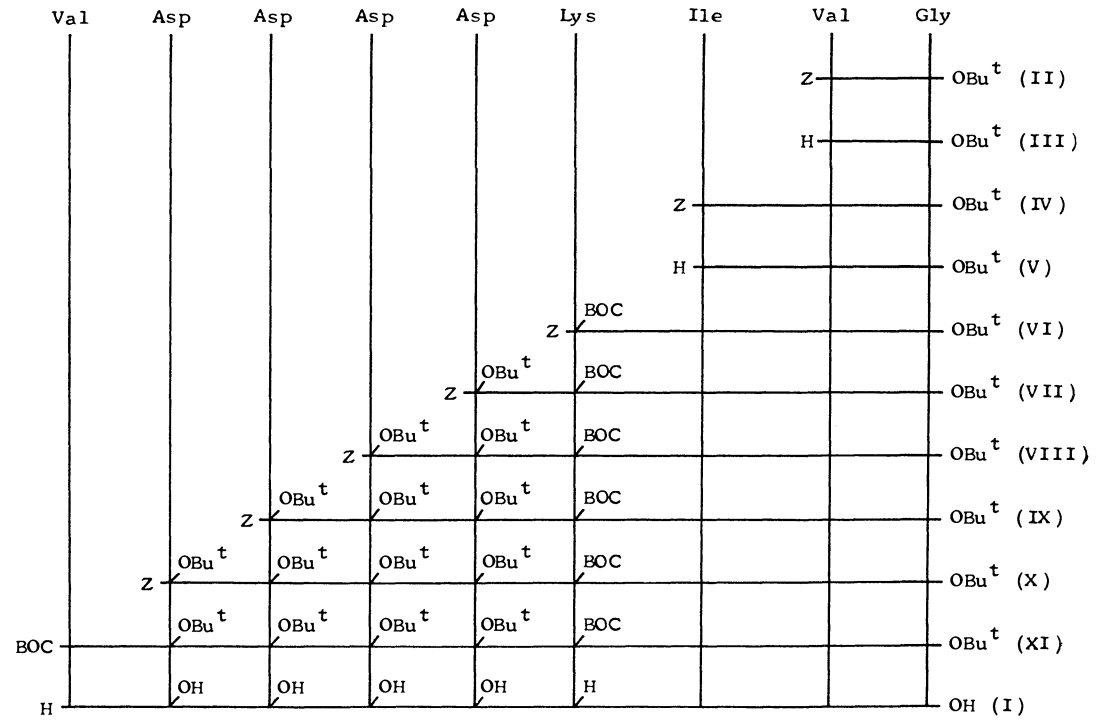

Fig. 1. Synthesis of the nonapeptide I using BOC and OBu^t protecting groups.

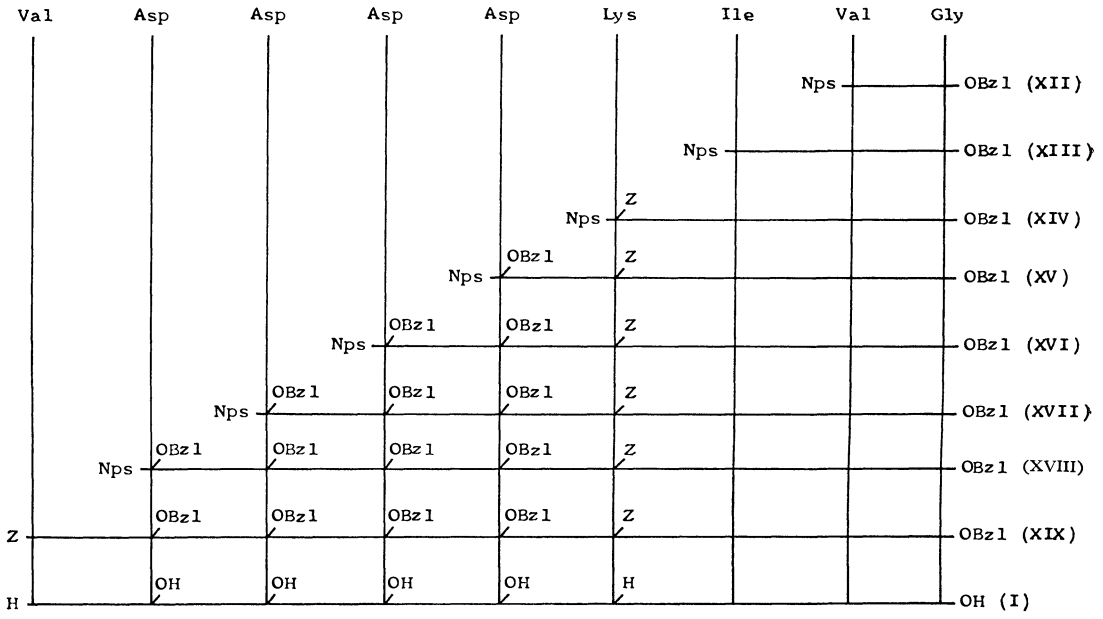

Fig. 2. Synthesis of I using Nps and OBzl groups.

ladium black. The protecting groups related to *t*-butyl alcohol were used for masking the side chain and the terminal functional groups. They are, BOC group for *N*-terminal amino group of valine and *ε*-amino group of lysine, and OBu^t group for *C*-terminal of glycine and *β*-carboxyl groups of four aspartic acid residues. In the coupling of each step, the mixed anhydride method using isobutylchloroformate as a coupling reagent generally gave good results. The use of 10—50% excess of each Z-amino acid brought satisfactory yield as in the cases of VII, VIII, IX and X. Z-

Val-Gly-OBu^t (II) was prepared with the esterification of Z-Val-Gly-OH[12] by the action of isobutylene in the presence of sulfuric acid as a catalyst. After hydrogenolysis of II, furnished dipeptide ester was coupled with the next amino acid, Z-Ile-OH. A similar procedure was repeated to attain the protected nonapeptide, BOC-Val-[Asp-(β-OBu^t)]$_4$-Lys(ε-BOC)-Ile-Val-Gly-OBu^t (XI), which was treated with trifluoroacetic acid to cleave all the protecting groups simultaneously. Although the BOC and OBu^t groups were reported previously to be easily cleavable,[13] all the acidolysis tested failed to give clear results. In addition to trifluoroacetic acid, hydrogen chloride in organic solvent, hydrogen bromide in acetic acid and liquid hydrogen fluoride were used as splitting reagents, but the product after acidolysis gave several ninhydrin-positive spots on their paper chromatograms and electrophoregrams. In order to purify the derived peptide from contaminations, chromatography on ECTEOLA cellulose column was found effective. Upon elution with dilute acetic acid, peptide I was obtained in a yield of about 30%. Anderson *et al.*[14] described the trifluoroacetic acid treatment to split five *t*-butyl esters from a protected macropeptide related to gastrin I and the chromatographic purification of the product, the over-all yield being lowered by the chromatographic procedure to about 10%.

Another route to synthesize the nonapeptide was planned in order to obtain I in better yield. In Fig. 2, Nps group[15] was used as α-amino protecting group except that of *N*-terminal valine. Z group and OBzl group were used to protect α-amino group of *N*-terminal valine, ε-amino group of lysine and all of the carboxyl groups, respectively, in order to hydrogenolyze all the protecting groups at once in the final stage of synthesis. Coupling of each protected amino acid with amino acid ester or peptide esters was accomplished *via* mixed anhydride method for syn-

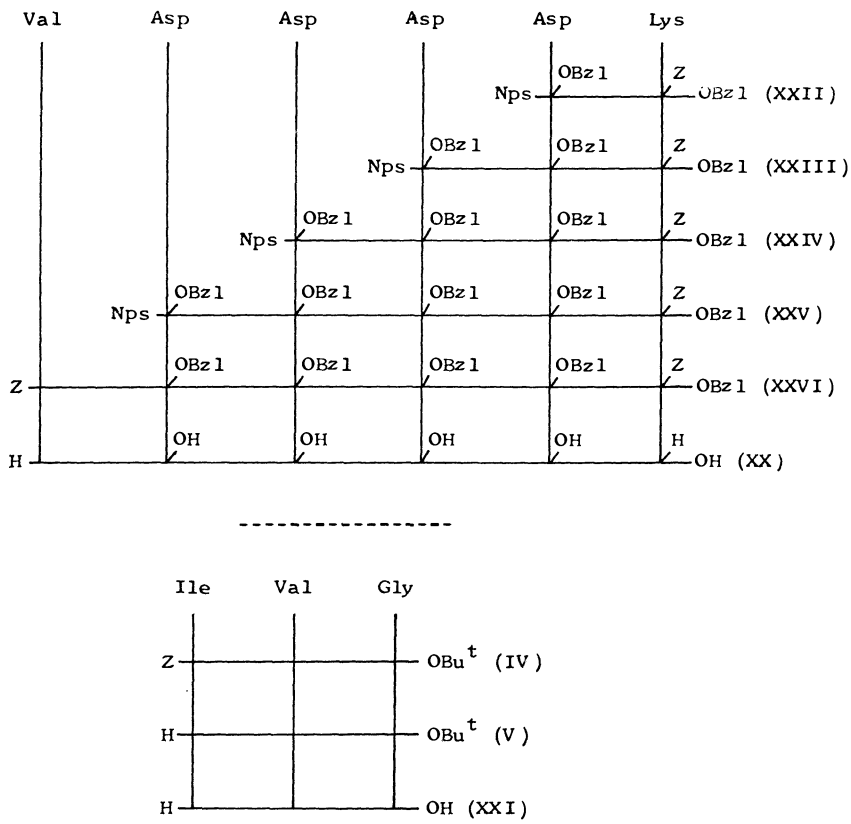

Fig. 3. Synthesis of the hexapeptide XX and tripeptide XXI.

thesis of XIV—XIX, and *via* DCC procedure for XII and XIII. In the latter case, the desired acylpeptide ester was obtained easily in good yield by the procedure mixing up each Nps-amino acid DCHA salt with the corresponding amine component, such as H-Gly-OBzl·*p*-TsOH, and DCC. In the case of the mixed anhydride, the use of excess Nps- or Z-amino acid gave satisfactory yield similar to the previous instances. Removal of Nps group was brought about by treatment with N hydrogen chloride in dioxane for XII—XIV, in dioxane-DMF for XV, and in dioxane-dimethylsulfoxide for XVI and XVII.

Protected nonapeptide ester thus obtained, Z-Val-[Asp(β-OBzl)]$_4$-Lys(ε-Z)-Ile-Val-Gly-OBzl (XIX), was applied to a column of Sephadex LH-20 to remove supposed contamination of Nps derivatives. The purified XIX was, then, catalytically hydrogenated and the product was applied to ECTEOLA cellulose column chromatography to give pure peptide I tetrahydrate in a 40% yield. The protected nonapeptide ester was treated with hydrogen fluoride also, but no improvement could be observed compared to the result of hydrogenolysis.

Figure 3 shows syntheses of hexapeptide (XX) and tripeptide (XXI), as authentic samples on enzymic experiment. There was no trouble in synthesis of protected hexapeptide ester, Z-Val-[Asp-(β-OBzl)]$_4$-Lys(ε-Z)-OBzl (XXVI). After purification using Sephadex LH-20 chromatography, hydrogenolysis of XXVI gave peptide XX quantitatively in a pure state. Paper electrophoretic behavior of XX was the same as that of peptide I in citrate buffer at pH 6.7 (Fig. 4). As shown in Fig. 4, crude products from XI and XIX contain several ninhydrin positive components other than I, but these compounds were not identified.

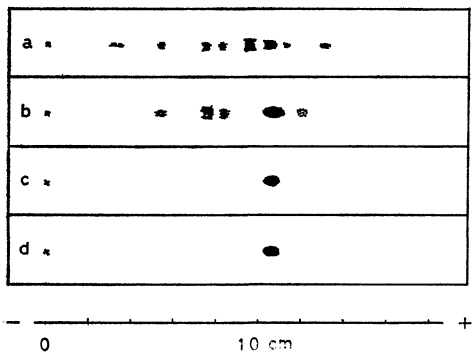

Fig. 4. Paper electrophoregrams of crude and pure peptides. Solvent, 0.01 M citrate buffer, pH 6.7; 600 V/30 cm; 1.5 hr. a, crude product by trifluoroacetic acid treatment on XI; b, crude product by hydrogenolysis of XIX; c, peptide I after ECTEOLA cellulose column chromatography; d, peptide XX.

H-Val-[Asp]$_4$-Lys-Ile-Val-Gly-OH (I)

↓ Trypsin

H-Val-[Asp]$_4$-Lys-OH (XX)

+ H-Ile-Val-Gly-OH (XXI)

Fig. 5. Scheme for tryptic cleavage of I.

Tryptic digestion of I (Fig. 5) was carried out in various conditions, and the progress of the reaction was followed by paper chromatography. In the absence of calcium ion, rate of tryptic hydrolysis of I was unexpectedly low at 30°C and the reaction was apparently inhibited at 47°C. On the contrary, when peptide I was digested with trypsin in the presence of 0.04 M calcium ion, the activating effect of calcium was always observed at 30°, 47° and 0°C, being especially remarkable at 47°C. In addition, susceptibility of I to trypsin was qualitatively compared with that of Bz-Arg-NH$_2$, one of the representative synthetic substrates of trypsin. For example, in a definite experimental condition described in Table 1, peptide I was digested by trypsin in 6 hr, while Bz-Arg-NH$_2$ was digested by one twentieth amount of trypsin in the same 6 hr interval. The results indicate that calcium ion accelerates tryptic digestion of I especially in high temperature as shown by Sipos and Merkel,[16] but the rate of digestion of I was found to be considerably low. This conclusion was compatible with the view given by Abita *et al.*[10] It should be noted that a similar promotion of hydrolysis of *N*-terminal undecapeptide of trypsinogen with calcium ion was also observed by Radhakrishnan *et al.*[11]

Experimental

Melting points were not corrected. Optical rotations were measured on a Yanagimoto Photometric Polarimeter OR-20 type. Paper chromatography and electrophoresis were carried out on Toyo Roshi No. 52 paper. Merck silica gel G was used for thin-layer chromatography. Developing solvents were *n*-butanol-acetic acid-pyridine-water (4 : 1 : 1 : 2, v/v) for paper and chloroform-methanol (5 : 1, v/v) for thin-layer except noted otherwise.

Z-Val-Gly-OBu^t (II). To a solution of Z-Val-Gly-OH[13] (2.53 g, 8.4 mmol) and sulfuric acid (0.3 m*l*) in methylene chloride (100 m*l*), isobutylene (10.7 g) was saturated at 0°C. The mixture in a vessel with a tight stopper was kept to stand for 2 days at room temperature and evaporated *in vacuo*. The residue was diluted with ethyl acetate (100 m*l*) and the solution was washed successively with water, 4% sodium bicarbonate solution and saturated sodium chloride solution, and then dried over sodium sulfate. It was evapo-

16) T. Sipos and J. R. Merkel, *Biochem. Biophys. Res. Commun.*, **31**, 522 (1968).

rated *in vacuo* and the crystals were collected by filtration with the aid of ether and petroleum ether. Recrystallization from ethyl acetate-ether-petroleum ether gave 2.64 g (86%); mp 146°C; $[\alpha]_D^{30}$ −4.2° (*c* 1, DMF), (Found: C, 62.92; H, 7.91; N, 7.68%). Savrda *et al.*[6] prepared II by the coupling of Z-valine *p*-nitrophenyl ester with H-Gly-OBu^t; mp 143.5—144.5°C; $[\alpha]_D^{20}$ −2.5±0.5° (DMF).

H-Val-Gly-OBu^t (III). A solution of II (2.55 g, 7 mmol) in ethanol (80 m*l*) was hydrogenated in the presence of palladium black. After removal of the catalyst, the filtrate was evaporated *in vacuo*; yield of an oil, 1.60 g (99%); R_f 0.90 on paper.

Z-Ile-Val-Gly-OBu^t (IV). This compound was prepared by the coupling of III with a mixed anhydride derived from Z-Ile-OH and isobutylchloroformate as described in literature;[17] yield, 67%; mp 164—166°C, $[\alpha]_D^{20}$ −7.9° (*c* 1, DMF) (Found: C, 62.73; H, 8.29; N, 8.62%). Savrda *et al.* reported essentially the same procedure; mp 169—171°C, $[\alpha]_D^{20}$ −9±0.5° (DMF).[6]

H-Ile-Val-Gly-OBu^t (V). A suspension of IV (1.67 g, 3.5 mmol) in ethanol (30 m*l*) was hydrogenated as described for III. Evaporation of the solvent gave oily product (1.26 g, 105%); R_f 0.95 on paper.

Z-Lys(ε-BOC)-Ile-Val-Gly-OBu^t (VI). Coupling of Z-Lys(ε-BOC)-OH with V *via* mixed anhydride procedure gave VI; yield, 91%; mp 202—203°C; $[\alpha]_D^{30}$ −16.9° (*c* 1, DMF) (Found: C, 61.03; H, 8.59; N, 9.85%); reported values mp 213—215°C and $[\alpha]_D^{22}$ −14.5±0.5° (DMF).[6]

Z-Asp(β-OBu^t)-Lys-(ε-BOC)-Ile-Val-Gly-OBu^t (VII). A mixture of VI (3.25 g, 4.6 mmol) in DMF (15 m*l*) was cooled at 0°C and hydrogenated. After hydrogen was passed for 15 min, chilled 0.39 N hydrogen chloride in methanol (13 m*l*, 5.1 mmol) was added. After the reaction had been completed, the filtrate from the catalyst was evaporated. The condensed DMF solution was used as it was in the next coupling. The hydrogenated tetrapeptide was coupled with 1.2 equivalent of mixed anhydride derived from Z-Asp(β-OBu^t)-OH.[18] Yield of VII, 91%; mp 211—212°C (decomp.); $[\alpha]_D^{30}$ −21.2° (*c* 0.8, DMF) (Found as hemihydrate: C, 59.67; H, 8.27; N, 9.58%); reported values, mp 226—228°C and $[\alpha]_D^{20}$ −17.5±0.5° (DMF).[6]

Z-[Asp(β-OBu^t)]$_2$-Lys(ε-BOC)-Ile-Val-Gly-OBu^t (VIII). A similar coupling procedure using 1.25 equivalent of the mixed anhydride gave VIII (84%); mp 208—212°C, $[\alpha]_D^{30}$ −22.6° (*c* 1, DMF) (Found as hemihydrate: C, 59.02; H, 8.26; N, 9.14%); reported values, 225—226°C and $[\alpha]_D^{18}$ −22.5±0.5° (DMF).[6]

Z-[Asp(β-OBu^t)]$_3$-Lys(ε-BOC)-Ile-Val-Gly-OBu^t (IX). A similar coupling procedure using 1.5 equivalent of the mixed anhydride gave IX (92%); mp 213—214°C (decomp.); $[\alpha]_D^{30}$ −23.4° (*c* 1, DMF) (Found: C, 59.40; H, 8.30; N, 9.28%); reported values mp 222—224°C and $[\alpha]_D^{23}$ −25.7±0.7° (DMF).[9]

Z-[Asp(β-OBu^t)]$_4$-Lys(ε-BOC)-Ile-Val-Gly-OBu^t (X). A similar procedure as described above gave X (93%); mp 211—213°C (decomp.); $[\alpha]_D^{30}$ −25.5° (*c* 1, DMF) (Found as hemihydrate: C, 58.42; H, 8.10; N, 9.17%); reported values, mp 224—225°C and $[\alpha]_D^{22}$ −28.9°±0.5° (DMF).[9]

BOC-Val-[Asp(β-OBu^t)]$_4$-Lys(ε-BOC)-Ile-Val-Gly-OBu^t (XI). A similar procedure using 1.5 equivalent of BOC-Val-OH gave XI (91%); mp 219—221°C (decomp.); $[\alpha]_D^{30}$ −27.8° (*c* 1, DMF) (Found for monohydrate: C, 57.07; H, 8.37; N, 9.66%); reported values, mp 249°C and $[\alpha]_D^{20}$ −29.2±0.5° (DMF).[9]

Homogeneity of XI was ascertained by column chromatography using Sephadex LH-20. A solution of XI (5 mg) in methanol (0.6 m*l*) was applied to a column (1.7×37 cm) of Sephadex LH-20, and the column was eluted with methanol at room temperature with a flow rate of one drop per 6 sec. Two milliliter fractions were collected, and a small amount of eluate in each test tube was spotted on a thin-layer plate. Compound on the plate was detected by spraying 47% hydrobromic acid and then ninhydrin. Only one peak (tube number 20—23) was obtained. The result showed the homogeneity of XI. Several di-Z derivatives of cyclic decapeptide were found to elute at the same position under similar experimental conditions.[19]

Nps-Val-Gly-OBzl (XII). To a chilled solution of Nps-Val-OH·DCHA salt[15] (18.1 g, 40 mmol) and H-Gly-OBzl·*p*-TsOH (13.5 g, 40 mmol) in chloroform (80 m*l*), DCC[20] (8.24 g) was added. The mixture was stirred for 3 hr at 0°C and allowed to stand overnight at room temperature. After removal of precipitate by filtration, the filtrate was evaporated and the residual oil was dissolved in ethyl acetate (100 m*l*). The solution was washed with 4% sodium bicarbonate solution, 10% citric acid and water, and dried over sodium sulfate. The filtrate was evaporated and the oily residue was solidified upon addition of petroleum ether. Recrystallization from ether-petroleum ether gave 15.9 g (96%); mp 97—98°C, $[\alpha]_D^{22}$ +52.5° (*c* 2, DMF); R_f 0.90 on thin-layer.

Found: C, 57.40; H, 5.45; N, 10.09%. Calcd for $C_{20}H_{23}O_5N_3S$: C, 57.55; H, 5.55; N, 10.07%.

Nps-Ile-Val-Gly-OBzl (XIII). A solution of XII (10.4 g, 25 mmol) in dioxane (60 m*l*) was treated with 2.5 N hydrogen chloride in dioxane (40 m*l*) at room temperature. After 1 hr the mixture was evaporated and the crystals were washed with ether by decantation. The dipeptide ester hydrochloride (XIIa) (7.70 g, 103%; R_f 0.65 on thin-layer) obtained was used in the next procedure without further purification. Into a solution of Nps-Ile-OH·DCHA salt[15] (11.7 g, 25 mmol), triethylamine (3.5 m*l*) and XIIa in chloroform (140 m*l*), was added DCC (5.15 g) at 0°C. Usual coupling procedure as described for XII gave crude crystals of XIII. The crystals were collected and recrystallized from DMF-dioxane-ethyl acetate. Yield, 11.4 g (86%); mp 185—186°C; $[\alpha]_D^{22}$ +20.0° (*c* 2, DMF); R_f 0.88 on thin-layer.

Found: C, 58.92; H, 6.45; N, 10.44%. Calcd for $C_{26}H_{34}O_6N_4S$: C, 58.85; H, 6.46; N, 10.56%.

Nps-Lys(ε-Z)-Ile-Val-Gly-OBzl (XIV). Compound XIII (8.50 g, 16 mmol) was treated with 2.5 N hydrogen chloride in dioxane to furnish tripeptide hydrochloride (XIIIa) in a similar manner as described

for XIII. Into a mixed anhydride of Nps-Lys(ε-Z)-OH[15] (7.51 g, 16.8 mmol) and isobutylchloroformate (2.18 ml) in tetrahydrofuran (100 ml), a solution of XIIIa (6.67 g, 16 mmol; R_f 0.71 on thin-layer) and triethylamine (2.24 ml) in DMF (120 ml) was added at −5°C. After being left overnight at room temperature, the solution was poured into water (1000 ml) and the precipitate deposited was collected by filtration, washed, and recrystallized from DMF-ethyl acetate. Yield, 11.4 g (90%); mp 223—225°C; $[\alpha]_D^{22}$ +23.0° (*c* 2, DMF); R_f 0.81 on thin-layer.

Found: C, 60.71; H, 6.62; N, 10.55%. Calcd for $C_{40}H_{52}O_9N_6S$: C, 60.59; H, 6.61; N, 10.60%.

Nps-Asp(β-OBzl)-Lys(ε-Z)-Ile-Val-Gly-OBzl (XV). Compound XIV (6.28 g, 7.9 mmol) was treated with 2.5 N hydrogen chloride in dioxane to give corresponding hydrochloride (XIVa). A solution of XIVa (4.99 g, 93%; R_f 0.61 on thin-layer) and triethylamine (1.02 ml) in DMF (55 ml) was added to a mixed anhydride of Nps-Asp(β-OBzl)-OH[15] (3.03 g, 8.04 mmol) in tetrahydrofuran (30 ml). The product was treated as described for the preparation of XIV. Recrystallization from DMF-ethyl acetate-ether gave 5.79 g (80%); 231—232°C; $[\alpha]_D^{22}$ −36.0° (*c* 1, HPT); R_f 0.88 on thin-layer.

Found: C, 61.38; H, 6.44; N, 9.77%. Calcd for $C_{51}H_{63}O_{12}N_7S$: C, 61.37; H, 6.36; N, 9.82%.

Nps-[Asp(β-OBzl)]$_2$-Lys(ε-Z)-Ile-Val-Gly-OBzl (XVI). A suspension of XV (4.24 g, 4.25 mmol) in DMF (120 ml) was treated with 2.5 N hydrogen chloride in dioxane (6.7 ml). The pale yellow crystals (3.74 g, 100%; R_f 0.74 on thin-layer) obtained were coupled with Nps-Asp(β-OBzl)-OH (1.93 g, 5.1 mmol) as described above. Recrystallization from dimethylsulfoxide-methanol-ether gave 4.02 g (79%); mp 222—223°C; $[\alpha]_D^{22}$ +15.6° (*c* 1, HPT); R_f 0.79 on thin-layer.

Found: C, 61.77; H, 6.49; N, 9.27%. Calcd for $C_{62}H_{74}O_{15}N_8S$: C, 61.88; H, 6.20; N, 9.31%.

Nps-[Asp(β-OBzl)]$_3$-Lys(ε-Z)-Ile-Val-Gly-OBzl (XVII). A solution of XVI (3.39 g, 2.82 mmol) in dimethylsulfoxide (10 ml) was treated with 2.5 N hydrogen chloride in dioxane (7.0 ml). The hexapeptide ester hydrochloride (3.06 g, 100%; R_f 0.59 on thin-layer) obtained was condensed with a mixed anhydride of Nps-Asp(β-OBzl)-OH (1.37 g, 3.64 mmol) in the usual manner. Recrystallization from dimethylsulfoxide-methanol gave 3.19 g (81%); mp 214—216°C; $[\alpha]_D^{22}$ +21.6° (*c* 1, HPT); R_f 0.88 on thin-layer.

Found: C, 61.97; H, 6.35; N, 9.09%. Calcd for $C_{73}H_{85}O_{18}N_9S$: C, 62.24; H, 6.08; N, 8.95%.

Nps-[Asp(β-OBzl)]$_4$-Lys(ε-Z)-Ile-Val-Gly-OBzl (XVIII). Compound XVII (1.15 g, 0.82 mmol) was treated with 2.5 N hydrogen chloride in dioxane; yield of hydrochloride (XVIIa), 1.06 g, 100%; R_f 0.64 on thin-layer. The crude product obtained from XVIIa and Nps-Asp(β-OBzl)-OH (433 mg, 1.15 mmol) was recrystallized from dimethylsulfoxide-methanol. Yield, 1.19 g (91%); mp 221—224°C; $[\alpha]_D^{22}$ +22.4° (*c* 1, HPT); R_f, 0.74 on thin-layer.

Found: C, 62.20; H, 6.44; N, 8.48%. Calcd for $C_{84}H_{96}O_{21}N_{10}S$: C, 62.52; H, 6.00; N. 8.68%.

Z-Val-[Asp(β-OBzl)]$_4$-Lys(ε-Z)-Ile-Val-Gly-OBzl (XIX). Compound XVIII (1.10 g, 0.68 mmol) was treated with 2.5 N hydrogen chloride as described above. The pale yellow powder (1.02 g, 100%; R_f 0.65 on thin-layer) obtained was coupled with Z-Val-OH (256 mg, 1.02 mmol). Recrystallization from DMF-ethyl acetate gave light yellow product; 1.06 g (92%); mp 241—243°C; $[\alpha]_D^{22}$ +27.6° (*c* 1, HPT); R_f 0.64 on thin-layer.

Found: C, 62.84; H, 6.25; N, 8.41%. Calcd for $C_{91}H_{108}O_{22}N_{10}\cdot 2H_2O$: C, 63.17; H, 6.52; N, 8.09%.

A solution of XIX (80 mg) in DMF (1 ml) was applied to a column (0.9×40 cm) with Sephadex LH-20. Elution was carried out with the same solvent at room temperature. The flow rate was one drop per 7 sec, and 1.5 ml fractions were collected; only one peak (tube number 8—12) was observed.

H-Val-[Asp]$_4$-Lys-Ile-Val-Gly-OH (I). *a. I·4H$_2$O from XIX.* A solution of XIX (100 mg, 59 μmol) in a mixture of acetic acid (12 ml), methanol (6 ml), and water (2 ml) was hydrogenated in the presence of palladium black at room temperature. The progress of the reaction was followed by paper electrophoresis. After some 40 hr, the filtrate from the catalyst was evaporated repeatedly, water being added. The precipitate which formed upon the addition of ethanol was collected and dried. The yield was 67 mg. Forteen milligram of this was dissolved in 0.5 M acetic acid and it was applied to a column (0.9×10 cm) of ECTEOLA cellulose, which had been equilibrated with 0.05 M acetic acid. The column was eluted with 0.05 M (50 ml), 0.1 M (50 ml), 0.2 M (25 ml), 0.3 M (25 ml) and 0.5 M acetic acid. The combined eluate from No. 15—No. 18 tubes (2 ml each) was evaporated repeatedly at room temperature, water being added. After ethanol was added to the residue, the precipitate deposited was collected after standing in a refrigerator for several hours; yield, 4.8 mg (40% from XIX); mp 292—295°C (decomp.); $[\alpha]_D^{22}$ +36.4° (*c* 0.5, water); R_f 0.12 on paper; amino acid ratios in acid hydrolysate, $Asp_{3.86}Gly_{1.03}Val_{1.95}Ile_{1.00}Lys_{1.06}$.[21]

Found: C, 45.91; H, 6.92; N, 13.21%. Calcd for $C_{40}H_{66}O_{18}N_{10}\cdot 4H_2O$: C, 45.88; H, 7.12; N, 13.37%. Savrda *et al.*[9] described the preparation of I without elemental analysis by the action of trifluoroacetic acid on XI.

b. I from XI. A solution of XI (73.6 mg, 50 μmol) in a mixture of trifluoroacetic acid (1 ml) and anisole (0.5 ml) was kept for 2 hr at room temperature and the solution was evaporated *in vacuo*. This procedure was repeated, and the dried residue weighed 61.6 mg. Fifty milligram of this was dissolved in 0.5 M acetic acid (0.8 ml) and the solution was applied to a column of ECTEOLA cellulose (0.9×18 cm) as described for the preparation of I from XIX. The eluate from No. 15—No. 20 tubes was evaporated, and the precipitate was collected with the aid of ethanol. It was recrystallized from water-ethanol; 13 mg (30%); R_f 0.12 on paper.

Nps-Asp(β-OBzl)-Lys(ε-Z)-OBzl (XXII). The compound was prepared from Nps-Asp(β-OBzl)-OH·DCHA salt (1.67 g, 3 mmol) and H-Lys(ε-Z)-OBzl-*p*-TsOH (1.63 g, 3 mmol) using DCC as described for the preparation of XII. Yield, 1.82 g (84%); mp 127—129°C; $[\alpha]_D^{22}$ −17.2° (*c* 1, DMF); R_f 0.91 on thin-layer.

Found: C, 62.58; H, 5.51; N, 7.83%. Calcd for $C_{38}H_{40}O_9N_4S$: C, 62.62; H, 5.53; N, 7.69%.

21) The authors are indebted to Mr. Kosaku Noda of this Laboratory for the amino acid analysis.

Nps-[Asp(β-OBzl)]$_2$-Lys(ε-Z)-OBzl (XXIII). Compound XXII (1.33 g, 1.82 mmol) was treated with N hydrogen chloride in dioxane (7.3 m*l*) for 1 hr. The mixture was evaporated and treated with ether. Colorless crystals (1.07 g, 96%; R_f 0.67 on thin-layer) obtained were coupled with Nps-Asp(β-OBzl)-OH (659 mg, 1.75 mmol) by the mixed anhydride procedure. Recrystallization from ethyl acetate-ether gave 1.40 g (84%); mp 137—138°C; $[\alpha]_D^{22}$ −1.4° (*c* 1, DMF); R_f 0.89 on thin-layer.

Found: C, 62.52; H, 5.42; N, 7.44%. Calcd for $C_{49}H_{51}O_{12}N_5S \cdot 1/2H_2O$: C, 62.41; H, 5.55; N, 7.43%.

Nps-[Asp(β-OBzl)]$_3$-Lys(ε-Z)-OBzl (XXIV). A solution of XXIII (1.78 g, 1.9 mmol) in N hydrogen chloride in dioxane (7.6 m*l*) was allowed to stand for 1 hr to give the tripeptide ester hydrochloride (1.29 g, 86%; R_f 0.79 on thin-layer), which was condensed with Nps-Asp(β-OBzl)-OH (746 mg, 1.97 mmol) as above. Yield, 1.61 g (89%); mp 123—125°C; $[\alpha]_D^{22}$ −25.0° (*c* 1, DMF); R_f 0.94 on thin-layer.

Found: C, 63.22; H, 5.50; N, 7.37%. Calcd for $C_{60}H_{62}O_{15}N_6S$: C, 63.25; H, 5.49; N, 7.38%.

Nps-[Asp(β-OBzl)]$_4$-Lys(ε-Z)-OBzl (XXV). Compound XXIV (365 mg, 0.32 mmol) was treated with hydrogen chloride as described above, and the corresponding hydrochloride (319 mg, 100%; R_f 0.67 on thin-layer) obtained was coupled with Nps-Asp(β-OBzl)-OH (196 mg, 0.52 mmol) as shown for XIV. Recrystallization from dioxane-ether gave 352 mg (82%); mp 143—145°C; $[\alpha]_D^{22}$ −32.0° (*c* 1, DMF); R_f 0.92 on thin-layer.

Found: C, 62.87; H, 5.39; N, 7.27%. Calcd for $C_{71}H_{73}O_{18}N_7S$: C, 63.42; H, 5.47; N, 7.29%.

Z-Val-[Asp(β-OBzl)]$_4$-Lys(ε-Z)-OBzl (XXVI). Nps group of compound XXV (310 mg, 0.23 mmol) was removed with hydrogen chloride in the usual manner, and the pentapeptide ester hydrochloride (XXVa, 250 mg, 0.205 mmol, R_f 0.97 on thin-layer) obtained was coupled with Z-Val-OH (75.4 mg, 0.3 mmol) by the mixed anhydride procedure. Recrystallization from dioxane-ethyl acetate gave pale yellow product; 258 mg (90%). A part (115 mg) of this product was applied to a column of Sephadex LH-20 (0.9×50 cm) using dioxane as a solvent. Fractions No. 7—No. 10 (2 m*l* each) were evaporated, and colorless crystals of XXVI were collected with the aid of ether. Recrystallization from dioxane-ether gave 94 mg (74% from XXVa); mp 151—158°C; $[\alpha]_D^{22}$ −37.0° (*c* 1, DMF); R_f 0.93 on thin-layer.

Found: C, 65.58; H, 5.96; N, 6.80%. Calcd for $C_{78}H_{88}O_{10}N_7$: C, 65.76; H, 6.01; N, 6.88%.

H-Val-[Asp]$_4$-Lys-OH (XX). A solution of XXVI (55 mg, 39 μmol) in a mixture of acetic acid (1.8 m*l*), methanol (0.9 m*l*), and water (0.3 m*l*) was hydrogenated in the presence of palladium black. After some 20 hr, the filtrate from the catalyst was evaporated repeatedly, water being added. The precipitate which formed upon the addition of ethanol was collected. Recrystallization from hot water-ethanol gave 24.7 mg (91%); mp 265—272°C(decomp.); $[\alpha]_D^{22}$ −38.0° (*c* 1, water); R_f 0.11 on paper; amino acid ratios in acid hydrolysate, $Asp_{3.91}Val_{1.00}Lys_{1.02}$[21])

Found: C, 43.16; H, 6.58; N, 12.99%. Calcd for $C_{27}H_{43}O_{15}N_7 \cdot 5/2\,H_2O$: C, 43.19; H, 6.45; N, 13.06%.

H-Ile-Val-Gly-OH (XXI). V from IV (0.5 mmol) was dissolved in trifluoroacetic acid (1.5 m*l*), and the solution was left to stand for 2 hr at room temperature and evaporated *in vacuo*. The residue dissolved in water (0.5 m*l*) was applied to a column of Dowex 50×8 (H^+ form, 0.9×7 cm). It was washed with water and eluted with 2 N ammonium hydroxide solution. The eluate was evaporated and the residue was collected with the aid of acetone. Recrystallization from water-acetone gave 122 mg (84%); mp 297—300°C (decomp.); $[\alpha]_D^{22}$ −16.0° (*c* 1, water); R_f 0.82 on paper.

Found: C, 53.77; H, 8.70; N, 14.53%. Calcd for $C_{13}H_{25}O_4N_3$: C, 54.33; H, 8.77; N, 14.62%.

Enzymatic Experiments. *a. Experimental Conditions.* Table 1 shows composition of reaction mixture used. Proceeding of enzyme reaction was followed

by means of paper chromatography of each reaction mixture during the course of time. Developing solvent system used was *n*-butanol-acetic acid-pyridine-water (15 : 3 : 10 : 12, v/v).

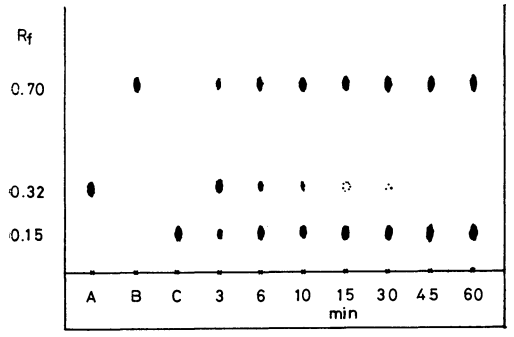

Fig. 6. Paper chromatograms of a reaction mixture of experiment No. 3 in Table 1. A, the nonapeptide I; B, the tripeptide XXI; C, the hexapeptide XX.

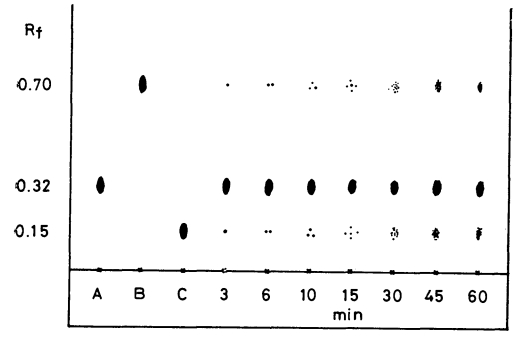

Fig. 7. Paper chromatograms of a reaction mixture of experiment No. 4. in Table 1.

b. Influence of Temperature Variation. Peptide I was digested with trypsin in the presence and absence of calcium ion at various temperatures. A comparison of the results of the experiments of No. 1—No. 6 indicates that the acceleration of hydrolysis with calcium was maximum at 47°C. Trypsin hydrolyzes peptide

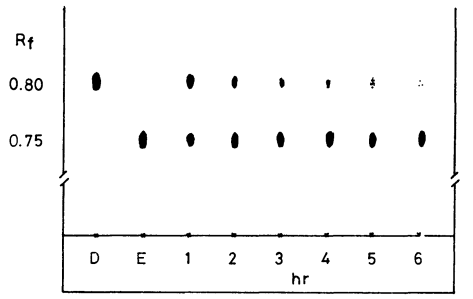

Fig. 8. Paper chromatograms of a reaction mixture of experiment No. 11 in Table 1. D, Bz-Arg-NH_2; E, Bz-Arg-OH.

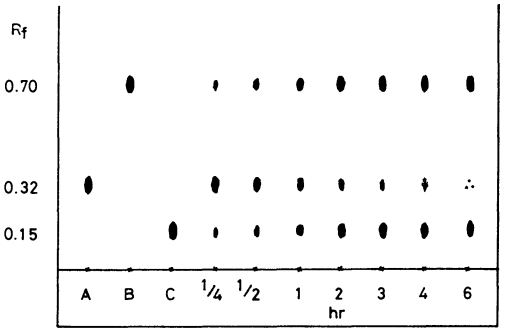

Fig. 9. Paper chromatograms of a reaction mixture of experiment No. 2 in Table 1.

I completely in 30 min with calcium (Fig. 6), but the hydrolysis was nearly inhibited without calcium (Fig. 7). At 30°C, complete digestion of I takes 2 hr and 6 hr in the presence and absence of calcium, respectively. At 0°C, peptide I disappeared after 14 hr with calcium, but it still remained after 19 hr without calcium.

c. Comparison of Hydrolysis Rates of I and Bz-Arg-NH_2. Experiments No. 7—No. 16 were carried out in order to compare the apparent rate of hydrolysis of I and Bz-Arg-NH_2, a typical synthetic substrate for trypsin. Experiment No. 11 (Fig. 8) showed that some one twentieth amount of trypsin was enough to hydrolyze Bz-Arg-NH_2 in the same time interval to hydrolyze I in experiment No. 2 (Fig. 9).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2920—2924 (1970)

Compounds Related to Acridine. VII.[1] The Synthesis of 9-Ethynylacridine and Its Reaction with *p*-Nitrosodialkylaniline

Otohiko Tsuge and Akiyoshi Torii

Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka

(Received March 13, 1970)

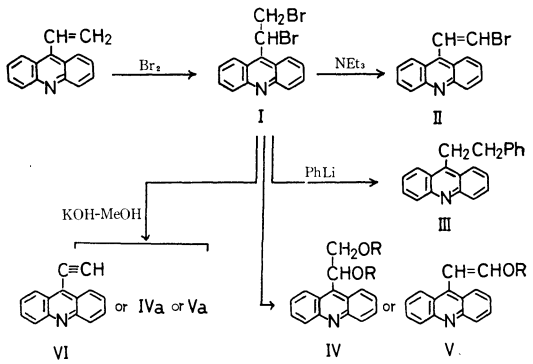
The dehydrobromination of 9-(1,2-dibromoethyl)acridine, which had easily been obtained by the bromination of 9-vinylacridine, to 9-ethynylacridine was attempted by several methods, and it has been established that this transformation can be effected in a 55% yield by the use of methanolic potassium hydroxide in dioxane. It has been found that the reaction of 9-ethynylacridine with *p*-nitrosodialkylaniline under the influence of hydrochloric acid in ethanol leads to the formation of the corresponding 1-(9-acridinyl)-1,2-bis(*p*-dialkylaminophenylimino)ethane N^1,N^2-dioxide. In addition, the configuration of the dioxide has also been proposed on the basis of spectroscopic studies and an inspection of the Dreiding models.

Previously, it has been found that hydrochloric acid (HCl) is an extremely effective catalyst for the condensation of acridine having an active methyl group with an aromatic nitroso compound.[2] Furthermore, even 9-ethylacridine reacts with two moles of *p*-nitrosodimethylaniline under the influence of HCl to give a mixture of 1-(9-acridinyl)-1,2-bis(*p*-dimethylaminophenylimino)ethane and its N^1-oxide.[3]

We decided to investigate the reactions of various acridine derivatives with aromatic nitroso compounds over a wider range. In the present work, several methods of the dehydrobromination of 9-(1,2-dibromoethyl)acridine to 9-ethynylacridine were studied, and a convenient synthetic method was established. It has been found that 9-ethynylacridine reacts with two moles of *p*-nitrosodialkylaniline to give 1-(9-acridinyl)-1,2-bis(*p*-dialkylaminophenylimino)ethane N^1,N^2-dioxide. In addition, the most reasonable configurations for the dioxide and for analogous compounds were decided upon.

Results and Discussion

Dehydrobromination Reactions of 9-(1,2-Dibromoethyl)acridine (I). No information has been available regarding the preparation and properties of 9-ethynylacridine (VI). The preparation of VI from 9-(1,2-dibromoethyl)acridine (I) which had easily been prepared by the bromination of 9-vinylacridine[1], by several manners was investigated, as is shown in Scheme 1.



Scheme 1

The acetylene VI was not obtained by the attempted dehydrobromination with triethylamine or phenyllithium. Instead, *trans*-1-(9-acridinyl)-2-bromoethylene (II) or 1-(9-acridinyl)-2-phenylethane (III) was obtained in a 97 or 57% yield in the respective reaction. The structures of II and III were confirmed by spectral studies as well as by elemental analyses.

Mitchell and Sondheimer[4] found that the dehydrobromination of 1,8-bis(1,2-dibromoethyl)-naphthalene to 1,8-diethynylnaphthalene in a 79% yield could be effected by the use of potassium *t*-butoxide in boiling *t*-butyl alcohol and dioxane.

However, the treatment of the dibromide I with several potassium alkoxides in the corresponding boiling alcohol and dioxane did not give the expected acetylene VI, but rather, 9-(1,2-dialkoxy-

3) O. Tsuge, M. Nishinohara and K. Sadano, *ibid.*, **38**, 2037 (1965).

4) R. H. Mitchell and F. Sondheimer, *Tetrahedron*, **24**, 1397 (1968).

ethyl)acridine (IV) or *trans*-1-(9-acridinyl)-2-alkoxyethylene (V) depending on the nature of the alkoxides; the reactions with methoxide, ethoxide, and *n*-propoxide gave the corresponding diether IVa—IVc respectively, while the treatment with *t*-butoxide afforded the vinylether Vb.

Although the dehydrobromination of the dibromide I to the acetylene VI caused such difficulties, it has been found that I reacted with methanolic potassium hydroxide in dioxane to give the corresponding diether IVa, *trans*-vinylether Va, or the expected acetylene VI, depending on the reaction conditions; the results are summarized in Table 1.

Table 1. Conditions and yields of products in the reaction of I with methanolic potassium hydroxide[a)]

MeOH:I mole ratio	Temp. (°C)	Time (min)	Yield (%) IVa	Va	VI
11:1	65	120	80	0	0
9:1	75—80	120	0	75	0
2:1	94—96	120	0	0	27
2:1	94—96	40	0	+[c)]	34
2:1	94—96	20	0	0	55
0[b)]	100	120	0	0	0

a) Mixtures of I (5.0 g), KOH (5.0 g), and specified amounts of MeOH were heated under definite conditions.
b) I was recovered.
c) A plus-sign, +, indicates a trace amount.

The data in Table 1 indicate that differences in the amounts of methanol result in serious differences. As the acetylene VI was proved to be a rather unstable substance, a considerable reduction in reaction time is desirable.

The structures of IV, V, and VI were confirmed by spectral studies as well as by elemental analyses. The infrared spectrum of VI showed the characteristic bands due to the ethynyl group at 3200 and 2130 cm^{-1}, while the NMR spectrum in deuteriochloroform ($CDCl_3$) exhibited signals at τ 5.8 (1H, ethynyl-proton, singlet) and 1.4—2.5 (8H, aromatic protons, multiplet).

Reaction of 9-Ethynylacridine (VI) with the Nitroso Compound VII. The reaction of VI with *p*-nitrosodimethylaniline (VIIa) was investigated under various conditions.

The acetylene VI did not react with VIIa in either the absence or presence of a basic catalyst such as potassium carbonate in ethanol, but the presence of HCl as a catalyst afforded the 1 : 2 adduct (VIIIa) ($C_{31}H_{29}O_2N_5$) as red prisms.

The effects of different amounts of HCl as a catalyst on the yield of VIIIa were also investigated; the results are shown in Table 2.

A similar reaction of VI with *p*-nitrosodiethylaniline (VIIb) gave the corresponding 1 : 2 adduct (VIIIb) as red needles. However, nitrosobenzene, *p*-methyl- or *p*-chloronitrosobenzene did not give the corresponding adduct under similar conditions; resinous materials were obtained exclusively in each case.

Table 2. Conditions and yields of VIIIa in the reaction of VI with VIIa[a)]

VI:VIIa mole ratio	HCl (m*l*)	Yield of VIIIa (%)
1:1	0.1	29
1:2	0.05	38
1:2	0.1	43
1:2	0.1	47[b)]
1:2	0.1	41[c)]
1:2	0.2	29
1:2	0.35	16

a) Reactions of VI (1.0 g) with specified amounts of VIIa and HCl (d^{27} 1.1748) were conducted in ethanol (15 m*l*) at room temperature for 2 hr.
b) Reaction temperature: 0°C.
c) Reaction time: 12 hr.

On the basis of the chemical transformations to the known compounds shown in Scheme 2, and on the basis of the spectroscopic evidence, the 1 : 2 adduct was established to be 1-(9-acridinyl)-1,2-bis(*p*-dialkylaminophenylimino)ethane N^1,N^2-dioxide (VIII).

The hydrolysis of VIIIa with 12% aqueous HCl afforded acridine-9-carbaldehyde (IX)[2)] in a 73% yield. When VIIIa was treated with cold 10% aqueous sulfuric acid, (9-acridinyl)formylmethylene-*p*-dimethylaminoaniline *N*-oxide (X),[3)] which was then subjected to decarbonylation to form (9-acridinylmethylene)-*p*-dimethylaminoaniline *N*-oxide (XI),[2)] was obtained in a 57% yield.

Furthermore, VIIIa was deoxygenated with triethyl phosphite to afford 1-(9-acridinyl)-1,2-bis(*p*-dimethylaminophenylimino)ethane (XII).[3)]

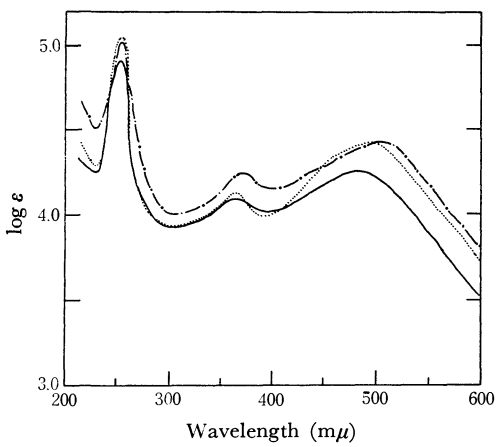

Fig. 1. Ultraviolet spectra in ethanol, VIIIa (——); VIIIb (—·—·); XIII (·····).

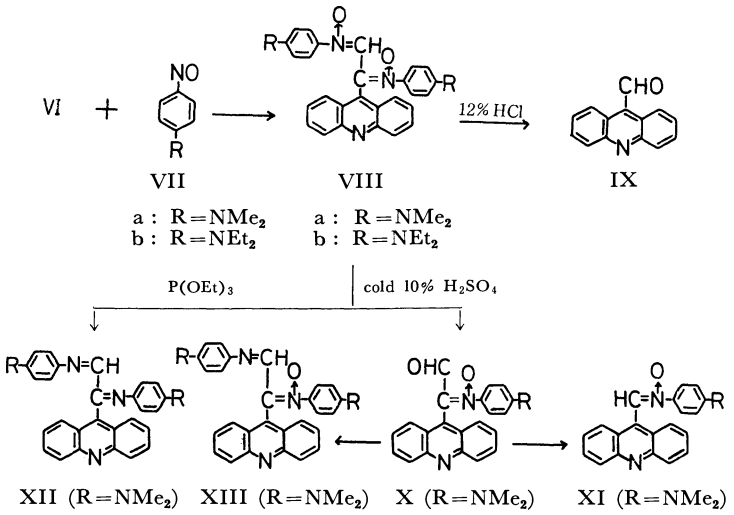

Scheme 2

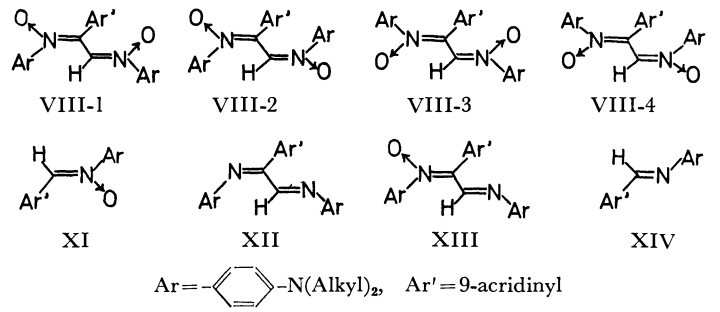

Fig. 2.

The condensation of X and *p*-dimethylaminoaniline gave 1-(9-acridinyl)-1,2-bis(*p*-dimethylaminophenylimino)ethane N^1-oxide (XIII).[3]

The spectral data of VIII are also compatible with the proposed structure. The ultraviolet (Fig. 1) and infrared spectra are very similar to those of XIII. The NMR spectrum of VIIIb in $CDCl_3$ showed signals at τ 9.12 and 8.78 (each 6H, methyl-protons, triplet), at τ 6.95 and 6.65 (each 4H, methylene-protons, quartet), at τ 1.7—4.2 (16H, aromatic protons), and at τ 0.87 (1H, methine proton).

Four geometrical isomers resulting from the *syn*- and *anti*-configurations are, then, possible for the structure of VIII (Fig. 2). An inspection of the Dreiding models for VIII indicates that there is an appreciable interaction between the acridine and phenyl rings in VIII-2—VIII-4, but not in VIII-1. Consequently, it may be thought that VIII-1 is the most favorable configuration for VIII.

Similar inspections of the Dreiding models for XI, XII, XIII, and (9-acridinylmethylene)-*p*-dimethylaminoaniline (XIV) indicate that the most favorable configurations for the above compounds are those shown in Fig. 2.

The NMR spectra in $CDCl_3$ showed the methine proton at τ 0.30, 0.33, 0.32, and 0.30 in XI, XII, XIII, and XIV respectively. Presumably, the appearance of the methine proton at an abnormally low field might be understood in terms of the deshielding effect of aromatic rings.[5] All the ultraviolet spectra of the compounds VIII and XI—XIV exhibited absorptions compatible with a long conjugated system.

The proposed configurations for the above compounds are supported by the above observations as well as by the inspections of the Dreiding models.

Experimental

All the melting points are uncorrected. The infrared spectra were measured in KBr disks, while the NMR spectra were determined at 60 MHz with a Hitachi R-20 spectrometer, using tetramethylsilane as the internal reference. The mass spectra were obtained on a Hitachi RMS-4 spectrometer at an electrode voltage of 70 eV.

5) J. F. King and T. Durst (*Can. J. Chem.*, **40**, 882 (1962)) have reported that the methine proton of benzylidenaniline appears at τ 1.65 in the NMR spectrum (carbon tetrachloride).

9-(1,2-Dibromoethyl)acridine (I). Into a solution of 2.0 g of 9-vinylacridine[1] in 20 m*l* of dry benzene, 1.6 g of bromine was added with stirring at 0°C. After the reaction mixture had then been stirred at room temperature for 20 min, filtration gave 3.45 g (quantitatively) of orange crystals. Recrystallization from ethanol afforded 9-(1,2-dibromoethyl)acridine(I) as orange prisms; mp 156—157°C (decomp.).

Found: C, 49.58; H, 2.72; N, 3.49%. Calcd for $C_{15}H_{11}NBr_2$: C, 49.31; H, 3.01; N, 3.84%.

The mass spectrum was also compatible with the dibromide I: parent peaks (M^+) at *m/e* 367, 365 and 363 (intensity 1 : 2 : 1); $(M-Br)^+$ at *m/e* 286 and 284 (intensity 1 : 1); $(M-2Br)^+$ at *m/e* 205 (base peak).

***trans*-1-(9-Acridinyl)-2-bromoethylene (II).** After a mixture of 1.5 g of the dibromide I in 5 m*l* of triethylamine had been refluxed for 4 hr, it was allowed to stand overnight, thus giving 1.15 g (97%) of yellow crystals. Recrystallization from benzene gave *trans*-1-(9-acridinyl)-2-bromoethylene (II) as pale yellow needles; mp 349—350°C (decomp.).

Found: C, 63.22; H, 3.21; N, 4.62%. Calcd for $C_{15}H_{10}NBr$: C, 63.38; H, 3.52; N, 4.92%. Infrared spectrum: 950 cm^{-1}. NMR spectrum in trifluoroacetic acid: τ 2.7 and 1.9 (each 1H, olefinic proton, doublet, J=14 Hz), 1.2—2.1 (8H, aromatic protons, multiplet).

1-(9-Acridinyl)-2-phenylethane (III). A solution of 3.0 g of the dibromide I and phenyllithium, which had been prepared from 7.5 g of bromobenzene and 0.7 g of lithium in 30 m*l* of diethyl ether, was stirred at 0°C for 40 min. After the reaction mixture had then been decomposed with ice water, the resulting mixture was extracted twice with 50-m*l* portions of benzene. The benzene extract was evaporated *in vacuo* to leave yellow crystals (mp 82—90°C), which were then dissolved in benzene. The benzene solution was chromatographed on alumina, affording 1.3 g (57%) of 1-(9-acridinyl)-2-phenylethane (III) as pale yellow needles; mp 100.5—101.5°C.

Found: C, 89.19; H, 6.14; N, 4.88%. Calcd for $C_{21}H_{17}N$: C, 89.01; H, 6.05; N, 4.94%. Mass spectrum: *m/e* 283 (M^+), 192 $[(M-C_7H_7)^+]$. NMR spectrum in carbon tetrachloride: τ 6.9—7.2 and 6.05—6.45 (each 2H, methylene-protons, multiplet), 1.65—2.8 (13H, aromatic protons, multiplet).

General Method for the Reaction of the Dibromide I with Potassium Alkoxide. *i*) Into a solution of 3.0 g of the dibromide I in 40 m*l* of dioxane was stirred, drop by drop and at room temperature, a methanolic solution of potassium methoxide, prepared from 4.4 g of potassium and 50 m*l* of methanol. After the reaction mixture had then been refluxed for 1 hr, the solvent was evaporated *in vacuo* to leave a residue, which was then quenched with water. The resultant mixture was extracted with 100 m*l* of diethyl ether, after which the ether extract was evaporated to leave a brown oily material which, on the chromatography of the benzene solution on alumina, gave 2.0 g of pale yellow crystals (mp 98.5—100°C). Recrystallization from petroleum benzine (bp 45—60°C) gave 9-(1,2-dimethoxyethyl)acridine (IVa), mp 101.5—102.5°C, as pale yellow prisms.

Found: C, 76.78; H, 6.52; N, 5.21%. Calcd for $C_{17}H_{17}O_2N$: C, 76.38; H, 6.41; N, 5.24%. Mass spectrum: *m/e* 235 $[(M-CH_3OH)^+]$, 220 $[(235-CH_3)^+]$, 192 $[(220-CO)^+]$. NMR spectrum in carbon tetrachloride: τ 6.75 (6H, methyl-protons, singlet), 6.25 (2H, methylene-protons, doublet), 5.3 (1H, methine-proton, triplet), 1.65—2.65 (8H, aromatic protons, multiplet).

A similar reaction of the dibromide I with potassium ethoxide or *n*-propoxide gave the corresponding diether.

9-(1,2-Diethoxyethyl)acridine (IVb): mp 65—66°C; yellow prisms. Yield, 83%. Found: C, 77.08; H, 7.26; N, 4.83%. Calcd for $C_{19}H_{21}O_2N$: C, 77.26; H, 7.17; N, 4.74%.

9-(1,2-Di-*n*-propoxyethyl)acridine (IVc): mp 71—72°C; yellow prisms. Yield, 78%. Found: C, 78.13; H, 8.14; N, 4.58%. Calcd for $C_{21}H_{25}O_2N$: C, 77.98; H, 7.88; N, 4.33%.

ii) Into a solution of 5.0 g of the dibromide I in 50 m*l* of dioxane was stirred, drop by drop and at room temperature, a solution of potassium *t*-butoxide, prepared from 5.5 g of potassium and 250 m*l* of *t*-butyl alcohol. After the reaction mixture had then been refluxed for 1 hr, a treatment similar to that described in *i*) was carried out; *trans*-1-(9-acridinyl)-2-*t*-butoxyethylene (Vb), mp 141.5—142.5°C, was thus obtained as yellow prisms. Yield, 3.4 g (87%).

Found: C, 82.44; H, 6.94; N, 4.97%. Calcd for $C_{19}H_{19}ON$: C, 82.28; H, 6.91; N, 5.05%. Infrared spectrum: 945 cm^{-1}. Mass spectrum: *m/e* 277 (M^+). NMR spectrum in carbon tetrachloride: τ 8.57 (9H, methyl-protons, singlet), 1.5—3.4 (10H, olefinic and aromatic protons).

Reaction of the Dibromide I with Methanolic Potassium Hydroxide. *i*) A solution of 5.0 g of the dibromide I and 5.0 g of potassium hydroxide in a mixture of methanol (7 g) and dioxane (2.5 m*l*) was heated, while being stirred, at 65°C for 2 hr, and then cooled. After water had been added to it, the mixture was extracted three times with 25-m*l* portions of ether. The ether solution was dried over sodium sulfate, and the ether was distilled off, leaving a brown oily material. The benzene solution was chromatographed on alumina, affording 2.9 g (80%) of pale yellow crystals; mp 99—101°C. Recrystallization from petroleum benzine (bp 45—60°C) gave pale yellow prisms, mp 101.5—102.5°C, whose infrared spectrum was identical with that of the diether IVa.

ii) A solution of 5.0 g of the dibromide I and 5.0 g of potassium hydroxide in a mixture of methanol (4 g) and dioxane (10 m*l*) was heated, while being stirred, at 75—80°C for 2 hr. A treatment similar to that described in *i*) gave a reddish-brown oily material from the ether extract. The benzene solution was chromatographed on alumina to give 2.4 g (75%) of yellow crystals, mp 123—125°C, which, on recrystallization from petroleum benzine (bp 45—60°C), afforded *trans*-1-(9-acridinyl)-2-methoxyethylene (Va), mp 125—126°C, as yellow needles.

Found: C, 81.65; H, 5.49; N, 5.64%. Calcd for $C_{16}H_{13}ON$: C, 81.68; H, 5.52; N, 5.95%. Mass spectrum: *m/e* 235 (M^+), 220 $[(M-CH_3)^+]$, 204 $[(M-OCH_3)^+]$. 192 $[(220-CO)^+]$. Infrared spectrum: 940 cm^{-1}.

iii) A solution of 5.0 g of the dibromide I and 5.0 g of potassium hydroxide in a mixture of methanol (1.0 g) and dioxane (2.5 m*l*) was heated, while being stirred, at 94—96°C for 20 min.

A similar treatment gave 1.5 g (55%) of brown crystals, mp 153—155°C (decomp.), from the ether extract. Recrystallization from benzene gave 9-ethynylacridine (VI), mp 157—158°C (decomp.), as yellow needles.

Found: C, 84.43; H, 4.70; N, 6.49%. Calcd for $C_{15}H_9N \cdot \frac{1}{2}H_2O$: C, 84.80; H, 4.71; N, 6.60%. Ultraviolet spectrum λ_{max}^{EtOH} mμ (log ε): 257 (5.3), 371 (4.1). Mass spectrum: *m/e* 203 (M^+).

The results of other reactions under varying conditions are shown in Table 1.

Reaction of the Acetylene VI with *p*-Nitrosodimethylaniline (VIIa). To a mixture of 0.3 g of the acetylene VI and 0.4 g of *p*-nitrosodimethylaniline (VIIa) in 5 m*l* of ethanol was added 0.03 m*l* of HCl at 0°C. The reaction mixture was then stirred at 0°C for 2 hr. Filtration gave 0.35 g (47%) of red crystals which, on recrystallization from pyridine, afforded 1-(9-acridinyl)-1,2-bis(*p*-dimethylaminophenylimino)-ethane N^1,N^2-dioxide (VIIIa), mp 217—218°C, as red prisms.

Found: C, 74.18; H, 5.91; N, 14.10%. Calcd for $C_{31}H_{29}O_2N_5$: C, 73.93; H, 5.80; N, 13.91%. Ultraviolet spectrum λ_{max}^{EtOH} mμ (log ε): 253 (4.9), 367 (4.1), 485 (4.3).

The results of other reactions under varying conditions are summarized in Table 2.

Reaction of the Acetylene VI with *p*-Nitrosodiethylaniline (VIIb). A similar reaction of 0.3 g of the acetylene VI with 0.53 g of *p*-nitrosodiethylaniline (VIIb) in the presence of HCl (0.03 m*l*) at 0°C for 2 hr gave the corresponding N^1,N^2-dioxide VIIIb, mp 190—191°C, as red needles. Yield, 0.41 g (50%).

Found: C, 75.54; H, 6.71; N, 12.16%. Calcd for $C_{35}H_{37}O_2N_5$: C, 75.10; H, 6.66; N, 12.31%. Ultraviolet spectrum λ_{max}^{EtOH} mμ (log ε): 254 (5.2), 368 (4.3), 505 (4.5).

Hydrolysis of the N^1,N^2-Dioxide VIIIa. *i*) A mixture of 0.2 g of the N^1,N^2-dioxide VIIIa in 2 m*l* of 12% aqueous HCl was heated at 90°C for 30 min, and then cooled. The precipitated crystals were collected and washed with ammonium hydroxide, giving 0.6 g (73%) of yellow crystals, mp 143—145°C. Recrystallization from a petroleum benzine-benzene mixture afforded yellow needles, mp 148°C. This compound was proved, by an admixed-mp determination and by a study of its infrared spectrum, to be identical with an authentic sample of acridine-9-carbaldehyde (IX), mp 147°C.[2]

ii) After 10 m*l* of 10% sulfuric acid had been added to 0.5 g of VIIIa under ice cooling, it was allowed to stand at 0°C for 30 min. Filtration gave dark yellow crystals which, when washed with ammonium hydroxide, afforded 0.2 g (57%) of orange crystals. Recrystallization from benzene gave orange needles, mp 206—207°C (decomp.), which were proved, by a study of their infrared spectrum, to be identical with an authentic sample of (9-acridinyl)formylmethylene-*p*-dimethylaminoaniline *N*-oxide (X), mp 208°C (decomp.).[3]

Decarbonylation of (9-Acridinyl)formylmethylene-*p*-dimethylaminoaniline *N*-Oxide (X). A suspension of 0.1 g of X and 1 drop of 20% aqueous sodium hydroxide in 5 m*l* of ethanol was refluxed for 3 hr. After the mixture had then been allowed to stand overnight, filtration gave 60 mg (67%) of red crystals. Recrystallization from pyridine gave red prisms, mp 243°C (decomp.). This compound was proved, by a study of its infrared spectrum, to be identical with (9-acridinylmethylene)-*p*-dimethylaminoaniline *N*-oxide (XI), mp 243°C (decomp.).[2]

Reaction of the N^1,N^2-Dioxide VIIIa with Triethyl Phosphite. A mixture of 0.22 g of VIIIa and 2.0 g of triethyl phosphite was gently refluxed under a nitrogen atmosphere for 10 hr. After the mixture had then been allowed to stand overnight, the precipitated crystals were filtered off and then washed with ethanol to give 0.1 g (50%) of red crystals.

Recrystallization from pyridine gave red prisms, mp 282—283°C (decomp.). These were proved, by a study of their infrared spectrum, to be identical with an authentic sample of 1-(9-acridinyl)-1,2-bis(*p*-dimethylaminophenylimino)ethane (XII), mp 283°C (decomp.).[3]

1-(9-Acridinyl)-1,2-bis(*p*-dimethylaminophenylimino)ethane N^1-Oxide (XIII). A mixture of 0.1 g of X, 0.2 g of *p*-dimethylaminoaniline, and 1 drop of acetic acid in 5 m*l* of ethanol was refluxed for 2 hr, and then cooled. Filtration gave 0.1 g (75%) of red crystals which, on recrystallization from benzene, afforded red prisms, mp 263—264°C (decomp.). This compound was proved, by a study of its infrared spectrum, to be identical with 1-(9-acridinyl)-1,2-bis(*p*-dimethylaminophenylimino)ethane N^1-oxide (XIII), mp 265°C (decomp.).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2925—2933 (1970)

The Cyclization of Ethyl Cyanoacetate and Salicylaldehyde or 3-Methoxysalicylaldehyde with Ketones by Means of Ammonium Acetate

Akio SAKURAI and Hiroshi MIDORIKAWA

and Yasuo HASHIMOTO

Tokyo Electrical Engineering College, Nishikicho, Chiyoda-ku, Tokyo

(Received March 26, 1970)

Various substituted benz[*f*]isoquinolines were readily prepared by the condensation of ethyl cyanoacetate and salicylaldehyde or 3-methoxysalicylaldehyde with aliphatic ketones (acetone, diethyl ketone, methyl pentyl ketone, methyl isopentyl ketone, *etc.*) or aromatic ketones (acetophenone, *o*-hydroxyacetophenone, *m*-nitroacetophenone, propiophenone, *etc.*) in the presence of ammonium acetate. On the other hand, condensation with cyclic ketones such as cyclopentanone and cyclohexanone gave benz[*f*]cyclopent[*c*]isoquinolines and benzo[*k*]phenanthridines respectively.

Previous papers have shown that ethyl cyanoacetate condensed with ketones[1] (aliphatic methyl, aromatic, cyclic, and α,β-unsaturated) or aldehydes[2] (salicyl and 3-methoxysalicyl) in the presence of ammonium acetate to afford substituted pyridones, quinolines (from ketone), and benzo[*h*]quinazolines (from aldehyde).

The present paper will deal with the syntheses of 6-oxabenz[*f*]isoquinoline, 7-oxabenz[*f*]-2,3-dihydro-1*H*-cyclopent[*c*]isoquinoline, and 8-oxa-1,2,3,4-tetrahydrobenzo[*k*]phenanthridine derivatives by the condensation of ethyl cyanoacetate, salicylaldehyde, or 3-methoxysalicylaldehyde, and a variety of ketones in the presence of ammonium acetate.

The reaction of ethyl cyanoacetate and salicylaldehyde or 3-methoxysalicylaldehyde with ketones was carried out by heating a mixture of ester, aldehyde, ketone, and ammonium acetate (molar ratio 1 : 1 : 1 : 1—1.5) in ethanol. In this case (Scheme 1), the dehydration of the amino group of I and the carbonyl group of ketone, cyclization between the methyl or methylene group of the ketone and the 4-position of the coumarin ring, and subsequent dehydrogenation took place to form 2- or 1,2-disubstituted-4-amino-5-oxo-6-oxabenz[*f*]isoquinolines (II).

When salicylaldehyde was heated with ethyl cyanoacetate and ammonium acetate in ethanol for few minutes, a crystalline product was obtained. Its infrared spectrum exhibited no characteristic absorption for a C≡N group. When dissolved in dilute hydrochloric acid, this substance afforded pale yellow needles. This compound was confirmed as the HCl salt of 3-amidinocoumarin (Ia) on the basis of elemental analysis and its infrared spectrum. Furthermore, when heated with ketones and ammonium acetate in ethanol, crude Ia gave compounds of the types II and V. The cyclization reaction in the present study, therefore, can reasonably be explained in terms of a two-step condensation. Ethyl cyanoacetate and salicylaldehyde condensed to give 3-cyanocoumarin, which in turn converts readily to 3-amidinocoumarin. Then, 3-amidinocoumarin condenses with ketones to give heterocyclic compounds of the types II, IV, and V. When 3-methoxysalicylaldehyde was used instead of salicylaldehyde, the condensation afforded the corresponding methoxy derivatives. The structural assignment of these products was based on the infrared and NMR spectra (Tables 3 and 5). For example, the NMR spectrum of IIa (prepared when acetone was employed as the ketone reactant) showed only a methyl singlet at 2.8 ppm corresponding to three protons in a higher field than the aromatic-ring region. This fact indicated that one methyl group of acetone was involved in this cyclization. In the infrared spectra of II, carbonyl and amino stretching bands shifted to slightly lower frequencies because of the presence of intramolecular C=O···H_2N bonding. The structure of the type II was further supported by the fact that the compound obtained by the condensation of 3-amidinocoumarin (Ia) and methyl *n*-propyl ketone in the presence of ammonium acetate was found to be

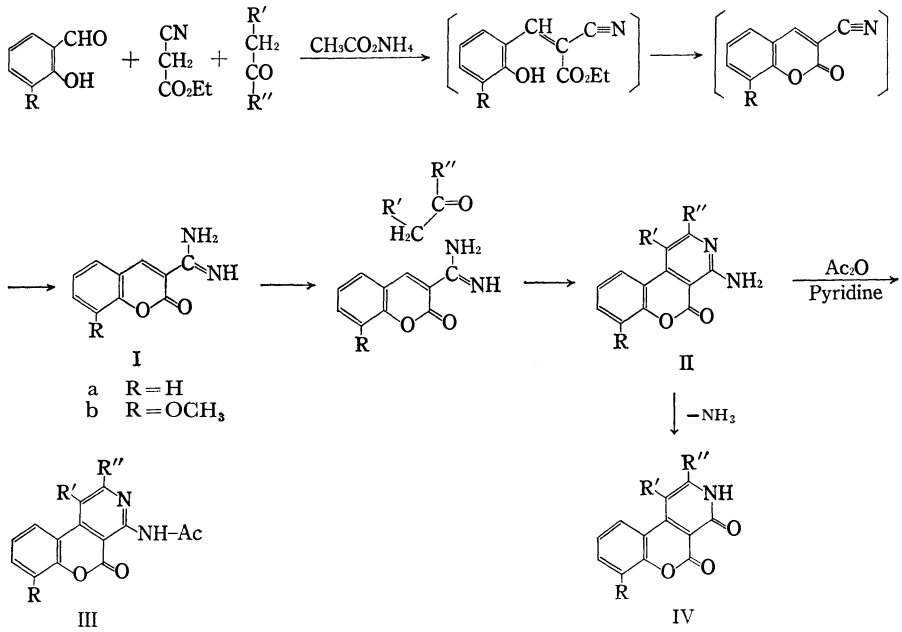

Scheme 1

identical with IIc by a comparison of their melting points and by infrared and elemental analyses.

The reaction of ethyl cyanoacetate and 3-methoxysalicylaldehyde with methyl isobutyl ketone gave a mixture of 4-amino-2-isobutyl-7-methoxy-5-oxo-6-oxabenz[*f*]isoquinoline (IIo) as the main product, plus a small ammount of 2-isobutyl-7-methoxy-5-oxo-6-oxabenz[*f*]-1(2*H*)-isoquinolone (IVa). In the infrared spectrum of IVa, the carbonyl band (5-position) shifted to higher frequencies (1750 cm^{-1}) than that of IIo, and a new, strong band appeared at 1640 cm^{-1}. This band was characteristic of a pyridone- or quinolone-type carbonyl. When methyl ethyl ketone was employed as the ketone reactant, two products, melting at 173 and 218°C, were isolated. Their elemental analyses indicated the formula of $C_{14}H_{12}O_2N_2$. NMR spectrum of the former (mp 173°C) exhibited a triplet corresponding to three protons (CH_3) and a quartet corresponding to two protons (CH_2). On the other hand, the latter (mp 218°C) showed only a singlet corresponding to six protons (CH_3). On the basis of these data, it seemed reasonable to assume the two structures of IIb and IIr for them, as is indicated below. The ratio of the formation of IIb to IIr was about 1 : 0.5, while that of III to IIu was about 1 : 1 (Scheme 2).

Reaction with ketones such as methyl nonyl ketone or methyl *s*-butyl ketone gave products, but in poor yields. However, methyl *t*-butyl, di-*n*-propyl, diisopropyl, or diisobutyl ketones gave no corresponding compounds of the type II.

Reaction with cyclic ketones (Scheme 3) proceeded much as in the case of the reaction with the straight-chain ketones described above. In

VIa		2.7(s, 3H)		2.3—2.9(m, 2H) 3.3—4.1(m, 4H)		7.2—8.1(m, 4H)	12.75(br, 1H)

a) Parts per million downfield from tetramethylsilane in CF_3CO_2H; s=singlet, d=doublet, t=triplet, q=quartet, qi=quintet, sx=sextet, sp=septet, m=multiplet, br=broad.

this case, cyclization occured between the methylene group adjacent to the carbonyl group of the ketone and the 4-position of the coumarin ring to form 5-amino-6-oxo-7-oxabenz[*f*]-2,3-dihydro-1*H*-cyclopent[*c*]isoquinoline (Va) (from cyclopentanone) and 6-amino-7-oxo-8-oxa-1,2,3,4-tetrahydrobenzo[*k*]phenanthridine (Vb) (from cyclohexanone). These structures were supported by a study of the infrared and NMR spectra (Tables 3 and 5). In addition, a product obtained by the condensation of Ia and cyclohexanone was identified with Vb. Reaction with methyl aryl ketones (Scheme 1) gave 4-amino-2-aryl-5-oxo-6-oxabenz[*f*]isoquinolines (IIv-y). On the other hand, the use of acetophenone or *p*-methoxyacetophenone as the ketone reactant afforded 2-aryl-5-oxo-6-oxabenz[*f*]-1(2*H*)-isoquinolones (IVb-d) as the main product under the same reaction conditions. The infrared spectra of IVb-d have strong bands at about 1750 and 1640 cm^{-1}. The former band shifted to frequencies higher by from 50 to 60 cm^{-1} than those of the compounds II. This fact shows the absence of intramolecular hydrogen bonding in the structure of the type IV, since the latter band (1640 cm^{-1}) can be attributed to the carbonyl group (4-position) of the quinolone type.

The reaction of ethyl cyanoacetate and salicylaldehyde with propiophenone gave 4-amino-1-methyl-5-oxo-2-phenyl-6-oxabenz[*f*]isoquinoline (IIz). The NMR spectrum revealed only a singlet corresponding to three protons (CH_3) in the high field. It is clear that the cyclization occurred between the methylene group of the ketone and the coumarin ring. The acetylation of the compounds of the types II and V, when treated with acetic anhydride in pyridine, afforded monoacetyl derivatives (III) and (VI) respectively (Table 2), while a diacetamino derivative was obtained from IIz under the same reaction conditions as produced those of the compounds III and VI.

Experimental

All the melting points are uncorrected. The infrared spectra were recorded on a Perkin-Elmer Model 521 grating spectrophotometer by means of potassium bromide pellets. The NMR spectra were obtained using a JNM-C-60 spectrometer; the peak positions are reported in δ values (parts per million downfield from tetramethylsilane).

Reaction of Ethyl Cyanoacetate and Salicylaldehyde. To a solution of ethyl cyanoacetate (4.52 g, 0.04 mol) and salicylaldehyde (4.88 g, 0.04 mol) in ethanol (5 m*l*), ammonium acetate (3.08 g, 0.04 mol) was added and heated for several minutes. The resulting crystals were filtered to give 4.8 g of crude 3-amidinocoumarin (Ia). When this crude Ia (3 g) was dissolved in dilute hydrochloric acid and allowed to stand at room temperature, pale yellow needles were formed. Recrystallization from ethanol afforded 1.5 g of 3-amidinocoumarin hydrochloride melting at 264—266°C (dec); ν_{max}^{KBr} 3390 (=NH), 3320, 3200 (NH_2), 1720 (C=O), 1670 (C=N), 1645 (δ NH_2), 1610, 1575, 1535 (ring); NMR {$(CD_3)_2SO$}, 7.4—8.0 (m, 4H, ring), 8.95 (s, 1H, ring), 9.6 ppm (br, 3H, NH_2 and =NH).

Found: C, 53.35; H, 4.01; N, 12.56; Cl, 16.20%. Calcd for $C_{10}H_8O_2N_2 \cdot HCl$: C, 53.46; H, 4.01; N, 12.47; Cl, 15.80%.

Reaction of Ethyl Cyanoacetate and 3-Methoxysalicylaldehyde. To a solution of ethyl cyanoacetate (2.26 g, 0.02 mol) and 3-methoxysalicylaldehyde (3.04 g, 0.02 mol) dissolved in ethanol (7 m*l*), ammonium acetate (1.51 g, 0.02 mol) was added. After the reaction mixture had been heated for several minutes, 3.4 g of 8-methoxy-3-amidinocoumarin (Ib) were obtained. When this crude Ib (1 g) was dissolved in dilute hydrochloric acid and allowed to stand at room temperature, a pale yellow precipitate was formed. It was then recrystallized from ethanol to afford 0.7 g of 8-methoxy-3-amidinocoumarin hydrochloride; mp 250°C (dec.).

Found: C, 51.53; H, 4.54; N, 10.87; Cl, 13.62%. Calcd for $C_{11}H_{10}O_3N_2 \cdot HCl$: C, 51.89; H, 4.32; N, 11.00; Cl, 13.92%.

Reaction of 3-Amidinocoumarin (Ia) and Methyl *n*-Propyl Ketone. A mixture of Ia (2 g), methyl *n*-propyl ketone (1 g), and ammonium acetate (1 g) in ethanol (3 m*l*) was heated for 1 hr. After cooling, the resulting precipitate was collected and recrystallized from ethanol-glacial acetic acid to give 1.1 g of colorless needles, mp 173—174°C, this substance was found to be identical with IIc by the elemental analyses and by a study of the infrared spectral data.

Reaction of 3-Amidinocoumarin (Ia) and Cyclohexanone. A mixture of Ia (2 g), cyclohexanone (1 g), and ammonium acetate (1 g) in ethanol (3 m*l*) was heated for 1 hr. A pale yellow crystalline matter precipitated out during the reaction; this was collected and recrystallized from glacial acetic acid to afford 0.8 g of pale yellow crystals, mp 225—227°C. This substance was proved to be identical with Vb by a study of their infrared spectra and by the results of elemental analyses.

Reaction of Ethyl Cyanoacetate and Salicylaldehyde or 3-Methoxysalicylaldehyde with Ketones. To a mixture of ethyl cyanoacetate (0.01 mol), salicylaldehyde or 3-methoxysalicylaldehyde (0.01 mol), and ketone (0.01 mol) in ethanol (3 m*l*), ammonium acetate (0.01—0.02 mol) was added, and the new mixture was refluxed for 0.5—2 hr. A crystalline compound precipitated out during the reaction or after the reaction mixture had been allowed to stand at room temperature. The experimental results and spectral data are summarized in Tables 1, 3, and 5. The molecular weight, as determined by means of high-resolution mass spectrometry, exhibited the following values: IIa, 226 (calcd for $C_{13}H_{10}O_2N_2$, 226.23), IIb, 240 (calcd for $C_{14}H_{12}O_2N_2$, 240.25), IId, 254 (calcd for $C_{15}H_{14}O_2N_2$, 254.27), IIr, 240 (calcd for $C_{14}H_{12}O_2N_2$, 240.25), IIs, 254 (calcd for $C_{15}H_{14}O_2N_2$, 254.27), Vb, 266 (calcd for $C_{16}H_{14}O_2N_2$, 266.29), IIv, 304 (calcd for $C_{18}H_{12}O_3N_2$, 304.29), IVb, 289 (calcd for $C_{18}H_{11}O_3N$, 289.28), IVd, 319 (calcd for $C_{19}H_{13}O_4N$, 319.3).

Acetylation of the Compounds II and V by Acetic Anhydride in Pyridine. To a solution of II or V (0.001 mol) dissolved in pyridine (2—4 m*l*), acetic anhydride (4—6 m*l*) was added, after which the

mixture was refluxed for 2—4 hr. After being cooled, the deposited precipitate was collected and washed with dilute methanol. The experimental results and spectral data are summarized in Tables 2, 4, and 6.

Acetylation of IIz. Acetic anhydride (7 m*l*) was added to a solution of IIz (0.5 g) dissolved in pyridine (4 m*l*), after which the mixture was refluxed for 4 hr. After cooling, ice water was added to the reaction mixture to afford a crystalline precipitate. The precipitate was collected, washed with cold dilute methanol, and dried. Recrystallization from glacial acetic acid gave 0.6 g of 4,4-diacetylamino-1-methyl-5-oxo-2-phenyl-6-oxabenz[*f*]isoquinoline, mp 205—207°C; ν_{max}^{KBr} 1740 (O–C=O), 1710, 1695 (CH_3–C=O), 1610, 1590, 1560, 1530 (hetero ring and phenyl), 775, 705 (δ CH); NMR (CF_3CO_2H) peaks at 2.35, 2.65 (s, 3H each, CO–CH_3), 3.0 (s, 3H, CH_3), 7.5—8.0 and 8.55—8.8 ppm (m, 9H, ring).

Found: C, 71.51; H, 4.75; N, 7.31%. Calcd for $C_{23}H_{18}O_4N_2$: C, 71.49; H, 4.70; N, 7.25%.

The authors wish to express their thanks to Dr. Taro Hayashi and Dr. Tatsuo Takeshima for their kind advice. Thanks are also due to Dr. Haruo Homma and his staff for their microanalyses, to Mr. Jun Uzawa for his measurements of the NMR spectra, and to Mr. Hironori Ogawa for his measurements of the infrared spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2933—2937 (1970)

Oxidation of *N,N'*-Diarenesulfonylhydrazines

Yoshio KOHARA, Michio KOBAYASHI and Hiroshi MINATO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo

(Received March 30, 1970)

N,N'-Diarenesulfonylhydrazine was oxidized with several oxidizing regents, but diarenesulfonyl diimide was not isolated. Diarenesulfonyl diimide produced immediately decomposed with evolution of 1 mol of nitrogen, and afforded the corresponding sulfonyl bromide, α-disulfone and sulfonic acid. Plausible mechanisms of decomposition were discussed.

By the analogy with other azo compounds such as azobisisobutyronitrile[1] and dibenzoyl diimide,[2] diarenesulfonyl diimide, $RSO_2N{=}NSO_2R$, is expected to decompose to form sulfonyl free radicals with liberation of nitrogen. Waters *et al.* made a study of the reactions of sulfonyl free radicals generated by photolysis of sulfonyl iodide.[3] Recently, Kwart and Khan reported the isolation of dibenzenesulfonyl diimide (I) by oxidation of the corresponding hydrazine (II).[4] We have been interested in the reactions of sulfonyl radicals, and attempted to produce diarenesulfonyl diimides according to their method. However, our experimental findings differ from theirs, and the diimides formed immediately decomposed in repeated experiments under various conditions. This paper will describe the results of careful products analyses and discuss the plausible mechanisms of its decomposition.

Results and Discussion

Formation of *N,N'*-di-*p*-toluenesulfonyl diimide (III) was attempted by oxidation of *N,N'*-di-*p*-toluenesulfonylhydrazine (IV) with bromine in anhydrous ethyl alcohol or aqueous acetonitrile according to the method of Kwart and Khan.[4] When an excess of bromine was dropped to the solution, 1 mol of nitrogen was instantaneously evolved and III was not isolated. Similarly, the oxidation of II resulted in evolution of 1 mol of nitrogen, and I was not isolated. Even when IV was oxidized at −40°C with bromine, the evolution of nitrogen was instantaneous. These experiments indicate that the azo compounds I and III are too unstable to be isolated as such.

Products of decomposition of I and III were analyzed. Products found were arenesulfonyl bromide, diaryl disulfone, arenesulfonic acid, and, in the case of decomposition in ethyl alcohol, ethyl arenesulfonate, as shown in Scheme 1. Amounts of these products produced under various conditions are shown in Tables 1 and 2.

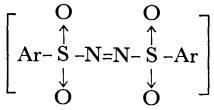
$$ArSO_2NH\text{-}NHSO_2Ar \xrightarrow[\text{aq. } CH_3CN \text{ or anhyd. EtOH}]{Br_2}$$



$$\longrightarrow N_2 + ArSO_2Br + ArSO_2\text{-}SO_2Ar$$
$$ArSO_3H + ArSO_2OEt \text{ (in EtOH)}$$

In the oxidation of II with bromine in aqueous acetonitrile and anhydrous ethyl alcohol, diphenyl disulfone was produced. Its melting point was 188—189°C, which is similar to that of diphenylsulfonyl diimide (193—194°C) reported by Kwart and Khan.[4] Diphenyl disulfone absorbed at 1300, 1325, 1345 cm^{-1} ($\nu_{as}SO_2$), 1130 cm^{-1} (ν_s-SO_2), 1580 and 1445 cm^{-1} (phenyl) in the infrared (KBr disc). Its mass spectrum (m/e) was quite similar to that reported for dibenzenesulfonyl diimide.

Various azo compounds, R–N=N–R′, are known; for instance, R=R′= PhCO,[2] R=R′= $(CH_3)_2$-CCN,[1] R=$PhSO_2$, R′=Ph,[5] and R=R′=Ph_2-CH.[6] In general, the more stabilized are the radicals R and R′, the more unstable is the azo compound. Sulfonyl radical is a very stable radical, and its stability is demonstrated by the fact that it does not attack a benzene ring.[3a] In view of these data, it is rather surprising that I is isolated and its melting point is as high as 193°C.

It was not possible to oxidize IV with bromine in anhydrous acetonitrile, and the starting materials were recovered. IV was not oxidized with bromine in acetonitrile under irradiation of light, and the starting materials were also recovered. Therefore, the presence of water is necessary for oxidation of diarenesulfonylhydrazines. The oxidizing species is probably the HOBr formed by the reaction of bromine and water.

IV was oxidized with chloranil, NBS (*N*-bromosuccinimide) or potassium permanganate, and di-*p*-tolyl disulfone was formed with evolution of nitrogen, as shown in Table 3. The presence of water is necessary for the oxidation of IV with NBS, as in the case with bromine. When a solution of IV and BPO (benzoyl peroxide) or AIBN (azobisisobutyronitrile) in acetonitrile was refluxed, IV was recovered. Therefore, dehydrogenation of IV to III could not be accomplished with such radicals as bromine atom, $PhCO_2\cdot$, or $(CH_3)_2\dot{C}CN$.

Waters *et al.* reported that sulfonyl radicals tended to disproportionate according to the equation;

$$6\ ArSO_2\cdot \longrightarrow 2\ (ArSO_2)_2O + ArSSO_2Ar$$

They verified the formation of $ArSO_2\cdot$ radicals by scavenging them with quinones, which converted

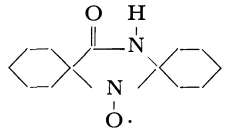
the radicals into sulfonates of quinols.[3b] However, in our conditions, no thiolsulfonate was found. When IV was oxidized with bromine in the presence of excess *p*-benzoquinone in aqueous acetonitrile, disulfonate of hydroquinone, which was a possible product from sulfonyl radical and *p*-benzoquinone, was not detected. Attempts to scavenge the free sulfonyl radicals by cyclohexane-1-spiro-2'-(4'-oxoimidazolidine-1'-oxyl)-5'-spiro-1'-cyclohexane (V), which was stable under the reaction conditions, was also unsuccessful.



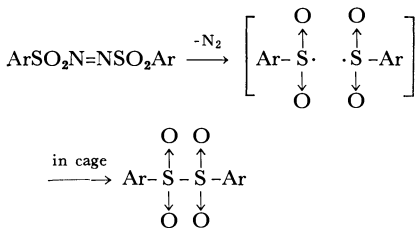
(V)

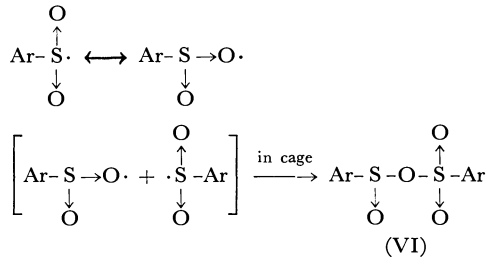
When IV was oxidized with bromine in aqueous acetonitrile in the presence of benzene or nitrobenzene, *p*-tolyl phenyl sulfone or *p*-tolyl nitrophenyl sulfone was not found. When IV was oxidized with NBS or potassium permanganate in the presence of toluene, neither *p*-tolyl benzyl sulfone nor *p*-toly tolyl sulfone was detected. These findings show that *p*-toluenesulfonyl radical does not attack benzene rings and does not abstract benzyl hydrogens.

When arenesulfonyl radicals were produced by the photolysis of arnenesulfonyl iodide, the reaction between two sulfonyl radicals always yielded a sulfinyl sulfonate (VI) without being accompanied by the formation of a disulfone.[3b] Therefore, the formation of a disulfone in our conditions can be rationalized only in terms of the recombination in a solvent cage. Oxidation of *N*-benzenesulfonyl-*N'*-*p*-toluenesulfonylhydrazine (VII) with bromine in aqueous acetonitrile gave phenyl *p*-tolyl disulfone free from any cross products, namely diphenyl disulfone or di-*p*-tolyl disulfone. This fact also supports our assumption that disulfones are the products of the recombination of the geminate sulfonyl radical pair.

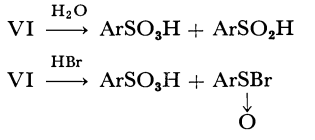
Formation of other products can be explained by the reaction steps shown below.

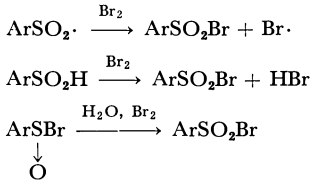
Mechanism I

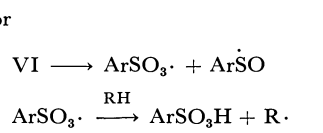


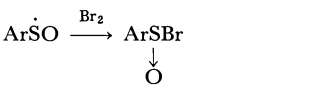


(VI)

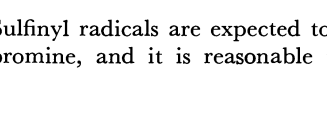








or



Sulfinyl radicals are expected to react readily with bromine, and it is reasonable that thiosulfonate,

the disproportionation product of sulfinyl radicals, was not found in our conditions. For oxidation of II and IV more than one mole of bromine per mole of disulfonylhydrazines had to be added for evolution of the quantitative amount of nitrogen. Undoubtedly part of bromine added was used for oxidation of species containing sulfinyl sulfur. Ethyl arenesulfonate was formed as below.

$$\mathrm{VI} \xrightarrow{\mathrm{EtOH}} \mathrm{ArSO_3H} + \mathrm{ArSOEt}$$

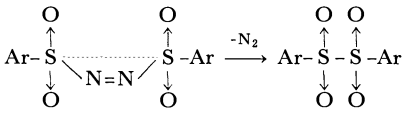
$$\mathrm{ArSOEt} \xrightarrow{\mathrm{Br_2}} \mathrm{ArSO_2OEt} + \mathrm{ArSO_2Br}$$

$$\mathrm{ArSO_2Br} \xrightarrow{\mathrm{EtOH}} \mathrm{ArSO_2OEt}$$

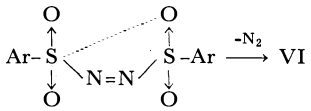
Ethyl *p*-toluenesulfonate was oxidized with bromine in ethyl alcohol at room temperature to afford *p*-toluenesulfonyl bromide and ethyl *p*-toluenesulfonate, and was produced by ethanolysis of *p*-toluenesulfonyl bromide.

The formation of the diaryl disulfone could be alternatively explained by means of a four-centered transition state:

Mechanism II



In a similar fashion intermediate VI could arise *via* a five-centered transition state.



At present it is not possible to determine which of these two mechanisms is correct.

Experimental

Materials. Acetonitrile and ethyl alcohol were purified by the usual method.[7]

Bromine, chloranil and potassium permanganate of first grade were used without further purification. NBS was recrystallized from water.

Synthesis of IV. Twelve grams of *p*-toluenesulfonylhydrazine, prepared from *p*-toluenesulfonyl chloride and hydrazine hydrate, was dissolved in 50 m*l* of ethyl alcohol. To this solution 6.5 g of *p*-toluenesulfinyl chloride was added at 60°C. After 1.5 hr, white crystals precipitated were filtered off, and recrystallized from acetone-water to afford 2.8 g of IV (20%); mp 205°C (decomp.), lit, 218—220°C (decomp.).[8]

Synthesis of II. A solution of 40 g of benzenesulfonylhydrazine and 20 g of benzenesulfonyl chloride in 50 m*l* of ethyl alcohol was refluxed for 4 hr. White crystals obtained were recrystallized from acetone-water; yield, 11 g (31%), mp 218°C (decomp.), lit, *ca.* 245°C.[9]

Synthesis of VII. VII was prepared by a modification of the procedure reported by Munshi *et al.*;[10] mp 185°C, lit, 184°C.[10]

Oxidation of IV with Bromine in Aqueous Acetonitrile. To the solution of 0.754 g of IV in 96% aqueous acetonitrile, 1.073 g of bromine was added. The evolution of nitrogen was measured by use of a gas burette. After reaction was completed, the products were extracted with methylene chloride, and dried over magnesium sulfate. Methylene chloride was removed, and the products were separated with elution chromatography on a silica gel column; *p*-toluenesulfonyl bromide was eluted with hexane-benzene (mp 93°C, lit, 96°C[11]), di-*p*-tolyl disulfone was eluted with benzene (mp 207°C, lit, 210°C[12] or 218—220°C[13]; IR: 1130 and 1340 cm^{-1}). *p*-Toluenesulfonic acid was precipitated as its *S*-benzylisothiuronium salt.

Oxidation of IV with Bromine in Anhydrous Acetonitrile. To a solution of 0.884 g of IV in 50 m*l* of anhydrous acetonitrile, 0.505 g of bromine was added drop by drop at room temperature. No evolution of nitrogen was observed even in 12 hr, and the starting materials were recovered.

Oxidation of IV with Bromine in Anhydrous Ethyl Alcohol. Oxidation was carried out in a similar way. Ethyl *p*-toluenesulfonate was isolated by elution chromatography on a silica gel column with benzene as solvent; IR: 1170 and 1360 cm^{-1}.

Attempt for Oxidation of IV with Bromine under Irradiation. A solution of 0.666 g of IV and 0.449 g of bromine in 50 m*l* of anhydrous acetonitrile was irradiated with a tungsten lamp for 15 hr. When acetonitrile was removed, the starting materials were recovered.

Oxidation of II with Bromine. Oxidation was carried out in a way similar to that of IV. Products were benzenesulfonyl bromide (IR: 1165 and 1365 cm^{-1}), ethyl benzenesulfonate (IR: 1180 and 1355 cm^{-1}), and diphenyl disulfone (mp 188—189°C, lit, mp 193°C[12]; mass spectrum, m/e (relative intensity), 282 (1.2), 250 (0.3), 234 (2.0), 218 (0.5), 154 (0.9), 153 (2.1), 152 (2.5), 151 (0.7), 141 (100), 125 (26.2), 110 (1.1), 109 (2.1), 108 (0.6) and 97 (9.3)). The mass spectrum was measured on a Hitachi mass spectrometer RMU 6E type, operated with 70 eV at 200°C.

Oxidation of IV with NBS. A solution of 0.820 g of NBS in acetonitrile was added drop by drop to a solution of 0.717 g of IV in 50 m*l* of 96% aqueous acetonitrile. The products were separated by elution chromatography.

Oxidation of IV with Potassium Permanganate. When a solution of 0.620 g of IV in 25 m*l* of anhydrous

acetonitrile was added drop by drop to a solution of 1.008 g of potassium permanganate in 50 m*l* of anhydrous acetonitrile, 0.110 g of di-*p*-tolyl disulfone was obtained.

Oxidation of IV with Chloranil. A solution of 0.700 g of IV and 1.049 g of chloranil in 85 m*l* of anhydrous acetonitrile was refluxed for 13 hr. Products were separated by chromatography on a silica gel column, and 0.178 g of di-*p*-tolyl disulfone was obtained.

Oxidation of IV with Benzoyl Peroxide. A solution of 1.4 g of IV and 1.0 g of benzoyl peroxide was refluxed for 13 hr in 5 m*l* of acetonitrile. When the solvent was removed, unchanged IV was recovered.

Oxidation of IV with Azobisisobutyronitrile (AIBN). A solution of 1.2 g of IV and 0.5 g of AIBN in 50 m*l* of acetonitrile was refluxed for 15 hr. When the solvent was removed, unchanged IV was recovered.

Oxidation of IV with Bromine in the Presence of *p*-Benzoquinone. When 1.107 g of bromine (6.93 mmol) was added at room temperature to a solution of 0.732 g of IV (2.16 mmol) and 3.1 g of *p*-benzoquinone (28 mmol) in 50 m*l* of aqueous acetonitrile, 39.2 m*l* of nitrogen was evolved. The products were extracted with methylene chloride, and an excess *p*-benzoquinone was removed by sublimation under reduced pressure. The residue was separated by elution chromatography on a silica gel column to afford *p*-toluenesulfonyl bromide, 0.226 g, and quinone mixtures. However no quinol sulfonate was found.

Oxidation of IV in the Presence of V. To a solution of 0.732 g of IV (2.15 mmol) and 1.005 g of V[14] (4.20 mmol) in 50 m*l* of acetonitrile, 0.956 g of bromine (5.98 mmol) was added drop by drop. The products were separated by elution chromatography on a silica gel column, and 0.461 g of *p*-toluenesulfonyl bromide, 0.048 g of di-*p*-tolyl disulfone and 0.750 g of unchanged V were recovered.

Oxidation of IV with Bromine in the Presence of Benzene. To a solution of 0.876 g of IV (2.58 mmol) and 2.080 g of benzene (26.6 mmol) in 50 m*l* of 96% aqueous acetonitrile, 1.353 g of bromine was added drop by drop. The products were separated by elution chromatography on a silica gel column. No *p*-tolyl phenyl sulfone was found.

Oxidation of IV with Bromine in the Presence of Nitrobenzene. To a solution of 0.702 g of IV (2.06 mmol) and 3.091 g of nitrobenzene (25.1 mmol) in 50 m*l* of 96% aqueous acetonitrile, 1.182 g of bromine (7.39 mmol) was added drop by drop. The products were separated by elution chromatography on a silica gel column. No *p*-tolyl nitrophenyl sulfone was found.

Oxidation of IV with NBS in the Presence of Toluene. A solution of 1.383 g of NBS (7.18 mmol) in acetonitrile was added drop by drop to a solution of 1.021 g of IV (3.00 mmol) and 6.6 g of toluene (71.8 mmol) in 50 m*l* of 96% aqueous acetonitrile. The products were separated by elution chromatography on a silica gel column to give 0.020 g of benzyl bromide, 0.741 g of *p*-toluenesulfonyl bromide and 0.106 g of di-*p*-tolyl disulfone, but no *p*-tolyl benzyl sulfone was detected.

Oxidation of IV with Potassium Permanganate in the Presence of Toluene. A solution of 2.197 g of IV and 13 g of toluene (141 mmol) in 50 m*l* of anhydrous acetonitrile was added drop by drop to a solution of 2.0 g of potassium permaganate (12.7 mmol) in 50 m*l* of anhydrous acetonitrile. The products were separated by elution chromatography on an alumina column. No *p*-tolyl benzyl sulfone nor *p*-tolyl tolyl sulfone was found.

Oxidation of VII with Bromine. To the solution of 0.795 g of VII (2.44 mmol) in 50 m*l* of aqueous acetonitrile, 1.066 g of bromine was added. The products were separated with elution chromatography on a silica gel column to give 0.084 g of *p*-tolyl phenyl disulfone (0.28 mmol, 11.5%); mp 162—163°C, lit, 166°C;[15] IR: 1125 and 1345 cm^{-1}. Neither diphenyl disulfone nor di-*p*-tolyl disulfone was detected.

Reaction between Ethyl *p*-Toluenesulfinate and Bromine. A solution of 1.114 g of ethyl *p*-toluenesulfinate (6.05 mmol) and 1.028 g of bromine (6.43 mmol) in 10 m*l* of anhydrous ethyl alcohol was allowed to stand at room temperature for 2 hr. Water was added to the solution and products were extracted with methylene chloride. The products were separated by elution chromatography, and 0.431 g of *p*-toluenesulfonyl bromide (1.95 mmol) and 0.094 g of ethyl *p*-toluenesulfonate (0.47 mmol) were found, and 0.217 g of unchanged ethyl *p*-toluenesulfinate (1.18 mmol) was recovered.

Reaction between *p*-Toluenesulfonyl Bromide and Ethyl Alcohol. A solution of 0.2507 g of *p*-toluenesulfonyl bromide (1.07 mmol) in 25 m*l* of anhydrous ethyl alcohol was allowed to stand at room temperature for 70 min. Water was added to the solution and products were extracted with methylene chloride. The products were separated by elution chromatography and 0.134 g of *p*-toluenesulfonyl bromide (0.57 mmol) and 0.051 g of ethyl *p*-toluenesulfonate (0.26 mmol) were found.

Grateful acknowledgement is made to the donors of the Petroleum Research Fund, administered by the American Chemical Society, for support of this research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2938—2941 (1970)

1,2-Dithiole-3-thione and 1,2,4-Trithiole from α-Cyanodithiocarboxylate

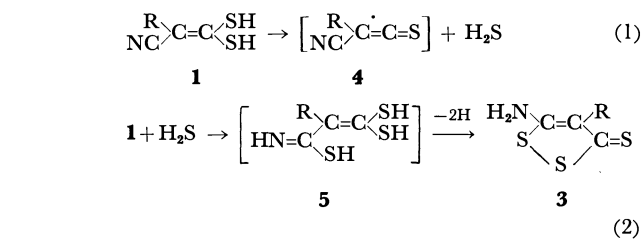
Masataka YOKOYAMA

Department of Chemistry, Faculty of Science, Chiba University, Chiba

(Received March 31, 1970)

1,2-Dithiole-3-thiones and 1,2,4-trithioles were synthesized by the reaction of α-cyanodithiocarboxylate, hydrogen sulfide, and bromine water. The reaction mechanism and the mass spectra of 1,2-dithiole-3-thiones were discussed.

Our attempt to isloate dimercaptomethylenecyanoacetamide (**1a**) from the reaction mixture of di(ammoniomercapto)methylenecyanoacetamide (**2a**) and mineral acid failed. Compound **1a** was unstable, degraded easily along with the evolution of hydrogen sulfide, and changed to 5-amino-4-carbamoyl-1,2-dithiole-3-thione (**3a**).



Scheme 1

The reaction mechanism shown in Scheme 1 may be considered to hold for the conversion of **1a** into **3a**. At the very beginning of the conversion, Compound **1a** may be changed into cyanothioketene (**4a**) by splitting off hydrogen sulfide (Eq. (1)). The hydrogen sulfide thus generated attacks the cyano group of **1a** to give an intermediate, **5a**, from which **3a** is produced by the formation of the 1,2-dithiole ring (Eq. (2)).

Resinous material which was considered to be a polymer of (4) was obtained in the above reaction. However, its identification was not achieved. The ammonium salt of **5d** could be prepared by the reaction of di(ammoniomercapto)methylenemalononitrile (diammonium salt of **1d**) and hydrogen sulfide, and then converted quantitatively into **3d** by the addition of acetic acid. The results suggest that the unstable intermediate, **5**, is easily dehydrogenated because of the formation of a stable 1,2-dithiole-3-thione derivative (**3**).[1]

From the decomposition mechanism, syntheses were undertaken for several 1,2-dithiole-3-thione derivatives by the reaction of α-cyanodithiocarboxylate (**2**), hydrogen sulfide, and acetic acid. Bromine water was used in place of acetic acid because of its moderate reactivity. Di(ammoniomercapto)methylenecyanoacetamide (**2a**), methyl di(sodiomercapto)methylenecyanoacetate (**2b**), ethyl di(sodiomercapto)methylenecyanoacetate (**2c**), and di(sodiomercapto)methylenemalononitrile (**2d**) gave 5-amino-4-carbamoyl-1,2-dithiole-3-thione (**3a**, yield 94%), 5-amino-4-methoxycarbonyl-1,2-dithiole-3-thione (**3b**, yield 81%), 5-amino-4-ethoxycarbonyl-1,2-dithiole-3-thione (**3c**, yield 83%), and 5-amino-4-cyano-1,2-

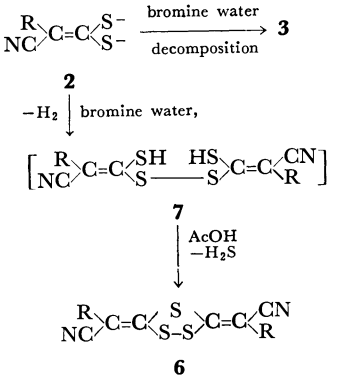
3) K. Gewald, *J. Prakt. Chem.*, **31**, 214 (1966).

dithiole-3-thione (**3d**, yield 82%) respectively, all in high yields. The UV spectra of **3b**, **3c**, and **3d** coincided with those reported by Mayer and Gewald (see Table 1). This is a new preparative method leading to 1,2-dithiole-3-thione derivatives through the intermediate, **5**. Most of the preparations reported so far have made use of elementary sulfur,[3] phosphorus pentasulfide or a mixture of both.[1]

When the α-cyanodithiocarboxylate (**2**) was mixed with acetic acid, hydrogen sulfide was evolved and **3** was obtained. This reaction was continued until **1** had been degraded completely. On the other hand, bromine water stopped the decomposition of **1** within several hours.

A mixture of α-cyanodithiocarboxylate and bromine water was allowed to stand at room temperature overnight. A small amount of **3** (usually, yield *ca.* 10%) was separated from the reaction mixture. When the filtrate was acidified with acetic acid, hydrogen sulfide was instantly evolved and 1,2,4-trithiole derivative was obtained in a high yield. **2a**, **2b**, and **2c** gave 2,5-di(carbamoylcyanomethylene)-1,2,4-trithiole (**6a**, yield 70%), 3,5-di(methoxylcarbonylcyanomethylene)-1,2,4-trithiole (**6b**, yield 74%), and 3,5-di(ethoxylcarbonylcyanomethylene)-1,2,4-trithiole (**6c**, yield 81%), respectively. An attempt to obtain the compound corresponding to **6d** was unsuccessful.

It seems that the conversion of **2** into **6** proceeds through an intermediate, **7**, which is easily changed to a stable compound, **6**, accompanying elimination of hydrogen sulfide on treatment with acetic acid (see Scheme 2). The IR spectrum of **6b** coincided with that of the compound synthesized from **2b** and ammonium peroxydisulfate by Gompper's method.[4] The UV spectra of **3** and **6** showed several characteristic absorptions (see Table 1).



2a, **6a**: R=$CONH_2$; **2b**, **6b**: R=CO_2CH_3; **2c**, **6c**: R=$CO_2C_2H_5$; **2d**: R=CN

Scheme 2

Kirby has proposed that **6** is presumably planar for the conjugation through the **3d** orbitals of sulfur.[5] The strong bands near 320 mμ and 335 mμ may be explained in terms of the through-conjugation. It was considered that **6** existed in a *trans* form with respect to R groups, because the two R groups were shown to be unequivalent from the results of NMR spectra (see Table 2).

Table 2. Chemical shifts and coupling constants for **6***

6a	4.10(br, NH_2)
6b	3.92(s, CH_3), 3.90(s, CH_3)
6c	4.38(q, CH_2, J=7 Hz), 4.36(q, CH_2, J=7 Hz), 1.35(t, $2CH_3$)

* NMR spectra were recorded with a JNM-C-60 high resolution NMR spectrometer operating at 60 MHz. Chemical shift values were shown in δ downfield from tetramethylsilane as an internal standard in deuteriodimethyl sulfoxide as solvent.

Table 3. Mass spectra for **3***, *m/e* (rel. int. %)

3a	**3c**	**3d**
194(23)	223(13)	176(7.5)

148(8.5)	148(40)	83(12)
128(45)	84(73)	64(8.5)
84(33)	72(13)	
64(10)	64(15)	

* Mass spectra were measured with a Nihon Densi JMS-01 SG mass spectrometer. Ionizing energy was maintained at 75 eV and the total ionizing current 200 μA.

Table 3 shows the mass spectra of **3**. Measurement of the fragments revealed different scissions of two sulfur atoms (see Scheme 3). Compound **3c** was changed into fragment (B) through fragment (A) by the removal of group R and then two sulfur atoms. In the case of **3d**, the separation of two sulfur atoms occurred to give fragment (C) from which group R was then separated to give fragment (B). Compound **3a** showed both types of scission.

Experimental

Compound **2a** was prepared by the reaction of ethyl cyanoacetate and carbon disulfide in aqueous ammonia (28%). Compounds **2b**, **2c**, and **2d** were prepared by Soderback's method.[6]

Isolation of Diammonium Salt of 5d. A mixture of malononitrile (25 g, 0.38 mol), carbon disulfide (57 g, 0.75 mol) and *ca.* 200 m*l* of liquid ammonia was stirred for 30 min under cooling with dry ice-methanol. The reaction mixture was then allowed to stand at room temperature. A yellow solid material was recrystallized from methanol-chloroform to give light yellow plates (65.5 g, di(ammoniomercapto)methylenemalononitrile).[7] The light yellow material (8 g) was dissolved in 100 m*l* of ethanol and hydrogen sulfide was passed through for 30 min. The whole was shaken for an additional 3 hr. The yellow material was collected, recrystallized from water, washed with ethanol, and dried: yellow plates (0.5 g, diammonium salt of **5d**), mp 136—137°C (dec.) (slow heating), 153—156°C (dec.) (rapid heating). IR (KBr): 3310 (s, ν NH), 3080, 2960 (s, br, ν NH_4^+), 2180 (s, ν CN), 1590 (s, ν C=N), 1505 (m, ν conj. C=C), 1415 cm^{-1} (s, br, δ NH_4^+). Found: C, 23.23; H, 4.83; N, 26.56; S, 45.36%; mol wt, 214.7 (vapor-pressure osmometer, in acetone). Calcd for $C_4H_{10}N_4S_3$: C, 22.86; H, 4.86; N, 26.66; S, 45.68%; mol wt, 210.15.

The ammonium salt of **5d** was methylated by dimethyl sulfate. Yellow needles (mp 219—220°C) were obtained and from analytical results, and was assigned the structure di(methylmercapto)methylenecyanoacetamide. The NMR spectrum in deuterioacetone revealed signals at δ 7.40 (br, 1, NH) and δ 1.80 (s, 1, SH).

Treatment of Diammonium Salt of 5d with Acetic Acid. To the diammonium salt of **5d** (2 g) in 100 m*l* of water was added acetic acid (4.5 m*l*). This was allowed to stand for 1 hr at 20°C. The crude product was collected and recrystallized from pyridine-water to give yellow prisms quantitatively. The IR spectrum agreed with that of **3d**.

Preparation of 3a. Through the mixture of **2a** (8 g, 0.04 mol) and water (50 m*l*) was passed hydrogen sulfide 30 min at room temperature. The reaction mixture was stirred for 3 hr, and treated under diminishing pressure at 30—40°C in order to remove unchanged hydrogen sulfide. To this was added 50 m*l* of a saturated bromine water and allowed to stand for several hours. The crude yellow material was filtered, washed with water and ether, and recrystallized from pyridine-water: 9.0 g of yellow prisms (**3a**, yield *ca.* 94%), mp 247—248°C. NMR (DMSO-d_6): δ 10.35 (br, $CONH_2$), δ 8.70 (br, NH_2); IR (KBr): 3280, 3260, 3220, 3140, 3020 (w, ν NH_2), 1650 (sh, ν CO), 1638 (s, δ NH_2), 1550 cm^{-1} (s, ν C=C). Found: C, 25.31; H, 2.16; N, 14.47; S, 49.95%; mol wt, 183.1 (vapor-pressure osmometer, in acetone). Calcd for $C_4H_4N_2S_3O$: C, 25.01; H, 2.10; N, 14.58; S, 49.95%; mol wt, 192.09.

Preparation of 3b. Compound **3b** was prepared by the same method as above. 8.1 g of yellow needles was produced from **2b** (15 g, 0.05 mol) and recrystallized from methanol (yield *ca.* 81%): mp 201—202°C (dec.). NMR (acetone-d_6): δ 9.20 (br, NH_2), δ 3.82 (s, CH_3); IR (KBr): 3270, 3150, 3100 (s, ν NH_2), 2950 (m, ν CH_3), 1658 (vs, ν C=O), 1572 (vs, δ NH_2), 1562 (sh, ν conj. C=C), 1332 cm^{-1} (vs, ν C–O–C). Found: C, 29.10; H, 2.62; N, 6.78; S, 46.09%; mol wt, 217.0 (vapor-pressure osmometer, in acetone). Calcd for $C_5H_5NS_3O_2$: C, 28.97; H, 2.44; N, 6.76; S, 46.39%; mol wt, 207.29.

Preparation of 3c. Compound **3c** was prepared as in the case of **3a**. Crude material was prepared from 10.6 g (0.03 mol) of **2c** and recrystallized from pyridine-water to give 6 g of yellow needles (**3c**, yield *ca.* 83%), mp 181°C. NMR (DMSO-d_6): δ 9.20 (br, NH_2), δ 4.32 (q, CH_2, J=6 Hz), δ 1.32 (t, CH_3, J=6 Hz); IR (KBr): 3340, 3200 (s, ν NH_2), 2980 (w, ν CH_3), 1652 (s, ν C=O), 1590 (vs, δ NH_2), 1340 cm^{-1} (s, ν C–O–C). Found: C, 32.80; H, 3.10; N, 6.49; S, 43.26%; mol wt, 226.4 (vapor-pressure osmometer, in acetone). Calcd for $C_6H_7NS_3O_2$: C, 32.59; H, 3.19; N, 6.34; S, 43.60%; mol wt, 221.12.

Another Preparative Method of 3b and 3c. Through the mixture of **2**, water and acetic acid (30 m*l*) was immediately passed hydrogen sulfide. Yellow material was collected and recrystallized. The yield was almost equal to that of the above method.

Preparation of 3d. Preparation was the same as for **3a**. Crude product was obtained from **2** (8.5 g, 0.035 mol) and recrystallized from methanol: 5 g of yellow prisms (**3d**, yield 82%), mp <300°C. NMR (DMSO-d_6): δ 9.58 (br, NH_2); IR (KBr): 3170 (m, br, ν NH_2), 2220 (s, ν CN), 1615 (vs, ν C=N), 1505 cm^{-1} (vs, ν C–C). Found: C, 27.77; H, 0.87; N, 16.35; S, 54.95%; mol wt, 180.0 (vapor-pressure osmometer, in acetone). Calcd for $C_4H_2N_2S_3$: C, 27.60; H, 1.15; N, 16.10; S, 55.00%; mol wt, 174.

Preparation of 6a. To the mixture of **2a** (7 g, 0.036 mol) and water (50 m*l*) was added 50 m*l* of the saturated bromine water. The solution was allowed to stand overnight at 20°C and 0.6 g of light yellow material (**3a**) was filtered off. The filtrate was added with 30 m*l* of acetic acid and kept to stand for 3 hr. Crude yellow material was collected and washed with water and a small amount of methanol. Recrystallization from dioxane gave 3.8 g of light yellow needles (**6a**, yield 70%), mp <300°C. IR (KBr): 3340, 3180 (s, ν NH_2), 2210 (s, ν conj. CN), 1670 (sh, ν C=O), 1655 (vs, δ NH_2), 1450 cm^{-1} (vs, probable ring stretching). Found: C, 33.79; H, 1.31; N, 19.80; S, 34.00%; mol wt, 283.5 (vapor-pressure osmometer, in acetone). Calcd for $C_8H_4N_4S_3O_2$: C, 33.81; H, 1.42; N, 19.72; S, 33.79%; mol wt, 284.14.

Preparation of 6b. Preparation was carried out as above. Crude product was obtained from **2b** (7 g, 0.023 mol) and recrystallized from dioxane: 2.5 g of light yellow needles (**6b**, yield 74%), mp 227—228°C (reported mp 225—228°C[4]). IR (KBr): 2960 (m, ν CH_3), 2220 (s, ν conj. CN), 1675 (vs, ν C=O), 1472 (vs, probable ring stretching), 1300 cm^{-1} (vs, ν C–O–C). Found: C, 38.33; H, 2.05; N, 9.13; S, 30.47%; mol wt, 314 (mass spectrum). Calcd for $C_{10}H_6N_2S_3O_4$: C, 38.22; H, 1.91; N, 8.92; S, 30.63%; mol wt, 314.18.

The Synthesis of a Series of *N*-*t*-Amyloxycarbonyl-oligo-L-proline

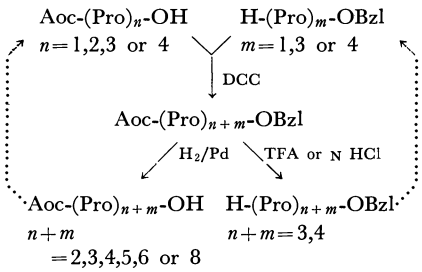
Muneji MIYOSHI,*1 Terutoshi KIMURA and Shumpei SAKAKIBARA*2

Peptide Center, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received April 1, 1970)

A series of *N*-protected L-proline oligomers, the di-, tri-, tetra-, penta-, hexa- and octamer, were synthesized by conventional methods. The proline imino-group was protected by the *t*-amyloxycarbonyl (Aoc) group, and the carboxyl group was protected as the benzyl ester during the synthesis. These Aoc-oligoprolines were valuable in elucidating the relationship between the conformation and the degree of polymerization of the polyprolines. The Aoc-protecting group was useful in purifying the intermediates and in obtaining crystals of the final compounds.

This paper will report the synthesis of a series of proline oligomers, which have been used in elucidating the relationship between the number of proline residues and the steric structure of the molecules.[1,2] Since a prolyl-prolyl linkage is susceptible to aqueous caustic alkali, the saponification of the ester group was avoided in the synthesis. Generally, the *t*-amyloxycarbonyl (Aoc) group[3] was used to protect an imino group of oligoprolines and the carboxyl groups were protected as benzyl esters. The Aoc-group is known to be stable under the conditions used for the catalytic hydrogenolysis of benzyl esters, and it can be removed by treatment with N hydrogen chloride in an organic solvent or by treatment with trifluoroacetic acid at room temperature for 30 min, the benzyl ester group being unaffected by this treatment.[3] Therefore, each of the protecting group can be removed independently. Furthermore, the use of these lipophilic protecting groups was advantageous in increasing the solubility of the proline oligomers in usual organic solvents and in obtaining many of them as nice crystals. The proline peptides were coupled by the dicyclohexylcarbodiimide (DCC) method, because there is no racemization problem in the activation of proline residues. Since Aoc-derivatives are very soluble in usual organic solvents, as has been mentioned above, urea or ureide compounds could be easily removed from the reaction mixture. Thus, a series of Aoc-oligoprolines were synthesized, as is shown in the following scheme:



The physical constants and solubilities of the compounds are summarized in Tables 1 and 2.

The molecular rotations of the respective compounds ($n+m$=2—8) seem to conform to the additive rule in this region, as is shown in Fig. 1.

4) The separated spots were located by a ninhydrin reaction at 100°C.

Experimental

The physical constants and solubilities of the compounds are shown in Tables 1 and 2. Each compound was dried over phosphorus pentoxide *in vacuo* at 80°C for about 10 hr before being subjected to elementary analysis. All the melting points were determined by the capillary method, and all are given as uncorrected values.

Aoc-L-prolyl-L-proline Benzyl Ester (III). DCC (51.5 g, 0.25 mol) was stirred into a solution of Aoc-L-proline (I) (57.2 g, 0.25 mol) in methylene chloride (150 m*l*) at 0°C. Then, a solution of L-proline benzyl ester hydrochloride (II) (61 g, 0.26 mol) and triethylamine (35 m*l*, 0.25 mol) in methylene chloride (250 m*l*) was added to the reaction mixture. Stirring was continued for 1 hr at 0°C, and then the mixture was left to stand overnight at room temperature. The *N,N*-dicyclohexylurea (DCU) formed during the reaction was removed by filtration. The filtrate was concentrated under reduced pressure, and the residue was dissolved in ethyl acetate. This solution was washed successively with water, 5% sodium bicarbonate, 0.25 N hydrochloric acid, and water. The washed solution was dried over sodium sulfate and concentrated to a syrup, which was then used in the next reaction without any further purification or characterization. The homogeneity of this material was checked by thin-layer chromatography on Silica-gel G using a mixture of chloroform - methanol - acetic acid (95 : 5 : 3 v/v/v) as the solvent.[4]

Aoc-L-prolyl-L-proline (IV).[5] Hydrogen gas was bubbled through a solution of the above syrup (III) in methanol (500 m*l*) in the presence of palladium charcoal (5%, 5 g) for about 10 hr at room temperature. The extent of hydrogenolysis was checked by thin-layer chromatography on Silica-gel G using a mixture of chloroform-methanol-pyridine (95 : 5 : 3 v/v/v) as the solvent.[4] After confirmation that the reaction has been completed, the catalyst was filtered off, and the filtrate was concentrated to a syrup under reduced pressure. The residue was crystallized from a small volume of ethyl acetate in a refrigerator. The product was then collected by filtration and recrystallized from ethyl acetate and *n*-hexane; wt, 67.2 g (yield 82.5%, calcd from I).

Found: C, 58.98; H, 8.02; N, 8.72%. Calcd for $C_{16}H_{26}N_2O_5$: C, 58.88; H, 8.03; N, 8.58%.

Aoc-tri-L-proline Benzyl Ester (V). DCC (24.8 g, 0.12 mol) was stirred into a solution of IV (39.1 g, 0.12 mol) in methylene chloride (150 m*l*) at 0°C. Then, a mixture of II (30.5 g, 0.12 mol) and triethylamine (16.8 m*l*, 0.12 mol) in methylene chloride (150 m*l*) was added to the reaction mixture. Stirring was continued for 1 hr at 0°C, and then the mixture was kept overnight at room temperature. The DCU formed was removed by filtration. The solvent was replaced by ethyl acetate, and a small amount of an insoluble material was filtered off; the ethyl acetate solution was thoroughly washed in succession with water, 5% sodium bicarbonate, 0.25 N hydrochloric acid, and water. The final solution was dried over sodium sulfate and concentrated to a syrup under reduced pressure. The residue was dissolved in acetone, and a small amount of an insoluble material was removed by filtration. The solvent was evaporated off, and the residue was crystallized from ethyl acetate and *n*-hexane. Crystals were collected and recrystallized from ethyl acetate and *n*-hexane as fine needles; wt, 48 g (yield 78%).

Found: C, 65.63; H, 7.70; N, 8.17%. Calcd for $C_{28}H_{39}N_3O_6$: C, 65.47; H, 7.65; N, 8.18%.

Aoc-tri-L-proline (VI). Hydrogen was bubbled slowly through a solution of V (30.8 g, 0.06 mol) in methanol (150 m*l*) in the presence of palladium charcoal (5%, 5 g). After we had confirmed by thin-layer chromatography that the reaction was complete, the catalyst was removed by filtration; the filtrate was then concentrated under reduced pressure. The residue was dissolved in ethyl acetate with the aid of a minimum volume of methanol, and the solution was kept overnight in a refrigerator. The crude product, which separated as crystals, was collected by filtration and then recrystallized as fine needles from a mixture of ethyl acetate and a small volume of methanol; wt, 22.5 g (89.1%).

Found: C, 59.63; H, 7.88; N, 9.75%. Calcd for $C_{21}H_{33}N_3O_6$: C, 59.55; H, 7.85; N, 9.92%.

Aoc-tetra-L-proline Benzyl Ester (VII). Compounds VI (16.9 g, 0.04 mol) and II (11.0 g, 0.04 mol) were treated with DCC (8.3 g, 0.04 mol) in chloroform as has been described for the syntheses of III and V. The DCU formed was removed by filtration, the chloroform was replaced by ethyl acetate, and the solution was thoroughly washed in succession with water, 5% sodium bicarbonate, 0.25 N hydrochloric acid, and water; the washed solution was dried over sodium sulfate and then concentrated to a residue under reduced pressure. The residue was dissolved in acetone, a small amount of an insoluble material was removed by filtration, and the solution was reconcentrated. The final residue was crystallized from ethyl acetate and *n*-hexane. Crude crystals were collected by filtration and recrystallized from ethyl acetate and *n*-hexane; wt, 19.5 g (80.1%).

Found: C, 64.15; H, 7.72; N, 9.02%. Calcd for $C_{33}H_{46}N_4O_7 \cdot \frac{1}{2} H_2O$: C, 63.96; H, 7.59; N, 9.03%.

Aoc-tetra-L-proline (VIII). Compound VII (10 g, 0.016 mol) was subjected to catalytic hydrogenolysis with hydrogen and palladium charcoal in methanol, as with VI. The catalyst was removed by filtration, and the filtrate was concentrated under reduced pressure to obtain the crude product, which was crystallized from ethyl acetate and *n*-hexane. Recrystallization from the same solvent system gave the final product; wt, 7.5 g (90%).

Found: C, 59.71; H, 7.64; N, 10.75%. Calcd for $C_{26}H_{40}N_4O_7$: C, 59.98; H, 7.74; N, 10.76%.

Aoc-penta-L-proline Benzyl Ester (IX). (a) Compound V (5.3 g, 0.011 mol) was dissolved in 10 m*l* of trifluoroacetic acid, after which the mixture was allowed to react for 30 min at room temperature. The excess trifluoroacetic acid was removed by evaporation under reduced pressure, and the residual syrup was dried over sodium hydroxide *in vacuo* for one day. The dried material was then dissolved in chloroform (50 m*l*), and the solution was treated with compound IV (3.6 g, 0.011 mol) and DCC (2.3 g, 0.011 mol) in chloroform, as in the syntheses of III and V. The DCU formed was removed by filtration, and the filtrate was washed successively with 0.25 N hydrochloric acid, 5% sodium bicarbonate, and water, and dried over sodium sulfate. The dried solution was concentrated, and the residue was dissolved in hot ethyl acetate. Crystals formed when this solution was left standing in a refrigerator. The product was collected and recrystallized from ethyl acetate; wt, 5.2 g (74.5%). Found: C, 64.34; H, 7.65; N, 9.77%. Calcd for $C_{38}H_{53}N_5O_8$: C, 64.48; H, 7.55; N, 9.89%. (b) Compound VII (5.2 g, 0.01 mol) was coupled with II (2.6 g, 0.011 mol) in chloroform using DCC (2.1 g, 0.01 mol), and the reaction mixture was treated as has been described above. The product was recrystallized similarly; wt, 5.5 g (78.5%). As is shown in Table 1, the properties of this product were almost the same as those of the compound obtained above.

Found: C, 64.58; H, 7.56; N, 9.92%. Calcd for $C_{38}H_{53}N_5O_8$: C, 64.48; H, 7.55; N, 9.89%.

Aoc-penta-L-proline (X). (a) A solution of compound IX-a (3.6 g, 0.005 mol) in methanol (100 m*l*) was subjected to catalytic hydrogenolysis in the presence of palladium charcoal, as in the syntheses of IV and VI. The catalyst was filtered off, the filtrate was concentrated under reduced pressure, and the residue was recrystallized twice from a minimum volume of methanol and ethyl acetate; wt, 2.55 g (82.7%).

Found: C, 59.95; H, 7.74; N, 11.52%. Calcd for $C_{31}H_{47}N_5O_8$: C, 60.27; H, 7.67; N, 11.34%.

(b) An indistinguishable compound was also obtained from IX-b, as is shown in Table 2.

5) S. Sakakibara and N. Inukai, This Bulletin, **39**, 1567 (1966).

Aoc-hexa-L-proline Benzyl Ester (VI). An Aoc-group was removed from V (5.14 g, 0.01 mol); the triproline benzyl ester thus obtained was coupled with VI (4.24 g, 0.01 mol) in chloroform (50 m*l*) by using DCC (2.1 g, 0.01 mol), as in the synthesis of IX-a. The crude product thus obtained was recrystallized from a mixture of ethyl acetate and methanol (2 : 1 v/v); wt, 5.1 g (69.4%).

Found: C, 63.84; H, 7.54; N, 10.25%. Calcd for $C_{43}H_{60}N_6O_9$: C, 64.16; H, 7.51; N, 10.44%.

Aoc-hexa-L-proline (XII). Compound XI (4.0 g, 0.005 mol) was subjected to catalytic hydrogenolysis in methanol, as with X, VIII, VI, and IV. The catalyst was removed by filtration, and the filtrate was concentrated to a residue which was then triturated with hot ethyl acetate to remove any soluble materials. The insoluble material remaining was dissolved in methanol, and the solution was treated with active charcoal to eliminate any colored impurities. The colorless methanol solution thus obtained was concentrated to a small volume, and the product was precipitated with ethyl acetate. The precipitate was collected by filtration and recrystallized from methanol and ethyl acetate; wt, 3.0 g (84.8%).

Found: C, 60.08; H, 7.48; N, 11.70%. Calcd for $C_{36}H_{54}N_6O_9$: C, 60.48; H, 7.61; N, 11.76%.

Aoc-octa-L-proline Benzyl Ester (XIII). Compound VII (3.05 g, 0.005 mol) was treated with trifluoroacetic acid (5 m*l*) as in the case of IX-a; the tetra-L-proline benzyl ester thus obtained was coupled with VIII (2.6 g, 0.005 mol) in chloroform by using DCC (1.1 g, 0.005 mol), as has been described previously. The DCU thus formed was removed by filtration; the chloroform solution was washed successively with 0.25 N hydrochloric acid, 5% sodium bicarbonate, and water. The solution was then dried over sodium sulfate and concentrated to a residue which was subsequently purified by two precipitations from methanol and ethyl acetate; wt, 2.9 g (59.5%).

Found: C, 63.52; H, 7.50; N, 10.93%. Calcd for $C_{53}H_{74}N_8O_{11}$: C, 63.70; H, 7.47; N, 11.22%.

Aoc-octa-L-proline (XIV). Compound XIII (2.0 g, 0.002 mol) was subjected to catalytic hydrogenolysis in methanol (25 m*l*) with palladium-charcoal, as has been described for the syntheses of similar compounds. After we had confirmed that the reaction was complete, the catalyst was removed by filtration and the solution was concentrated to a residue which was subsequently from methanol and ethyl acetate; wt, 1.5 g (86%).

Found: C, 60.43; H, 7.46; N, 12.16%. Calcd for $C_{46}H_{68}N_8O_{11}$: C, 60.77; H, 7.54; N, 12.33%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2944—2948 (1970)

Studies of Peptide Antibiotics. XXI. Synthesis of Tyrocidine C[1)]

Kenji KUROMIZU and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received April 3, 1970)

A cyclic decapeptide, *cyclo*-(L-Trp-D-Trp-L-Asn-L-Gln-L-Tyr-L-Val-L-Orn-L-Leu-D-Phe-L-Pro-), having the amino acid sequence of natural tyrocidine C has been synthesized. Chemical and biological properties of this product have been described. An antibiological activity of the product toward Gram positive microorganisms was found to be nearly the same degree as that of tyrocidine B.

In 1952 Battersby and Craig found that a crystalline tyrocidine contained at least three components, tyrocidine A (TA), B (TB) and C (TC), using a countercurrent distribution.[2)] In 1965 Craig and his coworkers isolated a pure crystalline hydrochloride of TC and determined its structure as shown in Fig. 1 by analyses on partial hydrolyzate with hydrochloric acid.[3)] However, they did not describe a quantitative feature of its antibacterial activity and some physical properties. Furthermore, a complete synthesis of TC was not accomplished.

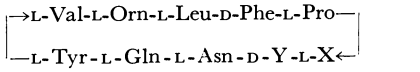

Fig. 1. Structure of TA (X,Y=Phe), TB (X=Trp, Y=Phe) and TC or IX(X, Y=Trp).

This paper will describe the synthesis of a cyclic decapeptide hydrochloride (IX·HCl) having an amino acid sequence of TC (Fig. 1), and the chemical and biological properties of a synthetic product.

Figure 2 indicates the scheme for synthesis of a

TABLE 1. INHIBITORY ACTIVITY OF THE COMPOUNDS ON MICROORGANISMS
Minimum inhibitory concentration, μg/ml

	Staphylococcus aureus	*Bacillus subtilis*	*Escherichia coli*	*Proteus vulgaris*	*Salmonella paratyphi*	*Pseudomonas aeruginosa*	*Shigella sonnea*	*Candida albicans*
IX	>100	6.25	>100	>100	>100	>100	>100	>100
TB	>100	3.13	100	>100	>100	>100	>100	>100
TA	>100	3.13	100	>100	>100	>100	>100	12.5
GS	1.56	0.78	25	>100	50	50	12.5	3.13

desired decapeptide (IX).[4] Some peptide derivatives shown in the scheme had been prepared previously; a pentapeptide H-Val-Orn(δ-Z)-Leu-D-Phe-Pro-OH was prepared during our synthetic studies on TA[5] or tyrocidine E[6] and an octapeptide trifluoroacetate (IV·CF_3COOH) during our synthetic studies on TB.[7]

Strategy for synthesis of decapeptide (IX) is essentially similar as reported for TB synthesis.[7] *p*-Methoxybenzyloxycarbonyldipeptide acid (III) was coupled with a neutral octapeptide (IV) by a method using reagents of HOSu and DCC, and an acyldecapeptide acid (V) was obtained as a crystalline product. It was assumed that no racemization occurred on the D-Trp residue of -L-Trp-D-Trp-L-Asn- sequence in a decapeptide (V or IX) since we had observed[7] that the use of HOSu and DCC in the same condition in the present experiment caused no racemization by an assay technique developed in this laboratory.[8]

A desired decapeptide (IX) was prepared as follows. Acyldecapeptide acid (V) was transformed into a corresponding *p*-nitrophenyl ester (VI), and its *p*-methoxybenzyloxycarbonyl group was removed by trifluoroacetic acid. The cyclization reaction of a decapeptide ester (VII) by the usual way[5,7] gave a benzyloxycarbonyl-substituted cyclic decapeptide (VIII), its molecular weight determination demonstrating that molecular size of VIII corresponds to that of cyclic decapeptide. Hydrogenolysis of VIII in the presence of an equivalent of hydrogen chloride afforded a crystalline cyclic decapeptide hydrochloride (IX·HCl). Its homogeneity was ascertained by thin-layer and paper chromatography, paper electrophoresis and an amino acid analysis. Patterns of ultraviolet spectra on IX, synthetic TA and TB indicated that insertion of one (TB) or two (TC) Trp residues instead of Phe in a TA molecule increased intensities of absorbance at 280.5 mμ.

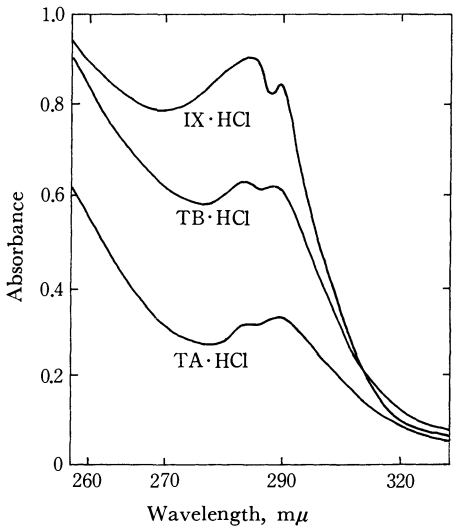

Fig. 3. Ultraviolet spectra of TA, TB and IX in 0.1 N NaOH-EtOH (1:1 v/v). Concentrations of TA·HCl, TB·HCl and IX·HCl; 9.04×10^{-5} M, 9.14×10^{-5} M and 7.05×10^{-5} M.

Antibacterial activities of IX toward several microorganisms are listed in Table 1, that of TA, TB and gramicidin S (GS) as reference compounds also being indicated. It was found that the degree of the activities of decapeptide (IX) was nearly the same as that of TA toward Gram positive (*Staph. aureus* and *B. subtilis*) and Gram negative microorganisms (*E. coli* and others) except for a microorganism, *Candida albicans*. The results indicate that both L- and D-Phe residues in a TA molecule can be replaced by L- and D-Trp residues, respectively, without a remarkable decrease in activity.

Experimental

Thin-layer chromatography was performed on Merck silica gel G with the following solvent systems: $R_f{}^1$, *n*-

4) Abbreviations; Z, benzyloxycarbonyl; Z(OMe), *p*-methoxybenzyloxycarbonyl; ONp, *p*-nitrophenyl ester; HOSu, *N*-hydroxysuccinimide; DCC, dicyclohexylcarbodiimide; TEA, triethylamine; DMF, dimethylformamide. Amino acid symbols denote L configuration otherwise noted.

butanol - acetic acid - pyridine - water 4 : 1 : 1 : 2 *v/v*; R_f^2, chloroform - methanol 5 : 1 *v/v*. Paper chromatography was performed with the following solvent system: R_f^1, the same solvent used for R_f^1.

H-D-Trp-OMe·HCl (I). D-Tryptophan (30 g, 14.7 mmol) and thionyl chloride (22 m*l*) in methanol (300 m*l*) were treated following the same procedure as for the preparation of L-isomer.[9] Yield, 40.8 g (92%); mp 212°C (decomp.); $[\alpha]_D^{20}$ −17.5° (*c* 1, MeOH). Reported values for the L-isomer; mp 216°C (decomp.)[9] and 214°C (decomp.).[10]

Z(OMe)-Trp-D-Trp-OMe (II). To a solution of Z(OMe)-Trp-OH dicyclohexylamine salt[7] (5.5 g, 10 mmol) and I (2.55 g, 10 mmol) in chloroform (40 m*l*) was added DCC (2.06 g, 10 mmol) at 0°C. After stirring had been continued for 3 hr at 0°C, the mixture was left to stand for overnight at room temperature. The mixture was evaporated *in vacuo*, and ethyl acetate was added to the residue. The filtrate from dicyclohexylurea was washed successively with 8% citric acid, 4% sodium bicarbonate solution and water, and dried over sodium sulfate. Evaporation of the filtrate yielded glass-like powder; 5.04 g (*ca.* 90%); mp 85—87°C; R_f^2 0.55; $[\alpha]^{20}$ −7.2° (*c* 1, MeOH).

Z(OMe)-Trp-D-Trp-OH (III). To a solution of II (2.54 g, 4.4 mmol) in methanol (16 m*l*) and dioxane (16 m*l*) was added N sodium hydroxide (8.8 m*l*). The solution was allowed to stand for 1 hr at room temperature. After addition of water (10 m*l*), the solution was concentrated *in vacuo* to remove organic solvent at 10—15°C, and acidified with 0.5 M citric acid under cooling. The oily product was extracted with ethyl acetate and the extract was dried over sodium sulfate. The filtrate was evaporated and the residue was crystallized by addition of ether and petroleum ether. It was recrystallized from ethyl acetate - ether - petroleum ether; yield, 2.10 g (86%); mp 115—116°C; R_f^2 0.34; $[\alpha]_D^{20}$ −21.6° (*c* 0.5, MeOH).

Found: C, 63.06; H, 5.78; N, 9.36%. Calcd for $C_{31}H_{28}O_6N_4 \cdot 2H_2O$: C, 63.25; H, 5.48; N, 9.52%.

H-Asn-Gln-Tyr-Val-Orn(δ-Z)-Leu-D-Phe-Pro - OH (IV). To a mixture of Z(OMe)-Asn-Gln-Tyr-Val-Orn(δ-Z)-Leu-D-Phe-Pro-OH[7] (0.65 g, 0.5 mmol) and anisole (0.5 m*l*) was added trifluoroacetic acid (3 m*l*) at −5°C. When swirled, the reaction mixture turned to a clear solution within some 10 min. After 15 min, the solution was evaporated *in vacuo* at 0°C and the oily residue was dissolved in DMF (5 m*l*). TEA (0.21 m*l*, 1.5 mmol) was added, the solution was evaporated *in vacuo*, and water (20 m*l*) was added to the residue. The precipitate collected was recrystallized from DMF - ethyl acetate - ether; yield, 0.453 g (80%); mp 285—287°C (decomp.); R_f^1 0.74; $[\alpha]_D^{20}$ −19.7° (*c* 0.8, DMF).

Found: C, 60.09; H, 6.86; N, 13.55%. Calcd for $C_{56}H_{77}O_{14}N_{11}$: C, 59.81; H, 6.88; N, 13.66%.

In a previous paper, we reported the preparation of IV trifluoroacetate as powder which was used for the coupling reaction with Z(OMe)-Trp-D-Phe-OH.[7]

Z(OMe)-Trp-D-Trp-Asn-Gln - Tyr - Val - Orn(δ - Z)-Leu-D-Phe-Pro-OH (V). To a chilled solution of III (0.276 g, 0.5 mmol) in ethyl acetate (3 m*l*) were added HOSu (0.067 g, 0.58 mmol) and DCC (0.095 g, 0.46 mmol) at 0°C. After the mixture had been stirred for 3 hr at 0°C, dicyclohexylurea precipitated was filtered off and washed with cold ethyl acetate. The filtrate was evaporated to dryness *in vacuo* at 0°C and the residue was dissolved in cold DMF (3 m*l*). To the solution was added a mixture of IV (0.48 g, 0.385 mmol) and TEA (0.055 m*l*, 0.39 mmol) in DMF (3 m*l*) at 0°C. After stirring had been continued for 5 hr at 0°C and for additional 2 hr at room temperature, the mixture was concentrated *in vacuo* to a small volume and the residue was treated with 0.5 M citric acid solution (10 m*l*). The precipitate collected was recrystallized from DMF - ether; yield, 0.436 g (68%); R_f^1 0.82; mp 208—209°C (decomp.); $[\alpha]_D^{20}$ −23.6° (*c* 1, DMF).

Found: C, 61.89; H, 6.28; N, 12.40%. Calcd for $C_{87}H_{105}O_{19}N_{15} \cdot H_2O$: C, 62.08; H, 6.41; N, 12.48%.

Z(OMe)-Trp-D-Trp-Asn-Gln - Tyr - Val - Orn(δ-Z)-Leu-D-Phe-Pro-ONp (VI). To a solution of V (0.333 g, 0.2 mmol) dissolved in DMF (3 m*l*) and pyridine (3 m*l*) was added di-*p*-nitrophenyl sulfite (0.65 g, 2 mmol). The solution was allowed to stand for 48 hr at room temperature and then evaporated *in vacuo*. After the oily residue was treated with a mixture of ether and petroleum ether, the powder was collected by filtration. The *p*-nitrophenyl ester content of this product (yield, 0.356 g) was estimated to be 104% measuring the optical density at 412 mμ.[7] This product was used for the next reaction without further purification.

***cyclo*-(Trp-D-Trp-Asn-Gln-Tyr-Val-Orn(δ-Z)-Leu-D-Phe-Pro-) (VIII).** To a mixture of VI (0.355 g) and 2-mercaptoethanol (0.05 m*l*)[11] in anisole (0.5 m*l*) was added trifluoroacetic acid (5 m*l*) at −5°C. After 10 min, the solution was evaporated at 0°C and the oily residue was triturated with ether. The powder was collected by filtration and washed with ether (yield of VII·CF_3COOH, 0.556 g). This was dissolved in a mixture of DMF (4 m*l*) and acetic acid (0.2 m*l*). The solution was added to pyridine (50 m*l*) kept at 55—60°C over 5 hr, stirring being continued for additional 3 hr at the same temperature. After evaporation, the residue was dissolved in 15 m*l* of a mixture of methanol - dioxane - water (1 : 2 : 1). The solution was passed successively through columns (0.9×12 cm) of Amberlite IRC-50 (H^+ form) and Amberlite IR-45 (OH^- form), the columns being washed with the same solvent. After the filtrate and washings (total 50 m*l*) were evaporated, the residual product was collected by filtration with the aid of water and recrystallized from DMF - ether; yield, 0.176 g (59% from V); mp 225—228°C (decomp.); R_f^1 0.82; $[\alpha]_D^{20}$ −36.1° (*c* 0.5, MeOH).

Found: C, 60.67; H, 6.63; N, 13.82%; mol wt 1550. Calcd for $C_{87}H_{95}O_{15}N_{15} \cdot 3H_2O$: C, 60.95; H, 6.62; N, 13.68%; mol wt 1537.[12]

***cyclo*-(Trp-D-Trp-Asn-Gln-Tyr - Val - Orn - Leu-D-Phe-Pro-) hydrochloride (IX·HCl).** A solution of VIII (76.8 mg, 0.05 mmol) in 0.02 N methanolic hydrogen chloride (2.5 m*l*) was hydrogenated in the presence of palladium black. After 4 hr, the filtrate from

12) Molecular weight was determined on a Hitachi Osmometer, type 115, using methanol as a solvent.

the catalyst was evaporated to dryness *in vacuo* and ether (4 m*l*) was added. Crystals collected were recrystallized from methanol - ethyl acetate - ether; yield of an air-dried product ($IX \cdot HCl \cdot 6H_2O$), 59.7 mg (82%); mp 218—220°C (decomp.); $[\alpha]_D^{20}$ —84.3° (*c* 0.5, MeOH).

Found: C, 56.35; H, 6.86; N, 13.83%. Calcd for $C_{70}H_{89}O_{13}N_{15} \cdot HCl \cdot 6H_2O$: C, 56.30; H, 6.88; N, 14.07%.

Ultraviolet spectra of TA·HCl, TB·HCl and IX·HCl with a Hitachi EPS-2 spectrophotometer are shown in Fig. 3. From the spectra, the characteristic features on each compound are observed; insertion of one (TB) or two (TC) Trp residues in a TA molecule increased intensities of absorbance in reasonable ratio.

Determination of Homogeneity of IX. Homogeneity of compound $IX \cdot HCl \cdot 6H_2O$ was ascertained further as follows. Data of TA·HCl, TB·HCl and GS·2HCl as reference peptides are also indicated.

(a) Thin-layer Chromatography. One spot was detected on IX; R_f^1 0.78 and R_f^2 0.02. That of TA·HCl; R_f^1 0.78 and R_f^2 0.02.

(b) Paper Chromatography. R_f^I 0.96 for IX, R_f^I 0.96 for TA·HCl and TB·HCl.

(c) Paper Electrophoresis.[13] Mobility of IX was found to be nearly the same as that of TA and TB; R_f, 0.60 × GS.

(d) Amino Acid Analysis.[14] Amino acid ratios in acid hydrolyzate were as follows; Asp 0.97, Glu 1.05, Tyr 0.82, Val 1.00, Orn 1.04, Leu 1.07, Phe 0.99, Pro 1.06 and NH_3 2.30. Molar ratios of Trp and Tyr were determined from ultraviolet spectrum of IX in a similar manner as described previously;[7] Trp 1.80, Tyr 1.05.

Microbiological assays.[15] The microorganisms employed are listed in Table 1. In addition to IX, a series of TA, TB and GS were examined as reference compounds. Table 1 indicates that the degree of activities of synthetic IX toward Gram positive (*Staph. aureus* and *B. subtilis*) and Gram negative (*E. coli* and others) microorganisms is nearly the same as that of TB, and TA except for a microorganism, *Candida albicans*.

13) Paper electrophoresis was carried out under the following conditions: solvent, formic acid - acetic acid - methanol - water (1 : 3 : 6 : 10 v/v, pH 1.8); voltage gradient, 20 V/cm.

14) We are indebted to Mr. K. Noda in this laboratory for the amino acid analysis.

15) We are indebted to Meiji Seika Co., Ltd. for microbiological assays.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2948—2952 (1970)

Hydrazinolysis of Sugar Sulfonates*[1]

Tetsuo SUAMI and Tadao SHOJI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received April 13, 1970)

Hydrazinolysis of methyl 4,6-di-*O*-acetyl-2,3-di-*O*-tosyl-α-D-glucopyranoside (I) or methyl 2,6-di-*O*-benzoyl-3,4-di-*O*-mesyl-α-D-glucopyranoside (VI), followed by catalytic hydrogenation and acetylation, afforded methyl 2,4-diacetamido-3,6-di-*O*-acetyl-2,4-dideoxy-α-D-idopyranoside (II). Also methyl 2,3-di-*O*-acetyl-4,6-di-*O*-mesyl-α-D-glucopyranoside (VII) was treated analogously as described above to give methyl 4,6-diacetamido-2,3-di-*O*-acetyl-4,6-dideoxy-α-D-galactopyranoside (IX). The structures were studied by means of proton magnetic resonance spectra. And a reaction mechanism was also discussed.

In the previous papers,[1-5] it has been described that hydrazinolysis of inositol sulfonate, followed by catalytic hydrogenation, affords diamino-dideoxyinositol of practical importance. Prior to these reports, Wolfrom and his coworkers described a displacement of sulfonyloxy group in a sugar derivative with hydrazine.[6-9]

Since a diamino-sugar has been found in several antibiotics, such as neomycin B, C,[10] kanamycin

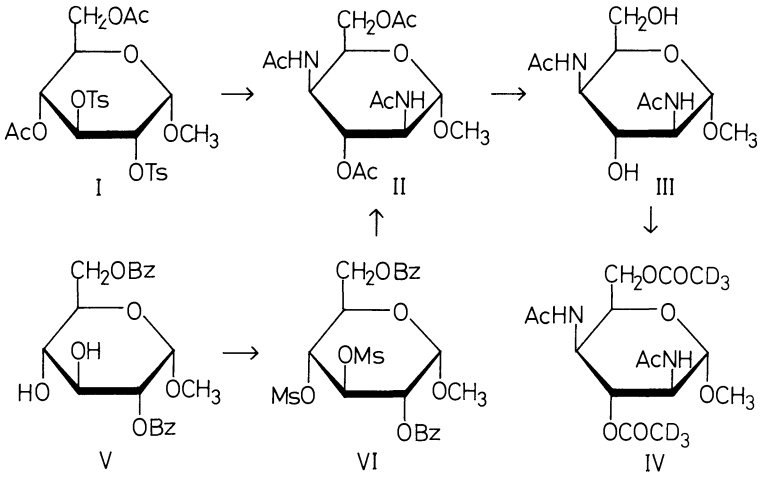

Scheme 1

B[11] and paromomycin,[12] it would be desirable to explore a new process for the synthesis of diaminosugars. For this aim, the above hydrazinolysis of sugar disulfonates seems to be an attractive method.

In the present article, it will be described that methyl 4,6-di-*O*-acetyl-2,3-di-*O*-tosyl-α-D-glucopyranoside (I), methyl 2,6-di-*O*-benzoyl-3,4-di-*O*-mesyl-α-D-glucopyranoside (VI) and methyl 2,3-di-*O*-acetyl-4,6-di-*O*-mesyl-α-D-glucopyranoside (VII) are treated with hydrazine and the reaction products are readily converted to methyl diamino-dideoxyhexosides by the catalytic hydrogenation.

The compound I was prepared by acetylation of methyl 2,3-di-*O*-tosyl-α-D-glucopyranoside which had been prepared by the method of Littmann and Hess.[13] When I was heated with anhydrous hydrazine in 2-methoxyethanol under reflux for 26 hr and the reaction product was hydrogenated in the presence of Raney nickel catalyst, an oily product was obtained. Acetylation of the product afforded methyl diacetamido-di-*O*-acetyl-dideoxyhexoside (II) as crystals of mp 245—247°C in a yield of 43%. A selective de-*O*-acetylation of II yielded methyl diacetamido-dideoxyhexoside (III) of mp 242—244°C in 74% yield.

To establish the structure of II, a proton magnetic resonance (PMR) spectrum was measured with 100 MHz spectrometer. The spectrum of II in deuteriochloroform showed three sharp signals at δ 1.99, 2.00 and 2.09 with a relative intensity of 3 : 3 : 6, which were attributed to four acetyl groups. To find the signal due to the acetamido groups, methyl di-*O*-trideuterioacetyl-diacetamido-dideoxyhexoside (IV) was prepared by trideuterioacetylation of III. The PMR spectrum of IV revealed the signal at δ 2.00 with an intensity of six protons, which was attributed to the two acetamido groups. Hence the signal at δ 2.09(6H) in the spectrum of II was ascribed to the two acetoxy groups. The two acetamido groups were considered to be in axial positions, because their signals appeared in a relatively low field.[14] One of the two acetoxy groups was on C-6, since an acetoxy group on C-6 of methyl α-D-glucopyranoside tetraacetate showed its signal at the same position (δ 2.09).[15] Another acetoxy group seemed to be axial but this was not definitive, because the signal was on an overlapped position of an axial and an equatorial acetoxy group.[14]

A more information on the conformation of II was obtained from the signal pattern of ring protons in a low field (Fig. 1). There were two doublets at δ 7.11 and 7.29 with a same coupling constant of 9.0 Hz, and these signals were removed by adding deuterium oxide to the sample (Fig. 1). Consequently, these signals were ascribed to the two NH protons of acetamido groups.

An anomeric proton should appear as a doublet, since there was only one proton on C-2 to couple with it. This doublet was found at δ 4.76 with a $J_{1,2}$ coupling of 3.5 Hz and the signal was slightly broadened by a long range coupling of less than 1 Hz. The small value of the coupling constant between H-1 and H-2 indicated that H-2 was not anti-parallel to H-1, and accordingly the C1 conformation was supported.

A triplet was observed at δ 4.97 with a coupling

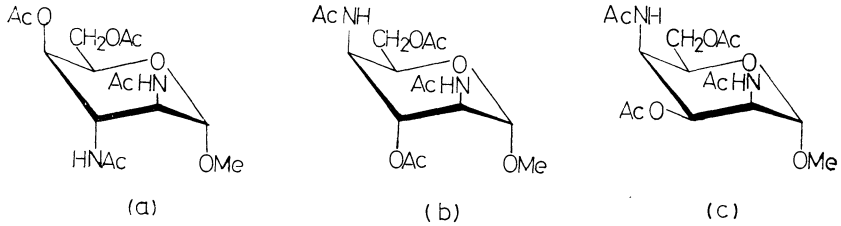
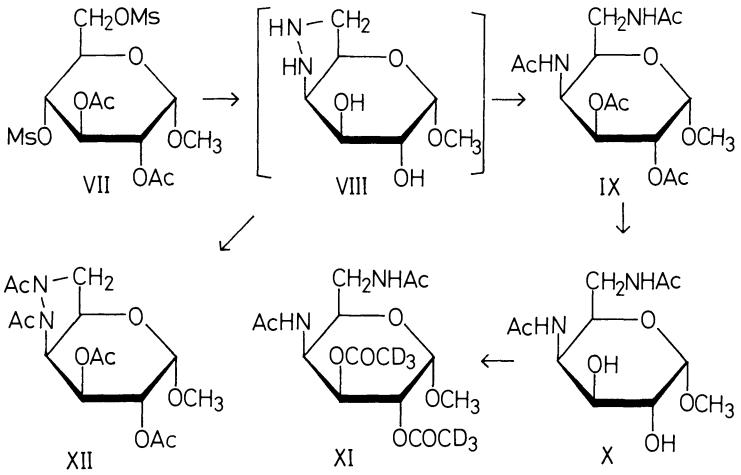


Scheme 2



Scheme 3

constant of 5.7 Hz. The fact that a magnitude of the coupling constant was not the same as $J_{1,2}$ showed that the signal was not due to H-2. Also, the triplet was not affected by the addition of D_2O, indicating that the proton was bonded to a carbon atom which held an acetoxy group. If the proton were on C-4, the configuration of II would be (a), and if it were on C-3, the configuration would be (b) or (c).

To establish the configuration, another synthetic study was carried out. When methyl 2,6-di-*O*-benzoyl-3,4-di-*O*-mesyl-α-D-glucopyranoside (VI) was treated with hydrazine and subsequently hydrogenated and acetylated, the compound II was obtained in 26% yield.

In the configuration (a), H-4 should appear as a quartet and therefore, this configuration could be omitted. If it were (c), the intermediary cyclic carbonium ions which were formed in the both reactions (I→II and VI→II) should be opened

in the *cis*-configuration. The *cis*-opening of the cyclic carbonium ion has not been observed in these reaction condition.[16] In the configuration (b), there was no such a contradiction and this configuration was consistent with all respects.

In 1968, Hill and his coworkers[17] described that 4,6-diamino-4,6-dideoxy-D-galactose derivative was prepared by a reaction between methyl 2,3-di-*O*-acetyl-4,6-di-*O*-mesyl-α-D-glucopyranoside (VII) and sodium azide. Very recently, it has been described by Paulsen and Stoye[18] that methyl 2,3-di-*O*-benzyl-4,6-di-*O*-mesyl-α-D-glucopyranoside was treated with hydrazine and subsequently hydrogenated to give the diamino-sugar.

Independently, the present authors have attempted to prepare a diamino-sugar by hydrazinolysis of VII, since hydrazine might induce a different reaction from that of sodium azide. In the present study, hydrazinolysis of VII, followed by catalytic hydrogenation and acetylation, afforded methyl diamino-dideoxyhexoside tetraacetate of mp 220—221°C which was identical with methyl 4,6-diacetamido-2,3-di-*O*-acetyl-4,6-dideoxy-α-D-galactopyranoside (IX) described by Hill *et al.*[17] A selective de-*O*-acetylation of IX yielded methyl 4,6-diacetamido-4,6-dideoxy-α-D-galactopyranoside (X).[18]

The conformation of the product was studied by PMR spectra. The spectrum of IX revealed three sharp signals at δ 2.00, 2.01 and 2.10 with a relative intensity of 3 : 3 : 6, which were ascribed to four acetyl groups. To find out a signal arisen from the acetamido groups, the spectrum of the trideuterioacetyl derivative of X was measured. In the spectrum, two sharp signals at δ 1.99 (3H) and 2.10 (3H) were observed as the two acetamido signals. The latter signal was in a lower field as compared with an acetamido signal given by the group on a pyranose ring, and this signal was thus ascribed to the one on C-6. The former signal was ascribed to an axial acetamido group.[14] Hence, the two signals at δ 2.01 (3H) and 2.10 (3H) were attributed to two equatorial acetoxy groups.

In the lowest field of the spectrum, a signal pattern of two protons appeared as a modified quartet centered at δ 6.5, which were ascribed to two NH protons. These signals were removed step by step by adding deuterium oxide to the $CDCl_3$ solution of the sample. In five minutes after the addition of D_2O, a signal pattern of one proton disappeared to leave a doublet with a coupling constant of 9.8 Hz. This doublet was further removed by warming the sample solution at 40—50°C for 10 min. These facts were not contradictory with the above mentioned structure.

The reaction mechanism was established by isolating the intermediary bicyclic compound (VIII) as the crystalline acetyl derivative (XII). That is, the attack of hydrazine occurred at C-6 of VII and then the hydrazino group on C-6 attacked C-4 to give VIII. The N-N linkage was cleaved by the catalytic hydrogenation to yield the product with the galacto-configuration.

Experimental

The melting points reported were determined on a Mitamura Riken micro hot stage. The melting point marked with an asterisk was measured in a liquid bath and was uncorrected. The PMR spectra of the samples were determined at 60 or 100 MHz in deuteriochloroform with tetramethylsilane as an internal standard. The peak positions are given in δ-values.

Methyl 4,6-Di-*O*-acetyl-2,3-di-*O*-tosyl-α-D-glucopyranoside (I). A 0.85 g portion of methyl 2,3-di-*O*-tosyl-α-D-glucopyranoside which had been prepared by the method of Littmann and Hess[13] was acetylated with acetic anhydride in pyridine at room temperature overnight. The mixture was evaporated under reduced pressure and the residue was crystallized in ethanol. Recrystallization of the crude product from ethanol-ether gave 0.89 g (90%) of I, mp 126—128°C; $[\alpha]_D^{22}$ + 31° (*c* 1, $CHCl_3$).

Found: C, 51.16; H, 5.49; S, 10.77%. Calcd for $C_{35}H_{30}O_{12}S_2$ (586.6): C, 51.19; H, 5.12; S, 10.92%.

Methyl 2,6-Di-*O*-benzyl-α-D-glucopyranoside (V). The product was prepared by the method of Lieser and Schweizer[19] in a yield of 31% from methyl D-glucopyranoside, mp 142°C; $[\alpha]_D^{22}$ + 81.9° (*c* 2, $CHCl_3$). Lit,[19] mp 144°C; $[\alpha]^{23}$ + 80.4° (*c* 4, $CHCl_3$).

Methyl 2,6-Di-*O*-benzoyl-3,4-di-*O*-mesyl-α-D-glucopyranoside (VI). To a solution of 1.78 g of V in 20 m*l* of pyridine, 4.5 m*l* of methanesulfonyl chloride was added under ice cooling. The mixture was settled at room temperature for 48 hr and was poured into a large amount of ice-water. The precipitate was collected by filtration and washed with water. The product was dissolved in ethanol and decolorized with charcoal. The solution was evaporated to give 1.51 g (61%) of amorphous powder: mp 59—64°C. The crude product was recrystallized from isopropanol to give crystals of mp 74—77°C: $[\alpha]_D^{22}$ + 138.0° (*c* 1, $CHCl_3$).

Found: C, 49.38; H, 4.84; S, 11.33%. Calcd for $C_{23}H_{26}O_{12}S_2$ (558.6): C, 49.45; H, 4.69; S, 11.48%.

Methyl 2,4-Diacetamido-3,6-di-*O*-acetyl-2,4-dideoxy-α-D-idopyranoside (II). (a) A mixture of 2.08 g of I and 4.4 m*l* of anhydrous hydrazine in 28 m*l* of 2-methoxyethanol was heated under reflux for 26 hr. The mixture was evaporated *in vacuo* and the residue was dissolved in water. The aqueous solution was treated with Amberlite IRA-400 to remove an acidic substance and then evaporated. The residue was hydrogenated in ethanol under the presence of Raney nickel catalyst in 3.4 kg/cm² of hydrogen atmosphere for 23 hr.

After the catalyst was removed by filtration, the filtrate was evaporated to give 1.02 g of an oily residue. Acetylation of the residue with acetic anhydride in pyridine afforded a crystalline product. Recrystallization of the product from ethanol afforded 0.55 g (43%) of crystals: mp* 245—247°C; $[\alpha]_D^{22}$ + 80° (*c* 1, water).

Found: C, 50.10; H, 6.78; N, 7.81%. Calcd for $C_{15}H_{24}N_2O_8$ (360.4): C, 49.99; H, 6.71; N, 7.77%.

(b) A mixture of 7.3 g of methyl 2,3-di-*O*-tosyl-α-D-glucopyranoside[13] and 15 m*l* of anhydrous hydrazine in 80 m*l* of 2-methoxyethanol was heated under reflux for 48 hr and subsequently treated as described in (a) to give 0.84 g (16%) of the product: mp 242—246°C. The product was identified with II by a mixed melting point determination and IR spectra.

(c) A 3.97 g portion of VI was heated with 20 m*l* of anhydrous hydrazine in 50 m*l* of 2-methoxyethanol for 22 hr under reflux. The reaction mixture was treated analogously as described in (a), giving 662 mg (26%) of II: mp 243—245°C.

Methyl 2,4-Diacetamido-2,4-dideoxy-α-D-idopyranoside (III). A 123 mg portion of II was selectively de-*O*-acetylated in 30 m*l* of methanol previously saturated with ammonia. The solution was evaporated under reduced pressure and the residue was washed with ethanol to give 70 mg (73%) of the product: mp 242—244°C. Recrystallization from ethanol afforded an analytically pure sample: mp 242—244°C; $[\alpha]_D^{22}$ +61° (*c* 0.2, water).

Found: C, 47.97; H, 7.32; N, 10.29%. Calcd for $C_{11}H_{20}N_2O_6$ (276.3): C, 47.82; H, 7.30; N, 10.14%.

Methyl 2,4-Diacetamido-3,6-di-*O*-trideuterioacetyl-2,4-dideoxy-α-D-idopyranoside (IV). A 55 mg portion of III was acetylated with 0.2 m*l* of acetic anhydride-d_6 in 0.6 m*l* of pyridine overnight. The mixture was evaporated *in vacuo* and the residue was crystallized in ethanol-ether to give 55 mg (76%) of the product: mp 240—244°C.

Methyl 2,3-Di-*O*-acetyl-4,6-di-*O*-mesyl-α-D-glucopyranoside (VII). The compound was prepared by the method of Hill *et al.*[17]

Methyl 4,6-Diacetamido-2,3-di-*O*-acetyl-4,6-dideoxy-α-D-galactopyranoside (IX). A 2.0 g portion of VII was heated under reflux in a mixture of 6 m*l* of anhydrous hydrazine and 30 m*l* of 2-methoxyethanol for 24 hr. After the mixture was evaporated under reduced pressure, the residue was hydrogenated in ethanol with Raney nickel catalyst at 3.4 kg/cm² of hydrogen stream at 40—50°C for 24 hr. The catalyst was removed by filtration and the filtrate was evaporated. The residue was acetylated with acetic anhydride in pyridine. An excess amount of the reagent was removed by evaporation, and the residue was crystallized from ethanol to give 0.45 g (28%) of the product: mp 220—221°C; $[\alpha]_D^{22}$ +121° (*c* 1, water). Lit,[17] mp 218—219°C; $[\alpha]_D$ +123° (*c* 1, water). Found: C, 50.15; H, 6.86; N, 7.86%.

Methyl 4,6-Diacetamido-4,6-dideoxy-α-D-galactopyranoside (X). A 32 mg portion of IX was selectively de-*O*-acetylated with methanolic ammonia, giving 16 mg (64%) of the product: mp 213.5—214°C; $[\alpha]_D^{24}$ +161° (*c* 1.1, MeOH). Lit,[17] mp 212—213°C; $[\alpha]_D$ +151° (*c* 1.0, water). Lit,[18] mp 215—216°C; $[\alpha]_D^{20}$ +153° (*c* 0.5, MeOH).

Methyl 4,6-Diacetamido-2,3-di-*O*-trideuterioacetyl-4,6-dideoxy-α-D-galactopyranoside (XI). An 89 mg portion of X was acetylated with 0.3 m*l* of acetic anhydride-d_6 in 0.7 m*l* of pyridine overnight. The mixture was evaporated under reduced pressure and the residue was crystallized in ethanol-ether to give 82 mg (70%) of the product: mp 218—219°C.

7,8-Di-*N*-acetyl-4,5-di-*O*-acetyl-3-*O*-methyl-7,8-diaza-2-oxabicyclo[4.3.0]nonane-3,4,5-triol (XII). A 1.3g portion of VII was heated with anhydrous hydrazine (4 m*l*) in 2-methoxyethanol (20 m*l*), and then the mixture was evaporated *in vacuo*. The residue was dissolved in ethanol and an insoluble material was removed by filtration. The filtrate was evaporated and the residue was acetylated with acetic anhydride in pyridine. After an excess reagent was evaporated *in vacuo*, the residue was crystallized in ethanol to give 184 mg (17%) of the product: mp 199—200°C. Recrystallization from ethanol did not raise its melting point. $[\alpha]_D^{22}$ +106° (*c* 0.5, $CHCl_3$); ν_{max}^{KBr} 1740 and 1687 cm^{-1}.

Found: C, 50.40; H, 6.30; N, 7.74%. Calcd for $C_{15}H_{22}N_2O_8$ (358.2): C, 50.27; H, 6.19; N, 7.82%.

This work has been supported financially in part by the grant of the Japanese Ministry of Education. We thank Professor Sumio Umezawa for his helpful advice and Mr. Saburo Nakada for performing elementary analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2953—2956 (1970)

Aminocyclitols. XXIII. A Synthetic Study of Streptozotocin Analogs*[1]

Tetsuo SUAMI and Tomoya MACHINAMI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei, Tokyo

(Received April 16, 1970)

Streptozotocin is an antibiotic which exhibits wide antimicrobial and antitumor activities, and its structure has been established to be *N*-carbamyl-*N'*-methyl-*N'*-nitroso-D-glucosamine. In the present article, streptozotocin analogs in which the pyranose ring was substituted for a cyclohexane ring were prepared. These compounds showed considerable activities against Ehrlich ascites tumor.

Streptozotocin,[1-4] an antibiotic produced by *Streptomyces achromogenes var.* 128 exhibits wide antimicrobial and antitumor activities *in vitro* and *in vivo*. The structure has been established to be *N*-carbamyl-*N'*-methyl-*N'*-nitroso-D-glucosamine, and this was further confirmed by the syntheses.[5,6]

In the present article, we wish to report a synthesis of *N*-carbamyl-*N'*-methyl-*N'*-nitroso derivatives of *scyllo*-inosamine,[7] *epi*-inosamine-2,[8-10] and *myo*-inosadiamine-1,3.[11,12]

When anisaldehyde was added to a mixture of *scyllo*-inosamine hydrochloride (I)[7] and 1N sodium hydroxide solution, *N*-[*p*-methoxybenzylidene]-*scyllo*-inosamine (II) was obtained in 84% yield. Acetylation of II in a mixture of acetic anhydride and pyridine afforded the pentaacetate (III), which was further converted to penta-*O*-acetyl-*scyllo*-inosamine hydrochloride (IV) by warming in 5N hydrochloric acid.

IV was treated with methyl isocyanate in the presence of silver carbonate to give penta-*O*-acetyl-*N*-carbamyl-*N'*-methyl-*scyllo*-inosamine (V) in a yield of 87%. Nitrosation of V with a mixture of nitrosyl chloride and pyridine afforded penta-*O*-acetyl-*N*-carbamyl-*N'*-methyl-*N'*-nitroso-*scyllo*-inosamine (VI) in 91% yield. An attempted deacetylation of VI in methanolic ammonia resulted in the formation of *N*-carbamyl-*scyllo*-isnosamine (VII) with a loss of diazomethane. Therefore, deacetylation was carried out before the nitrosation to give *N*-carbamyl-*N'*-methyl-*scyllo*-inosamine (VIII) in 64% yield from V.

An alternative method to prepare VIII (64% yield) was successfully carried out by treating I with methyl isocyanate in boiling aqueous acetonitrile in the presence of silver carbonate.

Nitrosation of VIII was achieved with sodium nitrite in aqueous acetic acid to give *N*-carbamyl-*N'*-methyl-*N'*-nitroso-*scyllo*-inosamine (IX) in 72% yield. Acetylation of IX by a conventional method afforded a penta-*O*-acetyl derivative which was identified to be VI.

N-Carbamyl-*N'*-methyl-*N'*-nitroso-*epi*-inosamine-2 (XI) and di-*N*,*N'*-(*N*-methyl-*N*-nitroso-carbamyl)-*myo*-inosadiamine-1,3 (XV) were prepared from *epi*-inosamine-2 hydrochloride (X) and *myo*-inosadiamine-1,3 dihydrochloride (XIII) respectively by analogous reactions described above.

These three compounds: IX, XI and XV, were active against Ehrlich ascites tumor and Hela carcinoma.

Experimental

The melting points reported were determined on a Mitamura Riken micro hot stage. The NMR spectra were determined with a Varian A-60D spectrometer.

***N*-[*p*-Methoxybenzylidene]-*scyllo*-inosamine (II).** To a solution of 949 mg of *scyllo*-inosamine hy-

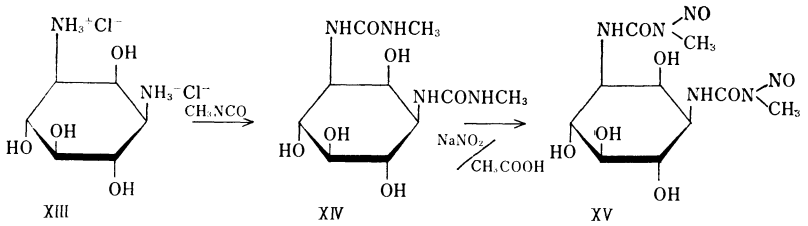

Scheme 3

drochloride (I)[7] in 4.5 m*l* of 1 N sodium hydroxide, 610 mg of anisaldehyde was added with an occasional shaking. After the reaction mixture was settled overnight in a refrigerator, crystals were collected by filtration and washed with a mixture of ethanol and ether (1 : 1). The product (1.087 g) was obtained in a form of fine powder: mp 243—249°C (dec.). A second crop of the product (92 mg) was obtained from the mother liquor. The total yield was 90.6%.

Penta-*O*-acetyl-*N*-[*p*-methoxybenzylidene]-*scyllo*-inosamine (II). A 1.087 g portion of II was acetylated with 3.3 m*l* of acetic anhydride in 5.9 m*l* of pyridine. After the reaction mixture was settled overnight at room temperature, crystals were collected by

filtration and washed with ethanol to give 1.412 g of the product, mp 228°C (dec.). The filtrate was diluted with 20 m*l* of ice-cold water to give 0.205 g of the product. The total yield was 87.2%.

The crude product was recrystallized from ethanol to give crystals, mp 228—229°C.

Penta-*O*-acetyl-*scyllo*-inosamine hydrochloride (IV). To a suspension of 1.412 g of III in 14 m*l* of boiling acetone, 0.57 m*l* of 5 N hydrochloric acid was added. After cooling, 15 m*l* of ethyl ether was added to the mixture and the mixture was stored overnight in a refrigerator. Crystals were collected by filtration and washed with ether to give 1.119 g (94.6%) of the product. The crude product was recrystallized from methanol to give needles melting at 220—222°C (dec.).

Found: C, 45.31; H, 5.93; N, 3.31; Cl, 8.45%. Calcd for $C_{16}H_{24}NO_{10}Cl$: C, 45.13; H, 5.68; N, 3.30; Cl, 8.33%.

Penta-*O*-acetyl-*N*-carbamyl-*N'*-methyl-*scyllo*-inosamine (V). To a suspension of 1.00 g of IV in 20 m*l* of acetonitrile, 1 m*l* of methyl isocyanate and 780 mg of silver carbonate were added. The reaction mixture was refluxed on a steam bath for 35 min. After cooling, precipitates were removed by filtration and the filtrate was evaporated under reduced pressure to give a crystalline residue. The residue was triturated with ethanol to yield 905 mg (86.8%) of the product, mp 255—257°C.

Recrystallizations from ethanol and from chloroform gave an analytically pure sample, mp 255—257°C.

Found: C, 48.71; H, 6.24; N, 6.19%. Calcd for $C_{18}H_{26}N_2O_{11}$: C, 48.43; H, 5.87; N, 6.27%.

Penta-*O*-acetyl-*N*-carbamyl-*N'*-methyl-*N'*-nitroso-*scyllo*-inosamine (VI). To a suspension of 1.00 g of V in 10 m*l* of pyridine, 4.0 m*l* of 1.2 M nitrosyl chloride in acetic anhydride was added drop by drop at 13°C under occasional shaking for 20 min. Then the reaction mixture was poured into 20 m*l* of ice and water. The yellowish crystals which precipitated in the aqueous solution were collected by filtration and washed with water to yield 975 mg (91.5%) of a crude product.

Recrystallization from acetone gave yellow cubic crystals melting at 192—196°C. IR: 1750 (OAc), 1530 (NH) and 1480 cm^{-1} (N–NO).

Found: C, 45.75; H, 5.53; N, 8.81%. Calcd for $C_{18}H_{25}N_3O_{12}$: C, 45.47; H, 5.30; N, 8.84%.

A presence of nitroso group was supported by a positive Liebermann nitroso test.

***N*-Carbamyl-*scyllo*-inosamine (VII).** A 300 mg portion of VI was added to 30 m*l* of methanol previously saturated with dry ammonia under ice cooling, and the mixture was settled in a refrigerator overnight. Colorless crystals which appeared in the mixture were collected by filtration and washed with methanol to give 99 mg of the product, mp 243—245°C, 70.7% yield. Recrystallization from aqueous ethanol did not raise its melting point.

Found: C, 37.59; H, 6.63; N, 12.67%. Calcd for $C_7H_{14}N_2O_6$: C, 37.84; H, 6.35; N, 12.61%.

***N*-Carbamyl-*N'*-methyl-*scyllo*-inosamine (VIII).** (a) A 294 mg portion of V was added to 40 m*l* of ethanol previously saturated with dry ammonia and the mixture was settled in a refrigerator overnight. Crystals which appeared in the mixture were collected by filtration and washed with ethanol to give 99 mg (64.0%) of the product, mp 225—226°C. Recrystallization from aqueous ethanol did not raise its melting point.

Found: C, 40.56; H, 6.98; N, 11.54%. Calcd for $C_8H_{16}N_2O_6$: C, 40.67; H, 6.83; N, 11.86%.

(b) To a solution of 390 mg of I in 10 m*l* of water, a mixture of 100 mg of methyl isocyanate, 20 m*l* of acetonitrile and 295 mg of silver carbonate was added. The reaction mixture was heated under reflux on a steam bath for 50 min. After the reaction mixture was cooled, a precipitate was removed by filtration. The filtrate was evaporated under reduced pressure to give a crystalline residue. The residue was recrystallized from aqueous ethanol to give 271 mg (63.8%) of colorless crystals, mp 225—226°C. The product was identified with the product obtained by the method (a), by a mixed melting point determination and a comparison of IR spectra.

***N*-Carbamyl-*N'*-methyl-*N'*-nitroso-*scyllo*-inosamine (IX).** To a solution of 300 mg of VIII in a mixture of 3.8 m*l* of glacial acetic acid and 5.0 m*l* of water, 17.5 m*l* of 0.1 M sodium nitrite solution was added under ice cooling. The reaction mixture was stored in a refrigerator overnight. Crystals (57 mg) appeared in the solution were collected by filtration and washed with acetone to give the product, mp 122—125°C. The filtrate was treated with Amberlite IR-120 to remove a sodium ion and then freeze-dried. The amorphous powder obtained by freeze-drying was recrystallized from aqueous acetone to give 185 mg of the product, mp 123—126°C. The total yield was 72.2%. IR: 1700 (C=O), 1550 (NH) and 1470 cm^{-1} (N–NO). Liebermann nitroso test was positive. NMR (D_2O): τ 6.77 (N–CH_3).

Found: C, 34.60; H, 6.03; N, 14.65%. Calcd for $C_8H_{15}N_3O_7 \cdot H_2O$: C, 33.90; H, 6.05; N, 14.84%.

Acetylation of IX (42 mg) with acetic anhydride (1.0 m*l*) in pyridine (2.0 m*l*) afforded 53 mg (70.7%) of a product, which was identified to be VI by a comparison of IR spectra.

***N*-Carbamyl-*N'*-methyl-*N'*-nitroso-*epi*-inosamine-2 (XI).** To a solution of 600 mg of *epi*-inosamine-2 hydrochloride (X) in 12 m*l* of water, a mixture of 200 mg of methyl isocyanate, 783 mg of silver carbonate and 24 m*l* of acetonitrile was added and the mixture was heated under reflux for 1 hr. The warm mixture was filtered and the filtrate was evaporated under reduced pressure. The residue was dissolved in a small amount of water and the solution was filtered. The filtrate was again evaporated *in vacuo* to give 720 mg of an oily residue.

The residue was dissolved in a mixture of 1 m*l* of water and 3 m*l* of glacial acetic acid. To the solution, 6.0 m*l* of 0.5 M sodium nitrite solution was added under ice cooling, and the mixture was settled at room temperature overnight. Then the reaction mixture was passed through a column of Amberlite IR-120 to remove a sodium ion, and the aqueous solution was freeze-dried. The crude product was recrystallized from methanol to give 592 mg (81.2%) of nice crystals melting at 104°C (dec.). IR: 1720 (C=O), 1540 (NH) and 1475 cm^{-1} (N–NO).

Found: C, 36.52; H, 6.71; N, 14.50%. Calcd for $C_8H_{15}N_3O_7 \cdot CH_3OH$: C, 36.36; H, 6.40; N, 14.14%.

Penta-*O*-acetyl-*N*-carbamyl-*N'*-methyl-*N'*-nitroso-*epi*-inosamine-2 (XII). Acetylation of XI

(180 mg) with 2 m*l* of acetic anhydride and 2 m*l* of pyridine afforded an oily product. The crude product was crystallized from ethanol to give 265 mg (82.1%) of pale yellow crystals, mp 114—116°C. IR: 1755 (OAc), 1530 (NH) and 1490 cm^{-1} (N–NO).

Found: C, 45.59; H, 5.58; N, 8.71%. Calcd for $C_{18}H_{25}N_3O_{12}$: C, 45.47; H, 5.30; N, 8.84%.

Di-*N*,*N*′-(*N*-methyl-carbamyl)-*myo*-inosadiamine-1,3 (XIV). A mixture of 1.32 g of *myo*-inosadiamine-1,3 dihydrochloride (XIII) and 600 mg of methyl isocyanate in 60 m*l* of 65% aqueous acetonitrile was heated under reflux in the presence of 2.0 g of silver carbonate for 70 min. The warm reaction mixture was filtered and the filtrate was evaporated under reduced pressure to give an oily residue. An insoluble material which was obtained by the filtration was extracted with hot water and from the aqueous extract, 676 mg of the product crystallized out as cubic crystals, mp 230—231°C.

The oily residue was dissolved in a small amount of water and ethanol was added to the solution to give a second crop of the product (222 mg), mp 229—231°C. The total yield was 58.9%.

Recrystallization from aqueous ethanol gave fine crystals, mp 230—231°C.

Found: C, 37.34; H, 7.60; N, 16.90%. Calcd for $C_{10}H_{20}N_4O_6 \cdot 2H_2O$: C, 36.58; H, 7.37; N, 17.07%.

Di-*N*,*N*′-(*N*-methyl-*N*-nitroso-carbamyl)-*myo*-inosadiamine-1,3 (XV). A 202 mg portion of XIV was dissolved in a mixture of 2 m*l* of acetic acid and 15 m*l* of water, and 16.4 m*l* of 0.1 M sodium nitrite solution was added to the solution under ice cooling with an occasional shaking. The mixture was mechanically agitated overnight under ice cooling. Then the clear solution was freeze-dried to give 184 mg (76.4%) of the crude product. Recrystallization from ethanol afforded crystals, mp 158—162°C. IR: 1700 (C=O), 1530 (NH) and 1475 cm^{-1} (N–NO). NMR (D_2O): τ 6.78 (N–CH_3).

Found: C, 34.14; H, 5.71; N, 24.32%. Calcd for $C_{10}H_{18}N_6O_8$: C, 34.28; H, 5.18; N, 23.99%.

Antitumor Activity. A detail of the antitumor activities against Ehrlich ascites tumor and HeLa carcinoma will be published elsewhere.

The authors are grateful to Professor Sumio Umezawa for his helpful advice, Dr. Tomoharu Okuda for a biological assay and Mr. Saburo Nakada for his elementary analyses. This research has been supported financially in part by a grant of the Japanese Ministry of Education, to which the authors' thanks are due.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2956—2959 (1970)

The Constituents of Hops. IV.[1] The Volatile Composition of *Humulus Lupulus* L. *var. cordifolius* Maxim.

Yoko NAYA and Munio KOTAKE

The Institute of Food Chemistry, Dojimanaka, Kita-ku, Osaka

(Received April 18, 1970)

The steam-volatile constituents of *Humulus Lupulus* L. *var. cordifolius* Maxim. have been studied, and 66 compounds of the oil have been identified. Besides the previously-reported principal hop components (myrcene, β-humulene, caryophyllene, β-selinene, δ- and γ-cadinenes), evidence was found for the presence in an abnormally high concentration of others: zingiberene, α-curcumene together with β-bisabolene, and β-sesquiphellandrene, selina-3,7(11)-diene, and selina-4(14),7(11)-diene. A number of oxygenated sesquiterpenoids were detected. The major one was found to be caryophyllene-oxide. The isolated components were identified by spectroscopic or chemical means.

The steam volatile constituents of the horticultural Japanese hop, "Shinshu-wase" (*Humulus Lupulus* L.), were examined; the characterization of most compounds in the oil has already been reported.[1-5] In the present paper, the isolation and identification of volatile compounds contained in the cone oil of a wild variety, "Karahanaso" (*Humulus Lupulus* L. *var. cordifolius* Maxim.), will be reported for the first time.

Experimental

Separation. The air-dried material (9.2 kg) was distilled with steam, and then the distillate was treated by usual methods to remove any acidic compounds.

The residual oil (17.8 g)(0.19%) was readily separated into the hydrocarbon and the oxygenated constituents by selective adsorption on neutral alumina. The amount of the hydrocarbon fraction was four times that of the oxygenated fraction. The hydrocarbon fraction was divided into three parts by fractional distillation under a pressure of 3 mmHg. Each part was separated into its constituents by a combination of adsorption chromatography (silica-gel or silica-gel impregnated with silver nitrate) and preparative gas-liquid chromatography (SF 96 and a Carbowax 20 M columns). Similar methods were applied to oxygenated compounds, using appropriate adsorbents and columns.

Apparatus. The analytical GLC was carried out using a Hitachi Model K-53 gas chromatograph provided with a flame-ionization detector. The stainless-steel capillary column (0.25 mm in diameter and 45 m in length) used for the analysis was coated with HB 2000; the column temperature was held isothermally at 100°C, and then it was flushed to 150°C. The nitrogen-carrier gas-inlet pressure was set at 1.5 kg/cm² for the initiation and 2.5 kg/cm² at the end.

For preparative gas chromatography, a Model 90-P Varian Aerograph equipped with a thermal conductivity detector was employed. Usually a 10-ft. × 3/8 in. aluminum column packed with 20% Carbowax 20 M on Chromosorb W (60—80 mesh) was used. Helium was the carrier gas, and the column temperature was 100—220°C.

The NMR spectra were measured in CCl_4, using TMS as an internal reference at 60 MHz on a JEOL Model C-60 spectrometer.

The mass spectra were measured with a Hitachi Model RMU-6 Mass Spectrometer; the operating conditions were as follows: ionization energy, 80 eV; ion-accelerating voltage of 2000 V, at temperatures of 250°C and 150°C in the ionization chamber and the sample injection block respectively.

Table 1. The constituents of hydrocarbons

Peak No. in Fig. 1	Identified compound
1	α-Pinene
2	β-Pinene
3	Myrcene
4	Undecane
6	Limonene
7	β-Phellandrene
8	γ-Terpinene
9	Dodecane

	Isocaryophyllene	204	93

GLC. Each separated compound was mixed with the original oil, and the peak on the programmed gas-chromatogram was confirmed by an appreciable increase in the height of the particular peak. Authentic compounds were obtained from reliable sources or were prepared by well-established methods. They were purified by GLC separation before use. Identifications are based on at least two physical methods (IR, MS, and NMR). Figure 1 shows a gas chromatogram of the steam volatile oil from "Karahanaso", together with that of the oil from the Japanese "Shinshu-wase," harvested in 1968,*1 for the sake of comparison. Significant differences in the composition are seen in the fingerprinting of GLC analysis. Myrcene, α- and β-humulenes, caryophyllene, β-selinene, α-muurolene, and δ- and γ-cadinenes have been known[1-3] to be major components of "Shinshu wase." In "Karahanaso," myrcene, β-humulene, α- and β-selinenes, and δ- and γ-cadinenes occur in considerable amounts; bisabolane-type sesquiterpene (zingiberene, α-curcumene, together with β-bisabolene, and β-sesquiphellandrene) in an abnormally high concentration, and caryophyllene, in the highest abundance. Unlike the case of "Shinshu-wase", no α-muurolene was detected, whereas evidence was found for the presence of two other selinenes, selina-3,7(11)-diene and selina-4(14),7(11)-diene.

Oxygenated sesquiterpenes occur in relatively small quantities, and caryophyllene-oxide, nerolidol, and β-caryophyllene alcohol have been isolated in certain amounts. The isolation of many GLC peaks with long retention times has shown that each peak is composed of a mixture of several compounds. Most of these appear to be sesquiterpenic alcohols with a molecular weight of 220 or 222.

The authors are deeply indebted to Professor Tsunematsu Takemoto of Tohoku University for supplying "Karahanaso," harvested in 1969 at Miyagi, and to Professor Akira Yoshikoshi for supplying the IR spectrum of synthetic bulnesol.

*1 Previous reports[1-3] have been concerned with "Shinshu-wase" harvested in 1963, the constituests of which were essentially the same as in that harvested in 1968.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2960—2965 (1970)

Studies on Aminosugars. XXV. The Synthesis of Position Isomers of α-D-Glucopyranosyl-2-deoxystreptamine*[1]

Yoshio NISHIMURA, Tsutomu TSUCHIYA and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received April 27, 1970)

Racemic *O*-isopropylidene derivative of *N,N'*-diethoxycarbonyl-2-deoxystreptamine was glucosidized with 2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl chloride to afford two kinds of position isomers of α-glucoside, which led to 4-*O*-(α-D-glucopyranosyl)- and 6-*O*-(α-D-glucopyranosyl)-2-deoxystreptamine. Structural assignments were made by the determination of Δ[M] of the glucosides in a tetramminecopper(II) sulfate solution.

The preparation of α-glucopyranosides in high yields remains an important problem of carbohydrate chemistry. The Koenigs-Knorr reaction provided a large number of glycopyranosides. However, the reaction leads to the formation of either α- or β-glycoside. In this reaction, the contributing factors for the ratio and the yields of α- and β-glycosides are the stabilities of the anomeric halides, the chemical and stereochemical properties of the group at C-2 in sugars, the interaction of polar substituents with the ring oxygen in sugars, the polar and steric interactions between substituents of both sugar and aglycone molecules in forming the glycosides and the solvent effects. These factors make the reaction complicated.

On the other hand, α-glycosides of 2-deoxystreptamine have received particular attention in recent years in the field of chemistry of antibiotics, since these kinds of glycosides are important components of useful antibiotics such as kanamycins, paromomycins, neomycins, gentamicins, hygromycin B and destomycin.

We have recently reported the total synthesis of kanamycins[1)] as well as the synthesis of paromamine[2)] and neamine[3)]. In relation to these syntheses, we took an interest in the glycosidation reaction between glucose and 2-deoxystreptamine with particular reference to the formation of anomeric *cis* derivatives. The glycosidation reaction involves several interesting problems, such as the difference in reactivity among the three hydroxyl groups of 2-deoxystreptamine for glycosidation, the reaction conditions to force the glucosyl halide into α-glycosidation, the procedure to separate the position isomers formed which are quite similar in their structures, and the method for determination of the position of 2-deoxystreptamine glycosidized. The present paper describes a detailed study of the modified Koenigs-Knorr reaction between 2,3,4,6-tetra-*O*-benzyl-α-D-glucosyl chloride (III) and the racemic *O*-isopropylidene derivative (II) of *N,N'*-diethoxycarbonyl-2-deoxystreptamine (I) as a basic research for the synthesis of more complex α-glycosides of 2-deoxystreptamine.

In order to make the formation of α-linkage favorable, the hydroxyl groups at C-2 and at other carbon atoms of the sugar halide were masked with benzyl groups, which are nonparticipating with the anomeric position and were successfully used in the case of the total synthesis of kanamycins.[1)] Regarding the *O*-isopropylidene derivative of 2-deoxystreptamine, we had already prepared another one, namely, *N,N'*-dicarbobenzoxy-mono-*O*-isopropylidene-2-deoxystreptamine for the synthesis of kanamycins. However, in the present study, the carbobenzoxyl groups were replaced with ethoxycarbonyl groups.

Synthesis of Glucosides. *N,N'*-Diethoxycarbonyldeoxystreptamine (I) was prepared from deoxystreptamine and ethyl chloroformate and acetonated with 2,2-dimethoxypropane in the presence of *p*-toluenesulfonic acid in dimethyl formamide (DMF) to give a racemic mixture (II) of *N,N'*-diethoxycarbonyl-4,5- and 5,6-*O*-isopropylidenedeoxystreptamine in a 71% yield.

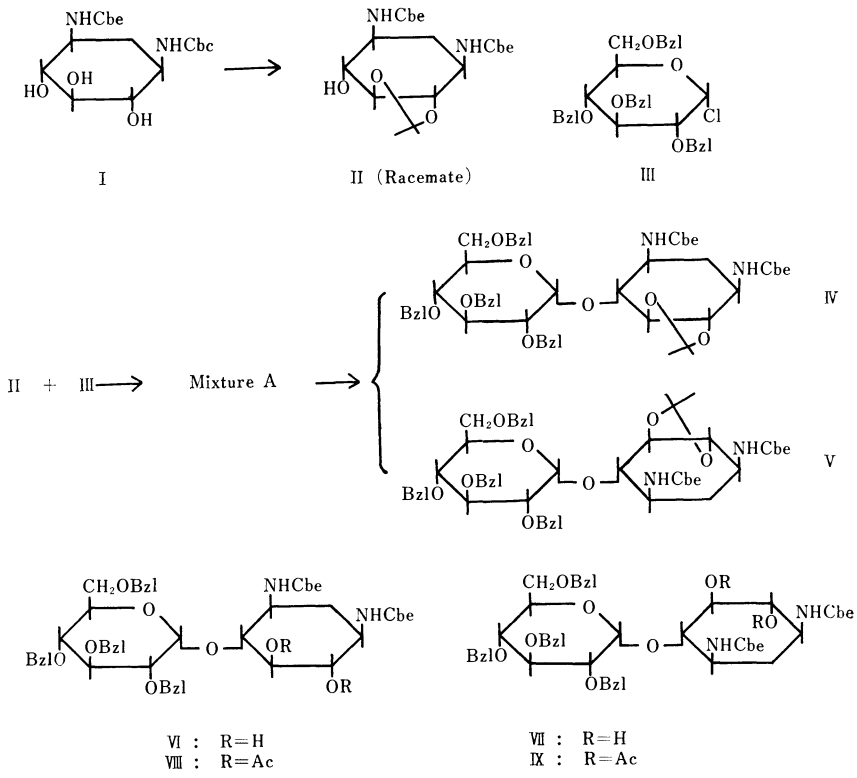

Chart 1. Cbe: $CO_2C_2H_5$ Bzl: $CH_2C_6H_5$

2,3,4,6-Tetra-*O*-benzyl-α-D-glucopyranosyl chloride (III) was prepared by the method of Austin *et al.*[4] The chloride proved to be a homogeneous anomer that was characterized through its NMR spectrum.

The racemic monoisopropylidene derivative (II) was condensed with chloride (III). As in the previous studies on the synthesis of kanamycins,[1] the condensation was similarly effected with the use of mercuric cyanide and Drierite in dioxane-benzene and under an extremely anhydrous condition, which is most important for glycosidation. The crude condensed products (here named mixture A), showed four spots (R_f 0.58, 0.54, 0.46, 0.40) on thin-layer chromatography (TLC). Separation of the mixture A into its components was performed by silica gel column chromatography, and the two products separated (R_f 0.46 and 0.40) were found to be 4-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyl-5,6-*O*-isopropylidenedeoxystreptamine (IV) and 6-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyl-4,5-*O*-isopropylidenedeoxystreptamine (V), respectively, by their elemental analyses, IR and NMR spectra and also by the fact that they were derivable to 4-*O*- and 6-*O*-(α-D-glucopyranosyl)deoxystreptamine (X and XI), respectively. There is a large difference between IV and V with respect to melting points (62 and 168°C), solubilities in chloroform and the NMR signals assignable to anomeric hydrogens (τ 4.51 and 4.90). This suggests that the products have fairly different conformations as a whole. Another separated, minor product (R_f 0.54) was supposed to be an isomer having β-anomeric configuration.

Compounds IV and V were deisopropylidenated with aqueous acetic acid and gave 4-*O*- and 6-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyldeoxystreptamine, respectively (VI and VII).

Separation of mixture A into its components by silica gel column chromatography described above, was, however, troublesome because deisopropylidenation of the compounds took place during chromatography. For this reason, after rough purification by column chromatography with ammonia-treated silica gel, the mixture was subjected to deacetonation by hydrolysis followed by acetylation. Although the hydrolyzate of mixture A showed the presence of products of the same R_f-value and the products could not be separated by chromatography, the acetylated products gave three spots (R_f 0.78, 0.71 and 0.65) on TLC and were successfully separated by column chromato-

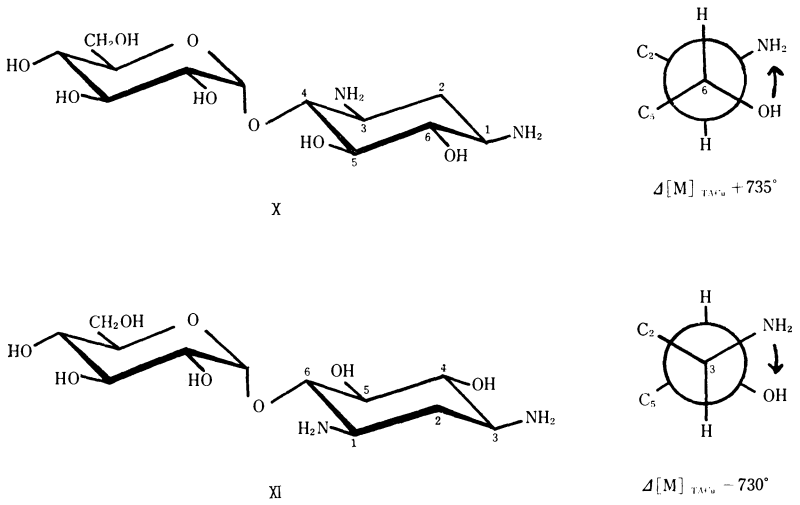

Chart 2.

graphy. The resulting diacetyl derivatives VIII (R_f 0.65) and IX (R_f 0.78) were identical with those derived from the above mentioned pure deisopropylidenation products (VI and VII) by acetylation, and the result indicated that VIII is 5,6-di-*O*-acetyl-4-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyldeoxystreptamine and IX is 4,5-di-*O*-acetyl-6-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-*N*,*N*′-diethoxycarbonyldeoxystreptamine. The overall yields of VIII and IX from II were 17 and 30%, respectively. It is noteworthy that the hydroxyl group at C-6 in 2-deoxystreptamine is more favorably glycosidated than the hydroxyl group at C-4. This indicates that the unsymmetrical structure of the sugar component greatly influences its approach to the 2-deoxystreptamine component.

VIII and IX were then hydrogenolyzed with palladium black and hydrogen to give debenzylated products, which were then deacetylated and de-*N*-ethoxycarbonylated in a hot barium hydroxide solution to give the final products 4-*O*- and 6-*O*-(α-D-glucopyranosyl)deoxystreptamine (X and XI) in 42 and 57% yield, respectively.

Photolysis of VII was attempted with the aid of bromine according to BeMiller, Meyers and Wing.[5] Removal of benzyl groups proceeded with ease. However, it was found that photolysis was always accompanied by hydrolysis of glycosidic linkage. Addition of powdered potassium hydroxide improved the situation. However, the yield of the product was still variable (95—30%).

Structural Assignment. The problem to differentiate the positional isomers was solved by the determination of Δ[M] in a tetramminecopper (II) sulfate solution (TACu). This reagent was first introduced by Umezawa, Tsuchiya and Tatsuta.[6] Unlike Cupra B[7] or ammoniacal cuprous chloride solution[6] (CuAm), this reagent forms a copper complex with vicinally situated amino and hydroxyl groups without being disturbed by the presence of any other vicinally situated hydroxyl groups. In a six-membered chair-form, a pair of vicinally situated *trans*-diequatorial amino and hydroxyl groups gives a value $\Delta[M]_{TACu}$*2 −900 or +900° according to whether the projection angle*3 between the pair groups (~60°) is clockwise or counterclockwise. X gave $\Delta[M]_{TACu}$ +735°. This value indicates that the copper complex is formed between 1-amino and 6-hydroxyl groups of 2-deoxystreptamine moiety, showing X to be 4-*O*-(D-glucosyl)deoxystreptamine. XI gave $\Delta[M]_{TACu}$ −730°, indicating XI to be 6-*O*-(D-glucosyl)deoxystreptamine.

Experimental

The NMR spectra were measured with a Varian A-60D spectrometer unless otherwise stated. Thin-layer chromatography was carried out on microscope slides coated with silica gel.

***N*,*N*′-Diethoxycarbonyl-2-deoxystreptamine (I).** To a solution of deoxystreptamine dihydrochloride (6 g) and anhydrous sodium carbonate (27 g) in water (150 m*l*) ethyl chloroformate (10.2 m*l*) was added with

vigorous stirring. The mixture was then stirred at room temperature for 4 hr and allowed to stand overnight. Inorganic precipitate was filtered and washed with methanol. The filtrate and the washings were combined and evaporated to give a residue, which was dissolved in hot dioxane, filtered, and the filtrate was evaporated. The resulting solid was recrystallized from methanol; yield 7.38 g (94%), mp 231—232°C, $[\alpha]_D^{19}$ ~0° (*c* 0.75, water); IR (KBr): 3450 (broad, OH), 3350 (amide, *ν* NH), 1695 (NHCOO), 1545 (amide II), 1470 (w), 1375 (w), 1305, 1240, 1045, 857, 780 cm^{-1}.

Found: C, 47.18; H, 7.26; N, 8.99%. Calcd for $C_{12}H_{22}N_2O_7$: C, 47.02; H, 7.24; N, 9.15%.

Racemic Mixture (II), *N,N'*-Diethoxycarbonyl-4,5 and 5,6-*O*-isopropylidene-2-deoxystreptamine. A solution of I (3.98 g), 2,2-dimethoxypropane (7 m*l*) and fuse-dried *p*-toluenesulfonic acid (82 mg) in DMF (46 m*l*) was heated on a bath (110°C) for 4 hr, cooled, and neutralized with ethanol-washed Amberlite IRA-400 (OH form). A thin-layer chromatogram (benzene-ethanol 5 : 1) of this solution showed that the starting material (I, R_f 0.16) disappeared and II (R_f 0.53) appeared as a single spot. The solution was evaporated *in vacuo* and further coevaporated with water and with a mixture of toluene and ethyl acetate to give a solid, which was recrystallized from ethyl acetate; yield 3.18 g (71%), mp 199—200°C, $[\alpha]_D^{21}$ ~0° (*c* 1, methanol); IR(KBr): ~3400 (broad), 3330; 1725, 1710, 1690 (amide I); 1560 (sh.), 1550, 1540 (amide II); 1450 (w); 1382, 1372 (isopropylidene); 1310, 1220, 1045, 840, 780 cm^{-1}; NMR(methanol-d_4): *τ*: 8.75 (6-p. t., *J* 7.1 Hz, $CH_2C\underline{H}_3$), 8.57 (6-p. s., isopropylidene), 8.2—9.0 (1-p. H_{ax}-2, overlapped with methyl and isopropylidene signals), 7.8 (1-p. doublet of triplets, *J* ~13 and ~3.5 Hz), 6.2—6.7 (5-p. m., H-1,3,4,5,6), 5.87 (4-p. q., $C\underline{H}_2CH_3$). NMR(DMSO-d_6) : *τ*: 8.81 (6-p. t., $CH_2C\underline{H}_3$), 8.62 (6-p. s., isopropylidene), 8.4—9.0 (H_{ax}-2 N), 8.2 (1-p. broad doublet, H_{eq}-2), 6.3—6.8 (5-p. m.), 5.95 (4-p. q., $C\underline{H}_2CH_3$), 4.9 (1-p.), 3.05 (1-p. d.), 2.83 (1-p. d.). NMR(pyridine-d_5): *τ*: 8.87 (6-p. t., CH_2-$C\underline{H}_3$), 8.52 (6-p. s.), 8.05 (1-p. q., *J* ~12 Hz, H_{ax}-2), 7.22 (1-p. doublet of triplets, *J* ~13 and ~3.5 Hz, H_{eq}-2), 5.6—6.3 (5-p. m.), 5.82 (4-p. q., $C\underline{H}_2CH_3$), 3.5 (1-p.), 2.18 (1-p. d., *J* 8 Hz), 1.98 (1-p. d., *J* 8 Hz).

In pyridine-d_5, the signals assignable to H_{ax}-2 appeared without being overlapped with other signals, and H_{ax}-2, H_{eq}-2 and skeleton hydrogens resonated at lower fields than that measured in methanol-d_4 or dimethyl sulfoxide-d_6.

Found: C, 51.83; H, 7.72; N, 8.03%. Calcd for $C_{15}H_{26}N_2O_7$: C, 52.01; H, 7.57; N, 8.09%.

2,3,4,6-Tetra-*O*-benzyl-*α*-D-glucopyranosyl Chloride (III). This compound was prepared by the method of Austin *et al*[4]. except that, in the final step, the product was purified by passing a short column of silica gel with dry benzene-methyl ethyl ketone (10 : 1). Syrup, $[\alpha]_D^{20}$ +116° (*c* 1, benzene)(lit,[4] +95° in benzene), R_f 0.89 (TLC, benzene - methyl ethyl ketone 10 : 1). NMR($CDCl_3$): *τ*: 5.6—6.6 (6-p. skeleton hydrogens), 4.8—5.6 (8-p. m., $C\underline{H}_2C_6H_5$), 3.85 (1-p. d., *J* 3.5 Hz, H-1), 2.5—2.8 (20-p. m., phenyl).

Preparation of Mixture A. To a solution of III (2.4 g) in dry benzene (18 m*l*) and dry dioxane (6 m*l*) II (1.2 g), freshly prepared powder Drierite (2.1 g), and well dried powder mercuric cyanide (2.2 g) were added, and the mixture was refluxed for 4 hr with vigorous stirring. The reaction mixture was filtered with the aid of Celite and the residue was washed with chloroform. The filtrate and the washings were combined and evaporated to give a viscous solid, which was dissolved in chloroform, filtered, and the solution was washed with 2% sodium bicarbonate solution, then with water, dried over sodium sulfate and evaporated to give a solid (3.2 g). On TLC with benzene - methyl ethyl ketone (5 : 1), the solid (mixture A) showed five spots of R_f 0.40 (V), 0.46 (IV), 0.54, 0.58 and 0.71, the last being 2,3,4,6-tetra-*O*-benzyl-D-glucose.

Separation of Mixture A into 4-*O*-(2,3,4,6-Tetra-*O*-benzyl-*α*-D-glucopyranosyl)-*N,N'*-diethoxycarbonyl-5,6-*O*-isopropylidene-2-deoxystreptamine (IV) and 6-*O*-(2,3,4,6-Tetra-*O*-benzyl-*α*-D-glucopyranosyl)-*N,N'*-diethoxycarbonyl-4,5-*O*-isopropylidene-2-deoxystreptamine (V). The chromatographic separation of the crude mixture A into its components with the use of silica gel (Mallinckrodt, or most kinds of silica gel purchased from Kanto-Kagaku, with or without treating with ammonia*[4]) was unsuccessful in most cases owing to de-*O*-isopropylidenation of the components during the procedure; a kind of silica gel purchased from Kanto-Kagaku successfully achieved the separation: The mixture A (3 g) was chromatographed on a silica gel column (Kanto-Kagaku, 300 g, 45×480 mm) with dry benzene - methyl ethyl ketone (9 : 2) and the portions containing pure IV and V, respectively, were separated from overlapping portions; the result of a typical run was as follows: the portion containing the substances of R_f 0.58 and 0.71 weighed 0.13 g; R_f 0.54, 0.25 g (part A); R_f 0.54 and 0.46, 0.32 g; R_f 0.46 (IV), 0.35 g (part B); R_f 0.46 and 0.40, 0.59 g; R_f 0.40 (V), 0.53 g (part C).

Part A was recrystallized from methanol to give crystals; mp 232—234°C, $[\alpha]_D^{19}$ +13° (*c* 1, chloroform); IR (Nujol): 3340 (*ν*NH), 1690, 1550, 1300, 1290, 1145, 1080, 1040, 775; 730, 712, 693 cm^{-1} (phenyl).

Found: C, 68.02; H, 6.96; N, 3.05%. Calcd for $C_{49}H_{60}N_2O_{12}$: C, 67.73; H, 6.96; N, 3.22%.

The substance was supposed to be an isomer having *β*-anomeric configuration.

Part B could not be crystallized from any solvent tested; amorphous solid (IV); mp 60—62°C $[\alpha]_D^{18}$ +31.7° (*c* 1, chloroform); IR(Nujol): 3330; 1725, 1710, 1695 (amide I); 1550 (sh.), 1530 (amide II); 1255, 1220, 1155, 1135, 1065, 1040, 1025, 840, 775; 730, 695 cm^{-1} (phenyl); NMR($CDCl_3$) : *τ* : 8.83 and 8.76 (3-p. t. each, *J* 7.1 Hz, $CH_2C\underline{H}_3$), 8.57 (6-p. s., isopropylidene), 5.9—6.8 (15-p. skeleton hydrogens and $C\underline{H}_2CH_3$), 4.95—5.6 (8-p, $C\underline{H}_2C_6H_5$), 4.51 (1-p. d., *J*~3.5 Hz, H-1′), 2.6—2.9 (20-p. m., phenyl).

Found: C, 67.94; H, 6.90; N, 3.11%. Calcd for $C_{49}H_{60}N_2O_{12}$: C, 67.73; H, 6.96; N, 3.22%.

Part C was recrystallized from methanol to give V; mp 167—168°C, $[\alpha]_D^{19}$ +53° (*c* 1, methanol). This compound, unlike the above compound (IV), is scarcely soluble in cold chloroform. IR(Nujol): 3340; 1690 (amide I); 1550 (sh.), 1530 (amide II); 1275, 1220, 1160, 1065, 1040, 840, 775; 730, 695 cm^{-1} (phenyl); NMR (in warm $CDCl_3$) : *τ* : 8.83 and 8.78 (3-p. t. each, *J* 7.1 Hz, $CH_2C\underline{H}_3$), 8.62 (6-p. s., isopropylidene), 5.7—6.8 (15-p., skeleton hydrogens and ($CH_2C\underline{H}_3$),

*4 See Experimental for the preparation of X and XI.

5.1—5.6 (8-p.) $C\underline{H}_2C_6H_5$), 4.90 (1-p. d., J ~3.5 Hz, H-1'), 2.6—2.9 (20-p. m., phenyl).

Found: C, 67.81; H, 7.16; N, 3.21%. Calcd for $C_{49}H_{60}N_2O_{12}$: C, 67.73; H, 6.96; N, 3.22%.

6-*O*-(2,3,4,6-Tetra-*O*-benzyl-α-D-glucopyranosyl)-*N*,*N*'-diethoxycarbonyl-2-deoxystreptamine (VII). The solution of V (0.30 g) in 80% aqueous acetic acid (4 ml) was heated at 80°C for 5 min. Product (VII) appeared as a single spot (TLC, R_f 0.36 with benzene-ethanol 10 : 1). The solution was poured into water and the resulting precipitates were filtered and washed throughly with water. The soild was recrystallized from acetone; yield 0.23 g (80%); mp 212—213°C, $[\alpha]_D^{18}$ +15° (c 1, chloroform); IR(KBr): 3580 (sh.), 3520, 3360, 1700, 1550, 1457 (w), 1355, 1305, 1270, 1250, 1230, 1110, 1080 (sh), 1065, 1030, 915 (w), 865 (w), 780, 748, 740, 697 cm^{-1}; NMR($CDCl_3$): τ : 8.84 and 8.78 (3-p. t. each, J 7.1 Hz, $CH_2C\underline{H}_3$), 5.92 and 5.87 (2-p. q. each, J 7.1 Hz, $C\underline{H}_2CH_3$), 5.05—5.65 (9-p. $C\underline{H}_2C_6H_5$ and an anomeric hydrogen(?)), 2.6—2.8 (20-p. m., phenyl).

Found: C, 66.81; H, 6.88; N, 3.40%. Calcd for $C_{16}H_{56}N_2O_{12}$: C, 66.65; H, 6.81; N, 3.38%.

4-*O*-(2,3,4,6-Tetra-*O*-benzyl-α-D-glucopyranosyl)-*N*,*N*'-diethoxycarbonyl-2-deoxystreptamine (VI). Compound IV was treated likewise as above and the product was recrystallized from acetone; yield 75%; mp 185—186°C, $[\alpha]_D^{20}$ +28° (c 1, chloroform); IR (KBr): 3580 (sh.), 3450 (broad), 3360, 1695, 1550 (sh.), 1540, 1457 (w), 1362, 1315, 1295, 1285, 1250, 1250, 1225, 1085, 1065, 1040, 1030 (sh.), 865 (w), 780, 745, 735, 697 cm^{-1}; NMR($CDCl_3$): τ : 8.84 and 8.78 (3-p. t. each, J 7.1 Hz, $CH_2C\underline{H}_3$), 5.95 and 5.88 (2-p. q. each, J 7.1 Hz, $C\underline{H}_2CH_3$), 5.05—5.6 (9-p., $C\underline{H}_2$-C_6H_5 and an anomeric hydrogen(?)), 2.6—2.8 (20-p. m., phenyl).

Found: C, 66.76; H, 7.19; N, 3.40%. Calcd for $C_{46}H_{56}N_2O_{12}$: C, 66.65; H, 6.81; N, 3.38%.

5,6-Di-*O*-acetyl-4-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-*N*,*N*'-diethoxycarbonyl-2-deoxystreptamine (VIII) and 4,5-Di-*O*-acetyl-6-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-*N*,*N*'-diethoxycarbonyl-2-deoxystreptamine (IX). *a*) As the chromatographic separation of mixture A into pure IV and V was troublesome, a mixture mainly consisting of IV and V was first obtained as follows: Mixture A (3.2 g) was chromatographed on a silica gel column (260 g, 33×730 mm) with chloroform ethyl acetate (3 : 1) and the portion (1.5 g) containing mainly IV and V was separated. The mass was again chromatographed by the same procedure to give a solid (1.26 g) which showed three spots (R_f 0.40 (V), 0.46 (IV) and 0.54) on TLC with benzene-methyl ethyl ketone (5 : 1). The silica gel used in this experiment was prepared[8] as follows: Mallinckrodt silica gel in 6N aqueous ammonia was allowed to stand overnight, filtered and activated at 150°C for 3 hr on a flat plate.

b) *Deisopropylidenation.* A solution of the solid (1.26 g) in 50% aqueous acetic acid (20 ml) was heated at 80°C for 1 hr. The products showed the same R_f-value (0.36, TLC with benzene-ethanol 10 : 1) The solution was poured into water and the precipitates were filtered to give a soild, 1.16 g (97%).

c) *Acetylation and Chromatography.* A solution of the solid (1.14 g) in pyridine (5 ml) and acetic anhydride (5 ml) was allowed to stand at 50°C overnight. The reaction mixture showed three spots (R_f 0.78, 0.71 and 0.65) on TLC with chloroform-ethyl acetate (3 : 1). The mixture was poured into water and the resulting syrup was dissolved in chloroform. The solution was washed throughly with water, dried over sodium sulfate and evaporated to give a pale yellow solid. This was chromatographed on a silica gel column (Mallinckrodt, 300 g, 33×750 mm) with chloroform-ethyl acetate (3 : 1), and the eluates containg the substance of R_f 0.78, 0.71 and 0.65 (TLC with the above solvent system) were separated respectively and evaporated to give amorphous solids 0.48 g (IX), 0.11 g and 0.26 g (VIII).

Compound VIII, mp 71—73°C, $[\alpha]_D^{19}$ +25° (c 1, methanol); IR(KBr): 3400; 1745, 1725 (ester); 1705 (amide I); 1540 (amide II); 1455, 1375 (sh.), 1365, 1230, 1150, 1090, 1070, 1035, 910, 850, 775, 735, 695 cm^{-1}; NMR (in $CDCl_3$ with a Japan Electron Optics 4H-100 spectrometer at a frequency of 100 MHz): τ: 8.86 and 8.78 (3-p. t. each, J 7.1 Hz, $CH_2C\underline{H}_3$), 8.18 and 7.98 (3-p. s. each, OAc), 6.1—6.8 (9-p. unresolved m.), 5.93 and 5.88 (2-p. q. each, J 7.1 Hz, $C\underline{H}_2CH_3$), 5.46, 5.30 and 5.15 (2-p. s. each, $C\underline{H}_2C_6H_5$), at τ 5.64, 5.46, 5.25 and 5.07 (2-p. AB quartet, $C\underline{H}_2C_6H_5$, J 11 Hz), 5.0—5.7 (2-p., overlapped with $C\underline{H}_2C_6H_5$; H-5,6), 4.92 (1-p. d., H-1', J~3 Hz), 2.6—2.8 (20-p. m., phenyl).

Found: C, 65.85; H, 6.47; N, 3.19%. Calcd for $C_{50}H_{60}N_2O_{14}$: C, 66.09; H, 6.58; N, 3.39%.

Compound IX, mp 61—63°C, $[\alpha]_D^{19}$ +61° (c 1, methanol); IR(KBr): 3340; 1750, 1725 (ester); 1705 (amide I); 1530 (amide II); 1455, 1375 (sh.), 1365, 1230, 1150, 1070, 1040, 910, 850, 775, 735, 695 cm^{-1}; NMR (100 MHz, in $CDCl_3$): τ : 8.86 and 8.78 (3-p. t. each, J 7.1 Hz, $CH_2C\mathit{H}_3$), 8.03 and 7.98 (3-p. s. each, OAc), 6.9—7.4 (1-p. m., $\underline{H}_{eq}$-2), 6.1—6.8 (9-p. unresolved m., H-1,3,6,2',3',4',5',6',6''), 5.93 and 5.88 (2-p. q. each, J 7.1 Hz, $C\mathit{H}_2CH_3$), 5.50, 5.23 and 5.10 (2-p. s. each, $C\underline{H}_2C_6H_5$), at τ 5.60, 5.42, 5.18 and 5.00 (2-p. AB quartet, $C\underline{H}_2C_6H_5$, J 11 Hz), 5.0—5.7 (2-p., overlapped with $C\underline{H}_2C_6H_5$; H-4,5), 4.90 (1-p. d., H-1', J ~3.5 Hz), 2.6—2.8 (20-p. m., phenyl).

Found: C, 66.31; H, 6.88; N, 3.13%. Calcd for $C_{50}H_{60}N_2O_{14}$: C, 66.09; H, 6.58; N, 3.39%.

The signals which differentiate VIII and IX are those assignable to one of the acetyls (the one lying in the higher field), the benzyls and the phenyls (VIII has one prominent peak and IX has three prominent peaks), and the feature suggests that VIII and IX have conformations differing as a whole from each other. The difference in chemical shifts assignable to the anomeric hydrogens in VIII and IX was unexpectedly small.

Preparation of VII from IX, and VI from VIII. To a solution of IX (444 mg) in methanol (8 ml) 2.4N sodium methylate in methanol (0.2 ml) was added and the solution was allowed to stand for 1 hr, whereupon some crystals deposited. Chloroform was added to the mixture and the resulting solution was treated with Dowex 50 W×8 (H^+ form). The resulting solution was evaporated to give a residue, which was recrystallized from acetone; colorless crystals (350 mg, 87%), mp 212—213°C, $[\alpha]_D^{20}$ +15° (c 1, chloroform). Its IR and NMR spectra were identical with those of the specimen obtained from V.

8) J. G. Buchanan and J. C. P. Schwarz, *J. Chem. Soc.*, **1962**, 4770.

VI was obtained similarly from VIII in 91% yield.

6-*O*-(α-D-Glucopyranosyl)-2-deoxystreptamine (XI). A solution of VII (286 mg) in a mixture of methanol (15 m*l*), water (7 m*l*) and acetic acid (3 m*l*) was hydrogenated with freshly prepared palladium balck and hydrogen at 45°C under 50 lb/inch pressure overnight. The starting material (R_f 1.0, TLC with benzene-ethanol 1 : 1) disappeared and a product having R_f-value of 0.4 appeared. The solution was filtered, the filtrate was evaporated to give a colorless solid which was dissolved in 1 N barium hydroxide (30 m*l*) and the solution was heated at 90°C for 2 hr. After neutralizing the mixture with a slight excess of 2 N sulfuric acid followed by centrifugation, the supernatant layer was treated with a small volume of Dowex 1×2 (OH form), and evaporated to give a solid (100 mg) which gave a single spot on paper chromatography ($R_{f\text{deoxystreptamine}}$ 0.70, with *n*-butanol-pyridine-water-acetic acid 6 : 4 : 3 : 1). An aqueous solution of the solid was then passed through a column of Dowex 1×2 (OH form, 8 m*l*) with water, and ninhydrin-positive fraction (with 0.5% ninhydrin in pyridine) was evaporated to give a colorless solid of XI (75 mg, 66%); mp 231—232°C (decomp.), $[\alpha]_D^{15}$ +102° (*c* 0.1, water), $[\alpha]_{436}^{15}$ +186° (*c* 0.1, water), $[\alpha]_{436}^{15}$ −40° (*c* 0.1, TACu), therefore, $\Delta[M]_{TACu} = -730°$ (Mol. wt. 324.3): IR(KBr): 3400 (broad), 1625 (NH_2), 1145, 1115, 1035, 940, 915 (w), 840, 770 cm^{-1}.

Found: C, 44.21; H, 7.45; N, 8.46%. Calcd for $C_{12}H_{24}N_2O_8$: C, 44.43; H, 7.15; N, 8.64%.

On hydrolysis of XI with 6 N hydrochloric acid at 90°C for 5 hr, paper chromatography (with *n*-butanol-pyridine-water-acetic acid 6 : 4 : 3 : 1) of the hydrolyzate showed two spots corresponding to deoxystreptamine and glucose ($R_{f\text{deoxystreptamine}}$ 3.4).

4-*O*-(α-D-Glucopyranosyl)-2-deoxystreptamine (X). A solution of VIII (150 mg) in a mixture of methanol (10 m*l*), water (5 m*l*) and acetic acid (2.5 m*l*) was hydrogenated likewise as in the preparation of XI. However, in this case, the hydrogenation had to be repeated with fresh catalyst in order to complete the reaction. The resulting product was hydrolyzed with barium hydroxide. The crude product (58 mg) was chromatographed on a cellulose column (10×150 mm) with *n*-butanol-water-ethanol (5 : 2 : 1) and the portion (36 mg) containing X ($R_{f\text{deoxystreptamine}}$ 0.81) was further purified by passing Dowex 1×2 (OH form, 5 m*l*) column to give a hygroscopic solid (27 mg, 46%); $[\alpha]_D^{15}$ +127° (*c* 0.15, water), $[\alpha]_{436}^{15}$ +238° (*c* 0.15, water), $[\alpha]_{436}^{15}$ +465° (*c* 0.15, TACu), $\Delta[M]_{TACu}$ = +735° (Mol. wt. 324.3); IR(KBr): 3300—3400, 1635, 1600, 1145, 1035, 920, 915 (w), 840, 770 cm^{-1}.

Found: C, 44.28; H, 6.90; N, 8.51%. Calcd for $C_{12}H_{24}N_2O_8$: C, 44.43; H, 7.15; N, 8.64%.

On hydrolysis with 6 N hydrochloric acid, X gave glucose and deoxystreptamine.

Preparation of XI by the Photolysis of VII. To a solution of VII (264 mg) in chloroform (15 m*l*) bromine (200 mg) and powered potassium hydroxide (70 mg) were added and the mixture was irradiated with a 60 W lamp from a close distance for 30 min at 0°C under vigorous stirring. More bromine (200 mg) was added and the irradiation was continued for 30 min. The supernatant solution was decanted and the insoluble matter was washed with chloroform. The combined solution and the washings were evaporated to give a solid which was dissolved in 1 N barium hydroxide solution (80 m*l*) and heated at 90°C for 2 hr. After neutralization with a slight excess of 2 N sulfuric acid followed by centrifugation, the supernatant layer was treated with a small volume of Dowex 1×2 (OH form) and the solution was evaporated to give a colorless solid, which showed two spots of $R_{f\text{deoxystreptamine}}$ 0.70 (XI, major) and 1.0 (deoxystreptamine, minor) on paper chromatography with *n*-butanol-pyridine-water-acetic acid (6 : 4 : 3 : 1). An aqueous solution of the solid was chromatographed on a column (10 m*l*) of Dowex 1×2 (OH form) with water and the eluate containing XI was evaporated to give a solid (95 mg, 92%), which was recrystallized from a mixture of ethanol-water-acetone; mp 230°C (decomp.) $[\alpha]_D^{15}$ +102° (*c* 0.3, water). $\Delta[M]_{TACu}$ and IR spectrum were identical with those of the specimen obtained from IX.

The authors wish to thank Mr. Saburo Nakada for carrying out elementary analysis.

Aminosugars. XVIII. Synthesis of 3-Acetamido-3,5-dideoxy-D-ribose*[1]

Hiroaki ANDO and Juji YOSHIMURA

Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 28, 1970)

3-Acetamido-3,5-dideoxy-1,2-*O*-isopropylidene-α-D-ribofuranose (**5**) was synthesized through two pass-ways: 1) starting from 3-acetamido-3-deoxy-1,2-*O*-isopropylidene-α-D-allofuranose which is obtained from D-glucose, through five steps; periodate oxidation, hydrogenation, 5-*O*-tosylation, 5-iodination and hydrogenation: 2) starting from 1,2-*O*-isopropylidene-3,5-di-*O*-tosyl-α-D-xylofuranose through four steps; 5-iodination, hydrogenation, 3-amination and *N*-acetylation. Total yields in the two pass-ways were 12.7% and 7.6% from the parent aldoses, respectively. Hydrolysis of **5** gave the titled compound as a sirup, which was converted to the crystalline osazone. The structure and conformation of intermediates in these syntheses were examined by NMR spectroscopy.

Since 3-amino-3-deoxy-D-ribose has been found as a component of puromycin[1] and synthesized,[2-4] a numerous homologues of pentoses and hexoses have been reported,[5] but 3-amino-3,5-dideoxy-D-ribose is not yet described in literatures. As an intermediate for a total synthesis of kasugamine,[6] the authors synthesized 3-acetamido-3,5-dideoxy-D-ribose (**9**) by two pass-ways.

Results and Discussion

Lemieux and Chu[3] have synthesized 3-amino-3-deoxy-D-ribose hydrochloride from 3-acetamido-3-deoxy-1,2;5,6-di-*O*-isopropylidene-α-D-allose[7] which is derived from 1,2 ; 5,6-di-*O*-isopropylidene-3-*O*-tosyl-α-D-glucofuranose, by partial hydrolysis to the corresponding 1,2-*O*-isopropylidene derivative (**1**), and followed by periodate oxidation, hydrogenation and hydrolysis. In this process, the authors have improved the condition of partial hydrolysis, and newly isolated 5,6-di-*O*-acetate of **1** and 3-acetamido-3-deoxy-1,2-*O*-isopropylidene-α-D-ribofuranose (**2**) as a crystalline form. Tosylation of **2** in pyridine gave the corresponding 5-*O*-tosylate (**3**) in 68% yield, which was then converted into the 5-iodo-5-deoxy derivative (**4**) in a quantitative yield by heating at 110°C for 2 hr with sodium iodide in acetonitrile. Hydrogenation of **4** in the presence of Raney nickel and triethylamine gave the corresponding 5-deoxy derivative (**5**) in 91% yield.

As another method for the preparation of **5**, 1,2-*O*-isopropylidene-3,5-di-*O*-tosyl-α-D-xylofuranose[8] (**6**) was treated with sodium iodide at 90°C for 20 hr in acetonitrile to give the corresponding 5-iodo-5-deoxy derivative (**7**) in 70% yield. Hydrogenation of **7** in the presence of Raney nickel gave in 70% yield the corresponding 5-deoxy derivative (**8**), which was then converted to **5** by heating with anhydrous hydrazine at 140°C, followed by hydrogenation and *N*-acetylation. Total yield of **5** in the two pass-ways mentioned above were 12.7% and 7.6% from D-glucose and D-xylose, respectively. Treatment of **5** with 60% acetic acid at 95°C for 3 hr gave **9** as a sirup in 95% yield. Crystallization of *N*-phenyl-glycosylamine of **9** was failed, but, further reaction of phenylhydrazine gave the corresponding osazone (**10**) as an yellow crystals.

Lemieux and Chu[3] have corrected the misunderstanding on the configuration of the 3-amino group of **1**[7] by comparison of X-ray powder photograph and IR spectrum of 3-amino-3-deoxy-D-ribose hydrochloride with that of the corresponding natural product, however, the structure of new compounds obtained here were proved by NMR spectra. As representative examples, the spectrum

TABLE 1. FIRST-ORDER ANALYSIS OF NMR SPECTRA OF 5-DEOXY-1,2-*O*-ISOPROPYLIDENE-α-D-RIBOSE AND -D-XYLOSE DERIVATIVES

Compound	Chemical shifts (τ), Coupling constants (Hz), and Dihedral angles[13]				
	H_1	H_2	H_3	H_4	H_5
4	4.16 (d) $J_{1,2}$=4.0 (47°)	5.36 (t) $J_{2,3}$=4.7 (43°)	5.82 (sex.) $J_{3,4}$=9.0*2 (161°)	6.27 (sep.) $J_{4,5}$=3.3 $J_{4,5'}$=6.6	6.55 (q.), 6.75 (q) $J_{5,5'}$=11.0
5	4.21 (d) $J_{1,2}$=4.0	5.46 (t) $J_{2,3}$=4.2 (46°)	5.97 (sex.) $J_{3,4}$=8.8*2 (159°)	6.16 (m) $J_{4,5}$=5.8	8.72 (d)
7	4.07 (d) $J_{1,2}$=4.0	5.21 (d) $J_{2,3}$=0 (80°)	5.10 (d) $J_{3,4}$=2.8 (55°)	5.58 (sep.) $J_{4,5}$=6.0*3 $J_{4,5'}$=9.0	6.84 (q), 7.01 (q) $J_{5,5'}$=10.0*3
8	4.15 (d) $J_{1,2}$=4.0	5.39 (d) $J_{2,3}$=0	5.36 (d) $J_{3,4}$=2.8	5.68 (m) $J_{4,5}$=6.4	8.86 (d)

*2 In both cases, $J_{3,NH}$=9.0.
*3 At 80°C, these coupling constants changed to $J_{4,5}$=5.7, $J_{4,5'}$=7.7 and $J_{5,5'}$=10.5.

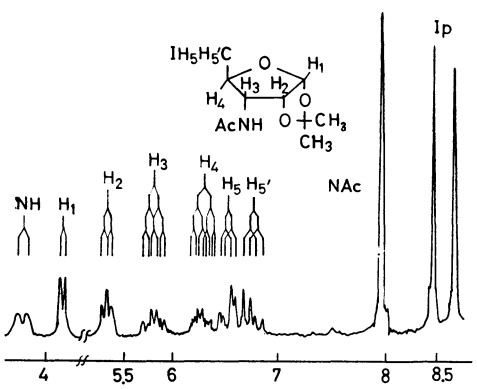

Fig. 1. NMR spectrum of 3-acetamido-3,5-dideoxy-5-iodo-1,2-*O*-isopropylidene-α-D-ribofuranose (**4**) (100 MHz, $CDCl_3$)

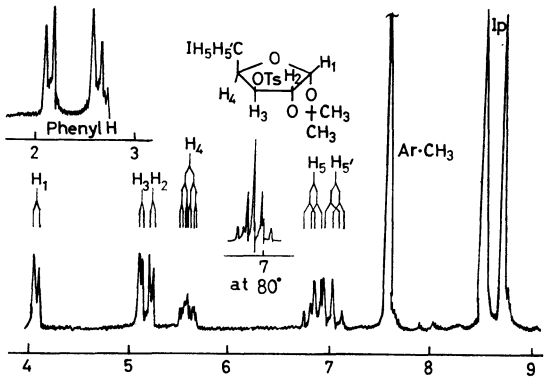

Fig. 2. NMR spectrum of 5-deoxy-5-iodo-5-iodo-1,2-*O*-isopropylidene-3-*O*-(*p*-toluenesulfonyl)-α-D-xylofuranose (**7**) (100 MHz, $CDCl_3$).

of **4** and **7** were shown in Figs. 1 and 2, and some NMR data were summarized in Table 1, in order to compare the conformation of *cis*-fused five-membered ring of 1,2-*O*-isopropylidene-α-D-xylose with that of α-D-ribose. The dihedral angles of ring protons in the both indicate that the conformation of the furanose ring is a twist in which C_2 and C_3 atoms are displaced in opposite senses

from the plane of the other ring atoms, as was shown by several workers by use of α-D-glucofuranose[9,10] and others.[11,12] Comparison of (H_3–H_4) dihedral angle of **4** and **7** with that of the individual planer conformation indicate that the displacement of C_3 in **7** is rather larger than that of **4**. This fact suggests that the nonbonded interaction between *cis*-oriented C_3-*O*-tosyl and C_4-iodomethyl groups effects simply in the former, while that of endo-C_3-acetamido and gauche C_4-iodomethyl or endo-methyl of isopropylidene groups behave reversely in the latter. It is noteworthy that the chemical shift of ring protons in **4** and **7** are to be shifted commonly to lower field than that of **5** and **8**, and that of H_3 in **7** and **8** are markedly shifted due to the inductive effect of the C_3-*O*-tosyl group. The higher shift of H_5 protons in **7** and **8** than that of **4** and **5** will be attributed to the anisotropic effect of the benzene ring.

On the other hand, the remarkable difference in the coupling constant of $J_{4,5}$ and $J_{4,5'}$ between **4** and **7** makes us deduce a hindered rotation of C_4–C_5 bond of **7**. The appearance of H_5 proton signals of **7** measured at 80°C changed markedly as was shown in Fig. 2, and the coupling constants approached to that of **4** (Table 1), while no change was observed in the case of **4**. A more detailed study along with such a line may offer a valuable information on rotational isomers.

Experimental

The solutions were evaporated under diminished pressure at a bath temperature not exceeding 45°C. All melting points are uncorrected. Optical rotations were measured in a 0.5-dm tube, with a Carl Zeiss Photoelectric Precision Polarimeter. The NMR spectra were taken in deuteriochloroform solution with a JNM-4H-100 MHz Spectrometer, using tetramethylsilane as an internal standard.

3-Acetamido-3-deoxy-1,2-*O*-isopropylidene-α-D-allofuranose (1). A solution of 3-acetamido-3-deoxy-1,2;5,6-di-*O*-isopropylidene-α-D-allofuranose[7] (42 g, 139 mmol) in 0.2 N-hydrochloric acid solution (300 m*l*) of acetone-water (1 : 1 in volume) was maintained at 20—23°C for 1.5 hr, and then neutralized with sodium hydrogencarbonate (6 g), concentrated to a sirup. The sirup was extracted with methanol, the methanol solution was treated with active carbon, and then addition of ether to it gave colorless crystals (29.5 g) in 81% yield. $[\alpha]_D^{23}$ + 158.3° (*c* 1.08, methanol); mp 154—155°C (lit,[3] 154—156°C). NMR: τ 8.63, 8.43 (two s, C–CH_3), 7.92 (s, NAc), 5.34 (t, H_2), 4.11 (d, H_1, J=4.0 Hz), 3.60 (d, NH, J=9.0 Hz).

This compound was acetylated to the corresponding di-*O*-acetate by acetic anhydride and pyridine in an usual manner. Mp 163—164°C; $[\alpha]_D^{23}$ + 66.6° (*c* 0.80, chloroform).

Found: C, 52.24; H, 6.51; N, 4.11%. Calcd for $C_{15}H_{23}NO_8$: C, 52.17; H, 6.71; N, 4.06%.

3-Acetamido-3-deoxy-1,2-*O*-isopropylidene-α-D-ribofuranose (2). To a solution of **1** (20.4 g, 75 mmol) in 100 m*l* of water was added sodium periodate (18 g, 84.5 mmol) in water (200 m*l*), and the solution was left to stand at room temperature for 2 hr, concentrated to 50 m*l*, then filtered. The filtrate was treated with sodium borohydride (1.6 g, 42.5 mmol) for 2 hr, and concentrated to a sirup which was crystallized from ethanol. Yield, 16.5 g (94.8%); mp 148—149°C; $[\alpha]_D^{23}$ + 151.2° (*c* 0.915, methanol); NMR: τ 8.65, 8.45 (two s, C–CH_3), 7.95 (s, NAc), 4.16 (d, H_1, J=3.5 Hz), 3.72 (d, NH, J=8.0 Hz).

Found: C, 51.76; H, 7.22; N, 5.83%. Calcd for $C_{10}H_{17}NO_5$: C, 51.94; H, 7.41; N, 6.06%.

This compound was converted to the corresponding 5-*O*-acetate by acetic anhydride and pyridine in an usual manner, which showed mp 132—133°C; $[\alpha]_D^{23}$ + 73° (*c* 1.0, chloroform); NMR: τ 8.66, 8.45 (two s, C–CH_3), 7.97 (s, NAc), 7.93 (s, OAc), 4.17 (d, H_1, J=3.8 Hz), 3.94 (d, NH, J=9.2 Hz).

Found: C, 52.85; H, 7.02; N, 5.20%. Calcd for $C_{12}H_{19}NO_6$: C, 52.74; H, 7.01; N, 5.13%.

3-Acetamido-3-deoxy-1,2-*O*-isopropylidene-5-*O*-(*p*-toluenesulfonyl)-α-D-ribofuranose (3). To a solution of **2** (8 g, 34.6 mmol) in dry pyridine (20 m*l*) was added *p*-toluenesulfonyl chloride (15 g, 78.9 mmol), and the reaction mixture was heated at 60°C for 10 min, allowed to stand overnight at room temperature, then poured into ice-water. The resultant solution was extracted three times with chloroform, and the combined extracts were washed with aqueous sulfuric acid, sodium hydrogencarbonate and then water, dried over anhydrous sodium sulfate, and concentrated to give a pale yellow sirup in 79% (10.5 g) yield. $[\alpha]_D^{23}$ + 52.6° (*c* 1.25, chloroform), NMR: τ 8.70, 8.51 (two s, C–CH_3), 8.02 (s, NAc), 7.57 (s, aromatic CH_3), 4.27 (d, H_1, J=4.0 Hz), 3.55 (d, NH, J=7,5 Hz).

Found: C, 52.86; H, 6.05; N, 3.67%. Calcd for $C_{17}H_{23}NO_7S$: C, 52.98; H, 6.02; N, 3.64%.

3-Acetamido-3,5-dideoxy-5-iodo-1,2-*O*-isopropylidene-α-D-ribofuranose (4). A solution of **3** (10.5 g, 27.3 mmol) and sodium iodide (8 g, 53.3 mmol) in acetonitrile (100 m*l*) was heated in a sealed tube at 110°C for 24 hr, and then concentrated, extracted three times with chloroform. The combined extracts were washed with water, dried over anhydrous sodium sulfate, concentrated to give a pale yellow sirup which crystallized from ether as needles. Yield, 8.0 g (99%); mp 134.5—135.5°C; $[\alpha]_D^{23}$ +38.1° (*c* 0.756, chloroform).

Found: C, 35.14; H, 4.36; N, 4.21%. Calcd for $C_{10}H_{16}INO_4$: C, 35.20; H, 4.69; N, 4.10%.

3-Acetamido-3,5-dideoxy-1,2-*O*-isopropylidene-α-D-ribofuranose (5). a) A solution of **4** (8 g, 26.7 mmol) in ethanol (100 m*l*) was hydrogenated at 40 atm pressure for 20 hr in the presence of Raney nickel (10 g) and triethylamine (2 m*l*). The reaction mixture was filtered, and the filtrate was concentrated to give a sirup which crystallized spontaneously. The crystals were purified two times by crystallization from ether-petroleum ether. Yield, 5.2 g (91%);

mp 98—101°C; $[\alpha]_D^{23}$ +87.8° (*c* 2.12, methanol).

Found: C, 55.92; H, 7.70; N, 6.57%. Calcd for $C_{10}H_{17}NO_4$: C, 55.80; H, 7.96; N, 6.51%.

b) A mixture of **8** (14.3 g, 47.3 mmol) and anhydrous hydrazine (150 m*l*) was heated in an oil bath at 140°C for 20 hr, and the solution was evaporated. The residue was dissolved in ethanol (100 m*l*), hydrogenated in the presence of Raney nickel at 40 atm pressure for 10 hr, and then filtered. The filtrate was evapporated to a sirup, and the dried sirup was acetylated with acetic anhydride (10 m*l*) and pyridine (10 m*l*). The reaction mixture was poured into ice-water, concentrated to a sirup, and then extracted three times with chloroform. The combined extracts were washed with a small amount of aqueous sulfuric acid, sodium hydrogen carbonate, and then water, dried over anhydrous sodium sulfate, concentrated to a sirup which crystallized from ether. Yield, 1.7 g (22.6%); mp 98—100°C.

5-Deoxy-5-iodo-1,2-*O*-isopropylidene-3-*O*-(*p*-toluenesulfonyl)-α-D-xylofuranose (7). A Solution of 1,2-*O*-isopropylidene-3,5-di-*O*-(*p*-toluenesulfonyl-α-D-xylofuranose)[8] (92 g, 184 mmol) and sodium iodide (42 g, 280 mmol) in acetonitrile (1 *l*) was refluxed for 150 hr at ordinary atmosphere, concentrated, and then extracted with chloroform. The extracts were washed with water, dried over anhydrous sodium sulfate, concentrated to dryness to give a pale yellow sirup. Yield, 79 g (89%); $[\alpha]_D^{23}$ −65.5° (*c* 2.0, chloroform). This sirup was analyzed without further purification.

Found: C, 40.02; H, 4.44; S, 7.32%. Calcd for $C_{15}H_{19}IO_6S$: C, 39.66; H, 4.22; S, 7.05%.

5-Deoxy-1,2-*O*-isopropylidene-3-*O*-(*p*-toluenesulfonyl)α-D-xylofuranose (8). A solution of **7** (79 g, 174 mmol) in methanol (200 m*l*) was hydrogenated at 100 atm pressure for 24 hr in the presence of Raney nickel(70 g) and triethylamine (12 m*l*). The reaction mixture was filtered, and the filtrate was concentrated to dryness, extracted with chloroform. The extracts were washed with water, dried over anhydrous sodium sulfate, and concentrated to give a sirup which couldn't be crystallized, and therefore, analyzed without further purification. Yield, 37.2 g (65%); $[\alpha]_D^{23}$ −16.8° (*c* 1.70, chloroform).

Found: C, 54.95; H, 6.27; S, 9.46%. Calcd for $C_{15}H_{20}O_6S$: C, 54.87; H, 6.14; S, 9.76%.

3-Acetamido-3,5-dideoxy-D-ribose (9). A solution of **5** (0.9 g, 4.16 mmol) in 60% acetic acid (30 m*l*) was heated at 80°C for 3 hr, decolorized with active carbon, and concentrated to a sirup which couldn't be crystallized. Yield, 0.7 g (96%); $[\alpha]_D^{23}$ +65.1°—+63.2° (*c* 1.09, for 12 hr in methanol).

As an crystalline derivative, the corresponding osazone (**10**) was prepared as follows: the above sirup (0.7 g, 4 mmol) and phenylhydrazine (2 g, 18.5 mmol) in 60% acetic acid (20 m*l*) was heated at 90°C for 2 hr and then concentrated to a sirup which crystallized after two days. The yellow crystals were recrystallized from ethanol-ether. Yield, 1.35 g, (95%); mp 215—216°C; $[\alpha]_D^{23}$ −7.36° (*c* 1.06, methanol).

Found: C, 64,60; H, 6.51; N, 19.35%. Calcd for $C_{19}H_{23}N_5O_2$: C, 64.57; H, 6.56; N, 19.82%.

The authors wish to express their thanks to Mr. Kiyofumi Fukukawa for measurements of NMR spectra, and to members of Laboratory of Organic Analysis for elemental analyses.

NOTES

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2970—2972 (1970)

Alpha-Benzildioxime Complexes of Copper(II) — A Study by Solvent Extraction —

Hisahiko EINAGA and Hajime ISHII

National Institute for Researches in Inorganic Materials, Science and Technology Agency, Hon-komagome, Bunkyo-ku, Tokyo

(Received November 12, 1969)

It is well known that α-benzildioxime forms complexes with nickel(II) and palladium(II), and has been used as a gravimetric or a spectrophotometric reagent for these metals[1] as a substitute for dimethylglyoxime. Studies have also been made on cobalt(II)[2] and iron(II)[3] complexes of α-benzildioxime. However, little has been made on copper(II) complex of α-benzildioxime, except for the determination of the formation constants of the complex in 50% dioxane-water system by the potentiometric method.[4] During the course of studies on the reaction of copper(II) with α-benzildioxime by the solvent extraction method, we found that copper(II) forms two kinds of complexes with α-benzildioxime; one is light brown bis(α-benzildioximato)copper(II) and the other light greenish yellow mono(α-benzildioximato)copper(II). This paper gives some results of the study on the complexes by the solvent extraction method.

Experimental

Reagents. A copper(II) solution (0.618 mg Cu(II)/m*l*) was prepared from copper(II) sulfate pentahydrate with the addition of a small amount of sulfuric acid to prevent the hydrolysis of copper(II). The solution was used with dilution to an appropriate concentration. Alpha-benzildioxime (Wako Pure Chemicals Ind., Ltd.) was recrystallized from methanol and a 0.02% methanolic solution of the purified reagent (mp 237°C) was used. A 2.5 M solution of ammonium nitrate was used as the ammonium salt solution.

Apparatus. Absorption spectra were recorded with a Hitachi automatic recording spectrophotometer, model EPS-3T, and other absorption measurements were carried out with a Hitachi spectrophotometer, model 139, with 10-mm quartz cells. A pH meter of Toa Dempa Co., Ltd., model HM-5A, was used for pH measurements. Solvent extraction was carried out with an Iwaki universal shaker, model V-D, at the rate of 300 rpm. All the experiments were carried out at about 23°C.

Results and Discussion

Absorption spectra of copper(II)-α-benzildioxime complex extracted into benzene are shown

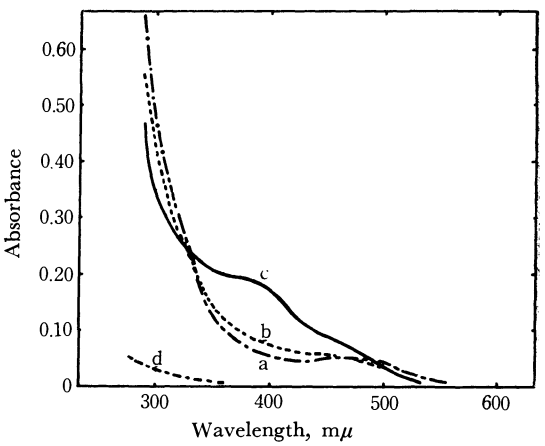

Fig. 1. Absorption spectra of copper(II)-α-benzildioxime complex in benzene.
[α-Benzildioxime]: 3.87×10^{-5} M.
a : [Cu(II)]/[α-Benzildioxime]=0.6 (mole fraction of Cu(II)=0.38).
b : [Cu(II)]/[α-Benzildioxime]=2.5 (mole fraction of Cu(II)=0.67).
c : [Cu(II)]/[α-Benzildioxime]=5.0 (mole fraction of Cu(II)=0.83).
d : α-Benzildioxime alone.
pH value of equilibrated aqueous phase: 8.2.
λ_{max} of curve a: 460 mμ.

in Fig. 1. Curve a in Fig. 1 is a spectrum of the complex obtained with an excess of α-benzildioxime (mole fraction of copper(II): 0.38) and has an absorption maximum at the wavelength of 460 mμ. The complex obtained under these conditions is light brown and moderately soluble in benzene, irrespective of the presence of ammonium salt in the aqueous phase. Curve c in Fig. 1, on the contrary, is a spectrum of the complex obtained with a large excess of copper(II) (mole fraction of copper(II): 0.83) and has no absorption maximum in the near ultraviolet and visible regions. The complex is light greenish yellow, and its solubility in benzene is very low unless ammonium salt is present in the aqueous phase. (Curve b in Fig. 1 can be considered as an intermediate of the above-mentioned two limiting cases).

Figures 2 and 3 show the results obtained by the method of continuous variations and the molar ratio method, respectively. The results indicate that there exists a 1 to 2 (metal to ligand) complex when mole fraction of copper(II) is less than about 0.6 (ratio of copper(II) to α-benzildioxime: about 2), and another kind of copper(II) complex is formed when copper(II) is in a large excess over α-benzildioxime (mole fraction of copper(II) is larger than about 0.8). As we could not determine the composition of the latter complex from these results, chemical analysis of the complex extracted with a large excess of copper(II) was carried out. The results are presented in Table 1. We see that the light greenish yellow complex has a composition of 1 to 1 (metal to ligand).

mato)copper(II) complex might be expressed as follows:

$$Cu^{2+} + 2H_2L_{(org)} \rightleftharpoons Cu(HL)_{2(org)} + 2H^+$$

$$K_{ex} = [Cu(HL)_2]_{(org)} \cdot [H^+]^2/[Cu^{2+}] \cdot [H_2L]^2_{(org)} \quad (1)$$

where H_2L denotes the undissociated α-benzildioxime, K_{ex} the extraction constant of the copper(II) complex, the suffix *org* the organic phase and no suffix the aqueous phase, respectively. To ascertain the validity of the extraction equilibrium represented above, the following considerations were made. Provided that the partition coefficients of α-benzildioxime and its copper(II) complex are sufficiently large and that the equilibrium concentrations of the intermediate species of α-benzildioxime and its copper(II) complex are negligibly low, $[Cu^{2+}]$ and $[H_2L]_{(org)}$ can be expressed in terms of the total concentration of copper(II). C_{Cu}, and that of α-benzildioxime, C_{H_2L}, when volumes of aqueous and organic phases are equal:

$$[Cu^{2+}] = C_{Cu} - [Cu(HL)_2]_{(org)} \quad (2)$$

$$[H_2L]_{(org)} = C_{H_2L} - 2[Cu(HL)_2]_{(org)} \quad (3)$$

When C_{Cu} and C_{H_2L} are taken so as to make $2C_{Cu} = C_{H_2L}$, Eq. (4) can be obtained by inserting Eqs. (2) and (3) into Eq. (1) and writing in logarithmic form:

$$\log C - 3 \log (C_{Cu} - C) = \log 4K_{ex} + 2pH \quad (4)$$

where C denotes the term $[Cu(HL)_2]_{(org)}$. Figure 4 shows the results obtained under the condition $2C_{Cu} = C_{H_2L}$ with varying pH values of the aqueous phase, which reveals that the extraction equilibrium of bis(α-benzildioximato)copper(II) complex can be correctly expressed as represented above.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2972—2974 (1970)

The Reaction of Bromobenzene with Copper(I) Chloride - Pyridine Complex in Nitrobenzene

Masaru SATO, Izumi MOTOYAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received November 29, 1969)

The Rosenmund - von Braun nitrile synthesis has been little studied from the viewpoint of its mechanism in spite of its usefulness as a synthetic procedure. Recently Bacon and Hill[1] investigated the substituent effect and the solvent effect in the reaction of aryl halide with copper(I) salts in polar solvents. However, the real reactive species were not elucidated. Ito and Watanabe[2] studied the kinetics of this reaction in nitrobenzene and pointed out an important role of the complexes of copper(I) salt and pyridine bases in the reaction. It was found that pyridine bases and copper(I) salt produced a 1 : 1 complex, and that the structure of pyridine bases affected the rate of the reaction. These results suggest that the Rosenmund - von Braun reaction and its related reactions must be reexamined in view of the reaction between organic halide and metal complex. Thus, the reaction of bromobenzene with copper(I) chloride - pyridine complex in nitrobenzene was investigated from this point of view.

2) T. Ito and K. Watanabe, This Bulletin, **41**, 419 (1968).

Results and Discussion

It has already been reported that the reaction of bromobenzene with copper(I) cyanide - pyridine complex is second-order, that is, first-order in each of bromobenzene and copper(I) cyanide - pyridine complex.[2] Therefore, we determined the activation parameter of this reaction in order to obtain further information concerning this reaction. The second-order rate constants in the reaction of bromobenzene with copper(I) chloride - pyridine complex*1 were measured in nitrobenzene at several temperatures. The results are summarized in Table 1. The activation enthalpy ($\Delta H^{\neq}$) of the reaction was calculated from the data in the table to be 8.6 kcal/mol, and the activation entropy ($\Delta S^{\neq}$), to be -38.4 e.u. (at 160°C). The activation enthalpy obtained in this study is not an unusual value in comparison with those of other reactions

*1 This complex is insoluble in hydrocarbons and alcohols, but soluble in nitrobenzene, nitromethane, acetonitrile, pyridines, and dimethyl sulfoxide. The halogen-exchange reaction could not take place in nitromethane and acetonitrile at temperatures below their boiling points.

Table 1. The rate constants at various temperatures[a)]

Temperature (°C)	k (l/mol·sec)
155.0	2.29
160.0	3.11
165.0	4.08
170.0	5.45
175.0	7.31

a) Bromobenzene, 1.0 ml; pyridine, 1.0 ml; copper(I) chloride, 0.94 g; nitrobenzene, 40 ml.

between organic halides and metal complexes. For example, the activation enthaply of the reaction of benzyl chloride with chromium(II) salt[3] is 14.0 kcal/mol, and that of the reduction of chloropentaamminechromium(III) complex with chromium(II) salt[4] is 11.1 kcal/mol. The transition these reaction is suggested to be a halogen-bridged state of activated complex (**1**) or (**2**):

$[ArCH_2\cdots Cl\cdots Cr_{aq}]^{2+}$ (**1**) $[(NH_3)_5Cr\cdots Cl\cdots Cr_{aq}]^{2+}$ (**2**)

The activation entropy of the reaction described above is −14.3 e.u. in the former[3] and −23 e.u. in the latter.[4] The larger negative activation entropy obtained in the present study supports the hypothetical four-center type (or double-bridge) transition state previously proposed.[2]

A similar halogen-exhange was observed in the reactions of bromoferrocene with copper(I) halide - pyridine complex.[5] The reactions took place in nitrobenzene, as well as in nitromethane and acetonitrile, at much lower temperatures than those at which the halogen-exchange reactions of bromobenzene could be observed.[6] In the reactions of bromoferrocene, an astonishing solvent effect was observed that can be explained not by the solvation but only in terms of the difference in the coordination-ability of the solvent toward the copper(I) ion.[6]

The Rosenmund - von Braun reaction takes place with ease in pyridine or quinoline,[7] and the halogen-exchange of aryl halide with copper(I) chloride proceeds easily in α-picoline.[8] 3-Halopyridine is converted more easily with copper(I) cyanide to 3-cyanopyridine than is halobenzene.[9]

These facts led us to a detailed investigation of the role of the pyridine base as a ligand in the intermediate complex in the reaction between bromobenzene and copper(I) chloride - pyridine base complex in nitrobenzene. When an equimolar amount of 4-methyl-, 3-methyl-, 2-methyl-, 3-acetyl-, or 4-methoxycarbonylpyridine was added to a mixture of nitrobenzene and copper(I) chloride at 160°C, a clean homogeneous solution was obtained, while 4-cyano-, 3-cyano-, or 3-chloropyridine gave a complex insoluble in nitrobenzene. In the latter cases, the observed second-order rate constants for the halogen-exchange reaction showed considerably deviating results. This is probably due to the insolubility of the copper(I) chloride - pyridine base complex (**3**) caused by the enhanced ionic character of the complex, which is brought about by an N←Cu back donation when an electron-attracting group is introduced to the pyridine nucleus coordinated to the copper atom in the complex. The results of the kinetic measurements using various pyridine bases are shown in Table 2.

Table 2. The effect of substituents on pyridine bases[a)]

Substituent	k (l/mol·min)[b)]	k (l/mol·min)[c)]
4-CH_3	5.2×10^{-2}	
3-CH_3		6.3×10^{-2}
H	4.3×10^{-2}	6.6×10^{-2}
4-$COOCH_3$	3.5×10^{-2}	
3-$COCH_3$		5.4×10^{-2}

a) Bromobenzene, 1.0 ml; nitrobenzene, 40 ml; copper(I) chloride, 0.94 g; pyridine bases, equimolar amount to copper(I) chloride.
b) Temperature, 160.2°C.
c) Temperature, 166.0°C.

The results are quite consistent with the observation by Ito and Watanabe.[2] The relative rate constants are in an almost linear relation to the pK_a's of the bases except for the case of 3-methylpyridine. This suggests that the reaction is accelerated by the strong coordination of pyridine bases to the metal in the complex (**3**).

Contrary to the favorable behavior of 4-methylpyridine, 2-methylpyridine was found to suppress the halogen-exchange reaction of bromobenzene; this fact has been explained in terms of steric hindrance of the methyl group at the 2-position toward the coordination of the pyridine base to copper(I) chloride.[2] A large size of a copper atom will cause a F-strain, proposed by Brown,[10] to the methyl group of 2-methylpyridine. Thus, the nitrogen atom of the pyridine base can be expected to coordinate more weakly to the copper

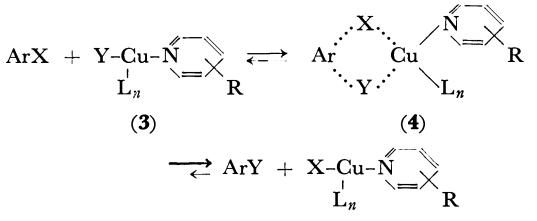
atom in the copper(I) salts - pyridine complex. In any case, it can be concluded that the weak coordination by steric and/or electronic factors brings about a retardation of the reaction of bromobenzene with copper(I) chloride - pyridine complex.

On the other hand, the effect of the substituents in pyridine bases upon the rates of halogen-exchange reactions between bromoferrocene and copper(I) chloride - pyridine complexes was found to be the opposite of that in the reactions of bromobenzene.[6]

The correlation of rate constants with the coordination abilities of pyridine bases may be explicable in terms of the four-center (double-bridge) mechanism which has been proposed in the preceding paper.[2] In the first stage, aryl halide will coordinate to the copper(I) chloride - pyridine complex (**3**) to form a metastable intermediate ($ArX \rightarrow CuY\langle^{Py}_{L_n}$). Such coordination is reasonable, because the complex, in which aryl halide coordinates to a certain transition metal, has been isolated.[11] The intermediate will turn into the final product through a four-center-type transition state (**4**). In the transition state (**4**), the increase in electron density on the copper atom will facilitate the attack of the halogen atom Y on the carbon atom in the aromatic nucleus (Y→C attack). Thus, an electron-releasing substituent on the pyridine base will accelerate the halogen-exchange reaction. The importance of the Y→C attack is also suggested by the fact that the substituent effect in the reaction of the substituted



(3) (4)

L=Pyridine base and/or solvent

aryl halide with the copper(I) complex was found to be somewhat nucleophilic.[1,5] On the contrary, the increase in electron density on the copper atom of the complex (**3**) will retard the attack of the halogen atom X on the copper atom in the complex (**3**) (X→Cu attack). Thus, the rate of the halogen-exchange reaction may be regulated by two counteracting factors, that is, the promotion of the Y→C attack and the retardation of the X→Cu attack. The contradiction between these two factors results in the facts that the effect of the substituent on both the aryl halide and pyridine bases upon the reaction rate is not so remarkable as in the ordinary substitution reactions. There would be a certain balance between the Y→C attack and the X→Cu attack. The reactions between bromobenzene and copper(I) chloride - pyridine base complex in nitrobenzene seem to be governed by the ease of the Y→C attack rather than by the X→Cu attack.

Experimental

Materials. Copper(I) chloride was prepared from commercial copper(II) chloride according to the literature.[12] Pyridine bases and nitrobenzene were purified by distillation under reduced pressure.

Kinetic Measurements. A typical procedure was as follows. In a 100-m*l*, three-necked, round-bottomed flask fitted with a sealed stirrer, a thermometer, a nitrogen-inlet tube, and a reflux condenser, were placed 40 m*l* of nitrobenzene, 0.94 g of copper(I) chloride, and 1.0 m*l* of pyridine. The contents were heated to 160°C on an oil bath. When the temperature was regulated to be constant (160±0.1°C), 1 m*l* of bromobenzene was added to the mixture. A small quantity of the reaction mixture was taken out every 5 min and analyzed by gas chromatography. From these measurements, the rate constant was calculated by the usual way.

Gas Chromatography. Apparatus: Ohkura Model 1100; column, 10% Carbowax 1500 on Celite; length, 3.5 m; temperature, 140°C; flow rate, 4 m*l*/min; carrier gas, H_2.

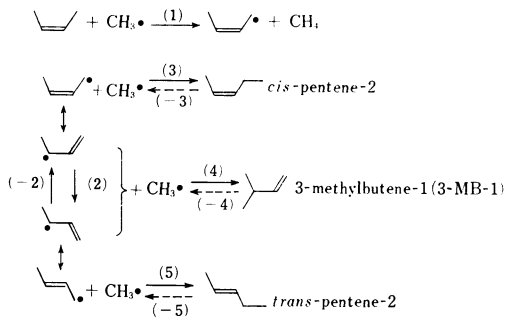
The Isomer Ratio of the Pentenes Formed by CH_3·-Butenyl Combination

Nobuo YOKOYAMA*1

Department of Chemistry, University of California, Davis, California, U.S.A.

(Received January 31, 1970)

Yokoyama and Brinton[1] studied the gas phase reaction of *cis*-butene-2 with CH_3· which was generated by pyrolysis of di-*t*-butylperoxide. Allylic hydrogen abstraction by CH_3· caused the formation of butenyl radical which gave three pentene isomers when combined with CH_3·. The process is illustrated by the scheme shown below, which includes allylic resonance and *cis-trans* rotation about the center bond.



(3) and (5) are the only mechanisms leading to the pentene-2 formation in this system, but 3-MB-1 is also formed by disproportionation of the pentyl radical which is present in the system. However, the quantity of 3-MB-1 formed *via* each route could be distinguished, and the present discussion is limited to 3-MB-1 formed *via* (4) only.

The average ratios of the quantities of pentene isomers were found to be nearly constant at a certain temperature. Their values are shown in Table 1, together with the equilibrium ratios of these pentenes calculated from the generally accepted data.[2]

It should be noted that *trans/cis* ratio exceeded that of the equilibrium in spite of the fact that the reaction was started with *cis*-butene-2. This ratio should have been equal to the equilibrium ratio if there had been the reverse reactions (−3), (−4), and (−5) taking place at sufficient rates. Or it should have been smaller than the equilibrium ratio if (2) had not been sufficiently faster than (3). In fact, the internal rotation (±2) must be much faster than (3), (4), and (5), for the same values were obtained for the isomer ratios when the reaction was started with *trans*-butene-2.

trans/cis equilibrium ratio b may be expressed as

$$b = \frac{k_2}{k_{-2}} \frac{k_{-3}}{k_3} \frac{k_5}{k_{-5}} \tag{6}$$

However, since (−3) and (−5) must be eventually non-existent and (±2) were proved to be sufficiently faster than (3) and (5), the following equation should hold for the observed *trans/cis* ratio

$$a = \frac{k_2}{k_{-2}} \cdot \frac{k_5}{k_3} \tag{7}$$

The following relation should then be valid

$$a/b = k_{-5}/k_{-3} \tag{8}$$

This is the ratio of the rates of bond cleavage to produce butenyl and methyl radicals from *trans*- and *cis*-pentene-2, which could not be directly measured in such temperature range. It is interesting to note that there seems to be a slight difference in the rates of this bond cleavage, *trans* form having a slightly faster rate than *cis*, and that it is not due to the difference in the bond energy. The present data show no evidence for non-zero difference in the activation energy which should be approximately equal to the bond energy itself, because its reverse reaction (radical-radical combination) should have zero or near-zero activation energy.

Exactly the same discussion is applicable to 3-MB-1/*trans*-pentene-2 ratio. In this case the electron density ratio of has a similar role to k_2/k_{-2} in the previous case, and the final result is

$$c/d = k_{-4}/k_{-5} \tag{9}$$

As is seen in Table 1, c/d shows a large divergency from unity, and again no non-zero activation energy difference can be detected. Thus, through this kinetic observation, the bond cleavages of the three pentene isomers (−3), (−4), and (−5) were found to have different rates, (−5) slightly faster than (−3), and (−4) appreciably faster than (−5), not due to the differences in the bond

energies.

It was concluded that the *cis*/*trans* internal rotation of the butenyl radical was fast enough to maintain the equilibrium under the employed conditions, compared with the rates of the competitive chemical reactions. In contrast to this finding, Walling and Thaler[3] reported the complete retention of *cis-trans* configuration of the butenyl radical at 40°C. Although the reaction conditions were entirely different (liquid phase, Cl abstraction as the competitive chemical reaction in their case), this extreme difference between 126—163°C and 40°C is quite interesting. Somewhere between these two temperature regions there might be a certain region in which the internal rotation and the competitive chemical reaction have comparative rates, which would enable one to determine the rate of *cis-trans* rotation of the butenyl radical by comparison with the rate of the competitive reaction, for which no other means of measurement is available at present.

Ionic Dissociation. III. An Extended Hückel Treatment of the Dissociation of Cyclohexanone

Hiroko YAMABE, Hiroshi KATO*1 and Teijiro YONEZAWA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received February 14, 1970)

It is said that the more stable its anion, the more easy is the dissociation of an acid.[1] As for the intermediate of the aldol condensation, Ingraham mentioned[2] that the ionization of the α-hydrogen will be aided: (1) if it is sterically in a favorable position and (2) if the anion can be stabilized. We have discussed these problems in our previous two papers.[3] In this note we will give another example, one concerning the dissociation of cyclohexanone, which should support the above description of the relative stability of a molecule and its anion.

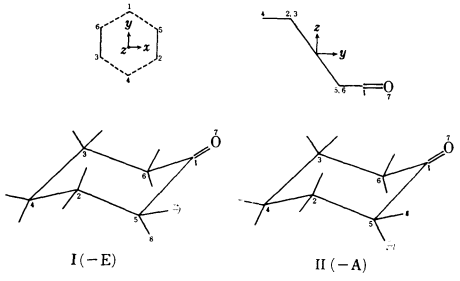

Fig. 1. Coordinate axes adopted and numbering of atoms.

It has been reported by Corey and Sneen[4] that the axial hydrogen of cyclohexane dissociates more readily than the equatorial one, since the former anion is stabilized by the σ-π delocalization. The resonance structure in the transition state is stabi-

lized when there is the conjugation between the orbital of the α-carbon, made available by the leaving hydrogen, and the orbital of the carbonyl group is possible. We confirmed their assertion by the Hoffmann's Extended Hückel calculation. The values of the parameters used have been given in a previous paper[3] and will not be repeated here.

In Fig. 1, the coordinate axes adopted and the numbering of the atoms are shown. The 2C, 3C, 5C, and 6C atoms are placed on the X-Y plane. The dissociations of the equatorial and the axial protons are indicated by (-E) and (-A), respectively. Table 1 gives the total energy of the anion, which is derived from the dissociation of a proton from cyclohexanone, and the atomic orbital populations and the atom populations of the several atoms close to the α carbon. From Table 1, it can be seen that anion (II) is more stable than the anion (I) which is in agreement with the experimental suggestion.[4] The atomic orbital population of the P_z AO of the 1C, 5C, and 7O atoms and that of the S orbital of 8H of the anion (II) are larger than the corresponding values of the anion (I). This relation is most prominent in the atomic orbital population of the P_z AO of the 5C atom in the highest occupied MO given in the 7th column of Table 1. That is the conjugation of the anion II is more prevalent than that of the anion I. This also agrees with the previous experimental suggestion.[4] This conclusion can also be deduced from Table 2. In Table 2 the atomic orbital bond populations between the 1C and 5C atoms are given for cyclohexanone and the anions I and II. The atomic orbital bond population in the Z direction increases in the order of cyclohexanone (0.028), the anion I (0.056), and the anion II (0.204). This means that the anion II is more highly conjugated than the anion I.

The calculation was carried out on a HITAC 5020 computer at the computation center of the University of Tokyo.

Polarographic Investigation of Oxidation Reaction of Vanadium(II) by Nitrate Ion

Kazuyoshi TANAKA,* Ken-ichi MORINAGA** and Kunio NAKANO*

* *Department of Chemistry, College of Science, Rikkyo (St. Paul's) University, Nishi-Ikebukuro Toshima-ku, Tokyo*

** *Department of Chemistry, Faculty of Science and Engineering, Saitama University, Shimo-Ohkubo, Urawa-shi, Saitama*

(Received March 17, 1970)

The polarographic behavior of V(II) species in various solutions has been investigated by Lingane and Meites.[1,2] Rates of the oxidation of V(II) by nitrate ion in perchlorate, sulfate, and halide solutions have been determined by means of polarography.[3] The polarographic method was applied because it was possible to measure the-rates at low acidities. It was found that sulfate ion increased the rate of oxidation to some extent. The relationship between the half-wave potentials and the rates of homogenous reactions has been suggested.[4] In the present work, the rates in various supporting electrolytes were determined by the polarographic method. It may be concluded that the difference in the rates was mostly related to that in the half-wave potentials of V(II) in the corresponding media. However, for the systems having similar half-wave potentials, the difference in the rates seems to be related to the polarographic reversibilities of the systems. The relationship will be discussed.

Experimental

All the reagents used were of analytical grade. The preparation and analysis of V(II) solution were reported elsewhere.[3] Ionic strength was adjusted to 0.5 by adding sodium perchlorate.

Measuremnet. An appropriate amount of V(II) perchlorate solution was added to the deaerated solution of a supporting electrolyte, and the polarographic measurements were carried out to obtain the half-wave potential and the reversibility of V(II) ion. While the solution was being stirred by passing N_2 gas, sodium nitrate was added to the solution, and the time dependence of the diffusion current was then recorded at a constant potential. Measurements were performed at 25°C.

Results and Discussion

Calculation of Rate Constants. The overall oxidation of V(II) by nitrate ion was proposed as follows:[3]

$$8V(II) + 2NO_3^- + 10H^+ \rightarrow 8V(III) + N_2O + 5H_2O$$

The reaction between V(II) and nitric oxide was involved in the oxidation paths, but its rate was considerably slow.[3] When excess nitrate ions in relation to V(II) ions are present, the amount of V(II) oxidized by nitrate ions is almost three times as large as that of nitrate ions consumed. Thus, the apparent second-order rate constant, k, corresponding to the decrease in V(II) ions can be calculated from the time dependence of the diffusion current using equation

$$kt = \frac{3}{3[NO_3^-]_i - [V(II)]_i} \times \ln\left\{\left(\frac{[V(II)]_i}{[NO_3^-]_i}\right)\frac{[NO_3^-]_i - X}{[V(II)]_i - X/3}\right\} \quad (1)$$

where X is the increment of reaction at any time, and i denotes the initial concentration. When the rate of oxidation is considerably small, a large excess of nitrate ions over V(II) ions is added to the solution in order to obtain feasible rates. In this case, the rate constant is also calculated from the half time assuming that the rate is pseudo first-order with respect to V(II).

Polarographic Behavior of V(II). The half-wave potentials and the polarographic reversibility as defined by Senda and Tachi[5] are shown in Table 1. From the half-wave potentials, it was concluded that the complex formation of V(II) ions took place in almost all the solutions, except for perchlorate, thiocyanate, and ammonium chloride solutions. In the thiocyanate solution, the concentration of thiocyanate ions was adjusted to 0.05 M in order to prevent the dissolution of mercury of the electrode, but at this concentration

* ppt=precipitation

V(II) ions might form a thiocyanato-complex as reported by Biermann and Wong.[6] In this solution, a polarographic minimum was observed at ~−0.05 V *vs.* SCE. From the fact that the half-wave potential shifted to more negative side with increasing oxalate concentration, V(II) ion seems to be able to form a mono-oxalato complex in the range of 0.1—0.25 M oxalate ions as suggested by Lingane and Meites.[2] The polarographic behavior of V(II) ion in fumarate, and succinate solutions were first investigated in this work. In these solutions, two polarographic waves were obtained, the more negative half-wave potentials being listed in Table 1. The a.c. polarographic measurement in fumarate solution indicated that the reversibility of the second wave (more positive) was almost twice as high as that of the first one, and the a.c. polarogram of the first wave was split into two peaks. The same phenomenon was found in a citrate solution.

Rates of Oxidation. A considerable variation in the rate constants was observed for this oxidation reaction. From their magnitudes the results may be divided into four groups as shown in Table 1. It was suggested by Vlček that the more negative the half-wave potential, the faster the rate of oxidation.[4] This relationship may hold among the groups in Table 1, but not always within each group. The difference in the rates between fluoride and succinate solutions, and salicylate and fumarate solutions, could not be related to their half-wave potentials, but probably to their reversibility. It is supposed qualitatively that the difference in the rates of the oxidation is related to the rates of the electrode reaction of V(II) species. For example, the difference in the rates between oxalate and citrate solutions, in which almost the same half-wave potentials were obtained, is considered to be related to their polarographic reversibility. The fastest rate of oxidation and the highest reversibility were obtained in EDTA solution. However, the relationship does not always hold, because the reversibility is easily changed by: (1) polarographic kinetics, and (2) adsorption of supporting electrolytes or depolarizer on mercury electrode. As shown in group IV, the rates in thiocyanate, and ammonium chloride solutions were slow, but their reversibility were higher than that in perchlorate solution. This is thought to be caused by the adsorption of each anion. It has been found that the rate of the oxidation decreased with increasing chloride ion concentration.[3]

No influence of sulfate ion on the rates could be observed in fumarate, and tartrate solutions. However, when 0.05 M sodium sulfate was present in thiocyanate solution, the rate increased about 10%, and after completion of oxidation the solution became pale yellow, indicating that a single two-electron oxidation step might be involved.[3]

As shown in Table 1, the rates of oxidation decreased as: oxalate>citrate>tartrate>thiocyanate. This decreasing order in the rates is in good agreement with the results obtained for the oxidation of Ti(III) by chlorate ion.[7]

The Fluorination of Carbon Monoxide, Carbonyl Chloride, and Carbonyl Fluoride*[1]

Shunji NAGASE, Takashi ABE, Hajime BABA and Kazuo KODAIRA

Government Industrial Research Institute, Nagoya, Kita-ku, Nagoya

(Received March 28, 1970)

This paper will deal with the electrochemical fluorination of carbon monoxide, carbonyl chloride, carbonyl fluoride, cyanogen, and hydrogen cyanide. These gaseous compounds have been subjected to fluorination by various methods,[1] but no work has yet been published on their electrochemical fluorination. The primary objective of this work was to extend the scope of the technique of electrochemical fluorination for gaseous compounds,[2] previously used mostly in the fluorination of organic gases,[3] to inorganic gases containing a carbon-oxygen or carbon-nitrogen multiple bond, and to clarify the behavior of these compounds in the fluorination.

The method of the fluorination involves the bubbling of metered starting materials through a bubbler into anhydrous liquid hydrogen fluoride in an electrolytic cell.[2] The fluorinated products were freed from hydrogen fluoride and then analyzed. It was found that carbon monoxide, carbonyl chloride, and carbonyl fluoride were fluorinated to give the anticipated products, while cyanogen and hydrogen cyanide were cleaved extensively by the fluorination. The reaction conditions for the electrochemical fluorination of carbon monoxide, carbonyl chloride, and carbonyl fluoride, and the results obtained are shown in Table 1.

In addition, oxygen difluoride was always found in the products. Small amounts of perfluorodimethyl ether and carbon dioxide were present in the products obtained from carbon monoxide. From carbonyl chloride, a considerable amount of chlorine was identified, besides a trace of chlorotrifluoromethane. This indicates the ease of the removal of chlorine of carbonyl chloride in the electrochemical process.*[2]

The electrochemical fluorination of carbon dioxide was also examined. The bulk of the starting material was recovered unchanged; traces of carbon tetrafluoride, hexafluoroethane, trifluoromethane, and a highly explosive product, which was not identified, were also found.

Table 1. Fluorination of carbon monoxide, carbonyl chloride and carbonyl fluoride

2) Part VI of this series: S. Nagase, T. Abe and H. Baba, This Bulletin, **42**, 2062 (1969).

3) See, for example, S. Nagase, T. Abe and H. Baba, *ibid.*, **40**, 684 (1967).

*2 Under pressure, carbonyl chloride is known to react with anhydrous hydrogen fluoride to yield carbonyl chlorofluoride and carbonyl fluoride, together with hydrogen chloride. [J. H. Simons, D. F. Herman and W. H. Pearlson, *J. Amer. Chem. Soc.*, **68**, 1672 (1946)]. This reaction was examined under the conditions used for the present work. When carbonyl chloride was bubbled into anhydrous hydrogen fluoride in a cell kept at 7°C without passing a current through, small amounts of carbonyl chlorofluoride and hydrogen chloride were produced.

The electrochemical fluorination of cyanogen and hydrogen cyanide resulted in an extensive cleavage of the carbon-nitrogen multiple bond, giving fragmented fluorinated products.[4] We will now give examples of the composition of the products obtained from the electrochemical fluorination of cyanogen and hydrogen cyanide, which was carried out under conditions similar to those described above. Cyanogen (feed rate, 56 m*l*/min; hydrogen fluoride, 1 *l*; temperature, 5—6°C) gave 59% nitrogen trifluoride, 35% hexafluoroethane, and 6% carbon tetrafluoride. From hydrogen cyanide (feed rate, 37 m*l*/min; hydrogen fluoride 1 *l*; temperature, −5°C), 48% nitrogen trifluoride, 42% carbon tetrafluoride, 7% trifluoromethane, and 3% trifluoromethyldifluoroamine were formed. The evolution of nitrogen was also observed.

Experimental

Materials. Carbon monoxide and carbonyl chloride from a commercial cylinder were used. The carbonyl fluoride[5] and cyanogen[6] were prepared by the methods described in the literature. The hydrogen cyanide was synthesized by a conventional method.

Procedures. The fluorination procedures used were essentially the same as those described in a previous paper.[2] Product identification and analysis were performed by means of gas chromatography,[*3] infrared spectroscopy (Hitachi EPI-S2 spectrometer), and mass spectrometry (Hitachi RMU-7 spectrometer).

4) T. Abe, S. Nagase and K. Kodaira, *ibid.*, **43**, 957 (1970).

[*3] Gas chromatography was carried out with a Shimadzu GC-2C model chromatograph using a 0.3 cm i.d. × 6 m column packed with 66% FC 43 (Minnesota Mining & Manufacturing Co.) on 60/80 mesh Celite 545 SK (Gaschro-Kogyo Co.). Column temperature, 0°C; carrier gas, helium.

In preliminary experiments, an attempt was made to analyze the products by a modification of Hempel's gas analysis, but the method was found not to be suitable for this purpose because of the reaction of carbonyl fluoride and trifluoromethyl hypofluorite with glass and with mercury covered with fluorocarbon oil respectively.

The Syntheses and Properties of the Complexes of Boron with Ethylenediaminetetraacetic Acid Analogs

Mitsuhisa NAKATANI, Yoshiaki TAKAHASHI, Akira OUCHI and Kunihiko WATANUKI

Department of Chemistry, College of General Education, University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received April 9, 1970)

In a previous paper[1] we reported the syntheses of the boron trifluoride complexes with ethylenediaminetetraacetic acid (H_4EDTA), cyclohexanediaminetetraacetic acid (H_4CDTA), and nitrilotriacetic acid (H_3NTA), as well as their infrared and ultraviolet spectroscopic properties. According to the results, the boron trifluoride forms 2 : 1 and 1 : 1 adducts with H_4EDTA and H_4CDTA respectively, and a 1 : 1 adduct, NTA·B, with H_3NTA.

Along the lines of extending this work, the boron trifluoride adducts with other aminocarboxylic acids, such as diethylenetriaminepentaacetic acid (H_5DTPA), iminodiacetic acid (H_2IDA), and *N*-hydroxyethylenediaminetriacetic acid (H_3EDTA-OH), were synthesized. New complexes, H_4DTPA·BF_2·$2H_2O$, HIDA·BF_2·H_2O and H_3EDTA-OH·$(BF_3)_2$, were obtained from boron trifluoride ethyl etherate (BF_3·$(C_2H_5)_2O$) and aminocarboxylic acids in acetonitrile media.

Experimental

Instruments. The infrared spectra were obtained by the nujol and hexachloro-1,3-butadiene mull procedure using a DS-403G infrared spectrophotometer of the Japan Spectroscopic Co., Ltd. The electronic spectra were obtained with a Hitachi EPS-2 automatic recording spectrophotometer.

Syntheses of Complexes. Table 1 shows the results of elemental analyses, the chemical formulae of the products as calculated from the analytical data, and the yields of the products.

Synthesis of H_4DTPA·BF_2·$2H_2O$. 0.8 g (0.002 mol) of H_5DTPA and 5 m*l* (0.017 mol BF_3) of a 45% ether solution of BF_3·$(C_2H_5)_2O$ were mixed with 5 m*l* of acetonitrile containing a small amount of water. The mixture was refluxed on a water bath for 30 min and then cooled to room temperature. A small insoluble

$H_5DTPA = C_{14}H_{23}O_{10}N_3$: Diethylenetriaminepentaacetic Acid
$H_2IDA = C_4H_7O_4N$: Iminodiacetic Acid
$H_3EDTA\text{-}OH = C_{10}H_{18}O_7N_2$: *N*-Hydroxyethylenediaminetriacetic Acid
* Yields were calculated for H_5DTPA, H_2IDA and $H_3EDTA\text{-}OH$.

residue was separated out, to which solution ether was added in order to obtain a white precipitate. This was filtered off and washed with ether. This product was dissolved in 10 : 1 (v/v) acetonitrile-water, and the mixture was heated under reflux for 45 min and then cooled. To the solution was then added an excess of ether, after which the mixture was kept at room temperature for several days in order to obtain a white crystalline product. This was filtered off, washed with acetonitrile and ether, and freed from the solvent under reduced pressure at room temperature.

Synthesis of $HIDA \cdot BF_2 \cdot H_2O$. 1.33 g (0.01 mol) of H_2IDA and 5 m*l* (0.017 mol BF_3) of a 45% ether solution of $BF_3 \cdot (C_2H_5)_2O$ were dissolved in 20 m*l* of acetonitrile containing a small amount of water at room temperature. After the filtration of the insoluble residue, the filtrate was kept overnight at room temperature to give a white crystalline product.

Synthesis of $H_3EDTA\text{-}OH \cdot (BF_3)_2$. 0.6 g (0.002 mol) of $H_3EDTA\text{-}OH$, 3 m*l* (0.01 mol BF_3) of a 45% ether solution of $BF_3 \cdot (C_2H_5)_2O$, and 10 m*l* of acetonitrile containing a small amount of water were mixed and dissolved by heating. After the solution had been refluxed for 2 hr, the precipitate thus obtained was filtered off.

Results and Discussion

Although the ultraviolet absorption spectra of acetonitrile solutions of these complexes are qualitative due to their low solubilities in common organic solvents, their patterns are closely similar to each other. The spectra of all the complexes show a characteristic absorption maximum at $39.3 \pm 0.1 \times 10^3$ cm^{-1} and two shoulders at 40.0 ± 0.1 and $38.2 \pm 0.1 \times 10^3$ cm^{-1}.

The typical pattern of the infrared spectra of these complexes is shown in Table 2. The tentative assignments of their infrared absorption bands are given with reference to the data about free H_5DTPA, H_2IDA, $H_3EDTA\text{-}OH$, and other BF_3 adducts with nitrogen-containing compounds.[1-6]

The crystalline H_5DTPA[3] has three strong bands of about the same intensity at 1731, 1700 and 1634 cm^{-1}. The former two correspond to the antisymmetric stretching bands of four $>N-CH_2COOH$-type carboxyl groups, while the last one corresponds to that of the $>NH^+-CH_2COO^-$-type group. $H_4DTPA \cdot BF_2 \cdot 2H_2O$ in the solid state shows antisymmetric stretching bands of the carboxyl group at 1725 and 1635 cm^{-1}, but the band at 1700 cm^{-1} of the free ligand disappears. The band at 1725 cm^{-1} probably corresponds to that of four $>N-CH_2COOH$-type carboxyl groups, as in the case of the free acid, and the band at 1635 cm^{-1} is probably to be identified as the band of the $>NBF_2^+-CH_2COO^-$-type carboxyl group, although the shift is not so great as that of the free ligand. The broad bands in the 1150—950 cm^{-1} region are probably to be identified as those of the B–F stretching mode or of a mixture with another vibration.[5,6]

At pH 2.2, the aqueous solution of H_2IDA shows two bands, at 1721 and 1619 cm^{-1}, which can be identified as the stretching bands of the $-NH_2^+-CH_2COOH$-type and the $-NH_2^+-CH_2COO^-$-type carboxyl groups respectively.[2] The solid metal complex of H_2IDA has antisymmetric carboxyl bands which are shifted to lower wave numbers.[4]

$HIDA \cdot BF_2 \cdot H_2O$ in the solid state has two antisymmetric stretching bands of carboxyl groups at 1720 and 1560 cm^{-1}. They can probably be identified as of the $-NHBF_2^+-CH_2COOH$ carboxyl group and the $-NHBF_2-CH_2COO$ carboxyl group respectively. Several bands appear in the 1150—1000 cm^{-1} region; not only the B–F band but also the B–N, C–N, and other band probably appear in this region.[5-7]

Solid $H_3EDTA-OH$ has bands at 1705 (shoulder), 1667, and 1629 cm^{-1}, all of which are identified as antisymmetric stretching bands of the carboxyl group,[3] while in the case of $H_3EDTA-OH \cdot (BF_3)_2$ the corresponding bands occur at 1762, 1720 (shoulder), and 1690 cm^{-1}. The shift to higher wave numbers of the bands of this complex is probably due to the effect of boron trifluoride, which is coordinated with the nitrogen atom in $H_3EDTA-OH$. As the boron trifluoride is a strong Lewis acid and is expected to take off electrons effectively from the nitrogen atom, the bands shift more. The broad bands appearing in the 1200—1000 cm^{-1} region may include the bands of the B–F band and others.[5,6]

The authors wish to thank Professor Yukichi Yoshino and their other colleagues for their helpful discussions.

Sesquiterpene Constituents of the Essential Oil of Mitsuba (*Cryptotaenia japonica* Hassk)

Toshiko OKUDE and Shûichi HAYASHI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received April 10, 1970)

The chemical constituents of the essential oil of Mitsuba, *Cryptotaenia japonica* Hassk, were investigated by Hirao[1] quite a long time ago; he isolated a sesquiterpene hydrocarbon which produced eudalene on sulfur dehydrogenation and suggested the name "mitsubaene" for it. However, the structure of this component has not yet been established.

As is shown in Fig. 1, a sesquiterpene portion of the essential oil showed eleven peaks on gas chromatography using Diasolid L-Carbowax 6000 (3%). These components, after being isolated upon fractional distillation, preparative gas chromatography, and/or elution chromatography, were characterized by various spectrometries and by gas-chromatographic comparisons with authentic specimens.

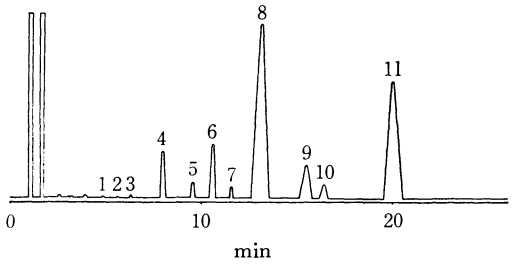

Fig. 1. Gas chromatogram of mitsuba oil (I) at 110°C on Diasolid L-Carbowax 6000.

(+)-α- and (+)-β-Selinenes. The component of the largest peak, 8, isolated by preparative gas chromatography is represented by the molecular formula of $C_{15}H_{24}$ (M^+, *m/e* 204); it was hydrogenated over Adams catalyst in acetic acid to produce a saturated hydrocarbon, $C_{15}H_{28}$ (M^+, *m/e* 208). This evidence indicates the component to be a bicyclic sesquiterpene. The IR spectrum, however, suggested that the component was a mixture of α- and β-selinenes[2]; the further separation into two components was accomplished by eluting it, step by step, over silver nitrate (10%)-coating silica gel with mixed solvents of benzene and *n*-hexane. One component, M^+ *m/e* 204, n_D^{25} 1.5040, $[\alpha]_D^{15}$ +6.31°, which was eluted more easily with a benzene and *n*-hexane-mixed solvent (v/v 10 : 90), exhibited IR and NMR spectra superimposable on those of α-selinene.[3,4] The other, M^+ *m/e* 204, n_D^{25} 1.5013, $[\alpha]_D^{15}$ +43.56°, which was eluted with a benzene and *n*-hexane mixture (v/v 15 : 85), exhibited IR and NMR spectra which were in good agreement with those of β-selinene.[5] Accordingly, the main constituents of the essential oil are (+)-α- and (+)-β-selinenes.

β- and (−)-γ-Elemenes. Both components from the 4 and 5 peaks possess the same molecular formula of $C_{15}H_{24}$ (M^+, *m/e* 204), and each uptook three molar equivalents of hydrogen on catalytic hydrogenation over Adams catalyst in acetic acid to give saturated compounds of $C_{15}H_{30}$ (M^+, *m/e* 210), whose IR spectra both coincided with that of hexahydroelemene.[3] The IR spectra of these components, however, were different from each other in the relative intensity of the absorption bands at 907 and 888 cm^{-1}; the IR spectrum of the component corresponding to the 4 peak was superimposable on that of β-elemene,[3] while that of the 5 peak on that of γ-elemene.[6] This result also agreed with those obtained by NMR and mass spectrometry and/or a gas-chromatographic comparison using an authentic specimen.[7] Although the γ-elemene isolated from this essential oil showed the following constants: n_D^{20} 1.5016, $[\alpha]_D^{20}$ −3.9°, there is some doubt whether these elemenes are natural products or artifacts, for the essential oil was collected by steam distillation. The physical constants of β-elemene were not taken.

α-Ylangene, α- and β-Copaenes, Eremophilene, Cuparene, δ-Elemene and α-Cubebene. In addition to the above components, five

8	(+)-β-selinene (+)-α-selinene	20.2 18.6	IR,[5] NMR,[5] mass IR,[3] NMR,[4] mass
9	eremophilene	9.1	IR,[16] NMR,[17] mass
10	unidentified	4.6	
11	cuparene	24.2	IR,[18] NMR,[15] mass[18]

components, α-ylangene, α- and β-copaenes, eremophilene, and cuparene, were isolated; they were identified by the methods listed in Table 1. Furthermore, two components of δ-elemene and α-cubebene were tentatively assigned by comparison with the authentic specimens obtained by gas chromatography using Gas Chrom P-Apiezon L.

The relative composition of the sesquiterpene components in the essential oil of mitsuba was calculated to be as shown in Table 1 from the peak areas on the gas chromatogram measured by the use of Carbowax 6000 at 110°C. Hirao's mitsubaene, which was separated by fractional distillation only, seems to be a mixture of these components. This conclusion does not contradict the fact that he obtained eudalene by the sulfur dehydrogenation of mitsubaene.

Experimental

The gas chromatograms were taken with a Shimadzu GC-2B apparatus equipped with a hydrogen-flame ionization detector by using two separation columns (4 mm×3 m), packed with Diasolid L-Carbowax 6000 (3%) and with Gas Chrom P-Apiezon L (4.6%). Preparative gas chromatography was carried out with Celite-Carbowax 6000 (20%) (8 mm×3 m). The NMR spectra were taken in a $CDCl_3$ solution, using tetramethylsilane as the internal standard.

Fractional Distillation of the Essential Oil of Mitsuba. As has been reported in a previous paper on the monoterpene constituents,[8] the essential oil obtained by the steam distillation of the whole herb of Mitsuba was fractionated into thirty-four fractions using a spining-band distillation column under reduced pressure. The fractions (Fr. 1—11), bp 82—140°C/50 mmHg, totaled 26.46 g; they corresponded to the monoterpene constituents used for the previous investigation. The present work was carried out on Fr. 12—34, bp 84.5—168.0°C/3 mmHg, 40.30 g. These fractions were further separated into individual components by means of preparative gas chromatography or elution chromatography over silica gel impregnated with silver nitrate.

NMR of γ-elemene: One tert-methyl (1.05 ppm, 3H, s), three allylic methyls (1.67, 6H, s and 1.71, 3H, d, J=1.2 Hz), and five olefin protons (4.63—5.20, 4H, m and 5.81, 1H, q, J=18 and 10 Hz).

The authors are deeply indebted to Professor Kenji Fukui of Hiroshima University for his kind measurement of the NMR spectra and to Kumiko Morikawa and Yoshimoto Ohta of the Institute of Food Chemistry for the donation of authentic specimens.

The Preparation of 2-Oxo-1,2-dihydro-10*aH*-imidazo[1,2-*a*]-(1,2,5)-oxadiazo[3,4-*b*]indole from Isatin

Masahiko TAKAHASHI

Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Hitachi-shi, Ibaraki

(Received April 10, 1970)

There are several studies in the literature concerned with isatin oximes. o-Cyanophenylisocyanate was obtained from isatin-*β*-oxime[1] by treating it with phosphorus pentachloride and also from *N*-asetylisatin dioxime.[2] Previous workers[3] have shown that the pyrolysis of isatin-*β*-oxime resulted in decomposition, yielding o-aminobenzonitrile.

In connection with our continuing interest in the reaction of isatin derivatives,[4] we have obtained a new tetracyclic compound from *N*-acetylisatin dioxime.

N-Acetylisatin dioxime (II), prepared from *N*-acetylisatin (I), was heated in acetic anhydride. A crystallizable compound, accompanied with uncontractable tars, was obtained in a low yield from the reaction mixture. Results of the elemental analysis and the mass spectra of the compound (III) supported the idea of the structure of $C_{10}H_7N_3O_2$ (*m/e* 201). The IR spectra (KBr) showed a C=O stretching frequency at 1810 cm^{-1}, but no NH or OH absorptions. The proton resonance (in DMSO-d_6) was observed at τ 1.7—2.4 (m, 4H), 5.92 (s, 1H), and 7.28 (s, 2H). Thus, the structure of III was established by these data to be the cyclized compound, 2-oxo-1,2-dihydro-10*aH*-imidazo[1,2-*a*]-(1,2,5)-oxadiazo[3,4-*b*]indole, which is a heterocycle with a new ring system.

The treatment of III with potassium hydroxide at room temperature afforded two crystalline compounds. The major product (IV) (45% yield) showed the NMR spectra (in DMSO-d_6) of methyl and oxime protons at τ 7.72 (s, 3H) and −0.18 (s, 1H) respectively, but no NH proton. However, the sharp absorption at 3340 cm^{-1} in the IR spectra (KBr) was apparently due to NH streching, along with the absorption at 3030—2700 cm^{-1} (OH) and 1635 cm^{-1} (C=N). The identification of IV as 3-hydroxyimino-2-methyliminoindoline was based on these data and the analytical value of $C_9H_9N_3O$ (*m/e* 175). IV must be a result of the scission of the imidazole skeleton of III, followed by decarboxylation.

The structure of the minor product (V) (8% yield) was established to be 4-acetyl-(1,2,5)-oxadiazo[3,4-*b*]indole, whose analogous compounds have not yet been synthesized, by the following data; NMR (in DMSO-d_6) τ 1.6—2.5 (m, 4H) and 7.28 (s, 3H); IR (KBr) 1800 cm^{-1} (C=O) 1640 cm^{-1} (C=N) and no NH or OH absorption; elemental analysis $C_{10}H_7N_3O_2$; mass spectral molecular ion at *m/e* 201.

Experimental

2-Oxo-1,2-dihydro-10*aH*-imidazo[1,2-*a*]-(1,2,5)-oxadiazo[3,4-*b*]indole (III). Two grams of *N*-acetylisatin dioxime were added to 20 m*l* of acetic anhydride,

and the mixture was heated at 120°C for 1 hr. Then the solution was poured into 100 m*l* of water, and, after several hours, the aqueous solution was then washed with water, and, after the solvent had been removed, the residue was washed with a small amount of MeOH, giving white solids (31—10% yield). White needles, mp 233—234°C, after recrystallization from MeOH. UV λ_{max}^{EtOH} mμ(ε) 260 (7900), 274 (5900), 284 (5500), 316 (4700), 330 (4400).

Found: C, 59.66; H, 2.99; N, 20.71%. Calcd for $C_{10}H_7N_3O_2$: C, 59.73; H, 3.50; N, 20.90%.

3-Hydroxyimino-2-methyliminoindoline (IV) and 4-Acetyl-(1,2,5)-oxadiazo[3,4-*b*]indole (V). To a stirred solution of 20 m*l* of 5% KOH (H_2O : MeOH–1 : 1), 660 mg of III were added, after which the mixture was stirred for 2 hr at room temperature. Then the solution was neutralized with dilute HCl. After the solution which contained the resulting precipitate had been extracted with 50 m*l* of $CHCl_3$, the materials insoluble in both layers were gathered by filtration to give 262 mg of IV (45% yield), mp 198—201°C; white powder after recrystallization from MeOH. UV λ_{max}^{MeOH} mμ (ε) 252 (57000), 261 (51000), 318 (26000).

Found: C, 61.72; H, 5.11; N, 23.72%. Calcd for $C_9H_9N_3O$: C, 61.75; H, 5.16; N, 24.00%.

The $CHCl_3$ solution was evaporated, and the crude residue was chromatographed on silica gel. Elution with $CHCl_3$ gave 56 mg of V (8% yield), mp 195—197°C, from MeOH. UV λ_{max}^{EtOH} mμ (ε) 236 (17000), 244 (23000), 250 (19000), 294 (4700), 305 (4400), 320 (2900).

Found: C, 59.77; H, 3.64; N, 21.22%. Calcd for $C_{10}H_7N_3O_2$: C, 59.73; H, 3.50; N, 20.90%.

I wish to thank Professor Tadashi Sasaki for his valuable discussions and for the measurement of the NMR and mass spectra.

The Synthesis of Methyl α-Methoxyacrylate

Norio OGATA, Shun-ichi NOZAKURA and Shunsuke MURAHASHI

Faculty of Science, Osaka University, Toyonaka, Japan

(Received April 13, 1970)

In the course of our study of the polymerization of internal olefins, we attempted to prepare methyl β-methoxyacrylate (β-MMOA) and undertook the reaction of sodium methoxide ($NaOCH_3$) with methyl α,β-dibromopropionate (I). It was found, however, that methyl α-methoxyacrylate (α-MMOA) is unexpectedly formed. This is in contrast with the case of α,β-dibromopropionic acid,[1] where it has been shown that α,β-dibromopropionic acid, on treatment with boiling methanolic $NaOCH_3$, yields β-methoxyacrylic acid.

α-MMOA has been prepared either by the reaction of phosphorous pentoxide with methyl α,α-dimethoxypropionate[2] or by the reaction of piperidine with methyl β-bromo-α-methoxypropionate.[3]

In the present study, the reaction of $NaOCH_3$ with compound I at various molar ratios at room temperature was examined, and the course of the reaction leading to the formation of α-MMOA was elucidated.

The reaction paths are summarized in Fig. 1. The reaction of more than 2 mol equivalents of $NaOCH_3$ with compound I gives α-MMOA in good yields. The structure of α-MMOA was

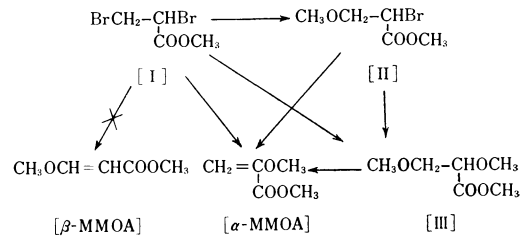

Fig. 1

established by the study of its NMR spectra and that of its hydrogenated product, methyl α-methoxypropionate, and by derivation to a known compound, α-methoxypropionamide. When the reactions were carried out in boiling methanol, similar results were obtained, but in somewhat lower yields.

When an equimolar amount of $NaOCH_3$ is used in the reaction, the main product is compound II, as has been reported in the literature.[4] The structure of compound II was confirmed by a comparison of its NMR and IR spectra with those of authentic methyl α-bromo-β-methoxypropionate prepared by the procedure of Carter.[5]

Table 1. Dependence of product distribution on the molar ratio of $NaOCH_3$ to compound I[a]

$NaOCH_3$/I (molar ratio)	Addition[b] procedure	Yield (%)[c] II	III	α-MMOA
1.15	B	77	19	0
1.20	A	75	24	0
1.48	A	45	52	3
1.82	A	9	62	21
1.85	B	4	53	36
2.05	A	0	8	67
2.31	A	0	7	75
2.38	B	0	6	79
2.99	A	0	5	79

a) After 5 days, at room temperature. Amounts of compound I and methanolic $NaOCH_3$ were 8 m*l* (6.35—6.50 mol) and 50 m*l*, respectively.
b) A: A methanolic $NaOCH_3$ was added to compound I at −4°C.
B: Compound I was added to $NaOCH_3$-methanol solution at −4°C.
c) Determined by gas chromatography using calibration curves.

When the reaction is carried out with 1.50—1.85 mol equivalents of $NaOCH_3$, the main product is methyl α,β-dimethoxypropionate (III). Its structural assignment was based on elementary analysis and its NMR spectrum.

The distribution of the product is remarkably affected by the molar ratio of $NaOCH_3$/I, but only slightly by the addition procedure, as is shown in Table 1. From these data, it seems reasonable to assume that the reaction of $NaOCH_3$ with compound I results in the formation of compound II in the first stage, followed by the formation of compound III and/or α-MMOA. In order to clarify these points, the behavior of compounds II and III in a high concentration of $NaOCH_3$ was examined. The reaction of compound II with methanolic $NaOCH_3$ (the molar ratio of $NaOCH_3$/II=0.98) resulted in the formation of α-MMOA (85%), together with a small amount of compound III (9%). By the reaction of compound III with methanolic $NaOCH_3$ (the molar ratio of $NaOCH_3$/III=1.64), α-MMOA was also obtained (80%). These results suggest that the reaction route is in the order:

$$\text{I}\rightarrow\text{II}\rightarrow\text{III}\rightarrow\alpha\text{-MMOA}.$$

Experimental

Equimolar Reaction of $NaOCH_3$ with Compound I. A solution of 7.7 g (0.34 mol) of sodium in 100 m*l* of dry methanol was added dropwise with mechanical stirring into 80.3 g (0.33 mol) of compound I (bp 97—98°C/24 mmHg) at −2——4°C. At the end of addition, the ice-salt bath was removed and the mixture was stirred at room temperature for 1.5 hr. After dry ice had then been added to neutralize remaining alkali, the precipitate was removed by filtration. Water was added to the filtrate, and it was extracted with chloroform. The chloroform solution was washed with water and dried over anhydrous magnesium sulfate. Distillation gave a product, II; bp 68—70°C/11 mmHg; yield, 48.5 g (76%). Found: C, 30.54; H, 4.69; Br, 40.0%. Calcd for $C_5H_9O_3Br$: C, 30.48; H, 4.60; Br, 40.6%. NMR (CCl_4, 60 MHz): τ= 6.22 (s, $COOCH_3$), 6.63 (s, OCH_3), 5.67—6.42 (m, α and β CH).

Methyl α-Bromo-β-methoxypropionate. Methyl α-bromo-β-methoxypropionate was prepared by the procedure of Carter[5b] from 54 g of methyl acrylate, 120 g of mercuric acetate, 72 g of potassium bromide, and 90 g of bromine. Yield, 54 g. The dibromoester was removed from the reaction mixture by gas chromatography (Apiezon M—Celite 545, 2 m; 130°C). (Found: C, 30.83; H, 4.69; Br, 41.0%).

Reaction of 2 Mol Equivalents of $NaOCH_3$ with Compound I. Compound I (110 g, 0.45 mol) was added to a solution of 21.6 g (0.94 mol) of sodium in 310 m*l* of dry methanol. The mixture was allowed to stand at room temperature overnight and then treated as has been described above. The product (47 g), which boiled at 43.5—54.0°C/7 mmHg, was found by gas chromatography to contain compounds II, III, and α-MMOA in 10, 43, and 47 mol% respectively. Compound III was purified by gas chromatography. Found: C, 48.29; H, 8.08%. Calcd for $C_6H_{12}O_4$: C, 48.62; H, 8.16%. NMR (CCl_4, 60 MHz): τ= 6.29 (s, $COOCH_3$), 6.63 and 6.68 (s, α and β OCH_3, respectively), 6.08—6.67 (m, α and β CH).

Reaction of 2.5 Mol Equivalents of $NaOCH_3$ with Compound I. Compound I (106 g, 0.43 mol) was similarly added to a solution of 25.3 g (1.1 mol) of sodium in 400 m*l* of dry methanol. The mixture was kept at room temperature for 10 days, until there were no peaks of compounds II and III in a gas chromatogram, and then worked up as before. Fractional distillation in the presence of 0.5 g of hydroquinone under a reduced pressure of nitrogen gave α-MMOA. Bp 50.5—51.0°C/10 mmHg (lit, 51.5—52.0°C/11 mmHg[3]). Yield, 38.9 g (78%). Found: C, 51.76; H, 6.94%. Calcd for $C_5H_8O_3$: C, 51.72; H, 6.94%. NMR (CCl_4, 60 MHz): τ=6.23 (s, $COOCH_3$), 6.39 (s, OCH_3), 4.78 and 5.47 d, J=2.4 Hz, $=CH_2$). IR (liq.): 3130 (w, $\nu_{=CH_2}$), 1625) cm^{-1} (vs, $\nu_{C=C}$). The hydrogenationof the ester was performed by Raney nickel to give methyl α-methoxypropionate. Bp 130.5—131.0°C. NMR (CCl_4, 60 MHz): τ=8.67 (d, J=6.8 Hz, CH_3), 6.01—6.37 (q, CH), 6.27 (s, $COOCH_3$), 6.67 (s, OCH_3). α-MMOA was converted by aqueous ammonia into α-methoxyacrylamide. Mp 108—110°C(lit, 109°C[3]), after recrystallization from benzene. The hydrogenation of α-methoxyacrylamide catalyzed by palladium chloride gave α-methoxypropionamide. Mp 83—84°C, after recrystallization from ligroin. NMR ($CHCl_3$, 60 MHz): τ=8.53 (d, J=6.9 Hz, CH_3), 6.00—6.35 (q, CH), 6.51 (s, OCH_3).

Reactions of $NaOCH_3$ with Compounds II and III. Compounds II and III were added to methanolic $NaOCH_3$. The reactions were followed by taking gas chromatograms of the reaction mixtures using calibration curves.

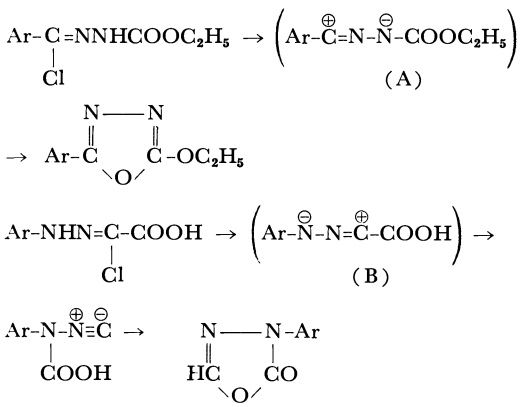
Studies of Heteroaromaticity. XLVI.[1] Syntheses of 2,5-Disubstituted 1,3,4-Oxadiazoles Containing Nitrofuran Nucleus

Tadashi SASAKI and Toshiyuki YOSHIOKA

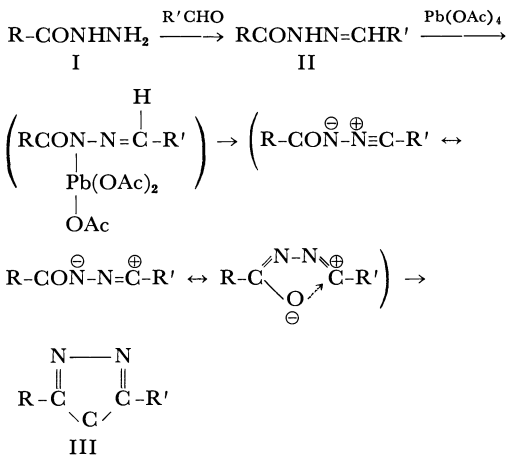
Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received April 13, 1970)

In a previous paper, we reported that aroyl and ary nitrile oxides have a similar reactivity in the 1,3-dipolar cycloaddition.[2] In continuation of our studies on similar reactivity of the nitrile imines,[3] this paper describes our attempts to prepare *N*-aroyl nitrile imines. 1-α-chlorobenzylidene-2-ethoxycarbonylhydrazine is reported to cyclize by triethylamine to 2-phenyl-5-ethoxy-1,3,4-oxadiazole[4] and in a similar manner, aryhydrazonochloroacetic acids cyclize to 4-aryl-5-oxo-1,3,4-oxadizol-2-ines.[5] Both cyclization reactions might be explained by postulating intermediate *N*-ethoxycarbonyl benzonitrile imine (A) and *C*-carboxynitrile imine (B), respectively.



As in the preparation of the nitrile imines,[3] lead tetraacetate-oxidation of the readily available aroylhydrazones (II) from aroylhydrazines (I) was carried out at room temperature. The products were characterized as 2,5-disubstituted 1,3,4-oxadiazoles (III), simple oxidation products of aroylhydrazones which provide general procedure for the preparation of 2,5-disubstituted 1,3,4-oxadiazoles.[6] The recent appearance of an article on a similar subject[7] prompted us to write this note. A sequence of the reaction and the mechanism postulated for the preparation of III are given below.



The results are summarized in Tables 1 and 2.

Experimental[8]

Starting Materials. Aroylhydrazines (Ia:[9] 5-nitro-2-furoyl, Ib:[10] 5-nitro-2-furylacroyl, and Ic:[11] benzoylhydrazine) and 5-nitro-2-furylacrolein[12] were prepared by the known procedures. All the other aldehydes were commercial products.

General Procedure. *Conversion of I to II.* A mixture of 0.6 g (3.5 mmol) of 5-nitro-2-furoylhydrazine

(Ia) and 0.4 g (3.5 mmol) of benzaldehyde was refluxed in 40 m*l* of ethanol for 7 hr. After cooling, the precipitates were collected and recrystallized from ethanol to give 0.85 g (85%) of 1-benzylidene-2-(5-nitro-2-furoyl)-hydrazine (IIa). The results of similar reactions using several aroyhydrazines and aromatic aldehydes are summarized in Table 1.

Conversion of II to III. To a stirred suspension of 0.5 g (2 mmol) of IIa in 100 m*l* of dichloromethane was added 1.3 g (3 mmol) of lead tetraacetate at room temperature. The mixture was stirred at room temperature for 2 days. After filtering off the undissolved materials, the solvent was removed under reduced pressure. The residue was recrystallized from ethanol-benzene-tetrahydrofuran to afford 0.38 g (80%) of 2-(5-nitro-2-furyl)-5-phenyl-1,3,4-oxadiazole (IIIa), 231—232°C (decomp.). Analytical and spectral data are summarized in Table 2.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 2991—2993 (1970)

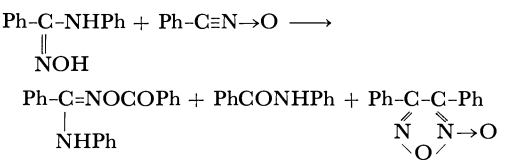
Reactions of Aromatic Hydroxamoyl Chlorides with Benzamidoxime Involving a Novel Synthesis of the 1,4-Dioxa-2,5-diazine Ring System[1]

Tadashi SASAKI, Toshiyuki YOSHIOKA and Yasuyuki SUZUKI

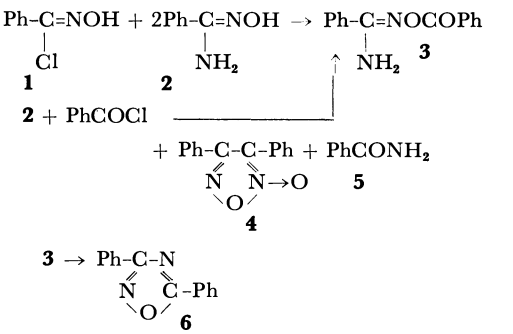
Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received April 16, 1970)

N-Phenylbenzamidoxime is known to react with benzonitrile oxide to afford the *O*-benzoyl oxime as a major product together with small amounts of benzanilide and diphenylfuroxan, but without detailed documentation for the formation mechanism.[2]



In a previous paper,[3] we have reported the 1,3-dipolar cycloaddition reactions of aromatic hydroxamoyl chlorides, a precursor to the nitrile oxides, with two equivalents amounts of basic dipolarophiles in ether at room temperature leading to the formation of five-membered heterocycles. Under similar conditions, we treated benzhydroxamoyl chloride (**1**) with benzamidoxime (**2**). Two products isolated from the ether-soluble part were characterized as *O*-benzoylbenzamidoxime (**3**) and diphenylfuroxan (**4**) together with benzamide (**5**) from the ether-insoluble part. Compound **3** was alternatively prepared from **2** and benzoyl chloride. When refluxed in toluene, **3** was converted to known 3,5-diphenyl-1,2,4-oxadiazole (**6**).



Considering that the types of these products are similar to those from the reaction of benzonitrile oxide with *N*-phenylbenzamidoxime, both reactions are concluded to proceed in the same manner as illustrated in Scheme 1; the nitrile oxide attacks to the hydroxyl, not to the amino group of **2**,[4] leading to the intermediate **7** or **8**, which was hydrolyzed[5] at (a) linkage to give *O*-benzoylbenzamidoxime or **3**, while the hydrolysis at (b) linkage afforded **4** and benzanilide or **5**. The results indicate that both types of the cleavage have occurred competitively.

Expecting similar results, 5-nitro-2-furyl-(**9**), *p*-(**10**) and *m*-nitrobenzhydroxamoyl chloride (**11**) were treated with **2** under similar conditions. From the reaction of **9** and **2**, two crystalline products, **12** and **13**, were isolated from the ether-soluble and insoluble part of the reaction mixture, respectively. The infrared spectrum (KBr) of **12** showed no absorptions due to amino and carbonyl but a strong one at 1200 cm^{-1} presumably due to cyclic ether, and medium ones at 1645 and 1610 cm^{-1} due to –C=N– instead of strong ones at 1600—1625 cm^{-1} characteristic in furoxan structure,[6] while **13** manifested amino (3500), hydroxyl (3225) and carbonyl (1750 cm^{-1}) absorptions, though the first amino absorption was slightly different from that of **3**, in which two amino-absorptions at 3450 and 3400 cm^{-1} indicate the presence of the primary amino group. The analysis of **12** supports a chemical formula $C_{12}H_7O_5N_3$, suggesting the so-called dimer-type structure of the nitrile oxide as expressed by **12′** and **12″**. Recently, Morrocchi *et al.*[7] have reported on the application of mass spectroscopy for distinguishing these isomeric dimers. We adopted this method for determining the structure. As depicted in Fig. 1, the most abundant peak corresponds to benzonitrile ion instead of disubstitued acetylene or aromatic carbonyl ions originated from **12′**

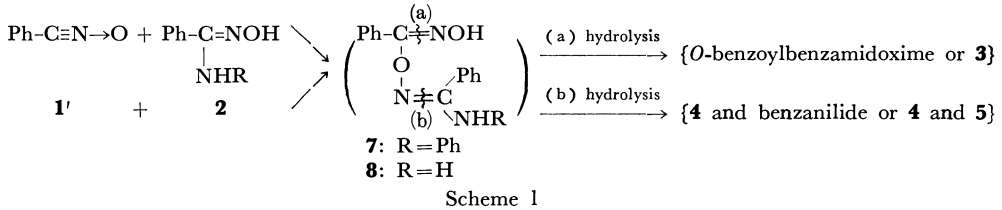
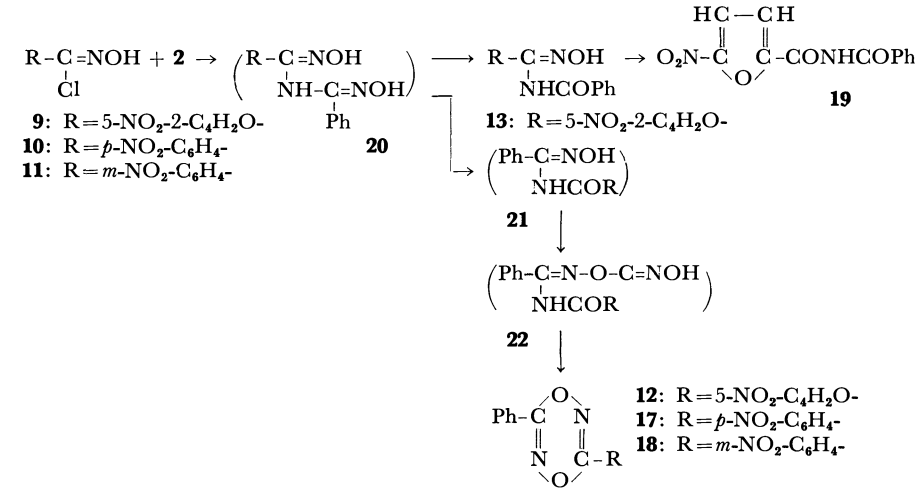


Scheme 1



Scheme 2

and **12''** respectively,[7] demonstrating the structure to be **12** having 1,4-dioxa-2,5-diazine structure. When refluxed in toluene for 8 hr, **12** was converted to benzonitrile and 5-nitro-2-furocarbonitrile in 50% conversion with 20% recovery of **12**.

On the other hand, the analysis of **13** indicated a chemical formula $C_{12}H_9O_5N_3$, the same as the corresponding *O*-benzoate **14**. This compound was independently prepared from the amidoxime **15** and benzoyl chloride; the infrared spectrum of **14** was, however, slightly different from **13**. Furthermore, **13** remained unchanged on refluxing in toluene for a long time, while **14** was readily converted to known 3-(5-nitro-2-furyl)-5-phenyl-1,2,4-oxadiazole (**16**) under similar conditions. **13** was hydrolyzed to the benzoyl amide **19**. Finally, we assigned to **13** an *N*-benzoylamidoxime structure. From similar reactions of **10** and **11** with **2**, products **17** and **18** were obtained 50 and 70% yields, respectively. Both products showed the infrared and mass spectral patterns similar to those of **12** (Fig. 2 and Experimental), indicating the presence of 1,4-dioxa-2,5-diazine ring as the common structure. It should be noteworthy that any ring-opened compound corresponding to **13** was not isolated from both reaction mixtures.

The 1,4-dioxa-2,5-diazine has been a ring system of not beyond assumption for a long time[8] until recently the preparation of the *symmetrically* disubstituted dioxadiazines has been reported by Morrocchi *et al.*[7] Our procedure provides the first example for synthesizing *unsymmetrically* disubstituted ones.

The mechanism for the formation is uncertain but may probably be depicted in Scheme 2; the initial attack of the hydroxamoyl chloride to the amino group of **2** at the chlorine atom activated by the electronegative R group, not to the hydroxyl group *via* the nitrile oxide as in Scheme 1, results in the substitution, affording an intermediate **20**, which is convertible to the *N*-benzoylamidoxime **13** upon hydrolysis. Another hydrolysis product **21** reacts with **9** to afford **22** and its cyclization by elimination of amide affords **12**.

Experimental[9]

Reaction of Benzhydroxamoyl Chloride with Benzamidoxime. A solution of 1 g of benzamidoxime in 30 m*l* of ether was added to a solution of 0.5 g of benzhydroxamoyl chloride in 20 m*l* of ether at room temperature with stirring. The reaction mixture was allowed to stand for one month. The resulting precipitates were collected by filtration, washed with a small amount of cold water, and recrystallized from water to give benzamide, mp 130°C. The solvent was removed from the filtrate and the residual oil was extracted with ether (10 m*l*×3). The ether extracts were dried (Na_2SO_4) and evaporated. The residue was chromatographed on silicic acid (Mallinckrodt, 100 mesh), using chloroform as the eluent. The first fraction (150 mg, 30%) was recrystallized from ethanol to give **4**, mp 118°C, which was identified by the infrared spectral comparison with an specimen.[10] The second fraction (300 mg, 40%) was recrystallized from benzene to afford **3** as colorless crystals, mp 153°C.

Found: C, 70.10; H, 4.94; N, 11.71%. Calcd for $C_{14}H_{12}O_2N_2$: C, 69.99; H, 5.03; N, 11.66%.

***O*-Benzoylbenzamidoxime (3).** To a stirred solution of 1.3 g of benzamidoxime and 1.1 g of triethylamine in 60 m*l* of benzene was added dropwise 1.4 g of benzoyl chloride under cooling with ice-water.

After stirring for one day at room temperature, the resulting precipitates were collected by filtration, washed with water and recrystallized from ethanol to give 1.9 g (80%) of **3**, mp 153°C.

3,5-Diphenyl-1,2,4-oxadiazole (6). A solution of 0.7 g of **3** in 30 m*l* of toluene was refluxed for 12 hr. The solvent was removed under reduced pressure and the residue was recrystallized from ethanol to give 0.6 g (85%) of **6**, mp 109°C (lit,[11] mp 109°C).

Reaction of 5-Nitro-2-furylhydroxamoyl Chloride with the Amidoxime. A solution of 0.5 g of 5-nitro-2-furylhydroxamoyl chloride[12] and 1 g of benzamidoxime in 40 m*l* of ether was stirred at room temperature overnight. The precipitates were collected by filtration, washed with water, dried in the air and recrystallized from benzene to give 0.32 g (30%) of **12** as pale yellow crystals, mp 203—205°C (dec.). UV λ_{max}^{EtOH} mμ (ε); 223 (20000) and 308 (8600).

Found: C, 53.19; H, 2.20; N, 15.55%. Calcd for $C_{12}H_7O_5N_3$: C, 52.75; H, 2.58: N, 15.38%.

Ether was removed from the filtrate and the residue was recrystallized from benzene-ethanol to give 0.14 g (15%) of **13**, mp 191—194°C (dec.).

Found: C, 52.59; H, 3.39; N, 15.43%. Calcd for $C_{12}H_9O_5N_3$: C, 52.37; H, 3.30; N, 15.27%.

***O*-Benzoyl-5-nitro-2-furocarbamidoxime (14).** This was prepared in 75% yield from 5-nitro-2-furocarbamidoxime (**15**)[13] and benzoyl chloride as pale yellow crystals, mp 214—217°C.

Found: C, 52.43; H, 3.19; N, 15.05%. Calcd for $C_{12}H_9O_5N_3$: C, 52.37; H, 3.30; N, 15.27%.

3-(5-Nitro-2-furyl)-5-phenyl-1,2,4-oxadiazole (16). Treatment of **14** similar to the preparation of **6** afforded 90% yield of **16**, mp 205°C (lit[11] mp 205°C).

3-(*p*-Nitrophenyl)-6-phenyl-1,4-dioxa-2,5-diazine (17). A solution of 1 g of *p*-nitrobenzhydroxamoyl chloride[3] and 1.4 g of benzamidoxime in 50 m*l* of ether was stirred at room temperature for several days. The resulting precipitates were collected by filtration, washed with water, dried in the air and recrystallized from benzene-ethanol to afford 0.52 g of **17** as yellow needles, mp 208—209°C (dec.). From the ethereal mother liquor, further 0.15 g of **17** was obtained. Total yield was 50%. IR (KBr): 1635 (–N=C–) and 1205 cm^{-1} (–O–).

Found: C, 59.55; H, 3.31; N, 14.88%. Calcd for $C_{14}H_9O_4N_3$: C, 59.36; H, 3.20; N, 14.84%.

3-(*m*-Nitrophenyl)-6-phenyl-1,4-dioxa-2,5-diazine (18). Similarly, 1 g (70%) of **18** was obtained as colorless crystals, mp 195°C (dec.), from *m*-nitrobenzhydroxamoyl chloride[3] (0.8 g) and benzamidoxime (1.5 g). IR (KBr): 1620 (–N=C–) and 1210 cm^{-1} (–O–). Mass Spectrum *m/e* (rel. intensity): 103 (100) and 148 (100).

Found: C, 59.35; H, 2.92; N, 14.93%. Calcd for $C_{14}H_9O_4N_3$: C, 59.36; H, 3.20; N, 14.84%.

Hydrolysis of 13 to *N*-benzoyl-5-nitro-2-furoylamide (19). A solution of **13** in ethanol was refluxed in the presence of 3% hydrochloric acid. The resulting precipitates after cooling were collected by filtration and recrystallized from ethanol-water to give 85% yield of **19**, mp 215°C.

Found: C, 55.45; H, 3.25; N, 10.65%. Calcd for $C_{12}H_8O_5N_2$: C, 55.39; H, 3.10; N, 10.77%.

9) Melting points are uncorrected. Infrared spectra were obtained on a Nippon-Bunko IR-S, ultraviolet spectra on a Nippon-Bunko ORD/UV-5 spectrometer. Mass spectra were measured on a Hitachi RMU-6D mass spectrometer at 70 eV.

The Photoconductivity in a CCl_4 Solution of *N,N*-Dimethylaniline

Shunsuke MATSUDA, Hiroshi KOKADO and Eiichi INOUE

Imaging Science and Engineering Laboratory, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 14, 1970)

We have examined the photoconductivity in the solution of *N,N*-dimethylaniline in carbon tetrachloride. The carbon tetrachloride used was of a spectrograde and was not purified further. The *N,N*-dimethylaniline was purified by repeated vacuum distillation. The solution showed a remarkable photoconductivity upon ultraviolet irradiation (320—400 nm).

Since carbon tetrachloride is transparent at the wavelength of the exciting light, the photocurrent must be associated with the excited *N,N*-dimethylaniline.

However, since the solution of *N,N*-dimethylaniline in inert solvents such as cyclohexane, *n*-hexane, or benzene was not photoconductive, the photocurrent seems to be caused by an interaction between *N,N*-dimethylaniline and carbon tetrachloride. There are two possibilities in the mechanism of the interaction: energy transfer from the amine to the halide, and charge transfer in the excited states.*1 The latter was proposed by Latowsky in studying the photo-reactions in an ethanolic solution of aromatic amines and aromatic halides.[1]

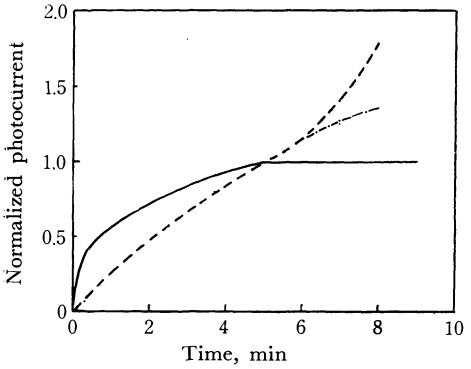

Fig. 1. Photocurrent profiles of solutions of three solutes in CCl_4.
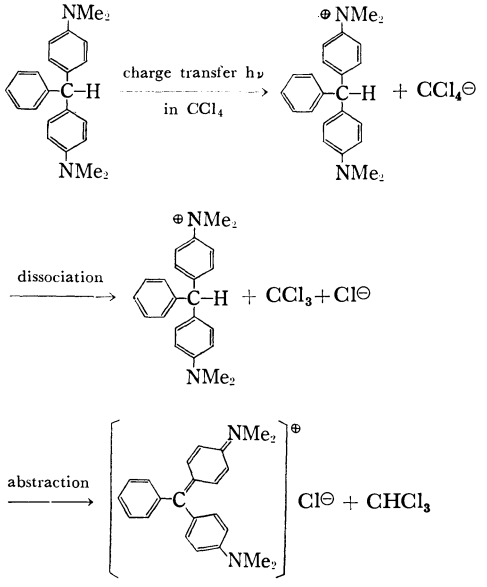
(—·—·) *N,N*-dimethylaniline
(- - - - -) MGCN
(———) MGH.
Exciting light, $\lambda = 320-400$ nm, from a 100 W high pressure Hg lamp. 3 V/cm.

In the charge-transfer mechanism the elementary processes are: (1) light absorption by *N,N*-dimethylaniline, (2) the electron transfer from the excited molecule to a carbon tetrachloride molecule, (3) the dissociation of the carbon tetrachloride anion to the chloride ion and the trichloromethyl radical,[2] and (4) various reactions which are initiated by the radicals.

To get some evidence for the charge-transfer mechanism, leuco malachite green (MGH) and malachite green leuconitrile (MGCN) were studied instead of *N,N*-dimethylaniline. The absorption spectra due to the dimethylanilino group in both materials are similar to those of *N,N*-dimethylaniline.[3]

Both materials, when dissolved in CCl_4, induced a photocurrent, the MGH solution became green, but the MGCN solution did not.

These results can be easily understood by assuming the charge-transfer mechanism for the initial photoinduced processes in these systems. A plausible mechanism for the dye formation is as follows:



*1 In this system, there is a possibility of a weak charge-transfer interaction even in the ground state. See K. M. C. Davis and M. F. Farmer, *J. Chem. Soc., B*, **1967**, 28

1) T. Latowsky, *Z. Naturforschg.*, **23a**, 1127 (1968).

2) N. R. Daly and R. G. Ridley, *Nature*, **202**, 895 (1964).

3) A. H. Sporer, *Trans. Faraday Soc.*, **57**, 983 (1961).

The failure of color to develop in the MGCN solution indicates that the CN abstraction from the center carbon atom of MGCN is difficult.

By analogy with the results on these leucobases of malachite green, we may deduce that the photoconduction of the system is caused by the charge transfer from excited *N,N*-dimethylaniline molecules to CCl_4 molecules.

Oxidation of Cyclododecane-1,5,9-triol

Shinsaku FUJITA and Hitosi NOZAKI

Department of Industrial Chemistry, Kyôto University, Yoshida, Kyôto

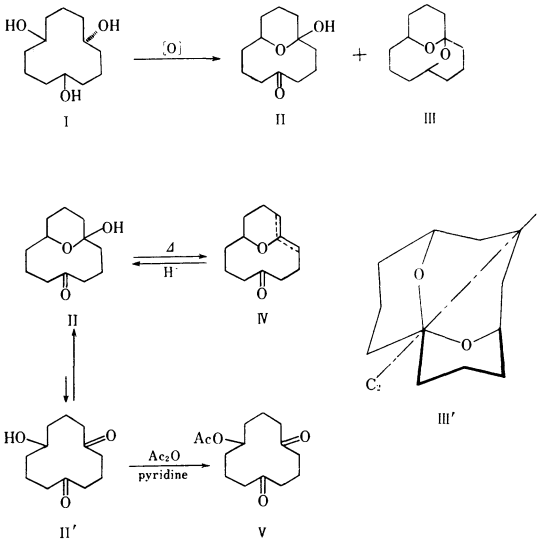
(Received April 15, 1970)

Although transannular reactions of 8-10-membered cyclic compounds have been well investigated,[1] few examples have been reported on cyclododecane derivatives.[2] The present paper deals with a new transannular interaction in the oxidation of *cis,cis,trans*-cyclododecane-1,5,9-triol (I).[3]

Oxidation of I by the Brown procedure (sodium dichromate-sulfuric acid-ether) gave a hemiacetal (II) and an acetal (III) (II : III=43 : 57). The product ratio was considerably changed (II : III= 74 : 26) in the Cornforth oxidation (chromium-(VI) oxide-pyridine-water) of I. No detectable amount of cyclododecane-1,5,9-trione was obtained in each case. Facile formation of six-membered cyclic acetals seems to prevent the oxidation from proceeding to the stage of trione.

Compound II exhibited IR absorptions at 3490 (ν_{O-H}) and 1697 cm^{-1} ($\nu_{C=O}$) and was dehydrated quite easily on distillation and/or gas chromatography to give the corresponding enol ether (IV) (1710 and 1677 cm^{-1}). The reverse hydration of IV afforded the starting compound II. Acetylation of II with acetic anhydride yielded 9-acetoxycyclododecane-1,5-dione (V). The structure of V was shown to be monocyclic, since its NMR spectrum exhibited the signal of a methine proton adjacent to acetoxyl group at δ 4.47 ppm. Consequently, compound II must be the intramolecular hemiacetal of 9-hydroxycyclododecane-1,5-dione (1-hydroxy-13-oxabicyclo[7.3.1]tridecan-5-one), which is in equilibrium with monocyclic hydroxydione II′ affording V on acetylation.

Another oxidation product (III) exhibited IR absorptions between 1250—900 cm^{-1} attributable to ethereal function. The absence of carbonyl group was proved by the IR spectrum. The parent peak at *m/e* 196 in the mass spectrum and the elementary analysis established the molecular formula of $C_{12}H_{20}O_2$. The NMR spectrum in carbon tetrachloride showed the signal of the methylene protons as a complex multiplet. Hence, III was concluded to be the intramolecular acetal of 5,9-dihydroxycyclododecanone (13,14-dioxatricyclo[7.3.1.$1^{1,5}$]tetradecane). Although the stereochemistry of III is not certain at present, the strainless configuration of C_2 symmetry (III′) may be preferred on the basis of the Dreiding model.



Experimental

Oxidation of *cis,cis,trans*-cyclododecane-1,5,9-triol (I). *(a) Brown's Oxidation.*[4] To a mixture of I (5.41 g, 25 mmol), water (25 m*l*) and ether (100 m*l*)

a mixture of sodium dichromate dihydrate (5.00 g, 17 mmol), 95% sulfuric acid (3.80 ml) and water (23 ml) was added dropwise for 20 min at 0°C. Stirring was continued for an additional 2 hr. The ether layer was separated and the aqueous layer was extracted twice with ether. The combined extracts were washed with aqueous sodium hydrogen carbonate and then with water, dried over sodium sulfate and concentrated *in vacuo* to give a crude mixture (4.50 g) of II and III. The ratio (II : III=43 : 57) was determined by gas chromatography (High Vacuum Silicone Grease 30% on Celite 545, 190°C). The two components were separated through a silica gel column using benzene as a solvent. The first elute was the acetal (III) (1.39 g, 28%), bp 137°C/21 mmHg. IR (neat): 1220, 1209, 1160, 1124, 1096, 1040, 1006, 962, 934, 899 and 870 cm^{-1}. NMR (CCl_4): δ 4.5—3.6 (2H, multiplet, O–CH) and 2.8—1.1 (18H, fine-structured multiplet). MS *m/e* 196 (M^+).

Found: C, 73.2; H, 10.2%. Calcd for $C_{12}H_{20}O_2$: C, 73.4; H, 10.3%.

The second elute was the hemiacetal(II) (1.21 g, 23%) as large plates, mp 54—56°C. IR (Nujol): 3490, 1697, 1320, 1237, 1206, 1180, 1158, 1141, 1118, 1086, 1046, 1017, 970, 958, 936 and 902 cm^{-1}. NMR (CCl_4): δ 4.1—3.4 (1H, multiplet, O–CH), 3.4—3.1 (1H, broad, OH) and 3.0—1.1 (18H, multiplet).

Found: C, 67.4; H, 9.5%. Calcd for $C_{12}H_{20}O_3$: C, 67.9; H, 9.5%.

Gas chromatographic separation (High Vacuum Silicone Grease, 30% on Celite 545, 198—225°C) of II resulted in dehydration to give IV as an oil, bp 115°C (bath temperature)/1 mmHg. IR (neat): 1710, 1678, 1302, 1225, 1183, 1155, 1082, 1050, 956 and 906 cm^{-1}. NMR (CCl_4): δ 4.5—4.3 (1H, multiplet, OC=CH) and 4.0—1.1 (17H. multiplet). MS *m/e* 194 (M^+).

Found: C, 74.2; H, 9.4%. Calcd for $C_{12}H_{18}O_2$: C, 74.2; H, 9.3%.

5) R. H. Cornforth, J. W. Cornforth and G. Popjàk, *Tetrahedron*, **18**, 1351 (1962).

(b) Cornforth's Oxidation.[5] To cooled pyridine (300 ml) was added an aqueous solution (25 ml) of chromium(VI) oxide (33.0 g, 0.33 mol) and then a solution of I (10.8 g, 0.050 mol) in pyridine (50 ml) during 10 min. Stirring was continued for an additional 30 min at 0°C and the mixture was allowed to stand at room temperature for 2 days. The mixture was poured into water and extracted with ether. The ether extracts were combined, washed successively with water, 5% hydrochloric acid and aqueous sodium hydrogen carbonate, and dried over sodium sulfate. After concentration, the residue (5.18 g) was subjected to gas chromatography (II : III=74 : 26).

Hydration of IV. A solution of IV (0.1 g) in ether (15 ml) and 5% hydrochloric acid (10 ml) were stirred overnight at room temperature. The aqueous layer was extracted with ether and dried over sodium sulfate. Evaporation of the solvent gave hemiacetal II which was identical with the authentic sample.

9-Acetoxycyclododecane-1,5-dione (V). A mixture of II (4.77 g, 22 mmol), acetic anhydride (15 ml) and pyridine (20 ml) was stirred at 100°C for 3 days. The reaction mixture was diluted with water (200 ml) and extracted with ether. The combined ether extracts were washed successively with water, 5% hydrochloric acid, aqueous sodium hydrogen carbonate and water. Drying over sodium sulfate and subsequent concentration gave the crude product (4.14 g) which was subjected to chromatographic separation on a silica gel column with benzene as a solvent. After the recovered hemiacetal (0.52 g, 11%) was eluted, the product (V) (2.03 g, 36%) was obtained as needles (*n*-hexane), mp 81—82°C. IR (CCl_4): 1737, 1711 and 1244 cm^{-1}. NMR (CCl_4): δ 4.6—4.2 (1H, multiplet, AcO-CH), 2.7—1.1 (18H, multiplet+singlet (δ 1.93, OAc)).

Found: C, 66.1; H, 8.9%. Calcd for $C_{14}H_{22}O_4$: C, 66.1; H, 8.7%.

The Reaction of Aldehydes with Dichloroacetate

Akira TAKEDA, Satosi WADA, Masatosi FUJII and Hideo TANAKA

Department of Synthetics Chemistry, School of Engineering, Okayama University, Tusima, Okayama

(Received April 18, 1970)

Base-catalyzed condensation of aldehydes with dichloroacetic ester has been reported by several workers.[1-3] Martynov and Titov[1] described that the condensation of benzaldehyde with methyl dichloroacetate in the presence of sodium methoxide afforded methyl 2-chloro-2,3-epoxy-3-phenylpropionate (**1**, R=C_6H_5, R′=CH_3). McDonald and Schwab,[2] on the contrary, assigned the structure of methyl chlorophenylpyruvate (**2**, R=C_6H_5, R′=CH_3) instead of **1** to the product of the above reaction suggesting that an anionotropic rearrangement of the intermediate **1** to form **2** has occurred. We also were unsuccessful in isolating aromatic homologs of **1** by the same reaction but obtained the corresponding arylpyruvic esters.[3] Meanwhile, the base-catalyzed cyclization of α,α-dichloro-β-hydroxyalkanecarboxylic esters to yield α-chloroglycidic esters (**1**) has been reported by Castro *et al.* recently.[4] Hence the success of the isolation of intermediate glycidates in these reactions seems largely dependent on their stability. In our attempt to prepare several alkyl-substituted chloropyruvates (**2**, R=alkyl) by the title reaction a mixture of **1** and **2** was formed in the varying ratios of the products depending on the conditions, *e.g.* temperature. In this paper we wish to report the Darzens type condensation of aliphatic aldehydes with dichloroacetic ester to afford **1** and the acid-catalyzed transformation of **1** and **2**.

$$\mathrm{R\text{-}CHO + Cl_2CHCO_2R' \longrightarrow R\text{-}\underset{\backslash O /}{CH}\text{-}\underset{|}{C}\text{-}CO_2R' \longrightarrow R\text{-}\underset{Cl}{CH}\text{-}\underset{O}{\overset{||}{C}}\text{-}CO_2R'}$$

pionaldehyde yielded the intermediate α-chloroglycidic esters (**1**) predominantly. It has been occasionally observed that the conversion of **1** to **2** has occurred partly in the reactions of butyraldehyde, and propionaldehyde with dichloroacetate. α-Chloroglycidic esters (**1**) listed in Table 1 were treated with dry hydrogen chloride in ether at 0°C to investigate the facility of the epoxy-carbonyl rearrangement.[5] Methyl 2-chloro-2,3-epoxyvalerate (**1b**) was thus converted readily to methyl 3-chloro-2-oxovalerate (**2**, $R=C_2H_5$, $R'=CH_3$) in 40.0% yield. On the other hand, an attempt to convert methyl 2-chloro-2,3-epoxy-4-methylvalerate (**1e**) in the same manner resulted in the recovery of the unchanged starting material. The treatment of ketones such as acetone, 3-heptanone, and acetophenone with dichloroacetate gave a small amount of product in each case, but we failed to detect any appreciable amount of either epoxyesters or pyruvates. Sodium methoxide was of no use in effecting the epoxy-carbonyl rearrangement of **1b**.

To establish the correlation in chemical properties of **1** and **2**, methyl 2-chloro-2,3-epoxyvalerate (**1b**) was heated under reflux with equimolar amount of thiourea in methanol. It afforded 2-amino-5-ethyl-4-methoxycarbonylthiazole (**3**) in a yield of 72.6%. This compound was prepared alternatively[6] by the reaction of methyl 3-chloro-2-oxovalerate (**2**, $R=C_2H_5$, $R'=CH_3$) with thiourea under the same condition in 71.4% yield.

Experimental[7]

The following experiments are shown as a typical run.

Methyl 2-Chloro-2,3-epoxyvalerate (1b). Dry powdered sodium methoxide (13.5 g, 0.25 mol) was added gradually to a mixture of propionaldehyde (11.6 g, 0.2 mol) and methyl dichloroacetate (28.4 g, 0.2 mol) dissolved in dry ether (100 m*l*) at 0±1°C. The resulting mixture was stirred at room temperature for 3 hr and treated with water. The ethereal extract was washed several times with water and dried ($MgSO_4$). After removal of the solvent it was distilled giving 9.4 g (31.6%) of **1b**: bp 93—95°C/24 mmHg; IR (cm^{-1}, liquid) 1750 (ester C=O); NMR (τ, $CDCl_3$) 6.60 (t, 1H, J=10 Hz, -CH-CCl).

Methyl 2-Chloro-2,3-epoxy-4-methylvalerate (1e). This product was prepared by the condensation of isobutyraldehyde (14.4 g, 0.2 mol) and methyl dichloroacetate (28.4 g, 0.2 mol) in the presence of dry sodium methoxide (13.5 g, 0.25 mol) in dry ether (100 m*l*), yield 24.2 g (67.9%): bp 92—93°C/16 mmHg; IR (cm^{-1}, liquid) 1750 (ester C=O); NMR (τ, $CDCl_3$) 6.99 (d, 1H, J=15 Hz, -CH-CCl).

Ethyl 3-Chloro-2-oxononanoate (2b). To a mixture of heptanal (11.4 g, 0.1 mol) and ethyl dichloroacetate (15.7 g, 0.1 mol) dissolved in anhydrous ether (50 m*l*) dry sodium ethoxide (8.5 g, 0.125 mol) was added at 0±1°C during the course of 1 hr, with stirring. The stirred mixture was allowed to warm up to room temperature and then refluxed for 2 hr. The ethereal layer was washed with water several times cautiously, dired ($MgSO_4$), and concentrated. The residue was distilled to give 10.7 g (45.5%) of **2b**: bp 134—136°C/13 mmHg; IR (cm^{-1}, liquid) 1760 (shoulder, keto C=O) and 1735 (ester C=O); NMR (τ, $CDCl_3$) 5.06 (t, 1H, J=11.2 Hz, -CHCl-C=O).

Methyl 3-Chloro-2-oxovalerate (**2**, $R=C_2H_5$, $R'=CH_3$). Methyl 2-chloro-2,3-epoxyvalerate (5.0 g, 0.03 mol) was treated for 5 hr with the stream of dry hydrogen chloride in dry ether (50 m*l*) at 0°C. The ethereal layer was washed with water, dried ($MgSO_4$), concentrated, and distilled to give 2.0 g (40.0%) of the product: bp 77—79°C/13 mmHg; IR (cm^{-1}, liquid) 1760 (shoulder, keto C=O) and 1735 (ester C=O).

Found: C, 43.39; H, 5.32%. Calcd for $C_6H_9ClO_3$: C, 43.78; H, 5.51%.

2-Amino-5-ethyl-4-methoxycarbonylthiazole (3). *(a) From* **1b** *and Thiourea.* A mixed solution of **1b** (3.3 g, 0.02 mol) and thiourea (1.5 g, 0.02 mol) in methanol (15 m*l*) was refluxed for 18 hr. The mixture was diluted with water and was made alkaline with aqueous ammonia to yield 2.7 g (72.6%) of the crude product: mp 131—133°C (from benzene); IR (cm^{-1}, nujol) 3400, 3200, 3100, 1690, 1610, 1555, and 1225.

Found: C, 45.36; H, 5.49; N, 14.65%. Calcd for $C_7H_{10}N_2O_2S$: C, 45.14; H, 5.41; N, 15.05%.

(b) From Methyl 3-Chloro-2-oxovalerate and Thiourea. A mixture of methyl 3-chloro-2-oxovalerate (2.5 g, 0.015 mol) and thiourea (1.1 g, 0.015 mol) dissolved in methanol (12 m*l*) was refluxed for 19 hr. The reaction mixture treated similarly as in (a) gave 2.0 g (71.4 %) of the same product as above: mp 131—133°C.

Tris(L-prolinato)nickel(II) Complex

Jinsai HIDAKA and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received April 18, 1970)

Only a few solid nickel(II) complexes of tris-(amino-acidato) type have been reported,[1,2] though the formation in solutions has been well established for many kinds of α-amino acids from stability constant measurements,[3,4] and from studies of $d \rightarrow d$ absorption spectra.[5,6]

Optically active prolinate ligand stands in a unique position among optically active α-amino acids because of its stereospecific coordination to a metal ion. In the case of tris(L-prolinato)cabalt-(III), the *mer(N)-Λ*[7] isomer can not exist[8] because of a large steric interaction between the ligands, and only the *fac(N)-Λ* isomer can be easily prepared because this shows no such steric interaction.[9] The other two Λ-isomers have more or less such steric interaction. However, Denning and Piper have succeeded to isolate these isomers in crystals.[8] As it seems that a similar stereo-specific situation also occurs in the case of tris(L-prolinato)nickel(II), we examined the preparation and optical properties of this complex and some of the related tris(amino-acidato)nickel(II) complexes. The following abbreviations will be used for the amino acid ligand:

gly=$CH_2(COO^-)NH_2$, L-ala=$CH_3CH(COO^-)NH_2$,

L-pro=$CH(COO^-)CH_2CH_2CH_2NH$ and

L-hypro=$CH(COO^-)CH_2CH(OH)CH_2NH$.

Experimental

Potassium Tris(amino-acidato)nickel(II). An aqueous solution containing freshly prepared nickle(II) carbonate, amino acid (L-proline, L-hydroxyproline, L-alanine or glycine) and potassium carbonate (the molar ratio was 1 : 5 : 2.5) was evaporated on a water bath at about 80°C until it became almost syrupy. After the crude product had been cooled to room temperature, the resulting blue precipitate was filtered by suction. Five grams of the blue powder obtained was suspended in 100 m*l* of methanol and it was refluxed for a few hours in order to extract the complex. The color of the solution changed from blue to dark blue. The resulting suspension was filtered and the dark blue filtrate was evaporated to dryness in a vacuum desiccator. The complex obtained was recrystallized from hot methanol and dried in a vacuum desiccator and then analyzed for C, H and N (Table 1).

Bis(amino-acidato)diaquonickel(II). Complexes of this type were prepared by a method similar to that of bis(glycinato)diaquonickel(II).[10] In the case of bis(L-prolinato) complex, dehydration of two moles of coordinated water occurred on heating *in vacuo* at 80°C for 16 hr; Found: 10.73%, Calcd of [Ni(L-$C_5H_8NO_2)_2(H_2O)_2$]: 11.15%. The content of C, H and N was determined after the sample had been dehydrated (Table 1).

The CD curves were obtained by a Roussel-Jouan dichrograph in the region of 800—300 mμ, and a Cary 14R*[1] or a Shimadzu QR-50 spectrophotometer with CD attachments in the region of 1150—800 mμ. The absorption measurements were made by a Beckman DU spectrophotometer. The absorption and CD curves are shown in Fig. 1 and the absorption data are summarized in Table 2.

Discussion

It is easily shown from the reported values of stability constants (*e.g.*, $\log \beta_1 = 5.69$, $\log \beta_2 = 10.50$ and $\log \beta_3 = 13.95$ for Ni(II)--glycinate system[4]) that no nickel(II) complexes of tris(amino-acidato) type dissociate the ligand to any extent. Therefore, the absorption curves of the present tris(amino-acidato)nickel(II) complexes agree well with that of the tris(glycinato) complex reported by Jørgensen[5] which was measured in a solution with

excess of glycinate, and the absorption spectrum of tris(L-prolinato) complex in methanol is almost the same as that in aqueous solution (Table 2). Recently Katzin and Gulyas[11] reported the circular dichroism (CD) spectra of solution complexes in the systems of nickel(II) and amino acids, but curiously enough excluded the possibility of existence of tris(amino-acidato) complexes. As shown in Fig. 1, the CD spectrum of the tris(L-prolinato) complex differs markedly from that of the bis(L-prolinato)diaquo complex; the CD bands of the latter complex are less intense than those of the former complex. The absorption and CD spectra of the tris(L-hydroxyprolinato) complex are similar to those of the tris(L-prolinato) complex; the only difference is that, in the former complex, the band II ($^3A_{2g}\rightarrow{}^3T_{1g}$(F) transition in an O_h approximation) has a positive component besides two or three negative components while the latter complex has only two negative components in this region.

As mentioned above, four isomers, whose stabilities differ markedly from each other, are possible for a tris(amino-acidato) complex; but, in the case of the tris(L-prolinato)nickel(II) complex, the CD spectrum presented in Fig. 1 is assumed to be predominantly that of the most stable *fac(N)*-Λ isomer because of lability of the nickel(II) complexes. Treptow[12] and Woldbye[13] have already assumed similar situations in the cases of [Ni(*l*-trans-1,2-diaminocyclohexane)$_3$]$^{2+}$ and [(Ni(*d*-2,3-diaminobutane)]$^{2+}$, respectively. Table 3 compares the CD band signs of five nickel(II) complexes, with those of the corresponding cobalt(III) complexes, whose comfigurations are the same as those of the nickel(II) complexes existing predominantly in solutions. It is evident from this Table that the sign characteristics in band I of the nickel(II) complexes ($^3A_{2g}\rightarrow{}^3T_{2g}$ in an O_h

approximation) are almost the same as those in band I of the cobalt(III) complexes ($^1A_{1g} \rightarrow {}^1T_{1g}$ in an O_h approximation). The behavior of the CD spectra in the region of bands II and III is rather irregular.

In conclusion, the absolute configuration of a nickel(II) complexes is reflected in the signs of its CD components in the region of the longest wavelength $d \rightarrow d$ absorption band as in the case of cobalt(III) complexes.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3002—3005 (1970)

The Synthesis of 5-Aminoisoxazolidines by the 1,3-Dipolar Cycloaddition Reaction of Nitrones with Enamines

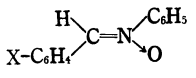
Yujiro NOMURA, Fumio FURUSAKI and Yoshito TAKEUCHI

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro, Tokyo

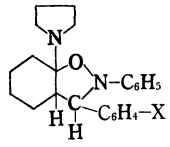
(Received April 24, 1970)

In a preliminary communication[1] it has been shown that 4,5-tetra(or tri)methylene-2,3-diphenyl-5-pyrrolidino(or morpholino)isoxazolidine was formed by the reaction of benzylideneaniline *N*-oxide(diphenylnitrone) (Ia : X=H) with 1-pyrrolidino (or morpholino)-1-cyclohexene (or cyclopentene) in dimethylformamide (DMF) at room temperature. The present note deals with the synthesis of a number of isoxazolidines by the nitrone-enamine cycloaddition in detail.

Isoxazolidines IIb—j with a substituent on 3-phenyl group were synthesized from the corresponding nitrones I and 1-pyrrolidino-1-cyclohexene. The results together with UV spectral data are summarized in Table 1.



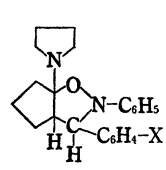
I



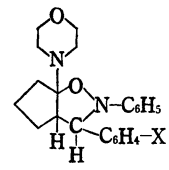
II

The reaction between I and 1-pyrrolidino-1-cyclopentene also gave 2,3-diaryl-4,5-trimethylene-5-pyrrolidinoisoxazolidines IIIa—i. Low yields of III together with the formation of a substantial amount of tar were observed at room temperature. The reaction temperature was controlled to obtain the best results which are tabulated in Table 2.

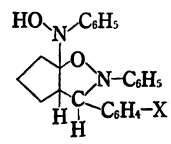
1-Morpholino-1-cyclopentene was rather sluggish against Ia in DMF at room temperature, and cycloadduct, 4,5-trimethylene-2,3-diphenyl-5-morpholinoisoxazolidine (IVa: X=H) was obtained in 4.2% yield after prolonged heating at 40°C. The main product in this reaction, however, was another isoxazolidine, which was identified as 4,5-trimethylene-2,3-diphenyl-5-(*N*-phenylhydroxyamino)isoxazolidine (Va: X=H, yield 12.9%) from elementary analysis, IR and above all, NMR spectra. Tsuge *et al.*[2] also reported that 4,5-tetramethylene-2,3-diphenyl-5-(*N*-phenylhydroxyamino)isoxazolidine was formed by heating Ia and 1-morpholino-(or 1-piperidino-)1-cyclohexene in boiling benzene.



III



IV



V

Experimental

UV and IR spectra were taken on a Hitachi EPS-2 and a Perkin Elmer 125 spectrophotometer, respectively. NMR spectra were determined in dimethyl sulfoxide-d_6 on a JEOL JNM-4H-100 spectrometer at 100 MHz with tetramethylsilane as the internal standard.

All melting points were uncorrected.

2,3-Diaryl-4,5-tetramethylene-5-pyrrolidinoisoxazolidines (IIa—j). A DMF (30 m*l*) solution of diphenylnitrone (Ia) (5.92 g, 0.03 mol) and 1-pyrrolidino-1-cyclohexene (5.45 g, 0.036 mol) was stirred at room temperature for 72 hr under a nitrogen stream. After removal of the solvent *in vacuo*, the residue was recrystallized from ethanol to afford 4,5-tetramethylene-2,3-diphenyl-5-pyrrolidinoisoxazolidine (IIa) (7.84 g, 74.8%). In a similar manner IIb-j were obtained from the corresponding nitrones and 1-pyrrolidino-1-cyclohexene. The results are summarized in Table 1.

2,3-Diaryl-4,5-trimethylene-5-pyrrolidinoisoxazolidines (IIIa—i). A DMF (30 m*l*) solution of Ia (3.94 g, 0.02 mol) and 1-pyrrolidino-1-cyclopentene (3.30 g, 0.024 mol) was prepared with ice-cooling and

*1 The reaction mixture was stirred for 10 hr under ice-cooling and then at room temperature.
*2 The reaction mixture was stirred for 4 hr under ice-cooling and then at room temperature.
*3 The reaction mixture was stirred for 24 hr under ice-cooling and then at 8°C.
*4 Purified by column (silica gel) chromatography (benzene-cyclohexane) followed by recrystallization from ethanol.

stirred for 10 hr. The stirring was continued for an additional 24 hr at room temperature. The oil obtained by evaporating the solvent *in vacuo* was taken up in ethanol and the solution was allowed to stand in a refrigerator overnight. The precipitate was collected and recrystallized from ethanol to give 4,5-trimethylene-2,3-diphenyl-5-pyrrolidinoisoxazolidine (IIIa) (3.20 g, 49.9%).

Similarly IIIb—i were obtained from the corresponding nitrones and 1-pyrrolidino-1-cyclopentene. The data together with the reaction conditions are listed in Table 2.

The Reaction between Diphenylnitrone (Ia) and 1-Morpholino-1-cyclopentene. A DMF (30 m*l*) solution of the nitrone Ia (3.94 g, 0.02 mol) and 1-morpholino-1-cyclopentene (3.68 g, 0.024 mol) was stirred at 40°C for 72 hr under a nitrogen stream, and treated as mentioned above. 4,5-Trimethylene-2,3-diphenyl-5-(*N*-phenylhydroxyamino)isoxazolidine (Va : X=H), sparingly soluble in hot ethanol, was isolated as colorless plates, mp 134.5°C (dec.); yield 1.03 g (12.9%).

Found: C, 77.25; H, 6.75; N, 7.54%. Calcd for $C_{24}H_{24}N_2O_2$: C, 77.39; H, 6.49; N, 7.52%.

UV: $\lambda_{max}^{ethanol}$ 247 mμ (ε 11500). IR (KBr): 3320 cm^{-1} (ν OH). NMR: τ 2.6—3.4 (15H, multiplet, aromatic protons); 5.09 (1H, doublet, $J_{3,4}$=8.0, Hz, 3-H); 6.38 (1H, doublet, $J_{3,4}$=8.0 Hz, 4-H); 6.73 (1H, singlet, OH); 7.9—8.8 (6H, multiplet, trimethylene protons).

From the ethanol-soluble fraction, 4,5-trimethylene-2,3-diphenyl-5-morpholinoisoxazolidine (IVa: X=H) was, after purification by chromatography (alumina-benzene), obtained as colorless needles, mp 125—126°C, yield 0.34 g (4.2%).

Found: C, 74.83; H, 7.51; N, 8.00%. Calcd for $C_{22}H_{26}N_2O_2$: C, 75.40; H, 7.48; N, 7.99%.

UV: $\lambda_{max}^{ethanol}$ 254.5 mμ (ε 8100).

The Reaction between *p*-Methoxybenzylideneaniline *N*-Oxide (Ic: X=*p*-CH_3O) and 1-Morpholino-1-cyclopentene. From 6.82 g (0.03 mol) of the nitrone Ic and 5.52 g (0.036 mol) of 1-morpholino-1-cyclopentene in 50 m*l* of DMF, 3-*p*-methoxyphenyl-4,5-trimethylene-2-phenyl-5-(*N*-phenylhydroxyamino)isoxazolidine (Vc: X=*p*-CH_3O) was obtained, mp 136—138°C (dec.) (from ethanol); yield 2.28 g (40.0%).

Found: C, 73.93; H, 6.70; N, 6.85%. Calcd for $C_{25}H_{26}N_2O_3$: C, 74.60; H, 6.51; N, 6.96%.

UV: $\lambda_{max}^{ethanol}$ 230 (ε 22300) and 246 mμ (ε 15800). NMR: τ 2.65—3.35 (14H, multiplet, aromatic protons); 5.15 (1H, doublet, $J_{3,4}$=8.0 Hz, 3-H); 6.32(3H, singlet, CH_3O); 6.47 (1H, doublet, $J_{3,4}$=8.0 Hz, 4-H); 6.72 (1H, singlet, OH); 7.8—8.2 (6H, multiplet, trimethylene protons).

In this reaction, no 5-morpholinoisoxazolidine IVc (X=*p*-CH_3O) could be isolated.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3005—3007 (1970)

Tungsten-185 and -181 in Atmospheric Precipitations at Niigata in 1968—69

Takeshi SOTOBAYASHI, Toshio SUZUKI and Tomohiko NODA

Department of Chemistry, Faculy of Science, Niigata University, Niigata

(Received April 30, 1970)

For the past five years we have made measurements of the fresh debris resulting from air[1,2] and underground[3–5] nuclear test explosions, and we have had some geochemical discussions of the results obtained. We have recently found unexpected fallout activities with a unique and marked 57.5-keV photon in 16 precipitation samples between December 21, 1968, and May 20, 1969, at Niigata, while a precipitation sample from December 10—20 (86 *l*) as well as earlier ones showed no such radioactivities. All the precipitation samples were γ-spectrometrically analysed by using a 3 in $\times$ 3 in NaI(Tl) scintillation detector equipped with a 800-channel pulse-height analyser. Figure 1 shows a γ-spectrum typical of the 16 precipitation samples in question. The γ-spectra of the samples collected in early January, 1969, had some short-lived fission products, such as ^{131}I, ^{132}Te–^{132}I, and ^{140}Ba–^{140}La, which resulted from the 8th Chinese nuclear test on December 27, 1968, but other samples showed only long-lived fission products, ^{95}Zr–^{95}Nb, ^{137}Cs, and ^{144}Ce–^{144}Pr, originating from other earlier nuclear tests as well as the 8th Chinese test.

In order to identify these unknown radioactivities, we applied a systematic chemical-separation procedure to a precipitation sample (64 *l*) collected on December 25, 1968. The present procedure involves a preliminary 6 M hydrochloric acid leaching in order to prepare a sample solu-

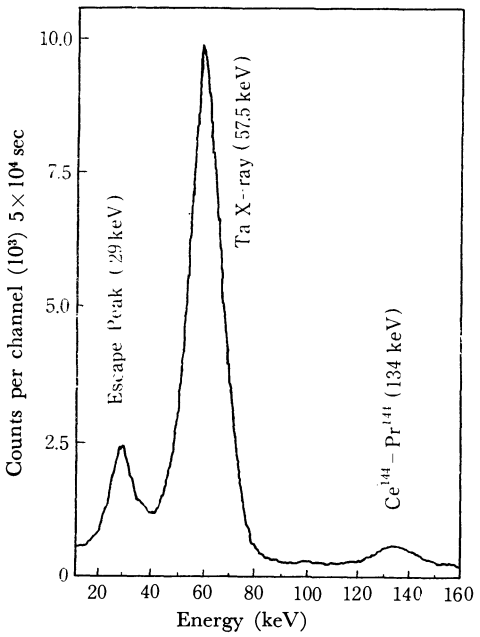

Fig. 1. A γ-ray spectrum of a precipitation sample on December 25, 1968 (64 *l*).

tion for further chemical analysis; it was followed by 3 successive liquid-liquid extractions using mineral acid-xylene solutions of TOA system consisting of 1N sulfuric, 4 N hydrochloric, and 10 N nitric acids, and of 5, 10, and 5% xylene solutions of TOA, respectively. According to the present procedure, one group of elements, V, Mo, Re, Ru, Os, W, and Sb, is expected to remain in the final aqueous phase; the γ-spectrum of the aqueous phase proved to have only a photopeak at 57.5 keV with a half-life of 140 d. As a result, a radionuclide of ^{181}W among the finally-separated 7 elements was expected to correspond to the one emitting such a photon.

For the purpose of reinforcing the present conclusion chemically, the following experiment was made on the residue fraction obtained in the above test. A sample solution for chemical analysis was prepared by the alkali fusion of the residue, followed by hot-water extraction. In this case, sodium tungstate was added to the sample solution as a carrier, and a purified tungsten trioxide was obtained by the usual cinchonine-hydrochloric acid method for tungsten analysis. A nuclide with a 57.5-keV photon was recovered nearly quantitatively, as was found by comparing the photopeak area at 57.5 keV between the residue and the trioxide.

The tungsten trioxide obtained was further submitted to 70-channel β-ray spectrometer equipment, because ^{185}W, a pure β emitter, was expected to be produced by a (n,γ) reaction of ^{184}W with a natural abundance of 30.6%. The trioxide sample proved to have a half-life of 75 d and maximum energy of 0.42 MeV (Fig. 2); these results agreed well with those of ^{185}W listed in the "Table of Isotopes."[6] Thus, it may be concluded that the 57.5-keV photon is a Ta X-ray emitted in the ^{181}W decay process (EC) and that the unknown activities in question originate from radiotungsten isotopes,^{181,185}W.

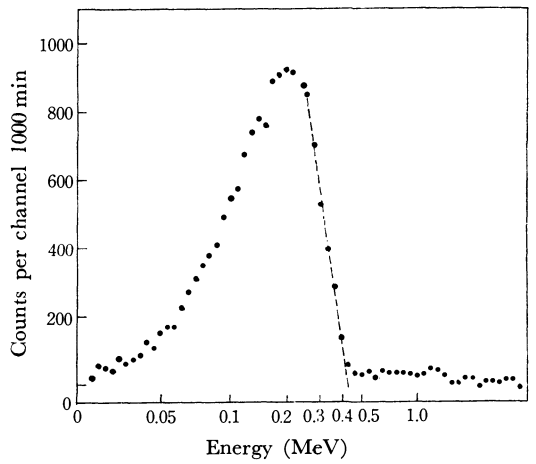

Fig. 2. A β-ray spectrum of a purified tungsten trioxide from a precipitation sample.

The radiotungsten was believed to have occurred in the chemical form of tungsten trioxide on the basis of following chemical behavior of the radiotungsten present in the precipitation samples: (1) Most of the radiotungsten (60—70%) was in the carrier-free state, extracted from precipitation samples into a sodium hydroxide solution (6 M), and when sodium tungstate was added as a carrier the extraction coefficient amounted to more than 95%. (2) No radiotungsten was leached from precipitation samples by distilled water, even in the presence of sodium tungstate as a carrier. (3) Though about 50% of the radiotungsten was leached with hydrochloric acid (6 M) from a precipitation sample in the carrier-free state, the leached radiotungsten was completely precipitated, together with the dehydrated silica produced, when the leachate solution was evaporated to dryness; the solid cake thus obtained was then dissolved in dilute hydrochloric acid.

Table 1 shows the day-to-day variation in the activity concentration of radiotungsten for the precipitation samples from between December 21—30, 1968, together with the averaged values for intervals from 7 to 20 days from December 21, 1968, to May 20, 1969. All the activity values in Table 1 are corrected for decay to the mid-col-

4/21—30	59.3	—	—
2/1—20	64	0.18	2.8

Relative activity; Photopeak area at 57.5 keV.

lection date. As may be seen, the levels of the radiotungsten concentration in precipitations were kept relatively high for the first 10-day period; then they dropped rapidly to about one-twentieth of the initial levels and remained unchanged until mid-February. Thereafter, the levels continued to decrease gradually. From this decrease rate, the half-time of the removal process for airborne radiotungsten from the atmosphere was roughly estimated to be 33 d. Such atmospheric behavior of airborne radiotungsten seems like that observed in 1965 at Niigata for airborne radiostrontium released by a Soviet underground nuclear test on January 15, 1965.[5]

The radiotungsten fallout was reported to be detected in Italy[7] and Finland.[8] The first arrival at Pisa, Italy (10°E, 44°N), of radioactive clouds with radiotungsten was on December 17, 1968, while it was on December 21 at Niigata (139°E, 38°N). Further, taking into consideration the atmospheric conditions (Niigata had several rain or snow storms, with strong convective activities, for a week before and after the day in question (Dec. 21)), it can possibly be assumed that 4 days were required for the radiotungsten to travel the 10000 km from Italy to Japan and that the radiotungsten travelled at a speed of about 100 km/hr from west to east along the 40th Parallel. This assumed speed was found comparable with that, 110—80 km/hr, observed at Niigata in connection with the recent, fresh Chinese nuclear debris.[9,10] This radiotungsten fraction which at first reached Niigata was probably carried in the jet stream in the tropopause levels. On the other hand, the highest activity concentration of radiotungsten was observed at Niigata on December 25, a week after the appearance of the highest one at Pisa (Dec. 18). This finding suggests that the cloud with the highest concentration of radiotungsten came here at a slower speed of 50 km/hr through relatively lower levels—perhaps about 5 km high—in the atmosphere. Though we found no volatilely-behaving, short-lived fission products in the precipitation samples in question, we may finally make the assumption, from the fallout pattern and the global circulation speed observed, that the radiotungsten in question is attributable to a US underground nuclear test at Nevada on December 8, 1968, which was reported to release radiotungsten-rich radioactivities into the atmosphere by a US Public Health Service report.[11]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3008—3010 (1970)

The Solvolytic Isomerization and Rearrangement of *cis*-4-*t*-Butylcyclohexyl *p*-Toluenesulfonate

Kunio OKAMOTO, Seiki SAITÔ and Haruo SHINGU

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received May 6, 1970)

In a previous paper, we have demonstrated that, during the course of the phenolysis, *cis*- and *trans*-4-*t*-butylcyclohexyl *p*-toluenesulfonates (*cis*- and *trans*-4-ROTs) are isomerized into their respective geometrical isomers, and that they also undergo 1,2-rearrangement to give the 3-*t*-butylcyclohexyl toslyates (*cis*- and *trans*-3-ROTs).[1] Accordingly, such a solvolytic isomerization and rearrangement of these tosylates should occur also in common hydroxylic solvents other than phenol. The interest of the previous investigators with respect to this *t*-butylcyclohexyl system has, however, been confined only rate and product studies;[2] no papers concerned with the solvolytic isomerization and rearrangement of this system have appeared except ours.[1]

To test this prediction, we conducted acetolysis and hydrolysis on *cis*-4-ROTs at 75 and 65°C respectively; after the interruption of the solvolysis at 74 and 70% completion, we identified the four isomeric tosylates, *i.e.*, *trans*-4-, *cis*-4-, *trans*-3-, and *cis*-3-ROTs, in the recovered tosylate mixtures. The results are tabulated in Table 1, along with the results in the phenol solvent.[1] In view of the facile occurrence of the solvolytic isomerization and rearrangement in the three solvent-systems shown in Table 1, one should consider these phenomena to be general in the solvolysis of the *t*-butylcyclohexyl system.

In Fig. 1, the percentages of *trans*-4-, *cis*-3-, and *trans*-3-ROTs in the recovered tosylate mixtures in the acetolysis are plotted against the effective concentration of sodium tosylate, which is designated as one-half of the concentration of the sodium tosylate, increased until the moment when the solvolysis is interrupted.

In a fashion similar to that of the explanation previously presented in the case of the phenolysis,[1] the trend of linear increase in the percentage of *trans*-4-ROTs (Fig. 1) can be explained as reflecting the following two reaction courses for the formation of *trans*-4-ROTs: (1) the S_N2-like attack of the tosylate anion on the *cis*-type ion-pair intermediate (*cis*-4-R^+OTs^-)[1]; (2) the internal return of the *trans*-type ion-pair intermediate (*trans*-4-R^+OTs^-),[1] which is "intramolecularly" formed by the rotation of the carbonium ion (R^+) in the *cis*-type ion-pair intermediate. The occurrence of the latter process is proved by the interception of the *trans*-4-ROTs line on the coordinate axis of Fig. 1. The two courses are illustrated in the following reaction scheme:

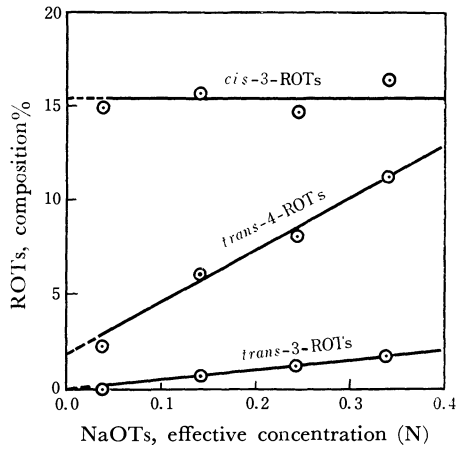

Fig. 1. The composition of the tosylate recovered at 74% completion in the acetolysis conducted in the presence of NaOAc (0.100 N) and of added NaOTs (0.00, 0.10, 0.20, and 0.30 N) at 75.0°C.

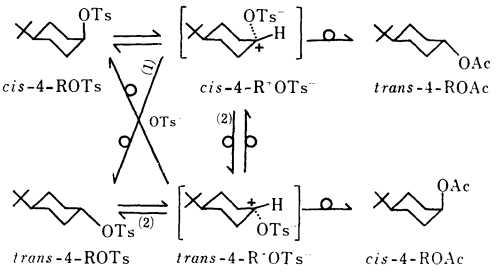

As was explained in the case of the phenolysis,[1] the invariability of the percentage of *cis*-3-ROTs (Fig. 1) indicates that the 1,2-rearrangement is almost intramolecular in nature, namely, that it

may be caused by the 1,2-hydride shift in the *cis*-type ion-pair intermediate (*cis*-4-R^+OTs^-); the linear increase in the percentage of *trans*-3-ROTs with an increase in the concentration of the added tosylate anion (Fig. 1) indicates that *trans*-3-ROTs is formed mostly by the intermolecular S_N2-like attack of the tosylate anion on the *cis*-3-R^+OTs^--type ion-pair intermediate, which can be formed intramolecularly from the *cis*-4-R^+OTs^--type ion-pair intermediate.

In Table 2, the compositions of the reaction products are presented; they show that, of the three solvents, the phenol solvent is the most effective for the formation of the retained substitution product, *i.e.*, *cis*-4-RY; the composition of olefins is not so much affected by the nature of the solvent.

The hypothesis[2a] that the retained product (*cis*-4-RY) comes from the hydrogen bridged ion-pair intermediate may be considered to be unnecessary, since the considerable solvolytic isomerization of *cis*-4-ROTs into *trans*-4-ROTs clearly indicates that, in these solvolyses, the appreciable part of the retained product (*cis*-4-RY) is actually produced by the course of the inversion of *trans*-4-ROTs or the trans-type ion-pair intermediate (*trans*-4-R^+OTs^-); this is illustrated in the above scheme. Furthermore, the interpretation[2b] that the isotope effect caused by the introduction of the deuterium atom into the 2-positions of *cis*-4-ROBs is to be ascribed to the formation of the hydrogen-bridged ion-pair intermediate seems unreasonable, because the isotope effect measured for *cis*-4-ROBs[2b] is seemingly not the effect of a single *cis*-4-ROBs but the composite effect of a brosylate mixture, *viz.*, a mixture of *cis*-4-, *trans*-4-, *cis*-3-, and *trans*-3-ROBs.

Experimental

Recovery of the Unchanged Tosylate from the Solvolysis Mixture and the Analysis of Its Composition. The solvolysis was interrupted after the desired time; then, after the evaporation of the solvent at 0—10°C, the mixture of the solvolysis product and the unchanged tosylate was distilled under 0.1—0.05 mmHg at room temperature to give the product as the distillate and to leave the tosylate as the residual solid; the IR spectra of the recovered tosylate showed that neither acetate nor alcohol was present (<0.5%). The recovered tosylate was cleaved into the parent al-

cohol using sodium-naphthalene in THF according to the method of Closson *et al.*[3] The alcohol was converted to the corresponding acetate by the method of Rickborn and Quartucci;[4] the analysis of the acetate was performed by glc using a 2 m×4 mm column with 30% PEG 6000 on selite 545 (Yanagimoto) at 130°C.

Product Analysis. The mixture of olefins obtained by the solvolysis was analyzed at 70°C by glc using the column described above. The mixture of the alcohol obtained by the hydrolysis was gas-chromatographically analyzed after its conversion to the corresponding acetate (see above).

The Electron-acceptor Strength of 2,5-Diazido-3,6-dichloro-*p*-benzoquinone

Shigeo KOIZUMI and Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received May 7, 1970)

It has been proposed by Hammond that unsaturated, uncharged compounds contained within the formula $C_wN_xO_yF_z$ comprise a class of organic π-electron acceptors.[1] Here fluorine may be considered as representative of other halogens.[2] He also showed that a high degree of unsaturation is a requisite for large electron affinities. From such a point of view, the evaluation of the effect of the azido group N_3 on the properties of a typical electron acceptor seemed to be of considerable interest. The acceptor strength of 2,5-diazido-3,6-dichloro-*p*-benzoquinone, $C_6N_6O_2Cl_2$, in terms of its complexing properties will be compared with that of *p*-chloranil, $C_6O_2Cl_4$.

The diazidoquinone was prepared by the reaction of sodium azide on chloranil dissolved in methanol and was then recrystallized from benzene.[3] The complexes of the diazidoquinone and *p*-chloranil with the following twenty-nine donors were examined in dichloroethane solutions for the charge-transfer absorptions: (1) phenothiazine, (2) *o*-tolidine, (3) phenoxazine, (4) perylene, (5) 1,5-diaminonaphthalene, (6) dimethyl-*p*-toluidine, (7) dichloro-*o*-tolidine, (8) benzidine, (9) dibromo-*o*-tolidine, (10) *N*-methylphenothiazine, (11) dimethylaniline, (12) phenyl-1-naphthylamine, (13) diphenylamine, (14) anthracene, (15) pyrene, (16) phenoxathiin, (17) *o*-anisidine, (18) 1,2-benzanthracene, (19) 4,4′-dimethoxybiphenyl, (20) *m*-toluidine, (21) *o*-toluidine, (22) *p*-dimethoxybenzene, (23) *p*-chloroaniline, (24) 1-naphthol, (25) aniline, (26) thianthrene, (27) 2-naphthol, (28) *m*-chloroaniline, and (29) triphenylene.

It is well known that one may write, as a good approximation:[4]

$$h\nu_{CT} = I_D - E_A - C, \quad (1)$$

where $h\nu_{CT}$ is the energy of charge-transfer absorption, where I_D is the ionization potential of the donor molecule, where E_A is the electron affinity of the acceptor molecule, and where C represents the electrostatic energy in the dative bond structure and some other minor terms. The difference in $h\nu_{CT}$ for the complexes of a given donor with two acceptors, 1 and 2, is, then:

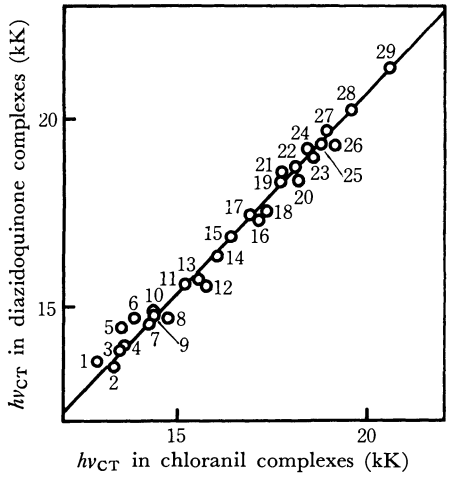

Fig. 1. Plots of wave numbers of maxima of the charge-transfer absorptions in the diazidoquinone complexes against those in the corresponding *p*-chloranil complexes. Point designation corresponds to the numbering of the donors given in the text.

1) P. R. Hammond, *Nature*, **206**, 891 (1965).
2) P. R. Hammond, *J. Chem. Soc., A*, **1968**, 145.
3) K. Fries and P. Ochwat, *Ber.*, **56**, 1291 (1923).
4) J. S. Ham, J. R. Platt and H. M. McConnell, *J. Chem. Phys.*, **21**, 66 (1953).

$$h\nu_{CT_2} = h\nu_{CT_1} + (E_{A_1} - E_{A_2}) + (C_1 - C_2). \quad (2)$$

The term (C_1-C_2) need not be zero, but it may be as large as a few kK if the sizes and shapes of the acceptor molecules are very different.[5] In Fig. 1 the wave numbers of the absorption maxima in the diazidoquinone complexes with each of the above-mentioned donors are plotted against those in the corresponding *p*-chloranil complexes. The line was fitted by the method of least squares. The slope was found to be 1.018, the value is in excellent agreement with that required by Eq. (2). Although the (C_1-C_2) in the complexes of the present quinones is probably small, the intercept, 0.1 kK, is certainly within the limits of uncertainty in this term. Therefore, we may conclude that the electron affinity of 2,5-diazido-3,6-dichloro-*p*-benzoquinone is essentially the same as that of *p*-chloranil, which has been found to be 2.46 eV (19.8 kK) by the magnetron technique.[6] In other words, the azido group appears to be as effective as chlorine in improving the acceptor strength of *p*-benzoquinone.

Some Observations on Ion Exchange Properties of Crystalline Zirconium Phosphate

Yoshitsugu HASEGAWA and Isao TOMITA

Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Bunkyo-ku, Tokyo

(Received May 13, 1970)

Many synthetic inorganic ion exchangers have been studied because of the fact that they are more stable than organic exchangers under certain conditions, *e.g.* high temperature or the presence of ionizing radiation.[1] Most attentions have been given to zirconium phosphates, gelatious and crystalline, and relation between the structure of the crystalline zirconium phosphate and the mechanism of ion exchange also has been discussed. However, the observations differed among investigators.[2-7] Present study was initiated in order to prepare crystalline zirconium phosphate (c-ZP) which has a constant chemical composition and gives reproducible results of ion exchange experiments, and to apply the product to the separation of alkali metals. Distribution coefficients and pH-titration curves of c-ZP for alkali metal ions were measured and it was found that ion exchange on c-ZP for rubidium and cesium was not ideal when the concentration of metal ions was 1×10^{-3} N.

Experimental

Reagents and Preparation of Crystalline Zirconium Phosphate. The preparation method of c-ZP reported by Clearfield and Stynes[3] has been modified in some points. All reagents used were of reagent grade and not purified further. Details of the preparation procedure are as follows: 100 m*l* of 18 v/v% phosphoric acid and 10 v/v% sulfuric acid solution was added slowly to 100 m*l* of well-stirred 10 v/v sulfuric acid solution of zirconyl chloride octahydrate at 70°C. After standing for two days, the gelatinous suspension was centrifuged and the resulting solid was washed several times with 2% phosphoric acid until free from sulfate ions and then with distilled water. It was dried in air at 110°C. The dried product was suspended in 6.7 M phosphoric acid and refluxed for 120 hr. After refluxing, the solution was stood for another 24 hr, then the precipitate was filtered and washed with 2% phosphoric acid and then with distilled water until free from phosphate ions. It was dried in air at 50°C and microcrystalline zirconium phosphate (c-ZP) was obtained. The dried micro-crystals were made into tablets under pressure of 400 kg/cm^2 and sieved to grain size of 100—200 mesh. This final product was used for further experiments. X-Ray powder patterns and optical microscopic observation showed that the solids obtained have a good crystallinity. The powder patterns were obtained with nickel filtered copper X-Ray using a Geigerflex (Rigaku Denki Co., Ltd.).

Distribution Coefficients. Batch distribution coefficients were measured at 25°C by equilibrating

weighed amounts of c-ZP with a known volume of suitable solutions, followed by analysis of the supernatant. The ratio of solution to solid was usually 100 m*l*/g.

For all alkali metal concentrations studied, the exchange reaction attained to equilibrium within 6 hr. Determination of the batch equilibrium coefficients has been made after reaction mixtures were shaken for at least 24 hr.

Analytical methods employed included the use of radioisotopes such as ^{22}Na, ^{86}Rb and ^{137}Cs as tracers. Measurement of radioactivity was taken on a well-type NaI(Tl) scintillation counter. Flame photometry was used for the determination of potassium.

pH-Titration Curves. 0.5 g of c-ZP was equilibrated with 50 m*l* of a solution containing the appropriate metal chloride and metal hydroxide, the total metal concentration being 0.1 N. pH of the sample solution was measured on a HM-5A pH-meter (Toa Electronics Ltd.). Throughout the measurement the sample was maintained at 25°C in a thermostat and bubbled with nitrogen gas to remove CO_2 gas.

Results and Discussion

X-Ray diffraction powder patterns are given in Table 1. The d values agreed with those reported by Clearfield and Stynes.,[3] though details differ from them. If the c-ZP was dried over P_2O_5 for two months it changed crystalline to amorphous. Hence the drying conditions, temperature and desiccants have to be selected carefully. Distribution coefficients K_d (mequiv/g of exchanger÷mequiv/m*l* solution at equilibrium) for alkali metal ions in neutral solutions on the hydrogen form of c-ZP are shown in Table 2. The K_d values for c-ZP are lower than those for gelatinous zirconium phosphate,[2] but the affinity series is identical *i.e.*, $Na^+ < K^+ < Rb^+ < Cs^+$.

When values of Kd for alkali metal ions as a funtion of acidity are plotted in the form log K_d

vs. pH, straight lines were obtained (Fig. 1). If ion exchange takes place ideally according to the reaction,

$$H^+ \cdot X^- + M^+ \rightleftarrows M^+ \cdot X^- + H^+,$$

they must show the slope of unity since only univalent cations are involved in ion exchange. The slopes of lines observed were 0.47 for Rb^+ and Cs^+ when $[M^+]=10^{-3}$ N, and 0.94 for Cs^+ when $[M^+]=10^{-5}$ N, respectively. It is apparent that ion exchange on c-ZP is not ideal when $[M^+]$ is 1×10^{-3} N, though it has been reported that ion exchange on gelatinous zirconium phosphate is ideal.[2] The reason why c-ZP and gelatinous zirconium phosphate exhibit the different behaviour may be substantially the structural change of c-ZP during ion exchange. As sodium ion is not exchanged in acid solution, the pH-Kd plot and the ideality of ion exchange can not be discussed for this ion. The pH-titration curves of c-ZP showed that, for sodium ion, hydrogen atoms in c-ZP matrix behave bifunctionally, whereas, for cesium, they appear to behave monofunctionally. The results agreed with those of Albertsson.[5]

The authors express their sincere thanks to Professor Kozo Nagashima of Tokyo Kyoiku University for his continuous interest and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3013—3015 (1970)

A Synthesis of Streptozotocin Derivatives

Tetsuo SUAMI and Tomoya MACHINAMI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received May 19, 1970)

In connection with a previous paper,[1] biologically active streptozotocin derivatives have been prepared in our laboratory.

Streptozotocin is an antibiotic produced by *streptomyces achromogenes var. 128*, which shows wide antimicrobial and antitumor activities.[2-5] The structure has been established to be *N*-carbamyl-*N'*-methyl-*N'*-nitroso-D-glucosamine.[6-7]

In the present paper, a preparation of methyl glycosides of streptozotocin by a two-step reaction will be described. Methyl β-D-glucosaminide hydrochloride (III) was prepared by the method of Neuberger and Rivers,[8] and then it was treated with methyl isocyanate under the presence of silver carbonate to give methyl *N*-carbamyl-*N'*-methyl-β-D-glucosaminide (IV).

Nitrosation of IV was carried out with sodium nitrite in aqueous acetic acid to give methyl *N*-carbamyl-*N'*-methyl-*N'*-nitroso-β-D-glucosaminide (V) as needle crystals of mp 149°C (dec.) in 70% yield.

Starting from methyl *N*-carbobenzyloxy-α-D-glucosaminide (VII),[8] methyl *N*-carbamyl-*N'*-methyl-*N'*-nitroso-α-D-glucosaminide (X) of mp 133°C was obtained in 33% yield by an analogous reaction process.

A mixture of V and X (XV) was also prepared by an analogous process in 28% yield, beginning with methyl *N*-carbobenzyloxy-D-glucosaminide (XII).

The three compounds: V, X and XV, were fairly active against Ehrlich ascites tumor.

Experimental

A melting point was determined on a Mitamura Riken micro hot stage. A melting point marked with an asterisk was measured in a liquid bath and uncorrected. The infrared spectra were determined in potassium bromide discs. The proton magnetic resonance (pmr) spectra were measured at 60 MHz with a Varian A-60D instrument and the peak position was expressed in τ-values.

Methyl *N*-Carbobenzyloxy-β-D-glucosaminide (II). The compound was prepared by the method of Neuberger and Rivers[8] in a yield of 15.2% from *N*-carbobenzyloxy-D-glycosamine (I).[9] Mp 166—

167.5°C, $[\alpha]_D^{25}$ −22.8° (*c* 1.00, pyridine).

Methyl β-D-Glucosaminide hydrochloride (III). The compound was obtained from II by the method of Neuberger and Rivers[8] in 94.3% yield. Mp 188°C (dec.), $[\alpha]_D^{25}$ −24.0° (*c* 1.00, water). The product showed a single spot at R_f 0.48 in a paper chromatogram in a solvent system of *n*-butanol : pyridine : water (6 : 4 : 3). Lit,[8] mp 190°C, $[\alpha]_D$ −24°.

Methyl *N*-Carbamyl-*N'*-methyl-β-D-glucosaminide (IV). A mixture of III (800 mg) and methyl isocyanate (200 mg) in 65% aqueous acetonitrile (60 m*l*) was heated under reflux for 1 hr in the presence of silver carbonate (580 mg). The reaction mixture was filtered to remove an insoluble matter and the filtrate was evaporated under reduced pressure. The residue was digested in ethanol to give 492 mg of the product, mp 239.5 −241°C. From the mother liquor, 63 mg of the product was obtained. The total yield of the crude product was 64.0%. Recrystallization from ethanol gave an analytically pure sample, mp 239.5—241°C.

Found: C, 43.36; H, 7.48; N, 11.52%. Calcd for $C_9H_{18}N_2O_6$: C, 43.19; H, 7.25; N, 11.20%.

Methyl *N*-Carbamyl-*N'*-methyl-*N'*-nitroso-β-D-glucosaminide (V). To a solution of IV (456 mg) in 23% aqueous acetic acid (13 m*l*), 4.3 m*l* of 0.5 M sodium nitrite solution was added dropwise in 20 min under ice cooling. The reaction solution was settled overnight in a refrigerator, and then was treated with Amberlite IR-120(H^+) to remove a sodium ion. After the resin was removed by filtration, the filtrate was freeze-dried to give a crude product. Recrystallization from ethanol afforded 354 mg (69.7%) of needle crystals: mp 149°C (dec.), mp* 118°C (dec.). $[\alpha]_D^{25}$ −23.7° (*c* 0.5, water). IR: 1720(C=O), 1550(NH), 1490(N-NO) and 875 cm^{-1} (β-anomeric C-H).[10]

Found: C, 39.06; H, 6.23; N, 14.87%. Calcd for $C_9H_{17}N_3O_7$: C, 38.71; H, 6.09; N, 15.05%.

Methyl 3,4,6-Tri-*O*-acetyl-*N*-carbamyl-*N'*-methyl-*N'*-nitroso-β-D-glucosaminide (VI). A 140 mg sample of V was acetylated with 2 m*l* of acetic anhydride in 3 m*l* of pyridine at room temperature overnight. The mixture was evaporated under reduced pressure and the residue was recrystallized from aqueous ethanol to give 152 mg (74.9%) of pale yellow crystals, mp 96—99°C. IR: 1745(OAc), 1710(C=O), 1540(NH), 1480(N-NO) and 900 cm^{-1} (β-anomeric C-H).[10]

Pmr (in $CDCl_3$): τ 5.16 (one proton doublet, $J_{1,2}$=8 Hz, H_1); 6.38 ($O-CH_3$)[11]; 6.75 ($N-CH_3$); 7.79, 7.85, 7.89 (singlets, three protons, three protons and three protons, OAc).

Found: C, 44.98; H, 5.86; N, 10.08%. Calcd for $C_{15}H_{23}N_3O_{10}$: C, 44.44; H, 5.72; N, 10.37%.

Methyl *N*-Carbobenzyloxy-α-D-glucosaminide (VII). The compound was prepared by the method of Neuberger and Rivers[8] in a yield of 79.0% from I. Mp 156—158°C, $[\alpha]_D^{25}$ +92.6° (c 2.4, pyridine). Lit,[8] mp 154—155°C, $[\alpha]_D$ +80° (pyridine).

Methyl *N*-Carbamyl-*N'*-methyl-α-D-glucosaminide (IX). A solution of VII (1.0 g) in ethanol (15 m*l*) was hydrogenated with 0.3 m*l* of 12 N hydrochloric acid under the presence of 0.2 g of palladium black at 3.4 kg/cm^2 of hydrogen stream for 21 hr. After the catalyst was removed by filtration, the filtrate was evaporated to give a crude product (735 mg) of methyl α-D-glucosaminide hydrochloride (VIII), which showed a single spot on a paper chromatogram at R_f 0.54 in a solvent system of *n*-butanol : pyridine : water (6 : 4 : 3). R_f of D-glucosamine hydrochloride was 0.41 in the same solvent system. The product was used in a successive synthesis without a further purification.

A mixture of VIII (735 mg), methyl isocyanate (200 mg) and 65% aqueous acetonitrile (45 m*l*) was heated under reflux for 45 min in the presence of silver carbonate (532 mg). After an insoluble matter was removed by filtration, the filtrate was evaporated under reduced pressure. The residue was recrystallized from ethanol to give 494 mg (64.7%) of the product, mp 189—191°C. Recrystallization from *n*-propanol gave crystals melting at 194.5—196°C. $[\alpha]_D^{23}$ +97.5° (*c* 1.0, water).

Found: C, 43.18; H, 7.39; N, 10.91%. Calcd for $C_9H_{18}N_2O_6$: C, 43.19; H, 7.25; N, 11.20%.

Methyl *N*-Carbamyl-*N'*-methyl-*N'*-nitroso-α-D-glucosaminide (X). A 400 mg portion of IX was treated with nitrous acid as described in the preparation of V to give 214 mg (50.5%) of crystals. Mp 129—133°C, mp* 89°C (dec.). $[\alpha]_D^{25}$ +107° (*c* 0.5, water). IR: 1705(C=O), 1540(NH), 1485(N-NO) and 850 cm^{-1} (α-anomeric C-H).[10]

Found: C, 38.81; H, 6.31; N, 14.78%. Calcd for $C_9H_{17}N_3O_7$: C, 38.71; H, 6.09; N, 15.05%.

Methyl 3,4,6-Tri-*O*-acetyl-*N*-carbamyl-*N'*-methyl-

***N'*-nitroso-α-D-glucosaminide (XI).** A 102 mg portion of X was acetylated analogously as described in the preparation of VI and the reaction mixture was poured into ice and water to give 116 mg (78.3%) of crystals, mp 114—115°C. Recrystallization from ethanol afforded pale yellow crystals melting at 115.5°C. IR: 1750(OAc), 1715(C=O), 1530(NH), 1480(N–NO) and 870 cm^{-1} (α-anomeric C–H).[10] PMR (in $CDCl_3$): τ 5.01 (one proton doublet, $J_{1,2}$=3.7 Hz, H_1); 6.45 (O–CH_3); 6.72 (N–CH_3); 7.77, 7.85, 7.91 (singlets, three protons, three protons and three protons, OAc).

Found: C, 45.04; H, 5.87; N, 10.23%. Calcd for $C_{15}H_{23}N_3O_{10}$: C, 44.44; H, 5.72; N, 10.37%.

Methyl *N*-Carbobenzyloxy-D-glucosaminide (XII). A mixture of I (1.78 g) in methanol (150 m*l*) and dry Amberlite IR-120(H^+) (18 m*l*) was heated under reflux for 2.5 hr. After the resin was removed by filtration, the filtrate was evaporated under reduced pressure. The residue was crystallized from ethanol to give 1.11 g (60.0%) of the product, mp 149—153°C, $[\alpha]_D^{25}$ +33.0° (*c* 2.5, pyridine). The compound consisted of 48% of α-anomer and 52% of β-anomer.

Methyl D-Glucosaminide hydrochloride (XIII). A 400 mg sample of XII was treated analogously as described above to give 162 mg (57.8%) of the product, mp 147—157°C (dec.). The product showed two spots at R_f 0.53 and 0.48 in a paper chromatogram in a solvent system of *n*-butanol : pyridine : water (6 : 4 : 3).

Methyl *N*-Carbamyl-*N'*-methyl-D-glucosaminide (XIV). A 400 mg portion of XIII was treated with methyl isocyanate as described above to give 240 mg (55.3%) of the product, mp 233—235°C. Recrystallization from aqueous ethanol afforded an analytically pure sample, mp 234.5—236°C.

Found: C, 43.39; H, 7.23; N, 11.30%. Calcd for $C_9H_{18}N_2O_6$: C, 43.19; H, 7.25; N, 11.20%.

Methyl *N*-Carbamyl-*N'*-methyl-*N'*-nitroso-D-glucosaminide (XV). A 180 mg sample of XIV was treated with nitrous acid as described above to give 172 mg (88.9%) of the crude product. Recrystallization from ethanol afforded needle crystals, mp 117—121°C (dec.), mp* 59°C (dec.). $[\alpha]_D^{23}$ −19.6° (*c* 0.5, water). The product consisted of 97% of β-anomer, since the β-anomer crystallized preferentially.

Found: C, 39.26; H, 6.26; N, 14.74%. Calcd for $C_9H_{17}N_3O_7$: C, 38.71; H, 6.09; N, 15.05%.

Antitumor activity. A detail of the antitumor activities of V, X and XV against Ehrlich mouse ascites tumor will be reported elsewhere.

The authors are grateful to Professor Sumio Umezawa for his helpful advice and Mr. Saburo Nakada for his elementary analyses.

SHORT COMMUNICATIONS

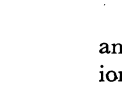
An Attempt to Estimate the Relative Stability of Tri(hetero)substituted Carbonium Ions*

Takeshi NAKAI, Kazuhisa HIRATANI and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 12, 1970)

In connection with our study on the structures and ambident reactivities of tri(hetero)carbonium ions containing α-alkylthio groups,[1,2] we attempted to estimate the relative stability of tri(hetero)carbonium ions from their electronic spectra and simple HMO calculations. A series of tri(hetero)-carbonium ions shown below were prepared as perchlorates and iodides.[3]



I, X, Y, Z=SMe; II, X, Y=SMe, Z=NMe_2 III, X, Y=NMe_2, Z=SMe; IV, X, Y, Z=NMe_2

In the electronic spectra we observed a well-defined trend, *viz.*, a strong shift of the absorption maxima to shorter wavelengths was observed with the progressive replacement of SMe in (I) by NMe_2.[4] This trend led us to postulate that *there is a linear correlation between the relative stability of the carbonium ion and the transition energy* ($1/\lambda_{max}$). In order to prove this hypothesis we made some attempts described below.

Firstly, it is expected that the stabilizing effect of α-heterosubstituents on carbonium ions concerned might be estimated *relatively* in terms of the Brown-Okamoto's substituent constants (σ_p^+), on the assumption that the additivity rule holds for the series. The observed frequencies of absorption maxima gave a definitely linear correlation with $\sum\sigma_p^+$[5] (Fig. 1), providing a positive criterion for the above hypothesis.

Another criterion for the hypothesis was obtained

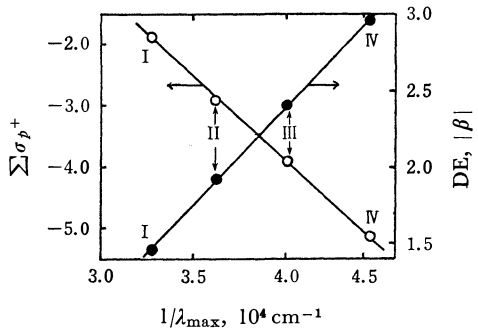


Fig 1. Plots of $1/\lambda_{max}$ (solvent, water) *vs.* $\sum\sigma_p^+$ (○) and DE (●).

from simple HMO calculations. In our calculations,[6] the values assumed for the Coulomb integral and resonance integral are as follows: $\alpha_S=\alpha+\beta$, $\alpha_N=\alpha+1.5\beta$; $\beta_{C-S}=0.6\beta$, $\beta_{C-N}=1.2\beta$[7] Using these parameters, we calculated the energies of the molecular orbitals, the transition energies (ΔE) and the delocalization energies (DE) in the usual manner. A linear correlation between ΔE and $1/\lambda_{max}$ was obtained. Furthermore, a definitely linear correlation of DE with $1/\lambda_{max}$ was obtained (Fig. 1). This correlation provides the second positive criterion.

We suggested that the rates of reactions of various bis(alkylthio)-dialkylaminocarbonium ions with hydroxide ion depend upon the relative stability of the carbonium ions.[2] The logarithms of the rate constants gave a nearly linear correlation with $1/\lambda_{max}$ for the open-chain and cyclic[8] carbonium ions. This may provide a third positive criterion. The relationship between the relative stability and the reactivity of tri(hetero)-carbonium ions will be discussed in full elsewhere.

A Study of the Paramagnetic Center in Vanadium Pentoxide

Kozo HIROTA, Keiji KUWATA and Yoshiya KERA

Faculty of Science, Osaka University, Toyonaka, Osaka

(Received March 23, 1970)

ESR studies of the V(IV)ion in vanadium pentoxide have been extensively carried out. The use of a single crystal gives more detailed information regarding the structure of the paramagnetic centers in V_2O_5.[1] In the present paper the esr spectrum of a new center in V_2O_5 is shown, and the mechanism of its formation is discussed.

The single crystal was prepared by the zone-melting method from pure V_2O_5 powder. The *g*-factor and the hyperfine coupling constant were determined at 77°K with DPPH ($g=2.0035$) and the Mn(II) ion in magnesium oxide, respectively.

When the static magnetic field was applied in parallel with the *b*-axis, clear hfs of 27 lines appeared, as is shown in Fig. 1; as the direction of

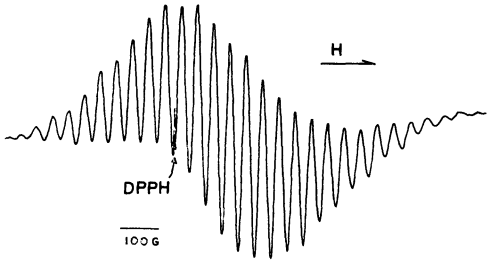

Fig. 1. ESR spectrum of a V_2O_5 single crystal with the static field applied in parallel with the crystallographic *b*-axis.

the field deviated from the *b*-axis on both the *ba*- and *bc*-planes, the hf splitting quickly decreased. On the basis of this finding, one of the principal axes for the hf interaction was estimated to be nearly the *b*-axis, and the maximal principal value was estimated to be 43.3 gauss.

The number of lines in hfs and the polynominal distribution of their intensities indicate the existence of a magnetic center in which four ^{51}V nuclei ($I=7/2$) interact equally with an unpaired electron.

The magnetic center including four ^{51}V atoms has been briefly discussed by Ioffe and Patrina,[1c] but neither detailed experimental results nor discussion was given regarding its structure.

The principal components of the *g*-tensor for this center were $g_{xx}=1.974_9$, $g_{yy}=1.988_7$, and $g_{zz}=1.931_3$, and the *x*, *y*, and *z*-axes nearly accorded with the *a*, *c*, and *b*-axes of the crystal with an orthorhombic symmetry, respectively. The relationship among the components of the *g*-tensor indicates that the V(IV) ion is in the field of fourfold symmetry.[2]

The fourfold symmetry can be obtained when an oxygen ion on the *b*-axis is lost. A pair of V ions formed by the elimination of such an oxygen ion had been proposed by Gillis *et al.*[1] as the paramagnetic center in V_2O_5.

On the basis of the present study, two neighbouring pairs of V ions were assumed to constitute a paramagnetic center containing four V atoms. The removal of the I and II oxygen ions in Fig. 2 produces such pairs (1-2 and 3-4 in Fig. 2). Similarly, 1-2 and 1′-2′ pairs, or 3-4

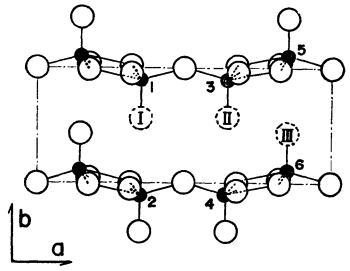

Fig. 2. Arrangements of paramagnetic center in the V_2O_5 crystal, whose structure was taken from Ref. 3. (large circles denote oxygen ions; small circles denote vanadium ions. For example, V atoms of 1′ and 2′ are placed just behind the 1 and 2 V atoms, respectively.)

and 5-6 pairs, can equally form the center. An unpaired electron is assumed to interact equally with the four V ions through fast exchange between these pairs. The center of this kind, as in Eq. (1), can be formed either by the direct elimination of two neibouring oxygen ions, or by the migration of the oxygen vacancy through the crystal lattice to form the two pairs of V ions:

$$2(V^{5+}-O^{2-}-V^{5+}) \rightarrow \begin{matrix} V^{5+}\ldots V^{5+} \\ \vdots \quad\quad \vdots \\ V^{5+}\ldots V^{4+} \end{matrix} + 2O + 3e^- \quad (1)$$

It is worthy of mention that the formation of such a defect could be predicted from the study of catalytic activity of this oxide.[4]

Syntheses of {Sulfato, *N,N'*-(2-pyridylalkyl)-oxamidatocopper(II)} copper(II)*[1]

Heijiro OJIMA and Kiyoko YAMADA

Department of Chemistry Aichi Kyoiku University, Kariya, Aichi

(Received May 13, 1970)

The present paper reports that the *N,N'*-bis-(2-pyridylalkyl)oxamidatocopper(II) acts as a bidentate ligand coordinating to cupric sulfate to form binuclear complexes with a subnormal magnetic moment: [Cu(PMoxd)-$CuSO_4$] and [Cu(PEoxd)-$CuSO_4$] (*cf.* Fig. 1). The $PMoxdH_2$ ligand was obtained in a 90% yield by the reaction 2 mol of 2-(aminomethyl)pyridine with 1 mol of diethyl oxalate at 150°C for 1 hr. Recrystallized from ethanol, mp 155—156°C. The $PEoxdH_2$ ligand was obtained similarly in a 95% yield using 2-(2-aminoethyl)pyridine and diethyl oxalate. Recrystallized from ethanol, mp 175—176°C. [Cu(PMoxd)-$Cu(OH_2)_2$]$SO_4 \cdot 5H_2O$ (A) was obtained as blue crystals by mixing 1 mol of the ligand and 2 mol of cupric sulfate in an aqueous solution at pH 5—6. Recrystallized from water. This complex was converted into [Cu(PMoxd)-$CuSO_4$] (B) concurrently with the elimination of 7 mol of water, by heating it at more than 80°C under vacuum conditions (*cf.* the change in the IR spectra, Fig. 2). The [Cu(PEoxd)-$CuSO_4$]$\cdot 2.5H_2O$ (C) was isolated as greenish-blue crystals from an aqueous mixture of 1 mol of the $PEoxdH_2$ ligand and 2 mol of cupric sulfate, in which mixture the pH value had been adjusted to 6. Recrystallized from water. It can be understood, considering the analytical data, that the conspicuous spectral change in the SO_4^{2-} region may be due to the change from ionic sulfate to chelated sulfate. The magnetic moment values of the complexes here isolated obviously reflect Cu-Cu interaction. It seems that the Cu-Cu interaction must take place through the π-pathway set up by using $3d_{yz}$(or $3d_{xz}$) orbitals of the cupric ions and $2p_\pi$ orbitals of the bridging oxamide group (*cf.* Fig. 3). When each sulfato complex was dissolved into an aqueous solution, the value of molar conductance fell into the range of 129—133 $\mho/cm^2$. This value reflects that a part of each sulfato complex changes into a divalent complex cation, [Cu(PMoxd)-$Cu(OH_2)_2$]$^{2+}$ or [Cu(PEoxd)-$Cu(OH_2)_2$]$^{2+}$.

Copper(II) Complexes of 3-Formyl-5-methylsalicylaldehyde and Its Schiff Bases with Alkyl Amines

Hisashi OKAWA

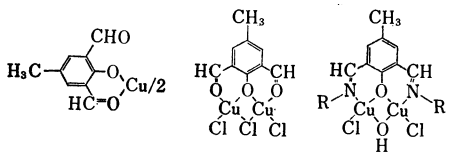
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received May 21, 1970)

Two new copper(II) complexes of 3-formyl-5-methylsalicylaldehyde,[1] bis(3-formyl-5-methylsalicylaldehydato)copper(II) (**1**) and dichloro-μ-chloro-μ-(2,6-diformyl-4-methylphenolato)dicopper-(II) (**2**) (Fig. 1), have been prepared by using copper(II) acetate monohydrate and copper(II) chloride dihydrate respectively as metal sources. Both were easily obtained by adding a solution of the copper(II) salt in ethanol to a solution of 3-formyl-5-methylsalicylaldehyde in ethanol.

In addition to these complexes, new series of oxygen-bridged binuclear copper(II) complexes (**3** type) have been synthesized by using the aldehyde, copper(II) chloride dihydrate, and alkyl amines (R-NH_2), in which R represents methyl, ethyl, isopropyl, *t*-butyl, or chclohexyl groups. The method of synthesizing the complexes was as follows. To a warm solution of the aldehyde and copper(II) chloride dihydrate in ethanol we added a solution of an amine in ethanol to give green or brown needles; these needles were collected and washed with ethanol. The results of the molecular-weight determinations of these complexes support the formula given for the complex **3** in Fig. 1. The analytical data of the complexes obtained are given in Table 1.

In the complexes **2** and **3**, the organic moiety acts as a quadridentate chelating agent with the bridging phenolic oxygen, and the copper atoms are held sufficiently close to each other to cause



1 **2** **3**

Fig. 1.

antiferromagnetic interactions; the magnetic moments determined for the complexes **2** and **3** at room temperature were 1.58 and 0.80—1.29 B. M. respectively. On the other hand, the complex **1** has a normal magnetic moment of 1.81 B. M.

The reflectance spectra of the complexes **2** and **3** each have one d-d transition band, located at 11,100 cm^{-1} for the complex **2** and at 12,000—14,400 cm^{-1} for the complex **3**; these energies are lower than those expected for mononuclear copper(II) complexes of similar ligands, supporting a binuclear structure and in agreement with the findings of Harris *et al.*[2] It is noteworthy that the complexes also have a binuclear structure in a solution, judging from the spectra in a solution, which are very similar to those measured by the diffuse-reflection method, although the complex **2** is decomposed in the presence of water to the complex **1**.

The details of this work will be reported shortly.

Effects of Wavelength and Matrix on Four-Center Type Photopolymerization of 2,5-Distyrylpyrazine and Its Photodepolymerization

Masaki HASEGAWA, Yasuzo SUZUKI and Takashi TAMAKI

Research Institute for Polymers and Textiles, Sawatari, Kanagawa-ku, Yokohama, Japan

(Received May 18, 1970)

In previous papers,[1-5] preparative, kinetical and crystallographic studies on four-center type photopolymerization in the solid state have been reported for a series of several diolefine compounds.

As a result, a number of new types of highly crystalline linear polymers with cyclobutane in the main chain has been prepared mostly in quantitative yield.

Recently the polymerization was found to be lattice-controlled, that is, the chain growth is strictly governed by three axes of the monomer crystal and proceeds through a direct rearrangement from monomer crystal to polymer crystal.

For example, crystals of 2,5-distyrylpyrazine (DSP) and poly-2,5-distyrylpyrazine (poly-DSP), belong to the same space group (Pbca).[6]

We have investigated the effects of wavelength and matrix on four-center type photopolymerization of 2,5-distryrylpyrazine and its photodepolymerization.

First, DSP oligomer (average molecular weight $\simeq$900, mp 285—290°C) was obtained from DSP crystals in water-methanol (4 : 6) nearly quantitatively by irradiation of the light with a wavelength longer than 400 mμ for about one hour at room temperature while DSP crystals were converted into a high molecular weight of the polymer (mol wt $>$100000) in a quantitative yield by xenon or high pressure mercury lamp under a similar condition.

DSP oligomer crystals (*as*-polymerized) were converted quantitatively into a high polymer by the irradiation of monochromatic light of 340 mμ from a Shimadzu Bausch & Lomb monochrometer.

DSP crystals show an absorption occurring at 440 mμ with a maximum peak at 380 mμ while DSP oligomer has no absorption of a wavelength longer than 380 mμ. It is presumed that a longer wavelength ($>$400 mμ) can excite only the monomer, and a shorter wavelength ($<$380 mμ) is required for further growth of terminal groups in the oligomer.

On the other hand, DSP oligomer crystals (recrystallized) which differ from the crystals (*as*-polymerized) from X-ray patterns, does not polymerize by the same light (340 mμ).

Moreover, a solution of the DSP oligomer in chloroform promptly returns to the monomer by the same light (340 mμ).

It is noteworthy that the DSP oligomer (*as*-polymerized) consists of thermally irreversible crystals as well as the resulting poly-DSP crystals[7]: DSP oligomer crystal (*as*-polymerized) can never be reproduced after the oligomer becomes amorphous and the oligomer with a different crystal form is reprecipitated from a solution of above oligomer crystal (*as*-polymerized).

DSP oligomer does not grow further into high polymer by the irradiation of 340 mμ without an effective "topotactic assistance", as is the case in the crystalline oligomer (as-polymerized).

It is interesting that chemically the same substance behaves in three different ways according to physical states.

This is a clear-cut example of matrix effect originating in the topochemical procedure.

Amorphous DSP oligomer results from the solution of DSP in chloroform by the prolonged irradiation of light with a wavelength longer than 380 mμ in nitrogen atmosphere. As expected, amorphous oligomer does not polymerize in the solid state and depolymerizes in the solution in the same way as the oligomers from DSP crystals.

A schematical diagram of photochemical interrelationship in DSP, DSP oligomers and poly-DSP is shown below:

Bitter Principles of *Picrasma ailanthoides* Planchon. Nigakihemiacetals A and B, and Nigakilactones G and H.

Tatsushi MURAE, Tôru IKEDA, Takahiko TSUYUKI, Tadaaki NISHIHAMA and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo

(Received June 15, 1970)

In addition to the previously reported nigakilactones A, B, C, D,[1] E and F,[2] four bitter principles (nigakihemiacetals A and B, and nigakilactones G and H) have been isolated from *Picrasma ailanthoides* Planchon (= *P. quassioides* Bennett). Recently, isolation of picrasin B[3] and A[4] from the same plant was recorded by Hikino *et al.*

Nigakihemiacetal A, mp 262—263°C, $C_{22}H_{34}O_7$, M^+ 410, $[\alpha]_D$+20° (*c* 0.22, in EtOH), λ_{max}^{MeOH} 272 nm (ε 5800), IR (nujol): 3560, 3470, 3360, 1668, 1634 cm^{-1}, PMR (Table 1), is a new bitter substance which has a hemiacetal instead of a lactone grouping. On oxidation with Ag_2O, this hemiacetal gave nigakilactone F[2] (I, R_1=OH, R_2=H, R_3=H, R_4=O). Thus, structure I (R_1=OH, R_2=H, R_3=H, R_4=OH, H) is given for nigakihemiacetal A.

Spectral data of nigakihemiacetal B, mp 230.5—231°C, $C_{22}H_{30}O_6$, M^+ 390, $[\alpha]_D$+20° (*c* 0.21, in EtOH), λ_{max}^{MeOH} 256 nm (ε 11400), IR (nujol): 3400, 1690, 1674, 1640, 1621 cm^{-1}, suggest that this substance would be neoquassin. Indeed, nigakihemiacetal B was shown to be identical with neoquassin[5] (II, R=OH, H) by the formation of quassin[5] (II, R=O) on oxidation of this hemiacetal with Ag_2O.

Nigakilactone H, mp 274.5—275.5°C, $C_{22}H_{32}O_8$, M^+ 424, $[\alpha]_D$+67° (*c* 0.14, in EtOH), λ_{max}^{MeOH} 271 nm (ε 4260), IR (nujol): 3450, 1725, 1675, 1640 cm^{-1}, is a new bitter principle containing one hydroxyl group more than nigakilactone F[2]. In the PMR spectrum, C_9-H (1H, δ 2.05) resonates as doublet (J=11 Hz), C_{11}-H (1H, δ 3.96) as quartet (J=11; 9 Hz), C_{12}-H (1H, δ 3.02) as doublet (J=9 Hz), C_3-H (1H, δ 5.51) as doublet (J=2.5 Hz) and C_7-H (1H, δ 4.56) as multiplet. These observations are best interpreted on the basis of the skeletal structure of known nigakilactone F[2] (I, R_1=OH, R_2=H, R_3=H, R_4=O). Nigakilactone H, when treated with $Na_2Cr_2O_7$, afforded a ketone, mp 161—163°C, $C_{22}H_{30}O_8$, M^+ 422, λ_{max}^{MeOH} 264 nm (ε 5920), IR (nujol): 3450, 1720, 1690, 1625 cm^{-1}. The PMR spectrum shows signals due to C_9-H (1H, δ 2.61, singlet), C_{12}-H (1H, δ 3.38, singlet), C_3-H (1H, δ 5.42, doublet, J=2.5 Hz) and C_7-H (1H, δ 4.53, multiplet); no signal due to C_{11}-H is observed. In the PMR spectra of nigakilactone H and its ketone, a signal due to two protons on C_{15} appears as *singlet* at δ 2.67 and at δ 2.89, respectively. This shows that the C_{14}-carbon is tertiary, and leads to the location of an extra hydroxyl group on C_{14} for nigakilactone H. Thus, nigakilactone H and its ketone should be represented by I (R_1=OH, R_2=H, R_3=OH, R_4=O, for nigakilactone H; R_1, R_2=O, R_3=OH, R_4=O, for its ketone) except for absolute configuration.

The Cation-radical Salts of *p*-Phenylenediamine. A Modified Method of Preparation and the Electrical Resistivity of the Salts

Kei-ichiro HATANO, Yuzaburo FUJITA and Takao KWAN

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 29, 1970)

A method of oxidation using Fe(III) salts was developed for preparing various types of cation radical salts of *p*-phenylenediamine (*p*PD) and its analogue in place of the familiar Br_2-oxidation method.[1,2] As an example, we will briefly describe below the method of preparing $pPD^+Cl^- \cdot H_2O$ and some physico-chemical properties of the salt.

In a cooled methanol solution of *p*PD, a methanol solution containing an equivalent amount of $FeCl_3 \cdot 6H_2O$ was added in small portions, while the reacting system was flushed with nitrogen (or helium) during the mixing. The precipitate formed in the deep green solution was collected, washed repeatedly with a methanol-ether mixture, dried, and stored in an evacuated desiccator. The product thus obtained was a lustrous brownish green powder; it was stable in air, at least at room temperature. Iron was not detected in the product by a colorimetric test. The results of the elemental analysis were as follows:

Found: C, 44.42; H, 6.25; N, 17.14; Cl, 22.03%. Calcd for $C_6H_{10}N_2OCl$: C, 44.59; H, 6.24; N, 17.34; Cl, 21.82%.

Among the observed IR absorption bands of this salt in a KBr disk, the one at 1395 cm^{-1} was characteristic and was common to all the pPD^+ salts prepared. The absorption band can probably be attributed to the C–N stretching in the *p*PD cation radical.

The aqueous solution of this salt ($\sim 10^{-3}$ M) was initially green, but it turned a dark violet within several minutes. The green solution exhibited an esr signal exactly identical to that reported for the cation radical of *p*PD,[3] although the signal soon disappeared as the color changed. The *p*PD cation radical was fairly stable in an ethanolic solution (yellow, $\sim 10^{-4}$ M) and gave rise to an esr signal significantly different in linewidth from that in an aqueous solution, suggesting that the ion-pair was formed between pPD^+ and Cl^-. The UV and visible absorption spectra of this salt in the ethanolic solution almost coincided with those reported by Iida and Matsunaga.[4] Judging from this information, it seems almost certain that the salt of the *p*PD cation radical was formed.

Electrical resistivity measurements were made with a disk of the salt (prepared under 500 kg/cm^2) in an atmosphere of nitrogen. Accordingly, the specific resistivity was $3 \times 10^8\ \Omega$ cm at 20°C, with a negative temperature coefficient of *ca.* 0.7 eV. Other salts, with different cations and counter anions, prepared by this method are listed in Table 1, together with their approximate electrical resistivity data.

TABLE 1. CATION-RADICAL SALTS AND THEIR PROPERTIES

Salts*1	Color of powder	Electrical resistivity at 20°C (Ω cm)
$pPD^+Br^- \cdot H_2O$*2	lustrous brown	10^9
$pPD^+NO_3^- \cdot H_2O$	black	10^6
$pPD^+p\text{-}CH_3\text{-}\phi\text{-}SO_3^- \cdot \frac{1}{2}H_2O$	violet	10^{13}
$Benzidine^+Cl^- \cdot \frac{1}{4}H_2O$	grey	10^{10}
$Benzidine^+Br^- \cdot \frac{1}{4}H_2O$	deep blue	10^6
$(pPD^+)_2[Fe_2(SO_4)_3]^{2-}$	greenish grey	10^{10}
$pPD^+[K_3Fe(CN)_6]^- \cdot nH_2O$*3	deep blue	10^7
pPD^+p-Chloranil$^-$	deep purple	10^7

Electron Spin Resonance and Cell Division in Silkworm Egg

Shizuo FUJIWARA, Hiroshi TADANO*1 and Makoto NAKAJIMA*2

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyoku, Tokyo

(Received June 29, 1970)

Several biological systems have so far been investigated by electron spin resonance (ESR).[1-3] The sources of ESR signals were generally identified and the results of investigation by ESR have presented direct information on the kinetic and chemical behaviors of the sample. ESR can also be used for looking at the free radicals of unknown identity, as this technique can be used as a means of seeing inside the living material without causing any distortion or damage.

Information hitherto given on the commercial silkworm[4] aroused our interest to investigate silkworm eggs by ESR. Studies were carried out on the eggs of six varieties of *Bombyx mori*, including two Japanese (KONJIKI and AOJYUKU), three Chinese (KANSEN, HIKO and SEKKO) and one European (ASCOLI). All showed ESR signal of the same g value, 2.004 ± 0.001, but of different intensity.

All measurements were carried out at room temperature. For the measurements, twenty eggs of each kind were loaded in a glass capillary of about 1 mm I.D. without sealing and placed in the field of ESR spectrometer. All eggs had previously been about one year in diapause. The g-value and signal intensity were measured with two reference substances, *i.e.*, the diphenylpicrylhydrazil and the manganous ions of a known number of spins in magnesium oxide. The g-value, of all six varieties did not change with time, either before incubation, or after the eggs were activated by treatment with hydrochloric acid.

In order to locate the radicals, ESR measurements were carried out on egg fractions of nucleus, mitochondria, and microsome, which were separated from each other according to standard procedures. The shell did not show any signal, and mitochondrial and microsomal fractions showed weak signals. We suspect that these signals are due to contamination with nuclear material. A very strong signal was observed with nucleus. The records of ESR signals are shown in Fig. 1.

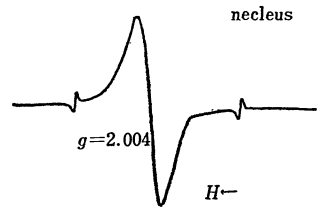

Fig. 1. ESR signal (central peak) in the nucleus of silkworm egg. Satellites in both sides of the central peak refer to the hyperfine signals of Mn^{2+} (in MgO), which has been added to the sample as the reference substance.

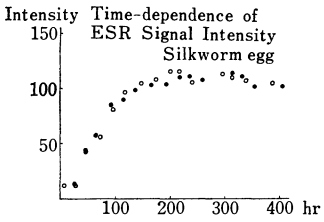

Fig. 2. Time-dependence of ESR signal intensity of silkworm egg.

Figure 2 shows the time dependence of the ESR signal in freshly laid eggs of HIKO. The origin of the time scale in Fig. 2 refers to the time of *OVIPOSITION*. Two sets of measurements were carried out: one was started 3 hr after *OVIPOSITION* (white circles in Fig. 2); the other after 12 hr (black circles).

As shown in Fig. 2, the signal intensity increases linearly during the first 180 hr and then plateaus. The intensity scale in Fig. 2 is arbitrary; after the 180th hour, the number of electron spins in one egg is about 1.4×10^{14}.

If we assume that an egg originally has n spins, and that they increase linearly until equilibrium is achieved, then there is approximately a 60-fold increase during this time.

Further effort has been made in order to locate the spins, *i.e.*, the nuclear material has been separated into DNA and protein by extracting nucleus with 1% Na_2CO_3 or 0.8% NaCl solution. Although a spurious signal is observed in the DNA part, spins are mainly located in that of protein. The principal problem is the source of the ESR signal in these eggs. Whatever the free radicals be, they increase systematically during the early hours of incubation and then stabilize in an equilibrium. Additional studies are being made.

Exciton Circular Dichroism of Chromium(III) Complexes Containing Two Nonidentical α-Diimines

Sumio KAIZAKI, Jinsai HIDAKA and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received July 3, 1970)

Application of the exciton theory to the circular dichroism (CD) spectra of tris- or bis-α-diimine metal complexes has been carried out intensively.[1-4] The exciton interaction between the nonidentical long-axis π-π^* transitions of the coordinated 2,2′-dipyridyl (dip) and 1,10-phenanthroline (phen) has been reported in the cases of the CD spectra of $[M(dip)_2(phen)]^{n+}$ and $[M(dip)(phen)_2]^{n+}$ complexes.[1,3] In order to confirm the interaction of this kind, it is most desirable to investigate the simpler mixed complex, $[M(dip)(phen)L_2]^{n+}$, which contains only one each of the nonidentical α-diimines.

A new binuclear μ-diol chromium(III) complex of this kind was prepared by the reaction of $[CrCl_3(dmf)(dip)]$ with phen·HNO_3 in water at 70°C. Found: C, 45.87; H, 4.09; N, 14.73%. Calcd for $C_{44}H_{46}N_{12}O_{20}Cr_2=[(dip)(phen)Cr(OH)_2Cr(dip)(phen)](NO_3)_4\cdot 6H_2O$: C, 45.29; H, 3.97; N, 14.40%. Another new mononuclear oxalato complex was obtained by heating the aqueous solution of the μ-diol complex with oxalic acid. Found: C, 49.25; H, 3.61; N, 11.66%. Calcd for $C_{21}H_{21}N_5O_{9.5}Cr=[Cr(ox)(dip)(phen)]NO_3\cdot 2.5H_2O$: C, 49.41; H, 3.63; N, 12.00%. The μ-diol and oxalato complexes were optically resolved by using resolving agents, potassium di-μ-L-tartrato(4-)diantimonate(III) trihydrate and $(-)_{589}$-$K[Cr(ox)_2(phen)]\cdot 4H_2O$, respectively. The $(-)_{589}$-isomers were isolated and characterized as a nitrate heptahydrate (μ-diol complex) and a perchlorate dihydrate (oxalato complex). As seen in Fig. 1, the absorption spectra of the present μ-diol and oxalato complexes have common bands with μ-diol tetra-dip or -phen complex and oxalato bis-dip or -phen complex, respectively.[3,4] The CD spectra in the ligand absorption band region of the present $(-)_{589}$ complexes show a typical exciton band pattern as in those of $(-)_{589}$-tetra-dip or -phen binuclear complex and of $(-)_{589}$-bis-dip or -phen mononuclear complex.[3,4] That is, from the longer wavelength side, an intense negative and a positive CD band are observed near the long-axis π-π^* transitions of the dip (310 mμ) and phen (275 mμ), respectively. If there were no interaction between the dip and phen transitions in the present complexes, the CD bands at 310 and 275 mμ would have the same sign for the same tris-chelate configuration as in the case of L-tartrato α-diimine chromium(III) complexes.[5] Thus, the present observation confirms the existence of the exciton interaction between the nonidentical π-π^* transitions of the dip and phen in a complex. From the behavior of the exciton CD bands at 310 and 275 mμ, the $(-)_{589}$-isomers of the present complexes are assigned to the $\Lambda(C_2)$ configuration.[1,2] This assignment agrees with the empirical one on the basis of a major CD band in the first *d*-*d* absorption band region.

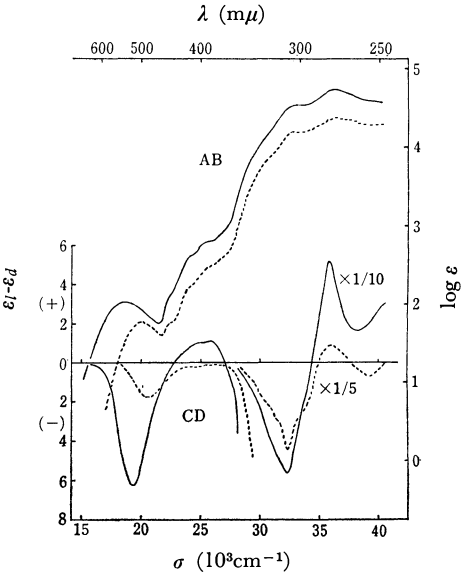

Fig. 1. Absorption (AB) and CD curves of $(-)_{589}$-$[(dip)(phen)Cr(OH)_2Cr(dip)(phen)](NO_3)_4\cdot 7H_2O$ (——) and $(-)_{589}$-$[Cr(ox)(dip)(phen)]ClO_4\cdot 2H_2O$ (----) in water.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3025—3028 (1970)

Chemical Species Produced from Iodine in Stretched PVA Sheets

Harjoto DJOJOSUBROTO*1 and Yoshié TANIZAKI

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo

and Toshihiko HOSHI

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Megurisawa-cho, Setagaya-ku, Tokyo

(Received December 24, 1969)

A qualitative dichroism analysis has been made on chemical species produced from iodine in stretched sheets of polyvinyl alcohol. The absorption bands at 290 mμ and 360 mμ have been attributed to the bent triiodine ion, and the transition moments of these bands have been found to be parallel to each other. From the optical density ratio (R_d) curve, the presence of a hidden band at about 420 mμ has been pointed out, and the band has been assigned to the absorption by the linear triiodide ion. Three different chemical species are absorbed in the visible region. By comparing the R_d values, the numbers of iodine atoms in the respective species have been estimated.

The absorption spectra of iodine in polyvinyl alcohol (PVA) sheets or aqueous solutions of PVA consist of several bands in the ultraviolet and visible regions. Two bands at 290 mμ and 360 mμ which may be considered to be due to the triiodide ion always appear, whatever the conditions. From the difference in dichroic properties, Tanizaki *et al.*[1] suggested that these bands originated with different chemical species. The other bands in the visible region are due to the longer polyiodide ions, and either appear or not depending upon the conditions of preparation.[1] Savko and Faerman[2] observed that the blue color (maximum absorption at 600 mμ) does not appear in solutions of PVA and iodine dissolved in aqueous solutions containing iodide ions, but that dried sheets prepared from these solutions show a very strong absorption at 600 mμ. They concluded, therefore, that water prevents the formation of a blue complex, by displacing the polarized configuration of iodine atoms bound to triiodide anions in the polymer network.[2] In the ioidne-PVA mixture, an excess of potassium iodide intensifies the 600 mμ band by completely binding the iodine to form triiodide ions.[3] Mokhnach and Propp[4] suggested that the iodine complex with polyvinyl alcohol absorbs at 600 mμ, and that the appearance of the 288 mμ band is due to triiodide ions, while that at 350 mμ is due to hypoiodite ions.[4]

Triiodide in various solvents shows two absorption bands, at 290 mμ and 360 mμ, the former being always higher in intensity than the latter.[5–7] By the continuous-variation method using mixtures consisting of tetramethylammonium iodide and iodine in ethylene chloride, it is confirmed that the only species which absorbs at 295 mμ and 365 mμ is the triiodide ion.[8] Robin found that the high intensity of the I_3^- bands could be explained using the MO theory only if the ion were bent.[9]

From the X-ray diffraction pattern of iodine in stretched PVA sheets, West[10] concluded that straight chains of polyiodides are formed, all of them parallel to the stretching direction. Rundle[11] pointed out that, in the one-dimensional array,

all of the I-I spacings are identical, and that all are somewhat shorter than the van der Waals separation.

In the present study, the identification of the various species formed from iodine in the stretched PVA sheets was attempted using their linear dichroism. The analysis of the dichroic spectra could not be applied in the present case because the chromophores in the sheet could not be oriented enough to allow the application of the theory.[12] Although quantitative analysis could not be carried out for this reason, useful qualitative information regarding the absorbing species, especially the triiodide ion, could be obtained.

Experimental

The preparation of PVA sheets from polyvinyl alcohol powder has been described elsewhere.[12] In this experiment, sheets about 0.2 mm thick were prepared from commercial PVA powder, whose polymerization degree was 1400. The adsorption of iodine was achieved by hanging the PVA sheet in a bottle with a mouth 500 m*l* wide and containing a few iodine crystals. Under a low humidity, iodine could not be diffused into the dry PVA sheet; therefore, a drop of water was added to the bottle. The sample sheets were prepared as follows:

(1) The iodine was adsorbed on a dry PVA sheet, and its absorption spectrum was measured using unpolarized light. The spectrum is shown as Curve *D* in Fig. 1.

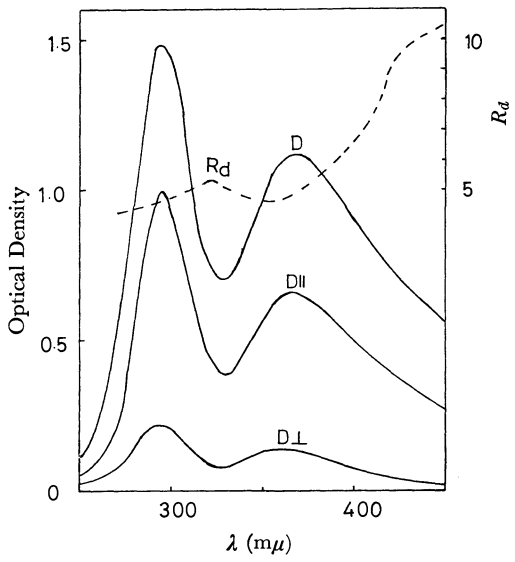

Fig. 1. Absorption spectra of iodine in dry PVA sheet. The *D* curve is the absorption for the non-stretched state. The $D_{||}$ and $D_{\perp}$ curves (dichroic spectra) are the absorptions of the stretched sheet for light with electric vector parallel and perpendicular, respectively, to the stretching direction. R_d means the ratio of $D_{||}$ and $D_{\perp}$.

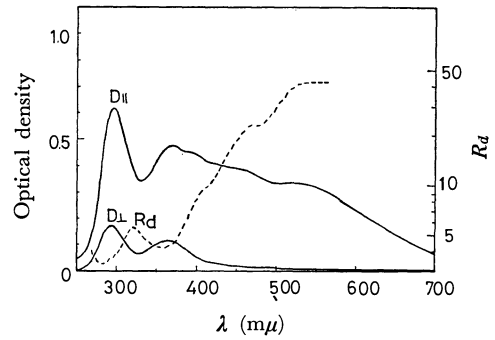

Fig. 2. Dichroic spectra of iodine adsorbed after stretching the dry sheet.

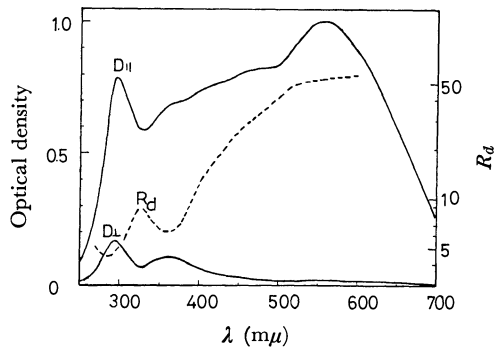

Fig. 3. Dichroic spectra of iodine adsorbed in humid atmosphere after stretching the dry sheet.

(2) After the iodine had been adsorbed, the sheet was stretched. The absorption spectra obtained using plane-polarized light are shown in Fig. 1 ($D_{||}$ and $D_{\perp}$), where $D_{||}$ and $D_{\perp}$ are the absorptions for the light with electric vector respectively parallel and perpendicular to the stretching direction of the sheet.

(3) After stretching, a piece of dry PVA sheet was put in the adsorption bottle. Its dichroic spectra are shown in Fig. 2. Fig. 3 shows the dichroic spectra of a sample sheet prepared in the same way as above, but here more water was added before the iodine adsorption.

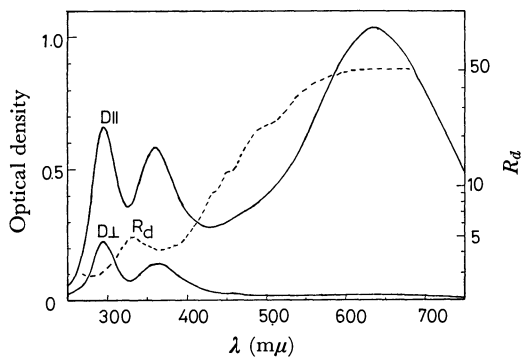

Fig. 4. Dichroic spectra of iodine in the blue-colored state.

(4) PVA sheet was digested in distilled water for at least two hours, and the wet sheet was put in the bottle and then stretched at room temperature. The sheet was air-dried overnight, and then its dichroic spectra were determined (see Fig. 4).

The adsorption of iodine was done at room temperature (about 20°C) until the iodine concentration was sufficient for spectrophotometric measurements. A dry sheet was stretched at 80°C by a stretching machine. The stretched ratio was 9 for the sheet which was stretched in the dry state, while that for the sheet stretched in the wet state was 8 as determined after the sheet became dry. (The stretch ratio was determined by a procedure described elsewhere,[12] but the deformation of the substrate by stretching did not satisfy the conditions required for the dichroism analysis).

The absorption measurements were made with a Shimadzu QR-50 spectrophotometer, equipped with a Glan-Thomson-type polarizer and a simultaneous rotation apparatus for sample and reference sheets.

Results and Discussion

Figure 1 indicates that the stretching does not induce any change in the absorption pattern. In fact, the absorption curve of an unstretched sample sheet coincided completely with the curve, D, obtained by $D=k(D_{\parallel}+2D_{\perp})$, where k is a constant. Moreover, as can be seen in the other figures, the intensity ratio at 290 mμ and 360 mμ of the $D_{\perp}$ curve is always constant at about 1.6. Therefore, both bands must be attributed to only one species, as has been shown by Buckles *et al.*,[8] this species may be considered to be the triiodide ion.

The triiodide ion can be either linear ($D_{\infty h}$) or bent (C_{2v}) in geometry. From the symmetry, the allowed transitions in the linear ion should have only one kind of polarization (long axis, Z), while the strong transitions in the bent ion can have two kinds of polarization (long axis, Z, and short axis, X).

The R_d curve in Fig. 1 is not flat over the region of the two bands, but rises with a sharp inclination from about 350 mμ to 430 mμ and shows a maximum between the two bands. Such a tendency of the R_d curve is also observed at the corresponding part in all the dichroic spectra shown in other figures. This implies that a different kind of absorption band with a higher R_d value (a smaller orientation angle) is hidden near the 360 mμ band.

According to the empirical facts of the dichroism investigation, a long molecule in a stretched PVA sheet will preferentially orient its long axis parallel to the stretching direction of the sheet. Moreover, if there are two bands orthogonal to each other and if the one has a R_d value larger than about 5, then the other must have a value smaller than 0.5. As for the 290 mμ and the 360 mμ bands, therefore, it can safely be said that their polarizations are parallel to each other; besides, they lie along the Z axis. This conclusion is in agreement with the prediction of Robin.[9]

The hidden band with a higher R_d value can be explained only by considering another species. From the point of view of dichroism, a linear molecule will show a higher R_d value than a bent one. Therefore, the hidden band can be attributed to absorption by a linear species. It seems very probable that a linear triiodide ion is another species which can exist besides the bent ion. The only allowed transition for the linear triiodide ion (calculated as a $a_{1g}\rightarrow a^*_{2u}$ by Robin[9]) will lie somewhere near the band region of 290 mμ and 360 mμ. The behavior of the R_d curve of Fig. 1 can be understood in terms of the existence of the linear triiodide ion.

The polarizations of all the absorptions in the visible region are much more parallel to the stretching direction than that of the triiodide ion. The R_d curve in Fig. 2 is complicated; in it the inflective parts correspond well to the shoulders of the $D_{\parallel}$ curve. Such a correspondence seems to indicate that there are absorptions at 450 mμ and 540 mμ. The long tail in the longer-wavelength side of 540 mμ suggests the presence of a hidden band in this region. Figure 3 shows the dichroic spectra of a sample containing more water than is the case in Fig. 2. The increase in the water content results in an intensifying of the 540 mμ band and shifting it to 570 mμ. The dichroic spectra of the sample (Fig. 4) treated in the wet state show a very intense band at 630 mμ and, at the same time, the disappearance of the 450 mμ and 540 mμ bands, though the R_d curve clearly indicates the existence of these bands.

Thus, taking into account the facts that the iodine atoms in a PVA-iodine complex are arranged in a one-dimensional array[10] and that the R_d value reflecting the orientation of the polarization, which should lie on the long axis of a linear species, is different from band to band, it may be considered that all the absorption bands in the visible region are to be attributed to different species. The only difference among the species is in the geometrical length. The longer the length (the larger the number of atoms) of the species, the longer the wavelength of absorption. This consideration is in agreement with the fact that the longer-wavelength bands have the larger R_d values. With respect to the R_d values, this means that the orientation angle (the angle between the orientation axis and the Z axis) becomes smaller as the length of the species increases.

If the orientation angles of the linear polyiodide ions, including the triiodide ion, have some relation to the lengths of the species, the length can be estimated from a comparison of the R_d values, taking the value of the linear triiodide ion as a standard; therefore, the number of iodine atoms in each species may be determined. The method is illustrated with a model in Fig. 5.

Unfortunately, we could not find the distribution

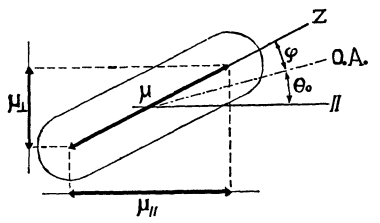

Fig. 5. Schematic illustration of the components ($\mu_\perp$, $\mu_{||}$) of transition moment (μ) of an oriented molecule representative of a species in a distribution state. O.A. represents the orientation axis, and || the stretching direction of the substrate.

function applicable to the present case. Nevertheless, for a stretched state there must be a distribution function which is common to all the species in a stretched sheet. Since the distribution indicates the distribution of an orientation axis (O.A.) of a species, the direction of O.A. must be common to all species. The only difference among species is, therefore, the difference in angle (φ) between O.A. and the transition vectors (μ). The transition vectors of the species are distributed uniformly with the φ around the O.A. axis. If θ_0 is representative of the distribution angle of O.A. to the stretching direction (||), the angle of μ about || can vary from $(\theta_0+\varphi)$ to $(\theta_0-\varphi)$. Allowing θ $(=<\theta_0\pm\varphi>)$ to denote an average angle of μ about the direction, we have:

$$R_d = \frac{D_{||}}{D_\perp} = \mu^2\cos^2\theta/\mu^2\sin^2\theta \qquad (1)$$

As may be seen in Figs. 1—4, the $D_\perp$ of the visible region is very small and is almost constant except for the region affected by the absorption of the bent triiodide ion. Regarding $D_\perp$ as constant for all species under consideration, we can express the ratio of the R_d values for the species A and B as follows:

$$\frac{R_d(B)}{R_d(A)} = \frac{\mu_{||}^2(B)}{\mu_\perp^2(A)} = \frac{\mu_B^2\cos^2\theta_B}{\mu_A^2\cos^2\theta_A} \qquad (2)$$

If we may assume that μ is proportional to the length (L) of the species, then Eq. (2) becomes:

$$R_d(B)/R_d(A) = L_B^2\cos^2\theta_B/L_A^2\cos^2\theta_A \qquad (3)$$

Since θ is very small, we can put $\cos^2\theta$ equal to unity for the first approximation. Using the ratio of the observed R_d values and taking the linear triiodide ion (Species A) as a standard, the lengths of the other species can be estimated. If we take 3.1 Å to be the distance between iodine atoms,[10] the number of atoms of the absorbing species can be estimated to be as is shown in Table 1. In the estimation, we use the value of the R_d curve at around 420 mμ, assuming that an absorption band of the linear triiodide ion is hidden in this region.

It is clear from Fig. 5 that the length-ratio obtained here does not mean the actual ratio of the species, but the ratio of the components parallel to the stretching direction. Naturally, the estimated value presented in Table 1 represents the maximum number of iodine atoms for the species in the PVA sheet; that is, the number of atoms of the actual species should not exceed the number shown in Table 1.

Table 1. Estimation of the number of iodine atoms in the species which have the visible absorption bands

Band	$\sqrt{\frac{R_d}{R_d(I_3^-)}} = \frac{L}{L(I_3^-)}$	Number of atoms
420 mμ	1.0	3
450 mμ	1.4—1.5	4
540 mμ	2.0	5
630 mμ	2.8	7

Several workers have estimated the number of iodine atoms in the species formed in the blue colored amylose-iodine system,[13–15] but their results have not always coincided. The reported values are for starch-iodine systems, so that a direct comparison with the PVA-iodine system is not possible. As has been confirmed by the X-ray diffraction analysis of the halogens incorporated within hydrophilic high polymers (including starch and PVA), the characteristic pattern is independent of the polymer in which the halogens are incorporated. The systems depend only on the type of halogens.[10] This fact suggests that a qualitative comparison is possible. According to the estimated values by Ono *et al.*,[13] for instance, a species consisting of more than one hundred iodine atoms is possible only if the iodine atoms in the polymer are helical or are arranged in a manner similar to that of helical. Since it is known that, in all cases, the iodine atoms are linearly arranged,[10] such large polyiodines are very difficult to understand from the point of view of dichroism.

From the results presented in Table 1, the following mechanism of the formation of polyiodide chains can be proposed, though there is no evidence for the mechanism of the formation of the triiodide ion at the present stage:

$$I_4 : I_2 + I_2 = I_4$$

$$I_5^-: I_3^- + I_2 = I_5^-$$

$$I_7^-: I_3^- + I_4 = I_7^- \text{ and/or } I_5^- + I_2 = I_7^-$$

One of the authors (H.D.) wishes especially to express his gratitude to the Japanese National Commission for UNESCO for the opportunity to study in Japan during the 1968—1969 academic year.

Ionic Dissociation. I. A Hückel Molecular-Orbital Treatment of the Dissociation of Carboxylic Acids and Several Azine Compounds

Hiroko YAMABE, Teijiro YONEZAWA and Hiroshi KATO*1

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received February 14, 1970)

The relationship between the pK_a value and the change in the electronic energy, ΔE, in the course of the dissociation, and the electronic structure of various mono-carboxylic acids and several azine compounds are discussed on the basis of the calculation by Hückel methods for σ and π electron systems. The parallelism between the pK_a and the calculated ΔE of the acids is observed. The σ electron densities of the -COOH proton and the O^- lone pair, which is constituted by the released electron on the dissociation, run parallel with the pK_a's. The delocalizability of the lone pair for the electrophilic reaction, and that of the proton for the nucleophilic reaction, have a linear relationship with the pK_a's. Similar relations are seen in several azine compounds. Therefore, it may be said that the protonation will take place by means of the electrophilic attack at the lone pair, and that the deprotonation occurs by means of the nucleophilic attack at the proton.

It is said that the strength of an acid depends on the relative stabilities of it and its anion.[1] The dissociation constant, pK_a, of conjugated acids and bases has been related to the change in π electronic energy in the course of the dissociation, and to the charge of the protonated heteroatom in these compounds.[2-4] However, as one of us has pointed out in a previous paper,[5] only a classical electrostatic theory[6] has been proposed in connection with the dissociation of saturated compounds, except for our previous calculation on the α-amino acids.[5] In this paper we will report the relationship between the value of pK_a and the change in the electronic energy, ΔE, and in other quantities of the electronic structures of various mono-carboxylic acids and several bases; our findings are based on the calculation by the Hückel method for σ and π systems.

The distinguishing characteristic of this work is the model it employed; in it the mechanism of the dissociation is taken into account in a simple way. Namely, the carboxylic acid is considered to be dissociated according to Eq. (1):

$$R\text{-}C(=O)\text{-}O\text{-}H \rightleftharpoons R\text{-}C(=O)\text{-}O^- + H^+ \qquad (1)^{*2}$$

The following model is assumed: in the anionic form, electrons released by the dissociation of the proton constitute, in a sense, a new lone pair of the oxygen delocalize over a whole molecule. This will be denoted as "the O^- lone pair" through-out the present paper. A recombination reaction to the left-hand side of Eq. (1) will take place by means of the attack of the dissociated proton (or a hydronium ion) on the O^- lone pair. The electron density of this lone pair is evaluated by the Hückel method for various acids.

After these comparative discussions, the following conclusion was obtained. There is a rough linearity between the pK_a value and the calculated ΔE value. The σ electron density of the O^- lone pair and the delocalizability,[6] D_r^E, for the electrophilic reaction of the O^- lone pair run parallel with the pK_a value, as well as with the σ electron density and the delocalizability,[6] D_r^N, for the nucleophilic reaction of the hydrogen atom of a carboxylic group. Further, similar relations are seen in azine compounds as will be described in detail later. Therefore, the protonation seems to take place by means of the electrophilic attack at the lone pair, while

the deprotonation seems to occur by means of the nucleophilic attack at the proton.

Calculations

The electronic energy change, ΔE, in the course of dissociation is due to the difference between the total energy of the final and the initial states in Eq. (1). This equation is adopted for a series of carboxylic acids, and the calculation of ΔE is performed according to the following formulae:[5]

$$\Delta E = E_\sigma(\text{final}) - E_\sigma(\text{initial}) - \sum_\mu \frac{Q_H Q_\mu e^2}{R_{H\mu}}$$
$$\Delta E_\sigma = E_\sigma(\text{final}) - E_\sigma(\text{initial}) \qquad (2)$$

Here, E_σ(initial) and E_σ(final) denote the energies of the protonated compounds and of the conjugate base respectively. The third term corresponds to the electrostatic interactions between the dissociable proton and the other atoms in the protonated compounds. Q_H is the net charge (in e units) of the proton, Q_μ is the net charge of the μ-th atom, and $R_{H\mu}$ is the distance between them. The calculation of $R_{H\mu}$ is carried out using a formula proposed by Eyring[7] and by Kirkwood and Westheimer.[8] The precise interpretation of Eq. (2) was given in a previous paper.[5] In that paper,[5] the variation in the total π electron energy is assumed to be constant. In this work we confirmed this by the performance of the Hückel calculation.*3

For the determination of the electronic energy and the electron distribution of σ and π electron systems, the Hückel approximation is employed. The parameters used in these calculations are tabulated in Table 1.

Results and Discussions

The electronic structures of σ and π electron systems are obtained for various acids. As an example, the σ-electron distribution of the CH_3COOH, CF_3COOH, and C_3H_5COOH molecules and their anions are shown in Fig. 1, together with the π electron distribution. In the anionic form, about 93% of the lone-pair electrons localize at the oxygen atom. Furthermore, the highest occupied orbital localizes largely at the O^- lone pair; that is, it becomes a lone-pair MO.*4 The results of the calculation are listed in Table 2, together with the experimantal values of pK_a for a series of carboxylic acids. In Table 2, ΔE_σ gives the variation in the total σ electronic energies in the course of the dissociation

*3 ΔE_π is calculated as 1.1277 β_π for all the acids except benzoic acid, for which the ΔE_π value is 1.1400 β_π.

*4 In the extended Hückel calculation of the CH_3COOH molecule, the highest occupied MO is a σ orbital. Moreover, the atomic orbital population of the x direction, which is one component of the lone pair, of the oxygen atom is considerably increased compared with that of the CH_3COOH molecule. Therefore, this MO has the character of a lone-pair MO.

in units of $-\beta$ and eV's respectively, where we have chosen 6 eV for $-\beta$.[5),*5] D^N_r indicates the values of delocalizability[6)] for an electrophilic reaction at the hydrogen atom of a -COOH group. D^E_r is the delocalizability[8)] for an electrophilic reaction at the O^- lone pair of a $-COO^-$ group. Q_H and Q_L give the electron densities of the H of a -COOH group and the O^- lone pair of a $-COO^-$ group respectively. From Table 2, a parallelism between the pK_a values and ΔE_σ's is observed, though the values of ΔE_σ's[*5] themselves are not very different for various acids. However, large deviations in CCl_3COOH and CF_3COOH from a linear relationship are seen.

In Fig. 2, the values of pK_a are plotted against ΔE(in eV),[*6] which is given by Eq. (2). Including the electrostatic interaction term[*7] of $Q_H Q_\mu e^2/R_{H\mu}$ the deviation in CCl_3COOH and CF_3COOH is greatly improved, as may be seen in Fig. 2 and Table 2.[*8] This indicates that the CCl_3 and CF_3 groups in these compounds are very electronegative and they attract the dissociable hydrogen, which is in agreement with Dewar's description.[*9] This effect will make an acid weaker than would be expected from the calculated ΔE_σ value. Further-

[*5] Only the relative values of ΔE_σ for the various compounds have meaning. There is some arbitrariness in the selection of the value of $-\beta$.

[*6] The absolute value of ΔE can not be discussed.

[*7] In Table 2, the following relation is noted: as the electrostatic interaction with the dissociable hydrogen, $\sum = Q_H Q_\mu e^2/\mu R_{H\mu}$ increases, the pK_a value decreases.

[*8] CF_3COOH is not included in Fig. 2 because the deviation in CF_3COOH is still large. Possibly this deviation is due to the extraordinarily heteroritic property of the three F atoms.

[*9] Dewar describes in his book (Ref. 1) that "in acids containing a highly polar group in proximity of the dissociable hydrogen, a direct electrostatic attraction or repulsion of the nascent proton may increase or decrease the dissociation energy."

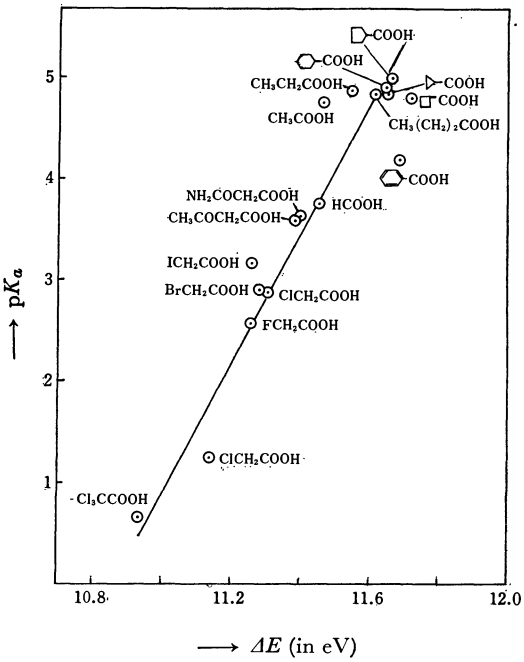

Fig. 2. The dissociation constant pK_a *vs.* ΔE, where $\Delta E=\Delta E_\sigma-\sum_\mu Q_H Q_\mu e^2/R_{H\mu}$.

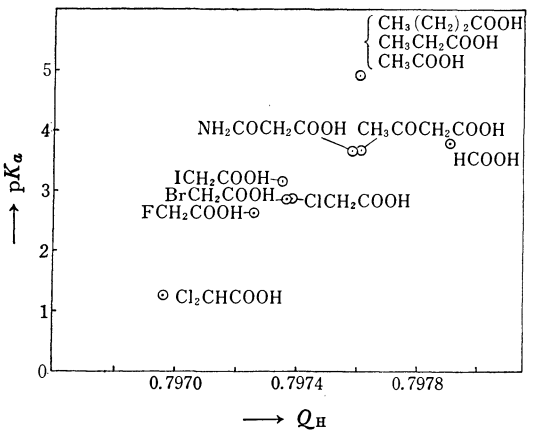

Fig. 3. The dissociation constant pK_a *vs.* Q_H of acids.

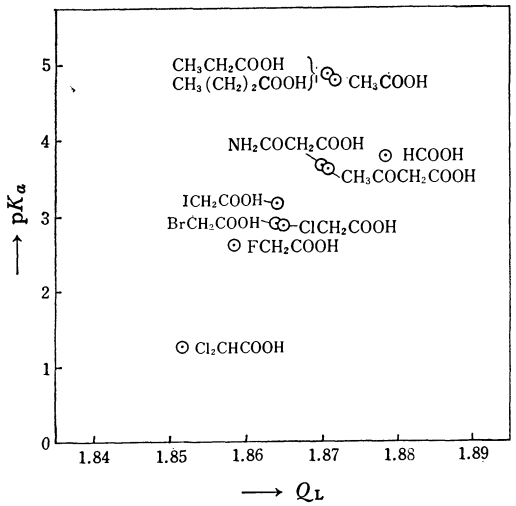

Fig. 4. The dissociation constant pK_a *vs.* Q_L of acids.

more, in Fig. 2 the difference in the values of ΔE for various acids become larger than in the case of ΔE_σ's. That is it may be noted that the electrostatic interaction term contributes to the relative acidity of the acids.

On the basis of these calculations, it may be said that ΔE_σ's calculated by Hückel method run parallel with the pK_a values for the compounds having not so polar a group. As for the molecule having a highly polar group, the contribution of the electrostatic interaction term to its acidity should not be ignored. Furthermore, it may be concluded that the acid dissociates more easily when its anion is more stable than that of the parent acid.

Also, a very rough linear relation is seen between the pK_a and D_r^N and the electron density of the hydrogen, Q_H. It is plotted in Fig. 3.*10 This means that the dissociable hydrogen may be attacked in a nucleophilic fashion by the H_2O molecule to give the $RCOO^-$ and H_3O^+ ions in the dissociation process. Also the D^E_r and the electron density of the O^- lone pair of the anion Q_L run parallen with the pK_a. It is plotted in Fig. 4.*10 This means that the ion recombination takes place by means of the attack on the O^- lone pair by the hydrogen atom of the H_2O molecule. These results suggest that the model employed here is plausible; that is, the electron released on the dissociation constitutes a new lone pair of O^- of the anion and delocalize over the whole molecule.

*10 In Fig. 4 and Fig. 5, CF_3COOH and CCl_3COOH are not included.

Dissociation of Azine Compounds

In the preceding part of this paper we found that, as far as we have treated, the ΔE_σ calculated by the Hückel method runs parallel with the pK_a value for the carboxylic acids having not so highly a polar group. Next, we will examine whether this relation holds in the cases of several azines,*11 though the azines calculated in the present work are few in number.

The dissociation equilibrium is assumed to be in the form of Eq. (3), in which pyridine is taken as an example.

*11 The interrelation between the ΔE_π and the pK_a values of some of these compounds has been discussed by several authors (Ref. 2).

Table 3. Calculated results and the observed pK_a values* for some azine compounds

Compound	pK_a	ΔE_σ (in $-\beta$)	D_H^N	D_L^E	Q_H	Q_L
Pyridine	5.23	1.7544	1.1579	10.8848	0.8345	1.7523
Pyrazine	0.6	1.7378	1.1547	11.2164	0.8351	1.7559
Pyrimidine	1.3	1.7394	1.1521	11.7104	0.8357	1.7581
Pyridazine	2.33	1.7493	1.1347	18.7290	0.8421	1.7708

(3)

The value of ΔE_σ is evaluated according to Eq. (4):

$$\Delta E_\sigma = E_\sigma(\text{protonated form}) - E_\sigma(\text{unprotonated form}) \quad (4)$$

The method of the calculation and the parameters employed are similar to those use for the carboxylic acids.

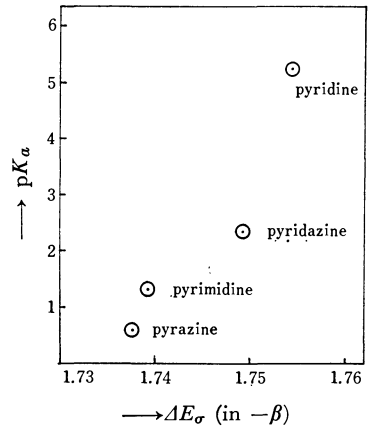

Fig. 5. The dissociation constant pK_a *vs.* ΔE_σ.

The calculated ΔE_σ values are shown in Table 3, together with the observed pK_a values; they are plotted in Fig. 5.*12 A parallelism between ΔE_σ and the pK_a of azines is observed.

In diazines it is observed that, in the anionic form, the electron density of the N lone-pair Q_L and the delocalizability, D_L^E of that lone pair for the electrophilic reaction run parallel with the pK_a.*13 Also, in the protonated form the electron density of the hydrogen, Q_H, and the delocalizability, D_H^N, of that proton for the nucleophilic reaction run parallel with the pK_a in diazines. This means that the protonation takes place by the attack on the N lone pair in Eq. (3) and that the deprotonation is induced by such a molecule as H_2O, which attacks the proton. These circumstances were observed previously in the case of acids.

An approximate linear relation between the pK_a value and the energy change, ΔE, of the acids and bases can naturally be expected. However, the coarse linearity obtained in the present work for some acids and bases seems to be a change result of the appropriate selections of the molecules to be calculated, the method of the approximation, and the various parameters. When the peculiarity of each molecule, which is induced by each substituent, the steric factor, and so on, can not be taken into account in the parameters, the linearity will not be obtained and some corrections for the calculation are needed. An example of the deviation caused by the steric factor has been reported in the calculation of the π energy change in the dissociation of the conjugated acids.[3)]

The calculations were carried out on a HITAC 5020 computer at the computation center of the University of Tokyo.

*12 The σ electron densities of the azines have been presented in one of our previous papers (Ref. 9).

*13 The paralellism between the σ electron density of the N lone pair of diazine and the blue shifts of n–π^* bands, accompanied by the change in the solvent from cyclohexane to aqueous solution, has been reported in our previous paper (Ref. 9).

The Mössbauer Effect in Triethyltin Phenyl Derivatives

Noriyuki WATANABE and Eiji NIKI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received February 19, 1970)

Substituent effect of triethyltin phenyl derivatives was investigated by means of the ^{119}Sn Mössbauer effect. The isomer shifts obtained for these compounds fall into the range -0.15—-0.18 mm/sec with respect to $Pd^{119m}Sn$ source. *p*-Cl and *m*-Cl derivatives show broadened spectra, which may be ascribed to an unresolved quadrupole splitting. This small quadrupole interaction may be interpreted in terms of the partial ionicity of the bond formed between tin and carbon in phenyl group.

The Mössbauer effect in organotin compounds provides useful information on the nature of the chemical bond formed by tin atom. The tin atom, which belongs to group IV, may act effectively as a probe embedded in organic compounds. Quadrupole splitting takes place by low symmetric distribution of the valence electron. Thus, it provides a measure of the partially ionic character of sp^3 hybrid bonding. Tin organic compounds have similar values of the isomer shift. A study of the isomer shift for a series of compounds may supply a great deal of information.

In the present paper, the Mössbauer spectra of triethyltin phenyl derivatives ($X\text{-}C_6H_4SnEt_3$, X= H, *p*-CH_3, *m*-CH_3O, *p*-Cl, *m*-Cl) at 80°K and the effects of substituent are described. The compounds showed essentially the same isomer shift. The Mössbauer spectra for *p*-Cl and *m*-Cl derivatives gave single but broadened lines. The broadened line may be decomposed into an unresolved quadrupole doublet, and it seems reasonable to expect that the chlorine atom makes the Sn-C bond character partially ionic through phenyl group due to its inductive effect.

Experimental

The Doppler velocity spectrometer has an electromechanical negative feedback system.[1-4] The circuit for this system is shown in Fig. 1. The velocity signal is 12.5 Hz sawtooth or triangular wave, *viz*, the constant acceleration mode. The velocity scale has been cali-

brated by the isomer shift values of β-Sn and SnO_2. For the triangular wave mode, zero velocity corresponds to the middle of the 100 and 101 channels and also that of the 300 and 301 channels. The isomer shift can be obtained with a good reproducibility within one channel. The source was $Pd^{119m}Sn$ containing about 0.2 mCi ^{119m}Sn. The source was used at room temperature, while the absorber were solidified by cooling with liquid nitrogen in the cryostat shown in Fig. 2. The absorbers are liquid at room temperature and were injected into the cell by a syringe. The cell is made of brass. The windows of the cell are of myler of 25 μ thickness. All of the Mössbauer spectra were obtained with absorber thickness 50—60 mg/cm^2 Sn.

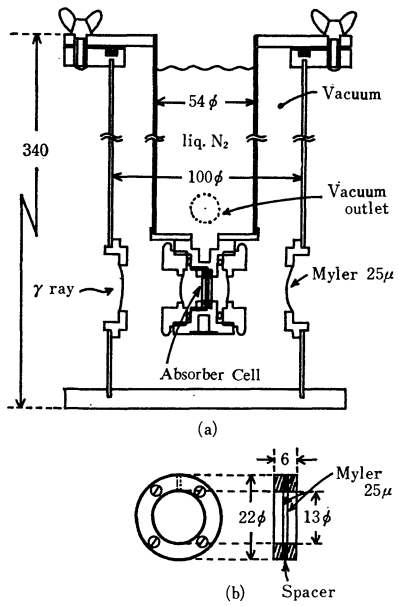

Fig. 2. Cryostat (a) and absorber cell (b). unit; mm

Triethyltin phenyl derivatives were prepared from triethyltin bromide and appropriate phenylmagnesium bromides in dry ether by the Grignard reaction.[5] They were purified by repeated fractional distillation at reduced pressure until GLC showed only one peak. They were identified by means of elementary analysis and infra- and farinfra-red spectra. The compounds can be synthesized easily, but the phenyl derivatives with polar functional group have not been synthesized as yet, for example, Grignard reagent cannot be made in dry ether or dry tetrahydrofuran in the case of m-NO_2 C_6H_4Br.

Results and Discussion

The isomer shifts in organotin compounds such as tetravalent tin fall in a narrow range. Tetravalent tin forms $5sp^3$ hybridization in many cases. An increase in s-electron density at the tin nucleus corresponds to an increase in isomer shift. Difference in s-electron density at the tin nucleus in various compounds mainly depends on the contribution from $5s$-electron density. However, it is important to consider not only $5s$-electron density but also the shielding of the $5s$-electron by the $5p$-electron. It may be considered that the partial ionicity of a bond in a sp^3 hybridization leads not only to a decrease in s-character but also to the compensation of a decrease of s-electron density through the decrease of shielding by the $5p$-electron. For tin compounds, the electric field gradient at the tin nucleus may appear as a result of the asymmetric distribution of the valence electron. Partial ionicity of a bond in sp^3 hybridization leads to an unbalanced state in a p-character of four bonding orbitals. Thus, it is important to obtain a correlation between the isomer shift and quadrupole splitting. A more theoretical treatment is required for this.

It has been suggested that only nonuniformity in dative π-bonding abilities of the atoms bonding to the tin atom can produce an electric field gradient large enough to give an observable quadrupole splitting.[6,7] However, in the Mössbauer spectra of compounds of the type $(C_6F_5)_{4-n}SnX_n$ (X=C_6H_5, CH_3, p-$CH_3C_6H_4$, n=1,2,3), observation of quadrupole splitting has been reported and interpreted in terms of electrostatic inductive and more predominant mesomeric effect of the pentafluoro phenyl group.[8] Similar results for R_3SnX (R=CH_3, C_6H_5, X=CF_3, C_6F_5, C_6Cl_5, C≡CC_6H_5) have shown that the quadrupole splitting can be induced by electrostatic inductive effects alone.[9] Recently, it has been reported that $(CH_3)_3Sn(p$-F-$C_6H_4)$ exhibits a single broader line suggesting unresolved splitting.[10]

We observed that the inductive effect of sub-

stituent causes a small quadrupole splitting. The results are summarized in Table 1. The isomer shift and quadrupole splitting are presented in the first and second columns of the table, respectively. A few examples of the spectra are shown in Fig. 3. The isomer shifts are shown relative to $Pd^{119m}Sn$ source, and all the numerical values are given in mm/sec. The isomer shifts of β-Sn and SnO_2 are +1.11 mm/sec and −1.58 mm/sec with respect to $Pd^{119m}Sn$ source, respectively. For X=H, p-CH_3, m-CH_3O in triethyltin phenyl derivatives X-$PhSnEt_3$, sharp, single lines with a half width of 1.14 mm/sec were observed. For p-Cl and m-Cl derivatives, however, apparently about 20 per cent broader, unsplit lines were observed. The isomer shifts were nearly equal within experimental error. The solids lines in Fig. 3(a), (b) are the single Lorentzian best fitted. However, the spectra obtained for p-Cl and m-Cl derivatives are fitted not by the single Lorentzian but by the overlap of two Lorentzians with a half width of 0.96 mm/sec (Fig. 3(c)). The broadened lines for p-Cl and m-Cl derivatives are possibly due to an unresolved quadrupole doublet. The small quadrupole splitting may be attributed to the increased ionicity of the Sn-C bond due to the inductive effect of chlorine atom. The s-character decreases through partially ionic character of the bond, but decreased p-character also compensates the decrease of the s-electron density at the tin nucleus through decreased shielding. Thus the increase of ionicity of the bond may not cause considerable change in isomer shift.

By means of the measurements of the electric dipole moment of the trimethyltin p-phenyl derivatives (p-$XC_6H_4Sn(CH_3)_3$, X=H, CH_3, CH_3O, $N(CH_3)_2$, Cl, Br), it has been concluded that for other derivatives with the exception of halogen derivatives, $d\pi$–$p\pi$ bonding ($(CH_3)_3Sn^-=^+C_6H_4X$), which compensates the contribution due to the difference of electronegativity between tin and carbon ($(CH_3)_3Sn^+-^-C_6H_4X$), may be present, but the negative inductive effect of the halogen atom outweighs the positive mesomeri, *i. e.*, $d\pi$–$p\pi$ bonding is not indicated in the halogen substituted tin compounds.[11,12] For triethyltin phenyl derivatives, the rates of electrophilic cleavage of phenyl-tin bond are rather small for p-Cl and m-Cl derivatives in comparision with those of others.[5]

From a consideration of the inductive effect caused by the substituents, the Mössbauer spectra of the derivatives with polar functional group, *e. g.*, m-$NO_2PhSnEt_3$, p-$NO_2PhSnEt_3$, *etc.*, can be measured, but the preparation of the compounds has not been achieved as yet.

The samples were kindly supplied by Professor H. Hashimoto of Department of Synthetic Chemistry, Tohoku University.[5]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3037—3043 (1970)

Ultrasonic and Thermodynamic Study on Solute-Solvent Interaction. Binary Mixtures of 1,2-Dichloroethane with Benzene, Toluene, *p*-Xylene and Cyclohexane

Osamu KIYOHARA and Kiyoshi ARAKAWA

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received February 19, 1970)

The sound velocity and density of binary mixtures of benzene, toluene, *p*-xylene and cyclohexane with 1,2-dichloroethane (DCE) as a common component were measured at temperature 20—40°C, and the excess molar volume and excess compressibility of these systems were calculated. They were found to be positive. The excess compressibility is independent of temperature in the DCE-benzene system. Thermodynamical properties and the nature of intermolecular interaction in the systems were discussed. It has been shown that there is a certain weak attraction between DCE and aromatic molecules, and that there is no complex formation *viz.*, hydrogen-bonding or change transfer complex. It has been proposed that the interaction between *gauche* form of DCE and aromatic molecules is of electrostatic nature (dipole-induced dipole or hyper-polarizability).

Binary solutions consisting of a halogen-substituted ethane and an aromatic solvent have long been studied from various viewpoints, but complete information is still lacking.

One approach to the liquid structure of the system is in the field of the molecular structure theory by means of Raman and infrared spectroscopy,[1-3] dielectric measurements,[4-7] and NMR.[8] The solvent dependence of the conformational equilibrium in halogen-substituted ethanes in the solution has been studied.[1-8] It has been found that aromatic solvents exhibit an anomaly in the conformational equilibrium of halogen-substituted ethanes in contrast to non-aromatic solvents.[3-8]

In a second approach, *viz.*, a thermodynamical consideration, the 1,2-dichloroethane-benzene system has been regarded as a nearly ideal solution,[9,10] because the excess free energy, enthalpy and entropy resulting from mixing are small. However, excess molar volume is large in comparison with other excess thermodynamical quantities.[11-14] Measurements of thermodynamical quantities have been made on this "pseudo-ideal" solution.[9-16]

By the analysis using the solution theory,[17] it has been shown that this system is not ideal, and that a certain kind of order is present between two components.[17]

As a third approach for the 1,2-dichloroethane-benzene system, ultrasonic studies, which present a useful means for the study of liquid structure in general, have been made by Staveley *et al.*,[18]

Kohler *et al.*[19] and others.[20]

This system is interesting as the object of studies of the interaction between polar molecules and π electrons, as well as that of studies of liquid structure.

We report here the results of an ultrsonic and thermodynamical investigation for the dichloroethane-aromatic systems and the dichloroethane-cyclohexane system which is taken as a reference system, and discuss the nature of the solute-solvent interactions in the systems.

Experimental

Samples of benzene, toluene, *p*-xylene, cyclohexane and 1,2-dichloroethane (DCE) were guaranteed reagents obtained from Wako Pure Chemical Industry Co. Ltd., and used on further purification.[21] The purity was examined by measurements of density at 20°C.

Sample	Density at 20°C	Lit. value[22]
Benzene	0.87904	0.87903
Toluene	0.86703	0.86696
p-Xylene	0.86105	0.68100
Cyclohexane	0.77853	0.77853
DCE	1.25297	1.25294

Sound velocity was measured using a usual crystal interferometer,[23] working at 3 Mc. The cell used is shown in Fig. 1. Measurements were made at 20, 30 and 40°C. The temperature was controlled within ±0.05°C. The measurement of sound velocity was reproducible within ±0.3 m/sec.

In order to test the apparatus, sound velocity was measured at 30°C for pure samples of benzene, *n*-hexane, cyclohexane and carbon tetrachloride. The results obtained were compared with data in literature.

Sample	Sound velocity at 30°C (m/sec)	Lit. value
Benzene	1275.4 (3 Mc)	1276.9,*1 1275.8*2
n-Hexnae	1062.8 (1 Mc)	1055.3*2
Cyclohexane	1228.6 (3 Mc)	1231.3,*3 1229.5*2
Carbon tetrachloride	908.6 (1 Mc)	905.9,*4 908*5

The agreement is satisfactory on the whole.

The merit of this apparatus is that the quantity of samples needed for measurements is small, 15—20 cc.

Density measurements were made using a pycnometer of usual type, whose capacity was about 15 cc. Accuracy of the density obtained was ±0.01%.

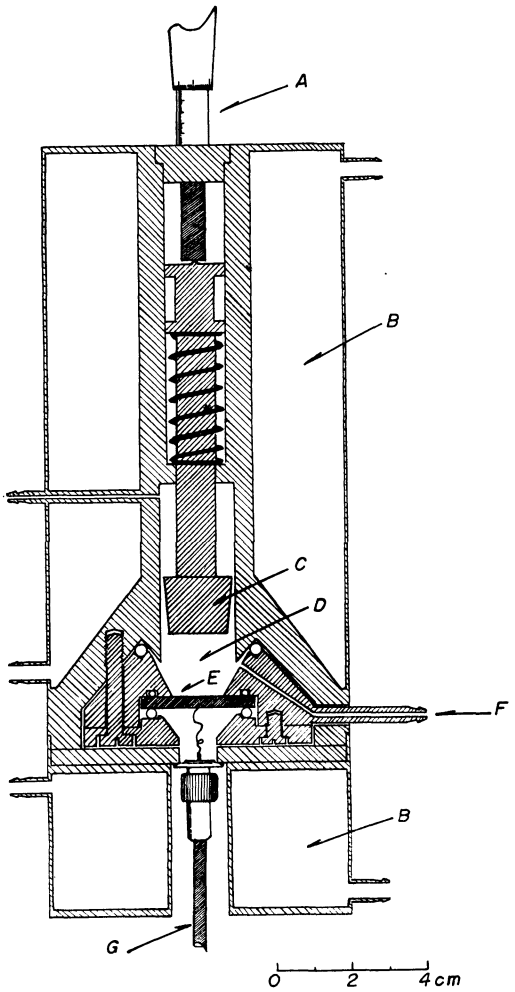

Fig. 1. Interferometer cell.

Results

Density d and sound velocity v were measured over the whole concentration range at 20, 30 and 40°C for the four systems: DCE-benzene, DCE-toluene, DCE-*p*-xylene and DCE-cyclohexane.

Excess Molar Volume on Mixing. Excess molar volume V^E was calculated from density data which are given in Figs. 2(a), (b), (c) and (d) for each system. Abscissa x represents the mole fraction of DCE. The accuracy of V^E is about ±0.02 cc/mole. V^E values of DCE-benzene system agree

with literature values.[12–14,19a] The trend of its temperature dependence is also in agreement with the data.[13,14,19a] The values of V^E increase in the order: toluene<benzene<*p*-xylene<cyclohexane.

Sound Velocity. Sound velocity v of all these mixtures deviates negatively from linear addivity in mole fraction, and the deviation decreases with rising temperature. Sound velocity *vs.* concentration curve of DCE-xylene system is shown in Fig. 3 as an example. The sound velocity of DCE-benzene system was measured by several workers,[18–20] and that of DCE-cyclohexane system by Kohler *et al.*[19b] Our data for these two systems are in good agreement with those of Kohler *et al.*

Compressibility. From the values of sound velocity v and density d, adiabatic compressibility

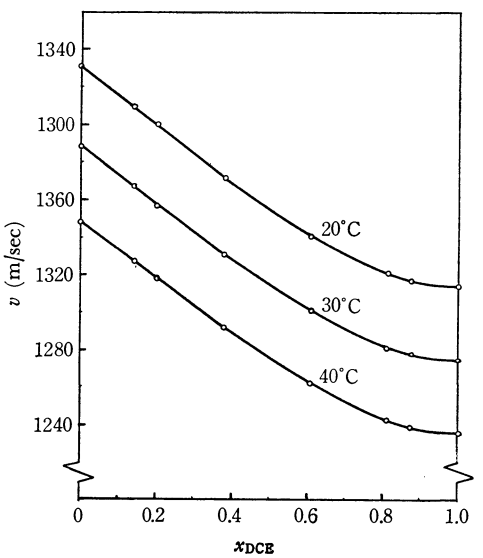

Fig. 3. Sound velocity for DCE-*p*-xylene system.

κ_s has been calculated by means of the relation

$$\kappa_s = \frac{1}{v^2 \cdot d} \tag{1}$$

The κ_s of the pure liquids obtained are given in Table 1. The uncertainty in κ_s is within $\pm 0.1\%$. Values of κ_s of pure liquids are in agreement with the values obtained by Kohler *et al.*[19]

The excess adiabatic compressibility κ_s^E and $(V\kappa_s)^E$ are calculated from κ_s and molar volume V of mixtures and pure components by the equations

$$\kappa_s{}^E = \kappa_s - \frac{1}{V}(x_A V_A \kappa_{s,A} + x_B V_B \kappa_{s,B}) \tag{2}$$

$$(V\kappa_s)^E = V \cdot \kappa_s - (x_A V_A \kappa_{s,A} + x_B V_B \kappa_{s,B}) \tag{2'}$$

$(V\kappa_s)$ becomes linear in mole fraction if a system behaves as an ideal solution.*6 $(V\kappa_s)^E$ *vs.* concentration curves are shown in Figs. 4(a), (b), (c) and (d) for each system.

All κ_s^E and $(V\kappa_s)^E$ are positive. The values increase in the order: benzene$\lesssim$toluene$<$xylene$<$cyclohexane. The temperature coefficients are all positive except for the DCE-benzene system, whose coefficient is found to be zero within experimental error.

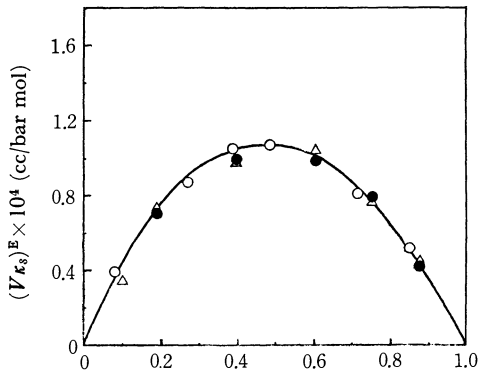

Fig. 4(a). $(V\kappa_s)^E$ for DCE-benzene system. Temperature: ○ 20°C, △ 30°C, ● 40°C

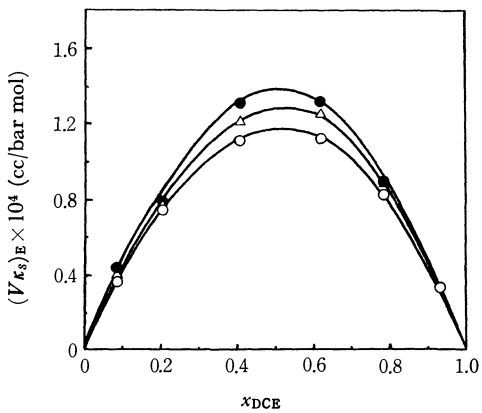

Fig. 4(b). $(V\kappa_s)^E$ for DCE-toluene system. Temperature: ○ 20°C, △ 30°C, ● 40°C

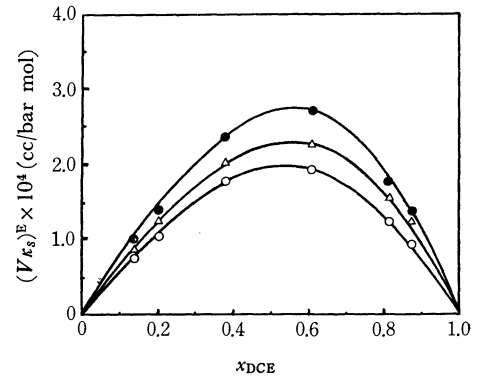

Fig. 4(c). $(V\kappa_s)^E$ for DCE-*p*-xylene system. Temperature: ○ 20°C, △ 30°C, ● 40°C

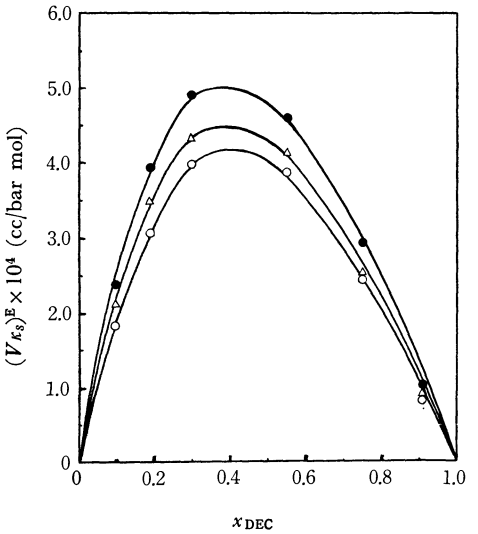

Fig. 4(d). $(V\kappa_s)^E$ for DCE-cyclohexane system. Temperature: ○ 20°C, △ 30°C, ● 40°C

The adiabatic compressibility of DCE-benzene system has been obtained by several workers.[18-20] Stavely *et al.*[18] reported that the temperature coefficient of κ_s^E for this system was slightly positive. However, in our measurements, the coefficient is almost zero within experimental error.

For each system, the data of excess adiabatic compressibility κ_s^E and the excess molar volume V^E

fit with the equation of the type

$$\kappa_s^E = x(1-x)\sum_{i=0}^{2}A_i\cdot(2x-1)^i$$

$$V^E = x(1-x)\sum_{i=0}^{2}B_i\cdot(2x-1)^i$$

where x is the mole fraction of DCE. The coefficients A_i and B_i, which were determined for each system by the method of least squares using FACOM 270—20 Computer, are given in Table 2.

Discussion

Thermodynamical Function. Let us discuss thermodynamical properties of the systems by means of the statistical theory given previously.[17] Excess volume V^E, excess entropy S^E and an interaction energy parameter θ*[7] are calculated for equimolar

mixtures, using the molecular parameter listed in Table 3. They are given in Table 4, together with the observed values of excess enthalpy H^E (lit. values) and V^E. The values for the 1,2-dibromoethane (DBE)-benzene system and those for the other four binary systems containing an aromatic solvent as a component are also given in Table 4 for comparison.

We see appreciable differences between the three DCE-aromatic solvent systems and others. The values θ for these systems are all positive, and their magnitudes are in the order of aromatic basicity.[26,27] On the contrary, those for six other systems, in which the DCE-cyclohexane and the DBE-benzene systems are included, are all negative. The values of $TS^E_{obs.}$ for the DCE-aromatic solvent systems are found to be less than those for the DBE-benzene system and those for the aromatic-alicyclic systems. This supports the idea that a certain specific but weak attraction is present between DCE and aromatic molecules. The values of $TS^E_{calc.}$ for the aromatic-alicyclic systems are about half as much as $TS^E_{obs.}$. This might be ascribed to the presence of a certain ordered structure in aromatic liquids.[17] The fact that the values of $V^E_{calc.}$ for these DCE-aromatic systems are less than those of $V^E_{obs.}$ in contrast to the good agreement between $V^E_{calc.}$ and $V^E_{obs.}$ for other systems is also attributed to a certain attraction between DCE and aromatic molecules.

Compressibility. The values of κ_s^E obtained for the DCE-aromatic system are found to increase in the order : benzene, toluene, xylene and cyclohexane. The values of $(V\kappa_s)^E$ and κ_s^E of DCE-xylene system are about half as small as those of DCE-cyclohexane system in spite of the fact that molar volume of xylene is larger than that of cyclohexane. This shows that DCE molecules is more interacting with aromatic molecules than with cyclohexane.

Let us compare theoretical values $\kappa^E_{t,calc.}$ with experimental ones, using an approximate formula on excess compressibility[28] derived from the solution theory.[17] We have

$$\kappa_t^E = \frac{1}{3RT}\left[\frac{(V-V^*)^2}{V} - \frac{1}{V}\{(V_A-V^*_{AA})^2x_A+(V_B-V^*_{BB})^2x_B\}\right] \quad (3)$$

where V^* is $V^*_A \cdot x_A + V^*_B \cdot x_B$ and other notations are the same as those in the preceding paper.[17] From the values of sound velocity, we can get the adiabatic compressibility κ_s. κ_s^E can be transferred to excess isothermal compressibility κ_t^E, using the thermodynamical relation

$$\kappa_t = \kappa_s + \frac{V \cdot T \cdot \alpha^2}{C_p} \quad (4)$$

The values of excess specific heat C_p^E are available from literature. The values of κ_t^E obtained for equimolar mixtures are given in column 7 of Table 5, together with the values of $V^E_{obs.}$, $C^E_{p,obs.}$ and $\kappa^E_{s,obs.}$ used (those of pure components are given in Table 3.). On the other hand, κ_t^E can be calculated by Eq. (3) from the observed V^E. The $\kappa^E_{t,calc.}$ are listed in the last column of Table 5, and those for the DBE-benzene system are included for comparison.

The $\kappa^E_{t,obs}$ for all the systems are in good agreement with $\kappa^E_{t,calc.}$. The agreement is good also with respect to its temperature dependence for the DCE-benzene and DCE-cyclohexane system. This supports the idea that the interaction between DCE and aromatic molecules obeys the 6th power rule with respect to intermolecular distance.[17]

Solute-Solvent Interaction. From the consideration on thermodynamical quantities and compressibility it is evident that there is a weak but specific interaction*[8] between DCE and aromatic molecules, which is too small and insufficient for the formation of a complex between solute and solvent molecules.

There have been two interpretations for the nature of this interaction. The first one was given by Ruiter,[14] Neckel and Volk[29] and others.[6,7] They proposed that it is a hydrogen-bonding (proton-donor-acceptor) interaction between the protons of *gauche* form of DCE and π electrons of aromatic molecules. However, the magnitude of $\varepsilon_{AB}-(\varepsilon_{AA}+\varepsilon_{BB})/2$*[8] is evidently too small to support the presence of a hydrogen-bonding between species A and B, where A is DCE and B is an aromatic. The situation is quite similar with respect to the presence of a charge transfer complex (electron-donor-acceptor). The hydrogen-bonding interaction can not explain the presence of "benzene effect" for the 2,3-dihalo-2,3-dimethylbutane-benzene system, in which all hydrogen atoms in DCE or DBE are replaced by methyl groups.[4]

This type of interaction, the so-called "benzene effect", is widely observed in binary mixtures of substituted dihaloethanes and haloketone with aromatic solvents.[5,30,31] The data on the shift of C–H stretching in Raman and infrared spectroscopy[6,32] do not support the presence of hydrogen-bonding in substituted dihaloethane-aromatic solvent systems.

It is concluded that there is no appreciable complex formation between DCE and aromatic molecules, and that the solute-solvent interaction is not ascribed to hydrogen-bonding or charge transfer.

There remains the second interpretation that it is an electrostatic interaction which is of a more general nature. The *gauche* form of DCE molecule has a large dipole moment and aromatic molecules are greatly polarizable. Thus, for the DCE-aromatic system the dipole-induced dipole interaction is considered to play an important role.

As seen in Table 4, the magnitudes of θ for DCE-aromatic systems are positive but at the most of the order of a few %. This shows that the interactions between DCE and aromatic molecules are of a similar nature to those between each identical molecules themselves, and supportes the results that it is the dipole-induced dipole interaction. The same idea was recently presented on the basis of NMR, dielectric and spectroscopy data.[30–33]

It is concluded that the interaction between DCE and aromatic molecules is not hydrogen-bonding and is of electrostatic nature (dipole-induced dipole or hyperpolarizability).

We wish to thank Mr. T. Kabashima for his cooperation in carrying out this study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3044—3048 (1970)

An Application of the Phase-inversion-temperature Method to the Emulsification of Cosmetics. I. Factors Affecting the Phase-inversion Temperature

Takeo MITSUI, Yasuhiko MACHIDA and Fuminori HARUSAWA

Shiseido Research Laboratory, Nippa-cho, Kohoku-ku, Yokohama

(Received February 24, 1970)

Recently, the PIT (phase-inversion-temperature) system was originated and developed by Shinoda and his collaborators as a guide to surfactant selection. In order to apply the PIT system to the cosmetic field, the effects of various factors on the PIT have been reinvestigated using cosmetic materials. POE alkyl ethers, whose distribution of EO chain lengths is broad, are widely used in cosmetics. In such a case, the effect of the distribution of the EO chain lengths is important. When a surfactant with a distribution of EO chain lengths was used, the PIT was lowered by an increase in the concentration of the surfactant, but when a monodisperse surfactant without any distribution was used, the PIT scarcely varied with the concentration of the surfactant. In the case of the surfactant with a distribution of EO chain lengths, however, if the ratio of oil to surfactant was kept constant, the PIT scarcely varied with the ratio of oil phase to water phase. This relationship can be used in estimating the PIT in the case of the practical production of an emulsion.

An emulsion stabilized with a certain non-ionic surfactant changes its type from the oil-in-water type (O/W) to the water-in-oil type (W/O) as the temperature rises. The emulsion tends to form a W/O type because the affinity of the ethylene oxide (EO) chain of the surfactant for water is weakened at higher temperatures.

The phase-inversion temperature (PIT), at which the emulsion inverts its phase, has been adopted by Shinoda[1] as a guide for choosing a suitable type of emulsifier and for estimating the effects of additives because of its precise indication of the characteristics of the emulsion.

The factors which affect the PIT of the emulsion are[1-12]:

1. the nature of the hydrophilic and lipophilic moieties of the surfactant;
2. the mixing of the surfactants;
3. the nature of the oil;
4. the nature of the additives of the oil and water phases;
5. the concentration of the surfactant;
6. the ratio of oil phase to water phase, and
7. the distribution of EO chain lengths in the surfactant.

In the present study the effects of the above-mentioned factors on the PIT were investigated using cosmetic materials in order to establish the application of the PIT system[1] to the emulsification of cosmetics.

Furthermore, as the PIT is greatly affected by the distribution of EO chain lengths in the surfactant when an oil-soluble surfactant on the market is used, a comparison test was carried out with monodisperse surfactants.

Experimental

Samples. Liquid paraffin, whose Saybolt viscosities were 50 sec, 70 sec and 350 sec at 100°F, dodecane (purity: 98.9%), tetradecane (purity: 99.5%), and squalane were used as the oil bases.

POE ($\bar{n}$=3.7, 4.8, 6.2, 6.9, 8.1 mol) oleyl ether, POE ($\bar{n}$=4.8, 5.9, 6.7, 7.5) stearyl ether, POE ($\bar{n}$=4.0, 5.0 mol) lauryl ether (Nihon Emulsion Co.), and POE (n=4.0, 5.0, 6.0, 7.0, 8.0 mol) lauryl ether (Nikko Chemical Co.; purity: 95—98%, a monodisperse surfactant) were used.

Solid paraffin (mp 62.8°C), oleic acid (purity: 88.0%), oleyl alcohol (purity: 79.5%), lauryl alcohol (purity:

95.0% or over), 2-octyldodecanol (Dehydag Co.), and castor oil (purity: 86.0%) were studied as additives.

Methods. Oil, water, and surfactant were weighed into the same beaker, and then heated with stirring in order to make an emulsion, the total amount being 100 g. The PIT of the emulsion was determined by an electric conductivity device. The reproducibility of the measurements was within ± 1°C.

Results and Discussion

Effect of the HLB Value of the Surfactant and the Nature of Oil on the PIT. Figure 1

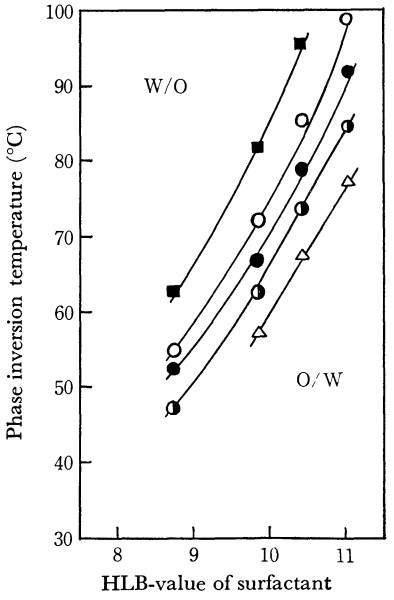

Fig. 1. Effect of different hydrocarbons on PIT *vs.* HLB-value of surfactant.
Surfactant: POE stearyl ether, 5 wt%/system
Phase ratio: 0.5 (wt).

shows the effect of the HLB value of the surfactant and the kinds of oils on the PIT. As has already been pointed out by Shinoda and Arai,[3] the PIT's rose almost linearly with the increase in HLB values, and the rising rates were almost identical in all the liquid paraffins used. The PIT's varied with the nature of the oils used, even though surfactants with the same HLB values were used; the greater lipophilic the oil, the higher the PIT. This fact can be explained in terms of the difference in the required HLB values of the oils.

Effect of Additives on the PIT. Shinoda *et al.* studied the effect of added salts in water on the PIT,[10] and Aoki *et al.* studied some oil-soluble components.[6] We have studied the effect of additives on the oil phase because cosmetics always contain several additives in the oil phase. Figure 2 shows

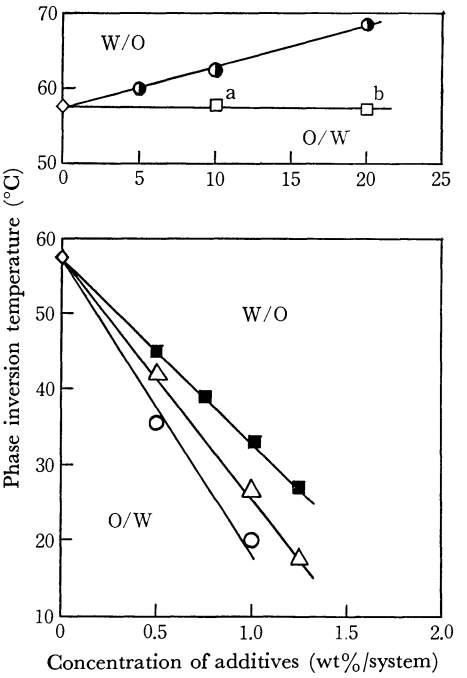

Fig. 2. Effect of different additives on PIT.
Oil: liquid paraffin (Saybolt vis. 70) plus additives.
Surfactant: POE ($\bar{n}$=4.8) oleyl ether, 4 wt%/system.
Phase ratio: 0.5 (wt).

the effects of some oil-soluble additives on the PIT of a three-component system, consisting of liquid paraffin (70 Saybolt viscosity at 100°F), POE (4.8 mol) oleyl ether, and water. When liquid paraffin was replaced with 20% of solid paraffin, which is a non-polar substance, the PIT rose about 10°C. On the contrary, when it was replaced with only 1% of oleyl alcohol, lauryl alcohol, or oleic acid, which are polar substances, the PIT fell about 20—40°C. When a mixture consisting of solid paraffin and oleyl alcohol (the former raises the PIT, while the latter lowers it) in an appropriate ratio was added to the system, it showed the same PIT as the one to which no additive had been added. Thus, when a small quantity of an additive was added to the oil phase, the PIT rose or fell monotonously according to the quantity added. In the cases of 2-octyldodecanol, castor oil, etc., however, as is shown in Fig. 3, the minimum value of the PIT appeared.

Effect of the Concentration of the Surfactant and the Ratio of Oil Phase to the Water Phase on the PIT. The relationship between the concentration of the surfactant and the PIT was in-

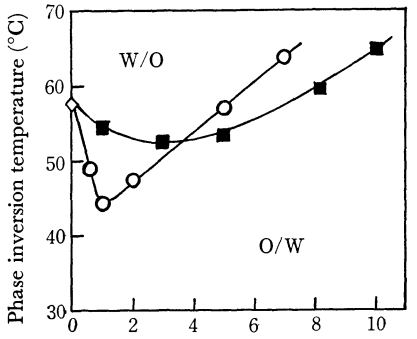

Fig. 3. Effect of castor oil and 2-octyldodecanol on PIT.

vestigated by Shinoda *et al.*[3,9,10] using POE alkyl phenyl ether. In the present study, this relationship was reinvestigated using POE alkyl ether, whose distribution of EO chain lengths is broad. The results are shown in Fig. 4. As the concentration of the surfactant increased, the PIT was lowered very steeply compared with the case[3] of POE alkyl

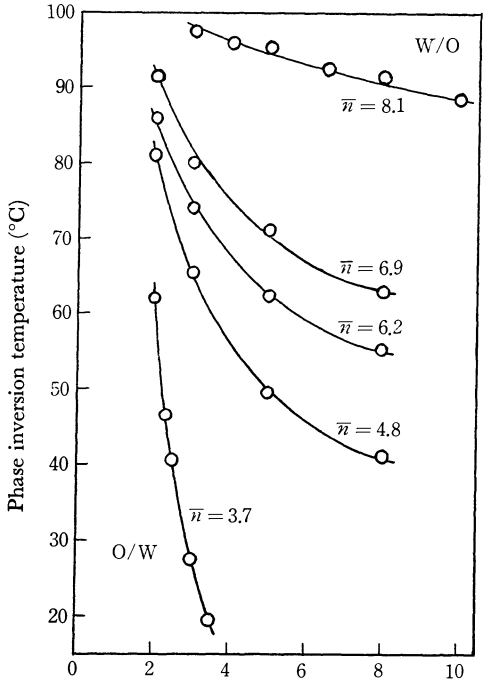

Fig. 4. Effect of ethylene oxide chain length on PIT *vs.* concentration of POE oleyl ether.

phenyl ether. Especially in the case of a surfactant with a shorter EO chain, the falling rate of the PIT was remarkable. It was found that the effect of the distribution of EO chain lengths on the PIT is greater when the average EO chain length is shorter.

The effect of the phase ratio on the PIT was studied using various concentrations of POE oleyl ether, the average EO chain length of which was 4.8 mol. The results are shown in Fig. 5. As the oil-phase ratio became higher, the PIT rose more steeply compared with the case[3] of POE alkyl phenyl ether in a non-polar oil. Furthermore, the lower the concentration of surfactant, the higher the rate of the rise of PIT. However, it can be found from Fig. 5 that when the ratio of the oil to the surfactant is constant, almost the same PIT can be obtained in the same manner as with POE alkyl phenyl ether.[12] For example, the PIT of 50°C is obtained when the oil-phase ratio: concentration of surfactant is 0.2 : 2%, 0.3 : 3%, or 0.4 : 4%.

Therefore, while keeping the ratio of oil to the surfactant fixed, the PIT's were measured at various oil-phase ratios. As is shown in Fig. 6, even though the ratio of oil phase to water phase varied in the range of 0.2—0.8, the PIT was almost constant if the ratio of the oil to the surfactant was fixed. Furthermore, the higher the ratio of the surfactant in the oil phase, the lower the PIT.

In the case of the practical production of emulsion, it would be very convenient if the PIT could be calculated. Therefore, utilizing the above-men-

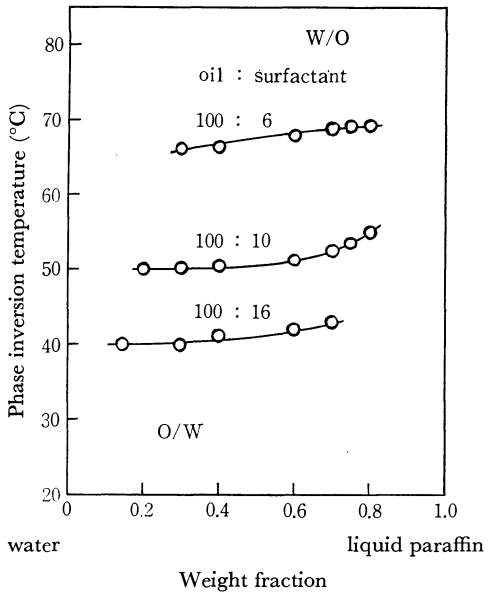

Fig. 6. Effect of phase ratio on PIT in various ratios of surfactant to oil.

Surfactant: POE ($\bar{n}$=4.8) oleyl ether.

tioned relationship, the PIT's were plotted *vs.* the ratio of the oil to the surfactant as well as the ratio of water to the surfactant, as is shown in Fig. 7. It can be found from Fig. 7 that the PIT rises almost linearly with the increase in the ratio of the oil to the surfactant. If such a straight line has been obtained by measuring two PIT's at two different ratios of oil to surfactant, the PIT of a given system can be estimated from its components, *i.e.*, the concentration of the surfactant and the ratio of oil phase to water phase. For example, in the case of a 3% concentration of the surfactant and an oil-phase ratio of 0.3, it can be estimated from Fig. 7 that the PIT is about 50°C.

Effect of the Distribution of the EO Chain Lengths in the Surfactant on the PIT. When the concentration of the surfactant was increased, the PIT was lowered, as is shown in Fig. 4. In the case of a surfactant whose average EO chain length is short, the falling rate of the PIT was very high.

Dodecane was used as the oil phase; it was emulsified with POE lauryl ethers with and without the distribution of EO chain lengths. The relationship between the PIT and the concentration of the surfactant is shown in Fig. 8. When a surfactant with a distribution of EO chain lengths was used, the PIT varied greatly with the concentration of the surfactant. However, when a monodisperse surfactant was used, the PIT scarcely varied, though the concentration of surfactant did vary. When a mixed surfactant of POE ($n=8$ mol) lauryl ether and POE ($n=4$ mol) lauryl ether, which are both monodisperse surfactants, was used, the PIT rose upon a decrease in the concentration of the mixed surfactant, as in the case of using a surfactant with a distribution of EO chain lengths. It can be assumed that the ratio of a surfactant with a shorter EO chain to one with a longer EO chain decreased at the interface upon a decrease in the concentration of the mixed surfactant, because the CMC of a nonionic surfactant in oil is far higher that the CMC in water; the average EO chain length of a surfactant affecting phase inversion increased, and the PIT rose.

From the same point of view, the relationship between the PIT and the mixing ratio of the surfactants was investigated using monodisperse surfactants. The results are shown in Fig. 9. The curves are convex, and when the surfactants are mixed the PIT moves to a higher position.

The Structure Theory of Water. III. The Order-Disorder Theory

Kiyoshi ARAKAWA and Katsutaka SASAKI

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received April 2, 1970)

Taking into account the cooperative nature of cluster formation, we applied the order-disorder theory, using Bragg and Williams's approximation, to liquid water based on a two state model. The two state model consists of hydrogen-bonded molecules arrayed on α-sites in a tetragonal lattice and non hydrogen-bonded molecules on β-sites in the lattice. A partition function was formulated and calculated. The calculated energy difference, ε, between the molecules on β-sites and those on α-sites decreased continuously with the rise of temperature. Thermodynamic variables of liquid water were calculated at each temperature, where no adjustable parameter was used. Agreement between calculated values and observed ones is fairly good.

The structure of liquid water has been studied by many workers recently,[1,2] but conclusive results are still lacking. In advancing the structure theory of water, the models used are classified into two groups, a multi-state theory and a uniform-state theory. In the former, it has been assumed that liquid water consists of several distiguishable molecular species. Némethy and Scheraga[3] proposed a statistical theory of liquid water based on the model. Eyring and coworkers[4] applied a "significant structure theory" to water. In the preceding paper,[2] we stated that a simple two state theory could explain thermodynamic properties of water. Thus, we pointed out that the principal feature of multi-state theories was described by the two state theory. Existence of two different molecular species in liquid water has been supported experimantally by Luck[5] and Walrafen[6] from spectroscopic data.

Recently, Frank and Franks[7] have discussed the structural change of water caused by the presence of solute in aqueous solutions of urea, using a two state model. The application of two state theory to aqueous solutions has given fairly good results,

as Holtzer and Emerson[8] and Ben-Neim and Stillinger[9] have reported. Our data of ultrasonic absorption[10] have shown that a two state model represents the structure of solvent water in aqueous solutions.

Studies based on the uniform-state model have been made since Pople[11] proposed a distored hydrogen-bond model. Einberg and Kauzmann[12] have pointed out the utility of distorted hydrogen-bond models. The "uniform nature" of the structure of water has been emphasized in the interpretation of spectroscopic data by Wall and Hornig,[13] Falk and Ford[14] and Franck and Roth.[15] However, no explanation of the origin of ultrasonic absorption such as made by Hall and others[16] using a two state model has been given by the uniform-state theory.

Though no decisive conclusion has been obtained, various attempts in the field of the structure theory of water have been made. However, one of the most important problems left unsolved at present is the direct introduction of the cooperative nature of the structure formation into theory. Thus, we attemped here an application of order-disorder theory[17] to explain thermodynamic properties of water on the basis of a two state model. The cooperative nature of "cluster" ("open-packed structure") formation are taken directly into account.

Theory

Model. As pointed out recently by Narten *et al.*[18] from X-ray diffraction data, liquid water consists of an ice-like structure and unbonded molecules.[18–20] The ice-like structure is believed to be a partly-broken lattice linked tetragonally by hydrogen bonds. It is seen that the number of first nearest neighbours in liquid water varied from 4.4 to 4.9 at temperatures 1.5—83°C.[21]

In the formulation of the following statistical theory, we assume that all molecules are distributed in a body-centered cubic lattice,[22] and that water is an equilibrium mixture of molecules arranged in two kinds of sites, α and β, in the lattice, as shown in Fig. 1. Hydrogen-bonded molecules occupy α-sites forming a tetragonal sub-lattice, and non-hydrogen-bonded molecules occupy β-sites. The energy level of molecules on β-sites is higher than that on α-sites. At 0°K in a "completely-ordered state" all molecules occupy only α-sites forming an ice-like structure. With the rise of temperature, population of α-sites decreases and that on β-sites increases, causing patial break-down of the ice-I-like structure. At a "completely-disordered state," two kinds of sites are occupied with equal probability.

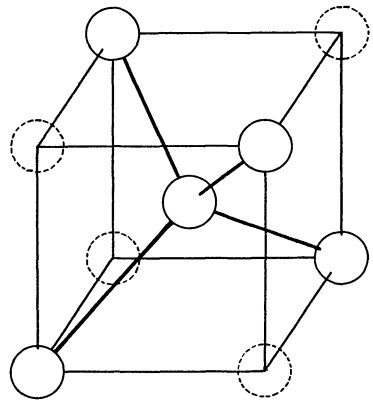

Fig. 1. α and β-site in a body-centered cubic lattice.
○ α-site, ◌ β-site

Application of Order-Disorder Theory. The total partition function, Z, is given by

$$Z = W f_\alpha^{N_\alpha} f_\beta^{N_\beta} \exp(-H/RT) \tag{1}$$

where W is a combinatorial factor, H potential energy, T temperature, N_α and N_β are the number of molecules arranged in each site, and f_α and f_β are the molecular partition functions for molecules in each site, respectively. The combinatorial factor and the potential energy are defined by

$$W = \frac{[\alpha]!}{N_\alpha!([\alpha]-N_\alpha)!} \cdot \frac{[\beta]!}{N_\beta!([\beta]-N_\beta)!} \tag{2}$$

$$H = N_\alpha V_\alpha + N_\beta V_\beta,\ N_\alpha + N_\beta = N \tag{3}$$

where $[\alpha]$ and $[\beta]$ are the number of each kind of lattice site ($[\alpha]=[\beta]=N$), V_α and V_α the potential

energy of molecules on α and β-sites, respectively, and N is the total number of molecules. We define as usual the degree of order, s, in relation to N_α and N_β.

$$N_\alpha = \frac{N(1+s)}{2},\ N_\beta = \frac{N(1-s)}{2} \tag{4}$$

Introducing Eq. (4) into Eq. (2), we obtain the combinatorial factor, *viz.*,

$$W = \left[\frac{N!}{\left\{\frac{N(1+s)}{2}\right\}!\left\{\frac{N(1-s)}{2}\right\}!}\right]^2 \tag{5}$$

The degree of order, s, is determined by minimization of the Helmholtz energy, A, with respect to s. Thus, in equilibrium, we have

$$\frac{\partial A}{\partial s} = 0 \tag{6}$$

where

$$A = -kT\ln Z \tag{7}$$

In carrying out calculation, Bragg and Williams's approximation[17] concerning the relation between the energy for the exchange of molecules on different kinds of sites and the degree of order s is applied.

When the approximation is made as usual, $V_\beta - V_\alpha$ should be proportional to s. Thus, we have

$$V_\alpha = \frac{V^0(1+s)}{2},\ V_\beta = \frac{V^0(1-s)}{2} \tag{8}$$

from the consideration that $V_{\alpha,s=0} = V_{\beta,s=0}$ in the completely-disordered state. This condition is regarded as a special case of $\mu_{\alpha,s=0} = \mu_{\beta,s=0}$ where μ_α and μ_β are chemical potentials of the molecule on each site. Thus, in the present case, $V_{\alpha,s=0} \neq V_{\beta,s=0}$,*1 because the molecular partition function f_α is not identical with f_β.

Let us put

$$V_\alpha = V_\alpha^0\left(\frac{1+s}{2}\right),$$
$$V_\beta = V_\beta^0\left(\frac{1-s}{2}\right) \tag{8'}$$

and $V_\alpha^0 \neq V_\beta^0$.

We assume that at boiling point a complete randomness is realized. Thus, s should vanish at boiling point, and the chemical potential of the molecule on α-site should be equal to that on β-site at that temperature, as follows:

$$\frac{V_\alpha^0}{2} - kT_b\ln(f_\alpha)_{T=T_b} = \frac{V_\beta^0}{2} - kT_b\ln(f_\beta)_{T=T_b} \tag{9}$$

and we have

$$V_\alpha^0 - V_\beta^0 = -2kT_b\ln\left(\frac{f_\beta}{f_\alpha}\right)_{T=T_b} \tag{9'}$$

where a subscript b represents boiling point. When Eqs. (5), (7), (8') and (9') are inserted into Eq. (6), we obtain

$$\ln\left(\frac{1+s}{1-s}\right) = -\frac{1}{4kT}(V_\alpha^0 + V_\beta^0)\,s + \frac{1}{2}\left\{\frac{T_b}{T}\ln\left(\frac{f_\beta}{f_\alpha}\right)_{T=T_b} - \ln\left(\frac{f_\beta}{f_\alpha}\right)\right\} \tag{10}$$

Equation (10) is a fundamental equation which determines s as a function of temperature. The second term on the right hand side of Eq. (10) vanishes at $s=0$ ($T=T_b$) more rapidly with the decrease of s than the first term. The usual procedure in the application of Bragg and Williams's approximation can be used. We have

$$V_\alpha^0 + V_\beta^0 = -8kT_b \tag{11}$$

and

$$V_\alpha^0 = -kT_b\left\{4 + \ln\left(\frac{f_\beta}{f_\alpha}\right)_{T=T_b}\right\} \tag{12}$$

$$V_\beta^0 = -kT_b\left\{4 - \ln\left(\frac{f_\beta}{f_\alpha}\right)_{T=T_b}\right\} \tag{12'}$$

Combining Eqs. (11) and (12) with Eq. (10), we have

$$\ln\left(\frac{1+s}{1-s}\right) = \frac{2T_b}{T}s + \frac{1}{2}\left\{\frac{T_b}{T}\ln\left(\frac{f_\beta}{f_\alpha}\right)_{T=T_b} - \ln\left(\frac{f_\beta}{f_\alpha}\right)\right\} \tag{13}$$

Eq. (13) is used for the calculation of s. Introducing Eqs. (4), (12) and (12') into Eq. (3), we have

$$H = -NkT_b(1+s^2) - \left\{\frac{NkT_b}{2}\ln\left(\frac{f_\beta}{f_\alpha}\right)_{T=T_b}\right\}s \tag{14}$$

Thus, we can calculate the Helmholtz energy A, internal energy E, and entropy S, from the following equations.

$$A = -NkT\{2\ln 2 - (1+s)\ln(1+s) - (1-s)\ln(1-s) + \frac{(1+s)}{2}\ln f_\alpha + \frac{(1-s)}{2}\ln f_\beta\} - NkT_b(1+s^2) - \left\{\frac{NkT_b}{2}\right)\ln\left(\frac{f_\beta}{f_\alpha}\right)_{T=T_b}\Big\}s \tag{15}$$

$$E = \frac{NkT^2}{2}\left\{\left(\frac{1+s}{f_\alpha}\right)\frac{\partial f_\alpha}{\partial T} + \left(\frac{1-s}{f_\beta}\right)\frac{\partial f_\beta}{\partial T}\right\} - NkT_b(1+s^2) - \left\{\frac{NkT_b}{2}\ln\left(\frac{f_\beta}{f_\alpha}\right)_{T=T_b}\right\}s \tag{16}$$

$$S = \frac{(E-A)}{T} \tag{17}$$

The molecular partition function for each site, f_α and f_β, are given by the following equations.[2]

$$f_\alpha = \prod_{i=1}^{6}\left\{1 - \exp\left(\frac{-h\nu_i}{kT}\right)\right\}^{-1} \tag{18}$$

*1 In an ordinary application of Bragg and Williams's approximation the difference between f_α and f_β is not taken into account. Thus, from the equal probability for the occupation of each site at $s=0$, it necessarily follows from the general condition $\mu_{\alpha,s=0} = \mu_{\beta,s=0}$ that $V_{\alpha,s=0} = V_{\beta,s=0}$.

$$f_\beta = \prod_{i=1}^{3} \left\{1 - \exp\left(\frac{-h\nu'_i}{kT}\right)\right\}^{-1} \cdot \frac{(8\pi kT)^{3/2}(\pi ABC)^{1/2}}{2h^3} \quad (19)$$

ν_i is the frequency of intermolecular vibration for α-site which includes translational and rotational ones. ν_i' is the frequency of translational vibrations for β-site. A, B and C are principal moments of inertia of water molecule. In the derivation of Eq. (19), the molecules on β-sites are assumed to be free rotators. In the calculations of f_α and f_β, the contribution from intramolecular vibrations is nearly 1 at temperatures 0—100°C, and thus ignored.

Results

Procedure of Calculation. As seen in Eq. (12), $V_\alpha{}^0$ is the potential energy of water molecules on α-sites at the completely-ordered state ($s=1$, 0°K) so that it is twice the energy for breaking hydrogen bond. The amount of energy can be calculated from Eq. (12) without any additional assumptions. The energy difference, ε, between the molecules on β-sites and those on α-sites is obtained as follows.

$$\varepsilon = V_\beta - V_\alpha = NkT_b\left\{4s + \ln\left(\frac{f_\beta}{f_\alpha}\right)_{T=T_b}\right\} \quad (20)$$

We evaluated the magnitude of ε at $s=1$ to be 4.33 kcal/mol and at $s=0$ 1.36 kcal/mol. The energy difference between two species of molecules for various treatments based on two state model is tabulated in Table 1. The values are distributed within the range 2.4—4.5 kcal/mol. Our value seems to be reasonable on the average compared with those by others.

The degree of order, s, is within the range of 0—1 at temperatures from 100°C to 0°K. The equilibrium value of s at a given temperarute is determined graphically using Eq. (13) as shown in Fig. 2, where the lines (a), (b) and (c) are the plot of the right hand side of Eq. (13) at 0, 50 and 100°C, respectively. The calculated values of s are plotted against temperature in Fig. 3. The obtained value of s at 0°C is 0.83.

In the assignment of intermolecular vibration of water molecules, there are some ambiguities.[1-3] For the three modes of translational vibrations on

each site, a common value of 180 cm^{-1} [23] is assigned, and 500, 650 and 750 cm^{-1} are assigned[24,25,2] for each mode of librations for α-site. The principal moments of inertia for a free rotator molecule is the same as in vapor state; $A=1.024\times10^{-40}$, $B=1.921\times10^{-40}$, and $C=2.947\times10^{-40}$ [2,26]

Calculation of Thermodynamic Variables. With the value of s determined graphically, calculation of thermodynamic functions has been made over the temperature range 0—100°C at 10°C intervals. The obtained values of Helmholtz energy A, internal energy E and entropy S are given in Table 2, and are plotted against temperature in Fig. 4—6. The results calculated are compared with the observed data for water.[27] The fraction $x=(1+s)/2$ of the molecules on α-sites is tabulated

together with other thermodynamic variables in Table 2. The calculated value of A are satisfactory on the whole. The calculated value of E increases rapidly with increasing temperature at higher temperatures. This can be interpreted by the variation of s with rising temperature, which falls off rapidly near boiling point. But deviation of the calculated results from experimental data is not so large. Agreement of thermodynamic functions calculated with observed values is satisfactory, taking into account the fact that no adjustable parameters are used in the present calculation as in the former theories.

Discussion

Cooperative Formation and Destruction of Ice-like Structure in Liquid Water. From various kinds of relaxational processes in water, Frank and Wen[28] pointed out that the lifetime of ice-like

structure in liquid water was the order of 10^{-11}—10^{-10} sec. The cooperative nature of the formation and destruction of ice-like structure (clusters) has been pointed out by many workers. However, the cooperative effect itself has never been directly treated theoretically in these studies. Consequently, the clusters in liquid water have been treated like a "solid". Gurikov[29] criticized Némethy and Scheraga's theory, in this respect. Perram and Levine[30] also pointed out an inadequate procedure in Némethy and Scheraga's theory in which geometrically impossible configurations of five species were included for the calculation of the combinatorial factor. In the present situation of the structure theory of water, it is emphasized that the cooperative process of cluster formation should be introduced directly in forming the theory. Thus, we have introduced the cooperative nature of cluster formation through the application of the order-disorder theory on the basis of a two state model.[19,20] This is an essential feature in the present theory.

Parameters used in Theories. In this study, the degree of order, s, has been used as only one parameter, which determines all thermodynamic variables of water. The value of s at equilibrium has been determined by minimizing the free energy. Thus, this theory has no adjustable parameter practically. In Némethy and Scheraga's theory, free volume, v_f, and energy difference, ε, between the tetra-hydrogen-bonded state and the unbonded state were used as adjustable parameters. In our previous paper,[2] v_f and ε were used as adjustable parameters, which were determined to give the best fit to experimental data as made in Némethy and Scheraga's theory. Thus, the present theory has a merit that no adjustable semi-empirical parameters are used.

Weissmann and Blum[31] have recently reported a cell theory in which no adjustable parameter is used. However, their results are far from the observed data. The calculated values in the present theory are seen in fair agreement with observed ones.

Two State Theory and Distorted Hydrogen Bond Theory. The multi-state theories of water have been developed in various forms: Némethy and Scheraga's five species model, Vand and Senior's continuous energy band model[32] and Buijs and Choppin's three state model.[33] We pointed out previously that two state theory could explain most of the observed data as well as multi-state theories. Various multi-state theories are practically reduced to two state theories. The number of states corresponds to the number of parameters which are introduced in the theory. In constructing a theory, the number of parameters is desired to be as small as possible. In this respect, a two state model is superior to a multi-state model consisting of more than two species.

In the discussion of the first report of this series of studies, the authors referred to the presence of a "third state" or "surface state" on the cluster. However, the emphasis of "surface state" has turned out to be inadequate, considering the very short lifetime and the cooperative nature of cluster formation.

On the other hand, various uniform-state models (distorted hydrogen-bonded model) have been proposed by several workers since the presentation of Pople's theory.[11] Eisenberg and Kauzmann[12] have recently claimed that, with rising temperature, hydrogen bonds of water molecules are bent rather than broken. However, concerning the uniform-state model, there are several shortcomings in the explanation of the structure and properties of water. Firstly, the cooperative behavior of cluster formation in liquid water can not be explained by the uniform-state theory. Secondly, the data of ultrasonic absorption have never been explained by the uniform-state theory, while Hall and others[16] succeeded in describing those data using a two state model.

Furthermore, the nature of "hydrophobic interaction" has never been explained by the uniform-state theory, but Némethy and Scheraga succeeded in explaining it by the multi-state theory.[34]

Thus, it may be said that the structure and properties of water have never been described successfully by any uniform-state theory.

The Energy Difference ε between Two States. In our results, the energy difference between both sites continuously decreases as the degree of order decreases with increasing temperature. The magnitude of ε (4.33 kcal/mol at $s=1$ and 1.36 kcal/mol at $s=0$) at each temperature is seem to be reasonable. Up to this time, the energy difference between two structures in the two state theories has been regarded as a constant value in the range of temperature 0—100°C. However, the circumstances of molecules vary with rising temperature, so that the energy difference should decrease as a result of cooperative process. The present theory has succeeded in describing the variation of ε with rising temperature.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3054—3063 (1970)

A Nuclear Magnetic Resonance Study of Copolypeptides of L-Proline with γ-Benzyl-L-glutamate*1,1)

Hirofumi Okabayashi,*2 Rume Sakai and Toshizo Isemura

Division of Physical Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received April 4, 1970)

The nuclear magnetic resonance spectra of the copolymers of L-proline with γ-benzyl-L-glutamate were measured in tetradeuteroacetic acid, deuterochloroform, a mixed solvent (CD_3COOD : $CDCl_3$=4 : 1), and trifluoroacetic acid. The time dependence of the α-CH resonance peaks of copoly-(3 : 1)-(L-proline, γ-benzyl-L-glutamate) and copoly-(1 : 1)-(L-proline, γ-benzyl-L-glutamate) was observed. The NMR spectra of copoly-(1 : 3)-(L-proline, γ-benzyl-L-glutamate) showed no time dependence which can be ascribed to the conformational change in tetradeuteroacetic acid and the mixed solvent. From these experimental facts we concluded that copoly-(3 : 1)-(L-proline, γ-benzyl-L-glutamate) and copoly-(1 : 1)-(L-proline, γ-benzyl-L-glutamate) can assume a poly-L-proline-like helical structure, while copoly-(1 : 3)-(L-proline, γ-benzyl-L-glutamate) can not. Moreover, the ratios of the γ-benzyl-L-glutamate residues which were incorporated into the stable poly-L-proline-II-like helical structure was estimated in copoly-(3 : 1)-(L-proline, γ-benzyl-L-glutamate) and copoly-(1 : 1)-(L-proline, γ-benzyl-L-glutamate).

Poly-L-proline can assume two different conformations, namely, the forms I and II. The structure of poly-L-proline II has been determined by the X-ray diffraction method by Cowan and McGavin[2] and Sasisekharan,[3] who found that the II form has a left-handed helix and that the peptide bonds are in a *trans* configuration. Traub and Shmueli[4] have also found by the X-ray diffraction method that the I form assumes a right-handed helix and that each peptide bond is in a *cis* configuration.

The poly-L-proline takes the I form immediately after the sample is dissolved in organic acids, water, and *m*-cresol. However, it is eventually transformed into the II form.

The first NMR spectra of the poly-L-prolines I and II were reported by Okabayashi, Sakai, and Isemura,[5–7] who observed a marked difference in the magnetic shielding values of the α-CH resonance peaks of the two polymers. The α-CH peaks of the I form appeared at the shielding values of 5.5 ppm in the mixed solvent (deuterochloroform : tetradeuteroacetic acid=8 : 1) and 5.4 ppm in tetradeuteroacetic acid, while that of the poly-L-proline II appeared at 5.2 ppm in tetradeuteroacetic acid. The marked shift of the α-CH resonance peak has been ascribed to the differences in the conformations of the two polymers. During the course of the I→II transition of poly-L-proline in tetradeuteroacetic acid, the two α-CH resonance peaks were observed at 5.2 and 5.4 ppm. However, when the spectrum was measured immediately after the sample has been dissolved in tetradeuteroacetic acid as rapidly as possible, the only α-CH resonance peak of the I form appeared at the magnetic shielding value of 5.4 ppm. The appearance of the α-CH resonance peak of the II form at 5.2 ppm and a gradual increase in the intensity of the resonance peak with the time was observed, whereas the α-CH resonance peak of the I form showed an accompanying decrease in intensity with the time (see Fig. 1).

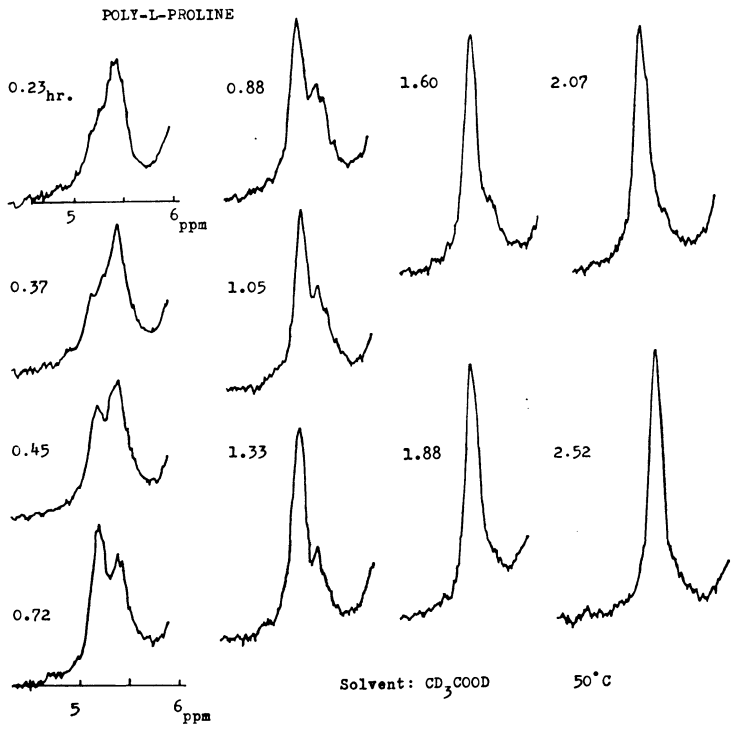
(a) at 26°C



(b) at 50°C

Fig. 1. The time dependence of the NMR spectra of poly-L-proline.

If the temperature is raised, such a transition progresses rapidly. From the ratios of the areas of the α-CH peaks of the I form to those of the II form, the percentages of the I form (or of the II form) during the transition were estimated. The results showed that the α-CH resonance peak of the I form disappeared in thirty hours at 26°C and that the I→II transition was completed within three hours at 50°C. The I→II transition can be concluded to proceed more rapidly than indicated by the measurement by means of the optical rotations.[6]

These studies have now been extended to copolypeptides of L-proline with γ-benzyl-L-glutamate.

In this work the NMR spectra of copoly-(3 : 1)-(L-proline, γ-benzyl-L-glutamate),*3 copoly-(1 : 1)-(L-proline, γ-benzyl-L-glutamate),*3 and copoly-(1 : 3)-(L-proline, γ-benzyl-L-glutamate)*3 were measured and compared with those of the poly-L-prolines I and II and poly-γ-benzyl-L-glutamate.

The steric structures of the copolymers of L-proline with γ-benzyl-L-glutamate in organic solvents have been investigated by Sakai, Ikeda, and Isemura[8] using the methods of the optical rotatory dispersion and the infrared absorption spectra. The results may be summarized as follows.

In 1,2-dichloroethane, which stabilizes the poly-L-proline-I helix and the α-helix of poly-γ-benzyl-L-glutamate, proline residues assume the *cis*-configuration if the copolymers have a proline content of more than 50%. On the other hand, in the copolymers with proline contents of less than 50%, the proline residues tend to take the *trans*-configuration. In an α-helicogenic solvent such as *m*-cresol, the proline residues of the copolymers have the *trans*-configuration, and most benzyl glutamate residues are in random coils in dichloroacetic acid.

Experimental

These copolypeptides, copoly-(3 : 1)-(L-proline, γ-benzyl-L-glutamate), copoly-(1 : 1)-(L-proline, γ-benzyl-L-glutamate), and copoly(1 : 3)-(L-proline, γ-benzyl-L-glutamate), which has been synthesized by one of the present authors, were used in these studies. Table 1 shows the residue mole fractions of the L-proline of the copolymers.[9]

Table 1. Residue mole fraction of L-proline in the copolymers

	A	B	C
Copoly-(3:1)	0.75	0.767	0.756
Copoly-(1:1)	0.50	0.535	0.528
Copoly-(1:3)	0.24	0.274	0.260

A : polymerization ratio,
B : fraction of proline determined from amino acid analysis
C : from absorbance of benzyl residues.

These copolypeptides were synthesized by the copolymerization of *N*-carboxy anhydrides of L-proline and γ-benzyl-L-glutamate in nitrobenzene.

The deuterochloroform (isotopic purity: 99%), tetradeuteroacetic acid (isotopic purity: 99%), trifluoroacetic acid, and tetramethylsilane for spectroscopy were purchased from Merck, Ltd; they were used without further purification.

All the proton magnetic resonance spectra were measured at 100 MHz with the use of a Japan Electron Optics Laboratory (Jeolco), model JNM-4H-100, NMR spectrometer.

A 5% solution of the copolypeptides was used at 26°C in all the experiments.

Results and Discussion

Figure 2 shows the NMR spectra of poly-L-prolines I and II, which were reported in our previous papers.[6,7] All the resonance peaks are fully developed, and their relative areas are proportional to the numbers of protons at the different sites in the polymers. In tetradeuteroacetic

acid the α-CH resonance peak of the I form completely disappeared at 26°C in thirty hours, thereafter only the α-CH resonance peak of the II form was observed, at 5.2 ppm. At 45°C the α-CH peak of the I form disappeared within five hours. During the I→II transition of poly-L-proline, no line broadening or decrease in area was observed.

Figure 3 shows the NMR spectra of poly-γ-benzyl-L-glutamate and those of poly-L-proline in trifluoroacetic acid. Table 2 gives the resonance positions of the NMR spectra of two poly-L-prolines and poly-γ-benzyl-L-glutamate. Bovey's data[10] are also listed in this table.

It is of interest to ascertain whether the changes in the α-CH resonance peak found in the NMR spectra of poly-L-proline can be observed in the copolypeptides of L-proline with γ-benzyl-L-glutamate.

(3 : 1) consists of only one component, which shows the agreement between the position of the α-CH resonance peak of the L-proline residues and that of the γ-benzyl-L-glutamate residues. Poly-γ-benzyl-L-glutamate in deuterochloroform has a right-handed α-helical structure, while the conformation of poly-L-proline in the solvent is considered to be a poly-L-proline-I-like helix, since the value of $[\alpha]_{546}$ is +30° in the mixed solvent (CD_3COOD : $CDCl_3$= 1 : 8).

Figure 4 (B) shows the NMR spectra of the copoly-(3 : 1) in the tetradeuteroacetic acid solution. By measuring the spectra immediately after the sample has been completely dissolved as rapidly as possible, the symmetrical α-CH resonance peak was observed. The magnetic shielding value, 5.45 ppm, of the α-CH resonance peak is almost the same as that of the NMR spectra of poly-L-proline I in tetradeuteroacetic acid. After thirty minutes, the NMR spectrum of the copoly-(3 : 1) gives two components of the α-CH resonance peak at 5.2 and 5.45 ppm. The component of 5.2 ppm is in accord with the α-CH peak of the poly-L-proline II in the position. Considering the α-CH peak at 5.2 ppm, the copolypeptide can be said to assume the structure of the poly-L-proline II. The resonance peak at 5.2 ppm increases in intensity with the time, while the peak at 5.45 ppm decreases in intensity with the time, as in the case of the I→II transition of poly-L-proline. Such behavior of the α-CH resonance peak of copoly-(3 : 1) clearly shows that the copolypeptide has the poly-L-proline-like structure. In the NMR spectra of the copoly-(3 : 1), no line broadening or loss of the peak area of the α-CH resonance was observed during the poly-L-proline-I-like→II transition.

In Fig. 5 the α-CH resonance peak of the copoly-(1 : 1) shows a transition of poly-L-proline I→II similar to that in the case of the copoly-(3 : 1). This fact also suggests that the copoly-(1 : 1) partially assumes a helical structure as does poly-L-proline. In the α-CH resonance of the copoly-(1 : 1), a shoulder at 5.2 ppm was observed, with a main peak of the α-CH resonance at 5.4 ppm in tetra-

Mixed solvent: (CD_3COOD: $CDCl_3$=4 : 1)

deuteroacetic acid. In deuterochloroform, a shoulder at 5.4 ppm was also found, with a main peak of the α-CH resonance at 5.6 ppm. The shoulder at 5.2 ppm may be interpreted as a function of the helical lengths of the copoly-(1 : 1), in which the short chains of the L-proline residues take a poly-L-proline II-like helical structure, judging from the results of our NMR study[11].

Figure 6 shows the NMR spectra of the copoly-(1 : 3) obtained by using a mixed solvent (CD_3-COOD : $CDCl_3$=4 : 1) solution, since the copolypeptide can not be dissolved in tetradeuteroacetic acid. Although the α-CH resonance peak of the copoly-(1 : 3) appears at the magnetic shielding value of 5.4 ppm, a value which agrees with the position of the α-CH resonance of poly-L-proline I in tetradeuteroacetic acid solution, the α-CH resonance peak of this copolymers can probably be ascribed to that of γ-benzyl-L-glutamate residues, which are contained in ratios of 76% within the copoly- (1 : 3).

However, the poly-L-proline I→II transition could not be observed in the NMR spectra of copoly-(1 : 3). This result suggests that copoly-(1 : 3) can not assume a poly-L-proline-like helical structure. In this copolymer, there are scattered L-proline residues or short chains of L-proline which can not assume a I poly-L-proline-like structure, even the benzyl-L-glutamate assumes a right-handed helix. The shoulder which was observed around 5.2 ppm, with the main peak of the α-CH resonance at 5.4 ppm, should be ascribed to the short chain of L-proline residues.[11]

Further considerations, however, of the NMR spectra of the copoly-(3 : 1) and the copoly-(1 : 1) in tetradeuteroacetic acid are needed; they will be of great importance in ascertaining the ratios of the incorporation of γ-benzyl-L-glutamate residues into the stable II poly-L-proline-like helical structure. The α-CH resonance peak of the two copolypeptides should also be investigated in more detail.

Figure 7 also shows the time dependence of the α-CH resonance peak of the copoly-(3 : 1) and the copoly-(1 : 1) in tetradeuteroacetic acid and the mixed solvent at 26°C. The changes in intensity in the two components of the α-CH resonance peaks of the two copolypeptides seem to stop within five hours, and the resonance peak at 5.45 ppm remains unchanged. This fixing of the site of the α-CH resonance peaks can be ascribed to γ-benzyl-L-glutamate residues which were not incorporated into the poly-L-proline-like helical structure. Assuming that the conformation of the γ-benzyl-L-glutamate residues is independent of that of the L-proline residues in the copoly-(1 : 1), the two components of the α-CH resonance peak can be

expected to have approximately the same intensity after the transition is completed. However, contrary to our expectations, a great difference in the intensities of the two α-CH resonance peaks was observed. These experiments clearly show the incorporation of parts of the γ-benzyl-L-glutamate residues into the stable II poly-L-proline-like helical structure. The measurement of the areas of the two α-CH resonance peaks can be considered to be a method of estimating the content of the II poly-L-proline-like structure of the γ-benzyl-L-glutamate residues, since hardly no line broadening or decrease in the area of the two α-CH resonance peaks in the copoly-(3 : 1) was observed and since the decrease in the area in the copoly-(1 : 1) is invariable, without any line broadening during the transition in either tetradeuteroacetic acid or the mixed solvent.

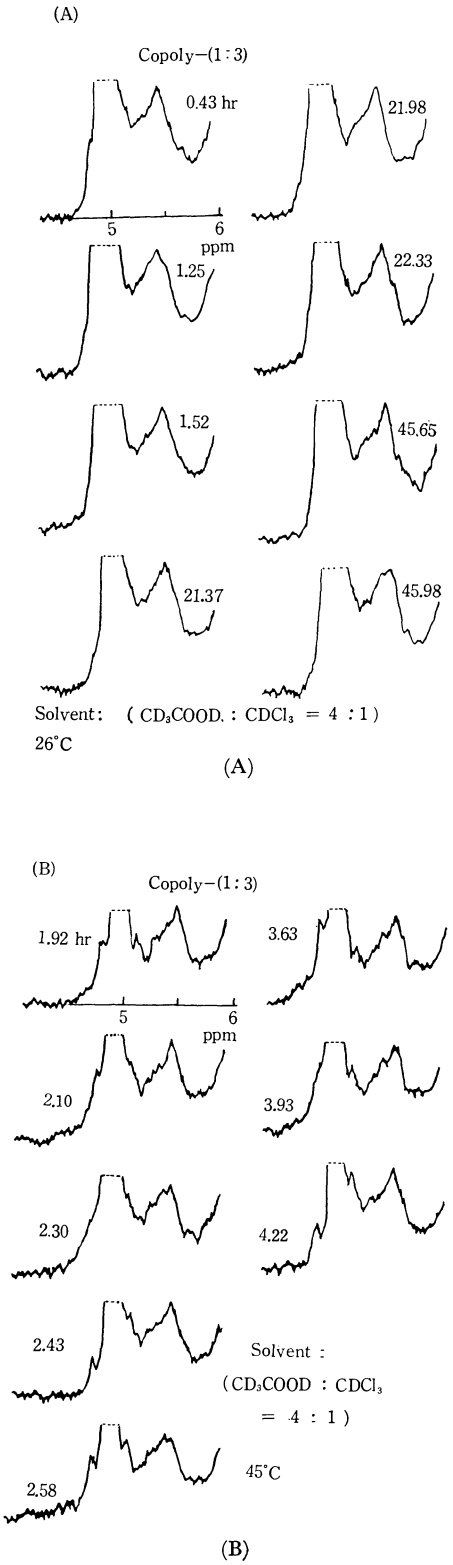

Fig. 9. The time-dependence of the α-CH resonance peak of the copoly-(1 : 3).

Figure 8 shows the time dependence of the ratios of the peak area of the α-CH resonance at 5.45 ppm to that of all the α-CH resonance peaks. These results demonstrate that, in copoly-(3 : 1), 10% of the γ-benzyl-L-glutamate residues were incorporated into the II poly-L-proline-like helical structure of the copolypeptides. Moreover, in copoly-(1 : 1) about 20% of the γ-benzyl-L-glutamate residues were incorporated into the helical structure. The α-CH resonance peak of copoly-(1 : 3) was observed in detail at 26°C and 45°C, as is shown in Fig. 9. However, the transition of copolypeptides such as poly-L-proline was not found. This observation suggests that the poly-L-proline-like structure can not be formed if a sufficient γ-benzyl-L-glutamate ratio exists in the copolypeptide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3063—3066 (1970)

Radiotracer Studies on Adsorption of Surface Active Substance at Aqueous Surface. II. The Effect of Excess Salt on the Adsorption of Sodium Dodecylsulfate

Kazuo TAJIMA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo

(Received April 4, 1970)

The adsorbed amount and the surface tension at the air-solution interface of the solution of tritiated sodium dodecylsulfate in the presence of excess common inorganic salt have been accurately measured at 25°C. The radioactivity of tritium β-rays over the solution was counted with a sheet scintillation counter and the surface tension of the solution was measured by a drop volume method. In the sodium dodecylsulfate solution containing sodium chloride of 0.115 mol/*l*, the adsorbed amount of dodecylsulfate ions was saturated to give 4.33×10^{-10} mol/cm^2 when the bulk concentration was higher than 5.0×10^{-4} mol/1000 g solution. In the presence of the excess inorganic salt common to the ionic surfactant in solution the Gibbs adsorption isotherm has been experimentally proved to be valid for $n=1$. Moreover, it was confirmed that the equation of state for the ionic adsorbed film on the salt-free solution proposed previously is also applicable to the ionic surfactant solution with the excess salt.

The behavior of the surface active substances at the air-solution interface has been studied by many investigators. In spite of the vast amount of studies published up to the present, there are few papers[1-3] which discuss the validity of the Gibbs adsorption isotherm on the basis of reliable data directly obtained for the system of surfactant solution with or without the addition of salt.

In the preceding paper,[4] the adsorbed amount at the air-solution interface was accurately measured by means of a radiotracer method by using the aqueous solution of tritiated sodium dodecylsulfate (TSDS). It was experimentally confirmed for TSDS solution in the absence of added inorganic salt that, if the activity coefficient is taken into account, the adsorption of detergent ions at the air-solution interface takes place in accordance with the Gibbs adsorption isotherm applied for the aqueous binary strong electrolyte solution.

In the present study, the adsorption experiments have been extended to the aqueous solution of TSDS in the presence of excess common inorganic electrolyte. The surface tension of the solution has been measured to check the Gibbs adsorption isotherm and to confirm the equation of state of adsorbed film established in the preceding paper.[4]

Experimental

Materials. The radioactive SDS was synthesized and purified as described in the preceding papers.[4,5] Its specific activity was 12.0 Ci/mol. Sodium chloride used as an inorganic salt was of extra pure grade, which was further purified by recrystallization from the saturated solution by passing HCl gas, by roasting, and then

by ethereal Soxhlet extraction. Such purification was repeated until surface tension of the salt solution reached the constant value. Water used in these experiments was triply distilled. For the preparation of the solution, TSDS was dissolved in the aqueous solution of sodium chloride of constant concentration (0.115 mol/l).

Method. The measurements were made in a glove box with nitrogen atmosphere, which was kept at $98\pm3\%$ humidity and 25 ± 0.2°C. The procedure used for the measurement of the adsorption of TSDS was the same as described in detail in the preceding papers.[4,6] The surface radioactivity was measured by a sheet scintillation counter.

The surface tension measurement was carried out with another portion of the solution used for the adsorption experiment. The drop volume method was adopted with applying the Harkins and Brown corrections.[7] The equilibrium drop volume was obtained within 5 min. The calculation of surface tension was made with the mean volume of 5—10 drops at least. Throughout all experiments, the pH of bulk solutions was controlled at 6 ± 0.2.

Results and Discussion

Figure 1 shows the time dependence of the total surface radioactivity over the solution, A_1, for TSDS solutions of varying concentrations. It was found that the rate of adsorption of dodecylsulfate ion was far greater than the rate of adsorption of salt-free solution, and that time dependence of A_1 did not appear even at concentration below the critical micelle concentration (CMC), except the case of very low TSDS concentration. These phenomena are qualitatively in agreement with the observation on the time dependence in surface tension lowering of the surfactant solution.[8] A_1 value at equilibrium adsorption was obtained as the steady counting rate of each curve in Fig. 1, and given in Fig. 2 as a function of SDS concentration. By subtracting the radioactivity, A_2, due to the bulk of the solution from A_1, surface radioactivity, was obtained and it was converted to surface excess, Γ, by multiplying the conversion factor in the same manner as in the preceding paper.[4]

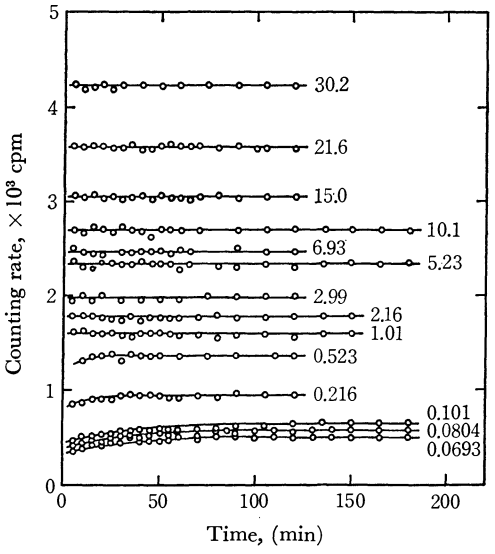

Fig. 1. Time dependence of total radioactivity at solution surface. Figures denote concentration of TSDS in bulk solution, in 10^{-4} mol/1000 g solution.

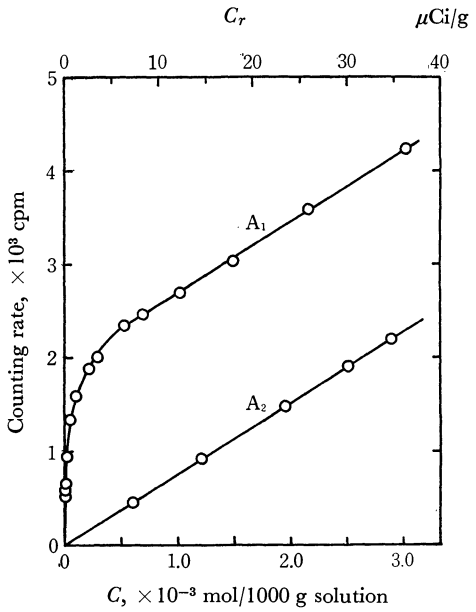

Fig. 2. A_1 and A_2 as a function of concentration of TSDS, C, and radioactive concentration, C_r, respectively.

Figure 3 shows the adsorption isotherm thus obtained at the air-solution interface of the TSDS solution containing excess sodium chloride. The

adsorbed amount increases rapidly with increasing bulk concentration and to attain the value of saturated adsorption (4.33×10^{-10} mol/cm^2) when the bulk concentration was higher than 5.0×10^{-4} mol/1000 g solution. The saturated adsorption was kept constant even above the CMC within the limit of error. The apparent area per surfactant molecule at saturated adsorption is 38.4 Å^2, while the corresponding value for salt-free solution is 52.0 Å^2 as reported in the previous paper.[4]

Nilsson reported[2] that, in a buffer solution of pH=6.5 and of sodium ion concentration $C_{Na^+}=0.1$ mol/l, the amount of adsorption increases gradually with increasing bulk concentration up to CMC and becomes constant above the CMC, the saturated adsorption of dodecylsulfate ion being nearly 5.3×10^{-10} mol/cm^2 at 25°C. Matuura *et al.*[3] also measured adsorption at the air-solution interface of ^{35}S-labelled SDS containing 0.1 mol/l NaCl, and showed a similar increase in adsorption up to CMC, the adsorbed amounts being somewhat lower than those by Nilsson. The present result does not agree with these results except for the occasional agreement in a region of low SDS concentration.

As to the disagreement of the adsorption isotherms among various investigators, it is pointed out that a 2π windowless gas-flow counter, which Nilsson adopted to measure the adsorption amount, gives much unavoidable influence on the adsorption as described in detail in the previous report.[4] The value obtained by such a method might generally be higher than that of the counter of end-window type. On the other hand, higher accuracy may be expected for the present result than for Matuura's at high SDS concentration, since the radiation from ^{3}H is far softer than ^{35}S. Thus, the results of the present experiment are considered to be most reliable among them.

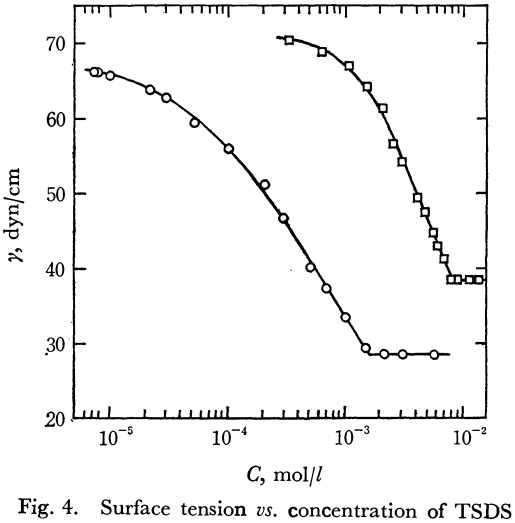

Fig. 4. Surface tension *vs.* concentration of TSDS solution.
—□—: salt-free solution
—○—: excess salt solution

Figure 4 shows the curve of the surface tension *vs.* concentration obtained under the same experimental conditions as reported in the preceding paper.[4] It is noted from Fig. 4 that a constant slope is obtained in the range of TSDS concentration from about 5.0×10^{-4} mol/l to the CMC.

Gibbs Adsorption Isotherm. The Gibbs adsorption isotherm is expressed as follows:

$$-\mathrm{d}\gamma = RT\sum\Gamma_i \mathrm{d}\ln a_i \qquad (1)$$

where γ represents the surface tension, Γ_i and a_i, the surface excess and the activity of ith ionic species in the solution, respectively. Assuming that the bulk solution is neutral and surface hydrolysis is absent (bulk pH was confirmed to be constant, independently of the TSDS concentration), Eq. (1) is rewritten for the TSDS solution containing sodium chloride as,

$$-\mathrm{d}\gamma = RT\Gamma_{Na^+}\mathrm{d}\ln a_{Na^+} + RT\Gamma_{D^-}\mathrm{d}\ln a_{D^-} + RT\Gamma_{Cl^-}\mathrm{d}\ln a_{Cl^-} \qquad (2)$$

where the subscripts Na^+, D^- and Cl^- denote sodium, dodecylsulfate and chloride ions, respectively. In the case of excess and constant concentration of NaCl, we have,

$$\frac{\mathrm{d}C_{Cl^-}}{\mathrm{d}C_{D^-}} = 0, \text{ and } \frac{\mathrm{d}C_{Na^+}}{\mathrm{d}C_{D^-}} \simeq 0 \qquad (3)$$

From Eq. (3) and the mean activity coefficient $f_\pm$, Eq. (2) can be written as,

$$-\frac{\mathrm{d}\gamma}{RT\,\mathrm{d}\ln C_{D^-}} = \Gamma_{D^-} + 2(\Gamma_{D^-}+\Gamma_{Cl^-})\frac{\mathrm{d}\ln f_\pm}{\mathrm{d}\ln C_{D^-}} \qquad (4)$$

The differential term in the right side of Eq. (4) can be evaluated as,

$$2\times\frac{\mathrm{d}\ln f_\pm}{\mathrm{d}\ln C_{D^-}} = 1.17\frac{C_{D^-}}{C_{Na^+}^{1/2}} = 5.27\times10^{-3} \qquad (5)$$

for $C_{NaCl}=0.115$ mol/l and $C_{D^-}=$CMC, with the assumption of the Debye-Hückel limiting law to be held. Thus, the differential term in Eq. (4) is seen to be negligible in this case. Then, Eq. (4) is reduced to

$$\Gamma = -\frac{\mathrm{d}\gamma}{RT\,\mathrm{d}\ln C} \qquad (6)$$

where C is the concentration of the surfactant and is taken to be equal to C_{D^-}, and $\Gamma=\Gamma_{D^-}$. The values of Γ calculated by Eq. (6) from the data of surface tension in Fig. 4 are plotted against SDS concentration in Fig. 5 together with the observed values for comparison. The calculated values are in good agreement with the observed values throughout the whole range of bulk concentration studied. When the surface attains the saturation with adsorbed surfactant at the concentration of 5.0×10^{-4}

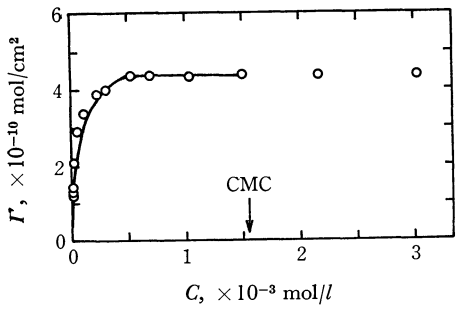

Fig. 5. Adsorption isotherm of SDS solution.
○: observed value
———: Eq. (6)

mol/*l* as shown in this figure, further increase of the bulk surfactant concentration produces no change in the amount of adsorption, while it causes a steady decrease of surface tension. Such a mode of adsorption isotherm was confirmed to persist even above the CMC. Roe and Brass[1] measured the surfate tension lowering of SDS solution of which pH and C_{Na^+} were held constant to 6.5 and 0.1 mol/*l*, respectively, by the use of the buffer solution, and calculated the amount of SDS adsorption by applying the Gibbs equation. They obtained 4.40×10^{-10} mol/cm^2 as the values of saturated adsorption. This value is also in good agreement with that measured in the present radiotracer study as far the saturation value is concerned.

Thus, the Gibbs adsorption isotherm is proved to be valid, when we put $n=1$ in the Gibbs equation[4] for TSDS solution in the presence of excess salt with the common cation.

Equation of State. The relation between the surface pressure, π, and molecular area, A, of the adsorbed film of TSDS on an excess salt solution was calculated from the data of Figs. 3 and 4 by using the following relationships:

$$\pi = \gamma_0 - \gamma$$

$$A = \frac{1}{\Gamma_{D^-} \times N}$$

where γ_0 is the surface tension of water and N Avogadro's number. The result is shown by circles in Fig. 6. In the preceding report[4] we proposed the equation of state for the adsorbed film on the salt-free SDS solution as follows:

$$(\pi + \frac{0.43\,kT}{A} + 6.03\,C_i^{1/2})(A-A_0) = kT \qquad (7)$$

where C_i is the total bulk concentration of ions, A_0 the coarea per molecule, k the Boltzmann constant and T the absolute temperature. In Fig. 6, Eq. (7) is shown by a solid line. An excellent agreement is seen between Eq. (7) and the experimental results. The value of A_0 was found to be about 25.0 Å^2/molecule, which was obtained by the same procedure as that in the preceding paper.[4] This value may be compared with the value of $A_0=38.4$ Å^2/molecule found in the case of salt-free solution. The effects of added salt on A_0 may be interpreted as being due to the shrinkage of diffuse double layers and the dehydration of adsorbed dodecylsulfate ion.

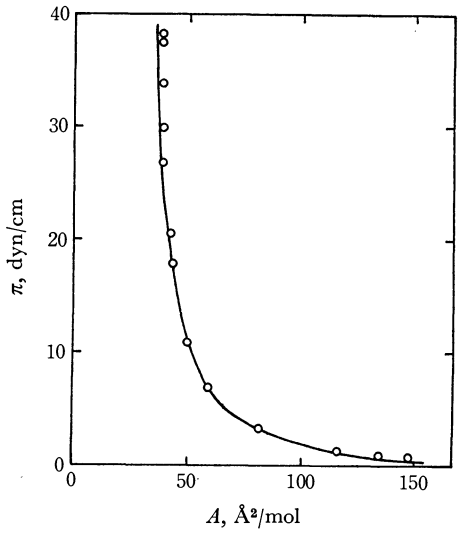

Fig. 6. π *vs.* A plot for adsorbed SDS monolayer on 0.115 mol/*l* NaCl solution at 25°C.
○ : observed value
———: Eq. (7)

It is confimed from Fig. 6 that Eq. (7) expresses satisfactorily behavior of the surface films adsorbed from ionic surfactant solutions with or without excess salts.

The author wishes to express his hearty thanks to Professor T. Sasaki for his encouragement and guidance throughout the experiments. He is grateful also to Assistant Professor M. Muramatsu, for his helpful discussion and advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3067—3069 (1970)

Some Aspects of Gaseous TCNE Complexes Including the Butene-TCNE

Jun-ichi AIHARA,*1 Motoyuki TSUDA*1 and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received April 13, 1970)

The absorption spectra of the gaseous olefin-TCNE complexes were successfully observed for the first time: the absorption maximum of the butene-TCNE complex was found at 28700 cm^{-1}. The CT band of the methyl derivatives was shifted to a higher-energy region because of their steric effect. The systematic collection of the gaseous data made it possible to estimate the magnitude of the steric effect.

1. The Absorption Spectra of the Gaseous Butene-TCNE Complex. Since Lang and Strong first measured the electronic absorption spectra of gaseous diethyl ether-iodine and also gaseous benzene-iodine complexes, various charge-transfer complexes have been investigated in the gas phase.[1-3] We have also measured the spectra of a series of gaseous aromatics-TCNE(tetracyanoethylene) and anthracene-chloranil complexes. These results have been reported in previous papers.[4-6]

Recently, Kroll studied the gaseous charge-transfer complexes, using TCNE as an electron acceptor.[7] However, according to his article, he failed to find the charge-transfer spectra for a gas-phase mixture of ethylene and TCNE, nor did he find the characteristic spectra for a gaseous mixture of butadiene and TCNE. Of course, it is widely known that ethylenic hydrocarbons form charge-transfer complexes with various acceptors in solution.[8,9]

We attempted to detect the charge-transfer band of the gaseous TCNE complex with one of the ethylenic hydrocarbons, *cis*-2-butene, and succeeded in the measurement of its spectrum. The experimental apparatus and procedures were the same as those employed in the previous experiments.[4] The *cis*-2-butene used was a commercial material, while the TCNE was purified by sublimation *in vacuo*. The spectroscopic measurements were made as rapidly as possible in order to observe the clean species. The electric furnace containing the optical cell was maintained at 200°C.

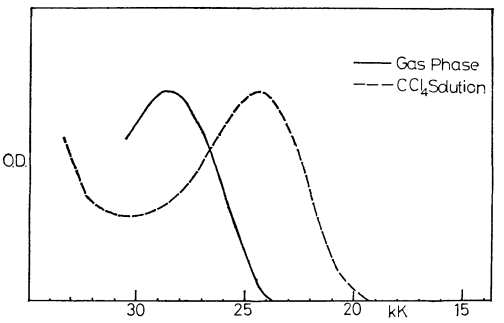

Fig. 1. The CT band of the butene-TCNE complex.

Figure 1 shows the gaseous spectrum of the butene-TCNE complex. The solution spectrum in carbon tetrachloride is added for the sake of comparison. To obtain the solution data, a sufficient amount of gaseous butene was introduced into a solution saturated with TCNE. In the gaseous phase, the characteristic charge-transfer band was observed in the near-ultraviolet region, where neither the vapour of butene nor that of TCNE absorbs. A peak is found at 28700 cm^{-1}; it corresponds to a blue shift of 4300 cm^{-1} from that found when both components are dissolved in carbon tetrachloride. The half-width determined from the long-wavelength part of the band is approximately 2200 cm^{-1}. It can be seen in Fig. 1 that gas and solution bands would coincide almost exactly if

TABLE 1. ADDENDUM TO THE LIST OF THE GASEOUS TCNE COMPLEXES

Donor	CT band (cm^{-1})		Gas-to-solution shift (cm^{-1})
	in gas phase	in CCl_4 solution	
cis-2-Butene	28700	24400	−4300
Acenaphthene	18100	15300	−2800

superimposed. In all respects, the nature of the butene-TCNE complex seems like that of usual TCNE complexes.

We also observed the spectra of another TCNE complex, that with acenaphthene at 200°C. These results are summarised in Table 1.

2. Steric Effects of Charge-transfer Complexes in the Gas Phase. Now, a fair amount of data on the gaseous TCNE complexes are available. Therefore, we can survey them from a different point of view. The observed band maxima($h\nu$) of the charge-transfer transition are plotted against the ionization potentials (Ip) of the donor molecules in Fig. 2. As usual, a linear relation between them can be derived:[10]

$$h\nu = aI_p - b \qquad (1)$$

Here, a and b are assumed to be characteristic constants for the complexes of any one acceptor.

The ionization potentials of the donors used were determined by Watanabe, Terenin and Vilessov, and Briegleb.[11–13] We newly determined those of pyrene (7.53±0.03 eV) and acenaphthene (7.66±0.03 eV) by the photoionization method. This simplified equation, which can often be a sufficient approximation, has been used to determine the unknown ionization potential of any donor. In the case of typical polycyclic aromatic hydrocarbons especially, the ionization potentials derived from Eq. (1) coincide well with those obtained from the polarographic oxidation potentials.[14] On the other hand, it is generally admitted that polymethyl-benzenes obey a slightly different equation; that is, they give higher transition energies than the values to be expected from the equation based on typical hydrocarbons.[15,16]

As is illustrated in Fig. 2, we can also broadly classify the gaseous data into two groups; one is the

● Gas phase
○ CCl_4 solution

group to which typical aromatic hydrocarbons belong, and the other is that to which their derivatives belong. Benzene, naphthalene, and pyrene can be ascribed to the former, while the other compounds belong mainly to the latter, though there are some exceptions.

For the typical hydrocarbons, we obtained the following relations:

$$h\nu = 0.948I_p - 5.07 \text{ (eV)} \qquad (2)$$

for the TCNE complexes in the gas phase, and

$$h\nu = 0.877I_p - 4.87 \text{ (eV)} \qquad (3)$$

for those in the carbon tetrachloride solution. The complexes with these compounds rigorously maintain a linear relation both in gas and in solution. The coefficient, "a", in the gas phase is almost equal to unity. This means that the charge-transfer transition of the TCNE complexes can be interpreted primarily in terms of a simple electron donation from the donor to the acceptor molecule. In other words, it can be expressed by the ionization potential of the donor minus the electron affinity of the acceptor and minus the Coulomb energy.

16) M. Kinoshita, This Bulletin, **35**, 1609 (1962).

In the case of complexes with substituted derivatives, the gradients of Eqs. (2) and (3) are not changed. However, the constant terms in them increase by approximately the amounts of 0.075 and 0.19 eV respectively. These situations are shown by the dotted lines in Fig. 2. The data for benzene, *p*-xylene, mesitylene, and hexamethylbenzene are cited from Ref. (7).

In order to explain the above tendencies, it is instructive to consider the steric effect of the substitutents of the donor molecules. Though our information on the stereochemistry of the gaseous complexes is quite deficient, the substitutents should often change the distance between the molecular planes in the complex to some extent.

According to Pauling's idea, the half-thickness of the aromatic ring is 1.85 Å, while the van der Waals radius of the methyl group is about 2.0 Å.[17] Briegleb has suggested that, if the intermolecular distance, R, between the donor and the acceptor increases by 0.01 Å near R=3.2 Å, the Coulombic attraction term contributing to the charge-transfer transition will decrease by 100 cm^{-1}.[15] On the basis of this statement, it may be concluded that the R of the methyl derivatives increases by 0.06 Å on the average. Though R must be interpreted as the distance between the centres of the donor and of the acceptor molecules, the interplanar distance of the complex might be roughly regarded as the same. Exceptionally, *p*-xylene and butene behave as if they are not affected by the steric effect. On the other hand, diphenyl and acenaphthene are apparently affected under these circumstances. This behaviour is reflected in the subsequent polarization energy, P, in the carbon tetrachloride solution. As the dipole moments of the complex are dependent on the ionization potential of the donor, the polarization energy will necessarily depend on it. In fact, the dipole moments in the ground state are 1.28D for the naphthalene-TCNE, 1.35D for the hexamethylbenzene-TCNE, and 2.0D for the pyrene-TCNE complex.[18,19] Theoretical studies have suggested that the dipole moments in the excited state also vary systematically.[15] The actual *Ip* dependence of the polarization energy was derived by Eqs. (2) and (3) for typical complexes:

$$P = 0.071I_p - 0.20 \text{ (eV)} \quad (4)$$

The polarization energy of the complex with the substituted compound is somewhat smaller than that of the typical complex. Supposing that Onsager's approximation is applicable to the dielectric media containing the charge-transfer complex, the solvent shift is inversely proportional to the cube of the cavity radius.[20,21] This assumption has been confirmed by an analysis of the TCNE complex in the solvent, a discussion presented in a previous paper.[5] Therefore, the change in the polarization energy can be shown by the augmentation of the molecular dimensions. The decrease of 30 percent in the polarization energy is equivalent to the increase of 13 percent in the cavity radius. This behaviour is also ascribable to the steric effect of the substitutents.

In the above discussion, we neglected various factors affecting the charge-transfer complex. Accordingly, we must admit that the criterion for the judgement of the steric effects seems somewhat obscure, as the several exceptions show. Such an amount of spectral change may occur by means of the geometrical variation of the complex.[22]

In the case of the stilbene-TCNE, the temperature dependence of the intensity ratio of the first and the second CT bands has been found in a methylene chloride solution.[23] This phenomenon has been explained in terms of geometrical isomerism. This isomerism may cause the location for it to deviate from the linearities. Strictly speaking, we need to examine the individuality of each complex in detail. Therefore, it seems very natural that the gaseous species behave well with fewer exceptions, since they are not influenced by a variety of ways of solvation and so on.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3070—3078 (1970)

The Crystal Structure of a Colored Complex, $C_7H_7OHg \cdot C_7H_6O_2N$, Obtained in the Millon Reaction of *p*-Cresol

Yoshiko KOBAYASHI, Yoichi IITAKA and Yasumasa KIDO

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo, Tokyo

(Received April 27, 1970)

The crystal structure of the complex of 2-mercuri-4-methylphenol and 2-nitroso-4-methylphenol obtained in the modified Millon reaction was determined using three-dimensional X-ray diffraction data. The complex crystallizes in triclinic system, space group $P\bar{1}$, with a unit cell of dimensions $a=10.26$ Å, $b=22.71$ Å, $c=5.61$ Å, $\alpha=97.2°$, $\beta=93.1°$, $\gamma=91.1°$, containing four complex molecules. Each of the two crystallographycally independent complex molecules both having essentially the same structure, forms a dimer with its nearest neighbor related by a center of symmetry through a pair of hydrogen bonds. The mercury atoms adopt a planar four-fold coordination with nitrogen, carbon and two oxygen atoms.

In the modified Millon reaction of *p*-cresol with Hopkins-Cole reagent, three kinds of pigment (pigment 1, 2 and 3) were produced depending upon the reaction condition. Pigment 1 is known as a complex of 2-mercuri-4-methylphenol (MMP) and 2-nitroso-4-methylphenol (NMP).[1,2] In order to determine the structure of the complex, two-dimensional X-ray analysis of pigment 1 was already carried out by Tamura, Iitaka and Kido[2] using the crystal grown from chloroform solution. However, this crystal contained chloroform as a solvent of crystallization and was so small and deteriorative against X-ray irradiation that it was not possible to determine the structure in three dimensions. Later, more stable and larger crystals were obtained from ethanol solutions. The present investigation was therefore undertaken to elucidate the detailed spacial structure of the complex molecule by X-ray diffraction using the new crystals.

Experimental

The crystals of pigment 1 were grown from ethanol solutions as massive aggregates of triclinic prisms elongated along the *c*-axis. They were dark red in color. The lattice constants and space group were determined from the *a*-, *b*- and *c*-axis equatorial precession photographs taken with Cu$K\alpha$ radiation. The density was measured by the floatation method using the mixed solutions of 1,1,2,2-tetrabromoethane and carbon tetrachloride. Unlike the crystals grown from chloroform solutions, the present crystal does not contain the solvent of crystallization.

Crystal Data. 2-Mercuri-4-methylphenol·2-nitroso-4-methylphenol complex $C_7H_7OHg \cdot C_7H_6O_2N$.

Mol wt: 444

Space group: triclinic $P\bar{1}$

Lattice constants:

$a=10.26\pm0.02$, $b=22.71\pm0.03$, $c=5.61\pm0.01$ Å,

$\alpha=97.2\pm0.2$, $\beta=93.1\pm0.2$, $\gamma=91.1\pm0.2°$

Volume of the unit cell: 1297 Å^3

Four structure units in the unit cell

Density measured: 2.25 g·cm^{-3}

Density calculated: 2.27 g·cm^{-3}

Linear absorption coefficient for Cu$K\alpha$ radiation: $\mu=237.6$ cm^{-1}

Three-dimensional intensity data were collected from multiple-film equi-inclination Weissenberg photographs taken with Cu$K\alpha$ radiation of the layers zero to fourth about the *c*-axis and zero to third about [101] axis. The intensities were measured visually with the aid of a calibrated intensity scale and they were corrected for Lorentz and polarization factors. The size of the specimens used for the intensity measurement was about 0.065×0.065 mm in cross section corresponding to the μR value of 1.53, but no absorption correction was applied. The structure factors obtained for the two axes were correlated and scaled to a common base. A total of 2418 independent structure factors was finally derived.

Determination of the Crystal Structure

The three-dimensional Patterson function yielded the positions of two mercury atoms involved in the asymmetric unit. A three-dimensional Fourier map was then calculated on the basis of the contribution of these two atoms which gave the *R* factor of 0.33. Although many spurious peaks were present on the Fourier map especially around the mercury atoms, the locations of the thirty six light atoms forming the two crystallographically independent complex molecules were determined by succesive use of Fourier and difference Fourier syntheses. The

1) Z. Tamura and Y. Kido, *Chem. Pharm. Bull.* (Tokyo), **16**, 1808 (1968).

2) Z. Tamura, Y. Iitaka and Y. Kido, *ibid.*, **17**, 1767 (1969).

refinement of the atomic positional and thermal parameters was first carried out by the block-matrix least-squares method, using the program HBLS.[3] Seven cycles of calculations including isotropic temperature factors for each atom reduced the R factor from 0.30 to 0.15. This factor was further reduced to 0.11 by three cycles of the least-squares calculations including individual anisotropic temperature factor parameters. The weighting system adopted in the calculations was:

$$\sqrt{w}=75/F_o, \text{ when } 75<F_o,$$

$$\sqrt{w}=1, \text{ when } 12<F_o\leq 75,$$

$$\sqrt{w}=0, \text{ when } F_o\leq 12.$$

The final atomic parameters and their standard deviations are listed in Table 1. In Table 2 the observed structure factors are listed. The atomic scattering factors used in the present structure determination were taken from *International Tables for X-ray Crystallography*.[4]

Figure 1 depicts the superposed three-dimensional electron density distribution function calculated on the basis of the atomic parameters listed in Table 1.

Discussion of the Structure

The present crystal contains two crystallographically independent complex molecules I and II. Each of these molecules forms a dimer with its nearest neighbor related by a center of symmetry through a pair of hydrogen bonds.

The bond lengths and angles of the complex molecules calculated from the coordinates given in Table 1 are shown in Fig. 2 along with their standard deviations. It is seen that they resemble each other considering their rather large standard deviations. Furthermore, the c-axis projection of the dimer molecule found in the crystal grown from chloroform solutions (Fig. 1 of the previous paper[2]) closely resembles those found in the present crystal, although the sturucture of the former was solved only in a two-dimensional projection and no detailed spacial arrangement of the atoms was given.

In the previous paper, two resonance forms of the complex were suggested as shown in Fig. 3 of the present paper, but it was not possible to decide which is more predominant. In Table 3, the length of the C–N and N–O bonds reported for various oximes, nitroso compounds and N-oxides are shown. The length of the C–N bonds found in the molecules I and II are both 1.25 Å indicating a strong double bond character. The N–O bond lengths in the molecules I and II differ considerably. In view of the rather large standard deviations, it can not be said that the difference is really significant, but the mean value of the two lengths, 1.27 Å, is nearly of the same order of magnitude as those found in nitroso compounds[12–16] or in N-oxides[17–20] and is clearly shorter than those found in oximes.[5–11]

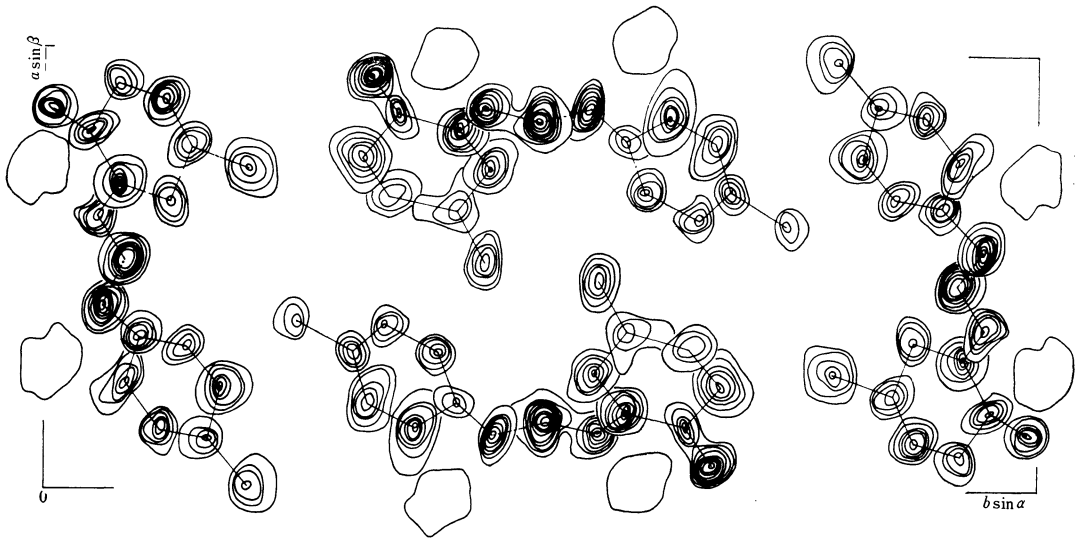

Fig. 1. Composite drawing of the electron density map viewed along the c-axis. Contours are drawn at intervals of 1 e. Å^{-3} starting at 2 e. Å^{-3}. Those for mercury atoms are not shown.

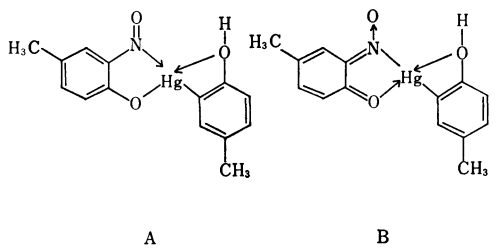

Fig. 3. The structures of the present complex molecule proposed in the previous paper.[2]

Although the location of hydrogen atoms are not shown in the present structure determination, a comparison of the N–O bond lengths in NMP-group which have double bond character and the C–O bond lengths in MMP-group which correspond to the carbon to phenolic oxygen bond lengths (C–OH), indicates that the latter oxygen atoms exist in the form of hydroxyl groups and act as hydrogen donors in the hydrogen bond systems.

From the discussions on the C–N and N–O bond lengths it may be concluded that the structure of the

packed together in the ***a*** direction mainly through the van der Waals interaction between the phenolic groups forming the layers of the dimer molecules. The two kinds of layers each consisting of the dimers I-I or II-II are packed together alternately along the *b*-axis. The packing of the layers in the ***b***-direction is rather loose and no close contact shorter than 3.75 Å is found between the layers.

In Figures 4 and 5 are shown intermolecular short distances less than 3.75 Å. It is to be noted that the dimers I-I and II-II are situated approximately in such positions that they are related by a rotation about the axis parallel to ***c*** followed by a mirror operation with the mirror plane parallel to ***c***. Comparison of Fig. 4 with Fig. 1 of the previous paper[2] indicates that the structure of the present crystal resembles, in some respect, that found in the crystal grown from chloroform solutions. The latter crystal contains chloroform molecules as the solvent of crystallization filling up the spaces between the II-II dimers. These spaces are filled by the dimers I-I in the present crystal.

The authors wish to express their sincere thanks to Professor Zenzo Tamura for his continuous encouragement.

The Fractionation of Tritium in the Crystallization of Inorganic Hydrates from a Tritiated Solution

Haruhiko TANAKA*1 and Hisao NEGITA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima

(Received April 27, 1970)

Bennema's theory of crystal growth from a solution was modified and used in explaining fractionations of tritiated water in the crystal-growth processes of several inorganic hydrated salts from concentrated aqueous solutions. It was suggested that some water molecules in the aqueous solutions were free to become growth units which are not necessarily activated for entering the crystal surface. The dilution of tritiated water in the crystal was observed; this was explained in a satisfactory way in terms of the surface-diffusion model originally proposed by Burton, Cabrera, and Frank. On the contrary, the volume diffusion model was inadequate for interpreting the fractionation of tritium.

The theory of crystal growth from the vapor phase has been extensively developed, and there is sufficient experimental evidence supporting the concept of surface diffusion which regulates the growth mechanism.[1] The crystal growth from a solution, however, has been scarcely at all treated from the theoretical point of view. The kinetics of crystallization from a solution becomes more complicated because of the interaction and solvation of constituent ions, although there is no essential difference between the growth from vapor and that from a solution.

The rate of crystal growth from a solution is assumed to depend on the advance velocity of the steps. It is, in turn, a problem whether or not a surface diffusion of growth units plays an essential role in the growth process. This point has been discussed on the basis of the morphological theory of Hartman and Perdok, and the surface diffusion has been found to be an essential process in the crystal growth.[2] Recently Bennema[2,3] has explained his accurate data on the crystal growth by assuming the surface-diffusion model of Burton, Cabrera, and Frank.[1]

On the basis of these works it has come to seem probable that crystal growth from solution at a low supersaturation also occurs with the surface-diffusion process. However, there has thus far been little discussion of the mechanism of the crystal growth of inorganic hydrates, especially those from concentrated aqueous solutions. This is probably due to the complicated behavior of growth units in solutions. The aim of the present paper is to discuss the mechanism of the crystal growth of several inorganic hydrated salts from aqueous solutions in the light of the fractionation of tritiated water.

There have been a few papers studying the fractionations of heavy water (but not that of tritiated water) in the growth processes.[4,5] These results have been discussed from the points of view of the vapor pressures of the ctystal and the solution or from that of the hydrogen bonding of water, but not on the basis of the theory of crystal growth from a solution. On the contrary, it may be possible, under the present experimental conditions, to use the crystal-growth theory from a solution, which is useful at low supersaturations up to *ca.* 20%, in explaining the fractionations of tritiated water. A trace amount of tritiated water was present in a solution of inorganic salt; its fractionation was examined when the salts were crystallized with water of hydration and much attention was paid to the behavior of water crystallized from the solution.

Experimental

Large single crystals of sulfates of cobalt, nickel, and copper were grown from unstirred solutions by evaporating the solvent containing a trace amount of tritiated water (*ca.* 1.0×10^{-6} mol/m*l*). A single crystal of cobalt sulfate was obtained at 30.0°C, while others

were obtained at 40.0°C. The rates of crystal growth were so slow that only 3 or 4 g of the crystals were obtained in two weeks. The water of hydration was recovered by heating the single crystal until no further dehydration was observed.

The tritium contents in the dehydrated water were compared with those of the mother liquid by observing their activities. The activity measurements were done by a liquid scintillation counter, a Packard Model 2002 Tri-Carb Scintillation Spectrometer. As the scintillant we used a solution composed of toluene, ethylene glycol monomethyl ether, 2,5-diphenyloxazole (PPO), and 1,4-bis-2′-(5′-phenyloxazolyl)benzene (POPOP).

Results and Discussion

The observed fractionations of tritiated water are summarized in Table 1; the table shows that all the separation factors are less than unity, implying the dilution of tritiated water in the hydrate crystal. The separation factor, S, for the equilibrium between solid and liquid phases is usually defined by:

$$S = \{N_s/(1-N_s)\}\{(1-N_l)/N_l\}, \quad (1)$$

where N_s and N_l are the mole fractions of a given isotope (tritiated water, in the present case) in the solid and liquid phases respectively. Since N_s and N_l are extremely small in the present study, Eq. (1) can be simplified to:

$$S = N_s/N_l. \quad (2)$$

Table 1. Separation factor of tritiated water, S, observed in the crystallization of the sulfate from its solution

Crystal	$S_{obs.}$
$CoSO_4 \cdot 7H_2O$	0.979 ± 0.007
$NiSO_4 \cdot 7H_2O$	0.972 ± 0.011[6]
$CuSO_4 \cdot 5H_2O$	0.956 ± 0.012[7]

Theories of Crystal Growth from a Solution. Recently, Bennema has applied the spiral crystal growth model of Burton *et al.*, derived from the vapor phase, to that from a solution.[3] According to his treatment, the rate of crystal growth, R, from a solution at a low supersaturation is given as follows:

$$R = \beta c_0 \Omega (kT/h) A N_0 \exp(-H/kT)(\sigma^2/\sigma_1) \tanh(\sigma_1/\sigma), \quad (3)$$

where the notations are as given below:

β=retarding factor arising if the relaxation time for a growth unit's entry into a kink is small
c_0=retarding factor arising if $x_s \ll x_0$
x_s=mean displacement of a growth unit on the surface
x_0=mean distance between the kinks
Ω=volume of a growth unit in the crystal
k=Boltzmann's constant
T=absolute temperature
h=Planck's constant
A=thickness of the adsorption layer
N_0=equilibrium concentration of growth units per cm^3 in the solution
H=dehydration activation energy for an entry of growth units into the adsorption layer
σ=relative supersaturation
$\sigma_1 = 9.5\ \gamma a/(\varepsilon k T x_s)$
γ=edge free energy of a step of the length of a
a=the shortest distance between growth units
ε=measure of the number of interacting spirals

Equation (3) may be useful in estimating the rate of integration of an ion into the crystal in the case of the growth of an ionic crystal from the aqueous solution.

A modified equation has to be used for estimating the rate of integration of water in the growth of hydrated ionic crystals from aqueous solutions, assuming for the moment that some water molecules integrate independently of ions. For this purpose, the spiral crystal-growth theory from vapor by Burton *et al.*[1] may properly be used. According to this theory, the following relation holds between R and σ, assuming that the diffusion of growth units on the surface determines the growth rate:

$$R = C(\sigma^2/\sigma_1) \tanh(\sigma_1/\sigma). \quad (4)$$

The constant, C, will be given below for a free water molecule integrating from the solution to the crystal surface.

Assuming, further, that the integration occurs without activation, we can use a model for the mobile adsorption layer[8] much like that used for the growth theory from vapor discussed by Bennema.[2] The n_{s0}/N_0 ratio is thus given as follows for the equilibrium between the water molecules (growth units in this case) in the solution and those on the surface:

$$n_{s0}/N_0 = \{h/(2\pi m k T)^{1/2}\} \exp(A/kT), \quad (5)$$

where n_{s0} is the equilibrium concentration of growth units per cm^2 on the surface, m is the mass of a growth unit, and A is the energy difference between growth units in the solution and those on the surface. We should note here that one translational degree of freedom is lost if a growth unit is adsorbed onto the surface from the bulk solution. In Eq. (5) we disregard the fractions of reflected molecules striking the surface and the changes in the degrees of freedom other than the translational.

Accordingly, it follows from Eq. (5) and some lengthy treatments[1,2] that:

$$C = \alpha \beta c_0 \Omega N_0 k T/(2\pi m k T)^{1/2}. \quad (6)$$

The α factor is introduced as a correction for the growth from a solution, which is assumed to be

8) S. Glasstone, K. J. Laidler and H. Eyring, "The Theory of Rate Processes," McGraw-Hill Book Co., Inc., New York (1941), P. 350.

independent of the hydrogen isotopes. If the surface diffusion of a growth unit is an essential process in the growth process, Eq. (6) is simplified and combined with Eq. (4) to give rise to:

$$R = \alpha c_0 \Omega N_0 (kT/2\pi m)^{1/2} (\sigma^2/\sigma_1) \tanh(\sigma_1/\sigma), \quad (7)$$

since the value of β becomes unity. On the other hand, if the volume-diffusion model for the growth from a solution is adopted, in which model a growth unit is directly transported from the solution to the kink without any surface diffusion, the rate of the crystal growth is given by:

$$R = \{2\pi\lambda\varepsilon\beta D N_0 \Omega k T/(19\gamma a x_0)\}\sigma^2, \quad (8)$$

where λ is the mean distance between one equilibrium position and a neighboring one in the solution, and where D is the volume-diffusion constant. The volume-diffusion model was discussed extensively by Bennema on the basis of the original theory of Burton *et al.*[2] We may note here that both Eqs. (7) and (8) are adequate in considering the crystal growth from a well-stirred solution at a low supersaturation.

Water and Ions in a Concentrated Solution. In concentrated aqueous solutions of inorganic salts, a given ion can not exist independently of other ions and water molecules; *i. e.*, the system is very complicated due to complex formation and the hydration of ions. The complexes can be divided into two types, outer-sphere and inner-sphere complexes.[9] The process of inner-sphere-complex formation in the sulfates of divalent cations may be formulated as follows, with the successive release of intervening water molecules:

$$M(OH_2)_p^{2+} + SO_4^{2-} \rightleftharpoons M(OH_2)_p^{2+}, SO_4^{2-}$$

$$\rightleftharpoons M(OH_2)_{p-q}^{2+}, SO_4^{2-} + qH_2O,$$

where p is the hydration number of the M^{2+} ion in the dilute aqueous solution and where q is the number of water molecules dehydrated in the inner-sphere-complex formation ($0 \leqq q \leqq p$). In the scheme, the hydration of the anion and any quantum mechanical interaction of the anion with the cation are ignored.

The value of q can be larger than unity; that is, the remaining water molecules in the inner-sphere complex are subject to further dehydration. This point has been discussed by many workers on the assumption that complex formation occurs fundamentally because of coulombic forces between the oppositely-charged ions.[10] Further dehydration seems to be very probable, particularly in the case of the weak hydration of cations, as is the case with the present study. We can thus assume in the succeeding argument that extra water molecules are released from the hydration sheath of cations in the complex under the present conditions.

Estimation of Separation Factors. Recognizing that molecules of the same chemical species but labeled with different isotopes have the same structure and electronic configuration, we can obtain the ratios of R_{HTO}/R_{H_2O} for two cases.

(a) In the case of the surface diffusion, the following relation is derived from Eq. (7):

$$R_{HTO}/R_{H_2O} = (m_{H_2O}/m_{HTO})^{1/2} = 0.949, \quad (9)$$

where R_{HTO}/R_{H_2O} is the ratio of the integration of HTO to that of H_2O molecules into the crystal and where m_{H_2O}/m_{HTO} is the mass ratio of H_2O to HTO molecules.

(b) In the case of the volume diffusion;

$$R_{HTO}/R_{H_2O} = D_{HTO}/D_{H_2O} = 1, \quad (10)$$

where D_{HTO}/D_{H_2O} is the ratio of the diffusion constants of HTO to H_2O molecules in the solution.

Equations (9) and (10) are supported by the following considerations:

(1) σ_1, which is a function of the mean displacement of a growth unit, X_s, may be independent of the mass of water, supposing that growth units in the activated state and those in the non-activated state on the surface have the same degrees of freedom.

(2) The retarding factor, β, in Eq. (8) is a function of relative supersaturations around the steps and the kinks, and the factor, c_0, is a function of both the mean distance between the kinks and the distance between successive turns of the spiral. Therefore, the values of β and c_0 should be unchangeable in a system with a trace amount of tritiated water, though these factors play an important role in determining the mechanism and the absolute value of R in the growth process.

(3) The value of D may be practically independent of the hydrogen isotope of the water molecule, as seen from the work by Wang *et al.*[11]

(4) The other factors in Eqs. (7) and (8) may also be unaffected by the presence of tritiated water.

Accordingly, we can estimate the separation factors from either Eq. (9) or (10), assuming that fractionations of tritiated water occur, if at all, only with free water molecules and not with the hydration water of cations. When hydrated cations

Table 2. Possible growth units and separation factor, S, calculated by Eq. (9)

Crystal	Growth units assumed	$S_{cal.}$
$CoSO_4 \cdot 7H_2O$	$Co(OH_2)_3^{2+}$, SO_4^{2-} and $4H_2O$	0.791
$NiSO_4 \cdot 7H_2O$	$Ni(OH_2)_3^{2+}$, SO_4^{2-} and $4H_2O$	0.971
$CuSO_4 \cdot 5H_2O$	$Cu(OH_2)_2^{2+}$, SO_4^{2-} and $3H_2O$	0.969

9) F. Basalo and R. G. Pearson, "Mechanisms of Inorganic Reactions," John Wiley and Sons, Inc., New York (1967), p. 34.

10) For example; J. E. Prue, *J. Chem. Educ.*, **46**, 12 (1969).

11) J. H. Wang, C. V. Robinson and I. S. Edelman, *J. Amer. Chem. Soc.*, **75**, 466 (1953).

are assumed to be "half-undressed" in the concentrated solutions, the values of S may be given as follows from Eq. (9):
(a) For $CoSO_4 \cdot 7H_2O$ and $NiSO_4 \cdot 7H_2O$ $S = (3 \times 1.000 + 4 \times 0.949)/7 = 0.971$, (b) for $CuSO_4 \cdot 5H_2O$ $S = (2 \times 1.000 + 3 \times 0.949)/5 = 0.969$. Table 2 shows the species of growth units assumed, and the corresponding values of S estimated, as above.

From Eq. (10), which is based on the volume-diffusion mechanism, on the other hand, the values of S become unity, irrespective of the number of free water molecules as well as of the species of the growth units.

Factors Affecting the Separation Factor. There are various factors which affect the separation factor. Among them, those cited below may be most important:

(1) Inner-sphere complexes may be easily formed with an increase in the concentration of the solution, giving rise to more free water molecules and, thus, to a larger fractionation of tritiated water.

(2) The dehydration of ions in a solution should tend to occur at higher temperatures, thus leading to an increase in the fractionation of tritiated water.

(3) The weaker hydration of the cation may favor the release of the molecules from the inner-sphere complex,[12] which will in turn make the fractionation larger.

(4) Rapid crystallization (growth from a highly-supersaturated solution) may result in less fractionation of tritiated water, since it can be assumed that the equilibrium is no longer attained between growth units in the solution and the crystal surface.

(5) The situation becomes complicated at a high concentration of the hydronium ion because of proton transfer through water and proton injection into the crystal.[13] The effect on the fractionation of tritium can be neglected when the concentration of H_2TO^+ is very low.

Fractionation of Tritium and Crystal Growth. (1) Since the agreement between the calculated values of S listed in Table 2 and the experimental values seems to be satisfactory, it may be noted qualitatively that some dilution of tritiated water occurs in the hydrated salts. This ambiguity, however, may be inevitable at this stage, because many assumptions are involved in the preceding argument, especially because the number of free water molecules is adjustable.

(2) The point in our argument is not the absolute value of crystal growth rate, R, but the ratio of R_{HTO}/R_{H_2O}. Although the crystal growth process from an unstirred solution is influenced by the mass-transfer of a growth unit, the ratio of R_{HTO}/R_{H_2O} may be unaffected by the mass-transfer, since the D_{HTO}/D_{H_2O} ratio is nearly equal to unity.

(3) Free water molecules, in fact, can not integrate into the crystal independently, but crystallize accompanying the ion with the lowest relaxation time, since growth units are fixed into the crystal in a stoichiometric way. We presume, however, that it should be possible to obtain the ratio of R_{HTO} to R_{H_2O} either from Eq. (7) or from (8).

(4) Even if the spiral-growth model employed above might be partly disturbed by two-dimensional nuclei formed between steps at a higher supersaturation,[14] it is probable that the surface-diffusion mechanism is not seriously affected by the possible disturbance. We can thus estimate the ratio of R_{HTO} to R_{H_2O} independently of the nucleation, since the growth of the nuclei results from the surface diffusion and the subsequent integration of growth units into the kinks.

(5) It may be generally accepted that water molecules of crystallization come partly from free water in a solution and partly from hydration water in the growth of a hydrated crystal, recognizing that, practically, the latter is not subject to the fractionation of tritiated water.

(6) From the fact that the concept of the surface diffusion for crystal growth from a solution is adequate to explain the experimental results, while the concept of volume diffusion is not, it may be concluded that: (a) some free water must enter the crystal by the surface-diffusion mechanism and (b) inogranic hydrated sulfates probably crystallize, also *via* a process of the surface diffusion of growth units.

The authors gratefully acknowledge Dr. Osamu Yamamoto's help with the tritium analyses. Thanks are also due to Mr. Asao Okinaka for his experiment on $CoSO_4 \cdot 7H_2O$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3083—3086 (1970)

Effect of Pressure on the Solubility of Diketopiperazine in Water*1

Keizo SUZUKI, Masao TSUCHIYA and Hideki KADONO

Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto

(Received April 27, 1970)

Diketopiperazine (DKP) was used as a model compound to investigate hydrogen bond interactions between the peptide bond and water under high pressure. The solubility of DKP in water was measured as a function of pressure up to about 6000 atm at 15, 25 and 35°C. It was observed that the solubility decreases with increasing pressure up to about 4500 atm, and then increases above this pressure. The solubility follows a simple exponential dependence upon pressure at least below 4500 atm. The volume change ΔV accompanying the dissolution of DKP in water is obtained from this pressure dependence of the solubility. The values of ΔV are 5.2 and 5.9 ml/mol at 25° and 35°C, respectively. These values coincide well with those obtained from dilatometric measurements at 1 atm. The reason why the solubility is inverted at the pressure above and below 4500 atm is ascribed to the change of water structure brought about by the compression. The effect of pressure on proteins reported in the previous paper is discussed in relation to the present solubility results.

There is evidence that the effect of pressure on proteines is inverted at the pressure above and below 3000 atm.[1] The reason for this curious inversion may be investigated through appropriate model systems. It is well known that hydrogen bonds play a primary role in maintaining the conformation of proteins.

Diketopiperazine (DKP, ) which is a cyclic compound formed through the condensation of 2 molecules of glycine, has been used as a model compound by Gill *et al.*[2] to investigate hydrogen bond interactions. The structure of DKP indicates the possibilities for hydrogen bonds. These possibilities are borne out in the studies of crystal structure[3] and the infrared spectrum using polarized radiation,[4] which show DKP molecules form linear hydrogen bonded polymers in the solid structure. The energy of hydrogen bond maintaining the DKP crystal has been found to be 7 kcal/mol-H bond from the measurements of vapor pressure of DKP by Seki *et al.*[5]

In this report the solubility of DKP in water was measured as a function of pressure to investigate the influence of pressure on the intermolecular forces between DKP-DKP molecules and DKP-water molecules and to gain insight into the behavior of pressure on proteins. The hydrogen bonded interactions between DKP-DKP molecules are analogous to those which maintain the folded structure of proteins. The dissolution of DKP in water is assumed to be analogous to the rupture of the folded structure of proteins.

The solubility measurements of solids under hydrostatic pressure above 1000 atm are seldom found in literatures. Therefore such an experiment is worthwhile to be performed not only for DKP but also for any compound.

The volume changes ΔV that accompany the dissolution of DKP in water were measured at 1 atm by dilatometry, since such a value is a valuable quantity for predicting the initial effect of pressure upon solubility and also for investigating the interactions between DKP-DKP and DKP-water.

Experimental

Sample Preparations. DKP was prepared by the method of Dunn.[6] The product was recrystallized twice from water. The product gave a negative ninhydrin test and was subjected to thin-layer chromato-

graphic analysis. The chromatography indicated no impurity.

Solubility Measurement. For the measurement of solubility of DKP a simple method of residue analysis was used. The solubility data at 25°C and 1 atm with this method was coincident with that obtained by refractive index method.[2]

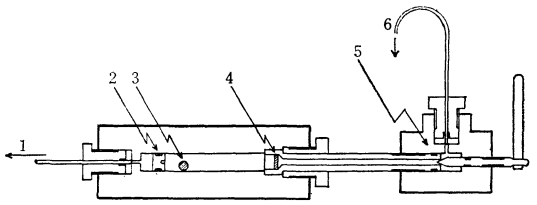

Fig. 1. High pressure equipment for measuring a solubility of solid.
1: To intensifier, 2: Piston, 3: Stainless steel ball, 4: Glass filter, 5: High pressure valve, 6: Outlet

Figure 1 shows the apparatus, which is constructed from a high pressure vessel for obtaining equilibrium solutions and high pressure valve. It is connected to an intensifier with 1/8″ diameter tubing. Glass filter is set at the outlet of the vessel to separate solid DKP from saturated solutions. High pressure measurements were performed with manganin electric-resistance gauge calibrated against Heise's precision pressure gauge of Bourdon type (50 psi scale up to 50000 psi). Paraffin oil was used as a pressure transmitting medium.

To obtain an equilibrium solution, the apparatus was shaken for about 4 hr like a seesaw in a constant temperature bath. The stainless steel ball inserted in the vessel was useful for stirring. Saturated solution was sampled out through high pressure valve by pushing the piston with oil-pump under the pressure as stable as possible. To check the apparatus and the procedures, the solubility of NaCl in water was measured at 25°C and 1000 atm. The accuracy was within ±0.2%, and the solubility data (27.06%) coincided well with that in the reference (27.07%[7]).

Dilatometry. Carlsberg type dilatometer[8] was used to measure the volume change accompanying the dissolution of DKP in water at 1 atm. Kelosine was used as the medium. It was ascertained that kerosine did not attack DKP. Before mixing, the occluded air in DKP sample was thoroughly evacuated. Thermostat was kept within ±0.003°C.

Results and Discussion

Solubility data are listed in Table 1, and are plotted in Fig. 2. These results show that solubility decreases with increasing pressure up to about 4500 atm, but this trend is inverted above this pressure.

In Fig. 3 DKP solubility data at 1 atm is plotted against temperature with the data of Gill *et al.*[2]

Table 1. Solubility of DKP (wt%)

atm / °C	1	1400	2800	4200	5600
15	1.16	0.88	0.68	0.55	0.67
25	1.66	1.25	0.93	0.68	0.82
35	2.32	1.66	1.17	0.90	1.15

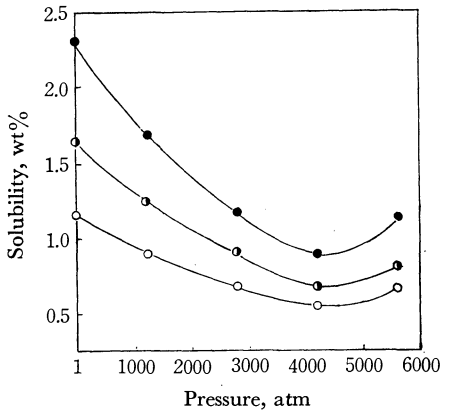

Fig. 2. Solubility of DKP *versus* pressure.
○: 15°C, ◑: 25°C, ●: 35°C

The data when plotted in logarithmic solubility (m_s, molality) *versus* $1/T$, are adequately represented by a straight line. The heat of solution ΔH is calculated from the slope using the relation

$$\left[\frac{\partial \ln m_s}{\partial(1/T)}\right]_p = \frac{-\Delta H}{R} \qquad (1)$$

The value of ΔH determined at 1 atm is 6.2 kcal/mol. This value decreases with increasing pressure, and ΔH value at 4000 atm is 3.3 kcal/mol. That is, the process of DKP dissolution in water is endothermic, and the solubility increases with rising temperature. It is noticed that the pressure effect below 4500 atm on the DKP solubility is opposite

to the result of temperature.

The effect of pressure on the solubility of solid in liquid is given by the following relation, assuming the activity coefficients of both the solute and solvent are independent of the pressure,

$$\left(\frac{\partial \ln m_s}{\partial p}\right)_T \approx \frac{V'-\bar{V}}{RT} = \frac{-\Delta V}{RT} \qquad (2)$$

where m_s is the molar concentration in the saturated solution, V' the molar volume of the solid, $\bar{V}$ its partial molar volume in the saturated solution and ΔV the volume change accompanying the dissolution of solid in liquid. The DKP solubility decreases with increasing pressure below 4500 atm. This means that $\bar{V}$ is larger than V', that is ΔV is positive. Above this pressure, on the other hand, ΔV changes the sign to negative. The relation between $\ln m_s$ and pressure is almost linear below 4500 atm, and the ΔV values obtained from the slope are listed in Table 2. The ΔV values above this pressure in Table 2 are calculated by Eq. (2).

Table 2. Volume change accompanying dissolution of DKP (ml/mol)

atm / °C	<4500	>4500	1*

25	+5.2	−5.3	+5.29
35	+5.9	−6.9	+5.88

* by dilatometric measurements

Figure 4 shows the dilatometric results measured at 1 atm. The ΔV values accompanying the dissolution of DKP at saturated concentration is obtained by extrapolating the straight line to the saturated concentration. The ΔV values thus obtained are also listed in the last column of Table 2, which coincide well with those from $\ln m_s$ *versus* pressure plot.

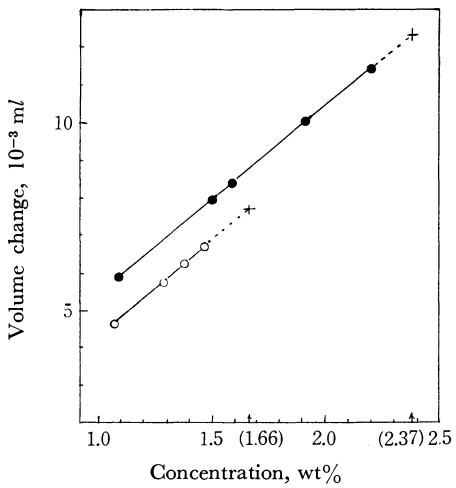

Fig. 4. Volume change accompanying dissolution of DKP.
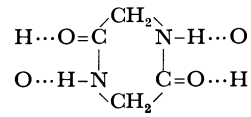
○: 25°C, ●: 35°C, +: Saturated point

The molar volume of solid DKP is found to be 71.7 and 72.1 ml/mol at 25 and 35°C from our measurements of specific gravity. Therefore the partial molar volume in the saturated solution can be estimated from $\bar{V}=V'+\Delta V$. The $\bar{V}$ values thus calculated are 77.0 and 78.0 ml/mol at 25 and 35°C, respectively. Therefore, the difference between V' and $\bar{V}$ is only 8—9%. This suggests that the DKP dissolution in water is mono-dispersion. In view of the observed linearity of the logarithmic solubility *versus* $1/T$ plot and of the logarithmic solubility *versus* pressure below 4500 atm, mono-dispersion is ascertained over the region investigated.

The intermolecular energy maintaining the DKP crystal is estimated to be 24.83 ± 0.51 kcal/mol from the heat of sublimation, which is the sum of the hydrogen bond energies (14.0 kcal/mol) and van der Waals energies (10.9 kcal/mol).[5] The fact that the DKP crystal dissolves in water can be understood as follows: the intermolecular forces forming the crystal are ruptured and each DKP molecule dissolves in water in hydrated state. As mentioned above, the heat of solution is 6.2 kcal/mol at 1 atm. The difference of both the values, 18.6 kcal/mol (=24.8−6.2) is to be assumed as the heat of interactions between DKP and water molecules when DKP dissolves in water. One kind of the interactions is undoubtedly the hydrogen bond between a DKP molecule and 4 molecules of water as follows:



The other kind of interaction between the hydrocarbon moiety of DKP and the surrounding water molecules is supposed when DKP molecule is transferred to water. However, the enthalpy change in the transfer of aromatic hydrocarbons to water has been found to be almost zero.[9] Therefore it will be unnecessary to consider the contribution of this interaction. As mentioned above, one molecule of DKP can interact with 4 molecules of water. Then the binding energy in a set of hydration is 4.7 kcal/mol-H bond as the mean value (18.6 kcal/mol is divided by 4). This seems to be reasonable value as the energy of hydrogen bond.

The volume change accompanying the DKP dissolution is the difference between the partial molar volume $\bar{V}$ and the molar volume of DKP crystal V' as already shown in Eq. (2). Thus, the volume change ΔV reflects the changes of intermolecular forces between DKP-DKP and DKP-

9) W. Kauzmann, *Advances in Protein Chem.*, **14**, 39 (1959).

water. The effect of pressure on V' is assumed to be too small to be neglected as compared to the effect on $\bar{V}$. The partial molar volume $\bar{V}$ is influenced by the hydrogen bonds between DKP and water, that is, NH···O and CO···H, and the interaction between hydrocarbon moiety of DKP and water such as in "icebergs".[10] The positive value of ΔV below 4500 atm means that $\bar{V}$ is larger than V', and the negative value of ΔV above 4500 atm means that V' is larger than $\bar{V}$. This inversion must be ascribed mainly to the decrease of $\bar{V}$ above 4500 atm. This volume contraction might be probably deduced, because the interactions between DKP and water molecules become very strong above 4500 atm owing to the change of water structure brought about by the compression.

It is very interesting to compare the pressure effect on the DKP solubility with the influence of pressure on proteins. The higher pressure above 3000 atm causes the denaturation of proteins, while the lower pressure below 3000 atm retards the heat denaturation of proteins and accelerates the recovery of proteins once denatured by heat and pressure.[1] The denaturation phenomenon in which the folded structure of proteins changes into the unfolded structure is analogous to the dissolution of DKP crystal in water. That is, the folded protein corresponds to the DKP crystal, and the unfolded protein corresponds to the dissolved DKP in the hydrated state. If V' is the molar volume of the folded protein, and $\bar{V}$ is that of the unfolded protein, the sign of the volume change ΔV ($=\bar{V}-V'$) defines the direction of the process: folded protein (native) $\rightleftharpoons$unfolded protein (denatured). It is plausibly supposed that at the higher pressure above 3000 atm where the proteins are denatured, ΔV becomes negative, while at the lower pressure below 3000 atm where the denatured proteins are recovered, ΔV becomes positive as in the case of the DKP dissolution in water. This inversion must be ascribed mainly to the large decrease of $\bar{V}$ above 3000 atm, because the interaction between protein and water molecules becomes so strong due to the change of water structure above this pressure that the interaction maintaining the folded structure of protein is ruptured. The discrepancy in the pressure (4500 atm in DKP and 3000 atm in proteins) where the inversion occurs is not fatal, because at least in proteins this inversion pressure is considerably influenced by the change of the state of medium such as pH, buffer, ionic strength and so on as well as the difference of proteins.

The authors wish to express their thanks to Professor W. Kauzmann of Princeton University for his valuable suggestions, and to Mr. N. Maeda for his assistance in carrying out the measurements. The cost of this research was paid by a Scientific Research Grant of the Ministry of Education.

Electronic Structures of the Ring-Protonated Aromatic Amines

Tsuguo YAMAOKA*1

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received April 27, 1970)

In order to study the electronic spectra and stabilities of the ring protonated aromatic amines, π-electron structure of nineteen amino-substituted pentadienyl cations were calculated by the composite molecule method. The lower electronic transitions of these ions are assigned to the charge transfer from amino groups to the pentadienyl cation. Stability of the ground state depends on the extent of intramolecular charge transfer, which is determined by the position and number of amino-substitution. The amino group on 1-, 3- or 5-carbon atom greatly stabilizes the ground state while contribution of the amino group on the other position is quite small. Occurrence of the ring or amino protonation for various amino-substituted benzenes is shown to be well predicted by the calculated stabilization energy.

Unlike the ordinary mode of protonation[1] to the aromatic amine, 1,3,5-triaminobenzene in a weakly

*1 Present address: Department of Printing, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba, Japan.

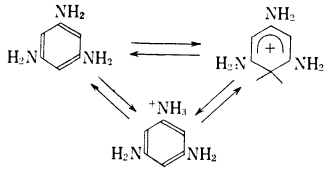
acidic solution is singly protonated to the ring carbon atom as well as to the amino group,[2] and the following equilibrium exists among the three components.



In a previous paper,[3] we reported that in this equilibrium system, ring protonation is predominant at room temperature while the species protonated on the amino group increases its concentration with decreasing temperature. It was demonstrated spectroscopically that ring protonation of this type also takes place for *N,N*-dimethyl-*m*-phenylenediamine in an acidified aqueous solution but not for *N,N*-dimethyl-*p*-phenylenediamine.

The mode of protonation seems to be determined by a slight difference in the stability of the protonated species, and therefore very sensitive to the number and position of the amino-substituent. For discussion on this point, the π-electron structures of several ring-protonated aminobenzenes have been calculated by the so called "composite molecule (CM) method." By this method the stabilization energy due to the transfer of π-electrons from amino groups to the benzene ring can be given. The specificity observed with the protonation to various aminobenzenes is discussed on the basis of the calculated stabilization energies.

Method of Calculation

Let us explain the calculation procedure taking 1,3,5-triaminobenzenium ion as an example. The so-called π-electron approximation is adopted and only the singlet states are considered. First the system was divided into two components, *i. e.*, benzenium ion (or pentadienyl cation with 4 π-electrons) and amino groups (with 2 π-electrons per group). The Hückel orbitals (1, 2,$\cdots$5) of the pentadienyl cation $C_5H_7^+$ were taken as the orbitals for benzenium ion, since they are not appreciably different from the SCF MO by the Pariser-Parr-Pople (PPP) method.[4] The three lone-pair orbitals of the amino groups are represented by n_i's where suffix i indicates the position of the carbon atom to which the respective amino groups are attached. Numbering of the atoms and geometry of the molecule are shown in Fig. 1. The bond distances

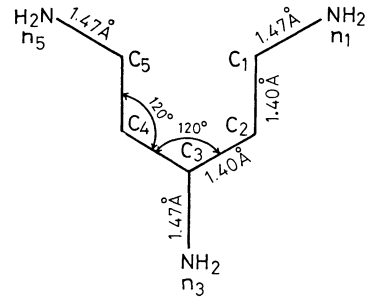


Fig. 1. Geometrical structure and numbering of 1,3,5-triaminopentadienyl cation.

and angles were assumed to be 1.40 Å for C=C bond and 1.47 Å for C–N bond, respectively. All the angles were assumed to be 120°. The two lone-pair orbitals (n_1 and n_5) of the amino groups were combined to give the symmetric n_{s15} and antisymmetric n_{a15} group orbitals

$$n_{s15} = (n_1+n_5)/\sqrt{2}$$
$$n_{a15} = (n_1-n_5)/\sqrt{2}.$$

With the use of the above-mentioned orbitals of the components, ground (G) and several locally-excited (LE's) and charge-transfer (CT's) configurations were constructed, as shown in Fig. 2. The energies of the lowest two locally-excited configurations (LE_1, LE_2) were those estimated from the transition energies of several methylated benzenium ions observed by Hanazaki and Nagakura,[5] while the energy of LE_3 was taken from the value calculated by the same authors. The energies of CT configurations were calculated by the relation, $I-A-\Delta C$, where I, A and ΔC stand for the ionization potential of an amino group (10.15 eV),[6] the electron affinity of the benzenium ion (estimated to be 7.50 eV*[2]) and the electrostatic interaction energy caused by an electron transfer from an amino group to the benzenium ion, respectively. We adopted the Pariser-Parr approximation[8] for evaluating the two-center Coulomb integrals necessary for the calculation of ΔC.

Non-zero off-diagonal matrix elements for the interactions of CT configurations with ground (G)

Results and Discussion

Table 1 shows calculated and observed energies and oscillator strengths for the lower transitions of 1,3,5-triaminobenzenium ion. Results of the Pariser-Parr-Pople type calculation were also cited from the previous paper.[3)] The wavefunctions of the ground and excited states are shown in Table 2 to clarify the nature of each transition. As evident from Table 1, the lowest two transitions at 360 mμ and 273 mμ are undoubtedly assigned to the charge-transfer from the amino groups to the ring, the direction of the transition dipoles being perpendicular and parallel to the molecular axis, respectively. The third transition, though not observed, has also a charge-transfer character (parallel band). The results are in good agreement with those obtained previously by the PPP method.

Figure 2 shows the configuration energies used for the present calculation and also the evaluated state energies. The energy of the ground state, 2.186 eV below zero, corresponds to the π-electron stabilization energy (ΔE) caused by the resonance between the ring and amino groups.

In Table 3 the calculated ΔE values of nineteen aminosubstituted benzenium ions are summarized, together with the lower π-electronic transition energies. For some compounds the calculated oscillator strengths are also given. It is apparent that the larger the number of amino groups, the more the ion is stabilized. On close inspection and least-squares calculation, ΔE is found to be additively increased by the amino groups on the ortho, meta and para positions to the protonated carbon with the following values:

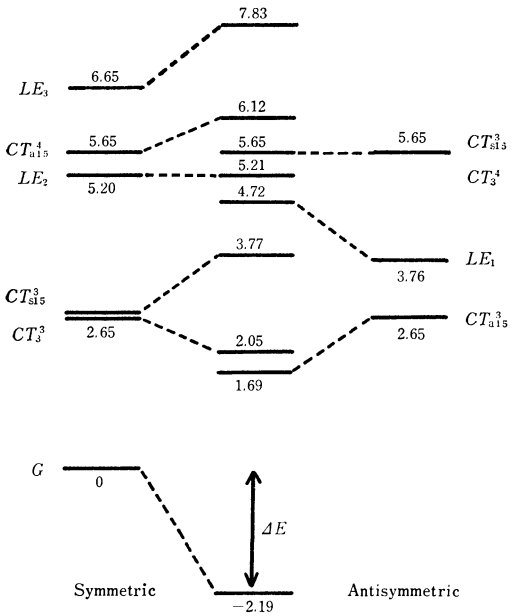

Fig. 2. Configurations used for the CM calculation and the evaluated state energies (eV) of the 1,3,5-triaminopentadienyl cation. Configurations are represented as follows.
$G=|1\bar{1}2\bar{2}n_{s15}\bar{n}_{s15}n_{a15}\bar{n}_{a15}n_3\bar{n}_3|$, $LE_1=\Psi(2\text{—}3)$, $LE_2=\{\Psi(2\rightarrow4)-2\Psi(1\text{—}3)\}/\sqrt{5}$, $LE_3=\{2\Psi(2\rightarrow4)-\Psi(1\text{—}3)\}/\sqrt{5}$, $CT^3{}_{s15}=\Psi(n_{s15}\rightarrow3)$, $CT^3{}_{a15}=\Psi(n_{a15}\rightarrow3)$, $CT_3{}^3=\Psi(n_3\rightarrow3)$, $CT^4{}_{s25}=\Psi(n_{s15}\rightarrow4)$, $CT^4{}_{a15}=\Psi(n_{a15}\rightarrow4)$, $CT_3{}^4=\Psi(n_3\rightarrow4)$, where $\Psi(a\rightarrow b)=\{|\cdots ab\cdots|+|\cdots ba\cdots|\}/\sqrt{2}$ and 1, 2 ··· are the Hückel MO's of the pentadienyl cation.

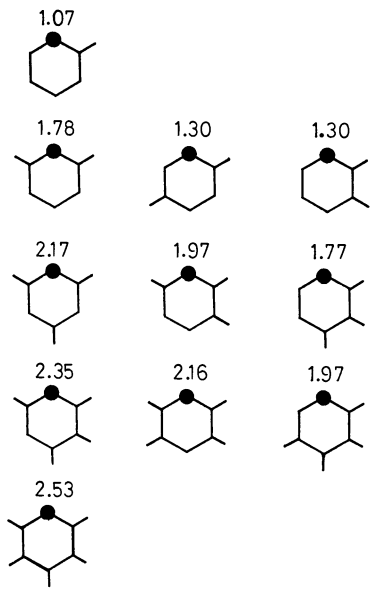

Fig. 3. The most probable sites of the ring-protonation of a series of amino-substituted benzenes are shown by the filled circles. Numbers show the values of ΔE in eV.

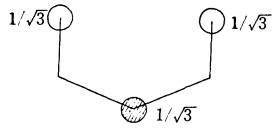
a) numbers show the position of substitution of the amino group.
b) with respect to molecular axis.

0.81 eV per *o*-NH_2
0.30 eV per *m*-NH_2
0.62 eV per *p*-NH_2.

This simple relationship can be easily explained on the basis of perturbation treatment, if one recalls the shape of the lowest vacant orbital of the

benzenium ion into which the electron migrates from the amino groups. The perturbation of the amino groups on the meta positions might be small because the coefficients of the lowest vacant orbital on these positions are almost zero as shown below.



Here we take 1.7 eV as the borderline value of ΔE between the ring and amino protonations, although it is difficult to determine definitely. The filled circles in Fig. 3 indicate the most probable sites of the ring-protonation of a series of amino-substituted benzenes. The fact that a spectrum of a ring-protonated species could be observed for *N,N*-dimethyl-*m*-phenylenediamine ($\Delta E = 1.78$ eV) but not for *N,N*-dimethyl-*p*-phenylenediamine ($\Delta E = 1.30$ eV) can be explained by the borderline value of ΔE. The electronic spectra and the mode of amino-substitution do not seem to be correlated with each other by a simple relation.

The author would like to express his grateful acknowledgment to Professor Saburo Nagakura, the Institute for Solid State Physics, the University of Tokyo for his valuable suggestions and encouragement. His thanks are also due to Professor Haruo Hosoya, Ochanomizu University, for much helpful advice and to Professor Takahiro Tsunoda, Chiba University, for his continued support during this work.

Scavengeable Electron Yield in the Radiolysis of Liquid and Solid Hydrocarbons

Toyoaki KIMURA, Kenji Fueki and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received May 1, 1970)

Yields of scavenged electrons have been measured in MCH, 3MP, cumene and *tert*-butylbenzene at 20°C and −196°C. It has been found that the yield of scavenged electrons is considerably lower at −196°C in the glassy state than at 20°C in the liquid state. The temperature effect on electron scavenging indicates that the difference in the yields of scavenged electrons between the liquid and glassy states is attributed to the variation not of temperature but of the physical conditions of the matrix. We have also investigated the effect of composition in MCH-MTHF mixtures and that of the viscosity of the matrix upon the yield of scavenged electrons at −196°C, which has led us to the assumption that the extent of interactions between thermalized electrons and the matrix would affect the yield of scavenged electrons at −196°C. Since such interactions may be related to the mean free path of electrons, we have calculated the contribution of the electron jump distance to the electron scavenging efficiency. The calculated results appear to explain qualitatively the experimental results.

Recent development in the techniques for measurement of reaction intermediates, such as ESR or optical absorption, has brought about very useful information in the field of radiation chemistry. These measurements have usually been made for reaction intermediates in rigid matrices. In order to utilize such information to understand primary processes in radiation chemistry or to correlate it with reaction mechanisms, the application of product analysis to rigid systems is highly desirable.

Our previous studies on the radiolysis of glassy hydrocarbons at −196°C unexpectedly revealed that the scavenged electron yield is much lower than that expected from the liquid phase experiments.[1,2] Shirom and Willard[3] and Shida and Imamura[4] have also reported low scavengeable electron yields in hydrocarbon glasses at −196°C.

However, we could little observe effect of irradiation temperature on hydrogen formation for a number of hydrocarbons.[5] These apparently conflicting observations should be clarified to get a complete understanding of radiolysis mechanisms in condensed phases. The question why the yield of scavenged electrons is much lower at −196°C is an important one. In this paper we present factors responsible for the lower yield of scavenged electrons in hydrocarbon glasses at −196°C.

We use bromobenzene or *o*-bromotoluene as an electron scavenger to obtain the yield of scavenged electrons. These substances scavenge an electron to form a phenyl radical, which immediately abstracts an H atom from a solvent molecule to form benzene and a solvent radical:

$$RH \rightsquigarrow RH^+ + e^- \quad (1)$$

$$C_6H_5Br + e^- \longrightarrow C_6H_5\cdot + Br^- \quad (2)$$

$$C_6H_5\cdot + RH \longrightarrow C_6H_6 + R\cdot \quad (3)$$

Benzene formation *via* Br atom abstraction by an H atom can be excluded.[6]

$$H + C_6H_5Br \xrightarrow{\times} C_6H_5\cdot + HBr \quad (4)$$

Thus we can determine the scavenged electron yield from the yield of benzene. To measure the yield of scavenged electrons, N_2O is widely used in the liquid phase, and biphenyl in the glassy state. However, there is ambiguity in the ratio of the nitrogen yield to the scavenged electron yield at −196°C,[1] and biphenyl cannot be used for conventional kinetic studies of liquid phase radiolysis. The merit of the use of halogen substituted benzene (or toluene) are (i) the yield of benzene is equal to the yield of electrons scavenged, and (ii) the method can be applied to both liquid and glassy states.

Experimental

Materials. Methylcyclohexane (MCH) was a product of Tokyo Kagaku Seiki (99.9%) and used without any treatment. Cumene and *t*-butylbenzene were Nakarai guaranteed reagents and fractionally distilled before use. Aldrich 3-methylpentane (3MP) was shaken with concentrated sulfuric acid in a separating flask, and washed with distilled water. After drying over sodium sulfate, 3MP was passed through a silica gel column and then fractionally distilled. Nakarai guaranteed reagent isopentane was used after the same purification as for 3MP. Bromobenzene and *o*-bromotoluene were Nakarai guaranteed reagents, and were fractionally distilled after passing through an activated alumina column. K & K 2-methyltetrahydrofuran (MTHF) was refluxed over potassium hydroxide, fractionally distilled, and passed through an activated alumina column. The middle fraction was used immediately after purification. Tokyo Kasei extra pure reagent biphenyl was used after being recrystallized three times.

Sample Preparation. Each sample was degassed in a 10 mm glass tube by the freeze-pump-thaw technique and then sealed off.

Irradiation. A 3000 Ci ^{60}Co source was used for γ irradiation. Irradiation doses were 2.14×10^{20} eV/g at 20°C, 1.69×10^{20} eV/g at −72°C, 5.05×10^{19} eV/g at −120°C, and 1.71×10^{20} eV/g at −196°C.

Analysis. Yields of benzene and toluene produced were determined by a Hitachi K 53 gas chromatograph with FID. The columns used were *n*-hexatriacontane and TCP. Optical absorption measurements were carried out as follows. Samples were degassed in a glass tube and transferred to a rectangular quartz cell (10 mm × 5 mm). After irradiation in the dark at −196°, absorption measurements were carried out with a Hitachi EPU-2 spectrophotometer. The dose was 9.85×10^{17} eV/g in the experiments.

Results and Discussion

Figure 1 shows benzene yields from bromobenzene-MCH systems γ-irradiated at 20°C and −196°C. Since the ionization potential of MCH is higher than that of bromobenzene, charge transfer from the MCH positive ion to bromobenzene may occur and contribute to benzene formation to some extent. For the sake of confirmations, we added cumene as a positive ion scavenger to the bromobenzene-MCH systems. The results obtained are shown in Fig. 1. The concentration of

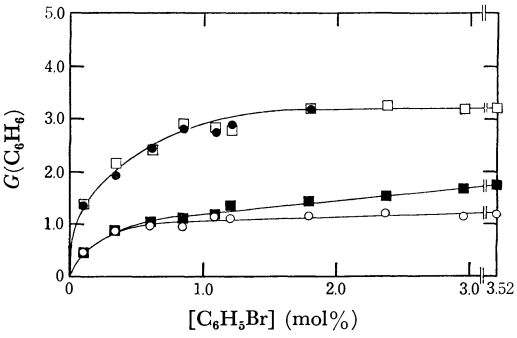

Fig. 1. Yields of benzene from γ-irradiated bromobenzene-MCH systems.
□ at 20°C in the absence of cumene, ■ at −196°C in the absence of cumene, ● at 20°C in the presence of 21.5 mol% of cumene, ○ at −196°C in the presence of 21.5 mol% of cumene

cumene (21.5 mol%) is high enough to scavenge MCH positive ions adequately.[2] Direct benzene formation from cumene was negligible as will be described later. In the liquid state at 20°C the benzene yield was not affected by the presence of cumene, but at −196°C it was lowered slightly at higher bromobenzene concentrations (above ~1 mol%). The reason for this may be that charge

5) T. Kimura, K. Fueki and Z. Kuri, This Bulletin, **43**, 1657 (1970).

transfer from MCH positive ions to bromobenzene molecules occurs both at 20°C and −196°C:*1

$$MCH^+ + C_6H_5Br \longrightarrow MCH + C_6H_5Br^+ \quad (5)$$

Bromobenzene positive ions seem to react with bromide ions at 20°C, but with electrons at −196°C, since more than half of the electrons are scavenged to form bromide ions at 20°C but only a small fraction at −196°C. The reaction of bromobenzene positive ions with electrons might lead to benzene formation, although that with bromide ions does not seem to yield benzene:

$$C_6H_5Br^+ + Br^- \longrightarrow \text{no } C_6H_6 \text{ at } 20°C \quad (6)$$

$$C_6H_5Br^+ + e^- \longrightarrow C_6H_6 \text{ at } -196°C \quad (7)$$

It is expected that cumene supresses reaction (5). Thus, in the presence of cumene the yield of benzene will decrease *via* suppression of reaction (7) at −196°C if reaction (7) occurs at all, but not at 20°C (reaction (6)). It has been found, however, that in the bromobenzene concentration range below 1 mol%, benzene yields from cumene-free systems coincide with those from cumene-added systems at both 20°C and −196°C. Therefore we can say that charge transfer from the MCH positive ion to bromobenzene contributes little to benzene formation in this bromobenzene concentration range and that the positive charge scavenger does not affect the efficiency of electron scavenging. The benzene yields in the presence of cumene shown in Fig. 1 are in agreement with previous results.[1]

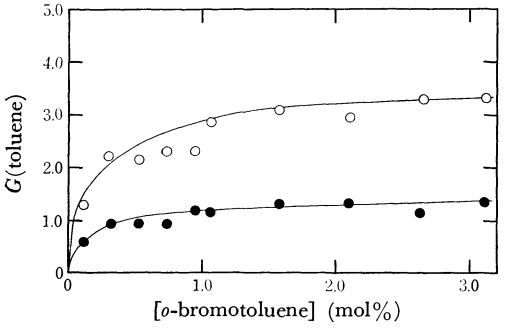

Fig. 2. Yields of toluene from γ-irradiated *o*-bromotoluene-3MP systems.
○ at 20°C, ● at −196°C

Figure 2 shows toluene yields from *o*-bromotoluene-3MP systems γ-irradiated at 20°C and −196°C. Since the limiting value of toluene yield at 20°C is 3.3 G and that at −196°C is 1.3 G, the contribution of positive charge transfer to toluene formation is negligible. The limiting toluene yield in 3MP at −196°C, namely, the scavengeable electron yield agrees well with that by Shirom and Willard.[3]

*1 We previously suggested that positive charge transfer is hardly affected by temperature.[2]

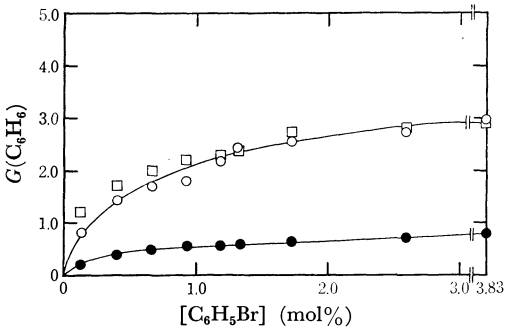

Fig. 3. Yields of benzene from γ-irradiated bromobenzene-cumene systems.
○ at 20°C, □ at −72°C, ● at −196°C.

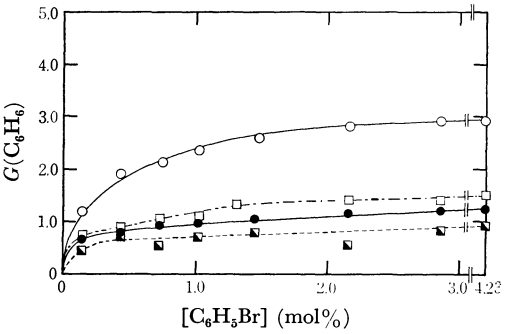

Fig. 4. Yields of benzene from γ-irradiated bromobenzene-*t*-butylbenzene systems: ○ at 20°C, □ at −72°C, ◪ at 120−°C, ● at −196°C.

In both cases of MCH and 3MP, the scavenged electron yields at −196°C are considerably lower than those at 20°C. Such a difference in the yield may be caused by the variation of temperature or the change in physical properties of the system (including phase change). To ascertain this, we investigated the temperature-dependence of electron scavenging. For this purpose we used cumene and *t*-butylbenzene because they form glass at −196°C, and their melting points lie in an experimentally feasible temperature region. Figures 3 and 4 show benzene yields from bromobenzene-cumene and bromobenzene-*t*-butylbenzene systems γ-irradiated at various temperatures. The benzene yield from pure cumene is 0.027 G at 20°C and 0.018 G at −196°C, and that from *t*-butylbenzene is 0.089 G at 20°C and is undetectably low −196°C. Since the ionization potentials of cumene and *t*-butylbenzene are lower than that of bromobenzene, positive charge transfer from solvent positive ions to solute molecules will not be possible. The limiting values of the yield of scavenged electrons in cumene and *t*-butylbenzene at 20°C are slightly lower than those in MCH and 3MP. Only the limiting value in cumene is somewhat lower at −196°C. In both cases of cumene and *t*-butylbenzene, the limiting values of scavenged electrons

at 20°C are considerably different from those at −196°C, as in the cases of MCH and 3MP. The experimental points for the yields of benzene produced from bromobenzene-cumene systems at −72°C and 20°C fit a single curve, though they deviate slightly at lower bromobenzene concentrations. The slight difference might be due to the change in density of cumene. On the other hand, in the case of *t*-butylbenzene, the experimental curve for benzene yield at −72°C is very similar to that at −196°C. Thus it can be concluded that the difference in scavenged electron yield between liquids and solids is not caused by the difference in temperature, but can be ascribed to the change in physical properties of solvents. We calculated the maximum scavengeable electron yield for a better understanding of the above situation. For this purpose the empirical equation proposed by Warman *et al.*[6] was used:

$$G(e^-) = G_{fi} + G_{gi}(\alpha_s[S])^{1/2}/\{1+(\alpha_s[S])^{1/2}\} \quad (8)$$

where G_{fi} is the yield of free electrons, G_{gi} is that of electrons which undergo geminate recombination, [S] is molarity of scavenger and α_s is an empirical parameter. The data were taken from experiments on *t*-butylbenzene systems at 20°C and −196°C (Fig. 4). The results calculated from the equation are plotted in Fig. 5. In the calculation, we assumed that the free electron yield, G_{fi}, is zero at 20°C and −196°C and that the density of *t*-butylbenzene at −196°C is 1.0. Since we have taken $G_{fi}=0$, the value extrapolated to [S]→∞ means the maximum scavengable electron yield. The maximum scavengable electron yields thus obtained are 4.0 G at 20°C and 1.8 G at −196°C.

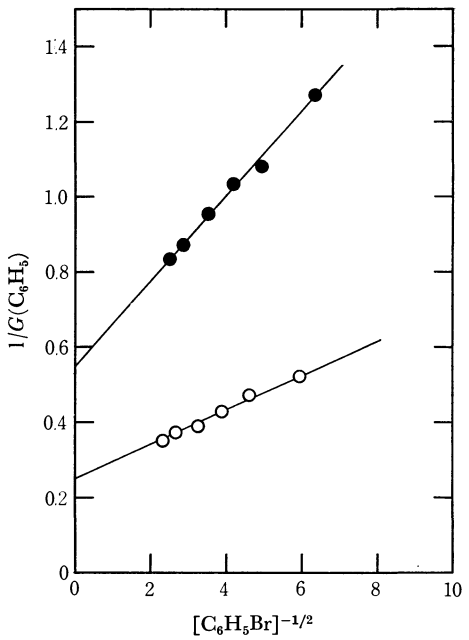

Fig. 5. Plot of $1/G(C_6H_6)$ as a function of $[C_6H_5Br]^{-1/2}$ in bromobenzene-*t*-butylbenzene systems irradiated at 20°C (○), at −196°C (●).

We can cite some possible reasons why the scavengable electron yield is much lower at −196°C: (i) decrease in the reactivity of solutes to electrons, (ii) decrease in the yield of initially ejected electrons, and (iii) recombination of a significant fraction of electrons with positive ions even in the presence of solutes in high concentrations. In order to test whether (i) is acceptable or not, we determined the values of α_s, which corresponds to the reactivity of the solutes to electrons, from the slopes of straight lines in Fig. 5. The values obtained are $\alpha_s=27.1$ at 20°C and $\alpha_s=22.5$ at −196°C. As these values indicate, the reactivity of bromobenzene to electrons at −196°C is not so different from that at 20°C, and so (i) cannot be a dominant factor. It is difficult to determine which is more probable, (ii) or (iii). Though the scavengeable electron yield in hydrocarbons at −196°C is lower, a major fraction of electrons can be scavenged in MTHF at −196°C[7,8]; the yield of biphenyl anion from γ-irradiated MTHF glass containing biphenyl as a solute reaches 2.8—3.0 G. Using the data by Kato *et al.*[8] and assuming $G_{fi}=0.15$, we obtain $G_{gi}=3.9$ in the same manner as that described above. Since the free ion yield in diethylether is 0.19 and that in *n*-butylether is 0.11,[9] the value assumed above for MTHF seems reasonable. Thus, we obtain a value of 4.05 as the total electron yield from γ-irradiated MTHF at −196°C. This indicates that there is no difference in the maximum scavengable electron yield between a liquid at 20°C and glass at −196°C. This contradictory result between MTHF and hydrocarbon glass seemed to suggest a clue to the problem. Thus we determined scavengable electron yields from mixtures of MTHF and a hydrocarbon at −196°C by measuring the yield of biphenyl anion from γ-irradiated MCH-MTHF glass at −196°C. The results are shown in Fig. 6. The absorption spectrum of biphenyl anion has λ_{max} at 409 mμ, and $\varepsilon_{409m\mu}$ 3.7×10^4 *l*/mol·cm.[7] Samples were prepared so as to contain 0.026 mol/*l* of biphenyl at room temperature. It is difficult to measure biphenyl anion in γ-irradiated pure MCH because of the cracking in MCH glass. In order to keep the system in transparent stable glass, 20 vol% of 3MP was added to MCH.

Since the scavenged electron yield in MCH is 1.55 G and that in MTHF is 2.75 G (Fig. 6), and if we assume that reason (ii) is right and that the yield of electrons initially ejected from MCH at

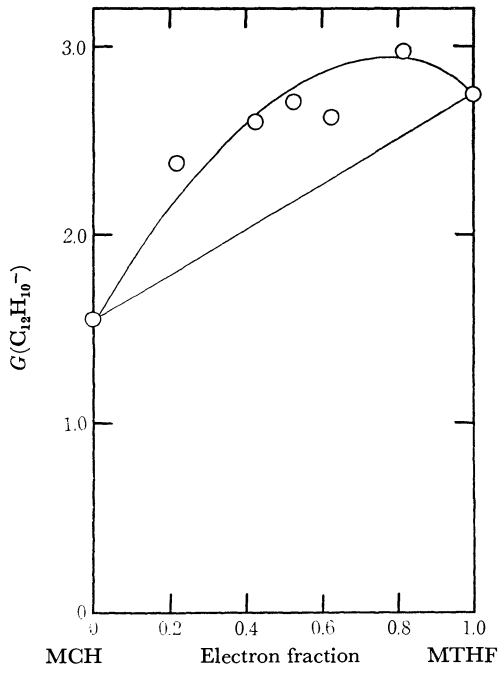

Fig. 6. Yields of biphenyl anion from γ-irradiated MCH-MTHF mixtures at −196°C, which contain 0.026 mol/l of biphenyl.

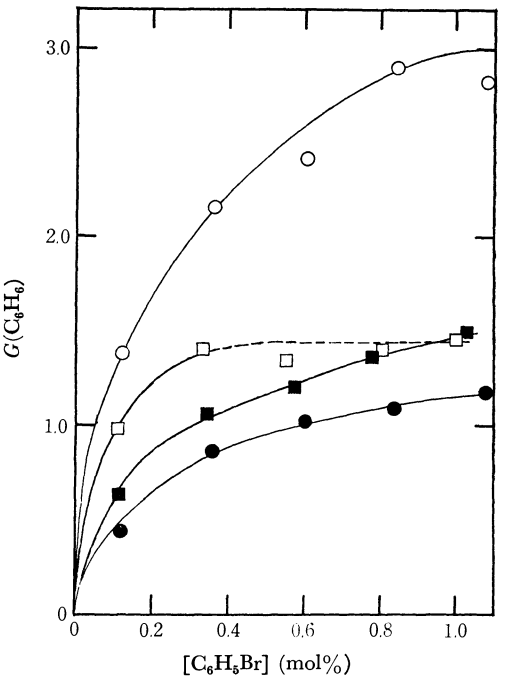

Fig. 7. Yields of benzene from γ-irradiated bromobenzene-hydrocarbon systems with various viscosities.
○ in liquid MCH at 20°C, □ in isopentane-MCH (10 : 1 Vol. ratio) mixed glass at −196 °C, ■ in isopentane-MCH (6 : 5 Vol. ratio) mixed glass at −196°C, ● in MCH glass at −196°C.

−196°C is 2.1 G,[4] about 70% of electrons are scavenged in both matrices. Accordingly, the yield of scavenged electrons from MCH-MTHF mixtures is expected to be proportional to the electron fraction; the experimental points are expected to be on the straight line in Fig. 6. However, all the experimental points for MCH-MTHF mixtures lie well above the straight line. For example, the scavenged electron yield, expected at an electron fraction of MTHF of 0.21, is $1.55(1-0.21)+2.75\times0.21$ G= 1.8G, but the observed yield is 2.38G. Since the yield of electrons initially ejected is $4.05\times0.21+2.1(1-0.21)$ G=2.5G in this case on the basis of the above assumption, it may be said that the efficiency of electron scavenging increases from 70% in MCH to 95% in this mixture. This would be explicable if a positive ion scavenger acts to increase the efficiency of electron scavenging in the region of electron scavenger concentrations studied, but the experimental results of Fig. 1 do not support this explanation. Thus, reason (ii) is not sufficient for the interpretation of our problem.

Finally, let us consider reason (iii). Why a significant fraction of electrons are recombined with positive ions without being scavenged by solutes at higher concentrations at −196°C remains to be answered. The maximum scavengeable electron yield is low in solid hydrocarbons, while it is about 4 in liquid hydrocarbons, and in liquid and solid MTHF. This suggests that interactions between thermalized electrons and solvent molecules affect the yield of scavengeable electrons. In cases of polar solvent, solvated or trapped electrons are observed, indicating strong interactions between electrons and solvents. In the case of liquid hydrocarbons, such interaction must exist to some extent because the motion of themalized electrons is diffusion-controlled. We consider that the electron-solvent interaction would be weaker in the case of solid hydrocarbons.

To develop such a consideration further, we measured the yield of scavenged electrons in hydrocarbon glass with various viscosities, which were prepared by adding isopentane to MCH. The results are shown in Fig. 7, together with the results on liquid and glassy MCH. As the solubility of bromobenzene in isopentane is low, the experimental curve reaches a plateau at lower bromobenzene concentrations in glass with higher concentrations of isopentane (the broken line in Fig.7). We can see that the yield of scavenged electrons depends upon the viscosity of the matrix. This seems to indicate that the electron-solvent interaction depends upon the viscosity of the solvent in hydrocarbon glass.

The interaction may be reflected by the distance of electron jump; the weaker the interaction, the

longer the electron jump distance, λ. Thus, we have calculated the effect of λ on the probability of electron scavenging at -196°C. The procedure of calculation is the same as that reported previously.[1] The probability of electron scavenging, Φ_-, is expressed as

$$\Phi_- = \phi_{fi} + \phi_-(1-\phi_{fi}) \quad (9)$$

$$\phi_{fi} = \exp(-r_c/y) \quad (10)$$

$$\log(1-\phi_-) = \frac{6\varepsilon(y^3-\lambda^3)}{4.32}(b_-/\lambda^2)(kT/e) \times \log(1-f_-N_s) \quad (11)$$

where $r_c=e^2/\varepsilon kT$, e is the charge on an electron, ε is the static dielectric constant, k is Boltzmann's constant, T is the absolute temperature, y is an initially separated distance between positive ion and a thermalized electron, b_- is the number of new neighbors that an electron encounters per diffusive jump, f_- is the encounter efficiency, and N_s is the mole fraction of the scavenger. The probability of electron scavenging at an average positive ion-electron distance at -196°C was calculated as a function of λ, using the values $b_-=6$ and $f_-=1$. The average positive ion-electron distance in liquid cyclohexane is reported to be 50—60 Å[10] and 65.8 Å.[11]

Since the distance between a positive ion and an electron appears to be inversely proportional to the density of the medium,[11] we used the value, $r_{av}=50$ Å, considering the change in density at -196°C. The calculated results at several solute concentrations are shown in Fig. 8. It can be seen that the probability of electron scavenging decreases rapidly with the increase of λ. We cannot obtain the theoretical absolute yield of scavenged electron from the results because we have not calculated the yield integrated over the electron distribution, but we can see how the electron-solvent interaction could contribute to the scavenged electron yield. It is likely that the extent of this interaction plays an important part in ionic processes, especially in the radiolysis of hydrocarbon glass.

Nucleation in Liquid Sulfur Droplets

Shuichi HAMADA, Yoshihiro NAKAZAWA and Toshiaki SHIRAI

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received May 9, 1970)

The freezing behavior of supercooled liquid sulfur droplets were studied by means of a microscopic method. The number fraction of the solidified droplets in the experiments of continuous cooling on well-purified sulfur was only about 15% over the temperature range from 120°C to −70°C at the cooling rate of 0.20°C/min, and no abruptly discontinuous nucleation was found in these supercooling temperatures. The number fractions of the solidified droplets were found to be related to their volumes below −20°C. The nucleations in the well-purified liquid surfur droplets were confirmed to be a homogeneous process under these conditions. The specific nucleation rates per unit of volume were estimated to be 0.450, 1.13, and 1.16 $cm^{-3}sec^{-1}$ at the specified temperatures of −20, −40, and −50°C respectively. The dependences of $(\ln I+\Delta F_A/kT)$ on $1/(\Delta T)^2T$ obeyed the theory of Turnbull and Fisher. The interfacial free energy of sulfur at the liquid-crystal surface was estimated to be 12.1 erg/cm^2; this value was considered to be an appropriate one according to the Zadumkin consideration.

At an initial step of transformation, a nucleation passes through a homogeneous or a heterogeneous process in an unstable phase. In the homogeneous nucleation process, the nuclei grow in number nearly in proportion to the time; therefore, the nucleation rates can be estimated. On the other hand, it is well known that instantaneous crystallizations are observed at low degrees of supercooling or supersaturation in the presence of small amounts of chemical or physical heterogeneities. These instantaneous crystallizations are recognized to be based on the heterogeneous nucleation process. In the heterogeneous nucleation process, the number of nuclei is governed by the amounts of the chemical or the physical heterogeneities; therefore, the rates of crystallization are mainly decided by the growth rates of the nuclei.

Gibbs[1] has introduced a theoretical approach to the homogeneous nucleation in supercooled liquids and in supersaturated, one-component vapors. Frenkel,[2] Volmer,[3] and Becker and Döring[4] developed further the theories of the homogeneous nucleation. Turnbull and Fisher[5] proposed absolute values for the rates of homogeneous nucleation in condensed systems on the basis of the Becker and Döring theory. The first experimental measurements on the nucleation rates were carried out by Vonnegut[6] using the dilatometric technique on a system of supercooled liquid metal droplets. An advantage of the technique using tiny droplets is that the homogeneous nucleation breaking up of heterogeneous nucleating centers is observable. Moreover, experiments concerned with the kinetics of the homogeneous nucleation of many metals, inorganic and organic compounds, and polymers have been reported by Pound[7] and Turnbull.[8,9] The nucleation phenomena in the supercooled liquid sulfur droplets have been reported by Ford *et al.*[10] and by Gorskii.[11] Gorskii has reported a measurable nucleation rate in the supercooled liquid sulfur droplets at a temperature of 50°C, but Ford *et al.* found a very small fraction of solidified droplets even at temperatures as low as −45°C in the aerosol states.

In this work, the rates of the nucleation of the supercooled liquid sulfur droplets were studied by means of the microscopic method.

Experimental

Materials. A guaranteed-grade sulfur was obtained from the Kanto Chemical Company. The sulfur was

recrystallized six or seven times with freshly-distilled carbon disulfide and then dried *in vacuo*. The carbon disulfide had been shaken with mercury before the distillation in order to remove hydrogen sulfide. The tests of the purification of the recrystallized sulfur were carried out using the following method of continuous cooling.

Procedure. The sample of liquid sulfur droplets was prepared in the following manner; the fine powder of the purified sulfur was dispersed on a clean microscopic cover-glass, and then it was melted in an electric heating block at 120°C for 15 min. The sample was slowly cooled from 120°C to 55°C in the heating block; then it was transferred into a cooling apparatus designed in our laboratory maintained at 55°C. The sample was placed on an aluminum block in contact with a cascade-type semiconductor thermo-module. The temperatures were controlled with an accuracy of ±0.1°C using the thermistor controller. The changes in the sample were microphotographed continuously through the quartz window. The droplets were photographed at specified intervals with the camera mounted on an Olympus reflecting microscope, Model STS, with an object-lens with a long working distance (10×, about 3.8 cm). The temperatures over the range from 120°C to −50°C were measured with a standard thermometer, and those lower than −50°C, with a chromel-alumel thermocouple which was calibrated using materials of known melting points. The errors in the temperature measurements were within the range of ±0.1°C.

The specimens were observed by means of continuous-cooling experiments over the temperature range from 55°C to −70°C for over-all liquid droplets, and by means of isothermal cooling experiments at −20, −40, and −50°C for several droplets classified as to diameter.

In both the experiments, only the nucleation rate is approximately observable, as the growth rate is generally greater than that of nucleation on tiny droplets. Therefore, the number fractions of solidified droplets with respect to the overall droplets or the classified droplets were employed in discussing the nucleation rates.

Results

The droplets were directly observed. Fortunately, the transmittances of the crystalline and the liquid sulfur are sufficiently different for the two kinds of droplets to be easily distinguishable even without the use of polarized light, as is shown in Phot. 1.

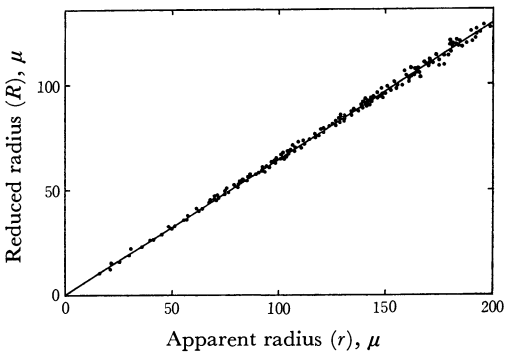

Fig. 1. Plot of reduced radius against apparent radius.

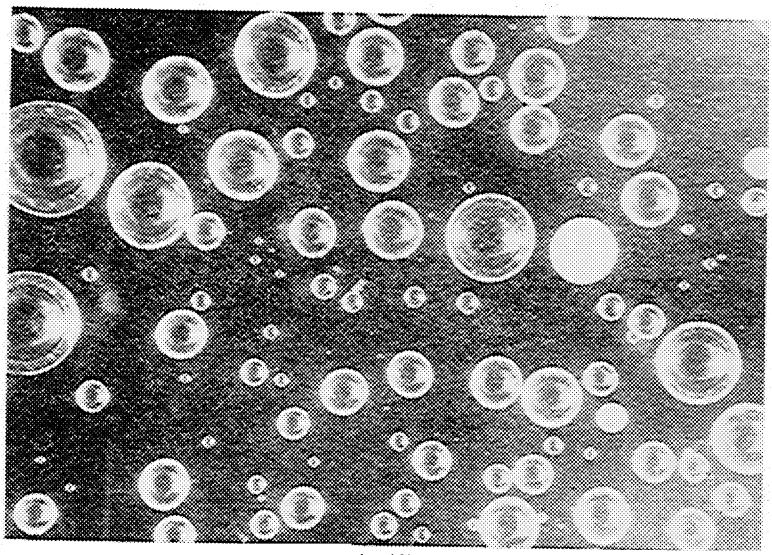
The liquid sulfur droplets on the microscopic cover-glass were regarded as approximately spherical segments, as is shown in Phot. 2. The volumes and the reduced radii of the individual droplets were calculated from the apparent radii and heights. Figure 1 shows the relationship between the apparent radii, r, and the reduced radii, R, of the sphere the volumes of which were the same as in the sulfur droplets. The R is related to the r as in the following equation; $R=0.645r$. The droplets were classified at intervals of 25μ in the apparent diameter, D.



(×40)

Phot. 2. Side view of liquid sulfur droplet.

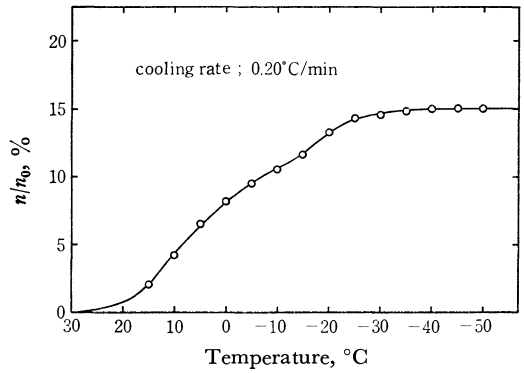

Fig. 2. Plot of number fraction of solidified droplets against temperature.

The Variation in the Number Fraction of the Solidified Droplets by the Continuous Cooling. The results of the continuous-cooling experiment over the size range from 10 μ to 400 μ in the apparent diameter are shown in Fig. 2. The specimen was continuously cooled at the rate of 0.20°C/min. This curve shows the number fractions, n/n_0, of the solidified droplets as a function of the temperatures from 30°C to −60°C. It is shown that the sulfur droplets scarcely crystallized at all at 30°C; moreover, only about 15% of the total droplets solidified even at −60°C —*i. e.*, the temperature of supercooling was 173°C. The crystallization in the whole droplets was not observed under the experimental conditions, while the critical supercooling at which an abruptly discontinuous crystallization occurred was observed to be 55°C in the liquid polyethylene droplets,[9] for example. On the contrary, imperfectly-purified liquid sulfur droplets crystallized entirely at the temperatures from 50°C to 30°C.

The Relationship between the Number Fractions of the Unsolidified Droplets and Radii. The samples were each kept at temperatures from 15°C to −50°C for 2 hr, and the number fractions of the unsolidified droplets were estimated with respect to their radii.

Turnbull[9] expressed the number fraction of the solidified droplets at the specified temperatures as follows:

$$1 - n/n_0 = \sum_{R=0}^{\infty} N_R^0 \exp(-k_R t)$$

where R is the radius of the droplets; N_R^0, the number fraction of the droplets with the radius of R; k_R, the specific nucleation rate of the droplets with the radius of R, and t, the cooling time. If the nucleation takes place throughout the volume of the droplets, *i. e.*, through the homogeneous nucleation process:

$$k_R = v_R I$$

where v_R is the volume of a droplet with the radius of R, and I, the nucleation rate per unit of volume at the specified temperature.

Concerning each droplet's range, the following expression is approximately applicable:

$$1 - (n/n_0)_R = \exp(-k_R t)$$

where $(n/n_0)_R$ is the number fraction of the solidified droplets in the narrow range of droplets with the radius of R. From the expression, the following equation is obtained if the temperature and the cooling time are specified:

$$\log(2 - \log N_{u,R}) = 3 \log R + C$$

where $N_{u,R}$ is the percentage of unsolidified droplets connected with the narrow-range droplets with the radius of R, and C, the constant.

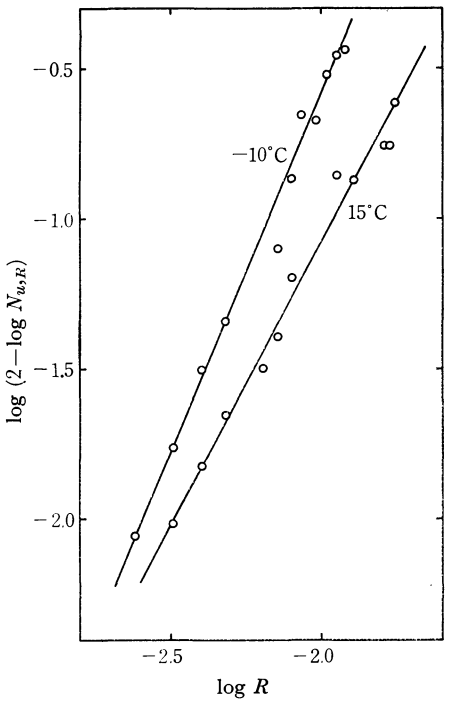

Fig. 3. Relationship between radius and number fraction of unsolidified dropets at 15 and −10°C.

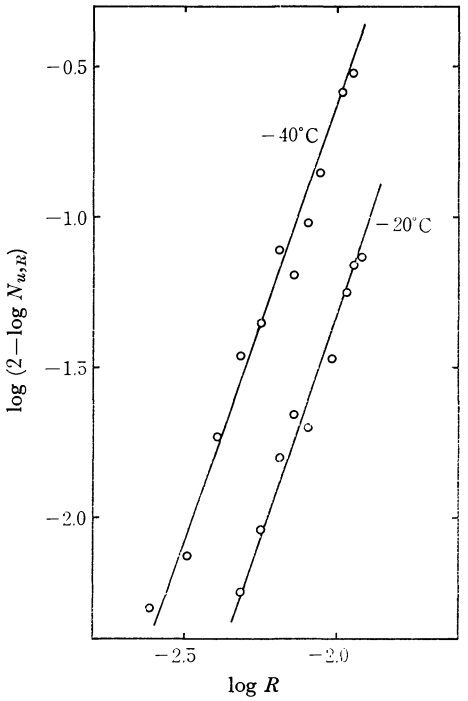

Fig. 4. Relationship between radius and number fraction of unsolidified droplets at −20 and −40°C.

If the nucleation in the sulfur droplets takes place through the homogeneous process, the log (2−log $N_{u,R}$) relation should vary linearly against the log R with the slope of 3 at specified temperatures and cooling times. Figures 3 and 4 show the relationships at 15 and −10°C, and at −20 and −40°C, respectively. At the temperatures of 15 and −10°C, the slopes were roughly estimated to be 2, but those at −20 and −40°C were nearly equal to 3. The slopes of the relationships between log (2−log $N_{u,R}$) and log R at several temperatures are summarized in Table 1.

Table 1. The slopes of the linear relationships between log (2−log $N_{u,R}$) and log R

Temp., °C	Slope	Temp., °C	Slope
15	1.88	−15	2.30
10	2.13	−20	3.00
5	1.94	−40	3.00
−10	2.39	−50	3.00

The slopes were estimated to be approximately 2 above −15°C, while they were close to 3 below −20°C, as is shown in Figs. 3 and 4 and in Table 1 respectively. The nucleations in the sulfur droplets under the conditions below −20°C were confirmed to be homogeneous, while those above −15°C were confirmed to be heterogeneous.

The Nucleation Rates in the Droplets through the Homogeneous Process. The dependences of the cooling times on the isothermal solidification were observed at the temperatures of −20, −40, and −50°C; the temperatures of supercooling were 133, 153, and 163°C respectively.

According to Turnbull's theory, the nucleation rate, k_R, of the droplets with the radius of R is expressed as follows:

$$\ln (n_{u,0}/n_u)_R = k_R t$$

where $(n_{u,0}/n_u)_R$ is the reciprocal of the number fraction of the unsolidified droplets with the radius of R, and t, the cooling time. The results of the experiment at −40°C are shown in Fig. 5. The values of $(n_{u,0}/n_u)_R$ were estimated by eliminating the number of droplets solidified above −15°C, based on the heterogeneous process. The elementary theory would predict that the homogeneous nucleation was a first-order reaction after several times. The figure shows the linear variations in the ln $(n_{u,0}/n_u)_R$ relation to the cooling times, though the variations did not obey the linear relationship before 30 min or 1 hr.

The values of k_R for each of the droplets with the radius of R were estimated from the slopes of the linear relationships. The specific nucleation rates, I, per unit of volume at the specified temperatures were calculated from the k_R values and the volumes of the droplets, as the k_R was expressed as follows: $k_R = v_R I$. The specific nucleation rates, I, were all given as approximately the same value with respect

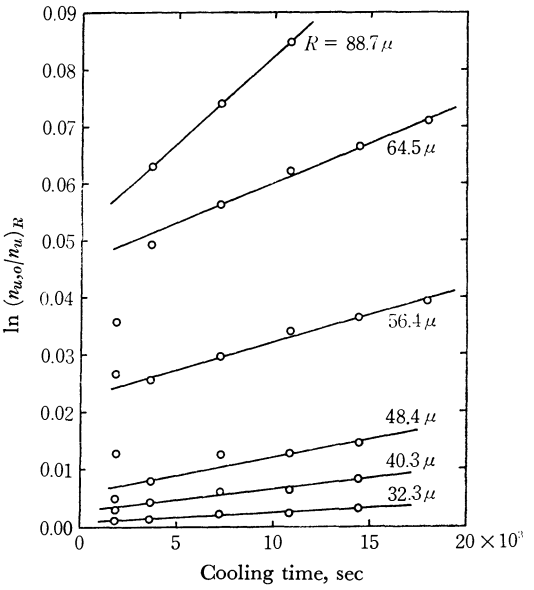

Fig. 5. Plot of $\ln (n_{u,o}/n_u)_R$ against cooling time at -40°C.

to the radii. Table 2 shows the values for k_R and I at -40°C.

TABLE 2. THE VALUES FOR k_R AND I AT -40°C

D, μ	R, μ	k, sec^{-1}	I, $cm^{-3}sec^{-1}$
100	32.3	1.59×10^{-7}	1.13
125	40.3	3.14	1.15
150	48.4	5.75	1.21
175	56.4	9.00	1.20
225	72.6	1.37×10^{-6}	1.09
250	80.6	2.40	1.05
275	88.7	3.06	1.05
		Average	1.13

The values for I were calculated to be 0.450, 1.13, and 1.16 cm^{-3} sec^{-1} at -20, -40, and -50°C respectively. These values were nearly equal to those for some molecular liquids, such as benzoic acid and white phosphorus.[12]

Discussion

The well-purified and imperfectly-purified sulfur droplets showed characteristic behavior in the crystallization phenomena in the experiments of continuous cooling. Gorskii[11] showed a measurable nucelation rate in the sulfur droplets, even at the temperature of 50°C. Presumably the sulfur used in his study contained second-phase impurities, which served to nucleate on the basis of the heterogeneous process, judging from the observations made in the continuous-cooling experiments. It is, therefore, meaningless to discuss the crystallization in Gorskii's temperature range in terms of the homogeneous nucleation processes. There then arises the question of whether the nucleation below 30°C is a heterogeneous or a homogeneous process. The probabilities of the crystallization in individual droplets depend on their sizes. Therefore, the homogeneity of nucleation can be examined from the derivative of Turnbull's theory. Under the conditions of the specified temperatures and the cooling times, the variations in $\log (2-\log N_{u,R})$ against $\log R$ should be linear, with a slope of 3 in the homogeneous process. As is shown in Figs. 3 and 4, the dependences of the number fraction of solidified droplets on the radii show a homogeneity in nucleation at temperatures below -20°C, though a heterogeneity remains at those above -15°C.

Turnbull and Fisher[5] proposed that the rate of the homogeneous nucleation in supercooled liquids was as follows:

$$I = (nkT/h) \exp(-\Delta F_A/kT) \times \exp[-16\pi\sigma^3 T_0^2/3\lambda^2 k(\Delta T)^2 T]$$

where n is the number of atoms or molecules per unit of volume; ΔF_A, the free energy of activation for the short-range diffusion across an interface of liquid and crystal; σ, the interfacial free energy between the liquid and crystalline nuclei; λ, the latent heat of fusion per unit of volume; T_0, the melting point, and ΔT, the difference between the melting point and the nucleating temperature, $T_0 - T$. This expression is derived by assuming the nuclei to be spherical and the entropy change to be independent of the temperature. Turnbull has applied his results to the freezing of supercooled liquid metals using the equation. These results agreed quantitatively with those obtained using the equation when the value of ΔF_A was assumed to be that of the activation energy for viscous flow.

The equation is transformed as follows, since the term of $\ln(nkT/h)$ is almost constant over the temperature range from -20°C to -50°C:

$$\ln I + \Delta F_A/kT = C - (16\pi\sigma^3 T_0^2/3\lambda^2 k)[1/(\Delta T)^2 T]$$

In this work, the value for ΔF_A was estimated to be 5.20 kcal/mol, a value which was obtained from the temperature dependences of the viscous flow in the λ-sulfur.[13] If the homogeneous nucleation is applicable to the liquid sulfur droplets, the variations in $(\ln I + \Delta F_A/kT)$ against $1/(\Delta T)^2 T$ should be linear. Figure 6 shows the relationship between $(\log I + \Delta_A F/2.303\, RT)$ and $1/(\Delta T)^2 T$. An excellent straight line was obtained. The value of the term of $16\pi\sigma^3 T_0^2/2.303\times 3\lambda^2 k$ was estimated to be 1.66×10^7 from the slope of the linear relationship. Assum-

ing the sulfur nuclei to be spherical, the σ was calculated to be 12.1 erg/cm^2 using the value of the melting point of α-sulfur, 386.0°K,[14] and that of the heat of fusion, λ, 9.13×10^8 erg/cm^3.[15]

Zadumkin[16] calculated the interfacial free energies of the melt-crystal for 36 elements involving the chalcogen elements to be 8—15% of the surface tension of their liquids at all the melting points except those of Ge, Si, and Sb. The interfacial free energy of sulfur at the liquid-crystal surface was estimated to be 20% of the surface tension of liquid sulfur at the melting point, 60.5 erg/cm^2. Since the interfacial free energy of selenium, which is an analogous element of sulfur, corresponds to 16% of the surface tension at its melting point,[17] the empirical value of that for sulfur may be considered to be an appropriate one.

(Received May 14, 1970)

New organic charge transfer salts composed of an organic cation (pyrylium or thiopyrylium) and an organic anion (1,1,3,3-tetracyanopropenide or tricyanomethanide) were prepared. The absorption spectra were studied both in solution and in a solid. These salts have the charge transfer band in the visible region as a result of the electronic transition from the anion to the cation. The charge transfer bands of these salts in solution are sensitive to the nature of the solvent. The charge transfer band is observed in solvents with a low polarity; this band shifts toward a shorter wavelength in solvents with a high polarity. The increase in the polarity of the solvent causes a decrease in the apparent molar extinction coefficient. The charge transfer band in the solid shifts toward a shorter wavelength compared with that in the solution. In a single crystal, the polarized absorption spectrum shows a remarkable dichroism.

The absorption spectra of heteroaromatic onium iodide salts[1] have been studied in solution, and their features have been understood in terms of the interionic charge transfer. For example, with *N*-alkylpyridinium iodides two new absorption bands were observed in addition to the bands of the component ions in non-polar solvents[2]; the new absorption bands were attributed to the charge transfer from the anion to the cation. The charge

transfer band was sensitive to the nature of the solvent and shifted toward a shorter wavelength with an increase in the polarity of the solvent.[3]

However, only a few brief studies have been reported concerning the absorption spectra of the organic charge transfer salts between the organic cation and the organic anion.[4] We have, therefore, attempted to make a systematic study of the organic charge transfer salts, and have reported the inter-ionic organic charge transfer band and the crystal structure of the salt between 2-dicyanomethylene-1,1,3,3-tetracyanopropanediide anion and quinolinium cation in previous papers.[5] From our consideration of the crystal structure and the optical studies in this salt, we confirmed that the charge transfer band was due to the electronic transition from the anion to the cation.

The present paper will deal with the charge transfer bands of the salts between the cyanocarbon-acid anion and the pyrylium or thiopyrylium cation.

Experimental

Materials. Tricyanomethanide (TCM) and 1,1,3,3-tetracyanopropenide (TCP) anions were used as the anions, while 2,4,6-triphenylpyrylium (TPP), 2,4,6-triphenylthiopyrylium (TPT), 4-anisyl-2,6-diphenylpyrylium (ADPP) and 4-anisyl-2,6-diphenylthiopyrylium (ADPT) cations were used as the cations.

Sodium-TCP (Na-TCP). Pyridinium-TCP (Py-TCP) was prepared by the method described in a previous paper.[6] Na-TCP was obtained from Py-TCP by the use of a cation-exchang resin, Amberlite CG 120 T-1.

Potassium-TCM (K-TCM). This compound was prepared according to Trofimenko's method[7] and was purified by the column chromatography using active carbon as the adsorbent and methanol as the developing solvent.

TPP-perchlorate (TPP-ClO_4), TPT-ClO_4, ADPP-ClO_4 and ADPT-ClO_4. These compounds were prepared according to Ulrich's method.[8]

The following organic charge transfer salts were prepared and used for measurement.

TPP-TCM. This salt was prepared by a double decomposition reaction between TPP-ClO_4 and K-TCM in methanol and was purified by recrystallization from methanol - water (4 : 1) or methanol. Mp 197—199°C. Found: C, 81.05; H, 4.01; N, 10.40%. Calcd for $C_{27}H_{17}N_3O$: C, 81.20; H, 4.26; N, 10.53%.

The other salts were prepared by a similar method.

TPT-TCP. Mp 203—204°C, Found: C, 80.28; H, 3.34; N, 12.56%. Calcd for $C_{30}H_{18}N_4O$: C, 80.00; H, 4.00; N, 12.44%.

TPT-TCM. Mp 156.5—158°C, Found: C, 78.22; H, 3.90; N, 9.77%. Calcd for $C_{27}H_{17}N_3S$: C, 78.07; H, 4.10; N, 10.12%.

TPT-TCP. Mp 142—143°C, Found: C, 77.23; H, 3.40; N, 11.94%. Calcd for $C_{30}H_{18}N_4S$: C, 77.26; H, 3.86; N, 12.02%.

ADPP-TCM. Mp 201—202.5°C. Found: C, 78.39; H, 4.48; N, 9.64%. Calcd for $C_{28}H_{19}N_3O_2$: C, 78.32; H, 4.43; N, 9.78%.

ADPP-TCP. Mp 243—245°C. Found: C, 77.38; H, 4.10; N, 11.67%. Calcd for $C_{31}H_{20}N_4O_2$: C, 77.50; H, 4.18; N, 11.68%.

ADPT-TCM. Mp 65—67°C. Found: C, 72.82; H, 4.56; N, 9.26; S, 6.94%. Calcd for $C_{28}H_{19}N_3OS$: C, 75.51; H, 4.27; N, 9.45; S, 7.19%.

ADPT-TCP. Mp 175—177°C. Found: C, 75.24; H, 3.95; N, 11.36%. Calcd for $C_{31}H_{20}N_4OS$: C, 74.99; H, 4.03; N, 11.29%.

All the solvents used were purified according to the usual method of purification.[9]

Measurements. The absorption spectrum of the solution and the diffuse reflectance spectrum of the solid were measured with a Hitachi spectrophotometer, EPS 3. The diffuse reflectance spectrum was measured using potassium bromide powder as a standard; it was then plotted using the Kubelka-Munk function, $f(R)=(1-R)^2/2R$, where R is the reflectance. The spectrum

in the single crystal was measured with a Shimadzu multipurpose spectrophotometer, MPS-50, with the use of a microspectrophotometer attachment.

Results and Discussion

The Electronic Absorption Spectra in Solution. The absorption spectrum of TPP-TCP in chloroform has four absorption bands (λ_{max}: 281, 351, 416, and 570 mμ), Na-TCP has one absorption band (λ_{max}: 345 mμ), and TPP-ClO_4 has three absorption bands (λ_{max}: 281, 372, and 414 mμ). The absorption band of Na-TCP is due to the TCP anion, and the absorption bands of TPP-ClO_4 are due to the TPP cation. Three absorption bands (λ_{max}: 281, 351, and 416 mμ) of TPP-TCP can be explained in terms of the superposition of the absorption bands of the parent cation and anion. The other absorption band (λ_{max}: 570 mμ) is characteristic of the TPP-TCP salt, because neither the parent cation nor the parent anion have any absorption in this region, as is shown in Fig. 1.

(S): shoulder

This fact suggests that the new band is an interionic charge transfer band. A new band of this type is also found in the absorption spectra of the other salts. The wavelengths of these new absorption bands are listed in Table 1.

The energies of the new bands in the TCM salts of TPP, TPT, ADPP, and ADPT are 2.30, 2.19, 2.34, and 2.30 eV respectively, while those in the TCP salts of TPP, TPT, ADPP, and ADPT are 2.18, 2.08, 2.30, and 2.18 eV respectively. These two series of energies have a linear relationship, as is shown in Fig. 2. Such a linear relationship has also been observed for usual donor-acceptor complexes between neutral molecules; it has been taken to be evidence of the absorption bands being charge transfer bands.[10] This consideration is thought to be applicable to the present organic salts, also.

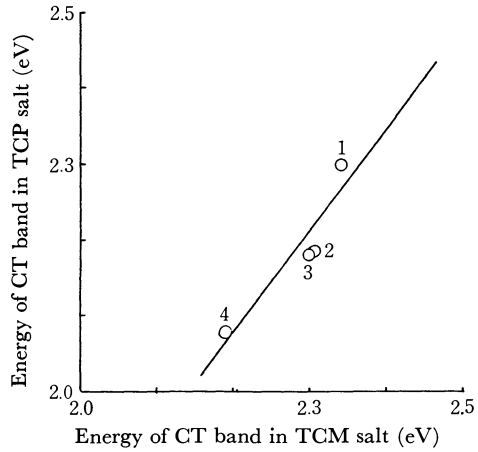

Fig. 2. Energies of charge transfer bands in salts of TCP with the cations: (1) ADPP, (2) ADPT, (3) TPP, (4) TPT, against the energies of the charge transfer bands in the salts of these cations with TCM.
1. ADDP, 2. ADDP, 3. TPP, 4. TPT

The new band is sensitive to the polarity of the solvent. The increase in the polarity of the solvent causes the absorption maximum to shift toward a shorter wavelength and the apparent molar extinction coefficient (ε_{app}) to decrease.

Figure 3 shows the plot of the λ_{max} energies of the new bands of TPT-TCP in various solvents *versus* the *Z*-value,[3] the empirical parameter of the solvent polarity. The linear relationship shows that the absorption maximum shifts to a shorter wavelength with an increase in the solvent polarity. The other salts give similar results. The solvent shift of the absorption bands in these salts can be explained by Kosower's theory presented in his

10) R. Foster, *Tetrahedron*, **10**, 96 (1960); K. Abe, Y. Matsunaga and G. Saito, This Bulletin, **41**, 2852 (1968).

consideration of the solvent effect of the absorption spectrum of organic iodides.[3] That is, the solvent shift of the absorption maximum depends on the stabilization in the ground state and the destabilization in the excited state. From the above results, it can be concluded again that the new bands of these salts are due to the electronic charge transfer from the anion to the cation. The slope in Fig. 3 is associated with the solvent sensitivity of the charge transfer band. If the slope is steep, the solvent sensitivity is low. In these salts, the slope of this straight line is 1.5—2.0. In tropylium iodide[11] and *N*-methylacridinium iodide,[12] the slope of this line is unity. It has been reported that the solvent sensitivity depends on the size of the anion and the delocalization of its charge, the increase in size and the increase in the delocalization of its charge causing the decrease in the solvent sensitivity.[12] In the present case, the size and the delocalization of the charge in TCM or TCP anion are larger than those of the iodide anion. It can, therefore, reasonably be understood that the solvent sensitivity for TCM or TCP is inferior to that of iodides. In ADPP and ADPT systems the new band was observed as a shoulder. It was, therefore, not possible in these salts to investigate the solvent effect in detail.

As these charge transfer bands are due to the interaction between the anion and the cation, both ions must be in the ion-pair form in order to exhibit charge transfer interactions. The salts are in the following equilibrium in solution:

$$AD \rightleftarrows D^- + A^+$$

where DA is an organic charge transfer salt in an ion-pair form and where D^- and A^+ are the component ions. In polar solvents the dissociation of the ion-pair proceeds and the concentration of the ion-pair from decreases, thus decreasing the apparent molar extinction coefficient (ε_{app}). At a certain concentration the ε_{app} values were measured in several different solvents. As is shown in Fig. 4,

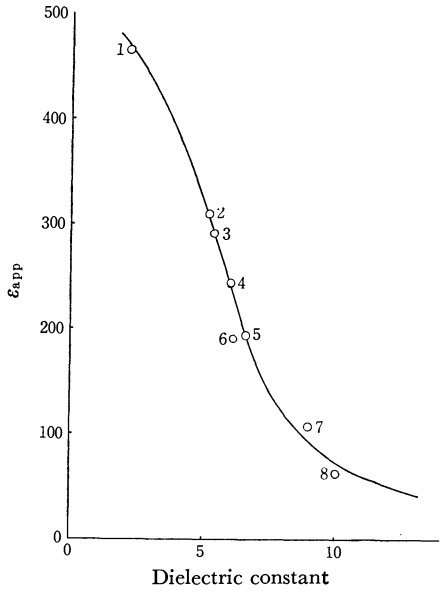

Fig. 4. Apparent molar extinction coefficient of TPT-TCP against the dielectric constants for the solvents used.
(1) Dioxane, (2) Chlorobenzene, (3) Bromobenzene, (4) Methyl acetate, (5) Ethyl acetate, (6) Acetic acid, (7) Dichloromethane, (8) 1,2-dichloroethane.

the ε_{app} values decrease with the increase in the dielectric constant of the solvent. The dissociation constants of these salts were calculated as follows from the concentration dependence of the charge transfer bands by a method similar to that used for *N*-dodecylpyridinium iodide.[13] Provided that the absorbance of the solution at the charge transfer

11) E. M. Kosower, *J. Org. Chem.*, **29**, 956 (1964).
12) T. G. Beaumont and K. M. C. Davis, *J. Chem. Soc., B*, **1968**, 1010.
13) A. Ray and P. Mukerjee, *J. Phys. Chem.*, **70**, 2138 (1966).

band is due entirely to the charge transfer absorption of the ion-pair present, and provided that the absorption due to the component ions is negligible in this wavelength region, the following equation is obtained:

$$D/C_0 = \varepsilon - (K\cdot\varepsilon)^{1/2}\cdot D^{1/2}/C_0$$

where D is the optical density for an optical length of 1 cm; C_0, the total concentration of the salt; ε, the molar extinction coefficient of the ion-pair, and K, the dissociation constant of the salt. The values of K and ε were calculated from the slope and intersection of the plots of D/C_0 *vs.* $D^{1/2}/C_0$; they are shown in Table 2 for chloroform solution. The values of K in Table 2 clearly show that, in chloroform, the anion and the cation exist as an ion-pair form. These results are also supported by the measurement of the conductivity of the solution. In a polar solvent the equivalent conductivity is proportional to $C^{1/2}$, and in a non-polar solvent, to $1/C^{1/2}$, where C is the concentration of the salt. This conductivity behavior suggests that these salts dissociate highly in a polar solvent and do not dissociate so much in a non-polar solvent.

Table 2. Dissociation constant and molar extinction coefficient in chloroform

	K	ε
TPP-TCM	$\sim 10^{-5}$ below	340
TPP-TCP	$\sim 10^{-5}$	310
TPT-TCM	$\sim 10^{-5}$ below	470
TPT-TCP	$\sim 10^{-4}$	370

In conclusion, the solvent shift of the charge transfer band can be explained by the term of Z-values, and the dissociation of the salt is closely related to the dielectric constant of the solvent.

In the interionic charge transfer salts, the following equation is also applicable:

$$E_{ct} = I_p(\mathrm{D}^-) - E_a(\mathrm{A}^+) + E_{coul}$$

where E_{ct} is the energy of the charge transfer transition; $I_p(\mathrm{D}^-)$, the ionization potential of the donor anion; $E_a(\mathrm{A}^+)$, the electron affinity of the acceptor cation, and E_{coul}, the coulomb energy for the separation of ions. The term of the coulomb energy (E_{coul}) is probably nearly the same in different interionic charge transfer salts. For the salts having the same cation, the difference in E_{ct}, therefore, represents the difference in $I_p(\mathrm{D}^-)$, that is, the energy difference between the highest occupied molecular orbitals of the anions. The values of Table 1 suggested that the ionization potential of TCM is larger than that of TCP. The simple Hückel LCAO calculation also supports this suggestion. A similar treatment to the salts composed of the same anion suggested that the electron affinity of TPP is smaller than that of TPT. It has been suggested that the polarographic half-wave potential is correlated with the electron affinity and, hence, with the charge transfer energy.[14] The half-wave potentials of these cations, measured as usual against the saturated calomel electrode, gave the values of -0.24 V for TPP and

14) M. Feldman and S. Winstein, *Tetrahedron Lett.*, **1962**, 853.

−0.17 V for TPT in absolute ethanol. The electron affinity of TPP is, therefore, smaller than that of TPT. From these results, it can reasonably be understood that the charge transfer bands of TPP-TCM and TPP-TCP are in a shorter wavelength region than those of TPT-TCM and TPT-TCP respectively.

The Electronic Absorption Spectrum in Solid. The absorption spectra in a solid were measured by diffuse reflectance spectroscopy. The spectra of TPP-TCM, TPP-TCP, and TPP-ClO_4 are shown in Fig. 5. The absorption band is at 530 mμ in TPP-TCM and at 565 mμ in TPP-TCP. These absorption bands in a solid are considered to correspond to the charge transfer bands in solution. The absorption peaks of other salts in the solid state are shown in Table 1.

The charge transfer band in the solid state lies in a somewhat shorter wavelength region than does the corresponding charge transfer band in the solution, as is shown in Table 1. This suggests that the stabilization by the neighboring ions in the solid state is larger than the stabilization by the neighboring solvent molecules in the solution. The data in Table 1 also suggest that the stabilization of the TPP system is smaller than that of the TPT system. This difference may be due to the differences in the crystal structure and the polarizability of the component ions.

The polarized absorption spectra of the single crystals of TPP salts show a remarkable dichroism in the charge transfer band, the optical density being large in the direction of the crystal growth (Fig. 6). Although the crystal sturcture has not yet been determined in this case, it seems certain that the cation and the anion are stacked in an alternating face-to-face arrangement in the growth direction, and that the charge transfer transition occurs from an anion to the nearest cation in this direction. A similar phenomenon has also been observed in quinolinium 2-dicyanomethylene-1,1,3,3-tetracyanopropanediide (Q_2DMTP). The crystal structure of Q_2DMTP is orthorhombic, and the cation and the anion are stacked alternately along the *a*-axis.[5] The optical density is higher in the *a*-polarization spectrum than in the *c*-polarization spectrum.[5]

All the results show that the new absorption band, both in a solid and in solution, is a charge transfer band between the anion and the cation.

Force Constants and Average Structures of AsF_3 and $AsCl_3$ as Determined by Electron Diffraction and Spectroscopy*1

Shigehiro KONAKA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received May 15, 1970)

The general quadratic potential constants of $AsCl_3$ have been determined by the use of a combination of the mean amplitudes observed by gas electron diffraction and the vibrational frequencies. Those of AsF_3 have been determined from the mean amplitudes, the centrifugal distortion constants given by microwave spectroscopy and the Coriolis coupling constants and the vibrational frequencies given by infrared spectroscopy on the basis of the molecular structure newly-determined by electron diffraction. By using these potential constants, zero-point average structures have been derived from the r_g structures obtained by electron diffraction. The results have been found to be consistent with the average rotational constants, B_z, derived from the effective rotational constants, B_0, observed by microwave spectroscopy according to the theory of vibration-rotation interactions. The final results, obtained by the use of a combination of the electron diffraction and microwave data, are:

$$r_z(\text{As–Cl}) = 2.1621 \pm 0.0009\ \text{Å}, \quad \theta_z(\text{ClAsCl}) = 98°38' \pm 22'$$

$$r_z(\text{As–F}) = 1.7080 \pm 0.0004\ \text{Å}, \text{ and } \theta_z(\text{FAsF}) = 95°58' \pm 17'.$$

Formulas for calculating the sum of perpendicular mean amplitudes for pyramidal XY_3-type molecules have been derived and used to reduce r_g to r_z.

If the anharmonic as well as the harmonic potential constants are known, the equilibrium structures (r_e-structures) of gaseous molecules can be determined by spectroscopy[1] and gas electron diffraction (ED).[2] The r_e-structures derived from ED agreed within the limits of experimental errors with those derived from spectroscopy for CH_4, CD_4,[2–4] and CS_2.[5,6]

Since the anharmonic potential constants are, however, not yet available except for a very limited number of molecules, the r_e-structures have not been obtained for most molecules. Even so, the zero-point average structures (r_z-structures) can be derived from the average rotational constants, B_z, which can themselves be reduced from the effective ground-state rotational constants, B_0, by using only the harmonic potential constants.[7–9] Since the thermal average distances, r_g, observed by ED can also be converted to the r_z distances, it is possible to make an exact comparison between the molecular structures obtained by the two different experimental techniques.[10–15] Furthermore, it is possible to combine both sets of results so as to obtain more precise structures.[16–21]

The r_g-structures of AsF_3 and $AsCl_3$ have been determined by the sector-microphotometer method of gas electron diffraction described in a preceding paper.[22] The ground-state rotational constants, B_0, obtained from the microwave spectra (MW) are 2147.2 ± 0.2 and 2044.7 ± 0.3 Mc for $As^{35}Cl_3$ and $As^{37}Cl_3$ respectively,[23] and 5878.971 ± 0.002 Mc for AsF_3.[24] In the present study, both sets of results have been converted to the r_z-structures or the corresponding average rotational constants, and then compared with each other. Furthermore, more accurate molecular structures have been obtained by the use of a combination of the electron-diffraction and the spectroscopic data.

It is necessary to know the quadratic potential constants for the above purpose. For the pyramidal XY_3-type of molecules, the quadratic potential constants can not be determined from only the observed vibrational frequencies. We must use certain additional physical quantities which can be related to the quadratic potential constants. The mean amplitudes of thermal vibration, which are observed by ED, can be used for such a purpose.[25,26]

There is no published work in which the force constants of $AsCl_3$ have been determined experimentally. In the present study, the intramolecular force field of $AsCl_3$ has been determined by using the observed mean amplitudes given in the preceding paper.[22]

Some investigations have already attempted to determine the force constants of AsF_3 by using the centrifugal distortion constants[27] or the Coriolis constants obtained by spectroscopy.[28,29] However, the bond angles of 98° [27] and 102° [28,29] assumed in these previous studies are appreciably larger than the bond angle of $95.9°\pm0.4°$ which has been determined by our own recent electron-diffraction study.[22] In the present study, the most probable set of the force constants of AsF_3 has been determined from the mean amplitudes,[22] the centrifugal distortion constants, and the Coriolis constants on the basis of the accurate molecular structure.

Determination of the Force Constants

The general quadratic force field for the pyramidal XY_3 molecule can be expressed in terms of the internal coordinates:

$$\begin{aligned}2V = &\sum f_r(\Delta r_i)^2 + 2\sum f_{rr}(\Delta r_i)(\Delta r_j) \\ &+ \sum f_\theta(r_e\Delta\theta_{ij})^2 + 2\sum f_{\theta\theta}(r_e\Delta\theta_{ij})(r_e\Delta\theta_{jk}) \\ &+ 2\sum f_{r\theta}(\Delta r_i)(r_e\Delta\theta_{ij}) + 2\sum f_{r\theta'}(\Delta r_i)(r_e\Delta\theta_{jk}). \quad (1)\end{aligned}$$

Here all the notations except for the equilibrium bond distance, r_e, are those used in Ref. 26.

The symmetry coordinates used are as follows:

$$\begin{aligned}S_1 &= \frac{1}{\sqrt{3}}(\Delta r_1+\Delta r_2+\Delta r_3), \\ S_2 &= \frac{1}{\sqrt{3}}r_e(\Delta\theta_{12}+\Delta\theta_{23}+\Delta\theta_{31}), \\ S_3 &= \frac{1}{\sqrt{2}}(\Delta r_1-\Delta r_2), \\ S_4 &= \frac{1}{\sqrt{2}}r_e(\Delta\theta_{23}-\Delta\theta_{31}), \\ S_5 &= \frac{1}{\sqrt{6}}(\Delta r_1+\Delta r_2-2\Delta r_3), \\ S_6 &= \frac{1}{\sqrt{6}}r_e(\Delta\theta_{23}+\Delta\theta_{31}-2\Delta\theta_{12}), \quad (2a)\end{aligned}$$

which may be written in a matrix form as:

$$\boldsymbol{S} = \boldsymbol{UR}. \quad (2b)$$

The relations between the force constants in the symmetry coordinates and those in the internal coordinates are:

$$\begin{aligned}F_{11} &= f_r + 2f_{rr}, \\ F_{12} &= f_{r\theta'} + 2f_{r\theta}, \\ F_{22} &= f_\theta + 2f_{\theta\theta}, \\ F_{33} &= f_r - f_{rr}, \\ F_{34} &= f_{r\theta'} - f_{r\theta}, \\ F_{44} &= f_\theta - f_{\theta\theta}. \quad (3)\end{aligned}$$

The elements of the $\boldsymbol{G}$ matrix in the symmetry coordinates are given as follows:

A_1 species:

$$\begin{aligned}G_{11} &= \mu_X(1+2c)+\mu_Y, \\ G_{12} &= -2\mu_X(1-c)(1+2c)/s, \\ G_{22} &= 2(1-c)(1+2c)[2(1-c)\mu_X+\mu_Y]/s^2, \quad (4)\end{aligned}$$

E species:

$$\begin{aligned}G_{33} &= G_{55} = \mu_X(1-c) + \mu_Y, \\ G_{34} &= G_{56} = \mu_X(1-c)^2/s, \\ G_{44} &= G_{66} = (1-c)[\mu_X(1-c)^2+\mu_Y(2+c)]/s^2. \quad (5)\end{aligned}$$

Here μ_X and μ_Y are the reciprocals of the atomic masses, m_X and m_Y, respectively, while s and c stand for $\sin\theta$ and $\cos\theta$ respectively.

The formulas for calculating the mean amplitudes of the pyramidal XY_3 molecules, $l(X-Y)$ and

l(Y–Y), are given as follows:[26]

$$[l(\mathrm{X\text{-}Y})]^2 = \frac{1}{3}(\sum_{11}+2\sum_{33}), \tag{6}$$

$$[l(\mathrm{Y\text{-}Y})]^2 = \frac{2}{3}(2\sum_{11}+\sum_{33})\sin^2\frac{\theta}{2} + \frac{4}{3}(\sum_{12}-\sum_{34})\sin\frac{\theta}{2}\cos\frac{\theta}{2} + \frac{1}{3}(\sum_{22}+2\sum_{44})\cos^2\frac{\theta}{2}. \tag{7}$$

Here $\sum_{ij}$ denotes the thermal average of the product of S_i and S_j. The values of $\sum_{ij}$ can easily be calculated from the force constants.[26]

When the four observed vibrational frequencies are used, the force constants have only two degrees of freedom. For a given value of F_{12}, the other force constants of A_1 species are calculated as:

$$F_{11} = (\gamma \pm \delta)/2G_{11}, \qquad F_{22} = (\gamma \mp \delta)/2G_{22}, \tag{8}$$

where:

$$\gamma = \lambda_1 + \lambda_2 - 2G_{12}F_{12}, \tag{9}$$

$$\delta = [\gamma^2 - 4G_{11}G_{22}(\lambda_1\lambda_2/(G_{11}G_{22}-G^2_{12})+F^2_{12})]^{1/2}, \tag{10}$$

$$\lambda_k = 4\pi^2c^2\nu_k^2. \tag{11}$$

Similar relations hold for the force constants of the E species. The relations in these force constants are shown in Fig. 1. The frequencies used in the calculation are tabulated in Table 1. The bond angles used are 98.5° and 95.9° for $AsCl_3$ and AsF_3 respectively.[22] The solid and dotted curves correspond to the upper sign and the lower sign of Eq. (8) respectively. In the solid curves, the

stretching force constants, F_{11} and F_{33}, are larger than the bending force constants, F_{22} and F_{44} respectively. Since such is not necessarily the case for the dotted curves, they should be abandoned. Thus, for a given set of F_{12} and F_{34}, all of the other force constants can be determined uniquely.

The mean amplitudes of $AsCl_3$ were calculated for the various values of F_{12} and F_{34}. The force constants allowed by the two observed mean amplitudes, l(As–Cl)=0.0470±0.0024 Å and l(Cl–Cl)=0.0945±0.0063 Å,[22] and the four vibrational frequencies are shown by the shaded area in Fig. 2. The corresponding values of the other force constants were determined from the solid curves in Figs. 1a and b. The values of the force constants in the symmetry coordinates thus determined are listed in Table 2, along with those in the internal coordinates.

The force constants of AsF_3 reported by earlier authors are listed in Table 3, along with the spectro-

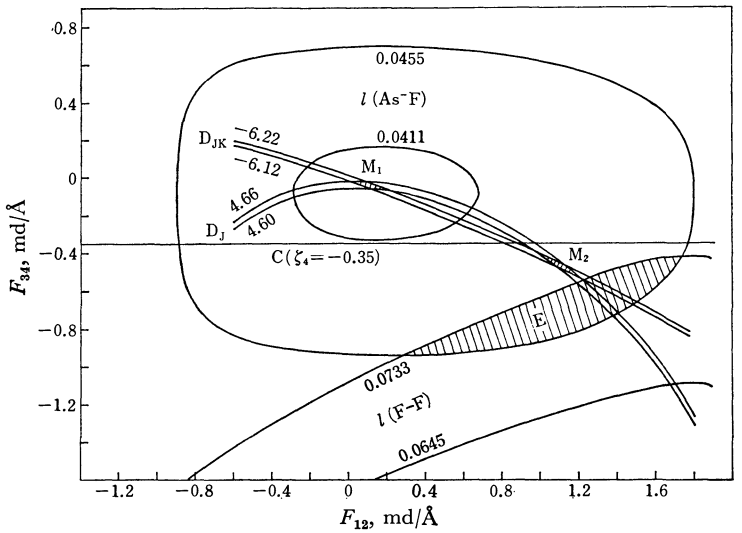

Fig. 3. Comparison of the allowed regions of the force field of AsF_3 which are compatible with the observed values of two mean amplitudes at 292°K (E), two centrifugal distortion constants (M_1 and M_2) and a Coriolis coupling constant (C).

scopic and structural data used in their calculations. The force constants of AsF_3 allowed by the observed mean amplitudes given in Table 4 are shown by the E region of Fig. 3. They are inconsistent with the force constants listed in Table 3.

The force constants reported by Levin and Abramowitz[28] and by Hoskins[29] were obtained by using the Coriolis constants, ζ_3 and ζ_4, which were estimated from the P–R splittings of ν_3 and ν_4 infrared bands respectively. The values of the Coriolis constants thus estimated depend on the assumed values of the bond angles. The value of $(\zeta_3+\zeta_4)$ given by the sum rule[31] also depends on the molecular geometry:

$$\zeta_3 + \zeta_4 = I_c^e/(2I_b^e) - 1. \qquad (12)$$

Here I_c^e and I_b^e are the equilibrium moments of inertia about the symmetry axis and about an axis perpendicular to it respectively. The theoretical values of $(\zeta_3+\zeta_4)$ are -0.22 for the bond angle of 102° and -0.29 for the bond angle of 95.9°.

For the bond angle of 95.9°, the Coriolis constant, ζ_4, was estimated to be -0.35 from the P–R separation of ν_4, 26.7 cm^{-1},[28,29] by the use of the relations given by Edgell and Moynihan.[32] Similarly, the P–R separation of ν_3, 15.4 cm^{-1},[29] led to $\zeta_3=0.32$. However, these values did not satisfy the sum rule. Since the position of the P-branch of the ν_3 band had been very obscure,[29,33] ζ_3 was not included in the present calculation of the force constants. By using the relation between ζ_4 and the force constants,[31] F_{34} was determined to be -0.35 md/Å from the ζ_4 value of -0.35.

The force constants reported by Mirri[27] had been obtained by using the centrifugal distortion constants, D_J and D_{JK}, observed by microwave spectroscopy. Since the bond angle of 98° had been used in her calculation, it was desirable to follow her calculation using the bond angle of 95.9°. The centrifugal constants were calculated from the force constants according to the theory of the semi-rigid rotator.[34,35] The allowed values of the force constants are shown by the two regions, M_1 and M_2, in Fig. 3. It is noticeable that two sets of solutions are present. The force constants reported by Mirri correspond to the M_1 region.

Although there exists no set of force constants compatible with the above five observed quantities, the force constants represented by the M_2 region satisfy all the observed values comparably well.

The final values of the force constants of AsF_3 were determined by the least-squares method.[36] The off-diagonal force constants, F_{12} and F_{34}, are chosen as parameters, while the observed values to be fitted are the l(As–F), l(F–F), D_J, D_{JK}, and ζ_4 values given in Table 4. The weights were taken to be inversely proportional to the squares of errors, ε_j, estimated in Table 4. That is, the most probable set of parameters was determined by the following condition:

$$\boldsymbol{V^*PV} = \sum_{j=1}^{5} \left(\frac{m_j^{obs} - m_j^{calc}}{\varepsilon_j}\right)^2 = \text{minimum}. \qquad (13)$$

The standard errors of parameters were evaluated as:

$$\sigma_i = \sqrt{B_{ii}^{-1}\frac{\boldsymbol{V^*PV}}{3}}\,. \qquad (14)$$

Here the notations correspond to those used in Ref. 36. The most probable set of force constants is given in Table 5, along with the limit of errors.

Three times σ_i was taken to be the limit of errors.

The mean amplitudes, the centrifugal distortion constants, and the Coriolis constants of $AsCl_3$ and AsF_3 were calculated from the force constants tabulated in Tables 2 and 5; they are compared with the observed values in Table 6. Agreements are good except for the case of l(F–F). The poor agreement for l(F–F) is perhaps due to some systematic errors in the observed l(F–F) overlooked in the preceding paper.[22]

The correlation of the mean amplitudes with the index of resolution in the analysis of the electron-diffraction data may be considered to be a possible source of systematic errors. However, it is impossible for the observed value of l(F–F) to increase while that of l(As–F) does not as long as a single index of resolution is used in the analysis. An attempt was made to take the two indices of resolution, k(As–F) and k(F–F), as independent variable parameters in the least-squares fitting of molecular scattering intensities instead of assuming that they were equal.[36] The results are compared with those obtained in the previous analysis in Table 7. Both results were consistent within the

TABLE 7. MOLECULAR PARAMETERS OBTAINED BY TAKING TWO INDICES OF RESOLUTION AS INDEPENENT VARIABLE PARAMETERS (COLUMN A) AND THOSE OBTAINED BY ASSUMING THAT THEY ARE EQUAL (COLUMN B)
(r_g and l in Å unit)

	A	*B*
r_g (As–F)	1.7089±0.0016	1.7089±0.0016
r_g (F–F)	2.5370±0.0055	2.5374±0.0055
l (As–F)	0.0429±0.0022	0.0433±0.0022
l (F–F)	0.0748±0.0066	0.0689±0.0044
k (As–F)	0.92 ±0.05	
		0.93 ±0.05
k (F-F)	1.06 ±0.13	

estimated limit of errors, although appreciable changes were found in l(F–F) and k(F–F). The l(F–F) value of Column A is consistent with the calculated value given in Table 6. It is, however, very doubtful that we should prefer the values of Column A to those of Column B, which were obtained in the previous analysis, since there is no sound physical basis for assuming an independent index of resolution for each of the atom-pairs in this molecule.*2

The P–R splitting of the ν_3 band of AsF_3 was estimated to be 22 cm^{-1} from the calculated value of the Coriolis constant, ζ_3. It is about 7 cm^{-1} larger than Hoskins' value.[29] However, it does not seem quite inconsistent with the ν_3 band observed by Hoskins and Lord.[33]

Zero-point Average Structure

Conversion of r_g to r_z. The r_z distance can be derived from the r_g distance observed by ED. The r_g distance has the following relation to the equilibrium distance, r_e:[10]

$$r_g = r_e + \langle \Delta z \rangle + \frac{\langle \Delta x^2 \rangle + \langle \Delta y^2 \rangle}{2r_e} + \delta r_{\text{rot}}, \qquad (15)$$

where the z-axis of the local Cartesian displacement coordinates is taken along the equilibrium positions of the atoms. Here $\langle\ \rangle$ denotes the thermal average, $\langle \Delta z \rangle$ and δr_{rot} are the stretchings due to anharmonic vibration and centrifugal force respectively, and $\langle \Delta x^2 \rangle$ and $\langle \Delta y^2 \rangle$ are perpendicular amplitudes. Since r_z is equal to $r_e + \langle \Delta z \rangle_{0°K}$, it is necessary to calculate the following three terms in order to convert r_g to r_z:

1. Centrifugal stretching, δr_{rot}
2. Stretching due to perpendicular thermal motion, $(\langle \Delta x^2 \rangle + \langle \Delta y^2 \rangle)/2r_e$, and
3. Thermal extension of $\langle \Delta z \rangle$, $\delta\langle \Delta z \rangle \equiv \langle \Delta z \rangle_T - \langle \Delta z \rangle_0$.

The centrifugal terms for $AsCl_3$ and AsF_3 were estimated by using the formulas derived by Iwasaki and Hedberg[37] by balancing the centrifugal force with Hooke's restoring force. The sum of the perpendicular mean amplitudes was calculated by the use of the formula expressed by Cyvin's $\sum$ matrix,[38] which was derived as shown in the Appendix.

The cubic potential constants must be known if we are to calculate the thermal change in $\langle \Delta z \rangle$, but they have not been available for almost all pyramidal XY_3 molecules. For X–Y bonds, however, the Morse potential for diatomic molecules can be used to estimate $\delta\langle \Delta r \rangle$ as:

$$\delta\langle \Delta r \rangle = \frac{3}{2} a_3 \delta\langle \Delta r^2 \rangle, \qquad (16)$$

where a_3 is the anharmonicity parameter of the Morse potential.[39] By using the following relation:

$$\langle \Delta r \rangle = \langle \Delta z \rangle + (\langle \Delta x^2 \rangle + \langle \Delta y^2 \rangle)/2r_e, \qquad (17)$$

the thermal extension of $\langle \Delta z \rangle$ for the X–Y bonds of $AsCl_3$ and AsF_3 was estimated as follows:

$$\delta\langle \Delta z \rangle = \frac{3}{2} a_3 \delta\langle \Delta r^2 \rangle - \delta((\langle \Delta x^2 \rangle + \langle \Delta y^2 \rangle)/2r_e). \qquad (18)$$

36) Y. Morino, K. Kuchitsu and Y. Murata, *Acta Crystallogr.*, **18**, 549 (1965).

*2 Added in Proof: According to a recent electron-diffraction investigation by Clippard and Bartell (*Inorg. Chem.*, **9**, 805 (1970)), the mean amplitudes of AsF_3 are 0.048±0.003 Å and 0.078±0.003 Å for l(As–F) and l(F–F) respectively. The l(F–F) value is in good agreement with the calculated value given in Table 6, while the l(As–F) value is not.

37) M. Iwasaki and K. Hedberg, *J. Chem. Phys.*, **36**, 2961 (1962).

38) S. J. Cyvin, *Spectrochim. Acta*, **15**, 828 (1959).

39) K. Kuchitsu and Y. Morino, This Bulletin, **38**, 805, 814 (1965).

The a_3 parameter was set as approximately equal to 2 Å^{-1}.[40] The above diatomic approximation is, however, not appropriate for non-bonded pairs. The thermal extension of $\langle \Delta z \rangle_{Y-Y}$ for $AsCl_3$ and AsF_3 was estimated by assuming that the thermal change of the average angle was negligible.[14] That is, the following approximation was used:

$$\delta\langle \Delta z \rangle_{Y-Y} = 2\delta\langle \Delta z \rangle_{X-Y} \sin\frac{\theta}{2} . \qquad (19)$$

The values of various correction terms were calculated for $AsCl_3$ and AsF_3 by using the potential constants listed in Tables 2 and 5. The results are tabulated in Table 8.

Table 8. Numerical values of the correction terms for reducing r_g to r_z (in 10^{-4} Å unit)

	$AsCl_3$		AsF_3	
	As–Cl	Cl–Cl	As–F	F–F
$(\delta r_{rot})_T$	6	15	5	6
$\langle \Delta r \rangle_T$	72		53	
$\left(\frac{\langle \Delta x^2 \rangle + \langle \Delta y^2 \rangle}{2r_e}\right)_T$	25	12	20	12
$\langle \Delta z \rangle_T$	47	71	33	49
$(\delta r_{rot})_0$	0	0	0	0
$\langle \Delta r \rangle_0$	54		48	
$\left(\frac{\langle \Delta x^2 \rangle + \langle \Delta y^2 \rangle}{2r_e}\right)_0$	10	5	12	7
$\langle \Delta z \rangle_0$	44	66	36	54
$\langle \Delta z \rangle_T - \langle \Delta z \rangle_0$	3	5	−3	−5
$r_g - r_z$	34 (±3)	32 (±9)	22 (±3)	13 (±9)

Note: T is equal to 291°K and 292°K for $AsCl_3$ and AsF_3, respectively. The values in parentheses are the uncertainties estimated.

Conversion of B_0 to B_z. The average rotational constant, B_z, corresponding to the r_z-structure can be derived by adding some correction terms to the effective constant, B_0.

$$B_z = B_0 + \delta B_{vib} + \delta B_{cent} + \delta B_{elect}. \qquad (20)$$

Here δB_{vib}, δB_{cent} and δB_{elect} are the vibrational, centrifugal, and electronic corrections respectively. For the pyramidal XY_3 molecule, Shaffer[41] and Nielsen[1] derived the relation of the rotational constant, B_0, to the equilibrium rotational constant, B_e, by neglecting the motion of electrons. The first two correction terms, δB_{vib} and δB_{cent} in Eq. (20) can be calculated by using their results.[13]

The last term in Eq. (20) can be estimated if the g tensor of the rotational magnetic moment is known.[7] Since the values of the g tensor were not available for AsF_3 and $AsCl_3$, δB_{elect} was assumed to be zero in the present study. The error caused by this assumption is, however, perhaps negligibly small since δB_{elect} is inferred to be, at most, ten percent of δB_{vib}, judging from the results on formaldehyde.[7] The values of $(B_0 - B_z)$ calculated for $As^{35}Cl_3$, $As^{37}Cl_3$ and AsF_3 are tabulated in Table 9, along with their uncertainties due to those of the force constants.

Table 9. Estimated values of $(B_0 - B_z)$ (in Mc unit)

	$As^{35}Cl_3$	$As^{37}Cl_3$	AsF_3
$B_0 - B_z$	2.70±0.04	2.52±0.04	10.93±0.41

Average Structures. The r_z-structures of $AsCl_3$ and AsF_3 were derived from the observed r_g distances[22] by using the correction values listed in Table 8. The moment of inertia, I_b^z, and the rotational constant, B_z, were calculated from the r_z distances. The results are summarized in Table 10.

The B_z constants were also obtained from the microwave B_0 values and the estimated values of $(B_0 - B_z)$. They are compared with the diffraction values in Table 10. There is no inconsistency between the experimental results of the microwave study and those of the electron-diffraction study.

Table 10. Zero-point average structures and average rotational constants derived from ED and MW data (r_z, I_b^z, and B_z are in Å, amu. Å^2, and Mc units, respectively)

	ED	MW

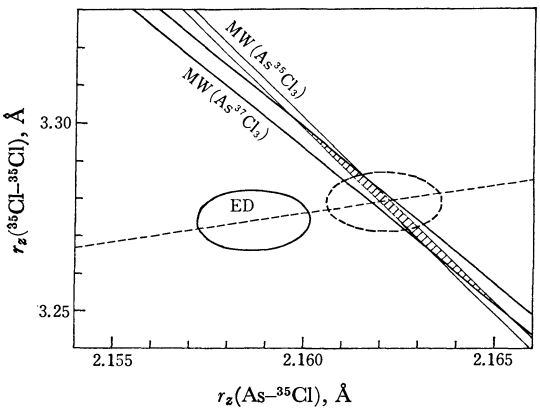

Fig. 4. r_z-Structures of $As^{35}Cl_3$ determined by microwave spectroscopy and electron diffraction. The values allowed by the MW rotational constants are shown by shadows. The ellipse described in solid line shows the ED values, which do not include the error estimated for the scale factor, while the dashed ellipse shows the ED values corrected for the scale factor. The most probable r_z values are obtained from the overlapping regions of the dashed ellipse and the MW region.

In the case of $AsCl_3$, the r_z-structures could be determined from only the microwave data by a tentative estimation of the isotope effects on the r_z distances, as is shown in Table 11. The relations of the r_z distances of $As^{35}Cl_3$ given by the two rotational constants are shown in Fig. 4. The two parallel lines correspond to the limits of errors of a rotational constant. The uncertainties in isotope effects are included as the spread of the curve, $MW(As^{37}Cl_3)$. The structures corresponding to the shaded area are compared with those determined by ED in Table 10. It may be noted that the error of the bond angle is about twice as large as that in the results for ED.

The errors due to the uncertainty of the scale factors are the largest possible systematic errors in the results of ED, so that a more precise structure can be expected if the scale-factor errors are eliminated by using the microwave rotational constants.

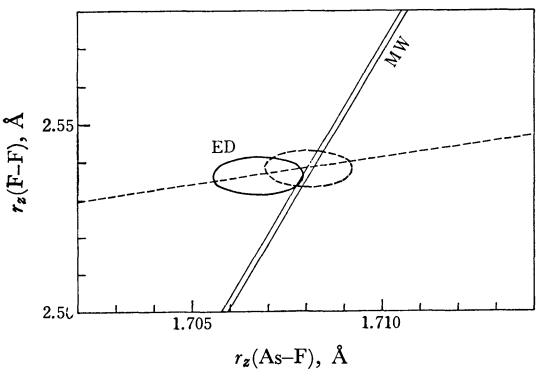

Fig. 5. r_z-Structures of AsF_3 determined by electron diffraction and microwave spectroscopy. See the caption of Fig. 4.

In Figs. 4 and 5, the solid ellipses show the errors associated with the diffraction values, without including the errors for the scale factors. It is mainly because of the scale-factor errors that the centers of the ellipses do not lie on the microwave lines. New ellipses were obtained by shifting the centers of the ellipses along the dashed lines, on which the ratio of r_z(As–Y) to r_z(Y–Y) was kept constant. The most probable average distances were obtained from the overlapping regions of the new ellipses and the microwave lines. They are listed in Table 12, along with the corresponding r_g distances. Because of the steep slopes of the microwave lines, the errors in the As–Y distances became very small.

TABLE 12. r_z AND r_g STRUCTURES OF $As^{35}Cl_3$, $As^{37}Cl_3$ AND AsF_3 OBTAINED BY THE COMBINED USE OF ED AND MW DATA (r in Å unit)

	$As^{35}Cl_3$	$As^{37}Cl_3$	AsF_3

The author wishes to express his thanks to Professor Masao Kimura and Dr. Takao Iijima for their encouragement and helpful discussions.

Appendix

Calculation of the Perpendicular Mean Amplitudes. For pyramidal XY_3 molecules, the formulas expressed in terms of the $\sum$ matrix[39] for calculating the parallel amplitudes $\langle\Delta z^2\rangle$ $(=l^2)$ have already been derived,[26] but those for the perpendicular amplitudes have not yet been presented. The formulas for calculating the sum of the perpendicular amplitudes, $\langle\Delta x^2\rangle$ and $\langle\Delta y^2\rangle$, can be derived by using the following realtion:

$$(\langle\Delta x^2\rangle + \langle\Delta y^2\rangle)_{ij} = \langle(\rho_i-\rho_j)^2\rangle - \langle\Delta z^2\rangle_{ij}. \quad \text{(A1)}$$

Here ρ_i and ρ_j are the displacement vectors of the i and j atoms respectively.

The internal coordinates can be expressed in terms of the displacement vectors, ρ_i, and the unit vectors, e_{ij}, which start from the i atom and which points to the j atom. The relation was derived in a matrix form as:

$$\boldsymbol{R} = \boldsymbol{T}\boldsymbol{\rho}, \quad \text{(A2)}$$

where:

$$\boldsymbol{\rho} = \begin{bmatrix} \rho_1 \\ \rho_2 \\ \rho_3 \\ \rho_4 \end{bmatrix}, \quad \text{(A3)}$$

and:

$$\boldsymbol{T} = \begin{pmatrix} -e_{14} & 0 & 0 & e_{14} \\ 0 & -e_{24} & 0 & e_{24} \\ 0 & 0 & -e_{34} & e_{34} \\ 0 & \frac{1}{s}e_{34} - \frac{c}{s}e_{24} & \frac{1}{s}e_{24} - \frac{c}{s}e_{34} & \frac{c-1}{s}(e_{24}+e_{34}) \\ \frac{1}{s}e_{34} - \frac{c}{s}e_{14} & 0 & \frac{1}{s}e_{14} - \frac{c}{s}e_{34} & \frac{c-1}{s}(e_{34}+e_{14}) \\ \frac{1}{s}e_{24} - \frac{c}{s}e_{14} & \frac{1}{s}e_{14} - \frac{c}{s}e_{24} & 0 & \frac{c-1}{s}(e_{14}+e_{24}) \end{pmatrix}. \quad \text{(A4)}$$

Here s and c are abbreviations of the sine and the cosine of the bond angle, θ, respectively. With this notation, the $\boldsymbol{G}$ matrix in the symmetry coordinates was expressed as:

$$\boldsymbol{G} = \boldsymbol{UTM}^{-1}\boldsymbol{T}'\boldsymbol{U}', \quad \text{(A5)}$$

where $'$ denotes transposed matrices, where $\boldsymbol{U}$ is a matrix defined by Eq. (2b), and where:

$$\boldsymbol{M}^{-1} = \begin{pmatrix} \mu_Y & & & \\ & \mu_Y & & \\ & & \mu_Y & \\ & & & \mu_X \end{pmatrix}. \quad \text{(A6)}$$

The elements of the $\boldsymbol{G}$ matrix are given in Eqs. (4) and (5).

The ρ_i vectors could be expressed in terms of the symmetry coordinates by using Eqs. (2b), (A2), and (A5):

$$\boldsymbol{\rho} = \boldsymbol{M}^{-1}\boldsymbol{T}'\boldsymbol{U}'\boldsymbol{G}^{-1}\boldsymbol{S}. \quad \text{(A7)}$$

This is essentially equal to the relation derived by Morino and Hirota.[42] By using Eq. (A7), the $<(\rho_i-\rho_j)^2>$ term in Eq. (A1) was expressed in terms of the $\sum$ matrix elements after a rather lengthy manipulation. From the results, the contribution of the parallel amplitudes given in Eqs. (6) and (7) were subtracted, and the following results were obtained:

$$(\langle\Delta x^2\rangle+\langle\Delta y^2\rangle)_{X-Y} = \frac{1}{6}\frac{1+c}{1+2c}\sum_{22} + \frac{2}{3}\frac{1+c}{2+c}\sum_{44} + \frac{2(1-c)(1+2c)}{2+c}\mu_X^2 \cdot P \quad \text{(A8)}$$

$$(\langle\Delta x^2\rangle+\langle\Delta y^2\rangle)_{Y-Y} = \frac{2}{3}\left\{\sin^2\frac{\theta}{2}\sum_{33} - 2\sin\frac{\theta}{2}\cos\frac{\theta}{2}\sum_{34} + \cos^2\frac{\theta}{2}\sum_{44}\right\} + \frac{2}{3}(1+2c)\mu_Y^2 \cdot P, \quad \text{(A9)}$$

where:

$$P = \{(2+c)^2\sum_{33} + 2(2+c)s\sum_{34} + s^2\sum_{44}\}/\{3(1-c)\mu_X + (2+c)\mu_Y\}^2. \quad \text{(A10)}$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3116—3121 (1970)

The Electron Spin Resonance of the Mn^{2+} Ion in Aqueous Surfactant Solutions*1

Akinori HASEGAWA, Yasuyoshi MICHIHARA and Masaji MIURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received June 8, 1970)

The ESR spectrum of the Mn^{2+} ion in an aqueous solution of a surfactant is affected by its concentration. Sodium dodecyl sulfate and sodium decyl sulfate were employed as surfactants in this study. The linewidth of the Mn^{2+} ion is independent of the concentration of the surfactant in the low-concentration range, but it increases over a certain concentration range and then becomes constant. Two values of CMC were observed by measurements of the conductivity corresponding to the concentrations, where the linewidth of Mn^{2+} changed abruptly with the concentration of the surfactant. The linewidth broadening above the first CMC was interpreted as being due to the formation of an outer-sphere complex of the Mn^{2+} ion with a surfactant micelle. The interaction between the counterion and micelle was also investigated on the basis of the ESR spectra of the Mn^{2+} ion with regard to the effects of the kind of surfactant, the temperature, foreign electrolytes, *etc.*

The manganese ion is a typical paramagnetic ion, and a number of ESR studies of this ion have been published.[1-3] Most of them have dealt with it in solid; trace amounts of cations in a solid are displaced by Mn^{2+} ions, and information with regard to the crystal field, the bond character, *etc.* can be obtained from the ESR spectrum of the Mn^{2+} ion. The method of the spin label of the cation with the Mn^{2+} ion is expected to be informative not only for solids but also for electrolytic solutions.

On the other hand, the formation of a complex ion between the Mn^{2+} ion and halogen ions, SO_4^{2-} ions, or $S_2O_4^{2-}$ ions has been studied by means of the ESR spectra of the Mn^{2+} ion.[4-6] In these studies, a two-step coordination model was proposed to explain the broadening of the ESR spectra of the Mn^{2+} ion and several parameters were estimated for the formation and dissociation of an inner- or outer-sphere complex. The electron-spin relaxation of the Mn^{2+} ion in a liquid solution has been investigated in terms of the solvent fluctuation model[7] and the ESR linewidths of the Mn^{2+} ion have been studied in various solvents.[8,9]

It is well-known that a counterion plays an important role in the formation of a surfactant micelle. In this paper, Mn^{2+} ion was added to an aqueous solution of a surfactant and the ESR spectra of the Mn^{2+} ion were observed. The interactions between the counterion and the surfactant micelle were discussed.

By the magnetic resonance technique, several attempts have been made to investigate the surfactant micelle. Some of them have been NMR studies using a hydrogen[10,11] or a fluorine[12-14] nucleus in a surfactant molecule, and others, ESR studies made by spin-labeling the micelle with a monoradical[15] or a biradical.[16] All of these methods

give information concerning the inner part of the micelle. In contrast to these investigations, the present study offers information with regard to the interactions between the counterion and surfactant micelle.

Theoretical

The theory of the ESR linewidth of the Mn^{2+} ion in a liquid solution has been developed in terms of the relaxation induced by the solvent fluctuation.[7] An outline of the theory will be given here.

The ESR spectra of the aqueous solutions of the Mn^{2+} ion exhibit six hyperfine components due to the electron spin, $S=5/2$, and the nuclear spin, $I=5/2$. Each of the hyperfine components also consists of five transitions for $m_s-1\leftrightarrow m_s$.

The linewidths for these transitions have been investigated in terms of the relaxation induced by solvent fluctuation. The theory was developed from the time-dependent spin-orbit interaction, using the spin density matrix. The resultant linewidths for the five transitions, $m_s-1\leftrightarrow m_s$, are:

$$\begin{aligned} \Delta H_{3/2,5/2} &= \Delta H_{-5/2,-3/2} = 2.633Z \\ \Delta H_{1/2,3/2} &= \Delta H_{-3/2,-1/2} = 2.312Z \\ \Delta H_{-1/2,1/2} &= 1.971Z \end{aligned} \qquad (1)$$

with

$$Z = C^2\tau_c/\hbar^2$$

where C is the trace of the perturbation Hamiltonian; τ_c, the perturbational correlation time, and $\hbar$, Planck's constant.

The spreads theoretically expected for these transitions, $m_s-1\leftrightarrow m_s$, were also demonstrated to depend upon the magnetic quantum number of nuclear spin by the calculation by means of the perturbation theory. The spread is the smallest, *ca.* 5 gauss, for $m_I=+1/2$ and the largest, *ca.* 30 gauss, for $m_I=-5/2$.

The apparent linewidth of $m_I=1/2$, therefore, is proportional to τ_c:

$$\Delta H_{m_I=1/2} \propto \tau_c \qquad (2)$$

Thus, the correlation time of the solvent fluctuation for the Mn^{2+} ion can be estimated from the linewidth of $m_I=1/2$.

In the present system, the linewidth of the Mn^{2+} ion may also result from the relaxation due to the modulation of zero-field splitting induced by the tumbling motion of the complex.[17-19] The linewidth of $m_I=1/2$ can, any event, be a measure of the correlation time, τ_c.

Experimental

Sodium dodecyl sulfate (SDS) and sodium decyl sulfate (NaDS) were used as surfactants in this study. The former was synthesized and purified by Nippon Yushi Co. Ltd., and the latter, in our laboratory. Different amounts of surfactants were added to an aqueous solution of 1×10^{-3}M $Mn(NO_3)_2$. The solution thus obtained was sealed in a capillary of glass, and the ESR spectra were measured at different temperatures by using a spectrometer described elsewhere.[20] The conductivity measurements were carried out at 50°C or 25°C. To investigate the effect of electrolytes, 1×10^{-2}M $NaNO_3$ or KNO_3 was added to a surfactant solution containing the Mn^{2+} ion.

Results and Discussion

The ESR spectrum of the Mn^{2+} ion in the aqueous solution was remarkably affected by the con-

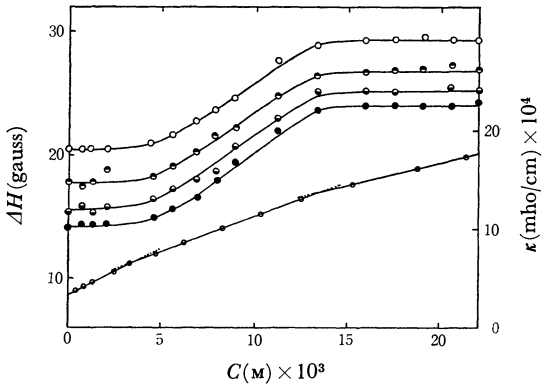

Fig. 2. The dependences of the linewidths (m_I: ○ −5/2, ◓ −3/2, ◒ −1/2 and ● 1/2) and the conductivity (○) on the concentration of SDS at 50°C. The concentration of Mn^{2+} ion is 1×10^{-3}M. Symbols in the following figures have the same meaning as those in this figure except for Fig. 6.

centration of the surfactant, as is shown in Fig. 1. The spectrum consists of six hyperfine structures, corresponding to the states of $m_I=-5/2$, $-3/2$, $-1/2$, $1/2$, $3/2$ and $5/2$ respectively, counting from the side of the lower magnetic field.

The variation in the linewidth is shown in Fig. 2, where the linewidths of four lines in the lower magnetic field are plotted against the concentration of SDS at 50°C. When the concentration of SDS is below 3×10^{-3}M, the linewidth is practically unaffected by the concentration. However, the linewidth increases with the concentration in the range from 3×10^{-3} to 13×10^{-3}M and becomes constant above 13×10^{-3}M. The linewidth of $m_I=1/2$, as is shown in Eq. (2), is proportional to the correlation time, τ_c, of the Mn^{2+} ion resulting from the fluctuation of the solvent shell. In the lower concentration range, the interaction between the Mn^{2+} ion and SDS seems negligibly small, because the correlation time is unaffected by the addition of SDS. The correlation time, however, increases over the concentration range from 3×10^{-3} to 13×10^{-3}M and then takes a constant value, which is 1.7 times that below 3×10^{-3}M.

The conductivity of the aqueous solution of SDS containing Mn^{2+} ions was measured at 50°C; the results are given in Fig. 2. Two broken points were observed, as may be seen in the figure, in the relation between the specific conductivity and the concentration. The concentrations at these broken points, which correspond to the first and the second critical micelle concentrations (CMC) respectively, counting from the lower concentration, are in good agreement with those observed in connection with ESR linewidth of the Mn^{2+} ion.

Similar results were obtained at 25°C, as may be seen in Fig. 3. Both the first and second CMC's decrease with a drop in the temperature, the rate

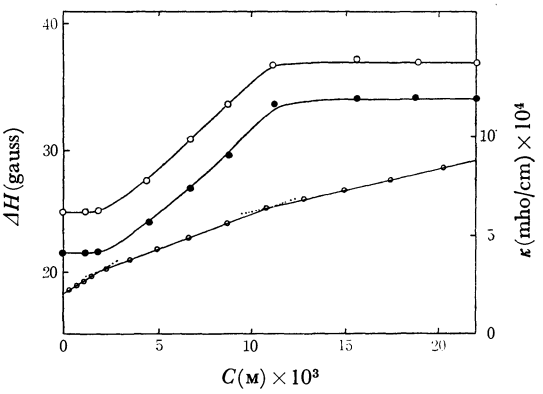

Fig. 3. The dependences of the linewidths and the conductivity on the concentration of SDS at 25°C. The concentration of Mn^{2+} ion is 1×10^{-3}M.

of decrease being larger for the second CMC than for the first. The correlation time of the Mn^{2+} ion takes a higher value at 25°C than at 50°C, and the value below the first CMC at the lower temperature is nearly equal to that above the second CMC at the higher temperature.

A molecule of SDS has a hydrocarbon chain consisting of 12 carbon atoms. The CMC of surfactant generally increases with a decrease in the number of the carbon atom. Thus, sodium decyl sulfate (NaDS), with 10 carbon atoms in a hydrocarbon chain, was investigated. A change in the ESR linewidth of the Mn^{2+} ion was also observed, accompanied by an increase in the concentration of NaDS; the concentrations, where the linewidth abruptly changed, were in excellent agreement with the CMC's determined by the conductivity measurements. The linewidth of $m_I=1/2$ above the second CMC is 22.5 gauss at 50°C, as may be seen in Fig. 4, which is 93% of that in the case of SDS at 50°C. The correlation time, therefore, is short compared with that in the case of SDS.

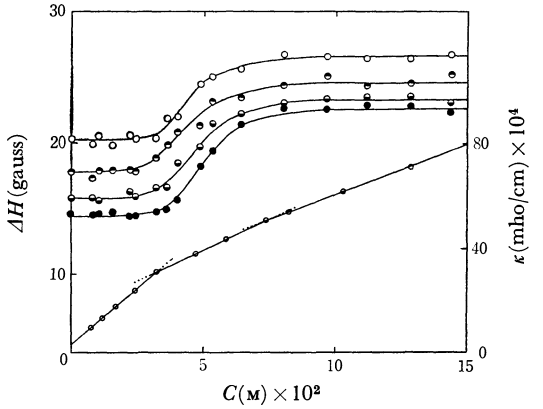

Fig. 4. The dependences of the linewidths and the conductivity on the concentration of NaDS at 50°C. The concentration of Mn^{2+} ion is 1×10^{-3}M.

The effects of the concentration of the Mn^{2+} ion on the two CMC's and on the linewidth of the ESR spectrum were investigated by using an NaDS solution containing Mn^{2+} ion in a concentration of 2×10^{-3}M. The increase in the concentration of the Mn^{2+} ion, as may be seen in Fig. 5, gave rise to the decreases in the CMC's and in the linewidth of the ESR spectrum above the second CMC.

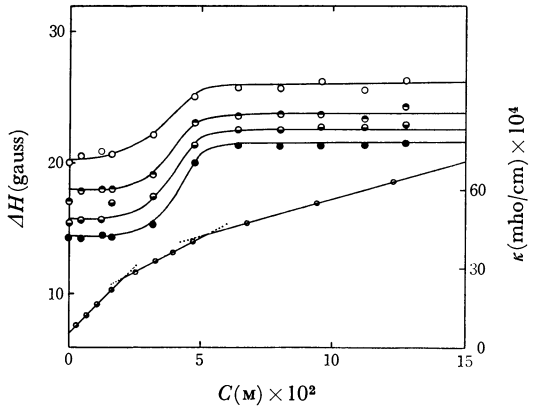

Fig. 5. The dependences of the linewidths and the conductivity on the concentration of NaDS at 50°C. The concentration of Mn^{2+} ion is 2×10^{-3}M.

Frenkel has proposed the following relation with regard to the structural correlation time, τ_c, in terms of the transient lattice model for liquids:[21]

$$\tau_c \propto \rho M/\eta T \tag{3}$$

where η is the viscosity; M, the apparent molecular weight of fluctuating solvent; ρ, the density, and T, the absolute temperature. This relation has been proved by an investigation of the linewidths of the ESR spectra of the Mn^{2+} ion in kinds of solvents.[7]

The equation of viscosity is shown by:[22]

$$\eta = \boldsymbol{h}N_A/v \exp(\Delta F^*/\boldsymbol{R}T) \tag{4}$$

where $\boldsymbol{h}$ is Planck's constant; N_A, Avogadro's number; v, the molar volume, and ΔF^*, the standard free energy of activation per mole in the elemental process of the viscous flow. From Eqs. (2), (3), and (4), the following relation can be obtained:

$$\ln(\rho T\Delta H_{m_I=1/2}) = \Delta F^*/\boldsymbol{R}T + \ln K \tag{5}$$

where K is the constant proportional to M. This equation shows the existence of a linear relation between $\ln(\rho T\Delta H_{m_I=1/2})$ and $1/T$. The ESR spectra of the Mn^{2+} ion in the aqueous solutions of the two surfactants were then measured at different temperatures. The results exhibited linear relations, as was to be expected from Eq. (5), and

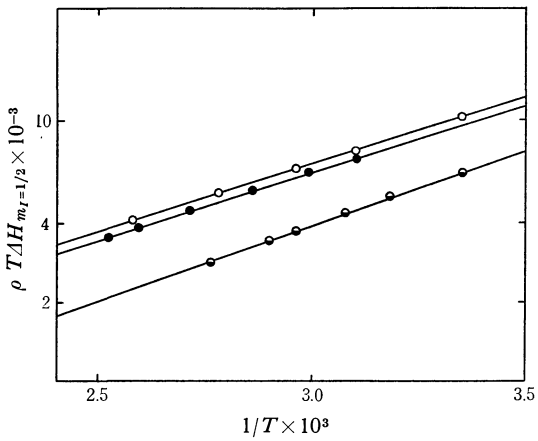

Fig. 6. The relations between $\rho T\Delta H_{m_I=1/2}$ and $1/T$.
◒: below the first CMC for SDS and NaDS
○: above the second CMC for SDS
●: above the second CMC for NaDS

as is shown in Fig. 6. The value of ΔF^* could be obtained from the gradient, and the constant, K, from the intercept. The values of ΔF^* for SDS and NaDS, both below the first CMC and above the second CMC, were determined to be equal to 2.0 kcal/mol in spite of the differences in the kind and concentration of the surfactant. On the other hand, the constant, K, which involves the apparent molecular weight of the solvent bringing about the fluctuation in the Mn^{2+} ion, changes with the kind and concentration of the surfactant. This may be attributed to the change in the apparent molecular weight of the solvent. From Eqs. (2) and (3), the apparent molecular weight of the solvent can be estimated by:

$$M \propto \Delta H_{m_I=1/2}\rho T/\eta \tag{6}$$

By using the ρ and η values of the aqueous solution measured at 25°C, and by assuming that the proportional constant in Eq. (6) is independent of the concentration of the surfactant, the apparent molecular weight of the solvent can be seen to increase over the region from the first CMC to the second CMC, and the ratio of the value above the second CMC to that below the first CMC can be determined to be 1.5 for the aqueous solution of SDS at 25°C.

From the fact that the broadening of the ESR spectrum of the Mn^{2+} ion is observed only above the first CMC, it is expected that the surfactant micelle participates in the solvent fluctuating the Mn^{2+} ion. As the micelle is very large compared with the water molecule, the apparent molecular weight of the solvent in the presence of the micelle might be expected to be much larger than that estimated above. It is, therefore, interesting to speculate about the interactions between the counter-ion and the micelle; one of the interactions is the ion-binding between them. One possible ion-

21) J. Frenkel, "Kinetic Theory of Liquids," Dover Publications, New York (1955), pp. 188—208.

binding is the formation of a complex in which the Mn^{2+} ion largely retains its full hydration sphere, an outer-sphere complex. At the other extreme, ion-binding is accomplished by the formation of an inner-sphere complex in which the Mn^{2+} ion is stripped of its hydration sphere.[5] The two-step process for complex ion formation can be shown by the following reaction equations:[5]

$$Mn^{2+}(H_2O)_n + X^{m-} \rightleftarrows Mn^{2+}(H_2O)_nX^{m-} \quad (I)$$

$$Mn^{2+}(H_2O)_nX^{m-} \rightleftarrows Mn^{2+}X^{m-} \quad (II)$$

where X^{m-} represents the micelle with negative charges. The two-step process has been proved for the Mn^{2+} ion in an aqueous solution containing an ion such as F^-, Cl^-, Br^-, I^-, SO_4^{2-}, or $S_2O_4^{2-}$.[4-6] In these studies, the first process was observed from a broadening of the ESR spectrum of the Mn^{2+} ion near room temperature, and the second one, from a broadening above 100°C. From these results, and from the fact that another broadening was found in an aqueous solution of surfactant near 130°C, the broadening of the ESR spectrum of the Mn^{2+} ion in a surfactant solution near room temperature is interpreted to be due to the process of the formation of an outer-sphere complex. Water molecules mainly, and surfactant micelles partially, participate in the fluctuation of the Mn^{2+} ion.

Accordingly, the "apparent molecular weight" described above is predominantly dependent on the forward and backward rate constants in the reaction (I) rather than an average size of the micelles. Several thermodynamic values for the reaction (I) could be evaluated on the basis of the broadening by the introduction of several assumptions, but that is far from our present purpose.

The broadening of the ESR spectrum above the first CMC may be interpreted in terms of the model in which the amount of the Mn^{2+} ion bound by the surfactant micelle increases with the amount of the micelle. Above the second CMC, no changes in the interaction between the Mn^{2+} ion and the micelle were observed from the ESR spectrum; this may suggest that practically all of the Mn^{2+} ions in the solution participate in the ion-binding with the micelle in the range from the first CMC to the second CMC.

The strength of the ion-binding or the forward rate constant of the reaction (I) is large for SDS as compared with that for NaDS.

The increase in the amount of the added Mn^{2+} ion, as may be seen in Figs. 5 and 6, gave rise to diminutions in both the first and the second CMC's and to a decrease in the correlation time above the second CMC. This may be due to the neutralization of the negative charges of the micelle with Mn^{2+} ions.

Next, the effect of electrolytes on a surfactant solution containing the Mn^{2+} ion was investigated. Numerous authors have reported that the addition of simple electrolytes lowers the CMC of an ionic surfactant and increases the average size of the micelles.[23] Although alkali halides, *e.g.*, NaCl. KCl, and NaBr, are generally used for this purpose, halogen ions are inadequate for the present study because halogen ions give rise to a broadening of the ESR spectrum of the Mn^{2+} ion by forming outer-sphere complexes with the Mn^{2+} ion. Thus, such nitrates as $NaNO_3$ and KNO_3 were used for the following experiments (Figs. 7 and 8), since

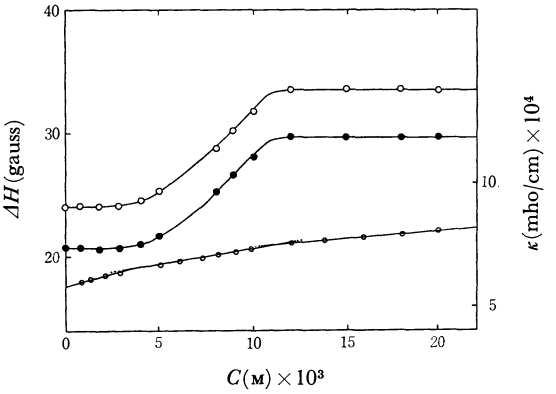

Fig. 7. The dependences of the linewidths and the conductivity on the concentration of SDS in the presence of 1×10^{-2}M $NaNO_3$, at 25°C. The concentration of Mn^{2+} ion is 1×10^{-3}M.

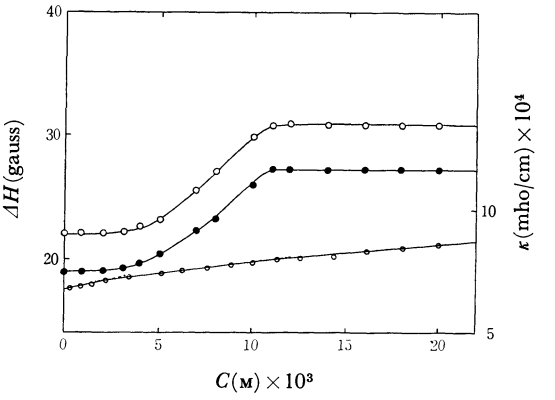

Fig. 8. The dependences of the linewidths and the conductivity on the concentration of SDS in the presence of 1×10^{-2}M KNO_3, at 25°C. The concentration of Mn^{2+} ion is 1×10^{-3}M.

the nitric ion has no appreciable effect on the Mn^{2+} ion. By the addition of 1×10^{-2}M $NaNO_3$ or KNO_3, the broadening of the spectrum is diminished and the effect of KNO_3 on the diminution is superior to that of $NaNO_3$. This may be explained as follows: the added electrolytes weaken the bond between the Mn^{2+} ion and the surfactant micelle. The narrowing of the ESR spectrum of the Mn^{2+}

23) M. J. Shik, *J. Phys. Chem.*, **68**, 3585 (1964).

ion arising from the addition of electrolytes observed below the first CMC corresponds to the fact that a linewidth narrowing was observed upon the initial addition of electrolytes to a solution of the Cr^{3+} ion.[24] This narrowing has been interpreted as being caused by a diamagnetic cation, which decreases the effective charge density of the anions in the outer-sphere.

Thus, by using a paramagnetic ion, the Mn^{2+} ion, as an indicator, several pieces of information with regard to the interaction between the counterion and the surfactant micelle were obtained from our measurements of the ESR spectrum of the ion.

Luminescence in DNA-Acridine Dye Complexes. I. Phosphorescence and Delayed Fluorescence Due to the Triplet-Triplet Annihilation of Acridine Dyes in the Complexes

Yukio KUBOTA

Department of Chemistry, Yamaguchi University, Yamaguchi

(Received June 15, 1970)

When DNA-acridine dye complexes were excited by a visible light which was not absorbed by DNA, phosphorescence and a delayed fluorescence of the dye were observed. It was found, by comparing the excitation spectra with the absorption spectra, that the monomeric dyes mainly contribute to the fluorescence and phosphorescence emissions. The delayed fluorescence was interpreted as a result of the triplet-triplet annihilation which arises from two triplet dye molecules placed very close together. The decrease in the delayed fluorescence on the denaturation of DNA indicates that the interaction between the two triplets is sensitive to the conformation of the macromolecule.

The interaction of acridine dyes with DNA has been extensively studied by various techniques in connection with the photodynamic and mutagenic actions of these dyes. At present, it is generally accepted that these dyes bind to DNA to form two types of complexes; one (Complex I) results from the dye-dye interaction on the outside of the DNA helix at low P/D[1] values,[2,3] and the other (Complex II) occurs at high P/D values, where the dye-nucleotide interaction is involved.[4] Lerman has proposed that, in Complex II, acridine dye molecules are intercalated in a sandwich-like way between adjacent base pairs in the double-stranded helix.[5] For the understanding of the above biological actions of acridine dyes, therefore, it seems very significant to make clear the mechanism of the interactions between the DNA bases and dye molecules and between the dye molecules in the complexes from the photophysical and photochemical points of view.

In a previous communication,[6] it was shown that the triplet states of acridine dyes play an important role in the photosensitized radical formation in the complexes. In order to obtain further information regarding the excited states of acridine dyes and the energy transfer in the DNA-acridine dye complexes, the luminescence of the complexes was studied in frozen aqueous solutions at 77°K. In this study, proflavine, acridine orange, and acriflavine were used. Recently, the present author reported his preliminary results on the luminescence in the complexes.[7,8] The present paper will describe in detail the luminescence properties of acridine dyes in the complexes upon excitation by visible light.

Experimental

Materials. The acridine orange (Tokyo Kasei) was purified by the method of Zanker.[9] The proflavine sulfate (G. R. of Tokyo Kasei) was precipitated as a free base from an aqueous solution by adding a dilute sodium hydroxide solution. The precipitate was recrystallized three times from an ethanol-water mixture. The acriflavine (Chroma) was purified by the method of Gailliot[10] and was recrystallized twice from methanol. To check the purity, these dyes were subjected to silica-gel thin-layer chromatography; the chromatogram showed only a single colored band for each dye.

Calf thymus DNA (Type I) was obtained from the Sigma Chemical Co. The concentration of the DNA phosphates was determined by analyzing the phosphorus by the method of Chen *et al.*[11] The atomic extinction coefficient per phosphorus was found to be 6700, which is characteristic of a native DNA.

The solutions of the complexes were made up in a 0.01 M phosphate buffer at pH 7.0. Each DNA solution contained 0.01 M sodium chloride to protect it from denaturation. The thermal denaturation of DNA was performed by heating the DNA solutions for 20 min in boiling water and by then rapidly cooling them in ice-water.

Measurements. All the solutions were degassed by the freezing, pumping, and thawing technique under a high vacuum. The glass of the sample solution was made at 77°K in a quartz tube (1.5—2 mm in internal diameter). The emission and excitation spectra at 77°K were measured with a Hitachi MPF-2A fluorescence spectrophotometer; the exciting light source was a 150-W xenon lamp, and the detector was a R-106 photomultiplier. A rotating-shutter phosphoroscope was used to separate the delayed emissions (phosphorescence and delayed fluorescence) from normal fluorescence. No correction of the emission spectra was made for the spectral sensitivity of the detector. The excitation spectra were corrected for the spectral-energy distribution of the exciting light. The intensity of the exciting light was varied by introducing calibrated wire screens. The decay of the delayed emission was generally measured at its maximum wavelength by using a Hitachi V-104 synchroscope.

The absorption spectra were measured with a Shimadzu MPS spectrophotometer at 77°K or at room temperature, using 0.1- and 0.2-cm quartz cells. This apparatus can detect a large fraction of the forward scattered light in addition to the transmitted light; thus, it gives an accurate absorption. We could obtain the reproducible absorption spectra by subtracting the apparent absorption of the reference solution from that of the sample solution, in spite of the development of cracks and translucency in the glass.

The ESR measurements of the lowest triplet state of the acridine dyes in the complexes were made using a JES-3BX ESR spectrometer in an ethylene glycol-water (1 : 1 by volume) mixture at 77°K.

Results and Discussion

Absorption Spectra of the Complexes. First, the absorption spectra of the complexes were measured at room temperature and at 77°K in order to ascertain the binding states of acridine dyes. It was found that the dye molecules predominantly exist as the monomeric species at a sufficiently high P/D value, and that they tend to associate with a decrease in the P/D value. The associative tendency appears to increase in the order of acridine orange, proflavine, and acrifivine and is more remarkable in the denatured DNA than in the native one. Typical examples of the absorption spectra at 77°K are shown in Figs. 1 and 2. They exhibit a red shift of about 10 nm and are well resolved as compared with those at room temperature.[2,4,12] The absorption band corresponding to the 0—1 transition generally overlaps with the dimer absorp-

tion band for each dye. In the case of $P/D<5$, absorption due to the aggregation of free dyes develops at wavelengths shorter than the 0—1 band.

Phosphorescence and Phosphorescence-Excitation (PE) Spectra of Acridine Dyes in the Complexes. The total emission and the delayed emission spectra of acridine dyes upon the excitation of the complexes by the visible light are shown in Figs. 1 and 2. The total emission seems to be mainly composed of normal fluorescence. The phosphorescence spectra at low dye concentrations (below 2.5×10^{-5}M) have peaks at 565, 604, and 574 nm for proflavine, acridine orange, and acriflavine respectively. These spectra are similar to those of acridine dyes in organic solvents at 77°K.[13,14] With an increase in the dye concentration, both phosphorescence and fluorescence spectra slightly shift to longer wavelengths; this may be due to self-absorption. The phosphorescence intensity decreases with a decrease in the P/D value; this phenomenon becomes remarkable in the case of denatured DNA.

Next, the PE spectra were measured in order to obtain information on the phosphorescing species by comparing them with the absorption spectra. As Figs. 1 and 2 show, the PE spectra at high and low P/D values are approximately identical and agree well with the absorption spectra at a high P/D value. Further, it was found that the PE spectra are identical with the fluorescence-excitation spectra. These results indicate that the monomeric dyes mainly contribute to the fluorescence and phosphorescence emissions. Thus, the decrease in the phosphorescence intensity with a decrease in the P/D value or in the case of denatured DNA may be interpreted as a result of the increase in the number of dimeric species.

Table 1. Phosphorescence lifetimes of acridine dyes in the complexes at 77°K (sec)

Dye concn. (M)	P/D	Acridine orange (500 nm)*1	Proflavine (460 nm)*1	Acriflavine (470 nm)*1
10^{-4}	100	1.27	1.77	1.89
5×10^{-5}	100	1.34	1.90	1.96
		1.34*2		1.95*2

		1.31*2		1.94*2
	10	1.25*3	1.81*3	1.90*3
	5		1.76*3	1.86*3
2.5×10^{-5}	200	1.50	1.98	2.06
10^{-5}	500	1.60	2.00	2.08

*1 Excitation wavelength.
*2 Denatured DNA.
*3 Slightly deviates from the exponentiality at the initial stage.

Finally, the mean lifetimes of the phosphorescence are summarized in Table 1. In general, these values are a little smaller than those in organic solvents at 77°K (*cf.* Table 2).[13]

ESR of the Lowest Triplet State of Acridine Dyes in the Complexes. The ESR spectra corresponding to the $\Delta M=2$ transitions of acridine dyes in the complexes were observed at a magnetic field of *ca.* 1600 gauss. From the maximum position on the low-field side of the derivative spectrum, one can calculate the root-mean-square zero-field splitting parameter (D^*), which is a measure of the electron spin-spin interaction.[15] As may be seen from Table 2, the D^* value at a high P/D

value is in good agreement with those corresponding to the monomeric dyes in organic solvents.[13] Therefore, the ESR results also support the idea that the monomeric dyes mainly contribute to the phosphorescence emission.

Delayed Fluorescence Due to the Triplet-Triplet Annihilation of Acridine Dyes in the Complexes. As Figs. 1 and 2 show, a delayed fluorescence of the dye was also observed. The peak of the delayed fluorescence shifts to a slightly longer wavelength, but this is trivial; this may be attributed to self-absorption. This delayed fluorescence has not yet been reported in the DNA-acridine dye complexes; an effort will be made hereinafter to investigate its nature.

The excitation spectrum of the delayed fluorescence coincides well with the absorption spectra at a high P/D value, where most of the dye molecules exist as the monomeric species (see Fig. 2). Therefore, it may be concluded that the excitation process of the delayed fluorescence is identical with that of the fluorescence or phosphorescence of the monomeric dyes.

Since the thermal excitation from the lowest triplet to the first excited singlet state is actually impossible at 77°K for acridine dyes, the delayed fluorescence observed cannot be interpreted as an α-phosphorescence; this phenomenon was found to become remarkable at temperatures above 200°K.

Following the method of Azumi and McGlynn,[16] we plotted the intensity of the delayed fluorescence against the square of the phosphorescence intensity; this gave a straight line, as is shown in Fig. 3. Further, as is shown in Fig. 4, the growth of the delayed fluorescence was observed to depend on the initial triplet concentration and to be nearly equal to the growth of the triplet concentration after a long period of darkness.[17] In view of these results, it seems reasonable to conclude that two triplets are involved in the phenomenon of the delayed fluorescence—that is, two neighboring

triplet molecules produce one singlet molecule, which is then responsible for the delayed fluorescence. Moreover, the first period of the decay of phosphorescence shows deviations from the exponentiality (Fig. 5); these deviations may be related to the existence of the triplet-triplet annihilation process.[16,18]

It is well known that the probability of the triplet-triplet annihilation falls off rapidly with an increase in the triplet-state separation. As may be seen in Fig. 1, the delayed fluorescence can be observed even at P/D values higher than 100. If the dye binding is homogeneous, the interaction between two triplets is unlikely to occur at $P/D \geq 100$. Consequently, it may be thought that the binding is heterogeneous and that, thus, the assembly of dye molecules is partly formed in the double-stranded helix. This is consistent with the results previously obtained.[19]

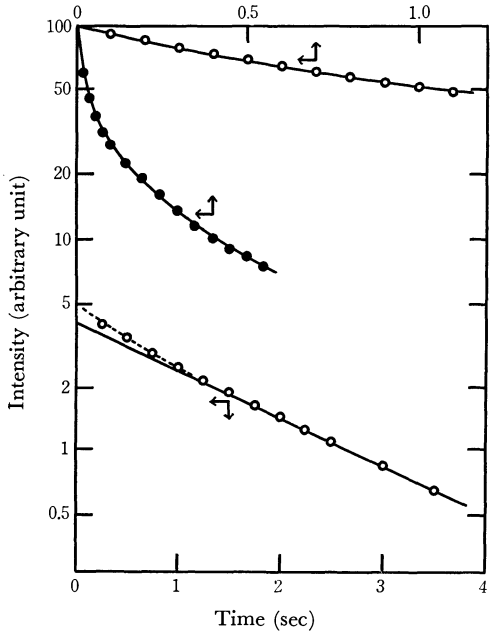

Fig. 5. The decay curves of phosphorescence (○) and delayed fluorescence (●) of acriflavine (5×10^{-5}M) in the complexes ($P/D=5$) at 77°K excited at 470 nm.
Phosphorescence decay in two parts: 0—1 sec and 1—4 sec.

On the other hand, if the triplet molecules are uniformly distributed and if the second-order processes are negligible, the delayed fluorescence will decay exponentially with twice the rate constant of phosphorescence decay.[16,18] In fact, as is shown in Fig. 5 in connection with the DNA-acriflavine complex, the decay of delayed fluorescence is not exponential; it decays very fast at the begining and then gradually becomes slower. The decay mode of the delayed fluorescence was independent of the P/D value and was similar to those of other acridine dyes. As has been mentioned above, a random distribution of dye molecules in the complexes is somewhat unlikely. Therefore, the initial rapid decay of the delayed fluorescence may be ascribed to the strong interaction between triplet molecules spaced very close together.

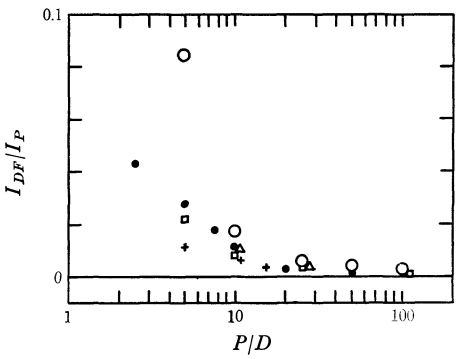

Fig. 6. The ratio of the intensity of delayed fluorescence to that of phosphorescence of the dye (I_{DF}/I_P) as a function of P/D. Both intensities are corrected for the spectral sensitivity of the detector.
○: acriflavine (5×10^{-5}M, I_{DF}/I_P values are 0.10 and 0.16 at $P/D=4$ and 2.5 respectively)
●: acriflavine (10^{-4}M)
+: acriflavine (10^{-4}M, denatured DNA)
□: proflavine (5×10^{-5}M)
△: acridine orange (5×10^{-5}M)

As may be seen in Fig. 6, the phenomenon of the delayed fluorescence seems to depend on the P/D value, the dye concentration, the kind of acridine dye, and the conformation of the macromolecular complex. First, the delayed fluorescence becomes remarkable with a decrease in the P/D value; this may be expected from the decrease in the mean distance between dye-dye molecules—that is, between two triplets. Second, the delayed fluorescence becomes weak with an increase in the dye concentration at a constant P/D value; this may be expected from the fact that dye association becomes more pronounced as the dye concentration increases. Third, the delayed fluorescence is observed most remarkably for acriflavine; this may be understood on the basis of the fact that acriflavine associates less than proflavine and acridine orange do. Finally, the denaturation of DNA leads to a marked diminution in the delayed fluorescence; this may be due to the difference between the conformations of the native and denatured DNA, where dye molecules associate remarkably. In the case of RNA, the delayed fluorescence is greatly decreased. Further, no triplet-triplet annihilation was found in the nucleotide-dye systems. Therefore, the double helical structure seems suitable for producing the annihilative process.

The author wishes to thank Professor Masaji Miura, Hiroshima University, for his helpful discussions and suggestions during this work. Thanks are also due to Professor Yasuo Fujisaki, Yamaguichi University, for his continuing interest and encouragement.

Luminescence in DNA-Acridine Dye Complexes. II. Sensitized Delayed Fluorescence in the Complexes

Yukio KUBOTA

Department of Chemistry, Yamaguchi University, Yamaguchi

(Received June 15, 1970)

When frozen aqueous solutions of DNA-acridine dye complexes or nucleotide-dye mixtures were excited by ultraviolet light, a sensitized delayed fluorescence of the dye was observed. This delayed fluorescence was interpreted by means of a mechanism in which the excitation energy is transferred from the triplet state of the nucleotides to the first excited singlet state of the dye. The efficiency and decays of the sensitized delayed fluorescence revealed that the energy transfer depends greatly on the separation between the energy donor and acceptor and that donor-acceptor pairs spaced very closely are important in the energy transfer. In DNA-acridine dye complexes, the thymine triplet seems to play the most important role as an energy donor. The decrease in the delayed fluorescence on the denaturation of DNA indicates that the energy transfer is sensitive to the conformation of the macromolecule.

In the preceding paper,[1] the luminescence properties of acridine dyes upon the excitation of DNA-acridine dye complexes by visible light have been reported. According to Lerman's intercalation model,[2] in which the dye molecules are in close proximity with purine-pyrimidine base pairs in the double-stranded helix, the electronic excitation-energy transfer between DNA bases and dye molecules may be expected to occur efficiently. Recently, three types of energy transfer, singlet-singlet,[3] triplet-singlet,[4] and triplet-triplet,[5] have been shown to occur in the complexes; DNA bases served as the energy donors, and the bound dye, as the energy acceptor. In order to obtain further information on the energy transfer between DNA bases and dye molecules, our investigations have now been extended to the luminescence properties of the complexes with excitation in the region of DNA absorption. A sensitized delayed fluorescence was observed for various acridine dyes in frozen aqueous solutions of the complexes;[6,7] this was interpreted in terms of energy transfer from the triplet state of the DNA bases to the singlet state of the dye, as was first suggested by Isenberg *et al.*[4] Further, a sensitized delayed fluorescence due to the triplet-singlet energy transfer has also been observed in frozen aqueous solutions of the nucleoside-, nucleotide-, and polynucleotide-acridine dye systems.[8] This paper will present the details of our further investigation of the DNA-proflavine and nucleotide-proflavine systems.

Experimental

Materials. Calf thymus DNA (Type I) and yeast RNA (Type XI) were obtained from the Sigma Chemical Co. The nucleotides*1 were purchased from either Sigma or Miles Laboratories, Inc. These materials were generally used without further treatment. The proflavine was the same as that described in Part I.[1]

Measurements. The emission and absorption measurements were described in Part I.[1] The measurements were carried out at 77°K in frozen aqueous solutions (0.01M phosphate buffer, pH 7.0). No correction of the emission and excitation spectra was made. Unless otherwise stated, all the luminescence data presented

in this paper were obtained by means of the excitation of the complexes or nucleotide-dye mixtures by 280 nm; the total nucleotide concentration was 5×10^{-3}M in phosphate units, and the proflavine concentration, 5×10^{-5}M. In general, the maximum intensity of the sensitized delayed fluorescence was obtained at a dye concentration of *ca.* 5×10^{-5}M.

Results and Discussion

Figure 1 shows the delayed emission spectra of the DNA-proflavine complex in a frozen aqueous solution. With an increase in the dye concentration, the DNA phosphorescence diminishes and two emissions appear; one, having a spectrum identical with the dye fluorescence, is identified as a delayed fluorescence of the dye, and the other, peaking at *ca.* 570 nm, as a phosphorescence of the dye.

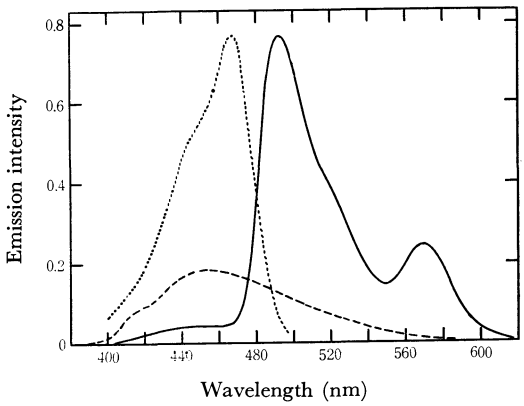

Fig. 1. Delayed emission spectra of DNA (----) and the DNA-proflavine complex (———) and absorption spectrum of the complex (---------). The scale of ordinates is the same on Figs. 1 and 5.

As is shown in Fig. 2, the excitation spectrum of the delayed fluorescence is not similar to that of the dye fluorescence or the phosphorescence, but it is identical with that of the DNA phosphorescence. Therefore, it may be concluded that the excitation of the DNA phosphorescence is responsible for the production of the delayed fluorescence; hereafter, this will be called a *sensitized delayed fluorescence*. The intensity of the sensitized delayed fluorescence is proportional to the intensity of the exciting light. Furthermore, the decay of the DNA phosphorescence is remarkably affected by the addition of the dye; it becomes faster than in the absence of the dye (see Fig. 3). This means that an additional pathway is introduced for the decay of the DNA triplet. In view of these results, it is reasonable to assume that the sensitized delayed fluorescence arises from the triplet-singlet energy transfer,[4] in which the

DNA bases are the triplet donors and the bound dye is the singlet acceptor.

The phenomenon of the sensitized delayed fluorescence was also found in the cases of denatured DNA and RNA. In both cases, the intensity of the sensitized delayed fluorescence greatly decreased with a decrease in the P/D value, the ratio of the number of nucleotides to that of dye molecules. Figure 4 shows that the ratio of the intensity of the

sensitized delayed fluorescence to that of the donor phosphorescence (I_{DF}/I_P) increases with an increase in the dye concentration, and then reaches a limiting value. In the case of denatured DNA or RNA, this value is smaller than that in the native DNA. In other words, the energy in the denatured DNA cannot be efficiently transferred to the bound dye in spite of a considerable enhancement of the DNA phosphorescence on denaturation.[9] This means that the energy transfer is sensitive to the conformation of the macromolecular complex; that is, the double helical structure is essential for the energy transfer to occur efficiently.

Next, our investigations were extended to the luminescence properties of the nucleotide-dye systems in order to ascertain how the DNA constituent bases contribute to the energy transfer. Some typical results are shown in Fig. 5. The sensitized delayed fluorescence was also observed in frozen

aqueous solutions of nucleotide-proflavine systems. This delayed fluorescence can also be interpreted in terms of the triplet-singlet energy transfer on the basis of the following observations: (1) the excitation spectrum of the sensitized delayed fluorescence is identical with the phosphorescence-excitation spectrum of each nucleotide, (2) the intensity of the sensitized delayed fluorescence varies linearly with the intensity of the exciting light, (3) the addition of the dye greatly quenches the phosphorescence of nucleotide, but has little effect on the fluorescence, and (4) the initial decay of the nucleotide phosphorescence becomes rapid upon the addition of the dye (see Fig. 6) and becomes more and more faster as the dye concentration increases. Furthermore, it is expected that the transfer proceeds with a high probability, since the dye absorption well overlaps with the phosphorescence spectrum of each nucleotide (Fig. 5).[10]

Nucleotide phosphorescence in the absence (□) and in the presence (△) of proflavine (5×10^{-5}M), sensitized delayed fluorescence of proflavine (○: 5×10^{-5}M, ●: 10^{-4}M)

As Figs. 3 and 6 show, the decays of both the nucleotide phosphorescence in the presence of the dye and the sensitized delayed fluorescence deviate remarkably from simple exponentials; they decay rapidly at the first stage, and then gradually become slower. The rapid decay at the first stage reflects the strong interaction between the energy donor and acceptor, located very close together. Further, in the frozen aqueous solutions, relatively low dye concentrations (below 5×10^{-6}M) are needed to observe the sensitized delayed fluorescence. On the other hand, the addition of alcohols before freezing the nucleotide-dye solutions resulted in a marked decrease in the sensitized delayed fluorescence despite the observation of a considerable enhancement in the nucleotide phosphorescence. However, the DNA-proflavine complexes exhibited a considerable sensitized delayed fluorescence, even in an alcohol-water mixed solvent. In the freezing of an aqueous solution, nucleotide molecules are considered to be excluded from the ice crystal and to form aggregates.[11] Proflavine also forms aggregates in the absence of a nucleotide, while it exists as the monomeric species in its presence (Fig. 5). Therefore, it seems likely that dye and nucleotide molecules form the stacked aggregates in which dye molecules are placed between nucleotide molecules by the face-to-face arrangement as well as at room temperature.[12,13] The decrease in the sensitized delayed fluorescence upon the addition of alcohols may be ascribed to the destruction of the aggregates. In conclusion, these results suggest that (1) the energy transfer depends greatly on the separation between the energy donor and acceptor; (2) most of donor and acceptor molecules are not distributed uniformly, but are spaced very closely; (3) the energy transfer takes place with a high efficiency between such molecules, and (4) the intercalation is most favorable for the efficient transfer.

The decay behavior of sensitized delayed fluorescence was independent of the kind of acridine dye (proflavine, acridine orange, acriflavine, *etc.*); that is, it appears that the rate constant of energy transfer is almost the same for these dyes. A meaningful transfer rate cannot be obtained because of the non-exponentiality of the decay, but the half-life ($\tau_{1/2}$) will serve as a qualitative measure of the transfer rate. In Table 1, the $\tau_{1/2}$ values are summarized, together with the lifetimes of the nucleotide phosphorescence (τ_P). It may be seen from Table 1 that $\tau_{1/2}$, which is dependent on τ_P, is about one tenth of τ_P, and that $\tau_{1/2}$ in the case of DNA is almost the same as that in the case of TMP. The phosphorescence spectrum of DNA resembles that of TMP. Its decay is composed of two exponen-

tials; the major component is the fast one, which has the same lifetime as that of TMP. Therefore, the triplet in DNA appears to reside mainly at the thymine residue; this is consistent with the recent observations by the optical and ESR measurements.[14,15] This phenomenon seems to be achieved by energy transfer to thymine from other bases; this is possible, since thymine has the lowest triplet.[11,16] Hence, the data of the sensitized delayed fluorescence in the complexes can tentatively be interpreted as follows: first, the base-to-base energy transfer produced the thymine triplet, and then a part of the excitation energy is efficiently transferred to the dye placed closest to it.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3130—3136 (1970)

The Interaction of Oxygen with Organic Molecules. II.[1] Oxygen Quenching of the Excited States of Adsorbed Aromatic Hydrocarbons

Hideyuki ISHIDA, Hiroshi TAKAHASHI and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received June 16, 1970)

Quenching of phosphorescence and fluorescence of aromatic hydrocarbons adsorbed on powdered porous glass or silica gel have been examined as a function of oxygen pressure. It has been found that the phosphorescence quenching at low temperature can be explained mostly by assuming that only those aromatic molecules having an oxygen molecule or molecules within an effective interaction radius are nonphosphorescent (static quenching model). The fluorescence quenching occurs only at much higher oxygen pressures and it has been proposed that contact pairs between aromatic and oxygen molecules, which have shorter intermolecular distances compared to the distances effective for the phosphorescence quenching and give rise to the charge-transfer absorption bands, are relevant. It has been observed that the excimer fluorescence of naphthalene appearing at a higher sample concentration is more strongly affected by oxygen than the monomer fluorescence. The emission spectra from naphthalene-porous glass adsorbate immersed in liquid oxygen and nitrogen have also been examined. The formation of the singlet oxygen ($^1\Delta_g$ or $^1\Sigma_g^+$) through the interaction of oxygen with triplet molecules has been confirmed by use of the peroxidation reaction of adsorbed anthracene.

The interaction of oxygen with electronically excited organic molecules is associated with a number of interesting phenomena.[2] For example, it is well known that molecular oxygen quenches both the excited singlet and triplet states of organic molecules. Theoretical investigation of the quenching of organic triplet states by oxygen indicated that singlet-state oxygen are formed by the intermolecular energy transfer.[3] This mechanism has now been supported by the results of recent experiments.[4-6] The oxygen quenching has been studied mainly in fluid media where the bimolecular quenching is controlled by the diffusion of oxygen and organic

molecules.[7–10] It has not been possible to estimate intrinsic quenching efficiencies from such diffusion-controlled reactions. Siegel and Judeikis have recently determined the relative interaction radius for the oxygen quenching of naphthalene triplet-state in rigid matrices where material diffusion is minimized.[11] Oxygen quenching of phosphorescence of aromatic molecules has been used to measure the diffusion rates of oxygen in polymer matrices.[12,13]

It is well known that molecules adsorbed on solid surface have relatively long lifetimes in their triplet states even at room temperature. The luminescent properties of adsorbed molecules have been extensively investigated in the presence of oxygen.[14–17] Previous investigations of oxygen quenching have almost extensively dealt with dye molecules adsorbed on silica gel. In the preceding paper, we have reported the extra charge-transfer absorption spectra caused by the interaction between adsorbed oxygen and organic molecules.[1] The present paper is mainly concerned with the effective quenching interaction between oxygen and electronically excited aromatic hydrocarbons adsorbed on porous glass or silica gel.

Experimental

Materials. Oxygen and naphthalene were purified in the same way as described in the preceding paper. Commercially available α-chloronaphthalene was distilled under reduced pressure. Anthracene and biphenyl were purified by recrystallization from benzene and ethanol, respectively, and by sublimation in vacuum. The particle sizes of silica gel and powdered porous glass[1] used here were 30—42 mesh, and were treated in the same way as described in the preceding paper. It was confirmed that no luminescence was detectable from porous glass itself by excitation in the near ultraviolet region even at liquid nitrogen temperature (77°K). The phosphorescence of silica gel itself at 77°K was negligible in comparison with that of adsorbed molecules.

Procedure. Naphthalene, α-chloronaphthalene and biphenyl were adsorbed from the vapor phase in the same way as described before.[1] Anthracene was adsorbed from the chloroform solution and the adsorbate was dried and thoroughly evacuated at 100—150°C. Sample concentrations ranged from 1×10^{-7}—5×10^{-6} mol/g of the adsorbent for the study of the fluorescence and phosphorescence quenching by oxygen. In this range we detected no luminescence characteristic of the aggregates or microcrystals of adsorbed molecules. However, when sample concentrations were increased (above 5×10^{-5} mol/g), a new band ascribable to excimer fluorescence was detected besides monomer fluorescence in the case of naphthalene or α-chloronaphthalene.

After adsorption, the sample in the ampoule was distributed into several cylindrical quartz cells, 4 mm in diameter, previously attached to the ampoule. Then oxygen was introduced into the vacuum system at room temperature and the quartz cells were sealed off carefully from the ampoule at desired oxygen pressure. Pressures below 5 Torr were read with a McLeod gauge. An ordinary mercury manometer was used for reading higher pressures.

The emission spectra were measured with an Aminco-Bowmann Spectrophotofluorometer. The lifetimes of the phosphorescence were determined from the decay curves traced on an osciloscope. Fluorescence decay curves were measured by exciting the samples with a device for producing nanosecond flash light.[18] The absorption spectra of adsorbed molecules was measured by the reflection method with a Shimadzu MPS-50L Recording Spectrometer as described in the preceding paper.

Results

Phosphorescence and Fluorescence of Adsorbed Aromatic Hydrocarbons. Phosphorescence spectra of the adsorbed molecules at 77°K were found to be nearly in agreement with those

measured for the same molecules dissolved in rigid matrices, although the spectra showed slight broadening of their vibrational structures in the adsorbed state. As an example, phosphorescence spectrum of naphthalene adsorbed on porous glass is shown in Fig. 1. The similar broadening was found also for fluorescence spectra. This broadening can be interpreted to be due to the wide energy distribution of the adsorbed molecules in the variety of the field of the polar adsorbent.

No difference in the luminescent properties of aromatic molecules have been found between silica gel and porous glass adsorbates. The phosphorescence lifetimes (τ_p) of adsorbed biphenyl, naphthalene and α-chloronaphthalene at 77°K were 4.0, 2.3 and 0.2 sec, respectively, at negligible oxygen pressures. These values also agree very closely with those in rigid matrices at 77°K.[19]

The band maxima of fluorescence show a slight blue shift when cooled down to 77°K. The fluorescence lifetime of naphthalene adsorbed on porous glass was 100 ns at room temperature, in good agreement with the values in the solutions.[18] Increase of the concentrations of naphthalene and α-chloronaphthalene resulted in the appearance of new broad bands almost identical with the corresponding excimer fluorescence in solutions.[20] The intensity ratio of this new band to the monomer fluorescence band depends on the wavelength of the exciting light as shown in Fig. 2 for the case of naphthalene. This ratio increases with increasing the sample concentration. The lifetimes of the new fluorescence band of naphthalene were found to

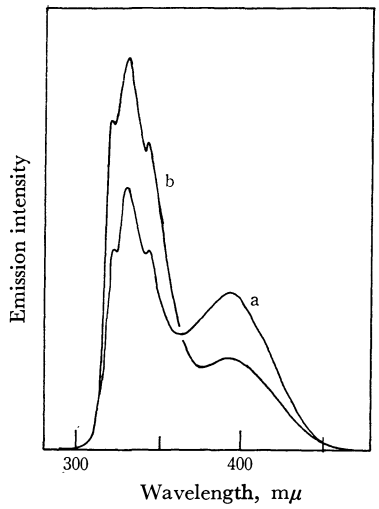

Fig. 2. Fluorescence spectra of naphthalene adsorbed on porous glass at 77°K.

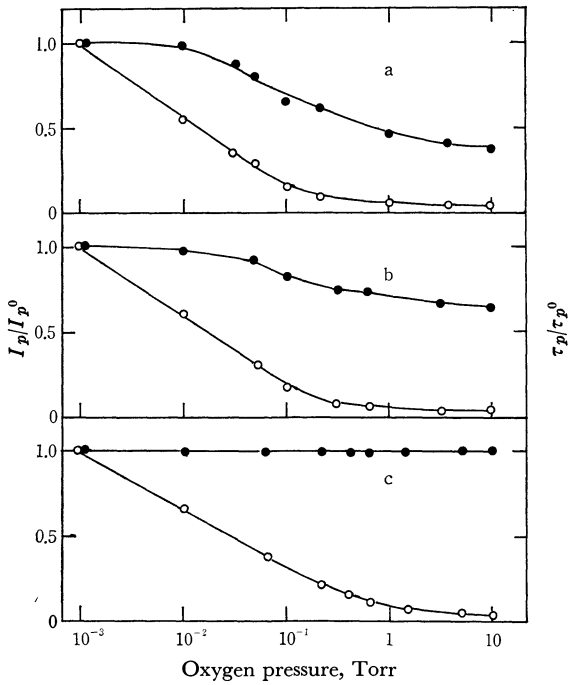

Fig. 3. The relative phosphorescence intensities I_p/I_p° (○) and lifetimes τ_p/τ_p° (●) of aromatic-porous glass adsorbates as a function of oxygen pressure at 77°K. (a), for biphenyl; (b), for naphthalene; (c), for α-chloronaphthalene. I_p° and τ_p° are, respectively, the phosphorescence intensity and lifetime at negligible oxygen pressures. The value of I_p/I_p° was normalized to be 1 at 10^{-3} Torr oxygen pressure. τ_p° at 77°K is 4.0 sec for biphenyl, 2.3 sec for naphthalene and 0.2 sec for α-chloronaphthalene.

be 65 and 100 ns at 300°K and 77°K, respectively, in good agreement with the long lifetimes characteristic of excimer fluorescence.[21] It is therefore concluded that, with increasing the sample concentration, adsorbed naphthalene molecules are forced to form loosely bound dimers on the surface and when this dimer is excited as well as monomer, the dimer is led to the configuration favorable to excimer formation.[22] The effect of oxygen on excimer fluorescence as well as monomer fluorescence is of considerable interest.

Quenching of Phosphorescence by Oxygen. The phosphorescence of the samples prepared in the way described in the experimental section was too weak at room temperature to examine the effect of oxygen quantitatively. Therefore, most of the studies were made at low temperature. The quenching effect of oxygen at 77°K is shown by the curves in Fig. 3, in which the values of the

relative phosphorescence intensities I_p/I_p^0 and the relative phosphorescence lifetimes τ_p/τ_p^0 are plotted as a function of oxygen pressure. I_p^0 and τ_p^0 are, respectively, the phsophorescence intensity and lifetime of the sample containing negligible amounts of oxygen. The phosphorescence decays at various oxygen pressures were found to obey the first order kinetics. The dependence of the phosphorescence lifetime on oxygen pressure was also examined at 203°K (−70°C) in the case of biphenyl. The temperature was obtained by dropping liquid nitrogen into the Dewar containing 99% ethanol. This curve, being different from that at 77°K, showed a rapid decrease in the lifetime with increasing the oxygen pressure. Although the absolute amount of adsorbed oxygen at each oxygen pressure is unknown, qualitative discussion on the interaction of oxygen with excited molecules can be made from these quenching curves.

Although oxygen pressure above 10 Torr is sufficient to quench phosphorescence totally, weak emission was detected from the naphthalene-porous glass adsorbate immersed in liquid oxygen at 77°K. This emission was observed to lie in almost the same region as the phosphorescence of naphthalene and could not be detected using a sector presumably because of the extremely short lifetime ($<10^{-3}$ sec). The phosphorescence of naphthalene from the naphthalene-porous glass adsorbate immersed in liquid nitrogen was strong and the lifetime was 1.4 sec. This short lifetime in liquid nitrogen compared to the original value (τ_p^0, 2.3 sec) may be due to impurities, such as oxygen, possibly contained in liquid nitrogen.

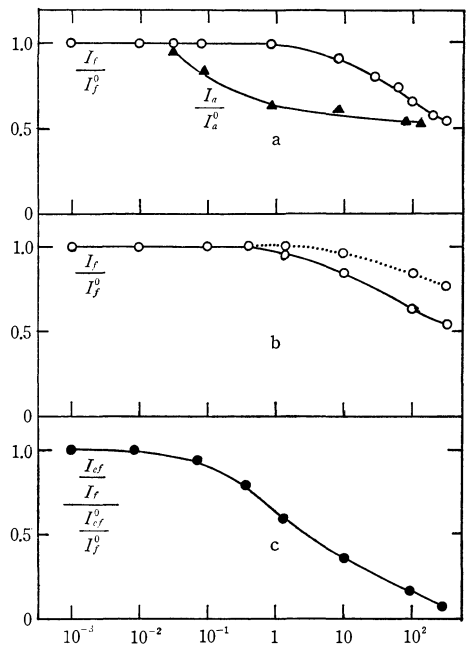

Fig. 4. The relative fluorescence intensities I_p/I_p° (○) and the relative ratios of the intensity of excimer fluorescence versus monomer fluorescence $(I_{ef}/I_f)/(I_{ef}^\circ/I_f^\circ)$ (●) of aromatic-porous glass adsorbates as a function of oxygen pressure at room temperature (———) and 77°K (-----). (a), for anthracene; (b) and (c), for naphthalene. I_f° and I_{ef}° are, respectively, the fluorescence intensities of monomer and excimer at negligible oxygen pressures. The relative absorption intensities I_a/I_a° (▲) of adsorbed anthracene are shown in (a) as a function of oxygen pressure, when the sample containing a known pressure of oxygen is irradiated. I_a° is the absorption intensity of adsorbed anthracene before irradiation.

Quenching of Fluorescence by Oxygen. The quenching effect of oxygen was examined mainly at room temperature. The quenching effect of oxygen on monomer fluorescence is shown in Fig. 4 (a) and (b) in cases of naphthalene and anthracene. The values of the relative fluorescence intensities I_f/I_f^0 are plotted as a function of oxygen pressure. It is found from the curves in Fig. 4 that the quenching curve of naphthalene is almost the same as that of anthracene in spite of the large difference between the fluorescence lifetimes (4.2 ns for anthracene[23] and 100 ns for naphthalene), and the quenching by oxygen is less effective at 77°K than at room temperature. No fluorescence quenching is found at oxygen pressures below 1 Torr where phosphorescence is quenched to some extent. Fluorescence quenching occurs gradually at oxygen pressures above 1 Torr where phosphorescence is quenched to a great extent. No difference was found between the quenching curves of anthracene for both porous glass and silica gel adsorbates.

The quenching effect of oxygen on excimer fluorescence is shown in Fig. 4 (c) in the case of naphthalene (5×10^{-5} mol naphthalene per gram of porous glass). The wavelength of the excitation was fixed at 275 mμ. The relative ratio of the intensity of excimer fluorescence versus monomer fluorescence is plotted as a function of oxygen pressure. It is found from this curve that excimer fluorescence is more strongly affected by oxygen than monomer fluorescence, though the lifetime of excimer fluorescence (65 ns) is rather short compared to monomer fluorescence (100 ns). The flourescence of monomer and excimer was little quenched by nitrogen gas admitted to the sample instead of oxygen.

Liquid oxygen also showed a remarkable effect on the fluorescence of naphthalene. The fluorescence intensity of the naphthalene-porous glass adsorbate immersed in liquid oxygen condensed at 77°K was roughly 1/7 of the original intensity (I_p^0). Liquid nitrogen showed no effect on the fluorescence of adsorbed naphthalene.

Discussion

Quenching of Phosphorescence by Oxygen. As shown in Fig. 3 the dependence of I_p/I_p^0 on oxygen pressure is obviously different from that of τ_p/τ_p^0 and the curves of I_p/I_p^0 for the three compounds show almost common behavior. I_p/I_p^0 decreases rapidly with increasing the oxygen pressure and approaches to zero at oxygen pressures above 10 Torr. The lifetimes of biphenyl and naphthalene are affected a little by oxygen, but do not decrease indefinitely with increasing the oxygen pressure in such a way as the intensities do, and the values approach approximately to 1.6 and 1.4 sec, respectively, so far as we could detect the phosphorescence. On the other hand, the lifetime of α-chloronaphthalene, naturally having a short lifetime (0.2 sec), is almost constant irrespective of oxygen presure.

In the case where the quenching of phosphorescence of adsorbed organic molecules is assumed to take place by the collision of these organic molecules with oxygen (dynamic quenching model), the lifetime of phosphorescence should be shortened in the presence of oxygen. Under such a condition, the curve of the relative phosphorescence intensity, I_p/I_p^0, should be almost in accord with that of the relative phosphorescence lifetime, τ_p/τ_p^0. On the other hand, in the absence of such collisional processes, the lifetime of the observed phosphorescence should be independent of oxygen pressure. In that case, it should be assumed that only those molecules that have oxygen molecules within an effective interaction radius before excitation are nonphosphorescent (static quenching model). Our results indicate that in the case of α-chloronaphthalene, the phosphorescence quenching is due to static quenching alone and in the cases of naphthalene and biphenyl, having naturally longer lifetimes compared to the former, there exists a slight contribution from the dynamic quenching as well as the static quenching. From these results, it is suggested that the dynamic quenching process is considerably slow at 77°K in the adsorbed state, although the quantitative interpretation of the curves of τ_p/τ_p^0 is impossible because of the inhomogeneity of the surface condition. As the dynamic process is controlled by the diffusion of oxygen, the observed behaviors of τ_p/τ_p^0 should be explained by the slow surface diffusion of oxygen at 77°K. This conclusion is supported by the result of the lifetimes of biphenyl phosphorescence measured at 230°K where the diffusion of oxygen must be faster than at 77°K.

As described in the preceding paper, we have found the existence of the contact pairs between the adsorbed oxygen and organic molecules at high oxygen pressures, which give rise to the charge-transfer absorption spectra. From the absence of any observed effect of oxygen on the absorption spectra at low oxygen pressures where phosphorescence quenching occurs to a large extent, it should be concluded that no contact pairs are formed at such oxygen pressures. It may be worthwhile to add that the effect of oxygen on the phosphorescence quenching is easily removed by evacuation. As it is reported that the binding energy between oxygen and aromatics is negligible in the ground state,[3,24] it is expected that oxygen is physically adsorbed at random on the aromatic-porous glass adsorbate at low oxygen pressures and the aromatic molecules form pairs with some of the adsorbed oxygen which can have an effective interaction for the phosphorescence quenching. The amount of these pairs is considered to increase with increasing the oxygen pressure, in agreement with the observed monotonous decrease of I_p/I_p^0 at low oxygen pressures. The relative situations between the adsorbed aromatic and oxygen molecules are illustrated schematically in Fig. 5.

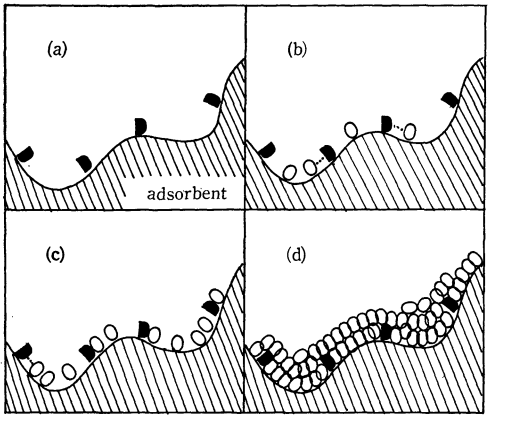

Fig. 5. Schematic illustrations indicating the relative situation between aromatic (◗) and oxygen (O) molecules in the adsorbed state. (a), before admitting oxygen; (b), at low oxygen pressures where phosphorescence quenching occurs; (c), at high oxygen pressures where contact pairs responsible for fluorescence quenching are formed between them; (d), when immersed in liquid oxygen.

Figure 6 shows the schematic potential curves for the states caused between aromatic and oxygen molecules versus the distance between them. Kearns *et al.*,[3] have suggested theoretically that a significant binding energy is expected through the interaction of triplet-state organic molecules with oxygen (curve b in Fig. 6). At a low oxygen pressure where effective phosphorescence quenching, but not the fluorescence quenching, occurs, we assume that most of the oxygen molecules are at distance r_2, or

24) H. Tsubomura and R. S. Mulliken, *J. Amer. Chem. Soc.*, **82**, 5966 (1960).

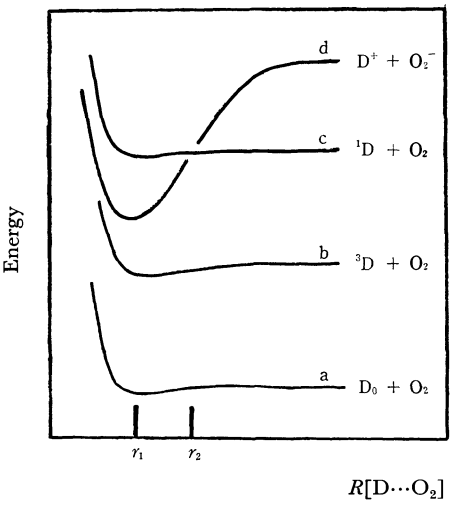

Fig. 6. Schematic potential curves for the states caused between aromatic (D) and oxygen (O_2) molecules versus the distance (R) between D and O_2. D_0 indicates the ground state of aromatic molecule. ^1D and ^3D indicate, respectively, the excited singlet and triplet states. In the adsorbed state, the intermolecular distance R is throught to decrease with increasing oxygen pressure.

larger, from the aromatic molecule D_0. When the aromatic molecule is excited to a ^3D level at such a distance, the interaction between ^3D and oxygen at that distance is thought to be sufficiently strong to cause a radiationless decay process which competes with the slow natural radiative decay process of the phosphorescent state, leading to the quenching of the phosphorescence.

Rosenberg and Humphries[17] have studied the phosphorescence quenching of acriflavine adsorbed on silica gel and suggested the existence of relatively nonphosphorescent complex between the dye and oxygen. Recently, Siegel and Judeikis[11] have investigated the oxygen quenching of naphthalene triplet state in 3-methylpentane glass at 77°K and found a slight contribution from the dynamic quenching process in addition to the static quenching process. They have also determined the effective interaction distance for the quenching to be 10.5 Å. These results seem to be consistent with our conclusion.

We have reported in the preceding paper that the S→T absorption spectrum of naphthalene is enhanced to a great extent when the naphthalene-porous glass adsorbate is immersed in liquid oxygen. The weak emission observed under such an environment may be assigned to the phosphorescence of naphthalene having a shortened lifetime, one possible explanation for this being that the T→S radiative decay process as well as the radiationless decay process is enhanced remarkably by the strong perturbation due to liquid oxygen (see Fig. 5d). The natural radiative lifetime of naphthalene triplet state, which can be calculated in the same way as described by McGlynn and Azumi[25] using the observed S→T absorption, was 9×10^{-4} sec. This value is very short compared to the unperturbed one, 11 sec,[26] in agreement with the observed shortlived emission.

Quenching of Fluorescence by Oxygen. Our results of fluorescence quenching show no difference in the characteristics between the two curves for naphthalene and anthracene despite of the large difference in their fluorescence lifetimes. This indicates that the decreases in I_f/I_f^0 are due to the static quenching alone at room temperature (21°C), and seems to indicate the surface diffusion of oxygen to be much slow compared to the decay of fluorescence. As described in the preceding paper, the extra charge-transfer absorption spectra caused through the interaction between adsorbed oxygen and organic molecules have been detected at high oxygen pressures where fluorescence quenching is observable. It can therefore be concluded that the fluorescence quenching occurs between oxygen and organic molecules in such a close contact as giving rise to the charge-transfer absorption bands, because of the fast decay of fluorescence (for example, at a distance r_1 in Fig. 6). The amount of contact pairs formed on the surface is thought to increase with increasing the oxygen pressure as Fig. 5 shows. From the results obtained for naphthalene fluorescence in liquid oxygen and at 77°K, it seems to be reasonable to assume that the radiationless decay process in contact pair becomes slow when cooled down to the low temperature and becomes comparable to the decay processes of fluorescence.

We have also found that the excimer fluorescence of naphthalene is affected more strongly by oxygen than the monomer fluorescence. This result is consistent with the earlier qualitative report on oxygen quenching of aromatic-hydrocarbon excimers in liquid solutions.[27] Chandross and Ferguson[28] found a very marked heavy-atom effect on the excimer fluorescence which can be explained by the increase in the intersystem crossing to the nearby triplet state of the excimer. Recently, the excimer phosphorescence of naphthalene has been observed in liquid solutions at low temperature.[29,30]

One possible explanation for the remarkable quenching of excimer fluorescence by oxygen is to take account of the smaller energy difference of excimer between the lowest singlet and triplet states compared to that of monomer.

The Relationship between the Oxygen Quenching and Peroxidation Reaction of Adsorbed Anthracene. Here we present the evidence for the formation of singlet oxygen ($^1\Delta_g$ or $^1\Sigma_g^+$) during the course of oxygen quenching by use of the well-established peroxidation reaction of anthracene with the singlet oxygen.[31] Anthracene adsorbed on silica gel was exposed to a known pressure of oxygen and irradiated with a 250 W high pressure Hg-lamp for five minutes at the wavelength of the first absorption band. The decrease in the first absorption band of anthracene due to the formation of anthracene peroxide was measured by use of the reflection method[1] as a function of oxygen pressure. The result is shown in Fig. 4 (a). The decrease of the anthracene absorption is seen to occur at low oxygen pressures where no fluorescence quenching is observed, although no decrease was observed by the irradiation of the sample without oxygen. This result has thus provided a rigorous experimental proof for the formation of singlet oxygen through the interaction between oxygen and triplet-state anthracene. The rate of peroxidation reaction showed a tendency to become independent of oxygen pressure in the region of high oxygen pressures where the fluorescence quenching begins to be observed and, no characteristic relationship was obtained between the rate of the peroxidation and the fluorescence quenching by oxygen. This seems to indicate that the singlet oxygen is not formed through the interaction with anthracene in the singlet excited state. However, further detailed experimental and theoretical investigations are necessary in order to establish the mechanism of fluorescence quenching by oxygen.

The authors are indebted to Professor N. Mataga and Mr. H. Ohari for the measurement of fluorescence lifetimes by use of a nanosecond flash apparatus.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3136—3142 (1970)

The Effect of Intramolecular Hydrogen Bonding on the Polarographic Reduction Potentials of Azomethines[1)]

Miyoshi UEHARA and Jun-ichi NAKAYA

Department of Chemistry, Faculty of Liberal Arts and Sciences, University of Osaka Prefecture, Mozu-Umemachi, Sakai-shi, Osaka

(Received January 16, 1969)

The effects of intramolecular hydrogen bonding on the polarographic reduction potentials ($E_{1/2}$) of several azomethines, such as *N*-salicylidenemethylamine, *N*,*N'*-bis(salicylidene)ethylenediamine, *N*-salicylideneaniline, *N*-salicylidene-*o*-aminophenol, and *N*-benzylidene-*o*-amino-*p*-substituted phenols, have been studied in aqueous and non-aqueous solutions. Contrary to expectations, a larger negative shift of $E_{1/2}$ was observed in the case of *o*-OH-substituted azomethines than in that of unsubstituted azomethines in buffer solutions. On the other hand, the $E_{1/2}$ of the substituted compounds shifted 0.3—0.4V toward the positive side in dimethylformamide or acetonitrile. The relative strengths of hydrogen bonds, as estimated from the positive shifts of $E_{1/2}$, were 6—10 kcal/mol. It has been proposed, from the hydrogen bond strength, the UV spectra, and the *p*-substituent effects, that the introduction of an *o*-OH group into the phenylimino ring provides not a periperpendicular conformation, but a coplanar configuration, by means of the formation of the O–H···N hydrogen bond.

The effects of intramolecular hydrogen bonds due to an *o*-OH substituent on the polarographic reduction potentials indicate a positive shift in contrast to the case with unsubstituted compounds because of the electron-withdrawing character of its substituent. These effects have actually been observed

1) Presented partly at the 16th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1963 and the 19th Symposium of Polarography, Osaka, Nov., 1967. Paper IV in a series of "Polarography of Azomethine Compounds."

with respect to *o*-nitrophenol by Astle,[2-4] Page,[5] and Pearson[6] in a buffer solution (pH<9). On the other hand, in the case of salicylaldehyde[7] or *o*-hydroxyacetophenone,[7] a negative potential shift of 50—70 mV was obtained for $E_{1/2}$, the potential shift by *o*-OH substituent in this case appears as an electron-donating effect. Doubts regarding the effects of hydrogen bonds on $E_{1/2}$[8] have recently been discussed by Zuman.[9]

We have first investigated polarographically the effects of intramolecular hydrogen bonding with several azomethines in aqueous solutions, in order to interpret the contradictory results for *o*-OH substituent and unsubstituted azomethines in previous works. It is believed that *o*-hydroxyazomethines probably form stronger hydrogen bonds than those of nitrophenol and salicylaldehyde because their O–H···N bond is more stable than the O–H···O bond, this is because of their larger polarizable structure between hetero atoms.

Secondly, we investigated the effect of intramolecular hydrogen bonding in an aprotic solvent, such as dimethylformamide (DMF) and acetonitrile (AN). Since the polarographic electrode reduction process of azomethine is accompanied by proton participation,[10] the study of such an aprotic solvent may be useful for estimating the relative strengths of hydrogen bonds.

Lastly, it has been shown that several interpretations can be made on the basis of the findings on hydrogen-bond strengths and UV spectra, especially at the N-side *o*-OH hydrogen bond of azomethines. If a "periperpendicular conformation[11-13]" can be assumed for *N*-benzylidene-*o*-aminophenols, it can be expected that the substituent effect will not appear at the *N*-side of the –CH=N– bond. These effects on $E_{1/2}$ were investigated in an aprotic solvent.

It can be considered that, together with spectroscopic data such as the IR and NMR data, the polarographic reduction potentials obtained in an aprotic solvent are useful values for studying hydrogen bonds.

Experimental

Materials. The azomethines used as samples were synthesized by the condensation of the corresponding aldehydes and amines in absolute ethanol. The bps and mps of the azomethines used were as follows: (I) *N*-salicylidenemethylamine bp 229°C, (II) *N*-benzylidenemethylamine bp 185°C, (III) *N,N'*-bis(salicylidene)ethylenediamine mp 125—126°C, (IV) *N,N'*-bis(benzylidene)ethylenediamine mp 53—54°C, (V) *N*-salicylideneaniline mp 50—51°C, (VI) *N*-benzylideneaniline mp 52°C, (VII) *N*-salicylidene-*o*-aminophenol mp 184—186°C, (VIII) *N*-benzylidene-*o*-aminophenol mp 89—90°C, (IX) *N*-benzylidene-*o*-amino-*p*-chlorophenol mp 94.2°C, (X) *N*-benzylidene-*o*-amino-*p*-methylphenol mp 88—88.5°C, (XI) *N*-(*o*-methoxybenzylidene)-aniline bp 91°C/5 mmHg, (XII) pyridinealdehyde-(2)-phenylhydrazone(syn-form) mp 88°C, and (XIII) pyridinealdehyde-(2)-phenylhydrazone(anti-form) mp174°C. The other samples, nitro- and aldehyde- compounds, were purified by the distillation or recrystallization of commercial guaranteed reagents. The DMF and AN were purified as has been described by Hatano[14] and by Coetzee[15] respectively. The water content of the DMF, as determined by Karl Fisher titration, was 0.03%.

Apparatus. All the polarograms were obtained by using a Yanagimoto pen-recording polarograph, Model PA-102. The dropping mercury electrode had the following characteristics on an open circuit: a value of $m^{2/3}t^{1/6}=0.99$ $mg^{2/3}sec^{-1/2}$ was obtained at $h=49$cmHg in distilled water, or under the same capillary conditions, a value of $m^{2/3}t^{1/6}=1.18$ $mg^{2/3}sec^{-1/2}$ was obtained in DMF. An aqueous saturated calomel electrode (SCE) was used as the external reference. The electric connection between the SCE and the non-aqueous solution in the polarographic cell was made by means of a DMF-methylcellulose bridge. The IR drop was corrected by measuring the ohmic resistance between the cathode and the anode with a Yokogawa universal bridge, Type BV-Z-13B. All the potentials were corrected with a Shimazu DC potentiometer, Type 3P. The UV spectra were obtained with a Hitachi, Type EPU-2A, spectrophotometer. The pH measurement was done with a Hitachi Model P glass electrode pH meter.

Procedure. The polarographic measurements were carried out with a 0.5 mmol/*l* depolarizer concentration in DMF or AN in which 0.1 mol/*l* n-Bu_4NClO_4 had been dissolved or in a Britton-Robinson buffer solution containing 50% ethanol and at a constant temperature of 20±0.5°C.

In a buffer solution, we used a method in which the hydrolysis of azomethines was avoided. Nitrogen was

passed through a base solution of 4.5 m*l* in the polarographic cell in order to remove the dissolved oxygen; to this we then added 0.5 m*l* of a sample stock solution which had previously been deaerated with nitrogen, the polarogram was recorded immediately after the solution had become homogeneous by bubbling in nitrogen.

Results and Discussion

Half-wave Potentials in a Buffer Solution. The half-wave potentials of the first reduction waves on *o*-OH substituted and unsubstituted azomethines were measured in a neutral pH range from 7 to 9, because their hydrolysis rates are large in an acidic medium[16] and because OH substituents dissociate in an alkaline medium.[17] The results are given in Fig. 1. The effect of the *o*-OH group on potentials between *N*-salicylidenemethylamine (I) and *N*-benzylidenemethylamine (II) proved to be a negative shift; this was contrary to the expectation of the positive shift as a result of intramolecular hydrogen bond formation, and the shifted value was 110—120 mV. This value is approximately equal to the negative shift of 90 mV for *p*-hydroxybenzylideneaniline[18] or to that of 120 mV for *p*-hydroxybenzaldehyde.[7] Thus, in the case of (I), the function of the *o*-OH substituent is not electron acceptance but electron donation; similar observations were made in the cases of salicylaldehyde and *o*-hydroxyacetophenone.[7] Most of the similar negative ortho shifts are shown in the data concerning the other compounds in Fig. 1, but in the case of III the reverse shift appears partly at low pH values.

It can be considered that there are two different types of intramolecular hydrogen bonds formed by the *o*-OH substituent. As the half-wave potentials of functional groups, such as $-NO_2$, $>C=O$, and $-CH=N-$, depend upon the hydrogen-ion concentration in an aqueous solution, the participation of a proton which accompanies the electron-transfer process in an electrode double layer should not be ignored. However, the participation of a proton

in the case of $-NO_2$ may be less active than that of >C=O and -CH=N- because of its stronger resonance effect. Thus, the hydrogen bond in *o*-nitrophenol is probably held in a favorable form for its reduction transition state. On the other hand, it is considered that the hydrogen bond in salicylaldehyde or salicylidenemethylamine is first replaced by proton addition in the diffusion layer and that the *o*-OH substituent acts as an electron donor.

Half-wave Potentials in a Non-aqueous Solvent. The effects of intramolecular hydrogen bonds on polarographic half-wave potentials were investigated under condition in which the potentials could be determined simply by the electron-transfer process. Therefore, the effects of hydrogen bonds on salicylideneamines and also on salicylaldehyde and nitrophenol were observed in DMF, an aprotic solvent, by comparing the difference in $E_{1/2}$'s between *o*-, *m*-, *p*-hydroxy-, or methoxy- substituted and unsubstituted compounds. In Table 1, the $E_{1/2}$ and $\Delta E_{1/2}$ values for these compounds are given, where $\Delta E_{1/2}$ is the difference in $E_{1/2}$ between *o*-, *m*-, and *p*-substituted and unsubstituted compounds. The effects of the *o*-OH substituent on $E_{1/2}$ appear as a uniform positive potential shift in the range of 0.20—0.45 V; this shift is considerably larger than the usual *m*- and *p*- substituent effect on $E_{1/2}$ which has been known in polarography.[18] In the case of the introduction of an OH group into the *m*- or *p*-position, and when it is impossible for a hydrogen bond such as OCH_3 to be formed even in the *o*-position, the negative shift of $E_{1/2}$ takes place because of the effect of their electron donor. The same behavior was observed in the AN (Table 2) used as an aprotic solvent.

Table 2. The effects of OH group on $E_{1/2}$ Sample: 0.5 mmol/*l* in AN

* OH substituent on benzylidene

For most of the compounds investigated in DMF, the polarographic Nernstian slopes (α) were similar to each other concerning the *o*-OH substituted compounds and the unsubstituted ones: α=62 mV (*N*-salicylideneaniline), 65 mV (*N*-benzylideneaniline), 58 mV (*N*-salicylidene-*o*-aminophenol), 65 mV (*N*-salicylidenemethylamine), 68 mV (*N*-benzylidenemethylamine), 63 mV (salicylaldehyde), 60 mV (benzaldehyde), 57 mV (*o*-nitrophenol), and 60 mV (nitrobenzene). The above facts suggest that the contribution of the irreversible process in the polarographic reduction may be approximately the same between the *o*-OH substituted compound and the unsubstituted compound. Concerning the polarographic reduction in the aprotic medium, it was expected that $E_{1/2}$ would be determined entirely by the electron-transfer process.

As for the reduction mechanism, it has recently been shown that the azomethines are reduced irreversibly to secondary amines in an aprotic medium through the stage of the formation of free radicals.[19,20] About the half-wave potentials of irreversible systems, the following relationship was derived by Delahay:[21]

$$E_{1/2} = \frac{RT}{\alpha nF} \ln 0.87\, k_f \sqrt{\frac{l}{D}}$$

The reduction mechanism and the values of the transfer coefficient, α, are similar when these compounds are compared, and these substances do not differ substantially in molecular shape or weight. Therefore, the influence of the substituent on the $E_{1/2}$ may be accounted for by the change in the free-activation-energy increment.[22,23]

$$\Delta E_{1/2} \sim \Delta\Delta F^{\pm}$$

The bulk of the azomethine molecules having *o*-OH groups must have been little changed by the formation of the intramolecular hydrogen bond. Therefore, the difference between the entropy change terms ($T\Delta S^{\pm}$) may be neglected compared with that of the enthalpy change ($\Delta H^{\pm}$).
Hence,

$$\Delta E_{1/2} \sim \Delta\Delta H^{\pm}$$

where $\Delta\Delta H^{\pm}$ is regarded as the difference in the lowest vacant MO energy[24] between the hydrogen bonding molecule in the *o*-OH substituted azomethine and the non-hydrogen bonding one. The strengthening of the hydrogen bond due to the electrostatic and mesomeric effects[25] may be considered to result in a lowering of the lowest vacant MO energy. The quite positive shifts of $E_{1/2}$ upon the introduction of an *o*-OH group can be attributed to the decrease in the electron density of the reducible position due to the formation of an intra-

molecular hydrogen bond. The facts in Table 1 suggest that the increase in $\Delta E_{1/2}$ may be caused by a strengthening of the hydrogen bond, and the $\Delta E_{1/2}$ is probably related to the relative hydrogen bond strength. Effects other than those of the hydrogen bond in the above case, *i.e.*, the contribution of an inductive effect as a usual electron donor of the OH group, is quite small, as is observed in the case of the $\Delta E_{1/2}$ of the *m*-OH and *o*-OCH_3 groups.

It was confirmed by the invariability of $E_{1/2}$ with the change in sample concentration that the hydrogen bond in this case is not intermolecular, but intramolecular. The invariability of $E_{1/2}$ at varying *N*-salicylideneaniline concentrations is shown in Table 3. In addition, the linear relationship between the concentration of sample and the limiting current seems to show that the diffusion coefficient resulting from the formation of an intermolecular hydrogen bond has not decreased (Table 3).

1.0	−1.57	1.21

Effects of Proton Donors on Half-wave Potentials in a Non-aqueous Solvent. The effects of several proton donors in a non-aqueous solvent on $E_{1/2}$ were investigated in order to study the intramolecular hydrogen bond in detail. When phenol, a proton donor, was added to *N*-benzylideneaniline (VI) in DMF, a new wave (*ba*°) appeared at the (−1.77 V) potential, a little more positive than the half-wave potential (−1.90 V) of the wave (*ba*) of VI (Fig. 2). An increase in the phenol concentration caused the (*ba*°) wave to increase at the expense of the (*ba*) wave. The addition of excess phenol to VI caused the (*ba*) wave to be replaced by the (*ba*°) wave. The effect of the addition of phenol on the reduction of VI may be attributed to the formation of the hydrogen-bonded complex that is reduced at a potential more positive than that of VI (wave (*ba*)). Similar behavior was observed regarding the influence of benzoic acid, as is shown in Fig. 3. However, no such effect of the acid was found with relation to the wave of *N*-salicylideneaniline (V) under the same conditions, and the $E_{1/2}$ (−1.58 V) of V remained constant. It may, therefore, be considered that the intramolecular hydrogen bond of the *o*-OH group in (V) prevents phenol from going close to the nitrogen atom. It seems reasonable to consider that the above facts support the existence and functions of the intramolecular hydrogen bond in V and the intermolecular hydrogen bond be-

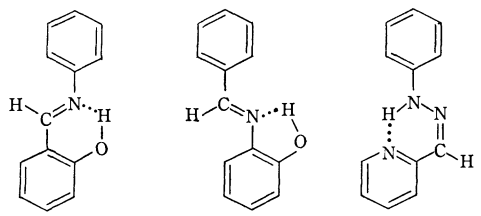
tween VI and phenol.

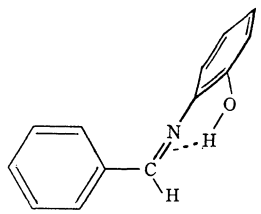
Some Interpretations Regarding the Relative Hydrogen-bond Strength. As has been explained in detail above, the effect of a positive shift of $E_{1/2}$ on several azomethine hydrogen bonds was evaluated to be from 0.31 to 0.45 V. In order to obtain some information on a six-membered ring hydrogen bond for azomethines, the $E_{1/2}$ of pyridinealdehyde-(2)-phenylhydrazone was measured in DMF. As a result it was found that it was −2.03 V for the *anti*-form (XIII) and −1.99 V for the *syn*-form (XII); the shifted values were so small as to be negligible. Thus, the structure required for a positive shifts as the effect of a hydrogen bond seems to be one in which the hydrogen bond is formed adjacent to the polarographic functional group, -CH=N-.



It can be understood from the data of the controlled potential electrolysis[19,20] and the electron paramagnetic resonance spectra[26] that the first step in the polarographic reduction of azomethines is due to a one-electron reduction corresponding to the formation of their anion radical. Therefore, if it is assumed that the $\Delta E_{1/2}$ of *N*-salicylideneaniline obtained from the measurement in DMF is 0.31 eV, the relative strength of the hydrogen bond can be estimated to be 7.1 kcal/mol for this molecule; this agrees with the value of 7 kcal/mol as the mean energy of the O-H···N hydrogen bond.[25] On the other hand, the relative hydrogen bond strength for the *o*-nitrophenol (5.8 kcal/mol), as estimated from the $\Delta E_{1/2}$, agrees with the mean energy, 6 kcal/mol, of the O-H···O hydrogen bond.[25] The relative strengths of the hydrogen bonds obtained from $\Delta E_{1/2}$ can be considered as being appropriate values because they agree with the values in the literature.[25]

Some increase in $\Delta E_{1/2}$ resulted from the introduction of a strong electron-donating substituent into the N-side of such azomethines as *N*-salicylidenealkylamines. It can thus be inferred that the O-H···N hydrogen bond is tightly bound by electrostatic attraction between nitrogen and hydrogen, and that the larger the electron density at N, the larger is the bond energy. The relative strength of the hydrogen bond in *N*-salicylidenemethylamine estimated from $\Delta E_{1/2}$ was about 8.8 kcal/mol.

The strength of the hydrogen bond in *N*-benzylidene-*o*-aminophenol etsimated from $\Delta E_{1/2}$ is much larger than the usual O-H···π hydrogen-bonding energy of 2 kcal/mol.[25] Therefore, it is entirely impossible to suppose an O-H···π hydrogen bond in the molecule; the O-H···N hydrogen bond should be supposed in this case.



Coplanarity of the Molecular Structure due to Hydrogen Bonding. It has been reported in detail that the azomethine molecule exists as a stable non-planar conformation in which the dihedral angle between the N-side phenyl and the rest of the molecule plane is distorted (periperpendicular conformation[11,12]). This interpretation was recently supported by Haselbach *et al.*[13] They showed that the absorption maxima on *trans*-stilbene and on *trans*-azobenzene were situated at wavelengths of about 230 and 320 mμ, while those of *N*-benzylideneaniline were at 262 and 315 mμ in cyclohexane. Moreover those data indicated that the absorption maximum of *N*-benzylideneaniline in concentrated sulfuric acid shifted to the longer wavelength of 340 mμ; this value agreed with that of 3,3-dimethyl-2-phenyl-indolenine. We have also measured some azomethines in absolute ethanol; the results are listed in Table 4.

In the case of *N*-benzylideneaniline (VI), the absorption maximum of the longer wavelengths (306—310 mμ) agrees approximately with the previ-

ous datum (315 mλ) and also with that of *N*,*N*′-bis(salicylidene)ethylenediamine (III) (316 mμ). It should also be noted that the maximum of the longer wavelength of VI was observed to be 344 mμ in the case of *N*-benzylidene-*o*-aminophenol (VIII). It is possible to give a new interpretation of this compound on the basis of these phenomena; *i.e.*, the two phenyl-rings are probably not distorted because of the hydrogen bond. In this compound, the value of 7.8 kcal/mol estimated to be the relative strength of the hydrogen bond from the $\Delta E_{1/2}$ value of 0.34 eV is slightly larger than that of *N*-salicylideneaniline (V).

Table 5. Half-wave potentials of *N*-benzylidene-*o*-amino-*p*-substituted phenols in DMF

Substituent	$E_{1/2}$ (V *vs.* SCE)	$\Delta E_{1/2}$
Cl	−1.45	+0.11
H	−1.56	
CH_3	−1.58	−0.02

ρ=0.30 V

The effect of *N*-phenyl-substituents on $E_{1/2}$ was investigated for *N*-benzylidene-*o*-aminophenols. As is shown in Table 5, the substituent effect appeared as the potential shift to negative upon the introduction of an electron donor, and as the shift to positive upon the introduction of an electron acceptor. The reaction constant that was obtained from a linear correlation between the reduction potentials and Hammett's substituent constants was 0.30V, similar to those of substituted benzaldehydes (0.31V), benzophenoneoximes (0.30V), stilbenes (0.25V), *etc.* The above results could not be interpreted by periperpendicular conformation. Therefore, the phenyl-ring of the N-side becomes a structure completely co-planar with the rest of the molecular plane, and the effect on $\Delta E_{1/2}$ seems to be one in which a special conjugation effect has been added to the usual hydrogen-bonding effect.

In Table 4, the hypsochromic shifts of the longest wavelength bands upon the introduction of an *o*-OH substituent were obtained with the following values: *N*-salicylideneaniline, 30 mμ; *N*-benzylidene-*o*-aminophenol, 35 mμ; and *N*-salicylidenealkylamines, 36—40 mμ; these values are directly proportional to the relative strengths of the hydrogen bonds of 7.1, 7.8, and 8.8—10.4 kcal respectively as calculated from the polarographic half-wave potentials.

The authors wish to thank Mr. Yasumichi Nakamura for his technical assistance.

An ESR Study of Monomeric Cobalt Oxygen Complexes in Solutions

Seiichiro KODA, Akira MISONO and Yasuzo UCHIDA

Department of Industrial Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received January 12, 1970)

Several mononuclear cobalt oxygen complexes in solutions have been investigated by means of ESR measurements. When a pyridine (and also substituted pyridines, *N*,*N*-dimethylformamide, dimethyl sulfoxide, and hexamethylphosphoramide) solution of a bis-salicylaldehyde-imine cobalt(II) complex (*N*,*N*′-ethylene-bis(salicylideneiminato)cobalt(II), and *N*,*N*′-ethylene-bis(3-methoxysalicylideneiminato)cobalt(II)) was exposed to oxygen, there appeared a reversible ESR signal, in which a hf structure of eight lines caused by a mononuclear cobalt was observed. This spectrum could be analysed by considering the species to be essentially a superoxide cobalt(III). We tried to explain the deviations in the A_{Co} and the *g* values of the species from solvent to solvent by considering that the solvent coodinates to the cobalt complex in the *trans* position against the coodinated oxygen. As a comparative study, the mononuclear oxygen adduct of di(salicylal)-3,3′-diimino-di-*n*-propylamine-cobalt(II) was also studied in the above solvents.

Though cobalt complexes carrying molecular oxygen have long been known, most of these are 2 : 1 cobalt oxygen adducts. Only recently have several examples of 1 : 1 reversible O_2 adducts been reported;[1-8] these reports have kept pace with the study of the present authors, who have investigated the possibility of obtaining mononuclear cobalt oxygen complexes and the physico-chemical properties of the obtained complexes for the past several years. Some of these results have already been reported.[1-3]

In this paper, the authors wish to report an ESR study of mononuclear cobalt oxygen complexes which may exist equilibrially ($Co \overset{O_2}{\rightleftharpoons} Co\text{–}O_2 \overset{Co}{\rightleftharpoons} Co\text{–}O_2\text{–}Co$) in some solutions. Several bis-salicylaldehyde-imine cobalt(II) complexes were dissolved in certain solvents under oxygen. The equilibrially-obtained mononuclear cobalt oxygen complexes were analysed by means of ESR measurements, though no reliable quantitative studies could be carried out because most of the solvents used were such as absorbed considerable microwave energies.

Results

The attempted complexes were *N*,*N*′-ethylene-bis(salicylideneiminato)cobalt(II)(Co(salen)), *N*,*N*′-ethylene-bis(3-methoxysalicylideneiminato)cobalt(II) (Co(3-MeOsalen)), bis(salicylaldimino)cobalt(II) (Co(sa)), and di(salicylal)-3,3′-diimino-di-*n*-propylamine-cobalt(II) (Co(salprtr)).

From the point of view of the solubility, Co(3-MeOsalen) was mainly investigated. When Co-(3-

MeOsalen) was dissolved in pyridine under nitrogen, a transparent red solution was obtained. The solution under nitrogen showed no ESR signal at room temperature.

When oxygen was added to the solution (oxygen was bubbled in or the nitrogen atmosphere above the solution was purged by pure oxygen), the red color of the solution under nitrogen was strengthened to some degree. The solution under oxygen showed an ESR signal which had an eight-line structure, as is shown in Fig. 1. The eight-line structure, all the lines of which had almost the same strength, could be considered to be caused by a certain interaction of a free spin with one cobalt nucleus, because the nuclear spin of ^{59}Co is 7/2. Spectra which were a little more resolved were observed at lower temperatures. When the solution was frozen, the spectrum changed to an anisotropic spectrum, but it was not so well resolved. This signal was observed to be rather stable. In fact, the strength of the signal did not decrease very much within several hours under oxygen at room temperature.

The ESR signal decreased when the solution was exposed to nitrogen, and increased again when the solution was again exposed to oxygen. The signal was suspected, therefore, to be due to a certain oxygen complex which was formed reversibly in the solution from oxygen and the cobalt complex.

Similar spectra could be observed in substituted pyridines, *N,N*-dimethylformamide (DMF), dimethyl sulfoxide (DMSO), and hexamethylphosphoramide (HMPT).

The ESR characteristics are summarized in Table 1. The A_{sol} caused by a cobalt nucleus is the mean interval between two adjacent lines among the eight lines (observed in solutions). The best resolved isotropic spectra were observed in the neighborhood of the cavity temperature described in the table. Some observed results in mixed solvents are shown in Table 2. In these mixed solvents, similar spectra were observed.

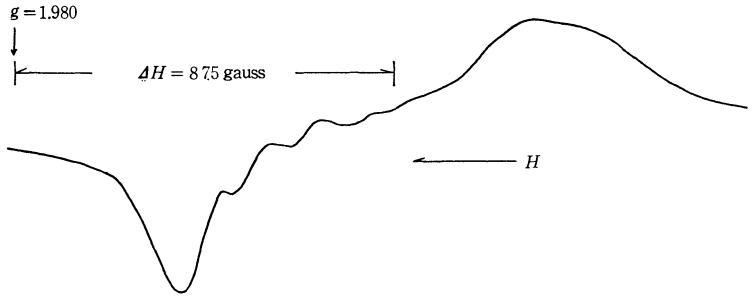

Fig. 3. ESR spectrum of Co(salprtr) in HMPT under oxygen (20°C).
complex conc. $=2.0\times10^{-2}$ mol/l oxygen pressure $=1$ atm

A rather well-resolved anisotropic ESR spectrum was observed for the species in a frozen mixed solvent of pyridine and HMPT (Fig. 2). The anisotropic g values and the corresponding A_{Co} values were roughly estimated, according to the method for randomly-orientated particles in a fixed position.[9]

The solution of Co(3-MeOsalen) in toluene (and benzene) showed no ESR signal under nitrogen; the situation was the same under oxygen at room temperature (the solubility of the complex in these solvents was not very large). When triphenylphosphine (PPh_3) was added to the solution (17 moles of PPh_3 *vs.* 1 mole of Co(3-MeOsalen)), however, a similar spectrum with an eight-line structure could be observed under oxygen.

Co(salen) behaved much like Co(3-MeOsalen) (investigated in a pyridine solution).

Kon *et al.*[4] have already reported on the ESR spectra of Co(salprtr) coordinated with oxygen in several solvents. The present authors investigated them in some other solvents (Fig. 3) in order to compare the spectra with those of Co(3-MeOsalen) (and Co(salen)) under oxygen. The signal shapes did not fully resemble those of Co(3-MeOsalen) under oxygen. This might well indicate the existence of some differences in geometrical structures and in electronic structures between the two kinds of cobalt mononuclear oxygen complexes.

When a red-colored solution of Co(sa) in pyridine was exposed to oxygen, the solution turned brown instantly. On the other hand, no ESR signal could be observed at room temperature several minutes after the exposure to oxygen. For comparison, it may be noted that no ESR spectra were observed when Co(3-MeOsalen) was dissolved in a mixed solvent of pyridine and methanol under oxygen at room temperature.

Discussion

It is naturally expected that some interactions may exist between such complexes as Co(salen), Co(3-MeOsalen), and Co(salprtr) and oxygen in some solvents. Calvin *et al.*[10] reported that two moles of activated Co(salen) absorbed one mole of oxygen and that one mole of Co(salprtr) absorbed one mole of oxygen in the solid state. The present authors have previously reported a reversible formation of mononuclear cobalt oxygen adducts from these complexes mixed in poly(4-vinylpyridine).[1,2] Floriani *et al.*[7] tried to isolate some oxygen complexes derived from these cobalt complexes which might be formed in some solvents. They isolated some binuclear oxygen adducts, such as $[Co(salen)\cdot DMF]_2\cdot O_2$, $[Co(salen)\cdot DMSO]_2\cdot O_2$, $[Co(salen)\cdot pyridine]_2\cdot O_2$, and $[Co(3\text{-}MeOsalen)]_2\cdot O_2\cdot DMSO$. Moreover, they could isolate $[Co(3\text{-}MeOsalen)]\cdot pyridine\cdot O_2$. The 1 : 1 oxygen adduct was isolated in only this case.

On the other hand, the present authors observed an ESR signal with an eight-line structure in both Co(3-MeOsalen) and Co(salen) solution (pyridine, DMF, DMSO, and HMPT) under oxygen, though no quantitative studies were pursued. The ESR signal at the position of a g_{sol} value of about 2 with an eight-line structure showed that the paramagnetic species was a certain radical containing one unpaired electron which interacted with one cobalt nucleus, because the nuclear spin of ^{59}Co is 7/2. In fact, a paramagnetic binuclear cobalt complex bridged by oxygen shows an ESR spectrum with a fifteen-line structure.*1, [11–14]

In view of the facts that the ESR signal appeared reversibly under oxygen, and that the A_{sol} value of the signal and that of a paramagnetic binuclear

cobalt oxygen complex were in the same range (for example,[12] A_{sol} of $[(NH_3)_5CoO_2Co(NH_3)_5](NO_3)_5$ in an acidic solution is 11.4 gauss), and also from a comparative consideration of the previously-published studies of similar complexes,*2,4-6) the signal which was observed under oxygen in the above solutions of Co(3-MeOsalen) (and Co(salen)) was considered to be due to some cobalt oxygen complexes. The ratio of 1 mole of cobalt *vs.* 1 mole of oxygen could also be said to be true, in view of the fact that the signal had an eight-line structure and by naturally assuming that the reversibly-produced binuclear cobalt oxygen complexes were diamagnetic. In fact, the binuclear complex, $[Co(salen)\cdot DMF]_2\cdot O_2$, and some similar complexes have been reported to be intrinsically diamagnetic, though with some temperature-independent paramagnetism.[7] Apparently, a 1 : 2 adduct could be identified as $Co(III)-O_2^{2-}-Co(III)$, which had no free spin, and a 1 : 1 adduct could be schematically considered to be $Co(III)-O_2^-$ or $Co(II)-O_2$, each of which has one unpaired electron.

Therefore, a mononuclear cobalt oxygen complex has been proved to exist equilibrially in these Lewisbase solvents of Co(salen) and Co(3-MeOsalen).*3

The observation that no ESR signal could be found in a toluene solution of Co(3-MeOsalen) under oxygen agrees with the reports of Ueno *et al.*,[7,15] who reported that oxygen could not interact to yield some stable oxygen adducts with Co(salen)'s in such solvents. That is, the coordination of a Lewis base such as pyridine may be necessary for the stable existence of mononuclear (and also binuclear) oxygen complexes. The idea is also supported by the experimental finding that an ESR signal appeared when PPh_3 was added to the solution.

Some decompositional reactions may proceed on the oxygen adducts when some protic solvents coexist. This seems to be a probable reason why no ESR signal could be observed in a pyridine solution of Co(3-MeOsalen) with some methanol under oxygen. In fact, Costa *et al.*[16] supposed that $Co(III)-OR^-$ might be produced from such systems. The same situation might hold in the case of Co(sa) in pyridine, because Co(sa) has protonic hydrogens in the ligands.

The Dependence of ESR Characteristics on Solvents. Let us now discuss the variation in g_{sol} and A_{sol} values from solvent to solvent.

The data in Table 1 show that the g_{sol} and A_{sol} values of the adducts of Co(3-MeOsalen) in pyridine, 4-methylpyridine, and 4-ethylpyridine are almost all the same. The g_{sol} and A_{sol} values of the adducts of Co(3-MeOsalen) are, however, considerably different in pyridine, DMF, DMSO, and HMPT. On the contrary, the difference are very small in the case of those of Co(salprtr), in which the *trans* position of the coordinated oxygen may not be occupied by the solvent (as a ligand) because of steric hindrances caused by the imine ligand. This situation is different from that of Co(3-MeOsalen). In fact, an X-ray analytical study of $[Co(salen)\cdot DMF]_2\cdot O_2$ by Calligaris *et al.*[17] has shown that the DMF's exist in the *trans* positions of the bridge-oxygen.

On the basis of the above discussion, the variation in the g_{sol} and A_{sol} values of the adducts of Co(3-MeOsalen) (and Co(salen)) can be explained by considering that the solvent behaves as the fifth ligand in a *trans* position relative to the coordinated oxygen acting as the sixth ligand. The solvent might possibly affect the coordinated oxygen in a direct way, but the effect on A_{sol} and g_{sol} values may be quite small in comparison with the effect of the solvent in the *trans* position, judging from the observation that the g_{sol} and A_{sol} values of the adducts of Co(salprtr) are almost independent of the solvent.

The data of Table 2 show that the stabilities of the oxygen adduct are in this order: HMPT$\approx$DMF$<$pyridine.*4 On the other hand, the A_{sol} values are in this order: HMPT$>$DMF$>$pyridine, and the g_{sol} values are in this order: HMPT$\approx$pyridine$<$DMF.

The *Dq* values of the solvents may be considered

*2 Recently, $[Co(BAE)\cdot pyridine]\cdot O_2$ and some similar oxygen adducts (Co(BAE)=bis(acetylacetone)-ethylenediiminecobalt(II)) were isolated.[8] ESR studies were attempted on superoxocobalamines ($Co/O_2=1/1$)[6] and also on $[Co(CN)_5O_2]^{3-}$.[5] These ESR spectra very much resemble those in this paper.

*3 Of course, the non-oxygenated complex and the corresponding binuclear oxygen adduct may exist simultaneously; moreover, the amounts of the latter may be larger than those of the mononuclear adduct in many cases (*cf.* the lit.[7]).

17) M. Calligaris, G. Nardin and L. Randassio, *Chem. Commun.*, **1969**, 763.

*4 The g_{sol} and A_{sol} values of the adduct in a mixed solvent of pyridine and DMF (and that of pyridine and HMPT) prove that the existing paramagnetic species in the mixed solvent is not a DMF (nor HMPT)-oxygen adduct, but a pyridine-oxygen adduct. The characteristic values of the paramagnetic species in the mixed solvent of DMF and HMPT (the volume ratio is 1/1; the mole ratio is, then, 2 moles of DMF *vs.* 1 mol of HMPT) may be explained if the species in the solvent is a mixture of a DMF-oxygen adduct and a HMPT-oxygen adduct (in the mole ratio of about 2/1). The observed g_{sol} (and also A_{sol}) value in the mixed solvent is considered to be the weighted mean value of that of the DMF-oxygen adduct and that of the HMPT-oxygen adduct.

to be in this order: HMPT$<^{?}$DMF<pyridine.*5

The above comparison shows that close relationships may exist among the stability, the A_{sol} (caused by the cobalt nucleus) value, and the *Dq* value of the solvent.*6

It seems that the larger the crystal field strength of the *trans* ligand (the solvent), the more stable the oxygen adduct. The A_{sol} value seems to decrease with the increase in the *Dq* value. The changes in g_{sol} values seem to be more complicated than those in A_{sol} values. The description by Crumbliss[8] that the adduct [Co(BAE)·DMF]·O_2 is less stable than [Co(BAE)·pyridine]·O_2 also agrees with the above discussion.

The Properties of the Coordinated Oxygen. It is very important and interesting to clarify the electronic structure of the mononuclear oxygen complexes. The ESR characteristics shall be analysed from this point of view.

Such investigations as have been pursued on paramagnetic species formed on the surfaces of some metal oxides from molecular oxygen by means of ESR spectroscopies[23,24] may be worthy of attention. It is regretable that no ESR studies seem to have been made on the oxygen complexes of so-called low valent transition metal complexes, such as $IrO_2X(CO)(PPh_3)_2$,[25] because of their diamagnetism.

There are two ways of analysing the ESR signals of the mononuclear cobalt oxygen complexes. The first one is based on the electronic structure, Co(II)–O_2 (in this structure, the unpaired electron is considered to be localized in metal orbitals. A low-spin d^7 cobalt(II) is coordinated by a diamagnetic oxygen (for example, a $^1\Delta_g$ oxygen)), while the other is based on the electronic structure, Co(III)–O_2^- (in this structure, the free spin is considered to be localized in an oxygen molecular orbital. A diamagnetic d^6 cobalt(III) is coordinated with a paramagnetic superoxide anion).

There are several low-spin cobalt(II) complexes which have been studied by means of ESR spectroscopy, for example, cobalt phthalocyanine(CoPc),[26,27] $Co(CH_3NC)_5^{2+}$,[28,29] and $Co(CN)_5^{3-}$.[28,29] These low-spin cobalt(II) complexes have *g* values which are relatively close to 2 (for example, $g_{||}=2.000$, and $g_\perp=2.117$ for $Co(CH_3NC)_5^{2+}$, and $g_{||}=1.992$, and $g_\perp=2.157$ for $Co(CN)_5^{3-}$). In general, however, the *A* values caused by the cobalt atom of these complexes are relatively large (for example, $A_{||}=78$ gauss and $A_\perp=57$ gauss for $Co(CH_3NC)_5^{2+}$, and $A_{||}=87$ gauss and $A_\perp=28$ gauss for $Co(CN)_5^{3-}$). From a consideration of these results, the *A* values of the oxygen cobalt complexes should be much larger than the measured values if the electronic structure of the adduct is considered to be mainly Co(II)–O_2. Of course, the smallness of the measured A_{sol} values does not mean necessarily the smallness of the individual anisotropic principal components of the *A* hf tensor (for example, $A_{||}$ and $A_\perp$). The individual anisotropic components are considered, however, not to be very large, as will be discussed later.

The finding that such small differences exist in the A_{sol} values of the adduct of Co(3-MeOsalen) in pyridine, 4-methylpyridine, and 4-ethylpyridine seems rather unacceptable if the unpaired electron exists mostly in the cobalt orbitals. For example, the $A_{||}$ value caused by the cobalt nucleus of a pyridine adduct of CoPc has been reported to be 78×10^{-4} cm^{-1}, and that of a 4-methylpyridine adduct of CoPc, 84×10^{-4} cm^{-1}.[27] If the situation is the same in the oxygen adduct of Co(3-MeOsalen), about 0.3 gauss*7 is expected to be the difference

*5 This order seems to be true in view of the generally-accepted spectrochemical series[18] ($Br^-<Cl^-\sim N_3^-<(NH_2)_2CO<H_2O<NH_3\sim$pyridine) and the results of Donoghue *et al.*[19] ($Cl^-\sim$HMPT$<N_3^-$). The relation between HMPT and DMF is not clear, but the *Dq* of HMPT may be the smaller, for the *Dq* of DMF may be in the neighborhood of that of $(NH_2)_2CO$. Their donor ability against a protic species may be in this order: HMPT>DMF (by $\Delta\tau_{CHCl_3}$),[20] DMF<pyridine (by $\Delta\nu_D$)[21] ($\Delta\tau_{CHCl_3}$ is the deviation of the τ value of the proton signal of $CHCl_3$ in a given solvent from that in a reference solvent: $\Delta\nu_D$ is the deviation of the O–D stretching wave number of CH_3OD in the given solvent from that in a reference solvent). Which has the larger donor ability, HMPT or pyridine, is not clear.

*6 PPh_3 should be omitted, because the properties of this ligand are rather complicated because of the existence of a strong π-ability. The DMSO seems not to be very different from DMF.[22]

*7 0.3 gauss$\fallingdotseq$(84×10^{-4} cm^{-1}—78×10^{-4} cm^{-1})×(13 gauss/84×10^{-4} cm^{-1})×(1/3); the contribution of the $A_{||}$ to the A_{sol} may be one-third of the total.

between the A_{sol} value of the cobalt oxygen complex in pyridine and that in 4-methylpyridine. Therefore, we suspect that the unpaired electron does not interact with the cobalt nucleus in a direct way. Very small differences were also observed between the signal characteristics of Co(3-MeOsalen) and that of Co(salen) in pyridine.

In due course, the analytical method based on the Co(III)–O_2^- electronic structure is expected to be more fruitful. This idea is also compatible with the fact that the A_{sol} value of the paramagnetic binuclear complex, $[(NH_3)_4Co(\mu\text{-}O_2)(\mu\text{-}NH_2)Co(NH_3)_4]^{4+}$,[12] the oxygen of which is considered to be superoxide-like as a result of analysing the A_{O17} values,[13] is in the neighborhood of those of the mononuclear oxygen complexes.

The superoxide anion can be analysed as having the following g values, according to Känzig *et al.*,[30,31] who derived the equations for superoxides of alkali metal ions:

$$g_1 = g_e + 2\left(\frac{\lambda^2}{\lambda^2+\Delta^2}\right)^{1/2} l$$

$$g_2 = g_e\left(\frac{\Delta^2}{\lambda^2+\Delta^2}\right)^{1/2} - \left(\frac{\lambda}{E}\right)\left[-\left(\frac{\lambda^2}{\lambda^2+\Delta^2}\right)^{1/2} - \frac{\Delta}{(\lambda^2+\Delta^2)^{1/2}} + 1\right]$$

$$g_3 = g_e\left(\frac{\Delta^2}{\lambda^2+\Delta^2}\right)^{1/2} - \left(\frac{\lambda}{E}\right)\left[\left(\frac{\lambda^2}{\lambda^2+\Delta^2}\right)^{1/2} - \frac{\Delta}{(\lambda^2+\Delta^2)^{1/2}} - 1\right]$$

The E and Δ values are shown in Fig. 4. The splitting, Δ, is caused by the crystal field constructed by surrounding ions. l is a correction to the angular momentum about the oxygen molecular axis caused by the crystal field. λ is the spin-orbit coupling constant. It has been reported that some superoxide anions adsorbed on metal oxides can be analysed by the above equations.[23,24] Theoretically speaking, these equations can be used in the case of the mononuclear cobalt oxygen complex, Co(III)–O_2^-, as the first approximation. The splitting, Δ, may be caused by the parent cobalt chelate (the parent cobalt chelate means the part of the cobalt oxygen adduct except the coordinated oxygen), which serves as a certain crystal field against the superoxide anion.

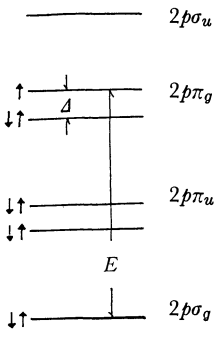

Fig. 4. The electronic levels of O_2^-.

Providing that l is equal to 1.00, that λ/E is negligibly small (the energy internal between $2p\pi_g$ and $2p\sigma_g$ is calculated to be 2.25 Rdg[32]), and that λ is 223 cm^{-1} [30] (or 115 cm^{-1} [24]),*8 the g_1 value of the 2.076 of the oxygen adduct in the mixed solvent of pyridine and HMPT (in Fig. 2; also, g_2, $g_3 \fallingdotseq 2.00$—2.01) is explainable if Δ is 6100 cm^{-1} (or 3050 cm^{-1}). The actual λ value is thought to be between the above two values.[33] This value of Δ (several thousand cm^{-1}) is comparable with those of adsorbed superoxide anions on some metal oxides;[24] it is also comparable with the theoretically-calculated value for an oxygen coordinated with iron phthalocyanine (with its molecular axis parallel to the complex plain).[34]

The g_{sol} value may be also calculated by using the relation:

$$g_{sol} = (1/3)(g_1+g_2+g_3)$$

The derivation in g_{sol} values of the adducts of Co(3-MeOsalen) from solvent to solvent seems not to correspond to the change in the Dq values of the solvent (acting as the *trans* ligand). There may be some complicated mechanism in the transport of the crystal-field effect of the *trans*-position ligand to the coordinated oxygen. It is also probable that there is some deviation of the individual l value from 1.00 and a change in the λ values.

As a summary of the preceding discussions about g values, it can be claimed that the coordinated oxygens in the mononuclear cobalt oxygen complexes can be considered to be rather superoxide-like.

An analysis of the A_{sol} and anisotropic components of the hf tensor is expected to clarify the electronic structure of the oxygen adduct more precisely. An exact analysis based only on the observed results is now, however, very difficult, because of our little knowledge about the geometrical structure and because of the probable disagreement of the directions of the g tensor with those of the A tensor. Therefore, only a rough analysis was attempted according to the method used by Kon *et al.*,[4] by assuming the geometrical structure to

be the one in which the oxygen molecule is coordinated to the parent chelate with its molecular axis oblique (the angle is θ; θ was assumed to be 60°) against the principal axis of the parent cobalt chelate.*9 The A characters used were: $|A_{sol}|=13.2$ gauss, $|A_1|=16.0$ gauss, and $|A_2|=|A_3|=14.7$ guass (for the oxygen adduct in the mixed solvent of pyridine and HMPT).

When it was assumed that the unpaired electron was in d_{z^2} and that $A\fallingdotseq-P(\kappa-4/7)$, $B\fallingdotseq-P(\kappa+2/7)$ (A and B are the probable principal components of the hf tensor under an axis symmetry. These equations are quite rough[36]). The dipolar part, $|A_d|$, was estimated to be 10.4 gauss.

When it was assumed that the unpaired electron was in d_{xz} (or d_{yz}) and that $A\fallingdotseq-P(\kappa+4/7)$, $B\fallingdotseq-(\kappa-2/7)$;[36] the $|A_d|$ was calculated to be 18 gauss.

Though the above assumptions and calculations are quite rough and insufficient, it may be possible to state that the unpaired electron density in the cobalt d orbital (ρ) is rather small, considering that $|A_d|=(4/7)P\rho$ and that the P value for cobalt is 0.022—0.025 cm^{-1}.[4,37]

The above conclusion agrees well with the intended analysis based on the Co(III)–O_2^- structure. It is likely that the larger the A_{sol} value (though it is not necessarily parallel to the A_d value), the more the spin density in cobalt d orbitals.

The observations that such a small deviation exists in the A_{sol} values of the adducts of Co(3-MeOsalen) in pyridine, 4-methylpyridine, and 4-ethylpyridine, and that the ESR characteristics of the oxygen adduct of Co(salen) are almost the same as those of Co(3-MeOsalen), seem to be acceptable in view of the fact that a small part of the unpaired electron is considered to exist in the cobalt orbitals.

Though many considerations should be pursued further, if we are to understand the electronic structure of the individual oxygen adduct exactly (for example, by drawing the molecular orbital energy diagram quantitatively), the coordinated oxygen in these mononuclear cobalt oxygen complexes can be safely stated to be a kind of superoxide anion which is modified by the parent cobalt chelate, and the properties of these oxygens can be changed in some degree by selecting the solvent (or the *trans* ligand). The deviation can be estimated according to the character of the solvent.

Experimental

Reagents. *N,N'-Ethylene-bis(salicylideneiminato)cobalt-(II).* This chelate was obtained according to the method in the literature[38] and was recrystallized from methanol.

Found: C, 58.85; H, 4.08; N, 8.62%. Calcd for $C_{16}H_{14}CoN_2O_2$: C, 59.10; H, 4.30; N, 8.63%.

N,N'-Ethylene-bis(3-methoxysalicylideneiminato)cobalt(II). This chelate was synthesized as a monohydrate by mixing cobalt(II) acetate tetrahydrate (commercially obtained, and recrystallized from aqueous acetic acid) and *N,N'*-ethylene-bis(3-methoxysalicylideneimine) (synthesized from ethylenediamine and 3-methoxysalicylaldehyde) in the mole ratio of 1/1 in a mixed solvent of DMF and water at 60°C.

Found: C, 53.41; H, 5.33; N, 7.07% Calcd for $C_{18}H_{18}CoN_2O_4\cdot H_2O$: C, 53.61; H, 5.00; N, 6.95%.

The monohydrate was dehydrated at 170—185°C for 1.5 hr *in vacuo*. The decrease in the weight: Found: 4.1%. Theoretical: 4.4%. The chelate was stored in dried nitrogen.

Bis(salicylaldimino)cobalt(II). This chelate was synthesized according to the method of Endo.[39] At first as a dihydrate:

Found: C, 50.94; H, 4.86; N, 7.91%. Calcd for $C_{14}H_{12}CoN_2O_2\cdot 2H_2O$: C, 50.16; H, 4.81; N, 8.36%.

Then, it was dehydrated at 130°C for 2.5 hr *in vacuo*.

Found: C, 56.18; H, 3.93%. Calcd for $C_{14}H_{12}CoN_2O_2$: C, 56.20; H, 4.04%.

As for this complex, *cf.* the literature.[1,2]

Di(salicylal)-3,3'-diimino-di-n-propylamine-cobalt(II). This chelate was synthesized according to the method in the literature[38] and was purified by reprecipitating it, by water from an ethanol solution, as a monohydrate.

Found: C, 57.81; H, 6.21; N, 10.21%. Calcd for $C_{20}H_{23}CoN_3O_2\cdot H_2O$: C, 58.00; H, 6.09; N, 10.14%.

Pyridine, 4-Methylpyridine, 4-Ethylpyridine, DMF, DMSO, and HMPT. Commercially obtained solvents were distilled under purified nitrogen or under reduced pressure, and were stored under purified nitrogen.

Methanol, Benzene and Toluene. Commercially obtained solvents were dehydrated by appropriate methods and were distilled under purified nitrogen.

Triphenylphosphine. The commercial product of a guaranteed reagent grade was used without further purification.

The Measurements of the ESR Spectra. In general, a cobalt complex was dissolved in a given solvent under purified nitrogen. A part of the solution was then injected into a slender tube ($\phi=1$ mm), and the ESR spectrum was measured under purified nitrogen. The remaining solution was then exposed to oxygen (from a commercially obtained bomb), and a part of it was injected into a tube which was kept under oxygen. The oxygen atmosphere above the solution could be changed to nitrogen, and *vice versa*.

The ESR spectra were observed with a Japan Optics Laboratory Co., Ltd., ESR spectrometer, Model JES-3BS-X. A manganese marker was used for the calibration. The cavity temperature could be changed over a wide range by means of an attached apparatus for the temperature control.

*9 Similar structures are common in the cases of binuclear cobalt oxygen complexes.[35] A similar structure has been also claimed in the case of [Co(BAE)·ligand]·O_2's, on the basis of their infrared spectra.[8]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3150—3155 (1970)

On the Preparations of Metal Complexes. V. The Preparations of Cholatoamminecomplexes of Cobalt(III) and Chromium(III)

Masayoshi NAKAHARA, Akio URUSHIYAMA, Yasuo SATOH and Yukio KONDO

Department of Chemistry, Faculty of Science, Rikkyo University, Nishi-ikebukuro, Toshima-ku, Tokyo

(Received March 23, 1970)

The mono-, di- and tricholatocobalt(III) and chromium(III) complexes and cobalt complex cholates, including the following new compounds, have been prepared: [Co chol $(NH_3)_5$] X_2 (X =chol, Cl), [M $chol_2$ en_2]Cl (M=Co, Cr), [Co $chol_3$ $(NH_3)_3$] and [Co en_3]$chol_3$. The absorption spectra of these complexes in the visible, ultraviolet, and infrared regions have been measured and compared with those of the corresponding acetato- or acido-complexes.

A number of Werner-type complexes of cobalt(III) and chromium(III) which contain alkyl carboxylic acids are known at present. Two series of complexes, [M $(RCOO)_2$ en_2]$^+$ (M=Co(III) and Cr(III), R=CH_3 to $C_{17}H_{35}$) have been prepared by Linhard and Stirn[1] and by Nakahara.[2] The diacido-type [Co $(RCOO)_2$ $(NH_3)_4$]$^+$,[3] the monoacido-type [Co RCOO $(NH_3)_5$]$^{2+}$,[4] and the triacido-type [Cr $(CH_3COO)_3$ $(NH_3)_3$][5] have also been prepared. One of the present authors (M.N.) has prepared the diacido-type complexes, [M-$(RCOO)_2$ en_2]$^+$ (M=Co(III), Cr(III)), containing fatty acids of various chain lengths (R=C_9H_{19} to $C_{17}H_{35}$) and has studied the *cis-trans* isomerisations.[2] It was found, in this investigation, that, in the case of the fatty acids, C>10, even though the *trans*-form complexes were used as the starting materials, the *cis*-form products were always obtained. This phenomenon has been explained in terms of the attraction between the long chains of the saturated fatty acids.

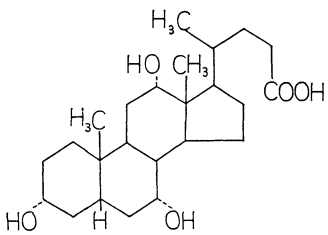

Fig. 1. Cholic acid (abbrev. cholH).

In the present work, cholic acid ($C_{24}H_{40}O_5$, cholH) (Fig. 1) is used as the carboxylic acid. This acid resembles the long-chain fatty acids mentioned above because the steroid skelton may be considered to be a condensed paraffin. However, it is rather different from the fatty acids in that the condensed part of the molecule is fairly bulky. Thus, it seemed that it would be interesting to compare the properties of cholatocomplexes with those of the fatty-acid complexes. For this purpose, three types of cholato complexes, [M chol $(NH_3)_5$]$^{2+}$, [M $chol_2$-en_2]$^+$, and [M $chol_3$ $(NH_3)_3$] (M=Co(III), Cr(III)) are prepared and their properties are investigated.

Experimental

Preparations. *1) Cholic Acid*, $C_{24}H_{40}O_5$. Reagent-grade cholic acid was dissolved in ethanol, and then, after active carbon had been added to the solution, it was recrystallized several times.

2) Sodium Cholate, $NaC_{24}H_{39}O_5$. Purified cholic acid was dissolved in water containing an equivalent amount of sodium hydroxide, and then the solution was evaporated to dryness on a water bath.

3) Silver Cholate, $AgC_{24}H_{39}O_5$. The sodium cholate was dissolved in water at about 50°C, and an aqueous solution of silver nitrate was added to this solution. The precipitate of the silver cholate was filtered, washed several times with water, acetone, and ether successively, and air-dried.

4) Tris(ethylenediamine)cobalt(III) Chloride, [Co en_3]-Cl_3,[6] *Chloropentaamminecobalt(III) Perchlorate*, [Co Cl $(NH_3)_5$] $(ClO_4)_2$,[7] *trans-Dichlorobis(ethylenediamine)cobalt-(III) Chloride*, *trans*-[Co Cl_2 en_2]Cl,[6] *cis-Dichlorobis-(ethylenediamine)cobalt(III) Chloride*, *cis*-[Co Cl_2 en_2]Cl,[7] *Trichlorotriamminecobalt(III)*, [Co Cl_3 $(NH_3)_3$],[8] *trans-Dichlorobis(ethylenediamine)chromium(III) Chloride*, *trans*-[Cr

7) *Ibid.*, Vol. 2, (1946), p. 223.
8) M. Mori, M. Shibata, K. Hirota, K. Masuno and Y. Suzuki, *Nippon Kagaku Zasshi*, **79**, 1251 (1958).

Cl_2 en_2]Cl,[9] *cis-Dichlorobis(ethylenediamine)chromium(III) Chloride*, *cis*-[Cr Cl_2 en_2]Cl.[10] These complexes were synthesized according to the method for each.

5) Tris(ethylenediamine)cobalt(III) Cholate, [Co en_3]-$chol_3$. Into a small amount of water we dissolved 0.4 g of [Co en_3]Cl_3, and then the solution was treated with freshly-precipitated silver oxide. The precipitate thus produced was filtered off, and 40 m*l* of methanol were added. One and a half grams of cholic acid in 40 m*l* of methanol were added to the solution, and the mixture was stirred. Then, after a large amount of ether had gradually been poured into the mixed solution, the solution was stirred vigorously with a glass rod until a yellow product was precipitated; this product was filtered, dissolved into methanol again, reprecipitated with ether, filtered, washed with ether, and then air-dried. Yield, 0.8 g (44%).

Found: Co, 4.21; C,*1; H, 9.66; N, 5.50%. Calcd: Co, 4.34; C,*1; H, 9.72; N, 5.75%.

Yellow powder, soluble in methanol, and insoluble in ether.

6) Chloropentaamminecobalt(III) Cholate, [Co Cl-$(NH_3)_5$]$chol_2$. One and a half grams of [Co Cl $(NH_3)_5$]-$(ClO_4)_2$, 2 g of sodium cholate, and 2 g of cholic acid were suspended in methanol, after which the solution was gently heated on a water bath using a reflux condenser. After an hour, the unreacted materials were filtered off from the red solution. A large amount of acetone was added to the filtrate, and the red product which was thus immediately precipitated was filtered, washed with acetone, and air-dried. It was dissolved in methanol again and reprecipitated with acetone for purification. Yield, 2.4 g (45%).

Found: Co, 5.85; C,*1; H, 9.65; NH_3, 8.30%.

Calcd: Co, 5.92; C,*1; H, 9.42; NH_3, 8.56%.

Red powder, soluble in methanol, slightly soluble in ethanol, and insoluble in water, acetone, and ether.

7) Cholatopentaamminecobalt(III) Cholate, [Co chol-$(NH_3)_5$]$chol_2$. In methanol we suspended 2.4 g of [Co-Cl $(NH_3)_5$]$chol_2$, 1 g of sodium cholate, and 1 g of cholic acid, after which, the solution was heated on a water bath with a reflux condenser. The fine purple-red crystals ([Co Cl $(NH_3)_5$]Cl_2) which separated out after an hour were filtered off. To the filtrate we then added 1 g of sodium cholate and 1 g of cholic acid, refluxing the mixture continuously. Then, after about 2 hr, when the solution had began to change its color from red to purple, the reflux condenser was removed and the solution was gently heated on a water bath in order to evaporate the solvent gradually. After a while, a beautiful purple precipitate (Co $chol_2 \cdot 1.5$cholH) was formed; when the purple color of the solution was changed to a light red-orange, the purple precipitate was filtered off. A large volume of ether was poured into the filtrate to precipitate pinkish products. Because they still contained a considerable amount of cholic acid, the crude products were dissolved into 50 m*l* of methanol; with the addition of 200m*l* of ether they were precipitated as a red-orange product which was then filtered, washed with ether, and dried in air. For further purification, the product was reprecipitated with acetone. Yield, 0.2 g (6%).

Found: Co, 4.18; C,*1; H, 9.48; NH_3, 6.21%.

Calcd: Co, 4.38; C,*1; H, 9.73; NH_3, 6.22%.

Red-orange powder, soluble in methanol and ethanol, insoluble in acetone, ether, and water.

8) Cholatopentaamminecobalt(III) Chloride, [Co chol-$(NH_3)_5$]Cl_2. Into 200 m*l* of methanol we dissolved 0.6 g of [Co chol $(NH_3)_5$]$chol_2$. After 10 m*l* of water had then been added to the solution, a few drops of concentrated hydrochloric acid were added and the mixture was stirred vigorously; then an appropriate amount of ether was poured into the solution to form a red-orange precipitate. This precipitate was filtered off and dissolved into 200 m*l* of methanol again, then, after the water and the concentrated hydrochloric acid had been added as before, it was reprecipitated with ether, filtered, washed with ether several times, and dried in air. Yield, 0.2 g (73%).

Found: 9.71; C,*1; H, 8.39; NH_3, 13.05%.

Calcd: 9.47; C,*1; H, 8.74; NH_3, 13.65%.

Red-orange powder, soluble in water, methanol, and ethanol, and insoluble in acetone and ether.

9) cis-Dicholatobis(ethylenediamine)cobalt(III) Chloride, *cis*-[Co $chol_2$ en_2]Cl. In 60 m*l* of ethanol we suspended 0.65 g of *trans*-[Co Cl_2 en_2]Cl or *cis*-[Co Cl_2 en_2]Cl and 2 g of sodium cholate; the solution was gradually heated on a water bath, using a reflux condenser. After about 3 hr, the red solution produced was filtered to remove the unreacted materials, and then about 4 volumes of ether were poured into the filtrate to form a pale red precipitate, which was filtered off and washed with ether. The precipitation from ethanol solution with ether was repeated several times in order to purify it. Yield, 1.7 grams (66%).

Found: Co, 5.65; C,*1; H, 9.17; ,N 5.49%.

Calcd: Co, 5.73; C,*1; H, 9.20; N, 5.44%.

Pale red powder, very soluble in methanol, ethanol, *n*-butanol and anhydrous acetic acid, and insoluble in acetone and ether.

10) cis-Dicholatobis(ethylenediamine)chromium(III) Chloride, *cis*-[Cr $chol_2$ en_2]Cl. Prepared by the same method as that described under 9) using 0.6 g of *trans*-[Cr Cl_2-en_2]Cl or *cis*-[Cr Cl_2 en_2]Cl and 2 g of sodium cholate. Yield, 1.5 g (63%).

Found: Cr, 4.79; C,*1; H, 9.17; N, 5.45%.

Calcd: Cr, 5.09; C,*1; H, 9.26; N, 5.48%.

Pale red powder, very soluble in methanol, ethanol, *n*-butanol, and anhydrous acetic acid, and insoluble in acetone and ether.

11) Tricholatotriamminecobalt(III), [Co $chol_3$ $(NH_3)_3$]. In a mortar we crushed 2.6 g of silver cholate, 0.4 g of [Co Cl_3 $(NH_3)_3$], and 0.3 g of cholic acid; the mixture was then warmed up to about 50°C by the use of hot air. Then a few drops of water was added to it, and the mixture was ground vigorously by the use of a pestle. After the bluish-green color of the mixture had turned

10) "Inorganic Syntheses," Vol. 2 (1946), p. 200.

*1 The found values of carbon were always less than the calculated values; for example, [Co Cl $(NH_3)_5$]-$chol_2$: Found 54.09; Calcd 57.09, [Co chol $(NH_3)_5$]-$chol_2$: Found 56.78; Calcd 63.23, [Co chol $(NH_3)_5$]Cl_2: Found 38.77; Calcd 46.31, [Co $chol_2$ en_2]Cl: Found 55.29; Calcd 60.65, [Cr $chol_2$ en_2]Cl: Found 54.18; Calcd 61.07. It was found that a considerable amount of carbon was contained in the residue whenever the sample was burned. Because of the high carbon-to-metal atomic ratios in the complexes, carbide or carbonate may be produced when they were burned.

to red-violet and the reaction was over, a soluble part was extracted from the mixture with 50 m*l* of ethanol and the insoluble silver chloride was filtered off. The red-violet precipitate which appeared as the appropriate amount of ether was poured into the filtrate was filtered, washed with ether, and dried in air. The product was reprecipitated twice from an ethenol solution with ether. Yield, 1.5 g (67%).

Found: Co, 4.56; C, 64.08; H, 9.58; NH_3, 3.96%.

Calcd: Co, 4.43; C, 64.80; H, 9.47; NH_3, 3.83%.

Red-violet powder, soluble in methanol and ethanol, and insoluble in acetone and ether.

Analysis. For the analysis of cobalt, the sample was first slowly burned with sodium hydrogensulfate in a crucible in order to change all the cobalt into $CoSO_4$, after which, the burned solid was dissolved into diluted hydrochloric acid. Then the cobalt was precipitated from the solution with α-nitroso-β-naphthol.

The chromium was determined as follows; the sample was decomposed, in a hot aqueous solution of sodium hydroxide, to chromium(III) hydroxide, which was oxidized by potassium peroxodisulfate to chromate(VI) ions, then, after the pH of the solution had been adjusted to 10, the intensities of the absorption at 348, 356, 388, and 396 mu were measured.

The nitrogen, carbon, and hydrogen were analyzed by ordinary microanalysis, except that the nitrogen which was contained as NH_3 was analyzed by Kjehldahl's method. The found values were in good agreement with the calculated values except in the case of carbon.

Infrared Absorption Spectra. The infrared absorption spectra were measured by Nujol mull method using a JASCO 301 (Japan Spectroscopic Co.) infrared spectrophotometer. The characteristic absorption maxima are listed in Table 1.

Visible and Ultraviolet Absorption Spectra. The visible and ultraviolet absorption spectra in solution were obtained with a Hitachi 139 spectrophotometer.

Results and Discussion

The authors succeeded in the preparation of various kinds of cholato-complexes, as has been described in the Experimental section. These are all red fine powders, insoluble in water and soluble in an organic solvent such as ethanol. We attempted to prepare [Cr chol $(NH_3)_5]^{2+}$ and [Cr-$chol_3$ $(NH_3)_3$] but neither of the pure products were obtained. For example, for the purpose of obtaining [Cr chol $(NH_3)_5]^{2+}$, when we employed method by which the corresponding cobalt complex had successfully been prepared, [Cr Cl $(NH_3)_5$]-$chol_2$ could be obtained, but further treatment was

* present work

not useful. That is, $[Cr\ Cl\ (NH_3)_5]^{2+}$ was easily decomposed and a ligand-exchange reaction between Cl^- and $chol^-$ was not performed smoothly. These phenomena are consistent with the fact that Co $chol_2$ was produced as the cholatopentaamminecobalt(III) salt was prepared. A very small amount of an impure $[Cr\ chol_3\ (NH_3)_3]$ was obtained by the reaction of Ag chol upon $[Cr\ Cl_3\ (NH_3)_3]$ because of the incomplete reaction.

It was found that, in the reaction of $[Co\ Cl(NH_3)_5](ClO_4)_2$ with Nachol, $[Co\ Cl\ (NH_3)_5]chol_2$ was first obtained, while in the case of $[M\ Cl_2\text{-}en_2]Cl$ (M=Co, Cr) the ligand substitution took place immediately and a cholate was not prepared. This fact aroused our interest in its reaction mechanism.

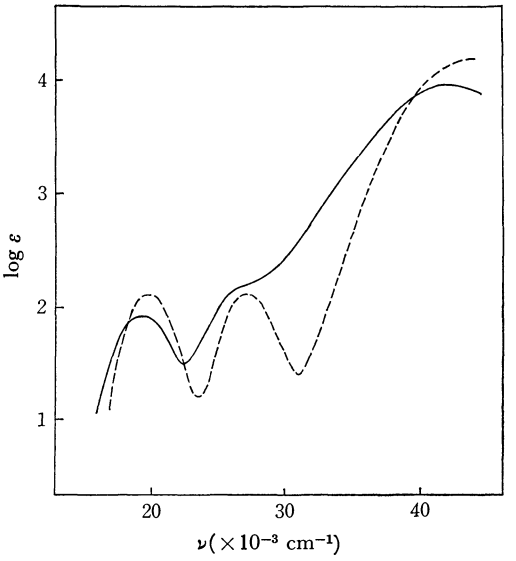

Fig. 5. Absorption spectra of tricholatocomplex.
——— $[Co\ chol_3\ (NH_3)_3]$ (in ethanol), ----- *fac*-$[Co\ gly_3]$.

As is shown in Table 2 and Figs. 2,3,4 and 5, each complex shows two spin-allowed bands which are characteristic of d^3 or low-spin d^6 complexes. An intense absorption band due to cholate ions was also seen in each case. The absorption band at 46500 cm^{-1} in [Co en_3]$chol_3$ coincides with the absorption band which is considered to be due to free cholate ions. Thus, in this case, the cholate ions are not at all coordinated. The spin-allowed bands of [Co en_3]$chol_3$ coincide with those of [Co en_3]Cl_3; this result confirmes that the compound must be a cholate salt of $[Co\ en_3]^{3+}$. However, in all the complexes except [Co en_3]$chol_3$ the cholate bands shifted to 42500 cm^{-1}; this shift suggests that it must be a specific absorption band of coordinated cholate ions. A similar result is also found in the case of $[Co\ chol\ (NH_3)_5]^{2+}$ (Fig. 3); either two ligand-field bands or a specific absorption band due to the cholate ion of [Co chol $(NH_3)_5$]$chol_2$ coincides well with that of [Co chol $(NH_3)_5$]Cl_2 in both the position and the intensity of the absorption maximum; furthermore, the absorption spectra of [Co chol $(NH_3)_5$] $chol_2$ have a band due to uncoordinated cholate ions at 46500 cm^{-1}, much like [Co en_3]-$chol_3$, while no such band is seen in [Co col $(NH_3)_5$]-Cl_2. The so-called "first" and "second" absorption bands of $[Co\ chol\ (NH_3)_5]^{2+}$ coincide with those of $[Co\ (CH_3COO)\ (NH_3)_5]^{2+}$ with respect to position and pattern. The intensity of the first band is slightly higher, and that of second band of $[Co\ chol\ (NH_3)_5]^{2+}$ is considerably higher, than that of the corresponding band of $[Co\ (CH_3COO)\ (NH_3)_5]^{2+}$. The increase in intensity in the case of the second band is evidently due to the overlap of the intense cholate band and the second band. Thus, the ligand-field bands of $[Co\ chol\ (NH_3)_5]^{2+}$ are essentially equal to those of $[Co\ (CH_3COO)\text{-}(NH_3)_5]^{2+}$, which means that the cholate ion coordinates to the cobalt through the carboxyl group.

The spin-allowed bands of [Co $chol_2$ en_2]Cl are similar to those of the corresponding *cis*-distearatocobalt(III)-complex. That is, the patterns and the positions of the absorption band of the two complexes agree well except for the intensity of the second absorption band of the cholato complex, which is again influenced by the specific absorption. Similarly, the absorption spectrum of [Cr $chol_2$ en_2]Cl is consistent with that of the corresponding complexes, $[Cr\ (C_{17}H_{35}COO)_2\ en_2]ClO_4$, in position and pattern. These two cholato cobalt(III) and chromium(III) complexes have the first absorption band characteristic of *cis*-diacido complexes. That is, the band does not show any splitting characteristic of *trans*-diacido-complexes. Thus, the complexes should have the *cis* structures.[11,12] The starting materials used here are [Co Cl_2 en_2]Cl and [Cr Cl_2 en_2]Cl respectively, and the *cis*- and *trans*- or complexes give the same product in each case. In other words, even though the *trans* complex is used as the starting material, the *cis* complex is obtained. The isomerisation reaction from *trans* to *cis* must take place. The situation is similar to the case of long-chain fatty acid complexes reported previously[2]; the reason for this isomerisation must be similar. That is, as the cholate ion is bulky, then the interaction between the cholate ion as ligand in this complex must strongly affect the *trans-cis* isomerisation reaction.

The absorption spectrum of [Co $chol_3$ $(NH_3)_3$] has two ligand-field bands and one specific absorption band (Fig. 5). The latter agrees well with the bands of the mono- and di-cholato complexes with respect to position. However, its intensity is fairly low, and its half-width is quite large. Moreover, there is a large shoulder on the longer-wavelength side of the specific absorption band. The specific absorption band covers the second absorption band and makes it obscure. The position of the maximum absorption of the second band was estimated to be at 27000 cm^{-1}, and the molar extinction coefficient was estimated to be about 100. These absorption bands agree with the absorption bands of *fac*-[Co $(NH_2CH_2COO)_3$], which possesses a similar *cis*-Co N_3O_3 configuration.[13] The complex obtained here should have a *fac*-configuration.

The infrared spectra are rather complicated in each case. However, many bands are associated with cholic acid. The characteristic absorptions are summarized in Table 1. It is observed that the absorptions assigned to the antisymmetric vibrations of COO^- are the considerably shifted to the lower-wave number side compared with the corresponding absorptions in free cholic acid. The absorption at 1537 cm^{-1} of [Co chol $(NH_3)_5$]$chol_2$ is fairly intense and has a small shoulder at 1640 cm^{-1} which is not listed in the table. Consequently, the absorption bands at 1537 cm^{-1} and 1545 cm^{-1} must be associated with the uncoordinated cholate ions in [Co chol $(NH_3)_5$]$chol_2$ and [Co en_3 $chol_3$] respectively. It is also found that the wave numbers of the COO^- antisymmetric vibration in the order; [Co chol $(NH_3)_5$]Cl_2, [Co $chol_2$ en_2]Cl, [Co $chol_3$-$(NH_3)_3$], and [Co en_3]$chol_3$. It is generally known that the absorption of a free carboxylic group should be at 1700—1730 cm^{-1} (in the free cholic acid at 1712 cm^{-1}), and that the absorption of a COO^- group coordinated to Co(III) or Cr(III) should be at 1620—1650 cm^{-1} and should be shifted to the lower-wave number side as the coordinate bond increases in ionic character.[14] These inter-

pretations were supported by the above results. That is, in the free cholic acid the maximum is at 1712 cm^{-1}; in the monocholato complex, at 1642 cm^{-1}; in the dicholato complex, at 1567 cm^{-1} (Co complex) and at 1584 cm^{-1} (Cr complex), and in the tricholato complex, at 1569 cm^{-1}. The absorption maxima of the monocholato complex are comparable with those of the monoacetato complexes. However, when there is such a large steric hindrance on the *cis* configuration as *cis*-dicholato and *fac*-tricholato complexes, the Co-O bond length may be lengthened by the hindrance and ionic character of the bonds may increase.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3155—3158 (1970)

The Hydrolysis of the Copper(II) Ion in Heavy Water*1

Hidetake KAKIHANA, Toshihiko AMAYA and Masunobu MAEDA*2

Research Laboratory of Nuclear Reactor, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 26, 1970)

The hydrolysis equilibria of the copper(II) ion in heavy water have been studied at 25°C by measuring the deuterium-ion concentration by means of a commercial glass electrode. The total copper(II) concentration was varied between 50 and 90 mM, while the concentration of the perchlorate ion was held constant at 3M by the addition of $NaClO_4$. A hydrolyzed copper(II) perchlorate solution was gradually acidified up to the point where hydrolysis was negligible by the use of constant-current coulometry. The experimental data, which indicate a slight hydrolysis in the log d range from -4.0 to -5.26, can be explained by assuming these equilibria;

$$Cu^{2+} + D_2O = CuOD^+ + D^+, \log \beta_{1,1} = -7.71 \pm 0.07;$$
$$2Cu^{2+} + 2D_2O = Cu_2(OD)_2^{2+} + 2D^+, \log \beta_{2,2} = -11.46 \pm 0.04.$$

It has been found that the hydrolytic reactions of metal ions in heavy water can be studied with the same accuracy as in light water.[1] We have previously reported on our studies of the hydrolysis of the beryllium ion and the uranyl ion in heavy water.[2-4]

The present work was carried out in order to obtain information on the hydrolysis species of the copper(II) ion in heavy water and to estimate their stability constants.

The hydrolysis equilibria of the copper(II) ion in light water have been studied by a number of investigators,[5-9] using glass electrodes. It has been concluded that the main product is the binuclear complex, $Cu_2(OH)_2^{2+}$, but the minor one is not yet precisely known.

Symbols

- B total concentration of copper(II)
- b concentration of free copper ions
- D analytical excess of deuterium ions $=[ClO_4^-]-2B-[Na^+]$

been described in Ref. 2.

The copper(II) perchlorate solution was prepared by dissolving copper(II) oxide of a commercial *p. a.* reagent in an excess of hot $HClO_4$ (*p. a* 70%) and by then recrystallizing it twice. The H_2O was expelled by evaporating the solution under an infrared lamp until crystals had formed, whereupon D_2O was added. No chloride or sulfate ions could be detected in the stock solution. The copper content of the stock solutions was measured by electrodeposition,[10] and the total perchlorate concentration was determined by neutralization after passing a definite amount of the solution through a column of the cation exchange resin, Dowex 50W-12, of the H^+ form.

Apparatus. All the apparatuses used were the same as those described in Ref. 3.

Procedures. Earlier investigations[7,9] have indicated that the hydrolysis becomes appreciable at log $h<-4.0$, and that only a small part of Cu^{2+} can be transformed to hydrolysis products before precipitation starts. Under such conditions, it is imperative to avoid contamination of the solutions to be studied by foreign protolytes. Furthermore, it has been pointed out that copper hydroxide precipitates slowly with a small excess of alkali.[7]

In the present work, in order to avoid contamination by foreign protolytes and the formation of any precipitates during titration, a "*back titration*" technique[9,11,12] was employed: a test solution saturated with copper(II)-hydrolyzed products was prepared and acidified by generating D^+ ions coulometrically.

The saturated solutions were prepared by employing apparatuses similar to those described in Refs. 9 and 12. A copper(II) perchlorate solution containing 3M ClO_4^- was put into a vessel. Then a NaOD solution prepared by the electrolysis of a 3M $NaClO_4$ solution was added until pale blue precipitates of copper(II) hydroxides were formed. The solution was stirred at least 40 hr by the use of a magnetic stirrer and filtered through G4 glass filters into a flask.

The turbidity was examined for several months with an aliquot of the filtered solution, but no suspended particles could be detected. Another portion was used for potentiometric titration.

All the preparations were carried out under a nitrogen atmosphere. Nitrogen gas was presaturated by passing it through D_2O and $NaClO_4$ in D_2O.

Emf Measurements. The general composition of a test solution is written as: BM Cu(II), DM D^+, $(3-2B-D)$M Na^+, 3M ClO_4^-, where D may be negative. For each titration, a definite volume of the test solution (v ml) was taken and the value of D was increased in a step-by-step fashion by constant-current coulometry, using the cell assembly reported as in Refs. 3 and 13.

After $v\mu F$ have been passed through the test solution, D is equal to:[13]

$$D = D_0 + (v/v) \times 10^{-3} \qquad (1)$$

where D_0 is the analytical excess of the deuterium-ion concentration in the starting test solution.

The deuterium ion concentration, d, was measured by the use of the cell assembly described in Ref. 3.

The emf of the cell may be written as follows:[1]

$$E = E_0 + 59.15 \log d \text{ (at 25°C)} \qquad (2)$$

where E_0 is the constant which includes the standard potential for the glass electrode and the term for the activity factor of the D^+ ion.

Each of the potentiometric titrations may be divided into two parts. In the first part, D_0 and E_0 were determined by measuring the emf in the region where log-$d>-3.5$; they were calculated by means of the Gran plot,[14] $10^{E/59.15}$ *vs.* v. In the second part, measurements were made at log $d<-3.5$, where the hydrolysis becomes appreciable. Then $Z=(d-D)/B$, the average number of OD groups bound per copper atom, was calculated by the use of Eqs. (1) and (2).

All the emf measurements were carried out at 25.00± 0.01°C in a paraffin oil thermostat, and the test solution was stirred by nitrogen gas presaturated by passing it through D_2O and $NaClO_4$ in D_2O.

Results and Calculations

The $Z(\log d)_B$ data are shown graphically in Fig. 1. The experimental data were analyzed by the graphical method. At first, the analysis was made in order to obtain information on the composition of the hydrolysis species and the approximate stability constants, then, on the basis of the

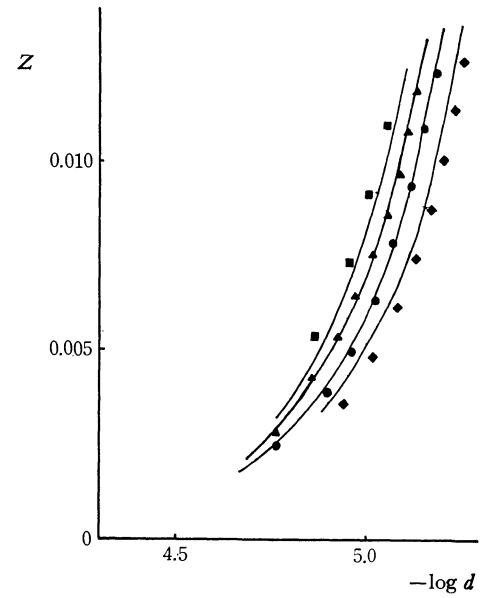

Fig. 1. Average number, Z, of OD bound per Cu, as a function of $-\log d$. Drawn curves were calculated with the stability constants given in Table 1.

information thus obtained, the accurate stability constants were determined.

1) The Evaluation of the Composition of the Hydrolysis Species. When we take into account the fact that, in test solutions, the maximal value of Z never exceeds 0.015, then, without introducing any appreciable error, we may simplify the preliminary calculations by using the approximation:

$$[Cu^{2+}] = b \cong B = \text{constant.} \quad (3)$$

The concentration of the deuterium ions set free by hydrolysis, BZ, is expressed by the equation:

$$BZ = \sum_p \sum_q p\,[Cu_q(OD)_p^{(2q-p)+}] = \sum_p \sum_q p\,\beta_{p,q}\,b^q d^{-p}. \quad (4)$$

Using Eq. (3), Eq. (4) can be written:

$$Zd = \sum_p \sum_q p\,B^{q-1}\beta_{p,q}d^{-(p-1)} = \sum_p p\,d^{-(p-1)}K_p. \quad (5)$$

where:

$$K_p = \sum_q B^{q-1}\beta_{p,q}. \quad (6)$$

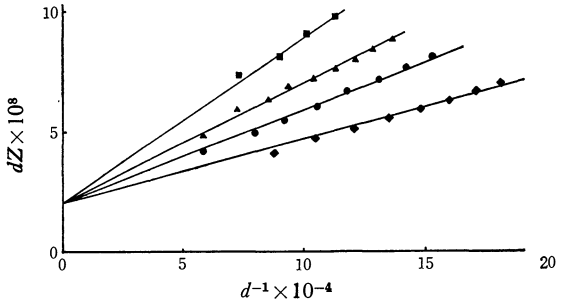

Fig. 2. dZ as a function of d^{-1} (see Eq. (5)). The straight lines are given by the stability constants; $\log\beta_{1,1}=-7.69$ and $\log\beta_{2,2}=-11.47$.

In order to find the prevailing values of p, plots of Zd against d^{-1} were constructed;[9] they are shown in Fig. 2. The plots closely approximate a set of straight lines with a common intercept. This result indicates that the prevailing values of p are 1 and 2.

Next, to determine the values of q, the data were compared at different values of B. The common intercept, $K_1=\sum_q B^{q-1}\beta_{1,q}$, of the previous plots shows that one of the prevailing values of q is 1. The other values were obtained from their slopes. The slope of the line is represented as $2K_2=2(\beta_{2,1}+B\beta_{2,2}+\cdots)$ at each value of B. Figure 3 shows a plot of these K_2 values against B, which gives a straight line passing through the point of

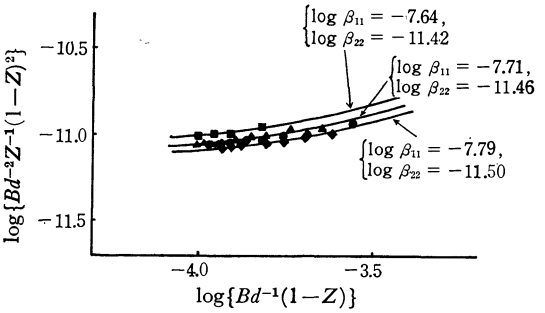

Fig. 4. $-\log\alpha$ as a function of $-\log\omega$, see Eq. (9). The curves were calculated with the $\log\beta_{1,1}$ and $\log\beta_{2,2}$ values given in the figure.

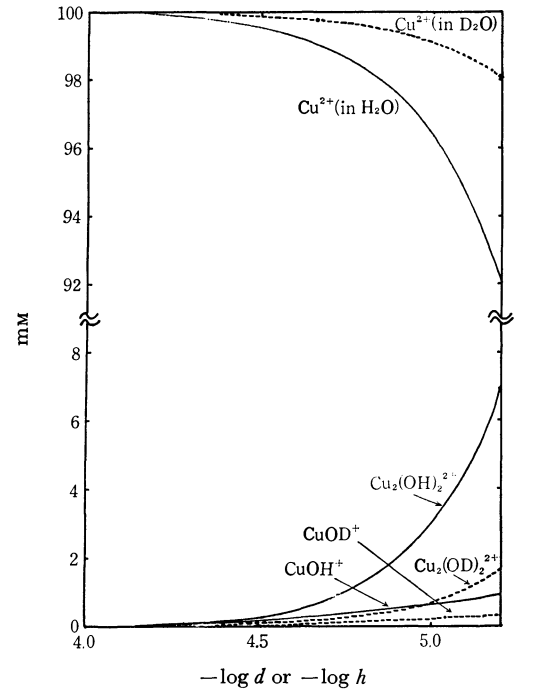

Fig. 5. The calculated distribution of the hydrolytic species in heavy water and in light water at total copper(II) concentrations of 100 mM. Dotted curves represent the distribution of the species in heavy water and full curves in light water.

origin. This indicates that another value of q is 2.

From the results, it can be concluded that the compositions of the hydrolysis species of the copper(II) ion are $CuOD^+$ and $Cu_2(OD)_2^{2+}$, and the approximate stability constants can be estimated to be $\log \beta_{1,1} = -7.69$ and $\log \beta_{2,2} = -11.47$.

2) The Evaluation of the Stability Constants of the Hydrolysis Species. The above analysis involved some approximation. It is, therefore, desirable to compare the data directly with the normalized function similar to that described in Ref. 15. We start from the fundamental equations:

$$Z = (\beta_{1,1}d^{-1}+2\beta_{2,2}bd^{-2})/(1+\beta_{1,1}d^{-1}+2\beta_{2,2}bd^{-2}) \quad (7)$$

$$B = b(1+\beta_{1,1}d^{-1}+2\beta_{2,2}bd^{-2}). \quad (8)$$

From Eqs. (7) and (8), and by eliminating $b=B\times(1-Z)$, the following equation is obtained:

$$\alpha = Zd^2B^{-1}(1-Z)^{-2} = \beta_{2,2}(2+\beta_{1,1}\beta_{2,2}^{-1}dB^{-1}(1-Z)^{-1}) = \beta_{2,2}(2+\beta_{1,1}\beta_{2,2}^{-1}\omega) \quad (9)$$

If we set $\alpha_1=\alpha\beta_{2,2}^{-1}$ and $\omega_1=\omega\beta_{1,1}\beta_{2,2}^{-1}$, Eq. (9) may be compared with the normalized function:

$$\log \alpha_1 = \log (2+\omega_1). \quad (10)$$

A plot of the log $\{Bd^{-2}Z^{-1}(1-Z)^2\}$ against log $\{Bd^{-1}(1-Z)\}$, which will be independent of B, can be fitted to a plot of α_1 against log $(2+\omega_1)$ at the particular values of $\beta_{1,1}$ and $\beta_{2,2}$. As shown in Fig. 4, we can obtain the following values:

$$-\log \beta_{1,1} = 7.71\pm0.07 \text{ and } -\log \beta_{2,2} = 11.46\pm0.04$$

These values are listed in Table 1, together with the values obtained by us in light water.

Table 1. The values for the stability constants of the hydrolysis species of copper(II) ion in heavy water and in light water containing 3M $NaClO_4$ as an ionic medium

	in heavy water	in light water
$\log \beta_{1,1}$	-7.71 ± 0.07	-7.22 ± 0.03
$\log \beta_{2,2}$	-11.46 ± 0.04	-10.75 ± 0.02

3) Distribution of the Species. The distribution of the hydrolysis species in heavy water and in light water, calculated at the total copper(II) concentration of 100 mM and assuming the values of the stability constants obtained by us, is shown in Fig. 5.

As has been mentioned earlier,[3,4] the species are less hydrolyzed in heavy water than in light water.

A more detailed discussion must be postponed until other hydrolytic reactions of metal ions have been investigated.

The Photometric Determination of Micro Amounts of Bromine in Silicate Rocks by Means of Its Catalytic Effect

Kazuyoshi TAKAHASHI, Minoru YOSHIDA, Takejiro OZAWA and Iwaji IWASAKI

Laboratory of Analytical Chemistry and Geochemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Tokyo

(Received March 31, 1970)

The catalytic action of bromide on the oxidation of to iodine iodate by potassium permanganate in sulfuric acid solution has been utilized for the microdetermination of bromine in silicate rocks. The method described consists of decomposing the silicate-rock sample by fusion with potassium hydroxide, leaching the melt with water, oxidizing bromide to bromine with potassium permanganate, extracting by benzene, and finally determining the bromine by the catalytic method. By this method, the bromine in samples with more than 0.04 ppm can be determined rapidly and accurately, using only 0.25—0.5 g of samples.

Data on the halogen contents of igneous rocks are important in discussing the relation between igneous rocks and magmatic emanations. The fluorine and chlorine contents have been reported by many investigators, but the data on bromine and iodine are rather scanty on account of the lack of a suitable analytical method. The results of a systematic investigation of bromine in rocks made by Behne[1] were long accepted as reliable, but the sensitivity of his analytical method (titrimetric) is too low to determine as low a bromine content as 1 ppm or less. In 1964, Filby[2] reported that the bromine content of two standard rocks collected by the U.S.Geological Survey, as determined by neutron activation analysis, was appreciably lower than Behne's average value. Recently, Sugiura[3] determined the bromine content of igneous rocks by a photometric method using rosaniline and molybdate after distillation. His values were also lower than those of Behne. Sugiura's method is applicable to rocks with more than 0.2 ppm bromine, but its sensitivity is not yet enough for many igneous rocks.

The sensitivities of usual photometric methods are too low for them to be used in the determination of bromine in igneous rocks. The neutron activation method has, indeed, a very high sensitivity, but it requires special equipment and time-consuming irradiation procedures.

One of the present authors (I.I.) and others[4] have previously reported a photometric method for the determination of bromide, a method based on the catalytic effect of bromide on the oxidation of iodine to iodate by potassium permanganate in a sulfuric acid solution. This method has an excellent sensitivity and sufficient accuracy and does not need any expensive equipment.

The present authors have first investigated in detail the iodine-potassium permanganate reaction in the presence of Br^- or Cl^- as a catalyst and have established optimum conditions for the microdetermination of bromine by means of its catalytic effect.

Although the catalytic action itself is highly selective, the method is affected by various coexisting substances. Because of the chemical complexity of usual silicate rocks, the isolation of bromine is necessary before using the catalytic method. We have established a rapid, sensitive, and accurate method for the determination of very small amounts of bromine (>0.04 ppm) in common silicate rocks.

Experimental

Apparatus. A Hirama photoelectric-colorimeter with a 460 filter (with maximum transmission at 460 mμ) and 10-mm cells was used to measure the absorbance.

The reactions were carried out in a water bath kept at 25.0±0.1°C with a Taiyo Thermo Unit.

Reagents. All the chemicals used were of analytical-reagent quality. Redistilled water was used for the reagent preparation and throughout the procedure.

Potassium Iodide Solution. Dissolve 1.31 g of potassium iodide and 2 g of sodium carbonate in water and dilute to 1 *l*; this yields 1 mg/m*l*.

Potassium Permanganate Solution (0.04M).

Potassium Bromide Solution. Prepare a 0.1M potassium bromide solution. The solution is standardized by Volhard's method.[5] Prepare the working solution by

diluting this solution adequately.

Sodium Chloride Solution. Dissolve 1.649 g of sodium chloride in water and dilute to exactly 1 *l*. This solution contains 1 mg of chloride per m*l*. The working solution is prepared by successive dilutions.

Sulfuric Acid Solution (1 : 1).

Ferric Ammonium Sulfate Solution. Dissolve 6 g of ferric ammonium sulfate in 100 m*l* of a 6N nitric acid solution. The solution is then stored in a brown glass bottle.

Mercuric Thiocyanate Solution. Solid mercuric thiocyanate was prepared as has been described by Utsumi.[6] Dissolve 0.3 g of mercuric thiocyanate in 100 m*l* of absolute ethyl alcohol.

Sodium Sulfite Solution (0.1M). Dissolve 1.26 g of anhydrous sodium sulfite in 100 m*l* of water. This solution is prepared afresh each week.

Potassium Dichromate Solution (0.01M).

Benzene. Wash guaranteed benzene with a 1N sodium hydroxide solution, a 1N sulfuric acid solution, and finally three times with water.

Procedure and Calibration Curve. 0.25 to 0.5 g of a finely-powdered sample is placed in a 30-m*l* nickel crucible. Add 3.0 g of potassium hydroxide pellets to the crucible. Cover the crucible, and heat it to about 500°C on an electric heater for 15 min. Leach the resulting fused cake with 35 m*l* of water. Centrifuge the resulting suspension in a 50-m*l* centrifuge tube. Transfer the supernatant liquid to a 100-m*l* separatory funnel. Add 10 m*l* of water to the residue, shake, and centrifuge again. Transfer the supernatant liquid to the above-mentioned separatory funnel.

To the solution in the separatory funnel add 1.5 m*l* of the sodium sulfite solution, and then 6.4 m*l* of the sulfuric acid solution (1 : 1).

After the solution has stood for about 10 min, add the potassium dichromate solution until the yellow color of the dichromate ion persists. After the subsequent addition of 30 m*l* of benzene, immerse the separatory funnel in a water bath kept at 25°C for about 15 min. Start shaking (360 strokes/min, using a shaker) immediately after adding 1.2 m*l* of the potassium permanganate solution. After 20 min's shaking, discard the aqueous layer. Shake the organic layer with 5 m*l* of 1.8N sulfuric acid for one minute. Discard the aqueous phase. To the organic layer, add 3.0 m*l* of a 1N sodium hydroxide solution and 16.8 m*l* of water, and shake the separatory funnel for 3 min. After the phase separation, transfer the aqueous layer to a 50-m*l* separatory funnel. Care must be exercised to completely exclude benzene, since even a small amount of benzene disturbs the subsequent procedure.

To the aqueous layer, add 3.2 m*l* of the sulfuric acid solution (1 : 1) and 1.0 m*l* of the potassium iodide solution, and then mix. Place the separatory funnel in a water bath at 25.0±0.1°C for about 15 min. Start the reaction by adding 0.5 m*l* of the potassium permanganate solution (at the same temperature). Swirl to mix thoroughly and let the separatory funnel stand in the water bath. Exactly 3 min after the addition of the potassium permanganate solution, add 10 m*l* of cold (about 0°C) carbon tetrachloride and immediately shake the separatory funnel for 15 sec.

After the phase separation, transfer the organic layer to a 50-m*l* separatory funnel. To the organic layer, add 10.0 m*l* of water, 2.0 m*l* of the ferric ammonium sulfate solution, and 1.0 m*l* of the mercuric thiocyanate solution, and shake the separatory funnel for about one minute. The aqueous layer is thus colored with ferric thiocyanate. Measure the absorbance of this aqueous layer at 460 mμ using a 10-mm cell and against water used as a reference.

The calibration curve shown in Fig. 1 was obtained by the procedure described above, using 45 m*l* of standard bromide solutions (or bromate solutions) of known concentrations and 3 g of solid potassium hydroxide.

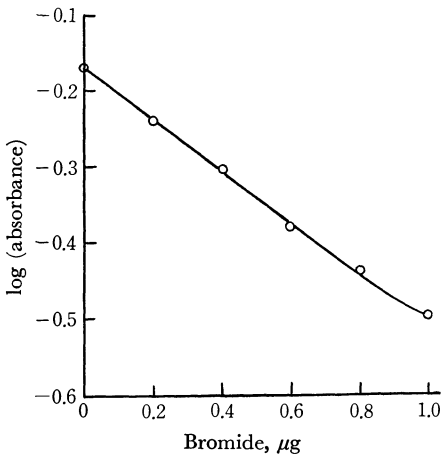

Fig. 1. Calibration curve.

Results and Discussion

The Catalyzed Oxidation Reaction of Iodine by Permanganate. The oxidation reaction between iodide and potassium permanganate in an acid medium is shown in Eqs. (1) and (2).

$$10\,I^- + 2MnO_4^- + 16H^+ \rightarrow 5I_2 + 2Mn^{2+} + 8H_2O \quad (1)$$

$$I_2 + 2MnO_4^- + 4H^+ \xrightarrow[\text{catalyst}]{Br^-,\ Cl^-} 2IO_3^- + 2Mn^{2+} + 2H_2O \quad (2)$$

The reaction (1) is very fast compared to the reaction (2), which is the rate-determining step. The rate of the reaction (2) was followed by the photometric determination of the change in the concentration of the unreacted iodine as a function of the time.

One of the present authors (I.I.) and others[7] have previously reported a photometric method for the determination of iodide by using ferric ammonium sulfate and mercuric thiocyanate. In order to examine the relationship between the amounts of unreacted iodine and the absorbance, a series of reaction mixtures containing various amounts of iodine was prepared. Into each separatory funnel, 20-m*l* portions of iodide solutions of known con-

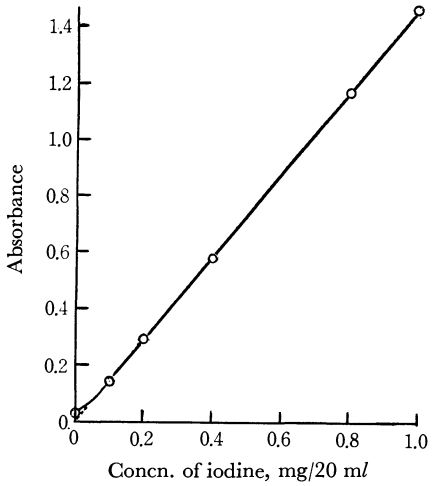

Fig. 2. Relationship between concentration of iodine and absorbance at 460 mμ.

centrations, 3 m*l* of sulfuric acid (1 : 1), and 3 m*l* of a 3% hydrogen peroxide solution were introduced. The resulting iodine was extracted with 10 m*l* of carbon tetrachloride and was colored with ferric thiocyanate as in the analytical procedure.

As is shown in Fig. 2, there is a linear relationship between the absorbance at 460 mμ and the concentration of iodine, but not at low concentrations. In order to exclude the nonlinear portion of the curve, absorbance readings were subsequently confined to the range of from 0.1 to 1 mg of iodine.

The concentration of sulfuric acid suitable for the oxidation reaction was first sought. The reaction proceeds smoothly when 3 m*l* of the sulfuric acid solution (1 : 1) are added to 20 m*l* of a sample.

After the most satisfactory conditions of acidity had been determined, the effect of potassium permanganate on the oxidation reaction in the absence of bromide or chloride was investigated by adding 0.5-m*l* portions of potassium permanganate solutions with various concentrations.

The plots of the log absorbance *vs.* the time yield fairly good straight lines, indicating a first order relationship with respect to iodine. From the slopes of the straight lines, the rate constants, *K*, were calculated; they were then plotted as a function of the initial concentration of potassium permanganate (Fig. 3). The direct proportionalities between the rate constants and the initial concentration of potassium permanganate indicate that the reaction is again first order with respect to potassium permanganate. (Variations in the ionic strength in this range produce no effect on the reaction rate; the rate did not change even in the presence of 0.1 mol/*l* of sodium sulfate).

The reaction rate increases sharply with an increase in the concentration of potassium permanganate, as is shown in Fig. 3. Consequently, the higher the concentration of potassium permanganate, the lower the accuracy of the present kinetic method because of the inevitable variation in the rate of the noncatalytic reaction. It is best to use 0.5 m*l* of a 0.04M potassium permanganate solution, because the reaction proceeds relatively slowly under these conditions.

The catalyst may influence the rate constant without altering the kinetic order of the noncatalytic reaction. Accordingly, using solutions containing bromide or chloride we carried out catalyzed reactions between iodine and potassium permanganate with 0.5 m*l* of a 0.04M potassium permanganate solution.

The reaction rate curves, II, III, and IV, in Fig. 4 were obtained by using 0.02- and 0.05-ppm bromide solutions and a 5-ppm chloride solution. The curve I was obtained by using redistilled water. The differences in absorbances among the three curves (I, II, and III) are largest after 3 minutes. A reaction time of 3 min is adequate for

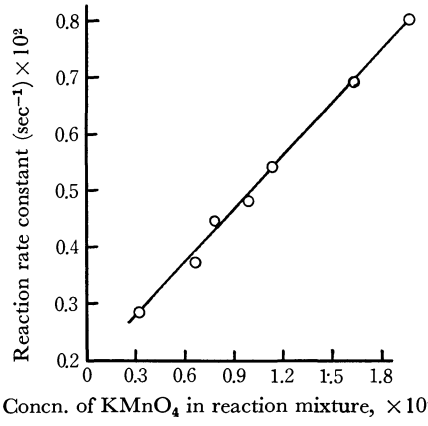

Fig. 3. Effect of potassium permanganate on the reaction rate constant.

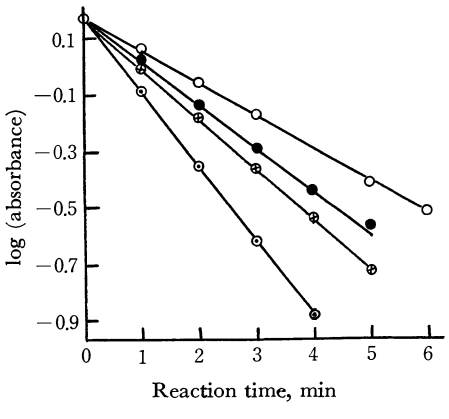

Fig. 4. Effects of bromide and chloride on the reaction rate.
○ redistilled water (I) ⊗ 0.02 ppm Br^- (II)
⊙ 0.05 ppm Br^- (III) ● 5 ppm Cl^- (IV)

the determination of bromide because of the high sensitivity. As can be seen in Fig. 4, the reaction follows approximately (pseudo) first order kinetics at each catalyst concentration, and the first order rate constant increases with the quantity of the catalyst. If the reaction is first order with respect to the catalyst, for the same initial concentration of potassium permanganate the log absorbance and the catalyst concentration should yield a linear relationship at a constant reaction time.

In order to confirm this point, experiments on a series of reaction mixtures containing various amounts of catalysts were carried out. In Fig. 5,

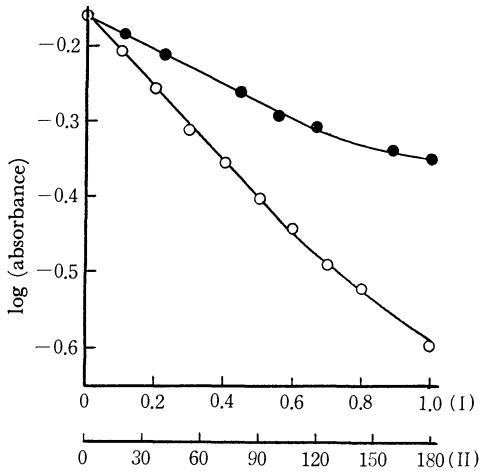

Fig. 5. Effects of amounts of bromide and chloride.
○ Br^- (I) ● Cl^- (II)

the resulting log absorbance are plotted against the catalyst concentration. At a low concentration of the catalyst, the linear relationship was recognized, but at a high concentration there was a departure from linearity. It seems that the catalyst dependence is first order at a low concentration. The catalytic effect of chloride is smaller than that of bromide. The abundance of chlorine in silicate rocks is, however, considerably greater than that of bromine.

Extraction. Utsumi *et al.*[8] have discussed the extraction of small amounts of bromine (order of 100 μg) by carbon tetrachloride in the determination of bromide in natural waters. Their procedure was based on the selective oxidation of bromide to bromine by potassium permanganate. In this investigation the present authors examined the extraction procedure of less than 1 μg of bromine. Bromide was oxidized to bromine by employing various oxidizing agents. The resulting bromine was extracted by benzene, stripped from the organic layer by a sodium hydroxide solution, and determined by the catalytic method. The use of carbon tetrachloride as the solvent was not suitable, because a minute amount of carbon tetrachloride retained in the aqueous layer remarkably promoted the iodine-potassium permanganate reaction in the subsequent procedure.

It was found that the oxidation of bromide to bromine by potassium dichromate or ceric ammonium sulfate is very slow and that the oxidation reaction by potassium permanganate proceeds fairly smoothly. However, the recovery of added bromide decreased with an increase in the standing time for the oxidation by permanganate, and satisfactory results were not obtained.

Recovery, %	70	70	72	71	71

Subsequently, the oxidation of bromide to bromine by permanganate and the extraction of the resulting bromine by benzene were made simultaneously. The extraction was carried out at 360 strokes/min using a shaker. As can be seen in Fig. 6, the absorbance at first changes rapidly with the shaking time, and then, after about 20 min, it does not change very much. In order to ascertain the recovery of added bromide after oxidation and extraction, some experiments were made using solutions containing various quantities of bromide.

The results listed in Table 1 show that recovery is about 70%, regardless of the amount of bromide. It was also found that the recovery of bromide increases slightly with an increase in the shaking

* The procedure of potassium hydroxide fusion was carried out.

rate. Even when bromine once extracted into benzene is shaken with a washing solution of 1.8N sulfuric acid, appreciable amounts of bromine do not move to the aqueous layer. Bromine extracted in benzene is stripped into the aqueous layer by shaking it for about 2 min with a sodium hydroxide solution.

The Effect of Diverse Ions. The effect of diverse ions on this method was studied, some experiments being made in the presence of 0.6 μg of bromide and in its absence. The experimental results given in Table 2 were obtained without fusion. Magnesium, iron, aluminum, and silicate do not interfere, even at high concentrations. Chloride interferes slightly at 500 μg. However, even if the sample contains a large amount of chloride, the bromine can be determined by decreasing amounts of the sample to be weighed, for fortunately, the bromine-to-chlorine ratios in igneous rocks are rather constant.[3],*1 Iodide does not interfere at 40 μg. As silver and mercuric ions react with bromide, they interfere even at low concentrations. However, the interference of mercury can be completely removed by fusion with potassium hydroxide. Most igneous rocks do not contain silver in concentrations which cause any serious interference.[9,10]

Table 3. Determination of bromine in some silicate rocks

Sample	Amount of sample, g	Br added μg	Br found μg		Br found in washed residue μg	Concn. of Br ppm (Average)

			0.37	0.40		1.48
	0.25	0.50	0.85	0.85		
III (Liparite)	0.25	—	0.64	0.63	(0.02)	
			0.61		(0.01)	2.51
	0.25	0.30	0.90	0.93		

*1 The results of the determination of bromine and other halogens in igneous rocks will be reported in a forthcoming paper.

9) K. Rankama and Th. G. Sahama, "Geochemistry," University of Chicago Press, Chicago (1950), p. 702.

10) M. Fleischer, *Geochim. Cosmochim. Acta*, **29**, 1263 (1965).

In practice, many metal ions occurring in silicate rocks are removed as precipitates by potassium hydroxide fusion. The amounts of bromine retained in the washed residue of fused silicate rock samples is small enough to be neglected. The amounts of bromine found in the washed residue are given in Table 3. These results were obtained by dissolving the washed residue with sulfuric acid (1.8N) and sodium sulfite solutions and using the method described under "Procedure and Calibration Curve."

The Results of Determination. The reproducibility of the method was tested by taking 0.25 to 0.5-g samples of various silicate rock samples and by then following the procedure described above. The method was also checked by adding known amounts of bromide to rock samples. The results shown in Table 3 demonstrate the reliability of the method.

According to these results, it may be concluded that the present method is satisfactory for the determination of bromine in rocks. By this method, bromine in samples with more than 0.04 ppm can be determined rapidly using only 0.25 to 0.5-g portions of the sample. The error in this method is about ± 0.03 μg at bromine of 0.50 μg and less at lower amounts.

The authors wish to express their sincere thanks to the Research Fund of the Kawakami Memorial Foundation for a research grant partly used in support of this work.

Spectrophotometric Determination of Diphenhydramine in Pharmaceutical Preparations

Masahiro TSUBOUCHI

Faculty of Education, Tottori University, Tottori

(Received May 29, 1970)

A spectrophotometric method is proposed for the determination of diphenhydramine in pharmaceutical preparations. The method is based on an addition-compound formation between diphenhydramine and the tetrabromophenolphthalein ethyl ester in 1,2-dichloroethane. Beer's law is obeyed over the range of 2.0×10^{-6}—1.0×10^{-5}M of diphenhydramine at 594 mμ. Optimum conditions are described. The effect of diverse substances and the composition of the colored species were also investigated.

The titrimetric method[1] has been used for the determination of diphenhydramine, which is widely used as antihistaminate. Cobalt nitrate - potassium thiocyanate - sulfuric acid[2] and nitric acid -sulfuric acid[3] have been described as spectrophotometric reagents for diphenhydramine. A fluorometric method[4] based on the oxidation of diphenhydramine has also been described.

Recently, plasmocorinth B[5] was proposed for the spectrophotometric determination of diphenhydramine by solvent extraction. This method can not, however, be used in the analysis of injections because it suffers from the interference of halide and calcium ions.

This paper will report the results of a study designed to develop a new spectrophotometric method for diphenhydramine by means of solvent extraction. The tetrabromophenolphthalein ethyl ester forms an addition compound with colorless diphenhydramine in 1,2-dichloroethane. In the absence of diphenhydramine, a yellow color was observed, while in its presence a red-violet color was developed.

Experimental

Apparatus. The spectrophotometric measurements were made with a Shimadzu QR-50 spectrophotometer, equipped with 10-mm cuvettes. An Iwaki Model KM shaker with a time switch was used for the extraction. The pH measurements were carried out with a Toa Denpa Model HM-5 pH meter.

Reagents. *Tetrabromophenolphthalein Ethyl Ester (TEE)*

1) J. P. VII-1, Part II, Nankodo (1965), p. 594.
2) G. Sekules and G. Guadagnini, *Boll. Chim. Farm.*, **103**, 432 (1964); *Chem. Abstr.*, 11853 (1964).
3) L. Molle, *J. Pharm. Belg.*, **5**, 339 (1950).
4) R. E. Jensen and R. T. Pflaum, *J. Pharm. Sci.*, **53**, 835 (1964).
5) H. Koike, K. Ohashi, M. Matsuo and A. Kawasaki, *Bunseki Kagaku*, **17**, 603 (1968).

Solution. Weighed amounts of tetrabromophenolphthalein ethyl ester potassium salt were dissolved in ethyl alcohol.

Standard Diphenhydramine Solution. A stock solution was prepared by dissolving 2.919 g of diphenhydramine hydrochloride (dried at 105°C) and diluting it to 1 *l* with water to make the solution 1.0×10^{-2}M. The stock solution was used to prepare the standard solution in the desired concentration.

Buffer Solution. The pH 8 buffer was prepared by mixing a 0.4M potassium dihydrogen phosphate solution and a 0.4M disodium hydrogen phosphate solution.

All the chemicals were of a reagent grade, and the water used was passed through an ion-exchange resin.

Procedure. *Standard Procedure.* Pipette 5 m*l* of a diphenhydramine solution (less than 5×10^{-5}M), 5 m*l* of a TEE solution (10^{-3}M), and 5 m*l* of the buffer solution into a 100-m*l* separatory funnel. Dilute the mixture to 25 m*l* with water and shake the solution for 2 min with 10 m*l* of 1,2-dichloroethane. After the separation of the two layers, run off the extract into a glass tube through filter paper to remove any droplets of water. Measure the absorbance of the extract at 594 mμ, using a reagent blank as a reference.

Injection. Dilute a sample with water and treat the solution in the same manner as with the standard procedure.

Powder and Tablet. Dissolve a sample containing about 5 mg of diphenhydramine in 50 m*l* of 0.01N sulfuric acid. Filter the solution with a glass filter and dilute the filtrate to 500 m*l* with water. Treat the solution in the same manner as with the standard procedure.

Ointment. Place a sample containing about 5 mg of diphenhydramine in a separatory funnel, and add 15 m*l* of ether. Extract the diphenhydramine three times with 30-m*l* portions of 0.03N sulfuric acid. Put all the extracts together into a 500-m*l* volumetric flask and make up to the mark with water. Treat the solution in the same manner as with the standard procedure.

Results and Discussion

Absorption Spectra. Figure 1 shows the visible absorption spectra of extracts treated as with the standard procedure. It can be seen that the presence of diphenhydramine leads to a considerable increase in the absorbance. The absorbance maximum of the extracts is at 594 mμ. This red-violet color in the organic layer may be attributed to the effect of the association between the TEE and the diphenhydramine.

Effect of pH. The absorbance of the extract is constant over the 7—9 pH range. In a more acidic or a more alkaline solution, the absorbance decreases, presumable because the TEE is not extracted into an organic solvent from a strong alkaline solution and because the diphenhydramine is not extractable from an acidic solution.

Effect of Reagents. Excess amounts of the phosphate buffer had no influence on the absorbance of the extract. When the buffer concentration was less than 0.05M in the aqueous layer, a good separation of the two layers was not observed.

The absorbance of the extract was constant if the TEE concentration was more than the 1.2×10^{-4}M initially present in the aqueous layer when the concentration of diphenhydramine was 1.0×10^{-5}M. With smaller amounts of TEE, low absorbances were obtained.

Solvent for Extraction. The behavior of various solvents in the extraction was studied. The solvents tested were benzene, butyl acetate, carbon tetrachloride, chloroform, cyclohexane, 1,2-dichloroethane, ether, ethyl acetate, *n*-hexane, isoamyl alcohol, methyl isobutyl ketone, monochlorobenzene, and toluene. Of these, dichloroethane was chosen for the present work because it gave the deepest color.

The Other Variables. Full color development took about 1 min of shaking. Continued shaking up to 5 min product no further change in the absorbance. The color intensity of the dichloroethane extracts remained constant for 1 hr. Normal room temperature fluctuations (14—26°C)

TABLE 1. EFFECT OF FOREIGN SUBSTANCES

Substance	Mole Ratio	Recovery (%)
Ammonium sulfate	1000	104.3
Calcium chloride	1000	99.0
Sodium carbonate	1000	102.1
Sodium chloride	1000	100.0
Sodium nitrate	1000	98.8
Potassium bromide	1000	100.0
Aniline	1000	99.7
Aminopyrine	5	125.1
Antipyrine	20	115.5
Benzyl alcohol	1000	99.6
Caffeine	10	117.7
Ethoxybenzamide	50	119.2
Glucose	1000	100.0
Lactose	1000	100.1
Noscapine	1	112.3
Phenacetine	5	116.5
Phenol	1000	93.8
Sodium acetate	1000	100.0
Sodium cirate	1000	100.2
Sodium salicylate	1000	99.8
Sodium tannate	1000	100.2
Vitamine C	1000	99.4
Starch	0.4 %	100.0

Diphenhydramine taken : 1.0×10^{-5}M

were without measurable effect on the absorbance.

Calibration and Precision. Figure 2 shows the calibration curve obtained according to the standard procedure.

The reproducibility of the proposed method was setimated from the results for ten sample solutions, each with a final diphenhydramine concentration of 1.0×10^{-5} M. The mean absorbance was 0.675, with a standard deviation of 0.006 absorbance unit.

Composition of the Colored Species. A sample (25 m*l*) containing 1.0×10^{-5}M of diphenhydramine was extracted with 10 m*l* of dichloroethane at pH 8. Then the amounts of diphenhydramine in the aqueous layer and organic layer were determined according to the proposed method. The extraction rate was about 94% in the absence of TEE, and 95% in its presence. These results indicate that diphenhydramine is extracted independently of TEE and is then associated with TEE in the organic solvent.

TABLE 2. ANALYSIS OF DIPHENHYDRAMINE IN COMMERCIAL SAMPLES

Sample	Diphenhydramine content	
	Titrimetric method	Proposed method
Injection*	9.98 mg/m*l*	9.97 mg/m*l*
Tablet*	91.0 mg/g	90.6 mg/g
Powder	99.7 mg/g	99.4 mg/g
Ointment	9.84 mg/g	9.87 mg/g

* Contained as diphenhydramine hydrochloride
All samples were obtained from a drugstore.

Continuous-variation plots were employed in order to investigate the composition of the colored species. The total concentration of TEE and diphenhydramine was kept constant at 1.6×10^{-5}M. The resulting curves at 594 and 560 mμ, in which the reagent blank has been subtracted, have a maximum at 0.5 mol fraction of diphenhydramine. It may, therefore, be suggested that a 1 : 1 addition compound is formed in the dichloroethane phase between TEE and diphenhydramine.

Effect of Foreign Substances. Table 1 shows the effect of diverse substances on the determination of diphenhydramine. Sodium chloride, tannate, benzyl alcohol, and starch, all of which are apt to be present in a pharmaceutical preparation with diphenhydramine, do not interfere.

Analysis of Practical Samples. Commercial samples used as antihistaminates were analyzed according to the proposed method and the titrimetric method.[1] The results obtained are summarized in Table 2.

The author would like to express his appreciation to Professor Y. Yamamoto of Hiroshima University for his valuable advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3167—3170 (1970)

Synthesis of Chelating Agents. VII.*1 Synthesis and Chelating Behavior of 2,3-Dinitrilo-1,2,3,4-tetrahydronaphthalene-*N*,*N*,*N*′,*N*′-tetraacetic Acid*2

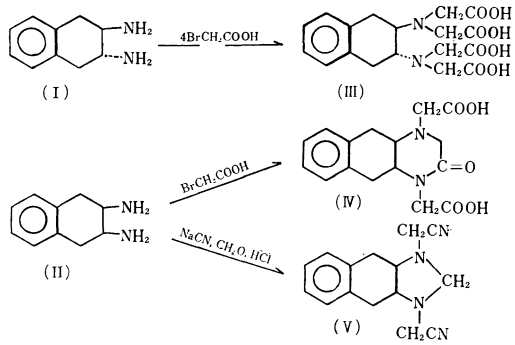
Tairoku YANO, Hiroshi KOBAYASHI and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received June 1, 1970)

trans-2,3-Dinitrilo-1,2,3,4-tetrahydronaphthalene-*N*,*N*,*N*′,*N*′-tetraacetic acid was synthesized by the carboxymethylation of *trans*-2,3-diaminotetrahydronaphthalene. The acid dissociation constants as well as the chelate stability constants for alkaline earth metal ions were determined by a potentiometric method. The results were compared with the values of other complexane ligands of the cycloalkane family.

Extensive investigations have been carried out on the relationship between the structures of complexane type ligands and their chelate stability constants.[1] In our previous paper, we reported on the effect of phenyl substitutions on the ethylenic carbons of ethylenedinitrilo-*N*,*N*,*N*′,*N*′-tetraacetic acid (EDTA) upon the chelate stability constants.[2] It was pointed out that the ease of taking a skew configuration with regards to the nitrilodiacetate groups plays an important role in governing the chelate stability constants of EDTA analogous ligands. In this connection, we have been interested in the synthesis of the derivatives of 1,2-cyclohexanedinitrilo-*N*,*N*,*N*′,*N*′-tetraacetic acid (C_yDTA) in which the ease of taking a skew configuration is controlled by fusing an additional cyclohexane or benzene ring to 4,5-position. This paper deals with the synthesis as well as the chelating behaviour of a new ligand, 2,3-dinitrilo-1,2,3,4-tetrahydronaphthalene-*N*,*N*,*N*′,*N*′-tetraacetic acid (THDTA). *trans*-THDTA was obtained by the carboxymethylation of *trans*-2,3-diamino-1,2,3,4-tetrahydronaphthalene, whereas *cis*-THDTA could not be obtained from the corresponding *cis*-diamine as in the case of *meso*-1,2-diphenyl ethylenedinitrilotetraacetic acid.[2] The acid dissociation constant and the chelate stability constants for alkaline earth metal ions of *trans*-THDTA, which were measured by the direct potentiometric titration method, were interpreted in relation to those of complexane ligands of the cycloalkane family.



Scheme

Experimental

IR spectra were measured with a Nippon Bunko Model DS 301 spectrophotometer, and NMR spectrum was obtained with a Varian A-60 spectrophotometer with tetramethylsilane as an internal standard.

Synthesis of Ligand. *trans-2,3-Dinitrilo-1,2,3,4-tetrahydronaphthalene-N, N, N′, N′-tetraacetic Acid (trans-THDTA) (III).* Tetraacetic acid was synthesized by the alkaline condensation of bromoacetic acid with *trans*-2,3-diamino tetrahydronaphthalene.*3 The condition of a typical run was as follows.

In a 100 m*l* reaction vessel, a solution of 1.8 g (0.008 mol) of *trans*-2,3-diamino tetrahydronaphthalene dihydrochloride in 30 m*l* of 50% ethanol was placed. The solution was neutralized to phenolphthalein with 7N aqueous sodium hydroxide. Into this solution, a solution of 6.86 g (0.046 mol) of bromoacetic acid in 10 m*l* of water which had been neutralized with sodium hydroxide solution below 10°C was added with stirring,

*3 *trans*-Diamine (I) and *cis*-diamine (II) are new compounds, and the details of the synthetic procedures and the structural proof will be reported elsewhere along with the other new 1,2-diamines such as 2,3-diaminodecahydronaphthalenes.

and the temperature of the mixture was raised to 40°C. The pH of the reaction mixture was maintained at 9—10 (red to phenolphthalein) with an occasional addition of 7N aqueous sodium hydroxide. After adding 0.032 mole of sodium hydroxide, the resulting mixture was acidified with concentrated hydrochloric acid to pH 1.6—1.8. Monosodium salt of *trans*-THDTA was obtained as colorless precipitates. The free acid of THDTA was prepared by dissolving the sodium salt into hot water, followed by the readjustment of the pH of the solution to 1.8. The crude acid was recrystallized from hot water, to give the pure *trans*-THDTA, which was dried over phosphorous pentoxide in vacuum at 60°C for 10 hr. Yield 40%. It decomposed at 245°C. IR: ν_{CO}, 1740. 1620 cm^{-1}.

Found: C, 54.90; H, 5.69; N, 6.98%; mol. wt. (Neutrl. equiv.) 391. Calcd for $C_{18}H_{22}N_2O_8$: C, 54.82; H, 5.62; N, 7.10%; mol. wt. 394.

Attempted Synthesis of cis-THDTA. In order to obtain the *cis* isomer of tetraacetic acid, various reactions such as the alkaline condensation of bromoacetic acid with *cis*-diamine (II),*3 the alkaline condensation of ethyl bromoacetate with diamine in ethanol, or the cyanomethylation of diamine using hydrocyanic acid and formaldehyde, were tried. However, the isolated products were, instead of *cis*-THDTA, a ketopiperazine derivative and an imidazolidine derivative which were the cyclocondensation products of the reaction intermediates.

In the case of the alkaline condensation of bromoacetic acid, which is carried out under a similar condition to that described in the synthesis of the *trans* isomer, white precipitates (IV) were obtained from the acidified reaction mixture. The pure material which was recrystallized from hot water, melted at 205—217°C with decomposition. Yield 63%. The result of elementary analysis and infrared spectrum confirmed that the product (IV) is 1,4-diaza-2-keto-1,2,3,4,4a,9,9a,10-octahydroanthracene-1,4-diacetic acid (IV). IR (KBr): ν_{CO}, 1760, 1680, 1620 cm^{-1};

Found: C, 60.43; H, 5.63; N, 8.69%. Calcd for $C_{16}H_{18}N_2O_5$: C, 60.63; H, 5.67; N, 8.80%.

In the case of the cyanomethylation, 1.3 g (0.016 mol) of 36% formaldehyde and 0.77 g (0.016 mol) of sodium cyanide were successively added into a cold solution of 1 g (0.004 mol) of the *cis*-diamine in 11 m*l* of 1.2N hydrochloric acid, and the resulting mixture was kept in a pressure bottle. It was allowed to stand for 45 hr at 40°C with occasional stirring. The white precipitates (V) from the reaction mixture was recrystallized from ethanol. Mp 180—183°C. From the result of elementary analysis, infrared spectrum and NMR spectrum, the product was proved to be 1,3-diaza-1,3-cyanomethyl-5,6-benzo-3a,4,7,7a-tetrahydroindane (V). IR (in Nujol): ν_{CN} 2220 cm^{-1}. NMR ($CDCl_3$): δ: 7.16 (strong singlet, 4H), 3.81 (doublet, J=3.5 Hz, 1H), 3.68 (strong singlet, 4H), 3.41 (doublet, J=3.5 Hz, 1H), 3.31 (broad band with fine structure, 2H), 2.73 (appreciable quartet, 4H).

Found: C, 71.49; H, 6.13; N, 22.69%. Calcd for $C_{15}H_{16}N_4$: C, 71.43; H, 6.35; N, 22.22%.

Determination of Acid Dissociation Constants and Chelate Stability Constants. The same apparatus as that described in a previous paper was employed.[4] Measurements were carried out at 25.0± 0.1°C in aqueous solutions under the ionic strength, μ, of 0.10 with potassium nitrate. For the determination of acid dissociation constants, 100 m*l* of a 0.8—0.9×10^{-3}M solution of the ligand was titrated with a solution of 0.1M potassium hydroxide freed from carbonate ion. For the determination of chelate stability constants with alkaline earth metal ions, the direct pH titration method was employed on 100 m*l* of a solution (8×10^{-4}M in ligand and in metal ions).

Calculations

Calculation of the Acid Dissociation Constants. The titration curve of *trans*-THDTA is shown in Fig. 1. The acid dissociation scheme of the ligand can be expressed as follows:

$$H_4Y \rightleftarrows H_3Y^- + H^+$$
$$Ka_1 = [H_3Y^-][H^+]/[H_4Y]$$
$$H_3Y^- \rightleftarrows H_2Y^{2-} + H^+$$
$$Ka_2 = [H_2Y^{2-}][H^+]/[H_3Y^-]$$
$$H_2Y^{2-} \rightleftarrows HY^{3-} + H^+$$
$$Ka_3 = [HY^{3-}][H^+]/[H_2Y^{2-}]$$
$$HY^{3-} \rightleftarrows Y^{4-} + H^+$$
$$Ka_4 = [Y^{4-}][H^+]/[HY^{3-}]$$

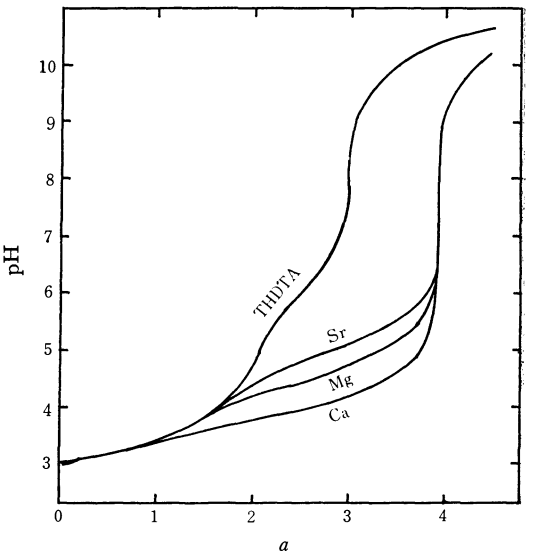

Fig. 1. Titration curves of THDTA.
Concn. of ligand and metal ions: 0.8×10^{-3}M
For the titration of ligand only: 0.9×10^{-3}M

It can be seen from Fig. 1 that the titration curve is essentially the same as that of EDTA and dissociation of the first two steps, third step and fourth step is clear. The acid dissociation constants of the ligand were calculated by two different methods; *i. e.*, the method of Schwarzenbach,[3] except that

3) G. Schwarzenbach, A. Willi and R. O. Bach, *Helv. Chim. Acta*, **30**, 1303 (1947).
4) T. Ando, This Bulletin, **36**, 1593 (1963).

an algebraic method of solution was used instead of a graphical one, and the method of Bjerrum as modified by McIntyre.[5]

a) Schwarzenbach's Method. The final equations for the first two dissociation steps are:

$$K_{a_2}[(2-a)C_A-[H^+]] - (aC_A+[H^+])[H^+]^2/K_{a_1} = [(a-1)C_A+[H^+]][H^+] \quad (1)$$

For the calculation of K_{a_3} and K_{a_4}, the following equations were used:

$$K_{a_3} = \{[H^+]\{(a-2)C_A+[H^+]-[OH^-]\}\}/\{C_A-\{(a-2)C_A+[H^+]-[OH^-]\}\} \quad (2)$$

$$K_{a_4} = \{[H^+](a-3)C_A-K_W\}/\{(4-a)C_A+[OH^-]\} \quad (3)$$

where a represents the moles of alkali added per mole of the ligand, C_A, the total ligand concentration and K_W, the ionic product of water.

b) Bjerrum's Method. The final equations for the first three dissociation steps are:

$$\bar{n} = J_1/K_{a_3} + J_2/K_{a_2}\cdot K_{a_3} + J_3/K_{a_1}\cdot K_{a_2}\cdot K_{a_3} \quad (4)$$

$$\bar{n}' = J_1'/K_{a_3} + J_2'/K_{a_2}\cdot K_{a_3} + J_3'/K_{a_1}\cdot K_{a_2}\cdot K_{a_3} \quad (5)$$

$$\bar{n}'' = J_1''/K_{a_3} + J_2''/K_{a_2}\cdot K_{a_3} + J_3''/K_{a_1}\cdot K_{a_2}\cdot K_{a_3} \quad (6)$$

where $\bar{n}$ represents the mean number of protons attached to the ligand, and

$$J_n = (n-\bar{n})[H^+]^n \quad (7)$$

For the calculation of K_{a_4}, equation (3) was used.

The results of both calculations are summarized in Table 1. The values for K_{a_2}, K_{a_3} and K_{a_4} are in fairly good agreement for both methods.

Calculation of the Chelate Stability Constants. By analogy with C_yDTA, THDTA will form almost exclusively the 1 : 1 chelate with multivalent metal ions.

$$M + Y \rightleftarrows MY \quad K_{MY} = [MY]/[M][Y] \quad (8)$$

Therefore, the calculation of the chelate stability constant K_{MY} can be carried out according to Bjerrum's standard procedure.[6] The final equation can be written as follows:

$$K_{MY} = \{C_A-\alpha[Y^{4-}]\}/\{C_M-C_A+\alpha[Y^{4-}]\}\cdot[Y^{4-}] \quad (9)$$

where C_A and C_M represent the total concentration of the ligand and the metal ion, respectively, and

$$\alpha = [H^+]^4/K_{a_1}\cdot K_{a_2}\cdot K_{a_3}\cdot K_{a_4} + [H^+]^3/K_{a_2}\cdot K_{a_3}\cdot K_{a_4} + [H^+]^2/K_{a_3}\cdot K_{a_4} + [H^+]/K_{a_4} + 1 \quad (10)$$

$$[Y^{4-}] = \{(4-a)C_A-[H^+]+[OH^-]\}/\{4[H^+]^4/K_{a_1}\cdot K_{a_2}\cdot K_{a_3}\cdot K_{a_4} + 3[H^+]^3/K_{a_2}\cdot K_{a_3}\cdot K_{a_4} + 2[H^+]^2/K_{a_3}\cdot K_{a_4}+[H^+]/K_{a_4}\} \quad (11)$$

The K_{MY} value was determined as a mean of K_{MY} values which were computed by Eq. (9) using Bjerrum's pK_a values, and a series of experimental values of a and $[H^+]$ during the course of titration. The results are summarized in Table 2.

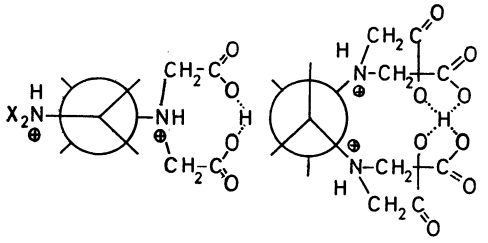
Results and Discussion

Acid Dissociation Constants. It may be convenient to discuss the acid dissociation constants and chelate stability constants of *trans*-THDTA in comparison with those of *trans*-C_yDTA which has a similar skeletal structure to *trans*-THDTA. As shown in Table 1, the pK_{a_1} and pK_{a_2} values are quite different from pK_{a_3} and pK_{a_4} values. Thus, *trans*-THDTA is expected to exist as zwitter ions in an aqueous solution as in the case of *trans*-C_yDTA, where the acid dissociations of the first two and the last two steps are known to correspond to the dissociation of carboxylic protons and ammonium protons, respectively.

In an aqueous solution, *trans*-C_yDTA is considered to exist as the skew form with regard to the nitrilodiacetate groups, as this form is more stable thermodynamically than the trans form because of the steric repulsions of axial protons at 3 and 5 positions and the axial nitrilodiacetate group at 1 position. On the other hand, the trans form is more stable than the skew form for EDTA because of the electrostatic repulsion of the two nitrilodiacetate groups. It is easily recognized from Table 3 that the smaller ΔpK_{2-1} (pK_{a_2}–pK_{a_1}) values are obtained for the ligands having the trans configuration, while the larger ΔpK_{2-1} values are obtained for the ligands having the skew configuration. This result may be explained as follows. After the dissociation of the first carboxylic proton, the second carboxylic proton will be bound by two carboxylic groups in the ligand of the trans form. On the other hand, the proton will be bound by four carboxylic groups in the ligand of a skew form. Therefore, the second proton is more difficult to dissociate in the skew form ligands, resulting in the larger ΔpK_{2-1} values. This situation is schematically shown in Fig. 2. Thus, *trans*-THDTA is also considered to take the skew configuration with regard to the nitrilodiacetate groups.



trans skew

Fig. 2. Hydrogen bonding in carboxylic groups.

TABLE 3. ΔpK_{2-1} AND ΔpK_{4-3} VALUES OF RELATED LIGANDS

Ligand	ΔpK_{2-1}	Favorable configuration of two nitrilodiacetate groups.
trans-THDTA	1.29	skew
trans-C_yDTA	1.15	skew
cis-C_yDTA	1.06	skew
EDTA[11]	0.67	trans
MEDTA[12]	0.43	trans
trans-CPDTA	0.51	trans

MEDTA: 1-Methylethylenedinitrilo-*N,N,N',N'*-tetraacetic acid.

The ease of dissociation of the third proton is usually correlated with the electrostatic repulsion of protonated nitrogens, and that of the fourth proton with the basicity of nitrogen as well as the ease of hydrogen bond formation between the two nitrogen atoms. It is seen from Table 1 that the smallest pK_{a_3} is observed for *cis*-C_yDTA and the largest for *trans*-CPDTA in cycloalkane derivatives. Kroll explained the differences of pK_{a_3} values by estimating the N–N distances of these ligands as 2.0 Å for *cis*-C_yDTA and 3.5 Å for *trans*-CPDTA.[1] However, his estimation for *cis*-C_yDTA does not seem to be reasonable. According to our estimation, the N–N distance of *cis*-C_yDTA, *trans*-(e,e)-C_yDTA as well as *trans*-THDTA have about the same value 2.8 Å. Therefore, the electrostatic repulsion of protonated nitrogens may be the same order for these ligands. It is likely that pK_{a_3} of these ligands are influenced by some other factors.

The values of pK_{a_4} are approximately the same except for *trans*-C_yDTA, and the result can not clearly be correlated with the effect caused by the fusion of aromatic ring to cyclohexane ring.

Chelate Stability Constants. The stability constants of the alkaline earth chelates of *trans*-THDTA are listed in Table 2, along with those of *trans*-C_yDTA and *trans*-CPDTA. Although the values for *trans*-THDTA lie in between those for *trans*-C_yDTA and *trans*-CPDTA, not much difference is found among those values. We should wait for more detailed discussion on the chelate stability constants, until we get other ligands of the cycloalkane family.

Thus, the fusing of benzene ring to the cyclohexane ring does not influence greatly the acid dissociation constants and the chelate stability constants. It is necessary to compare these results with that of the complexanes derived from trans decahydronaphthalene, where the puckering of cyclohexane ring is not allowed.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3171—3175 (1970)

A Spectrophotometric Study of Indoferron as a Color Reagent for Zirconium(IV) and Iron(III)*1

Takayoshi SAKAI

Hachinohe Technical College, Tamonoki, Hachinohe, Aomori

(Received June 10, 1970)

Indoferron is shown to be a useful spectrophotometric reagent for the determination of zirconium(IV) and iron(III). An excess reagent reacts with zirconium(IV) and iron(III) to form blue complexes, which have absorption maxima at 605 and 590 mμ respectively against the reagent blank. The maximum absorbances of the solutions containing the complexes are obtained in the pH range from 3.6 to 3.7 for zirconium(IV), and in that from 3.9 to 4.1 for iron(III). The former complex is stable for 1 hr, and the latter, for 4 hrs. The color systems obey Beer's law in 25 m*l* over the ranges up to 40 μg Zr and up to 50 μg Fe respectively. The molar absorptivities of the complexes are calculated to be 3.18×10^4 for zirconium(IV) and 1.81×10^4 for iron(III). The sensitivities of the reactions are 0.0038 μg Zr/cm^2 and 0.0039 μg Fe/cm^2 for an absorbance of 0.001. As for composition, the complexes used have a metal-to-ligand ratio of 1:3 for zirconium(IV) and 1:2 for iron(III). The apparent formation constant of the complex for iron(III) is calculated to be $7.81\times10.^{10}$

Indoferron [2,6-dibromo-3′-methyl-5′-*N*,*N*-di(carboxymethyl)aminomethyl-indophenol] was prepared by Körbl *et al.*[1] as a chromogenic dye-stuff. They studied the complex formation between this reagent and such metal cations as bismuth(III), thorium(IV), scandium(III), and iron(III), and discussed the molar absorptivities of the complexes thus formed. Recently, the spectrophotometric determination of scandium(III) with the reagent has been described by Shimizu and Ogami.[2]

A preliminary investigation was undertaken to evaluate the usefulness of indoferron as a spectrophotometric reagent for various metal cations: bismuth(III), thorium(IV), iron(III), zirconium(IV), vanadium(IV), gallium(III), indium(III), and copper(II). The reagent reacts with those metal cations in a slightly acidic medium (~pH 5.5) to form colored complexes. The results show that indoferron may be useful as a color reagent for the spectrophotometric determination of these metal cations; in every case, the chelation occurs instantaneously at room temperature; all the complexes formed are water-soluble; and their molar absorptivities are of the order of 10^4.

This paper will describe the fundamental conditions for the spectrophotometric determinations of zirconium(IV) and iron(III). Indoferron is not a very good reagent for these elements, but the properties of these complexes are worth being analysed.

Experimental

Reagents and Apparatus. *Indoferron* (abbreviated IF; MW, 560.12 as Na_2 salt) *Solution.* A 1×10^{-3}M IF solution was prepared by dissolving the Dotite IF reagent in water; fresh solutions were used for each set of experiments.

Zirconium(IV) Solution. A 1×10^{-2}M zirconium(IV) solution was prepared by dissolving a guaranteed zirconyl nitrate dihydrate in about 2N perchloric acid. The solution was standardized by EDTA titration, using xylenol orange as the indicator.[3]

Iron(III) Solution. About a 1×10^{-2}M iron(III) solution was prepared by dissolving purified iron(III) hydroxide in 1N perchloric acid. The solution was standardized by EDTA titration, using Cu-PAN as the indicator.[4]

Stock solutions of diverse ions were prepared from their reagent-grade chemicals in appropriate concentrations.

A 0.25 or 2M acetic acid - sodium acetate buffer solution was used for the pH adjustment.

A Hitachi recording spectrophotometer with 1-cm cells, Model 124, was used for the absorbance measurements. A Hitachi-Horiba glass-electrode pH meter,

Model M-5, was used for the pH measurments.

All the measurements were made at 25±0.5°C.

Results and Discussion

Absorption Curves. *Indoferron.* Measurements were made as a function of the pH. As is shown in Fig. 1, below pH 4, the solution has an absorption maximum at about 485 mμ. Between pH 5 and 9, however, the solution has an absorption maximum at about 617 mμ. Above pH 9, this absorption maximum shifts towards a lower wavelength; it is at 580 mμ in the pH range from 11 to 14.

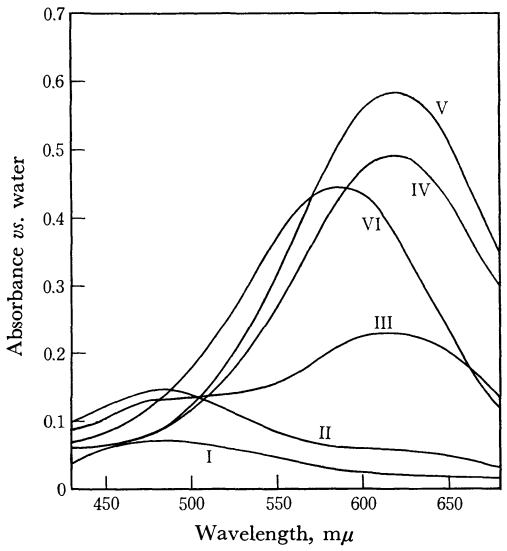

Fig. 1. Absorption curves of IF.
IF: 4.0×10^{-5}M, μ=01, pH—I: 2.0, II: 4.0, III: 4.9, IV: 6.1, V: 9.0, VI: 11—14.

Some Metal-IF Complexes. An attempt was made to evaluate the usefulness of indoferron as a spectrophotometric reagent for several metal cations. To a solution containing a 2.0×10^{-5}M (finally) metal cation in a 25-m*l* volumetric flask, we added 2 m*l* of a 1×10^{-3}M IF solution and 10 m*l* of a 0.25M acetate buffer solution adjusted in the pH range from 2.0 to 5.5 (at intervals of 0.5). The solution was then diluted to the mark with water. The absorbances of the colored complexes were measured against the reagent blanks. The data thus obtained are summarized in Table 1.

Zirconium(IV)-IF Complex. A colored solution containing 23.0 μg of zirconium(IV) was measured in the same way. In this case, 10-m*l* portions of a 2M acetate buffer solution adjusted to various pHs were used. As Fig. 2 shows, the maximum absorption is found at 625 mμ below pH 2.5, at 605 mμ between pH 3 and 3.5, and at 590 mμ at pH 4.5. From the viewpoint of the sensitivity of the reaction, the complex with its absorption maximum at about 605 mμ was used for the determination of zirconium(IV).

Iron(III)-IF Complex. A colored solution containing 32.2 μg of iron(III) was measured in a manner similar to that used for the zirconium. In this case, 1 m*l* of a 1×10^{-3}M IF solution and 10 m*l* of a 0.25M acetate buffer solution were used. The curves were characterized by an absorption maximum at 590 mμ in the pH range from 2.5 to 4.5. Some of the results are shown in Fig. 3.

The Effect of pH. The absorbances of the solutions containing the complexes were measured

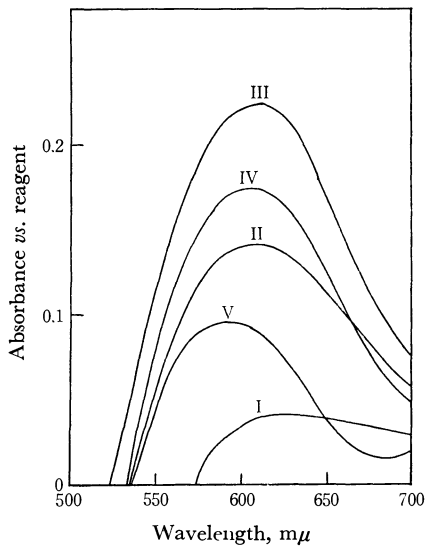

Fig. 2. Absorption curves of the solution containing complex in the presence of an excess of reagent over zirconium.
Zr: 23.0 μg (1.00×10^{-5}M), IF: 8.00×10^{-5}M, pH—I: 2.50, II: 3.00, III: 3.50, IV: 4.00, V: 4.50, μ=1.44.

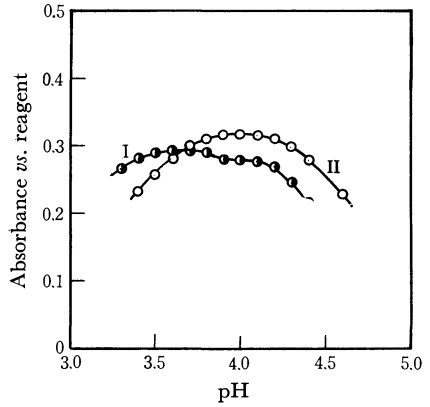

Fig. 4. Effect of pH.
I: Zr(IV); 25.1 μg, IF; 6.06×10^{-5}M, 605 mμ, μ; 1.44
II: Fe(III); 32.2 μg, IF; 4.00×10^{-5}M, 590 mμ, μ; 0.1

as a function of the pH. The ranges in which the highest absorbance was obtained were found to be pH 3.6—3.7 for zirconium(IV) and pH 3.9—4.1 for iron(III) (Fig. 4).

The Effect of the Reagent Concentration. A volume of 1.9—2.0 m*l* of a 1×10^{-3}M IF solution suffices for the complete development of color with less than 40 μg of zirconium, while 1.5—2.1 m*l* of a 1×10^{-3}M IF solution suffices with less than 50 μg of iron. The addition of more reagent decreased the absorbances.

Color Stability. The color of the zirconium system prepared at pH 3.65 was stable for 1 hr, while that of the iron system prepared at pH 4.0 was stable for 4 hr. Both color systems reached their maximum absorbances immediately after preparation.

Calibration Curves. From the foregoing results, the optimum conditions for determining zirconium and iron were derived. The procedures for preparing the calibration curves for these metal cations were as follows.

Zirconium(IV): To a sample solution containing up to 40 μg of zirconium in a 25-m*l* volumetric flask, we added 2.0 m*l* of a 1×10^{-3}M IF solution and 15 m*l* of a 2M acetate buffer solution with a pH of 3.65. After the solution had then been diluted to the mark with water, its absorbance was measured at 605 mμ against the reagent blank.

Iron(III): To a sample solution containing up to 50 μg of iron in a 25-m*l* volumetric flask, we added 1.8 m*l* of a 1×10^{-3}M IF solution and 10 m*l* of a 0.25M acetate buffer solution with a pH of 4.0. After the solution had then been diluted to the mark with water, its absorbance was measured at 590 mμ against the reagent blank.

The zirconium and iron systems obey Beer's law over the 2—40 and 1.5—50 μg ranges respectively in 25 m*l*. The optimum concentration ranges, as obtained from the curves drawn according to Ringbom,[5] are 10—30 μg for zirconium and 9—21 μg for iron. The molar absorptivities are 3.18×10^4 for zirconium and 1.81×10^4 for iron, while the sensitivities calculated[6] for $\log I_0/I=0.001$ are 0.0038 μg/cm² for zirconium and 0.0039 μg/cm² for iron. The reproducibilities of the methods, using 10 samples, each containing 20.94 μg of zirconium, and 9 samples, each containing 22.34 μg of iron, were then examined. The standard deviation were found to be 0.0028 absorbance unit, or 2.1%, for zirconium, and 0.0010, or 2.1%, for iron. The proposed method is comparable in sensitivity with the xylenol orange method[7] for zirconium and with the methylthymol blue method[8] for iron.

Considering the high sensitivity of zirconium(IV)-, iron(III)-, and others-IF complexes (Table 1), indoferron may well be considered a useful reagent for the spectrophotometric determination of these metal cations.

Effect of Diverse Ions. The effect of 29 cations and 12 anions on the zirconium(IV) and iron(III) determinations was examined separately. Many bi-, ter-, and quadrivalent metals and chelating agents interfered with both determinations, indicating that indoferron is not a selective reagent for zirconium and iron, in spite of its high sensitivity to these metals.

Composition of the Complexes. The compositions of the zirconium(IV) and the iron(III) complexes were determined by the method of con-

tinuous variation and by the mole-ratio method.

Zirconium(IV)-IF Complex. In the case of the former method, the maximum absorbance corresponded to a complex of the $Zr(Ligand)_3$ type at all the wavelengths investigated. The same results were also obtained by the mole-ratio method: the curves show sharp breaks at a zirconium(IV): ligand mole ratio of 1 : 3 (Fig. 5).

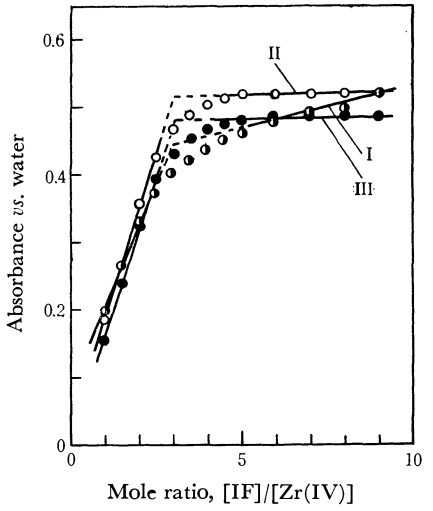

Fig. 5. Mole ratio method.
Zr(IV): 2.0×10^{-5}M, μ: 1.2, I: 565 mμ, II: 605 mμ III: 625 mμ, pH 3.65

Considering the ionic species of zirconium(IV) and the possibility of forming polymerized complexes, it is speculative to postulate a structure for the zirconium(IV)-IF complex. Therefore, no calculation of the formation constant was made.

Iron(III)-IF Complex. According to the method of continuous variation, the maximum absorbance corresponded to a complex of the $Fe(Ligand)_2$ type. Some of the results are shown in Fig. 6. The same results were also obtained by the mole-ratio method.

The apparent formation constant, K', was calculated from the curves shown in Fig. 6, using the relations:[9]

$$K' = C(1-\alpha)/(\alpha C)(2\alpha C)^2$$

$$\alpha = (E_m - E_s)/E_m$$

where C is the total concentration of the complex in moles per liter, α is the degree of dissociation, E_m is the maximum absorbance indicating that all the iron is present as a complex, and E_s is the absorbance at the stoichiometric molar ratio. The apparent formation constant at pH 4.0 was found to be 7.81×10^{10}.

Comparing the formation constants of the acetatocomplexes with those of hydroxocomplexes of iron(III),[10] it may be said that the latter complexes are not formed under the conditions investigated. Assuming that the indoferron serves as a terdentate ligand, the acetate ion in the acetatoiron(III) complexes may be eliminated by the chelate formation between iron(III) and indoferron. In other words, the coordination atoms of indoferron are found to be phenolic oxygen, nitrogen, and one of the two carboxyloxygens, and these atoms will coordinate with iron to form five- and six-membered rings.

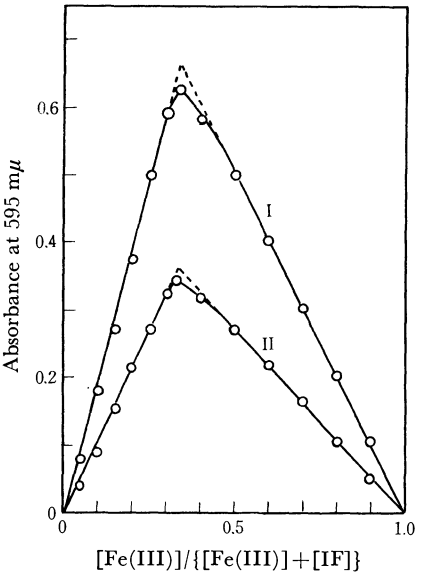

Fig. 6. Continuous variation method at pH 4.0.
[Fe(III)]+[IF]: I; 1.2×10^{-4}M, II; 0.6×10^{-4}M, μ: 0.5

Thus, this structure for the complex may be postulated:

The author wishes to express his hearty thanks to Professor Kôichi Tonosaki of Hirosaki University for his kind advice and instruction throughout this study, to Dr. Makoto Otomo for his helpful discussions, and also to Mr. Yoshinobu Wakamatsu and Mr. Keizo Demachi for their laboratory work.

Tri(hetero)substituted Carbonium Ions. III. Ring-size Effects on the Dual Reactivities of 2-Dimethylamino-1,3-dithiolanylium Ion and Its Ring Analogs as Ambident Electrophiles*1

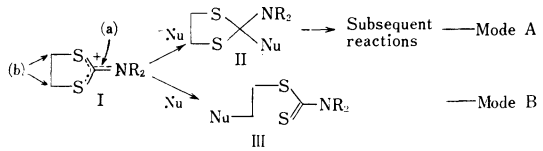
Takeshi NAKAI, Yoshio UENO and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro, Tokyo

(Received January 17, 1970)

The following ring analogs of 2-dimethylamino-1,3-dithiolanylium perchlorate (Ia) were prepared: 2-dimethylamino-1,3-dithianylium perchlorate (IV), 2-dimethylamino-1,3-dithiepanylium perchlorate (V) and an open-chain analog, bis(methylthio)dimethylaminocarbonium perchlorate (VI). In order to investigate the structural effect on the reactivities of the tri(hetero)-carbonium ions at two reactive sites, *i. e.*, the centered carbon (sp^2) (a) and the *S*-methylene carbon (sp^3) atoms (b), the reactions of these carbonium ions with hydroxide ion (mode A) and with *N,N*-dimethyldithiocarbamate ion (mode B), respectively, were studied at 30°C. The rates of mode A of these carbonium ions, relative to that of Ia, are 1 : 15.0 (IV) : 32.5 (V) : 1.06×10^4 (VI), and of mode B are 1 : 6.5 : 23.5 : $\approx2.0\times10^4$. In their electronic spectra a definite trend that as the ring-size increases there is a strong shift of absorption maxima toward the lower energies was observed. The fact suggests that the stability of the carbonium ion decreases with an increase in ring-size. On the basis of the schematic energy profiles for the two modes as well as the structural and kinetical aspects, it has been assumed that one of common factors contributing to the ring-size effect on both reactivities would be the stability of the carbonium ion.

In the preceding paper[1] we have reported that 2-dialkylamino-1,3-dithiolanylium ion (I) is an ambident electrophile with two reactive sites, (a) and (b), and reacts with the nucleophile ($^-$Nu) *via* reaction mode A and B to give cyclic product II (or its pyrolytic product) and ring-opening product III, respectively, according to the nucleophilicity of the attacking reagent used.



Furthermore, it has been assumed[1] that the reaction course is decided by the relative stability of the cation I to the kinetical adduct II. Thus, it is anticipated that both reaction course and dual reactivities of this type of tri(hetero)substituted carbonium ions would depend largely upon the structure of the carbonium ions.

In the present paper we will describe the ring-size effect on the dual reactivities of 2-dimethylamino-1,3-dithiolanylium ion (Ia) and its ring analogs as ambident electrophiles and discuss structural factors controlling the reactivities of these carbonium ions.

Results

Preparations of Carbonium Salts. Tri(hetero)substituted carbonium ions studied here are 2-dimethylamino-1,3-dithiolanylium ion (Ia) (five-membered), 2-dimethylamino-1,3-dithianylium ion (IV) (a six-membered analog), 2-dimethylamino-1,3-dithiepanylium ion (V) (a seven-membered analog) and bis(methylthio)-dimethylamino-

*1 Presented at the 18th Symposium on Organic Reaction Mechanisms, Kyoto, October, 1967.

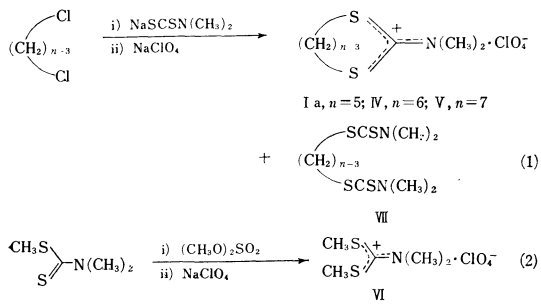
carbonium ion (VI) (an open-chain analog).[2] All these carbonium ions were isolated as perchlorates.

Cyclic carbonium perchlorates, Ia, IV and V, were prepared by the equimolar reaction of the corresponding α,ω-dichloroalkane with sodium *N,N*-dimethyldithiocarbamate in ethanol followed by treatment with sodium perchlorate (Eq. (1)).[3] In all cases the reaction was accompanied by the formation of the corresponding bis(dithiocarbamate) (VII), arising mainly from the interaction between the cyclic carbonium ion formed and the dithiocarbamate anion *via* mode B.[4] The yield of disubstituted product VII under the equimolar condition increases with the ring-size *n* (Table 1). The fact suggests that with an increase in ring-size participation of the dithiocarbamate function might be favorably involved in the second substitution process from the monosubstituted intermediate to the disubstituted VII.[4,5]

Open-chain carbonium perchlorate (VI) was prepared by methylation of *S*-methyl *N,N*-dimethyldithiocarbamate with dimethyl sulfate[6] followed by treatment with sodium perchlorate (Eq. (2)).



(1)

(2)

These carbonium ions were identified by elemental analyses and NMR spectra. Characterization and spectral data of carbonium perchlorates obtained are summarized in Table 1, along with yields of disubstituted product VII.

Reactions as Ambident Electrophiles. It has been reported that the reaction of five-membered cation Ia with hydroxide ion yielded β-mercaptoethyl *N,N*-dimethylthiolcarbamate (VIII, $n=5$).[1] Similarly six-membered IV and open-chain VI gave γ-mercaptopropyl thiolcarbamate (VIII, $n=6$)[3] and methyl thiolcarbamate, respectively. These hydrolytic products are best explained as the result of initial attack of hydroxide ion at the reactive site (a) followed by proton transfer (Eq. (3)). On the other hand, it has been shown that the reaction of Ia with *N,N*-dimethyldithiocarbamate anion yielded ethylene bis(dithiocarbamate) (VII, $n=5$) in the quantitative yield.[1] Similarly reactions of other cyclic carbonium ions and open-chain VI with the dithiocarbamate anion afforded the corresponding bis(dithiocarbamate) (VII) and methyl *N,N*-dimethyldithiocarbamate, respectively. The formation of these products may be explained by attack of the dithiocarbamate anion at site (b) presumably through the SN2-like mechanism (Eq. (4)).[1,4]

Thus, in order to estimate both reactivities at the two sites of each carbonium ion, the rates of reactions of the carbonium ion with hydroxide and the dithiocarbamate ions selected as typical reactions of mode A and B, respectively, were measured.

The reactions of the carbonium salt with hydrox-

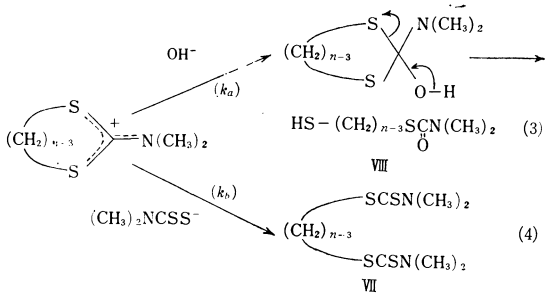
6) H. V. Rinteln and O. Riester [*Mitt. Forshungslab. Agfa Leverkusen-München*, **1**, 65 (1955); *Chem. Abstr.*, **51**, 7013 (1957)] have reported the formation of the methyl sulfate salts of bis(alkylthio)dialkylaminocarbonium ions, but no carbonium salts were isolated.



ide ion and water in aqueous solutions were undertaken in buffer solutions at 30°C under pseudo-first-order conditions. The rate of disappearence of the carbonium ion was followed by spectrophotometry. As the hydroxide concentration is essentially constant, the rate equation may be represented as

$$k_{obs} = k_{H_2O} + k_a[OH^-]$$

where $[OH^-]$ and k_{obs} refer to the hydroxide concentration and the observed pseudo-first-order rate constant, respectively. The plots of k_{obs} against $[OH^-]$ for these carbonium ions were linear in the ranges of the hydroxide concentrations studied. From the slopes and intercepts of these plots, we obtained the values of the second-order rate constant (k_a) for reaction with hydroxide ion and the pseudo-first-order rate constant (k_{H_2O}) for reaction with water (Table 2).

Table 2. Hydrolyses of carbonium perchlorates

Cation	Ring-size n	$[OH^-]$, mol/l	$10^5\,k_{obs}$ sec^{-1}	$10^6\,k_{H_2O}$ sec^{-1}	k_a $mol^{-1}l$ sec^{-1}

		12.6	12.3		

On the other hand, the reaction of the carbonium ion with sodium *N,N*-dimethyldithiocarbamate was studied in dimethylformamide (DMF) at 30°C under the equimolar condition. The rate of reaction was measured by following the disappearance of the dithiocarbamate anion using the previously-reported method.[4] From the slopes of the second-order rate plots (Fig. 1), we obtained the values of the rate constant (k_b) for reaction of the cyclic cations with the dithiocarbamate ion. The rate of reaction of open-chain VI with the anion was too large to be accurately measured by this method. The value of k_b for VI was found to be approximately 26.0 $mol^{-1}l\ sec^{-1}$. The values of the relative k_b obtained are shown in Table 3 together with those of the relative k_a.

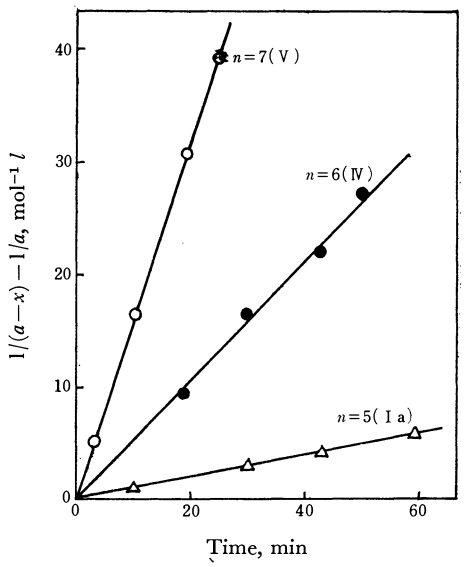

Fig. 1. Second-order rate plots for the cyclic carbonium ions at 30°C under the equimolar condition; a=0.03 mol/l.

Table 3. The relative k_a and k_b for the carbonium ions at 30°C

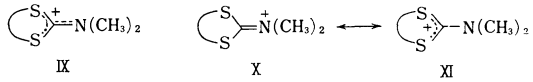
Discussion

Structural Aspects. The carbonium ions concerned are strongly stabilized by accepting electrons from α-hetro atoms, and so the positive charge is widely delocalized as expressed in formula IX.



The *exo*-iminium structure X would be more important rather than the sulfonium XI if the cation is not subject to any steric requirements as in the case of open-chain VI, since the electron-donating power of the dimethylaminogroup is much larger

than the alkylthio groups. In the electronic spectra of these carbonium salts (Table 1), there is a definite trend that as the ring-size increases there is a strong shift of absorption maxima (λ_{max}) toward the lower energies (the longer wavelengths) (Fig. 2).

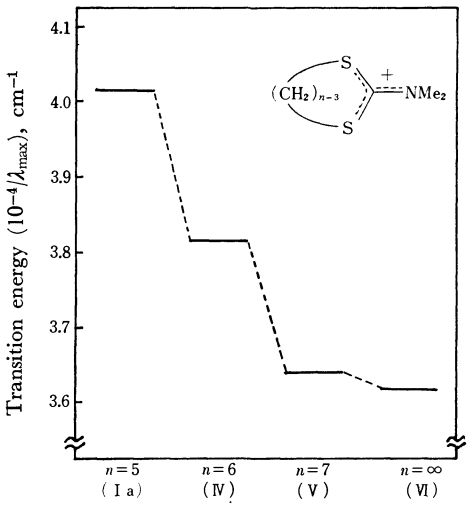


Fig. 2. The ring-size effect on the transition energy of the carbonium ions.

A similar trend has also been observed in the electronic spectra of a series of cyclic alkenylcarbonium ions.[7] This observation has been interpreted by the idea that one of factors contributing to the ring-size effect on a band shift may be that 1,3-π-overlap will be progressively more significant as the bond angle between the three conjugating carbon atoms decreases. The ring-size effect on band shifts is implicit in Mulliken's[8] and Walsh's[9] treatment of bonding in triatomic systems.

Appling the idea to the tri(hetero)carbonium ions concerned, the spectral trend suggests that α-hetero atoms stabilize the ground state more than the excited state[10] and, hence, as the ring-size decreases, the ground state is more stabilized presumably due to the more developed 1,3-overlap in the ring system, *i. e.*, $\overset{+}{\overbrace{S\cdots C\cdots S}}$, as found experimentally. In other words, contribution of the sulfonium structure XI to stabilization of the carbonium ion progressively increases with decrease in ring-size.

The ring-size effect on stabilization described above is also implicit in the NMR spectra (Table 1). A change in ring-size appears to affect the chemical shifts of the *S*-methylene protons in the ring more greatly rather than those of the *N*-methyl protons. The *S*-methylene protons of five-membered Ia are deshielded more than those of other ring analogs presumably due to more favorable contribution of the sulfonium structure.

Ring-size Effects on Reactivities. The kinetical results obtained indicate that reactivities of these carbonium ions at the two reactive sites are progressively enhanced as the ring-size increases (Fig. 3). In the light of these results our task is now to consider factors contributing to the ring-size effects on reactivities.

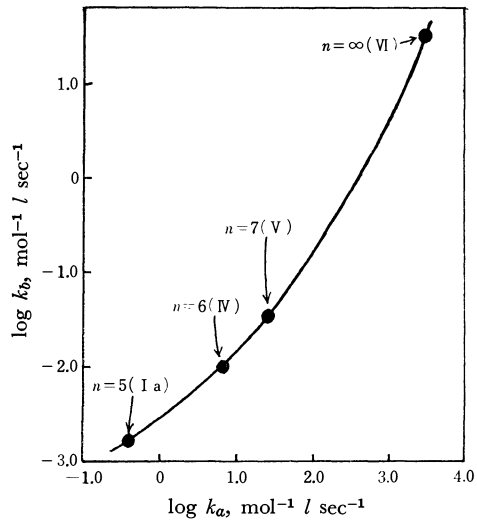

Fig. 3. Plot of log k_a (mode A) *vs.* log k_b (mode B).

As has been assumed,[1] the mode A process initially yields a kinetically-controlled product and the activation free energy ($\Delta F_A^{\neq}$) is small since the primary process of mode A involves an association between a cation and an anion. Thus, the reaction of the carbonium ion with hydroxide ion might be a expressed as follows:

$$R^+ + OH^- \overset{K}{\rightleftharpoons} ROH \underset{\text{(fast)}}{\longrightarrow} \text{VIII}$$

where R^+ and ROH are the carbonium ion concerned and the carbinol, respectively. The overall rate constants (k_a) would be proportional to the equilibrium constant (K). Consequently the rate of mode A should depend upon the relative position between R^+ and ROH in the energy diagram.

7) G. A. Olah, C. U. Pittman, Jr., and M. C. R. Symons, "Carbonium Ions," Vol. 1, G. A. Olah and P. von R. Schleyer, Ed., Interscience Publishers, New York (1968), Chapter 5.

8) R. S. Mulliken, *Can. J. Chem.*, **36**, 10 (1958).

9) A. D. Walsh, *J. Chem. Soc.*, **1953**, 2266.

10) Another definite evidence for this idea has been presented that as the methylthio group in tris(methylthio)carbonium ion is progressively replaced by the dimethylamino group, there is a strong shift of absorption maxima to the higher energies (the shorter wavelengths): T. Nakai, K. Hiratani and M. Okawara, the 3rd Symposium on Organic Sulfur Chemistry, Tokyo, 1969. Furthermore, this idea has been confirmed by simple HMO calculations: T. Nakai and M. Okawara, the 23rd Annual Meeting of the Chemical Society of Japan, Tokyo, 1970.

Although it is easy to estimate the stability of ROH, the relative stability of R^+ may be evaluated in terms of the absorption maximum (λ_{max}) as described above.

The kinetical result shows that increasing k_a-values are paralleled by increasing ring-sizes, *i. e.*, by decreasing stabilities of the carbonium ions; this fact suggests that an increase in ring-size would lower the stability of the carbonium ion, at least to a more extent, rather than that of the carbinol. On the basis of the schematic energy profile for mode A (Fig. 4),[11] the free energy gap between

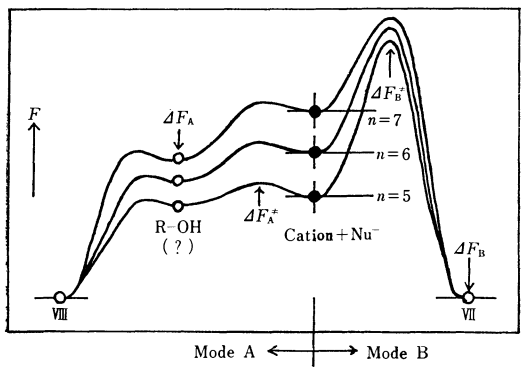

Fig. 4. Schematic energy profiles for mode A and B. Strictly speaking, the energy content of the initial system, cation and Nu^-, depends on the nature of Nu^-. However, since the nucleophile remains constant, this energy content of the respective mode is determined solely by the nature of the cation.

the cation and the carbinol (ΔF_A) increases as the ring-size increases. In short, it may be noted that the rate of mode A depends upon the stability of the carbonium ion varying mainly with ring-size.

On the other hand, the reaction of mode B is irreversible. Accordingly it can be assumed[1,11] that in contrast to mode A the rate of reaction with the dithiocarbamate ion is determined by the magnitude of the activation free energy ($\Delta F_B^{\neq}$) rather than that of ΔF_B in the schematic energy profile for mode B (Fig. 4). The kinetical result shows that the rate of mode B increases in the same order as that of mode A (Fig. 3); this fact suggests that an increase in ring-size would lower the stability of the carbonium ion, at least to a more extent, rather than that of the transition state. In consequence an increase in ring-size results in a stepwise lowering of the energy gap ($\Delta F_B^{\neq}$), as found experimentally. However, large differences in rate (k_a and k_b) between seven-membered V and open-chain VI, of which stabilities appear to be almost the same from their absorption maxima, cannot reasonably explained in the present stage.

In any case, these considerations permit only a qualitative conclusion that one of significant factors controlling both reactivities may be the stability of the ground state of the carbonium ion varying with the extent of 1,3-overlap in the ring system.

11) For similar considerations, *e. g.*, see S. Hünig, *Angew. Chem. Internat. Ed.*, **3**, 548 (1964) and Ref. 14 in the preceding paper.[1]

Experimental

General. Melting and boiling points are uncorrected. The IR and UV spectra were recorded with Hitachi EPI-S2 and EPS-2 spectrometers, respectively. The NMR spectra were determined with a Varian Associates A-60 spectrometer. Chemical shifts are reported in parts per million (ppm) from tetramethylsilane as an internal standard.

2-Dimethylamino-1,3-dithiolanylium Perchlorate (Ia). The carbonium perchlorate was prepared by the procedure reported in the previous paper[1]: mp 179—180°C.

2-Dimethylamino-1,3-dithianylium Perchlorate (IV). 1,3-Dichloropropane (12.3 g, 0.11 mol) was added to a solution of 20.0 g (0.11 mol) of sodium *N,N*-dimethyldithiocarbamate in 75 m*l* of ethanol. The mixture was stirred at 60°C for 6 hr. The mixture was concentrated in reduced pressure and then poured into 100 m*l* of cold water giving 2.4 g (23%) of disubstituted product VII ($n=6$): mp 108—109°C (ethanol).

Found: C, 38.25; H, 6.61; N, 9.87%. Calcd for $C_9H_{18}N_2S_4$: C, 38.26; H, 6.42; N, 9.92%.

The filtrate was extracted with ether and an excess of a saturated aqueous solution of sodium perchlorate was added to the aqueous layer giving 8.0 g (27%) of white precipitates of IV: mp 97—99°C (methanol).

Found: C, 27.73; H, 4.68; N, 5.59%. Calcd for $C_6H_{12}ClNO_4S_2$: C, 27.53; H, 4.62; N, 5.32%.

2-Dimethylamino-1,3-dithiepanylium Perchlorate (V). 1,4-Dichlorobutane (26.5 g, 0.21 mol) was added to a solution of 36.0 g (0.20 mol) of sodium *N,N*-dimethyldithiocarbamate in 75 m*l* of ethanol. The mixture was stirred at 60°C for 6 hr. The mixture was concentrated in reduced pressure and poured into cold water giving 12.4 g (48%) of disubstituted product VII ($n=7$): mp 112—113°C.

Found: C, 40.09; H, 6.95; N, 9.71%. Calcd for $C_{10}H_{20}N_2S_4$: C, 40.54; H, 6.80; N, 9.46%.

To the filtrate there was added 100 m*l* of a saturated aqueous solution of sodium perchlorate. The mixture was cooled in an ice box for a few days giving about 4.0 g (10%) of very hygroscopic white precipitates of V. These precipitates were washed several times with ether and dried *in vacuo*: mp 58—60°C.

Found: C, 29.94; H, 4.72; N, 4.97%. Calcd for $C_7H_{14}ClNO_4S_2$: C, 30.49; H, 5.12; N, 4.97%.

Bis(methylthio)-dimethylaminocarbonium Perchlorate (VI). *S*-Methyl *N,N*-dimethyldithiocarbamate (13.5 g, 0.01 mol) was dissolved in 12.6 g (0.01 mol) of dimethyl sulfate. When the mixture was heated to 60°C a vigorous exothermic reaction occurred. The reaction temperature was kept below 100°C. After the exothermic reaction ceased the mixture was further stirred at 90°C for 1 hr. The mixture was poured into 100 m*l* of a

saturated aqueous solution of sodium perchlorate giving 19.0 g (76%) of pale yellowish precipitates. The precipitates were washed with ether and recrystallized from methanol giving white precipitates: mp 84—86°C.

Found: C, 23.73; H, 4.68; N, 5.13%. Calcd for $C_5H_{12}ClNO_4S_2$: C, 24.05; H, 4.85; N, 5.61%.

Products. A. Hydrolyses of Carbonium Perchlorates. 2-Dimethylamino-1,3-dithiolanylium perchlorate (Ia) was hydrolyzed to afford β-mercaptoethyl *N,N*-dimethylthiolcarbamate.[1] Similarly 2-dimethylamino-1,3-dithianylium perchlorate (IV) gave γ-mercaptopropyl *N,N*-dimethylthiolcarbamate.[3] No attempt was made to isolate the hydrolytic product of V.

Bis(methylthio)-dimethylaminocarbonium perchlorate (VI) (12.5 g, 0.05 mol) was added to a solution of water (1.0 g, 0.05 mol) and triethylamine (5.0 g, 0.05 mol) in 50 m*l* of dioxane. The mixture was stirred at 80°C for 6 hr, then poured into water. The ethereal extract was dried over sodium sulfate and the solvent evaporated *in vacuo*. Distillation of the residue gave 3.7 g (62%) of *S*-methyl *N,N*-dimethylthiolcarbamate: bp 91—92°C/31 mmHg; n_D(21°C) 1.4964 (lit.[12] bp 115—116°C/89 mmHg; n_D(30°C) 1.4932); IR (neat): 1650 cm^{-1} (C=O). The IR spectrum of the distillate was in agreement with that of the authentic sample.

B. Reactions of Carbonium Perchlorates with Sodium *N,N*-Dimethyldithiocarbamate. The reaction of Ia with sodium *N,N*-dimethyldithiocarbamate afforded ethylene bis(*N,N*-dimethyldithiocarbamate) (VII(n=5)) in the quantitative yield.[1]

Six-membered IV (0.50 g, 2 mmol) and sodium *N,N*-dimethyldithiocarbamate (0.37 g, 2 mmol) were dissolved in 5 m*l* of DMF. The mixture was stirred at 60°C for 4 hr, then poured into water giving 0.48 g (78%) of white precipitates of disubstituted product VII (n=6). The IR spectrum of the product was in agreement with that of the authentic sample. Similarly seven-membered V gave disubstituted product VII (n=7) in the quantitative yield.

Bis(methylthio)-dimethylaminocarbonium perchlorate (VI) (2.5 g, 0.01 mol) and sodium *N,N*-dimethyldithiocarbamate (1.8 g, 0.01 mol) were dissolved in 20 m*l* of DMF. The mixture was stirred at 70°C for 3 hr, then poured into cold water giving 1.1 g (41%) of white precipitates of *S*-methyl *N,N*-dimethyldithiocarbamate: mp 44—46°C (lit.[13] 47°C). The IR spectrum of the product was in agreement with that of the authentic sample. The low yield would be due to partial dissolution of the product in the solvents.

Kinetic Runs. A. Rates of Hydrolyses of Carbonium Salts (Mode A). A Hitachi EPS-2 spectrophotometer equipped with a thermostated cell holder was used to record spectral data. The thermostated cell holder consisted of a brass block through which thermostated water was circulated. A spectrometer cell of 1.0 cm fits into a bore of the block. The rates of all reactions of these carbonium salts with water and hydroxide ion were studied in aqueous solutions buffered with the Clark-Lubs systems. A solution of the desired pH, which initially contained *ca.* 10^{-4} mol/*l* carbonium salt, was prepared in the cell and placed in the holder thermostated at 30±0.3°C. At various time intervals decreases in absorbance at the respective maximum absorption band (λ_{max}) were followed. The semilogarithmic plots of A_0/A_t against time were linear and yielded the observed first-order rate constants (k_{obs}). A typical example of the first-order rate plot is shown in Fig. 5. The second-order rate constants (k_a) for reactions with hydroxide ion, and the pseudo-first-order rate constants (k_{H_2O}) for reactions with water were determined from the slopes and intercepts, respectively, of plots of k_{obs} *vs.* concentrations of hydroxide ion. The values of pH studied ranged from 7.5 to 9.5 and from 5.7 to 6.1 for the cyclic and open-chain carbonium perchlorates, respectively. Results of these experiments are summarized in Table 2.

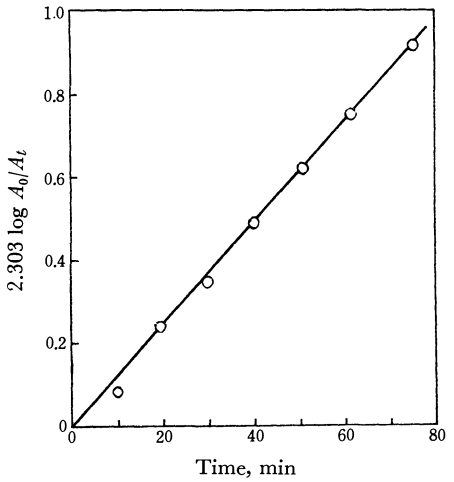

Fig. 5. An example of kinetic runs of carbonium ion IV at 262 mμ; pH=8.48.

Table 4. Reactions of IV with sodium *N,N*-dimethyldithiocarbamate

Time, min	N-salt formed, g	$1/a-x$, $mol^{-1}l$
0	0.122	30.6
15	0.105	35.5
30	0.081	45.9
40	0.074	50.5
50	0.065	57.5

B. Rates of Reactions of Carbonium Salts with Sodium *N,N*-Dimethyldithiocarbamate (Mode B). The rates of reactions with sodium *N,N*-dimethyldithiocarbamate were measured according to the procedures reported in our previous paper.[4] At various time intervals the remaining dithiocarbamate ion was gravimetrically determined from quantities of the nickel chelate precipitated by treatment of the aqueous solution of the sample with an excess of a saturated aqueous solution of nickel chloride. All reactions were carried out at 30°C in DMF solutions under the equimolar condition. The initial concentration was 0.03 mol/*l* for all reactions.

The carbonium perchlorate (0.15 mol) was dissolved in a solution of 0.805 g (0.15 mol) of sodium *N,N*-dimethyldithiocarbamate in 150 m*l* of DMF. The re-

12) H. Tilles, *J. Amer. Chem. Soc.*, **81**, 714 (1959).
13) J. v. Braun, *Ber.*, **35**, 3368 (1902).

action vessel was placed in a constant-temperature bath at 30±0.2°C. At various time intervals a 25.0-m*l* aliquot was removed and poured into cold water (*ca.* 100 m*l*) giving white precipitates of disubstituted product VII. The precipitates were filtered off and the aqueous filtrate was treated with an excess of a saturated aqueous solution of nickel chloride giving green precipitates of the nickel chelate. The nickel chelate was collected in a glass filter. The glass filter was completely dried *in vacuo*. An example of results is given in Table 4.

All plots of $1/a-x$ against time were linear and yielded the second-order rate constants (k_b) for reactions with the dithiocarbamate ion. The reaction of open-chain VI with the anion under these conditions was so fast that accurate measurements could not be made. A very rough estimate for the second-order rate constant for the open-chain analog was 26.0 $mol^{-1}l\ sec^{-1}$. Results of these experiments are shown in Fig. 1 and Table 3.

Photoinduced Reactions. XLII.[1] Homolytic Expulsion of 4-Substituent in the Photochemical Reaction of 2,5-Cyclohexadienones

Katsuyuki OGURA and Teruo MATSUURA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received January 24, 1970)

Irradiation of 2,4,6-tri-*t*-butyl-4-bromo-2,5-cyclohexadienone (X) in various solvents yielded 2,4,6-tri-*t*-butylphenol (XIII) in high yields. It was shown that 2,4,6-tri-*t*-butylphenoxy radical (XII) was formed as an intermediate and that the light of shorter wavelengths than 450 mμ accelerated the hydrogen abstraction of XII. The rate of the photochemical decomposition of X decreased in the order: *n*-hexane, *N*,*N*-dimethylformamide and acetic acid. This and the sensitized reaction suggest that the formation of XII from X may result from the n-π^* triplet state of X. On the other hand, irradiation of 2,4,6-tri-*t*-butyl-4-nitro-2,5-cyclohexadienone (XI) afforded 2,6-di-*t*-butyl-*p*-quinone (XV) and 2,4,6-tri-*t*-butylphenol (XIII), indicating a homolytic cleavage of the C–NO_2 bond.

2,5-Cyclohexadienones have been found to undergo two basic types of transformation on irradiation in neutral media; *i. e.*, (a) skeletal rearrangement, which furnishes bicyclo[3.1.0]hex-3-en-2-ones (the so-called "lumiketone"), and (b) expulsion of one of the 4-substituents followed by phenol formation.[2] Warszawski *et al.*[3] found that photolysis of 3-oxo-10β-hydroxy-17β-acetoxy-$\Delta^{1,4}$-oestradiene (Ia) and 3-oxo-10β,17β-diacetoxy-$\Delta^{1,4}$-oestradiene (Ib) resulted in the cleavage of the 10-substituent (hydroxyl and acetoxyl, respectively) and afforded the corresponding phenol II. It was also reported by Schuster and Polowczyk[4] that a spirodienone (III), photochemically, gave a biradical (IV), which abstracted hydrogen from the solvent to yield *p*-ethylphenol and an ether (V) as major products.

Recently, Schuster and Patel[5] reported the typical photochemical reaction of 2,5-cyclohexadienone, 4-methyl-4-trichloromethyl-2,5-cyclohexadienone (VI), which isomerizes in benzene to form predominantly 6-methyl-6-trichloromethylbicyclo[3.1.0]hex-3-en-2-one (VII) and affords *p*-cresol as the main product in ethyl ether, and two possible mechanisms for *p*-cresol formation were postulated. If such a species as VIII is involved, it seems possible that cleavage of one of the substituents at the C-4 position would give *p*-methylphenoxy radical, leading to *p*-cresol (path A). A mechanistic alternative to the formation of *p*-cresol is hydrogen abstraction from the solvent by VIII to give the dienone ketyl radical IX (path B). Schuster and Patel suggested from their experimental data that the latter mechanism is favorable.

The present paper reports on the photochemical

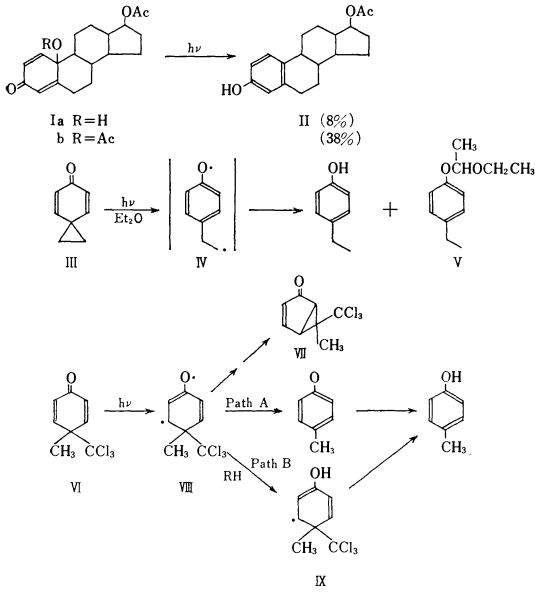
reactions of 2,4,6-tri-*t*-butyl-4-bromo-2,5-cyclohexadienone (X)[6] and 2,4,6-tri-*t*-butyl-4-nitro-2,5-cyclohexadienone (XI),[7] in which the process *via* path A seems preferable for the formation of 2,4,6-tri-*t*-butylphenol.



Results and Discussion

Irradiation of X in various solvents with a high-pressure mercury arc lamp filtered through Pyrex yielded 2,4,6-tri-*t*-butylphenol (XIII) in high yields (88% in ethyl ether; 81% in *n*-hexane; 56% in *N*,*N*-dimethylformamide; 56% in benzene). On photolysis of X in *N*,*N*-dimethylformamide, the solution became blue soon after the irradiation had been started. The color was extinguished by continued irradiation for a longer period of time or by bubbling oxygen. This blue solution showed a UV absorption at 630 mμ and an ESR spectrum (triplet, $a_H = 1.8$). Comparison of these spectra with those of 2,4,6-tri-*t*-butylphenoxy radical (XII), which was produced by the oxidation of XIII with lead dioxide, led us to the conclusion that the color was attributed to XII. Ultraviolet analysis indicated that the yield of the radical at a photostationary state amounted to 15%. The blue color also appeared, although weakly, on photolysis of X in *n*-hexane and benzene.

In order to see whether the recombination of the phenoxy radical XII and a bromine atom, which were produced by photolysis of X, occurs or not, X was irradiated under bubbling oxygen.

Table 1. Photolysis of X in various solvents[a]

Solvent	Irrad. time (min)	Bubbled gas	Yield (%)[b] X	XIII	XV
n-Hexane	45	N_2	—	81(81)	—
n-Hexane	13	N_2	63	27	1

a) A solution (500 mg in 70 m*l*) of X was irradiated with a 100-W high-pressure mercury arc lamp (Pyrex filter).
b) Yields in parenthesis were obtained by VPC analysis.
c) A solution (2.00 g in 70 m*l*) of X was irradiated for 6.75 hr and bromobenzene was detected in a 4.5% yield (by VPC analysis).

It is well known that in the presence of oxygen the phenoxy radical XII was easily converted into a peroxide (XIV)[6] and that XIV was photochemically decomposed to afford 2,6-di-*t*-butyl-*p*-quinone (XV) in a high yield.[8] When a solution of X in *n*-hexane was irradiated for a short period of time with a high-pressure mercury arc lamp under bubbling oxygen, a mixture of the products, which was shown by VPC analysis to contain XV (50%) and X (6%), was obtained. However, XIII, which was formed on irradiation of X in *n*-hexane under nitrogen for the same period of time (see Table 1), could not be detected in the reaction mixture. It should be noted that the yield of the recovered X decreased remarkably in the presence of oxygen, compared with that under nitrogen. This suggests that the recombination of the phenoxy radical XII and a bromine atom may take place in *n*-hexane under nitrogen. On the other hand, it was shown that recombination was slower in *N*,*N*-dimethylformamide than in *n*-hexane (Table 1). This conclusion was also confirmed by the fact that the

blue color of the phenoxyl XII produced on photolysis of X in *N,N*-dimethylformamide (15% of the amount of the starting material X) was extinguished very slowly under bubbling nitrogen.*1 These facts and the results shown in Table 1 indicate that the primary decomposition rate of X decreases in order of *n*-hexane, *N,N*-dimethylformamide, and acetic acid. Since the photochemical decomposition of X was sensitized by benzophenone as shown in Table 2, it may be reasonable to assume that the photochemical dissociation of X to XII and bromine results from a n-π^* triplet state of X.

There is another question concerning how the intermediary phenoxyl XII, which is known to be very stable in the dark, abstracts a hydrogen to afford XIII. Irradiation of the solution of the phenoxyl XII in benzene and petroleum ether with a high-pressure mercury arc lamp through a pyrex filter under bubbling nitrogen gave XIII in 47 and 71% yields, respectively. The photochemical disappearance of the phenoxyl XII in various solvents was followed by the decrease of the ultraviolet maximum at 630 mμ. The result shown in Fig. 2 indicates that the reaction rate of

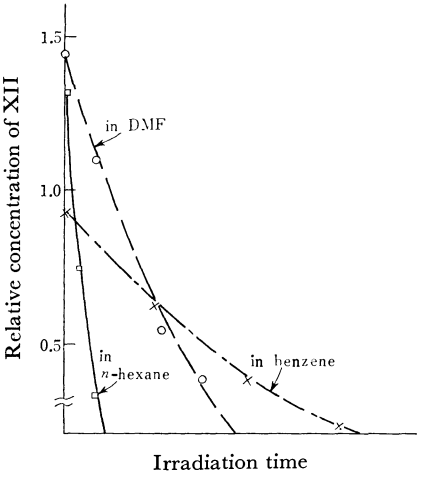

Fig. 2

XII increases in the order: benzene, *N,N*-dimethylformamide and *n*-hexane. Analogous phenomena have been observed in the photolysis of a stable radical, diphenylpicrylhydrazyl (DPPH), in various solvents. Pitts *et al.*,[9] reported that hydrogen abstraction of DPPH afforded diphenylpicrylhydrazine. The ultraviolet spectrum of the phenoxyl XII showed a maximum at 625 mμ and a minimum at 450 mμ in benzene. A light at 625±7 mμ did not accelerate the hydrogen-abstraction of XII, but that at shorter wavelengths than 450 mμ did.*2

*1 A kinetic consideration supports the conclusion that XII reacts with a bromine molecule. The mechanism shown in the following scheme is adequate to describe the disappearance of XII which was formed by irradiation of X in *N,N*-dimethylformamide.

$$XII + Br_2 \xrightarrow{k_1} X + Br \quad (1)$$

$$XII + Br \xrightarrow{k_2} X \quad (2)$$

$$XII \xrightarrow{k_3} \text{products} \quad (3)$$

$$2Br \xrightarrow{k_4} Br_2 \quad (4)$$

where, k_1 and k_2 are the rate constants for reactions (1) and (2), and k_3 for the first-order decomposition of XII (3). The disappearance of XII follows the next equation.

$$-\frac{d[XII]}{dt} = k_1[XII][Br_2] + k_2[XII][Br] + k_3[XII]$$

In the early stages, it is inferred that $1/2[XII]=[Br_2]$ and the fourth equation was neglected ($k_2[Br]=k_1[Br_2]$). In this case, the above-mentioned equation may be written as

$$-\frac{d[XII]}{dt} = k_1[XII]^2 + k_3[XII]$$

Integration of this equation gives the equivalent expression

$$\log\frac{[XIII]_0}{[XII]_0+k_3/k_1} - \log\frac{[XII]}{[XII]+k_3/k_1} = k_3t$$

where $[XII]_0$=the concentration of XII at time $t=0$. Supposing that k_3/k_1 is 0.05, a plot of log (XII/XII+k_3/k_1) against time is linear in the early stage (Fig. 1).

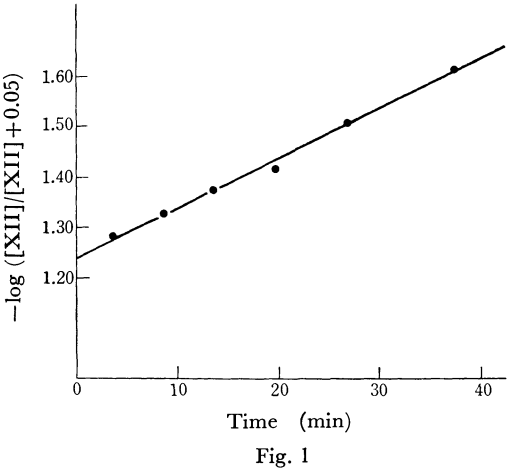

Fig. 1

This indicates that the disappearance of the phenoxyl XII may be largely attributed to its reaction with bromine molecules.

When a solution of 2,4,6-tri-*t*-butyl-4-nitro-2,5-cyclohexadienone (XI) in benzene was irradiated with a 450-W high-pressure mercury arc lamp (Pyrex filter) under bubbling nitrogen, the reaction mixture, was shown to contain 2,4,6-tri-*t*-butylphenol (XIII, 6%), 2,6-di-*t*-butyl-*p*-benzoquinone (XV, 11%) and 2,4,6-tri-*t*-butyl-4-hydroxy-2,5-cyclohexadienone (XX, trace). Irradiation (>318 mμ) of XI in petroleum ether yielded XV (17%), XX (10%) and 3,5-di-*t*-butyl-*o*-benzoquinone (XXI, 5%) along with a trace of XIII. On the other hand, XIII was formed as the main product of the photolysis of XI in polar solvents such as *N*,*N*-dimethylformamide (28%) and methanol (43%). The results are summarized in Table 3.

TABLE 3. PHOTOLYSIS OF XI

Solvent	Yield (%)[c]	
	XIII	XV
DMF[a]	28	—

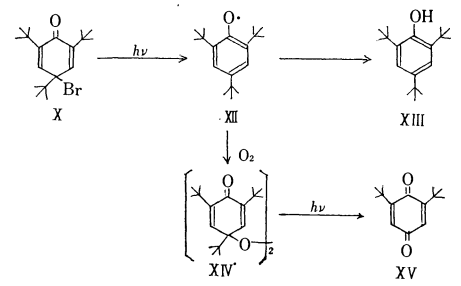
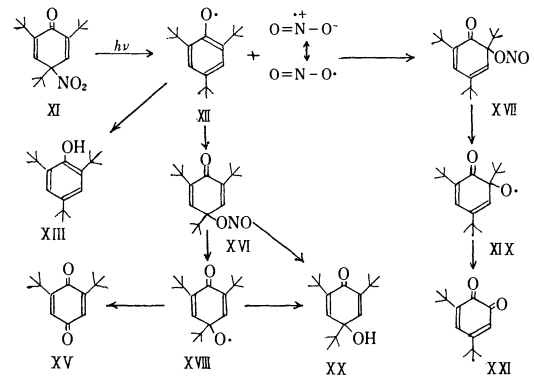
a) >280 mμ (Pyrex filter)
b) >318 mμ (through a 0.08 M solution of naphthalene in benzene)
c) Yields in parenthesis were obtained by VPC analysis.

The formation processes of these products may be rationalized as shown in Scheme II. In the first step, XI suffers homolytic decomposition to give XII and nitrogen dioxide, which has two resonance structures, O-radical and N-radical forms. The recombination of the radical XII and nitrogen dioxide (as the O-radical form) produces two isomeric nitrites (XVI and XVII). These nitrites undergo further photochemical cleavage of O–NO bond give XVIII and XIX, which are de-*t*-butylated to the corresponding benzoquinones, XV and XXI, respectively. The compound XX may be formed by hydrogen abstraction of XVIII or by hydrolysis of XVI during working up. Since XII and bromine recombine slowly in polar solvents, as mentioned already, it is expected that the recombination of XII and nitrogen dioxide is also a slow process. In fact, XIII was a major product in photolysis of XI in methanol and *N*,*N*-dimethylformamide, but XV could not be detected. Furthermore, it may be reasonable that the recombination of XII and nitrogen dioxide is a faster process in non-polar solvents, and that the formation of XV is predominant over the hydrogen abstraction of XII to afford XIII.



Scheme I



Scheme II

Experimental

Reaction of X in the Dark. Bromodienone X[6] was very unstable on silica gel and neutral alumina, but considerably stable in refluxed benzene. A solution of X (400 mg) in 10 m*l* petroleum ether was adsorbed on 20 g of silica gel and then allowed for half an hour at room temperature. Elution with 50 ml of petroleum ether gave 179 mg (56%) of colorless crystals which were identified as 2,4-di-*t*-butyl-6-bromophenol[6] (by IR). Further elution with 150 m*l* of petroleum ether afforded 110 mg (36%) of colorless crystals which were identified as 2,4,6-tri-*t*-butylphenol (XIII) (by IR). Elution with 50 m*l* of benzene yielded 3 mg of a yellow oil which was not further investigated. Continuous elution with 50 m*l* of benzene gave 28 mg (11%) of orange crystals which were identified as 2,6-di-*t*-butyl-*p*-benzoquinone (XV)[11] (by IR). The results were reproducible.

After X (300 mg) was adsorbed on 30 g of neutralized alumina (Woelm Co., Act. I), elution with 200 m*l* of petroleum ether and 100 m*l* of benzene gave 8 mg of a yellow oil which was not further investigated. Further elution with 150 m*l* of chloroform afforded 199 mg (83%) of pale yellow crystals which were identified as 2,4,6-tri-*t*-butyl-4-hydroxy-2,5-cyclohexadienone (XX)[11] (by IR).

A solution containing 200 mg of X in 20 m*l* of benzene was refluxed for 6 hr. The reaction mixture was evaporated under reduced pressure to yield pale yellow crystals which exhibited the same IR spectrum as that of X and were shown by TLC analysis not to contain

11) E. Müller and K. Ley, *Chem. Ber.*, **88**, 601 (1955).

2,4-di-*t*-butyl-6-bromophenol.

Photolysis of X. Since the starting material X was very unstable on silica gel and had a similar retention time on VPC to that of XIII to make VPC analysis difficult, the yield of the recovered X was estimated from the amount of 2,4-di-*t*-butyl-6-bromophenol which could be shown by TLC analysis not to exist in the photolysis mixture of X and which might be derived from the decomposition of X on silica gel.

a) In n-Hexane for a Long Period of Time under Bubbling Nitrogen. A solution containing 500 mg of X in 60 m*l* of *n*-hexane was irradiated for 45 min with a 100-W high-pressure mercury arc lamp surrounded by a Pyrex jacket under bubbling nitrogen. After addition of *n*-hexane (100 m*l*), the reaction mixture was washed with water and evaporated under reduced pressure. The residue was chromatographed on 20 g of silica gel. Elution with 200 m*l* of petroleum ether gave 309 mg (81%) of colorless crystals which were identified as XIII (by IR). In another run, VPC analysis of the reaction mixture (silicon DC 550, 1.5 m; 180°C; carrier gas: H_2, 1.5 kg/cm^2) showed that the yield of XIII was 81%.

b) In n-Hexane for a Short Period of Time under Bubbling Nitrogen. A solution containing 500 mg of X in 60 m*l* of *n*-hexane was irradiated for 13 min under the same conditions as described above. After evaporation of the solvent under reduced pressure, the residue was chromatographed on 20 g of silica gel. Elution with 50 m*l* of petroleum ether gave 41 mg of colorless crystals which were identified as 2,4-di-*t*-butyl-6-bromophenol (by IR). Further elution with 50 m*l* of petroleum ether afforded 153 mg of colorless crystals which were shown by IR analysis to consist of 101 mg of 2,4-di-*t*-butyl-6-bromophenol and 52 mg of XIII. Elution with 250 m*l* of petroleum ether yielded 134 mg of colorless crystals which were identified as XIII (by IR). Elution with 100 m*l* of benzene - petroleum ether (1 : 1) gave 20 mg of a yellow oil which was not further investigated. Continuous elution with 100 m*l* of benzene afforded 27 mg of orange crystals which were identified as XV. The yields of X, XIII and XV were 63, 27 and 2%, respectively.

c) In n-Hexane under Bubbling Oxygen. A solution containing 500 mg of X in 60 m*l* of *n*-hexane was irradiated for 14 min with a 100-W high-pressure mercury arc lamp (Pyrex filter) under bubbling oxygen. After evaporation of the solvent under reduced pressure, the residue was chromatographed on 20 g of silica gel. Elution with 300 m*l* of petroleum ether gave 12 mg of a colorless oil which was not further investigated. Further elution with 150 m*l* of benzene afforded 179 mg (56%) of orange crystals which were identified as XV (by IR).

d) In Benzene. A solution containing 2.00 g of X in 70 m*l* of benzene was irradiated for 6.75 hr under the same conditions mentioned in a). After removal of the solvent under reduced pressure, the residue was shown by VPC analysis to contain XIII and bromobenzene in 56 and 4.5% yields, respectively.

e) In Ether. A solution containing 500 mg of X in 60 m*l* of ether was irradiated under the same conditions described in a). The reaction mixture was evaporated under reduced pressure and the residue was shown by VPC analysis to contain XIII in a 88% yield.

f) In N,N-Dimethylformamide for a Long Period of Time. A solution containing 500 mg of X in 60 m*l* of *N,N*-dimethylformamide was photolyzed for 62 min under the same conditions mentioned in a). After addition of 200 m*l* of water, the reaction mixture was extracted with three 100-m*l* portions of ether. The ethereal layer was washed with water and dried on anhydrous sodium sulfate. After removal of the solvent under reduced pressure, the residue was shown by VPC analysis to contain XIII and XV in 56 and 7% yields, respectively.

g) In N,N-Dimethylformamide for a Short Period of Time. A solution containing 500 mg of X in 60 m*l* of *N,N*-dimethylformamide was irradiated for 15 min under the same conditions described in a). The resulting blue solution was allowed to stand for 2 hr under bubbling nitrogen to give a yellow solution. After addition of 150 m*l* of ether, the reaction mixture was washed with water and dried on anhydrous sodium sulfate. After evaporation of the solvent under reduced pressure, the residue, which was shown by TLC analysis not to contain 2,4-di-*t*-butyl-6-bromophenol, was chromatographed on 20 g of silica gel. Elution with 50 m*l* of petroleum ether gave 144 mg of colorless crystals which were identified as 2,4-di-*t*-butyl-6-bromophenol (by IR). Further elution with 50 m*l* of petroleum ether afforded 94 mg of colorless crystals which were shown by IR analysis to consist of 32 mg of 2,4-di-*t*-butyl-6-bromophenol and 62 mg of XIII. Elution with 250 m*l* of petroleum ether yielded 91 mg of colorless crystals which were identified as XIII (by IR). Elution with 200 m*l* of benzene - petroleum ether (1 : 1) gave 5 mg of a yellow oil which was not further investigated. The continuous elution with 100 m*l* of benzene - petroleum ether (1 : 1) afforded 25 mg of orange crystals which were identified as XV (by IR). The yields of X and XIII were 77 and 14%, respectively.

h) In N,N-Dimethylformamide under Bubbling Oxygen. A solution containing 500 mg of X in 60 m*l* of *N,N*-dimethylformamide was irradiated for 15 min under the same conditions mentioned in c). After addition of ether (150 m*l*), the mixture was washed with water and dried on anhydrous sodium sulfate. The ethereal solution was evaporated under reduced pressure and the residue, which was shown by TLC analysis not to contain 2,4-di-*t*-butyl-6-bromophenol, was chromatographed on 20 g of silica gel. Elution with 50 m*l* of petroleum ether gave 134 mg of colorless crystals which were identified as 2,4-di-*t*-butyl-6-bromophenol (by IR). Further elution with 200 m*l* of petroleum ether afforded 84 mg of colorless crystals which were identified as XIII (by IR). Elution with 50 m*l* of benzene - petroleum ether (1 : 1) yielded 10 mg of a yellow oil which was not further investigated. Continuous elution with 130 m*l* of benzene - petroleum ether (1 : 1) gave 62 mg of orange crystals which were identified as XV (by IR). The yields of X and XV were estimated to be 59 and 13%, respectively. In another run, the photolyzed mixture was shown by VPC analysis to contain X and XV in 68 and 24% yields, respectively.

i) In Dimethyl Sulfoxide. A solution containing 500 mg of X in 60 m*l* of dimethyl sulfoxide and 10 m*l* of benzene was irradiated for 30 min under the same conditions described in a). During photolysis, the solution did not show a blue color, but a deep yellow. After addition of ether (100 m*l*), the reaction mixture was washed with water and dried on anhydrous sodium sulfate. Evaporation of the solvent under reduced

pressure gave a yellow oil which was shown by IR and TLC analyses to contain mainly X. The oil was chromatographed on 20 g of silica gel. Elution with 150 m*l* of petroleum ether afforded 175 mg of pale yellow crystals which were identified as 2,4-di-*t*-butyl-6-bromophenol (by IR). Further elution with 150 m*l* of petroleum ether yielded 94 mg of colorless crystals, which were identified as XIII (by IR). Elution with 100 m*l* of benzene - petroleum ether (1 : 1) gave 10 mg of a yellow oil which was not further investigated. Continuous elution with 200 m*l* of benzene - petroleum ether (1 : 1) afforded 67 mg of orange crystals which were identified as XV (by IR). It was estimated from these results that the yields of X and XV were 77 and 10%, respectively.

j) In Acetic Acid. A solution containing 500 mg of X in 100 m*l* of acetic acid was irradiated for 1 hr under the same conditions mentioned in a). After addition of ether (200 m*l*), the reaction mixture was washed with water and an aqueous bicarbonate solution and dried on anhydrous sodium sulfate. Evaporation of the solvent afforded a yellow oil which was chromatographed on 20 g of silica gel. Elution with 50 m*l* of petroleum ether gave 120 mg of colorless crystals which were identified as 2,4-di-*t*-butyl-6-bromophenol (by IR). Further elution with 150 m*l* of petroleum ether yielded 128 mg of colorless crystals which were identified as XIII (by IR). Elution with 100 m*l* of petroleum ether and 70 m*l* of benzene afforded 30 mg of a pale yellow oil which was not further investigated. Elution with 50 m*l* of benzene gave 33 mg of orange crystals which were identified as XV (by IR). The estimated yields of X, XIII and XV were 53, 15 and 5%, respectively.

Photolysis of the Phenoxyl Radical XII. *a) In Petroleum Ether.* A solution of the phenoxy radical XII in 400 m*l* of petroleum ether, prepared from 4.00 g of 2,4,6-tri-*t*-butylphenol (XIII) according to the known method,[12] was irrradiated with a 450-W high-pressure mercury arc lamp surrounded by a Pyrex water-cooled jacket under bubbling nitrogen until the blue color of the solution disappeared (irradiation time: 15 hr). The reaction mixture was evaporated under reduced pressure and the residue was shown by VPC analysis to contain XIII and XV in 71 and 13% yields, respectively. Eight-ninths of the reaction mixture was chromatographed on 50 g of silica gel. Elution with 200 m*l* of petroleum ether gave 1.90 g of pale yellow crystals which were identified as XIII (by IR).

b) In Benzene. A solution of XII in 400 m*l* of benzene, prepared from 4.00 g of XIII, was irradiated for 43 hr under similar conditions to those described in a) to afford a yellow solution. The reaction mixture was shown by VPC analysis to contain XIII and XV in 47 and 7%, respectively. The mixture was evaporated under reduced pressure to give a brown oil which, by crystallization from methanol, yielded 155 mg of pale yellow crystals, identified as XIII (by IR and mixture mp).

c) With a Selected Light. The selected light was obtained by a concave radiating monochromator (Japan Spectroscopic Co., Model CRM-50).[8] A solution of XII was prepared from 150 mg of XIII in 50 m*l* of benzene, which was treated with 1.30 g of lead dioxide followed by filtration of the reaction mixture under nitrogen atmosphere.[6] Each 4 m*l* of the solution was placed in a quartz cell (1 cm square) and irradiated with the selected light. The solution completely absorbed the incident light of wavelengths longer than 570 mμ and shorter than 410 mμ. The progress of the reaction was followed by decrease of the absorbances at 550 and 530 mμ. The relative rates of disappearance of XII with various wavelength lights were 1.0 at 305±7 mμ, 0.6 at 341±7 mμ, 0.6 at 377±7 mμ, 0.3 at 413±7 mμ, 0.2 at 449±7 mμ, 0.0 at 485±7 mμ, and 0.0 at 625±7 mμ.

Photolysis of XI. *a) In Methanol.* A solution containing 1.00 g of XI in 60 m*l* of methanol was irradiated for 1.5 hr with a 100-W high-pressure mercury arc lamp through a Pyrex filter under bubbling nitrogen. Evaporation of the solvent under reduced pressure gave a brown oil which was chromatographed on 20 g of silica gel. Elution with 410 m*l* of petroleum ether afforded 310 mg (35%) of colorless crystals which were identified as XIII (by IR).

A solution containing 500 mg of XI in 60 m*l* of methanol was also irradiated for 52 min under the same conditions as described above. The reaction mixture was shown by VPC analysis (Silicon DC 550, 1.5 m, 170°C. carrier gas: H_2, 1.5 kg/cm^2) to contain XIII in 43%.

b) In N,N-Dimethylformamide. A solution containing 500 mg of XI in 60 m*l* of *N,N*-dimethylformamide was irradiated for 45 min under the same conditions mentioned in a). After addition of ether (150 m*l*), the reaction mixture was washed with water and dried on anhydrous sodium sulfate. Evaporation of the solvent under reduced pressure afforded a brown oil which was chromatographed on 20 g of silica gel. Elution with 130 m*l* of petroleum ether gave 121 mg (28%) of colorless crystals which were identified as XIII (by IR).

c) In Ether. A solution containing 1.00 g of XI in 400 m*l* of ether was irradiated for 4 hr and 11 min with a 100-W high-pressure mercury arc lamp under bubbling nitrogen through the filter solution, which contained 1 g of naphthalene in 100 m*l* of benzene and absorbed completely the incident light of wavelength shorter than 318 mμ. The reaction mixture was shown by VPC analysis to contain XV in 11%. Three-fourths of the reaction mixture was evaporated under reduced pressure and chromatographed on 20 g of silica gel. Elution with 30 m*l* of benzene - petroleum ether (1 : 1) yielded 53 mg of pale yellow crystals which were identified as XIII (by IR).

d) In Benzene. A solution containing 500 mg of XI in 60 m*l* of benzene was irradiated for 52 min under the same conditions described in a). The reaction mixture was shown by VPC analysis to contain XIII and XV in 6 and 11%, respectively. A solution containing 2.00 g XI in 60 m*l* of benzene was also photolyzed for 5.5 hr under the same conditions mentioned above. After removal of the solvent under reduced pressure, the residue was chromatographed on 60 g of silica gel. Elution with 25 m*l* of benzene - petroleum ether (1 : 1) gave 188 mg of pale yellow crystals which was shown by IR analysis to consist mainly of XIII. Further elution with 365 m*l* of benzene- petroleum ether afforded 350 mg of a brown oil which was not further investigated. Elution with 100 m*l* of the same solvent yielded 89 mg of orange crystals which were identified

12) E. Müller and K. Ley, *Chem. Ber.*, **87**, 922 (1954).

as XV (by IR). Elution with 350 m*l* of petroleum ether-benzene gave 190 mg of a orange oil which was not further investigated. Continuous elution with 150 m*l* of benzene afforded 46 mg of a pale yellow oil containing a small amount of colorless crystals (8 mg), which were separated by filtration and identified as XX (by IR).

e) In Petroleum Ether. A solution containing 1.00 g of XI in 400 m*l* of petroleum ether was irradiated for 3.5 hr under the same conditions as described in c). The reaction mixture was shown by VPC analysis to contain XV in 17%. Three-fourths of the reaction mixture was evaporated under reduced pressure and chromatographed on 30 g of silica gel. Elution with 500 m*l* of petroleum ether gave 29 mg of a yellow oil which was shown by TLC analysis to contain a trace of XIII. Further elution with 130 m*l* of petroleum ether - benzene (1 : 1) afforded 88 mg of a yellow oil which was not further investigated. Elution with 100 m*l* of petroleum ether - benzene (1 : 1) yielded 95 mg of orange crystals which were identified as XV (by IR). Elution with 150 m*l* of the same solvent gave 71 mg of pale yellow crystals which were identified as XX (by IR). Elution with 430 m*l* of benzene afforded 114 mg of a brown oil which was not further investigated. Continuous elution with 300 m*l* of benzene and with 100 m*l* of methylene chloride yielded 99 mg of purple crystals which were further purified by preparative TLC to give 27 mg of XXI[13] (identified by IR).

Photoinduced Reactions. XLIII. Photochemical Reactions of 4-Hydroxy-2,5-cyclohexadienones[1]

Katsuyuki OGURA and Teruo MATSUURA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received January 24, 1970)

Irradiation of 2,4-di-*t*-butyl-4,5-dihydroxy-2,5-cyclohexadienone (V) in methanol afforded a *β*-diketone (VIII) in a 68% yield. Diketone VIII was also formed on photolysis of a suspension of V in petroleum ether (62%) and an aqueous alkaline solution of V (56%). Photolysis of 2,4-di-*t*-butyl-4-hydroxy-5-methoxy-2,5-cyclohexadienone (VI) in various solvents yields IXa as a main product. On irradiation of VI in methanol, XI which might be formed by the addition of methanol to IXb was also isolated. Irradiation of 2,4,6-tri-*t*-butyl-3-methoxy-4-hydroxy-2,5-cyclohexadienone (VII) in a variety of solvents gave a cyclopentadienone (XIII) in high yields. It is reasonable to assume that the cyclopentadienone XIII is formed by elimination of methanol from a 2-cyclopentenone derivative (XII). The formation of XIII from VII was sensitized by benzophenone and acetophenone, and quenched by piperylene. The mechanisms of these reactions are discussed.

In the photochemical reaction of a 2,5-cyclohexadienone in neutral media, isomerization to a bicyclo[3.1.0]hex-3-en-2-one, the so-called lumi-type ketone, is the most common process (Eq. 1).[2] On the other hand, photolysis of certain 4-hydroxy-2,5-cyclohexadienones was reported to afford 4-acyl-2-cyclopentenones and two reaction pathways were proposed (paths 1 and 2 in Scheme 1). Ganter *et al.* found that the photochemical rearrangement of 3-oxo-10*β*-hydroxy-17*β*-acetoxy-$\Delta^{1,4}$-estradiene affords a 4-acyl-2-cyclopentenone derivative along with 17-*O*-acetylestradiol, and they proposed a zwitterion intermediate leading to the acylcyclopentenone *via* path 1 (Eq. (2)).[3] Altwicker and Cook[4] showed that irradiation of 2,6-di-*t*-butyl-4-hydroxy-4-phenyl-2,5-cyclohexadienone gives 2,5-di-*t*-butyl-4-benzoyl-2-cyclopentenone, and they considered the possibility of path 2 for its formation (Eq. (3)). Furthermore, Burkinshaw *et al.*[5] reported the photolysis of several 4-

hydroxy-2,5-cyclohexadienones to give 4-acyl-2-cyclopentenone derivatives, some of which undergoes further photochemical rearrangement to form Δ^1-butenolides (*e.g.*, Eq. (4)). Recently, we showed[6],*1 that the photolysis of 2,4,6-tri-*t*-butyl-4-hydroxy-2,5-cyclohexadienone (I) in non-polar media affords the products A and B which are unequivocally formed *via* a bicyclo[3.1.0]hex-3-en-2-one (II), a 4-acyl-2-cyclopentenone derivative IIIa and the further transformed product IVa. The photolysis of I in polar solvents gave the product (IVb) as the main product.

In the present study photochemical reactions of 2,4-di-*t*-butyl-4,5-dihydroxy-2,5-cyclohexadienone (V),[8] 2,4-di-*t*-butyl-4-hydroxy-5-methoxy-2,5-cyclohexadienone (VI),[8] and 2,4,6-tri-*t*-butyl-3-methoxy-4-hydroxy-2,5-cyclohexadienone (VII)[9] were examined in order to investigate the substituent effect upon the course of the photochemical reaction of 4-hydroxy-2,5-cyclohexadienones and to discuss the validity of two possible mechanisms (paths 1 and 2 in Scheme 1) for the formation of 4-acyl-2-cyclopentenones.

Results and Discussion

Photolysis of V. Irradiation of V in methanol with a high-pressure mercury arc lamp (Pyrex filter) afforded a β-diketone (VIII) in a 68% yield. The product was also obtained by the photolysis of a suspension of V in petroleum ether (62%) and of an aqueous alkaline solution of V (56%). The IR spectrum of VIII showed broad bands at 3500—2200, 2100—1750, and 1675—1400 cm^{-1}, indicating the presence of strong hydrogen bonding between a hydroxyl group and a carbonyl group. The UV absorption of VIII (λ_{max}^{EtOH} 248.5 mμ) suggests that VIII has an enone system. In the NMR spectrum of VIII, four singlets appear at τ 1.45 (1H), 4.91 (1H), 8.74 (9H), and 9.00 (9H), and two doublet signals at τ 5.80 and 7.20 (J=2 Hz). These data are consistent with formula VIII, which is the structure expected from the mechanism analogous to the photochemical reaction of 4-hydroxy-2,5-cyclohexadienones (Scheme 1). Since β-diketone VIII is unchangeable on treatment with a base*2 and the coupling constant (J=2 Hz) between C-4 and C-5 protons of VIII is similar to that of IIIa,[10] it is suggested that the steric relation between the *t*-butyl and pivaloyl groups of VIII is *trans*. The structure VIII for β-diketone was further supported from the spectral data of its methyl ethers. Treatment of a solution of VIII in absolute methanol with dry hydrogen chloride gave two 3-methoxy-2-cyclopentenone derivatives, IXa (mp 57—61°C) and Xa (mp 35—36°C). Both of them showed similar spectral data which were consistent with the structures IXa and Xa. 3-Methoxy-2-cyclopentenone with a higher melting point (57—61°C) exhibits its IR absorptions at 1705 (2-cyclopentenone), 1693 (pivaloyl) and 1627 cm^{-1} (strong, >C=C–O–), and its UV band at 240 mμ (ε 9200). The NMR spectrum of the cyclopentenone (mp 57—61°C) showed three singlets at τ 6.24 (3H, =C–OCH_3), 8.75 (9H, =C-*t*-Bu)[10] and 9.00 (9H, >C-*t*-Bu),[10] two doublets at τ 4.71 (1H, J=1 Hz) and 7.56 (1H, J=2 Hz), and a quartet at τ 5.83 (1H, J=1 and 2 Hz). On the other hand, in the NMR spectrum of the 3-methoxy-2-cyclopentenone with a lower melting point (35—36°C), six signals appeared at τ 4.79 (1H, singlet), 5.84 (1H, doublet, J=2 Hz), 6.14 (3H, singlet, =C–OCH_3), 6.99 (1H, doublet, J=2 Hz), 8.73 (9H, singlet, =C-*t*-Bu)[10] and 9.03 (9H, singlet, C-*t*-Bu).[10] The singlet (τ 4.79) and the doublet (τ 6.99) couple slightly with each other. The compound showed its IR bands at 1712 (2-cyclopentenone), 1685 (pivaloyl) and 1596 cm^{-1} (strong, >C=C–O–) and its UV absorption at 240 mμ (ε 16100). Formula IXa was assigned to the structure of the 2-cyclopentenone with a higher melting point, because the 2-cyclopentenone (IXa) was also obtained by photolysis of VI which is expected to give IXa (Scheme 1). Thus the lower melting 2-cyclopentenone is represented as formula Xa. It should be noted that a methoxyl signal of IXa appeared at a higher magnetic field (τ 6.26) than that (τ 6.14) of Xa. This may be due to the location of the methoxyl group of IXa in the deshielding area of its pivaloyl group.

Photolysis of VI. Irradiation of VI in methanol with a high-pressure mercury lamp through a Pyrex filter gave the 2-cyclopentenone IXa and a dimethoxycyclopentanone (XI) in 39 and 32% yields, respectively. Dimethoxycyclopentanone XI was shown from its IR bands at 1748 and 1694 cm^{-1} to have two carbonyl groups. The NMR spectrum of XI exhibits four singlets at τ 6.67 (3H, >C–OCH_3), 6.83 (3H, >C–OCH_3), 8.76 (9H, =C-*t*-Bu)[10] and 9.00 (9H, >C-*t*-Bu),[10] a doublet of doublet at τ 5.80 (1H, J=1 and 7 Hz), a multiplet at τ 7.50 (3H), and no signal at fields lower than τ 5.5. This compound was converted into IXa by mild treatment with a base. These data suggest that dimethoxycyclopentanone is formulated as XI. It is considered[6] that the hydrogen at C-5 position of IXa is derived from a solvent or the hydroxyl hydrogen at C-4 position of VI (*via* an intermolecular or intramolecular hydrogen transfer), and that therefore deuterated compounds IXc and XIa corresponding to IXa and XI should be formed on photolysis of VI in methanol-*O*-d_1.[6] In fact, irradiation of VI in methanol-*O*-d_1 afforded the products IXc and XIa. Deuteriocyclopentenone IXc showed its NMR signals corresponding to those of IXa except for the disappearance of the signal of IXa at τ 7.56. This indicates that, in the NMR spectrum of IXa, the proton at C-5 position is coupled with the C-4 proton (J=2 Hz) and the proton at C-2 with the C-4 proton (J=1 Hz). In the NMR spectrum of XIa, the signal at τ 5.80 appeared as a diffused singlet and the intensity of the multiplet signal at τ 7.50 was reduced as compared with that of XI. This supports the observation that the signal of XI at τ 5.80 is attributed to the C-4 proton and the coupling constant between the C-4 and C-5 protons is 7 Hz.

Photolysis of VII. Irradiation of VII in various

solvents with a high-pressure mercury arc lamp (Pyrex filter) gave an orange crystalline product XIII in yields of 76% in petroleum ether, 78% in benzene, 36% in methanol, 33% in acetic acid-ethanol - water (2 : 2 : 1) and 62% in *N*,*N*-dimethylformamide. The NMR spectrum of XIII showed four singlets at τ 8.77 (9H), 8.85 (9H), 8.90 and 3.71 (1H). The product XIII exhibited UV bands at 404 and 262 mμ and IR absorption at 1713 cm^{-1}, characteristic of a cyclopentadienone.[11]

11) E. N. Garbisch, Jr., and R. F. Sprecher, *J. Amer. Chem. Soc.*, **88**, 3433 (1966); **88**, 3434 (1966) and the references cited therein.

Reduction of XIII with zinc in acetic acid afforded cyclopentenones IIIa and IIIb.[10] This led us to assign structure XIII for the orange product.

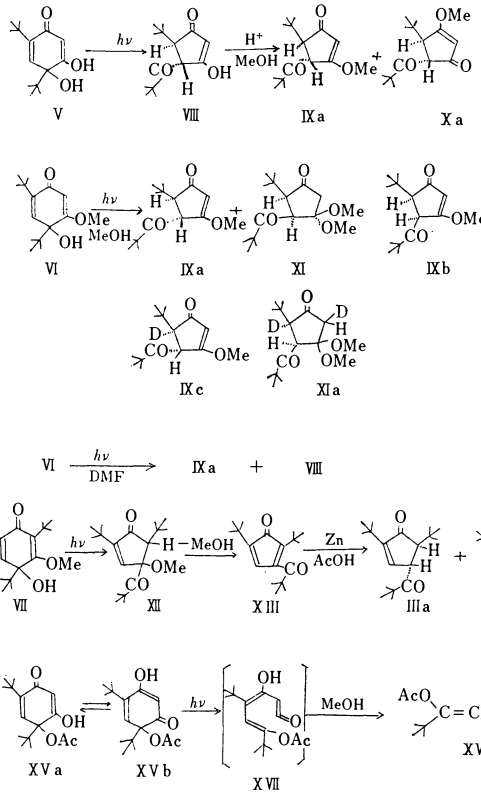
Since the formation of XIII was sensitized by benzophenone and acetophenone (Table 1) and quenched by piperylene as shown in Fig. 1 (Stern-Volmer plot), it is concluded that XIII is formed *via* the triplet state of VII. The n-π^* absorption of VII in cyclohexane showed its maximum at 360 mμ as shown in Fig. 2. Photolysis of VII with the selected lights (see Experimental) was performed, the results of which are summarized in Fig. 3. It follows from the experiments with the selected lights that both the n-π^* and π-π^* excitations are responsible for the formation of XIII.

Photolysis of 4,6-Di-*t*-butyl-3-hydroxy-4-acetoxy-2,5-cyclohexadienone (XV). The starting material was prepared by partial acetylation of V with acetic anhydride and pyridine. Irradiation of XV in methanol with a high-pressure mercury arc lamp through a Pyrex filter yielded a methyl ester in 30% yield, for which we assigned structure XVI. The ester showed its IR bands at 1750 (vinyl acetate), 1713 (ester) and 1680 cm^{-1}. In the NMR spectrum, five singlets appeared at τ 6.29 (3H, $COOCH_3$), 6.48 (2H, $-CH_2-$), 7.80 (3H, =C-OCO-CH_3), 8.93 (9H, =C-*t*-Bu)[10] and 9.05 (9H, >C-*t*-Bu),[10] and two doublets at τ 4.81 (1H, J=11 Hz) and 7.03 (1H, J=11 Hz) indicating the presence of a >CH–CH= group. These data are in accord with structure XVI. The formation of XVI can be explained by the addition of methanol to a ketene intermediate XVII which was produced by the photochemical ring fission from a tautomeric form of 2,4-cyclohexadienone (XVb).*3 Photolysis of XV in *N*,*N*-dimethylformamide or benzene gave a complex mixture of products.

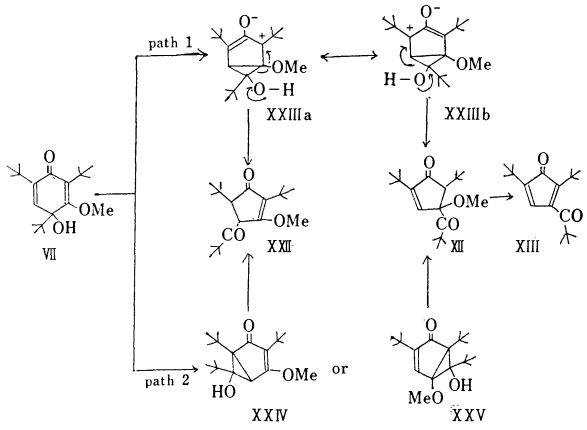
Mechanistic Consideration. The photochemical formation of XI from VI in methanol can be explained by methanol addition to 2-cyclopentenone IX. Considering the facts that XI was not formed by the photolysis of IXa in methanol and that a larger coupling constant (7 Hz) was observed*4 between the C-5 and C-4 protons in XI, it is reasonable to assume that XI is formed by the addition of methanol to *cis*-2-cyclopentenone IXb. However, we cannot distinguish the two following possibilities; *viz.*, methanol addition to IXb is easier than to IXa because of (1) the presence of a less-hindered site in IXb and (2) the decrease of the steric repulsion between the *t*-butyl and the pivaloyl groups by the

*3 Although it was reported[8] that only one tautomeric form V is predominant in solution, the UV spectrum of XV in ethanol showed two absorption bands at 285 and 249 mμ indicating the presence of, at least, two tautomeric forms, one of which might be XVb.

*4 *Cf.* The coupling constant between the C-4 and C-5 protons in IIIa is 2 Hz and that in IIIb 5 Hz.[10]



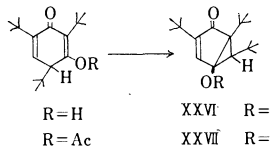
Scheme 2



Scheme 3

transformation of IXb in to XI. Formation of VIII on photolysis of VI in *N*,*N*-dimethylformamide can be also attributed to the addition of water to IXb followed by the elimination of methanol. It is probable that the formation of cyclopentadienone XIII arises from elimination of a methanol molecule from an intermediate XII, which is the product expected from the known transformation of 4-hydroxy-2,5-cyclohexadienones (Scheme 1).

For the formation of VIII from V, IX from VI and XIII from VII, two reaction routes, "path 1" and "path 2", as shown in Schemes 2 and 3 can be written. In the photochemical reactions of V and VI, we cannot explain the predominant formation of VIII and IX, respectively, by the "path 1" mechanism, because it appears reasonable that the resonance structure XIXb is more stabilized by the inductive effect of a *t*-butyl group than XIXa.



We cannot expect a large enough difference between the stabilities of XXIIIa and XXIIIb to control the reaction courses, XXIIIa→XXII and XXIIIb →XII, and the photochemical formation of XXIV from VII has an analogy in the photochemical reactions of 2,4,6-tri-*t*-butyl-3-hydroxy-2,5-cyclohexadienone[6] and 2,4,6-tri-*t*-butyl-3-acetoxy-2,5-cyclohexadienone[6] which were photochemically isomerized to form the corresponding lumiketones (XXVI and XXVII). Therefore, the "path 2" mechanism seems preferable in the photochemical reaction of VII.

Experimental

Photolysis of 2,4-Di-*t*-butyl-4,5-dihydroxy-2,5-cyclohexadienone (V). *(a) In Methanol.* A solution containing 4.00 g of V[8] in 500 m*l* of methanol was irradiated for 3.5 hr with a 450-W high-pressure mercury arc lamp (Ushio UM 450) surrounded by a Pyrex jacket under bubbling nitrogen. After removal of the solvent under reduced pressure, the residue was crystallized from petroleum ether to give 2.52 g of pale yellow crystals, which, by recrystallization from benzene-petroleum ether afforded β-diketone VIII as colorless crystals, mp 188—189°C: $\lambda_{max}^{cyclohexane}$ 245 mμ (log ε 4.24); λ_{max}^{EtOH} 248.5 mμ (log ε 4.10); $\lambda_{max}^{EtO\text{-}OH^-}$ 265 mμ (log ε 4.25); ν_{max}^{KBr} 3500—2200, 2100—1750, 1705 and 1675—1400 cm^{-1}; the NMR spectrum: τ^{CDCl_3} 1.45 (1H, singlet), 4.91 (1H, singlet), 5.80 (1H, doublet, J=2 Hz), 7.20 (1H, doublet, J=2 Hz), 8.74 (9H, singlet) and 9.00 (9H, singlet).

Found: C, 70.31; H, 9.61%. Calcd for $C_{14}H_{22}O_3$: C, 70.55; H, 9.31%. The mother liquor was evaporated and the residue was chromatographed on 60 g of silica gel. Elution with 300 m*l* of benzene and then with 800 m*l* of chloroform gave 991 mg of a pale yellow oil which was not further investigated. Elution with 100 m*l* of ether afforded 990 mg of semicrystals which, by recrystallization from benzene - petroleum ether yielded 205 mg of colorless crystals. These crystals were identified as β-diketone VIII (by IR). Total yield of VIII amounted to 68%.

(b) In Petroleum Ether. A suspension containing 1.00 g of V in 200 m*l* of petroleum ether was photolyzed for 10.5 hr with a 100-W high-pressure mercury arc lamp (Pyrex filter) under bubbling nitrogen. The reaction mixture was evaporated under reduced pressure and the residue was chromatographed on 40 g of silica gel. Elution with 450 m*l* of petroleum ether - benzene (1 : 1), 200 m*l* of benzene, 200 m*l* of chloroform and 90 m*l* of chloroform - acetone (19 : 1) gave 311 mg of a yellow oil containing a small amount of crystals which was not further investigated. Further elution with 100 m*l* of acetone - chloroform (1 : 9) afforded 616 mg of yellow crystals, which, on washing with petroleum ether and recrystallization from benzene, yielded colorless crystals, mp 185—187°C. These crystals were identified as β-diketone VIII (by IR and mixture mp).

(c) In an Alkaline Solution. A solution containing 1.00 g of V and 2.00 g of potassium hydroxide in 200 m*l* of water was irradiated for 10.5 hr under the same conditions as mentioned above. The reaction mixture was acidified with concentrated hydrochloric acid and extracted with three 150-m*l* portions of ether. After washing with water and drying on anhydrous sodium sulfate, the ethereal layer was evaporated under reduced pressure. Recrystallization of the residue from petroleum ether gave 560 mg of pale yellow crystals, mp 187—188°C, which were identified as β-diketone (by IR and mixture mp).

Etherification of VIII. A solution containing 2.29 g of VIII in 30 m*l* of absolute methanol was saturated with hydrogen chloride and allowed to stand for 3 hr at room temperature. After removal of the solvent under reduced pressure, the residue was chromatographed on 80 g of silica gel. Elution with 500 m*l* of chloroform gave 17 mg of a pale yellow oil which was not further investigated. Further elution with 500 m*l* of chloroform afforded 517 mg of a pale brown oil which soon crystallized. It was purified by a short-path distillation (100°C/3 mmHg) to yield cyclopentenone Xa as colorless crystals, mp 35—36°C: λ_{max}^{EtOH} 240 mμ (log ε 4.21); ν_{max}^{KBr} 1712, 1685 and 1596 cm^{-1}; the NMR spectrum: τ^{CDCl_3} 4.79 (1H, singlet), 5.84 (1H, doublet, J=2 Hz), 6.14 (3H, singlet), 6.99 (1H, J=2 Hz), 8.73 (9H, singlet) and 9.03 (9H, singlet).

Found: C, 71.11; H, 9.33%. Calcd for $C_{15}H_{24}O_3$: C, 71.39; H, 9.59%. Elution with 100 m*l* of chloroform gave 257 mg of a pale brown oil which was shown by TLC analysis to be a mixture of IXa and Xa. Continuous elution with 200 m*l* of chloroform afforded 638 mg of pale brown crystals, mp 56—59°C, which were identified as cyclopentenone IXa, the photolysis product of VI described below (by IR, VPC and mixture mp). Elution with 500 m*l* of chloroform yielded 118 mg of a pale brown oil which was not further investigated. Further elution with 300 m*l* of chloroform-acetone (9 : 1) gave 622 mg of colorless crystals which were identified as VII (by IR).

Photolysis of VI. *a) In Methanol.* A solution containing 500 mg of VI[8] in 180 m*l* of methanol was irradiated for 6 hr with a 100-W high pressure mercury arc lamp (Pyrex filter) under bubbling nitrogen. After evaporation of the solvent under reduced pressure, the residue was chromatographed on 15 g of silica gel. Elution with 200 m*l* of benzene gave 57 mg of a pale yellow oil which was not further investigated. Further elution with 150 m*l* of benzene and 280 m*l* of chloroform yielded 143 mg of colorless crystals, which, on recrystallization from petroleum ether, afforded dimethoxycyclopentanone XI as colorless crystals, mp 97—98°C: ν_{max}^{KBr} 1748 and 1694 cm^{-1}; the NMR spectrum: τ^{CDCl_3} 5.80 (1H, doublet of doublet, J=1 and 7 Hz), 6.67 (3H, singlet), 6.83 (3H, singlet), 7.50 (3H, multiplet), 8.76 (9H, singlet) and 9.00 (9H, singlet).

Found: C, 67.35; H, 9.89%. Calcd for $C_{16}H_{28}O_4$: C, 67.57; H, 9.93%. Elution with 50 m*l* of chloroform gave 115 mg of a yellow oil which was shown by VPC analysis to contain mainly IXa. Continuous elution with 50 m*l* of chloroform afforded 114 mg of a yellow oil, which was purified by a preparative VPC and a short-path distillation (130°C/3 mmHg) to yield cyclopentenone IXa as colorless crystals, mp 57—61°C: λ_{max}^{EtOH} 240 mμ (log ε 3.96); ν_{max}^{KBr} 1705, 1693 and 1627 cm^{-1}; the NMR spectrum: τ^{CDCl_3} 4.71 (1H, doublet, J=1 Hz), 5.83 (1H, quartet, J=1 and 2 Hz), 6.24 (3H, singlet), 7.56 (1H, doublet, J=2 Hz), 8.75 (9H, singlet) and 9.00 (9H, singlet).

Found: C, 71.69; H, 9.76%. Calcd for $C_{15}H_{24}O_3$:

C, 71.39; H, 9.59%.

b) In N,N-Dimethylformamide. A solution containing 500 mg of VI in 80 m*l* of *N,N*-dimethylformamide was irradiated for 6 hr under the same conditions as described in a). Ether (150 m*l*) was added into the reaction mixture, and then the solution was washed with water and dried on anhydrous sodium sulfate. After removal of the solvent under reduced pressure, the residue was chromatographed on 10 g of silica gel. Elution with 225 m*l* of chloroform gave 164 mg of a pale yellow oil which was not further investigated. Further elution with 30 m*l* of chloroform afforded 174 mg of a pale brown oil which was re-chromatographed on 10 g of silica gel and yielded 99 mg of IXa (identified by IR and VPC). Elution with 100 m*l* of chloroform gave 43 mg of pale yellow crystals which were identified as V (by IR).

c) Quantitative Analysis by VPC. A Pyrex tube (10 mm diameter) containing 100 mg of VI and 5 m*l* of a solvent was externally irradiated with a 450-W high-pressure mercury arc lamp, after the atomosphere was replaced with nitrogen. The reaction mixture was analyzed by VPC (silicon DC 550, 1.5 m; column temperature, 210°C. carrier gas; helium, 1.5 kg/cm^2). The yields of IXa were 28% in *n*-hexane, 32% in benzene, 44% in *N,N*-dimethylformamide and 39% in methanol. The yield of XI in methanol was 32%.

Treatment of XI with a Base. Forty mg of XI was added to 3 m*l* of 1 N methanolic potassium hydroxide and the mixture was allowed to stand for 1 hr at room temperature. After addition of 100 m*l* of water, the reaction mixture was extracted with two 15-m*l* portions of ether. The ethereal layer was washed with water and dried on anhydrous sodium sulfate. After evaporation of the solvent, the residue was purified by a short-path distillation (95°C/3 mmHg) to yield 32 mg of colorless crystals, mp 55—61°C, which were identified as IXa (by IR, VPC and mixture mp).

Photolysis of VII. *a) In Methanol.* A solution containing 500 mg of VII[9] in 150 m*l* of methanol was irradiated for 1.5 hr with a 100-W high-pressure mercury arc lamp surrounded by a Pyrex jacket under bubbling nitrogen. After evaporation of the solvent under reduced pressure, the residue was chromatographed on 15 g of silica gel. Elution with 20 m*l* of petroleum ether - benzene (7 : 3) gave 8 mg of a yellow oil which was not further investigated. Further elution with 40 m*l* of the same solvent afforded 160 mg (36%) of orange crystals, which, on recrystallization from methanol, yielded cyclopentadienone XIII as orange crystals, mp 75—76°C: λ_{max}^{KBr} 404 (log ε 2.66) and 262 mμ(3.30); ν_{max}^{KBr} 1713, 1683 and 1593 cm^{-1}; the NMR spectrum: τ^{CCl_4} 3.71 (1H, singlet), 8.77 (9H, singlet), 8.85 (9H, singlet) and 8.90 (9H, singlet); the mass spectrum: *m/e* 276 (parent peak).

Found: C, 77.22; H, 10.12%. Calcd for $C_{18}H_{28}O_2 \cdot 1/4CH_3OH$: C, 77.06; H, 10.28%.

b) In Petroleum Ether. A solution containing 500 mg of VII in 150 m*l* of petroleum ether was irradiated for 1 hr and 50 min under the same conditions as described above. After removal of the solvent under reduced pressure, the residue was chromatographed on 15 g of silica gel. Elution with 10 m*l* of petroleum ether - benzene (7 : 3) gave 6 mg of a yellow oil which was not further investigated. Further elution with the same solvent afforded 340 mg (76%) of orange crystals, which were purified by recrystallization from methanol to yield 207 mg of orange crystals, mp 74—76°C. These crystals were identified as cyclopentadienone XIII (by IR).

c) In Benzene. A solution containing 1.10 g of VII in 180 m*l* of benzene was irradiated for 3 hr under the same conditions as mentioned in a). The reaction mixture was evaporated under reduced pressure and the residue was chromatographed on 30 g of silica gel. Elution with 20 m*l* of petroleum ether - benzene (7 : 3) gave 7 mg of a yellow oil which was not further investigated. Further elution with 110 m*l* of the same solvent afforded 765 mg (78%) of orange crystals which were identified as XIII (by IR).

d) In N,N-Dimethylformamide. A solution containing 500 mg of VII in 80 m*l* of *N,N*-dimethylformamide was irradiated for 1 hr under the same conditions as described above. Ether (150 m*l*) was added to the reaction mixture and the ethereal solution was washed with water. After drying on anhydrous sodium sulfate and evaporating the solvent under reduced pressure, the residue was chromatographed on 20 g of silica gel. Elution with petroleum ether - benzene (1 : 1) gave 279 mg (62%) of orange crystals which were identified as XIII (by IR).

e) In Acetic Acid - Ethanol - Water. A solution containing 500 mg of VII in 80 m*l* of acetic acid - ethanol - water (2 : 2 : 1) was photolyzed for 1 hr under the same conditions as mentioned above. After ether (300 m*l*) was added, the reaction mixture was washed with water and then with aqueous bicarbonate solution. After being dried on anhydrous sodium sulfate and the solvent evaporated under reduced pressure, the residue was chromatographed on 30 g of silica gel. Elution with 100 m*l* of petroleum ether - benzene (7 : 3) gave 19 mg of a yellow oil which was not further investigated. Further elution with 80 m*l* of the same solvent afforded 146 mg (33%) of orange crystals which were identified as XIII (by IR).

f) Quenching Experiment. Seven samples were prepared as shown in Table 2 and the atmospheres were replaced with nitrogen. The samples were irradiated for 20 min with a 450-W high-pressure mercury arc lamp surrounded by a Pyrex water-cooled jaket using a merry-go-round apparatus.[12]

Table 2.

Exp. No.	VII (mg)	Solution A[a] (m*l*)	Benzene (m*l*)
1	62	—	20
2	62	1	19
3	62	2	18
4	62	3	17
5	62	4	16
6	62	5	15
7	62	6	14

a) Solution A was prepared by diluting 6.87 g of freshly distilled piperylene to 25 m*l* with benzene.

The yield of XIII in each sample was determined

12) A. A. Lamola and G. S. Hammond, *J. Chem. Phys.*, **43**, 2129 (1965).

by VPC analysis (silicon DC 550, 1.5 m; 210°C; Carrier gas; helium, 1.0 kg/cm²). The results are summarized in Fig. 1.

g) With Selected Light. Selected light was obtained by a concave radiating monochromator (Japan Spectroscopic Co., Model CRM-50).[9,13] The experiment was carried out with a solution of 0.167 mg of VII in 3 m*l* of cyclohexane. The progress of the reaction was followed by the increase of a maximum at 406 mμ attributed to the absorption of XIII. The results are summarized in Fig. 2.

Reduction of XIII with Zinc in Acetic Acid. Zinc dust (6.0 g) was added to a solution of XIII (222 mg) in 20 m*l* of acetic acid. The reaction mixture was warmed at 50°C until the orange color disappeared. After removal of the deposited solid by filtration, 60 m*l* of water was added to the filtrate and the mixture was extracted with two 100-m*l* portions of ether. After the ethereal layer was washed with water and with aq. bicarbonate solution and dried on anhydrous sodium sulfate, the solvent was evaporated under reduced pressure. The residue was chromatographed on 7 g of silica gel. Elution with 30 m*l* of petroleum ether - benzene (1 : 1) gave 14 mg of a yellow oil which was not further investigated. Further elution with 45 m*l* of the same solvent afforded 73 mg of pale yellow crystals which, on recrystallization from methanol, yielded 13 mg of colorless crystals, mp 76—77.5°C, identified as IIIb[10] (by IR). Elution with 175 m*l* of petroleum ether - benzene (1 : 1) gave 48 mg of pale yellow crystals, which was purified by recrystallization from methanol to yield 13 mg of colorless crystals, mp 75—78°C, identified as IIIa[10] (by IR and mixture mp).

Preparation of XV. A solution containing 4.00 g of V in 30 m*l* of acetic anhydride and 15 m*l* pyridine was allowed to stand overnight at room temperature. After 150 m*l* of ice was added, the deposited crystals were separated by filtration and purified by recrystallization from ether - petroleum ether to afford colorless crystals, mp 52—53°C (with very slow heating). The mp was raised by rapid heating to 82.5—84°C. This behavior of the mp may be due to thermal tautomerization of XV. ν_{max}^{KBr} 3500—2600, 1745, 1730, 1685, 1655, 1625, 1595 and 1555 cm^{-1}; $\nu_{max}^{CHCl_3}$ 1735, 1685 and 1740 (sh) cm^{-1}; λ_{max}^{EtOH} 285 (log ε 3.02) and 249 mμ (3.59); $\lambda_{max}^{cyclohexane}$ 251 mμ (3.51); the NMR spectrum: τ^{CDCl_3} 3.60 (1H, singlet), 6.50 (1H, doublet, J=21 Hz), 6.63 (1H, doublet, J=21 Hz), 7.91 (3H, singlet), 8.75 (9H, singlet) and 8.99 (9H, singlet).

Found: C, 64.03; H, 8.96%. Calcd for $C_{16}H_{24}O_4 \cdot H_2O$: C, 64.40; H, 8.78%.

Photolysis of XV. A solution containing 530 mg of XV in 170 m*l* of methanol was irradiated for 10 hr with a 100-W high-pressure mercury arc lamp (Pyrex filter) under bubbling nitrogen. After removal of the solvent under reduced pressure, the residue was chromatographed on 20 g of silica gel. Elution with 180 m*l* of chloroform gave 155 mg of a pale yellow oil which was not further investigated. Further elution with 250 m*l* of chloroform afforded 176 mg (30%) of pale yellow crystals, which, on recrystallization from petroleum ether, gave ester XVI as colorless crystals, mp 52.5—53°C: ν_{max}^{KBr} 1750, 1712 and 1680 cm^{-1}; λ_{max}^{EtOH} 255 mμ (log ε 3.50); the NMR spectrum: τ^{CDCl_3} 4.81 (1H, J=11 Hz), 6.29 (3H, singlet), 6.48 (2H, singlet), 7.03 (1H, doublet, J=11 Hz), 7.80 (3H, singlet), 8.93 (9H, singlet) and 9.05 (9H, singlet).

Found: C, 65.25; H, 9.29%. Calcd for $C_{17}H_{28}O_5$: C, 65.36; H, 9.03%.

The Carbon-13 NMR Spectra of Alkyl Vinyl Ethers, and Their Structures and Reactivities

Koichi HATADA, Kazuhiko NAGATA and Heimei YUKI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received January 26, 1970)

The ^{13}C NMR spectra of alkyl vinyl ethers were investigated at 22.5°C with neat liquid at 15.09 MHz. When the alkyl group of the ether becomes more electron-donating, the chemical shift of the α-carbon of the vinyl group shifts to a higher field, and that of the β-carbon, to a lower field. From these results, it was concluded that the contribution of the resonance form, $\bar{C}H_2-CH=\overset{+}{O}-R$, in the ether decreases in the order of the increasing electron-repelling power of the alkyl group. Good correlations were obtained between the chemical shifts of the vinyl group and the reactivity of vinyl ether in the cationic reaction. When the ether becomes more reactive, the chemical shift of the α-carbon shifts to a higher field, and that of the β-carbon to a lower field. This fact clearly shows that the attack of the proton on the β-carbon is not the rate determining step in the cationic reaction of the vinyl group. Linear relations were obtained between the chemical shifts of β-methylene protons and of β-carbon, but no correlation was obtained between the chemical shifts of the α-methine proton and of the α-carbon.

Carbon-13 chemical shifts (δ_c) have been reported for several olefinic compounds.[1-3] However, few data have been obtained on alkyl vinyl ethers.[3,4] In our preceding paper[5] we measured the ^1H NMR spectra of alkyl vinyl ethers and studied the resonance contribution in the ether. In this work, we will investigate the ^{13}C NMR spectra of alkyl vinyl ethers and will obtain direct evidence for the previous conclusions. The relationships between the reactivity of alkyl vinyl ether and the ^{13}C chemical shift of the vinyl group were also studied.

Experimental

The methyl vinyl ether was commercially obtained. The other vinyl ethers were prepared from methyl vinyl ether and alcohols by an ether-exchange reaction catalyzed by $Hg(OAc)_2$ in the presence of molecular sieves.[6] All the ethers were purified by refluxing them over lithium aluminum hydride and by subsequent distillation under a high vacuum.

The ^{13}C NMR spectrum was taken at 22.5°C on a JEOL C-60HL spectrometer with a 15.09 MHz RF unit and using a neat liquid in an 8 mmϕ sample tube. The signal to noise ratio of the spectrum was enhanced by the ^{13}C–H noise decoupling. The spectrum of *t*-butyl vinyl ether was also obtained by means of the accumulation over 16 scans using a JEOL JRA-1 accumulator. The chemical shift measurements were done with a nuclear resonance single side band technique;[7] their accuracies were within ± 0.2 ppm. Carbon disulfide was used as an external standard, the high field shifts being shown as positive values.

Results and Discussion

^{13}C Chemical Shifts of Alkyl Vinyl Ethers. The chemical shifts of alkyl vinyl ethers are given in Table 1, in which the vinyl ethers are arranged in increasing order of the electron-repelling power of their alkyl groups from the top to the bottom. When the alkyl group becomes more electron-donating, the chemical shift of the α-carbon shifts to a higher field, and that of the β-carbon, to a lower field.

The ^{13}C chemical shift of the vinyl group has been reported to be mainly controlled by the π-electron density and shows an upfield shift when the π-electron density on the carbon atom increases.[3,8] Therefore, the results in Table 1 show that the electron density of the α-carbon is mainly determined

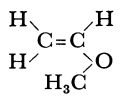
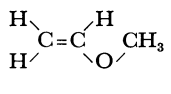
by the electron-repelling power of the alkyl group.

On the contrary, the electron density of the β-carbon decreases when the electron-repelling power of alkyl group becomes stronger. Alkyl vinyl ether takes the following resonance form: $\bar{C}H_2-CH=\overset{+}{O}-R$.[9] Our inspection of ^1H NMR spectra of alkyl vinyl ethers suggested that the resonance contribution decreases in the order of the arrangement shown in Table 1, from the top to the bottom.[5] The contribution of such a resonance form would lead to an increase in the π-electron density of β-carbon. Therefore, the results in Table 1 are considered to be direct evidence for the above suggestion.

The resonance will be most favorable when the olefinic π-orbital and the lone-pair p-orbital on the oxygen atom overlap. Therefore, the degree of this resonance contribution is considered to depend on the conformation of alkyl vinyl ether. If the oxygen atom is assumed to have essentially sp^3 hybridization and, hence, a tetrahedral disposition of its bonds and lone-pair electrons, the probable conformations are *cis*, *trans* and *gauche* forms. From the inspection of molecular models, the *cis* and *trans* forms are most favorable for the resonance,



cis



trans

while in the *gauche* form the resonance is almost entirely hindered. Infrared study[10] showed that, in methyl vinyl ether, the *cis* form is more stable at room temperature. As the alkyl group of vinyl ether is bulkier, the *cis* and *trans* forms become unstable because of the steric interaction between the alkyl group and α- or β-hydrogen of the vinyl group and the proportion of the gauche form gradually increases. Therefore, the degree of resonance contribution in alkyl vinyl ether is mainly controlled by the steric effect and decreases with an increase in the bulkiness of its alkyl group.

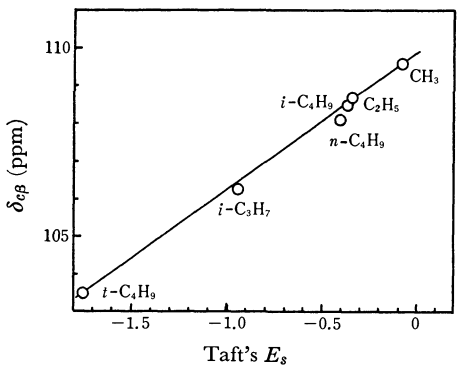

Fig. 1. Plots of $\delta_{c\beta}$ *vs.* E_s.

The order of the arrangement of the ether shown in the table is also in accordance with the increasing order of bulkiness of the alkyl group. By plotting the ^{13}C chemical shifts of β-carbon ($\delta_{c\beta}$) against the Taft steric parameter, E_s, of the alkyl group, a good linear relation was obtained; it is shown in Fig. 1, where the E_s value for R in the ether is that for the RCH_2 of RCH_2COOR'. These results clearly indicate the validity of the above theory.

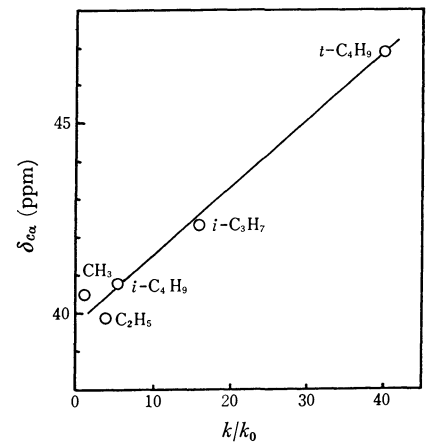

Fig. 2. Plots of $\delta_{c\alpha}$ *vs.* the relative rate of hydrolysis. The hydrolysis was carried out in acetone-water mixture (95/5 vol/vol) at 25°C using HCl catalyst.[11] The relative rate is represented by the ratio of the rate coefficient of respective vinyl ether to that of methyl vinyl ether.

^{13}C Chemical Shift and Reactivity of Alkyl Vinyl Ether. The carbon-13 NMR spectrum of alkyl vinyl ether may also give important information concerning its reaction mechanism. Therefore, let us now briefly discuss the mechanism of the cationic reaction of alkyl vinyl ether.

Alkyl vinyl ether is readily hydrolysed by dilute aqueous acids, and the relative rate of hydrolysis falls in the sequence;

$$CH_2{=}CHOR + H_2O \xrightarrow{H^+} ROH + CH_3CHO$$

R=t-C_4H_9>i-C_3H_7>i-C_4H_9>C_2H_5>CH_3. From their inspection of the ^1H NMR spectra of alkyl vinyl ethers, Ledwith and Woods[11] suggested that the electron release to the double bond of alkyl vinyl ether falls in the sequence: CH_3>i-C_3H_7>t-C_4H_9 and that, therefore, a simple, slow proton transfer to the terminal methylene group cannot be the rate-determining step in the acid-catalyzed hydrolysis.

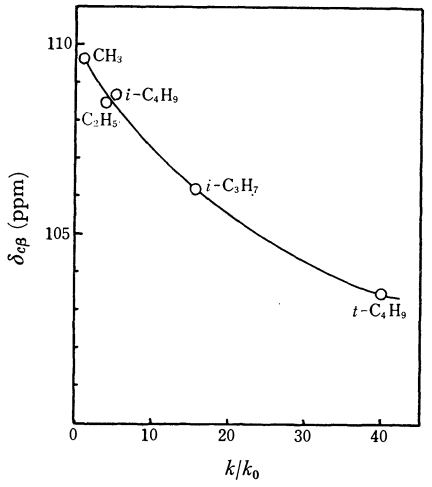

Fig. 3. Plots of $\delta_{c\beta}$ *vs.* the relative rate of hydrolysis.

As is shown in Figs. 2 and 3, a good correlations was obtained between the relative rate of hydrolysis[11] and the ^{13}C chemical shift of α- or β-carbon. These results show that the lower the electron density of β-carbon, and the higher that of α-carbon, the higher the reactivity in acid hydrolysis. This clearly indicates that the attack of the proton on the β-carbon is not the rate-determing step in this reaction. The π-electron density of α-carbon may play an important role in the rate-determining process in the hydrolysis.

The relative reactivity of alkyl vinyl ether in the cationic polymerization falls in the same order as that in the acid-catalyzed hydrolysis. In Figs. 4 and 5 the α- and β-carbon resonances are plotted against the relative reactivities of the ethers. Linear

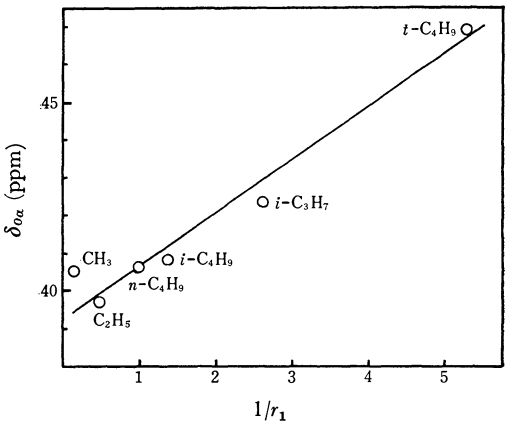

Fig. 4. Plots of $\delta_{c\alpha}$ *vs.* $1/r_1$ for alkyl vinyl ether.

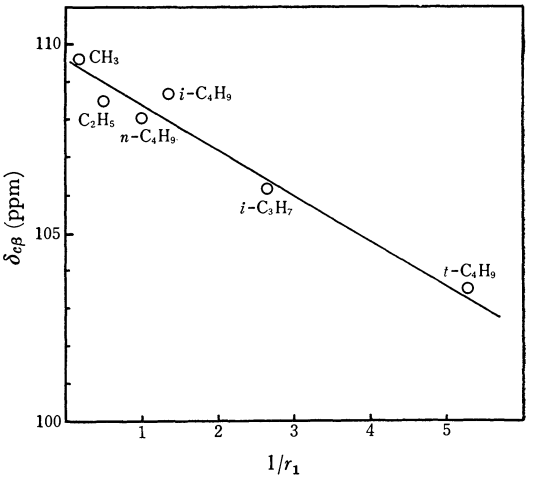

Fig. 5. Plots of $\delta_{c\beta}$ *vs.* $1/r_1$ for alkyl vinyl ether.

relations similar to those in Figs. 2 and 3 were obtained. The reactivities are represented by $1/r_1$, which was determined in the copolymerization of the respective vinyl ether (M_2) with n-butyl vinyl ether (M_1) at -78°C in toluene by the use of an $EtAlCl_2$ catalyst.[12]

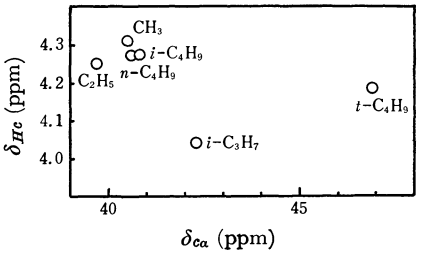

Fig. 6. Plots of $\delta_{H\alpha}$ *vs.* $\delta_{c\alpha}$.
The proton chemical shift was referred to the methyl signal of solvent toluene, low field shift being shown as positive value.

11) A. Ledwith and H. J. Woods, *J. Chem. Soc., B*, **1966**, 753.

12) H. Yuki, K. Hatada and M. Takeshita, *J. Polym. Sci., Part A-1*, **7**, 667 (1969).

Higashimura and his collaborator[13] studied the ^{13}C NMR spectra of *n*-butyl, isopropyl, and 2-chloroethyl vinyl ethers and found that the reactivity of vinyl ethers is not related to their chemical shifts. From this results, they concluded that the attack of the carbonium ion on the β-carbon is not the rate-determining step in the cationic polymerization of vinyl ether.

The results in Figs. 4 and 5 may give a strong evidence for Higashimura's suggestion, and may also suggest that the interaction of the carbonium ion with the α-carbon is an important consideration in determining the transition state of the rate-determining step.

Correlation of ^{1}H Chemical Shifts with ^{13}C Chemical Shifts. The chemical shift of the α-methine proton of alkyl vinyl ether has been reported to be independent of the electron-repelling power of the alkyl group.[5] No correlation was obtained between the chemical shifts of the α-methine proton and of the α-carbon (Fig. 6). These facts suggest that the chemical shift of this proton is controlled not only by the electron density at the α-carbon, but also by the diamagnetic shielding effect of an O–C bond in the OR group. On the other hand, linear relations were obtained between the chemical shifts of β-methylene protons and of the β-carbon, as is shown in Fig. 7. These relations show that the chemical shifts of β-methylene protons

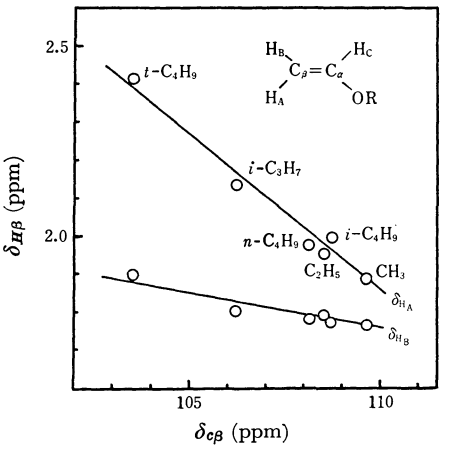

Fig. 7. Plots of $\delta_{H\beta}$ *vs.* $\delta_{c\beta}$.

shift to a higher field when the π-electron density of β-carbon increases. The diamagnetic shielding may have little effect on these protons; the chemical shifts are mainly controlled by the electron density at the β-carbon.

The authors are very grateful to Dr. M. Takeuchi and Dr. K. Gotoh of the Japan Electron Optics Laboratory Co., Ltd., for their measurements of the ^{13}C NMR spectra, and also to Mrs. F. Yano for her clerical assistance in preparing the manuscript.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3199—3205 (1970)

Studies of Tritylated Sucrose. I. Mono-*O*-tritylsucroses

Toshiki OTAKE

Nippon Electric Varian, Ltd., Azabu, Iigura-machi, Minato-ku, Tokyo

(Received February 2, 1970)

Two isomeric mono-*O*-tritylsucroses were isolated from a mixture of tritylated sucrose which had been obtained by the reaction of sucrose and trityl chloride in the ratio of 1 : 1.2 by mole. The structures of these two isomers were established by the application of gas chromatography and NMR spectroscopy to appropriate derivatives. One of the two substances is 6′-mono-*O*-tritylsucrose, and the other is 6-mono-*O*-tritylsucrose, which is crystallized as white needles. The detritylation of mono-*O*-trityl-*O*-acetylsucroses yielded hepta-*O*-acetylsucroses, which were confirmed by a study of their NMR spectra to be 2,3,4,6,1′,3′,4′- and 2,3,4,1′,3′,4′,6′-hepta-*O*-acetylsucrose. No migration of the acetyl group on the sucrose molecule was observed during the detritylation procedure.

Several works on tritylated sucrose have been reported during the past forty years. Josephson[1] in 1929 reported the synthesis of "tri-*O*-tritylsucrose" with 3 mol of trityl chloride. Later, McKeown and his co-workers[2] described that the product obtained by the Josephson's route was a mixture of tri-*O*-tritylsucrose, products with a lower trityl content, reducing sugar, and tritanol. McKeown reported also that tri-*O*-trityl-penta-*O*-acetylsucrose was conveniently prepared in a crystalline form, after the tritylation of sucrose in pyridine, by acetylation in the same solution. The detritylation of this crystalline substance by graded hydrolysis with acetic acid, followed by methylation and deacetylation, yielded 1′,6′,4-tri-*O*-methylsucrose. The structure of this tri-*O*-methylsucrose was established by the production of the corresponding *O*-methyl ethers of glucose and fructose.

However, according to McKeown,[3] his deacetylation of the same crystalline substance, followed by methylation and detritylation, gave a syrupy penta-*O*-methylsucrose, which was concluded to consist of 2,3,4,3′,4′-penta-*O*-methyl derivatives of sucrose by the specific rotation measurement and by the paper chromatography of the corresponding *O*-methyl ethers of glucose and fructose. Accodingly, McKeown and his co-workers concluded that the original positions of trityl groups were at the three primary carbons in the sucrose molecule and that the acetyl migration from C_4 to C_6 occurred during the detritylation or methylation reaction.

Subsequently, Bredereck and his co-workers[4] reported a crystalline tri-*O*-trityl-penta-*O*-acetylsucrose with a melting point equal with that of the crystalline substance prepared by McKeown. The mild detritylation of the tri-*O*-trityl-penta-*O*-acetylsucrose with hydrobromic acid in a cold acetic acid solution yielded 2,3,4,3′,4′-penta-*O*-acetylsucrose, which turned into 2,3,6,3′,4′-penta-*O*-acetyl derivative when treated with sodium bicarbonate. The structure of the penta-*O*-acetylsucrose was established by periodate oxidation.

Scanning through these reports, one cannot help noticing how often treacherous conclusions were obtained from chemical reactions alone; thus, McKeown and his co-workers were first beguiled with the position of trityl groups and speculated on migration during deacetylation or methylation, and later confirmed the structure through a complex reaction route and a purely chemical determination, leaving ambiguities inherently connected with the chemical analyses.

Our present objective is the synthesis and structural determination of mono- and di-*O*-tritylsucroses obtained through various separation techniques. Studies of these products with a lower trityl content by a direct physical method such as NMR spectroscopy will give a further confirmation of the structure of the tri-*O*-trityl derivative of sucrose by eliminating the ambiguity which would otherwise arise from the analysis of the chemical procedures. The hepta-*O*-acetylsucroses prepared from the mono-*O*-tritylsucroses will be compounds for the synthesis of oligosaccharides, such as raffinose and planteose. This paper will deal with two isomeric mono-*O*-tritylsucroses and hepta-*O*-acetylsucroses derived from these isomers.

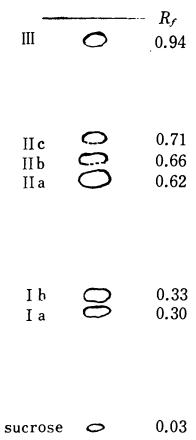

Fig. 1. The thin layer chromatogram of a reaction mixture of tritylation, effected on silica gel G with 20 : 20 : 3 : 57 (V/V/V/V) methanol-acetone-water-chloroform. Zones were located with 50% sulfuric acid.

Results and Discussion

The thin-layer chromatogram of a reaction mixture obtained from the treatment of sucrose with slightly overdosed trityl chloride in a pyridine solution is shown in Fig. 1. The chromatogram, which was detected by spraying with 50% sulfuric acid and by subsequent heating at 120°C, shows at least six kinds of tritylated sucroses, observable in the form of dark green spots. The tritylated sucroses, Ia and Ib, corresponding to the R_f values of 0.30 and 0.33 respectively, have been identified as mono-*O*-tritylated sucroses by UV spectroscopy, as will be described later. The tritylated sucroses, IIa, IIb and IIc, corresponding to the R_f values of 0.62, 0.66, and 0.71, are confirmed to be di-*O*-tritylsucroses by UV spectroscopy.

Of the total tritylated sucroses obtained, 47% by weight consisted of the combined yields of the di- and tri-*O*-tritylsucroses, this was quite a large figure in comparison with the overdosage of trityl chloride, in the molar ratio of 1.2 : 1, used for the treatment of sucrose. It is also noteworthy that the reaction mixture was about 10% free sucrose.

The reaction mixture was resolved in 1-butanol, and the butanol solution was washed with water to remove the free sucrose; the subsequent evaporation of the organic layer produced a mixture of tritylated sucroses as colorless glass. It was found that this mixture could conveniently be separated into mono-*O*-tritylsucrose and a mixture of substances with higher trityl contents by a counter-current distribution using a solvent system such as trichloroethylene - methanol - water; thus, the evaporation of the polar layer, consisting of methanol and water, yielded the mono-*O*-tritylsucrose 53% of the total tritylated sucroses, while the non-polar layer contained the remaining 47% the di- and tri-*O*-tritylsucroses.

Mono-*O*-tritylsucrose, Ib, was separated as white needles from a solution of 80% ethanol (mp 99—101°C; $[\alpha]_D^{20}$ +51.7° (*c* 4, *N*,*N*-dimethylformamide). The other isomeric mono-ether, Ia, was obtained as an amorphous powder from the concentrate of the mother liquid after Ib had been removed by means of recycling column chromatography.[5] The amorphous powder Ia softens at 149°C and has $[\alpha]_D^{22}$ +31.9° (*c* 4, *N*,*N*-dimethylformamide). A small amount of Ib was further recovered in a crystalline form from a fraction with a higher Ib content by recycling column chromatography; the total yield for the crystalline Ib was 35% as against 36% for Ia, relative to a mixture of mono-*O*-tritylsucroses.

The IR spectra of Ia and Ib, while each shows essentially the same pattern as that of free sucrose between 1400 and 800 cm^{-1}, both exhibited characteristic phenyl absorptions at 1600, 1495, and 1450 cm^{-1}. On the UV spectra of trityl chloride, Ia and Ib have also identical absorption patterns (λ_{max}=260 mμ) and assume almost the same values in the molar extinction coefficients (ε_{max}: Ia, 725; Ib 715; trityl chloride, 720). These spectroscopic observations confirm that Ia and Ib are mono-*O*-tritylsucroses.

The tritylated sucroses with higher R_f values, IIa, IIb, and IIc, take molar extinction coefficients of 1415—1460, which are twice as much as those of mono-*O*-tritylsucroses; this proves that IIa, IIb, and IIc, are di-*O*-trityl derivatives.

The methylation of both the mono-*O*-tritylsucroses according to the Kuhn procedure,[6] followed by column-chromatographic purification, produced mono-*O*-trityl-hepta-*O*-methylsucroses, IVa and IVb, in 77% and 83% yields respectively. Both the products were colorless glass, and IVb was crystallized from 80% ethanol as white plates, melting at 84°C. They showed a single spot of a dark green color in a thin-layer chromatogram and no hydroxy absorption in IR spectra, revealing that the methylation was completed in both IVa and IVb.

The NMR spectrum of IVa shows all seven methoxyl-group signals separately defined (δ 3.33 (3H), 3.36(3H), 3.41(3H), 3,43(3H), 3.47(3H), 3.54(3H), and 3.56(3H)). In IVb, two of the methoxyl-group signals overlap to give five 3-proton singlets and a coincident resonance of six protons (δ 3.30(3H), 3.32(6H), 3.39(3H), 3.42(3H), 3.50 (3H) and 3.62(3H)). These spectra further confirm that both products are hepta-*O*-methyl derivatives. The IVa and IVb products were then detritylated by Bredereck's procedure.[4] After column-chromatographic purification, hepta-*O*-methylsucroses, Va and Vb, were obtained as a colorless oil in yields

5) T. Otake and E. Tamate, *Nippon Kagaku Zasshi*, **90**, 388 (1969).

6) R. Kuhn, H. Trischmann and I. Low, *Angew. Chem.*, **67**, 32 (1955).

of 74% and 78% respectively. The phenyl absorptions were not observed, but the absorptions due to the hydroxy group were noticed in the IR spectra and the thin-layer chromatograms showed a single black spot each.

The detritylated products, Va and Vb, were subjected to methanolysis with 5% methanolic hydrochloric acid to yield a mixture of the fully and the partially-methylated methyl fructoside and methyl glucoside. These methanolysis products did not reduced Fehling's solution, and unreacted hepta-*O*-methylsucrose was not observed by thin-layer chromatography. The products of methanolysis were subsequently analyzed by gas chromatography, using the diethyleneglycol succinate polyester as the liquid phase. The gas chromatogram of the methanolysate of Va (Fig. 2) showed six peaks. Among

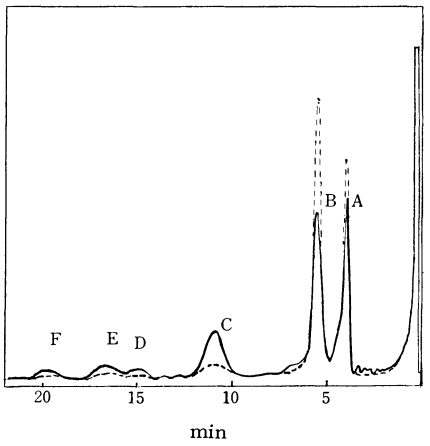

Fig. 2. The gas chromatogram of the methanolysis products of the hepta-*O*-methylsucrose derived from Ia. Conditions: 5′×1/8″, 20% diethyleneglycol succinate polyester on Chromosorb W 100/120 mesh at 170°, N_2 at 20 ml/min. Ditector: FID. ———, methanolysis products; -----, methanolysis products+permethylglucose.

these peaks, A and B were assigned to methyl 2,3,4,6 tetra-*O*-methyl β-, and α-D-glucopyranoside respectively, for they had the same retention volumes as authentic samples. The peaks with higher retention volumes, C, D, E, and F, may be assumed to be partially-methylated fructosides, but the assignment of each peak still remains to be done. The gas-chromatographic analysis reveals, however, that the trityl group of the original compound, Ia, is at the fructose moiety of the sucrose molecule.

All five peaks were observed in a gas chromatogram of the methanolysis product of Vb (Fig. 3). The peaks A′ and B′ which did not correspond to the permethyl glucose, were identified as methyl 1,3,4,6-tetra-*O*-methyl α- and β-D-fructofuranoside respectively by referring to Gee's data.[7] The D′

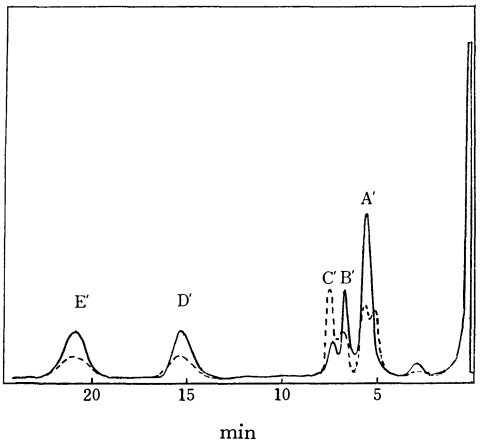

Fig. 3. The gas chromatogram of the methanolysis products of the hepta-*O*-methylsucrose derived from Ib. Conditions are same as for Fig. 2, except the column temperature ,which is 108°C. ———, methanolysis product; -----, methanoysis product+permethylglucose.

and E′ peaks were assigned to methyl 2,3,4-tri-*O*-methyl β- and α-D-glucopyranoside respectively by comparing them with authentic samples.

The relatively low peak, C′, was assigned to methyl 1,3,4,5-tetra-*O*-methyl-α-D-fructopyranoside, again by referring to Gee's results, in which both the anomeric isomers were assumed to be contained in the peak E′.

The two methyl glucosides of the peak E′ were actually separated into compounds by gas chromatography using a Chromosorb W-neopentyl-glycol-succinate-polyester (10% W/W) glass column. Though the route of the formation of the minor fructopyranosides is not clear, it may be concluded that the original compound, Ib, has a trityl group combined at the glucose moiety of the sucrose molecule. Mono-*O*-tritylsucroses (Ia and Ib) were acetylated with acetic anhydride in pyridine at room temperature; these products were then purified by chromatography on silica gel to obtain mono-*O*-trityl-hepta-acetylsucroses (VIa and VIb). The product VIb was crystallized from 80% ethanol as white prisms (mp 103—104°C). The thin-layer chromatograms of the products (VIa and VIb) showed a single spot of a dark green color on each, and no hydroxy absorption was observed in the IR spectra.

The mass spectra of the two products were identical on all the fragments with respect to the mass numbers. Both parent peaks were of a very low intensity, and the only prominent peaks appearing close to the parent peaks were at *m/e* 801 (M−77). There were, however, some differences in the mass spectra as regards the pattern coefficients of the two products; for example, the intensities of the M−77 ions of VIa and VIb relative to the peak

7) M. Gee and H. G. Wlker, Jr., *Anal. Chem.*, **34**, 650 (1962).

at *m/e* 243 were 2.4% and 0.8% respectively. It should be remembered that *m/e* 243 and M−77 are considered as coming mainly from the trityl cation and from the phenyl radical dissociation of the products respectively.

Turning to NMR spectroscopy, the integrated intensities of the acetyl, trityl, and other protons of VIa and VIb agreed with the theoretical values of the assumed mono-*O*-trityl-hepta-*O*-acetyl-derivatives.

The observed chemical shifts of the acetyl-group protons of VIa and VIb have low δ values, with certain differences between them (VIa: δ 1.93(3H), 1.99(3H), 2.00(3H), 2.07(9H) and 2.10(3H); VIb: δ 1.75(3H), 2.01(6H), 2.09(3H), and 2.12(9H), while the signals arising from the methine and the methylene protons fall in the region between δ 2.8—5.9; each spectrum can be subdivided into three non-overlapping regions, the region A (δ 2.7—3.5, 2H), the region B (δ 3.6—4.5, 6H), and the region C (δ 4.5—5.8, 6H).

The NMR spectrum of octa-*O*-acetylsucrose[8] shows no signal in the region A, but it does show signals in the region B which arise from eight protons assigned to the overlapped signal of H-5, of H-5′, and of the protons of the methylene groups to which *O*-acetyl groups are attached. The signals in the region C correspond to six protons, the number of protons in the region C of VIa and VIb, all of which can be assigned to the ring protons of sucrose other than H-5 and H-5′.

When we compare the NMR spectra of mono-*O*-trityl-hepta-*O*-acetylsucroses and octa-*O*-acetylsucrose, the signals of the region A in the spectra of VIa and VIb may be assigned to the protons of the methylene group to which an *O*-trityl group is directly attached. The acetyl derivatives, VIa and VIb, show apparent seven-line and eight-line signals respectively in the region A. Each of these

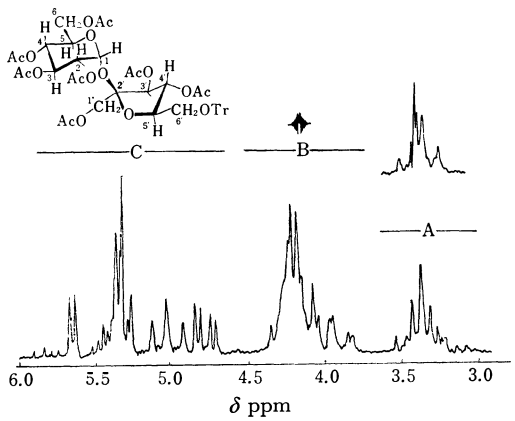

Fig. 4. Partial NMR spectra at 100 MHz of VIa in $CDCl_3$.

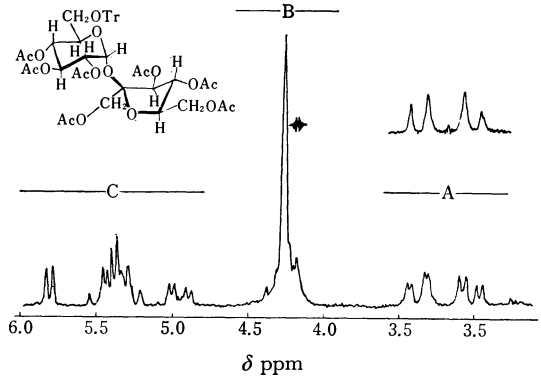

Fig. 5. Partial NMR spectra of 100 MHz of VIb in $CDCl_3$.

signals is considered to consist of the AB part in an ABX system. This assumption has been confirmed for both the products by irradiating them near δ 4.0 and by then observing the perturbation of the signals in the region A as it gives rise to the signals with four transitions, as is shown in Figs. 4 and 5. The following simulation spectra were obtained by a computer, thus confirming the proposed spin systems defined thus: for VIa δ (1) 3.30, (2) 3.43, (3) 4.16 and (4) 5.36 with J(1,2) −10.2, J(1,3) 5.4, J(2,3) 6.0 and J(3,4) 5.5Hz; for VIb δ (1) 3.01, (2) 3.36, (3) 4.16 and (4) 5.28 with J(3,4) −10.6, J(1,4) 3.6, J(2,3) 2.0 and J(3,4) 10.0Hz.

	1	2	3	4	5	6	7	8
VIa								
Observed	3.21	3.27	3.31		3.37	3.43	3.47	3.53
Generated	3.20	3.26	3.30		3.36	3.42	3.47	3.53
VIb								
Observed	2.93	2.97	3.04	3.07	3.31	3.33	3.41	3.43
Generated	2.94	2.98	3.05	3.08	3.31	3.33	3.42	3.43

On the basis of these observations, the signals in the region A can be assigned to the methylene protons of H-6 and H-6′. Combined with the data of gas chromatography, it can be concluded that the original compounds, Ia and Ib, are 6′-mono-*O*-trityl-sucrose and 6-mono-*O*-tritylsucrose respectively.

The products VIa and VIb were detritylated by Bredereck's method, using hydrobromic acid in an acetic acid solution. The oily chloroform extracts then separated from the trityl bromide and the unreacted mono-*O*-trityl-hepta-*O*-acetyl derivatives by column chromatography on silica gel, thus producing hepta-*O*-acetylsucroses, VIIa and VIIb, as colorless glass in 69% and 63% yields respectrively. The product VIIa was crystallized from 80% ethanol as white prisms which melted at 93—94°C.

The thin-layer chromatogram confirmed that both products were homogeneous and untritylated com-

pounds generating a single black spot. Their IR spectra noted to have absorptions in the O–H stretching region, and no phenyl absorption was observed. The NMR spectra of each of the products showed acetyl-group signals of the anticipated 21 protons (VIIa: δ 2.01(3H), 2.04(3H), 2.11(9H), 2.13(3H) and 2.21(3H); VIIb: δ 2.02(3H), 2.06(3H), 2.09(3H), 2.10(3H), 2.21(6H) and 2.20(3H)). The NMR spectrum of VIIa shows an apparent 2-proton octet between δ 3.5—4.0. The chemical shift of the octet consists of directly connecting the methylene group to the hydroxy group. The irradiation at δ 4.1 brings about the collapse of the octet to a four-line pattern (one line showing beat perturbation), as Fig. 6 shows. This 8-line pattern may be recognized as the AB part of an ABX system. The spectrum of VIIb appeared as a wide doublet of 2-protons, between δ 3.55—3.75, which reduces to a wide singlet with a half-width of 7Hz upon irradiation at δ 4.0 (Fig. 7).

Inasmuch as the chemical shift is almost identical to that of the above-mentioned octet, the observed wide doublet can also be assigned to the methylene protons of the hydroxymethyl group. Because the protons of the methylene group are practically equivalent, there are no other signals which appear on both sides of the wide doublet.

On the basis of the NMR data, the hydroxymethyl groups of VIIa and VIIb may be said to be those of the 6′- and 6-positions respectively. Thus, the detritylated products, VIIa and VIIb, must be 2,3,4,6,1′,3′,4′- and 2,3,4,1′,3′,4′,6′-hepta-*O*-acetylsucrose respectively.

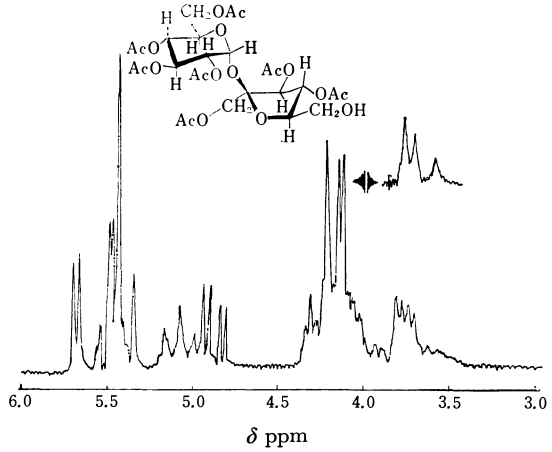

Fig. 6. Partial NMR spectra at 100 MHz of VIIa in $CDCl_3$.

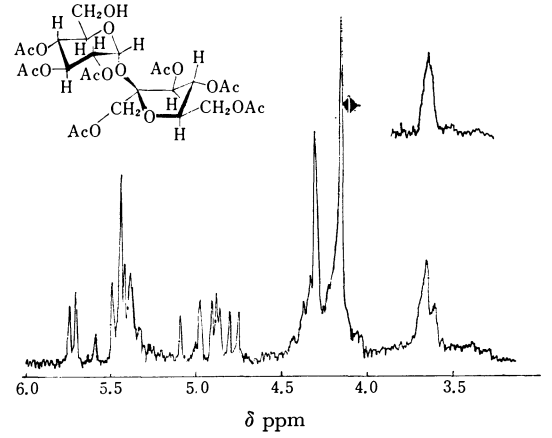

Fig. 7. Partial NMR spectra at 100 MHz of VIIb in $CDCl_3$.

Experimental

General Methods. Thin-layer chromatography was effected using Merck silica gel G as the adsorbent in a thickness of 0.25 mm and with these solvent systems: (A) methanol - water - acetone - chloroform (20 : 4 : 20 : 56) for tritylated sucrose and (B) methyl ethyl ketone (MEK)-toluene for the *O*-methyl and *O*-acetyl derivatives of sucrose. The developed plates were sprayed with 50% sulfuric acid and heated at 120°C. The column chromatography was performed using silica gel, 60—80 mesh, prepared by the Kanto Chemical Co., Japan.

The IR and the UV spectra were measured with a Hitachi EPI-II IR spectrometer and a Cary Model 14R recording spectrophotometer respectively. The mass spectra were recorded with a Varian M-66 mass spectrometer. The gas-liquid chromatography were performed with a Varian-Aerograph Model 1200 instrument with a hydrogen-flame ionization detector. The NMR spectra were recorded with a Varian HA-100D (100 MHz) spectrometer using chloroform-d, with tetramethylsilane as an internal lock; the signal positions were expressed in δ values. The NMR simulations were accomplished by a Varian Spectro System SS-100 equipped with a Varian 620/i computer.

Tritylation of Sucrose. Commercial granulated sucrose (34.2 g) was reacted with recrystallized trityl chloride (33.4 g) in dry pyridine (1 *l*) at room temperature. The reaction was assisted by the agitation of the reaction solution on a magnetic stirrier for 96 hours. At the end of the reaction period, the solution was dried *in vacuo* on a rotary evaporator. The residue was dissolved in 1-butanol (200 m*l*) and then washed with a McKirrvin buffer (pH 7.0) and water in order to remove the free sucrose. The evaporation of the butanol solution under reduced pressure left 59.5 g of tritylated sucrose as colorless glass.

6-Mono-*O*-tritylsucrose (Ib). A mixture of tritylated sucrose (55.1 g) was subjected to a counter-current distribution of six steps using an equilibrated system with methanol (1.75 *l*), a McKirrvin buffer (pH 7.0) (0.75 *l*), and trichloroethylene (2.5 *l*).

The polar layer, consisting of methanol and water, was dried *in vacuo* to yield 28.54 g of a mixture of mono-*O*-tritylsucroses. The evaporation of the combined polar layer under reduced pressure yielded 24.98 g of a glassy product which contained di- and tri-*O*-tritylsucrose.

A mixture of mono-*O*-tritylsucroses (25.92 g) was dissolved in 50% ethanol (200 m*l*); 7.5 g of 6-mono-*O*-tritylsucrose (Ib) were crystallized from this solution as white needles. Further, 2.8 g of Ib were separated

from the evaporated residue of the mother liquid by recycling column chromatography. After repeated recrystallizations from 70% ethanol, Ib had a mp of 99—101°C, $[\alpha]_D^{20}$ +51.7° (*c* 4, dimethylformamide (DMF)). The thin-layer chromatogram developed by the A solvent showed the crystalline product to be homogeneous with the R_f value of 0.33.

Found: C, 63.23; H, 6.62%. Calcd for $C_{31}H_{36}O_{17}$: C, 63.78; H, 6.16%.

6′-Mono-*O*-tritylsucrose (Ia). After the crystallization of Ib, the mother liquid was dried *in vacuo* to yield 16.56 g of the residue, which contained Ia as the major component.

The residue was chromatographed on silica gel (160 g) by means of graded elution with 1.6-*l* portion of 8, 12, and 16% methanol/chloroform solutions. The eluent was divided into twelve 400-m*l* fractions; after all the solvent had then passed through the column, the fractions were gradually returned to the column. The column was then washed with 800 m*l* of the 16% methanol/chloroform solution. The recycling procedure was repeated again to give 16 fractions of the eluent.

Each of the fractions was dried *in vacuo*, and each residue was chromatographed on thin-layer plates; this indicated that the residues of the 13th, 14th, 15th, and 16th fractions consisted of almost pure Ia. The admixture of the residues from those four fractions weighed 9.06 g and had a softening point of 149°C and $[\alpha]_D^{20}$ +31.9° (*c* 4, DMF). The spots on a thin-layer chromatogram (solvent A) of the combined residues were very faint for a R_f value of 0.33, while they were distinct for a R_f value of 0.30.

Found: C, 63.00; H, 6.58%. Calcd for $C_{31}H_{36}O_{17}$: C, 63.70; H, 6.16%.

6- and 6′-Mono-*O*-trityl-hepta-*O*-methylsucrose (IVa and IVb). Each of the mono-*O*-tritylsucroses, Ia and Ib (0.584 g) was methylated in dry *N,N*-dimethylformamide (DMF) (10 m*l*) with methyl iodide (10 m*l*) and silver oxide (5 g). Finely-divided anhydrous barium oxide (5 g) was added to each of the reaction solutions to ensure anhydrous conditions, and the reaction was assisted by the vigorous agitation of the reaction solution on a magnetic stirrer for 24 hr. At the end of the reaction period, the solution was filtered to remove any solids, and the residues were washed with an admixture of toluene and DMF (1 : 1 vol/vol) (10 m*l*). The combined filtrate and washings were then evaporated to yield a syrupy product. The product was resolved in an admixture of methyl ethyl ketone (MEK) and toluene (1 : 1 vol/vol) (20 m*l*), after which the solution was filtered to remove any insoluble matter. The filtrate was then dried *in vacuo* to yield a colorless glass.

Each of the products was resolved in 5 m*l* of toluene and chromatographed on a column of silica gel (5 g). The column was eluted with 5% MEK/toluene (100 m*l*) and 8% MEK/toluene (100 m*l*). The evaporation of the latter solvent yielded 0.447 g of IVa and 0.480 g of IVb in both cases as colorless glass. The IVb was crystallized from 90% methanol as white plates which melted at 84°C.

A thin-layer chromatogram with MEK/toluene (3 : 7 vol/vol) showed both IVa and IVb to be homogeneous, and both R_f values were 0.50 .

Found, IVa: C, 65.72; H, 7.76%. Found, IVb: C, 66.10; H, 7.28%. Calcd for $C_{38}H_{50}O_{17}$: C, 66.90; H, 7.34%.

2,3,4,6,1′,3′,4′- and 2,3,4,1′,3′,4′,6′-Hepta-*O*-methylsucrose (Va and Vb). Each of the methylation products (IVa and IVb) (200 mg) was detritylated in 0.6 m*l* of acetic acid with hydrogen bromide, which was added as a saturated acetic acid solution (0.06 m*l*) under ice cooling. The reaction solution was then allowed to remain for two minutes while being vigorously agitated. At the end of the reaction period, the solution was poured into iced water (10 m*l*) and the detritylation products were extracted from the suspension with 10 m*l* of chloroform. The chloroform solution was allowed to stand for three hours after calcium chloride (1 g) had been added, and then it was filtered to remove any solids. The filtrate was evaporated under reduced pressure, and the residue was chromatographed on 5 g of silica gel to free it from trityl bromide and the unreacted IVa or IVb.

The column was washed with 10 m*l* of 10% MEK/toluene and then with 100 m*l* of 15% MEK/toluene to elute the hepta-*O*-methylsucrose. The evaporation of the latter washing *in vacuo* yielded 103 mg of Va and 108 mg of Vb as colorless oil. A thin-layer chromatogram with MEK/toluene (6 : 4) showed both products, Va and Vb, to be homogeneous; they had R_f values of 0.25 and 0.21 respectively.

Methanolysis of Hepta-*O*-methylsucroses. Approximately 100 mg of each hepta-*O*-methylsucrose was methanolized at 60°C with 3 m*l* of 5% methanolic hydrochloric acid in a sealed tube for one hour. At the end of the reaction period, the reaction solution was passed through an anion exchanger column, *e.g.*, IRA 410 (Amberlite Rohm & Haas) (5 m*l*). Then the column was washed with approx. 50 m*l* methanol. The combined mixture of the eluent and the wasing was dried, and the evaporation residue was submitted to gas chromatography.

Mono-*O*-trityl-hepta-*O*-acetylsucroses (VIa and VIb). Each of the mono-*O*-tritylsucrose (Ia and Ib) (1.168 g, each) was dissolved in 10 m*l* of dry pyridine and then acetylated with acetic anhydride (2.8 m*l*). The solution was allowed to stand for 24 hr and then evaporated to yield a syrupy product. Each of the products was chromatographed on silica gel (10 g) column; the column was washed with 200 m*l* of toluene and then with 200 m*l* of 10% MEK/toluene to elute mono-*O*-trityl-hepta-*O*-acetylsucroses. The evaporation of the MEK-toluene fractions yielded 1.39 g of VIa and 1.42 g of VIb respectively, as both a white amorphous powder. Thin-layer chromatography with MEK/toluene (9 : 6) showed both products, VIa and VIb, to be homogeneous and to have R_f values of 0.55. One of the acetyl derivatives, VIb, was crystallized from 80% ethanol as white prisms with a mp of 103—104°C.

Found, VIa: C, 62.01; H, 6.08.% Found, VIb: C, 59.49; H, 5.86%. Calcd for $C_{45}H_{50}O_{24}$: C, 61.49; H, 5.69%.

Hepta-*O*-acetylsucroses (VIIa and VIIb). 0.878 g-portions of VIa and VIb were dissolved in 3 m*l* of glacial acetic acid saturated with hydrogen bromide under ice cooling. The reaction solution was allowed to stand with vigorous agitation for 5 min and then poured into cold water (20 m*l*). The reaction products were extracted twice with 20 m*l* of chloroform from the water suspension by washing the chloroform layers with water after which the combined chloroform solution was dried. The

evaporation residue was chromatographed on a silica-gel (10 g) column. The column was then washed with 200 m*l* of 10% MEK/toluene to elute trityl bromide and unreacted mono-*O*-trityl derivatives, and each hepta-*O*-acetylsucrose sample was eluted with 200 m*l* of the 20% MEK/toluene from the column. The evaporation of the 20% MEK/toluene fractions yielded 439 mg of VIIa and 401 mg of VIIb respectively, in both cases as colorless glass. Thin-layer chromatography with MEK/toluene (4 : 6) showed the final products to be homogeneous, with a R_f value of 0.25. VIIa was crystallized from 80% ethanol as white prisms which melted at 93—94°C.

Found, VIIa: C, 49.19; H, 5.80%. Found, VIIb: C, 49.16; H, 5.66%. Calcd for $C_{26}H_{36}O_{18}$: C, 49.06; H, 5.66%.

The author wishes to thank Professor Tetsuo Suami for his helpful advice and Mr. Iwao Miura for the determination of the NMR spectra.

The Photoreaction of 2,6-Diphenyl-4*H*-thiopyran-4-one and Its Related Compounds

Noboru SUGIYAMA, Yoshiaki SATO and Choji KASHIMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received February 16, 1970)

The irradiation of 2,6-diphenyl-4*H*-thiopyran-4-one (**1**) or 2,6-diphenyl-4*H*-pyran-4-one (**2**) in an alcohol in the presence of oxygen gave benzoic acid and a benzoylacetic acid ester, while that of **2** in benzene or 2,6-dimethyl-4*H*-thiopyran-4-one (**5**) in various solvents gave the corresponding cage dimer, (**9**) or (**10**). No photoreaction could be observed in case of the irradiation of 1,2,6-trimethyl-4-pyridone (**3**) and 6-methyl-1,2-diphenyl-4-pyridone (**4**). A reaction mechanism *via* the triplet state of the substrate was also proposed.

Previously we have reported that the irradiation of 2,6-diphenyl-4*H*-thiopyran-4-one (**1**) in non-polar solvents gave a head-to-tail, antidimer (**8**),[1] while that of 6-methyl-1,2-diphenyl-2,3-dihydro-4-pyridone (**6**) gave 6-methyl-2,5-diphenyl-2,3-dihydro-4(1*H*)-4-pyridone, 5-methyl-2,6-diphenyl-2,3-dihydro-4(1*H*)-4-pyridone and 2-anilino-6-phenyl-2,5-hexadiene-4-one.[2] Now we have found that the irradiation of **1** in polar solvents gave photooxidized products. For comparison, the photoreactions of **1** and its related compounds have been examined.

6

Results and Discussion

The irradiation of **1** in methanol or ethanol by means of a high-pressure mercury lamp with a Pyrex filter gave benzoic acid and methyl or ethyl benzoylacetate (**7a** or **b**), but in the reaction mixture **8** was not detected. The results of irradiation reactions of **1** under various conditions are summarized in Table 1.

In order to ascertain whether or not this reaction is characteristic of thiopyrones, we studied the photoreaction of 2,6-diphenyl-4*H*-pyran-4-one (**2**),[3] 1,2,6-trimethyl-4-pyridone (**3**)[4] and 6-methyl-1,2-diphenyl-4-pyridone (**4**),[5] in which the sulfur atom in the thiopyrone ring is replaced by an oxygen or nitrogen atom. When **2** in methanol was irradiated under the same conditions as **1**, similar

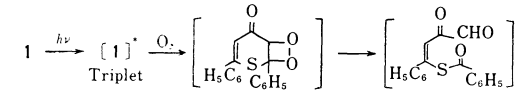
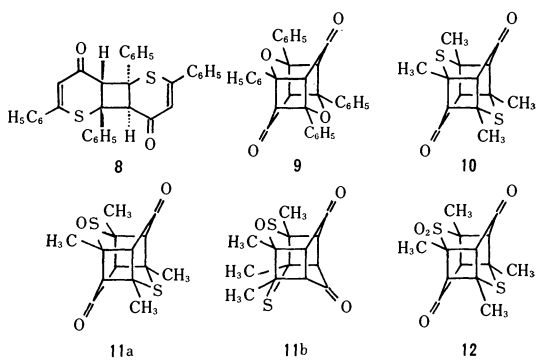
a) Pyrex filter was used. The atmosphere was air.
b) Nitrogen gas was passed through the reaction vessel.
c) Nitrogen gas was passed for an hour before the irradiation and the reaction vessel was sealed with a rubber stopper.

results of photooxidation were obtained, as is shown in Table 1. However, **3** or **4** under various conditions did not show any change, in contrast to the photolysis of **6**.[2]

The mechanism of these photooxidation was examined in detail. It was found that this reaction did not take place when an alcoholic solution of **1** or **2** was sealed in a nitrogen atmosphere before irradiation. Also, the photooxidation was not observed when the **1** in an alcohol was irradiated with a tungsten lamp, using methylene blue or rose bengal as a sensitizer. When **1** was treated with sodium hypochlorite and hydrogen peroxide,[6] no reaction occurred. This fact excluded the possible participation of O_2 in the above photooxidation. When oxygen or nitrogen gas was passed through an alcoholic solution of **1**, the UV absorption of **1** did not show any change; this suggests no participation of the charge-transfer complex at the ground state in this reaction.[7,8] Considering that oxygen seems to quench the excited state of **1**, as can be seen by comparing the disappearance rate of **1** under nitrogen with that under oxygen (Table 1), it can be speculated that the triplet state of **1** is an reactive species. This is also supported by the quenching effect with piperylene. The irradiation of **7** under the same conditions as in case of **1** or **2** did not give benzoic acid. All the above facts are in accord with the mechanism shown in Scheme 1, except that there is no clear evidence for the presence of dioxetane or keto-aldehyde intermediates.



Scheme 1



On the other hand, when a benzene solution of **2** was irradiated under a nitrogen atmosphere for a week, a dimer (**9**) was obtained in a 37% yield. The structure of **9** seems to be a head-to-tail cage dimer, judging from the following data. The results of elemental analysis and the mass spectrum [*m/e* 391 ($M^+-C_6H_5-C{\equiv}O^+$)] confirm that **9** is a dimeric compound. The UV, IR, and NMR spectra indicate a saturated carbonyl compound. The ther-

mal decomposition of **9** afforded only **2**.[9,10] The mass spectrum of **9** shows a strong monomeric peak (*m/e* 248, 36%).

Furthermore, we studied the photoreaction of 2,6-dimethyl-4*H*-thiopyran-4-one (**5**)[11,12] in a benzene, ether, or methanol solution. The irradiation of **5** under a nitrogen atmosphere for 72 hr gave a dimer (**10**) in about a 1% yield in each case. The structure of **10** was determined to be a head-to-tail cage dimer on the basis of the following data.

The results of elemental analysis, the mass (*m/e* 280), UV, IR, and NMR spectra, and the thermal decomposition support the idea that **10** is a cage dimer. The head-to-tail form of **10** is unequivocally confirmed by the NMR spectrum of **11a** as follows. The oxidation of **10** by hydrogen peroxide at room temperature gave monosulfoxide **11a** and monosulfone (**12**). The structures of **11a** and **12** are supported by the results of elemental analysis and and the UV, IR, NMR, and mass spectra. In the NMR spectrum of **12** methine protones show a singlet signal at τ 6.73, while in that of **11a** they show two singlet signals at τ 7.00 and 6.94, indicating that **11a** has a head-to-tail form, for the head-to-head form (**11b**) may be expected to show an AB quartet pattern.

Since the photodimerization of **2** or **5** is strongly inhibited in the presence of oxygen, it seems reasonable to deduce that the triplet state of **2** or **5** is responsible for the photodimerization. Moreover, the photoreaction of **2** or **5** gives a head-to-tail cage dimer, and that of **1** or **2** in the presence of oxygen gives oxidation products, *via* the triplet state.

The theory that the photoreaction depends on the electron density in this pyrone ring has been proposed with regard to the photoreaction of **1** in various solvents.[1] The UV spectra of **2** and **5** in benzene, ether, ethanol, and methanol show little difference compared with that of **1** as will be shown in the Experimental Section. Therefore, it is expected that the photoreaction of **2** or **5** in those solvents would show the similar reaction. Indeed, the same photodimer was isolated in the photoreaction of **5** in benzene, ether, and methanol, but the photolysis of **2** in benzene gave a dimeric product, while that of **2** in methanol gave no product.

Moreover, we found interesting facts in the UV spectra of **9** and **10** and the mass spectra of **10**, **11a**, and **12**. The UV absorption of the 2,6-dimethyl-4*H*-pyran-4-one cage dimer shows a strong charge-transfer absorption at 233 nm (ε 2410).[13] That of **9** shows an absorption at 220 nm (ε 26000, sh), and that of **10** shows an absorption at 240 nm (ε 345). These are very similar to that of 9-thiabicyclo[3.3.1]-non-6-en-2-one (240 nm, ε 290)[14] and that of tetrahydro-4*H*-thiopyran-4-one (233 nm, ε 507).[15] The mass spectrum of **10** does not show any fragments of *p*-benzoquinone (*m/e* 108) or tetramethyl-1,4-dithiahexadiene (*m/e* 172), but it does show that of the correspondine monomer, **5** (*m/e* 140, 80%), as well as those of 2,5-dimethylthiophene (*m/e* 112, base peak), *m/e* 97 (25%) and *m/e* 59 (17%).[16] In addition to the fragment of the monomer **5**, the mass spectra of **11a** and **12** show a desulfoxide or desulfone fragment at *m/e* 148 (3 or 23% respectively), accompanied by decarbonylation, demethylation, decarbonylation and fission to the 1,2-dimethylcyclobutadiene cation radical[16] (Fig. 1, Scheme 2).

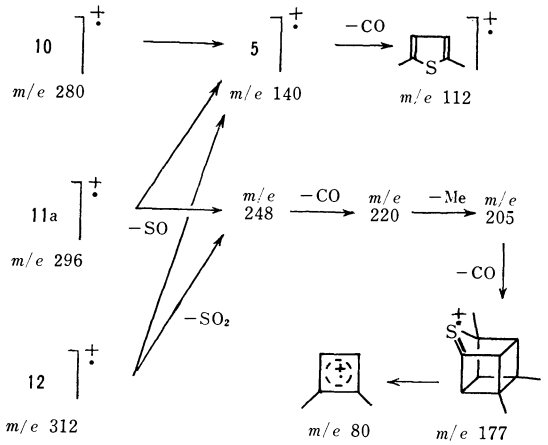

Scheme 2

Experimental

All the melting points are uncorrected. A Taika H-type 125 W high-pressure mercury lamp and a Toshiba 110 V, 200 W tungsten lamp were used as light sources. The UV, IR, NMR, and mass spectra were measured by means of a Hitachi EPS-3T-type spectrophotometer, a Hitachi EPI-S2-type spectrometer, a Hitachi H-60-type spectrometer, and a Hitachi RMU-6E-type spectrometer, respectively.

Photooxidation of 2,6-Diphenyl-4*H*-thiopyran-4-one (1). After a methanol solution (240 m*l*) of **1** (620 mg) has been irradiated by means of a high-pressure mercury lamp with a Pyrex filter while being stirred at room temperature for 48 hr, the methanol was removed and the residue was chromatographed on silica gel. From the benzene, benzene - ethyl acetate (1 : 1, v/v), and an ethyl acetate eluate, methyl benzoylacetate (**7a**) (33 mg, 8%), unreacted **1** (48 mg, 8%) and benzoic acid (270 mg, 48%) were obtained respectively. Each product was identified with the corresponding authentic sample by comparing the UV, IR, and NMR spectra as well as the R_f value on thin-layer chromatography on silica gel. The results of the photoreaction of **1** under various conditions are summarized in Table 1.

All the starting material was recovered when a methanol solution (30 m*l*) of **1** (100 mg) was treated with sodium hypochlorite (7 m*l*, containing 10—14% chlorine) and hydrogen peroxide (11 m*l*, 3%) by a previously-reported procedure,[6] or when a methanol solution (70 m*l*) of **1** (100 mg) containing methylene blue (5 mg) or rose bengale (5 mg) was irradiated with a tungsten lamp for 30 hr.

Preparation and Photolysis of Methyl Benzoylacetate 7a. By Hauser's method,[17] **7a** was prepared, as copper salt; mp 197—200°C (lit, mp 200—201°C). When a methanol solution (50 m*l*) of **7a** (200 mg) in a Pyrex tube was irradiated under the same conditions as have been described above, the formation of benzoic acid could not be observed.

Preparation of 2,6-Diphenyl-4*H*-pyran-4-one (2).

17) R. Leving and C. R. Hauser, *J. Amer. Chem. Soc.*, **66**, 1768 (1944).

By Hauser's method[3] **2** was prepared; mp 140—141.5°C (lit, mp 138.5—141.5°C). UV: $\lambda_{max}^{Benzene}$ nm (ε) 278 (24500), λ_{max}^{Ether} nm (ε) 257 (23600), 279 (26900), $\lambda_{max}^{Ethanol}$ nm (ε) 257 (22900), 283 (25800), $\lambda_{max}^{Methanol}$ nm (ε) 257 (22100), 285 (24000). IR: (KBr, cm^{-1}) 1645, 1600, 1380. NMR: (τ in $CDCl_3$) 3.19 (s, 2H), 2.53—2.3 (m, 6H), 2.3—2.04 (m, 4H).

Photooxidation and Photodimerization of 2. A methanol solution (240 m*l*) of **2** (600 mg) was irradiated; the photoproducts listed in Table 1 were obtained. After a benzene solution (2 m*l*) of **2** (300 mg) in a Pyrex tube had been irradiated at room temperature under a nitrogen atmosphere for a week, the solvent was removed and the reaction mixture was treated in chloroform to give undissolved white precipitates (**9**) (110 mg (37%)). Reprecipitation from chloroform afforded white powders; mp 268—274°C.

Found: C, 67.54; H, 4.37%. Cacld for $C_{34}H_{24}O_4$–$CHCl_3$: C, 68.35; H, 4.10%.

Recrystallization from methanol afforded colorless cubes; mp 271—278°C.

Found: C, 78.53; H, 5.49%. Calcd for $C_{34}H_{24}O_4$–CH_3OH: C, 79.52; H, 5.34%.

MS: *m/e* 391 (7%), 348 (4%), 248 (36%), 220 (100%), 149 (100%), 105 (40%), 102 (39%). UV: $\lambda_{max}^{Ethanol}$ nm (ε) 220 (26000) sh., 254 (2400) sh., 260 (1950) sh., 266 (1370), sh., 295 (186) sh. IR: (KBr, cm^{-1}) 1700, 1110, 1070. NMR: (τ in Pyridine-d_5) 5.61 (s, 4H), 3.0—2.7 (m, 12H), 2.6—2.2 (m, 8H).

The irradiation of **2** (300 mg) in a methanol solution (30 m*l*) for a week gave no product. When **9** was heated in a test tube, **9** turned quantitatively to **2** at 200°C, with a half life of 5 min, while it turned immediately at the melting point. Below 180°C, even at 10^{-4} mmHg **9** did not sublime at all. The 2,4-dinitrophenylhydrazone of **9** was an orange powder; mp 261—263°C (decomp.).

Found: C, 64.73; H, 3.98; N, 12.67%. Calcd for $C_{46}H_{32}O_{10}N_8$: C, 64.48; H, 3.76; N, 13.08%. UV: $\lambda_{max}^{Ethanol}$ nm (ε) 222 (44100), 256 (27200) sh., 366 (52800). IR: (KBr, cm^{-1}) 1615, 1593, 1510, 1335.

Preparation and Irradiation of 1,2,6-Trimethyl-4-pyridone (3) and 6-Methyl-1,2-diphenyl-4-pyridone (4). By Garratt's method[4] **3** was prepared; mp 245—247°C (lit, 247—248°C). By Hauser's method[5] **4** was prepared; mp 240—243°C (lit, 242—243°C). The irradiation of **3** or **4** in methanol, benzene, or aqueous hydrogen chloride (10%) in a Pyrex tube gave no product.

Preparation of 2,6-Dimethyl-4*H*-thiopyran-4-one (5). To a cold acetic acid solution (236 m*l*) of 2,6-dimethyl-4*H*-thiopyran-4-thione[18] (12 g), hydrogen peroxide (30%, 143 m*l*) and sodium acetate (23.6 g) were added. After the reaction mixture had then been stirred at room temperature for an hour, it turned dark blue; it was then poured into water (500 m*l*), extracted with chloroform, washed with water, and dried. The removal of the solvent gave a crude precipitate, which was recrystallized from water to afford colorless needles; 7.8 g (72%); mp 103—105°C (lit,[11] 104°C). UV: $\lambda_{max}^{Benzene}$ nm (ε) 288 (17700), 296 (13200) sh., λ_{max}^{Ether} nm (ε) 288 (15500), 296 (17700), $\lambda_{max}^{Ethanol}$ nm (ε) 288 (18200), 297 (18200), $\lambda_{max}^{Methanol}$ nm (ε) 288 (17800), 297 (17800). IR: (KBr, cm^{-1}) 1610, 1535. NMR: (τ in $CDCl_3$) 7.63 (s, 6H), 3.28 (s, 2H).

Irradiation of 5. After the irradiation of **5** in benzene (0.5 mol/*l*), ether (0.5 mol/*l*) or methanol (1 mol/*l*) in a Pyrex tube under a nitrogen atmosphere for 72 hr, the solvent was removed and the residue was chromatographed on silica gel with chloroform. The concentration of the eluted fraction gave crude products as pale yellow crystals; the crystals were collected, washed with methanol to afford colorless cubes (**10**) in a 1.3—0.9% yield in each case; mp 340—341°C (decomp.).

Found: C, 59.99; H, 5.75%. Calcd for $C_{14}H_{16}O_2S_2$: C, 60.23; H, 5.82%.

MS: *m/e* 280 (M^+). UV: $\lambda_{max}^{CH_3CN}$ nm (ε) 240 (345), 281 (319). IR: (KBr, cm^{-1}) 1693. NMR: (τ in $CDCl_3$) 8.35 (s, 12H), 6.83 (s, 4H).

In each case, most of the unreacted material (about 96%) was recovered. In the irradiation in the presence of oxygen, all of the starting material was recovered. When the photodimer **10** was heated above 220°C in a pressure tube under an atmosphere of nitrogen, the **10** was sublimed. When the **10** was heated at the melting point, the monomer **5** was obtained (R_f 0.25 on silica-gel thin-layer chromatography with ethyl acetate). Refluxing the photodimer **10** (5 mg) in ethanol (4 m*l*) and aqueous hydrogen chloride (10%, 2.5 m*l*) for an hour gave no other product.

Oxidation of the Photodimer 10 to the Monosulfoxide Dimer (11a) and the Monosulfone Dimer (12). To a cold acetic acid solution (10 m*l*) of **10** (48 mg), we added hydrogen peroxide (30%, 600 m*l*). After the reaction mixture had then been stirred at room temperature for an hour, the mixture was poured into water (50 m*l*) and extracted with chloroform. A procedure similar to that used for the isolation of **10** gave colorless cubes, (**11a**, 22 mg) and (**12**, 20 mg). **11a**; mp 335—340°C (decomp.).

Found: C, 56.47; H, 5.58%. Calcd for $C_{14}H_{16}O_3S_2$: C, 56.75; H, 5.44%.

MS: *m/e* 296 (M^+). UV: $\lambda_{max}^{CH_3CN}$ nm (ε) 223 (2840), 280 (170) sh. IR: (KBr, cm^{-1}) 1695, 1055. NMR: (τ in $CDCl_3$) 8.25 (s, 6H), 8.19 (s, 6H), 7.00 (s, 2H), 6.94 (s, 2H). **12**: mp 354—356°C (decomp.).

Found: C, 53.93; H, 5.22%. Calcd for $C_{14}H_{16}O_4S_2$: C, 53.84; H, 5.16%.

MS: *m/e* 312 (M^+). UV: $\lambda_{max}^{CH_3CN}$ nm (ε) 264 (367), 310 (42) sh. IR: (KBr, cm^{-1}) 1704, 1310, 1106. NMR: (τ in $CDCl_3$) 8.23 (s, 6H), 8.20 (s, 6H), 6.73 (s, 4H).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3210—3214 (1970)

Studies of the Reissert-Kaufmann-type Reaction of 4-Nitropyridine *N*-Oxide and Its Homologues

Eizo MATSUMURA, Masahiro ARIGA and Takahiko OHFUJI

Department of Chemistry, Osaka Kyoiku University, Tennoji-ku, Osaka

(Received March 2, 1970)

The Reissert-Kaufmann-type reaction of substituted *N*-methoxy-4-nitropyridinium methylsulfates gave the corresponding 2-cyano-4-nitropyridines in satisfactory yields. When 3-methyl-4-nitropyridine *N*-oxide was used as the starting material, a cyano group was introduced not into the 6-position, but into the 2-position. This preference may be explained by proposing a hyperconjugation effect of the 3-methyl group. The resulting nitriles were quantitatively hydrolyzed to the corresponding 4-nitropicolinic acids. These reactions provided a new route for the preparation of nitropyridinecarboxylic acids from pyridine homologues. Further, some nucleophilic substitution reactions of the products were carried out.

It has recently been established that the nitration of pyridine *N*-oxides with fuming nitric acid alone provides a convenient method for the preparation of 4-nitropyridine *N*-oxides.[1]

As is commonly known, the Reissert-Kaufmann reaction has offered a general synthetic method for heterocyclic nitriles in condensed heteroaromatic compounds such as quinoline and isoquinoline since it was reported by Reissert[2] and by Kaufmann *et al.*[3-6] Ochiai and Nakayama reported an example of the formation of a cyanopyridine by the nucleophilic attack of a cyanide ion on a pyridinium salt.[7] Thus, 4-chloro-2-cyanopyridine was obtained from 4-chloropyridine *N*-oxide. Further, Feely and Beavers[8] and Okamoto and Tani[9,10] independently extended the reaction to include various derivatives of pyridine *N*-oxides.

Tani also reported the reaction of 4-nitropyridine *N*-oxide,[11] but the reported neither a detailed investigation of the product nor the reaction of other homologues of 4-nitropyridine *N*-oxide.

In the present study, the Reissert-Kaufmann-type reaction of 4-nitropyridine *N*-oxide and its homologues was performed in order to prepare 2-cyano-4-nitropyridines and in order to clarify the electronic effects of the 4-nitro group in the reaction. The hydrolysis of 2-cyano-4-nitropyridines led to the corresponding acids, and the nucleophilic reactivity of the 4-nitro group of the nitriles and the carboxylic acids, were also examined.

Results and Discussion

The *N*-oxides used as starting materials were 4-nitropyridine *N*-oxide (**1a**), 2-methyl-4-nitropyridine *N*-oxide (**Ib**), 3-methyl-4-nitropyridine *N*-oxide (**Ic**), and 5-ethyl-2-methyl-4-nitropyridine *N*-oxide (**1d**). The *N*-oxides were treated at 65—70°C with 1—1.2 equivalents of dimethyl sulfate to form *N*-methoxypyridinium salts (**2**). But above this temperature the salts were liable to decompose, with the evolution of nitrogen dioxide. The resulting salts were hygroscopic crystals; they were used for subsequent reactions without purification. The

aqueous solution of the salts was treated with an aqueous solution of sodium cyanide under a nitrogen atmosphere in an ice-salt mixture in order to avoid any violent reaction and excessive tar formation. From the reaction mixture, the nitriles (**4**) were obtained, in the cases of (**a**), (**b**), and (**c**), as crystals (which were subsequently purified by recrystallization), and, in the case of (**d**), as an oil (which was subsequently purified by vacuum distillation).

The infrared spectra of all of the products indicated the presence of a nitro group (1350—1360, 1530 cm^{-1}), a nitrile group (2200 cm^{-1}), and no *N*-oxide group. The results of the micro analyses of the products were in good agreement the findings on the mono cyano derivatives of 4-nitropyridine and its homologues. In order to ascertain the position of the introduced cyano group, each of the products was converted to the corresponding pyridinecarboxylic acid; **4a** was converted to picolinic acid; **4b**, to 6-methyl-4-nitropicolinic acid; **4c**, to quinolinic acid, and **4d**, to 6-methylquinolinic acid. The acids were identified by a mixed-melting-point determination and by a comparison of the infrared spectra with those of authentic samples. From the above facts, the products are identified as 2-cyano-4-nitropyridine (**4a**), 2-cyano-6-methyl-4-nitropyridine (**4b**), 2-cyano-3-methyl-4-nitropyridine (**4c**), and 2-cyano-3-ethyl-6-methyl-4-nitropyridine (**4d**) respectively. The elementary analyses and some properties of the products are summarized in Table 1.

The fact that the nucleophilic attack of the cyanide ion on the methylsulfates occurred at the 2-position to form 1,2-dihydro intermediates (**3**), which then led to the corresponding nitriles with the elimination of a molecule of methanol, can be explained by presuming that the inductive and electromeric effects of quaternary nuclear nitrogen on the methylsulfates (**2**) are greater than those of the 4-nitro group.

With the reaction of 3-methyl-4-nitropyridine *N*-oxide (**1c**), a cyano group was introduced into the 2-position, this was contrary to the expectation that the inductive and steric effects of the 3-methyl group would tend to direct the entering cyano group to the 6-position of the pyridine nucleus. Analogous results have been reported with 3-methylpyridine *N*-oxide.[8,9] The result may rationally be explained as follows. Considering the hyperconjugation of the 3-methyl group in the dihydro-type structure (**3**), which is assumed to be an intermediate, the electron density is more extensively delocalized when a cyano group is introduced into the 2-position (**A**) than when it is introduced into the 6-position (**B**), as is shown in Fig. 1. Therefore, the **A** intermediate is preferentially formed to give the 2-cyano derivative.

The hydrolysis to 4-nitropicolinic acids (**5**) was successfully carried out, and the 4-nitro group was held, by heating with 90% sulfuric acid followed by treatment with sodium nitrite. The results

and analytical data are summarized in Table 2. The sequence of the reactions starting with pyridine homologues, *N*-oxidation, nitration with fuming nitric acid alone, cyanation, and hydrolysis, provides a new rout for the preparation of 4-nitropyridine-2-carboxylic acids, which attract our attention by their antibacterial and antifungal activities[12] and which have been scarcely obtained by other methods.

These cyanonitropyridines and their carboxylic derivatives were anticipated to undergo a nucleophilic substitution at the 4-position because of the strong electron-withdrawing property of the 2-cyano or the 2-carboxyl group. A concurrent substitution of the nitro group by the chloride ion has been observed on the hydrolysis of 2-cyano-4-nitropyridine with hydrochloric acid in a sealed tube.[11]

We obtained 4-chloropicolinic acids from 4-nitropicolinic acids in good yields under milder conditions by heating them with hydrochloric acid. The results and the analytical data are summarized in Table 3. It also became clear that the substitution of 2-cyano-4-nitropyridines by sodium ethoxide at the 4-position occurred more easily than that of 4-nitropyridine which was observed on heating.[13] Thus, 2-cyano-4-ethoxypyridines (**7**) were yielded from 2-cyano-4-nitropyridines (**4**) when they were treated with ethanolic sodium ethoxide in an ice-salt mixture. summarized in Table 4. The fact that nucleophilic substitution at the 4-position proceeds with such ease shows that the activity of the 4-nitro group as a leaving group toward the nucleophilic substitution and the reactivity are favoured by the inductive effects of the 2-substituents.

Experimental

All the melting points and boiling points are uncorrected. The infrared spectra were recorded on a Hitachi infrared spectrophotometer, Model EPI-S 2, as Nujol mulls.

2-Cyano-4-nitropyridine (4a). A mixture of 20.0 g of 4-nitropyridine *N*-oxide (**1a**) and 18.0 g of dimethyl sulfate was placed in a three-necked flask, equipped with a sealed stirrer, a thermometer, and a silica-gel tube. The mixture was heated at 65—70°C for 2 hr. Upon cooling, the salt crystallized out; it was then collected and dissolved in 50 m*l* of water, and the silica-gel tube was replaced by a dropping funnel. A solution of 14.6 g of sodium cyanide in 100 m*l* of water was added from the dropping funnel at −7—−8°C with vigorous stirring in a slow stream of nitrogen over a period of 7 hr. After standing overnight, the crystalline precipitates were collected and recrystallized from isopropyl ether to give 12.1 g (56.9%) of 2-cyano-4-nitropyridine (**4a**).

2-Cyano-6-methyl-4-nitropyridine (4b). Twenty grams of 2-methyl-4-nitropyridine *N*-oxide (**1b**) were worked up as in the foregoing experiment with 19.7 g of dimethyl sulfate and 14.0 g of sodium cyanide to give 14.2 g (67.1%) of 2-cyano-6-methyl-4-nitropyridine (**4b**).

2-Cyano-3-methyl-4-nitropyridine (4c). The treatment of 20.0 g of 3-methyl-4-nitropyridine *N*-oxide (**1c**) with 16.4 g of dimethyl sulfate and 12.7 g of sodium cyanide in the manner as described above gave 18.1 g (85.7%) of 2-cyano-3-methyl-4-nitropyridine (**4c**).

2-Cyano-3-ethyl-6-methyl-4-nitropyridine (4d). Twenty grams of 5-ethyl-2-methyl-4-nitropyridine *N*-oxide (**1d**) were treated with 15.6 g of dimethyl sulfate and 11.9 g of sodium cyanide according to the above procedure, and the resulting mixture was extracted with chloroform. The extract was worked up in the usual manner, and the residual oil was distilled *in vacuo* to give 17.3 g (82.4%) of 2-cyano-3-ethyl-6-methyl-4-nitropyridine (**4d**).

4-Nitropicolinic Acid (5a). A solution of 5 g of 2-cyano-4-nitropyridine (**4a**) in 50 g of 90% sulfuric acid was heated at 120°C for 2 hr. Into the reaction mixture, 5.6 g of sodium nitrite in 10 m*l* of water were added dropwise with stirring at 20—25°C over a period of 30 min. The mixture was kept at 20—25°C for an hour and then heated at 80°C for an additional hour. The resulting solution was poured onto 100 g of cracked ice and neutralized to pH 1.6 with sodium carbonate. The crystalline precipitates were then separated and recrystallized from acetone to give 5.4 g (97.6%) of 4-nitropicolinic acid (**5a**).

Other 4-Nitropicolinic Acids. 6-Methyl- (**5b**) (monohydrate), 3-methyl- (**5c**), and 3-ethyl-6-methyl-4-nitropicolinic acid (**5d**) were obtained by procedure described above.

4-Chloropicolinic Acid (6a). A solution of 5.0 g of 4-nitropicolinic acid (**5a**) in 50 m*l* of concentrated hydrochloric acid was heated at 100°C for 2 hr. The reaction mixture was then evaporated to dryness under reduced pressure and neutralized to pH 2.0 with sodium carbonate. The crystalline precipitates were collected and recrystallized from methanol - water to give 4.1 g (95.3%) of 4-chloropicolinic acid (**6a**).

Other 4-Chloropicolinic Acids. 4-Chloro-6-methyl- (**6b**) and 4-chloro-3-methylpicolinic acid (**6c**) were obtained by the above method, and both of them were recrystallized from benzene. 4-Chloro-3-ethyl-6-methylpicolinic acid (**6d**) was obtained as follows. 3-Ethyl-6-methyl-4-nitropicolinic acid (**5d**) was treated with concentrated hydrochloric acid, and the reaction mixture was neutralized as above. Evaporation to dryness, the extraction of the residue with benzene, and the removal of the solvent gave 4-chloro-3-ethyl-6-methylpicolinic acid (**6d**).

2-Cyano-4-ethoxypyridine (7a). A solution of 1 g of 2-cyano-4-nitropyridine (**4a**) in 30 m*l* of absolute ethanol was placed in a three-necked flask, equipped with a sealed stirrer, a dropping funnel, a thermometer, and a silica-gel tube. A solution of sodium ethoxide prepared from 0.18 g of sodium and 20 m*l* of absolute ethanol was added dropwise with stirring at −5—0°C over a period of an hour. After having been stirred for an additional hour, the reaction mixture was filtered and the filtrate was evaporated under reduced pressure. The residue was extracted with benzene, and from the extract 0.9 g (91%) of 2-cyano-4-ethoxypyridine (**7a**) was obtained. This was then recrystallized from petroleum benzine.

Other 2-Cyano-4-ethoxypyridines. 2-Cyano-4-ethoxy-6-methyl- (**7b**), 2-cyano-4-ethoxy-3-methyl- (**7c**), and 2-cyano-4-ethoxy-3-ethyl-6-methylpyridine (**7d**) were obtained by the same procedure.

Picolinic Acid. The catalytic reduction of 4-chloropicolinic acid (**6a**) with 5% Pd–C in methanol at room temperature gave picolinic acid in a 90.6% yield; mp 136°C; IR 1700 cm^{-1} (COOH); (Found: C, 58.38; H, 3.92; N, 11.35%). It was identified by a mixed-melting-point determination and by a comparison of the infrared spectra with those of an authentic sample.

6-Methyl-4-nitropicolinic Acid (Monohydrate). By applying the method for the preparation of 5-ethyl-4-nitropicolinic acid,[14] authentic 6-methyl-4-nitropicolinic acid melting at 129—130°C was prepared from 6-methyl-4-nitropicolinaldehyde, which had itself been obtained according to the directions of Furukawa.[15]

Quinolinic Acid. 3-Methylpicolinic acid melting at 114—115°C was obtained from 4-chloro-3-methylpicolinic acid (**6c**) by the same method as was used for picolinic acid in a 95.8% yield. 3-Methylpicolinic acid was oxidized with aqueous potassium permanganate at 90°C to give quinolinic acid in a 74.1% yield; decomp. 187; 229—230°C; IR 1700 cm^{-1} (COOH); (Found: C, 50.50; H, 2.84; N, 8.21%). It was identified by a mixed-melting-point determination and by a comparison of the infrared spectra with those of an authentic sample prepared by the oxidation of quinoline with

aqueous potassium permanganate.

6-Methylquinolinic Acid. 3-Ethyl-6-methylpicolinic acid boiling at 83—84°C (0.05 mmHg) was obtained from 4-chloro-3-ethyl-6-methylpicolinic acid (**6d**) in a 97.7% yield by the procedure described above. It was oxidized with aqueous potassium permanganate at 20°C to give 6-methylquinolinic acid in an 81.2% yield; mp 166—167°C; IR 1720 cm^{-1} (COOH); (Found: C, 53.04; H, 3.90; N, 7.77%). It was identified by means of a mixed-melting-point determination and by a comparison of the infrared spectra with the authentic sample prepared from 8-hydroxyquinaldine.[16]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3214—3219 (1970)

Studies of the Thiocarbonyl Compounds. II. Syntheses and Thermal Rearrangement of Aryl Thionobenzoates*1

Yoshiaki ARAKI and Aritsune KAJI*2

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received March 6, 1970)

Various aryl thionobenzoates were prepared. When maintained at elevated temperatures, they rearranged smoothly to aryl thiolbenzoates. The mechanism of this rearrangement was kinetically investigated. The rearrangement rates were correlated with the first-order kinetic equation, and the rearrangement was found to be facilitated by substitution with an electron-withdrawing group in the migrating aromatic rings. The Hammett ρ value was found to be 2.11 in diphenyl ether at 200.5°C. The entropies of activation were negative. A linear free-energy relationship existed between this rearrangement and the rearrangement of *O,S*-diaryl dithiocarbonates. From these observations, a four-membered cyclic structure can be suggested as the transition state for this rearrangement. The present results indicate that the existence of hetero atoms directly bound to the thiocarbonyl group is not essential for the thermal rearrangement with intramolecular 1,3 aryl migration from oxygen to sulfur.

In a previous paper,[1] the intramolecular thermal rearrangement of *O,S*-diaryl dithiocarbonates (Ia) to *S,S*-diaryl dithiocarbonates (IIa) at elevated temperatures was reported. In addition to this rearrangement, of the thermal rearrangements with intramolecular 1,3 aryl migration from oxygen to sulfur, the thermal rearrangement of aryl *N,N*-disubstituted thionocarbamates (Ib) to aryl *N,N*-disubstituted thiolcarbamates (IIb) (Miyazaki-Newman-Kwart rearrangement)[2–6] and the thermal rearrangement of diaryl thionocarbonates (Ic) to diaryl thiolcarbonates (IIc) (Schönberg rearrangement)[3,7–10] are known. All of the compounds I

have hetero atoms with lone-pair electrons, such as sulfur, nitrogen, and oxygen, in the R group. In order to ascertain the nature of this kind of thermal rearrangement, it is necessary to examine whether hetero atoms, which are connected to the thiocarbonyl group, are required in the R group for rearrangement. Accordingly, the thermal rearrangement of aryl thionobenzoates (III), which

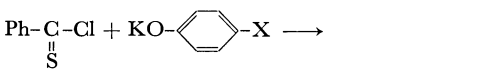
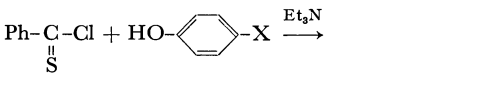
In regard to the thermal rearrangements of thionobenzoates to thiolbenzoates, the thermal rearrangements of dialkylaminoalkyl thionobenzoates[11-13] (an anchimerically-assisted rearrangement), allyl thionobenzoates[14,15] (an allylic rearrangement), and benzhydryl thionobenzoates[16] (a rearrangement through an intimate ion-pair) have been reported. Of the thermal rearrangement of aryl thionobenzoates, however, an example has been reported[4] in which the thermal rearrangement of *p*-*t*-butylphenyl thionobenzoate was qualitatively tested. The present authors have now studied the kinetics of the thermal rearrangement of aryl thionobenzoates in order to establish the reaction mechanism and in order to compare it with the thermal rearrangement of other compounds with the formula I which have hetero atoms in the R group.

Results

The various aryl thionobenzoates (III) were synthesized by the reaction of a *p*-substituted phenol with a thiobenzoyl chloride (Eqs. (3) and (4)). The results are shown in Table 1.

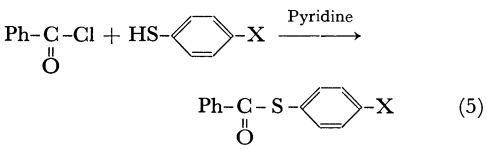


(3)



(4)

When maintained at 200°C without any solvent under a nitrogen atmosphere, the compounds III gradually rearranged to aryl thiolbenzoates (IV). The compounds thus obtained were identified by a mixed-melting-point test and by a comparison of the infrared spectra with those of the corresponding authentic samples prepared by the reaction of a *p*-substituted thiophenol with a benzoyl chloride (Eq. (5)).



(5)

In order to clarify the influence of the substituents upon the rates of the rearrangement, the kinetics of the rearrangement were studied in a diphenyl ether solution. The reaction rates were followed by the ampoule technique and were determined by ultraviolet spectrophotometric measurements. It was found that the rearrangement reaction

obeyed first-order kinetics fairly well. A typical run is shown in Table 2 and Fig. 1; there do not seem to be any drifts in the rate constants. The first-order rate constants were derived from the slopes of the straight lines obtained by plotting ln [III]/([III]+[IV]) against the time. The rate constants found for the rearrangement are summarized in Table 3. From these data, the energies and entropies of activation were calculated. These results are also shown in Table 3.

Discussion

As is shown in Table 3, the rearrangement is accelerated by the electron-withdrawing substituents at the *p*-position on the migrating group. The plot of the logarithms of the first-order rate constants at 200.5°C against Hammett's σ values showed a good linear relationship (Fig. 2). The value of the reaction constant, ρ, determined by the least-squares method is 2.11 (the correlation coefficient is 0.987).

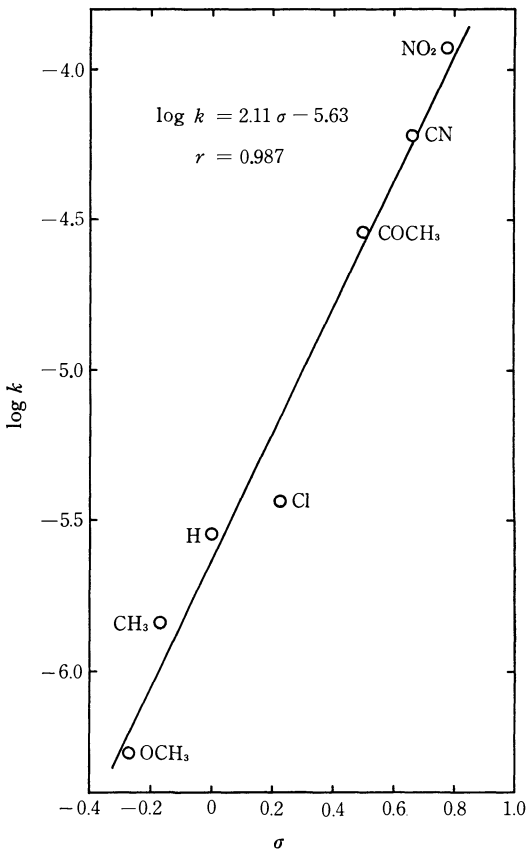

Fig. 2. Hammett plot for the rate of the rearrangement of  at 200.5±0.1°C.

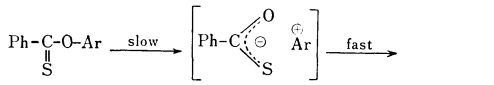
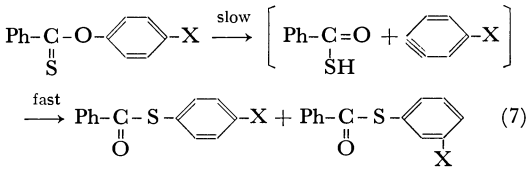
This result indicates that the rearrangement of aryl thionobenzoates is a nucleophilic reaction which may involve a nucleophilic attack of the thiocarbonyl sulfur atom in the rate-determining step.

The intermolecular reaction mechanism which involves a rate-determining initial ionization[16] (Eq. (6)) can be ruled out. In such a case, the rate should depend on the stability of the aryl cation which is stabilized by the electron-donating substituents.



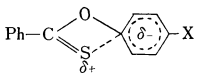
Ph-C-S-Ar (6)
‖
O

The fact that all of the *p*-substituted compounds III rearranged to only the *p*-substituted products, IV, with no accompanying *m*-substituted product, eliminates the benzyne mechanism (Eq. (7)).



The isokinetic temperature, β, was calculated to be 1300°K from the data in Table 3 (the correlation coefficient is 0.96). This shows that the rearrangement may be governed by the enthalpy of activation at temperatures near 200°C.

In addition to these results, the first-order kinetics and the negative entropies of activation (Table 3) lead to the conclusion that the rearrangement of aryl thionobenzoates may proceed *via* a four-membered cyclic transition state (Scheme 1) formed by a nucleophilic attack of the thiocarbonyl sulfur atom on the migrating aromatic ring.



Scheme 1

A very good linear free-energy relationship was found between the rearrangement of aryl thionobenzoates and the rearrangement of *O*-aryl *S*-phenyl dithiocarbonates, as is shown in Fig. 3 (the correlation coefficient is 0.999). The slope of the straight line is 1.12. This was rather astonishing considering the absence, in aryl thionobenzoates, of any hetero atoms, which may promote the rearrangement of this sort.

The present results indicate that the existence of hetero atoms in the R group of the formula I at the α position of the thiocarbonyl group is not essential for the thermal rearrangement with intramolecular 1,3 aryl migration from oxygen to sulfur. The rearrangements described above may all proceed analogously by means of an "intramolecular S_N-Ar" mechanism.

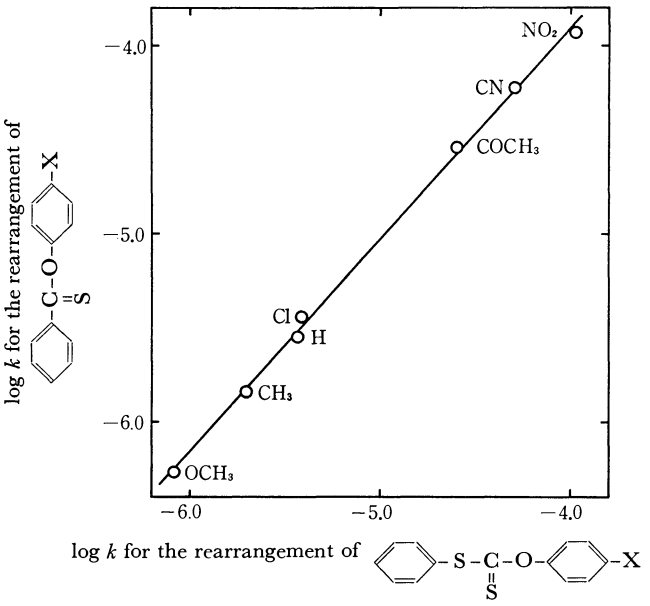


Fig. 3. Free-energy relationship between the rearrangement of aryl thionobenzoates and the rearrangement of *O*-aryl *S*-phenyl dithiocarbonates.

Experimental*3

Thiobenzoyl Chloride. This material was prepared by the method of Staudinger.[17]

Aryl Thionobenzoates (III). These compounds were prepared by two methods (Eqs. (3) and (4)). Method A (Eq. (3)) was generally employed, but Method B (Eq. (4)) was also used to prepare the compounds bearing electron-withdrawing substituents because of its convenience. The results are listed in Table 1.

Method A. To 20 m*l* of cold absolute methanol was added, in small portions, 0.78 g (0.02 mol) of potassium. After hydrogen evolution had ceased, 0.02 mol of *p*-substituted phenol was added. The resulting solution was then evaporated to dryness on a rotary evaporator. To the potassium *p*-substituted phenolate thus obtained was added 25 m*l* of dry acetone. This solution was cooled to 0°C in an ice-water bath, and then a solution of 3.13 g (0.02 mol) of freshly-distilled thiobenzoyl chloride in 20 m*l* of dry acetone was added all at once. The resulting mixture was then stirred for 3 hr at 5—10°C, after which the cooling bath was removed. After additional, overnight stirring at room temperature, the reaction mixture was poured into *ca.* 500 m*l* of cold water and then extracted with ether. The ethereal extract was washed with water, dried over anhydrous magnesium sulfate, and freed of solvent on a rotary evaporator. The crude product thus obtained was chromatographed on a silica-gel column, using benzene and/or *n*-hexane as the elution solvent, and then recrystallized from *n*-hexane, giving yellow crystals.

Method B. To a cold solution of 0.02 mol of *p*-substituted phenol and 3.13 g (0.02 mol) of freshly-distilled thiobenzoyl chloride in 40 m*l* of dry acetone in an ice-water bath, there was added, all at once, 2.03 g (0.02 mol) of triethylamine with vigorous agitation. The cooling bath was then removed, and stirring was continued overnight at room temperature. The reaction mixture was then poured into *ca.* 500 m*l* of cold water and extracted with ether. The ethereal extract was washed with water, dried over anhydrous magnesium sulfate, and freed of solvent on a rotary evaporator. The crude product thus obtained was chromatographed on a silica-gel column, using benzene and/or *n*-hexane as the elution solvent, and then recrystallized from *n*-hexane, giving yellow crystals.

Aryl Thiolbenzoates (IV). The following general procedure was employed for the synthesis of these compounds.

To a cold solution of 0.01 mol of *p*-substituted thiophenol and 1.41 g (0.01 mol) of benzoyl chloride in 20 m*l* of dry acetone in an ice-water bath, there was added, all at once, 0.79 g (0.01 mol) of dry pyridine with vigorous agitation. The cooling bath was then removed, and stirring was continued for two more hours at room temperature. The reaction mixture was poured into *ca.* 300 m*l* of cold water; colorless crystals were thus obtained quantitatively. These were recrystallized from a suitable solvent: IVa, colorless needles (from *n*-hexane), mp 100.0—100.5°C (lit,[18] mp 99—100°C). IVb, colorless prisms (from *n*-hexane), mp 76.0—76.5°C (lit,[19] mp 75—76°C). IVc, colorless prisms (from *n*-hexane), mp 56.0—57.0°C (lit,[19] mp 55—56°C). IVd, colorless prisms (from *n*-hexane), mp 75.5—76.0°C (lit,[20] mp 75—76°C). IVe, colorless needles (from benzene–*n*-hexane), mp 134.0—134.5°C (Found: C, 70.05; H, 4.65; S, 12.45%. Calcd for $C_{15}H_{12}O_2S$: C, 70.30; H, 4.72; S, 12.49%). IVf, colorless plates (from benzene–*n*-hexane), mp 101.0—102.0°C (Found: C, 70.00; H, 3.90; S, 13.35%. Calcd for $C_{14}H_9NOS$: C, 70.29; H, 3.79; S, 13.38%). IVg, pale yellow needles (from benzene–*n*-hexane), mp 125.0 — 126.0°C (lit,[21] mp 126—127°C).

Thermal Rearrangement of III. About 500 mg of III was placed in a test tube without any solvent and was heated at 200°C under a slow stream of nitrogen. The progress of the reaction could be followed by thin-layer chromatography on silica gel, with development by benzene and/or *n*-hexane. As a result, it was shown that the compound III was gradually converted to another compound. After the compound III had changed completely, the reaction mixture was chromatographed on a silica-gel column, using benzene and/or *n*-hexane as the elution solvent. After the solvent had been removed under reduced pressure, the product was recrystallized and identified by means of its IR spectrum and by a mixed-melting-point test with an authentic sample.

Kinetic Measurements. The rates were followed by the ampoule technique. That is, approximately 10 mg of III was dissolved in diphenyl ether, giving a final volume of 5 m*l*. This corresponds to *ca.* a 0.01 M solution. About a 0.8-m*l* portion of this solution was transferred to each of six ampoules. These ampoules were flushed with nitrogen and sealed. Five of these ampoules were then immersed in a constant-temperature bath controlled within ±0.1°C. These ampoules, taken out from the bath at appropriate intervals, were cooled immediately by immersion in cold water. From each run thus obtained, a 0.5-m*l* portion was accurately removed into a 5-m*l* measuring flask. The solution was made up to volume with chloroform, and then, further, the solution was diluted twenty times with chloroform to make it suitable for use as the sample for the ultraviolet spectrophotometric measurements.*4 The optical densities for each run were measured at 300—320 mμ.*5 The composition of III could be determined directly by substitution in the following equation:

$$\frac{[\mathrm{III}]}{[\mathrm{III}]+[\mathrm{IV}]} = \frac{\varepsilon_{\mathrm{III}}A_t-\varepsilon_{\mathrm{IV}}A_0}{\varepsilon_{\mathrm{III}}A_0-\varepsilon_{\mathrm{IV}}A_0}$$

where $\varepsilon_{\mathrm{III}}$ and $\varepsilon_{\mathrm{IV}}$ are the molar extinction coefficients of III and IV respectively at a stated wavelength, and

*5 In this range, the absorption of diphenyl ether could be negligible.

where A_t and A_0 are absorption intensities at the same wavelength, observed at time t and time 0 respectively. In all cases, a plot of the logarithms of [III]/([III]+[IV]) against the time gave a straight line, indicating the reaction to be of first-order (Fig. 1). The results of a typical kinetic run are illustrated in Table 2. From these data, the rate constants were calculated (Table 3).

The authors wish to express their sincere thanks to Dr. Jun-ichi Hayami for his invaluable discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3219—3223 (1970)

The Synthesis and Reaction of α,β-Unsaturated α-Nitrocarboxylic Esters[1]

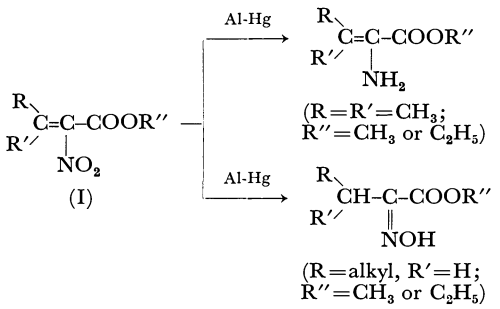
Chung-gi SHIN,[2] Mitsuo MASAKI and Masaki OHTA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 7, 1970)

Synthetic studies of α,β-unsaturated α-nitrocarboxylic esters and the corresponding α-amino compounds are described. When α,β-unsaturated carboxylic ester was treated with fuming nitric acid, two products, α,β-unsaturated α-nitrocarboxylic ester and α-hydroxy-β-nitrocarboxylic ester, were formed. The former was converted into β-methoxy-α-nitrocarboxylic ester by treatment with methanol in the presence of a base such as sodium methoxide or sodium acetate. Reduction of β-methoxy-α-nitrocarboxylic esters with aluminum amalgam and the subsequent distillation of the products afforded α,β-unsaturated α-aminocarboxylic esters and α-hydroxyamino-β-methoxycarboxylic esters, which were confirmed by their *N*-phthaloylglycyl derivatives.

It was previously reported that the reduction of methyl and ethyl esters of β-methyl-α-nitrocrotonic acid (I: $R=R'=CH_3$) with aluminum amalgam gave the corresponding α-aminocarboxylic esters (enamines), while α-oximinocarboxylic esters were formed in the reduction of β-monosubstituted α,β-unsaturated α-nitrocarboxylic esters.[3,4]



In the present paper, we report detailed studies on the preparation of α,β-unsaturated α-nitrocarboxylic esters (I), and the synthesis of α,β-unsaturated α-aminocarboxylic esters (VI) by the reduction of β-methoxy-α-nitrocarboxylic esters (III).

Nitration of α,β-unsaturated carboxylic esters with fuming nitric acid was reported by Bouveault[5] and Tatsuoka.[6] The reaction was reinvestigated under various conditions and it was found that two products were formed in the reaction. When methyl 4-methyl-2-pentenoate was treated with fuming nitric acid (sp.gr., 1.52) with vigorous stirring at about 30°C for more than 5 hr, methyl 4-methyl-2-nitro-2-pentenoate (Ie) and methyl 2-hydroxy-4-methyl-3-nitropentanoate (IIe) were obtained in 33 and 39% yields, respectively.

The nitroolefincarboxylic ester Ie was characterized by elementary analysis and infrared spectrum. The structure was also supported by the reduction with aluminum amalgam giving methyl 4-methyl-2-oximinopentanoate.[4]

In place of methyl 2-hydroxy-4-methyl-3-nitro-

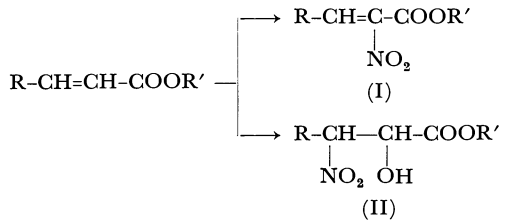
pentanoate, an alternative 3-hydroxy-2-nitro structure might be also possible from elementary analysis and infrared spectrum. However, methyl 3-hydroxy-4-methyl-2-nitropentanoate prepared by an authentic method[7] showed bp 102—114°C/3 mmHg, while compound IIe obtained from the above nitration method has bp 120—121°C/2 mmHg.

Thus the most probable structure for IIe was concluded to be methyl 2-hydroxy-4-methyl-3-nitropentanoate.

Nitration of analogous olefinic carboxylic esters afforded the corresponding α-nitrocarboxylic esters (Ia—d and If) and 2-hydroxy-3-nitrocarboxylic esters (IIb—d and IIf) under similar experimental conditions; results of the elementary analyses and infrared spectra of the products are shown in Table 1.



(I) (II)

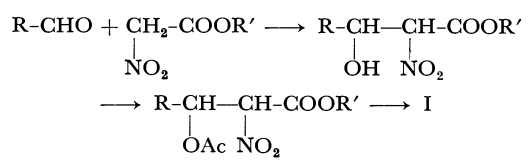
b) R=C_2H_5, R′=C_2H_5
c) R=n-C_3H_7, R′=CH_3
d) R=n-C_3H_7, R′=C_2H_5
e) R=i-C_3H_7, R′=CH_3
f) R=i-C_3H_7, R′=C_2H_5

Infrared spectrum of I showed bands of carbon-carbon double bond at 1640—1665 cm^{-1}, and of nitro group at 1540—1560 and 1350—1380 cm^{-1} regions. On the other hand, II showed infrared absorption bands of hydroxyl group at 3450 cm^{-1}, and of nitro group at 1555—1560 and 1370—1380 cm^{-1} regions.

The nitration method is useful for the preparation of α,β-unsaturated α-nitrocarboxylic esters (I), while Dornow and Menzel[8] and other workers[7,9] reported the preparation of I by a three-step reaction starting from aldehydes and nitroacetic ester *via* the route illustrated below.



When ethyl 4-methyl-2-nitro-2-pentenoate (If) was treated with methanol in the presence of sodium methoxide or sodium acetate below −10°C, ethyl 3-methoxy-4-methyl-2-nitropentanoate (IIIf) was obtained in a good yield. Other 3-methoxy-2-nitrocarboxylates (IIIb, IIIc and IIId) were also obtained from I under similar experimental conditions in good yields; the results are summarized in Table 2. When compounds III were heated at 150—160°C for 6 hr, the methoxyl group in the 3-position was eliminated to afford I.

Reduction of IIIf with aluminum amalgam in ether and the subsequently distillation of the resulting product under reduced pressure gave a small amount of ethyl 2-amino-4-methyl-2-pentenoate (VIf) as a lower boiling point fraction and ethyl 2-hydroxyamino-3-methoxy-4-methylpentanoate (IVf) as a higher boiling fraction in a 70% yield. The infrared spectrum of VIf exhibits two absorption bands at 1650 and 1735 cm^{-1} in carbonyl region and a broad band at 3350 cm^{-1} in amino region. The absorption pattern is essentially the

same as that of α,β-unsaturated α-aminocarboxylic ester.[4] Reduction of other β-methoxy-α-nitro compounds (IIIb—e) afforded also enamines (VIb—e) as minor products and α-hydroxyamino-β-methoxycarboxylic esters (IVb—e) as main products. Formation of enamines could be explained by the fact that elimination of methoxyl group in the 3-position as methanol occurred during the distillation of α-amino-β-methoxycarboxylic esters (V) which were the further reduced products of the initially formed hydroxyamino esters (IV). Compounds VI were unstable and gradually polymerized at room temperature. In order to establish the structure, the new enamines were converted into their *N*-phthaloylglycyl derivatives. When ethyl 2-amino-2-pentenoate (VIb) was treated with phthaloylglycyl chloride in benzene in the presence of pyridine at room temperature, ethyl 2-(phthaloylglycyl)amino-2-pentenoate (VIIb) was obtained as a colorless crystalline product in a 9% yield. Analogous treatment of other enamines (VIc—f) with phthaloylglycyl chloride afforded (phthaloylglycyl)amino derivatives (VIIc—f); the results are summarized in Table 4. The structures of these phthaloylglycyl derivatives were confirmed by elementary analyses and their infrared absorption spectra which are very similar to alkyl esters of 3-methyl-2-(phthaloylglycyl)aminocrotonic acid.[3,4] On the other hand, treatment of IVf with phthaloylglycyl chloride under similar conditions, afforded ethyl 3-methoxy-4-methyl-2-*N*-(phthaloylglycyl)hydroxyaminopentanoate (VIIIf). Analogous acylation of other α-hydroxyaminocarboxylic esters (IVb and IVe) afforded the corresponding (phthaloylglycyl) hydroxyamino derivatives (VIIIb and VIIIe) in a poor yield; the results are summarized in Table 4. All these (phthaloylglycyl)hydroxyamino derivatives gave red coloration with methanolic ferric chloride. The structures of these esters were assigned on the basis of elementary analysis and infrared spectrum.

When methyl 2-hydroxyamino-3-methoxy-4-

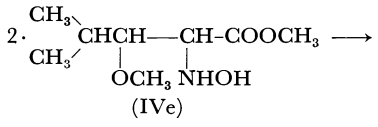
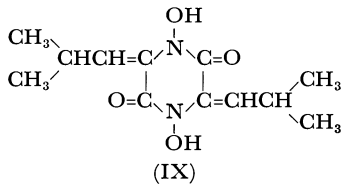
methylpentanoate (IVe) was allowed to stand at room temperature for two weeks, cyclic condensation took place and 1,4-dihydroxy-3,6-diisobutylidene-2,5-dioxopiperazine (IX) was obtained. Formation of the 2,5-dioxopiperazine ring supports 2-hydroxyamino structure of the reduction product and also the position of nitro group in the parent ester, methyl 4-methyl-2-nitro-2-pentenoate (Ie).



(IVe)



(IX)

Experimental

All melting and boiling points are uncorrected. The IR spectra were recorded with a Hitachi EPI-S2 Spectrometer.

Nitration of Methyl 4-Methyl-2-pentenoate with Fuming Nitric Acid. Methyl 4-methyl-2-pentenoate (20 g) was added drop by drop, with vigorous stirring, to fuming nitric acid (36 m*l*, sp.gr. 1.52) below 5°C. After addition of the ester had been completed, the mixture was stirred for several hr, while being allowed to warm to room temperature, and stirring was continued for additional 5 hr at 30°C. The mixture was added to ice water (200 m*l*) and then extracted several times with ether. The combined ethereal extracts were washed successively with water, saturated aqueous solution of sodium carbonate and finally with water. The extracts were dried over anhydrous sodium sulfate and then evaporated. Distillation of the residual oil afforded two fractions, as pale yellow oils, which were identified as methyl 4-methyl-2-nitro-2-pentenoate (Ie) and methyl 2-hydroxy-4-methyl-3-nitropentanoate (IIe).

Under analogous conditions, nitration of other olefinic carboxylic esters was performed and the corresponding α-nitro esters (Ia—d and If) and β-nitro esters (IIb—d and IIf) were obtained.

Ethyl 3-Methoxy-4-methyl-2-nitropentanoate (IIIf). The procedure was modified from the method of Yamagishi and Ishibiki.[10] A solution of ethyl 4-methyl-2-nitro-2-pentenoate (11 g) in methanol (70 m*l*) was added, with vigorous stirring, to 5% methanolic solution of sodium methoxide (from 4.8 g of sodium in methanol (70 m*l*)) cooled below −10°C. The temperature of the reaction mixture rose up to 15°C, at which stirring was continued for 20 min, and then a small amount of crushed dry ice was added portionwise. The cooled mixture was poured into water (500 m*l*), and the resulting solution was acidified with glacial acetic acid, whereby an oily product was separated out. The product was extracted several times with ether. The combined ethereal extracts were washed with water, dried over anhydrous magnesium sulfate, and then evaporated. Distillation of the residual oil afforded ethyl 3-methoxy-4-methyl-2-nitropentanoate as an almost colorless oil.

Analogous treatment of other α-nitroolefinic carboxylic esters with sodium methoxide afforded the corresponding β-methoxy-α-nitrocarboxylic esters (IIIb—e).

Reduction of Ethyl 3-Methoxy-4-methyl-2-nitropentanoate. A solution of IIIf (6 g) in ether (50 m*l*) was added drop by drop with vigorous stirring to a suspension of aluminum amalgam (from 4 g of aluminum) in ether (120 m*l*) at room temperature. In a few minutes ether began to reflux. During the addition of the above solution a few drops of water was added at 10-min intervals to maintain refluxing. After addition of the solution had been completed stirring was continued for additional 2 hr. The mixture was extracted thoroughly several times with ether. The combined ethereal extract was dried over anhydrous sodium sulfate and then evaporated. Distillation of the residual oil afforded two fractions, as pale yellow oils, which were identified as ethyl 2-amino-4-methyl-2-pentenoate (VIf) and ethyl 2-hydroxyamino-3-methoxy-4-methylpentanoate (IVf).

Analogous reduction of other α-nitrocarboxylic esters (III) afforded the corresponding enaminocarboxylic (VIb—e) and hydroxyaminocarboxylic esters (IVb—e).

Ethyl 2-(Phthaloylglycyl)amino-2-pentenoate (VII). Phthaloylglycyl chloride (0.65 g) was added

10) K. Yamagishi and Y. Ishibiki, *Nippon Kagaku Zasshi*, **81**, 971 (1960).

portionwise with vigorous stirring to ethyl 2-amino-2-pentenoate (VIb, 0.5 g) suspended in a solution of sodium hydrogencarbonate (0.3 g) in water (10 m*l*) at room temperature. After stirring for 30 min a syrup was precipitated. After one day the viscous syrup crystallized. The crystals were collected, washed well with water and recrystallized from a small quantity of ethanol to afford colorless needles. The product was characterized by the data given in Table 4.

Methyl 4-Methyl-2-(phthaloylglycyl)amino-2-pentenoate (VIIe). A solution of phthaloylglycyl chloride (2.5 g) in dry benzene (20 m*l*) was added drop by drop with vigorous stirring to a solution of methyl 4-methyl-2-amino-2-pentenoate (VIe, 1.8 g) at 20°C. After stirring for 3 hr, 30 m*l* of water was added to the resulting mixture and the insoluble substance was filtered off. The benzene layer was washed with water, dried over anhydrous sodium sulfate, and then evaporated. The residual viscous syrup crystallized gradually. Recrystallization from a small quantity of ethanol gave colorless needles, which were characterized as the expected phthaloylglycylamino compound by the data given in Table 4.

In an analogous manner, acylation of other α-aminocarboxylic esters (VIc and VId) was performed, and the corresponding α-phthaloylglycylamino esters (VIIc and VIId) were obtained in poor yields (Table 4).

Ethyl 3-Methoxy-2-*N*-(phthaloylglycyl)hydroxyaminopentanoate (VIIIb). Phthaloylglycyl chloride (0.65 g) was added portionwise with vigorous stirring to ethyl 2-hydroxyamino-3-methoxypentanoate (IVb, 0.6 g) suspended in a solution of sodium hydrogencarbonate (0.3 g) in water (10 m*l*) at room temperature. After stirring for 30 min, a viscous syrup began to separate. On being allowed to stand overnight at room temperature, the syrup became crystalline. The crystals were collected and washed with water. Recrystallization from ethanol afforded colorless prisms (Table 4).

Ethyl 3-Methoxy-4-methyl-2-*N*-(phthaloylglycyl)-hydroxyaminopentanoate (VIIIf). A solution of phthaloylglycyl chloride (1.1 g) in dry benzene (10 m*l*) was added drop by drop, with vigorous stirring, to a solution of ethyl 2-hydroxyamino-3-methoxy-4-methylpentanoate (IVf, 1 g) in dry benzene (10 m*l*) in the presence of pyridine (0.42 g) at room temperature. After stirring for 2 hr, 30 m*l* of water was added to the resulting mixture. The mixture was allowed to stand overnight at room temperature and the insoluble substance was filtered off. The benzene layer of the filtrate was washed with water, dried over anhydrous sodium sulfate, and then evaporated. The residual viscous syrup was crystallized by successive treatment of a small quantity of ether and di-*n*-butyl ether. Recrystallization from petroleum ether (bp 70—120°C) afforded the expected acylated compound as colorless needles.

In an analogous manner, α-hydroxyaminocarboxylic ester (IVe) was treated with phthaloylglycyl chloride to afford the corresponding α-(phthaloylglycyl)hydroxyaminocarboxylic ester (VIIIe) in a poor yield (Table 4).

1,4-Dihydroxy-3,6-diisobutylidene-2,5-dioxopiperazine (IX). Methyl 2-hydroxyamino-3-methoxy-4-methylpentanoate (IVe, 8 g) was allowed to stand for two weeks at room temperature, during which the ester became viscous, and then a small amount of crystals separated out gradually. The mixture was treated with ether and the crystalline product was collected. Recrystallization from a small quantity of methanol afforded colorless prismatic needles (2.1 g, 42%), mp 250—251°C (decomp.), which turned dark purple with methanolic ferric chloride. ν_{max}^{KBr} 3250, 1775, 1720, 1635 and 1610 cm^{-1}. λ_{max}^{EtOH} 221.5 mμ (ε=3500), 265.5 (4800) and 349 (9000).

Found: C, 56.29; H, 7.58; N, 11.09%. Calcd for $C_{12}H_{18}N_2O_4$: C, 56.68; H, 7.14; N, 11.02%.

Sugars Containing a Carbon-phosphorus Bond. II. Syntheses of Phosphinyl Sugars by the Michaelis-Arbuzov Reaction of Halogenated Sugars

Saburo INOKAWA, Yoshimi TSUCHIYA, Hiroshi YOSHIDA and Tsuyoshi OGATA*1

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received April 20, 1970)

3,5-*O*-Benzylidene-6-deoxy-6-diethoxyphosphinyl-1,2-*O*-isopropylidene-α-D-glucofuranose was prepared in an 80% yield by heating a solution of 3,5-*O*-benzylidene-6-deoxy-6-iodo-1,2-*O*-isopropylidene-α-D-glucofuranose (**1**) in an excess of triethyl phosphite (**5**). Similarly, 6-deoxy-6-diethoxyphosphinyl-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose was prepared in a 95% yield from 6-deoxy-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (**2**), and (**5**); 5-deoxy-5-ethoxyphenylphosphinyl-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose was prepared in a 90% yield from 5-bromo-5-deoxy-1,2-*O*-isopropylidenne-3-*O*-methyl-α-D-xylofuranose and diethyl phenylphosphonite; 3,5-*O*-benzylidene-6-deoxy-1,2-*O*-isopropylidene-6-(*N*,*N*′-tetraethyldiaminophosphinyl)-α-D-glucofuranose was prepared in a 44% yield from **1** and ethyl *N*,*N*′-tetraethylphosphorodiamidite (**7**); 6-deoxy-1,2;3,4-di-*O*-isopropylidene-6-(*N*,*N*′-tetraethyldiaminophosphinyl)-α-D-galactose was prepared in a 70% yield from **2** and **7**.

In the previous investigation,[1] sugars containing a carbon-phosphorus bond were synthesized by the photochemical addition of the phosphonates to the unsaturated sugars. This time, the Michaelis-Arbuzov reaction has been used in the preparation of the phosphorus sugars; the results will be reported here. As the halogenated sugars, 3,5-*O*-benzylidene-6-deoxy-6-iodo-1,2-*O*-isopropylidene-α-D-glucofuranose (**1**), 6-deoxy-6-iodo-1,2;3,4-di-*O*-isopropylidene-α-D-galactose (**2**), 5-bromo-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose (**3**), and 1-bromo-1-deoxy-2,3;4,5-*O*-isopropylidene-β-D-fructopyranose (**4**) were used, and as the phosphorus compounds, triethyl phosphite (**5**), diethyl phenylphosphonite (**6**), and ethyl *N*,*N*′-tetraethylphosphorodiamidite (**7**) were used. The structures of the products were determined by studying the NMR spectra and by elementary analyses.

Experimental

The infrared spectra were measured on a Hitachi-Perkin-Elmer 337 spectrophotometer. The nuclear magnetic resonance spectra were taken at 60 MHz on a Hitachi-Perkin-Elmer R-20 spectrometer, using tetramethylsilane as the internal reference. The thin-layer chromatogram were run on a silica-layer G[2]; phosphorus compounds were detected by spraying the plates with a cobalt chloride solution[3] and then by heating them. Periodic sampling and examination by thin-layer chromatography permitted the determination of the suitable reaction conditions for the preparation runs.

Materials. The 3,5-*O*-benzylidene-6-deoxy-6-iodo-1,2-*O*-isopropylidene-α-D-glucofuranose (**1**) was prepared by the method of Meyer and Reichstein;[4] mp 142°C. The 6-deoxy-6-iodo-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (**2**) was prepared by the method of Schmidt;[5] mp 72°C. The 5-bromo-5-deoxy-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose (**3**) was prepared by the method of Inokawa *et al.*;[6] bp 67°C/0.2 mmHg. The 1-bromo-1-deoxy-2,3;4,5-*O*-isopropylidene-β-D-fructopyranose (**4**) was prepared in a 65% yield by heating 2.5 g of 2,3;4,5-di-*O*-isopropylidene-1-*O*-(*p*-toluenesulfonyl)-α-D-fructopyranose[7] and 2.0 g of lithium bromide in 20 ml of dimethylformamide at 150°C for 55 hr; mp 49—50°C[8] after sublimation. The triethyl phosphite (**5**)[9] was used after distillation. The diethyl phenylphosphonite (**6**)[10] and ethyl *N*,*N*′-tetra-

ethylphosphorodiamidite (**7**)[11] were prepared in the usual way.

3,5-*O*-Benzylidene-6-deoxy-6-diethoxyphosphinyl-1,2-*O*-isopropylidene-α-D-glucofuranose (8). A solution of 2.0 g of **1** in 20 ml of **5** was heated at 150°C for 5 hr under a stream of nitrogen. The solution was then concentrated *in vacuo*; the residue was dissolved in ether, washed with water, dried over sodium sulfate, and concentrated *in vacuo* to give, in an 80% yield (1.6 g), a pale yellow oil (practically pure). An analytical sample was obtained by the use of a high vacuum at 125°C/10^{-2}—10^{-3} mmHg; $[\alpha]_D^{29}$ +17.4° (*c* 13.3, carbon tetrachloride).

Found: C, 55.0; H, 6.98%. Calcd for $C_{19}H_{29}O_8P$: C, 54.8; H, 7.02%. The PMR data (carbon tetrachloride) were as follows: 2.7 (five-proton multiplets, C_6H_5–), 4.1 (one-proton doublet, $J_{1,2}$=3.7 Hz, H_1), 4.4 (one-proton singlet, Ph–CH=), 5.4—6.3 [eight-proton multiplets, H_2, H_3, H_4, H_5, (P–O–CH_2–)$_2$], 7.7 (two-proton quartet, $J_{6,P}$=18 Hz, $J_{5,6}$=8.0 Hz, $H_{6,6'}$), 8.6, 8.8 [six-proton singlets, overlapping with (P–O–C–CH_3)$_2$; C(CH_3)$_2$], and 8.8 [six-proton triplets, overlapping with C(CH_3)$_2$; (P–O–C–CH_3)$_2$].

6-Deoxy-6-diethoxyphosphinyl-1,2;3,4-di-*O*-isopropylidene-α-D-galactopyranose (9). A solution of 2.0 g of **2** in 20 ml of **5** was heated at 160° for 3 hr under a stream of nitrogen. The resulting solution was treated as has been described above to give, in a 95% yield (1.9 g), a pale yellow oil (practically pure). An analytical sample was obtained by high-vacuum distillation at 110°C/10^{-2}—10^{-3} mmHg; $[\alpha]_D^{19}$ −48.0° (*c* 10, carbon tetrachloride).

Found: C, 50.0; H, 7.81%. Calcd for $C_{16}O_8H_{29}P$: C, 50.2; H, 7.62%. The PMR data (chloroform-*d*) were as follows: 4.7 (one-proton doublet, $J_{1,2}$=4.0 Hz, H_1), 5.3—6.4 (eight-proton multiplets, H_2, H_3, H_4, H_5, (P–O–CH_2–)$_2$], 7.8—8.3 (two-proton qualtet, $J_{6,P}$=18 Hz, $J_{5,6}$=6.8 Hz, $H_{6,6'}$), and 8.4—8.9 (twelve-proton multiplets, C(CH_3)$_2$, (P–O–C–CH_3)$_2$].

5-Deoxy-5-ethoxyphenylphosphinyl-1,2-*O*-isopropylidene-3-*O*-methyl-α-D-xylofuranose (10). A solution of 10 g of **3** in 30 ml of **6** was heated at 160°C for 5 hr. The resulting solution was treated as has been described above, and the oil thus obtained was distilled *in vacuo* to give, in a 90% yield, a colorless oil; bp 160—161°/0.1 mmHg, $[\alpha]_D^{25}$ −45.3° (*c* 10, chloroform).

Found: C, 57.7; H, 7.05%. Calcd for $C_{17}H_{25}O_6P$: C, 57.3; H, 7.07%. The PMR data (carbon tetrachloride) were as follows: 2.0—2.7 (five-proton multiplets, C_6H_5–), 4.3 (one-proton doublet, $J_{1,2}$=3.4 Hz, H_1), 5.5—6.5 (five-proton multiplets, H_2, H_3, H_4, P–O–CH_2–), 6.8 (three-proton doublet, –OCH_3), 7.4—8.0 (two-proton multiplets, $H_{5,5'}$), 8.6, 8.8 [six-proton singlets, overlapping with P–O–C–CH_3; C(CH_3)$_2$], and 8.8 (three-proton triplets, overlapping with C(CH_3)$_2$, P–O–C–CH_3).

3,5-*O*-Benzylidene-6-deoxy-1,2-*O*-isopropylidene-6-(*N*,*N*′-tetraethyldiaminophosphinyl)-α-D-glucofuranose (11). A solution of 1 g of **1** in 10 ml of **7** was heated at 140°C for 24 hr under a stream of nitrogen, and the solution was then concentrated *in vacuo*; the residue was dissolved in chloroform, washed with an aqueous sodium carbonate solution and water, dried over sodium sulfate, and concentrated *in vacuo*; the residue was extracted with petroleum ether under reflux, and the extract was evaporated *in vacuo* to give, in a 44% yield (0.5 g), a brown oil. High-vacuum distillation gave a pale yellow oil, pure enough for a NMR measurement but not enough for an elementary analysis; bp 120—130°C/10^{-2}—10^{-3} mmHg, $[\alpha]_D^{15}$ −55.5° (*c* 0.9, chloroform). The PMR data (chloroform-*d*) were as follows: 2.4—2.8 (five-proton multiplets, C_6H_5–), 4.0 (one-proton doublet, $J_{1,2}$=3.8 Hz, H_1), 4.4 (one-proton singlet, Ph–CH=), 5.3—5.6 (four-proton multiplets, H_2, H_3, H_4, H_5), 6.7—7.3 [eight-proton multiplets, [N–(CH_2–)$_2$]$_2$], 7.5—8.0 (two-proton multiplets, $H_{6,6'}$), 8.5, 8.7 [six-proton singlets, overlapping with [N–(C–CH_3)$_2$]$_2$; C(CH_3)$_2$], and 8.9 [twelve-proton triplets, overlapping with C(CH_3)$_2$; [N–(C–CH_3)$_2$]$_2$].

6-Deoxy-1,2;3,4-di-*O*-isopropylidene-6-(*N*,*N*′-tetraethyldiaminophosphinyl)-α-D-galactopyranose (12). A solution of 1 g of **2** in 10 ml of **7** was heated at 150—160°C for 5 hr under a stream of nitrogen. The resulting solution was treated as has been described above to give, in a 70% yield (0.7 g), a brown oil. High-vacuum distillation gave a pale yellow oil, pure enough for a NMR measurement but not enough for an elementary analysis; bp 90—100°C/10^{-2}—10^{-3} mmHg, $[\alpha]_D^{15}$ +18.5° (*c* 1.2, chloroform). The PMR data were as follows: 4.6 (one-proton doublet, $J_{1,2}$=4.4 Hz, H_1), 5.4—6.0 (four-proton multiplets, H_2, H_3, H_4, H_5), 6.7—7.3 [eight-proton multiplets, [N-(CH_2–)$_2$]$_2$], 7.7—8.3 (two-proton multiplets, $H_{6,6'}$), and 8.4—9.1 [eighteen-proton multiplets, C$(CH)_{32}$, [N–(C–CH_3)$_2$]$_2$].

Results and Discussion

The Michaelis-Arbuzov reaction is one of the most important reactions making a phosphorus-carbon bond, but the application of this reaction to carbohydrate chemistry has been made in only a few reports.[12] When a solution of the halogenated sugars, **1, 2, 3,** or **4** in an excess of **5** was heated at 150—160°C for several hr under a stream of nitrogen, **1, 2,** and **3** gave the corresponding phosphonyl sugars, **8, 9,** and **10,** in a good yield.

In the case of **4**, however, the reaction did not proceed practically.[13] The reason for this seems to be the steric effect of two isopropylidene groups and the electron-withdrawing effect from the anomeric acetal group, which would hinder the cleavage of the C-Br bond. For the same reason, the formation of **4** from the corresponding tosyl compounds with lithium bromide in dimethylformamide was very slow, as has been shown in the Experimental part. The reaction of **3** with **8** was also carried out with ease to give **10** in a good yield. The structures of **8**, **9**, and **10** were established by elementary analyses and by studies of the NMR

Intramolecular Hydrogen Bonds. XV.[1] Intramolecular Interaction in *N*-Alkylaminoalkanonitriles

Nobuo Mori, Yoshihiro Asabe, Junko Tatsumi and Yojiro Tsuzuki

Department of Chemistry, Science University of Tokyo, Shinjuku-ku, Tokyo

(Received April 27, 1970)

The ν_{NH} values of monomeric alkylmethylamines in carbon tetrachloride solutions are associated with the rotational isomerism about the N–C bond. In the series of *N*-alkylaminoalkanonitriles, the intramolecular hydrogen-bonding interaction of the NH group with the π-electrons of the CN group was deduced on the basis of the ν_{NH} values and a model examination; in the α-series, the NH group probably interacts exclusively, and in the β-series it partially interacts, but in the γ-series it shows no interaction.

There have been many reports on the intramolecular hydrogen bondings in which a hydroxyl group participates;[2] this subject has, indeed, hitherto been dealt with in this series of studies. The results have prompted us to investigate the intramolecular hydrogen bonding in which an amino group parcipitates, since the situation should be very similar in the two series of compounds.

The literature contains scant information on the intramolecular hydrogen bonding involving a secondary amino group. Several reports have, however, recently been published on the rotational isomerism around the N–C bond in *N*-alkylanilines[3] and on the intramolecular interaction between the NH group and the π-electrons in ω-secondary amino-alkylbenzenes;[3,4] the results are essentially omparable with those of the corresponding hydroxyl compounds.

The present paper will report on the rotational isomerism in alkylmethylamines and the intramolecular interaction between the NH group and the π-electrons of the CN group in *N*-alkylaminoalkanonitriles, and the results will be compared with those of the corresponding ω-hydroxyalkanonitriles previously reported on.[5]

Experimental

Samples. The dimethylamine was liberated from commercial aqueous dimethylamine, and the other alkylmethylamines were obtained by the reported method.[6] The α-*N*-alkylaminoalkanonitriles were prepared from the corresponding cyanohydrines by treating them with monoalkylamines in methanol.[7] The β-*N*-alkylaminopropionitriles were synthesized by the reaction of acryronitrile with alkylamines in methanol.[8] The γ-*N*-methylaminobutyronitrile was obtained by the reaction of γ-bromobutyronitrile with methylamine.[9] All the samples were purified through fractional distillation in an atmosphere of nitrogen; their physical constants agreed with those reported in the literature, and their purity was further proved by their gas chromatograms and/or NMR spectra. Compounds **7**, **8**, **9**, **10**, and **15** have not been reported previously; their analytical data are summarized in Table 2.

The carbon tetrachloride was fractionally distilled over phosphorus pentoxide.

Infrared Measurement. This was carried out at *ca.* 20°C, unless otherwise noted, in the same manner as has previously been described,[1] using a grating infrared spectrometer, Model DS-403G, of the Japan Spectroscopic Co.; the spectrometer was equipped with cells with a path-length of 5.0 cm. Each amine was weighed and dissolved in carbon tetrachloride in a concentration of 0.005 mol/*l* or less immediately before the measurement. The NMR examination of some amine solutions at a higher concentration indicated that no significant reaction of the amines with the solvent occurred during the period required for the infrared measurement.

Results and Discussion

The NH stretching absorption spectra of four alkylmethylamines are shown in Fig. 1A. The spectrum of ethylmethylamine is unsymmetric, with a widely-broadened part being centered at 3347

cm^{-1}, while those of dimethylamine and isopropylmethylamine are almost symmetrical. *t*-Butylmethylamine shows a broad adsorption.

A more detailed inspection of the band-shape was not performed because of the very low ε values. Moreover, even if it were made, it would not permit a confident discussion of the results. Accordingly, we will mainly discuss the peak frequencies, insofar as there is no intense shoulder or broadening. The apparent spectral data are summarized in Table 1.

Table 1. The spectral properties of ν_{NH} of alkylmethylamines, R-NH-CH_3

No.	R	ν^{a}_{max}, cm^{-1}	ε^{a}
1	CH_3	3348	5.4
2	C_2H_5	3347* 3331	3.9
3	$(CH_3)_2CH$	3334	3.8
4	$(CH_3)_3C$	3330	3.8

* Value at the center of the broadened part.

The unsymmetry of the spectrum of ethylmethylamine can not be caused by any molecular association, since no association explains the symmetry of the spectra of the other amines examined under the same conditions. The peak frequencies and the shapes of the spectra vary with the type of alkyl substituent (R); hence, the concept of the rotational isomerism about the C-N axis may be valid in explaining these facts, as has been made for a similar phenomenon observed in aliphatic alcohols[10] and in *N*-alkylanilines.[3]

According to the projection along the C_R-N bond (C_R is the carbon atom of an alkyl group, R, attached to the nitrogen atom), there are three possible types of steric environment around the N-H group, one or two of which can be taken by each amine depending on the type of R and on the rotational position to be favored. Fig. 2 shows the so-called Newman projection along the C_R-N bond, in which the nitrogen atom is described on the upper side, the circle denoted the C_R atom, and C is the methyl group.

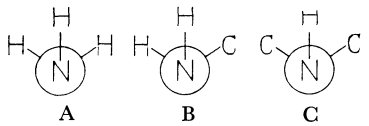

Fig. 2. Three types of steric environment around the NH group in alkylmethylamines.

In this model examination, the following three assumptions were made; (1) the tricovalently-bound nitrogen atom has a tetrahedron-like structure, with the N atom at the center of the tetrahedron and with the four electron orbitals pointing towards the vertices, since such a structure is generally seen in most aliphatic, sterically-uncrowded amines; (2) the steric size of the lone pair of electrons on the nitrogen atom is expected to be much smaller than that of any alkyl group, and almost equal to that of the hydrogen atom, on the basis of the conformational analysis of piperidine compounds,[11] and (3) the molecule takes a skew form, but not an eclipsed one. Hence, the hydrogen atom of the NH group in dimethylamine and also in *t*-butylmethylamine must be in the same steric environment, A or C respectively, because it always exists between two of the three hydrogen atoms or methyl groups on C_R, no matter in what rotational position it exists.

When the R group is ethyl, on the other hand, there are two possible steric environments, A and B. Similarly, two environments, B and C, are possible for the NH group of isopropylmethylamine. The spectral data seem to indicate that the NH group of ethylmethylamine exists in the environment B in a major proportion. This can probably be attributed to the steric effect of the methyl group for the following reasons: in Fig. 3, which shows the Newman projection along the N-C_R bond in each amine, dimethyl- and *t*-butylmethylamine can take only one conformation, I or IV respectively. Ethylmethylamine can exist in three conformations, IIa—c; IIa corresponds to the environment B and may be sterically preferable, while IIb and IIc may be less preferable. This interpretation can be suppoted by measuring the temperature dependence of the relative intensity of the two observed band-components. As Fig. 1B shows, the intensity of the maximum absorption relative to the broadened part decreases with an increase in the temperature. This phenomenon agrees with the thermodynamical generalization that the proportion of a stable conformation becomes higher at a lower temerature. On the other hand, isopropylmethylamine can exist in three conformations, IIIa—c. The two of them,

* Value at the center of the broadened part.

IIIa and IIIb, may be indistinguishable in steric preference from each other and correspond to the environments, B and C respectively. Therefore, the observed single NH bond seems to be due to the NH species in both environments, rather than in either of them. In fact, the band has been essentially identical with those observed at 10 and 40°C.

α-(*N*-Alkylamino)-alkanonitriles. Some NH spectra are shown in Fig. 1C, and the apparent spectral data are summarized in Table 2. The spectra of *N*-alkylaminoacetonitriles (**5**—**7**) are similar in general shape to, but are somewhat different in peak frequency from, those of the alkylmethylamines. When the alkyl group, R, is methyl or isopropyl, they show a single, almost symmetrical NH spectrum. When R is ethyl, the spectrum is widely broadened on the higher-frequency side. This may be explained in terms of the same alkyl effect as has been suggested as the origin of a similar phenomenon observed in alkylmethylamines, since the rotational isomerism about the C_R–N bond can be illustrated by Fig. 3, in which N–CH_3 is replaced by N–CH_2CN. On the other hand, in the projection along the C_α–N bond, all the acetonitriles predominantly prefer the same conformation, V, containing R and CN in a *trans* relationship, as is shown in Fig. 4. This conformer would involve an additional stabilization, one which should result from an attractive interaction which is probable between the NH group and the π-electrons of the CN group. As for the presence of the interaction, no evidence can be obtained from the spectral data of ν_{NH} and ε, and it can not, of course, be ascertained whether the interaction is of the usual charge-transfer type or of the electrostatic-attraction type. The observed ε values, much higher than those of alkylmethylamines, can not provide decisive evidence for the presence of the interaction, because both types of interaction and also the electron-attractive CN group would serve to increase the N–H bond moment and, thereby, to increase the ε value. The presence of the interaction is yet suggested in view of a situation similar to that in α-cyanohydrines, in which the interaction between the OH and the CN group results in no significant lowering of the OH stretching frequency.[5]

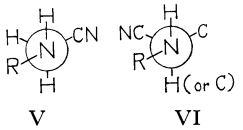

Fig. 4. Projection along the C_α–N bond in α-*N*-alkylaminoalkanonitirles.

In α-(*N*-alkylamino)-propionitriles (**8**—**10**) and -isobutyronitriles (**11** and **12**), the peak frequencies are lower by *ca.* 10 cm^{-1}, irrespective of the number of α-methyl groups, than those of the corresponding

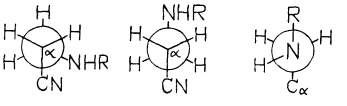
alkylaminoacetonitriles. This lowering seems to be attributable to the steric effect of the α-methyl groups, and its independence of the number of methyl groups seems to suggest that both series of nitriles involve an essentially equal steric environment around the N–H group when they contain the same R. These suggestions can be supported by an examination of their models; in the rotation around the C_R–N bond, the steric environment around the NH group is again as is shown in Fig. 2. On the other hand, the conformation, VI, about the C_α–N bond, which is shown in Fig. 4, may be preferable for both nitriles, if it is assumed that; (1) the CN group is much smaller in steric size than the methyl,[12] and that, hence, CH_3 and R are preferably *trans*, and (2) the interaction between the NH group and the π-electrons of the CN group is possible. This conformation contains one more methyl group skew to the NH group than does the conformation V of the alkylaminoacetonitriles. If the presence of this methyl group is responsible for the lowering of *ca.* 10 cm^{-1} in the NH frequency, the conformation VI may contribute to a major component of the band. Consequently, the above assignments can be summarized as in Table 3; the combination of the forms A and D, for example, gives the ν_{NH} of 3355 cm^{-1}.

Table 3. Relationship between the NH frequencies and the steric and/or interacting conditions

Projection along the N–C_R Bond / Projection along the N–C_α Bond		A	B
	D	3355	3336
	E	3345	3328

12) N. L. Allinger and W. Szkryblo, *J. Org. Chem.*, **27**, 460 (1962); B. Rickborn and F. R. Jensen, *ibid.*, **27**, 4606 (1962).

β-(*N*-Alkylamino)-propionitriles (13—15) and γ-(*N*-Methylamino)-butyronitrile (16). The NH spectra of the former contain apparently two resolved bands with a spacing of *ca.* 30 cm^{-1}, independent of the type of alkyl, as Fig. 1D shows; the lower and the higher frequency bands may be due to the interacted and the free NH species respectively. In the projection along the C_α—C_β bond, the CN and the NH group can be in a skew (VII) or *trans* relationship (VIII), as is shown in Fig. 5. In the skew form VII, the NH group can interact with the CN group, while most of the free NH species should exist in the sterically preferable *trans* form VIII.



VII VIII IX

Fig. 5. Projection along the C_α–C_β bond (forms VII and VIII) and along the N–C_β bond (form IX).

On the other hand, the projection along the N–C_β bond shows that the both interacted and free NH groups must be located in a position skew to the C_α atom in Form IX, which is sterically preferable. Accordingly, the difference in frequency among the alkylaminopropionitriles depends mainly on the type of R and may again be explained in terms of the same steric effect of R as that which has been mentioned above in the case of the α-alkylaminonitriles.

Finally, the γ-methylamino group does not interact with the nitrile group, probably because of the thermodynamically more difficult formation of a largering through interaction. The same phenomenon was observed in γ-hydroxybutyronitrile.[5]

Reactions between β-Propiolactone and Dialkyl Dimethylphosphoramidite-Ambident Character of β-Propiolactone and of Dialkyl Dimethylphosphoramidite

Jugo KOKETSU,*1 Seiji Kojima and Yoshio ISHII

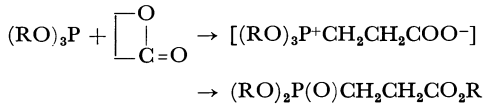
Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Nagoya

(Received April 30, 1970)

The reactions between dialkyl dimethylphosphoramidite, $Me_2NP(OR)_2$, and β-propiolactone were carried out in various solvents at 80°C. Two kinds of reaction products were separated on a silica gel by elution with benzene-ethanol (4 : 1 v/v). The first species eluted was *N,N*-dimethyl-*O*-alkyl 2-alkoxycarbonylethylphosphoramidate, $(RO)P(O)(NMe_2)CH_2CH_2CO_2R$. The fraction having lower R_f value contained dialkyl 2-*N,N*-dimethylcarbamoylethylphosphonate, $(RO)_2P(O)CH_2CH_2CONMe_2$. The reaction mechanism is discussed from kinetic study.

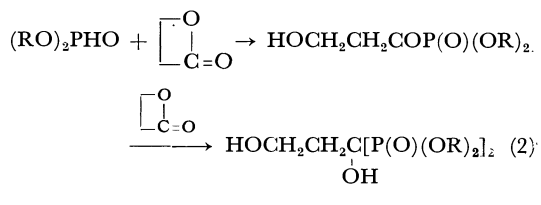
During the course of studies on the reactions of aminophosphines, we found that aminophosphines showed an ambident nature in their reactions with various kinds of electrophilic reagents, such as phenyl cyanate,[1] alkyl benzenesulfonate,[2] dialkyl sulfates,[2] acetic anhydride,[3] and cyclic carbonate esters.[4] On the other hand, β-propiolactone is well known to be cleaved through either alkyl-oxygen bond or acyl-oxygen bond in the reactions with various nucleophilic reagents. The mode of ring-opening of β-propiolactone depends upon the nature of nucleophiles. Therefore, in the reaction between aminophosphine and β-propiolactone, several reaction products would be obtained.

McConnell and Coover[5] reported that β-propiolactone reacted with trialkyl phosphite to give dialkyl 2-alkoxycarbonylethylphosphonate. This results from the attack of the trivalent phosphorus atom on the β-carbon atom of β-propiolactone followed by Arbuzove-like rearrangement, as shown by the following equation.



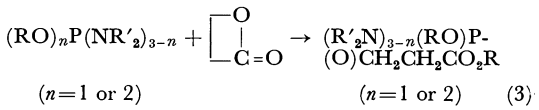
$$(RO)_3P + \text{β-propiolactone} \rightarrow [(RO)_3P^+CH_2CH_2COO^-] \rightarrow (RO)_2P(O)CH_2CH_2CO_2R \quad (1)$$

They also found[6] that acyl-oxygen bond fission occured in the reaction with dialkylphosphite:



$$(RO)_2PHO + \text{β-propiolactone} \rightarrow HOCH_2CH_2COP(O)(OR)_2 \xrightarrow{\text{β-propiolactone}} HOCH_2CH_2C[P(O)(OR)_2]_2 \quad (2)$$

As regards the reaction of β-propiolactone with dialkyl dialkylphosphoramidite and alkyl tetraalkylphosphorodiamidite, they disclosed in U. S. Patent[7] that the products obtained were *N,N*-dialkyl-*O*-alkyl 2-alkoxycarbonylethylphosphoramidate ($n=2$ in Eq. (3)) and *N,N,N',N'*-tetraalkyl 2-alkoxycarbonylethylphosphonic diamide ($n=1$ in Eq. (3)), respectively, and that the P–N bond was not cleaved at all.



$$(RO)_nP(NR'_2)_{3-n} + \text{β-propiolactone} \rightarrow (R'_2N)_{3-n}(RO)P(O)CH_2CH_2CO_2R \quad (n=1 \text{ or } 2) \quad (n=1 \text{ or } 2) \quad (3)$$

However, we found that diphenyl dimethylphosphoramidite reacted with β-propiolactone to give *N,N*-dimethylacrylamide and undistillable polymer containing P(O), P–O–Ph, and P–O–P groups, and that in the reaction of β-propiolactone with *N,N*-dimethyl diphenylphosphinous amide, poly-β-propiolactone was obtained quantitatively.[8]

It seemed worthwhile to reinvestigate the reaction between β-propiolactone and dialkyl dimethylphosphoramidite in order to elucidate the discrepancies between the above results.

Experimental

Commercial β-propiolactone was distilled before use. All the solvent were thoroughly dried over calcium hydride and distilled before use. The reactions and measurements of physical constants of the products were carried out under dry nitrogen. Infrared and NMR spectra were measured on a Nippon Bunko IR 403G Spectrometer and a Japan Electron Minimer spectrometer. Thin-layer chromatography was carried out on 250 mμ thick silica gel layer by using benzene - ethanol (4 : 1 v/v). Column chromatography was performed in a column 50 cm long (ratio of column length to diameter=20 : 1). Into the column filled with 40 g of 100 mesh silica gel (Mallinckrodt Chemical Works) was put 1—2 g of samples by the wet method and eluted by benzene - ethanol (4 : 1 v/v).

Synthesis of Dialkyl Dimethylphosphoramidites. To a solution of lithium alkoxide, prepared from the corresponding alcohol and *n*-butyllithium in petroleum ether, an equimolar amount of Me_2NPCl_2 was added slowly with ice-cooling. After stirring for 30 min at room temperature, the mixture was refluxed for 1 hr. Separation of lithium chloride and removal of the solvent gave crude phosphoramidite which was purified by column-distillation. Boiling points and the yields of the phosphoramidites are shown in Table 1.

Table 1. Dialkyl dimethylphosphoramidites

Compound		Bp (°C/mmHg)	Yield (%)
$(i\text{-PrO})_2PNMe_2$	Ia	62—65/7.0	75.5
$(s\text{-Bu})_2PNMe_2$	Ib	47—52/3.5	78.4
$(n\text{-PrO})_2PNMe_2$	Ic	75—84/5.4	73.0
$(EtO)_2PNMe_2$	Id	40—48/12.0	55.6

Reaction of $(i\text{-PrO})_2PNMe_2$ (Ia) with β-Propiolactone. β-Propiolactone (1.5 g, 21 mmol) was added to a solution of Ia (40 g, 20.9 mmol) in 40 m*l* of benzene, and the mixture was allowed to stand for 30 hr at 80°C. Completion of the reaction was confirmed by means of IR absorption spectrum. After removal of the solvent, a fraction having boiling point range of 50—100°C/0.007 mmHg was obtained in 75% yield (4.28 g). The fraction showed two spots on thin-layer chromtography at R_f=0.62 and 0.50. By column chromatographic treatment on silica gel, two species II and III were obtained. The first species II was identified as *N,N*-dimethyl-*O*-isopropyl 2-isoproxycarbonylethylphosphoramidate, yield 2.60 g (45% based on Ia), and the other III as diisopropyl 2-*N,N*-dimethylcarbamoylethylphosphonate, yield 1.67 g (29% based on Ia), by their NMR and IR spectra, respectively, shown in Tables 2 and 3, and by their elemental analyses.

II: Found: C, 49.26; H, 9.30; P, 11.53%. Calcd for $C_{11}H_{24}NO_4P$: C, 49.80; H, 9.12; P, 11.67%. III: Found: C, 49.74; H, 9.38; P, 11.59%. Calcd for $C_{11}H_{24}NO_4P$: C, 49.80; H, 9.12; P, 11.67%.

Reaction of $(s\text{-BuO})_2PNMe_2$ (Ib) with β-Propiolactone. The reaction betwene Ib (3.60 g, 16.2 mmol) and β-propiolactone (1.17 g, 16.2 mmol) was carried out in a similar way by refluxing their mixture in 30 m*l* of benzene for 46 hr. After the reaction was over, the reaction mixture was distilled under reduced pressure to give a fraction having the boiling point range of 39—110 °C/0.01 mmHg. By column chromatographic treatment on silica gel, two species IV and V were obtained. The first species IV eluted was proved to be *N,N*-dimethyl-*O*-*s*-butyl 2-*s*-butoxycarbonylethylphosphoramidate, yield 2.41 g (49% based on Ib), and the other V to be di-*s*-butyl 2-*N,N*-dimethylcarbamoylethylphosphonate, yield 1.52 g (31% based on Ib), by their spectral data shown in Tables II and III, and by elemental analyses.

IV: Found: C, 52.64; H, 10.19%. Calcd for $C_{13}H_{28}NO_4P$: C, 53.23; H, 9.62%. V: Found: C, 52.43; H, 9.82; P, 10.49%. Calcd for $C_{13}H_{28}NO_4P$: C, 53.23; H, 9.62; P, 10.91%.

Reactions of $(n\text{-PrO})_2PNMe_2$ (Ic) and $(EtO)_2PNMe_2$ (Id) with β-Propiolactone. The reaction between Ic (4.00 g, 21 mmol) and β-propiolactone (1.50 g, 20 mmol) was carried out by refluxing the benzene solution (40 m*l*) for 51 hr. Distillation of the reaction mixture gave a fraction which had a boiling point range of 39—119°C/0.02 mmHg (4. 91 g, 85% based on Ic). This distillate exhibited strong IR absorption at 1740 and 1658 cm^{-1} in equal intensity, which could be assigned to the stretching frequencies of an ester carbonyl and an amide carbonyl group, respectively. Other strong absorption bands appeared at 1245 (P=O) and 990 cm^{-1} (P–O–C). In the NMR spectrum, there were a doublet at τ 7.50 (J=10 Hz) which could be ascribed to P–NMe_2 protons, and two singlets at τ 7.45 and τ 7.60 assignable to –$CONMe_2$. However, when the reaction product was chromatographed on silica gel, it decomposed to various species such as di-*n*-propyl phosphite, a polymer which contained phosphoryl group and unidentified substances.

The same phenomenon as that of the above experiment was observed in the reaction of $(EtO)_2PNMe_2$ (Id) with β-propiolactone, and no identified product was obtained.

Reaction of II, III, IV and V with Elementary Sulfur. Equimolar amounts of elementary sulfur were added to a solution of II in ethyl ether. Even after refluxing this solution for two days, sulfur did not react, and phosphonamidate II was recovered quantitatively. In the cases of III, IV and V also, sulfur addition reaction did not occur at all.

Kinetic Study on the Reaction between Ib and β-Propiolactone. A solution containing 0.1807 mol/*l* of Ib and 0.2070 mol/*l* of β-propiolactone was prepared and divided into several ampoules filled with nitrogen and then sealed. The sealed ampoules were heated in a bath kept at 80±0.5°C. At an appropriate time interval, an ampoule was broken and the concentrations

of IV and V were determined from the intensity of the absorptions at 1743 and 1658 cm^{-1}, respectively.

Results and Discussion

Contrary to the results of McConnell *et al.*,[7] two kinds of products were obtained in the reaction between dialkyl dimethylphosphoramidite and β-propiolactone. The two products were identified to be *N,N*-dimethyl-*O*-alkyl 2-alkoxycarbonylethylphosphoramidate (II and IV) and dialkyl 2-*N,N*-dimethylcarbamoylethylphosphonate (III and V) by their chemical behavior and spectral data. None of them reacted with elementary sulfur. Thus, it is likely that they have a quinquevalent phosphorus atom rather than the trivalent phosphorus atom. In the NMR spectrum of II, shown in Table 2, the methyl protons of isopropyl group of II showed two doublets at τ 8.73 and 8.42, and in the case of IV, those of *s*-butyl group showed complex multiplets at τ 8.50—9.45. The results indicate that each of the two alkoxy groups attaches itself to different sites of the molecules. In addition, the β-substituted ethyl protons were observed over the range of τ 7.20—8.40 as a complex multiplet, which could be explained by the fact that the ethyl group attaches itself to the phosphorus atom.

In IR spectra, shown in Table 3, there were strong absorptions at 1740 and 1240 cm^{-1} in both II and IV, which could be assigned to the carbonyl stretching frequency of ester group and to P=O group, respectively. Thus, the structures of II and IV were confirmed as phosphoramidate.

By similar chemical and spectral evidence as that of the above discussion, it could be assumed that III and V have phosphonate structures. Therefore, it would be reasonable to assume that there are two routes to give different reaction products as visualized in the following equation.

$$(RO)_2PNMe_2 + \begin{array}{c} \\ \\ \text{—O—C(=O)—} \end{array} \begin{array}{l} \xrightarrow{\text{route(a)}} \text{ROP(O)(NMe}_2\text{)CH}_2\text{CH}_2\text{CO}_2\text{R} \\ \quad \text{II: R=}i\text{-Pr, IV: R=}s\text{-Bu} \\ \xrightarrow{\text{route(b)}} (RO)_2\text{P(O)CH}_2\text{CH}_2\text{CONMe}_2 \\ \quad \text{III: R=}i\text{-Pr, V: R=}s\text{-Bu} \end{array} \quad (6)$$

In order to elucidate the reaction mechanism, kinetic study on the reaction between Ib and β-propiolactone was carried out in various solvents by determining the absorbances of IR frequencies at 1743 and 1658 cm^{-1}, which are characteristic absorptions of IV and V, respectively. The rates of the formation of IV and V in the initial stage of the reaction satisfied typical first order kinetics. The first order rate constants [k_1(phosphoramidate) and k_1(phosphonate)] obtained in five solvents are sum-

Solvent	Dielectric constant (ε)	$10^5 k_1$ (phosphoramidate) (sec^{-1})	$10^5 k_1$(phosphonate) (sec^{-1})
Acetonitrile	3.75	very fast[b]	very fast[b]
o-Dichlorobenzene	9.93	5.43	1.73
Tetrahydrofuran	7.93	3.57	2.11
Tetralin	2.76	1.07	0.74
Benzene	2.28	0.75	0.67

a) $[Ib]_0=0.1807$ mol/*l*, $[\beta$-Propiolactone$]_0=0.2070$ mol/*l*.
b) The reaction was completed within 30 min.

marized in Table 4.

A fairly good linear relationship exists between the logalithms of the rate constants and the Kirkwood parameter $(\varepsilon-1)/(2\varepsilon+1)$, as shown in Fig. 1.

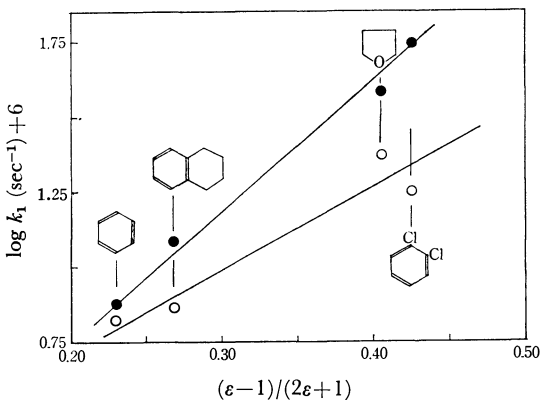

Fig. 1. Effect of solvent polarity on the rate constant; k_1 (phosphoramidate) —●— and k_1 (phosphonate) —○—.

Relative amounts of IV/V were determined in some solvents at the end point of the reaction by their IR absorption. The results are summarized in Table 5.

Table 5. Relative amount (IV/V) in various solvents at the termination of the reaction

Solvent	Dielectric constant (ε)	IV/V
Acetonitrile	37.5	5.77
o-Dichlorobenzene	9.93	2.31
Tetrahydrofuran	7.93	2.15
Benzene	2.28	1.58

It is clear from Fig. 1 and Table 5 that the overall rate of the reaction is more accelerated in polar solvent than in nonpolar solvent and that the relative amounts (IV/V) increase with increasing polarity of the solvent. This indicates that V was formed *via* the intermediate (VI) in which large charge-separation occurs. The mechanism of this reaction could be rationalized as follows: In the reaction of route(a) in Eq. (6), the sp^3 carbon of β-propiolactone is attacked by the phosphorus atom of the phosphoramidite to give betaine intermediate, and succeeding Arbuzov-like rearramgement of alkyl group gives phosphoramidate (II and IV) as shown in the following.

$$(RO)_2PNMe_2 + \begin{bmatrix} -O \\ | \\ -C=O \end{bmatrix} \downarrow [(RO)_2P^+(NMe_2)CH_2CH_2COO^-] \quad \text{VI} \quad \downarrow (RO)P(O)(NMe_2)CH_2CH_2CO_2R \quad (7)$$

II: R=*i*-Pr
IV: R=*s*-Bu

On the other hand, in the reaction of route (6) in Eq. (6). the sp^2 carbon of β-propiolactone is attacked by the nitrogen atom of the phosphoramidite with synchronous interaction between the oxygen atom of the ester group and the phosphorus atom as visualized by the following equation.

$$(RO)_2PNMe_2 + \begin{bmatrix} -O \\ | \\ -C=O \end{bmatrix} \rightarrow \left[\begin{array}{l} \quad\quad O \\ Me_2N\cdots C \\ (RO)_2P\cdots O \end{array} \right] \quad \text{VII} \quad \downarrow [Me_2NCOCH_2CH_2\cdots P(OR)_2] \quad (8)$$

$$\downarrow Me_2NCOCH_2CH_2P(O)(OR)_2$$

III: R=*i*-Pr
V: R=*s*-Bu

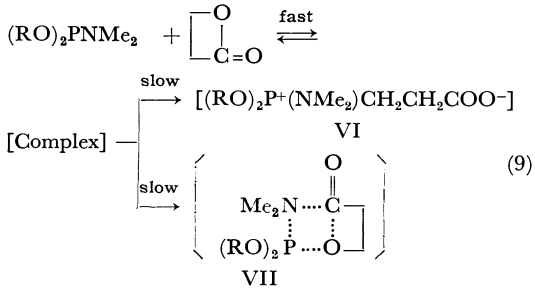
This four-centered mechanism explains the fact that the formation of V is less influenced than that of IV by solvent polarity.

In our former study on the reaction of aminophosphine with acetic anhydride[3] and cyclic carbonate esters,[4] the analogous four-centered mechanism was adopted.

According to Pearson, the sp^3 carbon atom may be a softer acid than the sp^2 carbon atom and also the phosphorus atom would be a softer base than the nitrogen atom. Therefore, it is relevant to as-

sume that in this reaction the softer phosphorus atom would attack preferably the sp^3 carbon atom of β-propiolactone, whereas the harder nitrogen atom interacts with the sp^2 carbon atom of β-propiolactone.

In this reaction, the rate determining step might be assumed from the solvent effect on the reaction to be the formation of betaine VI or four-centered intermediate VII. The fact that this reaction satisfied first order kinetics shows the existense of "complex" equilibrating quikly between phosphoramidite and β-propiolactone before the rate determing step:



(9)

Existence of this complex could not be identified spectroscopically or by other methods.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3236—3238 (1970)

Synthesis of 5-Styryltropolones

Hidehiro HIGASHI,*1 Kazu KUROSAWA and Hisashi MATSUMURA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

(Received May 1, 1970)

5-Styryl-, 5-(*p*-bromostyryl)-, 5-(*p*-chlorostyryl)-, 5-(*p*-methoxystyryl)-, 5-(*p*-methylstyryl)-, 5-(*m*-chlorostyryl)- and 5-(*m*-methylstyryl)tropolone were synthesized by the Wittig reaction of 5-formyltropolone. Their UV and NMR spectra were determined.

In connection with the studies on syntheses and chemical properties of 4-styryltropolones[1] in our laboratory, we also investigated on the synthesis of 5-stytyltropolenes by means of the Wittig reaction with *p*- and *m*-substituted benzylidenetriphenylphosphorane on 5-formyltropolone (III). Seven 5-styryltropolones (IVa—g) have been synthesized and the results are described in this paper.

5-Styryltropolone (IVa) has firstly been synthesized by Matsumura[2] through the abnormal substitution reaction of 2-tosyloxy-4-styryltropolone. When this synthetic scheme was applied to *p*-methoxystyryl- and *p*-nitrostyryltropolone, we found that the separation of 2-tosyloxy-4-(substituted styryl)-tropolone from 2-tosyloxy-6-(substituted styryl)-tropolone was extremely difficult.

It would be expected that the Wittig reaction of substituted benzylidenetriphenylphosphorane with III, which has been obtained by the Reimer-Tiemann reaction of tropolone,[3] could introduce a styryl group at the position in tropolone nucleus. The Wittig reagents were formed with *m*- and *p*-substituted benzyltriphenylphosphonium halides[4–9] on treatment with sodium ethoxide in anhydrous ethanol. The Wittig reaction usually took 4 to 25 hr depending upon the nature of the substituent of the ylids used and gave 5-styryltropolones in excellent yield. It was strange, however, that *p*-nitrobenzylidenetriphenylphosphorane did not react with III.

Yields and melting points of the 5-styryltropolones are listed in Table 1.

UV spectra of the 5-styryltropolones are shown in Table 2. The absorption in the region of 380—405 mμ could be correlated to the electronic effects

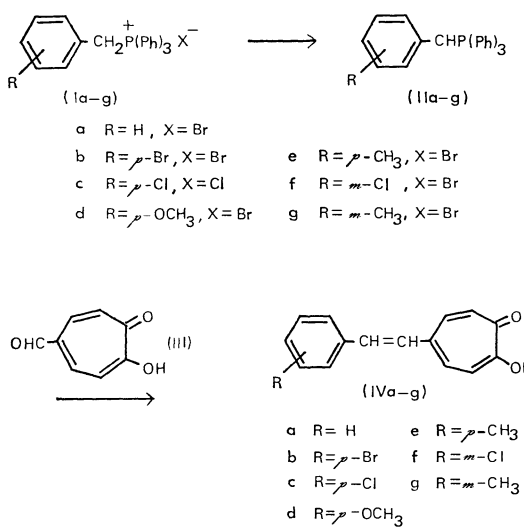
of *p*- and *m*-subtituents: *p*-CH_3O-, *p*-Br- and *p*-Cl- cause a bathochromic shift, while *m*-Cl- and *m*-CH_3- cause a little or none.

An absorption band at 950 cm^{-1} appeared in the IR spectra of all the 5-styryltropolones may indicate that the ethylenic double bond has a *trans* configuration.

NMR spectra of the 5-styryltropolones recorded in $CDCl_3$ are summarized in Table 3.

The ethylenic protons appeared as a sharp singlet and failed to show whether the configuration of the double bond is *trans* or *cis*. It was also observed that IVe showed two methyl protons and two



ethylenic protons, the intensities being 4 : 1. This indicates that the IVe is a mixture of *trans*- and *cis*-isomers. The presence of a band at 950 cm^{-1} in its IR spectrum is in favor of the *trans*-isomer being predominant.

pK_a measurements and a study of the correlation of pK_a values to the Hammett equation are now in progress.

Experimental

Measurements. IR spectra were determined in chloroform with a grating infrared spectrometer, Model DS 403G (Japan Spectroscopic Co. Ltd.). UV spectra were obtained in methanol with a recording spectrophotometer, Model EPS-2 (Hitachi Ltd.). NMR spectra were recorded in deuteriochloroform with TMS as an internal reference using a JNM C 60H (Japan Electron Optics Lab.). Melting points were determined with a Yanagimoto melting point apparatus.

5-Formyltropolone (III). 5-Formyltropolone was prepared according to the reference.[3] The work up procedure was, however, conveniently shortened by chloroform extraction of the products in place of continuous ether extraction and by chromatographic separation of III from the unchanged tropolone on silica (Wakogel C100) column.

Preparation of 5-Styryl- and 5-(*m*- and *p*-Substituted-styryl)tropolones (IVa—g). Phosphonium salt (I) (5.2 mmol) was treated with sodium ethoxide, prepared from metallic sodium (5.2 mmol) and anhydrous ethanol (13 m*l*). To the solution, there was added 5-formyltropolone (III) (1.67 mmol) and the mixture was stirred at a temperature between 30° and 60°C for a period of time shown in Table 1. The mixture was acidified with 2N sulfuric acid and extracted with chloroform. The chloroform was evaporated and the residue was chromatographed with chloroform on a silica column (Wakogel C100 (36 g) plus B10 (4 g)). The first fraction (100 m*l*) was taken and the chloroform was evaporated. The resulting solid was recrystallized from benzene or from a mixture of benzene and light petroleum (bp 30—70°C), giving 5-styryltropolone (IV) in 53—88% yield.

The authors wish to thank Professor Tetsuo Nozoe for his helpful discussions and encouragements throughout this work and Sankyo Co., Ltd., for supplying tropolone to us. The authors were also gratefully acknowledged to Professor Shin-ichi Sasaki and Mr. Hidetsugu Abe, of Miyagi University of Education for the measurements of the NMR spectra. We appreciate the Ministry of Education for the support by a grant to buy a grating infrared spectrometer, Model DS 403G (Japan Spectroscopic Lab.).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3239—3241 (1970)

The Acid-Catalyzed Ring-Opening of Cyclooctenimine Derivatives

Shinsaku FUJITA, Tamejiro HIYAMA and Hitosi NOZAKI

Department of Industrial Chemistry, Kyôto University, Yosida, Kyôto

(Received, May 1, 1970)

The acid-catalyzed ring-opening of 9-ethoxycarbonyl-9-aza-bicyclo[6.1.0]nonane (**1**) and -4-nonene (**2**) is reported to give normal products **3a** and **11a**, respectively, together with several transannular products.

The ring opening of cyclooctene oxide is well known,[1] and treatment of cyclooctenimine with perchloric acid results in recovery of the starting material.[2] We wish to report the acid-catalyzed aziridine ring cleavage of 9-ethoxycarbonyl-9-aza-bicyclo[6.1.0]nonane (**1**) and -4-nonene (**2**).

The reaction of **1** with perchloric acid gave ethyl *trans*-2-hydroxycyclooctane-1-carbamate (**3a**) along with two transannular products, **4** and **5**. The structure of **3a** was determined on the basis of spectral data and the following chemical correlation. Oxidation of **3a** with chromic acid gave the corresponding ketone **6** which was identical with the product prepared by the DMSO-oxidation of aziridine **1**.[3] The *trans*-configuration of **3a** was determined by hydrolysis which gave *trans*-2-aminocyclooctanol. Sodium borohydride reduction of **6** afforded **3a** as well as the *cis*-isomer (**3b**) whose configuration was established by conversion to *cis*-2-aminocyclooctanol. Heating **3b** at 170°C under reduced pressure afforded *cis*-4,5-hexamethylene-2-oxazolidone (**9**). The same compounds was obtained by thermolysis of *trans*-β-iodocarbamate (**10**). The formation of 2-oxazolidones from *N*-alkoxycarbonyl-β-aminoalcohols has not been reported.

The transannular product **4** was oxidized to the corresponding ketone (**7**) which exhibited an IR band at 1705 cm^{-1} characteristic of a medium-sized cyclic ketones. The elementary analysis and spectral data indicated that **4** was the isomer of **3a** and **3b**. The structure of **4** was tentatively assigned to be ethyl 4-hydroxycyclooctane-1-carbamate on the analogy of the formation of cyclooctane-1,4-diol in the solvolysis of cyclooctene

oxide.[1] The olefinic product (**5**) was identical with the authentic ethyl 4-cyclooctene-1-carbamate prepared by the acid-catalyzed addition of urethane to 1,5-cyclooctadiene.[3]

The acid-catalyzed cleavage of **2** in aqueous phase gave ethyl *trans*-8-hydroxy-4-cyclooctene-1-carbamate (**11a**), together with a small amount of transannular by-products whose structures have not been determined. The *trans*-configuration of **11a** was established by the fact that **11a** absorbed 1 molar equivalent of hydrogen to afford **3a**. Chromic acid oxidation of **11a** yielded the corresponding ketone (**12**) which was also prepared by the DMSO-oxidation of **2**.[3] Reduction of **12** with sodium borohydride afforded ethyl *cis*-8-hydroxy-4-cyclooctene-1-carbamate (**11b**) exclusively, which on catalytic hydrogenation gave **3b**. The difference between **6** and **12** in borohydride reduction should be ascribed to the rigidity[4] of the ring of **12** as compared with that of **6**. Ethyl *trans*-8-acetoxy-4-cyclooctene-1-carbamate (**13**) was obtained by treatment of **2** with dry acetic acid along with several bicyclic minor products.

Apparently, the acid-catalyzed aziridine ring-cleavage is favored by the presence of alkoxycarbonyl group on nitrogen. Initial protonation on carbonyl oxygen[5] would account for this rather unusual activation. Formation of the transannular products may be explained by intramolecular hydride shift analogous to the solvolysis of cyclooctene oxide.[1]

The normal addition products **3a** and **11a** have *trans* configuration, where the so-called "borderline" S_N2 mechanism should be involved in a stereochemical sence.[6]

Experimental

Acid-catalyzed Hydrolysis of 1. A solution of aziridine (**1**)[3] (1.27 g, 65 mmol) in ether (12 m*l*) was added dropwise for 5 min at room temperature to a mixture of water (0.80 g), ether (15 m*l*) and 60% perchloric acid (0.30 g). After being stirred for 6.5 hr, the reaction mixture was neutralized with aqueous sodium bicarbonate, extracted with ether and dried over sodium sulfate. Concentration and separation through a Silica gel column (benzene - ether (4 : 1) as a solvent) afforded ethyl 4-cyclooctene-1-carbamate (**5**) (0.56 g, 44%), which was identical with the authentic sample.[3]

Subsequent elution with ether gave ethyl *trans*-2-hydroxycyclooctane-1-carbamate (**3a**) (0.35 g, 25%), bp 140—145°C/0.05 mmHg, mp 42—43°C (*n*-hexane - acetone). IR (neat): 3450—3300 (broad), 1690, 1535, 1300, 1250—1235, 1090, 1035 cm^{-1}. NMR (CCl_4): δ 5.7—5.3 (broad, 1H, NH), 4.09 (q, 2H, $OC\underline{H}_2CH_3$), 4.0—3.3 (m, 3H, methines and OH), 2.4—1.0 (m, 12H, methylenes), 1.28 (t, 3H, $OCH_2C\underline{H}_3$).

Found: C, 61.4; H, 10.0; N, 6.8%. Calcd for $C_{11}H_{21}NO_3$: C, 61.4; H, 9.8; N, 6.5%.

The third eluent was ethyl 4-hydroxycyclooctane-1-carbamate (**4**) (0.36 g, 26%) bp 150—155°C/0.05 mm Hg IR (neat): 3450—3330 (broad), 1685, 1530, 1300, 1235, 1090, 1059, 1028 cm^{-1}. NMR (CCl_4): 6.0—5.3 (broad, 1H, NH), 4.3—3.4 (m+q, 5H, methines, OH and $OC\underline{H}_2CH_3$), 2.5—1.3 (m, 12H, methylenes), 1.25 (t, 3H, $OCH_2C\underline{H}_3$).

Found: C, 61.4; H, 10.0; N, 6.5%. Calcd for $C_{11}H_{21}NO_3$: C, 61.4; H, 9.8; N, 6.5%.

Oxidation of 4. (0.12 g, 0.56 mmol) by the Brown procedure[7] and subsequent preparative thin-layer chromatography (TLC) afforded ethyl 4-cyclooctanone-1-carbamate (**7**), bp 110—115°C/0.5 mm. IR (neat): 3350, 1705, 1675, 1530, 1380, 1340, 1225, 1040 cm^{-1}. NMR (CCl_4): δ 4.87 (s, 1H, NH), 4.14 (q, 2H, $OC\underline{H}_2CH_3$), 3.9—3.4 (m, 1H, methine), 2.7—1.0 (t+m, 15H, $OCH_2C\underline{H}_3$ (δ 1.30) and methylenes).

Found: C, 62.5; H, 9.1; N, 6.6%. Calcd for $C_{11}H_{19}NO_3$: C, 61.9; H, 9.0; N, 6.6%.

Oxidation of 3a. (0.12 g, 0.56 mmol) by the Brown procedure[7] gave ethyl 2-oxocyclooctane-1-carbamate (**6**), whose IR and NMR spectra were identical with those of the sample prepared by the DMSO-oxidation of **1**.[3]

Reduction of 6 with Sodium Borohydride. Sodium borohydride (0.10 g) was added in one portion to a solution of **6** (0.15 g, 0.70 mmol) in methanol at 0°C. After being stirred for 4 hr, and suspension was acidified to pH 4 by dilute hydrochloric acid, poured into water, extracted with ether and dried. Concentration and separation by preparative TLC afforded **3a** (0.025 g, 17%) as well as ethyl *cis*-2-hydroxycyclooctane-1-carbamate (**3b**) (0.040 g, 26%), bp 160°C/1 mmHg. IR (neat): 3450—3350 (broad), 1685, 1520—1510, 1310, 1248, 1107, 1090, 1060, 1035 cm^{-1}. NMR (CCl_4): δ 5.7—5.2 (broad, 1H, NH), 4.2—3.5 (m+q, 4H, methines and $OC\underline{H}_2CH_3$), 3.4—3.0 (broad, 1H, OH) 2.0—1.0 (m+t, 13H, methylenes and $OCH_2C\underline{H}_3$) (δ 1.20)).

Found: C, 61.3; H, 9.9; N, 6.2%. Calcd for $C_{11}H_{21}NO_3$: C, 61.4; H, 9.8; N, 6.5%.

Hydrolysis of 3a. A mixture of **3a** (0.26 g, 1.2 mmol), sodium hydroxide (1.5 g), methanol (10 m*l*) and water (10 m*l*) was refluxed under nitrogen atmosphere for 25 hr. Usual work-up gave *trans*-2-aminocyclooctanol (0.18 g) quantitatively, mp 72.6—73°C (lit,[8] mp 73—74°C).

Hydrolysis of 3b. (0.050 g, 0.23 mmol) with methanolic sodium hydroxide yielded *cis*-2-aminocyclooctanol (0.030 g, 90%) as a solid, whose IR spectrum was identical with that of the sample prepared from the oxazolidone (**9**).

***cis*-4,5-Hexamethylene-2-oxazolidone (9).** A solution of β-iodocarbamate **10**[3] (5.0 g, 15 mmol) in xylene (40 m*l*) was heated for 20 hr. Concentration and recrystallization gave the oxazolidone (**9**) (2.57 g) quantitatively, mp 106.5—107.5°C (acetone). IR (Nujol): 3260, 3170, 1745, 1725, 1260, 1235, 1090, 1080, 1042,

974 cm^{-1}. NMR (CCl_4): δ 7.4—7.1 (broad, 1H, NH), 4.8—4.2 (m, 1H, CH-O), 4.1—3.5 (m, 1H, CH-N), 2.4—1.0 (m, 12H, methylenes).

Found: C, 63.7; H, 9.1; N, 8.2%. Calcd for $C_9H_{15}NO_2$: C, 63.9; H, 8.9; N, 8.3%.

The same oxazolidone (**9**) was obtained by distillation of **3b** at 170°C/1.5 mmHg.

Hydrolysis of 9. (1.69 g, 10 mmol) with alcoholic potash afforded *cis*-2-aminocyclooctanol (1.40 g, 98%), mp 45—47°C (*n*-hexane - benzene) (lit,[8] mp 52—54°C).

Acid-catalyzed Hydrolysis of 2. Aziridine **2**[3] (4.68 g, 24 mmol) was treated with perchloric acid as described above. Recrystallization of the crude solid (5.6 g) gave ethyl *trans*-8-hydroxycyclooct-5-ene-1-carbamate (**11a**) (2.38 g), mp 98.8—99.5°C (ethyl acetate – *n*-hexane). IR (Nujol): 3420, 3290, 3090, 3040, 1690, 1550, 1260, 1329, 1154, 1130, 1060, 1042 cm^{-1}. NMR ($CDCl_3$): δ 5.8—5.5 (m, 2H, olefinic), 5.4—5.0 (broad, 1H, NH), 4.3—3.5 (m+q, 4H, methines and $OC\underline{H}_2CH_3$), 2.80 (s, 1H, OH), 2.7—1.3 (m, 8H, methylenes), 1.26 (t, 3H, $OCH_2C\underline{H}_3$).

Found: C, 61.7; H, 9.0; N, 6.5%. Calcd for $C_{11}H_{19}NO_3$: C, 61.9; H, 9.0; N, 6.6%.

The mother liquor was submitted to chromatography on Silica gel. Elution with benzene - ether (3 : 1) gave an isomerization product (0.68 g, 15%), bp 100—110°C/0.04 mmHg. IR (neat): 3320, 1690, 1525, 1230, 1080, 1045 cm^{-1}. NMR (CCl_4): δ 5.9—5.2 (m, 4H, olefinic and NH), 4.07 (q, 2H, $OC\underline{H}_2CH_3$), 2.7—1.3 (m, 8H, methylenes), 1.23 (5, 3H, $OCH_2C\underline{H}_3$). MS *m/e* 195 (M^+). The compound was tentatively assigned as ethyl 1,5-cyclooctadiene-1-carbamate.

Found: C, 67.4; H, 8.8; N, 7.0%. Calcd for $C_{11}H_{17}NO_3$: C, 67.7; H, 8.8; N, 7.2%.

Further elution with benzene - ether (1 : 1) gave additional **11a** (0.70 g, totally 3.08 g, 60%). The third component was an oil (0.24 g, 5%), bp 120—130°C/0.05 mmHg. IR (neat): 3450—3330, 1688, 1535, 1288, 1240, 1098, 1070, 1046 cm^{-1}. NMR (CCl_4): δ 5.7—5.4 (broad, 1H, NH), 4.9—4.5 (m, 1H, methine), 4.3—3.5 (m+q, methine and $OC\underline{H}_2CH_3$), 2.93 (s, 1H, OH), 2.6—0.8 (m+t, 13H, methylenes and $OCH_2C\underline{H}_3$). MS *m/e* 213 (M^+). The compound was tentatively assigned as ethyl 6-hydroxybicyclo [3.3.0] octane-2-carbamate, since the corresponding ketone obtained by its oxidation exhibited an IR band at 1735 cm^{-1} characteristic of a five-membered cyclic ketone.

Oxidation of 11a (0.43 g, 2.0 mmol) with chromic acid[7] gave an oil (0.37 g, 88%), which was identical with the sample of **12** prepared by the DMSO-oxidation of **2**.

Sodium Borohydride Reduction of 12 (0.75 g, 3.5 mmol) and subsequent chromatography on Silica gel column gave ethyl *cis*-8-hydroxy-4-cyclooctene-1-carbamate (**11b**) (0.63 g, 83%), mp 93.5—94.5°C (acetone). IR (Nujol): 3420, 3280, 1690, 1550, 1255, 1235, 1060, 1040 cm^{-1}. NMR ($CDCl_3$): δ 5.8—5.4 (m, 3H, olefinic and NH), 4.3—3.6 (m+q, 5H, OH, methines and $OC\underline{H}_2CH_3$), 2.9—1.5 (m, 8H, methylenes), 1.26 (t, 3H, $OCH_2C\underline{H}_3$).

Found: C, 61.8; H, 9.1; N, 6.4%. Calcd for $C_{11}H_{19}NO_3$: C, 61.9; H, 9.0; N, 6.6%.

Hydrogenation of 11a. A mixture of **11a** (0.50, 2.4 mmol), Raney's nickel (*ca.* 0.3 g) and ethanol (10 m*l*) was stirred under hydrogen atmosphere at room temperature until 1 molar hydrogen was absorbed (*ca.* 24 hr). The catalyst was filtered, washed exclusively with ether and the combined washings were evaporated *in vacuo*, yielding **3a** as an oil (0.51 g, quantitatively).

Hydrogenation of 11b. (0.26 g, 1.2 mol) gave **3b** (0.23 g, 90%) as a colorless oil, which was identical with the sample obtained by reduction of **6**.

Solvolysis of 2 in Acetic Acid. A solution of **2** (1.56 g, 8 mmol) in glacial acetic acid (5 m*l*) was added dropwise under nitrogen atmosphere to a mixture of acetic acid (8 m*l*), acetic anhydride (3 drops) and BF_3-etherate (10 drops) at 50—55°C. After stirring for 3 hr and usual work-up, chromatography on Silica gel gave the isomerization product (0.22 g, 14%) which was identical with the one obtained by the hydrolysis of **2**. The second eluent was ethyl *trans*-8-acetoxy-4-cyclooctene-1-carbamate (**13**) (0.92 g, 45%), bp 110—120°C/0.05 mmHg. IR (neat): 3350, 1724, 1700, 1530—1510, 1230, 1050, 1032 cm^{-1}. NMR (CCl_4): δ 5.8—5.5 (m, 2H, olefinic), 5.1—4.5 (m, 2H, methine and NH), 4.3—3.7 (m+q, 3H, methine and $OC\underline{H}_2CH_3$), 2.5—1.4 (m+s, 11H, methylenes and AcO (δ 2.00)), 1.22 (t, 3H, $OCH_2C\underline{H}_3$).

Found: C, 60.9; H, 8.3; N, 5.5%. Calcd for $C_{13}H_{21}NO_4$: C, 61.2; H, 8.3; N, 5.5%.

The authors are indebted to Professor Keiiti Sisido for his kind help. Financial support from the Ministry of Education, Japanese Government, and from Toray Science Foundation is acknowledged.

Syntheses of Some Derivatives of D-Glucuronic Acid*1

Takeshi IRIMAJIRI, Hiroshi YOSHIDA, Tsuyoshi OGATA
and Saburo INOKAWA

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu

(Received May 6, 1970)

The syntheses of some derivatives of D-glucuronic acid from D-glucofuranurono-6→3-lactone have been investigated. That is, 5-bromo-5-deoxy-1,2-*O*-isopropylidene-β-L-idofuranurono-6→3-lactone (**2**) and 5-bromo-5-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranurono-6→3-lactone (**3**) were prepared by heating 1,2-*O*-isopropylidene-5-*O*-(*p*-toluenesulfonyl)-α-D-glucofuranurono-6→3-lactone (**1**) with lithium bromide in dimethylformamide (DMF); methyl 5-*O*-(*p*-toluenesulfonyl)-β-D-glucofuranurono-6→3-lactone, 5-bromo-5-deoxy-α-L-idofuranurono-6→3-lactone, and 5-bromo-5-deoxy-β-D-glucofuranurono-6→3-lactone were prepared by heating **1**, **2**, and **3** respectively in methanol in the presence of strong acidic ion-exchange resins; 5-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranurono-6→3-lactone (**7**) was prepared by the reaction of **2** with thiolacetic acid of benzylmercaptan in pyridine or by the reaction of **2** with triethyl phosphite; 5-bromo-5-deoxy-1,2-*O*-isopropylidene-β-L-*ido*-hexodialdo-3,6-furanoid(6S)-1,4-furanose (**8**) was prepared by the reduction of **2** with lithium aluminum hydride; 1,2-*O*-isopropylidene-5-*O*-(*p*-toluenesulfonyl)-α-D-*gluco*-hexodialdo-3,6-furanoid-1,4-furanose and 1,2-*O*-isopropylidene-5-*O*-(*p*-toluenesulfonyl)-α-D-glucofuranose (**10**) were prepared by the reduction of **1** with lithium aluminum hydride, and 1,2;3,6-di-*O*-isopropylidene-5-*O*-(*p*-toluenesulfonyl)-α-D-glucofuranose and 3,6-di-*O*-acetyl-1,2-*O*-isopropylidene-5-*O*-(*p*-toluenesulfonyl)-α-D-glucofuranose were prepared by the acetonation and the acetylation of **10** respectively.

D-Glucuronic acid is of considerable biological importance; moreover, it is easily obtained as a commercial sugar. Therefore, it seemed that it would be interesting to investigate the preparation of its deribatives. The present paper will report on the syntheses of compounds derived from 1,2-*O*-isopropylidene-5-*O*-(*p*-toluenesulfonyl)-α-D-glucofuranurono-6→3-lactone (**1**). When a solution of **1** and lithium bromide in dimethylformamide (DMF) was heated and the progress of the reaction was monitored by thin-layer chromatography in a solvent (ethyl acetate and petroleum ether, 1 : 4), it was found that the starting compound **1**, R_f 0.2, was initially transformed into a product **2** having R_f 0.5, and that then another product **3** with R_f 0.3 appeared. After the **1** was gone, fractional recrystallization gave **2** and **3** in 34 and 28% yields respectively. The compound **2** was identified as 5-bromo-5-deoxy-1,2-*O*-isopropylidene-β-L-idofuranurono-6→3-lactone and **3**, as 5-bromo-5-deoxy-1,2-*O*-isopropylidene-α-D-glucofuranurono-6→3-lactone. The structures of **2** and **3** were established by elementary analyses and by studies of the NMR spectra. The coupling constants, $J_{4,5'}$ in **1** and **3** were 4.1 and 4.0 Hz respectively. The coupling constants of 3,6-anhydro-1,2-*O*-isopropylidene-α-D-glucofuranose and 3,6-anhydro-5-*O*-(*p*-toluenesulfonyl)-1,2-*O*-isopropylidene-α-D-glucofuranose have been reported to be 4.1 and 3.9 Hz[1] respectively. It seems reasonable to say that the structure of **3** is a D-*gluco*-form. In the case of **2**, however, the $J_{4,5}$ is about zero. As the conformation of the lactone ring in **2** is considered to be an envelope form (E_4), the structure of **2** must be L-*ido*-form. The compound **3** seems to be produced by the inversion of the initial product **2** by a displacement reaction with lithium bromide, as the tracing by TLC showed.

The treatment of **1**, **2**, and **3** in methanol with strong acidic ion-exchange resins[2,3] afforded methyl 5-*O*-(*p*-toluenesulfonyl)-β-D-glucofuranuronoside-6→3-lactone (**4**), methyl 5-bromo-5-deoxy-α-L-idofuranuronoside-6→3-lactone (**5**), and methyl 5-bromo-5-deoxy-β-D-glucofuranuronoside-6→3-lactone (**6**) respectively, all in good yields. The structures of **4**, **5**, and **6** were established by elementary analyses and/or by studies of the NMR spectra. The

*1 This work was presented at the 23rd Annual Meeting of the Chemical Society of Japan, Tokyo, April 4, 1970.

values of $J_{1,2}$ in **4** and **5** were near zero; therefore, the anomeric structures should be β-glucofuranoside and α-idofuranoside forms.[4] The structure of **6** also seems to be the same form, although the low solubility of **6** in chloroform-*d* did not give a clear NMR spectrum by which we could observed $J_{1,2}$.

The reaction of **2** in pyridine with thiolacetic acid or benzylmercaptan did not give the expected product having a carbon-sulfur bond at the C-5 position; instead, it gave 5-dioxy-1,2-*O*-isopropylidene-α-D-glucofuranurono-6→3-lactone (**7**)[5] with an uncertain mechanism. The reaction of **2** with triethyl phosphite also gave **7**, probably *via* the route of the Perkow reaction.[6]

The reduction of **2** in ether with lithium aluminum hydride (LAH) at −15°C gave 5-bromo-5-deoxy-1,2-*O*-isopropylidene-β-L-*ido*-hexodialdo-3,6-furanoid(6S)-1,4-furanose (**8**) in a 20% yield. The structure of **8** was established by elementary analysis and by studies of the NMR and IR spectra. The IR spectrum of **8** showed the absorption of a hydroxy group at 3400 cm^{-1} in place of the absorption of a carbonyl group at 1780 cm^{-1} in **2**. In the NMR spectrum of **8**, the coupling constants, $J_{4,5}$ and $J_{5,6'}$ were about zero. These values probably show that the conformation of C-6 is S-form, because the conformation of the γ-lactone seems to be an envelope conformation (E_4).[1] The reduction of **1** in tetrahydrofuran (THF) with LAH at −10°C gave 1,2-*O*-isopropylidene-5-*O*-(*p*-toluenesulfonyl)-α-D-*gluco*-hexodialdo-3,6-furanoid-1,4-furanose (**9**) in a 70% yield. The structure of **9** was established by elementary analysis and by studies of the NMR and IR spectra. The coupling constant, $J_{5,6'}$ was 3.0 Hz in its NMR spectrum. The conformation of C-6 remained uncertain. The

further reduction of **9** in THF with LAH at 0°C gave 1,2-*O*-isopropylidene-5-*O*-(*p*-toluenesulfonyl)-α-D-glucofuranose (**10**) in a 48% yield based on **1**. The structure of **10** was established by elementary analysis and by a study of the NMR spectrum.

The acetonation and acetylation of **10** gave 1,2;3,6-di-*O*-isopropylidene-5-*O*-(*p*-toluenesulfonyl)-α-D-glucose (**11**) and 3,6-di-*O*-acetyl-1,2-*O*-isopropylidene-5-*O*-(*p*-toluenesulfonyl)-α-D-glucofuranose (**12**) in a 33% and a quantitative yield respectively. The structures of these compounds were established by elementary analyses and by studies of the NMR spectra.

Considering that **12** was prepared in a 25% overall yield, and in only three steps, from D-glucuronolactone, the route through **12** from D-glucuronolactone seems to be an atractive one for the synthesis of 5-thio-D-glucopyranose.

Experimental

The infrared spectra were measured on a Hitachi-Perkin-Elmer 337 spectrophotometer. The nuclear magnetic resonance spectra were measured at 60 Mc on a Hitachi-Perkin-Elmer R-20 spectrometer, using tetramethylsilane as the internal reference. The thin-layer chromatograms were run on a silica-layer G[7] using various mixtures of ethyl acetate and petroleum ether, while sugars were detected by spraying the plates with a methanolic 20% sulfuric acid solution and then heating them. Periodic sampling and examination by thin-layer chromatography permitted the determination of the most suitable reaction conditions for the preparative runs.

Materials. The 1,2-*O*-isopropylidene-5-*O*-(*p*-toluenesulfonyl)-α-D-glucofuranurono-6→3-lactone (**1**), mp 185—187°C, was prepared in an 89% yield by a modification of the method of Hall *et al.*,[8] while 1,2-*O*-isopropylidene-α-D-glucofuranurono-6→3-lactone, mp 121.5—122.5°, was prepared in an 85% yield by the acetonation of D-glucuronolactone using the method of Schmidt.[9] The thiolacetic acid, bp 87—88°C and the benzylmercaptan, bp 111—112°C/54 mmHg were prepared by the method of Ellingboe[10] and by the method of Shishido *et al.*[11] respectively.

5-Bromo-5-deoxy-1,2-*O*-isopropylidene-β-L-idofuranurono-6→3-lactone (2) and 5-Bromo-5-deoxy-1,2-*O*-isopropylidene-α-d-glucofuranurono-6→3-lactone (3). A solution of 20 g of **1** and 5 g of lithium bromide in 50 m*l* of DMF was heated at 100°C for 8 hr. The solution was then concentrated *in vacuo*; the residue was dissolved in chloroform, washed with water, dried over sodium sulfate, and concentrated *in vacuo* to give a solid. After fractional recrystallization from ether and acetone, **2** was obtained in a 34% yield from the acetone solution and **3** was obtained in a 28% yield from the ether solution. The compound **2** had mp 146.5—147.0°C and $[\alpha]_D^{16}$ +35° (*c* 1.54, chloroform).

Found: C, 38.48; H, 3.90; Br, 27.8%. Calcd for $C_9H_{11}BrO_5$: C, 38.73; H, 3.97; Br, 27.7%. PMR (in carbon tetrachloride): τ 4.1 (one-proton doublet, $J_{1,2}$= 3.5 Hz, H_1), 5.0—5.3 (three-proton doublets, $J_{2,3}$=0.5, $J_{3,4}$=3.4 Hz, $H_{2,3,4}$), 5.9 (one-proton singlet, $J_{4,5}\fallingdotseq 0$, H_5), and 8.5, 8.7 [six-proton singlets, $C(CH_3)_2$]. The compound **3** had mp 135.0—137.5°C and $[\alpha]_D^{16}$ +68° (*c* 1.03, chloroform).

Found: C, 38.99; H, 4.06; Br, 26.9%. Calcd for $C_9H_{11}BrO_5$: C, 38.73; H, 3.96; Br, 27.7%. PMR (in carbon tetrachloride): τ 4.0 (one-proton doublet, $J_{1,2}$= 4.0 Hz, H_1), 5.1—5.0 (three-proton multiplets, $J_{2,3}\fallingdotseq 0$, $H_{2,3,4}$), 5.5 (one-proton doublet, $J_{4,5}$=4.0 Hz, H_5), and 8.5, 8.7 [six-proton singlets, $C(CH_3)_2$].

Methyl 5-*O*-(*p*-Toluenesulfonyl)-β-D-glucofuranuronoside-6→3-lactone (4). A solution of 2 g of **1** and 10 m*l* of methanol was refluxed with 3 g of acidic Amberlite IR-120B for 10 hr. The solution was then filtered, and the filtrate was concentrated *in vacuo* to give a sirup of **4** in an almost quantitative yield. The sirup was pure enough for the measurement of the NMR spectrum; $[\alpha]_D^{16}$ +21° (*c* 3.4, chloroform).*2 PMR (in chloroform-*d*): τ 2.1—2.7 (four-proton multiplets, $-C_6H_4-$), 4.8—5.3 (two-proton multiplets, $H_{4,5}$), 5.7 (one-proton singlet, $J_{1,2}\fallingdotseq 0$, H_1), 6.3—6.8 (two-proton multiplets, overlapping with $-OCH_3$, $H_{2,3}$), 6.8 (three-proton singlet, overlapping with $H_{2,3}$, $-OCH_3$), 6.9 (one-proton singlet, disappearing upon the addition of D_2O, –OH), and 7.6 (three-poroton singlet, Ar–CH_3).

Methyl 5-Bromo-5-deoxy-α-L-idofuranuronoside-6→3-lactone (5). A solution of 1 g of **2** in 5 m*l* of methanol was refluxed with 1.5 g of acidic Amberlite IR-120B for 3 hr. The solution was then concentrated *in vacuo* to give colorless needles (from ethyl acetate–petroleum ether) in a 90% yield; mp 116—117°C, $[\alpha]_D^{16}$ −87° (*c* 0.92, chloroform).

Found: C, 33.21; H, 3.66%. Clacd for $C_7H_9BrO_5$: C, 33.23; H, 3.58%. PMR (chloroform-*d*): τ 4.8—5.1 (three-proton multiplets, $H_{1,3,4}$), 5.5 (one-proton singlet, $J_{1,2}\fallingdotseq 0$, H_2), 5.7 (one-proton singlet, $J_{4,5}\fallingdotseq 0$, H_5), 6.8 (three-proton singlet, $-OCH_3$), and 7.0 (one-proton singlet, disappearing upon the addition of D_2O, –OH).

Methyl 5-Bromo-5-deoxy-β-D-glucofuranuronoside-6→3-lactone (6). The compound **3** was treated as has been described above. Recrystallization from ethyl acetate gave colorless needles in a 90% yield; mp 192—194°C, $[\alpha]_D^{16}$ −0.86° (*c* 1.2, methanol).

Found: C, 33.40; H, 3.60%. Calcd for $C_7H_9BrO_5$: C, 33.23; H, 3.58%.

5-Deoxy-1,2-*O*-isopropylidene-α-D-glucofuranurono-6→3-lactone (7). *a) The Reaction of* **2** *with Thiolactic Acid.* A solution of 1 g of **2** and 0.4 g of thiolacetic acid in 10 m*l* of pyridine was heated at 100°C for 3 hr under a nitrogen atmosphere; the solution was then concentrated *in vacuo*. The residue was extracted with chloroform; the solution was then washed with water, dried over sodium sulfate, and evaporated *in vacuo* to give cololess needles (from petroleum ether)

in a 40% yield; mp 90—90.5°C, $[\alpha]_D^{16}$ +104° (*c* 0.89, chloroform).[5]

Found: C, 54.27; H, 6.15%. Calcd for $C_9H_{12}O_5$: C, 54.00; H, 6.04%. PMR (in chloroform-*d*): τ 4.1 (one-proton doublet, $J_{1,2}$=3.5 Hz, H_1), 4.9—5.3 (three-proton multiplets, $H_{2,3,4}$), 7.32 (one-proton singlet, $J_{4,5}\fallingdotseq 0$, H_5), 7.34 (one-proton doublet, $J_{4,5'}$=2.8 Hz, $H_{5'}$), and 8.5, 8.7 [six-proton singlets, $C(CH_3)_2$].

b) The Reaction of **2** *with Benzylmercaptan.* A solution of 1 g of **2** and 0.5 g of benzylmercaptan in 10 m*l* of pyridine was heated at 90°C for 6 hr under a nitrogen atmosphere, and then treated as has been described above to give **7** in a 30% yield.

c) The Reaction of **2** *with Triethyl Phosphite.* A solution of 1 g of **2** and 10 m*l* of triethyl phosphite was heated at 150°C for 3 hr and then treated as has been described above to give **7** in a 10% yield.

5-Bromo-5-deoxy-1,2-*O*-isopropylidene-β-L-*ido*-hexodialdo-3,6-furanoid(6S)-1,4-furanose (8). A solution of LAH in ether was added, drop by drop, into a solution of 1 g of **2** in 20 m*l* of ether at 15°C until the spot of **2** disappeared on TLC with a solvent (ethyl acetate–petroleum ether, 1 : 4; R_f=0.3); the excess of LAH was then destroyed water-containing ether; the solution was filtered, and the filtrate was concentrated *in vacuo*. The residue was extracted with hot ether, the ether solution was concentrated *in vacuo*, and the residue was recrystallized from petroleum ether to give **7** in a 20% yield; mp 75.0—76.0°C; $[\alpha]_D^{16}$ +1.9 (*c* 1.07, chloroform).

Found: C, 38.46; H, 4.79. Calcd for $C_9H_{13}BrO_5$: C, 38.45; H, 4.66%. PMR (in chloroform-*d*); τ 4.1 (one-proton doublet, $J_{1,2}$=3.5 Hz, H_1), 4.5 (one-proton doublet, $J_{6,OH}$=9.0 Hz, H_6), 5.1—5.4 (three-proton doublets, $J_{2,3}$=0.5, $J_{3,4}$=4.0 Hz, $H_{2,3,4}$), 5.9 (one-proton singlet, $J_{5,6}\fallingdotseq 0$, H_5), 6.8 (one-proton doublet, disappearing upon the addition of D_2O, C_6–OH), and 8.6, 8.7 [six-proton singlets, $C(CH_3)_2$].

1,2-*O*-Isopropylidene-5-*O*-(*p*-toluenesulfonyl)-α-D-*gluco*-hexodialdo-3,6-furanoid-1,4-furanose (9). A solution of LAH in THF was added, drop by drop, into a solution of 2 g of **1** in 20 m*l* of THF at −10°C until the spot of **1** disappeared on TLC. The excess of LAH was destroyed with water-containing THF; the solution was then filtered, and the filtrate was concentrated *in vacuo*. The residue was extracted with hot ether; the ether solution was concentrated *in vacuo*, and the residue was recrystallized with ethyl acetate–petroleum ether to give **9** in a 70% yield; mp 141—143°C, $[\alpha]_D^{16}$ +54°(*c*1.5, chloroform).

Found: C, 51.47; H, 5.50%. Calcd for $C_{16}H_{20}O_8S$: C, 51.61; H, 5.41%. PMR (in chloroform-*d*): τ 2.1—2.7 (four-proton multiplets, $-C_6H_4-$), 4.1 (one-proton doublet, $J_{1,2}$=3.5 Hz, H_1), 4.6 (one-proton doublet, $J_{5,6}$=3.0 Hz, H_6), 5.1—5.5 (four-proton multiplets, $H_{2,3,5}$), 6.4 (one-proton broad, disappearing upon the addition of D_2O, C_6–OH), 7.5 (three-proton singlet, Ar–CH_3), and 8.5, 8.7 [six-proton singlets, $C(CH_3)_2$]. TLC: R_f 0.6 (ethyl acetate–petroleum ether, 1 : 1).

1,2-*O*-Isopropylidene-5-*O*-(*p*-toluenesulfonyl)-α-D-glucofuranose (10). To a solution of 0.2 g of LAH in 20 m*l* of THF, 5 g of **1** were added at −10°C under stirring; then a solution of LAH in ether was further added at 0°C untill the spots of **1** and **9** disappeared on TLC. The solution was then treated as has been described above. The recrystallization of the residue from ether gave **10** in a 48% yield; mp 124.0—125.5°C; $[\alpha]_D^{16}$ +11.6° (*c* 1.55, chloroform).

Found: C, 51.47; H, 6.04. Calcd for $C_{16}H_{22}O_8S$: C, 51.32; H, 5.92%. PMR (in chloroform-*d*): τ 2.1—2.7 (four-proton multiplets, $-C_6H_4-$), 4.1 (one-proton doublet, $J_{1,2}$=3.5 Hz, H_1), 5.1 (one-proton doublet of triplets, $J_{4,5}$=8.5, $J_{5,6}=J_{5,6'}$=3.5Hz, H_5), 5.5 (one-proton doublet, H_2), 5.6—5.9 (two-proton multiplets, $H_{3,4}$), 6.2 (two-proton triplet, $H_{6,6'}$), 6.6 (one-proton doublet, disappearing upon the addition of D_2O, $J_{3,OH}$= 4.5 Hz, C_3–OH), 7.4 (one-proton triplet, disappearing upon the addition of D_2O, $J_{6,OH}=J_{6'OH}$=6.0 Hz, C_6–OH), 7.7 (three-proton singlet, Ar–CH_3), and 8.5, 8.7 [six-proton singlets, $C(CH_3)_2$].

The acetonation of **10** by the usual method[9] gave 1,2; 3,6-di-*O*-isopropylidene-5-*O*-(*p*-toluenesulfonyl)-α-D-glucofuranose (**11**) in a 33% yield; mp 133.0—133.5°C (from ethyl acetate–petroleum ether); $[\alpha]_D^{15}$ +25° (*c* 0.73, chloroform).

Found: C, 54.78; H, 6.44%. Calcd for $C_{19}H_{26}O_8S$: C, 55.06; H, 6.32%. PMR (in chloroform-*d*): τ 2.1—2.8 (four-proton multiplets, $-C_6H_4-$), 4.2 (one-proton doublet, $J_{1,2}$=3.5 Hz, H_1), 5.2—5.6 (two-proton multiplets, $H_{2,5}$), 5.8—6.1 (three-proton multiplets, $H_{3,4,6}$), 6.5 (one-proton quartet, $H_{6'}$), 7.6 (three-proton singlet, Ar–CH_3), 8.6—8.7 [twelve-proton singlets, $[C(CH_3)_2]_2$].

The acetylation of **10** by the usual method[12] gave 3,5-di-*O*-acetyl-1,2-*O*-isopropylidene-5-*O*-(*p*-toluene-sulfonyl)-α-D-glucofuranose (**12**) in a quantitative yield; mp 131.5—132.5°C (from methanol); $[\alpha]_D^{16}$ −15° (*c* 2.9, chloroform). Found: C, 52.12; H, 5.88%. Calcd for $C_{20}H_{26}O_{10}S$: C, 52.39; H, 5.72%. PMR (in chloroform-*d*): τ 2.2—2.7 (four-proton multiplets, $-C_6H_4-$), 4.1 (one-proton doublet, $J_{1,2}$=3.5 Hz, H_1), 4.7—5.0 (two-proton multiplets, $H_{3,5}$), 5.3—6.0 (four-proton multiplets, $H_{2,4,6,6'}$), 7.6 (three-proton singlet, Ar–CH_3), 7.9, 8.0 [six-proton singlets, $(OCOCH_3)_2$], and 8.5, 8.7 [six-proton singlets, $C(CH_3)_2$].

The authors wish to express their deep gratitude to Professor R.L. Whistler of Purdue University for his continued interest in this work. They are also grateful to the Yodogawa Pharmaceutical Co., Ltd., for supplying them with D-glucuronolactone.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3246—3251 (1970)

Studies on Hydroxy Amino Acids. III.*1 The Synthesis of Cyclic Peptide Containing L-Serine

Michio Iwai, Kiichiro Nakajima, Akio Uno,*2 Satoe Hase,*3
Ikuko Takeuchi*4 and Kenji Okawa

Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Nishinomiya

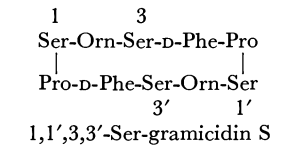
(Received May 6, 1970)

Modified gramicidin S peptides, *cyclo*(Ser-Orn-Ser-D-Phe-Pro)$_2$ and *cyclo*(Ser-Orn-Ser-D-Phe-Pro), were synthesized in order to clarify the correlation between the component amino acids and the antibiotic activity. To obtain the cyclic peptides, we examined several sets of conditions for cyclization reactions. The antibiotic activity of these peptides could not be found against some microorganisms *in vitro*. It was concluded that the lipophilic amino acids residues are the essential groups contributing to gramicidin S activity.

Many works concerning the synthesis of gramicidin S analogues have been investigated by several workers, especially Izumiya *et al.*, in order to study the correlation between the component amino acids and their biological activities.[1)]

We have been studying the synthesis of modified gramicidin S peptides, in which the lipophilic amino acids are replaced by hydrophilic amino acid, such as serine or threonine.

In the present work, the authors have studied the synthesis of a cyclic decapeptide containing L-serine, 1,1′,3,3′-L-seryl gramicidin S, and also cyclic pentapeptide, *cyclo* Ser-Orn-Ser-D-Phe-Pro (Fig. 1).*5



1,1′,3,3′-Ser-gramicidin S
(XIX)

(XXIV)

Fig. 1

The synthetic scheme of 1,1′,3,3′-L-seryl gramicidine S is shown in Fig. 2. The blocking groups were used as follows: the δ amino group of the ornithine was protected by the Z group, the carboxyl groups of the C terminus amino acids were blocked by the methyl ester, while the hydroxyl group of serine was protected by the benzyl and the BOC group was used as a protecting group for the amino group of serine.

The BOC-pentapeptide methyl ester (XI) was prepared by the usual coupling methods, DCCD, mixed anhydride, and the azide method, mp 138.5—139°C, $[\alpha]_D^{24}$ −40.8° (*c* 1.0, AcOH). The ester of pentapeptide (XI) was converted into the hydrazide (XII) by hydrazinolysis in methanol, while XI was also converted into the free ester (XIII) by the acid-catalyzed cleavage of the BOC group. These two components could be coupled by means of the azide method to form the BOC-decapeptide methyl ester (XIV) as a white powder in a 75.5% yield; $[\alpha]_D^{24}$ −47.8° (*c* 0.5, AcOH).

The BOC-decapeptide ester (XIV) was converted into the BOC-decapeptide *p*-nitrophenyl ester (XVI) by hydrolysis with sodium hydroxide in a methanol solution, followed by esterification with *p*-nitrophenol and *N*,*N*′-dicyclohexylcarbodiimide. The active ester (XVI) was confirmed by thin-layer chromatography on silica gel and by a study of its IR spectra at 1760 cm^{-1} (ester) and 1350 cm^{-1} (C–NO$_2$); it was used immediately for the next reaction. The *N*-terminal protecting group (BOC) of the decapeptide active ester (XVI) was removed by treatment with anhydrous trifluoroacetic acid. The

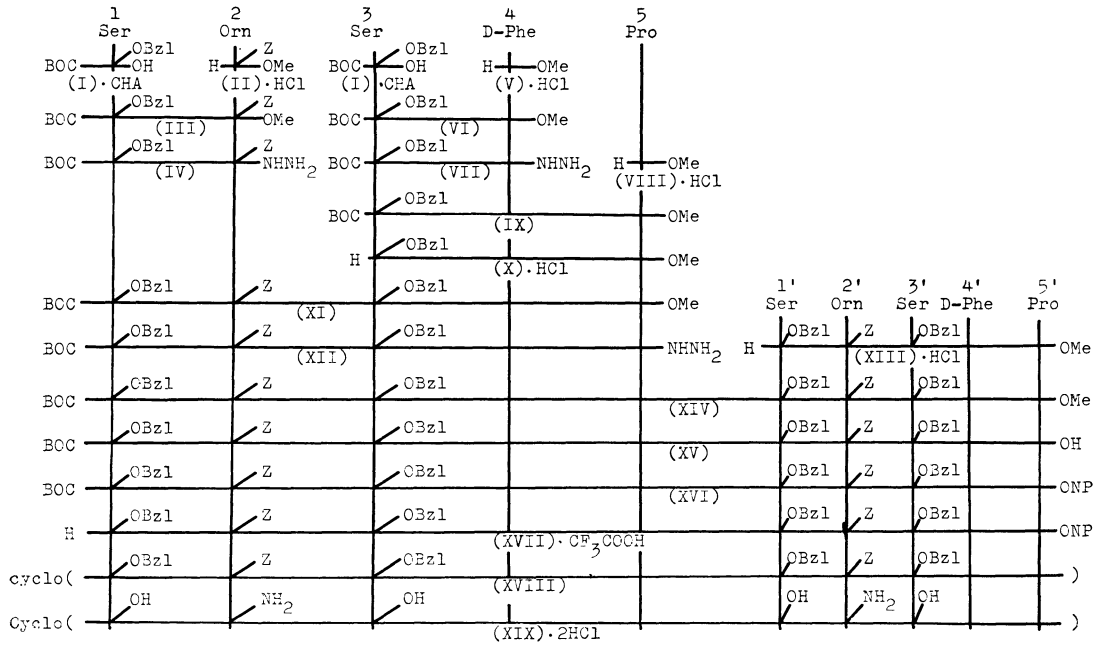

Fig. 2. Synthetic route of 1,1′,3,3′-Ser-gramicidin S (XIX).

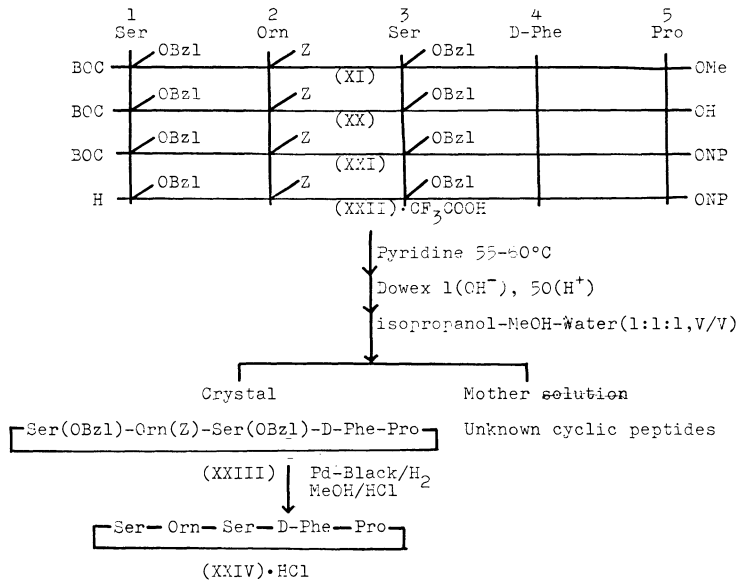

Fig. 3. Cyclization of linear pentapeptide.

cyclization of the free decapeptide *p*-nitrophenyl ester (XVII) trifluoroacetate was accomplished by means of Schwyzer's high-dilution method.[2] It was carried out by the drop-by-drop addition (4 hr 57°C) of XVII trifluoroacetate in DMF to a large amount of anhydrous pyridine (5×10^{-4}M solution). The crude product in methanol-water (10:1 V/V) was treated with Dowex 1(OH^-) and 50(H^+) to remove the linear peptide fractions. From the neutral part, *cyclo* (Ser(OBzl)-Orn(Z)-Ser(OBzl)-D-Phe-Pro)$_2$ (XVIII) was obtained as crystal in a 44.6% yield (mp 246—247°C, $[\alpha]_D^{24}$ −185.0° (*c* 0.2, AcOH)); it was confirmed by molecular-weight measurements. The protecting groups of XVIII were removed by catalytic hydrogenation, and the resulting 1,1′,3,3′-L-seryl gramicidin S (XIX) dihydrochloride was crystallized from methanol-ether

2) R. Schwyzer and P. Sieber, *Helv. Chim. Acta*, **40**, 624 (1957).

in a 75.7% yield; mp 320°C (dec.), $[\alpha]_D^{25}$ −126° (*c* 0.1, AcOH). This analogue (XIX) of gramicidin S has almost the same mobility on paper electrophoresis as the native gramicidin S (Fig. 4).

As an alternative approach to the synthesis of gramicidin S, Schwyzer and Sieber have reported that gramicidin S can be synthesized by the dimeric cyclization of the linear pentapeptide active ester.[3] Izumiya and Waki reported, however, that the linear pentapeptide active ester does not cyclize in the dimeric form exclusively, but that monomeric cyclization occurs.[4] The present authors have also at tempted the dimeric cyclization reaction of our pentapeptide (Fig. 3).

The BOC-pentapeptide methyl ester (XI) was saponified and then converted into the BOC-pentapeptide *p*-nitrophenyl ester (XXI) by estirification using DCCD. After the cleavage of the BOC group by treatment with anhydrous trifluoroacetic acid, the cyclization reaction were carries out as has been described above in the case of anhydrous pyridine. The molar concentrations of the pentapeptide active ester (XXII) trifluoroacetate in pyridine, 0.26×10^{-3} mol, 1.3×10^{-3} mol and 6.5×10^{-3} mol, were employed for the cyclization reactions. The resulting crude product was treated in methanol-water (5 : 1 v/v) with Dowex 1 (OH^-) and Dowex 50(H^+) to remove any linear peptide fractions. Cyclic pentapeptide (XXIII), *cyclo* Ser(OBzl)-Orn-(Z)-Ser(OBzl)-D-Phe-Pro, could be isolated as crystals from a solution of isopropanol-methanol-water (1 : 1 : 1 v/v) and was confirmed by molecular-weight measurements; mp 118—119°C, $[\alpha]_D^{24}$ −93.4° (*c* 0.7, AcOH). The resulting *cyclo* Ser-Orn-Ser-D-Phe-Pro (XXIV) hydrochloride was crystallized from methanol-ether in an 82.3% yield, mp 250°C (dec.), $[\alpha]_D^{24}$ −156.8° (*c* 0.5, AcOH), and was shown to have a smaller mobility than either the native gramicidin S or the cyclic decapeptide (XIX) on paper electrophoresis, as is shown in Fig. 4.

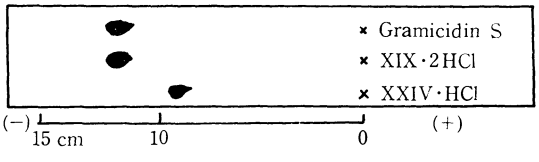

Fig. 4. Paper electrophoresis: solvent system AcOH 1M HCOOH 0.6M (pH 1.8) 600 V/30 cm 2 hr Toyo Roshi No. 50.

In the mother solution of XXIII, the presence of cyclic decapeptide (XVIII) and two other products was confirmed on thin-layer chromatography in each case, but no crystalline cyclic peptides other than cyclic decapeptide could be isolated. Under different concentrations of the cyclization, the yields of the cyclic pentapeptides were 76.3% (0.26×10^{-3} mol), 50.2% (1.3×10^{-3} mol), and 13.4% (6.5×10^{-3} mol) respectively.

The above results confirmed that the yield of the cyclic pentapeptide decreases proportionally to the increase in the reaction concentration, and that the monomeric cyclization proceeded predominantly more than the dimeric cyclization when the high-dilution method was used.

The biological activities of cyclic pentapeptide (XXIV) hydrochloride and 1,1',3,3'-L-seryl-gramicidin S (XIX) dihydrochloride against several microorganisms were investigated by the paper-disk method. No antibiotic activity could be found against *B. subtilis*, *St. albus*, *M. lysodakius*, and *E. coli*. From the above results, it may be concluded that the lipophilic amino acid residues are essential groups in contributing to gramicidin S activities.

Experimental

All the melting points are uncorrected.

***N*-*t*-Butyloxycarbonyl-*O*-benzyl-L-serine (I) Cyclohexylamine salt.** I was prepared from *O*-benzyl-L-serine[5] according to Anderson's method[6] in an 80% yield; mp 156—157°C, $[\alpha]_D^{24}$ +29.5° (*c* 1.3, MeOH).

Found: C, 63.78; H, 8.62; N, 7.14%. Calcd for $C_{21}H_{34}O_5N_2$: C, 63.93; H, 8.69; N, 7.10%.

N^{δ}-Benzyloxycarbonyl-L-ornithine Methyl Ester (II) Hydrochloride. II hydrochloride was prepared by the method of Boissonnas[7] in a 92.4% yield. N^{α},N^{δ}-dibenzyloxycarbonyl-L-ornithine[8] was treated with thionyl chloride in anhydrous ether-tetrahydrofuran (9 : 1 v/v), and with anhydrous methanol; mp 140—142°C, $[\alpha]_D^{24}$ +2.2° (*c* 1.0, AcOH).

Found: C, 53.30; H, 6.63; N, 8.86; Cl, 11.32%. Calcd for $C_{14}H_{21}O_4N_2Cl$: C, 53.08; H, 6.68; N, 8.84; Cl, 11.19%.

BOC-Ser(OBzl)-Orn(Z)-OMe(III). II (from the hydrochloride; 9.5 g, 0.03 mol) was treated with *N,N'*-dicyclohexylcarbodiimide (6.8 g, 0.03 mol) and I (from cyclohexylamine salt 11.8 g, 0.03 mol) in methylene chloride (200 m*l*) at 5°C for 1 hr. After the reaction mixture had then been allowed to stand overnight at room temperature, acetic acid (3 m*l*) was added and the reaction mixture was stirred for 15 min. The precipitate thus produced was filtered off; after the filtrate had been washed with 0.1N hydrochloric acid, N sodium bicarbonate, and water successively, it was dried over anhydrous sodium sulfate and then concentrated under reduced pressure. III was obtained from ethyl acetate - petroleum ether in a 90% (15 g) yield. The product was recrystallized from ethyl acetate - petroleum ether; mp 86—88°C, $[\alpha]_D^{24}$ +2.8° (*c* 1.1, AcOH).

Found: C, 62.47; H, 6.79; N, 7.44%. Calcd for $C_{29}H_{39}O_8N_3$: C, 62.46; H, 7.04; N, 7.53%.

BOC-Ser(OBzl)-Orn(Z)-NHNH$_2$ (IV). To III (54.64 g, 1.00 mol) in ethanol (200 m*l*), we added 80% hydrazine hydrate (63 g, 1.25 mol) in ethanol (100 m*l*) and then stirred the mixture for 1 hr in an ice-bath. After the reaction mixture had been kept at room temperature for 3 days, white crystals were formed; these were collected (45.50 g), and another crop of the hydrazide (8.29 g) was obtained from the mother liquor. The total yield was 53.79 g (98%). They were recrystallized from ethanol - water; mp 152—154°C, $[\alpha]_D^{24}$ −9.5° (*c* 1.0, AcOH).

Found: C, 60.39; H, 7.14; N, 12.60%. Calcd for $C_{28}H_{39}O_7N_5$: C, 60.31; H, 7.03; N, 12.56%.

BOC-Ser(OBzl)-D-Phe-OMe (VI). I (from cyclohexylamine salt (7.89 g, 0.02 mol)) was treated with ethyl chloroformate (2.17 g, 0.02 mol) and triethylamine in THF at −5°C. After the solution had stood for 20 min, D-phenylalanine methyl ester (V) (from hydrochloride[9] (4.31 g, 0.02 mol)) was added, drop by drop, to the above solution at −5°C. After the reaction mixture had then been allowed to stand overnight at room temperature, the precipitate thus produced was filtered off. The solvent was replaced by ethyl acetate (70 m*l*); after the solution had then been washed with water, 4% sodium bicarbonate, 0.5N hydrochloric acid, and water successively, it was dried over anhydrous sodium sulfate and concentrated under reduced pressure. VI was obtained from ethyl acetate – *n*-hexane in a 76.8% (7.03 g) yield. Recrystallization from ethyl acetate–*n*-hexane gave a pure material; mp 81.5—82°C, $[\alpha]_D^{13}$ −18.7° (*c* 1.1, AcOH).

Found: C, 65.82; H, 6.97; N, 6.13%. Calcd for $C_{25}H_{32}O_6N_2$: C, 65.77; H, 7.06; N, 6.14%.

BOC-Ser(OBzl)-D-Phe-NHNH$_2$ (VII). VI (6.7 g, 0.01 mol) was treated with 80% hydrazine hydrate (1.5 g, 0.03 mol) in anhydrous methanol (12 m*l*). After the reaction mixture had then been allowed to stand for 46 hr at room temperature, it was concentrated to dryness. The precipitate was recrystallized from ethyl acetate–*n*-hexane. The yield was 6.0 g (89.5%). Mp 114—115°C, $[\alpha]_D^{13}$ −6.3° (*c* 1.1, AcOH).

Found: C, 63.17; H, 7.04; N, 12.28%. Calcd for $C_{24}H_{32}O_5N_4$: C, 63.14; H, 7.06; N, 12.28%.

BOC-Ser(OBzl)-D-Phe-Pro-OMe (IX). Into a solution of VII (2.29 g, 5 mmol) in acetic acid (25 m*l*) and N hydrochloric acid (10 m*l*), we added N sodium nitrite (5 m*l*) drop by drop under cooling at −5——10°C. After stirring for 10 min, sodium bicarbonate (1.5 g) and ice-cold water (50 m*l*) were added to the above solution and the product was extracted with ice-cold ethyl acetate (50 m*l*). The organic layer was washed with ice-cold 0.5N sodium bicarbonate, and then immediately cooled to under −5°C. To this, the L-proline methyl ester (VIII) (from hydrochloride;[9] 0.94 g, 5.65 mmol) was stirred in, drop by drop; the stirring was thereafter continued for 3 hr at 0°C. After the reaction mixture had been allowed to stand overnight in a refrigerator, it was washed with 0.1N hydrochloric acid, N sodium bicarbonate, and water. The solution was dried over anhydrous sodium sulfate and then concentrated under reduced pressure. IX was obtained from ether–*n*-hexane in the theoretical yield; mp 62—63°C, $[\alpha]_D^{24}$ −46.6° (*c* 1.0, AcOH).

Found: C, 64.79; H, 7.22; N, 7.56%. Calcd for $C_{30}H_{39}O_7N_3$: C, 65.08; H, 7.10; N, 7.59%.

H-Ser(OBzl)-D-Phe-Pro-OMe (X) Hydrochloride. Through an ethyl acetate (45 m*l*) solution of IX (5.54 g, 0.01 mol) dry hydrogen chloride was bubbled for 30 min in an ice-bath. After the reaction mixture had then been allowed to stand at room temperature for 30 min, the solution was concentrated under reduced pressure. The addition of ether gave 4.65 g (95%) of a white powder; mp 189.5—190°C.

Found: C, 61.20; H, 6.52; N, 8.53; Cl, 7.32%. Calcd for $C_{25}H_{32}O_5N_3Cl$: C, 61.28; H, 6.58; N, 8.58; Cl, 7.24%.

BOC-Ser(OBzl)-Orn(Z)-Ser(OBzl)-D-Phe-Pro-OMe (XI). IV (12.27 g, 22 mmol) (5 m*l*) was coupled with X (from hydrochloride (10.47 g, 22 mmol)) in ethyl acetate (300 m*l*) by the azide method described in connection with compound IX. The subsequent crystallization from ethyl acetate gave 19.1 g of XI (88.8%); mp 138.5—139°C, $[\alpha]_D^{24}$ −40.8° (*c* 1.0, AcOH).

Found: C, 64.72; H, 6.92; N, 8.43%. Calcd for $C_{53}H_{66}O_{12}N_6$: C, 65.01; H, 6.79; N, 8.58%.

BOC-Ser(OBzl)-Orn(Z)-Ser(OBzl)-D-Phe-Pro-NHNH$_2$ (XII). Hydrazine hydrate (80%) (5.1 g, 102 mmol) in anhydrous methanol (10 m*l*) was added to an anhydrous methanol solution (40 m*l*) of XI (5 g, 5.1 mmol). The reaction mixture was then kept at 35—40°C for 3 days. After the excess hydrazine had then been removed under reduced pressure, a large amount of cold water was added. The product was soon solidfied; it was collected as a white powder, and dried in a desiccator over sulfuric acid to yield 4.80 g (96%). $[\alpha]_D^{23}$ −37.3° (*c* 0.7, AcOH).

Found: C, 63.85; H, 6.92; N, 11.21%. Calcd for $C_{52}H_{66}O_{11}N_8$: C, 63.78; H, 6.80; N, 11.45%.

H-Ser(OBzl)-Orn(Z)-Ser(OBzl)-D-Phe-Pro-OMe (XIII) Hydrochloride. Through an anhydrous dioxane (20 m*l*) solution of XI (2 g, 2.04 mmol), dry hydrogen chloride was bubbled for 20 min under cooling in an ice-bath. The reaction mixture was then allowed to stand room temperature for 1 hr. After the evaporation of the solvent and hydrogen chloride under reduced pressure, ether was added to the residual oil. The crude product was recrystallized from methanol–ether; yield, 1.72 g (92.4%); mp 168°C.

Found: C, 62.67; H, 6.78; N, 9.05; Cl, 4.11%. Calcd for $C_{48}H_{59}O_{10}N_6Cl$: C, 62.97; H, 6.50; N, 9.18; Cl, 3.87%.

BOC-(Ser(OBzl)-Orn(Z)-Ser(OBzl)-D-Phe-Pro)$_2$-OMe (XIV). XII (2.94 g, 3 mmol) and XIII (from hydrochloride (2.75 g, 3 mmol)) were coupled by the azide method in the same way as was used in the case of the synthesis of compound IX. The resulting oily material was chromatographed over silica gel using ethy acetate as a solvent. A white powder was subsequently obtained by the addition of *n*-hexane. Yield, 4.14 g (75.5%); $[\alpha]_D^{23}$ −47.8° (*c* 0.5, AcOH).

Found: C, 65.50; H, 6.67; N, 9.29%; mol wt,*6 1875. Calcd for $C_{100}H_{120}O_{21}N_{12}$: C, 65.77; H, 6.62; N, 9.20%; mol wt, 1826.

*6 Knauer Vapour Pressure Osmometer; solvent: methanol, standard curve; the solution of BOC-Ser-(OBzl)-D-Phe-OMe (VI) in methanol.

BOC-(Ser(OBzl)-Orn(Z)-Ser(OBzl)-D-Phe-Pro)$_2$-OH (XV). XIV (1.83 g, 1 mmol) in anhydrous methanol (20 ml) was treated with 2N sodium hydroxide (2 ml, 4 mmol) at room temperature. The solution was kept at 37°C until no turbidity appeared upon the addition of one drop of water (8 hr) After the solution had then been adjusted to pH 2 with N hydrochloric acid (about 4 ml) in an ice-bath, water (100 ml) was added to give a precipitate; yield, 1.54 g. Recrystallization from methanol - water yielded 1.32 g (73%) of pure crystals; mp 113—115°C, R_f 0.15*7 $[\alpha]_D^{23}$ −39.3° (*c* 0.9, AcOH).

Found: C, 65.66; H, 6.54; N, 9.34%; mol wt, 1820.*6 Calcd for $C_{99}H_{118}O_{21}N_{12}$: C, 65.62; H, 6.56; N, 9.28%; mol wt, 1820.

BOC-(Ser(OBzl)-Orn(Z)-Ser(OBzl)-D-Phe-Pro)$_2$-ONP (XVI). XV (500 mg, 0.27 mmol) and *p*-nitrophenol (70 mg, 0.5 mmol) were dissolved in methylene chloride (5 ml), and then a methylene chloride solution of *N,N'*-dicyclohexylcarbodiimide (62 mg, 0.30 mmol) was added, drop by drop, to the solution at 0—5°C. The reaction mixture was allowed to stand overnight in a refrigerator. After the addition of acetic acid (one drop), the dicyclohexylurea thus produced was filtered off and washed with cold ethyl acetate. The filtrate was concentrated under reduced pressure, and the resulting oily material was dissolved in a cold ethyl acetate solution. It was washed with N sodium bicarbonate and water to remove the excess *p*-nitrophenol, and then dried over anhydrous sodium sulfate. XVI was obtained from ethyl acetate–ether in the yield of 460 mg (88%); mp 110—112°C, R_f 0.89*7 ν_{max}^{Nujol} 1760 (ester), 1350 cm^{-1} (C–NO$_2$).

Found: C, 63.98; H, 6.26; N, 9.42%. Calcd for $C_{105}H_{121}O_{23}N_{13}\cdot 2H_2O$: C, 64.04; H, 6.39; N, 9.25%.

***Cyclo* (Ser(OBzl)-Orn(Z)-Ser(OBzl)-D-Phe-Pro)$_2$ (XVIII).** The BOC-decapeptide active ester (XVI) (200 mg, 0.1 mmol) was dissolved in anhydrous trifluoroacetic acid (3 ml), after which the solution was kept at 0°C for 1 hr. The trifluoroacetic acid was subsequently evaporated under reduced pressure at room temperature. The residual decapeptide *p*-nitrophenyl ester (XVII) trifluoroacetate was immediately dissolved in dimethylformamide (10 ml) without purification. A DMF solution containing 5 drops of acetic acid was added, drop by drop, to pyridine (200 ml) at 57°C over a 4 hr period, after which the stirring was continued for an additional 2 hr. The solution was then evaporated under reduced pressure and water was added to give a crude product. This colored product was collected, washed with water, and dissolved in a mixed solvent of methanol and water (5 : 1 v/v). After the insoluble substance had been filtered off, the filtrate was treated with a Dowex 1 (OH^-) column (1.5×20 cm) and a Dowex 50 (H^+) column (1.5×20 cm). The effluent (300 ml) was evaporated; the subsequent addition of water yielded a white powder which gave a negative ninhydrin reaction; 75.5 mg (44.6%). Purification with Sephadex LH-20 and recrystallization from ethanol - water yielded 50.7 mg (30% from XVI) of XVIII; mp 246—247°C, R_f 0.88,*7 $[\alpha]_D^{24}$ −185.0° (*c* 0.2, AcOH).

Found: C, 65.64; H, 6.46; N, 9.90%. Calcd for $C_{94}H_{112}O_{20}N_{12}$: C, 65.26; H, 6.53; N, 9.72%; mol wt,*6 1710, Calcd for $C_{94}H_{108}O_{18}N_{12}$; mol wt, 1694.

Amino acid ratios in acid hydrolyzate: Ser 1.94, Orn 0.89, Phe 1.00, Pro 1.03.

BOC-Ser(OBzl)-Orn(Z)-Ser(OBzl)-D-Phe-Pro-OH (XX). XI (4.9 g, 5 mmol) in dioxane (5 ml) was treated with N sodium hydroxide (5.25 ml) at room temperature for 2 hr. The reaction mixture was then adjusted to pH 2 with N hydrochloric acid, the reaction products were extracted with methylene chloride, and the organic layer was dried over anhydrous sodium sulfate. The solvent was evaporated under reduced pressure, and the residuals were crystallized from ethyl acetate–*n*-hexane (4.35 g (90.1%)). Recrystallization from methanol–water gave a pure material; mp 135.5—136°C, R_f 0.10,*7 $[\alpha]_D^{24}$ −35.2° (*c* 1.0, AcOH).

Found: C, 64.82; H, 6.94; N, 8.54%. Calcd for $C_{52}H_{64}O_{12}N_6$: C, 64.71; H, 6.68; N, 8.71%.

BOC-Ser(OBzl)-Orn(Z)-Ser(OBzl)-D-Phe-Pro-ONP (XXI). A solution of XX (9.7 g, 10 mmol) and *p*-nitrophenol (2.8 g, 20 mmol) in methylene chloride (30 ml) was treated with *N,N'*-dicyclohexylcarbodiimide (2.27 g, 11 mmol) at 0°C for 4 hr with stirring. After the dicyclohexylurea thus produced had been filtered off, the reaction mixture was washed with 10% citric acid, N sodium bicarbonate, and water successively, and then dried over anhydrous sodium sulfate. The solvent was evaporated under reduced pressure. The residual crystals were recrystallized from ethyl acetate–ether (8.99 g (82.6%)); mp 151—152°C, $[\alpha]_D^{24}$ −35.8° (*c* 1.0, AcOH), ν_{max}^{Nujol} 1770 (ester), 1345 cm^{-1} (C–NO$_2$).

Found: C, 63.35; H, 6.41; N, 9.23%. Calcd for $C_{58}H_{67}O_{14}N_7$: C, 64.13; H, 6.22; N, 9.03%.

***Cyclo* Ser(OBzl)-Orn(Z)-Ser(OBzl)-D-Phe-Pro (XXIII).** XXI (1.09 g, 1 mmol) was suspended in anhydrous trifluoroacetic acid (2.5 ml) containing anisole (0.25 ml), after which the mixture was allowed to stand at 0°C for 1 hr. After the solvent had been removed under reduced pressure at room temperature, the addition of absolute ether gave a white powder of XXII trifluoroacetate (1.03 g (93.6%)). This active ester was used immediately in the following cyclization procedure.

XXII trifluoroacetate (768 mg, 0.698 mmol), dissolved in DMF (10 ml) containing 6 drops of acetic acid, was stirred, drop by drop, into anhydrous pyridine (2685 ml, 0.26×10^{-3} molar concentration of XXII·CF_3COOH) at 55—60°C for 4 hr. After the stirring had been continued for 2 hr, the solvent was evaporated under reduced pressure. The residual oil was dissolved in methanol–water (5 : 1 v/v) and then treated with Dowex 1 (OH^-) and 50 (H^+). After elution with the same solvent (300 ml), the effluent was concentrated

*8 Thin-layer chromatography with Merck silica gel; solvent system; *n*-butanol: acetic acid: water: pyridine 4 : 1 : 2 : 1 (v/v).

under reduced pressure and the residuals were treated with isopropanol–methanol–water (1 : 1 : 1 v/v). *Cyclo* Ser(OBzl)-Orn(Z)-Ser(OBzl)-D-Phe-Pro (XXIII) was thus obtained as fine crystals; yield, 451 mg (76.3%), R_f 0.53*[7], mp 118—119°C $[\alpha]_D^{24}$ −93.4° (*c* 0.7, AcOH).

Found: C, 65.52; H, 6.45; N, 10.17%; mol wt*[6], 867. Calcd for $C_{47}H_{56}O_{10}N_6$: C, 65.24; H, 6.53; N, 9.72%; mol wt, 847.

In other cases using different concentrations of the active ester (1.3×10^{-3} mol and 6.5×10^{-3} mol), XXIII was also obtained as crystals, but in different yields (50.2% and 13.4% respectively). From the mother solution, cyclic decapeptide (XVIII), R_f 0.88*[7] and two other cyclic peptides, R_f 0.77*[7] and 0.85*[7] confirmed in each case on thin-layer chromatography, but no crystalline cyclic peptides have yet been isolated except for cyclic decapeptide (XVIII).

***Cyclo* Ser-Orn-Ser-D-Phe-Pro (XXIV) Hydrochloride.** XXIII (169 mg, 0.2 mmol) was hydrogenated in methanol (10 m*l*) with N hydrochloric acid (0.2 m*l*), using palladium black (200 mg) as the catalyst at room temperature for 13.5 hr. After the catalyst had then been filtered off and the solvent removed under reduced pressure, the addition of methanol–ether gave needle crystals (80 mg (75%)); mp 250° (dec.), $[\alpha]_D^{25}$ −156.8° (*c* 0.6, AcOH), R_f 0.55.*[8]

Found: C, 52.75; H, 6.61; N, 14.63; Cl, 6.47%. Calcd for $C_{25}H_{37}O_7N_6Cl$: C, 52.76; H, 6.55; N, 14.77; Cl, 6.23%. Amino acid ratios in acid hydrolyzate: Ser 1.93, Orn 0.87, Phe 1.00, Pro 0.94.

The authors wish to express their deep thanks to Mr. Kiyotaka Hori and his staff of the Fuji Photo Film Co., Ltd., for their amino acid analyses, and to the staff of the Toyo Jozo Co., Ltd., for their elemental microanalyses. They are also indebted to Dr. Homare Kuwana, Kwansei Gakuin University, Department of Biology, for the bioassays.

The Synthesis of a Partial Sequence of Proinsulin Using the A-Chain of Natural Insulin

Yasutsugu SHIMONISHI

The Institute of Scientific and Industrial Research, Osaka University, Suita-shi, Osaka

(Received May 23, 1970)

Elongation reactions of the *S*-sulfonate of the A-chain of bovine insulin were carried out with acylamino acid-active esters or with acylpeptide azide; the following derivatives of the A-chain were thus synthesized: *S*-sulfonates of N^G-nitro-L-arginyl-, L-lysyl-N^G-nitro-L-arginyl-, and L-prolyl-L-prolyl-L-glutaminyl-N^ε-benzyloxycarbonyl-L-lysyl-N^G-nitro-L-arginyl-A-chain. Thus, this was demonstrated to be a useful procedure for the partial synthesis of proinsulin.

Insulin has been successfully synthesized by binding a synthetic A-chain with a natural B-chain[1] or *vice versa*.[2] This is one so-called half-synthesis of complicated polypeptides. The possibility that natural peptide fragments may be used in the synthesis of longer molecules has already been suggested by Goldberger and Anfinsen,[3] and by Offord.[4] However, no examples of successful re- or half-syntheses of natural linear polypeptides from natural or synthetic fragments have yet been reported. Nevertheless, this type of synthesis can be an important preliminary step in the total synthesis of complicated natural polypeptides. The difficulties in this procedure stem from the structure of the peptide fragments involved: when a natural peptide fragment is used as an amino component, all the amino groups except that to be acylated must be protected with suitable groups, and when it is used as a carboxyl component, all functional groups with active hydrogen except that to be activated should be protected.

Recently, proinsulins, the single-chain precursor of insulin, have been isolated from several sources,[5–7]

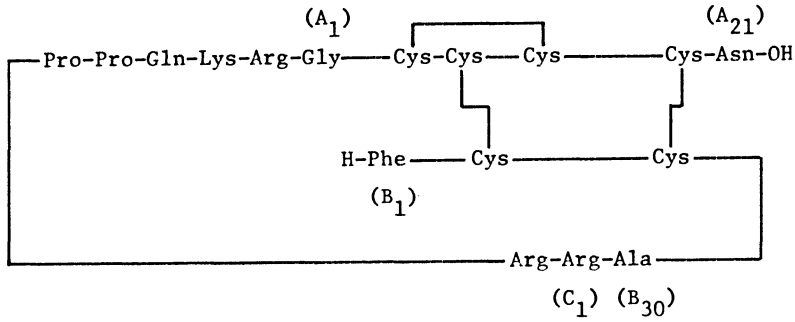

Fig. 1. Structural model of proinsulin from pig[5] and ox.[8]

and the primary structures of those of pig[5] and ox[8] have been elucidated. As is shown in Fig. 1, proinsulin is a linear polypeptide in which the amino terminus of the A-chain of insulin is linked to the carboxyl terminus of its B-chain by a connecting peptide (C-peptide). The A-chain of insulin has only one active amino group at the amino end of its peptide chain, and is readily obtainable from natural insulin. Thus, the natural A-chain seems to be a suitable starting material for the half-synthesis of proinsulin.

In the present study, the reactivities of the natural A-cain of insulin with acylamino acids and with acylpeptide were examined in the preliminary studies of the synthesis of proinsulin. First, the reactivity of A-chain *S*-sulfonate[9] was tested with acylamino acid-active esters. This *S*-sulfonate seemed suitable not only for the protection of the thiol functions, but also for the solubilization of the A-chain in an alkaline medium. Those properties should favor the use of this peptide in the coupling reactions. Next, the author attempted the azide coupling of an acylpeptide with A-chain *S*-sulfonate. The C-terminus of the connecting peptide in proinsulin is arginine, and the coupling of an acylpeptide, having an arginyl residue in the C-terminus, with the natural A-chain by the azide procedure seemed likely to be difficult. Therefore, the author attempted fragment condensation by the azide procedure after a one-step elongation of the A-chain with an N^G-nitro-L-arginine residue.

When this study had almost been completed, the author realized that Zahn *et al.*[10] had published a paper on the syntheses of three A-chain peptides; L-lysyl-, L-histidyl-, and L-arginyl-A-chain. Especially, Zahn *et al.* used DES-glysine-A-chain, obtained by the Edman-degradation of the A-chain, as a starting peptide for the synthesis of L-arginyl-A-chain. Their procedure may have advantages, since the acylated peptide, which is intended to be coupled with DES-glycine-A-chain, should have a glycine residue in the carboxyl terminus, and it may be activated by various coupling methods. However, this procedure seems unnecessarily complicated if the direct elogation of the A-chain with acylated peptide is possible. The possibility of the direct elongation of the A-chain received special attention in the present investigation.

Experimental

Crystalline bovine insulin was obtained from the Chemical Research Laboratories, Takeda Chemical Industries, Ltd. (Osaka), by the courtesy of Dr. M. Fujino. The *S*-sulfonate of the A-chain was prepared from insulin as has been described in the literature.[9,11-12] The dialysis tubing 24/32 was a product of the Visking Co. (Chicago). Sephadex G-25 fine was purchased from the Pharmacia Co. (Uppsala). The chemicals used were of a reagent grade and were used without further purification. Paper electrophoresis was performed at pH 2.1 in a 4M urea-3M formic acid buffer.[11] The purity of the A-chain derivatives thus synthesized was confirmed by paper electrophoresis and by the recovery of the constituent amino acids from acid hydrolysates upon amino-acid analysis. All the melting points given are uncorrected.

***S*-Sulfonate of N^G-Nitro-L-arginyl-A-chain.** The *S*-sulfonate of the A-chain (413 mg) was dissolved in water (3 ml) with sodium bicarbonate (0.16 g), and then a solution of the N^α-*p*-methoxybenzyloxycarbonyl-N^G-nitro-L-arginine pentachlorophenyl ester[13] (1.27 g) in dioxane (6 ml) was added. The mixture was mechanically agitated for 2 days at room temperature, washed with ethyl acetate, and then concentrated *in vacuo*. The residue was then again treated with the fresh N^α-*p*-methoxybenzyloxycarbonyl-N^G-nitro-L-arignine pentachlorophenyl ester (0.63 g) in the same way as has been described above, and the mixture was stirred for one day more at room temperature. Then the reaction mixture was washed with ethyl acetate, concentrated *in vacuo*, and dried over phosphorus pentoxide. The residual powder was dissolved in trifluoroacetic acid

(15 ml) together with anisole (0.7 ml), and the solution was allowed to stand for 30 min at room temperature. Then it was concentrated *in vacuo*, and the oily residue was dried over phosphorus pentoxide. It was then dissolved in 2% aqueous sodium bicarbonate and dialyzed against distilled water (500 ml) for 60 min at room temperature. The dialyzed solution was lyophilized. The lyophilizate was dissolved in a small volume of a 0.1M ammonium bicarbonate solution, charged on a column of Sephadex G-25 (2×50 cm), and eluted using the same buffer solution. The first peak in the eluate, with an absorption at 280 mμ (see Fig. 3), was collected and lyophilized to obtain the *S*-sulfonate of N^G-nitro-L-arginyl-A-chain as a solid; wt. 393 mg.

N^α,N^ε-Di-*t*-butyloxycarbonyl-L-lysine *N*-Hydroxysuccinimide Ester. N^α,N^ε-Di-*t*-butyloxycarbonyl-L-lysine[14,15] (1.38 g, 4.0 mmol) and *N*-hydroxysuccinimide (0.46 g, 4.0 mmol) were dissolved in absolute tetrahydrofuran (20 ml), after which the solution was cooled to −10°C. A solution of *N*,*N'*-dicyclohexylcarbodiimide (0.82 g, 4.0 mmol) in absolute tetrahydrofuran (10 ml) was added to the chilled solution. The solution was stirred for an hour at the same temperature and then for 24 hr at room temperature; the urea thus formed was filtered off and washed with ethyl acetate. The filtrate and washings were combined and concentrated to a syrup *in vacuo*, which was crystallized by trituration with petroleum ether; wt. 1.70 g. The crude material was recrystallized from ethyl acetate and petroleum ether; wt. 1.54 g (87.0%); mp 92—96°C, $[\alpha]_D^{18}$ −30.6° (*c* 2, ethanol).

Found: C, 54.18; H, 7.96; N, 9.19%. Calcd for $C_{20}H_{33}O_8N_3$: C, 54.16; H, 7.50; N, 9.48%.

S-Sulfonate of L-Lysyl-N^G-nitro-L-arginyl-A-chain. The *S*-sulfonate of N^G-nitro-L-arginyl-A-chain (104 mg) was dissolved in water (1.5 ml) containing sodium bicarbonate (0.04 g) and allowed to react with the N^α,N^ε-di-*t*-butyloxycarbonyl-L-lysine *N*-hydroxysuccinimide ester (0.22 g) dissolved in dioxane (2 ml). The reaction mixture was then treated as has been described for the synthesis of the *S*-sulfonate of N^G- nitro-L-arginyl -A-chain. The yield of the *S*-sulfonate of L-lysyl-N^G -nitro-L-arginyl-A-chain was 93.8 mg. This material had a slower mobility on paper by electrophoresis at pH 2.1 than the *S*-sulfonate of N^G-nitro-L-arginyl-A-chain.

***t*-Amyloxycarbonyl-L-prolyl-L-proline *N*-Hydroxysuccinimide Ester.** A solution of *t*-amyloxycarbonyl-L-prolyl-L-proline[16] (3.26 g, 10 mmol) and *N*-hydroxysuccinimide (1.15 g, 10 mmol) in absolute tetrahydrofuran (30 ml) was cooled to 0—5°C, and then *N*,*N'*-dicyclohexylcarbodiimide (2.06 g, 10 mmol) was added to the chilled solution. The mixture was stirred for an hour at the same temperature and then for 20 hr at room temperature, and the precipitate thus formed was removed by filtration. The filtrate was concentrated to a syrup *in vacuo*; crystals formed on storage in a refrigerator. The crude product was collected by filtration with petroleum ether; wt. 4.29 g. It was recrystallized from ethyl acetate and petroleum ether; wt. 4.04 g (95.5%), mp 111.5—112.5°C, $[\alpha]_D^{29}$ −103.8° (*c* 2, ethanol).

Found: C, 56.52; H, 7.91; N, 9.72%. Calcd for $C_{20}H_{29}O_7N_3$: C, 56.72; H, 6.90; N, 9.92%.

***o*-Nitrophenylsulfenyl-L-glutaminyl-N^ε-benzyloxycarbonyl-L-lysine Methyl Ester.** N^ε-Benzyloxycarbonyl-L-lysine methyl ester hydrochloride[17] (2.68 g, 8.09 mmol) and triethylamine (1.13 ml) were dissolved in dimethylformamide (25 ml), and then the *o*-nitrophenylsulfenyl-L-glutamine *N*-hydroxysuccinimide ester[18] (2.67 g, 6.74 mmol) was added to the solution. After having been stirred for 2 days at room temperature, the reaction mixture was diluted with ethyl acetate (*ca.* 200 ml). The solution was washed successively with 0.1N hydrochloric acid, 5% sodium bicarbonate, and water, and dried over anhydrous sodium sulfate. The dried solution was concentrated to obtain green crystals, which were then collected with ethyl acetate and petroleum ether; wt. 3.11 g. The crude product was recrystallized from methanol and water; wt. 3.00 g (77.3%), mp 155—157°C.

Found: C, 54.33; H, 5.60; N, 12.00; S, 5.47%. Calcd for $C_{26}H_{33}O_8N_5S$: C, 54.25; H, 5.78; N, 12.17; S, 5.57%.

***t*-Amyloxycarbonyl-L-prolyl-L-prolyl-L-glutaminyl-N^ε-benzyloxycarbonyl-L-lysine Methyl Ester.** The *o*-nitrophenylsulfenyl-L-glutaminyl-N^ε-benzyloxycarbonyl-L-lysine methyl ester (6.34 g, 11 mmol) was suspended in distilled dioxane (40 ml), and then treated with 4N HCl in dioxane (15 ml) for 15 min. The clear solution thus formed was concentrated to a syrup and dried over sodium hydroxide *in vacuo*. Then it was thoroughly washed with a mixture of acetone and ether. The residue was dissolved in dimethylformamide (40 ml), and triethylamine (1.6 ml) and the *t*-amyloxycarbonyl-L-prolyl-L-proline *N*-hydroxysuccinimide ester (3.95 g, 9.35 mmol) were added to the solution. After having been stirred for 2 days at room temperature, the reaction mixture was diluted with ethyl acetate (*ca.* 300 ml). The diluted solution was washed successively with 0.1N hydrochloric acid, 5% sodium bicarbonate, and water, and dried over anhydrous sodium sulfate. The dried solution was concentrated *in vacuo* to a syrup; wt. *ca.* 5.6 g. This material has not yet been crystallized.

***t*-Amyloxycarbonyl-L-prolyl-L-prolyl-L-glutaminyl-N^ε-benzyloxycarbonyl-L-lysine Hydrazide.** The syrupy material of the *t*-amyloxycarbonyl-L-prolyl-L-prolyl-L-glutaminyl-N^ε-benzyloxycarbonyl-L-lysine methyl ester (*ca.* 5.6 g) was dissolved in ethanol (80 ml), and then 100% hydrazine hydrate (8 ml) was added to the solution. After standing for 24 hr at room temperature, the mixture was concentrated to a syrup; crystals were obtained by rubbing the syrup with petroleum ether; wt. 5.40 g. The crude product was recrystallized from ethanol and ether; wt. 4.82 g (70.5% of the theoretical yield based on the content of the *t*-amyloxycarbonyl-L-prolyl-L-proline *N*-hydroxysuccinimide ester); mp 104°C, $[\alpha]_D^{18}$ −68.5° (*c* 2, ethanol).

Found: C, 57.47; H, 7.55; N, 15.04%. Calcd for

***S*-Sulfonate of L-Prolyl-L-prolyl-L-glutaminyl-N^{ε}-benzyloxycarbonyl-L-lysyl-N^{G}-nitro-L-arginyl-A-chain.** *t*-Amyloxycarbonyl-L-prolyl-L-prolyl-L-glutaminyl-N^{ε}-benzyloxycarbonyl-L-lysine hydrazide (366 mg) was dissolved in dimethylformamide (3 m*l*) and cooled to −40°C. The solution was mixed with 1N HCl in tetrahydrofuran (1.0 m*l*) and then with isoamylnitrite (70 mg) dissolved in tetrahydrofuran (1.0 m*l*) at the same temperature.[19] After 30 min, triethylamine (0.17 m*l*) and a solution of the *S*-sulfonate of N^{G}-nitro-L-arginyl-A-chain (280 mg) and sodium bicarbonate (0.12 g) dissolved in water (2 m*l*) were added to the solution. The mixture was stirred mechanically at −20°C for 2 days, and then dialyzed against distilled water (500 m*l*) for 60 min at room temperature and lyophilized. The residue was dried over phosphorus pentoxide *in vacuo* and then treated with trifluoroacetic acid (15 m*l*) at 5°C for 30 min. The solution was concentrated *in vacuo*, and the residual oil was dried over phosphorus pentoxide. This was dissolved in 2% aqueous sodium bicarbonate at room temperature. After 30 min, the solution was dialyzed against distilled water and lyophilized. The residue was dissolved in a small volume of a 0.1M ammonium bicarbonate solution and fractionated on a column of Sephadex G-25 (2×50 cm) using the same buffer solution. The first peak in the eluate with an absorption at 280 mμ, as has been described in the synthesis of the N^{G}-nitro-L-arginyl derivative, was collected and lyophilized. Thus L-prolyl-L-prolyl-L-glutaminyl-N^{ε}-benzyloxycarbonyl-L-lysyl-N^{G}-nitro-L-arginyl-A-chain *S*-sulfonate was obtained as a powder; wt. 163 mg.

Results and Discussion

The coupling reaction was, first, carried out by mixing an aqueous solution of A-chain *S*-sulfonate with a solution of the N^{α}-*p*-methoxybenzyloxycarbonyl-N^{α}-nitro-L-arginine pentachlorophenyl ester in dioxane under the standard conditions used in peptide synthesis.[20] A large molar excess of the N^{α}-*p*-methoxybenzyloxycarbonyl-N^{G}-nitro-L-arginine pentachlorophenyl ester was employed, since it was thought that the quantitative acylation of the A-chain *S*-sulfonate would facilitate the purification procedure. When a 10—15 fold molar excess of this reagent was allowed to react with A-chain *S*-sulfonate for 2 days at room temperature, a little unreacted A-chain was detected in the reaction mixture by paper electrophoresis using a formic acid buffer solution at pH 2.1. However, the repeated addition of 5—7 fold molar excesses of the pentachlorophenyl ester to the reaction mixture resulted in the quantitative acylation of the A-chain *S*-sulfonate, as is shown in Fig. 2. After removing the protective group with trifluoroacetic acid, the reaction product

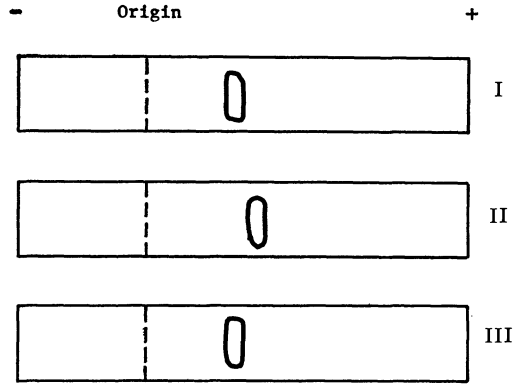

Fig. 2. Diagram of paper electropherogram stained with Pauly reagent (urea-formic acid buffer, pH 2.1, 7.5 V/cm). Bands I, II and III correspond to the *S*-sulfonate of A-chain, reaction mixture after reaction of the *S*-sulfonate of A-chain with N^{α}-*p*-methoxybenzyloxycarbonyl-N^{G}-nitro-L-arginine pentachloropyenyl ester, and the *S*-sulfonate of N^{G}-nitro-L-arginyl-A-chain, respectively.

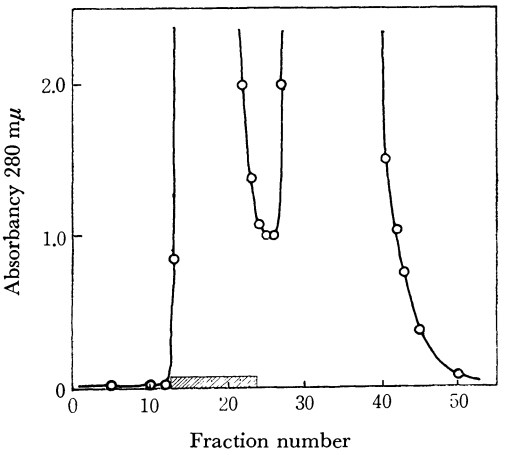

Fig. 3. Gel-filtration of mixture after reaction of the *S*-sulfonate of A-chain and N^{α}-*p*-methoxybenzyloxycarbonyl-N^{G}-nitro-L-arginine pentachlorophenyl ester and removing the *N*-terminal protective group by treatment with trifluoroacetic acid on Sephadex G-25 (2×50 cm).

was purified by gel-filtration on Sephadex G-25, using ammonium bicarbonate buffer as a solvent, as is shown on Fig. 3. The first fraction of the eluate, N^{G}-nitro-L-arginyl-A-chain *S*-sulfonate, was collected and lyophilized to yield a cotton-like residue. This compound was identified by paper electrophoresis and by an amino-acid analysis of its acid hydrolysate, as is shown in Fig. 2 and Table 1 respectively.

Second, the N^{G}-nitro-L-arginyl-A-chain *S*-sulfonate obtained above was allowed to react with the N^{α},N^{ε}-di-*t*-butyloxycarbonyl-L-lysine *N*-hydroxysuccinimide ester. The reaction was car-

19) J. Honzl and J. Rudinger, *Collect. Czech. Chem. Commun.*, **26**, 2333 (1961).

20) G. W. Anderson, J. E. Zimmerman and F. M. Callahan, *J. Amer. Chem. Soc.*, **86**, 1839 (1964).

ried out in the same way in dioxane-water under weakly alkaline conditions. The extent of the coupling reaction was also monitored by paper electrophoresis at pH 2.1, and L-lysyl-N^G-nitro-L-arginyl-A-chain *S*-sulfonate was isolated similarly. The amino-acid analysis of its acid hydrolysate also gave satisfactory results, as is shown in Table 1.

Table 1. Amino acid compositions of various derivatives of the A-chain[a)]

Amino acid	*S*-Sulfonate of A-chain[b)]	I[c)]	II[c)]	III[c)]
Asp	1.88 (2)	1.88	1.80	1.94
Ser	1.67 (2)	1.62	1.57	1.69
Glu	4.15 (4)	4.06	3.68	4.88
Pro				2.19
Gly	1.09 (1)	1.00	1.00	1.00
Ala	1.00 (1)	1.00	1.00	1.00
Cys	1.69 (2)	1.35	1.53	1.50
Val	1.67 (2)	1.56	1.63	1.69

Arg+Lys[d)]		1.06	1.78	1.81

a) Samples were hydrolyzed in 6N hydrochloric acid without added phenol in sealed tubes, for 24 hr, at 110°C, and analyzed in a Hitachi KLA-3B analyzer. All values shown are uncorrected.
b) This compound was analyzed for comparison with the synthesized compounds.
c) Compounds I, II and III mean *S*-sulfonates of N^G-nitro-L-arginyl-, L-lysyl-N^G-nitro-L-arginyl-, and L-prolyl-L-prolyl-L-glutaminyl-N^ε-benzyloxycarbonyl-L-lysyl-N^G-nitro-L-arginyl-A-chain, respectively.
d) Total values of lysine and arginine are showed, because lysine was not separated from ornithine derived from nitroarginine in this analysis.

Third, N^G-nitro-L-arginyl-A-chain *S*-sulfonate was coupled with *t*-amyloxycarbonyl-L-prolyl-L-prolyl-L-glutaminyl-N^ε-benzyloxycarbonyl-L-lysine by the azide procedure described in the introduction. In this case, the reaction product could not be detected by paper electrophoresis at pH 2.1, because it did not separate distinctly from unreacted *S*-sulfonate. The reaction was allowed to proceed for 2 days at −20°C, and then the product was isolated after removing the *N*-terminal protective group by treatment with trifluoroacetic acid. The product was found to migrate slower than A-chain *S*-sulfonate at pH 2.1, and seemed to be almost pure L-prolyl-L-prolyl-L-glutaminyl-N^ε-benzyloxycarbonyl-L-lysyl-N^G-nitro-L-arginyl-A-chain *S*-sulfonate. The amino-acid analysis of the hydrolysate also gave good results, as is shown in Table 1. This compound will be used as material for further elongation reactions, since the ε-amino group of the lysyl residue and the thiol group of cysteinyl residues are still suitably protected.

The above results clearly show that the natural A-chain of insulin can be used as a starting material in the partial synthesis of proinsulin, in which acylamino acid-active esters are used for step-by step elongation reactions and fragment condensation by means of the azide procedure can be applied the to N^G-nitro-L-arginyl-A-chain. The success of azide coupling with N^G-nitro-L-arginyl-A-chain is especially noteworthy. Thus, the use of Des-glycine-A-chain for the elongation reactions does not seem always to be necessary. Attempts at direct condensation with the A-chain by the azide procedure remain unsuccessful.

The author wishes to express his thanks to Professor S. Sakakibara of Osaka University and to Professor H. Zahn of the Deutsches Wollforschungsinstitut, Technischen Hochschule Aachen, for their encouragement throughout this investigation.

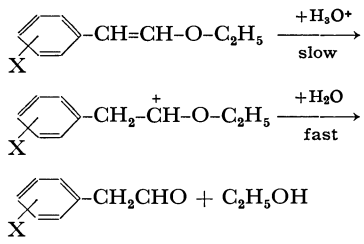
The acid-catalyzed hydrolysis of *cis*- and *trans*-styryl ethyl ethers (SEE) and several of their ring-substituted derivatives has been kinetically investigated in 80% aqueous dioxane. It has been found that these ethers are less reactive than vinyl ethyl ether by a factor of *ca.* 500 and that all the *cis* isomers studied are about twice as reactive as the corresponding *trans* isomers. The hydrolysis of the substituted ethers at 35°C has proved to obey the Hammett relation with the reaction constants $\rho=-1.07$ and -0.70 for the *cis* and the *trans* isomers, respectively. All these results appear to be interpretable at least qualitatively in terms of the reaction scheme involving the rate-determining protonation to the β-carbon atom.

It is generally accepted that the acid-catalyzed hydrolysis of α,β-unsaturated ethers involves irreversible protonation to the unsaturated bond. In a previous paper[1] of this series, the kinetic courses of hydrolysis of various alkenyl alkyl ethers were investigated and direct evidence that the protonation step is rate-determining was given. It was also shown that the effects of β-alkyl substitutions on the reactivity of vinyl ether can best be interpreted in terms of the conjugative stabilities of the intermediate carbonium ions which are formed on transfer of a proton from the hydronium ion to the ethers. Further, it was demonstrated both experimentally and theoretically that the electronic effect of α-alkoxyl groups is an important contribution to the rates of hydrolysis of ring-substituted phenyl vinyl ethers.[2]

In order to gain a deeper insight into the electronic factors of β-substituents influencing the vinyl ether hydrolysis, we have investigated the effect of ring substituents in the hydrolysis rates of *cis*- and *trans*-styryl ethyl ethers (SEE). The results were interpreted in terms of the reaction scheme involving the rate-determining protonation:



(1)

Experimental

Materials. Styryl ethyl ether (SEE) and its ring-substituted derivatives were prepared by the method of Dufraisse and Chaux[3,4] from diethyl acetals of appropriate substituted phenylacetaldehydes, which were obtained by the Grignard method[5] from benzyl bromides or chlorides. Methyl-, chloro-, and fluorobenzyl bromides were prepared by bromination of corresponding substituted toluenes.[6] *p*-Methoxybenzyl chloride was obtained by the solvolysis of *p*-anisyl alcohol. *p*- and *m*-fluorotoluenes were prepared from *p*- and *m*-toluidines, respectively, according to the procedure of Roe.[7]

The unsaturated ethers thus obtained were nearly equimolar mixtures of geometrical isomers, and their boiling points were as follows: H, 112—115°C/20 mmHg; *p*-CH_3O, 110—113°C/3 mmHg; *p*-CH_3, 87—89°C/5 mmHg; *m*-CH_3, 90—93°C/5 mmHg; *p*-F, 115—116°C/22 mmHg; *m*-F, 82—83°C/5 mmHg; *p*-Cl, 77—78°C/2 mmHg; *m*-Cl, 97—100°C/5 mmHg. Purities were checked by gas chromatography (>99%).

Dioxane, tetralin and carbon tetrachloride were obtained as described previously.[1]

out in 80% aqueous dioxane containing *ca.* 0.2N hydrochloric acid at a specified temperature between 25 and 45°C. Each SEE derivative was hydrolyzed as a mixture of *cis* and *trans* isomers, but the kinetic courses were followed for each isomer separately by simultaneous determination of the isomers by gas chromatography. A Shimadzu Model 4APT gas chromatograph with a 3-m column packed with Apiezon Grease L was operated at a column temperature of *ca.* 130°C with hydrogen as carrier gas. In all cases, the *trans* isomers had a greater retention time. The initial total concentration of the reactant ethers was typically *ca.* 0.15M. Tetralin or dichlorobenzene was used as internal standard. The internal standard method coupled with the half-height width evaluation of the peak areas was sufficient for the determination of the ethers. Other details of the procedures for the rate measurements were the same as those described previously.[1,2] Each rate constant was obtained as an average of three to five independent runs and accurate to within 5%.

Results

It is known that the acid-catalyzed hydrolysis of α,β-unsaturated ethers is first order in both ether and acid.[1,2] Although most of the kinetic courses investigated here were pursued with the mixture of geometrical isomers, the first-order decay was found to hold for each isomer separately over the range up to 80% conversion. Figure 1 shows an example.

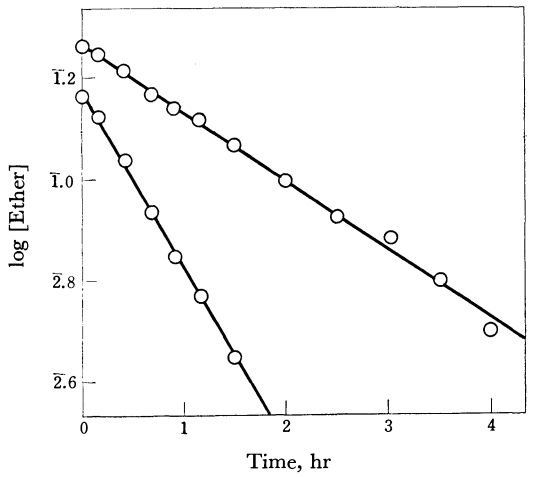

Fig. 1. First-order plots for the hydrolysis of *cis*- and *trans*-*p*-methylstyryl ethyl ethers.
[HCl], 0.189M. Temperature, 35°C.

The situation is in agreement with the previous observation that geometrical isomerization does not take place during the hydrolysis of alkenyl alkyl ethers.[1] This in turn endorses the conclusion that the hydrolysis involves the rate-determining protonation to an olefinic carbon atom. Formation of the products as expected from Eq. (1) was confirmed for the nonsubstituted compounds; the gas-chromatographic retention times of the products measured with the use of two different columns, polyethylene glycol and Apiezon Grease L, both exactly coincided with those of the authentic samples.

Table 1. Second-order rate constants for the acid-catalyzed hydrolysis of ring-substituted styryl ethyl ethers at 35°C

Substituent	10^4k_2, $M^{-1}sec^{-1}$	
	cis	*trans*
p-CH_3O	10.4_2	5.43
p-CH_3	11.8_4	4.72
m-CH_3	9.39	4.22
H	1.99[a]	1.14[a]
	7.33	3.85
	25.2[b]	13.8[b]
p-F	3.90	2.28
p-Cl	3.37	2.12
m-Cl	3.16	2.07

a) At 25°C.
b) At 45°C.

In Table 1 are summarized the second-order rate constants, $k_2=k_1/[HCl]$. In all the cases studied, *cis* isomers were *ca.* twice more reactive than the *trans* isomers, and their reactivities diminished with increasing electron-attracting ability of the ring substituents. From temperature dependence data, the heats and the entropies of activation, $\Delta H^{\neq}$ and $\Delta S^{\neq}$, were calculated for the unsubstituted SEE's: *cis*-SEE, $\Delta H^{\neq}=23.3$ kcal mol^{-1} and $\Delta S^{\neq}=2.7$ e.u.; *trans*-SEE, $\Delta H^{\neq}=21.4$ kcal mol^{-1} and $\Delta S^{\neq}=-4.9$ e.u.

Discussion

It has been reported[1] that the acid-catalyzed hydrolysis of vinyl ethyl ether in 80% aqueous dioxane at 25°C is $k_2=7.51\times10^{-2}M^{-1}\,sec^{-1}$. The reactivity of styryl ethyl ether toward proton is thus smaller than that of vinyl ethyl ether by a factor of *ca.* 500. This effect of the β-phenyl group in lowering the vinyl ether reactivity is far greater than that of a β-methyl group, which reduces the reactivity only by a factor of *ca.* 5.[1]

The effect of the β-phenyl group may be interpreted qualitatively from the greater stability of styryl ether in the ground state as compared with vinyl ether. Because of the excessive ground-state stability due to the conjugation between phenyl group and the olefinic bond, the π-electronic energy required for localizing an electron pair on the β-carbon ought to be greater for the styryl ether than for the vinyl ether. Simple calculations of the Hückel type readily confirm the above view. The difference in localization energy between the two ethers must reflect itself in the difference in

the activation energies for their hydrolysis.[8]

All the *cis*-SEE's are more reactive than the corresponding *trans* isomers in the temperature region studied here. Nonetheless, the heat of activation for *cis*-SEE was found to be greater than that for *trans*-SEE. Hence, the relative reactivities of *cis*- and *trans*-SEE's are entropy-controlled at the ordinary temperature region. The isomerization equilibrium experiments showed that *cis*-SEE is thermochemically less stable than *trans*-SEE in the liquid phase, and it was deduced that the former isomer is in a non-planar conformation in contrast to the planar structure for the latter.[9] This structural irregularity may have some bearing with the unusual entropy effect found between the activation profiles of *cis*- and *trans*-SEE's. A similar trend was also found in the cationic polymerization of SEE.[10]

As has been stated above, the reactivity of SEE is enhanced by electron-donating substituents and is lowered by electron-attracting substituents. As is seen in Fig. 2, the effects of the ring substituents obey the Hammett $\rho\sigma$ relationship for the *cis* and *trans* isomer series separately, although a relatively

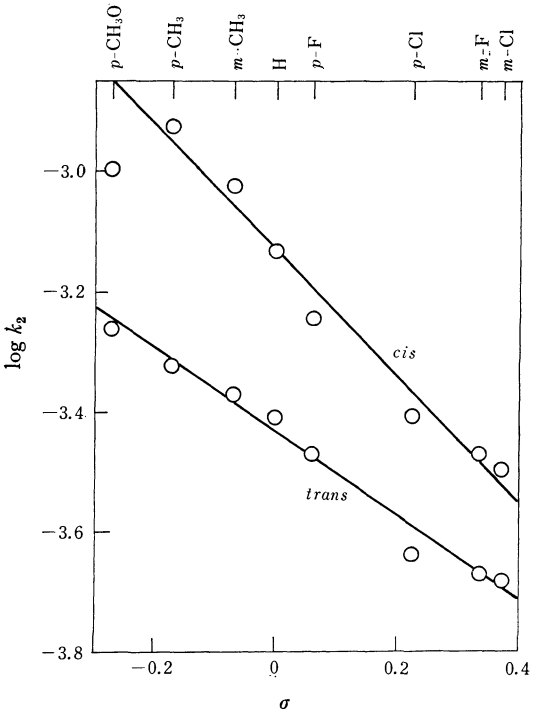

Fig. 2. The Hammett relationships of the hydrolysis rates of ring-substituted styryl ethyl ethers. Temperature, 35°C.

large deviation from the line was found for the *cis*-*p*-methoxy derivative. The reaction constants, ρ, are -1.07 ($r=0.990$, excluding a point for the *p*-methoxy compound) and -0.70 ($r=0.991$) for the *cis* and *trans* series, respectively.

That an electron-donating ring substituent enhances the rate of the acid-catalyzed reaction of SEE has by no means been intuitively obvious. In fact, Winterfeldt[11] observed that the *p*-$N(CH_3)_2$ group lowers the rate of the acid-catalyzed methanolysis of styryl ether and interpreted this rate lowering in terms of the "opposing" electron donation of the *p*-$N(CH_3)_2$ group. His observation thus conflicts with our present results on hydrolysis and, therefore, his interpretation is greatly dubious. It appears that, in the acidic medium where his measurement was carried out, the $N(CH_3)_2$ group was actually in the form of $N^+(CH_3)_2H$, which retarded the methanolysis rate.[12]

The ρ values (-1.07 and -0.70) for the SEE hydrolysis are somewhat small as compared with those for the usual electrophilic addition reactions to styryl compounds. For instance, the acid-catalyzed hydration of styrenes[13] and the chlorination of cinnamic acids[14] were reported to have the values of -3.42 and -4.01, respectively. These reactions occur with an electrophilic attack on the *beta* carbon atom with respect to the phenyl group.[15] In contrast to these reactions, the hydrolysis of styryl ether occurs with an *alpha*-attack of hydronium ion, as is shown in Eq. (1). The lower sensitivity of the present reaction to the ring substituents is undoubtedly due to the fact that the primary reaction center is the *alpha*-position. This is easily understandable considering that, in the intermediate carbonium ions, the cationic center is insulated out of the π-conjugation involving the phenyl group which carries a substituent.

8) The activation papameters for vinyl ethyl ether are $\Delta H^{\neq}=17.5$ kcal mol^{-1} and $\Delta S^{\neq}=-4.9$ e.u.

11) E. Winterfeldt, *Chem. Ber.*, **96**, 3346 (1963).

12) The ammonium groups are electron-attracting in nature, as may be judged from their σ-values [D. H. McDaniel and H. C. Brown, *J. Org. Chem.*, **23**, 420 (1958)]. Besides, part of the catalyst acid must have been consumed for the ammonium ion formation. These would have combined to act as a drawback of the electronic effect of the *p*-$N(CH_3)_2$ group which would otherwise have enhanced the rate of protonation to the olefinic carbon atom.

14) H. P. Rothbaum, I. Ting and P. W. Robertson, *J. Chem. Soc.*, **1948**, 980.

15) It is expedient to regard SEE as a derivative of styrene when chemical characteristics are to be compared between the two compounds. Thus, when we refer to those carbon atoms at the positions α and β with respect to the phenyl group, we make use of the word *alpha* and *beta* in order to avoid confusion with the α- and β-carbon atoms of an α,β-unsaturated ether. This expedience will be used whenever we discuss the properties of SEE in comparison with those of styrene.

Electrophilic reactions of styryl compounds involving the rate-determining *alpha*-attack do not seem to be very familiar at present. The only example that has been reported in connection with the substituent effects is the acid-catalyzed geometrical isomerization of substituted *cis*-stilbenes,[16] where the ρ value was noted to be -0.96 or -3.30, depending on whether the primary reaction center is the *alpha*- or the *beta*-carbon with respect to the phenyl group that carries the substituents to be examined. The present studies provide another example of the electrophilic *alpha*-attack reactions of styryl compounds which should have a ρ value relatively small in magnitude.

Properties of Vinyl Chlorides-Ethylene Copolymers

Akira MISONO and Yasuzo UCHIDA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

and Kunikazu YAMADA

Research Institute, Sekisui Chemical Co., Shimamoto-cho, Mishima-gun, Osaka

(Received May 14, 1970)

Properties of vinyl chloride-ethylene copolymers rich in vinyl chloride have been studied by means of infrared as well as NMR spectroscopy and dynamic mechanical testing. The infrared and NMR spectra of the copolymer indicate that crystallinity decreases with decreasing sequence length of the vinyl chloride segment. The copolymer containing more than 80 mol % vinyl chloride shows optical melting point, a plot of which *versus* logarithmic composition satisfies Flory's relationship. Temperature dispersion curve of elastic modulus E′ of the copolymer also indicates that the crystalline region of vinyl chloride segments disappears as the ethylene content increases. Glass transition temperature as determined by loss modulus E″ fits Gordon-Taylor's relationship well provided the coefficient k equals unity.

From the results of crystallographic,[1-3] mechanical[4-6] and thermal studies,[7] it is considered that polyvinyl chloride can be regarded as a semi-crystalline polymer, though its crystalline region is very small. On the other hand, Flory[8] has shown that the crystallinity of an original polymer decreases regularly depending on the amount of the comonomer incorporated. Many copolymer systems have been examined in relation to the melting point depression predicted by Flory.[9] Few vinyl chloride copolymers, however, have been studied in this respect probably because of their poor crystallinity. We reported the syntheses[10-12] and some aspects of structural problems[13,14] of vinyl chloride-ethylene copolymers. It has been suggested that the copolymer is more or less crystalline on the basis of our recent investigation. We wish to report on the results of a preliminary study on the properties of the copolymers.

Experimental

Copolymer samples were prepared by using the catalyst system consisting of tri-*n*-butylboron and *t*-butyl hydroperoxide in a water-methanol mixture (1 : 1 by volume).[1] The composition of the copolymer was determined from the results of elementary analysis of C and Cl. The infrared spectrum of the copolymer was measured with a JASCO 201 infrared spectrometer by the KBr disk method. The NMR spectrum of the copolymer was measured by a Japan Electron Optics high resolution NMR spectrometer, model JNM-60, in a 10 wt/vol% monochlorobenzene solution of the copolymer at 60 MHz and 110°C using tetramethylsilane as internal standard. The melting point of the copolymer was measured by a Yanagimoto hotstage polarizing microscope. The dynamic viscoelasticity of the copolymer was measured by Toyo Measuring Instruments Vibron viscoelastometer, model DDV-II, at 11 Hz using a sheet of sample prepared by hot-pressing at 100°C for 5 min under a pressure of 70 kg/cm².

Results and Discussion

In the region 700 to 600 cm^{-1} of the infrared spectrum of polyvinyl chloride, four absorption bands were observed at 690, 635, 615 and 603 cm^{-1}.[2] They are denoted by α, β, γ and δ, respectively. The δ-band cannot be observed in the spectrum measured by the KBr disk method. The four bands were assigned to the C–Cl streching modes from comparison with the spectrum of olyvinyl bromide. β- and δ-bands were assigned to the crystalline bands.[2,3] In Fig. 1 are shown the infrared spectra of vinyl chloride-ethylene copolymers together with that of polyvinyl chloride, observed in the KBr region. The α-band observed in polyvinyl chloride shifts to somewhat lower frequency and its intensity decreases as the vinyl chloride content of the copolymer decreases. Intensity of β-band also decreases with decreasing vinyl chloride content and, completely disappears in the spectrum of the copolymers containing less than 60 mol% vinyl chloride. In

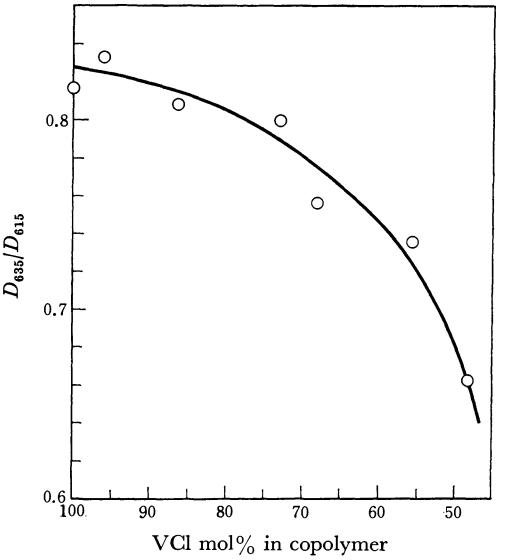

Fig. 2. D_{635}/D_{615} as a function of copolymer composition.

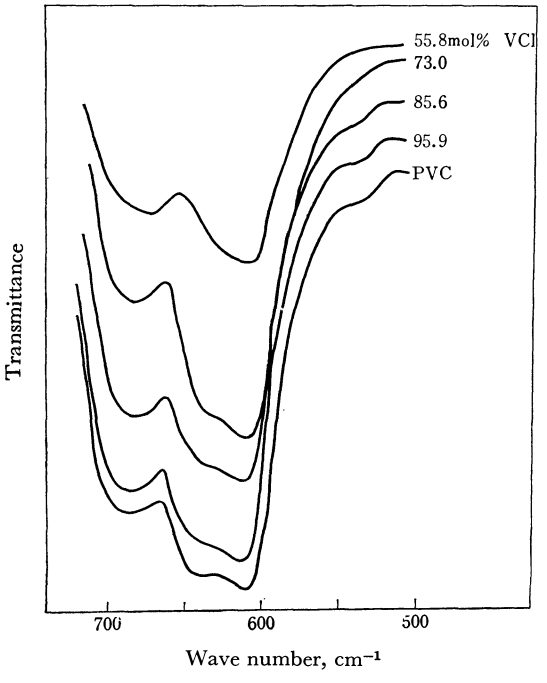

Fig. 1. Infrared spectra of polymers in KBr region.

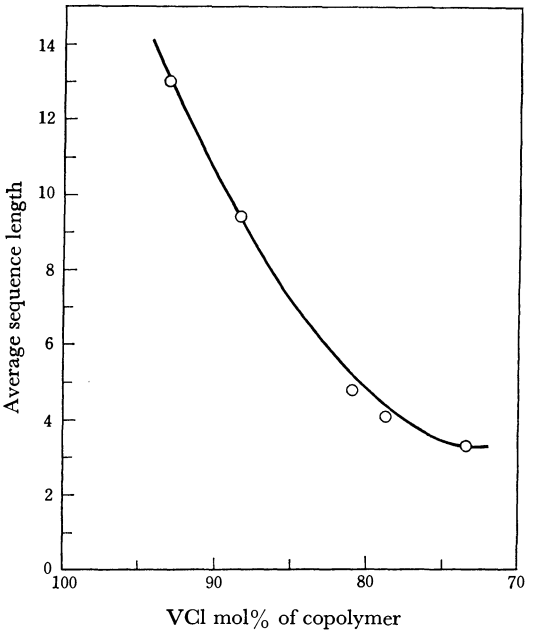

Fig. 3. Average sequence length of vinyl chloride unit of copolymer as a function of their composition.

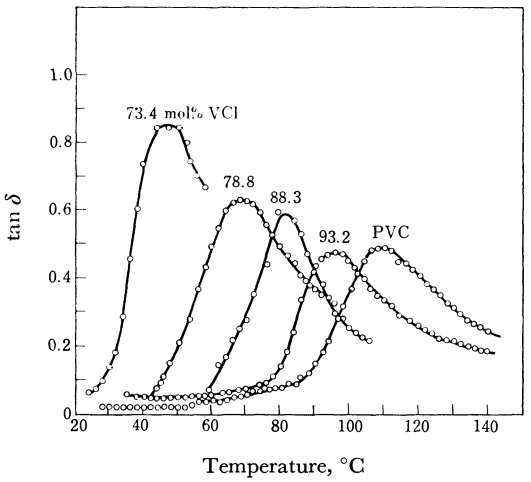

Fig. 4. Mechanical damping of polymers.

Fig. 2 the change in the ratio of optical densities of β- and γ-bands are shown. It may be seen that the crystallinity of the copolymer decreases with the decreasing vinyl chloride content. In Fig. 3 is shown the average sequence length of vinyl chloride units determined by NMR technique.[14] The decrease in the average sequence length of vinyl chloride units with the decreasing vinyl chloride content may be correlated with the decressing crystallinity observed in the infrared spectra.

The loss tangent curves of the copolymers are shown in Fig. 4. The temperature of the maximum loss tangent decreases linearly with the decreasing vinyl chloride content. This seems to correspond to the change in glass transition temperature according to the change in copolymer composition. Glass transition temperature of the copolymer will be discussed later on the basis of the temperature dependence of loss modulus E″. Decrease in the temperature of the maximum loss tangent with the decreasing vinyl chloride content seems to be analogous with what has been observed in plasticized polyvinyl chloride.[4] Increase in magnitude and decrease in half-height width of loss tangent with the increasing ethylene content, however, are in contrast with the increase in half-height width with the increasing amount of plasticizer in plasticized polyvinyl chloride.[4] The difference may reflect the mechanism of plasticizing functioning in each polymer. The plasticizer plasticizes polyvinyl chloride by decreasing the intermolecular interaction between chloride atoms located on each polymer chain, whereas the ethylene unit incorporated into the copolymer plasticizes the polymer by diminishing the number of chlorine atoms distributed along the polymer chain. We need to investigate the behavior of loss tangent in lower temperature regions, in order to see more closely the mechanism of plasticization. However, the viscoelastometer used in this study was not equipped with a low temperature bath, and no study was carried out.

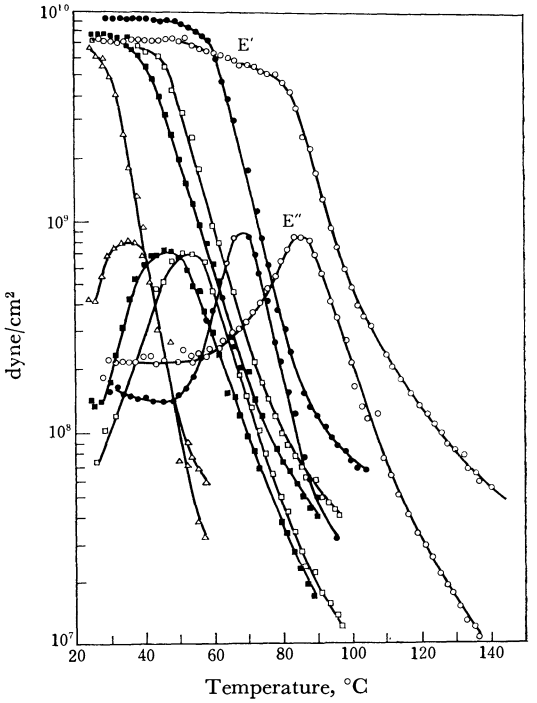

Fig. 5. Elastic and loss moduli of polymers.
○ PVC, ● 93.2 mol% VCl, □ 88.3 mol% VCl
■ 78.8 mol% VCl △ 73.4 mol% HCl

Dynamic elastic and loss moduli of the copolymers are shown in Fig. 5. The temperature where glass transition begins decreases with the increasing ethylene content of the copolymer and, the width of the transition region also decreases in the same manner. This is different from the behavior of plasticized polyvinyl chloride in which the width of transition region increases with the increasing amount of plasticizer.[4] The temperature dependence of elastic modulus of polyvinyl chloride has been studied, and the existence of the rubbery region continuing from the transition region has been elucidated in terms of microcrystallites occurring in vinyl chloride segments.[5,6] In our polymers, a part of such rubbery region is observed as a curvature of elastic modulus E′ continuing from the high temperature-end of the transition region. Such a curvature, however, disappears when the ethylene content exceeds about 10 mol%, where the average sequence length of vinyl chloride units is estimated as about 10. These results might indicate that more than about 10 monomer units of vinyl chloride are required appreciable crystallinity of the copolymer. Nambu[15] has concluded that as least 20 to 30 monomer units are necessary for the crystallization of vinyl chloride segments from the results

15) K. Nambu, *Kobunshi Kagaku*, **20**, 131 (1963).

of investigation on vinyl chloride-diethylfumarate copolymers, in which the bulky side group of the comonomer seems to render the vinyl chloride segment more difficult to crystallize than in vinyl chloride-ethylene copolymers.

It is established that the main dispersion of polyvinyl chloride, which is associated with glass transition, can be attributed to the motion of long segments of main chain. The peak temperature of loss modulus E″ varies monotonously according to the change in copolymer composition as shown in Fig. 6, and this relationship fits Gordon-Taylor's equation provided the coefficient k equals unity.[16]

$$c_2=(T_g-T_{g1})/\{k(T_{g2}-T_g)+(T_g-T_{g1})\}$$

where T_g, T_{g1} and T_{g2} are the glass transition temperatures of the copolymer, homopolymer 1 and homopolymer 2 respectively, c_2 the weight fraction of the comonomer 2 in the copolymer, and k is the ratio of the difference of expansion coefficients of the homopolymer 1 and 2 above and below the glass transition temperature. Glass transition temperatures thus determined are in good consistency with diatometrically observed ones.[17]

The copolymer containing more than about 80 mol% vinyl chloride shows appreciable birefringence under polarized light. The birefringence does not disappear on annealing the copolymer a little below melting point, hence cannot be due to internal strain of the sample. Birefringence was hardly observed in the copolymer containing less than 80 mol% vinyl chloride. The melting points of the copolymers are shown as a function of their composition in Fig. 6. Figure 7 shows a plot reciprocal melting point *versus* logarithmic compossition. This relationship can be expressed by Flory's equation[8]

$$1/T_m-1/T_m^0=-(R/\Delta H_u)\ln N$$

where T_m is the copolymer melting point, T_m^0 that of the crystallizable homopolymer, N the mole fraction of crystallizable units in the copolymer, and ΔH_u the heat of fusion per mole of repeating unit. The slope of the straight line gives about 3900 cal/mol as the heat of fusion, which is in good agreement with the reported value of 3040 cal/mol.[18]

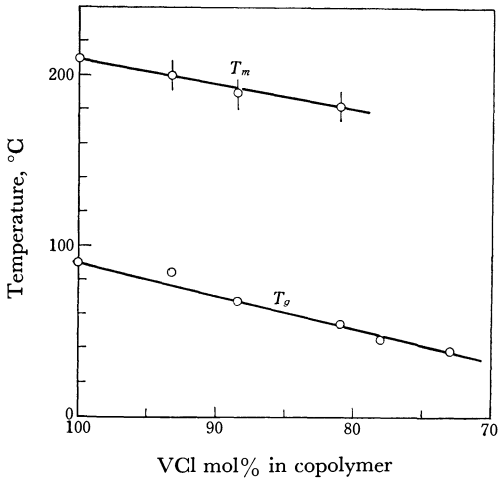

Fig. 6. Glass transition temperature and melting point of copolymers as a function of their composition.

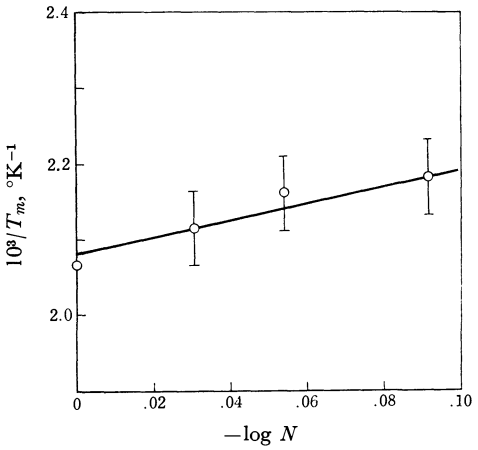

Fig. 7. Melting point depression of copolymer.

The results on the copolymer melting point, together with those on the infrared study and dynamic mechanical testing, prove that vinyl chloride-ethylene copolymers rich in vinyl chloride are more or less crystalline. From the linearity of Flory's plot the crystal structure of the original vinyl chloride segments does not seem to undergo change by copolymerization caused by the introduction of ethylene unit.

Some Thermal Properties of Deuterated Copper(II) Sulfate Pentahydrate

Hisaya Oki,*1 Eishin Kyuno and Ryokichi Tsuchiya

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received October 25, 1969)

Few papers can be found on the thermal behavior of the deuterated copper(II) sulfate pentahydrates except for that by Heinzinger and Rao,[1] who pointed out that the ratio of the quantity of the deuterium to that of hydrogen gradually increased as dehydration proceeded in partially deuterated copper(II) sulfate pentahydrates. The effect of deuteration in copper(II) salt hydrates upon thermochemical functions has been fully investigated so far.

The present work was undertaken to determine the thermochemical functions in the dehydration of copper(II) sulfate pentahydrates deuterated to different extents in order to find difference in thermal properties of hydrates.

Experimental

Preparation. Copper(II) sulfate pentahydrates, $CuSO_4\cdot 4H_2O\cdot D_2O$, $CuSO_4\cdot 3H_2O\cdot 2D_2O$, $CuSO_4\cdot 2H_2O\cdot 3D_2O$, $CuSO_4\cdot H_2O\cdot 4D_2O$ and $CuSO_4\cdot 5D_2O$ deuterated to different extents, were prepared according to the following schemes:

$$CuSO_4\cdot 5H_2O \begin{cases} \xrightarrow{50^\circ C} CuSO_4\cdot 3H_2O \xrightarrow{D_2O} CuSO_4\cdot 3H_2O\cdot 2D_2O \\ \xrightarrow{150^\circ C} CuSO_4\cdot H_2O \xrightarrow{D_2O} CuSO_4\cdot H_2O\cdot 4D_2O \\ \xrightarrow{260^\circ C} CuSO_4 \xrightarrow{D_2O} CuSO_4\cdot 5D_2O \end{cases}$$

$$CuSO_4\cdot 5D_2O \begin{cases} \xrightarrow{53^\circ C} CuSO_4\cdot 3D_2O \xrightarrow{H_2O} CuSO_4\cdot 2H_2O\cdot 3D_2O \\ \xrightarrow{150^\circ C} CuSO_4\cdot D_2O \xrightarrow{H_2O} CuSO_4\cdot 4H_2O\cdot D_2O \end{cases}$$

Each formula is reasonable for the preparation of respective hydrates.

Heavy water from Merck Co., Germany was used.

Measurements. Thermal analysis was carried out with a Metrimpex Derivatograph MOM Type-OD-102 made in Hungary, and the enthalpy changes and the activation energies on each step of dehydration were calculated by analyzing the DTA curves in the same manner as described previously.[2]

Infrared absorption spectra of these salts were measured in the Nujol mull state with a Nippon-Bunko DS-301 IR-Spectrophotometer. The X-ray powder patterns were obtained with a Rigaku-Denki Geiger-Flex X-ray Analyser.

Results and Discussion

Thermal Analyses. Dehydration of copper(II) sulfate pentahydrate and those deuterated partially or completely was found by derivatography to proceed in the following three distinct steps: the first and the second steps indicate liberation of each two moles of water from the hydrates and the DTA peaks in both steps are, to some extent, overlapped. The third one corresponds to the liberation of the last one mole of water.

The values of the weight loss percent due to the liberation of all the five moles of water determined from the derivatograms for the hydrates and the corresponding values calculated on the basis of each formula are listed in the second column of Table 1, together with the thermochemical data. We see that the above values of the two groups are almost consistent with each other in the respective hydrates. This supports the validity of the formulas for the hydrates.

The temperatures at which dehydration begins to take place are given in the third column of Table 1, where the values under I, II, and III deal with the first, second and third steps of dehydration, respectively. The activation energies, $E^{\neq}$, and enthalpy changes, ΔH, calculated by

analyzing the DTA curves are also included in both the forth and fifth columns of Table 1.

From these values the following information can be obtained. The temperatures at which the first step of dehydration begins are gradually elevated as the ratio of amounts of heavy water to those of ordinary water contained increases in the series of the hydrates except for $CuSO_4 \cdot 5H_2O$ and $CuSO_4 \cdot 4H_2O \cdot D_2O$ which have comparable data with each other, and the activation energies thereof also increase more and more in the same order. The results suggest that the liberation of ordinary water predominates in the first step of dehydration in both $CuSO_4 \cdot 5H_2O$ and $CuSO_4 \cdot 4H_2O \cdot D_2O$, whereas the ratio of heavy water against ordinary water liberated in the dehydration step becomes progressively greater in the order of $CuSO_4 \cdot 3H_2O \cdot 2D_2O$ through $CuSO_4 \cdot 5D_2O$.

On the other hand, the corresponding temperatures and the activation energies in the second step of dehydration are not so remarkably different from each other. The reason is not clear because of the ambiguity in the structure of each intermediate hydrates.

In the last step, the temperatures and activation energies of dehydration do not differ from each other as remarkably as in the first step, except for the especially smaller values for $CuSO_4 \cdot 5H_2O$. The results can be explained by assuming that the last one mole of water liberated is that of ordinary water in $CuSO_4 \cdot 5H_2O$, whereas in other hydrates, the last one mainly consists of heavy water, because the contribution of heavy water on dehydration becomes larger in the order of $CuSO_4 \cdot 4H_2O \cdot D_2O$ through $CuSO_4 \cdot 5D_2O$.

The enthalpy changes of dehydration do not differ sufficiently from each other in each step to give data for a discussion on dehydration.

X-Ray Powder Pattern. The X-ray powder patterns in several, stepwise deuterated copper sulfate pentahydrates were compared with each other in order to determine whether or not the structures of the salts differ depending upon the ratio of the amounts of heavy water to ordinary water. Their patterns are almost the same, however, and it seems that there is no appreciable structure deformation from the original according to the replacement of water by heavy water.

Infrared Absorption Spectra. Infrared absorption spectra of these copper(II) sulfate pentahydrates are shown Fig. 1. Despite the fact that the X-ray diffraction patterns of the sulfates are almost the same, the splitting of IR band assigned to SO_4 asymmetric vibration is complicated in the cases of $CuSO_4 \cdot 2H_2O \cdot 3D_2O$ and $CuSO_4 \cdot 3H_2O \cdot 2D_2O$. The reason is not clear. The ratio of the wave number of the absorption peak measured as the assignment to the stretching vibration of OH (3280 cm^{-1}) against that of OD (2410 cm^{-1}) was calculated to be 1.36, which is in good agreement with that generally accepted.

Syntheses of 4-Styryltropolones

Shunsuke NAKAMA,*1 Kimiaki IMAFUKU and Hisashi MATSUMURA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

(Received October 25, 1969)

The syntheses of colchicine and its derivatives led to the syntheses of many derivatives of 4-styryltropolone.[1-4] In order to examine the chemical reactivities of 4-styryltropolone, one of us (H. M.) investigated its reactions with various nucleophilic reagents.[5]

It was reported that the substituent on the tropolone ring affects the dissociation of tropolone derivatives.[6] It is of interest to know the extent of the effect of the substituent in the benzene ring of styryltropolones.

The present communication deals with the syntheses of 4-styryltropolones having *p*-methyl, *p*-chloro, *m*-chloro and *m*-nitro groups in the benzene ring.

Scheme 1

Syntheses

The starting material, 3-carboxy-4-carboxymethyltropolone (III), was prepared from pyrogallol (I) *via* purpurogallin (II).[7] Condensation of *p*-methyl-, *p*-chloro-, *m*-chloro- and *m*-nitrobenzaldehydes with III under a similar condition used for the synthesis of 4-styryltropolone[3] gave the substituted 3-carboxy-4-styryltropolones, IVb, IVc, IVd and IVe, respectively. 3-Carboxy-4-styryltropolones were heated under reduced pressure to afford the corresponding 4-styryltropolones, Vb, Vc, Vd and Ve, respectively.

Properties

Ultraviolet Absorption Spectra. The ultraviolet absorption spectra of 4-styryltropolones are shown in Fig. 1. The positions and molecular extinction coefficients of the maximum absorptions are listed in Table 1.

Table 1. UV Data of 4-styryltropolones: λ_{max}^{MeOH} mμ (log ε)

Va	236(4.14)	308(4.43)	338(sh.)	395(4.13)
Vb	239(4.19)	314(4.36)	352(sh.)	—
Vc	232(4.14)	310(4.33)	340(sh.)	390(4.00)
Vd	236(4.22)	306(4.45)	—	396(4.05)
Ve	223(4.11)	295(4.35)	—	394(3.95)

The pattern of all the absorption bands is very similar to that of 4-styryltropolone.[3,5] The absorption maxima in the 280—330 mμ region shift toward the long and short wavelengths with the presence of electron-donating and electron-attracting substituents, compared with that of 4-styryltropolone (308 mμ).

Infrared Absorption Spectra. The infrared spectral data of 4-styryltropolones are summarized in Table 2. As characteristic absorption bands, there are the $\nu_{C=O}$ and δ_{CH} (in *trans* –CH=CH–) absorption bands in 1610—1595 and 960—955 cm^{-1}, respectively.

Table 2. IR Data of 4-styryltropolones (in cm^{-1}; chloroform solution)

The ethylenic linkage which connects benzene ring with tropolone ring is found to be a *trans* configuration, because there is a very sharp absorption band in the 960—955 cm^{-1} region. This is also found in 3-carboxy-4-styryltropolones. It is found that the $\nu_{C=O}$ values are little affected by the substituents in the benzene ring.

Dissociation Constants. The dissociation constants were measured in 50% aqueous methanol. These values are listed in Table 3, and give the Hammett equation:

$$pK_a = 7.83 - 0.13\sigma$$

The details are described in another paper.[8]

Table 3. Dissociation constants of 4-styryltropolones

Compound	R	pK_a
Va	H	7.83
Vb	*p*-CH_3	7.85
Vc	*p*-Cl	7.81
Vd	*m*-Cl	7.76
Ve	*m*-NO_2	7.74

Experimental

Elementary analyses were performed in the Elementary Analyses Center of Kyushu University. All the melting points were measured on a Yanagimoto micro-melting point apparatus and are uncorrected. The infrared absorption spectra were taken on a JASCO DS-403G grating spectrophotometer in chloroform, and the ultraviolet absorption spectra on a Hitachi EPS-2 spectrophotometer in methanol.

3-Carboxy-4-styryltropolones (IVb—e). 3-Carboxy-4-carboxymethyltropolone (III) (10 mmol) was dissolved in acetic acid (30 ml) on gentle heating, and acetic anhydride (1.5 ml) was added to the solution at 50°C. After the solution was maintained at 80°C for 30 min, the solution was cooled down to 40°C, substituted benzaldehydes (10 mmol) and pyridine (0.7 ml) were added, and the mixture was kept at 40—45°C for 1 hr. The mixture was further heated up to 60°C, and stirring was continued for 3 hr after removal of the source of heat. The reaction mixture was poured into 10% hydrochloric acid (50 ml) which was cooled with ice to afford IVb—e. The yields and melting points are listed in Table 4.

Table 4. 3-Carboxy-4-styryltropolones

Compound	R	Yield (%)	Mp* (°C)
IVb	*p*-CH_3	83.1	196—199
IVc	*p*-Cl	85.5	204—206
IVd	*m*-Cl	81.5	169—172
IVe	*m*-NO_2	53.7	215—218

* Decomposition points.

4-Styryltropolones (Vb—e). 4-(Substituted styryl)-tropolones were obtained from IVb—e (5 mmol) by decarboxylation at 160—200°C/5 mmHg in a sublimation flask. The substances obtained were recrystallized from methanol. The yields, melting points and data of analyses are shown in Table 5.

The Carbon-13 NMR Spectra and *e*-Values of Vinyl Compounds

Koichi HATADA, Kazuhiko NAGATA and Heimei YUKI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received February 2, 1970)

The Q—e scheme has been proposed by Alfrey and Price[1] for systematizing large amounts of copolymerization data. In this scheme the Q value is associated with the resonance stabilization, and e is correlated with the polarity of the double bond or of free redical. Although these values have been determined for a wide variety of monomers and they agree fairly well with general chemical knowledge concerning the effect of substituents on resonance stabilization and on polarity,[2,3] direct evidence for their significance have not yet been obtained. In this paper we have correlated the e values of various monomers with the ^{13}C chemical shifts of their vinyl groups and have obtained additional support for the interpretation of the e values as a measure of polarity.

The ^{13}C chemical shifts of the vinyl group have been reported for several vinyl compounds (H_2C_β=$C_\alpha H$–X).[4-9] By plotting the ^{13}C chemical shifts of the β-carbon of the vinyl monomers, $\delta_{C\beta}$, against their e values, a fairly good straight line was ob-

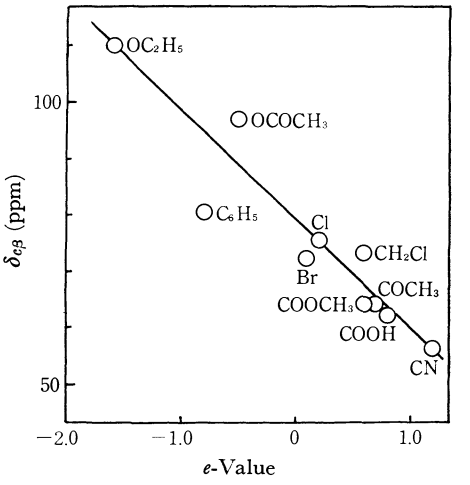

Fig. 1. $\delta_{C\beta}$ *vs.* e value.
δ is referred to CS_2, the high field shift being shown as the positive value.

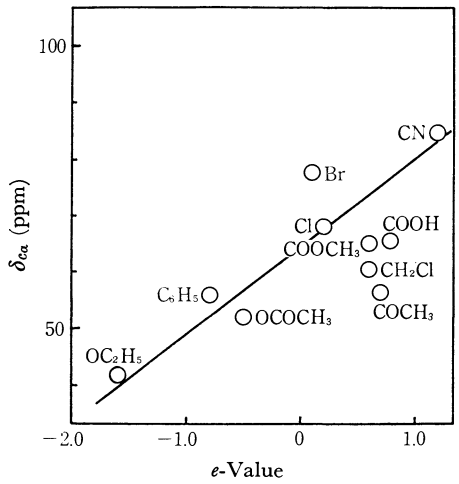

Fig. 2. $\delta_{C\alpha}$ *vs.* *e* value.

tained, as is shown in Fig. 1. The $\delta_{C\beta}$ value shifts to a lower field when the *e* value of the monomer becomes larger. A linear relationship was also obtained between the ^{13}C chemical shifts of α-carbon, $\delta_{C\alpha}$, and the *e* value, although the slope of the straight line was the reverse of that in Fig. 1 (Fig. 2). The ^{13}C chemical shift of the vinyl group has been reported to be mainly controlled by the π-electron density,[5,7,10] although it may also depend, to some extent, on some other factor such as the bond order or the average excitation energy. Therefore, it will show an upfield shift when the π-electron density on the carbon atom increases. Therefore, the results in Figs. 1 and 2 show that as the *e* value of the monomer increases, the π-electron density of the β-carbon decreases, and that of the α-carbon increases.

The vinyl compound with a positive *e* value generally has an electron-withdrawing substituent, and the π-electron in the double bond is drawn toward the substituent, so that the β-carbon is more electropositive. The reverse is the case with the monomer having a negative *e* value, and the β-carbon of the monomer of this type is more electronegative. The *e* value has been proposed as the measure of this polarity in the double bond. Therefore, the results mentioned above may be considered to be a convincing proof for the validity of the *e* value as a measure of the polarity.

The Acetylation of Acetamino-2,3-dimethylbenzofurans and the Synthesis of Furoquinolines*1

Yoshiyuki KAWASE and Shigeo KONDÔ

Department of Chemistry, Faculty of Literature and Science, Toyama University, Gofuku, Toyama

(Received February 17, 1970)

The acetylation of 2,3-dimethylbenzofuran derivatives has previously been reported in the cases of alkyl,[1–3] methoxyl,[4] hydroxyl,[5] halo,[6] acetyl,[7–9] and methoxycarbonyl[9] compounds. In the cases of the methoxyl, hydroxyl, and acetyl compounds, the acetylation occurred at the position under the influence of the substituent; it occurred at the 6-position under the influence of the furan ring in the cases of the methoxycarbonyl compounds, while it occurred at various positions in the cases of the alkyl compounds. It has also been reported that the nitration of the 5-acetamino-2,3-dimethyl-

*1 The major part of this work was presented at the 22nd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1969.

benzofuran afforded the 6-nitro derivative.[10]

Now, in the present experiments, the Friedel-Crafts acetylation of 4-, 5-, 6-, and 7-acetamino-2,3-dimethylbenzofurans[11] (**1**, **4**, **8**, and **12**) was carried out. The acetylated products (**2**, **5**, **9**, and **13**) obtained were hydrolyzed to the corresponding amino-ketones (**3**, **6**, **10**, and **14**), the structures of which were determined by the NMR data (see Table 2) and by converting the amino-ketones (**6**, **10**, and **14**) to the known 2,3-dimethyl-6- and -4-acetylbenzofurans (**7** and **11**) (see Chart 1). The coupling constants and δ-values in the NMR spectra indicate that **3** and **10** have aromatic *meta* protons, that **6** has *para* protons, and that **14** has *ortho* protons.

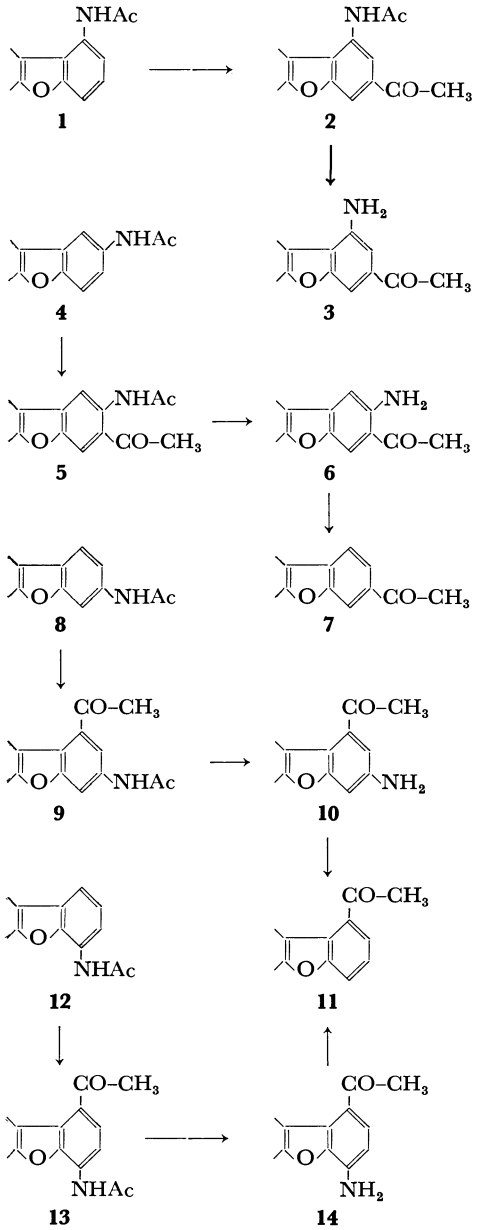

Chart 1

In conclusion, it may be considered that, in the electrophilic substitution, every position on the benzene ring of 2,3-dimethylbenzofuran, especially the 6-position, are activated by the furan ring, and that the acetylation of the compound **4** occurred at the 6-position, which is activated by both the furan ring and the acetamino group, while the compound **1** was acetylated at the 6-position, which is activated by the furan ring. Further, the compound **8** was acetylated at the 4-position, which seems to be fairly well activated by the furan ring, and the compound **12** was acetylated at the 4-position, which is activated by both the acetamino group and the furan ring.

Acetamino-ketone (**5**) was heated with an aqueous sodium hydroxide solution in ethanol to give a compound the structure of which was considered to be 2,3,8-trimethylfuro[2,3-*g*]-6(5*H*)-quinolone (**15**) on the basis of the data of elemental analysis and UV spectrum and on the basis of the analogous formation of 4-methyl-2(1*H*)-quinolone[12] by a similar reaction of *o*-acetaminophenyl methyl ketone (**17**). The treatment of **5** with polyphosphoric acid afforded a compound the structure of which was considered to be 6-(5-acetamino-2,3-dimethyl-6-benzofuranyl)-2,3,8-trimethylfuro[2,3-*g*]quinoline (**16**) on the basis of the data of elemental analysis and UV spectrum and on the basis of the analogous formation of 2-(*o*-acetaminophenyl)-4-methylquinoline (**18**) by a similar reaction of the acetamino-ketone (**17**). The quinoline (**18**) was also obtained by the acetylation of the corresponding amine (**20**), while the compounds **18** and **20** have been prepared by Camps[12] by the action of sodium hydroxide on **17** and amino-ketone (**19**) respectively. The quinoline (**16**) was also obtained in a low yield by the use of acetic acid and polyphosphoric acid on the acetaminobenzofuran (**4**) (see Chart 2).

a) From ethanol.

Experimental

All the melting points are uncorrected; the NMR spectra were measured on a JEOL Model JNM-C-60H (60 MHz) spectrometer, while the UV spectra were measured on a Hitachi Model 139 spectrophotometer. The melting points and elemental analyses are summarized in Table 1.

Acetylation of Acetaminobenzofurans. *a) By AcCl-$AlCl_3$.* Powdered aluminum chloride (1.3 g) was stirred into a mixture of **1**[11] (1 g), acetyl chloride (0.45 g), and carbon disulfide (20 m*l*); the new mixture was stirred for 3 hr at room temperature and then allowed to stand overnight. The mixture was poured into dilute hydrochloric acid and extracted with chloroform. The organic layer was washed with an aqueous sodium hydroxide solution. The residual product from the organic layer was crystallized from ethanol to give 4-acetamino-2,3-dimethyl-6-benzofuranyl methyl ketone (**2**); mp 181—182°C; 0.25 g (21%). Similarly, 5-acetamino-2,3-dimethyl-6-benzofuranyl methyl ketone (**5**) and 6- and 7-acetamino-2,3-dimethyl-4-benzofuranyl methyl ketones (**9** and **13**) were also obtained from acetaminobenzofurans (**4**, **8**, and **12**) in yields of 50, 58, and 20% respectively.

b) By Ac_2O-$AlCl_3$. Aluminum chloride (2.6 g) was added to a mixture of **1** (1 g), acetic anhydride (0.5 g), and carbon disulfide (20 m*l*), and the mixture was treated much as has been described in a) to give **2** in a yield of 50%. The other acetamino-ketones (**5**, **9**, and **13**) were also obtained in yields of 76, 71, and 35%.

Hydrolysis of the Acetamino-ketones. The acetamino-ketones (**2**, **5**, **9**, and **13**) were hydrolyzed by refluxing them for 1 hr with dilute hydrochloric acid in ethanol to give the corresponding 4- and 5-amino-2,3-dimethyl-6-benzofuranyl methyl ketones (**3** and **6**) and 6- and 7-amino-2,3-dimethyl-4-benzofuranyl methyl ketones (**10** and **14**) in yields of 41, 90, 85, and 41% respectively.

Deamination of the Amino-ketones. The amino-ketones (**6**, **10**, and **14**) were diazotized and then decomposed in the presence of copper powder by the usual procedure[13] to give 6-[1] and 4-benzofuranyl methyl ketones[9] (**7** and **11**) in yields of 57, 73, and 42% respectively.

The Catalytic Hydrogenation of 2,5-Diphenylfuran

Yutaka INAMURA

Department of Chemistry, Fukushima Medical College, Fukushima

(Received February 18, 1970)

The reductions of *trans*-1,2-dibenzoylethylene and its derivatives have been studied, and the reaction mechanisms have been discussed.[1)]

In the following experiment, the hydrogenation of 2,5-diphenylfuran, which was often obtained by these reductions, was carried out over several kinds of catalysts.

Experimental

2,5-Diphenylfuran (I). I was prepared from *trans*-1,2-dibenzoylethylene or 1,2-dibenzoylethylene oxide by the method of Lutz and Rowlett[2)] or by that of the present author.[1)]

Catalysts. The catalysts used were palladium-charcoal-A (5%), palladium-charcoal-B (5%), Raney nickel W-5, and Adams' platinum oxide, all of which were prepared by known methods.[3-6)]

Solvents. When Raney nickel was the catalyst, ethanol was used as the solvent, while in the case of the other catalysts, glacial acetic acid was used. One milliliter of concentrated hydrochloric acid or 0.05 g of sodium hydroxide was used as the additive.

Hydrogenation. I (1.1 g, 1/200 mol) was dissolved in 100 m*l* of a solvent, and reduction was then carried out over a catalyst (0.5 g, of Pd–C, 0.1 g of platinum oxide, or 0.5—1.5 g of Raney nickel) under atmospheric hydrogen pressure and at room temperature. After the reduction had been completed and the catalyst had been filtered out, the solvent was distilled off under reduced pressure. The residue was then recrystallized from 15 m*l* of ethanol. After the filtration of I, which was recovered as crystals, the filtrate was condensed to about 5 m*l*; the solution was subsequently kept below 0°C. After the substance, mp 54—55°C, had crystallized, it was filtered and the solvent of the filtrate was distilled off completely. This residue was recrystallized from *n*-hexane. A substance with a mp of 48—49°C was thus obtained. When platinum oxide was used as a catalyst, the raw reduction product was recrystallized from *n*-hexane after the filtration of the catalyst and the complete distillation of the solvent. The crystals thus obtained melted at 82—83°C. When the hydrogen uptake was stopped at less than 8 mol over platinum oxide, an oily substance, perhaps be a mixture of several intermediates, was produced.

1,4-Diphenyl-1-butanol (II) and 1,4-diphenyl-1-butanone (III), which had been prepared by the method of Stoemer and Schenck,[7,8)] were also reduced by the

same method as that described above.

Results

The results of the experiments are shown in Tables 1, 2, and 3. In the reduction of I, the maximum quantity of absorbed hydrogen was 3 mol when palladium-charcoal or Raney nickel was the catalyst, and 9 mol when Adams' platinum oxide was used. No effect was observed on the reduction products by the addition of an acid or an alkaline substance.

The substance (mp 48—49°C) yielded by the reaction of I with 2—3 mol of hydrogen with palladium-charcoal-B or Raney nickel as a catalyst was identified by a mixed-melting-point determination with 1,4-diphenyl-1-butanol, an authentic sample which had been synthesized by the method described in previous papers.[7,8] The IR spectrum of this substance showed an absorption at 3300 cm^{-1}.

The IR spectrum of the substance (mp 54—55°C) yielded by the reaction of I of 2 or 3 mol of hydrogen with palladium-charcoal-A, or that of the substance yielded by the reaction of 3 mol of hydrogen with palladium-charcoal-B or Raney nickel, showed no absorption of the hydroxyl group or the carbonyl group. The mixed-melting-point determination confirmed that this substance was 1,4-diphenylbutane (IV). The authentic sample of IV was prepared by the method of Freund[9] or by the hydrogenation of *trans*-1,2-dibenzoylethylene with 5 mol of hydrogen.[10]

The IR spectrum of the substance (mp 82—83°C) obtained in the hydrogenation of I over the Adams' platinum oxide catalyst showed an absorption at 3400 cm^{-1}. The chromic anhydride oxidation of this compound in glacial acetic acid gave an oily substance. The 2,4-dinitrophenylhydrazone made from it melted at 80—81°C. Moreover, the data of the elementary analysis of this substance (mp 82—83°C) proved it to be 1,4-dicyclohexyl-1-butanol (V).

Found: C, 80.51; H, 12.73%. Calcd for $C_{16}H_{30}O$: C, 80.61; H, 12.68%.

The ketone III was not obtained under any of the following conditions: that is, when large quantities of I were used, when the absorption period was shortened, when a small quantity of hydrogen was absorbed, or when the solvents were changed.

Discussion

The hydrogenation of furan derivatives has been well examined,[11] and the reductions of 2-phenylfuran and 2-phenyltetrahydrofuran have been reported on by Mitsui and his co-workers.[12] These reports indicate that hydrogenation mainly occurs when palladium-charcoal or Raney nickel is used as the catalyst, while hydrogenation and hydrogenolysis occur competitively over the platinum oxide catalyst.

The present results show that 2,5-diphenylfuran also undergoes hydrogenolysis to give II and IV

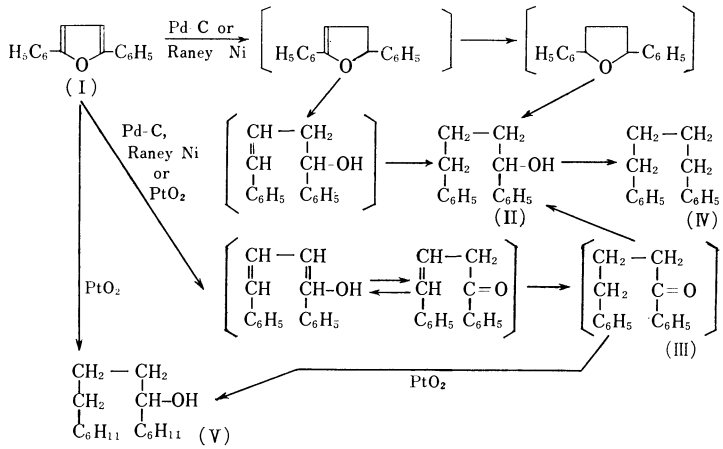

Fig. 1

over the palladium-charcoal or the Raney nickel catalyst.

Some possible courses of the reduction of I are shown in Fig. 1. The hydrogenation of I over Raney nickel gave more II than that over the palladium-charcoal catalyst. The results presented above and those of Table 2 show that the hydrogenation of I took the course: I→II→IV and that the II→IV course was more difficult over the Raney nickel catalyst than over the palladium-charcoal catalyst.

It is well known that the benzene ring is hydrogenated over the platinum catalyst.[13] In the present experiment, too, after the cleavage of the furan ring and the saturation of the benzene ring of I, V was produced. Though III easily gave II and IV, as is shown in Table 3, III was not obtained at all in the reduction of I.

The compounds described in brackets in Fig. 1 were not isolated; therefore, it is uncertain which course of those shown in Fig. 1 is mainly taken in this reaction. However, from the fact that III which, if present, is expected to crystallize easily, was not obtained under any of the conditions described above, and from the fact that 2-aryltetrahydrofuran is easily hydrogenated,[12] it can be said that the hydrogenation of I seems to take the reaction course of, first, the reduction of the furan ring, and then the reaction II→IV.

The author wishes to express his cordial thanks to Professor Sekio Mitsui, Faculty of Engineering, Tohoku University.

The Electron Spin Resonance Spectra of Dicyanobiphenyl Radical Anions

Hideo SHIKATA,*1 Kazuhiko ISHIZU,*1 Yasuo DEGUCHI and Hideo TAKAKI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received February 19, 1970)

Some of the radical anions of biphenyl and its derivatives, produced by the reduction with alkali metals, show ESR spectra which can be interpreted in terms of the pairing of the alkali metal cation with the anion. As a remarkable case, the dinitrobiphenyl radical anions[1] have their unpaired electron localized only one of the nitrophenyl rings. In the course of several previous studies,[1-3] the ESR spectra have been observed for the radical anions of several dicyanobiphenyls, substances which possess substituents with a weaker electron-withdrawing tendency than that of the nitro groups.

Experimental

Dicyanobiphenyls were synthesized by the following procedures:

2,2′-Dicyanobiphenyl. Diphenic acid[4] obtained from anthranilic acid with a Sandmeyer reaction was converted to its diamide by repetition of the anhydration with acetic anhydride and by treatment with ammonium hydroxide,[5] the diamide was finally anhydrated with acetic anhydride to its dinitrile, 2,2′-dicyanobiphenyl,[6] mp 177°C.

3,3′-Dicyanobiphenyl. 3,3′-Dinitrobiphenyl[7] was synthesized from *m*-iodonitrobenzene[8] by Ullmann's method. It was then reduced to 3,3′-diaminobiphenyl in the presence of Raney nickel. 3,3′-Diaminobiphenyl was tetrazotized and added to the hot $KCN-CuSO_4$ solution to obtain 3,3′-dicyanobiphenyl, mp 201°C.

4,4′-Dicyanobiphenyl. 4,4′-Dicyanobiphenyl[9] was prepared from benzidine by the same procedures as those used in the last step used in obtaining 3,3′-dicyanobiphenyl, mp 221°C.

All the final products were purified by vacuum sublimation or by recrystallization from ethanol several times.

The radical anions were prepared by reduction with potassium, sodium, lithium, or cecium in some solvent such as 1,2-dimethoxyethane, tetrahydrofuran, or tetrahydropyran. The reduction of 4,4′-dicyanobiphenyl gave a fairly stable radical anion at room temperature, whereas 2,2′-dicyanobiphenyl and 3,3′-dicyanobiphenyl radical anions were found to be stable only at the temperature of an acetone-dry ice bath. Therefore, the ESR spectra were examined in detail for only the 4,4′-diycanobiphenyl radical anions.

The ESR spectra were measured using a JEOL-3B X-band-type ESR spectrometer with a 100 kc/sec field modulation.

Results and Discussion

The observed spectra for dicyanobiphenyls are shown in Fig. 1. Rieger *et al.*[10] have reported that the radical anion produced by the electrolytic reduction of *p*-cyanoaniline showed the ESR spectrum of the 4,4′-dicyanobiphenyl radical anion. Our observation for synthesized 4,4′-dicyanobiphenyl supports their interpretation.

The hyperfine splitting constants for the proton summarized in Table 1, were assigned by taking into account the results of the McLachlan MO calculation, though those results are not unarbitrary. The experimental spin density for the ring carbon atoms is calculated from the McConnell relation, $a_H=Q\rho_C$, where $Q=23.7$ gauss, while for the nitrogen atom of the cyano group, $A_N=K\rho_N$ is used (according to Rieger and Fraenkell[11]), where $K=19.8$ gauss. The experimental spin density is then compared with that obtained from either the simple Hückel MO or the McLachlan MO calculation.

In contrast to the dinitrobiphenyl ion pairs, no alkali metal splitting was found for the 4,4-dicyanobiphenyl radical anion, though we repeatedly observed solutions with a variety of solvents, using different alkali metal and at temperatures from 20°C to −90°C. Moreover, the unpaired spin distribution was found to be symmetrical for two cyanophenyl rings of dicyanobiphenyl. These results suggest that the ion pairing, if any, is rather weaker in this case. The difference may be the weaker electron-withdrawing tendency of the cyano group than that of the nitro group.

When terephthalonitrile, which has a structure analogous to 4, 4′-dicyanobiphenyl, is reduced with lithium, it is known that the ESR spectrum

10) P. H. Rieger, I. Bernal, W. H. Reinmuth and G. K. Fraenkel, *J. Amer. Chem. Soc.*, **85**, 683 (1963).

11) P. H. Rieger and G. K. Fraenkel, *J. Chem. Phys.*, **37**, 2795 (1962).

shows an extra-hyperfine splitting of lithium and results in an asymmetric spin distribution of the anion.[12] In order to explain the difference in the ion pairing between the two cases, the π electron energy of these anions was estimated by the Hückel MO method on the following assumption: the accession of the alkali metal to one of the cyano groups leads to the variation of the Coulomb integral parameter, h_N, at its nitrogen atom, where $\alpha_N=\alpha+h_N\beta$. As the result of the calculations,

$$\left[\frac{\partial E}{\partial h_N}\right]_{h_N=1.0}(\text{terephthalonitrile}) - \left[\frac{\partial E}{\partial h_N}\right]_{h_N=1.0}(\text{4,4'-dicyanobiphenyl}) = 0.042\beta,$$

where E is the total π electron energy of the anion and where β is the resonance integral. This may mean that the 4,4'-dicyanobiphenyl radical anion is less stabilized by the ion-pair formation than is the terephthalonitrile radical anion. Though no consideration was made of the energy of the lone-paired electrons and of the solvation, this calculation can explain the experimental results qualitatively.

The authors are grateful to Drs. Kazuo Nakamura, Hiroaki Nishiguchi, and Kazuo Mukai for their kind discussions throughout the work. The authors also wish to thank Mr. Hideo Hasegawa for his simulation of the spectra.

Synthetic Studies of the Flavone Derivatives. XVIII.*1 The Syntheses of 5,7,3′-Trihydroxy-3,8,4′,5′-tetramethoxyflavone and Related Compounds

Mitsuru NAKAYAMA and Kenji FUKUI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

and Tokunaru HORIE and Mitsuo MASUMURA

Department of Applied Chemistry, Faculty of Engineering, University of Tokushima, Tokushima

(Received March 3, 1970)

Recently, a new pigment isolated from *Beyeria brevifolia* (Muell Arg.) Benth.[1] was identified as 5,7,3′-trihydroxy-3,8,4′,5′-tetramethoxyflavone (I).

The present paper will describe the syntheses of I and its related compounds from 3,ω-dimethoxy-2,4,6-trihydroxyacetophenone (II)[2] by a modification of a procedure reported earlier.[2–6]

According to the method of Allan-Robinson's flavone synthesis, the condensation of the ketone II with 3-benzyloxy-4,5-dimethoxybenzoic anhydride and potassium 3-benzyloxy-4,5-dimethoxybenzoate, followed by treatment with alcoholic potassium hydroxide, was expected to afford a mixture of 3′-benzyloxy-5,7-dihydroxy-3,6,4′,5′-tetramethoxyflavone (III) and the 3′-benzyl ether (IV) of I. The reaction mixture could be separated into two crystals, A (mp 159.5—160.5°C) and B (mp 126—127 and 135—135.5°C), by a fractional partition. The catalytic hydrogenolysis of A over Pd–C gave the 5,7,3′-trihydroxyflavone derivative (V), which was then converted into the triacetate (VI), triethyl (VII), and trimethyl ether (VIII) with usual methods. The properties of VIII were superimposable upon those of 3,5,6,7,3′,4′,5′-heptamethoxyflavone.[7,8] Further, in the NMR spectra data*2

of VII and VIII, the chemical shift (δ *ca.* 6.70) of the singlet peak (1H) was very similar to that due to the C-8 proton of some flavones reported in the literature.[2-9] From the above results, A and V may be formulated as III and 5,7,3′-trihydroxy-3,6,4′,5′-tetramethoxyflavone respectively. On the other hand, the singlet peak at δ 6.46 (1H) of B can be assigned to the C-6 proton of the flavone nucleus. Thus, B is identified as the benzyl derivative (IV) of I. The hydrogenolysis of IV gave the desired flavone, I, which was then easily derived to triacetate (IX) and triethyl ether (X). The properties of the synthetic flavones (I, IX and X) were consistent with those described in an earlier report.[1]

By a similar method, 5,7-dihydroxy-3,6,3′,4′,5′-pentamethoxyflavone (XI), which was easily converted into diacetate (XII) and diethyl ether (XIII), was prepared from II and 3,4,5-trimethoxybenzoic anhydride. XIII was also prepared by the reaction of the 4,6-diethoxy-5,ω-dimethoxy-2-hydroxyacetophenone (XIV)[2] with 3,4,5-trimethoxybenzoic anhydride. The dimethyl ether of XI was found to be identical with VIII by a direct comparison.

3′-Benzyloxy-5,7-dihydroxy-3,6,4′,5′-tetramethoxyflavone (III) and 3′-Benzyloxy-5,7-dihydroxy-3,8,4′,5′-tetramethoxyflavone (IV). A mixture of II (2.5 g),[2] 3-benzyloxy-4,5-dimethoxybenzoic anhydride (25 g), and potassium 3-benzyloxy-4,5-dimethoxybenzoate (9 g) was heated at 175—180°C under reduced pressure for 10 hr; the mixture was then treated by a method analogous with those of previous reports[2-6] to give an oily flavone mixture (*ca.* 3.5 g).

The mixture was dissolved with a 5% aqueous potassium hydroxide solution (50 m*l*) and then allowed to stand in a refrigerator. The precipitate thus separated was collected to give potassium salt of flavone. After the mother liquor had been acidified with hydrochloric acid, the resulting oily material was repeatedly treated with a solution of potassium hydroxide (1.2 g) and potassium carbonate (3.0 g) in water (20 m*l*). The second crop of the potassium salt was thus obtained.

The mother liquor was acidified with hydrochloric acid and extracted with ether. After the solvent had been removed, the residue was dissolved with absolute ether (*ca.* 10 m*l*) and then allowed to stand in a refrigerator. The crystals thus separated were collected and recrystallized from aqueous methanol to give a hydrate of IV as pale yellow needles; mp 95—100°C (67—68°C sinter); yield, 240 mg (4.5%). This was recrystallized from absolute ether to give yellow needles; mp 126—127°C and 135—135.5°C. UV: λ_{max} mμ (log ε); (EtOH) 278 (4.33), 314 (4.17), 370$_{sh}$ (4.05);*4 (EtOH–AcONa) 286 (4.39), 364 (3.99); (EtOH–$AlCl_3$) 288.5 (4.27), 314 (4.17), 349 (4.18), 420 (3.87). NMR:*2 6.46$_s$ (C_6–H), 7.40—7.60$_m$ (7H; $C_{2'}$–H, $C_{6'}$–H and $C_6\underline{H}_5CH_2$).

Found: C, 64.90; H, 5.18%. Calcd for $C_{26}H_{24}O_9$: C, 64.99; H, 5.04%.

The combined potassium salt of flavone was treated with diluted hydrochloric acid and extracted with ether. After the solvent had then been removed, the residue was recrystallized from ethanol to give III as pale yellow needles; mp 159.5—160.5°C; yield, 700 mg (13%). UV: λ_{max} mμ (log ε); (EtOH) 275 (4.21), 339 (4.29); (EtOH–AcONa) 277.5 (4.35), 304 (4.12), 352 (4.14); (EtOH–$AlCl_3$) 258 (4.09). 284 (4.17), 355 (4.27). NMR:*2 6.57$_s$ (C_8–H), 7.35—7.60$_m$ (7H; $C_{2'}$–H, $C_{6'}$–H $C_{6'}$–H and $C_6\underline{H}_5CH_2$).

Found: C, 64.75; H, 4.94%. Calcd for $C_{26}H_{24}O_9$: C, 64.99; H, 5.04%.

5,7,3′-Trihydroxy-3,6,4′,5′-tetramethoxyflavone (V). A solution of III (325 mg) dissolved in a mixture of ethyl acetate and methanol (1 : 1 : 100 m*l*) was shaken with Pd–C (10% : 140 mg) in hydrogen. The product was recrystallized from methanol to give V as yellow needles; mp 163.5—164.5°C; yield, 237 mg (90%). UV: λ_{max} mμ (log ε); (EtOH) 275 (4.21), 343 (4.28); (EtOH–AcONa) 277 (4.45), 304 (4.14), 378 (4.22); (EtOH–$AlCl_3$) 283 (4.20), 358 (4.29).

Found: C, 58.70; H, 4.82%. Calcd for $C_{19}H_{18}O_9$: C, 58.46; H, 4.65%.

Triacetate (VI). Mp 126—127°C (colorless prisms from ether). UV: λ_{max}^{EtOH} mμ (log ε); 248 (4.31), 327 (4.31).

Found: C, 58.23; H, 4.76%. Calcd for $C_{25}H_{24}O_{12}$: C, 58.14; H, 4.68%.

Triethyl Ether (VII). Mp 111.5—112.5°C (colorless needles from ether). UV: λ_{max}^{EtOH} mμ (log ε); 267$_{sh}$ (4.19), 328 (4.39). NMR:*2 6.72$_s$ (C_8–H), 7.37$_s$ (2H; $C_{2'}$–H and $C_{6'}$–H).

Found: C, 63.19; H, 6.43%. Calcd for $C_{25}H_{30}O_9$: C, 63.28; H, 6.37%.

Trimethyl Ether (3,5,6,7,3′,4′,5′-Heptamethoxyflavone) (VIII). Mp 153—154°C (colorless needles from methanol) (lit, mp 155—156°C,[7] 156—157°C[8]). UV: λ_{max}^{EtOH} mμ (log ε); 267$_{sh}$ (4.22), 327.5 (4.35). NMR:*2 6.74$_s$ (C_8–H), 7.38$_s$ (2H; $C_{2'}$–H and $C_{6'}$–H).

Found: C, 60.90; H, 5.51%. Calcd for $C_{22}H_{24}O_9$:

Laser-induced Chemical Reactions. IV. Reactions of Carbon Vapor with Hydrogen at Various Pressures

Ko TAKI, Pil Hyon KIM and Susumu NAMBA

The Institute of Physical and Chemical Research Yamato-machi, Saitama

(Received March 12, 1970)

In previous papers,[1-3] the present authors have described the reaction of carbon vapor produced by the irradiation of a focused laser beam with hydrogen and low hydrocarbons. In this paper the effect of the hydrogen pressure in the reaction of the carbon vapor from graphite carbon is investigated; the reactions of hydrogen with the carbon vapor from silicon carbide and boron carbide are also investigated. The experimental procedures were almost the same as those described in the previous papers. The ruby laser used was a normal laser, the output energy and pulse duration of which were 3 J and 0.5 msec respectively. The laser beam was focused by a lens 35 mm in focal length upon the carbon target. The surface temperature[4] of the carbon target was estimated to be 3000—4000°K. After 2—5 pulse irradiations, the products were analysed by gas chromatography.

Results and Discussion

In the reaction of carbon vapor with hydrogen, the main products are acetylene and methane, as has previously been shown. In order to examine the reaction in detail, experiments were carried out at various hydrogen pressures; the representative product yields per pulse were 0.0063×10^{-7} mol for methane and 1.8×10^{-7} mol for acetylene at 20 Torr H_2, and 0.12×10^{-7} mol for methane and 4.7×10^{-7} mol for acetylene at 350 Torr H_2. The ratio of the acetylene to the methane varied with the

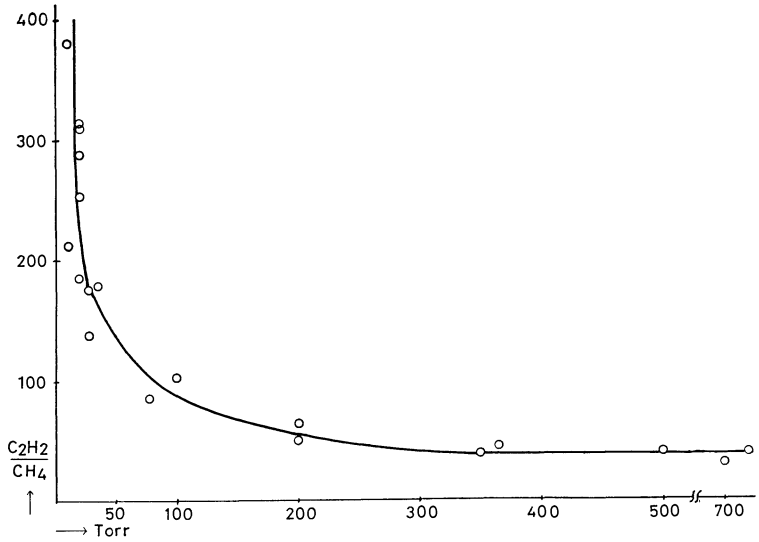

Fig. 1. Ratio of C_2H_2/CH_4 *vs.* hydrogen pressure.

hydrogen pressure, as is shown in Fig. 1. At a low hydrogen pressure, the methane yield is extremely small as compared with the acetylene yield, and the ratio of acetylene to methane increases. Such a variation was also observed in mixtures of helium or nitrogen: the C_2H_2/CH_4 ratio was about 150/1 at 30 Torr H_2 and 730 Torr He. From the above results, it may be considered that the ratio does not depend on the total pressure, but on the hydrogen concentration.

A pulse laser irradiated on a carbon target produces about a 10^{-6} mol carbon atom as a jet stream, which then reacts with the substrate*1 to form products. The volume of the carbon stream is estimated to be about 1 cm^3, as is shown in Fig. 2. A high hydrogen pressure (300—760 Torr)

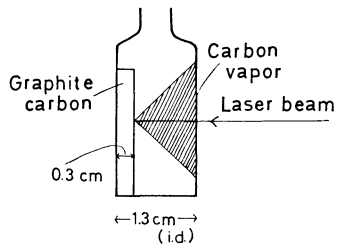

Fig. 2. Reaction cell for irradiation.

contains about 10^{-5} mol hydrogen molecules in each 1 cm^3 volume; therefore, the concentration of hydrogen in the reaction region is much higher than that of carbon vapor. On the other hand, at hydrogen pressures less than 100 Torr, the concentration of hydrogen is equivalent to or less than that of carbon vapor.

The reaction in a differently-designed cell*2 having a long passage (2.0 cm from the carbon target to the glass wall) gave a slightly smaller ratio of C_2H_2/CH_4 than in the former cell; the ratio of C_2H_2/CH_4 was about 200/1 at 20 Torr H_2. In this case, as the volume of carbon stream is larger than in the former cell, the concentration of carbon vapor is lower than in the former.

The above experimental facts indicate that acetylene and methane may not be produced from a common precursor. The acetylene and methane precursors may be C_2 and C_1 respectively, as has previously been shown.[1,2] Acetylene and methane are produced throughout several reaction steps. The details of the formation processes of acetylene and methane are not yet clear, and the rate constant of each step is also unknown, but the reaction may be as follows. In a low concentration of hydrogen, both the C_1 and C_2 species may react with hydrogen competitively. In this case, acetylene may be formed more easily than methane, because two hydrogen molecules are necessary for the formation of methane, while one molecule is enough for the formation of acetylene. It may also be considered that acetylene is formed by the reaction of the methane precursor with C_1, consequently increasing the C_2H_2/CH_4 ratio.

Similar experimental results were obtained in the C_3-compound formations. The ratio of C_4/C_3*3

*1 This reaction has been called an energetic carbon plasma-type reaction by Wiley and Veeravagu.[5]

5) R. H. Wiley and P. Veeravagu, *J. Phys. Chem.*, **72**, 2417 (1968).

*2 At pressures of less than 100 Torr of hydrogen, the reaction cell was contaminated by the deposited carbon vapor, but the long cell was less contaminated.

*3 The yields of C_3 and C_4 compounds were determined by the measurement of the yields of the propane and butane which are formed by the catalytic hydrogenation of products. The main C_4 compounds are diacetylene, and the main C_3 compounds are propylene and allene.

Table 1. Product yield of C_2, C_3 and C_4 compounds at various pressure of hydrogen in graphite carbon

Pressure of H_2 (Torr)	Number of irradiation	Product yield ($\times 10^{-7}$ mol)			Ratio	
		C_2-comp.	C_3-comp.	C_4-comp.	C_4/C_2	C_4/C_3
350	2	13	0.17	0.74	0.057	4.4
350	2	15	0.17	0.63	0.042	3.7
350	1	6.0	0.077	0.25	0.042	3.2
20	4	11	0.045	0.87	0.079	19
21	2	6.0	0.023	0.40	0.067	17

increases at a low hydrogen pressure, but the ratio of C_4/C_2 is almost constant, as is shown in Table 1. C_3 compounds need much more hydrogen than C_4 compounds need hydrogen.

Another experimental finding also supports the above discussion. When the power density of the irradiated beam was lowered by defocusing, the decrease in methane as compared with that in acetylene was not remarkable at hydrogen pressures of 20 Torr and 350 Torr, as is shown in Table 2. This result may be explained by the fact that the concentration of the carbon vapor produced by such weakened beam is lower than that of hydrogen.

Table 2. Product yield of methane and acetylene produced by the weakenned laser beam in graphite carbon

Power density	Pressure of H_2 (Torr)	Number of irradiation	Product yield ($\times 10^{-7}$ mol)		Ratio C_2H_2/CH_4
			CH_4	C_2H_2	
1/4 of the focused beam	350	2	0.078	3.0	38.0
	20	5	0.019	2.6	137
1/10 of the focused beam	350	4	0.16	6.5	40.6
	20	10	0.063	3.8	60.3

Moreover, from the fact that the product yields[2] were not affected by such radical scavengers as NO and O_2, it may be considered that the reaction is brought about in a jet stream of carbon vapor, and that, because of the high concentration of carbon vapor, all the scavengers react mainly with carbon vapor and do not react with the acetylene and methane precursors.

The carbon vapor from silicon carbide and boron carbide[*4] also gave acetylene and methane in the reaction with hydrogen. However, the product yields were about one-tenth as much as in the reaction of carbon vapor from graphite carbon. This may be explained by the fact that the concentration of the carbon vapor produced from silicon carbide and boron carbide is less than that from graphite carbon. The data are listed in Table 3. Spectroscopically, the Swan bands were also observed in the carbon vapor from silicon carbide, as had been observed in that from graphite carbon. In the reaction of the carbon vapor from silicon and boron carbide with hydrogen, no pressure dependence such as that described above was observed. These experimental results also support the explanation of the pressure dependence in acetylene and methane formation. The reaction occurs in a jet carbon stream.

Table 3. Product yield of methane and acetylene in silicon carbide(SiC) and boron carbide ($B_{12}C_3$)

Target	Pressure of H_2 (Torr)	Number of irradiation	Product yield ($\times 10^{-7}$ mol)		Ratio C_2H_2/CH_4

Reaction of 1-*t*-Butyl-2-cyanoazetidine with Silver Nitrate or Silver Perchlorate

Takayoshi MASUDA, Akiko CHINONE and Masaki OHTA

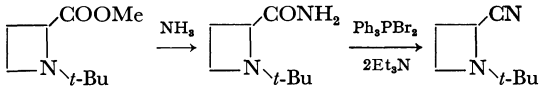
Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 30, 1970)

Studies on the syntheses and reactions of azetidine derivatives having functional substituent at 2-position are very few. Recently Rodebaugh and Cromwell[1] have reported the syntheses of methyl 1-alkylazetidine-2-carboxylates by the reaction of primary amines with methyl α,γ-dibromobutyrate, and these azetidine-2-carboxylates are suitable for our studies on the preparation and reactions of various azetidine derivatives.

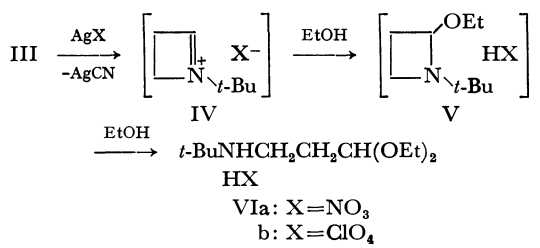
We wish to report on the synthesis of 1-*t*-butyl-2-cyanoazetidine and its reactions with silver nitrate or silver perchlorate in ethanol anticipating the intermediacy of 1-*t*-butyl-1-azetinium salt.

When methyl 1-*t*-butylazetidine-2-carboxylate (I) was allowed to react with liquid ammonia in a sealed tube at room temperature for a week, 1-*t*-butylazetidine-2-carboxamide (II) was obtained in good yield. Reaction of II with triphenylphosphine dibromide in the presence of two equivalents of triethylamine gave 1-*t*-butyl-2-cyanoazetidine (III) in 71% yield.



I II III

It is known that α-aminonitriles afford iminium salts by silver nitrate.[2] Treatment of III, which is cyclic α-aminonitrile, with silver nitrate or silver perchlorate in absolute ethanol gave *t*-butyl-(3,3-diethoxypropyl)ammonium nitrate (VIa) or perchlorate (VIb) instead of the expected 1-*t*-butyl-1-azetinium nitrate or perchlorate (IV). The structure of VI was determined by means of elementary analysis, infrared spectrum and NMR spectrum.



VIa: X=NO_3
b: X=ClO_4

In this reaction, silver cyanide was obtained almost quantitatively, which suggests the formation of azetinium salt (IV) as an intermediate. However, IV is highly strained and reacts easily with ethanol affording VI, presumably *via* 1-*t*-butyl-2-ethoxyazetidinium nitrate (Va) or perchlorate (Vb) as shown above. This mechanism is strongly supported by the fact that 1-phenyl-2-methoxy-3,3-dimethylazetidine is unstable and reacts with methanol to give anilinoacetal.[3] We found that 1-*t*-butyl-2-cyanoaziridine gave only adduct with silver perchlorate,[4] probably due to the difference of ring strain between azetidines and aziridines. Attempts to isolate IV by using aprotic solvents such as acetonitrile or methylene chloride were unsuccessful and gave only resinous product in spite of the formation of silver cyanide.

Experimental

1-*t*-Butylazetidine-2-carboxamide (II). A mixture of methyl 1-*t*-butylazetidine-2-carboxylate (8.6 g), liquid ammonia (50 m*l*) and aqueous methanol (1 : 1, 5 m*l*) was stirred in a sealed tube at room temperature for a week. Ammonia was evaporated by standing overnight at room temperature. Methanol and water were removed by vacuum distillation to give an oily residue which crystallized on standing for several hours. Recrystallized from *n*-hexane. Mp 80—81°C. Yield, 7.5 g (94%).

Found: C, 61.61; H, 10.02; N, 18.21%. Calcd for $C_8H_{16}ON_2$: C, 61.50; H, 10.32; N, 17.93%.

Picrate: mp 186.5—187.5°C.

Found: C, 43.91; H, 5.25; N, 18.11%. Calcd for $C_{14}H_{19}O_8N_5$: C, 43.64; H, 4.97; N, 18.18%.

1-*t*-Butyl-2-cyanoazetidine (III). To a solution of triphenylphosphine dibromide (prepared from 27.5 g of triphenylphosphine, 16.8 g of bromine and 21.2 g of triethylamine) in acetonitrile (120 m*l*) was added a solution of amide (II) in acetonitrile (30 m*l*). After heating for 20 min, acetonitrile was removed in a vacuum and the residue was extracted with petroleum ether, dried over anhydrous sodium sulfate and the solvent was removed by distillation. The residual oil was distilled under reduced pressure. Bp 55—56.5°C/2.5 mmHg. Yield, 8.6 g (71%). NMR ($CDCl_3$, τ): 8.98 (9H, singlet), 7.38—7.92 (2H, multiplet), 6.72—6.92 (2H, multiplet), 6.02 (1H, triplet).

Found: C, 69.57; H, 9.98; N, 20.00%. Calcd for $C_8H_{14}N_2$: C, 69.52; H, 10.21; N, 20.27%.

Picrate: mp 158—159°C (decomp.).

Found: C, 46.01; H, 4.43; N, 19.05%. Calcd for $C_{14}H_{17}O_7N_5$: C, 45.78; H, 4.69; N, 19.07%.

Perchlorate: mp 170—171°C (decomp.).

Found: C, 40.23; H, 6.04; N, 11.81%. Calcd for $C_8H_{15}O_4N_2Cl$: C, 40.26; H, 6.34; N, 11.74%.

Reaction of III with Silver Nitrate in Ethanol. To a suspension of silver nitrate (2.84 g) in 15 m*l* of ethanol, was added dropwise a solution of III in ethanol (5 m*l*). After stirring for 3 hr at room temperature, silver cyanide was filtered off, the filtrate was concentrated in a vacuum and absolute ether was added to give 2.9 g of VIa. Recrystallized from ethyl acetate–ligroin; mp 71.5—73°C.

Found: C, 49.36; H, 9.65; N, 10.71%. Calcd for $C_{11}H_{26}O_5N_2$: C, 49.60; H, 9.84; N, 10.52%. IR (KBr): 2700—2300, 2030, 1575 cm^{-1} (NH_2^+), 1405, 1370, 830 cm^{-1} (NO_3^-), 1135, 1110, 1075 cm^{-1} (C–O–C). NMR ($CDCl_3$, τ): 8.81 (6H, triplet), 8.60 (9H, singlet), 7.92 (2H, quartet), 6.87 (2H, broad singlet), 6.25—6.60 (4H, multiplet), 5.37 (1H, triplet), 1.55 (2H, broad singlet).

Reaction of III with Silver Perchlorate in Ethanol. The procedure was the same as described above. Starting from 2.76 g of III, 4.7 g of VIb was obtained; mp 89.5—90°C (ethyl acetate–ligroin).

Found: C, 43.64; H, 8.35; N, 4.85%. Calcd for $C_{11}H_{26}O_6NCl$: C, 43.49; H, 8.63; N, 4.61%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3282—3284 (1970)

Preparation of 5-Acetyl-8-quinolinol Derivatives

Konomu MATSUMURA, Hisashi OKUMA, Miyoko ONISHI and Akiko IKEMURA

Department of Chemistry, Kitasato University, Minato-ku, Tokyo

(Received April 9, 1970)

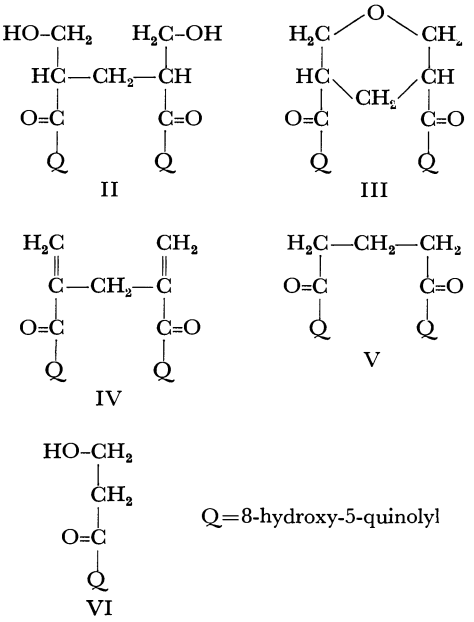
It has been reported[1,2] that 5-acetyl-8-quinolinol (I) was obtained by the Friedel-Crafts reaction of 8-quinolinol and when heated with formalin in the absence of base, I gave 1,5-bis-(8-hydroxy-5-quinolyl)-1,5-dioxopentane (V) instead of the expected methylol compound VI.

In the present experiments, it was found that 8-acetoxyquinolinium chloride on treating with aluminum chloride in nitrobenzene gave 5-acetyl-8-quinolinol (I) with a comparable yield as in the case of the Friedel-Crafts reaction.

The reaction of 5-acetyl-8-quinolinol (I) with formaldehyde as well as bromination of I were investigated.

It was found that reaction of I with formaldehyde in the presence of aqueous sodium hydroxide at room temperature led to the formation of 2,4-bis(8-hydroxy-5-quinolylcarbonyl)-1,5-pentanediol (II). In accordance with the structure II, strong intramolecular hydrogen bond was observed in the region on 3000 cm^{-1} in the IR spectrum of II.

On heating it in crystals at 180°C or in the concentrated sulfuric acid solution at water bath temperature, II was converted into 3,5-bis(8-hydroxy-5-quinolylcarbonyl)tetrahydropyrane (III). On the other hand, on heating of the solution in 30% sulfuric acid on a water bath, II afforded 2,4-bis(8-hydroxy-5-quinolylcarbonyl)-1,4-pentadiene (IV) in a good yield. On heating of ethanol or 6N hydrochloric acid solution of II at water bath temperature, a part of II was converted into



1) K. W. Rosenmund and G. Karst, *Arch. Pharm.* (Weinheim), **279**, 154 (1941); W. Borsche and H. Groth, *Ann. Chem.*, **549**, 238 (1941); K. Matsumura, *J. Amer. Chem. Soc.*, **52**, 4433 (1930).

2) K. Matsumura and C. Sone, *J. Amer. Chem. Soc.*, **53**, 1490 (1931).

III, whereas II could be safely recrystallized from hot benzene without any conversion into III showing that II is unstable to hot protic solvent. It was thought that II might have been formed through V[2] which was obtained through the reaction between 5-acetyl-8-quinolinol (I) and formalin in the absence of base. When V was treated with a mixture of formalin and sodium hydroxide solution, because of its insolubility to the mixture, V was recovered unaltered. From this the formation of II through V is not probable and II may be formed through the condensation of two moles of the methylol compound (VI) with one mole of formaldehyde. To these condensation products, the structures II, III and IV were assigned respectively in consideration of the analytical figures of the free bases, their hydrochlorides and acetyl derivatives.

When brominated with two equivalent atoms of nascent bromine, I gave 5-acetyl-7-bromo-8-quinolinol (VII) which on further bromination produced 5,7-dibromo-8-quinolinol[3] (VIII) in quantitative yield and the expected 7-bromo-5(α-bromoacetyl)-8-quinolinol could not be obtained. VII and VIII exhibited a deep red color with diazotized sulfanilic acid and alkali, showing that these bromines are easily displaced by arylazo group. 5-Acetyl-7-iodo-8-quinolinol,[4] on treating with iodine-potassium iodide or sodium hypoiodite solution at 10°C, no further iodination took place and the initial material was recovered.

Experimental

2,4-Bis(8-hydroxy-5-quinolylcarbonyl)-1,5-pentanediol (II). 5-Acetyl-8-quinolinol (1.87 g, 0.01 mol) was dissolved in a mixture of formalin (37%, 8.1 g, 0.05 mol) and 2.5N sodium hydroxide solution (5 g) with stirring at room temperature. After standing overnight, the solution was acidified (B.T.B. pH 3.6) with dilute acetic acid. A resinous material which soon turned to crystals separated from the solution. It formed orange yellow leaflets containing water of crystallization which was removed on standing *in vacuo* over potassium hydroxide at room temperature or on recrystallization from benzene. Yield, 1.8 g (67%).

Found: H_2O (water of crystallization), 5.21%. Calcd for $C_{25}H_{22}O_6N_2 \cdot 1.5H_2O$: H_2O, 5.71%.

On recrystallization from benzene, it formed light yellow prisms, melting at about 145°C, turning to a solid up to 180°C and unaltered at 300°C. IR (cm^{-1}, KBr) 3500, 3075, 2850 (OH), 1650 (>CO), 1280 (C_6H_5–CO–).

Found: C, 67.42; H, 4.99; N, 6.32%. Calcd for $C_{25}H_{22}O_6N_2$: C, 67.26; H, 4.93; N, 6.28%.

The Hydrochloride of II crystallized as colorless prisms from 3N hydrochloric acid, mp 255°C.

Found: C, 57.15; H, 4.71; N, 5.63%. Calcd for $C_{25}H_{22}O_6N_2 \cdot 2HCl$: C, 57.80; H, 4.62; N, 5.39%.

The Sulfate of II crystallized as columns from 30% sulfuric acid, mp 115—123°C.

Found: C, 43.82; H, 4.72; N, 4.55%. Calcd for $C_{25}H_{22}O_6N_2 \cdot 2H_2SO_4 \cdot H_2O$: C, 44.25; H, 4.43; N, 4.30%.

Tetraacetyl Derivative of II. A mixture of II (100 mg), fused sodium acetate (100 mg) and acetic anhydride (200 mg) was allowed to stand for 7 days at room temperature and then poured into ice water. The product crystallized as glistening colorless plates from ether, mp 115°C.

Found: C, 64.30; H, 5.16; N, 4.59%. Calcd for $C_{33}H_{30}O_{10}N_2$: C, 64.50; H, 4.89; N, 4.56%. The product obtained by heating a mixture of II and acetic anhydride for 3 hr at 130°C formed thick plates when crystallized from ether, mp 108—112°C (Found: N, 4.60%). From the estimated nitrogen content, it is evident that on heating at 130°C with acetic anhydride, dehydration which might be expected to take place between the two primary alcohols did not occur.

Treatment of II with Hot Ethanol. A solution of II (400 mg) in ethanol (20 m*l*) was heated at 80°C for one half hr and the crystals (9 mg), mp 298°C, which separated on cooling, were identified as III by comparison of the IR spectrum with the sample described below.

Treatment of II with 6N Hydrochloric Acid. A solution of II (200 mg) in 6N hydrochloric acid (2 m*l*) was heated at 98°C for 4 hr. The solid, which appeared on addition of sodium acetate to the cooled solution, was collected by filtration and repeatedly washed with hot ethanol. The crystals (10 mg), mp 300°C, which remained undissolved in ethanol were identified as III by comparison of the IR spectrum with that of the sample described below.

3,5-Bis(8-hydroxy-5-quinolylcarbonyl)tetrahydropyran (III). Method A. II (300 mg) was heated at 180° for one hr and the product crystallized as colorless plates from nitrobenzene. Mp: unaltered at 300°C. Yield, 200 mg. IR (cm^{-1}, KBr) 3075 (OH), 1660 (>CO), 1280 (C_6H_5–CO–), 1110, 480 (C–H_2–O–CH_2–).

Found: C, 70.27; H, 4.51; N, 7.11%; mol wt (Mass), 428. Calcd for $C_{25}H_{20}O_5N_2$: C, 70.01; H, 4.67; N, 6.54%; mol wt 428.

Method B. A solution of II (220 mg) in concentrated sulfuric acid (2.2 g) was heated at 100°C for one hr, poured into ice water. The resultant solution was made alkaline with sodium carbonate and then acidified with acetic acid. The separated solid (170 mg) was recrystallized as colorless leaflets from nitrobenzene, mp 300°C. The IR spectrum was identical with that of the product obtained by method A.

The Hydrochloride of III formed long needles on crystallization from 3N hydrochloric acid. The crystals were unaltered at 300°C and completely hydrolysed in water.

Found: C, 54.53; H, 4.85; N, 5.26%. Calcd for $C_{25}H_{20}O_2N_2 \cdot 2HCl \cdot 2.5H_2O$: C, 54.93; H, 4.95; N, 5.13%.

Diacetyl Derivative of III was prepared by heating a mixture III (80 mg), fused sodium acetate (80 mg) and acetic anhydride (400 mg) at 110°C for 3 hr. The product crystallized as colorless needles from acetone, mp 231—234°C.

3) A. Claus and H. Howitz, *J. Prakt. Chem.* [2], **44**, 444 (1891); K. Matsumura and M. Ito, *J. Amer. Chem. Soc.*, **77**, 6672 (1955).

4) K. Matsumura and M. Ito, *J. Org. Chem.*, **25**, 853 (1960).

Found: C, 68.18; H, 4.58; N, 5.55%. Calcd for $C_{29}H_{24}O_7N_2$: C, 67.97; H, 4.69; N, 5.47%.

2,4-Bis(8-hydroxy-5-quinolylcarbonyl)-1,4-pentadiene (IV). A solution of II (1.8 g) in 30% sulfuric acid (18 g) was heated at 95°C for 2 hr and, after cooling, poured into ice water and the solid (1.63 g) which appeared on addition of excess sodium acetate was collected by filtration and dissolved in hot 3N hydrochloric acid. After cooling, the separated fine needles (A) was collected and washed with water. On addition of sodium acetate to the combined filtrate and washings (charcoal), a yellow solid 1.38 g (84%), mp 155°C separated. On recrystallization from benzene (charcoal), it formed colorless prisms, mp 162—165°C (decomp.). IR (cm^{-1}, KBr) 3300 (OH), 1660 (—CO), 1280, 1240 C_6H_5-CO-, 1630 (CH_2=CH–).

Found: C, 73.21; H, 4.75; N, 7.57%. Calcd for $C_{25}H_{18}O_4N_2$: C, 73.17; H, 4.39; N, 6.83%.

(A) was treated with aqueous sodium acetate and the resultant needles, mp 300°C, was identified as III (Found: C, 73.21; H, 4.75; N, 7.57%) by comparison of IR spectrum with that of the sample prepared by another method.

The Hydrochloride of IV. It was prepared by dissolving IV in 3N hydrochloric acid, evaporating the solvent at room temperature to dryness and recrystallizing the residue from ethanol. It formed plates, mp 250°C (decomp.). Found: C, 56.52; H, 4.65; N, 5.79%. Calcd for $C_{25}H_{18}O_4N_2 \cdot 2HCl \cdot 2.5H_2O$:*1 C, 56.82; H, 4.73; N, 5.30%.

Found: C, 61.85; H, 4.27; N, 6.55%. Calcd for $C_{25}H_{18}O_4N_2 \cdot 2HCl$:*2 C, 62.11; H, 4.14; N, 5.80%.

The Diacetyl Derivative of IV. A mixture of IV (150 mg), acetic anhydride (200 mg) and fused sodium acetate (200 mg) was heated at 92°C for 2.5 hr. The product on recrystallization from ether, formed colorless prisms, mp 160—162°C (decomp. with foaming).

Found: C, 69.85; H, 4.99; N, 5.98%. Calcd for $C_{29}H_{22}O_6N_2$: C, 70.45; H, 4.45; N, 5.67%.

Fries Reaction with 8-Acetoxyquinoline.

8-Acetoxyquinolinium Chloride. A mixture of 8-hydroxyquinolinium chloride (1.83 g, 0.01 mol) and acetic anhydride (1.2 g, 0.01 mol) was heated on a water bath for 1.5 hr until complete dissolution resulted. After standing overnight the separated crystals were collected by filtration and dried at room temperature over potassium hydroxide *in vacuo*. Yield 1.9 g (85%). Mp 166—168°C.

Found: C, 58.51; H, 4.58; N, 6.47%. Calcd for $C_{11}H_9O_2N \cdot HCl$: C, 59.06; H, 4.47; N, 6.26%.

5-Acetyl-8-quinolinol. A mixture of 8-acetoxyquinolinium chloride (11.2 g, 0.05 mol), nitrobenzene (50 m*l*) and aluminum chloride (18 g) was gently shaken until complete dissolution resulted. The solution was heated at 75°C for 6 hr, then 85°C for 4 hr and finally 95°C for 5 hr (Calcium chloride tube). After cooling, ice (50 g) and 6N hydrochloirc acid (50 m*l*) were added to the solution. After the nitrobenzene was driven off with steam, the solution (charcoal) was concentrated if necessary and the separated hydrochloride was collected by filtration and washed with 3N hydrochloric acid. The hydrochloride was treated with an excess of aqueous sodium acetate to give the free base (I), yield 5.8—6.2 g (62—66%), mp 108—110°C. It formed colorless needles from benzene, mp 113°C. The identity with that obtained by Friedel-Crafts reaction[1] was established by comparison of IR spectra.

Fries reaction with 8-benzoyloxyquinolinium chloride failed to afford benzoyl-8-quinolinol.

5-Acetyl-7-bromo-8-quinolinol. To the solution of 5-acetyl-8-quinolinol (0.19 g, 0.001 mol) in 0.1N hydrochloric acid (36 m*l*), 0.1N bromate-bromide solution (20 m*l*) was added dropwise with stirring at 5°C. After standing for one hr sodium sulfite was added (iodide-starch paper) to the reaction mixture and the resultant solid was recrystallized from benzene as needles, mp 176°C. It exhibited a deep red color with diazotized sulfanilic acid and dilute sodium carbonate solution. On reaction of one mole of bromine in the form of either bromate-bromide solution or molecular bromine, it gave 5,7-dibromo-8-quinolinol[3] in quantitative yield and its identity was established by comparison of IR spectrum with that of authentic sample.

Found: C, 49.50; H, 3.28; N, 5.22%. Calcd for $C_{11}H_8O_2NBr$: C, 49.64; H, 3.01; ,N 5.26%.

*1 Dried at room temperature *in vacuo* over potassium hydroxide overnight.

*2 Dried at 110°C *in vacuo* over phosphorus pentoxide until constant weight.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3285—3286 (1970)

Effect of Solvent Acidity on the Rate of Nitric Acid Oxidation of Cumene*1

Yoshiro OGATA and Hiroshi TEZUKA

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku Nagoya

(Received April 15, 1970)

It is known that the nitric acid oxidation of cumenes gives acetophenones,[1] but the reaction scheme is unknown. Cumene is oxidized in our hands with 3.0M nitric acid for 6 hr at 90°C in 60% dioxane to give acetophenone as a major product in a yield of 70—76% together with benzoic acid (*ca.* 30%). The products were identified by means of UV and GLC. In view of these products, the intermediate may be dimethylphenylcarbinol, since, in our previous study, it has been observed that the nitric acid oxidation of triphenylmethane gives triphenylcarbinol quantitatively under the similar conditions to the present reaction.[2] The formation of acetophenone is considered to be the result of the oxidative demethylation of an intermediary dimethylphenylcarbinol. If *t*-alkoxy radical is formed, ketone is generally obtained.[3] In fact, under the present conditions, dimethylphenylcarbinol gave acetophenone in a yield of 71% together with benzoic acid after 6 hr. Also acetophenone was oxidized to benzoic acid with nitric acid under the present conditions.

Thus the pathway for the nitric acid oxidation of cumene is considered as follows:

$$PhCH(CH_3)_2 \rightarrow PhC(CH_3)_2OH \rightarrow PhCOCH_3 \rightarrow PhCOOH$$

Here, hydrogen atom abstraction from cumene is of interest in connection with the oxidation of triphenylmethane.[2] In excess nitric acid, the rate of consumption of cumene should be in agreement with that of hydrogen abstraction from cumene. The reaction mixture was extracted with chloroform at appropriate time intervals as described before,[2] and the rate was followed by measuring the consumption of cumene by means of GLC with a column of 1 m packed with Apiezon grease L 15% on Celite 545 at 100—160°C, using chlorobenzene as an internal standard.

In the nitric acid oxidation of diphenylmethane, triphenylmethane[2] and benzoin,[4] the rate was explained in terms of the ionization potential and bond-dissociation energy of the C–H bond which is cleaved, where the attacking species were considered to be both HNO_2^+ and NO_2. Since cumene is more reactive than toluene, the methyl group of cumene facilitates the oxidation in the present reaction. In order to disclose the attacking species in the oxidation of cumene, it is intended to measure the effect of acidity of solution on hydrogen abstraction.[2,4]

The first-order rate constants measured in excess nitric acid are shown in Table 1. As obvious in Table 1, the rate is first-order in cumene. The rate is independent of the amount of sodium nitrite added, but when a considerable amount of urea (a scavenger of nitrous acid) was added, a fairly long induction period was observed (Table 1).

Nitrous acid is an initiator but it does not affect the oxidation rate, *i. e.*, the concentration of NO_2 is constant at the stationary state as reported before;[4-6] hence, the rate is expressed as follows: $v=k$[cumene].

The acidity effect on the rate is shown in Fig. 1.

Table 1. Effect of initial concentrations of reactants in nitric acid oxidation of cumene in 60% dioxane at 90°C[a]

[PhCH-$(CH_3)_2$], M	[$NaNO_2$], M	Induction period, min	$10^4\,k$, sec^{-1}
0.058	0.01	10—20	2.1
0.034	0.01	10—20	2.1
0.059	0	~20	2.0
0.058	0.005	10—20	2.0
0.056	0.015	10—20	2.0
0.059	0.2[b]	>150	—

a) Initial concentration, $[HNO_3]=3.0$M.
b) $CO(NH_2)_2$ was added instead of sodium nitrite.

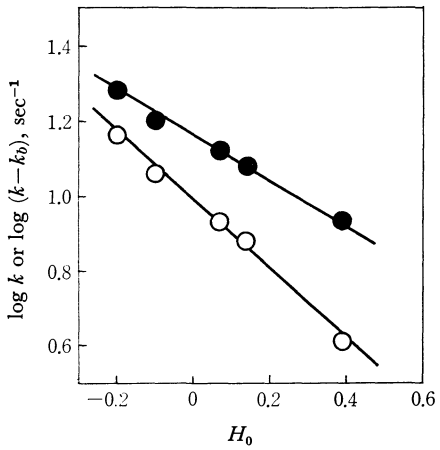

Fig. 1. Acidity effect of the solution on the rate for nitric acid oxidation of cumene in 60% dioxane at 90°C.
Initial concentration: $[HNO_3]=2.0$M, $[NaNO_2]=0.01$M, $[PhCH(CH_3)_2]=0.059$M, $[H_2SO_4]=0-1.0$M. ●, Plot of log k *vs.* H_0; ○, Plot of log $(k-k_b)$ *vs.* H_0.

The plot of log k *vs.* H_0 gave a line with a slope of a fractional number (−0.5), which is analogous to that for triphenylmethane, *etc.* (Fig. 1). Hence, k may be expressed as follows: $k=k_a h_0+k_b$. The plot of $10^5 k$ *vs.* h_0 gives the value of k_b to be 4.5×10^{-5}. The plot of $\log(k-k_b)$ *vs.* H_0 gave a straight line with a slope of *ca.* −1 as expected.

These facts suggest a mechanism involving simultaneous attack of both HNO_2^+ and NO_2 as in the case of diphenylmethane and triphenylmethane.

$$HNO_3 + HNO_2 \rightleftarrows 2NO_2 + H_2O \quad (1)$$

$$H^+ + NO_2\cdot \rightleftarrows HNO_2^+ \quad (2)$$

$$PhCH(CH_3)_2 + HNO_2^+ \xrightarrow{\text{slow}} \underset{\text{I}}{PhC(CH_3)_2} + H_2NO_2^+ \quad (3)$$

$$PhCH(CH_3)_2 + NO_2\cdot \xrightarrow{\text{slow}} \text{I} + HNO_2 \quad (4)$$

$$\text{I} + NO_2\cdot \rightarrow \underset{\text{II}}{PhC(ONO)(CH_3)_2} \quad (5)$$

$$\text{II} + H_2O \rightarrow PhC(CH_3)_2OH + HNO_2 \quad (6)$$

$$PhC(CH_3)_2OH \xrightarrow{HNO_3} PhCOCH_3 \xrightarrow{HNO_3} PhCOOH$$

It is known that alkyl nitrite is easily hydrolyzed even at 0°C.[7] Therefore, II may be rapidly hydrolyzed to dimethylphenylcarbinol, but the direct formation of acetophenone may not be excluded.

$$\underset{\text{II}}{PhC(ONO)(CH_3)_2} \rightarrow PhC(O\cdot)(CH_3)_2 + NO\cdot \rightarrow$$

$$PhCOCH_3 + CH_3NO$$

This mechanism leads to the rate equation:

$$v = (k_3[HNO_2^+]+k_4[NO_2\cdot])[\text{cumene}]$$
$$= (k_3K_2[H^+]+k_4)[NO_2\cdot][\text{cumene}]$$

Here, k and K are rate and equilibrium constants of subscripted steps, respectively.

The methyl group of cumene may facilitate the oxidation due to both lowering the ionization potential of C–H bond[8] and the stability of intermediate radical (I). Hence, two kinds of attacking species, NO_2 and HNO_2^+, should participate in the oxidation as observed in the case of di- and triphenylmethanes,[2] and benzoin.[4]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3287—3288 (1970)

Ring Expansion of Azetidines to Pyrrolidines*1

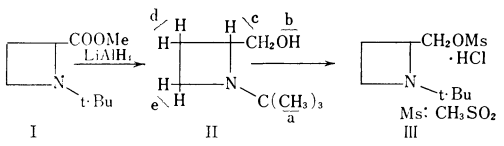
Takayoshi MASUDA, Akiko CHINONE and Masaki OHTA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 16, 1970)

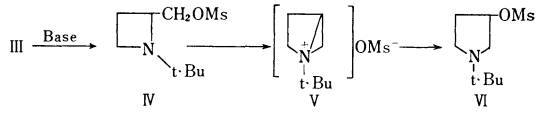
Many examples are reported in which nucleophilic participation by amino group both in acyclic and cyclic haloamines lead to ring expansion, contraction or cleavage *via* cyclic quaternary salts.[1,2]

We were interested in the behavior of ring-nitrogen atom of azetidine as a neighboring group, since azetidine is highly strained and one of the strongest bases in cyclic amines. Methyl 1-*t*-butylazetidine-2-carboxylate (I), synthesized recently by Rodebaugh and Cromwell,[3] seems to be the best starting material for the studies.



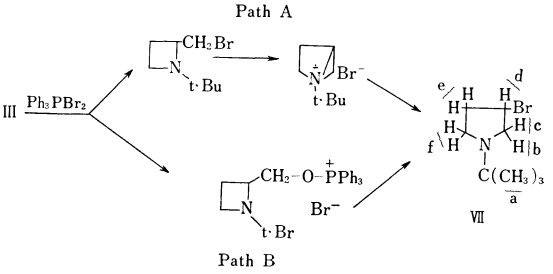
Reduction of I by lithium aluminum hydride afforded 1-*t*-butyl-2-hydroxymethylazetidine (II) in good yield. II was treated with methanesulfonyl chloride in anhydrous pyridine to give 1-*t*-butyl-2-methanesulfonyloxymethylazetidine hydrochloride (III) almost quantitatively. III was carefully neutralized with triethylamine or aqueous potassium carbonate in methylene chloride, the temperature being kept below 10°C. From the organic layer a crude base was obtained which gave a picrate. The NMR spectrum of the picrate shows that the crude base is 1-*t*-butyl-2-methanesulfonyloxymethylazetidine (IV). However, IV is unstable and readily undergoes rearrangement to 1-*t*-butyl-3-methanesulfonyloxypyrrolidine (VI) by standing for a few hours at room temperature, probably *via* bicyclic quaternary salt (V).

Owing to an insufficient amount of VI for purification, its structure was deduced on the basis of the elementary analysis and NMR spectrum of



the picrate prepared from the crude rearrangement product. The driving force for the rearrangement of IV to VI is probably due to the release of ring strain and the easiness of internal quaternization to V due to the strong basicity of azetidine.

Treatment of III with triphenylphosphine dibromide in the presence of equimolar amount of triethylamine gave 1-*t*-butyl-3-bromopyrrolidine (VII). The structure of VII is supported by the result of elementary analysis and NMR spectrum. Formation of VII might proceed either *via* bicyclic quaternary salt (pathway A) or *via* quaternary phosphonium salt (pathway B).



Experimental*2

1-t-Butyl-2-hydroxymethylazetidine (II). To a suspension of lithium aluminum hydride (2.28 g, 0.06 mol) in anhydrous ether (75 m*l*) was added dropwise a solution of methyl 1-*t*-butylazetidine-2-carboxylate (8.6 g, 0.05 mol) in anhydrous ether (50 m*l*) with stirring and cooling with ice-water. Stirring was continued for further 4 hr and the reaction mixture was left standing overnight. Sodium hydroxide (1 g), ether (55 m*l*) and water (3—5 m*l*) were then added successively with cooling with ice-water. After filtration with sintered glass filter, the ethereal solution was dried over potassium hydroxide and the solvent was distilled off to give a colorless oil which was distilled in a vacuum: bp 50—53.5°C/2.5 mmHg, yield 6.3 g (88%).

Found: C, 67.29; H, 11.95; N, 9.70%. Calcd for $C_8H_{17}ON$: C, 67.13; H, 11.89; N, 9.79%.

*2 All melting points were determined on a micro hot stage and are not corrected.

The NMR spectrum of II shows signals at τ 9.1 (H_a, singlet), 7.8—8.2 (H_d, multiplet), 6.8—7.1 (H_e, multiplet), 6.3—6.7 (H_c, multiplet) and 5.9 (H_b, singlet).

Picrate: mp 194—195°C (decomp.).

Found: C, 45.42; H, 5.26; N, 15.29%. Calcd for $C_{14}H_{20}O_8N_4$: C, 45.16; H, 5.41; N, 15.05%.

1-*t*-Butyl-2-methanesulfonyloxymethylazetidine Hydrochloride (III). To a stirred solution of II (7.15 g, 0.05 mol) in anhydrous pyridine (60 m*l*) was added dropwise methanesulfonyl chloride (6.5 g), the temperature being kept at 0—5°C by cooling. The mixture was stirred for 4—5 hr, kept in a refrigerator overnight and then anhydrous ether (200 m*l*) was added to precipitate the hydrochloride which was collected by filtration and washed with petroleum ether to remove pyridine. Recrystallized from ethyl methyl ketone: mp 108.5—109.5°C, yield 12.7 g.

Found: C, 41.98; H, 8.06; N, 5.44%. Calcd for $C_9H_{20}O_3NSCl$: C, 41.93; H, 7.82; N, 5.43%. IR (KBr): 2390—2670 cm^{-1} (ammonium salt).

Picrate: mp 148.5—149.5°C (decomp.). (CH_3CN–EtOH).

Found: C, 40.43; H, 4.82; N, 12.36; S, 7.05%. Calcd for $C_{15}H_{22}O_{10}N_4S$: C, 40.00; H, 4.92; N, 12.44; S, 7.12%. The NMR spectrum of the picrate exhibits at τ 8.67 (9H, singlet, *t*-butyl), 7.45—7.87 (2H, multiplet, methylene at 3-position of azetidine ring), 6.97 (3H, singlet, methyl of methanesulfonyl group), 5.83—6.15 (2H, multiplet, methylene at 4-position), 5.31—5.62 (3H, multiplet, methine at 2-position and methylene of methanesulfonyloxymethyl group) and 1.33 (2H, singlet, phenyl).

Reaction of III with Triphenylphosphine Dibromide. To a solution of triphenylphosphine dibromide in acetonitrile (50 m*l*) (prepared from 13.1 g of triphenylphosphine and 8.8 g of bromide) was added dropwise triethylamine (5.6 g, 0.055 mol) at 0—5°C and after 20 min 7.15 g (0.05 mol) of III was added below 10°C. The solution was stirred for 1 hr, heated up to 60—70°C and kept at this temperature for 20 min when the solution turned dark brown. After cooling, acetonitrile was distilled off under reduced pressure and the residue was extracted with petroleum ether. The extract was dried over magnesium sulphate and distilled to remove the solvent. The residual oil was distilled under reduced pressure and 6.5 g (63%) of III, bp 83.5—84°C/13 mmHg was obtained.

Found: C, 46.97; H, 7.78; N, 7.06%. Calcd for $C_8H_{16}NBr$: C, 46.62; H, 7.82; N, 6.80%.

Picrate: mp 193.5—195.5°C (decomp).

Found: C, 38.50; H, 4.27; N, 13.00%. Calcd for $C_{14}H_{19}O_7N_4Br$: C, 38.63; H, 4.40; N, 12.87%.

The NMR spectrum of VII shows signals at τ 8.91 (H_a, singlet), 7.40—8.05 (H_e, multiplet), 7.14—7.35 (H_f, multiplet), 7.09 (H_b, doublet of doublet), 6.67 (H_c, doublet of doublet) and 5.54—5.77 (H_d, multiplet).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3288—3290 (1970)

Excess Compressibility of Binary Liquid Mixtures

Osamu KIYOHARA and Kiyoshi ARAKAWA

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received April 16, 1970)

Excess compressibility is an important quantity related to intermolecular forces between unlike molecules.[1)]

The formulas of compressibility based on statistical theories have been derived by Prigogine,[2)] Flory[3)] and others. Flory's formula is very simple, and the values for nonpolar liquid mixtures calculated by the formula showed a fairly good fit with the observed data. Three parameters are included in Flory's solution theory and were determined experimentally.

A statistical thermodynamic theory for binary liquid mixtures based on the cell method and the Sutherland type potential function for pair interactions, has been successfully applied to nonpolar solutions.[*1,4)] From the theory, the excess compressibility equation has been derived for the relation between the compressibility and intermolecular energy. It is believed that the compressibility data gives a severe test to the statistical theory of solution.

The equation of state for a binary mixture consisting of nonpolar rigid spherical molecules (A and B) differing in size is given by the following equation.

$$-p = \frac{2\pi}{3}\frac{N^2}{V^2}\left[(\gamma\varepsilon^*)_A \cdot r_A^{*3} \cdot x_A + (\gamma\varepsilon^*)_B \cdot r_B^{*3} \cdot x_B\right] - RT\left[\frac{x_A}{\beta a_A^2 \cdot (a_A - r_A^*)} + \frac{x_B}{\beta a_B^2 \cdot (a_B - r_B^*)}\right] \quad (1)^{*2}$$

1) G. H. Findenegg and F. Kohler, *Trans. Faraday Soc.*, **63**, 870 (1967); R. J. Fort and W. R. Moore, *ibid.*, **61**, 2102 (1965).

2) I. Prigogine, "The Molecular Theory of Solutions," North-Holland Publishing Co., Amsterdam (1957).

3) A. Abe and P. J. Flory, *J. Amer. Chem. Soc.*, **87**, 1838 (1965).

*1 In the following, this paper is referred to as paper I and the number of the equation given in paper I is superscripted with a prime.

4) K. Arakawa and O. Kiyohara, This Bulletin, **43**, 975 (1970).

All notations used in the present note are the same as those in paper I.

Differentiating Eq. (1) with respect to pressure at constant temperature, we have

$$\left(\frac{\partial V}{\partial p}\right)_T = 1/\left[\frac{4\pi}{3}\cdot\frac{N^2}{V^3}\{(\gamma\varepsilon^*)_A\cdot r_A^{*3}\cdot x_A + (\gamma\varepsilon^*)_B\cdot r_B^{*3}\cdot x_B\} - RT(k_A\cdot x_A + k_B\cdot x_B)\right], \quad (2)$$

where

$$k_A = \left(\frac{1}{a_A^2\cdot(a_A-r_A^*)\cdot\beta}\right)^2\cdot\left(\frac{3a_A-2r_A^*}{3a_A}\right) \text{ and}$$

$$k_B = \left(\frac{1}{a_B^2\cdot(a_B-r_B^*)\cdot\beta}\right)^2\cdot\left(\frac{3a_B-2r_B^*}{3a_B}\right),$$

and, using the same approximate equation (Eqs. (17′)—(20′)), the isothermal compressibility κ_T for a binary mixture is expressed as follows.

$$\kappa_T^{(I)} = \frac{1}{3RT}\cdot\frac{(V-V^*)^2}{V\cdot\left[\frac{1+3\rho_A}{1+\rho_A}\cdot x_A + \frac{1+3\rho_B}{1+\rho_B}\cdot x_B\right] - 2\cdot(V-V^*)}. \quad (3)$$

For a pure liquid A, we have

$$\kappa_{T,A}^{(I)} = \frac{1}{3RT}\cdot\frac{(V_A^0-V_{AA}^*)^2}{V_A^0\left[\frac{1+3\rho_{AA}}{1+\rho_{AA}}\right]-2\cdot(V_A^0-V_{AA}^*)} \quad (4)$$

where

$$\rho_A = \frac{V-V^*}{3V_A^*},\ \rho_B = \frac{V-V^*}{3V_B^*},$$

$$V^* = V_A^*\cdot x_A + V_B^*\cdot x_B,\ x_A+x_B=1.$$

x_A and x_B are the mole fraction for each species, V_A^* and V_B^* are the "*hard core volume*"[3,4] for each species in solution, and V_{AA}^* and V_{BB}^* are those in pure liquid, respectively. V and V^0 are the volume of solution and pure liquid each.

The excess compressibility κ^E is given by the equation

$$\kappa^E = \kappa - \frac{1}{V}(V_A^0\kappa_A^0 x_A + V_B^0\kappa_B^0 x_B) \quad (5)$$

where κ_A^0 and κ_B^0 are the compressibility for each pure liquid. The $\kappa_T^{E,(I)}$ calculated*3 from the observed excess molar volume V^E (the 3rd column of Table 1) using Eqs. (3), (4) and (5) are compared with experimental results in the 5th column of Table 1. As the values of molecular parameters (molar volume and thermal expansion coefficient of pure liquid), those listed in paper I have been used.

The agreement between calculated and observed results is satisfactory on the whole.

Equation (3) can be simplified further, and we have an extremely simplified formula

Table 1. Excess compressibility for equimolar mixtures

System	T (°C)	V^E (cc/mol) Obsd	$\kappa_T^E\times10^3$ (cc/cal·mol) Obsd	Calcd (I)	Calcd (II)

$$\kappa_T^{(II)} = \frac{1}{3RT}\cdot\frac{(V-V^*)^2}{V}. \quad (6)^{*4}$$

Inserting Eq. (6) into Eq. (5), we obtain a simplified formula of excess compressibility as

$$\kappa_T^{E,(II)} = \frac{1}{3RT}\cdot\frac{1}{V}[(V-V^*)^2 - \{(V_A^\circ-V_{AA}^*)^2\cdot x_A + (V_B^\circ-V_{BB}^*)^2\cdot x_B\}] \quad (7)^{5)}$$

The formula of $\kappa_T^{E,(II)}$ has been tested by the same procedure as described above, and the results are shown in the 6th column of Table 1. The agreement between the observed and calculated is

*2 Eq. (1) is easily derived by differentiation of Eq. (16′).

*3 The values κ_T^E can also be calculated using $V_{calc.}^E$ calculated from the observed excess enthalpy H^E (see Eq. (30′)).

*4 Eq. (6) is derived from Eq. (3) by assuming $\rho_A<1$ and $\rho_B'<1$, and thus, by ignoring $V-V^*$ compared with V.

Reactions of Acetoin and Benzoin with Malononitrile

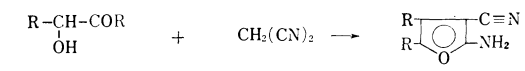
Toshio HAYASHI and Masahiro KAGAWA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received April 20, 1970)

Although the Knoevenagel reactions of aldehydes and ketones have been investigated by numerous workers,[1] little is known about the reactions involving acyloins and benzoins. The only reported examples involve the reaction of ethyl cyanoacetate with benzoin[2] and acetoins[3] in the presence of sodium ethoxide to give α,β-disubstituted γ-lactones.

The present paper deals with the reactions of malononitrile with acetoin (**1a**) and benzoin (**1b**) under the conditions used by Cope[4] to give 2-amino-3-cyano-4,5-disubstituted furans (**2**) in good yield. The structure of **2a** was inferred from elementary analysis and spectral studies. The NH_2 stretching



1a, R=Me **2a**, R=Me
1b, R=Ph **2b**, R=Ph

bands appeared at 3488 and 3400 cm^{-1}, and the conjugated CN group occurred at 2200 cm^{-1}. The NMR spectrum ($CDCl_3$) showed the broad NH_2 signal at 4.68 ppm and the two methyl at 1.92 and 2.07 ppm, which are just in the range expected for methylfurans.[5] The fact that the methyl protons show a sharp singlet suggests that **2a** is present almost completely in the amino form shown. This conclusion may be supported by the fact that the IR spectrum shows no imino absorption.

Recently, 2-amino-3-cyano-4,5-diphenylfuran (**2b**) has been synthesized by Russian workers from desyl chloride and malononitrile in the presence of sodium ethoxide.[6] The melting point of **2b** obtained in the present investigation agreed with that reported. The IR and NMR spectra suggest that **2b** is also present in the amino form.

Experimental

NMR spectra were obtained on a JNM-C-60 high-resolution NMR spectrometer at 19—20°C. Tetramethylsilane was used as an internal standard. IR spectra were determined in the chloroform solution using a Perkin-Elmer 521 spectrophotometer.

Reaction of Acetoin (1a) with Malononitrile. In a 200 m*l* round bottomed flask attached to a constant water separator,[4] were placed 11.4 g (0.12 mol) of acetoin, 6.6 g of malononitrile, 3.0 g of ammonium acetate, 2.0 m*l* of acetic acid, snd 60 m*l* of benzene. The solution was refluxed at 120°C in an oil bath till the formation of water ceased. After the solution had been cooled to room temperature, deposited crystals were recrystallized from ethanol-benzene. The yield of **2a**, melting at 167.5—168.5°C, was 7.4 g (54.4% based on malononitrile).

Found: C, 61.87; H, 6.08; N, 20.20%. Calcd for $C_7H_8N_2O$: C, 61.75; H, 5.92; N, 20.58%.

IR ($CHCl_3$) 3488 (m, NH), 3400 (m, NH), 2200 (s, C≡N), 1640 cm^{-1} (s, δNH_2); NMR ($CDCl_3$) 1.92 (s, CH_3), 2.07 (s, CH_3), and 4.68 ppm (broad, NH_2).

Reaction of Benzoin (1b) with Malononitrile. A mixture of 11.0 g of benzoin, 4.5 g of malononitrile, 3.0 g of ammonium acetate, and 2.0 m*l* of acetic acid in 60 m*l* of benzene was refluxed for 5 hr in an apparatus of the same type as used above. After the solvent had been removed, solid product was recrystallized from toluene and then from ethanol, giving 5.0 g of pale yellow needles (**2b**), melting at 205—206°C (uncor., lit,[6] 207—208°C), yield, 28% based on malononitrile.

Found: C, 78.28; H, 4.65; N, 10.79%. Calcd for $C_{17}H_{12}N_2O$: C, 78.44; H, 4.65; N, 10.76%.

IR ($CHCl_3$) 3490 (m, NH), 3400 (m, NH), 2200 (s, C≡N), and 1638 cm^{-1} (s, δNH_2); NMR (DMSO-d_6) 7.25 (s, Ph), 7.44 (s, Ph), and 7.79 (broad, NH_2).

The authors wish to thank Drs. Hiroshi Midorikawa and Isaburo Hori of this Institute for helpful discussions.

The Preparation of Highly-oriented Carbon Fiber from Pitch Material

Sugio Ōtani, Yukio Kokubo and Teruyo Koitabashi

Faculty of Technology, Gunma University, Kiryu, Gunma

(Received May 6, 1970)

In our previous papers[1-3] it was shown that carbon fiber can be prepared from pitch materials, moreover, Araki and Gomi[4] have succeeded in the production of carbon fiber from pitch material on a pilot-plant scale.

In the earlier reports[1,2] it was pointed out that the carbon fibers obtained from pitch had an isotropic structure and were "nongraphitizable." Recently, two methods for the preparation of highly-oriented carbon fiber from pitch material have been developed in our laboratory. One is a technique using a high-temperature treatment under stress in a range of temperature above 1800°C, while the second is a technique using a specific pitch-like material, such as pitch prepared from tetrabenzophenazine.

The object of this communication is to report some results obtained by the former method.

Experimental and Results

The original carbon fiber used in this work was prepared at 1000°C, on a pilot-plant scale, from a pitch which is a by product of the naphtha cracking process.[4] The high-temperature treatment was carried out under stresses ranging from 0.1 to 0.5 g per denier by the use of 2000—3000-denier bundles. The samples were heated by the use of a graphite-tube furnace in a stream of nitrogen and a rate of 125°C per minute up to 2500°C, which last temperature was maintained for about three minutes. A change in the length of the carbon fiber was clearly observed at temperatures over 1800°C, and it increased with increase in both the stress and the temperature applied. These results are shown in Fig. 1. The diameter of the carbon fiber finally obtained under a stress of 0.5 g per denier is 4.5—6.5 μ.

Stresses below 0.2 g per denier do not effectively improve the preferred orientation of crystallines. Improvement, however, gradually becomes clear with increase in the tension applied over 0.3 g per denier. In Fig 2, the intensity of the X-ray reflexion, $I(\phi)$, is plotted against ϕ, the angle between the C-axis of the reflecting crystallite and the fiber axis.

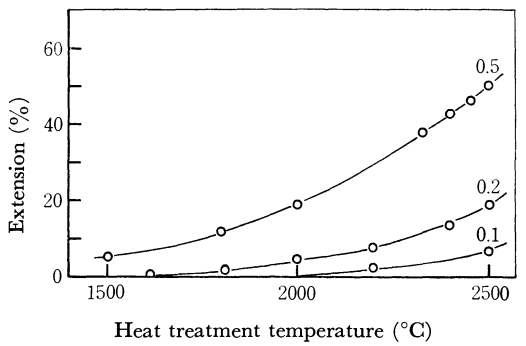

Fig. 1. Relation between the change in length and the stress applied at the heating process.
The numerals in the figure indicate the stress applied (g/denier).

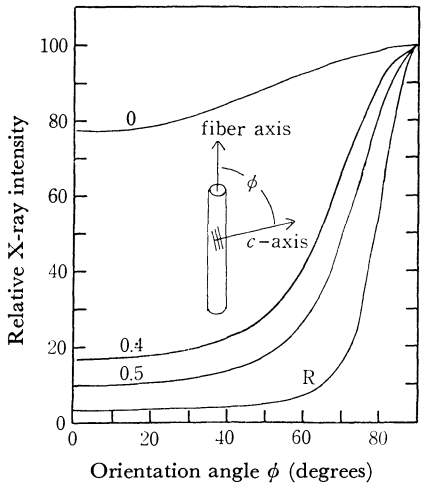

Fig. 2. Relation between the stress applied at the heating process up to 2500°C and the orientation of crystallites.
0: free from stress
0.4: stress of 0.4 g/denier
0.5: stress of 0.5 g/denier
R: RAE carbon fiber Type I (Control)

2) S. Ōtani, *ibid.*, **3**, 213 (1965).
3) S. Ōtani and K. Yamada, *Kogyo Kagaku Zasshi*, **69**, 626 (1966).
4) T. Araki and S. Gomi, *Applied Polymer Symposia*, No. 9, 331 (1969).

The results shown in Fig 2 indicate that the majority of the layer planes in the fiber treated under a stress of 0.5 g per denier are oriented within 30° of the fiber axis. The interlayer spacing and the crystallite size of the filament are 3.45 Å and about 45 Å respectively.

Heat treatment under stress improves the tensile strength and the modulus of the carbon fiber. The average tensile strength and the average modulus of the original carbon fiber are 9.5×10^6 g/cm^2 and 650×10^6 g/cm^2 respectively. The average values of the carbon fiber prepared at 2500°C under a stress of 0.5 g per denier are 18.3×10^6 g/cm^2 in strength and 2100×10^6 g/cm^2 in the modulus.

Discussion

These findings on the mechanical properties are not satisfactory when compared with those from the best high-modulus or high-strength carbon fiber obtained from other materials. It was, however, confirmed that a high-temperature treatment under stress is effective in causing a preferred orientation of carbon crystallites, even when the carbon fiber is prepared from pitch materials. In general, the structure and properties of carbon fiber prepared from pitch materials vary with the type of raw pitch material used, the temperature and the period of preoxidation, the oxidizing atmosphere, *etc.* For example, when a pitch material prepared from tetrabenzophenazine, which possesses highly-oriented molecules,[5] is used as the raw material, the application of stress at the heating stage is not necessary to prepare a highly-oriented carbon fiber. On the contrary, when using pitch fiber spun at a low speed from PVC pitch, it is unlikely that a high orientation can be obtained even when the heat-treatment is carried out under stress.[6]

In these experiments, the application of the higher temperatures and the greater stresses was not possible because of the design of the furnace. However, from the results described above and from general information concerning high-modulus carbon fiber from PAN and rayon,[7] it is likely that further improvements can be expected by the use of a higher treatment temperature and a greater stress.

The Iodine Affinity of Polyvinyl Acetate and Its Derivatives

Sadao HAYASHI, Takashi NAKABAYASHI and Kumiko YOSHIDA

Faculty of Fiber Science and Technology, Shinshu University, Tokiiri, Ueda

(Received May 9, 1970)

Polyvinyl acetate (PVAc)[1] and its derivatives, such as partially saponified PVAc[2], and polyvinyl alcohol (PVA),[3] are known to form colored complexes with iodine. The complex reaction of PVA with iodine has been reported on by several investigators, and various mechanisms have been suggested to explain the reaction. Zwick[4] proposed a helical complex structure, such as has been described in the case of amylose.[5] On the other hand, Tebelev *et al.* pointed out that complex iodine is taken up into the interstices between the aggregated PVA molecules.[6] In order to clarify the mechanism of the complex formation between these polymers and iodine, stoichiometric studies of the binding of iodine to the polymers are required. In the present paper, accordingly, we will attempt to clarify whether or not it is possible to determine the iodine affinity of PVAc and its derivatives by the potentiometric titration method.

Experimental

Materials. Both of the PVA's used were commercial products from the Nippon Synthetic Chemical Industry

Co., Ltd. The NL-05 was used as perfectly saponified PVA, while the GL-05 was used as partially saponified PVAc. The residual acetyl content in the partially saponified PVAc was 11.32 mol%. A PVAc suspension was used as the PVAc sample. The PVAc suspension was prepared both by the suspension polymerization of vinyl acetate and by the addition of the PVAc solution obtained by methanol-solution polymerization to water. The suspension polymerization of vinyl acetate was carried out at 70°C for 1.5 hr, using potassium peroxydisulfate as the initiator. The solid content thus obtained was 14.26%, and the mean particle diameter of the PVAc suspension, as determined by means of an electron microscope, was 0.17 μ. The excess initiator, the by-products formed by the decomposition of the initiator, and the residual vinyl acetate were removed by dialysis. The degree of polymerization of PVAc was calculated by measuring the intrinsic viscosity in acetone at 30°C, using the following equation first proposed by Nakajima;[7] $[\eta]=7.94\times10^{-4}P^{0.62}$. 0.5 g of commercial starch was dissolved in 100 m*l* of water, and its supernatant solution was used as the starch sample.

Measurements. A Yanagimoto potentiometric titrimeter equipped with a calomel cell and a bright platinum electrode, type KY-5, was used for the measurement of the iodine affinity of PVAc and its derivatives. The potentiometric titration was carried out as follows at room temperature according to the procedure reported by Bates *et al.*[8] The sample solution (50 m*l*) containing potassium chloride (0.3728 g) and potassium iodide (0.8300 g) was titrated with a 0.001N iodine solution prepared by dissolving iodine (0.1269 g), potassium iodide (8.3003 g), and potassium chloride (3.7278 g) in distilled water (1000 m*l*).

Results and Discussion

PVAc Derivatives. Figure 1 shows the potentiometric titration curves for PVAc derivatives. A blank curve was also obtained in the absence of the polymer sample. The PVA used in our experiment did not exhibit any color reaction with iodine in a dilute aqueous solution. The titration curve for the PVA was the same as that for a blank. The color reaction of the partially saponified PVAc with iodine was red-violet, and the complex solution possessed an absorption peak at 480—490 mμ. The iodine potentials of the titration curves for the partially saponified PVAc decreased with the increase in the concentration of the polymer, and the titration curves were all similar in type to those of amylopectin reported by Bates *et al.*[8] Consequently, the increase in iodine bound to partially saponified PVAc appears to be proportional to the increase in the concentration of free iodine.

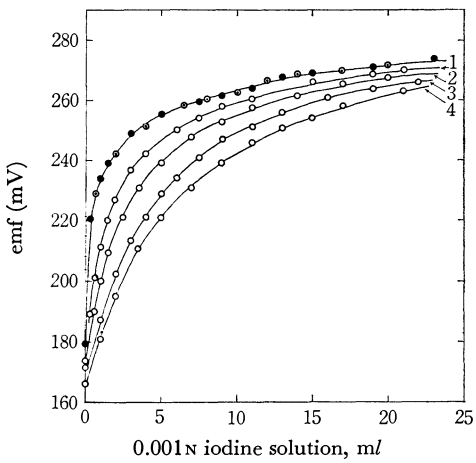

Fig. 1. Titration curves for PVA and partially saponified PVAc.
●: Blank, ⊙: PVA, 0.1500 g, ○: Partially saponified PVAc, 1: 0.0500 g, 2: 0.1000 g, 3: 0.1500 g, 4: 0.2000 g.

PVAc Suspension. The color of the iodine-PVAc suspension complex was the same red-violet as that of the iodine-partially saponified PVAc complex, and the absorption maximum was at 490—500 mμ. Figure 2 shows the potentiometric titration curves for the PVAc suspension, together with those for starch. The curves in Fig. 2 were obtained by the titration of PVAc and of starch in varying amounts. The curves for PVAc, as well as those for amylose, had horizontal parts for the iodine potentials, indicating that all the added iodine was consumed in the complex formation. Therefore, according to the calculation method of the iodine affinity suggested by Bates *et al.*,[8] it is possible to determine the amounts of iodine consumed in the complex formation with PVAc. As is shown in

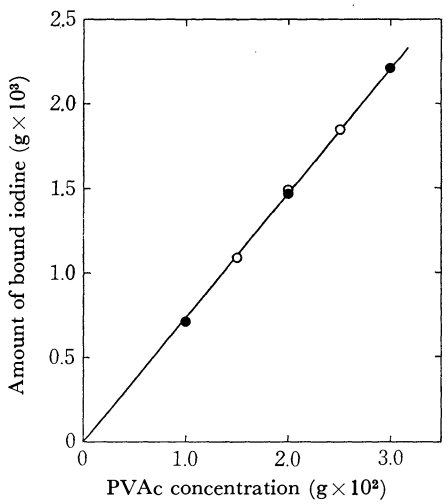

Fig. 3. Relationship between PVAc concentration and amount of bound iodine.
●: PVAc sample of suspension polymerization ($\bar{P}=3640$)
○: PVAc sample suspended polymer in water ($\bar{P}=510$)

Fig. 3, a linear relationship was obtained between the amount of iodine bound to PVAc and the PVAc concentration, regardless of the form of PVAc suspended in water, and the iodine affinity of PVAc (grams of iodine consumed by 100 g of PVAc) was found to be 7.3. All the iodine potentials of the horizontal parts for PVAc were higher than those for starch. It is already clear from the experimental results that amylose of a low molecular weight requires a higher iodine potential for a complex formation. However, there have not yet been any reports concerning the reason for this. In the case of PVAc, it is impossible to consider the relationship between the potential of a horizontal part and the degree of polymerization, because the spectrum of the complex is not influenced by the degree of polymerization.[9] Since the complex reaction of the partially saponified PVAc with iodine is also based on the number of the vinyl acetate units existing continuously in the polymer chain,[10] the mechanism of the complex formation of the partially saponified PVAc must be essentially identical with that of PVAc. When we compare Figs. 1 and 2, PVAc and partially saponified PVAc can be seen to indicate a remarkable difference in the titration curves. This seems to be because only PVAc among the samples examined was a heterogeneous system, since water is a nonsolvent for PVAc. Further, more detailed studies will be necessary to confirm the above results.

Intrinsic Electrical Conductivity of Violanthrene, $C_{34}H_{18}$

Yasurō Hori, Satoshi Iwashima*1 and Hiroo Inokuchi

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received May 9, 1970)

Since 1948, the electrical conductivity of aromatic crystals has been reported on by many workers. However, the conduction mechanism is still ambiguous because the measurement of the intrinsic conductivity is very difficult experimentally. In this study, we measured the electrical resistivity of high-purity violanthrene under a high vacuum.

The material used in the present study was violanthrene A (VEA). The VEA was synthesized from 16,17-dioxyviolanthrene by reduction.[1] The samples were two kinds of VEA. One of them was recrystallized from a 1,2,4-trichlorobenzene solution of the above-synthesized VEA three times and was sublimed once *in vacuo*. This sample will be denoted as VEA (I). In obtaining the second sample, further purification was applied to VEA (I): the sample was recrystallized once from trichlorobenzene and sublimed three times repeatedly. This further-purified sample will be denoted as VEA (II). The concentration of impurities, including that in these samples, was estimated to be 10^{-4} mol/mol for VEA (I) and less than 10^{-5} mol/mol for VEA (II). The single crystal of VEA (II), 5 mm × 8 mm × 70—100 μ in dimensions, was made by means of a sublimation method. Three sorts of specimens, the VEA (I) thin film, the VEA (II) thin film, and the VEA (II) single crystal, were used in the conductivity measurements.

*1 Present address: Department of Science and Technology, Meisei University, Hino, Tokyo, Japan.

1) J. Aoki, This Bulletin, **37**, 1356 (1964).

The resistivity of these specimens was measured at 10^{-7} Torr (of air) and 760 Torr in a high-vacuum bell-jar system; the details of the experimental procedure have been reported in a previous paper.[2] To make the surface-type cell, evaporated aluminum electrodes were attached on the thin film of VEA prepared by evaporation in a high vacuum. The preliminary X-ray analysis showed that, in the evaporated thin film of VEA (II), the *ab*-plane was parallel with the surface of the quartz substrate. Therefore, we established that the observed resistivity is that along the *ab*-plane.

For the single crystal specimen of VEA(II), silver paste was painted on both sides of that as electrodes. Silver wires, 0.1 mm in diameter, were stuck to the electrodes with the silver paste and connected with the resistivity measurement apparatus. The growth plane of the single crystal of VEA was the *ab*-plane; therefore, for the single crystal specimen, we observed the resistivity perpendicular to the *ab*-plane, this direction being denoted as the *c'*-axis.

The resistivity was measured in the temperature range from 20°C to 150°C, and a Cary 31-type vibrating-reed electro meter was employed for the high-resistivity measurements.

Table 1. The electrical resistivity and the apparent band gap of various types* of violanthrene A

Type	ρ_{15}** (Ωcm)	$\Delta\varepsilon$** (eV)
Powder	2.1×10^{14}	0.85
Surface-type	$\sim10^{9}$	0.9
Sandwich-type	$\sim10^{14}$	0.9

* H. Inokuchi, H. Kuroda and H. Akamatu, This Bulletin, **34**, 749 (1961).

** $\rho=\rho_0\exp(\Delta\varepsilon/2kT)$, at $T=288°$ K, $\rho=\rho_{15}$.

Some previous results concerning the resistivity of VEA are listed in Table 1. The present results show a large discrepancy from the previous ones; particularly, the effects of ambient oxygen and impurities are extraordinarily great. Table 2 illustrates the present results.

The resistivity of the evaporated VEA (I) thin film, observed at 760 Torr, was of the same order as the previous one. The value of the $\Delta\varepsilon$, derived from the equation in Table 1, of VEA (I), under a pressure of 10^{-7} Torr, was nearly nil; this was very different from the previous value. The resistivity at 10^{-7} Torr was, however, of the same order as that at 760 Torr.

The resistivity of the evaporated VEA (II) thin film could not be observed at a high vacuum because the resistivity was very large ($>10^{15}\Omega$ between 20—150°C) compared with that of the VEA (I) thin film and that of the VEA (II) at 760 Torr.

Further, the resistivity of the evaporated VEA (II) thin film at 760 Torr, was three orders higher than the previous ones and that observed for the VEA (I) thin film, and $\Delta\varepsilon$ was probably larger as well.

The results on the VEA (II) single crystal specimen were that the resistivity at 10^{-7} Torr was three orders higher than that at 760 Torr; further, the $\Delta\varepsilon$-value under a high vacuum, 1.95 eV, was the largest one ever observed. The resistivity and $\Delta\varepsilon$ at 760 Torr were larger than those of the evaporated VEA (II) thin film.

We concluded that the $\Delta\varepsilon$-value of the VEA (II) single crystal at 10^{-7} Torr, 1.95 eV, was the intrinsic value of violanthrene A, because the threshold value of the absorption spectrum of the violanthrene evaporated film was 2.0 eV and the threshold value of the spectral response of the photoconductivity was about 1.8 eV*[2]: However, we understand that this $\Delta\varepsilon$-value is not coincident with that of the band-gap energy. We presume that the electrical conduction of violanthrene A is produced through excitonic-carrier generation, because the 500 mμ-peak of the absorption spectrum of evaporated thin film may not be the conduction band absorption and is identified as the exciton level, for a very similar band has been found in a violanthrene A solution.*[2]

The nearly zero of $\Delta\varepsilon$-value of the evaporated VEA (I) thin film was interpreted as indicating that

Table 2. The electrical resistivity of violanthrene A *in vacuo* and in air

	in vacuo		in air	
Specimen	ρ_{15} (Ωcm)	$\Delta\varepsilon$ (eV)	ρ_{15} (Ωcm)	$\Delta\varepsilon$ (eV)
VEA (I) thin film	8.5×10^{8}	0.094	8.5×10^{8}	1.06
VEA (II) thin film	—	—	3.7×10^{12} 1.6×10^{13}	1.10 (<55°C) 1.65 (>55°C)
VEA (II) single crystal	3.8×10^{18}	1.95	6.5×10^{15}	0.99

*2 The details of these measurements, the photoconduction, and the absorption spectra of violanthrene A will be reported elsewhere by Y. H. and H.I.

2) Y. Maruyama and H. Inokuchi, This Bulletin, **39**, 1418 (1966).

the decrease in resistivity with the increase in temperature compensated for the increase in resistivity by the desorption of oxygen from the VEA (I) thin film with the increase in temperature; therefore, the $\Delta\varepsilon$-value apparently become nearly zero.

The $\Delta\varepsilon$-value of the VEA (II) single crystal, however, was not nearly zero. This may be for two reasons; the purity of VEA (II) was higher than that of VEA (I), so the number of active sites was less and oxygen was adsorbed more easily with the thin film than the single crystal. After all, the VEA (II) single crystal kept in a high vacuum (10^{-7} Torr) adsorbs so little oxygen that the increase in the resistivity by the desorption with an increase in the temperature does not appear. At an atmospheric pressure, the resistivity of the VEA (II) single crystal was three orders larger than that of the VEA (II) evaporated thin film. This was interpreted as indicating that the resistivity of the c'-axis was larger than that of the *ab*-plane. These phenomena also appeared in previous works on several kinds of polycyclic aromatic hydrocarbons.

The authors wish to thank Professor Junji Aoki, Toho University, and Dr. Yusei Maruyama of our Institute for their kind advice and discussion. They are also indebted to Professor Mizuka Sano, The University of Electro-Communications, for his preparation of the violanthrene A single crystals.

Electronic Absorption Spectrum of Tris(2,2′-bipyridine)-cobalt(I) Complex

Youkoh KAIZU, Yasuo TORII and Hiroshi KOBAYASHI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 11, 1970)

Very recently electronic absorption spectral studies have appeared on the lower valent tris-(2,2′-bipyridine)-complexes.[1-3] In these lower valent complexes, 'metal to ligand' charge-transfer bands are observed in the near infrared and visible region. In previous papers,[2,3] it was shown that the charge-transfer transitions can be identified since they give rise to a different spectral behavior from those of the (π,π^*) transition of the coordinating ligand or the (d,d^*) transition in the central metal ion, when a small perturbation such as methyl-substitution is introduced into the system of bipyridine.

In this note, a small perturbation technique was applied for assignment of the lower wave number absorption bands.[2,3] Figure 1 shows absorption spectra of the tris-bipyridine complexes of cobalt(I). The absorption bands were observed at 7200, 16400 and 26200 cm^{-1}. The 16400 cm^{-1} band is the same as the result of qualitative measurement by Waind and Martin,[4] who overlooked the 7200 and 26200 cm^{-1} bands and reported quite different ultraviolet spectrum[5] from ours. The lowest wave number band observed at 7200 cm^{-1} behaves as 'ligand to metal' charge-transfer band upon the dimethyl-substitutions. The band at 7200 cm^{-1} is shifted in the order: 4dmbip*1 (6700 cm^{-1}), bipy (7200 cm^{-1}), 5dmbip*1 (7500 cm^{-1}). On the contrary, the ultraviolet band is shifted in the order: 5dmbip (33200 cm^{-1}), bipy (34200 cm^{-1}), 4dmbip (34300 cm^{-1}). This indicates that the band observed at *ca.* 34000 cm^{-1} should be assigned to a (π,π^*) transition of the coordinating bipyridine. Martin *et al.*[5] reported the lowest (π,π^*) transition of the coordinating bipyridine at 35200 cm^{-1}. However, we observed the band at 34200 cm^{-1} when the solution of higher concentration was measured in a 0.1 cm quartz cell, otherwise the band appeared at 35300 cm^{-1}. The spectrum given by Martin *et al.* might be apparently shifted due to some contamination of free bipyridine. As a matter of fact, free bipyridine shows a band at 35500 cm^{-1}.

We showed that low energy charge-transfer bands are observed when electrons are trapped by the central metal ion upon the reduction of a complex,

*1 4,4′-dimethyl- and 5,5′-dimethyl-2,2′-bipyridine are abbreviated to 4dmbip and 5dmbip, respectively.

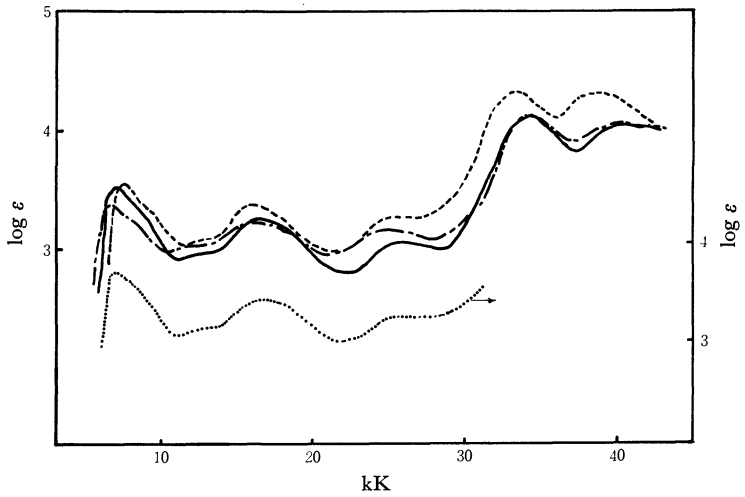

Fig. 1. Absorption spectra of the bipyridine complexes of cobalt(I) in methanol solution.
———: $[Co(bipy)_3]ClO_4$, — — —: $[Co-(4dmbip)_3]ClO_4$, – – – – –: $[Co(5dmbip)_3]ClO_4$, ·····: $Co(bipy)_2ClO_4$. The symbol (→) indicates the right ordinate.

while low energy (π,π^*) bands of the coordinating negative ion are observed when electrons are captured by the coordinating ligand.[2] Since we observed low energy charge-transfer bands, majority population of the electron furnished by reduction is concluded to localize at the central cobalt ion. The oxidation number of cobalt is +1. Since univalent cobalt has eight electrons in *d*-orbitals, two unpaired electrons are expected under the ligand field of D_3 symmetry. This is in good agreement with our observed magnetic moment 2.53 B.M.

In addition to tris(2,2′-bipyridine)cobalt(I) complex, it is well known that bis(2,2′-bipyridine)cobalt-(I) complex exists.[6] The bis-complex shows an intense and diffuse spectrum very similar to that of the tris-complex. From the fact that tris(2,2′-bipyridine)nickel(II) complex, an isoelectronic system of tris(2,2′-bipyridine)cobalt(I) complex, gives rise to (d,d^*) transitions in the visible region, the low energy absorption band observed in the bis-complex has been assigned to (d,d^*) transitions by Császár.[7] We are convinced from our data that the bands in the near infrared and visible region should be assigned to 'metal to ligand' charge-transfer transitions.

Experimental

Tris(2,2′-bipyridine)- and bis(2,2′-bipyridine)cobalt(I) perchlorates were prepared by the same method as given in the literature.[4,6] Tris(4,4′-dimethyl-2,2′-bipyridine)- and tris(5,5′-dimethyl-2,2′-bipyridine)-cobalt(II) perchlorate were prepared by the same method with some modifications. The four compounds are deep blue. Tris(2,2′-bipyridine)cobalt(I) perchlorate we prepared showed a magnetic moment of 2.53 B.M. at room temperature. Waind and Martin, however, reported that the tris-complex was diamagnetic.[4,8] The bis-complex gave a moment of 2.71 B.M. The results of elemental analysis are shown in Table 1.

Table 1.

Complex	Analysis Co (%)	
	Calcd	Found
$[Co(bipy)_3]ClO_4$	9.4	9.7

Infrared and Raman Spectra of Chlorosulfonyl Isocyanate

Isao KANESAKA and Kiyoyasu KAWAI

Faculty of Literature and Science, Toyama University, Gofuku, Toyama

(Received May 20, 1970)

Chlorosulfonyl isocyanate, $ClSO_2NCO$, was first prepared by Graf,[1] and the presence of -NCO and $>SO_2$ groups in this compound was shown by Onodera[2] in his study of the infrared spectra of this compound. Detailed studies of the infrared and Raman spectra of this compound are of interest not only in themselves, but also in comparison with those of such related compounds with -NCO or $>SO_2$ groups as sulfonyl diisocyanate, sulfuryl chloride, or sulfamide.

By using a liquid cell arranged so as to prevent the compound from hydrolysis, the infrared spectra were recorded in the NaCl region. The Raman spectra were observed photographically using Hg-e and -k lines for excitation. The polarization ratios were not determined, however. The frequencies of the infrared and Raman spectra are expected to be accurate to within ± 2 and ± 5 cm^{-1} respectively; their tentative assignments are listed in Table 1.

$ClSO_2NCO$ may be formed by replacing a Cl atom of SO_2Cl_2 with an NCO group; it belongs to the point group *Cs*, in which the plane containing the Cl-S-NCO group is perpendicular to that containing the SO_2 group. Accordingly, the fifteen normal vibrations of this compound are reduced to $\Gamma = 10A' + 5A''$ and are active in both infrared and Raman spectra.

All the strong and medium Raman bands, except for two medium bands, one at 85 cm^{-1} which is present as the anti-Stokes line from Hg-k, and one at 1412 cm^{-1}, are assigned to A′ modes of vibration. A strong band at 130 cm^{-1} could be assigned to the bending vibration of the S-N=CO group, and the band at 85 cm^{-1} to the torsional virbation of this group. The S-N stretching frequency of this compound, 741 cm^{-1}, is lower than those of $SO_2(NH_2)_2$,[3] 904 and 931 cm^{-1}. On the basis of these assignments, it is clear that the S-N=CO group does not have a linear form like $S^-=N^+=CO$, but a bent form. By comparing the normal frequencies of SO_2Cl_2,[4-10] $SO_2(NCO)_2$,[11] and $SO_2(NH_2)_2$[3] with those of $ClSO_2NCO$, the assignments of the observed frequencies listed in Table 1 may be seen to be probable.

Chloromethylation with Chloromethyl Methyl Ether and 60%-Fuming Sulfuric Acid. A Simple Synthesis of Some Nitropolymethylbenzyl Chlorides and Dihalopolymethylbenzyl Chlorides[1]

Hitomi SUZUKI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received May 29, 1970)

A common method to introduce chloromethyl group directly into aromatic nucleus is to treat an aromatic compound with formaldehyde and hydrogen chloride in the presence of a Lewis acid catalyst like zinc chloride.[2] However, nitropolymethylbenzenes and dibromopolymethylbenzenes were found to remain mostly unchanged in the attempted chloromethylation according to the ordinary procedure. The presence of the three or four activating methyl groups was not sufficient to counterbalance the deactivating effect of a nitro or two halogen atoms. The reported procedures[3] for the chloromethylation of deactivated aromatic systems generally requires a quite long reaction time to obtain a moderate yield. The use of stronger catalyst led to the extensive resinification of the substrate as well as the partial migration of bromine atom.

An excellent result of chloromethylation was obtained by dissolving these deactivated aromatic compounds in an excess of chloromethyl methyl ether and adding dropwise with shaking 60%-fuming sulfuric acid. The active reaction immediately took place. After standing for some minutes, the dark brown mixture was diluted with water to precipitate the desired benzyl chloride in good yield. Neither charring nor polymerization was observed under these conditions. The use of a large excess of chloromethyl methyl ether (bp 55—60°C) prevents the temperature of the system from rising too much and thus the reaction from going too far to form polymeric products. This modification also suppresses the formation of undesirable diarylmethane derivatives, which are often a major product in the chloromethylation of deactivated aromatic compounds under drastic conditions.[4]

With increasing amounts of fuming sulfuric acid and extended reaction time, or with the use of smaller amounts of chloromethyl methyl ether, the reaction proceeded very vigorously and the second chloromethylation giving bis(chloromethyl)benzenes as well as the condensation leading to polymeric substances became a prominent process. Owing to poor solubility and high melting point, bischloromethylated products readily separated as a crystalline mass from the hot reaction mixture.

In contrast to the case of lower alkyl homologs, the action of nitrating agent upon tri- or tetramethylbenzyl chlorides usually gives a complicated mixture of side-chain substituted products.[5] Thus, the present method provides the most simple direct route for the highly alkylated nitrobenzyl chlorides in high state of purity. Nine benzyl chlorides and four bis(chloromethyl)benzenes were prepared from nitro and dihalo derivatives of some polymethylbenzenes, and their physical properties are summarized in Table 1.

Experimental

Melting points were determined with a hot stage and are uncorrected. IR spectra were recorded on Nujol mulls with a Jasco DS-402G spectrophotometer and only prominent peaks are given. NMR spectra were determined in carbon tetrachloride solutions (TMS as internal standard) at 60 MHz with a JEOL JNM-3H 60 spectrometer. A commercial chloromethyl methyl ether of ordinary grade was used without purification.

2,5-Dibromo-3,6-dimethylbenzyl Chloride. 2,5-Dibromo-*p*-xylene (10 g) was dissolved in chloromethyl methyl ether (20 g) and 60%-fuming sulfuric acid (*ca.* 8—9 g) was added carefully with stirring. The dark hot mixture was stood for some minutes and then diluted with water. The oily precipitate soon solidified, which was collected by filtration, washed, and dissolved into a mixture of methylene chloride and ligroin. The solution was dried over anhydrous calcium chloride, and removal

*1 Bp in parentheses.
*2 Principal peaks in the regions, 650—1350 and 1500—2000 cm^{-1}.
*3 Numerals in parentheses refer to the number of methyl groups.
*4 The appearance of a methylene proton peak at lower field and of a ring proton peak at higher field than those of the two isomers favors this orientation over the alternative one, 2,6-dimethyl-3,5-dibromobenzyl chloride.
*5 NMR spectra were determined in deuteriochloroform solutions.

of the solvent, followed by fractional distillation under reduced pressure gave the unchanged starting material (2.9 g) at 110—112°C/7 mmHg and the chloride (5.3 g, 63%) at 154—156°C/6 mmHg. Crystallization of the latter fraction from light petroleum gave white fine needles, mp 94—96°C (lit,[3a] 96—97°C).

When a warm solution of dibromo-*p*-xylene (5 g) in chloromethyl methyl ether (5 g) was treated with 60%-fuming sulfuric acid (*ca.* 4—5 g), the reaction proceeded with vigorous evolution of heat and the mixture soon turned into a black crystalline mass. The product was washed with water, dissolved into a mixture of methylene chloride and ligroin, and freed from the colored polymeric substances through chromatography on a short alumina column. Removal of the solvent, followed by recrystallization of the product (4.5 g, 66%) from chloroform gave **1,4-bis(chloromethyl)-2,5-dibromo-3,6-dimethylbenzene** as colorless fine needles, mp 213—215°C. It sublimes on heating.

5,6-Dichloro-2,3,4-trimethylbenzyl Chloride. 4,5-Dichloro-1,2,3-trimethylbenzene (1 g) was dissolved in chloromethyl methyl ether (3 g) and 60%-fuming sulfuric acid (*ca.* 3 g) was carefully added with shaking. The mixture became dark brown and the active reaction immediately started. After the end of the reaction, the mixture was diluted with water and the precipitate

was collected by filtration, washed, and chromatographed on a short alumina column using a mixture of light petroleum and methylene chloride as eluant. Evaporation of the solvent from the eluate gave colorless prisms (0.9 g, 72%), mp 95—97°C.

3-Nitro-2,4,6-trimethylbenzyl Chloride. Nitromesitylene (3 g) was dissolved in chloromethyl methyl ether (3 g), to which was added dropwise and with frequent shaking 60%-fuming sulfuric acid (*ca.* 2—3 g). After the cease of the active reaction, the mixture was quenched with water. Working up as above, followed by crystallization from light petroleum gave colorless prisms, mp 61—62°C. Yield, 2.9 g (75%).

When a further amount (*ca.* 2—3 g) of fuming sulfuric acid was added to the above mixture, a vigorous exothermal reaction followed and the content soon solidified to a dark crystalline mass, which was washed with water, taken up into hot benzene, and decolorized through chromatography on a short alumina column. Evaporation of the solvent from the eluate gave **2,4-bis(chloromethyl)-6-nitro-1,3,5-trimethylbenzene** (4.2 g, 88%) as colorless prisms, mp 168—169°C.

Homolytische aromatische Benzoyloxylierung bei der Prévost-Reaktion

Tadashi SUEHIRO, Mikio HIRAI und Machiko NIITSU

Chemisches Institut, Gakushuin Universität, Mejiro, Tokyo

(Eingegangen am 1. Juni, 1970)

Olefine werden bei der Umsetzung mit benzoesaurem Silber und Jod in Dibenzoyloxy-Verbindungen übergeführt.[1] Wenn aber die Reaktion in benzolischer Lösung durchgeführt wird, entstehen nebenbei Benzoesäure-phenyl-ester.[2] Weiter ist es auch bekannt, daß das Olefin, das einen phenolischen Ring im Molekül trägt, sich nicht nur an der Doppelbindung hydroxylieren sondern auch an dem aromatischen Kern jodieren läßt.[3] Diese aromatische Jodierung geschieht wahrscheinlich elektrophil wie bei der Hansdiecker-Reaktion, aber die mechanistischen Untersuchugen über die Ester-Bildung in benzolischer Lösung sind noch nicht vollzogen. Wir arbeiten seit einiger Zeit über die homolytische Tritylierung der Aromaten und über den Zusammenhang zwischen Tritylierung und Benzoyloxylierung.[4] In dieser Beziehung nahmen wir Interesse an dem Verhältnis zwischen Jodierung und Ester-Bildung in der Prévost-Reaktion.

Um die Benzyloxylierung zu klären, haben wir die Prévost-Reaktion in einer Mischung von Toluol und Benzol untersucht. Die Ergebnisse der Umsetzung bei 80—160°C sind in der Tabelle aufgestellt.

Tabelle 1. Isomere-Verhältnisse und relative Reaktivität des Toluols in a) Benzoyloxylierung und b) Jodierung bei der Prévost-Reaktion

Reakt. Nr.	Temp. °C	Isomere-Verhältnis %			Ausb. %	k_{PhCH_3}/k_{PhH}
		o-	*m*-	*p*-		
a) 1	80	46.2	24.1	29.7	9.1—10.7	3.01
2	80	42.8	29.8	27.4	—	—
3	100	47.5	27.5	24.0	—	—
4	120	46.5	29.0	24.5	—	—
5	140	46.6	32.5	20.9	—	—
6	160	43.8	29.2	27.0	—	—
b) 1	80	~32	~0	~68	36—46	17

Nr. 1: Ansatz von 30 mMol benzoesaurem Silber, 30 mMol Jod in 60 m*l* Toluol-60 m*l* Benzol, 4 Stunden im Dunkel.

Nr. 2—6: Ansätze von 1.3 mMol benzoesaurem Silber, 1.3 mMol Jod in 5 m*l* Toluol in Einschlußrohr im Dunkel.

Die Umsetzungen sind alle unter Stickstoff-Atmosphäre durchgeführt. Toluol und Jod gaben in Abwesenheit des Silber-Salzes das Jodtoluol in einer Ausbeute weniger als 0.24%.

Neben Jodtoluolen und Benzoesäure-estern von Kresolen entstehen bei der Umsetzung bei 80°C *o*-, *m*- und *p*-Methylbiphenyle und Bibenzyl insgesammt in *ca.* 10% Ausbeute, und in rein toluolischer Lösung nur wenig Jodbenzol (weniger als 0.2%). Im letzteren Fall wurde überhaupt kein Benzoesäure-phenyl-ester gefunden.

2) C. Prévost und J. Wiemann, *Compt. Rend.*, **204**, 989 (1937).

3) M. Sletzinger und C. R. Dawson, *J. Amer. Chem. Soc.*, **68**, 345 (1946); *J. Org. Chem.*, **14**, 671 (1949).

4) T. Suehiro, S. Igeta, O. Kuwabara und M. Hirai, *Tetrahedron*, **26**, 963 (1970).

Die Isomere-Verhältnisse der Benzoesäure-ester von Kresolen (*o*/*m*/*p*=46/24/30) ähneln denen der Produkte von Benzoyloxylierung des Toluols mettels Benzoylperoxyds in Gegenwart von Kupfer(II)-chlorid[5] (56/18/26) bzw. in Gegenwart von Jod[6] (53/16/31). Die relative Reaktivität k_{PhCH_3}/k_{PhH}= 3.01 steht im guten Einklang mit derjenigen Werte der entsprechenden Reaktionen, d.h. 2.51[5] bzw. 2.85[6] und 2.82[4]. Die homolytische Natur des Zerfalls von Benzoylperoxyd in Gegenwart von Kupfer(II)chlorid,[5] Jod[6] und Trityl[4] ist zweifellos klar und demnach verläuft die Benzoyloxylierung bei der Prévost-Reaktion sehr wahrscheinlich über das Benzoyloxy Radikal.

Homolytischer Zerfall von benzoesaurem Silber-Jod Komplex ist in einigen Beispielen angedeutet worden, z.B. in der Bildung von α-Methyl-β-phenyl-propionsäure-α-methylphenäthyl-ester aus α-Methyl-β-phenylpropionsaurem Silber und Jod.[7] Zu der Bildung von Benzcoumarin aus Biphenyl-*o*-carbonsaurem Silber und Jod[8] gaben aber die Autoren auf Grund der Abhängigkeit der Ausbeute von der Substituenten vielmehr elektrophile Substitution. Diese Abhängigkeit der Ausbeute kann man jedoch besser der elektrophilen Eigenschaft des freien Aroyloxy Radikals zuschreiben, genau so wie es in der abnehmenden Tritylierung bei der Aromaten mit Elektronen anziehenden Substituenten der Fall ist.[4]

Jodierung des Toluols bei der Prévost-Reaktion ist *o*- und *p*-orientierend und die relative Reaktivität k_{PhCH_3}/k_{PhH} ist 17. Das ist viel großer als 3 bei der Benzoyloxylierung. Dies weist auf die heterolytische Jodierung hin.

Jodbenzol kann auch aus Phenyl Radikal und Jod gebildet werden, weil wärend der Prévost-Reaktion Benzoyloxy Radikal auftritt, welches thermisch in Phenyl Radikal zerfallen kann. Man kann dies aber übersehen, weil die Bildung des Jodbenzols aus Phenyl Radikal höchstens nur 0.2% beträgt.

Was dem Wert 17 betrifft, ist er, obwohl er bei 80°C bestimmt wurde, viel kleiner als 344 für Cl_2-[9] bzw. 605 für Br_2-[10] Halogenierung. Immernoch ist er kleinier als 60 für Cl^+-[11] bzw. 36 für Br^+-[12] Halogenierung (alle bei 25°C). Einen etwas größeren Wert, mehr als 140, kann man für die Jodierung mit JCl-Zinkchlorid[13] errechnen. Die Jodierung bei der Prévost-Reaktion muß also durch J^+ oder durch ein analoges reaktionsfähiges Reagens hervorgerufen worden sein. Ein Beispiel der Prévost-Reaktion, wo J^+ Rolle spielt, findet man bei der Umsetzung von 3,3,3-Triarylpropen,[14] deren Zwischenprodukt, d.h. Carboniumion, Aryl-Umlagerung erleidet.

Beschreibung der Versuche

Bestimmung der Benzoesäure-ester von Kresolen. Man entfernt Jod und Silber Salz von der Reaktionsmischung und untersucht die neutrale Produkte gaschromatographisch. Die Analyse wurde bei 210°C mit einer Kolonne von Apiezon L 25%, 3 m, mit Helium 15 ml/15 Sek durchgeführt. Der innere Standard war *o*-Nitrotoluol.

Bestimmung der Jodtoluole. Man destilliert zunächst die Reaktionsmischung mit Wasserdampf ab und nimmt NMR-Spektrum von dem eingeengten Destillat in Tetrachlorkohlenstoff mit dem inneren TMS Standard auf. Die Signale in τ-Wert für *o*-Jodtoluol, 2.27d (8 Hz), 7.61s; *m*-Jodtoluol, 2.58s, 3.09s, 7.72s; *p*-Jodtoluol, 2.52d (8 Hz), 3.20d (8 Hz), 7.72s.

Methyl-Protonen von Jodtoluolen wurden durch Vergleich mit denen von *o*-Nitrotoluol als innerem Standard gestimmt. Weil die Signale der Methyl-Protonen von *m*- und *p*-Jodtoluolen sich übereinander lagern, wurde der *m*-Isomer aus den Signalen im Bereich τ 2—3 ermittelt, wo keine bei τ 2.58 und bei 3.09 gefunden wurden. Die Ausbeuten von Jodbenzol und Jodtoluolen wurden gaschromatographisch mit einer 3 m Kolonne von Apiezon L bei 155°C ermittelt.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3303—3304 (1970)

Zur Reaktionsgeschwindigkeit bestimmenden Stufe der homolytischen aromatischen Triphenylmethylierung (der Wielandschen Reaktion)

Tadashi SUEHIRO, Shinichi IGETA, Osamu KUWABARA, Mikio HIRAI, Mototoshi ISHIDA und Junji YAMAZAKI

Chemisches Institut, Gakushuin Universität, Mejiro, Tokyo

(Eingegangen am 3. Juni 1970)

Die Tritylierung der Aromaten verläuft in folgender Weise:[1)]

$$(C_6H_5COO)_2 + Ph_3C\cdot \longrightarrow C_6H_5COOCPh_3 + C_6H_5COO\cdot \quad (1)$$

$$C_6H_5COO\cdot + Ph_3C\cdot \longrightarrow C_6H_5COOCPh_3 \quad (2)$$

$$C_6H_5COO\cdot + C_6H_6 \longrightarrow C_6H_5COO(H)C_6H_5\cdot \quad (3)$$

$$(I) + Ph_3C\cdot \longrightarrow C_6H_5COO(H)C_6H_5(H)CPh_3 \quad (II) \quad (4)$$

$$(II) \longrightarrow C_6H_5CPh_3 + C_6H_5COOH \quad (5)$$

Die Reaktion (2) läuft mit (3)—(5) nebeneinander. Wir haben festgestellt, dass Reaktion (3) die Geschwindigkeit bestimmende Stufe der Tritylierung ist. Dieser Schluss beruhte auf der Übereinstimmung der Reaktivität Toluols in Tritylierung mit der dessen Benzoyloxylierung.[2)] Die Charakterisierung der Geschwindigkeit bestimmenden Stufe wurde weiter verfolgt.

a) Einfluss der Konzentration Trityls auf die Ausbeute an Tetraphenylmethan. Wenn die Konzentration von Trityl kleiner wird, muss die Reaktion (2) verlangsamt werden, dagegen muss Reaktion (3) genau so schnell wie früher verlaufen. Die Ausbeute an Tetraphenylmethan nimmt also zu, wenn (3) Geschwindigkeit bestimmend ist. Bei der Tabelle 1 ersieht man die Zunahme der Ausbeute und daraus rechnet man die Herabsetzung der Geschwindigkeit von (2) bis zur Hälfte. Aus dem Verdünnen von Hexaphenyläthan von 3.3×10^{-2} bis zu 2.1×10^{-3} Mol/l wird die Abnahme der Geschwindigkeit der Reaktion (2) bis zu ein fünftel berechnet. Falls die Reaktion (4) bzw. (5) Geschwindigkeit bestimmend ist, muss die Ausbeute an Tetraphenylmethan unverändert bleiben.

b) Einfluss der Polarität des Lösungsmittels auf die Ausbeute an Tetraphenylmethan. Die Ausbeute wird durch Verdünnen der Aromaten mittels Nitrobenzols vermindert. Nitrobenzol spielt hier zuerst als unwirksames Lösungsmittel gegen

TABELLE 1. ABHÄNGIGKEIT DER AUSBEUTE AN TETRAPHENYLMETHAN VON DER KONZENTRATION TRITYLS UND VON POLARITÄT DES LÖSUGSMITTELS

Lösungsmittel			Konz. $(Ph_3C)_2$ Mol/l	Ausbeute an $ArCPh_3$		
	ml	Nitrobenzol ml		mMol*	%	Berechnete** %

	45	45	1.6×10^{-2}	0.867±0.047	60	(50)
Chlorbenzol	90	—	1.6×10^{-2}	0.512±0.039	36	—
	45	45	1.6×10^{-2}	0.398±0.039	29	(22)

* Durch Isotopie-Verdünnungsmethode bestimmt.

** Berechnet unter der Annahme, dass die Konz. der Atomaten durch Verdünnen bis zur 1/2 vermindert wird.

1) T. Suehiro, S. Igeta, O. Kuwabara und M. Hirai, *Tetrahedron*, **26**, 963 (1970).

2) M. E. Kurz, P. Kovacic, A. K. Bose und I. Kugajevsky, *J. Amer. Chem. Soc.*, **90**, 1819 (1968).

Tritylierung[3] und die berechnete Ausbeute sind im Klammer aufgestellet. Die experimentelle Ergebnisse stehen in erster Annäherung im Einklang mit der berechneten, aber sind, genauer gesagt, etwa grösser als sie. Nitrobenzol muss zweitens als polares Lösungsmittel zur Erhöhung der Polarität des Mediums beitragen.

Die Geschwindigkeit der Reaktion kann je nach der Eigenschaft des Übergangszustandes durch die Polarität des Lösungsmittels beschleunigt werden.[4] Wenn man als Model des Übergangszustandes der Reaktionen (2), (3) und (4) oder (5) jeweils Benzoesäuretritylester (1.06D),*1 Benzoesäurephenylester (1.96D)*1 und Benzoesäure-*p*-tritylphenylester (1.36D)*1 wählt und r^* durch Molgewicht ersetzt, so erhält man für μ^{*2}/r^{*3} 3.03×10^{-3}, 1.94×10^{-2} und 4.20×10^{-3}. Daraus ergibt sich, dass die Reaktion (3) durch die Polarität mehr beschleunigs wird als (2), (4) und (5).

c) Isotopie-Effekt der Tritylierung. Die Isomere-Verhältnisse der Methyltetraphenylmethanen bei der Tritylierung Toluols hängt von den *o*-Substituenten der Aroyloxy Radikale ab (Tabelle 2). Dass die Zunahme des *m*-Isomern nicht einfach von den räumlichen Bedingungen der *o*-Substituenten herbeigeführt wird, ist aus der Reihenfolge, CH_3O–, Br–>Cl–>CH_3–, NO_2–, CH_3SO_2–, klar.

Tabelle 2. Die Isomere-Verhältnisse der *o*-, *m*- und *p*-Methyltetraphenylmethane bei der Tritylierung Toluols (25°C)

Bis-α-thenoyl	10.9	81.6	7.5
Bis-*p*-methoxybenzoyl	13.6	74.0	12.4
Benzoyl	13.0	74.8	12.2
Bis-*p*-nitrobenzoyl	10.5	77.5	12.0

* Bestimmt durch NMR-Spektrum,[1] Fehlergrenze ±2.

** Analyse, Gef: C, 87.34; H, 5.78%. Ber. für 2-(3'-Tritylphenyl)benzoesäure $C_{32}H_{24}O_2$: C, 87.24; H, 5.49%.

Isotpie-Effekte k_H/k_D der Tritylierung waren 1.03 beim Bis-*o*-methoxybenzoylperoxyd und 1.04 beim Bis-*o*-methylbenzoylperoxyd. Dies bedeutet, dass die Geschwindigkeit bestimmende Stufe nicht in (5) liegt und dass Benzoyloxy Radikale durch *o*-Methoxy- oder *o*-Halogen-Gruppe so stabilisiert werden, dass sie immermehr spezifisch an die *o*- und *p*-Stellungen Toluols angreifen können.

Aus diesen Befunden wird festgestellt, dass die Stufe (3) in der Tritylierung Geschwindigkeit bestimmend ist.

Beschreibung der Versuche

Die Umsetzungen von Trityl mit Benzoylperoxyden wurden alle wie früher[1] bei 25°C unter Stickstoff im Dunkel durchgeführt.

Isotopie-Effekt. Die Isotopie-Effekte wurden aus der Konzentration deuterierten Benzols und Tetraphenylmethans berechnet. Als Lösungsmittel verwendet man eine Mischung von Benzol und Benzol-d_6 und reinigt durch Vakuum Destillation (Probe 1). Man destilliert aus der Reaktionsmischung das Lösungsmittel im Vakuum zurück (Probe 2), nimmt den Rückstand in Benzol auf, zersetzt den Überschuss Peroxyd mit Natriumjodid, zieht Carbonsäure aus und chromatographiert den neutralen Teil an Florisil (Benzol-Petroläther). Die rohe Kristalle Tetraphenylmethans sublimiert man im Vakuum und isoliert das Sublimat bei 200°C. Man kristallisiert das Produkt aus Benzol um bis konstanter Schmp. 285.5—286.5°C (Einschlussrohr) erreicht wird (Probe 3). Die Kristalle aus der Mutterlauge chromatographiert man nochmals und reinigt wie oben (Probe 4). Die Fehlergrenze der massenspektrometrischen Analyse war ±1%. Für die massenspektrometrische Bestimmung danken wir Herrn Dr. Y. Moriyama der Universität Tokyo herzlichst.

Study on Oxazolopyrimidines. IV. The Preparation of 7-Aminooxazolo[5,4-*d*]pyrimidine 6-Oxide

Yozo Ohtsuka and Kikuo Sugimoto

Sagami Chemical Research Center, Onuma, Sagamihara, Kanagawa

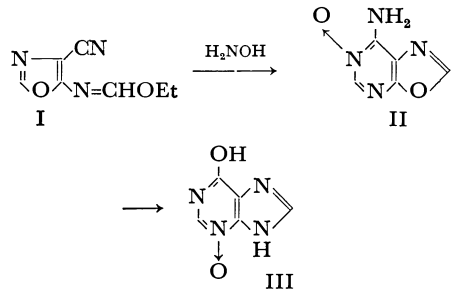
(Received June 8, 1970)

Various *N*-oxides of nitrogen-containing heteroaromatic compounds have been prepared, and several purine *N*-oxides have been shown to exhibit biological activities.[1,2] Although amino-substituted purines[3] and 7-aminothiazolo[5,4-*d*]pyrimidine[2] have been known to yield the corresponding *N*-oxides with peroxyacetic acid, the treatment of 7-aminooxazolo[5,4-*d*]pyrimidine under similar oxidizing conditions led to the formation of 6,8-dihydroxypurine.[4] Another way to *N*-oxide has recently been provided by the preparation of adenosine 1-oxides by the treatment of 5-amino-4-cyanoimidazole derivatives with ethyl orthoformate, followed by hydroxylamine.[5] A similar approach was previously used for the synthesis of hypoxanthine 1-oxide.[6]

The synthesis of 7-aminooxazolo[5,4-*d*]pyrimidine 6-oxide (II) has now been accomplished in a 61% yield by the treatment of 4-cyano-5-ethoxymethyleneaminooxazole (I)[7] with hydroxylamine. By the same treatment, 4-cyano-5-ethoxymethyleneaminoimidazole[8] gave adenine 1-oxide.

The structure of the *N*-oxide (II) was supported by the results of elementary analysis, its spectroscopic data, and its rearrangement to hypoxanthine 3-oxide (III) when stirred in an aqueous alkali for 2 days, but an attempt to obtain 7-aminooxazolopyrimidine by catalytic hydrogenation with Pt/C was unsuccessful.

The present method for the preparation of the *N*-oxide of the pyrimidine derivative by the cyclization of cyanoethoxymethyleneamino compound with



hydroxylamine can generally be applied to a variety of systems, including a relatively unstable system such as oxazolopyrimidine.

Experimental

Preparation of 7-Aminooxazolo[5,4-*d*]pyrimidine 6-Oxide (II). 4-Cyano-5-ethoxymethyleneaminooxazole (I)[7] (1.65 g) was added to an ice-cooled solution of hydroxylamine hydrochloride (0.70 g) and sodium hydroxide (0.4 g) in water (5 m*l*). A precipitate was formed at an early stage of the reaction. When the mixture was stirred at room temperature, it gradually dissolved and then crystals deposited again. The product (0.92 g) was collected after 15 min and washed with water and ethanol. Recrystallization from water gave colorless needles, mp>300°C.

This compound gave a positive $FeCl_3$ test (violet) and a negative TTC (triphenyltetrazolium chloride) test. Its mass spectrum showed a pattern identical with that of 7-aminooxazolopyrimidine[7] except for the peak of the molecular ion, $m/e=152$ (14.4% in intensity relative to the peak, $m/e=136$). The relatively small pH-dependence of the UV spectra seems to support the oxazolopyrimidine structure (λ_{max} (mμ), logε; 231, 4.45; 256, 3.94; 300, 3.34 (pH=2.9): 230, 4.52; 259, 3.96; 301, 3.40 (pH=8.5): 226, 4.41; 259, 3.85; 289, 3.63 (pH=12.0)). This compound possessed paper chromatographic R_f values of 0.53 and 0.27 in solvents A and B[9] respectively.

Found: C, 39.45; H, 2.93; N, 36.73%. Calcd for $C_5H_4N_4O_2$: C, 39.48; H, 2.65; N, 36.84%.

Adenine 1-Oxide. 4-Cyano-5-ethoxymethyleneaminoimidazole[8] (0.22 g) was treated by the same procedure as has been described above. The product (0.10 g) was identified as adenine 1-oxide[3] from its IR spectrum

and R_f value.

Conversion of the Oxide II to Hypoxanthine 3-Oxide (III). The *N*-oxide (II, 0.8 g) was stirred in a 4N aqueous NaOH solution (10 m*l*) at room temperature for 2 days. After this period, the reaction mixture was acidified with acetic acid. The product was collected and purified by reprecipitation from an aqueous alkali with acetic acid. The yield was 42% (0.52 g). The structure of the compound was identified as hypoxanthine 3-oxide[10] on the basis of its UV spectra at various pH (pH=3, 8.5 and 12) and R_f values in solvents A, B, and C.[9]

On the Precipitation of Siderite and Magnetite from Homogeneous Solutions as Observed by Means of Visual Autoclaving

Tominosuke KATSURAI* and Masayuki UDA

Pilot Laboratory, Hiratsuka-Kanagawa and The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received June 11, 1970)

Visual autoclaving was worked out for the purpose of following the hydrothermal changes which take place during the course of autoclaving.[1] The method is useful not only in the sense seeing is believing, but it also makes it possible for us to observe the change taking place in a homogeneous solution above 100°C.[2] Precipitation from homogeneous solutions has been extensively studied in the field of analytical chemistry for obtaining compact, easily filtrable precipitates. However, it seems that the studies were restricted to temperatures below 100°C. We would like to describe the results which we obtained with homogeneous ferrous and ferrous-ferric solutions. The solutions were subjected to visual autoclaving in the presence of urea, and the structures of the resulting precipitates were confirmed by means of X-ray diffraction. Commercial reagents of the best grade were used in the experiments. The results were found to be of interest in relation to mineral synthesis.

Formation of Siderite. Preparation of pure siderite is known to be difficult. However, we found that it can be obtained by autoclaving a solution of ferrous ammonium sulfate in the presence of urea. A solution containing ferrous ammonium sulfate (0.1M) and urea (0.4M) was used. A white bulky precipitate appears at 150°C. It begins to coagulate at 170°C and at 200°C becomes compact. This snow-white precipitate contains a small amount of dark magnetic particles which can easily be removed by a magnet. It was found that the white precipitate is siderite ($FeCO_3$) and the dark particles magnetite. The magnetite is derived from the ferric compound contained in ferrous ammonium sulfate in a small amount as an impurity. This can be illustrated by the formation of magnetite from a ferrous-ferric solution in the presence of urea.

Formation of Magnetite. The following solutions (a) and (b) were subjected to autoclaving at 200°C for 1 hr. For the sake of comparison, a ferrous-ferric solution (c) was also studied.

Solution (a): 0.05M in $FeSO_4 \cdot (NH_4)_2SO_4$, 0.1M in $FeCl_3$ and 1M in $CO(NH_2)_2$. A brown precipitate

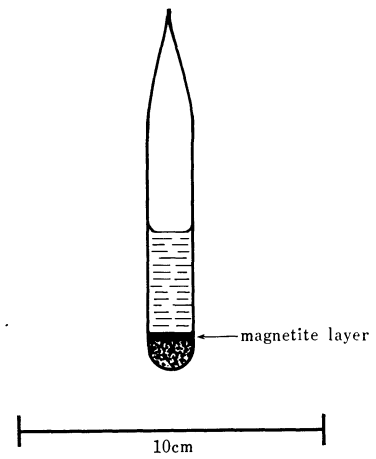

Fig. 1. Formation of magnetite.

Table 1

No.		Composition of solution	Autoclaving product
1		0.1M in $FeSO_4 \cdot (NH_4)_2SO_4$ 0.4M in $CO(NH_2)_2$	Siderite ($FeCO_3$) Magnetite (Fe_3O_4), small amount
2	(a)	0.05M in $FeSO_4 \cdot (NH_4)_2SO_4$ 0.1M in $FeCl_3$ 1M in $CO(NH_2)_2$	Magnetite (Fe_3O_4) Siderite ($FeCO_3$), small amount α-FeO·OH, small amount Hematite (α-Fe_2O_3), trace
	(b)	0.2M in $FeSO_4 \cdot (NH_4)_2SO_4$ 0.04M in $FeCl_3$ 1M in $CO(NH_2)_2$	Magnetite (Fe_3O_4) Siderite ($FeCO_3$), small amount
	(c)	0.05M in $FeSO_4 \cdot (NH_4)_2SO_4$ 0.1M in $FeCl_3$	Hematite (α-Fe_2O_3)

is formed at about 100°C. It turns to brick red at 150°C. The upper liquid turns colorless at 160°C. The surface of the precipitate turns black above 170°C. The black layer thickens with the rise of temperature. The principal constituent of the autoclaving product is magnetite. Siderite, αFeO·OH and a trace of hematite are found as minor constituents.

Solution (b): 0.2M in $FeSO_4 \cdot (NH_4)_2SO_4$, 0.04M in $FeCl_3$ and 1M in $CO(NH_2)_2$. The process of the formation of magnetite could be demonstrated more clearly than for (a). At 100°C a brown precipitate is formed and the upper liquid phase becomes turbid. With temperature rise up to 140°C, the precipitate turns brick red and the contact surface of precipitate with the liquid phase begins to blacken. The thickness of the black layer gradually increases in a downward direction (Fig. 1). At 170°C two distinct phases are formed, *viz.*, an almost colorless, clear upper liquid phase and a compact, black precipitate. The gradual formation of magnetite in two steps, *viz.*, formation of hematite and that of magnetite by the interaction between hematite and the ferrous ion in solution, could be followed.

Solution (c): 0.05M in $FeSO_4 \cdot (NH_4)_2SO_4$ and 0.1M in $FeCl_3$. In contrast to cases (a) and (b), hematite only and no magnetite was obtained. The same formation of hematite as in the autoclaving of $FeCl_3$ solution only takes place.[3] This is in line with the previous results in which no magnetite was formed by the autoclaving of the solutions containing various pairs of ferrous and ferric salts.[4] For the sake of illustration, the results are summarized in a table (Table 1).

Far Infrared Spectra of Glucose and Saccharose

Masakazu HINENO and Hiroshi YOSHINAGA

Department of Applied Physics, Faculty of Engineering, Osaka University, Osaka

(Received June 13, 1970)

Infrared spectra of sugars have been measured and internal vibrations in the ring have been analysed by Barker *et al.*[1] However, the observed spectra are limited to the mid-infrared region down to 400 cm^{-1}. Absorption bands caused by inter-ring interactions are expected to appear in the far infrared region. To obtain information about inter-ring interactions glucose and saccharose seem to be suitable compounds as considered from their structural formulae. In this note far infrared absorption spectra of glucose and saccharose are reported.

Samples were powdered and suspended in the Nujol null, and were then inserted between thin polyethylene sheets. The samples were checked by measuring infrared absorption spectra from 4000 to 400 cm^{-1}.

Far infrared spectra were measured in the region from 500 to 50 cm^{-1} by using a vacuum single beam grating spectrometer constructed in our laboratory.[2] The results are shown in Figs. 1 and 2. In order to determine the wavenumbers of the far infrared bands precisely, the scale of the logarithm in wavelength is used in the spectral chart of this

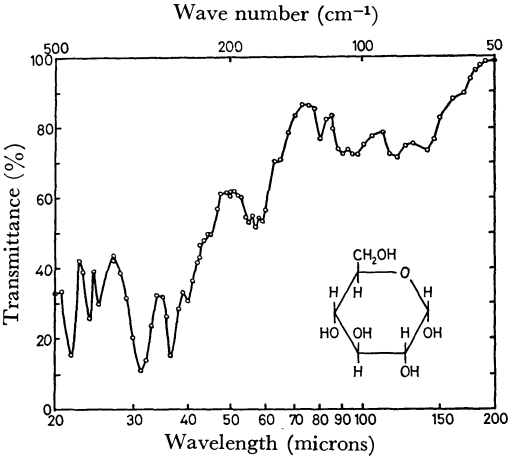

Fig. 1. Far infrared absorption spectrum of glucose in the region from 500 to 50 cm^{-1}.

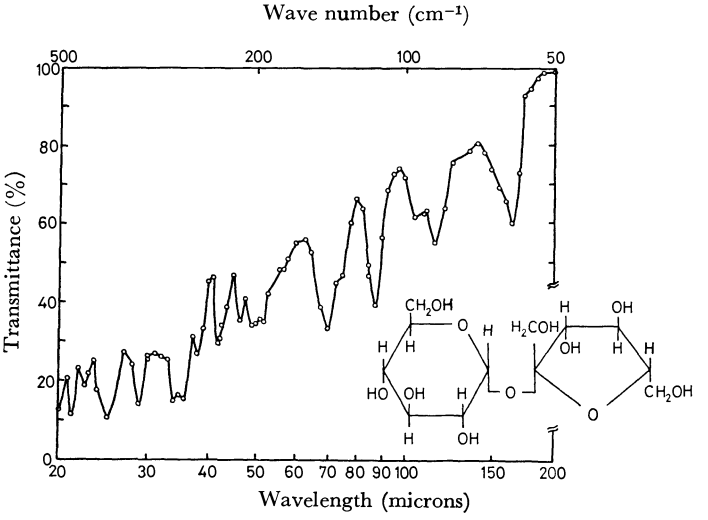

Fig. 2. Far infrared absorption spectrum of saccharose in the region from 500 to 50 cm^{-1}.

TABLE 1. FAR INFRARED ABSORPTION BANDS OF GLUCOSE AND SACCHAROSE

Glucose cm^{-1} (μm)				Saccharose cm^{-1} (μm)			
459	(21.8) (m)	113	(88.1) (w)	472	(21.2) (m)	215	(46.5) (w)
420	(23.8) (m)	106	(93.9) (w)	444	(22.5) (w)	204	(49.0) (w)
400	(25.0) (m)	84.0	(119) (w)	401	(24.9) (s)	195	(51.3) (w)
320	(31.3) (s)	70.7	(141) (w)	345	(29.0) (m)	143	(70.0) (s)
274	(36.5) (s)			294	(34.0)(m)	114	(87.4) (s)
250	(40.0) (w)			280	(35.7) (m)	94.8	(106) (m)
175	(57.0) (m)			263	(38.0) (w)	87.0	(115) (s)
124	(80.9) (m)			235	(42.5) (m)	61.0	(164) (s)

(s), (m), and (w) indicate strong, medium, and weak in relative intensity, respectively.

spectrometer. In this measurement interference fringes which cause trouble to find weak absorption bands were not observed.

Observed bands of glucose and saccharose are listed in Table 1. Strong absorption bands which are observed in the region below 100 cm^{-1} may arise from inter-ring modes. It is considered that absorption bands of 87.0 and 61.0 cm^{-1} are caused by inter-ring deformation modes such as twisting and bending vibrations between two rings of saccharose, because the bands appear in saccharose but not in glucose.

Reactions of Group IV Organometallic Compounds. XXI.[1] Addition and Decomposition Reactions of Arenesulfonyl Iso(thio)-cyanates with Trimethylsilyl Ethyl Sulfide and Bis(trimethylsilyl) Sulfide

Kenji Itoh, Nobukatsu Kato and Yoshio Ishii

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa, Nagoya

(Received June 16, 1970)

In our previous report,[1] the addition reactions of arenesulfonyl isocyanates with trimethylsilylamines or *N*-methyldisilazane were found to occur exothermically at room temperature, giving the 1 : 1 adducts quantitatively, along with the pyrolysis results (150°C, 72 hr) of these adducts, as is shown in Eq. (1).

$$p\text{-X-C}_6\text{H}_4\text{SO}_2\text{-N=C=O} + (\text{Me}_3\text{Si})_2\text{NMe} \longrightarrow$$

$$p\text{-X-C}_6\text{H}_4\text{SO}_2\text{-N(SiMe}_3\text{)-C=O} \xrightarrow{\Delta}$$

$$\text{Me}_3\text{Si-NMe}$$

$$p\text{-X-C}_6\text{H}_4\text{SO}_2\text{N(SiMe}_3\text{)}_2 + \text{Me-N=C=O} \quad (1)$$

In continuation of the paper,[1] this note deals with new reactions between arenesulfonyl isocyanates or isothiocyanates and trimethylsilyl ethyl sulfide or bis(trimethylsilyl) sulfide. Formerly, we found that in the case of the reaction between phenyl isocyanate and bis(trimethylsilyl) sulfide,[2] it was necessary to heat the mixture at 80°C for 24 hr to give the 1 : 1 aduct in 80% yield, due to relatively low reactivity of bis(trimethylsilyl) sulfide.

Results and Discussion

The equimolar mixtures of *p*-X-substituted benzenesulfonyl isocyanate (X=H, Me and Cl) and trimethylsilyl ethyl sulfide were allowed to react at 30—40°C in glass ampoules, and the characteristic absorption at 2240 cm^{-1} ($\nu_{SO_2N=C=O}$) in their IR spectra disappeared completely after ten days. The adducts were thermally unstable and were readily decomposed into starting compounds when heated above 80°C on vacuum distillation (Eq. (2)).

2) K. Itoh, K. Matsuzaki and Y. Ishii, *J. Chem. Soc., C*, **1968**, 2709.

$$p\text{-X-C}_6\text{H}_4\text{SO}_2\text{-N=C=O} + \text{Me}_3\text{Si-SEt} \xrightarrow[80°\text{C}]{30—40°\text{C, 10 days}}$$

Ia—c

(Ia X=H, b X=Me, c X=Cl)

$$p\text{-X-C}_6\text{H}_4\text{SO}_2\text{-N(SiMe}_3\text{)-CO-SEt} \quad (2)$$

IIa—c

These adducts (IIa—c) could be obtained solely as residues by distilling off the unreacted starting compounds under 0.03 mmHg, and their IR and NMR spectral data are shown in Experimental. In the case of the reaction with phenyl isocyanate,[2] rather drastic conditions (80°C, 80 hr) was necessary and the 1 : 1 adduct could be isolated on vacuum distillation. The reaction of Me_3SiNEt_2 with benzoyl isocyanate took place at 80°C for 24 hr, giving the 1 : 1 adduct, bp 72—79°C/0.002 mmHg.[3]

On the other hand, the reactions of arenesulfonyl isocyates (Ia—c) with bis(trimethylsilyl) sulfide did not occur at 30—40°C. These reactions did take place when the equimolar mixtures were heated at 110—120°C for 16 hr in glass ampoules filled with dry argon gas. However, the obtained were *N,N*-bis(trimethylsilyl) arenesulfonamides (IIIa—c) and carbonyl sulfide, which are the decomposition products of the 1 : 1 adducts (Eq. (3)).

$$p\text{-X-C}_6\text{H}_4\text{SO}_2\text{-N=C=O} + (\text{Me}_3\text{Si})_2\text{S} \longrightarrow$$

Ia—c

$$\left[p\text{-X-C}_6\text{H}_4\text{SO}_2\text{-N(SiMe}_3\text{)-C(=O)-S-SiMe}_3 \right] \longrightarrow$$

$$p\text{-X-C}_6\text{H}_4\text{SO}_2\text{N(SiMe}_3\text{)}_2 + \text{COS} \quad (3)$$

IIIa—c

We tried to isolate the 1 : 1 adducts under various conditions, but in vain. Bp and yields of IIIa—c are shown in Experimental.

On the other hand, the reaction of phenyl isocyanate with bis(trimethylsilyl) sulfide occurred at 80°C for 24 hr to give a colorless needle-like crystalline 1 : 1 adduct (mp 54°C) in 79% yield.

The reactions between benzenesulfonyl or *p*-toluenesulfonyl isothiocyanate (IVa, b) and bis-(trimethylsilyl) sulfide were quite similar to those reactions as are formulated in Eq. (3). The products obtained were *N,N*-bis(trimethylsilyl)arenesulfonamides (IIIa, b) and carbon disulfide (Eq. (4)).

$$p\text{-X-C}_6\text{H}_4\text{SO}_2\text{-N=C=S} + (\text{Me}_3\text{Si})_2\text{S} \longrightarrow$$

IVa, b

(IVa X=H, b X=Me)

$$\left[p\text{-X-C}_6\text{H}_4\text{SO}_2\text{-N(SiMe}_3\text{)-C(=S)-S-SiMe}_3 \right] \longrightarrow$$

$$p\text{-X-C}_6\text{H}_4\text{SO}_2\text{N(SiMe}_3\text{)}_2 + \text{CS}_2 \quad (4)$$

IIIa b,

In conclusion, the results obtained in this note and in the previous paper[1] confirmed the enhanced acceptor power of arenesulfonyl isocyanate, due to the electron-withdrawing property of sulfonyl group, compared with phenyl of benzyl isocyanate.

3) I. Matsuda, K. Jinda, K. Itoh and Y. Ishii, unpublished results.

Experimental

Three arenesulfonyl isocyanates and two isothiocyanates were prepared as described in the previous paper.[1] IR and NMR spectra were measured using Nippon-Bunko IR-S and JEOL Minimar MH-60, respectively. Microanalyses were carried out with Yanagimoto apparatus.

Ethylthiol Ester of *N*-(Benzenesulfonyl)-*N*-trimethylsilyl Carbamate (IIa). The mixture of 10 mmol of benzenesulfonyl isocyanate and 10.5 mmol of trimethylsilyl ethyl sulfide was heated at 30—40°C for ten days. Then, the reaction product showed no ν_{SO_2NCO} absorption at 2240 cm^{-1} in IR spectrum, and was evacuated under 0.03 mmHg to remove unreacted starting compounds. The adduct IIa had IR (CCl_4) cm^{-1}: 1710 (CO), 1360 (SO_2, as), 1185 (SO_2, s) and 1253 ($SiMe_3$) and NMR (CCl_4) τ: 9.70 (s, Me_3Si), 8.72 (t, CH_3), 7.12 (q, CH_2) and 2.25—2.88 (C_6H_5).

Ethylthiol Ester of *N*-(*p*-Toluenesulfonyl)-*N*-trimethylsilyl Carbamate (IIb). The reaction was carried out analogously as was described above. The adduct IIb had IR (CCl_4) cm^{-1}: 1710 (CO), 1360 (SO_2, as), 1177 (SO_2, s) and 1250 ($SiMe_3$) and NMR (CCl_4) τ: 9.70 (s, Me_3Si), 8.72 (t, CH_3), 7.60 (s, *p*-CH_3), 7.12 (q, CH_2) and 2.25—2.89 (C_6H_4).

Ethylthiol Ester of *N*-(*p*-Chlorobenzenesulfonyl)-*N*-trimethylsilyl Carbamate (IIc). IIc had IR (CCl_4) cm^{-1}: 1710 (CO), 1360 (SO_2, as), 1180 (SO_2, s) and 1252 ($SiMe_3$) and NMR (CCl_4) τ: 9.70 (s, Me_3Si), 8.72 (t, CH_3), 7.12 (q, CH_2) and 2.25—2.88 (C_6H_4).

Reactions of Bis(trimethylsilyl) Sulfide with Three *p*-X-Benzenesulfonyl Isocyanates (Ia—c). The equimolar amounts of $(Me_3Si)_2S$ (0.50—0.52 g) and *p*-X-substituted benzenesulfonyl isocyanate (0.50—0.52 g) were allowed to react at 110—120°C for 1 hr in glass ampoules filled with argon. The products obtained were the pyrolysis products of the 1 : 1 adducts, *i.e.*, *N,N*-bis(trimethylsilyl)arenesulfonamides (IIIa—c) and COS. The bp and yields of IIIa—c were as follows: IIIa (X=H) 106—110°C/0.35 mmHg, 79%; IIIb (X=Me) 121—122°C/0.4 mmHg, 72%; IIIc (X=Cl) 120—122°C/0.5 mmHg, 61%. The other product, COS, was confirmed by its characteristic IR absorption at 2030 cm^{-1} (CCl_4). IIIa—c were identified by their IR and NMR spectral data (which were reported in our previous paper[1]), together with the confirmation of mixed mp and IR spectra of their hydrolysis products.

Reactions of Bis(trimethylsilyl) Sulfide with Benzenesulfonyl Isothiocyanate (IVa) or *p*-Toluenesulfonyl Isothiocyanate (IVb). The equimolar amount of benzenesulfonyl isothiocyanate (IVa) 0.52 g and bis(trimethylsilyl) sulfide 0.46 g were heated in a glass ampoule filled with argon gas at 110—120°C for 16 hr. The products obtained were *N,N*-bis(trimethylsilyl)benzenesulfonamide (IIIa) and CS_2 in 60% and 55% yields, respectively.

The reaction of *p*-toluenesulfonyl isothiocyanate (IVb) with bis(trimethylsilyl) sulfide at 110—120°C for 16 hr gave *N,N*-bis(trimethylsilyl)-*p*-toluenesulfonamide (IIIb) and CS_2 in 55% and 61% yield, respectively.

These products IIIa and IIIb coincided completely with those products obtained in the reactions between $(Me_3Si)_2S$ and Ia or Ib.

The Synthesis of Desmethylencecalin

Mitsuru NAKAYAMA, Mikoto OHNO, Shûichi HAYASHI and Kenji FUKUI

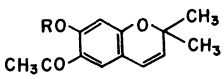
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received July 3, 1970)

Recently, desmethylencecalin[1] (eupatoriochromene)[2] was isolated along with several acetophenone derivatives from the roots of *Helianthella uniflora* and some *Eupatorium* species. Its structure was identified as 6-acetyl-7-hydroxy-2,2-dimethyl-2H-chromene (I) on the basis of the spectral evidence.[1,2] Encecalin (methyl ether of I) (II) was also isolated from *Encelia californica*.[3]

The present paper will describe the synthesis of I from 7-hydroxy-2,2-dimethylchroman (III) *via* the corresponding acetophenone (IV).

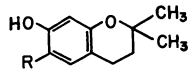
The Hoesch reaction of III[4] with acetonitrile afforded a hydroxy-acetophenone derivative, which was then easily converted into an acetate and may be expected to have one of two structures (IV or V). The NMR spectrum of the acetophenone shows two proton signals, at δ 7.50 and 6.35 ppm (each 1H, singlet) (para positions at C-5 and C-8 on the aromatic ring). Therefore, it can be formulated as 6-acetyl-7-hydroxy-2,2-dimethylchroman (IV). The dehydrogenation of IV with 2,3-dichloro-5,6-dicyano-*p*-quinone in anhydrous benzene gave the desired chromen I. Then, the I was easily converted into acetate (VI) and methyl ether (II) by the usual methods.



I R = H

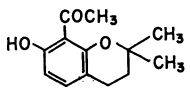
II R = CH_3

VI R = CH_3CO



III R = H

IV R = $COCH_3$



V

The properties of the synthetic I and II were superimposable upon those recorded for natural desmethylencecalin and encecalin.[1-3]

Experimental*1

6-Acetyl-7-hydroxy-2,2-dimethylchroman (IV). A mixture of III[4] (2.0 g), acetonitrile (0.7 g), and anhydrous zinc chloride in anhydrous ether (50 m*l*) was saturated with dried hydrogen chloride in an ice bath and then allowed to stand for 24 hr. After the ether layer had been decanted, the ketimine hydrochloride was washed with anhydrous ether and then hydrolyzed with water (100 m*l*) on a steam bath for 1 hr. The precipitates were then collected and recrystallized from methanol to give IV as colorless plates; mp 119.5—120°C; yield, 0.6 g (24%). IR: 1649 (C=O) cm^{-1}. UV: λ_{max} mμ (log ε); 236 (3.98), 242_{sh} (3.93),*2 283 (4.18), 327 (3.85). NMR: 1.36_s (6H) ($(CH_3)_2C<$); 1.82_t, 2.76_t (each 2H, J=7.0 Hz) ($-CH_2-CH_2-$); 2.54_s (3H) (CH_3COC); 6.35_s (C_8–H); 7.50_s (C_5–H); 12.38_s (OH).

Found: C, 70.80; H, 7.43%. Calcd for $C_{13}H_{16}O_3$: C, 70.89; H, 7.32%.

Acetate. Mp 141.5—142°C (colorless needles from ethanol). IR: 1768, 1671 (C=O) cm^{-1}. UV: λ_{max} mμ (log ε); 230 (4.17), 275 (4.16). NMR: 1.36_s (6H) ($(CH_3)_2C<$); 1.83_t, 2.80_t (each 2H, J=7.0 Hz) ($-CH_2-CH_2-$); 2.34_s (3H) (CH_3COO); 2.49_s (3H) (CH_3COC); 6.52_s (C_8–H); 7.67_s (C_5–H).

Found: C, 68.76; H, 6.83%. Calcd for $C_{15}H_{18}O_4$: C, 68.68; H, 6.92%.

Desmethylencecalin (6-Acetyl-7-hydroxy-2,2-dimethyl-2H-chromene) (I). A mixture of IV (0.1 g) and DDQ (0.1 g) in anhydrous benzene (30 m*l*) was refluxed for 1.5 hr. After the solution had then been cooled, the precipitated hydroquinone derivative was filtered off and the solvent was removed as far as possible. The chromatography of the resulting viscous oil on silica gel (8 g) with benzene gave a pale yellow solid, a soild which crystallized from ethanol as pale yellow needles,

*1 The melting points are uncorrected. The infrared spectra were measured in Nujol, while the ultraviolet spectra were measured in an ethanol solution. The NMR spectra were measured with a Hitachi R-20 spectrometer (60 MHz), using tetramethylsilane as the internal standard (δ-value in $CDCl_3$): s, singlet; d, doublet; t, triplet. The mass spectra were measured with a Hiatchi RMS-4 mass spectrometer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3312—3313 (1970)

Organophosphorus Compounds. XI. Action of Trialkyl Phosphites on *p*-Quinoneimines

M. M. SIDKY and M. F. ZAYED

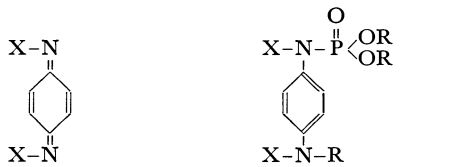
National Research Centre, Dokki, Cairo, U.A.R.

(Received October 20, 1969)

Although the action of trialkyl phosphites on *p*-quinones is well established,[1] their action on *p*-quinoneimines has hitherto not been investigated. We have found that trimethyl phosphite and triethyl phosphite react with *p*-quinoneimines (Ia, b) to give the corresponding phosphoramidate derivatives (IIa—d).

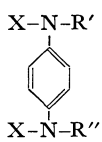
The IR spectrum of IIa, taken as example, revealed the absence of NH absorption and its NMR spectrum showed the following assignments:

(a) $\tau=7.04$ and $\tau=6.76$ (for protons of SO_2CH_3 groups, 2 singlets), (b) $\tau=6.6$ (for N–CH_3 protons, singlet), (c) $\tau=6.2$ (for protons of $P(O)(OCH_3)_2$ groups, doublet with $J_{HP}=11.4$ Hz), (d) $\tau=2.63$ (for aromatic protons, singlet). The integration ratio is 6 : 3 : 6 : 4.



Ia, X=SO_2CH_3
b, X=$SO_2C_6H_5$
c, X=COC_6H_5

IIa, R=CH_3; X=SO_2CH_3
b, R=C_2H_5; X=SO_2CH_3
c, R=CH_3; X=$SO_2C_6H_5$
d, R=C_2H_5; X=$SO_2C_6H_5$



IIIa, R′=X=H; R″=CH_3
b, R′=H; R″=CH_3; X=SO_2CH_3
c, R′=R″=CH_3; X=SO_2CH_3
d, R′=R″=H; X=$SO_2C_6H_5$
e, R′=R″=H; X=COC_6H_5

Adduct IIa, when treated with alcoholic alkali yielded IIIb. The identity of the latter compound was established by an unequivocal synthesis, namely by the methanesulphonylation of *N*-methyl-*p*-phenylenediamine (IIIa) in pyridine. Compound IIIb reacted with diazomethane to give IIIc, in contrast to compound IIa which is stable towards this reagent. When treated with concd. H_2SO_4, IIIb afforded IIIa. This reaction represents a new route for the preparation of *N*-alkyl-*p*-phenylenediamines when the adducts II are subjected to hydrolysis.

From the above results, it appears that *p*-quinoneimines (Ia, b) add trimethyl and/or triethyl phosphite in a 1 : 6 pattern with the creation of a new phosphorus-nitrogen bond, in a similar way to that for *p*-quinones[1] where a phosphorus-oxygen bond is likewise formed.

Quinoneimine Ic is reduced mainly to *p*-phenylenedibenzamide (IIIe), when treated with trialkyl phosphites under similar conditions. This disparity in behaviour of quinones Ia, b on the one hand and Ic on the other towards trialkyl phosphites is in accord with the differences in their behaviour towards a number of various reagents.[2]

Experimental

All melting points are uncorrected. The IR spectra were taken as KBr wafers in a Perkin-Elmer 237B Grating Spectrophotometer. The NMR spectra were run in $CDCl_3$ at 60 Mc, with TMS as internal reference.

Dimethyl [*p*-(*N*-Methylmethanesulphonamido)-phenyl](methanesulphonyl)phosphoramidate (IIa). A mixture of Ia[3] (0.001 mol), trimethyl phosphite[4] (0.001 mol) and dry bezene (10 m*l*) was kept under N_2 for 48 hr at 20°C. The crystalline product obtained was filtered and recrystallized from benzene to give IIa as colourless crystals, mp 150—152°C, yield 85%. (Found: C, 34.22; H, 4.91; N, 7.28; P, 7.95; S, 16.50%. Calcd for $C_{11}H_{19}N_2O_7PS_2$: C, 34.19; H, 4.95; N, 7.25; P, 8.01; S, 16.59%.) [IR: 7.81 (P=O),[5] 8.51 and 9.62 μ ($POCH_3$)[5]]

Similarly, triethyl phosphite[4] reacted with quinone Ia (in benzene at reflux for 6 hr) to give IIb as colourless crystals from chloroform - petrolerum ether (bp 40—60°C), mp 142—143°C, yield 80%. (Found: C, 39.21; H, 6.11; N, 6.47; P, 7.15; S, 14.90%. Calcd for $C_{14}H_{25}N_2O_7PS_2$: C, 39.24; H, 5.89; N, 6.53; P, 7.23; S, 14.96%.

***N*-Methyl-*N*,*N*′-dimethanesulphonyl-*p*-phenylenediamine (IIIb).** Compound IIa (0.1 g) was treated with 10% alcoholic NaOH (10 m*l*) and the mixture was refluxed for 6 hr. Alcohol was evaporated and the mixture was cooled and acidified with 10% aq. HCl. The precipitate was filtered off and crystallized from acetic acid to give IIIb as colourless crystals, mp 175—176°C, yield 90%. Compound IIIb proved to be identical (mixed mp), with that obtained by the following procedure: To a cold solution of IIIa[6] (1.2 g) in pyridine (5 m*l*), was added methanesulphonyl chloride (2.3 g) and the reaction mixture was left overnight at room temperature. Acidification with 10% aq. HCl precipitated IIIb, mp 175—176°C (from acetic acid). (Found: C, 38.94; H, 5.16; N, 10.19; S, 23.03%. Calcd for $C_9H_{14}N_2O_4S_2$: C, 38.83; H, 5.07; N, 10.06; S, 23.03%.) [IR: 3.12 μ (N-H)].

***N*-Methyl-*p*-phenylenediamine (IIIa).** A solution of IIIb (0.5 g) in concd. H_2SO_4 (sp. gr. 1.98) was kept at room temperature for 24 hr. The resulting solution was cooled, made alkaline with 15% aq. NaOH, and extracted with two 25 m*l* portions of ether. The combined extracts were dried over $MgSO_4$ (anhydrous) and evaporated to dryness. The oily residue thus formed was crystallized from pentane to give IIIa as colourless crystals, mp 35—36°C.[6]

***N*,*N*′-Dimethyl-*N*,*N*′-dimethanesulphonyl-*p*-phenylenediamine (IIIc).** To a suspension of IIIb (0.1 g) in dry ether (10 m*l*), was added an ethereal solution of diazomethane. Methanol (1 m*l*) was added and the reaction vessel was kept in a refrigerator for 72 hr. The ethereal solution was evaporated and the solid residue thus obtained (*ca.* 90%) was crystallized from acetic acid to give IIIc, mp 220°C, yield 80%. (Found: C, 40.98; H, 5.44; N, 9.49; S, 21.85%. Calcd for $C_{10}H_{16}N_2O_4S_2$: C, 41.07; H, 5.51; N, 9.58; S, 21.93%.) [IR: N-H absent.]

Dimethyl [*p*-(*N*-Methylbenzenesulphonamido)-phenyl](benzenesulphonyl)phosphoramidate (IIc). A mixture of Ib[3] (0.001 mol), trimethyl phosphite (0.001 mol) and dry benzene (10 m*l*) was kept under N_2 at room temperature for 24 hr. The ppt (A) thus formed was filtered. The colourless oil that remained after evaporation of the volatile materials was solidified in a refrigerator. Crystallization from benzene - petroleum ether (bp 40—60°C) gave IIc as colourless crystals, mp 78°C, yield 70%. (Found: C, 49.34; H, 4.49; N, 5.42; P, 6.11; S, 12.51%. Calcd for $C_{21}H_{23}N_2O_7PS_2$: C, 49.40; H, 4.54; N, 5.48; P, 6.07; S, 12.56%.) Spectral characteristics: bands at 7.78 (P=O), 8.55 and 9.62 ($POCH_3$), and 10.1 μ (P–N);[7] a $3H^1$ singlet at 6.88, a $6H^1$ doublet (J_{HP}=11.4 Hz) at 6.25, and a $14H^1$ multiplet at 2.66 τ.

Compound (A) upon recrystallization from acetic acid gave *p*-phenylenedibenzenesulphonamide (IIId),[3] mp 243°C, yield 15%.

IId was obtained similarly, together with a small amount of IIId (*ca.* 10%), by the action of triethyl phosphite on quinone Ib. Compound IId was crystallized from benzene - petroleum ether mp 85°C, yield 60%. (Found: C, 52.10; H, 5.24; N, 5.07; P, 5.59; S, 11.55%. Calcd for $C_{24}H_{29}N_2O_7PS_2$: C, 52.16; H, 5.29; N, 5.07; P, 5.60; S, 11.60%.)

Action of Trimethyl Phosphite on Quinone Ic. To a solution of quinone Ic[8] (0.32 g) in dry benzene (10 m*l*) was added trimethyl phosphite (0.13 g) and the mixture was refluxed for 10 hr. After cooling a colourless crystalline product was separated. It was filtered off, washed with ethanol, dried, crystallized from dimethylformamide and proved to be *p*-phenylenedibenzamide (IIIe), mp 340°C,[8] yield 95%.

SHORT COMMUNICATIONS

Mechanism of Benzene Formation in the Radiation-Induced and Photochemical Reactions of Acetylene

Shoji SHIDA, Masao TSUKADA, Noboru FUJISAKI and Takefumi OKA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received July 17, 1970)

It is known that acetylene polymerizes to give benzene and solid polymers in radiation-induced and photochemical reactions. For the formation of benzene, radical mechanism[1-4] and excited molecule mechanism[5-11] have been proposed, but no decisive conclusion has been reached.

Table 1 shows the distribution of isotopic benzenes formed in equimolar C_2H_2-C_2D_2 mixtures. In mercury photosensitization[10] and direct photolysis,[11] the distribution is almost constant above 20 mmHg of acetylene pressure. In Table 1, distributions for photolyses are given by average values within this pressure range.

The distribution in radiolysis[12] may be regarded as constant within the acetylene pressures applied and is almost the same as that in the mercury-photosensitized reaction and the direct photolysis at 1849 Å.

It has been shown that the distribution could be explained by a modified excited molecule mechanism[10,11] as well as, or more favourably, by the free radical mechanism, for the photolytic reactions.

The results suggests that benzene is formed in the same mechanism irrespective of the kind of active rays. Detailed studies are in progress.

The Singlet Sensitized Decomposition of Benzoyl Peroxide

Toshio NAKATA and Katsumi TOKUMARU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received July 17, 1970)

In spite of recent investigations by several groups of workers,[1-5] the mechanism of the photochemical decomposition of benzoyl peroxide remains puzzling. We wish to present clear evidence that irradiation of benzoyl peroxide in benzene in the presence of aromatic hydrocarbons such as chrysene, anthracene, pyrene, naphthalene or phenanthrene, under nitrogen with light of 366 nm or over 300 nm at room temperature leads to the sensitized decomposition of the peroxide (denoted by P) by the added hydrocarbons (denoted by S) in their excited singlet states through the following mechanism.

$$S^*(S_1) + P(S_0) \xrightarrow{k_t} X \quad (1)$$

$$X \xrightarrow{k_r} S(S_0) + \text{Decomposition Fragments} \quad (2)$$

$$X \xrightarrow{k_d'} S(S_0) + P(S_0) \quad (3)$$

Thus, the excited singlet sensitizer, on interaction with the peroxide, forms an exciplex (process 1), which subsequently undergoes either decomposition leading to products (process 2) or deactivation (process 3).

The above mechanism for the singlet sensitization is supported by the following findings. First, the quantum yield of the decomposition of the peroxide (0.02M) in the presence of chrysene or phenanthrene was scarcely reduced by the addition of 1,3-pentadiene. For example, the quantum yield observed with added chrysene (0.0064M) was 0.38 and 0.37 in the absence and in the presence (0.08M) of 1,3-pentadiene, respectively. Secondly, fluorescence of the aforementioned hydrocarbons in benzene was effectively quenched by benzoyl peroxide,*1 obeying the following Stern-Volmer equation: $I_0/I = 1 + k_t\tau_0[P]$, with $k_t\tau_0$ 105, 39, 171 and 160 $mol^{-1}\ l$ for chrysene, anthracene, pyrene and naphthalene respectively, where I_0 and I represent the intensities of the fluorescence of the hydrocarbons in the absence and in the presence of the peroxide in the concentration [P], respectively, and τ_0 denotes the average life time of the excited singlet state in the absence of the peroxide. Thirdly, plots of the reciprocals of the quantum yields for the decomposition of the peroxide (Φ) measured in the presence of a constant concentration(0.007M) of chrysene irradiated with 366 nm light were shown to be linear with the reciprocals of varying concentrations of the peroxide, and were analyzed according to the following Stern-Volmer equation, which is derived from the aforementioned mechanism: $1/\Phi = (1 + k_d'/k_r) \cdot (1 + 1/k_t\tau_0[P]))$. The value for k_d'/k_r was shown to be 0.98 and that for $k_t\tau_0$ to be $1.87 \times 10^2\ mol^{-1}l$. The latter value agrees satisfactorily with the aforementioned value for $k_t\tau_0$, $1.05 \times 10^2\ mol^{-1}l$, obtained from the quenching of the fluorescence of chrysene. Fourthly, the experimental values for $k_t\tau_0$ for the hydrocarbons examined, on being divided by the reported values for τ_0,[6] give the values for k_t in the range of 10^9—$10^{10}\ mol^{-1}l\ sec^{-1}$ (for example, $9.8 \times 10^9\ mol^{-1}l\ sec^{-1}$ for anthracene, with τ_0 reported to be 4×10^{-9} sec[6]), nearly equal to the magnitude of the diffusion-controlled rate constant. The fluorescence spectra of the above hydrocarbons do not overlap with the absorption spectrum of the peroxide, the former being in longer wave length region than the latter. These facts rule out the possibility that the excited singlet hydrocarbon undergoes energy transfer to the peroxide by resonance mechanism[7] or by simple collisional mechanism,[7] therefore supporting the mechanism shown in the above scheme in which the energy transfer takes place through the formation of the exciplex.[7]

The present conclusion together with previous results[1-5] clearly demonstrates that, among sensitizers, aromatic hydrocarbons act in their excited singlet states, and aromatic ketones (if they act at all) in their excited triplet states to sensitize the decomposition of benzoyl peroxide.

*1 Fluorescence was measured without exclusion of atmospheric oxygen, with exciting light of 366 nm except for naphthalene which was excited with 300 nm.

Photoionization of *s*-Tetracyanobenzene - Toluene Complex in Its Lowest Excited Singlet State

Hiroshi MASUHARA, Motoo SHIMADA and Noboru MATAGA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received July 18, 1970)

The electron donor-acceptor interactions in *s*-tetracyanobenzene (TCNB) - aromatic hydrocarbon complexes in their lowest excited singlet state have been studied in detail by Mataga and Murata[1] by means of fluorescence measurements. They showed clearly that there is a considerable difference in energy as well as structure between the excited Franck-Condon state and equilibrium state. This difference was considered to originate from the large difference between the electronic structures in the ground and excited states of the complex including the surrounding solvent, and the electronic structure in the excited equilibrium state way supposed to be quite polar.

Another useful way for investigating the behaviors of excited EDA complexes might be the measurements of the absorption spectra of these species by means of the laser photolysis method.[2] In this paper, we report the results of measurements on the TCNB-toluene-acetonitrile system. We might expect for this system the ionic dissociation of the complex at the lowest excited singlet state, since the excited complex seems to have a quite polar electronic structure and the radical ions can be stabilized strongly in a polar solvent. Although there are many examples[3] of the ion radical formation in the excited singlet state when the electron donor and the acceptor are not associated with each other in the ground state, we have hardly any results for the photo-excitation of the EDA complex which is stable in the ground state. Moreover, in many cases, the electron transfer reaction, $D^*+A \rightarrow D_s^+ + A_s^-$ or $D+A^* \rightarrow D_s^+ + A_s^-$, in a strongly polar solvent does not seem to proceed *via* the intermediate EDA complex having a definite structure, but occurs due to a very weak interaction in a loose encounter complex.[4] The TCNB-toluene system, though it is a weak complex, seems to have a definite structure. Accordingly, the electron transfer in this system may be considered as a rearrangement relaxation process from the excited Frank-Condon state to the ion-pair state and dissociated ion-radical state. However, the problem whether the electron transfer and ionic dissociation occur at all in the lowest excited singlet state of an EDA complex, when it is excited by light absorption exclusively at the CT band, does not seem to have been elucidated yet. The present study will give a more or less clearcut information on this problem.

We have used a Q-switched ruby laser with an output power of *ca.* 1 J. The exciting light pulse was produced by an ADP frequency doubler with conversion efficiency of about 8%. The light pulse has a duration of 15—20 nsec. The transient absorption spectra were measured photographically or by means of photomultiplier and synchroscope. The laser breakdown sparks produced in O_2 and Xe was used as spectroflashes.

The absorption spectra of the transient species at room temperature obtained by exciting the TCNB-toluene complex to its lowest excited singlet state in acetonitrile solution are very similar to those of the TCNB anion.[5]

Our kinetic analysis showed that the light-induced production of the transient species was completed rapidly(during the time range smaller than a few 10 nsec). Thus, the observed spectra may be ascribed to the dissociated TCNB anion or to the solvated ion-pair A_s^----D_s^+, although it was not possible to identify the transient spectra of toluene cation. It is also possible that the transient spectra are assigned to the excited singlet-singlet absorption of the complex in view of its polar structure in the excited equilibrium singlet state.[1]

In order to identify the transient species, we have measured the photoconductivity induced by laser photolysis.[6] The rise and decay curves of the photoconductivity were practically the same as those of the absorbance of transient spectra. This kinetic relation is an evidence for the ionic dissociation of the complex at the lowest excited singlet state.

pH and Temperature Pulses during the Periodic Decomposition of Hydrogen Peroxide

Isao MATSUZAKI,*1 John H. WOODSON*2 and Herman A. LIEBHAFSKY

Department of Chemistry, Texas A & M University, College Station, Texas 77843, U.S.A.

(Received June 1, 1970)

Among the large number of homogeneous, liquid-phase, and non-enzymic reactions only two are so far known to be periodic in nature; they are the decomposition of H_2O_2 by IO_3^- and I_2[1-4] and of malonic acid by Ce^{3+}, Ce^{4+}, and BrO_3^-.[5-7] Owing to their complexity, neither reaction has so far been given a satisfactory mechanism; only one aspect of the former reaction, *i.e.* the periodic change in $[I_2]$ ([ ] means mol/*l*), has been qualitatively reproduced[8] *via* computer for a hypothetical mechanism.

In our reinvestigation[9] of the $IO_3^- - I_2 - H_2O_2$ system, we have found pulses in $[I^-]$ that are closely related to previously discovered pulses[1,3,4] in $[I_2]$ and dO_2/dt (rate of oxygen evolution). We have now succeeded in finding pulses also in pH and in temperature. To find these new pulses, it was necessary to have sensitive measuring instruments and to choose the proper reaction conditions. As evidence for this, we mention that Peard and Cullis,[3] apparently the first to look for pH pulses, failed to find them.

Reaction mixtures (140 cc) consisting of approximately 0.6M KIO_3, 0.052M $HClO_4$, and 0.5M H_2O_2 were subjected to both pH and temperature measurements. The reaction vessel, which was surrounded by a water jacket at 50°C, was equipped as needed with instruments for the measurements. Recording of pH was by means of a glass electrode connected to a mV recorder *via* a digital pH/mV meter. Temperature recording was by means of Cu-constantan thermocouple connected to a mV recorder *via* a microvoltometer. Supplementary measurements of $[I_2]$, pI, and dO_2/dt were made with a spectrophotometer, an iodide selective electrode,[10] and a mass flowmeter, respectively.

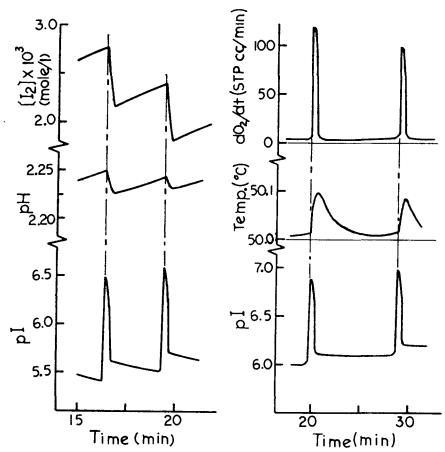

Fig. 1. Pulses in pI, pH, $[I_2]$, temperature, and dO_2/dt. pH pusles were perceptible for the first hour. Replenishment of 0.3M H_2O_2 at time= 150 min resulted in their reappearance at time= 180 min.

Figure 1 shows the observed pulses in pH and temperature and the concomitant pulses in $[I_2]$, pI, and dO_2/dt. Preliminary analysis of the data supports the view that the pH decrease results mainly from the reaction $I_2 + 5H_2O_2 = 2H^+ + 2IO_3^- + 4H_2O$, the incomplete dissociation of HIO_3 being considered. The heat evolved during the temperature pulses appears to result from the reaction just given (responsible for the $[I_2]$ decrease) and from $H_2O_2 = H_2O + \frac{1}{2}O_2$ (responsible for the oxygen evolution). Work is continuing on the relationship of the pulses and their interpretation in terms of known reactions.

Unusual Solvent Effects on the *ortho*:*para* Ratio in the Chlorination of Anisole*[1]

Kazuyoshi SEGUCHI, Tsutomu ASANO, Akira SERA and Ryozo GOTÔ

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto

(Received June 8, 1970)

In the uncatalyzed molecular chlorination of aromatic compounds, no relationship has been observed between the *ortho*:*para* ratio and the dielectric constants of the media.[1] However, the present authors wish to report an interesting correlation between the dielectric constants of the solvents and the *ortho*:*para* ratios in the chlorination of anisole. Anisole was chlorinated[2] in a series of solvents; the logarithms of the *ortho*:*para* ratios are plotted against $1/\varepsilon$ in Fig. 1.

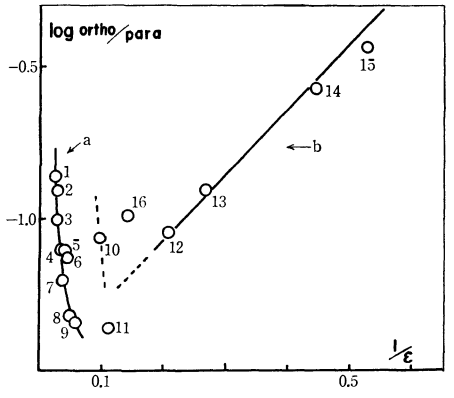

Fig. 1. Plot of log *o*/*p* against $1/\varepsilon$.
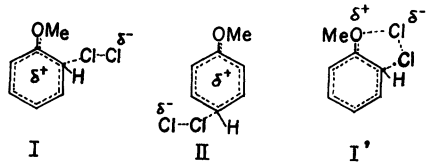
a: in alkyl cyanides and nitroalkanes; 1, $MeNO_2$; 2, MeCN; 3, DMF; 4, $EtNO_2$; 5, *iso*-$PrNO_2$; 6, *n*-$PrNO_2$; 7, EtCN; 8, *n*-PrCN; 9, *n*-BuCN.
b: in halogenated hydrocarbons; 10, $(CH_2Cl)_2$; 11, CH_2Cl_2; 12, $CHCl_3$; 13, $CHCl_2CCl_3$; 14, CCl_4; 15, *n*-C_6H_{14}; 16, *s*-BuCl.



The results show that: (1) in the aprotic media with relatively high dielectric constants, the *ortho*: *para* ratio decreases with a decrease in the dielectric constant, and (2) in the aprotic media with relatively low dielectric constants, the ratio increases unexpectedly with a decrease in the dielectric constant. These results can be interpreted qualitatively in terms of the following two factors; that is, (a) the difference in the solvation of the cationic moiety, $Ar^{\delta+}$, in I and II, and (b) the interaction of $-Cl^{\delta-}$ with $-O^{\delta+}-CH_3$ in the *ortho*-transition state, as in I'. In the chlorination of anisole, the positive charge generated during the activation process will delocalize more extensively in the transition state II than in I. Accordingly, I will be solvated more strongly than II, and the difference in solvation in these two species will become larger with an increase in the polarity of the medium. The observed increase in the *ortho*:*para* ratio with increase in the dielectric constant (curve a) may be mainly ascribable to this difference in solvation between I and II. The effect of pressure on the *ortho*:*para* ratio in aprotic solvents supports this suggestion.[3] The *ortho*:*para* ratios increase with an increase in the pressure in acetonitrile and DMF.[4] This means that the activation volume in *ortho* substitution is smaller than that in *para* substitution ($\delta\Delta V^{\neq} = -1.6 \sim -2.4$ ml/mol[5]). This difference in the activation volumes must result from the difference in solvation between I and II.[6]

On the other hand, the *ortho*: *para* ratio decreases with an increase in the dielectric constants of media in halogenated hydrocarbons (curve b). This fact suggests that, in less polar solvents in this series, an additional stabilization of the *ortho*-transition state arises from an interaction between positively and negatively charged atoms in the molecule (I'). Such stabilization will become less important in more polar solvents. In the medium with a dielectric constant of about 9, the two effects, the difference in the solvation of $Ar^{\delta+}$ and the stabilization by the interaction between $-Cl^{\delta-}$ and $-O^{\delta+}-CH_3$ are balanced and the *ortho*: *para* ratio reaches its minimum value.[7]

Lilac Alcohol-a and -b, New Naturally Occurring Odorous Ingredients

Seiji WAKAYAMA and Satoshi NAMBA

Chemical Laboratory, Hokkaido University of Education, Sapporo

and Masaji OHNO

Basic Research Laboratory, Toray Industries, Inc., Kamakura

(Received June 16, 1970)

No constituents of lilac flower oil, *Syringa vulgaris* L. are known.[1] We could isolate and identify eighteen constituents from the oil obtained by steam distillation of the concrete (*n*-hexane extract of flowers). The main components which amount to 70 per cent of the oil have been found to be four new stereoisomeric terpene alcohols named lilac alcohol-a, -b, -c, and -d. They have the most exquisite floral fragrance. Lilac alcohol-a and -b have been assigned to the diastereomers of (2R, 5R)-β,5-dimethyl-5-vinyl-2-tetrahydrofuranethanol (I).

Lilac alcohol-a $[\alpha]_D^{25}+15.5°$ ($c=0.515$ in $CHCl_3$) and -b, $[\alpha]_D^{25}-2°$ ($c=0.535$ in $CHCl_3$) have the same molecular formula $C_{10}H_{18}O_2$ (M^+, 170). The close similarity of their spectroscopic evidence such as IR, NMR and MS suggests that they are stereoisomers. The IR spectra show the presence of hydroxy (3520 cm^{-1}) and vinyl group (1640, 990, 920 cm^{-1}), and ether linkage (1015 cm^{-1}). The hydroxyl function has been shown to be primary by a prominent peak at *m/e* 31 (C^+H_2OH), and the presence of tetrahydrofuran ring has been shown by the characteristic α-fission of α-substituted tetrahydrofuran derivatives[2] (*m/e*, 155 ($M-CH_3$)$^+$; 143 [$M-(-CH=CH_2)$]$^+$; 111 [$M-(-CH-Me-CH_2OH)$]$^+$; 43 $CH_3{}^+C=O$). The NMR spectra (Table 1) of lilac alcohol-a and -b are reasonably consistent with the proposed structure (I).

A clear proof of the structure has been achieved by the transformation of lilac alcohols and *trans*-linalool oxide[3,4] (II) into the same derivative as shown below. Hydrogenation of II over Pt followed by acetylation and pyrolysis afforded 5-ethyl-2-isopropenyl-5-methyl-tetrahydrofuran (III), which gave a mixture of diastereomers of 5-ethyl-β,5-dimethyl-2-tetrahydrofuranethanol (IV) by hydroboration. Dihydrolilac alcohol-a and -b obtained by catalytic hydrogenation of I were confirmed to be identical with one diastereomer (Rt, 12.6 min) and another (Rt, 9.8 min) respectively.

TABLE 1. NMR SPECTRAL DATA
(δ in ppm, in $CDCl_3$)*

Lilac alcohol		a	b
s-CH_3		0.94 d $J=6.0$	0.80 d $J=6.0$
t-CH_3		1.31 s	1.30 s
$-CH_2-CH_2-$ $-C-$ $H/\ \backslash CH_3$		1.82m	1.80m
$>C(H)-CH_2OH$		3.66 (ABX)	3.62 (A_2X)
$>C(H)-O-$		4.12m	3.80m
$H_3\backslash\ /H_1$ $C=C$ $/\ \backslash H_2$	H_1* H_2 H_3	4.99 5.17 5.87	5.01 5.19 5.89

* The signals of alcohols appear at 2.96—2.60 δ, depending on the concentration, and typical signals of a vinyl group are observed with $J_{1,2}=1.6$ Hz, $J_{1,3}=8.0$ Hz and $J_{2,3}=18$ Hz.

Functional Group Analysis by Gas Chromatography. III.[1] Pyrolysis of Organic Compounds in Sulfur Vapor

Tadashi HARA and Susumu ITO

Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto

(Received July 9, 1970)

Many papers have been published on the reactions between gaseous sulfur and organic compounds.[2] However, they have never been utilized in analytical chemistry. This paper deals with the pyrolysis of organic compounds in sulfur vapor, with special reference to the relationship between the pyrolytic products and functional groups.

Two grams of sulfur was placed in a quartz tube 10 mm dia. × 180 mm (Fig. 1) and melted on the tube wall under helium atmosphere. Either a glass boat or a capillary tube containing 10—30 mg solid or liquid sample was inserted into the reaction tube. The tube was then filled with helium, and heated at 850—880°C by means of a movable electric furnace. The time required for the reaction was about 10 min. The stroke pump was then driven and the sample was gas-chromatogramed under the following conditions: column 2 m, charged with silica gel (60—80 mesh); column temp. 100°C; and carrier gas He, 40 ml/min.

The results are shown in Table 1, and a typical pyrogram of sulfanilic acid in Fig. 2.

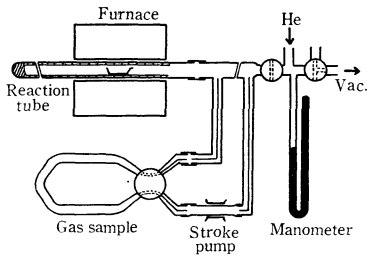

Fig. 1. Apparatus.

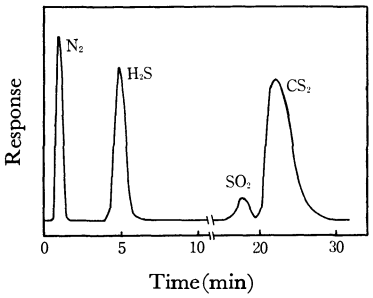

Fig. 2. Pyrogram of sulfanilic acid.

TABLE 1. RELATIONSHIP BETWEEN THE TYPE OF COMPOUND AND PYROLYTIC PRODUCTS

Type of compounds	Compounds	Products found	CO/CO_2 mol ratio
R–COOH	Stearic-, Fumaric-, Cinnamic- and Adipic-acids, Potassium acetate	CO_2 H_2S	
Ar–COOH	Benzoic- and Terephthalic-acids	CS_2	
R–CO–R′	Acetylacetone		>1
R(Ar)–CO–R′	Acetophenone, Benzophenone		<1
(Ring C)=O	Cyclohexanone		<1
Ar–CHO	Benzaldehyde	CO	>1

Synthesis and Reactivities of 1-Carbobenzoxy-3-substituted-aziridinones

Muneji MIYOSHI

Chemical Research Laboratory, Tanabe Seiyaku Co., Ltd., Higashiyodogawa-ku, Osaka

(Received July 13, 1970)

Interest in aziridinones has increased since Baumgarten[1] first proved the existence of *N*-*t*-butyl-3-phenylaziridinone by spectral studies. Recently, some analoges were obtained in crystalline forms and their chemical properties were reported.[2-6]

I wish to report a new synthetic route and the reactivities of 1-carbobenzoxy-3-substituted-aziridinones (I) derived from the corresponding carbobenzoxy-L-amino acids (ZAA). Dehydration of ZAA was carried out successfully in THF at −20°C, with the aid of dehydrating agents containing two reactive halogen atoms in the molecule ($COCl_2$, $SOCl_2$, $POCl_3$, *etc.*), and subsequently by dropwise addition of triethylamine (TEA) exactly to neutralize. 1-carbobenzoxy-3-benzylaziridinone (Ia) was obtained as crystalline needles, mp 73.0—73.5°C. $[\alpha]_D^{20}$ −36.0° ($c=1$, THF), mass M^+ 281. NMR ($CDCl_3$, δ): 7.21 (*bs*, 5H), 7.37 (*bs*, 5H), 5.30 (*s*, 2H), 4.55 (*t*, 1H), 3.26 (*dd*, 2H), 3.03 (*dd*, 2H). Found: C, 72.60; H, 5.33; N, 5.11%. Calcd for $C_{17}H_{15}NO_3$: C, 72.58; H, 5.37; N, 4.98%. I showed 1840 cm^{-1} band in IR (Fig. 1) which was characteristic of aziridinones.[1,2]

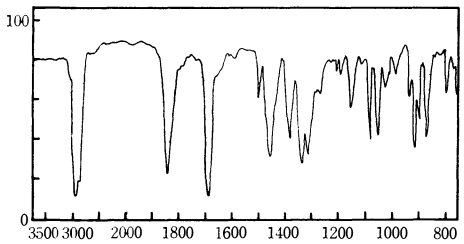

Fig. 1. IR spectrum of Ia.

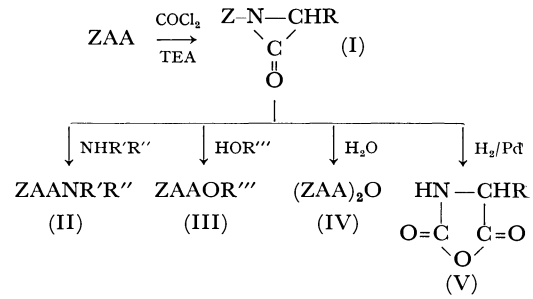
I was found to be quite sensitive to the nucleophiles and ring opening took place always between N and C=O bond selectively. Typical reactions with I are as follows.



Usually it was convenient for I to be treated directly with the desired nucleophile at −20°C without isolation from the reaction mixture. So far, no racemization has been observed (Table 1).

Table 1. Results of reactions with I

R	Nucleophile	Product	Yield (%)	mp (°C)	$[\alpha]_D^{20}$ ($c=1$)
$CH_2C_6H_5$	H·Gly·OEt	(II)	83.8	111	−16.8 (EtOH)
$CH_2C_6H_5$	$NHCHCO_2CH_3$ $H_3C\ CH(CH_3)_2$	(II)	81.0	81	−70.0 (MeOH)

A New Protective Group Suitable for Masking Specific Amino Groups during Peptide Synthesis

Shumpei SAKAKIBARA, Tsunehiko FUKUDA, Yasuo KISHIDA and Ichiro HONDA

Peptide Center, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received July 14, 1970)

The benzyloxycarbonyl (Z) group is considered to be stable under conditions necessary for the removal of a *t*-butyloxycarbonyl (Boc) group, and a combination of these two protective groups has been widely used in syntheses of lysine-peptides. For instance, N^{α}-Boc-N^{ε}-Z-lysine was used in the solid-phase synthesis of lysine-peptides.[1] However, on the repeated removal of Boc-groups with N HCl/AcOH or with trifluoroacetic acid, a partial cleavage of the ε-Z-groups has been noted, and it has been claimed that the resulting unprotected ε-amino groups cause the branching of the peptide bonds.[2] The present communication is concerned with the use of the diisopropylmethyloxycarbonyl (Dipmoc)-group as a new amino-protecting group. The introducing reagents were synthesized by keeping a mixture of diisopropylcarbinol[3] (0.5 mol) and phosgene (70 m*l*) in tetrahydrofuran (70 m*l*) at −20°C for 3 days. The excess phosgene was removed by evaporation under reduced pressure at room temperature, and the remaining tetrahydrofuran solution was used as the Dipmoc-Cl solution without further purification. Dipmoc-hydrazide was synthesized by a procedure previously used for the synthesis of *t*-amyloxycarbonyl-hydrazide;[4] mp 62.5—64.5°C; yield 78% (Found: N, 15.80%. Calcd: N, 16.08%). The hydrazide was converted to the azide by a method which has been reported before,[4] and this was used without purification. ε-Dipmoc-L-lysine was synthesized with the copper-lysine complex using Dipmoc-Cl or Dipmoc-N_3; the same ε-Dipmoc-L-lysine was thus obtained in a 57—58% yield; mp 198.5—200.5°C (decomp); $[\alpha]_D^{25}$ +22.3° (*c* 1.0, N-HCl) (Found: N, 9.78%. Calcd: N, 9.71%). Z-L-Pro-L-Lys(Dipmoc)-Gly-NH_2 (I) was synthesized by conventional methods; mp 174.5—176.5°C, $[\alpha]_D^{26}$ −39.9° (*c*, 1.0, EtOH). The stability of the protective group against N HCl/AcOH is shown in Fig. 1 in comparison with those of the Z group and of the *p*-chlorobenzyloxycarbonyl [Z(Cl)] group.[5] The Dipmoc-group could be removed completely by treatment with HF[6] in the presence of anisole at 20°C for 60 min. This cleavage was demonstrated with Compound I; L-Pro-L-Lys-Gly-$NH_2 \cdot 2HCl \cdot \frac{1}{2}H_2O$ was thus obtained in a 92.3% yield as an amorphous powder; $[\alpha]_D^{26}$ −40.0° (*c* 1.8, H_2O) (Found: C, 41.25; H, 7.58; N, 17.87%. Calcd: C, 40.94; H, 7.40; N, 18.36%). Thus, the usefulness of this procedure was confirmed.

Absorption Spectra of Charge-Transfer Complexes in the Molten State

Jun-ichi AIHARA, Akira SASAKI and Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 15, 1970)

Since Mulliken set forth the distinguished charge-transfer theory, a considerable amount of effort has been devoted to explaining the various interactions responsible for the actual charge-transfer complexes.[1,2] However, as previous investigations were interested in the interactions around room temperature for the sake of convenience, our knowledge of the complexes is necessarity confined to those in solution and, to lesser degree, those in the solid state.

In our previous papers, we overcame the experimental difficulties due primarily to the thermal instability of the complexes and succeeded in measuring the gaseous absorption spectra of typical TCNE complexes.[3,4] On the other hand, attempts to detect the liquid-phase complex have been completely lacking. The observation of the spectra in the molten state might be useful for the analysis of the liquid-phase structure.

Recently, we investigated the charge-transfer complexes in the molten state and, for the first time, succeeded in the optical detection of the fused complexes. The absorption spectra were derived from the diffuse reflection spectra. The measurements were made at temperatures considerabley higher than the melting points, using a Beckman DK-2A spectroreflectometer.

We first prepared the *N,N*-dimethylaniline-*s*-trinitrobenzene 1:1 complex from an *N,N*-dimethylaniline solution of *s*-trinitrobenzene. The observation in the liquid phase was made at 150°C, which is higher by 50°C than the melting point of the complex. Figure 1 shows the liquid-phase absorption specrtum of the *N,N*-dimethylaniline-*s*-trinitrobenzene complex. The spectra in the solid state and in the *n*-heptane solution are added for the sake of comparison. In the solid, two characteristic charge-transfer bands were observed at 19300 and at 23300 cm^{-1}. However, the second band was missing in the other phases. The absorption maximum in the molten state was found at 21100 cm^{-1}, which corresponds to a blue shift of 1800 cm^{-1} from that found in the crystal. On the other hand, it was located at 21400 cm^{-1} in the *n*-heptane solution. It can be easily seen therein that, though each band-width is somewhat different, the absorption bands in the liquid phase and in the solution are almost superimposed upon each other. The naphthalene-TCNE complex also has similar tendencies in the liquid-phase spectrum.

It is widely known that, in the crystal, the presence of nearby charge-transfer complexes markedly alters the properties of the isolated complex. The complexes generally from an $\infty:\infty$ complex instead of distinct 1:1 complexes. Though we can expect such situations in the liquid phase, at least in view of the optical absorption, we can not characterize them in the spectra. However, this fact dose not preclude the possibility that interactions inducing such phenomena as the liquid-phase exciton and the quite high conductivity exist in the liquid-phase complexes.[5,6]

We are now continuing to examine other type of charge-transfer complexes in the molten state.

Transition in Solution of Polyvinyl Acetate in Toluene

Satoru MASHIMO, Yoshio OTSUBO and Keniti HIGASI

School of Science and Engineering, Waseda University, Shinjuku, Tokyo

(Received July 29, 1970)

The dielectric properties of polyvinyl acetate in toluene were studied over a frequency range of 1—150MHz at various temperatures. Molecular weights of the polyvinyl acetate were determined by intrinsic viscosities to be 7900, 17200, 43000, 165000, and 387000. Dielectric measurements[1] on these five samples were carried out at the same concentration, *viz.*, 5% by weight.

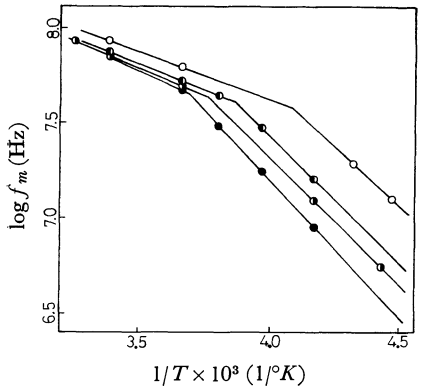

Fig. 1. Plot of $\log f_m$ *vs.* $1/T$.
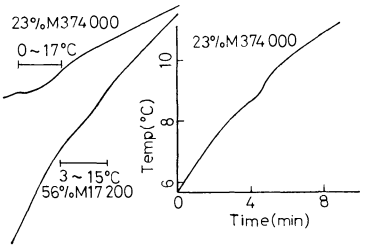
○: 5%M 7900; ◐: 5%M 17200; ◑: 5%M 43000
●: 5%M 165000, 5%M 387000.

When the logarithm of the frequency of maximum dielectric absorption is plotted against the reciprocal of absolute temperature, two straight lines are obtained (Fig. 1). The point at which two lines intersect is taken tentatively as transition temperature. The apparent activation energy is 2.8 kcal/mol above this temperature, and 6.3 kcal/mol below it. The dielectric behavior of the sample changes at this temperature. This is similar to the transition temperature of solid hydrogen halides[2] or of solid polymers.[3] The values of ε_0, ε_∞ obtained from the Cole-Cole plot change at this temperature; above it Cole's distribution parameter α decreases with increasing temperature, while it remains constant below.



DTA Heating curve

Fig. 2. Results of heat capacity measurements.

The results of differential thermal analysis are shown in Fig. 2. A small but abrupt change of heat capacity could be observed in all the samples having sufficiently high concentrations. The change is detected also in the heating curve (Fig. 2).

The transition temperature determined from heat capacity measurements slightly differs that of dielectric measurement. However, it appears certain that they would approach each other, if the solution of the same concentration could be employed for the two sorts of measurements.

The transition phenomenon thus depends on the concentration and also the molecular weight of the solute. When the transition temperature is plotted against $1/M$, the following equation for a straight line appears to be valid:

$$T_{\text{transition}} = 272 - 2.2 \times 10^5/M \quad (^\circ\text{K}) \qquad (1)$$

This equation is very similar to that between the glass transition temperature T_g and the molecular weight M of polyvinyl acetate in the solid state

$$T_g = 310 - 1.8 \times 10^5/M \quad (^\circ\text{K}) \qquad (2)$$

which is obtained from studies on nuclear magnetic resonance.[4]

The Crystal and Molecular Structure of Bromoanhydrotetrodoic Lactone Hydrobromide

Akio FURUSAKI, the late Yujiro TOMIIE and Isamu NITTA

Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received February 26, 1970)

The absolute configuration of bromoanhydrotetrodoic lactone, $C_{11}H_{14}O_7N_3Br$, has been determined on the basis of an X-ray study of its hydrobromide. The crystals are orthorhombic, with four chemical units in a unit cell of these dimensions: $a=10.88\pm0.04$, $b=15.95\pm0.05$, and $c=8.55\pm0.03$ Å; the space group is $P2_12_12_1$. The observations for Bijvoet inequalities were made on equi-inclination integrating Weissenberg photographs taken with Cu$K\alpha$ radiation around the a axis. On the other hand, the calculations were carried out with the parameters at the stage of the R factor of 11.9% and with anomalous dispersion correction of -0.9 for $\Delta f'_{Br}$ and 1.5 for $\Delta f''_{Br}$. The observed and calculated inequalities for ten pairs of reflections were all in agreement with each other, so the absolute configuration was determined without any uncertainty. In addition to the X-ray determination of the absolute configuration mentioned above, the present paper will describe the details of the crystal and molecular structure.

Tetrodotoxin is well-known as a highly poisonous principle of the puffer fish, but, to say nothing of its molecular structure, even its chemical formula remained uncertain till quite recently. In 1964, through independent investigations, Tsuda *et al.*, Hirata *et al.*, and Woodward *et al.* arrived at the same molecular structure for this poison.[1-3] All their results were based on X-ray structure analyses of halogen-containing derivatives of tetrodotoxin.[3-6] In cooperation with the organic chemical investigation by Hirata *et al.*, the structure of one of the derivatives, bromoanhydrotetrodoic lactone hydrobromide, was studied in our laboratory by means of X-ray methods, an outline of the results having already been published at the stage when the R factor was 15.4%.[6] Although very delayed in publication due partly to the unexpected death of one of the authors, Yujiro Tomiie, the present account will describe the X-ray determination of the absolute structure, which had been already reported at the Third International Symposium on the Chemistry of Natural Products held in Kyoto in 1964, and will discuss in detail the molecular and crystal structure thus obtained.

Structure Determination

The crystal data obtained from the oscillation and Weissenberg photographs taken with Cu$K\alpha$ radiation are summarized in Table 1. The crystal structure was elucidated by means of the minimum-function and Fourier methods, using the 1860 structure factors which were obtained from equi-inclination integrating Weissenberg photographs taken around the a and c axes. The approximate atomic coordinates thus obtained were refined at first by the diagonal-matrix least-squares method, assuming isotropic thermal motions for all the atoms, and then by the block-diagonal-matrix least-squares method, assuming anisotropic thermal motions only for the bromine atoms. The latter

refinement was carried out using a program devised by Yoshiharu Okaya, IBM Thomas Watson Research Center.*1 Thus, the R factor reached a value of 11.9%. The final atomic parameters are given in Table 2. Tables of the observed and calculated structure factors are preserved by the Chemical Society of Japan.*2

Determination of the Absolute Configuration

The absolute configuration of the present crystal structure was determined by using the anomalous dispersion effects of bromine atoms for Cu$K\alpha$ radiation. For the present point group 222, $|F(h\bar{k}l)|^2$ should be equal to $|F(\bar{h}\bar{k}\bar{l})|^2$ even if the anomalous dispersion effects are taken into account. Accordingly, the intensities of the hkl reflections were compared with those of $h\bar{k}l$ instead of with those of $\bar{h}\bar{k}\bar{l}$ on integrating Weissenberg photographs around the a axis. The observed signs of $\Delta|F(hkl)|^2$'s for ten reflections are listed in Table 3, together with the values calculated, using $\Delta f'_{Br}=-0.9$ and $\Delta f''_{Br}=1.5$, from the final atomic parameters in Table 2. Table 3 clearly shows that the atomic coordinates which have been so far used correspond exactly to the actual absolute configuration.

Results and Discussion

Molecular Structure. The framework of the molecular ion of bromoanhydrotetrodoic

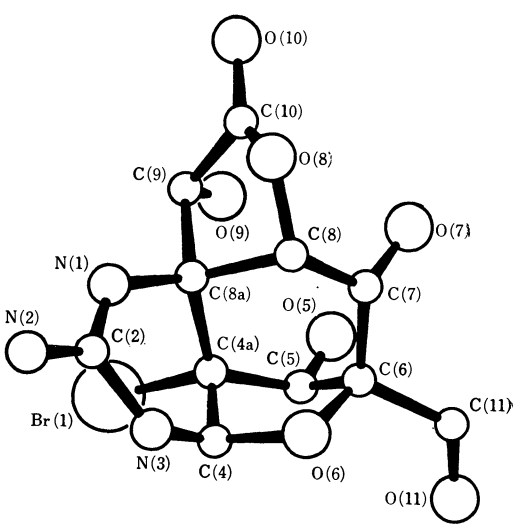

Fig. 1. The framework of the bromoanhydrotetrodoic lactone ion.

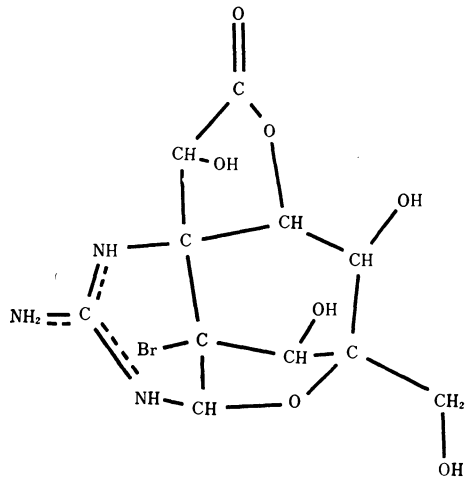

Fig. 2. The structural formula corresponding to Fig. 1.

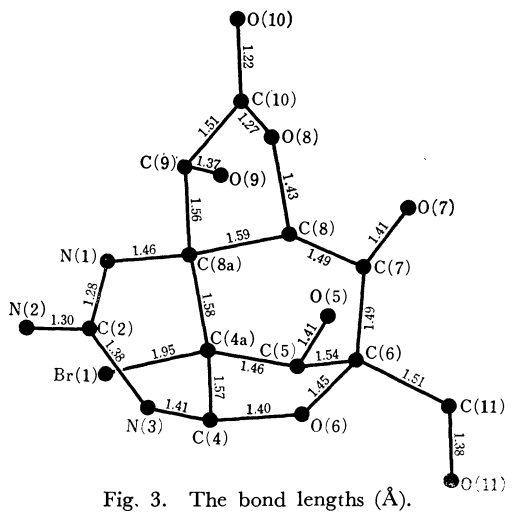

Fig. 3. The bond lengths (Å).

lactone and the corresponding structural formula are shown in Figs. 1 and 2 respectively. The bond lengths and angles calculated from the final atomic coordinates are given, respectively, in Fig. 3 and Table 4. The average standard deviations of the interatomic distances are 0.016 Å for C–Br, 0.021 Å for C–O, 0.022 Å for C–N, and 0.023 Å for C–C. Considering these standard deviations, the molecular dimensions calculated are all reasonable, except for the C(10)–C(8) bond distance (1.27 Å).

The skeleton of the present molecular ion is composed of two six-membered and two five-membered rings. One of the first two rings is heterocyclic, with two nitrogen atoms of a guanidinium group, while the other is homocyclic, with a somewhat distorted chair form. These two rings are joined to each other in the *cis* configuration. On the other hand, both of the five-membered rings are heterocyclic; one of them is a γ-lactone ring attached in the *cis* configuration to the second of the six-membered rings mentioned above, while the other contains an ethereal oxygen atom which bridges, additionally, the two fused six-membered rings. Since, moreover, a bromine atom, a hydroxymethyl group, and three hydroxyl groups are connected to the skeleton, the molecular ion assumes quite a complicated stereostructure and includes very close interatomic contacts. Such intramolecular contacts are listed in Table 5, together with the distances.

* hydrogen-bonded

The guanidinium group is almost planar, and C(4) and C(8a) are apart from the mean plane of this group by about 0.23 and 0.22 Å respectively; C(4) is on the same side of the plane as the C(4a) atom, while C(8a) is on the opposite side.

The hydroxyl oxygen atoms, O(5) and O(7), are both attached in the axial orientation to the cyclohexane ring of the chair form; consequently, these atoms are very close to each other, their distance being about 2.82 Å. Though this distance may be taken numerically to correspond to the hydrogen bonding, it is not so, as will be described later. Further, O(5) and O(7) approach closely to the hydroxyl oxygen O(9) and the lactone oxygen O(8) respectively. The former contact occurs at a distance of 2.63 Å and corresponds to an intramolecular hydrogen bond. On the other hand, the latter contact, although the distance is also very small, 2.62 Å, and although the azimuthal angle between C(7)-O(7) and C(8)-O(8) around C(7)-C(8) is only about 31° which is small considering that O(7) and O(8) occupy roughly the axial and equatorial positions of the cyclohexane ring, is not due to hydrogen-bond formation, but to the distortion of the ring. This point will be explained later.

The lactone ring deviates considerably from a planar structure. The distances of the atoms from the mean plane through the four atoms, C(9), C(10), O(8), and O(10), are given in Fig. 4. From this figure, it is found that the lactone ring takes a conformation close to the half-chair form. In this molecule, such a ring conformation seems to favor to some degree the relaxation of the repulsions between Br(1) and O(9) and between O(7) and O(8).

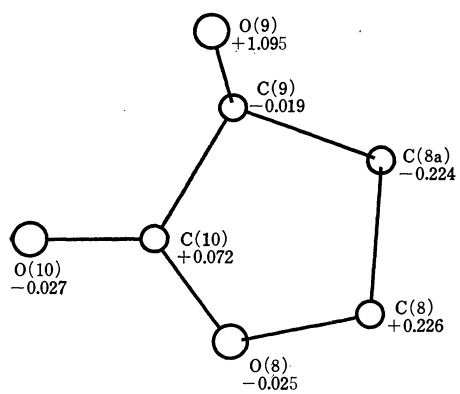

Fig. 4. The deviations from the mean plane through C(9), C(10), O(8) and O(10).

The five-membered ethereal ring takes a conformation of the envelope type; C(4), C(4a), C(6), and O(6) are nearly coplanar, and the remaining C(5) is considerably apart from the mean plane of the first four atoms. The deviations of the atoms from the plane are shown in Fig. 5.

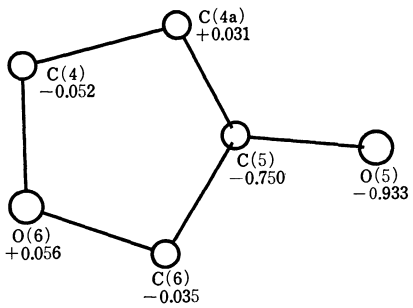

Fig. 5. The deviations from the mean plane through C(4), C(4a), C(6) and O(6).

The hydroxymethyl group is linked to the C(6) of the cyclohexane ring in the equatorial orientation. The C(11)-O(11) bond makes azimuthal angles of about 32° with C(5)-C(6) and 100° with C(6)-O(6) around C(6)-C(11). Consequently, O(11) is much closer to C(5) than to O(6), in spite of the larger van der Waals radius of the former, the O(11)—C(5) distance being only about 2.82 Å.

Crystal Structure. The projections of the present crystal structure along the *a* and *c* axes are shown in Figs. 6 and 7 respectively. The molecular and bromide ions are connected by several hydrogen bonds, forming a three-dimensional hydrogen-bonded structure. Each bromide ion makes three hydrogen bonds with its adjacent molecular ions; one is formed with O(7) at a distance of 3.17 Å; another, with O(11) at 3.34 Å, and the remaining one, with N(1) at 3.23 Å. Besides these, each molecular ion forms four additional hydrogen bonds; one of them is the O(5)-H···O(9) intramolecular bond, as has already been mentioned. The remaining three hydrogen bonds, N(2)-H···O(11′), N(3)-H···O(10″), and O(9)-H···O(7‴), connect molecular ions around screw axes along the *a*, *b*, and *c* axes respectively, their distances being 2.78, 2.88, and 2.69 Å respectively. As for the first two of these, if the protons of the nitrogen atoms are in the plane of the guanidinium group, it follows that they are considerably off the hydrogen bond directions.

It has been mentioned already, without any explanation, that neither of the intramolecular close approaches, O(7)···O(8) and O(5)···O(7), is due to hydrogen bonding. This may be explained as follows. As for the former approach, since O(7) donates its proton to the bromide ion to form the O(7)-H···Br(2) hydrogen bond, while O(8) has no proton, these two oxygen atoms can not make a hydrogen bond with each other. On the other hand, as for the latter approach, if O(5) forms a hydrogen bond with O(7), the proton donor in this bond should be the former oxygen for the same reason. Therefore, in this case, the O(5)···O(9) approach can not be accepted as a

hydrogen bond, because, if it is so assumed, O(9) would donate a proton to O(5) and, consequently, could not form the O(9)···O(7‴) intermolecular hydrogen bond. If, on the contrary, O(5) forms a hydrogen bond with O(9), it follows that O(5) does not form one with O(7). Thus, it is the key to the present problem which of the two hydroxyl oxygens, O(7) and O(9), forms a hydrogen bond with O(5). Considering the facts that the distance between O(5) and O(9) is much smaller than that between O(5) and O(7), and that the C(5)-O(5)··· O(9) angle, 99°, is closer to the H-O-H angle, 104.5°, of a water molecule in the gas phase than to that of C(5)-O(5)···O(7), 83°, the latter possibility, *i.e.*, O(5)-H···O(9), seems to be more probable, though the evidence is not quite conclusive.

Intermolecular distances smaller than 4.0 Å in the present crystal are listed in Table 6. These values are all reasonable except for the distance of 3.02 Å between C(9) of the I molecule and O(5) of II. This approach may be called a kind of hydrogen bonding, since C(9) is expected to carry a considerable amount of positive charge because of the existence of two more electronegative groups, a hydroxyl and a lactone group. This view is also supported by the fact that the estimated position of the hydrogen atom at C(9) is not far off the C(9)···O(5) line; the C(9)-H bond and the C(9)···O(5) line make an angle of only about 28°, and hence the atomic distance between H and O(5) is no more than 2.12 Å.*3 As may be seen from Table 6, each bromide ion Br(2) is surrounded by four molecular ions. Of these four, three approach the anion by hydrogen bonds, as has already been mentioned. As for the remaining one, the smallest interatomic distance, 3.71 Å, is found between Br(2) and C(8). This value is somewhat smaller than the sum of the van der Waals radii, 3.95 Å.

In conclusion, the authors would like to express their hearty thanks to Professor Yoshimasa Hirata, Nagoya University, for providing them with the samples. The authors also wish to express their thanks to Professor Yoshiharu Okaya, State University of New York at Stony Brook, for his kind help in the structure refinement.

*3 In the estimation of the position of the H atom, it was assumed that the four unit vectors from C(9) to C(8a), C(10), O(9), and H are in tetrahedral directions and that the atomic distance between C(9) and H is 1.09 Å.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3332—3341 (1970)

The Crystal and Molecular Structure of Tetrodotoxin Hydrobromide

Akio FURUSAKI, the late Yujiro TOMIIE and Isamu NITTA

Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received February 26, 1970)

The crystal and molecular structure of the hydrobromide of tetrodotoxin itself, $C_{11}H_{17}O_8N_3 \cdot HBr$, have been studied by means of three-dimensional X-ray analysis. The crystals are triclinic, with two formula units in a unit cell of the dimensions; $a=8.79$, $b=9.02$, $c=9.51$ A, $\alpha=106°51'$, $\beta=88°1'$, and $\gamma=96°23'$; the space group is $P\bar{1}$. The intensities of reflections were recorded on equi-inclination Weissenberg photographs taken with Cu$K\alpha$ radiation around the b and c axes, and were measured visually with a calibrated intensity scale. The structure was elucidated by means of the Fourier and least-squares methods, and was refined by the block-diagonal-matrix least-squares method, the anisotropic thermal motion being assumed only for bromine atoms. The stereostructures of the two crystallographically-independent molecules of tetrodotoxin thus obtained are almost identical and correspond to that deduced by Tsuda *et al.*, by Hirata *et al.*, and by Woodward *et al.*, all in 1964. It is noteworthy that, in both of the two molecules, the C–O distance for the free hydroxyl group in the ortho-ester part (1.36 and 1.39 Å) is somewhat smaller than the ordinary aliphatic C–O distance, 1.43±0.01 Å, and that it is rather closer to the phenolic C–O distance, 1.36±0.01 Å.

The molecular structure of tetrodotoxin, one of the most poisonous natural substances, had remained unknown for a long time in spite of extensive organic chemical investigations, until it was, in 1964, at last elucidated independently by Tsuda *et al.*, by Hirata *et al.*, and by Woodward *et al.*[1-3] All of these three groups derived the same structure for the poison from those structures determined by X-ray crystal analyses for its different derivatives.[3-6] The X-ray determination of one of the derivatives, bromoanhydrotetrodoic lactone hydrobromide, was carried out in our laboratory in cooperation with Hirata *et al.* of Nagoya University.[6,7] Since Professor Yoshimasa Hirata kindly provided us also with single crystals of the hydrobromide of tetrodotoxin itself, a three-dimensional X-ray crystal analysis was later undertaken in order to confirm directly the molecular structure deduced from those of the derivatives.

Experimental

The crystal data were obtained from oscillation and Weissenberg photographs taken with Cu$K\alpha$ radiation around the three principal axes; the results are summarized in Table 1. The intensities were recorded on equi-inclination Weissenberg photographs taken with Cu$K\alpha$ radiation for 0—8 layers around the b axis and for 0—3 layers around the c axis, and were measured visually with a calibrated intensity scale. No absorption correction was applied, though the

samples used were not sufficiently small (about 0.5 mm in diameter). After the Lorentz and polarization correction, these data were put on an absolute scale by means of Wilson's method. The overall temperature factor obtained at this stage was 2.08 Å^2. Thus, the absolute values of the structure factors of 2839 independent reflections were derived.

All the photographs used for the present study were taken in the Crystallography Laboratory, University of Pittsburg, when one of the authors (Y. T.) was there (1963).

Structure Determination

A Patterson function, $P(u, v, w)$, was calculated at intervals of 1/30 for u, for v and for w. The resulting map showed that if one of two bromine atoms in a unit cell, Br(a), was placed at the point of origin (0, 0, 0), the other Br(b) should be situated close to the (1/2, 1/2, 1/2) position. In order to refine the latter position, the diagonal-matrix least-squares method was applied. After three cycles, the R factor dropped from the initial value of 0.554 to 0.345, and the bromine position became (0.5180, 0.5276, 0.4900). On the other hand, we tried to estimate the positions of light atoms from the Patterson map on the basis of the proposed molecular structure of tetrodotoxin. In this way, out of the positions of forty-four independent light atoms present in an asymmetric unit, twenty were found. Using the two bromine positions and these positions, and assuming all the light atoms to be carbon, the first Fourier synthesis was carried out; the calculated R factor was 0.312. The map thus obtained had many maxima; out of these forty-eight higher maxima were taken as temporary atomic positions and were tested for the divergence of temperature factors.[8] After three cycles of the least-squares method, nine positions were found to be inadequate. Then, using the thirty-nine remaining positions, the second Fourier map was calculated. From the map drawn, forty-seven maxima were chosen again as positions of the light atoms and were tested again by the least-squares method. The results after three cycles are given in Table 2, which shows that, out of the forty-seven positions, the three marked with asterisks may be inadequate. However, from a comparison of these positions with the structure determined on the basis of the chemical evidence, it turned out that not all the forty-four light-atom positions which seemed adequate before, in view of the results of the least-squares test, were actually cor-

8) M. Nishikawa, K. Kamiya, M. Tomita, Y. Okamoto, T. Kikuchi, K.Osaki, Y. Tomiie, I. Nitta and K. Coto, *J. Chem. Soc., B*, **1968**, 652.

rect for the two of them marked with a double asterisk were inadequate.

The reason why the temperature factors corresponding to the two positions do not diverge remains unknown, but this fact seems to warn against the formal use, without criticism, of the divergence of the temperature factors as a structure test.

The two remaining atomic positions were obtained from the third Fourier map. The coordinates of the forty-six atoms thus obtained were refined by the block-diagonal-matrix least-squares method using isotropic temperature factors for all the atoms. After four cycles, the R factor dropped to 0.150. Next, the atomic coordinates were further refined by the above-mentioned method, using anisotropic temperature factors only for the bromine atoms; the final R factor was 0.130. The atomic parameters thus obtained and the electron density distribution calculated with these parameters are given in Table 3 and Fig. 1 respectively. Tables of the observed and calculated structure factors are preserved by the Chemical Society of Japan.*1

Results and Discussion

Molecular Structure. The bond lengths and angles of the two crystallographically-independent tetrodotoxin molecules, A and B, are listed in Tables 4 and 5, together with the arithmetical means of the corresponding values of the two. The average standard deviations of the atomic distances are estimated to be 0.033 Å for C–C, 0.031 Å for C–N, and 0.029 Å for C–O. If these deviations are taken into consideration, the dimensions of the two independent molecules are in good agreement with each other. Thus, from the present results, it may be concluded that the stereostructures of the two tetrodotoxin molecules, A and B, are almost identical and that they correspond to that derived from the organic chemical investigations.[1–3] In Figs. 2 and 3, the framework of one of the two independent molecules and the corresponding structural formula are, respectively, drawn with reference to the absolute configuration based on that of the derivative of the poison, bromoanhydrotetrodoic lactone hydrobromide.[7]

The molecules are characterized by an ortho-ester system rarely found in natural products. This system makes a part of an adamantane-like cage structure and might have some close connection with the powerful toxicity. It has been reported by Tamura *et al.* that the remarkable system in the molecule is still preserved in the derivative, diacetylanhydrotetrodotoxin hydroiodide.[5] The geometry of the ortho-ester part found in the present molecule is shown in Fig. 4, as is that in the derivative.*2

*2 Since, for both the present substance and the derivative, the crystals contain two crystallographically-independent molecules, the respective mean values are given in Fig. 4.

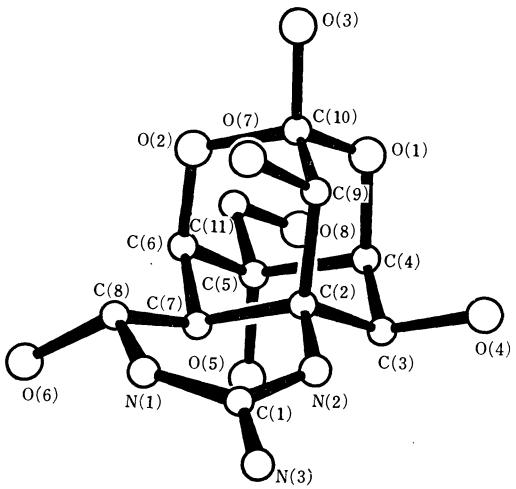

Fig. 2. The framework of the tetrodotoxin ion (A).

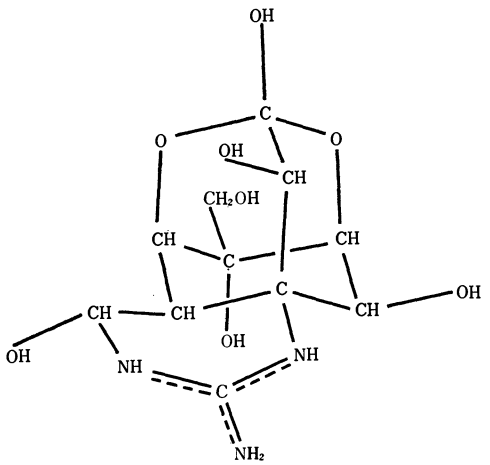

Fig. 3. The structural formula corresponding to Fig. 2.

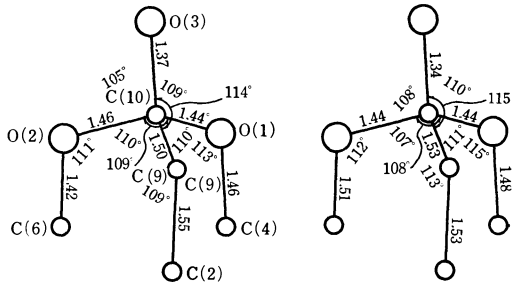

Fig. 4. The geometry of the ortho-ester parts.
II: in tetrodotoxin.
II: in diacetylanhydrotetrodotoxin.

Though neigher of the analyses has a sufficiently high accuracy for a detailed discussion, the two results show some common characteristics. For example, the bond distance between the free hydroxyl oxygen atom and the central carbon atom of the ortho-ester is 1.37 Å in the present molecule and 1.34 Å in the derivative; both of these values are considerably smaller than the ordinary aliphatic C–O distance, 1.43±0.01 Å, and rather closer to the phenolic C–O distance, 1.36±0.01 Å.[9]

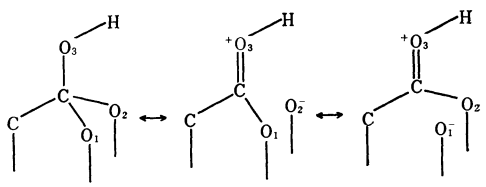

Fig. 5. The resonance of the ortho-ester.

This shortening of the C–O bond may be explained by the resonance, shown in Fig. 5. In this resonance, in addition to the ortho-ester structure, I, two ionic structures of the ordinary ester type, II and III, take part, and both of these contribute to the shortening of the C–O bond under consideration. In an acidic solution where the free hydroxyl oxygen O(3) has a proton, the structures

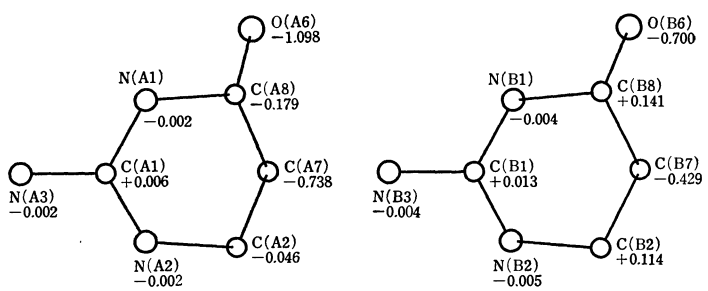

Fig. 6. The deviations from the guanidinium planes.

9) "Tables of Interatomic Distances and Configuration in Molecules and Ions," ed. by L. E. Sutton *et al.*, Burlington House, London (1958).

II and III may contribute only a little to the resonance. However, in an alkaline solution where O(3) loses a proton and where it becomes easy to feed electrons to C(10), the contribution of structures corresponding to II and III would increase and, consequently, the molecules would become more unstable with respect to C(10)–O(1) and C(10)–O(2). As another of the common characteristics, it is further found that the bond angle C(9)–C(10)–O(3) and the corresponding angle in the derivative are 114° and 115° respectively, both larger than the tetrahedral angle, 109.5°.

It is of interest to compare the two independent molecules of tetrodotoxin with each other. Though almost identical, strictly speaking, these two may be conformational isomers since they appear, so far as the present results are concerned, to be different only in conformation and different only in part. Thus, appreciable conformational differences are found in two parts of the molecules; one of them is the hydroxymethyl group, and the other is the six-membered ring containing a guanidinium group. The former part is different in respect to the conformation of the hydroxyl oxygen O(8) around C(5)–C(11); in one of the molecules, A, O(8) is *trans* to C(6), while, in the other, B, it is *trans* to C(4). Since the potential energy curve for the internal rotation of O(8) around the C(5)–C(11) bond seems to be approximately symmetrical with respect to the plane through C(5), C(11), and O(5), the two observed conformations which are almost related to each other by the mirror plane may not be appreciably different in energy. Accordingly, which of the two conformations the molecule takes seems to

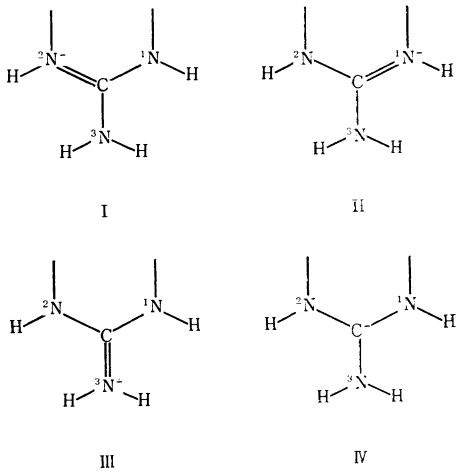

Fig. 7. The four predominant formulae for the resonance of the guanidinium group.

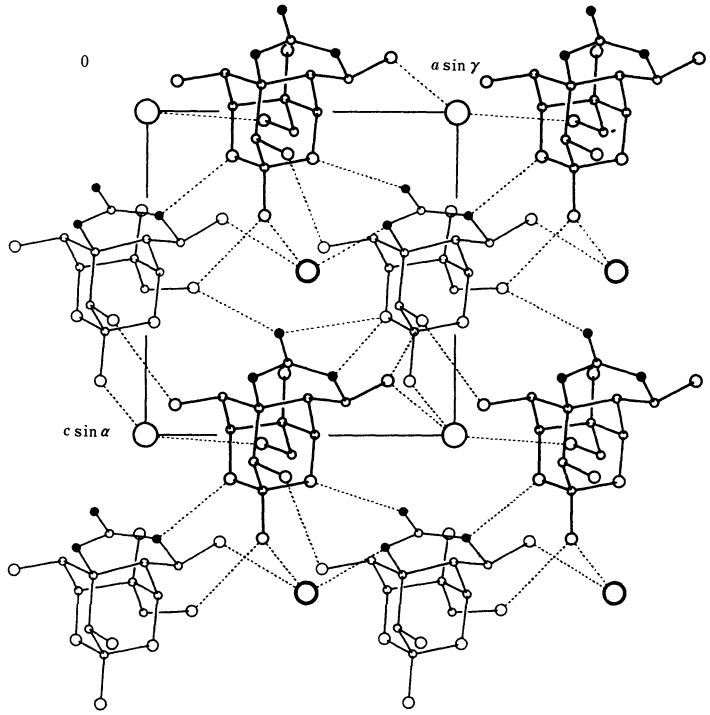

Fig. 9. The crystal structure viewed along the *b* axis.

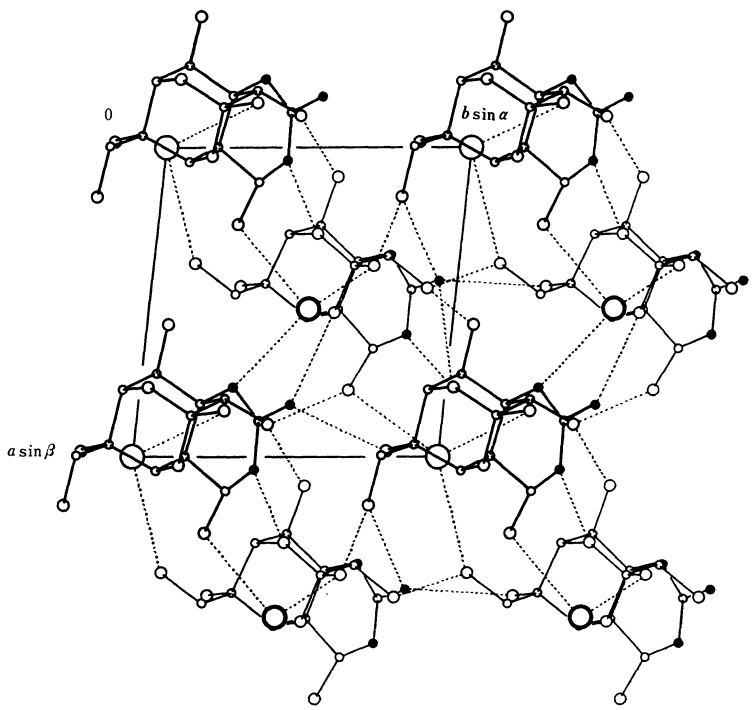

Fig. 10. The crystal structure viewed along the *c* axis.

depend on the intermolecular rather than on the intramolecular interactions. On the other hand, the six-membered rings with a guanidinium group are different in overall form; in A, the ring is in rather the boat form, while, in B, it is in the chair form, though, in either case, the five atoms, C(2), N(2), C(1), N(1), and C(8), lie roughly on a plane. The guanidinium group itself is almost planar in both of the molecules. The deviations of the atoms from the mean plane of the group are shown in Fig. 6 for the respective molecules. In A, C(2) and C(8) deviate from the guanidinium plane in the same sense as C(7), while, in B, the two atoms are on the opposite side of the plane to C(7). This shows that the two corresponding rings take different conformations, as has already been mentioned.

Considering the resonance of the guanidinium group, the two molecules have parallel characteristics, as may be seen from the bond distances in Table 4. To this resonance, the four formulae given in Fig. 7 seem to contribute mainly. In view of the bond distances, in both molecules, out of the three formulae containing a double bond, I would seem to be the most predominant, and III, the least. That I is superior to II is consistent with the fact that, in both molecules, C(8) deviates more considerably from the guanidinium plane than does C(2); in other words, the twisting of the bond C(1)–N(1) is larger than that of the C(1)–N(2) bond.

Crystal Structure. The projections of the crystal structure viewed along the *a*, *b*, and *c* axes are shown in Figs. 8, 9, and 10 respectively. Further, in Table 6, possible hydrogen bonds are listed, together with the distances, in consideration of the correspondence between the two independent molecules. Since the present molecules have many proton donors and acceptors, the crystal takes quite a complicated three-dimensional hydrogen-bonded structure; for A molecules, each makes fourteen hydrogen bonds with adjacent molecules and bromide ions, while, B molecules make thirteen.

Both of the bromide ions, Br(a) and Br(b), form three hydrogen bonds with their adjoining tetrodotoxin molecules. For the former bromide ion, the three hydrogen bonds are all of the O–H···Br^- type; the distances are 3.23 Å for O(A6)–H···Br(a) and 3.36 Å for O(B3)–H···Br(a) and O(A8)–H···Br(a). On the other hand, for the latter, out of the three hydrogen bonds, two are O–H···Br^- and the other is N–H···Br^-; the distances are 3.14 Å for O(A3)–H···Br(b), 3.24 Å for O(B6)–H···Br(b), and 3.26 Å for N(B2)–H···Br(b). So far as only the atomic distances smaller than 4.0 Å are concerned, Br(b) is surrounded merely by the three molecules which make hydrogen bonds with it, while Br(a) is approached by two additional molecules as well.

In some of the hydrogen bonds found in the present crystal, the proton seems to be, to a considerable degree, off the line joining the proton donor and acceptor. Since, for the four protons of the guanidinium grouping, their approximate positions can be estimated on reasonable assumptions,*3 the deviations of the N–H bond directions from the respective donor-acceptor lines have been calculated; the results are listed in Table 7. The maximum deviation is found for N(B2)–H···Br(b), the angle being no less than about 47°. Nevertheless, the approach between N(B2) and Br(b) may be taken as hydrogen-bonded because the proton at N(B2) is separated from Br-

(b) by only 2.68 Å; this distance is much smaller than the sum of the van der Waals radii, 3.15 Å. That such large deviations of the hydrogen bond directions are found in the present crystal is probably related with the fact that the molecules make extremely numerous hydrogen bonds.

As has been found for Br(a) and Br(b), for the two independent molecules also the hydrogen bond natures are different in some respects. The most interesting of these differences is that, in the O(5)···N(3) hydrogen bond, for the A molecule the proton seems to be donated by the former atom, while, for the B, it seems to be donated by the latter. As for the A molecule, the estimated positions of the two protons at N(A3) are separated from O(B1) and O(B8) respectively by only 2.26 and 1.99 Å, and hence the two approaches to N(A3) are considered hydrogen-bonded. On the other hand, since O(A5) is sufficiently separated from both of the protons (2.70 and 3.17 Å), these two protons have little relation with the close approach between O(A5) and N(A3). Considering the facts that the O(A5)···N(A3) direction makes a relatively small angle of about 33° with the normal of the guanidinium plane and that the π-electrons are localized to some extent at N(A3), since, out of the three important formulae for the resonance of the guanidinium group, III is the least predominant, as has been mentioned above, O(A5) and N(A3) seem to make a hydrogen bond of the O–H···N type. On the other hand, as for the B molecules, since O(B5) is only 2.28 Å apart from the proton at N(B3), the O(B5)··· N(B3) approach would seem to be due to a hydrogen bond of the N–H···O type.

All the small intermolecular atomic distances except the hydrogen-bonded ones are listed in Table 8. These distances nearly correspond to the van der Waals contacts, though some of them are somewhat smaller than the ordinary values because of the intermolecular approach due to hydrogen bonding and other forces.

In conclusion, the authors wish to express their thanks to Professor Yoshimasa Hirata, Nagoya University, for providing them with the samples. The authors would also like to express their thanks to the staff of the X-ray group, University of Pittsburgh, for their kind help in the collection of the intensity data.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3341—3344 (1970)

Pyrolysis-Gas Chromatographic Investigation of Chlorinated Polystyrenes

Shin TSUGE, Hajime ITO and Tsugio TAKEUCHI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received April 22, 1970)

The distribution of chlorine atoms in radically chlorinated polystyrenes was studied by means of pyrolysis gas chromatography. Degradation products such as styrene, benzene, toluene and chlorobenzenes are related to different structures of the chlorinated polymers. The sequence distribution of each structure was discussed over a wide range of degree of chlorination. Chlorine atoms are first substituted with α- then β-hydrogen in the main chain of polystyrene. The first ring substitution of chlorine occurs competitively at *p*-position even before both α- and β-hydrogens are substituted.

Many types of chlorinated polymers have been synthesized in a search for improved thermal characteristics such as flammability, heat-distortion temperature and thermal stability. Thermal properties are closely associated with the microstructres of polymers, especially with the distribution of chlorine atoms.

Chlorinated polystyrenes have been synthesized by both ionic and radical mechanisms and their structures have been studied by various methods.[1-3]

Bachmann *et al.*[1] reported on the depolymerization of some ionically chlorinated polystyrenes to elucidate their structures. They identified halogenated styrenes such as *p*-chlorostyrene and 3,4-dichlorostyrene after fractional distillation of the depolymerized mixture.

Teyssie *et al.*[2] also carried out an ionic chlori-

nation of polystyrene and characterized the resulting structure by chemical and infrared spectrometric analysis. The chlorination reaction takes place concurrently on the aromatic nucleus and on the main chain. The chlorine, which is substituted on the aromatic nucleus, is preferentially bonded to the para position and secondarily to the ortho position. The second chlorine is then introduced mainly in 3 position with respect to *p*-chlorostyrene unit and in 5 position with respect to *o*-chlorostyrene unit to form 3,4- and 2,5-dichlorostyrene units, respectively.

Jenkins *et al.*[3] prepared chlorinated polystyrenes by means of the radical method using ultraviolet radiation and determined the changes in the infrared spectrum, glass transition temperature and molecular weight of the polymers. In contrast to the ionic reaction, the radical chlorination reaction proceed mainly by substitution at the α-hydrogen position in the main chain. Main chain scission also took place as the chlorination reaction proceeded.

In our previous work, we characterized chlorine containing polymers such as vinyl chloride-vinylidene chloride copolymers,[4] chlorinated polyethyrenes[5] and chlorinated polyvinylchlorides[6] by means of pyrolysis-gas chromatography (PGC).

The purpose of the present work is to characterize the distribution of chlorine atoms in radically chlorinated polystyrenes with the use of PGC. Degradation products of the polymers at 455°C were separated chromatographically and identified to be styrene monomer, benzene, toluene, chlorobenzenes. Benzene and toluene, which are related with the structures produced by substituting the main chain, are observed concurrently with chlorobenzenes which are originated from the structures of substituted aromatic rings. The sequence distribution of each structure was discussed as a function of degree of chlorination.

Experimental

Chlorination. Polystyrene (PSt) was dissolved in chloroform and filtered. The polymer was chlorinated by slowly passing Cl_2 gas into the solution (55 g/*l*) under the illumination of a mercury lamp. Samples of the solution (30 m*l*) were removed from the reaction flask, neutralized and precipitated in sodium hydroxide-methanol solution. The samples were dried in a vacuum oven.

Pyrolysis-Chromatography. The gas chromatograph was a GCG-550F with flame ionization detectors and the pyrolysis apparatus a GP-1000, both supplied by Yanagimoto Co., Ltd. The sample holder and the precut portion of the pyrolysis apparatus were modified to increase the precision of the data and to trap hydrogenchloride gas evolved at the pyrolysis, respectively.[4,5] Operating conditions were as follows.

Column: 3 mm×2 m copper column packed with Diasolid L(80—100 mesh) coated with PEG 6000 (10 wt% to the support)

Carrier gas: nitrogen gas flowing at the rate of 20 cc/min

Pyrolysis temperature: 455°C

Infrared Spectrometry. Infrared spectra were obtained on a Nihon Bunko IR-S by the KBr disc methoed.

The chlorine content of the polymers were chemically determined. In the following, the degree of chlorination D is defined as the number of chlorine atoms per styrene monomer unit.

Results and Discussion

The pyrograms of the polymers with various *D* are shown in Fig. 1. Raw PSt yields nearly quantitatively styrene monomer. As the chlorine content increases, peaks for benzene, toluene and

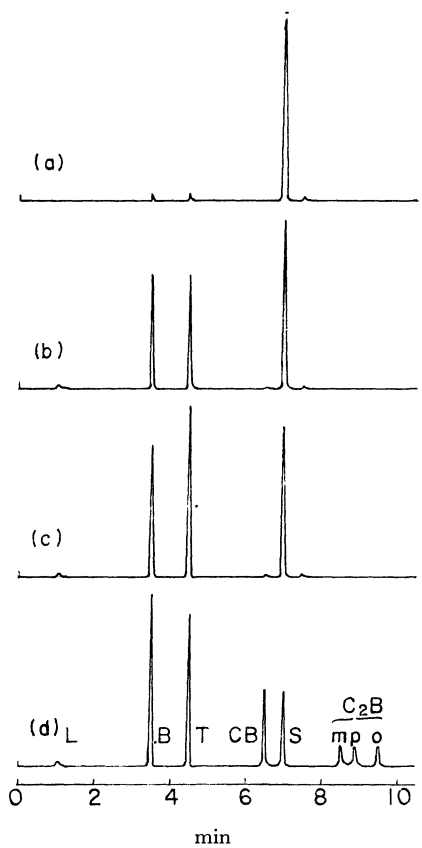

Fig. 1. Typical programs of PSt and chlorinated PSt at 455°C.
(a): PSt, (b)—(d): chlorinated PSt; (b): D=0.57, (c): D=1.50, (d): D=2.25, where D is the degree of chlorination (the number of chlorine atoms per monomer unit).

chlorobenzenes appear on the pyrograms, while the yield of styrene monomer decreases.

The relationships between the relative yields among the aromatic products and D are shown in Fig. 2, where a small amount of low boiling point products appearing in the earliest retention time is neglected for the sake of simplicity.

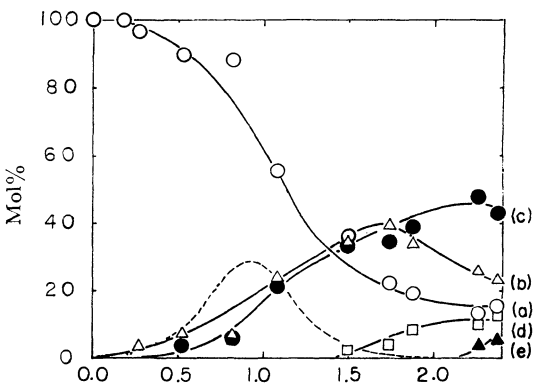

Fig. 2. Relationships between the degree of chlorination (D) and the yield of the degradation products from chlorinated PSt.
A: styrene monomer, B: toluene, C: benzene, D: chlorobenzene, E: dichlorobenzenes.
Dotted curve is calculated from Eq. (2) for $n=3$.

The yield of styrene monomer decreases monotonously as a function of D. The yield of toluene is first observed at $D=0.27$ and shows a maximum (40 mol%) at $D=1.74$. On the other hand, benzene, which first appears at $D=0.53$, increases monotonously up to $D=2.26$. The appearance of chlorobenzene starts at $D=1.50$. Dichlorobenzenes are observed above $D=2.26$.

Each characteristic product is closely related to the structure of the polymers as follows:

Styrene Monomer. PSt with molecular weight higher than ten thousand was depolymerized nearly completely to monomer.[7] PSt with lower molecular weight, however, yielded such additional products as toluene and benzene. Thus the relative yield of styrene monomer decreases with the decrease of molecular weight.

In the case of chlorination of PSt, we must consider competitive reactions such as substitution of the hydrogen atoms in the main chain of PSt or in the aromatic ring of PSt and simple scission of the main chains. Each reaction causes shorter sequences of styrene unit than that of the raw PSt and accordingly is responsible for the reduction of the yield of styrene monomer.

Toluene. The chlorination reaction of PSt proceeds mainly by substituting at the α-hydrogen in the main chain.[3] For chlorinated PSt with D above 1.0, some monomer units have two chlorine atoms at both α- and β-positions, since no ring protons are substituted until $D=1.5$ as described below.

The relative yield of toluene in the pyrolysis products of PSt increases rapidly with the decrease of its degree of polymerization.[7] Thus we consider the apparent reduction of the sequence of unsubstituted styrene unit in chlorinated PSt as follows.

For the sake of simplicity, it is assumed that chlorination reaction takes place almost at rondom at α- or β-hydrogen, but that of α-substitution occurs in preference to β-one.[3] The substitution of ring protons is not taken into consideration.

Sequences (I), (II) and (III) are formed with the probabilities of ac^na, ac^nb+bc^na and bc^nb, respectively, where a and b are the probabilities of substitution of only α- and both α- and β-hydrogens, respectively, and c is that of non-substitution and n is sequence number of styrene unit. Consequently, the following equation is expected to hold for the total number of the unstubstituted styrene units.

$$N=\sum_{k=1}^{n} Pc^k(a^2+2ab+b^2)$$

where P is the degree of polymerization of PSt and $a+b+c=1$. The number of the hydrogen atoms that can be substituted is $2P$, provided that the substitution reactions take place at α-hydrogen and one of β-hydrogens. On the other hand, the number of chlorine atoms contained in chlorinated PSt is $D\times P$. When we assume random substitution, the probability of introduction of one chlorine atom is $D\times P/2P=D/2$ and that of non-substitution is $\{1-(D/2)\}$. Consequently, we have $a=2(D/2)\{1-(D/2)\}$, $b=(D/2)^2$ and $c=\{1-(D/2)\}^2$.

Thus, N can be shown as a function of D, where we have only to consider relatively small n value (at most $n=10$).

$$N=\sum_{k=1}^{n} P\{1-(D/2)\}^{2k}[4(D/2)^2\{1-(D/2)\}^2 +4(D/2)^3\{1-(D/2)\}+(D/2)^4] \quad (2)$$

As shown in Fig. 2 with a dotted curve, the function always passes through a maximum between $D=0$ and 2.0. The observed yield of toluene shows a maximum value between $D=0$ and 2.0 ($D\sim1.6$).

7) S. Tsuge, T. Okumoto and T. Takeuchi, *J. Chromatogr. Sci.*, **7**, 250 (1969).

The results suggest that toluene may be closely associated with the short sequences mentioned above. However, the fact that the theoretical curve deviates at high D may be attributed to the rough assumptions, where the substitution of ring protons and reduction of molecular weight during chlorination are neglected. Strictly speaking, reduction of molecular weight of PSt during chlorination also leads to the yield of toluene. However, if this had been predominant, the yield of toluene should have had a monotonously increasing inclination as the rise of D.

Benzene. The yield of benzene, which is very small even in PSt with low molecular weight,[7] increases almost monotonously up to $D=2.25$ as the rise of D. This suggests that the mole fraction of both α- and β-disubstituted styrene unit increases as chlorination proceeds. However, the fact that the yield exhibits a decreasing tendency above $D=2.26$ implies that a substitution of the hydrogen atoms considerably participates in the aromatic ring of PSt.

Chlorobenzenes. Chlorobenzene is first observed at $D=1.50$. The infrared spectrum of chlorinated PSt with $D=1.50$ has an absorption band near 1080 cm^{-1}, which is characteristic for *p*-substituted styrene unit.[2] It is very interesting that the substitution of ring protons begins at $D=1.50$, where α- and β-hydrogens in the main chain are not completely substituted. The first ring substitution occurs at *p*-position, but the second one seems to proceed at random since *o*-, *m*- and *p*-dichlorobenzenesappear almost at the same time above $D=2.25$.

The π-Electronic Structures of Five-membered Heterocycles Containing Two or Three Heteroatoms and Their Benzo-derivatives

Mamoru KAMIYA

Shizuoka College of Pharmacy, Oshika, Shizuoka

(Received May 13, 1970)

The semiempirical Pariser-Parr-Pople SCF method combined with configuration-interaction has been applied for calculation of the electronic spectrum, ionization potential and electron affinity, π-electron distribution and total π-energy of such heterocycles as oxazole, isoxazole, oxadiazoles, imidazole, pyrazole, triazoles and their monobenzo-derivatives, and the theoretical results have been compared with the available spectral data and miscellaneous chemical properties including the position-dependency on substitution reactions, novel photochemical isomerization of several compounds and so forth.

The π-electronic structures and chemical properties of the titled compounds are of interest because the parent five-membered heterocycles are known as small aromatic molecules exhibiting unique chemical behaviour, and it is only recently that the chemistry of these compounds has made a remarkable progress. Several molecular orbital calculations have been performed for such compounds; Hückel-type calculations, both simple and modified, have been applied chiefly for evaluating dipole moment, reactivity index and resonance energy,[1-7] and an extended Hückel method including all valency electrons has also been used for the calculation of charge distribution of imidazole, pyrazole, *v*-triazole, and the four possible oxadiazoles,[8] which indicates that the calculated σ-polarizations are almost independent of the π-electron distributions. SCF calculations have also been performed for explanation of electronic spectra and dipole moments of the several molecules and have given good agreement with the experimental data by adopting proper semiempirical para-

meters.[9-13]

It seems, however, that no attempts have been made for SCF calculations which systematically treat both the electronic spectra and chemical properties of the molecules mentioned above. In this work the standard Pariser-Parr-Pople SCF method with configuration-interaction procedure has been carried out for all the molecules in the title, such as oxazole, isoxazole, oxadiazoles, imidazole, pyrazole, triazoles, and their benzo-derivatives.

Calculation Method

Calculations have been performed on the basis of the Pariser-Parr-Pople method[14] with configuration-interaction including all singly excited configurations. The elements of F matrix are taken as

$$F_{\mu\mu} = -I_\mu + (1/2)q_\mu\gamma_{\mu\mu} + \sum_{\nu\neq\mu}(q_\nu - n_\nu)\gamma_{\mu\nu},$$

$$F_{\mu\nu} = \beta_{\mu\nu} - (1/2)p_{\mu\nu}\gamma_{\mu\nu},$$

where q_μ and $p_{\mu\nu}$ are the diagonal and off-diagonal elements, respectively, of the bond order-charge density matrix, and n_ν is the number of electrons donated to the π-electron system by the νth atom. The values of valence-state ionization potential (I) and electron affinity (A) are determined as follows referring to the paper of Hinze and Jaffe.[15]

I (eV): 11.16 (-C=), 14.12 (-N=), 26.70 (-N(H)-), 32.90 (-O-)

A (eV): 0.03 (-C=), 1.78 (-N=), 9.26 (-N(H)-), 11.37 (-O-)

The two-center repulsion integral ($\gamma_{\mu\nu}$) is computed according to the Nishimoto-Mataga approximation. The core-resonance integral ($\beta_{\mu\nu}$) is evaluated using the equation $\beta_{\mu\nu} = -1/2\, S_{\mu\nu}(I(\mu)+I(\nu))$, where the overlap integral ($S_{\mu\nu}$) is calculated using Slater-type atomic orbital.[16] For comparison the calculation is performed both including and neglecting the $\beta_{\mu\nu}$ over non-neighbouring atomic pairs.

The comparison is meaningful in view of the present purpose of explaining both electronic spectra and chemical properties at the ground state; it is well-known that a good description of the ground state by using semiempirical parameters, in particular the core-resonance integral $\beta_{\mu\nu}$ adjusted to experimental spectral data is difficult, since the ground state which can be represented by a single Slater determinant does not mix with any of the corresponding singly excited states.

Molecular structures of all the heterocycles studied herein are tentatively approximated as a regular hexagon and pentagon with a bond length of 1.395 Å on account of lack in enough available expermental data.

The present calculations have been performed using HITAC 5020-E computer at the University of Tokyo.

Results and Discussion

Optical Properties. The calculated results of singlet π–π* transition energy, corresponding oscillator strength and polarization direction, and excitation energy of the lowest $^3(\pi, \pi^*)$ state are summarized in Table 1(a) and 1(b), the experimental spectral data being collected in Table 2.

In the case of the five-membered heterocyclic molecules the predicted values of the first π–π* transition energy are remarkably (0.4—1.0 eV) lowered by the calculation including the $\beta_{\mu\nu}$ over non-neighbouring atomic pairs (This procedure will be denoted as method I and the other as method II), and these values tend to be slightly smaller than those observed. It is of interest to note that the predicted first π–π* transitions of vicinal-triazoles are more bathochromic and stronger in intensity than those of symmetrical-ones. It is also known that the direction of the first transition moment tends to be of a positive angle for isoxazole and pyrazole, and of a negative angle for oxazole and imidazole.

As for the benzo-derivatives, such as 1,2-benzisoxazole (indoxazene), 2,1-benzisoxazole (anthranil) and benzimidazole, fairly good agreement is found between the calculated (by method I) and experimental spectra, even though the core-resonance integral ($\beta_{\mu\nu}$) is not chosen so as to reproduce individual transition energy. The observed spectrum of indazole is in better agreement with the calculated one (by method I) of 1*H*-tautomer rather than that of 2*H*-tautomer for the relative intensities of the lowest two bands. In the case of benzotriazole also, the observed transition energies of the lowest two bands seem to be in better agreement with the calculated values (by method I) of the 1*H*-tautomer rather than those of the 2*H*-

ΔE_s = singlet π-π^* transition energy.

* = excitation energy of the lowest $^3(\pi$-$\pi^*)$ state.

f = oscillator strength, where the transition moment of $i \rightarrow j$ singly excited transition is obtained as $(\boldsymbol{m}_{i\rightarrow j})_x = \sqrt{2}\sum_r C_r^i C_r^j \bar{x}_{rr}$, $(\boldsymbol{m}_{i\rightarrow j})_y = \sqrt{2}\sum_r C_r^i C_r^j \bar{y}_{rr}$ and $(\boldsymbol{m}_{i\ j})_z = 0$.

α = polarization direction measured counterclockwise to the x-axis.

tautomer. Experimentally, it is reported[17] that the first π–π^* band of benzotriazole is characteristic of a quinoid chromophore and its second band is characteristic of a benzenoid chromophore.

The polarization direction of the initial three transitions are much affected by introducing benzene ring, but the general trends of variation are not affected appreciably by the replacement of the pyrrole-nitrogen with the furan-oxygen. In this case also, the first π–π^* transition of the molecules with NH (O)-N bond tends to polarize along the bond, in contrast to the other-type molecule in which the corresponding transition polarizes in remarkably different directions. As to benzimidazole, indazole and benzotriazole it has been revealed[18] from fluorescence polarization data that the polarization directions of the lowest two absorptions are remarkably different to each other, and the first and third bands of benzimidazole have moderately close polarization directions. The calculated angle (by method I) between the two transition moments is 57° in benzimidazole, 48° (40°) in indazole and 85° (90°) in benzotriazole, the angle between the first and third transition moments in benzimidazole being 17°. According to method II the calculated angle is 73° in benzimidazole, 48° (40°) in indazole and 73° (90°) in benzotriazole, the angle between the first and third transition moments in benzimidazole being 6°. Such results are in line with the experimental facts.

The excitation energy of the lowest triplet state has been given for benzimidazole, indazole and benzotriazole as about 2.8, 2.6 and 2.8 eV, respectively.[18] The calculated excitation energy of the lowest triplet state of these molecules is by 0.4—1.2 eV (by method I) and 0.5—1.0 eV (by method II) lower as compared to the experimental values.

It may be said that the present calculations by method I on spectroscopic properties are in rather good correlation with the experimental results, although no specific adjustment of the core-resonance integral to the experimental transition energy is made. This encourages us to predict various chemical properties on the basis of the presently obtained π-electron distributions.

Chemical Properties. The calculated results on the π-electron distributions at the ground state, such as π-electron density and π-bond order, and the orbital energies of the highest occupied and lowest vacant ($\varepsilon_{h.o.}$ and $\varepsilon_{l.v.}$) are presented in Fig. 1(a), and for comparison the similar results evaluated by method II are also given Fig. 1(b). Comparative survey of the whole system will be useful especially for recognizing the effect of atom-rearrangements since the standardization of molecular geometry may remove complicated perturbations on the semiempirical integrals accompanied by geometrical variations.

As concerns oxazole and isoxazole molecules several features are eminent in the given molecular diagrams; the π-bond order of the N–O bond in isoxazole is very low as compared to those of the neighbouring bonds (particularly by method I), and the largest localized dipole is associated with the N–O bond. This predicts that the bond may be a preferred point of attack for any hydrolytic reagent. This bond, in fact, undergoes nucleophilic cleavage in sodium ethylate solution, differently from other azoles, and the cleavage is more facilitated in the state with a free 3-position than that with a free 5-position.[19] This preference of the position is also predicted by the presently given order of $q^{\pi}_{(C-3)} < q^{\pi}_{(C-5)}$. The present result indicates that oxazole gives less contribution of a shortly polarized ionic structure to hybrid resonance than isoxazole. The calcu-

lated total π-energy of isoxazole is close to that of oxazole, and it seems probable that the π-energy stabilization in isoxazole is caused by the electrostatic interaction of the two oppositely polarized N and O atoms in spite of the reduced cyclic conjugation.

The relation of $q^{\pi}_{(c-4)} > q^{\pi}_{(c-2)}$ in oxazole is different from the result of a previous SCF calculation using the furan- and imidazole-type parameters for the empirical parameters.[9] The present result predicts that among the carbon atoms in oxazole ring the 5-atom has the largest π-electron density which is in line with a remark of other workers.[20] There is, however, a claim that the 2-atom should be expected to have a larger q^{π} than the other two carbon atoms.[21] Electrophilic substitution on isoxazole is normally predicted to occur selectively at the C-4 position analogously to the β-position substitution in pyridine. This indicates that the influence of the nitrogen atom is predominant.

From comparison of the molecular diagrams of the four possible oxadiazole it is known that the π-electron density on the oxygen atom is almost invariant for all the molecules. This may indicate that with the same regular pentagon geometry the ionic structure with O(+) is equally predominant for all the molecules. It is of interest to note that the accepted mechanism for nucleophilic fission of the N–O bond in 1,2,4-oxadiazole is also accounted for by the low N–O π-bond order and π-electron density at the C-3. Electrophilic substitution such as nitration, halogenation or Friedel-Crafts' reaction are known not to occur at the C-3 or C-5 position of mono-substituted 1,2,4-oxadiazole.[22] This is in harmony with the present result which shows that these positions are markedly electron-deficient to favour nucleophilic substitutions.

In the case of the benzo-derivatives of oxazole, isoxazole and oxadiazoles the following effects of fused benzene-ring upon the π-electron distribution in each heterocyclic ring are known from the given molecular diagrams; in benzoxazole π-electrons on the hetero-ring are smoothly attracted toward the delocalized benzene-ring. In anthranil and benzofurazan the similar π-electron-migration occurs selectively along the O–N–C and O–N linkages, respectively. In 1,2,3-benzoxadiazole and indoxazene in which the π-dipole of the polar O(+)–N(−) bond is in direction against the fused benzene-ring, such migration is prohibitive. Electrophilic (nucleophilic) substitutions on indoxazene are predicted to occur in the increasing order of 7>5 (3>4,6), while the C-5 is assigned from experiment to the preferred point of electrophilic attack such as nitration[23] and bromination,[24] and the C-3 to the site of the initial nucleophilic attack in the N–O bond fission in alkaline solution,[25] respectively. Electrophilic (nucleophilic) substitution on anthranil is predicted to occur in the order of 5≈7 (3,6>4), and electrophilic halogenation[26] and nitration[27] are reported to occur at the 5-position. The corresponding orders in 1,2,3-benzoxadiazole and benzoxazole are 7>5 (6>4 by method I and 4>6 by method II), and 7>4,5,6 (2), respectively. The hydrolysis of benzoxazole in alkaline solution is possibly due to a nucleophilic attack on the C-2, but its electrophilic substitution such as nitration is known to occur at the C-6.

Concerning the negatives of the highest occupied orbital and lowest vacant orbital energies which represent ionization potential and electron affinity, respectively, it is of interest to note that the presence of the polar N–O bond in the benzo-derivatives as well as the five-membered heterocycles tends to increase both values so as to justify the contribution of the electrostatic interaction to π-energy stabilization. However, few experimental data are available to check the predicted tendency.

It is known[28] that indoxazene undergoes photochemical isomerization into benzoxazole and at the same time ring-cleavage into the nitrile of salicylic acid. The present calculation indicates that excitation into the lowest $^1(\pi, \pi^*)$ and/or $^3(\pi, \pi^*)$ state induces decrease of the π-bond orders in the O–N–C linkage of indoxazene and favours bond-lability (See the corresponding molecular diagrams in Fig. 2(a) and 2(b).).

More discussions will be made for the nitrogen-containing heterocycles; firstly, the experimental basic pK_a values of five-membered heterocycles (6.95(imidazole), 2.53 (pyrazole), 2.55 (1,2,4-triazole))[29a] are found in bad correlation with the ordering of the π-electron density on the pyridine-type nitrogen. It is probable that the present disagreement is partly due to difference in the protonation energy except π-energy term, since a recent CNDO-type calculation of the total

molecular protonation energy assuming the same regular pentagon geometry[29b] can predict correctly the experimental order of pK_a. Also, the predicted relations, $q^{\pi}_{=N-}$(pyrazole)$>q^{\pi}_{=N-}$(imidazole) and $q^{\pi}_{-\underset{H}{N}-}$(pyrazole)$\sim q^{\pi}_{-\underset{H}{N}-}$(imidazole) appear as incompatible with the observed order[30] of strength of the autoassociating hydrogen-bond in these molecules, indicating that the autoassociation involves complicated polymerization as usually accepted.

In the case of pyrazole the charge distribution predicts that electrophilic substitution occurs in the order of $4>5>3$, in agreement with the accepted fact that the ordinary electrophilic substitutions proceed readily at the 4-position. But the theoretical prediction for pyrazole should be modified because it is known that there is a tautomeric exchange of the position of the N–H bond so that the 3- and 5-positions should be considered as equivalent. As for imidazole the predicted order of electrophilic substitution is $5>2>4$, while nitration[31] and sulfonation[32] occur at the 5- and 4-positions. This may also be due to the equivalence of both positions associated with tautomerism. It should be mentioned here that diazonium coupling has been found to occur at the 2-position in imidazole, in disagreement with the predicted ordering. Electrophilic substitution on benzimidazole, 2*H*-indazole and 1*H*-indazole is predicted to occur in the order of $7\geqq6\geqq5\geqq4$ (by method I) and $7\geqq5\geqq6\geqq4$ (by methodII), $3>5>7>4$, and $7>5$, respectively, while it is known that nitration of benzimidazole occurs at the 5(6)-position,[33] and nitration[34] and halogenation[35] of indazole occur at the C-5 and C-3(5), respectively.

Electrophilic substitution on 1,2,3-triazole is predicted to occur at the 5-position, while actual bromination is known to give the 4,5-dibromoderivative.[36] In the case of 1,2,4-triazole with π-electron-deficient C atoms, such electrophilic substitutions as halogenation, sulfonation and Friedel-Crafts' alkylation of the nucleus are unknown. Electrophilic substitution on 1*H*-benzotriazole is predicted to occur at the C-5 and C-7 positions, while nitration[37] and chlorination[38] are known to occur at the 4,7- and 4,5,6,7-positions,

respectively.

It is known that the calculated ionization potential becomes higher by the increase of π-electron localization; among the five-membered diazoles and triazoles the largest value is found in 1,2,5-triazole with a polar N–NH–N linkage, and in the case of the molecules with one NH–N bond it is enhanced most for 1,2,4-triazole with alternate arrangement of plus and minus charges. The calculated electron affinity is in parallel relation with the corresponding ionization potential except for the case of 1,2,3- and 1,2,4-triazoles. So far as the present result is concerned, the effect of atom-rearrangement upon the relative orderings of both value is not affected by the replacement of pyrrole-nitrogen with furan-oxygen. On fusing the benzene-ring the ionization potential tends to be lowered, and the difference of the ionization potential and electron affinity is minimized at benzo-1,2,5-triazole in which the pyrrole-nitrogen mostly donates its π-electron to the whole conjugated system. Now, the lower ionization potentials calculated by method I are higher by $\sim$0.5 eV than those evaluated by a generalized free-electron model.[7]

It is known, by analogy with indoxazene, that 1*H*-indazole and pyrazole undergo photoisomerization into benzimidazole and imidazole, respectively.[39] But the mechanism in detail is unknown excepting that the presence of quinoid-type tautomer and the introduction of electron-donating group into the 5- or 6-position appears to favour the isomerization of 1*H*-indazole. For reference the π-electron distributions for the lowest $^1(\pi, \pi^*)$ and $^3(\pi, \pi^*)$ which were calculated with the CI procedure are given in Fig. 2(a) and 2(b). The result indicates that such excitations on 1*H*-indazole and pyrazole give rise to increased convertibility of 1*H*-indazole into 2*H*-tautomer as expected from the photoexcited change in the π-electronic state on the –NH–N–C– system, and to the increased lability of the pyrazole ring as expected from the much reduced π-bond orders.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3353—3357 (1970)

The Distribution of the Acid Strength on Zeolite Catalyst — Estimation from the Heats of Adsorption —

Yasuaki OKAMOTO, Toshinobu IMANAKA and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Machikaneyama, Toyonaka, Osaka

(Received May 15, 1970)

The distribution of the acid strength on two zeolites, 13X and 10X, and on the copper form of X-type zeolite were estimated from the differential heats of *n*-butylamine adsorption in a benzene solution. The acid sites on these zeolites were revealed to have two kinds of acid strengths, that is, the cation-dependent one and the cation-independent one. The former corresponds to the stronger acid strength, and the latter, to the weaker. The IR spectra of the residual surface OH groups on these catalysts were also investigated. The strongest acid sites on each zeolite were considered to be those of the cation-dependent OH group which has the lowest frequency. The interaction between surface OH groups and immersed benzene was assumed to be a π-type hydrogen bond.

It is expected that the properties of catalytic reaction on an acidic catalyst can be explained in terms of the distribution of acid strength on it. The distribution of surface acid strength has usually been measured by means of the indicator method[1] and the volumetric-base adsorption method.[2,3] The former method, however, is incapable of measuring the acid strength of colored solids which include many cation-exchanged zeolites and other useful acidic catalysts. The number of useful indicators is limited, and their pKa values lie only between -8.2 and $+6.8$

discontinuously. Therefore, this method has disadvantages for obtaining a continuous value and for providing both the stronger and weaker acid strengths. From the fraction of the base which desorbs slowly, the latter method allows some estimation of the number of effective acid sites and the average acid strength of the sites, as measured by the activation energies for desorption. As this method gives only the average acid strength, however, it is not effective in discussing the relation between the acid properties and the acid catalytic reactions. Consequently, the distribution of the differential adsorption heats of base must be measured in order to clarify the behavior of acidic catalysts of varying activities in terms of a site-energy distribution, that is, the number of acid sites and their individual strength.

Direct measurements of the adsorption heat of a base on acidic catalysts have been carried out by several workers. Richardson and Benson[3] measured the heat of adsorption of trimethylamine on Davison DA-1 cracking catalysts at 300°C with a crude adiabatic calorimeter, but gave only average values. Chessick and Zettlemoyer[4,5] determined quantitatively the site-energy distributions on attapulgite, silica-aluminas, and kaoline cracking catalysts on the basis of immersional heats in butylamine.

In this paper, the differential heats of the adsorption of *n*-butylamine in benzene are used for the elucidation of the acid-strength distributions on zeolites. Moreover, the relation between the acid strength and the frequencies of the IR adsorption bands of the residual surface OH group is discussed.

Experimental

Materials. The molecular Sieves, 13X and 10X, were supplied by the Union Carbide Company. In order to prepare copper-form X-type zeolite (CuX), sodium ions in 13X zeolite were 48.1% exchanged in a conventional method for Cu(II) with a copper sulfate solution. The *n*-butylamine was of a commercial grade and was used in adsorption experiments as a benzene solution. The benzene was purified by dehydration with sodium metal and subsequent distillation. The concentration of *n*-butylamine in benzene was determined in the following manner. *n*-Butylamine in benzene was extracted from the benzene phase to the water phase by pouring water into it, and then it was neutralized with a dilute aqueous HCl solution in the water phase, using phenolphthalein as an indicator. The normality of the amine solution was in the range of 0.165—0.0025 N.

Procedure. After zeolite had been treated in a glass ampoul at 400°C for several hours under a vacuum, it was used in the adsorption experiments. The over-all heat, which evolved when the treated zeolite was immersed in a benzene solution of *n*-butylamine at 25°C, was measured with a micro calorimeter manufactured by the Applied Electric Lab., Ltd. The amount of amine adsorbed on zeolite was elucidated by washing the immersed zeolite with benzene several times and then by using the neutralization method described in the previous section in connection with a material balance.

The amounts of *n*-butylamine adsorbed on zeolite from the gas phase were determined with a thermanobalance at different temperatures. Zeolite was dehydrated to a constant weight in a flowing stream of nitrogen at 400°C and then cooled to an adsorption temperature in it. *n*-Butylamine was introduced on the dehydrated, constant-weight zeolite at that temperature by the passage of nitrogen gas through a saturator containing *n*-butylamine. The increase in weight in comparison with that of the dehydrated zeolite is due to the physically- and chemically-adsorbed *n*-butylamine. In order to determine the amount of *n*-butylamine chemisorbed, the zeolite saturated with *n*-butylamine was flushed with nitrogen gas in order to remove the physically-adsorbed *n*-butylamine. After this treatment, the increase in weight was considered to reflect the amount of *n*-butylamine chemisorbed at that temperature.

The behavior of the residual OH groups on these zeolites was observed by means of studying the infrared spectra with a Hitachi IR spectrometer. The disks of zeolites were heated at 200—300°C in an IR cell under a vacuum. The disks were prepared by pressing zeolites between two polished stainless steel plates to a pressure of about 5 ton/cm^2.

The H-D exchange reaction of OH groups on the zeolites used was carried out with D_2O (supplied by the Merck Co.) in an IR cell at 400—500°C.

Results and Discussion

The surface properties of zeolite are assumed to be dependent on the amount of water on the surface. Figure 1 shows that the heats of immersion for 13X and 10X zeolites in benzene vary with the preheating temperature. The value for 13X

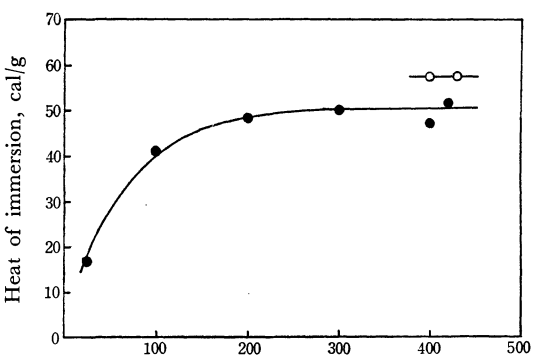

Fig. 1. Dependency of immersion in benzene on preheating temperature.

gradually increases up to about 300°C and then becomes constant at about 400°C. The heats of immersion contain the surface energy of the solid and liquid and the energy of interaction between the surfaces of the solid and molecules in a liquid. Thus, it may be supposed, from the constancy of the heats of immersion, that the interaction between them is not dependent upon the preheating temperature beyond about 300°C. When these catalysts are dehydrated in a flowing stream of nitrogen gas at an incremental temperature, the change in their weights becomes constant beyond about 300°C. It is revealed by the IR spectra that the change in their weights is due to the adsorbed water. The amount of water adsorbed depends on the treating temperature as does the heat of immersion. The results suggest that the properties of the surfaces of the 13X and 10X zeolites are dependent mainly on the amount of adsorbed water and that they remain almost constant beyond 300°C.

The distribution of the acid strength on an acidic catalyst is expressed as that of the differential heats of adsorption of a base on its acid site. In our experiments, the acid-strength distribution of zeolites is determined from both the differential heats of the adsorption of *n*-butylamine in benzene and the amount of *n*-butylamine chemisorbed from the benzene phase.

The total heat which evolved in the system when zeolite was immersed in a benzene solution of *n*-butylamine includes the heat of the immersion of zeolite in benzene and the adsorption heats of *n*-butylamine on the acidic sites. When the sum of the coverage of the immersed benzene and that of the adsorbed base is assumed to be unity, the following equations can be derived;

$$\theta_A + \theta_B = 1 \quad (1)$$

$$Q_T(\theta_A, \theta_B) = Q_A(\theta_A, \theta_B) + Q_B(\theta_A, \theta_B) \quad (2)$$

where θ_A and θ_B are the coverages of the adsorbed *n*-butylamine and the immersed benzene respectively; Q_T, the total heat evolved in the system (cal/g); Q_A, the evolved heat due to adsorbed *n*-butylamine, that is, the integral heats of adsorption (cal/g), and Q_B, the evolved heat due to immersed benzene (cal/g). If the interactions between adsorbed *n*-butylamine and immersed benzene are neglected, $Q_B(\theta_A, \theta_B)$ is $Q_B^\circ \times \theta_B$ and $Q_A(\theta_A, \theta_B)$ is $Q_A(\theta_A)$, where Q_B° is the heat of immersion in the absence of adsorbed *n*-butylamine. Therefore,

$$Q_T(m_A) = Q_A(m_A) + Q_B^\circ \times [1-(m_A/m_A^\circ)]$$
$$\theta_A = m_A/m_A^\circ \quad (3)$$

where m_A is the amount of *n*-butylamine adsorbed on acid sites on zeolite (mol/g) and m_A°, the saturated amount of it. Figure 2 shows the $Q_T(m_A)$ values of 13X, 10X, and CuX.

The m_A° value of each catalyst is deduced from the amount of *n*-butylamine adsorbed on zeolite from the gas phase, as determined with a thermanobalance at 25°C. The m_A° values are 2.7 mmol/g, 3.2 mmol/g, and 2.7 mmol/g for 13X, 10X, and CuX respectively. Figure 3 shows clearly that $Q_A(m_A)$ consists of two straight lines. The differential heat of the adsorption of *n*-butylamine is obtained from Eq. (3):

$$dQ_A(m_A)/dm_A = dQ_T(m_A)/dm_A + Q_B^\circ/m_A^\circ \quad (4)$$

On the basis of the value of $dQ_A(m_A)/dm_A$ calculated from Eq. (4), Figure 4 shows the acid-strength distribution on these zeolites in terms of the differential heats of adsorption; that is, the acid strength and the ordinate show the acidity corresponding to each acid strength. It is interestingly found that acid sites of each zeolite have a distinct distribution of differential heats of adsorption with two peaks, indicating two kinds of acid strengths. The stronger acid site varies with the

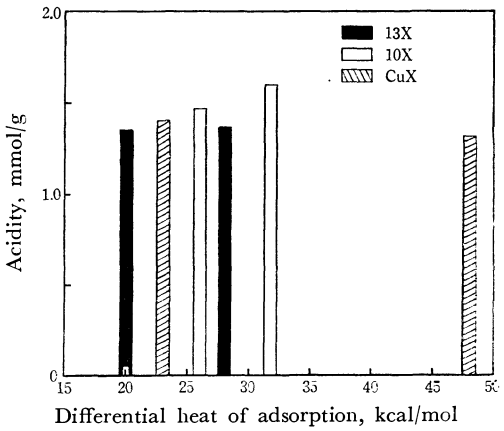

Fig. 4. Distributions of acid strength.

three zeolites used, but the weaker one is about constant. Therefore, the stronger acid site is cation-dependent, and the weaker one is cation-independent. It is considered that the reaction activities of these catalysts are dependent on the stronger one rather than on the weaker one. Thus, it is well and quantitatively shown that the activity of a reaction on cation-exchanged zeolite changes with the kind of the cation on zeolite.

The distribution of acid strength is estimated from the amount of *n*-butylamine adsorbed from the gas phase at an incremental temperature. Figure 5 shows the amounts of *n*-butylamine chemisorbed at various desorption temperatures. The curves are divided into two parts; one is in the region of desorption temperatures lower than about 150°C, while the other is in a higher temperature region than this. This behavior of the adsorbed amine also suggests that the acid sites on the zeolites have two kinds of acid strengths. This result is in agreement with that from the calorimetric method.

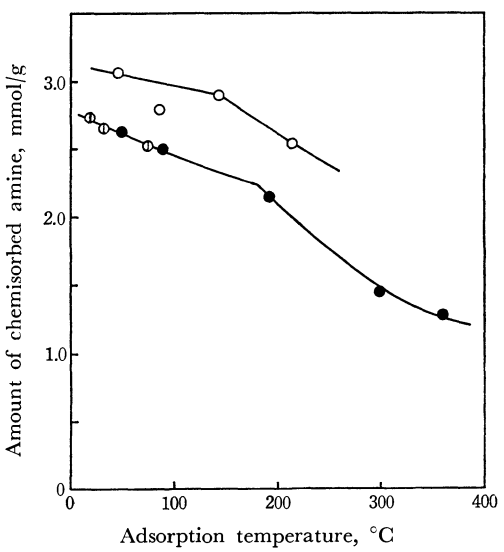

Fig. 5. Temperature dependency of chemisorbed amount of *n*-butylamine.

● 13X, ○ 10X, ⓘ CuX

It has been reported[6] that the acid sites of zeolite which is pretreated under a vacuum at 400°C consist almost entirely of Brönsted acid, that is, of residual surface OH groups. Therefore, the distribution of acid strength which is estimated here from the calorimetric method corresponds to that of the acid strength of the Brönsted acid sites. The acid strength of the Brönsted sites is deduced to be depend on the frequency of the residual OH group. It has previously been shown [7-9] that each zeolite has a few kinds of residual surface OH groups. It is interesting, therefore, to clear up the relation between the distribution of acid strength and that of the frequencies of the surface residual OH groups on zeolites. In this paper, the IR spectra of zeolites were investigated. The stretching vibrations of surface OH groups appear in the region of 3750 cm^{-1}—3600 cm^{-1}, but in this region

of the spectrum, the stretching vibrations of OH groups of water adsorbed on KBr windows appear also and the transmission of infrared rays is small because of their large divergence. Thus, the surface residual OH groups were turned into OD groups with D_2O. The solid lines in Fig. 6 show the IR spectra of the OD groups on the zeolites used. 10X and CuX have three species of residual OD groups, while 13X has only two. These OD groups are classified into two groups according to the dependency on the cation of the zeolite; that is, group (I) contains OD groups which are independent of the kind of the cation, while in group (II) they are dependent on it. Group (I) contains the 2733-cm^{-1} band on 13X, 10X, and CuX, and the 2699-cm^{-1} band on 10X and CuX, while group (II) includes the 2645-cm^{-1}, 2665-cm^{-1}, and 2668-cm^{-1} bands on CuX, 10X, and 13X respectively. It is shown above that the acid sites of zeolites have two kinds of acid strengths, namely, the cation-independent and cation-dependent acid strengths. The relation between the distribution of the acid strength and the behavior of residual surface OD groups can be obtained on the basis of these observations. Figure 7 shows that the differential heat of the adsorption of *n*-butylamine on the stronger acid sites depend linearly upon the frequency of the OD group which is lowest one on each zeolite. Therefore, it may be concluded that the stronger acid sites, which are cation-dependent, correspond to the cation-dependent OH group which has the lowest frequency. It may also be deduced that the reaction activity on zeolite generally depends on the lowest frequency of the residual OH group.

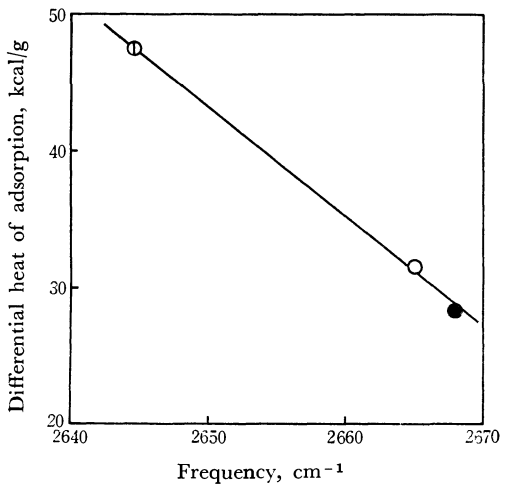

Fig. 7. Relation between differential heats of adsorption on *n*-butylamine and frequencies of residual surface OD groups.
● X, ○ 10X, ⓘ CuX

As the heats of the adsorption of *n*-butylamine were measured in benzene, the surface OH groups were affected by the immersed benzene. The influence of the immersed benzene can be estimated from the change in the IR spectra of the OH group due to adsorbed benzene. The dotted lines in Fig. 6 show that the spectra of surface OH groups are broadened and that these groups are shifted to lower frequencies. The behavior of these group is the reverse of the adsorption and desorption of benzene molecules. When the surface OH group is hydrogen-bonded, the spectrum shows a similar behavior. On the basis of this fact and the properties of benzene, it may be concluded that the changes in the spectrum are due to the interaction between the π-electron system of the benzene molecule and the surface OH groups, that is, the π-type hydrogen bond.[10]

Conclusions

The acid-strength distribution of zeolite was estimated from the differential heats of *n*-butylamine adsorption in benzene. The acid strengths of the zeolites used were of two kinds, cation-dependent and cation-independent. The residual surface OH groups are classified into two groups, the cation-dependent group, which has the lowest frequency, and the cation-independent one. The stronger acid site, whose strength is dependent on the cation corresponds to the cation-dependent OH groups on zeolites which have the lowest frequencies. The π-electron system of the benzene molecule adsorbed on zeolite interacts with residual surface OH groups; this interaction are estimated to consist of a π-type hydrogen bond.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3358—3363 (1970)

Electron Spin Resonance Study on Radical Anions of Acridine and Its Halogen Derivatives

Shiro KONISHI, Shigeya NIIZUMA and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira, Sendai

(Received May 16, 1970)

ESR spectra of radical anions produced by bringing 9-chloro-, 2,7-dibromo-9-chloro-, and 2,4,5,7-tetrabromo-9-chloroacridine into contact with alkali metal (sodium and potassium) in tetrahydrofuran were measured at room temperature and/or at lower temperatures, and the analysis of them was made by means of a simulation method. Hyperfine coupling constants of acridine anion radicals, produced by the similar method in tetrahydrofuran and also by the electrolytic reduction in acetonitrile with the flow method, were determined, taking those of halogen derivatives into consideration. ESR spectra of acridine and 9-chloroacridine anion radical were found to involve the coupling of sodium, showing that these radicals were in the form of ion pair. The coupling constants of bromoacridine anion radicals did not give any difference between the sodium and the potassium reduction. The couplings of halogen atoms were not observed. Good agreement was obtained between the coupling constants calculated from spin densities and those determined experimentally. In general, the solution of radical anions of halogenides gradually yields brownish aggregates at lower temperatures (−20∼−30°C), their ESR spectra becoming weaker and unresolved. The temperature change is reversible and qualitatively resembles the behavior of acridine anion radical.

In a previous paper,[1] the physicochemical behavior of the radical anions of acridine paired with alkali cations in THF was investigated in detail. It was found that the paramagnetic monovalent anion transforms to the diamagnetic dianion in the presence of excess alkali metal and that a certain association reaction of the $n(A^-Na^+) \rightleftarrows (A^-Na^+)_n$ type (n, perhaps 2) occurs in THF. It was further found that this equilibrium shifts to right with lowering the temperature. Furthermore, we obtained the ESR spectrum consisting of more than fifty lines most plausibly attributable to the radical anion of acridine, but an attempt for analysis was postponed.

When we succeeded in taking the ESR spectrum with hyperfine structure, there was no such work found in literature. But in the course of our investigation, two papers dealing with the ESR of acridine radical anion appeared. One is Hoeve and Yeranos's[2] and the other, Szwarc *et al.*'s.[3] The hfs constants of the acridine radical anion produced by electrolysis in pyridine were determined by the former workers, while by the latter workers the similar determination was made for the radical anion produced by the alkali metal method in hexamethylphosphoramide.

In continuance of our study we have succeeded in obtaining the ESR spectrum of acridine radical anion produced electrolytically in acetonitrile. Although the radical anion thus produced was rather unstable, its hfs could be studied successfully by employing the flow method. Further, we have taken the ESR spectra of radical anions originating from a few halogen substituted acridines which also displayed good hfs. As is well known, the substitution of halogen atoms for aromatic ring protons generally makes the analysis of the spectrum easier because of the disappearance of the proton coupling[4] at the substitution positions (there is some line broadening, however, and in the case of chlorine substitution there are some papers reporting on the resolution of hfs coupling of chlorine,[5,6] which is rather remarkable).

The results for the radical anions of (I) have been found to be in good agreement with those in literature except for the case of sodium reduction, in which the sodium coupling was observed and other coupling constants were somewhat different from those in other cases. This implies that the radical anion in the latter cases exists

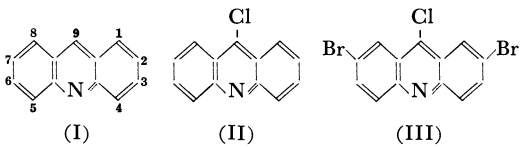
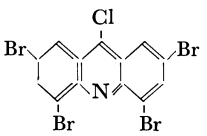
essentially as free (at least from the viewpoint of ESR) while with sodium cation the formation of ion pair occurs. It has been established that the coupling constants obtained, satisfy McConnell's relation moderately well.



(I) (II) (III)



(IV)

Experimental

A JEOL P-10 type ESR spectrometer was used. Its characteristics and the apparatus for temperature control are the same as descrived in the previous paper.[1]

Materials. THF was purified in the same way as in the previous paper.[1] First grade acetonitrile from Wako Junyaku was distilled, dried on calciumhydride and then stored in vacuo. (I) was purified in the way described in the previous paper.[7] (II) was synthesized from *N*-phenylanthranylic acid after Albert and Ritchie,[8] (III) and (IV) from acridon after Acheson and Robinson[9] and recrystalized from THF. Mass spectra of these halogenides were in good agreement with the theoretical distribution. Electronic spectra of these compounds are shown in Fig. 1.

Procedure. Anion radicals were prepared by bringing 2 m*l* degassed THF solutions containing several mg of acridines into contact with a sodium mirror deposited by vacuum evapolation. In the case that an anion was unstable at room temperature, the contact was carried out in dry ice methanol bath. A flow method apparatus as shown in Fig. 2 was devised for the steady current electrolysis. The flow was controlled by cock C, and checked by the time interval necessary for one drop to fall down from the tip of capillary, F. The optimum flow rate was 10.3 sec/one drop. 5 to 6 V was applied between anode and cathod, A and B.

Spin Density Calculation and Simulation of ESR Spectrum. The spin densities on nitrogen, carbon and halogen atoms of acridines were calculated by a simple LCAO-MO method. For simulation of ESR spectra, the simulation program was composed in our laboratory. The calculation and the simulation were carried out on the NEAC-2200 Model 500 Electronic Computer in the Calculation Center of Tohoku University.

Results and Discussion

2,4,5,7-Tetrabromo-9-chloroacridine (IV). ESR spectrum obtained by making contact with sodium mirror at room temperature, is shown in Fig. 3(a). The spectrum changes from (a) to (d) as the temperature is lowered and this temperature change is reversible. It is seen that the signal is more resolved at lower temperature, and at room temperature it becomes highly broadened with no apparent reduction in intensity. Any difference was not observed between sodium and potassium as a reducing agent. This means that the two anion radicals have the similar structures, suggesting that they exist as free ions. But these two ion pairs which are equally unstable at room temperature show quite different modes of destruction.

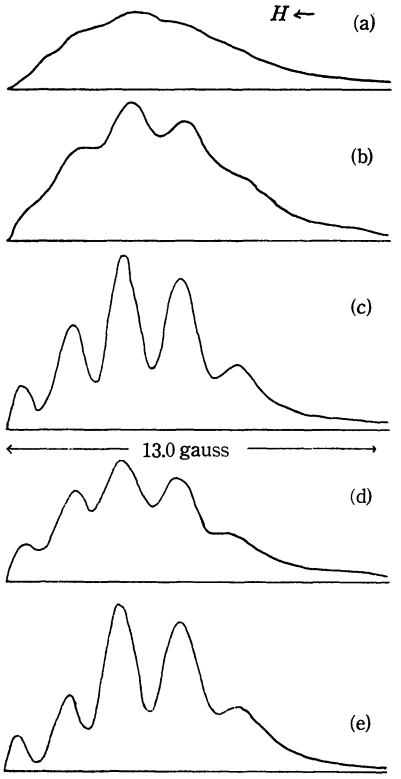

Fig. 3. ESR spectra of radical anion of IV. (a); at +15°C, (b); at −16°C, (c); at −55°C, (d); at −70°C, (e); Simulated spectrum, corresponding to (c).

Thus the ion pair with sodium cation decays according to the first order rate formula with a half life of 180 min (at 22°C) while the potassium ion pair obeys the second order (Fig. 4a, b). Furthermore the solution after reaction becomes yellowish brown in the former case while in the latter it is colorless and the electronic absorption spectrum strongly suggests the destruction of acridine frame.

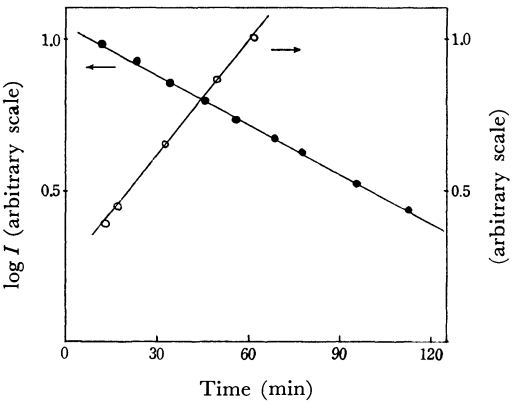

Fig. 4. The decay curve of ESR signal intensity for radical anion of IV.
● Sodium reduction, at 22°C
○ Potassium reduction, at 0°C

By assuming that the coupling of halogen atoms is not resolved and by neglecting the coupling of sodium, hfs was analysed satisfactorily. The simulation spectrum obtained by taking only a nitrogen atom and two pairs of magnetically equivalent protons, is shown in Fig. 3(e) which corresponds to the observed one (c). The parameters used for simulation and the calculated spin densities are listed respectively in Tables 1 and 2 given later, together with those for the other compounds.

* C_N carbon atom adjacent to nitrogen.
** The value in the parenthesis is the spin density at the position substituted by halogen.

2,7-Dibromo-9-chloroacridine (III). The radical anion originating from this compound has four sets of atoms which are responsible for hfs, *i.e.*, a nitrogen and three pairs of magnetically equivalent protons. The anion radical produced from III by using sodium as a reducing agent was stable at room temperature and gave a ESR spectrum shown in Fig. 5(a). Signal intensity decreased with lowering temperature, as is shown in in Fig. 5(b) and (c). This change was reversible and qualitatively the same as observed in the acridine radical anion.[1] The similar ESR signal was obtained by using potassium as a reducing agent and the values of hfs constants were equal to the ones for the sodium reduction. The simulated spectrum, (d) in Fig. 5, corresponds to the observed one, (a) in Fig. 5.

9-Chloroacridine (II). The anion radicals of II were stable at room temperature. Their ESR spectra were measured in the best condition at −55°C for the sodium reduction and at −66°C for the potassium reduction and are shown in Fig. 6(a) and (b) respectively. The analysis of the spectrum for the sodium reduction was accomplished by taking account of sodium coupling, 0.80 gauss as shown in Fig. 6(c). It may be due to the absence of metal coupling that the ESR spectrum for the potassium reduction differs from that for the sodium reduction.

By the prolonged contact with alkali metal, the THF solution of II turned red and ESR signal disappeared. This diamagnetic species is considered to be a dianion by analogy with I.

produced from I with the sodium reduction and with the potassium reduction, although they were already given in the previous paper,[1] are shown again in Fig. 7 in order to make a comparison with the simulated spectra and with the spectrum of the anion produced by electrolytic reduction.

The anion radical produced by electrolysis of the acetonitrile solution of I was so unstable that we could not make the ESR measurement under the static condition. In the initial stage of electrolysis, the green layer appeared in the solution close to the anode surface, but in several minutes after electrolysis the solution turned pink and proved to be diamagnetic. Therefore we had to use the technique of flow method. By employing the apparatus shown in Fig. 2 and by electrolyzing the acetonitrile solution containing ~1 mM acridine and 30 mM tetra-*n*-propyl ammonium perchlorate we could obtain the ESR spectrum which is shown in Fig. 7.

From Fig. 7 it is evident that only for the sodium reduction, there exists the effect of counter ion (metal cation) on the ESR spectrum. The hfs constant was determined to be 0.56 guass. In spite of the difference in solvent, coupling constants for the potassium reduction are in good

agreement with the ones for the electrolytic reduction. Only the values for the sodium reduction are different, and this is certainly due to the formation of ion pair.

The parameters which correspond to the coupling constants and line widths used are listed in Table 1. These values are reliable within ± 0.05 gauss. The assignment was made by taking the spin density from a molecular orbital calculation into consideration. The data in Table 2 are electron densities of the lowest vacant orbital for the four compounds under consideration. In the calculation according to the simple LCAO-MO method, the values of the Coulombic integrals and of the resonance integrals were assumed as follows:

$$\alpha_N = \alpha + 0.7\beta, \quad \alpha_{C'-N} = \alpha + 0.1\beta, \quad \beta_{C-N} = \beta$$
$$\alpha_{Cl} = \alpha + 1.8\beta, \quad \alpha_{C'-Cl} = \alpha + 0.18\beta, \quad \beta_{C-Cl} = 0.8\beta$$
$$\alpha_{Br} = \alpha + 1.4\beta, \quad \alpha_{C'-Br} = \alpha + 0.14\beta, \quad \beta_{C-Br} = 0.7\beta$$

α and β are the Coulombic integral of carbon atom and the resonance integral of the C–C bond respectively. The subscripts N, Cl and Br imply the values for nitrogen, chlorine and bromine atom, C'–N *etc.* for carbon atom connecting with nitrogen atom *etc.*, and C–N *etc.* for C–N bond etc.

Spin densities (given in Table 2) *vs.* hfs constants (given in Table 1) are plotted in Fig. 8 to give a linear relation. From its slope, the McConnell's Q-value is obtained as 28 gauss. The coupling constant of nitrogen, a_N was calculated from the following equation,

$$a_N = Q_N \rho_N + \sum Q_{C_i} \rho_{C_i}$$

where ρ_N and ρ_{C_i} are the unpaired spin density on nitrogen and carbon atoms adjacent to nitrogen, C_i. As the values of Q_N and Q_{C_i}, 20 gauss and 7 gauss were used, which had been proposed by Smid.[10]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3364—3372 (1970)

ζ-Potentials of Synthetic Fibers in Aqueous Solutions of Sodium Alkyl Sulfates and Viscosities of Their Solutions*1,*2

Yoshio IWADARE

Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima

(Received May 23, 1970)

In order to study the surface-adsorption behavior of anionic surfactants on fibers, the ζ-potentials of some synthetic fibers in aqueous solutions of sodium alkyl sulfates and their mixtures mainly above the critical micelle concentration (CMC), were measured. Further, the viscosities of aqueous solutions of pure surfactants were determined. Consequently, it can be presumed, on the basis of the viscosity data, that the structure of the micelles of these agents varies at the break of the η_{sp}/c_m *vs.* c_m curve. The ζ-potentials (negative) of fibers in aqueous solutions of the agents rapidly changed with an increase in the agent concentrations, but it remained nearly constant above the CMC. At much higher concentrations, the ζ values gradually changed; thereafter, passing a break or a minimum, they became approximately constant again. The concentration at the break or the minimum observed nearly corresponded to that at the break of the η_{sp}/c_m *vs.* c_m curve. It may, therefore, be suggested that the change in ζ-potentials at high concentrations is connected with that in the structure of the micelles. The ζ-potentials (negative) of fibers in aqueous mixed solutions changed sharply with an increase in the concentration of the mixtures and thereafter, passing a maximum in the vicinity of the CMC, complicatedly changed as the total concentrations and mixing ratios changed.

The determination of the adsorption behavior of surfactants on solid surfaces, especially on fiber surfaces, is of fundamental importance in a study of the mechanism of the detergent action. A few investigators[1-4] previously attempted to elucidate the adsorption behavior of surfactants on fiber surfaces, mainly below the critical micelle concentration (CMC), by measuring the ζ-potential of the fiber-solution interface, but little work was done in systems above the CMC.[1,2]

The present author has, therefore, tried to make clear the adsorption behavior of anionic surfactnats on the surfaces of several fibers, mainly near and above the CMC. In a previous experiment,[5] in order to ascertain the surface-adsorption properties of sodium dodecyl sulfate (SDS) on fibers, the ζ-potentials of natural and synthetic fibers in aqueous solutions of the agent were measured, and then the amounts of SDS adsorbed per unit of area of the fiber surfaces were calculated from the ζ values thus obtained. In another investigation,[6] the viscosities of aqueous solutions of SDS and sodium tetradecyl sulfate (STS) were determined as part of a study of the structure of the micelles of these agents. Further, the relation between the change in the ζ-potentials of fibers and that in the structure of SDS micelle was discussed in detail.[7]

In this investigation, in order to clarify the structure of micelles of aqueous sodium alkyl sulfates, the viscosities of aqueous solutions of sodium hexadecyl sulfate (SHS) were determined in a manner similar to that mentioned previously.[6] The ζ-potentials of some synthetic fibers in aqueous of the pure surfactants were measured, and then the relation between the change in the ζ-potentials of these fibers and that in the structure of the surfactant micelles was discussed. In addition, the ζ-potentials of fibers in aqueous solutions of

mixtures of the two surfactants (that is, SDS-STS and STS-SHS mixtures) were measured and compared with those obtained in pure surfactant solutions.

Experimental

Apparatus and Procedures. *ζ-Potential.* The ζ-potential was determined by the method of the streaming potential, which has been described previously.[5,8] The streaming potential was measured by using a Transistorized Dynamic-Condenser Electrometer, Model UFE 26301 H (Tokyo Shibaura Electric Co., Ltd.). The conductance of the solutions was obtained from a Yanagimoto Conductivity Outfit, Model MY-7 (Yanagimoto MFG. Co., Ltd.).

The streaming potential was accurately proportional to the pressure in the range from 30 to 60 mmHg above the CMC, as well as below it,[7] regardless of the kinds of the fibers, the kinds, mixing ratios and concentrations of the surfactants, and the temperatures. Actually, the streaming potential measurements were carried out at 50 mmHg and at 25±0.02°C for SDS and the SDS-STS mixture, at 40±0.02°C for STS, and at 45±0.02°C for SHS and the STS-SHS mixture. The solutions examined contained 10^{-4} mol/*l* of sodium chloride.

Viscosity. Viscosity measurements were made with an Ostwald viscometer, as has been described in a previous paper.[6] The flow time for the water was 448.2 sec at 45±0.02°C. The Reynolds' number was about 65. The kinetic energy correction was less than 1 part in 1000 over the whole concentration range investigated. From three to five flow-time measurements were made on each solution. The solution contained 10^{-4} mol/*l* of sodium chloride.

Critical Micelle Concentration (CMC). The critical micelle concentration was determined by measuring the surface tension, the conductance, and the viscosity of aqueous surfactant solutions in the presence of 10^{-4} mol/*l* of sodium chloride, as has been described previously.[7]

Materials. *Fibers.* The polypropylene Pylen, polyamide Nylon 6, polyacrylonitrile Cashimilon, and polyvinyl alcohol Vinylon fibers were the same as those used in previous works.[5,7]

Surface Active Agents. The sodium dodecyl (SDS) and tetradecyl (STS) sulfate used were the same as in a previous study.[6] The sodium hexadecyl sulfate (SHS) was prepared from hexadecyl alcohol which contained 0.6% C_{14} and 1.2% C_{18} alcohols as impurities.

This substance was twice recrystallized from ethanol and then carefully extracted with petroleum ether for 50 hr in order to remove unreacted alcohol. The purified substance had a purity of at least 99.85%; most of the impurity was moisture. The surface tension *vs.* log concentration curve was free of a minimum. The CMC values obtained are given in Table 1.

Table 1. The CMC of sodium alkyl sulfates of 10^{-4} mol/*l* of sodium chloride

Surfactants	CMC (mol/*l*)×10^3		
	Surface tension	Conductivity	Viscosimetry
SDS (25°C)	7.1	7.61	7.0
STS (40°C)	2.13	2.20	2.0
SHS (45°C)	0.61	0.71	0.6

Results and Discussion

Viscosities and Structure of Micelles of Aqueous Sodium Alkyl Sulfates

Viscosities of SDS and STS Solutions and Change in the Structure of SDS and STS Micelles. The viscosities of aqueous SDS and STS solutions were reported in a previous paper.[6] The reduced viscosities for the micelles of these agents, η_{spm}/c_m (c_m: the micellar concentration),*3 increased rapidly with the c_m as long as the c_m was small; thereafter, passing a break, they gradually increased with the increase in c_m. The break was observed in the (20—25)×10^{-3} mol/*l* concentration range for SDS and at (8—10)×10^{-3} mol/*l* for STS. The intrinsic viscosity,[11] the hydration,[11,12] and the hydrodynamic volume[12] for the micelle observed in the higher concentration range, above the break, were much larger than those of the lower concentration range, below it.

From Guth and Simha's equation,[13-15] the effective specific volumes,[14,15] of these agents including hydrated water were calculated. They increased with the agent concentrations, but thereafter, passing a break, remained nearly constant. The break nearly corresponded to that of

*3 As has been shown in previous papers, the following operations were performed[9,10]

$$c_m = c_s - c_{c(1)}$$

$$\eta_{spm}/c_m = \{(\eta_r/\eta_{rc(1)}) - 1\}/(c_s - c_{c(1)})$$

where;

c_s: surfactant concentration.

$c_{c(1)}$: the 1st CMC.

η_{spm}/c_m: reduced viscosity for the micelle.

$\eta_{rc(1)}$: relative viscosity at $c_{c(1)}$.

Inset: enlarged in the vicinity of the CMC.

the η_{spm}/c_m *vs.* c_m curve.

The results calculated from the experimental data using Jones and Dole's equation[11,16,17] showed two distinct breaks. The first break corresponded to the 1st CMC of these agents, while the second corresponded approximately to the break in the η_{spm}/c_m *vs.* c_m curve.

From these results, it may be presumed that the structures of the micelles of these surfactants in an aqueous solution would vary at the break of the η_{spm}/c_m *vs.* c_m curve.

Viscosity of SHS Solution and Change in the Structure of SHS Micelle. *i) Viscosity of Aqueous SHS Solution.* The results of viscosity measurements for an aqueous SHS solution are shown in Fig. 1. Curve I clearly breaks at the concentration of 0.6×10^{-3} mol/*l* (*cf.* inset). The gentle upward curvature with η_r above the break seems to result from mutual interference between micelles in motion during the flow.[12] Curve II shows a minimum at the break of curve I. The minimum point is believed to correspond to the CMC[9,10] and agrees well with the CMC value obtained by surface-tension measurements (*cf.* Table 1). The behavior of η_{spm}/c_m was similar to those in SDS[6] and STS[6] micelles. A break of its curve was observed in the concentration range of $(3\text{—}4)\times10^{-3}$ mol/*l*. The intrinsic viscosity of the SHS micelle obtained from the higher concentration range, above the break, was much larger than that of the lower concentration range below it.

On the other hand, Grindley and Bury[12,18] and Suzuki and Sasaki[19] have indicated that the size of the micelles increases to a maximum over a narrow transition range of concentration. From the results mentioned above, it may be presumed that the size of the SHS micelle increases to some extent with an increase in the agent concentration on the portion (a).

As the solution becomes more concentrated, the counter-ion concentration steadily increases, with a resulting decrease in the degree of ionization of the micelle; the stability of the micelles is thereby enhanced.[20] It can, therefore, be assumed that the micellar properties remain unchanged over a relatively wide range of concentration on the portion (b), suggesting that the size and shape of micelles remains constant.[15,21]

ii) Effective Specific Volume. Guth and Simha's equation[13–15] was used for the calculation of the effective specific volume of the surfactant, including hydrated water.[14,15] The results obtained are shown in Fig. 2. The concentration at the break in the curve corresponded well to that at

the break of curve III in Fig. 1. The constancy of the effective specific volume is indicative of a spherical micelle.[14,15] Therefore, the shape and size of SHS micelle must remain unchanged in the range of concentration above the break, but is not unchanged below it.

iii) Change in the Structure of the SHS Micelle Observed from Jones and Dole's Equation. The results calculated from the experimental data using Jones and Dole's equation[11,16,17] are shown in Fig. 3. It is recognized that there are two distinct breaks, at points a and b. Point a corresponds to the 1st CMC of this agent, while point b corresponds well to the break of curve III in Fig. 1.

It is suggested that the formation of the micelle is attended by a change in the structure of the solvent, that is, by an interaction between the micelle and the solvent.[12] Therefore, if the change in the structure of micelle is attended by a change in the structure of water, the coefficient B in the equation will be variable.*4 It is noticed that the coefficient B evidently changes at point b.

From these results it may be presumed that the structure of the SHS micelle in an aqueous solution would change at point b in Fig. 3, that is, at the break of curve III in Fig. 1.

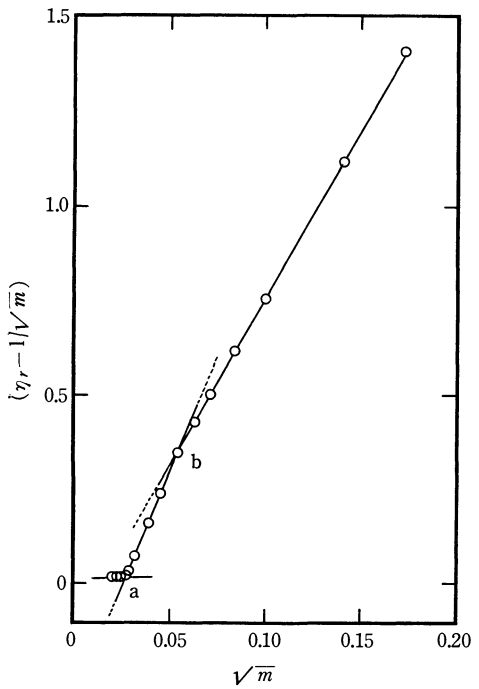

Fig. 3. Behavior of viscosity of aqueous SHS solution observed from Jones and Dole's equation (45°C).

ζ-Potentials of Fibers in Aqueous Solutions of Pure Sodium Alkyl Sulfates

ζ-Potentials of Synthetic Fibers in an Aqueous SDS Solution. The ζ-potentials of natural and synthetic fibers in an aqueous SDS solution were reported in detail in a previous paper.[7] As an example, the ζ-potentials of four synthetic fibers are shown in Fig. 4.

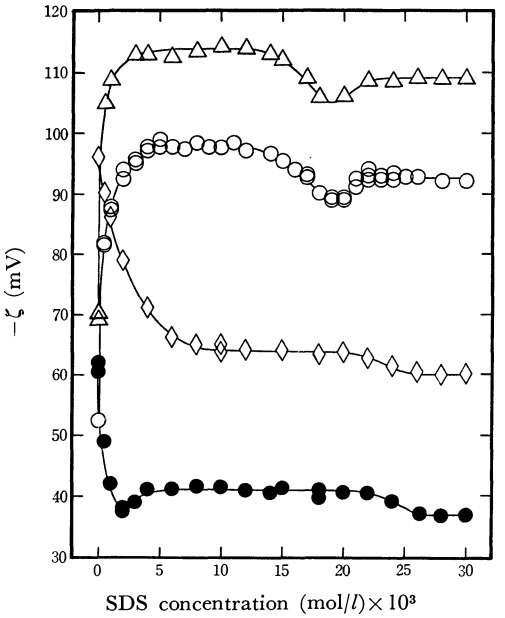

Fig. 4. ζ-Potentials of synthetic fibers in SDS solution (25°C).
(△) Pylen; (○) Nylon 6; (◇) Cashimilon; (●) Vinylon.

The ζ values obtained were all negative and changed rapidly with an increase in the SDS concentration, but remained approximately constant near and above the CMC. As the solution became more concentrated, they gradually changed again and thereafter, passing a minimum or a

*4 It is believed that the coefficient B for a particle in water is a positive quantity, indicating a structure-forming tendency. On the other hand, if the electrolyte particle tended to destroy the structure of water and produce disorder, then the coefficient B would be a negative quantity.[17,22]

22) M. Abu-Hamdiyyah, *J. Phys. Chem.*, **69**, 2720 (1965).

break, became nearly constant again. The concentration of the minimum or the break at high concentrations roughly corresponded to that of the break of the η_{spm}/c_m *vs.* c_m curve (*cf.* Fig. 1 in Ref. 6). It was, consequently, suggested that the change in ζ-potentials at high concentrations may be connected with that in the structure of the SDS micelle.[7]

ζ-Potentials of Synthetic Fibers in an Aqueous STS Solution. *i) ζ-Potentials below the CMC.* The results obtained are shown in Fig. 5.

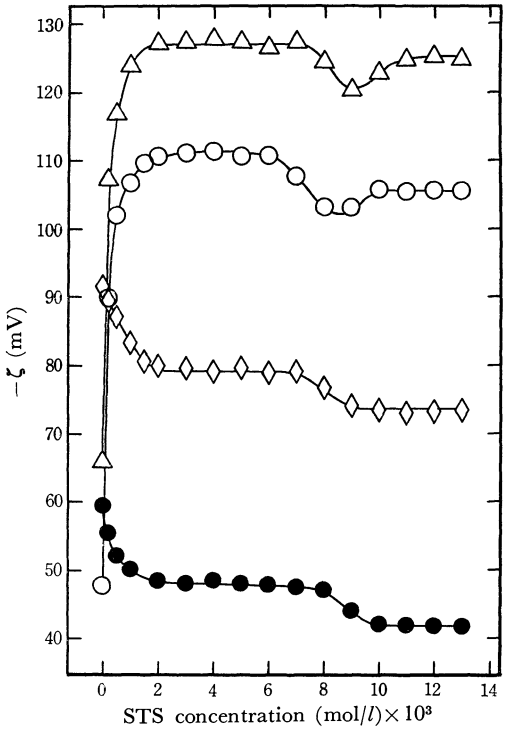

Fig. 5. ζ-Potentials of synthetic fibers in STS solution (40°C).
(△) Pylen; (○) Nylon 6; (◇) Cashimilon; (●) Vinylon.

The ζ-potentials (negative) for Pylen and Nylon 6 fibers increased sharply with an increase in the STS concentration below the CMC. This fact suggests that the amounts of STS adsorbed on the surfaces of these fibers rapidly increase with an increase in the agent concentration. The absolute ζ values of this system were considerably larger than those of the SDS system. It may, therefore, be suggested that the interaction between the hydrocarbon chain of the anionic surfactant and the hydrophobic part of fibers is important for the adsorption of the agent on the fibers.[3]

On the other hand, the ζ-potential (negative) for Cashimilon fiber decreased with an increase in the STS concentration. The decrease in ζ values with an increase in the concentration may be due to the compression of the diffuse double layer, because the total ionic strength in solutions increases with an increase in the concentration. The behavior of the ζ-potential for Vinylon fiber was similar to that obtained for Cashimilon fiber.

ii) ζ-Potentials above the CMC. The ζ values of the fibers examined remained nearly constant for some distance above the CMC. It can, therefore, be presumed that the surface adsorptions of STS on the fibers remain approximately constant in the range of concentrations larger than the CMC.

As the solution became more concentrated, the ζ values gradually changed again and thereafter, passing a minimum or a break, became constant once more. It is worth noting that the concentration of the minimum or the break observed corresponds roughly to those of the break of the η_{spm}/c_m *vs.* c_m curve (*cf.* Fig. 4 in Ref. 6) and of point β (*cf.* Fig. 6 in Ref. 6).

From these facts, it may be assumed that if the structure of the STS micelle in an aqueous solution changed at the concentration for the break or at that for point β, the structure of the diffuse double layer would be variable, resulting in a change of the ζ-potentials of the fibers.

In the more concentrated solutions, the properties of the STS micelle are invariable over a relatively wide range of concentration, suggesting that the size and the shape of the micelle remain nearly constant, as is shown by the viscosity data.[6] It can, therefore, be understood that the ζ-potentials of fibers are kept constant again at a high concentration, for the structure of the double layer is stable.

ζ-Potentials of Synthetic Fibers in an Aqueous SHS Solution. *i) ζ-Potentials below the CMC.* As is shown by Fig. 6, the variations in the ζ-potential (negative) with the concentration for Pylen and Nylon 6 fibers in an aqueous SHS solution were depicted by curves similar to those of SDS and STS systems. The absolute values of the ζ of the SHS system were appreciably larger than those of the latter. It may, therefore, be suggested that these fibers combine mainly with the SHS anion by means of the van der Waals force.[3]

On the other hand, the ζ-potential (negative) of Cashimilon or Vinylon fiber increased with an increase in the SHS concentration and thereafter, passing a maximum, gradually decreased with the concentration. This behavior was fairly different from that of the SDS and STS systems. The difference seems to result from the fact that the adsorption properties of the SHS anion on the fiber are superior to those of the SDS and STS anions.[3]

ii) ζ-Potentials above the CMC. The relation between the ζ-potentials and the surfactant concentrations of this system was very similar to those of the SDS and STS systems. The constancy of the ζ-potentials, therefore, implies that the sur-

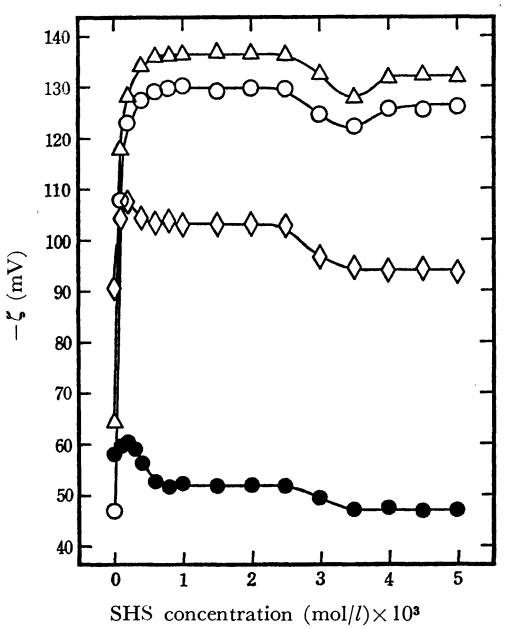

Fig. 6. ζ-Potentials of synthetic fibers in SHS solution (45°C).
(△) Pylen; (○) Nylon 6; (◇) Cashimilon; (●) Vinylon.

face SHS adsorptions on the fibers are unchanged in the range of concentration of $(0.6—2.5)\times10^{-3}$ mol/*l*. It may also be suggested that the surface-surfactant adsorptions of this system are considerably larger than those of the SDS and STS systems, because the absolute ζ values of this system are considerably larger than those of the latter above the CMC, as well as below it. The surfactant concentration corresponding to a minimum or a break in the ζ *vs.* concentration curves is very consistent with that of the break in the η_{spm}/c_m *vs.* c_m curve and that of point b in Fig. 3. It can, consequently, be presumed that the change in ζ-potentials above the CMC is connected with that in the structure of the SHS micelle.

In more concentrated solutions, the ζ values again became constant. This fact may be correlated with the stable structure of the diffuse double layer, as has been mentioned for SDS[7] and STS systems.

Mixed Micelle Compositions and CMC of Mixed Sodium Alkyl Sulfates

Mysels and Otter[23] suggested, from the conductivity data on aqueous solutions of pure sodium decyl and dodecyl sulfates and their mixtures, that the micelles initially formed are strongly enriched by the higher homolog, that the micellar compositions continue to change even after the CMC has been exceeded severalfold, and that, at higher concentrations, they tend to return to the initial composition. Tokiwa *et al.*[24] and Shedlovsky *et al.*[25] determined the mixed micelle compositions of the SDS-STS system. Their results were similar to those of Mysels and Otter.

In this study, the mixed micelle compositions of the SDS-STS and STS-SHS systems were determined in the same way as was used by Mysels and Otter; the results are shown in Figs. 7—10. It can be seen from Figs. 8 and 10 that the results are similar to those of Mysels and Otter. It can, consequently, be understood why some conclusions drawn from these results show a marked resemblance to those of Mysels and Otter.

ζ-Potentials of Fibers in Aqueous Solutions of Mixed Sodium Alkyl Sulfates

ζ-Potentials of Synthetic Fibers in an Aqueous Solution of the SDS-STS Mixture. *i) Mixed System Containing 85 mol% SDS.* The results obtained are shown in Fig. 11. The ζ-potential (negative) for Nylon 6 fiber rapidly increased with an increase in the concentration of the mixture below the CMC. This behavior was similar to that of the pure SDS and STS systems. However, the absolute ζ values of this mixed system were considerably larger than those of the pure SDS system, but smaller than those of the pure STS system. It can, therefore, be noted that the surface-adsorption properties of the higher homolog on the fiber are superior to those of the lower homolog.

On the other hand, the ζ-potential (negative) for Cashimilon fiber quickly decreased with an increase in the concentration and thereafter, passing a minimum, gradually increased. This behavior is different from that of the pure SDS and STS systems. It may be suggested that the decrease in the absolute ζ values is due to the compression of the double layer and that the increase is due to a preferential uptake of the higher homolog anions on the fiber. In the vicinity of the CMC, the ζ-potentials showed a maximum for each of the fibers. This may be due to the adsorption of the STS anion in preference to that of the SDS anion, because the concentration of the monomeric anion of the higher homolog reaches a maximum at the CMC.[23] Further, it may be due to the change in the mixed-micelle compositions.[23] However, it is not clear why the maximum appears in the vicinity of the CMC.

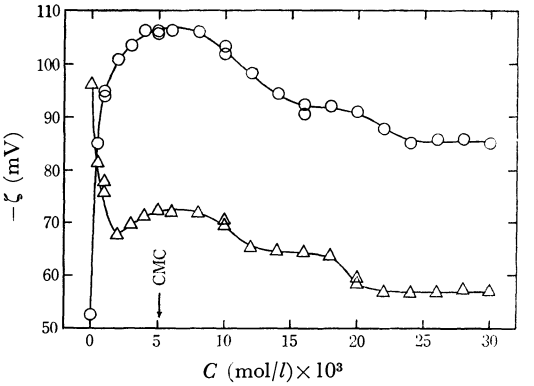

Fig. 11. ζ-Potentials of synthetic fibers in SDS-STS mixed system containing 85 mol% SDS (25°C).
(○) Nylon 6; (△) Cashimilon.

As the solution became more concentrated, the absolute ζ values of both the fibers decreased, step by step. This may be associated with the change in the compositions of the mixed micelles or with that in the compositions of the monomeric ions of the mixtures.

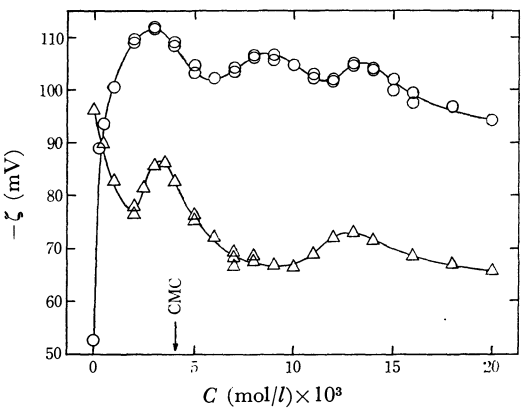

Fig. 12. ζ-Potentials of synthetic fibers in SDS-STS mixed system containing 75 mol % SDS (25°C).
(○) Nylon 6; (△) Cashimilon.

26) D. W. Fuerstenau, *J. Phys. Chem.*, **60**, 981 (1956).

ii) Mixed System Containing 75 mol% SDS. The ζ-potentials of this system changed in a complicated fashion, showing a few maxima, with an increase in the concentration of the mixtures, as is shown by Fig. 12. The first maximum, in the vicinity of the CMC, seems to be due to the cause described in the previous section. The maximum observed at a slightly lower concentration than the CMC may at least partly be interpreted as follows: with an increase in the concentration, sufficient surfactant anions diffuse into the fiver-solution interface and are condensed there because of the increased adsorption; consequently, the adsorbed ions reach a certain critical concentration at the interface in the concentration range below the CMC.[26] A maximum corresponding to the second maximum of Nylon 6 fiber was not observed in the case of Cashimilon fiber. This may result from the difference between the adsorption properties of mixtures on the two fibers.

The third maximum of Nylon 6 fiber corresponds to the second of Cashimilon fiber. It is, however, not clear why these maxima appear in the high concentration range.

iii) Mixed System Containing 50 mol% SDS. The ζ-potentials (negative) of both the fibers also showed a small maximum in the vicinity of the CMC, and thereafter decreased, step by step, with an increase in the concentration, as is shown in Fig. 13. The maximum was observed at a lower concentration than that of the former mixed system because of the decrease in the CMC. This is due to the cause mentioned in connection with the mixed system containing 85 mol% SDS. Further, it shifted somewhat to a lower concentration than the CMC. This partly results from the same cause, as has been described above. The step-by-step decrease in the ζ-potentials is connected with the change in the compositions of mixed micelles or with that in those of monomeric ions of the mixtures.

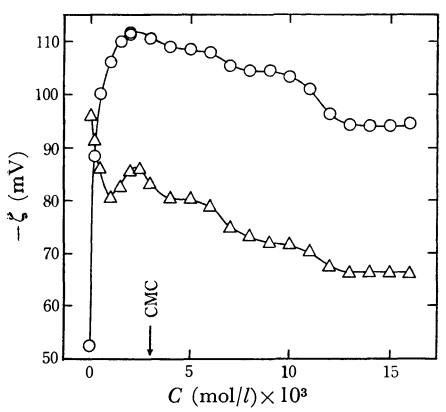

Fig. 13. ζ-Potentials of synthetic fibers in SDS-STS mixed system containing 50 mol% SDS (25°C).
(○) Nylon 6; (△) Cashimilon.

ζ-Potentials of Synthetic Fibers in Aqueous Solutions of STS-SHS Mixtures. The ζ-potentials of two synthetic fibers in mixed systems containing 85, 75 and 50 mol% STS are shown in Figs. 14, 15, and 16 respectively. The behavior of ζ-potentials for Nylon 6 fiber below the CMC was similar to those obtained in the pure STS and SHS systems, but the absolute values of ζ, which increased in the order of the composition: 85,

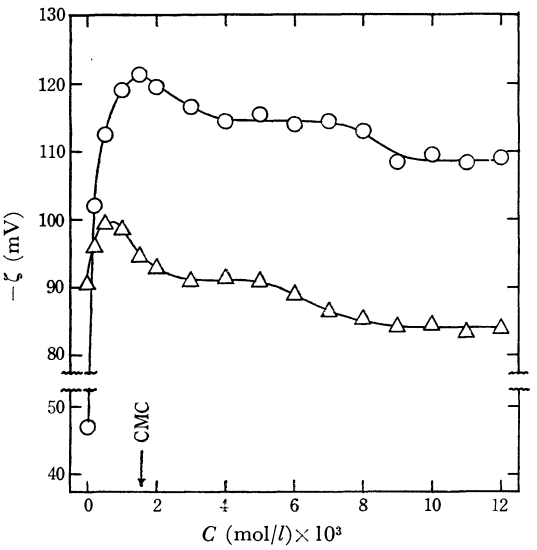

Fig. 14. ζ-Potentials of synthetic fibers in STS-SHS mixed system containing 85 mol % STS (45°C).
(○) Nylon 6; (△) Cashimilon.

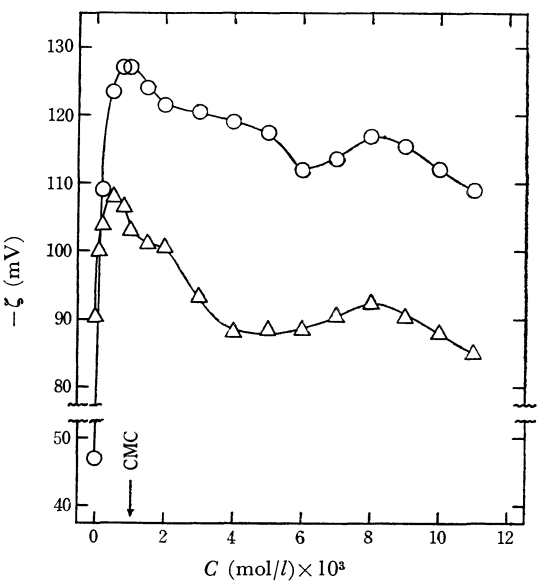

Fig. 15. ζ-Potentials of synthetic fibers in STS-SHS mixed system containing 75 mol % STS (45°C).
(○) Nylon 6; (△) Cashimilon.

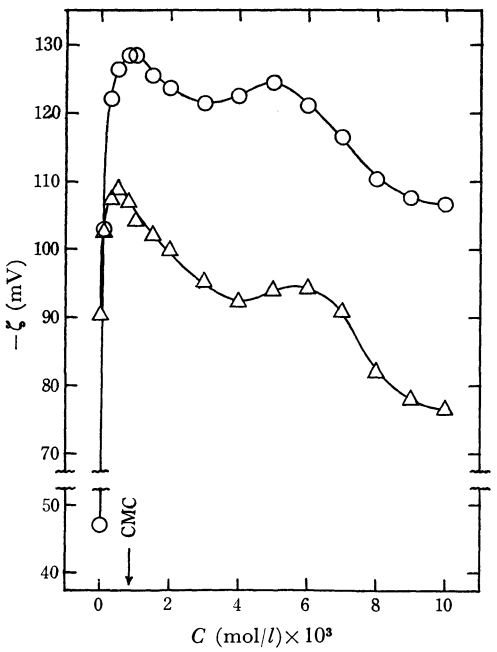

Fig. 16. ζ-Potentials of synthetic fibers in STS-SHS mixed system containing 50 mol % STS (45°C).
(○) Nylon 6; (△) Cashimilon.

75 and 50 mol% STS, were intermediate between those of the pure systems. The results suggest that the surface adsorptions of the higher homolog on the fiber are larger than those of the lower homolog.

On the other hand, the behavior of ζ-potentials for Cashimilon fiber below the CMC is similar to that of the pure SHS system, and different from that of the pure STS system. This results from the preferential adsorption of the SHS anion on the fiber.

In the vicinity of the CMC, a maximum of ζ-potentials for both the fibers was observed in all the mixed systems studied. The maximum shifted to low concentrations in the order of the composition: 85, 75 and 50 mol% STS, because of the decrease in the CMC. This may be attributed to the same cause as has been mentioned in connection with SDS-STS mixed systems.

As the solution became more concentrated, the absolute values of ζ for the mixed system containing 85 mol% STS decreased, step by step. This behavior was similar to that obtained for the mixed system containing 85 mol% SDS. It is connected with the change in the mixed micelle compositions or with that in the monomeric ion compositions of mixtures. On the other hand, the ζ-potentials of both the fibers in the mixed systems containing 75 and 50 mol% STS changed in an intricate manner, showing a maximum and a minimum, with an increase in the concentration of the mixtures. The behavior of the ζ-potentials is roughly analogous to that observed for the mixed system containing 75 mol% SDS.

The author wishes to thank Professor T. Suzawa, Faculty of Engineering of Hiroshima University, for many helpful discussions and suggestions during this work. Thanks are also due to Professor M. Miura, Faculty of Science of Hiroshima University, for his continuing interest and encouragement. In addition, the author wishes to thank the Toray Co., Ltd., the Kurashiki Rayon Co., Ltd., and the Asahi Chemical Industry Co., Ltd., for providing him with the fibers, and the Nippon Oils & Fats Co., Ltd., and the Nikko Chemicals Co., Ltd., for providing him with the surfactants.

The Phosphorescence Bands of Anthraquinone in Crystalline Solvents at 77°K

Akira KUBOYAMA

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received May 23, 1970)

The phosphorescence bands of anthraquinone in the solvents used in this work are all safely assigned to the $\pi^*\rightarrow n$ bands on the basis of their short lifetimes. In *n*-paraffins (*n*-hexane, *n*-heptane, and *n*-octane), two phosphorescence bands which are close to each other are found. Considering the dependence of the relative intensities of these two phosphorescence bands on the carbon-numbers of the *n*-paraffins, it is assumed that the longer- and the shorter-wavelength bands are due to the anthraquinone molecules with the C–O bond axis parallel to and perpendicular to the longitudinal axis of the planar zig-zag form of the *n*-paraffin molecules in the *n*-paraffin crystals respectively. In chloroform and dioxane, a broad phosphorescence band shows a blue-shift relative to the corresponding band in the alkane solvents. In chloroform a sharp phosphorescence band was also observed for a solution which was rapidly cooled. This sharp band is assumed to be due to the anthraquinone molecules with a certain geometry relative to the surrounding chloroform molecules.

In a previous work,[1] we studied the phosphorescence bands of various *o*- and *p*-quinones and α-diketones in solutions and in fine crystals at 77°K. All the solutions studied there were glassy. However, valuable information on the properties of phosphorescence bands, on solute-solvent interactions, and on the arrangements of solutes in solvents is expected to be obtained from the study of the phosphorescence bands in crystalline solutions at low temperatures.[2,3] From this point of view, the phosphorescence bands of anthraquinone in solutions at 77°K have been studied by using various kinds of solvents, all of which form a crystalline state at 77°K.

Experimental

Measurements. The phosphorescence spectra and their lifetimes have been measured in the manner described in our previous paper.[1] The exciting light used was a mercury 313-mμ line emitted from a Hanovia xenon mercury lamp of 150 W. The solvents used were *n*-hexane, *n*-heptane, *n*-octane, 3-methylpentane, isooctane, methylcyclohexane, chloroform, and dioxane. The concentrations used ranged from 10^{-4}—10^{-5} M. The measurements were carried out at the liquid-nitrogen temperature (77°K) in air. Two kinds of cooling speeds, fast and slow, were used. For the rapid cooling, capillary quartz or Pyrex cells were plunged in liquid nitrogen. On the other hand, for the slow cooling the capillary cells were steeped in liquid nitrogen after having been hung immediately above the surface of liquid nitrogen for about 15 min. The solutions used were in polycrystalline states at 77°K except for methylcyclohexane and 3-methylpentane solutions, which were glassy at 77°K.

Materials. Commercially-available anthraquinone was purified by recrystallization. The melting point of the purified sample agreed with that reported in the literature. As for solvents, commercially-available spectro-grade *n*-hexane, *n*-heptane, *n*-octane, isooctane, methylcyclohexane, and chloroform were used without further purification. Aromatic impurities in commercially-available 3-methylpentane were removed with silica gel. After the treatment, the 3-methylpentane was distilled. Dioxane of a special grade was dried over sodium and distilled.

n-Octane	496
Methylcyclohexane (Crystalline state)	497
Methylcyclohexane	495
3-Methylpentane	495
Isooctane	495
Chloroform	492
Chloroform (Rapid-cooling)	486
Dioxane	490

for the response of the photomultiplier, and the scales of the ordinates are arbitrary. In Table 1, the wavelengths of the strongest peaks near 500 mμ in the phosphorscence spectra in various solvents are given. The observed lifetimes of the phosphorescence bands were all close to that (3.3 msec) in methylcyclohexane and methanol-ethanol (1 : 4) mixture obtained in our previous work.[1)]

Discussion

The phosphorescence bands in the solvents used in this work can all saelfy be assigned to the $\pi^* \rightarrow n$ band on the basis of their short lifetimes.

As is shown in Figs. 1—3, the phosphorescence spectra in the *n*-paraffins show sharp, fine struc-

tures. Previously, Shpol'skii[2] found that, when the longitudinal dimention of the planar zig-zag form of an *n*-paraffin molecule used as a solvent is close to the molecular dimension of a solute aromatic hydrocarbon, for example, anthracene (7.5 Å) in *n*-heptane (7.6 Å),[4] the fluorescence spectrum of the solution shows a very sharp, fine structure. This Shpol'skii effect has been generally observed for the electronic absorption and emission spectra of various aromatic compounds which have a rigid molecular structure. Anthraquinone has a rigid molecular structure, and the dimension (7.4 Å) of its long axis (perpendicular to the C–O bond axis) is close to that of *n*-heptane, while that (5.3 Å) of its short axis (parallel to the C–O bond axis) is relatively close to that (6.3 Å) of *n*-hexane. That of *n*-octane is 8.9 Å.[4] Therefore, it may be surmised that the sharp phosphorescence band in the *n*-paraffins mentioned above are due to the Shpol'skii effect. In *n*-heptane (Fig. 2), the peaks corresponding to the two main peaks near 500 and 540 mμ in methylcyclohexane (Fig. 4) have doublet structures. Similar doublet structures are also found in *n*-hexane and *n*-octane (Figs. 1, 3). In *n*-hexane the intensity of the shorter wavelength peak relative to that of the longer wavelength one in each doublet structure is considerably weaker than that in *n*-heptane. On the other hand, in *n*-octane the intensity of the longer-wavelength in each doublet structure is considerably weaker than that of the corresponding shorter-wavelength peak, contrary to the cases of *n*-heptane and *n*-hexane.

The effect of the cooling speed on the doublet structures is as follows. The relative intensity of the weaker peak (shorter-wavelength peak) to that of the stronger peak in each doublet structure increases in the case of *n*-hexane (Fig. 1), and decreases in the case of *n*-heptane (Fig. 2), for solutions which are rapidly cooled. On the other hand, in the case of *n*-octane (Fig. 3), the intensity of the weaker peak (longer-wavelength peak) relative to that of the stronger peak in each doublet structure becomes considerably stronger for solutions which are rapidly cooled. In these paraffins the wavelengths of peaks in the phosphorescence band are all the same, irrespective of the cooling speed. Though the reproducibility of the doublet structures in each case is not very good, the difference in the relative intensity of the two peaks of the doublet structure among the three paraffins is always definite.

From these facts it may be concluded that, in these paraffins, two phosphorescence bands closely overlap,[5] and that, in *n*-hexane, the longer-wavelength phosphorescence band and, in *n*-octane, the shorter-wavelength band appear more intensely. The energy difference between these two phosphorescence badns is *ca.* 100 cm^{-1}. On the basis of a comparison of the phosphorescence spectra in these paraffins, the peaks identifiable with the shorter-wavelength band are denoted with an arrow in Fig. 2. These two phosphorescence bands in these paraffins are assumed to be due to the anthraquinone molecules incorporated in two different ways in the paraffin crystals.

Since no complete single-crystal X-ray-analysis has been made for these paraffin crystals, precise structural details are unknown. However, considering the crystal data[6] for other *n*-paraffins, it may be assumed that, in the paraffin crystals used in this work, the paraffin molecules with the planar zig-zag form are arranged in parallel rows.[2] As for the anthracene in *n*-heptane crystals, mentioned before, it may be assumed that the anthracene molecules are arranged with their long axis parallel to the longitudinal axis of *n*-heptane molecules in *n*-heptane crystals.[2] It may analogically be assumed that, in the three paraffin crystals, anthraquinone molecules are incorporated in two different ways, namely, with their C–O bond axis parallel to and perpendicular to the longitudinal axis of the paraffine molecules, and that the above two phosphorescence bands are due to the anthraquinone molecules arranged in these two ways. If so, the difference in the relative intensities of the two phosphorescence bands between *n*-hexane and *n*-octane, mentioned before, can be explained on the reasonable presumption that, in *n*-hexane, most anthraquinone molecules are situated with their C–O bond axis parallel to the longitudinal axis of *n*-hexane molecules, while in *n*-octane most quinone molecules direct the C–O bond axis perpendicular to the longitudinal axis of *n*-octane molecules, and that the longer- and the shorter-wavelength phosphorescence bands are due to the anthraquinone molecules with the C–O bond axis parallel to and perpendicular to the longitudinal axis of the paraffin molecules. The situation in *n*-heptane can be assumed to be intermediate between those in *n*-hexane and *n*-octane. It can also be assumed that, in *n*-heptane, a majority of the anthraquinone molecules direct the C–O bond axis (short axis) parallel to the longitudinal axis of the *n*-heptane molecules, unlike as in the case of anthracene. This situation may be mainly due to the dipole-induced dipole interaction between the polar carbonyl groups of the quinone molecules and the *n*-heptane molecules, which may be stronger in the case of the anthraquinone molecules directing the C–O bond axis parallel to the

4) In obtaining these data, hydrogen atoms are neglected. The value for anthracene is that of the long axis.

5) The similar conclusion was obtained by D. N. Shygorin *et al.* ("Advances in Spectroscopy," Vol. 1 (1957), p. 672).

6) J. M. Robertson, "Organic Crystals and Molecules," Cornell Univ. Press. Ithaca (1953), p. 165.

longitudinal axis of the *n*-heptane molecules than in the other case because of the anisotropy of the polarizability of the *n*-heptane molecules.

Methylcyclohexane solutions at 77°K usually form glassy states and show the same phosphorescence band, irrespective of the cooling speed. When the solution is cooled slowly, it occasionally becomes polycrystalline, and the phosphorescence band in the crystalline solution is different from that in the glassy solution. The phosphorescence band in the crystalline solution shifts toward wavelengths longer by *ca.* 80 cm^{-1} and becomes sharper than that in the glassy solutions (Fig. 4). Both in polycrystalline isooctane and in glassy 3-methylpentane the phosphorescence band is unaffected by the cooling speed and is very similar to that in the methylcyclohexane glass.

In chloroform (Fig. 5), a broad phosphorescence band appears for the slowly-cooled solutions. On the other hand, the rapidly-cooled solutions exhibit a sharp phosphorescence band, accompanied by a weak, broad band on its longer wavelength side. The weaker band situated at the same position as the broad band observed for the slowly-cooled solutions. It may be assumed that the sharp band is due to the anthraquinone molecules incorporated in the crystalline part of the chloroform matrix and that the broad band is associated with the anthraquinone molecules in the amorphous part of chloroform.

Generally speaking, the solvent effects on the energies of an absorption band and the corresponding emission band of solutions at 77°K are expected to be similar, since both the solute and solvent molecules can hardly move at 77°K. As a result, the solvent effects on the energies of the $\pi^* \rightarrow n$ phosphorescence band at 77°K and the corresponding $n \rightarrow \pi^*$ absorption band at room temperature can also be expected to be similar to some extent. Therefore, the blue shift of the phosphorescence bands in chloroform relative to those in the saturated hydrocarbons may be attributed to the hydrogen-bond formation between anthraquinone and chloroform.

In dioxane (Fig. 6), the same broad phosphorescence band is found for both the slowly- and rapidly-cooled solutions. This broad band may also be due to the anthraquinoe molecules in the disordered crystals of dioxane. A blue shift of the phosphorescence band in dioxane relative to those in the saturated hydrocarbons may be due to the π-*n*-type charge-transfer interaction between anthraquinone and dioxane molecules.[7]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3377—3382 (1970)

The Electron Spin Resonance of the Mn^{2+} Ion on the Surface of Magnesium Oxide

Takemi YAMAMURA,*1 Akinori HASEGAWA, Yoshio YAMADA and Masaji MIURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received June 1, 1970)

The behavior of the Mn^{2+} ion on the surface of MgO was studied by using the ESR technique. The powder of MgO, the surface of which was doped with the Mn^{2+} ion, was calcined at different temperatures from 100 to 1000°C in a vacuum, and then the ESR spectra were observed at room temperature. It was noticed that the spectral intensity showed a minimum at about 500°C, that the zero-field splitting parameter, D, increased with the temperature, and that the hyperfine coupling constant, A, decreased enormously at about 700°C. The environments around the Mn^{2+} ion on the surface of MgO were discussed on the basis of these results. When H_2, CO, or O_2 was added after the calcination, the D and A values changed in the temperature range above 500°C. Especially when O_2 was introduced, the D value fell to zero upon treatment at 1000°C. The crystal field around the Mn^{2+} ion and the bonding between the Mn^{2+} ion and its environments were discussed by taking into account the results of the magnetic-susceptibility measurements of the manganese ion on MgO.

Many studies have been done on the ESR of the Mn^{2+} ion doped in the bulk of solids. These have dealt with the phase transition,[1] the defects,[2] the crystal field of solids,[3] *etc.* Several studies have also been done on the ESR of the Mn^{2+} ion on the surfaces of ion-exchange resin[4] and zeolite.[5-7] The character of the bonding between the Mn^{2+} ion and the adsorbent, the kind of adsorption site,[5,6] and the crystal field around the Mn^{2+} ion[7] have been discussed in these studies.

In this paper, the Mn^{2+} ion is selected as a probe for the surface of magnesium oxide in the expectation that information about the Mn^{2+} ion and its environments on the surface will be obtained from the ESR spectrum of the ion. The information, if any is obtained, may also be useful in discussing the surface reactivity of magnesium oxide doped with transition metal ions.[8,9] The ESR spectrum of the Mn^{2+} ion offers several parameters: the spectral intensity, the hyperfine coupling constant, and the zero-field splitting parameter. The intensity of the spectrum, which is proportional to the concentration of the Mn^{2+} ion, can be taken as a measure of the oxidation or reduction of the manganese ion, because the ion takes different valencies. The hyperfine coupling constant, as revealed by van Wieringen[10] and Matsumura,[11] is correlated with the ionic character in the bond between the Mn^{2+} ion and its environments. The zero-field splitting parameter gives information about the crystal field, that is, the symmetry of the environments around the Mn^{2+} ion.

Changes in the valence state and in the environment of the manganese ion on the surface of magnesium oxide, resulting from the thermal treatment and the introduction of various gases, were investigated by the ESR technique and by magnetic-susceptibility measurements.

Experimental

The powder of magnesium oxide was prepared by the calcination of magnesium hydroxide, which had itself been obtained from the methylation of magnesium

metal, followed by the hydrolysis of the methylate, in an atmosphere of oxygen for 4 hr at 700°C. The magnesium metal (99.9999%) was supplied by the Material Research Corporation (U. S. A.). The calcination temperature is sufficiently high to bring about the complete dehydration of magnesium hydroxide.[12,13] The resulting magnesium oxide gave none of the ESR spectrum of paramagnetic species.

Silica gel was prepared from water glass and sulfuric acid and was calcined at 500°C for 5 hr.[14]

The powders of magnesium oxide and silica gel were immersed into an aqueous solution of manganese nitrate, and the products were dried at 110°C for 24 hr in air. The amount of the adsorbed Mn^{2+} ion is 0.3 wt% of the Mg^{2+} ion. As the surface area of the magnesium oxide is determined to be 69 m^2/g by the B. E. T. method from the nitrogen adsorption, the mean distance between Mn^{2+} ions is estimated to be about 11.4 Å when the Mn^{2+} ions are distributed homogeneously. If the latter situation is granted, the contribution of the dipole-dipole interaction between Mn^{2+} ions is assumed to be negligible in the ESR spectra and the features of the spectra may be treated on the basis of the crystal field around the Mn^{2+} ion.

These specimens were calcined at various temperatures from 100 to 1000°C for 4 hr in a vacuum and were exposed to such gases as oxygen, hydrogen, and carbon monoxide at each temperature and at 0.5 atm. Oxygen gas was also introduced under the same conditions as above after the magnesium oxide containing the Mn^{2+} ion on its surface had been calcined at 1000°C.

The specific susceptibilities of the manganese ion on the magnesium oxide (Mn/Mg=0.03 by weight, ten times the concentration in the case of the ESR measurement), treated at room temperature and at 500, 800, and 1000°C for 4 hr in a vacuum (10^{-4}—10^{-5} Torr), were measured to give information as to the valence state of the manganese ion. The specific susceptibility of the manganese oxide prepared by heating manganese nitrate at 110°C for 24 hr was also determined after treatment under the same conditions. The measurements of the specific susceptibility were carried out at room temperature by the Faraday method, using a Cahn RG electrobalance.

Estimation of the *D* Value and the Ionicity.

Since the Mn^{2+} ion has $S=5/2$ and $I=5/2$ and since its ground state is ^6S, the hyperfine and fine structures are expected to occur in the ESR spectrum. However, since the specimen used is in a powder state and has a small zero-field splitting, the observed spectrum of the Mn^{2+} ion on the surface of magnesium oxide consists of six hyperfine structures due to the allowed transition, $\Delta m_I=0$, and the weak lines, observed between hyperfine structures, due to the forbidden transitions, $\Delta m_I=\pm 1$, as may be seen in Fig. 1.

The following two methods have been proposed for the estimation of the zero-field splitting parameter, *D*, or the distortion of the crystal field from cubic symmetry on the basis of the ESR spectrum of the Mn^{2+} ion. One is Allen's method,[15] which utilizes the relation, shown in Fig. 2, between the value of *D* and the ratios of the intensity of the hyperfine line of $m_I=-5/2$ to those of $m_I=-1/2$ and $m_I=-3/2$. An alternative method is to use the intensity ratio of the forbidden lines to the allowed lines; this method has been proposed by Bleaney and Rubins[16] and by de Wijn and van Balderen.[17] Though the value estimated by this method is in considerable agreement with that ob-

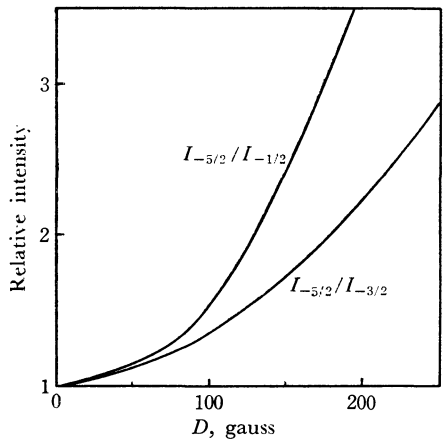

Fig. 2. The relations between relative intensity and D value proposed by Allen.[15]

tained by Allen's method, this method is not adopted in the present study since the estimation of the intensities of the forbidden lines is accompanied by a rather large error.

An almost linear relation between the coupling constant of the hyperfine structure, A, and the ionicity of the bonds between the Mn^{2+} ion and the environments has been proposed by Matsumura. It is shown in Fig. 3,[11] where the ionicity has been calculated from the electronegativities of the Mn^{2+} ion and the surrounding negative ions and the number of the latter ions, after Pauling.[18] The ionicity of the bonds was. therefore, estimated in terms of this relation.

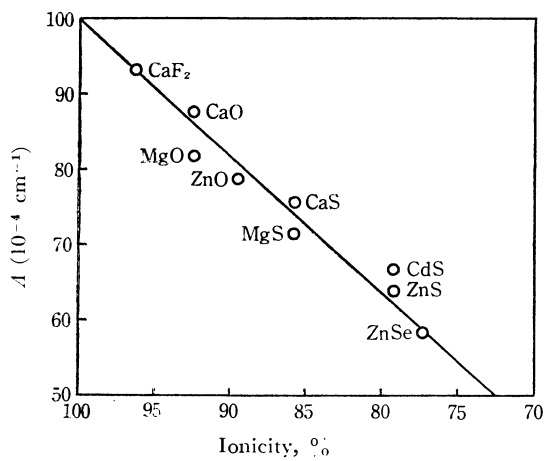

Fig. 3. The relation between A value and ionicity proposed by Matsumura.[11]

Results and Discussion

ESR Spectra of the Mn^{2+} Ion on the Surface of MgO in Air at Room Temperature. After the magnesium oxide containing the Mn^{2+} ion on its surface had been dried at 110°C for 24 hr in air, the ESR spectrum was measured at room temperature (Fig. 1). The zero-field splitting parameter, D, was evaluated to be 46 gauss from the relative intensities of their spectral lines by using the relations shown in Fig. 2. The ionicity was estimated to be 90% from the observed value of the hyperfine coupling constant, A, (89.4 gauss) and Fig. 3. The value of g was also determined to be 2.0022.

Effect of the Calcination Temperature in a Vacuum on the ESR Spectrum of the Mn^{2+} Ion on MgO. The intensity of the ESR spectrum of the Mn^{2+} ion on magnesium oxide changed with the calcination temperature, as is shown in Fig. 4,

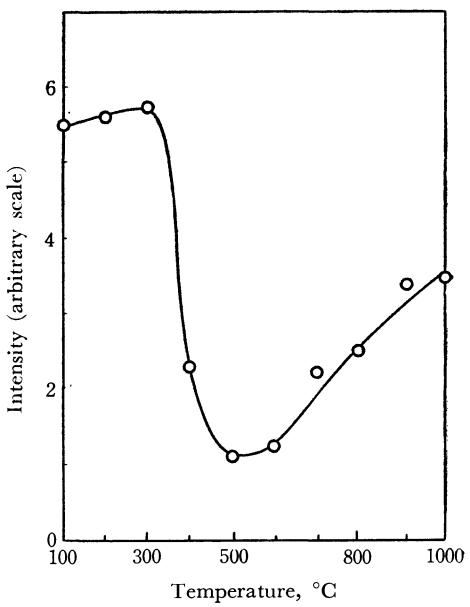

Fig. 4. The variation in ESR spectral intensity of Mn^{2+} ion by the treatment at different temperatures.

while the g value hardly changed at all from 2.0022. The intensity should be proportional to the concentration of the Mn^{2+} ion, since the Mn^{3+} ion does not participate in the ESR spectrum because of the strong spin-lattice interaction and since the spectrum of the Mn^{4+} ion, with $g=1.9980$ and $A=76$ gauss, is considerably different from those obtained here.[19-21] Accordingly, the concentration of the Mn^{2+} ion falls remarkably with a rise in the temperature, reaches a minimum at about 500°C,

and then increases to some extent with a further rise in the temperature. On the other hand, the calcination up to 1000°C brings about a small decrease in the surface area of the magnesium oxide, from 69 to 60 m^2/g.

Specific Susceptibility. The specific susceptibilities of magnesium oxide containing the Mn^{2+} ion on the surface and of manganese oxide prepared from manganese nitrate were measured after the samples had been calcined at 500, 800, and 1000°C. The results are shown in Table 1.

TABLE 1. SPECIFIC SUSCEPTIBILITY OF MANGANESE OXIDE TREATED AT VARIOUS TEMPERATURES IN A VACUUM

	χ*			
	Room temp.	500°C	800°C	1000°C
Manganese on MgO	120.88	87.50	134.66	151.51
Manganese oxide	30.03	80.46	55.03	50.81

* unit of χ: 10^{-6} cgs emu

TABLE 2. SPECIFIC SUSCEPTIBILITY OF VARIOUS MANGANESE OXIDES

	χ*	Ref.
MnO	75.9	22
Mn_3O_4	55.8	22
Mn_2O_3	69.0	22
MnO_2	38.4	22
^{55}Mn	9.9	22
8MnO-5MgO	91.63	23
2MnO-11 MgO	126.87	23

* Unit of χ: 10^{-6} cgs emu

The value of the former is considerably decreased by the calcination at 500°C and then increased by the treatment in the higher-temperature range; the values at 800 and 1000°C are rather higher than that at room temperature. On the other hand, the value of the latter exhibits a remarkable increase at 500°C and then decreases with a further rise in the temperature. For comparison with these results, the values of various manganese oxides and of manganese oxide in magnesium oxide (mMnO–nMgO) are presented in Table 2.[22,23]

The electronic configurations of various manganese ions are as follows:

$Mn^{1+}\cdots(3d)^5(4s)$ $\quad$ $Mn^{3+}\cdots(3d)^4$

$Mn^{2+}\cdots(3d)^5$ $\quad$ $Mn^{4+}\cdots(3d)^3$

The specific susceptibility, therefore, should decrease with the increase in the valence of the manganese ion.

The data in Tables 1 and 2 and the results shown in Fig. 4 lead us to the following speculation: the manganese ions on magnesium oxide are mainly bivalent at room temperature, but some of them are oxidized to a higher valence state, namely Mn_2O_3, by calcination at 500°C in a vacuum, and these oxidized ions are in turn reduced to bivalence or, further, to univalence when treated at 800 and 1000°C. On the other hand, as may be seen from these tables, the manganese ion in manganese oxide may be Mn^{4+} at room temperature, and it may then be reduced to Mn^{2+} by heating at 500°C in a vacuum. This discrepancy may be attributed to the influence of the ground.

Variations in *D* and *A* Values. The values of D and A of the Mn^{2+} ion on magnesium oxide were estimated to be as is shown in Figs. 5 and 6 after calcination at 100, 300, 500, 800, and 1000°C in a vacuum, followed by the addition of hydrogen, carbon monoxide, or oxygen at each temperature.

The D value increases with the temperature, particularly abruptly from 500°C. When hydrogen is added after the calcination, the value also increases with the calcination temperature above 500°C, but the value is low as compared with that in the absence of hydrogen. The introduction of carbon monoxide causes the value to reach a maximum near 500°C. In the case of oxygen, it changes slightly from room temperature to 500°C, but thereafter it falls to almost zero at 1000°C.

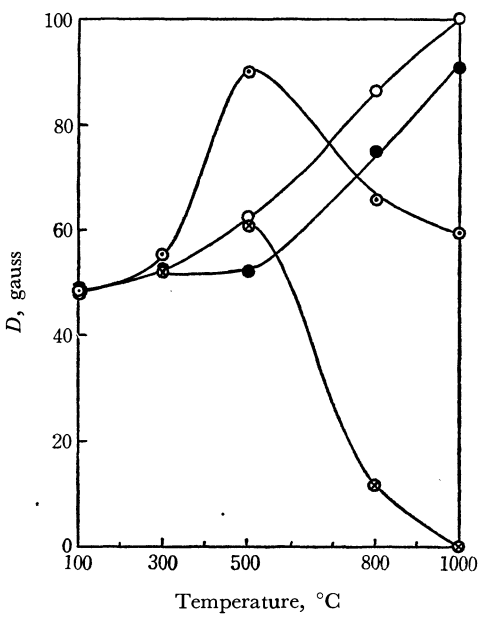

Fig. 5. The variations in D value by the addition of gases at different temperatures; ○: in a vacuum, ●: H_2, ⊙: CO, and ⊗: O_2.

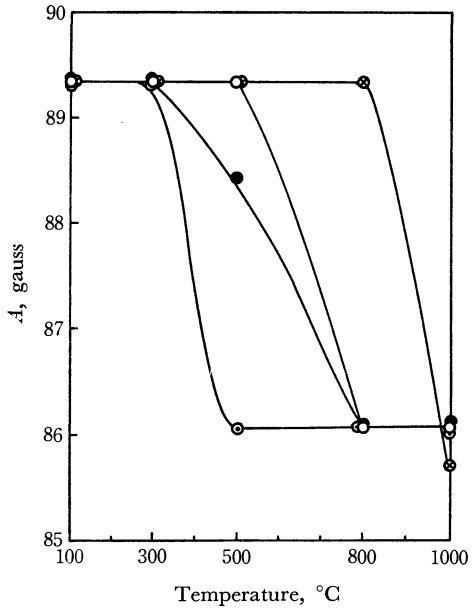

Fig. 6. The variations in A value by the addition of gases at different temperatures. Symbols in this figure have the same meaning as those in Fig. 5.

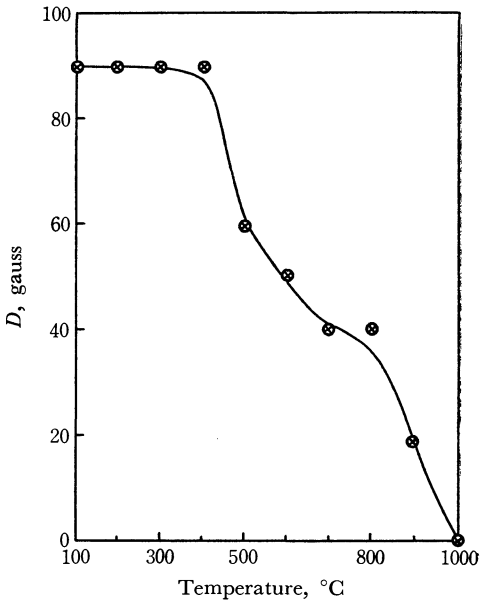

Fig. 7. The variations in D value by the addition of O_2 at different temperatures for the specimen precalcined at 1000°C.

Upon calcination in a vacuum, the value of A decreases remarkably above 500°C and remains constant, 86.2 gauss, at temperatures higher than 800°C. The bonding between the Mn^{2+} ion and its surroundings, accordingly, has a high degree of covalent character in the temperature range above 500°C. When hydrogen is added, the A value is steadily reduced by the treatments from 300 to 800°C, and then it remains constant, 86.2 gauss. By the addition of carbon monoxide, however, the A value already reaches to 86.2 gauss at 500°C and remains unchanged when treated at higher temperatures. When oxygen was introduced, the A value hardly changes till 800°C, but it reaches its lowest value, 85.7 gauss, at 1000°C.

Two effects are entangled with each other in the results of these experiments; one is due to the calcination, and the other, to the introduction of gas at different temperatures. Therefore, we attempted to remove the former effect by precalcining the magnesium oxide with the Mn^{2+} ion at 1000°C for 4 hr in a vacuum. The zero-field splitting parameter, D, was estimated when oxygen was added at different temperatures from 100 to 1000°C, as is shown in Fig. 7. The value falls abruptly to zero upon treatment at a temperature above 500°C. From the results, it is conceivable the oxygen is coordinated to the Mn^{2+} ion and that the crystal field around the ion is less distorted and becomes almost cubic-symmetrical at 1000°C. Such a cubic symmetry may be attributed to the cubic bulk structure of magnesium oxide.

The Mn^{2+} Ion on the Surface of Silica Gel. The ESR spectrum of the Mn^{2+} ion on the surface of silica gel was also investigated. The values of D, A, and ionicity are, respectively, 72 gauss, 98 gauss, and 95%, these values being obtained from the spectrum (Fig. 8) of the sample dried at 110°C for 24 hr in air. By a comparison of these values with those on magnesium oxide under the same conditions, it may be concluded that, on the surface of silica gel, the bonding between the Mn^{2+} ion

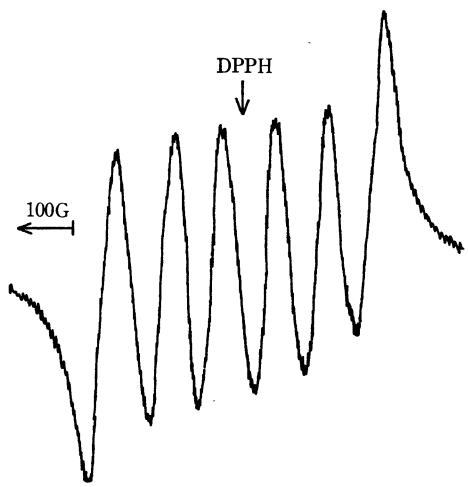

Fig. 8. ESR spectrum of Mn^{2+} ion on silica gel treated at 110°C for 24 hr in air.

and its environments has a higher degree of ionic character and that the crystal field around the Mn^{2+} ion is more distorted from the cubic symmetry than on the surface of magnesium oxide. The calcination of the sample in the same way as in the case of magnesium oxide brings about a complete disappearance of the six hyperfine structures of the Mn^{2+} ion above 300°C. This may be attributed to the fact that the signal becomes broad and smeared out with a rise in the temperature because of an increase in the D value. Even when hydrogen, carbon monoxide, and oxygen were introduced, the six hyperfine structures did not come out again.

Behavior of the Mn^{2+} Ion on MgO. We will discuss the behavior of the adsorbed manganese ion on the basis of the results of the ESR and susceptibility measurements. When the sample is treated up to 300°C, the coupling constant, A, is comparatively large, which means that the bonding between the Mn^{2+} ion and the environments has a high degree of ionic character, and the zero-field splitting parameter, D, is relatively small. The Mn^{2+} ion, therefore, combines weakly with magnesium oxide and surface hydroxyl groups. Upon treatment at 500°C, however, the distortion of the crystal field increases and the A value decreases; that is, the bonding of Mn^{2+} has a low degree of ionic character. Furthermore, both the ESR spectral intensity shown in Fig. 4 and the susceptibility measurement shown in Table 1 show that the concentration of the Mn^{2+} ion reaches a minimum. This may be interpreted as follows: the Mn^{2+} ion combines with oxygen as a result of the removal of the surface hydroxyl groups by a condensation dehydration, and some Mn^{2+} ions assume a higher valence state, Mn^{3+}. With the treatments at higher temperatures, the distortion of the crystal field increases and the bonding of the Mn^{2+} ion comes to take a much lower ionic character, thus reflecting the strong covalent bonding with oxygen. The increase in both the intensity of the ESR spectrum and the specific susceptibility above 500°C is caused by the elimination of oxygen, accompanied by the reduction of Mn^{3+} to Mn^{2+} or, partially, that of Mn^{2+} to Mn^{1+}. The possibility of the existence of Mn^{1+} may be speculated from the higher value of the susceptibility and the lower intensity of the ESR spectrum at 1000°C than those at room temperature. The presence of the Mn^{2+} ion may also mean that there is little oxygen on the surface of magnesium oxide at 1000°C.

It is somewhat doubtful that the information with regard to the surface of magnesium oxide obtained from the ESR spectra of Mn^{2+} ion can be directly applied to a discussion of its clean surface. Nevertheless, the cationic site, namely, the Mg^{2+} ion, on the surface of magnesium oxide doped with transition metal ions may be in a situation analogous to that of the Mn^{2+} ion observed in the present study, since the adsorption capacity of magnesium oxide increases remarkably upon the addition of a trace of transition metal ions to the bulk of magnesium oxide.[8,9]

The addition of hydrogen after the calcination in a vacuum leads to an increase in the distortion of the crystal field above 500°C, as is shown in Fig. 5. The value of A falls steadily above 300°C, as is shown in Fig. 6. This may be interpreted as follows: a part of the added hydrogen combines with the oxygen adjacent to the Mn^{2+} ion to form water, and then the Mn^{2+} ion enters into combination with the water molecules and the oxygen atoms of magnesium oxide in such a manner that the distortion of the crystal field around the Mn^{2+} ion is relatively small and the bonding bears a high degree of covalent character.

When carbon monoxide is introduced into the system, the A value decreases and the D value reaches a maximum at 500°C. The carbon monoxodie, having a greater reduction ability than hydrogen, easily draws out the oxygen coordinated weakly to the Mn^{2+} ion, and the ion, in turn, combines strongly with the oxygen on the surface of magnesium oxide and is subject to a large distortion of the crystal field from cubic symmetry. Such a distortion may be reduced by a coordination of carbon monoxide or carbon dioxide to the Mn^{2+} ion resulting from treatment at a higher temperature.

On the addition of oxygen, the A value shows no change below 800°C, but it abruptly decreases at 1000°C, while the D value decreases gradually above 500°C and becomes almost zero at 1000°C. It may, therefore, be suggested that oxygen atoms around the ion is slightly distorted from the cubic symmetry below 800°C, and that the bonding is strengthened by the thermal treatment, with the result that the oxygen atoms surrounding the Mn^{2+} ion have a cubic symmetry in the same manner as in the bulk of magnesium oxide.

On the other hand, none of the effects of gases are observed in the case of silica gel; this may indicate that the effect of the gas conceals itself behind the strong influence of the silica-gel surface. As to the manganese ion on the surface of magnesium oxide, the information obtained through the ESR spectrum may also be characterized by the cationic lattice point, Mg^{2+}, activated by the addition of the Mn^{2+} ion. It may, therefore, be mentioned that the manganese ion plays a significant role as a probe for the surface of magnesium oxide and, at the same time, contributes to the surface reactivity of the magnesium oxide in reaction to gases.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 3383—3390 (1970)

Measurement of Negative Ions Formed by Electron Impact. VII. Negative Ion Mass Spectra from Alkyl Cyanides

Satoru TSUDA, Akira YOKOHATA and Toshikatsu UMABA

Department of Chemistry, Faculty of Engineering, University of Hiroshima, Senda-machi, Hiroshima

(Received June 4, 1970)

The negative ion mass spectra from alkyl (methyl, ethyl, *n*- and *iso*-propyl) cyanides with electron energies of 80 eV, 40 eV and 9.5 eV were measured by a Hitachi RMU-6D mass spectrometer with emphasis on the relative abundance of negative ions to positive ions with electron energies of 80 eV, 40 eV and 15 eV. In every sample, the electron impacts with 80 eV and 40 eV gave almost the same distribution of *m/e* for negative ion mass spectra. Then, the peak of *m/e* 26(CN^-) ions was the most intense and also the relatively strong peak of 25(C_2H^-) ions was found through all samples. On the other hand, the formations of 38(C_2N^-), 39($CHCN^-$) and 41(CH_3CN^-) ions from methyl cyanide, of 50(C_3N^-) ions from ethyl cyanide, *n*- and *iso*-propyl cyanides, of 40(CH_2CN^-) ion from *n*-propyl cyanide were characteristic of each sample. The ratio of the yield of negative ions to positive ions was respectively of the order of $\sim 10^4$ for CH_3CN^+/CN^- (CH_3CN), $C_2H_4^+/CN^-$ (C_2H_5CN), $C_3H_5^+/CN^-$ (*n*-C_3H_7CN) and $C_3H_6^+/CN^-$ (*iso*-C_3H_7CN) at 80 eV and 40 eV electron energies. At 9.5 eV, *m/e* 26 (CN^-) ions predominated over other negative ions for all the samples and a much larger peak of 40 (CH_2CN^-) ions in *n*-C_3H_7CN than in *iso*-C_3H_7CN was also observed. Then, we got the values of 19$\sim$65 for CH_3CN^+/CN^-, $C_2H_4^+/CN^-$, $C_3H_5^+/CN^-$ and $C_3H_6^+/CN^-$ (15 eV for positive ions). This work also gave linear relationship of the yield of each negative ion to the pressure in the range used for an usual chemical analysis.

Collisions of electrons of low velocity with molecules may produce charged fragments of the molecules. The data on the minimum electron energy necessary to produce these fragments, their identification, and the processes involved may permit one to determine the electron affinity of fragments and the heat of dissociation of the molecule. The relative abundance of ion products and the probability of a process as a function of the electron energy are also of interest.

If the kinetic energy of the electron in a gaseous medium is below the ionization potential of the molecules, the electron would lose energy to electronic excitation as long as its kinetic energy is above the first excitation potential of the medium. When the electron energy is below the first excitation potential, moderation occurs through elastic and inelastic collisions leading to vibrational and rotational excitation of the molecules. A subexcitation electron may lose energy also through various types of electron attachment processes and the excitation of compound negative ion states. Compound negative ion states can decay purely elastically, give vibrationally excited molecules, or lead to dissociative attachment.[1-6]

Especially, of interest and practical importance are the processes which result in the formation of negative ions. As described frequently,[7] they are classified into the following types: a) resonance capture, b) dissociative resonance capture and c) ion pair formation. Under the normal operating conditions (80—40 eV) of a mass spectrometer, all processes may occur. As they are pressure dependent, the relative ion intensities in negative ion mass spectra would change with the sample pressure. In the formation of $CH_2NO_2^-$ ions from *n*- and *iso*-nitropropanes,[8] the authors reported the linear relationship of their yield to the pressure in the region used for an usual analysis, and also their yield is $\sim$100 times greater in *n*-nitropropane than in isonitropropnane. This shows clearly the usefulness of the measurement of

negative ions for chemical analysis. Also, the formation of molecular anions by resonance capture would permit the determination of the molecular weight, and in some cases might be useful for structural and stereochemical problems.[9]

Unfortunately, however, a very little has been published on negative ion mass spectrometry. There also appear to be discrepancies in the published experimental results which calls for further work. For the purpose of gathering the data of negative ions and establishing their pattern in comparison with positive ions under various electron energies, this series of studies[10] has been begun. This work is an extension to alkyl cyanides, with emphasis on a comparative study of negative and positive ions.

Experimental

Experiments were performed on a Hitachi RMU-6D mass spectrometer equipped with the T-2M ion source having a rhenium filament. The ion detection circuit consisted of a ten stage electron multiplier having Ag–Mg dynode and of a Faraday collector. All the spectra were measured with a total emission current of 20 μA, an accelerating voltage of 3.6 kV and an electron multiplier voltage of 2.5 kV, under the electron energies of 80 eV, 40 eV, 9.5 eV (80 eV, 40 eV and 15 eV for positive ions) and a pressure of $\sim 10^{-6}$ mmHg in the source. An ionizing current showed a constant value of 10.5 μA down to $\sim$10 eV. The energy scale was calibrated in every measurement by the vanishing current method as compared to the ionization potential of argon or the appearance potential of m/e 16(O^-) ions

from carbon monoxide, carbon dioxide and oxygen as described previously.[10] The repeller voltage was adjusted respectively to the best condition to collect the ions in positive and negative ion measurements. All chemicals were of research grade.

Results and Discussion

Negative Ion Mass Spectra. *Methyl Cyanide.* In 80 eV electron impact experiments (Fig. 1a), the foregoing spectra were observed where they are shown in decreasing order of yield; m/e 26

(CN^-), 25 (C_2H^-), 24 (C_2^-), 38 (C_2N^-), 39 ($CHCN^-$), 40 (CH_2CN^-), 12 (C^-), 27 (HCN^-), 13 (CH^-), 41 (CH_3CN^-) and 14 (CH_2^-). The comparison of the yield of CN^- ion with that of CH_3CN^+ (*m/e* 41, the most intense peak among the positive ions) gave a value of $\sim 2.8 \times 10^4$ for CH_3CN^+/CN^-.

For 40 eV electron energies (Fig. 1b) the pattern of the negative ions was almost the same as that for 80 eV except for a small change in the relative abundance of C_2H^-, C_2^- and $CHCN^-$ ions, and the ratio of CH_3CN^+ to CN^- was $\sim 3.5 \times 10^4$.

For 9.5 eV electron energies (Fig. 1c) CN^- ions predominated over other negative ions. A value of ~26 for CH_3CN^+/CN^- was obtained where 15 eV electron energies are used for positive ions.*1. Table 1 shows the yield of minor negative ions for 80 eV, 40 eV and 9.5 eV.

Then, the formation of parent negative ion, CH_3CN^- at 80 eV and 40 eV was observed while at 9.5 eV it was not. It is noticed[11] that the appearance potential, AP_{obs} value of CH_3CN^- ions from methyl cyanide is ~23 eV and the effect of an additive xenon suggests the possibility of the occurrence of the reaction; $Xe^* + CH_3CN \rightarrow Xe^+ + CH_3CN^-$. Also, the formation of C_2H^- and C_2^-

*1 Since at 9.5 eV electron energies the positive ions are not observed, the energy of 15 eV was substitutionally used.

11) T. Sugiura and T. Arakawa, presented at the annual meeting of 22nd Chemical Society of Japan, Tokyo (1969).

ions from the compounds containing two carbon atoms besides hydrogen atoms may be regarded to be a general phenomenon as found in ethane,[7] nitroethane[10] and ethyl chloride.[12] Furthermore, in the case of compounds containing cyano group, CN^- and C_2N^- ions should be added to them. These are qualitatively understood on the basis of EA(C_2)$\simeq$3.1 eV[13] and EA (CN)$\simeq$ 3.4 eV[8] while a value of $\gtrsim$2.3 eV is expected for EA (C_2N).[14] The data on EA (HCN), EA (CHCN) and EA (CH_2CN) will be reported in the next paper.

Ethyl Cyanide. The 80 eV electron impact gave the following spectra (Fig. 2a), being shown in the decreasing order of yield: *m/e* 26 (CN^-), 50 (C_3N^-), 25 (C_2H^-), 24 (C_2^-), 38 (C_2N^-), 39 ($CHCN^-$), 36 (C_3^-), 40 (CH_2CN^-), 51 (HC_3N^-), 27 (HCN^-), 12 (C^-), 13 (CH^-), 52 ($H_2C_3N^-$), 37 (C_3H^-), 14 (CH_2^-), 53 ($H_3C_3N^-$) and 54 ($H_4C_3N^-$). The comparison with $C_2H_4^+$ ions (*m/e* 28, the most intense peak among the positive ions) gave a value of $\sim 2.0\times10^4$ for $C_2H_4^+/CN^-$.

For 40 eV electron energies (Fig. 2b), almost the same pattern as 80 eV was observed except for a relatively small change in the yield of C_2H^-, C_2^-, and C_3N^- ions, and a value of $C_2H_4^+/CN^-$ was estimated to be $\sim 3.3\times10^4$.

For 9.5 eV electron energies (Fig. 2c), CN^- ions predominated over other negative ions, where

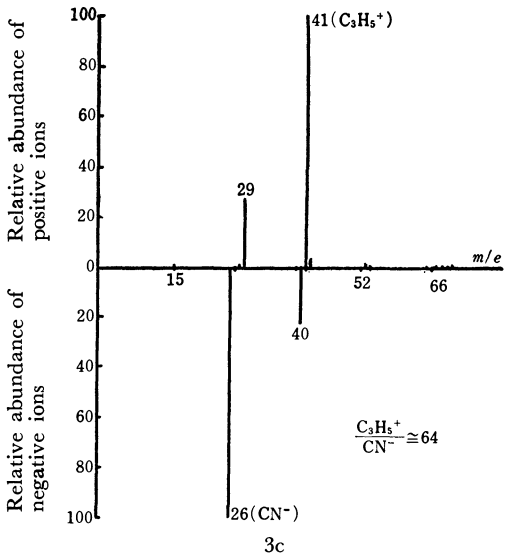
3b



3c

Fig. 3. Positive and negative ion mass spectra of n-C_3H_7CN.
a 80 eV, b 40 eV, c 15 eV for positive ions, 9.5 eV for negative ions

a value of $C_2H_4^+/CN^-\simeq 19$ was found. Table 2 shows the yield of minor negative ions for 80 eV, 40 eV and 9.5 eV.

It is of interest to note that a relatively strong peak of C_3N^- ions was observed. This can be understood on the basis of a relatively high value (55 kcal/mol) of EA(C_3N) obtained by Dibeler *et al.*[14] in a mass spectrometric study of cyanogen and cyanoacetylenes, in which the measurement of appearance potentials of positive ions was made mainly. On the other hand, C_2N^- ions decrease in a considerable amount when compared with those in methyl cyanide. Another difference

large peak of 40 (CH_2CN^-) ion in *n*-C_3H_7CN. The parent ion, *m/e* 69 ($C_3H_7CN^-$) was not observed for both compounds.

It is of great interest to note that a relatively strong peak of *m/e* 25 (C_2H^-) ion has been observed among the negative ions arising from the propyl group. This is consistent with the situation in propyl alcohol[7] and nitropropane.[8] Also, *m/e* 50 (C_3N^-) ion was observed to be comparatively strong as in the case of C_2H_5CN.

Especially, we should like to emphasize here

that a relatively strong peak of *m/e* 40 (CH_2CN^-) was found only in *n*-C_3H_7CN, the situation being very similar to that[8] of *m/e* 60 ($CH_3NO_2^-$) obtained from nitropropanes. The comparison of the yield of CN^- ion with that of $C_3H_5^+$ and $C_3H_6^+$ ions (*m/e* 41 and 42, the most intense peaks among the positive ions from *n*- and *iso*-propyl cyanides) gave the following values for $C_3H_5^+/CN^-$ and $C_3H_6^+/CN^-$; $\sim 3.1\times10^4$ and $\sim 2.2\times10^4$ at 80 eV respectively, $\sim 4.6\times10^4$ and $\sim 3.2\times10^4$ at 40 eV, respectively.

At 9.5 eV, *m/e* 26 (CN^-) ions predominated over other negative ions (Fig. 3c and Fig. 4c). Moreover, a relatively large yield of *m/e* 40 (CH_2CN^-) from *n*-C_3H_7CN is very characteristic, while in *iso*-C_3H_7CN it is found only as a relatively small peak. This finding would be useful for one of the identification methods of *n*-C_3H_7CN. The reason for a small cross section of CH_2CN^- ion formation from *iso*-C_3H_7CN would probably be that it is the rearrangement ion. The ratio of the yield of $C_3H_5^+$ and $C_3H_6^+$ to CN^- gave values of $\sim$64 and $\sim$25, respectively. Tables 3 and 4 show the yields of minor negative ions from *n*- and *iso*-propyl cyanides in relation to the electron energy.

Normalized to CN^- (yield=100)

Effect of Pressure. Figure 5 shows the relation between the yields of *m/e* 26 (CN^-), 38 (C_2N^-), 39 ($CHCN^-$), 40 (CH_2CN^-) and 50 (C_3N^-) ions and the pressure for each sample (5a for *m/e* 26 ion, 5b for *m/e* 38 ion, 5c for *m/e* 39 ion, 5d for *m/e* 40 ion and 5e for *m/e* 50 ion) under the electron energy of 80 eV. All the results show good linearities against the pressure under given experimental conditions. Also, this linear relationship was independent of the electron energy as shown in Fig. 6, where the *m/e* 26 (CN^-) ion from CH_3CN is shown as an example. A similar linear relationship had been reported for the *m/e* 1 (H^-) ion produced from hydrogen[15] under the electron energies of 6.8 eV, 10.0 eV and 14.2 eV in the range of pressure from 1×10^{-4} mmHg to 4×10^{-4} mmHg, for the *m/e* 39 (CH_3CC^-) ion[16] from methylacetylene in the range of pressure up to about 5×10^{-5} mmHg and for *m/e* 46 (NO_2^-), 16 (O^-), 26 (CN^-) and 42 (CNO^-) ions[8] from nitroalkanes in the range of pressure used for usual analysis. Of course,

the pressure dependency may become complicated at higher pressures because of the occurrence of ion-molecule reactions. In the present work, however, such a study was not made because of instrumental difficulty.

The Formation of Negative Ions. As mentioned above, the yield of negative ions is dependent on electron energies and cross sections of formation processes which are very different from those of positive ions, especially in their behaviors in the low energy region. Here, we should like to add a few words on the formation of parent negative ions and the excitation of negative ions.

It is generally accepted that a parent negative ion is formed by the capture of a free electron by a molecule, with the vibrational excitation of the molecular ion and its subsequent stabilization in a collision with another molecule ($e^- + AB \rightarrow [AB^-]^*$; $[AB^-]^* + X \rightarrow [AB^-] + X +$ kinetic energy.[17] However, we should not overlook that electron attachment may be significantly impeded when the formation of a stable negative ion requires a substantial deformation from the neutral geometry. For example, although N_2O containing 16 valence electrons is linear in the ground electronic state,[18] a compound with 17 electrons is bent in the ground

state, *e.g.*, NO_2 with $\alpha=134.1°$. The energy necessary to bend N_2O from 180° to 134° can be estimated to be about 1 eV, using a harmonic bending force constant. On the other hand, the appearance potential of the reaction; $e^-+N_2O\rightarrow O^-+N_2$, is said to be ~0.21 eV on the basis of $D(N_2-O)=1.677$ eV and $EA(O)=1.465$ eV. Thus, energetic electrons do not attach to N_2O but rather cause dissociative attachment. The failure to form N_2O^- by a simple transfer of an electron*2 could be understood on this basis. Very recently, Chantry[19] showed that the prominent peak of O^- ion via dissociative attachment in N_2O occurs at or very close to zero (0—0.05 eV) in the high temperature (1050°K). This leads us to conclude that the cross section increases very rapidly with increasing vibrational excitation of the initial molecule. It seems to be a feature of many dissociative attachment processes.

MacNeil *et al.*[20] also report that production of negative ions is clearly influenced by the size, symmetry and bonding of the molecule being bombarded with electrons; in general, large, symmetrical molecules containing multiple linkages tend to undergo less fragmentation and consequently to form larger negative ions, sometimes including the molecular ion.

Next, let us discuss on the excitation of the negative ion. It is known that it is unlikely that negative ions with stable discrete excited states exist with appreciable binding energy. For example, in the case of CN^- ions it seems reasonable to assume that the electron attaching to the CN radical will go into the $(x\sigma)$ orbital*3 of N_2^+ or CO^+ ions which is isoelectronic with the CN radical.[21] Then, it leads to a molecule which is isoelectronic with the N_2 and CO molecules. Examination of the energy level diagrams of these molecules shows that the first excited singlet levels are between 8 and 9 eV above the ground state. Thus, it would seem improbable that it could be produced in a low-lying electronically excited state. Of course, the production in the vibrational excited state would be possible.

*2 The possibility of formation of N_2O^- via ion-molecule reactions in N_2O cannot be excluded. (P. J. Chantry, *J. Chem. Phys.*, **51**, 3380 (1969)).

Structure of Polynucleotide Complex with Non-Complementary Nucleosides. I. Poly A,G+Poly U

Hideo AKUTSU and Masamichi TSUBOI

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 4, 1970)

Copolymers of riboadenylic and riboguanylic acids (poly A,G) with guanylic acid contents of 8.5—29.6% were prepared. The ultraviolet and infrared absorptions were examined of aqueous solutions of mixtures of poly A,G and polyribouridylic acid (poly U) of various mole ratios. It has been shown that in a solvent with 0.1 M Na^+ a triple-helical structure is formed with a A$\begin{matrix}\cdot\cdot U\\ \cdot\cdot U\end{matrix}$ type inter-base binding as well as a double-helical structure with a A···U type binding, while in a solvent with 0.01 M Na^+ only double-helical structure is formed. A guanine residue in the copolymer remains within the helix structure when its neighbors are mostly adenine residues, whereas it rotates out when there are many guanine residues in its vicity. On heating the solution, the structures just mentioned were found to be broken. The process of such a breaking down was followed also by means of the ultraviolet and infrared absorption measurements.

Polyriboadenylic acid (poly A) and polyribouridylic acid (poly U) are known to form a double- or triple-stranded helical structure in aqueous solution (see Figs. 1 (a) and 1(b)).[1,2] In such a structure, adenosine (A) and uridine (U) residues are considered to be strongly bound with each other through specific hydrogen bonds; A and U are considered to be complementary. In the present work, we have introduced the guanosine residue (G), which is not complementary to U, into the poly A chain, to examine its effect upon the structure. The question is whether the structure becomes like Fig. 1(c), 1(d), 1(e), or 1(f). In the structure Fig. 1(c) or 1(d), the G residues remain within the interior of the helix. They merely replace the A residues, and the outline of the structure here remains almost the same with that without the G residues (Fig. 1 (a) or 1 (b)). While, in the structure Fig. 1 (e) or 1 (f), the G residues rotate out of the helix in such a manner as to enable complementary A···U binding in the the subsequent regions of the polynucleotide chains.

As was shown previously,[3-8] the structures (c), (d), (e), and (f) in Fig. 1 can be distinguished by examining the mixing curve—*i.e.*, by examining the mole ratio poly A, G/poly U (on the basis of the phosphorus analysis), at which the maximum hypochromicity (minimum absorbance) appears for a proper ultraviolet radiation (at 259 mμ, for example). The mole ratio should be 50/50 for (c), 33.3/66.7 for (d), $100/x$ for (e), and $100/2x$ for (f), where x(%) is the mole % of A in the copolymer of A and G (poly A, G) now in question. On the other hand, the hydrogen-bonded A···U and A$\begin{matrix}\cdot\cdot U\\ \cdot\cdot U\end{matrix}$ structures are known to give characteristic infrared absorptions in D_2O solution which are distinguished from each other and from A and U residues free from hydrogen-bonds.[9] We attempted the ultraviolet and infrared absorption measurements of our poly A, G+poly U in aqueous solutions, keeping these previous demonstrations in mind.

Preparation of the Polynucleotide Samples

The polynucleotide samples used were prepared by the use of polynucleotide phosphorylase obtained from *Micrococcus lysodeikticus* or from *Azotobacter vinelandii*. The compositions of the reaction mixtures and the incubation times are given

Table 1. An example of reaction mixture in enzymatic preparation of polynucleotide

Buffer solution[a)]	1.0 m*l*
Enzyme solution	1.5[b)]
Adenosine-5′-diphosphate (21 mg/m*l*)	1.1
Adenosine-5′-triphosphate (25 mg/m*l*)	0.5
Guanosine-5′-diphosphate (11 mg/m*l*)	0.9
$(NH_4)_2SO_4$ solution (saturated)	1.25
Total	6.25 m*l*

a) This buffer solution was prepared by mixing 1.25 m*l* of 2 M Tris, 3 g of urea, and 2 m*l* of 2 M $MgSO_4$, by adding 12 M HCl to reach pH 9, and then by adding 0.5 M mercaptoethanol so that the total volume become 25 m*l*.

b) Usually this amount contains 10—20 units of enzyme. 1 units=amount of enzyme which can liberate 1 μmol of orthophosphate in the enzymatic reaction of 15 min. The most efficient amount of enzyme was determined by several trial experiments with smaller scale (1/200 of that described here).

in Tables 1 and 2. The incubation temperature was 37°C for the enzyme from *M. lysodeikticus* and 30°C for that from *A. vinelandii*. After the enzymatic reaction, the product was precipitated with perchloric acid or with ethanol and then purified by the method of phenol extraction and by dialysis.

Base Composition and Some Other Characterization of the Copolymers

The base composition of each poly A,G sample was determined by hydrolyzing it with 1 N HCl, by the paper-chromatographic separation of the resulting adenine and guanine, and by ultraviolet absorption measurements of them. The composition thus determined is given in Table 2. The base sequences in these copolymers are not known, but it is probable that they are nearly random. Saigo, Uchida and Egami (private communication) made an analysis of the products obtained by a digest of a poly A,G in which G content is 30% with ribonuclease T_1. In a DEAE-Sephadex column chromatography with 7M urea they found more than ten peaks, each of which corresponds to $(A_p)_nG_p$ where $n=0,1,2,\cdots$. The relative amounts of these oligonucleotides were not found to be greatly different from what are expected for the random sequence.

The degrees of polymerization of the polymers prepared were not determined, but they are considered to be sufficiently high on the basis of the

sedimentation constants given in the last column of Table 2. These were measured in distilled water with no salt except for poly A,G(4) and poly A,G(5). The sedimentation constants of the latter two were examined in 0.1 M NaCl+0.01 M Na-cacodylate buffer (pH 6.5).

Experimental

Ultraviolet absorption measurements were made with an Ito spectrophotometer Model QU-3. The temperature of the samples was controlled as previously described.[10] The polynucleotide concentration was determined by measuring phosphorus content.[11]

Infrared absorption measurements were made of D_2O solutions by the use of a Perkin-Elmer 621 spectrometer. Each D_2O solution was placed in a cell with CaF_2 windows and of 50 μ in optical path length. The temperature of the solution was controlled by an electric heating device constructed by ourselves, and the temperature was measured by the use of a thermocouple.

UV Mixing Curves: Effect of Salt

Solutions of poly A,G and poly U of various mole ratios were made, and their ultraviolet absorbance at 259 mμ recorded. The results are shown in Figs. 2—6. From such an absorbance versus mole-ratio profile, we may judge whether the two polymers in question have no interaction or whether they form a complex. When a complex is formed, its stoichiometric ratio may also be determined from the observed profile of the mixing curve.

As may be seen in Figs. 2—6, every poly A,G shows evidence of interaction with poly U. Each of the mixing curves consists of two straight lines which intersect at a proper mole ratio. As has been stated in the introduction of this paper, the intersection should take place at poly A,G/poly U = 50/50, 33.3/66.7, 100/x, or 100/2x if the structure of the cmplex is respectively like (c), (d), (e), or (f) of Fig. 1. Actually, however, the intersection does not always take place exactly at one of these four expected mole ratios (see Figs. 2—6).

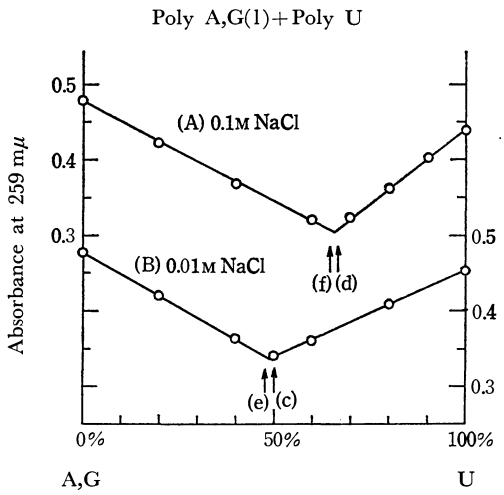

Fig. 2. Mixing curves for poly A,G(1) and poly U.

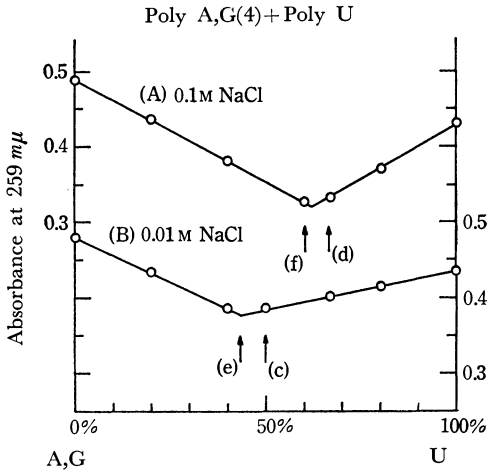

Fig. 5. Mixing curves for poly A,G(4) and poly U.
Abscissa: mol% of poly U, ordinate: absorbance at 259 mμ. Total nucleotide concentration in the solution was kept at 0.48×10^{-4} M. (A) In 0.1 M NaCl plus 0.01 M Tris buffer, pH 8.0; at 12.9°C. (B) In 0.01 M NaCl plus 0.001 M Na-cacodylate buffer, pH 7.0; at 12.6°C.

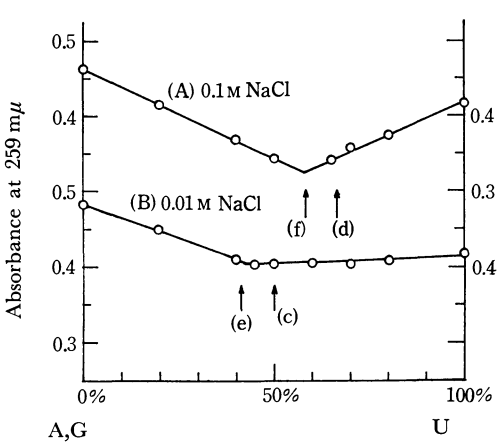

Fig. 6. Mixing curves for poly A,G(5) and poly U.
Abscissa: mol% of poly U, ordinate: absorbance at 259 mμ. Total nucleotide concentration in the solution was kept at 0.48×10^{-4} M. (A) In 0.1 M NaCl plus 0.01 M Na-cacodylate buffer, pH 7.0; at 13.0°C. (B) In 0.01 M NaCl plus 0.001 M Na-cacodylate buffer, pH 7.0; at 16.7°C.

This is in contrast to the case of poly A, U + poly U, where the stoichiometric ratio of the complex was found to be always $100/x$ or $100/2x$[3] (x= mole % of A in the copolymer of A and U).

The intersection appears always in the vicinity of poly A, G/poly U = 33.3/66.7 for solutions with 0.1 *M* NaCl, and in the vicinity of 50/50 for solutions with 0.01 *M* NaCl (with one exception). When the guanine content in poly A, G is smaller, the intersection appears at a point between those expected for (d) and (f) or between those expected for (c) and (e) (see Figs. 2, 3, and 4). When the guanine content in poly A, G is higher, on the other hand, the intersection appears at a point which is very near to that expected for (f) or (e) (see Figs. 5 and 6). These facts indicate that in a solvent with 0.1 *M* Na^+ a triple-helical structure is formed

Table 3. Observed and calculated minima in the mixing curve of poly A,G and poly U

Copolymer	Total G %	G in A_pG_pA %	Minimum point in the mixing curve with poly U	
			Expected (% of U)	Observed (% of U)
Poly A,G(1)	8.5	7.4	66.4	66.0
Poly A,G(2)	14.5	10.8	65.7	65.0
Poly A,G(3)	20.0	12.8	65.0	64.5
Poly A,G(4)	24.0	13.9	64.2	62.5
Poly A,G(5)	29.6	14.7	62.9	58.0

with a A⋮U type inter-base hydrogen bonding, while in a solvent with 0.01 *M* Na^+ a double-helical structure is formed with a A···U type hydrogen-bonding. These facts also show that some of the guanine residues in the copolymer remain within the helix structure and some rotate out of the helix; in other words, some parts of the structure are like Fig. 1 (c) or (d) and some parts like (e) or (f). When the guanine content in the copolymer becomes greater the parts like (e) or (f) predominate. This may be taken as indicating that an isolated guanine residue is incorporated into the helix whereas a guanine cluster is looped out of the helix.

By assuming the random sequence, the amount of the isolated guanylic acid residue (that is the guanylic acid whose two neighbors are both adenylic acids, like $A_pG_pA_p$) was calculated from the total amount of the guanylic acid residue in each copolymer (Table 3). By assuming further that only such an isolated guanine residue is incorporated into the helix and that other guanine residues rotate out of the helix, the stoichiometric ratios poly A,G/poly U were calculated for poly A,G-poly U complexes. The results are given in Table 3. As may be seen here, the calculated ratio is always slightly higher than the observed ratio, and the discrepancy becomes greater as the guanylic acid content in the copolymer becomes higher. Thus, it is probable that a guanine residue is incorporated into the helix only when there are some adenine residues in its vicinity, and that the number of such adenine residues requires in its vicinity is *greater* than two.

Copolymer A,G(2) is found to be somewhat anomalous. Even in a solvent with 0.01 *M* Na^+ the minimum of the mixing curve (with poly U) does not appear in the vicinity of the mole ratio 50/50. Instead, the minimum is found with a good reproducibility at poly A, G/poly U = 45/55 (see Fig. 3). No explanation is yet given for this fact, but it may be pointed out here that, when a homopolymer poly A (instead of poly A,G) was mixed with poly U, the minimum of the mixing curve was always observed at poly A/poly U = 33.3/66.7, and never at 50/50.[12] Therefore, it is probable that copolymer A, G (2) happens to have a long···$A_pA_pA_p$···cluster in it, which behaves like a homopolymer poly A.

UV Mixing Curves: Effect of Temperature

The profile of the mixing curve just mentioned changes not only with the ionic strength but also with the temperature of the solution. As has been already described, the minimum in the mixing curve appears in the vicinity of poly A,G/poly U = 1/2 at a lower temperature in a higher ionic strength. As may be seen in Figs. 7 and 8, the minimum is shifted into the vicinity of poly A,G/poly U = 1/1 at an elevated temperature. This fact indicates that a triple-helical complex poly A,G–poly U–poly U first decomposes into double-

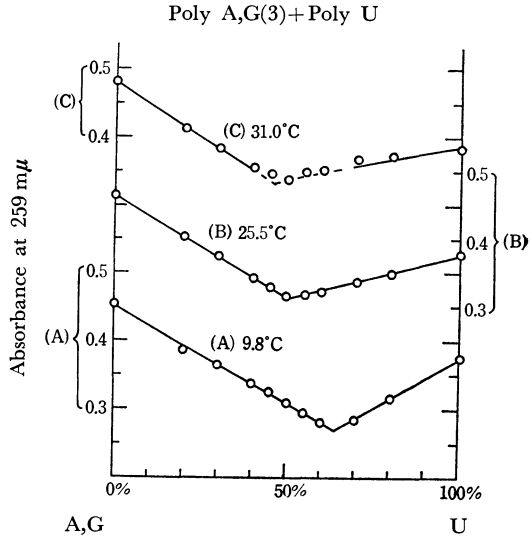

Fig. 7. Mixing curves for poly A,G(3) and poly U.

12) S. Higuchi and M. Tsuboi, This Bulletin, **39**, 1886 (1966).

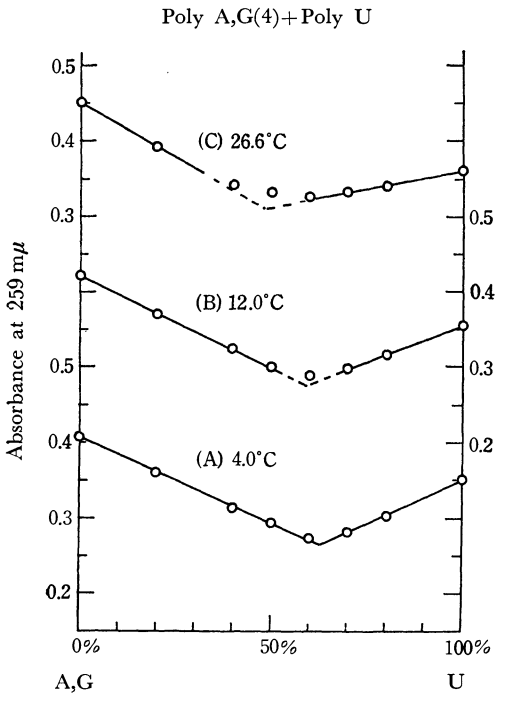

Fig. 8. Mixing curves for poly A,G(4) and poly U.
Abscissa: mol% of poly U, ordinate: absorbance at 259 mμ. Total nucleotide concentration in the solution was kept at 0.48×10^{-4} M. Solvent: 0.05 M NaCl plus 0.005 M Na-cacodylate buffer, pH 7.0. (A) At 4.0°C. (B) At 12.0°C. (C) At 26.6°C.

helical complex poly A,G–poly U and single-stranded poly U, before it completely melts into single-stranded random coils. Thus, the melting process is given as

$$\text{poly A,G·poly U·poly U} \longrightarrow \text{poly A,G·poly U + poly U} \longrightarrow \text{poly A,G + poly U + poly U} \quad (1)$$

This is similar to the melting process known of the the triple-helical complex without G, *i.e.*, poly A–poly U–poly U.[12–14]

As is illustrated in Fig. 8, the minimum in a mixing curve observed at a higher temperature is often less sharp than that a at lower temperature. In the curve obtained at 12.0°C or at 26.6°C given in Fig. 8, the angle is rounded off at the minimum. For this, the last course of the melting process (1) is considered to be responsible. Thus, if a certain fraction of helices melts into random coils, a hyperchromicity takes place whose amount should be proportional to the amount of helices. The amount of hyperchromicity should be greatest at the minimum where the amount of helices is greatest. At an extremely high temperature, at which all the helices melt into random coils, the mixing curve should be a single straight line and have no minimum.

UV Heating Curves

Absorbance-temperature profiles of each of the 1 : 2 (molar) mixtures of poly A,G and poly U are shown in Figs. 9 and 10.

The triple-helical complex poly A,G(1)–poly U–poly U shows a two-step melting (at 43 and 51°C) in a solvent with 0.1 *M* Na^+ (Fig. 9(A)), whereas it shows a single-step sharp melting (at 34.5°C) in 0.01 *M* Na^+ (Fig. 10 (A)). Similar melting profiles were observed of the triple-helical complex without G, *i.e.* poly A–poly U–poly U.[12–14] For the latter, however, every melting temperature is found slightly higher than the corresponding melting temperature observed here for the complex with poly A,G(1). For the system of 1 : 2 (molar) mixture of poly A and poly U, a phase diagram shown in Fig. 11 was constructed.[12–14] For the system of 1 : 2 (molar) mixture of poly A,G(1) and poly U, now in question, a similar phase diagram would be valid. On the basis of the melting profiles just described (Figs. 9 (A) and 10 (A)), such a phase diagram is drawn with the broken lines in Fig. 11. The difference of the two phase diagrams (full and broken lines in Fig. 11) is considered to be caused by the 8.5% guanine residues in poly A,G(1).

As is shown in Figs. 9 and 10, the melting temperature becomes lower as the guanine content in

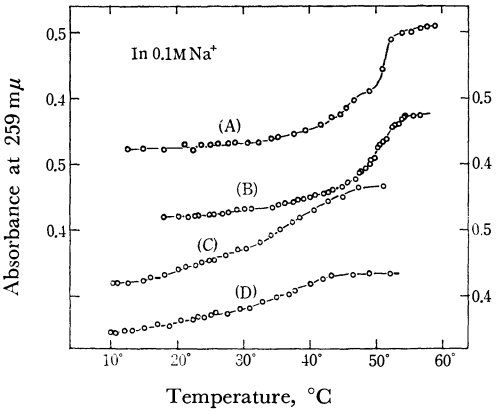

Fig. 9. Variation of the absorbance at 259 mμ with temperature of mixture solutions of poly A,G and poly U.
Mole ratio, poly A,G/poly U, was always 1/2. Solvent: 0.1 M NaCl plus buffer. (A) Poly A,G(1)+poly U. (B) Poly A,G(2)+poly U. (c) Poly A,G(4)+poly U. (D) Poly A,G(5)+poly U.

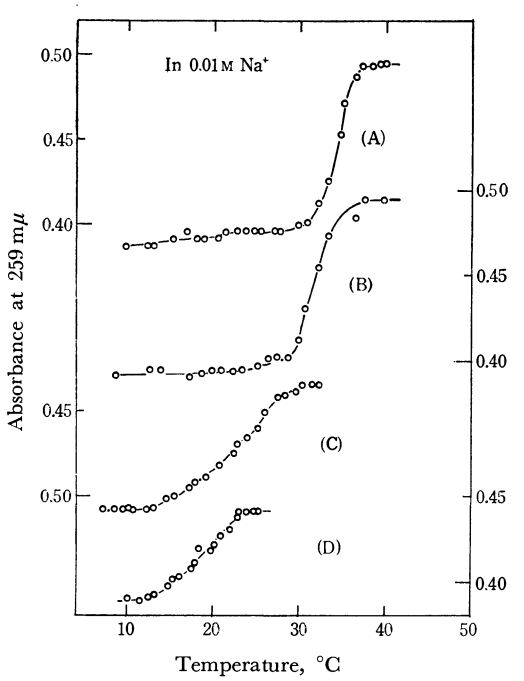

Fig. 10. Variation of the absorbance at 259 mμ with temperature of mixture solutions of poly A,G and poly U.
Mole ratio, poly A,G/poly U, was always 1/2. Solvent: 0.01 M NaCl plus buffer. (A) Poly A,G(1)+poly U. (B) Poly A,G(2)+poly U. (C) Poly A,G(4)+poly U. (D) Poly A,G(5)+poly U.

the copolymer poly A,G becomes higher. At the same time, the melting region becomes broader and total amount of hyperchromicity in the melting becomes smaller. These facts show that the secondary structure of a complex with poly A, G with a higher G content is less definite.

Infrared Spectra

Poly A,G(1) in heavy water solution (with 0.2 M Na^+) gives a strong absorption band at 1624 cm^{-1} at pD=7.0 and at 36°C (Fig. 12). This band is assignable to a double-bonds stretching vibration in the deuterated adenine ring.[15] On heating the solution this band is shifted slightly towards lower frequency (1620 cm^{-1} at 75°C).

Figure 13 shows the infrared spectrum of a 1 : 1 (molar) mixture of poly A,G(1) and poly U. At 38°C, it shows strong absorption peaks at 1689, 1671, and 1630 cm^{-1}. These are assigned respectively to $C_2=O$ stretching vibration of uracil, $C_4=O$ stretching vibration of uracil, and double-bonds stretching vibration of adenine residues involved in the Watson-Crick type A···U base pair.[15,16] This is definitely different from the infrared spectrum expected from A⋱U type interbase bonding plus free adenine residue.[15-17]

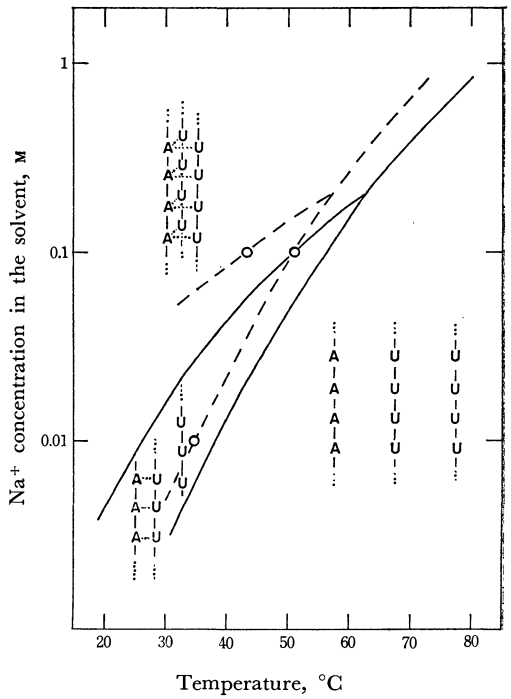

Fig. 11. Equilibrium diagram for 1:2 (molar) mixtures of poly A and poly U (full lines).
Broken lines show the effect of introduction of the guanine resideue into poly A. The small circles indicate melting temperatures observed for 1:2 complex of poly A,G(1) and poly U.

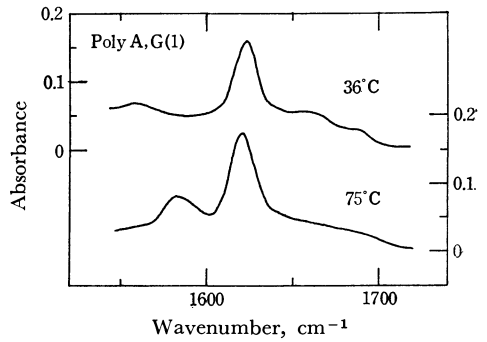

Fig. 12. Infrared absorption spectrum of poly A,G(1) in D_2O + 0.2 M NaCl + 0.01 M Nacacodylate buffer, pD 7.0.
Approximate concentration of poly A,G(1) is 0.02 M.

17) S. Higuchi, Doctor Thesis, Tokyo University, 1968.

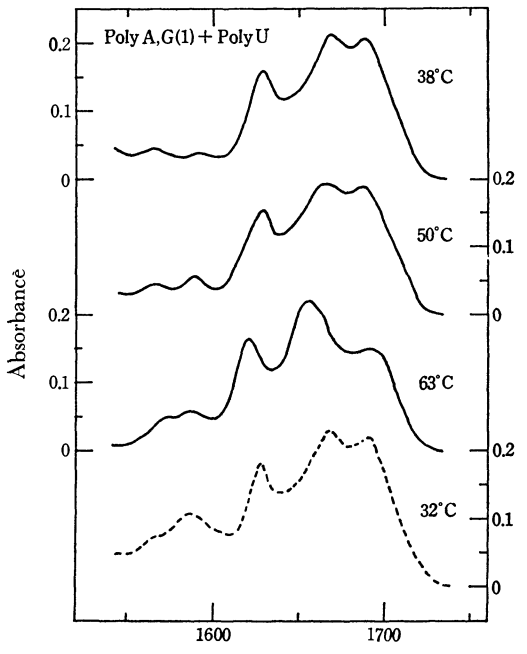

Fig. 13. Infrared absorption spectrum of 1:1 (molar) mixture of poly A,G(1) and poly U.
Solvent: D_2O + 0.2 M NaCl + 0.01 M Na-cacodylate buffer, pD 7.0. Total concentration of nucleotides: about 0.04 M. The lowest curve was obtained when the solution heated up to 63°C was cooled again to 32°C.

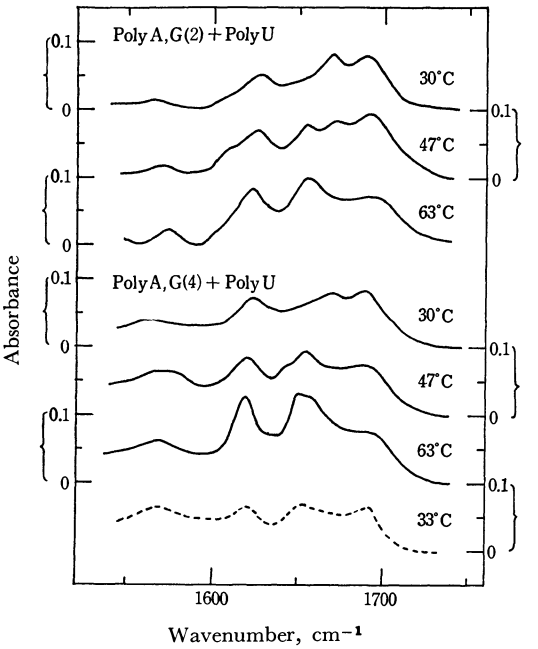

Fig. 14. Infrared absorption spectra of 1:1 (molar) mixtures of poly A,G(2)+poly U and of poly A,G(4)+poly U.
Solvent: D_2O + 0.2 M NaCl + 0.01 M Na-cacodylate buffer, pD 7.0. Total concentration of nucleotide: about 0.02 M. The lowest curve was obtained when the poly A,G(4)+poly U solution heated up to 63°C was cooled again to 33°C.

Therefore, it is evident that 1 : 1 (molar) mixture of poly A,G(1) and poly U forms a double-helical complex, poly A,G(1)–poly U, in 0.2 M Na^+ at 38°C. The ultraviolet (259 mμ) mixing curve shown in Fig. 2 (A) does not show any bend in the vicinity of the mole ratio 1/1, and therefore this might be taken as indicating that a 1 : 1 (molar) mixture of poly A,G(1) and poly U consists of a triple-helical poly A,G(1)–poly U–poly U and single-stranded poly A,G(1) in the solvent with 0.1 M or more Na^+. By means of the infrared absorption measurement, however, this is not found to be actually the case. We consider that here is a double-helical complex, poly A,G(1)–poly U, and that this is not distinguishable from the triple-helix plus single poly A,G(1) by the ultraviolet absorbance at 259 mμ. Similar situation was already found for 1 : 1 (molar) mixture of poly A and poly U in high-salt solution.[12,14,16]

Infrared spectra of 1 : 1 (molar) mixtures of poly A,G(2) & poly U and of poly A,G(4) & poly U are given in Fig. 14. Both of these show the characteristic bands (1690, 1670, and 1630 cm^{-1}) of Watson-Crick type A···U structure in 0.2 M Na^+ and at 30°C.

The melting process of these double-helical complex, poly A,G–poly U, was examined by means of the infrared absorption measurement, and the results are shown also in Figs. 13 and 14. At this salt concentration (0.2 M Na^+), the double-helical structure seems to decompose directly into single-stranded poly A,G and poly U. These give strong bands at 1692 cm^{-1} (C_2=0 stretching of uracil), 1657 cm^{-1} (C_4=0 stretching of uracil), and 1621 cm^{-1} (double-bonds stretching of adenine). On lowering the temperature of the solution again to 32 or 33°C, the A···U base-pair is reformed for poly A,G(1) + poly U (see the lowest curve in Fig. 13), but not for poly A, G (4) + poly U (lowest curve in Fig. 14).

The guanine residues involved in the copolymer should give absorptions in the 1600—1550 cm^{-1} region. There is certainly an absorption band observed in this spectral region in every spectrum of poly A, G (Fig. 12) and of poly A, G + poly U (Figs. 13 and 14). It appears at 1565 cm^{-1} for lower temperatures, and on elevating the temperature it is shifted to higher frequency (at about 1590 cm^{-1}). On lowering the temperature, however, the band does not come back to 1565 cm^{-1} even when the absorption bands (at 1689, 1671, and 1630 cm^{-1}) due to the A···U base-pair are restored (see the lowest curve in Fig. 13). This fact shows that the environment of the G residues

changes on breaking down the double-helical structure of the complex molecule and that this change is not easily reversed even when the A···U base-pairs are reformed. No interpretation however is yet given of the spectral change (1565→1590 cm^{-1}).

Discussion

Present ultraviolet and infrared spectroscopic data are well explained by postulating the following items:

(1) In the solvent with 0.1 M or more Na^+, both of the double-helical complex, poly A,G–poly U, with the Watson-Crick type A···U base-pair and the triple-helical complex, poly A,G–poly U–poly U, with the A⋮U⋱U type inter-base binding are to be formed at 10°C. What are formed depend upon the mol % of poly U in the solution:

0 to 50%	single poly A,G and double helix
50%	double-helix
50 to 66%	double-helix and triple-helix
66%	triple-helix
66 to 100%	triple-helix and single poly U.

(2) On heating such a solution, the triple-helical complex first decomposes into double-helix and single poly U, and then at a higher temperature melts into three single-stranded random coils.

(3) In the solvent with Na^+ concentration as low as 0.01 M, only double-helical complex is formed at 10°C.

(4) A guanine residue in the copolymer poly A,G remains within the helical structure when its neighbors are mostly adenine residues. Otherwise, it rotates out from the helix so that the complementary A···U binding can be formed in the subsequent region of the polynucleotide chains.

What is described in item (4) here may be related with the "wobble hypothesis" of Crick.[18] It has now been established that three base-pairs are formed between the "codon" of a messenger RNA and the "anticodon" of a transfer RNA in a certain step of translation of a genetic code in a biological system. Crick[18] suggested that while the standard base-pairs (A···U and G···C) are used rather strictly in the first two positions of the three codon-anticodon pairings, there may be some wobble in the pairing of the third base. He pointed out several possible base-pairs for the third position, and among them the G···U pair is included. It may also be pointed out here that guanine and uracil residues are often located in a primary structure of a transfer RNA molecule at a position in which we usually postulate a strong A···U or G···C base pair in other transfer RNA molecules.[19] Our present experiment indicated that such a "G···U base-pair" certainly takes place if there are a number of standard base-pairs formed in its neighborhood. Our experiment also indicated, however, that such "G···U base-pairs" are not stable enough to support a helical structure by themselves.

We wish to express our thanks to Professor Makoto Ishimoto and Mr. Kaoru Saigo for their instruction in our preparation of polynucleotides by the use of the enzyme from *Micrococcus lysodeikticus*, to Professor Sanae Mii for her providing wet cells of *Azotobacter vinelandii*, and to Dr. Kimiko Matsuo for her valuable advices. The Effect of Chloromethanes on Hydrogen Formation in the Radiolysis of Methylcyclohexane and 3-Methylpentane at −196°C

Toyoaki KIMURA, Mitsuharu FUKAYA, Minoru HADA, Terunobu WAKAYAMA, Kenji FUEKI and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusaku, Nagoya

(Received June 4, 1970)

The effect of chloromethanes (CH_2Cl_2, $CHCl_3$ and CCl_4) on hydrogen formation from γ-irradiated methylcyclohexane (MCH) and 3-methylpentane (3MP) at −196°C was investigated. It was found that the decrease in hydrogen yield by the presence of CH_2Cl_2 was almost the same as that caused by an electron scavenger such as N_2O, *n*-butyl chloride, SF_6 or iodobenzene, but the hydrogen yield was much lower in the presence of $CHCl_3$ or CCl_4 than other electron scavengers. Although the yield of $CCl_3\cdot$ radicals formed from dissociative electron attachment to CCl_4 in CCl_4-MCH systems was ~1.4 *G*, the decrease in hydrogen yield was ~3 *G*. A similar result was obtained for $CHCl_3$-MCH systems. Thus we have ascribed the effect of CH_2Cl_2 on hydrogen formation to electron scavenging and that of $CHCl_3$ or CCl_4 to excitation transfer as well as electron scavenging. ESR studies on radical formation from these systems also support the above interpretation.

It is not easy to determine the role of excited molecules in radiolysis. Energy transfer from cyclohexane to benzene, originally proposed by Manion and Burton,[1] does not seem to be excitation transfer, but positive charge transfer in the light of recent studies.[2-7] Though excitation transfer was proposed for quenching of fluorescence from a γ-irradiated cyclohexane system,[8] some ionic process was recently suggested for this phenomenon.[4-7] A study which clearly demonstrated excitation transfer was that by Collinson *et al.*,[9] who found a sudden increase in the reduction yield of $FeCl_3$ in benzene when the temperature of the system was lowered below the melting point and ascribed it to excitation transfer.

We have shown in a previous work[10] that carbon tetrachloride lowers the yields of hydrogen and of solvent radicals from γ-irradiated methylcyclohexane (MCH) at −196°C much more than electron scavengers, such as SF_6 or N_2O, and ascribed the effect of carbon tetrachloride to excitation transfer as well as electron scavenging. We have extended the previous study of CCl_4 in MCH to other chloromethanes ($CHCl_3$ and CH_2Cl_2) in order to investigate their effects on the hydrogen yield from MCH γ-irradiated at −196°C. We also examine the effect of these chloromethanes on the radiolysis of 3-methylpentane (3MP) systems. In order to examine the possibility of excitation transfer from 3MP to chloromethanes, it was necessary to investigate the effect of electron scavengers on hydrogen yields from 3MP. Though 3MP has been widely used as a matrix for measurements of reaction intermediates, only a few studies on hydrogen formation have been reported.[11,12] Thus we attempted to investigate the effect of N_2O as an electron scavenger on the hydrogen formation from γ-irradiated 3MP.

Experimental

Materials. MCH was Tokyo Kagaku Seiki 99.9% and used as received. Aldrich 3MP was shaken with concentrated sulfuric acid in a separating flask, washed with distilled water, and then dried over sodium sulfate. After passing through a silica gel column, 3MP was fractionally distilled before use. Carbon tetrachloride, chloroform and methylene dichloride were

Nakarai Kagaku specially prepared reagent and used as received. N_2O was Takachiho Shoji Co. 99.9% and used as received.

Sample preparation. Amounts of liquid materials were measured volumetrically. Usually 1 m*l* of MCH or 3MP was used for a sample. Solutions in irradiation cells equipped with a break-seal (usually 2 m*l*) were degassed by the freeze-pump-thaw technique and then sealed off. N_2O was introduced into a bulb of known volume to the desired pressure and then condensed into the irradiation cell.

Irradiation. A 3000 Ci ^{60}Co source was used for γ-irradiation. Irradiation doses were 2.51×10^{20} eV/g at 20°C, 1.97×10^{20} eV/g at −72°C and 2.23×10^{20} eV/g at −196°C.

Analysis. Gaseous products noncondensable at liquid nitrogen temperature were collected by a Toepler pump and their quantities were determined by the PVT method. To convert hydrogen into water, the gas was circulated about 20 times through a cupric oxide furnace, heated at 220—260°C, and a liquid nitrogen trap, and then the residual gas was recollected and its quantity was measured. Yields of solvent and solute radicals were determined by ESR technique in the same manner as reported[10] previously.

Results and Discussion

Figures 1, 2 and 3 show the effect of N_2O on hydrogen formation from γ-irradiated 3MP at 20°C, −72°C and −196°C, respectively. The decrement of hydrogen yield with increasing N_2O concentration at −196°C is lower than at 20°C and −72°C, while the nitrogen yield at 20°C is somewhat lower than those at −72°C and −196°C. It has been proposed that the nitrogen yield is twice the yield of scavenged electrons in the radiolysis of cyclohexane at room temperature.[13] It can be seen from Fig. 1 that the ratio of the nitrogen yield to the decrease in hydrogen yield is about 3 in N_2O-3MP systems at 20°C. The difference in the ratio, $G(N_2)/\Delta G(H_2)$, between cyclohexane and 3MP may be explained in terms of the difference in the decomposition pattern between branched and non-branched hydrocarbons[12]; a part of energy which is consumed in C–H bond cleavage in the case of non-branching hydrocarbons is spent for C–C bond cleavage in the case of branching hydrocarbons. Recently Asmus *et al.* have suggested that the efficiency of hydrogen formation from ion recombination is 0.6 in the case of 3MP.[14] With this value, the yield of electrons scavenged by N_2O at 20°C is given by $(1/0.6)\Delta G(H_2)$. Thus the ratio of the nitrogen yield to the yield of scavenged electrons is $G(N_2)/\{(1/0.6)\Delta G(H_2)\}=\sim2$. Such

argument may be applied to the case of N_2O-3MP systems at $-72°C$, although the nitrogen yield at $-72°C$ is slightly higher than that at 20°C. The nitrogen yield at $-196°C$ is almost the same as that at 20°C and $-72°C$, but we do not think that the yields of scavenged electrons in these three cases are the same. We have shown that the ratio of the nitrogen yield to the decrease in hydrogen yield in N_2O-MCH systems γ-irradiated at $-196°C$ depends upon the N_2O concentration and it increases from 1 to 4 with increasing N_2O concentration, and that the neutralization of an MCH positive ion with an electron leads to the formation of one hydrogen molecule.[15] Our result in which the efficiency of hydrogen formation from ion recombination is $\sim$1 is in rough agreement with that by Asmus *et al.*[14] Thus we have estimated the ratio of the nitrogen yield to the yield of electrons scavenged by N_2O in N_2O-MCH systems at $-196°C$ $\sim$4 at higher N_2O concentrations. Using the result by Asmus *et al.*,[14] the ratio of the nitrogen yield to the yield of scavenged electrons, $G(N_2)/G(e^-)$, in 3MP at $-196°C$ is $G(N_2)/\{(1/0.6)\cdot \Delta G(H_2)\}=\sim 4$. The process of nitrogen formation other than Eq. (1) is not clear, but the relation $G(N_2)/G(e^-)=\sim 4$ holds for 3MP as well as MCH at $-196°C$.

$$N_2O + e^- \longrightarrow N_2O^- \longrightarrow N_2 + O^- \qquad (1)$$

The mechanism of nitrogen formation other than Eq. (1) may be short chain reactions,[16] excitation transfer[17] or negative charge transfer from O^- to N_2O.[15] Considering the relation $G(N_2)/G(e^-)=\sim 4$ in 3MP and MCH, it seems that nitrogen is formed via negative ion processes such as Eq. (1). Assuming that $G(N_2)/G(e^-)$ is 4 in 3MP at $-196°C$, $G(e^-)$ is estimated to be 1.57 at the highest N_2O concentration studied, which is considerably lower than that at 20°C. Such a low yield of scavenged electrons in 3MP at $-196°C$ has been reported by us.[18] Therefore we can say that the hydrogen yield and the yield of scavenged electrons at $-196°C$ are lower than those at 20°C in the case of 3MP as well as MCH.

Hydrogen yields from γ-irradiated MCH and 3MP at $-196°C$ in the presence of CH_2Cl_2, $CHCl_3$ or CCl_4 are shown in Figs. 4 and 5, respectively. The yield of hydrogen was calculated using the following equation:*1

$$G(H_2) = \frac{P - G'(H_2)\cdot D'\cdot W_s}{D\cdot W} \qquad (I)$$

where P is the number of hydrogen molecules produced, $G'(H_2)$ is the yield of hydrogen from pure solute, D and D' are the doses absorbed by solvent of unit weight and that by solute of unit weight, respectively, and W and W_s are the weights of solvent and solute, respectively. The values of $G'(H_2)$ were 0.186 for CH_2Cl_2 and 0.109 for $CHCl_3$. Although the solubility of CH_2Cl_2 at $-196°C$ is poor compared with that of $CHCl_3$ or CCl_4, solutions of CH_2Cl_2 in MCH form a transparent glass in the concentration range below 3 mol%. The dashed lines in Figs. 4 and 5 indicate that the solutes are not adequately soluble. The decrement of the hydrogen yield from CH_2Cl_2-MCH systems in Fig. 4 agrees well with that from N_2O-MCH

*1 The G value usually employed in a binary system (A-B), *viz.*, the number of product molecules per 100 eV of the energy absorbed by both A and B, is useful only for knowing whether there is an interaction between A and B. The merit of Eq. (I) is that we can see the extent of the interaction; if there is no interaction, G value from Eq. (I) is constant but if there is an interaction it varies corresponding to the extent of the interaction.

systems.[15] Thus the effect of CH_2Cl_2 on the hydrogen formation can be regarded as the same as that of an electron scavenger such as N_2O or SF_6. However, both $CHCl_3$ and CCl_4 suppress the hydrogen formation much more than CH_2Cl_2. The effects of these chloromethanes in 3MP (Fig. 5) are similar to that for MCH.

We now examine the reason for the abnormal suppression of hydrogen formation by $CHCl_3$ or CCl_4. We previously suggested the possibility of excitation transfer.[10] It was shown that H atoms abstract chlorine atoms from $CHCl_3$ or CCl_4 in cyclohexane at room temperature.[19,20] Further, Teplý and Janovský reported the suppression of hydrogen formation by CCl_4 in γ-irradiated glassy methanol at -196°C and ascribed it to Cl atom abstraction from CCl_4 by H atoms in addition to the suppression of charge neutralization.[21] However, Stone denied Cl atom abstraction by H atoms at -196°C.[22] We have shown that the hydrogen yields from thermal H atoms at -196°C are 0.5 G in MCH and 0.65 G in 3MP.[12] Thus, the decrements of hydrogen yield from MCH and 3MP at -196°C in Figs. 4 and 5 cannot be explained only by Cl atom abstraction by thermal H atoms.

The abnormal suppression of hydrogen yield by $CHCl_3$ or CCl_4 is explicable if the yield of electrons scavenged by $CHCl_3$ or CCl_4 is higher than that by other electron scavengers. If this is true, the yield of scavenged electrons in MCH should be $\sim$3 G at the highest CCl_4 concentration studied because the decrement of the hydrogen yield is $\sim$3 G. Thus, the yield of $CCl_3\cdot$ radicals in MCH produced by Reaction (2) is expected to be $\sim$3 G. For the sake of confirmation, we attempted to determine the yields of $CCl_3\cdot$ radicals in MCH by ESR and the results are shown in Fig. 6. The yield of $CCl_3\cdot$ radicals in MCH increases with increasing CCl_4 concentration and reaches a constant value at CCl_4 concentrations above 2 mol %. The experimental curve for the yield of $CHCl_2\cdot$ radicals produced by Reaction (3) was very similar to that for $CCl_3\cdot$ radicals although the former was somewhat lower in the lower solute concentration range.

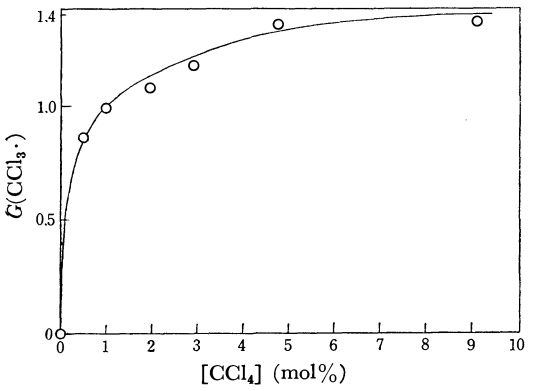

Fig. 6. Yields of $CCl_3\cdot$ radicals from γ-irradiated CCl_4-MCH systems at -196°C.

$$CCl_4 + e^- \longrightarrow CCl_3\cdot + Cl^- \quad (2)$$

$$CHCl_3 + e^- \longrightarrow CHCl_2\cdot + Cl^- \quad (3)$$

The limiting value of $CCl_3\cdot$ radicals in Fig. 6 is 1.4 G which agrees well with the yield of scavenged electrons in MCH glass obtained by the different procedures.[18,23] Thus the yield of $CCl_3\cdot$ radicals produced from Cl atom abstraction by H atoms seems to be very low, if produced at all. We are inclined to ascribe the abnormal suppression of hydrogen yield by $CHCl_3$ or CCl_4 to the excitation transfer from excited solvent molecules to solutes.

Another support for the excitation transfer mechanism was obtained from ESR experiments. We determined the yields of MCH· radicals in γ-irradiated MCH glasses containing CH_2Cl_2, $CHCl_3$ or CCl_4. The results are shown in Fig. 6.

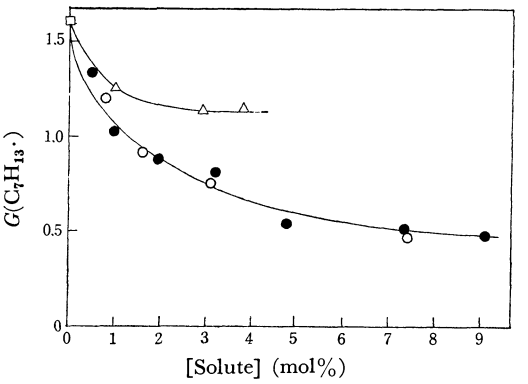

Fig. 7. Yields of MCH· radicals from γ-irradiated pure MCH (□) containing CH_2Cl_2 (△), $CHCl_3$ (○) and CCl_4 (●) at -196°C.

In a previous work we have shown that electron scavengers such as SF_6 or n-butyl chloride suppress the formation of MCH· radicals by $\sim$25% at a solute concentration of about 5 mol%.[10] This implies that the suppression of neutralization of solvent positive ions with electrons leads to the decreases in solvent radical yield of about 25%. Thus, the origin of solvent radicals seems to be mainly the decomposition of directly excited molecules and only partly the neutralization of positive

ions with electrons. Since the decrement of MCH· radical yield by the addition of CH_2Cl_2 is nearly equal to that by SF_6 or *n*-butyl chloride,[10] the effect of CH_2Cl_2 on radical formation can be ascribed to electron scavenging, which is consistent with the result on hydrogen formation. We can see from Fig. 7 that both $CHCl_3$ and CCl_4 suppress the formation of solvent radicals to a greater extent than CH_2Cl_2. Thus, we can ascribe the effect of $CHCl_3$ or CCl_4 on the radical formation to excitation transfer in addition to electron scavenging.

If we exclude the role of excitation transfer for the abnormal suppression of the yields of hydrogen and solvent radicals, the only possible cause for this will be electron scavenging by $CHCl_3$ and CCl_4 which is nondissociative.

$$CHCl_3 + e^- \longrightarrow CHCl_3^- \quad (4)$$

$$CCl_4 + e^- \longrightarrow CCl_4^- \quad (5)$$

Suppression of radical formation by these solutes can be explained by Reactions (4) and (5), if radicals are mainly formed by neutralization of positive ions with electrons. At present, however, we have no evidence for nondissociative electron capture by these solutes in condensed systems. Thus it appears reasonable to ascribe the abnormal suppression of hydrogen and radical formation by $CHCl_3$ or CCl_4 to excitation transfer.

The Diffuse Reflection Spectra of 1-Arylazo-2-naphthols Diluted with Sodium Chloride

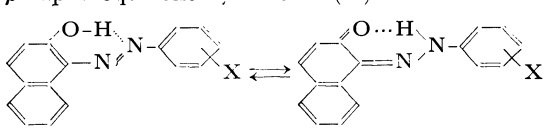
Chihiro DEHARI, Yoshio MATSUNAGA*1 and Kensuke TANI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received June 8, 1970)

The diffuse reflection spectra of sixteen 1-arylazo-2-naphthols diluted with sodium chloride were measured at concentrations of 1, 0.1, and 0.01% in the range from 350 to 700 mμ. The spectra indicate the coexistence of the azo and hydrazone tautomers in this solid, two-component system. Moreover, the spectra were found to be markedly modified in many cases by elevating the temperature, especially at a concentration of 0.01%. These changes were shown to be thermally reversible and were attributed to the movement of the tautomeric equilibrium. The direction depends upon the kind and position of the substituents, *e.g.*, towards the hydrazone tautomer in the case of the *p*-Cl and *o*-NO_2 derivatives and towards the azo tautomer in the case of the *p*-NO_2 and *o*-OH derivatives. It was suggested that the present systems are not simple mixtures of pulverized 1-arylazo-2-naphthols and sodium chloride, but that some fraction of the organic components is well dispersed and adsorbed on the highly polar surface of the alkali halide.

A large number of studies have been carried out to elucidate the structure of 1-arylazo-2-naphthols,*2 which may exist as true azo compounds (I) or as β-naphthoquinone hydrazones (II).[1]



(I) (II)

On the basis of the electronic spectra in various solvents, Burawoy *et al.* have clearly demonstrated that they exist in solution as tautomeric equilibria.[2] For example, the spectrum of 1-phenylazo-2-naphthol in hexane shows an absorption region consisting of two coalescent bands at about 420 and 460 mμ, whereas in alcohol, chloroform, and 50% alcohol the intensity of the former band is consistently reduced, and that of the latter, increased. The two bands correspond to the azo and the hydrazone tautomers respectively, the former being present in an appreciable quantity only in a hexane solution.

A few years later Hadzi discovered that the electronic spectrum of solid 1-phenylazo-2-naphthol

*1 To whom inquiries may be addressed.

*2 This designation is used throughout this paper for convenience; it is not intended to define the structure of the compounds.

pressed with potassium bromide into a disc consists of two bands, at 410 and 486 mμ.[3] The first maximum was assigned to the azo tautomer, and the second, to the hydrazone tautomer. His finding was rather surprising, as Hadzi himself noted. To the best of our knowledge, compounds exhibiting tautomerism in solution are known to be in one form only in the crystalline state. Therefore, Hadzi suggested that the two types of molecules have very similar bond lengths, that the proton changes its position from oxygen to nitrogen with time, and that thus the two types of molecules give, on the time-average, a single set of bond dimensions. It is noteworthy that the general character of the electronic spectrum of the solid corresponds to that of solutions in polar solvents. Recently Bansho *et al.* extended the spectral measurement by the same technique to cover a number of derivatives.[4] By comparing the extinctions in the regions from 410 to 420 mμ and from 480 to 500 mμ, they concluded that 60 to 70% of the molecules in the solids exist as hydrazones. Further evidence for the presence of the tautomerism in solid 1-arylazo-2-naphthols has been provided by the infrared spectra examined by Morgan and also by the fluorescence studied by Rau.[5,6]

If the compounds exist as tautomeric equilibria in solids, the temperature dependence of the electronic spectra may be observed. To confirm this expectation, we started measurements of the diffuse reflection spectra. As our preliminary attempts indicated that the spectra, which are much better resolved than the transmission spectra presented by Hadzi, depend appreciably on the degree of dilution, concentrations of 1, 0.1, and 0.01% were used throughout this work.

Experimental

Materials. The compounds were prepared by the usual diazo-coupling reactions with 2-naphthol. The derivatives carrying one of the following substituents in the *o*-, *m*-, or *p*-position on the phenyl ring were included in the present work: methyl, chloro, hydroxy, methoxy, and nitro. They were recrystallized twice from appropriate solvents selected from among methanol, benzene, toluene, and acetic acid, and were finally sublimed in *vacuo*.

Measurements. The compounds were diluted with dried sodium chloride in the desired concentrations. The well-ground mixture was mounted on a brass block in which a 60-W heater is embedded. The temperature near the surface of the mixture was monitored by a copper-constantan thermocouple and was kept constant with the aid of a Chino temperature-indicating controller, Type E 500. The difference in reflectance between the mixture heated to a desired temperature and pure sodium chloride kept at room temperature was recorded in the range from 350 to 700 mμ by a Beckman DK 2A spectroreflectometer. The spectra were then plotted using the Kubelka-Munk function $f(R)=(1-R)^2/2R$, where R is the reflectance. The measurements were carried out at three different temperatures, namely, room temperature (about 20°C), the highest temperature selected (at least 50°C below the melting point of each compound), and one between these two. As the reflectance is strongly affected by the thermal dispersion of the compound as the temperature rises, only the spectra measured as the temperature fell were employed in our considerations. The room-temperature spectra are those recorded after cooling by storage in a desiccator over silica gel. Even with these precautions, the absorption intensity depends somewhat upon how the mixture was heated and cooled; therefore, the maximum was arbitrarily taken as 1.00 in each spectrum.

Results and Discussion

1-Phenylazo-2-naphthol (Fig. 1). The room-temperature spectra at concentrations of 1, 0.1, and 0.01% are presented in Fig. 1. There are a broad band covering the region from 350 to 425 mμ and a sharp strong doublet appearing at 480 and 525 mμ. The former band is assigned to the azo tautomer, and the latter, to the hydrazone tautomer. In the present case, the spectra at the three concentrations are rather similar to each other. As the compound is strongly absorbing, the deviation from the Kubelka-Munk theory due to regular reflection may be considered to be the cause of the apparent flattening of the spectra at high concentrations. However, the spectral change observed in the case of the *p*-NO_2 derivative (shown in Fig. 9) undoubtedly indicates that the deviation from the theory cannot be the sole cause of the concentration dependence of the spectra. The marked depression in the relative

intensity of the broad band by dilution found in Fig. 1 may be partially attributed to the movement of the equilibrium towards the hydrazone tautomer. We do not expect such movements if the samples are simple mixtures of pulverized substances. Therefore, the contribution from the molecules adsorbed on the surface of the diluent to the observed spectra should be taken into consideration. Even if the concentration is as high as 1%, the spectrum may still not be that of a true solid, but, on the other hand, it may not be far from that. Our spectrum at a concentration of 0.01% is in good agreement with the one reported by Rau, who measured it by the same technique and at the same concentration.

When the temperature was raised to 75°C, no change occurred in the spectrum at any of the concentrations examined except for a small broadening of the doublet.

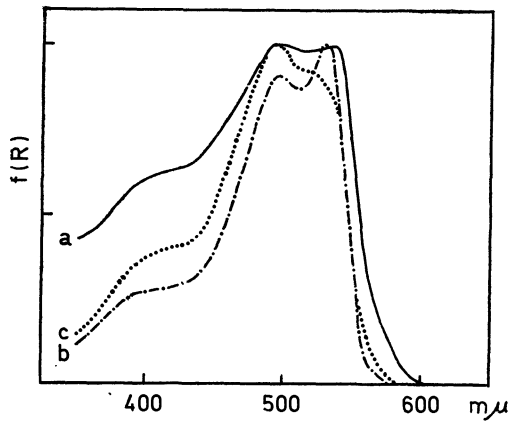

Fig. 2. Spectra of 1-(*o*-tolylazo)-2-naphthol diluted with sodium chloride; (a) 1%, (b) 0.01% at room temperature and (c) 0.01% at 75°C.

1-Tolylazo-2-naphthols (Fig. 2). The spectra of these compounds are almost identical with that of 1-phenylazo-2-naphthol (presented in Fig. 1). Although the relative intensity in the region from 350 to 450 mμ cannot be directly correlated with the amount of the azo tautomer, it is interesting to note that the intensity at a concentration of 1% increases in this order of substituents: *o*-Me∼H<*m*-Me<*p*-Me. This order is nearly the same as that found in an ethanolic solution by Burawoy *et al.*: *o*-Me<*m*-Me∼H<*p*-Me.[2]

A change in the spectrum upon an elevation of the temperature was observed in the case of the *o*-Me derivative, most clearly at 0.01%. As is shown in Fig. 2, the intensities in the region from 350 to 500 mμ measured at 75°C are higher than those at room temperature. This observation indicates that the equilibrium moves towards the azo tautomer at high temperatures. The change in the spectrum upon dilution is also illustrated in this figure. In the case of the *m*-Me derivative, none of the spectra recorded at 75°C were found to be different from those at room temperature. The spectrum of the *p*-Me derivative is modified a little bit only at 0.01% when the temperature is raised to 75°C. The direction of the change is the same as that found in the *o*-Me derivative.

1-Chlorophenylazo-2-naphthols (Figs. 3 and 4). The spectra of the *o*-Cl and *m*-Cl derivatives are shown in Fig. 3. No temperature dependence was observed in these cases; however, a movement of the equilibrium towards the hydrazone tautomer upon heating to 75°C was found in the *p*-Cl derivative. It must be added that this movement is in the direction opposite to that observed in the *o*-Me and *p*-Me derivatives. At a concentration of 1%, the presence of a doublet due to the hydrazone tautomer is clearly noted only in the *m*-Cl derivative. In the other two cases, the

absorptions in the region from 350 to 450 mμ are so high that the sharp peaks due to the hydrazone tautomers cannot be resolved. The relative intensities measured at 1% in the above-mentioned region increase in this order: H<*m*-Cl<*p*-Cl~*o*-Cl, an order which is not in accordance with that drawn from the data obtained in an ethanolic solution: *o*-Cl<*m*-Cl<*p*-Cl~H.[2] When the compounds are much more diluted with sodium chloride, the relative intensities in the region from 350 to 450 mμ are drastically decreased, as is generally found in a solid, two-component system. Nevertheless, the order remains essentially the same: H<*m*-Cl<*o*-Cl<*p*-Cl. Therefore, the effect of chlorine substitution on the tautomeric equilibrium in our system is apparently very different from that observed in solution by Burawoy *et al.*

1-Hydroxyphenylazo-2-naphthols (Figs. 5 and 6). The *o*-OH derivative is one of the compounds showing a very pronounced temperature dependence in the spectra. In Fig. 5 the spectra measured at room temperature and at 100°C are presented. The room-temperature spectrum at 1% is very similar to that of 1-phenylazo-2naphthol examined under the same conditions. However, the whole spectrum is shifted to the long-wavelength side. The doublet to be assigned to the hydrazone tautomer is located at 500 and 540 mμ. It is apparent that the equilibrium moves towards the azo tautomer when the temperature is elevated. Contrary to the case of the *o*–OH derivative, the absorption due to the azo tautomer is dominant in the spectrum of the *m*–OH derivative at a concentration of 1%. A small movement of the equilibrium towards the hydrazone tautomer is noted upon heating to 100°C only at 0.01%. The spectra of the *p*–OH derivative shown in Fig. 6 bear some similarity to those of the *o*–OH derivative, but the change upon an elevation of the temperature is in the opposite direction.

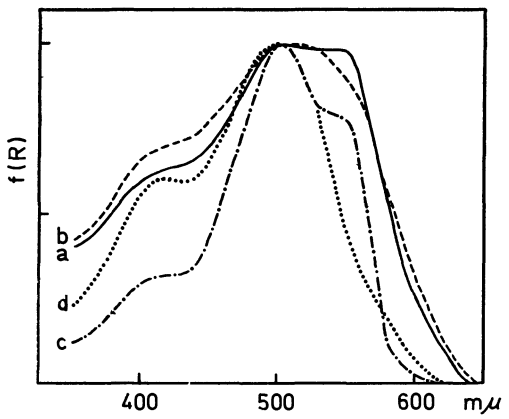

Fig. 5. Spectra of 1-(*o*-hydroxyphenylazo)-2-naphthol diluted with sodium chloride; (a) 1% at room temperature, (b) 1% at 100°C, (c) 0.01% at room temperature and (d) 0.01% at 100°C.

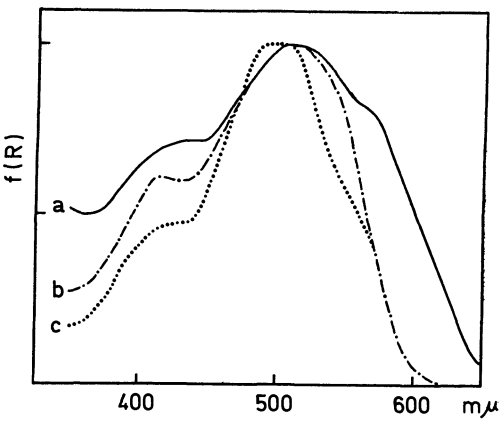

Fig. 6. Spectra of 1-(*p*-hydroxyphenylazo)-2-naphthol diluted with sodium chloride; (a) 1%, (b) 0.01% at room temperature and (c) 0.01% at 100°C.

1-Anisylazo-2-naphthols (Fig. 7). The doublet to be assigned to the hydrazone tautomer is located at 500 and 540 mμ in the spectrum of the *o*–MeO derivative. By heating to 100°C, the peak at the longer wavelength disappears. The equilibrium seems to move slightly towards the azo tautomer upon an elevation of the temperature. The *m*–MeO derivative shows a spectrum similar to that of the *o*-MeO derivative; however, no temperature dependence was detected in this case. The spectrum of the *p*-MeO derivative shown in Fig. 7 suggests that a fairly large amount of the azo tautomer is present, even at a concentration of 0.01%. The change caused by heating discloses that high temperatures favor the hydrazone tautomer. The spectrum examined as a potassium bromide disc by Bansho *et al.* is like ours measured at 0.01%. The concentration of the azo tautomer in solution was reported by Burawoy *et al.* to increase in this order: *o*-MeO

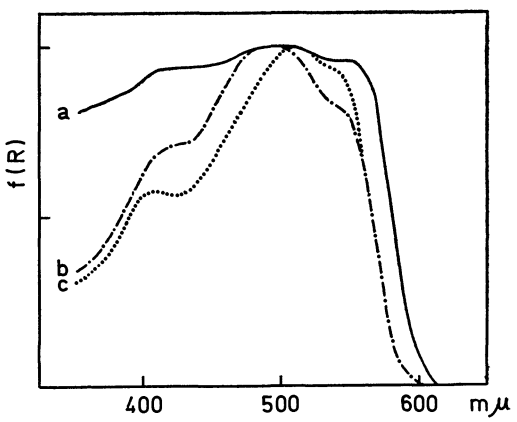

Fig. 7. Spectra of 1-(*p*-anisylazo)-2-naphthol diluted with sodium chloride; (a) 1%, (b) 0.01% at room temperature and (c) 0.01% at 75°C.

$<m$-MeO$<$H$<p$-MeO.[2] In our solid, two-component system, the effect of the substituent on the equilibrium is quite different from theirs. The relative intensity in the region between 350 and 450 mμ is found to be in this order: H$<$ m-MeO$\sim o$-MeO$<p$-MeO at a concentration of 1%.

1-Nitrophenylazo-2-naphthols (Figs. 8 and 9). As is shown in Fig. 8, the spectrum of the o-NO_2 derivative at room temperature is dominated by the broad absorption assigned to the azo tautomer. The change upon an elevation of the temperature is well demonstrated, even at a concentration of 1%. Apparently the amount of the hydrazone tautomer increases at high temperatures. In the spectra of the m-NO_2 derivative, the doublet due to the hydrazone tautomer can be seen in this case, but only weakly, at a concentration of 1%. As the absorption assigned to the azo tautomer at 100°C is stronger than that at room temperature, the hydrazone tautomer appears to be more stable than the azo tautomer.

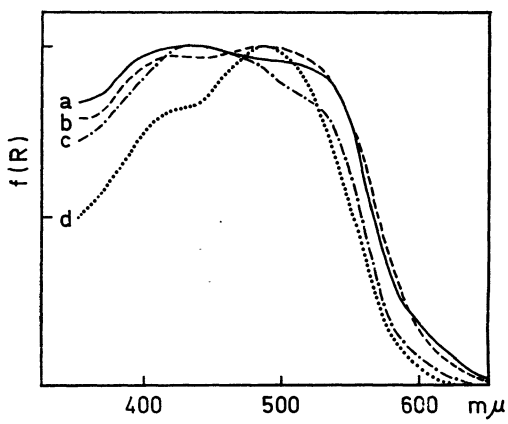

Fig. 8. Spectra of 1-(o-nitrophenylazo)-2-naphthol diluted with sodium chloride; (a) 1% at room temperature, (b) 1% at 125°C, (c) 0.01% at room temperature and (d) 0.01% at 125°C.

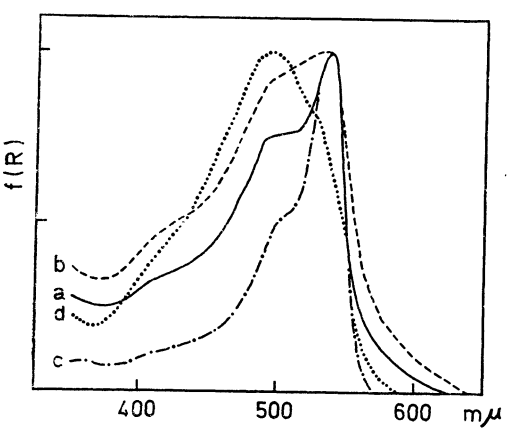

Fig. 9. Spectra of 1-(p-nitrophenylazo)-2-naphthol diluted with sodium chloride; (a) 1% at room temperature, (b) 1% at 150°C, (c) 0.01% at room temperature and (d) 0.01% at 150°C.

The most pronounced temperature dependence of the spectrum has been observed with the p-NO_2 derivative. There is a sharp peak at 538 mμ, with a shoulder around 500 mμ. Upon heating to 150°C, the shoulder is appreciably intensified. Especially at a concentration of 0.01%, the change is quite remarkable. The peak at 538 mμ, which is supposed to be assigned to the hydrazone tautomer, is nearly completely obscured by a strong absorption appearing at 500 mμ. The latter may be assigned to the azo tautomer. Our high-temperature spectrum obtained at 0.01% closely resembles the one reported by Bansho *et al.*[4] It must be pointed out that the high-temperature spectrum at 0.01% differs greatly from that at 1%. This observation confirms the dependence of the tautomeric equilibrium on the degree of dilution. Burawoy *et al.* stated that the concentration of the hydrazone tautomer in these nitro derivatives is the highest among the 1-arylazo-2-naphthols examined.[2] However, the spectra of the o-NO_2 derivative given in Fig. 8 are not consistent with their finding.

General Remarks. Since the true maxima and intensities of the bands of the individual tautomers are not known, a quantitative analysis of the equilibria cannot be made. Bansho *et al.* reported that 60 to 70% of the molecules in solid 1-arylazo-2-naphthols exist as hydrazone tautomers, regardless of the kind and position of the substituents examined, *i.e.*, Me, MeO, Cl, and NO_2.[4] In their estimations, the relative intensities of the bands due to the azo and hydrazone tautomers were assumed to be constant throughout the derivatives examined and were taken to be equal to those of 4-(o-chlorophenylazo)-1-naphthol in solution. The temperature dependence of the electronic spectra reported in the present work indicates that some of the Bansho estimations are too high.
