all of the dyes investigated. Apparently the efficiency of sensitization increases in the following order: methylene blue<thionine<new methylene blue.

Effect of Reducing Agent, Allylthiourea. The fact that the fluorescence of thionine (or methylene blue) was not quenched by HMTC in ethanol suggests that the excited singlet state of dye does not participate in the sensitization. If the sensitization occurs from the semiquinone radicals which are formed from the excited triplet state of the sensitizer, the efficiency of sensitization will be increased by adding a weak reducing agent, such as triethanolamine or allylthiourea.[3,4] Figure 4 shows the effect of allylthiourea on the sensitization by methylene blue. Allylthiourea did not increase the efficiency of the sensitization. Allylthiourea was regarded rather a quencher for the chemically-active state of the dye. The present investigation suggests that a reducing agent is not necessary for dye-sensitization. It may be inferred that the sensitization does not take place *via* the semiquinone radical, while in the dye-sensitized photopolymerization,[3,4] this type of process is quite common.

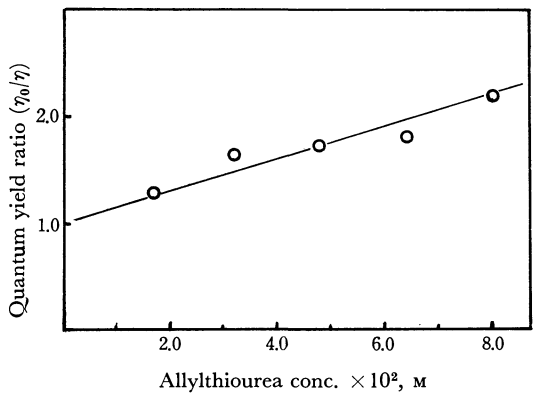

Fig. 4. Effect of allylthiourea on the quantum yield.
initial HMTC conc.$=3.96\times10^{-4}$M; methylene blue conc.$=4.0\times10^{-5}$M; η and η_0 indicate the quantum yields for the system with and without allylthiourea, respectively

Effect of Oxygen. Some representative results of photolysis in a deaerated solution are presented here. Table 1 gives the results for 4.0×10^{-5}M thiazine dye. Table 1 also includes the results obtained in solutions into which oxygen or nitrogen containing a small amount of oxygen had been bubbled in. Remarkable sensitization did not take place in the deaerated systems. This finding indicates the presence of a mechanism different from the photolysis by UV light or sensitized-photolysis by benzophenone, which was almost unaffected by oxygen, as has been reported previously.[1,2] It may be inferred that sensitization by thiazine dyes takes place not by energy transfer from the excited triplet state of the dye to HMTC, as has been proposed in connection with the sensitization of benzophenone,[2] but *via* the interaction of triplet state of dyes with oxygen. Methylene blue appeared to be more sensitive to oxygen than was thionine or new methylene blue. This is identical with what Chaberek has said regarding the effects of thionine and methylene blue on the dye-sensitized photopolymerization.[4]

Sensitization Mechanism. On the basis of the above results, the mechanism of the main reactions may be represented by the following scheme:

	Rate	
$D \xrightarrow{h\nu} D^*$	aI	(1)
$D^* \xrightarrow{k_1} D$	$k_1[D^*]$	(2)
$D^* + D \xrightarrow{k_2} 2D$	$k_2[D^*][D]$	(3)
$D^* + O_2 \xrightarrow{k_3} X$	$k_3[D^*][O_2]$	(4)
$X + \text{HMTC} \xrightarrow{k_4}$ Decomposed HMTC	$k_4[X][H]$	(5)
$X \xrightarrow{k_5} ? \ (D+O_2)$	$k_5[X]$	(6)

where a is the efficiency of the conversion of initially-excited singlets to the triplet states (D*)

TABLE 1

Sensitizer	$[H]_{ini} \times 10^4$	η[a]	η'[b]	η''[c]	η'''[d]
Thionine	5.33	0.251	0	0.128	—
Methylene blue	5.57	0.227	0	0	0.310
New methylene blue	4.86	0.263	0	0.056	—
Benzophenone	3.78	0.160	0.130	—	—

a) atmospheric condition b) deaerated condition
c) saturated with nitrogen to contain little oxygen d) saturated with oxygen

and where I is the rate of red-light absorption by dye (D) in Einsteins/min. Reaction (2) represents the thermal deactivation of D* to the ground state. Reaction (3) denotes the quenching of D* by the dye of the ground state. Reaction (4) is the interaction between D* and oxygen (O_2) to form an unknown substance, X, which then reacts with HMTC as is shown by Reaction (5). Reaction (6) presents the thermal deactivation of X. According to this scheme, and assuming the steady-state condition, the quantum yield can be expressed by Eq. (7):

$$\eta = a\{k_3[O_2]/(k_1+k_2[D]+k_3[O_2])\}\{k_4[H]/(k_5+k_4[H])\} \quad (7)$$

or by

$$1/\eta = (1/ab)(1+k_5/k_4[H]) \quad (8)$$

$$b = k_3[O_2]/(k_1+k_2[D] + k_3[O_2]) \quad (9)$$

$$1/\eta = (1/ac)\{1+(k_1+k_2[D])/k_3[O_2]\} \quad (10)$$

$$c = k_4[H]/(k_5+k_4[H]) \quad (11)$$

The good fit of the data to Eqs. (8) and (10) is shown in Figs. 3 and 2. To introduce the illumination time into the rate equation, let us consider the following rate equation:

$$-\mathrm{d}t/\mathrm{d}[H] = (1/abI)(1+k_5/k_4[H]) \quad (12)$$

If $k_5/k_4[H]$ is sufficiently large, as is shown in the slope of Fig. 3, Eq. (12) becomes:

$$\log([H]_0/[H]) = (k_4/k_5)abIt \quad (13)$$

where H_0 is the initial concentration of HMTC. Figure 1 shows that a linear relation between log ($[H_0]/[H]$) and t holds experimentally. However, the greater concentration of HMTC will allow the plots to deviate from the relationship of Eq. (13). The presence of oxygen is essential to the sensitization by thiazine dyes, as is shown in Table 1. This finding contrasts with what we had earlier found, that oxygen was not necessary for the sensitization by benzophenone or for the direct photolysis. It is well-known that singlet oxygen can be generated from exogenous photo-sensitizers such as methylene blue in the photooxygenation.[5] The sensitized photolysis of HMTC by thiazine dyes may proceed by means of the singlet oxygen formed by energy transfer from the triplet sensitizer. One conceivable mechanism involves the (a) reaction;

$$^1O_2 + \mathrm{HMTC} \rightarrow {}^3O_2 + {}^3\mathrm{HMTDC} \quad (a)$$

This is tenable only if the triplet energy of HMTC is below or near that of singlet oxygen (the $^1\Delta_g$ state is at 22.5 kcal). Unfortunately, the triplet energy is not known, but such a low energy would be unreasonable. The following reaction, (b) is, thus:

$$^1O_2 + \mathrm{HMTC} \rightarrow \mathrm{Decomposed\ HMTC} \quad (b)$$

This is the only mechanism which is consistent with our present knowledge, though the mechanism is not yet understood in detail. It should be noted that, in the reactions of amines with singlet oxygen, tertiary aliphatic amines are known to yield no reactive products, but rather act as inhibitors of the oxidation of known reactive acceptors of singlet oxygen.[6] Further studies are necessary to examine the above possibility.

Biradical Spin-Labeled Micelles

Shun-ichi OHNISHI, Theodore J. R. CYR*1 and Hiroko FUKUSHIMA

Department of Biophysics, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received August 6, 1969)

A biradical spin-label, *N,N'*-di-[4-(1-oxyl-2,2,6,6-tetramethylpiperidyl)] urea, has been used for studying the dynamic structure of a micelle, sodium dodecyl sulfate (SDS). Analysis of the ESR spectra of the label has shown that the biradical was incorporated in the micelle. The tumbling motion of the label in the micelle was not strongly inhibited, suggesting a dynamic character of the micelle structure. The exchange rate of the biradical between the micelle and the water phases was slower than 10^7 sec^{-1}. The partition coefficient expressed as the ratio of the concentration of the biradical in the micelle to that of the biradical in the water phase was approximately 6×10^5 in the SDS concentration lower than 2×10^{-2}M. The biradicals form aggregate in the micelle, when they are present in excess in the solution.

In the present paper we describe the results of a preliminary study of the paramagnetic resonance of a biradical acting as a solubilizate (spin-label) in a micelle system. Micelles may be a simple model of biological membranes, and are chosen in this study to illustrate a possible application of a biradical, such as I, to biological systems.

(I)

The spin-label technique has yielded a great deal of information on the dynamic properties of biological systems such as hemoglobin, enzymes, and nucleic acids.[1] More complex systems, for example membranes, are also examined.[2-4] Labels used for the investigations have been mostly nitroxide *monoradicals*. The rate of tumbling motion of the labels is sensitively reflected in the ESR spectra and indicates some of the dynamic and structural characteristics of the environment of the labels. *Biradicals* can also be used as spin-labels and their ESR spectra can yield more information on the environment, since the spectra depend on the intramolecular spin-spin exchange interaction, in addition to the *g*-factor and hyperfine interaction. The exchange interaction is determined by the molecular configuration which, in turn, may be affected by the environment. Hsia and Piette[5] were the first to use biradical spin-labels in the study of hapten-antibody interactions.

The results of the present investigation complement and extend those of Waggoner *et al.*[6] who used nitroxide monoradical spin-labels to study the same micelle system.

Materials and Methods

The spin-label used for the present study is the nitroxide biradical (I), *N,N'*-di-[4-(1-oxyl-2,2,6,6-tetramethylpiperidyl)] urea. This label was prepared by mixing stoichiometric amounts of 2,2,6,6-tetramethyl-4-aminopiperidine-1-oxyl and phosgene in benzene. After several days the reaction mixture was washed with water and dried. The product was purified first by recrystallization from benzene and then by column chromatography on alumina using benzene, ether, and ethanol, needle crystals of mp 145°C (uncorrected) being obtained. Sodium dodecyl sulfate (SDS) was used as the micelle forming compound in water. Its critical micelle concentration (CMC) and aggregation number in water are reported to be 8.1×10^{-3}M

and 62, respectively.[7] Commercial SDS from Wako Chemical Co. was purified by recrystallization from hot ethanol.

ESR spectra of the biradical aqueous solutions containing various amounts of SDS were measured at room temperature with a commercial X-band spectrometer (JEOLCO Model JES-P-10S).

Results and Discussion

ESR Spectrum of the Biradical Aqueous Solution. The ESR spectrum of the biradical in water shown in Fig. 1a, can be accounted for in terms of the spin-Hamiltonian,[8]

$$\mathcal{H}_s = g\beta\mathbf{H}\cdot(\mathbf{s}_1+\mathbf{s}_2) + a_N(\mathbf{I}_1\cdot\mathbf{s}_1+\mathbf{I}_2\cdot\mathbf{s}_2) + J\mathbf{s}_1\cdot\mathbf{s}_2$$

where a_N is the isotropic hyperfine coupling constant of the nitroxide N^{14} nucleus and J is the exchange interaction between the two unpaired electrons in a biradical. The spectra in Fig. 1 consist of the "triplet"-"triplet" or T resonances and the "singlet"-"triplet" or S resonances. The J/a_N value can be easily estimated from the relative S resonance positions. The value obtained for the biradical in water was $J/a_N=1.35$ resulting $J=23.1$ G, since $a_N=17.1$ G. The J values of the biradical in organic solvents (for example 18 G in hexane) were always smaller than that in water, suggesting that the biradical assumes a folded configuration in water and more or less extended forms in organic media.[9] This is consistent with the hydrophobic nature of the biradical as judged from solubility data.

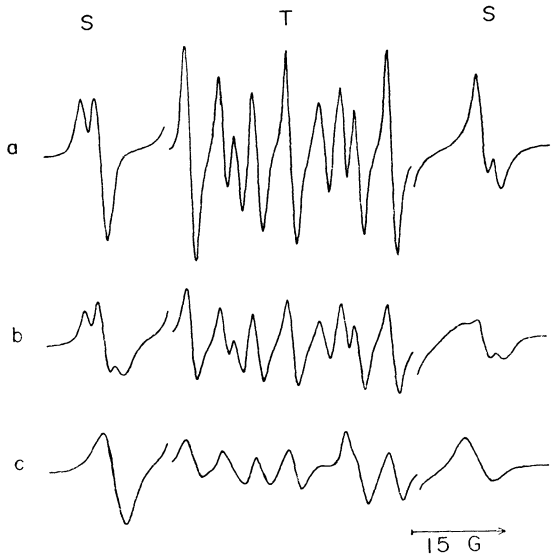

Fig. 1. ESR spectrum of biradical I in a) water, b) aqueous SDS solution of 1.4×10^{-2}M, and c) aqueous SDS solution of 6.9×10^{-2}M. Concentration of the biradical, R_0, is 4.4×10^{-5}M. The "S" resonance spectra are recorded at 6 times higher gain than that of the "T" resonances, since the S resonances are due to the "forbidden" transitions.

Effect of SDS on the Biradical Spectrum. A series of ESR spectra were recorded with aqueous solutions containing a fixed concentration (R_0) of the biradical and various concentrations of SDS. The ESR spectra remained unchanged until the concentration of SDS became larger than the critical value, 7×10^{-3}M, which is very close to the reported CMC of SDS, 8.1×10^{-3}M. At higher concentrations, the spectrum changed in both T and S resonance regions and new peaks became observable at inner field positions (Fig. 1b) in the latter. As the SDS concentration increased, these new peaks grew in intensity at the expense of the initial resonances. The final spectrum is broad (Fig. 1c), slightly asymmetric with respect to the field and corresponds to a slower rate of tumbling motion of the biradical. Moreover, since the new peaks locate at inner field positions, the J value of the biradical is smaller in the presence of micelles ($J/a_N=1.18$, $a_N=16.9$ G, $J=19.9$ G). The biradical has smaller J values in organic solvents. The results suggest that the biradical is incorporated in the micelle, has organic surroundings and experiences a slower rate of tumbling motion.

State of the Biradical in Micelle. The biradical is not strongly immobilized in the micelle, since the spectrum in Fig. 1c is similar to that of the biradical in ethyleneglycol at *ca.* 30°C. A rough estimation of the correlation time for the tumbling motion in the ethyleneglycol medium gives a value of the order of 10^{-9} sec. If the biradical were to tumble with the micelle as a whole, the correlation time would be of the order of 10^{-8} sec and the breadth of the spectral components would be much larger. This reflects the dynamic character of the micelle structure, in agreement with conclusions drawn from a monoradical spin-label study.[6] Exchange of the biradical between micelle and water, however, is not so fast as to average out the two spectra in Fig. 1a and 1c. The exchange rate is, therefore, slower than the difference in J and a_N, *i. e.* 10^7 sec^{-1}.

The S resonance portions of the spectra were recorded on an expanded scale with solutions containing various concentrations of SDS and $R_0=4.4\times10^{-5}$M. It can be seen from Fig. 2 that isosbestic points are present in the superposition

of the S resonance spectra. This demonstrates that the biradicals are present in only two environments, *i. e.* in the micelle and in the water phase. The fraction of the biradical in each phase is easily obtained from Fig. 2 and some values are given in Table 1.

character was removed. This is evident in Fig. 3 where the S resonance spectra for $R_0=4.4\times10^{-4}$M and $R_0=2.8\times10^{-3}$M are shown. We should note that the solubility limit of the biradical in water is approximately 1×10^{-3}M, and that, in the presence of micelles, the excess biradical beyond this limit is quickly solubilized. Other features seen only at higher biradical concentrations were the decrease in the apparent spectral intensity (*cf.* Fig. 4) and the presence of a background signal increasing monotonously in the field range shown in Fig. 3. The background signal is most pronounced in the spectrum c in Fig. 3B, and from the full spectrum we see that the background is the tail part of a broad single line spectrum. The broadening is interpreted to be due to the interbiradical spin-spin exchange interaction, and can be expected when more than one biradicals dissolve in a micelle particle and the distances among them become small. In Table 1 we listed the number of the biradicals per micelle particle, which was around 2 at low SDS concentrations for $R_0=4.4\times10^{-4}$M. In such cases, the apparent S resonance intensities decrease by an amount equal to the number of biradicals in aggregation. The isosbestic character, observed at lower value of R_0, diappears since there are at

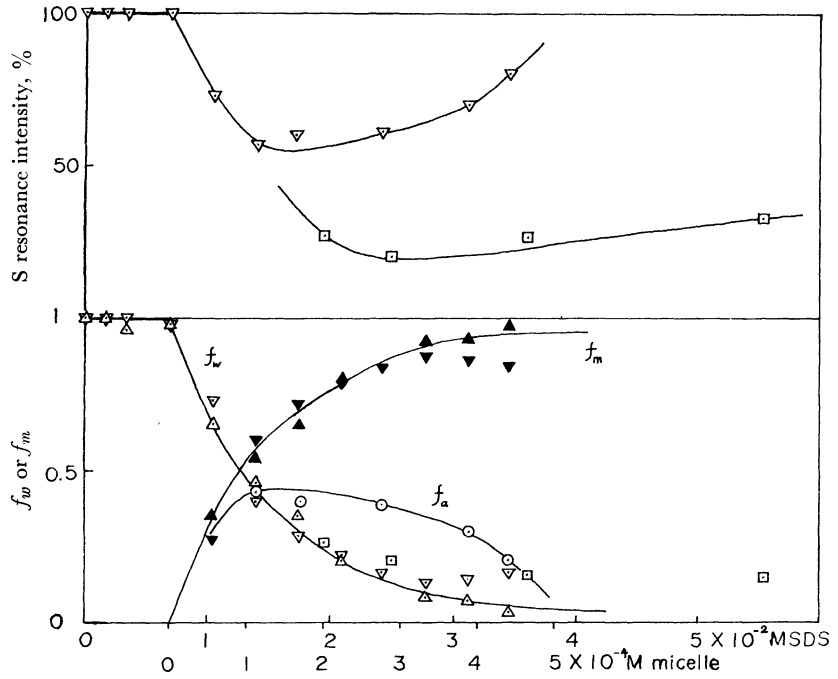

Fig. 4. Upper: The relative S resonance intensity *vs.* SDS concentration. ▽ for $R_0=4.4\times10^{-4}$M and ⊡ for $R_0=2.8\times10^{-3}$M.
Lower: The fraction of biradical in water, f_w, and micelle, f_m, *vs.* SDS concentration. △ and ▲; f_w and f_m for $R_0=4.4\times10^{-5}$M. ▽, ▼, and ⊙; f_w, f_m, and f_a for $R_0=4.4\times10^{-4}$M. ⊡; f_w for $R_0=2.8\times10^{-3}$M. f_a is the fraction of biradical aggregates in micelle.

least three different spectra of various intensities depending on the micelle concentration.

The results suggest that the biradicals in the micellar solutions can be divided into three fractions: those remaining dissolved in water (f_w), those incorporated individually in micelles (f_s), and those forming aggregates in micelles so that the biradicals give exchange-broadened ESR spectra (f_a). The fraction of biradical in a micelle, f_m, is equal to f_a+f_s. The ratio, f_s/f_w, can be estimated from the S resonance spectral shape, and f_a from the decrease in the total S resonance intensity. The values obtained for biradical solutions of various concentrations are given in Table 1 and are plotted in Fig. 4 against the SDS concentration. The micelle concentration, also given on the ordinate, is calculated by assuming that all the SDS molecules form micelles of molecular weight 62×288 above CMC. In the most dilute biradical solution, there is no apparent decrease in the S resonance intensity, suggesting that the biradicals do not aggregate within micelles. At the first measurement above CMC, the calculated micelle concentration, 6×10^{-5}M, is already larger than the biradical concentration, 4.4×10^{-5}M. On the other hand, in the more concentrated biradical solutions, there are fewer micelles than biradicals and the radicals aggregate. The f_a *versus* micelle-concentration curve, after reaching a maximum value, decreases towards zero at higher micelle concentration. If the f_a curve is extrapolated, f_a reaches zero at about 5×10^{-4}M micelles, which is close to the biradical concentration 4.4×10^{-4}M. The radicals, therefore, appear to distribute themselves fairly evenly among the micelles and aggregate only when there are not enough micelles present.

The Partition Coefficient. The f_w and f_m *versus* SDS-concentration curves for the various biradical concentrations fall on the same curve, indicating that the partition of the biradicals in the water and micelle phases is independent of the biradical concentration. The presence of biradical aggregates does not appear to affect the partition. We can define the partition coefficient P as $P=(f_m/f_w)(c_w/c_m)$, where c_w and c_m represent the concentrations of water and micelle in the solution, respectively. The calculated coefficients are fairly constant, 6×10^5 within experimental error, in the smaller SDS concentration region ($<\sim2\times10^{-2}$M) (see Table 1). P seems to tend to increase, however, in the larger SDS concentration region, although the relative error in the evaluation of P becomes greater for larger f_m or f_w values. This might suggest some change in the mode of micelle formation in more concentrated SDS solutions, since, in the calculation of P, we assumed a monotonous linear increase in the micelle concentration.

The Crystal Structure and the Molecular Behaviour of 2,3-Dibromo-2,3-dimethylbutane at Room Temperature

Yoshiyuki NAMBA, Tsutomu ODA, Nobuto FUKUDA and Osamu TAKADA

Department of Chemistry, Osaka Kyoiku University, Tennoji-ku, Osaka

(Received August 9, 1969)

The crystal structure of 2,3-dibromo-2,3-dimethylbutane at room temperature has a disordered nature. In the crystal, *trans*-form molecules have at least four orientations of equal statistical weight around the axes parallel to the [001] direction. Therefore, in spite of the low symmetry of the molecule, the crystal belongs to the tetragonal system and has the space group of $I\bar{4}/mmm$, while $a=7.38$ Å, $c=8.12$ Å and $Z=2$.

The crystal of 2,3-dibromo-2,3-dimethylbutane has three modifications, phase I (high-temperature modification) appearing above 80°C,[1] phase II (room-temperature modification) existing between −90°C and 80°C, and phase III (low-temperature modification) appearing below −90°C.[2] An X-ray investigation of the room-temperature modification (phase II) has already been carried out by Yardley,[3] who has given useful crystal data and suggested some possible crystal structures. Yamada and Taguchi[4] have pointed out that phase I is cubic, the molecules rotating as a whole in the crystal.

A reexamination of the structure of phase II will be described in this paper.

Experimental

The material was synthesized by mixing hydrogen bromide and pinacol at 0°C (Thiele's method[5]). It was purified by several vacuum sublimations. Single crystals were obtained from an ethanol solution. They were colourless needles which were elongated along the [001] axis and were flexible. The crystals, enclosed in thin-walled terex-glass capillary tube to protect them from sublimation and contamination, were used in the X-ray investigations.

The unit-cell dimensions were determined from Weissenberg photographs superimposed on a powder pattern of pure sodium chloride. The density was measured by the floatation method. Laue photographs were also taken to determine the crystall class.

Crystal data:
2,3-dibromo-2,3-dimethylbutane, $C_6H_{12}Br_2$
mol wt 243.9, mp 182°C.

Tetragonal, $a=7.38$Å, $c=8.12$Å. $U=442.2$Å^3. Density (observed) 1.82 g/cm^3, Density (calculated) 1.83 g/cm^3, $Z=2$. Laue symmetry: $4/mmm$.*1

The absent spectra are:

$$hkl\colon\ h+k+l=2n+1,$$
$$hk0\colon\ h+k=2n+1,$$
$$hhl\colon\ l=2n+1,$$
$$0kl\colon\ k+l=2n+1.$$

Thus, the space group was selected as one of the following: $I422$, $I4mm$, $I\bar{4}m2$, $I\bar{4}2m$, or $I4/mmm$.

The intensity data were obtained from equi-inclination Weissenberg photographs, $hk0$, $hk1$, $hk2$, and $hk3$, taken by means of CuK_α radiation filtered through nickel foil. The multiplefilm technique was used, and the intensities were estimated visually by comparison with a calibrated scale. The intensities were corrected for the Lorentz and polarization factors to obtain the relative values of $|F|^2$.

Structure Determination

Since the body-centered unit cell contains two molecules, the centers of the molecules must be placed at 0,0,0 and 1/2, 1/2,1/2.

Even though the crystals belong to one of the possible space groups mentioned above, the point symmetry of these positions must at least contain a four-fold rotation axis or a four-fold inversion axis. On the other hand, when the configuration of a free molecule is considered, the *trans*-form is taken as the highest symmetric one, for it possesses the symmetry C_{2h}. This symmetry does not, however, satisfy requirement of a high symmetrical nature such as C_4 or S_4 for the molecules in the crystal. This inconsistency in symmetry consideration proves some disordered character in the crystal.

3) K. Yardley (Mrs. Lonsdale), *Proc. Roy. Soc., Ser. A*, **118**, 485 (1928).
4) Private communication. See also Ref. 2.
5) Thiele, *Ber.*, **27**, 455 (1894).

*1 It is to be noted that these crystal data are in harmony with those of Yardley.

To obtain preliminary knowledge on the structure, a Patterson map, $P(u,v)$, was synthesized. As is shown in Fig. 1, there is no predominant peak except at the point of origin and at 1/2,1/2, indicating that the Br–Br axis in the molecule is oriented almost parallel to the c-axis. Hence, it is reasonable that the *trans* molecules placed at 0,0,0 and at 1/2,1/2,1/2 with their Br–Br axis parallel to the [001] axis remain some disordered orientation about the [001] axis, thus having, on the average, a symmetry higher than 4 or $\bar{4}$.

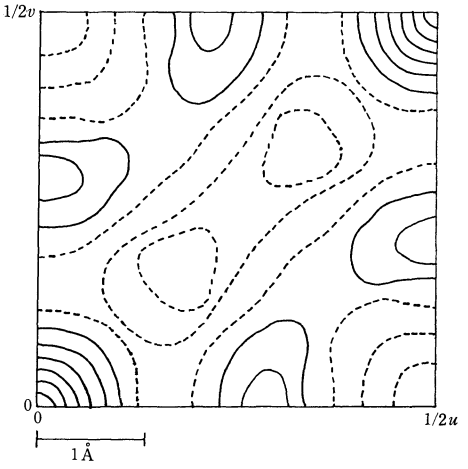

Fig. 1. Patterson map: $P(u,v)$.

Let us now proceed with the structure analysis using the trial-and-error method.

The configuration of molecule used in the trial calculations is an ordinary *trans* one; that is to say, the bond lengths used are 1.54 and 1.91 Å for C–C and C–Br bonds respectively, while normal tetrahedral bonds are taken for the carbon atom. For convenience in calculating, we used the value of $3/2f_c$ for the scattering factor of carbon atoms belonging to methyl groups, moreover, the precise contribution of hydrogen atoms was not calculated, as it is thought to be small.

The adopted arrangements of the molecules in the crystal and the results of the calculated structure factors are as follows:

Case I. Axial Rotation. As the first example in this case, let us consider a model in which the "axial rotation" of the molecule about its Br–Br axis is taking place freely, the Br–Br axis coinciding with the [001] direction. This is called model I. The calculated values of the structure factors are compared with the observed values in Fig. 4a. The general correspondence seems to be satisfactory. However, the aspects in (220), (310), (400), and especially in (hkl) do not give sufficient agreement.

In order to improve this inconsistency in the case of model I, a slightly modified model was considered. That is, in the second model, we assumed that the bromine atoms also rotate about the axis parallel to [001]. This model is shown in Fig. 2b. However, this treatment produces no remarkable improvement, as may be seen in Fig. 4b.

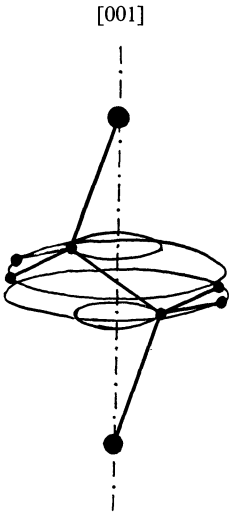

Fig. 2a. Model I.

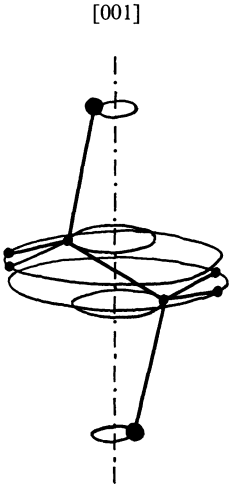

Fig. 2b. Model II.

Case II. Static Statistical Structure. Now, we can also assume static statistical structures in which the *trans* molecules with their Br–Br axis in the direction of the [001] axis occupy laterally four orientations about [001], with an equal statistical weight of 1/4, resulting in a four-fold nature of the [001] axis.

The atomic parameter values selected for this model, III, were as follows:

Br: $x = y = 0.00$, $z = 0.28$;

C: $x = y = 0.06$, $z = 0.05$;

C (methyl group): x=0.26, y=0.016, z=0.018.

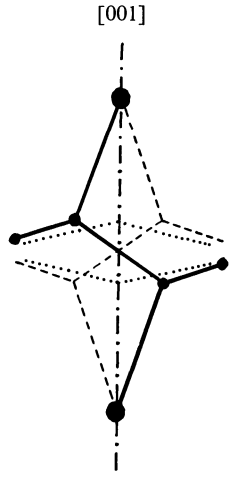

Fig. 3a. Model III.

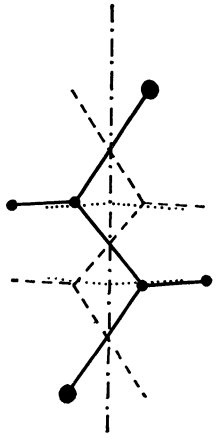

Fig. 3b. Model IV.

The calculated structure factors are shown in Fig. 5a. The correspondence of F_c and F_o is fairly good. This structural model may be said to represent well the structure of the present crystal.

Now, in this case, the central C–C bond of each molecule is on the plane on the (110) type. The methyl groups are, then, lying nearly on the plane of the (100) type. Speaking only on the basis of a consideration of the statistical symmetry, another arrangement of molecules is also possible, one where the central C–C bond is not on the (110)-type plane but on the (100)-type plane. However, in this model the agreement of F_c and F_o is far less than with the model III.

In model III, the Br–Br axis of a molecule has been taken as parallel to the [001] direction. In this arrangement, the intermolecular Br–Br distance along the [001] direction is calculated as 3.73 Å. This value can be seen to be slightly shorter than the normal distance, 3.90 Å, of Van der Waals contact. In view of this, we further assumed the model IV, in which the Br–Br axis of the molecule is slightly inclined to the [001] direction. In this case, four statistical positions must be considered for bromine atoms, also.

The atomic parameter values used were as follows:

Br: $x=y=0.029$, $z=0.278$;

C: $x=y=0.051$, $z=0.068$;

C (methyl group): $x=0.014$, $y=0.257$, $z=0.051$.

The calculated structure factors are shown in Fig. 5b. In this case the coincidence of F_c and F_o is better than in the case of model III.

In the analyses hitherto described, the *trans* configuration has been adopted as that of the free molecule. We have also tried an analysis using the *gauche* form of the molecule. However, such a form does not explain the observed values of the structure factors. Therefore, the *gauche* configuration can be disregarded.

Conclusion

The results obtained above for the present crystal structure can explain the mechanism of the transitions at about 70°C and at −120°C. When the temperatures are raised from room temperature, the thermal motion of the *trans* molecules possessing an orientational or rotational disorder around the Br–Br axes almost parallel to the [001] axis is more and more enhanced, and at 70°C the crystal is transformed to its cubic phase, in which the molecules rotate spherically as a whole, their Br–Br axes being randomly oriented. In this high-temperature modification, it may be possible for the molecules to take the *gauche* configuration.

When the temperatures are lowered from room temperature, the cessation of the axial rotation of the molecules around their Br–Br axes occurs below −120°C, the crystal taking an ordered structure.

Furthermore, it is of interest to compare the present structure with that given for the dichloroethane crystal above its transition temperature at −70°C. It has been reported by Reed and Lipscomb[6] that the molecules in that phase rotate axially about their Cl–Cl axes, the molecules also possessing the *trans* configuration. This structure is quite similar to the present one given for the 2,3-dibromo-2,3-dimethylbutane crystal at room temperature.

However, the 2,3-dibromo-2,3-dimethylbutane crystal shows a high-temperature transition at 70°C, whereas there is no corresponding transition in the case of dichloroethane crystals.

The onset of the spherical rotation of the molecules as a whole in the high-temperature modification

in the case of 2,3-dibromo-2,3-dimethylbutane may be closely related to the "ellipsoidal" shape of the molecules in contrast to the elongated "rectangular" shape of dichloroethane.

Turning to the low-temperature transition, it is desirable to investigate the crystal structure below -120°C in order to give a precise explanation of the mechanism of the low-temperature transition.

The authors wish to thank Professor S. Seki for his interest in this work and also Professor T. Watanabe for his helpful discussions.

Studies of the Structure of Polyurethane Elastomers. I. The Number-average MW Determination of the Hard-segment in the Poly(Ether)Urethane Elastomer by Means of Perchloric Acid Depolymerization

Hajime Suzuki and Hiroshi Ono

Katata Research Institute, Toyobo Co., Ltd., Honkatata, Otsu

(Received August 18, 1969)

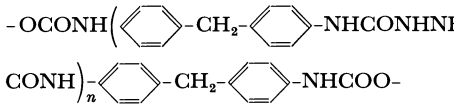
Urea segment which is called a hard-segment in the poly(ether)urethane elastomer (PEUE) consisting of a polyether segment,urethane segment,and urea segment was isolated by means of perchloric acid depolymerization. The number-average molecular weight (MW) of the urea segment obtained by the above method was determined by elemental analysis and by volumetric analysis. By comparing the analytical results with the results calculated for a random polymerization, the number-average MW of the hard-segment was found to deviate from that expected from the equal reactivity of the two isocyanate groups in 4,4'-diphenyl methane diisocyanate (MDI). Therefore, an apparent reactivity ratio of two isocyanate groups in MDI (A) can be calculated from the number-average MW of the hard-segment isolated by means of perchloric acid depolymerization.

There have been a number of reports concerning the determination of randomness[1] and copolymer compositions[2] by means of the high-resolution NMR, but the determination of the sequence length of the hard-segment in PEUE has not been successful, mainly because of the complication of the spectra of poly (ether) urethane elastomers. Therefore, we have studied the isolation of three segments by means of the difference in the cleavage rate of three segments in a typical PEUE prepared from MDI, polyoxytetramethylene glycol (PTG), and hydrazine (HD). Although the structure of the PEUE can not be written in one formula, it may be expressed by the following three segments:

polyether segment, $(-CH_2CH_2CH_2CH_2O-)_n$

urethane segment,

urea segment,



By determining the MW of the urea segment, we were able to show the blockiness in the PEUE, and also the apparent reactivity ratio of two isocyanate groups in MDI. These studies will be very useful for the elucidation of the relationship between the structure and the physical properties of the elastomers.

Experimental

Materials. The PEUE's used in this work were synthesized by the prepolymer method. The prepolymer was prepared by reacting 0.02 mol (20 g) of PTG (MW, *ca.*, 1000) with MDI (0.03—0.07 mol, as in Table 1) in 60 m*l* of *N,N*-dimethyl acetamide at 30°C for 3 hr. The completeness of the prepolymer reaction was ascertained by the *n*-dibutylamine titration method reported by Otey *et al.*,[3] and the PEUE's were prepared from the prepolymer and HD as a chain extender. The molar ratios of the various monomers in the polymers prepared in this way are listed in Table 1.

Poly(ether)urethane (PEU) was synthesized by reacting PTG (MW, *ca.* 1000) with the equivalent mole of MDI as polyether and urethane segment models.

Depolymerization of PEUE. The depolymerization was carried out by placing the PEUE (5 g) in perchloric acid (60%, 60 m*l*) for 24 hr at room temperature, and by then treating it at 70°C for 40 hr in a water bath. An excess of water was added to the mixture to precipitate the perchlorate of the amine end group of the urea segment. The salt was collected by filtration, and then washed with water and dried.

The completeness and the selectivity of depolymerization reaction were ascertained by the following procedure. A mixture of 5 g of model compounds of PEU and 2 g of the urea segment obtained by the above depolymerization was depolymerized by perchloric acid (60%, 60 m*l*) under the same conditions as in the depolymerization of PEUE. After the depolymerization of this mixture,

the weight loss was measured, and the change in the MW of the urea segment was measured by the titration method.

MW Determination of the Hard-segment. The MW of the hard-segment was determined by elemental analysis and by titration. In the elemental analysis the MW was calculated directly from the chlorine content.

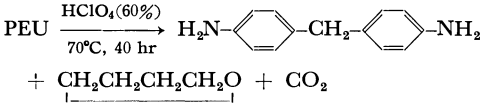
In the titration method, about 30 mg of the hard-segment obtained by the above method was immersed in 10 m*l* of a N/100 aqueous solution of NaOH and titrated by a N/100 aqueous solution of HCl, using methyl orange as the indicator. The MW of the hard-segment was calculated by the following equation:

$$\text{MW of hard-segment} = \frac{2\{\text{Weight of hard-segment (mg)} - 100.5 \times (T_B - T_S)(\text{ml}) \times 1/100 \times F\}}{(T_B - T_S)(\text{ml}) \times 1/100 \times F}$$

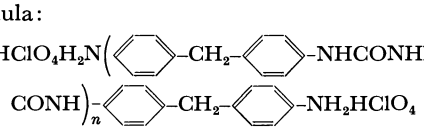
where F is a factor of an aqueous solution of HCl and where T_S and T_B are the volume of an N/100 aqueous solution of HCl required for the titration of the sample and the blank solution respectively.

Results and Discussion

Depolymerization Reaction. A previous paper[4] has described how THF is formed quantitatively in the reaction of PTG and perchloric acid. After the reaction of PEU and perchloric acid, an aqueous solution of sodium hydroxide was added to the reaction mixture until the pH value reached 9; 4,4′-diaminodiphenylmethane (mp, 93—94°C) was thus obtained. From these findings, the reaction of PEU and perchloric acid may be assumed to proceed as follows:



After the depolymerization reaction of PEUE under the conditions described above, precipitates were obtained by adding an excess of water to the reaction mixture. The IR absorption spectrum of the precipitate is shown in Fig. 1. A comparison of the IR absorption spectra of the precipitate (B) and of PEUE (A) shows that the 2900 cm^{-1} region due to the methylene group and the 1700 cm^{-1} region due to the urethane group disappeared in B. The IR absorption spectrum of the precipitate washed with an aqueous solution of sodium hydroxide is shown in C of Fig. 1. The comparison of the IR absorption spectra of C and B in Fig. 1 shows that the absorption at 1100 cm^{-1} can not be seen in C, but this absorption C was again coincident with the IR absorption spectrum of B after this precipitate had been washed with perchloric acid; therefore, the absorption in the 1100 cm^{-1} region in B may be due to the perchlorate of amine. On the other hand, the absorption in the 1100 cm^{-1} region in A is due to the ether segment in PTG. From the above results, the precipitate obtained by the perchloric acid depolymerization can be written by the following formula:



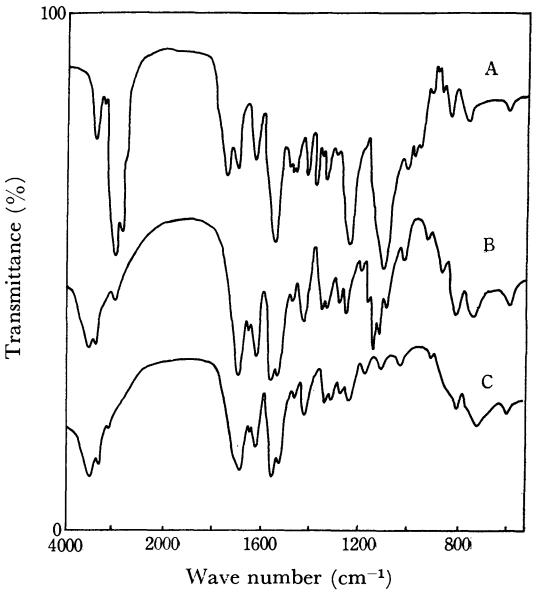


Fig. 1. IR spectra of PEUE and hard-segment. A: PEUE, B: urea segment with the perchlorate of the amine endgroups, C: urea segment with amine endgroups

4) H. Suzuki and H. Ono, *Kogyo Kagaku Zasshi*, **72**, 1593 (1969).

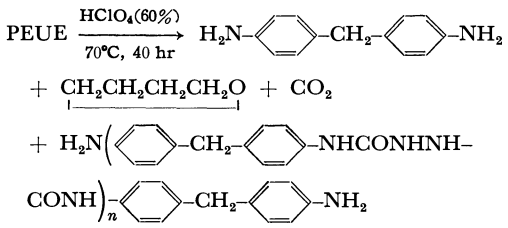
The results of the elementary analysis of the above hard-segments of the PEUE's are given in Table 1. The calculated values shown in Table 1 were obtained from the analytical results of the chlorine.

To ascertain the recovery of the hard-segment from PEUE, the mixture of PEU and the hard-segment obtained by the above experiment was depolymerized by perchloric acid under the same conditions as above. In this experiment, the recovery and the MW of the hard-segment were measured. Table 2 shows these results.

Table 2. Recovery and MW of hard-segment

Recovery (wt%)	MW before re-depolymerization	MW after re-depolymerization
99.7	782	779
99.2	828	808
99.5	931	945
99.7	1213	1215
98.3	1333	1315
99.0	1573	1575

From these results, the reaction of PEUE with perchloric acid can be assumed to proceed as follows:



Since 4,4′-diaminodiphenylmethane, which came from the urethane segment, was soluble in perchloric acid, while the hard-segment was insoluble, it could be separated by precipitation.

Table 3. MW of hard-segment

No.	[Urea]/[Urethane] molar ratio	MW of Hard-segment: Titration method	MW of Hard-segment: Elemental analysis method	MW of Hard-segment: Calcd value
1	1/2	782	789	621
2	1.5/2	828	842	691.5
3	2/2	931	921	762
4	3/2	1213	1172	903
5	4/2	1333	1295	1044
6	5/2	1573	1482	1185

Table 3 shows the number-average MW of the hard-segment. The calculated values in Table 3 were obtained in a manner to be shown later.

MW of the Hard-segment. The reactivity between MDI and alcohols has been reported on by many authors.[5,6] Naito and Tanaka[7] have shown the equal reactivity of two isocyanate groups in MDI for the reactions with low-molecular-weight alcohols. Moreover, Ferstandig and Scherrer[8] reported that the reactivity ratio ($A=K_2/K_1$) of two isocyanates in MDI was about 0.33. Although there has been no report concerning the reactivity between the polymer diol and MDI, we assumed an equal reactivity of the isocyanate group in MDI in the prepolymer reaction and in the chain-extender reaction.

The PEUE composition is given by:

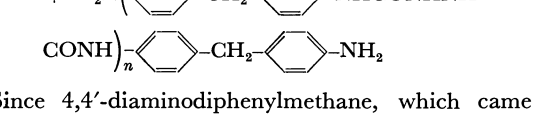
$$C = E + H \tag{1}$$

where C, E, and H are the numbers of moles of MDI, PTG, and HD respectively. After the prepolymerization, the concentration ratio of the three structural units could be obtained by a probability calculation, as is shown in Table 4.

Table 4. Concentration ratio of three structural units after prepolymerization

Structural unit	Concentration ratio
$CH_2\left(\bigcirc\text{-NHCOO-}\right)_2$	$P_{E\text{-}I\text{-}E}=E^2/C^2$
$CH_2\left(\bigcirc\text{-NCO}\right)_2$	$P_{H\text{-}I\text{-}H}=(C-E)^2/C^2$
OCN-⬡-CH-⬡-NHCOO-	$P_{H\text{-}I\text{-}H}=1-\{E^2+(C-E)^2\}/C^2$

After the prepolymerization, the prepolymer was polymerized by HD to give the following structure:



The probability to produce a sequence of $n=1$ is given by:

$$\frac{1/2[1-\{E^2+(C-E)^2\}/C^2]}{(C-E)^2/C^2+1/2[1-\{E^2+(C-E)^2\}/C^2]}=E/C \tag{2}$$

and the probability for $n=2$ is given by:

$$\frac{(C-E)^2/C^2}{(C-E)^2/C^2+1/2[1-\{E^2+(C-E)^2\}/C^2]}\times E/C = \{(C-E)/C\}\times E/C \tag{3}$$

Generally, the probability for $n=m$ is given by:

$$\{(C-E)/C\}^{m-1}\times E/C \tag{4}$$

and the sum of the hard-segment is given by the

5) M. E. Bailey, V. Kriss and R. G. Spaunburgh, *Ind. Eng. Chem.*, **48**, 794 (1956).

6) J. Burkus and C. F. Echert, *J. Amer. Chem. Soc.*, **80**, 5948 (1958).

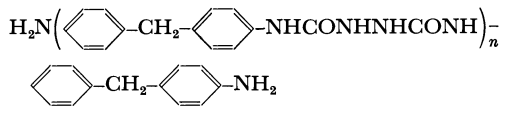
7) K. Naito and M. Tanaka, Preprints for 19th Annual Meeting of the Chemical Society of Japan, Hiyoshi (1963), p. 76.

8) L. L. Ferstandig and R. A. Scherrer, *J. Amer. Chem. Soc.*, **81**, 4838 (1959).

following equation:

$$\sum_{n=1}^{\infty}\{(C-E)/C\}^{n-1}\times E/C = 1 \qquad (5)$$

The hard-segment obtained by the perchloric acid depolymerization of the PEUE has the following structure:



The MW for $n=1$ is 480, and that of the repeating unit is 282, so the number-average MW of the hard-segment is calculated as:

$$\sum_{n=1}^{\infty}\{480+282(n-1)\}\{(C-E)/C\}^{n-1}E/C = 480 + 282(C-E)/E \qquad (6)$$

In the case of the random polymerization, the MW of the hard-segment may be calculated from the monomer content by means of Eq. (6).

The contents of the urea linkage and the urethane linkage in PEUE do not depend on the way of polymerization, as is shown in Table 5.

Table 5. Concentration ratio of each linkage in PEUE

Linkage	Concentration ratio
[NHCONH]	$(C-E)/C=H/C$
[NHCOO]	E/C
[NHCONH]/[NHCOO]	$(C-E)/E=H/E$

A plot of [NHCONH]/[NHCOO] *versus* the absorbance ratio at 1680 cm^{-1} and 1740 cm^{-1} gives a straight line, as is shown in Fig. 2. As may be seen from Fig. 2, the [Urea]/[Urethane] ratio in PEUE is obtained by the IR measurement, and by inserting the above result into Eq. (6), the MW of the hard-segment can be determined. The results are shown in Table 3. These results show that the distribution of the monomer unit deviates from that expected from the equal reactivity of the two isocyanate groups in MDI.

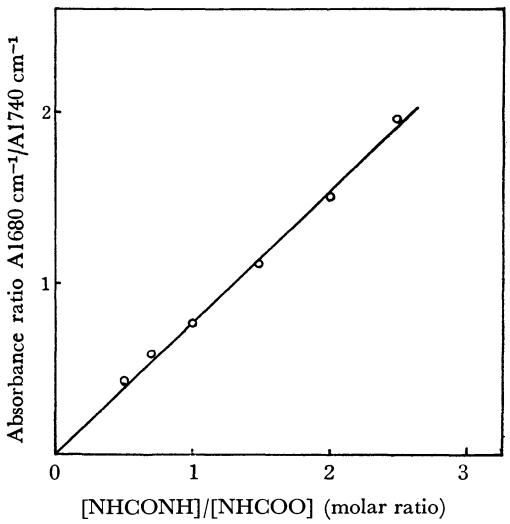


Fig. 2. Absorbance ratio at 1680 cm^{-1} and 1740 cm^{-1} of PEUE.

Apparent Reactivity Ratio of Two Isocyanate Groups in MDI. In the case of the random polymerization, the distribution of monomers in PEUE may be decided by the reactivity ratio of the two isocyanate groups in MDI. The apparent reactivity ratio of the two isocyanate groups is calculated from the MW of the hard-segment in the following way.

In the prepolymerization, the following reaction scheme may hold:

$$\text{OCN–I–NCO} + \text{HO–E–OH} \xrightarrow{k_{11}} \text{HO–E–OCONH–I–NCO} \qquad (7)$$

$$\text{OCN–I–NHCOO–} + \text{HO–E–OH} \xrightarrow{k_{21}} \text{HO–E–OCONH–I–NHCOO–} \qquad (8)$$

$$\text{OCN–I–NCO} + \text{HO–E–OCONH–} \xrightarrow{k_{12}} \text{OCN–I–NHCOO–E–OCONH–} \qquad (9)$$

$$\text{OCN–I–NHCOO} + \text{HO–E–OCONH} \xrightarrow{k_{22}} \text{–OCONH–I–NHCOO–} \qquad (10)$$

where OCN–I–NCO and HO–E–OH denote MDI and PTG respectively and where k denotes a rate constant. Assuming that $k_{11}=k_{12}=k_1$ and that $k_{21}=k_{22}=k_2$, the reactivity ratio of the two isocyanate groups in MDI is given by:

$$A = k_2/k_1$$

Thus, the rate of the reaction may be expressed by the following equations:

$$d[I_1]/dt = -2k_1[I_1][E] \qquad (11)$$

$$d[I_2]/dt = k_1[I_1][E] - k_2[I_2][E] \qquad (12)$$

$$d[E]/dt = -k_1[I_1][E] - k_2[I_2][E] \qquad (13)$$

where $[I_1]$, $[I_2]$, and [E] are the concentrations of isocyanate in MDI, in OCN–I–NHCOO–, and in PTG respectively. From Eqs. (11) and (12),

$$d[I_2]/d[I_1] = (k_2/2k_1)\cdot[I_2]/[I_1] - 1/2 \qquad (14)$$

In the case of $A\neq 2$, the integration of Eq. (14) from time 0 to T, which is the time for the prepolymer reaction, gives the following result:

$$1/(1-A/2)\ln\frac{(1-A/2)[I_2]_T/[I_1]_T+1/2}{(1-A/2)[I_2]_0/[I_1]_0+1/2} = -\ln[I_1]_T/[I_1]_0 \qquad (15)$$

These are also the following relations:

$$[I_1]_0 = 2\times 1 \qquad [I_1]_T = 2\times P_{\text{H–I–H}}$$

$$[I_2]_0 = 0 \qquad [I_2]_T = P_{\text{H–I–E}}$$

By inserting the above relations into Eq. (15), we obtained:

$$2/(2-A)\log\{1-(1-A/2)P_{H\text{-}I\text{-}E}/P_{H\text{-}I\text{-}H}\} = \log(1/P_{H\text{-}I\text{-}H}) \quad (16)$$

Similarly, for $A=2$ we obtained:

$$P_{H\text{-}I\text{-}E}/P_{H\text{-}I\text{-}H} = \ln(1/P_{H\text{-}I\text{-}H}) \quad (17)$$

The values of $P_{H\text{-}I\text{-}E}$, $P_{H\text{-}I\text{-}H}$, and $P_{E\text{-}I\text{-}E}$ are determined by the following known procedure. Inserting the experimental results in Table 3 into Eq. (18), the average sequence length (L_{nH}) of the hard-segment of PEUE is calculated:

$$\overline{L_{nH}} = (\overline{MW}-198)/282 \quad (18)$$

Since the molar fractions of a hard-segment and a soft-segment in PEUE correspond to those of HD and PTG in PEUE respectively, the following equations may be obtained.

$$[\text{Urea}] = [\text{HD}] = P_{H\text{-}I\text{-}H} + \frac{1}{2}P_{H\text{-}I\text{-}E} \quad (19)$$

$$[\text{Urethane}] = [\text{PTG}] = P_{E\text{-}I\text{-}E} + \frac{1}{2}P_{H\text{-}I\text{-}E} \quad (20)$$

The following equation can also be written:

$$P_{H\text{-}I\text{-}H} + P_{E\text{-}I\text{-}E} + P_{E\text{-}I\text{-}H} = 1 \quad (21)$$

Therefore, the number-average sequence length of the hard-segment is given by:

$$\overline{L_{nH}} = \frac{P_{H\text{-}I\text{-}H}+\frac{1}{2}P_{H\text{-}I\text{-}E}}{\frac{1}{2}P_{H\text{-}I\text{-}E}} \quad (22)$$

By inserting the experimental results derived from Table 3 into Eqs. (16) and (17), the reactivity ratio, A, may be calculated. Table 6 shows the reactivity ratio calculated by using an electronic computer.

Table 6. Reactivity ratio of two isocyanate groups in MDI

No.	[Urea]/[Urethane]	$P_{H\text{-}I\text{-}H}$	$P_{H\text{-}I\text{-}E}$	A
1	1/2	0.172	0.322	1.86
2	1.5/2	0.237	0.384	1.68
3	2/2	0.307	0.386	1.79
4	3/2	0.433	0.334	2.40
5	4/2	0.501	0.332	2.25
6	5/2	0.568	0.292	2.69

These calculated apparent reactivity ratios of the two isocyanate groups in MDI (A) are obtained on the assumption of a homogeneous reaction in the prepolymer and chain-extender reactions. It is also necessary to consider the cases of $K_{11} \neq k_{12}$ and $K_{21} \neq k_{22}$. Therefore, thses results deviate from the results obtained by many previous authors.[7,8]

The composition analysis of PEUE's by NMR will become increasingly important since it often provides a direct, simple fingerprint of the various structures.

We should like to express our gratitude to Mr. Hiroo Yanagawa, to Dr. Yasushi Nishimura, and to Dr. Reizo Yamadera for his helpful discussion and examination of this paper. We also wish to express our gratitude to Director Dr. Eiichi Nagai of this Institute for permission to publish this paper.

Studies of the Structure of Polyurethane Elastomers. II. The Determination of the Blockiness of Poly(Ether)Urethane Elastomes

Hajime SUZUKI and Hiroshi ONO

Katata Research Institute, Toyobo Co., Ltd., Otsu

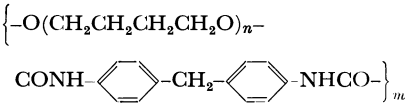
(Received August 18, 1969)

Two types of poly(ether)urethane elastomers (PEUE), which had the same composition ratio but different degrees of blockiness, were synthesized by the reaction of 4,4′-diphenyl methane diisocyanate (MDI), polyoxytetramethylene glycol (PTG), and hydrazine (HD) or ethylenediamine (EDA) by means of the prepolymer method. The degree of blockiness of the PEUE thus synthesized by the reaction of MDI, PTG, and HD was determined by measuring the molecular weight of a hard segment (urea segment), itself obtained by perchloric acid depolymerization. The values of the blockiness of PEUE which had been synthesized by the prepolymer method without any solvent or in a solvent by means of a prepolymer reaction were about 0.4 and 0.7 respectively. The degree of the blockiness of the PEUE prepared from MDI, PTG, and HD, as measured by the above method, corresponded to the infrared absorbance ratio of the PEUE synthesized by the reaction of MDI, PTG, and EDA at 1740 cm^{-1} and 1720 cm^{-1}. From these results two infrared absorbances, at 1740 cm^{-1} and 1720 cm^{-1}, were assigned to the urethane linkage in a soft segment and at the end of an urea segment respectively.

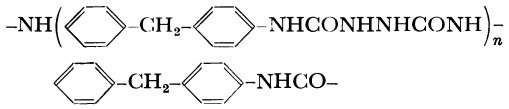
The determination of the blockiness of PEUE would be very helpful in elucidating the relationship between the structure and the physical properties of the elastomer, but previous attempts to determine the blockiness of PEUE were not successful. Therefore, we have attempted to determine the blockiness by the perchloric acid depolymerization method and by means of infrared spectroscopy.

Although the structure of the PEUE synthesized from MDI, PTG, and HD can not be written in one formula, it may be expressed by the following two segments:

soft segment (poly(ether)urethane segment):



hard segment (urea segment):



By expressing PEUE by means of the above two segments, the blockiness of PEUE may be determined in the same way as with a vinyl copolymer or a stereoregular polymer.[1,2]

It was thought that the hard segment was composed of a paracrystalline state,[3] and that the soft segment was composed of a liquid-like state; therefore, the infrared absorbance due to an urethane linkage in the soft segment or at the end of the hard segment was assumed to be assignable to two different absorbances.

Experimental

Materials. The PEUE used in this work had been synthesized by the prepolymer method. The prepolymer was prepared by reacting various molar ratios of PTG (MW, *ca.* 1500) and MDI without any solvent at 75°C for 1 hr and the PEUE was prepared from the prepolymer and HD or EDA as a chain extender in *N*,*N*-dimethylacetamide (DMAC) at 7°C. Between the prepolymer reaction and the chain-extender reaction,

MDI was added to make the molar ratio [Urea]/[Urethane]=1.

The various molar ratios of the monomers in the prepolymers prepared in this work are listed in Table 1.

The PEUEs which were synthesized in a solvent by means of the prepolymer reaction were described in a previous paper.[4]

$\overline{MW}$ Determination of the Hard Segment. The hard segment of PEUE prepared from MDI, PTG, and HD was obtained by the perchloric acid depolymerization method described in our previous communication;[4] it was examined by the titration method, and the number-average molecular weight (MW) of the hard segment was calculated by means of the following equation:

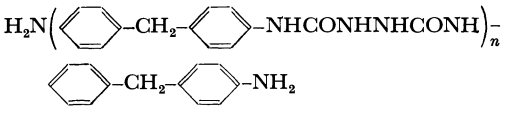
$$\overline{MW} = \frac{2\{W(\text{mg}) - 100.5 \times (T_B - T_S)(\text{ml}) \times 1/100 \times F\}}{(T_B - T_S)(\text{ml}) \times 1/100 \times F}$$

where W is the weight of the hard segment, F is a factor of an aqueous solution of HCl, and T_B and T_S are the volumes of an N/100 aqueous solution of HCl required for the titration of the blank and the sample solutions respectively.

Infrared Spectra Measurement. The infrared spectra of PEUE prepared from MDI, PTG, and EDA were obtained with a Hitachi EPI-S2-type infrared spectrophotometer, using thin films cast on glass from the DMAC solution of PEUE. The samples were heat-treated at 100°C for 10 min in order to evaporate the solvent.

Results and Discussion

The structure of the hard segment of PEUE prepared from MDI, PTG, and HD can be written as follows:



Therefore, the average sequence length of a hard segment can be calculated by the following equation:

$$\overline{L_{n\text{H}}} = (\overline{MW} - 198)/282 \quad (1)$$

Table 1 shows the number-average molecular weight and the sequence length of the hard segment, both values having been measured by the perchloric acid depolymerization method.

If the number-average sequence length of the hard segment is determined to be as is shown in Table 1, one can determine the blockiness of PEUE by the following known procedure.[1,5] If $P_{\text{H-I-H}}$, $P_{\text{H-I-E}}$, and $P_{\text{E-I-E}}$ show the molar fraction of each segment in PEUE, Eq. (2) can be evolved:

$$P_{\text{H-I-H}} + P_{\text{H-I-E}} + P_{\text{E-I-E}} = 1 \quad (2)$$

Since the molar fractions of a hard segment and a soft segment in PEUE correspond to those of HD and PTG respectively in PEUE, the following equations may be obtained:

$$[\text{Urea}] = [\text{HD}] = P_{\text{H-I-H}} + \frac{1}{2}P_{\text{H-I-E}} \quad (3)$$

$$[\text{Urethane}] = [\text{PTG}] = P_{\text{E-I-E}} + \frac{1}{2}P_{\text{H-I-E}} \quad (4)$$

The number-average sequence length of the ($\overline{L_{n\text{H}}}$) hard segment can be determined by inserting the number-average MW of the hard segment into Eq. (5):

$$\overline{L_{n\text{H}}} = (\text{MW} - 198)/282 \quad (5)$$

The values of $P_{\text{H-I-H}}$, $P_{\text{H-I-E}}$, and $P_{\text{E-I-E}}$ are calculated by means of Eqs. (6) and (9). If one could inspect the units along the soft-segment-hard-segment chain in PEUE from one end to the other, the probability of finding a soft segment unit next to a hard segment unit would be:

$$P_{\text{HE}} = \frac{\frac{1}{2}P_{\text{H-I-E}}}{P_{\text{H-I-H}} + \frac{1}{2}P_{\text{H-I-E}}} \quad (6)$$

Similarly, a hard segment unit exists next to a soft segment unit with a probability of:

$$P_{\text{EH}} = \frac{\frac{1}{2}P_{\text{H-I-E}}}{P_{\text{E-I-E}} + \frac{1}{2}P_{\text{H-I-E}}} \quad (7)$$

The degree of blockiness is defined by:

$$B = P_{\text{HE}} + P_{\text{EH}} \quad (8)$$

If $B<1$, these units tend to cluster in blocks of each unit, and finally $B=0$ in a homopolymer mixture, whereas if $B>1$, the sequence length becomes shorter, and $B=2$ in an alternative copolymer.

The number-average sequence length of the $\overline{L_{n\text{H}}}$ hard segment and the $\overline{L_{n\text{E}}}$ soft segment are given by:

$$\overline{L_{n\text{H}}} = 1/P_{\text{HE}} \quad (9)$$

$$\overline{L_{n\text{E}}} = 1/P_{\text{EH}} \quad (10)$$

Table 2 shows the values of the blockiness (B) of the PEUEs listed in Table 1; these values were calculated by means of Eqs. (1)—(10). The value of the blockiness (B) of the PEUEs prepared in DMAC by means of a prepolymer reaction are shown in Table 3. Sample 1 in Table 2 has the same composition ratio as sample 3 in Table 3, but the blockiness of sample 1 in Table 2 is greater than that of sample 3 in Table 3. When there is no solvent in the prepolymer reaction, the reaction between PTG and MDI occurs through the solvation of MDI into PTG: the reaction rate of MDI with PTG may then shows the effects of viscosity and agitation. Therefore, the greater

6	0.568	0.140	0.292	0.512	0.205	0.717

blockiness of sample 1 in Table 2 in comparison with sample 3 in Table 3 may be due to the heterogeneity of agitation in the prepolymer reaction. On the other hand, the prepolymer reaction in DMAC is a homogeneous reaction; therefore, the difference in the blockiness of sample 3 in Table 3 and the expected blockiness from a random reaction may be small.

The infrared spectra between 1800 cm^{-1} and 1700 cm^{-1} of the PEUE prepared from MDI, PTG, and EDA in Table 1 are shown in Fig. 1.

There have been no reports concerning the two peaks due to urethane linkage, but these peaks are assumed to be assignable to the urethane linkage for two different states, such as the para-crystalline part of a hard segment[3] and a liquid-like state of a soft segment. Figure 2 shows the relationship between the absorbance ratio at 1740 cm^{-1} and 1720 cm^{-1} and the degree of blockiness of PEUE.

From the above results, the absorptions at 1740 cm^{-1} and 1720 cm^{-1} may be assigned to the C=O stretching vibration of urethane linkage in a soft segment without any hydrogen bond and to that of the urethane linkage at the end of the hard segment with a hydrogen bond for the para-crystalline state.

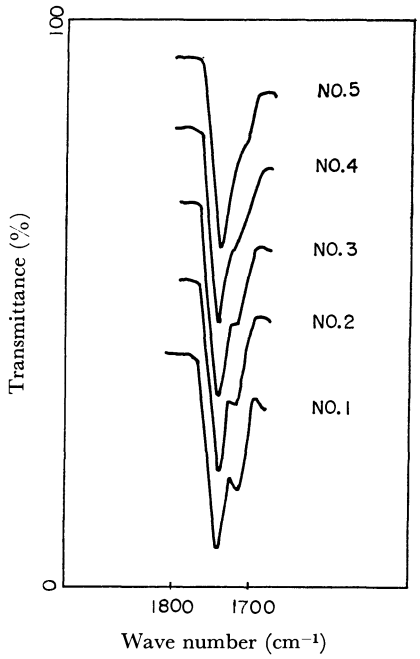

Fig. 1. Infrared spectra of PEUE synthesized from MDI, PTG and EDA in the region 1800—1700 cm^{-1}.

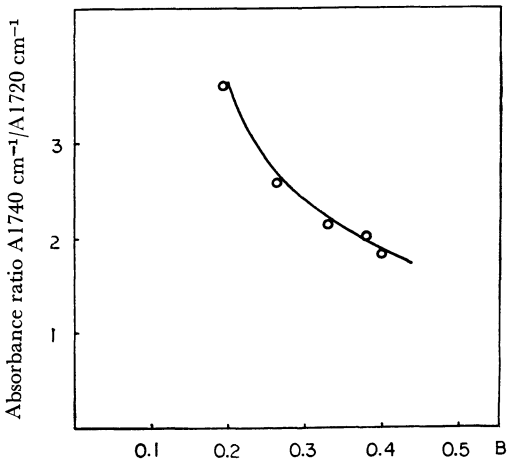

Fig. 2. Relationship between the absorbance ratio at 1740 cm^{-1} and 1720 cm^{-1} and the degree of blockiness.

We should like to express our gratitude to Drs. Yasushi Nishimura and Reizo Yamadera for his helpful discussion and the inspection of this paper. We also wish to express our gratitude to Director Dr. Eiichi Nagai of this institute for permission to publish this paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 690—697 (1970)

Far-Infrared Spectra and Lattice Vibrations of Barium Chloride Dihydrate

Kunio FUKUSHIMA and Hiroaki KATAIWA

Department of Chemistry, Faculty of Science, Shizuoka University, Oya-cho, Shizuoka

(Received August 25, 1969)

The far-infrared spectra of barium chloride dihydrate and its deutero analog were measured in the region of 60—4000 cm^{-1}. The assignment of the infrared bands due to crystal water and crystal heavy water was made on the basis of the band frequency shift associated with deuteration. The optically-active lattice vibrations were calculated in order to assign the far-infrared bands and elucidate the nature of the vibrations.

There are many types of crystal water molecules in crystals from the point of view of their coordination to the surrounding ions and the electron-acceptor groups. Chidambaram has classified crystal water molecules on the basis of their coordination to ions and electron-acceptor groups.[1]

In the present study, barium chloride dihydrate (b.c.d.) was adopted as a representative of B-type crystal water molecules in Chidambaram's classification, and a spectroscopic investigation in the IR spectral region and a normal coordinate treatment of the crystal as a whole were made in order to elucidate the nature of the optically-active lattice vibrations and the potential in the crystal. As measurements of the IR spectra in the region of 300—4000 cm^{-1} had already been made by several investigators for b.c.d. and its deutero analog (b.c.d.-d),[2-5] this paper will primarily present the results of the measurement of the far IR spectra in the 60—300 cm^{-1} region of these compounds.

Experimental

The sample for the measurements was obtained by the recrystallization of a special-grade b.c.d. of the Wako Pure Chemical Co., Ltd., from an aqueous solution. The IR spectra of the sample in Nujol mull were measured with a Perkin-Elmer Model 521 spectrophotometer and a Hitachi FIS-3 far-infrared spectrometer. The deuterated sample was made by the recrystallization of b.c.d. from a heavy water solution. The IR spectra of the deuterated sample in Nujol mull were also measured. The results of the measurements are shown in Figs. 1, 2, 3, and 4. The degree of deuteration is manifested in the relative intensities of the O–H stretching bands in the region of 3100—3400 cm^{-1} and of the O–D stretching bands in the region of 2200—2700 cm^{-1} in Fig. 3.

Assignment of IR Absorption Bands

The assignment of the IR absorption bands in the region of 800—4000 cm^{-1} have already been made by several investigators.[2-4] The shift of the IR-band frequencies on deuteration in the present study (3300 cm^{-1}, 3200 cm^{-1}, 1639 cm^{-1}, 1603 cm^{-1} →2545 cm^{-1} 2440 cm^{-1}, 1198 cm^{-1} 1173 cm^{-1}) confirms the assignment[2,3] of the bands at 3300 cm^{-1} and 3200 cm^{-1} to O–H stretching vibrations, and the bands at 1639 cm^{-1} and 1603 cm^{-1} to H_2O bending vibrations. In the region of 300—800 cm^{-1}, Elsken and Robinson found that the bands at 690 cm^{-1}, 560 cm^{-1}, and 520 cm^{-1} shift to lower frequencies on deuteration.[5] This fact was confirmed in the present study, in addition, it was found that the bands at 710 cm^{-1} and 405 cm^{-1} also shift to 500 cm^{-1} and 308 cm^{-1} respectively, as is shown in Figs. 2 and 4. The band at about 720 cm^{-1} in Fig. 4 is due to Nujol, and the weak band at 600 cm^{-1} is considered to be due to an overtone or to a combination band.

In the region of 60—400 cm^{-1}, a comparison of the spectra of b.c.d. with those of b.c.d.-d (Figs. 1 and 2) leads to the following conclusions. The band of b.c.d., which corresponds to the band at 264 cm^{-1} of b.c.d.-d, is considered to be overlapped by the band 405 cm^{-1} of b.c.d., as the frequency ratio (264/405) is close to $1/\sqrt{2}$, which is a rough measure of the frequency ratio of deuteration, while the band at 264 cm^{-1} may be due to a rotational lattice vibration of crystal heavy water. The IR absorption bands in the region of 220—800 cm^{-1}, which are concluded to be due to the rotational lattice vibrations of crystal water and crystal heavy water, are shown in Table 1. Those frequencies in the table correspond to the peak frequencies in neutron-scattering spectra:[6] 710 cm^{-1} (664 ±40 cm^{-1}), 684 cm^{-1} (664±40 cm^{-1}), 555 cm^{-1}

(536 +32cm^{-1}), 525 cm^{-1} (480±24 cm^{-1}), 405 cm^{-1} (384±16 cm^{-1}), 234 cm^{-1} (224±16 cm^{-1}). The figures in parentheses are the peak frequencies in neutron-scattering spectra and their errors.

The number of the observed bands is less than the number derived from a factor group analysis of b.c.d.

This may be interpreted as being due to small frequency differences between A_u and B_u vibrations or to the weak intensities of some bands.

Normal Coordinate Treatment

The crystal structure of b.c.d. was investigated by Jensen,[7] by Padmanabhan *et al.*,[8] and by Padmanabhan *et al.*,[9] the investigators concluded that the space group was $P2_1/n$ for the crystal. In the present study, on the basis of the investigation by Padmanabhan *et al.*,[9] which determined the locations of the hydrogen atoms of crystal water molecules by the neutron diffraction method, the optically-active vibrations were calculated. According to the investigations, b.c.d. is monoclinic and the lattice parameters are $a=6.738$ Å, $b=10.86$ Å, $c=7.136$ Å, and $\beta=90°57'$. The Bravais lattice of the crystal is a simple monoclinic lattice (P), in which four chemical units, $4(BaCl_2\cdot 2H_2O)$, belong to each lattice point.

The optically-active lattice vibrations were calculated according to the method developed by Shimanouchi *et al.*[10]

The optically-active cartesian and internal symmetry coordinate vectors, X_{op} and R_{op}, are expressed by the cartesian and internal symmetry coordinate vectors, $(X_s)^{i,j,k}_{\text{Bravais}}$ and $(R_s)^{i,j,k}_{\text{Bravais}}$ respectively, associated with the Bravais cell (i,j,k).

$$X_{op} = \lim_{n_1,n_2,n_3\to\infty} (n_1n_2n_3)^{1/2} \sum_{i=0}^{n_1}\sum_{j=0}^{n_2}\sum_{k=0}^{n_3} (X_s)^{i,j,k}_{\text{Bravais}}$$

$$R_{op} = \lim_{n_1,n_2,n_3\to\infty} (n_1n_2n_3)^{1/2} \sum_{i=0}^{n_1}\sum_{j=0}^{n_2}\sum_{k=0}^{n_3} (R_s)^{i,j,k}_{\text{Bravais}}$$

The components of the vectors, $(X_s)^{i,j,k}_{\text{Bravais}}$ and $(R_s)^{i,j,k}_{\text{Bravais}}$, are shown in Tables 3 and 4. In the tables, for example, the superscript, I, of X^{I}_i or R^{I}_i represents the chemical unit number, and the underscript, i, of X^{I}_i represents the atom number in one chemical unit. The underscript of R^{I}_i represents simply the coordinate number. In Table 4, $\Delta\alpha_{l(i,j,k)m(i,j,k)n(i,j,k)}$ represents the change in the angle formed by the l atom in the Bravais cell (i,j,k), the m atom in the Bravais cell (i,j,k), and the n atom in the Bravais cell (i,j,k). (In the case of ion, the word "atom" must be replaced by "ion".) The optically-active B matrix, B_{op}, and the optically-active F matrix, F_{op}, are defined as follows:

$$R_{op} = B_{op}X_{op}$$

$$F_{op} = F_{000} + F_{100} + \tilde{F}_{100} + F_{010} + \tilde{F}_{010} + F_{001} + \tilde{F}_{001} + \cdots$$

Here, F_{000} is related to one Bravais cell, and F_{100}, F_{010}, F_{001}, ⋯ are interaction matrices between the Bravais cell and the surrounding Bravais cells.

The lattice vibration frequencies were calculated

by solving the secular equation, $|M^{-1}F_{xs}-\lambda E|=0$. M is diagonal matrix having diagonal elements of masses of atoms or ions, and $F_{xs}=B_{op}F_{op}B_{op}$. The following potential was assumed: $V=V_{H_2O}+V_{inter}$. V_{H_2O} is the Urey-Bradley force field[11] associated with crystal water molecules, and V_{inter} represents the interaction potential between crystal water molecules and ions, between ions, and also between water molecules.

$$\begin{aligned}2V_{inter} = &\sum f_i(Cl^-\cdots H)(\Delta q_i(Cl^-\cdots H))^2\\ &+ f_i(Ba^{2+}\cdots O)(\Delta q_i(Ba^{2+}\cdots O))^2\\ &+ f_i(Ba^{2+}\cdots Cl^-)(\Delta q_i(Ba^{2+}\cdots Cl^-))^2\\ &+ f_i(O\cdots O)(\Delta q_i(O\cdots O))^2\\ &+ \sum f_i(O\cdots Cl^-)(\Delta q_i(O\cdots Cl^-))^2\\ &+ \sum f_i(Cl^-\cdots Cl^-)(\Delta q_i(Cl^-\cdots Cl^-))^2\\ &+ \sum H_i(H\text{–}O\cdots Ba^{2+})r^i_{O\text{-}H}r^i_{Ba^{2+}\cdots O}(\Delta\alpha^i_{HO\cdots Ba^{2+}})^2\\ &+ \sum H_i(Ba^{2+}\cdots O\cdots Ba^{2+})r^i_{Ba^{2+}\cdots O}r^i_{Ba^{2+}\cdots O}\\ &\quad\times(\Delta\alpha^i_{Ba^{2+}\cdots O\cdots Ba^{2+}})^2\\ &+ 2a(\Delta\alpha^k_{H\text{-}O\cdots Ba^{2+}})(\Delta\alpha^l_{H\text{-}O\cdots Ba^{2+}})\\ &+ 2b(\Delta\alpha^m_{Ba^{2+}\cdots O\text{-}H})(\Delta\alpha^n_{Ba^{2+}\cdots O\text{-}H})\end{aligned}$$

In the above equation, the Δq_i's and $\Delta\alpha_i$'s represent changes in the interatomic distances and in the bond angles respectively, and the r's represent equilibrium interatomic distances. The force constants, a and b, are the interaction force constant between two $\Delta\alpha_{H-O\cdots Ba^{2+}}$'s which share a O–H bond and that between two $\Delta\alpha_{Ba^{2+}\cdots O-H}$'s which share a $Ba^{2+}\cdots O$ bond respectively. The atom-atom, atom-ion, or ion-ion interactions with interatomic distances of more than 4.0 Å were neglected. The interactions taken into account are shown for the chemical unit, I, in Table 5.

The first-trial set of force constants are shown in Table 7 as set I. $K(Cl^-\cdots Cl^-)$ and $K(O\cdots O)$ were calculated by the assumed formula: $K=A\exp(-Br)$, in which r represents the interatomic distance. The parameters, A and B, were determined from two values of $Cl^-\cdots Cl^-$ force constants (0.11 mdyn/Å, 0.15 mdyn/Å), corresponding to two values of interatomic distances (3.29 Å, 3.18 Å)[12] and from seven values of O···O force constants (5.14 mdyn/Å, 3.02 mdyn/Å, 3.03 mdyn/Å, 1.74 mdyn/Å, 1.05 mdyn/Å, 0.76 mdyn/Å, and 0.555 mdyn/Å) corresponding to seven values of interatomic distances (2.09 Å, 2.20 Å, 2.21 Å, 2.27 Å, 2.36 Å, 2.47 Å, and 2.48 Å).[13] The formula for $K(Cl^-\text{–}Cl^-)$ was used for the estimation of $K(O\cdots Cl^-)$. $K(H\cdots Cl^-)$ was estimated from the $K(H\cdots Cl^-)$ values in Ref. 14. $H(H\text{–}O\cdots Ba^{2+})$ and $H(Ba^{2+}\cdots O\cdots Ba^{2+})$ were taken from Ref. 13. $K(Ba^{2+}\cdots O)$ and $K(Ba^{2+}\cdots Cl^-)$ were estimated to be twice the $K(Cs^+\cdots O)$ and $K(K^+\cdots Cl^-)$ values in Ref. 14. The results of the calculation showed a good agreement of the calculated frequencies with the frequencies of the far IR bands in the region of 60—250 cm^{-1}. Therefore, only the force constants, K(O–H), H(H–O–H), $H_i(H\text{–}O\cdots Ba^{2+})$'s, $H_i(Ba^{2+}\cdots O\cdots Ba^{2+})$'s, a and b were adjusted by the method of least squares[15] in order to obtain the best fit of the observed frequencies with the calculated frequencies.

The cartesian coordinate values of the atoms and ions in the chemical unit, I, are shown in Table 6. The coordinate axes, X, Y, and Z, are chosen in such a way that the symmetry elements of the factor group, $\mathbf{C}_2$ and σ, coincide with the Z axis and the XY plane respectively. Therefore, the cartesian coordinate values of the atoms and ions in other chemical units, II, III, and IV, can be obtained by the operation of σ, $\mathbf{i}$ and $\mathbf{C}_2$ respectively on the coordinates of the chemical unit, I. Here, σ, $\mathbf{i}$ and $\mathbf{C}_2$ mean (translation, $(\boldsymbol{a}+\boldsymbol{c})/2$)+(reflection with respect to the XY plane), inversion, and (translation, $\boldsymbol{b}/2$)+(rotation of 180°) respectively.

Discussion

The calculated frequencies and the significant terms of the potential energy distributions for the set II force constants in Table 7 are shown in Tables 8, 9, 10, and 11, along with the observed frequencies. For the vibrations primarily associated with rotational lattice vibrations of crystal water and crystal heavy water, the following coordinates were used for the expression of the potential energy distributions.

$$\Delta R'_{s35} = (\Delta R_{s35}+\Delta R_{s36}+\Delta R_{s38}+\Delta R_{s39})/2$$
$$\Delta R'_{s36} = (\Delta R_{s35}-\Delta R_{s36}+\Delta R_{s38}-\Delta R_{s39})/2$$
$$\Delta R'_{s38} = (\Delta R_{s35}-\Delta R_{s36}-\Delta R_{s38}+\Delta R_{s39})/2$$
$$\Delta R'_{s39} = (\Delta R_{s35}+\Delta R_{s36}-\Delta R_{s38}-\Delta R_{s39})/2$$
$$\Delta R'_{s40} = (\Delta R_{s40}+\Delta R_{s41}+\Delta R_{s43}+\Delta R_{s44})/2$$
$$\Delta R'_{s41} = (\Delta R_{s40}-\Delta R_{s41}+\Delta R_{s43}-\Delta R_{s44})/2$$
$$\Delta R'_{s43} = (\Delta R_{s40}-\Delta R_{s41}-\Delta R_{s43}+\Delta R_{s44})/2$$
$$\Delta R'_{s44} = (\Delta R_{s40}+\Delta R_{s41}-\Delta R_{s43}-\Delta R_{s44})/2$$

$\Delta R'_{s36}$ and $\Delta R'_{s41}$, $\Delta R'_{s38}$ and $\Delta R'_{s43}$, and $\Delta R'_{s39}$ and $\Delta R'_{s44}$ represent H_2O (or D_2O) wagging, H_2O (or D_2O) twisting, and H_2O (or D_2O) rocking motions respectively. As is shown in the potential energy distributions, the IR bands at 710 cm^{-1}, 684 cm^{-1}, 555 cm^{-1}, and 525 cm^{-1} of $BaCl_2\cdot 2H_2O$ are due to the coupled vibrations of H_2O wagging and H_2O twisting vibrations, while the bands at 405 cm^{-1} and 330 cm^{-1} are due to H_2O rocking vibrations. The corresponding bands of the coupled D_2O wagging and D_2O twisting vibrations of $BaCl_2\cdot 2D_2O$ appear at 500 cm^{-1}, 488 cm^{-1}, and 380 cm^{-1}, while the bands due to D_2O rocking vibrations appear at 308 cm^{-1} and 264 cm^{-1}, as shown is in Tables 8 and 9. The frequency, 330 cm^{-1}, of the very weak band of $BaCl_2\cdot 2H_2O$ and the frequency shifts of the Raman lines listed in the Tables 10 and 11[16] were not used for the adjustment of the force constants.

There are two crystal water molecules per chemical unit, $BaCl_2\cdot 2H_2O$; these molecules differ in the type of bonding to the surrounding ions. In order to ascertain the bound state of the crystal water molecules, the force constants for rotation around the principal axes of the moment of inertia, k_A, k_B, and k_C, were calculated as follows. The following symbols were used:

atoms, H, O, H : i, j, k

F : Potential energy matrix having the coordinates which change by the displacement of the i, j, and k atoms as its bases

B : Matrix transforming the displacements of the i, j, and k atoms to the coordinates forming bases of F.

$\Delta\theta_m$ (m=A, B, C) : Angle of rotation around the principal axis, m.

The potential energy change, ΔV_m, due to the displacements of the i, j, and k atoms, ρ_{mn} (m=

16) A. Galy, *Compt. Rend.*, **235**, 1504 (1952).

A,B,C; $n=i,j,k$), is shown as:

$$2\Delta V_m = \sum_n \tilde{\rho}_{mn}\tilde{B}FB\rho_{mn} = k_m(\Delta\theta_m)^2$$

$$\rho_{An} = Y_n\Delta\theta_A e, \quad \rho_{Bn} = X_n\Delta\theta_{BC} \quad (n=i,j,k)$$

$$e = (r_{ji}\times r_{jk})/(|r_{ji}||r_{jk}|\sin\alpha_{ijk})$$

$$\rho_{Ci} = \sqrt{X_i^2+Y_i^2}\,e_1$$

$$e_1 = ((r_{gi}/|r_{gi}|)\cos\alpha_{igj} - (r_{gj}/|r_{gj}|))/\sin\alpha_{igj}$$

$$\rho_{Cj} = \sqrt{X_j^2+Y_j^2}\,e_2$$

$$e_2 = ((r_{gi}/|r_{gj}|)\cos\alpha_{jgk} - (r_{gk}/|r_{gk}|))/\sin\alpha_{jgk}$$

$$\rho_{Ck} = \sqrt{X_k^2+Y_k^2}\,e_3$$

$$e_3 = ((r_{gk}/|r_{gk}|)\cos\alpha_{igk} - (r_{gi}/|r_{gi}|))/\sin\alpha_{igk}$$

···	55	$\Delta R_{s23}(0.13)$, $\Delta R_{s8}(0.12)$, $\Delta R_{s14}(0.10)$	···	55	$\Delta R_{s23}(0.14)$, $\Delta R_{s8}(0.12)$

* Observed frequencies were taken from Ref. 16.

In the above formulae, g represents the center of gravity of the H_2O molecule, and X_n and Y_n ($n=i, j, k$) represent the cartesian coordinates of the i, j, and k atoms with respect to the cartesian coordinate system, X–Y–Z, having its origin at the center of gravity and the coordinate axes coinciding with the principal axes of the moment of inertia. The vector, from i to j, is expressed by r_{ij}.

Using the above formulae and the force constants in Set II in Table 7, the following values were obtained for k_A, k_B, and k_C:

$k_A = 0.138$ mdyn·Å, $k_B = 0.283$ mdyn·Å,

$k_C = 0.115$ mdyn·Å

for H_2O I $(6(i,j-1,k)4(i,j-1,k)7(i,j,k))$

$k_A = 0.138$ mdyn·Å, $k_B = 0.307$ mdyn·Å,

$k_C = 0.165$ mdyn·Å

for H_2O II $(8(i,j,k)5(i,j,k)9(i,j,k))$

From these values, it can be concluded that both the crystal water molecules, H_2O I and H_2O II, are more strongly bound around the principal axis, B, than around the principal axes, A and C.

The authors express their gratitude to Professor T. Miyazawa of Osaka University for allowing them to use FIS-3 Far Infrared Spectrometer and Perkin-Elmer 521 spectrophotometer and to Dr. T. Kitagawa and Miss M. Tsuchida of Professor Miyazawa's laboratory for their kind assistance during the measurements of IR spectra.

Their thanks are also due to Professor T. Shimanouchi of The University of Tokyo for allowing them to use the programs, BGLZ and LSMA, and to Dr. I. Suzuki of Professor Shimanouchi's laboratory for his kind instruction of use of the programs and also to Professor S. Shibata of our Department for allowing them to use IBM key punch.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 698—704 (1970)

Semi-empirical Unrestricted SCF-MO Treatment for Valence Electron Systems. II. The Angular Dependence of the Methyl Group *hfs* Constants

Hiroshi NAKATSUJI, Hiroshi KATO*1 and Teijiro YONEZAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received August 27, 1969)

Since the spin-polarization contribution to the methyl-group *hfs* constant of the ethyl radical has been recognized to be important, the angular dependence of the β-proton *hfs* constants is re-examined for various radicals. Thus, the observed relation, $Q(\theta)=B_0+B_1\cos^2\theta$, is interpreted as being the sum of the following two equations.

$$Q_{SD}(\theta) = (B_1)_{SD}\cos^2\theta$$
$$Q_{SP}(\theta) = (B_0)_{SP} + (B_1)_{SP}\cos^2\theta,$$

where SD and SP denote the spin delocalization and spin polarization contributions respectively. θ is the rotational angle about C–C single bond. A molecular orbital description of the above angular dependences is also given.

The methyl-group proton *hfs* constants of aliphatic and aromatic hydrocarbon radicals have been extensively studied from both experimental[1] and theoretical[2] points of view. The theoretical studies of the methyl proton spin densities have been carried out mainly by two different methods, namely by the valence bond (VB) and molecular orbital (MO) methods,[3] and an interesting view of the spin-appearing mechanisms was presented by Lazdins and Karplus.[2g] They stated that the methyl-group proton spin density in the ethyl radical is due to nearly 60% "exchange polarization" and nearly 40% "electron transfer" contributions. In a previous MO study[4b] it was shown that the methyl-proton spin density is due to 74% "spin delocalization (SD)" and 26% "spin polarization (SP)" contributions.[5]

The angular dependence of the β-proton *hfs* constant on the rotation about the C_α–C_β single bond has been well established experimentally and is explained by the relation[1]:

$$a_\beta^H = Q(\theta)\rho_C^\pi, \tag{1}$$

where ρ_C^π is the spin density in the $2p_{C\alpha}$ atomic orbital of the contiguous π-carbon atom, and where $Q(\theta)$ is expressed as:

$$Q(\theta) = B_0 + B_1\cos^2\theta, \tag{2}$$

where θ is the angle between the axis of the $2p_{C\alpha}$ orbital and the C_β–H bond, both projected on a plane perpendicular to the C_α–C_β bond. Aono and Higuchi[2c] studied the angular dependence of the β-proton *hfs* constant theoretically by considering only the spin delocalization (spin-hyperconjugation) mechanism; they successfully derived the $Q(\theta)=B_1\cos^2\theta$ relation, where B_1 is a constant. However, since the β-proton spin density is in large part due to the SP mechanism, it seems necessary to examine the angular dependence of the SP contribution in order to interpret the observed relation (2).

In the present study, the methyl-proton *hfs* constants of the various doublet radicals (ethyl, *n*-propyl, methyl-substituted allyl radicals, and toluene ion-radicals) are calculated by the unrestricted Hartree-Fock (UHF) method reported

Table 1. The methyl proton spin density in the ethyl radical

Angle θ	UHF spin density ρ_{uhf}	From Eq. (2)	$(\rho)_{SP}$	From Eq. (3)	$(\rho)_{SD}$	From Eq. (4)	AA ρ_{aa}
0	0.072	(0.072)	0.020	(0.020)	0.053	(0.053)	0.059
15	0.067	0.067	0.018	0.018	0.050	0.049	0.055
30	0.054	0.053	0.014	0.014	0.039	0.039	0.044
45	0.035	0.035	0.009	0.009	0.026	0.026	0.029
60	0.017	0.017	0.003	0.003	0.013	0.013	0.014
75	0.003	0.003	0.000	0.000	0.004	0.004	0.003
90	−0.002	(−0.002)	−0.002	(−0.002)	0.000	0.000	−0.001

in a previous study of this series,[6] and the mechanistic contributions to the *hfs* constants are diveded by means of the method previously proposed by the present authors.[7,4] The conclusions are that the SP contribution to the methyl-proton *hfs* constant has the angular dependence expressed by:

$$Q_{SP}(\theta) = (B_0)_{SP} + (B_1)_{SP}\cos^2\theta \quad (3)$$

and that the observed relation (2) is to be understood as the sum of the angular dependence of the SD contribution.

$$Q_{SD}(\theta) = (B_1)_{SD}\cos^2\theta \quad (4)$$

and that of the SP contribution (Eq. (3)). Thus, the constants, B's, in Eq. (2) are expressed as:

$$B_0 = (B_0)_{SP}$$

and:

$$B_1 = (B_1)_{SP} + (B_1)_{SD}. \quad (5)$$

Moreover, for the isotropic γ-carbon *hfs* constants, one may expect the same dependences as those for the methyl-proton *hfs* constants. This is certainly true for the 2*s* AO spin density of the γ-carbon atom of the *n*-propyl radical.

In the last section, a molecular orbital description of the above angular dependences is given. It is shown that the intrinsic restriction of the UHF method, compared with the configuration interaction method, does not much affect the above conclusions.

Results and Discussion

Angular Dependence. In Table 1 the methyl-proton spin densities in the ethyl radical are given for the various angles, and then they are illustrated in Fig. 1. For the total spin density, ρ_{uhf}, the relation (2) holds fairly satisfactorily, while for the SP and SD contributions Eqs. (3) and (4) excellently represent their angular dependences. The curves obtained from Eqs. (2), (3), and (4) almost overlap with the corresponding curves shown in Fig. 1.

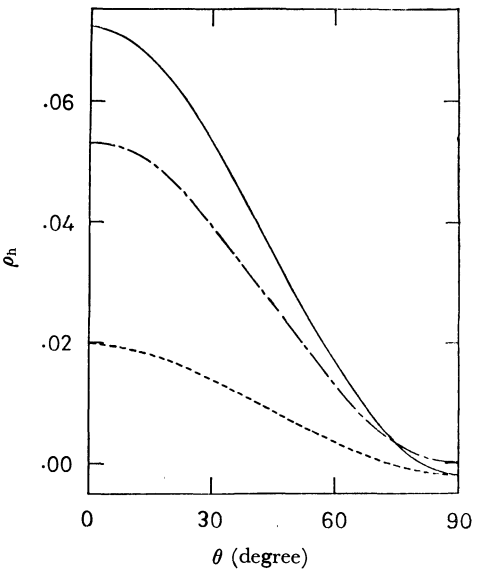

Fig. 1. Angular dependence of the methyl proton spin density in the ethyl radical.
——, ρ_{uhf}; - —, $(\rho_{uhf})_{SD}$; -----, $(\rho_{uhf})_{SP}$

The coefficients, B, calculated from the results shown in Table 1, are given in Table 2.

For the *n*-propyl radical, the situation is very similar to that of the ethyl radical. For the β-proton spin density, the dependences of ρ_{uhf}, $(\rho_{uhf})_{SP}$, and $(\rho_{uhf})_{SD}$ on the rotational angle, θ, is illustrated in Fig. 2. The relation (2) deviates only slightly from the calculated dependence; this deviation is mainly due to the SD contribution. The constants, B, in Eqs. (2), (3), and (4) were obtained by fitting the calculated curves; they are given in Table 2.

For the isotropic γ-carbon *hfs* constants of the *n*-propyl radical, one may expect the same dependences as those for the methyl proton *hfs* constants in the ethyl radical. This is certainly true for the 2*s* AO spin density of the γ-carbon atom. The angular dependences of the 2*s* AO spin density and of the mechanistic contributions are illustrated in Fig. 3. The curves of this figure are very well represented by $\rho_{uhf} = -0.001 + 0.018\cos^2\theta$, $(\rho_{uhf})_{SD} =$

a) The values of B are given in gauss unit.
b) $B_0=(B_0)_{SP}$

$0.005\cos^2\theta$, and $(\rho_{uhf})_{SP}=-0.001+0.013\cos^2\theta$.

Among the methyl-substituted allyl radicals, the 2-methylallyl radical is of great interest. Since the singly-occupied π-orbital of this radical has a node on the C_2 atom, the spin density of the methyl group is expected to be due only to the SP mechanism and to be negative in sign. This is certainly true, as Tables 2 and 3 show. Thus, the angular dependence of the methyl proton spin density of the 2-methylallyl radical is well represented *only* by

TABLE 3. THE METHYL PROTON SPIN DENSITY OF THE 2-METHYLALLYL RADICAL

Angle	UHF spin density				AA

——, ρ_{uhf}; - —, $(\rho_{uhf})_{SD}$; -----, $(\rho_{uhf})_{SP}$

Eq. (3), as is shown in Table 3.

For the other methyl-substituted allyl radicals (*cis*-1-methylallyl and *trans*-1-methylallyl), the situations are similar to that of the ethyl radical. The SD contributions to the methyl proton spin densities of these radicals are nearly 60%, small compared with those of the ethyl radical (See Table 2). Much

	30	−0.006	−0.006	−0.006	−0.006	0.000	0.000	−0.002
	45	−0.004	−0.005	−0.004	−0.005	0.000	0.000	−0.001
	60	−0.003	−0.003	−0.003	−0.003	0.000	0.000	−0.001
	90	−0.001	(−0.001)	−0.001	(−0.001)	0.000	0.000	0.000
Cation	0	0.033	(0.033)	0.012	(0.012)	0.021	(0.021)	0.025
	30	0.024	0.025	0.009	0.009	0.015	0.016	0.018
	45	0.016	0.016	0.006	0.006	0.010	0.010	0.012
	60	0.007	0.008	0.002	0.003	0.005	0.005	0.006
	90	−0.001	(−0.001)	−0.001	(−0.001)	0.000	0.000	0.000

as with the above examples, the angular dependences of the SP and SD contributions are well represented by Eqs. (3) and (4). The values of B in these equations are given in Table 2.

The methyl-proton spin densities of the toluene-ion radicals are summarized in Table 4. Although the tolune ions have nearly degenerate symmetric and antisymmetric electronic states with respect to the C_2 operation, only their ground electronic states (the symmetric electronic state for the cation and the antisymmetric state for the anion) are calculated for the present purposes. For the antisymmetric state of the anion radical, its singly-occupied π-orbital has a node on the 1-carbon (the carbon to which the methyl group is attached); therefore, the spin density of the methyl proton is due only to the SP mechanism and is negative, similar to that of the 2-methylallyl radical. By referring to Table 4, Eq. (3) is found to apply satisfactorily. For the symmetric state of the cation radical, the SD contribution to the methyl proton spin density is nearly 60%. As is shown in Table 3, Eqs. (2), (3), and (4) hold very satisfactorily. The values of B in these equations are given in Table 2. Note that the B_1 values of the anion and cation differ greatly.

One conclusion from Table 2 is that the methyl proton spin densities are composed of a major (60—75%) SD contribution and of a minor (25—40%) SP contribution, except for the special cases of the 2-methylallyl radical and the antisymmetric state of the toluene anion. Note that the B values of the 2-methylallyl and toluene anion radicals, in which only the SP mechanism is important, deviate greatly from the average B values. Another conclusion of the present study is that the observed relation, (2), can be interpreted as the sum of Eqs. (3) and (4), and that this relation may also hold for the 2*s* AO spin density of the γ-carbon atom (as is shown in the case of the *n*-propyl radical).

***hfs* Constants.** The proton *hfs* constants[8] calculated by assuming the free rotation of the methyl group are compared with the experimental results in Tables 5 and 6. Although the toluene ions have nearly degenerate electronic states, the calculated values given in Table 5 correspond only to the lower electronic states (the symmetric state for the cation and the antisymmetric state for the anion). For a more rigorous discussion of the *hfs* constants, the thermal and vibronic coupling effects must be considered,[1d] as Purins and Karplus did recently.[9] Note, however, that the inclusion of

b) J.K. Kochi and P.J. Krusic, *J. Amer. Chem. Soc.*, **90**, 7157 (1968).

these effects, which are expressed by the weighted mean of the *hfs* constants of the symmetric and antisymmetric electronic states, will improve the calculated *hfs* constants of the toluene anion.[10]

Since Fessenden and Schuler[11] observed the different *hfs* constants for the terminal methylene protons of the allyl radical, the observed *hfs* constants have been assigned theoretically by several investigators.[6,12-14] This finding was of particular interest since the well-known McConnell rule cannot interpret the observed difference. Recently, however, Kochi and Krusic[15] settled this assignment by observing the *hfs* constants of the methyl-substituted allyl radicals; they proved that the assignment by the present authors[6,12] was correct. Here, we calculated the proton *hfs* constants of these methyl-substituted allyl radicals. The results are summarized in Table 6. The assignments of the *hfs* constants of the $H_{3\alpha}$ and $H_{3\beta}$ protons of the *cis*- and *trans*-1-methylallyl radicals agree with the experimental results, although the differences in the calculated *hfs* constants of these two protons are rather small compared with the experimental values. In the 2-methylallyl radical, the methyl-proton *hfs* constants are calculated to be due only to the SP mechanism and to be negative in sign. The calculated *hfs* constants of the $H_{1\alpha}$ proton of the *cis*-form and of the $H_{1\beta}$ proton of the *trans*-form are too large (absolute value) compared with the experimental values.

Origin of the Angular Dependence. Here, we shall give a molecular orbital description of the angular dependences expressed by Eqs. (2), (3), and (4). For the present purposes the configuration interaction (CI) treatment may be most suitable. As has been shown previously, the UHF wave-function is expressed by the following CI form to a first-order approximation:[7]

$$\Psi_{\mathrm{uhf}} = \Psi^{\mathrm{rf}} + \sum_i C^{\mathrm{se}}(ii^*)\,\Psi^{\mathrm{se}}(ii^*), \tag{6}$$

where the second term is due to the spin polarization perturbation. Ψ^{rf} is the restricted function composed of the natural orbitals,[16,4b] λ_i and μ, of the UHF wave-function and Ψ^{se} (ii^*) represents the normalized singly-excited configuration expressed by the one-electron jump from λ_i to ν_i:

$$\Psi^{\mathrm{rf}} = |\lambda_1\alpha\ \lambda_1\beta\cdots\lambda_q\alpha\ \lambda_q\beta\mu\alpha|$$

$$\Psi^{\mathrm{se}}(ii^*) = |\lambda_1\alpha\ \lambda_1\beta\cdots\nu_i\lambda_i\ \frac{1}{\sqrt{2}}(\alpha\beta+\beta\alpha)\cdots\lambda_q\alpha\lambda_q\beta\mu\alpha| \tag{7}$$

$2q+1$ is the number of electrons in the radical. The natural orbitals, λ, μ, and ν, correspond, respectively, to the doubly-occupied, singly-occupied, and unoccupied orbitals of the restricted function, Ψ^{rf}, and are orthonormal to each other.[16] Note that λ_i and ν_i correspond to the bonding and antibonding partner MO's of the alternant molecular orbital method.[16,4b]

From Eq. (6), the SP and SD contributions to the UHF spin density are given by[4b]:

$$(\rho_{\mathrm{uhf}})_{\mathrm{SD}} = \langle\Psi^{\mathrm{rf}}|\rho|\Psi^{\mathrm{rf}}\rangle = \mu^2 \tag{8}$$

10) The observed *hfs* constant of the methyl proton of the toluene anion is positive in sign; E. de Boer and J. P. Colpa, *J. Phys. Chem.*, **71**, 21 (1967).

and:

$$(\rho_{uhf})_{SP} = 2\sum_i C^{se}(ii^*) <\Psi^{rf}|\boldsymbol{\rho}|\Psi^{se}(ii^*)> = 2\sqrt{2}\sum_i C^{se}(ii^*)\,\lambda_i\nu_i, \quad (9)$$

where $\boldsymbol{\rho}$ is the spin-density operator.

Now let us enter upon a description of the angular dependence of the methyl group proton spin density. In Table 7 the natural orbitals, λ and μ, of the ethyl radical, as calculated by the present method, are given for the two rotational configurations, and in Table 8 the coefficients of the singly-excited configurations, $C^{se}(ii^*)$, are summarized.[4] Table 8 shows that the coefficients, $C^{se}(ii^*)$, are almost independent of the rotational angle, θ. Thus, we have only to consider the angular dependence of the AO coefficients of the natural orbitals.

The local-group orbitals constructed from the three hydrogen 1s AO's of the methyl group may be written as:

$$\begin{aligned} \phi_\sigma &= h_1 + h_2 + h_3, \\ \phi_{\bar{\pi}} &= h_1 - h_2, \\ \phi_\pi &= h_1 + h_2 - 2h_3. \end{aligned} \quad (10)$$

ϕ_σ is totally symmetric about the rotation, while $\phi_{\bar{\pi}}$ and ϕ_π are the quasi-π-orbitals and are perpendicular to each other. Thus, the angular dependence of the coefficients of the one particular hydrogen 1s AO, h, in various molecular orbitals (i) may be grouped into the following three types:

$$\begin{aligned} &\sigma\text{-type: } a_i \cdot h, \\ &\bar{\pi}\text{-type: } b_i \sin\theta \cdot h, \\ &\pi\text{-type: } c_i \cos\theta \cdot h, \end{aligned} \quad (11)$$

where a_i, b_i, and c_i are the AO coefficients of the molecular orbital, i, at $\theta=90°$ or at $\theta=0°$. In Table 7 the orbitals are divided into the above three groups. For the π-electron radicals, the angular dependence of the coefficient of the methyl hydrogen is, of course, of the π-type. Hence, the

SD contribution to the methyl-proton spin density is given by:

$$(\rho_{\mathrm{uhf}})_{\mathrm{SD}} = c_{\mu}^{2} \cos^{2}\theta \cdot \qquad (12)$$

From Eqs. (9) and (11) the SP contribution is similarly expressed by:

$$\begin{aligned}(\rho_{\mathrm{uhf}})_{\mathrm{SP}} &= 2\sqrt{2}\{\sum_{i}^{\sigma} C^{\mathrm{se}}(ii^{*})\, a_i a_{i^{*}} \\ &\quad + \sum_{i}^{\pi} C^{\mathrm{se}}(ii^{*})\, b_i b_{i^{*}} \sin^{2}\theta \\ &\quad + \sum_{i}^{\pi} C^{\mathrm{se}}(ii^{*})\, c_i c_{i^{*}} \cos^{2}\theta\} \\ &= (\rho_0)_{\mathrm{SP}} + (\rho_1)_{\mathrm{SP}} \cos^{2}\theta, \qquad (13)\end{aligned}$$

where:

$$(\rho_0)_{\mathrm{SP}} = 2\sqrt{2}\{\sum_{i}^{\sigma} C^{\mathrm{se}}(ii^{*})\, a_i a_{i^{*}} + \sum_{i}^{\pi} C^{\mathrm{se}}(ii^{*})\, b_i b_{i^{*}}\}$$

$$(\rho_1)_{\mathrm{SP}} = 2\sqrt{2}\{\sum_{i}^{\pi} C^{\mathrm{se}}(ii^{*})\, c_i c_{i^{*}} - \sum_{i}^{\pi} C^{\mathrm{se}}(ii^{*})\, b_i b_{i^{*}}\}.$$

$\sum^{\pi}$ denotes the summation over the π-type orbitals. Eqs. (12) and (13), and the sum of them, correspond to Eqs. (4), (3), and (2) respectively.

Note here that the conditions for the local symmetry orbitals expressed by Eq. (10) (the conditions for the definite grouping of MO's by Eq. (11)) are not satisfactorily fulfilled in cases of poor symmetry,[17] and that, in the usual CI treatment, the transitions other than $i \rightarrow i^{*}$ (i and i^{*} have, of course, the same type of local symmetry) must be included.[18] (Compare this with Eq. (6)). In these cases, Eqs. (12) and (13) may include types of angular-dependent terms other than $\cos^{2}\theta$. One example of the poor symmetry is the *n*-propyl radical, where the curves obtained by Eqs. (2), (3), and (4) deviate slightly from the calculated curves. Nevertheless, the relations (2), (3), and (4) are still good approximations to the angular dependences of the β-proton spin density of the *n*-propyl radical (See Fig. 2).

The effects of the inclusion of the $i \rightarrow j^{*}$ ($i \neq j$) transitions are not certainly determined numerically by the present study, but they can be estimated as follows. The $i \rightarrow j^{*}$ transitions may be grouped into two groups; one is composed of the transitions where i and j^{*} have the same local symmetry, and the other is composed of the transitions where i and j^{*} have different local symmetries. By including the former type of transition, the angular dependence expressed by Eq. (13) is not altered. Only the coefficients may be changed. For the latter type of transition, which may produce types of angular-dependent terms other than $\cos^{2}\theta$, their CI coefficients, $C^{\mathrm{se}}(ij^{*})$, can be expected from symmetry considerations to be very small. Thus, the inclusion of the $i \rightarrow j^{*}$ ($i \neq j$) transitions will not much alter the type of angular dependence expressed by Eq. (13).

One of us (H. N.) wishes to thank Dr. T. Kawamura for his helpful discussions. The computation was carried out by a HITAC 5020E computer at the Computation Center of the University of Tokyo.

17) For example, the condition of the local symmetry expressed by Eq. (10) is already broken in the ethyl radical (See Table 7). However, the relations (2), (3) and (4) are very satistactory as shown in the previous section.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 704—708 (1970)

Microwave Spectra of *o*-Difluorobenzene in the Excited Vibrational States*1

Aritada HATTA and Kunio KOZIMA

Laboratory of Molecular Spectroscopy, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 6, 1969)

The microwave spectra of *o*-difluorobenzene in various excited vibrational states have been measured in the frequency region from 10- to 30-GHz. The R- and Q-branch transitions of the a-type have been assigned. The rotational constants for the $v_1=1$ state are $A=3254.77$, $B=2226.85$, and $C=1324.67$ MHz, and those for the $v_2=1$ state are $A=3269.76$, $B=2220.48$, and $C=1322.94$ MHz. The inertial defects in the excited states have been used in order to make vibrational assignments. It is very probable that the v_1 and the v_2 mode are the out-of-plane vibration of A_2 and the in-plane vibration of A_1 respectively.

Previous studies[1,2] of the microwave spectrum of *o*-difluorobenzene in the ground vibrational state have shown that the molecule is planar and that the angle made by two C–F bonds is probably

larger than 60°.

The infrared and Raman spectra of *o*-difluorobenzene have been investigated by Green *et al.*,[3] Scott *et al.*,[4] and Nonnenmacher and Mecke.[5] However, the vibrational assignments by these authors in the far-infrared region ($<400\ cm^{-1}$) are different from each other. The present study has been carried out in order to investigate the microwave spectra of *o*-difluorobenzene in the excited vibrational states and to obtain information about their vibrational assignments.

Experimental

The spectra were measured over the frequency range from 10- to 30-GHz with a conventional Stark modulation microwave spectrometer, employing 110-kHz square-wave or sine-wave modulation. The absorption-line frequencies were measured by the same method as has been previously reported by the present authors.[1]

All the measurements were made at room temperature. The sample of *o*-difluorobenzene was prepared from commercial *o*-fluoroaniline by the method of Schiemann and Pillarsky.[6]

Results

The rotational spectra were obtained for six excited vibrational states. The states will be designated hereafter by using the vibrational quantum numbers of v_i.

Assignments of the microwave spectra for the excited states were difficult because of the weakness of the lines and the complexity of the spectra. Because the spectra of the low-J R-branch transitions for the excited states, particularly for the $v_1=1$ state, overlap with the corresponding ground-state lines, an analysis for the low-J transitions was not easy. The lines of the excited states with the relatively high-J values, however, are well separated, and little overlapping occurs. The observations of the qualitative Stark patterns of the spectra were very helpful in the assignments. A least-squares procedure was used to get the best fit between the observed and the calculated frequencies. Agreement is as good as in the case of the ground state. A FACOM 222 digital computer was used in carrying out these calculations. For the $v_3=1$ state, only two transitions are assigned on the basis of their Stark effects and the relative intensities. The rotational constants were obtained for the states of the over-tones ($v_1=1$, 2, and 3, and $v_2=1$) and for that of the combination tone ($v_1=1+v_2=1$). The observed frequencies and the assignments in the excited states are listed in Table 1, together with the differences between the observed frequencies and those calculated by the use of the rigid rotor rotational constants given in Table 2.

As may be seen in Table 1, the centrifugal distortion effect is not important in the transitions studied. The rotational constants and the asymmetry parameters obtained are listed in Table 2. The principal moments of inertia derived from the rotational constants and the resulting inertial defects are listed in Table 3. As is shown in Tabel 3, the inertial defect, $\Delta_{v_1}(=I_c-I_a-I_b)$, becomes progressively more negative as the vibration is excited to higher over-tone states. For the $v_2=1$ state, $\Delta_{v_2=1}$ is also negative, though less in magnitude than $\Delta_{v_1=1}$.

The difference in the inertial defects between the first excited state and the ground state of v_1, $\delta\Delta_1$, is -0.757 amu·Å^2. That of v_2, $\delta\Delta_2$, is -0.197 amu·Å^2.

The measurements of relative intensity were made on the selected transitions of the ground and the first two excited states of v_1 and the first excited state of v_2.

Because of the richness of the spectrum, there were only a few transitions for which reliable measurements could be made. By the use of isolators the relative intensities were obtained by a direct comparison of the line heights on a recorder. The lines are so closely spaced that the variations in the microwave powder were limited to about 10% during these measurements. The results are shown in Table 4.

Discussion

Because the molecule of *o*-difluorobenzene, $^{12}C_6H_4F_2$, has a C_{2v} (or C_2) symmetry, the total wave-function should change in sign under the effect of the rotation operation of 180° about the two-fold axis of symmetry. Since the ratio of the number of the symmetric spin functions to that of the antisymmetric spin functions is 36 : 28, the antisymmetric rotational states (with K_{-1} odd) are more populated than the symmetric rotational states (with K_{-1} even) by this ratio for the ground vibrational state.

In the first vibrationally-excited state the value of the ratio must change to its inverse only for the vibrational mode of B_1 or B_2. As can be seen from Table 4, the relative intensities of the rotational transitions for the same vibrationally-excited state do not depend upon whether K_{-1} is even or odd. Therefore, it can be concluded that the vibration of the v_1 or the v_2 mode belongs to the A_1 or the A_2 type. In this paper the letters representing the frequencies and the relating quantities for different

* Assignments for out-of-plane vibrations.

vibrational modes are designated by the numerical suffixes which number the vibrations from lower to higher. From the data of the intensities, the mean values of the vibrational frequencies of ω_1 and ω_2 were calculated to be 208 cm^{-1} and 255 cm^{-1} respectively. In view of the experimental error for the intensity measurements, these results are in agreement with those obtained by means of the Raman spectra,[4,5] as is shown in Table 5. For the v_3 mode, only two rotational transitions could be observed, as is shown in Table 1. The relative intensity of the $4_{13}\rightarrow5_{14}$ transitions could not be accurately measured because of the overlapping of the other band.

The relative intensity of the $6_{33}\rightarrow 7_{34}$ transitions for the $v_3=0$ and 1 states is shown in Table 4. From this value, the frequency of ω_3 is calculated to be 298 cm^{-1} if the v_3 mode is of the B_1 or the B_2 type. On the other hand, the value is calculated to be 348 cm^{-1} if the v_3 mode is of the A_1 or the A_2 type. As the value of 298 cm^{-1} is in good agreement with that of the Raman spectrum, the former assignment seems to be correct. Therefore, it is reasonable that the v_3 mode is of the B_2 type, according to the assignment given by Green *et al.*[3]

Until now three different assignments for the vibrational type have been reported. However, only for the v_4 and v_5 modes the assignments agree with each other, as is shown in Table 5. Let us, then, proceed to assign the v_1 and v_2 modes by assuming that the assignments for the v_4 and v_5 modes are correct. For this purpose the values of the inertial defect are useful. For a planar molecule a general formula for inertial defect, Δ, has been given by Oka and Morino[7] as follows:

$$\Delta = \Delta_{\text{vib}} + \Delta_{\text{cent}} + \Delta_{\text{elec}}$$

$$\Delta_{\text{vib}} = \sum_r (v_r+1/2)\Delta_r = \sum_r \frac{h}{\pi^2 c}(v_r+1/2) \times \sum_s{}' \frac{{\omega_s}^2}{\omega_r(\omega_r{}^2-\omega_s{}^2)} \{(\zeta_{rs}^{(a)})^2+(\zeta_{rs}^{(b)})^2-(\zeta_{rs}^{(c)})^2\} + \sum_t \frac{h}{\pi^2 c}\cdot\frac{3}{2\omega_t}(v_t+1/2) \quad (1)$$

where ω_r and ω_s are the wave numbers of different modes of vibrations, ζ's are Coriolis coupling constants, and the last term is taken into account only when the modes of r belong to the out-of-plane vibrations. The superscripts refer to the molecular fixed principal axes along which a vibrational angular momentum is produced. From this equation the difference between the total values of the inertial defect for two adjacent vibrational states can be expressed as follows:

$$\Delta v_{r+1} - \Delta v_r = \frac{h}{\pi^2 c}\left[\sum_s{}' \frac{{\omega_s}^2}{\omega_r(\omega_r{}^2-\omega_s{}^2)} \{(\zeta_{rs}^{(a)})^2 + (\zeta_{rs}^{(b)})^2 - (\zeta_{rs}^{(c)})^2\} + \frac{3}{2\omega_t}\right] \quad (2)$$

In Eq. (2) the difference between the values for Δ_{cent} are negligibly small and can be omitted, together with the difference in Δ_{elec}.

From the character table for C_{2v}, it can be seen that the nonvanishing elements of the Coriolis coupling constants for this molecule are $\zeta_{A_1A_2}^{(a)}$, $\zeta_{B_1B_2}^{(a)}$, $\zeta_{A_1B_2}^{(b)}$, $\zeta_{A_2B_1}^{(b)}$, $\zeta_{A_1B_1}^{(c)}$, and $\zeta_{A_2B_2}^{(c)}$, where the subscripts refer to the vibrational modes. The C_2 axis of symmetry is the a-axis, and the axis perpendicular to the molecular plane is the c-axis.

Equation (2) shows that the vibrational modes and their frequencies directly affect the inertial defect through the Coriolis interactions and that the interactions fall off with an increase in the frequency difference because of the $({\omega_r}^2-{\omega_s}^2)$ terms in the denominator. Hence, we can assume that the higher vibrations ($s>5$) are not important in these discussions.

It is very probable that the v_1 and v_2 modes are mainly due to the C–F deformation vibrations. Since it is clear, from symmetry considerations, that the out-of-plane vibrational modes belong to the A_2 and B_2 species and that the in-plane modes belong to the A_1 and B_1 species, the possibility that both the v_1 and v_2 modes belong to A_1 or A_2 can be excluded.

Additional evidence for this can also be obtained from the considerations based on Eq. (2). Therefore, there remain only the following two possibilities:

	ω_1	ω_2	ω_3	ω_4	ω_5
Case (1)	A_2	A_1	B_2	B_1	B_2
Case (2)	A_1	A_2	B_2	B_1	B_2

For Case (1), the following equations can be written on the basis of Eq. (2):

$$\frac{h}{\pi^2 c}\left[\frac{{\omega_2}^2}{\omega_1(\omega_1{}^2-\omega_2{}^2)}(\zeta_{12}^{(a)})^2 - \frac{{\omega^2}_3}{\omega_1(\omega_1{}^2-\omega^2{}_3)}(\zeta_{13}^{(c)})^2 + \frac{3}{2\omega_1}\right] = \delta\Delta_1$$

$$\frac{h}{\pi^2 c}\left[\frac{{\omega_1}^2}{\omega_2(\omega_2{}^2-\omega_1{}^2)}(\zeta_{12}^{(a)})^2 + \frac{{\omega_3}^2}{\omega_2(\omega_2{}^2-\omega_3{}^2)}(\zeta_{23}^{(b)})^2\right] = \delta\Delta_2$$

where the terms containing $(\zeta_{14}^{(b)})^2$ and $(\zeta_{15}^{(c)})^2$ in the former equation and the terms containing $(\zeta_{25}^{(b)})^2$ and $(\zeta_{24}^{(c)})^2$ in the latter equation could be considered to be approximately cancelled out, because the value of ω_4 is not very different from that of ω_5. By using the wave numbers reported by Scott *et al.*,[4] the possible values of the squares of the Coriolis coupling constants could be estimated as follows:

$$(\zeta_{12}^{(a)})^2 = 1.0 - 0.85, \quad (\zeta_{13}^{(c)})^2 = 0.26 - 0.0,$$
$$(\zeta_{23}^{(b)})^2 = 0.83 - 0.72$$

where the conversion factor of $h/\pi_2 C=134.8599$ amu·Å^2·cm^{-1} was used. These values seem to be reasonable. On the other hand, for Case (2) no reasonable values of the squares of the Coriolis coupling constants could be obtained.

Therefore, it can be concluded that the assignments of Case (1) are correct. The assignments obtained are analogous to those obtained for *o*-dichlorobenzene by Nonnenmacher and Mecke[5] and by Scherer.[8]

Diffuse Reflection Spectra of Acid Clays Colored with Benzidine and Some Other Diamines

Akihiko HAKUSUI, Yoshio MATSUNAGA*1 and Kenji UMEHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received September 9, 1969)

In order to identify the species responsible for the coloration of acid clay upon the addition of benzidine and related aromatic diamines, the diffuse reflection spectra of colored clays in the presence of water, methanol, and benzene were examined in the range from 4 to 29 kK. The coloration appeared to be due to the oxidation of the diamines held between the silicate sheets to the mono- and di-valent cations. The former cations were found to be in various modes of intermolecular interaction, depending on the kind and amount of the liquid. The lightening of the color upon drying was attributed to the disproportionation of the monovalent cations to the divalent cation and the protonated molecule.

It has been known that the addition of benzidine and other aromatic diamines to some clay minerals produces deep colors.[1,2] Examining the absorption spectra of acid clays suspended in benzene and colored by benzidine and its tetramethyl derivative, Hasegawa has concluded that the quinoidal and meriquinoidal forms of the diamines are responsible for the coloration.[3] In recent years much knowledge of the electronic spectra of ion radicals, including those derived from the diamines, has accumulated. It is now clear that the electronic spectra depend considerably on the mode of aggregation, *e.g.*, monomeric, dimeric or polymeric. Even in the solid state the presence of various modes of intermolecular interactions has been pointed out on the basis of the spectra.[4] As the diamine molecules held between the silicate sheets are in the form of a double layer,[5] it is not likely that the cation radicals in colored clays are free from intermolecular interaction. Therefore, no complete identification of the colored species in acid clays as the monovalent cations can be made without considering the mode of aggregation. In addition, a lightening of the colors on drying and a deepening on wetting have been noted by Hauser and Leggett and also by Takahashi.[2,5] To measure the spectral changes in such processes it seemed to us that the method of diffuse reflection has great advantages.

Experimental

Materials. The acid clay supplied by Wako Pure Chemical Industries, Ltd., was refined by repeated elutriations. Colored clays were prepared by mixing a diamine dissolved in a suitable organic solvent and the clay suspended in the same; the mixture was then filtered and washed throughly with the solvent. The samples thus prepared were quickly dried in a vacuum and then moistened with the liquid selected for the spectral measurements. For example, a 0.37-g portion of benzidine dissolved in 20 m*l* of methanol was added to 3.0 g of the clay suspended in 20 m*l* of methanol. The color was blue, but it turned green and finally yellow on drying. The carbon content of the dried sample was found by elemental analysis to be 1.48%, corresponding to a benzidine content of 1.89%. The diamines and the solvents used for sample preparations were as follows: benzidine in methanol, *o*-tolidine in methanol, *N,N,N′,N′*-tetramethylbenzidine in benzene, and 1,6-diaminopyrene in acetone. The cation radical salts of the first three diamines were prepared according to the methods of Hughes and Hush.[6] The solid bromides of the mono- and di-valent 1,6-diaminopyrene cations were made by the oxidation of the diamine dissolved in xylene with bromine, as has been described by Scott *et al.*[7]

Measurements. The difference in reflectance between a colored clay and the dry refined acid clay was recorded by means of a Beckman DK 2A spectroreflectometer. The spectra were plotted using the Kubelka-Munk function, $f(R)=(1-R)^2/2R$, where R is the reflectance. The function is supposed to be equal to the absorption coefficient divided by the scattering coefficient. As both the coefficients are affected by the pres-

ence of a liquid, we must seek a set of conditions such that the change in the absorption coefficient is of major importance in determining the change in the spectra. When colored clays are only slightly moistened, *e.g.*, by a few drops of liquid per gram of the clay, the spectra were found to be approximately comparable with each other. The procedures used for the spectral measurements of the solid ion-radical salts were described in an earlier paper.[4]

Results

Benzidine-acid Clay. The dried sample is yellow, and the spectrum has only one absorption maximum, located at 22.5 kK. As is shown in Fig. 1, a weak, continuous absorption can be seen

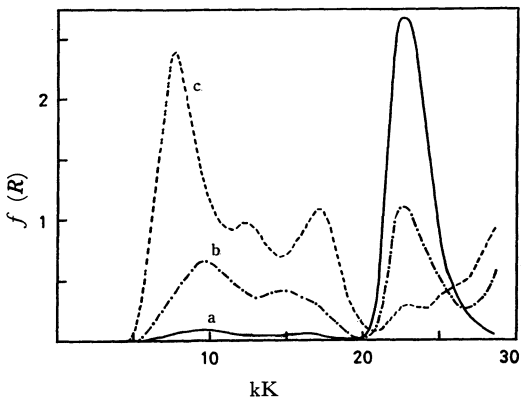

Fig. 1. Diffuse reflection spectra of benzidine-acid clays moistened with water; (a) nearly completely dried, (b) moistened, (c) moistened further.

in the low-energy region if the sample is not quite dry. On slight moistening with water, the absorption in the low-energy region is intensified and that at 22.5 kK is considerably weakened. The presence of maxima at 9.5 and 14.5 kK and a shoulder at 16 kK can be clearly noted. (Hereafter this will be called the pattern B-2). The further addition of water to the sample modifies the spectrum drastically. The absorption at 22.5 kK almost decays out, and absorption maxima at 7.5, 12.0, 17.0, and about 27 kK form the pattern B-1. When the sample is very wet, the pattern remains the same as the pattern B-1, but the intensities may be hundreds of times higher than those shown in Fig. 1.

The spectra of the samples moistened with methanol are shown in Fig. 2. The pattern B-2 can be more clearly observed here than in the clays moistened with water. An absorption maximum now clearly appearing at 26 kK is considered to be a part of this pattern. This figure presents a good example of how the spectral change by the addition of a liquid is reversible. A slightly moistened sample was examined first (curve a). Then the sample

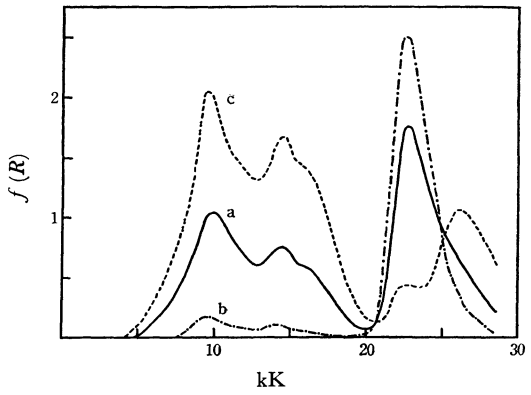

Fig. 2. Diffuse reflection spectra of benzidine-acid clays moistened with methanol; (a) moistened, (b) nearly completely dried, (c) moistened again.

was nearly completely dried (curve b), and finally it was moistened again with methanol (curve c). The pattern B-1 can be observed in this combination, too, provided that the samples are soaking wet.

Moistening the dried samples with benzene results in the appearance of a spectrum entirely different from that described above. The pattern B-3, found in Fig. 3, consists of absorption maxima at 11.5, 15.2, and somewhere around 27 kK.

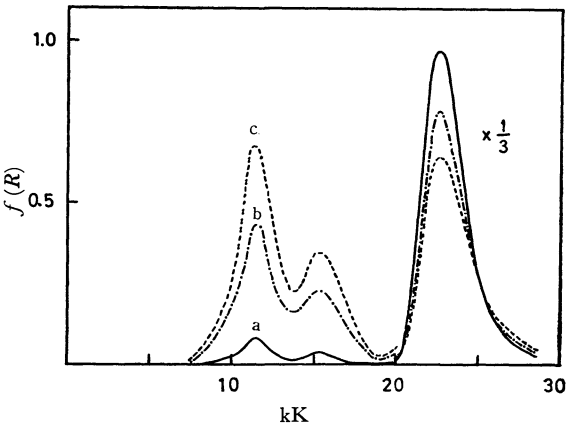

Fig. 3. Diffuse reflection spectra of benzidine-acid clays moistened with benzene; (a) nearly completely dried, (b) moistened, (c) moistened further.

The results given in Figs. 1, 2, and 3 were all obtained using freshly-prepared samples. On storage the absorption at 22.5 kK is slowly intensified and the sample becomes less sensitive to moisture. Long after preparation, the deep color does not develop on either moistening or soaking.

***o*-Tolidine-acid Clay.** In this system the samples moistened with methanol show essentially the same spectra as those moistened with water. Figure 4

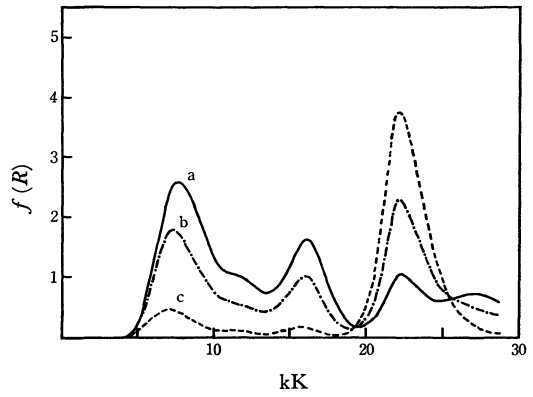

Fig. 4. Diffuse reflection spectra of *o*-tolidine-acid clays moistened with methanol; (a) moistened, (b) moistened less, (c) nearly completely dried.

presents the spectra obtained by the former combination. The pattern T-1 characteristic of the deep-colored clays consists of absorption maxima at 7.5, 16.0, and 27.0 kK and a shoulder at 11.5 kK; it bears a close resemblance to the pattern B-1.

On moistening with benzene absorption maxima are observed at 10.7, 14.5, and 27 kK. The pattern shown in Fig. 5 may be designated as T-3 because

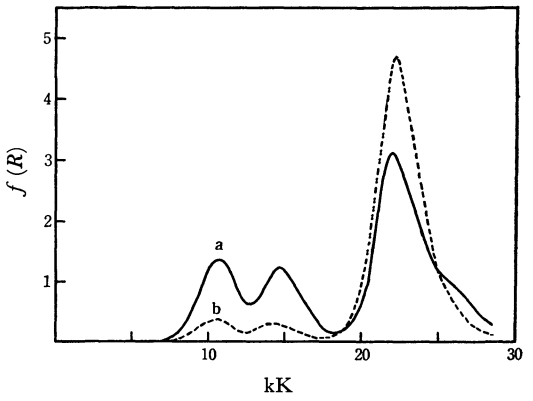

Fig. 5. Diffuse reflection spectra of *o*-tolidine-acid clays moistened with benzene; (a) moistened, (b) nearly completely dried.

of its similarity to the pattern B-3. It should be noted that the spectra given in Figs. 4 and 5 were taken in the process of drying.

Tetramethylbenzidine-acid Clay. The sample prepared in benzene is green. This color lightens only very slowly on drying. The spectrum (curve a) given in Fig. 6 was obtained after three weeks' storage over silica gel. By the addition of methanol, the absorptions at 7—7.5, 14—14.5, and 25 kK are intensified. The spectrum exhibited by the moistest sample in the figure (curve c) is practically the same as that exhibited by the sample freshly prepared in benzene.

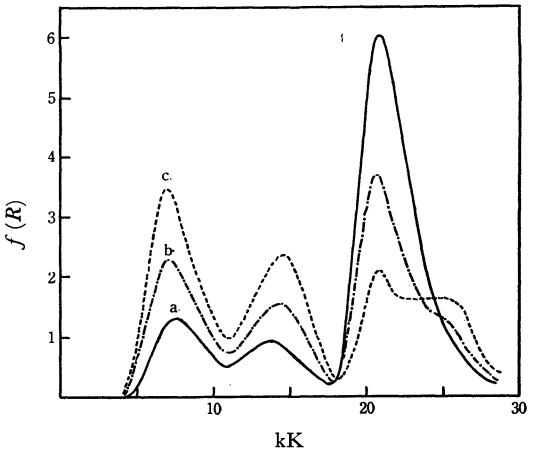

Fig. 6. Diffuse reflection spectra of tetramethylbenzidine-acid clays moistened with methanol; (a) nearly completely dried, (b) moistened, (c) moistened further.

Diaminopyrene-acid Clay. The freshly-prepared sample is dark brown. The color turns to a reddish brown on standing. As is shown in Fig. 7,

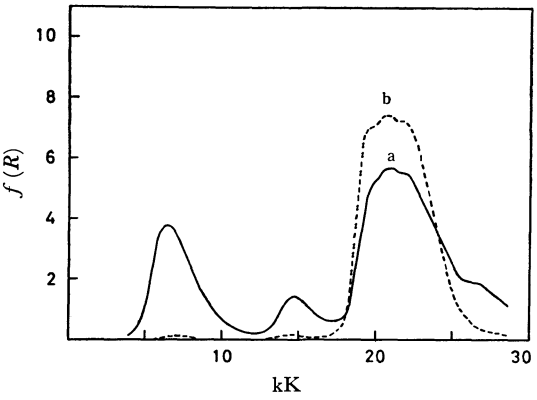

Fig. 7. Diffuse reflection spectra of dry diaminopyrene-acid clays; (a) freshly prepared, (b) stored for three days.

the disappearance of absorptions at 6.5, 14.7 and about 26 kK is the cause of this color change. As grinding and moistening accelerate this change, the effects of the added liquid cannot be ascertained.

Bromides of Mono- and Di-valent Cations. The spectra of the cation radical salts derived from benzidine and its tetramethyl derivative were described in a previous paper.[4] The bromide of the monovalent *o*-tolidine cation gives a spectrum very similar to them. The locations of the absorption maxima are as follows: 6.8, 15.5, and 26.0 kK in the benzidine bromide, 7.5, 16.0, and 27.0 kK and a shoulder at 11.5 kK in the *o*-tolidine bromide, and 8.0, 14.7, and 25.0 kK in the tetramethylbenzidine bromide.

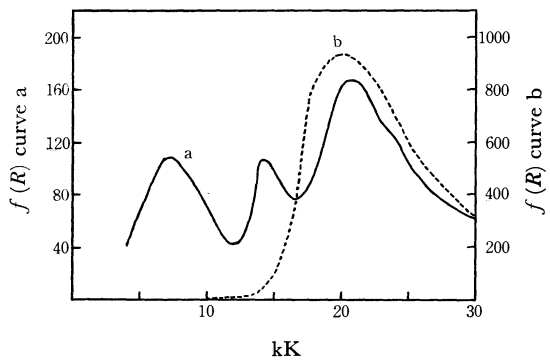

Fig. 8. Diffuse reflection spectra of diaminopyrene bromides; (a) monobromide, (b) dibromide.

The bromides of mono- and di-valent diaminopyrene cations show the spectra given in Fig. 8. It must be added that the intensity of the absorption near 20 kK in the dibromide is about five times stronger than that in the monobromide. In addition to a broad absorption appearing around 21 kK, the monobromide exhibits absorption maxima at 7.0 and 14.0 kK.

Discussion

First of all we must note that none of the spectra of the colored clays studied here exhibits a pattern which can be assigned to the monomeric form of the cation radicals. The patterns B-1 and T-1 and that in the spectra of the clay colored with tetramethylbenzidine resemble those of the solid bromides. Furthermore, the pattern B-3 is close to that of the dimeric cation radicals in solution. The latter is known to consist of absorption maxima at 12.4, 16.4, and 27.8 kK.[8] Perhaps only the cation radicals can show such pronounced variations and coincidence of the spectra. Therefore, the patterns B-1 and T-1 and that in the spectra of the clays colored with tetramethylbenzidine may be assigned to the univalent diamine cations in more-than-by-pairs interactions, while the patterns B-3 and T-3 may be assigned to the cations in pair-by-pair interactions. The presence of the pattern B-2 indicates that there is another mode of more-than-by-pairs interaction in this particular case.

The absorption spectra of the acid clays colored with benzidine and with its tetramethyl derivative reported by Hasegawa[3] are in agreement with those we give in Fig. 3 (pattern B-3) and Fig. 6 respectively. Although the monovalent cations, Hasegawa's meriquinoidal forms, are responsible for the deep colors developed in these two systems, it must be pointed out that the cations are in different modes of intermolecular interaction.

Hasegawa has reported that the quinoidal form, presumably the divalent cation in our nomenclature, of tetramethylbenzidine dissolved in ethanol exhibits an absorption at 21.3 kK. The absorption at 20.8 kK in Fig. 6 may be assigned to this species. We may conclude that the species giving strong absorptions in the range between 20 and 23 kK of Figs. 1—5 are also the divalent diamine cations. This conclusion is in accordance with the observation that these absorptions are slowly intensified on storage until finally these are the only ones to be detected.

1,6-Diaminopyrene has been known to form solid bromides of the mono- and di-valent cations.[7] The spectra in Fig. 8 may well be compared to those of the clays colored with this diamine in Fig. 7. The freshly-prepared sample shows the pattern characteristic of the monobromide, but after three days' storage only the absorption to be assigned to the dibromide can be observed. These findings are consistent with our observations concerning the clays colored with benzidine and its derivatives.

As has been mentioned before, the spectra in each figure from 2—6 are only approximately in the same scale; however, there is no doubt about the presence of isosbestic points. This implies that the mono- and di-valent diamine cations are in equilibrium. Since these two species are in different oxidation states, if follows that the diamine itself is also a participant in the equilibrium. However, the absence of the absorption to be assigned to the diamine, *i. e.*, 30.0 kK for benzidine and 28.7 kK for tetramethylbenzidine in the solid state, suggests that the diamine molecules in acid clay are in the protonated form.

Summing up our conclusions, the following equilibrium may be conceived in acid clay:

$$D^{2+} + DH^{+} \rightleftarrows 2D^{+} + H^{+},$$

where D is a diamine molecule. On being moistened, protonated diamine molecules dissociate into protons and diamine molecules, and the electron transfer from the latter to the divalent cations leads to the formation of deeply-colored aggregates of the monovalent cations. According to the proposed mechanism of the lightening of the color on drying and the deepening on moistening, Hauser and Leggett have observed that mineral and organic acids either inhibit or lighten the color.[2] Moreover, the same equilibrium as that described above has been proposed by Hasegawa to explain the pH dependence of the absorption spectrum of the "meriquinoid compound" of tetramethylbenzidine in a 30% ethanol solution.[3]

Charge-Transfer Complexes of Maleic Anhydride and Dichloromaleic Anhydride with Various Aromatic Compounds

Takayoshi KOBAYASHI,* Suehiro IWATA** and Saburo NAGAKURA*

* *The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo*

** *The Institute of Physical and Chemical Research, Yamato-machi, Saitama*

(Received September 19, 1969)

Absorption, fluorescence and fluorescence excitation spectra were measured at room temperature and at low temperature for charge-transfer complexes containing maleic anhydride and dichloromaleic anhydride as electron acceptors. Benzene, toluene, mesitylene, durene, hexamethylbenzene, aniline, dimethylaniline, naphthalene and anthracene were used as electron donors. The charge-transfer absorption and fluorescence bands were observed for these complexes, their peak positions being linearly dependent upon the ionization potentials of donors for the same electron acceptor. From the comparison of the charge-transfer absorption or fluorescence peaks of maleic anhydride complexes with the corresponding values of dichloromaleic anhydride complexes, the difference in electron affinity between these two electron acceptors was obtained to be 0.4 eV. The electronic structures of the maleic anhydride complexes with benzene, naphthalene and anthracene were studied theoretically by considering the configuration interaction among the ground, locally-excited and charge-transfer configurations. The stable geometrical configurations in the ground and lower excited states of the complexes were discussed by the aid of the energy levels calculated for various relative orientations between electron donor and acceptor.

Maleic anhydride (abbreviated hereafter to MA) is one of the most important dienophilic substances in the Diels-Alder reaction. The charge-transfer (abbreviated hereafter to CT) complexes between MA and some aromatic hydrocarbons are suggested to take part in some Diels-Alder photoreactions.[1] This seems to be supported by the fact that MA and benzene which can form a CT complex is led to the Diels-Alder reaction.[2] The reaction is sensitized by benzophenone, and is inhibited by benzil.[2,3] The triplet-energy transfer from the sensitizer to the CT complex and therefore the sensitization of the Diels-Alder reaction may be possible, if the lowest triplet state of the former is higher than that of the latter. In this connection, it seems to be important to determine the positions of the lower excited states, especially the lowest triplet state, of CT complexes containing MA as an electron acceptor.

In the present work, we have undertaken to measure the absorption and emission spectra of the complexes between MA and various electron donors such as benzene, toluene, mesitylene, durene, hexamethylbenzene, aniline, dimethylaniline, naphthalene and anthracene. Furthermore, to clarify the character of the MA complexes, the study has been extended to complexes containing dichloromaleic anhydride (DCMA) which is stronger as an electron acceptor than MA.

Furthermore, from the theoretical point of view, we have undertaken to study by the semi-empirical MO method the electronic structures of CT complexes between MA and benzene, naphthalene or anthracene, the calculated energy of CT excited states being discussed in connection with the Diels-Alder photoreaction mechanism.

Experimental

Commercially available MA (Wako, reagent grade) and DCMA (Tokyo Kasei, reagent grade) were purified by sublimation *in vacuo* and by zone refining. Benzene, toluene, mesitylene, aniline and dimethylaniline (abbreviated hereafter to DMA) were purified by distillation. Commercially available durene, hexamethylbenzene (abbreviated hereafter to HMB), naphthalene and anthracene were purified by repeated recrystallizations from ethanol. A mixture 1 : 1 of ethyl ether and isopentane (abbreviated hereafter to EP) was used for the spectrophotometric study at low temperature. The single crystals of complexes between MA or DCMA and aromatic hydrocarbons were prepared by mixing the acceptor and one of the donors in methylene chloride or chloroform and by evaporating slowly the solvent at room temperature.

MA	Aniline	powder	21.3	7.69
DCMA	HMB	single crystal	19.5	7.85

* Fluorescence was measured at 77°K in all cases.

Absorption spectra of solutions and of thin films on quartz plates[4] were measured with a Cary recording spectrophotometer Model 14M. Polarized absorption spectra of small single crystals were measured with a microspectrophotometer constructed in our laboratory.[5]

Emission spectra at liquid nitrogen temperature were measured with a JASCO Model CT-50 grating monochromator with an RCA 1P28 or EMI 9529A photomultiplier tube as a detector, glassy solutions or crystals being irradiated by a high pressure 500 W Hg lamp combined with Toshiba UV D1A and UV D2 filters in order to select 3650 Å light which excites the CT complexes only. The fluorescence spectra and their excitation spectra of powder samples (MA-aniline) were measured with an Aminco-Bowman spectrophotofluorometer (4-8202B) located at Government Chemical Industrial Research Institute.*1

The spectra observed with the MA and DCMA complexes are shown in Figs. 1, 2, 3 and 4, and the peak positions of the absorption and emission spectra are tabulated in Tables 1 and 2.

Theoretical

In the present paper, the interaction between electron donor and acceptor is taken into account by the configuration interaction among the ground, CT and locally-excited (abbreviated hereafter to LE) configurations.[6,7] For this calculation we need the MO's of each component. We adopt the SCF MO's of MA calculated by S. Hosoya and H. Hosoya by the aid of the Pariser-Parr-Pople method.*2 The electron donors taken in the present theoretical study are benzene, naphthalene and anthracene.

For the sake of simplicity, we consider only the highest two occupied MO's (ϕ_1, ϕ_2 and θ_1, θ_2) and the lowest two vacant MO's (ϕ_3, ϕ_4 and θ_3, θ_4) of MA and aromatics. The wave functions

of the ground and lowest CT configurations[8] are given by the Slater-type determinant

$$\Phi_G = |\phi_1\bar{\phi}_1\phi_2\bar{\phi}_2\theta_1\bar{\theta}_1\theta_2\bar{\theta}_2|$$

$$\Phi_{CT_1} = 1/\sqrt{2}\{|\phi_1\bar{\phi}_1\phi_2\bar{\phi}_2\theta_1\bar{\theta}_1\theta_2\bar{\phi}_3| - |\phi_1\bar{\phi}_1\phi_2\bar{\phi}_2\theta_1\bar{\theta}_1\bar{\theta}_2\phi_3|\}$$

$$\Phi_{CT_2} = 1/\sqrt{2}\{|\phi_1\bar{\phi}_1\phi_2\bar{\phi}_2\theta_1\bar{\phi}_3\theta_2\bar{\theta}_2| - |\phi_1\bar{\phi}_1\phi_2\bar{\phi}_2\bar{\theta}_1\phi_3\theta_2\bar{\theta}_2|\}$$

$$\Phi_{CT_3} = 1/\sqrt{2}\{|\phi_1\bar{\phi}_1\phi_2\bar{\phi}_2\theta_1\bar{\theta}_1\theta_2\bar{\phi}_4| - |\phi_1\bar{\phi}_1\phi_2\bar{\phi}_2\theta_1\bar{\theta}_1\bar{\theta}_2\phi_4|\}$$

$$\Phi_{CT_4} = 1/\sqrt{2}\{|\phi_1\bar{\phi}_1\phi_2\bar{\phi}_2\theta_1\bar{\phi}_4\theta_2\bar{\theta}_2| - |\phi_1\bar{\phi}_1\phi_2\bar{\phi}_2\bar{\theta}_1\phi_4\theta_2\bar{\theta}_2|\}$$

In addition to the above-mentioned configurations, the following LE configurations corresponding to the lower excited states of the component molecules are taken into consideration.

$\Phi^{MA}_{L_1} = \Phi^{MA}(\phi_2^{-1}\phi_3)$ (5.96 eV)
for local excitation in MA

$\Phi^{B}_{L_1} = 1/\sqrt{2}\{\Phi^{B}(\theta_1^{-1}\theta_4) - \Phi^{B}(\theta_2^{-1}\theta_3)\}$ (4.71 eV)
for $^1B_{2u}$ local excitation in benzene

$\Phi^{N}_{L_1} = 1/\sqrt{2}\{\Phi^{N}(\theta_1^{-1}\theta_3) - \Phi^{N}(\theta_2^{-1}\theta_4)\}$ (4.06 eV)
for $^1B_{3u}^-$ local excitation in naphthalene

$\Phi^{N}_{L_2} = \Phi^{N}(\theta_2^{-1}\theta_3)$ (4.45 eV)
for $^1B_{2u}^+$ local excitation in naphthalene

$\Phi^{A}_{L_1} = \Phi^{A}(\theta_2^{-1}\theta_3)$ (3.31 eV)
for $^1B_{2u}^+$ local excitation in anthracene

$\Phi^{A}_{L_2} = 1/\sqrt{2}\{\Phi^{A}(\theta_1^{-1}\theta_3) + \Phi^{A}(\theta_2^{-1}\theta_4)\}$ (4.93 eV)
for $^1B_{3u}^+$ local excitation in anthracene

The energies of the LE configurations are taken from the transition energies observed with MA, benzene,[9a] naphthalene[9b] and anthracene.[9b] Their values are given in the parentheses after the wave functions of the corresponding LE configurations.

The energies of the CT configurations, the ground configuration energy being taken as the standard, is obtained as follows, for example, for the CT_1 configuration:

$$E_{CT_1} = \varepsilon(\phi_3) - \varepsilon(\theta_2) - \iint \phi_3(1)\phi_3(1)\frac{e^2}{r_{12}}\theta_2(2)\theta_2(2)d\tau_1 d\tau_2$$
$$= I(\theta_2) - A(\phi_3) - C_{23}$$

where $\varepsilon(\phi_3)$ and $\varepsilon(\theta_2)$ are the orbital energies, and $I(\theta_2)$ and $A(\phi_3)$ are the ionization potential of the donor and the electron affinity of the acceptor, respectively. The ionization potentials of benzene, naphthalene and anthracene are 9.245, 8.10 and 7.37 eV, respectively.[10] The electron affinity of MA can be determined to be 0.6 eV from the peak of the first CT band of MA-DMA complex on the assumption that the Coulomb term in Eq. (1) given later is 3.6 eV.[11] The electron affinity for the second lowest vacant orbital can be determined from the value for the lowest vacant orbital by assuming that the difference in the electron affinity is equal to that in the corresponding SCF orbital energies. The off-diagonal matrix elements of the total electron Hamiltonian each of which represents the interaction between two different configurations can be evaluated.[12] For example, those between the CT configuration and the ground or LE configurations can be represented in terms of the core resonance integral β which is approximately represented by the following equation:[13]

$$\beta = -KS_{ij}$$

where K is an experimental parameter and S_{ij} is the overlap integral between the electron donating orbital θ_i and the electron accepting orbital ϕ_j. It is represented by the sum of the overlap integrals between the Slater type atomic orbitals. We set K equal to 10.[6,7]

By solving secular equations constructed by the above-mentioned diagonal and off-diagonal matrix elements, we evaluate the energies of the ground and lower excited states for the MA complexes with benzene, naphthalene and anthracene,[14] taking various geometrical configurations under the following limitations;

1) The molecular planes of electron donor and acceptor are parallel with each other and their distance is 3.4 Å.

2) The C=C bond of MA is parallel to the symmetry axis parallel to a bond of each donor molecule.

Results and Discussion

Complexes in Solution. The absorption spectra of MA and DCMA in chloroform, benzene, toluene and mesitylene are shown in Fig. 1. A very weak absorption of MA (curve 1 in Fig. 1) due to an n–π^* transition[15] appears at 31000 cm^{-1}—34000

8) Since the wave functions include spin functions, strictly speaking, these configurations should be called the "zero-order ground singlet state" and the "zero-order CT singlet state." Here we use "configuration" instead of "zero-order singlet state" because of simplicity.

15) From the low value of the molar extinction coefficient and from the analogy with similar carbonyl compounds, the absorption band near the 360 mμ is clearly attributed to the n–π^* transition.

cm^{-1} in chloroform. In the other solvents, MA exhibits a new band conceivably due to the CT interaction with surrounding molecules. The situation is the same for the DCMA solutions.

Concerning the electron donors other than benzene, toluene and mesitylene, absorption and fluorescence spectra were measured with ternary solutions containing electron donor and acceptor in chloroform, with the results shown in Figs. 2 and 3 for the MA and DCMA complexes, respectively. A new absorption band neither due to electron donor nor acceptor is observed for the MA complexes with HMB and DMA and for the DCMA complexes with DMA, anthracene, HMB and durene. Furthermore, a shoulder appears for the MA complex with durene, and for the DCMA complex with naphthalene. In order to certify that these bands and shoulders are due to the CT transition, we examine the relationship between the peak positions and the ionization potentials of donors.

The peak wave numbers of the CT bands for a series of complexes with a fixed electron acceptor are related to the ionization potentials (I_D) of donors by the following equation:

$$h\nu_{CT} = I_D - C_1 + \frac{C_2}{I_D - C_1} \qquad (1)$$

where C_1 and C_2 are constants to be determined experimentally. C_1 is mainly composed of two factors, the electron affinity of the electron acceptor (A_A) and the Coulomb attraction between the donor and acceptor orbitals (C): that is to say, $C_1 = A_A - C$. Using the observed ionization potentials of the donors and taking the CT band maximum of the MA-DMA or DCMA-DMA complex as the standard, we can calculate the CT band positions for the MA and DCMA complexes. They are indicated by the arrows in Figs. 1, 2 and 3. The calculated peak positions are in good agreement with the observed ones. This supports the CT assignment of the absorption bands under consideration.

Figures 2 and 3 show that the fluorescence spectrum of each complex in EP solution at liquid nitrogen temperature satisfies the mirror image relation with the CT absorption spectrum observed for the chloroform solution at room temperature. This means that the observed fluorescence spectra are of the CT character.

From Eq. (1), we may expect that a linear relation can be approximately satisfied between ν_{CT} and I_D in the case where the latter is changed in a rather narrow range. Plotting these two quantities for both the fluorescence and the absorption spectra observed for a series of complexes containing the fixed electron acceptor, we obtain a straight line relationship, as is shown in Fig. 5. From this figure, it is found that the lines for the absorption maxima observed for the MA and DCMA complexes are parallel with each other and they cross the

3 and 4; fluorescence maxima—I_D plots for the MA and DCMA complexes, respectively.

ordinate with the energy difference of ~0.4 eV. This is mainly due to the difference in C_1 in Eq. (1) between the DCMA and MA complexes. That is to say, the electron affinity of DCMA may be higher by ~0.4 eV than that of MA.

Complexes in Solid State. The polarized absorption was measured with a single crystal of the DCMA-HMB complex, for the purpose of obtaining an additional support for the CT assignment of the band at ~22000 cm^{-1}. The needlelike crystal of this complex is unstable and decomposed within a few days at 5°C. Therefore the measurement was carried out as quickly as possible after the crystallization. The result is shown in Fig. 4. Furthermore, the fluorescence and fluorescence excitation spectra of this crystal measured at liquid nitrogen temperature are also shown in this figure. An absorption at 22000 cm^{-1} is polarized parallel to the crystal growth axis with the dichroic ratio more than 4. Since crystals of this kind usually grow up in the direction perpendicular to the planes of the stacked component molecules, the above result seems to mean that the transition moment of the band is directed perpendicular to the molecular plane. This supports the interpretation that the absorption band at ~22000 cm^{-1} is the CT one and therefore the corresponding fluorescence at ~20000 cm^{-1} is of the same character.[16]

16) The similar experimental work has been carried out for the single crystal of the DCMA-durene complex. In this case too, the CT absorption polarized parallel to the crystal growth axis is observed.

Theoretical Result. The energies of the ground and lowest CT states were calculated for the MA complexes with benzene, naphthalene and anthracene by the method described in the "Theoretical" part. Concerning the MA complex with benzene, the stable geometrical configuration of the ground state is predicted to be similar to that of the lowest CT state. In both the ground and the lowest CT state, the center of the C=C double bond of MA is located above the point close to the center of benzene. However, the gradient of energy surface is about 10 times steeper in the excited state than in the ground state.

Theoretical results on the MA complexes with naphthalene and anthracene are shown in Figs. 6 and 7, respectively. These figures show energy contour maps for the ground and lowest CT state, which are obtained by plotting the state energies against the positions of the center of the C=C bond of MA.

The MA-naphthalene and MA-anthracene complexes in the ground state have, respectively, two and three energy minima which are located near the center of each benzene ring, while in the excited state they have only one minimum near the center of donor molecule. As an example, the stable geometrical structure of the MA-anthracene complex predicted by the present theoretical consideration is shown in Fig. 8. According to this figure,

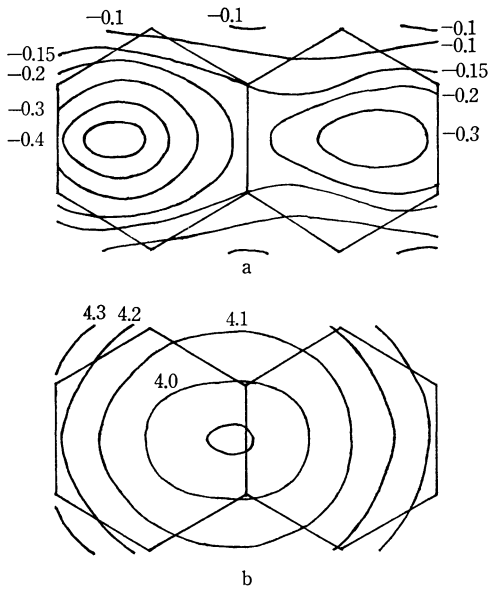

Fig. 6. The dependence of energy (in eV) on the geometrical configuration for the MA-naphthalene complex.
a, ground state
b, lowest CT state

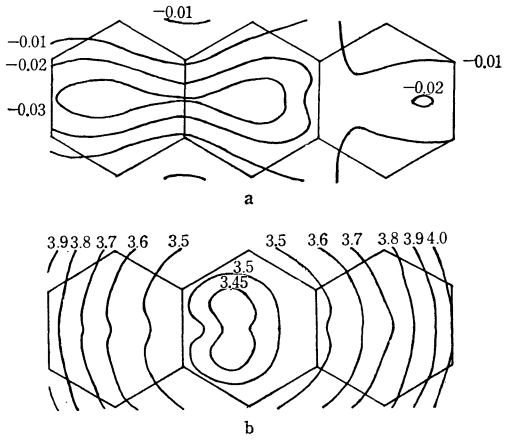

Fig. 7. The dependence of energy (in eV) on the geometrical configuration for the MA-anthracene complex.
a, ground state
b, lowest CT state

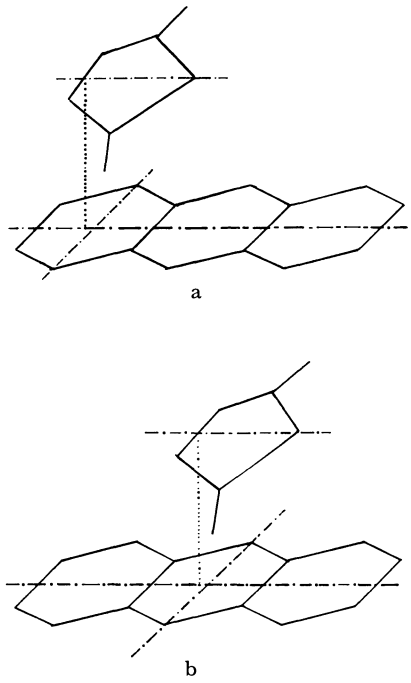

Fig. 8. The stable geometrical configuration of the MA-anthracene complex.
a, ground state
b, lowest CT state

the MA molecule moves to the energy minimum position above the center of the anthracene molecule in the excited state from the position above one of the end benzene rings in the ground state. This seems to be interesting in connection with the fact that in the Diels-Alder reaction the C=C double bond of MA reacts with anthracene on the 9 and 10 positions. The positions of photochemical dienophile addition in this case seems to be reason-

ably explained by assuming that the reaction occurs through the excited CT state of the complex.

Next, we add a brief descrption on the mechanism of thermal Diels-Alder reaction of MA. In view of the electron accepting ability mentioned above, it may be considered that the CT interaction takes part in the reaction. That is to say, in the initial stage of the reaction, we can except the formation of the π (outer)-complex which takes the structure shown in Fig. 8a.[17] In this stage the degree of the electron transfer from anthracene to MA may be small. With the progress of the reaction, the CT degree may increase and the system may approach gradually the structure shown in Fig. 8b. Therefore in the stage of the actual formation of the new C–C bonds between MA and anthracene, the system may probably take the structure similar to that in Fig. 8b.[18] Thus, by the aid of CT state structure shown in Fig. 8b we can explain reasonably the fact that the thermal dienophile addition occurs at the 9 and 10 positions of anthracene.

We are greatly indebted to Dr. Keitaro Yoshihara, the Institute for Solid State Physics, for his helpful advice.

17) The present discussion is made on the assumption that the thermal Diels-Alder reaction proceeds through the π (outer)-complex in the initial stage.

18) The actual process of the bond formation is not clear. There are two possibilities that the two C–C bonds are simultaneously formed, and that each of them is formed separately and the bond formation proceeds in the two steps. In the latter case, we may expect the inner (σ)-complex formation in which electron transfer occurs to a great extent and a new C–C bond is formed between MA and anthracene.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 720—725 (1970)

The Reactivity of the Electron Donor-Accepter Complex—Catalysis by 1,3-Dimethylalloxazine in an Enzymatic Model Reaction

Yasuhiro Iwasawa, Mitsuyuki Soma, Takaharu Onishi and Kenzi Tamaru

Department of Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received September 29, 1969)

The effect of electron donor-accepter(EDA)-complex formation upon the reactivity (or catalytic activity) of 1,3-dimethylalloxazine, a model compound of co-enzyme, FMN, was examined in the redox reaction between methylene blue and ascorbic acid. The 1,3-dimethylalloxazine exhibited a behavior similar to the enzyme, having an optimal pH for the redox reaction. The characteristic behavior of 1,3-dimethylalloxazine was demonstrated in the presence of both 1,3-dimethylalloxazine and pyrene; such behavior was not to be observed upon the addition of either of them. It was accordingly suggested that the EDA complex formation would play an important role in the enzymatic reactions *in vivo*. The influence of various aromatic hydrocarbons upon the enzyme-like catalysis was examined.

It is generally accepted that the electron-transfer process in a living body is frequently associated with the formation of adenosine triphosphate (ATP), thus accumulating energy. As to the mechanism of the electron-transfer process, various hypotheses have been proposed, such as conduction band theories,[1,2] exciton models,[3,4] and charge-transfer models.[5] No crucial evidence, however, has ever been presented to elucidate the reaction mechanism or its reaction intermediate for the redox process catalyzed, for instance, by the flavin enzyme. Especially, the reason why the co-enzymatic action appears, the role of protein in the enzyme, and its reaction site and intermediate still remain important problems to be solved.

The present authors have been working for several years with the problems of the reactivity of electron donor-acceptor (EDA) complexes of

aromatic compounds, and they have demonstrated that the reactivity of aromatic compounds, is in general, markedly influenced by the formation of the EDA complexes.[6] Accordingly, in connection with the mechanism of the co-enzyme action, 1,3-dimethylalloxazine*1 has been employed as a model compound of co-enzyme, flavin mononucleotide (FMN),*2 and its reactivity or its catalytic activity and the effects of the EDA complex formation thereon have been examined for the redox process between methylene blue and ascorbic acid from the view point of the EDA-complex formation.

It was found that the 1,3-dimethylalloxazine accelerates the redox reaction and that the formation of the EDA-complexes markedly affects the catalytic activity.

Experimental

The 1,3-dimethylalloxazine (DMA)[7] was synthesized from caffeine and *o*-phenylendiamine, while commercial ascorbic acid and methylene blue were employed. The aromatic hydrocarbons, such as naphthacene, perylene, anthracene, pyrene, *p*-terphenyl and phenanthrene, were purified by sublimation. The reactor consisted of a quartz cell for visible spectra and of three glass tubes, containing solutions of ascorbic acid, methylene blue, and DMA or its EDA-complexes, respectively. The reactants were always handled in the absence of air or oxygen. In the oxidation-reduction reaction, ascorbic acid was used as the hydrogen donor, while methylene blue was used as the hydrogen acceptor. The decrease in the absorption peak of methylene blue at 650 mμ was employed as a measure of the extent of the redox reaction to follow the reaction rate. Three different sorts of experiments were carried out as follows: (1) The DMA was used as a catalyst for the redox reaction between ascorbic acid and methylene blue, and the dependence of the rate upon the pH, the reaction temperature, and the addition of electron-donating and -accepting compounds, such as pyrene and tetracyanoethylene (TCNE), was examined.

As an aqueous solution of ascorbic acid (3.27×10^{-4} mol/*l*, 2 m*l*), a solution of methylene blue (3.27×10^{-4} mol/*l*, 1 m*l*), a tetrahydrofuran (THF) solution of DMA (1.64×10^{-4} mol/*l*, 2 m*l*), and a phosphate buffer (20 m*l*) were mixed in the absence of oxygen and the rate of the reduction of methylene blue was studied at various temperatures and at various pH values, as controlled by the phosphate buffer.

(2) The influence of the EDA-complex formation upon the catalytic activity of DMA was studied. In this case, a 1,2-dichloroethane solution of DMA and pyrene (2 to 1 molar ratio; 3.27×10^{-7} mol and 1.64×10^{-7} mol, respectively, in a 4.5 m*l* solution) was added to a redox system of a 1,2-dichloroethane solution of ascorbic acid (3.27×10^{-4} mol/*l*, 1 m*l*) and methylene blue (3.27×10^{-4} mol/*l*, 1 m*l*).

(3) The reduction of methylene blue by ascorbic acid was affected by the addition of various aromatic hydrocarbons, such as naphthacene, perylene, anthracene, pyrene, *p*-terphenyl, and phenanthrene, as electron-donating compounds for the methylene blue, and the influences of these aromatic additives were examined in the 1,2-dichloroethane solution.

Results and Discussion

(1) Catalysis by 1,3-Dimethylalloxazine (DMA). The reduction reaction of methylene blue by ascorbic acid was accelerated to a facter of 50 by the addition of DMA. The reaction was first-order with respect to methylene blue. The higher the temperature of the reaction, the greater the rate of the reaction, when the pH was constant, as is shown in Fig. 1. When the pH was changed

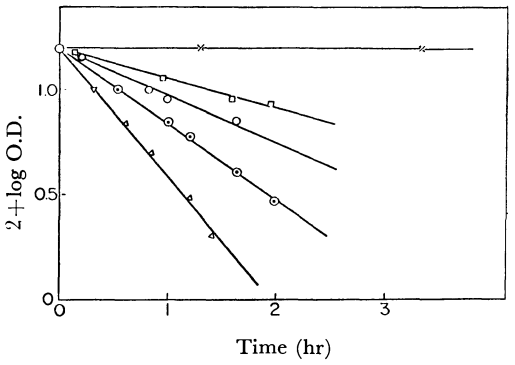

Fig. 1. Dependence of the rate constants *k*, $-d(Mb)/dt=k(Mb)$, upon temperature in the redox reaction between ascorbic acid and methylene blue (Mb) catalyzed by DMA.

—□— at 0°C, pH 12.0
—△— at 25°C, pH 12.0

at a constant temperature, 13°C, the gradient of the rate against the pH became less steep in the region of pH 10 and approached a saturation value in the region higher than pH 12. At a constant temperature, 0°C, on the other hand, a maximum peak appeared in the reaction rate in the range from pH 9 to pH 10, as is shown in Fig. 2. A minimum activation energy for the reaction was also found in the same region (Table 1). When an electron-donating compound, such as pyrene, or an electron-accepting compound, such as TCNE, for the DMA was added to the system of the redox

* Without DMA

reaction of ascorbic acid, methylene blue, and DMA, the rates of the reduction reaction of methylene blue decreased to approximately one-third.

The activity of enzymes is, in general, high in weak alkaline solution and has an optimal temperature range to work in. It is interesting to note that the DMA, a model compound of the co-enzyme, FMN, exhibited a catalysis similar to that of the enzyme and that the optimal pH values were demonstrated in the activity of the redox reaction; this suggests that the behavior of the active site of the enzyme is similar to that of the co-enzyme model.

(2) Effects of the EDA Complex Formation between DMA and Pyrene in the Redox Reaction. The 1,2-dichloroethane solutions of ascorbic acid, methylene blue, and a mixture of DMA-pyrene (2 : 1) were mixed at 0°C in the absence of oxygen. For 10 to 15 min the time-concentration relation for methylene blue exhibited a valley-shaped curve; thereafter, the reaction reached an equilibrium, as Fig. 3 shows. This valley curve can be explained not as an equilibrating reaction

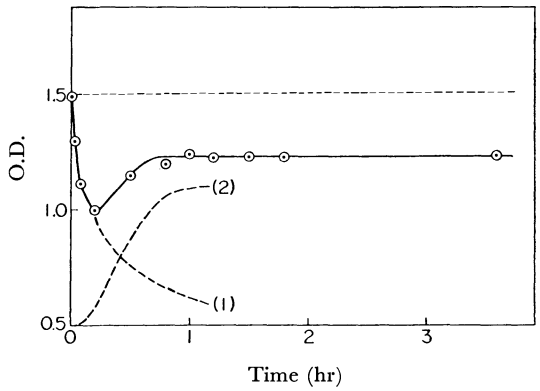

Fig. 3. The reduction of methylene blue by ascorbic acid in the presence of DMA and pyrene at 0°C in 1,2-dichloroethane solution.
------ O.D. of methylene blue at $t=0$.
----(1) forward reaction, Eqs. (b) and (c)+(c').
----(2) back reaction, Eq. (e).

with a single reaction path, but as a successive reaction to consume the methylene blue, followed by its reproduction.

Such characteristic behavior appeared only in the presence of both DMA and pyrene, was not observed upon the addition of either of them or in a phosphate buffer as has been described in Section (1), where the interaction between them is very weak. Consequently, the following experiment was undertaken: first, ascorbic acid and methylene blue were reacted in the presence of only pyrene, and then DMA was introduced into the system during the course of the redox reaction. The results are given in Fig. 4. The results in Fig. 4 exhibit a behavior similar to those shown in Fig. 3.

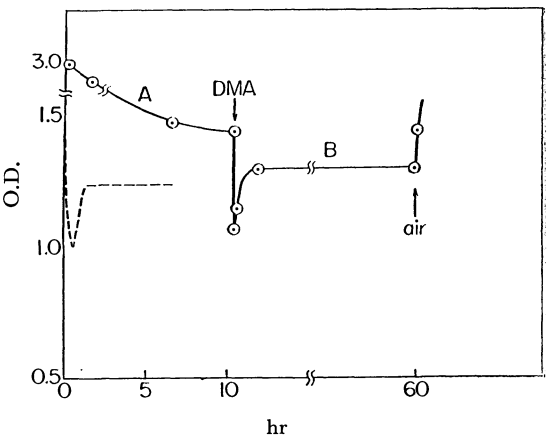

Fig. 4. Effect of the formation of EDA complex in the redox reaction of methylene blue with ascorbic acid at 0°C:
---- in the presence of DMA and pyrene
A: catalyzed by pyrene.
B: DMA addition into A.

When the temperature of the reaction was kept constant at 26°C, the valley in Fig. 3 became more shallow.

The characteristic behavior shown in Fig. 3 was not observed for lower concentrations of both DMA and pyrene in comparison with methylene blue; for instance, when the molar ratios of DMA and pyrene to methylene blue were 1/22.5 and 1/45, respectively or 1/45 and 1/90, respectively, no valley could be detected. When leuco-methylene blue which had been obtained by bubbling hydrogen gas over a platinum catalyst in a dichloroethane solution of methylene blue was introduced into a solution containing both DMA and pyrene, it was oxidized to methylene blue rather rapidly. DMA and pyrene form a solid EDA complex with a molar ratio of 2 : 1 and with a charge-transfer band in the region from 400 to 500 mμ.[8] It was concluded, in accordance to these results, that the appearence of the characteristic curve shown in Fig. 3 is due to the complex formation between DMA and pyrene.

It is also confirmed spectroscopically and theoretically that the enzymes or co-enzymes form EDA complexes.[9-11] When DMA, a model compound of the co-enzyme, FMN, of the flavin enzyme formed an EDA complex with pyrene, there was a controlled reaction; this suggests that the EDA complex formation plays an important role in the enzymatic reaction *in vivo*.

Mechanisms. In the presence of both DMA and pyrene (P), the mechanism of the reduction reaction of methylene blue (Mb) by ascorbic acid (AsH_2) may be as follows:

$$AsH_2 + Mb \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} As + MbH_2 \qquad (a)$$

$$AsH_2 + \left(\frac{P}{2}\cdot Mb\right) \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} As + \frac{P}{2} + MbH_2 \qquad (b)$$

$$AsH_2 + DMA \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} As + DMAH_2 \qquad (c)$$

$$DMAH_2 + Mb \underset{k_{-3'}}{\overset{k_{3'}}{\rightleftharpoons}} DMA + MbH_2 \qquad (c')$$

$$AsH_2 + \left(\frac{P}{2}\cdot DMA\right) \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} As + \frac{P}{2} + DMAH_2 \qquad (d)$$

$$MbH_2 + \left(\frac{P}{2}\cdot DMA\right) \underset{k_{-5}}{\overset{k_5}{\rightleftharpoons}} Mb + \frac{P}{2} + DMAH_2 \qquad (e)$$

where (P/2·Mb) and (P/2·DMA) represent the complexes between pyrene and methylene blue, and between pyrene and DMA, respectively. The reaction (a) is first-order with respect to ascorbic acid and also to methylene blue, and it is expressed by the following equation:

$$-\frac{d}{dt}(Mb) = k_1(AsH_2)(Mb)$$

The step (b) is a reaction catalyzed by pyrene, while the steps (c) and (c') show that the redox reaction is catalyzed by DMA. When the steady-state method of Birggs and Haldan is applied to this reaction system, the rate equation of the reaction is given as follows:

$$-\frac{d}{dt}(Mb) = k_3'(DMAH_-)(Mb)$$

$$= k_3'(DMA)_0(Mb)\frac{1}{1 + \dfrac{k_{-3}(As)}{k_3(AsH_2)} + \dfrac{k_3'(Mb)}{k_3(AsH_2)}}$$

where $(DMA)_0$ represents the initial concentration of DMA, and under the conditions when $(DMA)_0 \ll (AsH_2)_0$ and $(Mb)_0$, $16(Mb)_0 = (AsH_2)_0$, and $k_3 \approx k_3'$:

$$\frac{1}{1 + \dfrac{k_{-3}(As)}{k_3(AsH_2)} + \dfrac{k_3'(Mb)}{k_3(AsH_2)}}$$

becomes about unity, following equation is thus obtained:

$$-\frac{d}{dt}(Mb) = k_3'(DMA)_0(Mb) = k_3''(Mb)$$

Under these circumstances, the reaction was first-order with respect to methylene blue, and the rate constant, k_3'', is proportional to the initial concentration of DMA, as is shown in Fig. 5. The dihydro-1,3-dimethylalloxazine ($DMAH_2$) in Eqs.

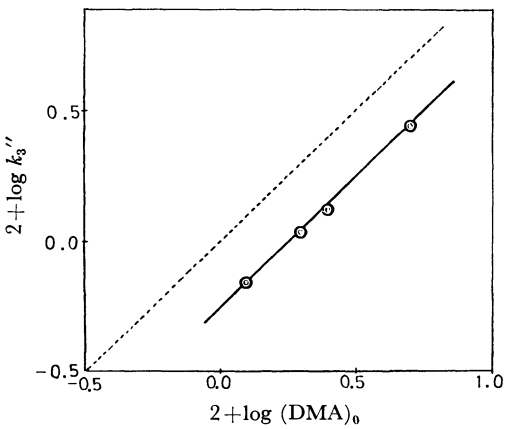

Fig. 5. The dependence of the rate constant k_3'' upon the initial concentration of DMA; $-d(Mb)/dt = k_3'(DMA)_0(Mb) = k_3''(Mb)$, where $(DMA)_0$ and (Mb) represent the concentration of DMA at time zero and methylene blue, respectively. Solid line runs parallel with broken line (slope of 45°).

—— DMA in THF
---- DMA plus ascorbic acid
---- DMA plus HCl (45°C heating)

Table 2. The reduction of methylene blue by ascorbic acid

Steps		Rate constant
(a)*	k_1	$2.0\times10^2\ l\cdot mol^{-1}\cdot hr^{-1}$
(b)*	k	$0.0058\ hr^{-1}$
(c)(c')*	k_3'	$1.0\times10^4\ l\cdot mol^{-1}\cdot hr^{-1}$
(e)*	k'	$\sim2\ hr^{-1}$

* (a): $-d(Mb)/dt = k_1(AsH_2)(Mb)$
(b): $-d(Mb)/dt = k_2'(Ar)_0{}^{1/2}(Mb) = k(Mb)$
(c)(c'): $-d(Mb)/dt = k_3'(DMA)_0(Mb) = k_3''(Mb)$
(e): $-d(MbH_2)/dt = k'(Mb)$, when $(DMA)_0 \gg (Mb)_0$, where (Mb), (MbH_2), (AsH_2) and $(DMA)_0$ represent the concentrations of methylene blue, leuco-methylene blue, ascorbic acid and the DMA at $t=0$, respectively.

(c) and (c') was detected by UV spectroscopy, as is shown in Fig. 6.[12]

The steps (d) and (e) form another reaction path resulting from the formation of the EDA complex of DMA with pyrene, while the back reaction in Fig. 3 is due to the step (e).

The rate constants of all the steps, (a), (b), (c), (c'), and (e), are given in Table 2.

(3) Influences of Various Aromatic Hydrocarbons in the Redox Reaction. Various aromatic hydrocarbons, such as naphthacene, perylene, anthracene, pyrene, *p*-terphenyl, and phenanthrene, all electron donors for methylene blue but with different ionization potentials, accelerated the reduction reaction of methylene blue by ascorbic acid, though they are generally considered to be inert in the reaction.

When the aromatic hydrocarbons form EDA complexes with methylene blue of a molar ratio of 1 : 2, the reaction equation is given as follows:

$$\tfrac{1}{2}(Ar) + Mb \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} (\tfrac{1}{2}Ar\cdot Mb) \qquad (g)$$

$$(\tfrac{1}{2}Ar\cdot Mb) + AsH_2 \xrightarrow{k_2} MbH_2 + \tfrac{1}{2}Ar + As \qquad (h)$$

where (Ar) represents aromatic hydrocarbons:

$$K = \frac{k_1}{k_{-1}} = \frac{(\tfrac{1}{2}Ar\cdot Mb)}{(Ar)^{1/2}(Mb)}$$

Accordingly,

$$\frac{d}{dt}(MbH_2) = k_2(\tfrac{1}{2}Ar\cdot Mb)(AsH_2) = k_2K(AsH_2)(Ar)^{1/2}(Mb).$$

When $(AsH_2)_0 \gg (Mb)_0$:

$$-\frac{d}{dt}(Mb) = k_2K(AsH_2)_0(Ar)_0{}^{1/2}(Mb) = k_2'(Ar)_0{}^{1/2}(Mb) = k(Mb)$$

where $(Ar)_0$ is the initial concentration of the aromatic hydrocarbons.

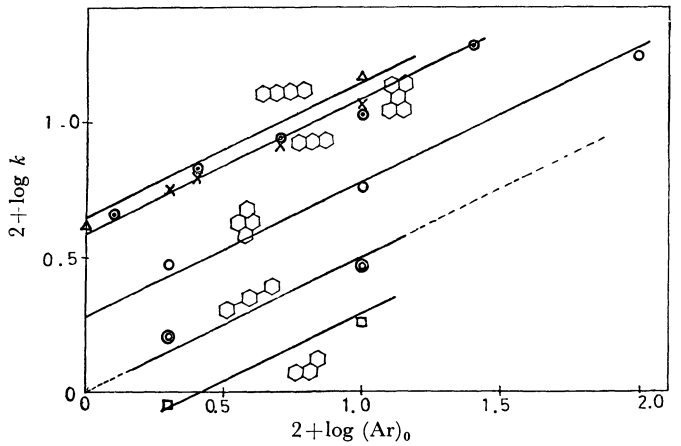

Fig. 7. The linear dependence of rate constants k upon the initial concentrations of aromatic hydrocarbons $(Ar)_0$:
$-d(Mb)/dt = k_2'(Ar)_0{}^{1/2}(Mb) = k(Mb)$.

TABLE 3. THE REDUCTION OF METHYLENE BLUE BY ASCORBIC ACID, CATALYZED BY AROMATIC HYDROCARBONS

Catalysts \ k*	Molar ratios+ 1/4	1/10	1/20	1/40	1/50	1/80	1/100
Naphthacene		0.15					0.043
Perylene		0.12	0.083	0.064	0.058		0.034
Anthracene	0.19	0.11	0.090	0.069		0.038	0.030
Pyrene		0.058			0.030		
p-Terphenyl		0.030			0.017		
Phenanthrene		0.018			0.009		

* $-\mathrm{d(Mb)}/\mathrm{d}t = k_2'(\mathrm{Ar})_0{}^{1/2}(\mathrm{Mb}) = k(\mathrm{Mb})$
where, $(\mathrm{Ar})_0$ represents the initial concentrations of aromatic hydrocarbons.
\+ Molar ratios of aromatic hydrocarbons to methylene blue (1.64×10^{-4} mol/l).

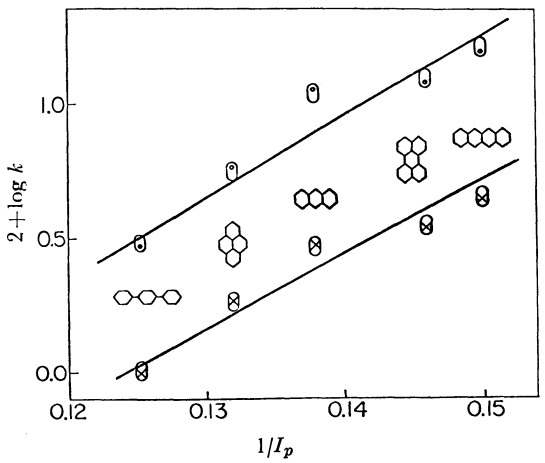

Fig. 8. The relation between the rate constants k, $-\mathrm{d(Mb)}/\mathrm{d}t=k(\mathrm{Mb})$, and ionization potentials (I_p) of aromatic hydrocarbons (Ar):
—⊙— $(\mathrm{Ar})_0$, $1/10\times5.45\times10^{-5}$ mol/l
—⊗— $(\mathrm{Ar})_0$, $1/100\times5.45\times10^{-5}$ mol/l

It can be seen in Fig. 7 that the first-order rate constant, k, is proportional to the square root of the initial concentration of aromatic hydrocarbons.

The rate constants of the redox reaction catalyzed by various aromatic hydrocarbons are given in Table 3.

The stabilization energies for the formation of the EDA complexes of aromatic hydrocarbons with methylene blue have been obtained by the second-order perturbation theory,[13] but if the EDA complex formation makes a contribution to a decrease in the activated state of the redox reaction, some correlation must be found between the stabilization energies and the activation energies. In fact, the plots of the logarithms of the rate constant, a measure of the activation energy, against the reciprocal of the ionization potential, a measure of the stabilization energy, gave a good linear relation, as is shown in Fig. 8.

The Crystal Structure of Copper Yunainate Trihydrate, $Cu(C_5H_8O_3NS)_2 \cdot 3H_2O$

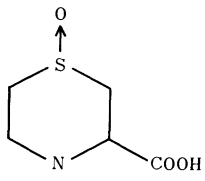
Akio Furusaki and Yujiro Tomiie*1

Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received September 29, 1969)

The crystal structure of copper yunainate trihydrate, $Cu(C_5H_8O_3NS)_2 \cdot 3H_2O$, has been studied by means of three-dimensional X-ray analysis. The crystal is monoclinic, with two formula units in a unit cell of the dimensions: $a=15.94$, $b=6.33$, $c=8.60$ Å, and $\beta=95.6°$; the space group is $P2_1$. The intensities were measured visually from equi-inclination integrating Weissenberg photographs taken with Cu$K\alpha$ radiation around the b and c axes. The structure was elucidated by Sim's method, and refined by the block-diagonal-matrix least-squares method, assuming anisotropic thermal motions for all the atoms. The final R factor is 9.2%. The copper atom is coordinated by imino nitrogen and carboxyl oxygen atoms of two yunainate groups, and a water oxygen atom. The first four atoms lie almost on a plane and make a square configuration of the *trans* type. The last one is bonded to the copper atom nearly in the direction of the normal of the plane. Thus, the coordination number of copper is five in the present crystal. Of the three sorts of water of crystallization, one is connected with the copper atom, as has already been mentioned, and the remaining two are lattice water, forming a hydrogen-bonded spiral chain around the screw axis. Further, these water molecules connect complex molecules to one another by their hydrogen bonds, forming a three-dimensional hydrogen-bonded structure.

Yunaine (I) is a kind of natural amino acid isolated from a seaweed, *Chondria crassicaulis* Harvey (Japanese name "Yuna"), by Professor Tsunematsu Takemoto.[1] A projection of the crystal structure of the copper salt of this amino acid, *i.e.*, copper yunainate trihydrate, has already been reported.[2] That work not only confirmed the structural formula (I), but also revealed some interesting facts about the molecular and crystal structure. In order to obtain more detailed information about these aspects, a three-dimensional X-ray crystal analysis of the copper salt has now been carried out.



(I)

Experimental

The sample of yunaine was kindly supplied by Professor Tsunematsu Takemoto, Tohoku University. The copper salt was prepared by dissolving copper carbonate in an aqueous solution of yunaine. Single crystals, suitable for the structure determination, were obtained as blue needles from the aqueous solution by slow evaporation in a desiccator.

The crystal data of copper yunainate trihydrate, obtained from oscillation and Weissenberg photographs in the present experiment, are given in Table 1.

Table 1. Crystal data of copper yunainate trihydrate

Monoclinic	$a=15.94\pm0.04$ Å
	$b=6.33\pm0.03$
	$c=8.60\pm0.03$
	$\beta=95.6\pm0.3°$
Space group	$P2_1$
Z	2
$\rho_{calcd.}$	1.70 g/cm³

Equi-inclination integrating Weissenberg photographs were taken with Cu$K\alpha$ radiation from the zeroth to the fourth layer around the b axis and from the zeroth to the sixth layer around the c axis. The intensities were estimated visually by the multiple-film technique and were corrected for the Lorentz and polarization factors. Though the cross-sections of the samples used were about 0.2×0.3 mm² for the b axis and 0.2×0.4 mm² for the c, no correction was made for the absorption effect. The partial resolution of α_1—α_2 doublets was not taken into account, and only the α_1 spot intensities were measured where the doublets were completely resolved.

The approximate scale and mean temperature factors were estimated by Wilson's method,[3] the latter being 2.83 Å^2. Thus, the absolute values of the structure factors of 1699 independent reflections were obtained out of about 1970 possible reflections.

All the calculations necessary to derive the structure factors in an absolute scale from the intensity data were carried out on a Bendix G-20 at the C. Itoh Electronic Computing Service Co., Ltd., using a program devised in this laboratory.

Structure Determination

A three-dimensional Patterson function, $P(u,v,w)$, was calculated on the computer mentioned above. From the Patterson map, the y parameters of the copper and two sulfur atoms were obtained easily, since the x and z parameters of these atoms had already been determined by two-dimensional analysis.[2] For the elucidation of the positions of the light atoms, the Fourier synthesis using Sim's method[4] was carried out on a HITAC 5020 computer at the University of Tokyo using a program written by the present authors. In case of non-centrosymmetry, the statistical weight for each structure factor, W, is given by the following equation:

$$W = I_1(X)/I_0(X)$$
$$X = 2|F||F_H|/\sum f_L^2$$

where F is the observed structure factor in an absolute scale, F_H is that calculated with heavy atoms alone, $\sum f_L^2$ is the sum of the squares of the scattering factors of the light atoms in a unit cell, and I_0 and I_1 are, respectively, the zero-order and first-order modified Bessel functions of the first kind.

From the Fourier map thus obtained, the peaks corresponding to all twenty-one light atoms could be easily picked out because of the distinct difference in height between these peaks and the ghost peaks. These atomic parameters were refined at first by the diagonal-matrix least-squares method, with individual isotropic temperature factors, on the HITAC 5020 computer. After three cycles of the refinement, the R factor dropped from 0.159 to 0.125. In these calculations, the standard atomic scattering factors listed in "International Tables for X-Ray Crystallography, Vol. III" were used. For the carbon, nitrogen, oxygen, and sulfur atoms, the scattering factors of neutral atoms were used, while for the copper atom, that of the Cu^{2+} ion was used without any correction for the anomalous dispersion. Figure 1 shows a composite diagram of the (010) sections, taken as through the centers of the atoms, of the three-dimensional electron density distribution at this stage. The positional parameters were further refined by the block-diagonal-matrix least-squares method, with anisotropic temperature factors of the form:

$$\exp(-B_{11}h^2-B_{22}k^2-B_{33}l^2-B_{12}hk-B_{23}kl-B_{31}lh)$$

After six cycles of the refinement, including a real dispersion correction of the copper atom for Cu$K\alpha$ radiation, $\Delta f' = -2.1$, the R factor dropped to 0.092, excluding non-observed reflections. The final atomic coordinates and anisotropic temperature factors are given in Table 2.

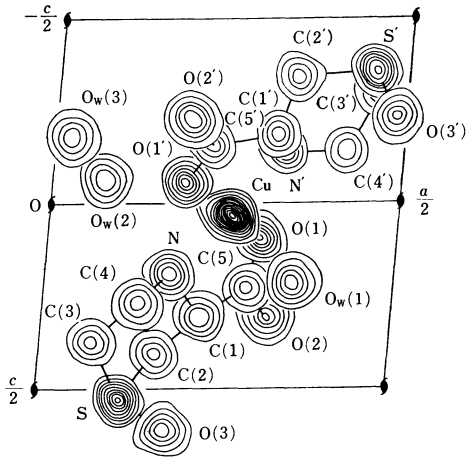

Fig. 1. The electron density distribution of copper yunainate trihydrate. A composite diagram of the (010) sections taken as through the atomic centers. Contours are at intervals of 5 e/Å^3 for a copper atom, 4 e/Å^3 for sulfur atoms and 2 e/Å^3 for the others, beginning at 2 e/Å^3.

Discussion

The molecular framework of the yunainate ions thus obtained is given in Fig. 2. Since the yunaine molecule has been proved to be of the L-type,[1] the yunainate ions should have the absolute configuration shown in Fig. 2, as long as the inversion into the D-type does not occur in the process of the mild reaction of yunaine with copper carbonate.

The two yunainate ions surrounding a copper atom are crystallographically independent. The bond lengths and angles of these two kinds of yunainate ions are given in Fig. 3. The average standard deviations of the atomic coordinates are 0.018 Å for carbon atoms, 0.013 Å for nitrogen and oxygen atoms, 0.005 Å for sulfur atoms, and 0.003 Å for the copper atom. Therefore, the mean standard deviations of various interatomic distances are estimated to be as is shown in Table 3. Some of the corresponding bond lengths and angles of the two kinds of yunainate groups are somewhat different from each other, but these differences do not seem to be significant in view of the accuracy of the present experiment. These bond lengths and

angles agree, within the limits of experimental error, with those found in the hydrochloride of cycloalliin, a methyl derivative of yunaine.[5]

In either of the two kinds of yunainate ions, the heterocyclic ring takes a chair form similar to that of cyclohexane. The sulfinyl oxygen atom is attached to the sulfur in the axial configuration, while the carboxyl group, a bulky substituent of the ring, is equatorial. The copper atom occupies the equatorial position of the nitrogen; hence, the hydrogen atom of the imino group should be axial.

The configuration of the atoms bonded to the sulfur is geometrically similar to that in dimethyl

sulfoxide.[6] The average length of the four independent sulfur-carbon bonds and that of the two independent sulfur-oxygen bonds found in the present molecules are 1.82 and 1.48 Å respectively, while the corresponding values in dimethyl sulfoxide are 1.82 and 1.47 Å respectively. The mean value of the four C–S–O angles and that of the two C–S–C angles are 106 and 97° respectively, while the corresponding angles in dimethyl sulfoxide are 107 and 100° respectively.

The mean of the two C–N–C angles, 111°, is very close to the tetrahedral angle, 109.5°, while the average value of the four nitrogen-carbon bond distances, 1.52 Å, is nearly in agreement with that in copper D,L-proline dihydrate, 1.525 Å.[7]

The conformation of the carboxyl group around the C(1)–C(5) or C(1′)–C(5′) bond is somewhat different in the two kinds of yunainate ions; that is, the azimuthal angle of the C(1)–N and C(5)–O(1) bonds around the C(1)–C(5) bond is about 19°, while the corresponding angle of the C(1′)–N′ and C(5′)–O(1′) bonds is about 30°.

As is shown in Fig. 4, the copper atom is coordinated by two imino nitrogen atoms, two carboxyl oxygen atoms, and a water oxygen atom.

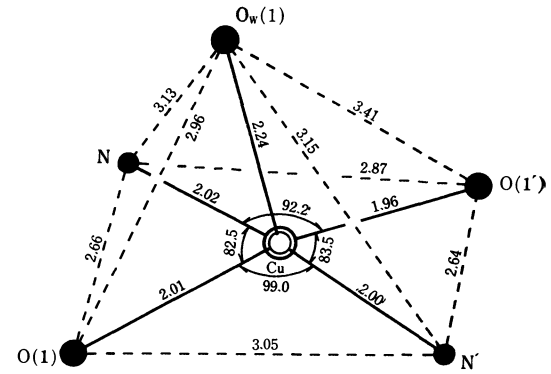

Fig. 4. The tetragonal pyramid of the five coordinating atoms.

The first four atoms lie almost on a plane and make a square configuration of the *trans* type. The last one is bonded to the copper atom nearly in the direction of the normal of the plane.

In the present crystal, there is no atom at a distance smaller than 3.5 Å from the copper atom except for the coordinated five atoms and except for some carbon atoms which are forced to approach the copper in consequence of the formation of the square coordination. On the side of the coordination square opposite to the coordinated water molecule described above, two oxygen atoms are present at distances of 3.57 and 3.67 Å respectively from the copper; one of them is the oxygen atom, $O_W(2)$, of another water molecule, and the other, the sulfinyl oxygen, O(3), of the adjacent complex molecule. However, both of these approaches to the copper seem to be due to the formation of hydrogen bonds with the N and N′ nitrogen atoms respectively rather than to the formation of the coordination bond with the copper. Thus, it is reasonable to conclude that the coordination number of the copper atom is five in the present crystal.

In the present case, the absence of the sixth atom

6) O. Bastiansen and H. Viervoll, *Acta Chem. Scand.*, **2**, 702 (1948).

7) A. M. Mathieson and H. K. Welsh, *Acta Crystallogr.*, **5**, 599 (1952).

to be coordinated to the copper may be closely connected with the fact that, as has already been mentioned, the two oxygen atoms, $O_W(2)$ and O(3), form hydrogen bonds with the N and N′ nitrogen atoms respectively in the axial direction of the six-membered ring and lie just in the neighborhood of the sixth coordination position. If, on the contrary, one of the water oxygen atoms should, for example, occupy the sixth position, neither of the two imino nitrogen could form a normal hydrogen bond because of the steric hindrance of the sixth coordinating atom. It is an interesting fact that, as is actually found, the formation of one of coordination bonds of a copper atom is given up, and instead that of two hydrogen bonds of the nitrogen atoms is achieved.

The five atoms, N, O(1), N′, O(1′), and $O_W(1)$, connected with the copper form a tetragonal pyramid, as is shown in Fig. 4. The lengths of two of the edges, N–O(1) and N′–O(1′), are nearly equal, while those of the other two edges, N–O(1′) and N′–O(1), are somewhat different from each other, the latter being 0.18 Å larger. This distortion of the tetragonal configuration may come from the deformation of the whole complex molecule of copper yunainate, a deformation which is due to the formation of hydrogen bonding at several parts of the complex. It is further found that the orientation of the Cu–$O_W(1)$ bond is inclined to some extent toward the side of the O(1) atom. This inclination may also be due to the strong hydrogen bond formed at a distance of 2.63 Å with the O(1) oxygen atom of the adjoining molecule. The two copper-nitrogen distances, Cu–N and Cu–N′, are 2.02 and 2.00 Å respectively, while the two copper-oxygen distances, Cu–O(1) and Cu–O(1′), are 2.01 and 1.96 Å respectively. These correspond approximately to the ordinary values found in many other copper complexes, such as copper D,L-proline dihydrate (1.99 Å for Cu–N and 2.03 Å for Cu–O).[7] The remaining copper-oxygen bond, Cu–$O_W(1)$, is somewhat weaker than the other two Cu–O bonds, its length being 2.24 Å. This value also nearly corresponds to that in cupric acetate dihydrate, 2.20 Å.

The best plane determined by the least-squares method throughout the four atoms, N, O(1), N′, and O(1′), is described by the equation:

$$0.5577X + 0.5182Y + 0.6484Z = 2.253$$

where X, Y, and Z are rectangular coordinates in the Å unit; $X=x+z\cos\beta$, $Y=y$, and $Z=z\sin\beta$. The deviations of the atoms from this plane are shown in Fig. 5. The copper atom is about 0.23 Å displaced from the plane toward the coordinated water molecule, and the direction of the Cu–$O_W(1)$ bond makes an angle of about 10° with the normal of the plane.

It may be said that the whole complex molecule, composed of a copper atom, a water molecule, and two yunainate groups, has approximately a symmetry of C_2. The centers of all the atoms in the puckered complex molecule lie between two parallel planes, a distance of about 1 Å apart, except in some hydrogen atoms and three oxygen atoms; the latter three oxygen atoms, O(3), O(3′), and $O_W(1)$, stand out to the same side of the plane.

The arrangements of the complex molecules, viewed down along the b and c axes, are shown in Figs. 6 and 7 respectively, together with some intermolecular distances smaller than 4.0 Å. The copper atom, the approximate center of gravity of a complex molecule, is situated very close to the particular position of $x/a=1/4$ and $z/c=0$. Consequently, the arrangement of the copper atoms alone forms nearly a (001) face-centered lattice; the smallest distance among the copper atoms is 6.33 Å along the b axis.

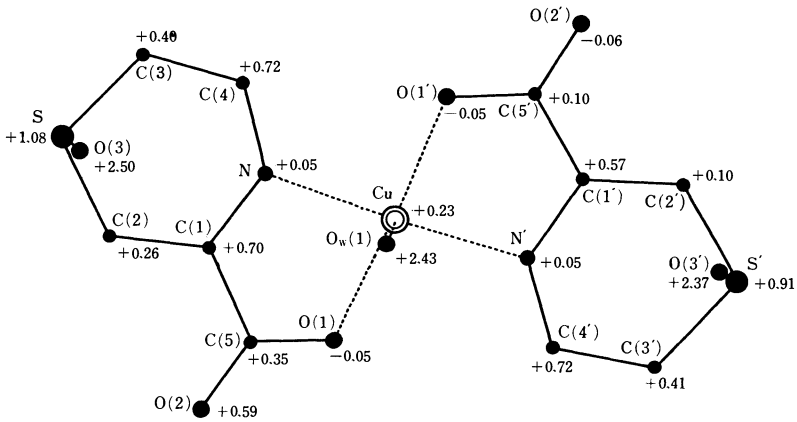

Fig. 5. The deviations (Å) from the square coordination plane, $0.5577X+0.5182Y+0.6484Z-2.253=0$. The complex molecule is viewed down along the normal of this plane.

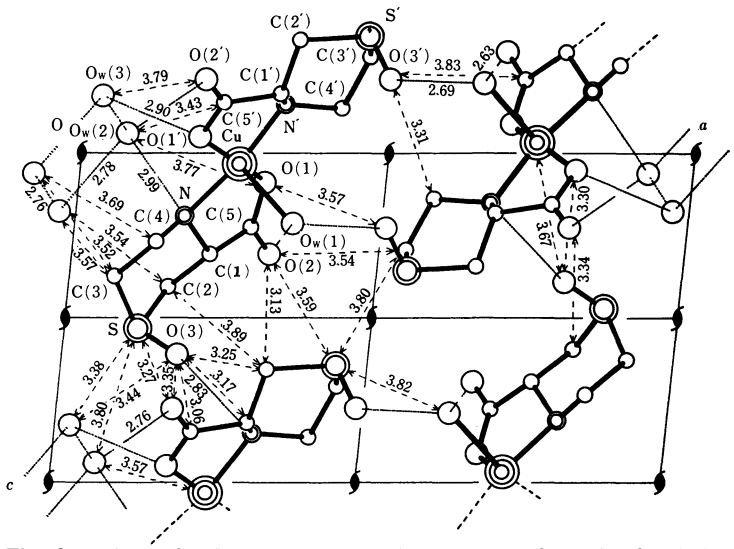

Fig. 6. The molecular arrangement viewed down along the *b* axis in the copper yunainate trihydrate crystal.

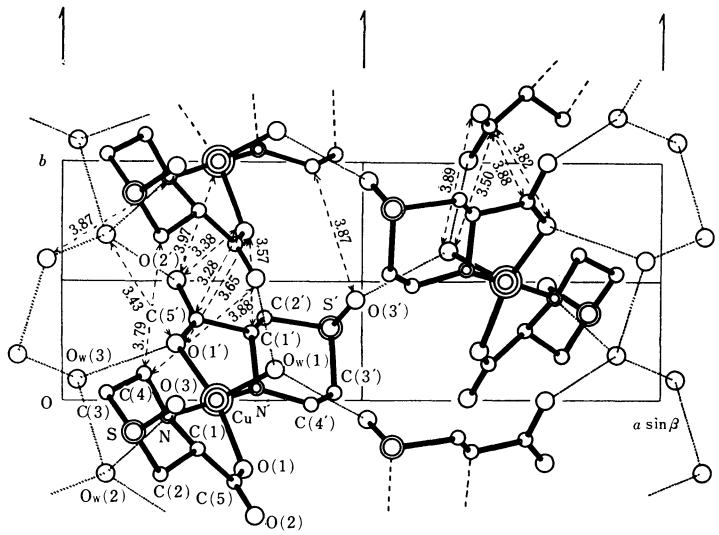

Fig. 7. The molecular arrangement viewed down along the *c* axis in the copper yunainate trihydrate crystal.

The three kinds of water of crystallization contained within the crystal seem to play an important part in connecting the complex molecules with one another. The W(1) water molecule, coordinated to the copper atom, binds not only two complex molecules adjoining along the *b* axis by the Cu-O_W(1) coordination bond and the O_W(1)–H···O(2) hydrogen bond, but also those related by the screw axis with each other, by the O_W(1)–H···O(3′) hydrogen bond. By these bonds and another hydrogen bond, N′–H···O(3), a molecular layer is formed parallel to the (100) plane. Such molecular layers are further connected by several hydrogen bonds formed by water molecules of the two remaining kinds, W(2) and W(3), which form a hydrogen-bonded spiral chain around the two-fold screw axis.

As has been described above, the W(1) water molecule forms two hydrogen bonds, O_W(1)–H··· O(2) and O_W(1)–H···O(3′), their lengths being 2.63 and 2.69 Å respectively. The two hydrogen atoms of the water molecule seem to be considerably off the O···O line, since the O(2)–O_W(1)–O(3′) angle, 130°, is markedly larger than the H–O–H angle of free water molecules in the gas phase, 104.5°.[8] Both of the two hydrogen bonds make

8) R. Mecke and W. Baumann, *Phys. Z.*, **33**, 833 (1932); B. T. Darling and D. M. Dennison, *Phys. Rev.*, **57**, 128 (1940); D. W. Posener and M. W. P. Standberg, *ibid.*, **95**, 374 (1954).

an angle of about 114° with the $O_W(1)$–Cu coordination bond. The total sum of the three angles, O(2)-O_W(1)-O(3′), Cu-O_W(1)-O(2), and Cu-O_W(1)-O(3′), 358°, is very close to the angle (360°) which would be found if the three bonds were coplanar.

The N′–H···O(3) hydrogen bond is the only one formed directly between two complex molecules, its length being 2.83 Å. As is shown in Fig. 8, the direction of this hydrogen bond is fairly much inclined to the side of the carboxyl group (C(1′), O(1′) and O(2′)) from the plane which bisects the C(1′)–N′–C(4′) angle perpendicularly. This may be due to some strong attractive force between the sulfinyl oxygen atom, O(3), and the carboxyl group, since they approach each other quite closely, as will be described later in more detail.

The hydrogen-bonded spiral structure of water molecules alone is one of the remarkable features found in the present crystal. The two kinds of hydrogen bonds, $O_W(2)\cdots O_W(3)$ and $O_W(2)\cdots O_W$-(3′), making the spiral are, respectively, 2.76 and 2.78 Å in length; these lengths are nearly comparable to that found in the hexagonal structure of ice, 2.76 Å, while the angles between the hydrogen bonds, $O_W(2)\cdots O_W(3)\cdots O_W(2')$ and $O_W(3)\cdots O_W$-$(2)\cdots O_W(3')$, are 97 and 108° respectively. The spiral is about 3 Å in diameter if only the nuclei of the water oxygen atoms are taken into account, and it is so right-handed a one that it takes, on the average, a rotation of about 1 radian to move it by 1 Å forward in the direction of the *b* axis.

Besides the hydrogen bonds mentioned above, the W(2) and W(3) water molecules form several hydrogen bonds with the complex molecules around them. The former makes two hydrogen bonds, one with the carboxyl oxygen atom, O(2′), and the other with the nitrogen atom, N; their lengths are 2.76 and 2.99 Å respectively. On the other hand, the latter water molecule forms a hydrogen bond with the carboxyl oxygen atom, O(1′), its length being 2.90 Å. It seems certain that the W(2) and W(3) water molecules direct one of their two hydrogen atoms toward the O(2′) and O(1′) atoms respectively, since neither of these carboxyl oxygen has any hydrogen atom. On the other hand, it is difficult to determine distinctly whether the other hydrogen of W(2) is donated to W(3), and that of W(3), to W(2′), or *vice versa*. Judging only from the angles among the hydrogen bonds shown in Fig. 9, the former case seems to be more reasonable. If, in this case, the hydrogen atoms lie exactly on the O···O lines, the H–O–H angles of the W(2) and W(3) water molecules should be about 115 and 102° respectively.

As is shown in Figs. 6 and 7, in the present crystal some close intermolecular contacts are found aside from the hydrogen-bonded ones already discussed. In particular, the approach between the sulfinyl group (S and O(3)) and the carboxyl

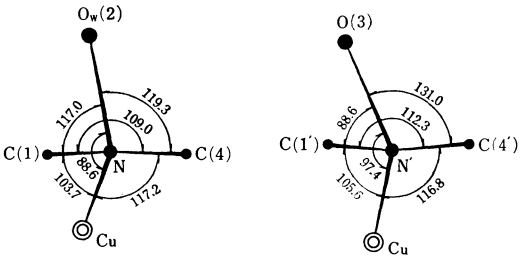

Fig. 8. The bond angles (°) of the imino nitrogen atoms.

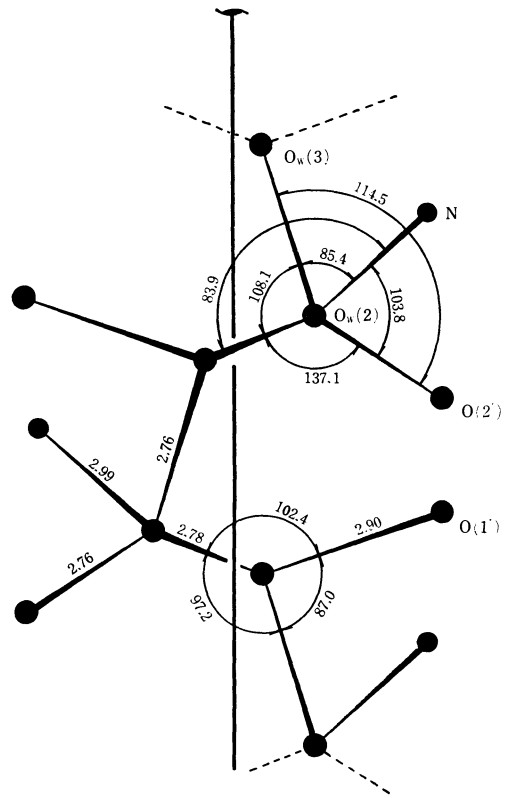

Fig. 9. The hydrogen-bonded spiral chain of the water molecules.

group (O(1′), O(2′), and C(5′)) is of interest in connection with the strong interaction between the two polar groups. The sulfinyl group of a complex molecule is close to the carboxyl groups of the two complex molecules adjoining each other along the *b* axis. The O(3) oxygen atom is in quite close contact with one of the two molecules at four points in all, *i.e.*, O(1′), C(1′), C(2′), and C(5′); the distances of these four atoms from O(3) are, respectively, 3.30, 3.17, 3.25, and 3.06 Å. On the other hand, the sulfinyl group is in contact with the carboxyl oxygen atom, O(2′), of the other complex molecule, the S···O(2′) and O(3)···O(2′) distances being 3.27 and 3.35 Å respectively. The former corresponds nearly to the sum of the van

der Waals radius of sulfur atoms, 1.85 Å, and that of oxygen atoms, 1.40 Å. These close contacts, particularly that of the O(3)···C(5′), seem to suggest that the O(3) sulfinyl oxygen atom and the carboxyl group exert some strong attractive force on each other.

Few atoms are in close contact with the other sulfinyl group (S′ and O(3′)) except for the hydrogen-bonded one which is in close contact with the W(1) water molecule. The sulfinyl groups of this kind are arranged, sufficiently apart from one another, around the two-fold screw axis.

It is interesting to notice that the C(1) carbon atom has no intermolecular contact with a distance smaller than 4.0 Å. This may be partly due to the environment of the other atoms in the same yunainate group, but it does not seem to be attributable to only that cause, since the C(1′) carbon atom, in a similar condition, has contacts with the O(1) and O(3) oxygen atoms of the adjacent molecule. This vacancy around the C(1) atom may be caused by the formation of many hydrogen bonds, which disturb the very close packing of the complex molecules.

Tables of the observed and calculated structure factors are preserved by the Chemical Society of Japan.

The authors are very grateful to Professor Tsunematsu Takemoto, Tohoku University, for providing them with the sample. Thanks are also due to the staff of the C. Itoh Electronic Computing Service Co., Ltd., for allowing the use of their Bendix G-20 computer.

The Crystal Structure of *cis*-Dinitrotetraamminecobalt (III) Nitrate

Isao OONISHI, Hiroto FUJIMAKI,*1 Fumio MUTO and Yoshimichi KOMIYAMA*2

Department of Applied Chemistry, Faculty of Engineering, Yamanashi University, Kofu

(Received October 3, 1969)

The crystal structure of *cis*-dinitrotetraamminecobalt(III) nitrate, $[Co(NO_2)_2(NH_3)_4]NO_3$, has been determined from three dimensional X-ray diffraction data. The dimensions of the orthorhombic unit cell are: $a=12.19$ Å, $b=7.18$ Å, $c=10.92$ Å, and $Z=4$. The space group is $P2_12_12_1$. The structure has been refined by the three-dimensional Fourier and least-squares methods to $R=0.095$. The complex ion has a slightly distorted octahedral coordination, with six N atoms at 1.96 ± 0.02 Å. The complexes are tightly bound together by N–H···O interactions, thus forming a three-dimensional network.

In our series of investigations into the crystal structures of nitroamminecobalt(III) complexes,[1] the crystal structure of *cis*-dinitrotetraamminecobalt-(III) nitrate, $[Co(NO_2)_2(NH_3)_4]NO_3$, has been determined. In crystals of *trans*-$[Co(NO_2)_2(NH_3)_4]$-$NO_3\cdot H_2O$,[1] $[Co(NO_2)_3(NH_3)_3]$,[2] and $NH_4[Co-(NO_2)_4(NH_3)_2]$[3] in which all the complex ions (or molecules) possess at least a pair of nitro groups coordinated in *trans*-positions, the complex ions form a three-dimensional network connected by N–H···O interactions. Moreover, the arrangement of the cobalt atoms always exhibits a higher symmetry than that of the corresponding space groups.

It seemed that it would be of interest to investigate the crystal structure of a *cis*-form of dinitrotetraamminecobalt(III) salt and compare the results with those for the *trans*-form. In this paper, the crystal structure of *cis*-$[Co(NO_2)_2(NH_3)_4]NO_3$ will be reported on.

Experimental

The crystals were prepared by the method of Jörgensen.[4] Recrystallization from water containing a small amount of acetic acid yielded prismatic crystals. The unit-cell dimensions were determined from the higher-order reflections of Weissenberg photographs (Ni$K\alpha$, $\lambda=1.6591$ Å). The systematic absences were: $h00$ for h odd, $0k0$ for k odd, and $00l$ for l odd. Hence,

the space group was unequivocally determined. The crystal data are listed in Table 1. Sets of multiple-film equi-inclination Weissenberg photographs were taken about the *c*-axis (0 to 8th layers), the *a*-axis, and *b*-axis (0th layer). Ni$K\alpha$ radiation was used throughout. The intensities were estimated visually with a standard film strip and were converted to $|F_o(hkl)|^2$ and $|F_o(hkl)|$ by applying the usual Lorentz, polarization, and spot-shape corrections. 847 independent reflections were observed. This number is about two-thirds of those within the nickel sphere. The crystal used was a rod with the dimensions of $0.2\times0.15\times1.0$ mm. No correction was made for absorption or extinction.

Structure Analysis

At first, a three-dimensional Patterson synthesis was calculated. From the Patterson maps, the position of the Co atom and the approximate orientation of the complex ion were easily deduced, but those of the nitrate anion could not be fixed. The structure factors were calculated from the parameter values of the atoms of the complex ion. At this stage the discrepancy factor, *R*, was 0.35. Preliminary three-dimensional Fourier syntheses were calculated using all the $F(hkl)$'s except $|F_{obs.}|>2|F_{cal.}|$. From these Fourier maps, the positions of the nitrate ions were determined. The discrepancy factor calculated with the parameter values of all the atoms was 0.26.

The structure thus obtained was refined by three-dimentional difference synthesis to $R=0.143$, and later again by a block-diagonal least-squares method using an HBLS-4 program written by T. Ashida. In this least-squares calculation, anisotropic temperature factors were introduced and six cycles of refinement were carried out. A weighting scheme employed was:

$\sqrt{w}=0.2$ if $F_0 \leqq F_{min.}$ $(=5.5)$
$\sqrt{w}=1.0$ if $F_{min.}<F_0 \leqq F_{max.}$ $(=100.0)$
$\sqrt{w}=F_{max.}/F_0$ if $F_0>F_{max.}$

The final discrepancy factor, $R=\sum||F_0|-|F_c||/\sum|F_0|$, was 0.095 for all the reflections. The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[5] The final atomic parameters and their standard deviations are summarized in Table 2. The observed and calculated structure factors are listed in Table 3.

Description of the Structure and Discussion

A perspective drawing of the complex ion, *cis*-$[Co(NO_2)_2(NH_3)_4]^+$, is given in Fig. 1. The bond lengths and bond angles, with their e.s.d.'s

Table 2. Atomic parameters and their e.s.d.'s* (10^4)

The expression of the temperature factor is $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+hkB_{12}+hlB_{13}+klB_{23})]$.

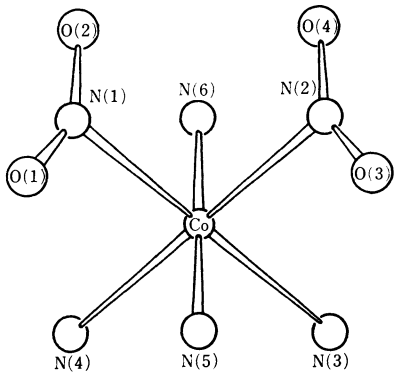

Fig. 1. A perspective drawing of the complex ion, *cis*-$[Co(NO_2)_2(NH_3)_4]^+$

calculated on the basis of the atomic parameters in Table 2, are listed in Table 4. A projection of the contents of one unit cell onto the (010) plane is presented in Fig. 2. The important intermolecular contacts (*i.e.*, those less than 3.5 Å) are listed in Table 5. The interatomic distances and bond angles were calculated by using the RSDA-4 program written by T. Sakurai.

The cobalt atoms are surrounded by nitrogen atoms of two nitro groups and of four ammonia molecules, which form a slightly distorted octahedron. Two nitrogen atoms of nitro groups are coordinated to a cobalt atom in *cis*-positions. The distortion of the coordinated octahedron is more marked than that of the *trans* isomer described in a previous paper.[1] For example, the N(1)–Co–N(6), N(2)–Co–N(3), N(3)–Co–N(6), and N(1)–Co–N(2) angles are 87.5, 88.2, 92.6, and 91.3° respectively. This is partly due to the repulsion of the two nitro groups in *cis*-positions. However, in the *trans* isomer[1] the greatest deviation of N–Co–N angles from 90° are 1.1°; the other deviations are within 1°. Two nitro groups are inclined in the direction opposite to the mean plane consisting of N(1), N(2), N(3), and N(4), with angles of 60 and −64° respectively. Such an inclination in the opposite direction of the nitro groups is also found in $[Co(NO_2)_3(NH_3)_3]$,[2] where the inclination angles are −16, 13, and 18° to the mean plane, consisting of four nitrogen atoms of three nitro groups and one ammonia molecule respectively. In Table 6 the distances between the central cobalt atom and the ligand atoms in various complex ions are compared. The distances are in agreement with those found in the related compounds. Generally

e.s.d.'s $\times 10^3$ in parentheses

the distances of Co–N (NH_3) seem to be longer than those of Co–N (NO_2). An inspection of Table 6 would seem to support in the previous paper[1] that the distances of Co–N (NO_2) increase with an increase in the number of nitro groups. In Table 7 the N–O distances and the O–N–O angles of nitro groups in various complex ions are listed. The N–O distances range from 1.16 to 1.27 Å, and the O–N–O angles, from 114 to 127°.

The nitrate ion has an approximate threefold axis, and the N atom is 0.02 Å apart from the plane composed of three O atoms. The mean value of N–O distances (1.24 Å) agrees with that found in *trans*-$[Co(NO_2)_2(NH_3)_4]NO_3 \cdot H_2O$ (1.25Å).

Table 6. The intratomic distances between cobalt and its ligand atoms

The structure is built up of complex cations $[Co(NO_2)_2(NH_3)_4]^+$ and nitrate ions; thus, it is essentially ionic. The closest approach between the complex ion and the nitrate ion occurs between the oxygen atom of the nitrate ion and the nitrogen atom of the coordinated ammonia. The binding

8) Y. Komiyama, This Bulletin, **29**, 300 (1956).

force between the complex ions is mainly due to the N–H···O interactions between NH_3 and NO_2 groups. By means of these N–H···O interactions the complex ions and the nitrate ions are bound tightly together, forming a three-dimensional network. It is interesting to note here that no special networks consisting of the complex ions are found in this structure such as those found in *trans*-$[Co(NO_2)_2(NH_3)_4]NO_3 \cdot H_2O$,[1] $[Co(NO_2)_3(NH_3)_3]$,[2] and $NH_4[Co(NO_2)_4(NH_3)_2]$,[3] in which all the complex ions (or molecules) possess at least a pair of nitro groups coordinated in *trans*- positions and in which the arrangement of the cobalt atoms themselves have a higher symmetry than that required by the corresponding space group:

	Space group	Pseudo-symmetry
trans-$[Co(NO_2)_2(NH_3)_4]NO_3 \cdot H_2O$	D_2^4-$P2_12_12_1$	D_{2h}^{25}-*Immm*
$[Co(NO_2)_3(NH_3)_3]$	D_2^4-$P2_12_12_1$	D_{2h}^{17}-*Bbmm*
$NH_4[Co(NO_2)_4(NH_3)_2]$	D_2^4-$P2_12_12_1$	D_{2h}^{16}-*Pbnm*

$[Co(NO_2)(NH_3)_5]Br_2$[6] and $[Co(NO_2)(NH_3)_5]Cl_2$[7] also do not possess such a particular type of network nor any such array of cobalt atoms with a higher symmetry.

It may be concluded that the binding force between the complex ions in the crystals of nitroamminecobalt(III) complexes are mainly the N–H···O interactions between NH_3 and NO_2 groups. In particular, if the two nitro groups and the two ammonia groups are both coordinated in *trans*-positions, the two-dimensional network formed by the complex ions possesses a particularly high symmetry and the arrangement of the cobalt atoms exhibits pseudo-symmetry.

The numerical calculations were carried out on the FACOM231 computer of this University and on the HITAC5020 computer of the Computer Center, The Tokyo University. BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 739—744 (1970)

Substituent Effects on Spectral Properties of Protonated Azo Compounds

G. L. EIAN and Charles A. KINGSBURY

Department of Chemistry, University of Nebraska, Lincoln, Nebraska, U.S.A.

(Received January 29, 1969)

The effect of a remote substituent upon the NMR and visible spectra, and upon hydrogen-deuterium exchange in certain phenylazophenol systems is reported. Electron donating substituents uniformly lower the NMR chemical shift function, $\Delta\delta$, cause bathochromic shifts in the visible spectra, and increase the rate of deuterium exchange. Correlations between the above measurements and also with Hammett constants are reported. In particular the logarithm of $t_{1/2}$ is linear with δ_o, the chemical shift of the position adjacent to the position attacked by deuterium.

Correlations involving the nuclear magnetic resonance (NMR) parameters with the several types of linear free energy parameters have been successful for many classes of organic compounds.[1] In recent years the substituent effects on NMR spectra have been reported for pyridines,[2,3] anilines,[4] amines,[5] aldoximes,[6] phenols,[7,8] alkylbenzenes,[9] styrenes,[10] stilbenes,[11] diphenylethylenes,[12]

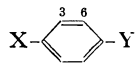
phenylacetylenes,[13a] esters,[13b] phosphines,[14] acetophenones,[15] pyrazoles[16] and other heterocycles,[17] metalocenes,[18,19] protonated benzophenones,[20] and carbonium ions.[21] In other works, the effect of substituent upon coupling constants in various fluorine systems has been investigated.[22,23]

In particular, the NMR spectra of many types of cations have been investigated, principally by Olah and co-workers.[24] In other work, the chemical shift of the proton donated to the various substituted acetophenones has been correlated with σ^+ parameters.[25]

The deshielded character of certain chemical shifts in carbonium ion systems has been related to the charge delocalization of the ion.[26] In cyclopropenium ions additive ring current effects also have a profound effect on the chemical shifts of the various groups.[27]

One salient feature of the NMR spectrum of *para* substituted benzene derivatives is illustrated in Scheme I.[28]



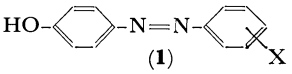
X	Y	δH_A	δH_B	$\Delta\delta$
NO_2	CH_2CN	8.25	7.57	−0.68
NO_2	$NH-CH_3$	8.10	6.55	−1.55
CH_3O	CH_3	6.80	7.05	+0.25
CH_3	CHO	7.02	7.83	+0.81

Scheme I

As noticed by many of the workers cited above, when there is a significant resonance interaction between X and Y, the difference in chemical shift between H_a and H_b (hereafter termed $\Delta\delta$) is large. Little resonance interaction produces a much smaller $\Delta\delta$.

Corio and Dailey[29] have interpreted the chemical shifts of the various ring protons in terms of the same resonance and inductive parameters of a given substituent which enhance or detract from aromatic substitution rates. Jackman[30] however considers the anisotropy of the various groups to be important.

The subject of this work is a series of 4-phenylazophenols (**1**), and their protonated analogues (**1H**). The effect of the remote substituent (ring B)



(**1**)

Ring A Ring B

on the chemical shift function ($\Delta\delta$) of ring A is of interest. In this context if should be noticed that any anisotropy effects of X will have little effect on the NMR spectrum of ring A. In other cases the visible spectra in system **1H** will be compared to the NMR data. The influence of X on the hydrogen-deuterium exchange in ring A will also be considered.

Results and Discussion

Table 1 lists the NMR data for the series of azophenols (**1**). The function $\Delta\delta$(ring A) is rather small for electron donating substituents and is largest for $X=NO_2$, but the total change is small, and rather irregular. The effect of substituent of the protons of its own immediate ring are of course much larger. In the two extreme cases, $X=CH_3O$ and $X=NO_2$, $\Delta\delta$(ring B) is large and of opposite sign.

The chemical shift of the *ortho* protons of both rings is relatively constant at δ *ca.* 7.8. This absorption, however, occurs rather far downfield compared to certain stilbenes, in which analogous protons absorb at δ *ca.* 7.0—7.3. Similarily, the chemical shifts of methyls substituted in the 2′

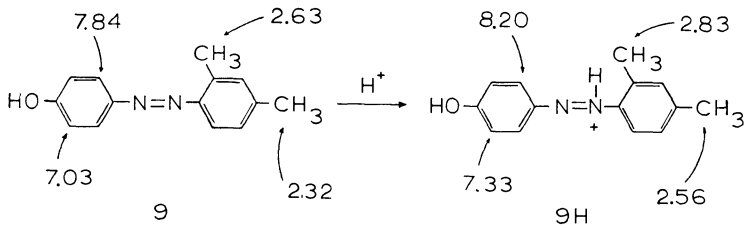
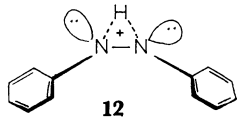
a) Solutions were prepared by dissolving 100 mg of substrate in 1 m*l* of trifluoroacetic acid containing 29.4% sulfuric acid by weight. Chemical shifts are taken relative to tetramethylsilane as 0 ppm.
b) The same solvent mixture was used for the visible spectra (*vide supra*).
c) δ_o refers to the aromatic protons *ortho* to the azo group, in ppm.



position (ring B) occur considerably downfield of the methyls in the 3′ or 4′ positions. The azo group may be somewhat electron withdrawing compared to the unsaturated carbon analogue in the stilbene system, but more likely the anisotropy of the azo group has a deshielding influence on the neighboring *ortho* protons.

The data for the protonated azophenols are listed in Table 2. Relevant chemical shifts for a typical compound and its conjugate acid are given above. The particular position of protonation is given for illustration purposes only.

Every group in the cation is deshielded compared to its counterpart in the unprotonated structure, as the result of the interplay of resonance, inductive and anisotropy effects. The downfield absorption of the 2′ methyl in **9H** compared to the 4′ methyl is suggestive that the anisotropy of the azo function persists in the cation form. Other types of cations shown the opposite trend, the 4′ methyl



12

Scheme II

being downfield compared to the 2′ methyl.[20]

As Table 2 shows the change in $\Delta\delta$ (ring A) is now larger and quite regular. The increased electron demand of the cationic system renders it more sensitive to the various substituents. Moving from electron donating substituents X to electron withdrawing substituents involves a steady increase in $\Delta\delta$. In fact a plot of $\Delta\delta$ *vs.* σ^+ of the remote substituent is reasonably linear (Fig. 1).

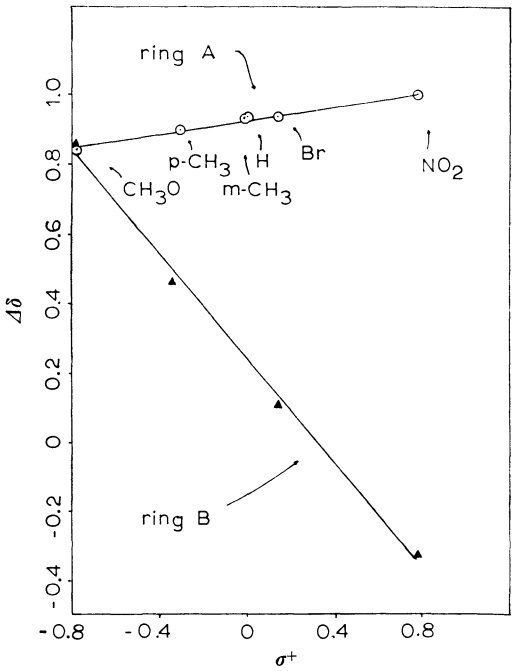


Fig. 1. A plot of the NMR chemical shift function, $\Delta\delta$ *vs.* Okamoto-Brown σ^+ constants.

For ring B, again the effect of the substituent is much greater. The trend of $\Delta\delta$ is now the opposite from that in ring A. Electron withdrawing substitutents produce smaller values of $\Delta\delta$. A plot of $\Delta\delta$ *vs.* σ^+ is again reasonably linear.[31] In ring B the anisotropy of the substituents would be expected to affect the chemical shift of the *meta* protons, thus a linear plot was somewhat unexpected.

The position of protonation of the azo structure remains a question of interest. One likely possibility is that the acid attacks one of the non-bonded pairs on nitrogen. This type of protonation would leave the pi orbitals of the system essentially undisturbed. An equilibrium between structures in which the proton has attacked the α nitrogen and structures resulting from β nitrogen attack seems likely. With electron withdrawing substituents the former structure would seem less probable due to the instability of the resonance froms involving a charge in ring B. In either case the transmission of electronic effects from substituent X through the pi system to affect ring A would be possible.

The symmetrically protonated structure **12** does

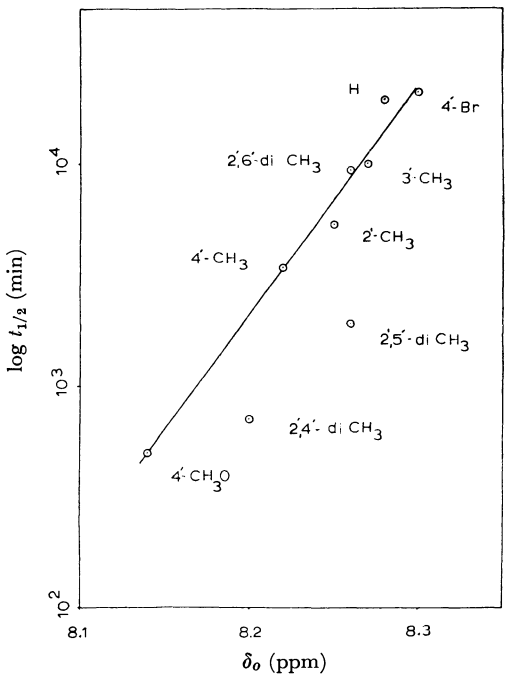

Fig. 2. A plot of log half-life of hydrogen-deuterium exchange in the *meta* position (ring A) *vs.* the chemical shift of the *ortho* proton (ring A) for the various remote substituents indicated.

31) Y. Okamoto and H. C. Brown, *J. Org. Chem.*, **22**, 485 (1957).

not appear to be generally accepted.[32]

For comparison purposes, two model systems have been investigated. The first system, *para* substituted anilinium ions[33] in trifluoroacetic acid, illustrated the effect of a localized charge on a nitrogen attached to one ring. The $\Delta\delta$ values vary with substituent as follows: CH_3O, 0.30; CH_3, *ca.* 0.0; Br, −0.33; $CH_3\overset{O}{\overset{\|}{C}}$, −0.54; NO_2, −0.65. Quite similar values result when small amounts of sulfuric acid are added to the solvent mixture.

The second model system of interest is that of the *para* substituted benzenediazonium chlorides, in which some delocalization of charge from a two nitrogen system into a single ring is possible. The $\Delta\delta$ values vary with substituent as follows: CH_3O, 0.74; Br, 0.32; and NO_2, |0.21|.

Although a strict comparison is not possible due to solvent differences, ring B of system **1H** seems somewhat closer to the anilinium ion model (taking into consideration the anisotropy of the protonated azo function). Thus in the equilibrium between α and β nitrogen protonation, the latter would seem somewhat more important for most substituents.

The visible spectral parameters for the cations **1H** are given in Table 2. The λ_{max} and ε decrease as the electron donating character of X diminishes, in the order **2H**>**3H**>**4H**. However, these parameters increase for **5H** and **6H**. The absorption bands are rather broad and possibly result from the superposition of two or more bands.[34] One band may undergo a bathochromic shift for electron donating substituents X whereas the other band undergoes a bathochromic shift for electron withdrawing substituents. Changes in the site of protonation also would affect λ_{max}, but the direction of change is difficult to predict.

Compound **11H** (2′,6′ dimethyl) exihibits a significantly lower λ_{max} and ε compared to **9H** and **10H**. Although $\Delta\delta$ value is similar, the chemical shifts of the 2′ and 6′ methyl groups occur upfield from the 2′ methyl groups in all other compounds. Ring B in this case (**11H**) appears to be somewhat out-of-plane.

In deuteriotrifluoroacetic acid - deuteriosulfuric acid mixtures, hydrogen-deuterium exchange occurred smoothly in the meta positions of ring A. The half-lives of exchange are recorded in Table 3. It is noteworthy that 4′-electron donating substituents markedly accelerate exchange in the *meta* position (ring A) even though no resonance form can be written in which the 4′ substituent stabilizes the σ complex intermediate. Thus, methyl groups in the 2′ or 4′ of ring B accelerate the exchange in ring A by a factor of 4—5 compared to the case where X=H. A methyl group in the 3′ position is less effective however. The 2′ substituent does not appear to hinder coplanarity of ring B to any great extent, in agreement with the spectral data.

However, the slowness of exchange in ring A of **11H** compared to **9H** is consistent with the out-of-plane character of the former, in which the activating effect of the methyls is reduced. However in ring B, **11H** exchanges much faster than **9H**. Although other explanations are possible, some exchange through a dication intermediate may be in effect. Since ring B of **11H** is not planar with the rest of the pi system, ring B would be less deactivated than the planar system **9H**.

Two aspects of the data in Table 3 are particularly interesting. One aspect concerns compound **7H**. In this case ring B exchanges more rapidly than the much more highly activated ring A. Again exchange directly on the protonated form **7H** may be in effect, rather than exchange *via* the small amount of **7** present in equilibrium with **7H**.

Table 3. Exchange half-lives for substituted phenylazophenols (**1H**) in trifluoroacetic acid-d - 29.4% sulfuric acid-d_2 at 30°C

	X	Ring A	Ring B
2H	4′-CH_3O	500 min	*ca.* 500
3H	4′-CH_3	3400	
4H	H	19000	
5H	4′-Br	21000	
6H	4′-NO_2	very slow[a]	
7H	3′-CH_3	10000	1700[b]
8H	2′-CH_3	5300	
9H	2′,4′-$(CH_3)_2$	700	
10H	2′,5′-$(CH_3)_2$	*ca.* 1900	[c]
11H	2′,6′-$(CH_3)_2$	*ca.* 9200	*ca.* 9200[b]

a) No exchange was observed in 30 days.
b) Three protons exchange.
c) The degeneration of the spectrum over a period of time was probably indicative of sulfonation.

The second aspect worthy of comment is shown in Fig. 2. Although plots of the log exchange half-life ($t_{1/2}$) *vs.* δ_m (ring A) or $\Delta\delta$ are reasonably linear for monosubstituted ring B compounds, the best correlation occurs by plotting log $t_{1/2}$ *vs.* δ_o (ring A). The remote substituent can supply or withdraw electrons from the *ortho* position by resonance. The modified electron density will in turn affect the chemical shift. However, the effect of the electron donation by X to the *ortho* position on hydrogen-deuterium exchange in the adjacent *meta* position is considered to be an inductive effect.

Experimental

Preparation of 4-Phenylazophenols (1). The phenylazophenols were prepared by the coupling reaction of the appropriately substituted diazonium chloride with phenol. A typical procedure is the preparation of **10**. The diazotization was carried out by dissolving 2,5-dimethylaniline (6.0 g, 0.05 mol) in a solution of 12.5 m*l* of concd. hydrochloric acid in 50 m*l* of water. This solution was cooled in an ice bath and an aqueous solution of sodium nitrite was added until a positive test for nitrous acid was obtained. Sodium hydroxide (4.8 g, 0.12 mol) and phenol (4.6 g, 0.05 mol) in 30 m*l* of water was placed in a three necked flask, equipped with stirrer, *etc.* The diazonium salt was added to the cooled phenoxide solution. The resulting bright orange mixture was filtered and the filtrate acidified with hydrochloric acid. The product was filtered off, thoroughly washed, and recrystallized from benzene, mp 98—100°C, 7.2 g, 65% yield.

Found: C, 74.21; H, 6.25%. Calcd for $C_{14}H_{14}ON_2$: C, 74.31; H, 6.24%.

Compound **11** was prepared similarly, mp 147—148°C.

Found: C, 74.17; H, 6.25%. Calcd for $C_{14}H_{14}ON_2$: C, 74.31; H, 6.24%.

The following were literature preparations: **2**, mp 136—137°C, (lit,[35] 142°C): **3**, mp 150—151°C (lit,[36] mp 151°C); **4**, mp 150—151°C (lit,[37] 152°C); **5**, mp 160—161°C (lit,[38] 162°C); **6**, mp 206—207°C (lit,[39] mp 211°C); **7**, mp 142—143°C (lit,[40] 141°C); **8**, mp 101—102°C (lit,[41] mp 102—103°C); **9**, mp 134—135°C (lit,[35] mp 134°C).

The anilines from which the diazonium salt NMR data were taken were commercial products recrystallized twice, usually from ethanol. In each case the literature melting point was obtained.

Sulfuric acid-d_2 was obtained from Merck, Sharp and Dohme of Canada and was used as received. Trifluoroacetic acid-d was prepared from the anhydride (Mathieson) by the procedure of Taylor and Templeman.[42] On distillation the fraction boiling at 71°C was collected. The isotopic purity was greater than 96%.

The NMR data were taken on a Varian-A-60 instrument. The chemical shift data (taken *vs.* tetramethylsilane or *vs.* tetramethylammonium bromide in acid solutions) are considered good to ±0.03 ppm, and the $\Delta\delta$ values to ~0.01 ppm. The latter are less sensitive to concentration than the chemical shifts. The NMR solvents 29.4% sulfuric acid-d_2 in trifluoroacetic acid-d were made up by weight. Stronger acid solutions showed rather diffuse peaks whereas weaker solutions did not appear to protonate the substrate fully in all cases. For the diazonium salt runs, the solvent was 18% hydrochloric acid in water.

The ultraviolet data were taken on a Cary Model 14 instrument. The λ_{max} data are considered good to ±2—3 mμ due to rather broad peaks in some cases.

The rate solutions were made up and run as described previously.[20]

This work was begun at Iowa State University.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 745—749 (1970)

Formation Constants of Chromium(II) Complexes with (O,O)-, (O,N)- and (N,N)-Type Ligands and Comparison with Those of the Other First Transition Metal Complexes*1

Yutaka FUKUDA,*2 Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received March 26, 1969)

The formation constants of the bivalent chromium complexes with various chelating ligands were determined by the pH titration method at the ionic strength $\mu=0.1$ and at 25°C. The values of the formation constants for (O,O)-type complexes were log $k_1=3.85\pm0.05$ and log $k_2=2.96\pm0.05$ for oxalate ion, log $k_1=3.92\pm0.05$ and log $k_2=3.21\pm0.05$ for malonate ion, and log $k_1=9.89\pm0.05$ for sulfosalicylate ion: for (O,N)-type complexes we obtained log $k_1=7.72\pm0.05$ and log $k_2=7.54\pm0.05$ for glycine, log $k_1=9.05\pm0.05$ for 8-hydroxyquinoline, and log $k_1=7.53\pm0.05$ for β-alanine. Based on these values together with the corresponding values of the (N,N)-type complexes, the effect of the coordinating atoms and of the number of members in a chelate ring upon the stabilities was discussed. These values were compared with those for the other transition metal complexes.

There are many unknown formation constants on the complexes of d^4-type metal ions, such as vanadium(I), chromium(II), manganese(III) and iron(IV). This may be mainly attributed to their variable valencies owing to the easy oxidation to d^3-type electronic state as shown by the standard reduction potential such as $E_{298}^0=-0.41$ V[1] for Cr^{2+}–Cr^{3+} system or to the easy reduction to d^5-type state as shown by the standard oxidation potential such as $E_{298}^0=1.51$ V[1] for Mn^{2+}–Mn^{3+} system. The corresponding potentials for V^+–V^{2+} and Fe^{3+}–Fe^{4+} are not known. Thus, because of the instability of the bivalent chromium ion in an aqueous solution, the formation constants have not been determined except for a few complexes, such as sulfosalicylic and salicylic acids,[2] acetylacetone,[3] ethylenediamine[4] and α,α'-bipyridyl.[5]

The present work was undertaken (1) to provide enough data on the formation constants of the chromium(II) complexes to find the effect of the coordinating atoms on the stabilities among the (O,O)-, (O,N)- and (N,N)-type complexes, (2) to know the effect of the number of members forming the chelate upon the stabilities and (3) to clarify the position of the chromium(II) complexes in the series of the stability order.

Experimental

Ligand Materials. The (O,O)-type chelating ligands were oxalic, malonic and sulfosalicylic acids, and the (O,N)-type ligands were glycine, 8-hydroxy-

quinoline and β-alanine. They were all of special grade reagents from Wako Pure Chemical Industries. For the sake of convenience, the structures of the ligands are given in Fig. 1.

Preparation of Chromium(II) Perchlorate. A solution of chromium(II) perchlorate was prepared by the electrolytic reduction of a solution of hexaaquochromium(III) perchlorate.[6] The cell for electrolysis consists of three compartments:[2] in one compartment the so-called Winkler platinum electrode was inserted as an anode and in another one mercury was used as a cathode. The starting voltage was 2—3 V in the electrolysis. The applied voltage was gradually raised to about 6 V, keeping the electric current at about 0.5 A. Electrolysis was continued under these conditions for 7—8 hr, nitrogen being passed through all the apparatus not only during the electrolysis but also for 2—3 hr before the electrolysis to protect the bivalent chromium ion from oxidation. Nitrogen was purified by passing it through a basic pyrogallol solution and a chromium(II) ion solution.

The color of the electrolytic solution changed from reddish-violet to blue as the reduction proceeded. The absorption spectrum of the resulting solution in a *d–d* transition region was found to coincide with that of aquo chromium(II) complex.[7] Determination of the chromium(II) ion content was carried out iodometrically: a standard solution of potassium iodate, in the presence of potassium iodide and a few drops of starch solution as indicator, was titrated with the chromium(II) perchlorate solution prepared by electrolytic reduction, and the concentration of chromium(II) ion was calculated from the titres. The reactions concerned can be expressed by the following:

$$IO_3^- + 5I^- + 6H^+ \rightarrow 3I_2 + 3H_2O$$
$$3I_2 + 6Cr^{2+} \rightarrow 6I^- + 6Cr^{3+}$$

Total concentration of chromium was spectrophotometrically determined as bichromate. Although the accuracy of the determination of total chromium content is about ten times less than that of the chromium(II) content evaluated from the iodometric titration, it could be confirmed by this procedure that more than 99% of the chromium was reduced.

Formation Constant Measurement. The aqueous solution of each ligand was titrated with alkali hydroxide solution at an ionic strength $\mu=0.1$ and at 25°C, in the presence as well as in the absence of the hexaaquochromium(II) perchlorate. The ligand materials were used in excess in comparison to the chromium(II) perchlorate added. Thus the change of the concentration of the ligands in complex formation can be neglected as compared with the total concentration of the ligands added. The ionic strength of the solution was adjusted to 0.1 by adding an appropriate amount of sodium perchlorate.

Results

When the ligand materials behave as bidentate chelating agents, the acid dissociation constants*3 are given by

$$H_2L = H^+ + HL, \quad K_1 = [H^+][HL]/[H_2L],$$
$$HL = H^+ + L, \quad K_2 = [H^+][L]/[HL],$$

where the square brackets, [ ], express the concentration of relevant species, and the ionic charges are omitted except for hydrogen ion. From the equations, the concentration of the free ligand bound neither with proton nor with metal ions, [L], is calculated by the equation:

$$[L] = K_1K_2[C_L]/\{K_1K_2 + K_1[H^+] + [H^+]^2\}, \quad (1)$$

where $[C_L]$ is the total concentration of the ligand.

The average number of the coordinated ligands per one chromium(II) ion, $\bar{n}$, is expressed by the equation

$$\bar{n} = C_{OH}[OH^-]/2C_MV_M, \quad (2)$$

where C_{OH} and C_M are the initial concentrations of alkali hydroxide and chromium(II) perchlorate solution, respectively, V_M is the titres of the chromium(II) perchlorate solution and $[OH^-]$ is the difference between the titres obtained from pH titration curves in the presence and absence of the metal ion at the same pH value of the solution. $[OH^-]$ corresponds to the amount of the ligand participating in the complex formation.[8]

The values, $\bar{n}$ and the logarithm of the reciprocal concentration of the free ligand, p[L], are calculated by using equations, (1) and (2). The formation curves, $\bar{n}$—p[L], are plotted in Fig. 2.

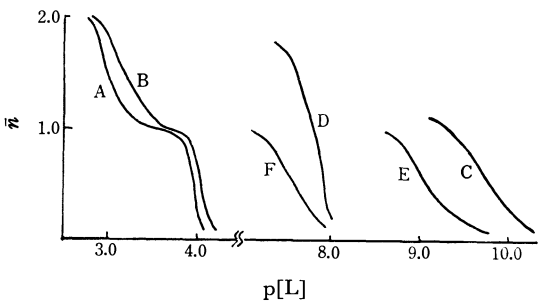

Fig. 2. The formation curves, $\bar{n}$—p[L], for chromium(II)-various ligands systems.

Discussion

Comparison of the Formation Constants. It may be deduced from Fig. 2 that the chromium(II) complexes having two ligand molecules at highest appear in aqueous solution. This may be due to the so-called Jahn-Teller effect in d^4-type complexes, the electronic configuration preferring the high-spin state.

The 1 : 3 complex was found only in α,α′-bipyridyl in an aqueous solution.[5] It was also confirmed by preliminary experiment that the yellow crystalline tervalent chromium complex with α,α′-bipyridyl was obtained by oxidizing the crystalline black chromium(II) complex prepared in nitrogen atmosphere in the air. The fact that chromium(II) forms 1 : 3 complex only with α,α′-bipyridyl may suggest that only the complex with α,α′-bipyridyl is in the low-spin state.

In the case of chromium(III) complexes, the stability is known to increase, in general, in the order of the ligands giving the coordination types, *viz.*, (O,O)<(O,N)<(N,N).[6] This may be due to the fact that the polarizing ability of the chromium(III) ion is relatively stronger owing to its greater ionic charge and smaller ionic radius than that of the chromium(II) ion and that the polarizability of nitrogen as a soft base[15] is larger than that of oxygen.

In chromium(II) complexes, the following results are given in Fig. 2 and Table 1. For the ligands forming five-membered chelate ring with metal, the formation constants of the (O,N)-type complexes such as glycinate and 8-hydroxyquinolinate are larger than those of the (O,O)-type complexes such as oxalate. This is in line with the results obtained with the chromium(III) complexes.[6] The same stability order applies also to the ligands forming six-membered chelate ring: the formation constants of the (O,N)-type complexes such as β-alaninate are larger than those of the (O,O)-type complexes such as malonate or acetylacetonate.

The formation constants of the (N,N)-type complexes such as ethylenediamine and α,α′-bipyridyl are slightly larger than those of the (O,O)-type complexes such as oxalate or malonate. This may be explained as above with respect to the corresponding chromium(III) complexes: the strength as Lewis base is larger in nitrogen than in oxygen atoms, or nitrogen is a more soft base than oxygen.[9]

However, the formation constants of chromium(II) complexes with ethylenediamine and α,α′-bipyridyl are, contrary to expectation, smaller than those of the (O,N)-type complexes such as glycinate and 8-hydroxyquinolinate. This fact was not found with the chromium(III) complexes reported in an earlier paper.[6]

It is known that the complexes having five-membered chelate ring are, in general, more stable than those having six-membered chelate ring. Nevertheless, so far as chromium(II) complexes are concerned, the difference is not appreciable between the formation constants of complexes forming five-membered and those forming six-membered chelate rings as seen in the (O,O)-type complexes such as oxalate and malonate or in the (O,N)-type complexes such as glycinate and β-alaninate.

The salicylate and sulfosalicylate complexes, however, have exceptionally larger formation constants than those of malonate complexes having the same six-membered chelate ring of (O,O)-type. 8-Hydroxyquinolinate complex has a larger value of the formation constants than that of glycinate complex having the same five-membered ring of (O,N)-type. Salicylic and sulfosalicylic acids have benzene ring, and 8-hydroxyquinoline has a pyridine ring besides a benzene ring. The reason why the complexes containing such chelating ligands are extraordinarily stable comes from the possibility of the resonance effect resulting from the presence of a

benzene or pyridine ring and/or the change of the electronic configuration in chromium(II) ion from the high-spin to the low-spin state.

In the case of α,α′-bipyridyl complexes, the second stepwise formation constant is larger than the first one as shown by their data.[5] The normal order where the first stepwise formation constant is larger than the second one as seen in most complexes is not applied to the case of α,α′-bipyridyl complexes. Such an abnormal result suggests that the electronic configuration in these complexes may be changed from the high-spin to the low-spin state when the 1 : 1 complex is converted to 1 : 2 complex.

The fact that the acetylacetonate complexes have larger values of formation constants than the malonate ones which have the same six-membered ring as seen in Table 1 may be explained by considering the presence of the quasi-aromaticity in the former.

Comparing the formation constants of chromium(II) complexes with the corresponding acid dissociation constants, we see that, when the latter becomes larger, the former tends to increase. The linear relationships between the logarithmic values of the formation constants and of the respective acid dissociation constants are verified by the approximately constant values of $(\log k_1)/pK_2$ except for oxalate, ethylenediamine and α,α′-bipyridyl complexes. Calculated values are listed in Table 2.

TABLE 2. THE VALUES OF $(\log k_1)/pK_2$

Position of the Stability of Chromium(II) Complexes in the First Transition Metal Complexes. So far enough data of the formation constants of the bivalent chromium complexes have not been obtained, and the position of the constants in the so-called Irving-Williams series[16] is ambiguous. In order to survey the stability sequence in various complexes of the first bivalent transition metal, ion formation constants of some chelates of these metals ion are plotted against the metal series following their atomic numbers in Fig. 3.

16) H. Irving and R. J. P. Williams, *J. Chem. Soc.*, **1953**, 3192.

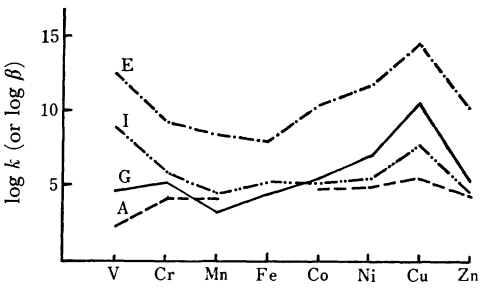

Fig. 3. Comparison of the stabilities of the bivalent metal complexes with various chelate ligands.
E: 8-hydroxyquinoline, I: acetylacetone, G: ethylenediamine, A: oxalic acid.

A approximate order of the stability of the first transition metal complexes including chromium is found to be Zn<Cu>Ni>Co≳Cr>Fe>Mn. The stability of chromium(II) complexes seems to be situated between that of iron(II) and cobalt(II) complexes, so far as the chelating lignads such as 8-hydroxyquinoline and ethylenediamine are concerned.

The order found for cobalt(II), iron(II) and chromium(II) complexes may be explained on the basis of the ligand field theory as follows: if the electronic configuration in these complexes is in the high-spin state as given in Fig. 4, the ligand field stabilization energy can be calculated as $4/5\Delta$, $2/5\Delta$ and $3/5\Delta$ for Co(II), Fe(II) and Cr(II) complexes, respectively, in octahedral environment, where Δ is the splitting energy dependent upon the strength of the ligand field. Since all the values of Δ are not known, the explanation by the ligand field theory is not always applicable to each stability sequence over the first transition metal complexes with various chelating ligands.

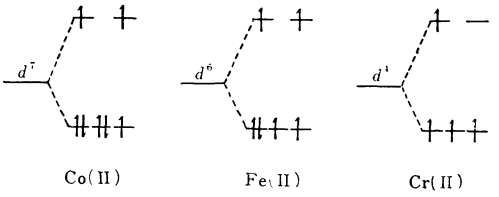

Fig. 4. Ligand field splitting in Co(II), Fe(II) and Cr(II) complexes in high-spin state.

It will be found from Fig. 3 that the stability of the chromium(II) complexes which contain the π-character ligands such as 8-hydroxyquinoline or acetylacetone is lower than that of the corresponding vanadium(II) complexes, whereas, in the case of the complexes containing normal ligands such as oxalic acid or ethylenediamine, their stabilities are in reverse order. The reason might be as follows: since the radius of chromium(II) ion is smaller than that of vanadium(II) ion, the former is a harder acid than the latter, so that the chromium-

(II) complex is more stable than vanadium(II) for a common chelating ligand having no π-character, whereas the strength of the back-coordination is larger in chromium(II) than in vanadium(II) for a π-character ligand, so that the stability order might become reverse.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 749—755 (1970)

On the Ligand Exchange Equilibrium in the Propylene-Mercury(II) Complex

Itsuro KAWAI, Riichiro NAKAJIMA and Tadashi HARA

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto

(Received May 15, 1969)

The equilibrium between the propylene-mercuric complex and either Cl^-, Br^-, I^-, or EDTA, and their dependences on the pH were investigated manometrically. The propylene-mercuric complexes present in the above equilibrium were found to be $(HO^-)_n$-Hg^{2+}-Propylene ($n=0$, 1 and 2) and $(HO^-)_n$-Hg^{2+}(X^-)-Propylene ($n=0$ and 1), and their equilibrium equations were:

$$(HO^-)_n\text{-}Hg^{2+} + \text{Propylene} \overset{K_{p1}}{\rightleftharpoons} (HO^-)\text{-}Hg^{2+}\text{-Propylene}$$

$$X^-\text{-}Hg^{2+}\text{-}(HO^-)_n + \text{Propylene} \overset{K_{p2}}{\rightleftharpoons} (HO^-)_n\text{-}Hg^{2+}(X^-)\text{-Propylene.}$$

By introducing $K_{p1}=K'_{p1}$ and $K_{p2}=K'_{p2}$ when $n=0$, the dependences on the pH were shown by:

$$\log K_{p1} = \log K'_{p1} + 2\cdot\text{pH}, \quad \log K_{p2} = \log K'_{p2} + \text{pH}$$

where $K'_{p1}=2.2\times10^5$, $K'_{p2(Cl)}=4.1\times10^5$, and $K'_{p2(Br)}=2.7\times10^6$ at 25°C and $\mu=0.8$. As was to be expected from the above equilibrium, K'_{p1} was idependent of the presence of Cl^-, Br^-, I^-, and EDTA, while K'_{p1} varied in the presence of Cl^-, Br^-, and I^-. The above relationships were also derived theoretically.

It has been well known that the mercuric ion in an aqueous solution can be made to react with olefin to form a stable complex[1] and that the complex can be decomposed by adding a chloride ion to an olefin and mercuric complex.[2]

Though the mercuric chloride-olefin system has been studied by many people, no satisfactory explanation of the equilibrium has been given. The equilibrium constant for the mercuric chloride-ethylene system was estimated by Allen *et al.*,[2] but they could not explain the effect of sodium chloride and perchloric acid on the equilibrium. The equilibrium between *cis*- or *trans*-butene-2 and mercuric chloride was also investigated by Kreevoy *et al.*,[3] but their study was limited to the range in which $HgCl_3^-$ and $HgCl_4^{2-}$ can be neglected.

The present study was carried out in order to make clear the species present in an aqueous solution and to calculate the equilibrium constants. On the basis of the species and the equilibrium constants thus obtained, the ligand-exchange reactions between the propylene-mercury(II) complex and chloride, bromide, iodide, and ethylenediaminetetraacetate were satisfactorily explained.

It has been reported in a preceding paper[4] that the mercury(II) in an aqueous solution can be determined indirectly by adding such ligand as chloride, bromide, iodide, and ethylenediaminetetraacetate to the propylene-mercury(II) complex and by then measuring the amount of propylene evolved.

The amount of propylene evolved in these ligand-exchange reactions decreased with an increase in the pH in the pH range of >0.15 for chloride, >2.10 for bromide, and >4.00 for iodide, while it decreased with a decrease in the pH in the range of pH<4.90 for ethylenediaminetetraacetate. These phenomena seemed to be very interesting from the standpoint of understanding the mechanism of oxymetallation, they could be explained satisfactorily using the species and the equilibrium con-

stants, as has been mentioned above.

No discussion including oxymetallation has been given for an equilibrium in the propylene-mercury-(II) system in which the formation constants of mercuric halide are taken into consideration.

In the present paper, all the species, such as $HgX_i^{(2-i)+}(i=1—4)$, $(HO^-)_n$-Hg^{2+}-Propylene ($n=0$, 1 and 2), $(HO^-)_n$-$Hg^{2+}(X^-)$-Propylene ($n=0$ and 1), and $Hg(OH)_i^{(2-i)+}$ ($i=0$, 1 and 2), were taken into consideration in an equilibrium. The above-mentioned phenomena were attributed to the difference in the formation constants of mercuric halide complexes and to the affinity between the α-carbon in propylene and the hydroxyl groups produced by the hydrolysis of the hydrated propylene-mercury(II) complex.

Experimental

The amount of propylene evolved or absorbed was measured by the same apparatus and procedure as in the preceding paper.[4] With the objective of examining the hydrolysis of the aquo mercuric complex, the absorption spectra of 8×10^{-4}M Hg(II) solutions (pH: 0, 1, 2, 3, 5 and 7; ionic strength with sodium perchlorate : 1) were obtained over 210—300 mμ at 25°C by means of a Shimadzu QR-50 spectrophotometer, using 1-cm cells. The acidity was regulated with a 10^{-3}M sodium hydroxide solution after a preliminary run had been made. With the same objective as above, 5×10^{-2}M Hg(II) solutions (0.7N in perchloric acid concentration) in the presence and in the absence of 0.15M chloride or bromide or iodide were titrated with 0.97N NaOH, and the pH during titration was measured by means of a Horiba M-5 pH-meter.

Results

The amounts of propylene absorbed into mercuric solutions at various concentrations are shown in Table 1, along with the apparent formation constant,

TABLE 1. APPARENT FORMATION CONSTANT (K_p) BETWEEN MERCURIC ION AND PROPYLENE

$t=25$°C, P_{tot}=total pressure of propylene=1 atm, $\mu=0.85$, $[HClO_4]=0.7$N, Total volume=7.00 ml

[$\sum$Hg] mol/l	Propylene absorbed sample ml (mol/l)	Formation constants (K_p) l/mol
2.867×10^{-2}	5.70 (3.340×10^{-2})	3.0×10^4
3.584×10^{-2}	6.88 (4.029×10^{-2})	1.5×10^4
4.301×10^{-2}	8.12 (4.756×10^{-2})	2.3×10^4
5.017×10^{-2}	9.30 (5.445×10^{-2})	1.5×10^4
		Av.=2.1×10^4

Blank 0.84 ml (4.92×10^{-3} mol/l)

which was directly estimated from the experimental data. Since the mole ratio of propylene to mercury is 1 : 1, the composition of the propylene-mercury-(II) complex can also be expected to be 1 : 1. The reaction is thus given by Eq. (1):

$$Hg^{2+} + CH_3\text{-}CH{=}CH_2 \overset{K_p}{\rightleftharpoons} \begin{matrix} & CH_3 & \\ & | & \\ HC & & \diagdown Hg^{2+} \\ | & & \\ H_2C & & \end{matrix} \quad (1)$$

The equilibrium constant is, therefore, shown by Eq. (2), and the values of K_p are as shown in Table 1.

$$K_p = \frac{[Hg^{2+}\text{-Propylene}]}{[Hg^{2+}]\cdot[\text{Propylene}]} = \frac{[\text{Total amount of propylene absorbed}] - [\text{Blank}]}{\{[\sum Hg] - [\text{Total amount of propylene absorbed}] + [\text{Blank}]\}\cdot[\text{Blank}]} \quad (2)$$

Where [Blank] indicates the amount of propylene absorbed into the solution containing no mercuric ion, and [Total amount of propylene absorbed] corresponds to the propylene absorbed into the Sample as shown in Table 1. Hereafter, [Propylene] and [Hg^{2+}-Propylene] will be abbreviated as [P] and [Hg^{2+}-P] respectively.

Though the values of K_p were obtained directly from the experimental data, they are not very accurate since the value of [Blank] contains something of an experimental error. Therefoer, the value of K_p was estimated indirectly by means of Eq. (9), using the equilibrium data concerning the Hg(II)-EDTA and propylene-Hg(II)-EDTA systems. For the former system, Eqs. (3), (4), (5) and (6) are given:

$$Hg^{2+} + L^{4-} \overset{K_{EDTA}}{\rightleftharpoons} Hg\text{-}L^{2-} \quad (3)$$

$$K_{EDTA} = \frac{[HgL^{2-}]}{[Hg^{2+}]\cdot[L^{4-}]} \quad (4)$$

$$H_{5-i}L^{1-i} \overset{K_{ai}}{\rightleftharpoons} H_{4-i}L^{-i} + H^+ \quad (5)$$

$$K_{ai} = \frac{[H_{4-i}L^{-i}]\cdot[H^+]}{[H_{5-i}L^{1-i}]} \quad (i=1—4) \quad (6)$$

For the latter system, Eqs. (7), (8) and (9) are given:

$$Hg^{2+}\text{-Propylene} + L^{4-} \overset{K_{p3}}{\rightleftharpoons} Hg\text{-}L^{2-} + \text{Propylene} \quad (7)$$

$$K_{p3} = \frac{[HgL^{2-}]\cdot[P]}{[Hg^{2+}\text{-P}]\cdot[L^{4-}]} \quad (8)$$

$$K_{p1} = \frac{K_{EDTA}}{K_{p3}} \quad (9)$$

where K_{p1} is theoretically equal to K_p, but it is differentiated from K_p since K_{p1} is indirectly calculated. Table 2 shows the experimental data obtained in the preceding paper; these data show the residual amount of the propylene mercuric complex on the addition of chloride, bromide, iodide, and ethylenediaminetetraacetate. The values of K_{p3} were estimated from the data (Table 2) obtained at pH 5 and at varying mole ratios of EDTA to Hg(II); they are shown in Table 3.

X: Cl, Br

Formation constants (K_{p1} and K_{p2}) were calculated using Sillén's[6] stability constants;

Cl: $K_1=5.49\times10^6$, $K_2=3.02\times10^6$, $K_3=7.08$, $K_4=1.26\times10$

Br: $K_1=1.12\times10^9$, $K_2=1.91\times10^8$, $K_3=2.57\times10^2$, $K_4=1.82\times10$

Table 6, Eqs. (13) and (14) held:

$$[\sum X] = \sum_{i=1}^{4}(i\cdot[HgX_i^{(2-i)+}]) + [X^-] \quad (13)$$

$$[\sum Hg] = \sum_{i=1}^{4}[HgX_i^{(2-i)+}] + [Hg^{2+}] + [Hg^{2+}\text{-P}] \quad (14)$$

By combining Eqs. (11)—(14), Eq. (15) was obtained:

$$\left(\prod_{i=1}^{4}K_i\right)\cdot[X^-]^5 + \left(\prod_{i=1}^{3}K_i\cdot(1-K_4\cdot[\sum X]-4[\sum Hg])\right)\times[X^-]^4 + \left(\prod_{i=1}^{2}K_i\cdot(1-K_3([\sum X]+3[\sum Hg]))\right)\cdot[X^-]^3 + (K_1(1-K_2([\sum X]-2[\sum Hg])))\cdot[X^-]^2 + (1+K_1\cdot([\sum Hg]-[\sum X]))\cdot[X^-] - [\sum X] = 0 \quad (15)$$

The value of [X^-] in Eq. (15) was obtained by the method of halving by a computor, followed by the calculation of the constituent concentration and of K_{p1}. Though the value of K_{p1} was expected to be constant, it varied with the kind and with the concentration of the halide. This seemed to be attributable to the fact that Hg^{2+}-P alone was adopted as the propylene-mercury(II) complex in the above equilibrium. However, those data are not shown since they are not useful in explaining the equilibrium. Paul and Brandt[7] took the monohalogeno propylene mercuric complex alone into consideration in examining an equilibrium of the propylene-Hg(II)-halide system, but the present authors took both the monohalogeno-propylene mercuric complex and the propylene mercuric complex into consideration. Therefore, Eqs. (16) and (17), in addition to Eqs. (1) and (11), were considered:

$$HgX^+ + \text{Propylene} \overset{K_{p2}}{\rightleftharpoons} X\text{-}Hg^+\text{-Propylene} \quad (16)$$

$$K_{p2} = \frac{[X\text{-}Hg^+\text{-P}]}{[HgX^+]\cdot[P]} \quad (17)$$

Eqs. (13) and (14) were rewritten as Eqs. (18) and (19):

$$[\sum X] = \sum_{i=1}^{4}(i\cdot[HgX_i^{(2-i)+}]) + [X^-] + [X\text{-}Hg^+\text{-P}] \quad (18)$$

$$[\sum Hg] = \sum_{i=1}^{4}[HgX_i^{(2-i)+}] + [Hg^{2+}] + [Hg^{2+}\text{-P}] + [X\text{-}Hg^+\text{-P}] \quad (19)$$

By combining Eqs. (12), (17), (18), and (19), the equation corresponding to Eq. (15) was derived; here [Hg^{2+}-P] and [X-Hg^+-P] were included, while K_{p1} and K_{p2} were calculated by the method of trial and error after having assigned arbitrary values to [Hg^{2+}-P] and [X-Hg^+-P]. The results obtained are shown in Table 6, while the mole fraction of the complexes is plotted against the mole ratio of halide to mercury in Fig. 2. Thus, the value of K_{p1} became independent of the kind and of the concentration of the halide. The value of K_{p1} obtained at pH 0.15 from Eq. (10) agreed approximately with those in Table 6; therefore, the values of K_{p2} for chloride and bromide were calculated using the values of K_{p1} at various pH values. The results obtained are shown in Table 7, while the mole fractions of the complexes are shown in Fig. 3. The data concerning K_{p2} and pH in Table 7 are shown as B and C in Fig. 1. From Fig. 1, the relationship between K_{p2} and pH is given by Eq. (20):

$$\log K_{p2} = \log K'_{p2} + \text{pH} \quad (20)$$

where the K'_{p2} values for chloride and bromide are 4.1×10^5 and 2.7×10^6 respectively.

The absorption spectra of mercuric perchlorate solutions are shown in Fig. 4; there are two isosbestic points among the curves (2), (3), (4), and (5).

The titration curves of mercuric perchlorate solutions in the presence and in the absence of chloride, bromide, and iodide are shown in Fig. 5.

Discussion

Since there were two isosbestic points in Fig. 4, the aquo complex seems to be more or less subject to hydrolysis at pH 2—7. The process of hydrolysis can be understood more precisely from the titration curves in Fig. 5. The amount of sodium hydroxide corresponding to $\overline{AB}$ in Fig. 5 is exactly equivalent to the amount of mercury(II) used in the experiment, and the hydrolysis of the aquo complex begins and ends at approximately pH 2. On the other

hand, the hydrolysis of the aquo complex in the presence of halide begins at pH>7, judging from the titration curves (2), (3), and (4). Since a precipitate was produced in the presence of iodide, no further analysis was carried out.

The values of the formation constant (at pH 0.15) shown in Table 1 are smaller than those of K_{p1} in Table 6 and the value of K_{p1} (4.4×10^5) at pH 0.15 as calculated by Eq. (10). This is probably because of the experimental error in the direct method, since the propylene-mercury complex was quite stable and the equilibrium was shifted remarkedly to the right-hand side of Eq. (1).

Eqation (10) is derived as follows. The propyl-

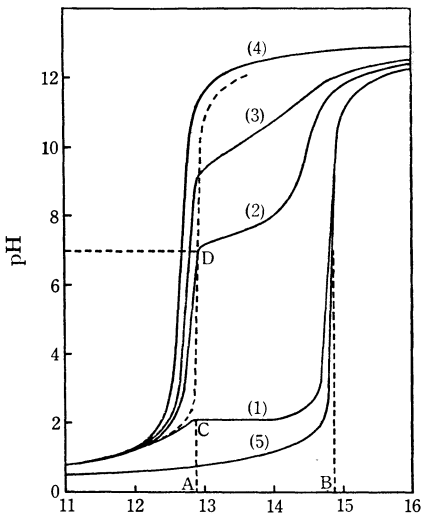

Fig. 5. Titration of mercuric perchlorate solutions; t=25°C, μ=1, [∑Hg]=5×10^{-2} mol/l, [∑X]/[∑Hg]=3, X$^-$: Cl$^-$, Br$^-$, I$^-$

(5): Perchloric acid solution

enemercury complex seems to undergo hydrolysis at pH 2—5 in accordance with Eq. (21):

$$Hg(OH_2)_2^{2+}\text{-}P \overset{k_1}{\rightleftharpoons} Hg(OH)_2\text{-}P + 2H^+ \quad (21)$$

$$k_1 = \frac{[Hg(OH)_2\text{-}P]\cdot[H^+]}{[Hg(OH_2)_2^{2+}\text{-}P]} \quad (22)$$

$$[Hg(OH)_2\text{-}P] = k_1\cdot[Hg(OH_2)_2^{2+}\text{-}P]\cdot[H^+]^{-2} \quad (23)$$

Since the Hg^{2+}-P in Eq. (8) is actually present as $Hg(OH)_2$-P, the K_{p3} in Eq. (8) is given by K_{p4}:

$$K_{p4} = \frac{[Hg\text{-}L^{2-}]\cdot[P]}{[Hg(OH)_2\text{-}P]\cdot[L^{4-}]} = \frac{[Hg\text{-}L^{2}]\cdot[P]\cdot[H^+]^2}{k_1\cdot[Hg(OH_2)_2^{2+}\text{-}P]\cdot[L^{4-}]} \quad (24)$$

Hence, Eq. (25) is obtained instead of Eq. (9):

$$K_{p1} = \frac{K_{EDTA}}{K_{p4}} = \frac{[Hg(OH_2)_2^{2+}\text{-}P]\cdot k_1}{[Hg^{2+}]\cdot[P]\cdot[H^+]^2} = K_{p1E}\cdot k_1\cdot[H^+]^{-2} \quad (25)$$

where $K_{p1E}=[Hg(OH_2)_2^{2+}\text{-}P]\cdot[Hg^{2+}]^{-1}\cdot[P]^{-1}$
Eqation (25) is then rewritten as Eq. (26);

$$\log K_{p1} = \log K_{p1E} + 2\cdot pH + \log k_1 \quad (26)$$

The K_{p1E} in Eq. (26) indicates the formation constant of the propylene-mercury(II) complex at very low pH values. On the other hand, the K'_{p1} in Eq. (10) indicates the intercept (pH=0) on the ordinate in Fig. 1. Therefore, the values of K_{p1E} and K'_{p1} may be expected to be approximately equal, and $\log k_1$, to be approximately zero. Therefore, Eqs. (10) and (26) become indentical.

Equation (20) is derived as follows. As can be seen form Fig. 5, the aquo complex in the presence of three times as many moles of halide as those of mercury is not subject to hydrolysis up to pH 7. However, the monohalogeno propylene mercuric complex seems to be more or less subject to hydrolysis and to stabilize in accordance with Eq. (27):

$$X\text{-}Hg(OH_2)^+\text{-}P \overset{K_e}{\rightleftharpoons} X\text{-}Hg(OH)\text{-}P + H^+ \quad (27)$$

$$K_e = \frac{[X\text{-}Hg(OH)\text{-}P]\cdot[H^+]}{[X\text{-}Hg(OH_2)^+\text{-}P]} \quad (28)$$

$$[X\text{-}Hg(OH)\text{-}P] = K_e\cdot[X\text{-}Hg(OH_2)^+\text{-}P]/[H^+] \quad (29)$$

Hence, Eq. (17) may be rewritten as Eq. (30):

$$K_{p2} = \frac{[X\text{-}Hg(OH)\text{-}P]}{[X\text{-}Hg^+]\cdot[P]} = \frac{[X\text{-}Hg(OH_2)^+\text{-}P]\cdot K_e}{[X\text{-}Hg^+]\cdot[P]\cdot[H^+]} = K'_{p2}\cdot K_e\cdot[H^+]^{-1} \quad (30)$$

$$\log K_{p2} = \log K'_{p2} + pH = \log K_e \quad (31)$$

Since the K_{p2} values in Eqs. (20) and (31) are identical and since the K'_{p2} values in Eqs. (20) and (31) are approximately equal, $\log K_e$ may be expected to be around zero. Therefore, Eqs. (20) and (31) become identical.

In the practical experiment of the propylene-mercury(II)-halide system, a definite amount of halide is added to the $Hg(OH)_2$-P, and the X-Hg(OH)-P is formed by the replacement of the hydroxyl group with the halide ion. The formation of the X-Hg(OH)-P is considered to proceed with an increase in the stability of the halogeno mercuric complex. This makes K_{p2} in Eq. (30) large and locates the K_{p2}(Br) line over the K_{p2}(Cl) line, as is shown in Fig. 1.

The results obtained are summarized in the following schematic diagram:
EDTA-Mercury(II)-Propylene system, assumed species:

Hg^{2+}-P, $Hg(OH)_2$-P, $Hg(OH^-)_n$ (n=0—2),
Hg-L^{2-}, $H_{5-i}L^{1-i}$ (i=1—4), P, L^{4-}.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 755—758 (1970)

Hydrodynamic Voltammetry with the Convection Electrode. IV. The Measurements of the Kinetic Parameters of the Electrode Reaction. Part II

Junsuke SUZUKI

Faculty of Education, Shizuoka University, 836, Oya, Shizuoka

(Received June 11, 1969)

The convection electrode system was applied to the determination of the kinetic parameters of the electrode reaction. By analyzing the observed current-voltage curve, the parameters of α and k° were calculated; for the ferric-ferrous system in 0.1M perchloric acid, α and k° were found to be 0.63 and 7.6×10^{-3} cm/sec respectively, while for the hexammine cobaltic-cobaltous system in 1M ammonia-ammonium chloride, they were 0.65 and 4.5×10^{-6} cm/sec respectively.

In the preceding paper[1] the convection electrode system with the rotating disk as a stirrer was applied to the measurement of the rate constant of the electrode reaction. The results were in good agreement with the published data.[2]

In investigating the kinetics of the electrode reaction using the voltammetry, the rate of mass transfer should be faster than that of electron transfer. At the present convection electrode the rate of mass transfer can be increased by increasing the tangential velocity of the rotating disk. That is, any reversible current-voltage curve can apparently be made irreversible due to such an increased mass transfer. Therefore, it is considered that the use of the convection electrode is very suitable for the determination of a moderately fast electron-transfer rate by voltammetry.

In the present investigation, the kinetic parameters for the Fe(III)-Fe(II) system in a 0.1M perchloric acid solution, and for the Co(III)-Co(II) system in an ammonia-ammonium chloride solution, will be measured, and good results will be obtained.

Experimental

Materials. All the chemicals used were of a chemically pure grade.

Electrodes and Apparatus. The electrode system and the apparatus were the same as had been described in a previous paper.[3] In the present investigation, the pretreatment of the platinum electrode was carried out as follows: the platinum electrode was oxidized anodically for 1 min at +1.5 V *vs.* SCE in 0.1M perchloric acid, and then 0 V *vs.* SCE was applied to it for 3 min in nitrogen-bubbled 0.1M perchloric acid.

Measurements. A Yanagimoto Polarograph, Model PA 102, was used for recording the current-voltage curve. A saturated calomel electrode was used as a reference electrode. An electrolytic solution was kept at 25 ± 0.1°C.

Results and Discussion

The Upper Limit of the Tangential Velocity of the Rotating Disk. It would be possible to determine the rate parameters of a moderately rapid electron-transfer process by increasing the

3) J. Suzuki, *Rev. Polarog.* (Kyoto), **15**, 21 (1968).

mass transfer sufficiently, that is, by increasing the tangential velocity of the rotating disk. When the tangential velocity exceeds a certain value, however, the flow passing through the electrode changes from a laminar to a turbulent one. Since the relations derived in the previous paper[1] for the determination of the rate parameters can be applied only to the laminar flow, the tangential velocity of the rotating disk must be limited to the value below which the flow is kept laminar.

On the other hand, one can anticipate, from the value of dimentionless parameter, the Reynolds number (*Re*), whether or not the conditions of the flow passing over the electrode surface will be laminar. However, the critical *Re* value for the present convection electrode, the value at which the flow passing through the electrode changes from a laminar to a turbulent one, is not clear. Nevertheless, assuming that the condition of the flow passing over the convection electrode surface is similar to that of the flow passing through the rotating disk electrode,[4] the critical *Re* value at the convection electrode can be estimated to be of the order of 10^4.

Assuming a diameter of the convection electrode surface (working part plus shield) of 0.50 cm and the kinematic viscosity of an electrolytic solution of 10^{-2} cm^2/sec, the highest velocity for the laminar flow is found to be about 200 cm/sec; this corresponds to a tangential velocity of the rotating disk of about 500 cm/sec.

Upper Limit of the Rate Constant which can be determined. Under the initial condition of $C_R=0$, Eq. (12), which was derived in the preceding paper,[1] is transformed into this form:

$$i = \frac{i_l^c}{1+e^{\zeta}} \cdot \frac{A e^{-\alpha\zeta}(1+e^{\zeta})}{0.61+A e^{-\alpha\zeta}(1+e^{\zeta})} \qquad (1)$$

where:

$$\zeta = \frac{nF}{RT}(E-E_{1/2}^r) \qquad (2)$$

and:

$$A = k^\circ\left(\frac{f_O}{D_O^{2/3}}\right)^{1-\alpha}\left(\frac{f_R}{D_R^{2/3}}\right)^{\alpha}\left(\frac{v}{d}\right)^{-1/2}\nu^{1/6} \qquad (3)$$

Here, i_l^c is the cathodic limiting current; the other symbols have been identified in the preceding paper.[1]

Equation (1) is completely analogous to the general equation of the current-voltage curve, which was derived theoretically by Matsuda, for the reduction or oxidation process in polarography[5] and in voltammetry.[6]

According to the magnitude of k°, the characteristics of the current-voltage curve can be classified into three kinds:[1] (a) reversible, (b) quasi-reversible,[7] and (c) irreversible. The magnitude of k° corresponding to each of these cases can then be estimated, as is shown in Table 1.

Table 1. Characters of the current-voltage curve

Character	Magnitude of k°
Reversible	$>1.5\times10^{-2}(v/d)^{1/2}$
Quasi-reversible	$1.5\times10^{-2}(v/d)^{1/2}>k^\circ>1.3\times10^{-6}(v/d)^{1/2}$
Totally irreversible	$<1.3\times10^{-6}(v/d)^{1/2}$

Assuming $f_O=f_R=1$, $D_O=D_R=10^{-5}$ cm^2/sec, $\alpha=0.5$, and $\nu=10^{-2}$ cm^2/sec.

In order to determine the rate constant by analyzing the current-voltage curve, it is necessary in practice that the curve have a quasi-reversible or an irreversible character. Therefore, the upper limit of the rate constant, k°, which could be determined by the present hydrodynamic voltammetry is considered to be about 1.5×10^{-2} $(v/d)^{1/2}$ (*cf.* Table 1). On the other hand, the highest tangential velocity of the rotating disk, v, for the laminar flow is 500 cm/sec, as has been mentioned above. Consequently, the upper limit of the rate constant so determined can be estimated to be 0.47 cm/sec, when d is 0.50 cm.

Fe(III)-Fe(II) System in Perchloric Acid Media. It is well-known that the redox reaction of a ferric-ferrous system in a perchloric acid solution is a moderately fast one-electron transfer

process.

The current-voltage curves for the reduction of a ferric ion in absence of a ferrous ion were recorded at the tangential velocities of the rotating disk ranging from 62.8 to 188.4 cm/sec. A typical current-voltage curve thus obtained is shown in Fig. 1.

The rate constant of electron transfer can be evaluated only when the observed current-voltage curve shows a sufficient deviation from a reversible character. Such deviation can be most easily checked by means of the following equation:[8]

$$E_{3/4} - E_{1/4} = \frac{0.059}{n} \text{ V} \qquad (4)$$

where $E_{3/4}$ and $E_{1/4}$ are the potentials at the three-quarter and at the one-quarter limiting currents respectively. That is, if the current is controlled only by mass transfer, the difference between the potentials at $E_{3/4}$ and $E_{1/4}$ on the observed current-voltage curve equals $(0.059/n)$ V. In the present case, this difference was evaluated as 81 mV from Fig. 1 at the tangential velocity of the rotating disk of 188.4 cm/sec.

From the observed current-voltage curve at the tangential velocity of 188.4 cm/sec, a series of values of the rate constants, k_R, at the applied potential, E, were calculated by using Eq. (5), which was itself obtained by rearranging the Eq. (13) derived in the preceding paper.[1] Then the plots of log k_R *vs.* $(E-E^\circ)$ were made for each current-voltage curve.

$$k_R = k^\circ \exp\left[\alpha(E^\circ - E)n\boldsymbol{F}/\boldsymbol{R}T\right] = \frac{1}{\frac{i_l{}^c - i}{i} \cdot \frac{f_O}{m_O} - \frac{f_R}{m_R} \exp\left[(E-E^\circ)n\boldsymbol{F}/\boldsymbol{R}T\right]} \qquad (5)$$

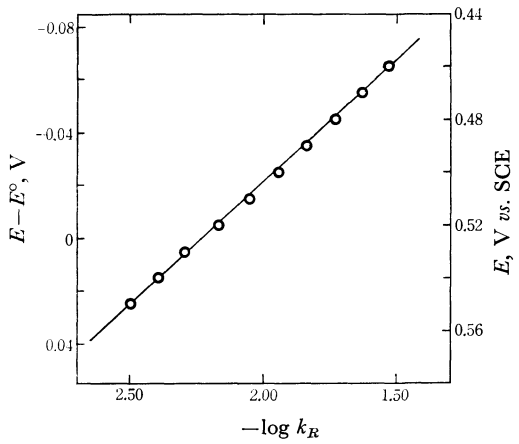

Fig. 2. The plots of log k_R *vs.* E.
Concentration of Fe^{3+}: 3.72×10^{-4}M in 0.1M $HClO_4$
Tangential velocity of rotating disk: 188.4 cm/sec

where m is the mass transfer coefficient.[3,9,10] A typical plot is shown in Fig. 2.

As was predicted by Eq. (5), a linear relation between log k_R and $(E-E^\circ)$ was obtained. Therefore, the slope of this line equals 2.303 $\boldsymbol{RT}/\alpha n$ and the intercept at $E=E^\circ$ equals (2.303 $\boldsymbol{RT}/\alpha n$) log k°. The rate parameters obtained are given in Table 2.

The value of k° obtained is considered to be reliable on the basis of a comparison with the results of Jordan and Javick,[10] and of Randles and Somerton.[11]

Co(III)-Co(II) System in Ammonium Buffer Media. It is well-known that ammine complexes of cobalt(III) are inert, and those of cobalt(II), labile. The heterogeneous electroreduction of hexammine cobaltic salts has already been investigated in detail by several workers.[12-15] The results showed that the character of the electrode reaction of cobaltic to cobaltous species is a totally irreversible process, followed by a chemical reaction. This mechanism may be shown as follows:

$$Co(NH_3)_6^{3+} + e \xrightarrow{\text{irrev.}} Co(NH_3)_6^{2+} \qquad (6)$$

$$Co(NH_3)_6^{2+} \overset{\text{fast}}{\rightleftharpoons} \sum_{n=0}^{6} Co(NH_3)_{6-n}^{2+} \qquad (7)$$

The proportions of the complexes with various n values in Reaction (7) depend upon the concentration of free ammonia in the supporting electrolyte solution.

Because the electron transfer step of Reaction (6) is totally irreversible,[14,16,17] the succeeding

chemical reaction of Reaction (7) has no effect upon the reduction step of hexammine coblat(III) ions. Therefore, the rate constant for the heterogeneous electrode reaction of hexammine cobalt-(III) can be evaluated using the same equation as that used for an ordinary totally irreversible process.[1)]

The kinetics of the electrode reaction of the hexammine cobalt(III) ion in 1 M ammonia-ammonium chloride was investigated by using a convection electrode. A typical current-voltage curve for the reduction of hexammine cobalt(III) is shown in Fig. 1.

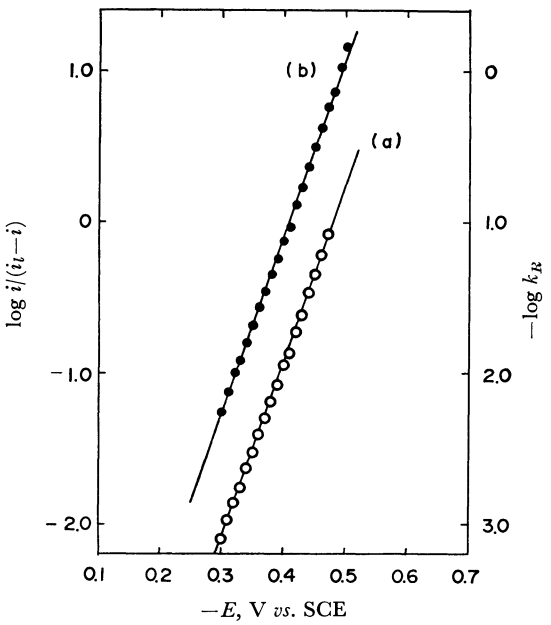

Fig. 3. The polts of $\log k_R$ *vs.* E and of $\log i/(i_l-i)$ *vs.* E.
(a) Plots of $\log k_R$ *vs.* E, (b) Plots of $\log i/(i_l-i)$ *vs.* E. Concentration of $Co(NH_3)_6^{3+}$: 1×10^{-4} M in 1 M NH_3+1 M NH_4Cl. Tangential velocity of the rotating disk: 188.4 cm/sec

The values of the rate constant, k_R, can be calculated from the i/i_l ratio at various potentials on the current-voltage curve. Figure 3 shows the plots of $\log k_R$ *vs.* E and of $\log i/(i_l-i)$ *vs.* E; both plots give straight lines. The kinetic parameters, α and k°, can be estimated from Fig. 3.

The former was calculated from the slope of line (a) or line (b), and the latter, from the intercept at the standard potential, E°, to line (b). The standard potentials of the hexammine cobaltic-cobaltous couple were calculated from Latimer's data[18)] as -0.100 V *vs.* SCE. They are summarized in Table 3.

Table 3. Kinetic parameters for $Co(NH_3)_6Cl_3$ system in 1 M NH_3+1 M NH_4Cl

Tangential velocity v, cm/sec	α	k° $\times10^{-6}$ cm/sec
94.2	0.67±0.01	5.0±0.4
125.6	0.65±0.02	5.5±0.8
157.0	0.64±0.02	3.5±0.5
188.4	0.65±0.02	4.1±0.2
Average	0.65	4.5

The values of the kinetic parameters obtained at the convection electrode are in good agreement with those in a previously-published paper,[17)] in which the parameters of α and k° are 0.61 and 6×10^{-6} cm/sec respectively in 1 F ammonia-ammonium chloride; these values were obtained by using the tubular platinum electrode.

The author wishes to express his thanks to Professors Nobuyuki Tanaka of Tohoku University and Tokuro Ozaki of Shizuoka University for their helpful discussion, and to Misses Mihoko Imura and Junko Takashima for their earnest assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 759—763 (1970)

The Reaction between Mercury(II) and Organic Compounds. VIII. Titrimetric Determination of Mercury(II) with *o*-(2-Thiazolylazo)-2,4-dichlorophenol as a Metallochromic Indicator

Fumiaki KAI

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

(Received June 20, 1969)

The reaction between mercury(II) and *o*-(2-thiazolylazo)-2,4-dichlorophenol (TADC) was investigated spectrophotometrically. A mixture containing TADC and a large excess of mercury(II) showed the absorption maxima in the range of pH 2.3—5.0 at 570 mμ. The composition of the chelate was considered to be as Hg(II) : TADC=1 : 2. No homologous color was obtained by the reaction between TADC and the other metal ions in the above pH range. Therefore, TADC was suggested as a suitable metallochromic indicator for the direct titrimetric determination of mercury(II) ions with EDTA at pH 3.8—5 (citric acid plus disodium hydrogenphosphate buffer). Sharp color changes were observed from deep violet to orange or to reddish orange at an equivalence point. The titrimetry could be carried out satisfactorily within a range of error of ±0.5% at mercury(II) concentrations of more than 2×10^{-4}M by the present method.

The stability constants of the complexes formed between the *o*-(2-thiazolylazo)-phenols and mercury(II) and the availability of these reagents as chromogenic or spectrophotometric reagents for the determination of mercury(II) were reported previously.[1-3]

In the present paper, the reactivity of mercury(II) ions with *o*-(2-thiazolylazo)-2,4-dichlorophenol (TADC) was studied spectrophotometrically, and the applicability of TADC as a chromogenic reagent for the determination of mercury(II) ions was examined. In previous papers[1-3] it was reported that titrimetric determinations of mercury(II) ions using *o*-(2-thiazolylazo)-cresol (TAC),[1] *o*-(2-thiazolylazo)-4-methoxyphenol (TAM)[2] and *o*-(2-thiazolylazo)-4-chlorophenol (TACL)[3] as indicators were carried out in a weakly alkaline medium in all cases. As for the titrimetry using TADC as a metalloindicator, the optimum pH range was found to be 3.8—5. (This range was wider than those of Cu-PAN (pH 3—3.5),[4] XO (pH 6),[5] and MTB (pH 6).[6]) Therefore, there was no trouble in precipitating mercury(II) oxide in this acidic medium; thereby a considerably larger amount of mercury(II) ions than those reported in previous papers[1-3] could be determined accurately. Sharp color changes, *i. e.*, from deep violet to orange or to reddish orange, were observed at equivalence points. Except for a few anions and nickel(II), there were no interfering ions. Accordingly, TADC was also considered to be as a suitable metallochromic indicator as TAC, TAM and TACL for the direct titrimetric determination of mercury(II) ions with EDTA in an acidic medium.

Experimental

Preparation of TADC. TADC was prepared according to the method in the literature.[7] Several recrystallizations were repeated from hot ethanol. This crystals were obtained in a yield of 18%; mp 112—116°C (decomp.). Found: C, 40.04; H, 1.90; N, 14.65%. Calcd for $C_9H_5N_3OSCl_2$: C, 39.44; H, 1.84; N, 14.65%. IR: 3420 cm^{-1} (νO–H); 3100 cm^{-1} (νC–H of phenyl); 1248 cm^{-1} (δO–H); 1170 cm^{-1} (νC–O) and 730 cm^{-1} (νC–Cl).

Buffer Solutions. Buffer solutions with definite pHs were prepared by properly mixing 0.1M citric acid and 0.1M disodium hydrogenphosphate solutions.

The methods of purifying dioxane and of preparing a solution of the EDTA titrant and a stock solution of mercury(II) were the same as those described previously.[1-3]

Instruments. The absorption spectra were obtained with a Hitachi recording spectrophotometer (EPS-2) and a Hitachi electric spectrophotometer (EPU-2) with 10-mm silica cells. The infrared spectrum was obtained using an infrared spectrometer (DS-403G, Japan spectro-

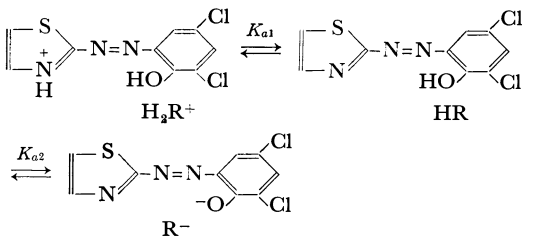
scopic Co., Ltd.). The pH was measured with a glass electrode pH meter (Hitachi-Horiba, F-5).

Results and Discussion

Acid Dissociation Constant of TADC in a 10% v/v Dioxane-Water Solution. The dissociation scheme of TADC is as follows:



The constants were obtained spectrophotometrically. If the acid dissociation constants are given by:

$$K_{a1} = \frac{[HR][H^+]}{[H_2R^+]} \text{ and } K_{a2} = \frac{[R^-][H^+]}{[HR]} \quad (1)$$

then the second step of the dissociation could be given as:

$$pK_{a2} = pH - \log \frac{A - \varepsilon_{HR}C_R}{\varepsilon_R - C_R - A} \quad (2)$$

where A is the total absorbance; C_R, the analytical concentration of TADC, and ε_x, the molar absorptivity of the species x.

The molar absorptivity was calculated from the horizontal lines of the pH-absorbance plots.

The absorption spectra of TADC scanned over pH 4.8—6.45 are illustrated in Fig. 1. There is an isosbestic point at 463 mμ, and the absorption maximum appears at 505 mμ. At higher pH values than 4.7 it is red or orange.

Though the figure is not given, the absorption curves in the range of pH 3.3—4.7 also showed the absorption maxima near 500 mμ, in accordance with the increasing pH values, but they have no isosbestic point at 463 mμ. The pK_{a2} value, therefore, was calculated from the absorbance at 505 mμ between pH 4.8 and 6.45 having the isosbestic point at 463 mμ, by means of Eq. (2). As a result, the second acid dissociation constant, pK_{a2}, was obtained as 5.3_8 in 10% v/v dioxane-water at μ=0.1 (KNO_3) and at room temperature. This value was, of course, lower than that of the mono-chloro derivative,[3] but was almost the same as that obtained in 20% v/v dioxane-water.[7]

The first step acid dissociation constant, pK_{a1}, was not estimated precisely because it was considered to be at a pH$<$0 value.

Absorbances and Absorption Spectra of the Mercury(II)-TADC Chelate in a Dioxane-Water Solution. A mixture of a large excess of mercury(II) and TADC was a clear violet. The maximum absorbance was obtained when the solution was prepared by mixing mercury(II) of 50-fold against TADC at pH 4.15 (Fig. 2). Figure 3 shows the absorption spectra of this mixture at various pHs, using water as the reference. In the pH range 2.3—5.0, the spectra showed an isosbestic point at 450 mμ and the absorption maxima at 570 mμ. The maxi-

pH: 1=2.29; 2=2.78; 3=3.35; 4=4.16; 5=5.03

mum molar absorptivity obtained from Fig. 3 was 11000; this was calculated by assuming the composition of the chelate to be mercury(II) : TADC=1 : 2. No discoloration was observed for 24 hr. Thus, it was suggested that TADC could by used as a suitable metallochromic indicator for the direct titration of mercury(II) ions in an acidic medium.

The absorption spectra of the mixtures containing equimolar solutions could not be scanned because precipitation tended to occur in a 10% v/v dioxane-water solution.

The pH adjustments in all the solutions described above were made with a citric acid and disodium hydrogenphosphate buffer system because the characteristic violet colour of the chelate was shown only when the pH adjustment was made with this buffer, whereas with other buffer systems, *e. g.*, a phosphate system and an acetic acid and sodium acetate system, the colour was not violet, but orange or reddish orange being considered to be a color due to a free reagent at those pHs. The reason of this phenomenon can not be explained.

Compositions of the Chelate. In order to examine the composition of the chelate, continuous variation plots at pH 4.50 and mole-ratio plots at pH 4.00 were made. In the case of continuous variation, the total concentration of mercury(II) plus TADC, and in the case of the mole ratio, the mercury(II) concentration, was kept constant at 10^{-4}M. The results are shown in Fig.4. As is

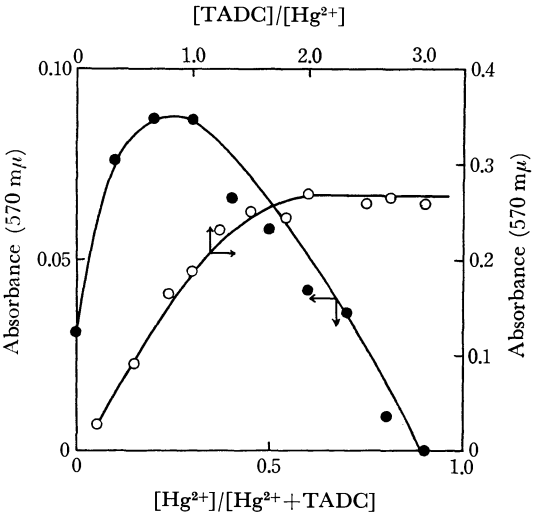

Fig. 4. Composition of the Hg(II)-TADC chelate.
—●— continuous variation. [Hg^{2+}+TADC]=1×10^{-4}M; pH=4.50.
—○— mole ratio. [Hg^{2+}]=1×10^{-4}M; pH=4.00.
10% (v/v) dioxane-water; μ=0.1 (KNO_3); room temp.; Ref.=water

shown in this figure, mercury(II) probably forms only a 1 : 2 chelate with TADC, regardless of the pH value. Moreover, the round refraction points of these plots suggest that the chelate is unstable.

Photometric Titration Curve. Photometric titrations at various pHs were carried out. The concentration of mercury(II) was 10^{-2}M, and several drops of alcoholic TADC solution (*ca.* 10^{-2}M) was added to the sample solution. A deep violet solu-

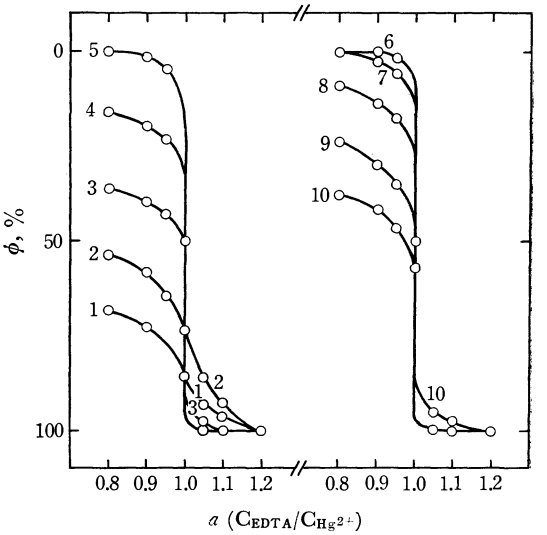

Fig. 5. Photometric titration curves.
$C_{Hg^{2+}}=10^{-2}$M; 10^{-1}M EDTA; Citric acid+Na_2HPO_4 buffer soln.
pH: 1=2.60; 2=2.90; 3=3.20; 4=3.59; 5=3.82; 6=4.49; 7=4.99; 8=5.51; 9=6.00; 10=6.50

tion was thus obtained. The concentration of the aqueous EDTA titrant was 10^{-1}M. The ϕ values were checked by means of the absorbances at 570 mμ. As can be seen in Fig. 5, in the pH range 3.8—5, sharp color changes, *i. e.*, from deep violet to orange or to reddish orange, were observed at the equivalence point. At the other pH values tested, color changes were observed before the equivalence point. In the pH 2.6—3.2 range and at 6.5, a tailing of the color change after the equivalence point was observed. The optimum pH range for the titration, therefore, was pH 3.8—5. This pH range was wider than that of such other indicators as Cu–PAN,[4] XO,[5] and MTB[6] used in acidic media.

Detectable Limit of Mercury(II). The detectable limit of the mercury(II) concentration by the titrimetry using TADC as the indicator was determined by checking the recoveries of mercury(II) ions at pH 4.50. Table 1 shows that there were

Table 1. Recovery of mercury(II) at various concentration at pH 4.50

Taken mg as Hg^{2+}/100 m*l*	Found mg as Hg^{2+}/100 m*l*	Error %
1.35	1.11	−10.4
2.26	2.36	+ 4.6
2.74	2.71	− 1.0
5.61	5.58	− 0.5
88.17	88.43	+ 0.3
104.90	104.79	− 0.1
250.30	251.30	+ 0.4
366.42	367.89	+ 0.4
487.19	485.73	− 0.3

large errors at concentrations of mercury(II) up to 2.74 mg/100 m*l* (corresponding to *ca.* 10^{-4}M as Hg(II)). These large errors can, for the reason mentioned in Fig. 2, be attributed to the weak color intensity of the chelate, which results in an uncertainty of color changes at the equivalence point. On the other hand, small errors within an accuracy range of $\pm 0.5\%$ were given at concentrations of more than 5.61 mg/100 m*l* (corresponding to *ca.* 2×10^{-4}M). Because of the lesser hydrolytic property of mercury(II) owing to an acidic media, the concentration of mercury(II) ions being determined was considerably higher than those*1 reported previously for TAC, TAM, and TACL.

Effect of Diverse Ions. An interference study was carried out. The depressions of the absorbances at 570 mμ were checked after the titration of aqueous sample solutions containing various amounts of diverse ions with an EDTA titrant (10^{-2}M). A 100 m*l* portion of the sample solution (10^{-3}M as Hg(II) ions) was kept at pH 4.5. The results are listed in Table 2. Negative errors were given by anions which form complex ions with mercury(II), whereas positive errors were given by metal ions forming complexes with the EDTA titrant. Cyanide, thiocyanate, ammonium, and halide, except when there is an excess of chloride, gave negative errors. As to metal ions, a large positive error was given by nickel(II) because the Ni(II)–TADC chelate showed an analogous violet color to that of the Hg(II)–TADC chelate at this pH. A 3 mg of cobalt(II), a 5 mg of iron(II) and a 10 mg of cadmium(II) gave small positive

Metal ions were added as nitrate.

*1 In previous papers[1-3] it was reported that the detectable limit was restricted to concentrations below 10^{-2}M, because hydrolysis of mercury(II) is likely to occur at concentrations higher than 10^{-2}M, as a result of the weakly alkaline media.

errors. However, no interference was caused by the presence of silver(I), copper(I), calcium(II), strontium(II), barium(II), manganese(II), lead(II), aluminum(III), chromium(III), and iron(III) ions up to 10 mg. Iron(III) ions seem generally to give a positive error, for the formation constant of FeY ($\log K_{FeY}=25.1$) is larger than that of HgY ($\log K_{HgY}=21.8$). However, there was no error by iron(III) ions in this experiment. It seems reasonable to assume that iron(III) forms, with the citric acid used as the buffer solution, a stable chelate whose formation constant ($\log K_{Fe-citr.}=25.0$[8]) is larger than that of the iron(III)-EDTA chelate.

The titration could be carried out accurately without heating the sample solution.

The above observations demonstrate that TADC can be utilized as a metallochromic indicator of mercury(II) with as high a sensitivity and accuracy as TAC, TAM, and TACL.

The author wishes to thank Professor Daisei Yamamoto of Kumamoto University for his encouragement throughout the work. The author's thanks are also due to the Ministry of Education for its financial support.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 763—769 (1970)

Kinetics of the Ligand Substitution Reaction of the Cobalt(II)-(Ethylene glycol)bis(2-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetate Complex with 4-(2-Pyridylazo)resorcinol

Shigenobu FUNAHASHI and Motoharu TANAKA

Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received July 10, 1969)

The kinetics of the ligand substitution reaction of the cobalt(II)-(ethylene glycol)bis(2-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetate complex (Co(II)-EGTA) with 4-(2-pyridylazo)resorcinol (PAR) have been studied photometrically in the pH range 8—9.4 at an ionic strength of 0.1 and at 25°C. The reaction proceeds simultaneously through two different reaction paths. Thus the rate law can be written as

$$\frac{d[CoR_2^-]}{dt} = k_1[CoY^{2-}][HR^-] + k_2[CoHY^-][HR^-]$$

where Y^{4-} and R^{2-} refer to tetravalent EGTA and divalent PAR respectively. Rate constants, k_1 and k_2 are $3.2 M^{-1}sec^{-1}$ and $2.1\times10^4 M^{-1}sec^{-1}$. Possible mechanism for the substitution is discussed. The stability constants for mercury(II)-EGTA complexes and cobalt(II)-EGTA complexes are determined by the mercury electrode method at $\mu=0.1$ and 25°C in order to analyze the substitution reaction: $K_{HgY}=10^{23.86\pm0.10}$, $K^H_{HgHY}=10^{3.06\pm0.10}$, $K_{CoY}=10^{12.3\pm0.1}$, $K^H_{CoHY}=10^{4.9\pm0.1}$, $K^H_{CoH_2Y}=10^{3.3\pm0.3}$.

In a previous paper,[1] the ligand substitution reaction of the zinc(II)-4-(2-pyridylazo)resorcinol complex (Zn(II)-PAR) with (ethylene glycol)-bis(2-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA) has been reported. The reaction was found to proceed, under the experimental conditions, through one path involving predissociation equilibrium of the Zn(II)-PAR complex. The rate constants were determined and the possible mechanism was discussed.

Since it seemed worth while to extend the study to the substitution reaction involving the other metal ion, the ligand substitution reaction of the cobalt(II)-(ethylene glycol)bis(2-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetate complex with 4(-2-pyridylazo)resorcinol:

$$\text{Co-EGTA} + \text{PAR} \rightleftharpoons \text{Co-PAR} + \text{EGTA} \quad (1)$$

was undertaken, where EGTA and PAR represent (ethylene glycol)bis(2-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic acid and 4-(2-pyridylazo)resorcinol respectively, and are abbreviated as H_4Y (hexadentate) and H_2R (tridentate) respectively. This paper gives the results.

Experimental

Reagents. *Cobalt(II) Perchlorate.* The reagent grade cobalt(II) chloride was recrystallized twice from distilled water. The recrystallized cobalt(II) chloride was then dissolved in perchloric acid, and hydrochloric acid and excess perchloric acid were expelled by an infrared lamp. The cobalt(II) perchlorate was recrystallized further from distilled water. The concentration of cobalt(II) ion was determined by a standard EDTA solution using xylenol orange as an indicator.

Mercuric Perchlorate. Mercuric perchlorate was prepared from mercuric nitrate by the same method as that for cobalt perchlorate. The solution was standardized against a standard EDTA solution using Erio T as an indicator.

Methods of preparation of all other reagents have been described previously.[1)]

Apparatus. The following instruments were used: a Horiba Model P pH meter; a Sharp Model TEB-10 thermoelectric circulating bath; a Beckman Model DU spectrophotometer with a thermostated cell compartment; a Jasco Model ORD/UV-5 optical rotatory dispersion recorder.

Determination of the Stability Constants of Cobalt(II)-EGTA Complexes. It is necessary to determine the stability constants of cobalt(II)-EGTA complexes in connection with the kinetic study of the substitution reaction. These stability constants were determined at ionic strength $\mu=0.1$ (sodium perchlorate) and 25°C.

Procedure of Measurements of Potential and pH. Potentials were measured by pH meter with the J shape tube mercury electrode using a saturated calomel electrode as a reference electrode. The latter was jacketted with a tube containing 1M potassium nitrate solution in order to avoid contamination of chloride ion. The pH was varied by the dropwise addition of carbonate-free sodium hydroxide or perchloric acid in an atmosphere of nitrogen.

Calculation of Stability Constants of Mercury-(II)-EGTA Complexes. The potential of a mercury electrode at 25°C is given by the following equation:

$$E = E^{\circ}_{Hg} + 0.0296 \log [Hg^{2+}]. \quad (2)$$

The value of the standard potential, E°_{Hg}, of the mercury electrode has been given by Latimer[2)] as 0.612 V *vs.* saturated calomel electrode at 25°C. The conditional stability constant, K'_{HgY}, of the mercury(II)-EGTA complex was determined from potential of the mercury electrode in a solution containing free EGTA and mercury(II)-EGTA complex. The potential is given by the relationship:

$$E = E^{\circ}_{Hg} + 0.0296 \log \frac{[HgY^{2-}]\alpha_{H(Y)}}{[Y']K'_{HgY}}, \quad (3)$$

where $[Y']=[Y^{4-}]\alpha_{H(Y)}$ and $\alpha_{H(Y)}$ is the side reaction coefficient taking into account the protonation of Y^{4-}. $K'_{HgY}=[HgY']/[Hg^{2+}][Y^{4-}]$ and [HgY'] refers to the total concentration of normal and protonated complexes of mercury(II)-EGTA. As the concentration of EGTA added is about twice that of mercury ion added and the stability constant of mercury(II)-EGTA is very high, the following relationships hold with a good approximation:

$$[HgY'] = C_{Hg}, \quad [Y']=C_Y-C_{Hg}, \quad (4)$$

where C_{Hg} and C_Y are the total concentrations of added mercury ion and EGTA respectively. Thus we have

$$E = E^{\circ}_{Hg} + 0.0296 \log \frac{C_{Hg}\alpha_{H(Y)}}{(C_Y-C_{Hg})K'_{HgY}}. \quad (5)$$

Therefore K'_{HgY} can be calculated from potential-pH measurements. Values of log K'_{HgY} at various pH's are tabulated in Table 1.

Table 1. Values of log K'_{HgY} at various pH's for determination of the stability constants of HgY^{2-} and $HgHY^{-}$
$C_{Hg}=2\times10^{-3}$M, $C_Y=4\times10^{-3}$M, 25°C, $\mu=0.1$

pH	log K'_{HgY}	pH	log K'_{HgY}
2.69	24.35	4.28	23.83
2.82	24.33	4.94	23.85
3.09	24.15	6.20	23.92
3.24	25.08	8.32	23.88
3.54	23.98	8.52	23.88
3.94	23.93	9.29	23.80

Since the log K'_{HgY}-pH diagram gives a curve of a limiting slope of unity at lower pH, the presence of protonated complex of mercury(II)-EGTA is anticipated. Thus

$$K'_{HgY} = \frac{[HgY^{2-}]+[HgHY^{-}]}{[Hg^{2+}][Y^{4-}]} = (1+K^{H}_{HgHY}[H^+])K_{HgY}, \quad (6)$$

where

$$K_{HgY} = \frac{[HgY^{2-}]}{[Hg^{2+}][Y^{4-}]} \text{ and } K^{H}_{HgHY} = \frac{[HgHY^{-}]}{[HgY^{2-}][H^+]}.$$

In the pH range 5 to 9 K'_{HgY} is independent of hydrogen ion concentration. This value is obviously equal to K_{HgY} from the definition of K'_{HgY}. The following values are obtained: log $K_{HgY}=23.86\pm0.10$, log $K^{H}_{HgHY}=3.06\pm0.10$. The value of log K_{HgY} compares favorably with the value 23.8 reported by Holloway and Reilley.[3)]

Stability Constants of Cobalt(II)-EGTA Complexes. As the stability constant of HgY^{2-} is higher than that of CoY^{2-} and the total concentration of EGTA and that of cobalt ion added, C_Y and C_{Co}, are about twice that of mercury ion, the following relationships hold:

$$C_{Hg} = [HgY'] \quad (7)$$

$$C_Y - C_{Hg} = [CoY'] + [Y'] \quad (8)$$

$$[Co'] = C_{Hg} + C_{Co} - C_Y + [Y'] = [Co^{2+}]\alpha_{OH(Co)} \quad (9)$$

$$E = E^{\circ}_{Hg} + 0.0296 \log \frac{K'_{CoY}C_{Hg}[Co']}{K'_{HgY}[CoY']\alpha_{OH(Co)}}. \quad (10)$$

where $\alpha_{OH(Co)}$ is the side reaction coefficient taking into account the hydrolysis of cobalt ion. We can calculate

2) W. M. Latimer, "Oxidation Potentials," 2nd Ed., Prentice-Hall, New York (1952), p. 179.

3) J. H. Holloway and C. N. Reilley, *Anal. Chem.*, **32**, 249 (1960).

pY from the following equation:

$$E = E^{\circ}_{Hg} + 0.0296 \log \frac{C_{Hg}}{K'_{HgY}} + 0.0296\,pY. \quad (11)$$

Thus with a knowledge of [Y′], [CoY′] and [Co′] are obtained from Eqs. (8) to (9) respectively, and K'_{CoY} is calculated from Eq. (10). As shown in Fig. 1,

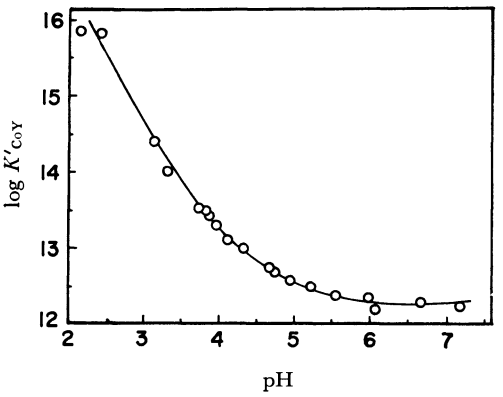

Fig. 1. Determination of the stability constants of CoY^{2-}, $CoHY^{-}$ and CoH_2Y. Solid line is the theoretical curve calculated with values obtained by means of the curve fitting. At μ=0.1, 25°C.

the log K'_{CoY}-pH diagram tends to give a curve of limiting slope of 2 at lower pH. This fact points to the presence of CoY^{2-}, $CoHY^{-}$ and CoH_2Y species. Then

$$K'_{CoY} = \frac{[CoY^{2-}]+[CoHY^{-}]+[CoH_2Y]}{[Co^{2+}][Y^{4-}]}$$

$$= K_{CoY}(1+K^{H}_{CoHY}[H^+]+K^{H}_{Co_2HY}K^{H}_{CoHY}[H^+]^2), \quad (12)$$

where

$$K_{CoY} = \frac{[CoY^{2-}]}{[Co^{2+}][Y^{4-}]}, \quad K^{H}_{CoHY} = \frac{[CoHY^{-}]}{[CoY^{2-}][H^+]}$$

and

$$K^{H}_{Co_2HY} = \frac{[CoH_2Y]}{[CoHY^{-}][H^+]}.$$

By means of a "curve fitting" method the following results were obtained: log K_{CoY}=12.3±0.1, log K^{H}_{CoHY}=4.9±0.1, log $K^{H}_{CoH_2Y}$=3.3±0.3. The value of log K_{CoY} compares favorably with the previous finding 12.3.[3] These constants are used in the analysis of the kinetic data.

Equilibrium. As seen from the values of stability constants of EGTA (log K^{H}_{HY}=9.43, log $K^{H}_{H_2Y}$=8.85, log $K^{H}_{H_3Y}$=2.68, log $K^{H}_{H_4Y}$=2.07[4]), Y^{4-}, HY^{3-}, and H_2Y^{2-} species may be present in the pH range 8 to 9.4 investigated. The 1 : 1 normal cobalt(II)-EGTA complex exists under these experimental conditions. In the pH range 8 to 9.4, the dominant species of PAR is found to be the monoionic species (HR^{-}) from the stability constants of PAR (log $K^{H}_{H_2R}$=2.69, log $K^{H}_{H_2R}$=5.50, log K^{H}_{HR}=12.31[5]). The monoionic species has maximum absorption at 410 nm and the absorbance of PAR is independent of pH in this pH range. The molar absorption coefficient is 8.14×10^2 at 510 nm. The molar ratio of cobalt to PAR in cobalt-PAR complex is 1 : 2.[6,7] Cobalt-PAR complex has maximum absorption at 510 nm and its molar absorption coefficient is 6.40×10^4 at 510 nm.

The equilibrium 1 is much favored to the right under the present experimental conditions, so that the reverse reaction can be neglected in the kinetic study. Therefore the stoichiometry of the present substitution reaction is expressed as

$$CoY^{2-} + 2HR^{-} \rightarrow CoR_2^{-} + Y', \quad (13)$$

where Y′ denotes nonmetallized EGTA.[8]

Procedure of Measurement of the Substitution Reaction Rate. pH of the cobalt-EGTA solution, prepared by mixing cobalt perchlorate solution with EGTA solution in excess, is buffered with borax and boric acid or sodium hydroxide and the ionic strength maintained constant (μ=0.1) with sodium perchlorate. The cobalt-EGTA solution and the PAR solution are brought to the temperature equilibrium in a bath kept at 25±0.2°C. The velocity of the substitution reaction is sufficiently slow to be studied by manual mixing techniques. The reaction is commenced by mixing these two solutions. A portion of the reaction mixture is transferred to a spectrophotometer cell at different intervals, and the absorbance of cobalt-PAR complex is measured at 510 nm, a spectrophotometer being used with a thermostated cell compartment capable of temperature control±0.3°C. All experiments are carried out in a room thermostated at 25±1°C.

Results

Beer's law is obeyed for the cobalt-PAR complex and the reaction(13) goes to completion. Therefore, if the substitution reaction of cobalt-EGTA with PAR in large excess is of the pth order with respect to cobalt-EGTA, the order of the reaction with respect to cobalt-EGTA is given by the slope, p, of the straight line obtained in a plot[1] of log $d(E_t-E_0)/dt$ against log $(E_\infty-E_t)$. The plot gave a straight line of slope 1. Therefore the reaction is of the first order in cobalt-EGTA. Thus for the reactions with a large excess of PAR the rate law is expressed as:

$$\frac{d[CoR_2^{-}]}{dt} = k_{0(R,H)}[CoY^{2-}], \quad (14)$$

5) W. J. Geary, G. Nickless and F. H. Pollard, *Anal. Chim. Acta*, **27**, 71 (1962).

6) A. Corsini, Q. Fernando and H. Freiser, *Inorg. Chem.*, **2**, 224 (1963).

7) A. I. Busev, V. M. Ivanov and Zh. I. Nemtseva, *Zh. Neorg. Khim.*, **13**, 511 (1968).

8) We assume trivalent cobalt to be in the cobalt-PAR complex according to a previous finding (T. Iwamoto and M. Fujimoto, *Anal. Chim. Acta*, **29**, 282 (1963)). However, electron transfer does not seem to make any obstacle in studying the present ligand substitution reaction (see Discussion).

where $k_{0(R,H)}$ denotes the conditional rate constant[1] involving the concentration terms of PAR and hydrogen ion.

The kinetic studies performed with a 20—50-fold excess of the entering group PAR showed that the reaction was of the first order in PAR. The fact is also supported by the good linearity of the second order plots concerning cobalt-EGTA and PAR:

$$\frac{1}{C_{PAR}-2C_{Co}} \ln \frac{C_{Co}(C_{PAR}-2[CoR_2^-])}{C_{PAR}(C_{Co}-[CoR_2^-])} = k_{0(H)}t.$$

Typical second order plots are shown in Fig. 2.

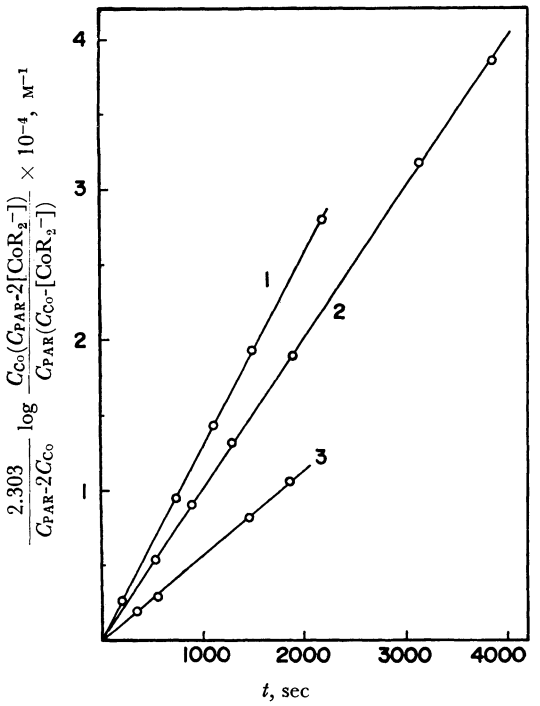

Fig. 2. Typical second order plots. For these runs the experimental conditions were as follows: $C_{Co}=1.09\times10^{-5}$M, $C_{PAR}=7.00\times10^{-5}$M, $C_Y=5.00\times10^{-5}$M, 1: pH=8.33; 2: pH=8.45; 3: pH=8.86, ionic strength=0.1M ($NaClO_4$), reaction temperature=25°C.

Under the experimental condition, predominant species of PAR is HR^- ($K^H_{HR}=10^{12.31}$ and $K^H_{H_2R}=10^{5.50}$).[5] Therefore, the rate law is expressed as

$$\frac{d[CoR_2^-]}{dt} = k_{0(H)}[CoY^{2-}][HR^-], \qquad (15)$$

where $k_{0(H)}$ refers to the conditional second order rate constant. The conditional rate constant $k_{0(H)}$ was determined at various pH's, concentrations of EGTA and concentrations of PAR.

Some results obtained are tabulated in Table 2. The values of $k_{0(H)}$ are plotted against the hydrogen ion concentration in Fig. 3, which indicates a linear relationship between $k_{0(H)}$ and $[H^+]$ within experimental error regardless of the concentration

Table 2. Conditional second order rate constants for the substitution reaction of cobalt-EGTA with PAR

μ=0.1, 25°C, $C_{Co}=9.78\times10^{-6}$M (Runs No. 1—14) or 1.09×10^{-5}M (Runs No. 15—23).

Run No.	C_{PAR} (M)	C_Y (M)	pH	$k_{0(H)}$ ($M^{-1}sec^{-1}$)

10	2.00×10^{-4}	2.00×10^{-3}	8.00	19.0
11	2.00×10^{-4}	2.00×10^{-3}	8.04	19.8
12	2.00×10^{-4}	2.00×10^{-3}	8.09	16.6
13	2.00×10^{-4}	2.00×10^{-3}	8.12	16.8
14	2.00×10^{-4}	2.00×10^{-3}	8.25	12.8
15	7.00×10^{-5}	2.00×10^{-5}	8.63	7.82
16	7.00×10^{-5}	5.00×10^{-5}	8.33	12.9
17	7.00×10^{-5}	5.00×10^{-5}	8.45	10.1
18	7.00×10^{-5}	5.00×10^{-5}	8.86	5.60
19	7.00×10^{-5}	1.00×10^{-4}	8.62	7.85
20	7.00×10^{-5}	1.00×10^{-3}	8.52	8.88
21	7.00×10^{-5}	1.00×10^{-3}	8.18	14.5
22	7.00×10^{-5}	2.00×10^{-3}	8.11	15.9
23	7.00×10^{-5}	2.00×10^{-3}	8.37	9.39

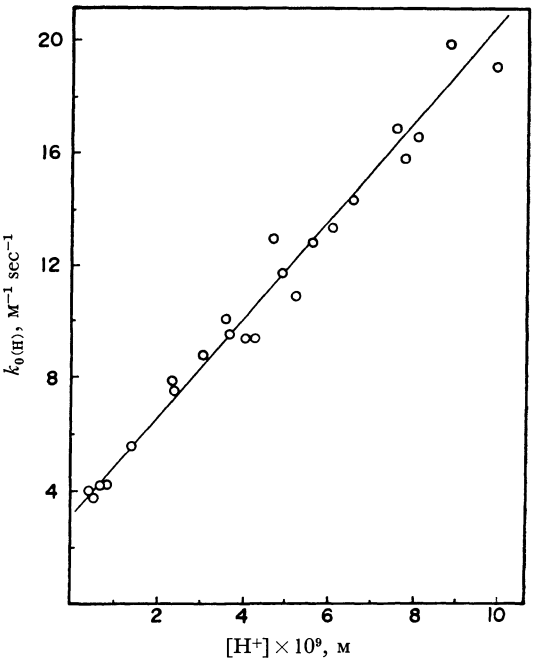

Fig. 3. $k_{0(H)}$ as a function of hydrogen ion concentration C_{Co}=about 10^{-5}M, $C_Y=2\times10^{-5}$ to 2×10^{-3}M, $C_{PAR}=7\times10^{-5}$ to 4×10^{-4}M, μ=0.1, 25°C.

of EGTA. Thus we obtain the following rate expression:

$$\frac{d[CoR_2^-]}{dt} = k_1[CoY^{2-}][HR^-] + k_2'[H^+][CoY^{2-}][HR^-]. \quad (16)$$

From the intercept and slope in Fig. 3 k_1 and k_2' may be obtained: $k_1=3.2\,M^{-1}\,sec^{-1}$ and $k_2'=1.7\times10^9\,M^{-2}\,sec^{-1}$. The second term of Eq. (16) shows the participation of the proton complex $CoHY^-$. Thus substituting the stability constant of $CoHY^-$ determined in the present study, we have

$$\frac{d[CoR_2^-]}{dt} = k_1[CoY^{2-}][HR^-] + \frac{k_2'}{K^H_{CoHY}}[CoHY^-][HR^-]$$
$$= k_1[CoY^{2-}][HR^-] + k_2[CoHY^-][HR^-]. \quad (17)$$

The rate constants k_1 and k_2 at ionic strength $\mu=0.1$ and 25°C are $3.2\,M^{-1}\,sec^{-1}$ and $2.1\times10^4\,M^{-1}\cdot sec^{-1}$, respectively.

Discussion

Mechanism of the Present Ligand Substitution Reaction. PAR forms a 1 : 2 complex with cobalt and the formation of cobalt-PAR is of the first order in the concentration of PAR. The rate of the addition of the second PAR is much faster than the rate of addition of the first PAR.

The first step of complexation is in general rate-determining: the fact that the rate constants increase with increasing degree of association of ligand with metal has been provided by Hammes and Steinfeld[9] in successive substituion of nickel or cobalt with glycine. Honaker and Freiser[10] reported that the addition of the first ligand is rate controlling in the rate of extraction of zinc dithizonate from aqueous solution. Pearson and Ellgen[11] have shown that in the complex formation reactions of nickel(II) ion with dithioxalate or maleonitriledithiolate the formation of monoligand nickel(II) complex is rate-determining. Recently, the labilizing effect of a coordinated ligand in the substitution reaction has been quantitatively accounted for by a study of kinetics of the formation of nickel(II)-PAR complex from some monovalent monoacidopentaaquonickel(II) complexes.[12]

Proton transfer reactions are extremely rapid and the proton will tend to be in the position of the greatest basicity. Usually the reaction rate increases with decreasing pH if the protons are more attracted to the leaving group.[13]

It is suggested therefore that the first order dependence of the cleavage rate on hydrogen ion concentration is due to a rapid acid-base reaction preceding the rate-determining step. From this consideration, in the present case, the second term of Eq. (17) clearly shows the participation of a protonated complex $CoHY^-$ which is in equilibrium preceding the rate-determining step. From the stability constant K^H_{CoHY} of $10^{4.9}$ determined in the present study, the concentration of protonated complex $[CoHY^-]$ is found only 0.1 to 0.01% of that of the total cobalt-EGTA complex in the range of pH 8 to 9. Nevertheless the reaction path through the protonated complex is important in the present substitution reaction, because $CoHY^-$ is much more reactive than CoY^{2-}.

Margerum and Rosen[14] have recently shown a clear evidence for a series of intermediates in equilibrium with one another in the reaction of EDTA with mono- and bis(diethylenetriamine)-nickel(II) complexes. In the present case, there may be a successive dissociation of donor atoms in EGTA, before three sites of coordination at least are available for the incoming PAR. Thus the cleavage of nitrogen atom bonded to the central metal in the mixed ligand intermediates, RCoY and RCoHY, should be rate-determining.[1] The coordination of the second PAR molecule to the resulting 1 : 1 cobalt-PAR complex is fast.[12]

Reactions of CoY^{2-} and $CoHY^-$ with PAR are schematically given in Fig. 4. We assume the partial dissociation of cobalt-EGTA bonds (Steps K_I and K_I') followed by the incorporation of PAR to form the mixed ligand intermediates, RCoY and RCoHY (Steps K_{II} and K_{II}'). According to the proposed mechanism, the rate law (17) can be rewritten as

$$\frac{d[CoR_2^-]}{dt} = k_1[CoY^{2-}][HR^-] + k_2[CoHY^-][HR^-]$$
$$= \frac{k_1}{K_IK_{II}}[RCoY] + \frac{k_2}{K_I'K_{II}'}[RCoHY]$$
$$= k_I[RCoY] + k_{II}[RCoHY],$$

where $k_I=k_1/K_IK_{II}$ and $k_{II}=k_2/K_I'K_{II}'$. The estimation of the ratio k_I/k_{II} may be interesting. We have immediately.

$$\frac{k_I}{k_{II}} = \frac{k_1}{k_2}\frac{K_I'K_{II}'}{K_IK_{II}}$$

As it appears reasonable to assume that $K_I'/K_I=K_{CoY}/K^{HY}_{CoHY}$ and that the value of K_I does not differ appreciably from K_{II}', we put $K_{II}\simeq K_{II}'$. Then with the observed rate and formation con-

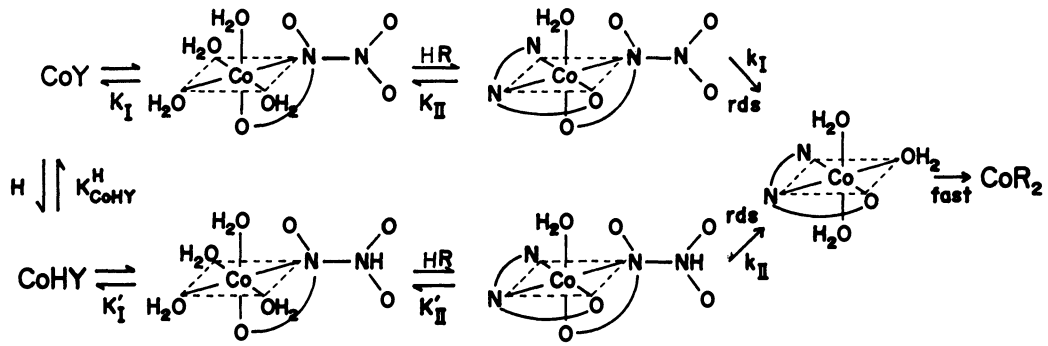

Fig. 4. Proposed mechanism of the substitution reactions of CoY and CoHY with PAR. EGTA and PAR are symbolized respectively as  and N–N–O. Charges are omitted for simplicity.

stants, we obtain $k_{II}/k_I=5$, *i.e.*, k_I and k_{II} are of the same order of magnitude. In other words the difference between k_1 and k_2 is mostly determined by the difference between the overall formation constants of the mixed ligand intermediates, $K^R_{RCoY}=K_IK_{II}$ and $K^R_{RCoHY}=K_I'K_{II}'$. The ratio K_{CoY}/K^{HY}_{CoHY} would be a measure of k_2/k_1 in the proposed mechanism.

Oxidation State of Cobalt in the Product CoR_2 and in the Intermediate RCoY. 1-(2-Pyridiylazo)-2-naphthol (PAN) is similar to PAR and forms 1:2 cobalt-PAN complex. On mixing a cobalt(II) solution with an excess of PAN the color of the solution (pH 8) change gradually from red to green in a few minutes. This corresponds to the oxidation of the red cobalt(II)-PAN complex to the green cobalt(III) complex by atmospheric oxygen. On the other hand, mixing a cobalt(II) solution with a PAR solution results immediately in a red solution, which does not change in color. The trivalent state of cobalt in the green PAN complex and in the red PAR complex has been confirmed by magnetic susceptibility measurements.[15]

We studied qualitatively the rate of the acid dissociation reactions of cobalt-PAN and cobalt-PAR complexes. Solutions of red cobalt-PAN, green cobalt-PAN and red cobalt-PAR complexes were made acidic (pH 1 or lower) with 10 M perchloric acid. Then the color of the red cobalt-PAN complex changed immediately to reddish yellow which is the color of protonated PAN, while the color of the green cobalt-PAN and red cobalt-PAR complexes remained unchanged for at least a week. Similar experiments were carried out on nickel complexes. Upon acidification with perchloric acid, the color of the red nickel-PAN and nickel-PAR complexes changed to the color of a free ligand.

As expected from the inertness of trivalent cobalt complexes, the reaction of cobalt(III)-EDTA complex with PAN and that of cobalt(III)-PAN with EDTA do not proceed at all, for at least a week. Thus the cobalt in the labile red cobalt-PAN complex is divalent, while the cobalt in the inert (or thermodynamically very stable) green cobalt-PAN and the inert red cobalt-PAN complexes is trivalent. The result agrees with the previous conclusion drawn from the magnetic susceptibility of these complexes.[15] Trivalent state of cobalt seems to be more stabilized in the cobalt-PAR complex than in the corresponding PAN complex by the effect of the electron flow from the dissociated *para*-hydroxyl group of PAR into benzene ring. The same effect seems to be responsible for the fact that the cobalt(III)-PAR complex absorbs at a shorter wavelength than the cobalt(III)-PAN complex.

The rate of electron transfer in the system of tris-(1,10-phenanthroline)-cobalt(II)——tris(1,10-phenanthroline)-cobalt(III) is faster by about five orders of magnitude than that of cobalt(II)-EDTA ——cobalt(III)-EDTA. This fact has been explained on the basis of the difference in the ligand field strength.[16,17] If the cobalt in the intermediate RCoY were trivalent, the dissociation of EGTA from the intermediate would be impossible. Thus the cobalt in the intermediate RCoY should be divalent. Since the ligand field of PAR is stronger than that of EGTA, it seems reasonable that the oxidation of cobalt(II) occurs immediately after the incorporation of the second PAR molecule.

On the other hand, the substitution of nickel(II)-EGTA complex with PAR[18] is about 10 times slower than the corresponding reaction of cobalt(II) complexes studied in the present work. This is just as expected from the ligand field theory and

agrees with a great number of experimental results.

It seems plausible that, in the step of the dissociation of EGTA from the intermediate RCoY, cobalt is divalent. The oxidation of cobalt(II) occurs after the dissociation of EGTA followed by the incorporation of the second PAR molecule.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 769—773 (1970)

Kinetics of the Ligand Substitution Reaction of the Copper(II)-4-(2-Pyridylazo)resorcinol Complex with (Ethylene glycol)-bis(2-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic Acid

Shigenobu FUNAHASHI, Shinkichi YAMADA and Motoharu TANAKA

Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received July 21, 1969)

The kinetics of the ligand substitution reaction of the copper(II)-4-(2-pyridylazo)resorcinol complex (Cu(II)-PAR) with (ethylene glycol)bis(2-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA) has been studied spectrophotometrically at pH 9—10 at μ=0.10 ($NaClO_4$) and at 25.0°C. The reaction proceeds through the 1 : 1 Cu(II)-PAR complex resulting from the predissociation equilibrium of the 1 : 2 Cu(II)-PAR complex:

$$-d[CuR_2^{2-}]/dt = 10^{6.15}[CuR_2^{2-}][H^+][Y']/[HR^-] = 10^{2.9}[CuR][Y']$$

where R^{2-} refers to the divalent anion of PAR (H_2R) and Y′ the free EGTA not combined with any metal. The release of PAR from the mixed ligand intermediate RCuY is the rate-determining step. The substitution reaction for the copper(II)-PAR complex proceeds in the same mechanism with that for the zinc(II)-PAR complex. The difference in reactivity of these complexes is discussed. Cu-PAR bond is weakened in a distorted octahedron of the intermediate RCuY before the release of PAR.

Many works have been devoted to the kinetics and mechanisms of the exchange of polyaminocarboxylic acid anion (*e.g.* EDTA) between metal ions. A general mechanism has been proposed by Margerum and Bydalek[1] for the exchange of a multidentate ligand between metal ions that involves a dinuclear intermediate species, in which the multidentate ligand is partially unwound from the initially complexed metal ion and partially attached to the attacking metal ion. We have studied the substituion of metal chelates with multidentate ligands which are often involved in the complexometric titration and the solvent extraction of metal chelates.

In a previous paper,[2] the ligand substitution reaction of the zinc(II)-4-(2-pyridylazo)resorcinol complex (Zn(II)-PAR) with (ethylene glycol)bis-(2-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA) has been reported. The reaction was found to proceed through one path involving predissociation equilibrium of the zinc(II)-PAR complex, and the possible mechanism was discussed.

It seemed worth while to extend the study to the substitution reaction involving the other metal ion, and the ligand substitution reaction of the copper(II)-4-(2-pyridylazo)resorcinol complex with (ethylene glycol)bis(2-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic acid

$$\text{Cu(II)-PAR} + \text{EGTA} \rightleftharpoons \text{Cu(II)-EGTA} + \text{PAR} \quad (1)$$

was undertaken, where EGTA and PAR represent (ethylene glycol)bis(2-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic acid and 4-(2-pyridylazo)resorcinol respectively and are abbreviated as H_4Y (hexadentate) and H_2R (tridentate) respectively. This paper gives the results.

Results

It is necessary to determine the stability constants of copper(II)-PAR complexes in connection with

1) T. J. Bydalek and D. W. Margerum, *J. Amer. Chem. Soc.*, **83**, 4326 (1961); *Inorg. Chem.*, **1**, 852 (1962); **2**, 678 (1963); **2**, 683 (1963).

2) M. Tanaka, S. Funahashi and K. Shirai, *Inorg. Chem.*, **7**, 573 (1968).

the equilibria involved in the substitution reaction. Thus the stability constants of the copper(II)-PAR complexes have been determined spectrophotometrically at $\mu=0.10$ ($NaClO_4$) and at 25.0°C:

$$[CuHR^+]/[Cu^{2+}][HR^-] = 10^{9.90\pm0.05},$$
$$[CuHR^+]/[CuR][H^+] = 10^{5.00\pm0.05},$$
$$[CuR]/[Cu^{2+}][R^{2-}] = 10^{17.20\pm0.05},$$
$$[CuR_2^{2-}]/[CuR][R^{2-}] = 10^{9.1\pm0.2}.$$

Details will be reported elsewhere.[3]

Methods of preparation of the reagents and kinetic measurements have been described previously.[2-4]

Under the present experimental conditions the copper(II) forms with PAR quantitatively the 1 : 2 complex CuR_2^{2-}. The absorbance of the copper(II)-PAR complex is constant over a pH range 9 to 10. The molar absorption coefficient is 6.87×10^4 at 515 nm. The dominant species of PAR is the singly charged species (HR^-), and the species of EGTA involves Y^{4-}, HY^{3-} and H_2Y^{2-}. The copper(II)-EGTA complex is the 1 : 1 complex CuY^{2-} ($K_{CuY}=10^{17.8}$).[5] Equilibrium (1) is much favored to the right so that the substitution reaction of the copper(II)-PAR complex with EGTA goes substantially to completion and the reverse reaction can be neglected.

For the reaction with large excesses of PAR and EGTA the rate law can be expressed as

$$-\frac{[CuR_2^{2-}]}{dt} = k_{0(H,R,Y)}[CuR_2^{2-}], \qquad (2)$$

where $k_{0(H,R,Y)}$ is the conditional rate constant[6] involving concentration of PAR, EGTA and hydrogen ion. The rate plots of $\log (E_0-E_\infty)/(E_t-E_\infty)$ *vs.* t were linear at least for over 90% of reaction. The conditional rate constant $k_{0(H,R,Y)}$ was determined from the slope of the straight line. The values of conditional rate constants at various concentrations of PAR, at a concentration of EGTA, and at constant pH are given in Table 1 (Runs No. 1—9). These data indicate clearly a linear relationship between $k_{0(H,R,Y)}$ and the reciprocal concentration of PAR with the zero intercept. In Fig. 1, the values of $k_{0(H,R,Y)}$ determined at various pH's and concentrations of EGTA and PAR are plotted against the hydrogen ion concentration and some data of $k_{0(H,R,Y)}$ are tabulated in Table 1. It is evident from Fig. 1 that $k_{0(H,R,Y)}$ is linearly related to hydrogen ion concentration and that the rate increases with increasing EGTA concentration. The plots give the zero intercept (Figs. 1 and 2). The substitution reaction is of first order with respect to EGTA and hydrogen ion. Thus the rate law is given by

$$-\frac{d[CuR_2^{2-}]}{dt} = k_0\frac{[CuR_2^{2-}][H^+][Y']}{[HR^-]}. \qquad (3)$$

This rate law is consistent with the reaction mechanism:

$$CuR_2^{2-} + H^+ \rightleftharpoons CuR + HR^-, \qquad (4)$$
$$CuR + Y' \rightleftharpoons RCuY \rightleftharpoons CuY^{2-} + HR^-. \qquad (5)$$

EGTA reacts with CuR in equilibrium with CuR_2^{2-}. Substituting the equilibrium constants in Eq. (4),

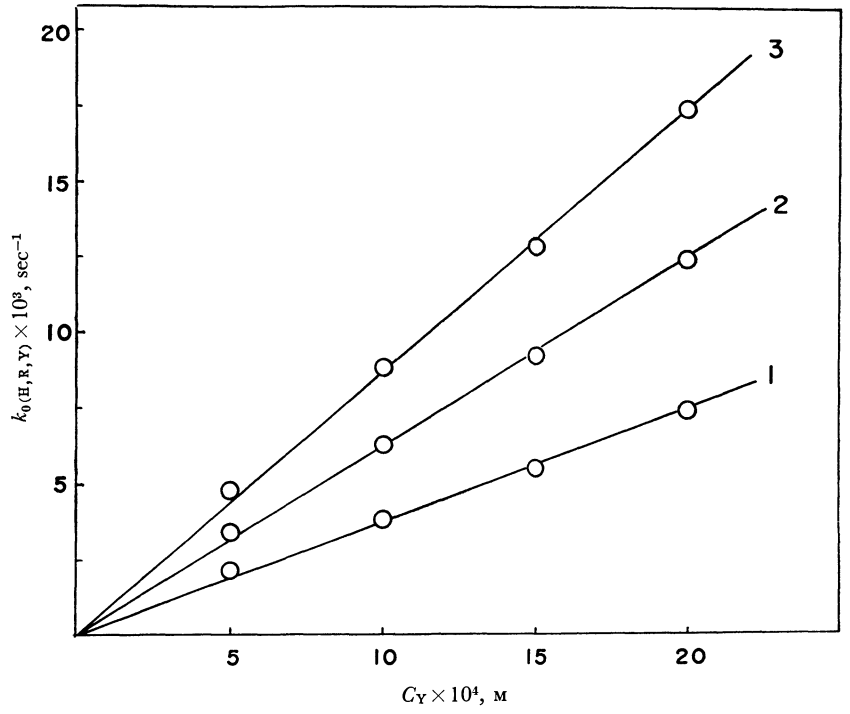

Fig. 2. $k_{0(H,R,Y)}$ as a function of EGTA concentration.
$C_{Cu}=1.00\times10^{-6}$M; $C_R=1.00\times10^{-4}$M; pH=1, 9.52; 2, 9.30; 3, 9.16; $\mu=0.10$($NaClO_4$); temperature, 25.0°C

the rate law can be rewritten as

$$-\frac{d[CuR_2^{2-}]}{dt} = k_0\frac{K^R_{CuR_2}}{K^H_{HR}}[CuR][Y'] = k[CuR][Y'], \quad (6)$$

where

$$K^R_{HR} = [HR^-]/[R^{2-}][H^+] = 10^{12.30}\ ^{6)}.$$

Under the present experimental conditions, Y^{4-}, HY^{3-} and H_2Y^{2-} are present. However, we observe no variation of the rate with varying proportion of these species of EGTA. The rate constants k_0 and k determined in this investigation are $1.4\pm0.4\times10^6$ M^{-1} sec^{-1} and $8.8\pm0.3\times10^2$ M^{-1}·sec^{-1}, respectively.

Discussion

Margerum and Rosen[7] have recently shown a clear evidence for a series of intermediates in equilibrium with one another in the reaction of EDTA with mono- and bis(diethylenetriamine)-nickel(II) complexes. We have reported the kinetics of the ligand substitution reaction of the zinc(II)-4-(2-pyridylazo)-resorcinol complex with (ethylene glycol)bis(2-aminoethyl ether)-*N,N,N',N'*-tetraacetic acid. The substitution reaction of copper(II)-PAR proceeds through the same mechanism with that of zinc(II)-PAR, *i.e.*, the cleavage of PAR bonded to the central metal in the mixed ligand intermediate, RMY, should be rate-determining (M denotes Zn or Cu).[2]

We assume the 1 : 1 M-PAR complex and EGTA are in rapid equilibrium with the mixed ligand complex in which EGTA is bonded to the central metal ion with a segment of EGTA and the rate-determining step is the loss of PAR from the mixed ligand intermediate. Since PAR is not as flexible as aliphatic polyamines, it is not likely that EGTA reacts with PAR complexes *via* a stepwise removal of donor atoms of PAR from the central metal as postulated previously in the substitution of polyamine complexes of nickel with EDTA.[8] As soon as one donor atom of PAR is removed from the central metal ion in the intermediate RMY, the other two will also be detached. This step should be the rate-determining step. Thus the reaction of ZnR and CuR with EGTA is given by

$$MR + Y' \overset{K_{RMY}}{\rightleftharpoons} RMY \overset{k_R^M}{\longrightarrow} MY^{2-} + HR^-, \quad (7)$$

where $K_{RMY}=[RMY]/[MR][Y']$ is the stability constant of the intermediate. If the reaction follows the mechanism given in Eq. (7), the experimentally determined rate constants, k^M, can be equated with the corresponding rate constants for metal-PAR bond rupture, $k_R{}^M$, by

$$k^M = K_{RMY}k_R{}^M. \quad (8)$$

According to the proposed mechanism, the rate law (6) can be rewritten as

$$-\frac{d[MR_2^{2-}]}{dt} = k^M[MR][Y'] = \frac{k^M}{K_{RMY}}[RMY] = k_R{}^M[RMY]. \quad (9)$$

It is interesting to compare the ratio k_R^{Cu}/k_R^{Zn} with the ratio of rate constants of dissociation of PAR from CuR and ZnR. Unfortunately, experimental K_{RMY} values are not available for the system studied. Consequently, it is necessary to rely on estimates. The second stability constants, $K^X_{MX_2}=[MX_2]/[MX][X]$, for copper(II) and zinc(II) with various tridentate ligand similar to PAR and a segment of EGTA are compared. Plots of $\log K^X_{CuX_2}$ *vs.* $\log K^X_{ZnX_2}$ are shown in Fig. 3. The plots lie close to a straight line with a slope of unity and zero intercept: the value of $K^X_{CuX_2}$ does not seem to differ appreciably from $K^X_{ZnX_2}$. Thus it appears reasonable to assume $K_{RCuY}\cong K_{RZnY}$. Then

$$\frac{k_R{}^{Cu}}{k_R{}^{Zn}} = \frac{k^{Cu}/K_{RCuY}}{k^{Zn}/K_{RZnY}} = \frac{k^{Cu}}{k^{Zn}} = 10^{-1.5}, \quad (10)$$

where the value of k^{Zn} is 2.4×10^4M^{-1} sec^{-1} at 25.0°C and $\mu=0.10$.[2]

The release of a water molecule from an aquo metal ion is the rate-determining step in the complex formation.[9-12] Though the rate constants for formation of CuR and ZnR are not yet available, they will very probably be comparable to the rate constants $k^M_{H_2O}$ of the substitution of coordinated water molecules of corresponding aquo metal ion M. Therefore, the rate of dissociation of CuR and ZnR can be estimated from the stability constants and the rate constants of formation of these complexes. We have immediately the ratio of the rate constants of dissociation of PAR from the 1 : 1 M-PAR complexes:

$$\frac{k^{Cu}_{H_2O}/K^R_{CuR}}{k^{Zn}_{H_2O}/K^R_{ZnR}} = 10^{-4.5} \quad (11)$$

where the values of $k^{Cu}_{H_2O}$ and $k^{Zn}_{H_2O}$ are 2×10^8 sec^{-1} at 25°C[13] and 3×10^7 sec^{-1} at 25°C[14], respectively, and the value of K^R_{ZnR} is $10^{11.9}$ at 25°C and

μ=0.10.[2] The ratio of dissociation rate of PAR from M-PAR (Eq. (11)) is by three orders of magnitude lower than the ratio of the rate constants of dissociation of PAR from the intermediates (Eq. (10)). This difference points to the possible change of the structure of the assumed intermediate RMY during the reaction. Since the *d* electron configuration of copper(II) ion is $(t_{2g})^6(e_g)^3$, we expect to find four short bonds coplanar with the metal atom and two longer ones completing a distorted octahedron (Jahn-Teller distortions). We know that zinc(II) ion with the configuration d^{10} is spherical. In 1 : 1 Cu-PAR complex, PAR is coordinated in the same plane with the central metal and two of the three water molecules in the complex are coordinated weakly with copper. These water molecules are substituted by EGTA in the formation of the intermediate RCuY. The bond Cu-PAR should then be necessarily forced to be longer and weaken in the distorted octahedron of the intermediate before the cleavage of Cu-PAR bond. In other words, the dissociation of PAR in the mixed ligand intermediate RCuY should be strongly driven due to Jahn-Teller distortions.[15]

The financial support given by the Ministry of Education is gratefully acknowledged.

15) The stepwise stability constants of the zinc(II)-PAR complexes are different by less than a factor of 10^2: $K^{R}_{ZnR}=10^{11.9}$ and $K^{R}_{ZnR_2}=10^{10.3}$. [2] The second stability constant of the copper(II)-PAR complex, however, is smaller than the first by a factor of 10^8. The greatly reduced stability of the 1 : 2 copper(II)-PAR complex must be attributed to Jahn-Teller distortions.

Polarography of Iron(III)- and Europium(III)-Acetylacetonate Complexes in *N,N*-Dimethylformamide

Seizo Misumi, Makoto Aihara and Yasuomi Nonaka

Inorganic Chemistry Laboratory, Faculty of Science, Kyushu University, Fukuoka

(Received July 14, 1969)

The reduction potentials of $Fe(acac)_3$ and $Eu(acac)_3$ in DMF are shifted to more positive potentials by the addition of cations (Li^+ and Mg^{2+}) to the supporting electrolyte of tetraethylammonium perchlorate. Studies of the complexes show that the effect is caused by coordinative relaxation reaction of the $Fe(acac)_3^-$ reduction product in which acetylacetonate ligand becomes transferred to the cation. However, in the case of $Eu(acac)_3^-$, acetylacetonate ligands seemed to be completely stripped off. Cyclic voltammetric data indicate reduction and reoxidation processes of the complexes.

Polarography in non-aqueous solvent is more advantageous for the study of a metal complex than that in aqueous solution, and investigations in non-aqueous solvents have been reported recently. However, the interaction of the supporting electrolyte with either the electrode reactant or product which remains innocuous in aqueous medium, should be taken into consideration in lower dielectric solvents such as in acetonitrile ($\varepsilon=37.5$) and dimethylformamide, DMF ($\varepsilon=36.7$). Schaap[1] developed polarographic theory for ion pairing of metal ion reactant with electrolyte anions. Murray and Hiller[2] studied the interaction of $Fe(acac)_3^-$ reduction product with Li^+ ion in acetonitrile. We are interested in the interaction of the supporting electrolyte with electron transfer products of a neutral complex in non-aqueous solvents and wish to describe cation (Li^+ and Mg^{2+}) effects on the iron(III)- and europium(III)-acetylacetonate complexes, ($Fe(acac)_3$ and $Eu(acac)_3$) in DMF.

Experimental

Solvent and Materials. *N,N*-Dimethylformamide by Wako Junyaku Co. of extra pure reagent grade was used. DMF was shaken with potassium carbonate anhydride and sodium sulfate, left standing for several days and then upper layer of the solution was distilled three times under reduced pressure in a nitrogen atomosphere. Moisture in the distillate was determined by Karl-Fischer titration to be only 0.03%. There were no impurities, which caused a detectable current at negative potentials less than −2.8 V in the polarogram. $Fe(acac)_3$ and $Eu(acac)_3$ were prepared by the ordinary method.[3]

Found: C, 50.90; H, 5.89%. Calcd for $Fe(acac)_3$: C, 51.01; H, 5.99%.

Found: C, 38.07; H, 4.88%. Calcd for $Eu(acac)_3 H_2O$: C, 38.55; H, 4.96%.

Tetraethylammonium perchlorate (abbreviated as TEAP) was prepared through the reaction of tetraethylammonium bromide with perchloric acid, recrystallized in water and dried at 60°C over $Mg(ClO_4)_2$.

Found: C, 41.89; H, 8.71; N, 5.96%. Calcd for $(C_2H_5)_4NClO_4$: C, 41.83; H, 8.77; N, 6.09%.

All other reagents were of extra pure grade.

Apparatus. The electrolysis cell has two diaphragms of sintered glass and consists of three electrodes as shown in Fig. 1. The reference electrode was SCE with a salt bridge devised by Takaoka.[4] DME was used as the working electrode ($m=0.833$ mg/sec, $t=4.50$ sec in 0.1M TEAP-DMF medium at −1.7 V *vs.* SCE).

2) R. W. Murray and L. K. Hiller, Jr., *Anal. Chem.*, **39**, 1221 (1967).
3) J. G. Stites, C. N. McCarthy and L. L. Quill, *J. Amer. Chem. Soc.*, **83**, 4533 (1961); T. Moeller and W. F. Ulrich, *J. Inorg. Nucl. Chem.*, **2**, 164 (1956).
4) K. Takaoka, *Rev. Polarog.* (Kyoto), **14**, 63 (1966).

for recording polarograms. Cyclic voltammograms were recorded by Iwasaki Synchroscope SS-5302 with preamplifier SP-O1H-A.

Triangular potential signals were obtained from a Yokogawa-Hewlett-Packard 3300A Function Generator. A compensator P8-PT was used as a potentiostat. A Pt wire electrode was used for a counter electrode. Current-measuring resistance was 10—30Ω.

Procedure. A sample of 0.1M TEAP-DMF, containing $Fe(acac)_3$ or $Eu(acac)_3$ (10^{-3}M), was taken into a cell. After dried nitrogen gas was passed through it for 20 min, DME and the agar bridge connected with SCE were inserted in the cell. A polarogram was then recorded. The junction potential was measured by using SCE with a slowly flowing-type aqueous saturated KCl salt bridge. All experiments were carried out at 25.0±0.1°C. Cyclic voltammogram was photographed during the growth of a mercury drop and the value of its maximum current was analysed.

Results

$Fe(acac)_3$ in 0.1M TEAP. The polarogram of 1 mM $Fe(acac)_3$ in 0.1M TEAP in DMF developed a well-defined wave (Fig. 2). The half-wave

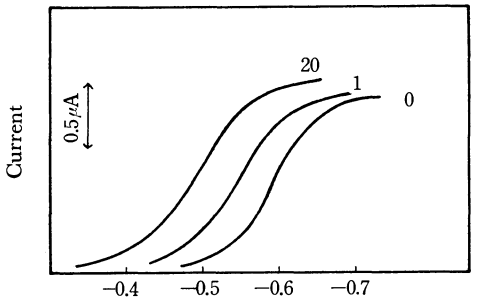

Fig. 2. Polarograms for 1.00 mM $Fe(acac)_3$ in 0.1M TEAP in DMF. Numbers above curves are mM of $LiClO_4$ added.

potential was −0.58 V *vs.* SCE. The electrode reaction was found to be a reversible (reciprocal slope: 52 mV) one-electron reduction and diffusion-controlled.

$Fe(acac)_3$ in TEAP-$LiClO_4$ Electrolyte Mixtures. As shown in Fig. 2 the reduction wave of 1 mM $Fe(acac)_3$ was shifted to less negative potentials by increasing concentrations of $LiClO_4$ in 0.1M TEAP medium. In this case, the electrode reaction was diffusion-controlled. As is seen in Table 1, the half-wave potential is shifted to more negative potential by increasing concentrations of $Fe(acac)_3$ with constant concentration of 30 mM $LiClO_4$.

$Fe(acac)_3$ in TEAP-$Mg(ClO_4)_2$ Electrolyte Mixtures. The same results as those for TEAP-$LiClO_4$ electrolyte mixtures were obtained (Table 2).

$Eu(acac)_3$ in 0.1M TEAP. A single wave with the half-wave potential of −1.55 V *vs.* SCE, was obtained for 1 mM $Eu(acac)_3$ in 0.1M TEAP in DMF (Fig. 3). The electrode reaction was diffusion-

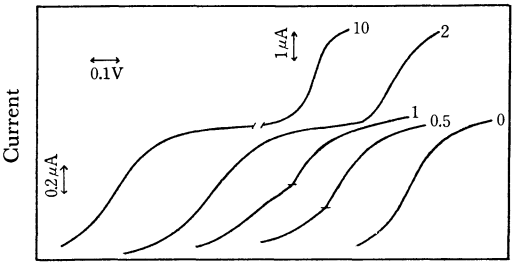

Fig. 3. Polarograms for 1.00 mM $Eu(acac)_3$ in 0.1M TEAP in DMF. Numbers above curves are mM of $LiClO_4$ added.

controlled. Addition of water up to 0.5% has no effect on the half-wave potential and the diffusion current remained. However, addition of water more than 0.5% caused the decrease of the diffusion current.

$Eu(acac)_3$ in 0.1M TEAP-$LiClO_4$ Electrolyte Mixtures. Differing from the case of $Fe(acac)_3$, the original single wave of the complex split into two waves by addition of $LiClO_4$ and a new wave

appeared at less negative potentials than the original. The height of this wave increased with increasing $LiClO_4$ concentrations and the original wave disappeared, whereas the new wave remained and was shifted again to less negative potentials at $[LiClO_4]/[Eu(acac)_3] \geqq 2$ (Fig. 3). The electrode reaction was diffusion-controlled. As shown in Table 3-1, the half-wave potential was shifted to more negative potentials by increasing concentrations of $Eu(acac)_3$ with constant concentration of $LiClO_4$. By addition of $LiClO_4$ at $[LiClO_4]/[Eu(acac)_3] \geqq 2$, a second wave appeared close to the potential of -2.0 V *vs.* SCE. The diffusion current became almost constant at $[LiClO_4]/[Eu(acac)_3] \geqq 10$(Fig. 3 and Table 3-2).

$Eu(acac)_3$ in 0.1M TEAP-$Mg(ClO_4)_2$ Electrolyte Mixtures. Differing from the case of $LiClO_4$, by addition of $Mg(ClO_4)_2$ to 1 mM $Eu(acac)_3$ in 0.1M TEAP medium the wave split into three steps and became considerably complicated.

Positive shifts in the half-wave potentials of the reduction waves of $Fe(acac)_3$ and $Eu(acac)_3$ were observed by addition of the cations (Li^+ and Mg^{2+}). Negative shifts in the half-wave potentials of those waves resulted from the increase of both complex concentrations at a constant concentration of the cation.

Assuming that metal complex ML_p is reduced reversibly with n-electron transfer, the electrode reaction is given by

$$ML_p + ne \rightleftharpoons ML_p^{n-} \quad (1)$$

If metal-ligand bond in ML_p^{n-} reduction product is more labile than that in ML_p complex, then ligand dissociation may occur from ML_p^{n-}. The extent of such dissociation is limited by the nature of the cation C^+. According to Murray and Hiller,[2] this particular interaction is a "theft" of ligand(s) from ML_p^{n-} by C^+ (coordinative relaxation), which produces a positive shift of the reduction potential of the reaction (1). In this case it seems that a sequence of the following coordinative relaxation reaction may occur.

$$\left.\begin{aligned} ML_p^{n-} + C^+ &\rightleftharpoons ML_{p-1}^{(n-1)-} + CL \\ &\vdots \\ ML_{p-q+1}^{(n-q+1)-} + C^+ &\rightleftharpoons ML_{p-q}^{(n-q)-} + CL \end{aligned}\right\} \quad (2)$$

Denoting the overall equilibrium constants of the above relaxations as K_1, K_2, $\cdots$, K_q, and solving for $[ML_p^{n-}]$, we obtain from the Nernst equation

$$E = E^0 + \frac{0.059}{n} \log \frac{[ML_p][1+\sum K_j[C^+]^j/[CL]^j]}{[ML_p^{n-}]_{total}} \quad (3)$$

where $[ML_p^{n-}]_{total}$ is the total concentration of all forms of the product complex.

If $n=q=1$ and essentially complete relaxation to ML_{p-1} is assumed, Eq. (3) is reduced to

$$E = E^0 + 0.059 \log \frac{K_r K_{CL} K_1}{K_0} + 0.059 \log [C^+] + 0.059 \log \frac{i_d - i}{i^2} \quad (4)$$

where K_r, K_0 and K_{CL} are the current-concentration proportionality constants for ML_{p-1}, ML_p and CL, respectively. Eq. (4) shows that the half-wave potential $E_{1/2}$ is shifted positively with increase in $[C^+]$ and is shifted negatively with increase in the concentration of the complex (at $i=i_d/2$, the last term of Eq. (4) is reduced to $0.059 \log (2/i_d)$). Plots of $E_{1/2}$ for $Fe(acac)_3$ and $Eu(acac)_3$ complexes against log $[Li^+]$ are shown in Fig. 4, where the following dissociation constants were used to calculate the concentration of dissociated lithium ions, $[Li^+]$.

$(K_a)_{LiClO_4} = 65.5$ (calculated by using the data of electric conductivity of Prue and Sherrington)[5]

$(K_a)_{TEAP} = 4.0$ (obtained by Peover and Davies)[6]

In the case of $Fe(acac)_3$ complex, $\Delta(E_{1/2})/\Delta\log[Li^+] = 0.062$. This value coincides with the theoretical value 0.059 for $q=1$. Consequently, the overall electrochemical process should be

$$Fe(acac)_3 + e \rightleftharpoons Fe(acac)_3^- \quad (5)$$

$$Fe(acac)_3^- + Li^+ \rightleftharpoons Fe(acac)_2 + Li(acac) \quad (6)$$

5) J. E. Prue and D. J. Sherrington, *Trans. Faraday Soc.*, **57**, 1795 (1967).

6) M. E. Peover, J. D. Davies, *J. Electroanal. Chem.*, **6**, 46, (1963).

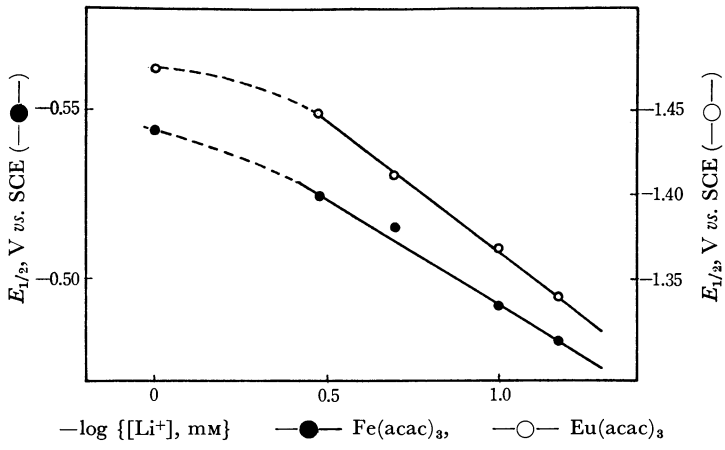

Fig. 4. Plot of $E_{1/2}$ values against log{[Li+]}.

However, in the case of $Eu(acac)_3$ complex we have $\Delta(E_{1/2})/\Delta\log[Li^+]=0.16$. This value is almost equal to the theoretical value of coordinative relaxation reaction of three ligands by Li^+ ions (Eq. (8)). As the half-wave potential of the second wave corresponds to that for the reduction of Eu(II) $\rightarrow$Eu(0) in DMF ($(E_{1/2})_2$: −2.0 V *vs.* SCE), it seems that all ligands of the reduction product of $Eu(acac)_3^-$ are completely stripped off by the addition of $LiClO_4$. The electrode reaction is presumed to be quasi-reversible and one-electron transfer, but the wave denotes apparently the value of the slope of an irreversible wave, caused by the succeeding controlled reaction in coordinative relaxation reaction. Thus, the overall electrochemical reaction would be

$$Eu(acac)_3 + e \rightleftharpoons Eu(acac)_3^- \quad (7)$$

$$Eu(acac)_3^- + 3Li^+ \rightleftharpoons Eu^{2+} + 3Li(acac) \quad (8)$$

$$Eu^{2+} + 2e \rightleftharpoons Eu^0 \quad (9)$$

In a low concentration of $LiClO_4$, a stepwise relaxation reaction of ligand sould occur by the deficiency of Li^+ ions. Though the effect of Mg^{2+} ion on the electrode process of $Fe(acac)_3$ complex is similar to that of Li^+ ion, a quantitative treatment was omitted because of the lack of data for ion association constants.

The cyclic voltammetry for $Fe(acac)_3$ complex was carried out. As shown in Fig. 5, both peaks of reduction and reoxidation were obtained only for $Fe(acac)_3$ complex, the results being ΔE_{peak} equals 60 mV.

An increase in $[LiClO_4]$ shifted the cathodic wave

positively and its reoxidation process appeared. These data indicate Eq. (6) to be reversible under this condition. However, as given in Fig. 6, under fast scan of the applied voltage and high lithium concentration, the coordinative relaxation reaction by Li^+ becomes rate-controlled and prevents complete generation of $Fe(acac)_3^-$ species which will give the anodic wave. It was observed that the anodic wave decreased in this case.

In the cyclic voltammetry for $Eu(acac)_3$ complex, as shown in Fig. 7, ΔE_{peak} was found to be approximately 80 mV.

An increase in $[LiClO_4]$ also shifted the cathodic wave positively as the wave in the D.C. polarography. However, the value of ΔE_{peak} became very large and seemed to be an irreversible electrode process controlled by the following coordinative relaxation reaction. This fact supports the results obtained by D.C. polarography of the complex.

The authors wish to thank the Ministry of Education for the financial support given to this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 778—782 (1970)

Stability of Tropolone Chelates of the Bi- and Tervalent Metal Ions

Michio HIRAI and Yoshinaga OKA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received July 30, 1969)

The reaction of tropolone with several bi- and tervalent metal ions has been studied spectrophotometrically. Their stability constants (k_1) have been found to be 7.4_0, 3.8_2, 3.0_6, 2.4_5, 7.4_6, 4.6_0, and 6.2_5 for Be(II), Mg(II), Ca(II), Sr(II), Y(III), Cd(II), and La(III) respectively, at 25 ± 0.1°C and at an ionic strength of 0.10. A plot of log k_1 against e^2/r gave a straight line for all the non-polarizable metal ions except Be(II) and Mg(II). The log k_1 values for all the polarizable metal ions are large. The correlation of log k_1 with the second or the third ionization potentials for bi- and tervalent metal ions gave a fairly straight line.

Several metal chelates of troponoid have been studied by many investigators.[1-7] Bryant *et al.* made their studies in 50 per cent dioxane because of the insolubility of metal chelates of troponoid in water.[1-2] The stability constants of copper and zinc chelates with 4-isopropyltropolone have been determined by Dryssen by the solvent extraction technique.[3]

Oka *et al.* have studied the effect of substitution on the stability of iron(III) chelates using 3-, 4- and 5-substituted tropolones.[8-11]

In a previous paper, the present authors have reported the results of their investigations of the tropolone chelates of manganese(II), cobalt(II), nickel(II), copper(II), and zinc(II).[12,13] In this paper their studies of the beryllium(II), magnesium(II), calcium(II), strontium(II), cadmium(II), yttrium(III), and lanthanum(III) chelates with tropolone will be described. In these studies the stability constants have been spectrophotometrically determined.

Experimental

Materials. The tropolone was purified by sublimation at 40°C under reduced pressure, 20 mmHg. All the metal salt solutions were prepared as perchlorate from pure oxides, chlorides or nitrates. The water used was double-distilled. For the adjustment of the ionic strength (0.10), sodium perchlorate was used.

Measurements. For the measurement of absorbance, Hitachi Model EPU-2 and EPS-2 spectrophotometers were used. The pH of the solutions was measured with a Hitachi-Horiba Model M-5 pH meter.

Results and Discussion

Acid Dissociation Constant of Tropolone. Tropolone is amphoteric, and its absorption spectrum changes with variations in the pH of the solution. In the pH range from 1.5 to 3.4, the spectrum I in Fig. 1 was obtained; this is the absorption spectrum of tropolone itself. Above pH 9.6, tropolone dissociates completely and gives the spectrum II. In a strong acidic solution, in a 2N $HClO_4$ solution for example, the spectrum III was obtained, indicating the formation of the dihydroxytropylium ion (I).

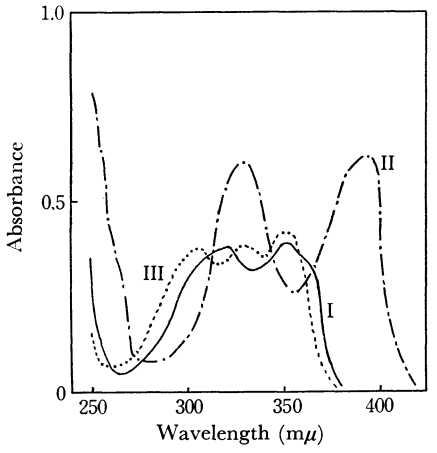

Fig. 1. Absorption spectra of tropolone.
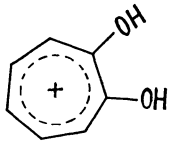
tropolone: 6.06×10^{-5} mol/l
I; pH 1.5—3.4, II; pH >9.6, III; $HClO_4$ 3.2N

The acid dissociation constant, K_a, of tropolone was evaluated spectrophotometrically at an ionic strength of 0.10 and at 25.0±0.1°C.



(I) Dihydroxytropylium ion

When tropolone (HL) dissociates as follows:

$$HL = L^- + H^+$$

the following equation is derived, as has been reported previously:[14]

$$\frac{a}{(A-A')} = \frac{1}{(\varepsilon_2-\varepsilon_1)} + \frac{1}{(\varepsilon_2-\varepsilon_1)K_a}\cdot[H^+] \qquad (1)$$

where A is the total absorbance of the solution at various pH values, a is the analytical concentration of tropolone, ε_1 and ε_2 are the molar extinction coefficients of tropolone and the tropolonate ion respectively, and A' is equal to $\varepsilon_1 a$. Equation (1) shows that a plot of $a/(A-A')$ against $[H^+]$ may give a straight line. The acid dissociation constant, K_a, may, then, be calculated from the intercept and the slope of the straight line.

Keeping the analytical concentration of tropolone $1.21_2\times10^{-4}$ mol/l, and varying the pH-values of the solution in the range from 6.40 to 6.91, the total absorbances were measured, the ionic strength being adjusted to 0.10. The plots of $a/(A-A')$ against $[H^+]$ are shown in Fig. 2. Good straight lines were obtained at various wavelengths. The acid dissociation constant calculated is shown in Table 1.

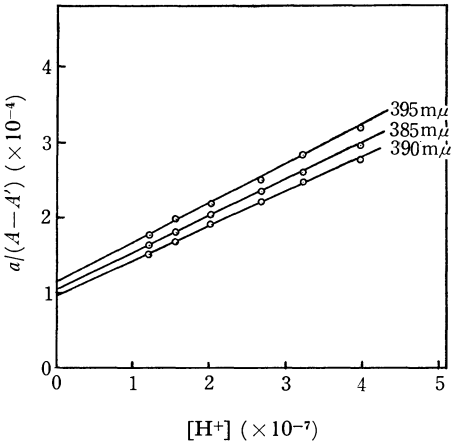


Fig. 2. Correlation of $a/(A-A')$ with $[H^+]$.

Stability Constants of Metal Chelates (1 : 1) with Tropolone. Each of the metal perchlorate solutions was added in excess into a tropolone solution, the ionic strength being kept at 0.10 with sodium perchlorate. The pH values of the solutions were varied in the range where the hydrolysis of metal ions does not occur in any appreciable extent. As an example, the absorption spectra of strontium-(II)-tropolone system are shown in Fig. 3. At pH

14) a) Y. Oka and R. Tanaka, *Nippon Kagaku Zasshi*, **81**, 1846 (1960). b) H. A. Benesei and J. H. Hildebrand, *J. Amer. Chem. Soc.*, **71**, 2703 (1949).

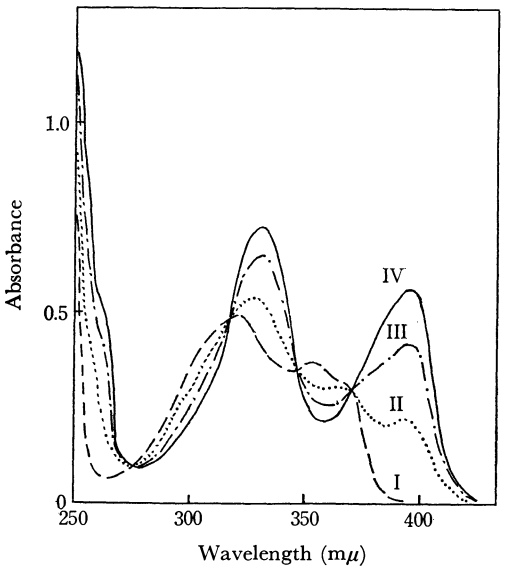

Fig. 3. Change of absorption spectrum of Sr(II)-tropolone system depends on pH in the presence of excess metal ion.
Tropolone: 6.01×10^{-5} mol/l
$Sr(ClO_4)_2$: 1.65×10^{-2} mol/l
I, pH 1.72; II, 5.93; III, pH 6.70; IV, pH 8.41

1.72 a spectrum I identical with that of tropolone was obtained. In this pH region, therefore, it may be considered that tropolone does not react with strontium. Above pH 5.9, the spectra II, III, and IV were obtained.

If, in the presence of an excess of the metal ion, tropolone (HL) reacts following Eq. (2):

$$M^{n+} + HL = ML^{(n-1)+} + H^+ \qquad (2)$$

the equilibrium constant, K_1, can be expressed as follows:

$$K_1 = \frac{[ML^{(n-1)+}][H^+]}{[M^{n+}][HL]} \qquad (3)$$

Then,

$$K_1 = \frac{x[H^+]}{(b-x)(a-x)} \qquad (4)$$

where x is the equilibrium concentration of the metal chelate formed, and a and b are the total concentrations of the tropolone and the metal ion respectively. When the concentration of the metal ion is large enough, we may safely assume that $(b-x)\fallingdotseq b$.

Next, when measurements are made in the wavelength range where the molar extinction coefficient of the metal ion is zero, the total absorbance, A, is expressed as follows:

$$A = \varepsilon_1[HL] + \varepsilon_3[ML^{(n-1)+}] = \varepsilon_1(a-x) + \varepsilon_3 x \qquad (5)$$

where ε_1 and ε_3 are the molar extinction coefficients of the tropolone and the metal chelate respectively.

From Eqs. (4) and (5), Eq. (6) is derived:

$$\frac{a}{(A-A')} = \frac{1}{(\varepsilon_3-\varepsilon_1)} + \frac{1}{(\varepsilon_3-\varepsilon_1)k_1}\cdot\frac{[H^+]}{bK_a} \qquad (6)$$

where k_1 is the stability constant.

In case when a chelate is formed in the pH range above 3.4, the dissociation of tropolone is not negligible. Then, Eq. (7) is derived:

$$\frac{a}{A} = \frac{1}{\varepsilon_3} + \frac{1}{\varepsilon_3 k_1 b}\cdot\frac{(A-A')[H^+]+(A-A'')K_a}{AK_a} \qquad (7)$$

where $A'=\varepsilon_1 a$, $A''=\varepsilon_2 a$, and ε_1 is the molar extinction coefficient of tropolone, and ε_2, that of the tropolonate ion. A plot of $a/(A-A')$ against $[H^+]/bK_a$ or of a/A against $\{(A-A')[H^+]+(A-A'')\cdot K_a\}/AK_a$ will give a straight line.

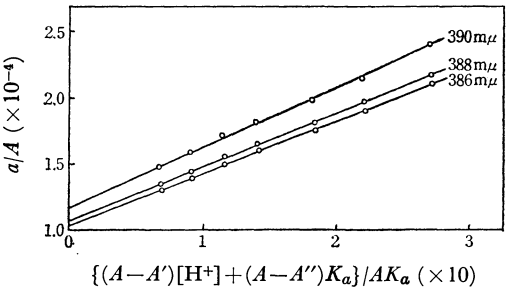

Fig. 5. Correlation of a/A with $\{(A-A')[H^+]+(A-A'')K_a\}/AK_a$ (Ca(II)-tropolone system).
Tropolone: $1.20_2\times10^{-4}$ mol/l
$Ca(ClO_4)_2$: $2.24_1\times10^{-2}$ mol/l
25.0±0.1°C, ionic strength 0.10, pH 5.22—5.82

For the beryllium(II)-, magnesium(II)-, yttrium(III)-, cadmium(II)- and lanthanum(III)-systems, Eq. (6) is used, while for the calcium(II)- and strontium(II)-systems, Eq. (7) is used. In all cases, good straight lines are obtained. Some sample results are shown in Figs. 4 and 5. Therefore, it can be safely concluded that 1 : 1 chelates are formed in such circumstances.

From the slopes and the intercepts of the straight lines, the stability constants are calculated to be as shown in Table 2.

TABLE 2. STABILITY CONSTANTS (k_1) OF METAL CHELATES (1 : 1) WITH TROPOLONE

	388	4.61
	390	4.59
	average	$4.6_0\pm0.0_1$
La(III)	380	6.24
	382	6.25
	384	6.25
	386	6.25
	average	$6.2_5\pm0.0_0$

The stability constants increase from strontium to copper in the following order:

Sr(II)<Ca(II)<Mg(II)<Cd(II), Mn(II)<Co(II)<Zn(II)<Ni(II)<La(III)<Be(II)<Y(III)<Cu(II)

For chelates of the primarily "ionic" type, the strength of chelation should increase with an increase in the ionic charge of both metal ion and donor, and with a decrease in the ionic radius of the metal ion. Martell *et al.* have discussed the

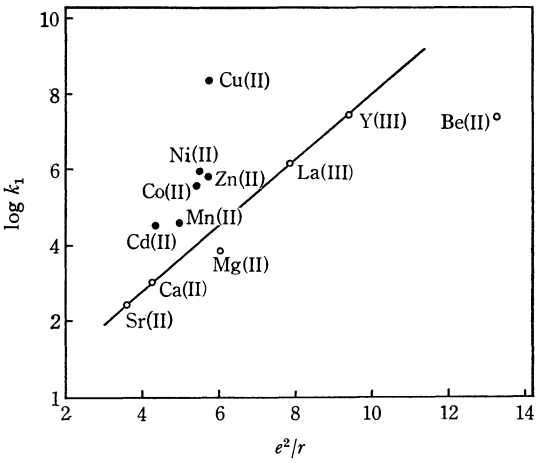

Fig. 6. Correlation of log k_1 with e^2/r for metal complexes (1 : 1) with tropolone.
○: non-polarizable metal ion

n=3 for tervalent metal ion

stability constants with respect to charge(e)/radius(r) and e^2/r for a number of chelates which would be expected to form a primarily ionic bond.[15-17] They have found that e^2/r is superior. Where electrostatic interaction is predominant, $\log k_1$ may have a direct correlation with e^2/r. A similar treatment was attempted in the case of tropolone chelates; the results shown in Fig. 6 were obtained. A good straight line is observed for all the non-polarizable metal ions except beryllium(II) and magnesium(II). Their $\log k_1$ values are smaller than those expected. The ionic radii of these metal ions are small. It seems possible, therefore, that the steric effect hinders the stability. On the other hand, the values of $\log k_1$ for all polarizable metal ions are large. The polarization of the metal ion should be expected to enhance the stability of the chelates. Figure 7 shows the correlation of $\log k_1$ with the second and third ionization potentials for chelates of bi- and tervalent metals.[18] A fairly good correlation is observed.

The authors would like to express their thanks to Dr. Hiroshi Sugiyama, The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, who kindly provided us with the tropolone.

The Cation-exchange Separation of Nitrosylruthenium(III) from Ruthenium(III and IV) and Its Radiochemical Applications

Eiichi MIKI, Tatsujiro ISHIMORI and Hisateru OKUNO

Department of Chemistry, College of Science, Rikkyo University, Toshima-ku, Tokyo

(Received August 12, 1969)

The cation-exchange separation was made on a 0.1 M perchloric acid solution of the evaporated residue of a hydrochloric acid solution which contained nitrosylruthenium(III) of 10 mg—100 μg Ru and ruthenium(III and IV) of 100—10 μg Ru; the nitrosylruthenium species were eluted by the use of 80—90 m*l* of 0.1 M perchloric acid, and the ruthenium species, by the use of 100 m*l* of 3 M hydrochloric acid containing 50 vol% ethyl alcohol for the columns (3—8 m*l*) of the HR type. It was found by means of the separation that a ^{106}Ru-nitrosylruthenium tracer can be quantitatively prepared by passing nitric oxide into a hydrochloric acid solution of ^{106}Ru-ruthenium(III and IV). The separation on dipotassium pentachloronitrosylruthenate(III) irradiated by thermal neutrons indicated that the specific activities caused by ^{103}Ru in the ruthenium fractions are a few hundred times as high as those in the nitrosylruthenium fractions.

In acid aqueous solutions, both ruthenium(III and IV) and nitrosylruthenium(III) species are present as stable species. However, the chemical behavior of nitrosylruthenium(III) is different from that of ruthenium(III) and (IV). The separation of the nitrosylruthenium(III) species from the ruthenium(III or IV) species is necessary in order to study the chemistry of ruthenium. Kepak and Kanka have reported that an efficient separation was achieved by adsorption on iron(II) hydroxide.[1)]

We attempted to separate small amounts of ruthenium(III and IV) and nitrosylruthenium(III) species in hydrochloric acid solutions by the use of the cation-exchange technique.

The separation can be carried out on a perchloric acid solution of the evaporated residue of a hydrochloric acid solution of 10 mg—100 μg nitrosylruthenium(III) and 100—10 μg ruthenium(III and IV). This paper will also report on such applications of the separation to the radiochemistry of ruthenium as preparing the labeled nitrosylruthenium(III) species and the separation of ^{103}Ru with high specific activities from dipotassium penta-

chloronitrosylruthenate(III) irradiated by thermal neutrons.

Experimental

Ru(III and IV)*1 in a hydrochloric acid solution was prepared by distilling ruthenium tetroxide into an alcoholic hydrochloric acid solution, evaporating the distillate, and dissolving the evaporated residue with a hydrochloric acid solution, or by dissolving the commercial $RuCl_3 \cdot 3H_2O$ with a hydrochloric acid solution. Ru(III)NO in a hydrochloric acid solution was prepared by bringing nitric oxide into contact with Ru(III and IV) in a hydrochloric acid solution.[2]

The sample solutions for the cation-exchange separation were prepared by evaporating hydrochloric acid solutions of Ru(III and IV) or/and Ru(III)NO, dissolving the evaporated residue in 10 m*l* of a 0.1M perchloric acid solution, and allowing the solution to digest for thirty minutes in a boiling-water bath.

Dipotassium pentachloronitrosylruthenate(III) was prepared by adding an excess of potassium chloride in a hydrochloric acid solution of Ru(III)NO and was recrystallized from a 0.1M hydrochloric acid solution.[3]

The ^{106}Ru was purchased from the Radiochemical Centre, Amersham, England, and was purified by the distillation of the tetroxide. The radiochemical purity of the ^{106}Ru was examined by means of its γ-ray spectrum; no impurity was found with respect to γ-emitters. The tracer solutions of the ^{106}Ru were prepared by the same procedures as the solutions containing the ordinary amount of Ru(III and IV) or Ru(III)NO.

The cation exchanger used was Dowex 50, X-4, with a hydrogen-ion form. The chromatographic procedures were carried out with columns 1 cm in diameter and 3—8 m*l* in volume at the flow rate of 1 m*l*/min.

The ruthenium was determined spectrophotometrically by the phenanthroline method[4] and the thiourea method.[4] The latter could not, however, be applied to the samples containing Ru(III)NO species. The radioactivities of ^{106}Ru or ^{103}Ru in solutions were measured as gross γ-activities with a well-type NaI(Tl) scintillator.

Results and Discussion

Sorption of Ruthenium and Nitrosylruthenium Species in Perchloric Acid Solutions on Cation-exchange Resins. The study of the species of ruthenium(IV) in perchloric acid solutions has indicated that the average charge on the aqueous species is +2, and extensive polymerization was observed in these solutions.[5] In the perchloric acid solution of the ruthenium(III and IV) chloride*2 prepared as has been described above, almost all the ruthenium species were found by iodometric titration to be in the Ru(IV) state and were expected to be cationic from their strong sorption on the cation exchanger. The species in the solution of the nitrosylruthenium(III) chloride*2 will be discussed later.

The distribution coefficients (K_d) of ruthenium and nitrosylruthenium species between the cation exchanger and perchloric acid-hydrochloric acid solutions were determined with ^{106}Ru tracers of the ruthenium and nitrosylruthenium species. A part of the perchloric acid in the solutions was replaced by hydrochloric acid in order to observe the effect of chloride ions on the distribution coefficients. As will later be decribed in more detail, we found a certain abnormal behavior of the radioactive tracer of the ruthenium species on the cation exchanger, and the values of the distribution coefficients obtained were not considered to give a strict measure of the sorption of ruthenium species on the cation exchanger. The values of K_d for the ruthenium species were great over the range of chloride concentration less than 0.04M at the 0.15M hydrogen-ion concentration (log K_d:

*2 In this paper, the ruthenium(III and IV) and the nitrosylruthenium(III) chlorides are the evaporated residues of a hydrochloric acid solution of Ru(III and IV) and of Ru(III)NO respectively. The ruthenium chloride has been thought to be $Ru(OH)Cl_3$ (N. V. Sidgwick, "Chemical Elements and Their Compounds," Vol. II, Oxford, (1950), p. 1476). The nitrosylruthenium(III) chloride is considered to be $H_2[RuCl_4OHNO] \cdot 2H_2O$ and $RuCl_3NO \cdot nH_2O$.[3]

*Ru: The ^{106}Ru-tracer stored in 0.2M HCl.
**Ru: The ^{106}Ru-tracer eluted in the ruthenium fraction with a carrier in the separation. This was stored in 3M HCl and used within several days after the preparation.
1) To *Ru solution, an equal volume of 6M HCl was added and then the solution was evaporated.
2) The *Ru was digested as 3M HCl solution and evaporated. Then, the carrier was added and the mixture was evaporated.
3) The *Ru and the carrier were mixed and the mixture was digested as 6M HCl solution after addition of Br_2(aq) and evaporated.
4) The mixture was evaporated.

about 3.0 for $[Ru_{aq}]$=the order of 7×10^{-8}M) and decreased upon the addition of hydrochloric acid to the solution phase ($\log K_d$: 2.9 for $[Cl^-]=0.16$, $[H^+]=0.31$; 1.8 for $[Cl^-]=0.5$, $[H^+]=0.65$, $[Ru_{aq}]=7\times10^{-8}$M). The K_d values for the nitrosylruthenium species were less than 10(ml/g) over the chloride-concentration range of 10^{-3} to 0.1M and the hydrogen-ion concentration range of 0.02 to 0.4M.

Mutual Separation of the Ruthenium(III and IV) and the Nitrosylruthenium(III) Chlorides by Cation-exchange Technique. The separation method was examined using sample solutions of the 0.1M perchloric acid solution of the ruthenium or/and the nitrosylruthenium chlorides and a cation-exchanger column 1 cm in diameter and 8 ml in volume. For ruthenium species less than 100 μg Ru and nitrosylruthenium species less than 10 mg Ru, the separation was satisfactorily done by the following procedure: the sample solution (10 ml) was passed through the column, and then 80—90 ml of 0.1M perchloric acid was passed to elute the nitrosylruthenium species. The ruthenium species absorbed were eluted by 100 ml of 3M hydrochloric acid containing 50 vol% ethyl alcohol. The results of the separation are given in Table 1. The use of a perchloric acid solution in the cation-exchange separation of this type has been reported on the separation of platinum from palladium, rhodium, and iridium.[6]

The recoveries of ruthenium and nitrosylruthenium species were often less than 100%; the average deviation(%) on the recovery was −2.3% for 11 samples of ruthenium species containing 100 μg of Ru and −1.4% for 11 samples of nitrosylruthenium species containing 10.9 mg Ru. When ruthenium species more than 100 μg Ru were present in the sample solutions, the ruthenium species were not eluted quantitatively with an ethanolic hydrochloric acid solution. Incomplete recoveries in the ion-exchange separations have also been described in connection with the separation of platinum metal species.[7] The nitrosylruthenium species eluted were thought to be anionic, neutral, and univalent cationic chloro complexes; the anionic and neutral species were eluted, and then the univalent cationic complex was eluted as a single band. This cationic species was identified as $[RuCl_2(H_2O)_3NO]^{1+}$ by comparing the visible spectrum of its solution with the data provided by Mercer and Campbell.[8] The bivalent and tervalent cationic species of nitrosylruthenium were not present in the perchloric acid solution of the nitrosylruthenium chloride.

It was observed that the behavior of the radioactive ruthenium species was in part different from that of the carrier of ruthenium species in the cation-exchange separation (Table 2). The separations were carried out using columns 1 cm in diameter and 3 ml in volume. The ^{106}Ru-tracer of ruthenium (III and IV) had been stored in 0.2M hydrochloric acid, and its concentration was estimated to be 10^{-7}M. About 40% of the activity was eluted with 0.1M perchloric acid in the nitrosylruthenium fraction. Similar phenomena were observed even when 100 μg ruthenium species was added to the radioactive ruthenium species as a carrier and the mixture was evaporated after the addition of hydrochloric acid. When the radioactive species and the

carrier eluted in the ruthenium fraction were treated again by the same separation procedure, almost all the activities were found in the ruthenium fraction.

There have been studies[9-12] of a variety of ruthenium(III) and (IV) species in hydrochloric acid solutions, and the equilibria among the species have been considered to be complicated. It can be suggested that part of the radioactive tracers of ruthenium species may form neutral and/or anionic species, or polymers, and that they can not be converted to the species of the carrier even by evaporating them with the carrier in a hydrochloric acid solution.

The data in Table 2 indicate that no appreciable exchange of ruthenium atoms between ruthenium and nitrosylruthenium species occurred under the experimental conditions used.

Preparation of the Radioactive Nitrosylruthenium Tracer. It has been reported that the nitrosylruthenium tracer can be prepared in a good yield by treating the evaporated residue of a hydrochloric acid solution of ^{106}Ru with fuming nitric acid.[13] Nitrosylruthenium(III) in ordinary amounts has been prepared by passing nitric oxide into a dilute hydrochloric acid solution of ruthenium-(III and IV).[2] We determined the yield when the nitrosylruthenium tracer was prepared with fuming nitric acid or with nitric oxide. The method of preparing with fuming nitric acid was as follows; 1 m*l* of a dilute hydrochloric acid solution of ^{106}Ru was evaporated to dryness, and then a few drops of fuming nitric acid were added and the mixture was evaporated on a boiling-water bath. The evaporation with fuming nitric acid was then repeated. The residue was dissolved in 1 m*l* of concentrated hydrochloric acid and evaporated; a 0.1 M hydrochloric acid solution of radioactive nitrosylruthenium(III) was thus prepared. The method of preparing with nitric oxide was as follows; nitric oxide was passed into a dilute hydrochloric acid solution of the ^{106}Ru tracer for about twenty hours; the solution was then evaporated and again evaporated after the addition of hydrochloric acid. A 0.1 M hydrochloric acid solution of radioactive nitrosylruthenium(III) was thus prepared.

The carriers of ruthenium(III and IV) and nitrosylruthenium(III), each containing 100 μg Ru, were added to the radioactive nitrosylruthenium-(III), and a cation-exchange separation was carried out on the mixture in order to determine the yield in the preparation of radioactive nitrosylruthenium-(III). The results are shown in Table 3. It was found that the radioactive nitrosylruthenium tracer was prepared in a much better yield with nitric oxide than with fuming nitric acid. It was also observed that a part of the activity escaped in air in the preparation with fuming nitric acid if the reaction mixture was heated at a considerable temperature by means of a boiling-water bath or an infrared lamp.

Table 3. Examination of the yield in the preparation of radioactive nitrosylruthenium tracer

Method	Activity found in RuNO-fraction %	Activity found in Ru-fraction %

The Separation on Dipotassium Pentachloronitrosylruthenate(III) Irradiated by Thermal Neutrons. Dipotassium pentachloronitrosylruthenate(III) was irradiated by thermal neutrons to prepare a ^{103}Ru-tracer with a high specific activity by the use of the hot-atom reactions. The irradiation was carried out on a rotatory specimen rack (about $3.5\times10^{11}n_{th}$ cm^{-2} sec^{-1}) in a nuclear reactor of the TRIGA MARK II type at Rikkyo University.

In a typical example, $K_2[RuCl_5NO]$ (10 mg) was irradiated for 15 hr over 4 days and then cooled at room temperature for several days. The irradiated sample was thereafter dissolved in an ethanolic hydrochloric acid solution and evaporated. The residue was dissolved in a 0.1M perchloric acid solution to prepare the solution for the cation-exchange separation. The separation was carried out with a column 1 cm in diameter and 3 m*l* in volume. The results of the separation are shown in Fig. 1. The γ-activities could be measured excluding the β-activity of ^{35}S produced by ^{35}Cl(n, p)^{35}S. The γ-activities caused by ^{97}Ru and ^{105}Ru, the daughter of ^{105}Ru, were estimated to be very small parts of the total γ-activity. A small contribution by ^{42}K was possible in the activity of fraction 1 in Fig. 1. The γ-activities of fractions 1, 2, 3 and 4 were identified as those of ^{103}Ru by measuring their γ-spectra and their half-lives. The specific activities (cpm/mg Ru) of the ruthenium fractions (fractions 3 and 4) were a few hundred times as large as those of the nitrosylruthenium fractions (fractions 1 and 2). The activity in the ruthenium fraction was 23% of the total activity. The separation included elution with 1M perchloric acid (fraction 3 in Fig. 1); the species eluted was a ruthenium species with a high specific activity.

It was shown that the cation-exchange separation is useful in the preparation from the irradiated nitrosylruthenium complex of a ^{103}Ru-tracer with a high specific activity.

We have prepared ^{15}N-nitrosylruthenium(III) complexes in a semimicro scale.[14,15] The separation method has then been usefully used to examine the formation of nitrosylruthenium(III) by the use of limited amounts of nitric oxide.

Cobalt(III) and Chromium(III) Complexes with Ethylenediaminemonoacetic Acid*1

Yuki Fujii,*2 Eishin Kyuno and Ryokichi Tsuchiya

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received August 21, 1969)

Cobalt(III) and chromium(III) complexes with ethylenediaminemonoacetic acid (EDMA), $[Co(edma)_2]Cl \cdot 2H_2O$ and $[Cr(edma)_2]Cl \cdot 3H_2O$, (edma: $H_2NCH_2CH_2NHCH_2COO^-$), were prepared. The former complex was isolated as two geometrical isomers. From the electronic absorption spectra, the two isomers were assigned to *trans* and *cis* forms with respect to the carboxylate oxygen atoms coordinated. Chromium(III) complex was concluded to have the *trans* form by comparing the IR spectrum with those of the above two isomers of cobalt(III) complexes.

Terdentate chelating ligands can take various coordination forms in octahedral environment, depending upon the steric requirements of the ligands and the character of the central metal ion, especially upon the kind of coordination sites the ligands contain. As typical representatives of the terdentate ligands of (N,O,O)-, (N,N,O)- and (N,N,N)-types, iminodiacetic acid, ethylenediaminemonoacetic acid (abbreviated as EDMA)[1] and diethylenetriamine can be chosen.

In the present work EDMA, a simple, artificial and basic amino acid, was selected as the terdentate ligand. There are only a few reports[2,3] on the metal complexes with EDMA. In order to in-

*1 Presented, in part, at the 21st Annual Meeting of the Chemical Society of Japan, Osaka, March, 1968.

vestigate the stereochemistry of the complexes, the following two purposes were presented: (1) preparation of the EDMA complexes of cobalt(III) and chromium(III) ions, and (2) approach to the structures of the complexes by comparing their electronic and IR spectra with those of the related complexes.

Experimental

Preparation of the Complexes. *1) trans-Bis(ethylenediaminemonoacetato)cobalt(III) Chloride Dihydrate, trans*-[Co(edma)$_2$*[3]]Cl·2H$_2$O (I). 25.2 g (0.12 mol) of ethylenediaminemonoacetic acid dihydrochloride monohydrate (Hedma·2HCl·H$_2$O) was dissolved into 50 m*l* of water and the solution was neutralized with 20 g (0.24 mol) of sodium hydrogencarbonate. To this solution was added a solution of 10.4 g (0.044 mol) of cobalt(II) chloride hexahydrate in a very small amount of water and 10 m*l* of hydrogen peroxide (10%), and the mixture was warmed on a water bath to nearly 40°C. After the solution was evaporated to about 60 m*l*, an equal volume of ethanol was added to the resulting solution. The solution was kept in a refrigerator. Reddish purple crystals were separated out and recrystallized from 50% ethanol solution. Yield, 5.2 g (32.5%).

Found; C, 26.04; H, 5.87; N, 15.78%. Calcd for [Co(edma)$_2$]Cl·2H$_2$O: C, 26.34; H, 6.09; N, 15.36%.

2) cis-Bis(ethylenediaminemonoacetato)cobalt(III) Chloride Dihydrate, cis-[Co(edma)$_2$]Cl·2H$_2$O (II). To a solution of hexaamminecobalt(III) chloride (5.4 g, 0.02 mol), 9.4 g (0.045 mol) of Hedma·2HCl·H$_2$O was added and the mixture was warmed to nearly 70°C on a water bath. Potassium hydroxide (6.7 g) in 200 m*l* of water was added slowly to the solution, which was warmed, until the odor of ammonia vanished. After adjusting the pH of the solution to 7 with hydrochloric acid, an equal volume of ethanol was added to the resulting solution. After cooling to 0°C, orange yellow crystals were separated out and recrystallized from the aqueous solution. Yield, about 2.1 g (28.8%).

Found: C, 25.75; H, 6.15; N, 15.19%. Calcd for [Co(edma$_2$)]-Cl·2H$_2$O: C, 26.34; H, 6.09; N, 15.36%.

An orange yellow complex of cobalt(III) of *cis* form was also prepared by using cobalt(II) chloride hexahydrate as the starting material in an aqueous solution at high temperature.

3) trans-Bis(ethylenediaminemonoacetato)chromium(III) Chloride Trihydrate, trans-[Cr(edma)$_2$]Cl·3H$_2$O (III). Two isomers, *cis* and *trans* forms of the cobalt(III) complexes could be prepared by suitably selecting the starting materials as described above, in 1) and 2).[4] However, in the case of chromium(III) complexes, it was impossible to prepare the *cis* form even by starting from hexaamminechromium(III) iodide in a manner similar to that used in the preparation of the corresponding cobalt(III) complex in 2).

Only the *trans* form was obtained for the chromium(III)-EDMA system. To a solution of 5.3 g (0.02 mol) of chromium(III) chloride hexahydrate in a small amount of water, Hedma·2HCl·H$_2$O (9.2 g, 0.044 mol) was added and the mixture was heated on a water bath. After adjusting the pH of the solution to 7, an equal volume of ethanol was added to the resulting solution. When it was cooled to 0°C, red crystals were separated out and recrystallized from 10% ethanol solution. Yield, 5.5 g (72.5%).

Found: C, 25.47; H, 6.46; N, 15.42%. Calcd for [Cr(edma)$_2$]Cl·3H$_2$O: C, 25.57; H, 6.40; N, 14.91%.

Preparation of Ligand. *Ethylenediaminemonoacetic Acid Dihydrochloride Monohydrate,* Hedma·2HCl·H$_2$O. The solution of 94.5 g (1 mol) of monochloroacetic acid in 100 m*l* of water was neutralized with 84 g (1 mol) of sodium hydrogencarbonate, and 60 g (1 mol) of ethylenediamine (98%) was added to the solution. After being added 40 g of sodium hydroxide in 80 m*l* of water, the mixture was acidified with 6N hydrochloric acid and the solvent was then evaporated off. After filtration, ethanol three times in volume was added to the filtrate, when the oilish liquid was produced. This syrupy substance was treated by separating funnel and then concentrated hydrochloric acid was added to the syrup. After being added the mixture of ethanol and ether to the solution, it was kept in a refrigerator for a day. White crystals were separated out and recrystallized from 50% ethanol solution. The method is new and simple for the preparation of the ligand material. Yield, 140 g (70%).

Found: C, 22.94; H, 6.72; N, 12.96%. Calcd for C$_4$H$_{10}$N$_2$O$_2$·2HCl·H$_2$O: C, 22.97; H, 6.76; N, 13.50%.

Results and Discussion

Electronic Absorption Spectra. The visible absorption spectra for all the complexes in aqueous solutions are shown in Figs. 1 and 2, together with those of *cis*-[Co(edda)*[4](en)]Cl·3H$_2$O, *trans*-[Co(edda)(en)]NO$_3$·H$_2$O[5] and [Cr(ox)(en)$_2$]I[6] for

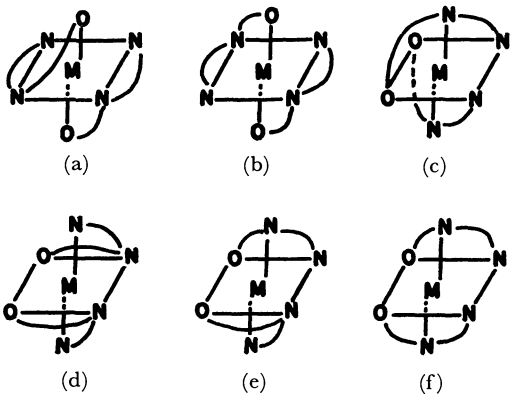

Fig. 3. The possible six geometrical isomers of bis(ethylenediaminemonoacetato)cobalt(III) and chromium(III) ion:
(a) *trans,cis,cis* (with respect to carboxylate oxygen, primary amine nitrogen and secondary amine nitrogen) (b) *trans,trans,trans*, (c) *cis,cis,trans*, (d) *cis,trans,cis*, (e) *cis,cis,cis*, (f) *cis,cis,trans*.

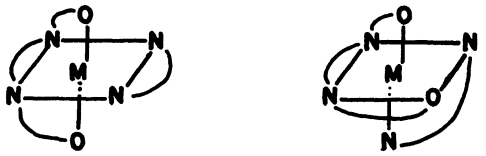

Fig. 4. The possible two geometrical isomers of [Co(edda)(en)]$^+$: (g) *trans* form, (h) *cis* form (with respect to carboxylate oxygen atoms).

comparison. Numerical values concerning their absorption maxima are given in Table 1.

The spectrum of complex I has a band which is remarkably split into two components Ia and Ib, at 18.9 and 22.0 (shoulder). It has another band at 28.2×10^3 cm^{-1}. The shape of the spectrum and the positions of the absorption peaks are in close agreement with those of *trans*-[Co(edda)(en)]-NO$_3$·H$_2$O.

The possible chelate configurations in six geometrical isomers of [M(edma)$_2$]$^+$-type complex and those in two isomers of [Co(edda)(en)]$^+$ complex are given in Figs. 3 and 4, respectively. It is possible to assume from the appearance of the splitting in the first bands of both complex I and *trans*-[Co(edda)(en)]$^+$ in Fig. 1 that the structure of complex I has either configuration (a) or (b) in Fig. 3, which has *trans* configuration with respect to the coordinated carboxylate oxygens.[7,8] However, the choice of (a) or (b) for the structure of complex I is not clear.

The spectrum of complex II has a broad first band, which is slightly split into two components Ia and Ib of nearly equal intensity, at 20.0 and 21.5, and a second band at 28.9×10^3 cm^{-1}.

The spectrum of complex II does not completely agree with that of *cis*-[Co(edda)(en)]$^+$ ion. A slight splitting of the first band makes us believe that complex II has a structure of *cis* configurations. However, the choice of (c), (d), (e) or (f) for the structure of complex II can not be done easily, as they have identical coordination forms except for the difference of the chelating features as seen in Fig. 3.

The spectrum of complex III shows the first band at 19.8 with a small shoulder at 21.7 and the second band at 26.3×10^3 cm^{-1}. On the other hand, the spectrum of [Cr(ox)(en)$_2$]I[5] shows two bands at 20.3 and 27.1×10^3 cm^{-1} with no shoulder near the first band. Since the shoulder at 21.7×10^3 cm^{-1} in complex III is thought to be one of the components of the first band, its configuration is assumed to be *trans* form.

IR Spectra. The infrared absorption spectra

8) H. Yamatera, *ibid.*, **31**, 95 (1958).

of the three new complexes synthesized were measured in the nujol mull state in the range 4000—700 cm^{-1}. Since the strong band appearing at 1730 cm^{-1}, which is assigned to free carboxylic acid in the ligand itself, is found to be shifted to 1630 cm^{-1} in cobalt(III) complexes and to 1645 cm^{-1} in chromium(III) complex, it is obvious that all the carboxylate groups are coordinated to central metal ions in all the three complexes.[9]

Though all the complexes show very similar spectra, the bands appearing at 1220 cm^{-1} (assigned to C–CN stretching vibration)[4] and at 1040 cm^{-1} (assigned to NH_2 twisting)[4] are split into two bands in the case of complexes I and III but not in II. Appearance of the splitting in IR spectra in complexes I and III also supports the conclusion that both complexes I and III have *trans* configuration with respect to the coordinated carboxylate oxygen atoms, since the splitting is observed in the first band of the electronic spectra.

The Thermal Decomposition of Potassium Trioxalatoferrate(III) Trihydrate

Nobuyuki TANAKA and Katsuya SATO

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received August 29, 1969)

The thermal decomposition of $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$ in solid state was studied by the thermogravimetric, the infrared spectroscopic and the manometric methods. It was found that, with elevating temperatures, three moles of water were evolved as the first step to form an anhydrous complex $K_3[Fe(C_2O_4)_3]$, which was then decomposed as the second step by an electron transfer from a ligand to the central iron(III) with the formation of an iron(II) complex. $K_2[Fe(C_2O_4)_2]$, $K_2C_2O_4$ and CO_2 were found as products in the second step. The total pressure of CO_2 gas evolved was measured at suitable time intervals. The shape of a curve of α (the fraction isothermally decomposed) *vs.* t (time) was sigmoidal. The initial part of the decomposition reaction was kinetically of a first-order and the activation energy was obtained to be 43.6 kcal/mol. A main part of it ($0.2<\alpha<0.8$) was of a second-order and obeyed the Prout-Tompkins' law. The activation energy was calculated to be 35.3 kcal/mol.

The thermal decomposition of anhydrous trioxalatoferrate(III) in solid state has been investigated by several researchers. From the polarographic and the infrared studies, Tanaka and Nanjo[1] reported that the thermal decomposition of this complex was initiated by an electron transfer from the coordinated oxalate ion to the central iron(III) forming iron(II) complex. From the thermogravimetric analysis (TGA) and the differential thermal analysis (DTA), Broadbent *et al.*[2] also indicated that a reduction of iron(III) to iron(II) takes place during the decomposition reaction. However, the stoichiometry of this reaction has not been fully determined and no kinetic studies have been reported. Therefore, it is worth while to determine the stoichiometry and to investigate the kinetics of this decomposition reaction. In this paper, the decomposition products which were identified by the thermogravimetric and the infrared spectroscopic methods and the kinetic parameters of this reaction which were obtained by the manometric method are presented. On the basis of the experimental results, possible reaction mechanisms are discussed.

Experimental

Materials. $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$ was prepared with $FeCl_3\cdot 6H_2O$ and $K_2C_2O_4\cdot H_2O$. $K_2[Mn(C_2O_4)_2]$, $K_2[Co(C_2O_4)_2]$ and $K_2C_2O_4$ were prepared from their hydrates. $K_2[Mn(C_2O_4)_2]\cdot 2H_2O$ was prepared with $MnSO_4\cdot 4\sim 6H_2O$, $H_2C_2O_4\cdot 2H_2O$ and $K_2C_2O_4\cdot H_2O$. $K_2[Co(C_2O_4)_2]\cdot 6H_2O$ was prepared with $Co(NO_3)_2\cdot 6H_2O$, $H_2C_2O_4\cdot 2H_2O$ and $K_2C_2O_4\cdot H_2O$.

Apparatus and Procedure. The thermogravimetric curve was recorded with an automatic-recording thermobalance, Shimadzu Thermano Balance Type RT-2, in a nitrogen atmosphere. Two hundred milligrams of sample was used in each measurement. The furnace heating rate was about 4°C per min. The

1) N. Tanaka and M. Nanjo, This Bulletin, **40**, 330 (1967).

2) D. Broadbent, D. Dollimore and J. Dollimore, *J. Chem. Soc.*, *A*, **1967**, 451.

particle size of the sample was smaller than 200 mesh.

A Hitachi EPI-2G double-beam infrared spectrophotometer equipped with a potassium bromide foreprism and gratings was used for the measurement of the infrared absorption spectra. The potassium bromide disk method was employed except the case of the identification of gaseous product.

The reflectance spectra were obtained on a Hitachi photo-electric spectrophotometer EPU-2 equipped with a standard reflectance attachment. Powdered magnesium oxide was used as a standard.

Decomposition pressure-time curves of the isothermal decomposition reaction were obtained by the manometric method. The temperature of the sample was controlled in a range of ± 0.5°C by means of a mercury regulator and an electric furnace. The measurement of isothermal decomposition of anhydrous trioxalato complex was carried out after hydrate sample was previously dehydrated at 120°C for 4 hr in each run. Samples which were smaller than 200 mesh in size weighed 33.5 mg in each run unless otherwise stated. The fraction decomposed in the pyrolysed sample, α, is calculated according to the equation,

$$\alpha = \frac{\text{Total } CO_2 \text{ pressure at time } t}{\text{Total } CO_2 \text{ pressure at the completion of reaction}}$$

The rate constants of the isothermal decomposition were obtained from the kinetic analysis of α-t curves. The kinetic parameters were calculated according to the Arrhenius equation.

Results and Discussion

Stoichiometric Studies. From the TGA curve of the trioxalatoferrate(III) as shown in Fig. 1, it

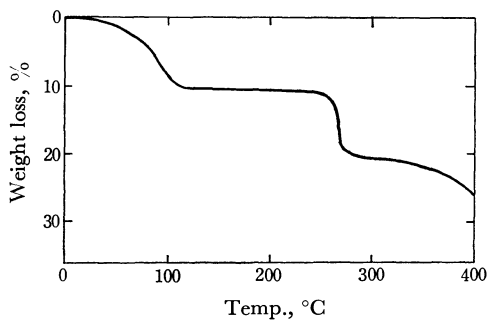

Fig. 1. Thermogravimetric curve of $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$ obtained in nitrogen atmosphere.

can be seen that the first stage in the decomposition reaction begins at 30°C and completes at 120°C. The weight loss in this stage was determined to be 10.6%. This result agrees with the calculated weight loss of 11.00% for the loss of 3 mol of water. This dehydrated complex is thermally stable up to 230°C. The second stage in the decomposition reaction begins at 250°C and completes at 300°C. The weight loss was found to be 9.5% and the color change from green to yellow was observed. This weight loss is compared with the calculated value of 8.96% for the evolution of carbon dioxide, which was identified by the measurement of infrared spectra of the gaseous product.

In order to identify the solid-state decomposition products, infrared spectra were obtained with the samples which were completely decomposed and with some of other anhydrous complexes. They are shown in Fig. 2. The decomposition products

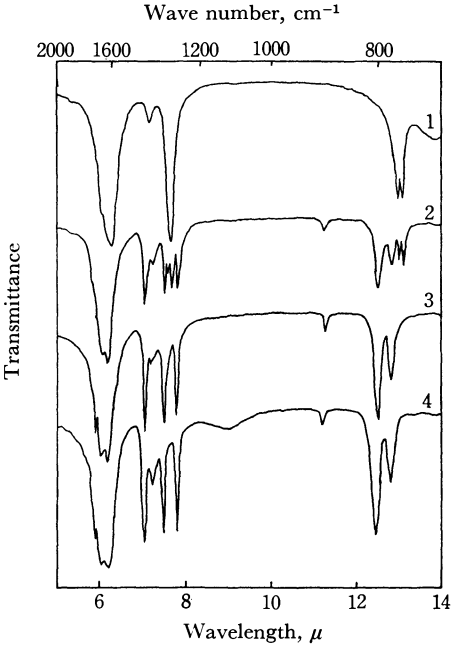

Fig. 2. Infrared absorption spectra of (1) $K_2C_2O_4$, (2) decomposition products, (3) $K_2[Mn(C_2O_4)_2]$ and (4) $K_2[Co(C_2O_4)_2]$. Transmittance scale is displaced arbitrarily.

give absorption bands at 764.5, 771.0 and 1305 cm^{-1} which are also observed with anhydrous potassium oxalate. This means that one component of the solid-state products is anhydrous potassium oxalate. The rests of the absorption bands of the products are similar to those of $K_2[Mn(C_2O_4)_2]$ and $K_2[Co(C_2O_4)_2]$. This indicates that another component of the products will be $K_2[Fe(C_2O_4)_2]$. The absorption band at 1289 cm^{-1} of the product, which was not observed with $K_2[Mn(C_2O_4)_2]$ and $K_2[Co(C_2O_4)_2]$, may be a characteristic one of $K_2[Fe(C_2O_4)_2]$. Unfortunately, however, the infrared absorption spectra of $K_2[Fe(C_2O_4)_2]$ could not be obtained because of the difficulty in the preparation of the complex. From the chemical analysis and the reflectance spectroscopic studies, Wendlandt and Simmons reported that decomposition products of the corresponding complexes of manganese(III)[3] and cobalt(III)[4] were also dioxalato complexes of

3) E. Simmons and W. Wendlandt, *J. Inorg. Nucl. Chem.*, **27**, 2325 (1965).

4) W. Wendlandt and E. Simmons, *ibid.*, **27**, 2317 (1965).

manganese(II) and cobalt(II), respectively. These facts support, though indirectly, the results obtained in this study.

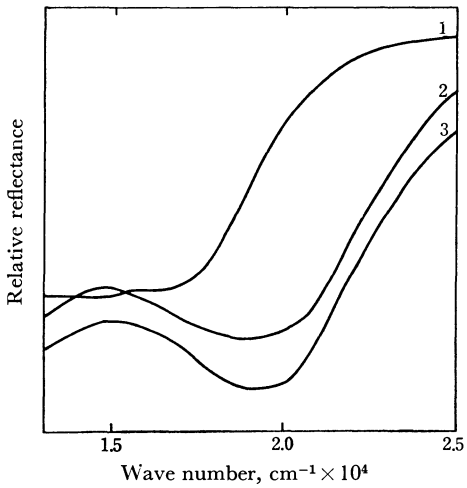

Fig. 3. Reflectance spectra of (1) decomposition products, (2) $K_3[Fe(C_2O_4)_3]$ and (3) $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$. Relative reflectance scale is displaced arbitrarily.

The reflectance spectra of $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$, $K_3[Fe(C_2O_4)_3]$ and its decomposition products are shown in Fig. 3. In the case of $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$ and its anhydride, the absorption bands due to the d–d transition appear at 14925 cm^{-1} and 14706 cm^{-1}, respectively. Above 19000 cm^{-1}, the absorption of both compounds increases with increasing wave numbers. This means that the structure of $[Fe(C_2O_4)_3]^{3-}$ ion in $K_3[Fe(C_2O_4)_3]$ is similar to that in $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$; the structure of $[Fe(C_2O_4)_3]^{3-}$ ion in the latter is octahedral. Of the decomposition products, which must be $K_2C_2O_4$ and $K_2[Fe(C_2O_4)_2]$, $K_2C_2O_4$ is transparent throughout all of the visible region of the spectrum, and therefore the absorption may be due to $K_2[Fe(C_2O_4)_2]$. It can be assumed that the structure of $[Fe(C_2O_4)_2]^{2-}$ ion is either tetrahedral or planar. If it is tetrahedral, only one absorption may appear, whereas if planar, several absorptions may appear because of a lower symmetry of crystal field. Actually, as $K_2[Fe(C_2O_4)_2]$ gives an absorption which increases gradually with increasing wave numbers as shown in Fig. 3 and its color is yellow, its structure may be tetrahedral. From all of these informations obtained in this study, the stoichiometry of the thermal decomposition reaction was estimated to be:

i) $K_3[Fe(C_2O_4)_3]\cdot 3H_2O \rightarrow K_3[Fe(C_2O_4)_3] + 3H_2O$

ii) $K_3[Fe(C_2O_4)_3] \rightarrow K_2[Fe(C_2O_4)_2] + \frac{1}{2}K_2C_2O_4 + CO_2$

In the case of photolysis,[5] the reduction product is a monooxalatoiron(II) complex. This means that the mechanism of the electron transfer to iron(III) is different from each other in the cases of the thermal and the photolytic decomposition.

Kinetic Studies. The kinetics of the decomposition reaction was investigated by the manometric measurements. A plot of α *vs.* t was sigmoidal when the anhydride was decomposed completely. It may be divided from the standpoint of kinetics into two stages; (a) the initial reaction which is fitted to a first-order rate law where α is smaller than 0.05, and (b) the main reaction which is fitted to the Prout-Tompkins' equation[6] where α is between 0.2 and 0.8.

(a) The Initial Reaction. At lower temperatures, the curves of α *vs.* t show the initial stage of the decomposition reaction. (See Fig. 4). The rate constant in this stage, k_1, was expressed by the equation,

$$\frac{d\alpha}{dt} = k_1(1-\alpha) \qquad (1)$$

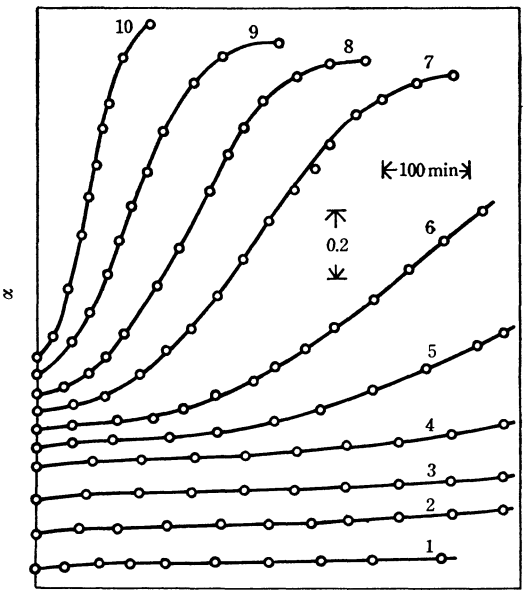

Fig. 4. Fractional decomposition as a function of time at (1) 180.5, (2) 183.2, (3) 184.0, (4) 186.5, (5) 190.5, (6) 195.3, (7) 201.0, (8) 205.0, (9) 210.5, and (10) 216.0°C.

Equation (1) is converted to

$$\ln(1-\alpha) = -k_1 t \qquad (2)$$

and the values of k_1 were determined from the slopes of $\log(1-\alpha)$ *vs.* t (Table 1). The Arrhenius plot for this stage is shown in Fig. 5. The kinetic equation derived from the Arrhenius plot is

5) W. Wendlandt and E. Simmons, *J. Inorg. Nucl. Chem.*, **28**, 2420 (1966).

210.5	—	4.58
216.0	—	8.51

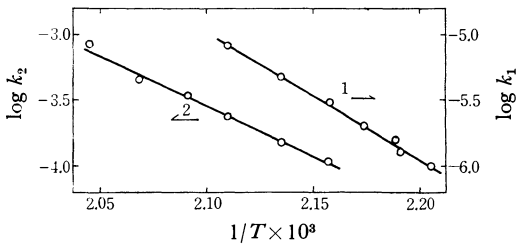

Fig. 5. Arrhenius plots for (1) the initial reaction (k_1) and (2) the main reaction (k_2).

$$\log k_1 = \frac{-43600}{2.3RT} + 14.9 \qquad (3)$$

(b) The Main Reaction. At higher temperatures, the experimental results were fitted to the Prout-Tompkins' equation,

$$\frac{d\alpha}{dt} = k_2(1-\alpha)\alpha \qquad (4)$$

over the range of $\alpha=0.2$ to 0.8. (See also Fig. 4). Equation (4) is converted to

$$\ln\frac{\alpha}{1-\alpha} = k_2 t \qquad (5)$$

The rate constant of the main reaction, k_2, was determined from the slope of $\log \alpha/(1-\alpha)$ *vs.* t (Table 1). The Arrhenius plot for this stage is also shown in Fig. 5. The activation parameters were determined as usual from the Arrhenius equation:

$$\log k_2 = \frac{-35300}{2.3RT} + 12.6 \qquad (6)$$

In the region where the rate obeyed to the Prout-Tompkins' law, the effects on the reaction rate were investigated under several experimental conditions. Changes in sample weight and particle size were found to give little difference in the rate constant as shown in Table 2; sample weight was changed from 10.0 to 33.5 mg and particle size, from 150~200 mesh to smaller than 200 mesh. The effect of pressure of carbon dioxide gas was also investigated. Pressure-time curves A, B and C measured are shown in Fig. 6. When curves B and C are shifted

TABLE 2. EFFECTS OF SAMPLE WEIGHT AND PARTICLE SIZE ON THE RATE CONSTANT k_2 FOR THE REACTION

Temp. °C	Sample weight* mg	Particle size mesh	$k_2\times10^4$ sec^{-1}

208.0	20.0	150~200	3.96

* Weight is converted for hydrate.

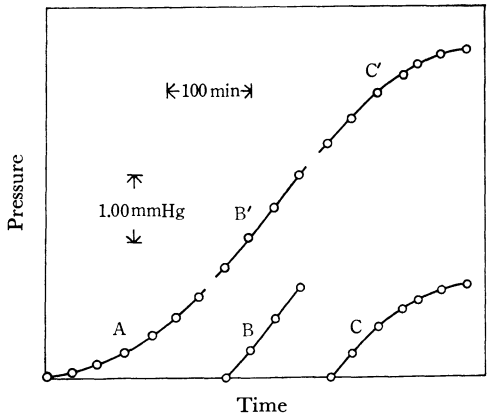

Fig. 6. Decomposition pressure of $K_3[Fe(C_2O_4)_3]$ as a function of time at 201.0°C, when system was evacuated at suitable time intervals (Curves A, B, and C). Curves B′ and C′ are obtained by shifting curves B and C in a proper way.

parallel to pressure axis, curves B′ and C′ are obtained. The shape of curve A-B′-C′ is identical with that obtained under the condition that the decomposition gas was not removed. This means that the rate of the decomposition reaction is not affected by the pressure of carbon dioxide gas. In order to investigate the reaction process, the mixture of $K_3[Fe(C_2O_4)_3]$ and its actual decomposition product and also the mixture of $K_3[Fe(C_2O_4)_3]$ and anhydrous $K_2C_2O_4$ were subjected to the thermal decomposition, because $K_2C_2O_4$ was considered to be one of the decomposition products. The rate constants obtained were compared with those ob-

TABLE 3. EFFECTS OF DECOMPOSITION PRODUCTS AND $K_2C_2O_4$ ON THE RATE CONSTANT k_2 FOR THE REACTION AT 208°C

Material added to $K_3[Fe(C_2O_4)_3]\cdot3H_2O$ and its wieght percentage in parentheses	Total weight mg	$k_2\times10^4$ sec^{-1}
None	20	3.96
Actual decomposition product (16.7%)	25	3.83
$K_2C_2O_4\cdot H_2O$ (20%)	25	4.20

tained with $K_3[Fe(C_2O_4)_3]$ alone, when no significant difference was observed (Table 3). It was found that, as far as the main reaction is concerned, neither products nor potassium oxalate react chemically with $K_3[Fe(C_2O_4)_3]$, and they have no catalytic role in the decomposition reaction. It is said that chemical processes which give α *vs.* t plots of sigmoidal shape usually result from reactions which take place at the reactant-product interface.[7] This indicates that, when the decomposition products are mixed mechanically with the reactant before heating, the effective area of the reactant-product interface is much smaller than that which is actually produced in the course of reaction. The Prout-Tompkins' equation means the existence of the acceleration and the deceleration period. The former corresponds to the increase in the area of the reactant-product interface. In the latter, the reaction interface still continues to grow towards the central unreacted regions of the particle, but the interfacial area begins to overlap, and therefore the rate becomes deceleratory until the decomposition of the reactant is completed. Presumably, this reaction is controlled by the diffusion of the interface. Further evidence is necessary to state the relationship between the reaction mechanism and the Prout-Tompkins' law.

Synergistic Effect in Solvent Extraction—Effect of Oxygen and Nitrogen Containing Organic Bases on the Stability of Zinc(II) and Cobalt(II) β-Diketonate Adducts—

Tsunenobu SHIGEMATSU, Takaharu HONJYO,*1 Masayuki TABUSHI and Masakazu MATSUI

Institute of Chemical Research, Kyoto University, Uji, Kyoto

(Received September 5, 1969)

The effect of the organic Lewis bases acting as a synergist on the extraction of zinc(II) and cobalt(II) with benzoyltrifluoroacetone was studied. *n*-Hexyl alcohol, TBP, TBPO and TOPO were used as oxygen-containing bases, and quinoline, isoquinoline, lepidine, acridine and quinaldine as nitrogen-containing bases. The stability constants between metal chelates and the adduct forming materials in the organic phase were obtained by curve fitting method. The results are summarized as follows: (1) Zinc(II) and cobalt(II) chelates formed adducts including one or two molecules of the bases per metal ion. Adduct formation was carried out successively. (2) The stability of adducts with oxygen-containing organic bases increased in the order, *n*-hexyl alcohol$<$TBP$<$TBPO$\approx$TOPO. This is the same order with that of the basicity of donor oxygen in the compounds. The stability of adducts with nitrogen-containing bases increased in the order, quinaldine$<$acridine$<$quinoline$<$lepidine$<$isoquinoline. In this case, however, the steric effect of the bases preferably contributed to the adduct formation. (3) The overall stability constants of the adducts are affected by the coordination number of the metal ions. Cobalt(II) adducts are more stable than zinc(II) adducts.

In many extraction systems of metal β-diketone chelates, the presence of some neutral organic Lewis bases extremely enhances the extractability. Such phenomena, called "synergistic effect" can be explained by adduct formation between the metal chelates and the Lewis bases. The authors have made a systematic study on synergistic extraction,[1-4]

and reported on the influence of terminal groups of β-diketones in zinc-β-diketone-TOPO system.[4] In the present research, the effect of organic Lewis bases on the synergistic extraction of zinc(II) and cobalt(II) with benzoyltrifluoroacetone was studied, and the stability constants of the adducts were determined.

Experimental

The radioisotopes, zinc-65 and cobalt-60 were supplied by the Radiochemical Centre, Amersham, England, as chlorides in hydrochloric acid solution. They were converted to the perchlorates and diluted with 0.01M perchloric acid to make stock solutions. Sodium perchlorate was prepared by dissolving sodium carbonate in perchloric acid and purified by recrystallization from water. Benzoyltrifluoroacetone (BFA) was obtained from the Dojindo Co. Organic bases; TOPO (tri-*n*-octylphosphine oxide), TBPO (tri-*n*-butylphosphine oxide), *n*-hexyl alcohol, quinoline, isoquinoline, lepidine, quinaldine and acridine were obtained commercially. TBP was purified by washing successively with a dilute sodium hydroxide solution, a dilute hydrochloric acid solution and a saturated sodium chloride solution, followed by centrifugation. All the other reagents were GR grade materials and used without further purification.

Experimental procedure was almost the same as previously described.[1-4] Five milliliters of aqueous solution containing zinc(II) or cobalt(II) ions (a few ppm), sodium perchlorate (0.1M) and acetic acid (0.01M) were adjusted to a desired pH, and shaken with 5 m*l* of benzene solution containing 0.05M benzoyltrifluoroacetone and various amount of organic bases, for one to three hours, at 20±1°C. After separating two phases, 2 m*l* of each of the phases was pipetted into test tubes (14 mm in diameter), and radioactivity was measured with a NaI(Tl) well-type scintillation counter. The pH values of the aqueous layers after the extraction were again measured, and the data were used for plotting the distribution curves.

Theoretical

The extraction constants of metal chelates, K, and the stability constants of adducts, β_n, were calculated by the equations

$$K = [MR_2]_o[H^+]^2/[M^{2+}][HR]_o^2, \quad (1)$$

$$\log K = \log D - 2\log [HR]_o - 2pH, \quad (2)$$

$$\beta_n = [MR_2L_n]_o/[MR_2]_o[L]_o^n, \quad (3)$$

$$\log D^*/D = \log(1 + \sum_{n=1}^{n} \beta_n[L]_o^n), \quad (4)$$

where D and D^* were the distribution ratios in the absence or presence of organic bases, M stood for metal, HR for β-diketone and L for organic bases; and [ ] and [ ]$_o$ designated the concentration of the chemical species in the aqueous and organic phase, respectively.

The equilibrium concentration of the bases, $[L]_o$, can be assumed to be equal to the initial concentration, C_L, in the case of oxygen-containing bases, because the amount of metal ions is negligibly small and the bases are scarcely distributed to the aqueous phase. However, nitrogen-containing bases can form the cationic species such as LH^+ in acidic aqueous solution, and accordingly the $[L]_o$ value may not be the same with, but lower than the C_L value. Using the dissociation constant, $K_{LH} = [H^+][L]/[LH^+]$, and the partition coefficient, $P_L = [L]_o/[L]$, the relation between these two concentrations may be given as follows:

$$C_L = [L]_o(1 + P_L^{-1} + P_L^{-1}K_{HL}^{-1}[H^+]) \quad (5)$$

The $\log P_L$ values of quinoline and isoquinoline are about 2 at 20±2°C and the pK_{LH} values are 4.85 (quinoline) and 5.14 (isoquinoline) (Ref. 5). In the pH region studied (pH 4.5—6.0), more than 90 per cent of the base must be present in organic phase, and therefore, the error caused by using C_L for $[L]_o$ can be neglected. The $\log P_L$ and pK_{LH} values of the other three bases are unknown or uncertain. However, as they are almost insoluble in water, and their K_{LH} values may not be so low as to cover their very high P_L, we might assume that the situation is similar to the case of quinoline and isoquinoline.

Results and Discussion

Fugures 1 and 2 show the $\log D$ *vs.* pH plots and the $\log D$ *vs.* $\log [HR]_o$ plots in the extraction of zinc(II) and cobalt(II) with BFA only. All the plots give an almost straight line with a slope of 2, indicating that over all extraction equilibrium can be written as follows:

$$M^{2+} + 2HR(org) \rightleftharpoons MR_2(org) + 2H^+ \quad (6)$$

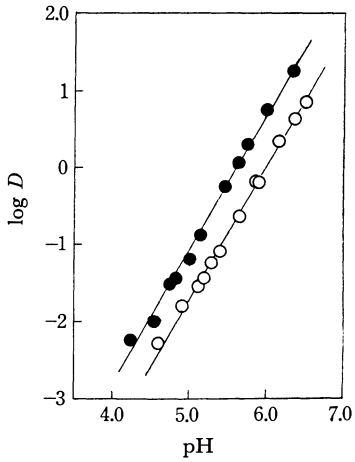

Fig. 1. Variation of the distribution ratio of zinc-(II) (—●—) and cobalt(II) (—○—) as a function of pH.
Organic phase: 0.05M BFA in benzene
Aqueous phase: 0.1M $NaClO_4$

5) H. M. N. H. Irving and N. S. Al-Niaimi, *J. Inorg. Nucl. Chem.*, **27**, 1671 (1965).

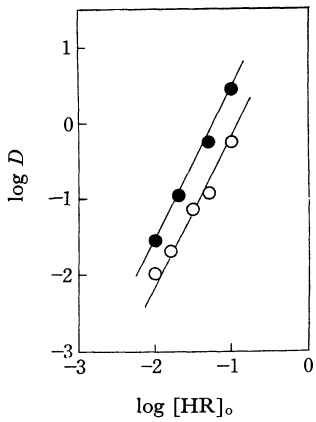

Fig. 2. Variation of the distribution ratio of zinc-(II) (—●—) and cobalt(II) (—○—) as a function of chelate ligand concentration.
Organic phase: BFA in benzene
Aqueous phase: 0.1M $NaClO_4$, pH=5.5

The extraction constants, K, can be calculated by Eq. (2).

The change in the distribution ratio of zinc and cobalt resulting from the addition of organic Lewis bases is shown in Figs. 3 and 4, as the log D^*/D *vs.* log $[L]_o$ plots (actually, log D^*/D *vs.* log C_L plots). When the metal chelates react with organic bases to form adducts in organic phase, the equilibrium may be written as follows:

$$MR_2(org) + nL(org) \rightleftharpoons MR_2L_n(org) \qquad (7)$$

Since the slope of linear log D^*/D *vs.* log $[L]_o$ plots or the slope of an asymptote of curved plots indicates the maximum number of the base molecule, it is considered that cobalt BFA chelate forms MR_2L type adduct with TBPO, TOPO, quinaldine

* MR_2L_2 type adduct was not observed.
** Taken from Ref. 4.

The stability of zinc and cobalt adducts with oxygen-containing Lewis bases increases in the order, *n*-hexyl alcohol<TBP<TBPO≈TOPO, which is the

6) T. Sekine and D. Dyrssen, *ibid.*, **26**, 1727 (1964).

same with that of the donating power of lone-pair electron of oxygen atom. In other words, the stability directly corresponds to the basicity of the base. A similar tendency has been observed in rare earth metals-BFA,[1] zinc-TTA[6-8] and europium-TTA systems.[9] In the TTA systems, the increasing order of the stability found in carbon tetrachloride was: hexone<TBEP<TBP<TBPO≈TOPO. From the fact that TBPO adducts as well as the TOPO adducts are stable it may be deduced that the length of hydrocarbon chain of alkyl phosphine oxides or alkyl phosphate does not give important effect on the stability of the adducts.

The over all stability of the adducts with nitrogen containing Lewis bases increases in the order, quinaldine<quinoline<isoquinoline for zinc, and quinaldine<acridine<quinoline<lepidine<isoquinoline for cobalt. The order of stability does not only correlate with the basicity, but results preferably from the steric effect by methyl or phenyl groups of the bases. A similar result has been observed in the adduct formation between cobalt acetylacetonate and pyridine derivatives, where the apparent stability of the adducts increases as, α-picoline<2,6-lutidine<2,4-lutidine<β-picoline<γ-picoline.[10]

The effect of the basicity of oxygen-containing Lewis bases and the steric effect of nitrogen-containing bases reflect the maximum number of the base molecule involved in the adduct. *n*-Hexyl alcohol forms MR_2L_2 type adduct with both zinc and cobalt chelates, TBP forms the same type adduct with cobalt chelate, but TBPO and TOPO forms only MR_2L type adduct. Steric hindrance appears similarly in the formation of MR_2L_2 type cobalt adduct with nitrogen-containing bases. Maximum mole ratio of the base to cobalt chelate is 2 for quinoline, isoquinoline and lepidine adducts, but 1 for quinaldine and acridine adducts.

In general, cobalt BFA chelate forms more stable adduct than zinc chelate. This may be due to the fact that cobalt ion has a coordination number of six and takes octahedral configuration, while zinc ion has a coordination number of four and usually forms tetrahedral complexes, although octahedral configuration with a coordination number of six should be expected in some cases.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 796—800 (1970)

Synergistic Effect in Solvent Extraction—Effect of the Chelating Ligands on the Stability of Lutetium Mixed Chelates with β-Diketones and Their Adducts with TOPO—

Tsunenobu SHIGEMATSU and Takaharu HONJYO*1

Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received September 5, 1969)

The effect of the chelating ligands on the stability of mixed chelates of lutetium with β-diketones and the stability of their adducts with TOPO in benzene was studied by extracting lutetium with mixtures of two β-diketones, benzoylacetone (BzA) and dibenzoylmethane (DBM), and benzoylacetone and benzoyltrifluoroacetone (BFA), in the absence or in the presence of TOPO. The results are summarized as follows. (1) The extraction constants of Lu-BzA-DBM mixed chelates are almost the same as statistically calculated, while those of Lu-BzA-BFA mixed chelates are somewhat lower than the theoretical values. (2) The stability of the TOPO adducts of the mixed chelates increases in the order, $M(BzA)_2(DBM) \approx M(BzA)(DBM)_2 < M(BzA)_2(BFA) < M(BzA)(BFA)_2$, which is almost the same as that found among the extraction constants of the mixed chelates. The fluoromethyl group stabilizes the adduct more than phenyl group. (3) All the mixed chelates of lutetium β-diketonates bind one molecule of TOPO per metal chelate.

In the solvent extraction of rare earth β-diketonates, the presence of TOPO brings about the considerably enhancement of the extractability, which results from the adduct formation between the metal chelates and TOPO. The authors investigated the

*1 Present address: Faculty of Science, Kanazawa University, Kanazawa

effects of the size of central rare earth metal ions and of the terminal group of β-diketones on the synergistic extraction, and concluded that the stability of the adducts increased as the ionic radius of rare earth metal ions increased[1] or the terminal groups of β-diketones were substituted with aliphatic, aromatic and fluoromethyl groups.[2]

Recently, Sekine and Dyrssen[3,4] described the extraction of copper, zinc, indium and europium with mixtures of TTA and β-isopropyltropolone, and presented the extraction constants of the mixed chelates of these metals and the stability constants of the adducts of europium chelates with undissociated chelating agent, β-isopropyltropolone. However, the stability of the adducts formed between mixed chelates and neutral Lewis bases such as TOPO was reported neither by them nor by other investigators.

As it seems interesting to know how the stability of such adducts depends upon the successive formation of various mixed chelates, and it is also important to obtain more detailed information about the effect of the chelating ligands on the stability of the adducts, the authors attemped to deal with this subject. In the present research, the extraction behaviors of lutetium with mixtures of two β-diketones, benzoylacetone and dibenzoylmethane, and benzoylacetone and benzoyltrifluoroacetone in benzene were studied in the absence or in the presence of TOPO, and the extraction constant of the mixed chelates and the stability constants of their adducts with TOPO were obtained.

Experimental

Materials. The radio-isotope, lutetium-177 was produced by irradiating pure lutetium oxide in a thermal neutron flux of about 5×10^{12}n/cm^2·sec in the Research Reactor of Kyoto University. After the irradiated sample was dissolved in hot hydrochloric acid, lutetium was extracted at pH 5 with 0.05M BFA in benzene and stripped into 0.1M perchloric acid. The resulting solution was evaporated to fume and the residue was dissolved with an appropriate amount of perchloric acid to make a stock solution. Specific activity of the tracer was sufficiently high for this investigation. Sodium perchlorate was prepared by dissolving sodium carbonate in perchloric acid and purified by recrystallization. Benzoylacetone (BzA), dibenzoylmethane (DBM), benzoyltrifluoroacetone (BFA) and tri-*n*-octylphosphine oxide (TOPO) were obtained from the Dojindo Co.

Procedure. Experimental procedure was almost the same as previously described.[1,2] Five milliliters of an aqueous solution containing lutetium (a few ppm), sodium perchlorate (0.1M) and acetic acid (0.01M), and having a desirable pH, were shaken with 5 m*l* of a benzene solution including β-diketones and various amount of TOPO, for one to three hours at 20±1°C. After separating both phases, 2 m*l* of each phase were pipetted into test tubes (14 mm in diameter), and the radioactivities were measured with a NaI(Tl) well-type scintillation counter. The pH value of the aqueous layers after extraction was again measured with a glass electrode pH meter.

Theoretical

When tervalent ions, M^{3+}, are extracted with a mixture of two chelating acids, HA and HB, the ideal extraction equilibrium may be written as

$$M^{3+} + mHA(org) + (3-m)HB(org) \rightleftharpoons MA_mB_{3-m}(org) + 3H^+ \quad (1)$$

The extraction constants of the reaction, $K_{m,3-m}$ and the distribution ratio of the metal, D, can be given by

$$K_{m,3-m} = [MA_mB_{3-m}]_o[H^+]^3[M^{3+}]^{-1}[HA]_o^{-m} \times [HB]_o^{-(3-m)} \quad (m = 0, 1, 2, 3) \quad (2)$$

$$D = \sum_{m=0}^{3}[MA_mB_{3-m}]_o[M^{3+}]^{-1} \quad (3)$$

where [ ] and [ ]$_o$ designate the concentration of chemical species in the aqueous and organic phase, respectively.

From Eqs. (2) and (3), a fundamental equation of the curve fitting method is obtained as follows:

$$\log D[H^+]^3[HB]_o^{-3} - \log K_{0,3} = \log\{1+K_{0,3}^{-1}K_{1,2}([HA]_o/[HB]_o) + K_{0,3}^{-1}K_{2,1}([HA]_o/[HB]_o)^2 + K_{0,3}^{-1}K_{3,0}([HA]_o/[HB]_o)\} \quad (4)$$

Comparing the experimental curves, $Y=\log D\cdot[H^+]^3[HB]_o^{-3}-\log K_{0,3}$, $X=\log([HA]_o/[HB]_o)-\frac{1}{3}\log K_{0,3}K_{3,0}^{-1}$, with the normalized curves, $Y=\log(1+pv+qv^2+v^3)$, $X=\log v$, the following relations can be obtained.

$$K_{1,2} = p(K_{0,3}^2K_{3,0})^{1/3} \quad (5)$$

$$K_{2,1} = q(K_{0,3}K_{3,0}^2)^{1/3} \quad (6)$$

The statistical relation between these equilibrium constants can be given as, $K_{1,2}=3(K_{0,3}^2K_{3,0})^{1/3}$ and $K_{2,1}=3(K_{0,3}K_{3,0}^2)^{1/3}$ (*cf.* Ref. 4).

When metal chelates, MA_mB_{3-m} form the adducts with a neutral Lewis base, L, in the organic phase, the equilibrium may be expressed as

$$MA_mB_{3-m}(org) + nL(org) \rightleftharpoons MA_mB_{3-m}L_n(org) \quad (7)$$

The stability constants of the adducts, β_n, and the distribution ratio, D^*, are given by

$$\beta_n = [MA_mB_{3-m}L_n]_o/[MA_mB_{3-m}]_o[L]_o^n \quad (8)$$

$$D^* = \{[MA_mB_{3-m}]_o + \sum_{n=1}^{n}[MA_mB_{3-m}L_n]_o\}/[M^{3+}] \quad (9)$$

From Eqs. (3) and (9), the following equations can be obtained,

1) T. Shigematsu, M. Tabushi, M. Matsui and T. Honjyo, This Bulletin, **40**, 2807 (1967).
2) T. Honjyo, *ibid.*, **42**, 995 (1969).
3) T. Sekine and D. Dyrssen, *J. Inorg. Nucl. Chem.*, **26**, 2013 (1964).
4) T. Sekine and D. Dyrssen, *ibid.*, **29**, 1489 (1967).

$$D^*/D = 1 + \sum_{n=1}^{n} \beta_n [\mathrm{L}]_o^n \quad (10)$$

or

$$\log D^*/D = \log \left(1 + \sum_{n=1}^{n} \beta_n [\mathrm{L}]_o^n\right) \quad (11)$$

The derivations of the equations are described in previous papers.[1,3,4]

Results and Discussion

Lutetium-β-Diketone System. Figures 1 and 2 show the extraction of lutetium with BzA, DBM and BFA alone in benzene as a function of pH and the chelating agent concentration, respectively. All the plots give almost a straight line with a slope of 3 indicating that the extraction of lutetium is ideally performed.

	$Lu(DBM)_3$	−15.16		6.15

* The values were estimated from Eqs. (5) and (6) by assuming $p=3$ and $q=3$ (theoretical value).

mixtures of BzA and DBM, and BzA and BFA in benzene with different mixing ratios. From the plots, p and q values of the normalized curves were obtained by the curve fitting method, and the extraction constants of mixed chelate, $K_{1,2}$ and $K_{2,1}$ were calculated by Eqs. (5) and (6), using $K_{0,3}$ and $K_{3,0}$ values which were obtained by extraction with each β-diketone. The results are listed in Table 1. The extraction constants experimentally obtained of the BzA-DBM mixed chelates are almost the same with the value statistically calculated, while those of the BzA-BFA mixed chelates are somewhat lower than the calculated values. Similar results have been observed on europium-TTA-IPT and indium-TTA-IPT mixed chelates.[4]

The $\log D[H^+]^3[HB]_o^{-3}$ *vs.* $\log([HA]_o/[HB]_o)$ plots have two asymptotes with the slope of 0 (for $[HA]_o/[HB]_o \to 0$) and 3 (for $[HA]_o/[HB]_o \to \infty$). The slope of the tangent gently changing from 0 to 3, indicates the composition of the metal chelates extracted under the condition. Namely, MA_3, MA_2B, MAB_2 and MB_3 may each exist as a predominant species in the region where the slope of the tangent is 0, 1, 2 and 3, respectively.

Lutetium-β-Diketone-TOPO System. Figures 4 and 5 indicate the log D *vs.* pH plots in the extraction of lutetium ions with the mixtures of two β-diketones in the absence and presence of 10^{-3}M TOPO in benzene: The mixing ratio of two β-diketones lies in the region where the predominant species is MA_2B (Fig. 4) and MAB_2 (Fig. 5). The large enhancement of the extraction observed in the

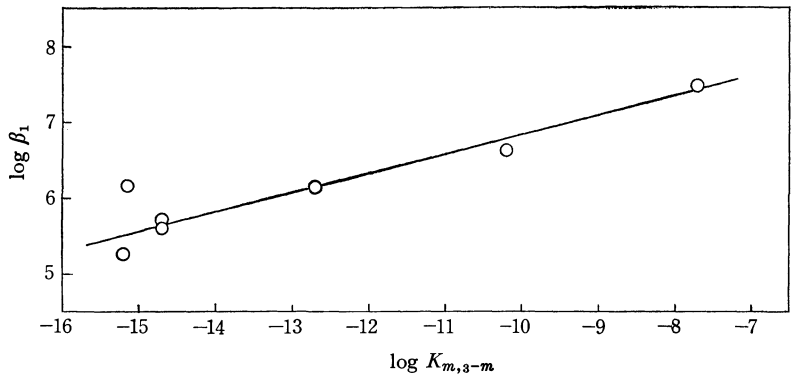

Fig. 7. Stability constant of lutetium β-diketonate adducts with TOPO as a function of the extraction constant of lutetium β-diketonates.

presence of TOPO shows that the mixed chelates, MA_2B and MAB_2 form adducts with TOPO as the simple chelates MA_3 and MB_3.

Figure 6 indicates $\log D^*/D$ *vs.* $\log [TOPO]_0$ plots in the extraction of lutetium with each of three β-diketones or with mixtures of two β-diketones. All the plots give the straight line with a slope of 1, showing that one molecule of TOPO binds to one molecule of the metal chelates. The apparent stability constants of the adducts with TOPO are summarized in Table 1. The stability of the adduct of the mixed chelates increases in the order, $Lu(BzA)_2(DBM) \approx Lu(BzA)(DBM)_2 < Lu(BzA)_2(BFA) < Lu(BzA)(BFA)_2$.

Figure 7 shows the relation between $\log K$ and $\log \beta_1$. Both values linearly correlate with each other and in the BzA-BFA mixed system, increase smoothly without showing any irregularity, as BzA is successively replaced by BFA. The fact leads to the following conclusions: (1) The concept that metal chelates having higher K value form more stable adducts is true of the mixed chelates, as well as of the simple chelates. (2) Asymmetry of the structure of mixed chelates does not give a measurable effect on the adduct formation. (3) Fluoromethyl group, irrespective of simple chelates or mixed chelates, makes the chelates form stable adducts. (3) can be explained by the electron withdrawing effect of fluoromethyl group.[2)]

The authors are grateful to Drs. M. Tabushi and M. Matsui (Institute for Chemical Research, Kyoto University) for their helpful advice and discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 801—804 (1970)

The Thermal Annealing Behavior of Recoil Manganese Atoms Produced in Alkali Metal Permanganates by (n, 2n) and (n, γ) Reactions*1

Takanobu SHIOKAWA and Teikichi SASAKI*2

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received October 3, 1969)

The thermal annealing behavior of recoil manganese atoms produced in alkali metal permanganates by $^{55}Mn(n,2n)^{54}Mn$ and $^{55}Mn(n,\gamma)^{56}Mn$ reactions was studied. In the case of potassium permanganate, the thermal annealing of ^{54}Mn proceeded faster than that of ^{56}Mn. The retention of ^{54}Mn in the annealing curve decreased after an initial increase when it was treated at 180°C, whereas this anomaly was not observed in the case of ^{56}Mn. These differences in the annealing behavior of the two nuclides were ascribed to the effects of background gamma radiation during the neutron irradiation and also to the differences in recoil energies. An effect of the counterpart cations of permanganate was also observed in the thermal annealing behavior, and was interpreted in terms of the ionization potential of alkali metal.

It is well known that the chemical behavior of recoil atoms of the same element produced in a crystal by different nuclear processes is often not exactly the same. However, very little work has been carried out on their thermal annealing behaviors.

Aten and his co-workers[1] studied the thermal annealing of iodine atoms produced in potassium iodate by $^{127}I(n,2n)^{126}I$ and $^{127}I(n,\gamma)^{128}I$ reactions and observed that the thermal annealing of both recoils proceeded at the same rate, while the initial retention of ^{128}I recoils is higher than that of ^{126}I recoils. Jach and Harbottle[2] found that the thermal annealing of ^{82}Br recoils in bromate crystal irradiated with thermal neutrons proceeded faster than that of ^{80m}Br recoils. These isotope effects on thermal annealing behavior have been ascribed to the differences in the initial recoil energies of the various isotopes and also to differences in the electric charge of the recoil atoms. However, more detailed investigations are necessary in order to elucidate the effect of the recoil energy on thermal annealing.

This paper will deal with the thermal annealing behavior of recoil manganese atoms produced in alkali metal permanganates by $^{55}Mn(n,2n)^{54}Mn$, and $^{55}Mn(n,\gamma)^{56}Mn$ reactions from the point of view of the influences of the recoil energy and the effect of the alkali metal cation. The initial kinetic energy of ^{54}Mn recoils produced by the (n,2n) reaction is about 1000 times that of ^{56}Mn recoils produced by the (n,γ) reaction. The differences in the thermal annealing behavior of the two recoil atoms will be discussed in relation to the effects of the recoil damage and of gamma radiation during the neutron irradiation. Further, a remarkable effect of counterpart cations in the permanganate on the thermal annealing of the manganese recoils will be interpreted in terms of the electrostatic character of the alkali metal ion.

Experimental

Sample. The alkali metal permanganates were prepared by the method described in a previous paper.[3] All the samples were sealed in quartz or glass ampoules for neutron irradiation after the ampoules had been evacuated to a pressure below 10^{-4} mmHg.

Neutron Irradiations and Thermal Annealing Procedure. For the $^{55}Mn(n,2n)^{54}Mn$ reaction, about 500 mg of the sample was irradiated with 14 MeV neutrons for 5 hr at room temperature. The neutron flux at the irradiation position was 1×10^{7} n/cm^2/sec, and the gamma dose rate was about 5 R/hr.

On the other hand, for the $^{55}Mn(n,\gamma)^{56}Mn$ reaction, a few mg of the sample were irradiated for 6 min at the reactor temperature (*ca.* 40°C) with thermal neutrons in a pneumatic tube of the KUR at Kyoto University. The thermal neutron flux was 4×10^{12} n/cm^2/sec, and the gamma dose rate was estimated to be 2×10^{7} R/hr.

After irradiation, all the samples were stored at the temperature of dry ice. The thermal annealing ex-

periment was carried out by using an oil bath, its temperature controlled within ± 1°C.

Analytical Procedure for Chemical Species. The irradiated samples were dissolved into redistilled water at room temperature. The chemical species of radioactive manganese were separated into three fractions ($*Mn^{2+}$, $*MnO_2$ and $*MnO_4^-$ ions) by employing a simplified adsorption method based on an earlier worker's.[4] The radioactive permanganate ion was separated from the reduced species by shaking with 200 mg of manganese dioxide, followed by filteration through a glass filter. This procedure was repeated three times, each time using fresh manganese dioxide. Then the manganese dioxide which contained radioactive manganese dioxide and manganous ions was washed with neutral water until the purple color of the permanganate ion disappeared completely. The radioactive manganous ion was then eluted with 20 m*l* of a 10% manganous nitrate solution and 10 m*l* of 3N nitric acid from the manganese dioxide fraction. Finally, the latter was reduced into a solution by hydrochloric acid containing a small amount of hydrogen peroxide.

Radioactivity Measurements. The radioactivity was measured by means of a multi-channel pulse-height analyzer connected with a well-type NaI (Tl) detector (2in × 1¾in). The intensities of 0.84 and 0.85 MeV gamma rays were counted for ^{54}Mn and ^{56}Mn respectively.

Results and Discussion

No radiolytic decomposition of the samples through fast or reactor neutron irradiation was observed, except that the lithium salt was decomposed slightly as a consequences of the $^6Li(n,\alpha)^3H$ reaction in the case of reactor irradiation.

The $*MnO_2$-yield in each of the three fractions described above was independent of the type of nuclear reaction and was 4—8% for all samples except the potassium permanganate annealed at 180°C.

The retentions for the samples irradiated with fast neutrons are listed in Table 1. The tabulated values are the means of at least two determinations. The results of isothermal annealing for the samples irradiated with reactor neutrons are given in Table 2. As may be seen in this table, the yield depends slightly on the heating time when it is longer than 90 min. It is noticeable that the retentions for ^{54}Mn recoils in every permanganate treated at room temperature are higher than those for the ^{56}Mn recoils which were reported in the previous paper.[3]

4) For example, D. J. Apers and G. Harbottle, *Radiochim. Acta*, **1**, 189 (1963).

The isothermal annealing curves of the manganese recoils produced in the potassium permanganate are shown in Figs. 1 and 2. The rapid increase in retention by heating corresponds to the decrease in the $*Mn^{2+}$-yield for both nuclides. In treatment at 180°C, the retention for ^{54}Mn recoils decreased after a rapid initial increase, while the $^{54}MnO_2$-yield increased slowly with the heating time. Nothing similar was observed in the case of ^{56}Mn recoils.

Figure 3 shows isochronal annealing curves obtained by 5 hr heating, together with the results of the thermal decomposition of the samples which had been irradiated with 14 MeV neutrons for 5 hr before heating. Although, for both nuclides, the difference in retention was not very large in room-temperature treatment, at a higher temperature the thermal annealing of ^{54}Mn recoils proceeded more rapidly. In other words, the thermal annealing

of ^{56}Mn recoils seems to be somewhat prevented at temperatures under 160°C, this tendency becomes more remarkable with the increase in the annealing temperature. On the other hand, the anomalous behavior in the thermal annealing of ^{54}Mn recoils at 180°C was not due to either thermal or radiolytic decomposition, because a macroscopic decomposition of the samples occurred over 190°C.

As is shown in Tables 1 and 2, the retentions of the samples treated at the same temperature increase in the order of the atomic number of the alkali metal in the permanganate. Because the retention values are very low[3,5],*3 in the lower-temperature treatment of the permanganates, the tabulated values may be considered to indicate the fractions annealed at the respective temperatures. These do not depend on any steric character of the crystal,

*3 For potassium and rubidium permanganates which were irradiated with thermal neutrons at −196°C and then dissolved in cold acetone of −78°C, the retention values were 5.8±2.1 and 2.0±1.8% respectively.

such as the crystal configuration or the crystal free space of permanganate, but on the electrostatic character of the alkali metal ion. The relationships between the retention and the first ionization potential of alkali metal are shown in Fig. 4. The trends in this figure show that the thermal annealing is promoted by the decrease in the ionization potential of alkali metal or by the increase in the electron density of the inactive permanganate ion. These findings imply that the thermal annealing of manganese recoils proceeds by means of a mechanism similar to the transfer annealing suggested for potassium chromate crystal doped with chromic ions,[6] through interaction between the permanganate ion and the reduced species of those manganese recoils which are positively-charged.

The assumptions listed above may be supported by the experimental results on the thermal annealing of bromine recoils produced in alkali metal bromate crystals,[2,7,8] in which a decrease (ΔR) in annealed fractions was observed with an increase in the first ionization potential of alkali metal. The contradictory results are presumably due to the fact that the reduced species in the permanganate is detected as positive, while that in the bromate is detected as nagative. Thus, it is clear that the electrostatic characteristics of the lattice constituents influence the thermal annealing of the recoils.

These processes are different for each nuclide, as is shown in Fig. 3. In the case of iodine recoils in iodates, Aten and his coworkers[1] have ascribed the isotope effects observed in the thermal annealing to the differences in the de-excitation processes of the compound nucleus and the composite nature of the reduced species of the recoils. However, the following noticeable fact, which may account for the different annealing behavior of the manganese recoils, was found in correlated investigations.

The potassium permanganate which had been irradiated with 14 MeV neutron was exposured to gamma rays of a ^{60}Co source for 1 hr (total gamma dose: 2.0×10^6 R) and then heated for 90 min at 130°C. These gamma rays caused the retention to decrease from 58.7±1.4 to 33.7±2.2%, almost the same as for the samples irradiated with reactor neutrons (36.8±0.9%). These findings for permanganate are peculiar compared with the findings for the other oxianion salts, such as chromate,[9] bromate[10] and phosphate,[11,12] in which the retentions increased upon exposure to gamma radiation. As no macroscopic decomposition of the samples was observed, the present results suggest that the thermal annealing processes in the permanganate crystals are prevented by gamma irradiation. Therefore, the different annealing behavior in the two nuclides at temperatures under 150°C probably resulted from the different total gamma dose, which were 25 and 2.0×10^6 R, respectively, in the fast neutron and in the reactor neutron irradiations.

On the other hand, the anomalous behavior in the thermal annealing of ^{54}Mn recoils observed at 180°C arose from the peculiar properties of the recoil site, because a thermal decomposition of the sample began to occur over 190°C. By approximate calculation, the initial kinetic energy of the recoils is estimated to be 370 keV for the ^{55}Mn(n,2n)^{54}Mn reaction and 330 eV for the ^{55}Mn(n,γ)^{56}Mn reaction. The linear range of ^{54}Mn recoils in the potassium permanganate crystal is calculated to be 6900 Å according to the range-energy relations proposed by Nielsen;[13] hence, a recoil damage of a few ten Å at least may be created. It is well known[14,15] that the temperature of thermal decomposition is lowered when potassium parmanganate contains a small amount of an impurity such as carbon dioxide or manganese dioxide. Therefore, the rapid decrease in retention may be explained as follows: the recoil site of ^{54}Mn acts as an impurity in the crystal, thus promoting catalytically the localized thermal decomposition in the post-thermal treatment, even at a temperature lower than that of thermal decomposition. These conclusions may be supported also by the experimental finding that the $^{54}MnO_2$-yield increased with the lapse of the time of thermal annealing at 180°C. Thus, the recoil energy strongly influences the thermal annealing behavior in the temperature region of thermal decomposition.

The authors wish to thank Dr. K. Yoshihara and Dr. T. Omori for their useful discussions.

Macro Chelate Rings. II.*1 Syntheses and Properties of 2,7-Dimethyl-4,5-bis(salicylideneaminomethyl)xanthone as a Quadridentate Chelating Agent and Its Metal Complexes

Hisashi Okawa and Tamotsu Yoshino

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received October 15, 1969)

2,7-Dimethyl-4,5-bis(salicylideneaminomethyl)xanthone, a new quadridentate chelating agent, was synthesized by a sequence of steps and subsequently characterized. Some divalent metal complexes of the ligand were isolated, and their properties were characterized on the basis of infrared spectra. The non-coplanar structure of the complex derived from the ligand was suggested by the resolution of a cobalt(II) complex into optical isomers.

No detailed study has been reported on the metal chelate with a macro chelate ring, in spite of the great interest in the configuration of the complex. In a preceding paper[1] we studied the syntheses and properties of a quadridentate chelating agent, 2,7-dimethyl-4,5-bis(salicylideneaminomethyl)acridone, and its metal complexes. Neither the complexes nor the ligand, however, was sufficiently stable for our ultimate purpose to utilize it as a catalyst for an assymmetric synthesis. One reason for the unstability of the ligand may be the presence of the acridone nucleus in it; this problem could be overcome by the replacement of the acridone nucleus by another more stable one with a similar structure, such as the xanthone nucleus.

In this work, therefore, the syntheses and the properties of a new quadridentate chelating agent, 2,7-dimethyl-4,5-bis(salicylideneaminomethyl)xanthone (I) (abbreviated as H_2SAX), with the xanthone nucleus in place of the acridone nucleus, were investigated, as were those of its metal complexes.

Results and Discussion

The synthetic scheme of the ligand I is shown in Chart 1. Although there have been some reports upon the synthesis of 2,7-dimethylxanthone V, in which the most reactive sites of xanthone are blocked by methyl groups, all of them are impractical for preparation in large quantities. We newly synthesized 2,7-dimethylxanthone V as follows. Starting from 2-bromo-4,4′-dimethyldiphenyl ether II, which had been obtained from 4,4′-dimethyldiphenyl ether, 2-cyano-4,4′-dimethyldiphenyl ether III was made by means of a modification of the Rosenmund-von

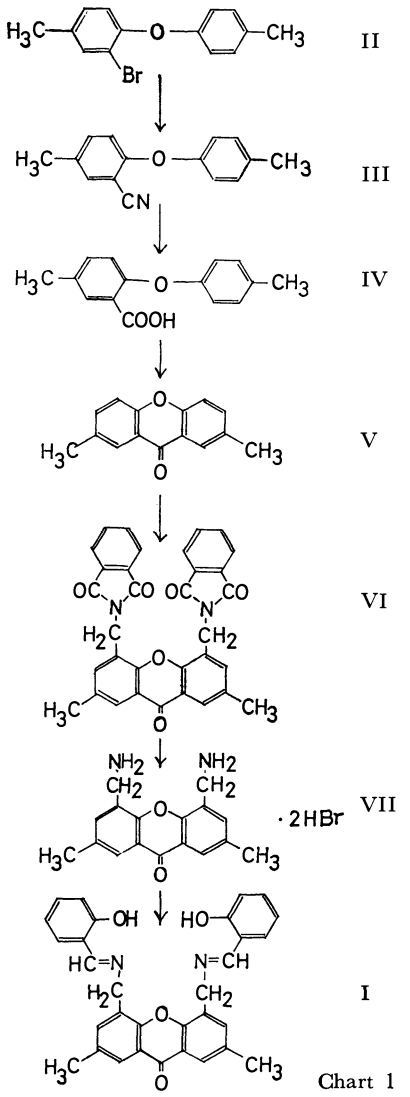

Chart 1

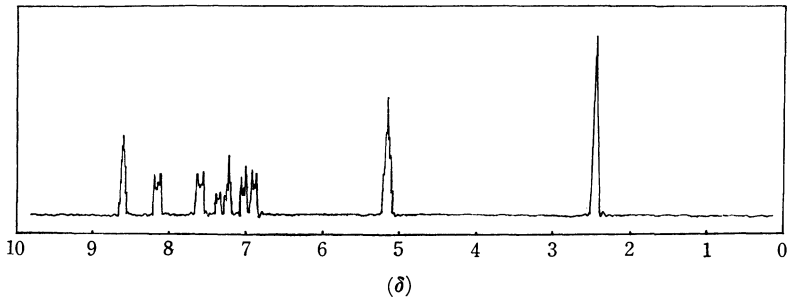

Chart 2. NMR spectrum of H_2SAX.

Braun reaction;[2] the bromide II and cuprous cyanide were treated in *N,N*-dimethylformamide, and then with a ferric chloride solution. The cyanide III thus separated was hydrolyzed with sodium ethoxide to give 4,4′-dimethyldiphenyl ether-2-carboxylic acid (IV), which was then converted to 2,7-dimethylxanthone V by treatment in hot sulfuric acid.

Like 2,7-dimethylacridone,[1] 2,7-dimethylxanthone could also be converted to 2,7-dimethyl-bis-(phthalimidomethyl)xanthone (VI) by treatment with *N*-hydroxymethylphthalimide; the compound VI was hydrolyzed in a mixture of hydrobromic acid and acetic acid to give 2,7-dimethyl-di(aminomethyl)xanthone dihydrobromide (VII). The di-(aminomethyl)derivative VII seemed stable only in its salt form, and the attempt to isolate the free diamine was unsuccessful. Because of the instability of the free diamine of VII, in addition to the insolubility of the compound VI, in most organic solvents, the positions of the substitution were tentatively assigned to 4 and 5 positions from a consideration of the meta-directing action of the carbonyl group in xanthone. The appropriateness of the assignment, however, was supported by the NMR spectrum of the compound I, which could be prepared from the diamine dihydrobromide VII and salicylaldehyde in the presence of an alkali.

The NMR spectrum of the ligand is given in Chart 2. The signal at $\delta=8.18$ can be attributed to protons at the 1 and 8 positions; both are strongly shielded by the carbonyl group in xanthone. On the other hand, the signal at $\delta=7.60$ is to be ascribed to the protons at the 3 and 6 positions, because the coupling constants of the peaks at $\delta=8.18$ and 7.60 are at least 1.7 Hz; this is consistent with the result given by Mathis and Goldstein.[3] The coupling constant, J_{13}, in xanthone itself is 1.78 Hz, while J_{14} is only 0.50 Hz. In this connection, two salicylideneaminomethyl groups must be at the 4 and 5 positions. The protons on the benzene rings are in the range of $\delta=6.95$—7.40. The protons of the methyl and methylene groups are at $\delta=2.45$ and 5.13 respectively, while the protons on the two azomethin groups appear at $\delta=8.61$, strongly shielded both by the phenyl group and by the C=N group.

The structure of the compound I was further confirmed by elementary analysis and by a study of the infrared spectrum, which indicated the existence of the chelated azomethin group at 1636 cm^{-1}. The C=O stretching vibration was observed at 1650 cm^{-1}.

Some stable divalent metal complexes have been derived from the ligand. They are listed in Table 1. Metal acetates were successfully used as a metal source, while metal chlorides and metal sulfates caused the decomposition of the ligand into salicylaldehyde and the diamine salt. The complex XIII was derived from XII by heating it under reduced pressure. Furthermore, we obtained two additional mixed complexes, XIV and XV, starting from XIII. The structures of the complexes thus obtained were confirmed by elementary analyses and by a study of the infrared spectra, which indicated a shift of the C=N stretching vibration from 1636 cm^{-1} in the ligand to near 1600 cm^{-1} and the appearance of a new absorption band in the range of 1535—1540 cm^{-1}; we could not assign the latter phenomenon, but it was useful for detecting a complex formation.

In the comparison of the infrared spectra of the ligand and the complexes, a recognizable blue shift of the C=O stretching vibration was observed in each case, demonstrating some interaction between a central metal atom and the ether oxygen atom. The bonding between them, however, was neglected because the infrared absorption peaks due to the ether bonding in the xanthone nucleus given by Kimoto[4] did not recognizably shift upon the complex formation, as would be expected from the very weak coordinating ability of the oxygen atom in diphenyl ether (Table 1). Thus, the ligand I acts as a quadridentate (Chart 3a) rather than as a quinquedentate chelating agent (Chart 3b). The blue shift (about 5 cm^{-1}) in the complexes XI, XIV and XV, which were characterized by their insolu-

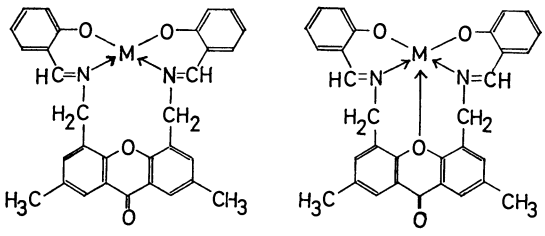
a) The absorption parenthesized could be detected as a shoulder on a strong C=C vibration peak.
b) The peak could not be detected by a strong absorption of phenolic oxygen.



a b

Chart 3

bility in most organic solvents and which were expected to possess an octahedral configuration, was smaller than that (about 10 cm^{-1}) in other, supposedly tetrahedral-configurational complexes (Table 1). The blue shift of the C=O stretching vibration upon a complex formation can be interpreted as the inhibition of the mesomery as a result of interaction between a metal cation and the positively-charged oxygen atom in a canonical form of the xanthone nucleus (Chart 4), while the larger blue shift in

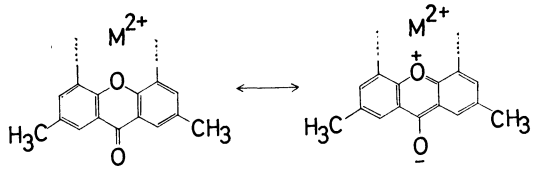


Chart 4

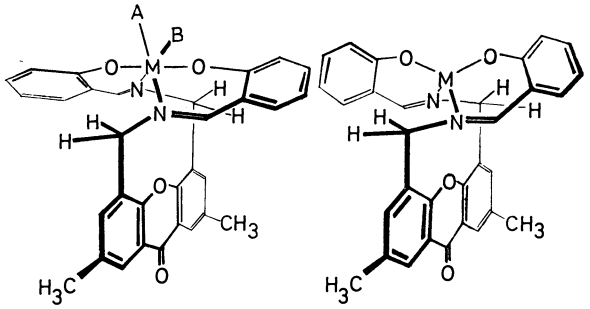
a tetrahedral complex than in an octahedral complex can be explained by the shorter distance between a metal and the ether oxygen in the former than in the latter. That is, the interatomic distance, which was roughly estimated from the model, between a metal and the ether oxygen in an octahedral complex was about 3.5 Å, while that in a tetrahedral complex was about 2.8 Å.

We have already suggested a non-coplanar structure for the complex derived from the ligand similar to I.[1] The visible spectrum of the copper complex, VIII, measured in chloroform had an absorption band centered around 720 mμ; this band was located at a longer wavelength than that at 580 mμ in a typical square planar copper(II) complex, bis-(salicylaldehyde)ethylenediimine-copper(II). This indicated that the copper complex VIII was nearly tetrahedral, but not planar. Another experimental fact regarding a non-coplanar structure was obtained by resolving the complex derived from I into optical isomers. Krebs *et al.*[5] observed that there was no separation unless the compound was soluble in water or an aqueous organic solvent, and that separation was better, in general, in water than in a solvent mixture when starch was used as an adsorbent. However, it seemed possible to resolve a complex using benzene as the eluent when D-glucose was utilized as an adsorbent. The only available complex for the separation was the complex XIII, which easily soluble in benzene and which could be recovered without any change in the complex. The eluate was separated into fifty fractions using a fraction collector. The combined first five fractions showed dextro-rotatory ($[\alpha]_D^{15}$ $+0.32°$), while the combined last ten fractions indicated levo-rotatory ($[\alpha]_D^{15} -0.98°$).



a b

Chart 5. Probable structures for an octahedral complex (a) and a tetrahedral complex (b).

5) H. Krebs, J. Diewald and J. A. Wagner, *Angew. Chem.*, **67**, 705 (1958).

The appropriateness of a non-coplanar structure of a metal and four donor atoms in a complex was, therefore, assured by the partial resolution of the compound XIII into optical isomers. The supposed, most probable structures for an octahedral and a tetrahedral complex are given in Chart 5.

Experimental

Apparatus. The NMR spectrum was recorded on a Varian Associates A-60 model, using tetramethylsilane as the internal standard and $CDCl_3$ as the solvent. A Hitachi infrared spectrometer EPI-S2 was used for the measurement of the infrared absorption spectra in the 4000—650 cm^{-1} region. The visible spectra were measured on a Hitachi EPS-3T spectrophotometer. The specific rotations were measured using a Yanagimoto OR-20 polarimeter.

Syntheses. All melting points and boiling points are uncorrected.

2-Bromo-4,4′-dimethyldiphenyl Ether (II). To a solution of 4,4′-dimethyldiphenyl ether (99 g, 0.5 mol) in acetic acid (300 m*l*) containing iodine (0.1 g), we added bromine (81.6 g, 0.51 mol) at 80°C over a period of two hours. After the reaction mixture had then been heated on a boiling bath for one hour, it was poured into water. The bromide was extracted with benzene and distilled at 155—165°C/7 mmHg. The yield was 113 g.

Found: C, 60.39; H, 4.88%. Calcd for $C_{14}H_{13}OBr$: C, 60.67; H, 4.73%.

2-Cyano-4,4′-dimethyldiphenyl Ether (III). A mixture of the bromide II (110.8 g, 0.40 mol) and cuprous cyanide (45 g, 0.5 mol) in *N,N*-dimethylformamide (200 m*l*) was refluxed on an oil bath for five hours. The reaction mixture was then filtered out and poured into a solution of ferric chloride ($FeCl_3 \cdot 6H_2O$ 180 g, concd. HCl 30 m*l*, water 300 m*l*); after which the mixture was heated on a water bath for half an hour. The nitrile III thus separated was extracted with benzene and purified by distillation at 163—170°C/6 mmHg to give a colorless liquid (57 g), which soon solidified.

Found: N, 5.87%. Calcd for $C_{15}H_{13}NO$: N, 6.27%.

4,4′-Dimethyldiphenyl Ether-2-carboxylic Acid (IV). The nitrile III (57 g) was placed in an alcoholic sodium hydroxide solution (300 m*l*) and heated on an oil bath while being stirred. After forty hours a white mass of sodium salt of 4,4′-dimethyldiphenyl ether-2-carboxylic acid IV separated. It was collected and neutralized with hydrochloric acid; the free acid thus obtained was crystallized from alcohol to give colorless needles with a mp of 112—113°C. The yield was almost theoretical.

Found: C, 74.04; H, 5.84%. Calcd for $C_{15}H_{14}O_3$: C, 74.36; H, 5.82%.

2,7-Dimethylxanthone (V). Crude 4,4′-dimethyldiphenyl ether-2-carboxylic acid IV (50 g) was dissolved in concentrated sulfuric acid (150 m*l*), and then the mixture was heated on a boiling bath for two hours. After it had cooled, the reaction mixture was poured onto ice water to give a white precipitate. This precipitate was collected, washed with a 10% sodium bicarbonate solution and then with water, and crystallized from alcohol as colorless needles with a mp of 144°C. The yield was almost quantitative.

The compound, V, made by this new method was identified by the coincidence of our description with that of Kimoto *et al.*[6]

2,7-Dimethyl-4,5-bis(phthalimidomethyl)xanthone (VI). 2,7-Dimethylxanthone (15 g) and *N*-hydroxymethylphthalimide (25 g) were dissolved in chilled concentrated sulfuric acid (200 m*l*), after which the mixture was left standing at room temperature for a week. Then the reaction mixture was poured onto ice water to give a white precipitate, which was collected and washed with a 10% sodium bicarbonate solution and then with water. A portion was crystallized from acetic acid or dioxane for analysis. It formed colorless prisms with a mp of 262—265°C. The yield was 80—90%.

Found: C, 72.98; H, 4.17; N, 5.09%. Calcd for $C_{33}H_{22}N_2O_6$: C, 73.06; H, 4.09; N, 5.16%.

2,7-Dimethyl-4,5-di(aminomethyl)xanthone Dihydrobromide (VII). The compound VI (10 g) was suspended in a mixture of acetic acid (100 m*l*) and 40% hydrobromic acid (100 m*l*), and then the mixture was heated on an oil bath for eighty hours under stirring. The hot reaction mixture was filtered and cooled to give white needles, which were collected and recrystallized from water as colorless needles. The yield was about 2.5 g.

Found: C, 42.27; H, 5.25; N, 5.96%. Calcd for $C_{17}H_{10}N_2O_2Br_2$: C, 42.52; H, 5.04; N, 5.83%.

2,7-Dimethyl-4,5-bis(salicylideneaminomethyl-xanthone (I). The diamine dihydrobromide VII (2.0 g) and salicylaldehyde (1.5 g) were dissolved in a hot dilute ethanol (50%, 50 m*l*). To it was added a dilute aqueous sodium bicarbonate solution until neutralization; pale yellow needles (1.7 g) were thus obtained. These needles were recrystallized from dioxane as pale yellow needles with a mp of 225—226°C.

Found: C, 75.94; H, 5.58; N, 5.71%. Calcd for $C_{31}H_{26}N_2O_4$: C, 75.90; H, 5.34; N, 5.71%.

CuSAX (VIII). A solution of the ligand I (50 mg) in dioxane (15 m*l*) was added to a solution of copper acetate monohydrate (25 mg) in ethanol (10 m*l*). The mixture was heated on a water bath for one and a half hours. The greenish-brown precipitate which separated was collected and washed with ethanol.

Found: C, 67.48; H, 4.65; N, 5.19; Cu, 11.18%. Calcd for $C_{31}H_{24}N_2O_4Cu$: C, 67.44; H, 4.38; N, 5.09; Cu, 11.51%.

NiSAX (IX). This was obtained from the ligand (50 mg) and nickel acetate tetrahydrate (30 mg) as a green precipitate, which was collected and washed with ethanol.

Found: C, 67.85; H, 4.37; N, 5.30%. Calcd for $C_{31}H_{24}N_2O_4Ni$: C, 68.04; H, 4.05; N, 5.13%.

ZnSAX (X). This was prepared from the ligand (50 mg) and zinc acetate dihydrate (30 mg) as a yellow precipitate.

Found: C, 67.76; H, 4.51; N, 4.71%. Calcd for $C_{31}H_{24}N_2O_4Zn$: C, 67.22; H, 4.37; N, 5.06%.

MnSAX·2H$_2$O (XI). To a solution of I (50 mg) in pyridine (15 m*l*) there was added a solution of manganese acetate tetrahydrate (25 mg) in pyridine (15 m*l*); the mixture was then heated on a water bath for two hours

6) S. Kimoto, S. Sakai and K. Ohkuma, *Yakugaku Zasshi*, **69**, 155 (1949).

to give a whitish-brown precipitate, which was subsequently collected and washed with ethanol.

Found: C, 63.87; H, 4.67; N, 4.80; Mn, 9.89%. Calcd for $C_{31}H_{24}N_2O_4Mn \cdot 2H_2O$: C, 64.25; H, 4.87; N, 4.83; Mn, 9.48%.

CoSAX•H_2O•2Py (XII). A solution of I (100 mg) in pyridine (30 m*l*) was added to a solution of cobalt acetate tetrahydrate (60 mg) in pyridine (30 m*l*), and then the mixture was heated on a water bath for half an hour. After the reaction mixture had been concentrated to 10 m*l* and left standing over night, yellow prisms separated. These prisms were collected, recrystallized from pyridine, and air-dried at room temperature.

Found: C, 68.03; H, 5.11; N, 7.87; Co, 8.31%. Calcd for $C_{31}H_{24}N_2O_4Co \cdot H_2O \cdot 2Py$: C, 68.05; H, 5.01; N, 7.76; Co, 8.14%.

CoSAX•1/2H_2O (XIII). The compound XII was heated at 110°C/30 mmHg for five hours to give a brown powder which could subsequently be crystallized from dry benzene as orange needles.

Found: C, 67.02; H, 4.59; N, 5.20; Co, 10.69%; mol wt, 561(Chf). Calcd for $C_{31}H_{24}N_2O_4Co \cdot \frac{1}{2}H_2O$: C, 66.91; H, 4.59; N, 5.03; Co, 10.59%; mol wt, 556.49.

CoSAX•phen•2H_2O (XIV). The compound XIII (20 mg) and an excess of 1,10-phenanthroline were dissolved in ethanol (20 m*l*), and then the mixture was heated on a water bath for two hours. The orange precipitate which separated was collected and washed with ethanol. It was characterized by its insolubility in most organic solvents.

Found: C, 68.03; H, 4.58; N, 7.15%. Calcd for $C_{43}H_{32}N_4O_4Co \cdot 2H_2O$: C, 67.63; H, 4.75; N, 7.34%.

CoSAX•dipy•H_2O (XV). This was also prepared from the compound XIII (20 mg) and 2,2′-dipyridyl (excess) as a reddish-brown precipitate. It was also insoluble in most organic solvents.

Found: C, 68.33; H, 4.47; N, 4.55%. Calcd for $C_{41}H_{32}N_4O_4Co \cdot H_2O$: C, 68.24; H, 4.47; N, 4.76%.

Resolution of the Complex XIII. The conditions for the separation of the complex XIII were:

Adsorbent: anhydrous D-glucose (guaranteed reagent)
Diameter of column: 1.8 cm
Height of bed: 150 cm
Sample: Complex XIII, 70 mg
Eluent: benzene
Flow rate: about 6 m*l*/min.

The eluate was separated into fifty fractions by the use of a fraction-collector apparatus, Toyo Fraction Collector SF-200A. The first five fractions were combined, and the solvent was evaporated. A solution of the complex (1.25 mg) in chloroform (1.0 m*l*) showed a specific rotation of $[\alpha]_D^{15}$ +0.32°. The last ten fractions were combined, and the benzene was evaporated. A solution of the complex (0.90 mg) in chloroform (1.0 m*l*) showed a levo-rotation of $[\alpha]_D^{15}$ −0.98°.

Syntheses of Benzodiazepine Derivatives

Shinichi MOTOKI, Chikahiro URAKAWA, Akio KANO, Yukio FUSHIMI, Tōru HIRANO and Katsumi MURATA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Shinjuku-ku, Tokyo

(Received April 30, 1969)

This communication deals with the syntheses of the aza-analogues of benzoheptafulvene. Acetylacetone or benzoylacetone reacted with benzophenone chloride in the presence of sodium ethoxide to form 3-(α-phenylbenzylidene)pentane-2,4-dione (XIVa) or 1-phenyl-2-(α-phenylbenzylidene)butane-1,3-dione (XIVc) respectively. Treatment of *o*-phenylenediamine with XIVa in acetic acid - ethanol resulted in forming 2,4-dimethyl-3-(α-phenylbenzylidene)-3*H*-benzo[*b*]-1,5-diazepine (XVa) which has a 3,6-diaza-4,5-benzoheptafulvene ring skeleton. Similarly, substituted *o*-phenylenediamines reacted with XIVa to give 7-substituted 2,4-dimethyl-3-(α-phenylbenzylidene)-3*H*-benzo[*b*]-1,5-diazepines (XVb)—(XVd). Reaction of XIVa with hydrazine gave only the monohydrazone of XIVa. The ketene dimer reacted with *o*-phenylenediamines to give 4-methyl-2,3-dihydro-2-oxo-1*H*-benzo[*b*]-1,5-diazepines (Xa)—(Xc). However, the condensation of Xa with aldehyde gave an undesirable product.

Although a number of seven membered ring compounds containing nitrogen have been prepared by several workers,[1] aza-analogues of tropone, heptafulvene and fulvene have not been investigated extensively. Only the following are known of the compounds involving such ring systems: 3-hydroxyimino-2,4-dimethyl-3*H*-benzo[*b*]-1,5-diazepine (I),[2] 2,4-diphenyl-3-oxo-3*H*-benzo[*b*]-1,5-diazepine

(II),[3] 8-oxo-8*H*-dibenzo[*a*,*c*]azepine (III)[4] and 2,4-dimethyl-3-piperonylidene-3*H*-benzo[*b*]-1,5-diazepine (IVa).[2] In this paper, the syntheses of various aza-analogues of benzoheptafulvenes (XVa)—(XVd) have been described.

The benzodiazepine such as IVa may be synthesized either by scheme A or scheme B as illustrated in Fig. 1. In scheme A, *o*-phenylenediamine is first condensed with *β*-diketones (V) to benzodiazepines (VI) which are then condensed with aldehydes at their 3 position. In scheme B, *β*-diketones are converted to *α*-alkylidene- or arylidene-*β*-diketones (VII) preceding the ring formation and then condensed with *o*-phenylenediamine. Similarly, a compound such as VIII may be prepared by the reaction of hydrazine and VII in accordance with scheme B. Barltrop *et al.*[2] reported that the condensation of VIa with piperonal gave IVa whereas the reaction with benzaldehyde took place at the methyl group in VIa to give the undesirable compound (IX). In our experiment, the diazepine (VIb) which posseses no methyl group in the side chain was allowed to react with benzaldehyde. However, the reaction did not proceed even under various conditions and the starting materials were recovered.

Accordingly, the condensation of 4-methyl-2,3-dihydro-2-oxo-1*H*-benzo[*b*]-1,5-diazepine (Xa) with aldehydes was examined, since the methylene group of Xa appeared to be more reactive than that of VI. Although several procedures for the preparation of Xa are available,[5-7] the method by the reaction of the ketene dimer with *o*-phenylenediamine[5] was found to be the most convenient. Xa and 7- or 8-substituted 4-methyl-2,3-dihydro-2-oxo-1*H*-benzo[*b*]-1,5-diazepines (Xb and Xc) were prepared by the reaction of the ketene dimer with *o*-phenylenediamine, 3,4-diaminotoluene and 3,4-diaminochlorobenzene. Xa reacted with benzaldehyde in the presence of piperidine to give a condensation product. The NMR spectra of the product in $CDCl_3$ exhibited one methylene singlet but no methyl singlet in contrast with those of Xa. Thus the product was assumed to be 4-styryl-2,3-dihydro-2-oxo-1*H*-benzo[*b*]-1,5-diazepine (XI). Similarly, condensation of Xa with other aromatic aldehydes or furfural occurred at the methyl group of Xa.

As we found that the syntheses of the compound of the type IV were unsuccessful by scheme A, a different synthetic approach was investigated following scheme B. *α*-Alkylidene- or arylidene-*β*-diketones (VII) are readily prepared by the condensation of *β*-diketones with aldehydes. Barltrop *et al.*[2] reported that the reaction of 3-benzylidenepentane-2,4-dione (VIIb) with *o*-phenylenediamine yielded 2-phenylbenz[*d*]imidazole (XII) or diazepine (VIa) depending upon the reaction conditions. We examined the reaction of 3-ethylidenepentane-2,4-dione (VIIa) with *o*-phenylenediamine or hydrazine under various conditions. The attempts were also unsuccessful and the product isolated was diazepine (VIa) or dimethylpyrazole (XIII).

Although the reaction of diamines with VII is complicated and may yield a variety of products depending upon the reaction conditions, Pauly[8] reported that the reaction of ethyl *α*-isopropylideneacetoacetate with phenylhydrazine gave 1-phenyl-3-methyl-4-isopropylidene-5-pyrazolone which contains exo double bond. This fact suggests that the

* The products were recrystallized from methanol.

β-diketone such as XIV would undergo the ring closure with diamines in the desired manner. Compound XIV is extremely inaccessible as compared with VII because the direct condensation of β-diketones with ketones to form XIV is difficult. However, when acetylacetone (Va), dibenzoylmethane (Vb) and benzoylacetone (Vc) was allowed to react with benzophenone chloride in the presence of sodium ethoxide, 3-(α-phenylbenzylidene)pentane-2,4-dione (XIVa) and 1-phenyl-2-(α-phenylbenzylidene)butane-1,3-dione (XIVc) were obtained. In the case of XIVb the reaction product was a waxy solid and could not be identified owing to difficulties in purification.

When XIVa was heated with *o*-phenylenediamine in ethanol-acetic acid, a crystalline product was obtained. The elementary analysis of the product indicated the empirical formula, $C_{23}H_{20}N_2$ and the NMR spectra showed only two signals, one for phenyl protons (2.8 τ, multiplet, 14H) and the other for methyl protons (8.0 τ, singlet, 6H), while the IR spectra showed no NH stretching band. Thus the product was identified as 2,4-dimethyl-3-(α-phenylbenzylidene)-3*H*-benzo[*b*]-1,5-diazepine (XVa) which has a 3,6-diaza-4,5-benzoheptafulvene ring skeleton. Similarly, treatment of XIVa with 3,4-diaminotoluene, 3,4-diaminochlorobenzene and 3,4-diaminonitrobenzene gave the corresponding 7-substituted benzodiazepines (XVb)—(XVd). The reaction of XIVb with *o*-phenylenediamine was also examined but no identified product was obtained. On the other hand, the reaction of XIVa with hydrazine in acetic acid gave high melting white crystals. Its analytical values agreed better with the calculated values for XVII than those for diazafulvene (XVI) and the IR spectra clearly exhibited a broad NH stretching band. Therefore, the product is assumed to be 4-hydrazono-3-(α-phenylbenzylidene)pentan-2-one.

Experimental

4-Methyl-2,3-dihydro-2-oxo-1*H*-benzo[*b*]-1,5-diazepine (Xa). This compound was prepared by the method given in literature.[5]

4,7(or 8)-dimethyl-2,3-dihydro-2-oxo-1*H*-benzo[*b*]-1,5-diazepine (Xb) and 7(or 8)-chloro-4-methyl-2,3-dihydro-2-oxo-1*H*-benzo[*b*]-1,5-diazepine (Xc) were prepared similarly by the reaction of the ketene dimer with 3,4-diaminotoluene and 3,4-diaminochlorobenzene. The results are summarized in Table 1.

4-Styryl-2,3-dihydro-2-oxo-1*H*-benzo[*b*]-1,5-diazepine (XI). A solution of 3.5 g of Xa, 2.0 g of benzaldehyde and three drops of piperidine in 15 ml of benzene was refluxed for 15 hr. After cooling, precipitated product was filtered, recrystallized from ethanol and 1.1 g of XI was obtained; yield 21.2%, yellow needles, mp 218—219°C.

Found: C, 78.10; H, 5.17; N, 10.57%. Calcd for $C_{17}H_{14}ON_2$: C, 77.84; H, 5.38; N, 10.68%.

3-(α-Phenylbenzylidene)pentane-2,4-dione (XIVa). Into a solution of sodium ethoxide, prepared from 15.3 g of sodium and 300 ml of ethanol, 66.7 g of acetylacetone was added. The mixture was then heated under reflux and 79 g of benzophenone chloride was added over a period of 1 hr. After addition of the chloride, the mixture was refluxed a further 2 hr. Carbon dioxide was passed through the cooled reaction mixture for 10 min and the precipitate was filtered and washed with ethanol repeatedly. The filtrate was steam-distilled to remove most of the ethanol and excess of acetylacetone. An oily product separated in the residue was extracted with ether and the extract was dried over anhydrous sodium sulphate. After the ether was removed, the residue was distilled and a fraction boiling at 165—181°C/7 mmHg was collected. The distillate solidified immediately in the receiver and was recrystallized from ligroin to give 34.4 g (39.1%) of XIVa, colorless needles, mp 120—121°C.

Found: C, 81.52; H, 6.23%. Calcd for $C_{18}H_{16}O_2$: C, 81.79; H, 6.10%.

1-Phenyl-2-(α-phenylbenzylidene)butane-1,3-dione (XIVc). As in the preceding procedure, 23.2 g of benzophenone chloride was treated with sodium benzoylacetonate, prepared from 4.6 g of sodium and 32.4 g of benzoylacetone in 100 ml of ethanol. After the reaction was over, carbon dioxide was passed through the reaction mixture and the precipitate was filtered and washed with 10 ml of ethanol. The filtrate was cooled in an ice-salt bath and the crystalline product separated

was collected and recrystallized from ethanol. XIVc was obtained as light yellow needles, mp 126°C, yield 4.7 g (14.7%).

Found: C, 84.78; H, 5.50%. Calcd for $C_{23}H_{18}O_2$: C, 84.64; H, 5.56%.

2,4-Dimethyl-3-(α-phenylbenzylidene)-3*H*-benzo[*b*]-1,5-diazepine (XVa). A solution of 2.6 g of XIVa and 1.1 g of *o*-phenylenediamine in 10 m*l* of ethanol containing 1 m*l* of acetic acid was refluxed for 3 hr. After cooling, the product precipitated was filtered and recrystallized from methanol. XVa was obtained as white needles, mp 156—157°C, yield 2.1 g (62.5%).

Found: C, 85.37; H, 5.67; N, 8.53%. Calcd for $C_{24}H_{20}N_2$: C, 85.68; H, 5.99; N, 8.33%.

Similarly, 7-substituted 2,4-dimethyl-3-(α-phenylbenzylidene)-3*H*-benzo[*b*]-1,5-diazepines (XVb)—(XVd) were prepared by the reaction of XIVa with 3,4-diaminotoluene, 3,4-diaminochlorobenzene and 3,4-diaminonitrobenzene respectively. The results are summarized in Table 2.

4-Hydrazono-3-(α-phenylbenzylidene)pentan-2-one (XVII). A mixture of 2.6 g of XIVa, 0.5 g of hydrazine hydrate and 6 m*l* of acetic acid was refluxed for 1 hr. After cooling, 100 m*l* of water was added and the mixture was allowed to stand for 2—3 hr. Precipitated product was filtered and recrystallized from methanol to give 1.6 g of XVII, mp 217—219°C.

Found: C, 77.71; H, 6.20; N, 9.99%. Calcd for $C_{18}H_{18}ON_2$: C, 77.67: H, 6.52; N, 10.07%.

The authors wish to express their thanks to Professor Yojiro Tsuzuki for his helpful advice and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 813—817 (1970)

Effects of Additives on the Alternating Copolymerization of Aziridines with Cyclic Imides

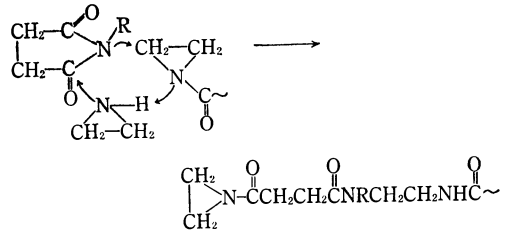
Tsutomu KAGIYA and Teruho ADACHI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received May 8, 1969)

The effect of the addition of 2-methyl-2-oxazoline, which is an isomer of the growing chain end, was examined. The rate of the copolymerization of ethylenimine with succinimide increased upon the addition of 2-methyl-2-oxazoline. On the basis of this result and of the NMR spectrum of the copolymer, the mechanism of propagation *via* an activated state similar to oxazoline was proposed. The copolymerization was accelerated by the addition of sodium iodide, which is the catalyst of the isomerization of the growing chain end. The property of the copolymer obtained was different from that of the copolymer obtained without sodium iodide. Sodium iodide also affected the copolymerization of *N*-ethylethylenimine with succinimide, while it did not affect that of ethylenimine with *N*-ethylsuccinimide. The reduced viscosity of the copolymer increased with the reaction time. The reaction mechanism of the copolymerization in the presence of the catalyst was discussed on the basis of the facts mentioned above.

The present authors have previously reported[1,2] that the growing chain end in the alternating copolymerization of ethylenimine with cyclic imides



was the *N*-acylethylenimine ring and that the propagation proceeded *via* a six-membered ring by means of the hydrogen migration of the ethylenimine and the ring opening of cyclic imide.

In this mechanism, it is also plausible that the oxygen atom of *N*-acylethylenimine coordinates to the hydrogen atom of ethylenimine. In relation to this coordination, it has been reported[3] that this growing chain end, *N*-acylethylenimine, easily isomerized to the oxazoline ring with a catalyst such as sodium iodide. In this isomerization, it is considered that the oxygen atom of the carbonyl group and the carbon atom of the ring coordinate

to the cation and anion of the catalyst respectively.

In order to examine the coordination of the oxygen atom, the effect of the oxazoline or isomerization catalyst on the copolymerization was studied.

Experimental

The methods of preparing and purifying the monomers were described in a previous paper.[1] The 2-methyl-2-oxazoline was prepared by the isomerization of *N*-acetylethylenimine according to the literature.[3] The sodium iodide and *N,N*-dimethylformamide were obtained commercially (G.R. grade) and were used without further purification.

A measured amount of the cyclic imide and a solid additive were placed in a glass ampoule. After the mixture had been dried under reduced pressure, a certain volume of aziridine and a liquid additive were placed in the ampoule with a syringe under a nitrogen atmosphere. The ampoule was then sealed and kept in a constant-temperature bath for a definite period. The reaction products were washed with acetone to remove the residual monomers and then dried *in vacuo*.

The composition of the copolymer was determined by elementary analysis. The infrared spectra were obtained by the potassium-bromide-pellet technique on a Shimadzu infrared spectrophotometer, Model IR-27. The NMR spectra were recorded in D_2O at room temperature with JEOL model JNM-3H-60 at 60 MHz. The reduced viscosity of the copolymer was calculated from the viscosity measurement of a 0.5% solution of formic acid at 35°C.

Results and Discussion

(1) Effect of 2-Methyl-2-oxazoline. In order to examine the oxygen coordination mechanism described above, 2-methyl-2-oxazoline was added to the system of the copolymerization of ethylenimine with succinimide. The results are shown in Table 1.

TABLE 1. EFFECT OF ADDITION OF 2-METHYL-2-OXAZOLINE*

Expt. No.	2-Methyl-2-oxazoline g (mol)	Reaction time min	Yield g	Rate** g/min

* Monomer: Ethylenimine 1.291 g (0.03 mol)
Succinimide 2.973 g (0.03 mol)
Reaction temperature: 70°C

** Reaction was stopped at almost the same yield, and a reaction rate was expressed in a value of yield divided by time.

*** Shown as a reference.

The copolymerization was accelerated by the addition of 2-methyl-2-oxazoline, and the copolymer obtained was a white, powdery polymer. The rate was almost the same as that of the copolymerization in the presence of the same amount of *N*-acetylethylenimine (Exp. No. 5). The NMR spectrum of the copolymer shown in Fig. 1-a displayed peaks which could be assigned to the methylene proton of the repeating unit, $-(-C\underset{a}{H_2}C\underset{a}{H_2}-NHCOC\underset{b}{H_2}C\underset{b}{H_2}-CONH-)-$, at $\tau=6.72$ (a), 7.48 (b).[1] It also displayed peaks assignable to the end groups of *N*-acylethylenimine ($\tau=7.56$) and *N*-substituted succinimide ($\tau=7.25$). The peak intensity of the latter was quite small compared with that in the spectrum (Fig. 1-b) of the copolymer obtained without additives. This phenomenon was also observed in the NMR spectrum (Fig. 1-c) of the copolymer obtained by the copolymerization of ethylenimine and succinimide in the presence of *N*-acetylethylenimine. Since the copolymer initiated by 2-methyl-2-oxazoline or *N*-acetylethylenimine has no amide end, it is difficult for the cyclization reaction[2] at the polymer end to form the structure of *N*-substituted succinimide to occur.

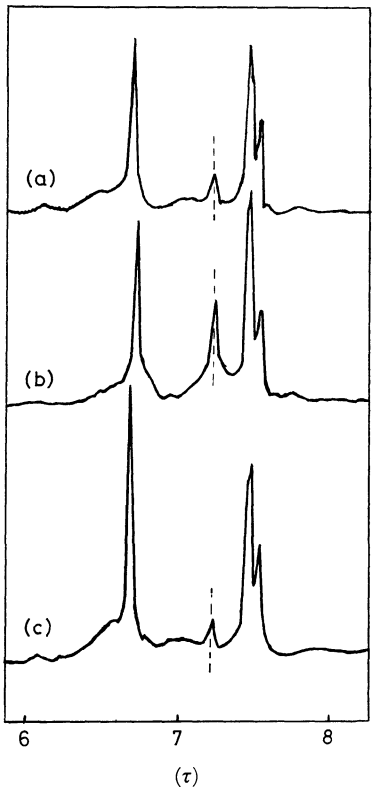

Fig. 1. The NMR spectra of the copolymers of ethylenimine with succinimide obtained in the presence of 2-methyl-2-oxazoline (a), without additive (b) and in the presence of *N*-acetylethylenimine (c).

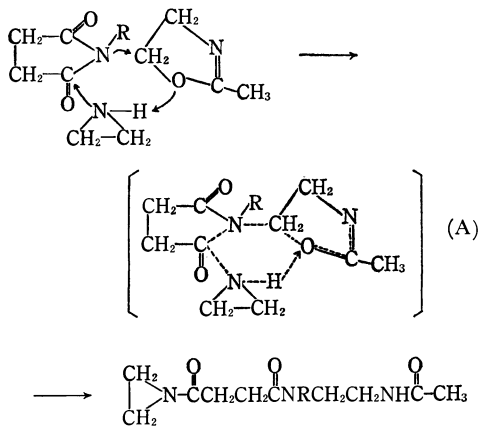
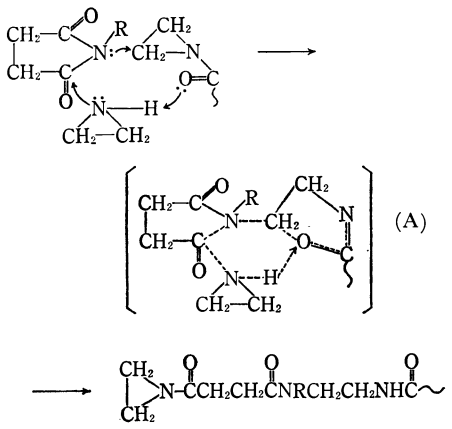
On the basis of the facts that the acceleration by 2-methyl-2-oxazoline was almost the same as the acceleration by *N*-acetylethylenimine, that the peaks which should be assignable to the oxazoline ring were not observed in the spectrum (a) and that the structure of the copolymer was the same as the structure of the copolymer obtained in the presence of *N*-acetylethylenimine, the following mechanism for initiation by oxazoline is proposed: the oxazoline ring quickly opens *via* the activated state (A) and the *N*-acylethylenimine end is yielded. Moreover, the effect of 2-methyl-2-oxazoline on the copolymerization is similar to that of *N*-acetylethylenimine.



On the basis of the above consideration, the mechanism of the propagation reaction may be considered to be analogous: (i) it is not the nitrogen atom, but the oxygen atom, of the *N*-acylethylenimine end of polymer that coordinates to the hydrogen of ethylenimine, and (ii) the hydrogen-migration-propagation reaction proceeds *via* an activated state (A) similar to that in the oxazoline structure.



(2) Effect of Isomerization Catalyst. It has been reported that *N*-acylethylenimine is isomerized to oxazoline by a catalyst such as sodium iodide.[3] In case the reaction proceeds *via* the mechanism proposed above and the isomerization is the rate-determining step, it can be expected that the propagation reaction will be accelerated by the addition of sodium iodide. The results shown in Table 2 are in accordance with this expectation.

These findings seem to support the mechanism proposed above, but the copolymer obtained was a yellow or brown, hygroscopic or greasy polymer, and the properties of the copolymer were different from those of a copolymer obtained without sodium iodide. The infrared spectrum of the copolymer displayed the characteristic peaks of amide, but the NMR spectrum (Fig. 2) of the copolymer

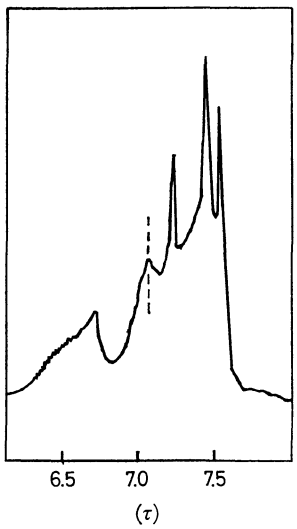


Fig. 2. The NMR spectrum of the copolymer of ethylenimine with succinimide obtained in the presence of sodium iodide.

displayed an extra peak at $\tau=7.07$ which had not been found in the specturm of the copolymer shown in Fig. 1-b.

In order to clarify the role of sodium iodide in the structure of the copolymer obtained, the following experiments were performed (Table 3). Ethylenimine or succinimide was not polymerized by sodium iodide. Moreover, *N*-acetylethylenimine neither copolymerized with succinimide nor homopolymerized in the presence of sodium iodide. Therefore, it can be concluded the structure of the copolymer is neither $-(-CH_2CH_2-N(-COCH_2CH_2CONH-)-)_n$ nor $-(-CH_2CH_2-N(-CO\sim)-)_n$.

In view of the fact that sodium iodide acts as a catalyst of the isomerization of the *N*-acylethylenimine end to oxazoline, the reaction of succinimide with 2-methyl-2-oxazoline was carried out and examined, with particular care. From the

fact that no polymer was obtained, it may be concluded that sodium iodide does not give the structure of $-(-CH_2CH_2-N(-CO-)CH_2-CH_2CONH-)-_n$ which is that of the copolymer of succinimide with an oxazoline ring.

On the other hand, it is plausible that sodium iodide does not only affect the *N*-acylethylenimine, but also activates either succinimide or ethylenimine to give the copolymer with a different structure. In the light of the mechanism described above, the effect of sodium iodide on the copolymerization of ethylenimine with *N*-substituted succinimide was also examined (Table 4, Nos. 1 and 2). No effect was, however, observed. As has been mentioned in a previous paper.[2] *N*-ethylethylenimine did not copolymerize with succinimide. However, in the presence of sodium iodide, this copolymerization occurred to give a greasy polymer. This result is similar to that in the copolymerization of *N*-ethylethylenimine with succinimide by water.[2]

On the basis of these results, it may be considered that sodium iodide does not affect the ring opening of succinimide, but that it does affect the ring opening of ethylenimine to yield *N*-(β-aminoethyl)-succinimide, which is then able to give a polyamide by polyaddition reaction in analogy with the copolymerization by water.

The copolymerization of ethylenimine with succinimide was carried out quantitatively in an *N,N*-dimethylformamide solution in order to verify the polyaddition mechanism. The polymer yield and the reduced viscosity of the polymer obtained were then plotted against the reaction time (Fig. 3). In the early stage, an acceleration

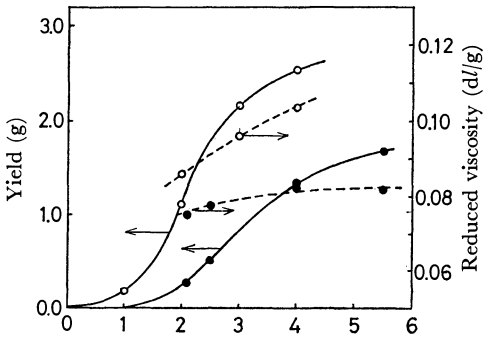

Fig. 3. The plots of polymer yield or reduced viscosity *vs.* reaction time.

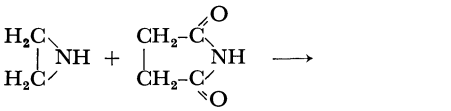
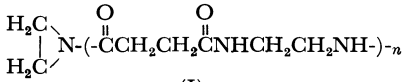
● No additive
Solvent: *N,N*-Dimethylformamide 5 cc
Temperature: 70°C

of the rate was observed. The reduced viscosity of the copolymer obtained in the absence of sodium iodide was almost constant regardless of the reaction time, while that obtained in the presence of sodium iodide increased. After the copolymer obtained by sodium iodide was again dissolved in *N,N*-dimethylformamide and kept at 70°C for 47 hr, the reduced viscosity increased from 0.103 to 0.131 (dl/g). These two facts suggest that the reaction between polymers, namely, polyaddition reaction, occurs, at least in part.

On the basis of the facts presented above, the following is proposed as a possible reaction mechanism in the presence of sodium iodide:

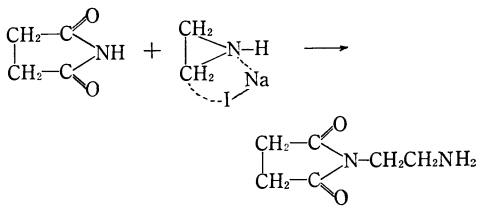
(i) The same reaction as that which occurs without a catalyst.



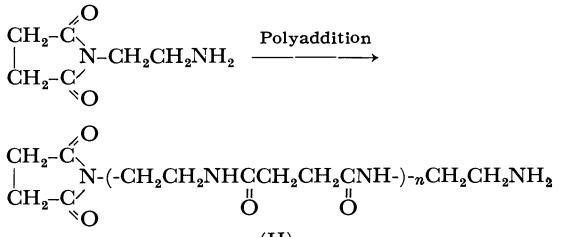


(I)

(ii) Polyaddition of *N*-(*β*-aminoethyl)succinimide. *N*-(*β*-Aminoethyl)succinimide is formed by the ring-opening reaction of ethylenimine with sodium iodide.

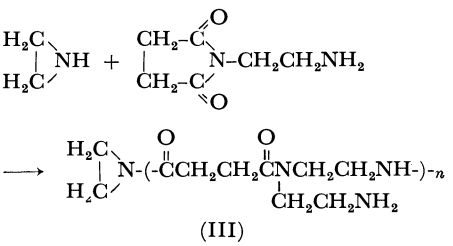


N-(*β*-Aminoethyl)succinimide is considered to give a polyamide by a polyaddition in which the ring of succinimide opens with amine.[2,4,5]



(II)

(iii) Copolymerization of ethylenimine with *N*-(*β*-aminoethyl)succinimide.



(III)

Since ethylenimine is able to copolymerize with *N*-substituted succinimide, *N*-(*β*-aminoethyl)succinimide may be considered to act as an active *N*-substituted succinimide.

The NMR spectrum of the copolymer obtained by sodium iodide at 30°C displayed the peak assigned to *N*-acylethylenimine. On the other hand, at 30°C, the copolymerization without sodium iodide did not occur (*cf.* Table 2, No. 4). This indicates that the (i) reaction did not occur. Therefore, the *N*-acylethylenimine end was considered to be produced by the reaction (iii). Moreover, the peak of the NMR spectrum at $\tau=7.07$ in Fig. 2 might be assignable to the methylene proton of the *N*-(*β*-aminoethyl) group.

Therefore, it may be concluded that the copolymer obtained by a catalsyt of the isomerization of *N*-acylethylenimine, such as sodium iodide, is a mixture of the copolymers (I), (II), and (III).

Authors gratefully acknowledge the encouragement of Professor Ken-ichi Fukui during this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 818—823 (1970)

Studies on the Substrate Specificity of Taka-amylase A. III. Syntheses of Some New Derivatives of Phenyl α-Maltoside

Hitoshi ARITA, Mamoru ISEMURA, Tokuji IKENAKA and Yoshio MATSUSHIMA

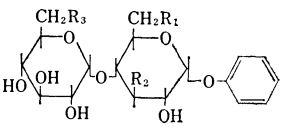
Department of Chemistry, Osaka University, College of Science, Toyonaka

(Received June 19, 1969)

In order to obtain information of the interaction between various portions of the substrate molecule and the enzyme protein, mono-*O*-methyl derivatives of phenyl α-maltoside and its analogues were synthesized and the enzymatic action was investigated. The purity and chemical structure of the compounds were confirmed by chromatographic method, phenol determination, and elemen talanalyses. The anomeric configuration of the glycosidic linkage to phenol was presumed to be of an alpha type on the basis of the high positive value of specific rotation. Some regularities in the enzymatic action on these synthetic substrates were observed.

Elucidation of the interaction through definite atoms or atomic groups between the substrate and the enzyme molecule is an important problem in understanding enzymatic action as a whole, as shown by Blake *et al.*[1] in an X-ray crystallographic investigation of hen egg-white lysozyme. A useful chemical approach to this problem will be an investigation of the enzymatic action on the substrates with different but analogous chemical structures. Helferich and Gruenler[2] and Pigman and Richtmyer[3] investigated the action of β-glucosidase of almond emulsion on phenyl β-glucoside and its *O*-methyl derivatives and analogues. The enzyme preparations at that time were far from being pure. Isemura *et al.*[4] studied the Taka-amylase action on partially *O*-methylated amylose, and obtained some information on the substrate specificity of the enzyme.

Taka-amylase A [EC 3.2.1.1. α-1,4-glucan-4-glucanohydrolase, *Aspergillus oryzae*] crystallized by Akabori *et al.*[5] has been known to liberate phenol from a synthetic substrate, phenyl α-maltoside.[6] The present authors synthesized the compounds shown in the following formulae, and investigated the enzymatic action on them. The structure of the compounds and the ratio of the initial rate of phenol liberation by the enzyme are summarized in Table 1.



[VI, VII, IX, XI, XIX, XXIV, XXVII, XXXI, XXXIV]

Maltosan hexaacetate was obtained by the alkali treatment of phenyl β-maltoside followed by acetylation.[7,8] 1,6-Anhydro-ring of maltosan hexaacetate was cleaved by treatment with titanium tetrachloride in chloroform,[9,10] and the hydroxyl on position-6 was set free. The hydroxyl on the position-6′ was set free according to the method of Dutton and Slessor.[11] Introduction of chlorine into the 6- or 6′-position was performed with the use of sulfuryl chloride in pyridine.[12] *O*-Methyl derivatives were prepared through methylation with diazomethane in the presence of boron trifluoride as a catalyst. We found a convenient method for leading 3,6-anhydro-ring into sugar by treating terminal tosyloxy compound with Dowex 1 (OH^-) at room temperature. Using this method, phenyl 3′,6′-anhydro-α-maltoside was prepared from phenyl 6′-*O*-*p*-toluenesulfonyl α-maltoside in good yield. Dick and co-workers[13] havereported that acetylation of β-maltose monohydrate with acetylpyridinium chloride gave acetylated maltose which had free hydroxy at 3-position. This method was used for preparing 3-*O*-substituted phenyl α-maltoside. Phenyl glycosidation was accomplished by the fusion of *O*-acetylated disaccharides with phenol and zinc chloride,[14] followed by deacetylation with sodium methoxide in anhydrous methanol.

In order to eliminate the ambiguity of the structure of the compounds which might arise from the migration of the acetyl groups during the course of syntheses, confirmation was carried out by means of analytical methods: (1) Position of the substitution on the glucose residue. (2) Moiety of the glucose residues which underwent substitution.

Experimental

Maltosan Hexaacetate (I). Maltosan hexaacetate was prepared from phenyl β-maltoside hexaacetate[7] by alkali treatment according to the method of Karrer and Kamienski.[8] Crystallization in methanol gave colorless needles which melted at 182—184°C. Found: C, 50.23; H, 5.58%. Calcd for $C_{24}H_{32}O_{11}$: C, 50.00; H, 5.56%.

1,2,3,2′,3′,4′,6′-Hepta-*O*-acetyl-β-maltose (II). This compound was prepared from I by cleaving 1,6-anhydro ring with titanium tetrachloride following the method

of Asp and Lindberg[9] in principle. Crystallization in cold methanol-water (1 : 5) gave colorless needles which melted at 140—142°C. Found: C, 49.59; H, 5.81%. Calcd for $C_{26}H_{36}O_{18}$: C, 49.65; H, 5.66%.

6-*O*-*p*-Toluenesulfonyl-1,2,3,2′,3′,4′,6′-hepta-*O*-acetyl-β-maltose (III). II (4 g) was converted into III by the method of Asp and Lindberg.[9] Recrystallization from methanol gave pure substance (4 g) which melted at 138—141°C. Found: C, 49.06; H, 5.30; S, 3.98%. Calcd for $C_{33}H_{42}O_{20}S$: C, 50.10; H, 5.31; S, 4.03%.

6-Iodo-6-deoxy-1,2,3,2′,3′,4′,6′-hepta-*O*-acetyl-β-maltose (IV). This compound was prepared from III (4.0 g) according to the method of Asp and Lindberg.[9] Crystallization in methanol gave colorless crystals (3.2 g) which melted at 129—131°C. Found: C, 41.69; H, 4.27; I, 16.34%. Calcd for $C_{26}H_{35}O_{17}I$: C, 41.82; H, 4.70; I, 17.00%.

6-Deoxy-1,2,3,2′,3′,4′,6′-hepta-*O*-acetyl-β-maltose (V). IV (3.0 g) was dissolved in a mixture of dioxane (50 m*l*), ethanol (150 m*l*) and pyridine (2 m*l*). Reduction with hydrogen over 10% palladium-charcoal (3.0 g) at 70°C was repeated twice. The solution was extracted with chloroform, and the extract was washed with 5% aqueous sodium thiosulfate and water, and was dried over anhydrous sodium sulfate. After chloroform had been evaporated, the residue was crystallized in methanol (10 m*l*). Colorless crystals thus obtained (2.1 g) melted at 163—164.5°C. $[\alpha]_D^{19}$ +17° (*c*, 1.00, chloroform), Found: C, 50.24; H, 5.81%. Calcd for $C_{26}H_{36}O_{17}$: C, 50.32; H, 5.80%.

Phenyl 6-Deoxy-α-maltoside (VI). Zinc chloride (0.5 g) was dissolved in phenol (3 m*l*), and to this mixture was added V (2.5 g). The mixture was heated for 30 min at 115—120°C under vigorous stirring. Benzene (40 m*l*) was poured into the reaction mixture, which was washed with 1N sodium hydroxide and then with water. The benzene layer was dried over anhydrous sodium sulfate and was evaporated. The residual syrup was dissolved in a solution of 0.1M sodium methoxide in methanol (20 m*l*), and the solution was kept for 20 min at room temperature. The alkoxide was excluded by the addition of Dowex 50×8(H^+ form). The product was purified by passing through a column of Biogel P-2(polyacrylamide gel for chromatographic use, purchased from BIO. RAD Laboratories). The freeze-dried substance gave $[\alpha]_D^{24}$ +176° (*c* 1.00, water). Found: C, 54.05; H, 6.40%. Calcd for $C_{18}H_{26}O_{10}$: C, 53.73; H, 6.47%.

Phenyl 6-Iodo-6-deoxy-α-maltoside (VII). IV (2.0 g) was reacted with phenol (3.5 m*l*) in the presence of zinc chloride (0.35 g) in a manner similar to that described above, followed by deacetylation with sodium methoxide. The product was passed through Biogel P-2 column. The fraction of phenyl 6-iodo-6-deoxy-α-maltoside was lyophilized and crystallized in methanol. The yield of crystals which melted at 174°C (decomp.) was 150 mg. $[\alpha]_D^{24}$ +128° (*c* 0.50, water). Found: C, 40.45; H, 4.81; I, 24.17%. Calcd for $C_{18}H_{25}O_{10}I$; C, 40.92; H, 4.77; I, 24.02%.

6-Chloro-6-deoxy-1,2,3,2′,3′,4′,6′-hepta-*O*-acetyl-β-maltose (VIII). II (2.0 g) was dissolved in anhydrous pyridine (20 m*l*). The solution was cooled in ice-water, and then sulfuryl chloride (2.0 m*l*) was added dropwise under stirring, and the mixture was kept at room temperature for 12 hr. A brown solution thus obtained was extracted with chloroform (2×25 m*l*), and the extract was washed several times with water, dried over calcium chloride and concentrated *in vacuo*. The syrupy residue was dissolved in methanol and decolorized with Norit A. Colorless needles were obtained in a methanol solution, which were recrystallized in the same solvent. The yield of the specimen which melted at 138—139°C was 1.38 g. $[\alpha]_D^{19}$ +50° (*c* 1.00, pyridine). Found: C, 47.51; H, 5.36; Cl, 5.39%. Calcd for $C_{26}H_{35}O_{17}Cl$: C, 47.67; H, 5.38; Cl, 5.41%.

Phenyl 6-Chloro-6-deoxy-α-maltoside (IX). VIII (1.2 g) was reacted with phenol (3 m*l*) and zinc chloride (0.2 g) at 115°C for 30 min. After deacetylation with sodium methoxide, the product was purified by passing through a column of Biogel P-2, and was crystallized in methanol. The yield of the colorless crystals which melted at 184—186°C was 240 mg. $[\alpha]_D^{20}$ +142° (*c*, 0.50, water). Found: C, 49.19; H, 5.82; Cl, 7.86%. Calcd for $C_{18}H_{25}O_{10}Cl$: C, 49.49; H, 5.77; Cl, 8.12%.

6-*O*-Methyl-1,2,3,2′,3′,4′,6′-hepta-*O*-acetyl-β-maltose (X). II (2.5 g) was dissolved in anhydrous dichloromethane (20 m*l*) and methylated with diazomethane in the mixture of ether (100 m*l*) and boron trifluoride (5 m*l* of boron trifluoride etherate-dichloromethane, 1 : 25). The reaction was carried out in a dry ice-acetone bath. After 12 hr, the reaction mixture was filtered off from insoluble substance and extracted with chloroform. The extract was washed with water and dried over calcium chloride. Rapid crystallization occurred in methanol. Recrystallization in the same solvent gave in 80% yield 6-*O*-methyl-1,2,3,2′,3′,4′,6′-hepta-*O*-acetyl-β-maltose which melted at 135—136°C. $[\alpha]_D^{20}$ +60.7° (*c*, 1.36, chloroform). Found: C, 49.56; H, 5.87%. Calcd for $C_{27}H_{38}O_{18}$: C, 49.84; H, 5.88%.

Phenyl 6-*O*-Methyl-α-maltoside (XI). X (1.8 g) was reacted with phenol (4 m*l*) in the presence of zinc chloride (0.3 g) in a similar manner as described above, followed by deacetylation with sodium methoxide. The syrup thus obtained was purified by gel filtration using Biogel P-2. The yield of an amorphous product obtained was 390 mg. $[\alpha]_D^{20}$ +168° (*c*, 0.67, water). Found: C, 52.14; H, 6.56%. Calcd for $C_{19}H_{28}O_{11}$: C, 52.77; H, 6.53%.

Maltosan (XII).[11] Hexa-*O*-acetyl-maltosan (I) was deacetylated with sodium methoxide. Crystals were obtained in methanol which melted at 149—150°C. Found: C, 43.00; H, 6.23%. Calcd for $C_{12}H_{20}O_{10}$: C, 44.44; H, 6.17%.

6′-*O*-Trityl-penta-*O*-acetyl-maltosan (XIII).[11] Maltosan (XII, 11 g) was dissolved in anhydrous pyridine (125 m*l*). To the solution was added freshly recrystallized trityl chloride (15 g). After standing three days at room temperature, the starting material disappeared on a thin layer chromatogram. The mixture was then acetylated with acetic anhydride (20 m*l*) at room temperature for 12 hr. The solution was extracted with chloroform, washed with sodium bicarbonate and then with water, dried over calcium chloride and evaporated *in vacuo*. The acetylated trityl compound contaminated with triphenyl carbinol was used without purification in the next procedure.

2,3,2′,3′,4′-Penta-*O*-acetyl-maltosan (XIV). The product XIII (5 g) was detritylated in 80% aqueous acetic acid (200 m*l*) by the method of Dutton and Slessor.[11] Crystallization in methanol gave XIV (2.4 g) almost free from triphenyl carbinol, which melted at

82—83°C. Found: C, 49.51; H, 5.71%. Calcd for $C_{22}H_{30}O_{15}$: C, 49.44 H, 5.62%.

6′-*O*-*p*-Toluenesulfonyl-penta-*O*-acetyl-maltosan (XV).[11] XIV (5.5 g) was dissolved in anhydrous pyridine (80 ml) and *p*-toluenesulfonyl chloride (7 g) was added to the solution. After 24 hr, needles appeared on addition of water (30 ml). Recrystallization in methanol gave pure 6′-*O*-*p*-toluenesulfonyl-penta-*O*-acetyl-maltosan (6.0 g) which melted at 170—171°C. Found: C, 50.51; H, 5.23; S, 4.44%. Calcd for $C_{29}H_{36}O_7S$: C, 50.58; H, 5.23; S, 4.65%.

6′-Iodo-6′-deoxy-penta-*O*-acetyl-maltosan (XVI).[11] XV (6 g) was dissolved in acetone (120 ml) and sodium iodide (15 g) was added to the solution. The mixture was refluxed for 15 hr and then extracted with chloroform. The extract was evaporated after it had been washed with 5% sodium thiosulfate and then with water. A syrupy residue was crystallized in methanol.

Recrystallization in methanol gave 6′-iodo-6′-deoxy-penta-*O*-acetyl-maltosan (5.5 g) which melted at 193—195°C. Found: C, 40.97; H, 4.57; I, 19.77%. Calcd for $C_{22}H_{29}O_{14}I$: C, 40.99; H, 4.50; I, 19.72%.

6′-Deoxy-penta-*O*-acetyl-maltosan (XVII). XVI (5.5 g) was dissolved in a mixture of ethanol (200 ml), dioxane (100 ml) and pyridine (1 ml), and reduced with hydrogen over 10% palladium-charcoal (6 g) according to the method of Dutton and Slessor.[11] Crystallization in methanol gave XVII (3.2 g) which melted at 140—141°C. $[\alpha]_D^{19}$ +42° (*c*, 1.00, chloroform). Found: C, 50.88; H, 5.88%. Calcd for $C_{22}H_{30}O_{14}$: C, 50.96; H, 5.77%.

6′-Deoxy-hepta-*O*-acetyl-maltose (XVIII). XVII (1.5 g) was dissolved in an acetolysis-mixture (30 ml of sulfuric acid-acetic anhydride-acetic acid, 1 : 70 : 30), and treated according to the method of Dutton and Slessor.[11] Crystallization in ethanol - *n*-hexane (3 : 1) gave XVIII (1.5 g) which was a mixture of α- and β-anomer. Thus the melting point (85—87°C) was different from that (mp 183—185°C) given by Dutton and Slessor.[11] $[\alpha]_D^{19}$ +85° (*c*,1.00, chloroform). Found: C, 49.45; H, 5.83%. Calcd for $C_{26}H_{36}O_{17}$: C, 50.32; H, 5.80%.

Phenyl 6′-Deoxy-α-maltoside (XIX). XVIII (2.0 g) was dissolved in phenol (4 ml), and zinc chloride (0.35 g) was added to the solution. The mixture was treated as described above. After deacetylation with sodium methoxide, the product was passed through a column of Biogel P-2. The fraction of the product was freeze-dried, but it did not crystallize. $[\alpha]_D^{19}$ +170° (*c*, 0.96, water). Found: C, 53.42; H, 6.48%. Calcd for $C_{18}H_{26}O_{10}$: C, 53.73; H, 6.47%.

6′-*O*-*p*-Toluenesulfonyl-hepta-*O*-acetyl-maltose (XX). XV (1.5 g) was dissolved in the above acetolysis mixture. After standing for three hours at room temperature, 10% aqueous barium acetate was added to the mixture, which was extracted with chloroform (3×50 ml), after barium sulfate was removed by centrifugation. A white powder (1.5 g) was obtained by evaporation *in vacuo*. Though the product gave a single spot on a thin-layer chromatogram, it did not crystallize. $[\alpha]_D^{24}$ +100° (*c*, 2.00, dioxane). Found: C, 50.63; H, 5.50; S, 3.96%. Calcd for $C_{33}H_{42}O_{20}S$: C, 50.12; H, 5.35; S, 4.05%.

Phenyl 3′,6′-Anhydro-α-maltoside (XXII). A mixture of XX (2.0 g), phenol (3.5 ml) and zinc chloride (0.35 g) was heated under stirring on an oil bath at 118—120°C for 30 min. Benzene (50 ml) was added to the hot reaction mixture, which was washed with 1N sodium hydroxide, water, and evaporated *in vacuo*. The syrupy product was dissolved in methanol (30 ml), and Dowex 1×4 (OH^- form) was added to the solution under stirring at room temperature. After two hours, the resin was filtered and the filtrate was concentrated *in vacuo*. The product was purified by passing through a column of Biogel P-2. The fraction of the product was crystallized in methanol. The colorless crystals (0.2 g) melted at 194—195°C. $[\alpha]_D^{24}$ +136° (*c*, 0.90, water). Found: C, 53.85; H, 5.99%. Calcd for $C_{18}H_{24}O_{10}$: C, 54.00; H, 6.00%.

6′-Iodo-6′-deoxy-hepta-*O*-acetyl-maltose (XXIII). XX (2.5 g) was dissolved in acetone (30 ml), and sodium iodide (5.0 g) was added to the solution. The solution was refluxed for 10 hr and was extracted with chloroform. The extract was washed with 5% aqueous sodium thiosulfate and then with water. Evaporation of chloroform gave a syrupy product, which did not crystallize. $[\alpha]_D^{20}$ +102° (*c*, 2.00, dioxane). Found: I, 16.41%. Calcd for $C_{26}H_{35}O_{17}I$: I, 17.00%.

Phenyl 6′-Iodo-6′-deoxy-maltoside (XXIV). XXIII (2.0 g) was treated with phenol (4 ml) and zinc chloride (0.3 g) by the method described above. The product was deacetylated with 0.1M sodium methoxide for five minutes under cooling with ice-water bath. Column chromatography using Biogel P-2 gave a single product, which did not crystallize. $[\alpha]_D^{27}$ +130° (*c*, 1.00, water). Found: C, 40.45; H, 4.81; I, 24.17%. Calcd for $C_{18}H_{25}O_{10}I$: C, 40.92; H, 4.77; I, 24.02%.

6′-*O*-Methyl-penta-*O*-acetyl-maltosan (XXV). XIV (3.0 g) was dissolved in dichloromethane (25 ml). After the solution was cooled in a dry ice-acetone bath, diazomethane in ether (140 ml) and boron trifluoride (7 ml of boron trifluoride etherate-dichloromethane, 1 : 25) were added dropwise during two hours. Insoluble substance was filtered off, and the solution was extracted with chloroform. The extract was washed with water and dried over calcium chloride. The chloroform extract was evaporated to a syrup which crystallized in methanol. Recrystallization in the same solvent gave 6′-*O*-methyl-penta-*O*-acetyl-maltosan (2.5 g) which melted at 164°C. $[\alpha]_D^{20}$ +20° (*c*, 1.00, chloroform). Found: C, 50.06; H, 5.95%. Calcd for $C_{23}H_{32}O_{15}$: C, 50.36; H, 5.88%.

6′-*O*-Methyl-hepta-*O*-acetyl-maltose (XXVI). XXV (2.0 g) was dissolved in the acetolysis mixture (40 ml) and the mixture was kept at room temperature for three hours. Five per cent barium acetate solution was added to the reaction mixture, and the resulting barium sulfate was removed by centrifugation. The mixture was extracted with chloroform, and the extract was washed with sodium bicarbonate and repeatedly with water. Evaporation of chloroform gave a syrupy product, which gave a single spot on a thin-layer chromatogram, though it did not crystallize. Found: C, 49.97; H, 5.93%. Calcd for $C_{27}H_{38}O_{18}$: C, 49.98; H, 5.89%.

Phenyl 6′-*O*-methyl-α-maltoside (XXVII). XXVI (1.5 g) was reacted with phenol (3.5 ml) in the presence of zinc chloride (0.4 g) in a similar manner, and the deacetylated product was purified by gel filtration as described above. $[\alpha]_D^{18}$ +183° (*c*, 0.48, water). Found: C, 52.72; H, 6.57%. Calcd for $C_{19}H_{28}O_{11}$: C, 52.77; H, 6.53%.

6′-Chloro-6′-deoxy-penta-*O*-acetyl-maltosan (XXVIII). 2,3,2′,3′,4′-Penta-*O*-acetyl-maltosan (XIV, 3.0 g) was dissolved in freshly distilled pyridine and the solution was cooled in an ice-water bath, and sulfuryl chloride (1 ml) was added dropwise. The reaction was continued for 12 hr at room temperature. Water was poured into the mixture in order to destroy excess sulfuryl chloride, and the mixture was extracted with chloroform. The extract was washed with sodium bicarbonate and water. Evaporation of chloroform *in vacuo* gave a syrup, which crystallized rapidly in methanol. The crystals thus obtained (2.3 g) melted at 129°C. $[\alpha]_D^{18}$ +53.8° (*c*, 1.30, chloroform). Found: C, 47.28; H, 5.60; Cl, 6.07%. Calcd for $C_{22}H_{29}O_{14}Cl$: C, 47.79; H, 5.28; Cl, 6.41%.

6′-Chloro-6′-deoxy-hepta-*O*-acetyl-maltose (XXIX). XXVIII (2.0 g) was dissolved in the acetolysis mixture (40 ml) and the mixture was kept at room temperature for three hours. Aqueous barium acetate was added to the mixture in order to remove sulfuric acid. The chloroform extract was evaporated to a syrup (1.8 g) which did not crystallize.

Phenyl 6′-Chloro-6′-deoxy-hexa-*O*-acetyl-α-maltoside (XXX). XXIX (1.5 g) was converted into a phenyl glycoside in a similar manner, and a syrupy product was obtained which was crystallized in ethanol. Recrystallization from the same solvent gave colorless crystals (0.2 g) which melted at 133—134°C. $[\alpha]_D^{18}$ +186.9° (*c*, 0.57, chloroform). Found: C, 52.55; H, 5.36; Cl, 5.23%. Calcd for $C_{30}H_{37}O_{16}Cl$: C, 52.29; H, 5.41; Cl, 5.14%.

Phenyl 6′-Chloro-6′-deoxy-α-maltoside (XXXI). XXX (0.143 g) was dissolved in chloroform (3 ml) and 0.1M sodium methoxide in methanol (20 ml) was added to this solution. After 20 min, the solution was treated with Dowex 50(H^+ form), followed by filtration and evaporation. A syrup thus obtained was purified by gel filtration through Biogel P-2 column. Found: C, 48.89; H, 5.89; Cl, 7.68%. Calcd for $C_{18}H_{25}O_{10}Cl$: C, 49.49; H, 5.77; Cl, 8.12%.

1,2,6,2′,3′,4′,6′-Hepta-*O*-acetyl-β-maltose (XXXII). Maltose (10 g) was mixed with pyridine (30 ml) and dry benzene (200 ml), and acetylated with acetyl chloride (18 ml) following the method of Dick and coworkers.[13] The syrup (5 g) was chromatographed through a column of silica-gel using an elution solvent (ethyl acetate, benzene, 1 : 1).[15] The syrup obtained (1.4 g) showed a single spot on a thin-layer chromatogram, though it did not crystallize. $[\alpha]_D^{15}$ +77.3° (*c*, 0.97, chloroform). Found: C, 48.82; H, 5.66%. Calcd for $C_{26}H_{36}O_{18}$: C, 49.06; H, 5.70%.

1,2,6,2′,3′,4′,6′-Hepta-*O*-acetyl-3-*O*-methyl-β-maltose (XXXIII). XXXII (2.5 g) was dissolved in dichloromethane (25 ml) and was methylated with diazomethane and boron trifluoride in a dry ice-acetone bath. Methylation was not complete, and the same procedure was repeated three times. The product showed contamination of a small amount of the starting material on a thin-layer chromatogram, and we carried out the next procedure without further purification.

Phenyl 3-*O*-Methyl-α-maltoside (XXXIV). Crude XXXIII (2.0 g) was reacted with phenol and deacetylated in the similar manner as described above. The product was purified by passing through a column of Biogel-P-2. $[\alpha]_D^{17}$ +199° (*c*, 0.80, water). Found: C, 52.25; H, 6.41%. Calcd for $C_{19}H_{28}O_{11}$: C, 52.77; H, 6.53%.

Discussion

The purity of the phenyl glycosides obtained was examined by the determination of phenol content using the colorimetric method.[16] It was shown that all samples contained one mole of phenol per mole of sample. The results, together with those of the elemental analyses show a high degree of

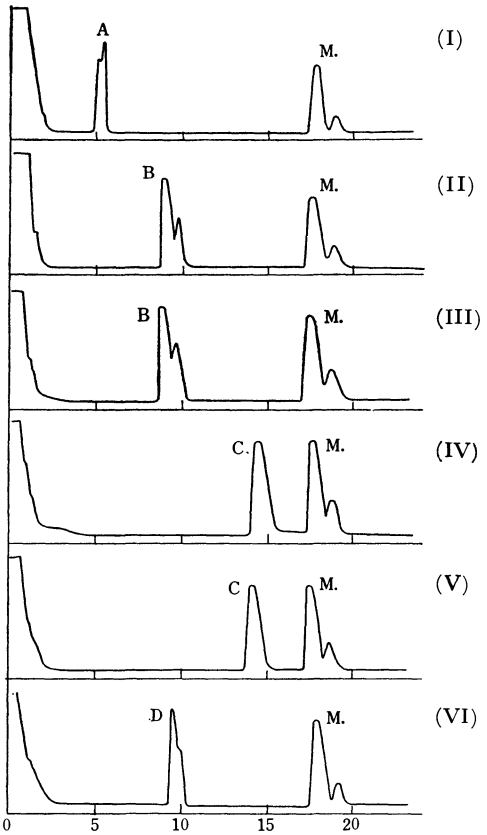

Fig. 1. Gas-liquid chromatograms of methanolyzed and trimethylsilylated compounds.

purity of the specimens.

The position of substitution on the glucose residues, which might be an unexpected one due to possible migration of acetyl groups during the course of synthesis, was confirmed by gas-liquid chromatography. Samples were methanolyzed and trimethylsilylated with hexamethyl disilazane and trimethylsilyl chloride.[17] The peaks in the gas-chromatograms were identified with the authentic derivatives of D-glucose.[18-22] The substitution occurred at the expected positions of glucose residues as shown in Fig. 1. As the iodine derivatives were the precursor of the deoxy compounds in the course of synthesis (Schemes 1 and 2), the position of iodine was also confirmed.

Gas-liquid chromatography was also used for determining which of the two glucose residues in the phenyl maltosides was substituted. As shown in Fig. 2, the precursor disaccharides of the phenyl glycosides were reduced with borohydride, after the *O*-acetyl groups had been removed, and the products were methanolyzed and analyzed by means of gas liquid chromatography. The reducing-end groups of the original disaccharides appeared in the chromatogram as corresponding sugar alcohols.

Compound XXXIII gave 3-*O*-methyl-glucitol and the compounds XXVI, XVIII and XXIX gave glucitol. These results confirm the structure of the phenyl glycosides XXXIV, XXVII, XIX and XXXI. As a counterpart of XIX, compound VI had an identical composition, and showed different behavior toward the enzymatic action (Table 1), the structure of VI was confirmed. Similarly XI was the counterpart of XXVII and IX was of XXXI, and structures of VI and IX were also confirmed. A slight ambiguity remained about the position of chlorine in the chloro-derivatives, because gas-chromatographic analysis of the chloro-deoxy-glucose had been unsuccessful.

Phenyl 3′,6′-anhydro-α-maltoside (XXII) was prepared from tosyloxy derivative (XV) which was a precursor of 6′-deoxy derivative (XVII). Thus the position of 3,6-anhydro ring was confirmed.

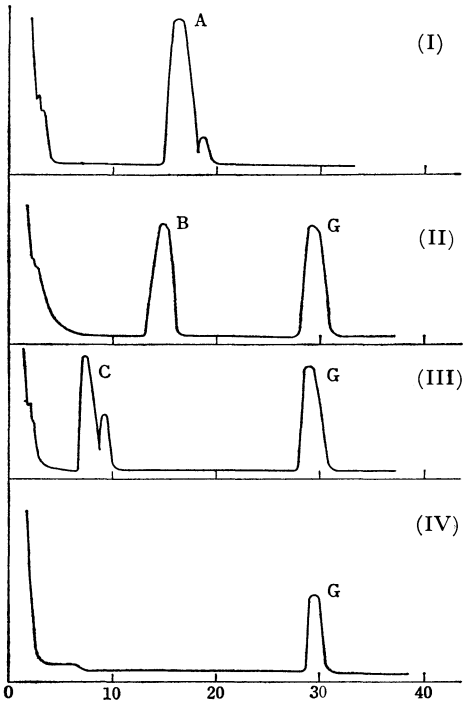

Fig. 2. Reducing-end analyses by gas-liquid chromatography.
(I) 3-*O*-Methyl-maltose derived from XXXIII.
(II) 6′-*O*-Methyl-maltose derived from XXVI.
(III) 6′-Deoxy-maltose derived from XVIII.
(IV) 6′-Chloro-6′-deoxy-maltose derived from XXIX.
The position of peak (A) is identical with that of authentic 3-*O*-methyl-glucitol, (B) with methyl 6-*O*-methyl-glucoside, (C) with methyl 6-deoxy-glucosides and (G) with glucitol. The analyses were performed after borohydride reduction and methanolyzation. All the procedures were carried out at 185°C under a 1.6 atm pressure of carrier nitrogen.

It is of interest that Taka-amylase A showed different hydrolysis rate on each substrate (Table 1). As regards the non reducing-end glucose of substrate, electronegativity at 6-position seems to be very necessary, but the steric factor is not so important for enzymatic action. On the other hand, data for the reducing-end group show that the steric factor has great significance as well as the role of electronegative residues at 6-position. These results are in line with a data presented by Isemura *et al.*[23]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 824—826 (1970)

Synthesis of Furonaphthoquinones

Hiroshi KAKISAWA and Mitsuru TATEISHI

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo

(Received June 19, 1969)

The reaction of 2-acetoxy-1,4-naphthoquinone with *N*-(1-propenyl)morpholine in an ordinary atomsphere afforded 3-methylnaphtho[2,3-*b*]furan-4,9-quinone in a modest yield. When this reaction was carried out in an atmosphere of nitrogen, the reaction product was an aminodihydronaphthofuran XII, which was then converted into 3-methylnaphtho[1,2-*b*]-2,3-dihydrofuran-4,5-quinone by succesive treatments with ferric chloride, sodium borohydride, and sufuric acid.

Since the presence of orange-red pigments, the tanshinones, in the roots of *Salvia miltiorrhiza* Bunge was reported by Nakao in 1934,[1] more than ten tanshinones have been isolated from the roots, and their structures have been determined by various groups.[2] These pigments are classified into two groups according to their structural characters: the members of the first group have a furo-*o*-quinone chromophore, while those of the second group have a furo-*p*-quinone chromophore, as is shown by the examples of cryptotanshinone (I)[2a] and isotanshinone-II (II)[2b] respectively.

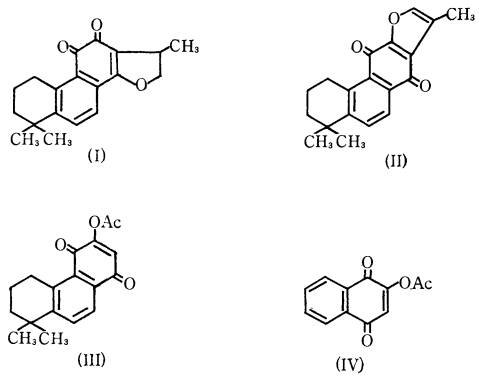

Fig. 1

These tanshinones seem to be synthesized from an intermediate (III) through constructing an appropriate furan group fused to the quinone ring. To develop a synthetic route from the intermediate (III) to the tanshinones, some attempts have been made with a model compound; the present report will deal with a new synthesis of 3-methylnaphtho[1,2-*b*]-furan-4,9-quinone (VIII) and 3-methylnaphtho[1,2-*b*]-2,3-dihydrofuran-4,5-quinone (XV) from 2-acetoxy-1,4-naphthoquinone.

For the synthesis of furonaphthoquinones from the acetoxynaphthoquinone (IV), it is preferable to introduce at the C-3 position of the quinone, an isopropyl group bearing an appropriate oxygen function. The reaction of the quinone with an enamine made from propionaldehyde was expected to give either formylethylnaphthol or an equivalent addition compound. Although a reaction of enamine with unsubstituted quinone (V) has been reported by Brannock *et al.*[3] to give a cyclic addition compound such as VI, no reaction of an acyloxyquinone with an enamine has yet been reported.

When 2-acetoxy-1,4-naphthoquinone (IV) was allowed to react with an equivalent amount of 4-(1-propenyl)morpholine (VII)[4] in methanol, there was obtained, by direct crystallization, a nitrogen-free product, $C_{13}H_8O_3$, in a 44% yield. The structure of this yellow product was identified as 3-methylnaphtho[2,3-*b*]furan-4,9-quinone (VIII) from its spectral properties. The IR spectrum of the product shows a quinonoid carbonyl absorption at 1675 cm^{-1} besides furano absorptions[5] at 3150, 1590, and 1525 cm^{-1}. The presence of the furan group in the reaction product was supported by its NMR spectrum, which exhibits the signal of a methyl group at 2.36 (3H, d. J=2 Hz) and that of an olefinic proton at 7.45 (1H, q. J= 2 Hz), attributable to the coincidence with the CH_3–C(I)=CH–O– group, in addition to aromatic protons at 7.65 and 8.05. The UV spectrum of

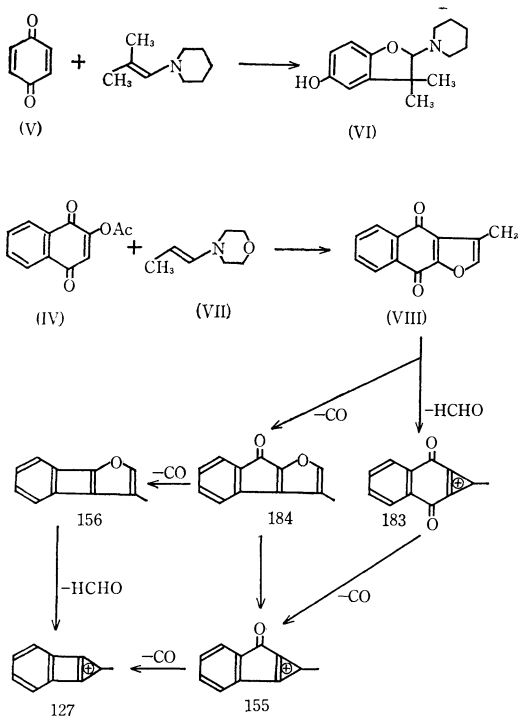

Fig. 2

the product, λ_{max} 246 (21500 sh), 251 (22000), 268 (6100), 305 (4100) and 360 nm (4300), is almost superimposable upon that of isotanshinone-II (II), which has a naphtho[2,3-*b*]furan-4,9-quinone chromophore. The mass spectrum shows main peaks at 212, 184, 183, 156, 155, and 127 mu; these fragmentation patterns are characteristic[6] of the 3-methylnaphtho[2,3-*b*]furan-4,9-quinone derivatives. This reaction, which has made possible the synthesis of the furo-*p*-quinone by a simple reaction from 2-acetoxy-1,4-naphthoquinone, will be useful for the synthesis of isotanshinones.[7]

The above addition reaction of the enamine (VII) to the acetoxynaphthoquinone (IV) was expected first to afford an aminodihydronaphthofuran, either XI or XII, by the nucleophilic addition of the enamine to the quinone and by subsequent cyclization, but the fact that the furonaphthoquinone (VIII) was formed without any oxidative reagent makes it obvious that air oxidation must have taken place during the condensation process. Therefore, the condensation of 4-(1-propenyl)morpholine (VII) to 2-acetoxy-1,4-naphthoquinone (IV) in an atmosphere of nitrogen has been attempted in order to obtain the intermediates, XI and/or XII. The reaction product was formed of white crystals having a molecular composition of $C_{19}H_{21}O_5N$; the UV spectrum (λ_{max} 246 and 305 nm) indicates the presence of a naphthol group, while the IR spectrum (ν_{max} 3350 and 1750 cm^{-1}) shows the presence of hydroxy and enol-acetate groups. Although two structures XI and XII were possible for the reaction product, the possibility of structure XI was disregarded in the following reactions. The oxidation of the adduct XII with ferric chloride gave a substance shown to be XIII. Three carbonyl absorptions, at 1780, 1720, and 1660 cm^{-1}, in the IR spectrum of XIII point to the presence of enol-acetate, unconjugated aldehyde, and quinonoid carbonyl groups respectively, and the NMR spectrum shows the presence of a formylethyl group at 1.35 (3H, d. J=8 Hz), 3.75 (1H, q. J=8 Hz), and 9.6 (1H, s), and of an acetyl group at 2.31 (3H, s). The UV spectrum of the oxidation product, showing absorption maxima at 248, 268, and 335 nm, is almost the same as that of 2-acetoxy-1,4-naphthoquinone.

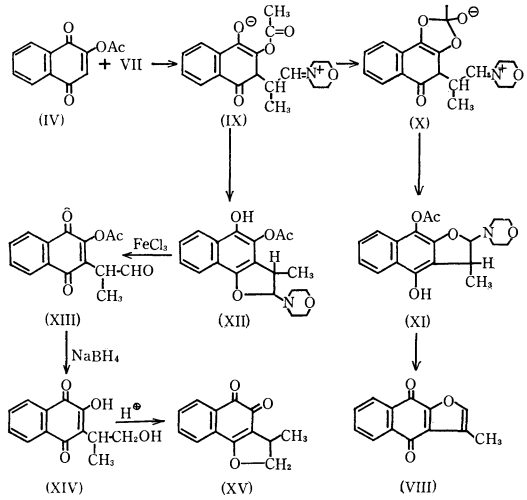

Fig. 3

The sodium borohydride reduction of XIII and the subsequent base hydrolysis of the acetyl group afforded a diol XIV (ν_{max} 3400, 1660 cm^{-1}). The diol XIV was prepared directly from the aminodihydrofuran (XI) by alkaline hydrolysis followed by reduction with sodium borohydride in an ordinary atmosphere. The treatment of the diol (XIV) with cold sulfuric acid in ethanol afforded, selectively, 3-methyldihydronaphtho[1,2-*b*]-2,3-dihydrofuran-4,5-quinone (XV), whose structure was confirmed by spectral data. The IR absorption bands at 1680, 1650, and 1625 cm^{-1} are compatible with the *o*-naphthoquinone. The NMR spectrum has signals at 1.36 (3H, d, J=8 Hz) and 3,40—5.06 (3H, m) assignable to the CH_3–CH–CH_2–O–

6) T. Hayashi, Y. Inouye, M. Ohashi, H. Kakisawa, A. Tatematsu and S. Kinoshita, *Org. Mass Spect.*, **2**, (1970), in press.

7) Recently this reaction has been applied to the synthesis of matsurinone, a natural product having the structure of 3,5-dimethylnaphtho[2,3-*b*]furan-4,9-quinone; H. Kakisawa and Y. Inouye, *Tetrahedron Lett.*, **1969**, 1929.

grouping besides those due to aromatic protons at 7.60 (2H, m) and 8.10 (2H, m). Finally, the structure (XV) is established by the UV spectrum (λ_{max} 262, 333, and 460 nm), whose shape is very similar to that of cryptotanshinone (I). This synthetic method from IV to XV can be applied to the total synthesis of cryptotanshinone.

Experimental

All the melting points are determined in a liquid bath and are uncorrected. The infrared spectra were measured on a Hitachi EPI-S2 spectrophotometer as KBr disks. The UV spectra were determined on a Hitachi EPS-3T spectrometer, and the NMR spectra were recorded on Hitachi R-20 spectrometer, with tetramethylsilane as the internal standard.

3-Methylnaphtho[2,3]furan-4,9-quinone (VIII). 4-(1-Propenyl)morpholine (0.32 g) was added to an ice-cooled mixture of 0.54 g of 2-acetoxyl-1,4-naphthoquinone and 2 m*l* of methanol. The reaction mixture was allowed to stand for 2 hr at room temperature, and then left in a refrigerator overnight in order to separate crystals. The crystals were collected and recrystallized from ethanol to give 0.235 g (44%) of light yellow needles; mp 206°C; λ_{max}^{EtOH} (ε) 246^{sh} (21500), 251 (22000), 268^{sh} (6100), 305 (4100), 360 nm (4300); ν_{max} 3150, 1675, 1590, 1525, 1020 cm^{-1}; NMR ($CDCl_3$) 2.36 (3H, d, J=2 Hz), 7.45 (1H, q, J=2 Hz), 7.65 (2H, m), 8.05 (2H, m); MS 212, 184, 183, 157, 156, 155, 128, 126, 105, 102, 77 mu.

Found: C, 73.69; H, 3.88%. Calcd for $C_{13}H_8O_3$: C, 73.58; H, 3.80%.

2,3-Dihydro-4-acetoxy-5-hydroxy-3-methyl-2-morpholinonaphtho[1,2-*b*]furan (XII). Into a suspension of 2-acetoxy-1,4-naphthoquinone (100 mg) in 0.5 m*l* of methanol was gradually stirred 60 mg of 4-(1-propenyl)morpholine in an atmosphere of nitrogen. The yellow quinone thus dissolved, and white crystals were separated. After standing in a refrigerator for 24 hr, the crystals were filtered and washed with ether several times to give 65 mg (40%) of aminodihydronaphthofuran (XII). Although the product was difficult to purify by recrystallization, the crystals were pure enough for further experiments; mp 150—151°C; λ_{max}^{EtOH} (ε) 246 (48500), 305 (6700) nm; ν_{max}^{KBr} 3350, 1750, 1640, 1590 cm^{-1}.

Found: C, 67.03; H, 6.37; N, 4.26%. Calcd for $C_{19}H_{21}O_5N$: C, 66.46; H, 6.16; N, 4.08%.

2-(3-Acetoxy-1,4-naphthoquinonyl)propionaldehyde (XIII). A solution of 250 mg of ferric chloride hexahydrate and 0.6 m*l* of hydrochloric acid was stirred, drop by drop, into a suspension of 120 mg of aminodihydronaphthofuran (XII) in an atmosphere of nitrogen. After the reaction mixture had then been stirred for 10 min at room temperature, the solution turned orange-red; the mixture was then extracted with ether. The ether extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo* to afford oil; λ_{max}^{EtOH} 248, 268, 335 nm; $\nu_{max}^{CHCl_3}$ 1780, 1720, 1660 cm^{-1}; NMR ($CDCl_3$) 1.35 (3H, d, J=8 Hz), 2.31 (93H, s), 3.75 (1H, q, J=8 Hz), 7.7 (2H, m), 8.1 (2H, m), 9.61 (1H, s).

2-(3-Hydroxy-1,4-naphthoquinonyl)-1-propanol (XIV). To a solution of 95 mg of naphthoquinonylpropionaldehyde (XIII) in 5 m*l* of ethanol, was added 25 mg of sodium borohydride dissolved in 5 m*l* of methanol. After stirring at room temperature for 10 min, 2 m*l* of 2N sodium hydroxide solution was added and the mixture was stirred for a further 10 min. The deep red reaction mixture was neutralized with dilute hydrochloric acid and extracted with ether. The ether extract was washed with water, dried over anhydrous sodium sulfate, and evaporated to give naphthoquinonylpropanol (XIV): $\nu_{max}^{CHCl_3}$ 3400 1660, 1590 cm^{-1}.

This diol XIV was made directly from the adduct XII. To a suspension of the adduct XII (165 mg) in 12 m*l* of ethanol was added 8 m*l* of a 0.1N aqueous potassium hydroxide solution, whereupon the solution turned deep red. After the solution had then been stirred for 1 hr at room temperature, the solution was acidified with dilute hydrochloric acid and extracted with ether. The ether extract was washed with water, dried and evaporated *in vacuo*. The residue was dissolved in 10 m*l* of ethanol and treated with excess sodium borohydride dissolved in aqueous ethanol. After standing for 1 hr at room temperature, the solution was treated with dilute hydrochloric acid and extracted with ether. The treatment of the ether solution as usual afforded oil (50 mg) whose IR spectrum was the same as that of the diol (XIV).

3-Methylnaphtho[1,2-*d*]-2,3-dihydrofuran-4,5-quinone (XV). A solution of 75 mg of diol (XIV) in 1 m*l* of ethanol was treated with a mixture of sulfuric acid and ethanol (1 : 1) at 80°C. After 5 min, the mixture was poured into ice water to give a red solution. The aqueous solution was then extracted with ether. The ether extract was washed with water, dried over magnesium sulfate, and evaporated to give red crystals. Recrystallization from ethanol yielded furonaphthoquinone (XV) (50 mg); mp 150—151°C; λ_{max}^{EtOH} (ε) 253^{sh} (12600), 262 (16800), 271^{sh} (14500), 288^{sh} (4100), 333 (1400), 460 nm (1500); $\nu_{max}^{CHCl_3}$ 1680, 1650, 1625 cm^{-1}; NMR ($CDCl_3$) 1.36 (3H, d, J=8.0 Hz), 3.40—5.06 (3H, m), 7.60 (2H, m), 8.10 (2H, m).

Spiro Compound Formation. IV.[1] Acid-catalyzed Reactions of 2-Cyclohexylidenecyclohexanone Oxide

Masatomo NOJIMA, Keniti HINOUE and Niichiro TOKURA

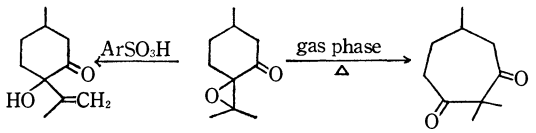
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received July 16, 1969)

The reactions of 2-cyclohexylidenecyclohexanone oxide in the presence of (i) sulfuric acid, (ii) fluorosulfonic acid, (iii) boron trifluoride etherate, and (iv) antimony pentachloride have been studied. The products consisted of spiro[5.6]dodecane-7,12-dione, 2-(1-cyclohexenyl)-2-hydroxycyclohexanone, and 1,2,3,4,6,7,8,9-octahydrodibenzofuran. The ratio of the products was found to depend on the differences in the catalysts and solvents.

Although the reactions of α,β-epoxyketones under acidic conditions have been performed energetically from synthetic points of view,[2] only a few examinations aiming at a systematic clarification of the effects of catalysts upon the reaction mechanism have been performed.

Reusch, Anderson, and Johnson[3] recently reported that the gas-phase pyrolysis of pulegone oxide (I) at 200°C produced 2,2,5-trimethylcycloheptane-1,3-dione (II); they concluded that this reaction involved the rearrangement of I absorbed at Lewis acid sites on the Pyrex glass surface. Contrary to the above results, however, the reaction of I with *p*-toluenesulfonic acid led to the unsaturated hydroxyketone (III). These results suggest that the mechanism of the reaction of α,β-epoxyketones with Lewis acid is different from the mechanism of the reaction which is performed in the presence of Brønsted acid.



(III) (I) (II)

In order to investigate in more detail the dependence of the reaction pathways upon the difference in catalysts, we examined the reaction of 2-cyclohexylidenecyclohexanone oxide(IV)[4] in the presence of (i) sulfuric acid. (ii) fluorosulfonic acid, (iii) boron trifluoride etherate, and (iv) antimony pentachloride respectively. Liquid sulfur dioxide and cyclohexane were used as the solvents, and the solvent effects upon the reaction were also examined. The reactions were performed under the conditions described in Table 1.

TABLE 1. ACID-CATALYZED REACTIONS[a] OF IV AND VI

Substrate	Catalyst	Solvent	Total yield, %[b,h] V[d]	VI[e]	VII[f]
IV[c]	$SbCl_5$	SO_2	93.2	0	6.8
	BF_3-Et_2O	SO_2	82.8	0	17.2
	FSO_3H	SO_2	27.7	0	72.3
	H_2SO_4	SO_2	41.8	10.6	47.6
	$SbCl_5$	Cyclohexane	30.2	44.3	25.5
	BF_3-Et_2O	Cyclohexane	41.3	35.4	23.3
	FSO_3H	Cyclohexane	6.6	49.2	44.2
	H_2SO_4[g]	Cyclohexane	8.5	0	91.5
VI	H_2SO_4	SO_2	0	13.0	87.0

a) 0.1 g Substrate, 0.1 m*l* catalyst in 10 m*l* of SO_2 at 0°C or in 10 m*l* of cyclohexane at 15°C for 1 hr.
b) Calculated from the glpc peak areas.
c) 2-Cyclohexylidenecyclohexanone oxide.
d) Spiro[5.6]dodecane-7,12-dione.
e) 2-(1-Cyclohexenyl)-2-hydroxycyclohexanone.
f) 1,2,3,4,6,7,8,9-Octahydrodibenzofuran.
g) The reaction was performed for 21 hr.
h) The total yields were almost quantitative.

Gas-liquid partition chromatography showed that the products consisted of spiro[5.6]dodecane-7,12-dione (V), 2-(1-cyclohexenyl)-2-hydroxycyclohexanone (VI), and 1,2,3,4,6,7,8,9-octahydrodibenzofuran (VII). The products were isolated by column chromatography and were characterized by physical measurements and by their chemical transformations.

The compound V was a white crystalline solid of

1) Part III; M. Nojima and N. Tokura, This Bulletin, **42**, 1351 (1969).

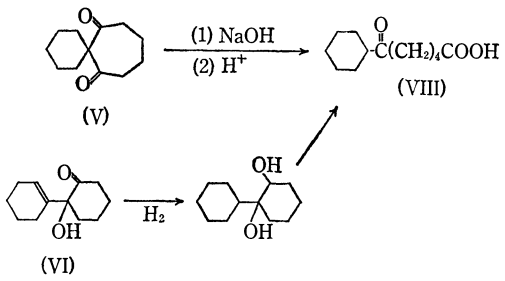
2) R. E. Parker and N. S. Issacs, *Chem. Rev.*, **59**, 737 (1959).

3) W. Reusch, D. F. Anderson and C. K. Johnson, *J. Amer. Chem. Soc.*, **90**, 4988 (1968).

4) House and Wasson examined the pyrolytic rearrangement of IV to yield spiro[5.6]dodecane-7,12-dione (V). Although the reaction of IV with BF_3 etherate was also performed in benzene or diethyl ether, they failed to obtain the same compound V; H. O. House and R. L. Wasson, *J. Amer. Chem. Soc.*, **78**, 4394 (1956).

mp 69—70°C. Mass spectroscopy established a molecular formula $C_{12}H_{18}O_2$ (Calcd for $C_{12}H_{18}O_2$: 194, Found: 194). V exhibited a carbonyl absorption at 1682 cm^{-1}, forming a semicarbazone, mp 218—223°C. The treatment of V with aqueous sodium hydroxide gave 6-cyclohexyl-6-oxohexanoic acid (VIII).[4]

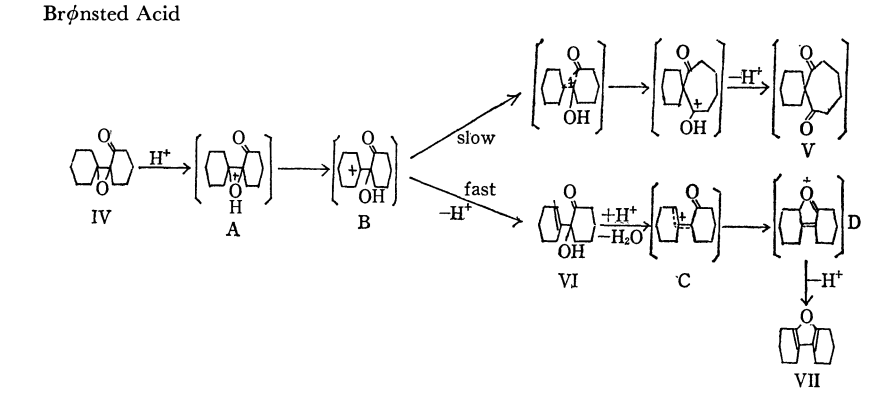
VI exhibited carbonyl and hydroxyl absorptions at 1700 and 3460 cm^{-1} respectively. The NMR spectrum displayed signals at 4.35 τ (one-proton multiplet) and 6.25 τ (one-proton singlet). Mass spectroscopy established the molecular formula of $C_{12}H_{18}O_2$ (Calcd for $C_{12}H_{18}O_2$: 194, Found: 194). When the diol obtained by the hydrogenation of VI using Raney Ni as the catalyst was oxidized by chromic acid, it gave VIII. The IR spectrum of VII (ν_{max}, 1600, 1140 cm^{-1}) indicated the presence of a furan ring, and the molecular ion in the mass spectrum was observed at *m/e* 176. Conclusive evidence for the structure assigned to VII was obtained by a comparison of the maleic anhydride adduct of VII with an authentic sample.[5]

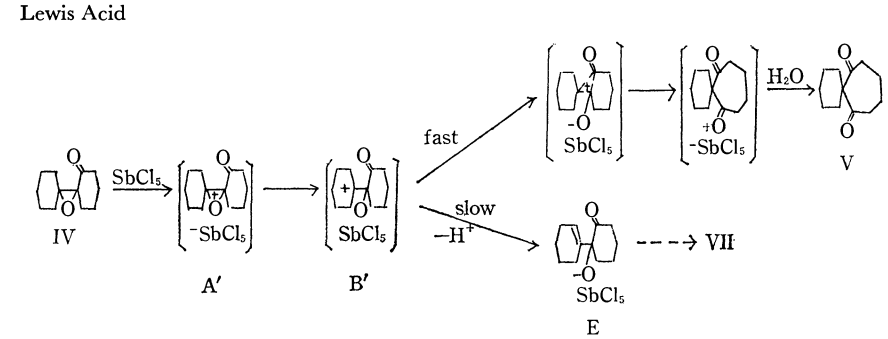


In Table 1 the results obtained from the reactions of IV under various conditions are summarized; it is obvious that the ratio of the products varied drastically with the change in the experimental conditions. From these data, Scheme I may be considered to be the most plausible reaction scheme.

When the Brønsted acid was used as the catalyst, much VI and VII were formed. In addition to this result, we established the selective formation of VII by the reaction of VI with sulfuric acid in liquid sulfur dioxide; this seems to show that VI is the intermediate for the formation of VII. As is shown in Table 1, the spiro compound V was also obtained.

These results seem to show that the reaction of IV with Brønsted acid is very similar to the pinacol rearrangement of 1,1-dihydroxydicyclohexyl[6]; IV is attacked by a proton to form the intermediate B after the ring opening. The B intermediate then probably disappears following one of two pathways; that is, either it rearranges to form V or loses a proton to form VI. The tertiary carbonium ion is





Scheme 1

5) T. A. Spencer, R. W. Britton and D. S. Watt, *J. Amer. Chem. Soc.*, **89**, 5727 (1967).

6) M. Qudrat-I-Kuda and A. K. Ray, *J. Indian Chem. Soc.*, **16**, 525 (1939).

well known to deprotonate very rapidly,[7] and so it may be considered that the rate of deprotonation from B to form VI is very rapid. It is reasonable to consider that the allylic alcohol VI is not stable in the presence of an acid catalyst and that VI is attacked by a proton to form the intermediate C after the dehydration. The cation cite of C may be attacked by the lone-pair electrons of oxygen to form VII with a furan ring after the deprotonation.

For the formation of the spiro compound V, Lewis acid was more effective than Brønsted acid; V was obtained in a 93.2% yield when the reaction was performed with antimony pentachloride in liquid sulfur dioxide. This is probably due to the instability of the intermediates B and E because of the steric hindrance of a large volume of Lewis acid. In order to diminish this steric hindrance, the ring-enlargement reaction to form V seems to be more profitable than the deprotonation to form VI.

We can not propose a good explanation of the solvent effects upon the reaction of IV, but it seems probable that the rearrangement of the intermediate B to form V is accelerated by the stabilization of the transition state due to the solvation of the liquid sulfur dioxide. When cyclohexane is used as the solvent, there is no factor to stabilize the transition state and the deprotonation to form VI seems to be an important part of this reaction.

Experimental

2-Cyclohexylidenecyclohexanone Oxide (IV) was prepared by the method of Reese.[8] From 21.0 g of 2-cyclohexylidenecyclohexanone and 21 m*l* of a 30% hydrogen peroxide solution, we obtained 10.0 g (47.6% yield based on 2-cyclohexylidenecyclohexanone) of 2-cyclohexylidenecyclohexanone oxide; mp 96.5—97°C (lit,[5] mp 96.5—97°C).

1,2,3,4,6,7,8,9-Octahydrodibenzofuran (VII) was prepared by the action of zinc dust with 2-bromocyclohexanone[5]; bp 88—89°C/2 mmHg. The adduct of VII with maleic anhydride was prepared by the following method; maleic anhydride (1 g) and 2 g of VII were dissolved in 5 m*l* of benzene, after which the mixture was allowed to react at room temperature for 24 hr. The solid obtained was recrystallized from cyclohexane; mp 166—167°C (lit,[9] 167—168°C).

The Reaction of 2-Cyclohexylidenecyclohexanone Oxide (IV) in Liquid Sulfur Dioxide. To 200 mg of IV and 10 m*l* of liquid sulfur dioxide, was added 0.1 m*l* of the acid catalyst at −68°C, after which the mixture was allowed to react at 0°C for 1 hr. The reaction mixture was then rapidly cooled, diluted with water, and extracted three times with ether. The combined organic layers were washed with saturated brine and dried over anhydrous sodium sulfate. The volume of the extraction solvent was kept small so that no concentration step was neccesary in vpc analysis.

The products were analyzed by a Hitachi K-53 vpc apparatus, with a flame ionization detector, on a SE 30 column operated at 130—170°C.

The Reaction of 2-Cyclohexylidenecyclohexanone Oxide (IV) in Cyclohexane. To 200 mg of IV and 10 m*l* of cyclohexane was added 0.1 m*l* of the acid catalyst, after which the mixture was allowed to react at 15°C for 1 hr. When sulfuric acid was used as the catalyst, the reaction was performed for 21 hr. The reaction mixture was treated and analyzed as has been described in the preceding experiment.

Reaction Products from 2-Cyclohexylidenecyclohexanone Oxide (IV). 2-Cyclohexylidenecyclohexanone oxide (1.0 g), 0.5 m*l* of sulfuric acid, and 20 m*l* of sulfur dioxide were maintained at 0°C for 1 hr and then extracted with ether and dried over anhydrous sodium sulfate. The residue after the removal of the solvent was chromatographed on 50 g of silica gel. Elution with ten 50-m*l* portions of petroleum ether gave 0.4 g of an oil, which was then fractionated. Vpc on a SE 30 column indicated that this product was 99% pure. The infrared and mass spectra were identical with those of authentic 1,2,3,4,6,7,8,9-octahydrodibenzofuran (VII), and a mixed melting-point determination of the maleic anhydride adduct of the isolated product with the authentic maleic anhydride adduct of VII was undepressed.

Elution with thirteen 50-m*l* portions of benzene gave 0.1 g of a solid, which was then recrystallized from petroleum ether; mp 69—70°C. The physical data were identical with those of spiro[5,6]dodecane-7,12-dione.[4] In order to clarify the structure of this solid (V), the following reaction was performed; a solution of 0.5 g of V and 2.5 m*l* of 6N aqueous sodium hydroxide in 15 m*l* of ethanol was boiled under reflux for 30 min, diluted with water, acidified with hydrochloric acid, and extracted with ether. The extract was dried over anhydrous sodium sulfate and concentrated to leave a white solid. This keto acid was crystallized from petroleum ether as colorless plates; mp 56—58°C, mixed mp 56—58°C.

2-(1-Cyclohexenyl)-2-hydroxycyclohexanone (VI) was also isolated from the reaction mixture by chromatography. Elution with ten 50-m*l* portions of methanol gave 0.4 g of an oil which was then fractionated and thus confirmed to be 99% pure by vpc; bp 104°C/4 mmHg.

VI was hydrogenated using Raney nickel and hydrogen at 40—50°C; a white crystalline solid (IX) was obtained in a quantitative yield; *m/e* 198; ν_{max} 3300 and 3400 cm^{-1}. By the oxidation of IX with chromic acid at 50°C, 6-cyclohexyl-6-oxohexanoic acid (VIII) was obtained; mp 56—58°C (lit,[4] 56.5—58°C).

The Metal-Catalyzed Autoxidation of Cumene

Yoshio KAMIYA

Department of Fuel Engineering, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received July 18, 1969)

The catalysis of metal carboxylates and metal phthalocyanines in the autoxidation of cumene was kinetically studied. The limiting rate of oxidation of cumene was just over half the theoretical rate of $k_p^2(RH)^2/2k_t$ suggesting that the induced decomposition of cumyl hydroperoxide due to cumyloxy radical proceeds rapidly. The effect of metal catalyst in the autoxidation of cumene was concluded to be caused by the decomposition of hydroperoxide and not by the activation of oxygen, since the rate of oxidation increased with the increase in the rate of metal-catalyzed decomposition of hydroperoxide. The synergistic effect on the metal-catalyzed autoxidation of cumene was proved to result from the synergistic effect of metal salts on the decomposition of hydroperoxide. The oxidation products of cumene varied remarkably according to reaction conditions.

The rate of oxidation of hydrocarbons catalyzed by metal salts reaches a constant value as the metal concentration is increased, and the value is in good agreement with the theoretical value of $k_p^2(RH)^2/2k_t$ in the cases of tetralin[1,2] and ethylbenzene.[3] These results strongly suggest that the metal catalysis is caused by the production of radicals from the hydroperoxide decomposition.

$$ROOH + Metal \longrightarrow \text{radicals } (RO\cdot \text{ and } RO_2\cdot) \quad (1)$$

$$R\cdot + O_2 \longrightarrow RO_2\cdot \quad (2)$$

$$RO_2\cdot + RH \xrightarrow{k_p} ROOH + R\cdot \quad (3)$$

$$RO_2\cdot + RO_2\cdot \xrightarrow{k_t} \text{inactive products} + O_2 \quad (4)$$

The autoxidation of cumene has been studied by a number of workers,[4-9] but its metal catalysis has not yet been completely clarified. Blanchard[4] concluded that the role of metal salt in the autoxidation is not to initiate chain by the activiation of oxygen but to produce radicals by the decomposition of hydroperoxide. Kropf[5] suggested that the chain initiation due to copper phthalocyanine-oxygen complex occurs by the hydrogen abstraction from cumene because there is an almost quantitative production of hydroperoxide at temperatures below 105°C when copper phthalocyanine was used as the catalyst. However, Minkov[7] has shown that cumyl hydroperoxide can be decomposed by copper phthalocyanine.

Recently, we found that copper phthalocyanine remarkably initiates the chain of autoxidation of α-methylstyrene[10] by the addition mechanism. The following mechanism can be postulated.

$$CuPc + O_2 \longrightarrow (CuPc)^{\delta+}O_2^{\delta-} \quad (5)$$

$$(CuPc)^{\delta+}O_2^{\delta-} + \rangle C{=}C\langle \longrightarrow (CuPc)^{\delta+}O_2^{\delta-}-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}\cdot \xrightarrow{\text{olefin, } O_2} (-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-O_2-)_n \quad (6)$$

It was intended to make clear by precise experiments the two kinds of catalytic effect in the autoxidation of cumene owing to metal catalyst, that is, the production of radicals by the decomposition of hydroperoxide and the activation of oxygen molecule.

Experimental

The oxidation technique has been described previously.[1] All experiments were carried out at 60°C except otherwise stated. The catalysts used are cobaltous and manganous acetates and the cobaltous, manganous and cupric decanoates along with cobalt phthalocyanine-(CoPc) and α- and β-copper phthalocyanine(CuPc). Oxygenated copper phthalocyanine was prepared by the oxidation of copper phthalocyanine with 45% nitric acid at −5 to 0°C as reported by Bansho and coworkers.[11] The analysis of oxygenated copper phthalocyanine gave the formula CuPc-O_2-CuPc, which was converted to copper phthalocyanine after reduction.

The oxidation products of cumene were determined by gas-liquid chromatography.

Results and Discussion

The Limiting Rate of Metal-Catalyzed Autoxidation of Cumene

The effect of three metal decanoates on the rate of oxidation of cumene at 60°C was examined over a range of metal concentrations from 0.001 to 0.1M in Fig. 1.

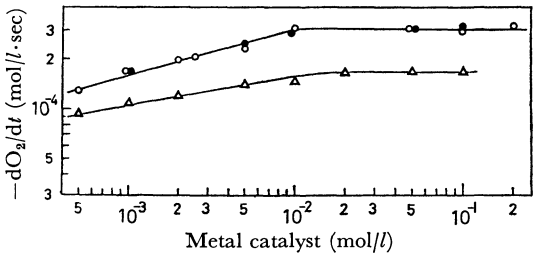

Fig. 1. The steady rate of oxidation of cumene as a function of metal decanoate concentration.
○ cobalt, ● manganese, △ copper.

As in the usual case, the cumene contained about 0.001M of hydroperoxide. In general, oxygen absorption proceeded linearly until several percent of cumene was consumed. The induction period of autoxidation was less than ten minutes and the metal catalysts were slowly deactivated during the oxidation as observed in the case of tetralin.

It can be seen that in the cobalt or manganese concentrations between 0.01 to 0.1M the measured maximum rate (ρ_m) reaches a limit of 3.1×10^{-4}M/sec, which is just over half the theoretical limit 6.0×10^{-4}M/sec. The theoretical value was calculated by the following equation, using the results of azobisisobutyronitrile initiated oxidation of cumene.

$$-dO_2/dt = k_p^2(RH)^2/2k_t \qquad (7)$$

ρ_m reaches a lower limit of 1.7×10^{-4}M/sec in the case of copper salt. This lower value might be due to the solubility as in the case of tetralin.[2]

The rate of oxidation of cumene in acetic acid reaches a limit of 7.8×10^{-5}M/sec in an acetic acid — cumene mixture (1 : 1 by volume) as shown in Fig. 2 at cobalt concentrations above 0.05M. The limiting value after correcting $(RH)^2$ term of equation (7) will be 3.12×10^{-4}M/sec as in the case of neat cumene.

Recently, it was suggested that the rate of oxidation depends on the dielectric function of solvent.[12-14] Therefore, the true rate of oxidation

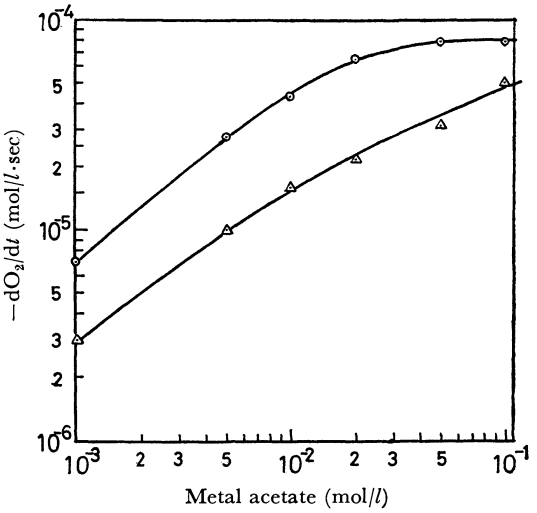

Fig. 2. The steady rate of oxidation of a 1 : 1 by volume cumene acetic acid mixture as a function of the metal acetate concentration.
○ cobalt, △ manganese.

in acetic acid after correcting the dielectric function will be a little lower than 3.12×10^{-4}M/sec and probably around 2.5×10^{-4}M/sec according to the results of tetralin.[14] The disaccordance between the experimental and the theoretical values might be due to the very fast induced decomposition of cumyl hydroperoxide by cumyloxy radical, because the ratio of cumyl alcohol to acetophenone in the oxidation products is higher than 1.7 (see Table 2). Recently, Hiatt and his co-workers,[16] Howard and Ingold[15] have shown that the chain length of the decomposition of tertiary hydroperoxide is as long as ten. If the induced decomposition of hydroperoxide by cumyloxy radical resulting from the metal catalyzed decomposition of hydroperoxide proceeds preferentially to hydrogen abstraction from cumene, the theoretical limiting rate will be $k_p^2(RH)^2/4k_t$, which is just half of the theoretical value and is in good agreement with the experimental values. The possibility of oxidation inhibition due to phenol can be ruled out, since we could not isolate any appreciable amount of acetone or phenol in the oxidation products.

The disaccordance between the theoretical and experimental rates of oxidation of neat tetralin[1] was explained well by the effect of $(RH)^2$ term because the rate of oxidation of tetralin in acetic acid is in excellent agreement with the theoretical limiting rate.

The decomposition of cumyl hydroperoxide by cobalt salt at 2×10^{-4}M was of first order with respect to hydroperoxide, and the half life of 18 min

increased by a factor of one hundred, when acetic acid was used as the solvent instead of chlorobenzene.

These results correspond to the fact that the rate of oxidation in acetic acid reaches a limiting value at higher cobalt concentration than in the case of neat cumene.

In acetic acid, the manganese salt was a weak catalyst compared with cobalt as observed in the case of tetralin[2] and ethylbenzene.[3]

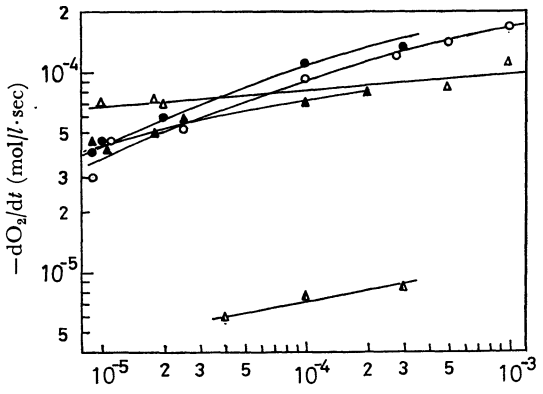

Fig. 3. The steady rate of oxidation of cumene as a function of metal decanoate or metal phthalocyanine concentrations at concentrations from 10^{-5} to 10^{-3} mol/l.
○ cobalt decanoate, △ copper decanoate, ● cobaltphthalocyanine, ◭ α-copper phthalocyanine, ▲ β-copper phthalocyanine

Metal-Catalysis by Phthalocyanines and Decanoates in the Autoxidation of Cumene. The rate of oxidation of cumene at metal concentration below 0.001M is shown in Fig. 3. At metal concentration of 1×10^{-5}M, 0.05M of cumyl hydroperoxide was added before the oxidation in order to reduce the induction period and to obtain a reproducible value of the rate of oxidation, since a metal catalyst was deactivated before reaching the maximum rate.

The chain length in the metal-catalyzed autoxidation of cumene was calculated to be 13 in the case of cobalt decanoate and 8 in the case of copper decanoate at the catalyst concentration of 1×10^{-5}M, using the results in Fig. 3 and the following equation obtained by the azobisisobutyronitrile initiated oxidation of cumene.

$$-dO_2/dt = 9\times10^{-4}(\mathrm{AIBN})^{1/2} \qquad (8)$$

It seems peculiar that the rate of oxidation with copper becomes higher than with cobalt at low metal concentrations. The rate of decomposition of cumyl hydroperoxide with cobalt decanoate was higher than with copper decanoate by a factor of four at metal concentrations from 10^{-3} to 10^{-4}M, suggesting that cobalt gives a two fold higher rate of oxidation than copper.

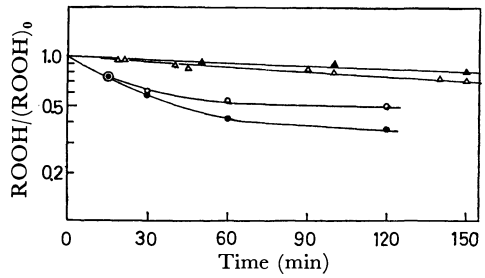

Fig. 4. The decomposition of cumyl hydroperoxide by metal decanoate or metal phthalocyanine at metal concentration of 6.3×10^{-5} mol/l in chlorobenzene.
$[ROOH]_0$ 0.025 mol/l; ○ cobalt de canoate, △ copper decanoate, ● cobalt phthalocyanine, ▲ β-copper phthalocyanine.

However, the plots of hydroperoxide decomposition at catalyst concentration of 6.3×10^{-5}M (Fig. 4) indicate that cobalt catalysts are deactivated quickly at the beginning of hydroperoxide decomposition and copper compounds retain their activity for a longer time.

Cobalt phthalocyanine was deactivated more slowly than cobalt decanoate probably due to its stable structure, and it showed a little higher rate of oxidation than cobalt decanoate.

At the steady state of oxidation (after 30 to 60 min) the reactivity of copper decanoate will be equal to that of cobalt phthalocyanine according to Fig. 4.

The first order rate constant (k) of hydroperoxide decomposition increased by a factor of three in the case of copper decanoate when hydroperoxide concentration was increased from 0.025 to 0.125M, while k remained constant in the case of cobalt decanoate.

Thus, it is not surprising to find that copper compounds give a higher rate of oxidation than the value expected from the rate of hydroperoxide decomposition in Fig. 4, since the concentration of hydroperoxide at the steady state of oxidation will reach a value higher than 0.1M. The higher rate of oxidation by copper decanoate than by cobalt compounds at concentration of 1×10^{-5}M can be attributed to the higher rate of decomposition of hydroperoxide by copper decanoate.

The k value with β-CuPc was higher than with α-CuPc by a factor of sixty at metal concentration 6.3×10^{-5}M. It should be mentioned that α-CuPc, which is a very effective initiator in the autoxidation of α-methylstyrene[10] by the addition mechanism, is exceptionally inactive for the decomposition of hydroperoxide.

For comparison, the autoxidation of tetralin in the presence of various catalysts is shown in Fig. 5. In this case β-CuPc is much more active than α-CuPc. From the hydroperoxide decomposition experiment by copper catalysts at initial hydroperoxide concentration 0.02M and metal concentra-

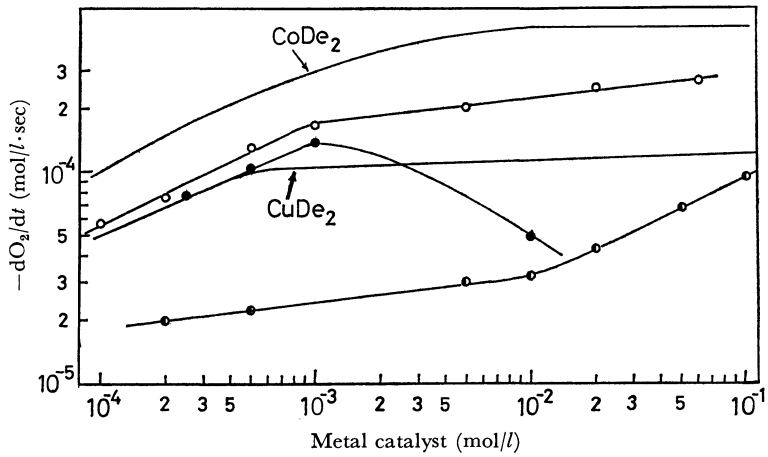

Fig. 5. The steady rate of oxidation of tetralin as a function of metal concentration at 50°C.
○ cobalt phthalocyanine, ◐ α-copper phthalocyanine, ● β-copper phthalocyanine

tion 0.001M in chlorobenzene at 50°C, the half life of tetralyl hydroperoxide decomposition was found to be 80 min in the cases of $CuDe_2$ and β-CuPc and 1500 min in the case of α-CuPc. Thus, the rate of oxidation of tetralin is roughly proportional to the square root of the rate of hydroperoxide decomposition. Although the rate of oxidation with β-CuPc is a little higher than with $CuDe_2$ at concentration of 0.001M, the two rates of oxidation at catalyst concentrations below 5×10^{-4}M coincide well as in the case of half lives of hydroperoxide decomposition.

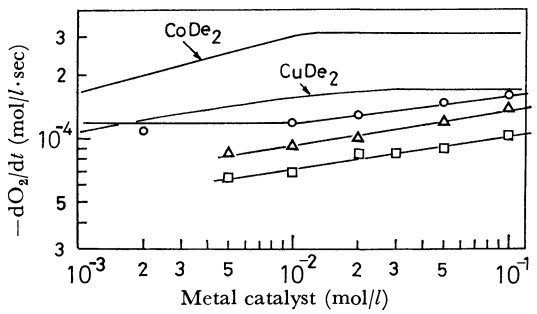

Fig. 6. The steady rate of oxidation of cumene as a function of metal phthalocyanine concentration at concentrations below 0.1 mol/l.
○ cobaltphthalo cyanine, △ α-copper phthalocyanine, □ oxygenat ed copper phthalocyanine

The activation of oxygen by CuPc and the direct oxidation by the oxygenated copper phthalocyanine(CuPcO) were further examined at high concentration of catalyst (Fig. 6). The rate of oxidation of cumene at metal concentrations from 10^{-4} to 10^{-2}M was entirely constant in the cases of CoPc, β-CuPc and CuPcO, but it gradually increased with the increase of metal concentrations above 0.01M. The direct oxidation of cumene by the complex of metal phthalocyanine or by the oxygenated metal phthalocyanine might occur at high concentration of metal complex.

In conclusion, the results of hydroperoxide decomposition account for the relative rate of oxidation with various catalysts. The autoxidation of cumene catalyzed by CuPc should not involve the chain initiation step due to hydrogen abstraction from cumene by $(CuPc)^{\delta+}O_2^{\delta-}$, since the effect of hydroperoxide decomposition is overwhelming. The reactivity of $(CuPc)^{\delta+}O_2^{\delta-}$ is undoubtedly not so large as peroxy radical, although we found that copper phthalocyanine initiates the chain of autoxidation of α-methylstyrene.

According to Kropf,[5] the observed rate of oxidation of cumene by his copper phthalocyanine is about one-hundredth of our value by β-CuPc. The chain initiation due to copper phthalocyanine and oxygen will be about one–ten thousandth of the rate of radical production by the decomposition of hydroperoxide, even if his copper phthalocyanine could not decompose any amount of hydroperoxide. Therefore, production of radicals by the metal-catalyzed decomposition of hydroperoxide occurs predominantly as compared with hydrogen abstraction by copper phthalocyanine and oxygen.

A complex situation arizes from the fact that α-CuPc which is quite inactive for hydroperoxide decomposition can be gradually converted to β-CuPc in an aromatic solvent even at temperatures below 100°C. It was observed that α-CuPc, which was used in the autoxidation of α-methylstyrene at 60°C for 120 min, decomposed cumyl hydroperoxide with the rate as fast as that of $CuDe_2$, that is, the rate of decomposition of hydroperoxide by α-CuPc increases considerably in the course of reaction probably after isomerizing to β-CuPc or another active form of CuPc especially in the presence of peroxy radicals. Minkov[7] has also

TABLE 1. OXIDATION PRODUCTS OF CUMENE

Reaction conditions	Oxidation of neat cumene	Oxidation of cumene acetic acid mixture (1 : 1 by volume)	Decomposition of cumyl hydroperoxide of 0.08M in chlorobenzene
Metal catalyst	Cobalt and manganese decanoates from 0.001 to 0.1M	Cobalt and manganese acetate from 0.01 to 0.1M	Cobalt decanoate from 0.002 to 0.01M
Products distribution of cumene (mol %)			
α-Methylstyrene	3.3	1.7	2.0
Acetophenone	15.8	36.4	36.0
Cumyl alcohol	70.7	61.3	59.3
Dicumyl peroxide	10.2	2.5	2.7
The ratio of cumyl alcohol to acetophenone	4.5	1.7	1.64

pointed out that the activity of CuPc in the decomposition of hydroperoxide shows a maximum as the reaction proceeds.

Oxidation Products of Cumene. The oxidation products were cumyl alcohol, acetophenone, dicumyl peroxide, cumyl hydroperoxide and α-methylstyrene. No acetone or methyl alcohol were detected. Oxidation products other than hydroperoxide are shown in Table 1.

The ratio of alcohol to ketone is about 1.6, when cumyl hydroperoxide is decomposed in chlorobenzene by cobalt decanoate. However, autoxidation in acetic acid gives a value of about 1.7 and the ratio increases to 4.5 in the case of neat cumene. Since α-methylstyrene can be obtained from cumyl alcohol, the true ratio will be higher than the observed value.

The chain termination mechanism of cumyl peroxy radicals can be described as follows,[9]

$$RO_2\cdot + RO_2\cdot \longrightarrow [ROOOOR] \longrightarrow ROOR + O_2$$
$$\searrow\ 2RO\cdot + O_2$$
$$RO\cdot \xrightarrow{O_2} CH_3O_2\cdot + C_6H_5COCH_3$$
$$CH_3O_2\cdot + RO_2\cdot \longrightarrow C_6H_5C(CH_3)_2OH + HCHO + O_2$$

When all alkoxy radicals formed by the decomposition of hydroperoxide due to metal catalysis result in cumyl alcohol, and all methyl peroxy radicals result in cumyl alcohol and formaldehyde after terminating with cumyl peroxy radical, the ratio of alcohol to ketone will be two. Thus, it can be concluded that some alkoxy radicals from the termination reaction in the solvent cage slip out of the cage and abstract hydrogen atom from hydroperoxide or cumene to yield alcohol.

If the solvent cage is composed of a viscous and inactive solvent for hydrogen abstraction, the probability of the alkoxy radical slipping out of the cage and abstracting hydrogen from the substrates will be decreased.

The effect of the amount of solvent was studied using chlorobenzene as a solvent (Table 2). As

TABLE 2. EFFECT OF SOLVENT ON THE RATIO OF ALCOHOL TO KETONE IN THE AUTOXIDATION OF CUMENE CATALYZED BY 0.02M COBALT DECANOATE

Cumene/chlorobenzene (volume/volume)	1/0	1/1	1/3	1/5
Cumyl alcohol/acetophenone (mol/mol)	4.5	2.7	1.94	1.67

the solution is diluted with chlorobenzene, the ratio of alcohol to ketone decreases remarkably. Much lower ratio in acetic acid (Table 1) seems to indicate that the physical properties of solvent affects the strength of the cage.

The formation of alkoxy radical from the bimolecular termination of peroxy radicals gives two different effects on the rate of oxidation. The induced decomposition of hydroperoxide will cause a decrease in the rate of oxidation, since the initiation reaction by the decomposition of hydroperoxide will be retarded. On the other hand, the hydrogen abstraction from cumene will result in the increase in the rate of oxidation. We can not exactly evaluate these influences, since the rate constants of elementary steps are not known and the two reactions will proceed simultaneously.

However, the effect of alkoxy radical from the cage on the rate of oxidation of cumene may not be so large because the rate of oxidation of neat cumene is in excellent agreement with the rate in acetic acid solution after correcting $(RH)^2$ term. Even if the dielectric effect is corrected, the effect on the rate enhancement will probably be about 20% according to the results of tetralin oxidation.[14]

The higher ratio of alcohol to ketone in the case of neat cumene can be attributed to the increase of dicumyl peroxide and to the decrease of acetophenone rather than to the decrease of cumyl alcohol. The bimolecular termination reaction of alkoxy radicals seems to be relatively fast.

Catalysis by Cobalt and Bromide Ions. In Fig. 7 the steady rate of oxidation of cumene is

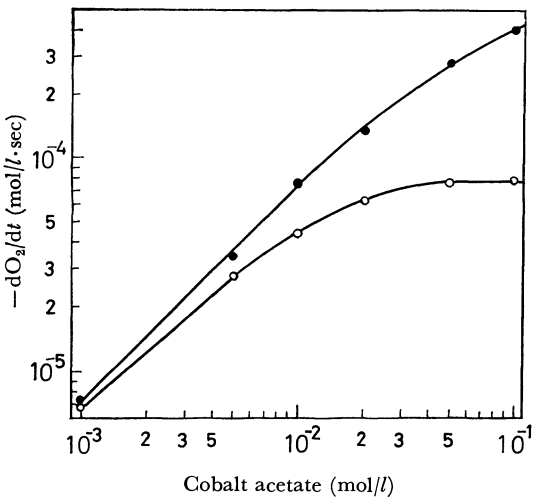

Fig. 7. The steady rate of oxidation of 1 : 1 by volume cumene: acetic acid mixture as a function of cobalt acetate concentration ○ in the presence or ● in the absence of sodium bromide.

plotted against the cobalt concentration in the presence and absence of sodium bromide. Two moles of sodium bromide per one mole of cobalt are used, since at this ratio the rate of oxidation has shown a limiting value as the amount of sodium bromide is varied.

The rate of oxidation of cumene in acetic acid reaches the limiting value 7.8×10^{-5}M/sec at 0.05M of cobalt. The rate of oxidation in the presence of sodium bromide tends to increase as the cobalt is increased. The difference of two rate curves due to the addition of sodium bromide to the solution is very small at cobalt 0.001M and is of first order with respect to cobalt concentration. The effect of bromide ion on the rate of oxidation of cumene is comparable as in tetralin[17] and not so remarkable as in *p*-xylene.[18] However, the steady concentration of cumyl hydroperoxide increased and the rate of decomposition of cumyl hydroperoxide decreased in the presence of bromide ion in contrast to the case of tetralin.[17]

The Synergistic Effect Due to Metal Catalysts. A synergistic effect of metal catalyst was observed, *i.e.*, by replacing 20% of the cobalt acetate of 0.02M by manganese acetate an approximately 1.3 fold increase in the rate of oxidation of cumene was observed (Fig. 8).

However, the synergistic effect could not overcome the experimental limiting rate of oxidation. It is interesting that at total metal concentration of 0.05M no more synergistic effect can be observed as seen in Fig. 8.

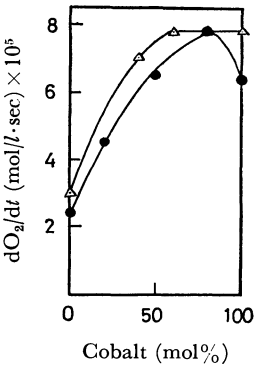

Fig. 8. The synergistic effect by cobalt and manganese acetates on the rate of oxidation of a 1 : 1 by volume cumene : acetic acid mixture at total metal concentration of ● 0.02 mol/l and △ 0.05 mol/l.

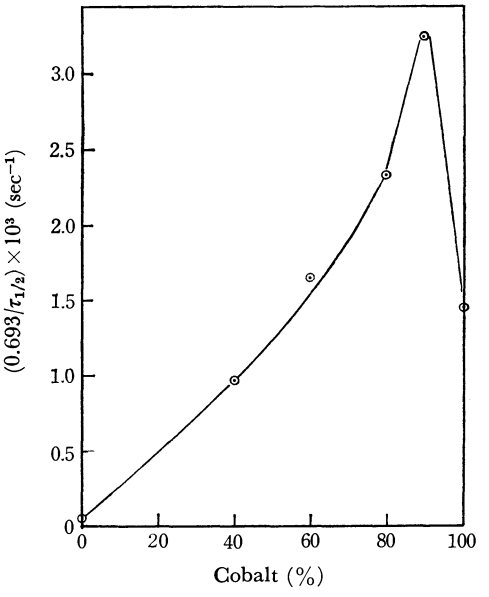

Fig. 9. The synergistic effect of cobalt and manganese acetates on the decomposition of cumyl hydroperoxide in an acetic acid : chlorobenzene mixture (1 : 1 by volume) at total metal concentration of 0.01M. $\tau_{1/2}$ represents the half life of 0.05M hydroperoxide.

A synergistic effect was observed also in the rate of decomposition of cumyl hydroperoxide by metal acetate as shown in Fig. 9, corresponding to the result in which the rate of oxidation is of nearly half order with respect to the first order rate constant of hydroperoxide decomposition. Therefore, the rate enhancing effect by the mixing of metal catalysts can be attributed to the chain initiation step by the metal-catalyzed decomposition of cumyl hydroperoxide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 836—841 (1970)

The Reductive Coupling Reactions of Some Chloromethylbenzene Derivatives with Iron(II) and Copper(I) Complexes*1

Kazuhiko ONUMA, Junzo YAMASHITA and Harukichi HASHIMOTO

Department of Synthetic Chemistry, The University of Tokyo, Bunkyo-ku, Hongo, Tokyo

(Received July 23, 1969)

The reductive coupling reactions of some chloromethylbenzene derivatives with ferrous and cuprous chloride in ethanol or in acetonitrile and the effect of some additives on this reaction have been investigated. Benzotrichloride has been reduced selectively to tolan tetrachloride with ferrous chloride, while with cuprous chloride-ethylenediamine (a stronger reductant than ferrous chloride) mixtures of tolan and tolan dichloride or tolan tetrachloride are obtained depending on the condition. Similarly benzal chloride, diphenylmethyl chloride and diphenyldichloromethane are also reduced to give coupling products. In case of ferrous chloride the addition of ethylenediamine or pyrophosphoric acid raises the yield considerably and in case of cuprous chloride selection of the ratio, organic halide: copper (I): ethylenediamine, makes it possible to control the product distribution. The reaction mechanism and the effect of the additives are discussed.

Progress in the study of the iron- or copper ion catalyzed organic reactions[1-12] has revealed some catalytic features of these ions. As an example, the iron- or copper ion catalyzed addition of organic chloride to olefins[1,2] can be understood through the redox-transfer chain mechanism, metal ion being a chlorine-atom transfer agent.

$$RCl + M^{(n-1)+} \rightarrow R\cdot + M^{n+}Cl \quad (1)$$

$$R\cdot + \text{>C=C<} \rightarrow R\text{–}\overset{|}{C}\text{–}\overset{|}{C}\cdot \quad (2)$$

$$R\text{–}\overset{|}{C}\text{–}\overset{|}{C}\cdot + M^{n+}Cl \rightarrow R\text{–}\overset{|}{C}\text{–}\overset{|}{C}\text{–}Cl + M^{(n-1)+} \quad (3)$$

Reaction (3) is a relatively well studied "ligand transfer oxidation" process.[13-16] On the other hand step (1), which is just the reverse reaction of step (3), may be named tentatively "ligand transfer reduction" and about this much is left to be learned.

From this point of view we investigated previously the reductive coupling reaction of benzyl chloride by copper(I) complexes.[17] In this paper, application of this reductive coupling reaction with ferrous or cuprous chloride to some polyhalomethylbenzene derivatives and the effect of some additives will be studied.

Results and Discussion

Reductive Coupling by Ferrous Chloride. Simple ferrous ion is only a weak reductant compared with iron metal[18-20] and little is known

about the interaction of ferrous ion with organic halides except for the case of ferrous porphyrin.[21] Actually, benzyl chloride does resist ferrous ion. It is well known, however, that the replacement of hydrogen atom attached to methyl carbon by phenyl group or chlorine atom considerably activates the molecule, and several polychloromethylbenzene derivatives were reduced by ferrous chloride. The reactions were carried out mostly in ethanol solvent and in a few cases in acetonitrile, under a nitrogen atmosphere and in the range from 70°C to reflux temperature. The results with benzotrichloride, benzal chloride, diphenyldichloromethane and diphenylmethyl chloride are tabulated in Tables 1—5.

Ethanol is a good solvent for both reactants but the ethanolysis of organic halides is unavoidable and always competes with the reduction reaction. In the case of acetonitrile homogeneity can be reached only at reflux temperature.

Table 1. Reductive coupling of benzotrichloride by ferrous chloride tetrahydrate in ethanol

$C_6H_5CCl_3$: 2.00×10^{-2} mol
Solvent C_2H_5OH: 50—60 m*l*
Reaction temperature: 72.0±3.0°C

Additive	$C_6H_5CCl_3$: $FeCl_2\cdot4H_2O$: additive (mole ratio)	Reaction time hr	$C_6H_5\cdot CCl_2\cdot CCl_2\cdot C_6H_5$[a] %
—	1 : 1	6	49
	1 : 3	6	67
en[b]	1 : 1 : 1	4	54
	1 : 1 : 2	4	74
	1 : 1 : 3	4	87
$H_4P_2O_7$	1 : 1 : 0.5	4	70
	1 : 1 : 1	4	81

a) In every run ethyl benzoate was recognized as a solvolysis product.
b) "en" is ethylenediamine and in this case the reaction system is heterogeneous.

Table 2. Reductive coupling of benzotrichloride by ferrous salts

$C_6H_5CCl_3$: 2.00×10^{-2} mol
Ferrous salt: 2.00×10^{-2} mol
Solvent: 50 m*l*

Ferrous salt	Solvent	Temp. °C	Reaction time hr	$C_6H_5\cdot CCl_2\cdot CCl_2\cdot C_6H_5$ %
$FeCl_2\cdot4H_2O$	CH_3CN	82	6	71[a]
$FeSO_4\cdot6H_2O$[b]	C_2H_5OH	71	2.5	8.1[c]
$FeCl_2\cdot4H_2O$	C_2H_5OH	r.t.	70	9.8[c]

a) 17% of benzoic acid was obtained other than coupling product.
b) Heterogeneous system.
c) Ethyl benzoate and unreacted benzotrichloride were recognized.

CuCl	1 : 1 : 2	100	

a) 1.00×10^{-2} mol of $(C_6H_5)_2CHCl$ was used.
b) 39% of hydrolyzed benzhydrol was obtained.

Reduction Products. From Tables 1 and 2 it can be seen that for benzotrichloride the yield of coupling product increases with increase of ferrous ion concentration, and the additive such as ethylenedi-

amine (en) or pyrophosphoric acid increases the yield considerably. The product is always tolan tetrachloride showing that ferrous ion is a weak reductant and additives have no marked effect on reducing power of ferrous ion.

$$2C_6H_5CCl_3 + 2Fe^{II}Cl_2 \rightarrow C_6H_5CCl_2 \cdot CCl_2C_6H_5 + 2Fe^{III}Cl_3 \quad (4)$$

Low yield in the case of ferrous sulfate seems to be due to the insolubility of the salt.

Table 3 contains the result of diphenyldichloromethane. It is noted that the product is tetraphenylethylene, being all chlorine atom split off. It seems that tetraphenylethylene is formed by step-wise reduction, that is, tetraphenyldichloroethane which is formed intermediately is further reduced because of steric and electronic instability.

$$2(C_6H_5)_2CCl_2 \xrightarrow{2Fe^{II}} (C_6H_5)_2CClCCl(C_6H_5)_2 \xrightarrow{2Fe^{II}} (C_6H_5)_2C{=}C(C_6H_5)_2 \quad (5)$$

However, the possibility of the formation of diphenylcarbene cannot be ruled out since this carbene is known to be fairly stable.[22] It was reported recently that dichlorocarbene was produced from tetrachloromethane and ferrous chloride.[1e]

As seen from Table 4 benzal chloride can not be reduced by ferrous chloride only. However, when ethylenediamine is added as an additive, reduction takes place and stilbene dichloride is obtained though the yield is poor. Some discussions on this effect will be made later.

Diphenylmethyl chloride is also reduced to produce tetraphenylethane (Table 5). It is of interest to note that in case of the use of ferrous chloride *tetrahydrate* in acetonitrile *N*-benzhydrylacetamide is also produced. Evidently this amide results from interaction of diphenylmethyl chloride or its hydrolysis product, benzhydrol with acetonitrile by the aid of ferrous or ferric chloride as a Lewis acid (this is a variation of well known Ritter reaction[23]).

These reactions give only coupling products as the reduction products. No hydrogenated materials are detected in contrast to the case of chromous ion.[24]

Effect of Additives. As pointed out before, when ethanol is used as solvent the solvolysis reaction of organic halides inevitably competes the reduction reaction (Tables 1—4). In addition ferric chloride is known to be a good catalyst for hydrolysis of organic halides. In fact preliminary experiment showed that a) at 70.5°C benzotrichloride is solvolyzed in ethanol and after 4 hr about 20% of the halide is converted to ethyl benzoate b) addition of 1/10 equiv. ferric chloride increases the solvolysis rate twice. If this solvolysis is suppressed by some means, increase of the yield of coupling product will be expected. As mentioned before, additives such as ethylenediamine and pyrophosphoric acid increase the yield of coupling products considerably. It seems reasonable that the primary effect of these additives lies in the suppression of the solvolysis of the organic substrates. Additives which can coordinate to ferric (or ferrous) ion will occupy the catalytic sites and suppress the solvolysis. The reaction of benzal chloride in acetonitrile (Table 4) supports this idea. Here in the presence of ferrous chloride *tetrahydrate* benzal chloride is completely converted to benzaldehyde (hydrolysis product of benzal chloride). But when ethylenediamine is added the starting material is recovered except for 3% of coupling product. This means that ethylenediamine expels water from the metal ion sphere and suppresses hydrolysis.

It may also be necessary to consider some other factors on the effect of ethylenediamine. As seen in Table 4 addition of ethylenediamine gives rise to form stilbene dichloride from benzal chloride which can not be reduced by ferrous ion only. This suggests the coordination of ethylenediamine to ferrous ion enhances the reducing power of the ion just as in the case of cuprous chloride (see below). Instability of Fe(III) complexes of amines is generally explained as Fe(III) state having half-filled d^5 system and, therefore, no CFSE in high spin state. Recently, however, ethylenediamine complex of ferric chloride—$Fe(en)_3Cl_3$—was reported to be synthesized and have spin-paired d^5 system.[25] Thus, it is not improbable to conceive that ethylenediamine has some coordination effect.

Some comments should be made on the possibility of the interaction of the organic halides with ethylenediamine as the reaction of amines with organic halides are fairly well known. Actually products which were thought to be formed from organic halides and ethylenediamine were detected. But they are only trace amount and supplementary experiments on the ethanolysis rate of benzotrichloride showed ethylenediamine has practically no effect on the rate. Moreover electronic spectra of benzotrichloride in ethanol does not change on addition of ethylenediamine in contrast to carbon tetrachloride which forms charge-transfer complexes with some amines.[26,27] These facts indicate that there is no need to consider the specific interaction.

Reductive Coupling by Cuprous Chloride.

22) C. E. Coffey, *J. Amer. Chem. Soc.*, **83**, 1623 (1961).
23) B. Prajsnar, *Chem. Anal.* (Warsaw), **8**, 255 (1963).

27) W. J. Lautenberger, E. N. Jones and J. G. Miller, *ibid.*, **90**, 1110 (1968).

Cuprous chloride as well as ferrous chloride is only a weak reductant. Still it may be surprising that even diphenylmethyl chloride can not be reduced in acetonitrile. In dimethyl sulfoxide solvent, on the other hand, benzal chloride and benzotrichloride were reported to give coupled products by cuprous chloride.[28] Therefore this unusual inertness of cuprous chloride is attributable to a specific interaction with acetonitrile. In fact redox potential of Cu^{I}-Cu^{II} couple shows clearly stability of low valent state.[29,30]

As reported by us previously,[17] however, addition of ethylenediamine enhances the reducing power of cuprous ion strikingly and bibenzyl has been obtained from benzyl chloride. Here some application of this reaction is made and the results are in Tables 5—7. From diphenylmethyl chloride 100% yield is obtained, whereas the yield does not exceed 80% in case of benzal chloride and benzotrichloride. Probably side reactions leading to resinous products have occurred partly by relatively activated Cu(I) - ethylenediamine system.

It is of interest to note that selection of the ratio, organic halide: cuprous chloride: ethylenediamine, can control the product distribution (Tables 6 and 7). This also suggests that the reaction proceeds stepwise, that is, from benzotrichloride tolan tetrachloride is produced first and this tetrachloride is again reduced to dichloride in the presence of excess active reductant.

$$2C_6H_5CCl_3 \xrightarrow{2Cu(I)\text{-}en} C_6H_5CCl_2\text{–}CCl_2C_6H_5$$
$$\xrightarrow{2Cu(I)\text{-}en} C_6H_5CCl{=}CClC_6H_5 \qquad (6)$$

As shown in a previous report,[17] copper complexes which have been taken out after the reaction are $Cu^{II}(en)_nCl_2$ ($n=1$ or 2), and this shows that, in this case too, cuprous complexes of the type $Cu^{I}(en)_nCl$ are the intrinsic reagent. Such reactivity may reflect the effect of ligands on redox potential[31] (see Ref. 17).

An Approach to Reaction Mechanisms. From the mechanism of ligand transfer oxidation by ferric or cupric chloride, the most plausible mechanism of the reduction seems to be the reverse process of the oxidation as follows (in the following equations iron ion is used as metal ion for convenience).[1e,17,32]

$$RCl + Fe^{II}Cl_2 \rightleftharpoons RCl\cdot Fe^{II}Cl_2 \qquad (7)$$
$$RCl\cdot Fe^{II}Cl_2 \rightarrow R\cdot ClFe^{III}Cl_2 \qquad (8)$$

A kinetic study of the reduction of benzotrichloride by ferrous chloride *tetrahydrate* in ethanol has shown that plots of the initial rate of disappearance of Fe(II) *vs.* both initial concentration of organic halide and ferrous ion have first order dependence (Fig. 1), and the rate law is written as follows.

$$R = k[RCl][Fe(II)] \qquad (9)$$

This is compatible with the mechanistic scheme if we take step (8)—electron transfer or in other word chlorine transfer step—as rate determining step.

Another information to support this scheme is available from electronic spectra of cuprous chloride. On addition of benzotrichloride to the system of cuprous chloride - acetonitrile new absorption mixima appear at 310 and 463 mμ (75°C, under nitrogen). The absorption at the same wavelength is also observed in the case of benzal chloride. The fact that these absorption maxima

are the same with both organic halides suggests that the absorption is caused from the interaction between cuprous chloride and acetonitrile with the help of organic halide but it is also possible that the interaction between cuprous chloride and halogen atom of organic chloride is causative of the band. At any rate formation of intermediate complex between organic halide and cuprous chloride is indicative and in case of cuprous ion, unlike ferrous ion, electron transfer in the complex may be sustained.

The latter part of the reaction path is more complicated.[32,33] The formation of cupling products suggests radical feature of the reaction, whereas absence of hydrogen atom abstration products makes it uncertain. It should be noted also that solvent effect on product yield was hardly appreciable in the previous study.[17] From these facts the existence of radical in its free state seems unacceptable. Even if such a radical species is formed intermediately, it may be trapped by ferrous ion immediately (see Ref. 17).

Experimental

Materials. Reagent grade ferrous chloride tetrahydrate, ferrous sulphate hexahydrate and ferric chloride hexahydrate were used without further purification. As the hydration number of ferrous chloride was not accurately 4, Fe(II) equivalent was determined by ceric titration method. Reagent grade anhydrous cuprous chloride was further purified by the usual method.

Reagent grade benzotrichloride and diphenyldichloromethane and first grade benzal chloride, checked by NMR and gas chromatography, were used without further purification. Diphenylmethyl chloride was prepared from benzhydrol by the modification of Grice's method[34] for the preparation of *p*-methoxybenzyl chloride. Ethylenediamine (reagent grade) was distilled and used. Pyrophosphoric acid was used without further purification.

Absolute ethanol was purified by the conventional method and acetonitrile was purified according to O'Donnell's method.[35]

Typical Reaction Procedure. Ferrous or cuprous chloride (2.00×10^{-2} mol for example) was dissolved in 40 m*l* of absolute ethanol or acetonitrile in a four-necked, 50 m*l*, round-bottomed flask equipped with a 30 cm Dimroth condenser, a nitrogen inlet, a thermometer, a dropping funnel and a magnetic stirrer. The solution was then swept with oxygen-free nitrogen and heated to the required temperature. To this a solution of organic halide (2.00×10^{-2} mol) and, if necessary, ethylenediamine or pyrophosphoric acid in 10 m*l* solvent was added through the dropping funnel. The reaction was continued for required time under nitrogen stream.

Product Analyses. *A. Reduction of Benzotrichloride by Ferrous Chloride Tetrahydrate.* When the reaction was carried out in homogeneous system in ethanol solvent, the reaction mixture was cooled and 200 m*l* of water was added. The precipitated organic substance was filtered off and the filtrate was extracted with benzene, dried on sodium sulfate, concentrated to about 5 m*l* volume and the precipitated organic substance was also filtered and combined with the former. The filtrate was analyzed by g.l.c. to check the unreacted benzotrichloride and the solvolysis product, ethyl benzoate. The organic product was dried *in vacuo*, weighed for crude product yield and analyzed by IR, NMR, mp and also elementary analysis after recrystallization. The product was tolan tetrachloride, $C_6H_5\cdot CCl_2CCl_2\cdot C_6H_5$, mp 162.5—163.0°C (Found: C, 52.65; H, 3.13; Cl, 44.59%. Calcd: C, 52.54; H, 3.15; Cl, 44.31%). When the reaction mixture was heterogeneous insoluble iron complexes were filtered, washed four times with 50 m*l* hot benzene and the combined benzene solution was washed with water, dried on sodium sulfate, concentrated to about 5 m*l* volume and analyzed. When acetonitrile was used as solvent the reaction mixture was treated as in section D and the extracted benzene layer was again extracted by aqueous sodium bicarbonate for benzoic acid.

B. Reduction of Diphenyldichloromethane by Ferrous Chloride Tetrahydrate in Ethanol. Reaction mixture was treated as above. The product was 1,1,2,2-tetraphenylethylene, $(C_6H_5)_2C=C(C_6H_5)_2$, mp 223.5—224.0°C (Found: C, 93.80; H, 5.82%. Calcd: C, 93.94; H, 6.06%).

C. Reduction of Benzal Chloride by Ferrous Chloride Tetrahydrate. Reaction mixture was treated as in section A. The product was stilbene dichloride, $C_6H_5\cdot CHCl\text{-}CHCl\cdot C_6H_5$, mp 189.0—191.0°C (lit, for *meso* 191—193°C, racemic 93—94°C) (Found: C, 66.55; H, 4.61%. Calcd: C, 66.95; H, 4.82; Cl, 28.23%).

D. Reduction of Benzotrichloride and Benzal Chloride by Cupurous Chloride in Acetonitrile. As ethylenediamine was used as additive all runs were heterogeneous and the reaction was carried out under reflux temperature.

33) J.K. Kochi and F.F. Rust, *J. Amer. Chem. Soc.*, **83**, 2017 (1961); J.K. Kochi and P.E. Macadlo, *J. Org. Chem.*, **30**, 1134 (1965).

34) R. Grice and L. N. Owen, *J. Chem. Soc.*, **1963**, 1947.

35) J. F. O'Donnell, J. T. Ayres and C. K. Mann, *Anal. Chem.*, **37**, 1161 (1965).

After the reaction was ended the solvent was removed by distillation from the reaction mixture taking an hour, then the remainder was filtered and washed with hot benzene. The benzene filtrate was dried, concentrated and analyzed. The product was, if necessary, pretreated with column chromatography (300 mesh alumina) to remove resinous materials. When the products were mixtures of tolan and tolan dichloride (it was proved by IR, NMR and g.l.c.) the percentage of both substances were calculated from elementary analysis value or by g.l.c. peak area with *p*-nitrotoluene as a marker. The mp of the mixture was 60.5—62.5°C (lit, tolan; 62.5°C; tolandichloride *cis*, 142°C; *trans*, 63°C). *trans*-Stilbene was also produced form benzal chloride, C_6H_5–CH=CH–C_6H_5, mp 124.0—125.5°C (Found: C, 92.90; H, 6.46%. Calcd: C, 93.29; H, 6.71%).

E. Reduction of Diphenylmethyl Chloride by Ferrous Chloride Tetrahydrate of Cuprous Chloride. All runs were treated similarly. When the products were mixtures of tetraphenylethane and *N*-benzhydrylacetamide, they were easily separated from the difference of the solubility to benzene (this amide is hardly soluble to benzene). Hydrolysis product, benzhydrol was also separated because of the easy solubility. 1,1,2,2-Tetraphenylethane, $(C_6H_5)_2 \cdot CH \cdot CH \cdot (C_6H_5)_2$, mp 210.5—211.0°C (Found: C, 93.22; H, 6.53%. Calcd: C, 93.37; H, 6.63%). *N*-Benzhydrylacetamide, $(C_6H_5)_2CH \cdot NH \cdot CO \cdot CH_3$, mp 148.0—149.0°C, (Found: C, 79.62; H, 6.67; N, 6.12%. Calcd: C, 79.97; H, 6.71; N, 6.22; O, 7.10.%)

Other Experimental Procedures. For the rate of the solvolysis of benzotrichloride the modification of Vorhard's method was used and for the kinetics of the reduction of benzotrichloride by ferrous chloride tetrahydrate, the decrease in concentration of Fe(II) ion was followed by titration with cerium(IV) solution, ferroin as indicator.[36]

The visible and ultraviolet spectra were measured using Shimadzu MPS-50L multipurpose spectrophotometer and for g.l.c. a 2-m silicone DC550 column was employed.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 841—848 (1970)

Nitroalkenylferrocene. V. New Reactions of α-Halonitroolefins in the Presence of Sodium Alkoxides

Mikio SHIGA, Masaaki TSUNASHIMA, Hiromichi KONO, Izumi MOTOYAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received August 4, 1969)

The reactions of 1-iodo-2-ferrocenyl-1-nitroethylene (**1**) and β-bromo-β-nitrostyrene (**5**) with various sodium alkoxides were investigated. The reaction in the presence of an excess of alkoxides gave nitroketones, (**2**) and (**6**), and nitroacetals (**3**) and (**7**). The thermal decomposition of the nitroacetals in a nitrogen atmosphere afforded β-alkoxynitroolefins (**8**), which were found to be useful for obtaining asymmetric nitroacetals (**9**) with different alkoxy groups. The reaction mechanism was discussed by postulating the intervention of a nitrocarbene (**12**) and β-alkoxynitroolefin (**8**). The intermediacy of the nitrocarbene was supported by an experiment using vinylferrocene as a carbene scavenger.

Some information has been given[1,2] on the reactivity of the α-carbon of nitroolefins in preceding papers of this series. With a view to get further information, reactions of 1-iodo-2-ferrocenyl-1-nitroethylene (**1**)[2] and the phenyl analogs, β-bromo-β-nitrostyrene (**5**)[3]in the presence of various sodium alkoxides were investigated. The mechanism of the reaction of β-bromo-β-nitrostyrene with sodium methoxide was discussed by the aid of a reaction in the presence of vinylferrocene. The nitroacetals and β-alkoxynitroolefins which were obtained in these reactions have not yet appeared in the literature. Especially, acetals of an asymmetric structure with different alkoxy groups were first prepared in this investigation.

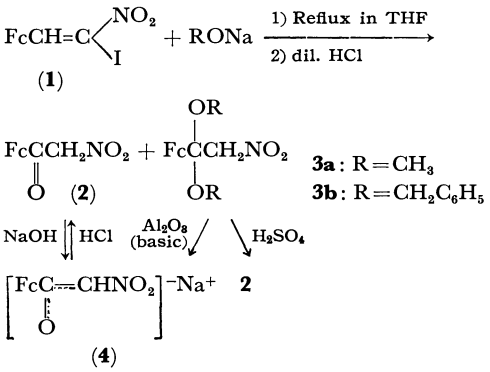
were confirmed by their elemental analyses and by a study of their IR and NMR spectra, which are listed in Tables 4 and 5.



The refluxing of the solution of 1-iodo-2-ferrocenyl-1-nitroethylene (**1**) in tetrahydrofuran with an excess of sodium methoxide gave (nitroacetyl)-ferrocene (**2**) as reddish-orange crystals (mp 97—98°C) and its dimethyl acetal (**3a**) as a dark brown oil, along with a small amount of formylferrocene and an unidentified carbonyl compound.

When an ethereal solution of (nitroacetyl)ferrocene (**2**) was shaken with a dilute solution of sodium hydroxide, the substance easily transferred to the aqueous layer, forming its sodium salt. Because of the strong acidity of **2**, a sodium salt (**4**) was also formed during the chromatographic purification of **2** on basic alumina or on basic Florisil. Especially, the chromatography on basic Florisil using methanol as a solvent gave a pure red solid of the sodium salt, which in turn easily regenerated the original nitroketone by means of dilute hydrochloric acid. The dimethyl acetal (**3a**) was easily converted into nitroketone (**2**) of treating it with sulfuric acid. The chromatography of **3a** on alumina gave sodium salt of the nitroketone (**4**) in a quantitative yield.*1 The results of similar reactions using varying amounts of sodium methoxide are summarized in Table 2, in which the yield of **2** is shown as a total yield of **2** after the coexisting dimethyl acetal has been completely converted into the nitroketone. The maximum yield was attained when ten equivalents of methoxide were used (see also Table 1).

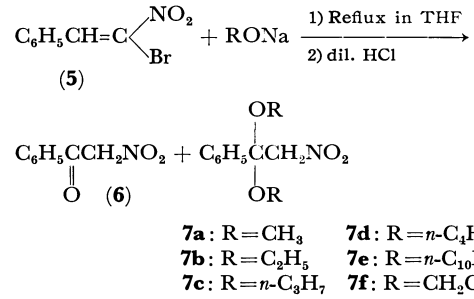
* The yields were expressed as the nitroketones, the nitroacetals being converted to the former by the treatment with alumina.

The reaction of **1** with sodium benzyl oxide gave nitroketone (**2**) and its dibenzyl acetal (**3b**) in 55% and 8% yields respectively. Though the acetal (**3b**) was obtained as a dark brown oil, it was too unstable to be purified; therefore, its yield was estimated by converting it completely into nitroketone (**2**).

A similar reaction with sodium isopropoxide and *t*-butoxide gave nitroketone (**2**) in 51% and 45% yields respectively, but the corresponding acetals could not be found in the products.

The Reactions of β-Bromo-β-nitrostyrene with Sodium Alkoxides. The reaction conditions and the products are summarized in Table 3. The IR and NMR spectra of the reaction products are listed in Tables 4 and 5.



*1 The sodium ion may be supplied from basic alumina for the chromatography.

* These ε-values were calculated by the usual method on the basis of integrated ratio of *cis* to *trans* isomer obtained from their NMR spectra.

The reaction of β-bromo-β-nitrostyrene (**5**) with an excess of sodium methoxide gave ω-nitroacetophenone (**6**)[4] as white crystals (mp 108—109°C) and its dimethyl acetal (**7a**) as a pale yellow oil (bp 97.5—98°C/1.0 mmHg) in 18% and 78% yields respectively. The increase in the amount of sodium methoxide from five to twenty equivalents to the bromonitroolefin brought about a marked increase in the yield of nitroacetal (**7a**), as is shown in Table 3. The reactions of **5** with sodium ethoxide, *n*-propoxide, and *n*-butoxide gave diethyl, dipropyl, and dibutyl acetal (**7b, c, d**) of ω-nitroacetophenone respectively as the main products, all in good yields. Each reaction also gave small amounts of ω-nitroacetophenone (**6**) and benzoic acid, the latter of which had been found to be formed by the decomposition of the intervening alkoxynitroolefins, as will be described later. The reactions of **5** with sodium decyl oxide and sodium benzyl oxide gave a pale yellow oil consisting of nitroacetals (**7e**) and (**7f**), in 83.2% and 82.4% yields respectively. Besides the oily main product, traces of ω-nitroacetophenone and benzoic acid were obtained as crystalline products in each reaction. Each of the oily products proved to be pure enough, judging from the results of thin-layer chromatography. These nitroacetals are indifferent to aqueous alkali and to dilute acid, and also to heating.

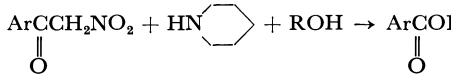
a) 2,5-Protons b) 3,4-Protons c) R=H

Sodium isopropoxide and sodium *t*-butoxide reacted with **5** to give neither nitroacetals nor ω-nitroacetophenone, but it did afford a large amount of benzoic acid.

The Reactions of Nitroketones. The nitroketones (**2** and **6**) were found to act as acids, thus easily forming sodium salts by means of a sodium hydroxide solution or by means of basic alumina during chromatography, as has been described above. When the nitroketones were treated with piperidine and alcohol, they decomposed to give the esters of ferrocenecarboxylic or benzoic acid.



The Reactions of Nitroacetals (7). It was found that the thermal decomposition of nitroacetals (**7**) in air gave alkyl benzoates. On the contrary, the thermal decomposition of nitroacetals (**7**) under an atmosphere of nitrogen afforded quantitatively α-alkoxy-β-nitrostyrene (**8**) and the respective alcohols, the former of which was found to be a mixture of *cis* and *trans* isomers by a

	trans (%)	*cis* (%)
8a: R=CH_3	79	21
8c: R=*n*-C_3H_7	73	27
8f: R=$CH_2C_6H_5$	75	25

study of its IR, UV, and NMR spectra. For example, the IR spectra of α-benzyloxy-β-nitrostyrene (**8f**) (bp 153—154°C/0.005 mmHg) obtained from **7f** showed strong absorption peaks at 1504 cm^{-1} (asym. NO_2) and 1356 cm^{-1} (sym. NO_2) for one isomer, and weak absorption peaks at 1490 cm^{-1} (asym. NO_2) and 1320 cm^{-1} (sym. NO_2) for the other.

The geometric relation between the nitro and phenyl groups in these compounds can be distinguished in the manner described by Watarai *et al.*[5] It is reasonable to consider that the former has a *trans*, and the latter a *cis* configuration with regard to the nitro and phenyl groups, because the absorbance of the asymmetrical NO_2-stretching absorption is weaker than that of the symmetrical one in the case of the former, while the relation is the inverse in the case of the latter.

The UV spectrum of **8f** shows two characteristic absorption maxima, at 268 and 290 mμ, the latter of which can be considered to be due to the *trans* configuration because of the more favorable conjugation of nitro group with the phenyl group. The NMR spectrum of **8f** also indicated the presence of stereoisomers (see Fig. 1); one of these exhibits two singlet peaks, at τ 5.05 and 2.94, due to methylene and olefinic protons respectively, while the other exhibits two corresponding singlet peaks, at τ 4.95 and 3.13 respectively. The signal of the *O*-methylene protons of the *trans* isomer is expected to shift toward a higher magnetic field than that of the *cis* isomers by anisotropy of the nitro group. Since the integrated intensity ratio of the methylene and olefinic protons of the former to those of the

5) S. Watarai, K. Yamamura and T. Kinugasa, This Bulletin, **40**, 1448 (1967).

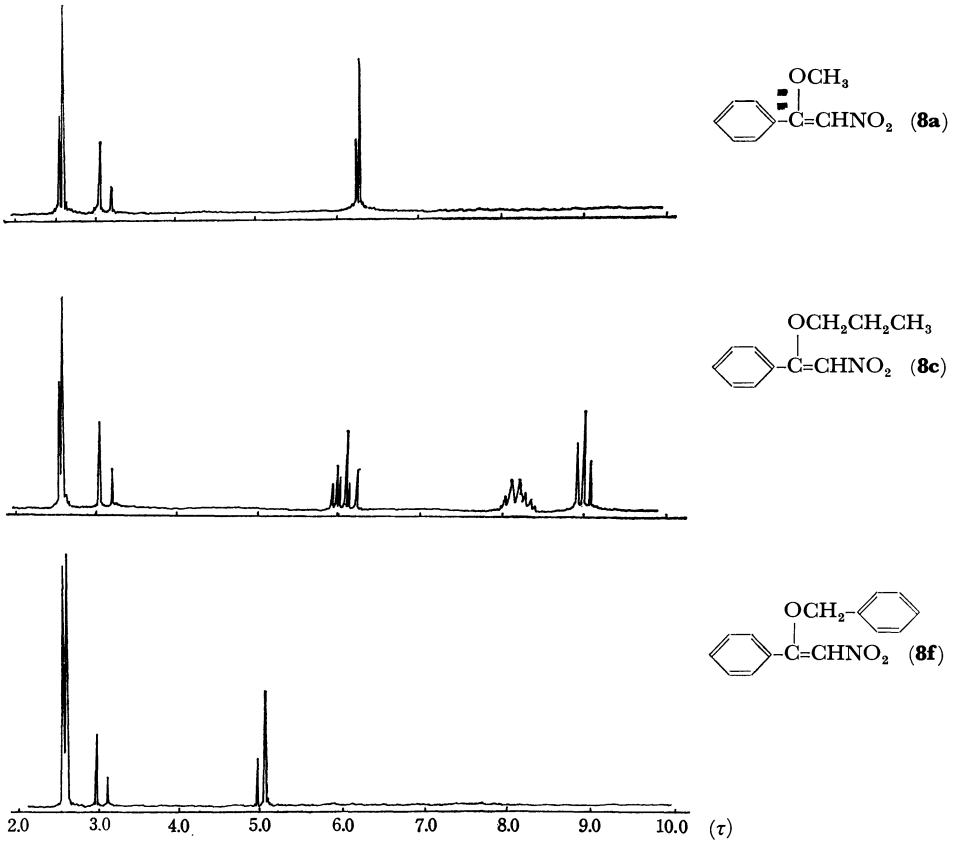


Fig. 1. NMR spectra of α-alkoxy-β-nitrostyrenes.

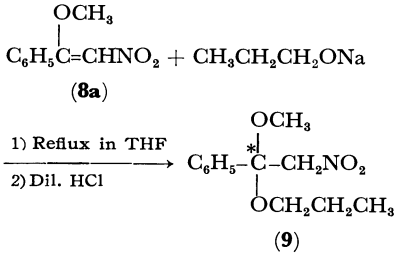
latter is about 3 : 1, **8f** was considered to be a mixture composed of approximately 75% *trans* and 25% *cis* isomers. The pale yellow viscous oil of **8f** gradually solidified on standing in air. In the IR, UV, and NMR spectra of the solidified product, a decrease in the relative strength of the absorption band to the *cis* isomer was observed. After standing for 5 days, the percentage of the *trans* isomer increased from 75% to 98%, judging from the intensity ratio of the NMR spectra.

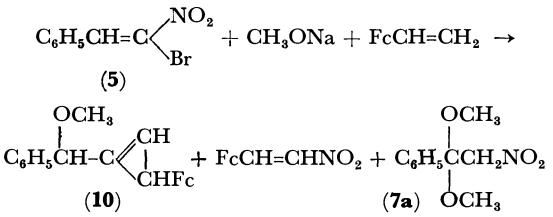
ω-Nitroacetophenone dimethyl acetal (**7a**) and dipropyl acetal (**7c**), on being heated under a nitrogen atmosphere, gave a yellow oil of α-methoxy-β-nitrostyrene (**8a**) (bp 110°C/0.35 mmHg) and an α-propoxy analog (**8c**) (bp 115—116°C/0.2 mmHg) in 96% and 95% yields respectively. The ratios of the *trans* to the *cis* isomers in **8a** and **8c** were similarly calculated to be 3.8 : 1 and 2.7 : 1 respectively from their NMR spectra (Fig. 1).

The Reactions of Alkoxynitroolefins. The alkoxynitroolefins (**8**) were easily converted into ω-nitroacetophenone (**6**) or sodium benzoate by treating them with hydrochloric acid or sodium hydroxide solution respectively. The reaction of sodium alkoxide on the alkoxynitroolefins (**8**) leads to the reverse formation of the nitroacetals (**7**). Thus, asymmetric acetals with different alkoxy groups can be prepared by this reaction. For instance, the reaction of sodium propoxide on α-methoxy-β-nitrostyrene (**8a**) afforded ω-nitroacetophenone methyl propyl acetal (**9**) (bp 89—90°C/0.3 mmHg) in an 84% yield. The acetal was obtained as a racemic compound; its resolution into optically active enantiomers has not yet been attempted.



The Reaction of β-Bromo-β-nitrostyrene with Sodium Methoxide in the Presence of Vinylferrocene. Since the reaction of β-bromo-β-nitrostyrene (**5**) with sodium alkoxide to form nitroacetals (**7**) was supposed to proceed through a carbene intermediate, an experiment to capture the

carbene was attempted. When β-bromo-β-nitrostyrene was refluxed with equimolar portions of sodium methoxide and vinylferrocene, 3-ferrocenyl-1-(α-methoxybenzyl)cyclopropene (**10**) was obtained as yellow-brown crystals (mp 88—90°C) in a 6.9% yield, besides small amounts of 1-ferrocenyl-2-nitroethylene,[6] ω-nitroacetophenone dimethyl acetal, and another unidentified nitro compound.

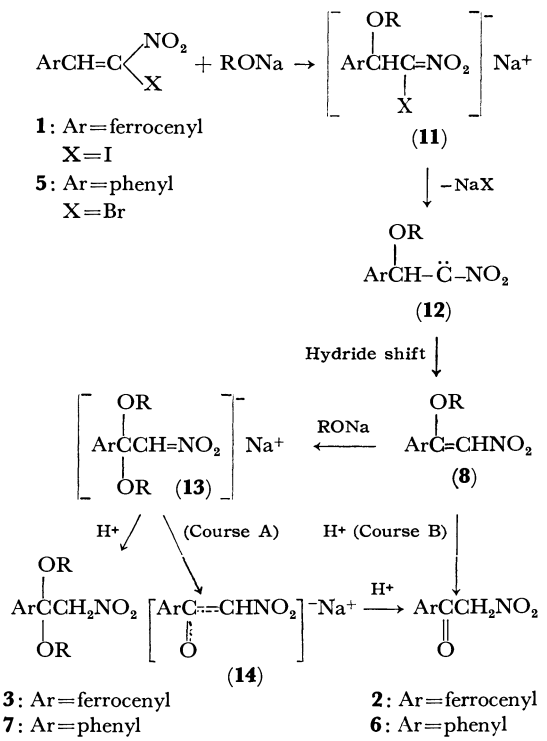


The NMR spectrum of **10** exhibits four singlet peaks, at τ 2.59, 4.79, 5.83, and 6.56, due to phenyl protons, methine in the side chain, ferrocenyl, and methoxy protons respectively, and two doublet peaks, at τ 5.91 and 7.02, corresponding to olefinic and methine protons in the cyclopropene ring. The IR spectrum of **10** shows a strong absorption peak at 1104 cm^{-1} (C–O).

Discussion

As is shown in Scheme 1, sodium alkoxides easily reacted with 1-iodo-2-ferrocenyl-1-nitroethylene (**1**) or β-bromo-β-nitrostyrene (**5**) to give adducts (**11**). The adducts were found to be very stable in organic solvents at room temperature, but they were decomposed into the original halonitroolefins by the action of dilute hydrochloric acid. On the other hand, they were converted into sodium salts of nitroacetals (**13**) or of nitroketones (**14**) when heated above 90°C with an excess of sodium alkoxides. These reactions can be considered to proceed through nitrocarbenes (**12**), which are generated by the α-elimination of sodium halide from the adducts (**11**), followed by an immediate hydride shift to give β-alkoxynitroolefins (**8**). This consideration is based on the fact that alkylcarbenes cause intramolecular insertion into neighboring β- or γ-carbon–hydrogen bonds to give olefins or cyclopropanes respectively.[7]

In order to get evidence of the existence of such a nitrocarbene as a reaction intermediate, the thermal reaction of β-bromo-β-nitrostyrene was attempted in the presence of vinylferrocene. As a result, a small amount of 3-ferrocenyl-1-(α-methoxybenzyl)cyclopropene (**10**) was obtained instead of the expected nitrocyclopropane (**15**), as is shown in Scheme 2. Since Darling and Spanagel have reported that nitrocyclopropane (**19**) was easily



Scheme 1. Reaction mechanism.

converted into cyclopropene (**20**) by the action of sodium methoxide (Scheme 2),[8] the formation of 3-ferrocenyl-1-(α-methoxybenzyl)cyclopropene (**10**) can reasonably be considered to be an indirect evidence of the existence of nitrocyclopropane (**15**) as an intermediate. An alternative cyclopropene derivative (**18**) was not obtained in this reaction. The exclusive formation of **10** may stem from the fact that the intermediate α-ferrocenylcarbanion (**17**) is less stable than the isomeric carbanion (**16**) because of the electron-releasing character of the neighboring ferrocene nucleus.

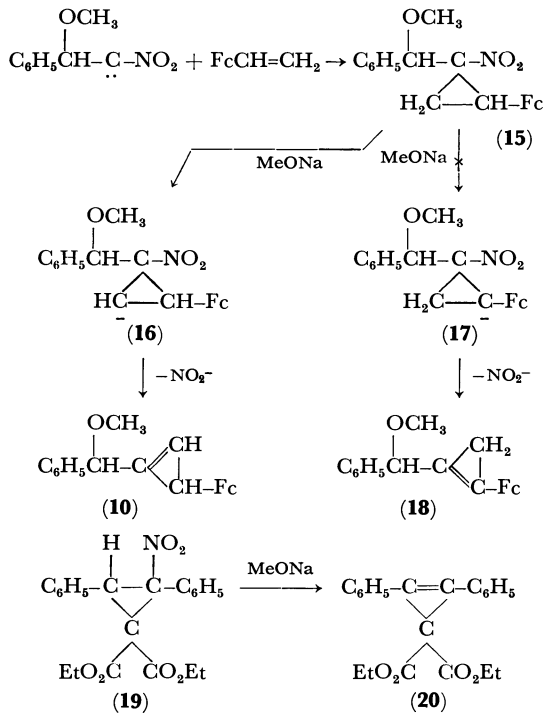
β-Alkoxynitroolefins (**8**), which were expected to be the hydride-shift products from the nitrocarbene (**12**), could not be isolated in these reactions. The further addition of sodium alkoxide to the β-alkoxynitroolefin (**8**) led to the formation of sodium salts of nitroacetals (**13**), which were then easily converted into nitroacetals (**3** or **7**) by dilute hydrochloric acid. Phenylnitroacetals (**7**) were found to be much more stable than ferrocene analogs (**3**). The difference in stability appears to be due to the larger steric hindrance and the larger electron-releasing character of the ferrocene nucleus.

As for the mechanism affording nitroketones (**2** or **6**) two pathways can be considered, as Scheme 1 shows. Course A involves the thermal decomposition of sodium salts of nitroacetals (**13**) into sodium salts of nitroketones (**14**), while Course B involves

6) M. Shiga, H. Kono, I. Motoyama and K. Hata, This Bulletin, **41**, 1897 (1968).

7) W. Kirmse, "Carbene Chemistry," Academic Press, New York and London (1964), p. 52.

8) S. F. Darling and E. W. Spanagel, *J. Amer. Chem. Soc.*, **53**, 1117 (1931).



Scheme 2. Reaction of nitrocarbene.

the direct attack of hydrochloric acid on β-alkoxynitroolefins (**8**). Course B can be ruled out on the basis of the observation that the reaction of β-bromo-β-nitrostyrene (**5**) with equimolar sodium methoxide gave neither ω-nitroacetophenone, its dimethyl acetal, nor benzoic acid at all; if the reaction followed course B, ω-nitroacetophenone or benzoic acid should be isolated from the reaction mixture when it was treated with dilute hydrochloric acid. Thus, the nitroketone must be produced *via* sodium salts of nitroacetals (**13**) by means of course A.

The effect of the bulk of the alkyl group in sodium alkoxides was not so evident in the reactions with 1-iodo-2-ferrocenyl-1-nitroethylene, but it was striking in those with the phenyl analog. The reaction of β-bromo-β-nitrostyrene with an excess of sodium isopropoxide or *t*-butoxide gave a large amount of benzoic acid, along with a small amount of ω-nitroacetophenone (**6**), while the ferrocene analog (**1**) gave (nitroacetyl)ferrocene (**2**) as the main product. The difference can be interpreted in terms of the stability of the intermediate sodium salts of nitroacetals (**13**). The intermediate sodium salts (**13**) of ferrocenyl series are so unstable because of their much larger steric crowding that they are predominantly converted into the sodium salts of nitroketones (**14**) rather than decomposed to alkyl benzoates. On the other hand, the corresponding intermdiates (**13**) of the phenyl series are considerably stable and give nitroacetals (**3**) preferably; diisopropyl and di-*t*-butyl acetals of ω-nitroacetophenone or their sodium salts can be easily decomposed to isopropyl or *t*-butyl benzoate, followed by hydrolysis to benzoic acid at the reaction temperature (90—95°C), while primary alkyl acetals such as dimethyl acetal are stable at that temperature and are decomposed to benzoate only at a much higher temperature (180—200°C).

Experimental

(Nitroacetyl)ferrocene (2) and Its Dimethyl Acetal (3a). To 0.001 mol (0.38 g) of 1-iodo-2-ferrocenyl-1-nitroethylene in 20 m*l* of dry THF, 0.01 mol (0.54 g) of sodium methoxide was added. After it had been refluxed for 2 hr on a water bath, the reaction mixture was poured into a mixture of 100 m*l* of a 5% sodium hydroxide solution and 20 m*l* of benzene. The benzene layer was then separated off, and the aqueous layer was washed three times with benzene. After the aqueous solution had been acidified with 5% hydrochloric acid, it was extracted with 30 m*l* of benzene. When the benzene solution was shaken with 100 m*l* of a 5% NaOH solution, the nitroketone moved to the aqueous layer, forming its sodium salt, while the nitroacetal remained in benzene unchanged. The benzene layer was washed three times with 100-m*l* portions of water and dried over anhydrous magnesium sulfate. Then, the benzene was removed by distillation to give 0.04 g (14% yield) of a dark brown oil of **3a**.

Found: C, 51.00; H, 4.83; N, 4.07%. Calcd for $C_{14}H_{17}FeNO_4$: C, 52.66; H, 5.32; N, 4.38%.

The aqueous alkaline layer, on the other hand, was acidified with 5% hydrochloric acid and extracted three times with 20-m*l* portions of benzene, after which the benzene solution was dried over anhydrous magnesium sulfate. After the removal of the solvent, 0.199 g of crude (nitroacetyl)ferrocene (**2**) was obtained. Recrystallization from a mixture of *n*-hexane and methylene dichloride (3 : 1) gave 0.16 g (54% yield) of orange crystals (mp 97—98°C).

Found: C, 53.04; H, 3.77; N, 5.04%. Calcd for $C_{12}H_{11}FeNO_3$: C, 52.74; H, 4.02; N, 5.12%.

(Nitroacetyl)ferrocene Dibenzyl Acetal (3b). Following the procedure described above, (nitroacetyl)-ferrocene dibenzyl acetal was prepared from 1-iodo-2-ferrocenyl-1-nitroethylene and sodium benzyl oxide in an 8% yield. The dark brown oil thus obtained is unstable and is apt to decompose to (nitroacetyl)-ferrocene even on standing in the air.

ω-Nitroacetophenone Dimethyl Acetal (7a). To 0.005 mol (1.14 g) of β-bromo-β-nitrostyrene in 60 m*l* of dry THF, 0.05 mol (2.7 g) of sodium methoxide was added. After having been refluxed for 2 hr on a water bath, the reaction mixture was poured into a mixture of 200 m*l* of 10% hydrochloric acid and 30 m*l* of benzene. The aqueous layer was separated off, and the benzene layer was shaken three times with 100-m*l* portions of water and then with 100 m*l* of a 5% sodium hydroxide solution. Thus, ω-nitroacetophenone was separated as its sodium salt. The benzene layer, which contained the acetal **7a**, was washed three times with 100-m*l* portions of water and then dried over anhydrous magnesium sulfate. The benzene solution, after the removal of the solvent, gave 1.1 g of crude ω-nitroacetophenone dimethyl acetal, which was distilled under reduced

pressure to give 0.82 g (78.0% yield) of **7a** as a pale yellow oil (bp 97.5—98°C/1.0 mmHg).

Found: C, 57.11; H, 6.53; N, 6.76%. Calcd for $C_{10}H_{13}NO_4$: C, 56.87; H, 6.16; N, 6.63%.

The aqueous alkaline layer, which contained the nitroketone, was acidified with 5% hydrochloric acid and then extracted three times with 20-m*l* portions of benzene. The benzene solution thus obtained was dried over anhydrous magnesium sulfate. After the removal of the solvent, the residual pale yellow crystals were dissolved in 3 m*l* of benzene and chromatographed on basic alumina, using methanol as the eluent. The first yellow fraction gave the sodium salt of ω-nitroacetophenone,*2 which was treated with 5% hydrochloric acid and then extracted with 30 m*l* of benzene. The benzene extract gave 0.1 g (12.5% yield) of white crystals of ω-nitroacetophenone (**6**) (mp 108—109°C). ω-Nitroacetophenone was also easily obtained by the chromatography of the acetal (**7**) on basic alumina, using methanol as the eluent.

ω-Nitroacetophenone Diethyl Acetal (7b), Dipropyl Acetal (7c) and Dibutyl Acetal (7d). Following the procedure described above, pale yellow oils of ω-nitroacetophenone diethyl acetal (bp 91.5—92°C/0.6 mmHg), dipropyl acetal (bp 104—105°C/0.2 mmHg) and dibutyl acetal (bp 120—121°C/0.2 mmHg) were obtained by reactions with sodium ethoxide, *n*-propoxide, *n*-butoxide respectively in 71%, 94.4%, and 77.4% yileds.

Found: C, 60.44; H, 6.95; N, 5.84%. Calcd for $C_{12}H_{17}NO_4$ (**7b**): C, 60.25; H, 7.11; N, 5.85%.

Found: C, 63.30; H, 8.10; N, 5.30%. Calcd for $C_{14}H_{21}NO_4$ (**7c**) C, 62.92; H, 7.86; N, 5.24%.

Found: C, 64.74; H, 7.94; N, 4.86%. Calcd for $C_{16}H_{25}NO_4$ (**7d**): C, 65.08; H, 8.47; N, 4.74%.

ω-Nitroacetophenone Didecyl Acetal (7e). A similar procedure using sodium decyl oxide gave the didecyl acetal (**7e**). It was obtained as a yellow oil after 1-decanol had been removed under reduced pressure from the alkali-insoluble fraction of the reaction product. Though an attempt to purify it by vacuum distillation resulted in failure, it was proved to be almost pure nitroacetal (**7e**) by means of thin-layer chromatography and IR spectrum. The yield of **7e** was calculated to be 83.2% after converting it completely into ω-nitroacetophenone by chromatography on alumina.

ω-Nitroacetophenone Dibenzyl Acetal (7f). The dibenzyl acetal was obtained similarly using sodium benzyl oxide; its yield was calculated to be 82.4% in the manner described for **7e**.

α-Methoxy-β-nitrostyrene (8a). ω-Nitroacetophenone dimethyl acetal (**7a**) (1 g) was heated for 2 hr at 180—200°C under an atmosphere of nitrogen. The yellow oil of **8a**, obtained by thermal decomposition, was purified by distillation under reduced pressure (bp 110°C/0.35 mmHg, 0.81 g, 96% yield).

Found: C, 60.41; H, 5.38; N, 7.71%. Calcd for $C_9H_9NO_3$: C, 60.32; H, 5.02; N, 7.82%.

α-Propoxyl-β-nitrostyrene (8c). On heating 1 g of ω-nitroacetophenone dipropyl acetal (**7c**) at 200°C for 2 hr under an atmosphere of nitrogen, a yellow oil of **8c** was obtained. It was purified by distillation under reduced pressure (bp 115—116°C/0.2 mmHg, 0.73 g, 95% yield).

Found: C, 64.51; H, 6.21; N, 6.54%. Calcd for $C_{11}H_{13}NO_3$: C, 63.76; H, 6.28; N, 6.76%.

α-Benzyloxy-β-nitrostyrene (8f). A similar procedure using 1 g of ω-nitroacetophenone dibenzyl acetal (**7f**) (180°C, 1 hr) afforded an orange-yellow oil of **8f** (bp 153—154°C/0.005 mmHg, 0.42 g).

Found: C, 70.97; H, 5.34; N, 5.03%. Calcd for $C_{15}H_{13}NO_3$: C, 70.58; H, 5.09; N, 5.49%.

ω-Nitroacetophenone Methyl Propyl Acetal (9). To 0.005 mol (0.89 g) of α-methoxy-β-nitrostyrene (**8a**) in 50 m*l* of dry THF, 0.02 mol (1.64 g) of sodium *n*-propoxide was added. After having been refluxed for 1 hr on a water bath, the reaction mixture was treated in the manner described for the preparation of **7a**. A pale yellow oil of **9** was then isolated by distillation under reduced pressure (bp 89—90°C/0.3 mmHg, 0.99 g, 84% yield).

Found: C, 60.58; H, 7.31; N, 6.41%. Calcd for $C_{12}H_{17}NO_4$: C, 60.25; H, 7.11; N, 5.85%.

3-Ferrocenyl-1-(α-methoxybenzyl)cyclopropene (10). To 0.005 mol (1.14 g) of β-bromo-β-nitrostyrene in 50 m*l* of dry THF, 0.005 mol (0.27 g) of sodium methoxide and 0.005 mol (1.06 g) of vinylferrocene were added. After having been refluxed for 20 min on a water bath, the reaction mixture was poured into a mixture of 200 m*l* of water and 30 m*l* of benzene. The benzene layer was separated, washed three times with 100-m*l* portions of water, and dried over magnesium sulfate. After the removal of the solvent, the residue was dissolved in 5 m*l* of a mixture of benzene and *n*-hexane (1 : 1) and chromatographed on Florisil, using a mixture of benzene and *n*-hexane (1 : 1) as the eluent. The second blue fraction gave 0.14 g of 1-ferrocenyl-2-nitroethylene. The third fraction gave yellow-brown crystals of 3-ferrocenyl-1-(α-methoxybenzyl)cyclopropene (**10**) (mp 88—90°C, 0.12 g, 6.9% yield).

Found: C, 72.66; H, 5.61%. Calcd for $C_{21}H_{20}FeO$: C, 73.25; H, 5.81%.

The first fraction consisted of recovered vinylferrocene. The fourth fraction gave pale yellow crystals of the sodium salt of ω-nitroacetophenone, which was found to be produced from its dimethyl acetal during the chromatography, because ω-nitroacetophenone was not detected in the original reaction mixture.

Decomposition of Nitroketones in the Presence of Piperidine and Alcohol. A mixture of 1.3 g (0.005 mol) of (nitroacetyl)ferrocene (**2**), 30 m*l* of absolute methanol, and 4 g of piperidine was stirred at 0°C for 20 hr. Then the reaction mixture was poured into a mixture of 10% hydrochloric acid (100 m*l*) and benzene (30 m*l*), followed by stirring for a few more minutes. The benzene layer was washed three times with 50-m*l* portions of water and then dried over magnesium sulfate. After the benzene had been removed by distillation, the residue was dissolved in 3 m*l* of benzene and chromatographed on alumina, using benzene as the solvent. The first fraction of the chromatography gave 0.92 g (76% yield) of methyl ferrocenecarboxylate.

A similar procedure using ethanol instead of methanol afforded ethyl ferrocenecarboxylate (8% yield). Similarly, the reaction of ω-nitroacetophenone with methanol and ethanol in the presence of piperidine gave methyl benzoate and ethyl benzoate respectively in 54 and 9% yields.

*2 ω-Nitroacetophenone was found to be converted into its sodium salt during chromatography on basic alumina.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 849—855 (1970)

The Formation of Pyrazolo[1,5-*a*]pyrimidine Derivatives[1)]

Isaburo Hori, Koji Saito and Hiroshi Midorikawa

The Institute of the Physical and Chemical Research, Yamato-machi, Kitaadachi-gun, Saitama

(Received August 5, 1969)

The combination reactions of 3-alkyl-2-cyano-3-methoxyacrylic esters (I) and their 3-hydrazino derivatives (II) in the presence of pyridine in alcohol at room temperature mostly gave chain intermediates, whose cyclizations led to the formation of only 2,7-dialkyl-5-hydroxypyrazolo-[1,5-*a*]pyrimidine derivatives. On the other hand, the reaction of Ia (3-Me) with the 5-aminopyrazole derivative (IIIa) obtained by the cyclization of IIa (3-Me) gave 7-hydroxy- and 7-aminopyrazolopyrimidine derivatives in alcohol under reflux *via* an intermediate. The reactions of 2-cyano-3-ethoxycrotononitrile with IIa or IIIa both afforded 7-aminopyrazolopyrimidine derivatives directly.

Many pyrazolo[1,5-*a*]pyrimidines, such as the 7-hydroxy and 7-amino derivatives, have, in recent years, been synthesized by the condensation of 1-ethoxyalkylidene-1,3-dicarbonyl compounds with 5-aminopyrazoles.[2-4)] The present investigation will describe mainly the formation of several 5-hydroxypyrazolo[1,5-*a*]pyrimidine derivatives by means of the condensation of 3-alkyl-2-cyano-3-methoxyacrylic esters (I) with their 3-hydrazino derivatives (II),[5)] obtained previously by the action of hydrazine on I.

The reaction of I with the corresponding 3-hydrazino compounds (II) in the presence of pyridine in ethanol at room temperature afforded first the chain intermediates, bis(2-alkoxycarbonyl-1-alkyl-2-cyanovinyl)hydrazines (IV). The symmetrical structure of IV was confirmed by a study of the NMR spectra, shown in Table 1. The intermediates (IV), upon heating in ethanol or even upon treatment in the presence of an acid or base catalyst, readily cyclized to form only 6-cyano-2,7-dialkyl-5-hydroxypyrazolo[1,5-*a*]pyrimidine-3-carboxylic esters (V), with the loss of one molar equivalent of alcohol; they were unchanged upon heating in acetic acid. The saponification of V(a—c) with aqueous sodium hydroxide gave the corresponding 3,6-dicarboxylic acids (VI), which were then decarboxylated by being heated above the melting point to give 2,7-dialkyl-5-hydroxypyrazolo[1,5-*a*]pyrimidines (VIII). The Vd compound on similar alkaline treatment, was converted into 6-carbamoyl-3-carboxylic acid (VII), which gave VIIIc upon further hydrolysis with diluted sulfuric acid.

Table 1. NMR spectra of bis(2-alkoxycarbonyl-1-alkyl-2-cyanovinyl)hydrazines (IV)*

Compound	R	COOR′	NH
IVa	2.31(3)	1.34(3), 4.26(2)	11.09(1)
IVb	2.31(3)	3.82(3)	11.06(1)
IVc	1.29(3), 2.14(2)	3.81(3)	11.12(1)
IVd	0.96(3), 1.20—1.30(4), 2.10(2)	3.82(3)	11.12(1)

* The chemical shifts of protons are expressed as δ value and deuteriochloroform was used as solvent. Relative peak intensities in parentheses.

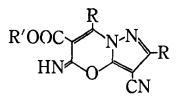
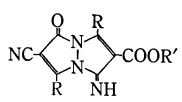
The other structures (V′ and V″) considered on the basis of the differential ring closure of IV on dealcoholation can be excluded on the basis of the following chemical evidence.

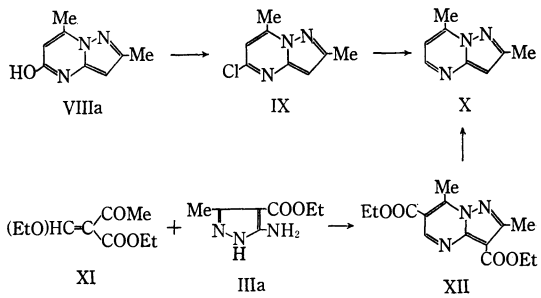


V′



V″

The VIIIa compound was chlorinated, by the action of phosphoryl chloride, to a chloro derivative (IX), which was then catalytically reduced to 2,7-dimethylpyrazolo[1,5-*a*]pyrimidine (X). On the other hand, X could be derived from the condensate (XII) obtained by the reaction of ethyl 2-acetyl-3-ethoxyacrylate (XI) with ethyl 3-methyl-5-aminopyrazole-4-carboxylate (IIIa).

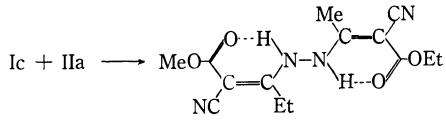


VIIIa IX X

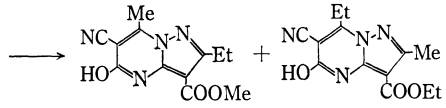
XI IIIa XII

In order to compare this process with the formation of 2,7-dialkyl-5-hydroxypyrazolo[1,5-*a*]pyrimidines described above, the condensation of ethyl 2-cyano-3-methoxycrotonate (Ia) with IIIa, the cyclized compound of IIa, was carried out in ethanol under reflux. The resulting intermediate (XIII) cyclized upon heating in ethanol containing an acid catalyst to give two products, hydroxy- (XIV) and aminopyrazolo[1,5-*a*]pyrimidine derivatives (XV). The hydrolysis and the subsequent decarboxylation of the latter product with diluted sulfuric acid led to the known 7-amino-2,5-dimethylpyrazolo[1,5-*a*]pyrimidine (XVI), prepared by a different procedure.[6] The former gave the 7-hydroxy derivative (XVII) by similar treatment. The compound XVII could also be prepared by acid hydrolysis and by the subsequent decarboxylation of the condensate (XVIII) isolated by means of the reaction of ethyl acetoacetate with IIIa. Isomeric hydroxy derivatives (VIIIa and XVII) were distinguishable from each other by means of IR and NMR spectral comparisons. From these results, it is clear that VIII and its original compound (V) are 2,7-dialkyl-5-hydroxypyrazolo-[1,5-*a*]pyrimidine derivatives.

The reaction of Ic (3-Et) with IIa gave the chain intermediate, 1-(2-cyano-2-ethoxycarbonyl-1-methylvinyl)-2-(2-cyano-1-ethyl-2-methoxycarbonylvinyl)hydrazine (XIX). In its cyclization, two kinds of dealcoholation are possible because XIX has an unsymmetrical structure. In fact, when XIX was heated in ethanol or above the melting point, two condensates, XX and XXI, were obtained as a mixture in approximately a 5 : 3 ratio and were isolated by fractional recrystallization. These two structures, XX and XXI, were confirmed to be methyl 6-cyano-2-ethyl-5-hydroxy-7-methylpyrazolo[1,5-*a*]pyrimidine-3-carboxylate and ethyl 6-cyano-7-ethyl-5-hydroxy-2-methylpyrazolo[1,5-*a*]-pyrimidine-3-carboxylate respectively by means of the molecular formula and by NMR spectral observations.

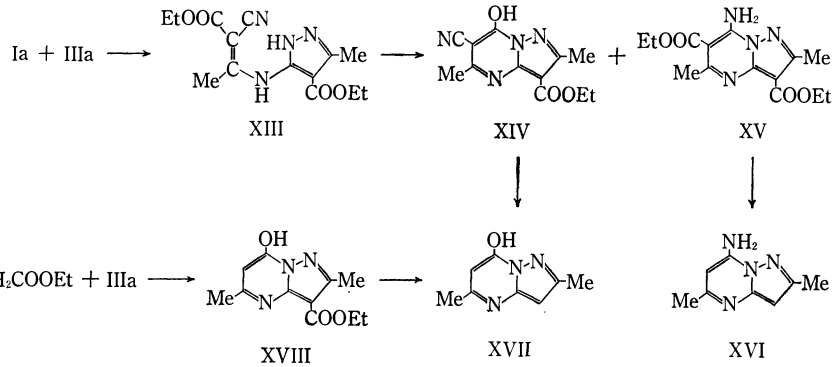


XIX



XX XXI

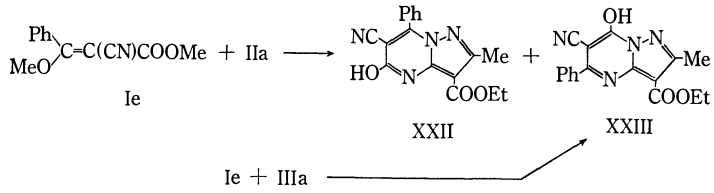
The reaction of Ie (3-Ph) with IIa directly formed two isomeric cyclized products, XXII and



XIII XIV XV

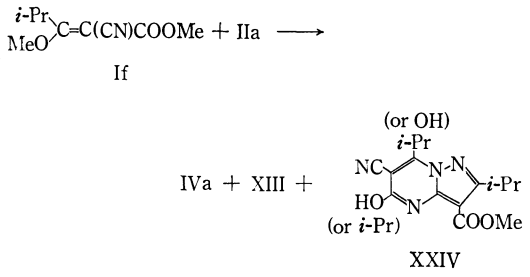
XVIII XVII XVI

6) A. Takamizawa and Y. Hamashima, Japan. 18755 (1965); *Chem. Abstr.*, **64**, 12696g (1966).

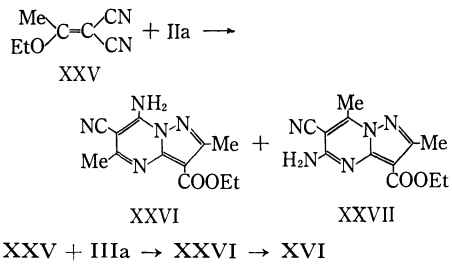


XXIII, but no intermediate could be isolated. The latter product was identical with the condensate prepared from the reaction of Ie with IIIa. Therefore, XXIII is ethyl 6-cyano-7-hydroxy-2-methyl-5-phenylpyrazolo[1,5-*a*]pyrimidine-3-carboxylate, and perhaps XXII is ethyl 6-cyano-5-hydroxy-2-methyl-7-phenylpyrazolo[1,5-*a*]pyrimidine-3-carboxylate.

The reaction of If (3-*i*-Pr) and IIa afforded predominantly IVa and XIII, which were identical with those obtained by the reactions involving the Ia and IIIa related to IIa, as has been described previously, and also a small quantity of methyl 6-cyano-5(or 7)-hydroxy-2,7(or 2,5)-diisopropylpyrazolo[1,5-*a*]pyrimidine-3-carboxylate (XXIV). Though the main products (IVa and XIII) were considered to be formed by the self-condensation of the reactant IIa only, the blank experiment without If did not give any product. These results suggest a certain interaction between the two reactants in this reaction, but the reaction mechanism is not clear.



On a similar condensation of 2-cyano-3-ethoxycrotononitrile (XXV) with IIa, the formation of 5-aminopyrazolo[1,5-*a*]pyrimidine derivative can be expected. However, this reaction at room temperature or even below (near 0°C) gave mostly ethyl 2,5-dimethyl-6-cyano-7-aminopyrazolo[1,5-*a*]-pyrimidine-3-carboxylate (XXVI), along with a very small amount of its isomeric substance, mp 301°C (XXVII). The structure of XXVI was proved by the following experiments. The XXVI compound was identical with the product obtained by the reaction of XXV with IIIa in ethanol under reflux, and the treatment of XXVI with diluted sulfuric acid led to the 7-amino-2,5-dimethylpyrazolo[1,5-*a*]pyrimidine (XVI). The minor product (XXVII) seems likely to be the expected 5-amino derivative.



The hydroxyl and amino groups at the 5- and 7-positions of pyrazolo[1,5-*a*]pyrimidine are capable of tautomerism to keto and imino forms respectively. Makisumi[2] has observed, in the IR spectra, that the hydroxyl groups at both positions show the keto form, while the amino group at the 7-position shows the amino form in a neutral medium. The IR data of the pyrazolo[1,5-*a*]pyrimidine derivatives obtained in the present work are presented in Table 2. From these data, it can be said that all the 5-hydroxy compounds exist in the keto form, whereas the 7-hydroxy and 7-amino derivatives exist as tautomeric mixtures in the solid state.

Experimental[7]

Reactions of 3-Alkyl-2-cyano-3-methoxyacrylic Esters (I) with the Corresponding 3-Hydrazino Compounds (II). To a solution of I (3 mmol) and II (3 mmol) dissolved in ethanol at room temperature, a few drops of pyridine were added, and then the mixture was allowed to stand overnight at the same temperature. The precipitate which formed was separated by filtration, washed with ethanol, and recrystallized to give bis(2-alkoxycarbonyl-1-alkyl-2-cyanovinyl) hydrazines (IV) as colorless crystals. The results are given in Table 3.

Cyclization of IV; 6-Cyano-2,7-dialkyl-5-hydroxypyrazolo[1,5-*a*]pyrimidine-3-carboxylic Esters (V). *a*) A mixture of IV in ethanol was refluxed; the IV soon dissolved, and then crystals began to precipitate. After refluxing for 4 hr and cooling, the crystals formed were collected by filtration, washed with methanol,

7) All the melting points are uncorrected. The IR spectra were measured with a Shimadzu 27A spectrophotometer in Nujol mulls. The NMR spectra were obtained with a Nihon-denshi JNM-C-60 high-resolution NMR spectrometer (60 MHz), using tetramethylsilane as the internal reference; the chemical shifts of the protons are presented in terms of δ values; s: singlet, bs: broad singlet, d: doublet, t: triplet, q: quartet, sep: septet, m: multiplet.

and recrystallized from chloroform-methanol to afford V as colorless needles. The yields were 80—90%. The products (V) obtained are listed in Table 4.

b) To a mixture of 0.61 g of IVa in 40 m*l* of ethanol, 0.41 g of concentrated hydrochloric acid was added, and then the mixture was refluxed for 2 hr. The resulting crystals were separated by filtration to give 0.38 g of colorless needles, mp 228°C, which did not

show any depression when the needles were mixed with the Va obtained above. The mother layer was concentrated to dryness under reduced pressure, and to the residue 15% hydrochloric acid was added. The solid precipitated was filtered and washed with water to give 0.11 g of a colorless solid, which was found to be a mixture of the starting substance (IVa) and Va by a comparison of their IR spectra. The filtrate did not give any precipitate after the solution had been made alkaline with sodium carbonate.

c) The treatment of 0.61 g of IVa with 3 m*l* of acetic acid at 100°C for 3 hr resulted in the recovery of 0.50 g (90%) of the starting substance.

Hydrolysis of V. *a*) A mixture of 0.26 g of Va in 2.5 m*l* of 20% aqueous sodium hydroxide was heated under reflux for 4.5 hr, thus producing a clear solution. After cooling, the solution was diluted with water and acidified with 15% hydrochloric acid. The precipitate formed was separated by filtration, washed with water, and recrystallized from acetone-water to afford colorless needles of 2,7-dimethyl-5-hydroxypyrazolo[1,5-*a*]pyrimidine-3,6-dicarboxylic acid (VIa), mp 243—244°C (dec); yield, 0.17 g (67%).

Found: C, 47.78; H, 3.45; N, 16.85%. Calcd for $C_{10}H_9O_5N_3$: C, 47.81; H, 3.61; N, 16.73%.

b) From 0.24 g of Vb, 0.18 g of VIa was obtained by the same procedure. Found: N, 16.78%.

c) A suspension of 0.50 g of Vc in 5 m*l* of 20% aqueous sodium hydroxide was refluxed for 5 hr. Water was then added to the reaction mixture, and it was acidified with 15% hydrochloric acid. The precipitate thus formed was collected by centrifugation and recrystallized from acetone to give 0.31 g of colorless needles of 2,7-diethyl-5-hydroxypyrazolo[1,5-*a*]pyrimidine-3,6-dicarboxylic acid (VIb), mp 207°C (dec).

Found: C, 51.32; H, 4.90; N, 15.04%. Calcd for $C_{12}H_{13}O_5N_3$: C, 51.61; H, 4.69; N, 15.05%.

d) Compound Vd (0.25 g) was treated as above (*a*) with 3 m*l* of 20% aqueous sodium hydroxide to form 0.20 g of colorless crystals of 2,7-di-*n*-butyl-6-carbamoyl-5-hydroxypyrazolo[1,5-*a*]pyrimidine-3-carboxylic acid (VII), mp 210°C (dec).

Found: C, 57.21; H, 6.34; N, 16.56%. Calcd for $C_{16}H_{22}O_4N_4$: C, 57.47; H, 6.63; N, 16.76%.

2,7-Dialkyl-5-hydroxypyrazolo[1,5-*a*]pyrimidine (VIII). *a*) Compound VIa (2.25 g) was heated on an oil bath at 250°C until the evolution of carbon dioxide ceased. The crude substance thus formed was treated with charcoal in methanol. After the methanol had been concentrated, the residue afforded 1.25 g of colorless needles of pure VIIIa, mp 244—245°C, by the recrystallization from acetone. NMR in CF_3COOH: 2.72 (s, C_2–Me), 2.85 (s, C_7–Me), 6.63 (overlap, C_3– and C_6–H).

Found: C, 58.72; H, 5.52; N, 25.56%. Calcd for $C_8H_9ON_3$: C, 58.88; H, 5.56; N, 25.75%.

b) At 210—215°C, 0.30 g of VIb was heated. After the evolution of carbon dioxide had ceased, this mixture was treated as above. The residue thus obtained was recrystallized from acetone to yield 0.18 g of light yellow needles of VIIIb, mp 125—125.5°C. NMR in CF_3COOH: 1.47 (t) and 3.02(q) (C_2–Et), 1.51 (t) and 3.14(q) (C_7–Et), 6.63 (overlap, C_3– and C_6–H).

Found: C, 62.62; H, 6.59; N, 21.74%. Calcd for $C_{10}H_{13}ON_3$: C, 62.80; H, 6.85; N, 21.98%.

c) A mixture of 0.20 g of VII and 3 m*l* of 50% sulfuric acid was heated under reflux for 2 hr to make it a clear solution. After cooling, water was added to the mixture, and the resulting crystals were filtered, washed with water, and dried in a desiccator. Colorless needles of VIIIc were thus obtained; mp 82—83°C; yield, 0.14 g. NMR in CF_3COOH: 1.04(t), 1.08(t), 1.35—2.05(m), 3.03(t) and 3.15(t) (C_2– and C_7-*n*-Bu), 6.60 (overlap, C_3– and C_6–H).

Found: C, 67.79; H, 8.77; N, 17.00%. Calcd for $C_{14}H_{21}ON_3$: C, 67.98; H, 8.56; N, 16.99%.

5-Chloro-2,7-dimethylpyrazolo[1,5-*a*]pyrimidine (IX). A solution of VIIIa (0.55 g) in 7 m*l* of phosphorus oxychloride was refluxed for 4 hr. After the excess phosphorus oxychloride had then been removed under reduced pressure, the residual syrup was decomposed with crushed ice. The precipitate thus obtained was collected by filtration, washed with water, and recrystallized from ethanol to form 0.50 g of fine, light yellow needles of IX, mp 100—101°C. NMR in $CHCl_3$: 2.45 (s, C_2–Me), 2.66 (s, C_7–Me), 6.30 (s, C_3–H), 6.50 (s, C_6–H).

Found: C, 52.87; H, 4.51; N, 23.13%. Calcd for $C_8H_8N_3Cl$: C, 52.90; H, 4.43; N, 23.16%.

Reduction of IX; 2,7-Dimethylpyrazolo[1,5-*a*]pyrimidine (X). A suspension of 0.18 g of IX and 0.08 g of sodium acetate in 10 m*l* of ethanol was reduced over 0.08 g of 5% palladised charcoal, and then one equivalent mole of hydrogen was taken up. After the catalyst had been removed by filtration, the solution was concentrated to dryness under reduced pressure, and the residue was dissolved in water and extracted with chloroform. The chloroform extracts were dried over sodium sulfate, and the chloroform was removed to give a colorless oil which solidified after cooling. The recrystallization of this solid from light petroleum-benzene gave 0.12 g of hygroscopic, colorless needles of X, mp 35—36°C. NMR in $CDCl_3$: 2.53 (s, C_2–Me), 2.73 (s, C_7–Me), 6.33 (s, C_3–H), 6.46 (d, J=4.2 Hz, C_6–H), 8.17 (d, J=4.2 Hz, C_5–H).

Found: C, 64.95; H, 6.17; N, 28.13%. Calcd for $C_8H_9N_3$: C, 65.28; H, 6.16; N, 28.55%.

Reaction of Ethyl 2-Acetyl-3-ethoxyacrylate (XI) with IIIa. A mixture of 1.86 g of XI and 1.69 g of IIIa in 15 m*l* of acetic acid was heated on a steam bath for 2.5 hr. After the reaction mixture had been diluted with water, the white precipitate formed was separated by filtration and recrystallized from ethanol-water (3 : 1) to give 2.20 g of colorless needles of diethyl 2,7-dimethylpyrazolo[1,5-*a*]pyrimidine-3,6-dicarboxylate (XII), mp 95—97°C. IR: 1727, 1698, 1610 cm^{-1}.

Found: C, 57.73; H, 5.54; N, 14.59%. Calcd for $C_{14}H_{17}O_4N_3$: C, 57.72; H, 5.88; N, 14.43%.

Hydrolysis of XII. A mixture of 1.00 g of XII and 5 m*l* of 50% sulfuric acid was refluxed for 5 hr. After cooling, the mixture was basified with 20% aqueous sodium hydroxide, and then the violet-brown oil thus formed was extracted with chloroform. The chloroform layer was dried over sodium sulfate and chromatographed on alumina. The benzene eluate was recrystallized from light petroleum-benzene to give 0.58 g of hygroscopic, colorless needles, mp 35—36°C, which did not show any depression when the needles were mixed with X; the IR spectrum of the product was identical with that of X.

Reaction of Ethyl 2-Cyano-3-methoxycrotonate (Ia) with IIIa. A solution of 1.10 g of Ia and 1.10 g

of IIIa in 20 m*l* of ethanol was heated under reflux for 5 hr and then concentrated to about 5 m*l* under reduced pressure. After cooling, the colorless crystals thus obtained were recrystallized twice from ethanol to give 0.80 g of colorless needles of ethyl 2-cyano-3-(4-ethoxycarbonyl-3-methyl-5-pyrazolylamino) crotonate (XIII), mp 175°C. IR: 3215, 3115, 2217, 1704, 1678 cm^{-1}.

Found: C, 54.61; H, 5.77; N, 18.39%. Calcd for $C_{14}H_{18}O_4N_4$: C, 54.89; H, 5.92; N, 18.29%.

Cyclization of XIII; XIV and XV. To a solution of 0.30 g of XIII in 60 m*l* of ethanol, 4 m*l* of concentrated hydrochloric acid was added drop by drop, and then the mixture was refluxed for 3 hr. The solution was concentrated under reduced pressure and diluted with 40 m*l* of water, and then the white precipitate thus formed was separated by filtration. The recrystallization of the precipitate from ethanol gave 0.15 g of colorless needles of ethyl 6-cyano-2,5-dimethyl-7-hydroxypyrazolo-[1,5-*a*]pyrimidine-3-carboxylate (XIV), mp 262—263°C. NMR in CF_3COOH: 2.80 (s, C_2–Me), 2.97 (s, C_5–Me), 1.55(t) and 4.59(q) (COOEt).

Found: C, 55.36; H, 4.36; N, 21.45%. Calcd for $C_{12}H_{12}O_3N_4$: C, 55.38; H, 4.65; N, 21.53%.

The mother layer of the reaction was made basic with aqueous sodium carbonate. The precipitate thus formed was washed with water, dried in a desiccator, and then recrystallized from ethanol-acetic acid to give 0.09 g of colorless needles of diethyl 7-amino-2,5-dimethylpyrazolo[1,5-*a*]pyrimidine-3,6-dicarboxylate (XV), mp 175°C. NMR in CF_3COOH: 2.76 (s, C_2–Me), 3.21 (s, C_5–Me), 1.55(t), 4.60(q) and 4.65(q)(2COOEt), 8.80(bs) and 10.25(bs) (NH_2).

Found: C, 54.94; H, 5.71; N, 18.48%. Calcd for $C_{14}H_{18}O_4N_4$: C, 54.89; H, 5.92; N, 18.29%.

Hydrolysis of XIV; 2,5-Dimethyl-7-hydroxypyrazolo[1,5-*a*]pyrimidine (XVII). A mixture of 0.50 g of XIV and 10 m*l* of 50% sulfuric acid was heated under reflux for 3 hr; then, after cooling, the pH of the reaction mixture was adjusted with ammonium hydroxide to about 5. The precipitate thus formed was separated by filtration, washed with water, and recrystallized from ethanol to give 0.32 g of colorless needles of XVII, mp 250—251°C. NMR in CF_3COOH: 2.65 (s, C_2–Me), 2.74 (s, C_5–Me), 6.34 (s, C_3–H), 6.61 (s, C_6–H).

Found: C, 58.97; H, 5.49; N, 25.52%. Calcd for $C_8H_9ON_3$: C, 58.88; H, 5.56; N, 25.75%.

Reaction of Ethyl Acetoacetate with IIIa. A mixture of 0.60 g of ethyl acetoacetate and 0.80 g of IIIa in 1.5 m*l* of acetic acid was refluxed for 2.5 hr. After the mixture had then been diluted with water, the precipitate thus obtained was collected by filtration, washed with water, and dried in a desiccator. The recrystallization of the precipitate from ethanol and benzene afforded 0.75 g of colorless needles of ethyl 2,5-dimethyl-7-hydroxypyrazolo[1,5-*a*]pyrimidine-3-carboxylate (XVIII), mp 150—151°C. NMR in CF_3COOH: 2.75 (s, C_2–Me), 2.95 (s, C_5–Me), 6.43 (s, C_6–H), 1.55(t) and 4.63(q) (COOEt).

Found: C, 55.91; H, 5.47; N, 17.91%. Calcd for $C_{11}H_{13}O_3N_3$: C, 56.16; H, 5.57; N, 17.86%.

Hydrolysis of XVIII. A mixture of 0.50 g of XVIII and 10 m*l* of 50% sulfuric acid was heated under reflux for 2.5 hr. After cooling, the mixture was treated with ammonium hydroxide to adjust its pH to about 5. The precipitate thus formed was washed with water and then recrystallized from ethanol to give 0.38 g of colorless needles, mp 250—251°C, which did not show any depression when the needles were mixed with the XVII obtained above; the IR and NMR spectra of the product were identical with those of XVII.

Hydrolysis of XV; 7-Amino-2,5-dimethylpyrazolo[1,5-*a*]pyrimidine (XVI). A mixture of 0.50 g of XV and 10 m*l* of 50% sulfuric acid was refluxed for 3.5 hr; then, after cooling, the mixture was diluted with 10 m*l* of water and basified with ammonium hydroxide to give a white precipitate. The recrystallization of the precipitate from ethyl acetate afforded 0.33 g of colorless needles, mp 198—200°C, which did not show any depression on admixture with an authentic sample of 7-amino-2,5-dimethylpyrazolo[1,5-*a*]pyrimidine (XVI).[6] NMR in CF_3COOH: 2.64 (s, C_2–Me), 2.69 (s, C_5–Me), 6.47 (overlap, C_3– and C_6–H), 8.30 (bs, NH_2).

Reaction of Methyl 2-Cyano-3-ethyl-3-methoxyacrylate (Ic) with IIa. Into a solution of 1.32 g of Ic and 1.32 g of IIa dissolved in ethanol at room temperature, a few drops of pyridine were added. After the solution had then been allowed to stand overnight at room temperature, the white precipitate thus formed was collected by filtration and washed with ethanol. The recrystallization of this from chloroform-ethanol (1 : 2) gave 1.36 g of colorless needles of 1-(2-cyano-2-ethoxycarbonyl-1-methylvinyl)-2-(2-cyano-1-ethyl-2-methoxycarbonylvinyl)hydrazine (XIX), mp 165°C (dec). IR: 3165, 2217, 1689, 1672, 1587 cm^{-1}. NMR in $CDCl_3$: 2.33 (s, vinyl Me), 1.28(t) and 2.64(q) (vinyl Et), 3.82 (s, COOMe), 1.34(t) and 4.25(q) (COOEt), 10.95 (s, NH), 11.07 (s, NH).

Found: C, 54.60; H, 5.87; N, 18.39%. Calcd for $C_{14}H_{18}O_4N_4$: C, 54.89; H, 5.92; N, 18.29%.

Cyclization of XIX; XX and XXI. A mixture of 0.55 g of XIX in 40 m*l* of ethanol was heated under reflux; soon the XIX completely dissolved, and then a white precipitate was separated out. The whole mixture was refluxed for 3 hr. After cooling, the precipitate formed was collected by filtration. The treatment of this with fresh boiling ethanol gave 0.16 g of insoluble methyl 6-cyano-2-ethyl-5-hydroxy-7-methylpyrazolo-[1,5-*a*]pyrimidine-3-carboxylate (XX) in hot ethanol as colorless prisms, mp 258—260°C. NMR in CF_3COOH: 1.40(t) and 3.16(q) (C_2–Et), 3.09 (s, C_7–Me), 4.15 (s, COOMe).

Found: C, 55.21; H, 4.68; N, 21.54%. Calcd for $C_{12}H_{12}O_3N_4$: C, 55.38; H, 4.65; N, 21.53%.

The mother layer of the boiling-ethanol treatment was concentrated to give colorless crystals, the recrystallization of which from dioxane afforded 0.21 g of colorless needles of ethyl 6-cyano-7-ethyl-5-hydroxy-2-methylpyrazolo[1,5-*a*]pyrimidine-3-carboxylate (XXI), mp 209—210°C. NMR in CF_3COOH: 2.73 (s, C_2–Me), 1.52(t) and 3.45(q) (C_7–Et), 1.56(t) and 4.62(q) (COOEt).

Found: C, 56.70; H, 5.01; N, 20.17%. Calcd for $C_{13}H_{14}O_3N_4$: C, 56.93; H, 5.15; N, 20.43%.

Reaction of Methyl 2-Cyano-3-methoxycinnamate (Ie) with IIa. Compound Ie (1.08 g) and 0.84 g of IIa were dissolved in 35 m*l* of ethanol by slightly warming the solution, and to this a few drops of pyridine were added; then the mixture was allowed to stand at room temperature for 4 days. The resulting white precipitate was separated by filtration, washed with ethanol, and recrystallized from ethanol to give 0.38 g of

colorless needles of ethyl 6-cyano-5-hydroxy-2-methyl-7-phenylpyrazolo[1,5-*a*]pyrimidine-3-carboxylate (XXII), mp 227—228°C. NMR in CF_3COOH: 2.67 (s, C_2–Me), 7.47 (m, C_7–Ph), 1.53(t) and 4.66(q) (COOEt).

Found: C, 63.27; H, 4.11; N, 17.77%. Calcd for $C_{17}H_{14}O_3N_4$: C, 63.35; H, 4.38; N, 17.38%.

The mother layer of the reaction was concentrated to a small volume under reduced pressure. After the residue had been stored in an ice-box, the precipitate was separated out and washed with ethanol. The recrystallization of this from ethanol gave 0.60 g of the hydrate of ethyl 6-cyano-7-hydroxy-2-methyl-5-phenylpyrazolo[1,5-*a*]pyrimidine-3-carboxylate (XXIII) as colorless plates, mp 144—146°C.

Found: C, 61.16; H, 4.29; N, 16.95%. Calcd for $C_{17}H_{14}O_3N_4 \cdot 1/2H_2O$: C, 61.62; H, 4.56; N, 16.91%.

The water of crystallization could be driven off by heating at 110°C in reduced pressure; XXIII was thus obtained as colorless crystals, mp 190—191°C. NMR in CF_3COOH: 2.90 (s, C_2–Me), 7.80 (m, C_5–Ph), 1.63(t) and 4.67(q)(COOEt).

Found: C, 63.46; H, 4.37; N, 17.58%. Calcd for $C_{17}H_{14}O_3N_4$: C, 63.35; H, 4.38; N, 17.38%.

Reaction of Ie with IIIa. A mixture of 0.54 g of Ie and 0.42 g of IIIa in 5 m*l* of ethanol was heated under reflux for 2 hr. The ethanol was removed under reduced pressure, and the residue was washed with ethanol and recrystallized twice from dioxane-water to give 0.58 g of colorless needles, mp 144—145°C. The heating of the needles at 110°C under reduced pressure afforded colorless crystals, mp 190—191°C, which did not show any depression when the crystals were mixed with the XXIII obtained above; the IR and NMR spectra of the product were identical with those of XXIII.

Reaction of Methyl 2-Cyano-3-isopropyl-3-methoxyacrylate (If) with IIa. To a solution of 2.75 g of If and 2.54 g of IIa in 40 m*l* of ethanol, a few drops of pyridine were added, and then the solution was allowed to stand at room temperature overnight. The precipitate thus formed was collected by filtration, and washed with ethanol; the recrystallization of this from chloroform-ethanol gave 1.25 g of colorless needles, mp 183°C (dec), which were proved to be identical with the IVa obtained from the reaction of Ia and IIa by a mixed-melting-point measurement and by an IR spectral comparison. The second crop was 0.05 g. The mother layer of the reaction was evaporated under reduced pressure, and the residue was dissolved in water and acidified with 15% hydrochloric acid. The precipitate thus formed was collected and recrystallized from ethanol to give 0.32 g of colorless crystals, mp 175°C. This was found to be identical with XIII obtained from the reaction of Ia with IIIa by a mixed-melting-point measurement and by an IR spectral comparison.

The filtrate of the acidic solution contained an oily substance which solidified after having been stored in an ice-box. The solid thus separated was washed with water, dried in a desiccator, and recrystallized from ethanol to give 0.43 g of colorless needles of methyl 6-cyano-5 (or 7)-hydroxy-2,7-(or 2,5)-diisopropylpyrazolo[1,5-*a*]pyrimidine-3-carboxylate (XXIV), mp 164—165°C. IR: 3279, 2212, 1724, 1695, 1610 cm^{-1}. NMR in $CDCl_3$: 1.41(t), 1.43(t) and 3.49(sep) (2 *i*-Pr), 3.45 (s, COOMe).

Found: C, 59.74; H, 5.69; N, 18.85%. Calcd for $C_{15}H_{18}O_3N_4$: C, 59.59; H, 6.00; N, 18.53%.

Blank Experiment without If in the Above Reaction. To a solution of 0.63 g of IIa in 10 m*l* of ethanol, a few drops of pyridine were added; the solution did not give any precipitate after having been allowed to stand at room temperature for 10 days. The evaporation of the solution resulted in the recovery of the starting substance.

Reaction of 2-Cyano-3-ethoxycrotononitrile (XXV) with IIa. *a*) To a solution of XXV (0.68 g) and 0.84 g of IIa dissolved in 25 m*l* of methanol at room temperature, a few drops of pyridine were added, and then the mixture was allowed to stand at the same temperature for 3 days. The precipitate thus formed was collected by filtration and recrystallized from acetone to afford 0.09 g of light brown plates of, probably, ethyl 5-amino-6-cyano-2,7-dimethylpyrazolo[1,5-*a*]pyrimidine-3-carboxylate (XXVII), mp 301°C (dec). IR: 3448, 3247, 3145, 2227, 1698, 1642, 1610 cm^{-1}. NMR in CF_3COOH: 2.73 (s, C_2–Me), 3.18 (s, C_7–Me), 1.55(t) and 4.60(q) (COOEt), 8.25 (bs, NH_2).

Found: C, 55.33; H, 4.89; N, 26.71%. Calcd for $C_{12}H_{13}O_2N_5$: C, 55.59; H, 5.05; N, 27.02%.

The mother layer of the reaction was evaporated under reduced pressure, and the residue thus obtained was recrystallized twice from ethanol-water to give 1.03 g of fine, colorless needles of ethyl 7-amino-6-cyano-2,5-dimethylpyrazolo[1,5-*a*]pyrimidine-3-carboxylate (XXVI), mp 281—282°C. NMR in CF_3COOH: 2.80 (s, C_2–Me), 3.15 (s, C_5–Me), 1.58(t) and 4.66(q) (COOEt), 9.05 (bs, NH_2).

Found: C, 55.70; H, 5.03; N, 26.94%. Calcd for $C_{12}H_{13}O_2N_5$: C, 55.59; H, 5.05; N, 27.02%.

b) When the above reaction was carried out near 0°C, the same results as in *a*) were obtained.

Reaction of XXV with IIIa. A mixture of 0.68 g of XXV and 0.84 g of IIIa in 20 m*l* of ethanol was heated under reflux for 7 hr. After cooling, the precipitate thus obtained was collected by filtration, washed with ethanol, and recrystallized twice from ethanol-water to form 1.17 g of colorless needles, mp 282—283°C, which were proved to be identical with the foregoing XXVI by a mixed-melting-point determination and by IR and NMR spectral comparisons.

Found: C, 55.64; H, 5.01; N, 27.08%.

Hydrolysis of XXVI. Compound XXVI (0.50 g) was dissolved in 10 m*l* of 50% sulfuric acid, and then the mixture was refluxed for 4 hr. After cooling, the reaction mixture was diluted with water and basified with ammonium hydroxide. The precipitate thus formed was collected, washed with water, and dried in a desiccator. The recrystallization of this from ethyl acetate gave 0.35 g of colorless needles, mp 199—201°C, which did not show any depression on admixture with the XVI obtained from the hydrolysis of XV.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 856—860 (1970)

Reactions of Nitrones with Free Radicals. I. Radical 1,3-Addition to Nitrones

Michiko IWAMURA and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received August 16, 1969)

Reactions of the aldonitrones with α,α′-azobisisobutyronitrile or dimethyl α,α′-azobisisobutyrate gave trisubstituted hydroxylamines as addition products, whose structures were determined to be radical 1,3-addition products to the nitrones. Reactions of *N*-benzyl-α-phenylnitrone with di-*t*-butyl peroxide and aralkyl hydrocarbons possessing at least one α-hydrogen atom gave similar 1,3-adducts and substituted *N*-benzylaldonitrones. Reaction of α,*N*-diphenylnitrone with phenylazotriphenylmethane gave similarly α,α,*N*-triphenylnitrone. Mechanisms for the formation of these products were discussed.

Inamoto and Simamura found that the reaction of α,α′-azobisisobutyronitrile (AIBN) with nitrobenzene at 100°C gave *N*,*O*-bis(1-cyano-1-methylethyl)phenylhydroxylamine, acetone and hydrogen cyanide in 3% yields.[1,2] In the reaction of AIBN with azoxybenzene or *N*,*N*-dimethylaniline *N*-oxide at 100°C, azobenzene or *N*,*N*-dimethylaniline was isolated in 1—1.5% yield, together with acetone (1—1.5%) and hydrogen cyanide.[3] From the results it was considered that the free radicals generated from AIBN are able to abstract the oxygen atom from some N→O bonds by addition-elimination mechanism.

In connection with the results, the reactions of AIBN or related compounds with aldonitrones were attempted. It was found that two 1-substituted 1-methylethyl radicals add to the nitrones in good yields.[4] This paper describes the addition reactions of free radicals to nitrones in detail.

Results and Discussion

Addition of Free Radicals Generated from Aliphatic Azo Compounds. When AIBN was decomposed in xylene containing an equimolar amount of α,*N*-diphenylnitrone (I) at 90—110°C, an addition product (IV) was obtained in 63% yield. Similar addition products were obtained in the reactions of *N*-benzyl-α-phenylnitrone (II) and glyoxal-bis-*N*-phenylnitrone (III). In the case of the dinitrone (III), an addition product to only one nitrone group was produced even with an excess of AIBN. Dimethyl α,α′-azobisisobutyrate (MAIB) behaved similarly as a radical source under similar conditions. The results are summarized in Table 1.

Table 1. Addition products of 1-substituted 1-methylethyl radicals to nitrones

	Addition product		Elemental analysis (%)			
	%	Mp (°C)		C	H	N
IV	63	142.5—143.5	Found	75.52	6.86	12.65
			Calcd	75.64	6.95	12.65
V	46	114—115	Found	75.94	7.54	12.09
			Calcd	76.05	7.25	12.10
VI	50	55—56	Found	69.47	7.56	3.69
			Calcd	69.15	7.32	3.51
VII	40	51—52	Found	69.56	7.53	3.40
			Calcd	69.71	7.56	3.39
VIII	15	134—134.5	Found	70.24	6.55	15.17
			Calcd	70.18	6.43	14.88

In these reactions, it is required that the nitrones are stable under the reaction conditions. However, most of the nitrones are susceptible to heat and

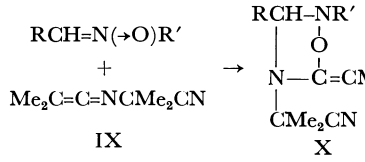
undergo isomerization to amides or decomposition.[5] Therefore, the aliphatic aldonitrones were not used.

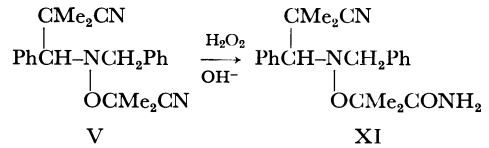
Structure of Addition Products. Elemental analyses (see Table 1), NMR and IR spectra of the addition products (IV—VIII) support the proposed structures, trisubstituted hydroxylamines. For example, the NMR spectrum of IV in deuteriochloroform showed signals at δ 1.14 (3H), 1.35 (3H), 1.75 (3H), 1.95 (3H), 3.50 (1H, broad), 6.88, 7.05, 7.08 (5H in total), and 7.19 (5H), and the IR spectrum in KBr disk showed absorption peaks at 2220 (CN), 1592, 1277, 1220, 1198, 1160, 1083, 1030, 1015, 970, 950, 925, 915, 902, 890, 764, 740, 713, and 700 cm^{-1} (phenyl and trisubstituted hydroxylamine[6]).

However, some uncertainty remains in the cases of IV, V and VIII for the following reason. It is known that the decomposition of AIBN gives the keteneimine (IX) as an intermediate.[7,8] The nitrones are well known as 1,3-dipolar substrates.[9] If the nitrones react with IX by 1,3-dipolar cycloaddition, it would be expected to yield a five-membered ring compound such as X, which has the same molecular formula as the radical addition product.



Distinction between the two or more structures was difficult from only the spectral data. Thus dimethyl-*N*-(1-cyano-1-methylethyl)keteneimine (IX) was allowed to react with the nitrone (II) at room temperature for two days. However, only the same compound as the radical addition product (V) was obtained from the reaction mixture, and it was impossible to determine the structure by this method.

The addition product (IV) gave hydrogen cyanide and acetone by heating with hydrochloric acid in ethanol. This fact indicates that one 1-cyano-1-methylethyl group was attached to the oxygen or nitrogen atom. Treatment of the compound (V) with an alkaline hydrogen peroxide gave a nitrile-amide (XI), which was inert to an alkaline hydrogen peroxide even under more vigorous conditions. If the structure (V) is correct, the structure of the nitrile-amide is assumed to be XI, because the 1-cyano-1-methylethyl group bonded to the oxygen atom seems to be sterically more favorable for hydrolysis. These facts support the structures, IV and V, rather than the structure X. However, several attempts to correlate the cyano compound (IV or V) to the methoxycarbonyl compound (VI or VII) were unsuccessful.



Compound (VI) was reduced with lithium aluminum hydride to a diol (XII). The same treatment of compound (VII) was assumed to afford diol (XIII), but pure substance was not obtained.

1-Methoxycarbonyl-1-methylethyl radicals generated from MAIB can not give a keteneimine type of intermediate. Similar addition products were also obtained by the reactions of MAIB with nitrones. As an example, the NMR spectrum of VI in carbon tetrachloride exhibited signals at δ 0.85 (3H), 1.24 (3H), 1.42 (3H), 1.52 (3H), 2.99 (3H), 3.75 (3H), 4.55 (1H, broad), 6.97 (5H), and 7.10 (5H). Therefore, it is reasonable that the addition products (IV—VIII) are trisubstituted hydroxylamines produced by the 1,3-addition of two radicals to the carbon and oxygen atoms in the nitrone system.

Addition of Other Carbon Radicals. The reaction of *N*-benzyl-α-phenylnitrone (II) with di-*t*-butyl peroxide (DTBP) in *t*-butylbenzene at 135°C for 12 hr gave only the decomposition products and no starting nitrone was recovered. In the aralkyl hydrocarbons possessing at least one α-hydrogen, however, reaction products with radicals were isolated. In these cases, nitrone II was mainly used, because it is considerably stable during heating for a long time. Toluene, ethylbenzene, isopropylbenzene, tetralin and diphenylmethane were used as aralkyl hydrocarbons. These facts show that the nitrones have an ability as a radical scavenger.

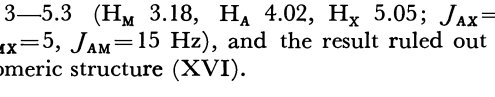
The addition products (XIV) are determined to be 1,3-radical addition products, trisubstituted hydroxylamines, from the spectral data. All the 1,3-adducts except for that derived from toluene are colorless oils.

The structures of the new aldonitrones (XV) were confirmed by NMR spectra. For instance, the NMR spectrum of XVa shows an AMX spin system (at 60 MHz in $CDCl_3$) in the region of δ 3—5.3 (H_M 3.18, H_A 4.02, H_X 5.05; $J_{AX}=9$, $J_{MX}=5$, $J_{AM}=15$ Hz), and the result ruled out an isomeric structure (XVI).



XVI XVa

The nitrones (XVa, XVb, and XVd) have the coupling constant J_{AX} of about 10 Hz, indicating that H_A and H_X are located in a *trans* position to each other.

A similar reaction was attempted with α,N-diphenylnitrone (I), using isopropylbenzene or tetralin as an aralkyl hydrocarbon. In both cases, crude 1,3-adducts were obtained as viscous oil by means of column chromatography, but attempts to isolate pure adducts were unsuccessful.

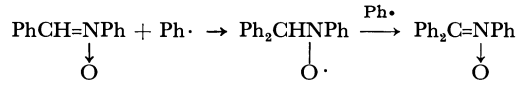
As seen from Table 2, the yields of the 1,3-adduct are affected by the amount of DTBP; that is, the yields are better in condition b), where a smaller amount of DTBP was used, than in condition a). The results indicate that the addition reaction to the nitrone competes with decomposition of the nitrones by DTBP.

Reaction of α,N-diphenylnitrone (I) with phenylazotriphenylmethane in refluxing benzene gave α,α,N-triphenylnitrone.

Formation Mechanism. It was confirmed that the rate of evolution of nitrogen gas from AIBN was almost the same either in the presence or in the absence of the nitrones. This finding shows that the nitrones react with free radicals generated from AIBN.

As the addition products are trisubstituted hydroxylamines, it is reasonable to consider that two radicals could add to the nitrones in a 1,3-fashion. It has been found that nitroxides were formed instead of expected trisubstituted hydroxylamines in the cases of the *N-t*-butylnitrones.[10] In the reaction of a cyclic nitrone, 5,5-dimethyl-Δ^1-pyrroline *N*-oxide, with AIBN, it was confirmed by ESR technique that nitroxide was the intermediate of the 1,3-adduct.[10] These facts indicate that, in the reaction of the nitrones with free radicals, radicals first add to the carbon atom and then to the oxygen atom of the nitrone system.

The fact that the reaction of α,N-diphenylnitrone (I) with phenyl radical generated from phenylazotriphenylmethane gave α,α,N-triphenylnitrone supports that a radical first adds to the carbon atom to produce nitroxide radical, from which reactive phenyl radical abstracts a hydrogen atom to afford a new ketonitrone, as shown below.



It was recently reported that the reaction of 4,5,5-trimethyl-Δ^1-pyrroline *N*-oxide (XVII) with substituted benzenediazonium salts gave the 2-aryl derivatives (XVIII) in the presence of sodium acetate, sodium sulfite and cupric sulfate.[11]

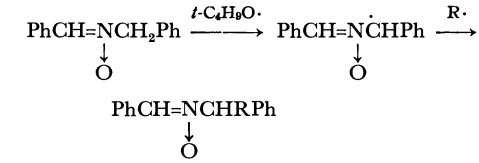
XVII XVIII

This result also supports the mechanism mentioned above.

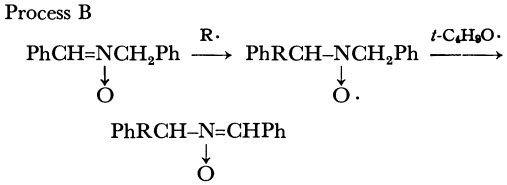
The ketonitrone such as α,*N*-dimethyl-α-phenylnitrone, did not afford a 1,3-adduct with AIBN. This result is analogous to the fact that Grignard reagents add to the aldonitrones in a 1,3-fashion but the reactions with ketonitrones produce Schiff bases.[5]

As for the mechanism of the formation of the new aldonitrones in the reactions of nitrone II with DTBP and aralkyl hydrocarbons, the following two processes might be conceivable.

Process A



Process B



If the nitroxide was assumed to be a common intermediate in formation of both nitrone and 1,3-adduct as shown in Process B, the nitroxide might afford an isomeric ketonitrone instead of the isolated aldonitrone, because abstraction of a tertiary hydrogen atom is usually easier than that of a secondary one. Therefore, it is considered that Process A might be more reasonable than Process B.

Experimental

Materials. Commercial α,α′-azobisisobutyronitrile (AIBN) was recrystallized from ethanol, mp 103—105°C. Dimethyl α,α′-azobisisobutyrate (MAIB) was prepared from AIBN,[12] mp 29—31°C. Commercial di-*t*-butyl peroxide (DTBP) was dried over anhydrous calcium chloride and distilled at 21—22°C/17 mmHg. Benzene, toluene, xylene, ethylbenzene, cumene, tetralin, and diphenylmethane were used after usual purification. Phenylazotriphenylmethane was prepared by Gomberg's method,[13] mp 111—112°C (dec). Nitrones were prepared by the methods described in literature: α,*N*-diphenylnitrone (I),[14] mp 112—114°C; *N*-benzyl-α-phenylnitrone (II),[15] mp 81—83°C; glyoxal-bis-*N*-phenylnitrone (III),[16] mp 181—182°C; α,*N*-dimethyl-α-phenylnitrone,[17] mp 113—114°C.

Addition Reactions of Nitrones with AIBN. A typical procedure is described for α,*N*-diphenylnitrone (I). Nitrone I (18.7 g, 0.1 mol) in 80 m*l* of xylene was heated on a steam bath and AIBN (15.6 g, 0.1 mol) was added little by little to the solution. The mixture was heated for 7 hr, and distilled with steam. Acetone was isolated as its 2,4-dinitrophenylhydrazone (0.22 g, 0.924 mmol, 0.46%) from the distillate. From the residue, a crude addition product (IV), which was recrystallized from methanol, was obtained in a 63% yield (19.8 g). The same product (IV) could be isolated by the following procedure. From the reaction mixture, xylene and other volatile compounds were distilled off under reduced pressure, and then petroleum ether was added to the residue. The precipitate thus obtained was recrystallized from methanol. The results are summarized in Table 1.

Addition Reactions of Nitrones with MAIB. A typical procedure is described for the reaction of *N*-benzyl-α-phenylnitrone (II). Nitrone (II) (7.0 g, 0.033 mol) and MAIB (7.0 g, 0.030 mol) in 35 m*l* of xylene were heated at 120—125°C with stirring. After the evolution of nitrogen gas had ceased, xylene and other volatile components were distilled off *in vacuo*. The residual oil was chromatographed on silica gel with petroleum ether (60—80°C). From the fractions eluted with petroleum ether, 8 g of colorless oil was obtained. The IR spectrum of this oil was different from that of the dimethyl tetramethylsuccinate derived from MAIB. After standing for ten days, it solidified, and then was recrystallized from petroleum ether. The results are summarized in Table 1.

Decomposition of Adduct (IV) with Hydrochloric Acid. IV (1.2 g) dissolved in 30 m*l* of 10% aqueous hydrochloric acid by adding ethanol was refluxed for 10 hr, during which hydrogen cyanide was detected. From the ethanol distilled from the reaction mixture, acetone was detected as its 2,4-dinitrophenylhydrazone (70 mg).

Formation of Nitrile-amide (XI) from Adduct V. V (7.0 g, 0.021 mol) was dissolved in 48 m*l* of 10% hydrogen peroxide containing 2 m*l* of 6N sodium hydroxide by adding 200 m*l* of ethanol. The solution was heated at 50°C for 2 days, and then poured into 500 m*l* of water. Crude nitrile-amide (6.5 g, 89%) was collected by filtration and recrystallized from 95% ethanol, mp 182.5—183°C. IR (in Nujol): 3500(NH), 3180(NH), 2230(C≡N), and 1690 cm^{-1} (C=O).

Found: C, 72.56; H, 7.47; N, 11.62%. Calcd for $C_{22}H_{27}N_3O_2$: C, 72.30; H, 7.45; N, 11.50%.

Formation of Diol (XII) from Adduct VI. An anhydrous ether solution of VI (2 g, 0.005 mol) and lithium aluminum hydride (0.4 g, 0.01 mol) was refluxed for 4 hr. The excess lithium aluminum hydride was decomposed by ethyl acetate and the solution was poured into alkaline water. The solution was extracted

with ether and dried over anhydrous magnesium sulfate. By chromatography on silica gel and then recrystallization from benzene and petroleum ether, 1 g of diol (XII) was obtained, mp 89—90°C. NMR (in $CDCl_3$): δ 0.84 (3H), 1.10 (3H), 1.15 (3H), 1.20 (3H), 2.98, 3.23, 3.42, 3.70, 3.88 ($2CH_2$+2OH, 6H in total), 4.08 (1H), 7.00 (5H), and 7.12 (5H).

Found: C, 73.14; H, 8.58; N, 4.07%. Calcd for $C_{21}H_{29}NO_3$: C, 73.43; H, 8.51; N, 4.08%.

Reaction of Nitrone II with Aralkyl Hydrocarbons and DTBP. A typical procedure is described for the reaction of II with ethylbenzene and DTBP. A mixture of II (32.11 g, 0.01 mol), ethylbenzene (21.2 g, 0.2 mol) and DTBP (2.90 g, 0.02 mol) was heated at 135°C for 12 hr under nitrogen with frequent shaking. Ethylbenzene and other volatile products were then distilled off under reduced pressure. The residue was chromatographed on silica gel. With petroleum ether-benzene, 2,3-diphenylbutane was eluted and then 2.56 g of addition product (XIVb) was eluted. With benzene-ethyl ether, nitrone (XVb) (0.18 g) was eluted. After XVb had been eluted, a small amount of II was eluted. The crude addition product (XIVb) was diluted with ethyl ether dried over anhydrous sodium sulfate. Ether was then evaporated and XIVb was dried *in vacuo* under nitrogen. The crude nitrone (XVb) was recrystallized from benzene and petroleum ether. The results are summarized in Tables 2 and 3.

Reaction of Nitrone I with Phenylazotriphenylmethane. Phenylazotriphenylmethane (7.4 g, 0.021 mol) was allowed to react with a solution of the nitrone I (4.2 g, 0.021 mol) in 80 m*l* of benzene for 2 hr at 70—80°C with stirring under argon atmosphere. After addition of petroleum ether, precipitates thus obtained (mainly α,α,N-triphenylnitrone) were recrystallized from benzene as white needles, mp 216—219°C (dec.) (lit, 216—217°C (dec.)[18] or 220°C[19]). Yield 2.2 g (38%) (Found: C, 83.64; H, 5.72; N, 5.09%). This reaction was carried out qualitatively, and no further treatment was done.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 860—863 (1970)

Reactions of Nitrones with Free Radicals. II. Formation of Nitroxides

Michiko Iwamura and Naoki Inamoto

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received August 16, 1969)

Reactions of *N*-*t*-butylaldonitrones with free radicals gave stable nitroxides, one of which was isolated in pure state. The stability of the nitroxides was explained by the steric effect around the nitrogen and α-carbon atoms. In the reaction of 5,5-dimethyl-Δ^1-pyrroline *N*-oxide with AIBN, nitroxide was detected by ESR technique, and 1,3-adduct and ketonitrone were isolated from the reaction mixture. From the results, it was confirmed that nitroxide is the intermediate of the 1,3-adduct formation and that a radical first adds to the carbon atom and then adds to the oxygen atom of the nitrones.

In the reactions of the aldonitrones with several carbon radicals, we have found new radical 1,3-addition to the carbon and oxygen atoms of the nitrone system.[1] We found that *N*-*t*-butylaldonitrones and the related compounds reacted with carbon radicals to give extremely stable nitroxides. This paper describes the formation of nitroxides by the addition reactions to the nitrones.[2]

Results and Discussion

Formation of Nitroxides from *N*-*t*-Butylaldonitrones.

The reaction of α,α′-azobisisobutyronitrile (AIBN) with *N*-*t*-butyl-α-phenylnitrone (I) in xylene at 110°C gave *N*-*t*-butyl-*N*-[α-(1-cyano-1-methylethyl)benzyl]nitroxide (III) in a 3.2% yield. Analysis of the ESR spectrum and elemental analysis support the structure (see Table 1 and Experimental). The nitroxide (III) is quite stable to a diffused light, at temperatures below 100°C and also during chromatography on alumina. No change was observed after over one year in air. However, one drop of hydrochloric acid or aqueous sodium hydroxide quenches ESR signals. Addition of one drop of benzyl mercaptan to a benzene solution of III gave almost no change in ESR spectrum, but, when the mixture was warmed for a little while, ESR signals were almost quenched.

The reaction of nitrone I with dimethyl α,α′-

1) a) M. Iwamura and N. Inamoto, This Bulletin, **40**, 702 (1967); b) *ibid.*, **43**, 856 (1970).

2) Preliminary report: M. Iwamura and N. Inamoto, *ibid.*, **40**, 703 (1967).

azobisisobutyrate (MAIB), and the reactions of glyoxal-bis-*N*-*t*-butylnitrone (II) with AIBN or MAIB under similar reaction conditions also gave stable nitroxides (IV—VI), which were detected by ESR spectra but not isolated in pure state. The reaction of nitrone I with tetraphenylsuccinodinitrile at 160°C in *t*-butylbenzene similarly produced the nitroxide VIII. The data are summarized in Table 1.

Table 1. ESR spectra of nitroxide radicals

Reactant	Nitroxide	a_N*1	a_H*1	Solvent
I+AIBN	III*2	14.6	3.07	THF
I+MAIB	IV	13.4	3.7	Xylene

I+$(Ph_2CCN)_2$	VIII	14.0	8.7	*t*-C_4H_9Ph

*1 In gauss. *2 g=2.0044.
*3 Not determined because of broadening of signals.

The reaction of nitrone I with di-*t*-butyl peroxide (DTBP) and cumene also gave stable nitroxide (VII) which was detected by means of ESR spectroscopy (Table 1). In the cases of toluene, ethylbenzene and tetralin in the place of cumene, however, ESR spectra showed only triplet, whose splitting constants (a_N) are 14.7, 14.4 and 14.4 gauss, respectively. The structures of the nitroxides remain uncertain. A characteristic common to these cases is that the radicals generated from aralkyl hydrocarbons are RR'ĊH; always having at least one α-hydrogen atom. As the nitroxides (IX) are considered to be the intermediate, abstraction of the β-hydrogen atom from the nitroxides (IX) would be easier than that from the starting hydrocarbon $RR'CH_2$, and thus the following reactions would give the nitroxide (X) possessing no α-hydrogen atom.

$$RCH{=}N(\rightarrow O)\text{-}t\text{-}C_4H_9 + R'\cdot \rightarrow R'RCH\text{-}N(t\text{-}C_4H_9)O\cdot$$

I: R=Ph
II: R=*t*-C_4H_9-N(→O)=CH-
III: R=Ph, R'=Me_2CCN
IV: R=Ph, R'=Me_2CCO_2Me
V: R=*t*-$C_4H_9N(\rightarrow O)$=CH-, R'=Me_2CCN
VI: R=*t*-$C_4H_9N(\rightarrow O)$=CH-, R'=Me_2CCO_2Me
VII: R=Ph, R'=$PhCMe_2$
VIII: R=Ph, R'=Ph_2CCN

$$RR'\overset{\beta}{C}H\text{-}\overset{\alpha}{C}HPh\text{-}N(t\text{-}C_4H_9)\text{-}O\cdot \xrightarrow{t\text{-}C_4H_9O\cdot}$$

IX

$$RR'\dot{C}\text{-}CHPh\text{-}N(t\text{-}C_4H_9)\text{-}O\cdot \xrightarrow{t\text{-}C_4H_9O\cdot}$$

$$RR'C{=}CPh\text{-}N(t\text{-}C_4H_9)\text{-}O\cdot$$

X

Therefore, it is probable that the detected nitroxides may be the nitroxides X.

Janzen and Blackburn[3] recently reported detection and identification of short-lived free radicals by ESR trapping technique with *N*-*t*-butyl-α-phenylnitrone (I), using our preliminary results.[2] Vincent and Grubbs also reported the formation of the corresponding nitroxide by the reaction of *N*-benzhydryl-α,α-diphenylnitrone with AIBN.[4]

It is known that the reactions of the nitroso compounds with free radicals give trisubstituted hydroxylamines,[5] and that the nitroxides are the intermediate in the above addition reactions.[6]

$$R\text{-}N{=}O + R'\cdot \rightarrow RR'N\text{-}O\cdot \xrightarrow{R'\cdot} RR'N\text{-}OR'$$

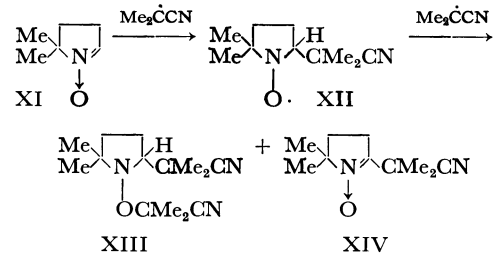
Thus, it is considered that the reactions of the nitrones with free radicals are analogous to those of the nitroso compounds.

After a xylene solution of *N*-benzyl-α-phenylnitrone or glyoxal-bis-*N*-phenylnitrone was heated with AIBN at 130°C for 5 min, ESR spectra were measured immediately, but there was no paramagnetic species, indicating the very short lifetime of the corresponding nitroxides.

Reaction of Δ^1-Pyrroline *N*-Oxides with AIBN. The reaction of 5,5-dimethyl-Δ^1-pyrroline *N*-oxide (XI) with AIBN in xylene at 105—110°C gave a 1,3-adduct (XIII) and a new ketonitrone (XIV). Their yields are listed in Table 2.

Table 2. Reaction of XI with AIBN

XI (g)	AIBN (g)	Xylene (ml)	Products (%) XIII	XIV
5.65	10	10	47.5	23
2.82	5	10	44.2	6.5



The reactions of 2,4,4-trimethyl- (XV) and 3,3,5,5-tetramethyl-Δ^1-pyrroline *N*-oxides (XVI) with AIBN gave no radical addition product.

XV XVI XVII

It was shown by ESR technique that there were two kinds of nitroxides in the reaction mixture of the nitrone (XI) with AIBN. The ESR spectrum of one of the nitroxides showed doublet of triplets ($a_N=14.6$, $a_H=20.4$ gauss), from which the structure was confirmed to be XII by comparison with the hyperfine coupling constants ($a_N=14.9$, $a_H=19.6$ gauss) of pyrrolidine-*N*-oxyl (XVII).[7] Although the nitroxide (XII) was stable at least for two days, it was not isolated by column chromatography on silica gel. The other nitroxide, which is more stable, showed nitrogen splitting constant of 14.6 gauss and no further splitting was observed. The structure remains uncertain.

The results in Table 2 indicate that the radical addition to the nitrone is more favorable than the disproportionation of XII in a lower concentration, and that radical addition is almost independent of concentration. It is plausible that the nitroxide is the intermediate in the radical 1,3-additions and that a radical adds first to the carbon atom of the nitrone group and then to the oxygen atom.

Since ketonitrones did not react with free radicals,[1b] we see that nitrone XV did not give addition product. In the case of nitrone (XVI), it is assumed that the geminal dimethyl groups at the C-3 atom sterically hinder the addition of a radical to the C-2 atom, although the nitroxide derived from XVI would be considered to be very stable if it was once formed.

Stability of Nitroxides. Unhindered aliphatic nitroxides such as dimethylnitroxide[7] or diethylnitroxide[8] are known to decompose through disproportionation. The nitroxides containing aromatic rings such as *N*-*t*-butyl-*N*-phenylnitroxide[9] and diphenylnitroxide[10] decompose to disproportionation products by oxygen-atom transfer.

The stability of bis(trifluoromethyl)nitroxide[11] is attributed to impossibility of disproportionation. The stability of nitroxides such as di-*t*-butylnitroxide[12] and 2,2,5,5-tetramethyl-4-oxopiperidine-*N*-oxyl[13] is attributed to steric effect by bulky groups attached to the nitrogen atom.

It is known that nitroxides having at least one α-hydrogen atom may disproportionate to a nitrone and a hydroxylamine.[7] Recently, it was reported that norpseudopelletierine-*N*-oxyl[14] was stable in spite of the presence of α-hydrogen atom. The reason is attributed to prohibition from the disproportionation by Bredt's rule. Therefore, it is noteworthy that the nitroxides (III—VIII) we obtained are quite stable in spite of the presence of α-hydrogen atom. Thus these nitroxides are a new type of stable nitroxides, and regarded as the first examples of nitroxides prohibited from disproportionation because of a spatial congestion around the α-hydrogen atom.

Although nitroxide XII is similar to the nitroxides (III—VIII) it is less stable. This indicates that the steric effect around the α-carbon atom in XII might be not so large as III—VIII, because the nitroxide group of XII is fixed in the ring.

In conclusion, the aldonitrones react with free radicals to give trisubstituted hydroxylamines as addition product or stable nitroxides, and the difference seems to be explicable in terms of the steric effect around the nitrogen and α-carbon atoms of the nitrone group.

Experimental

Materials. The nitrones were prepared by the methods in literature. *N*-*t*-Butyl-α-phenylnitrone (I),[15] mp 75—76°C; glyoxal-bis-*N*-*t*-butylnitrone,[15] mp 193—194°C; 5,5-dimethyl-Δ^1-pyrroline *N*-oxide,[16] bp 75°C/1.5 mmHg; 2,4,4-trimethyl-Δ^1-pyrroline *N*-oxide,[16] bp 92—95°C/3 mmHg; 3,3,5,5-tetramethyl-Δ^1-pyrroline *N*-oxide,[16] mp 31—32°C. Tetraphenylsuccinodinitrile was prepared by Kharasch's method,[17] mp 217—218°C (dec.).

***N*-*t*-Butyl-*N*-α-(1-cyano-1-methylethyl)benzylnitroxide (III).** Nitrone (I) (4.5 g, 0.025 mol) and AIBN (5 g, 0.03 mol) in xylene (30 ml) were heated at 115—120°C until the evolution of nitrogen ceased. Xylene was evaporated *in vacuo* and the reaction mixture was heated at 100—110°C under a pressure of 2 mmHg in order to sublimate most of tetramethylsuccinodinitrile derived from AIBN. The residue was chromatographed on silica gel. Nitroxide (III) was eluted with petroleum ether (bp 30—60°C), and recrystallized from methanol as red needles, mp 121—122°C. λ_{max}^{EtOH}: 437 mμ ($\varepsilon=22$).*1 Yield 0.2 g (3.2%).

Found: C, 73.25; H, 8.70; N, 11.47%. Calcd for $C_{15}H_{21}N_2O$: C, 73.43; H, 8.63; N, 11.42%.

(THF) is listed in Table 1.

Solutions of Nitroxides. The solutions of nitroxides were prepared by the reaction of *N*-*t*-butylaldonitrones with an equimolar AIBN or MAIB in a suitable solvent at 110—120°C until the evolution of nitrogen ceased. In the cases of the reactions with DTBP and aralkyl hydrocarbons, the solutions of nitroxides were prepared by the reaction of nitrone I (*ca.* 0.2 g) with an aralkyl hydrocarbon (5 m*l*) and DTBP (1 m*l*) at 130—140°C for 1.5 hr. In the reaction of nitrone (I) with tetraphenylsuccinodinitrile, the equimolar mixture was heated in *t*-butylbenzene at 160°C for 2 hr. After the reaction had completed, the reaction mixture was transferred to an ESR sampling tube and then ESR spectra were taken after evacuation. To avoid any broadening due to dipole-dipole interaction, the reaction mixture was sometimes diluted with the dry solvent.

ESR Measurement. ESR spectra were taken on an X-band TES-3B spectrometer. Calibration was carried out with the NMR signal of water.

Reaction of 5,5-Dimethyl-Δ^1-pyrroline *N*-Oxide (XI) with AIBN. A typical procedure is as follows. *N*-Oxide (5.65 g, 0.05 mol) and AIBN (10 g, 0.06 mol) were dissolved in 10 m*l* of xylene and the solution was heated at 105—110°C with stirring until the evolution of nitrogen ceased. Xylene was evaporated *in vacuo* and the reaction mixture was chromatographed on silica gel. With petroleum ether, 7 g of the 1,3-adduct (XIII) (47.5%) was eluted. Tetramethylsuccinodinitrile (3.8 g) was eluted with benzene. A small amount of the starting *N*-oxide was eluted with ether, and the nitrone (XIV) (2.7 g, 23%) was eluted with acetone. The crude 1,3-adduct (XIII) was recrystallized from benzene, mp 88—88.5°C. NMR (in CCl_4): δ 1.23 (3H), 1.32 (3H), 1.35 (3H), 1.45 (3H), 1.69 (3H), 1.74 (3H), 1.2—1.8 (4H, broad), and 3.34 (1H, multiplet).

Found: C, 67.45; H, 9.33; N, 16.92%. Calcd for $C_{14}H_{23}N_3O$: C, 67.43; H, 9.30; N, 16.85%.

The crude nitrone (XIV) was recrystallized from benzene and methanol, mp 93.5—94.5°C. NMR (in CCl_4): δ 1.35 (6H), 1.70 (6H), 2.02 (2H, triplet, J=7.5 Hz), and 2.78 (2H, triplet, J=7.5 Hz).

Found: C, 66.83; H, 8.95; N, 15.43%. Calcd for $C_{10}H_{16}N_2O$: C, 66.63; H, 8.95; N, 15.55%.

Aromatic Substitution of Olefin. X. Formation of Biphenyl Derivatives by Means of Olefin-Palladium Chloride Complexes and Silver Nitrate*1

Yuzo FUJIWARA, Ichiro MORITANI, Katsuhiko IKEGAMI, Ryohei TANAKA and Shiichiro TERANISHI

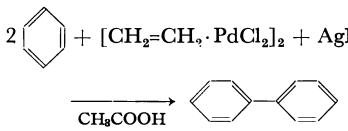
Department of Chemistry, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka

(Received August 20, 1969)

The system, olefin-palladium chloride complex-silver nitrate has been shown to cause the oxidative coupling reaction of the aromatic compounds to afford biphenyl derivatives. The mechanism was also discussed in connection with the aromatic substitution of olefins by palladium salts.

We have reported a novel method of arylation by substitution of aromatic compounds for hydrogen on the double bond of the olefin.[1)]

In the course of this work, it has been found that the system, olefin-palladium(II) chloride complex-silver(I) nitrate does cause the oxidative coupling reaction of aromatic compounds to give biaryl derivatives easily.



On the formation of biaryl derivatives by palla-

dium salts, van Helden and Verberg[2] have reported that benzene gives biphenyl in the presences of palladium(II) chloride and sodium acetate in an 82% yield, and Davidson and Trigg[3] have described a similar biphenyl formation by palladium(II) acetate and that when perchloric acid is used with palladium(II) acetate, the yield of biphenyl increases up to 55%.

We have investigated the biaryl derivative formation reaction involving palladium chloride complexes and silver nitrate. Interesting aspects of the present reaction are that the olefin palladium(II) chloride complex and silver(I) nitrate are employed together and that the yield of biphenyl is almost quantitative (99%) with respect to palladium(II) when the ethylene-palladium(II) chloride complex is used with silver(I) nitrate.

The present paper reports a study of the coupling reaction of benzene derivatives by means of the olefin-palladium(II) chloride complex and silver(I) nitrate.

Results and Discussion

In the course of the study on the aromatic substitution of olefin, we have performed the reaction of the ethylene-palladium(II) chloride complex with benzene in the presence of silver(I) nitrate in a hope of preparing styrene directly.[4] Unexpectedly, no styrene was formed, but biphenyl was obtained in almost quantitative yield[5] with a very small amount of chlorobenzene. The result is reproducible on triplicate reactions. This higher yield of biphenyl comparing to van Helden (82%) and Davidson's results (55%) prompted us to investigate the oxidative coupling of benzene derivatives in the system, olefin-palladium(II) chloride complex-silver(I) nitrate in detail.

The oxidative coupling of benzene derivatives takes place in the homogeneous solution of olefin-palladium(II) chloride complexes, silver(I) nitrate (equal mol equivalent to Pd(II) in the olefin-palladium complex)[6] and the benzene derivatives (large excess) in acetic acid. The solution is stirred in the presence of air for 20 hr to give several per cent to 99% yield of biphenyl derivatives.

Effect of Olefin-$PdCl_2$ Complex. As the ethylene complex-silver nitrate system affords biphenyl from benzene quantitatively, the effect of the similar olefin complexes such as styrene or cyclohexene has been investigated under the same condition. Table 1 shows the yields of biphenyl.

TABLE 1. BIPHENYL FORMATION BY OLEFIN-PALLADIUM CHLORIDE COMPLEX-SILVER NITRATE SYSTEM

Olefin-complex	Biphenyl yield, %[a]
$[CH_2{=}CH_2 \cdot PdCl_2]_2$	99[b]
	68[c]
	3[d]
$PdCl_2$	40

a) Yields are based on palladium(II) of the complex.
b) A trace amount of chlorobenzene was also obtained.
c) A 22% yield of 1-phenylethyl acetate and a 7% yield of tetraphenylethylene were also formed.
d) A 9% yield of isomeric terphenlys was also obtained.

It can be seen that the yield of biphenyl decreases in the following sequence:

ethylene > styrene > cyclohexene

That this sequence is consistent with the stability of the olefin-complex[7] suggests that the reactivity depends upon the ease with which the olefin ligand on Pd(II) exchanges with benzene. Table 1 also shows that biphenyl can be formed in the presence of $PdCl_2$ and $AgNO_3$, but the yield is low indicating

TABLE 2. EFFECT OF METAL SALTS[a]

$PdCl_2$	Metal slat	Biphenyl yield, %[b]
○	$AgNO_3$	40
○	×	×
×	$AgNO_3$	×
○	AgOAc	45
○	Ag_2O	24
○	HgOAc	23
○	$Cu(OAc)_2$	22

a) Reactions were carried out at 80°C with stirring for 20 hr, charging 25 mmol of $PdCl_2$, an equal mole amount of $AgNO_3$, 280 m*l* of benzene, and 40 m*l* of acetic acid.
b) Yields are based on palladium (II) chloride.

2) R. van Helden and G. Verberg, *Rec. Trav. Chim. Pays-Bas*, **84**, 1263 (1965).
3) J. M. Davidson and C. Trigg, *Chem. Ind.* (London), **1966**, 457.
4) It has been known that styrene can be prepared directly from ethylene and benzene by palladium acetate.[1f]
5) Interestingly, in the absence of siliver nitrate, no biaryl derivatives are formed except the arylated products in the aromatic substitution of olefins by means of palladium salts.[1]
6) When 1/2 mol equivalent of $AgNO_3$ to Pd(II) was used, a greenish black complex was obtained after the reaction. As it has a function to cause the coupling of benzene, it can be considered to be one of the reaction intermediates. Owing to the insolubility, purification is not practical, but approximate composition is $Ag_2Pd_2(OAc)_2Cl_4$.
7) M. S. Kharasch, R. C. Seiler and F. R. Mayo, *J. Amer. Chem. Soc.*, **60**, 882 (1938).

that the ethylene-$PdCl_2$ complex is the most effective for the oxidative coupling of benzene.

Effect of Metal Salts. Further, the effect of metal salts was studied. The results are shown in Table 2.

It can be seen that $PdCl_2$ alone or $AgNO_3$ alone can not effect the coupling of benzene, indicating that coexistence of $PdCl_2$ and $AgNO_3$ is necessary for the present reaction.[8] Of metal salts, mercuric or copper salts, rather than $AgNO_3$ can also act as cocatalysts but silver salts are the most effective. From these results, it becomes clear that the system, ethylene-$PdCl_2$ complex-$AgNO_3$ is the most useful one for the oxidative coupling of benzene.

Now, we have investigated the coupling reactions of benzene derivatives using the present system.

Reaction of Benzene Derivatives. The coupling reactions of toluene, chlorobenzene, nitrobenzene, and *p*-xylene are carried out using the ethylene-$PdCl_2$-$AgNO_3$ system at 80°C. Table 3 summarizes the results.

Table 3. Coupling reaction of benzene derivatives

Benzene derivative	Product, %[a]
Toluene	 61 10 8
Nitrobenzene	 60 21
Chlorobenzene	 70
p-Xylene	 38 25 13

a) Yields are based on palladium (II) of the complex.

In the cases of toluene and chlorobenzene, five isomeric dimethylbiphenyls[9] and dichlorobiphenyls are formed in 61% and 70% yields respectively. Contrary to this, nitrobenzene gives only *m,m'*-dinitrobiphenyl as the coupling product. *p*-Xylene also undergoes a coupling reaction in lower yield (38%) due to the steric hindrance of methyl groups. From the data in Table 3, it seems that the reactivity of benzene derivatives such as toluene or nitrobenzene will not be influenced by the substituent. In order to clarify this point, the relative reactivities were examined by competitive reactions. The typical examples are shown in Table 4.

Table 4. Competitive reactions of some benzenes[a]

Benzene derivative	Product ratio (mole)
	 1.0 0.24
	 1.0

a) Reactions were performed at 80°C with stirring for 20 hr, charging an equal amount (1.5 mol) of two benzene derivatives, the ethylene-$PdCl_2$ complex (25 mmol as a monomer), $AgNO_3$ (25 mmol), and acetic acid (40 m*l*).

It can be seen that the yield of mononitrobiphenyl decreases sharply and none of the dinitro derivative was detected in the reaction mixture. This result shows that the substituent on a benzene ring excerts an effect, that is, a methyl group (electron donating) increases the reactivity, and a nitro group (electron attracting) decreases it.[2] This is marked contrast to the fact that the substituent on a benzene ring does not influence on the reactivity in the aromatic substitution of olefins by palladium salts.[1h]

Finally, the mechanism of the present coupling reaction appears to be closely related to the aromatic substitution of olefins proposed in a previous paper.[1i] The reaction may proceed through a sigma bonded benzene-palladium complex.[10] This benzene-palladium sigma bond formation step is fast in the aromatic substitution of olefins and hence the substituent did not influence the reactivity.[1h] However, in the present case, this must be included in the rate determining step, and therefore, the reactivity becomes a function of the substituent.

The present reaction provides a convenient method for the synthesis of biphenyl derivatives.

Experimental

All melting points and boiling points are uncorrected.

8) That $PdCl_2$ without $AgNO_3$ or NaOAc can not cause both the oxidative coupling and the aromatic substitution of olefins shows the role of $AgNO_3$ or NaOAc to be that Ag^+ or Na^+ abstracts the Cl^- ligand from the Pd(II) and then, it becomes possible for benzene to coordinate with Pd(II).[1f]

10) J. M. Davidson and C. Trigg, *J. Chem. Soc., A*, **1968**, 1324.

Infrared spectra were recorded by a Hitachi EPI-S2 IR spectrometer and UV spectra were recorded on a Hitachi EPS-2U spectrophotometer. The NMR spectra were obtained by a Japan Electron Optics JNM-4H-100 spectrometer using tetramethylsilane as an internal standard. Chemical shifts are given in τ units together with splitting patterns and relative integrated area. Analyses of products were carried out by a column chromatograph or a Yanagimoto GCG-3 gas chromatograph using an Apiezon L column. Identities with the products formed were proved by mixture melting point, IR and NMR comparison with authentic samples. Olefin-$PdCl_2$ complexes used were prepared according to the method described by Kharasch *et al.*[7] Benzene, toluene, *p*-xylene were refluxed with sodium metal and distilled. Chlorobenzene and nitrobenzene were dried over Na_2SO_4 and distilled. Acetic acid was dried over P_2O_5 and distilled.

Coupling of Benzene with Ethylene-$PdCl_2$ Complex and $AgNO_3$. In a 500-m*l*, three necked flask provided with a condenser and a stirrer, was placed a solution of 4.13 g (25 mmol as a monomer) of the ethylene-complex, 4.25 g (25 mmol) of $AgNO_3$, 280 m*l* of benzene, and 40 m*l* of acetic acid. The solution was stirred for 20 hr at 80°C. During the reaction, ethylene gas, hydrogen chloride gas, and nitrogen dioxide gas evolved. The resulting mixture was filtered to remove palladium metal and AgCl, and the filtrate was poured into water and then the organic layer was separated. The organic layer was treated with aqueous sodium bicarbonate solution, washed with water to free it from acetic acid and then dried over Na_2SO_4. After evaporation of the benzene, the residue was chromatographed on a column of alumina. Elution with petroleum ether and recrystallization yielded 3.81 g, mp 69—70°C (lit,[11] 70°C) (99%, based on Pd(II) in the complex) of a colorless crystalline material which was assigned as biphenyl by comparison of the IR spectra and mixture melting point. IR (Nujol): 2995, 1575, 1480, 900, 728, and 695 cm^{-1}. Found: C, 93.38; H, 6.62%. Calcd for $C_{12}H_{10}$: C, 93.50; H, 6.52%.

From the benzene evaporated, a trace amount of chlorobenzene was also detected by glpc.

Coupling of Benzene with Styrene-$PdCl_2$ Complex and $AgNO_3$. The same procedure was followed as above, charging 25 mmol (as a monomer) of the syrene-complex, 25 mmol of $AgNO_3$, 280 m*l* of benzene, and 40 m*l* of acetic acid. After work-up as described above there were obtained biphenyl (68%), tetraphenylethylene (7%),[1f] mp 219.5—221°C (lit,[12] 223—224°C) and 1-phenylethyl acetate (22%).[1b]

Coupling of Toluene with Ethylene-$PdCl_2$ Complex and $AgNO_3$. The same procedure was followed as above. After evaporation of toluene, the residue was distilled under reduced pressure (10 mmHg), to give 0.45 g (10%) of the colorless liquid, bp 120—121°C (10 mmHg) which was assigned as *p*-(1-acetoxylethyl)toluene. IR (neat): 3015, 1750, 1240, 1085, 890, 820, and 745 cm^{-1}. NMR (CCl_4): 2.9 (multiplet, 4), 4.3 (quadruplet, 1), 7.8 (singlet, 3), 8.1 (singlet, 3), 8.6 (doublet, 3). Found: C, 74.28; H, 7.91%. Calcd for $C_{11}H_{14}O_2$: C, 74.15; H, 7.86%.

The distillation residue was chromatographed on a column of alumina. Elution with *n*-hexane yielded a colorless substance which crystallized partly. Recrystallization from ether gave 0.86 g (19%) of *p,p'*-dimethylbiphenyl, mp 123—124°C (lit,[13] 121°C). IR (Nujol): 3020, 1500, 1210, 810 cm^{-1}. Found: C, 92.51; H, 7.63%. Calcd for $C_{14}H_{14}$: C, 92.26; H, 7.74%.

The oil part (1.91 g, 42%) was subjected to gas chromatograph (Apiezon L, 2m, 190°C) to detect four components. The four components were separated into A and B by preparative glpc.

The component A: IR (neat): 3040, 1600, 1480, 1100, 820, 755, 726, 708 cm^{-1}. Found: C, 92.32; H, 7.68%. Calcd for $C_{14}H_{14}$: C, 92.26; H, 7.74%.

The component B: IR (neat): 3040, 1610, 1480, 1092, 880, 820, 775, 700 cm^{-1}. Found: C, 92.40; H, 7.78%. Calcd for $C_{14}H_{14}$: C, 92.26: H, 7.74%. From these results, the oil part (A and B) can be considered to be a mixture of four isomeric dimethylbiphenyls. Further elution with benzene afforded 0.25 g (8%) of isomeric chlorotoluenes, mp 153—158°C. IR (Nujol): 3020, 1600, 1475, 1080, 885, 810, 750, 715 cm^{-1}. Found: C, 66.30; H, 5.51; Cl, 28.20%. Calcd for C_7H_7Cl: C, 66.41; H, 5.53; Cl, 28.06%.

Coupling of Chlorobenzene with Ethylene-$PdCl_2$ Complex and $AgNO_3$. The same procedure was followed as above. After evaporation of the chlorobenzene, the residue was chromatographed on a column of alumina. Elution with petroleum ether gave 0.78 g (14%) of a crystalline material which was assigned as *p,p'*-dichlorobiphenyl by comparison with an authentic sample. Mp 147—148°C (EtOH) (lit,[14] 148—149°C), IR (Nujol): 3050, 1590, 1090, 1000, 810, 700 cm^{-1}. Found: C, 64.65; H, 3.70; Cl, 32.12%. Calcd for $C_{12}H_8Cl_2$: C, 64.57; H, 3.60; Cl, 31.84%. Further elution with petroleum ether resulted 3.12 g (56%) of a liquid substance which was gas chromatographed to detect four components. The four components were separated into C and D by preparative glpc.

The component C: IR (neat): 3000, 1575, 1030, 825, 785, 750, 700 cm^{-1}. Found: C, 64.77; H, 3.48; Cl, 32.02%. Calcd for $C_{12}H_8Cl_2$: C, 64.57; H, 3.60; Cl, 31.84%.

The component D: IR (neat): 3000, 1580, 1555, 1450, 1085, 1055, 750, 700 cm^{-1}. Found: C, 65.00; H, 3.64; Cl, 32.16%. Calcd for $C_{12}H_8Cl_2$: C, 64.57; H, 3.60; Cl, 31.84%. From these results, the liquid substance (C and D) can be considered to be a mixture of four isomeric dichlorobiphenyls.

Coupling of Nitrobenzene with Ethylene-$PdCl_2$ Complex and $AgNO_3$. The products were *m,m'*-dinitrobiphenyl (60%) and *m*-chloronitrobenzene (21%): *m,m'*-Dinitrobiphenyl: mp 201—202°C (*n*-hexane-benzene) (lit,[14] 198.5—199°C). IR (Nujol): 2950, 1515, 1340, 1260, 1100, 855, 800, 726, 700 cm^{-1}. Found: C, 59.08; H, 3.28; N, 11.49%. Calcd for $C_{12}H_8N_2O_4$: C, 59.02; H, 3.28; N, 11.48%.

Coupling of *p*-Xylene with Ethylene-$PdCl_2$ Complex and $AgNO_3$. The products were 2,5,2',5'-tetramethylbiphenyl (38%), 2-chloro-*p*-xylene (25%) and

β-Ferrocenyl-α,β-unsaturated Ketones. II.[1] The Reduction of β-Ferrocenyl-α,β-unsaturated Ketones and Their Relative Reactivities

Hiromichi KONO, Masayoshi ISHIGE, Koji SAKAI, Mikio SHIGA, Izumi MOTOYAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received August 21, 1969)

The catalytic reduction of several β-ferrocenyl-α,β-unsaturated ketones was investigated using Urushibara nickel A (U-Ni-A) or precipitated nickel (ppt-Ni) as the catalyst, and their relative reactivities toward the catalytic reduction were discussed in comparison with those of the phenyl analogs. Some anomalies observed in the NMR spectra of the reduction products was also discussed.

The preceding paper[1] in this series has reported on synthetic and spectroscopic studies of β-ferrocenyl-α,β-unsaturated ketones. This paper will deal with a study of the reduction of these unsaturated ketones and related compounds. Although a considerable number of works on the hydrogenation of α,β-unsaturated ketones have previously reported in some detail,[2-5] the reduction of the unsaturated ketones conjugated with the ferrocene group has scarcely been studied at all. Recently, the reduction of various organic compounds with water as a hydrogen donor in the presence of precipitated metal as a catalyst has been extensively investigated in our laboratory.[6,7] When 1,3-diferrocenyl-2-buten-1-one (**1**) was refluxed in a mixture of water and dioxane in the presence of precipitated nickel (ppt-Ni in abbreviation), 1,3-diferrocenyl-1-butanone was obtained almost quantitatively, while the reduction of dypnone (**2**) under the same conditions yielded 1,3-diphenylbutane exclusively. This interesting

observation prompted us to more detailed investigations of the catalytic reduction of β-ferrocenyl-α,β-unsaturated ketones and related compounds in the hope of getting some information about the particular effect of the ferrocenyl group on the conjugated system.

Catalytic Hydrogenation of β-Ferrocenyl-α,β-unsaturated Ketones. β-Ferrocenyl-α,β-unsaturated ketones were hydrogenated with Urushibara nickel A (abbreviated as U-Ni-A)[8] under an atmospheric pressure of hydrogen at room temperature, using dioxane as the solvent. When the reaction was stopped after the absorption of equimolar hydrogen, the corresponding saturated ketones were obtained in most cases. The reaction conditions and the results are listed in Table 1. The products were purified by chromatography on alumina, and they were identified by means of elemental analyses and by a study of their IR and NMR spectra. The NMR data are summarized in Table 2.

e) J=8 Hz.

The hydrogenation of 4-ferrocenyl-3-buten-2-one (**3**), 1-ferrocenyl-1-penten-3-one (**4**), and 1-ferrocenyl-5-methyl-1-hexen-3-one (**5**) gave the corresponding saturated ketones in good yields. The C=C stretching absorption bands at 1615 and 1591 cm^{-1} and the C=O stretching absorption bands at 1665 and 1684 cm^{-1}, due, respectively, to *s-trans* and *s-cis* isomerism observed in the spectrum of the unsaturated ketone (**3**), completely disappear in that of the hydrogenation product (**3a**), in which only the C=O absorption band at 1703 cm^{-1} appears.[1)]

The hydrogenation of 1,5-diferrocenyl-1,4-pentadien-3-one (**6**) proceeded at only a slow rate and gave a dark orange reaction mixture, the chromatographic separation of which on alumina gave 1-ferrocenyl-1-penten-3-one (**6a**) from the first fraction in an 18.1% yield and 1-ferrocenyl-3-pentanone (**6b**) from the second one in a 35.1% yield. There is some obscurity in the structural elucidation of **6** in terms of its IR spectrum, since the ethylenic absorption band at 1614 cm^{-1} was observed to be unusually stronger (ε'*1=1740/2) than the carbonyl absorption bands at 1649 (ε'=416) and 1665 cm^{-1}. However, the spectroscopic data of the reduction products, **6a** and **6b**, provided decisive evidence as to the cross-conjugated structure for the original ketone (**6**); that is, distinct carbonyl absorption bands were observed at 1660 and 1690 cm^{-1} for **6a**, and at 1710 cm^{-1} for **6b**.

The reduction of 2-(ferrocenylmethylene)cyclohexanone (**7**) afforded 2-(ferrocenylmethyl)cyclohexanone (**7a**), mp 75—77°C, in a 41% yield, whereas 2,6-di(ferrocenylmethylene)cyclohexanone (**8**) could not be hydrogenated under the conditions employed here, probably because of steric hindrance to the adsorption of the unsaturated system on the surface of the calalyst.

1,3-Diferrocenyl-2-buten-1-one (**1**) was slowly hydrogenated to the corresponding saturated ketone, 1,3-diferrocenyl-1-butanone (**1a**), in a 30% yield under the conditions shown in Table 1.

An interesting result was obtained with regard to the NMR signal of four methylene protons between the ferrocenyl and carbonyl groups in the reduction products, **3a**, **4a**, **5a**, **6a**, and **6b**. That is, these protons gave only one signal as a singlet peak in the τ 7.25—7.42 region, whereas the phenyl analogs, for example, 4-phenyl-2-butanone and 1,5-diphenyl-3-pentanone, gave the corresponding methylene signals as multiplet peaks[9)] at τ 7.47 and 7.26, and at τ 7.63 and 7.26, respectively. The present observations suggest that the two methylenes between the ferrocenyl and carbonyl groups are equivalent in magnetic field. A similar observation, that [3]ferrocenophane gave only a singlet peak for its six methylene protons, has been presented by Rosenblum *et al.*, who interpreted their observation by assuming a rapid inversion of the bridged methylene groups.[10)] Different alkyl groups on the carbonyl group do not cause any splitting of the signal, although the position of the signal is somewhat shifted. However, the corresponding aryl ketones, such as **9** and **10**, showed a multi-splitting of the methylene signal in their NMR spectra (see Table 2). The reason for the apparent magnetic equivalence of the four methylene protons in the ferrocenylethyl ketones (**3a**—**6b**) is not yet clear, but the following consideration may be pertinent. The chemical shift of the methyl protons of methylferrocene is found at τ 8.04,[11)] while that of toluene is found at τ 7.66.[12)] Thus, the deshielding effect exerted by a ferrocenyl group can be expected to be somewhat smaller than that by a phenyl group, and this might bring about an accidental coincidence of the chemical shifts of both methylene protons on α- and β-carbons to the carbonyl group. Moreover, the consideration may be extended to the possibility that some kind of participation of the iron atom of the ferrocene nucleus contributes to averaging the chemical shifts of these methylenes.

Ppt-Ni Catalyzed Reduction of β-Ferrocenyl-α,β-unsaturated Ketones. The effectiveness of ppt-Ni, which is prepared from an aqueous nickel chloride solution and zinc dust,[8)] as a catalyst for the reduction of various unsaturated compounds has been demonstrated in previous papers.[6,7)] Several β-ferrocenyl-α,β-unsaturated ketones were reduced by refluxing them with water in the presence of ppt-Ni. In this reaction water served as a hydrogen donor, and dioxane was used in order to keep the reaction mixture homogeneous. The results of these experiments are summarized in Table 3.

The reaction generally gave a reduction product, in an excellent yield, consisting of a mixture of a ketone and an alcohol. For example, 4-ferrocenyl-2-butanone (**3a**) and 4-ferrocenyl-2-butanol (**3b**) were obtained from 4-ferrocenyl-3-buten-2-one (**1**) in 10% and 90% yields respectively. The formation of alcohol as the main product suggests that the ppt-Ni-catalyzed reduction may be more drastic than the U-Ni-A-catalyzed one. The survival of the carbonyl group in the reduction of 1-ferrocenyl-5-methyl-1-hexen-3-one (**5**) may be attributed to the steric hindrance around it.

* Every 10 g of ppt-Ni contains 1 g of nickel.

Catalytic Hydrogenation. It is known that the hydrogenation of an α,β-unsaturated carbonyl compound proceeds competitively through several reaction pathways, which involve either the 1,2- or the 1,4-addition of hydrogen.[13,14] The kinetic investigation of the hydrogenation of β-ferrocenyl-α,β-unsaturated ketones with U-Ni-A is expected to be useful for the elucidation of the reaction pathway, since U-Ni-A has been found to be particularly effective for the hydrogenation of ethylenic compounds over carbonyl compounds. The reaction rate was followed by measuring the hydrogen uptake. During the initial stage of the reaction, a linear relation holds between log $(H_\infty - H)$ and the reaction time (t) as a first-order reaction, where H_∞ is the total hydrogen uptake at the end point of the reaction and where H is the hydrogen uptake at each point of time. The slope of the straight line represents the initial rate constant (k) of the reaction. Thus, the initial rate constant in the first order (k) was calculated for each compound; these constants are listed in Table 4. The rate constants, obtained from the hydrogenation of several α,β-unsaturated ketones other than ferrocene derivatives under the same conditions as those employed in the ferrocene series, are listed in Table 5.

TABLE 4. RELATIVE REACTIVITY IN HYDROGENATION OF β-FERROCENYL-α,β-UNSATURATED KETONES IN THE PRESENCE OF U-Ni-A

Although the bulkiness of the ferrocenyl group had been expected to retard the reaction, the reaction rates of the hydrogenation of β-ferrocenyl-α,β-unsaturated ketones were found to be relatively high. This fact implies that the ferrocenyl group

13) K. Hotta and T. Kubomatsu, The 21st Annual Meeting of the Chemical Society of Japan, Osaka, April, 1968, Proceeding Vol. I, p. 154.

14) F. J. McQuillin, W. O. Ord, and P. L. Simpson, *J. Chem. Soc.*, **1963**, 5996.

in the molecule approaches the surface of the catalyst with its less hindered side in the adsorbed transition state, as is shown sketchily in Fig. 1 (a).

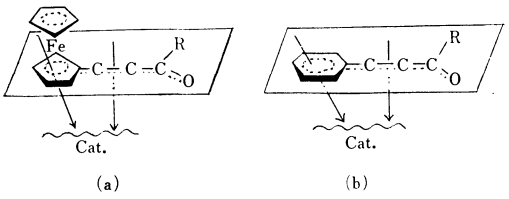

Fig. 1

Thus, the fact that 4-ferrocenyl-3-buten-2-one (**3**) was reduced easier than mesityl oxide (**11**) can be explained in terms of the cooperation of the ferrocenyl group. The larger rate constant of benzylideneacetone (**12**) can also be interpreted in the same manner. As is shown in Fig. 1 (b), the planar structure of the benzylideneacetone molecule may permit the facile adsorption of the conjugated system on the surface of the catalyst from either side of the molecule. On the other hand, the adsortpion of 4-ferrocenyl-3-buten-2-one (**3**) is permitted from only one side of the conjugated system, the other side being sterically hindered by a cyclopentadienyliron moiety. Hence, the reaction rate of the ferrocenyl compound (**3**) can naturally be expected to be considerably smaller than that of the phenyl analog.

Compounds with ferrocenyl groups at both ends of the molecule, such as **6** and **1**, were found to have far smaller reaction rates, as would be expected from the above-mentioned consideration. In the ferrocenylmethylene derivatives of cyclohexanone (**7** and **8**), the conjugated system is largely distorted from coplanarity. The steric environment retards the approach of the ethylenic bond to the surface of the catalyst, and results in a decrease in the rate constant. Especially, 2,6-di(ferrocenylmethylene)-cyclohexanone (**12**) could not be reduced under the conditions employed.

The steric effect of the alkyl groups on the carbonyl group was apparently not observed in this U-Ni-A catalyzed reaction, though it may be expected to affect the conformation of the ketone.[1] This fact implies that the coordination of the substrate molecule to the catalyst might occur preferentially on the part of the ferrocenyl and ethylenic groups.

The reaction pathways for the hydrogenation of β-ferrocenyl-α,β-unsaturated ketones can be considered to be as is shown in Scheme 1.[14]

From the results mentioned above, it can be concluded that the path A, involving α,β-addition, is more favored than the others, while there may be some reaction by the path B at a higher reaction temperature, forming alcohol as a by-product. The path C, which may give an unsaturated alcohol, does not play any important role in this hydrogenation, for the reaction rate is not significantly affected by the nature of the alkyl substituent on the carbonyl group. On the other hand, the striking drops in the reaction rates of 1,3-diferrocenyl-2-buten-1-one (**1**) and the phenyl analog (**13**) clearly support the mechanism *via* the path A.

There is no evidence that any kind of electronic effect of the ferrocenyl group was operative in the reduction of these unsaturated ketones, though remarkable steric effects of the ferrocenyl group were observed.[7]

The electronic effects of the ferrocenyl group have been discussed by several authors,[15-17] especially the effect on the unusual stability of α-ferrocenylcarbonium ions. If such an anchimeric assistance by the *d*-orbital of the iron atom cooperates in the delocalization of the π-electron system of the α,β-unsaturated ketone, it would favor the coplanarity of the conjugated system including the ferrocenyl group, thus promoting the reaction *via* the path A.

used in this study were synthesized according to the procedures reported in a preceding paper.[1]

Catalyst. Ppt-Ni. Ppt-Ni was prepared by a procedure reported previously.[6]

U-Ni-A. U-Ni-A was prepared from the ppt-Ni by digesting it with a 13% aqueous acetic acid solution, but the usual digestion procedure reported previously[8] was somewhat modified as follows: 10 g of ppt-Ni was placed in a 200-m*l* Erlenmeyer flask, and then about 20 m*l* of 13% aqueous acetic acid solution was added all at once. With occasional shaking, the temperature of the solution was kept at about 30°C for several minutes; then 100 m*l* of the acetic acid was added in 20-m*l* portions over a period of about 20 min. After the evolution of gas had become gentle, the supernatant liquid was decanted away and the solid was washed several times with 50-m*l* portions of distilled water, methanol, and finally dioxane by decantation. Thus, 1 g of U-Ni-A was obtained.

General Procedure for Hydrogenation Using U-Ni-A. Freshly-prepared U-Ni-A (1 g) was placed, together with 10 m*l* of dioxane, in a hydrogenation vessel which was connected with a gas-buret containing hydrogen and stirred vigorously for about half an hour after the air in the vessel had been replaced with hydrogen. When the absorption of hydrogen by the catalyst ceased, a solution containing 5×10^{-3} mol of the respective unsaturated ketone in 10 m*l* of dioxane was introduced into the vessel. Then, the shaking was continued until the absorption of hydrogen in the buret became almost unrecognizable.*2 At this time, the reaction was stopped and the reaction mixture was filtered. The solid on the filter was washed several times with methanol. The filtrate and the washings were then combined and dried over anhydrous magnesium sulfate. After the solvent had been removed under reduced pressure, a crude reaction product was purified by chromatography on alumina, using *n*-hexane except otherwise stated.

4-Ferrocenyl-2-butanone (3a). A yellow solid which had been obtained by chromatography was recrystallized from *n*-hexane to give yellow needles, mp 42—43°C,*3 in about an 80% yield. IR (KBr disk): 3100, 2940, 1708, 1470, 1410, 1360, 1162, 1104, 1040, 1020, 999, and 816 cm^{-1}.

Found: C, 66.48; H, 5.54%. Calcd for $C_{14}H_{16}OFe$: C, 65.66; H, 6.25%.

1-Ferrocenyl-3-pentanone (4a). Yellow crystals; mp 51—52°C. IR (KBr disk): 3120, 2950, 1712, 1412, 1360, 1104, 1039, 1020, 998, and 817 cm^{-1}.

Found: C, 66.72; H, 6.50%. Calcd for $C_{15}H_{18}OFe$: C, 66.70; H, 6.67%.

1-Ferrocenyl-5-methyl-3-hexanone (5a). Yellow oil. IR (liq. film): 3110, 2950, 1710, 1467, 1408, 1367, 1288, 1224, 1102, 1070, 1039, 1020, 998, and 813 cm^{-1}.

Found: C, 68.27; H, 6.96%. Calcd for $C_{17}H_{22}OFe$: C, 68.49; H, 7.40%.

2-(Ferrocenylmethyl)cyclohexanone (7a). Yellow crystals; mp 75—77°C; 41% yield. IR (KBr disk): 3100, 2940, 2860, 1707, 1475, 1446, 1410, 1355, 1309, 1269, 1243, 1219, 1123, 1100, 1032, 1014, 994, 812, 749, and 670 cm^{-1}.

Found: C, 68.94; H, 6.39%. Calcd for $C_{17}H_{20}OFe$: C, 68.95; H, 6.78%.

1,5-Diferrocenyl-1-penten-3-one (6a) and 1,5-Diferrocenyl-3-pentanone (6b). A reddish-orange, oily product, which had been obtained by the reduction of 1,5-diferrocenyl-1,4-pentadien-3-one (**6**), was chromatographed on alumina using a mixture of benzene and *n*-hexane (1 : 1) as the solvent. 1,5-Diferrocenyl-3-pentanone (**6b**) was obtained from the first fraction as greenish-yellow needles, mp 110—111°C, in a 35% yield, while 1,5-diferrocenyl-1-penten-3-one (**6a**) was obtained from the second fraction as reddish-orange plates, mp 113—114°C, in an 18.1% yield. IR (KBr disk): (**6a**) $\nu_{C=O}$ 1660, 1690 cm^{-1}; $\nu_{C=C}$ 1604, 1621 cm^{-1}. (**6b**) $\nu_{C=O}$ 1710 cm^{-1}.

General Procedure for Hydrogenation Using Ppt-Ni. A solution of a given amount of unsaturated ketone (Table 3) in a mixture of dioxane (5 m*l*) and water (10 m*l*) was refluxed vigorously in the presence of 3.0—4.0 g of ppt-Ni for 18 hr. Then, the reaction mixture was filtered while hot, and the ppt-Ni on filter was washed several times with ether. The filtrate was extracted with ether. All the ethereal solutions were combined and dried over anhydrous magnesium sulfate. After the removal of the solvent, a yellowish-orange residue was chromatographed on alumina using a mixture of *n*-hexane and benzene (1 : 1) as the solvent to fractionate the products shown in Table 3.

4-Feffocenyl-2-butanol (3b). The crude mixture, obtained by the ppt-Ni-catalyzed reduction of 4-ferrocenyl-3-buten-2-one (**3**), was carefully chromatographed on deactivated alumina (100—200 mesh, exposed to air for 1.5 hr) in order to prevent such a reoxidation of the alcohol (**3b**) in the crude mixture to the ketone (**3a**) during alumina chromatography as was observed by Decombe *et al.*[18] 4-Ferrocenyl-2-butanone (**3a**) was obtained in a 10% yield as the first fraction, using a mixture of *n*-hexane and benzene (1 : 1) as the solvent. After the ketone (**3a**) had been completely removed, elution with ether gave 4-ferrocenyl-2-butanol (**3b**) as red oil (90% yield). The structure of **3b** was established by means of its IR and NMR spectra. IR (liquid film): 3400 (OH), 3100, 2940, 1455, 1415, 1376, 1125, 1105, 1040, 1020, 998, 950, 925, and 812 cm^{-1}. NMR (in $CDCl_3$): Fc–$\overset{1}{CH_2}$–$\overset{2}{CH_2}$–$\overset{3}{CH}$($\overset{4}{OH}$)–$\overset{5}{CH_3}$; τ 5.89 (5H, unsub. ring H, singlet), 5.93 (4H, sub. ring H, singlet), 6.15 (1H, H^3, multiplet), 7.56 (2H, H^1, multiplet), 8.39 (3H, H^2 and H^4, complex) and 8.83 (3H, H^5, doublet, J=7 Hz).

2-(Ferrocenylmethyl)cyclohexanol (7b). A dark brownish-red product, which had been obtained by the ppt-Ni-catalyzed reduction of 2-(ferrocenylmethylene)-cyclohexanone (**7**), was chromatographed on deactivated alumina using a mixture of *n*-hexane and benzene (1 : 1) as the solvent. 2-(Ferrocenylmethyl)cyclohexanone (**7a**) was obtained in a 25% yield from the first fraction. After the ketone (**7a**) had been completely removed, elution with ether afforded 2-(ferrocenylmethyl)cyclohexanol (**7b**) as a red oil in a 60% yield; this was identified by means of its IR spectra. IR (liquid film): 3430 (OH), 3100, 2940, 2870, 1450, 1104, 1038, 1018, 998, 972, 924, and 810 cm^{-1}.

*2 When the hydrogenation was continued further, a very slow absorption of hydrogen was again observed due to the hydrogenation of the carbonyl group.

*3 The melting point was observed to be somewhat lower than that previously reported (mp 45—46°C[18]).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 873—876 (1970)

The Structure of Salts of β-Dione Dioximes

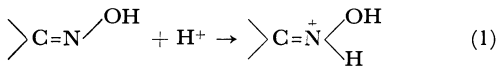
Yoshio IWAKURA, Keikichi UNO and Kazuo HAGA*1

The Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo

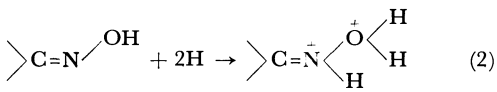
(Received August 21, 1969)

Cyclohexane-1,3-dione dioxime hydrochloride was prepared and investigated with reference to its structure. Analysis and a study of its NMR and IR spectra suggested that the salt is the enamine form of the oxime. Further, the salts of 5-methylcyclohexane-1,3-dione dioxime, 5,5-dimethylcyclohexane-1,3-dione dioxime and acetylacetone dioxime were prepared and found to have the same structure.

For the structure of ketoxime salt, the structure of cyclohexanone oxime hydrochloride was investigated by Saito.[1] The proton was known to be attached to the nitrogen of the hydroxyimino group as in Eq. (1). Further, an excess of strong acid was found to make another kind of salt containing two molecules of acid. Here, protons bond with the nitrogen and the oxygen of oxime as in Eq. (2). The salt with two molecules of acid, however, is so unstable that it easily releases one molecule of hydrogen chloride at room temperature.



(1)



(2)

In our series of studies to synthesize cyclic diamides, the Beckmann rearrangement of the dioximes of alicyclic diones has been carried out. During the study of the rearrangement, the characteristic structures of the salts of β-dione dioximes were found. β-Dione dioxime gave only one kind of stable salt, with one molecule of hydrogen chloride, in spite of the presence of two hydroxyimino groups. In the present study, the structure of the salt of β-dione dioxime will be discussed on the basis of a study of the NMR and IR spectra.

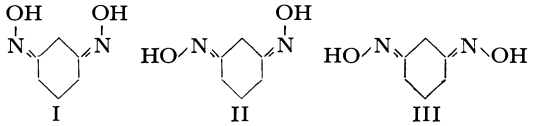
Results and Discussion

The β-dione dioximes were derived from β-diones according to the usual method. The β-diones used as starting materials were cyclohexane-1,3-dione, 5-methylcyclohexane-1,3-dione, 5,5-dimethylcyclohexane-1,3-dione and acetylacetone. The salts of these β-dione dioximes were obtained as crystals on adding various acids in acetic acid solutions. The results are summarized in Table 1, along with the data of elementary analyses.

Cyclohexane-1,3-dione dioxime was expected to act as a diacid base. An elementary analysis of the salt, however, showed that the salt contains only one molecule of hydrogen chloride. Even if an excess of hydrogen chloride was added, dihydrochloride was not obtained.

Since the results obtained seemed to be anomalous, a further attempt to prepare various salts of β-dione dioximes was made to confirm that β-dione dioximes act as monoacid bases. In every case here, the salts of β-dione dioximes contained an equivalent of acid. The addition of a half mole of sulfuric acid to 1 mol of cyclohexane-1,3-dione dioximes gave a quantitative yield of the salt; this salt, on the addition of another half mole of sulfuric acid, dissolved in acetic acid again, we could not isolate the product. For the sake of comparison, we studied how to obtain γ-dione dioxime monohydrochloride by the same method, but in the case of cyclohexane-1,4-dione dioxime, monohydrochloride was not obtained, rather, hygroscopic crystals of dihydrochloride were precipitated by the addition of an excess of hydrochloric acid. In view of the above facts, the salts of β-dione dioximes seemed to have structures different from those of the salts of the other oximes such as cyclohexanone oxime.

The Structure of 5,5-Dimethylcyclohexane-1,3-dione Dioxime. As a structure of cyclohexane-1,3-dione dioxime, the presence of three kinds of isomers were proposed, as is shown below:



I II III

Here, in the NMR spectrum of the dioxime, methylene protons at the 2 position gave three peaks

corresponding to the protons of the structures I, II, and III, while the methylene protons at the 4, 5, and 6 positions gave very complicated signals.[2] In the present study the NMR spectrum of 5,5-dimethylcyclohexane-1,3-dione dioxime was found to give a rather simple chart, as is shown in Fig. 1, because the carbon at the 5 position has no hydrogen.

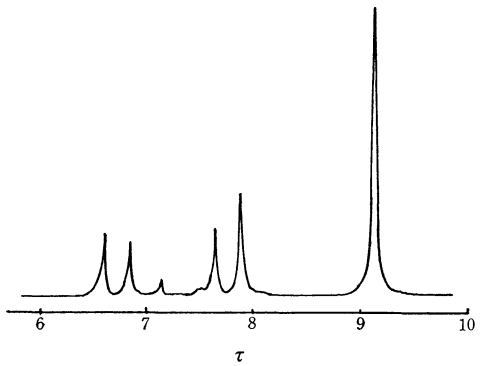

Fig. 1. NMR spectrum of 5,5-dimethylcyclohexane-1,3-dione dioxime. (DMSO-d_6 60MHz)

The methylene protons at the 2 position are observed around τ 6.5—7.2 as three signals. The central signal of these three can be assigned to the structure II analogous to results previously reported.[2] The assignment of the other two signals, one of which corresponds to the syn-syn or anti-anti form, has not been made. The ratio of the intensities of the three signals of the methylene protons at the 2 position in 5,5-dimethylcyclohexane-1,3-dione dioxime is 6 : 3 : 1.

The signals of the methylene protons at the 4 and 6 position are observed as two peaks around τ 7.5—8.0. These seemed to correspond to syn and anti protons with respect to the hydroxyimino group. The protons at the 4- and 6-methylene of Form I are all anti protons, and those of Form III are all syn; moreover in Form II either the protons of 4-methylene or those of 6-methylene are syn, and the other are anti protons. Finally, without regard to the differences between Forms I, II, and III, the methylene protons at the 4 and 6 positions are divided into just two classes. From the ratio of the intensities of the signals of 2-methylene, the ratio of syn and anti protons at 4- and 6-methylenes, was calculated to 1 : 3. This calculated value coincides with the experimental result. The separation between the two peaks indicates the difference in the shielding constants of the syn and anti protons. The value obtained is 0.24 ppm, which is expected to be consistent with the separations between both side peaks and the central one of 2-methylene; however, the actual values related to 2-methylene are 0.24 and 0.29 ppm. A further, detailed discussion of this point is required.

NMR Spectra of Salts of β-Dione Dioximes. The NMR spectra of the β-dione dioxime monohydrochlorides are shown in Fig. 2.

If the structure of the salt of β-dioxime is IV, as is expressed in Eq. (3), in which the proton is attached to one of the two nitrogens, the signal of the methylene protons between the two oxime groups would shift toward a lower field by about 0.3 ppm because of the influence of protonated oxime, as has been indicated by Saito, and the signal would be observed as a doublet due to the anisotropic effect of the syn and anti forms of the oxime group which was not protonated. The spectrum actually obtained, however, gave a quite

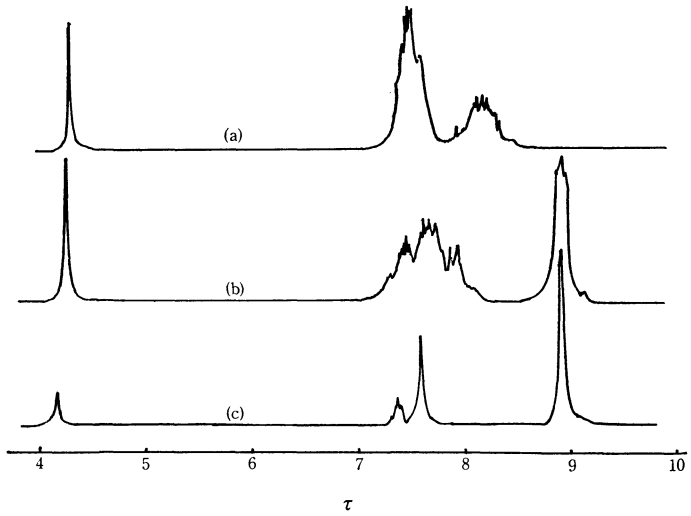

Fig. 2. NMR spectra of cyclohexane-1,3-dione dioxime hydrochloride (a), 5-methylcyclohexane-1,3-dione dioxime hydrochloride (b), 5,5-dimethylcyclohexane-1,3-dione dioxime hydrochloride (c), (DMSO-d_6 60MHz).

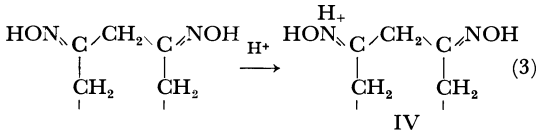
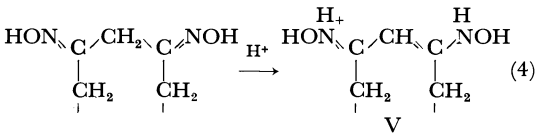
different figure from that assumed from the above consideration.



(3)

IV

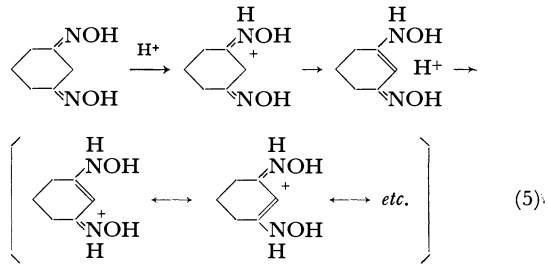
The methylene signals which have been observed in 5,5-dimethylcyclohexane-1,3-dione dioxime around τ 6.5—7.2, disappear completely, and a new signal is found at about τ 4. Further, the same phenomenon is observed in each of our experiments. The number of the proton which gave the signal at τ 4 is estimated by comparison with those of the other methylene or methyl protons to be one. Therefore, it is reasonable to consider that the structure of β-dione dioxime changes from the imine form to the enamine form V by means of salt formation, as is shown in Eq. (4):



(4)

V

It is well known that β-diketone exists mainly as an enol form, while β-dione dioxime does not take an enamine form. This is interpreted as being due to the difference in electron-withdrawing tendencies between carbonyl and oxime groups. If β-dione dioxime is protonated, the electron-withdrawing character of the oxime will increase very much and the hydrogens of methylene between the two oxime groups will become acidic. Consequently, the salt of β-dione dioxime will have a structure of an enamine, as is shown in Eq. (5):



(5)

This resonance stabilization can explain how the β-dione dioxime acts as a monoacid base. The structure described above is also supported by the fact that the protons of the 4 and 6 positions of 5,5-dimethylcyclohexane-1,3-dione dioxime hydrochloride show a single signal.

IR Spectra of the Salts. The absorption band of the carbon nitrogen double bond of cyclohexanone oxime (1669 cm^{-1}) was reported to shift to the higher-wave-number region of 1696 cm^{-1} upon salt formation.[1] However, 5,5-dimethylcyclohexane-1,3-dione dioxime gave just the opposite result.

The IR spectra of 5,5-dimethylcyclohexane-1,3-dione dioxime and its hydrochloride are illustrated in Fig. 3. The absorption at 1655 cm^{-1} shifts to the lower-wave-number region of 1578 cm^{-1} upon salt formation. Further, a new absorption, which seems to be attributable to a C=C double bond, appears at 1610 cm^{-1}. Some bands of the IR absorptions of various β-dione dioximes and other oximes, and of these hydrochlorides, are shown in Table 2.

If the structure of the salt of β-dione dioxime were IV, in which the proton is added to one nitrogen of the two hydroxyimino groups, two peaks related to C=N and C=N$^+$ streching would

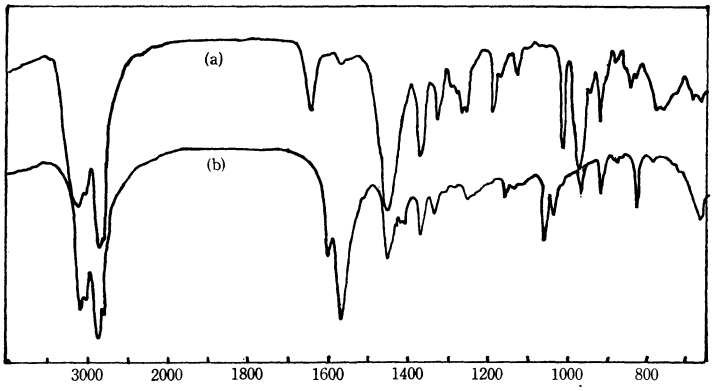


Fig. 3. IR spectra of 5,5-dimethylcyclohexane-1,3-dione dioxime (a) and its hydrochloride (b).

TABLE 2. INFRARED ABSORPTION FREQUENCIES OF THE DIOXIMES AND THEIR SALTS (cm^{-1})

	Dioximes		The oxime hydrochlorides		
	OH	C=N	OH	N^+H	$C=N^+$

Cyclohexane-1,4-dione dioxime	3200, 3100	1665	3300	2600	1710
Cyclohexanone oxime	3190, 3110	1650	3350	2600	1695

appear. In the case of the structure V, the resonance of $C=N^+$ and C=N can explain why the peak shifts to a low-frequency region and the intensity is very strong. Therefore, the experimental results of the IR absorption spectra seem to support the structure V, too.

The wave number of the carbon-nitrogen stretching of the salt of β-dione dioxime varies with the number of methyl groups at the 5 position. The chemical shift of the methine proton of the salt varies also, as is shown in Table 3. These differences seem to have some correlation with the change of the conformation of the ring, though this question has not yet been elucidated.

TABLE 3. THE CHEMICAL SHIFTS OF THE METHINE PROTON AND IR ABSORPTION FREQUENCIES OF CN^+ STRETCHING OF THE DIOXIME HYDROCHLORIDES

	τ (ppm)	$C=N^+$ (cm^{-1})
Cyclohexane-1,3-dione dioxime hydrochloride	4.28	1595
5-Mthylcyclohexane dioxime hydrochloride	4.26	1582
5,5-Dimethylcyclohexane-1,3-dione dioxime hydrochloride	4.15	1578

Experimental

The cyclohexane-1,3-dione,[4] 5-methylcyclohexane-1,3-dione,[5] and 5,5-dimethylcyclohexane-1,3-dione[6] were synthesized by the methods given in the literature. The acetylacetone was obtained from a commercial source. The dioximes of these diones were prepared by the usual method.

Cyclohexane-1,3-dione Dioxime Hydrochloride. Cyclohexan-1,3-dione dioxime was dissolved in acetic acid. An equivalent weight of concentrated hydrochloric acid was added to the solution, and then the hydrochloride was precipitated. The hydrochloride was reprecipitated from methanol by the addition of ether (Method A).

5-Methylcyclohexane-1,3-dione Dioxime Hydrochloride. 5-Methylcyclohexane-1,3-dione dioxime was dissolved in acetic acid. After the addition of an equivalent weight of hydrochloric acid, a small amount of ether was added, and then hydrochloride was precipitated (Method B).

Other salts of the dioximes were prepared by the method A or B, as is shown in Table 1.

Synthetic Reactions by Complex Catalysts. XVI. The Dimerization of Acrylonitrile and Acrylate by Means of the Metal-Isocyanide Complex

Takeo SAEGUSA, Yoshihiko ITO, Hideo KINOSHITA and Shimpei TOMITA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received August 29, 1969)

Acrylonitrile and acrylate were dimerized to 2-methyleneglutaronitrile and 2-methyleneglutarate respectively by the binary catalyst system of a copper compound and an isocyanide in the presence of a protic solvent such as *t*-butanol. Transition metal acetylacetonates, such as Fe(II and III), Co(II and III), and Ni(II), in combination with isocyanide were also effective for this dimerization. A mechanistic discussion has been presented.

This paper will describe the dimerization of acrylonitrile and acrylate by a new type of catalyst, a metal-isocyanide complex. The catalytic dimerization of acrylonitrile and methyl acrylate has been extensively investigated. Trialkylphosphines and transition metal compounds are known to be excellent catalysts. By the phosphine catalyst, acrylonitrile[1a] and methyl acrylate[1b] can be dimerized to produce α-methylene-glutaronitrile (Ia) and glutarate (Ib) respectively.

$$CH_2{=}CHX \xrightarrow{P(n\text{-}C_4H_9)_3} CH_2{=}\underset{\displaystyle CH_2CH_2X}{\overset{\displaystyle |}{C}}{-}X \qquad (1)$$

a: X=CN [I]
b: X=CO_2CH_3

On the other hand, rhodium- and ruthenium-trichloride catalyzes the dimerization of methyl acrylate[2a] and acrylonitrile[2b] to produce dimethyl 2-hexendioate (IIa) and 1,4-dicyanobutene-1 (IIb) respectively.

$$CH_2{=}CHX \xrightarrow{RhCl_3 \text{ or } RuCl_3} XCH{=}CHCH_2CH_2X \qquad (2)$$

a: X=CO_2CH_3 [II]
b: X=CN

The binary system of cuprous oxide and alkyl isocyanide is a new type of catalyst for the dimerization of polar olefins. Previously, we reported[3a] the dimerization of β-alkyl-α,β-unsaturated carbonyl and such nitrile compounds as methyl crotonate and crotononitrile by means of a cuprous oxide-alkyl isocyanide system:

$$RCH{=}CHX \xrightarrow{Cu_2O\text{-}RNC} RCH{=}\underset{\displaystyle RCHCH_2X}{\overset{\displaystyle |}{C}}{-}X \qquad (3)$$

a: X=CO_2CH_3 [III]
b: X=CN

When acrylonitrile was treated with the system of cuprous oxide and cyclohexyl isocyanide, acrylonitrile was polymerized in an almost quantitative yield, even at room temperature. The IR spectrum of the acrylonitrile polymer thus obtained resembled that of the polymer produced by the anionic catalyst. This finding prompted us to explore the dimerization of acrylonitrile. The treatment of acrylonitrile with the cuprous oxide-cyclohexyl isocyanide system in the presence of a mixture of *t*-butanol and acetonitrile produced Ia, along with a low-molecular-weight polymer.

$$CH_2{=}CH{-}CN \xrightarrow{Cu_2O\text{-}C_6H_{11}NC} \left(CH_2CH\right)_n \quad [III]$$

$$CH_2{=}CH{-}CN \xrightarrow[\text{in } t\text{-}C_4H_9OH\text{-}CH_3CN]{Cu_2O\text{-}C_6H_{11}NC} CH_2{=}\underset{\displaystyle CH_2CH_2CN}{\overset{\displaystyle |}{C}}{-}CN \quad [Ia]$$

$$+ \left(CH_2CH\right)_m \quad [IV]$$

$n > m$

The polymeric product was soluble in acetone, and its average molecular weight was about 1500. The yield of the dimer was low (6%). The structure of the dimer was confirmed by a comparison of its IR and NMR spectra with those of the authentic sample prepared by means of a trialkylphosphine catalyst. The combination of copper acetylaceto-

nate and alkyl isocyanide in the presence of a mixture of *t*-butanol and acetonitrile gave much better results; *i. e.*, this system produced Ia exclusively. The presence of a protic solvent mixture was essential for dimerization. In the absence of a protic solvent mixture, the copper acetylacetonate-isocyanide system induced only the acrylonitrile polymerization. Cuprous and cupric chlorides with isocyanide were quite inactive in the dimerization and polymerization of acrylonitrile.

Besides copper acetylacetonate, the acetylacetonates of iron(II and III), cobalt(II and III), and nickel(II) in combination with isocyanide and a protic solvent were also active in the acrylonitrile dimerization. The results of the dimerization of acrylonitrile are summarized in Table 1.

Table 1. Dimerization of acrylonitrile and methyl acrylate catalyzed by metal compounds—isocyanide*

Olefin	Metal compound	Yield of Dimer (%)	
		t-C_4H_9NC	$C_6H_{11}NC$
CH_2=CHCN	$Cu(acac)_2$	31	34
	$Co(acac)_2$	26	32
	$Co(acac)_3$	40	50
	$Fe(acac)_2$	52	14**
	$Fe(acac)_3$	49	11**
	$Ni(acac)_2$	3	—**
CH_2=$CHCO_2CH_3$	Cu_2O	11	11
	$Cu(acac)_2$	2	1
	$Co(acac)_2$	2	—

* Olefin (20 mM), isocyanide (20 mM), metal compound (0.4 mM), *t*-butanol (2 m*l*), acetonitrile (5 m*l*) at 110°C, 20 hr.

** Cyclohexyl isocyanide was polymerized in these reactions.

When acetylacetonates of iron(II and III), and nickel(II) were used as the catalyst components, cyclohexyl isocyanide was polymerized; hence, the catalyst activity was decreased. Generally, *t*-butyl isocyanide was not polymerized, and so it could be usefully employed.

Acrylate is much less reactive than acrylonitrile in a reaction by a metal-isocyanide system. In the absence of a protic solvent, methyl acrylate is scarcely polymerized at all by the cuprous oxide-cyclohexyl isocyanide system and remains unchanged under room-temperature conditions. The treatment of methyl acrylate in *t*-butanol and acetonitrile by a copper-isocyanide system at a higher temperature produced the dimer Ib in a lower yield. The dimer was identified by a comparison of its IR and NMR spectra with those of dimethyl α-methyleneglutarate.

Mechanism

The catalytic behavior of the cuprous oxide-alkyl isocyanide system has been characterized on the basis of several important observations in the dimerization of β-alkyl-α,β-unsaturated nitrile and carbonyl compounds:[3b] (i) β,γ-unsaturated nitrile compounds are rapidly isomerized to the corresponding α,β-unsaturated species by the catalyst system; (ii) the *cis-trans* isomerization of β-alkyl-α,β-unsaturated nitrile and carbonyl compounds is caused by the catalyst system, and (iii) the exchange between the hydrogen at the α-position and that of the γ-position in β-alkyl-α,β-unsaturated nitrile and carbonyl compounds is caused by the catalyst system. A reaction mechanism involving an allyl carbanion copper isocyanide complex (V) was proposed to explain these findings:

$$\underset{\ominus}{\text{RCHCH=CHX}} \longleftrightarrow \text{RCH=}\underset{\ominus}{\text{CH}}\text{CHX}$$

[V] (X=CN, CO_2CH_3)

By analogy with the allyl carbanion copper isocyanide complex obtained from β-alkyl-α,β-unsaturated species, a vinyl carbanion complex (VI) may be assumed to be the key intermediate in the dimerization of acrylonitrile and acrylate. In the complex (VI), the vinyl carbanion probably exists as a ligand of the copper-isocyanide complex. The formation of VI is supported by the deuterium/hydrogen exchange at the α-position of acrylonitrile upon treatment with the copper acetylacetonate-cyclohexyl isocyanide system in the presence of *t*-butanol-d.

$$\text{CH}_2\text{=CH-CN} \xrightleftharpoons{\text{Cu compd.-RNC}} [\text{CH}_2\text{=}\underset{\ominus}{\text{C}}\text{CN}]$$

[VI]

The nucleophilic addition of VI to the second molecule of acrylonitrile in a Michael-type addition produces the dimeric anion (VII). The protonation of VII by a protic solvent gives rise to the formation of a dimer. On the other hand, in the absence of a potent proton donor the successive addition of carbanion to the acrylonitrile monomer takes place to produce a polymer.

$$\text{CH}_2\text{=CHX} \xrightleftharpoons{\text{catalyst}} [\text{CH}_2\text{=}\underset{\ominus}{\text{C}}\text{X}] \xrightarrow{\text{CH}_2\text{=CHX}}$$

[VI]

$$\left[\begin{array}{l}\text{CH}_2\text{=CX}\\ \quad\ \ |\\ \quad\text{CH}_2\underset{\ominus}{\text{C}}\text{HX}\end{array}\right] \xrightarrow{\text{H}^+} \begin{array}{l}\text{CH}_2\text{=CX}\\ \quad\ \ |\\ \quad\text{CH}_2\text{CH}_2\text{X}\end{array}$$

[VII] $\xrightarrow{\text{CH}_2\text{=CHX}}$ polymer $\left(\text{-CH}_2\text{CH(X)-}\right)_n$

The copper acetylacetonate-isocyanide system also catalyzes the Michael-type addition.[4] The addition of VI to the second monomer corresponds to the

4) T. Saegusa, Y. Ito, S. Tomita and H. Kinoshita, unpublished results.

addition of the anion to an α,β-unsaturated nitrile in the usual Michael addition. Furthermore, the Michael addition catalyzed by the copper-isocyanide system is characterized by the coordination of α,β-unsaturated compounds to the catalyst.[4] In the dimerization, the coordination of acrylonitrile may facilitate the addition of VI.

Experimental

Reagents. The acrylonitrile and the methyl acrylate were commercial reagents and were purified by distillation. The cuprous oxide and the acetylacetonates of copper, iron(II and III), cobalt(II and III), and nickel(II) were commercial reagents; all were used without purification. The cyclohexyl and the *t*-butyl isocyanide were prepared according to Ugi's procedure.[5]

Oligomerization and Dimerization of Acrylonitrile. A mixture of 2.18 g (20 mmol) of cyclohexyl isocyanide, 40 mg (0.28 mmol) of cuprous oxide, and 1.06 g (20 mmol) of acrylonitrile in 2 m*l* of *t*-butanol and 5 m*l* of acetonitrile was heated at 65°C for 20 hr. The reaction mixture was then poured into about 100 m*l* of methanol, after which the insoluble oligomer of acrylonitrile was removed by filtration. The oligomer was dissolved in acetone, and the acetone solution was filtrated and poured into methanol. The purified oligomer (0.334 g (32%)) was soluble in acetone and *N,N*-dimethylformamide. The methanol solutions were concentrated and subjected to gas-liquid-phase chromatography (glpc) analysis. The yield of the dimer was 6%. The dimer was isolated by preparative glpc and was identified by a comparison of its glpc retention time and NMR and IR spectra with those of an authentic sample which had been prepared by means of a tri-*n*-butyl phosphine catalyst.

NMR of the dimer (in CCl_4): τ 4.00 ppm and 4.11 $\left(2s, \underline{H}\!>\!C\!=\!C\!<\underline{H}\right)$, 7.39 (s, $-C\underline{H}_2C\underline{H}_2-$).

Principal IR bands (neat): 2325 (w) and 1624 (w) cm^{-1}.

Dimerization of Acrylonitrile. A mixture of 2.18 g (20 mmol) of cyclohexyl isocyanide, metal acetylacetonate (0.4 mmol), and 1.06 g (20 mmol) of acrylonitrile in 2 m*l* of *t*-butanol and 5 m*l* of acetonitrile was heated at 110°C for 20 hr. The reaction mixture was then distilled at 62—64°C/0.1 mmHg. The distillate was subjected to glpc analysis.

Dimerization of Methyl Acrylate. A mixture of 2.18 g (20 mmol) of cyclohexyl isocyanide (or 1.66 g (20 mmol) of *t*-butyl isocyanide), cuprous oxide (57 mg (0.4 mmol)), and 1.72 g (20 mmol) of methyl acrylate in 2 m*l* of *t*-butanol and 5 m*l* of acetonitrile was heated at 110°C for 20 hr. The reaction mixture was then distilled at 82—84°C/3 mmHg. The distillate was subjected to glpc analysis. The product was identified by a comparison of its glpc retention time and NMR and IR spectra with those of an authentic sample which had been prepared by the tri-*n*-butyl phosphine-catalyzed reaction of methyl acrylate. The yield of the dimer was 11%.

NMR of dimer (in CCl_4): τ 3.89 ppm and 4.42 $\left(2d, J_{H-H}=2.0\ Hz, \underline{H}\!>\!C\!=\!C\!<\underline{H}\right)$, 6.26 and 6.37 (2s, $-COO-C\underline{H}_3$), 7.50 (s, $-C\underline{H}_2C\underline{H}_2-$).

Principal IR bands (neat): 1725 (s) and 1629 (w) cm^{-1}.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 879—883 (1970)

Intermediate Stages of the Nitration of Hexamethylbenzene to Dinitroprehnitene[1)]

Hitomi SUZUKI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received August 29, 1969)

A syrupy substance formed in quantity during the nitration of hexamethylbenzene to dinitroprehnitene has been found to be a complex mixture of varying amounts, depending markedly on the conditions, of 2,3,4,5,6-pentamethylbenzyl nitrate, 5,6-bis(nitrooxymethyl)-1,2,3,4-tetramethylbenzene, nitropentamethylbenzene, 6-nitro-2,3,4,5-tetramethylbenzyl nitrate, 2,3,4,5,6-pentamethylphenylnitromethane, bis(2,3,4,5,6-pentamethylbenzyl) ether, pentamethylbenzaldehyde, and several other unidentified carbonyl compounds, nitrite esters, and aliphatic nitro compounds. On the basis of the products isolated, a possible path by which hexamethylbenzene can be converted into dinitroprehnitene has been suggested.

Electrophilic attack on hexaalkylbenzenes usually leads to the replacement of alkyl groups by the attacking reagent.[2)] However, some instances are known in which the result is the side-chain sub-

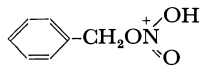
stitution, and the replacement of alkyl group by nitro group during the nitration of polyalkylbenzenes has been suggested to proceed through the intermediacy of the nitrate.[3] Recently, Illuminati and co-workers explained the side-chain chlorination of hexamethylbenzene in acetic acid by stating that the attacking reagent undergoes the rearrangement from nucleus to side chain to yield a benzylic compound.[4] An extension of this idea to the nitration and sulfonation of polyalkylated benzenes has been presented.[5,6] In this connection, hexamethylbenzene seems to be a convenient substrate for investigating the mode of alkyl replacement since there is no nuclear hydrogen atom to be replaced and all the methyl groups are equivalent. The reduced complexity of the products is expected—a very considerable advantage over the other polyalkylated systems.

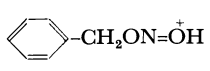
Hitherto little has been reported on the direct nitration of hexamethylbenzene. Willstätter and Kubli treated hydrocarbon with benzoyl nitrate in carbon tetrachloride and obtained bis(2,3,4,5,6-pentamethylbenzyl) ether and a bis(nitromethyl)-tetramethylbenzene in an unspecified yield.[7] No mention was made on the details of the reaction. Smith and Harris carried out nitration with fuming nitric acid in the presence of sulfuric acid and obtained as much as 22% yield of dinitroprehnitene (5,6-dinitro-1,2,3,4-tetramethylbenzene).[8] However, a significant proportion of the starting material remained unaccounted for. The present study was undertaken in order to separate and identify the various intermediate products formed when hexamethylbenzene is nitrated to dinitroprehnitene.

When hexamethylbenzene was nitrated in methylene chloride with excess of fuming nitric acid (d=1.5), at temperatures between −5 and 0°C, there resulted a white crystalline product, which showed strong infrared bands at 1272 and 1612 cm^{-1} ($-ONO_2$); PMR peaks at 4.41 τ ($-CH_2ONO_2$) in accord with the expected formation of 2,3,4,5,6-pentamethylbenzyl nitrate (I) as the initial product. If the dark brown mixture was allowed to stand at room temperature, a further reaction soon took place under active liberation of brown fume to give a slightly pasty, pale yellow solid, the infrared spectrum of which showed strong absorptions at 1277 and 1626 cm^{-1} ($-ONO_2$); PMR peak at 4.36 τ ($-CH_2ONO_2$). Neglecting the minor peaks due to by-products and comparing it with an authentic specimen, the major product was readily identified as 5,6-bis(nitrooxymethyl)-1,2,3,4-tetramethylbenzene (II). A close inspection of the infrared spectra ruled out the possibility of the concurrent formation in significant amounts of other isomers, 4,6-bis-(nitrooxymethyl)-1,2,3,5-tetramethylbenzene (III) or 3,6-bis(nitrooxymethyl)-1,2,4,5-tetramethylbenzene (IV).

Chromatography of the nitration products on alumina gave an appreciable amount of bis(2,3,4,5,6-pentamethylbenzyl) ether (V) as an early light petroleum eluate. In the presence of a strong acid, the benzyl nitrate or nitrite will form the conjugate acid,[9] VI or VII, which can act as an alkylating agent when there is appropriate nucleophile in the system.



(VI)



(VII)

Thus, V seems to be derived from the nucleophilic displacement of the ester oxygen on the benzylic carbon.[10] A similar case has been reported by Paraille during the decomposition of p-nitrobenzyl perchlorate in nitromethane to give bis(p-nitrobenzyl) ether.[11] Pentamethylbenzaldehyde (VIII) and other carbonyl compounds were obtained from the late light petroleum eluates, or from the benzene eluates. Nitrate I was hydrolyzed during the elution and appeared as 2,3,4,5,6-pentamethylbenzyl alcohol (IX), but dinitrate II was adsorbed so firmly on alumina that chromatographic treatment did not give satisfactory results at all. Even the prolonged elution with ether gave only small amounts of 5,6-bis(hydroxymethyl)-1,2,3,4-tetramethylbenzene (X) besides some non-crystallizable syrupy substances.

When the reaction mixture was allowed to stand overnight in an ice-bath, a light brown oily solid was obtained. Its PMR spectrum contained six peaks in the nitrooxymethylene proton region. Besides two strong peaks due to I (4.41 τ) and II (4.37 τ), the third peak at 4.31 τ became prominent. Its infrared spectrum showed an increased broad absorption due to $-NO_2$ group at 1545—1565 cm^{-1}, suggesting the presence of some aliphatic nitro

10) Treatment of fully substituted benzyl nitrates with a catalytic amount of sulfuric acid usually gives some bis-benzyl ether. However, if nuclear hydrogen atom is available, preference for the ring substitution is observed. Thus, nitration of pentamethylbenzene yields as by-products 2,2′,3,3′,4,4′,5,5′,6-nonamethyldiphenylmethane and 2,2′,3,3′,4,4′,5,5′-octamethyl-6-nitrooxymethyldiphenylmethane rather than bis(2,3,4,5-tetramethylbenzyl) ether (H. Suzuki and K. Nakamura, This Bulletin, **43**, 473 (1970).

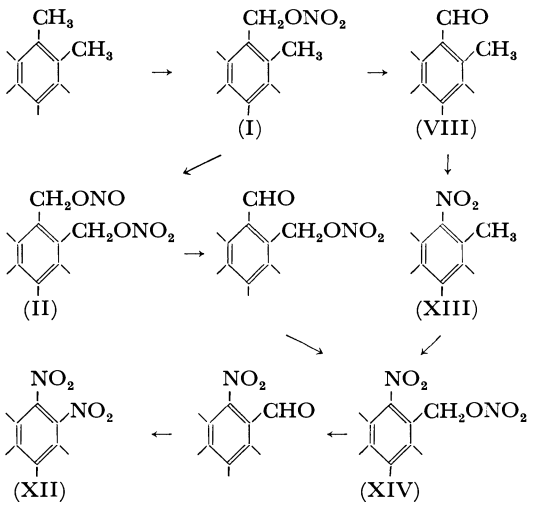
compounds. If the concentration of the nitrous acid formed was lowered either by passing a gentle stream of dry nitrogen into the mixture, or by using a large excess of nitric acid, the peak could be weakened.

Evidence of nitroalkane formation was obtained by the isolation of a crystalline product. Nitration of hexamethylbenzene in methylene chloride saturated with nitrogen trioxide gave a yellow pasty solid. Chromatography of this product on alumina gave unchanged hydrocarbon and the ether V from the light petroleum eluates; some carbonyl compounds from the benzene eluates; and the alcohol IX from the early ether eluates. Further prolonged elution with ether gave a dark yellow syrup, which gradually separated prisms (mp 80—84°C) and was identified as 2,3,4,5,6-pentamethylphenylnitromethane (XI) by comparison with the authentic specimen. Since the homolytic reaction was less probable under these conditions, aliphatic nitro compounds seem to have been formed by the union of the benzylic portion of the conjugate acid, VI or VII, with the nitrogen atom of the nitrite ion. The process is analogous to that of the Victor Meyer reaction in which phenylnitromethane and benzyl nitrite are formed from benzyl halide and silver nitrite.[12] When the above reaction mixture was kept overnight in an ice-salt bath, to which no further amount of ice was added, there resulted a non-crystallizable, sticky, pale yellow syrup. The mixture was found to contain, in addition to the anticipated products, appreciable amounts of nitrite esters, carbonyl compounds and aliphatic nitro compounds. Chromatographic separation did not give any satisfactory results.

Treatment of hexamethylbenzene with fuming nitric acid alone always gave nitrates as the principal product. Dinitroprehnitene (XII) was not formed in any significant amount. Since XII was obtained by Smith and Harris as much as in 22% yield by carrying out the reaction in presence of a large excess of sulfuric acid,[8] the effect of sulfuric acid on the product composition has been examined. Addition of a small amount of sulfuric acid to the reaction mixture was found to facilitate the side-chain substitution greatly, and the hydrocarbon was readily converted into the mono or dinitrate, depending on the amount of nitric acid used. With the increase of sulfuric acid, the yield of V fell rapidly, while those of nitropentamethylbenzene (XIII), 6-nitro-2,3,4,5-tetramethylbenzyl nitrate (XIV) and XII rose progressively. Carbonyl compounds (aldehyde and carboxylic acid) also increased, but aliphatic nitro compounds diminished. The results are consistent with the proposal by Smith and Horner that the group $-CH_2ONO_2$ can be replaced by a nitro group in the presence of sulfuric acid.[3]

While the results reported here do not provide a basis for describing in a precise way the mode of the alkyl replacement, they seem to provide valuable insights. Noteworthy is the marked increase in the formation of carbonyl compounds, especially aldehyde such as VIII when some sulfuric acid is added to the nitrating system. Considering the ease of electrophilic displacement of the formyl group at suitably activated or blocked positions,[13] a mechanism involving the preliminary transformation of the benzyl nitrate into the aldehyde, followed by the nitrodeformylation now seems worthy of consideration. One of the possible courses which can lead hexamethylbenzene to dinitroprehnitene is shown below:



In fact, a catalytic quantity of sulfuric acid can lead the benzyl nitrate to the benzaldehyde as well as benzoic acid,[14] and the replacement of formyl group by nitro group is a quite common occurrence.[15] The behavior of various polysubstituted benzyl nitrates towards sulfuric and nitric acids are now being investigated. We hope to clarify the role of the aldehyde in these anomalous nitrations in a later paper.

Experimental

Infrared spectra were run as Nujol mulls on a DS-402G

spectrophotometer. Only prominent peaks were recorded. PMR measurements were carried out on a Varian A-60A spectrometer with deuteriochloroform as solvent and tetramethylsilane as internal standard. All melting points were determined in hot stage and not corrected.

Hexamethylbenzene was prepared by methylation of commercial xylene mixture and crystallized from ethanol.[16] Pentamethylbenzaldehyde (VIII) was prepared from 2,3,4,5,6-pentamethylbenzyl chloride[17] by oxidation with 2-nitropropane.[18] Bis(2,3,4,5,6-pentamethylbenzyl) ether (V) was prepared from 2,3,4,5,6-pentamethylbenzyl alcohol[19] according to Rhoad and Flory.[20]

2,3,4,5,6-Pentamethylbenzyl Nitrate (I). A solution of silver nitrate (12 g) in acetonitrile (30 m*l*) was added all at once to a solution of 2,3,4,5,6-pentamethylbenzyl chloride (12 g) in acetonitrile (20 m*l*). The mixture was stirred for 5 hr at room temperature. Silver chloride was removed by filtration and the solvent was pumped off. The product was crystallized from light petroleum to yield 12.2 g (90%) of white leaflets, mp 95—97°C. IR: 760, 855, 875, 900, 962, 1272 ($-ONO_2$), 1301, 1612, and 1625 cm^{-1} ($-ONO_2$); PMR (in CCl_4), 7.80 (3*[1] CH_3), 7.72 ($2CH_3$), and 4.42 τ (CH_2).

Found: C, 64.4; H, 7.9; N, 6.0%. Calcd for $C_{12}H_{17}NO_3$: C, 64.6; H, 7.7; N, 6.3%.

5,6-Bis(nitrooxymethyl)-1,2,3,4-tetramethylbenzene (II). A warm solution of silver nitrate (2.0 g) in acetonitrile (10 m*l*) was added all at once with stirring, to a hot solution of 5,6-bis(chloromethyl)-1,2,3,4-tetramethylbenzene (1.5 g, mp 133—137°C; lit,[21] 138—139°C) in acetonitrile (30 m*l*). The mixture was stirred for several hours, and silver chloride was separated by filtration. Evaporation of the solvent *in vacuo*, followed by crystallization of the residue from ligroin gave white needles (0.7 g), mp 127—129°C. IR: 697, 732, 755, 859, 876, 954, 964, 1277 ($-ONO_2$), and 1626 cm^{-1} ($-ONO_2$); PMR, 7.74 ($2CH_3$), 7.68 (2*[1]CH_3), and 4.36 τ (CH_2).

Found: C, 50.9; H, 5.8%. Calcd for $C_{12}H_{16}N_2O_6$: C, 50.7; H, 5.6%.

A product of low purity first separated as an oil from the solution and gradually turned into a powder-like solid. Repeated recrystallization gave no improved result.

The above procedure applied to 4,6-bis(chloromethyl)-1,2,3,5-tetramethylbenzene (mp 115—117°C)[20] and 3,6-bis(chloromethyl)-1,2,4,5-tetramethylbenzene (mp 194—196°C)[20] gave *4,6-bis(nitrooxymethyl)-1,2,3,5-tetramethylbenzene (III,* mp 126—128°C) and *3,6-bis(nitrooxymethyl)-1,2,4,5-tetramethylbenzene (IV,* mp 203—205°C), respectively. IR: (III), 694, 757, 818, 873, 950, 1275 ($-ONO_2$), and 1622 cm^{-1} ($-ONO_2$); (IV), 727, 759, 871, 895, 964, 1014, 1274 ($-ONO_2$), 1297, 1614, and 1625 cm^{-1} ($-ONO_2$). PMR: (III), 7.78 (CH_3), 7.68 ($2CH_3$), 7.60 (CH_3), and 4.44 (CH_2); (IV), 7.70 ($4CH_3$) and 4.43 τ (CH_2).

2,3,4,5,6-Pentamethylphenylnitromethane (XI). A solution of 2,3,4,5,6-pentamethylbenzyl chloride (4 g) in acetonitrile (10 m*l*) was poured into a stirred mixture consisting of silver nitrite (5 g), a small amount of calcium carbonate, and acetonitrile (30 m*l*). After 5 hr, the reaction mixture was worked up as usual, and the residue obtained after removal of the solvent was taken up in ethanol and boiled for some minutes to destroy the accompanying nitrite ester. The solution was evaporated to dryness *in vacuo* and the residue was extracted with three portions each of 20 m*l* cold light petroleum to separate from the less soluble alcohol IX. Spontaneous evaporation of the combined extracts gave XI as large plates, and recrystallization from light petroleum gave prisms (0.6 g),[22] mp 86—88°C. IR: 711, 764, 834, 1065, 1271, 1304, 1369 ($-NO_2$), and 1547 cm^{-1} ($-NO_2$); PMR, 7.78 ($3CH_3$), 7.73 ($2CH_2$), and 4.46 τ (CH_2).

Found: C, 69.8; H, 8.3%. Calcd for $C_{12}H_{17}NO_2$: C, 69.6; H, 8.2%.

5,6-Bis(hydroxymethyl)-1,2,3,4-tetramethylbenzene (X). 5,6-Bis(chloromethyl)-1,2,3,4-tetramethylbenzene was converted into the diacetate,[20] which without further purification was saponified by refluxing in 10% ethanolic potassium hydroxide for several hours. The product was recrystallized from benzene-ligroin mixture to give white needles, mp 174—175°C.

Found: C, 74.1; H, 9.2%. Calcd for $C_{12}H_{18}O_2$: C, 74.2; H, 9.3%.

Nitration of Hexamethylbenzene. Typical examples are shown below. Products were identified by spectral comparison and mixed melting as far as the authentic specimens were available.

i) Fuming nitric acid (16.8 g, d=1.5) was added over a period of thirty minutes to a vigorously stirred solution of hexamethylbenzene (8.1 g) in methylene chloride (50 m*l*), keeping the temperature between −5 and 0°C by the use of an ice-salt bath. The organic layer was separated and washed with dilute sodium bicarbonate and then with water. Removal of the solvent left a white crystalline solid, chromatography of which (5 g) on alumina gave the unchanged hydrocarbon (1.2 g) and V (0.5 g) from the light petroleum eluates; carbonyl compounds (0.3 g) from the benzene eluates; and finally IX (0.8 g) from the ether eluates.

ii) Nitration of the hydrocarbon (8.1 g) with the 1 : 1 mixture of fuming nitric acid (23.4 g) and sulfuric acid (23.4 g) under a similar condition gave an orange-yellow pasty solid. The product (5 g) dissolved in a minimum amount of methylene chloride was placed on the top of the alumina column. Elution with light petroleum gave XIII (0.1 g), XIV (0.3 g),[5] and XII (0.5 g); and with benzene some carbonyl compounds. Dinitrate II which constituted the bulk of the nitration product could not be eluted successfully even with ether.

iii) When the hydrocarbon (8.1 g) was treated with fuming nitric acid (15.8 g) in the presence of an excess of sulfuric acid (48 g), a light brown oily solid was obtained. Because of the difficulties encountered in the

22) Resourse to chemical separation gave even poorer yield of the product.

chromatographic separation, a part of the product (14.2 g) was fractionally extracted with light petroleum using a Soxhlet's extractor. Each extract was monitored by infrared spectroscopy and those of a similar composition were combined. Chromatography of the earlier extracts on alumina gave, besides some unchanged hydrocarbon, V (0.4 g); VIII (0.4 g); XII (1.9 g); an unidentified carbonyl compound (0.5 g; Found: C, 70.9; H, 7.3%. $C_{12}H_{15}NO_2$ requires C, 70.2; H, 7.3%) which melted partly at 150—153°C, soon solidified in another crystalline form, and remelted at 223—227°C with partial sublimation and decomposition; IX (0.6 g); and an unidentified hydroxy compound (0.6 g; mp 153—154°C; Found: C, 74.6; H, 9.1%; strong IR bands at 993, 1524, and 3310 cm^{-1}) as well as a little X. Later extracts were mainly a complicated mixture of several carbonyl compounds (1.5 g). A light brown half-resinous substance (5.2 g) which had broad, deep absorptions due to –OH, >C=O, and $-NO_2$, was left in the thimble.

iv) A solution of hexamethylbenzene (8.1 g) in methylene chloride (50 m*l*) was saturated with nitrogen trioxide at −10—−5°C. Fuming nitric acid (15.8 g) was introduced with vigorous stirring over a period of 30 min and the mixture was worked up as usual. A pasty yellow product (5 g) was chromatographed on alumina to give the recovered hydrocarbon (2.5 g), V (0.2 g), aldehydes (0.3 g), and IX (0.7 g). A further prolonged elution with ether gave a yellow syrup, which was dissolved in a small amount of light petroleum and set aside. A solid product (0.2 g, mp 74—84°C) separated out and recrystallized from the same solvent to give prisms, mp 80—84°C, identical with the authentic specimen of XI.

Photochemical Studies of the Esters of Aroylphosphonic Acids

Ken-ichi TERAUCHI and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka

(Received September 2, 1969)

The photochemical behavior of several dialkyl benzoylphosphonates and *para*-substituted benzoylphosphonates in various solvents has been studied using product isolation, ultraviolet-spectral change, the electron spin resonance (ESR) technique, and quantum yield measurements. Upon irradiation to a degassed solution of these benzoylphosphonates through a Pyrex filter, the photo-pinacolization reaction was observed, except in the case of diethyl benzoylphosphonate; it was effectively quenched by 1,3-pentadiene or oxygen. On the other hand, the ESR spectra of photo-irradiated aroylphosphonates at 77°K have a large anisotropic doublet of 53—128 gauss separation; this separation is thought to be due to the interaction between an unpaired electron and the phosphorus nucleus. The structure of these radicals is also discussed. From these observations, it can be considered that the photochemical reaction proceeds *via* the ketyl radical formed by the hydrogen abstraction of the lowest excited triplet state of these aroylphosphonates. Irradiation to the diethyl benzoylphosphonate solutions in various solvents gave, not the pinacolized product, but 2,4,6-triphenyl-2,4,6-tris[diethylphosphoryl]-1,3,5-trioxane almost quantitatively. The quantum yields (Φ) of the disappearance of several *para*-substituted derivatives are highly sensitive to the electron-inductive abilities of the substituents; that is, Φ drops from 2.10 in the *p*-methoxybenzoylphosphonate derivative to 1.79 in the *p*-chloro derivative at room temperature. Such a substituent effect can be considered to result in the difference in the conformation between the carbonyl and phosphoryl groups. On the basis of these studies, the mechanism of the photochemical reaction of aroylphosphonates is described and discussed.

In a previous paper,[1] we demonstrated that dialkyl aroylphosphonates had a moderately strong n-π^* transition of the carbonyl group occurring around 320—390 mμ because of the interaction with the phosphorus *d*-orbitals. Therefore, as an extension of the previous work, we wish now to report on the photochemical behavior and on the reaction mechanism of these aroylphosphonates.

The photochemistry of organo-phosphorus derivatives has received only a little attention. In general, photochemical studies of organo-phosphorus compounds have been undertaken out of an interest in synthesis; that is, Griffin and his co-worker[2] have demonstrated the synthesis of a variety of nuclear

1) K. Terauchi and H. Sakurai, This Bulletin, **42**, 821 (1969).

2) R. Obrycki and C. E. Griffin, *J. Org. Chem.*, **33**, 632 (1968).

substituted phenylphosphonates and other aryl-(1-naphthyl-, 2-thienyl-, 2-furyl-) phosphonates by the photolysis of the corresponding aryl iodides in an excess of trialkyl phosphite. Also, Petrellis and his co-worker[3] have reported that the irradiation of a solution of 1,3,2-dioxaphospholans in 2-methyl-2-butene or 2,3-dimethyl-2-butene provided the corresponding phenylcyanocyclopropanes. However, the study of the reactivity is important to the same extent for the photochemistry of organophosphorus compounds. From this point of view, we have studied the effect of substituents on the reactivity and the low-lying excited-state structure of these aroylphosphonates.

Results and Discussion

1) Irradiation to Dialkyl Benzoylphosphonates. Before describing the experimental results, it will be useful to clarify the primary photochemical process of dialkyl benzoylphosphonates.

The ultraviolet absorption spectra of a solution of dialkyl benzoylphosphonates are very similar to those of diethyl benzoylphosphonate.[1] The spectra of all the degassed cyclohexane solutions of dialkyl benzoylphosphonates were drastically altered by irradiation through a filter cutting off below 3200 Å; such a filter causes the light to be almost completely absorbed by only the n–π^* transition bands of benzoylphosphonates.

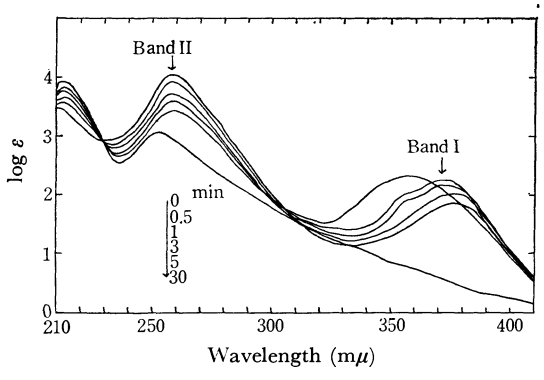

Fig. 1a. The progressive spectral change of diethyl benzoylphosphonate on irradiation in cyclohexane. Numbers refer to irradiation time.

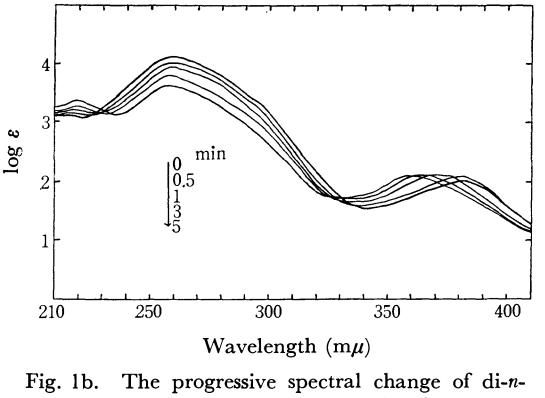

Fig. 1b. The progressive spectral change of di-*n*-butyl benzoylphosphonate on irradiation in cyclohexane. Numbers refer to irradiation time.

a) Photochemical Reactions of Diethyl Benzoylphosphonate. Figure 1a shows the progressive spectral change in a cyclohexane solution of diethyl benzoylphosphonate at an irradiation above 3200 Å. The absorption band II (258 mμ) decreased, and a new band appeared with maxima of 213 and 245 mμ, as the irradiation time increased. On the other hand, the I absorption band (379 mμ) increased with the hypsochromic shift and disappeared after 30 min, as is shown in Fig. 1a. One isosbestic point was observed, at 228 mμ. It may reasonably be considered that the increase in the n–π^* absorption is due to the formation of the ketyl radical or the kethyl radical ion, which might serve as reaction intermediates. Such an intensification of the n–π^* absorption has also been observed in a solution of the other aroylphosphonates used in the present work. The photoproduct, which had its absorption maxima at 213 and 245 mμ in a cyclohexane solution, as can be seen from Fig. 1a, was confirmed to 2,4,6-triphenyl-2,4,6-tris-[diethylphosphoryl]-1,3,5-trioxane (III) by a study of its infrared spectra, by elemental analysis, and by molecular-weight measurements.

b) Photochemical Reactions of Diisopropyl- and Di-n-butyl benzoylphosphonates. Figure 1b shows the progressive spectral change in a solution of di-*n*-butyl benzoylphosphonate. The absorption band II (259 mμ) decreased and a new band with the maximum of 220 mμ gradually appeared, but no clear isosbestic point was observed. As is shown in Fig. 1b, the absorption band I (380 mμ) increased for only the first 10 min in a pattern similar to that of diethyl benzoylphosphonate. A similar progressive spectral change was also observed in the case of diisopropyl benzoylphosphonate.

On the other hand, the photochemical reaction of diisopropyl- and di-*n*-butyl benzoylphosphonates solutions afforded the corresponding pinacols, IIb and IIc respectively, which were identified by means

of elemental analysis, a study of their infrared and UV spectra, and molecular-weight measurements, as is shown in Tables 6 and 7.

2) Irradiation to *para*-Substituted Benzoylphosphonates. The photochemical reactions of three *para*-substituted benzoylphosphonates, *p*-chloro, *p*-*t*-butyl, and *p*-methoxy derivatives, were investigated in the same manner. The spectra of all the degassed cyclohexane solutions of *p*-substituted benzoylphosphonates were also markedly changed by irradiation.

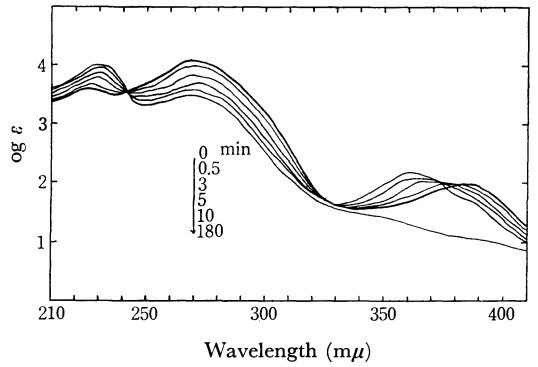

Fig. 2a. The progressive spectral change of diethyl *p*-chlorobenzoylphosphonate in cyclohexane.
Numbers refer to irradiation time.

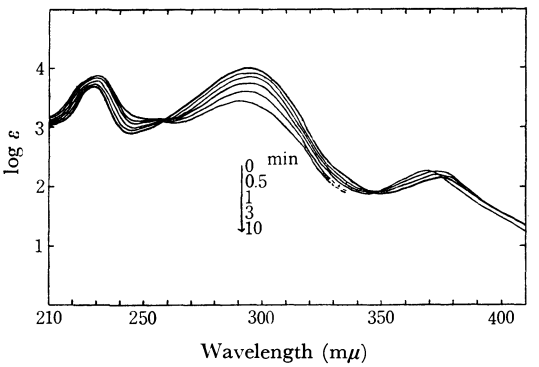

Fig. 2b. The progressive spectral change of diethyl *p*-methoxybenzoylphosphonate on irradiation in cyclohexane.
Numbers refer to irradiation time.

Photochemical Reactions of p-Chloro-, p-t-Butyl- and p-Methoxybenzoylphosphonates. The progressive spectral change in the absorption spectrum of *p*-chlorobenzoylphosphonate at an irradiation above 3200 Å is shown in Fig. 2a, where an isosbestic point is observed at 241 mμ. As the irradiation time increases, both the absorption bands, II (270 mμ) and I (385 mμ), decrease, and new bands, with maxima at 228 mμ and 360 mμ, appear. The new absorption band at 360 mμ, however, began to decrease at the irradiation time of 95 min and completely disappeared within 180 min.

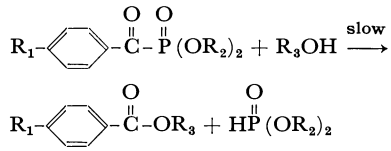
The isolated photoproduct from the irradiated solution was identified as the corresponding pinacol, IId. As is to be expected from the findings on the spectral change, this pinacol has only one high, intense band, at 228 mμ, with no shoulders in the 320—450 mμ region. Similar results have been observed from the experiments with *p*-*t*-butylbenzoylphosphonate.

On the other hand, in *p*-methoxybenzoylphosphonate the photoproduct had very poor solubility in cyclohexane at room temperature, and hence no data on the spectral change over 3 min could be obtained. Figure 2b shows the progressive spectral change in a solution of *p*-methoxybenzoylphosphonate. In this case, the II absorption band (295 mμ) decreased, new bands with maxima at 227 and 366 mμ appeared, and an isosbestic point was observed at 258 mμ.

3) Solvent Effects on the Photochemical Reactions. In order to examine the solvent effect on the photochemical reaction, irradiation through a Pyrex filter was carried out in degassed solutions of aroylphosphonates in various solvents at room temperature. The solvents used in this study were methanol, acetonitrile, carbon tetrachloride, benzene, *N*,*N*-dimethylformamide, dioxane, and *n*-pentane.

The results thus obtained are summarized in Table 8 in the Experimental section. As is obvious from Table 8, the photoproduct from the photolysis of the diethyl benzoylphosphonate solution was the trioxane derivative III in any solvent. On the other hand, the photolysis of di-*n*-butyl benzoylphosphonate under similar conditions in benzene, acetonitrile, and carbon tetrachloride afforded the pinacol IIc in every case much as in cyclohexane.

In the case of the methanol solution, we found, by the observation of the NMR and UV spectra, that the following reaction could proceed in the dark slowly at room temperature.



R_1=H, *p*-Cl, *p*-*t*-Bu, *p*-CH_3O
R_2=C_2H_5, iso-C_3H_7, *n*-C_4H_9
R_3=CH_3, C_2H_5, iso-C_3H_7

Further, it has been confirmed that any aroylphosphonate used in this study similarly reacts with alcohols, methanol, ethanol, and isopropyl alcohol. This reaction (for example, R_1=H, R_2=C_2H_5, R_3=CH_3) was observed to proceed to a 73% conversion in 17 hr in the dark at room temperature.

In addition, we could not find any evidence in these photochemical reactions for the corresponding products to undergo a Norrish type-I cleavage, that is, the predissociation of the C–P bond in the phosphonates by irradiation.

These results, obtained in various solvents, afford useful information on photochemical reaction mechanism. The finding of photopinacol formation in the aprotic solvents that the photochemical-excited state of di-*n*-butyl benzoylphosphonate must be able to abstract a hydrogen atom from the other phosphonate molecules to from ketyl radicals. Such a process are similarly suggested by the experiments on the quantum yield of aroylphosphonate disappearance in various solvents, as will be discussed in the next section. If this reaction is operative, the overall quantum yield of aroylphosphonate disappearance may then be greater than unity.

4) Quantum Yields of the Disappearance of Aroylphosphonates. *a) p-Substituted Aroylphosphonates.* The quantum yields of the disappearance of *p*-chloro-, *p-t*-butyl-, and *p*-methoxybenzoylphosphonates in a cyclohexane solution were determined in spectrophotometry. We found that the quantum yield of disappearance depended significantly upon the concentration of the solution in all cases; that is, the higher the concentration, the higher was the quantum yield obtained. A plot of the Φ^{-1} *vs.* the resiprocal of the phosphonate concentration is shown in Fig. 3.

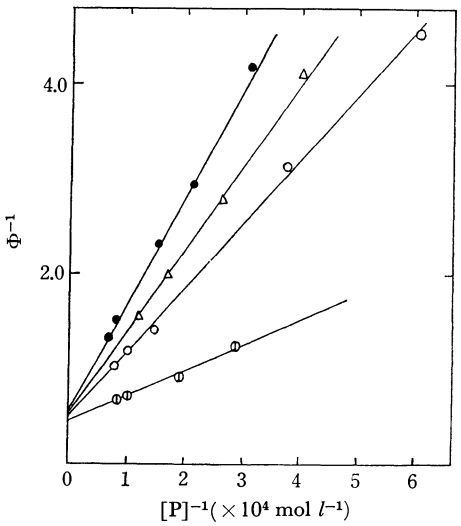


Fig. 3. Plot of Φ^{-1} against the reciprocal of diethyl *p*-substituted aroylphosphonate concentration.
● Cl; ○ $(CH_3)_3C$; △ H; ⓘ CH_3O

As can be seen from Fig. 3, the relation does result in a good linear relationship. These results are of particular interest. Although it is considered that many processes are probably operative in a photochemical reaction, a quantitative treatment of the dependence of quantum yield on the aroylphosphonate concentration will require knowledge concerning the extremely complex inhomogeneous distribution of radicals throughout the volume of the cell.

Furthermore, it was observed that the limited quantum yields of disappearance were significantly altered by the introduction of substituents into the aromatic ring of the phosphonate.

TABLE 1. SUBSTITUENT EFFECTS ON THE QUANTUM YIELD OF DISAPPEARANCE OF AROYLPHOSPHONATE

Substituent	Φ	σ
p-CH_3O	2.100	−0.268
p-$(CH_3)_3C$	2.000	−0.197
p-H	1.850	0
p-Cl	1.792	+0.227

The results obtained are shown in Table 1. Such a substituent effect on the quantum yield has previously been reported in *para*-substituted benzoylphosphonates by Pitts and his co-workers;[4] they demonstrated that the quantum yields of the disappearance of *para*-substituted benzophenones decreased with an increase in the electron-donating ability of the substituent.

However, as is shown in Table 1, we found that, on the contrary, the quantum yields of the disappearance of *para*-substituted aroylphosphonate dropped from 2.10 in *p*-methoxybenzoylphosphonate to 1.79 in *p*-chloro derivatives. This is also evident from Fig. 4, a plot of Φ *vs.* the Hammett σ constants, in which the trend toward a lower quantum yield with an increase in the σ value is pronounced.

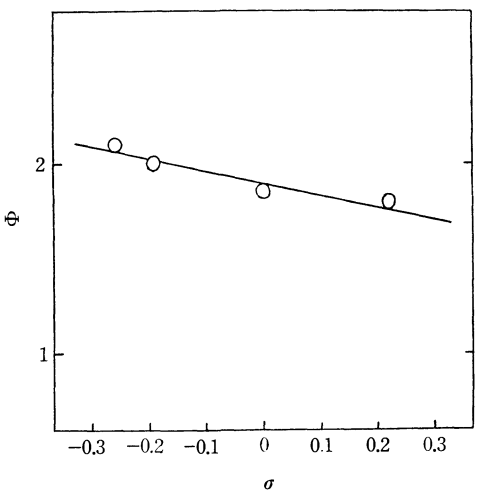

Fig. 4. Plot of Φ against Hammett σ values.

Assuming that a reduction of electronic density occurs on the carbonyl oxygen atom during an n–π^* transition, the Φ *vs.* σ relation indicates that

4) J. N. Pitts, Jr., H. W. Johnson, Jr., and T. Kuwana, *J. Phys. Chem.*, **66**, 2456 (1962); L. H. Piette, J. H. Sharp, T. Kuwana and J. N. Pitts, Jr., *J. Chem. Phys.*, **36**, 3094 (1962); E. J. Baum, J. K. S. Wan and J. N. Pitts, Jr., *J. Amer. Chem. Soc.*, **88**, 2652 (1966).

electronwithdrawing substituents reduce the reactivity of the excited carbonyl group. These facts may be explained in terms of the steric effect concerning the preferred conformation in the aroylphosphonates. The NMR data suggest free rotation around the C–P bond.[5] Dipole-moment measurements have been reported the values of 2.93D for Ia, 3.20D for If, and 2.64D for Id.[6] These values of Id and If are lower and higher respectively than those of the corresponding aldehydes (reported[7] as 3.70D and 2.03D respectively), suggesting that the powerful electron-inductive abilities of the methoxy and chloro functions cause a change in the electron density on the carbonyl carbon atom. That is, the more the electron density on the carbonyl carbon increases, the more the life-time of the conformation in which the carbonyl and phosphoryl groups are opposite may increase. Therefore, it is reasonable to consider that the conformation between the carbonyl and phosphoryl groups can alter the intermolecular hydrogen atom-abstracting ability of the excited carbonyl group.

Although it is recognized that the quantum yield data indicate the excited state reactivities, while, on the other hand, the σ constants and the dipole moment involve ground states only, such a linear relationship between the Φ and σ values appears worthy of comment. Unfortunately, no kinetic data involving σ constants for *para*-substituted benzoylphosphonate in a reaction in which a hydrogen atom or ion is transferred have yet been reported.

However, such a substituent effect is significant and may apply to rate constants.

b) Quenching Effect of 1,3-Pentadiene and O_2. In order to examine this photoreduction mechanism, the effect of the addition of such a quencher as 1,3-pentadiene and oxygen, both of which are well-known as triplet quenchers, was investigated. The quenching efficiency of these additives was found to be significantly sensitive. The quantum yields of the di-*n*-butyl benzoylphosphonate disappearance against the 1,3-pentadiene (piperylene) concentrations are summarized in Table 2. The concentration of benzoylphosphonate was essentially constant throughout these measurements. As is obvious from Table 2, the quantum yield of disappearance in cyclohexane decreased markedly with an increase in the quencher concentration. A plot of Φ^{-1} *vs.* the quencher coccentrations is given in Fig. 5.

Table 2. Quenching effect of 1,3-pentadiene on photoreduction of 3.11×10^{-4}M cyclohexane solutions of di-*n*-butyl benzoylphosphonate

[1,3-Pentadiene] $\times 10^5$	Φ
0	1.309
0.126	1.250
0.530	1.144
1.060	0.925
2.120	0.776

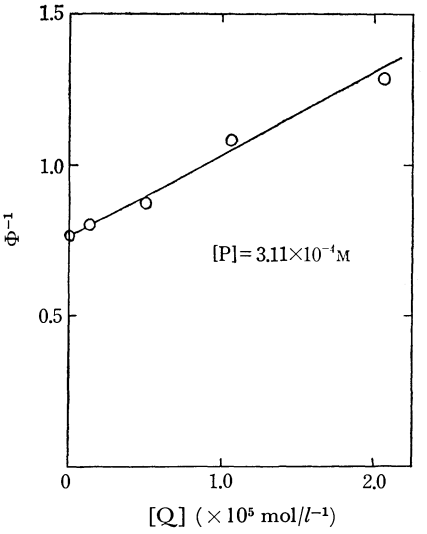

Fig. 5. Plot of Φ^{-1} against 1,3-pentadiene concentration.

A linear relationship of Φ^{-1} against the concentration of piperylene was obtained. Therefore, it is clear that the photochemical reaction proceeds *via* the excited triplet state of aroylphosphonate.

Moreover, the quenching effect of oxygen was examined. In a 1.14×10^{-4}M solution of di-*n*-butyl benzoylphosphonate, the value of the quantum yield of disappearance was 0.870 in a degassed solution, while in a nondegassed solution was 0.377; this observation may be considered to provide evidence for the quenching action of the presence of dissolved oxygen.

c) Solvent Effects on the Quantum Yield of Disappearance. The quantum yields of di-*n*-butyl benzoylphosphonate disappearance were determined in various solvents. The results obtained are summarized in Table 3. As can be seen from Table 3, the quantum yields of disappearance in aprotic solvents indicate smaller values than those in hydrogen-donating solvents. These facts suggest that the excited phosphonate molecule can be abstracting, to a smaller extent, a hydrogen atom from the solvent to form a ketyl radical. However, it should be noted that the quantum yield of disappearance indicates only a little variation depending on whether the solvent is hydrogen-deficient or -donating. As compared with the hydrogen-donating

TABLE 3. THE QUANTUM YIELDS OF DISAPPEARANCE OF PHOSPHONATE IN VARIOUS SOLVENTS AT ROOM TEMPERATURE

Solvent	λ_{max} (mμ)	ε	Φ	conc. (mol·l^{-1})
Cyclohexane	259	12880	0.745	1.0×10^{-4}
Ether	259	8850	0.782	1.1×10^{-4}
n-Pentane	259	10380	0.752	1.0×10^{-4}
Acetonititle	261	7920	0.660	1.0×10^{-4}
Carbon tetrachloride	259	8990	0.621	1.0×10^{-4}

solvents, it would be reasonable to conclude that such a high quantum yield of disappearance in aprotic solvents implies the formation of ketyl radicals. As has been mentioned earlier, we know that the solvent effect in photochemical reaction is almost negligible. Consequently, it can be deduced that the excited triplet state of the phosphonate abstracts a hydrogen atom from other phosphonate molecules in the ground state in a photochemical reaction.

5) Electron Spin Resonance Spectra of Irradiated Aroylphosphonates. A low-temperature (77°K) ESR technique was used to investigate whether the triplet state of phosphonate could be detected. When a degassed solution of aroylphosphonate Ia-f was irradiated at 77°K with a filter transparent above 3200 Å, the ESR signal (at *ca.* 1500 gauss) attributable to the triplet state of benzoylphosphonate caused by the transitions between the highest and lowest sublevels and corresponding to $\Delta Ms=2$ was not detected. However, a strong phosphorescence was noted during irradiation in a rigid medium, and an ESR signal (at *ca.* 3000 gauss) attributable to a free radical species of benzoylphosphonate was observed at 77°K. These ESR spectra have a large anisotropic doublet of 53—128 gauss separation and a *g* value almost close to the free spin value.

In a previous paper,[8] we proposed, on the basis of the calculation of these signals, that the greater part of an unpaired electron was localized in the carbonyl carbon atom and was partially delocalized over the P–O group, perhaps through the vacant d orbitals on phosphorus.

In connection with the experimental results on the photochemical reactions in solution, it seems most reasonable to conclude that the structure of the observed radicals is previously postulated for the ketyl radical, which is produced by the hydrogen abstraction of an electron-deficient oxygen atom in the n–π^* triplet state of the carbonyl group in aroylphosphonate Ia-f.

6) Estimated Mechanism of Photopinacolization Reaction. On the basis of these studies, the possible photochemical reaction scheme of aroylphosphonates at an irradiation above 3200 Å can be written as is shown in Eqs. (1)—(8), where P, PH, Q, and RH are the phosphonate molecule, the ketyl radical, the quencher, and the solvent respectively.

$$\mathrm{P} \xrightarrow{h\nu} \mathrm{P}^* \quad (1)$$

$$\mathrm{P}^* + \mathrm{RH} \rightarrow \mathrm{PH} + \mathrm{R}\cdot \quad (2)$$

$$\mathrm{P}^* \rightarrow \mathrm{P} \quad (3)$$

$$\mathrm{P}^* + \mathrm{P} \rightarrow \mathrm{PH} + \mathrm{P}'\cdot \quad (4)$$

$$\mathrm{P}^* + \mathrm{Q} \rightarrow \mathrm{P} + \mathrm{Q}^* \quad (5)$$

$$\mathrm{P}'\cdot + \mathrm{RH} \rightarrow \mathrm{P} + \mathrm{R}\cdot \quad (6)$$

$$\mathrm{R}\cdot + \mathrm{P} \rightarrow \mathrm{PH} + \mathrm{R}' \quad (7)$$

$$2\mathrm{PH} \rightarrow \mathrm{P\text{–}P} \quad (8)$$

It is unlikely that the reaction (7) will occur in the solvents used in this study. The fact that the observed quantum yields of aroylphosphonate disappearance tend toward near 2 can be explained if the reaction (4) is operative. At high concentrations of phosphonate, reaction (4) is thought to become relatively more important.

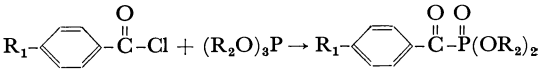
Finally, we are now investigating the reason why the difference in the alkyl function in the phosphoryl group or the introduction of *para*-substituents drastically changes the product in a photochemical reaction in solution.

Experimental

Preparation of Dialkyl Aroylphosphonates Ia-f. The acid chloride was stirred, drop by drop, into the trialkyl phosphite at 10—20°C in a nitrogen atmosphere. The temperature was raised slowly to room temperature during about a 1-hr period.

The reaction mixture was then distilled under reduced pressure to give dialkyl aroylphosphonate as a yellow oil. The data are listed in Table 4.

TABLE 4. PREPARATION OF AROYLPHOSPHONATES



Compound	R_1	R_2	bp °C	bp mm	Yield %	Phosphite: Acid chloride
Ia	H	C_2H_5	142	1.0	70	4 : 3

Ic	H	*n*-C_4H_9	175	4.0	32	4 : 3
Id	*p*-Cl	C_2H_5	159	2.0	57	4 : 3
Ie	*p*-$(CH_3)_3C$	C_2H_5	163	0.8	29	4 : 3
If	*p*-CH_3O	C_2H_5	158	0.5	79	4 : 3

Repeated distillation under reduced pressure was used to purify all the compounds needed. The purity was confirmed by the presence of only one spot after development by the thin-layer chromatographic method. Carbon tetrachlorde, benzene, acetonitrile, *n*-hexane, *n*-pentane, dioxane, *N*,*N*-dimethylformamide (DMF),

8) K. Terauchi and H. Sakurai, This Bulletin, **42**, 2714 (1969).

methanol, and ethanol were purified by ordinary methods.

Steady-light Experiment. The light source employed was a Toshiba high-pressure mercury lamp (Model HLS-4002Å type), while for cutting off below 3200 Å a UV-35 Toshiba filter was used. Aliquots (4 m*l*) of solutions in various concentrations were pipetted into the Pyrex tube equipped with a quartz spectroscopic cell (path-length 10 mm) at the side-arm, and then tubes degassed in four cycles of the freeze-melt technique.

The absorption spectra were taken with a Hitachi EPU-2 spectrophotometer.

Measuremtnt of the Quantum Yield. The chemical change occurring in the photolyte was determined from the change in the optical density at the wavelength of the absorption maximum. The quantum yields of the disappearance of the photolyte were calculated from the form of the absorption spectrum before and after irradiation. The extinction coefficients of aroylphosphonates in cyclohexane which were used for the calculation of the quantum yields are given in Table 5.

Table 5. Extinction coefficients of aroylphosphonates in cyclohexane

Compound	λ_{max} (mμ)	ε, $l\ mol^{-1}\cdot cm^{-1}$
Ia	258	11220
	379	83
Ib	258	11880
	379	82

	380	103
Id	268	12600
	385	93
Ie	271	11500
	375	145
If	294	10250
	373	152

The amount of irradiation absorbed by the solution was determined by the use of a potassium ferrioxalate actinometer[9] with filtered irradiation from a Toshiba high-pressure mercury lamp (HLS-4002A). After irradiation, aliquots of the ferrioxalate solution were treated with phenanthroline and analyzed for the ferrous ion. The mean value for the irradiation absorbed was 3.22×10^{16} quanta/sec without the photolyte solution and 3.189×10^{16} quanta/sec with the photolyte solution. The difference between these two quantities, 3.507×10^{14} quanta/sec, is the quantity of irradiation absorbed by the aroylphosphonate solution.

General Procedure of the Photolysis of Aroylphosphonates in Cyclohexane. A mixture of 1.0 g of aroylphosphonate and 30 m*l* of cyclohexane in a Pyrex tube was degassed by the freezement technique and then irradiated with a 400-Watt high-pressure mercury are at room temperature. The irradiation was carried out until the yellow color of the solution was entirely bleached out. After irradiation evaporating the solvent at reduced pressure, either a white solid or a colorless, oily photoproduct was obtained. These products were dried under a high vacuum for several hours. The analytical and spectral data of these photoproducts are summarized in Tables 6 and 7.

Table 6. Analytical data for the photoproducts from aroylphosphonates Ib—f

* Measured in acetonitrile solution.

On the basis of these data, the photoproducing agent was identified as the pinacol II. The treatment of the photopinacol II with dilute or concentrated hydrochloric acid in an attempt to produce the phosphonic acid derivative was unsuccessful, giving only tar. After alkaline hydrolysis with a 17% potassium hydroxide solution, treatment with 2,4-dinitrophenylhydrazine in ethanol gave the hydrazone derivatives. This hydrazone was washed by 20% aqueous methanol and dried under reduced pressure over calcium chloride. The benzaldehyde 2,4-dinitrophenylhydradrazone

melted at 241—242°C (lit, mp 237°C). These observation suggest that the pinacol undergoes carbon-carbon bond cleavage to form the α-hydroxy phosphonic ester, which is then further hydrolyzed by the excess base to yield the aldehyde.

Photolysis of Ia and Ic in Various Solvents. The photolyses were carried out by a similar method. The analytical data of the photoproducts are summarized in Table 8.

The IR spectrum of the photoproduct from no solution of Ia showed any carbonyl absorption. IR(KBr disk); 1600, 1440 (phenyl), 1220 (P=O), 1160, and 1020 (P–O–C) cm^{-1}. The UV spectrum had only one high intense band ($\lambda_{max}^{CH_3CN}$ 245 mμ, log ε 3.27), with no shoulders in the 280—450 mμ region. Attempts to lead from this compound to the phosphonic acid by acid or alkaline hydrolysis under any conditions were unsuccessful.

No useful information on the structure could be obtained from the NMR spectrum. Although the structure of the trimer contains several configurations, the structure, III, we have proposed seems to accord best with the observed data.

On the other hand, the product from Ic was identified as the IIc pinacol by means of the same spectral data, as is shown in Table 7, and by means of the analytical data (Table 8).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 890—897 (1970)

Stereospecific Polymerization of Allyl Vinyl Ether by $BF_3 \cdot OEt_2$

Heimei YUKI, Koichi HATADA, Koji OHTA and Takashi SASAKI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received September 8, 1969)

The polymerization of allyl vinyl ether was carried out by means of $BF_3 \cdot OEt_2$. The reaction proceeded through the vinyl double bond, and a polymer with allyl ether side chains was obtained. The effects of the polymerization conditions on the stereoregularity of the polymer were studied by means of NMR spectroscopy using a spin decoupling technique. A highly isotactic polymer was obtained at −78°C in toluene. The isotacticity of the polymer decreased slightly with a rise in the reaction temperature and with an increase in the initial monomer concentration. When the reaction was carried out in a mixture of toluene and nitroethane, a marked decrease in the isotacticity and the solution viscosity of the polymer was observed with an increase in the amount of nitroethane. The solution viscosity of the polymer decreased with an increase in the polymerization temperature and the catalyst concentration, and increased with an increase in the initial monomer concentration. The reaction between the polymer and HBr in acetic acid yielded a ternary copolymer consisting of vinyl alcohol, vinyl acetate, and vinyl bromide units.

Many papers have been published on the stereospecific polymerization of vinyl ethers.[1-6] However, only a few investigations have been done on the

polymerization of allyl vinyl ether (AVE) by cationic catalysts,[7,8] and there have been no information concerning the stereospecific polymerization of this monomer.

The present authors studied the polymerization of AVE by $BF_3 \cdot OEt_2$ and found that the polymerization proceeded through the vinyl double bond and that a polymer containing one allyl double bond per monomer unit was obtained. The tacticity of the polymer were analyzed by means of NMR spectroscopy using a spin decoupling technique, and the effects of the polymerization conditions on the stereoregularity of the polymer were investigated. The reaction of poly(allyl vinyl ether) (PAVE) with hydrogen bromide was also studied.

Experimental

Reagents. AVE was prepared from isobutyl vinyl ether and allyl alcohol by transetherification using mercuric acetate as the catalyst.[9] The crude product was purified by refluxing it over calcium hydride and then over lithium aluminum hydride under nitrogen pressure, after which it was distilled *in vacuo*. Bp, 67.0°C. The purified AVE was sealed in an ampule under dry nitrogen and stored at −20°C.

The isobutyl vinyl ether was purified by shaking it several times with 5% aqueous sodium hydroxide, dried with anhydrous potassium carbonate, and then refluxed over calcium hydride. It was finally distilled from calcium hydride using an efficient column. Bp, 82.8—83.0°C.

The allyl alcohol was dried with molecular sieves 4A and distilled under nitrogen pressure. Bp, 96.0—97.0°C.

The toluene was purified and dried by a usual method and was distilled from calcium hydride. Then the distillate was mixed with a small amount of *n*-butyllithium in a toluene solution and distilled on a vacuum line before use.

The *n*-hexane and *n*-heptane were purified by usual methods and stored over calcium hydride. Each was mixed with a small amount of *n*-butyllithium in the same solvent and distilled on a vacuum line just before use.

The nitroethane was purified by distillation, dried with molecular sieves 4A, and distilled under a high vacuum just before use.

The methylene chloride was shaken with concentrated sulfuric acid, washed with aqueous sodium hydroxide and water, dried over calcium chloride, and distilled. The distillate was dried with a mixture of calcium hydride and molecular sieves 4A and then distilled again under a vacuum just before use.

The tetralin, dioxane, and acetic acid were purified and dried by usual methods.

The hydrogen bromide was prepared by dropping dry bromine into tetraline at 60°C under nitrogen pressure.

The nitrogen was dried by being passed through molecular sieves 4A cooled at −78°C.

The boron trifluoride etherate ($BF_3 \cdot OEt_2$) was purified by distillation under reduced nitrogen pressure and was used as a toluene solution.

Polymerization. A vessel equipped with a three-way stop-cock was flushed with dry nitrogen. The monomer and a solvent were introduced with hypodermic syringes. To this solution, cooled at a given temperature, the catalyst solution was then added, drop by drop, using a syringe. The polymerization was stopped by adding a small amount of ammoniac methanol which had been cooled at the same temperature as the reaction mixture. The mixture was then poured into a large amount of methanol containing a small amount of phenyl-β-naphthylamine. The precipitated polymer was collected by filtration, washed thoroughly with the same methanol, and dried *in vacuo* at room temperature for 2 days. The polymer was stored under nitrogen atmosphere at −20°C to avoid the formation of cross-linked insoluble polymer. When the polymer was low-molecular and was soluble in methanol, the solution was concentrated to dryness under a high vacuum; the residual polymer was then redissolved in benzene in order to free it from inorganic materials and dried by the freeze-drying method.

Reaction of PAVE with HBr. Dry hydrogen bromide was bubbled through a solution of PAVE in toluene at room temperature under nitrogen pressure. After the reaction has been completed, dry nitrogen was passed through the reaction mixture in order to remove the excess hydrogen bromide, and then the mixture was poured into a large amount of methanol in order to precipitate the product. After the mixture had stood overnight, the resultant polymer was collected, washed with methanol, and dried *in vacuo*.

When the reaction was carried out in acetic acid, the polymer was not completely soluble in the medium at the begining, but it was gradually dissolved in the course of the reaction. In the reaction the formation of poly(vinyl acetate) was expected. However, the reaction product did not contain a methanol-soluble part.

Measurements of NMR Spectra. NMR spectra were obtained with a JEOL JNM-4H-100 spectrometer at 100 MHz by using a 5 w/v% solution containing a small amount of tetramethylsilane as an internal standard. The spectra of the polymer and AVE were measured in carbon tetrachloride at 60°C and in chloroform at 22.5°C respectively.

Measurements of IR Spectra. The IR spectra of the polymer were taken on a JASCO IR-S spectrometer, casting the polymer film on a rock salt plate from a benzene solution.

Viscosity Measurements. The solution viscosity of the polymer was measured on its benzene solution (0.1 g/dl) at 30.0±0.03°C using an Ostwald viscometer.

Results

NMR Spectra and Structure of PAVE. Figure 1 shows the NMR spectrum of PAVE obtained at −78°C in toluene, together with the spectrum of AVE. The spectrum of PAVE consists of five peaks which correspond to the β-methylene, α-methine, allyl methylene protons, and terminal methylene and methine protons in an allyl double

bond with a decrease in the magnetic field. The intensity ratio of these five peaks is 2.1 : 1.0 : 2.0 : 1.9 : 1.1. There is no resonance at about 3.6 and 5.6—6.0 τ, where the resonances due to the protons of vinyl group in the polymer may appear, if they exist, as is observed in the spectrum of AVE. These results suggest that AVE polymerizes exclusively through the vinyl double bond and that the polymer contains one pendant allyl group per monomer unit.

The polymers obtained under various conditions showed the same spectra as that of PAVE obtained at −78°C in toluene, suggesting that the mode of polymerization did not depend on the reaction conditions.

Determination of Tacticity of PAVE. In the undecoupled spectrum of PAVE (Fig. 1B) it was impossible to discriminate the respective multiplets arising from the nuclei in different stereochemical sequences because the spin-spin coupling complicated the spectrum greatly. However, the resonance of the β-protons appeared to be sensitive to the stereochemical configuration in the spin decoupled spectrum, as is shown in Fig. 2.

The β-proton resonance of PAVE obtained at −78°C in toluene showed a typical AB quartet (Fig. 2A) when decoupled from the α-proton, suggesting that the polymer is highly isotactic.

On the other hand, the decoupled resonance of PAVE obtained in nitroethane exhibited five components, as is shown in Fig. 2B. Generally in cationic polymerization vinyl ether gives a less isotactic polymer as the reaction medium is more polar.[10-12] Therefore, the above resonance may

be considered to be the overlap of an AB quartet due to the isotactic methylene and a singlet due to the syndiotactic methylene, which are equivalent. Although the spectral resolution was not sufficient, the fraction of the tactic dyad can be estimated from the relative areas of the AB quartet and singlet within an error of $\pm 5\%$.

The resonance of the α-proton seems not to be so sensitive to the stereochemical configuration of the polymer chain that the fraction of the tactic triad can not be determined by NMR spectroscopy.

Effect of Polymerization Temperature. The polymerizations were carried out in toluene at various temperatures ranging from -78 to 0°C. The results are shown in Fig. 3. The polymerization

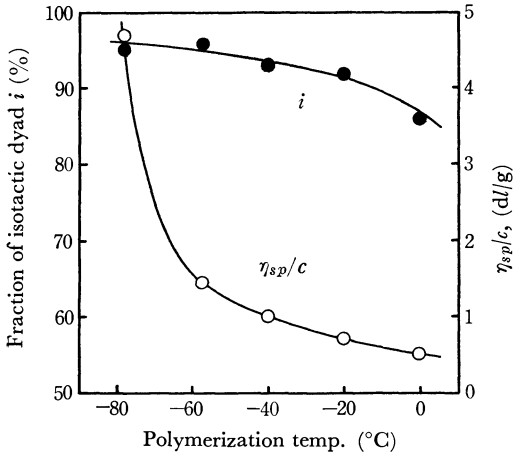

Fig. 3. Effect of temperature on the polymerization of allyl vinyl ether by $BF_3 \cdot OEt_2$ in toluene for 1 hr.

was always almost completed within one hour even at -78°C. The isotacticity of the polymer decreased slightly with a rise in the polymerization temperature. On the other hand, a marked decrease was observed in the molecular weight of the polymer at higher polymerization temperatures. The polymer obtained at 0°C was a viscous oil and was soluble in methanol.

Effect of Catalyst Concentration. Figure 4 shows the results of the polymerizations carried out with various catalyst concentrations at -78°C in toluene. The polymerization was always almost completed in one hour at any catalyst concentration above 4.6×10^{-3} mol/*l*. The solution viscosity of the polymer remarkably decreased with an increase in the catalyst concentration.

Effect of Monomer Concentration. The polymerization was carried out at various monomer concentrations in toluene at -78°C. The results are given in Fig. 5. The isotacticity of the polymer was enhanced with a decrease in the initial monomer concentration. The solution viscosity of the polymer

increased with an increase in the initial monomer concentration.

Polymerization in Various Solvents. The results of polymerizations in various solvents at -78°C are listed in Table 1. The isotacticity of the polymer was lowered in a polar solvent. In the polymerization in *n*-hexane or *n*-heptane, the polymer produced was precipitated during the course of the reaction, and the yield and the isotacticity of the polymer were both lowered.

The polymerization was carried out in toluene-nitroethane mixtures at -78°C. The results are shown in Fig. 6. A gradual decrease in the isotacticity and a rapid decrease in the solution viscosity of the polymer were observed with an

When the reaction was performed in acetic acid, the product was not soluble in methanol, but it was soluble in toluene, benzene, acetone, and chloroform. It also contained about 40% of bromine. As is shown in Fig. 7 the infrared spectrum of this product was almost identical with that of poly(vinyl acetate) except for an absorption at 3490 cm^{-1} due to an OH group. These results suggest that the product was composed of vinyl acetate and vinyl alcohol units, plus a unit containing bromine. The possible structures for the constituent units are summarized in Table 3. Among the bromine-containing units, the vinyl bromide unit is most relevant because the other three units have a bromine content close to that of the product, which may be assumed to contain considerable amounts of vinyl acetate and vinyl alcohol units.

The NMR spectrum of the reaction product of PAVE and HBr is shown in Fig. 8 and compared with that of poly(vinyl acetate). In the spectrum there are a sharp singlet resonance of the acetoxy methyl proton, a broad multiplet probably due to the β-methylene proton overlapping with the methyl resonance, and three peaks, at 6.40, 5.93, and 4.93 τ, in the region of the methine proton resonance. The literature[13] indicates that the τ values corresponding to the methine protons in the structures of –CH(OH)–, –CHBr–, and –CH(OCOCH$_3$)– are 6.4, 5.9, and 5.0 τ respectively. Therefore, the three peaks at 6.40, 5.93, and 4.93 τ may be tentatively assigned to the methine protons in the structural units of vinyl alcohol, vinyl bromide, and vinyl acetate respectively.

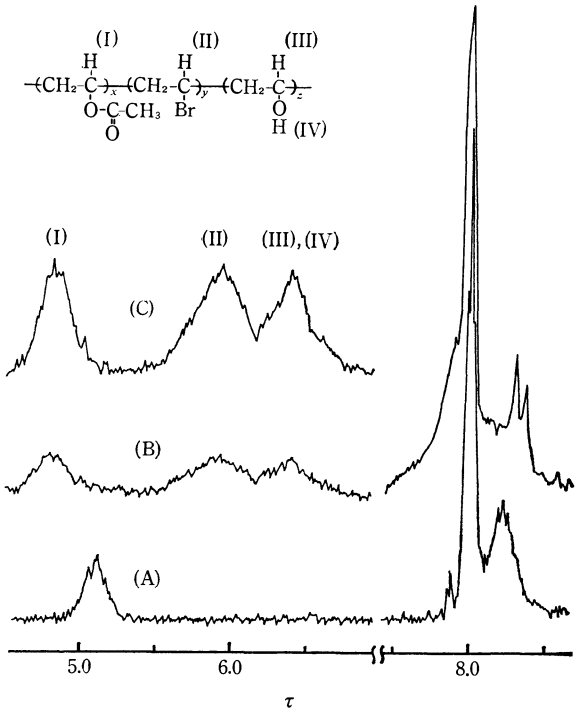

Fig. 8. NMR spectra of (A) PVAc prepared by AIBN, (B) reaction product of PAVE with HBr in AcOH and (C) the slow sweep of B.

On the basis of this assignment, the fraction of the three structural units in the reaction product can be estimated from the intensity ratio of these three methine resonances, assuming that the resonance of the hydroxy proton in the vinyl alcohol

unit overlaps with its methine resonance at 6.40 τ. The results are shown in Table 4. The elementary compositions calculated for the determined ratio of the three structural units is in good agreement with that observed by the analysis. This shows the validities of the assignment of the NMR spectrum and the structure of the reaction product presumed to be a ternary copolymer of vinyl acetate, vinyl alcohol, and vinyl bromide.

Discussion

Two double bonds in AVE are expected to participate in the polymerization reaction, either independently or together as in the cyclopolymerization of α,ω-diolefin.[14] However, all the PAVEs obtained by $BF_3 \cdot OEt_2$ under various conditions gave NMR spectra in which the resonances characteristic of the vinyl protons disappeared and the peaks due to the protons of the allyl double bond remained unchanged (Fig. 1). This shows that, by means of the $BF_3 \cdot OEt_2$ catalyst, this monomer polymerized exclusively through the vinyl double bond, leaving the allyl double bond unaffected during the polymerization. The polymer could subsequently be cross-linked through the allyl side chains over a long period at room temperature.

The solution viscosity of the PAVE obtained in toluene at -78°C increased with the increase in the monomer concentration (Fig. 5). This suggests that there is no or only a little chain-transfer reaction to the monomer in the polymerization. The marked decrease in the viscosity of the polymer with a rise in the polymerization temperature (Fig. 3) indicates that the contribution of the chain-transfer or termination reaction becomes greater at elevated temperatures. The decrease in the viscosity with an increase in the catalyst concentration (Fig. 4) will indicate the existence of a chain-transfer reaction to the catalyst. However, this is not conclusive, because a temporary elevation of the temperature in the reaction mixture was observed at a higher concentration of catalyst; this may cause the depression of the molecular weight of the polymer.

A number of NMR studies of poly(alkyl vinyl ether) have been reported, and the tacticity of polymer has been determined with[15] and without[2,16,17] the spin decoupling technique. In this work we have determined the fraction of the tactic dyad in PAVE by analysis of the decoupled spectrum, in which the resonance of β-protons decoupled from the α-proton was sensitive to the stereochemical configuration.

Generally the cationic polymerization at a low temperature gave an isotactic polymer in a non-polar solvent and a syndiotactic one in a polar solvent. This was explained by the ion-pair mechanism in a non-polar system and by the free-ion propagation in a polar system.[11,3] *t*-Butyl vinyl ether[11] and trimethylsilyl vinyl ether[18] gave isotactic polymers in toluene and rather syndiotactic polymers in nitroethane or methylene chloride. On the other hand, in the polymerization of benzyl vinyl ether[2] a fairly isotactic polymer was obtained even in a polar solvent and the isotacticity of the polymer decreased only slightly at elevated temperatures. The specific participation of the benzyl group was suggested in this stereoregulated polymerization.

Allyl vinyl ether gave a highly isotactic polymer at -78°C in toluene, and the decrease in the isotacticity was very small at higher temperature (Fig. 3), although it was observed remarkably in a polar medium (Table 1 and Fig. 6). This behavior of AVE may be attributable to the similarity between the allyl group and the benzyl group in benzyl vinyl ether.

It has been previously reported that an isotactic poly (benzyl vinyl ether) gave an isotactic poly(vinyl alcohol) by debenzylation reaction with HBr in toluene.[19] The reaction of PAVE with HBr in

toluene or dioxane gave an insoluble product containing a considerable amount of bromine. It was probably cross-linked through the allyl side chains by a cationic mechanism. In the reaction in acetic acid, the product was revealed to be a ternary copolymer of vinyl alcohol, vinyl acetate, and vinyl bromide by IR and NMR spectroscopies. The vinyl acetate unit must have been produced by a further reaction of the vinyl alcohol unit and acetic acid. It is not certain at present whether the vinyl bromide unit was formed by the reaction of the vinyl alcohol unit and HBr or by the cleavage of the ether linkage by HBr on the opposite side.

The authors wish to express their sincere thanks to Mr. Y. Terawaki for the NMR experiments and to Mr. K. Nagata and Mrs. F. Yano for clerical assistance in preparing the manuscript.

The Total Synthesis of Dehexyl-deisovaleryloxy-antimycin A_1*1

Mitsuhiro KINOSHITA and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received September 8, 1969)

A biologically active prototype of antimycin A series has been synthesized. The dilactone moiety was synthesized from a masked L-threonine and γ-hydroxyvalerate and condensed with an *O*-masked derivative of 3-nitrosalicylic acid *N*-hydroxysuccinimide ester. Hydrogenation followed by formylation afforded the anti-fungal substance. This synthesis established a possible general synthetic pathway to the members of antimycin A.

In 1949 F. M. Strong and his co-workers[1] isolated antimycin A and by later works[2] it was revealed that the crystalline antibiotic was a complex of at least four closely related active components. Antimycin A is a potent antibiotic against fungi and, especially, owes its interest to the fact that it is remarkably effective in inhibiting the hydrogen transport systems of aerobic organisms.[3]

The structures of antimycin A_1 (**1b**) and A_3 (**1c**) were elucidated by several research groups[4] on chemical and spectral evidences, and variations in the higher alkyl side chains account for structural differences between the members of the antimycin complex.

	1a	**1b**	**1c**
R_1:	H	n-C_6H_{13}	n-C_4H_9
R_2:	H	i-C_4H_9COO	i-C_4H_9COO

The most striking characteristic of the structure of antimycin A is its dilacton ring linked *via* an amide linkage to 3-formamidosalicylic acid. We were interested in the total synthesis of antimycin A, and attempted, in the first place, to synthesize a prototype in which the structure of dilactone moiety was made somewhat simpler than that in the natural antimycin A. This paper presents the total synthesis of dehexyl-deisovaleryloxy-antimycin A_1 (**1a**) which differs from natural antimycin A

in that the acyloxy and higher alkyl side chains in its dilactone ring are replaced by hydrogen atoms.

As for the amino acid moiety in the dilactone ring, L-threonine was incorporated as it was in the natural antimycin A, because the characteristic antibiotic activity of antimycin A seems to be strictly dependent upon the maintenance of the stereochemical feature of the amino acid moiety.

t-Butyl levulinate was prepared from levulinic acid and isobutene by a modification of the method of Gal and Sletzimyer[5] in a good yield.

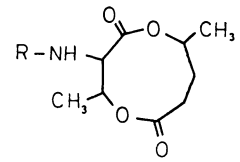
Catalytic reduction of *t*-butyl levulinate over Raney Ni W-5 afforded *t*-butyl γ-hydroxyvalerate in a 91.8% yield.

t-Butyl γ-hydroxyvalerate was allowed to react with *N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonine[6] in the presence of *N*,*N*′-dicyclohexylcarbodiimide and pyridine in ether according to the condition in which Hassall *et al.*[7] had obtained the excellent result on the preparation of benzyl β-(*N*-benzyloxycarbonyl-*O*-*t*-butyl-DL-seryloxy)propionate. In our case, however, the reaction was accompanied by byproduction of a considerable amount of acyl dicyclohexyl urea. Separation of the condensation product from the by-product was effected on a silica gel column chromatography with a *n*-hexane-diisopropyl ether-ether (2 : 2 : 1) system to afford *t*-butyl γ-(*N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonyloxy) valerate (**2**) in a 45% yield as a syrup.

	2	**3**
R:	*t*-C_4H_9	H

Treatment of **2** with trifluoroacetic acid, followed by purification through a silica gel column with *n*-hexane-ethyl acetate-acetic acid (20 : 10 : 1) system gave γ-(*N*-benzyloxycarbonyl-L-threonyloxy)-valeric acid (**3**) in a 90% yield. The free linear ester acid **3** was cyclized by high dilution technique in a benzene solution by adding 2 mol of trifluoroacetic anhydride at 75°C during 19 hr.[8]

Treatment of the reaction product with ether gave crystal **A** in a 2.6% yield. The mother-liquor was concentrated and chromatographed on a silica gel column with a benzene-diisopropyl ether-ether (6 : 2 : 1) system to give two fractions. The first fraction gave crystal **B** in a 16.7% yield. On the basis of elemental analysis, infrared spectrum and molecular weight determination by mass spectrum, the crystal **B** was found to be the desired intramolecular cyclization product, namely, 3-(benzyloxycarboxamido)-4,9-dimethyl-1,5-dioxa-2,6-cyclononadione (**4**).



4 **5**

R:	$C_6H_5CH_2OCO$	NO_2 $OCH_2C_6H_5$ -CO

The second fraction of the chromatography gave a crystalline solid, which, on treatment with ether, was further devided into crystal **C** and syrup **D**. Each of the crystal **A** and **C** and syrup **D** proved to be a diastereomer of dimeric intermolecular cyclization products by the results of elemental analyses, IR-spectra, molecular weight determinations and optical rotatory powers.

When the cyclization reaction was carried out by directly using a freshly prepared crude ester-acid **3** without purification through a silica gel column, the yields of cyclization products markedly increased (about twice).

On NMR spectrum of the compound **4**, the proton signals of the two methyl groups were observed as four doublets having coupling constant $J=7.5$ Hz at τ values in deuteriochloroform 8.53, 8.60, 8.69 and 8.76 (Fig. 1). This indicates that the compound **4** is a mixture of two diastereomers. The presence of the two diastereomers is natural because racemic *t*-butyl γ-hydroxyvalerate was used as one of the starting materials, and the diastereomeric rela-

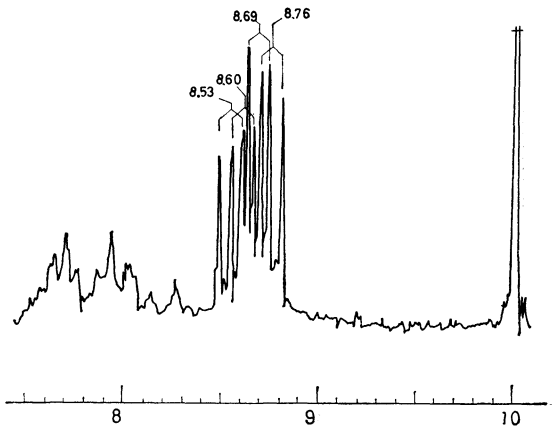


Fig. 1. Partial NMR spectrum of the compound **4** in $CDCl_3$ at 60 MHz.

5) Levulinic anhydride was used instead of levulinic acid in a patent by G. Gal and M. Sletzimyer, Fr. 1384248 (1965); *Chem. Abstr.*, **62**, 16197b (1965).

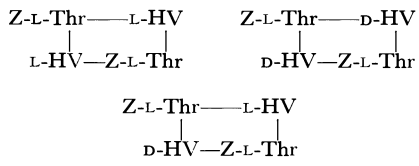
6) E. Schröder, *Ann.*, **670**, 127 (1963).

7) C. H. Hassall, T. G. Martin, J. A. Schofield and J. O. Thomas, *J. Chem. Soc., C*, **1967**, 997.

8) O. Th. Schmidt and W. Staab, *Chem. Ber.*, **81**, 388 (1954).

tionship is concerned with the two possible configurations at C-9 of the dilactone molecule.[9]

The formation of three kinds of cyclic dimers may reasonably explained by the theoretical combinations of *N*-benzyloxycarbonyl-L-threonine (Z-L-Thr), D- and L-γ-hydroxyvaleric acid (D-HV, L-HV) as shown in the schematic diagram.



The benzyloxycarbonyl group of **4** was removed by catalytic hydrogenolysis over palladium black in methanol to give the free amino dilactone, which was directly *N*-acylated with an active ester, *O*-benzyl-3-nitrosalicylic acid *N*-hydroxysuccinimide ester in tetrahydrofuran. A silica gel column chromatography of the reaction product with *n*-hexane-ethyl acetate (5 : 3) system gave 3-(*O*-benzyl-3-nitrosalicyloylamido)-4,9-dimethyl-1,5-dioxa-2,6-cyclononadione (**5**) as crystals in a 72.4% yield.

The compound **5** was then hydrogenolysed over palladium black in methanol to yield *N*-(3-aminosalicyloyl)amino dilactone which was immediately *N*-formylated with 98% formic acid and dicyclohexylcarbodiimide. Column chromatography of the crude product followed by recrystallization afforded dehexyl-deisovaleryloxy-antimycin A_1 (**1a**) which was considered to be a diastereomeric mixture in a 54% yield based on the compound **5**.

The UV spectrum of **1a** showed the characteristic absorption maxima at 226 and 320 mμ which correspond to the *N*-formyl-3-aminosalicyloyl chromophore as a constituent portion of antimycin A.

The IR spectrum of **1a** also was similar to that of antimycin A in respect of the characteristic absorptions assignable to ester carbonyl, formamido and aromatic amido groups.

Bioassay: The synthetic dehexyl-deisovaleryloxy-antimycin A_1 showed strong inhibition against certain fungi. Minimal inhibitory concentrations (mcg/ml) of the synthetic specimen against tested fungi were as follows: *Corticium rosii* 50, *Gloeosporium lacticola* 100, *Glomerella cingulate* 100, *Leptosphaeria sulvinii* 50 by dilution method with Sabouraud medium, 27°C 5 days; *Piricularia oryzae* 0.1, *Trichophyton asteroides*-429 12.5 by agar dilution method with 1% glucose nutrient agar, 27°C 42 hr.

9) A possibility of racemization at C-4 which may occur during the ring closure reaction with trifluoroacetic anhydride might be excluded on the basis of the fact that Taub *et al.* had elucidated in their synthetic studies on zearalenone;[9] D. Taub, N. N. Girotra, R. D. Hoffsommer, C. H. Kuo, H. L. Slates, S. Weber and N. L. Wendler, *Tetrahedron*, **24**, 2443 (1968).

Experimental

Melting points were determined on a micro hot stage and were uncorrected. Thin-layer chromatography (TLC) was conducted by the use of silica gel (Daiichi Pure Chemical Co., Inc.). Silica gel column chromatography was carried out by using the silica gel (Kanto Chemical Co., Inc. and Junsei Chemical Co., Inc.) which was activated at 110°C for 1 hr. Infrared spectra were recorded on a Hitachi IPI-2 spectrometer. Ultraviolet spectra were taken in a Hitachi Perkin-Elmer UV-VIS spectrometer 139. NMR spectra was recorded on a Varian A-60D spectrometer (TMS as an internal standard). In general, all concentrations were carried out in a rotary evaporator at reduced pressure below 40°C.

***t*-Butyl Levulinate.** Liquid isobutene (100 ml, *ca.* 1.2 mol) was added to a solution of levulinic acid (20 g, 0.172 mol) in a mixture of dichloromethane (100 ml) and conc. sulfuric acid (1 ml) which was cooled at −30°C in a 500-ml round-bottomed flask. The stoppered flask was allowed to stand at room temperature for 70 hr. The reaction mixture was neutralized with triethylamine (2.52 ml) and evaporated. The residue was taken with ethyl acetate (100 ml) and the solution was washed with water (20 ml × 3) and saturated sodium chloride solution (20 ml) and dried over sodium sulfate. After evaporation of the solvent, the residue was distilled at reduced pressure. The fraction boiling at 49.5—51.0°C/0.8 mmHg was collected: yield 25.8 g (87%); n_D^{20} 1.4232; $\nu_{max}^{CHCl_3}$ 1735 cm^{-1} (C=O and ester). [lit,[5] bp 72—74°C/2 mmHg].

Found: C, 62.94; H, 9.50%. Calcd for $C_9H_{16}O_3$: C, 62.76; H, 9.36%.

***t*-Butyl γ-Hydroxyvalerate.** *t*-Butyl levulinate (14 g) was hydrogenated with Raney Ni W-5 (1.5 ml) in an initial hydrogen pressure of 75 kg/cm^2 at 66—68°C for 2 hr. After removal of the catalyst, the filtrate was distilled at reduced pressure to afford a colorless liquid: yield 13.27 g (91.8%); bp 70—73°C/1 mmHg; n_D^{20} 1.4291; $\nu_{max}^{liq.}$ 3420 (OH) and 1735 cm^{-1} (ester).

Found: C, 62.26; H, 10.58%. Calcd for $C_9H_{18}O_3$: C, 62.04; H, 10.41%.

***t*-Butyl γ-(*N*-Benzyloxycarbonyl-*O*-*t*-butyl-L-threonyloxy)valerate (2).** A solution of *N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonine[6] (8.00 g, 25.9 mmol) in dry ether (15 ml) was added dropwise during 40 min to a stirred solution of *t*-butyl γ-hydroxyvalerate (4.50 g, 25.9 mmol), *N,N'*-dicyclohexylcarbodiimide (DCCI) (5.89 g, 28.6 mmol) and dry pyridine (2.2 ml, 25.9 mmol) in dry ether (20 ml) cooled to 0°C. Stirring at 0°C was continued for a further 1 hr. After standing at 0°C for 23 hr, the precipitate of *N,N'*-dicyclohexylurea (3.54 g, 55.2%) was filtered off and the filtrate was treated with acetic acid (2 ml) under stirring at 0°C for 2 hr. An additional urea was removed by filtration and the filtrate was diluted with ether. The solution was then washed with 5% sodium hydrogen carbonate solution, 5% citric acid solution and saturated sodium chloride solution, dried over sodium sulfate, and concentrated to dryness. The oily residue (13.4 g) was chromatographed on a silica gel column (2.2 kg, 8 × 54 cm). Elution with a *n*-hexane-diisopropyl ether-ether (2 : 2 :1) system gave a straw-colored syrup (5.42 g, 45%) as a first fraction which behaved as a homogeneous compound

having R_f-value of 0.66 on TLC using the same solvent system as in the column chromatography: $[\alpha]_D^{19}$ −4.1°C (c, 2.0, ethanol); $\nu_{max}^{liq.}$ 3480, 3380 (NH), 1740 (ester and amide I) and 1510 cm^{-1} (amide II).

Found: C, 64.78; H, 8.60; N, 3.22%. Calcd for $C_{25}H_{39}O_7N$: C, 64.49; H, 8.44; N, 3.01%.

The second fraction of the column chromatography gave a syrup (3.05 g) having R_f-value of 0.56 on TLC. A part of the syrup was purified through a silica gel column with the same solvent system to afford *N*-(*N*-benzyloxycarbonyl-*O*-*t*-butyl-L-threonyl)-*N*,*N*'-dicyclohexylurea as a colorless glass.

Found: C, 67.61; H, 8.44; N, 7.80%. Calcd for $C_{29}H_{45}O_5N_3$: C, 67.54; H, 8.80; N, 8.15%.

γ-(*N*-Benzyloxycarbonyl-L-threonyloxy)valeric Acid (3). A mixture of **2** (692 mg) and trifluoroacetic acid (12 m*l*) was kept at room temperature with occasional swirling for 20 min, after which the reaction mixture was evaporated below 20°C. The residual syrup was then dissolved in ether and again evaporated. This procedure was repeated thrice to remove trifluoroacetic acid. The final residue was chromatographed on silica gel (25 g) with a *n*-hexane-ethyl acetate-acetic acid (20 : 10 : 1) system. The eluents containing **3** were evaporated to afford the pure sample of **3** (475 mg, 90%) as a pale-yellow syrup: $[\alpha]_D^{21}$ −16.4°C (c 2.0, ethanol); $\nu_{max}^{liq.}$ 3340 (NH and OH), 2700—2500 (carboxyl OH), 1720 (ester, carboxyl and amide I) and 1525 cm^{-1} (amide II).

Found: C, 57.91; H, 6.85; N, 4.08%. Calcd for $C_{17}H_{23}O_7N$: C, 57.78; H, 6.56; N, 3.96%.

Cyclization of 3. a) A mixture of **3** (991 mg, 2.81 mmol) purified by column chromatography, dry benzene (70 m*l*) and trifluoroacetic anhydride (0.39 m*l*, 2.81 mmol) was heated at 75°C for 10 hr, after which additional trifluoroacetic anhydride (0.39 m*l*) was added and again heated at the same temperature for 9 hr. The reaction mixture was evaporated and the resulting syrup was dissolved in absolute ether. On ice-cooling of the solution, there was obtained a crystalline product **A**, which was collected by filtration: mp 206—208°C; yield 24.5 mg (2.6%). Recrystallization of the product **A** from ethyl acetate-petroleum ether (bp 40—60°C) gave colorless needles: mp 208—210°C; $[\alpha]_D^{11}$ −45° (c 2.0, chloroform); m/e 670; ν_{max}^{KBr} 3340 (NH), 1732 (ester), 1715 (amide I) and 1530 cm^{-1} (amide II).

Found: C, 61.44; H, 6.16; N, 4.41%. Calcd for $(C_{17}H_{21}O_6N)_2$: C, 60.88, H, 6.31; N, 4.18%.

The mother liquor of the crystal **A** was concentrated and chromatographed on silica gel (200 g) with a benzene-diisopropyl ether-ether (6 : 2 : 1) system to afford two fractions having R_f-values, 0.55 and 0.43 on TLC with the same solvent stysem. The first fraction (R_f 0.55) gave a crystalline product **B** (158 mg, 16.7%); mp 99—103°C. Recrystallization of **B** from ethyl acetate-petroleum ether gave a pure sample of 3-benzyloxycarboxamido-4,9-dimethyl-1,5-dioxa-2,6-cyclononadione (**4**): mp 105—107°C; $[\alpha]_D^{21}$ +14° (c 2.0, ethanol); $[\alpha]_D^{21}$ +31° (c 1.0, chloroform), m/e 335; ν_{max}^{KBr} 3320 (NH), 1745 (ester), 1693 (amide I) and 1539 cm^{-1} (amide II); τ^{CDCl_3} 8.53, 8.60, 8.69 and 8.76 (d, C_4- and C_9-CH_3, J=7.5 Hz).

Found: C, 61.21; H, 6.70; N, 4.37%. Calcd for $C_{17}H_{21}O_6N$: C, 60.88; H, 6.31; N, 4.18%.

The second fraction (R_f 0.43) afforded a crystalline product melting at 151—154°C (26.6 mg, 2.8%). The product (71 mg) was washed with ether (4 m*l*) and the resulting crystal (46 mg) was recrystallized from ethyl acetate-petroleum ether to afford crystals **C**: mp 167—169°C; $[\alpha]_D^{13}$ +1.3° (c 2.0, chloroform); ν_{max}^{KBr} 3340 (NH), 1732 (ester), 1710 (amide I) and 1525 cm^{-1} (amide II); m/e 670.

Found: C, 61.00; H, 6.57; N, 4.23%. Calcd for $(C_{17}H_{21}O_6N)_2$: C, 60.88; H, 6.31; N, 4.18%.

The ether washing was concentrated and worked up with petroleum ether to give additional crystals **C** (5 mg). The filtrate was evaporated to afford a syrup **D** (14 mg): $[\alpha]_D^{18}$ +15° (c 1.0, chloroform); $\nu_{max}^{CCl_4}$ 3450 (NH), 1746—1732 (ester and amide I) and 1505 cm^{-1} amide II); m/e 670.

Found: N, 4.35%. Calcd for $(C_{17}H_{21}O_6N)_2$: N, 4.18%.

b) Treatment of **2** (162 mg) with trifluoroacetic acid (2.6 m*l*) for 10 min, followed by rapid evaporation below 10°C afforded crude **3**, which was immediately subjected to cyclization by the same procedures as described above. The concentrated reaction mixture afforded the product **A** (3.6 mg, 3.08%, mp 205—208°C), product **B** (**4**) (38 mg, 32.5%, mp 98—101°C, and product **C**+**D** (6.3 mg, 5.38%, mp 151—154°C).

***O*-Benzyl-3-nitrosalicylic Acid *N*-Hydroxysuccinimide Ester.** To a solution of *O*-benzyl-3-nitrosalicylic acid[10] (1.38 g, 5.05 mmol) and *N*-hydroxysuccinimide (0.58 g, 5.05 mmol) in dry tetrahydrofuran (16 m*l*) was added a solution of DCCI (1.04 g, 5.05 mmol) in tetrahydrofuran and the mixture was kept at room temperature overnight. The precipitated *N*,*N*'-dicyclohexylurea (1.08 g, 95.6%) was filtered off and the filtrate was evaporated to dryness. The residue (1.92 g) was recrystallized from ethanol (80 m*l*) to afford pure title compound as pale-yellow needles: yield 1.62 g (87%); mp 140—141°C; ν_{max}^{KBr} 1810, 1780, 1741, 1600, 1540, 1360, 770 and 700 cm^{-1}.

Found: C, 58.56; H, 3.79; N, 7.27%. Calcd for $C_{18}H_{14}O_7N_2$: C, 58.38; H, 3.81; N, 7.57%.

3-(*O*-Benzyl-3-nitrosalicyloylamido)-4,9-dimethyl-1,5-dioxa-2,6-cyclononadione (5). A solution of **4** (crystal **B**) (138 mg, 0.413 mmol) in methanol (6 m*l*) was stirred with palladium black (*ca.* 15 mg) for 50 min under bubbling with hydrogen. The filtered reduction mixture was evaporated to yield the free amino dilactone (85 mg) which showed a single ninhydrin positive spot on TLC with a benzene-diisopropyl ether-ether (6 : 2 : 1) system. The free amino dilactone (83 mg, 0.413 mmol) was dissolved in dry tetrahydrofuran (2 m*l*) and *O*-benzyl-3-nitrosalicylic acid *N*-hydroxysuccinimide ester (153 mg, 0.413 mmol) was added. The mixture was kept for 20 hr at room temperature, after which it was allowed to stand for 27 hr at 36°C in an incubator. The resulting solution was concentrated to afford a yellow crystalline mass which was purified through silica gel (45 g) column. Elution with *n*-hexane-ethyl acetate (5 : 3) system gave the title compound (**5**) as pale-yellow crystals: yield 135 mg (72.4%), mp 186—189°C. Recrystallization from tetrahydrofuran-petroleum ether (bp 60—70°C): mp 188—189.5°C; $[\alpha]_D^{23}$ +20° (c 2.0, tetrahydrofuran); ν_{max}^{KBr} 3300 (NH), 1743 (ester), 1645 (amide I) and 1532 cm^{-1} (amide II and NO_2).

Found: C, 60.57; H, 5.48; N, 6.11%. Calcd for

We wish to thank Professor H. Umezawa for his helpful advice, Mr. S. Nakada for the microanalyses and Mr. F. Kishimoto for his technical assistance. We also wish to thank Professor S. Zen of Kitasato University for the measurement of mass spectra, Dr. M. Hamada of Institute of Microbial Chemistry and Mr. S. Fukatsu of Meiji-Seika Co. for their microbiological tests.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 901—904 (1970)

Syntheses of 2,3-Dihydro-4(1*H*)-pyridones

Noboru SUGIYAMA, Makoto YAMAMOTO and Choji KASHIMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo

(Received September 10, 1969)

The condensation of β-diketones with benzaldazine yields 1-benzylidenimino-2,3-dihydro-4-pyridones, which may be catalytically hydrogenolyzed to the corresponding 2,3-dihydro-4(1*H*)-pyridones. Some reactions of 2,3-dihydro-4(1*H*)-pyridones are discussed.

Previously we described that β-diketones may be condensed with benzylidenaniline in the presence of three molar equivalents of potassium amide in liquid ammonia to produce 1-phenyl-2,3-dihydro-4-pyridones.[1] We also reported that these 1-phenyl-2,3-dihydro-4-pyridones were prepared by the cyclization of the correspoding aminodiketones.

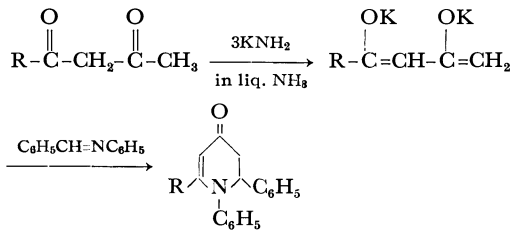

Fig. 1

However, the 1-unsubstituted dihydropyridones, namely 2,3-dihydro-4(1*H*)-pyridones are more important than 1-phenyl ones in view of the organic reactions and biochemical studies. Now we wish to report that β-diketones when condensed with benzaldazine give 1-benzylidenimino-2,3-dihydro-4-pyridones, which on hydrogenolysis lead to 2,3-dihydro-4(1*H*)-pyridones. The present paper also described some of the reactions of these compounds.

Results and Discussion

Acetylacetone (II) was condensed with benzaldazine (I) in the presence of three molar equivalents of sodium amide in liquid ammonia to give 1-benzylidenimino-6-methyl-2-phenyl-2,3-dihydro-4-pyridone (V). The yield was 6.2%. When potassium amide was used instead of sodium amide, the yield of V increased to 11.0%.

The structure of V was determined from the spectral data and the elemental analyses (see Experimental). The nuclear magnetic resonance spectrum supported the structure of V, *i.e.*, the two singlets at τ 7.52 and 4.82 were assigned to the methyl and the olefinic protons. The ABX type signals in the region τ 6.49—7.70 were assigned to the C-3 methylene protons coupled with C-2 methine proton at τ 4.50 as a quartet. The signal at τ 2.40—3.05 displayed 10 aromatic protons and

a proton of –N=CH– group as a multiplet.

By the same procedure, 1-benzylidenimino-2,6-diphenyl-2,3-dihydro-4-pyridone (VI) was obtained in 9.2% yield from I and benzoylacetone (III). Using I and 6-phenyl-2,4-hexanedione (IV), 1-benzylidenimino-6-phenethyl-2-phenyl-2,3-dihydro-4-pyridone (VII) and its isomer 3-benzyl-1-benzylidenimino-6-methyl-2-phenyl-2,3-dihydro-4-pyridone (VIII) were obtained in the yields of 52% and 21%, respectively. In the reaction of I and IV, the condensation took place not only at C-1 but also C-5 position of IV. The ratio of VII to VIII was about 5 : 2, similar to that of the reaction of IV with benzylidenaniline.

Schiff bases are reduced to secondary amines by hydrogen in the presence of nickel or platinum catalyst,[2] and hydrazocompounds are reduced to amines.[3] On the other hand, neither the carbonyl group nor the double bond of 2,3-dihydro-4-pyridone ring is hydrogenolyzed by platinum oxide catalyst in methanol or ethanol solution.[4] However, 2,3-dihydro-4-pyridone is reduced in the presence of platinum oxide to a corresponding 4-piperidinol or 4-piperidone in acetic acid solution.[5] When 1-benzylidenimino-2,3-dihydro-4-pyridone is catalytically hydrogenolyzed in the presence of platinum oxide in alcohol solution, 1-benzylamino- or 2,3-dihydro-4(1*H*)-pyridone may be expected. Hydrogenolysis of VII in ethanol catalyzed by platinum oxide gave only 2,3-dihydro-4(1*H*)-pyridone, 6-phenethyl-2-phenyl-2,3-dihydro-4(1*H*)-pyridone (XI), but no 1-benzylaminodihydropyridone. The structure of XI was confirmed by the spectral data and the results of elemental analyses (see Table 1).

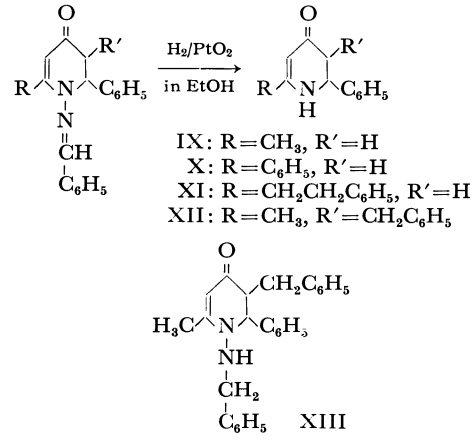

Fig. 3

By the same procedure, 6-methyl-2-phenyl-2,3-dihydro-4(1*H*)-pyridone (IX), 2,6-diphenyl-2,3-dihydro-4(1*H*)-pyridone (X) and 3-benzyl-6-methyl-2-phenyl-2,3-dihydro-4(1*H*)-pyridone (XII) were

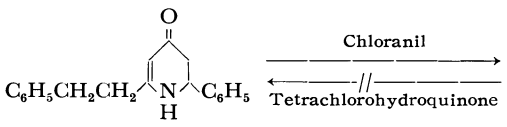
5) N. Sugiyama, M. Yamamoto and C. Kashima, This Bulletin, **42**, 2690 (1969).

obtained from V, VI and VIII, respectively. The spectral data are summarized in Table 1.

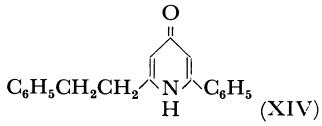
When equimolar hydrogen is absorbed, 1-benzylamino-2,3-dihydro-4-pyridone may be expected to be formed as an intermediate. However, after absorbing about 3/2 molar hydrogen, VIII gave 20% of 1-benzylamino-3-benzyl-6-methyl-2-phenyl-2,3-dihydro-4-pyridone (XIII) together with 45% of XII.

The structure of XIII was proved by the spectral data. The infrared spectrum showed bands at 3300, 1630 and 1550 cm^{-1} for NH, conjugated carbonyl and C=C double bonds. The nuclear magnetic resonance spectrum showed at τ 6.33—6.66 (broad triplet, 1H) and τ 6.13 (doublet, 2H) for amino proton and methylene protons of 1-benzylamino group. By treatment with D_2O, the former disappeared and the latter changed to a singlet. The other signals are similar with those of VIII. From these results it is apparent that 1-benzylidenimino-2,3-dihydro-4-pyridone was first hydrogenolyzed to 1-benzylamino-2,3-dihydro-4-pyridone and this benzylamino compound underwent hydrogenolysis to yield the corresponding 2,3-dihydro-4(1*H*)-pyridone.

In a previous paper, we reported that 1-phenyl-2,6-disubstituted dihydropyridones were dehydrogenated in the presence of a hydrogen acceptor.[5] XI was also dehydrogenated by treating with chloranil in tetrahydrofuran to yield the corresponding pyridone, 6-phenethyl-2-phenyl-4(1*H*)-pyridone (XIV). XIV was identical with the authentic sample[6] on thin-layer chromatography. However, conversion from XIV into XI with tetrachlorohydroquinone was not successful. This proved that XI was easily oxidized with chloranil to XIV and the reaction was not of the equilibrium type.



(XI)



(XIV)

Fig. 4

It is well known that I is decomposed to hydrazine and benzaldehyde by treating with dilute acid. Taylor *et al.* reported[7] that the isopropylidenimino group of 3-isopropylidenimino-4(3*H*)-pteridinone undergoes a reductive elimination in dilute acid solution to give 3-amino-4(3*H*)-pteridinone. If VII is treated with dilute acid, the corresponding *N*-amino dihydropyridone is expected to produce.

Compound VII was treated with dilute hydrochloric acid, but *N*-aminodihydropyridone was not obtained, and instead of *N*-aminodihydropyridone, a red viscous substance, which could not be purified, was obtained.

The present method is generally applicable for the synthesis of 2,3-dihydro-4(1*H*)-pyridones.

Experimental

Syntheses of 1-Benzylidenimino-dihydropyridone. General Procedure: In a 500 m*l* three necked flask, about 300 m*l* of anhydrous liquid ammonia was introduced. A small amount of potassium was then added and completely dissolved. A catalytic amount of ferric chloride was then added to the stirred blue solution, followed by 4.7 g (0.12 g atom) of potassium in small portions. The solution turned dark gray within 90 min. To this solution was added 0.04 mol of β-diketone in 30 m*l* of anhydrous ether. After stirring for 45—60 min, 0.02 mol of I[8] in 50 m*l* of anhydrous ether was added. After stirring for another 3.5—4 hr at −33°C, 100 m*l* of ether was added from a dropping funnel, followed by the rapid evaporation of ammonia on a water both. To the ethereal solution, excess ammonium chloride (10 g) in 100 m*l* water was added. The ethereal layer was then separated and the aqueous layer was extracted with 100 m*l* of ether. The ethereal layer was washed with water and dried over anhydrous sodium sulfate. The remaining aqueous layer was acidified with dilute hydrochloric acid, and again extracted with 200 m*l* of chloroform. The chloroform extract was dried over calcium chloride. After concentration under reduced pressure, both residue gave condensation products.

The crude product was chromatographed on a silica gel (Merck 7734, 0.05—0.2 mm) column with a benzene-ethyl acetate mixture. The fraction showing a green color on a ferric chloride test was collected and concentrated *in vacuo* to give crude 1-benzylidenimino-2,3-dihydro-4-pyridone. The latter was then crystallized from ethyl acetate to yield pure dihydropyridone. By this procedure, V, VI, VII and VIII were obtained.

1-Benzylidenimino-6-methyl-2-phenyl-2,3-dihydro-4-pyridone (V). From I and II, V was synthesized. Fractionating solvent: Benzene-ethyl acetate 2 : 1 (*v*/*v*) mixture. Pale yellow prisms, mp 176—177°C.

Found: C, 78.40; H, 6.42; N, 9.59%. Calcd for $C_{19}H_{18}N_2O$: C, 78.59; H, 6.25; N, 9.65%. IR (KBr): ν_{max} 1635 (νC=O), 1580 (νC=N) and 1560 cm^{-1} (νC=C). UV(mμ(ε)): λ_{max}^{EtOH} 229(9900), 234(9500), 282(3600) and 364(44000).

In this reaction, 72% of II and 49% of I were recovered. In spite of elongation of the reaction time (for 6.5 hr), the yield of V was 10.2% and 65% of II, 35% of I also recovered.

1-Benzylidenimino-2,6-diphenyl-2,3-dihydro-4-pyridone (VI). VI was prepared from I and III in

9.2% yield. Fractionating solvent: Benzene-ethyl acetate 4 : 1 (*v/v*). Yellow plates, mp 178—179°C.

Found: C, 81.88; H, 5.83; N, 8.06%. Calcd for $C_{24}H_{20}N_2O$: C, 81.79; H, 5.72; N, 7.95%. IR (KBr): ν_{max} 1645 (νC=O), 1570 (νC=N) and 1550 cm^{-1} (νC=C). UV(mμ(ε)): λ_{max}^{EtOH} 238(15400), 281(9430) and 368 (31700). NMR (in $DCCl_3$): τ6.36—6.76 (ABX type, quartet, 1H, C-3 methylene proton, J_{AB}=16.5 Hz, J_{AX}=7.5 Hz), 6.96—7.34 (ABX type, quartet, 1H, C-3 methylene proton, J_{BX}=1.5 Hz), 4.68 (singlet, 1H, C-5 olefinic proton), 4.40(quartet, 1H, C-2 methine proton) and 2.35—2.84 (multiplet, 16H, a proton of -N=CH- group and aromatic protons).

In this reaction, 57% of II was also recovered. But III was merely 18.5% recovered.

1-Benzylidenimino-6-phenethyl-2-phenyl-2,3-dihydro-4-pyridone (VII). VII was prepared from I and IV[9] in 52% yield. Fractionating solvent: Benzene-ethyl acetate 2 : 1 (*v/v*). Yellow plates, mp 118—121°C.

Found: C, 81.71; H, 6.34; N, 7.35%. Calcd for $C_{26}H_{24}N_2O$: C, 82.07; H, 6.36; N, 7.36%. IR (KBr): ν_{max} 1635 (νC=O), 1575 (νC=N) and 1550 cm^{-1} (νC=C). UV(mμ(ε)): λ_{max}^{EtOH} 231(12000), 236(11100), 283(3850) and 365(39000). NMR (in $CDCl_3$): τ 6.88 (singlet, 4H, phenethyl ethylene protons), 4.51—4.91(ABX type, quartet, 1H, C-3 methylene proton, J_{AB}=16.2 Hz, J_{AX}=7.4 Hz), 7.11—7.43(ABX type, quartet, 1H, C-3 methylene proton, J_{BX}=1.5 Hz), 4.81(singlet, 1H, C-5 olefinic proton), 4.50 (quartet, 1H) and 2.40—2.96 (multiplet, 16H).

3-Benzyl-1-benzylidenimino-6-methyl-2-phenyl-2,3-dihydro-4-pyridone (VIII). VIII was obtained from the same reaction mixture as VII. On column chromatography with benzene-ethyl acetate 2 : 1 (*v/v*) VIII eluted ahead of VII. On silica gel (Wako gel B-500) thin layer chromatography with benzene-ethyl acetate 2 : 1 (*v/v*), VIII showed the R_f 0.37, while that of VII was 0.29. VIII was concentrated and recrystallized from benzene-*n*-hexane giving 21% yield. Yellow neeldes, mp 129—131°C.

Found: C, 81.32; H, 6.51; N, 7.27%. Calcd for $C_{26}H_{24}N_2O$: C, 82.07; H, 6.36; N, 7.36%. IR(KBr): ν_{max} 1640 (νC=O), 1580 (νC=N) and 1560 cm^{-1} (νC=C). UV(mμ(ε)): λ_{max}^{EtOH} 228(11800), 234(11100), 284(3280) and 363(28200). NMR (in $CDCl_3$): τ 6.68—7.32 (multiplet, 3H), 7.48 (singlet, 3H), 4.96 (singlet, 1H), 4.81 (singlet, 1H) and 2.40—3.30 (multiplet, 16H).

Reduction of 1-Benzylidenimino-2,3-dihydro-4-pyridones by Catalytic Hydrogenolysis: Using 100 mg of platinum oxide, 200—300 mg of 1-benzylidenimino-2,3-dihydro-4-pyridone in 30 m*l* ethanol was hydrogenolyzed at room temperature and atmospheric pressure. After absorbing about two molar equivalents of hydrogen the catalyst was filtered off. The ethanol solution was concentrated *in vacuo*, and the residue was chromatographed on a silica gel (Merck 7729, 0.08 mm) column with benzene-ethyl acetate 2 : 1 (*v/v*). Fractions showing a dark brown color with ferric chloride were collected, concentrated and recrystallized to give 2,3-dihydro-4-pyridone. IX, X and XI were prepared by this method. The spectral data are listed in Table 1.

6-Methyl-2-phenyl-2,3-dihydro-4(1*H*)-pyridone (IX). IX was prepared by using 210 mg of V. Yield 62 mg (46%), colorless needles, mp 160—161°C.

Found: C, 76.92; H, 7.10; N, 7.73%. Calcd for $C_{12}H_{13}NO$: C, 76.97; H, 7.00; N, 7.48%.

2,6-Diphenyl-2,3-dihydro-4(1*H*)-pyridone (X). X was prepared from 200 mg of VI. Yield 92 mg (65.0%), yellow cubics, mp 149—151°C.

Found: C, 81.50; H, 6.13; N, 5.69%. Calcd for $C_{17}H_{15}NO$: C, 81.90; H, 6.06; N, 5.62%.

6-Phenethyl-2-phenyl-2,3-dihydro-4(1*H*)-pyridone (XI). XI was obtained from 300 mg of VII in 92% (201 mg) yield, mp 124—126°C, colorless needles.

Found: C, 82.08; H, 6.95; N, 5.22%. Calcd for $C_{19}H_{19}NO$: C, 82.28; H, 6.91; N, 5.05%.

3-Benzyl-6-methyl-2-phenyl-2,3-dihydro-4(1*H*)-pyridone (XII). VIII (250 mg) was hydrogenolyzed by the procedure described above. Twenty m*l* of hydrogen (calculated 31 m*l*) was absorbed and the product was chromatographed on a silica gel (Merck 7729) column with a benzene-ethyl acetate 2 : 1 (*v/v*) mixture. Fractions with R_f values 0.23 were collected and concentrated to give 65 mg (45%) of XII, colorless prisms, mp 159—160°C.

Found: C, 82.20; H, 6.89; N, 5.05%. Calcd for $C_{19}H_{19}NO$: C, 82.28; H, 6.91; N, 5.05%.

3-Benzyl-1-benzylamino-6-methyl-2-phenyl-2,3-dihydro-4-pyridone (XIII). From the same column, XIII was obtained. R_f value: 0.42. Yield, 51 mg (20%) as a yellow oil. UV(mμ): λ_{max}^{EtOH} 328. NMR(in $CDCl_3$): τ 7.80 (singlet, 3H, methyl protons), 7.20—6.70 (multiplet, 3H, C-3 methine proton and benzyl methylene protons), 6.66—6.33 (broad triplet, 1H, amino proton), 6.13 (doublet, 2H, methylene protons of benzylamino group), 5.41 (quartet, 1H, C-2 methine proton), 5.03 (singlet, 1H, C-5 olefinic proton) and 3.11—2.60 (multiplet, 15H, aromatic protons).

Dehydrogenation of XI. In 30 m*l* tetrahydrofuran were dissolved 80 mg of XI and 75 mg of chloranil. After refluxing for 5.5 hr, the mixture was cooled and the formation of XIV was confirmed on thin layer by the comparison with the authentic sample.[6]

Hydrolysis of VII. Compound VII (0.8 g) was dissolved in 40 m*l* of 50% aqueous ethanol and then 5 m*l* of concentrated hydrochloric acid was added. The mixture was refluxed for one hour on a water bath, and was made alkaline with sodium hydroxide. Extraction with chloroform and analysis of extract by means of silica gel (Wako gel B-500) thin layer chromatography (benzene-ethyl acetate, 2 : 1 *v/v*) showed two spots with R_f value 0.00 and 0.30. The latter was identified as VII. The former was a red viscous substance which could not be purified.

Mechanism of Decomposition of Carboxylic Sulfurous Anhydrides*1

Michio KOBAYASHI, Hiroshi MINATO and Yoshikuni OGI

Department of Chemistry, Tokyo Metropolitan University, Setagaya, Tokyo

(Received September 11, 1969)

Ethyl benzoyloxysulfinate, prepared from ^{18}O-labeled benzoic acid and ethyl chlorosulfite, was decomposed and the products were analyzed. The ^{18}O analyses showed that; 1) prior to decomposition the ^{18}O of the mixed anhydride was scrambled due to the formation and the internal return of an ion-pair, $C_6H_5C^{+}{}^{-}OSOEt$ (O O); 2) ethyl benzoate, benzoic anhydride and diethyl sulfite were produced *via* an ionic chain mechanism involving successive attack of ethoxide anion and benzoate anion on the carbonyl carbon and sulfinyl sulfur of the mixed anhydride.

In the thermal decomposition of mixed anhydride (I), formed from a carboxylic acid and an alkyl hydrogen sulfite, products are sulfur dioxide, a carboxylic ester, a carboxylic anhydride, and dialkyl sulfite, as shown in Eqs. (1) and (2).[1] In a previous paper[2] we described the isolation and the infrared spectra of I with various R and R′, and discussed the mechanism of the formation of a carboxylic ester by use of ^{18}O-labled methyl and phenyl benzoyloxysulfinates.

In order to clarify the mechanism of the formation of all the decomposition products, the ^{18}O contents of all the products from the decomposition

$$R\text{-}CO_2Na \text{ (or } RCO_2^{-}{}^{+}NEt_3) + Cl\text{-}S\text{-}OR' \rightarrow$$

(H, O)

$$R\text{-}C(=O)\text{-}O\text{-}S(O)\text{-}OR' + NaCl \quad (1)$$

(I)

$$(I) \rightarrow R\text{-}C(=O)\text{-}O\text{-}R' + SO_2 \quad (2)$$

$$(I) \rightarrow R\text{-}C(=O)\text{-}O\text{-}C(=O)\text{-}R + R'O\text{-}S(O)\text{-}OR' + SO_2 \quad (3)$$

of ^{18}O-labeled ethyl benzoyloxysulfinate (Ia, R= -Ph, R′=$-C_2H_5$) have been analyzed in detail, and the results are presented in this paper.

Results and Discussion

When ^{18}O-labeled sodium benzoate and ethyl chlorosulfite were mixed and the sirupy mixture formed was heated at 110—120°C, it decomposed with vigorous evolution of sulfur dioxide. The sulfur dioxide was collected in a dry ice-acetone trap, and was converted to benzyl phenyl sulfone for the ^{18}O analysis according to the equation.

$$SO_2 \xrightarrow{PhMgBr} (PhSO_2)_2Mg \xrightarrow{Na_2CO_3} Ph\text{-}SO_2Na$$

$$\xrightarrow{PhCH_2Br} Ph\text{-}S(=O)(=O)\text{-}CH_2Br \quad (4)$$

After the decomposition was complete, the products were separated by repeated fractional distillation. In order to distinguish the carbonyl oxygen and the ether oxygen in the benzoic anhydride, the anhydride was converted to benzoic acid and benzanilide by reaction with aniline in dichloromethane as shown in the equation.[5]

$$Ph\text{-}C(=O)\text{-}O\text{-}C(=O)\text{-}Ph + Ph\text{-}NH_2 \rightarrow$$

$$Ph\text{-}CO_2H + Ph\text{-}C(=O)\text{-}NH\text{-}Ph \quad (5)$$

(O)

*1 Organic Sulfur Compound. XX.

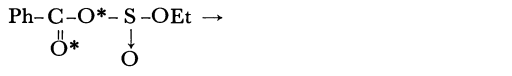
1) M. Kobayashi and A. Yamamoto, This Bulletin, **39**, 961 (1966).

2) M. Kobayashi and R. Kiritani, *ibid.*, **39**, 1782 (1966).

3) D. B. Denney and M. A. Greenbaum, *J. Amer. Chem. Soc.*, **79**, 3701 (1957).

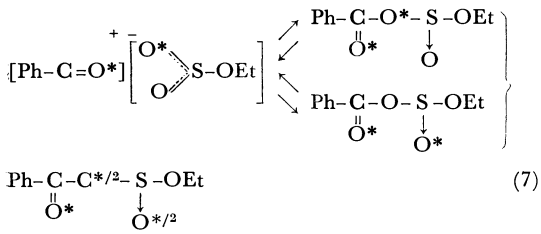
The results of ^{18}O analyses of all the reaction products are shown in Table 1.

The ^{18}O-atom % of ethyl benzoate was one half of that of the starting sodium benzoate. This finding indicates that, as shown previously, the ester was formed not by the reaction between ethyl chlorosulfite and benzoic anhydride, but formed directly by the decomposition of the mixed anhydride Ia. It should be noted that diethyl sulfite contained an appreciable amount of ^{18}O, and the ^{18}O content observed for benzoic anhydride was smaller than the value calculated on the basis of the reaction



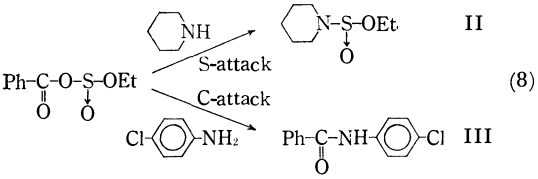
$$\text{Ph-C(=O*)-O-S-OEt} \rightarrow \tfrac{1}{2}\text{Ph-C(=O*)-O-C(=O*)-Ph} + \tfrac{1}{2}(EtO)_2SO + SO_2 \quad (6)$$

The unexpected data can be explained by the assumption that Ia dissociates reversibly to form an ion pair of benzoyl cation and ethoxysulfinate anion according to Eq. (7). When the scrambling of ^{18}O due to internal return of the ion pair is taken into consideration, the ^{18}O contents and distribution in other products are also explained.



$$[\text{Ph-C(=O*)}]^{+}\left[\text{O*, O, S-OEt}\right]^{-} \rightleftharpoons \text{Ph-C(=O*)-O-S-OEt} \rightleftharpoons \text{Ph-C(=O*)-O-S-OEt (O*)} \quad (7)$$

Reaction between Ia and Bases. Piperidine and *p*-chloroaniline were used as examples of a strong base and a weak base respectively. The only product isolated from the reaction between piperidine and Ia was the S-attack product, II,[4] whereas the only product isolated from the reaction between *p*-chloroaniline and Ia was the C-attack product, III, as shown in the following equation.



$$\text{Ph-C(=O)-O-S(=O)-OEt} \xrightarrow{\text{NH, S-attack}} \text{N-S-OEt (=O)} \quad \text{II}$$

$$\text{Ph-C(=O)-O-S(=O)-OEt} \xrightarrow{\text{Cl-C}_6\text{H}_4\text{-NH}_2,\ \text{C-attack}} \text{Ph-C(=O)-NH-C}_6\text{H}_4\text{-Cl} \quad \text{III} \quad (8)$$

Since each of two derivatives contains a carbonyl oxygen and a sulfinyl oxygen, respectively, it is possible to determine the ^{18}O-distribution in Ia by the analyses of these two derivatives. The ^{18}O atom % found for II and III are shown in Table 2.

The ^{18}O content of the S-attack product, II, increased with time between the formation of Ia and the addition of piperidine, whereas that of the C-attack product, III, remained constant and was equal to that of the original benzoic acid. These findings indicate that it takes a little while for the oxygens to be scrambled completely through formation and internal return of ion-pairs at room temperature.

TABLE 2. SPECIFICITY OF ^{18}O-LABELING

Sample	% ^{18}O-excess
Starting PhCOOH	1.32
II (12 hr after formation of Ia)*	0.19
II (36 hr after formation of Ia)*	0.22
III	1.32

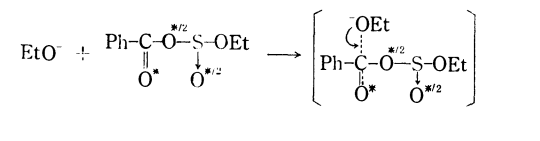
* at room temperature

Both the reaction between Ia and aniline and that between Ia and hydrazine yielded unidentifiable brown tar, which was probably produced from the decomposition of the S-attack products, Ph-NH-S-OEt and H_2NNH-S-OEt. Neither *p*-nitroaniline nor 2,5-dichloroaniline reacted with Ia when they were mixed with Ia and the mixture was allowed to stand at room temperature for several hours.

Isolation of Ia. Ia was unstable to water and was hydrolyzed rapidly. However, it was thermally stable, and it was possible to obtain white crystals of Ia by distillation in a high vacuum.

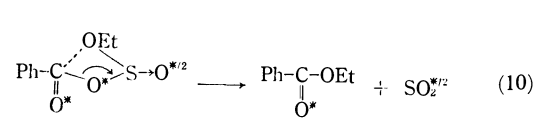
Reaction Mechanisms. The observed ^{18}O contents of all the reaction products are best explained by the reaction steps involving formation and internal return of the ion-pair and the successive attack of both benzoate anion and ethoxide anion to Ia by an ionic chain mechanism.

The most plausible route for formation of ethyl benzoate is direct attack of ethoxide anion to the carbonyl carbon of Ia, Eq. (9), or to that of the ion pair, Eq. (7). However, an S_Ni-type mechanism, as shown in Eq. (10) cannot be ruled out by the results of the ^{18}O analyses alone. The fractions shown in the parentheses under the ^{18}O-containing compounds indicate the ratio of the excess ^{18}O content calculated for the compound versus the excess ^{18}O content of the starting benzoic acid.



$$EtO^- + \text{Ph-C(=O)-O-S(=O)-OEt} \longrightarrow \left[\text{Ph-C(=O)(OEt)-O-S(=O)-OEt}\right]^- \longrightarrow \text{Ph-C(=O)-OEt} + SO_2 + {}^-OEt \quad (9)$$

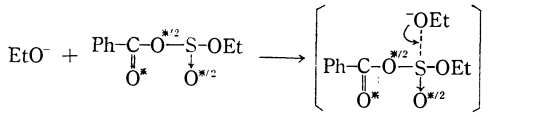
(1/2) (1/2)

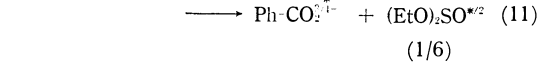


$$\text{Ph-C(=O)(OEt)-O-S(=O)} \longrightarrow \text{Ph-C(=O)-OEt} + SO_2 \quad (10)$$

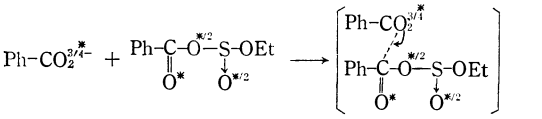
4) G. Zinner, *Chem. Ber.*, **91**, 969 (1958).

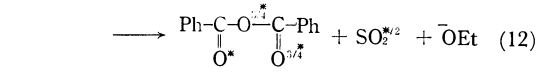
The attack of the ethoxide anion on the sulfinyl sulfur atom of Ia will yield ethyl sulfite and benzoate anion, and the attack of the benzoate anion thus formed on the carbonyl carbon of Ia will yield benzoic anhydride, according to Eqs. (11) and (12). The analyses of the ^{18}O content of the products should determine whether or not Eq. (11) or (12) represent the reaction taking place in this medium. The benzoic anhydride was converted to benzanilide and benzoic acid according to Eq. (13). The result of the ^{18}O analyses of benzoic anhydride, benzoic acid, ethyl sulfite and sulfur dioxide (see Table 1) shows that Eqs. (11) and (12) actually represent the reaction taking place in this medium.



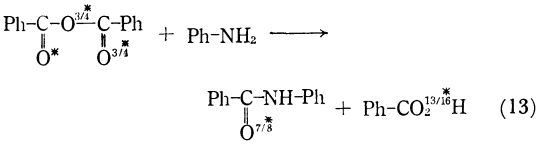


(1/6)





(5/6)



Experimental

^{18}O-Labeled Benzoic Acid. According to a previous method[2] a mixture of 25 g of benzotrichloride and of $H_2{}^{18}O$ (1.30 excess-^{18}O atm %) was refluxed and shaken for 20 hr in a bath at 110°C. After the hydrogen shaken for 20 hr in a bath at 110°C. After the hydrogen chloride formed and excess water were removed under reduced pressure, and the crystals of the benzoic acid remaining were converted to sodium benzoate by addition of the equimolar amount of a sodium hydroxide solution. The sodium salt was recrystallized from distilled water, ground to fine powder, and then dried in a vacuum at 100°C for 2 hr. Yield 14.2 g.

Ethyl Chlorosulfite. To 100 g of thionyl chloride 35.8 g of methanol was slowly added while the temperature was kept low with ice-cooling. The mixture was allowed to stand at room temperature for three days. Distillation under reduced pressure gave 61.5 g of ethyl chlorosulfite (bp 34.5°C/23 mmHg). Yield 61.5%.

Thermal Decomposition of Ethyl Benzoyloxysulfinate (Ia). When 17.85 g of ethyl chlorosulfite was added to 10 g of well-dried sodium benzoate-^{18}O, a slightly exothermic reaction occurred. The milky reaction mixture was then heated at 110—130°C for 2 hr. The sulfur dioxide which evolved vigorously during this period was dried with calcium chloride and introduced into an ethereal solution of phenylmagnesium bromide.[5] The yield of sodium benzenesulfinate was 6.63 g. After the salt was recrystallized from absolute methanol and dried, it was converted to phenyl benzyl sulfone by heating it with benzyl bromide in a sealed tube at 110°C for 5 hr.

The residual reaction mixture was refluxed at 190°C for 2 hr to complete the decomposition. The cooled reaction mixture was treated with 40 m*l* of methylene chloride, and the sodium chloride precipitated was filtered off. After the solvent was removed in a vacuum, repeated fractional distillation of the residue under reduced pressure yielded 2.1 g of diethyl sulfite (bp 68°C/30 mmHg), 0.7 g of ethyl benzoate (bp 105—108°C/30 mmHg), and 2.1 g of benzoic anhydride (bp 190—200°C/30 mmHg).

The benzoic anhydride obtained above was converted to benzanilide and benzoic acid by allowing a mixture of 1.0 g of benzoic anhydride and 0.5 g of aniline to stand at room temperature for a few minutes. White crystals of benzanilide which precipitated were filtered off and recrystallized from ethanol; yield, 500 mg. The filtrate was shaken well with a sodium carbonate solution, and the aqueous layer yielded, upon acidification with a diluted hydrochloric acid, crystals of benzoic acid, which were recrystallized from *n*-hexane; yield, 300 mg.

Reaction between Ia and Piperidine. To 500 m*l* of a carbon tetrachloride solution containing 2 g of benzoic acid and 2.1 g of ethyl chlorosulfite was added 2 g of triethylamine drop by drop with ice-cooling. When 1.7 g of piperidine was added to this mixture, the solution turned pale yellow. After it was allowed to stand overnight at room temperature, 50 m*l* of water was added to remove triethylamine hydrochloride. The organic layer separated was dried over magnesium sulfate. After the solution was removed in a vacuum, the residual yellow-brown liquid was distilled under reduced pressure and 0.5 g of an oil boling at 90°C/5 mmHg was obtained, which was found to be II by comparison of its infrared spectrum with that of the authentic sample prepared from ethyl chlorosulfate and piperidine.

Reaction between Ia and *p*-Chloaniline. To 30 m*l* of benzene solution containing 2 g of benzoic acid and 2.1 g of ethyl chlorosulfite was added 2 g of triethylamine with ice-cooling. The triethylamine hydrochloride precipitated was filtered off, and 30 m*l* of a carbon tetrachloride solution containing 2 g of *p*-chloroaniline was added to the filtrate. After the mixture was allowed to stand at room temperature for one hour, white crystals of *p*-chlorobenzanilide precipitated; yield, 130 mg.

Isolation of Ia. When 5 g of well-dried sodium benzoate and 10 g of ethyl chlorosulfite were mixed, an exothermic reaction takes place and the mixture became sirupy. Distillation in a high vaccum yielded a crystalline distillate at 94 °C/4×10^{-3} mmHg, which was found to be Ia on the basis of its infrared spectrum and the finding that upon addition of an ethereal solution of

5) C. F. H. Allen and S. Converse, "Organic Syntheses," Coll. Vol. I, 226 (1956).

p-chloroaniline it yielded crystalline *p*-chlorobenzanilide.

^{18}O-Analyses. The ^{18}O analyses were carried out according to the method of Rittenberg and Ponticorvo.[6] Each sample was pyrolyzed in the presence of mercuric chloride and mercuric cyanide at 400°C for 4 hr, and the ^{18}O atom % of the carbon dioxide produced was determined by use of a Hitachi RMU-6D type mass spectrometer.

(Received September 16, 1969)

It was found that diaryldiazosulfides (I) reacted at an appreciable rate with β-naphthol in alkaline ethanol to produce azo-dyes. This is contrary to Hantzsch's observation. The initial-rate constants of the reaction were determined at various temperatures. The electron-donating substituents accelerated the rate when they were in the *N*-aryl part of I (substituent X) but retarded when in the *S*-aryl part of I (substituent Y). A set of ρ-values which have opposite signs, $\rho_X = -2.96$ and $\rho_Y = 3.93$, suggested that the rate-determining step in this reaction is the heterolytic rupture of the N–S bond of I. This was supported by the negative values of the entropy of activation and by such a solvent effect as that the rate was significantly increased when the polarity of the solvent increased. As the change in the concentration of β-naphthol affected the rate, the possibility of the participation of the transition state or of the intermediate including β-naphthol was also discussed.

It has been known that the thermolysis of diaryldiazosulfides is available as a preparative route for the generation of aromatic thiyl radicals.[1] Recently, Zwet and Kooyman[2] also reported on kinetic studies of the homolysis of diazosulfides. However, few reports have been presented on the ionic reaction of diazosulfides. Hantzsch and Freese[3] reported that diazosulfides dissociate to diazonium chloride and thiophenol in concentrated hydrochloric acid and that they do not give the coupling product with β-naphthol in alkaline ethanol.

We found that diaryldiazosulfides (I) reacted at an appreciable rate with β-naphthol in alkaline ethanol, thus producing azo-dyes (II).

In this paper, we wish to report our findings in a kinetic study of the reaction of diaryldiazosulfides with β-naphthol in alkaline ethanol.

used in the present work all have their absorption maxima at 330—350 mμ (Table 6). According to the UV spectral discussion by Zwet and Kooyman,[2b] all the diaryldiazosulfides (I) prepared in the present work may be assigned as the *trans* form. This assignment of their configuration is supported by such a phenomenon as the polymorphism; that is, the crystals of I prepared at a low temperature change in forms when left standing at room temperature (see Experimental Section). This change is probably to be ascribed to the isomerization from the *cis* form to the *trans*.

Reaction of Diaryldiazosulfides (I) with β-Naphthol in Alkaline Ethanol. Contrary to Hantzsch's observation,[3] diazosulfides (I) reacted at an appreciable rate with β-naphthol in alkaline ethanol, thus producing azo-dyes (II). The products were identified by thin-layer chromatography (TLC).

The first-order rate plots of the reaction tended to curve more or less with the increase in the time (Fig. 1). This may be ascribed to the concurrent decomposition of I to diarylsulfides or disulfides,[2c] the rates of which, in alkaline ethanol, are comparable to the rate of the reaction of I with β-naphthol,[4] although the decomposition is overwhelmed by the coupling with β-naphthol and, accordingly, prevented fairly well in the presence of excess β-naphthol. Therefore, the initial-rate constants summarized in Table 1 will be utilized in the following discussion.

The electron-donating substituents accelerated the rate when they were in the *N*-aryl part of I, but retarded it when in the *S*-aryl part of I. A Hammett correlation of the rate constants at 35°C for diazosulfides (I) with substituents (Y) in the *S*-aryl part gives an excellent straight line, with

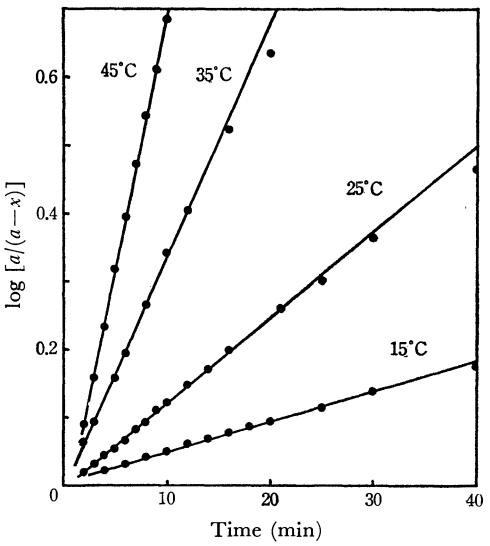

Fig. 1. First-order plots for the reaction of diazosulfide (Il) with β-naphthol in alkaline ethanol at various temperatures.

a slope ρ_Y of 3.93 ($r = 0.9997$) (Fig. 3), whereas a Hammett correlation for diazosulfides with substituents (X) in the *N*-aryl part shows a little poorer linearity, with a slope ρ_X of -3.92 ($r = 0.979$). However, this latter linearity can be improved by eliminating the points for *p*-CN and *p*-NO_2 ($\rho_X = -2.96$, $r = 0.985$) (Fig. 2). The deviation of these points below the line in Fig. 2 may be ascribed to an additional conjugation such as III and IV, which decreases the positive charge upon the diazonium part. Similar behavior was observed in the substituent effect on the rearrangement of *N*-methyldiaryltriazenes.[5]

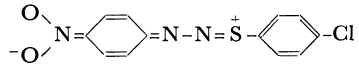
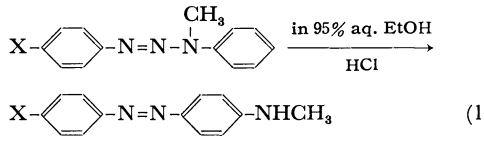
III



IV

A set of ρ-values which have opposite signs suggests that the heterolytic rupture of the N–S bond of diazosulfides (I) is the rate-determining step in this reaction, because a negative ρ_X-value and a positive ρ_Y-value suggest the stabilization of the diazonium cation by the substituents (X) in the *N*-aryl part and that of the thiophenoxide anion by the substituents (Y) in the *S*-aryl part. Similar substituent effects have been previously reported; for example, the following triazene rearrangement showed $\rho = -3.63$ (at 30.0°C).[5] The rate-determining step in the rearrangement was, therefore, concluded to be the dissociation of protonated triazene.



(1)

On the other hand, for the dissociation of *m*- and *p*-substituted thiophenols in 95% aqueous ethanol, $\rho = 2.847$ (at 20—22°C) has been reported.[6] In this case, the use of σ^- rather than σ reduced the scatter in Hammett correlation. According to Tsuno,[7] the dissociation constants of *m*- and *p*-substituted thiophenols gave a good correlation with a value, 0.52, of the parameter, *r*, in the Yukawa-Tsuno equation. However, in the present reaction of I with substituents (Y) in the *S*-aryl part, a Hammett correlation using σ shows an excellent linearity ($r = 0.9997$). Therefore, the contribution of the additional resonance stabilization by electron-withdrawing substituents seems to be less important in stabilizing the transition state in this reaction than in the case of the dissociation of thiophenols. This may be because the transition state of the reaction of I with *β*-naphthol may have a smaller charge separation than that of the dissociation of thiophenols.

TABLE 2. ACTIVATION PARAMETERS FOR THE REACTION OF DIAZOSULFIDES WITH *β*-NAPHTHOL IN ALKALINE ETHANOL

Diazosulfide	Substituent X	Substituent Y	E_a kcal/mol	$\Delta S^{\neq}$(35°C) e.u.

Il	Cl	$COCH_3$	17.5	− 8.9
Im	Cl	CN	15.7	−12.4

The thermodynamic parameters (Table 2) also suggest that the ionization of diazosulfides is rate-determining, because the values of E_a and $\Delta S^{\neq}$ fall within the range of the values found for a case in which the dissociation of neutral molecules to

6) H. H. Jaffe, *Chem. Rev.*, **53**, 191 (1953).
7) Y. Tsuno, "Summary of the Symposium on the Hammett Relationship," the Chemical Society of Japan (1967), p. 4.

ions is rate-determining.[8] A plot of E_a against $\Delta S^{\neq}$ is found to show a linearity ($\beta \fallingdotseq 470°K$) (Fig. 4). The large negative values of $\Delta S^{\neq}$ for Ia and Ib may due to the substantial contribution of the entropy term to the reaction.

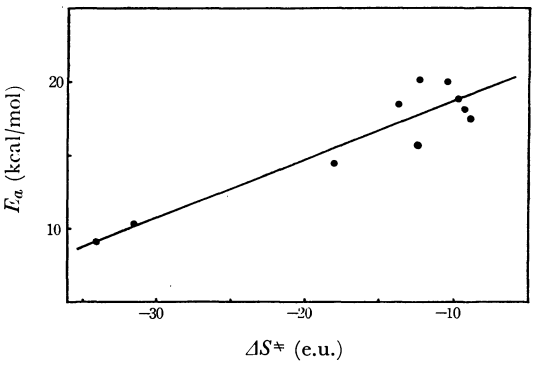

Fig. 4. Plot of E_a *vs.* $\Delta S^{\neq}$ for the reaction of diazosulfides with β-naphthol in alkaline ethanol.

According to Ingold's criterion,[9] this consideration can be supported by the findings concerning the solvent effect upon the rate constants; the rate significantly increased when the polarity of the solvent, ethanol, was increased by the addition of water (Table 3).

30	17.2
50*2	26.3

* [Diazosulfide] $= 1.0 \times 10^{-4}$M, [β-Naphthol] $= 1.0 \times 10^{-3}$M, [KOH] $= 1.1 \times 10^{-3}$M

*2 [Diazosulfide] $= 5.0 \times 10^{-5}$M, [β-Naphthol] $= 5.0 \times 10^{-4}$M, [KOH] $= 5.5 \times 10^{-4}$M

Table 4 shows that the increment in the concentration of KOH resulted in only a slight increase in the rate, while the addition of KCl also increased the rate in aqueous ethanol. These results can reasonably be interpreted in terms of the salt effect.

From the available evidence, the most probable mechanism can be assumed to be as follows: dia-

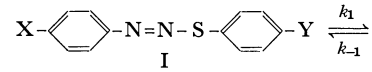
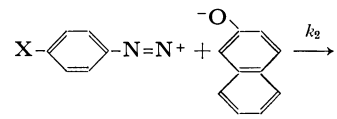
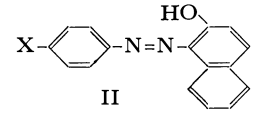
zosulfide dissociates to the diazonium cation and the thiophenoxide anion, and, then the former cation couples with the β-naphthoxide anion to produce azo-dye. The rate-determining step is the dissociation of diazosulfide; *i. e.*, $k_1 \ll k_2$, k_{-1}.



I

(2)



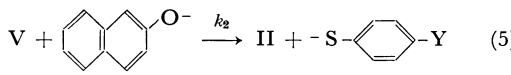


II (3)

However, it is possible that the intermediate is an ion pair (V) rather than a free diazonium cation; that is, the ion pair intermediate (V) may be formed in the rate-determining step (Eq. (4)) and attacked by β-naphthol to produce II (Eq. (5)) ($k_1 \ll k_2$, k_{-1}).

(4)

V, ion pair



(5)

As is shown in Table 5, the change in the concentration of β-naphthol has an effect on the rate. The rate enhancement with the increase in β-naphthol is fairly large, but not so large that the order of reaction is one with respect to β-naphthol. Therefore, we may suggest the possibility of a

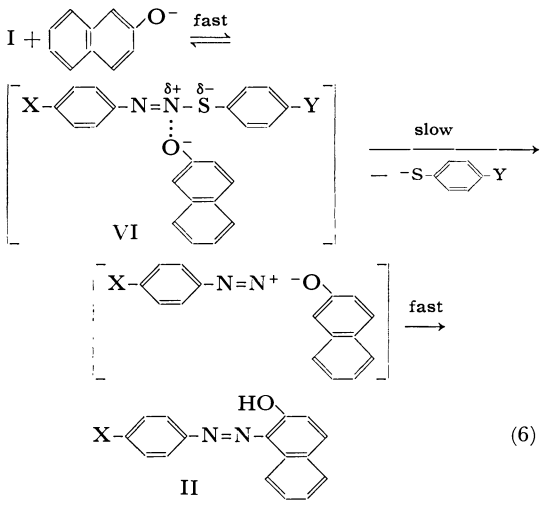
C: solvent, EtOH (50%) + Buffer solution (pH 9.4) (50%)

"borderline" case[10] between S_N1 and S_N2; *i.e.*, in Eqs. (4) and (5), the rate of step 1 is comparable that of step 2. On the other hand, the possibility of an alternative mechanism through a loose "complex" (VI) containing β-naphthoxide cannot be disregarded (Eq. (6)).



(6)

However, the determination of the reaction order was difficult because the decomposition of I became predominant and made the rate plot complex in the presence of a low concentration of β-naphthol; thus, the role of β-naphthol in the rate enhancement is ambiguous.

On the basis of the above results, we consider the mechanism through the ion pair (Eqs. (4) and (5)) to be most likely in the reaction of I with β-naphthol. The rate enhancement with the increase in β-naphthol may be ascribed to the salt effect.

Zwet and Kooyman[2b] reported that the *cis* isomers react with β-naphthol in alkaline ethanol to form red azo-dye, whereas the *trans* isomers do not. Thus, they concluded that the ionization of diazosulfide could occur with only the *cis* isomers.

According to our present data on the substituent effect and the difference in the thiol acidities,[11] there is a considerable possibility that the following is true: the *trans*-diazosulfides studied by Zwet and Kooyman may also dissociate only very slowly, and this very slow dissociation seems to have led them to the mistaken conclusion that the *trans* isomer cannot undergo ionization. The same possibility may hold in the case of Hantzsch's report;[3] the diaryldiazosulfides used by Hantzsch and Freese may dissociate very slowly, judging from our results, and thus it seems that they failed to observe the reaction of diazosulfides with β-naphthol.

However, it becomes necessary to question whether or not the *trans* isomers dissociate through the *cis* forms. We intend to pursue this question through the isolation of *trans* and *cis* isomers of diazosulfides and by studying them kinetically in a subsequent paper.

Experimental

Preparation of Materials. *Most of the diaryldiazosulfides (I)* were synthesized by the following general method:[12]

A solution of 0.02 mol of *p*-substituted aniline in 20 m*l* of 7% hydrochloric acid was diazotized with 0.023 mol of sodium nitrite in 5 m*l* of water. The diazonium solution was then slowly added to an ice-cold, stirred solution of 0.02 mol of *p*-substituted thiophenol in 20 m*l* of a 10% aqueous sodium hydroxide solution. The yellow crystals which immediately formed were filtered, thoroughly washed with cold water, and dried *in vacuo* over calcium chloride. The crude products were dissolved in acetone at room temperature and recrystallized by cooling them in an acetone-dry ice refrigerant.

In the preparation of I, the following phenomena were observed. When the *S*-coupling was carried at 5—10°C, pale yellow crystals were first formed, but they soon rose to the surface of the liquid and became brownish. The brown solids were recrystallized from acetone to give pure yellow diazosulfide. On the other hand, when the *S*-coupling was carried below 0°C, the pale yellow crystals were obtained in a fairly stable form. However, they turned brownish upon filtration or desiccation at room temperature. Especially, when a large amount (0.1 mol) of Id was prepared, the yellow crystals turned exothermically into a brown mass, but a pure Id was obtained by several recrystallizations of the crude material. After recrystallization, no such change in I could be observed besides a gradual thermal decomposition.

Diazosulfides (Im and Ik) were prepared as follow: *p*-aminobenzonitrile (5.9 g) was treated by the usual procedure[13] to convert an amino group to a mercapto group, but in order to avoid the hydrolysis of a cyano group, the hydrolysis of the intermediate, *p*-cyanophenyl ethyl xanthate, was carried out by standing overnight at room temperature. Nevertheless, a mixture of *p*-cyanothiophenol and *p*-carbamoylthiophenol was obtained. From this mixture, a mixture (9 g) of diazosulfides, Im and Ik, was obtained by the procedure described above. The mixture was added to benzene (90 m*l*), stirred well at room temperature, and filtered from the insoluble material. To filtrate, after the benzene was distilled off *in vacuo*, was purified by elution chromatography over the activated alumina, using benzene as the eluent. The compound that was first eluted, the predominant component, was identified as diazosulfide (Im) on the basis o the elementary analysis and a study of the infrared spectrum (ν_{CN}=2270 cm^{-1}). The yield of Im was 6 g. On the other hand, the insoluble material (1.2 g) was recrystallized from acetone and gave diazosulfide (Ik) ($\nu_{C=O}$=1693 cm^{-1}, ν_{NH_2}= 3480, 3590 cm^{-1}). The analytical data and the ultraviolet spectral data of I are summarized in Table 6.

α-(p-Substituted phenylazo)-β-naphthols (II) were prepared by the reaction of the corresponding aryldiazonium chlorides and β-naphthol in an aqueous alkaline solution by the usual procedure, and were purified by several recrystallizations from ethanol (Table 7). The λ_{max} and ε values for II, summarized in Table 7, were measured, under conditions similar to those holding in the reaction of diazosulfides with β-naphthol, as follows: an ethanol solution (1 m*l*) of II (10^{-3}M), 1 m*l* of a 1.1×10^{-2}M KOH ethanol solution, and 0.9 m*l* of $1.0\times$

13) D. S. Tarbell and D. K. Fukushima, "Organic Syntheses," Coll. Vol. III, p. 809 (1955).

10^{-2}M β-naphthol ethanol soultion were placed in a 10-m*l* measuring flask, and then, by the subsequent addition of ethanol, the solution was made up to volume. This solution was used as the sample for the visible spectra measurements.

Kinetic Measurements. The rate constants were determined spectrophotometrically. A Hitachi Perkin-Elmer 139 UV-VIS spectrophotometer equipped with a thermostated cell compartment was used.

One m*l* of a β-naphthol ethanol solution (10^{-2}M), 1 m*l* of a KOH ethanol solution (1.1×10^{-2}M), and about 6.5 m*l* of ethanol were placed in a 10-m*l* measuring flask immersed in a thermostated water bath. The reaction was initiated by the addition of 1 m*l* of an ethanol solution of diazosulfide (10^{-3}M), freshly prepared at the same temperature, to the flask. The entire solution was then quickly made up to volume with ethanol, and the solution was transferred into a 10-mm stoppered quartz cuvette set in a thermostated cell compartment.

The optical densities were measured at appropriate intervals at the maximum-absorption wavelength of the azo-dye produced.

In the present work, it was assumed that the amount of azo-dye produced (x) was equal to that of diazosulfide consumed; thus, the rate constants were evaluated from the slope of the plot of log ($a/(a-x)$) against t, where a is the initial concentration of diazosulfide. A typical example is shown in Fig. 1. In most of the reactions, the rate decreased with time, and so the initial rates were measured (Table 1).

On the reaction in a mixture of ethanol and a buffer solution, Clark-Lubs's buffer solution (pH 9.4) was used, and the initial concentrations of I and β-naphthol were half as much as those in the general procedure described above because of the low solubility of the azo-dye produced in this solvent.

The authors wish to thank Professor Ryozo Goto for his encouragement of this work. They are also indebted to Dr. Jun-ichi Hayami for his valuable discussions.

Studies of Peptide Antibiotics. XV. The Synthesis of *cyclo*-(L-Valyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolyl-glycyl-glycyl)

Okitoshi ABE,[1] Kenji KUROMIZU, Michio KONDO[2] and Nobuo IZUMIYA[3]

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received September 17, 1969)

A cyclic heptapeptide, *cyclo*-(L-Val-L-Orn-L-Leu-D-Phe-L-Pro-Gly-Gly-), was synthesized in order to investigate a contribution for an antibacterial activity of a ring size of a cyclic peptide. A linear heptapeptide *p*-nitrophenyl ester, in which an δ-amino function of ornithine residue was protected with benzyloxycarbonyl group, was transformed to the cyclic benzyloxycarbonyl-substituted heptapeptide which was hydrogenated to afford the desired cyclic heptapeptide as hydrochloride. The cyclic peptide thus obtained showed no activity against any of microorganisms tested.

In studies of the relationship between chemical structure and biological activity of antibacterial cyclic peptides, the cyclic penta- and hexapeptide, cyclosemigramicidin S[4] and *cyclo*-(L-Val-L-Orn-L-Leu-D-Phe-L-Pro-Gly-)[5], which contain the partial amino acid sequence found in gramicidin S and tyrocidines, were prepared, and their biological activities examined. However, in spite of its apparent resemblance to those natural antibiotics, the cyclic penta- and hexapeptide were found to be inactive. Furthermore, a cyclic hexapeptide designated as gramicidin J_2 was synthesized, and the peptide showed no activity.[6] Although the reason for the inactivity is not yet clear, other structural features such as appropriate ring sizes may be necessary in this type of molecule for the exhibition of the activity. Therefore, it became of interest to determine whether or not a larger cyclic peptide with an appropriate amino acid sequence would exhibit the antibacterial properties.

This paper is concerned with the synthesis and an antibacterial assay of a cyclic heptapeptide,

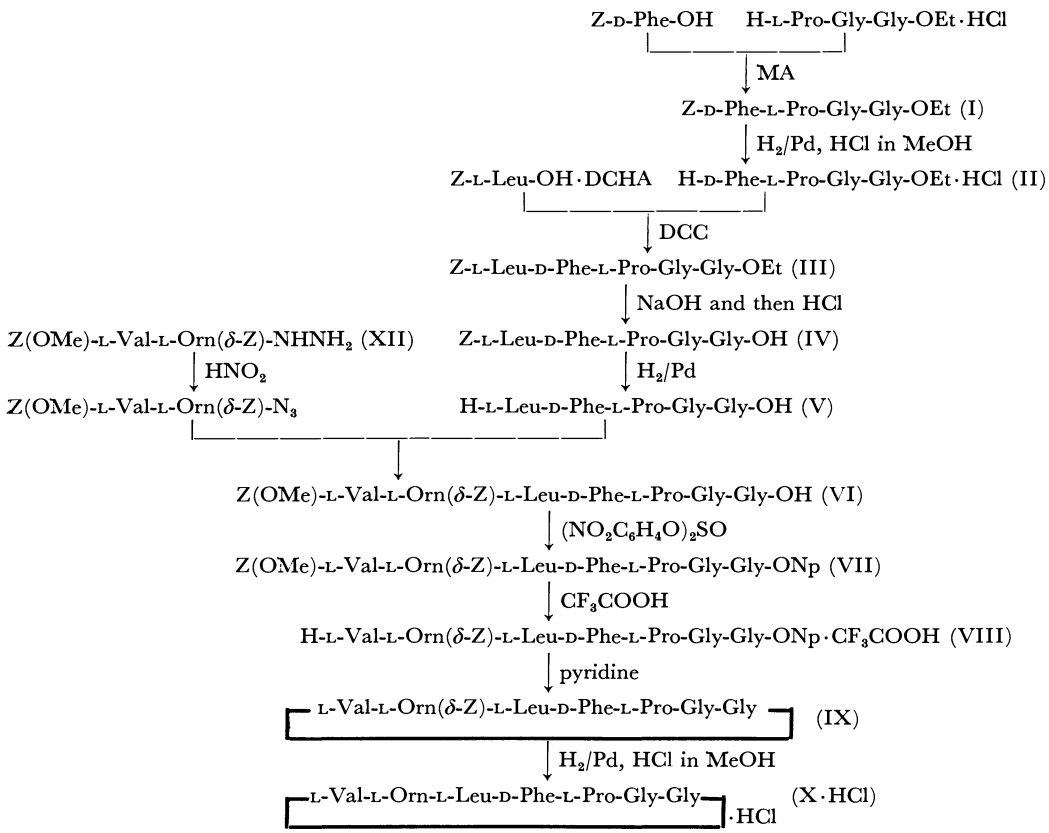

Fig. 1. Cyclization of linear heptapeptide active ester

cyclo-(L-Val-L-Orn-L-Leu-D-Phe-L-Pro-Gly-Gly-), which contains the partial sequence -L-Val-L-Orn-L-Leu-D-Phe-L-Pro- found in the natural antibiotics mentioned above.

Figure 1 indicates the route for the synthesis of the cyclic heptapeptide (X·HCl). *p*-Methoxybenzyloxycarbonyl-heptapeptide acid (VI) was prepared by the coupling reaction of the acyl-dipeptide azide derived from XII with the neutral pentapeptide (V), and then VI was converted to the benzyloxycarbonyl-substituted heptapeptide *p*-nitrophenyl ester trifluoroacetate (VIII). The cyclization reaction of the trifluoroacetate in pyridine gave the benzyloxycarbonyl-substituted cyclic peptide (IX) which was purified by passing it through columns of Dowex 50 and Dowex 1. The molecular-weight determination demonstrated that the molecular size of IX corresponds to that of cyclic heptapeptide. The final product, X·HCl, was obtained upon the hydrogenolysis of IX in the presence of one equivalent of hydrogen chloride as crystals with five moles of water; its homogeneity was demonstrated by several chromatographic techniques.

The antibacterial activity of the cyclic peptide (X) toward several microorganisms was examined. The compound X showed no activity against any of the microorganisms even at 100 μg per m*l* of the assay medium. Hence, it appears that even the presence of seven amino acid residues in a cyclic peptide does not satisfy the requirements for antibacterial activity.

Experiments on the preparations and the properties of several cyclic peptides with larger ring sizes, such as a cyclic octapeptide, are in progress in this laboratory in order to extend this study further.

Experimental

All the melting points are uncorrected. Prior to analysis, the compounds were dried over phosphorus pentoxide to a constant weight at 80°C and 2 mmHg, except for the cyclic peptide (X·HCl·5H_2O).

Z-D-Phe-Pro-Gly-Gly-OEt (I).[7] To a solution of benzyloxycarbonyl-D-phenylalanine (2.57 g, 8.5 mmol), H-Pro-Gly-Gly-OEt·HCl[8] (2.54 g, 8.6 mmol) and triethylamine (1.2 m*l*) in tetrahydrofuran (40 m*l*) was

7) The following abbreviations are used according to *Biochemistry*, **5**, 2485 (1966); Z-, benzyloxycarbonyl; Z(OMe)-, *p*-methoxybenzyloxycarbonyl; -ONp, *p*-nitrophenyl ester; -OEt, ethyl ester; DCC, dicyclohexylcarbodiimide; DMF, dimethylformamide. Amino acid symbols except D-Phe denote the L configuration.

8) H. N. Rydon and P. W. G. Smith, *J. Chem. Soc.*, **1956**, 3642.

added DCC (1.77 g, 8.6 mmol) at 0°C. After the stirring had been continued for 2 hr at 0°C, the mixture was left to stand for overnight at room temperature. The mixture was then evaporated *in vacuo*, and ethyl acetate was added to the residue. After the dicyclohexylurea was filtered off, the filtrate was washed successively with 4% sodium bicarbonate solution and 2% hydrochloric acid and dried over sodium sulfate. The filtrate was evaporated *in vacuo*. The residual foam weighed 4.07 g (88%); R_f 0.95.[9]

H-D-Phe-Tro-Gly-Gly-OEt·HCl (II). A solution of I (4.07 g) in 0.4N methanolic hydrogen chloride (20.8 ml) was subjected to hydrogenolysis in the presence of palladium black. The filtrate from the catalyst was evaporated to dryness *in vacuo*; yield of oil, 3.37 g (102%); R_f 0.80[9] and 0.95.[10]

Z-Leu-D-Phe-Pro-Gly-Gly-OEt (III). To a solution of benzyloxycarbonyl-L-leucine dicyclohexylamine salt[11] (3.35 g, 7.5 mmol) and II (4.03 g) in chloroform (50 ml) was added DCC (1.45 g, 7.5 mmol) at 0°C. The reaction mixture was treated as has been described for the preparation of I. The residual foam weighed 4.61 g (94%); R_f 0.94.[9]

Z-Leu-D-Phe-Pro-Gly-Gly-OH (IV). To a solution of III (4.37 g, 6.7 mmol) in methanol (50 ml), N sodium hydroxide (13.4 ml) was added. After the solution had been allowed to stand two days at room temperature, N hydrochloric acid (27 ml) was added and the solution was evaporated *in vacuo*. The oily product was extracted with ethyl acetate and the solution was dried over sodium sulfate. The filtrate was evaporated, and the residue was crystallized by the addition of ether. It was recrystallized from ethanol-ether; yield, 2.97 g (71%); mp 178—180°C; $[\alpha]_D^{20}$ −4.4° (*c* 1, MeOH).

Found: C, 61.49; H, 6.69; N, 10.98%. Calcd for $C_{32}H_{41}O_8N_5$: C, 61.62; H, 6.63; N, 11.23%.

H-Leu-D-Phe-Pro-Gly-Gly-OH (V). A solution of IV (2.50 g, 4.01 mmol) in a mixture of acetic acid-methanol-water (6 : 4 : 1, 40 ml) was subjected to hydrogenolysis in the presence of palladium black. The filtrate was evaporated to dryness *in vacuo*, and the residual crystals were collected with the aid of ether. It was recrystallized from ethanol-ether; yield, 1.76 g (90%); mp 158—159°C (dec.); $[\alpha]_D^{20}$ −20.0° (*c*, 1, MeOH); R_f 0.64.[9]

Found: C, 57.07; H, 7.42; N, 13.47%. Calcd for $C_{24}H_{35}O_4N_5 \cdot H_2O$: C, 56.78; H, 7.36; N, 13.80%.

Z(OMe)-Val-Orn(δ-Z)-Leu-D-Phe-Pro-Gly-Gly-OH (VI). The azide[5] derived from Z(OMe)-Val-Orn(δ-Z)-$NHNH_2$ (XII) (1.63 g, 3 mmol) was added to a solution of V (1.47 g, 3 mmol) and triethylamine (0.42 ml) in DMF (50 ml). The mixture was stirred for 3 days at 0°C and evaporated *in vacuo*. The resideu was triturated with 10% citric acid, and the precipitate was collected by filtration and washed with water. It was recrystallized from methanol-ether-petroleum ether; yield, 2.71 g (90%); mp 119—120°C $[\alpha]_D^{20}$ −8.0° (*c* 1, DMF); R_f 0.75.[9]

Found: C, 59.26; H, 6.82; N, 10.85%. Calcd for $C_{51}H_{68}O_{13}N_8 \cdot 2H_2O$: C, 59.05; H, 7.01; N, 10.80%.

***cyclo*-(Val-Orn(δ-Z)-Leu-D-Phe-Pro-Gly-Gly-) (IX).** To a solution of VI (0.50 g, 0.5 mmol) in pyridine (25 ml), di-*p*-nitrophenyl sulfite[12] (1.62 g, 5 mmol) was added, and the reaction mixture was then allowed to stand for 24 hr at room temperature. After evaporation of the solvent, the product was triturated with petroleum ether and washed repeatedly with a mixture of ether and petroleum ether (1 : 1) by decantation (yield of VII, 578 mg). The *p*-nitropheynl ester content was estimated to be 90% by measuring the optical density at 412 mμ.[13]

To VII (576 mg) thus obtained were added anisole (1 ml) and trifluoroacetic acid (6 ml) at 0°C. After 20 min, the solution was evaporated, and the solid was collected with the aid of a mixture of ether and petroleum ether. The heptapeptide *p*-nitrophenyl ester trifluoroacetate (VIII) thus obtained was dissolved in DMF (10 ml) with acetic acid (0.5 ml). The solution was added dropwise into pyridine (300 ml) at 55—60°C during 5 hr and the stirring was continued for additional 2 hr. After removal of the solvent, the residue was dissolved in a mixture of methanol-water (5 : 1, 150 ml). The solution was treated with columns (1.8×15 cm) of Dowex 1 (OH^- form) and Dowex 50 (H^+ form). The columns were washed with the same solvent (400 ml), and the combined effluent was evaporated to dryness. The residual product was collected by filtration with the aid of water and dried (249 mg). It was recrystallized from dioxane-methanol-ether; yield of air-dried product, 202 mg (50% form VI); mp 149—151°C (decomp.); $[\alpha]_D^{20}$ −4.0° (*c* 1, MeOH); R_f 0.94.[9]

Found: C, 60.69; H, 7.17; N, 13.25%; mol wt, 850.[14] Calcd for $C_{42}H_{58}N_8O_9 \cdot \frac{1}{2}H_2O$: C, 60.91; H, 7.20; N, 13.53%: mol wt, 828.

The air-dried product lost 1.00% of its weight after

Microbiological Assays.[16] The microorganism employed are listed in Table 1. The minimum amount of the compound necessary for the complete inhibition of growth was determined by a dilution method using a bouillon agar medium and a synthetic medium. As is shown in Table 1, the cyclic heptapeptide was found to be devoid of activity in reaction against any of the microorganisms utilized.

Hydrogenation and Hydrogenolysis. XII.[1] The Hydrogenation of Isomeric Dimethoxybenzenes with Platinum Metal Catalysts*1

Yuzuru TAKAGI and Sadayoshi ISHII

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

and Shigeo NISHIMURA

Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei-shi, Tokyo

(Received September 26, 1969)

The catalytic hydrogenation and hydrogenolysis of isomeric dimethoxybenzenes over six platinum metals have been investigated at elevated temperature and pressure. The hydrogenolysis of methoxyl group occurred more extensively over Group $VIII_3$ metals than over Group $VIII_2$ metals. The *meta* isomer hydrogenolyzed to greater extent and gave smaller *cis*/*trans* ratio of dimethoxycyclohexane, than the *ortho* and *para* isomers. The greater tendency of the *meta* isomer toward hydrogenolysis supports the previously proposed explanation according to which the electron-releasing group at *meta* position would promote hydrogenolysis.

Only few studies have been described in the literature on the catalytic hydrogenation of dimethoxybenzenes and most of them are not comparative or not quantitative.[2-6] Smith and Thompson[5] studied the hydrogenation of various methoxybenzenes with Adams platinum and rhodium-on-alumina catalysts in acetic acid at 20—50°C under the initial hydrogen pressure of 40—60 psi. Their results indicated that the hydrogenolysis of methoxyl group was less extensive over the supported rhodium catalyst than over the platinum catalyst and that it increased with respect to the three isomers of dimethoxybenzene in the order *ortho*>*meta*>*para* over the platinum catalyst, while with the rhodium catalyst the *meta* isomer underwent slightly more hydrogenolysis than the *ortho* and *para* isomers.

In this study the catalytic hydrogenation and hydrogenolysis of isomeric dimethoxybenzenes over six platinum metals have been investigated at elevated temperature and pressure, mainly with the object to know the behaviors of the three isomers toward hydrogenolysis.

Experimental

Materials. Tokyo Kasei G. R. dimethoxybenzenes were purified by distillation. *o*-Dimethoxybenzene:

1) Part XI: S. Nishimura and H. Yoshino, This Bulletin, **42**, 499 (1969).

bp 105°C/26 mmHg, n_D^{25} 1.5316; *m*-dimethoxybenzene: bp 106.5°C/26 mmHg, n_D^{20} 1.5248; *p*-dimethoxybenzene: bp 110°C/26 mmHg, mp 55°C.

Catalysts. Unsupported ruthenium, rhodium, iridium and platinum catalysts were prepared by reducing the corresponding hydroxides in water at 80°C (at 30°C for platinum hydroxide) for 20 min under 80 kg/cm² of hydrogen. Unsupported osmium catalyst was prepared by reducing osmium tetroxide in isopropyl alcohol at 60°C for 20 min under 80 kg/cm² of hydrogen. The metals thus prepared were washed with distilled water until the filtrate became neutral and then dried in vacuum at room temperature. The palladium-on-carbon catalyst (5% Pd) was obtained from the Nippon Engelhard Co.

Hydrogenation. Dimethoxybenzene (0.1 mol) was hydrogenated in a 100-ml bomb of up-and-down stirring type driven electromagnetically, using 20 mg of unsupported catalyst at 80°C or 200 mg of the supported catalyst at 120°C under the hydrogen pressure of 80—100 kg/cm².

Analysis of Products. Hydrogenation products were analyzed by gas chromatography using 10% PEG 20M on 60—80 mesh Chromosorb W (column dimension: 3 mm × 2.25 m; column temperature: 128°C; carrier gas: helium at 70 ml/min). Relative retention times of dimethoxybenzenes and their hydrogenation products are summarized in Table 1. Table 2 summarizes the mol percent composition of reaction mixtures.

TABLE 1. RELATIVE RETENTION TIMES OF DIMETHOXYBENZENES AND THEIR HYDROGENATION PRODUCTS

Compound	Relative retention time
Cyclohexane	1.0
Methanol	1.2
Methoxycyclohexane	1.9
Cyclohexanone dimethyl acetal	3.4
trans-1,2-Dimethoxycyclohexane	3.8
cis-1,2-Dimethoxycyclohexane	4.8

m-Dimethoxybenzene	27.3
trans-1,4-Dimethoxycyclohexane	5.3
cis-1,4-Dimethoxycyclohexane	6.3
p-Dimethoxybenzene	25.2

Results

Table 3 shows the amount of hydrogenolysis which occurred during hydrogenation of dimethoxybenzenes over platinum metal catalysts. The figures in the table are based on the amount of the cleaved methoxyl group. It is seen that in most cases the hydrogenolysis is more extensive over Group $VIII_3$ metals (osmium, iridium and platinum) than over Group $VIII_2$ metals (ruthenium, rhodium and palladium). It can also be seen that the *meta* isomer hydrogenolyzes more extensively than the *ortho* and *para* isomers with only one exception in osmium, where the *para* isomer underwent slightly more hydrogenolysis than the *meta* isomer. The greater tendency of the *meta* isomer toward hydrogenolysis is more prominent over Group $VIII_2$ metals than over Group $VIII_3$ metals.

Figures 1 and 2 compare the rates of hydrogenation of isomeric dimethoxybenzenes with ruthenium and rhodium catalysts, respectively. The decreasing

$$\frac{\left[\text{mol(methoxycyclohexane}\right.}{\left.\text{+cyclohexane}\times 2)\times 100\right]}$$
$$\overline{\left[\text{mol(dimethoxycyclohexane}\right.}$$
$$\left.\text{+methoxycyclohexane+cyclohexane)}\right]$$

rate during the hydrogenation of the *meta* isomer is noteworthy with both catalysts. This decrease in the rate is probably caused by the methanol produced by hydrogenolysis which occurs extensively in the case of the *meta* isomer. The addition of methanol to reaction mixture was found to retard the hydrogenation of *o*- and *m*-dimethoxybenzene with ruthenium catalyst as indicated in Fig. 1.[7]

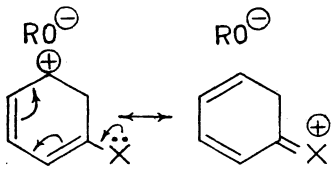
Table 4 summarizes the percent *cis* isomer in the dimethoxycyclohexane formed in hydrogenation of the corresponding dimethoxybenzene. It is of

7) This retardation caused by methanol is probably due to the formation of dimethyl acetals which may result from the addition of methanol to vinyl type ethers formed during hydrogenation. A small amount of cyclohexanone dimethyl acetal has been detected in the product from *m*-dimethoxybenzene. Formation of a considerable amount of 4-methylcyclohexanone diethyl acetal has been observed in hydrogenation of ethyl *p*-tolyl ether over a rhodium catalyst in ethanol, with a decreasing rate in the course of the hydrogenation [S. Nishimura, M. Uramoto and T. Watanabe, *Shokubai*, **11**, 149 (1969)].

interest that formation of *cis* isomer is greater in the *ortho* and *para* isomers than in the *meta* isomer.

Discussion

The results shown in Table 3 clearly indicate that *m*-dimethoxybenzene hydrogenolyzes more readily than the *ortho* and *para* isomers. This conclusion is also true when the rates of formation of hydrogenolysis products (*cf.* Ref. 1) are compared. Although osmium caused slightly less hydrogenolysis in the *meta* isomer than in the *para* isomer, the same conclusion can also be obtained in this case if we compare the rate of formation of hydrogenolysis products which is greater for the *meta* isomer than for the *para* isomer. The greater tendency of the *meta* isomer toward hydrogenolysis has also been observed in the hydrogenation of methoxy- and ethoxyanilines with ruthenium catalyst and for this an explanation based on the ionic cleavage of the carbon-oxygen bond has been proposed.[1] According to this explanation the electron-releasing group at the *meta* position may stabilize the transition states of carbonium ion character when the allyl type ethers formed on the catalyst undergo hydrogenolysis, as shown below in one example of dihydro intermediates.



The same effect may also be expected in the allyl type tetrahydro intermediates. In *m*-dimethoxybenzene both methoxyl groups can take part in such stabilization of the transition states leading to hydrogenolysis products and therefore the tendency of the *meta* isomer toward hydrogenolysis is expected to be more pronounced in dimethoxybenzenes than in methoxyanilines. The results in Table 3 which are in accord with this expectation may provide a strong support to the explanation proposed previously. It is to be noted that the more extensive hydrogenolysis in the *meta* isomer was not observed or less pronounced in the hydrogenation of dimethoxybenzenes in acetic acid.[8]

Another important factor which may have an effect on the relative amount of hydrogenolysis between *ortho*, *meta* and *para* isomers is the probability of the formation of allyl type ethers from parent aromatic compounds.[9] It will be difficult, however, to discuss on this point from the data now available and further detailed studies are needed for this purpose.

The stereochemistry of hydrogenation of dimethoxybenzenes is noteworthy in that the *meta* isomer gave smaller yields of the *cis* isomer than the *ortho* and *para* isomers, when compared with the hydrogenation of isomeric xylenes where formation of *cis* isomer decreases in the order *ortho*>*meta*>*para*.[10] It might be possible that the extensive hydrogenolysis in *m*-dimethoxybenzene would decrease the *cis* content of the resulting dimethoxycyclohexane, if the hydrogenolysis of the methoxyl group would occur by the S_N2 type mechanism.[11] But this fails to account for the results with osmium catalyst in which the *meta* isomer underwent less hydrogenolysis than the *para* isomer, whereas the *cis* content of dimethoxycyclohexane was smaller in the *meta* isomer.

8) The *meta* isomer hydrogenolyzes to less extent than the *ortho* and *para* isomers in the rhodium-catalyzed hydrogenation of methoxy- and ethoxyanilines in isopropyl alcohol added by one equivalent of acetic acid (S. Nishimura and Y. Takagi, Abstracts of the Research Meeting of the Catalysis Society of Japan, p. 31, Sendai, October, 1968). In *t*-butyl alcohol differences in the amount of hydrogenolysis are small between three isomers of methoxy- or ethoxyaniline [S. Nishimura, H. Uchino and H. Yoshino, This Bulletin **41**, 2194 (1968)].

9) Hydrogenolysis in vinyl type ethers may also be possible over some platinum metals. But the contribution of this type hydrogenolysis seems not important, especially in hydrogenation with Group $VIII_2$ metals, and was not considered here (Unpublished observations; *cf.* also Ref. 10, p. 444).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 921—925 (1970)

Syntheses of Optically Active α-Amino Acids from Esters of α-Keto Acids by Hydrogenolytic Asymmetric Transamination, A Solvent Effect[1]

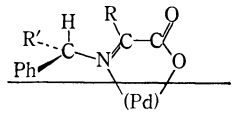
Kaoru HARADA and Takao YOSHIDA

Institute of Molecular Evolution and Department of Chemistry, University of Miami, Coral Gables, Florida 33134, U. S. A.

(Received September 29, 1969)

Optically active α-amino acids were synthesized from esters of α-keto acid azomethines by catalytic hydrogenation. Solvent effect of the reaction was studied and the possible steric courses are discussed.

Several studies on the asymmetric syntheses of α-amino acids from their corresponding α-keto acids have been reported.[2-10] Hiskey and Northrop[4] demonstrated the synthesis of optically active amino acids by catalytic hydrogenation and subsequent hydrogenolysis of the Schiff bases of α-keto acids with optically active α-methylbenzylamine (hydrogenolytic asymmetric transamination). The steric course of the hydrogenolytic asymmetric transamination reactions has been studied in this laboratory.[8,9] It was proposed that the possible conformation of the substrate in the catalytic hydrogenation could be a five-membered cyclic complex with the catalyst, as shown in structure I.[8] The



I

proposed intermediate I was supported by the study of a solvent effect of the asymmetric synthesis.[9]

In this investigation, the Schiff bases of α-keto acid esters with optically active amines were subjected to hydrogenation in order to examine the existence of structure I type chelated intermediates in these reactions. α-Keto acids used were ethyl pyruvate and ethyl α-ketobutyrate. Optically active amines used were (S)(−) and (R)(+)-α-methylbenzylamine, (R)(+)-α-ethylbenzylamine, and (R)(+)-1-(1-naphthyl)ethylamine. Solvents used in these reactions were benzene, ethyl acetate, isopropyl alcohol, ethanol, and methanol. Results are summarized in Table 1.

In each six sets of reactions, a solvent effect of the asymmetric synthesis was examined by the use of methanol, ethanol, propanol-2, ethyl acetate, and benzene (dielectric constant ranging from 32.6 to 2.3; Table 1). It was found that when a polar solvent was used, the optical purity of the resulting amino acid was lower and when less polar solvent was used the optical purity increased steadily. These solvent effects in the reactions suggest that the conformations of the substrate molecule changed depending on the solvent used. These results are similar to those obtained in the study of solvent effect in the hydrogenolytic asymmetric transamination between α-keto acids and optically active amine.[9] Therefore, similar conformation of the substrate in the hydrogenolytic asymmetric transamination between optically active amine and α-keto acid ester could be assumed as shown in structure II. Because electrostatic attraction between substrate and catalyst in a less polar solvent is stronger than in a polar solvent and also the solvation of the substrate in the less polar solvent is weak, so that the substrate could react easily with the catalyst to form the intermediate complex II. On the other hand, when polar solvent was used, electrostatic attraction between substrate and catalyst was weaker and the stronger solvation of the

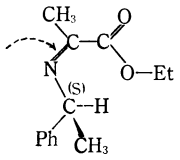
II

III



IV

substrate interfered with the attraction between substrate and catalyst to form the intermediate complex II. Therefore, it could be assumed that the conformation of substrate in polar solvent could be more in the form of structures III and IV. Structure IV is rather sterically hindered so that the structure III could be increased in proportion by the use of polar solvent. Structures II and III would be adsorbed at the less bulky side of the molecule and the hydrogenation takes place. When (S)-amine was used, (S)- and (R)-amino acid would be expected from structures II and III respectively. Therefore the use of polar solvent increases the proportion of structure III, and this would result in the formation of amino acid of lower optical purity. From the results obtained, structure II could be the major conformation throughout the reactions.

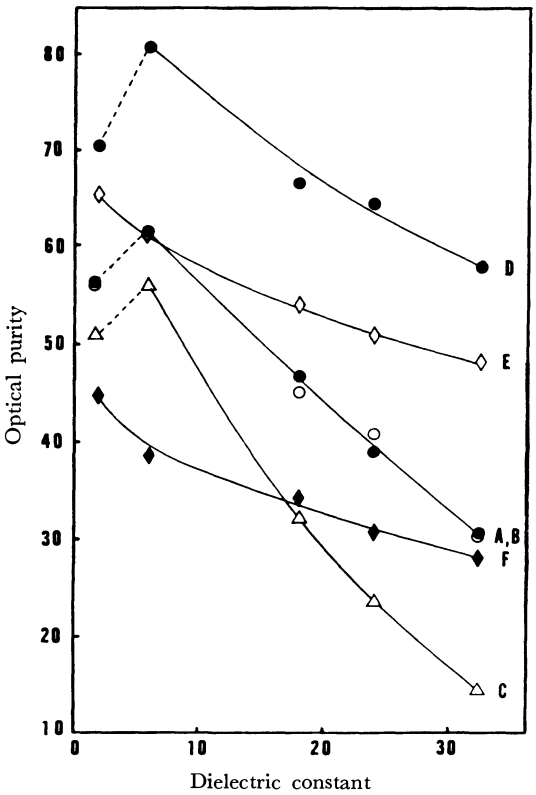


Fig. 1. Relationship between optical activities of synthesized amino acids and dielectric constants of the solvents used.

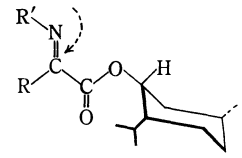
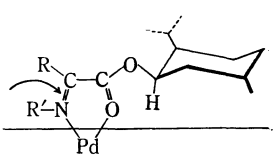
E. ala, reactions 21—25
F. α-NH_2-Bu, reactions 26—30

Figure 1 shows the relationship between the dielectric constants of the solvents used and the optical activities of synthesized amino acids. The effect of the catalyst, palladium hydroxide on charcoal or palladium on charcoal, was observed. By the use of palladium hydroxide on charcoal,[4] optical activity of amino acids dropped when benzene was used as a solvent (Fig. 1). Optical activities of amino acids increased rapidly when less polar solvents were used. On the other hand, by the use of palladium on charcoal optical activities of amino acids obtained increased slowly in the less polar solvents. A decrease in optical activity of amino acid by the use of benzene was not observed. High optical activity of amino acid (82%) was observed when R(+)-1-(1-naphthyl)-ethylamine was used. The reason for this is understandable from the steric effect in the intermediate complex II.

In the previous studies, hydrogenation of oximes and Schiff bases of α-keto acid *l*-menthyl esters has been studied. It was discussed that the conformation of the substrate might be transoidal, as shown in structure IV.[6,8] From the results obtained in the present investigation, it could also be possible



IV



V

to explain the steric course by a cisoidal conformation which forms chelate intermediate with the catalyst as shown in structure V. The menthyl group would be situated as in structure V because of the steric hindrance between menthyl residue and catalyst. Then, the structure V could be adsorbed on the catalyst at the less bulky side of the molecule, and hydrogenation would take place. From structure V, R-amino acid would be expected, which agrees with the experimental results.[6]

In order to examine the newly postulated intermediate (V) in the hydrogenation of α-keto acid *l*-menthyl ester oxime, a similar study of solvent effect was carried out. The substrates used were *l*-menthyl pyruvate oxime, *l*-menthyl α-ketobutyrate oxime, and the Schiff base of *l*-menthyl pyruvate

with (R)(+)-α-methylbenzylamine. Results are summarized in Table 2.

However, in these reactions, the solvent effect observed was rather small compared with that of the previous study[9] or with the results summarized in Table 1. Also observed was the discontinuation of optical purities of amino acids in these series of reactions (Fig. 2). The optical purities increased by the use of ethanol compared to that use of methanol. However, optical purities dropped by the use of isopropyl alcohol and increased steadily by the use of less polar solvent. The factors which affect the optical purity of amino acids in these reactions seem to be complex and it is difficult to explain these results at the present time. However, from the results obtained from the hydrogenolytic transamination summarized in Tables 1 and 2 the existence of intermediate complex structure V seems likely.

On the other hand, catalytic reduction of α-keto acid esters with optically active alcohols has been discussed and the reduction was found to follow the Prelog rule.[11] The results obtained in the present study suggest that the formation of α-hydroxy acid from α-keto acid ester with optically active alcohol by catalytic hydrogenation could also be explained by the chelated intermediate hypothesis.[8,9] The study on the synthesis of optically active α-hydroxy acid from α-keto acid amide with optically active amine also supports the chelation hypothesis.[12]

Optically active free amino acids were obtained by the use of a Dowex 50 column. However, these amino acids still contain some impurities. To avoid fractionation of optically active isomers during the purification process, all amino acids were treated with 2,4-dinitrofluorobenzene.[13] The resulting DNP-amino acids were purified by the use of celite column[14] treated with pH 7.0 citrate buffer without fractionation of partially optically active amino acids. Therefore, the values of optical purities of DNP-amino acids are more reliable and consistent (Table 1).

Experimental[15]

Alanine from Ethyl Pyruvate and S (−)-α-Methylbenzylamine. Ethyl pyruvate (1.16 g, 0.01 mol) and S(−)-α-methylbenzylamine (1.21 g, 0.01 mol) were dissolved in 20 m*l* of benzene at room temperature. After about ten minutes the solution became cloudy by separation of water. Anhydrous sodium sulfate was added and the mixture was stirred for one hour at room temperature. Sodium sulfate was removed by filtration and the sodium sulfate was washed with benzene. The combined benzene solution was evaporated to dryness under reduced pressure on a water bath (45°C). A light yellow oil was obtained. This was dissolved in 30 m*l* of methanol and the solution was subjected to hydrogenation and hydrogenolysis by the use of 1.0 g of palladium hydroxide on charcoal[4] for 12 hr. The first mole of hydrogen was absorbed in a few minutes. However, the second mole of hydrogen for hydrogenolysis required a much longer time. After the reaction was over, the catalyst was removed by filtration. The catalyst was washed with hot methanol several times. The combined methanol solution was evaporated under reduced pressure at 40°C. The residue was hydrolyzed under reflux with 60 m*l* of 3N hydrochloric acid for 4 hr. The hydrolyzate was extracted once with ether and the hydrochloric acid solution was evaporated to dryness under reduced pressure. Water was added to the residue and it was evaporated again to minimize the remaining free hydrochloric acid. The residual amino acid hydrochloride was dissolved in 10 m*l* of water and the solution was applied to a Dowex 50×2 column (hydrogen form, 100—200 mesh, 25×1.8 cm). The acidic component was washed with water, then alanine was eluted with 1N aqueous ammonia. Fractions containing alanine were combined and were evaporated to dryness. Free alanine, 0.67 g, was obtained. This is pure on paper chromatograph. $[\alpha]_D^{25}=+4.5°$ (*c* 4.0, 5N HCl), optical purity 31%. After one recrystallization with water and ethanol, elemental analysis was carried out.

Found: C, 40.65; H, 8.01; N, 15.58%. Calcd for $C_3H_7ON_2$: C, 40.44; H, 7.92; N, 15.72%.

A part of the unrecrystallized alanine (100 mg) was converted to DNP-alanine in a conventional manner.[13] DNP-Alanine obtained was purified by the use of celite column treated with pH 7 citrate buffer (0.2M).[14] These procedures are similar to those described in earlier reports.[6,8]

DNP-Alanine, mp 172—174°C dec., $[\alpha]_D^{25}=+46.4°$ (*c* 1.1, 1N NaOH), optical purity 32%.

Found: C, 42.42; H, 3.66; N, 16.64%. Calcd for $C_9H_9N_3O_6$: C, 42.36; H, 3.55; N, 16.47%.

Other experiments were carried out in the same way as described above. Results are summarized in Table 1.

Amino Acids from α-Keto Acid *l*-Menthyl Ester. The experimental procedures for the synthesis of optically active amino acids from α-keto acid *l*-menthyl esters were similar to those already described in the earlier papers[6,8] except for the use of different solvents. Alanine and α-aminobutyric acid obtained by saponification of menthyl esters were converted to their DNP-derivatives. These DNP-amino acids were similarly purified by the use of celite column.[14] Results are summarized in Table 2.

This work was supported by grant number NGR 10-007-052 from the National Aeronautics and Space Administration.

15) All hydrogenations and hydrogenolyses were carried out by the use of the Parr 3910 shaker type hydrogenation apparatus. All optical rotations were measured by the use of Durrum-JASCO ORD/UV-5 automatic spectropolarimeter. Some of the optical rotations of free amino acids were measured by the use of the Rudolph model 80 polarimeter with a PEC-101 photometer.

(Received September 24, 1969)

The soft carbon samples PV-15, -17 and -20, and the hard carbon samples PH-15 and -20, which were prepared by pre-heat-treatment of a polyvinylchloride coke PV-7 at 1500, 1700 and 2000°C and a phenolformaldehyde resine char PH-7, at 1500 and 2000°C, respectively, under reduced pressure, were re-heat-treated under quasi-hydrostatic pressure of 5 kbar. The structural changes in these carbons by the re-heat-treatment under pressure were studied by X-ray diffraction analysis. On the soft carbons, the rate of development of graphitic component was found to become small with the increase in temperature of pre-heat-treatment. On these samples, especially on PV-20, the normal homogeneous graphitization of turbostratic component was observed above about 1700°C besides the heterogeneous graphitization. However, the hard carbon samples PH-15 and PH-20 showed the same abrupt heterogeneous graphitization at around 1500°C as the original PH-7. These results suggest that the structure of carbon sample is related to the heterogeneous graphitization under high pressure. One can deduce a conclusion from the results of this series of experiments that the heterogeneous graphitization is more dominant in a carbon sample having a lower degree of graphitization, for example, a larger c_0-spacing and a smaller crystallite size.

Both soft and hard carbons have been found to be graphitized very rapidly around 1400—1500°C under high pressure.[1-5] Under high pressure, the graphitization proceeds heterogeneously, that is a part of original carbon transforms directly to graphite having three dimensional ordering, while the other part of the specimen remains almost unchanged. The direct transformation of turbostratic structure to graphitic structure occurs in whole domain without going through intermediate state of graphitization. This heterogeneous graphitization under high pressure is reflected in the composite (00*l*) diffraction profile of the sample. The observed composite profile consists of two kinds of component profiles which correspond to turbostratic and graphitic components.

Under normal or reduced pressure, however, the graphitization proceeds homogeneously as being demonstrated by the continuous shift of almost symmetrical (00*l*) diffraction line toward higher angle side.

In the preliminary experiment,[1] the carbons pre-heat-treated above 1500°C under reduced pressure was found not to show any abrupt graphitization around 1400—1500°C under the pressure of 10 kbar. The purpose of the present work is to investigate more precisely the effect of pre-heat-treatment on graphitization of carbon under high pressure.

Experimental

Preparation of Samples. The original samples used were a polyvinylchloride coke (PV-7), which was carbonized to 680°C[1] and a phenolformaldehyde resine char (PH-7), which was carbonized to 700°C. Pre-heat-treated soft carbons PV-15, -17 and -20 were prepared by the heat-treatment of PV-7 at 1500, 1700 and 2000°C, respectively, for 60 min under the reduced pressure of 10^{-2} Torr. The c_0-spacings of these samples were 6.885, 6.858 and 6.845 Å, respectively. Pre-heat-treated hard carbons PH-15 and PH-20 were prepared at 1500 and 2000°C, respectively, from PH-7, through the same procedure as the soft carbons. The c_0-spacing of the samples PH-15 and -20 was 6.959 and 6.927 Å, respectively. Only the c_0-spacing of PV-20 was smaller than 6.85 Å and those of the other samples were larger. Therefore, PV-20 was on the second stage[6] of graphitization process and the other samples were on its first stage.

The furnace and the procedure used for the pre-heat-

treatments were the same as those reported in detail elsewhere.[7] Time necessary for heating and cooling to and from pre-heat-treatment temperature was both less than a few minutes.

Heat-Treatment under High Pressure and X-Ray Diffraction Analysis. A piston-cylinder type high pressure apparatus,[2,3] made from tool steel, was used for heat-treatments of the samples under 5 kbar. The pressure cell arrangement used was exactly the same as reported previously.[2] The heat-treatment temperature (HTT) was determined by using the relation between specimen temperature and consumed electric input power, which was established beforehand for each sample from the measurement of temperature by using a thermocouple inserted into the specimen under 5 kbar. The heat-treatments under 5 kbar were performed at various temperatures ranging from 1200 to 1900°C.

The central part of the heat-treated specimen was sampled for X-ray diffraction analysis. In this part, the temperature gradient along axial direction has been hardly observed.[4]

Profiles of (004) and (002) diffraction lines of the heat-treated samples were measured by using Ni-filtered Cu $K\alpha$ radiation and a recording goniometer. The composite profile observed was graphically separated by trial and error method into two component profiles which corresponded to the graphitic component G and turbostratic one A. The details of the separation procedure were reported previously.[2,5,8] The c_0-spacing and crystallite size Lc were measured for each separated component profile by referring to the inner standard of silicon, and the content of the graphitic component G_S* or G_H* was obtained from the ratio of the area under the profile of the graphitic component to the total area of the composite profile. The area ratio was corrected for crystallite orientation in the X-ray specimen.[3]

Results

Soft Carbon Samples. Change of (004) diffraction profile of the sample PV-15 with HTT under 5 kbar is shown in Fig. 1a). Above 1500°C, a profile corresponding to the graphitic component G_S appeared on the high angle side of the profile of the turbostratic component A_S. The intensity of diffraction of the component G_S gradually increased

up to 1670°C. This change in profile had the same trend as that observed previously for the original sample PV-7,[2] except that the temperature of appearance of the component G_S in PV-15 was somewhat higher than that in PV-7. Above 1670°C, the intensity of diffraction of the component G_S did not increase or rather decreased gradually and the profile of the component A_S began to shift to higher angle side together with sharpening. For the sample PV-17, change of (004) diffraction profile with HTT was similar to that observed for the sample PV-15. The same but more marked trend of change in diffraction profile with HTT can be seen in the case of PV-20, which is shown in Fig. 1b). The component A_S had a little higher diffraction angle, that is, a smaller c_0-spacing than those of the sample PV-7, -15 and -17. The profile of the component G_S appeared at 1500°C and developed gradually with the increase in HTT. Above 1800°C, it became markedly small, and the profile for the component A_S began to shift to higher angle side.

The content of the component G_s for the samples PV-15, -17 and -20 is plotted against HTT in Fig. 2. The variation of content of the component

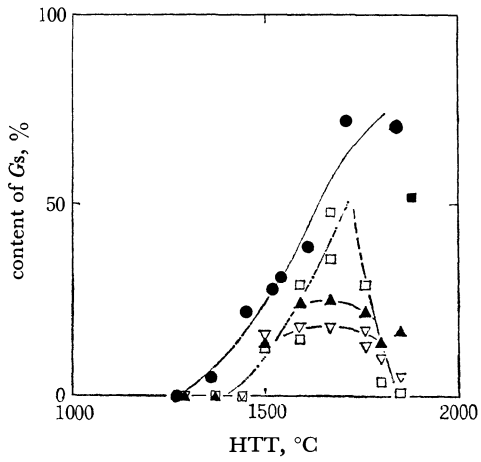

Fig. 2. Variations of content of G_S with HTT under 5 kbar for 60 min for pre-heat-treated soft carbons.
●; PV-7, ▲; PV-15, ▽; PV-17, □; PV-20, ■; PV-20 heat-treated at 1740°C and then at 1880°C under 5 kbar.

G_S for the original sample PV-7 is shown in the same figure. An anomalous change of content of G_S for the sample PV-20 is seen in this figure. In the case of PV-20, the content of the component G_S increased gradually up to 1700—1800°C and became small above this temperature. The similar but small decrease in the content of the component G_S was also observed in the cases of PV-15 and -17 above about 1700°C. The point marked by solid square in Fig. 2 represents the content of G_S for the sample PV-20 which was heat-treated at 1740°C for 60 min and then, without cooling, heat-treated further at 1880°C for 60 min under 5 kbar. It shows a large content of G_S which corresponds to the value for the temperature of the first heat-treatment, that is, 1740°C.

The variations of content of the component G_s with residence time at 1590 and 1800°C under 5 kbar are shown in Figs. 3a) and 3b). In the

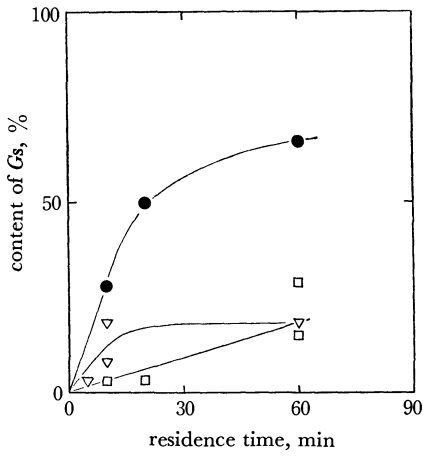

Fig. 3a

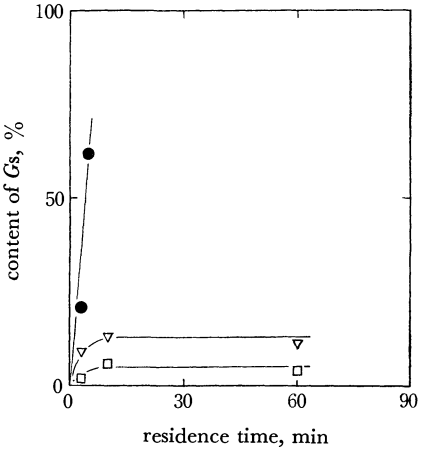

Fig. 3b

Fig. 3. Variations of content of G_S with residence time of HTT under 5 kbar for pre-heat-treated soft carbons.
●; PV-7, ▽; PV-17, □; PV-20
a) at 1590°C under 5 kbar, b) at 1800°C under 5 kbar

case of PV-7, the content of G_S increased very rapidly with residence time. In the cases of PV-17 and -20, the rate of development of the component G_S was depressed and seemed to approach a small limiting value.

The variations of the c_0-spacing of the component A_S and G_S with HTT are shown in Fig. 4. The

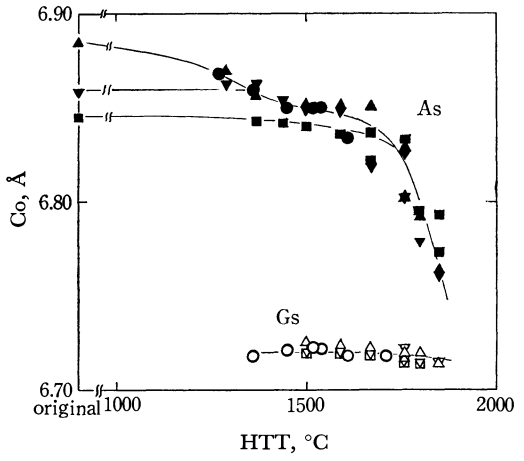

Fig. 4. Variations of c_0-spacing of the component A_S and G_S with HTT under 5 kbar for 60 min for pre-heat-treated soft carbons.

A_S	●	▲	▼	■
G_S	○	△	▽	□

samples PV-15 and -17 showed gradual decrease in the c_0-spacing of the component A_S down to about 6.85 Å. After the c_0-spacing of the component A_S reached about 6.85 Å, it remained almost constant and the component G_S, whose c_0-spacing was about 6.72 Å, began to appear. Above around 1700°C, however, the c_0-spacing of the component A_S decreased rapidly. The sample PV-20, whose c_0-spacing was smaller than 6.85 Å, showed no change in the c_0-spacing of the component A_S until about 1700°C, while the component G_S was detected even at 1500°C. Above about 1750°C, the c_0-spacing of the component A_S for PV-20 decreased rapidly along the same line as PV-15 and -17.

The mutual relation in the change of crystallite size L_c of the component A_S with HTT among the four soft carbon samples PV-7, -15, -17 and -20 was the same as that in the c_0-spacing and is shown in Fig. 5.

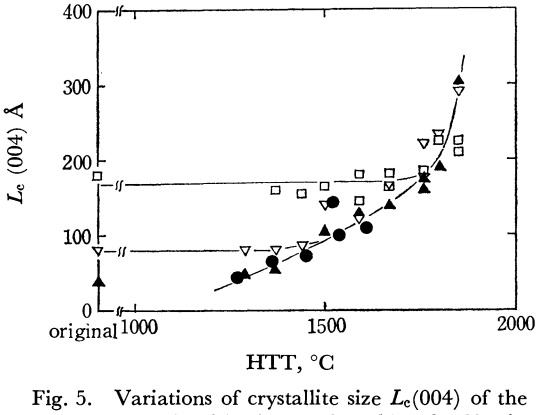

Fig. 5. Variations of crystallite size L_c(004) of the component A_S with HTT under 5 kbar for 60 min for pre-heat-treated soft carbons.
●; PV-7, ▲; PV-15, △; PV-17, □; PV-20

Hard Carbon Samples. Changes of (002) diffraction profile with HTT for the samples PH-15 and PH-20 were almost the same as that for the original sample PH-7, which was previously reported.[5] The variations of content of the graphitic component G_H with HTT for the samples PH-7, -15 and -20 are shown in Fig. 6. No appreciable difference in the change of content of the component G_H among three samples can be made, because there was a relatively large error in the determination of HTT in the case of the hard carbon.[9] The c_0-spacing of the turbostratic component A_H had a constant value of about 6.88 Å and the graphitic component G_H of about 6.72 Å.

Discussion

The starting of the heterogeneous graphitization under pressure, that is, the first appearance of the graphitic component G_S, of the pre-heat-treated soft carbons was retarded about 100°C from that of the original un-treated carbon sample PV-7. In the case of the sample PV-7, the content of the component G_S increased with increase in HTT, but in the cases of the pre-heat-treated carbons, a maximum value at about 1700°C was observed in the plot of the content of G_S against HTT. The apparent decrease of the content of G_S dose not mean the actual disappearance of the graphitic component once formed, but it comes from the fact that the formation of G_S largely depressed at higher HTT in the cases of the pre-heat-treated carbons, as it can be seen from Fig. 3. This conclu-

9) K. Kamiya, S. Yugo, M. Inagaki, H. Saito and T. Tsuzuku, This Bulletin, **41**, 2782 (1968).

sion is also confirmed by an experimental result represented by a solid square mark in Fig. 2. The sample PV-20 was first heat-treated at 1740°C for 60 min and then further at 1880°C for 60 min. The content of G_S of the sample after these heat-treatments was about 50%. This value corresponds to the one which can be obtained by the first heat-treatment at 1740°C. This suggests that the high content of G_S formed by the heat-treatment at 1740°C remained unchanged by the subsequent heat-treatment at 1880°C.

For the sample PV-15 and -17, the heterogeneous graphitization process was dominant in the range around 1400°C to 1700°C, in which the c_0-spacing of the structural components A_S and G_S remained unchanged at 6.85 and 6.72 Å, respectively. However, above 1700°C the homogeneous graphitization process became dominant and the profile of the turbostratic component A_S shifted to higher angle side. For the sample PV-20, the heterogeneous graphitization process began from about 1500°C and was dominant up to about 1800°C. It seemed that the direct transformation of the turbostratic component A_S to the graphitic component G_S, without having the intermediate structure, was slowed down when the c_0-spacing of the component A_S decreased below 6.85 Å. For the sample PV-7, only the heterogeneous graphitization has been observed by the heat-treatment under pressure, because it proceeded so rapidly that almost all of the component A_S transformed to the component G_S at temperatures below about 1700°C. For the pre-heat-treated carbons, one could observe the homogeneous graphitization of the component A_S, because the rate of the direct transformation of A_S to G_S was slowed down by the pre-heat-treatment.

In the previous work,[1] it was reported that the pre-heat-treated soft carbons showed no heterogeneous graphitization under 10 kbar. The residence time in that work was 3 min, but this residence time seems not to be enough for the graphitic component to develope, as it can be deduced from Fig. 3. Therefore, heterogeneous graphitization under pressure was probably not detected. It has been also mentioned that the graphitization of carbon under high pressure might be related to the dehydrogenation of carbon. This assumption was deduced from the fact that, under high pressure, carbon containing hydrogen, such as PV-7, was graphitized more rapidly than pre-heat-treated carbons which had been deprived of hydrogen. In the present work, however, the pre-heat-treated hard carbons PH-15 and PH-20 were shown to be graphitized as rapidly as original un-treated hard carbon sample PH-7. The sample PH-20 seemed to be almost completely dehydrogenated. This suggests that the dehydrogenation of the sample is not important factor for the rapid graphitization under high pressure.

The c_0-spacing of the samples, PH-7, PH-15, PH-20, PV-7, PV-15, PV-17 and PV-20, used in the present work was 7.01, 6.96, 6.93, 6.91, 6.885, 6.858 and 6.845 Å, respectively and the crystallite size $L_C(002)$ was 17, 17, 21, 28, 72, 150 and 260 Å, respectively. Among these seven samples PH-7, PH-15, PH-20 and PV-7 showed only heterogeneous graphitization under high pressure. However, for other samples, which had smaller c_0-spacings and larger crystallite sizes than the above four samples, the homogeneous graphitization was observed to occur side by side with the heterogeneous one even under high pressure. From this fact one can conclude that the heterogeneous graphitization is more dominant in a carbon sample which has a lower degree of graphitization.

The course of developement of the component G_S and A_S of the sample PV-20 was a little different from the other pre-heat-treated samples as shown in Figs. 1b) and 2. It seems to be related to the fact that the sample PV-20 was already on the second stage of normal graphitization process, while the others were on its first stage. However, the reason why the maximum value of the content of G_S was so large for PV-20 can not be understood.

The authors wish to thank Mr. M. Mizutani for his assistance. The carbon materials used were supplied by Tokai Electrode Mfg. Co.

Thin-layer Chromatography of Inorganic Salts. III. Study of the Hydration of Anions by Means of Chromatography of Crystal Violet Cation

Tetsuo BABA,*1 Koji SAKUSHIMA*2 and Hayami YONEDA*3

Department of Chemistry, Wakayama University, Masago-cho, Wakayama

(Received March 29, 1969)

Our object was to obtain information concerning the behavior and the dissolved state of ions in solution by means of chromatography. We suggested that a complex cation is eluted mainly through ion-pair formation with anions contained in a developer.[1] The ion-pair formation reduces the apparent positive charge of a complex cation, which results in the decrease of the electrostatic attraction of an adsorbent and the increase of the R_f value of the complex.

It is well known that a number of anions can be extracted from an aqueous solution into an organic solvent through ion-pair formation between anions and dyestuff cations.[2] The extractability of anions seems to depend largely on the kind of anion and to reflect the behavior of anions towards ion-pair formation. Thus different R_f values of the dyestuff are expected when it is developed with solutions of various salts.

The object of this work is to clarify the effect of hydration of anions on ion-pair formation by means of chromatography of the dyestuff.

Experimental

As an adsorbent, Merck's silica gel H, prepared for thin-layer chromatography was used without further purification. This was spread on glass plates of 20 cm length with 0.25 mm thickness.

The dyestuff used was crystal violet. This was dissolved in ethanol to make 1/1000M solution, and 0.25 μl of the solution was applied at a starting point, 5 cm above the lower edge of the plate.

The following thirteen anions were chosen to form an ion-pair with the crystal violet cation: Cl^-, Br^-, I^-, NO_2^-, NO_3^-, ClO_3^-, ClO_4^-, $CH_3CO_2^-$, $CH_2ClCO_2^-$, $CHCl_2CO_2^-$, CO_3^{2-}, SO_3^{2-} and SO_4^{2-}. The sodium salts of these anions were dissolved in 50% ethanol-water solution to make 0.2M solutions, and they were used as a developer (In the case of sulfate and sulfite, 30% ethanol-water solution was used). Development was carried out at room temperature (17—18°C), until the solvent front rose to about 12—13 cm from the starting point. No special procedure was necessary for visualization of the spot, as it was sufficiently colored.

Results and Discussion

In Table 1 are listed the R_f values of crystal violet developed with alcoholic aqueous solutions of various salts, and typical examples of the chromatograms are shown in Fig. 1. As is seen in these data, the R_f value of the dyestuff cation depends

TABLE 1. R_f VALUES OF CRYSTAL VIOLET DEVELOPED WITH ALCOHOLIC AQUEOUS SOLUTIONS OF SALTS

a) Developed with 50% alcoholic aqueous solutions containing monovalent anions in 0.2M

Anions	R_f values	Anions	R_f values
$CH_3CO_2^-$	0.48	ClO_3^-	0.53

2) As examples, the crystal violet-benzene system was used for extraction of ClO_4^- and IO_4^- (C. E. Hedrick and B. A. Berger, *Anal. Chem.*, **38**, 791 (1966)), and for $[Ag(CN)_2]^-$ (J. J. Markham, *Anal. Chem.*, **39**, 241 (1967)). The methylene blue-dichloroethane system was used for extraction of BF_4^- (J. Mrozinski, *Chem. Anal.* (Warsaw), **12**, 93 (1967)).

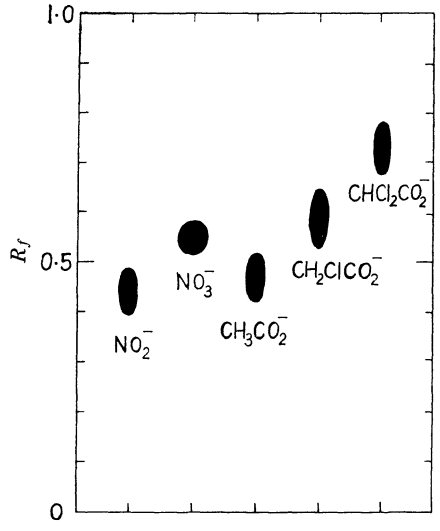

Fig. 1. Chromatogram of crystal violet developed with 50% aqueous alcoholic solutions containing monovalent anions in 0.2M concentration.

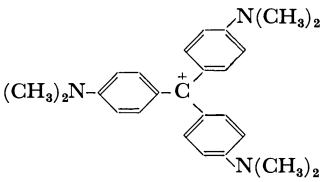
on the kind of anion in a developer. Comparison of the R_f values in the pairs (ClO_4^->ClO_3^- and NO_3^->NO_2^-) and the set ($CHCl_2CO_2^-$>$CH_2ClCO_2^-$>$CH_3CO_2^-$) leads us to the following conclusion. The crystal violet cation is dissolved from the adsorbing silica gel surface more easily with a stronger acid anion than with a weaker acid anion. The surface of silica gel is charged negatively in contact with water and adsorbs cations strongly.[4] Thus, the increase of the R_f value of the dyestuff in the salt solution seems to result from the decrease of the apparent positive ionic charge of the dyestuff cation due to the ion-pair formation between the anions and the dyestuff cations. The results suggest that a stronger acid anion can form an ion-pair with a dyestuff cation more easily than a weaker acid anion. As is seen from the structural formula



the crystal violet cation seems to be very poorly hydrated in solution. Presumably a weaker acid anion is more hydrated than a stronger one. Thus we might conclude as follows. The poorly hydrated dyestuff cation can form an ion-pair more easily with the less hydrated anion than with the more hydrated one. In fact, the R_f values of crystal violet increase in the order Cl^-<Br^-<I^-. This is just the order of the decrease of hydration. The R_f value in the divalent sulfate and carbonate anions is much lower than that in the monovalent anion. The large R_f value was obtained in the case of the sulfite anion. This can be explained as a result of the reduction of the dyestuff. Thus, the R_f value of the dyestuff is considered to give the relative measure of the degree of hydration of various anions.

Coordination Chemistry of Lanthanide Elements. II.[1] Cationic Lanthanide Complexes of Trimorpholino Phosphine Oxide

J. T. DONOGHUE

Department of Chemistry, University of Arkansas, Fayetteville, Arkansas, U.S.A.

(Received July 12, 1969)

In earlier studies,[2,3] it was found that the phosphoryl donor, hexamethyl phosphoramide (HMPA), formed six coordinate complexes with lanthanide ions. The occurrence of coordination number six for lanthanide ions, although not unique for this ligand, is unusual enough to warrant further study of the factors which give rise to it. The ligand, trimorpholino phosphine oxide exhibits behavior similar to that of HMPA[3] in forming complexes with transition metals. It was found that this ligand also gives complexes of the type $LnCl_3 \cdot 3L$.[4] It was of interest to investigate cationic lanthanide complexes of this phosphoryl donor.

Experimental

Synthesis of Complexes. The complexes were synthesized by metathesis according to the equation

$$LnCl_3 + 3AgClO_4 + 6L \longrightarrow Ln(ClO_4)_3 \cdot 6L + 3AgCl.$$

0.001 mol of lanthanide halide was dissolved in 15 m*l* of hot alcohol. To this was added a solution of 0.003 mol of $AgClO_4$ in 15 m*l* of hot alcohol. The precipitated silver chloride was filtered after cooling. The filtrate, under nitrogen, was treated with 0.006 mol of ligand in 15 m*l* of hot alcohol. After the resulting solutions had cooled to room temperature, they were treated with 75 m*l* of absolute ether to precipitate the complexes. The solid complexes were filtered and dried under nitrogen and were stored *in vacuo* over H_2SO_4. Analytical results are presented in Table 1.

Infrared Spectra. Infrared spectra of Nujol mulls of the complexes and free ligand were obtained using a Perkin-Elmer, model 337, recording infrared spectrophotometer. In all complexes studied, the phosphoryl frequency of the ligand was displaced to lower energies on complexation. The results are shown in Table 2.

Conductance Measurements. Conductances of 0.001M solutions in nitromethane were obtained using an Industrial Instruments Conductivity Bridge which was frequently calibrated with 0.01N KCl. Results are presented in Table 3.

Reagents. The lanthanide halides were obtained from Trona Chemicals and were of 99.9+% purity.

Trimorpholino phosphine oxide was obtained from Aldrich Chemical Co. and was used without further purification.

All other chemicals employed in this study were of reagent-grade quality.

Results

Analytical. Analytical data for the ligand and its lanthanide complexes are given in Table 1.

Infrared. Absorption frequencies for the P=O group in the complexes are given in Table 2.

Conductivity. Molar conductivities obtained for 10^{-3}M solutions of the complexes in CH_3NO_2 are given in Table 3.

Discussion

The ligand trimorpholino phosphine oxide is similar to hexamethyl phosphoramide in many ways in that the infrared phosphoryl frequencies are nearly identical at 1204 cm^{-1} and 1208 cm^{-1} respectively. The coordination behavior of the two ligands toward transition metals is very similar in that both form pseudo tetrahedral complexes with nickel(II) and cobalt(II).[5,6] However, in terms of steric requirements, trimorpholino phosphine oxide, $\left(O\langle\begin{smallmatrix}CH_2CH_2\\CH_2CH_2\end{smallmatrix}\rangle N\right)_3PO$, is expected to show a stronger resemblance to triphenyl phosphine oxide $(C_6H_5)_3PO$ than to HMPA, $[(CH_3)_2N]_3PO$.

The conductivity results indicate that the perchlorate anion is not coordinated in nitromethane. Unfortunately, strong ligand absorption in the infrared in the region expected for perchlorate absorption made it impossible to determine if perchlorate is weakly coordinated in the solid state. It must be assumed that the perchlorate anion is uncoordinated in the solid state as well as in nitromethane solution.

The behavior of trimorpholino phosphine oxide toward lanthanides was observed to be quite similar to that of HMPA and other oxygen donor ligands, such as diphenyl sulfoxide.[7,8]

On the basis of the data reported above, it is concluded that the apparent coordination number of the lanthanide elements in these complexes is uniformly six.

Obviously, the steric requirements of triphenyl phosphine oxide and trimorpholino phosphine oxide should be similar, but the coordination numbers exhibited for trimorpholino phosphine oxide in complexes of the type $[LnL_6]^{+3}$ are apparently six. Since the cationic lanthanide complexes of triphenyl phosphine oxide are unknown, a direct comparison between triphenyl phosphine oxide and trimorpholino phosphine oxide is not possible but is desirable. Future work will involve investigation of the cationic lanthanide complexes of triphenyl phosphine oxide.

I would like to acknowledge the aid of the Donors of the Petroleum Research Fund of the American Chemical Society through Grant No. 1108-G3.

The Photolysis of Sodium *N,N*-Dimethyldithiocarbamate and Hexamethyleneammonium Hexamethylenedithiocarbamate

Toshihiro YAMASE, Hiroshi KOKADO and Eiichi INOUE

Imaging Science and Engineering Laboratory, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received July 29, 1969)

We have previously reported that sodium *N,N*-dimethyldithiocarbamate (SMTC) is photolyzed by light of the wavelength of 2537 Å. The absorption was attributed to the excitation of a sulphur-conjugated system. We also found carbon disulfide in the photo-decomposition products.[1] It was then considered desirable to make a more quantitative assessment of carbon disulfide for the purpose of elucidating the kinetics of the photolytic process.

Unless otherwise stated, the experiments were carried out with SMTC or hexamethyleneammonium hexamethylenedithiocarbamate (HMTC) solutions of $3—6\times10^{-5}$M. A deaerated solution was photolyzed in the same manner as before.[1] The produced carbon disulfide was transformed into potassium methylxanthate, which shows an optical absorption at 300 nm in methanol. The amount of the methylxanthate produced, and consequently the yield of carbon disulfide, increased as the

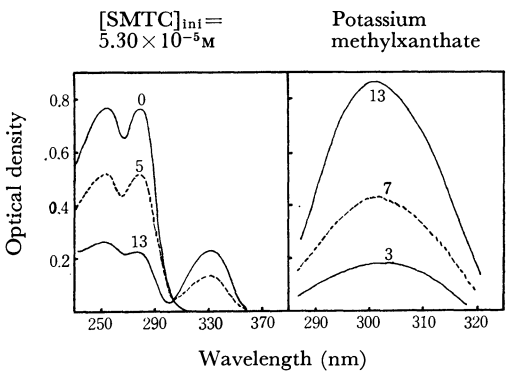

Fig. 1. Absorption spectra of SMTC solution and formed potassium methylxanthate.
Numbers indicate the illumination time (min) of SMTC solution

dithiocarbamate was photolyzed (Fig. 1). The experimental results can be represented as in the following equation, as was anticipated in the previous paper[1]:

$$-dC/dt=kC=dC'/dt=k(C'_\infty-C')$$

where C is the concentration of dithiocarbamate in mol/l and where C' and C'_∞ are the concentrations of carbon disulfide in mol/l at the illumination times of $t=t$ and $t=\infty$ respectively. Representing the concentration by the optical density of each absorption, some log plots derived from the rate formula are shown in Fig. 2. Juging from Fig. 1, the quantity of produced carbon disulfide

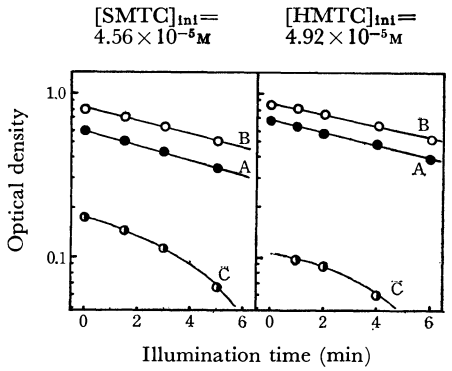

Fig. 2. Optical density as a function of illumination time:
A indicates optical density (O.D) of SMTC and HMTC at 280 nm and 282 nm, respectively.
B and C indicate $O.D_\infty$—O.D at 300 nm and 330 nm, respectively.

can be regarded as the same as the decrease in dithiocarbamate. When the initial concentrations of SMTC were 5.92×10^{-5}M and 4.56×10^{-5}M, the amounts of carbon disulfide produced by prolonged photolysis were 5.70×10^{-5}M and 4.49×10^{-5}M respectively. There remains scarcely any doubt that carbon disulfide is produced by a unimolecular reaction and that the photolysis proceeds by first-order kinetics.

After the photolysis of SMTC, the optical density at 330 nm was decreased and a new absorption appeared at 264 nm. It may be inferred that a stable species was produced *via* an unstable species with the absorption maximum at 330 nm. The change in the absorption of the solution after photolysis is shown in Fig. 3. Such a spectrum was

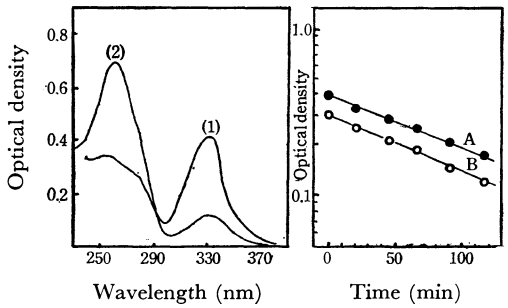

Fig. 3. Dark reaction after photolysis.
(1) and (2) indicate spectra of SMTC after 0 and 170 min, respectively;
A indicates optical density (O.D) at 330 nm.
B indicates $O.D_\infty$—O.D at 264 nm.
$[SMTC]_{ini}=1.06\times10^{-4}$M

not identified with that of dimethylamine, acetaldehyde, formaldehyde, or *N*-methylformaldehyde in an aqueous solution of pH 10, although all those substances had been anticipated as photoproducts. The quantum yield was unknown with regard to HMTC; however, we can easily infer that the quantum yield of HMTC is not far from the 0.11 which is observed in SMTC. This is evident from the fact that those two dithiocarbamates had almost the same slopes of photolytic rates and almost the same absorption coefficients[2]. The substance which has the absorption at 330 nm may be ascribed to an amine or imine derivative which reacts by the first-order process to show an absorption at 264 nm.

Dynamic Differential Effect of Alkali Ions on the Desorption of Calcium Ion from Lipid Film

Hideo KIMIZUKA, Shōzō NISHIDA and Taketoshi HIDESHIMA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received August 8, 1969)

The study of the interaction between the surface film and the solute of an underlying solution is essential in order to elucidate the reactions occurring at the interface of the cellular membrane. Recently, some evidence has been accumulated to show that Ca^{2+} is involved in regulating the ion movement across the cell membrane.[1] It is of importance, therefore, to examine the interactions between Ca^{2+} and other ions within lipid film. Since the phenomenon of ion movement is kinetic in nature, it may be more intimately related to the rate of adsorption or desorption than to any static property such as the equilibrium adsorption. It was shown in the preceding papers that the rate of desorption of Ca^{2+} brought about by K^+ was greater than that brought about by Na^+, whereas the equilibrium adsorptions were almost the same.[2] This differential effect was tentatively explained by assuming that the rate-determining step in the exchange reactions is the removal of the water molecule from the hydrated K^+ and Na^+. A further test of this hypothesis would require similar experiments by the use of other alkali ions such as Li^+, more hydrated than Na^+, and such as Cs^+ and Rb^+, less hydrated than K^+. This paper will describe the result of experiments carried out with these ions.

The samples as well as the apparatus used have been described elsewhere;[2] the temperatures were 25±1°C. The films of stearic acid or phospholipid were spread over the 5 m*l* of a solution containing radioactive calcium, and the calcium bound to the lipid film was measured with the G–M counter. When the equilibrium had been attained, 1 m*l* of a solution of alkali chloride was injected into the underlying solution by means of a syringe and the time-dependence of the desorption of Ca^{2+} was measured.[2] The results are shown in Figs. 1 and 2 together with the preceding results.[2] It may be seen in these figures that Li^+ acts like Na^+, whereas Rb^+ and Cs^+ behave like K^+, *i. e.*, the former indicates the induction period prior to the Ca^{2+} desorption, while the latter cause the desorption immediately. In contrast to the desorption behavior, the equilibrium adsorptions were nearly the same. These phenomena were found to be reproducible regardless of the concentrations of the alkali chloride solutions.

The results of the present paper, together with those of preceding papers,[2] suggest that the alkali ions may be classified into two groups, the 1st consisting of Li^+ and Na^+, and the 2nd, of K^+, Rb^+, and Cs^+, according to their dynamic behaviors at the interface. In addition, it may be pointed out that this classification may be attributed to the kinetic property of the alkali ion itself, since the phenomena are independent of the kind of anionic site.

According to Samoilov,[3] alkali ions are divided

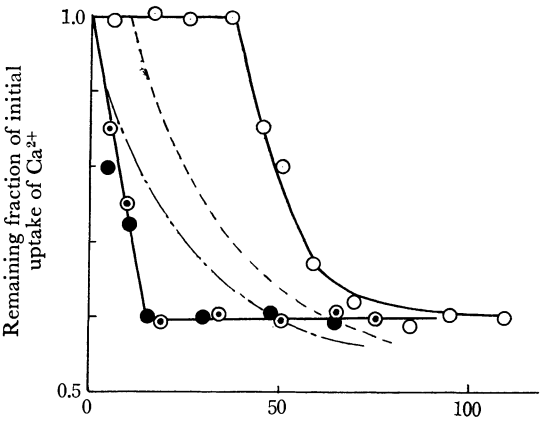

Fig. 1. Desorption of Bound Ca^{2+} from stearate film with time.
Open, dotted and filled circles indicate the effect of Li^+, Rb^+ and Cs^+, respectively. Concentration of Ca^{2+} was 4.72×10^{-5}M and those of the alkali ions, 0.1M (pH, 7.1—7.2).
Dotted and broken lines indicate the effect of Na^+ and K^+, respectively.[2] Concentration of Ca^{2+} was 1.62×10^{-5}M and those of Na^+ and K^+, 0.4M (pH, 8.0—8.2).

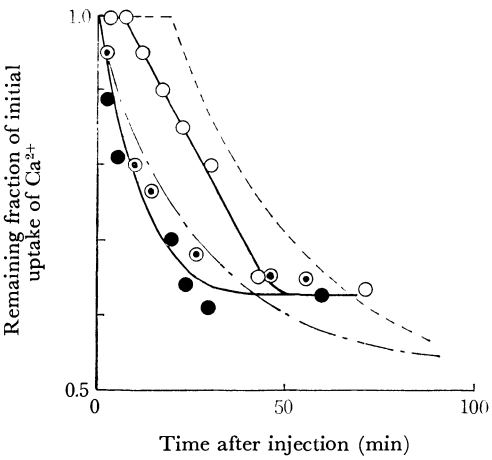

Fig. 2. Desorption of bound Ca^{2+} from lipid film with time.
Open, dotted and filled circles indicate the effect of Li^+, Rb^+ and Cs^+, respectively. Concentration of Ca^{2+} was 2.15×10^{-4}M and those of alkali ions, 1M (pH, 7.1—7.2).
Dotted and broken lines indicate the effect of Na^+ and K^+, respectively.[2] Concentration of Ca^{2+} was 5×10^{-4}M and those of alkali ions, 1.12M (pH, 7.1—7.2).

into two groups on the basis of the kinetic features of hydrated water, *i. e.*, the ions of positive hydration, Li^+ and Na^+, and those of negative hydration, K^+, Rb^+, and Cs^+. The hydrated water molecules of the former and of the latter are, respectively, less and more labile than molecules of pure water. This proposal corresponds to the concept of the structural temperature[4] or the order-disorder structure[5] of hydrated water.

Thus, this concept of the state of hydration may offer a plausible explanation for the present results providing that the rate-determining step of the ion-exchange reaction occurring at the surface film is the dehydration process of the alkali ion.

The similar differentiation has already been established in some biophysicochemical properties, such as the movements of alkali ions across the cell membrane[6] and the activation phenomena of some enzymes by those ions.[7] Since these phenomena are also kinetic in nature, it is conceivable that these biophysicochemical properties are closely related to the kinetic behavior of alkali ions at boundaries.

Synthesis of 4-(2-Thienyl)pyrimidine Derivatives. Studies on Heterocyclic Chemistry. VI[1]

Tarozaemon NISHIWAKI

Department of Chemistry, Yamaguchi University, Yamaguchi City

(Received August 11, 1969)

4-(2-Thienyl)pyrimidines are little studied.[2,3] In connection with other programmes some of their derivatives (IX, X, XI, XII) were prepared from the corresponding β-diketones having a thiophene ring and guanidine or urea.

The Wolff-Kishner reduction of 2-isovalerylthiophene (I) gave 2-isoamylthiophene (II) in better yield of 77% than the reported Clemmensen procedure of 32% yield.[4] Reduction of I with lithium aluminum hydride afforded an alcohol III, which was obtained in a pure state only by its acetylation to IV and subsequent hydrolysis to III, because repeated fractional distillations of the crude reaction product could not give an analytically pure sample.

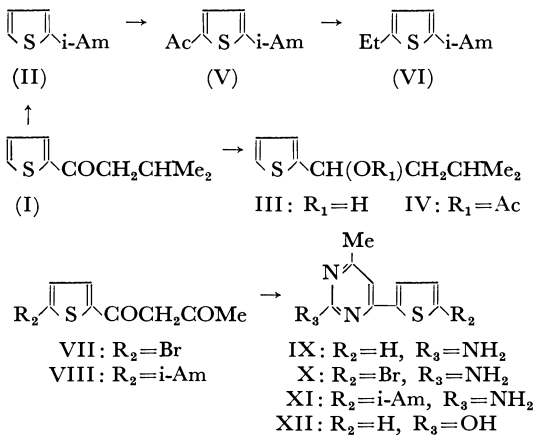
Table 1. NMR spectra of 4-(2-thienyl)pyrimidines IX, X, XI, XII[a,b]

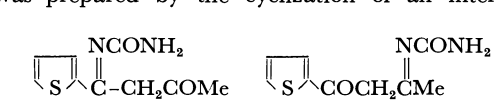
Compound	Chemical Shifts (τ Values, J (Hz))			
	Pyrimidine	Thiophene		
	C_5–H	C_3–H	C_4–H	C_5–H
IX	3.06	2.22 (dd, J_{34}=4.5) (J_{35}=1.5)	2.87 (dd, J_{45}=5.3) (J_{34}=4.5)	2.36 (dd, J_{45}=5.3) (J_{35}=1.5)
X	3.00	2.30 (d, J_{34}=4.2)	2.71 (d, J_{34}=4.2)	
XI	3.14[c]	2.40 (d, J_{34}=4.2)	3.14[c]	
XII	3.18	1.97 (dd, J_{34}=4.2) (J_{35}=1.5)	2.65 (dd, J_{34}=4.2) (J_{45}=5.4)	2.08 (dd, J_{45}=5.4) (J_{35}=1.5)

a) The spectra were determined in dimethyl sulfoxide or its d_6-analogue at room temperature or at 60°C (for XII).
b) dd, double doublet.
c) Broad peak due to overlapping.



Friedel-Crafts reaction of II with acetic acid in the presence of polyphosphoric acid produced 2-isoamyl-5-acetylthiophene (V), from which a β-diketone VIII was derived. The structure of V was verified by NMR spectrum,[5] which showed in carbon tetrachloride two β-protons of thiophene ring at τ 3.22 (dd, J=4.0 Hz and J=1.0 Hz,*1 C_3–H) and τ 2.52 (d, J=4.0 Hz, C_4–H). An additional support is provided by reduction of V to 2-isoamyl-5-ethylthiophene (VI), the NMR spectrum of which exhibited in carbon tetrachloride only one signal at τ 3.60 corresponding to two β-protons. A β-diketone VII was similarly derived from 2-bromo-5-acetylthiophene.

2-Hydroxy-4-(2-thienyl)-6-methylpyrimidine(XII) was prepared by the cyclization of an intermediate uramido compound which has two possible structures, XIII and XIV.



The structures of the pyrimidines (IX—XII) were characterized by NMR spectra in the aromatic region as shown in Table 1.

Experimental

Melting points were determined on a Yanagimoto hot stage and uncorrected. NMR spectra were taken at 60 MHz with a JNM-3H-60 spectrometer with TMS as an internal standard.

2-Isoamylthiophene (II). 2-Isovalerylthiophene[4] (I) (29.9 g, 0.18 mol), hydrazine hydrate (80%) (34 m*l*, 0.70 mol), and ethylene glycol (400 m*l*) were stirred at 120—130°C for 2 hr. After cooling the mixture to 50°C, a solution of potassium hydroxide (30.0 g) in ethylene glycol (100 m*l*) was added at once to this mixture. The mixture was heated at 130—140°C for 1 hr with stirring, left overnight and distilled at atmospheric pressure up to 220°C. The distillate was extracted with ether and the extracts were washed with water, 2N hydrochloric acid, and water successively, dried (Na_2SO_4), and distilled to give II, 21.2 g (77%), bp 56—57°C/2 mmHg, n_D^{20} 1.4951, (lit,[4] bp 72—77°C/11 mmHg). (Found: C, 70.0; H, 9.0; S, 21.0%).

Reduction of 2-Isovalerylthiophene (I) with Lithium Alminum Hydride. A solution of the ketone (I) (13.4 g, 0.08 mol) in anhydrous ether (40 m*l*) was slowly added to a suspension of lithium aluminum hydride (6.0 g, 0.16 mol) in anhydrous ether (200 m*l*). The mixture was refluxed for 3 hr and worked-up in the usual manner to afford an oil, the gas chromatogram of which showed the presence of at least five components. This oil was heated with a mixture of acetic anhydride (11.5 g) and anhydrous sodium acetate (1.5 g) at 100°C for 2 hr and poured into water. Ether extraction and distillation afforded an acetate (IV), 10.1 g (60%), bp 69—70°C/0.4 mmHg, $\nu_{C=O}^{Neat}$ 1745 cm^{-1}.

Found: C, 62.5; H, 7.8; S, 15.8%. Calcd for $C_{11}H_{16}O_2S$: C, 62.2; H, 7.6; S, 15.1%.

This acetate (9.8 g, 0.05 mol) was refluxed with potassium hydroxide (3.1 g) in ethanol (30 m*l*) for 2 hr. The mixture was poured into water and extracted with ether. Distillation of the dried (Na_2SO_4) extracts gave an alcohol (III), 5.4 g (68%), bp 71—72°C/0.8

*1 Coupling with the side chain.

5) R. White, "Physical Method in Heterocyclic Chemistry," Vol. 2 ed. by A. R. Katritzky, Academic Press, New York, (1964), p. 103.

mmHg, n_D^{20} 1.5168, ν_{OH}^{Neat} 3280 cm^{-1}.

Found: C, 63.5; H, 8.5; S, 18.6%. Calcd for $C_9H_{14}OS$: C, 63.5; H, 8.3; S, 18.8%.

2-Isoamyl-5-acetylthiophene (V). A mixture of polyphosphoric acid (200 g), acetic acid (33.3 g) and 2-isoamylthiophene (II) (30.0 g, 0.19 mol) was stirred at 80—85°C for 1 hr and the mixture was poured into water and extracted with ether. The etheral extracts were dried (Na_2SO_4) and distilled at 89—92°C/0.2 mmHg to give a compound (V), 31.5 g (83%), n_D^{20} 1.5277, $\nu_{C=O}^{Neat}$ 1660 cm^{-1}.

Found: C, 67.2; H, 8.5; S, 16.4%. Calcd for $C_{11}H_{16}OS$: C, 67.3; H, 8.2; S, 16.3%.

The 2,4-dinitrophenylhydrazone, mp 170—171°C (from benzene-ligroin), (Found: C, 53.9; H, 5.3; S, 8.4%. Calcd for $C_{17}H_{20}N_4O_4S$: C, 54.2; H, 5.4; S, 8.5 %). The semicarbazone, mp 215—216°C (from methanol), (Found: C, 56.9; H, 7.85; N, 16.14%. Calcd for $C_{12}H_{19}N_3OS$: C, 56.9; H, 7.6; N, 16.6%).

2-Isoamyl-5-ethylthiophene (VI). A mixture of the ketone (V) (10.0 g, 0.05 mol), diethylene glycol (150 m*l*), and hydrazine hydrate (80%) (10 m*l*, 0.26 mol) was heated at 120°C for 2 hr. After cooling to 50°C, a solution of potassium hydroxide (10.0 g) in diethylene glycol (50 m*l*) was added to this mixture at once and heated at 140°C for 1 hr. The mixture was distilled up to 230°C and the distillate was treated as before to give VI, 8.0 g (86%), bp 58—60°C/0.6 mmHg, n_D^{20} 1.4930.

Found: C, 72.1; H, 10.0%. Calcd for $C_{11}H_{18}S$: C, 72.5; H, 9.95%.

2-Isoamyl-5-thenoylacetone (VIII). A solution of V (9.8 g) in ethyl acetate (15.0 g) was added to a suspension of powdered sodium (1.3 g) in anhydrous ether (70 m*l*). The mixture was refluxed for 2 hr with stirring. The sodium salt was filtered off, dissolved in water and extracted with ether. The aqueous solution was acidified and extracted with ether. The dried (Na_2SO_4) extracts afforded the β-diketone by distillation at 102—106°C/0.2 mmHg, 2.6 g (22%), n_D^{20} 1.5676.

Found: C, 65.9; H, 7.7%. Calcd for $C_{13}H_{18}O_2S$: C, 65.5; H, 7.6%.

2-Bromo-5-thenoylacetone (VII). This was prepared similarly from 2-bromo-5-acetylthiophene in 38% yield after recrystallization from methanol, mp 132—133°C.

Found: C, 38.8; H, 2.85%. Calcd for $C_8H_7BrO_2S$: C, 38.9; H, 2.85%.

2-Amino-4-(5-isoamyl-2-thienyl)-6-methylpyrimidine (XI). The β-diketone (VIII) (1.7 g) and guanidine carbonate (0.8 g) were melted at 140—150°C for 1 hr. After cooling, the mixture was washed with water and insoluble product (1.6 g, 84%) was recrystallized twice from *n*-heptane as pale yellow needles, mp 126°C.

Found: C, 64.2; H, 7.3%. Calcd for $C_{14}H_{19}N_3S$: C, 64.3; H, 7.3%.

2-Amino-4-(2-thienyl)-6-methylpyrimidine (IX). This compound was obtained from 2-thenoylacetone and guanidine carbonate in 79% yield and recrystallized from ethanol, mp 173—174°C.

Found: C, 56.4; H, 5.0%. Calcd for $C_9H_9N_3S$: C, 56.5; H, 4.75%.

2-Amino-4-(5-bromo-2-thienyl)-6-methylpyrimidine (X). This compound was prepared from VII and guanidine carbonate in 90% yield and recrystallized from acetone, mp 200—201°C.

Found: C, 40.2; H, 3.0%. Calcd for $C_9H_8BrN_3S$: C, 40.0; H, 3.0%.

2-Hydroxy-4-(2-thienyl)-6-methylpyrimidine (XII). A mixture of 2-thenoylacetone (8.4 g), urea (3.00 g), anhydrous ethanol (50 m*l*), and hydrochloric acid (0.5 m*l*) was left for 40 hr at room temperature with occasional shaking. Homogeneous solution resulted after a few hours and then pale yellow soild began to precipitate. Two recrystallizations from ethanol gave an uramido compound, 5.39 g (51%), as pale yellow plates, mp 192—194°C (decomp.).

Found: C, 51.5; H, 5.0; N, 13.2; S, 15.1%. Calcd for $C_9H_{10}N_2O_2S$: C, 51.4; H, 4.8; N, 13.3; S, 15.25%.

This compound (1.18 g) was heated with potassium hydroxide (0.5 g) in water (10 m*l*) until a clear solution had resulted. After cooling, the solution was acidified and precipitates (0.90 g, 84%) were recrystallized from water as colourless needles, mp 280—282°C (decomp).

Found: C, 56.3; H, 4.0; N, 14.2; S, 16.7%. Calcd for $C_9H_8N_2OS$: C, 56.2; H, 4.2; N, 14.6; S, 16.7%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 939—941 (1970)

Successive and Simultaneous Solubilizations of Two Different Water-insoluble Dyes by Detergents

Fumikatsu TOKIWA

(Received August 15, 1969)

Although the solubilization of water-insoluble materials by detergents is a familiar phenomenon,[1] this subject is not neccessarily well understood. During the course of other work,[2,3] the present author observed an interesting aspect of behavior,

as will be described below, with respect to the solubilization of two different water-insoluble dyes.

This note will describe two types of solubilization for two different dyes. The first type is a successive solubilization in which two dyes are solubilized step-by-step in a detergent solution after the saturation of either of the two. The second type is a simultaneous solubilization in which two dyes are solubilized at the same time. From among the many water-insoluble dyes, two sets of dye combinations, Yellow OB and Sudan Blue GN, and Yellow OB and Aniline Blue, have been chosen by taking into account the possibility of an easy, separate determination by their optical densities. As solubilizing agents, anionic, cationic, and nonionic detergents were used to ascertain the effect of their electrical character on the solubilization.

Experimental

Materials. The sodium dodecyl sulfate ($NaC_{12}S$) and dodecyl nonaoxyethylene ether ($C_{12}(EO)_9$) were samples similar to those used in previous works.[2,3] Dodecyltrimethylammonium chloride ($C_{12}NCl$) was a laboratory-prepared sample purified by repeated recrystallization from acetone. The yellow OB (YW), 1-*o*-tolyl-azo-2-naphthylamine, was described in a previous paper.[2] The Sudan Blue GN (SB), 1-*m*-toluidine-4-methylaminoanthraquinone, and Aniline Blue (AB), *N*-phenylated rosaniline, which were both of a reagent grade, were obtained from Chroma-Gesellschaft, Germany. They were purified by recrystallization from a methanol-water solvent and an acetone-water solvent respectively. Mixed solubilizates were prepared by dissolving two different dyes in an acetone-benzene solvent and by then evaporating the solvent at 50°C.

Solubilization and Absorption Spectra. Solubilization runs were carried out in a water bath at 25°C for 50 hr, a method described elsewhere[2] being employed. The determination of the amount of solubilized dye was made by optical-density measurements at the wavelength of the absorption maximum. The absorption spectra of the dyes were measured by using a Shimadzu Model MPS-50 spectrophotometer at about 25°C.

Results and Discussion

Before discussing the successive and simultaneous solubilizations, the common solubilization of single dyes will be described briefly. Table 1 gives the saturation values of YW, SA, and AB in the aqueous solutions of $NaC_{12}S$, $C_{12}NCl$, and $C_{12}(EO)_9$. These values were obtained from the slope of the linear portion of the solubilization curve, in which the amount of the solubilized dye is plotted against the concentration of the detergent, as has been described in a previous paper.[2] The saturation value of YW in a $C_{12}NCl$ or $C_{12}(EO)_9$ solution is quite high as compared with the other values. It has been shown from spectral study[2] that, in the $NaC_{12}S$ solution, the solubilization of YW occurs mainly in the hydrocarbon interior of the micelle, while in the $C_{12}(EO)_9$ solution it occurs in both the hydrocarbon core and the polyoxyethylene shell of the micelle. This explains the large value for YW in the $C_{12}(EO)_9$ solution. With YW in the $C_{12}NCl$ solution, the probable locus of solubilization is the surface of the micelle (otherwise, we can not explain such a large value).

Table 1. Saturation values of oil-soluble dyes in detergent solutions

Detergents	Saturation Values (g of dye/g of detergent $\times 10^3$)		
	YW	SB	AB
$NaCl_{12}S$	10.7	4.45	18.0
$C_{12}NCl$	67.8	5.00	10.7
$C_{12}(EO)_9$	52.9	4.34	5.90

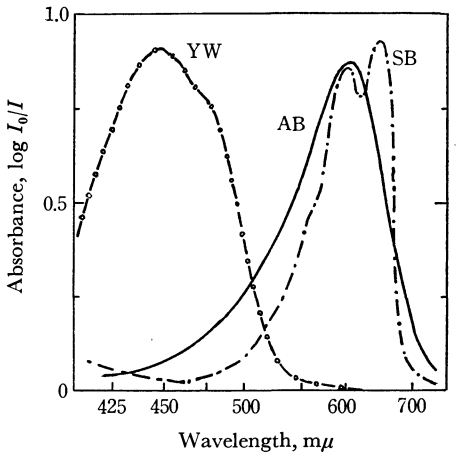

Fig. 1. The absorption spectra of YW, SB and AB in ethanol: concentration, approximately 1.7×10^{-3}%.

Successive Solubilization. The absorption spectrum of each of these three dyes in ethanol is shown in Fig. 1. The spectra indicate that each dye can be separately determined from its optical density in the presence of the other if YW-SB and YW-AB are chosen as the solubilizates.

Table 2 gives the saturation values of YW and SB in detergent solutions when they were solubilized step-by-step through the processes of YW→SB and SB→YW. In the YW→SB process, for example, YW is solubilized before SB; SB is solubilized after the saturation of YW. This table also gives the saturation values of YW and AB obtained through the YW→AB and AB→YW processes. When we compare the values shown in Table 2 with those in Table 1, we can see that the saturation value of each dye in any detergent solution is not very much influenced by the order of solubilization. For example, the YW once solubilized remains

Table 2. Saturation values of oil-soluble dyes by successive solubilization

Combination of Dyes	Order of Solubilization	Saturation Values (g of dye/g of detergent × 10^3)								
		In $NaC_{12}S$ Soln.			In $C_{12}NCl$ Soln.			In $C_{12}(EO)_9$ Soln.		
		YW	SB	AB	YW	SB	AB	YW	SB	AB
YW & SB	YW→SB	10.6	4.21	—	67.3	4.89	—	52.1	4.38	—
	SB→YW	10.6	4.38	—	68.4	4.76	—	52.9	4.54	—
YW & AB	YW→AB	10.9	—	17.4	69.2	—	10.7	53.6	—	5.75
	AB→YW	10.4	—	18.6	69.9	—	11.3	55.0	—	5.70

in the micelle after the solubilization of SB or AB; further, the saturation value of YW in the detergent solution containing solubilized SB or AB is roughly equal to the value in the same detergent solution containing no other dye. The following explanation seems plausible in according for this.

Let us assume that each dye, at least each of those examined here, has a specific locus of solubilization in the micelle where the dye is to be solubilized. With $NaC_{12}S$ and $C_{12}NCl$, the probable locus is the hydrocarbon interior and/or its charged surface, while with $C_{12}(EO)_9$ it is the hydrocarbon core and the polyoxyethylene shell of the micelle. If this is the case, the dye first solubilized in its own locus remains in the micelle without being influenced by the second dye, which will also be solubilized in the other locus irrespective of the presence of the first dye, as long as the solubilization is carried out step-by-step.

It is known that the addition of small amounts of long-chain alcohols or hydrocarbons to a detergent solution enhances the solubilization capacity of the detergent for oil-soluble dyes.[1,4] This has been ascribed to an increase in the space available to dye molecules by the penetration of the additive into the micelle. However, this type of solubilization is essentially different from the successive solubilization described here.

Simultaneous Solubilization. The solubilization of the mixture of two dyes, *e. g.*, YW and SB, or YW and AB, in detergent solutions was achieved by changing the mixing ratio from 0.2 to 4.0 by weight. However, reproducible saturation values could not be obtained for all of the three dyes, and the values are generally smaller, although in some cases they are larger, than those given in Table 1. As examples, typical results for the simultaneous solubilization of the mixture of YW and SB in the solutions of $NaC_{12}S$ and $C_{12}(EO)_9$ are shown in Fig. 2. In these two cases, the saturation

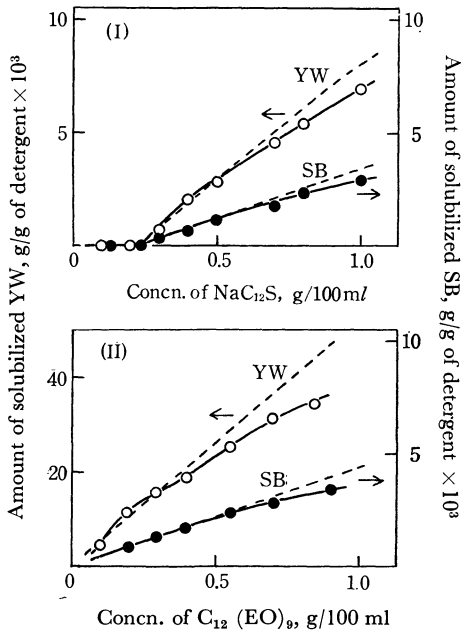

Fig. 2. The simultaneous solubilization of YW (○) and SB (●) mixed in a ratio of 1 : 1 in the solutions of $NaC_{12}S$ (I) and $C_{12}(EO)_9$ (II). The broken line indicates the solubilization curve for single YW or SB.

value of YW or SB at a fixed detergent concentration is neither constant nor reproducible, and the points given in Fig. 2 are only examples of scattered, observed values. The interpretation of these results is difficult at this stage. Probably, interactions between the two dyes, and between the micelles and the dyes in the process of solubilization, are related to the above phenomenon in a complicated way.

The author expresses his thanks to Dr. Hisahiro Kita for encouragement and permission to publish this paper.

Kinetic Studies of the Graphitization Process. III. Stages of Graphitization Process

Michio INAGAKI,* Yoshio MURASE,* Hajime SAITO* and Tokiti NODA**

* *Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya*

** *Mie University, Tsu, Mie-ken*

(Received August 29, 1969)

The dependence of the graphitization degree of carbon on residence time has been studied by many authors.[1-13] However, the rate equations of graphitization have not been clarified. In the present work, the dependence of c_0-spacing on residence time was measured on a coke in a limited range of heat treatment temperature, and the results were discussed in relation to the stages of graphitization process.

The sample used was a polyvinylchloride coke (PV-7) calcined to 680°C and pulverized to particle size 0.4—1.2 mm. The sample was heat-treated at temperatures 1950, 2000, 2100, 2200, 2300 and 2400°C for various residence times under a reduced pressure of about 0.01 Torr. The details on the procedure of heat treatment were reported.[11] When a graphite heater was used for the heat treatment above 2000°C under reduced pressure, the wall of the heater became thin due mostly to evaporation, and partly probably to the oxidation of graphite. This reduced the stability of heat treatment temperature (HTT). Therefore, the long time run of heat treatment was carried out by the repetition of short time runs (mostly 60 min), by replacing the used heater with a new one each time. It was confirmed previously[11] that the repeated heat treatment has the same effect on the c_0-spacing of the carbon sample as the continuous one if the total residence time is equal in each case.

For each heat-treated sample, mean value of c_0-spacing was measured from (004) diffraction line by referring to the inner standard of silicon. Diffraction profile of the line was obtained by using Ni-filtered CuKα radiation and a recording goniometer with a Geiger counter.

The changes of c_0-spacing with total residence time at different HTT are shown in Fig. 1, by means of the plot of c_0-spacing against logarithm of residence time, log t. The rate of change of the c_0-spacing with residence time is found to increase at about 6.84 Å and decrease again at about 6.76 Å for every HTT. Thus, the dependence of

c_0 on log t can be divided into three stages, *i. e.*, $c_0>6.84$, $6.84>c_0>6.76$, and $6.76\,\text{Å}>c_0$. In the stage $6.84>c_0>6.76$ Å, the c_0-spacing seems to decrease linearly with logarithm of residence time, and the lines for every HTT are parallel to each other.

The superimposing method[4] can be applied to the present result, and the amount of shifting is determined more accurately. The effective activation energy obtained was 200 kcal/mol which was close to those obtained in previous works.[8,9,11] The dependence of c_0 on residence time t in the stage $6.84>c_0>6.76$ Å is expressed by the equation

$$c_0 - c_0^0 = \beta \log (t/t_0),$$

where c_0^0 is a constant independent of HTT, β the slope of the line shown in Fig. 1 and t_0 is the value of t for $c_0=c_0^0$. t_0 corresponds to the amount of shift in the superimposing method.

In the figures of c_0 *vs.* log t, the linear relation between c_0 and log t can be found only in a small range of c_0.[4,8,9,11] A pyrolytic carbon reported by Fischbach[4] showed a linear dependence of c_0 on log t in the range 6.82—6.73 Å.

The same data were analysed by the method proposed by Murty *et al.*[14] The relations obtained between $\log\{(6.910-c_0)/t\}$ and $\log(6.910-c_0)$ are shown in Fig. 2, where the value of 6.910 Å is the

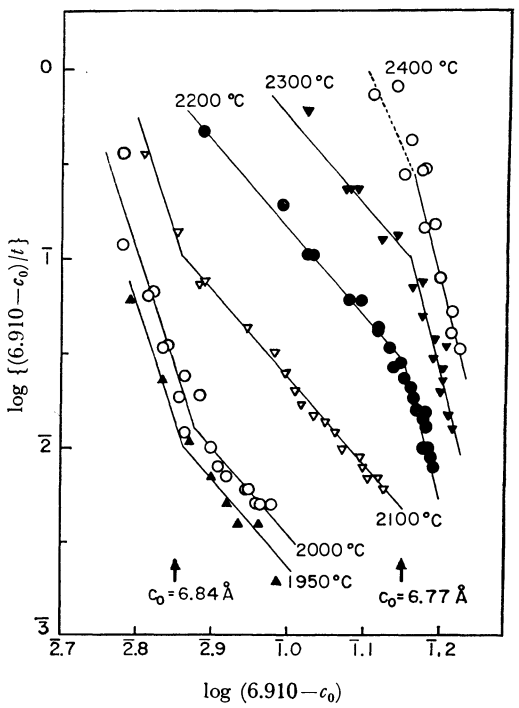

Fig. 2. The relation between $\log\{(6.910-c_0)/t\}$ and $\log(6.910-c_0)$.

14) H. N. Murty, D. L. Biederman and E. A. Heintz, *J. Phys. Chem.*, **72**, 746 (1968).

c_0-value of the original sample PV-7. In this case, the relation between $\log\{(6.910-c_0)/t\}$ and $\log(6.910-c_0)$ seems also to be linear. However, it appears to break at the c_0-values 6.84 and 6.77 Å. The lines are nearly parallel to each other in the range $6.84>c_0>6.77$ Å. The dependence of c_0 on t can be expressed by

$$(6.910-c_0) = A\cdot t^n.$$

The value of n was obtained as 0.18 from the slope of these lines, and the activation energy of 200 kcal/mol was obtained from the linear dependence of intercept of the lines on HTT.

For the stages, *i. e.*, $c_0>6.84$ and $6.76\,\text{Å}>c_0$, no details on the residence time dependence of c_0-spacing could be discussed, because of insufficient data.

From the results, the graphitization process of soft carbon can be concluded to consist of three successive stages, $c_0>6.84$, $6.84>c_0>6.76$, and $6.76\,\text{Å}>c_0$. In the second stage, the change of c_0 from 6.84 to 6.76 Å is fairly large, though the corresponding range of HTT is narrow as 1950—2400°C.

The dividing of the graphitization process at c_0-spacing of about 6.85 Å is consistent with the results of other authors. Kuroda[15] has shown, by means of electron microscopy, that above 1850°C (below the c_0-spacing 6.85 Å in the petroleum coke) c-axes of crystallites align parallel to the normal of the grain. Mazza,[5] Mazza *et al.*,[6] and Forchioni *et al.*[7] have studied the development of the properties, including X-ray parameters, and shown that the graphitization process is divided into two stages, below HTT of 1900°C and above 1900°C (corresponding to the c_0-spacing 6.84 Å in the pitch coke). Inagaki *et al.*[16,17] have reached almost the same conclusion as that of Mazza *et al.*[6] on a petroleum coke and a polyvinylchloride coke from X-ray parameters. The main structural change in the first stage is the development of two-dimensional graphite-like layers. In relation to this stage, Inagaki[18] has proposed the idea of dewrinkling of carbon layers.

The dividing of the graphitization process around 6.76 Å has been reported only by Maire and Mering.[19] They have shown by Fourier analysis of (00l) diffraction lines that below the g-value of about 0.6 (above 6.77 Å in c_0-spacing), the crystallite size L_C increases and above 0.6 the strain decreases with graphitization.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 944—945 (1970)

Photolysis of *meta*-Disubstituted Benzenes in Low Temperature Matrices

Akio EGAWA, Katsumi KIMURA[1] and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received September 4, 1969)

Photolysis of *para*-disubstituted benzenes in low temperature matrices has been studied extensively in our laboratory.[2] It has been concluded that photo-ionization occurs predominantly for the compounds having amino-substituents, and the β-fission in the side-chain occurs predominatly for the compounds having hydroxyl or methoxyl groups. In the present note, studies on the photolysis of *m*-aminophenol, *m*-phenylenediamine, *m*-anisidine and *m*-methoxyphenol are reported.

Organic solvents used as transparent matrices are ethanol, EPA (ether-isopentane-ethanol, 5 : 5 : 2 by volume), EP (ether-isopentane, 1 : 1), EM (ether-methylcyclohexane, 1 : 1), and MP (methylcyclohexane-isopentane, 1 : 3). Approximately 8 m*l* of a 1×10^{-4}M solution was put into a quartz cell of 1 cm path length, degassed by the freeze-pump-thaw technique, and the cell was sealed. The transparent samples in liquid nitrogen contained in a quartz Dewar were illuminated for 20—60 sec using a 250 W high-pressure mercury lamp and appropriate filter combinations.

Assignment of the Species Formed by the Photolysis Electronic absorption spectra of free radicals formed by ultraviolet irradiation of *m*-aminophenol are shown in Fig. 1a (region B). It is concluded that the products are cation radicals by reasons similar to those discussed in Ref. 1, that is to say: (1) When biphenyl, as an electron acceptor, was added to the EPA solution of *m*-aminophenol irradiated at 77°K, the absorption spectrum of biphenyl anion appeared together with the cation spectrum. (2) The absorption spectrum was obtained by irradiation in polar solvents, but not in non-polar solvents. (3) By irradiation in the infrared region or by heating the photo-product, luminescence attributable to the recombination of cation radicals and ejected electrons was observed.

By the similar reasons to those for the case of *m*-aminophenol, it has been concluded that the products of photolysis of *m*-phenylenediamine and *m*-anisidine at 77°K are assigned to their cation radicals. For the case of *m*-phenylenediamine irradiated at 77°K a spectrum (from 420 to 490 mμ) appeared at first which is undoubtedly attributable to the cation radical. On prolonged irradiation, the spectrum in this region gradually weakened and after irradiation for 15 min, a new spectrum began to appear in the region from 330 to 350 mμ. At least a large part of this new spectrum remained after warming to room temperature, and hence seems to be due to a permanent dissociation product.

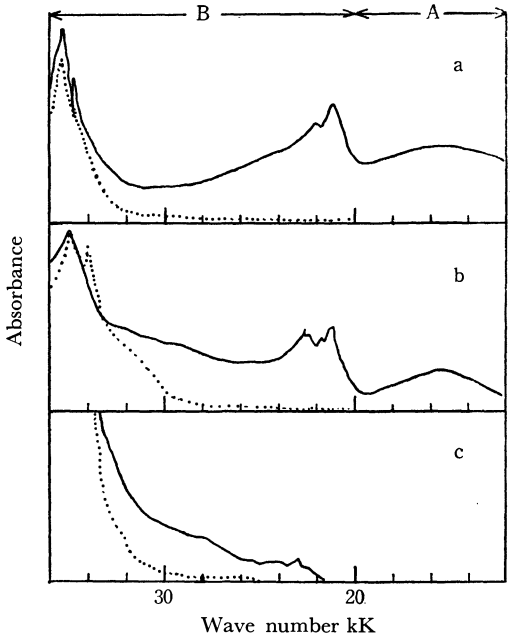

Fig. 1. Electronic absorption spectra of free radicals (region B) and solvated electrons (region A).
The dotted line shows the spectrum before UV irradiation. a, *m*-aminophenol. b, *m*-aminophenol in an alkaline EPA solution. c, *m*-methnoxyphenol.

The irradiation of *m*-aminophenolate anion in alkaline EPA solution caused a spectrum shown in Region B of Fig. 1b. The product has been assigned to the radical $H_2NC_6H_4O\cdot$ by the similar reasons as those described in a previous paper.[2] For *m*-methoxyphenol, it has been concluded by the following reasons that the irradiation yielded the neutral radical, $H_3COC_6H_4O\cdot$, whose spectrum is shown in Fig. 1c.: (1) The radical was produced even in a non-polar solvent, MP. (2) The broad absorption spectrum of the solvated electron did not appear in the near infrared region. (3) Even if biphenyl was added to the MP solution of *m*-

2) K. Kimura, K. Yoshinaga and H. Tsubomura, *J. Phys. Chem.*, **71**, 4485 (1967).

methoxyphenol, the absorption bands of biphenyl anion did not appear. (4) The shape of the absorption spectrum is similar to that of *m*-benzosemiquinone radical, $HOC_6H_4O\cdot$, obtained by Land and Porter using flash photolysis.[3]

Solvated Electron Spectra. When *m*-aminophenol in various organic matrices is irradiated at 77°K in the ultraviolet region using a Toshiba UV-D25 glass filter which transmits light from 275 to 370 mμ and from 700 to 750 mμ, the matrix colored yellow owing to the formation of cation radicals. On the other hand, when a Toshiba UV-D25 filter was combined with an aqueous nickel sulfate (transmitting light from 275 to 370 mμ), the matrix colored bluish yellow. The absorption spectrum is shown in Fig. 1a, and the broad absorption band in the near infrared region (region A) can be attributable to the solvated electrons by the following reasons: (1) The sample showed a very feeble afterglow at 77°K to dark-adapted eye. It also showed emission stimulated by the infrared light or by warming. The luminescence spectra was found to correspond to the fluorescence and phosphorescence of *m*-aminophenol. (2) The intensity of the broad absorption band in the near infrared region decreased by the infrared irradiation of the sample. (3) The absorption maximum in the near infrared region shifts to the shorter wavelength as the solvent becomes more polar (Fig. 2). The similar shift was observed by Dorfman and his co-workers for the spectra of solvated electrons obtained by pulse-radiolysis.[4] For *m*-phenylenediamine and *m*-anisidine, similar absorption spectra of solvated electrons are also observed.

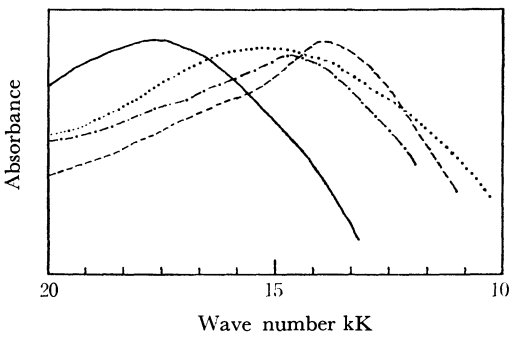

Fig. 2. Electronic absorption spectra of solvated electrons formed by UV irradiation of *m*-aminophenol in various solvents.
——— ethanol, ····· EPA, ------ EP, —·—· EM

Albrecht states that the great majority of electrons photoejected from TMPD have a very limited range in rigid 3-methyl pentane, each electron finding a matrix trap within the coulomb field of its partner TMPD cation radical.[5] In our results, it may also be concluded that the solvated electrons are under the influence of the cation radicals since a small but definite shift of the absorption maxima is observed for different cation radicals (Fig. 3).

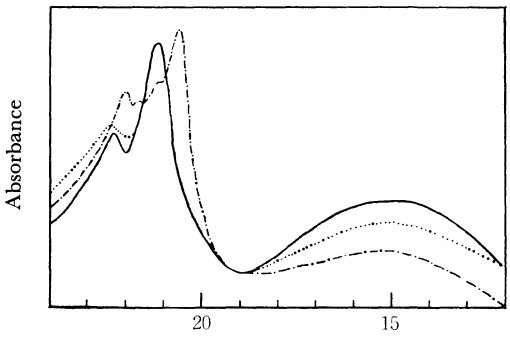

Fig. 3. Electronic absorption spectra of solvated electrons formed by UV irradiation of *m*-aminophenol (———), *m*-anisidine (·····), and *m*-phenylenediamine (—·—·).

It has been reported by McClain and Albrecht that TMPD cation radicals cannot be bleached perfectly by infrared irradiation in 3-MP at 77°K, and some more energetic photons (385 mμ) did bleach some of the $TMPD^+$ remaining after the infrared effect was exhausted.[5] They concluded that the incompleteness of the IR bleaching was due to very deep trapping of some of the electrons. However, in our work the broad absorption band of solvated electrons (300—800 mμ) disappeared completely by irradiation with red light (wavelengths longer than 600 mμ). The intensity of the absorption spectrum of the cation radicals decreased only slightly. This decrease was still more slight in the solvents containing ethanol. From these facts, the following conclusion may be drawn: The traps of the solvated electrons are not very deep, but rather shallow. A small part of the electrons stimulated by irradiation recombine with cation radicals and the remaining part of them react with impurities or with the solvent itself, especially with ethanol.

The Non-sensitized Photoreaction of Azoxybenzene

Masaaki IWATA and Sakae EMOTO

The Institute of Physical and Chemical Research, Yamato-machi, Kita-Adachi-gun, Saitama

(Received September 5, 1969)

Since Knipscheer[1] reported the photochemical rearrangement of azoxybenzene to 2-hydroxyazobenzene, its rearrangement has been postulated to be intramolecular[2] and, by means of tracer methods, this postulation has been confirmed.[3-5] Through a recent study of the photoreduction of azoxybenzene, Tanikaga concluded that the irradiation of azoxybenzene without benzophenone as a sensitizer never affords azobenzene in an ethanol solution and, thus, that azobenzene is formed from an excited triplet state of azoxybenzene,[6] while the rearrangement product of azoxybenzene and its isomerization product are formed through an excited singlet state of *trans*-azoxybenzene.[7] This paper will describe some different results from Tanikaga's photoreduction product of azoxybenzene and the overlooked irradiation product.

trans-Azoxybenzene was irradiated with a high-pressure mercury lamp in a chloroform (fairly concentrated) solution at room temperature for 113 hr. After the removal of the solvent under mild conditions, the irradiated mixture was chromatographed on silica gel by elution with benzene. In the column, the mixture showed at least eight colored adsorption bands. These components were designated as A, B, C, D, E, F, G, and H in their order of separation. After the removal of the solvent under reduced pressure, petroleum ether was added to each fraction, if possible, in order to crystallize it. Of these eight components, A, B, and G were obtained in a crystalline form. Then high-resolution mass spectroscopic measurements were made of all of these components. The mass spectra of both the products A and F showed a parent peak at 182 *m/e*, a base peak at 77 *m/e*, and similar fragmentational patterns between these peaks in each fragment. Exact mass measurements showed that both A and F had the molecular formula of $C_{12}H_{10}N_2$. On the basis of these results, and also their IR spectra and melting points, the products A and F were deduced to be *trans*- and *cis*-azobenzene respectively, as a similar phenomenon appeared when the mixture of *trans*- and *cis*-azoxybenzene was chromatographed; the former was eluted faster than the latter by benzene. Product B, the main product, was shown to be 2-hydroxyazobenzene from its mass spectral fragmentational pattern, its exact mass measurement (molecular formula, $C_{12}H_{10}N_2O$), its IR spectrum, and its melting point. Product G was postulated to be 4-hydroxyazobenzene on the basis of its melting point and its fragmentational pattern in the mass spectrum, which was extremely analogous to that of the product B. From these two spectra, the relatively intensive fragment, 121*m/e*, could be used to distinguish hydroxyazobenzene from azoxy-[8] and azobenzene. Fraction C was the starting material. For the other products, D, E, and H, the structural analyses attempted using by the method of mass spectroscopic analysis and exact mass measurements were unsuccessful because of impurities present in each case.

In our experimental results, it is interesting that we detected the reductive formation of azobenzene from azoxybenzene and the production of 4-hydroxyazobenzene which results from the unusual photochemical rearrangement of azoxybenzene. First, the formation of azobenzene without a sensitizer leads us to suggest that this may be due to the solvent effect or to the yield of azobenzene being detectable only in a large-scale experiment. Recent studies have progressively clarified the solvent effects on the photochemical pathway;[9] however, more information is required before we can decide that the difference in results between Tanikaga's and ours are due only to the solvent effect. Now, it seems better to consider that the formation of azobenzene had been overlooked because of its low yield. This may also be true for the formation of 4-hydroxyazobenzene. This compound is a well-known Wallach rearrangement

product of azoxybenzene[10] upon heating with concentrated sulfuric acid. The photochemical mechanism of its formation suggests that it might be accompanied by an intermolecular reaction or a solvated oxygen atom, one which comes from the reduction of azoxybenzene, with its photoreaction to the extent that azobenzene is produced.

Experimental

As the light source, a UVL-100p (Rikoh Kagaku Co., Ltd.) high-pressure mercury lamp was used; mass spectra and exact mass measurements were performed and measured by means of a JMS-OlSG (Japan Electron Optics Lab.) double-beam focused high-resolution mass spectrometer with an ionizing voltage of 75 eV. The mp's are uncorrected.

Irradiation of Azoxybenzene. The azoxybenzene (Tokyo Kasei, once chromatographed on silica gel before use) (2 g) was dissolved in 25 m*l* of chloroform, sealed in an Erlenmeyer flask, and then irradiated with the lamp for 113 hr at room temperature. After the removal of the solvent under reduced pressure, the mixture was chromatographed on silical gel (Kieselgel, 7734, Merck); upon elution with about 3 *l* of benzene, the eight components described above were separated in aliphabetical order. The yields (in weight) were 6 mg for A, 79.8 mg for B, 1.8 g for C, 3.0 mg for D, 2.08 mg for E, 2.18 mg for F, and 2.68 mg for G (H was not weighed, but it appeared to be almost the same amount as E.).

Product A showed IR absorption bands at 690, 770, 920, 1018, 1065, 1150, 1220, 1300, 1456, 1480, 1580, 1700—2000, and 3030 cm^{-1} (KBr) and fragments in the mass spectrum (relative abundance) at 182 (96.2), 154 (2.9), 105(20.8), and 77(100)*m/e*, and it melted at 67.0—67.5°C (rhombic). These data and exact mass measurements supported the idea that this was azobenzene.

Product B showed IR absorption bands at 670, 750, 760, 805, 910, 930, 990, 1010, 1020, 1060, 1100, 1140, 1180, 1210, 1240, 1280, 1305, 1310, 1360, 1410, 1455, 1485, 1530, 1550, 1595, 1700—2000, and 3030 cm^{-1} (KBr) and fragments in mass spectrum (relative abundance) at 198(100), 121(13.3), 105(4.7), 93(21.7), and 77(37.4)*m/e*, and it melted at 83.5—84.0°C (needles). These data and exact mass measurement supported the idea that this was 2-hydroxyazobenzene.

Product F showed almost the same IR spectrum as A, and its mass spectral fragmentational pattern was quite coincident with that of A. Thus, it was deduced to be a isomer of A, that is, *cis*-azobenzene. Product G melted at 131.8—132.1°C (orange prisms), and its mass spectrum had almost the same characteristic fragments for hydroxyazobenzene as B. Therefore, this may be deduced to be a isomer of B, that is, 4-hydroxyazobenzene. Component C was the starting material; for the other products, D, E, and H, the structural analyses were unsuccessful for the reason presented above.

The Reaction of *o*-Lithio-*N*,*N*-dimethylbenzylamine with Metal Carbonyls

Ilsong RHEE, Yoshikazu HIROTA, Membo RYANG and Shigeru TSUTSUMI

Department of Chemical Technology, Faculty of Engineering, Osaka University
Yamadakami, Suita, Osaka

(Received September 6, 1969)

We have previously reported that lithium aroyl or acylmetal carbonylates, $Li[RCOM(CO)_n]$ (M= Ni, Fe), are formed as intermediates in the reaction of organolithium compounds with mononuclear metal carbonyls at low temperature (−50—−70°C). Fischer and Maasböl[1] have also described the formation of lithium benzoylmetal pentacarbonylate by the reaction of phenyllithium with metal hexacarbonyl (metal=Cr, Mo and W); they also revealed that these carbonylates are stable mononuclear-transition metal carbene complexes.

Although an attempt to isolate the pure complexes of the corresponding nickel or iron carbonylate was unsuccessful, their synthetic applications were investigated since lithium aroyl or acylmetal carbonylates showed useful reactivities in organic reactions. However, the nickel complexes showed different reaction behavior from the iron or the Group VI transition metal complexes. For example, lithium aroylnickel carbonylate gave acyloins by hydrolysis,[2] 1,4-diketones by reaction with acetylenes,[3] and α-diketones by thermal decomposition[4] (Eq. 1), while lithium aroyl or acylmetal carbonylates (metal=Fe,[5a] Cr, Mo and W[5b]) gave alde-

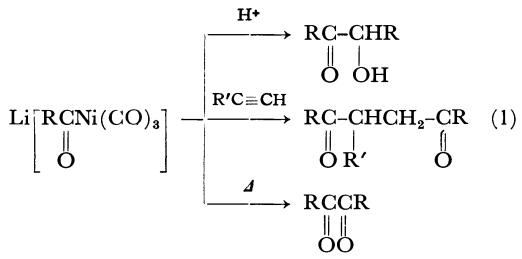
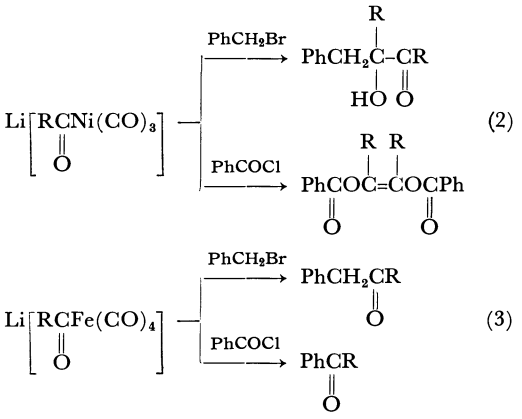
hydes in good yields by hydrolysis, but did not give 1,4-diketones from the reaction with acetylenes.[3]



Furthermore, lithium aroylnickel carbonylates gave acyloins by a reaction with benzyl bromide and en-diol-diesters by a reaction with benzoyl chloride (Eq. 2), whereas lithium aroyliron carbonylates yielded ketones[6] (Eq. 3).



The above results suggest that lithium aroylnickel and -iron carbonylates behave toward various reagents as if the former is a dinuclear, and the latter, a mononuclear complex, for two aroyl or acyl groups are introduced into the products in the case of the nickel complex and one aroyl or acyl group in the case of the iron complex, although the relationship between the structure of the intermediate and the products has not yet been established. Furthermore, it has been reported that the mononuclear iron carbonylate anion exists, but no mononuclear nickel carbonylate anion exists.[7] These results provide one suggestion regarding the structure of the present nickel complexes.

Hereupon, it was considered to be probable that when a nitrogen-containing substituent which has a coordinating ability with the transition metal is present at the *ortho* position of phenyllithium, the nickel carbonylate would also behave as a mononuclear intermediate complex similar to iron carbonylate. In this paper, we wish to report on our study of the reactions of lithium-*o*-*N*,*N*-dimethylaminomethyl phenylmetal (iron or nickel) carbonylates with such organic halides as benzyl bromide or benzoyl chloride and the decomposition of the carbonylates with an iodine-methanol solution.

Results and Discussion

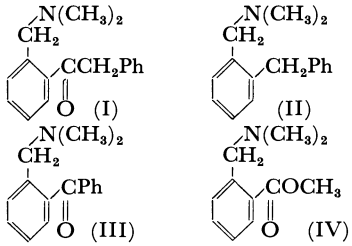
In general, alkyl or aryllithium is very reactive toward nickel carbonyl and the reaction proceeds exothermically even at −70°C, but the reaction of *o*-lithio-*N*,*N*-dimethylbenzylamine[8] with nickel carbonyl took place at −20°C. After stirring had been continued for 10 hr, organic halide was added and the mixture was stirred at 12°C for 2 hr. The resulting reaction mixture was treated and the products were isolated by ordinary methods; the results are summarized in Table 1.

Table 1. The reactions of *o*-lithio-*N*,*N*-dimethylbenzylamine with organic halide and iodine–methanol

	Li[RCOFe(CO)$_n$]		Li[RCONi(CO)$_m$]*	
$PhCH_2Br$	I	II	I	II
	26.7%**	trace	5.0%	11.1%
PhCOCl	III		III	
	12.6%		27.2%	
I_2/CH_3OH	IV		IV	
	18.1%		5.2%	

* R=*o*-*N*,*N*-dimethylaminomethylphenyl.

** All the yields in this paper are based on the *N*,*N*-dimethylbenzylamine used. Unreacted *N*,*N*-dimethylbenzylamine was recovered, while the high-boiling residue formed in these reactions was not examined.



As may be seen in Table 1, the same products are formed in the cases of both nickel and iron, although the yields of the products are low, while such results have not yet been observed from the reaction of nickel carbonyl with aryllithium which does not contain an amino group at the *ortho* position. Consequently, it may be considered that the structure of the nickel complex becomes similar to that of the iron complex by an intramolecular

6) Y. Sawa, M. Ryang and S. Tsutsumi, unpublished work.

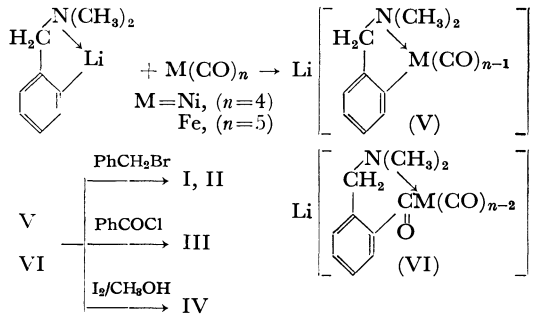
8) A. C. Cope, *J. Organometal. Chem.*, **8**, 531 (1967).

coordination of the nitrogen to the nickel atom; that is, a mononuclear nickel carbonylate complex will be formed.

Cope[8] has reported that the stable carbon-cobalt σ-bonding complex was isolated from the reaction of cobalt dichloride with *o*-lithio-*N*,*N*-dimethylbenzylamine. However, cobalt dichloride reacts with phenyllithium or phenylmagnesium bromide to give an unstable diphenylcobalt, which then decomposes to form biphenyl above $-20°C$.[9]

In an attempt to isolate the intermediate nickel complex which would be stabilized by the coordination of nitrogen, a white solid was obtained after the solvent had been removed under nitrogen, but the structure has not yet been determined. Although the structures of the intermediates are not clear, the present reaction may be considered to proceed according to the following paths;



Namely, in the reaction with benzyl bromide (V) and (VI) react to give ketone (I) and coupling product (II), and in the reaction with benzoyl chloride to give ketone (III) (α-diketone was not detected), although it is not evident whether the carbonyl group in ketone came from benzoyl chloride or from (VI). In the reaction with an iodine-methanol solution, (VI) reacts first with iodine; methanolysis then gives the ester (IV).

Fischer and Kiener[10] have recently reported that a dinuclear iron complex was isolated from the reaction of lithium aroyliron carbonylate with trityl chloride. However, the complex isolated does not necessarily reflect the precise structure of the proceeding anionic complex, since the possibility can not be completely neglected that the oxidation of the anionic mononuclear complex with trityl chloride results in the dimerization of the neutral complex thus produced.

The structures of the synthetically useful anionic complexes of iron and nickel are still open to question, and the relationship between the structure of a complex and its reactivity is one of the most interesting problems in organic synthesis using metal carbonyls.

Experimental

The *N*,*N*-dimethylbenzylamine, benzyl bromide, and benzoyl chloride used were obtained by the purification of commercial reagents by fractional distillation. A hexane solution of *n*-butyllithium was used without purification. The diethyl ether was dried over sodium wire, and all the reactions were carried out under a dry argon atomosphere.

a) The Reaction of Benzyl Bromide with Lithium *o*-*N*,*N*-dimethylaminomethylphenylmetal Carbonylate. *N*,*N*-dimethylbenzylamine (0.04 mol) was added to *n*-butyllithium (0.048 mol) in *n*-hexane (60 m*l*), and then the mixture was refluxed for 16 hr. The reaction mixture thus changed from a colorless solution to a suspension of a white solid of *o*-lithio-*N*,*N*-dimethylbenzylamine. The ether solution (60 m*l*) of iron pentacarbonyl (0.04 mol) was added to the mixture at $-50°C$, and the reaction mixture was stirred for 10 hr at $-20°C$; the color of the mixture thus changed from orange-red to red-brown. After the addition of the ether solution (15 m*l*) of benzyl bromide (0.04 mol), the reaction was carried out at an elevated temperature (12°C) for 2 hr, after which the reaction mixture was separated into a benzene-soluble and a benzene-insoluble part. The benzene solution was distilled under reduced pressure to give the following fractions: (1) bp~120°C (1.0 mmHg), 1.3 g; (2) bp 140°C (1.0 mmHg), a trace, and (3) bp 150°C (1.0 mmHg), 2.7 g. Fraction (1) was found by vpc analysis to be a mixture of the following materials: bibenzyl (0.4 g, 11.0%) and dibenzyl ketone (0.8 g, 19.2%) [Column, S. E. 30, 2.25 m; column temperature, 230°C; flow rate of carrier gas (helium), 7 m*l*/min; flame ionization detecter; retention time, 4.8 and 9.7 min]. Fraction (2) was identified as *o*-benzyl-*N*,*N*-dimethylbenzylamine on the basis of the following data: Found: C, 85.28; H, 8.50%. Calcd for $C_{16}H_{19}N$: C, 85.04; H, 8.77%. NMR (τ): 7.90 (6H, singlet), 6.80 (2H, singlet), 5.91 (2H, singlet) and 2.95 (9H, multiplet). Mass (m^+/e): 225. IR: ν_{NCH} 2800 cm^{-1}. Fraction (3) was confirmed to be *o*-*N*,*N*-dimethylaminomethylphenyl benzyl ketone (26.7%); Found: C, 80.33; H, 7.73%. Calcd for $C_{17}H_{19}ON$: C, 80.57; H, 7.56%. NMR (τ): 7.83 (6H, singlet), 6.41 (2H, singlet), 5.86 (2H, singlet) and 2.73 (9H, multiplet). Mass (m^+/e): 253. IR ν_{CO} 1700, ν_{NCH} 2800 cm^{-1}.

In the case of nickel carbonyl, the reaction and treatment were carried out by a method similar to that described in the case of iron pentacarbonyl. The benzene solution was distilled under reduced pressure to give the following materials: *o*-*N*,*N*-dimethylaminomethylphenyl benzyl ketone (0.5 g, 5.0%), *o*-benzyl-*N*,*N*-dimethylbenzylamine (1.0 g, 11.1%), bibenzyl (1.1 g, 30.2%) and dibenzyl ketone (0.2 g, 4.8%).

b) The Reaction of Benzoyl Chloride with Lithium *o*-*N*,*N*-dimethylaminomethylphenylmetal Carbonylate. The reaction and treatment were similar to those described in (a). In the case of iron pentacarbonyl, the following fraction was given by distillation under reduced pressure: bp 113°C (1.0 mmHg), 1.2 g (12.6%). This material was confirmed to be *o*-*N*,*N*-dimethylaminomethyl benzophenone: Found: C, 80.13;

9) M. Ryang, K. Yoshida, H. Yokoo and S. Tsutsumi, This Bulletin, **38**, 636 (1965).

10) E. O. Fischer and V. Kiener, *Chem. Commun.*, **1968**, 1378.

H, 7.25%. Calcd for $C_{16}H_{17}ON$: C, 80.30; H, 7.16%. NMR (τ): 8.08 (6H, singlet), 6.61 (2H, singlet), and 2.67 (9H, multiplet). Mass (m^+/e): 239. IR :ν_{CO} 1670, ν_{NCH} 2800 cm^{-1}.

In the case of nickel carbonyl, *o-N,N*-dimethylaminomethyl benzophenone was given in a yield of 27.2%. The reaction of benzoyl chloride with *N,N*-dimethylbenzylamine under these conditions as well as those described above did not give that ketone.

c) The Reaction of Iodine-methanol Solution with Lithium *o-N,N*-dimethylaminomethylphenylmetal Carbonylate. An iodine-methanol solution (11 g/50 m*l*) was added to lithium *o-N,N*-dimethylaminomethylphenyliron carbonylate, which had been prepared in the manner described in (a) at −20°C. Stirring was continued for 4 hr at room temperature, followed by refluxing for 3 hr. The benzene-soluble part obtained by the ordinary method was distilled under reduced pressure to give the following fraction: bp 105°C (13 mmHg), 1.4 g. The fraction was identified as methyl *o-N,N*-dimethylaminomethylbenzoate (18.1%): Found: C, 68.21; H, 7.80; N, 7.20%. Calcd for $C_{11}H_{15}NO_2$: C, 68.37; H, 7.82; N, 7.25%. NMR (τ): 7.81 (6H, singlet), 6.32 (2H, singlet), 6.17 (3H, singlet) and 2.56 (4H, multiplet). Mass (m^+/e): 193. IR: ν_{CO} 1740, ν_{COC} 1280, 1130 and ν_{NCH} 2800 cm^{-1}.

In the case of nickel carbonyl, methyl *o-N,N*-dimethylaminomethylbenzoate was obtained in a yield of 5.2%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 950—952 (1970)

Amylose-Iodine Complex. V. An Estimation of Number of Anhydroglucose Units of Helical Segments in Amylose-Iodine Complex*1

Takehiko WATANABE, Kozo OGAWA*2 and Sôzaburo ONO

Laboratory of Biophysical Chemistry, College of Agriculture, University of Osaka Prefecture, Sakai

(Received September 9, 1969)

The amylose molecules in neutral or acidic aqueous solution would take a conformation of deformed helix;[1-5] the individual helical segments are connected by random segments. The dissolved amylose-iodine complex has a similar structure as stated above, *i. e.* a single amylose molecule contains more than one independent polyiodine chains. According to Szejtli *et al.*[5] the number of anhydroglucose units composing the helical segment was about 120 which was obtained from the study of the correlation between the degree of polymerization of amylose molecule and the iodine-binding capacity or the wavelength of the maximum absorption peak of amylose-iodine complex.

In the present paper, the number of anhydroglucose units per helical segment was estimated from spectrophotometric measurement of the change in the absorbance at 288, 352 and 630—660 mμ with addition of amylose to iodide-iodine solution.

Experimental

The amylose subfraction used is the one described in the previous report[4], having viscosity-average molecular weight ($\bar{M}_v$) 1×10^6 calculated from limiting viscosity number, $[\eta]$ (ml/g) in dimethyl sulfoxide at 25°C, using the following equation proposed by Everett and Foster[6], $[\eta]=3.06\times10^{-2}\ \bar{M}_v^{0.64}$.

The spectrophotometric measurements were carried out by using Hitachi Recording Spectrophotometer Model EPS-3 with silica cells 1.00 cm thick.

Results and Discussion

The iodide-iodine solution possesses two absorption peaks (at wavelength, 288 and 352 mμ), which have been attributed by Awtrey and Connick[7] to the I_3^- ion. On the addition of amylose to the solution, blue colored complex is formed and the complex solution possesses three absorption peaks at 288, 352 and 630—660 mμ. Absorbance of iodide-iodine solution with and without amylose

changes with the concentration of iodide as shown in Figs. 1 and 2. In the solution of iodide-iodine-amylose, the following equilibria will hold

$$\mathrm{Am(h)} + n\mathrm{I_2} + m\mathrm{I^-} \rightleftharpoons \mathrm{Am(h)(I_2)}_n(\mathrm{I^-})_m \quad (1)$$

$$\mathrm{I_2} + \mathrm{I^-} \rightleftharpoons \mathrm{I_3^-} \quad (2)$$

where Am(h) is the helical segment of amylose molecule and $\mathrm{Am(h)(I_2)}_n(\mathrm{I^-})_m$ is the iodine complex. The dissociation constant of $\mathrm{I_3^-}$ in Eq. (2), K, was given by Davies and Gwynne[8] as follows.

$$K = 1.22 \times 10^{-3} \quad (\text{at } 20^\circ\mathrm{C}) \quad (3)$$

The concentration of $\mathrm{I_3^-}$ ion in iodide-iodine solution can be calculated from the molar extinction coefficients given by Awtrey and Connick;[7] 40000 at 288 mμ and 26400 at 352 mμ.

As shown in Figs. 1 and 2, absorbance at 352 mμ of iodide-iodine solution increases with the addition of amylose in the range of low iodide concentration, therefore the complex is assumed to have appreciable contribution to this absorption peak as well as the $\mathrm{I_3^-}$ ion in solution. On the other hand, absorbance at 288 mμ of the iodide-iodine solution is always suppressed by the addition of amylose. However, the amount of iodine in the complex calculated by the following equation, was not in agreement with that predicted from the experimental results shown in Figs. 1 and 2.

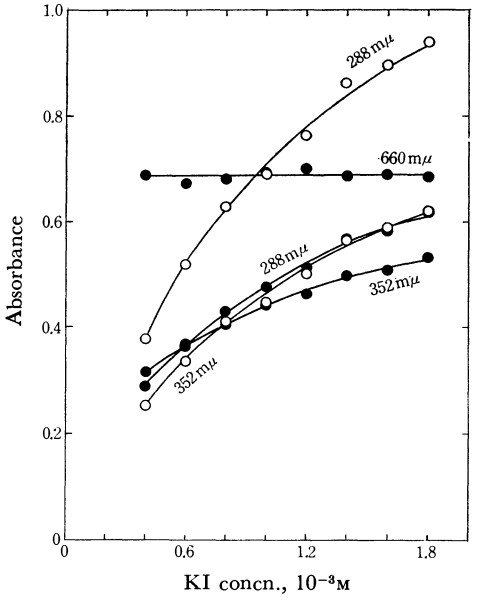

Fig. 1. Relation between the absorbance (at 288, 352 and 660 mμ) and KI concentration of iodide-iodine solution with (—●—) and without (—○—) amylose: concn. of $\mathrm{I_2}$, 4×10^{-5}M; concn. of amylose, 0.02 g/l; at 20°C.

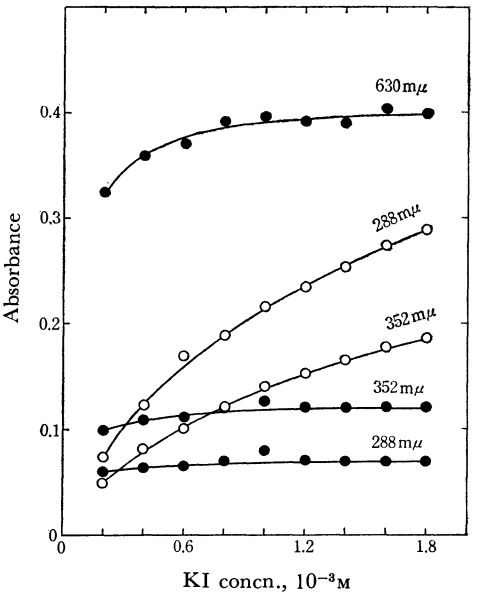

Fig. 2. Relation between the absorbance (at 288, 352 and 630 mμ) and KI concentration of iodide-iodine solution with (—●—) and without (—○—) amylose: concn. of $\mathrm{I_2}$, 1.2×10^{-5}M; concn. of amylose, 0.02 g/l; at 20°C.

(amount of iodine in the complex)
= (amount of iodine dissolved)
$$-\left[\begin{pmatrix}\text{amount of iodine present as } \mathrm{I_3^-} \text{ ion calculated}\\ \text{from the relation, } \{\text{absorbance at 288 m}\mu/40000\}\end{pmatrix} + \begin{pmatrix}\text{amount of iodine in equilibrium with}\\ \text{the } \mathrm{I_3^-} \text{ ion calculated by Eq. (3)}\end{pmatrix}\right] \quad (4)$$

Therefore, polyiodine chain in the complex may have some contribution to the peak at 288 mμ. Thereupon, the molar extinction coefficient of the iodine complex was evaluated by trial-and-error solution and the most probable values per mol iodine obtained were as follows; 0.7×10^4 at 288 mμ, 1.2×10^4 at 352 mμ and 4×10^4 at 630—660 mμ. The latest value at 630—660 mμ is in good agreement with the proposed one by Rundle *et al.*[9] The above values of extinction coefficient were obtained on the basis of the following assumption; both ends of the polyiodine chain are in the form of $\mathrm{I_3^-}$ and these $\mathrm{I_3^-}$ as well as the free $\mathrm{I_3^-}$ ion in solution, take part in the equilibrium, existing in solution according to Eq. (2), with free iodine. The most probable values of n and m were obtained as 11 and 2, respectively. Therefore, the polyiodine chain in the complex is assumed to be composed of linearly linked 11 iodine molecules and the both ends of the chain are in the form $\mathrm{I_3^-}$ such as shown as follows; $^-\mathrm{I_3(I_2)_9I_3^-}$. When one helical turn

8) M. Davies and E. Gwynne, *ibid.*, **74**, 2748 (1952).

9) R. E. Rundle, J. F. Foster and R. R. Baldwin, *ibid.*, **66**, 2116 (1944).

consists of 6 anhydroglucose units, the helical segment will be expected to be composed of $6\times 11=66$ anhydroglucose units provided the condition for the complex formation *i. e.* one iodine molecule per one turn of the helix is maintained. This amount 66 is in good agreement with the maximum number of anhydroglucose units composing a stable single helix obtained from the correlation between the wavelength of the maximum absorption peak of iodine-complex and the degree of polymerization of maltodextrin.[10] The amount of iodine combined in the complex in the presence of excess amount of iodine in solution (Fig. 1), was about 83% of the saturation (2.06×10^{-5} mol iodine per 0.02 g amylose), therefore a random segment between two helical segments in the helical segments may be assumed to be composed of about 14 anhydroglucose units.

The Effect of Urea on the Viscosity of Polymer Aqueous Solutions

Kunio TAMAKI, Yōko ŌHARA and Katsuhide KOMORI

Department of Chemistry, Yokohama City University, Kanazawa-ku, Yokohama

(Received September 10, 1969)

The effect of urea on the behavior of such hydrocolloids as proteins, synthetic polymers, and micelles of amphiphilic compounds in the water phase has been studied by several investigators. We will here report our experimental results on the change in the viscosity of the aqueous solutions of polyvinylpyrrolidone and sodium polystyrenesulfonate upon the addition of urea.

Experimental

Two kinds of polyvinylpyrrolidone (PVP), K-30 and K-90, with molecular weights of 4×10^4 and 9×10^5 respectively, were purchased from the Tokyo Kasei Kogyo Co. Sodium polystyrenesulfonate (NaPSS) was prepared by the neutralization of polystyrenesulfonic acid with a sodium hydroxide solution. Polystyrenesulfonic acid was prepared by the sulfonation of polystyrene (molecular weight 2.0×10^5) with concentrated sulfuric acid in the presence of silver sulfate, and it was purified by successive dialysis.[1] The degree of sulfonation was found to be 0.73. The urea was a reagent-grade product of the Koso Chemical Co. The 1,3-dimethylurea was an E. P.-grade product of the Tokyo Kasei Kogyo Co.; it was recrystallized from a chloroform-ether mixture.

The viscosity measurements were carried out with Ostwald viscometers with an outflow time for water of about 90 sec and with a total volume of 5 m*l* in a water bath at 25 ± 0.02°C.

Results and Discussion

It was found that the change in the reduced viscosities of PVP upon the addition of urea and 1,3-dimethylurea was very small, as is indicated in Figs. 1 and 2. Jirgenson[2] has reported that the reduced viscosities of PVP were reduced by the addition of urea and guanidine hydrochloride, whereas Klotz and Russell[3] have shown that urea had very little effect on the reduced viscosities of

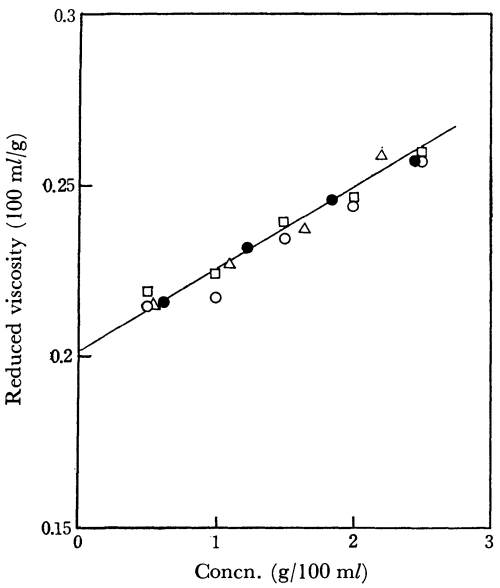

Fig. 1. Reduced viscosity of PVP, K-30, as a function of concentration in g per 100 m*l*; ● in water, ○ in 2M urea, □ in 4M urea, △ in 6M urea.

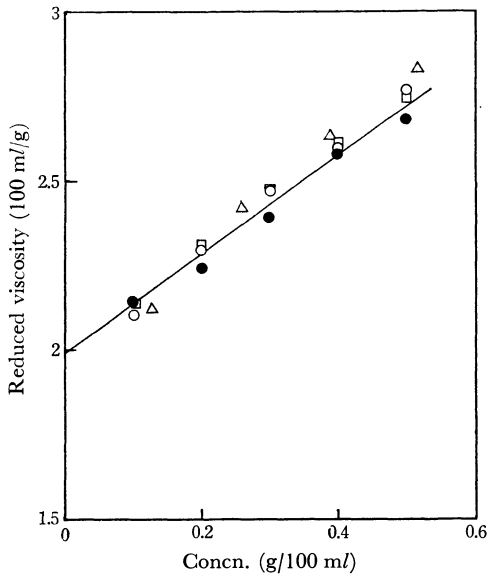

Fig. 2. Reduced viscosity of PVP, K-90, as a function of concentration in g per 100 ml; ● in water, ○ in 2M urea, □ in 2M 1,3-dimethylurea, △ in 4M urea.

PVP. Our results are in agreement with those of Klotz and Russell.[3]

Several different results regarding the change in the viscosity of other water-soluble polymers upon the addition of urea have been reported. Urea did not affect the reduced viscosities of polyacrylamide;[4] this behavior is similar to that of PVP discussed in this paper. Urea addition increased the reduced viscosities of polyvinylalcohol,[5-7] polyethylene glycol,[8] and un-ionized polyacrylic acid in hydrochloric acid.[4] Urea addition decreased the reduced viscosities of un-ionized polymethacrylic acid in hydrochloric acid.[4]

Urea, a well-known protein denaturant, is believed to behave as a structure breaker of water,[9-11] although a contrary opinion has also been reported.[12] Klotz[13] proposed the idea that the modification of water structure by the addition of urea can change the conformation and behavior of macromolecules, markedly different even in their primary structure, in a similar way. However, the experimental results reported in this paper as well as in the literature suggest the existence of some kinds of specificity[14] in the interaction of polymers with urea.

The reduced viscosities of NaPSS were greatly diminished by the addition of urea, as is shown in Fig. 3. NaPSS belongs to a strongly-ionized polyelectrolyte. The depression of ionization seems to be improbable, because the dielectric constant of aqueous urea solutions is slightly higher than that of pure water. Iso[15] obtained results showing a decrease in the reduced viscosities of sodium polyacrylate in the presence of urea. The decrease in the viscosity of strongly-ionized polyelectrolytes by the addition of urea seems to be a common feature, although the mechanism is still unknown.

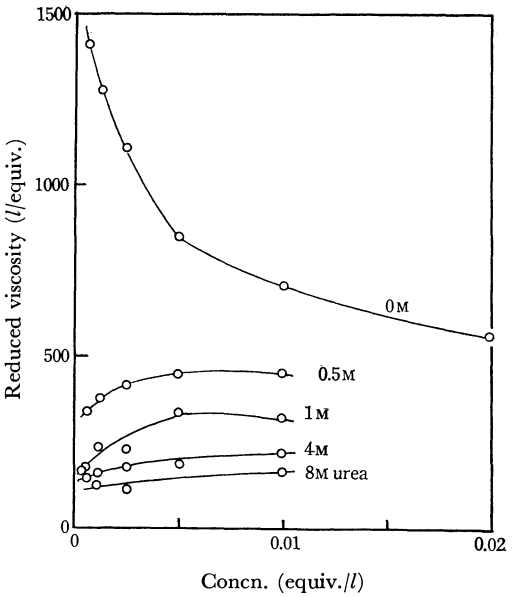

Fig. 3. Reduced viscosity of NaPSS as a function of concentration in equiv. per liter.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 954—955 (1970)

Study on Oxazolopyrimidines. II. Conversion of 7-Aminooxazolo-[5,4-*d*]pyrimidines into Hypoxanthine Derivatives

Yozo Ohtsuka

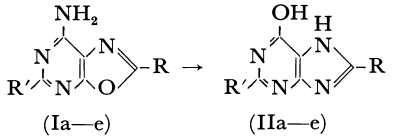
Sagami Chemical Research Center, Onuma, Sagamihara, Kanagawa

(Received September 16, 1969)

Several 7-aminooxazolo[5,4-*d*]pyrimidines have been synthesized from oxazole derivatives.[1] During the examination of the chemical behavior of these compounds, a new transformation of 7-aminooxazolopyrimidines into hypoxanthine derivatives was found.

Hitchings *et al.*[2] have converted some oxazolopyrimidines into purine derivatives by heating with alcoholic ammonia at 160°C for a long period. These conditions are similar to those of the well-known conversion of oxazoles into imidazoles.[3,4] In these cases, severe conditions are required for the substitution of oxygen atom by imino group. On the other hand, Ishidate and Yuki[5] found that 7-mercaptooxazolopyrimidine derivative was converted into 7-hydroxythiazolopyrimidine derivative under such mild conditions as by boiling with dilute acid for 20 min or by heating the crystals at 270—300°C.

The conversion of 7-aminooxazolopyrimidines into hypoxanthines proceeds under mild conditions. Thus, the treatment of the oxazolopyrimidines with aqueous 4N sodium hydroxide solution at room temperature followed by warming at 60—80°C, was found to be the most appropriate for the transformation.



(Ia—e) (IIa—e)

a: R=R′=H
b: R=H, R′=CH_3
c: R=CH_3, R′=H
d: R=R′=CH_3
e: R=H, R′=OC_2H_5

By this treatment, 2- and/or 5-substituted 7-aminooxazolopyrimidines can be converted into the corresponding hypoxanthines. The yields of the hypoxanthines were 60 to 80% but more careful workup seemed to improve them. The structures of the products, IIa—d, were confirmed by comparison with authentic samples. The structure of IIe was confirmed by acid hydrolysis to afford xanthine.

All the hypoxanthines examined here are easily soluble in aqueous alkaline solution, while oxazolopyrimidines have sparing solubilities in the solvent. Therefore, it was thought that completion of the initial step of the reaction could be estimated from the time required for complete dissolution of the starting materials.

Table 1. The time of complete dissolution of several 7-aminooxazolopyrimidine
(45°C aq 4N NaOH solution)

Compound	Time (hr)
Ia	0.2
Ib	2.5
Ic	2.7
Id	7.5
Ie	5.0

The results in Table 1 show that when R and R′ are substituted by CH_3 or OEt, a longer time is needed for dissolution of the starting materials. This would mean the initial attack by alkali is retarded by these substituents.

The reaction proceeds through oxazole ring rupture by attack of OH^- followed by imidazole ring formation. This reaction provides a new route to hypoxanthine derivatives under mild conditions. The scope and applications of the reaction are under investigation.

Experimental

The IR, NMR and mass spectra were recorded with Perkin-Elmer 337, Varian HA-100 and Hitachi RMU-6E spectrometer respectively. The synthesis of the starting material has been described in the previous paper.[1]

Conversion of 7-Aminooxazolopyrimidines into Hypoxanthine Derivatives. General method: 7-Aminooxazolo[5,4-*d*]pyrimidine (1 g) and aqueous 4N sodium hydroxide solution (10 ml) were stirred at room temperature for 30 min. Then the mixture was warmed at 60—80°C for 30 min, and after cooling, the reaction

5) M. Ishidate and H. Yuki, *Chem. Pharm. Bull.* (Tokyo), **8**, 137 (1960).

mixture was acidified with conc. HCl. The resultant precipitates were filtered, and the products, about 60—80% yields, were recrystallized from water. These were identified by the comparisons of their IR, NMR and mass spectra with authentic samples (IIa: commercial product, IIb and IId,[6] and IIc[7]; prepared by known procedures). 2-Ethoxyhypoxanthine (IIe); colorless needles, mp >330°C. Found: C, 46.69; H, 4.49; N, 31.14%. Calcd for $C_7H_8N_4O_2$: C, 46.66; H, 4.48; N, 31.10%. NMR in DMSO-d_6 (δ-values): 7.90 (C_8-proton), 1.33, 4.35 (OEt).

7-Aminooxazolopyrimidine, Ia, was most easily converted into hypoxanthine, IIa; heating of Ia at the melting point, solids which were confirmed to be hypoxanthine deposited while other oxazolopyrimidines gave only degraded products. Moreover, on refluxing with acetic anhydride for 2 hr, Ia afforded IIa (60%). With more dilute alkali or at higher initial temperature, 7-aminooxazolopyrimidines were decomposed to acid soluble materials, which by the IR spectra are probably aminohydroxypyrimidine derivatives although they have not been confirmed.

Acid Hydrolysis of 2-Ethoxyhypoxanthine. 2-Ethoxyhypoxanthine (1 g) and 4N hydrochloric acid (20 m*l*) were heated under reflux for 4 hr. After neutralization of the reaction mixture with alkali, 0.7 g of product was obtained. The IR and NMR spectra of the product were identical with those of authentic xanthine.

Determination of the Time of Complete Dissolution. 7-Aminooxazolopyrimidines (2 mg) were suspended in aqueous 4N NaOH solution (1 m*l*) and the mixtures were stirred in the temperature-controlled bath. The time of complete dissolution was measured two or three times in each samples, and the mean deviation of those data were about ±20%.

The Conductances of Alizarine Saphirol SE in Water-dioxane Mixtures at Various Temperatures

Masaru MITSUISHI, Mieko HASHIZUME, Akira KATAYAMA*1 and Nobuhiko KUROKI*1

Faculty of Textile Science and Technology, Shinshu University, Ueda, Nagano

(Received September 16, 1969)

It was reported, in our previous paper,[1] that Alizarine Saphirol SE forms the ion-associates in water-dioxane mixtures with low dielectric constants.

In the present paper, the thermodynamic properties of the ion-association reactions of Alizarine Saphirol SE in 70 and 82% dioxane are examined.

Experimental

Materials. The Alizarine Saphirol SE (sodium salt of 1,5-dihydroxy-4,8-diaminoanthraquinone-2-sulfonic acid) was a laboratory stock used in a previous work.[1]

The dioxane was purified by the same method as that described in the previous work.[1]

Conductance Measurements. These measurements were carried out at 15, 25, and 35°C by the same procedures as those described in the previous work.[1]

Results and Discussion

The conductances of Alizarine Saphirol in water-dioxane mixtures at 15, 25, and 35°C are shown in Fig. 1.

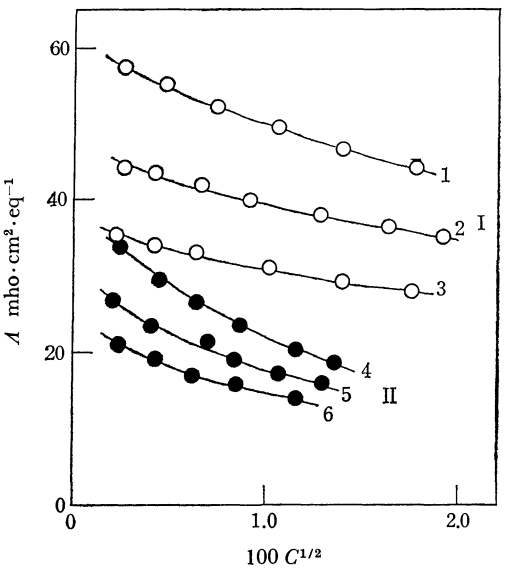

Fig. 1. Equivalent conductances of Alizarine Saphirol SE in 70 and 82 %dioxane. I, 70% dioxane (1 : 35, 2 : 25, 3 : 15°C), II 82% dioxane (4 : 35, 5 : 25, 6 : 15°C).

*1 College of Engineering, University of Osaka prefecture, Sakai, Osaka.

1) M. Mitsuishi, Y. Funatsu and N. Kuroki, This Bulletin, **42** 2384 (1969).

From the results of the conductance measurements indicated in Fig. 1, the equivalent conductances at an infinite dilution, Λ_0, and the ion-association constants, K_A, were calculated by means of Shedlovsky's treatment[2] based on the Onsager limiting equation in a manner similar to that described in the previous work;[1] the results are shown in Table 1.

Table 1. Calculated parameters

Dioxane	t °C	D	100 η poise	Λ_0	$\Lambda_0\eta$	K_A
70.0%	15	18.72	2.483	35.6	0.884	1.31×10^3
	25	17.69	1.918	45.3	0.869	1.39×10^3
	35	16.72	1.522	58.2	0.886	1.63×10^3
82.0%	15	10.01	2.106	23.0	0.484	8.67×10^3
	25	9.53	1.671	27.5	0.460	9.86×10^3
	35	9.06	1.356	36.5	0.495	1.30×10^4

D: Dielectric constant of the solvent.
η: Viscosity coefficient of the solvent.[3]

From Table 1, the K_A values of the dye in water-dioxane mixtures are found to increase with the rise in the temperature of the solvents. The Walden products, $\Lambda_0\eta$, are essentially constant in the solvents of a constant composition, even if the temperatures are different.

The relation among K_A, the dielectric constant, D, and the temperature, T, of the solvent is given by this equation:[4]

$$K_A = e^b, \tag{1}$$

where,

$$b = e^2/aDkT. \tag{2}$$

In Eq. (2), e is the electron charge, a is the center-to-center distance of the ions in an associate and k is the Boltzmann constant.

In accordance with Eq. (1), the plot of log K_A against DT must be linear. The plots of log K_A *vs.* the DT of Alizarine Saphirol in 70 and 82% dioxane are shown in Fig. 2; the plots are found to be linear. These evidences suggest that the ion associates of Alizarine Saphirol in 70 and 82% dioxane are due entirely to the electrostatic interactions between the dye ion and the counter ion.

The a values of Alizarine Saphirol in 70 and 82% dioxane can be obtained from the slopes of the plot of log K_A *vs.* DT; they are indicated in Table 2. As can be seen from Table 2, the a value in 70% dioxane is larger than that in 82% dioxane.

In the ion-association reaction of Alizarine Saphirol in water-dioxane mixtures, the enthalpy change (ΔH) and the entropy change ($\Delta S°$) can be obtained from Eqs. (3) and (5) respectively:

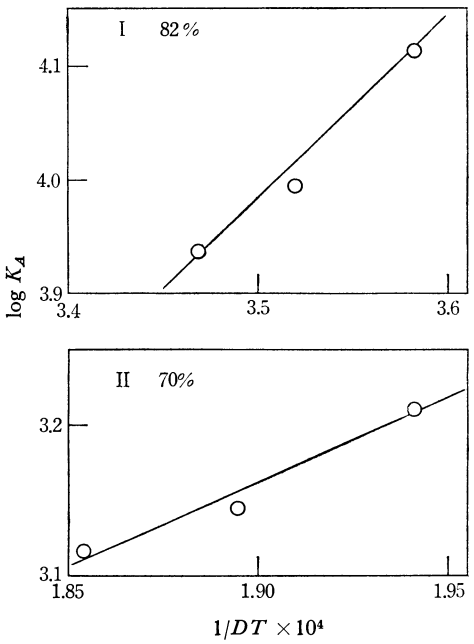

Fig. 2. The relation between log K_A and $1/DT$ in 82% (I) and 70% dioxane (II).

Table 2. Thermodynamic parameters of the ion association reaction of Alizarine Saphirol SE in water–dioxane mixtures at 25°C

Dioxane	$K_{A_{298}}$	ΔH (kcal/mol)	$\Delta G°$ (kcal/mol)	$\Delta S°$ (cal/deg·mol)	a (Å)
70.0%	1.39×10^3	1.93	−4.3	21.1	6.72
82.0%	9.86×10^3	3.57	−5.5	30.5	4.74

$$\mathrm{d}\ln K_A/\mathrm{d}(1/T) = -\frac{\Delta H}{R}, \tag{3}$$

$$\Delta G° = -RT\ln K_A, \tag{4}$$

$$\Delta G° = \Delta H - T\Delta S°, \tag{5}$$

where R is the gas constant.

From the best straight line given by the method of least squares for the log K_A *vs.* $1/T$ plot over the whole temperature range, the ΔH values are obtained, the $\Delta S°$ values are obtained from Eq. (5), and are as indicated in Table 2.

As is shown in Table 2, since the ΔH values are positive, the reaction is endothermic; these ΔH values are comparable to those of the ion-association reactions of several inorganic salts in water.[5,6]

The $\Delta S°$ values of the reactions are positive.

6) G. H. Noncolls, *Discuss. Faraday Soc.*, **24**, 108 (1957).

These results are considered to reflect the evidence that the degree of freedom of the system increases, since the solvent molecules are removed from the solvation sphere of the ions when the dye ion forms an ion associte with the counter ion.

The authors wish to thank Professors Haruo Gotoh and Masatoki Yokoi for their helpful discussions.

The Electrochemical Fluorination of *s*-Triazines

Takashi ABE, Shunji NAGASE and Kazuo KODAIRA

Government Industrial Research Institute, Nagoya Kita-ku, Nagoya

(Received September 26, 1969)

A great many papers have described the fluorination of nitrogen compounds with a carbon - nitrogen multiple bond.[1] However, the information given in the literature about the electrochemical fluorination of nitrogen compounds has not extended to nitriles and imines other than acetonitrile[2] and guanidine.[3] The present investigation was undertaken mainly in order to study the general behavior of the carbon - nitrogen multiple bond upon electrochemical fluorination.*1 Trifluoroacetonitrile and perfluoroalkyl iminosulfur difluorides were subjected to electrochemical fluorination. Furthermore, such *s*-triazines as cyanuric fluoride, thiocyanuric acid and 1,3,5-triamino-*s*-triazine were also fluorinated.

It was found that, upon electrochemical fluorination, these samples were cleaved extensively, giving fluorocarbons, nitrogen trifluoride, and perfluoroamines. The evolution of nitrogen gas was also observed. In addition, sulfur hexafluoride was obtained from the compounds containing sulfur.

When trifluoroacetonitrile (bp 65°C) was subjected to fluorination electrochemically (reaction conditions: sample feed rate, 14 ml/min, He, 20 ml/min; anodic current density, 2.0 A/dm^2; cell voltage, 5.7—6.7 V; cell temp, 13°C; NaF added, 5 g), the product consisted of tetrafluoromethane (28 mol%), trifluoromethane (2%), hexafluoroethane (28%), and nitrogen trifluoride (42%). When the sample feed rate was increased (27.1 ml/min), pentafluoroethyldifluoroamine was obtained in a very low yield (<1%), along with other fluorinated compounds. The product composition (mol%) was as follows: tetrafluoromethane (21%), trifluoromethane (1%), hexafluoroethane (33%), nitrogen trifluoride (44%) and pentafluoroethyldifluoroamine (1%). Similarly, trifluoromethyl iminosulfur difluoride (bp −7——5°C), pentafluoroethyl iminosulfur difluoride (bp 22—24°C), and *N*-fluoroformyl iminosulfur difluoride (bp 54°C) underwent breakdown upon electrochemical fluorination, giving the compounds depicted below:

Sample	Products*2
$CF_3N{=}SF_2$	→ CF_4, NF_3, SF_6, CF_3NF_2, $(CF_3)_2NF$ and CHF_3
$C_2F_5N{=}SF_2$	→ C_2F_6, SF_6, NF_3, CF_4, $C_2F_5NF_2$, C_2F_5H and CHF_3
$FC(=O)N{=}SF_2$	→ COF_2, NF_3, SF_6, CF_4 and CF_3OF

The reaction conditions and the results with the electrochemical fluorination of *s*-triazines as well as methyl thiocyanate and methyl isothiocyanate are shown in Table 1. In this fluorination, only cleaved products were yielded; tetrafluoromethane and nitrogen trifluoride were the main products from these starting materials. The results are in contrast to those obtained by the fluorination of these compounds with elementary fluorine. It has been reported by Ruff that the fluorination of trifluoroacetonitrile[4] and perfluoroalkyl iminosulfur difluoride[5] with fluorine gave fully-fluorinated,

*a Electrolysis was continued until the cell voltage was raised up to 7.6 V.
*b (total mol of products/mol of sample)

saturated compounds as the main products, without any fission of the carbon - nitrogen bond or the nitrogen - sulfur bond. However, upon electrochemical fluorination, no formation of any fluorinated compounds, such as R_fNFSF_5 (R_f = trifluoromethyl, pentafluoroethyl and fluoroformyl) and *N,N*-difluoroaminosulfur pentafluoride, was detected from the corresponding starting material, even when an increased amount of sample was fed into anhydrous hydrogen fluoride; a higher feed rate of the sample makes the reaction milder.[6] Further perfluoroalkylazo compounds (*e. g.*, $CF_3N{=}NCF_3$ and $C_2F_5N{=}NC_2F_5$) which have been reported to be found in the products of the direct fluorination of these compounds with an unsaturated carbon - nitrogen bond[7] were not detected in the present fluorination reaction.

Experimental

Materials. Trifluoroacetonitrile,[8] trifluoromethyl iminosulfur difluoride, pentafluoroethyl iminosulfur difluoride,[9] *N*-fluoroformyl iminosulfur difluoride,[10] cyanuric fluoride[11] and thiocyanuric acid[12] were prepared and purified by the method in the literature. The 1,3,5-triamino-*s*-triazine, methyl thiocyanate, and methyl isothiocyanate were obtained commercially.

The purity of the anhydrous hydrogen fluoride was better than 99%.

Apparatus and Procedures. Two types of electrolytic cells were employed in these experiments. For the fluorination of trifluoroacetonitrile, trifluoromethyl iminosulfur difluoride, pentafluoroethyl iminosulfur difluoride, and *N*-fluoroformyl iminosulfur difluoride, an iron cell (300 m*l* capacity) was employed. A monel cell (1 *l* capacity) was employed for the others. The anodic surface areas were 7.7 dm^2 and 9.2 dm^2 respectively. The bottoms of these cells were equipped with a bubbler. In both cases, the anodic current density was 2.0 A/dm^2.

As for the gaseous samples, the procedures are essentially the same as those described in the preceding paper,[13] but the reflux condenser was kept at −20°C and the gaseous product was analysed by studying the G.C. (column; FC 43*3 66% on Celite 545 SK, KelF #3*3 30% on Chromosorb PAW) and IR spectra, taking the sample directly from the sampling valve fixed next to the hydrogen fluoride absorber.

For the other samples the electrolysis were carried out by batch. The procedures thereafter were the same as have been described previously.[6] The tetrafluoromethane and nitrogen trifluoride were analysed by G.C. (conditions: column, silica gel 60—80 mesh, 1.5 m length × 3 mm id; carrier gas, He; temp., 0°C).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 959—960 (1970)

Photolysis of Tetraphenylcyclobutadienenickel Bromide

Takahiro HOSOKAWA and Ichiro MORITANI

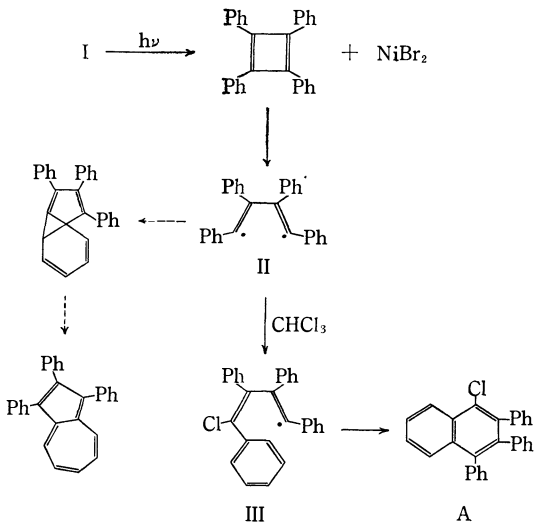
Department of Chemistry, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka

(Received September 27, 1969)

Thermal behavior of some cyclobutadiene-metal complexes has been well studied.[1] Much less is known, however, about the photochemical reaction of the complexes except for the results of the photolysis of cyclobutadieneiron tricarbonyl by Masamune *et al.*[2] An interesting point in such a reaction is the photochemical behavior of the unstable cyclobutadiene-ligands which are liberated by photodecomposition. Therefore, we have investigated the photolysis of tetraphenylcyclobutadienenickel bromide (I).

The complex I was prepared from 1,1-dimethyl-2,3,4,5-tetraphenylstannole by Freedman's method.[3] The irradiation of I was carried out in a chloroform solution under a nitrogen atmosphere at 10—16°C for 12 hr by using a 500 W high pressure mercury lamp.[4] After irradiation, the insoluble material which resulted from the reaction was filtered off and characterized as nickel bromide. Thus it can be considered that in the reaction the complex I is decomposed by light, thus liberating tetraphenylcyclobutadiene. After the solvent had been evaporated *in vacuo*, the reaction products were separated by alumina-column chromatography. Elution with petroleum ether and recrystallization gave colorless needles (A). The other products were a large quantity of a tarry matrial and an uncharacterized complex. The compound A was found to be 1-chloro-2,3,4-triphenylnaphthalene by an elemental analysis, a molecular-weight determination, and a study of its spectroscopic data. The structure of A was further confirmed by converting it to 1,2,3-triphenylnaphthalene[5] by treatment with metal lithium and then methanol.

The photochemical reaction of diphenylacetylene in *n*-hexane has previously been reported to give 1,2,3-triphenylnaphthalene and 1,2,3-triphenylazulene *via* a tetraphenylcyclobutadiene intermediate.[6] In contrast to this reaction, interestingly, only a chlorinated naphthalene was obtained in our reaction, not azulene. Accordingly, a chlorine atom must be abstracted from the solvent in one stage of the reaction. Therefore, we propose the following reaction scheme including the diradical intermediate (II). The diradical II abstracts the chlorine atom more easily to afford the monoradical III than II rearranges itself intramolecularly since no azulene is formed in this reaction.[7]



Thus, it can be said that this may depend upon the ease with which the chlorine atom is abstracted from the solvent. In fact, when (4-bromo-1,2,3,4-tetraphenyl-*cis*,*cis*-1,3-butadienyl)dimethyltin bromide was irradiated in benzene, only 1,2,3-tri-

7) Very recently such an intermolecular naphthalene formation has been reported for the dimerization of phenylpropiolic acid by H. W. Whitlock, Jr., E-M. Wu and B. J. Whitlock in *J. Org. Chem.*, **34**, 1857 (1969).

phenylazulene was formed,[8] whereas in chloroform only the naphthalene A was obtained.[9]

Experimental

Irradiation of Tetraphenylcyclobutadienenickel Bromide (I). A solution of 2.43 g (4.23 mmol) of I[3] in 1 liter of chloroform, agitated by the bubbling of nitrogen gas, was irradiated with a 500 W high pressure mercury lamp, and then the reaction vessel was cooled with ice water. The reaction was followed by studying the ultraviolet spectrum. After the solution had been irradiated for 12 hr, the characteristic ultraviolet peak near 300 mμ, present in I, disappeared. The nickel bromide (*ca.* 718 mg, 3.29 mmol) which appeared during the irradiation was filtered off, and the chloroform was evaporated *in vacuo*. Into the residue, there was added petroleum ether, and then the undissolved amorphous material was filtered off. The filtrate was chromatographed on a column of alumina (48 g). Elution with petroleum ether (55 m*l*) gave pale yellow crystals (133 mg), which were then further chromatographed and recrystallized from petroleum ether. We thus obtained 76 mg (0.19 mmol) of 1-chloro-2,3,4-triphenylnaphthalene (A) as colorless crystals, mp 187—188°C. IR (Nujol): 1070, 1028, 883, 763, 700, and 645 cm^{-1}. UV: λ_{max}^{EtOH} 238 (log ε=4.79), 270[sh] (4.20), and 297 mμ (4.04). NMR (CCl_4): multiplet at τ 1.65—1.70 (1H), multiplets centered at τ 2.55 (3H), 2.97 (11H), and 3.27 (4H). Its UV and NMR spectra were very similar to those of 2,3,4-triphenyl-1-naphthol.[11]

Found: C, 85.38; H, 4.87; Cl, 9.01%. Calcd for $C_{28}H_{19}Cl$: C, 86.03; H, 4.89; Cl, 9.07%.

Reduction of A with Lithium, 1,2,3-Triphenylnaphthalene. A solution of 58 mg of A in 10 m*l* of dry ether was refluxed with stirring in the presence of 10 mg of clean lithium shavings. A purple-brown lithium compound was formed after 8 hr, after which the reflux was continued for an additional 3 hr. The excess lithium was decomposed with methanol, and then the mixture was poured into water. The organic layer was extracted with ether, dried over anhydrous sodium sulfate, and concentrated. The residue was chromatographed on a column of alumina (3.9 g). Elution with petroleum ether (40 m*l*) gave 45 mg of 1,2,3-triphenylnaphthalene (mp 153—156°C (from ethanol-benzene)). The IR spectrum of this compound was superimposable upon that of an authentic material prepared from diphenylacetylene and lithium,[5] and a mixed melting point was undepressed.
