A Study of the Decomposition Reaction of Cumene Hydroperoxide in the Presence of Triphenylsulfonium Chloride

Katsutoshi OHKUBO, Tokio YAMABE and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received March 29, 1969)

The homogeneous decomposition reaction of cumene hydroperoxide in cumene was studied by the use of triphenylsulfonium chloride over a low-temperature range (30—80°C). The hydroperoxide was decomposed remarkably in the presence of the sulfonium catalyst, whereas in the absence of the catalyst it was decomposed only a little. Among the homolytic decomposition products, acetophenone and dicumyl peroxide were found to be the main products, while α-cumyl alcohol was formed in only a small amount. Moreover, methyl alcohol was found in appreciable amounts. Traces of heterolytic reaction products, such as phenol and acetone, were also detected. After discussing the reaction mechanism and the nature of catalytic action, it is concluded that the partially-occupied *d* orbital of the sulfonium cation may play a role in breaking the oxygen-oxygen bond of the hydroperoxide homolytically. The counter chloride anion seems to take part in the heterolytic reaction to some extent.

The thermal decomposition of cumene hydroperoxide (CHP) above 100°C in various kinds of solvents has been studied by several authors.[1-7] Most of these studies have been based on kinetic methods. However, there are some discrepancies in their results,[2,3] particularly in the kinetic order of decomposition reaction. These discrepancies may be attributed to the distribution of the decomposition products which depends on the polarity of the solvents, the reaction temperature, and the presence or absence of catalysts.

CHP itself is thermally stable in hydrocarbons up to 130—140°C,[3] but by catalysts such as ferrous salt[4] and peroxides[4] it is decomposed even below 80°C. We found that sulfonium salts also decompose CHP at low temperatures (below 80°C), even though the character of the catalytic action is different from that of the above catalysts.

In the low-temperature decomposition of CHP by the use of triphenylsulfonium chloride, the main decomposition products are homolytic products: acetophenone (AP), dicumyl peroxide (DCP), and α-cumyl alcohol (CA). It is noticeable that the sulfonium salt catalyses the formation of methyl alcohol, which is scarcely at all found in the usual thermal decomposition of CHP in cumene.[1-3] This decomposition reaction is of a heterolytic nature because of the formation of phenol and acetone. Such processes of a heterolytic nature may be caused by an action of the counter chloride anion of the sulfonium catalyst. A presumption is made that the partially-occupied *d* orbitals[8] of the sulfonium cation might play an important role in the decomposition of CHP.

Experimental

Reagents. Commercial cumene hydroperoxide (CHP) (purity below 70%) was distilled in order to collect a fraction, 60°C/0.1 mmHg. In order to free it from traces of impurities, the fraction was extracted with sodium bicarbonate, filtered chromatographically through activated alumina (200—300 mesh), and stored in a nitrogen atmosphere at 0°C. The cumene was purified as has previously been described.[8,9] The sample of α-cumyl alcohol (CA) used (free from acetophenone) was recrystallized several times from ligroin. The dicumyl peroxide (DCP) and hydroquinone employed were of a commercially pure grade. The triphenylsulfonium chloride was prepared by the method described in a previous report.[10]

Analysis of Reaction Products. The CHP, DCP, AP, and CA were determined in a way previously described.[9] The gaseous reaction products were collected by condensation at −76°C and were determined by gas chromatography as well as by an Orsat apparatus. For oxygen absorption, Fieser's solution[11] and a pyrogallol solution were used. The determination of the products obtained in trace amounts was also performed. The phenol was converted to tribromophenol.[12] The acetone was estimated on the basis of the iodoform equivalent.[13]

Reaction Procedure. The decomposition reaction of CHP in the presence of triphenylsulfonium chloride was carried out as follows. Triphenylsulfonium chloride was introduced into a reaction vessel containing CHP (22.5 mmol) and cumene (20 m*l*). The homogeneous reaction mixture was stirred with a magnetic stirrer at the desired temperature. The evolved gas was then collected at −76°C by a gas trap attached to an Orsat apparatus. The decomposition of CHP in cumene was followed by iodometric titration.

Results and Discussion

It is worthy of emphasis that CHP in cumene decomposes appreciably in the presence of sulfonium salts at relatively low temperatures (below 80°C), even though CHP is thermally so stable that little decomposition takes places in 48 hr at 100°C.[14] These phenomena are indicated in Fig. 1, where the thermal decomposition is very little, while the catalytic reaction is accelerated with the increase in the amount of the sulfonium catalyst and in the reaction temperature. The decrease in catalytic ability for CHP decomposition with the reaction time, especially at 80°C, may be connected with the masking action[9] of the products and of

CHP itself, since the kinetic order of the reaction rate to the amount of the catalyst gradually decreases with the reaction time considering a first-order cleavage of CHP[3,6,7] (from the 0.55th order at the initial step to the 0.51st order and 0.47th order at 2.0 hr and 3.0 hr respectively). Table 1 indicates the distribution of reaction products with the reaction time. The formation of AP, DCP, and CA suggests that the catalytic decomposition of CHP is homolytic, while the small quantities of

c) Gaseous products were not analyzed but tentatively assumed as methane.

phenol and acetone produced imply that this reaction might include the heterolytic cleavage of CHP. Moreover, as is shown in Table 2, one of the products of this reaction is an appreciable amount of methyl alcohol, which is hardly ever found in a usual homolytic thermal decomposition reaction in such non-polar solvents as cumene. From these results, the mechanism of this low-temperature reaction may be discussed.

$$\mathrm{ROOH} + (C_6H_5)_3SCl \longrightarrow \left[\begin{array}{c} H \\ \overset{\alpha}{O}\text{–}\overset{\beta}{O}\cdots\overset{+}{S}(C_6H_5)_3\cdots Cl^- \\ R \end{array}\right] \longrightarrow \mathrm{RO}\cdot + \cdot\mathrm{OH} + (C_6H_5)_3SCl \quad (1)$$

$$(R = C_6H_5(CH_3)_2C\text{–})$$

In the first step of this reaction, sulfonium salt may cleave the oxygen-oxygen bond of CHP into two parts, α-cumyloxy and hydroxy radicals. In all the bonds of CHP, the oxygen-oxygen bond is the weakest in the sense that the dissociation energy of this bond is considerably smaller than those of the other bonds. Following a molecular orbital calculation by Fukui *et al.*,[15] the lowest vacant orbitals of hydroperoxides are the $p\sigma$-type anti-bonding orbitals of the O–O bond. In the catalytic process, the electron of the partially-occupied *d* orbital[8] of the central sulfur atom of the sulfonium cation may be transferred to this lowest vacant orbital. The interaction of this orbital with electron-donor molecules would take place in the direction of the bond axis from the β-oxygen side, since the partial population of the β-oxygen of this vacant orbital is larger than that of the α-oxygen.[15] The charge transferred from the sulfonium moiety to the oxygen-oxygen bond may increase the antibonding character of the bond and promote the scission. This circumstance is portrayed in Fig. 2. In this figure, the structure of the triphenylsulfonium ion is assumed to be a propeller-like D_3 symmetry, like the triphenylcarbonium cation.[16] In this connection the mode of the interaction between the $p\sigma$-orbital of the O–O bond and the "partially occupied" *d*-orbital[8] on the sulfonium sulfur atom comes into question. From both energetic and steric points of view, the d_{z^2}-orbital seems to the most probable *d*-orbital interacting with CHP. Several reasons for this can be mentioned: (1) d_{xy} and $d_{x^2-y^2}$ orbitals in the field of the sp^2-hybridized S atom[8] are energetically unstable because of the interaction with three sulfur-phenyl bonds; (2) the interaction of the *d*-orbitals (d_{xy} and $d_{x^2-y^2}$) with CHP will be sterically hindered by phenyl groups; (3) d_{xy} and d_{yz} orbitals become somewhat unstable by the interaction, through d-π-type conjugation, with π-orbitals of phenyl groups,[17-19] while phenyl rings also sterically hinder the interaction with CHP to some extent (see Fig. 2), and (4) the d_{z^2}-orbital is most acceptable because it has no conjugation with the π orbitals of phenyl groups and because it has only a small interaction with sulfur-phenyl bonds.

In the transition state shown in the scheme of reaction (1), the hydroxyl group may bear a somewhat ionic character in view of the large electron affinity of the HO radical (~136 kcal).[20] At this stage, the partially-ionic hydroxyl group would exhibit a counter-anion like behavior.*1 In conformity with the liberation of the OH radical, the

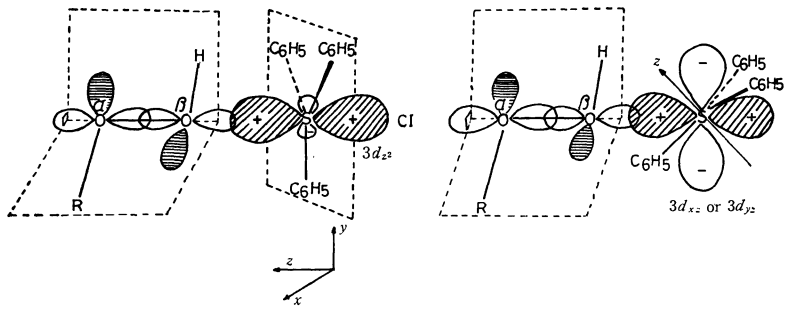

Fig. 2. Assumed mode of reaction between ROOH and $(C_6H_5)_3SCl$.

electron migration would take place, again through the central sulfur, to an opposite-side-lying chlorine atom, thus regenerating the triphenylsulfonium chloride. Actually, triphenylsulfonium hydroxide is never formed in the final system. The α-cumyloxy radicals primarily formed are then readily converted to the major reaction products (presented in Table 1) through reactions (2a), (2b), and (2c).

$$\mathrm{RO}\cdot \xrightarrow{\beta\text{-scission}} \mathrm{AP} + \mathrm{CH_3}\cdot \quad (2a)$$

$$\mathrm{RO}\cdot \xrightarrow[\mathrm{RO}\cdot]{\text{coupling}} \mathrm{DCP} \quad (2b)$$

$$\mathrm{RO}\cdot \xrightarrow[\mathrm{RH}]{\text{hydrogen abstraction}} \mathrm{ROH} + \mathrm{R}\cdot \quad (2c)$$

(R = α-cumyl)

The reaction of the RO radical with ROOH is not presented because the reaction does not seem essential; the concentration of ROOH is much lower than that of RH.

Among the above products, DCP and AP are formed predominantly. The formation of such large amounts of the former may be attributed to its thermal stability in this temperature range. However, an accumulation of DCP causes gradual decomposition as the reaction proceeds, because DCP is decomposed by the sulfonium catalyst[9] to some extent. The results are shown in Table 1. The remarkable formation of AP may be attributed to the ease of the β-scission of a carbon-methyl bond in the α-cumyloxy radical. After the α-cumyloxy radical is formed from the cleavage of the O–O bond of CHP, the odd electron may conjugate with the sigma electrons of a $C–CH_3$ bond through π-type orbital overlapping. This is a pi-participation of the oxygen *p*-electron in the β-methyl fission.

Interestingly, CA is formed only in small amounts. No such result was observed in the thermal decomposition at higher temperatures,[3,4] where both CA and AP are produced in comparable amounts. The CA formation may be depressed at lower reaction temperatures by the steric hindrance of both bulky reactants (α-cumyloxy radical and cumene). The small quantity of CA formation will be discussed below.

On the other hand, the hydroxy radical primarily formed from CHP readily undergoes conversion to CH_3OH and H_2O through hydrogen abstraction or through coupling with the methyl radical.

$$\cdot\mathrm{OH} \xrightarrow[\mathrm{RH}]{} \mathrm{H_2O} + \mathrm{R}\cdot \quad (3a)$$

$$\cdot\mathrm{OH} \xrightarrow[\mathrm{ROOH}]{} \mathrm{H_2O} + \mathrm{RO_2}\cdot \quad (3b)$$

$$\cdot\mathrm{OH} \xrightarrow[\cdot\mathrm{CH_3}]{} \mathrm{CH_3OH} \quad (3c)$$

Reactions (3a) and (3c) are probable because water*2 and methyl alcohol are found in the products in appreciable amounts (see Tables 2 and 3). Reaction (3b) seems not very likely to occur since the oxygen evolution expected from the recombination of the cumylperoxy radical*3 was not observed. Kharasch[3] also argued the difficulty of reaction (3b) from the kinetic point of view. The coupling and disproportionation of the OH radical must also be mentioned.

$$\cdot\mathrm{OH} + \cdot\mathrm{OH} \rightleftharpoons \mathrm{H_2O_2} \quad (3d)$$

$$\cdot\mathrm{OH} + \cdot\mathrm{OH} \longrightarrow \mathrm{H_2O} + \cdot\mathrm{O}\cdot \quad (3e)$$

However, these reactions are obviously much less important than (3a) and (3c). In reaction (3d), the reverse reaction is dominant in the present case. Reaction (3e) may be difficult energetically; actually, no evolution of gaseous oxygen was observed.

*1 This is expected from the fact that triphenylsulfonium chloride is actually very hygroscopic and that an air-polluted sample shows an appreciable OH peak in the infrared region. It should here be stressed, however, that in spite of such a strong affinity to OH groups, triphenylsulfonium salt does not decompose easily in polar sovents containing OH groups, such as water, hydroperoxides and various kinds of alcohols, and can even be recrystallized from them. It should further be emphasized that no products formed by the coupling of R· or CH_3· with the chlorine atom, such as α-cumyl chloride and methyl chloride, result from this decomposition reaction.

*2 The quantitative determination of the amount of water was not performed in our experiments.

*3 Cumylperoxy radicals (RO_2·) easily combine with each other to evolve gaseous oxygen: $2RO_2\cdot \rightarrow [RO_4R] \rightarrow 2RO\cdot + O_2$

Radicals produced secondarily by dismutation or by reaction with the solvent (RH) may take part in the decomposition of CHP.[1,2] In the first place, the methyl radical formed mainly from the β-scission of the α-cumyloxy radical contributes to the formation of methyl alcohol reaction (4a) as well as to the formation of gaseous products through reactions (4b) and (4c):

$$\bullet CH_3 \xrightarrow{ROOH} CH_3OH + RO\bullet \quad (4a)$$

$$\bullet CH_3 \xrightarrow{RH} CH_4 + \bullet R \quad (4b)$$

$$\bullet CH_3 \xrightarrow{RO\bullet} C_2H_6 + AP \quad (4c)$$

Reaction (4a) may be promoted by the sulfonium catalyst for the same reasons as is the decomposition of CHP (see reaction (1)). Reactions (4b) and (4c) appear to take place more readily than (4a), since gaseous products are actually formed in larger amounts than methyl alcohol*4 (see Tables 2 and 3).

In the second place, the slight CA formation, compared with that of AP, would be explained by the behavior of the α-cumyloxy radicals (RO$\bullet$) formed in the primary step (1) and in the secondary step (4a). The possible reactions of CA formation may be reactions (2c), (5a), and (5b):

$$RO\bullet \xrightarrow{RH} ROH + R\bullet \quad (2c)$$

$$RO\bullet \xrightarrow{ROOH} ROH + RO_2\bullet \quad (5a)$$

$$RO\bullet \xrightarrow{H_2O} ROH + HO\bullet \quad (5b)$$

If the ease of the hydrogen abstraction of the RO radical depends mainly on the bond-dissociation energy in hydrogen donors, reactions (2c) and (5a) will be more predominant than (5b), because the dissociation energies of R–H ($\sim$85 kcal) and ROO–H ($\sim$89.5 kcal)*5 are considerably lower than HO–H ($\sim$120 kcal[10]). However, reaction (5a) is unlikely, like (3b), because of the low concentration of ROOH compared with RH; the absence of reaction (5a) can be ascertained from the lack of any evolution of oxygen, even though ROOH is as good a hydrogen donor as RH. Hence, it may be reasonable to conclude that CA is formed predominantly through the reaction path (2c). At any rate, the small amount of CA may be attributed to the prevalence of the intramolecular reaction (2a) over the intermolecular one (2c).

In the third place, it should be noted that the coupling product of α-cumyl radicals (R$\bullet$), namely, bi-α-cumyl (R–R), is not found in any appreciable amount. From the facts that the R radicals formed tend to be easily deactivated by the trapping of the RH solvent or of other solvents (ROOH and H_2O), and that the amount of active R radicals may be small, the chance of coupling may be small.

In the thermal decomposition of CHP in cumene at the temperatures of 128°C and 158°C, Kharasch and his co-workers[3] confirmed the negligible amount of bi-α-cumyl in spite of the remarkable formation of R radicals. They attributed this result to the reaction of the R radical with ROOH, which contributes to the CA formation through the following path:

$$ROOH + R\bullet \rightleftarrows \text{Complex A}$$

$$\text{Complex A} + RH \longrightarrow 2ROH + R\bullet$$

However, such a complex was not confirmed. As for the explanation of the negligible formation of bi-α-cumyl, the difficulty of R–R formation must first of all be mentioned, especially in the low-temperature reaction of our experiments.

The homolytic nature of the low-temperature decomposition by the sulfonium chloride may have been clarified in the above discussions. However, the reaction seems to involve a somewhat heterolytic part. The formations of phenol and acetone in measurable amounts (as is shown in Tables 1 and 2) should be regarded as the result of heterolytic decomposition. In this connection, the role of the chloride anion of sulfonium salt should be noticed. It may be reasonable to presume, as was indicated in the works by Barb and his co-workers,[23,24] by Kolthoff and Medals,[25,26] by Taube and Bray,[27] and by Allen,[28] that the chloride anion is converted to the chlorine atom through charge-transfer to the hydroxy radical:

$$Cl^- + \bullet OH \longrightarrow Cl\bullet + OH^- \quad (6a)$$

$$Cl\bullet + RH \longrightarrow HCl + R\bullet \quad (6b)$$

(or ROOH) (or RO_2)

$$C_6H_5C(CH_3)_2O_2H \xrightarrow{H^+(HCl)} C_6H_5OH + (CH_3)_2CO + H^+(HCl) \quad (6c)$$

The possibility of (6a) is also supported by the fact that reaction (6a) has the very small activation energy of 3 kcal.[20] The chlorine atom thus formed

*4 The methane formation should be ascribed to the hydrogen abstraction of $CH_3\cdot$. The activation energy of the reaction $CH_3\cdot + ROOH$ (R=*t*-butyl) $\rightarrow CH_4 + RO_2\cdot$ is 8.1 kcal, while that of $CH_3\cdot + RH$(*n*-hexane) $\rightarrow CH_4 + R\cdot$ is 11.7 kcal.[21]

b) The gase evolved in this experiment was not fully analyzed, but contained mainly methane.

will react with RH or ROOH to produce HCl, which behaves as a catalyst for reaction (6c). However, in the sulfonium chloride, the supply of free Cl^- can not be expected because of the appreciable covalent nature[8] of the bond between the sulfonium cation and the counter-anion. Actually, more than 70% of the triphenylsulfonium chloride can be recovered from the reaction mixture, even after a 13-hr reaction. Hence, the contribution of the chloride anion is limited, even if it takes part in the heterolytic decomposition. This is reflected in the very small amounts of phenol and acetone formed.

Another possibility for the heterolytic decomposition of CHP has been postulated by Kharasch and his co-workers[3] in the following self-decomposition of CHP ((7) and (8)):

$$C_6H_5(CH_3)_2COOH \xrightarrow{\text{heterolytic cleavage}} C_6H_5(CH_3)_2CO^+ + OH^- \quad (7)$$

$$C_6H_5(CH_3)_2CO^+ \xrightarrow{\text{rearrangement}} C_6H_5O(CH_3)_2C^+ \quad (8)$$

The cation formed is capable of further conversion to give phenol and acetone. However, it seems difficult for reaction (7) to occur without traces of acidic impurities; therfore, the small amounts of phenol and acetone formed may be ascribed to the contribution of the chloride anion.

The temperature effect on the catalytic decomposition of CHP is shown in Table 3. As the table shows, the homolytic decomposition proceeds even at 55°C, but it disappears at 30°C. The increase in the temperature depresses the DCP formation, implying the thermal decomposition of DCP, whereas AP and CA increase to some extent.

It is necessary to investigate the effect of the decomposition products on the reaction in order to clarify the mechanism. Table 4 indicates the additive effect of CA, DCP, and hydroquinone. Hydroquinone is employed as an additive of the hydrogen donor. At first, the reaction system initially containing CA as an additive evolves gaseous oxygen, which is undetectable in the absence of the alcohol. This phenomenon may be attributed to the heterolytic decomposition of CHP, as was first pointed out by Kharasch and his co-workers.[3],*6 It is obvious that the catalytic decomposition is markedly prevented by the addition of CA. This fact may be directly connected with the masking action[9] of the additive. Such a masking action of CA depresses the catalytic activity on the homolytic decomposition of CHP, leading to the heterolytic decomposition.

Secondary, the effect of DCP addition is apparently confirmed in the remarkable formation of AP and CH_3OH. This result suggests that the growth of the RO· concentration caused by the DCP decomposition promotes reaction (2a) and subsequently (4a).

Thirdly, it is well known that hydroquinone is a good hydrogen donor as well as a radical scavenger. The remarkable effect of its addition appears to be the reaction with RO radicals to give ROH. Furthermore, hydroquinone depresses the catalytic activity through the masking action caused by the hydrogen bonds of hydroquinone molecules and disturbs the dismutation or recombination of RO radicals by the exclusive formation of ROH.

In connection with the CHP decomposition by triphenylsulfonium chloride, the reactions of CHP with such other sulfur compounds as sulfide and thiophene were also carried out. Diphenyl sulfide produced CA mainly, while thiophene formed AP predominantly, as is shown in Table 5. The sulfides have no electron in *d*-orbitals, but have lone-pair

*6 They have suggested the following mechanism of the oxygen evolution:

$$ROOH + ROH \rightleftharpoons ROO^- + ROH_2^+$$
(conjugate base) (conjugate acid)

$$ROO^- + ROOH \longrightarrow ROH + O_2 + RO^-$$

$$RO^- + ROH_2^+ \longrightarrow 2ROH$$

(R=α-cumyl)

electrons in the *p*-orbitals. They may act on CHP as nucleophiles and come to be sulfoxides themselves, which means that the hydrogen atom of CHP might migrate to the RO radical to form ROH in the transition state of the reaction. Detailed discussions will not be undertaken here, however, since the mechanism of the reaction of sulfides with hydroperoxide has been extensively discussed by many authors.[29-33]

In conclusion, the decomposition mechanism of cumene hydroperoxide by triphenylsulfonium chloride is schematically illustrated in Fig. 3.

The features of the present experiments may be summarized thus:

a) In the low-temperature range (55—80°C), triphenylsulfonium chloride decomposes CHP remarkably. The partially-occupied $3d_{z^2}$ orbital of the central sulfur atom of the sulfonium salt may participate in the cleavage of the O–O bond of CHP.

b) The chloride anion of the sulfonium catalyst seems to be connected with the heterolytic decomposition of CHP.

c) Among the decomposition products, AP and DCP are mainly formed, while CA is found only in small quantities.

d) Methyl alcohol is formed in appreciable amounts. The catalyst is likely to aid its formation.

e) The hydroxy radicals primarily formed are consumed to produce H_2O and CH_3OH.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 8—12 (1970)

Absorption Spectra of ^2E States of Some Chromium(III) Complexes Revealed by Flash Method

Takeshi OHNO and Shunji KATO

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received April 9, 1969)

Excited states of some chromium(III) complexes were studied by a flash technique at −196°C. Transient species with strong absorption bands in visible and near UV regions were observed to decay at the same rate as their phosphorescence for $Cr^{III}(acac)_3$, $K_3[Cr^{III}(NCS)_6]$, $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$, and $Cr^{III}(exan)_3$. They are therefore ^2E states (phosphorescent states). A strong absorption band for $Cr^{III}(acac)_3$ is assigned to a charge transfer transition from ^2E state based on the intensity and energy of the transition. A transition to localized excited states in ligand with a small extinction coefficient was observed in near infrared region for $Cr^{III}(acac)_3$.

It is known that triplet excited states of organic compounds play important roles in photochemical reactions.[1] Triplet excited states have often been confirmed in rigid media at low temperature by their phosphorescence and ESR signals.[2] However, they are scarcely observed in fluid media at room temperature, at which photochemical reactions usually take place. Absorption spectra of triplet excited states are observed with less difficulty by means of flash technique even in a condition where neither phosphorescence nor ESR signals were detected.[3]

Among coordination compounds of transition metals, many chromium(III) complexes are known to emit phosphorescence in rigid solvents[4]; the most prominent example is ruby laser.[5] The phosphorescent state has been assigned to ^2E state.[6] Although no phosphorescence has been observed for the complexes in fluid media at room temperature, ^2E states are believed to have a significant part in photoreactions.[7] Direct observation of these states is desirable for a precise discussion of the mechanism of the photochemical reactions of the complexes. These states are expected to be detected as absorption spectra in fluid media by means of flash technique.

For this purpose, it is desirable to examine favorable complexes which have high extinction coefficients in the excited states. Absorption bands due to *d–d* transition from ^2E state will be weak since such transitions are all parity-forbidden. It is hard

to analyze such weak bands because the measurements will be seriously interferred by the absorption of the ground state unchanged after flash irradiation. For this reason $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$, $K_3[Cr^{III}(NCS)_6]$, $Cr^{III}(acac)_3$,*1 and $Cr^{III}(exan)_3$,*2 were examined, the ^2E states of which were expected to show intense charge transfer absorptions in visble or near UV regions. In the present investigation, identification of transient absorption bands for these complexes was made, and the decay of the absorption bands was compared with that of their phosphorescence.

Experimental

Chromium(III) Complexes. They were prepared by the usual methods. Preparation of $NH_4[Cr^{III}(NCS)_4(NH_3)_2]\cdot 3/2H_2O$, $K_3[Cr^{III}(NCS)_6]\cdot 4H_2O$, $Cr^{III}(acac)_3$, and $Cr^{III}(exan)_3$ was based on the method by Dakin, Repsler, Cooperstein, and Dubsky respectively.[8]

Solvents. Ethanol was dried over calcium oxide, followed by refluxing with silver nitrate and distillation. Ether was dried over calcium chloride and distilled over metallic sodium. Isopentane was distilled over metallic sodium.

Polymer Rods doped with Chromium(III) Complexes. Methyl methacrylate monomer solution of a chromium(III) complex was polymerized in a glass tube at 40°C for three days using azobis-butyronitrile. The polymer rod thus prepared was cut in a length of 10 cm and polished at the ends with a fine emery. The polymer rods were clear and had no serious stria.

Measurements. A schematic diagram of the optical system is shown in Fig. 1. The output of the photomultiplier was recorded by a Hitachi synchroscope V-116. Two flash lamps were connected in series to a 4μF capacitor and fired at 10 kV. Cut-off filter transmitted light of wave numbers lower than 27 kK. A photomultiplier IP-28 (Hamamatsu TV Co.) was used for higher wave numbers, and a photomultiplier 7102 (Hamamatsu TV Co.) for lower wave numbers than 16 kK.

A quartz cell, 8 mm in inner diameter and 10 cm in optical path, was placed in a quartz Dewar vessel filled with liquid nitrogen. The polymer rod was placed in a coolant without cover.

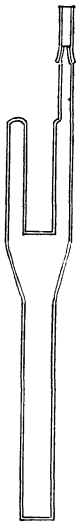

Fig. 2. Cross section of the quartz cell.

Results

When $Cr^{III}(acac)_3$, $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$, $K_3[Cr^{III}(NCS)_6]$, and $Cr^{III}(exan)_3$ were irradiated with flash light in EPA or rigid polymethyl methacrylate at −196°C, transient absorption spectra were observed without any permanent change. The spectra shown in Fig. 3 were constructed from the absorbances measured on the oscillograms obtained for different wave numbers of monitoring light, 20 μsec after the triggering of the photolysis flash. A typical oscillogram is shown in Fig. 4.

In Fig. 3, ΔA in the ordinate is the transient increase in absorbance caused by flash irradiation. ΔA is expressed as follows,

$$\Delta A = (\varepsilon_T C_T + \varepsilon_G \Delta C_G) l \qquad (1)$$

where ε_T and ε_G represent the molar extinction coefficients of the transient species and the complex in the ground state, respectively, C_T the concentration of the transient species, ΔC_G the transient decrease in the concentration of the ground state and l the optical path length. In order to obtain the

$Cr^{III}(acac)_3$: 5×10^{-4}M in EPA. Point upper left is 0% transmission, straight line at bottom 100% transmission, and one division 5 msec. Monitoring light is 18.5 kK.

true absorption spectrum of the transient species, a correction must be made for the term $\varepsilon_G \Delta C_G$. Although the number of molecules in the ground state transiently consumed by light absorption is difficult to estimate, it cannot exceed the number of photons absorbed by the sample. The number was measured by using the aqueous solution of the same complex as an actinometer, the quantum yield of which is known to be 0.28. The highest value of $-\Delta C_G$ thus obtained was 4.3×10^{-5} mol/l for $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$ in polymer. It follows that the correction to obtain true absorbance of the transient species is estimated to be 0.04 in the *d–d* bands at the largest. In the region of wave numbers lower than 15 kK, there is practically no absorption of the ground state to be corrected.

For the same concentrated solutions of $Cr^{III}(acac)_3$ and $K_3[Cr^{III}(NCS)_6]$ with that of $NH_4[Cr^{III}(NCS)_4(NH_3)_2]$, the highest values of $-\Delta C_G$ are similar to that of the last, because both solutions of the complexes have very similar absorption spectra to that of the last in visible regions. Over

—●—: phosphorescence at 12.8 kK
* I_p=intensity of phosphorescence

27 kK in the case of $Cr^{III}(acac)_3$, the largest correction (0.14) appears. Even this largest possible value is less than one fifth of the observed absorbance change. Thus the ΔA spectra in Fig. 3 can be regarded as the spectra of the transient species without correction.

The general features of transient spectra resemble each other, although peaks in UV regions for some complexes are obscure on account of the interference of the intense charge transfer absorption of the ground states. A weak absorption band appears in near IR regions only for $Cr^{III}(acac)_3$. For other complexes, no such band was detected even in the conditions of higher flash energy.

Table 1. Life-time of the trasient species at −196°C

Complex	Solvent	Life-time (msec) Absorption	Phosphorescence	
$Cr^{III}(acac)_3$	EPA	0.33	0.36	0.42*
$Cr^{III}(acac)_3$	polymer	0.44	0.44	
$Cr^{III}(exan)_3$	EPA	0.28	0.31	
$K_3[Cr^{III}(NCS)_6]$	EPA	10.1	9.6	2.38*

* measured by L. S. Forster at −140——150°C in ethylene glycol and water (2 : 1) except for $Cr^{III}(acac)_3$ in EPA at −188°C.[9]

9) K. K. Chatterjee and L. S. Forster, *Spectrochim. Acta*, **20**, 1603 (1964); D. C. Bhatnagar and L. S. Forster, *ibid.*, **21**, 1803, (1965); K. DeArmond and L. S. Forster, *ibid.*, **19**, 1687, (1963).

The transient absorption decayed in a first order process (Fig. 5), and the decay constant for each complex was independent of the monitoring wave number. This result proves that the whole spectrum is due to a single transient species.

Phosphorescence also decayed in a first order process (Fig. 5). The rate constants are represented in Table 1 with those for the transient absorptions. The coincidence between the life-time of the transient absorption and that of the phosphorescence for each complex indicates that both measurements were made for the same species in different ways.

Molar extinction coefficients of the transient species can be calculated from the absorbances and the numbers of photon absorbed, if the quantum yields of the species are known.

The values ε' in Table 2 are calculated on a tentative assumption that the quantum yields are equal to unity. A discussion for ε will be given.

Table 2. Life-time of the transient species at −196°C

Complex	Solvent	Peak kK (cm^{-1})	ε'	ε
			10^3 l/mol·cm	
$NH_4[Cr^{III}(NCS)_4(NH_3)_2]$	polymer	18.6	1.1	3.8
		27	0.8	2.8
$K_3[Cr^{III}(NCS)_6]$	EPA	18.6	1.8	3.8
		26	1.9	4.0
$Cr^{III}(acac)_3$	EPA	13.5	0.2	0.3
		18.5	2.2	3.3
		27	1.4	2.1

Discussion

1) Origin on the Transient Spectra. It is established that the phosphorescence states of trivalent chromium complexes in rigid media are ^2E states. The good agreement of the life-time of the transient spectrum with that of the phosphorescence for each complex may lead to the conclusion that the spectrum is due to the ^2E state. The life-time obtained in the present investigation is comparable with the values measured by Forster at −140——150°C as seen in Table 1.

2) Assignments of the Transient Absorption Bands. The extinction coefficients of the transient species ^2E estimated by assuming that the quantum yields Φ_E of the doublet states are unity, are the lowest possible values. These values are high to attribute the transient absorption bands to the *d–d* transition from ^2E state because they are parity-forbidden. The most probable assignments are charge transfer transitions as expected at the beginning.

Forster *et al.* reported the phosphorescence quantum yields (Φ_P), the natural life-times (τ_0), and the actual life-times (τ) of some chromium complexes. Employing these values, Φ_Es of NH_4-

$[Cr^{III}(NCS)_4(NH_3)_2]$, $Cr^{III}(acac)_3$, and $K_3[Cr^{III}(NCS)_6]$ are calculated by the following equation to be 0.29, 0.67, and 0.47, respectively.

$$\Phi_E = \frac{\tau_0}{\tau} \times \Phi_P \qquad (2)$$

The extinction coefficients corrected on the basis of these values are given in the last column of Table 1.

Barrunum assigned the electronic spectrum of $Cr^{III}(acac)_3$ by comparing it with many acetylacetonate complexes.[10] Hanazaki and Nagakura calculated completely the energy levels of the same complexes, using "composite molecule method" and obtained assigments similar to Barrunum's[10]. In Fig. 6 solid lines show the energy levels observed in the absorption spectrum of the complex and assigned by Hanazaki and Nagakura. The levels of doublet states represented by broken lines are calculated by the method presented by Tanabe and Sugano[12] using parameters, $Dq=1.78$, $B=0.57$, and $C=4\times B=2.28$ kK.

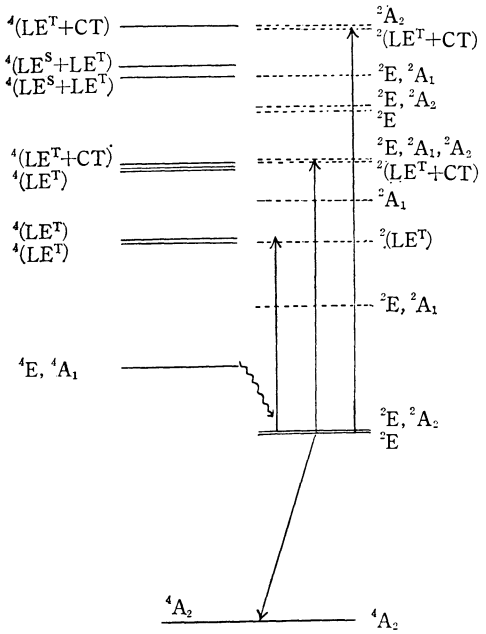

Fig. 6. Energy levels of $Cr^{III}(acac)_3$.
Solid line shows energy level of the quartet state, broken line a calculated energy level of the doublet state, and solid arrow the transition observed in this work.
LE^T: triplet state on localized excitation in ligand
LE^S: singlet state on localized excitation in ligand
CT: charge transfer excited state

Quartet charge transfer states are located 30.1 and 39.2 kK above the ground $^4A_2$ state. The energy levels of the doublet charge transfer states may not be much apart from that of the corresponding quartet state. Since ^2E state is 12.8 kK higher than the ground state, the energy differences between the doublet charge transfer states and ^2E state are 17.3 and 26.3 kK, which agree with the wave numbers of the peaks of the transient absorption spectrum.

The weak band at 13 kK for $Cr^{III}(acac)_3$ might be due to a d–d transition from ^2E state considered from the magnitude of the extinction coefficient. The energy level of $^2A_1$ state is calculated to be 14.95 kK above ^2E state, which is only 1.5 kK greater than the observed value. However, it is difficult to explain why similar bands in near IR regions were not observed for other compounds.

Another possible assignment of this band is the charge transfer transition to $^2(LE^T)$ state, which is inferred to be located 13 kK higher than ^2E state as seen in Fig. 6. This assignment is more plausible because the transition to $^4(LE^T)$ state appears in the spectrum of the ground state only for $Cr^{III}(acac)_3$ among all compounds examined.

The authors are grateful to Dr. Ichiro Hanazaki for his help to assign the transitions from ^2E state of $Cr^{III}(acac)_3$. A financial support from Fuji Photo Film Co., Ltd. is acknowledged.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 13—19 (1970)

Temperature Dependence of Fluorescence Spectra and Fluorescence Polarization of Some Organic Compounds in Polar Solvents. The Franck-Condon Excited States

Hiroaki BABA and Chie MUGIYA*1

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received May 30, 1969)

Fluorescence and absorption spectra and fluorescence polarization were measured at different temperatures, ranging from room temperature to 77°K, for 9,10-diazaphenanthrene, 2-naphthol and 2,3-naphthalenediol in polar solvents. At about 120°K, the fluorescence spectra shifted rapidly to the blue as the temperature was lowered. This observation is quantitatively interpreted on the basis of a kinetic scheme involving competitive rate processes, *viz.*, radiative transition from the Franck-Condon excited state, as defined for the dipole orientation of the solvent, and relaxation of the Franck-Condon state into the equilibrium excited state. The Franck-Condon destabilization energies are evaluated from the observed blue shifts. Along with the fluorescence blues hifts, the degrees of polarization increased rapidly, but at a somewhat higher temperature of about 140°K. This phenomenon is related to the rotational relaxation of the solute molecule, and is discussed in comparison with the fluorescence blue shift.

It is generally accepted that, in organic compounds in solution, absorption and emission transitions occur according to the Franck-Condon principle.[1-4] The effect of this principle on the electronic spectra is of especial importance when both solute and solvent molecules are polar, and there is a difference in the dipole moment between the ground and excited states of the solute. At the instant of the formation of its excited state, the solute molecule is considered to be surrounded by the solvent molecules whose orientation is appropriate to the ground state of the solute. Such a situation is referred to as the Franck-Condon excited state. This state may pass into the equilibrium excited state, where the solvent orientation is appropriate to the excited state, through a process of relaxation. Thus the fluorescence transition originates usually from the equilibrium excited state.

A few attempts have been made to obtain experimental evidence for the participation of the Franck-Condon principle in the solvent effect on the electronic spectra of aromatic compounds.[2-4] These investigations are based on the idea that the relaxation process mentioned above should be inhibited if the solvent has such a high viscosity that the relaxation time is longer than the fluorescence lifetime.

In addition to the relaxation of the solvent orientation from the Franck-Condon into the equilibrium excited state, rotational relaxation of the solute molecule may occur during the fluorescence lifetime, which leads to the depolarization of the fluorescence.[5-7] The two relaxation processes would be correlated with each other through the viscosity and hence the temperature of the solvent.

The purpose of the present study is to obtain detailed and definite information as to the Franck-Condon excited state by dealing quantitatively with these relaxation phenomena. Thus, absorption and fluorescence spectra along with degrees of fluorescence polarization were measured in a wide range of temperature with 9,10-diazaphenanthrene, 2-naphthol and 2,3-naphthalenediol as polar solutes. It has been reported[8] that for the diazaphenanthrene the dipole momet is smaller in the fluorescent

excited state, which is of an (n,π^*) type,[9] than in the ground state.

Experimental

Materials. 9,10-Diazaphenanthrene (Aldrich Chemical Co., U.S.A.) was purified either by the method described in a previous paper[8] or by zone melting. 2-Naphthol and 2,3-naphthalenediol were recrystallized from ligroin and from water, and were further purified by vacuum sublimation.

Mixtures of isopentane and *n*-butyl chloride (volume ratio, 6.5 : 3.5) and of ethyl ether, isopentane and ethanol (volume ratio, 8 : 3 : 5) were used as polar solvents; these mixtures, abbreviated to PB and EPA respectively, give good rigid glasses at 77°K. Isopentane was passed through a freshly activated silica-gel column, and the other solvents were purified by methods described in "Organic Solvents."[10]

Apparatus and Procedure. Absorption spectra were obtained with a Hitachi EPS-3 spectrophotometer, and fluorescence spectra and their polarizations were measured with an apparatus constructed in our laboratory.[11] All these measurements were made on sample solutions in a 1-cm square quartz cell which was placed in a glass Dewar with quartz windows. For cooling the sample cell, nitrogen gas was passed through liquid nitrogen, and then led to the Dewar. The cell could be maintained at any desired temperature between 280 and 77°K by controlling the flow velocity of the nitrogen gas. The errors in the temperature were estimated to be ±1°K. The degrees of polarization, P,[11] were measured by the method of photoselection, and were corrected for instrumental factors in the usual manner.[11]

Results

The fluorescence and absorption spectra of 9,10-diazaphenanthrene, 2-naphthol and 2,3-naphthalenediol observed at different temperatures are shown in Figs. 1—3. To avoid confusion the spectral curves are moved upward successively. The position of the fluorescence maximum or peak is plotted against temperature in Figs. 4—6.

The P values for the fluorescence with respect to excitation into the lowest singlet excited state were determined at different temperatures. The results are shown in Figs. 4—6.

Discussion

Since polar substances were employed as solutes and solvents in this study, the solute dipole-solvent dipole interaction is expected to play a major role in understanding the behavior of the observed electronic spectra. The ground state of a solute molecule will hereafter be denoted by g, and the lowest singlet excited state in which we are interested will be denoted by e. Thus, the dipole moments in the g and e states are expressed as μ_g and μ_e, respectively.

For 9,10-diazaphenanthrene, $\mu_g = 3.9$D;[12] the e state is known to be of an (n,π^*) type,[9] and the value of μ_e was determined to be 1.15D from the solvent effect on the absorption and fluorescence spectra.[8] Thus the electronic transition $g \rightarrow e$ is accompanied by a marked decrease in the dipole moment. For 2-naphthol, $\mu_g = 1.4$D;[12] the e state is the $L_b(\pi,\pi^*)$, and the dipole moment increases by 0.5—1D on going from the g to the e state.[13] As regards 2,3-naphthalenediol no pertinent data are available for μ_g and μ_e values, but the situation is probably similar to that in 2-naphthol.

Franck-Condon Blue Shift. An absorption transition occurs in general from the equilibrium ground state to the Franck-Condon excited state.

12) A. L. McClellan, "Tables of Experimental Dipole Moments," W. H. Freeman and Company, San Francisco (1963).

13) N. Mataga, Y. Kaifu and M. Koizumi, This Bulletin, **29**, 465 (1956).

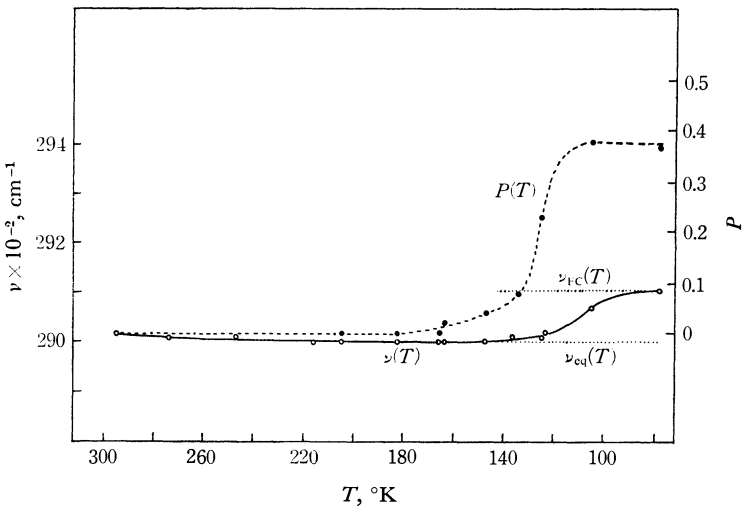

Fig. 6. Plots of ν and P *vs.* T for 2,3-naphthalenediol in EPA.
ν represents the frequency of the fluorescence peak at about 29000 cm^{-1}.

If it is assumed that there is complete reorientation of the solvent dipoles in the excited state, the fluorescence transition will start from the equilibrium excited state for the Franck-Condon ground state where the solvent orientation is appropriate to the excited state.

Dielectric constants (D) and refractive indices (n) of solvents will increase with a decrease of the temperature. On the above assumption, we expect from the theory of the solvent effect[13,14] that as the temperature decreases both the absorption (corresponding to $g \rightarrow e$) and fluorescence (corresponding to $e \rightarrow g$) spectra are gradually displaced to the blue for 9,10-diazaphenanthrene in which $\mu_e < \mu_g$, and to the red for 2-naphthol and 2,3-naphthalenediol in which $\mu_e > \mu_g$. This expectation is fulfilled in the case of the absorption spectra (*cf.* Figs. 1—3). The fluorescence spectra show similar behaviors at temperatures higher than 120°K.

With all the solute compounds studied, the fluorescence spectrum shifts rapidly to the blue as the temperature is lowered below 120°K. At such low temperatures the solvent becomes rigid, and the reorientation of the solvent dipoles will be inhibited partly or completely, depending on the viscosity of the solvent. The blue shift is therefore attributable to the fact that the fluorescence transition occurs also from the Franck-Condon excited state. The blue shift of this kind will be called a "Franck-Condon blue shift." In the light of the foregoing discussions, it can readily be understood that such a blue shift does not take place in the case of the absorption transition.

In Figs. 4—6, $\nu(T)$ represents the frequency in wavenumbers of the fluorescence maximum or peak which was actually observed as a function of temperature. Let $\nu_{eq}(T)$ and $\nu_{FC}(T)$ represent the corresponding frequencies which would be observed if the fluorescence were to originate exclusively in the equilibrium excitated state and the Franck-Condon excited state, respectively. At high temperatures $\nu_{eq}(T)$ will agree with $\nu(T)$, whereas in the low-temperature region where the Franck-Condon blue shift takes place, $\nu_{eq}(T)$ must deviate from $\nu(T)$. For the latter region, $\nu_{eq}(T)$ curve was obtained by extrapolation from the $\nu(T)$ curve at higher temperatures. (See the dotted lines in Figs. 4—6.)

On the other hand, $\nu_{FC}(T)$ is considered to agree with the observed $\nu(T)$ at temperatures near 77°K. The $\nu_{FC}(T)$ curve for the higher temperatures was obtained again by extrapolation.

Now, let $\nu_{eq}(T)$ and $\nu_{FC}(T)$ at 77°K be written as ν^0_{eq} and ν^0_{FC}. Then, the difference

$$\delta\nu^0_{FC} = \nu^0_{FC} - \nu^0_{eq} \ (= E^0_{FC}/\boldsymbol{hc}) \qquad (1)$$

corresponds to the sum of the Franck-Condon destabilization energies, denoted by E^0_{FC}, for the

Table 1. Constants related to temperature dependence of fluorescence spectra and fluorescence polarization

	9,10-Diazaphenanthrene in PB	2-Naphthol in EPA	2,3-Naphthalenediol in EPA

$E_{a,r'}$ (kcal/mol)	6.5	8.3	7.0

14) E. G. McRae, *J. Phys. Chem.*, **61**, 562 (1957).

excited and ground states at 77°K. In Eq. (1), h is the Planck constant, and c is the volocity of light. The values of $\delta\nu^0_{FC}$ and E^0_{FC} are given in Table 1.

In general, absorption and fluorescence bands of a polar solute molecule will undergo frequency shifts on changing the solvent from a nonpolar to a polar substance. Their respective frequency shifts will be designated as $\Delta\nu_a$ and $\Delta\nu_f$. If, at a given temperature, the viscosity of the solvent is so low that the fluorescence is observed only from the equilibrium excited state, $\Delta\nu_a-\Delta\nu_f$ corresponds to the sum of the Franck-Condon destabilization energies, denoted by E_{FC}, at that temperature. According to McRae,[14] $\Delta\nu_a-\Delta\nu_f$ $(=E_{FC}/hc)$ is approximately given as*2

$$\Delta\nu_a-\Delta\nu_f=\frac{E_{FC}}{hc}\simeq\frac{2}{hc}\frac{(\mu_g-\mu_e)^2}{a^3}\left[\frac{D-1}{D+2}-\frac{n_D^2-1}{n_D^2+2}\right] \quad (2)$$

where a is the cavity radius, and n_D and D are the refractive index for the sodium D line and dielectric constant of the polar solvent. Equation (2) shows that E_{FC} should be large when dipole moments differ greatly between the ground and excited states and the solvent has a large orientation polarization.

For 9,10-diazaphenanthrene in PB, $\delta\nu^0_{FC}$ amounted to 610 cm^{-1}, while $\Delta\nu_a-\Delta\nu_f$ at 23°C was found to be 250 cm^{-1} with n-pentane as the nonpolar reference solvent; that is, the E_{FC} value is much larger at 77°K than at room temperature. This observation is in agreement with the expectation that when the temperature is lowered the D value of the solvent will increase to a far greater extent than its n_D value.

It is seen in Table 1 that E^0_{FC} for 9,10-diazaphenanthrene is considerably large as compared with E^0_{FC} for the naphthalene derivatives. This might be interpreted as due to the fact that $(\mu_g-\mu_e)^2$ is of much higher value for the diazaphenanthrene.

Relaxation from the Franck-Condon Excited State into the Equilibrium Excited State. Let $\delta\nu(T)$ denote the difference between $\nu(T)$ and $\nu_{eq}(T)$:

$$\delta\nu(T)=\nu(T)-\nu_{eq}(T) \quad (3)$$

The experimental results shown in Figs. 4—6 were found to be reproduced very well by empirical relations of the following type:

$$\delta\nu^0_{FC}/\delta\nu(T)=1+c_1\exp(-c_2/T) \quad (4)$$

where c_1 and c_2 are constants inherent to each of the solute-solvent systems. In Fig. 7 are shown the $\delta\nu(T)$ curves as obtained from Eq. (4) with the constants c_1 and c_2 given in Table 1. In the same figure are also given the experimental points, which

*2 The meaning of the symbol $\Delta\nu$ used in this paper is different from that of the same symbol in McRae's paper. It can be shown, however, that in either case $\Delta\nu_a-\Delta\nu_f$ is expressed in the same form.

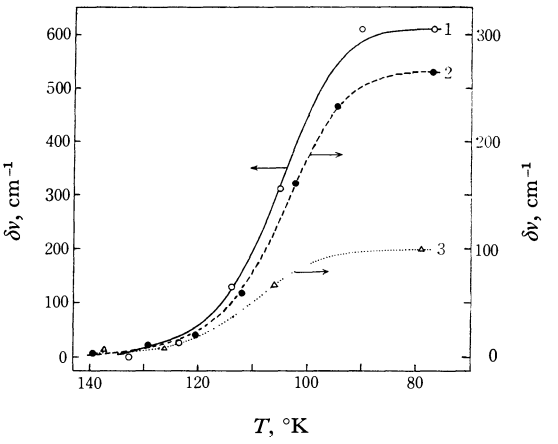

Fig. 7. Calculated $\delta\nu(T)$ curves and experimental points.

are seen to fall on the $\delta\nu(T)$ curves.

The relaxation process in which the solvent molecules surrounding the excited solute molecule reorient themselves from the Franck-Condon to the equilibrium state is assumed to be of the first order with respect to the solute. The deactivation processes of the solute molecule can then be represented by a kinetic scheme shown in Fig. 8, with the rate constants denoted by k's. Here the asterisk refers to the excited state, f and q mean fluorescent and nonfluorescent transitions, respectively, and the subscript r indicates the relaxation process mentioned above. Among the various rate constants, k_r is considered to be particularly sensitive to temperature; hence it is written as $k_r(T)$, the other constants being regarded as independent of temperature.

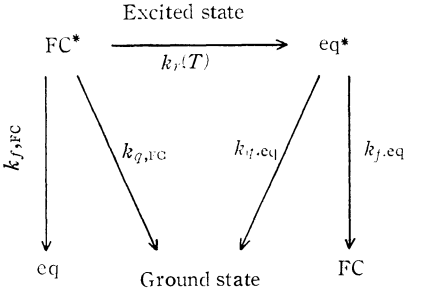

Fig. 8. Kinetic scheme of deactivation processes.

Let $\phi_{FC}(T)$ and $\phi_{eq}(T)$ denote the quantum yields of the fluorescence emissions from the Franck-Condon and equilibrium excited states, respectively. Then it follows from the scheme of Fig. 8 that

$$\phi_{FC}(T)=\frac{k_{f,FC}}{k_r(T)+k_{f,FC}+k_{q,FC}} \quad (5)$$

$$\phi_{eq}(T) = \frac{k_r(T)}{k_r(T) + k_{f,FC} + k_{q,FC}} \times \frac{k_{f,eq}}{k_{f,eq} + k_{q,eq}} \quad (6)$$

It is to be expected that, if both $\phi_{FC}(T)$ and $\phi_{eq}(T)$ are of finite values, there appear simultaneously two kinds of fluorescence spectra associated with FC*→eq and eq*→FC transitions. Actually this is not the case, as is seen from Figs. 1—3, so that the two spectra in question are assumed to coalesce into a single spectrum. It is further assumed that the frequency of the fluorescence maximum or peak is expressed as

$$\nu(T) = \frac{\phi_{FC}(T)}{\phi_{FC}(T) + \phi_{eq}(T)}\nu_{FC}(T) + \frac{\phi_{eq}(T)}{\phi_{FC}(T) + \phi_{eq}(T)}\nu_{eq}(T) \quad (7)$$

A combination of Eqs. (3) and (5)—(7) leads to the following equation:

$$\delta\nu^0_{FC}/\delta\nu(T) = 1 + \tau_f k_r(T) \quad (8)$$

where τ_f is the lifetime of the fluorescence from the equilibrium excited state, *i. e.*,

$$\tau_f = 1/(k_{f,eq} + k_{q,eq})$$

In the derivation of Eq. (8), assumptions have been made that

$$k_{f,FC} \simeq k_{f,eq}$$

and

$$\nu_{FC}(T) - \nu_{eq}(T) = \delta\nu_{FC}(T) \simeq \delta\nu^0_{FC}$$

The latter relation is to be reasonable in the limited range of T under consideration.

Let us express $k_r(T)$ by an equation of the Arrhenius type, that is

$$k_r(T) = A\exp(-E_{a,r}/RT) \quad (9)$$

and put

$$\tau_f A = c_1 \quad (10)$$

$$E_{a,r}/R = c_2 \quad (11)$$

Then Eq. (8) becomes identical in form with Eq. (4). In other words, in the empirical relation of Eq. (4), c_1 is related to the fluorescence lifetime τ_f, and c_2 to the activation energy $E_{a,r}$ of the relaxation process. It may be noted in this connection that the natural lifetimes, τ°_f, of 9,10-diazaphenanthrene, 2-naphthol and 2,3-naphthalenediol as obtained from the absorption intensities are 5.0×10^{-7}, 5.7×10^{-8} and 4.5×10^{-8} sec, respectively. From these τ°_f values and a knowledge of the fluorescence quantum yields, the actual lifetime, τ_f, was estimated to be about 5×10^{-8} sec for 9,10-diazaphenanthrene and about 1×10^{-8} sec for the two naphthalene derivatives. The values of $E_{a,f}$ obtained from the c_2 values are given in Table 1.

The relaxation time for the process FC*→eq* (Fig. 8) will be denoted by $\tau_r(T)$. Since $\tau_r(T) = 1/k_r(T)$, it follows from Eq. (8) that

$$\frac{\delta\nu^0_{FC}}{\delta\nu(T)} = 1 + \frac{\tau_f}{\tau_r(T)} \quad (12)$$

It is seen that, at the temperature where $\delta\nu(T) = (1/2)\,\delta\nu^0_{FC}$, $\tau_r(T)$ is equal to τ_f; that is, the relaxation time is of the order of 10^{-8} sec.

In the foregoing argument the fluorescence lifetime τ_f was defined with respect to the equilibrium excited state. It would not be unreasonable to presume that

$$k_{q,FC} \simeq k_{q,eq}$$

Then, if $k_r(T)\to0$, the lifetime of the Franck-Condon excited state becomes equal to τ_f. With finite values of $k_r(T)$, the former lifetime will be shorter than τ_f. Even in such cases, however, the mean lifetime of the excited solute molecules as a whole, which include the molecules belonging to the Franck-Condon excited state and to the equilibrium excited state, is found to be given by τ_f.*3 Thus, in the following discussion, τ_f will be used as the fluorescence lifetime regardless of the vlaues of $k_r(T)$.

Temperature Dependence of Fluorescence Polarization and Rotational Relaxation. As is seen in Figs. 4—6, the fluorescence P values increase rapidly as the temperature is lowered below 140°K; this temperature is somewhat higher than the temperature where the fluorescence blue shifts begin.

The temperature dependecnce of the fluorescence polarization is obviously related to the rotational relaxation of the solute molecule. At 77°K, the viscosity of the solvent must be too high for the solute molecule to rotate within the fluorescence lifetime τ_f. The value of P at this temperature, denoted by P_0, will therefore be regarded as its value in the absence of rotational relaxation. At higher temperatures the rotational depolarization of fluorescence may take place, and the P value will be given by [6,7]

$$\frac{1/P(T) - 1/3}{1/P_0 - 1/3} = 1 + \frac{\tau_f}{\tau_{r'}(T)} \quad (13)$$

where $\tau_{r'}(T)$ stands for the relaxation time for rotation of the solute molecule. It should be noted that Eq. (13) is analogous to Eq. (12).

Since $k_r(T) = 1/\tau_r(T)$, it follows from Eq. (9) that

$$1/\tau_r(T) = A\exp(-E_{a,r}/RT) \quad (14)$$

Similarly, $1/\tau_{r'}(T)$ is expressed as

*3 This statement is based on the following considerations. According to the kinetic scheme of Fig. 8

$$dN^*_{eq}/dt = -[k_r(T) + k_{f,FC} + k_{q,FC}]N^*_{FC}$$

$$dN^*_{eq}/dt = k_r(T)N^*_{FC} - (k_{f,eq} + k_{q,eq})N^*_{eq}$$

where N^*_{FC} and N^*_{eq} are the numbers of molecules belonging to the FC* and eq* states, respectively. Combining these equations on the assumption that $k_{f,FC} \simeq k_{f,eq}$ and $k_{q,FC} \simeq k_{q,eq}$, we obtain

$$d(N^*_{FC} + N^*_{eq})/dt = -(k_{f,eq} + k_{q,eq})(N^*_{FC} + N^*_{eq})$$

$$1/\tau_{r'}(T) = A' \exp(-E_{a,r'}/RT) \quad (15)$$

The $P(T)$ curves shown in Figs. 4—6 were found to be satisfactorily represented by Eq. (13) with $\tau_{r'}(T)$ in the form of Eq. (15). Thus, the activation energies $E_{a,r'}$ were determined from the analysis of the $P(T)$ curves, with the results listed in Table 1.

Comparison of the Two Relaxation Processes. We are concerned with two relaxation processes; one is associated with the passage from the Franck-Condon to the equilibrium excited state, and the other is the rotational relaxation of the solute. These relaxation processes will hereafter be represented by R and R′, respectively.

The relation between the relaxation R′ and fluorescence depolarization is generally established, and is represented by Eq. (13). The temperature dependence of ν, on the whole, is similar to that of P, and the observed $\nu(T)$ curve at low temperatures can be explained by the kinetic scheme of Fig. 8, which leads to Eq. (8) or (12). As has been pointed out, Eq. (12) is analogous to Eq. (13). Both equations are of the same form, and involve one and the same fluorescence lifetime, τ_f. Furthermore, τ_r and $\tau_{r'}$ are dependent on a common factor, *i. e.*, the viscosity of the solvent. Thus, we might conclude that the rapid blue shift of the fluorescence spectra at low temperatures is due to prohibition of the relaxation process R.

Let us turn to discussion of the difference between the two relaxation phenomena. It was experimentally found that, in every case, the ratio of the left-hand side of Eq. (12) to that of Eq. (13) was larger than unity in the temperature region of interest (*cf.* Figs. 4—6). This along with the expressions of Eqs. (12) and (13) means that $\tau_r(T) < \tau_{r'}(T)$; further, it is seen in Table 1 that $E_{a,r} < E_{a,r'}$

The above observations may be rationalized by considering the difference between the detailed mechanisms of the two relaxation processes. In the relaxation R, the solvent dipoles in the vicinity of the solute molecule reorient themselves to a configuration which is energetically favorable in relation to the charge distribution of the excited state of the solute. On the other hand, in the relaxation R′ the excited solute molecule must rotate with reference to laboratory-fixed coordinate axes, and such a rotational motion is presumably hindered by attraction between solute and solvent molecules, produced by dipole-dipole interaction or hydrogen bonding. Therfore, one may expect that the relaxation R occurs more easily than the relaxation R′, and that $\tau_r(T) < \tau_{r'}(T)$ and $E_{a,r} < E_{a,r'}$.

Other Related Problems. For 2-naphthol and 2,3-naphthalenediol, EPA was used as the solvent; accordingly, a hydrogen-bonded complex was probably formed between the solutes and the solvent. In general, the Franck-Condon principle should be taken into account also with respect to hydrogen bonding.[15] It is inferred, however, that in the case of the hydrogen-bonded complex in question the relaxation from the Franck-Condon to the equilibrium excited state of the complex is completed within the fluorescence lifetime, even at 77°K.[16] For this reason, in the discussion of the fluorescence blue shift, no consideration has been given to the relaxation process involving hydrogen bonding.

It has been recognized that often the Arrhenius equation is not applicable to the temperature dependence of dielectric and other relaxation processes in liquids at low temperatures where the liquid substances show glassy behavior.[17] As has been stated, however, the present experimental results were satisfactorily analyzed with the relaxation times $\tau_r(T)$ and $\tau_{r'}(T)$ expressed in the forms of Eqs. (14) and (15) which are based on the Arrhenius equation.

In Figs. 1—3 are shown in part the second electronic absorption bands. In 9,10-diazaphenanthrene the second absorption band corresponds to the $g \rightarrow L_b$ transition, and in the naphthalene derivatives it corresponds to the $g \rightarrow L_a$. On lowering the temperature, each of these absorption bands is gradually displaced to the red as may be expected.

The authors wish to express their thanks to Dr. Satoshi Suzuki for his help in carrying out the polarization measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 20—23 (1970)

Steric Structure of L-Proline Oligopeptides. III. Calculated Absorption Spectra of L-Proline Oligopetides

Hirofumi OKABAYASHI and Toshizo ISEMURA

Physical Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received June 2, 1969)

The electronic excited states in L-proline oligopeptides were derived from molecular-exciton theory. The dipole-dipole approximation was used in the calculation of transition energies. The calculated absorption spectra related to the conformation of L-proline oligopeptides were compared with observed ones. A satisfactory agreement between the calculated and observed results was obtained.

In previous papers[1,2] the ultraviolet absorption spectra of *N*-tertiary amyloxy carbonyl-L-prolyl oligopeptides synthesized in a stepwise manner were reported. The red shifts of the absorption maxima were related to the conformation. By means of ORD[1] and CD[1] spectra, it was established that the appearance of the helical conformation commences at the tetramer, while the pentamer, hexamer and octamer have the poly-L-proline II-like conformation. Band splitting of the absorption spectra of the dimer was observed. The very broad absorption spectrum of the trimer might be due to three absorption maxima with almost the same intensities. It was also found that the absorption maxima on the longest-wavelength side of the tetramer, pentamer, hexamer and octamer are identical with the shoulder around 200 mμ found in the dimer, but with an increased intensity. Consequently, the absorption band with perpendicular polarization is expected to appear as a shoulder at about 185 mμ (Table 1[1,2] and Fig. 1[1,2]).

According to these results, the absorption maximum around 203 mμ of poly-L-proline II has been identified as the shoulder with an increased intensity around 200 mμ found in the spectra of the dimer.[1,2]

Some investigators[3] have tried to observed band

splitting of the absorption spectra of poly-L-proline I and II without success.

In this study the calculations of the absorption spectra of L-proline oligopeptides were attempted by Tinoco's method[4-6] and compared with the observed absorption spectra. Good agreement between the calculated and the observed absorption spectra was found.

Optical properties of the α-helix and the 3_{10}-helix of polypeptides have been calculated by Tinoco and Woody[5] and the chainlength dependence of the absorbance was thoroughly discussed. Tinoco and Woody[5] have also found that there was satisfactory agreement between experimental absorption spectra and the calculated results. However, the calculated absorption spectra of oligopeptides have not yet been compared with experimental results.

Theory

Following the general expressions used by Tinoco *et al.*;[5,6] the ground state wave function of a oligomer is represented by

$$\Psi = \phi_1\phi_2\phi_3 \cdots \phi_N \tag{1}$$

and a singly excited state, localized at molecule i, by

$$\Psi'_i = \phi_1\phi_2\phi_3 \cdots \phi'_i \cdots \phi_N \tag{2}$$

where ϕ_i and $\phi_{i'}$ are the residue ground- and singly excited state wave functions, respectively, and N is the number of residue.

The perturbed, singly excited states of the oligopeptides are written as follows:

$$\Psi'_K = \sum_{i=1}^{N} C_{iK}\Psi'_i \qquad K = 1, 2, 3, \cdots N \tag{3}$$

The Hamiltonian of the oligomer is represented by

$$\boldsymbol{H} = \sum_{i}^{N} H_i + \sum_{i<j}^{N} \boldsymbol{V}_{ij} \tag{4}$$

where $\boldsymbol{V}_{ij}$ is the interaction operator between residue i and j.

The coefficients, C_{ik}, and the eigenvalues, E_k, are obtained by solving the secular equation

$$D_N = |\, V_{ij} - \delta_{ij}E \,| = 0 \tag{5}$$

The secular determinant D_H has the form,

$$D_N = \begin{vmatrix} V_{11}-E & V_{12} & V_{13} & \cdots & V_{1N} \\ V_{21} & V_{22}-E & V_{23} & \cdots & V_{2N} \\ V_{31} & V_{32} & V_{33}-E & \cdots & V_{3N} \\ V_{41} & V_{42} & V_{43} & \cdots & V_{4N} \\ \vdots & \vdots & \vdots & & \vdots \\ V_{N1} & V_{N2} & V_{N3} & \cdots & V_{NN}-E \end{vmatrix} \tag{6}$$

where $V_{ij} = \langle \phi_i | \boldsymbol{H} | \phi'_i \rangle$ $(i \neq j)$ and $V_{ij} = \langle \phi_i | \boldsymbol{H} | \phi'_i \rangle$

Calculation and Results

Figure 2 shows the coorodinate system[7] for the calculation of the absorption spectra of L-proline oligopeptides. The three fold axis of the oligopeptides is identical with the z axis perpendicular to the plane of the paper. Each residue of the oligomers is located around the three fold axis on the assumption that the tetramer, pentamer, hexamer and octamer exist entirely in a poly-L-proline II-like structure and the dimer and trimer assume the same conformation as found in the helical structure of poly-L-proline II.

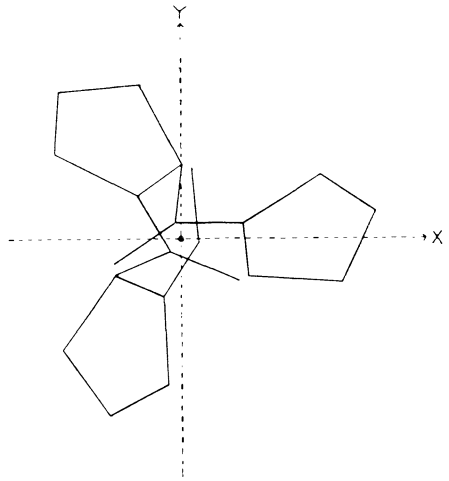

Fig. 2. Schematic representation of the poly-L-proline II-like structures of L-proline oligopeptides. Cowan and McGavin's coordinate system[7] is used.

It is assumed that the magnitude and direction of the π–π^* transition moment μ in the peptide groups of L-proline oligomers are the same as those of π–π^* transition moment (μ=3.05D) for the absorption at 190 mμ in myristamide.[8] This assumption seems to be the most reasonable approximation at the present time. In the calculations the

dipole-dipole approximation for the interaction potential was used:

$$V_{ij} = \frac{(\mu_i \cdot \mu_j)}{R_{ij}^3} - 3\frac{(\mu_i \cdot \boldsymbol{R}_{ij})(\mu_i \cdot \boldsymbol{R}_{ij})}{R_{ij}^5} \qquad (7)$$

where μ_i is the π-π^* transition dipole moment of the ith peptide group with $\mu_i = \mu$ and R_{ij} the distance between the $\pi = \pi^*$ transition dipole moment of the ith peptide group and that of the jth peptide group, and moreover the nearest neighbor interaction and all neighboring interaction were considered.

The calculated values of the absorption maxima and the dipole strengths of L-proline oligopeptides are shown in Fig. 3.

The absorption band maxima with parallel polarization at the longest-wavelength side apparently are displaced to red with increasing chain length. Moreover, the calculated absorption maxima also are convergent as are the observed ones. Naturally the perpendicular band maxima should converge. In these calculations the maxima of the calculated perpendicular bands tend to converge at about 186 mμ.

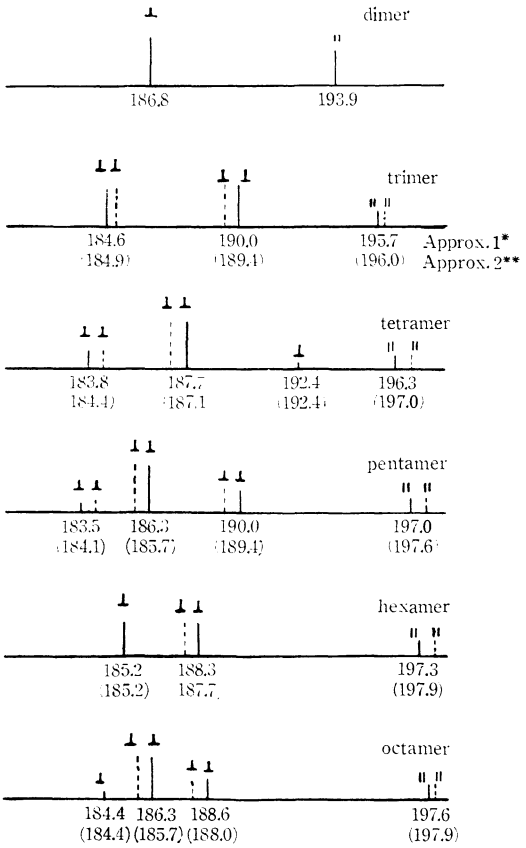

Fig. 3. Calculated absorption spectra and calculated dipole strengths of L-proline oligopeptides. The values and the direction of μ are chosen to coincide with those of the 1900 A transition in myristamide.

* The calculations were carried out by the nearest neighbor approximation.

** All neighboring interactions were considered in this approximation.

The solid lines are obtained by approximation 1 and the broken lines by approximation 2.

The change in the intensity of the observed absorption spectra and the calculated values of the dipole strengths of L-proline oligopeptides should be compared.

In the dimer the calculated dipole strengths are in good accord with the observed intensity of the peak and the shoulder of the dimer.

The present calculations indicate that the absorption spectra of the trimer should have two perpendicular bands and a parallel band. This result should be regarded as the theoretical prediction for the broadening which was observed in the asborption spectra of the trimer.

There is a noteworthy change in the intensity of the band maxima at about 200 mμ of the tetramer, pentamer and hexamer. In particualr, the change of the intensity between the trimer and other three oligomers (tetramer, pentamer and hexamer) is notable and seems to be associated with the helical structure of the oligomers.

However, the present calculations for the change of dipole strengths with increasing chain length do not agree with that of the observed intensities. That is, the calculated dipole strengths of four oligomers (trimer, tetramer, pentamer and hexamer) are almost the same, and moreover there is no increase in the dipole strengths between the trimer and the tetramer.

Disagreement between the calculated dipole

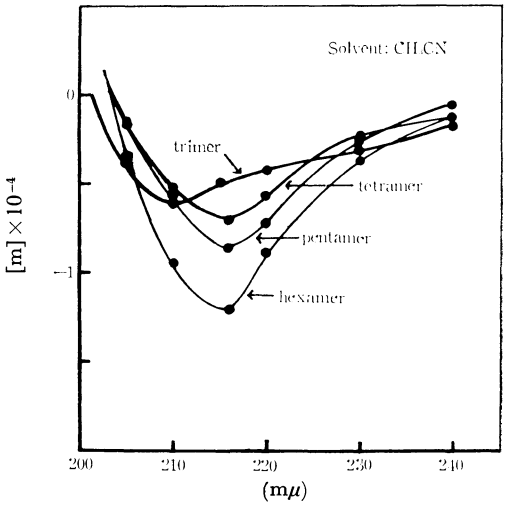

Fig. 4. The ORD curves of L-proline oligopeptides in acetonitrile.
Trimer, concn. = 1.590 mg/20 m*l* of CH_3CN
Tetramer, concn. = 1.65 mg/20 m*l* of CH_3CN
Pentamer, concn. = 1.61 mg/20 m*l* of CH_3CN
Hexamer, concn. = 1.64 mg/20 m*l* of CH_3CN
Quartz cells of 1 mm path length were employed.

strengths and the observed intensity of these oligomers may depend upon the calculation in which zero-order exciton wave functions were used. For a satisfactory explanation of the intensity the use of first-order exciton[9] wave functions or other developed methods[10,11] may be required.

The ORD curves of the trimer, tetramer, pentamer and hexamer were obtained. The measurements were carried out on a Jasco Model ORD/UV-5 Spectropolarimeter.

The position of the minimum and cross-over point in the ORD curve of the trimer is at about 210 mμ and 201 mμ.

The ORD curves of the three oligomer (tetramer, pentamer and hexamer exhibit the same minimum and cross-over points[2] as does poly-L-proline II (see Fig. 4).

These facts clearly indicate that the helical structure of the poly-L-proline II type as measured by absorption spectra appears at the tetrapeptide and that the pentamer and hexamer have complete poly-L-proline II-like structures. These observations were in aqueous solutions and in methyl alcohol as well as in acetonitrile. Although the absorption spectra of the dimer and trimer differ from that found for the poly-L-proline II-like structure, the calculated and observed results agree sufficiently well to ascertain that these oligomers likewise assume a poly-L-proline II-like conformation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 23—30 (1970)

Isotopic Exchange between Hydrogen Sulfide and Deuterium on the Surface of Cuprous Sulfide

Kazuo FUEKI, Hideaki INABA and Takashi MUKAIBO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 5, 1969)

The isotopic exchange between H_2S and D_2 has been followed in the temperature range 425—525°C on a cuprous sulfide specimen. At high sulfur activities of Cu_2S, the predominant reaction is $H_2S+D_2=H_2+D_2S$, and at moderate sulfur activities the same reaction is predominant in the initial period. Analysis of kinetic data shows that the exchange reaction is first order. From the first-order rate constant, k_i, the rate constant of sulfidation of Cu_2S by "hydrogen sulfide"* and k_i', the rate constant of reduction of Cu_2S by "hydrogen"* are determined. It is shown that k_i is inversely proportional to the sulfur activity of Cu_2S and that k_i' is independent of it. Dependence of k_i and k_i' on sulfur activity is interpreted on the basis of a theory proposed by Kobayashi and Wagner. The formation of HD becomes remarkable as the sulfur activity of Cu_2S decreases. This finding shows that the reaction, $H_2S+D_2=HD+HDS$, becomes appreciable with the decrease in sulfur activity.

Oxidation and sulfidation of metals and reduction of oxides and sulfides at high temperatures implies the reaction at the gas-solid interface as an elementary step. Since not only gaseous reactants but also species in the solid phase take part in the reaction at the gas-solid interface, it is necessary to determine the reaction rate as a function of the activity of reactants in the solid phase as well as the partial pressure of reactant gases in order to discuss the reaction mechanism.

Kobayashi and Wagner[1] have constructed solid-state electrochemical cells, such as $Ag|AgI|Ag_2S|Pt$ and $Cu|CuI|Cu_2S|Pt$, and determined the rate of reduction of Cu_2S and Ag_2S by H_2 as a function of the sulfur activity, using the coulometric titration technique. They have proposed a new theory for interpreting the dependence of reaction rate on the

*1 Terms such as "hydrogen" and "hydrogen sulfide" are used in a generic sense, irrespective of isotopic species.

1) H. Kobayashi and C. Wagner, *J. Chem. Phys.*, **26**, 1609 (1957).

sulfur activity of sulfides and discussed the reaction mechanism.

On the basis of the theory proposed by Kobayashi and Wagner, several kinetic studies[2-5] have been carried out on the reaction at the gas-solid interface. As to experimental technique, the isotopic exchange method and the chemical relaxation method have been developed in addition to the coulometric titration technique.

In the present work, the isotopic exchange between H_2S and D_2 on the surface of Cu_2S is studied, and the rate of sulfidation of Cu_2S by H_2S and the rate of reduction of the sulfide by H_2 are determined as a function of the sulfur activity of Cu_2S.

From the result, the mechanism of reaction on the surface of Cu_2S is discussed.

Experimental

Apparatus. The apparatus is shown in Fig. 1. A is a Cu_2S specimen placed in a reaction vessel B, which is heated by an electric furnace C. A magnetic pump D and valves E are used for circulating the gas mixture in the reaction system in the direction indicated by arrows. M is a mercury manometer. F is used to collect a small portion of gas. G is a U-shaped glass trap for the separation of "hydrogen sulfide" from "hydrogen". H is a bulb to transfer samples of gas to a mass spectrometer. I, J, and K are reservoirs for purified D_2, H_2S, and H_2, respectively, and L a reservoir for gas mixtures of H_2S and D_2.

Materials. *a) Purification of* H_2. Hydrogen of commercial grade was passed through paradium-asbestos catalyser heated at 450°C to convert the trace of oxygen into water vapor. The gas was then dried by means of a tube filled with desiccating agent $Mg(ClO_4)_2$ and stored in a gas reservoir.

b) Purification of D_2. Heavy water supplied by the Showa Denko Co. was electrolysed in a U-shaped electrolytic cell equipped with a diaphragm of sintered glass. Impurity oxygen was removed in the same way as in the purification of H_2. A typical composition of deuterium gas was 96% D_2, 3.1% HD and 0.9% H_2.

c) Purification of H_2S. Hydrogen sulfide gas, 99.9% pure, was passed through a desiccating tube of $Mg(ClO_4)_2$ and condensed in a trap cooled by liquid nitrogen. The trap then was evacuated to remove uncondensed gaseous impurities and the condensed hydrogen sulfide was evaporated by removing liquid nitrogen.

d) Preparation of Cu_2S *Specimen.* A copper specimen, 9.0 cm long and 4.2 cm wide, was taken from a high purity copper sheet with thickness 0.22 mm. After being polished with a 1000-emery paper, the specimen was cleaned by petroleum ether and stored in a desiccator. The finished copper specimen was then folded and placed in a pyrex tube. High purity sulfur with an amount 5% more than that necessary for the formation of stoichiometric cuprous sulfide was added to the tube. After evacuation, the tube was sealed and placed in a furnace heated at 400°C to let copper react with sulfur to form Cu_2S. After the completion of sulfidation, the specimen was annealed in a H_2S-H_2 gas mixture.

Experimental Procedure. Prior to the isotopic exchange reaction, a H_2S-H_2 gas mixture, the sulfur activity of which was the same as that of a H_2S-D_2 gas mixture to be used in the isotopic exchange reaction, was admitted to the reaction vessel and the Cu_2S specimen was kept in the atmosphere for a period until equilibrium was attained between the Cu_2S specimen and the H_2S-H_2 gas mixture. The H_2S-H_2 gas mixture

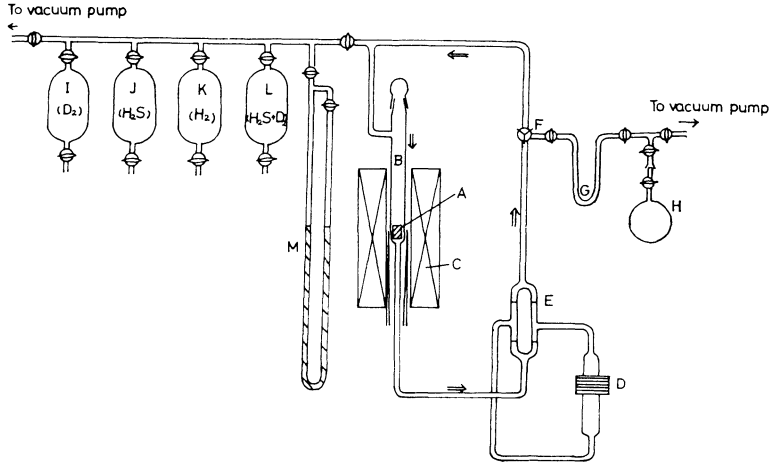

Fig. 1. Apparatus for the isotopic exchange experiment

was removed and a H_2S-D_2 gas mixture was introduced into the reaction system and circulated by a circulation pump.

Small portions of the mixture were collected in F, and then expanded to G. After "hydrogen sulfide" in the U-shaped tube G was frozen out with liquid nitrogen around the trap, "hydrogen" was transferred to the bulb H to be analyzed by means of a mass-spectrometer.

Results and Discussion

Blank Experiment. In order to investigate whether or not the isotopic exchange reaction between D_2 and H_2S occurs in the absence of Cu_2S, a blank experiment has been carried out at various temperatures. No exchange was observed below 525°C, and about 5% of the initial amount of D_2 was found to have exchanged after 3 hr of reaction at 575°C. Thus the experiment was carried out below 525°C.

Change in Mole Fractions of H_2, HD and D_2 with Time. From the data of mass-spectroscopic analysis, mole fractions of H_2, HD and D_2 were calculated, where the mole fraction is the number of moles of a specific kind of hydrogen divided by the total number of moles of "hydrogen." The mole fractions are denoted by x_{H_2}, x_{HD} and x_{D_2}.

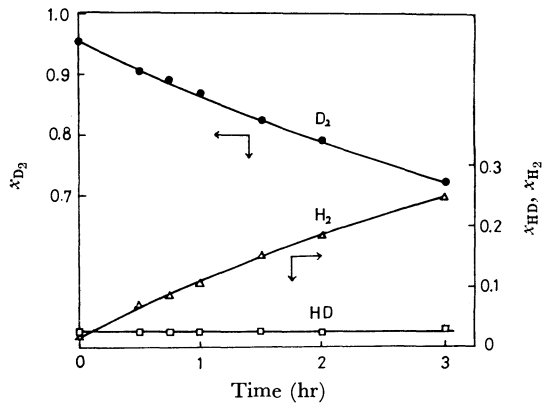

Fig. 2. Change in x_{D_2}, x_{HD} and x_{H_2} with time. (478°C, $P^\circ_{H_2S}$=160 mmHg, $P^\circ_{D_2}$=20 mmHg, a_S=4)

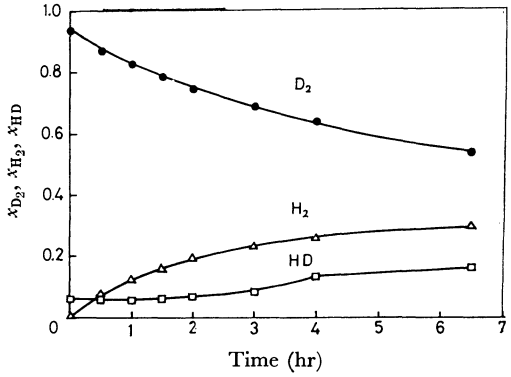

Fig. 3. Change in x_{D_2}, x_{DH} and x_{H_2} with time. (478°C, $P^\circ_{H_2S}$=20 mmHg, $P^\circ_{D_2}$=20 mmHg, a_S=1)

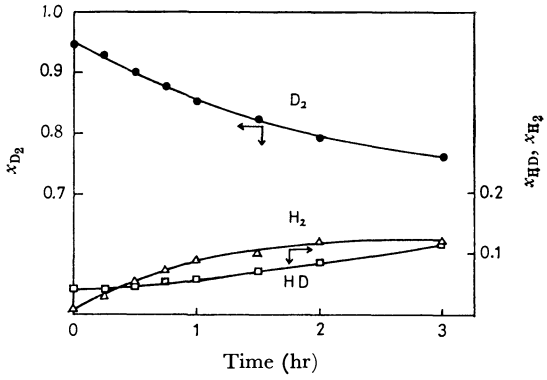

Fig. 4. Change in x_{D_2}, x_{HD} and x_{H_2} with time. (478°C, $P^\circ_{H_2S}$=40 mmHg, $P^\circ_{D_2}$=160 mmHg, a_S=1/4)

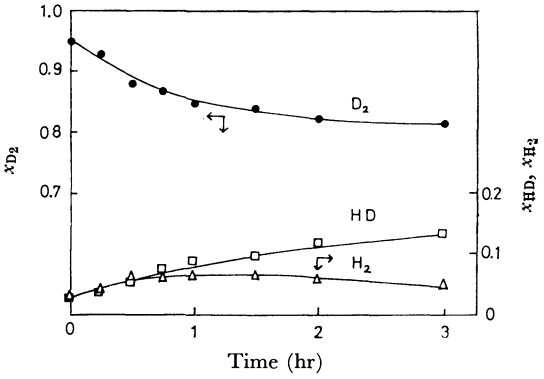

Fig. 5. Change in x_{D_2}, x_{HD} and x_{H_2} with time. (478°C, $P^\circ_{H_2S}$=40 mmHg, $P^\circ_{D_2}$=400 mmHg, a_S=1/10)

Figures 2 to 5 give the plots of x_{H_2}, x_{HD} and x_{D_2} against time at different sulfur activities. The sulfur activity, a_S, was defined as the pressure ratio of "hydrogen sulfide" to "hydrogen." Figure 2 shows the change in x_{H_2}, x_{HD} and x_{D_2} with time in the case where a_S is 4. As seen from the figure, x_{HD} remains unchanged, whereas x_{H_2} increases and x_{D_2} decreases. Thus, the predominant exchange reaction is

$$H_2S + D_2 = D_2S + H_2 \quad (1)$$

This reaction proceeds *via* the sulfidation of Cu_2S by H_2S and the reduction by H_2 as follows:

$$H_2S = H_2 + \text{"S(a)"} \quad (2)$$

$$D_2 + \text{"S(a)"} = D_2S \quad (3)$$

where "S(a)" denotes sulfur atoms or ions on the surface of Cu_2S. Accordingly, the rate of sulfidation of Cu_2S by H_2S can be obtained from the kinetic of reaction (1).

The change in mole fractions of H_2, HD, and D_2 at $a_S=1$ is given in Fig. 3. x_{HD} is constant during the initial period of reaction and then increases with time. As seen in Fig. 4, the change in mole fractions with time at $a_S=1/4$ is similar to that at $a_S=1$, but the initial period where x_{HD} is constant is shorter. At $a_S=1/10$, the formation of HD is remarkable. HD would be formed by the reaction

$$H_2S + D_2 = HDS + HD \quad (4)$$

Reaction (4) probably proceeds *via* steps,

$$H_2S = H(a) + HS(a) \quad (5)$$

$$D_2 = 2D(a) \quad (6)$$

$$H(a) + D(a) = HD \quad (7)$$

$$HS(a) + D(a) = HDS$$

where H(a), D(a), HS(a) represent H, D and HS adsorbed on the surface of Cu_2S.

It is noteworthy that the mechanism of reaction at the gas-solid interface changes with the activity of reactants in the solid phase.

Order of Reaction and Rate Constants of Sulfidation and Reduction. According to McKay's law,[6] the rate of isotopic exchange is first order regardless of the individual forward or reverse reactions. If only reaction (1) occurs and the reaction obeys McKay's law, the rate of exchange per unit area of Cu_2S specimen is given by the equation

$$\frac{\dot{n}_{D_2}}{A} = k_i P_{D_2S} - k_i' P_{D_2} \quad (9)$$

or

$$\frac{\dot{n}_{H_2}}{A} = k_i P_{H_2S} - k_i' P_{H_2} \quad (10)$$

where A is the apparent surface area of Cu_2S specimen, n_{H2} and n_{D2} are, respectively, numbers of moles of H_2 and D_2 in the reaction system at the time of t, k_i is the rate constant of sulfidation of Cu_2S by "hydrogen sulfide" and k_i' is the rate constant of reduction of Cu_2S by "hydrogen."

Let us solve Eq. (9). The equation is rewritten as

$$\frac{\dot{n}_{D_2}}{A} = \frac{RT}{V}(k_i n_{D_2S} - k_i' n_{D_2}) \quad (11)$$

where V is the dead volume of the reaction system. Since only reaction (1) is assumed to occur, $n^\circ_{D_2}$, the number of moles of D_2 at the beginning of reaction, is equal to the sum of n_{D_2} and n_{D_2S} at the time of t, thus

$$n^\circ_{D_2} = n_{D_2} + n_{D_2S} \quad (12)$$

Insertion of Eq. (12) into Eq. (11) yields

$$\frac{\dot{n}_{D_2}}{A} = \frac{RT}{V}\{k_i n^\circ_{D_2} - (k_i + k_i')n_{D_2}\} \quad (13)$$

At equilibrium $n_{D_2}=0$, accordingly,

$$\frac{n^e_{D_2}}{n^\circ_{D_2}} = \frac{k_i}{k_i + k_i'} \quad (14)$$

where $n^e_{D_2}$ represents the number of moles of D_2 at equilibrium. Inserting Eq. (14) into Eq. (13), we obtain

$$\dot{n}_{D_2} = -\frac{ART}{V}(k_i + k_i')(n_{D_2} - n^e_{D_2}) \quad (15)$$

Integration of Eq. (15) yields

$$-\log \frac{n_{D_2} - n^e_{D_2}}{n^\circ_{D_2} - n^e_{D_2}} = \frac{ART(k_i + k_i')}{2.303V}t \quad (16)$$

By replacing n_{D_2}, $n^\circ_{D_2}$ and $n^e_{D_2}$ by x_{D_2}, $x^\circ_{D_2}$ and $x^e_{D_2}$, respectively, Eq. (16) is rewritten as

$$-\log \frac{x_{D_2} - x^e_{D_2}}{x^\circ_{D_2} - x^e_{D_2}} = \frac{ART(k_i + k_i')}{2.303V}t \quad (17)$$

If we denote the slope of the polt of $-\log\{x_{D_2} - x^e_{D_2})/(x^\circ_{D_2} - x^e_{D_2}\}$- against t by α, we have

$$\alpha = \frac{ART(k_i + k_i')}{2.303V} \quad (18)$$

k_i and k_i' are represented by the following equations.

$$k_i = \frac{2.303\alpha V}{ART}\frac{x^e_{D_2}}{x^\circ_{D_2}} \quad (19)$$

and

$$k_i' = \frac{2.303\alpha V}{ART}\left(1 - \frac{x^e_{D_2}}{x^\circ_{D_2}}\right) \quad (20)$$

Therefore, if α is determined experimentally, k_i and k_i' can be calculated by Eqs. (19) and (20).

The solution of Eq. (10) has a form

$$-\log \frac{x^e_{H_2} - x_{H_2}}{x^e_{H_2} - x^\circ_{H_2}} = \frac{ART(k_i + k_i')}{2.303V}t \quad (21)$$

The slope of the plot of $\log\{(x^e_{H_2} - x_{H_2})/(x^e_{H_2} - x^\circ_{H_2})\}$ *vs.* t. is the same that of the plot of $\log\{(x_{D_2} - x^e_{D_2})/(x^\circ_{D_2} - x^e_{D_2})\}$ *vs.* t. Therefore, it is also possible to calculate the values of k_i and k_i' from the data for H_2.

The plot of $\log\{(x_{D_2} - x^e_{D_2})/(x^\circ_{D_2} - x^e_{D_2})\}$ *vs.* t for the data given in Fig. 2 is shown in Fig. 6. In this figure the plot of $\log\{(x^e_{H_2} - x_{H_2})/(x^e_{H_2} - x^\circ_{H_2})\}$ *vs.* t

is also given. $x^e_{D_2}$ and $x^e_{H_2}$ are calculated by the equations

$$x^e_{D_2} + x^e_{H_2} = 1 \tag{22}$$

$$\frac{x^e_{D_2}}{x^e_{H_2}} = \frac{P^o_{D_2}}{P^o_{H_2S}} \tag{23}$$

where $P^o_{D_2}$ and $P^o_{H_2S}$ are the partial pressures of D_2 and H_2S at the beginning of reaction, respectively.

Both plots are straight and coincide well with each other.

Similar plots for the data given in Fig. 3 and

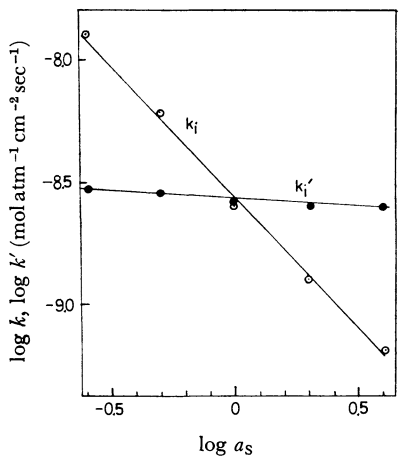

Fig. 9. Plots of log k_i and log k_i' against log a_S.

Fig. 4 are shown in Fig. 7 and Fig. 8, respectively. McKay's law holds in the initial period where x_{HD} remains constant, and the straight line portion for D_2 well agrees with that for H_2.

The values of k_i and $k_{i'}$ calculated by Eqs. (19) and (20) are listed in Table 1. It is seen from the table that the value of k_i is the same irrespective of the total pressure, if the values of a_S is the same.

Dependence of k_i and $k_{i'}$ on a_S. Figure 9 gives the plot of log k_i *vs.* log a_S and that of log $k_{i'}$ *vs.* log a_S. Both plots are linear. The slope for the former plot is -1.07 and that for the latter is -0.07. Such dependence of k_i and $k_{i'}$ on a_s is explained on the basis of the theory by Kobayashi and Wagner as follows.

The reaction between H_2S and H_2 on the surface of Cu_2S proceeds by the following parallel reactions

$$H_2S \rightleftarrows H_2 + S \quad (24\text{ A})$$

$$H_2S + e^- \rightleftarrows H_2 + S^- \quad (24\text{ B})$$

$$H_2S + 2e^- \rightleftarrows H_2 + S^{2-} \quad (24\text{ C})$$

where e^- denotes electrons in Cu_2S, and S, S^- and S^{2-} are adsorbed sulfur atoms, monovalent sulfur ions and divalent sulfur ions, respectively.

Assuming that adsorbed sulfur atoms and sulfur ions are in equilibrium with those in bulk of cuprous sulfide, we obtain the following rate equations:

$$\left(\frac{\dot{n}_{H_2}}{A}\right)_A = k_1 P_{H_2S} - k_1' P_{H_2} a_S \quad (25\text{ A})$$

$$\left(\frac{\dot{n}_{H_2}}{A}\right)_B = k_2 P_{H_2S} a_e - k_2' P_{H_2} a_{S^-} \quad (25\text{ B})$$

$$\left(\frac{\dot{n}_{H_2}}{A}\right)_C = k_3 P_{H_2S} (a_e)^2 - k_3' P_{H_2} a_{S^{2-}} \quad (25\text{ C})$$

where a_S, a_S^-, a_S^{2-} and a_e represent the activities of respective species. The first terms on the right side are the rate of sulfidation of Cu_2S and the second ones are the rate of reduction.

There are also several equilibrium relationships in solid phase. They are:

$$S^- \rightleftarrows S + e^-$$

$$\frac{a_S a_e}{a_{S^-}} = K_1 \quad (26)$$

$$S^{2-} \rightleftarrows S + 2e^-$$

$$\frac{a_S (a_e)^2}{a_{S^{2-}}} = K_2 \quad (27)$$

Moreover, for cuprous sulfide, we have

$$(a_{Cu})^2 a_S = K_3 \quad (28)$$

According to Wagner and Wagner[7] the activity of cuprous ions in cuprous sulfide is independent of the composition of Cu_2S. Hence

$$a_{Cu} = K_4' a_{Cu^+} a_e = K_4 a_e \quad (29)$$

From Eqs. (28) and (29), we obtain

$$a_e = K_5 (a_S)^{-1/2} \quad (30)$$

Combination of Eqs. (26), (27) and (30) yields

$$a_{S^-} = K_6 (a_S)^{1/2} \quad (31)$$

$$a_{S^{2-}} = K_7 \quad (32)$$

Inserting Eqs. (30), (31) and (32) into Eqs. (25 A), (25 B) and (25 C), we obtain

$$\left(\frac{\dot{n}_{H_2}}{A}\right)_A = k_1 P_{H_2S} - k_1' P_{H_2} a_S \quad (33\text{ A})$$

$$\left(\frac{\dot{n}_{H_2}}{A}\right)_B = k_2 K_5 P_{H_2S} (a_S)^{-1/2} - k_2' K_6 P_{H_2} (a_S)^{1/2} \quad (33\text{ B})$$

$$\left(\frac{\dot{n}_{H_2}}{A}\right)_C = k_3 K_5^2 P_{H_2S} (a_S)^{-1} - k_3' K_7 P_{H_2} \quad (33\text{ C})$$

These equations are summarized into a generalized formula

$$\frac{\dot{n}_{H_2}}{A} = v_{ox} - v_{red} = k P_{H_2S} (a_S)^{-m/2} - k' P_{H_2} (a_S)^{n/2} \quad (34)$$

or

$$\frac{\dot{n}_{H_2}}{A} = k P_{H_2S} (a_e)^m - k' P_{H_2} (a_e)^{-n} \quad (35)$$

where m and n are constants characteristic of reaction mechanism, namely,

$m=0$, $n=2$ for mechanism (24 A)

$m=1$, $n=1$ for mechanism (24 B)

$m=2$, $n=0$ for mechanism (24 C)

From a comparison of Eq. (34) with Eq. (9) or (10) we obtain

$$k_i = k (a_S)^{-m/2} \quad (36)$$

$$k_i' = k' (a_S)^{n/2} \quad (37)$$

As mentioned already, the slope of the plot of log k_i *vs.* log a_S is -1.07 and that of the plot of log $k_{i'}$ *vs.* log a_S is -0.07. It is thus concluded that m is 2 and n is 0. This result shows that mechanism (24 C) prevails in this case.

7) J. B. Wagner and C. Wagner, *J. Chem. Phys.*, **26**, 1597 (1957).

Comparison of the Data of the Isotopic Exchange with That of Copper Sulfidation. The authors[8] have studied the sulfidation of Cu by H_2S and H_2S-H_2 gas mixtures and found that; (1) the reaction obeys the linear rate law, (2) the linear rate constant is proportional to the partial pressure of H_2S, and (3) the linear rate constant is nearly independent of the partial pressure of hydrogen. The findings show that the sulfidation of Cu by H_2S is mainly controlled by the reaction at the gas sulfide interface. k_L°, the linear rate constant at 1 atm of H_2S, is listed in the second column of Table 2.

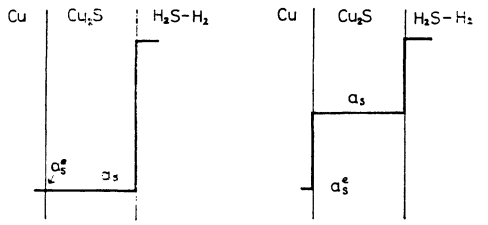

Fig. 10. Schematic representations of distribution of sulfur activity during the sulfidation of copper.

If the reaction at the gas-sulfide interface is much slower than the reaction at the metal-sulfide interface and the diffusion of materials across the sulfide, the sulfur activity would drop at the gas-sulfide interface appreciably, because a large driving force is needed at the interface to advance the reaction. In an ideal case, the sulfur activity at the gas-sulfide interface is equal to the sulfur activity in coexistence of Cu and Cu_2S, as schematically shown in Fig. 10(a). In this case, the rate of sulfidation of Cu by H_2S should be equal to k_i at a_S^e. The fifth column in Table 2 gives the estimated k_i values at a_S^e, assuming that the relationship between k_i and a_S found in the present work holds down to a_S^e. The calculated k_i value at a_S^e is about two orders higher than the observed linear rate constant k_L° in magnitude.

A possible explanation for this discrepancy is as follows. If the reaction at the metal-sulfide interface is as slow as the reaction at the gas-sulfide interface, the sulfur activity also drops at the metal-sulfide interface as shown in Fig. 10(b). Accordingly, a_S, the sulfur activity of Cu_2S at the gas-sulfide interface, is higher than a_S^e, and the k_i value at a_S is smaller than that at a_S^e. Further experiment is needed to elucidate the cause of the discrepancy.

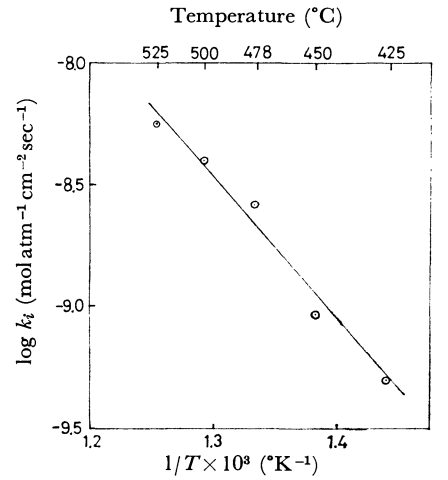

Fig. 11. Arrhenius plot for k_i at $a_S=1$.

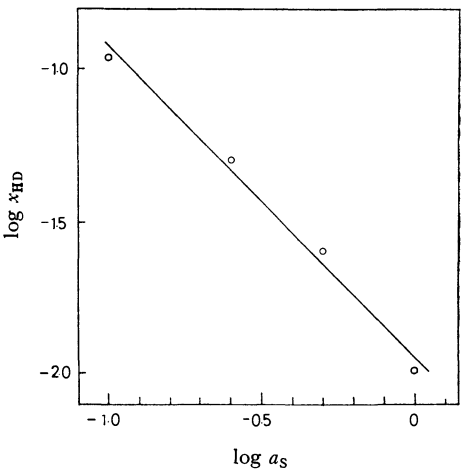

Fig. 12. Relationship between x_{HD} and a_S at 15% conversion of D_2. (478°C)

The Arrhenius plot of k_i at $a_S=1$ is given in Fig. 11. Activation energy determined from the slope is 27.8 kcal/mol. On the other hand, the activation energy of sulfidation of Cu in H_2S is 21.3 kcal/mol. In the latter case, the sulfur activity of Cu_2S surface would change with tempera-

8) M. Takeda, K. Fueki and T. Mukaibo, *J. Electrochem. Soc. Jap.*, **36**, 95 (1968).

ture. The difference in the activation energy might be due to the difference in the temperature dependence of sulfur activity on Cu_2S surface.

Formation of HD. As already mentioned, the formation of HD becomes remarkable as the sulfur activity of Cu_2S decreases. Figure 12 shows the relationship between the sulfur activity of Cu_2S and the mole fraction of HD at the time where 15% of the initial amount of D_2 has been exchanged. Correlation between the formation of HD and the sulfur activity is evident. However, because of the lack of adequate kinetic data, detailed discussion on the mechanism of formation of HD is difficult for the time being.

Summary

(1) The isotopic exchange between H_2S and D_2 on Cu_2S was investigated as a function of temperature and a_S, the sulfur activity of Cu_2S.

(2) It was found that when a_S is high the exchange reaction $H_2S+D_2=H_2+D_2S$ is predominant and the formation of HD is small. It was also found that when a_S is low the formation of HD proceeds after an initial period of reaction.

(3) The rate of exchange reaction $H_2S+D_2=H_2+D_2S$ was found to obey McKay's law, and the first-order rate constants were obtained. k_i, the rate constant of sulfidation of Cu_2S by H_2S, and k_i', the rate constant of reduction of Cu_2S by H_2 were calculated from the first-order rate constants.

(4) Both plots of $\log k_i$ *vs.* $\log a_S$ and $\log k_i'$ *vs.* $\log a_S$ were linear. The slope of the former plot was -1.07 whereas that of the latter was -0.07.

(5) Based on the theory proposed by Kobayashi and Wagner, the predominant reaction mechanism for the reaction $H_2S+D_2=H_2+D_2S$ was discussed.

(6) Activation energy was found to be 27.8 kcal/mol.

The authors wish to express their sincere thanks to Dr. M. Tsuchiya of the Faculty of Engineering, University of Tokyo, for his help in carrying out mass-spectroscopic analysis.

Measurement of Contact Potential Difference for Organic Crystals. Work Function of Violanthrene

Masahiro KOTANI and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 6, 1969)

A vibrating-reed type cell for measuring contact potential difference was constructed and successfully applied for organic crystals. From the observed contact potential difference for violanthrene against graphite, the work function has been estimated as 4.50 ± 0.1 eV. In association with the activation energy for electrical conductivity, 0.8—0.9 eV, the electronic energy diagram for violanthrene has been illustrated, which revealed the extrinsic nature of semiconduction and the energy gap, 2.3—2.5 eV, being comparable with the first excited singlet state of violanthrene molecule.

The electrical properties of organic compounds in crystalline state, made of conjugated π-electron systems, have been extensively investigated and their semiconductive characters are now widely accepted.[1] Such a molecular crystal may be approximated to be an assembly of neutral molecules, the interactions between them being relatively weak. In contrast to covalent semiconductors such as silicon or germanium, there are no dangling bonds on the surface of molecular crystals which may give rise to unfilled energy levels in the forbidden gap. The electrical properties of molecular crystals may thus be expected to be relatively simple with respect to surface conditions. However, a number of cases have been reported where the electrical properties of such crystals are influenced by the surface conditions. In spite of its potential significance relatively few studies have been made on the surface properties of molecular crystals. This may be attributed partly to the lack of appropriate methods for investigation. Conductivity measurements are sometimes unsatisfactory with respect to reproducibility and the effect of impurity doping has not been well understood for this calss

of crystals.

Measurements of work function can be used as an efficient means for surface studies. The work function is a quantity which depends on the surface as well as on the bulk properties. When data are obtained for clean surfaces they can be used in discussing how surface and bulk properties are related to each other. Further, gas adsorption experiments may yield information about interactions between the adsorbed molecules and the crystal surface.

Measurements of contact potential differences of organic crystals were reported by several authors. However, numerical data published on work function are still very scarce. From the experiments on photoemission the threshold energy can be obtained. This quantity corresponds to the energy of the filled band, whereas the work function gives the location of the Fermi level. Nelson has reported measurements of contact potential differences[2] using the electron beam retardation technique. His data are mainly on organic dyes deposited on inorganic semiconductors such as cadmium sulfide. The same technique was applied to the measurements of the contact potential differences of several organic compounds.[3] The vibrating condensor method was applied to the photovoltage measurements.[4] Irradiation with light produced change in contact potential difference. This was attributed to the difference of diffusion of mobile electrons and holes, *i. e.*, the Dember photovoltage. Analogous information was obtained by Putzeiko[5] using a related technique, Bergmann's condensor method. The surface under test and a transparent conducting plate, a mica plate made half transparent by vacuum evaporation of platinum, constituted the capacitor. The surface was irradiated an by intermittent light through the transparent electrode. This gave rise to an alternating photovoltage. Harada *et al.*[6] have published the results of several experiments on photoemission. They include contact potential differences obtained from current-voltage characteristics for several aromatic compounds, from which the work functions for the organic crystals can be evaluated.

The present paper describes the determination of the work function for organic crystals through measurements of contact potential differences using the vibrating condensor method. Compared to other methods such as thermionic or photoelectric emission which are employed in surface studies, this method is advantageous in that it allows measurements without introducing distubances on the surface; it requires a sample to be neither heated nor irradiated. Further, it does not require vacuum; it allows measurements in various gases at wide range of pressure. The electronic structure of crystalline violanthrene will be discussed on the basis of the work function observed.

Experiment

A vibrating-reed type cell, made of Pyrex glass, was constructed for measuring contact potential differences (Fig. 1). A copper disc (1) with an area of about 1.5 cm^2) coated with gold by vacuum evaporation served as a substrate. It was set over an oven (3) where the sample was sublimed onto the surface. The disc covered with a layer of the sample was then transferred to the centre of the cell by an iron wire pulled by turning a ground joint (4). It constituted a parallel plate capacitor coupled with a reference electrode (2). The two electrodes were about 1 mm apart. The reference electrode was a film of colloidal graphite (Aquadag) which was painted on a thin Pyrex plate and treated in air at 500°C for an hour. The reference electrode was held by a glass rod. A piece of iron was attached to the glass rod which brought the reference electrode into resonant vibration by means of an electromagnet, which was driven by an audio range oscillator coupled with a power amplifier. The frequency of vibrations ranged from 50 to 70 Hz. The glass rod was covered with conductive silver paint and served as a lead.

The inner wall of the spherical part of the cell was coated with gold by vacuum evaporation and grounded in order to avoid disturbances due to charging. The coating served also as a shielding against electric fields outside.

A gold film was used also as an auxiliary standard electrode, which was formed by vacuum evaporation onto a Pyrex plate. The contact potential difference between the freshly evaporated gold film and a standard graphite surface showed a large drift immediately after

evaporation, but after several hours of exposure to the air it attained a stationary value which was found to be fairly reproducible. The work function of this "aged" surface was determined to be 5.1 eV from the contact potential difference against the graphite surface.

A potentiometer made of a mercury battery and a Helipot, a precision variohm, supplied potential for the reference electrode. The signal from the sample electrode was amplified with a preamplifier with imput resistance of 10^{12} ohm and was put into an oscilloscope. The cell and the preamplifier were placed in a shielding cage. The null indication procedure was employed in which the potentiometer was adjusted to give a minimum magnitude of the signal. In order to minimize the hum noize of commercial frequency (50 Hz), the lead connecting the sample and the preamplifier should be as short as possible. The cell was not quite satisfactory as the lead was designed to serve also as a cable to carry the sample electrode. To maintain steady vibrations of the reference electrode and to avoid vibrations in other parts of the cell, care must be taken to prevent mechanical disturbances.

The sensitivity of the apparatus was ± 1 mV for a uniform metal surface. When the surface was covered by an organic film, it exhibited a higher noise level and gave a lower sensitivity. The sensitivity of measurements for organic films was generally 20 to 30 mV. The reproducibility of the surface is a factor which must be considered. It was the principal factor for the experimental error in the case of violanthrene.

Measurements were carried out in a vacuum of 10^{-5} Torr, but the cell was designed for measurements in various ambient gases. Sublimation of organic compounds was performed in the cell in order to measure uncontaminated films. Ground joints and grease were used.

Conductivity measurements were made with a vibrating reed electrometer. A surface type arrangement was employed, with Aquadag electrodes.

Violanthrene was prepared from violanthrone, a commercial product, by reduction with powdered zinc metal. After it was treated by usual chemical methods, the final purification was made by successive sublimation in vacuum.

Results and Discussion

The work function of an electrical conductor can be evaluated by the relation

$$\Phi = \Phi_0 - \Delta$$

where Φ denotes the work function of the sample, Φ_0 that of the references material and Δ the contact potential difference. For this relation to be valid the thermal equilibrium of electrons between the sample and the reference material must be attained. If the equilibrium is not attained, the observed contact potential difference depends not only on the sample but also on the substrate materials employed. The preliminary experiments were made for violanthrene film deposited on several kinds of metals. The results are summarized in Table 1. For Φ_0, the value of 4.74 ± 0.1 eV for graphite was adopted after Apker *et al.*[7] In evaluating from the observed contact potential differences, it is essential that the work function of the reference surface be constant throughout the measurements. We did not measure the work fuction of the graphite films used. However, the contact potential difference measurements revealed that the constancy of the work function of the graphite film made by the procedure described above was kept within the range of ±0.05 eV. The work function of the sample thus evaluated shows a good constancy within the experimental error irrespective of the substrate metal and indicates that the above relation is valid.

TABLE 1. THE EFFECT OF THE SUBSTRATE MATERIAL ON THE OBSERVED WORK FUNCTION OF VIOLANTHRENE

Substrate	Reference	Φ (eV)
Pt	Aquadag	4.5
Cu	Aquadag	4.4
Brass	Aquadag	4.5
Au	Aquadag	4.5
Au	Au	4.5
Ni	Au	4.5

Having thus verified that the observed contact potential difference does not depend on the choice of the substrate metal, we employed gold as the substrate. As an auxiliary standard a gold film evaported on a Pyrex plate was also used. Its work function was determined to be 5.1 eV using graphite as the primary standard, Table 2 shows the results of the measurements. For both reference materials the same value of 4.50 ± 0.1 eV was obtained for the work function of violanthrene.

TABLE 2. THE WORK FUNCTION OF VIOLANTHRENE

Reference	CPD (eV)	Φ (eV)
Au	0.5	4.6
Au	0.63	4.47
Au	0.70	4.40
Au	0.6	4.5
Aquadag	0.2	4.5
Aquadag	0.24	4.50
	mean	4.50 ± 0.1

The temperature dependence for the electrical conductivity of violanthrene was measured with a surface type arrangement. It is well expressed by the relation

$$j = j_0 \exp(-E/kT)$$

within the temperature range of 53 to 191°C, where

j is the observed current. The activation energy E was found to be 0.8—0.9 eV.

A tentative electronic energy diagram can be constructed, as shown in Fig. 2, using experimental and theoretical data available. Figure 2 represents energy levels of violanthrene for gaseous and crystalline states. The ionization energy of gaseous violanthrene is estimated to be 6.84 eV.[8] For alternant hydrocarbons Mulliken's electronegativity, $\chi=(I+A)/2$, can be approximated by the mean value of the energy of the highest occupied orbital and the energy of the lowest vacant orbital, where I and A denote the ionization energy and the electron affinity respectively. This quantity has been estimated from experimental data for alternant hydrocarbons to be 4.15 eV.[9]

In Fig. 2 are also shown the energy levels of graphite which stands in the electrical equilibrium with crystalline violanthrene. The contact potential difference between violanthrene and graphite was observed to be 0.24 eV.

When an electron is emitted from a neutral crystal it leaves behind a positive charge which polarizes the medium surrounding it. This stabilizes the electric charge in a dielectric atmosphere compared to the isolated charge in the vacuum. The polarization energy corresponds to the difference in ionization energies of gaseous and crystalline states. An analogous discussion leads to the conclusion that the electron affinity of a molecule must be larger for the crystalline state than for the gaseous state. The energy difference, the polarization energy due to a negative charge in a crystal, seems to be the same as that for positive charge in the crystal. As the Fermi level must be located half way between the top of the filled levels and the lowest conducting level in an intrinsic semiconductor, we conclude that the work function of crystalline alternant hydrocarbons is equal to the molecular electronegativity χ. Energy levels are illustrated in Fig. 2, in which 0.8—0.9 eV, obtained as the activation energy for dark conduction, is assigned as the energy difference between the top of the filled band and the Fermi energy. Thus the ionization energy and the band gap are evaluated to be 5.3 to 5.4 eV and 2.3 to to 2.5 eV, respectively.

The ionization energy of 5.20 eV for crystalline violanthrene was obtained form the threshold energy for photoelectric emission.[10] Kearns and Calvin have reported measurements of photoelectric emission for several crystalline compounds including violanthrene.[11] Their values for crystal ionization energy are generally lower than those obtained by other investigators by 0.5 to 0.6 eV, as in pentacene and metal-free phthalocyanine.

In conclusion, the Fermi level does not lie midway between the valence band and the conduction band. The origin of its extrinsic nature, whether it comes from the presence of some chemical or structural impurities in the bulk or from some surface conditions such as gas adsorption, remains to be explored. It is worth noteing that the band gap is comparable with the energy for the first excited singlet state of violanthrene molecule, *i.e.*, 2.5 eV.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 34—38 (1970)

Electrical Conductivity of Graphite Bromine Lamellar Compounds

Tadashi SASA, Yoichi TAKAHASHI and Takashi MUKAIBO

Department of Nuclear Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 12, 1969)

Polycrystalline graphite was allowed to react with bromine vapor, and the change of its electrical conductivity during the course of bromination and debromination was studied. The graphite was found to behave in two different ways depending on the process of bromination. When the vapor pressure of bromine was changed stepwise, following the equilibrium line of bromine absorption of graphite, the electrical conductivity showed a reversible change. On the other hand, when a graphite sample was brominated with the saturated vapor, an increase of the electrical conductivity steeper than that of the former case was observed. These results were discussed in relation to the structural analysis of the brominated graphite. A metastable phase of graphite bromide, the electrical conductivity of which remained unchanged in spite of a considerable increase of absorbed bromine, was found. The electrical conductivity of the residue compounds was also investigated, and a steep decrease was observed at high concentrations of bromine.

Graphite reacts with bromine at room temperature to form a lamellar compound. The saturated composition of the graphite bromine lamellar compound is C_8Br, and its structure was clarified by Rüdorff[1] as the second stage structure, where the bromine atoms are intercalated in every other layer spacing of graphite. The mechanism of bromine absorption of graphite has been investigated by several workers. Mukaibo and Takahashi[2] measured the rate of bromination of graphite, and obtained an apparent activation energy of the reaction of 5—7 kcal/mol. Saunders *et al.*[3] measured the dimensional change of pyrolytic graphite by bromine absorption, and observed a metastable structure which has a practically full expansion along the direction of *c*-axis by only about one-third of the limiting uptake. Hooley *et al.*[4,5] also investigated the rate of absorption and the dimensional change, and proposed a mechanism in which all layers are open to the intercalation at a relatively initial stage. The authors[6] measured the change of X-ray diffraction pattern of graphite during the course of bromination, and confirmed that the second stage structure of the lamellar compound appeared in the initial stage of the reaction.

Knowledge of electrical properties of the compounds gives valuable information about the electronic state of the species intercalated in graphite. Hennig[7] reported that the electrical resistance of polycrystalline graphite decreases with bromine uptake, and suggested that one-seventh of the intercalated bromine atoms would be ionized. Blackman *et al.*[8] measured the electrical resistance of pyrolytic graphite reacting with bromine vapor in the direction of both the *a*-axis, and the *c*-axis, and observed an initial steep decrease of the resistance in the *a*-axis direction.

We have investigated changes of the electrical conductivity of graphite with bromine absorption in two different processes, *i.e.*, the stepwise bromination and the rapid bromination. In the former case, the vapor pressure of bromine was increased stepwise, and the relation between the electrical conductivity and the equilibrium concentration of the absorbed bromine at every step has been investigated. In the latter, the change of the electrical conductivity of the graphite sample during the course of the reaction with saturated bromine vapor has been measured.

2400°C, $c_0=3.364\pm0.001$ Å, specific resistivity 1.7×10^{-3} Ω·cm (type A).

2) Similar artificial graphite, heat-treated at 3000°C, $c_0=3.361\pm0.001$ Å, specific resistivity 1.4×10^{-3} Ω·cm (type B).

3) Natural graphite with pitch-binder, heat-treated at 3000°C, $c_0=3.356\pm0.002$ Å, specific resistivity 1.1×10^{-3} Ω·cm (type C).

The samples were cut in small specimen of 1.5 mm × 2 mm × 20 mm for measurements of the electrical conductivity and the weight gain.

GR-grade bromine was distilled and forced to pass through concentrated sulfuric acid before use.

Apparatus. The apparatus is shown in Fig. 1. It was difficult to measure both the electrical conductivity and the weight gain with the same specimen. Two graphite specimens cut from a homogeneous block were used for the measurements. The electrical conductivity was measured with one of the specimens by means of a four cantact potentiometric method, with a current of 60—80 mA and a detected potential of 0.3—3 mV. The specimen and the four platinum contacts are shown enlarged in Fig. 2. The other specimen was suspended by a quartz spring balance (sensitivity 20 mm/g), and the concentration of absorbed bromine was measured by means of a running microscope. The reaction temperature was in the range of 20—30°C, and was controlled to ±0.01°C by a controller connected with a photo-transistor detector. The bromine container A, in Fig. 1, provided the vapor of saturation pressure. The container B was controlled at desired temperatures by means of a water bath or an alcohol bath cooled by solid carbon dioxide. Thus the vapor pressure of bromine was controlled at desired values.

The whole system was evacuated before the run, and the bromine vapor was allowed to enter into the reaction tubes by the stop-cock A or B. On debromination, the container B was cooled so as to trap the bromine vapor. After the bromine vapor was completely pumped out, the electrical conductivity of the bromine residue compound was measured.

Results

Stepwise Bromination. Figure 3 shows the relation between the relative vapor pressure of bromine and the bromine uptake by graphite of the type C at 20.6°C. Open circles represent the equilibrium state of bromine absorption while the bromine vapor pressure was increased stepwise, and solid circles represent that while the vapor pressure was decreased. There existed a threshold pressure of bromine absorption, over which two stages of bromine absorption process was observed. It is consistent with the result obtained by Maire and Mering.[9] The electrical conductivity *vs.* bromine

uptake curve corresponding to Fig. 3 is shown in Fig. 4. Here, σ represents the conductivity of the graphite bromide, and σ_0 that of the virgin graphite. The change was found to be almost completely reversible on bromination and debromination. The dashed line represents Hennig's work[7] on polycrystalline graphite. Similar results have been obtained also with graphite of types A and B.

Rapid Bromination. The solid line in Fig. 5 shows the change of the electrical conductivity of type C graphite reacting with bromine vapor of saturation pressure. The dashed line represents the case of the stepwise bromination of Fig. 4. The electrical conductivity increased more steeply in the rapid bromination, and reached the final value on bromine uptake of only about one-third of the limiting value.

Dashed line: stepwise bromination

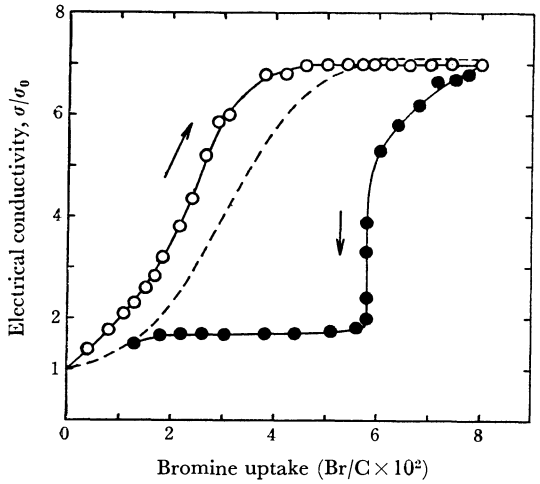

Fig. 6. Change of electrical conductivity of graphite (type B) by rapid bromination. (22°C)
○ on bromination
● on debromination
dashed line: stepwise bromination

Similar results have been obtained on graphite of types A and B. The latter case is shown in Fig. 6. A remarkable hysteresis has been observed. Moreover, an anomalous discontinuous change of electrical conductivity has been observed on debromination.

The residue compound thus formed was again allowed to absorb bromine by stepwise bromination. The curve of electrical conductivity *vs.* bromine content is shown in Fig. 7. In the earlier stage of this rebromination, the electrical conductivity of residue compound showed little change, while the

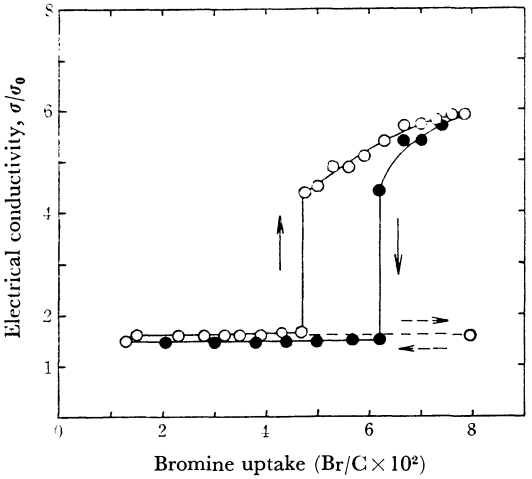

Fig. 7. Effect of stepwise bromination on electrical conductivity of the residue compound formed by the rapid bromination.

● on debromination

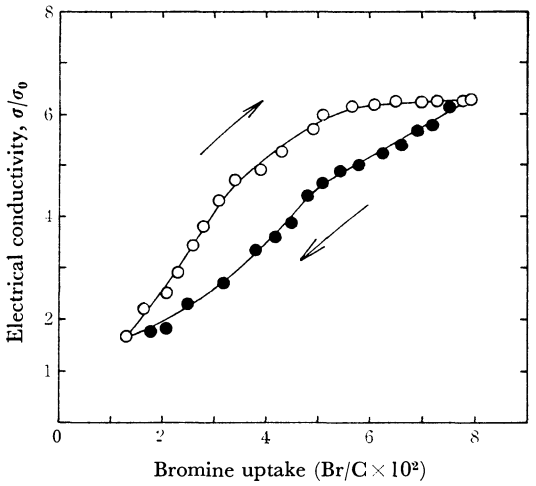

Fig. 8. Effect of rapid bromination on electrical conductivity of the residue compound formed by the stepwise bromination.
○ on bromination (rapid)
● on debromination

progress of bromine absorption was observed by weight gain. By a careful increase, a little at a time, of the reacting bromine vapor pressure, the graphite could absorb bromine almost to the saturated concentration without any change in electrical conductivity (dashed line). However, if the sample, during the course of rebromination of this type, was left to contact with bromine vapor of a constant pressure for a sufficient length of time such as 24 hr, the electrical conductivity increased to the value of the equilibrium state of the same bromine concentration (solid line). It should be noted that no bromine absorption or desorption was accompanied during the transition in electrical conductivity. The curve on debromination showed again a discontinuous change of conductivity.

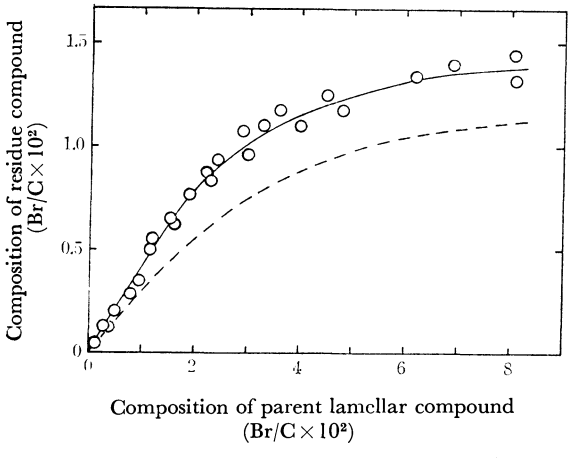

Fig. 9. Dependence of the composition of residue compound on the composition of parent lamellar compound. (dashed line: after Hennig)

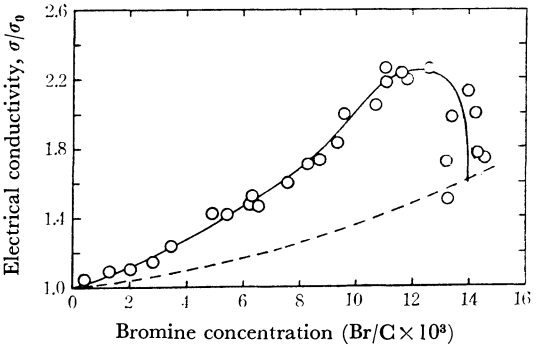

Fig. 10. Electrical conductivity of graphite bromine residue compound.
Solid line: residue compound
Dashed line: lamellar compound

The residue compound, on the other hand, formed by the stepwise bromination of the virgin graphite, followed by debromination, was later forced to absorb bromine by rapid bromination. Figure 8 shows the result of the reaction. The change was reversible, and such a discontinuous change of electrical conductivity as in Fig. 7 was not observed.

Residue Compounds. Figure 9 gives the dependence of the composition of the residue compound on the composition of the parent lamellar compound. The result coincides with Hennig's work[10] qualitatively. The electrical conductivity of the residue compound is plotted against the bromine content by the solid line in Fig. 10. The electrical conductivity increased with the bromine content over the range up to about Br/C$=1.2\times 10^{-2}$. Beyond this concentration the conductivity decreased rather steeply.

The dashed line in Fig. 10 represents the electrical conductivity of the lamellar compound. The residue compound has a larger conductivity than the lamellar compound of the same bromine concentration. The results presented above are consistent with the works by Hennig[10] and Kosai[11].

Discussion

1) Electrical Conductivity of Graphite Bromide in Equilibrium. A single relation could be found between the electrical conductivity and the bromine concentration of the compound in equilibrium state of absorption.

Figure 3, which illustrates the relation between the vapor pressure and the bromine uptake, suggests that the bromine absorption of graphite can be divided into two stages at about half the saturated concentration of absorbed bromine. The curve of electrical conductivity *vs.* bromine content, however, did not show such a break. The single relation could be applied both during the course of bromina-

11) A. Kosai, *Oyobutsuri*, **30**, 402 (1961).

tion and debromination.

The curve in Fig. 4 shows a discrepancy from Hennig's result. It may be attributed to the differences in the type and the degree of crystallization of the graphite samples used.

2) The Mechanism of Bromine Absorption of Graphite. A steeper increase of the electrical conductivity was observed on the rapid bromination of graphite than in the case of the stepwise bromination for the same bromine concentration. It may be related to the difference in the structure between the rapidly brominated graphite bromide and the graphite bromide brominated stepwise.

The authors have reported[6] the change of the layer structure of graphite in the rapid bromination. As the reaction proceeded, distinct double peaks were observed in the X-ray diffraction pattern. These peaks were attributed respectively to the virgin graphite remaining and the second stage structure of the graphite bromine lamellar compound. No other phase could be found through the reaction. It is consistent with the result which Saunders *et al.*[3] reported on the measurement of the dimensional change of pyrolytic graphite with bromine absorption. The results suggest that the bromine intercalation into graphite layers would proceed as follows. At the first stage of the reaction, when the bromine vapor of saturation pressure contacts graphite, bromine begins to invade every other layer spacing of graphite. After a while, the absorbed bromine may be distributed dilutely in the crystallite and the second stage is formed.

It was also reported[6] that when the vapor pressure of the reacting bromine was increased stepwise, the (00l) peaks in the X-ray diffraction pattern of graphite showed gradual and continuous shifts to the lower diffraction angles, and finally reached that of the second stage structure of the saturated graphite bromide. Thus, bromine appears to be distributed rather orderly in the graphite lattice in the course of the stepwise bromination. The number of layer spacings occupied by bromine is dependent on the relative vapor pressure of bromine, and the bromine layer intercalated between the carbon layers seems to have a relatively high density. In the case of the above mentioned stepwise bromination, it may be probable that a certain fraction of the intercalated bromine is ionized as suggested by Hennig.[7] On the other hand, the more dilute distribution of bromine in the transient condition of the rapid bromination is supposed to increase the fraction of ionized bromine. It explains why the electrical conductivity of the rapidly brominated graphite for the same bromine concentration was higher than that of the sample brominated stepwise.

3) Metastable Phase of Graphite Bromide. In Figs. 6 and 7, a strange phase of graphite bromide is found, which contains a sufficient quantity of bromine, but the electrical conductivity of which remains unchanged. The phase was apparently not a stable one, and appeared only during the course of bromination and debromination. Only the normal phase is stable, the electrical conductivity of which increases with bromine concentration. The transition between the metastable phase and the normal phase was observed as a discontinuous change of electrical conductivity. The structural analysis of the metastable phase by X-ray diffraction was attempted, but adequate conditions for the appearance of the metastable phase could not be established.

The metastable phase was found only in rapidly brominated graphite, and the method of the first bromination process of virgin graphite is supposed to determine its succeeding behavior. Once a virgin graphite sample has been rapidly brominated, the memory strongly remains in it, and the residue compound also forms the metastable phase in any condition of bromination. No satisfactory explanation is found for the phenomena at present. The role of the bromine in the metastable phase of graphite bromide is interesting.

4) Residue Compounds. Figure 9 shows the retention of bromine in the graphite lattice. About half of the bromine absorbed by graphite was retained in the dilute region. The fraction of the retained bromine is higher than Hennig's result, which may be attributed to the difference of the type of the graphite sample.

The steep decrease of the electrical conductivity of the bromine residue compound at the higher bromine concentration was also observed by Hennig[7] and Kosai.[11] They explained this phenomenon to be the result of the mechanical disintegration of graphite crystal by a considerable dimensional change with bromination. This is plausible in a way. The reproducibility of the data was fairly good, and the point of the saturated residue compound coincided with the line of lamellar compound. It may be possible to consider the decrease of the electrical conductivity as a transition from the electronic state of the residue compound to that of the lamellar compound.

Far Infrared Spectra of Potassium Oxalate Monohydrate and Its Deutero Analog

Kunio FUKUSHIMA

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Sizuoka

(Received June 12, 1969)

The far infrared spectra of potassium oxalate monohydrate and its deutero analog in their crystalline state were measured. Assignment of the infrared absorption bands was made on the basis of frequency shift associated with deuterium substitution of hydrogen atoms in water of crystallization and also on the basis of comparison of neutron scattering spectra of the compounds with the infrared spectra.

Molecules of the water of crystallization form various types of bondings with surrounding atoms and ions through hydrogen bond and lone-pair coordination. Chidambaram *et al.* classified molecules of the water of crystallization on the basis of their coordination to ions and electron accepter groups.[1] In the present study, potassium oxalate monohydrate (p.o.m.), which belongs to type A,[1] was chosen as a representative of crystals containing molecules of the water of crystallization whose lone pairs are not specifically directed to any of the surrounding atoms and ions. A spectroscopic investigation in the region of 4000—60 cm^{-1} was carried out. The IR spectra of p.o.m. and its deutero analog (*d*-p.o.m.) have been observed by several investigators.[2-4] In the lower frequency region, measurement of Raman spectra of metal oxalate in aqueous solution was made.[5] However, no measurement of far IR spectra has been reported so far. In the present investigation, far IR spectra of p.o.m. and *d*-p.o.m. were measured in order to obtain optically active lattice vibration frequencies and to assign several IR absorption bands.

Experimental

The far IR spectra of p.o.m. in Nujol mull were measured in the region of 400—60 cm^{-1} with a Hitachi FIS-3 Far IR Spectrometer. Sample for the measurement was obtained by recrystallization of a special grade reagent p.o.m. of Koso Chemical Co., Ltd. from aqueous solution. The measurement was made for the sample in Nujol mull, sealed in a thin polyethylene sack. *d*-p.o.m. was prepared by vacuum distillation of p.o.m.-heavy water solution and vacuum drying of the residue. The far IR spectra of the Nujol mull were measured. The far IR spectra are shown in Figs. 1 and 2. IR spectra of the same samples in the region of 4000—400 cm^{-1} were measured with a Perkin-Elmer 521 Spectrophotometer and a Hitachi EPI-L Spectrophotometer. The spectra are shown in Figs. 3 and 4.

Assignment of IR Absorption Bands

Assignment of IR absorption bands in the region of 4000—300 cm^{-1} has been discussed by Schmelz *et al.*[3] and also by Pedersen.[4] However, several new experimental facts found in the present study suggest the following assignment of some IR absorption bands.

As the relative intensities of O–H and O–D stretching bands of the residue show that deuteration was carried out almost perfectly, IR spectra of the residue may be interpreted as those of deuterate. (see Figs. 2, 3 and 4).

Schmelz *et al.* and Pedersen did not point out the presence of a shoulder band at the higher frequency side of the strong band at 1580 cm^{-1} of p.o.m.[3,4] In their studies, IR spectra were recorded with a spectrometer equipped with prism optics. In the present study, IR spectra were obtained with grating spectrometers having higher resolving power. From the result the presence of a shoulder band at 1608 cm^{-1} and the shift of shoulder band to lower frequency on deuteration were confirmed. A band corresponding to the shoulder band appears at 1225 cm^{-1} in the spectra of *d*-p.o.m. Therefore, the two bands at 1608 cm^{-1} and 1225 cm^{-1} are assigned to H_2O bending and D_2O bending vibration, respectively. Schmelz *et al.* and Pedersen found a shift of frequency of the band at 710 cm^{-1} associated with deuteration.[3,4] In accordance with their results, the band of p.o.m. at 718 cm^{-1} shifts to lower frequency on deuteration as shown in Fig. 3, and the corresponding band appears at 505 cm^{-1} for *d*-p.o.m. It was also found that the band of p.o.m. at 614 cm^{-1} shifts to lower frequency on deuteration and two bands appear at 432 cm^{-1} and 358 cm^{-1} for *d*-p.o.m. as shown in Figs. 2 and 3. The results along with the observed neutron scattering peaks, 700 cm^{-1}, 605 cm^{-1}, 500 cm^{-1} (p.o.m.) and 505 cm^{-1}, 450

cm^{-1}, 370 cm^{-1} (*d*-p.o.m.),[6] confirm assignment of the IR absorption bands at 718 cm^{-1}, 614 cm^{-1}, 524 cm^{-1} (p.o.m.) and the bands at 505 cm^{-1}, 432 cm^{-1}, 358 cm^{-1} (*d*-p.o.m.) to the rotational lattice vibrations primarily associated with molecules of the water of crystallization and with those of the heavy water of crystallization, respectively. This assignment is consistent with the fact that the IR absorption bands due to molecules of the water of crystallization and of the heavy water of crystallization molecules were observed in the region of 900—300 cm^{-1} in the case of aquo complexes.[7] No shift of frequency of the band at 524 cm^{-1} (p.o.m.) on deuteration may be explained by overlapping of CO_2 wagging band. The band at 710 cm^{-1} (p.o.m. and *d*-p.o.m.) is considered to be due to Nujol.

Far IR absorption bands in the region of 250—60 cm^{-1} (Figs. 1 and 2) may be due to translational lattice vibrations. Assignment of these bands will have to be discussed on the basis of calculation of lattice vibrations and other experimental data. In this paper, only the correspondence of frequencies of IR absorption bands with those of neutron scattering peaks[6] is pointed out for the bands at 190 cm^{-1}, 115 cm^{-1}, 92 cm^{-1} (p.o.m.) and 195 cm^{-1}, 125 cm^{-1}, 115 cm^{-1}, 93 cm^{-1} (*d*-p.o.m.) as shown in Table 1.

The author wishes to thank Professor T. Miyazawa of Osaka University for kindly allowing him use of the Hitachi FIS-3 Far Infrared Spectrometer, Perkin-Elmer 521 Spectrophotometer and Hitachi EPI-L Spectrophotometer. Thanks are also due to Dr. T. Kitagawa and Miss M. Tsuchida for their kind assistance during the course of measurements.

The Phosphorescence Processes in Pyrimidine and 2-Chloropymidine

Nobuyuki NISHI, Ryoichi SHIMADA and Yoshiya KANDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received June 14, 1969)

The phosphorescence spectra of pyrimidine and 2-chloropyrimidine have been observed at 4.2°K. A detailed vibrational analysis of the pyrimidine spectrum suggests that the emission arises from two components of the emitting triplet state. The phosphorescence lifetimes of pyrimidine and 2-chloropyrimidine have been measured for the 0–0 band and the strongest "vibronic band" (the phosphorescence maximum), which involves various modes of vibrations, at different temperatures between 77 and 1.5°K. The decay curve observed for the 0–0 band has been resolved into two exponential components, and that for the vibronic band, into three exponential components, where the third component was extremely weak in intensity at a very low temperature. From the comparison of the observed and calculated lifetimes of the individual phosphorescence components and their relative intensities, it was deduced that: (1) the 0–0 band involves emissions arising from the B_2 and A_1 components of the $^3B_1(n,\pi^*)$ state, while the vibronic band involves an additional, third emission which very likely arises from the A_2 component; (2) the $^1A_2(n,\pi^*)$ state is located below the $^1B_1(n,\pi^*)$ state; (3) the $^3A_1(\pi,\pi^*)$ state is located below the $^1A_2(n,\pi^*)$ state, and (4) the major intersystem crossing takes place from both the $^1A_2(n,\pi^*)$ and $^1B_1(n,\pi^*)$ states to the $^3A_1(\pi,\pi^*)$ state in pyrimidine and 2-chloropyrimidine.

The phosphorescence spectrum of pyrimidine has been studied by Shimada[1] and by Krishna and Goodman,[2] who assigned the emitting triplet state to a $^3B_1(n,\pi^*)$ state on the basis of vibrational analysis and the solvent effects. Their assignment agreed with the result calculated by Goodman and Harrell.[3] Krishna and Goodman[4] confirmed this assignment by polarization measurements. Furthermore, they[5] calculated the transition probability of the triplet-singlet transition and concluded that

two components can radiatively combine with the ground state in the lowest triplet state of pyrimidine. The same conclusion has, very recently, been obtained by Yonezawa, Katô and Kato.[6] Cohen and Goodman[7] measured the quantum yields of the phosphorescence, fluorescence, internal conversion, and intersystem crossing in pyrimidine and determined the rate constants for these radiative and non-radiative processes. They concluded that the phosphorescence process in pyrimidine is $^1B_1(n,\pi^*) \rightsquigarrow {}^1A_2(n,\pi^*) \rightsquigarrow T(n,\pi^*) \rightarrow {}^1A_1$.*1

de Groot, Hesselmann, Schmidt and van der Waals[8] and Hall, Armstrong, Moomaw and El-Sayed[9] studied the phosphorescence decays of quinoxaline and pyrazine respectively and showed that the decay curves of these compounds were non-exponential at very low temperatures ($\sim$1.5°K). The different phosphorescence components, which were analyzed from the decay curves, were ascribed to the transitions from the different sublevels of the lowest triplet state to the ground state. Very recently, Azumi and Nakano[10] measured the phosphorescence lifetime of quinoxaline at various temperatures and estimated the rate constants of the radiative and non-radiative processes from three sublevels of the lowest triplet state to the ground state.

It should be interesting to study the phosphorescence decay of pyrimidine, because the phosphorescence is emitted from two sublevels of the lowest triplet state through first-order perturbation in pyrimidine, while in quinoxaline or pyrazine the phosphorescence is emitted from only one sublevel, and the phosphorescence emitted from two sublevels can provide more information about the phosphorescence processes. This study was undertaken in order to investigate the phosphorescence processes of pyrimidine and 2-chloropyrimidine in more detail through careful analyses of the phosphorescence spectra and decay curves.

Experimental

The pyrimidine was obtained through the reductive dechlorination of trichloropyrimidine with Pd-charcoal.[11] The 2-chloropyrimidine was synthesized with 2-aminopyrimidine, $NaNO_2$, and HCl by means of a diazo reaction.[12] The samples were purified by repeated vacuum distillation just before the experiments.

The phosphorescence spectrum was observed in a methylcyclohexane matrix at 4.2°K with a Hilger spectrograph, type E2. The optical setup and the other apparatus used in this work were the same as those described previously,[13] except that quartz dewars and a thin pyrex sample-cell were used in this case. The 3131 Å Hg-line which was isolated from a 1-kW high-pressure mercury arc lamp, type Orc-CHM-612, with a filter combination of a saturated $NiSO_4$ aqueous solution and a Corning 7-54 glass filter,[14] was used for the excitation of the sample. The necessary exposure time was 24 hr with a slit-width of 25 μ and an Eastman Kodak 103a-O plate. The concentration of the sample was 10^{-4}M.

The lifetime measurement was carried out for each of the 0–0 bands and for one of the vibronic(phosphorescence maximum) bands of the phosphorescence spectrum obtained in methylcyclohexane and benzene matrices at different temperatures between 77 and 1.5°K. The exciting and phosphorescence beams were chopped off with a shutter device designed particularly for this study. The sample was placed between two shutters which were connected with strings and pulleys. First the excitation path was opened and the emission path was closed by a rear shutter so that the excitation could be saturated. Immediately after the excitation path was closed by a front shutter, which was operated by a trigger, the emission path was opened. The two shutters worked so quickly that a short lifetime such as $\sim$5 msec could be determined quite precisely. The lifetime was analyzed with a Bausch & Lomb 500-mm grating monochromator, fixed at a constant wavelength (*e.g.*, the wavelength of the phosphorescence 0–0 band), and with an Iwasaki synchroscope, type SS-5004. The slit-width of the monochromator ranged from 0.5 to 2.5 mm depending on the phosphorescence intensity.

Results

Pyrimidine and 2-chloropyrimidine emit blue phosphorescences in methylcyclohexane and benzene matrices at 4.2°K. The spectra observed at 4.2°K consist of very sharp and highly-resolved bands compared with those observed at 90°K.[1] Their spectral data and microphotometer tracings are given in Table 1 and Fig. 1 respectively.

The decay curves of the phosphorescence lifetimes of pyrimidine and 2-chloropyrimidine, measured for the 0–0 and vibronic bands obtained in methylcyclohexane and benzene matrices at 1.5°K, are shown in Fig. 2. These curves are non-exponential. The curves for the 0–0 bands can be resolved into two components, which give lifetimes of 15 and 58 msec in methylcyclohexane and of 13 and 150 msec in benzene for pyrimidine, and lifetimes of 14

and 56 msec in methylcyclohexane and of 30 and 178 msec in benzene for 2-chloropyrimidine. The decay curves for the vibronic bands contain a third, very weak component in addition to the above two. This gives a lifetime of 160 msec in methylcyclohexane and one of 200 msec in benzene for pyrimidine. The intensity of this third component was too weak for it to be analyzed for 2-chloropyrimidine.

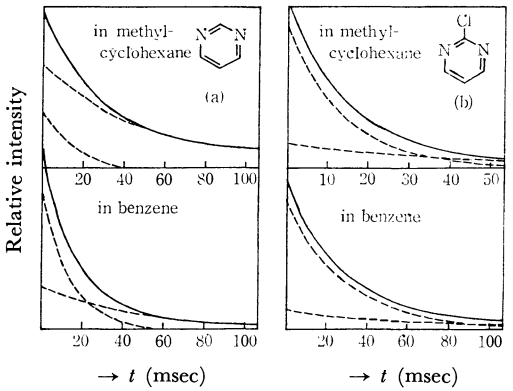

Fig. 2. The phosphorescence decay curves of (a) pyrimidine and (b) 2-chloropyrimidine observed in methylcyclohexane and benzene at 1.5°K —, and analyzed exponential decay curves ----.

We will hereafter call these three lifetime components "short-", "medium-" and "long-lifetime components".

In pyrimidine, the phosphorescence intensity of the medium-lifetime component, which was estimated through the extrapolation of the analyzed exponential curve to $t=0$, is stronger than that of the short-lifetime component in methylcyclohexane, while the former is slightly weaker than the latter in benzene at 1.5°K. In 2-chloropyrimidine, the intensity of the short-lifetime component is stronger than that of the medium-lifetime component in both matrices at 1.5°K. The long lifetime component is very weak in intensity in both matrices. The short-lifetime components increase their intensities with an increase in the temperature for both molecules.

The medium-lifetime component shows a characteristic temperature dependence. The lifetime remains almost constant at temperatures ranging from 1.5 to about 4.2°K. Above 4.2°K, the lifetime begins to decrease with an increase in the temperature, and then it again comes to show a constant value from about 30°K. The values of the lifetime measured in methylcyclohexane at various tempera-

tures are given in Table 2.

The phosphorescence decay curves of the 0–0 and vibronic bands observed at 77°K for both molecules were practically exponential in both matrices. The lifetimes were found to be 27 and 26msec in methylcyclohexane and 29 and 93msec in benzene for pyrimidine and 2-chloropyrimidine respectively. These values are the same as those of the medium-lifetime components measured at 30°K.

Discussion

Vibrational Analysis of the Phosphorescenc Spectrum of Pyrimidine.

The Raman and infrared spectra of pyrimidine have been studied by many workers,[15-18] but the assignments they have given for the fundamental vibrational frequencies do not entirely agree with each other. We will use here the fundamental frequencies given by Sbrana, Adembri, and Califano[17] because their assignments seem to be the most reliable. We will use the same coordinate orientation as that used by Lord, Marston, and Miller;[15] that is, the x axis is perpendicular to the plane of the molecule, and the z axis, along the C_2 axis.

The vibrational analysis of the phosphorescence spectrum observed at 4.2°K is essentially the same as that observed at 90°K,[1] except that the highly-resolved fine structure obtained at 4.2°K enables us to carry out the vibrational analysis in much more detail.

A band at 24214 cm^{-1}, highest in wave number and strongest in intensity, was taken to be the 0–0 band of the spectrum. The very strong bands, which are separated by 679, 1053, 1071 and 1132 cm^{-1} from the 0–0 band, were assigned to the totally symmetric vibrations ν_{6a}, $\nu_{16b}+\nu_{10b}$, ν_{12}, and ν_{9a}*2 respectively. The splitting of the ν_{12} band and the $\nu_{16b}+\nu_{10b}$ band, which is intensified by the Fermi-resonance, is quite remarkable. The rather weak bands separated by 989, 1402, and 1571 cm^{-1} from the 0–0 band were assigned to the ν_1, ν_{19a}, and ν_{8a} totally symmetric vibrations respectively. All the other prominent bands were assigned to combinations and overtones of these totally symmetric vibrations.

Several extremely weak bands, separated by 398, 716, and 802 cm^{-1} from the 0–0 band, were observed between the 0–0 and 1132 bands. These frequencies may be assigned to three nontotally symmetric vibrations, ν_{16a}, ν_{10b}, and ν_{11} respectively, on the basis of their intensities and frequencies. The first belongs to the a_2 species, and the latter two, to the b_1 species. These vibrations also appear as overtones and combinations with the ν_{6a} and ν_{9a} vibrations in the longer-wavelength region. The detailes of the vibrational analysis are summarized in Table 1.

The degrees of the polarization of the $^3B_1(n,\pi^*)\rightarrow {}^1A_1$ phosphorescence relative to excitation into the $^1B_1(n,\pi^*)$ and $^1B_2(\pi,\pi^*)$ states were observed by Krishna and Goodman to be -0.25 and $+0.15$ respectively.[4] These values are about 75 and 30% of the expected values of -0.33 and $+0.5$ for the angles of $\theta=90°$*3 and 0° respectively. Although their values were not at the ideal limits, these results clearly indicate that the transition moment of the $^3B_1\rightarrow {}^1A_1$ phosphorescence is not completly along the y axis, but partially along the z axis.

Our vibrational analysis of the phosphorescence spectrum also supports this finding. The observation of the a_2 and b_1 vibrations suggests that there are at least two emitting components in the $^3B_1(n,\pi^*)$ state. The transitions to the a_2 and b_1 vibrational levels in the ground state can proceed from the B_2 and A_1 components of the $^3B_1(n,\pi^*)$ state respectively by borrowing intensities from the electronically-allowed $^1B_1(n,\pi^*)$–$^1A_1$ transition through second-order spin-orbit-vibronic interaction. The emission from the A_2 component is negligibly weak because of the vanishingly small matrix element of the spin-orbit interaction between the $^1A_2(n,\pi^*)$ and $^3B_1(n,\pi^*)$ states.

The absorption and phosphorescence spectra of 2-chloropyrimidine very closely resemble those of pyrimidine. Polarization measurements of the phosphorescence relative to the absorptions indicate that these two molecules have quite similar electronic structures.[19] Some nontotally symmetric vibrations were also observed in the phosphorescence spectrum of 2-chloropyrimidine. A detailed vibrational analysis of this molecule will be published soon.

Lifetime of the Phosphorescence. The decay

curve of the 0–0 band of the phosphorescence observed below 4.2°K consists of two exponential components. Above 4.2°K the lifetime of the medium component shortens with an increase in the temperature. This may indicate that below 4.2°K the spin-lattice relaxation process between the triplet state multiplets is slower than both the triplet→triplet internal conversion process and the triplet→ground state radiative process. Hence spin-polarization is nearly preserved, while above 4.2°K the spin-lattice relaxation takes place and the deactivation of the triplet-state-energy *via* a triplet component, from which the phosphorescence is emitted with a short lifetime, gradually increases. This also explains the increase in the intensity of the short-lifetime component with an increase in the temperature. When the temperature goes up above 30°K, the spin-lattice relaxation process fully exceeds other processes and the deactivation of the triplet-state-energy comes approximately to obey the following expression,

$$\tau \approx \frac{3}{k_{qx}+k_{py}+k_{qy}+k_{pz}+k_{qz}} \approx \frac{3}{k_{py}+k_{pz}} = \frac{3}{\frac{1}{\tau_{py}}+\frac{1}{\tau_{pz}}}$$

where k_p and k_q are radiative and non-radiative rate constants respectively, and where x, y, and z are the indices of the three components of the triplet state.

If the lifetime values of pyrimidine and 2-chloropyrimidine observed in benzene at 1.5°K are substituted into this expression, one obtains 36 and 75 msec respectively. These values approximately agree with those observed at 77°K within the limit of experimental error. If the values observed in methylcyclohexane are substituted into it, however, the agreement becomes rather poor. This may be mainly due to the fact that the ratio of the lifetime values of the medium component to those of the short component is not sufficiently large in this matrix. Therefore, the short-lifetime component was analyzed to be slightly longer in lifetime than the real one.

The transition probability of the $^3B_1(n,\pi^*)$–$^1A_1$ transition of pyrimidine has been calculated by Goodman and Krishna[5] and by Yonezawa, Katô, and Kato.[6] They have shown that: (1) the $^3B_1$–$^1A_1$ transition borrows its intensity from the electronically-allowed S–S and T–T transitions through the first-order spin-orbit interaction; (2) the transition moment is mainly along the y axis, but partially along the z axis also; (3) the $^3B_1\rightarrow{}^1A_1$ phosphorescence polarized along the y axis originates from the B_2 component of the $^3B_1(n,\pi^*)$ state and has a lifetime of about 4 msec,[5] and (4) the $^3B_1\rightarrow{}^1A_1$ phosphorescence along the z axis originates from the A_1 component and has a lifetime of about 70 msec.[5]

These considerations lead to the conclusion that the short-lifetime component should be ascribed to the $^3B_1(n,\pi^*)B_2\rightarrow{}^1A_1$*[4] transition, and the medium-lifetime component, to the $^3B_1(n,\pi^*)A_1\rightarrow{}^1A_1$ transition.

The long-lifetime component with an extremely weak intensity that has been observed only in the vibronic bands can perhaps be ascribed to the $^3B_1(n,\pi^*)A_2\rightarrow{}^1A_1$ transition, but there is no positive evidence in support of this assignment.

Phosphorescence Process. The splitting of two (n,π^*) states of A_2 and B_1 symmetry species in pyrimidine has been calculated to be 1590 and 275 cm^{-1} in the singlet and triplet states respectively, with the A_2 state below the B_1 state in the singlet and with the opposite order in the triplet state.[20] The $^3A_1(\pi,\pi^*)$ state was calculated to be located lower in energy than the $^1B_1(n,\pi^*)$ state by about 1.4 eV.[21] On the other hand, the $^3B_2(\pi,\pi^*)$ state may be expected by analogy with the low-lying triplet states of benzene to lie above the $^1B_1(n,\pi^*)$ state.[21]

Cohen and Goodman[7] have indicated, on the basis of the quantum yields of the radiative and non-radiative processes, that: (1) the rate constants of the $^1B_1(n,\pi^*)\rightarrow{}^1A_1$, $T_1(n,\pi^*)\rightarrow{}^1A_1$, $^1B_1(n,\pi^*)\rightsquigarrow{}^1A_2(n,\pi^*)$ and $^1B_1$ or $^1A_2(n,\pi^*)\rightsquigarrow T$ are 5×10^6, ~50, 9.1×10^8 and 1.2×10^8 sec^{-1} respectively; (2) the intersystem crossing proceeds from the $^1A_2(n,\pi^*)$ state because the internal conversion has the fastest rate constant, hence, the phosphorescence process in pyrimidine is $^1B_1(n,\pi^*)\rightsquigarrow{}^1A_2(n,\pi^*)\rightsquigarrow{}^3B_1(n,\pi^*)\rightarrow{}^1A_1$, and (3) the intersystem crossing rates are largely dependent on factors other than the matrix element of the first-order spin-orbit interaction. Their considerations are based on the assumption that the $^3A_1(\pi,\pi^*)$ state is located above the $^1A_2(n,\pi^*)$ state.

The intersystem crossing which proceeds from the $^1A_2(n,\pi^*)$ state to the A_2 component of the $^3B_1(n,\pi^*)$ state must take place through the first-order spin-orbit interaction, and that to the B_2 or A_1 component, through the second-order spin-orbit-vibronic interaction. The first-order intersystem crossing between the $^1A_2(n,\pi^*)$ and $^3B_1(n,\pi^*)$ states must be extremely inefficient because of the vanishingly small values of one- and two-center integrals of the matrix element of the spin-orbit interaction and because of the very small Franck-Condon factor, as has been pointed out by El-Sayed.[22] The second-order intersystem crossing between the $^1A_2(n,\pi^*)$ and $^3B_1(n,\pi^*)$ states through the intermediate (π,π^*) states is expected to be much less efficient than the first-order intersystem crossing between the $S(\pi,\pi^*)$

*4 $^3B_1(n,\pi^*)B_2$ denotes the B_2 component of the $^3B_1(n,\pi^*)$ state.

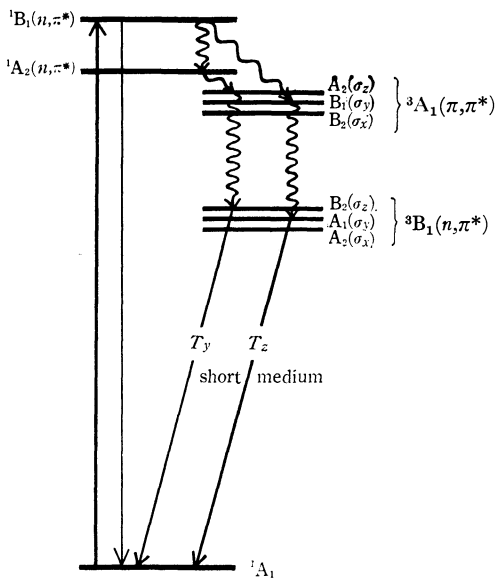

Fig. 3. Phosphorescence processes in pyrimidine and 2-chloropyrimidine.

state of the B_2 or A_1 symmetry and the $^3B_1(n,\pi^*)$ states. In pyrazine, the intersystem crossing proceeds from the $S(n,\pi^*)$ state to the $T(\pi,\pi^*)$ state through the first-order spin-orbit interaction,[7,22] this leads to the strong phosphorescence. Therfore, if Cohen and Goodman's conclusions were correct, pyrimidine should phosphoresce considerably less efficiently than pyrazine. This is, however, contrary to the results of their quantum yield measurements, which show that the rate constant of the intersystem crossing in pyrimidine is smaller than that in pyrazine by a factor of only two.

The observed rather high phosphorescence yield of pyrimidine indicates that the phosphorescence must arise from a non-radiative process, either (1) $^1B_1(n,\pi^*)\rightsquigarrow{}^3A_1(\pi,\pi^*)\rightsquigarrow{}^3B_1(n,\pi^*)$ or (2) $^1A_2(n,\pi^*)\rightsquigarrow{}^3A_1(\pi,\pi^*)\rightsquigarrow{}^3B_1(n,\pi^*)$. The former process requires that the intersystem crossing proceed from the second excited singlet state, while the latter requires that the $^3A_1(\pi,\pi^*)$ state lie below the $^1A_2(n,\pi^*)$ state.

The fact that the 0–0 band of the phophorescence spectrum involves two types of emissions, those due to the $^3B_1(n,\pi^*)A_1\rightarrow{}^1A_1$ and $^3B_1(n,\pi^*)B_2\rightarrow{}^1A_1$ transitions, at 1.5°K indicates that both the above two requirements are satisfied in pyrimidine, because these emissions must originate from the non-radiative paths of $^1B_1(n,\pi^*)\rightsquigarrow{}^3A_1(\pi,\pi^*)B_1\rightsquigarrow{}^3B_1(n,\pi^*)A_1$ and $^1B_1(n,\pi^*)\rightsquigarrow{}^1A_2(n,\pi^*)\rightsquigarrow{}^3A_1(\pi,\pi^*)A_2\rightsquigarrow{}^3B_1(n,\pi^*)B_2$ respectively. The internal conversion processes between triplet states comply with the requirement of the preservation of spin-polarization (see Fig. 3).

The fluorescence spectrum of pyrimidine was first observed by Börresen[23] and by Cohen, Baba and Goodman.[24] It was assigned to the $^1B_1(n,\pi^*)\rightarrow{}^1A_1$ transition by Cohen and Goodman.[7] This assignment was confirmed by the experimental findings[25] that: (1) the 0–0 band of the fluorescence spectrum exactly coincides with the 0–0 band of the $^1B_1(n,\pi^*)\leftarrow{}^1A_1$ absorption spectrum, and (2) the spectral structure of the fluorescence agrees exactly with the hot bands of the absorption. Neither the absorption nor the fluorescence due to the $^1A_2(n,\pi^*)-{}^1A_1$ transition has been observed. The fact that the fluorescence comes from the second excited singlet state supports the idea that the intersystem crossing can proceed from the $^1B_1(n,\pi^*)$ state.

Halosubstitution induces a blue shift for (n,π^*) states and a red shift for (π,π^*) states. An increase in the energy difference between the $^1B_1(n,\pi^*)$ and $^3A_1(\pi,\pi^*)$ states in 2-chloropyrimidine decreases the rate constant of the intersystem crossing between these two states and hence increases the rate constant of the competing internal conversion between the $^1B_1(n,\pi^*)$ and $^1A_2(n,\pi^*)$ states. This results in an increase in the relative intensity of the short-lifetime component in 2-chloropyrimidine, although its overall phosphorescence intensity is weaker in intensity than that of pyrimidine.

In conclusion, our experimental results support the generally-accepted assumption that the $^1A_2(n,\pi^*)$ state is located below the $^1B_1(n,\pi^*)$ state. Further work is now being undertaken to obtain conclusive evidence regarding the order of these two (n,π^*) states.

(Received June 16, 1969)

The initial rate and the aging effect of ethylene polymerization with $TiCl_4$- and $TiCl_3$-$AlEt_3$ catalyst were investigated. The initial rate, r, was expressed by the equation; $r=k_1P_E+k_2P_E^2$, where p_E is the ethylene partial pressure and where k_1 and k_2 are constants. The explanation of the equation is as follows:

$$\text{(active site)} + M \xrightarrow{k_1} \text{(polymerization site)}, \text{ rate, } k_1P_E$$

$$\text{(polymerization site)} + M^* \xrightarrow{k_2} \text{(propagation)}, \text{ rate, } k_2P_E^2$$

M shows the ethylene monomer which is liberated by the catalyst formation or which is introduced into the system. M* is the monomer which is introduced into the system. The initial rate decreased in the $TiCl_4$-$AlEt_3$ system with the aging-time interval; on the other hand, in the $TiCl_3$-$AlEt_3$ system the rate showed its maximum at about half an hour's aging. The optimum aging temperature was found to be 20°C. The decrease in the rates between the two systems may be ascribed to the reduction of the Ti atom in the initial valence state of the reaction to the lower valence.

In a preceding paper,[1] the kinetics in the stastionary state of ethylene polymerization and the effect of hydrogen on the rate in connection with the $TiCl_3$-$AlEt_3$ catalyst system were described. This paper will be concerned with the initial rate and the aging effect of ethylene polymerization by the $TiCl_4$- and $TiCl_3$-$AlEt_3$ systems. It is well known that the catalyst systems of the Ziegler-Natta type consist of the reaction products resulting from titanium halides in conjugation with alkylaluminum compounds. We have confirmed that the active sites of the catalyst result from the reaction of titanium halides ($TiCl_4$ or $TiCl_3$) and alkylaluminum, while the polymerization sites result from the addition of monomer molecules to the active sites.

When triethylaluminum as alkylaluminum is employed, the liberation of ethylene and other saturated hydrocarbons has been verified by different authors.[2-7] By the addition to the active sites of ethylene liberated in the reaction of titanium halides with triethylaluminum, some polymerization sites will be formed prior to the introduction of the ethylene monomer into the reaction system. A considerable number of active sites will also exist on the catalyst surface. If the polymerization starts at the active sites, the initial rate will be second-order with respect to the monomer concentration, but if it starts at the polymerization sites, the order will be first. This is bacause a molecule of ethylene reacts with an active site to produce a polymerization site; then another molecule affects the polymerization site and the propagation proceeds.

In order to verify this, we studied the initial rate of ethylene polymerization with the $TiCl_4$- and $TiCl_3$-$AlEt_3$ catalyst systems.

The aging effects of the catalysts on the initial rate are still controversial. Very few studies have been made of the aging effect in the $TiCl_4$- and $TiCl_3$-

$AlEt_3$ catalyst systems.[8-11] Simon and Gyhmes[8] investigated the aging effect on the polymerization rate of ethylene in the $TiCl_4$-$AlEt_3$ catalyst system, and indicated that the effect did not appear at a particular temperature. Kodama and his co-workers[9] found that the activity of such a catalyst decreased considerably with time at 60°C, although the catalyst activity did not change much at 30°C for up to 4 hr. Hoeg and Liebman[10] studied the aging effect on the propylene polymerization, using $TiCl_3$ and $Al(iso\text{-}Bu)_3$, and found that these catalysts were thermally unstable. Schnecko and his co-workers[11] examined the difference in the aging effect by monomers upon the ethylene, propylene, and butene-1 polymerization rates by the $TiCl_3$-$AlEt_3$ and $TiCl_3$-$AlEt_2Cl$ systems. Thus, the different aging effects reported by various authors may be ascribed to the formation of lower valence states of titanium, which presumably are less stable and less efficient as catalysts, or to the coagulation of catalyst particles, whereby the available surface is decreased.

We examined the time and temperature effect of aging on the initial rate and attempted to analyze the valence state of titanium in the course of aging, which presumably causes the rate decrease.

Experimental

Reagents. The titanium tetrachloride was purified by distillating it several times with Cu powder until the distillate lacked color and by then diluting it to 10 wt% solution with *n*-heptane. The *δ*-Type of titanium trichloride supplied by the Toho Titanium Co. was used without any purification. The triethylaluminum was employed as 10 wt% *n*-heptane solution given by the Mitsubishi petrochemical Co. The toluene was purified by rectification in the presence of metallic sodium. The ethylene and nitrogen were dried under NaOH pellets and P_2O_5.

Polymerization Apparatus and Technique. The apparatus is shown in Fig. 1. Polymerization was carried out in a 500-m*l* separable flask provided with three depressed sides. Agitation was kept at 1000 rpm

sufficient to obtain non-diffusion controlled conditions regarding the polymerization rate.

In a 500-ml flask replaced with nitrogen, 200 ml of toluene and the required amounts of $TiCl_4$ or $TiCl_3$ and $AlEt_3$ were in this order intorduced by syringes under a nitrogen atmosphere. Stirring at a constant speed was accomplished, and the flask was immersed in a water bath which was adjusted to keep the fluctuation of the temperature within 0.1°C.

The rather excessive mole ratio of $AlEt_3$ to titanium halides was chosen so that the $AlEt_3$ reacted enough with titanium halides and so that the rate of polymerization was independent of the $AlEt_3$ concentration;[12] *i.e.*, the Al/Ti ratio in the catalyst system was chosen to be 4, while the concentration of titanium halides was 1 mmol.

After the evacuation of the reaction apparatus, ethylene was fed through a needle valve; the time of polymerization was recorded immediately. The rate of ethylene consumption in polymerization was measured by a wet-flow meter.

Analysis of Titanium. The valence state of titanium was analysed by the method described by Martin and Stedefeder.[13] In a three-necked, 300-ml flask equipped with a stirrer and containing a catalyst solution, 30 ml of alcohol and 10 ml of 2N HCl solution, both of which had already been cooled, are added under nitrogen at −50——70°C; the solution is then titrated with a 0.1M $FeCl_3$ solution, using methyleneblue as the indicator. No effect of nitrogen on the rate of ethylene consumption was observed, as is shown in Fig. 2. Even at the low partial pressure of ethylene of 10 cmHg, with or without nitrogen, and even on the introduction of nitrogen during polymerization, the rate of ethylene consumption did not alter. Therefore, all the polymerizations at low ethylene partial pressures were carried out with the addition of nitrogen, keeping the total reaction pressure at the atmospheric level.

As may be shown in Fig. 3, ethylene, when dissovled, reaches the saturated state within a few minutes after the introduction of ethylene at rather high partial pressures, but at pressures of ethylene lower than 10 cmHg, satulation was reached after at least 10 min. During this interval, the polymerization and the dissolution of ethylene will take place at the same time; therefore, we chose the polymerization at ethylene partial pressures higher than 10 cmHg. Meaningful flowmeter readings began only after 3 min due to the filling-up of the reaction flask.

Results and Discussion

Initial Rate of Polymerization. The ethylene consumption *versus* the time had a linear relationship for about 10 min. Some representative results are shown in Figs. 4 and 5. The initial rate of polymerization, r, was defined in terms of the decline of the straight lines dotted for an interval from 3 min to 10 min. About the relation of initial rates to the partial pressure of ethylene, P_E, we found that r/P_E was proportional to P_E (Figs. 6 and 7). Therefore, r is expressed by the following equation:

$$r = k_1 P_E + k_2 P_E^2 \quad (1)$$

In this equation k_1 and k_2 are constants. The values of the constants, k_1 and k_2 are shown in Table 1; the activation energies calculated using

k_1 and k_2 are listed in the last column of the table. The first term, k_1P_E, refers to the initial rate starting from the polymerization sites resulting in a catalyst complex formation, while the second term, k_2P_E, refers to the rate starting from the polymerization sites built up by the reaction of the active sites and ethylene molecules introduced.

The activation energies in the $TiCl_3$-$AlEt_3$ system are larger than those in the $TiCl_4$-$AlEt_3$ system. Consequently, the polymerization sites in the two catalyst systems will be different. The difference in the activation energies calculated by k_1 and k_2 will be the energy required for the formation of the active sites.

Schindler[14] described the rate equation in ethylene polymerization by the $TiCl_4$-Al(iso-Bu)$_2$ system as:

$$R_p = \frac{KP_E^2}{1 + K'P_E} \qquad (2)$$

* Activation energy (kcal/mol)

14) A. Schindler, *J. Polym. Sci., Part C*, **4**, 81 (1963).

Here R_p is the rate of the polymerization, and K and K' are constants. The equation expresses the second-order kinetics with respect to the ethylene partial pressure as long as the pressure remains low enough in order to make $K'P_E$ small compared to unity. The values of k_1 in Eq. (1) are not as small as the k_2 values, which can be neglected, as may be seen in Table 1.

At a low pressure the rate will be first-order with respect to P_E, judging from our data. Keii and his co-workers[15] reported that the rate of the initial state in propylene polymerization was second-order with respect to the propylene partial pressure. In this case, the rate starting from the polymerization sites which were already formed during the catalyst complex formation will be neglected in the propylene polymerization; *i. e.*, the first term in Eq. (1) will be neglected in comparison with the second term. Consequently, the polymerization sites constructed in the reaction of the active sites with the propylene monomers introduced will be more active than the other polymerization sites already present as a result of the catalyst formation. Though the activation energies almost agree with those obtained by Fukui, Kagiya and their co-workers,[16] the energies seem to be rather small in comparison with those reported by other authors.[17-18] Our lower values are difficult to ascribe to the diffusion control of ethylene into the solvent, so it seems that our values are attributable to the ethylene polymerization in the initial stage.

Aging Effect

The relation of the aging time to the initial rate in the $TiCl_4$ and $TiCl_3$-$AlEt_3$ systems at 20°C is shown in Fig. 8. The initial rate decreases with the aging interval in the $TiCl_4$-$AlEt_3$ system, and in the $TiCl_3$-$AlEt_3$ system the rate attains its maximum value after about half an hour of aging. The maximum in $TiCl_3$-$AlEt_3$ may be due to an increase in the concentration of the active sites, followed by an increase in the effective surface area by the collapse of $TiCl_3$ particles. On the other hand, the decrease in r may be ascribed to the

reduction of titanium to the state of the lower valences of titanium in the $TiCl_4$- and $TiCl_3$-$AlEt_3$ systems.

The results of the analysis are shown in Table 2. The titanium ion is reduced to the lower valence state with the aging time. Especially, $TiCl_4$ is more easily reduced than $TiCl_3$. After an aging time of more than 3 hr, $TiCl_4$ is almost completely reduced, but the activity of ethylene polymerization remains. Some of the Ti^{3+} or Ti^{4+} remains, for the active sites of polymerization will be titanium ions with the valences higher than two.[19-21] Even if the active species are di- or tri-valent titanium, they may be changed through oxidation or disproportionation to mono- or tetra-valent titanium by the hydrochloric acid added in analysis.

The decrease in the initial rate with the aging time may be ascribed to reduction into the lower-valence state of titanium. The fact that the sum of the Ti^{2+} and the Ti^{3+} present in the $TiCl_3$-$AlEt_3$ system is not 100 per cent may come from the titanium of the valence state lower than two, or tetravalent titanium may be present. The relation between the initial rate and the aging temperature after an hour's aging is shown in Fig. 9. The optimum aging temperature is found to be 20°C. The initial rate in $TiCl_3$-$AlEt_3$ was not much affected by the temperature, but in $TiCl_4$-$AlEt_3$ it was affected remarkably. The decrease in the rate caused by the aging temperature may also be ascribed to the reduction of the titanium atoms.

A more accurate determination of the cause of the aging effect will have to await another analytical method, because not all the valence states of titanium can be detected by the method of Martin and Stedefeder.[13] We are still in the process of developing a better analytical method to detect all the valence states of titanium.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 52—56 (1970)

Chemical Reactivity of Adamantane and Related Compounds

Hiroshi FUJIMOTO, Yoshihiko KITAGAWA,*1 Hideyuki HAO*1 and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received June 17, 1969)

The chemical reactivity of hydrogens in adamantane and substituted adamantanes has been calculated. The results of calculation have shown that the bridgehead hydrogens are most reactive toward electrophilic reagents or radicals. The chemical reactivity of hydrogens in diamantane, triamantane, and tetramantane has also been predicted. A discussion has been made of the stable configuration of the 1-adamantyl cation, radical, and anion and of the nature of the back-side conjugation between the two tertiary carbons in these species. A mode of the electrocyclic polymerization of *p*-quinodimethane to form polyamantane has been predicted on the basis of the symmetry properties of the frontier orbitals in the pi and sigma parts of *p*-quinodimethane.

Recently the chemistry of adamantane and its homologues has been developed in connection with the chemical reactivity of the bridgehead hydrogen atoms. Stetter and Wulff have shown that the ionic bromination of adamantane occurred exclusively at the bridgehead.[1] The homolytic abstraction of hydrogen of adamantane and substituted adamantanes has also been reported, demonstrating the occurrence of the predominant removal of the bridgehead hydrogen atoms.[2,3] It has been shown that one of the theoretical reactivity indices, delocalizability, can be a good measure of the reactivity of hydrogens in aliphatic systems.[4,5] Here we will present the results of

calculations on adamantane and related compounds undertaken in order to test the validity of the theoretical reactivity indices for such compounds with bridgehead atoms. Calculations have also been carried out on three adamantane homologues, diamantane, triamantane and tetramantane, in an effort to predict the favorable course of the homolytic abstraction of hydrogens. In addition, the potentiality of an ingenious method for the preparation of polyamantane will be suggested.

The Chemical Reactivity of Adamantane and Substituted Adamantanes. It is well known that the quantum-mechanical theory of chemical reactivity has been successfully applied to organic molecules. Of the various chemical reactivity theories thus far presented, the delocalization approach is unique in that this method can be applied to both saturated and unsaturated molecules in a unified manner. The delocalization approach has also achieved a fair success in explaining or predicting the favorable steric course of electrocyclic processes.[6,7] By an application of the molecular orbital (MO) perturbation theory to the chemical reaction, the chemical reactivity indices, superdelocalizability (S_r) and delocalizability (D_r), have been derived.[8,9] Of these, the former is used for unsaturated molecules, and the latter, for saturated molecules. The index D_r is a reliable measure of the reactivity of hydrogens in paraffin hydrocarbons and their derivatives toward abstraction reactions.

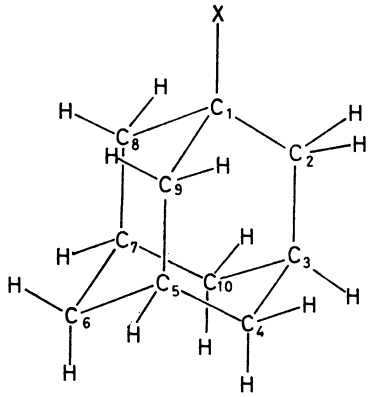
The values of delocalizability for electrophilic attack, $D_r^{(E)}$, are shown in Table 1 with respect to adamantane and several 1-substituted adamantanes. Calculation was made by the simple LCAO MO method for saturated compounds which had previously been employed for paraffin hydrocarbons.[9] We can see that bridgehead hydrogens have the largest chemical reactivity toward attacking electrophiles.

The values of delocalizability for radical attack, $D_r^{(R)}$, are given in Table 2. The experimental findings that the bridgehead hydrogens are most readily removed can be successfully interpreted in terms of $D_r^{(R)}$.[2] Owens *et al.* showed that the relative rate of the homolytic abstraction of bridgehead hydrogen in adamantane and in substituted adamantanes decreased in the order:[3]

$$-CH_3 > -H > -OCH_3 > -COOCH_3 > -CN$$

Because of the rough setting of parameters for oxygen hybrids, we can not make a sharp comparison between the results of calculation given in

Table 1. The delocalizability at hydrogen atoms for electrophilic abstraction



X	Position of attack		
	2	3	4
H	1.0387	1.0407	1.0387

Table 2 and the experimental order of reactivity. However, it should be noted that the calculation gave a correct order with respect to adamantane and 1-methyl adamantane, and also with respect to methoxy, carbomethoxy, and cyano deirvatives.

The $D_T^{(B)}$ values of hydrogens in diamantane, triamantane, and tetramantane are shown in Fig. 1. It can be predicted that, in all of these adamantane homologues, the bridgehead hydrogens can most readily be removed by a radical.

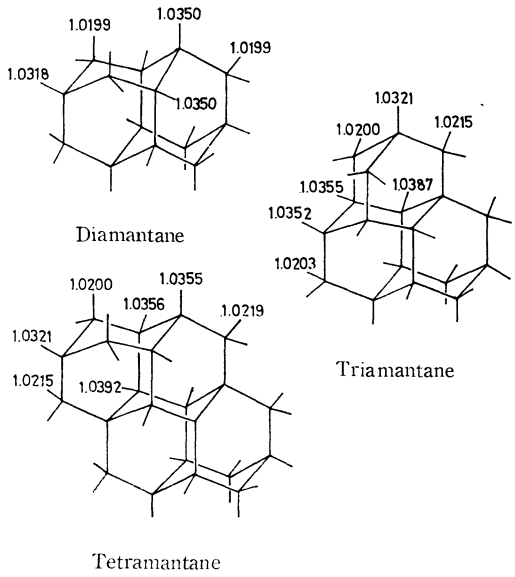

Fig. 1. The delocalizability at hydrogen atoms for homolytic abstraction.

The Electronic Structure of Adamantane, the Adamantyl Radical and Ions. The atom populations and atom-bond populations of adamantane and 1-chloroadamantane, as calculated by the extended Hückel MO method,[10] are shown in Fig. 2. The underlined values indicate the atom populations, while those in parenthesis are those obtained by a SCF MO method for valence electrons with an approximation of the zero-differential overlaps.[11] It can be seen that bridgehead hydrogen have larger electron populations than as secondary hydrogens. The effect of the substituent at the bridgehead carbon, namely, the change in populations, is transmitted in opposite fashions to the adjacent secondary carbons and to the other bridgehead carbons. A similar relation also holds with respect to hydrogens attached to the secondary and tertiary carbons.

The results of the calculations by the extended Hückel MO method on the stable configurations of the 1-adamantyl cation, radical and anion are shown in Fig. 3. In these calculations, only the position of the carbon atom 1 was changed upwards or downwards along the C_3 symmetry axis from its normal position; the positions of the other atoms were unchanged. Here, it should be noted that the most stable position of the carbon 1 in the radical is found to be almost the same as in the parent

compound. The cation becomes more stable as the angle θ increases up to about 117°, while the anion is most stable at about $\theta=101°$. The broken line in Fig. 3 indicates the change in the energy of the orbital, ε_f, housing an electron in radical; this we may term the "frontier orbital." As we employ a one-electron approximation in the extended Hückel MO method, we can see that the stable configuration of the radical and the anion largely depends on the change in the energy of this particular orbital along with the configuration change.

It has been pointed out that the back-side interaction between the hybrids at the carbons 1 and 3 has a significant influence upon the physical properties of the adamantly cation.[12] Here, let us discuss the nature of the stabilization and unstabilization due to the back-side conjugation in the 1-adamantyl cation, radical and anion. The conjugation energy between the two hybrids, χ_1 and χ_3 (see the figure in Table 3), at the carbons 1 and 3 is given by:

$$E_{\chi_1\chi_3} = 2\sum_i v_i C_{\chi_1}^{(i)} C_{\chi_3}^{(i)} h_{\chi_1\chi_3},$$

where v_i is the occupation number of the ith MO (0, 1 or 2), $C_{\chi_1}^{(i)}$ is the coefficient of χ_1 in the ith MO, $h_{\chi_1\chi_3}$ is the resonance integral between the hybrids χ_1 and χ_3, and $\sum$ implies the summation over all the MO's. We tentatively take the sp^3 hybrid as χ_3, while the hybrid χ_1 is determined by the relation between the hybridized state and the bond angle,[13] corresponding to the most stable configuration of each species shown in Fig. 3. The results of calculation are given in Table 3. It may be seen that the stabilization due to the back-side conjugation between the hybrids χ_1 and χ_3 is larger in the cation than in the radical or anion. The partial conjugation energy arising from the frontier orbital,

$$E_{\chi_1\chi_3}^{(f)} = 2C_{\chi_1}^{(f)} C_{\chi_3}^{(f)} h_{\chi_1\chi_3},$$

is +0.0124 eV (contributing to unstabilization) with regard to the most stable configuration of the radical.

The partial valence-inactive population[14] of the hybrid, χ_1, in the half-occupied MO is found to be 0.7154, which is important in the event of chemical interaction with other chemical systems. This result makes us suppose that the unpaired electron in the half-occupied level might be somewhat delocalized over the other constituent atoms. The sum of the one-electron energies of the 2-adamantyl radical with the sp^2 hybridized state at the carbon 2 was found in the extended Hückel MO calculation to be lower than that of 2-adamantyl with the sp^3 state at the carbon 2 by the amount of ~0.6 eV.

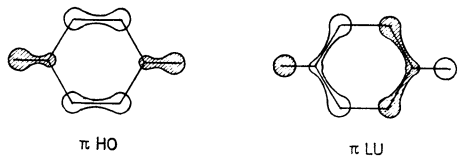

Fig. 4. The nodal property of HO and LU in the pi-electronic part of *p*-quinodimethane.
The shaded and unshaded areas correspond to the positive and negative regions of the wave functions, respectively

A Potential Route to Polyamantane. Now let us present a proposition regarding the potentiality of the preparative method of polyamantane. When we concentrate on the larger homologues of adamantane, we can find that an elemental unit of the repeated sequence has the same constituents as *p*-quinodimethane. Therefore, polyamantane might be produced by the electrocyclic polymerization of *p*-quinodimethane, as long as the methods of the initiation and termination are successfully devised in order to arrange that both chain-end rings have the normal valency. The nodal properties of the highest occuped (HO) MO and one of the lowest unoccupied (LU) MO in the pi-electronic part are shown in Fig. 4. The charge-transfer interaction due to the transfer of one electron from the HO of one molecule into the LU of another molecule favors such an eight-centric cyclic interaction as is shown in Fig. 5, leading to the formation of a polyamantane chain with the adamantane sequence of the form **I.**

We must here make a reservation that the consideration of sigma-pi interaction[7] predicts the

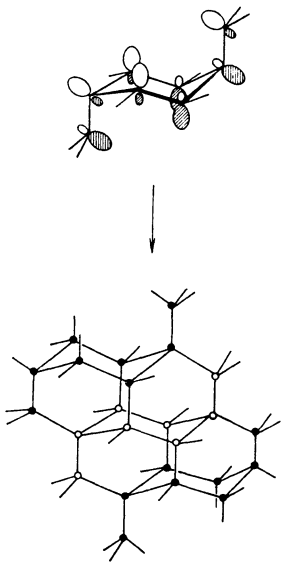
formation of a somewhat different sequence. In the chemical interaction of planar conjugated systems in which hybridization change takes place, it has been pointed out,[7] the interaction between the pi part and the sigma part can not be neglected. The interaction between the HO of the pi-electronic part and the LU of the sigma part is usually most



II

Fig. 7. A schematic representation of the mode of the intramolecular sigma-pi overlap interaction in *p*-quinodimethane.

important. The nodal properties of these MO's are given in Fig. 6. Therefore, the sigma-pi interaction favors such configuration change a way as is shown in Fig. 7; this may cause the predominant formation of polyamantane of the form II. However, in usual multi-centric interaction between two conjugated molecules, the stereo-controlling effect due to the intramolecular sigma-pi interaction is rather weak and is overcome by that due to the intermolecular pi-pi interaction between two reactants. This point would be clarified if the preparation of polyamantane by the thermally-induced polymerization of *p*-quinodimethane should be achieved.

The calculations were carried out partly on the HITAC 5020E computer at the Computer Center of the University of Tokyo and partly on the FACOM 230.60 at the Computer Center of Kyoto University.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 57—63 (1970)

The Effect of Pressure on the Electronic Absorpion Spectra of TCNQ Ion Radical Salts

Nobuko SAKAI, Ichimin SHIROTANI and Shigeru MINOMURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received June 20, 1969)

The effect of pressure up to 7 kbar on the electronic absorption spectra of the crystalline TCNQ anion radical salts and Li(TCNQ) in PVA has been studied. For simple TCNQ salts such as Li(TCNQ), a blue shift with an increase in the pressure has been observed in the absorption band associated with the intramolecular transition. The magnitude of the blue shift is between 45 and 86 cm^{-1}/kbar. The observed shift has been discussed in terms of the crystal-field effect of the cations. For *N*-MePhe(TCNQ) and $M(TCNQ)_2$, composed of the formally-neutral TCNQ and its anion radical such as $TEA(TCNQ)_2$, a pressure-induced absorption band has been observed at around 20 kK; it may be assigned to the charge-transfer band between the anion radicals.

The electronic absorption spectra of most organic compounds exhibit a red shift with an increase in the pressure.[1-3] However, the absorption band at 18.5 kK of the quaterrylene ($C_{40}H_{20}$) evaporated film is less affected by the pressure,[4] and in the cases of azulene, ferrocene, and the *trans*-stilbene-2,3-dichloro-5,6-dicyano-*p*-benzoquinone complex, a small blue shift is observed at high pressures.[5] In a previous paper,[6] a large blue shift with the pressure has been reported in several ion radical salts which possess an ionic structure in the ground state.

The electrical conductivity of the anion-radical salts of 7,7,8,8-tetracyanoquinodimethane (TCNQ) depends greatly on the nature of the cation.[7] The salts with metal cations generally show low to intermediate conductivity (10^{-5}—10^{-2} $\Omega^{-1}cm^{-1}$), while the salts with cations of planar aromatic heterocyclic molecules show high conductivity ($\sim 10^{2}$ $\Omega^{-1}cm^{-1}$). The conductivity of these solids arises from the motion of the odd π electron among the TCNQ sites. Their conduction mechanism has been discussed by several authors.[8-10]

Recently, the crystalline electronic spectra of TCNQ salts have been studied at room temperature.[10-12] The crystalline spectra are quite different from that of the TCNQ anion radical monomer and depend greatly on the nature of the cations. Boyd and Phillips have reported the absorption spectra of the monomer [$(TCNQ^{-})$] and the dimer [$(TCNQ^{-})_2$] in an aqueous solution of Li(TCNQ).[13] The crystalline spectrum of Li(TCNQ) is similar to that of the dimer in an aqueous solution.

We have studied the absorption spectra of several TCNQ salts in the visible region at high pressures and have found spectral blue and red shifts with the pressure in the low-conductive salts and a pressure-induced absorption band in the high-conductive compounds. In this paper these results will be discussed.

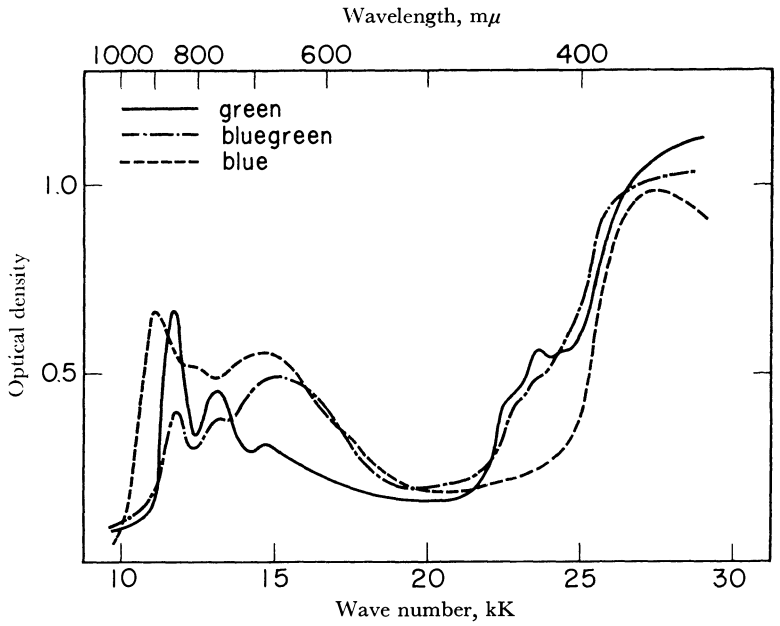

Fig. 1. The absorption spectra of Li(TCNQ) PVA films of three different concentrations; ——— the green, -·-·-· the blue green, and ·-·-·-·- the blue PVA film.

quinolinium [Q(TCNQ)$_2$], bipyridinium [BiP(TCNQ)$_2$], 4-amino-2,3,5,6-tetramethylanilinium [DAD(TCNQ)$_2$], triethylammonium [TEA(TCNQ)$_2$] and cobalticinium [CoC(TCNQ)$_2$]. These compounds were provided by Kondow, who has previously reported their preparations in detail.[10] Li(TCNQ)-polyvinylalcohol (PAV) film was prepared by drying a 10 wt% warm aqueous slurry of PVA in which Li(TCNQ) was dissolved. A uniformly-colored plastic film was formed after the evaporation of the solvent. The absorption spectra were measured on powdered samples rubbed on a quartz glass plate and on PVA film at room temperature by using a Shimazu SV-50A spectrophotometer. The high-pressure optical cell has been described elsewhere.[4] A hydrostatic pressure up to 7 kbar was applied by means of a pressure-transmitting medium (kerosene or white gasoline) through a pressure-intensifier. The pressure was determined by a Harwood manganine resistance gauge and a Heise Bourdon tube gauge.

Results and Discussion

Figure 1 shows the absorption spectra of Li(TCNQ) PVA film of three different concentrations at 1 bar. In the green PVA film, the absorption peaks almost agree with that in acetonitril. Therefore, Li(TCNQ) seems to be in a monomer state in the green film. The absorption spectrum of the blue PVA film is similar to that of the dimer of the TCNQ anion radical in an aqueous solution, and it has a new absorption peak at 11.0 kK which does not exist in the monomer state. In the blue green PVA film, the dimer and the monomer may be supposed to coexist. The absorption peak at 11.0 kK in the dimer state revealed a small red shift (-18 cm^{-1}/kbar) with an increase in the pressure, while the other absorption peaks of these PVA film were insensitive to the pressure up to 7 kbar.

Figure 2 shows the effect of the pressure on the absorption spectra of the crystalline K(TCNQ). The crystalline spectra of K(TCNQ) exhibited absorption bands located at 8.3, 16.1, and 27.5 kK. The two peaks in the visible region showed a large blue shift with an increase in the pressure ($+45$ and $+58$ cm^{-1}/kbar for the 16.1 and 27.5 kK peaks respectively). Similar results on Li(TCNQ) have been reported in a previous paper.[6] The rates

a) Ref. 5.

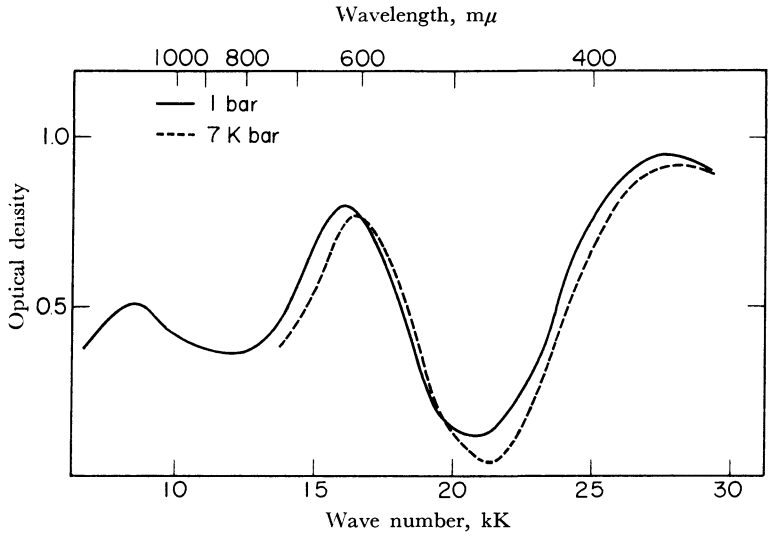

Fig. 2. The pressure dependence of the absorption spectra of the crystalline K(TCNQ).

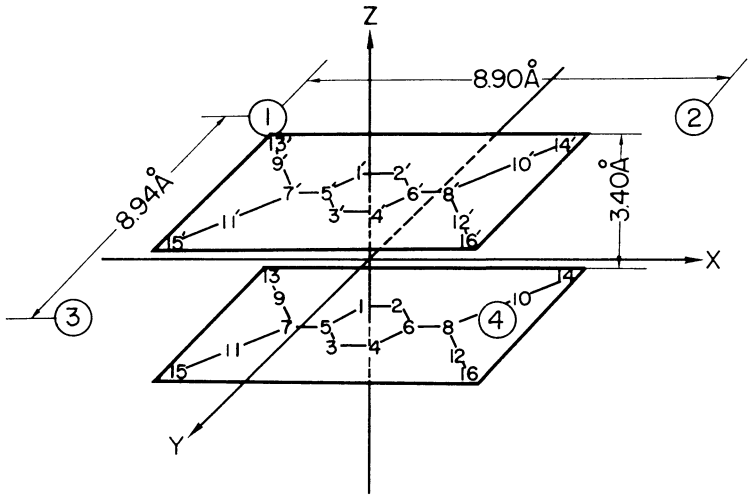

Fig. 3. The assumed crystal field for K(TCNQ).

of the pressure shift of several TCNQ salts are given in Table 1. The energy shifts are approximately proportional to the applied pressure.

The absorption spectra of crystalline Li(TCNQ) and K(TCNQ) are similar to that of the dimer in an aqueous solution. The spectroscopic evidence supports a bimolecular association of the TCNQ ion radicals in the solid. As has been stated earier, the absorption bands of the dimer observed in the PVA film were insensitive to the pressure. Therefore, it seems that the major contribution to the blue shift arises from the crystal field*1 of metal-positive ions.

In accordance with Menefee and Pao,[8] the pressure dependence on the splitting of energy levels brought about by a model crystal field of the cations was tentatively calculated to explain the large blue shift. The crystal field was assumed on the basis of the crystal structure of K(TCNQ)[14] which is shown in Fig. 3; two molecules of $TCNQ^-$ are stacked face to face with a spacing of 3.4 Å, and four positive nuclei with a point charge of $+e/4$ are put on the corners of the rectangle (8.94×8.90 Å) formed in the middle between two molecules and the parallel to the $TCNQ^-$ molecular plane. Since this cluster belongs to the D_{2h} symmetry group, the new molecular orbitals are given by:

$$\Phi_{n-} = A_{n-}(\psi_n - \psi_{n'}),\ \Phi_{n+} = A_{n+}(\psi_n + \psi_{n'}),$$

*1 "Crystal field" means the electrostatic field by ions in the crystal.

14) G. R. Anderson and C. J. Fritchie, Jr., Paper for Second National Meeting of the Society for Applied Spectroscopy, San Diego (1963), p. 111.

where ϕ_n and $\phi_{n'}$ are the nth molecular orbitals centered on the first and second $TCNQ^-$ radical ions respectively, and where A is the normalization coefficient. For $\phi_{n'}$, the results of the open-shell SCF-LCAO-MO calculations by Lowitz[15] were used here;

$$\begin{aligned}\phi_8(b_{1u}) = &-0.22901(\phi_1+\phi_2+\phi_3+\phi_4)\\ &+0.18931(\phi_5+\phi_6)+0.50263(\phi_7+\phi_8)\\ &+0.01933(\phi_9+\phi_{10}+\phi_{11}+\phi_{12})\\ &-0.23007(\phi_{13}+\phi_{14}+\phi_{15}+\phi_{16}),\\ &(E=1.92061\text{ eV}),\ (n=8)\\ \phi_9(b_{2g}) = &-0.25063(\phi_1-\phi_2+\phi_3-\phi_4)\\ &-0.26414(\phi_5-\phi_6)+0.45618(\phi_7-\phi_8)\\ &+0.08375(\phi_9-\phi_{10}+\phi_{11}-\phi_{12})\\ &-0.20304(\phi_{13}-\phi_{14}+\phi_{15}-\phi_{16})\\ &(E=4.4249\text{ eV}),\ (n=9,\text{ highest occupied level})\\ \phi_{10}(b_{1u}) = &-0.19752(\phi_1+\phi_2+\phi_3+\phi_4)\\ &+0.51425(\phi_5+\phi_6)-0.19426(\phi_7+\phi_8)\\ &-0.16327(\phi_9+\phi_{10}+\phi_{11}+\phi_{12})\\ &+0.18226(\phi_{13}+\phi_{14}+\phi_{15}+\phi_{16}),\\ &(E=8.89412\text{ eV}),\ (n=10,\text{ lowestvacant level})\end{aligned}$$

where ϕ_i is the atomic orbital for the ith atom and where E is the eigenvalue. The stabilization energy by the crystal field is given by;

$$\begin{aligned}\Delta E &= \int \Phi_n V \Phi_n d\tau\\ &= (-e^2/4)\int \Phi_n(1/r_1+1/r_2+1/r_3+1/r_4)\Phi_n d\tau,\end{aligned}$$

where r_a is the distance from each atom of $TCNQ^-$ to the nucleus, a, which was obtained from the bond lengths shown in Table 2 and from the bond angles (assumed to be 120 or 180°). The calculated values of ΔE (for $n=8,9,10$) and the splitting energy by the assumed crystal field at the atmospheric pressure and at 10 kbar are shown in Table 3.*2 It was assumed that, at 10 kbar, $TCNQ^-$ salts were isotropically compressed in volume to 90.5%*3 without a change in the $TCNQ^-$ molecular structure. The stabilization energy and the splitting energy by the crystal field were larger on the low-energy level than on the high energy level, and both increased with an increase in the pressure. Table 3(b) gives the pressure-induced shift of some of the transitions considered; this shift was calculated according to the results shown in Table 3(a). A considerable blue shift was obtained. On the basis of the calculated results, it seems reasonable to conclude that the large blue shift of the electronic

15) D. A. Lowitz, *J. Chem. Phys.*, **46**, 4698 (1967).

*2 In the calculation of ΔE, as usual, terms coming from nonadjacent atoms were ignored, and for the integrals in terms of atomic orbitals, the following approximations were made;

$$\int \phi_i^2/r_a d\tau \simeq 1/r_{a'},\ \int \phi_i\phi_j/r_a d\tau \simeq \tfrac{1}{2}(1/r_{ai}+1/r_{aj})S_{ij},$$
$$\int \phi_i\phi_{i'}r_a d\tau \simeq 1/r_a\delta_{ii'}$$

where r_{ai} is the separation of the positive nucleus, a, and the i atom, where S_{ij} is the overlap integral, and where $\delta_{ii'}$ is the overlap integral which refers to the same kind of atoms located on two $TCNQ^-$ molecules. For $S_{CC'}$, S_{CN} and $\delta_{CC'}$ (or $\delta_{NN'}$), the approximate expressions which Roothaan [*J. Chem. Phys.*, **19**, 1445 (1951)] has given for three two-center integrals, ($2p\pi_C$-$2p\pi_C$), ($2p\pi_C$-$2p\pi_N$), and ($2p\sigma_C$-$2p\sigma_C$) respectively, were used.

*3 This value is the volume change with the pressure for general crystals of aromatic molecules, as extrapolated from Bridgman's data [Samara and Drickamer, *J. Chem. Phys.*, **37**, 474 (1962)]. The compressibility of ion radical salts has not been measured, but it is probably less than that of ordinary hydrocarbon solids.

transition observed in Li(TCNQ) and K(TCNQ) arises from the crystal field of metal cations.

Li(TCNQ) and K(TCNQ) have the absorption band in the near-infrared region. The effect of the pressure on these peaks has not yet been studied becasue of interference by the absorption of water contained in the pressure-transmitting medium. This band can be assigned to the charge-transfer band between the anion radicals.[12] It is well-known that the charge-transfer band of molecular complexes shows a red shift at high pressures.[2] A similar effect may be expected for $TCNQ^-$ ion radical salts.*4 The electrical resistance of Li(TCNQ) drops rapidly in the low-pressure region and levels off at high pressures. The values of the activation energy decreases from 0.32 eV at 1 bar to 0.07 eV at 169 kbar.[16] Since the near-infrared band is located in the energy region of twice the activation energy for electrical conductivity, the study of the pressure effect on this band is important. The new absorption band at 11.0 kK in the blue PVA film of Li(TCNQ) can be assigned to the charge-tranfer band between TCNQ-anion radicals which corresponds to the crystalline absorption band in the near-infrared region, for this band does not exist in the monomer state and the spectral red shift was observed at high pressures.

Figure 4 shows several isobars of the absorption spectra for *N*-MePhe(TCNQ). The pressure effect on the bands at 11.5 and 17.0 kK is not clear, for these bands are appreciably weak and diffused. The pressure shift of the band at 26.0 kK was not observed, at least up to 7 kbar. However, a remarkable pressure effect was observed; that is, the pressure-induced absorption band was found at around 20 kK at high pressures. The absorption intensity of this band increased with an increase in the pressure. This bahaviour was reversible with a decrease in the pressure. *N*-MePhe(TCNQ) shows an unusually high conductivity ($1.4\times10^2\Omega^{-1}\cdot cm^{-1}$) in spite of a simple salt of the M(TCNQ) type.[7] According to the crystal structure analysis by Fritchie,[17] $TCNQ^-$ molecules pack face to face to form a regular linear chain column with an interplanar spacing of 3.26 Å. This interplanar spacing is much shorter than the van der Waals distance. Therefore, the strong charge-transfer interaction may be expected to have been induced by compression. The absorption intensity increased remarkably with the pressure. As has been expected from Mulliken's charge-transfer theory,[18] the absorption intensity of the charge-transfer band increases with the pressure[2]. Thus, the pressure-induced absorption band at 20 kK may be ascribed to a new charge-transfer absorption band.

Figures 5 and 6 show several isobars of the absorption spectra for $TEA(TCNQ)_2$ and $Q(TCNQ)_2$. The pressure-induced absorption band was found at around 20 kK at high pressures. The absorption intensity of this band increased with an increase in the pressure. On the other hand, the absorption intensity of the weak peak at 17 kK, the nature of

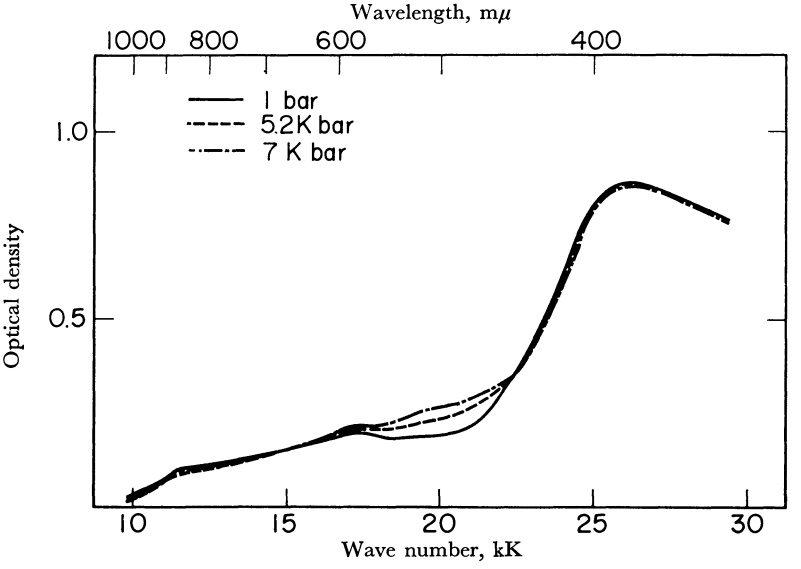

Fig. 4. The pressure dependence of the absorption spectra of the crystalline *N*-MePhe(TCNQ).

*4 In the case of Na(chloranil) salt, the inter-radical charge-transfer band has shown a red shift with an increase in the pressure.[6]

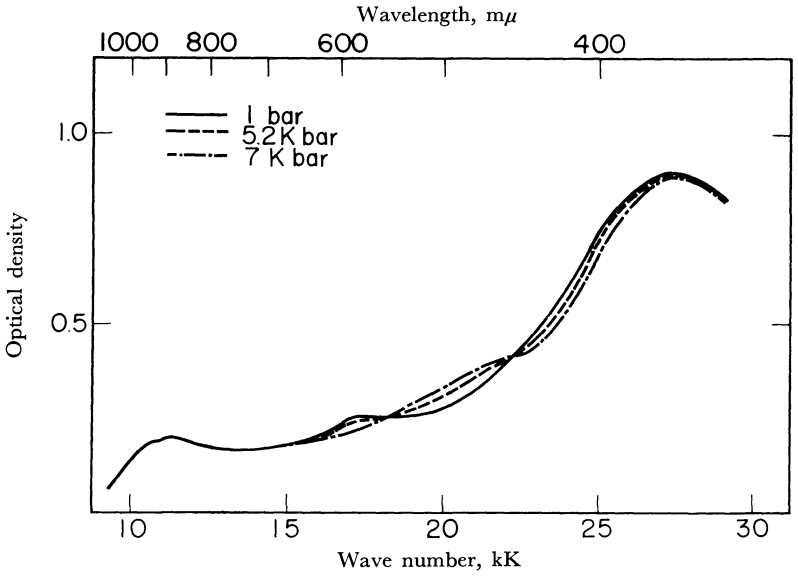

Fig. 6. The pressure dependence of the absorption spectra of the crystalline Q(TCNQ)$_2$.

which was not clear, decreased with an increase in the pressure. These pressure effects were reversible with a decrease in the pressure. Similar results were also obtained for BiP(TCNQ)$_2$, CoC(TCNQ)$_2$, and DAD(TCNQ)$_2$.

The TCNQ salts of the M(TCNQ)$_2$ type show a high conductivity and a small activation energy.[7] The crystalline structure has been analysed for TEA(TCNQ)$_2$ and Q(TCNQ)$_2$.[19] TCNQ$^-$ molecules pack face to face with an interplanar spacing of 3.21—3.32Å. The strong charge-transfer interaction may be expected to be induced by compression in these TCNQ anion radical salts, also. Thus, the pressure-induced absorption band may be ascribed to a new charge-transfer absorption band.

The pressure shift of the bands at 11 and 27 kK associated with the intramolecular transition was not obaserved, at least up to 7 kbar. The energy shift with the pressure may arise from the characteristic crystalline structure of TCNQ salts. Further, in the case of the M(TCNQ)$_2$ type, the crystal-field effect is considered to be weakened by the

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 63—67 (1970)

Comparison of the Recoil Reactions in the ^{80m}Br-CH_4 and ^{82m}Br-CH_4 Systems

Enzo Tachikawa

Division of Chemistry, Japan Atomic Energy Research Institute, Tokai-Mura, Ibaraki

(Received June 24, 1969)

The reactions of ^{80}Br and ^{82}Br excited by the isomeric transition processes with CH_4 have been compared with each other. Similar reaction processes; energetic and thermal ionic, are involved in both cases. However, the isotope effect appears in the energetic process to form CH_3Br, but not in the thermal ionic process to form CH_3Br and CH_2Br_2. The difference in the γ-transitions of ^{80m}Br and ^{82m}Br to the ground states is responsible for the above results. It is concluded that at least a part of the recoil Br atoms enter chemical combinations with surrounding molecules within 10^{-8}sec, the life-time of the excited ^{80}Br atom. Furthermore, the yield of $CH_3{}^{80}Br$, lower than that of $CH_3{}^{82}Br$, is discussed on the basis of the different kinetic energies achieved on the Br atoms.

The atom or ion formed as result of nuclear transformation loses its energy or its charge, or both, in collisions with other molecules of the medium until most of the charges have been lost and its energy reduced to tens or *ev.* or even below, at which time it may enter a permanent stable combination if an appropriate reaction path is available.[1]

The investigations of such processes in the gas phase have now been extended by many workers to studied of the nature of the reactive species in the reaction of Br formed by the (I. T.) process with methane. Using additives, it has been concluded that CH_3 ^{82}Br in gaseous methane must, principally, result from an atom with excess kinetic energy, and CH_2 ^{82}BrBr, from the thermal ionic Br atom.[2,3]

Other experiments[4] strongly indicate that the reaction of the ^{80}Br from the ^{79}Br(n,γ)^{80}Br process with CH_4 is probably not dependent upon the charge. This remarkable difference in reactive species must result from the characteristics of the Br atoms activated by the different nuclear reactions; the (n, γ) process is strictly a high-energy recoil phenomenon, while on the other hand, the (I.T.) process involves little recoil and a high positive charge, ranging from $+1$ to $+14$.[5,6]

It was though interesting to see if differences in the product distribution could also be found between the ^{80}Br and the ^{82}Br formed by (I. T.) processes in the reactions with CH_4, since the γ-transitions involved are somewhat different in the two species. The γ-transition of ^{82m}Br to the ground state is performed in a single transition, whereas that of ^{80m}Br is attained in two steps.[7]

Nicholas and Rack[8] dealt with a comparison of the total organic yields from ^{80m}Br-CH_4 and ^{82m}Br-CH_4. The difference found between them does not exceed the experimental uncertainties. However, this does not provide any comparisons of the individual reaction processes, the energetic and thermal ionic processes.

In the present paper, we will deal in more detailed investigations of the reactions in these systems; particular, we look for a possible isotope effect between them in order to obtain some information on the time scale of the reactons of the recoil Br atom.

Experimental

The general experimental techniques are quite similar to those used in earlier bromine experiments.[2] The ^{80m}BrBr was formed by irradiating gaseous Br_2, sealed in a thin-wall quartz capillary, with thermal neutrons for one minute; it was used in the I.T. experiments 2—3 hr after irradiation. As a neutron source, the JRR-4 reactor in the JAERI was used.

Under these conditions, the percentage of ^{82}Br activity for which correction had to made was less than one per cent. The ^{80m}BrBr reaction mixture was allowed to stand more than 2 hr to permit a ^{80m}Br-^{80}Br parent-daughter equilibrium to be established. The sample were then analyzed by a radio-gas-chromatograph equipped with a G-M counter. The total activity was also measured by a G-M counter and corrected for ^{82}Br activity. The results obtained were expressed in per cent yields by applying decay corrections. In the experiments on the ^{82m}Br-CH_4 system, the neutron-irradiated bromine was mixed with CH_4 before the decaying-out of ^{82m}Br. The products were analyzed 48 hr later. The radioactive assays in a radio-gas-chromatograph and the total activity measurements were performed by a scintillation counter (2″×2″ well-type NaI(Tl) scintillator). A correction for ^{80}Br was not required in these procedures.

The experiments were carried out a total pressure of 51±2 cmHg. The ratio of Br_2 as a scavenger to CH_4 was kept constant. In some experiments, however, a constant amount of Br_2 was used.

Materials. The methane was obtained from the Takachiho Chemical Co., had a listed purity of 99.5%. The bromine used was the highest grade available. Xenon and argon, supplied by the Takachiho Chemical Co. and the Nihon Sanso Co., were used without additional purification (the listed purities are 99.995% and 99.994% respectively).

Result

CH_3Br and CH_2Br_2 are the only products from the reactions of ^{80}Br or ^{82}Br with gaseous methane; this is consistent with the finding in the early observations.[3]

The moderator effects on these products have been studied under a constant pressure of 5 cmHg Br_2 in both systems, ^{80m}Br-CH_4 and ^{82m}Br-CH_4. The results obtained using Xe are summarized in Table 1. A significant difference between the two systems is seen in the yields of CH_3Br; $CH_3{}^{82}Br$ is higher than $CH_3{}^{80}Br$ over the entire range of mole fractions of Xe. However, both could be extrapolated to 0.0±0.3% at 1.0 m.f. of Xe. Contrarily, both $CH_2{}^{80}BrBr$ and $CH_2{}^{82}BrBr$ decrease from 1.1±0.2% to 0.5±0.3% upon the addition of Xe.

As was the case in Table 1, the presence of a constant amount of Br_2 alters the reaction conditions so that the amount of Br_2 relative to CH_4 varies with the mole fraction of the moderator. Accordingly, the probability of the reactive collision of the energetic or thermal ionic Br atom with Br_2, relative to that with CH_4, rapidly increases with the amount of the moderator. In a highly-moderated system, thus, the Br-flux available to the reaction with CH_4 is very much reduced.

The most suitable conditions for studying the moderator effect specifically on these products is, thus, to keep the value of Br_2/CH_4 constant over the entire range of mole fractions of the moderator. Table 2 shows the results obtained with the addition of Br_2/CH_4=0.11±0.01, using Ar as a moderator.

$CH_3{}^{80}Br$ and $CH_3{}^{82}Br$ are moderator-sensitive, and both are extrapolated to $0.5\pm0.3\%$ at 1.0 mol fraction of Ar. On the other hand, both $CH_2{}^{80}BrBr$ and $CH_2{}^{82}BrBr$ are constant within range of experimental uncertainty over the whole range of mole fractions of Ar.

Discussions

Reaction of Br with CH_4. The most convenient way to differentiate the energetic reaction from the kinetic enregy-independent (thermal ionic) reactions is through the addition of inert gas as an energy sink of the energetic Br atom. Judging from the ionization potentials of the inert gas and the Br atom, the charge transfer from the Br^{+1} atom to the inert gas molecule seems not to be important.

Thus, if a product is formed *via* the kinetic energy process, its yield should be reduced by the addition of inert gas. The conclusion drawn from the results shown in Table 2 is that $3.5\%-0.5\%=3.0\%$ for $CH_3{}^{80}Br$ and $5.0\%-0.5\%=4.5\%$ for $CH_3{}^{82}Br$ are moderator-sensitive and formed *via* an energetic process, probably through the direct substitution reaction of hydrogen by energetic ^{80}Br and ^{82}Br, neutral or ionic.[2] One-half per cent of $CH_3{}^{80}Br$ and $CH_3{}^{82}Br$ and 1.1% of $CH_2{}^{80}BrBr$ and $CH_2{}^{82}BrBr$ are formed *via* thermal ionic processes.

Nicholas and Rack have discussed the nature of the thermal ionic reaction and suggested the following equation:[8]

$$CH_4 + Br^{+1} \longrightarrow CH_3Br^{+1} + H \qquad (1)$$

However, the formation of CH_2Br_2 can hardly be explained by this equation. Instead, we suggest the formation of CH_4Br^{+1*} through the ion-molecule reaction of thermal Br^{+1}:

$$CH_4 + Br^{+1} \longrightarrow CH_4Br^{+1*} \qquad (2)$$

Such a reaction is very favored energetically and more probable for the CH_2Br_2 formation.[9,10]

Comparison of the Reactions of ^{80}Br and ^{82}Br. The finding that similar reaction mechanisms are involved in the two systems is rather to be expected, since the orginal physical properties of ^{80}Br and ^{82}Br are similar. However, the importance of a careful inspection of the results is that there is an isotope effect between ^{80}Br and ^{82}Br on the energetic reaction (1.5 ± 0.2), but not on the thermal inoic reactions.

Nicholas and Rack[8] measured the total organic yield from the recation of ^{82}Br with CH_4 and compared it with the value found by Spicer and Gordus[11] in the ^{80m}Br-CH_4 system. They attemped to conclude the same organic yield from the reaction of the (I.T.)-induced ^{80}Br and ^{82}Br with CH_4, based upon the value (1.1 ± 0.1) for the ratio. A possible explanation for the discrepancy between the present results and the reported results is that the ratio of the total organic yields ($CH_3Br+CH_2Br_2$) from the present systems turns out to be 1.3 ± 0.2, instead. This indicates that the comparison of the total organic yields makes the difference between them less significant. Furthermore, under the conditions adopted by Spicer and Gordus, containing a smaller amount of Br_2 as a scavenger, the yield increases[8,12] considerable and the ratio between them is closer to unity. In addition, the differences in the experimental procedure might be at least partly responsible for this discrepancy.

The same yields for the thermal ionic process in both systems are consistent with the previous conclusion[2,3] that the ionization potential of the reactant relative to that of Br is the most important controlling factor in the thermal ionic process.

Among the explanations for the isotope effect in the energetic reaction which must be considered is that CH_4 shows a different efficiency in the energy degradation for ^{80}Br and ^{82}Br.[13,14] Thus, the spectrum of the Br atom in the energetic reaction range could be different in ^{80m}Br-CH_4 and in ^{82m}Br-CH_4. Under the present conditions, no precise information concerning the encrgy degradation of the Br atom is available. As a crude evaluation, however,[14] the average logarithmic energy loss, α, of ^{80}Br and ^{82}Br in collision with CH_4 can be calculated using the atom-molecule elastic collision model. The value of 1.03 has been obtained for the $\alpha^{80}{}_{Br-CH_4}/\alpha^{82}{}_{Br-CH_4}$ ratio.

It is well known that the actual collisions of the recoil atom are generally of a highly inelastic nature,[15] with a strong bond coupling of the atoms in the molecule attacked. Thus, the above gives only qualitative information concerning the difference in the energy degradation between the two systems. It is very unlikely, therfore, to explain the observed isotope effect.

Here it will be very interesting to check the decay schemes[7] of ^{80m}Br and ^{82m}Br precisely (see Fig. 1). The γ-transition of ^{82m}Br to the ground

8) J. Nicholas and E. P. Rack, *J. Chem. Phys.*, **48**, 4085 (1968).

9) Neutralization[10] of the CH_4Br^{+1*} probably takes place *via* the charge transfer and results in decomposition to fragments, such as CH_3Br, CH_2Br, and so on. The formed CH_2Br radical could be scavenged by Br_2 to form CH_2Br_2.

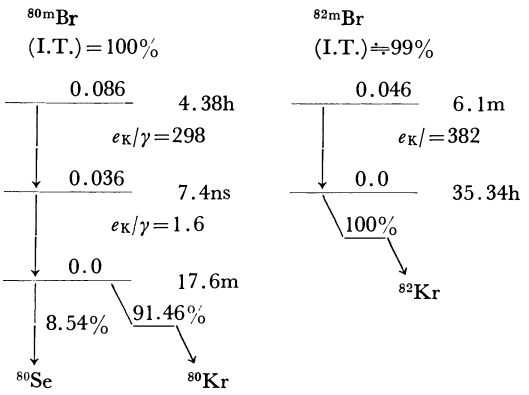

Fig. 1

state is attained in a single transition, the internal conversion ratio of which is 382. This means that 99.7% of the ^{82m}BrBr explodes,[16] to result in the highly-charged ^{82}Br atom with excess kinetic energy. On the other hand, ^{80m}Br is converted to the gronud state by two successive γ-transitions. The first transition (49 keV) is fully converted, while the second transition (37 keV) is partly converted (62%). The time required for the completion of the charging process initiated by nuclear internal conversion ranges from 10^{-15} to 10^{-16} sec.[17]

The charge and kinetic energy distributions on the excited ^{80}Br resulting from the molecular explosion of ^{80m}BrBr will be identical with those on ^{82}Br. However, the excited ^{80}Br has a successive transition to the ground state with a hilf-life of 7.4×10^{-9} sec. Thus, there are two possibilities, depending upon the length of the lifetime in the excited state relative compared to the time required for the atom to have a chemical reaction with the surrounding molecules: 1) the lifetime is too short for the atom to have a chemical reaction prior to the transition to the ground state or 2) the lifetime is long enough for the atom to react chemically with its environment during that period.

In Case 1, the following internal conversion leads to an additional build-up of the charge on the free atom, but it does not affect the kinetic energy of the atom. Most of the freshly built charges are also neutralized in the subsequent collisions with the environment.[5] The chemical consequences of the atom will, thus, be essentially the same as if the atom had not undergone the second internal conversion. As a result, if this is the case, it is probable that no isotope effect appears between ^{80}Br and ^{82}Br.

In Case 2, the kinetic energy achieved on the ^{80}Br atom in the chemical combination as a result of the γ-emission is of an order of a few-hundredths eV;[5,18] this energy is not sufficient to break any bond in the molecule, only to produce a little excitation of it. On the other hand, the ^{80}Br ion freed *via* the molecular explosion following the internal conversion has a kinetic energy which is very much dependent on the remainder of the molecule containing the Br atom.[16] If the excited ^{80}Br atom is in a chemical combination with surrounding atoms other than ^{80}BrBr*, then it is probable that the kinetic energy achieved on the ^{80}Br in the molecular explosion is different from that on the ^{82}Br freed from ^{82m}BrBr and that an isotope effect between them might appear on the energetic reaction, whereas the thermal ionic yields are more or less the same in both systems as long as the reaction occurs with the thremal Br^{+1} atom.

Most of the physicochemical stage, such as the energy-transfer, dissociation and ion-molecule reactions, terminated before 10^{-9} to 10^{-10} sec.[19] This also suggests that at least a part of the ^{80}Br in the excited state reacts chemically with the surrounding molecules. Thus, alternatively, the present results might be understood to indicate that the time scale of the reaction of the recoil Br atom is less than the order of 10^{-8} sec, the life-time of the excited ^{80}Br atom.

It is tempting to ascribe the yield of $CH_3{}^{80}Br$, which is lower than that of $CH_3{}^{82}Br$, to these differences in kinetic energy. Gordus and Willard[20] measured the total organic yields from the reaction of ^{80}Br in different parent compounds with CH_4. They showed that the yield increases with an increase in the mass of the residue to which ^{80m}Br is orginaly attached, that is, in the following order: $HBr < CH_3Br < C_2H_5Br < Br_2 < CCl_3Br < CHBr_3$. Qualitatively, this is in the same order as the increasing kinetic energy achieved on ^{80}Br in the molecular explosion.

Generally the reaction schemes[21,22] of the recoil halogen atom are very similar to those of the recoil tritium atom as far as the energetic reactions are concerned. One of the most important reactions of the recoil tritium is well known to be a hydrogen abstraction reaction to form HT.[23] As the present results show, the total organic yield in the reaction

of the Br atom with CH_4 is less than 10%. It can reasonably assumed that the hydrogen abstraction reaction of the excited ^{80}Br freed from the molecular explosion of the $^{80m}BrBr$ is very popular. The kinetic energy achieved on the Br atom as a result of the explosion of the $H^{80}Br^*$ will be in the range of a few electron volts, which will already be in the range for the energetic reaction. On the other hand, the initial kinetic energy of the Br atom, resulting from the explosion of Br_2, as in the ^{82m}Br-CH_4 system, could be of the order of 100 eV. The atom having such a high kinetic energy shows a complete spectrum over the entire range of the energetic reaction. This implies that the average number of possible collisions of atom in the reaction range is smaller for the ^{80}Br atom than for the ^{82}Br atom; that is, the flux of the ^{80}Br atom in the energetic reaction range is greately reduced compared to that of the ^{82}Br atom.

The author is very grateful to Mr. T. Ohkubo for his assistance throughout this work. He is also indebted to Drs. K. Motojima and M. Koike for their encouragement during the Course of the work.

The Photochemical Rearrangements of *N*-Acetyl Diphenylamine and *N*-Acetyl Carbazole

Haruo SHIZUKA, Motonobu KATO, Toshio OCHIAI, Kohji MATSUI and Toshifumi MORITA

Department of Chemistry, Gunma University, Tenjin-cho, Kiryu

(Received June 30, 1969)

The photochemical reactions of *N*-acetyl diphenylamine and *N*-acetyl carbazole in solution have been studied. *N*-Acetyl diphenylamine and *N*-acetyl carbazole undergo the photo-Fries-rearrangement by means of 2537Å irradiation. The reaction products consist of the *ortho*- and *para*-isomers, plus corresponding amines transformed through the deacetylation of the original compounds. The quantum yields in the early stages of the rearrangement were measured under various conditions by spectrophotometry. The reaction mechanism has been discussed on the basis of the relation between the rate constants of the rearrangement and the odd π electron densities obtained from simple Hückel MO calculations.

Recently, the photo-Fries-rearrangements have been extensively stidied.[1-18] There are two mechanisms which have been proposed for the photo-Fries-rearrangement. One is a molecular pathway, involving a bridged intermediate proposed by

Anderson and Reese[2] or a concerted, symmetry-allowed process proposed by Sander *et al.*[18] The other is a radical mechanism, as has been proposed by Kobsa,[3] by Finnegan *et al.*,[7-9] and by Shizuka *et al.*[13-17]

In the study of the photochemical reactions of acetanilide and phenyl acetate, it has been shown that, in the liquid phase, the photo-Fries-rearrangement occurs *via* the predissociation by the intersystem crossing $^3\sigma_0(\text{N–C}) \leftarrow S_1(\pi\pi^*)$, forming pair radicals which recombine efficiently in a solvent cage into the original substance, *o*- and *p*-isomers.[13-15,17]

The photochemical reactions of acetanilide have been exmained in the vapor phase at 120°C and in a rigid matrix at −196°C, but no photochemical rearrangement was observed in either case.[16] Bellus *et al.* have reported that the radiolysis of phenyl esters in solution yielded the same products as those of the photo-Fries-rearrangement and involved the radical mechanism due to homolytic fission.[19]

On the other hand, the photocyclization of diphenylamine to carbazole has been reported.[20-24] Therefore, the photochemical reaction of *N*-Acetyl diphenylamine may be expected to be either a photo-Fries-rearrangement or a photocyclization.

In the case of *N*-Acetyl carbazole, it has also been predicted that its photochemical reaction may occur through the photo-Fires-rearrangement or though a photochemical isomerization such as *N*-acetyl pyrrole,[25] since *N*-acetyl carbazole has a *N*-$COCH_3$ group like acetanilide and since the nitrogen atom is present in such a five-membered ring as that of *N*-acetyl pyrrole. It has been shown that *N*-acetyl pyrrole upon 2537 Å irradiation in both the liquid and vapor phases, converts to an intermediate *via* the lowest excited singlet state and is subsequently changed to 2-acetyl pyrrole or to the ground state of the original substance; its isomerization mechanism involves a molecular pathway.[25] For these reasons, it seemed that it would be interesting to ivestigate the photochemical reactions of *N*-acetyl diphenylamine and *N*-acetyl carbazole. This paper will report on the photochemical reactions of these compounds at 2537 Å in the liquid phase, and will also include a discussion of the photo-Fries-rearrangement.

Experimental

The experimental procedure and solvents were almost the same as those previously described.[13-17] *N*-Acetyl diphenylamine and *N*-acetyl carbazole were prepared by treating the corresponding amines with acetic anhydride and were purified by repeated recrystallizations from ligroin.

A low-pressure mercury lamp with a Vycor glass filter was used as the 2537 Å radiation source, while a mercury xenon lamp with a diffraction grating was used as the 2800 Å range radiation source. Actinometry was carried out in a reaction cell (quartz) using a ferric oxalate actinometer solution.[26] The light intensity at 2537 Å and at 2800 Å were 4.9×10^{14} photon·sec^{-1}·ml^{-1} and 2.4×10^{14} photon·sec^{-1}·ml^{-1} respectively.

The mixture of the photo-products after a long irradiation at 2537 Å was condensed by an evaporator, separated by column chromatography (silica gel), and purified by repeated recrystallizations from ligroin. The components of the photoproducts were determined by thin-layer chromatography. The reaction products were identified by means of UV, IR, mp, and elementary analysis. The quantum yields in the early stages of the photochemical reaction were determined spectrophotometrically.

Results and Discussion

Reaction Products. *a) N-Acetyl Diphenylamine (N-Ace DA).* Figure 1-1 shows the sepctral change of the cyclohexane solution of *N*-Ace DA. The absorption band (246 mμ) of *N*-Ace DA decreased, and new bands with maxima at 227, 288, 320, and 381 mμ appeared as the irradiation time increased; the spectrum had two isosbestic points, at 238 and at 265 mμ.

The reaction products were separated from *N*-Ace DA by column chromatography and were crystallized after a long irradiation at 2537 Å on a highly-concentrated solution of *N*-Ace DA. It was comfirmed by thin-layer chromatography that the photoproducts comprised three compounds; 2-acetyl diphenylamine (2-Ace DA), 4-acetyl diphenylamine (4-Ace DA), and diphenylamine (DA). They were identified by means of UV, IR, mp, and elementary analysis in comparison with authentic samples. Neither *N*-acetyl carbazole (*N*-Ace CA) not any carbazole derivative was obtained from the irradiated solution. Therefore, it can be said that a photocyclization of *N*-Ace DA such as that of DA did not occur, but that the photo-Fries-rearrangement did occur. Figure 1-2 shows the absorption spectra of 2-Ace DA, 4-Ace DA,

and DA respectively in a cyclohexane solution.

b) N-Acetyl Carbazole (N-Ace CA). The spectrum of the cyclohexane solution of *N*-Ace CA changed by 2537 Å irradiation is shown in Fig. 2-1.

The reaction products of *N*-Ace CA at 2537 Å were identified by the same procedure as was used for *N*-Ace DA. The photochemical reaction of *N*-Ace CA yielded 1-acetyl carbazole (1-Ace CA), 3-acetyl carbazole (3-Ace CA), and carbazole (CA). Figure 2-2 shows the absorption spectra of these products. In view of the above facts, the photochemical rearrangement of *N*-Ace CA seems to be a photo-Fries-reaction and not to be analogous to the photochemical isomerization of *N*-acetyl pyrrole, which gives only the product (2-acetyl pyrrole).[25]

The quantum yields for the formation of these photoproducts were measured spectrophotometrically. The molar extinction coefficients of the original compounds and the photoproducts are summarized in Table 1.

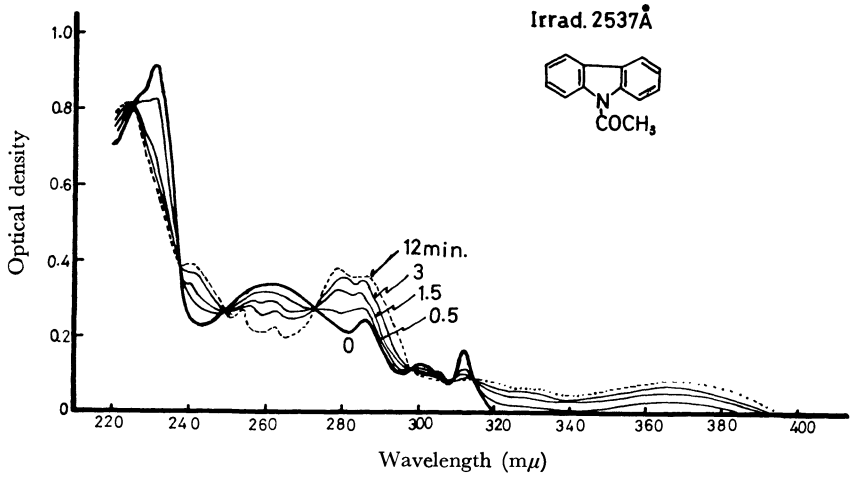

Fig. 2-1. Spectral change of cyclohexane solution of *N*-Ace DA at 2537 Å.

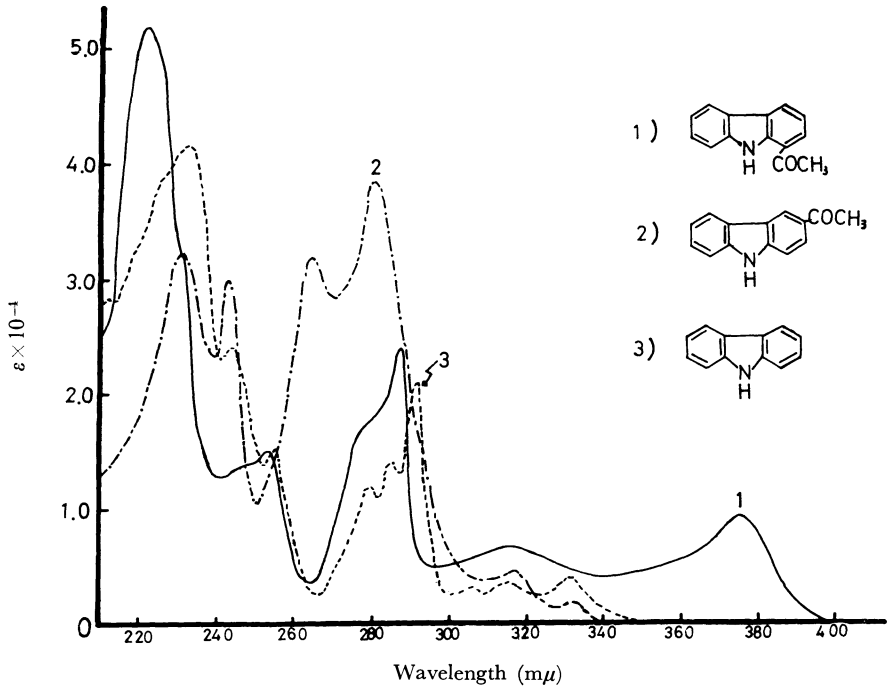

Fig. 2-2. Absorption spectra of the photo-products from *N*-Ace CA: 1) 1-Ace CA, 2) 3-Ace CA, and 3) CA.

Effect of Irradiation Time, Concentration, and Triplet Quencher on Quantum Yields. The quantum yields were measured under various condition; the results are shown in Fig. 3 and in Table 2.

The quantum yield for 2-Ace DA formation from *N*-Ace DA at 2537 Å did not change with the variation in the *N*-Ace DA concentration ($<\sim 10^{-3}$ mol/*l*), as is shown in Fig. 3. The photo-Fries-rearrangement of *N*-Ace DA is an intramolecular reaction, as has been proposed by several workers.[1,2,13,15,17] The addition of piperylene as a triplet quencher (E_T=2.48 eV)[13,17,27-29] did not affect the quantum yield for this isomerization in the concentration range from 10^{-4} to 5×10^{-2} mol/*l*, as is shown in Fig. 3(c). Dissolved oxygen had scarcely any effect on the quantum yields. Similar results were obtained regarding the quantum yields

Table 2. Quantum yields for the product formations of *N*-Ace DA at 2537 Å and 20°C

Substance	Solvent	Φ_O	Φ_P	Φ_{NH}	Φ_Σ
N-Ace DA	CH	0.20	0.096	0.048	0.344
	EtOH	0.15	0.064	0.045	0.259
N-Ace CA	CH	0.10	0.09	0.06	0.25
	EtOH	0.07	0.05	0.05	0.17

Φ_O, Φ_P, and Φ_{NH} are the quantum yields for the formations of 2-Ace DA, 4-Ace DA, and DA, and those for the formations of 7-Ace CA, 3-Ace CA, and CA, respectively.

$$\Phi_\Sigma = \Phi_O + \Phi_P + \Phi_{NH}$$

for the product formations from *N*-Ace CA at 2537 Å. The quantum yields decreased in a polar solvent, as is shown in Table 2. However, the variation in the rearrangement quantum yields with the solvent was smaller than that of acetanilide.[14] The dependences of the quantum yields of *N*-Ace DA and *N*-Ace CA on the solvent resemble those of phenyl acetate and *p*-substituted phenyl acetates.[17] As was described in a previous paper,[17] they may be due to the fact that *N*-Ace DA and *N*-Ace CA have no hydrogen atom to form hydrogen bonds with a proton acceptor. In the photo-Fries-rearrangement of acetanilide, a hydrogen-bond formation between the lowest excited singlet state in acetanilide and ethanol causes the decrease in the rearrangement quantum yields of acetanilide.[14] Sandner *et al.* have reported that the quantum yield of the photo-Fries product from any given ester did not vary with the solvent.[18] Their finding differs from ours. These differences might be caused by the experimental conditions; Sandner *et al.* performed the photochemical rearrangement of *p*-tolyl acetate in a very high concentration (0.556 mol/*l*) and with a very long irradiation (28—136 hr).

The primary process of the photo-Fries-rearrangement occurs from the lowest excited singlet state, as has been shown by Shizuka and Tanaka.[13] In the cases of *N*-Ace DA and *N*-Ace CA, their primary processes are the same as those described before, because these is no dependence of the rearrangement quantum yields on piperylene and dissolved oxygen, which are triplet quenchers, and no effect of the excitation wavelengths from 2537 to 2800 Å on the quantum yields.

The photo-Fries-rearrangements of *N*-Ace DA and *N*-Ace CA are similar to those of acetanilide[13-15] and phenyl acetate.[17] It may be assumed that their reaction mechanism involves the predissociation forming pair radicals and a subsequent recombination reaction between the pair radicals in a solvent cage.

Relations between the Rearrangement Quantum Yields and the Odd π Electron Densities. The recombination reaction between the pair

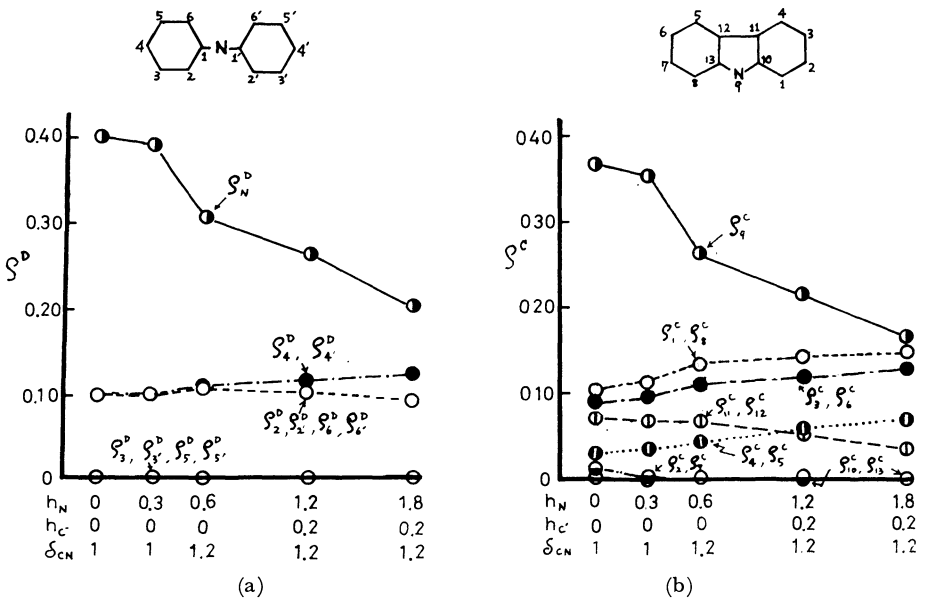

Fig. 4. Odd π electron densities of diphenyl amino (a) and carbazolyl (b) radicals as functions of h_N, $h_{C'}$, and δ_{CN}.
See the foot note.*2

radicals consists of a back reaction and of *o*- and *p*-rearrangements in a solvent cage. It has been shown that the rates of this recombination reaction in a solvent cage are proportional to the odd π electron densities of the anilino or phenoxy radical.[15,17]

The approximate odd π electron densities (ρ) of diphenyl amino and carbazolyl radicals were obtained from a simple Hückel MO calculation using the various values of Coulomb integrals (α) and resonance integrals (β). Figure 4 (a) and (b) show the odd π electron densities*1 of the diphenyl amino and carbazolyl radicals respectively.

The h_N parameter, which is equal to 0.6, is an appropriate value in the valency state of a nitrogen atom such as that of the pyridine molecule.[30-32] It is assumed that the valency state of the nitrogen atom in the case of the diphenyl amino or carbazolyl radical is nearly the same as that of pyridine, since the odd π electron on the nitrogen atom is considered to migrate to the benzene ring of their radicals. Therefore, we took the h_N value (0.6) in the present estimation. The relation between the quantum yields (Φ) and the odd π electron densities (ρ) is as follows:

N-Ace DA:

$$k_O^D : k_P^D = \frac{1}{4}\Phi_2^D : \frac{1}{2}\Phi_4^D \quad (1)$$

$$= 1 : 0.96$$

$$\rho_2^D : \rho_4^D = 0.11037 : 0.11438 \quad (2)$$

$$= 1 : 1.04$$

$$k_O^D : k_P^D \approx \rho_2^D : \rho_4^D \quad (3)$$

N-Ace CA:

$$k_O^C : k_P^D = \frac{1}{2}\Phi_1^C : \frac{1}{2}\Phi_3^C \quad (4)$$

$$= 1 : 0.9$$

$$\rho_1^C : \rho_3^C = 0.13498 : 0.11243 \quad (5)$$

$$= 1 : 0.83$$

$$k_O^D : k_P^C \approx \rho_1^C : \rho_3^C \quad (6)$$

where k_O and k_P are the rate constants of the *ortho*- and *para*-rearrangements respectively.

The rate constants (k) of the *o*- and *p*-rearrangements were proportional to the odd π electron densities on the radicals, as are shown in Eqs. (3) and (6). These results lend some support to the radical mechanism for the secondary processes in the photo-Fries-rearrangement as has been tentatively suggested by Kobsa[3] and has been shown by Shizuka *et al.*[15,17] On the other hand, Sandner

*1 The odd π electron densities were obtained from the square of the coefficient of the atomic orbital in the highest-occupied molecular orbital, ϕ_7.

*2 $\alpha_N = \alpha_C + h_N\beta_{CC}$, $\alpha_{C'} = \alpha_C + h_{C'}\beta_C$, $\beta_{CCN} = \delta_{CN}\beta_{CC}$
where α_C: Carbon atom Coulomb integral, α_N: Nitrogen atom Coulomb integral. $\alpha_{C'}$: Coulomb integral of the carbon atom next to the nitrogen atom, β_{CC}: carbon-carbon resonance integral, β_{CN}: carbon-nitrogen resonance integral, h_N, $h_{C'}$, and, δ_{CN}: parameters of α_N, $\alpha_{C'}$, and, β_{CN} respectively.

30) C. A. Coulson and J. Jacobs, *J. Chem. Soc.*, **1949**, 1983.
31) S. F. Mason, *ibid.*, **1958**, 674.
32) R. D. Brown, *ibid.*, **1959**, 3451.

et al. have proposed that the photo-Fries-rearrangement originates from an upper singlet state and proceeds to the products by a molecular pathway that is independent of its reaction environment.[18] Considering Sandner *et al.*'s formulation, which involves a concerted, symmetry-allowed process, it may be predicted that the quantum yield for the product formations in the photo-Fries-rearrangement is medium-independent and the *ortho*/*para* ratio is wavelength-dependent. However, the quantum yields for the product formations in the early stages of the photochemical reaction are medium-dependent[14,17] and are also dependent on the reaction phase.[16],*3

If the photo-Fries-rearrangement had occurred through a molecular pathway, the rearrangement products would be obtained in the vapor phase, since the photoisomerization of benzene[33-38] or *N*-acetyl pyrrole,[25] which involves a molecular pathway, yields the corresponding isomers even in the vapor phase. On the basis of the study of the benzene photosensitization of acetanilide,[13] the solvent effect on the rearrangement quantum yields,[14] and the effect of the excitation wavelength on the yields,[14] it is not reasonable that the photo-Fries-rearrangement originated from the upper excited singlet state, as has been proposed by Sandner *et al.*[18] The results obtained in the present work are consistent with the mechanism of the photo-Fries-rearrangement proposed by Shizuka *et al.*[13-17]

The estimations of the dissociation and the back reaction quantum yields of *N*-Ace DA and *N*-Ace CA were carried out as is described below. It is reasonable to consider that the rate constant of the back reaction, k_B, is also proportional to the odd π electron density at the position of the nitrogen atom, because the recombination rate constants, k_O, k_P, and k_B, are parallel to the odd π electron densities, ρ_O, ρ_P, and ρ_N respectively.[15,17]

N-Ace DA:

$$\frac{k_B^D}{k_0^D} = \frac{\Phi_B^D}{(1/4)\Phi_0^D} = \frac{\rho_N^D}{\rho_2^D} = \frac{0.30747}{0.11035} \approx 2.8 \qquad (7)$$

$$\Phi_B^D \approx 0.14$$

N-Ace CA:

$$\frac{k_B^C}{k_0^C} = \frac{\Phi_B^C}{(1/2)\Phi_0^C} = \frac{\rho_N^C}{\rho_1^C} = \frac{0.26368}{0.13498} \approx 2.0 \qquad (8)$$

$$\Phi_B^C \approx 0.10$$

The dissociation quantum yields (Φ_{dis}) are given by:

$$\Phi_{dis}^D = \Phi_\Sigma^D + \Phi_B^D \approx 0.48 \qquad (9)$$

$$\Phi_{dis}^C = \Phi_\Sigma^C + \Phi_B^C \approx 0.35 \qquad (10)$$

The recombination ratios (γ) between the pair radicals are quite high, just as in the cases of acetanilide[15] and phenyl acetate.[17]

$$\left.\begin{aligned} \gamma^D &= \frac{\Phi_O^D + \Phi_P^D + \Phi_B^D}{\Phi_{dis}^D} = 0.91 \\ \gamma^C &= \frac{\Phi_O^C + \Phi_P^C + \Phi_B^C}{\Phi_{dis}^C} = 0.81 \end{aligned}\right\} \qquad (11)$$

These results indicate that the recombination reaction between the pair radicals occurs efficiently in a solvent cage. From these results, it can be said that the photochemical rearrangement of *N*-Ace DA and *N*-Ace CA can be explained by a mechanism similar to those of acetanilide and phenyl acetate described in previous papers.[13-17]

In general, the quantum yields for the product formations in the photo-Fries-rearrangement are parallel to the odd π electron densities described above. There are some exceptions in the case of *N*-Ace CA. The values of ρ^C_{11}, ρ^C_{12}, ρ^C_4, and ρ^C_5 on the carbazolyl radical (see Fig. 4(b)) are not very small. However, no shift of the acetyl group to their positions by UV light could be observed. The non-occurrence of the shift to the positions 11 and 12 may be understood from the fact that their positions are blocked by phenyl groups. It is well known that the photo-Fries-rearrangements of *p*-substituted phenyl acetate[3,17] and *p*-substituted acetanilide[15] do not take place at the *p*-positions on their molecules, but at the *o*-positions. For both the 4 and 5 positions, it may be assumed that a transient complex formed in the recombination reaction between pair radicals has an unstable structure because of the lack of resonance energy compared with that of the *o*- or *p*-position. Finally, the reaction schemes of *N*-Ace DA and *N*-Ace CA at 2537 Å in the liquid phase are as follows:

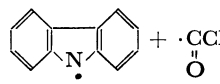
$$S_0 + h\nu \longrightarrow S_1(\pi\pi^*) \qquad (12)$$

$$S_1(\pi\pi^*) \xrightarrow{k_s} S_0 \qquad (13)$$

$$S_1(\pi\pi^*) \xrightarrow{k_f} S_0 + h\nu' \qquad (14)$$

$$S_1(\pi\pi^*) \xrightarrow{k_c} T_1(\pi\pi^*) \qquad (15)$$

$$S_1(\pi\pi^*) \xrightarrow{k_{dis}} \text{  } + \cdot CCH_3 \quad (\text{or}) \qquad (16)$$



*3 We examined the photochemical reaction of phenyl acetate in the gas phase at 2537 Å and at room temperature. The rearrangement products were not observed.

Calculation of the Hyperfine Coupling Constants of Some σ Electron Radicals

Teijiro YONEZAWA, Takashi KAWAMURA and Hiroshi KATO

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received August 4, 1969)

The isotropic hyperfine coupling constants of cyclopropyl, vinyl, formaldiminoxy, formyl, and hydrogen cyanide anion radicals are calculated by a method which corresponds to the extension of the McLachlan procedure. These hyperfine coupling constants are then studied, and the contributions from the spin delocalization and spin polarization mechanisms are estimated. The role of one-center exchange integrals in the estimation of these hyperfine coupling constants is also studied; it is shown to be important in the claculation of the hyperfine coupling constants of the nuclei of the radical-center atom and of the atoms bonded to it.

Recently the hyperfine coupling constants of σ-electron radicals have attracted much theoretical interest; many authors have calculated them with the hyperconjugation method,[1] with the extended Hückel method,[2,3] and with the semiempirical or *ab initio* unrestricted SCF methods.[4-7]

In this work, we will calculate the isotropic hyperfine coupling constants of some σ-electron radicals containing hydrogen, carbon, nitrogen, or oxygen atoms by a method[8] which is an extension of the McLachlan procedure.[9] The results of the present calculations will then be compared with the results obtained by other methods, and the effects of the spin polarization will be shown to be important even in the case of σ-electron radicals.

Method and Parameters

The differences between Fock's operators for α and β spin electrons in the unrestricted SCF method can be treated as a perturbation. Taking the first-order approximation with respect to exchange

interaction, the elements of the spin-density matrix can be written as:[8]

$$\rho_{vw} = p^0_{vw} - \frac{1}{4}\sum_r\sum_s(\pi^{\alpha}_{vw,rs}+\pi^{\beta}_{vw,rs})\sum_t\sum_u p^0_{tu}(rt|us), \quad (1)$$

where the electron repulsion integral is denoted as:

$$(rt|us) = \iint \chi_r(1)\chi_t(1)(e^2/r_{12})\chi_u(2)\chi_s(2)\,dv_1dv_2$$

and where $\pi^{\alpha}_{vw,rs}$ and $\pi^{\beta}_{vw,rs}$ are mutual polarizabilities defined as:

$$\pi^{\alpha}_{vw,rs} = 2\sum_{j<0}\sum_{i\geqq 0}(C_{iv}C_{jw}+C_{jv}C_{iw})C_{ir}C_{js}/(\varepsilon_i-\varepsilon_j)$$

$$\pi^{\beta}_{vw,rs} = 2\sum_{j\leqq 0}\sum_{i>0}(C_{iv}C_{jw}+C_{jv}C_{iw})C_{ir}C_{js}/(\varepsilon_i-\varepsilon_j). \quad (2)$$

The molecular orbitals (MO), obtained by an extended Hückel MO method, are denoted by i and j; a positive number represents a doubly-occupied MO, zero is for the singly occupied MO, and vacant MO's are expressed by negative numbers. The coefficient of the rth atomic orbital (AO), χ_r, in the ith MO and its orbital energy are denoted as C_{ir} and ε_i respectively, while p^0_{tu} represents the "odd-electron" density matrix element, $C_{0t}C_{0u}$.

When multicenter integrals for the Dirac delta function are neglected, the isotropic hyperfine coupling constant of the nucleus Y, a^Y, becomes:

$$a^Y = \frac{8\pi}{3}g_Y\beta_N\sum_v^{\text{on}}\sum_w^{Y}\rho_{vw}\langle\chi_v|\delta(r_Y)|\chi_w\rangle \text{ gauss}, \quad (3)$$

where $\delta(r_Y)$ is the Dirac delta function and where g_Y and β_N have their usual meanings. As to the AO's χ_v and χ_w in Eq. (3), the valence-shell and inner-shell AO's are taken into consideration, while the effects of outer-shell AO's are neglected. Inner-shell electrons are assumed to be localized in one inner-shell AO in a zero-order approximation to exchange interaction.

Under these approximations, a^Y can be divided into three terms according to their mechanisms; the spin-delocalization term, a^Y_D: the spin-polarization term due to valence-shell electrons, a^Y_{PV}, and the spin-polarization term concerning inner-shell electrons, a^Y_{PI}, as:

$$a^Y = a^Y_D + a^Y_{PV} + a^Y_{PI}. \quad (4)$$

The contribution to a^Y from the term due to the spin-delocalization mechanism, a^Y_D, can be given from Eq. (3) and the first term of Eq. (1) as:

$$a^Y_D = A^Y_V P^0_{vv} \quad (5)$$

$$A^Y_V = \frac{8}{3}\pi g_Y\beta_N\langle\chi_v|\delta(r_Y)|\chi_v\rangle, \quad (6)$$

where χ_v is the valence-shell s AO of the atom Y. The values of A^Y_V adopted in this work for ^{1}H, ^{13}C, ^{14}N, and ^{17}O are listed in Table 1.

The valence-electron spin-polarization term, a^Y_{PV}, comes from the second term of Eq. (1) and is given by:

$$a^Y_{PV} = -\frac{1}{4}A^Y_V\sum_r\sum_s(\pi^{\alpha}_{vv,rs}+\pi^{\beta}_{vv,rs})\sum_t\sum_u p^0_{tu}(rt|us), \quad (7)$$

where the suffix v denotes the valence-shell s AO of the atom Y. In the estimation of the multicenter electron erpulsion integrals, the zero-differential-overlap approximation is adopted. One-center exchange integrals, which are expected to play an important role in the calculation of hyperfine coupling constants, are taken into account. The one-center Coulomb integral, $(rr|rr)$, is estimated by Pariser approxiamtion[10] by using the valence-state ionization potentials and electron affinities tabulated by Pritchard and Skinner.[11] The one-center exchange integrals are estimated from the table of Hinze and Jaffe.[12] To assure rotational invariance, the one-center Coulomb integral between p_π AO and p_σ AO is evaluated as:

$$(\sigma\sigma|\pi\pi) = (\sigma\sigma|\sigma\sigma) - 2(\sigma\pi|\pi\sigma).$$

The other Coulomb integrals are estimated by means of the Ohno approximation.[13]

The inner-shell-electron spin-polarzation term, a^Y_{PI},s come from the second term of Eq. (1):

$$a^Y_{PI} = -\frac{1}{4}A^Y_I\sum_r\sum_s(\pi^{\alpha}_{vw,rs}+\pi^{\beta}_{vw,rs}+\pi^{\alpha}_{wv,rs}+\pi^{\beta}_{wv,rs}) \times\sum_t\sum_u p^0_{tu}(rt|us), \quad (8)$$

Table 1. Values of A^Y_V, A^Y_I, and one-center electron repulsion integrals including inner-shell AO's

where v and w denote the valence-shell $2s$ and the inner-shell $1s$ AO's respectively, and where A_I^Y is given by:

$$A_I^Y = \frac{8}{3}\pi g_Y \beta_N \langle \chi_v | \delta(r_Y) | \chi_w \rangle, \quad (9)$$

the values of which are listed in Table 1. The multicenter electron repulsion integrals in Eq. (8), including the inner-shell AO's, may be ignored because the differential overaps between the inner-shell AO and the AO's centered on the other atoms are negligible. The energy differences between the inner-shell orbitals and the valence-shell vacant MO's are approximated as the negative values of the inner-shell-electron X-ray term values listed by Slater.[14] Therefore, we obtain:

$$a_{PI}^Y = \frac{A_I^Y}{2E_w}\left(\sum_{f<0} + \sum_{f\leqq 0}\right)\left[\sum_{r}^{\text{VAO's on Y}} \sum_{t} \sum_{u} C_{fv} C_{fr} p_{tu}^0 (rt|uw)\right], \quad (10)$$

where E_w is the X-ray term value of the inner-shell $1s$ AO of the atom Y (χ_w), where r, t, and u denote valence-shell AO's on the atom Y, and where v represents the valence-shell $2s$ AO of the atom Y. For the computation of a one-center electron repulsion integral including both inner-shell $1s$ AO and valence-shell $2s$ AO, $1s$ and $2p$ Slater AO's[15] and the following orthogonalized $2s$ AO function are adopted:

$$\chi'_{2s} = (1-S^2)^{-1/2}(\chi_{2s} - S\chi_{1s}),$$

where S is the overlap integral between Slater AO's χ_{1s}-χ_{2s}. The estimated values of the integrals are listed in Table 1. The evaluated values of $(1s\ 2p|2p\ 2s)$ are reliable when compared with the other estimation,[8] but the estimation of the other electron-repulsion integrals concerning inner-shell $1s$ AO's seems to be less reliable.

The zero-order MO's are calculated with an exended Hückel MO method by solving a secular equation:

$$|H_{rs} - \delta_{rs}\varepsilon| = 0$$

where r and s cover all the valence-shell AO's of the radical. The diagonal element of the Hamiltonian, H_{rr}, is approximated as the negative value of Mulliken's orbital electronegativity, as tabulated by Pritchard and Skinner.[11] The off-diagonal elements of the Hamiltonian are estimated as:

$$H_{rs} = \begin{cases} (K/2)S_{rs}(H_{rr}+H_{ss}) & \text{(for nearest neighbors)} \\ 0 & \text{(for non-nearest neighbors)}, \end{cases} \quad (11)$$

where S_{rs} is the χ_r-χ_s overlap integral: the Wolfsberg-Helmholz[16] parameter, K, will be fixed

to fit selected experimental values of hyperfine coupling constants in the following section. We use Slater 2*s* and 2*p* AO's for first-row elements and the Slater-type 1*s* AO with the orbital exponent of 1.2 for hydrogen.

Results and Discussion

The numberings of the atoms and the conformational parameters of the calculated radicals are shown in Fig. 1.

Wolfsberg-Helmholz Parameter, *K*, and Calculated Coupling Constants. To obtain the appropriate value of the parameter, *K*, of Eq. (11), the ^{1}H and ^{13}C hyperfine coupling constants of methyl and ethyl radicals are calculated by changing the value of *K*.

The hyperfine coupling constants of the protons of the methyl radical and the α protons (3H and 4H) of the ethyl radical arise mainly through the valence-electron spin-polarization mechanism. The spin densities which appear through valence-and inner-shell-electron spin-polarization determine the ^{13}C coupling constants of the methyl and ethyl radicals. On the other hand, the hyperfine coupling constant of the β protons (5H, 6H, and 7H) of the ethyl radical are determined mainly by the spin delocalization. Therefore, the contributions of the spin delocalization, the valence-shell-electron spin-polarization, and the inner-shell-electron spin-polarization mechanism to the hyperfine coupling constants will be estimated with the set of parameters which gives good calculated values of the hyperfine coupling constants of these radicals.

The calculated values of the hyperfine coupling constants of the methyl and ethyl radicals are listed in Table 2, together with the values of *K* used. The best results are obtained for $K=0.7$, so we will use this value in the following calculations.

Cyclopropyl Radical. The geometry of this radical is assumed to be the same as that of cyclopropane[17] except for the angle between the 1C–8H bond and the carbon plane. This angle, θ, varies in the calculations. The calculated hyperfine coupling constants are listed in Table 3, together with the contributions from the spin-delocalization, the valence-electron spin-polarization, and the inner-shell-electron spin-polarization mechanisms. These results show that the spin-polarization mechanism is important in the estimation of the hyperfine coupling constants of the nuclei of the radical-center atom and of the atoms bonded to it. Dixon[1] successfully calculated the hyperfine coupling constants of the β protons of this radical with the assumed geometry of $\theta=54.75°$. Drago and Petersen[2b] calculated the hyperfine coupling constants of the protons of this radical by the extended Hückel method. They obtained 7.56, 22.00, and 18.96 gauss for 8H, 5H, and 4H respectively, when $\theta=20°$. These results agree with the experimental values[18]; they predicted that the angle would be approximately 20°. The present results show that the spin-polarization mechanism contributes about −14 gauss to the hyperfine coupling constant of 8H, even when $\theta=60°$. The extended Hückel calculation presents only the spin density due to the spin-delocalization mechanism. When the present results and their extended Hückel calculations are compared, the angle is predicted to be large than 20°. The sign of the hyperfine coupling constant of 8H can not be fixed, because the present estimation of the positive contribution of the spin-delocalization mechanism to the 8H coupling constant (+2.4 gauss, $\theta=60°$) appears too small when compared with the results of other calculations.[2,3] The present calculation predicts that, when θ increases, the constant of 1C will steeply increase, mainly because of the increase in the *s*-nature of the odd-electron orbital on 1C. As is shown in Table 3, the hyperfine coupling constants of β protons (4H and 5H) arise dominantly from spin-delocalization. Therefore, the hyperfine coupling constants of β protons can be estimated directly by Roothaan's restricted open-shell SCF MO method[19] or by a simple MO

method such as the extended Hückel method.

Vinyl Radical. The geometry of the vinyl radical is assumed to be planar, with a 1.34 Å CC bond, 1.08 A CH bonds, and a 120° H–C–H bond angle. The bond angle of 1C–2C–5H, θ, varies in the calculations. Table 4 shows the calculated hyperfine coupling constants of the vinyl radical and the contributions of the spin-delocalization, the valence-electron spin-polarization, and the inner-shell-electron spin-polarization mechanisms. The comparison between the calculated and the experimental ratios of $|a^{3H}/a^{4H}|$ and $|a^{1C}/a^{2C}|$ shows that the angle θ may be in the $130° < \theta < 150°$ range. The results in Table 4 show that only the hyperfine coupling constants of β protons (3H and 4H) can be directly calculated with a restricted MO method, because the spin-polarization mechanism makes a minor contribution to them. The present calculation predicts that the 1C and 5H hyperfine coupling constants will be negative; the prediction for the former coincides with that of the unrestricted SCF calculation done with the INDO approximation of Pople, Beveridge and Dobosh.[6] The sign of the calculated 5H coupling constant agrees with our semiempirical unrestricted SCF calculation.[4] The present calculation shows that the odd-electron density on 2C attracts, through exchange interaction, electrons with the same spin as the odd electron, resulting in negative spin densities at the nuclei of 1C and 5H.

Formaldiminoxy Radical. Although the electron-spin-resonance spectrum of the formaldiminoxy radical has, so far as we know, not been reported, the hyperfine coupling constants of this radical have been calculated and compared with those of the aldiminoxy radicals. The geometry of this radical is assumed to be planar, with bond lenghts of $r(CH) = 1.08$Å, $r(CN) = 1.28$Å, and $r(NO) = 1.24$Å, and with bond angles of $\angle HCH = 120°$ and $\angle CNO = 125°$. The calculated values are summarized in Table 5. The calculated hyperfine coupling constant of ^{14}N agrees with the experimental values of the acetaldiminoxy and benzaldiminoxy radicals. The proton *trans* to the odd-electron orbital on the nitrogen has a larger coupling constant than that of the *cis* proton, as in the case of the vinyl radical. The ^{17}O coupling constant

of the iminoxy radical can be predicted to be about −8 gauss.

Formyl and Hydrogen Cyanide Anion Radicals. The formyl and hydrogen cyanide anion (HCN^-) radicals are isoelectronic, and both radicals are predicted to have essentially the same conformation and electronic configuration from Walsh's scheme for the molecular orbitals of HAB molecules.[20] The formyl radical has been prepared by Adrian *et al.*;[21] the isotropic proton hyperfine coupling has the extremely large value of 137 gauss, and the ^{13}C coupling is 134.7 gauss.[22] The electron-spin-resonance spectrum of the HCN^- radical was studied by Symons and his co-workers,[23] who reported that the hyperfine coupling constants of ^{1}H, ^{13}C, and ^{14}N are 137, 74, and 6.5 gauss respectively. The isotropic hyperfine coupling constants of the formyl radical have been calculated by the extended Hückel method,[2] the unrestricted SCF method with CNDO/2 approximations,[5] and the *ab initio* unrestricted SCF MO method.[7]

The geometry of the formyl radical used in the present calculation has a 1.09Å CH bond, a 1.198Å CO bond, and a bond angle of 119.5°. The structure of the hydrogen cyanide anion radical is assumed to have $r(CH)=1.09$Å, $r(CN)=1.26$Å, and $\angle HCN=120°$. The calculated hyperfine coupling constants of these radicals are listed in Table 6. The calculated proton coupling constants for HCO and HCN^- are too small when compared with the experimental values, as when calculated with the extended Hückel method.[2] The results for the ^{13}C constants are passable. Inner-shell electrons make minor contributions to these ^{13}C coupling constants. It is interesting to point out that the spin-polarization of valence-electrons gives about 1/4 of the coupling constant of the nucleus of the radical-center atom of these σ electron radicals.

The present calculation predicts that the ^{17}O coupling constant will be small and negative; this prediction coincides with the calculation by the *ab initio* unrestricted SCF MO method.[7] The calculated value of the ^{14}N coupling constant of HCN^- agrees fairly well with the experimental value. The present calculation show that a positive spin density arises at the position of the oxygen or the nitrogen nucleus of the HCO or HCN^- radical.

Table 7. Contributions to a_{PV}^Y from one-center exchange integrals between atomic orbitals centered on the radical-center atom (in unit of gauss)

Radical	Nucleus Y[a]	a^Y [b]	a_{PV}^Y [b]	Condtribution[c]

	H	38.7	−10.1	−8.78

a) Numbering of atoms are shown in Fig. 1.
b) Calculated value listed in Tables 3—6.
c) The contribution to the hyperfine coupling constant of nucleus Y from one-center exchange integrals between AO's centered on the radical-center atom. Estimated as $-(1/4)A_V^Y\sum'_{r,s,t,u}(\pi^\alpha_{vv,rs}+\pi^\beta_{vv,rs})p^0_{tu}(rt|us)$, where $\sum'$ denote the summation over one-center exchange integrals between AO's on the radical center atom and v expresses the valence shell s AO atom Y.

20) A. D. Walsh, *J. Chem. Soc.*, **1953**, 2288.
21) F. J. Adrian, E. L. Cochran and V. A. Bowers, *J. Chem. Phys.*, **36**, 1661 (1962).
22) F. J. Adrian, E. L. Cochran and V. A. Bowers, *ibid.*, **44**, 4626 (1966).
23) K. D. J. Root, M. C. R. Symons and B. C. Weatherley, *Mol. Phys.*, **11**, 161 (1966).

The mechanism of these spin densities is as follows: the spin density on the 2*s* AO of the oxygen or the nitrogen atom arises from the valence-electron spin-polarization contribution, a^{O}_{FV} or a^{N}_{FV}. The main part (about 120%) of a^{O}_{FV} or a^{N}_{FV} comes from terms containing odd-electron density matrix elements, p^{o}_{lu}, between the AO's of the oxygen atom or of the nitrogen atom. That is, the odd electron in the in-plane orbital on the radical-center carbon atom delocalizes into the in-plane lone-pair orbital on the oxygen or the nitrogen atom, which in turn induces a positive spin density on the 2*s* AO of the oxygen or the nitrogen atom of the HCO or HCN^{-} radical through the exchange interaction, as in the case of π-electron radicals. This situation is also observed in the case of the ^{17}O coupling constant of the formaldiminoxy radical.

Role of One-center Exchange Integrals. For the calculation of the hyperfine coupling constants of σ electron radicals with a semiempirical unrestricted SCF MO method, Atherton and Hincliffe[5] adopted CNDO/2 approximations, whereas Pople, Beveridge and Dobosh[6] used INDO approximations. In the former method, one-center exchange integrals are neglected, while in the latter they are included. Although it is well established that one-center exchange integrals are essential in the calculation of the hyperfine coupling constants of π electron radicals,[24,25] the role of these integrals in the calculation of the hyperfine coupling constants of the σ electron radicals has not yet been sufficiently studied. The present method can give the contribution from each electron repulsion integral to the hyperfine coupling constants.

Table 7 shows the contributions through one-center exchange integrals between valence-shell AO's centered on the radical-center atom to the hyperfine coupling constants of the calculated σ electron radicals. Except for the ^{17}O coupling constants of HCO and the formaldiminoxy radical, and the ^{14}N coupling constant of HCN^{-}, the one-center exchange integral contributions listed in Table 7 approximately determine the value of a^{X}_{FV}, the hyperfine coupling which arises through the valence-electron spin-polarization, of the nuclei of the radical-center atoms and of the atoms bonded to them. As has been mentioned in the preceding section, the hyperfine coupling constants of the ^{17}O of HCO and H_2CNO or of the ^{14}N of HCN^{-} arise through the odd-electron density delocalized into the in-plane lone-pair orbital on the oxygen atom or on the nitrogen atom, and the contribution listed in Table 7 is not important.

The results listed in Tables 3—7 show that, in the case of σ-electron radicals, spin-polarization make contributions to the hyperfine coupling constants of the nuclei of radical-center atoms and the atoms bonded to them that cannot be neglected, and that, in estimating these contributions, one-center exchange integrals should be included in the calculations.

The calculations were carried out on the HITAC 5020E electronic computer of the University of Tokyo and on the FACOM 230 computer of Kyoto University. The authors wish to acknowledge the help of the staff of each computer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 81—84 (1970)

Benzyl Bromide-Amine Reaction in Nitrobenzene-Ethanol Mixtures

P. S. RADHAKRISHNAMURTI and G. P. PANIGRAHI

Department of Chemistry, Khallikote College, Berhampur (Gm), Orissa, India

(Received September 11, 1968)

The reactions between benzyl bromide and various bases as well as *p*-nitrobenzyl bromide and various bases have been studied in nitrobenzene-ethanol mixtures (80 : 20 v/v). The reaction is total second order as stated earlier. Comparison is made with the previous work on the same reaction with benzyl chloride and *p*-nitrobenzyl chloride.

In our earlier communications[1,2] we reported the kinetics of reaction of benzyl chloride as well as of *p*-nitrobenzyl chloride with bases in nitrobenzene-ethanol mixtures. We report here the kinetics of reaction of benzyl bromide as well as of *p*-nitrobenzyl bromide with bases in nitrobenzene-ethanol mixtures (80 : 20 v/v).

Experimental

Materials. All substances are of AnalaR grade. Nitrobenzene is also of AnalaR grade.

Rate Measurements. The reactions were followed as per the procedure stated earlier.[1,2] Solvolysis correction was also done with benzyl bromide reaction.

Discussion

The second order rate constants for benzyl bromide and bases are given in Table 1. A glance at the table indicates that all the aliphatic amines react much faster than the aromatic amines. All the compounds react in consonance with their basicity except for a few where other factors seem to operate, such as the *ortho* effect. A plot of log *k* *vs.* pK_a showed linearity.

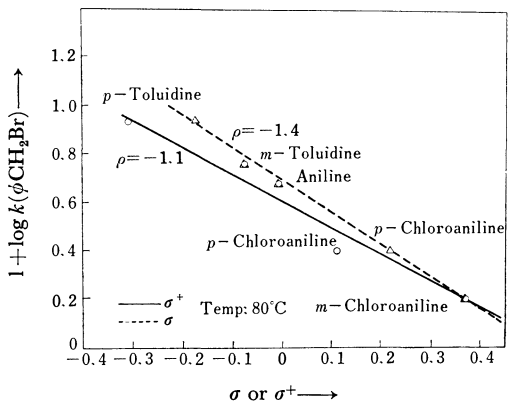

Fig. 1

Where ever σ and σ^+ are different σ and σ^+ points are indicated by △ and ○ respectively.

To analyze the data a correlation was made with Hammett's substituent constants for aromatic amines. A plot of log *k* *vs.* σ and σ^+ showed linearity (Fig. 1). The slopes were −1.4 and −1.1 respectively. All these establish that the attack by amine on the benzyl bromide is facilitated by electron releasing groups in the base and retarded by electron attracting groups in the substrates.

p-Nitrobenzyl bromide was also subjected to react with all these bases. The reactions were uniformly slower compared to benzyl bromide. This establishes that electron withdrawing groups

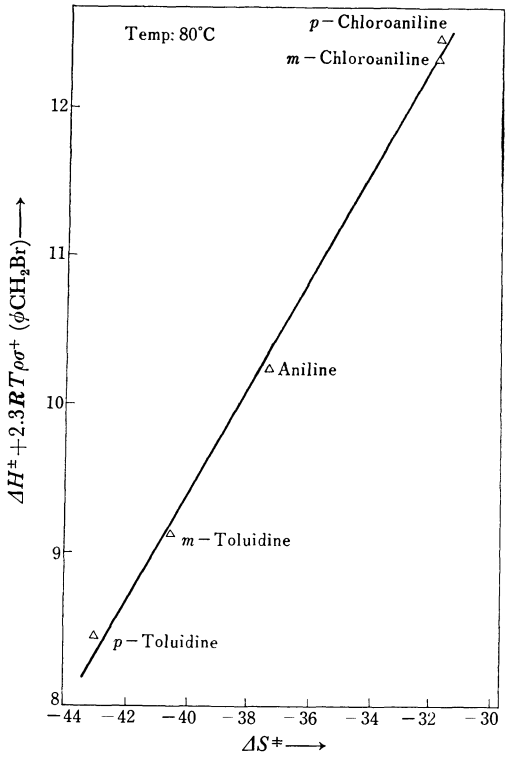

Fig. 2

either in the substrate or in the attacking base retard the process. The important features in these reactions are: (1) Anionisation of the halogen, (2) the coordination of the basic nitrogen atom with the adjacent methylene group by means of the unshared electron pair. These two are affected in turn by electron withdrawing substituents and hence retardation. The rate constants are given in Table 2.

log k *vs.* pK_a as well as log k *vs.* σ and σ^+ showed linearity. The ρ values are −1.75 and −1.4

respectively. The most reactive base is diethylamine. The two aliphatic primary amines react quite in consonance with their electron availability.

In the aromatic series, *N*-methylaniline certainly reacts faster than aniline as the pK_a values indicate. All toluidines react faster than the corresponding chloro compounds. Similar reasoning explains the reactivity of these bases with *p*-nitrobenzyl bromide.

Comparison of the Reactivity of Benzyl Chloride and Benzyl Bromide. It is interesting to note that bromide derivative reacts faster than the chloride derivative (Table 3). This is quite in accord with the well known theories of substituent effects.[3]

Mechanism of the Process. It was postulated that it is possible to rationalize the inactivity of benzyl chloride with primary aromatic amines in pure nitrobenzene on the basis of a four centered transition state. It was also suggested that alternatively the abnormality could be due to specific solvent influences. The present work with benzyl bromide and *p*-nitrobenzyl bromide rules out the possibility of a likely four centered transition state. All these reactions, in general, are through a three centered transition state. Any inactivity or abnormality is to be traced to solvation phenomena.

Our arguments are based on the following facts: (1) Benzyl chloride and *p*-nitrobenzyl chloride are unreactive in pure nitrobenzene medium but reactive in nitrobenzene-ethanol mixture, nitrobenzene-dimethylformamide mixture, nitrobenzene-dimethylsulfoxide mixture and nitrobenzene-acetic acid mixture. This reaction did not occur in nitrobenzene-benzene, nitrobenzene-chlorobenzene, nitrobenzene-dioxane and nitrobenzene-acetonitrile mixtures. The relative reactivity in the solvent mixtures is nitrobenzene-DMSO (80 : 20 v/v)> nitrobenzene-ethanol (80 : 20 v/v)> nitrobenzene-acetic acid (80 : 20 v/v)> nitrobenzene-DMF (80 : 20 v/v).

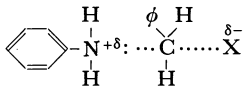
(2) Benzyl bromide and *p*-nitrobenzyl bromide did react in pure nitrobenzene medium but crystallization occured at a very early stage of the reaction.

3) E. S. Gould, "Mechanism and Structure in Organic Chemistry" (1965), pp. 260—261.

Hence the kinetics of these derivatives were studied in nitrobenzene-ethanol mixtures. A complete analysis of solvent influence on bromide derivatives will be dealt with in a separate communication.

These two facts put together mean that the abnormal inactivity noticed with benzyl chloride and *p*-nitrobenzyl chloride is due to greater ground state solvation. The bromide derivatives react in nitrobenzene indicating greater transition state solvation though crystallization occurs.

A plot of log k of benzyl chloride *vs.* log k of benzyl bromide is perfectly linear indicating a similar process in both chlorides and bromides. The mechanism as mentioned earlier is a three centered transition state as follows:



(Three centered transition state)

X=Cl, Br, *etc.*

The reaction is an S_N2 reaction having a dominant S_N1 character.

Thermodynamic Parameters. The values of activation energies, frequency factor and other derived thermodynamic constants for benzyl bromide-amine reaction are collected in Tables 4 and 5. Both the parameters E and $\log_{10} PZ$ tend to increase together. Linearity is obtained by plotting $\log_{10} PZ$ against $1/\sqrt{E}$ as it should be on the basis of thermodynamic considerations[4] (Fairclough-Hinshelwood relationship) if both the Arrhenius parameters are the controlling factors of the rate.

The small frequency factors would mean that standard entropy of activation $\Delta S^{\pm}$ has a relatively larger negative value or that the transmission coefficient is small.

Enthalpy-Entropy Relationship. It was of interest to examine the relationship between activation enthalpy and entropy. The possibility of correlation between $\Delta S^{\pm}$ and $\Delta H^{\pm}$ was investigated by a conventional isokinetic plot. It appears that the plot showed a tendency of scatter which is discriminating and characteristic of the nature and position of the groups. This observation together with ideas put forward by Hepler[5a,b,c] and others suggested that if the enthalpy and entropy changes are resolved into external and internal components a relationship may exist between the external parameters. In this treatment external contributions to enthalpy and entropy are associated with solvent interactions, and the internal contributions arise from differences in enthalpy and entropy within the reactant molecules and the transition state. If the reasonable assumption is made that the internal motions of the substituents do not contribute to the free energy, *viz.*, internal entropy changes are zero, the following equation[6a,b] may be used as a test of external entropy and enthalpy relationship.

$$(\delta\Delta H^{\pm}+2.303\boldsymbol{R}T\rho\sigma^{+}) = b\delta\Delta S^{\pm}$$

where δ and Δ operator symbols represent the effect of the substituents and of chemical reaction on the activation enthalpy and entropy, σ^{+} is the electrophilic substituent constant of Brown and Okamoto, ρ is the Hammett reaction constant which is -1.1 at 80°C for benzyl bromide-amine reaction; b is a constant characteristic of the reaction and can be obtained from the slope of a plot of $\delta\Delta H^{\pm}+2.303\boldsymbol{R}T\rho\sigma^{+}$ against $\delta\Delta S^{\pm}$. The plot

5) a) L. G. Hepler, *J. Amer. Chem. Soc.*, **85**, 3089 (1963). b) K. J. Laidler, *Trans. Faraday Soc.*, **55**, 1725 (1959). c) C. D. Ritchie and W. F. Sager, *Progr. Phys. Org. Chem.*, **2**, 323 (1964).

6) a) I. Lee, *J. Korean Chem. Soc.*, **7**, 211, 238 (1963). b) I. Lee, *Chem. Abstr.*, **61**, 5015e, 7770e (1964).

shows perfect linearity (Fig. 2). The right hand side of the equation represents external entropy change. Since $\delta\Delta S^{\pm}=\delta\Delta S(\text{internal})+\delta\Delta S(\text{external})$, then for $\delta\Delta S(\text{internal})=0$, $\delta\Delta S^{\pm}=\delta\Delta S(\text{external})$. Similarly the left hand side of the equation represents the external enthalpy changes due to the substituents, provided that the term "$2.303\,\boldsymbol{R}\boldsymbol{T}\rho\sigma^{+}$" may be identified with $\delta\Delta H$ (internal). This assumption is consistent with Hammett's original concept in which substituent constants represent changes in the potential energy of the system.

It is pertinent to refer to the work of Campbell and Hogg[7] wherein they found, in their reactions of electrophilic additions to alkenes, that there is no alteration of the reaction mechanism with changes in solvent polarity.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 84—89 (1970)

Thermal Decomposition of Uranyl Dihydrogen Orthophosphate Trihydrate

Mutsukazu KAMO*1 and Shigeru OHASHI

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka

(Received April 21, 1969)

The thermal decomposition of uranyl dihydrogen orthophosphate trihydrate was studied by means of paper chromatography, X-ray diffractometry, differential thermal analysis, thermogravimetric analysis, infrared spectroscopy and chemical analysis. From these studies, it was revealed that in the thermal decomposition of the uranyl salt the following reactions take place. 1) The formation of condensed phosphates with relatively small polymerization degrees such as di- and triphosphates takes place below 300°C, accompanied by the elimination of water. 2) A uranyl salt of long-chain metaphosphate, $[UO_2(PO_3)_2]_n$ is produced bewteen 300 and 840°C. 3) The metaphosphate is melted at about 900°C, while uranium(VI) is reduced to uranium(IV) at the same time. 4) As a result of the reduction, the formation of uranium(IV) diphosphate, UP_2O_7, starts. 5) Finally, almost pure uranium(IV) diphosphate is produced at 1200°C.

Condensed phosphates of uranium prepared hitherto are di- and triphosphates of uranium(VI), di- and metaphosphates of uranium(IV) and diphosphates of uranium(IV and VI).[1-3] It has not been decided whether uranium(IV) metaphosphate is a cyclic or linear phosphate. Uranyl diphosphate is only one condensed phosphate of uranium(VI) which has so far been prepared by dehydration condensation. It appears that uranyl ion is not stable against heating. When uranyl salts are heated with orthophosphoric acid or phosphorus pentoxide, uranium(VI) is reduced to uranium(IV).[3] Uranyl diphosphate, $(UO_2)_2P_2O_7$ is also reduced to diuranium(IV and VI) trioxide diphosphate, $U_2O_3P_2O_7$ at 1020°C.[4] The purpose of the present investigation is to determine what chemical reactions take place and what kinds of condensed phosphates of uranium are produced during the process of the thermal decomposition of uranyl dihydrogen orthophosphate trihydrate (UDOT).

When dihydrogen orthophosphate of a certain metal ion with a charge n, M^{n+} is heated until all water of constitution is lost, metaphosphate, $[M(PO_3)_n]_x$ is produced by the reaction

$$x\cdot M(H_2PO_4)_n \longrightarrow [M(PO_3)_n]_x + x\cdot n\cdot H_2O \quad (1)$$

Metaphosphates are usually divided into two groups, cyclic and linear metaphosphates. Cyclic metaphosphates have ring structures, and their molecular weights are usually not very high. Linear metaphosphates have open-chain structures, and their molecular weights are considerably high.

Thilo and Grunze have found a certain relation between the structure of metaphosphate and the

size and charge of metal ion. If metal ions with the same charge are considered, metaphosphates of the metal ions with medium sizes are the cyclic ones, while those of the metal ions with smaller or larger sizes are the linear ones.[5,6]

It is of principal interest to determine which kind of metaphosphate of uranium(VI) will be produced when UDOT is heated. According to the rule mentioned above, the formation of a linear metaphosphate is expected for the uranyl salt because of the big size of uranyl ions. The present studies were carried out by means of paper chromatography, X-ray diffractometry, differential thermal analysis, thermogravimetric analysis, infrared spectroscopy and chemical analysis.

Experimental

Preparation of Uranyl Dihydrogen Orthophosphate Trihydrate (UDOT), $UO_2(H_2PO_4)_2 \cdot 3H_2O$.[7] Before the preparation of UDOT, uranyl monohydrogen orthophosphate tetrahydrate was first prepared from uranyl nitrate hexahydrate and orthophosphoric acid by the usual method.[8] UDOT was prepared by shaking a mixture of 10 g of the uranyl monohydrogen orthophosphate tetrahydrate and 35 m*l* of 85% orthophosphoric acid for 2—3 weeks at 20°C and then by filtering the resulting solid with a glassfilter (yield 3.5 g). By addition of another 10 g of the uranyl monohydrogen orthophosphate tetrahydrate to the filtrate UDOT was prepared with yield higher than that of the first procedure (yield 12.7 g). The wet solid was washed with acetone and then carbon tetrachloride and dried in a vacuume desiccator over calcium chloride for 12 hr. Analytical results of the UDOT thus prepared are as follows.

Found: UO_3, 55.2%; P_2O_5, 28.0%; H_2O, 16.8% (by difference). Calcd for $UO_2(H_2PO_4)_2 \cdot 3H_2O$: UO_3, 55.22%; P_2O_5, 27.40%; H_2O, 17.38%.

The X-ray diffraction pattern (Fig. 4) was identical with the one reported by Dunn.[9]

Analysis of Uranium. A volumetric method with dichromate[10] was used for the analysis of uranium in uranium phosphate samples obtained by heating the UDOT. A sample was dissolved in a mixed solution of sulfuric acid and orthophosphoric acid. Uranium(VI) in the solution was then reduced to uranium(IV) with Jone's reductor. After the addition of iron(III) chloride solution, the resulting iron(II) was titrated with a standard solution of potassium dichromate.

Analysis of Phosphorus. A pH titration method was used for the determination of phosphorus in the uranium phosphate samples. Since uranium disturbs the determination of phosphorus by this method, uranium should be removed from a sample solution before titration.

A sample was dissolved in a 1M hydrochloric acid solution. The solution was passed through a cation-exchange resin column of Dowex 50W-X 8 of hydrogen form. The column was then washed with water until the washings were neutral to litmus. After condensed phosphates in the effluent mixed with the washings were completely hydrolyzed, the resulting orthophosphate was titrated with a standard solution of sodium hydroxide with a Hirama automatic recording titrator.

Preparation of Sample Solutions for Paper Chromatography. Paper chromatography was used to determine the distribution of condensed phosphate species in the uranium phosphate samples. Thus, the samples must be dissolved in a nearly neutral solution without heating in order to prevent condensed phosphates from hydrolysis. Since uranium interferes with the normal behavior of condensed phosphates in paper chromatography, it must be removed from sample solutions. It was found that the following method is suitable for this purpose.

For the dissolution of a sample containing approximately 0.1 mmol of uranium, about 10 m*l* of a 0.6M sodium hydrogen carbonate solution was used. Three 15 m*l* portions of a mixed benzene solution of TTA (thenoyltrifluoroacetone) and TBP (tributyl phosphate), with concentrations 0.2M and 0.1M, respectively, were used to extract uranium from the solution. When the extraction of uranium was performed, no phosphate species were extracted into the organic phase.

The samples heated in the temperature range between 100 and 750°C were dissolved by the simultaneous use of the aqueous solution of sodium hydrogen carbonate and the benzene solution of TTA and TBP. However, the samples heated at higher temperature than 750°C were not dissolved by this procedure. Thus, these samples were first dissolved in the aqueous solution of sodium hydrogen carbonate, and then the extraction of uranium was carried out with the benzene solution of TTA and TBP. For the most insoluble samples which were produced by heating the UDOT at 1000, 1100 and 1200°C, it took about a month to dissolve them in the sodium hydrogen carbonate solution.

Paper Chromatographic Separation and Determination of Phosphates. For one-dimensional paper chromatography fifter paper of Toyo Roshi No. 51A, 20×18 cm was used. A developing solvent was prepared by mixing 250 m*l* of a 20% trichloroacetic acid solution (100 g of trichloroacetic acid and 7 m*l* of 28% aqueous ammonia per 500 m*l* of the solution), 100 m*l* of water and 650 m*l* of acetone.[11] Development was performed at 20°C for about 4 hr by the ascending method.

An acidic molybdate solution was sprayed to detect phosphates on the filter paper. The paper was then dried and placed under ultraviolet rays until blue spots of phosphates appeared.[12]

Determination of phosphate species on the paper chromatogram was performed by a colorimetric meth-

od.[13] Each phosphate species on the paper was leached with an aqueous ammonia and treated with a Mo(V)–Mo(VI) reagent.[14] The absorbance of the sample solution was measured at 830 mμ.

Two-dimensional paper chromatography[15] was carried out to identify phosphate species which were contained in oily substances derived from the heating products of the UDOT between 800 and 940°C. Filter paper of Toyo Roshi No. 51A, 40×40 cm was used. The first development was carried out at 5°C for 40 hr with the basic solvent[15] which was a mixture of 20 m*l* of 2-propanol, 20 m*l* of *N*,*N*-dimethylformamide, 20 m*l* of methyl ethyl ketone and 1 m*l* of 28% aqueous ammonia. After developing with the basic solvent and then drying, the second development was performed at 5°C for 16 hr at a right angle to the direction of the first development with the acidic solvent[15] which was prepared by mixing 60 m*l* of methanol, 10.3 m*l* of a trichloroacetic acid solution (20 g of trichloroacetic acid and 4.6 m*l* of 28% aqueous ammonia in 100 m*l* of water), 5 m*l* of acetic acid and 10 m*l* of water.

Instruments. X-Ray diffraction patterns for powder samples were obtained with a Rigaku-denki X-ray diffractometer Model D-3F, nickel-filtered Cu*K*α radiation being used.

Thermal analyses were carried out at a heating rate of 12°C/min in static air with a Shimazu thermoanalyzer DT-2A. As a reference material, α-alumina was used. Samples were not diluted.

Infrared spectra were measured with a Hitachi EPI-S2 spectrophotometer by the usual KBr-disk method.

Results and Discussion

A thermogravimetric analysis (TGA) curve and differential thermal analysis (DTA) curves for the UDOT are given in Figs. 1 and 2, respectively. From the TGA curve, it seems that the first two water molecules are eliminated up to 120°C, the additional two water molecules are eliminated between 120 and 200°C and the last one is gradually eliminated between 200 and 700°C. An explanation for the weight loss observed at nearly 900°C will be mentioned later.

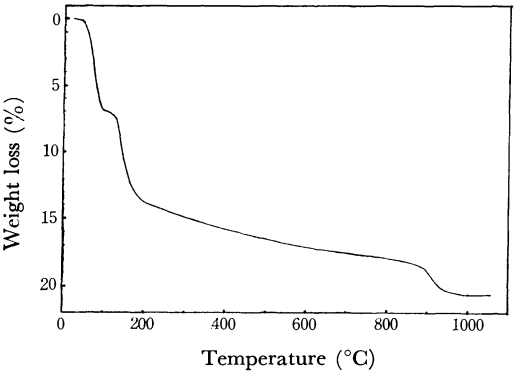

Fig. 1. Thermogravimetric analysis of $UO_2(H_2PO_4)_2 \cdot 3H_2O$.

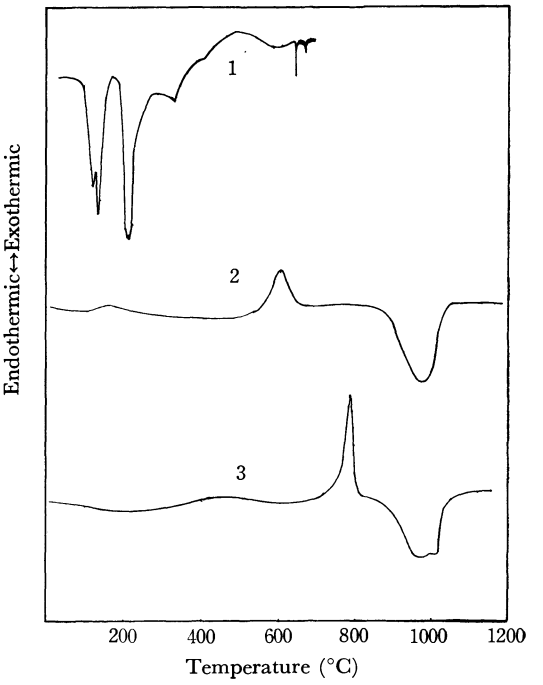

Fig. 2. Differential thermal analysis.
1) $UO_2(H_2PO_4)_2 \cdot 3H_2O$
2) The sample produced by heating $UO_2(H_2PO_4)_2 \cdot 3H_2O$ at 600°C
3) The sample produced by heating $UO_2(H_2PO_4)_2 \cdot 3H_2O$ at 800°C

When the UDOT was heated in a cell for the DTA measurement, the sample fused and overflowed the cell at about 650°C. Thus two samples which had been heated at 600 and 800°C in an electric furnace were used for the observation of the behavior in DTA at temperatures higher than 600°C.

The two endothermic peaks in the temperature range lower than 300°C in curve 1 of Fig. 2 correspond to the two-step change of the weight loss in the temperature range in the TGA curve of Fig. 1. Thus, they are due to the evaporation of water. There is no sufficient data to discuss thoroughly the exothermic peaks at 600 and 800°C in curves 2 and 3 of Fig. 2, respectively. However, these exothermic peaks seem to be due to the transformation of amorphous substances from an unequilibrium state to an equilibrium state and/or the crystallizaton of amorphous substances. The endothermic peaks observed at about 1000°C will be discussed later.

From these curves, fifteen points of heating temperature were selected in order to investigate the distribution change of phosphate species during the process of the thermal decomposition; they were

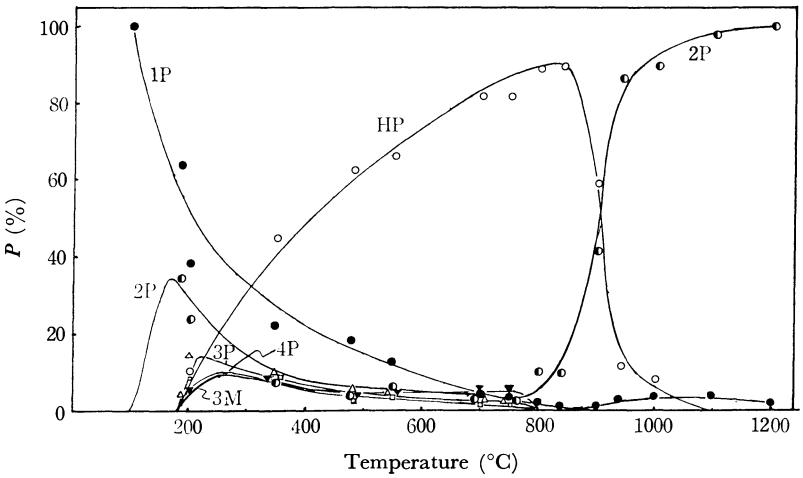

Fig. 3. Distribution of condensed phosphate species in heating products of $UO_2(H_2PO_4)_2 \cdot 3H_2O$. 1P(●): Orthophosphate, 2P(◐): Diphosphate, 3P(△): Triphosphate, 4P(□): Tetraphosphate, HP(○): Highpolyphosphate, 3M(▲): Trimetaphosphate

100, 180, 205, 350, 480, 550, 700, 750, 800, 840, 900, 940, 1000, 1100 and 1200°C. Phosphate species in the samples heated in air at these temperatures were analyzed by the dissolution procedure and paper chromatography. The distribution of the phosphate species thus obtained are given in Fig. 3, where the "high polyphosphate" means both the linear phosphates longer than tetraphosphate and the cyclic phosphates larger than trimetaphosphate.

In the case of samples heated at 800, 840, 900 and 940°C, when extraction was carried out, oily substances resulted at the bottom of the aqueous solutions. The oily substances were separated from the aqueous and benzene solutions and dissolved in water. The phosphate species in these aqueous solutions were proved to be highly polymerized phosphate (probably metaphosphate with a long-chain structure) by two-dimensional paper chromatography. The P% values of the high polyphosphate in Fig. 3 represent the amount of phosphorus in the oily substances.

Figure 3 shows that di-, tri-, tetra- and trimetaphosphates are formed in the temperature range between 180 and 350°C. At temperatures higher than 350°C, the amount of orthophosphate and these condensed phosphates except for diphosphate decreases with temperature and approaches nearly zero at 840°C. On the other hand, the amount of high polyphosphate increases with temperature and reaches about 90% at 840°C. At nearly 900°C, an abrupt change takes place, *i.e.*, the high polyphosphate undergoes decomposition, while diphosphate is formed again. At 1200°C the amount of diphosphate become almost 100%. Since the dissolution of the samples heated at a higher temperature than 900°C took a long time, the hydrolytic degradation of the samples during the dissolution must be taken into consideration. However, it can be concluded that the extent of this hydrolytic degradation was not large, because only small

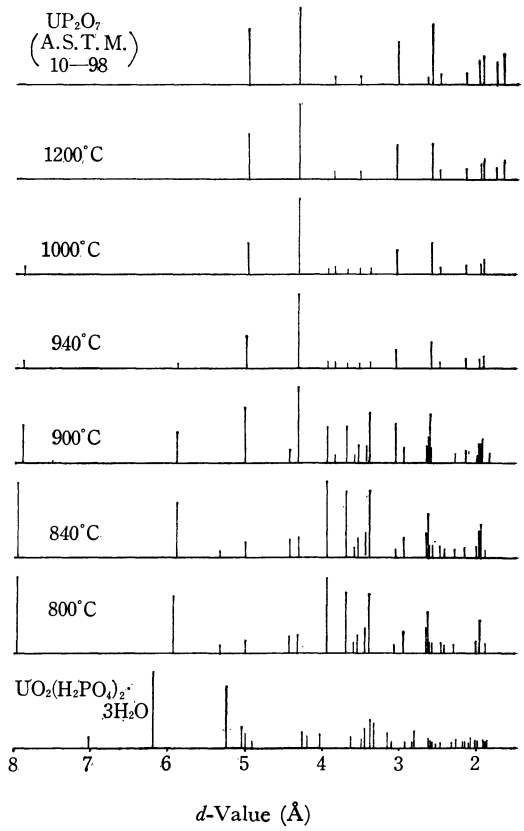

Fig. 4. X-Ray diffraction patterns of $UO_2(H_2PO_4)_2 \cdot 3H_2O$ and its heating products.

amounts of orthophosphate were observed in the solutions of the samples in question.

The results of the X-ray diffractometric analysis are given in Fig. 4. The uranium phosphate samples heated at temperatures higher than 750°C are crystalline, while those obtained in the temperature range between 100 and 750°C are amorphous. The diffraction pattern for the sample heated at 1200°C is in good agreement with that of uranium(IV) diphosphate, UP_2O_7, which is described in an A.S.T.M. card 10—98. The diffraction pattern for the sample heated at 800°C, which was confirmed to be the uranyl salt of long-chain metaphosphate by the paper chromatographic analysis, has not so far been reported.

The X-ray diffraction patterns for the samples producted in the temperature range between 800 and 1200°C show the gradual increase of the content of the uranium(IV) diphosphate and the gradual decrease of that of the uranyl salt of long-chain metaphosphate with temperature. This fact essentially agrees with the results of paper chromatographic analysis.

An infrared spectrum for the sample heated at 1200°C is similar to that for silicon, tin, titanium and zirconium diphosphates.[16] The composition of the sample heated at 1200°C is as follows.

Found; UO_2, 67.0; P_2O_5, 34.6%. Calcd for UP_2O_7; UO_2, 65.55; P_2O_5, 34.45%.

These data also indicate that the sample in question is uranium(IV) diphosphate.

We see that the most reasonable reactions which take place in the process of the thermal decomposition of the UDOT are as follows.

In the temperature range between room temperature and 100°C the reaction

$$UO_2(H_2PO_4)_2\cdot 3H_2O \longrightarrow UO_2(H_2PO_4)_2\cdot H_2O + 2H_2O \quad (2)$$

is expected to take place, because no condenced phosphates appear in the products, and the TGA curve indicates the elimination of two water molecules.

In the temperature range between 100 and 180°C, one more molecule of crystallization water may be eliminated.

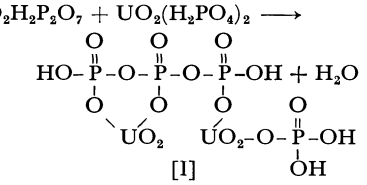
$$UO_2(H_2PO_4)_2\cdot H_2O \longrightarrow UO_2(H_2PO_4)_2 + H_2O \quad (3)$$

However, the formation of diphosphate was confirmed by means of paper chromatography. Thus, the reaction

$$UO_2(H_2PO_4)_2 \longrightarrow UO_2H_2P_2O_7 + H_2O \quad (4)$$

also occurs. In the temperature range between 180 and 200°C, further dehydration reaction takes place. Until the temperature reaches 200°C, four water molecules were eliminated as a whole. Thus, if reactions (2), (3) and (4) are completed, there might be no orthophosphate in the product. However, a considerable amount of orthophosphate was observed in the sample heated at 200°C by means of paper chromatography. Thus in addition to reactions (3) and (4), condensation reactions may take place in the temperature range between 100 and 200°C:

$$UO_2H_2P_2O_7 + UO_2(H_2PO_4)_2 \longrightarrow$$



$$+ H_2O \quad (5)$$

[I]

$$n\cdot UO_2H_2P_2O_7 \longrightarrow (UO_2)_nH_2P_{2n}O_{6n+1} + (n-1)H_2O \quad (6)$$

Here n is relatively small in this temperature range.

At nearly 300°C, the contents of tri-, tetra- and trimetaphosphates reach their maxima. When the temperature rises from 300 to 800°C, the contents of ortho-, di-, tri-, tetra- and trimetaphosphates decrease, while the content of the high polyphosphate still increases. Accordingly, in this temperature range the condensation reactions such as reactions (5) and (6) mainly occur, and the intermediates such as product [I] in reaction (5) seem to be the sources of ortho-, di-, triphosphate, *etc.* in the sample solutions.

At 800°C the condensation reactions are over, and the main component of the sample is the uranyl salt of long-chain metaphosphate, *i.e.*, uranyl metaphosphate, $[UO_2(PO_3)_2]_n$.

$$(UO_2)_nH_2P_{2n}O_{6n+1} \longrightarrow [UO_2(PO_3)_2]_n + H_2O \quad (7)$$

It was confirmed by visual observation that the melting of the sample occurs at about 900°C, and the product swells at the same time. The wide endothermic peak at 900—1000°C in the DTA curve might be due to the melting of the sample and the reduction of uranium(VI) to uranium(IV) accompanied by the formation of oxygen gas. The reduction of uranium(VI) to uranium(IV) was ascertained by the titration of the sample solutions with dichromate. This titration did not give quantitative data for uranium(IV) because a part of it was oxidized during the dissolution of the samples. Owing to the reduction of uranyl ions, UO_2^{2+} to uranium(IV) ions, U^{4+}, the positive charge of the cations increases from 2 to 4. Since the balance between the positive charge of the uranium(IV) cations and the negative charge of the phosphate anions should be kept, the degradation of the long-chain metaphosphates occurs to form finally uranium(IV) diphosphate.

$$[UO_2(PO_3)_2]_n \longrightarrow n\cdot UP_2O_7 + n/2\cdot O_2 \quad (8)$$

However, it must be noted that the thermal decomposition of reaction (8) occurred in air. Thus, the weight loss at about 900°C on the TGA curve is due to the escape of oxygen gas from the sample. The total weight loss of the UDOT exactly coincides

16) E. Stege and G. Leukroth, *ibid.*, **303**, 169 (1960).

with the calculated value, 20.6% which is derived on the assumption that the UDOT, $UO_2(H_2PO_4)_2 \cdot 3H_2O$ is completely changed into uranium(IV) diphosphate, UP_2O_7.

The authors wish to express their thanks to the staff of the Government Industrial Research Institute, Kyushu for the thermal analysis. This work was supported in part by grant-in-aids from the Ministry of Education and Asahi Press.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 89—94 (1970)

The Chemistry of Americium. I. A Study of the Preparation of Am(V) and Its Behavior by Means of TTA Extraction

Mitsuo HARA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira-cho, Sendai

(Received May 8, 1969)

The method for preparing Am(V) in various solutions was investigated by utilizing the difference in extractability between Am(V) and Am(III) in an TTA-isobutanol extraction system; Am(III) was quantitatively extracted with 0.1 M TTA in isobutanol from a 1 M acetate buffer solution at a pH greater than 3, while the percentage of Am(V) extracted into the organic phase was increased substantially with an increase in the pH from 3 to 5. When the organic phase containing Am(V) was shaken with an aqueous phase having a proper pH value and composition, Am(V) was selectively stripped into the aqueous phase. The stability of the valency state of Am(V) in the perchlorate, the acetate, and the sulfate solutions was then studied by examining the variation in the percentage of americium extracted as a function of the standing time. The rate of change in the valency state in the acetate and the perchlorate media is very slow, while it is rather rapid in the sulfate medium. This difference may be attributable to the faster rate of the disproportionation reaction of Am(V) in the last medium than in the former two. By applying the above results, the chemical behavior of Am(V) in the aqueous solution was investigated by TTA extraction; it was found that Am(V) would be in the form of AmO_2^+ in the absence of a complexing reagent. By the addition of acetate ions, the step-by-step formation of the acetate complex of Am(V) was observed. The stability constants of $[AmO_2Ac]$ and $[AmO_2Ac_2]^-$ were determined to be (25.0 ± 3.1) $(mol/l)^{-1}$ and (12.8 ± 1.2) $(mol/l)^{-2}$ respectively.

Although many papers on the chemical behavior of Am(III), which is the most stable oxidation state of americium in aqueous solutions, have been published, the knowledge concerning that of americium in higher oxidation states in rather poor, especially when a tracer concentration is involved. Investigations of americium in higher oxidation states have been limited to work on the absorption spectra of Am(V) and Am(VI) in various solutions,[1-5] the disproportionation reaction of Am(V),[1-3,6-9] and the self-reductions of both Am(V) and Am(VI).[1-3,6,10,11] The backwardness in this study is primarily due to the technical difficulty involved in the experimentation and does not reflect any lack of importance in these valency states. Americium is the heaviest of the actinide elements which are known to have pentavalent and hexavalent

oxidation states. In contrast to americium, the chemical properties of uranium, neptunium, and plutonium at higher oxidation states have been established comparatively well; therefore, a complete understanding of the properties of Am(V) or of Am(VI) is especially important for us if we are to understand the properties of the actinide series as a whole. Furthermore, for the separation and recovery of americium it is very effective to utilize the chemical properties of the higher oxidation states of americium.

It is well known that lanthanide(III,IV) and actinide(III,IV,V) ions coprecipitate with lanthanum fluoride under selected conditions.[12] However, Moore found that Am(VI) did not coprecipitate with lanthanum fluoride; he used this unique property of Am(VI) toward coprecipitation in separating and purifying americium.[13] Stokely and Moore developed a method for the purification of americium based on TTA-xylene extraction.[14] They suggested that Am(VI) was readily reduced to Am(V) when the pH was adjusted to 4—5 by the addition of an acetate buffer to Am(VI) solutions. In this pH range lanthanide(III,IV) and actinide(III,IV,VI) ions had been known to be extracted into a 0.5M solution of TTA,[15] but they found that Am(V) remained in the aqueous phase and was efficiently separated from the other metal ions. In order to study the chemistry of Am(V), it is necessary to establish a simple method for the preparation of a Am(V) solution and to find the conditions in which the oxidation state will continue as long as possible. Stokely and Moore's method is helpful for the preparation of Am(V). By their method, however, Am(V) is obtained only in an acetate buffer solution which contains many foreign materials, such as the peroxysulfate and sulfate ions; therefore, their method is not sufficient for general use.

The purpose of the present investigation is to establish a method for the production of Am(V) in various solutions and to get some idea of the stability of the valency state in these media. Furthermore, the usefulness of the method has been confirmed by showing its practical application to the determination of the stability constant of the acetate complex of Am(V), although the accuracy is limited because of the technical difficulty involved in the experiment due to the instability of Am(V).

Experimental

Reagents. $^{241}AmO_2$ which had been obtained from the Oak Ridge National Laboratory was dissolved in conc. nitric acid. The solution was then evaporated to dryness, and the residue was dissolved with 2N nitric acid and diluted to 1N in a nitric acid concentration. This solution served as the stock solution of americium. Before use, an aliquot of the stock solution was diluted to about 10^{-6}M with respect to americium with a nitric acid solution of a suitable concentration, thus making the acidity 0.1N. The radiochemical purity of ^{241}Am was confirmed by α- and γ-ray spectrometry. The xylene and isobutanol were purified by distillation, and the other chemicals, such as 2-thenoyltrifluoroacetone (TTA), ammonium persulfate and silver nitrate, were of the highest purity.

Apparatus. In order to check the radiochemical purity, the γ-ray spectra were measured with a $1\frac{3}{4}'' \times 1''$ NaI(Tl) detector coupled with a Kobe-Kogyo 100-channel pulse-height analyzer, Model AN-100, while the α-ray spectra were measured with an Osaka-Denpa gridded ionization chamber coupled with a TMC-400 channel pulse-height analyzer. For the determination of the distribution ratio, the γ-activity was counted with the above-mentioned scintillator coupled with a Kobe-Kogyo scaler, Model SA-250. For the solvent extraction, an Iwaki universal mechanical shaker, Model V-S, was used. A Toa-Denpa-Kogyo pH-meter, Model PE-2, was used for the pH measurements.

Procedure. The experiments were carried out by the following procedure except as otherwise noted.

Procedure for the Preparation of an Am(V) Solution. To 20 m*l* of a sample solution of americium in a beaker, 5 m*l* of a 0.5M ammonium persulfate solution and 1 m*l* of a 0.2% silver nitrate solution were added. The mixture was heated for 10 min in a water bath at 90—95°C. Then 1 m*l* more of the ammonium persulfate solution was added and the solution was heated for a few more minutes. Immediately after its removal from the hot water bath, the beaker was placed in an ice bath and left standing for at least 10 min. Then 5 m*l* of a 1M ammonium acetate solution which had previously been cooled was added, and the combination was mixed completely. The solution was transferred into a separatory funnel and 25 m*l* of a 0.1M TTA solution of isobutanol were added. The separatory funnel was mechanically shaken for 5 min, and the aqueous phase discarded. Then, Am(V) was back-extracted into the aqueous phase of a suitable composition, leaving Am(III) and Am(VI) in the organic phase. This solution was used as an aqueous phase for the following solvent extraction experiments.

Procedure for the Extraction. The solvent extraction was carried out by bringing in contact 10-m*l* portions of an organic phase and of an aqueous phase for 3 min at room temperature. After shaking, a suitable aliquot of each phase was placed in a polyethylene test tube and its γ-activity was counted with an accuracy of $\pm 2\%$. The rest of the aqueous phase was used for the measurement of the pH.

The distribution ratio (D) and the percentage extracted ($E\%$) were calculated by means of the usual relationship:

$$D = \frac{\gamma\text{-activity per ml of the organic phase}}{\gamma\text{-activity per ml of the aqueous phase}}$$

$$E\% = \frac{100 \cdot D}{D + V_{aq}/V_{org}}$$

where V_{aq} and V_{org} are the volumes of the aqueous and organic phases respectively.

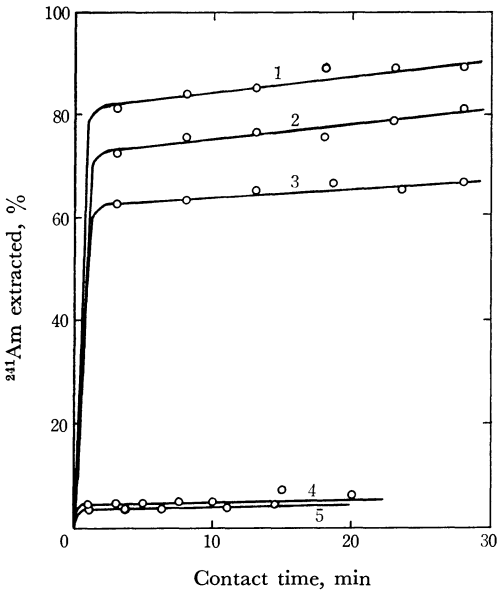

Fig. 1. The effect of the contact time on the TTA extraction of Am(V).
0.1M TTA-isobutanol: 1. pH=5.5, 2. pH=5.3, 3. pH=5.1
0.5M TTA-xylene: 4. pH=5.1, 5. pH=3.9

Results and Discussion

The Effect of the Contact Time on the TTA Extraction of Am(V). The effects of the contact time on the extraction of Am(V) with TTA solutions were investigated. A freshly-prepared Am(V) solution in 0.1M acetic acid-ammonium acetate was mixed with either 0.5M TTA in xylene or 0.1M TTA in isobutanol. The percentage of americium extracted is shown in Fig. 1 as a function of the contact time. As is clearly shown in Fig. 1, the percentage of americium extracted instantly reaches a nearly constant value and gradually increases afterward. This tendency holds irrespective of the kind of diluent and the pH value of the aqueous phase.

The gradual increase in the percentage of americium extracted may be attributable to the reduction of Am(V) to Am(III) in both phases during extraction, because Am(III) is much more extractable than Am(V). Am(V) is probably reduced either by the organic substances or by the radiolysis products produced in the solution by the absorption of alpha rays of ^{241}Am. In the TTA-xylene system the latter mechanism is more probable than the former, since the rate of the reduction of Am(V) is estimated from Fig. 1 to be several per cents/hr, a value which nearly agrees with the rate of self-reduction reported by Hall and Markin.[2] However, a portion of Am(V) is probably reduced isobutanol because the percentage of americium extracted in the isobutanol system increases at a rate which can not be explained simply by the self-reduction reaction of Am(V). In order to minimize the contribution of Am(III) to the distribution ratio of Am(V), it is desirable to select as short a contact time as possible. In view of both this and the rate of extraction, it has been decided to bring the two phases into contact for 3 min.

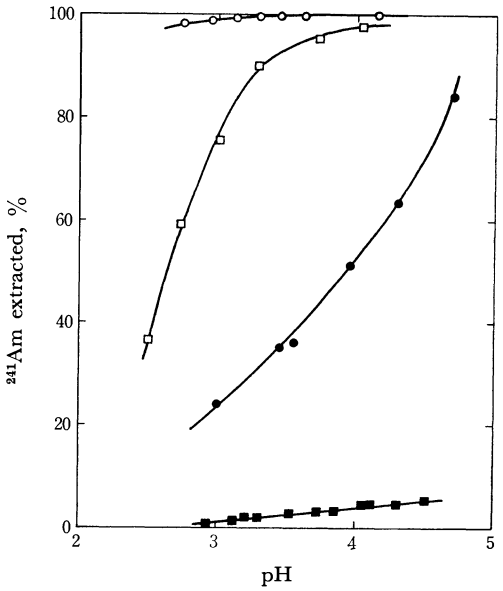

Fig. 2. The effect of pH on the extraction of Am(V) and Am(III) with TTA.
0.1M TTA-isobutanol: ○ Am(III), ● Am(V)
0.5M TTA-xylene: □ Am(III), ■ Am(V)

The Effect of the pH on the TTA Extraction of Am(V). Fig. 2 shows the effect of the pH of the aqueous phase on the extraction of Am(V) and Am(III). Am(III) is quantitatively extracted by the 0.1M TTA solution of isobutanol from 1M acetate buffer solutions when the pH of the solution is higher than 3. On the other hand, only 25% of Am(V) is extracted at pH 3, 40% at pH 4, and nearly 100% at pH 5. These results suggest the possibility of the preparation of Am(V) solutions; that is, when the aqueous solution which contains Am(III) and Am(V) is in contact with a 0.1M TTA solution of isobutanol, Am(III) and Am(V) will be extracted into the organic phase. When the organic phase is mixed with a new aqueous phase with a proper pH value, Am(V) will be selectively stripped into the aqueous phase, while

all the Am(III) will remain in the organic phase. It is this fact that is used in the present study for the preparation of aqueous solutions of Am(V).

The dependence of the percentage of Am(V) and of Am(III) extracted on the pH in a 1.0M acetate buffer-0.5M TTA solution of the xylene system is shown in Fig. 2. Am(III) is also quantitatively extracted at pH above 4, while Am(V) is only partially extracted (10% at most). Besides xylene, chloroform, carbon tetrachloride, benzene and cyclohexane all failed to extract Am(V). Cyclohexanone and hexone extracted the Am(V) complex, but less readily than isobutanol did.

The influence and the role of the solvent in the extraction of chelate compounds have been discussed from various points of view, such as the polarity of the solvent, the solubility of the chelate compounds in the organic solvent, and the coordination of the solvent with or the addition of the solvent to the central atoms in chelate compounds, but no final conclusions have yet been reached. Alimarin and Zolotov, however, discussed the solvent effect from the point of view of the coordination number of the central atom in chelates;[16] their conclusion seems to be capable of explaining the results obtained in the present work. The molecules of a polar solvent displace the water molecules which occupy the free coordination positions of the central atom, making the chelate more organophilic; thus such polar solvents as isobutanol, cyclohexanone, and hexone extract the Am(V)-TTA chelate better than non-active solvents do.

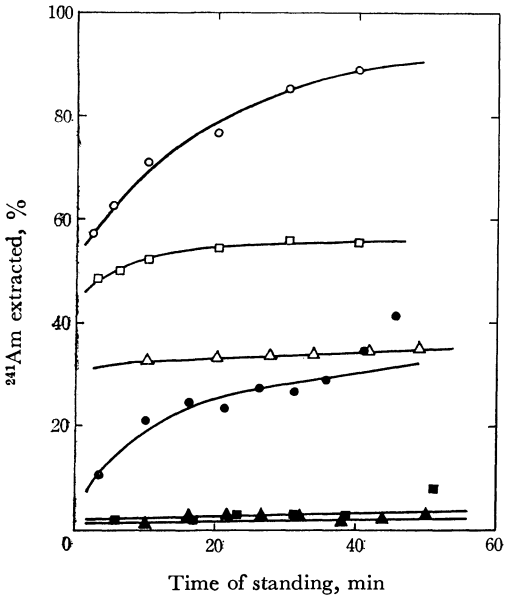

Fig. 3. Effect of time of standing in the TTA extraction of Am(V).

● 0.5M TTA-xylene/1.0M sulfate (pH=4.1)
■ 0.5M TTA-xylene/1.0M acetate (pH=3.4)
▲ 0.5M TTA-xylene/1.0M perchlorate (pH=4.5)

The Stability of the Valency State of Am(V) in Various Aqueous Solutions. The perchlorate, acetate, and sulfate solutions of Am(V) were stored at 0°C. Suitable aliquots of the solutions were subjected to TTA extraction after a definite time of standing. The variation in the percentage of americium is shown in Fig. 3 as a function of the time. In the cases of the acetate and perchlorate solutions, the variation in the percentage of americium extracted is about 3%/hr, which may be due to the reduction of Am(V) to Am(III), as has been discussed before. Thus, Am(V) is not very stable in either perchlorate or acetate solutions, but the contribution of Am(III) to the distribution ratio is negligible within about 10 min after the preparation of the Am(V) solutions. As Am(III) is gradually generated during storage, it is necessary before use to remove Am(III) by extraction with a 0.5M TTA solution of xylene at a pH value above 4. On the other hand, the tendency of the percentage of americium extracted in the sulfate system to increase with the standing time is faster than in the perchlorate and the acetate systems; that is, Am(V) seems to be less stable in sulfate solutions. The cause of the instability of Am(V) in sulfate media is not clear, but Coleman's observation[7] seems to suggest one reason; he

16) I. P. Alimarin and Yu. A. Zolotov, *ibid.*, **9**, 891 (1962).

studied the rate of the disproportionation of Am(V) in various acid media and found that the rate constant in a sulfuric acid medium was many times greater than that in other acids, such as nitric and hydrochloric acids. In any case, the dependence of the rate of the decrease of Am(V) on the nature of the coexisting anion deserves further study. Attempts to prevent Am(V) from reduction using such holding oxidants as $(NH_4)_2S_2O_8$–Ag^+ and ozone failed; what is worse, a part of the TTA was decomposed by such strong oxidizing reagents.

The Determination of the Stability Constant of the Acetate Complex of Am(V). The pH dependence of the distribution ratio of Am(V) between a 0.5M TTA solution of xylene and a 1.0 or 0.1M acetate solution is shown in Fig. 4. The distribution ratios in the 0.1M acetate system are larger than those in the 1.0M acetate system at the same pH value; this observation suggests the formation of acetate complexes of Am(V). The curves in the figure in both systems approach a straight line with a slope of about one with the decrease in the pH. Irving and Edgington extracted Np(V) in a 0.05M HNO_3 solution with 0.05M TTA in cyclohexane, and demonstrated the first-order dependency of the distribution ratio on pH.[17]

As the chemical properties of Am(V) are expected to be similar to those of Np(V), the deviation of the distribution ratio from the straight line (the dotted line in Fig. 4) can be understood in terms of the formation of the acetate complexes of Am(V). It is apparent from the following equation that the acetate ion concentration, [Ac$^-$], increases with an increase in the pH at a constant total acetic acid concentration, $[HAc]_i$:

$$\log \frac{[HAc]_i - [Ac^-]}{[Ac^-]} = pK_a - pH$$

where pK_a is the acid constant of acetic acid. The dependency of the distribution ratio on the TTA concentration in xylene is found to be second-order as is shown in Fig. 5; the same tendency holds in the case of Np(V).[17] Considering these results, it may be assumed, by analogy with Np(V), that Am(V) would be found in the form of AmO_2^+ in an aqueous solution containing no complex-forming reagent. This assumption is also warranted by the results of infrared spectroscopy by Jones and Penneman.[18] In the presence of acetate ions, AmO_2^+ forms acetate complexes. The species extracted in the organic phase are the neutral chelate compounds of AmO_2^+ and TTA. Therefore, the equilibria concerned in the extraction and in the acetate complex formation of Am(V) can be written as:

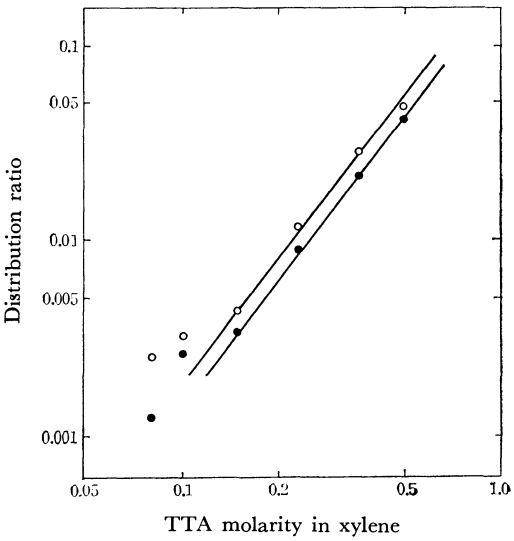

Fig. 5. Relationship between the distribution ratio and the concentration of TTA in xylene in the extraction of Am(V) from 0.1M acetate solution.
○ pH=4.6 ● pH=3.6

$$AmO_2^+ + 2HA_{org} \rightleftharpoons AmO_2HA_{2,org} + H^+ \quad (1)$$

$$AmO_2^+ + Ac^- \rightleftharpoons AmO_2Ac \quad (2)$$

$$AmO_2Ac + Ac^- \rightleftharpoons AmO_2Ac_2^- \quad (3)$$

where HA and Ac$^-$ indicate the TTA molecule and the acetate ion respectively. The subscript "org" indicates the organic phase, while the unsubscripted species refer to the aqueous phase. The formation of a complex higher than $AmO_2Ac_2^-$ may be neglect-

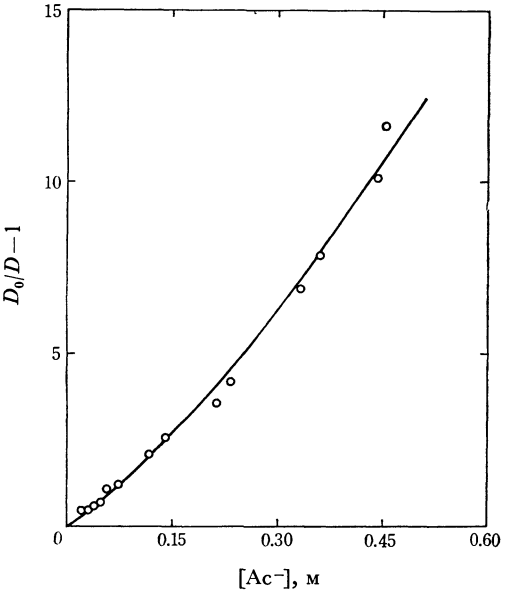

Fig. 6. Relationship between $(D_0/D-1)$ and acetate ion concentration.

17) H. Irving and D. N. Edgington, *J. Inorg. Nucl. Chem.*, **20**, 314 (1961).

18) L. H. Jones and R. A. Penneman, *J. Chem. Phys.*, **21**, 542 (1953).

ed in the range of acetate-ion concentrations investigated. The distribution ratio of Am(V), D, can then be defined as:

$$D = \frac{[\mathrm{Am(V)}]_{org}}{[\mathrm{Am(V)}]_{aq}} = \frac{[\mathrm{AmO_2HA_2}]_{org}}{[\mathrm{AmO_2^+}]+[\mathrm{AmO_2Ac}]+[\mathrm{AmO_2Ac_2^-}]} \quad (4)$$

If one uses K_0 for the equilibrium constant of Reaction (1) and β_1 and β_2 for the stability constants of AmO_2Ac and $AmO_2Ac_2^-$ respectively, Eq. (4) is reduced to:

$$D = \frac{K_0[\mathrm{HA}]_{org}^2}{[\mathrm{H^+}](1+\beta_1[\mathrm{Ac^-}]+\beta_2[\mathrm{Ac^-}]^2)} \quad (4')$$

where $[HA]_{org}$ is the concentration of TTA in the organic phase and while $[H^+]$ and $[Ac^-]$ are the concentrations of hydrogen ions and acetate ions respectively in the aqueous phase. One can then rewrite Eq. (4') as:

$$D = D_0(1+\beta_1[\mathrm{Ac^-}]+\beta_2[\mathrm{Ac^-}]^2)^{-1} \quad (5)$$

where D_0 is the distribution ratio when the acetate ion is absent and is defined as the inclination of the dotted line in Fig. 4. Using the experimental values of D and the corresponding values of D_0 read from the dotted line, the magnitudes of $(D_0/D-1)$ are calculated. The relation between $(D_0/D-1)$ and $[Ac^-]$ is shown in Fig. 6. Using the method of least squares, the best-fit values for β_1 and β_2 were founds to be $(25.0\pm3.1)(\mathrm{mol}/l)^{-1}$ and $(12.8\pm1.2)(\mathrm{mol}/l)^{-2}$ respectively.

This author wishes to thank Professor Shin Suzuko and Dr. Yasushi Inoue for their kind and valuable advice throughout this study. A part of the expence has been defrayed by a grant-in-aid from the Ministry of Eduction.

Activity Coefficient of Sodium in Dilute Sodium and Gold Alloy at 1400°K

Kazushi HIROTA and Takashi KATSURA

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 12, 1969)

The equilibria between the molten Na_2CO_3 and the Au-Na alloys were determined at 1400°K under $CO+CO_2$ gaseous mixtures. The activity coefficient of Na in the Au-Na alloys was constantly 0.0392 ± 0.0028 at concentrations ranging from 0.2 to 0.02 wt% Na.

In the thermodynamic study of ionic solutions, the electromotive force measurement between the solution and a pure metal has generally proved very useful when the pure liquid or solid metal is stable at a desired temperature. However, if the vapor pressure of the pure metal is high, it is not practical to construct the cell. This is just the case with the liquid metallic sodium at a high temperature. At 1400°K, for example, the vapor pressure of sodium is about 6.2 atm.[1] To avoid such difficulty, an attempt was made to determine precisely the activity coefficients of sodium in the gold-sodium alloys, especially at low sodium concentrations.

Experimental

The quenching method was adopted to obtain the equilibrium concentration of sodium in the alloy. About 2 g of purified gold, or a sodium-gold alloy, and about 10 g of pure sodium carbonate were put into an alumina crucible (Nippon Kagaku Togyo Co., SSA-H-010). The crucible was then heated in a vertical-type tube furnace at 1400°K, through which there had previously been passed a desired gaseous mixture, $CO+CO_2$, until equilibrium was attained between the condensed and the gas phases. A small-size alumina tube (Degussa, AL-23) was dipped into the liquid sodium carbonate phase to bubble in the same gaseous mixture as that of the inside of the furnace. The crucible was then quenched as quickly as possible after equilibrium was attained between the condensed and gas phases.

Pure gold was obtained as follows: Commercially-pure gold was first dissolved in aqua regia, and then treated with hydrochloric acid to expel the nitric acid. The gold complex was then extracted by diethyl ether. The gold metal was precipitated from the hydrochloric acid solution by sulfur dioxide gas.

The temperature was calibrated against the gold and diopside points; the fluctuation of the temperature was within ±2°K throughout the study. The gases, CO_2 (99.95% purity or more) and CO (99.5% or more),

1) M. M. Makansi, C. H. Muendel and W. A. Selke, *J. Phys. Chem.*, **59**, 40 (1955).

were mixed by an apparatus previously described[2]; the fluctuation in mixing ratio, CO_2/CO, was estimated to be within $\pm 0.5\%$.

Analytical Method for Determining Na in Na-Au Alloy. A flame-photometric method was mainly adopted. About 0.2 to 3 g of the alloy sample was dissolved on a hot plate by the use of 20 m*l* of aqua regia in a quartz glass beaker; after almost dried, exactly 5 m*l* of concentrated sulfuric acid was added to expel the remaining nitric acid. The residual mass was treated by hot water, and then sulfur dioxide was passed through this hot solution for about 20 min in order to effect the complete precipitation of the gold.

After filtration, the solution was evaporated almost to dryness in order to expel the excess sulfuric acid. The residue was dissolved in water to make the solution up to 100 m*l*. The solution almost free from sulfuric acid was determined for sodium by the flame photometer (EPU-2A, H-2, Hitachi Co.). The concentration of sodium in the 100 m*l* solution was kept around 10 ppm Na by adjusting the sample weight of the alloy. The effect of the sulfuric acid in the sample solution was negligible in such a low concentration of sulfuric acid. The contamination from reagents was determined to be constantly 0.03 ± 0.01 mg Na. Some duplicated analyses showed the deviation of ± 0.003 wt% Na at a high Na content and that of ± 0.002 wt% Na at a low content.

Criteria for Equilibrium. Two methods were applied to criticize the attainment of equilibrium; one was based on the both-side reactions (b.s.r. in Table 1), and the other, on the electromotive force measurement (emf in Table 1). The former is the reaction of gold-sodium alloy, comprising an arbitrary concentration of sodium, with sodium carbonate under a desired $CO+CO_2$ gaseous mixture; it finally obtains the equilibrium concentration value in between the concentrations of the starting alloys. The other method adopted was the electromotive force measurement of the following cell:

Na-Au alloy $|Na_2CO_3$ melt $|CO+CO_2$ mixed gas

The apparatus for this purpose is shown in Fig. 1. The electromotive force of this cell was corrected for the thermoelectromotive force of the lead wire in the cell. The system was assumed to be in equilibrium when the corrected electromotive force was observed to be zero. Iridium and Pt-Rh wires do not react with liquid gold and liquid sodium carbonate respectively.

Results and Discussion

The results are summarized in Table 1. Liquid sodium carbonate was practically pure under the equilibrium condition. After quenching, the sodium carbonate mass was immediately dissolved in water; no evolution of gas was ascertained. This means that the amount of metallic sodium in the carbonate phase is negligible under the present experimental conditions. The dissolution of the alumina crucible and alumina tube into sodium carbonate increases with a decrease in the CO_2 partial pressure; at most, 0.03 wt% Al_2O_3 was found in sodium carbonate after 22 hr heating when the CO_2 partial pressure was 0.05 atm. The dissolution of gold into liquid sodium carbonate was found to be 0.05 wt% as Au, for example, when the composition of the gaseous mixture was 20% CO_2 and 80% CO. The dissolution of gold seems to be a function of the CO partial pressure in the gaseous mixture.

In the present experiment, the following reactions may be expected in the system:

$$CO(g) + Na_2CO_3(1) = 2Na(g) + 2CO_2(g) \quad (1)$$

$$Na_2CO_3(1) = Na_2O(1) + CO_2(g) \quad (2)$$

The standard free energy of the reaction (2) can be calculated to be 33.094 kcal/mol at 1400°K.[3] Then,

$$\log (a_{Na_2CO_3}/a_{Na_2O} \cdot P_{CO_2}) = 5.166 \quad (3)$$

where P_{CO_2} is the partial pressure of CO_2 in atm. $a_{Na_2CO_3}$ and a_{Na_2O} are the activities of Na_2CO_3 and of Na_2O respectively, referred to the liquid state. Therefore, the decomposition of the sodium carbonate melt into the sodium oxide and carbon dioxide gas is negligible under the present experimental conditions. The similar decomposition reactions of sodium carbonate into NaO, Na_2O_2, *etc.* are also negligible. Judging from these results, it may be concluded, within the present limits of experimental error, that the partial pressure of the CO and CO_2 of the gaseous mixture are unaffected by being brought into contact with the sodium carbonate melt.

At the equilibrium of the system, the partial pressure of monatomic sodium, P_{Na}, may be represented by:

$$-\ln P_{Na} = \Delta G^\circ(1)/2\boldsymbol{R}T + \ln P_{CO_2} - (1/2)\ln P_{CO} - (1/2)\ln a_{Na_2CO_3} \quad (4)$$

where $\Delta G^\circ(1)$ is the standard free energy of the reaction (1) at 1400°K, $\boldsymbol{R}$ is gas constant, T is the absolute temperature, and P_{CO_2} and P_{CO} are the partial pressures of CO_2 and CO in the gas mixture respectively. $a_{Na_2CO_3}$ is the activity of Na_2CO_3 referred to the liquid state. At the equilibrium of the system, the partial pressures of monatomic sodium, calculated from Eq. (4), were ranged from 2 mmHg to 0.2 mmHg.

From Eq. (4) and the fact that the carbonate phase was essentially pure, that is to say, assuming the activity of sodium carbonate to be unity, we obtain:

$$\Delta G^\circ(1)/4.606\boldsymbol{R}T + \log (P_{Na}/N_{Na}) = (1/2)\log P_{CO} - \log P_{CO_2} - \log N_{Na} \quad (5)$$

where N_{Na} is the atom fraction of Na in the alloy. By the use of the right hand side of Eq. (5), the left hand side was calculated; the results are given in the last column of Table 1. It may be concluded from these results that the P_{Na}/N_{Na} is almost constant within the limits of experimental error in the concentration range of the present investigation, about 0.02 to 0.2 wt% Na. We obtain the following result:

$$\Delta G^\circ(1)/4.606\boldsymbol{R}T + \log (P_{Na}/N_{Na}) = 2.44 \pm 0.03 \quad (6)$$

The $\Delta G^\circ(1)$ can be calculated from the values of the standard free energies of the formations of CO(g), CO_2(g), and Na_2CO_3 (1) at 1400°K. The standard free energies of the formation of CO and CO_2 gases are known to be highly reliable, and are taken from the literature.[3] Also a recent compilation by "JANAF"[3] gives the standard free enery of the formation of Na_2CO_3 (1) to be -173.627 kcal/mol. Thus, if we use these values, $\Delta G^\circ(1)$ can be calculated to be $+40.557$ kcal/mol. By substituting proper values into Eq. (6), we obtain the following result at concentrations ranging from 0.2 to 0.02 wt% Na:

$$P_{Na}/N_{Na} = 0.188 \pm 0.013 \text{ (atom)} \quad (7)$$

at 1400°K.

When we choose the pure liquid standard state for the activity of sodium, a_{Na}, the activity coefficient, $\gamma_{Na} = a_{Na}/N_{Na}$, can be calculated from (7) as follows:

$$\gamma_{Na} = 0.0392 \pm 0.0028 \quad (8)$$

where the values of the standard free energy change of the condensation of monatomic sodium gas to the pure liquid sodium used in the calculation were $+4.373$ kcal/mol.[3]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 97—99 (1970)

Cobalt(II, III), Nickel(II) and Copper(II) Complexes with Tetra- and Hexamethylenediaminetetraacetate

Hiroshi OGINO, Shigeru KOBAYASHI and Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received May 28, 1969)

Synthesis of new complexes of cobalt(II), cobalt(III), nickel(II) and copper(II), $[Co_2hdta]\cdot 6.5H_2O$, $K[Co\ tdta]\cdot 3H_2O$, $[Ni_2\ hdta]\cdot 6.5H_2O$, $Na_2[Cu\ tdta]\cdot 6H_2O$, $[Cu_2\ tdta]\cdot 1.5H_2O$ and $[Cu_2\ hdta]\cdot 6.5H_2O$, has been carried out, where tdta and hdta represent $(OOCCH_2)_2N(CH_2)_4N(CH_2COO)_2^{4-}$ and $(OOCCH_2)_2N(CH_2)_6N(CH_2COO)_2^{4-}$, respectively. The infrared, nuclear magnetic resonance and visible and ultraviolet absorption spectra were measured. The infrared and the NMR spectra of the Co(III) complex with tdta indicate that a quadrivalent tdta anion behaves as a hexadentate in this complex.

The preparation and properties of the cobalt(II), cobalt(III), nickel(II) and copper(II) complexes with ethylenediaminetetraacetate (edta) have been extensively investigated. The stability constants of complexes with higher homologues of EDTA have also been reported.[1-3] This paper presents the synthesis and properties of cobalt(II), cobalt(III), nickel(II) and copper(II) complexes with tetramethylenediaminetetraacetate ($(^-OOCCH_2)_2N(CH_2)_4N(CH_2COO^-)_2$) and hexamethylenediaminetetraacetate ($(^-OOCCH_2)_2N(CH_2)_6N(CH_2COO^-)_2$).

Experimental

Preparation. H_4tdta[1] and H_4hdta[2] have been prepared by Schwarzenbach and Ackermann and by Müller and Bersin, respectively, where tdta and hdta represent quadrivalent anions of tetra- and hexamethylenediaminetetraacetate, respectively. In this study, however, these compounds were prepared with procedures similar to that applied to the synthesis of trimethylenediaminetetraacetic acid by Tanaka and Ogino.[4]

Tetramethylenediaminetetraacetic Acid: Monochloroacetic acid (170 g; 1.8 mol) was dissolved in 50 m*l* of water, to which 144 g (3.6 mol) of sodium hydroxide dissolved in 100 m*l* of water was added drop by drop with stirring at about 10°C, followed by the addition of 28 g (0.3 mol) of tetramethylenediamine. The resulting solution was heated at 100°C for 1 hr and was left standing overnight. The pH of the solution was adjusted to 2.3 with concentrated hydrochloric acid. The solution was evaporated on a water-bath, and the white powder containing sodium chloride was collected. This mixture was washed with water to remove as much sodium chloride as possible. The compound was recrystallized from hot water, when the hydrate was obtained. Recrystallization was repeated five times. Found: C, 40.22; H, 6.85; N, 7.76%. Calcd for $C_{12}H_{20}N_2O_8\cdot 2H_2O$: C, 40.45; H, 6.74; N, 7.87%.

Hexamethylenediaminetetraacetic Acid: Hexamethylenediaminetetraacetic acid was prepared with the same procedure as for tetramethylenediaminetetraacetic acid, except that 35 g (0.3 mol) of hexamethylenediamine was added instead of 28 g (0.3 mol) of tetramethylenediamine. The compound was recrystallized from hot water. Found: C, 47.98; H, 7.22; N, 7.89%. Calcd for $C_{14}H_{24}N_2O_8$: C, 48.28; H, 6.90; N, 8.05%.

$Na_2[Cu\ tdta]\cdot 6H_2O$: Copper(II) chloride dihydrate (3.4 g; 0.02 mol) was dissolved into 50 m*l* of water. Tetramethylenediaminetetraacetic acid (7.1 g; 0.02 mol) suspended in 50 m*l* of water was dissolved by adding 2.12 g (0.02 mol) of sodium carbonate. This solution was added to the copper(II) solution. The pH of the mixture was adjusted to about 7 with sodium bicarbonate. The resulting solution was evaporated on a water-bath to a volume of 20 m*l* and cooled in an ice-bath. A light blue crystalline compound appeared, which was collected and washed with water, alcohol and ether. The compound was recrystallized from hot water. Found: C, 26.83; H, 5.67; N, 5.31; H_2O, 21%. Calcd for $Na_2[CuC_{12}H_{16}N_2O_8]\cdot 6H_2O$: C, 26.99; H, 5.25; N, 5.25; H_2O, 20.2%.

$[Cu_2tdta]\cdot 1.5H_2O$: Copper(II) chloride dihydrate (6.8 g; 0.04 mol) was dissolved in 50 m*l* of water. Tetramethylenediaminetetraacetic acid (7.1 g; 0.02 mol) suspended in 50 m*l* of water was dissolved by adding 2.12 g (0.02 mol) of sodium carbonate. This solution was added to the copper(II) solution. The pH of the mixture was adjusted to about 6 with sodium bicarbonate. A dark blue crystalline compound was crystallized immediately. The compound was collected and washed with water, alcohol and ether. Since it was not sufficiently soluble in water, it was purified in the following way: The compound was dissolved into dilute nitric acid solution and filtered. The pH of the solution was

adjusted to 6 with sodium carbonate, and the compound deposited was collected. Found: C, 30.52; H, 4.57; N, 6.13; H_2O, 6%. Calcd for $[Cu_2C_{12}H_{16}N_2O_8]\cdot 1.5H_2O$: C, 30.64; H, 4.04; N, 5.96; H_2O, 5.7%.

$[Co_2hdta]\cdot 6.5H_2O$: Cobalt(II) chloride hexahydrate (9.5 g; 0.04 mol) was dissolved in 50 m*l* of water. Hexamethylenediaminetetraacetic acid (7.0 g; 0.02 mol) suspended in 50 m*l* of water was dissolved by adding 2.12 g (0.02 mol) of sodium carbonate. The solution was added to cobalt(II) solution. The resulting solution was left standing overnight. Pink powder was collected and washed with water, alcohol and ether. Since the compound was not sufficiently soluble in water, it was purified in the same way as for $[Cu_2tdta]\cdot 1.5H_2O$. Found: C, 29.22; H, 6.03; N, 5.06; H_2O, 19%. Calcd for $[Co_2C_{14}H_{20}N_2O_8]\cdot 6.5H_2O$: C, 29.03; H, 5.70; N, 4.84; H_2O, 20.2%.

$[Ni_2hdta]\cdot 6.5H_2O$: This compound was prepared in the same way as for $[Co_2hdta]\cdot 6.5H_2O$. Found: C, 28.88; H, 5.99; N, 5.08; H_2O, 19.5%. Calcd for $[Ni_2C_{14}H_{20}N_2O_8]6.5H_2O$: C, 29.05; H, 5.71; N, 4.84; H_2O, 20.2%.

$[Cu_2hdta]\cdot 6.5H_2O$: This compound was prepared in the same way as for $[Co_2hdta]\cdot 6.5H_2O$. Found: C, 28.38; H, 5.89; N, 4.65; H_2O, 20%. Calcd for $[Cu_2C_{14}H_{20}N_2O_8]\cdot 6.5H_2O$: C, 28.57; H, 5.61; N, 4.76; H_2O, 19.9%.

K[Co tdta]$\cdot 3H_2O$: H_4tdta (7.1 g; 0.02 mol), potassium acetate (12.0 g; 0.12 mol) and cobalt(II) acetate tetrahydrate (5.0 g; 0.02 mol) were dissolved into 100 m*l* of water, to which 2.85 g of lead dioxide was added. The pink solution turned to dark blue immediately. The solution was filtered and the filtrate was evaporated under reduced pressure to 50 m*l* at about 50°C. After the solution was cooled to 0°C, alcohol was added drop by drop, when dark blue crystals were deposited, which were collected and washed with cold water, alcohol and ether. The compound was recrystallized from water of about 50°C by the addition of alcohol. The crystals decompose at about 100°C. Found: C, 31.05; H, 4.93; N, 5.97; H_2O, 11%. Calcd for $K[CoC_{12}H_{16}N_2O_8]\cdot 3H_2O$: C, 30.77; H, 4.70; N, 5.98; H_2O, 11.5%. It should be noted that the preparation of cobalt(III)-HDTA complexes was not successful because no suitable oxidizing agent was found to oxidize cobalt(II)-HDTA complexes to the cobalt(III) state.

Measurement. The crystalline water of the complexes was determined by a Shimadzu RT-2 recording thermobalance. The infrared spectra were obtained with a Hitachi EPI-2G recording infrared spectrophotometer by the potassium bromide disk method. The proton NMR spectra were obtained with a Varian A-60 high resolution nuclear magnetic resonance spectrometer, and the visible and ultraviolet absorption spectra, with a Hitachi EPS-3 spectrophotometer.

Result and Discussion

Infrared Absorption Spectra. In Table 1 are given the frequencies of the absorption bands of H_4edta, H_4tdta$\cdot 2H_2O$, H_4hdta, $Na_2[Cu\ tdta]\cdot 6H_2O$, $[Cu_2tdta]\cdot 1.5H_2O$, $[Co_2hdta]\cdot 6.5H_2O$, $[Ni_2hdta]\cdot 6.5H_2O$, $[Cu_2hdta]\cdot 6.5H_2O$, Na[Co edta]$\cdot 4H_2O$ and K[Co tdta]$\cdot 3H_2O$. The values obtained for H_4hdta almost agree with those in literature.[4]

** Relative chemical shifts of two AB protons are given in parentheses.

5) J. L. Sudmeier and C. N. Reilley, *Anal. Chem.*, **36**, 1698 (1964).

6) J. B. Terill and C. N. Reilley, *Inorg. Chem.*, **5**, 1988 (1966).

It has been reported that in the case of such divalent metal complexes as dealt with in this study, coordinated and free carboxyl ions cannot be distiguished from each other by their infrared absorption spectra.[7] The cobalt(III) complex with tdta gave a strong carboxylate band at higher frequencies than those of the absorption band due to free COO^-. Although the carboxylate band of $K[Co\ tdta]\cdot 3H_2O$ splits into two absorption peaks at 1639 cm^{-1} and 1619 (sh) cm^{-1}, both peaks are considered to be associated with the coordinated carboxyl groups. This suggests that a quadrivalent tdta anion in the cobalt(III) complex behaves as a hexadentate.

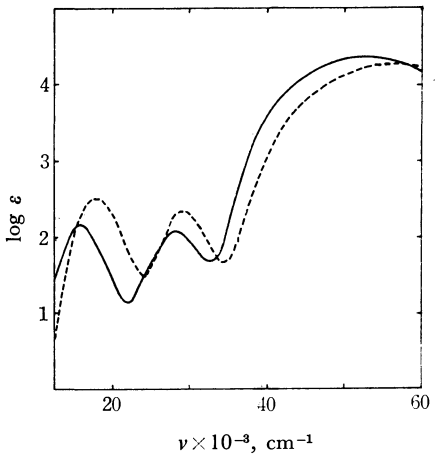

Fig. 2. Visible and ultraviolet absorption spectra of $K[Co\ tdta]\cdot 3H_2O$ (full line) and $Na[Co\ edta]\cdot 4H_2O$ (broken line).

Nuclear Magnetic Resonance Spectra. Proton NMR spectra of tdta and hdta anions were measured in 0.2M aqueous sodium hydroxide solution and those of cobalt(III) complex with tdta, in D_2O. The latter is shown in Fig. 1. In Table 2 are given the chemical shifts of proton NMR spectra of these compounds.

$K[Co\ tdta]\cdot 3H_2O$: Spectrum of the acetate protons splits into eight peaks in a region from 3.0 ppm to 4.2 ppm, indicating two AB patterns. The coupling constants are also given in Table 2. The two AB patterns show that four acetates are divided into two groups; the acetates of one group are of the out-of-plane type while those of the other group are of the in-plane type, when the plane involving two nitrogen atoms and a central metal ion is considered.

Table 3. Frequencies and log ε of visible and ultraviolet absorption maxima for Co(III) complexes with edta and tdta

Compound	I band		II band		Specific band	
	$\bar{\nu}\times 10^{-3}$ cm^{-1}	log ε	$\bar{\nu}\times 10^{-3}$ cm^{-1}	log ε	$\bar{\nu}\times 10^{-3}$ cm^{-1}	log ε
$Na[Co\ edta]\cdot 4H_2O$[8]	18.6	2.51	26.0	2.36	44.3	4.33
$K[Co\ tdta]\cdot 3H_2O$	17.2	2.13	25.4	2.08	42.0	4.37

Visible and Ultraviolet Absorption Spectra. The visible and ultraviolet absorption spectra of cobalt(III) complexes with edta and tdta are shown in Fig. 2, and wave numbers and log ε of absorption maxima for cobalt(III) complexes with edta and tdta are given in Table 3. The first and the second absorption bands of the cobalt(III) complex with tdta give a red shift as compared with edta, indicating that the spectrochemical series is in the order of edta > tdta.

The Solvent Extraction of Metal Ions from Sulfuric Acid Solutions with a Mixed Extractant — Long-chain Primary Amine and Di-2-ethylhexylphosphoric Acid

Hiroto WATANABE

Department of Industrial Chemistry, Muroran Institute of Technology, Muroran, Hokkaido

(Received May 31, 1969)

The distribution of metal ions between phases of dilute sulfuric acid and carbon tetrachloride containing long-chain primary amine (Primene JM) and di-2-ethylhexylphosphoric acid (D2EHPA) has been investigated. The degree of the extraction of bi- and tervalent metal ions, such as zinc, iron(III), indium, lanthanum, and cerium(III), is found to be the lowest when the organic phase contains 5 g/*l* of Primene JM and 7—8 g/*l* of D2EHPA, while a minimum extraction of thorium occurs at a different composition of the organic phase. Thus, thorium can be quantitatively separated from most other metals by extraction from a 0.1 N sulfuric acid medium with carbon tetrachloride containing 5 g/*l* of Primene JM and 7—8 g/*l* of D2EHPA. Under these extraction conditions, a single extraction is sufficient for the quantitative separation of thorium from high concentrations of lanthanide metals. Contrary to the usual method of extraction using long-chain amines, which involves a tedious multiple extraction, the mixed-extractant technique described is simple and will find many uses in the determinations of thorium in a variety of samples.

Solutions of long-chain amines in water-immiscible solvents have been found capable of extracting a wide variety of metal ions from acid solutions.[1] In particular, it has generally been accepted that ter- and quadrivalent metal ions can be readily extracted from a sulfuric acid solution by long-chain primary amines.[2-5] In this aspect, the present author has investigated the extraction of indium and iron(III) from dilute sulfuric acid solutions with Primene JM dissolved in carbon tetrachloride.[6] Such long-chain amines have frequently been called the "liquid anion exchangers." In contrast to the amines, there is another group of extractants that have been named the "liquid cation exchangers." Di-2-ethylhexylphosphoric acid, which is representative of the acidic organophosphorus compounds, has been used as a cationic extractant for a large number of aqueous cations.[7,8]

For both types of extractants, a synergistic effect has been demonstrated.[1,9-11] As in the case of uranium(VI) extraction, the addition of neutral organophosphorus compounds to D2EHPA enhances the distribution ratio of uranium(VI) by a factor of from ten to hundreds. The synergistic effect for the acidic organophosphorus compounds has been investigated extensively and used for the separation of metals. Although there have been a number of studies of the synergism in the extraction of metals, both with β-diketones, particularly thenoyl trifluoroacetone, and with bases,[12-16] little attention has been paid to the influence of certain acidic extractants on the metal extraction

with high-molecular-weight amines. Deptula[9,17] has examined the extraction behavior of such compounds as H_2PtCl_6, $H_2Cr_2O_7$, and UO_2SO_4 from sulfuric acid solutions by a mixture of long-chain tertiary amines and dialkylphosphoric acids in benzene. He found that the extent of extraction was increased or decreased depending on the sulfuric acid concentrations, suggesting a synergistic or an antagonistic effect of the amine with the alkylphosphoric acid. However, no further attempt has been made at formulating a quantitative explanation of the extraction mechanism applicable to the mutual separation of metal ions.

A similar effect can be expected for the extraction of other metal ions. By a combination of long-chain amines and alkylphosphoric acids, it will be possible to change the selectivity of long-chain amines or alkylphosphoric acids to the metal ions. In this respect the present attempt was made to extract zinc, iron(III), indium, lanthanum, cerium(III), and thorium from sulfuric acid solutions with a mixture of Primene JM and D2EHPA in carbon tetrachloride. The results of the present experiment establish that thorium can be quantitatively separated from large amounts of bivalent and tervalent ions without multiple extraction or scrubbing.

Experimental

Apparatus. An Iwaki-V-S Shaking Unit was used for equilibration.

Reagents. The purification of D2EHPA[18] in carbon tetrachloride involves the scrubbing of the sodium monoalkylphosphate with an equal volume of a 10% sodium carbonate solution,[19] followed by acidification with an equal volume of a 1N sulfuric acid solution.

Primene JM,[20] trialkylmethylamine, a homologous mixture of C_{18-24} amines, was converted into the sulfate form by washing the amine solution in carbon tetrachloride with an equal volume of a 1N sodium hydroxide solution and by then equilibrating it twice with an equal volume of a 1N sulfuric acid solution. The concentration of the D2EHPA solution was determined by potentiometric titration with a standard sodium hydroxide solution in an ethanol medium.

Organic solutions of mixed extractants are prepared as follows. A constant portion of a purified amine solution and of various volumes of a purified D2EHPA solution are mixed together in a 100-ml volumetric flask, and the mixture is diluted to the mark with purified carbon tetrachloride. Then, these solutions are equilibrated with an equal volume of a 0.1N sulfuric acid solution. After the phases have separated, the organic phase was filtered through paper to remove the entrained aqueous phase.

The aqueous solutions used for the extraction of iron(III), zinc, lanthanum, indium, and thorium were prepared by the precipitation of the metal hydroxides and by the subsequent dissolution in a sulfuric acid solution of an appropriate concentration. The solution of cerium(III) was obtained by dissolving cerium(IV) sulfate into a sulfuric acid solution of an appropriate concentration and by subsequent reduction to cerium(III) with a suitable amount of hydrogen peroxide.

Procedure. For all the operations, 15-ml portions of the aqueous and the organic solutions were mixed together in a 100-ml glass separatory funnel and the mixture was equilibrated at room temperature. A fifteen-minutes shaking period at a rate of 200 strokes per minute was more than adequate. Then, the aqueous phase was filtered through paper to remove the entrained organic phase. The metal content in the aqueous phase was determined either spectrophotometrically or complexometrically.[21-23] The analytical procedures used are summarized in Table 1. The amount of metals in the organic phase was calculated by means of a material balance.

Table 1. The analytical methods used

Metals	Spectrophotometric	Complexometric
Th	Xylenol Orange	EDTA, Xylenol Orange
Fe	*o*-Phenanthroline	EDTA, Variamine Blue B HCl
In	Xylenol Orange	EDTA, Xylenol Orange
La, Ce		EDTA, Xylenol Orange
Zn		EDTA, BT

Results

The effect of the D2EHPA concentration on the iron(III) extraction was examined at fixed concentrations of Primene JM and iron(III), and at various fixed concentrations of sulfuric acid. It follows from Fig. 1 that the degree of iron(III) extraction passes through a minimum and then increases with an increase in the D2EHPA concentrations. The composition of the organic phase at which an appreciable decrease in the iron(III) extraction occurs depends on the sulfuric acid concentration.

Similar behavior is observed with the extraction of indium and lanthanum from a 0.1N sulfuric acid solution as can be seen in Fig. 2. The degree of extraction decreases with the increase in the initial concentration of iron(III) because of the fixed amount of extractant in the organic phase, but the concentration ratio of Primene JM to D2EHPA at which minimum extraction is observed does not

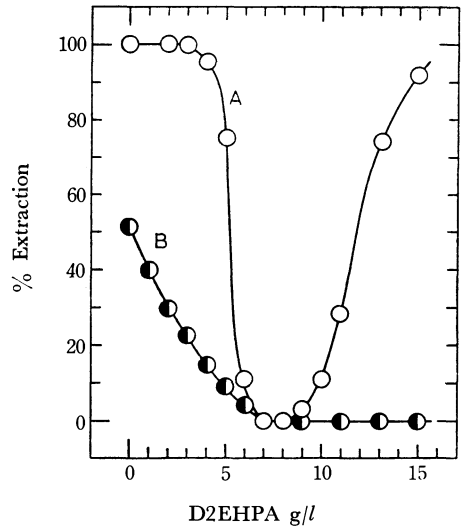

Fig. 2. The influence of D2EHPA on In^{3+} and La^{3+} extraction from 0.10N H_2SO_4 with Primene JM(5 g/l); (A) 3.48×10^{-5}M total indium, (B) 2.29×10^{-3}M total lanthanum.

change appreciably with the initial concentration of iron(III), as is shown in Fig. 3. In order to examine the extraction behavior of bivalent cations, zinc was extracted from a 0.1N sulfuric acid solution. As is shown in Fig. 3, no extraction of zinc was obtained when iron is not extracted. On the contrary, thorium was found to be extractable when bi- and tervalent ions are not extracted, the minimum extraction occurring in the higher D2EHPA-concentration range. This is demonstrated in

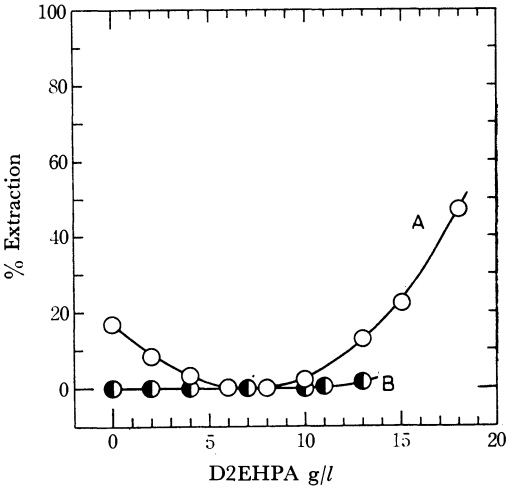

Fig. 3. The influence of D2EHPA on Fe^{3+} and Zn^{2+} extraction from 0.10N H_2SO_4 with Primene JM(5 g/l); (A) 8.40×10^{-3}M total iron(III), (B) 2.15×10^{-3}M total zinc.

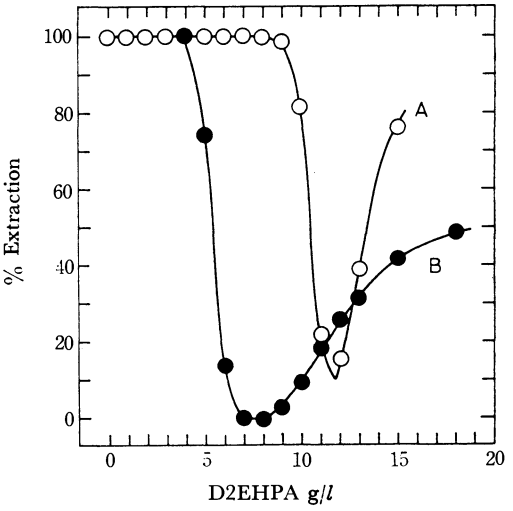

Fig. 4. The influence of D2EHPA on Th^{4+} and Fe^{3+} extraction from 0.10N H_2SO_4 with Primene JM(5 g/l); (A) 1.08×10^{-5}M total thorium, (B) 1.70×10^{-4}M total iron(III).

Fig. 4 for the case where the initial concentration of thorium is 1.08×10^{-5}M. In this figure, the extraction curve of iron(III) from the 0.1N sulfuric acid solution is shown for the sake of comparison with that of thorium. When the initial concentration of thorium is higher, the extractant concentration should be increased to achieve the complete recovery of thorium in the aqueous phase. For a high concentration of Primene JM, say 50 g/l,[24] thorium was completely extracted throughout the D2EHPA-concentration range studied. This

24) Tributyl phosphate was used to avoid any third-phase formation; the TBP concentration was 100 g/l.

(C) 8.25×10^{-3}M total cerium(III) in 0.1N H_2SO_4

extraction behavior of thorium is quite different from that of lanthanum and cerium(III), as can be seen in Fig. 5.

Discussion

As is shown in Fig. 1, the extraction curve for iron(III) shows a minimum at a certain D2EHPA concentration. This can be explained, as has been done by Deptula,[9] on the basis of the interaction between amine sulfate and dialkylphosphoric acid in the organic phase. It is well known that iron(III) is extractable by either Primene JM or D2EHPA from dilute sulfuric acid solutions.[4,5] The appearance of a minimum in Fig. 1 may be due to the formation of an extremely stable complex by means of Eq. (1), which reduces the free concentration of both extractants participating in the extraction reactions and, hence, the degree of extraction.

$$(RNH_3)_2SO_4 + (HR)_2 = ((RNH_3)_2SO_4)(HR)_2 \quad (1)$$

Note that HR, $(RNH_3)_2SO_4$, and R are D2EHPA, amine sulfate, and an alkyl chain respectively. Equations (2) and (3) are the simplest generalized expressions for the iron(III) extraction.[25,26]

$$Fe^{3+} + 3(HR)_2 = Fe(HR_2)_3 + 3H^+ \quad (2)$$

$$Fe^{3+} + OH^- + SO_4^{2-} + (RNH_3)_2SO_4 = (RNH_3)_2FeOH(SO_4)_2 \quad (3)$$

In Fig. 1, the descending portion of the extraction curve corresponds to the decrease in the free concentration of amine sulfate, and the increase in the extent of extraction beyond the minimum is due to the increase in the free concentration of D2EHPA.

As can be seen in Fig. 1, the extraction curves depend on the sulfuric acid concentration. This is attributable to the strong affinity of the protonated amine for D2EHPA in the organic phase. The formation reaction of protonated amine is shown by Eq. (4):

$$2RNH_2 + 2H^+ + SO_4^{2-} = (RNH_3)_2SO_4 \quad (4)$$

For a decrease in the sulfuric acid concentration in the aqueous phase and, hence, for a small concentration of amine sulfate in the organic phase, a small amount of D2EHPA may be sufficient to complete the formation of $((RNH_3)_2SO_4)(HR)_2$, thereby resulting in the shift of the minimum in the extraction curve to the left. The concentration range of D2EHPA depressing the iron(III) extraction is broadened by increasing the sulfuric acid concentration. This trend may be caused by the competitive reaction of the hydrogen ion and the iron(III) ion against D2EHPA, as is represented by Eq. (2). If the equilibrium constant for the formation of $Fe(HR_2)_3$ or $(RNH_3)_2FeOH(SO_4)_2$ is comparable to that for the formation of $((RNH_3)_2SO_4)(HR)_2$, the minimum of the extraction curve will be found in the higher D2EHPA-concentration range. This is the case for thorium, as can be seen in Fig. 4. Thorium can be quantitatively extracted in the region in which no iron(III) is extracted. For high concentrations of Primene JM, say 50 g/*l*, thorium is quantitatively extractable over the whole range of D2EHPA studied (Fig. 5). This different extraction behavior from that indicated in Fig. 4 may be due to the higher concentration of Primene JM. As the concentration of Primene JM increases, the shape of the extraction curve at the minimum point tends to become sharp and the minimum point moves towards higher concentration ranges of D2EHPA. This can be explained by the concept that the equilibrium constant for the formation of extractable thorium species is comparable to that for the formation of $((RNH_3)_2SO_4)(HR)_2$.

The above treatment is not very accurate, however, since no account is taken of the presence of bisulfate species. In other words, Eqs. (1), (3) and (4) should have contained the terms of the bisulfate species.[27] However, the explanation using simple Eqs. (1)—(4) appeared to be satisfactory enough since the object of this investigation was to find the conditions which would enhance the selectivity

of extraction with high-molecular-weight amines.

It was found that the separation of thorium by extraction from many other metals can be carried out very easily using the present mixed-extractant system. That is, thorium can be completely extracted in the region in which no iron(III) is extracted (Fig. 4); tervalent indium, lanthanum, cerium, and also bivalent zinc behave analogously to iron(III), as can be seen Figs. 3 and 5.[28] As Figs. 2, 3, and 5 show, the initial concentrations of bi- and tervalent ions seem to have no appreciable influence on the thorium extraction. Thus, for the extraction of thorium these results may provide an improved method, one with a number of advantages over the previous methods using Primene JM as a single extractant.[5] A dilute solution of sulfuric acid can be used as the aqueous phase, and the complete separation of thorium can be achieved from large amounts of bi- and tervalent metals without multiple extraction and scrubbing. Further, there is the additional advantage that the separation of the two phases is very rapid compared to the case when single extractant is used. It was ascertained that thirty seconds are more than adequate for the complete separation.

From these experiments it is apparent that the degree of the extraction of bi- and tervalent metals can be successfully controlled by the combination of Primene JM with D2EHPA. This suggests that, with a proper combination, the selectivity of metal extraction with the high-molecular-weight amines and, presumably, with other extractants such as D2EHPA will be enhanced to an appreciable extent. Thus, there is good a possibility of developing a highly selective method of extraction for a certain metal ion on the basis of these findings.

The author wishes to express his sincere appreciation to Professor Masayo Murozumi of Muroran Institute of Technology, Professor Masaichi Nagayama and Dr. Katsumi Goto of Hokkaido University for their valuable discussions and for criticizing the manuscript.

28) Lanthanide metals show a different extraction behavior from that of iron(III), indium and zinc; above a certain D2EHPA concentration, the extraction remains completely depressed.

Volumetric Determinations of Cyanide, Thiocyanate, and Iodide Ions with Mercury(II) Ethylenediaminetetraacetate Using These Mixed-ligand Complexes as Indicators

Toshiaki NOMURA

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto

(Received June 2, 1969)

Mercury(II) complexes of EDTA, methylthymolblue, or cresolphthaleincomplexone form mixed-ligand complexes with cyanide, thiocyanate, or iodide ions. These anions can be determined with mercury(II) ethylenediaminetetraacetate, using the other mercury(II) complexes as indicators, because of the difference between the stability constant of the mixed-ligand complex of EDTA and that of the other complexes. The previously reported methods, however, require a calibration curve. The determination was simplified by Titer methods, using these mixed-ligand complexes as indicators. To the anion-sample solutions adjusted to a given pH value with a buffer solution, 5 m*l* portions of 1×10^{-4}M mercury(II), an organic reagent, and anion solutions were added, these mixtures were then titrated with a 1×10^{-2}M standard mercury(II) ethylenediaminetetraacetate solution. These solutions change in color from pale pink (PC) or yellow (MTB) to red-violet (PC) or blue (MTB) by the end point. The Titer values were determined by the use known of standard anion solutions.

Mercury(II) reacts with ethylenediaminetetraacetate (EDTA) to form mercury(II) ethylenediaminetetraacetate (Hg-EDTA). This colorless complex was found to react with cyanide, thiocyanate, iodide, bromide, *etc.* to form colorless mixed-ligand complexes.[1] The cyano complex among these mixed-ligand complexes reacts with an

1) S. Komatsu and T. Nomura, *Nippon Kagaku Zasshi*, **87**, 841 (1966); **87**, 845 (1966); **88**, 63 (1967).

excess cyanide to form mercury(II) cyanide and EDTA.[2]

Cresolphthaleincomplexone (PC, pale pink) reacts with mercury(II) to form mercury(II)-cresolphthaleincomplexone (Hg-PC),[3] which is red-violet in color and which reacts with cyanide[4] or iodide. The solutions containing the mixed-ligand complex produced with Hg-PC and cyanide or iodide ions are pale pink.

Mercury(II)-methylthymolblue (Hg-MTB, yellow or yellowish green)[5] reacts with cyanide, thiocyanate,[6] iodide, bromide, or chloride[7] to form these mixed-ligand complexes, which are blue in color. The cyano or iodo mixed-ligand complexes among these complexes react with excess cyanide or iodide to form mercury(II) cyanide or iodide and MTB.

Some of these mixed-ligand complexes have low stability constants, and dissociate to mercury(II) anion complexes and organic reagents in the presence of an excess amount of anions. Therefore, the volumetric determination of anions can be achieved with a standard Hg-EDTA solution using the mercury(II)-organic reagent complex as indicator,[8-10] in just the same fashion as in the volumetric determination of metal ions with EDTA using metal indicators.[11] In these methods, the required volume (equivalent weight) of the standard Hg-EDTA solution is not equal to the equivalent weight of anions in the sample solution, because the color change of the solution at the end point is caused by the appearance of the color of the mixed-ligand complex of the mercury(II)-organic reagent-anion, *i. e.*, the required volume of the standard Hg-EDTA solution corresponds to the equivalent weight of anions minus the equivalent weight of the mixed-ligand complex formed in the sample solution. Therefore, the usual Titer method, in which the anions are determined by multiplying the required volume of the standard solution by the weight of anions necessary to titrate one m*l* of the standard Hg-EDTA solution, can not be applied to this procedure; the calibration curves are necessary for the determination. However, if one uses a mixed-ligand complex as an indicator, the Titer method can be used for the determination of these anions. This paper will describe this method, in which the anions can be determined with a good reproducibility. The proposed methods are especially suitable for anion concentrations of the order of 0.01 M and are satisfactorily simple and reproducible. The interfering anions will also be discussed.

Experimental

Reagents. All the reagents were analytical grade and were used without further purification.

1×10^{-4} M Cresolphthaleincomplexone (PC) Solution. The stock solution of 1×10^{-3} M was prepared by dissolving 320 mg of Dotite PC and by then diluting to 500 m*l* with methyl alcohol. This solution was stored in a brown glass bottle. The working solution of 1×10^{-4} M was prepared by dilution with water.

1×10^{-4} M Methylthymolblue (MTB) and 1×10^{-2} M Standard Thiocyanate-ion Solution. These solutions were prepared as in a preceding experiment.[9]

1×10^{-2} M Standard Cyanide-ion Solution. This solution was prepared as in a preceding experiment.[8]

1×10^{-2} M Standard Iodide-ion and Standard Hg-EDTA Solutions. These solutions were prepared as in a preceding experiment.[10]

1×10^{-4} M Hg-SCN, Hg-CN, and Hg-I Solutions. These solutions were prepared by the addition of 10 m*l* portions of mercury(II) nitrate and the corresponding standard anion solutions of 1×10^{-2} M and by subsequent dilution to 1 *l* with water.

Buffer Solutions. Buffer solutions having a given pH value were prepared by properly mixing the following solutions; pH<8, 0.1 M potassium dihydrogen phosphate and 0.1 M disodium hydrogen phosphate solutions; between pH 8 and 9, 0.1 M potassium dihydrogen phosphate and 0.05 M borax solutions; pH>9, 0.1 M sodium carbonate and 0.1 M sodium hydrogen carbonate solutions or 0.1 M disodium hydrogen phosphate and 0.1 M sodium hydroxide solutions.

Apparatus. The titrations of anion solutions were carried out with a 1/20 graduated microburette. A Hitachi-Horiba M-4-type pH meter was used for the measurement of the pH values.

Procedure. The pH values of the anion sample solutions were adjusted to an appropriate value with a buffer solution, to which 5 m*l* portions of organic-reagent (MTB for SCN^- or I^-, PC for CN^- or I^-) and Hg-X (X=anion=SCN^-, CN^- or I^-) solutions of 1×10^{-4} M were added. Then the solutions were diluted to about 50 m*l* with water. The solutions were titrated with a standard 1×10^{-2} M Hg-EDTA solution until the solutions changed in color from yellow or a greenish-yellow (MTB) or pale pink (PC) to blue (MTB) or red-violet (PC) with respect to the blank solution, which had been prepared by the same procedure as has been described above, except for the addition of the anion sample solution. The amount of the anion in the sample solution was calculated by multipling the required vol-

ume of the standard Hg-EDTA solution (*titer*) by the Titer which was determined on a solution with a known concentration.

Results and Discussion

Determination of the Thiocyanate Ion Using the Hg-MTB-SCN Complex as an Indicator. In the volumetric determination of the thiocyanate ion using the Hg-MTB complex as an indicator,[9] the optimum pH range being 6.3—6.8. A sample solution containing up to 11.0 mg of thiocyanate ion was titrated by the standard procedure at pH 6.7 in the presence of MTB and Hg-SCN. The color change by the end point was from yellow to blue. The Titer was calculated from the volume of the standard Hg-EDTA solution required to titrate 2.745 mg of the thiocyanate ion:

$$1\ ml \text{ of a } 1\times10^{-2}\text{M standard Hg-EDTA solution} = 0.5434\ \text{mg of } SCN^- \quad (1)$$

The results are shown in Table 1. The *titer* value was an average of two titrations. In the determination of a small amount of the thiocyanate ion, the relative error was large, while in the determination of a larger amount of the thiocyanate ion (above 11 mg), the color change at the end point became indistinct, resulting in an even greater error.

Table 1. Determination of the thiocyanate ion by means of the Titer method

Taken (mg)	*Titer* (ml)	Found (mg)	Error (mg)	Error (%)
0.137	0.25	0.136	−0.001	0.73
0.274	0.50	0.272	−0.002	0.73
0.549	1.02	0.554	+0.005	0.91
1.098	2.02	1.098	0	0
2.745	5.05	2.744	−0.001	0.04
5.489	10.08	5.477	−0.012	0.22
8.234	15.10	8.205	−0.029	0.35
10.98	20.12	10.93	−0.05	0.41

1 m*l* of a 1×10^{-2}M standard Hg-EDTA solution = 0.5434 mg of SCN^-

In the previous method,[9] the end point was determined visually by the color change from yellow to blue, without any standard color reference, so there was a relatively large error. In addition to this, a preliminary test for the existence of an excess of the thiocyanate ion was necessary. In the present method, however, the color at the end point is compared with that of the reference blank solution. Therefore, the individual error is smaller than that in the previous method. In addition to this advantage, no preliminary test is necessary. When the thiocyanate ion is not present in the sample, the color of the solution before the titration is blue, while when the thiocyanate ion is present, the color is yellow, as is shown in Eq. (2):

$$\underset{\text{blue}}{\text{Hg-MTB-SCN}} + SCN^- \rightleftharpoons \text{Hg}(SCN)_2 + \underset{\text{yellow}}{\text{MTB}} \quad (2)$$

The blue color at the end point, however, gradually changes to green upon the addition of an excess of the Hg-EDTA solution because the Hg-EDTA-SCN complex is more stable than the Hg-MTB-SCN complex. That is, at the end point:

$$\text{Hg}(SCN)_2 + \text{MTB} + \text{Hg-EDTA} \rightleftharpoons \text{Hg-EDTA-SCN} + \underset{\text{blue}}{\text{Hg-MTB-SCN}} \quad (3)$$

and after the addition of an excess amount of the standard solution:

$$\text{Hg-MTB-SCN} + \text{Hg-EDTA} \rightleftharpoons \text{Hg-EDTA-SCN} + \underset{\text{green}}{\text{Hg-MTB}} \quad (4)$$

However, this color change does not disturb the end-point determination.

Determination of the Iodide Ion Using the Hg-MTB-I Complex as an Indicator. The method used here was virtually identical with that described in a previous paper,[10] but here the Hg-MTB-I complex was used as an indicator.

A sample solution containing up to 31 mg of the iodide ion was titrated at pH 7.5 in the presence of MTB and Hg-I. The color change at the end point was form greenish yellow to blue. The Titer was calculated from the volume of the standard Hg-EDTA solution required to titrate 6.225 mg of the iodide ion:

$$1\ ml \text{ of a } 1\times10^{-2}\text{M standard Hg-EDTA solution} = 1.186\ \text{mg of } I^- \quad (5)$$

The results are shown in Table 2. The *titer* value was an average of two titrations. This method had the same advantages as in the case of the determination of thiocyanate described above.

The blue color appearing after the end point did not change upon the addition of the *titer*, for the stability of Hg-MTB-I is greater than that of Hg-EDTA-I. When an excess of iodide existed in the solution, the color was greenish yellow, as is shown in Eq. (6):

$$\text{Hg-MTB-I} + 2I^- + \text{Hg-EDTA} \rightleftharpoons \text{Hg-EDTA-I} + \text{HgI}_2 + \underset{\text{greenish yellow}}{\text{MTB}} \quad (6)$$

Hg-MTB-I dissociated to mercury(II) iodide and MTB with an excess of iodide, but Hg-EDTA-I did not.

Interfering anions, such as sulfide, cyanide, and thiocyanate,[10] could be removed the hydrogen peroxide method, which will be described in the section concerned with the determination of iodide.

Table 2. Determination of the iodide ion by means of the Titer method

Taken (mg)	*Titer* (ml)	Found (mg)	Error (mg)	Error (%)
0.311	0.26	0.308	−0.003	0.96
0.623	0.52	0.617	−0.006	0.96
1.245	1.04	1.233	−0.012	0.96

31.13	26.31	31.20	+0.07	0.22

1 ml of a 1×10^{-2}M standard Hg-EDTA solution = 1.186 mg of I^-

Bromide could not, however, be removed by this method.

Determination of Cyanide Using the Hg-PC-CN Complex as an Indicator. The method used here was virtually identical with that described in a previous paper,[8] but the Hg-PC-I complex was used as an indicator.

A cyanide-sample solution (up to 6.2 mg) was titrated at pH 11.2 in the presence of PC and Hg-CN. The color change at the end point was from a pale pink to red-violet. The Titer was calculated from the volume of the standard Hg-EDTA solution required for 1.241 mg of cyanide. The results are shown in Table 3.

1 ml of a 1×10^{-2}M standard Hg-EDTA solution = 0.2434 mg of CN^- (7)

Table 3. Determination of the cyanide ion by means of the Titer method

Taken (mg)	*Titer* (ml)	Found (mg)	Error (mg)	Error (%)
0.062	0.25	0.061	−0.001	1.61
0.124	0.50	0.122	−0.002	1.61

6.205	25.40	6.182	−0.023	0.37

1 ml of a 1×10^{-2}M standard Hg-EDTA solution = 0.2434 mg of CN^-

Determination of Iodide Using the Hg-PC-I Complex as an Indicator. Iodide could also be determined using the Hg-PC-I complex as an indicator.

Hg-PC-I Complex. The iodide ion reacts with Hg-PC (red-violet) to form a mixed-ligand complex. The color of this complex was a pale pink. The molar ratio of Hg-PC to iodide in the mixed-ligand complex was found to be 1 : 1 by the molar ratio method and by the continuous variation method. The mixed-ligand complex does not dissociate to mercury(II) iodide and PC in the presence of the excess iodide.

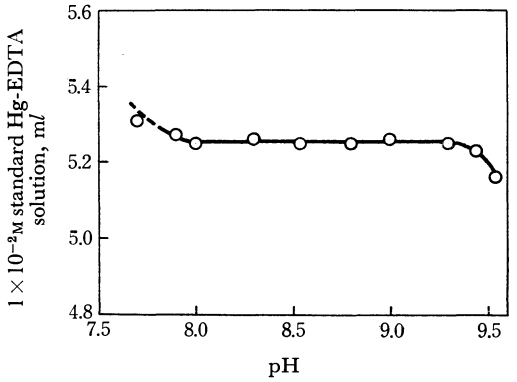

Fig. 1. Effect of pH.
Each 5 ml of PC and Hg-I solutions of 1×10^{-4}M, 6.225 mg of iodide ion.

Effect of pH. The effect of the pH on the titration of iodide was investigated by the same method as in the case of cyanide. The sample solution containing 6.225 mg of iodide was adjusted to an appropriate pH value with a buffer solution, to which 5 ml portions of PC and 1×10^{-4}M Hg-I solutions were added. The results are shown in Fig. 1.

At pH values below 7.9 it was difficult to distinguish the end point. At pH values above 9.5, however, the solution gradually changed from a pale pink to violet at the beginning of the end point. Between pH 8.0 and 9.3, the color of the solution at the end point changed from pink to red-violet.

Table 4. Determination of the iodide ion by means of the Titer method

Taken (mg)	*Titer* (ml)	Found (mg)	Error (mg)	Error (%)
0.311	0.27	0.320	+0.009	2.89
0.623	0.53	0.629	+0.006	0.96
1.245	1.04	1.233	−0.012	0.96
2.490	2.10	2.491	+0.001	0.04
6.225	5.25	6.227	+0.002	0.03
12.45	10.48	12.43	−0.02	0.16
18.68	15.69	18.61	−0.07	0.37
24.90	21.01	24.92	+0.02	0.08
31.13	26.25	31.13	0	0

1 ml of a 1×10^{-2}M standard Hg-EDTA solution = 1.186 mg of I^-

Titer Method. Iodide was determined by titration at pH values between 8.0 and 9.3 in the presence of PC and Hg-I. The color change at the end point was from a pale pink to red-violet. The Titer was calculated from the volume of the standard Hg-EDTA solution required for 6.225 mg of iodide.

$$1\,ml \text{ of a } 1\times10^{-2}\text{M standard Hg-EDTA solution} = 1.186 \text{ mg of } I^- \quad (8)$$

The results are shown in Table 4.

Diverse Ions. In this method, various cations interfered, as in the case reported in a previous paper.[10] Some anions, such as sulfide, cyanide, and thiosulfate, interfered in minute amounts. Bromide, chloride, fluoride, thiocyanate, sulfate, nitrate, and perchlorate, however, did not interfere at all. The interfering anions could be removed by the following procedure.

TABLE 5. REMOVAL OF INTERFERING ANIONS

Iodide ion taken in (mg)	Interfering anions added			Iodide ion found (mg)
	S^{2-} (mg)	CN^- (mg)	$S_2O_3^{2-}$ (mg)	
2.490	—	—	—	2.491
2.490	0.32	0.52	0.56	2.467
6.225	—	—	—	6.227
6.225	0.32	0.52	0.56	6.215

To an iodide-ion sample solution (pH 8.0—9.3), 2 m*l* of 3% hydrogen peroxide were added. This solution was then boiled until large bubbles appeared, it was then cooled to room temperature, and 5 m*l* portions of PC and Hg-I soultion of 1×10^{-4}M were added, and the solution was treated in the usual way.

Some representative results of this method are shown in Table 5. Excess hydrogen peroxide did not interfere.

TABLE 6. SIMULTANEOUS DETERMINATION OF CYANIDE AND IODIDE IONS

Taken		Found	
CN^- (mg)	I^- (mg)	CN^- (mg)	I^- (mg)
0.238	1.245	0.241	1.242
0.238	6.225	0.239	6.224
1.191	1.245	1.193	1.240
1.191	6.225	1.198	6.219

1 m*l* of a 1×10^{-2}M standard Hg-EDTA solution = 0.2434 mg of CN^- = 1.186 mg of I^-

Simultaneous Determination of Cyanide and Iodide Ions. When cyanide and iodide ions were both present in the same sample, the simultaneous determination of these ions was performed with a standard Hg-EDTA solution, using the Hg-PC-I complex as an indicator. However, when iodide ions did not exist in the sample solution, cyanide could not be determined by this method.

An aliquot of a sample solution containing cyanide and iodide was titrated with the standard Hg-EDTA solution using the Hg-PC-I complex according to the procedure of iodide determination (*titer* A). Another, identical aliquot was treated according to the procedure described in the Diverse Ions section for the determination of iodide ion, also using the Hg-PC-I complex (*titer* B). The volume of the standard Hg-EDTA solution required for cyanide is given by, (A—B) and the volume for iodide, B. These results are shown in Table 6.

The author wishes to thank Professor S. Komatsu for his many helpful discussions and suggestions during this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 109—113 (1970)

The Hydrolysis of the Beryllium Ion in Heavy Water*1,*2

Hidetake KAKIHANA and Masunobu MAEDA

Research Laboratory of Nuclear Reactor, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 26, 1969)

The hydrolysis of Be^{2+} ion in heavy water containing 3M $NaClO_4$ as an ionic medium was investigated at 25°C by potentiometric titrations, employing a technique of constant-current coulometry. The deuterium-ion concentrations was measured by the use of a commercial glass electrode. The emf data in the range of the total beryllium concentration from 2.5 to 10 mM can be explained on the basis of the following complex formation: $Be_2(OD)^{3+}$, $-\log\beta_{1,2}=3.28\pm0.04$; $Be_3(OD)_3{}^{3+}$, $-\log\beta_{3,3}=9.399\pm0.007$; $Be(OD)_2$, $-\log\beta_{2,1}=11.89\pm0.07$. The composition of the species formed in heavy water is the same as that in light water, but the values of the stability constants are smaller in heavy water than in light water.

Since the discovery of deuterium oxide, many investigations of the chemical reactions in heavy water have been made; these investigations played important roles in the investigation of the mechanisms of chemical reactions.

As for the hydrolytic reactions of metal ions, several investigations have been made in heavy water.[1-4] However, as far as we know, the investigations made so far have been only of the mononuclear hydrolysis species; there have been none of the polynuclear species in heavy water.

The present work was carried out in order to ascertain the differences in the hydrolytic reactions of metal ions in heavy water and in light water.

The hydrolysis of the beryllium ion was chosen as the first of a series of studies of the hydrolysis in heavy water. The hydrolysis of the beryllium ion in light water has been investigated by several researchers,[5-12] and it has been confirmed that $Be_3(OH)_3{}^{3+}$ is the main hydrolysis species. The hydrolysis of the beryllium ion in H_2O-D_2O mixed solvents has previously been studied by the present authors;[13] we found that the composition of the main hydrolysis product is the same as that in light water and that the value of the stability constant of the main species decreases gradually with an increase in the deuterium-atom fraction.

analyzed as has been described in Ref. 10 under an infrared lamp, while adding heavy water. The beryllium content of the stock solution was determined by the method described in Ref. 5.

Sodium Perchlorate. This was prepared by neutralizing a $HClO_4$ solution with recrystallized Na_2CO_3. The sodium perchlorate was dried at about 120°C and stored in a glass bottle.

Sodium Chloride of Analytical Grade. This was heated for a few hours at 360°C in an electric oven and then stored in a glass bottle.

Apparatus. *Apparatus Used.* These were, unless otherwise stated, the same as those described in Ref. 13.

The Titration Cell. This consisted of a Wilhelm-type half cell[14] for emf measurements and a modified one for constant-current coulometry.

Coulometric Analyzer. Such an analyzer (Leeds & Northrup Co., Philadelphia) was used as a constant-current power source.

Experimental Procedures. All the measurements were carried out in a paraffin-oil thermostat kept at 25.00 ± 0.01°C and placed in a room thermostated at 25 ± 1°C.

The hydrolysis of the Be^{2+} ion in heavy water was followed by measurements of the deuterium-ion concentration.

$NaClO_4$ was added to all the test solutions so that they contained 3M ClO_4^- as an ionic medium; the total Be(II) concentration was kept constant in each series of experiments.

The deuterium-ion concentration of a test solution was measured by means of this cell;

$$\text{Ref}\,|\,B\text{M Be}^{2+},\ D\text{M D}^+,\ (3-D-2B)\text{M Na}^+,\ 3\text{M ClO}_4^-|\text{GE}, \qquad \text{(A)}$$

where GE denotes a glass electrode, and Ref, the reference half-cell;

$$|3\text{M NaClO}_4 \text{ in heavy water}|2.99\text{M NaClO}_4 \text{ and } 0.01\text{M AgClO}_4 \text{ in light water}|\text{AgCl-Ag}.$$

The emf of the cell(A) can be denoted as follows:[15]

$$E = E_0 + 59.15\log d + E_j, \qquad (1)$$

where E_0 is a constant and E_j, a liquid junction potential at the junction, test solution | 3M $NaClO_4$ in heavy water. E_j was disregarded since the concentration of the deuterium ion was maintained at less than 0.01M in the present work.[15] Therefore, the emf of the cell (A) can be denoted as follows:

$$E = E_0 + 59.15\log d. \qquad (2)$$

The total beryllium concentration in a test solution was maintained in the 2.5—10 mM range. The concentration of the deuterium ion in the cell (A) was varied by generating D^+ ions or OD^- ions by means of constant-current coulometry, using the same cell assembly as that described by Biedermann and Ciavatta.[16–18]

As an inert salt in the salt bridge, "3M $NaClO_4$ in heavy water" was used. A constant current of 6.43 mA was passed in small steps (a few microfaradays). The potentiometric titrations were conducted in both directions. First, the "forward titration" was carried out by generating OD^- ions, and then the "back titration" was performed to reacidify the hydrolyzed beryllium solution by generating D^+ ions. A steady emf was usually attained within fifteen minutes for $Z\lesssim0.8$, while in solution with $Z>0.8$ a steady emf was obtained within two or three hours. During the measurements, a test solution was stirred by a vigorous stream of nitrogen which had been purified by leading it through heavy water and 3M $NaClO_4$ in heavy water.

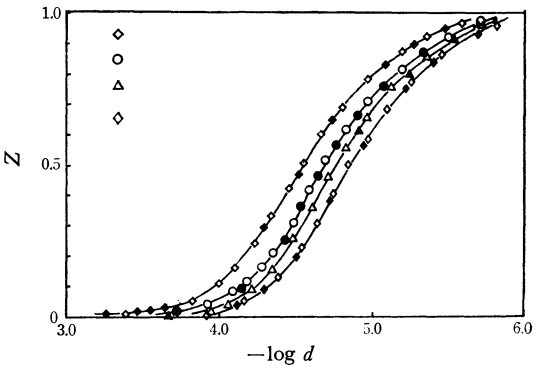

Fig. 1. Average number, Z, of OD bound per Be, as a function of $-\log d$.

Results and Calculations

The $Z(\log d)_B$ data, which were calculated from the potentiometric measurements by the use of Eq. (2), are shown graphically in Fig. 1.

The experimental data were analyzed by graphical methods and by computer calculations. The hydrolysis data were first submitted to graphical analysis in order to obtain preliminary information on the composition of the hydrolytic species formed; then, on the basis of the information obtained, computer analysis was made to evaluate the most probable hydrolysis scheme and the stability constants of the species formed.

(1) The Evaluation of the Composition of the Hydrolysis Products by Graphical Analysis. The average compositions of the hydrolysis products, $\bar{p}$ and $\bar{q}$, were calculated by the integration method described by Sillén.[19]

The average composition calculated thereby is plotted in Fig. 2 in the form of $\bar{q}$ *vs.* $(2\bar{q}-\bar{p})$.[20]

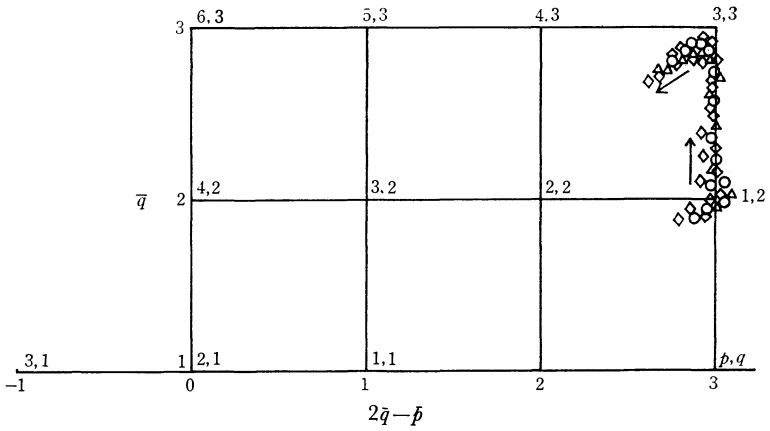

Fig. 2. Average composition of the complexes $\bar{q}(2\bar{q}-\bar{p})$. Direction of an arrow carresponds to the increase in Z. All the points are shown using the same symbols as in Fig. 1.

From this figure, some qualitative information may be obtained on the composition of the hydrolytic species. From Fig. 2, it may be seen that the (1,2) species may be present at low Z and that the (3,3) species is predominant in the main region of Z; moreover, some other minor species may be present at high Z, the composition of which would be either (2,2), (3,2), (2,1) or (3,1), judging from the directions of the plots.

(2) The Evaluation of the Composition and the Stability Constants of the Hydrolysis Products by Computer Analysis. On the basis of the restrictions suggested above, and with the help of an electronic computer (HITAC 5020) the generalized least-squares method was used to determine the most probable hydrolysis scheme containing the lowest number of species which would suffice to account for the experimental data and for the stability constants of the species formed.

The least-squares calculations on the electronic computer were carried out in order to make the error square sum $U=\sum(Z-Z_{calcd})^2$ minimum for the set of stability constants. Z_{calcd} denotes the $Z_{calcd}=\sum\sum p\beta_{p,q}b^q d^{-p}/B$ for a particular set of stability constants.

(2-1) Hydrolysis Scheme in the Lower Region of Z (When Z is less than 0.5). On the basis of the restrictions described in the section of the graphical analysis, we chose the two-species scheme of (1,2)—(3,3). The values for the stability constants of the species calculated by the generalized least-squares method are listed in Table 1, together with the error square sum. In addition, apart from the suggestion made by the graphical analysis and based upon the assumption that the minor species at low Z is less polymerized than the main species, $Be_3(OD)_3^{3+}$, we chose seven different minor species, each of which was paired with $Be_3(OD)_3^{3+}$. The results calculated are also collected in Table 1.

From the results shown in Table 1 and from the fact that the (1,2)—(3,3) scheme gives an excellent fit with the experimental data, it is evident that, at low Z, $Be_2(OD)^{3+}$ is the most probable of the minor species chosen.

(2-2) Hydrolysis Scheme in the Higher Region of Z (when Z is more than 0.5). Based on the information obtained by the graphical analysis, we chose four species, (2,2), (3,2), (2,1), and (3,1); each of them was combined with the (1,2)-(3,3) scheme, which is significant in the $Z<0.5$ region.

Table 1. The error square sums and values of the stability constants for the schemes of $Be_q(OD)_q^{(2q-p)+}-Be_3(OD)_3^{3+}$, where $Z\lesssim 0.5$

(p,q)	$\beta_{p,q}$	$\beta_{3,3}$	U
(1,2)	5.33×10^{-4}	4.00×10^{-10}	1.40×10^{-3}
(1,1)	6.33×10^{-3}	3.99×10^{-10}	9.90×10^{-3}
(1,3)	8.12×10^{-2}	4.32×10^{-10}	3.30×10^{-3}
(2,1)	1.09×10^{-14}	4.01×10^{-10}	9.90×10^{-3}
(2,2)	1.21×10^{-10}	4.01×10^{-10}	9.85×10^{-3}
(2,3)	8.29×10^{-6}	3.41×10^{-10}	7.36×10^{-3}
(3,1)	1.22×10^{-8}	3.99×10^{-10}	9.93×10^{-3}
(3,2)	2.27×10^{-17}	4.00×10^{-10}	9.90×10^{-3}

Table 2. The error square sums and the values of the stability constants for the schemes of $Be_2(OD)^{3+}-Be_3(OD)_3^{3+}-Be_q(OD)_q^{(2q-p)}$, where the values of the stability constants of $Be_2(OD)^{3+}$ and $Be_3(OD)_3^{3+}$ respectively are allowed to vary

(p,q)	$\beta_{1,2}\times10^4$	$\beta_{3,3}\times10^{10}$	$\beta_{p,q}$	U
(2,2)	4.70	4.13	3.71×10^{-10}	7.90×10^{-3}
(3,2)	5.57	3.98	9.98×10^{-15}	2.46×10^{-3}
(2,1)	5.30	3.98	1.28×10^{-12}	2.40×10^{-3}
(3,1)	4.69	4.07	1.04×10^{-18}	3.31×10^{-3}

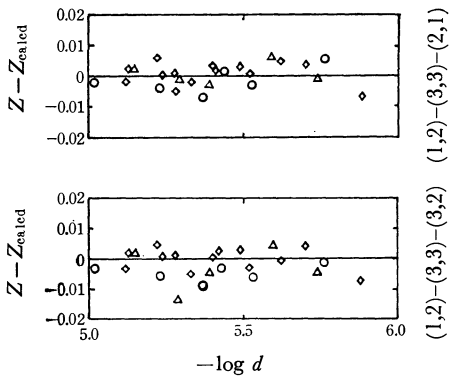

Fig. 3. $(Z-Z_{calcd})$ as a function of $-\log d$ for $Z>0.7$. Symbols are the same as those in Fig. 1.

The values of the stability constants for each set of the three-species schemes were allowed to vary, and the corresponding error-square sums were calculated over the whole range of Z.

The results calculated thereby are listed in Table 2, together with the stability constants of the species. Table 2 shows that the scheme containing the (2,1) species gives rise to the least-error square sum of the schemes chosen, and that the scheme containing the (3,2) species gives rise to the second least-error square sum. Figure 3 shows that the systematic deviations from the experimental data for $Z>0.7$ are slightly less for the scheme containing the (2,1) species than for the scheme containing the (3,2) species.

From the above evidence, it seems reasonable

TABLE 3. THE VALUES FOR THE STABILITY CONSTANTS OF THE HYDROLYSIS SPECIES OF BERYLLIUM ION IN HEAVY WATER AND IN LIGHT WATER CONTAINING 3M $NaClO_4$ AS AN IONIC MEDIUM*

	in heavy water	in light water
$-\log \beta_{1,2}$	3.28 ±0.04	3.16 ±0.05
$-\log \beta_{3,3}$	9.399±0.007	8.662±0.007
$-\log \beta_{2,1}$	11.89 ±0.07	11.16 ±0.06

* The uncertainties of the constants were estimated by multiplying by three the standard deviations.

to prefer $Be(OD)_2$ as the third species that exists at higher Z values.

The above considerations lead to the conclusion that the data in heavy water can be explained on the basis of the $Be_2(OD)^{3+}$-$Be_3(OD)_3{}^{3+}$-$Be(OD)_2$ scheme within the limits of accuracy of the present experiments.

The final values for the stability constants are tabulated in Table 3, together with the results we have obtained in light water employing the same method as that used for the heavy-water system.

(3) Distribution of the Species. The distribution of the hydrolytic species in heavy water and in light water, calculated at the total beryllium concentrations of 1 mM and 10 mM, and assuming the values of the stability constants in Table 3, are represented in Fig. 4. There is a general tendency for the species to be less hydrolyzed in heavy water than in light water at a given pH. The dominance of the (3,3) species in the accessible pH region is apparent both in heavy water and in light water. The amount of the (1,2) species increases and the amount of the (2,1) species decreases with an increase in the total concentration of beryllium.

Conclusion

In the present work, it has been found that the compositions of the species formed in heavy water, *i. e.*, $Be_2(OD)^{3+}$, $Be_3(OD)_3{}^{3+}$, and $Be(OD)_2$, are the same as those in light water, while the values of the stability constants of the hydrolysis products in heavy water are smaller than those in light water.

The fact that the values for the stability constants of the hydrolysis products of the beryllium ion, which can be regarded as a weak acid, are smaller in heavy water than in light water has been seen to be consistent with the results for the dissociation of the weak acids[21] and with those for the mononuclear hydrolytic reactions of the metal ions.[1-3]

The authors wish to express their gratitude to Dr. Hitoshi Ohtaki, Nagoya University, for his valuable advice and discussions.

Selectivity in the Metal-Complex-Catalyzed Decarboxylation of Oxaloacetic Acid and a Role of Metal Ion in an Enzyme System

Megumu MUNAKATA, Masakazu MATSUI, Masayuki TABUSHI and Tsunenobu SHIGEMATSU

Institute for Chemical Research, Kyoto University, Uji

(Received July 9, 1969)

The catalytic action of metal ions in the presence of various coordinating agents and a role of metal ions for the activations of an enzyme in a decarboxylation reaction were investigated. Many of the ligands studied decreased the catalytic activity of metal ions. However, α,α'-dipyridyl selectively enhanced the catalytic activities of divalent metal ions, except Cu^{2+}. The activity of Cu^{2+} was specifically enhanced only with histidine and its derivatives. Histidine destroyed Ni^{2+} and Co^{2+} catalysis. The specific enhancement may be due to the increase in the electronegativities of the metal ions with $d\pi$(metal)–$p\pi$(ligand) back donation and to the stereo-configuration of the metal complexes. The catalytic behavior in these metal ion coordinating agent systems was different from that in the metal-enzyme systems. It was assumed that the activation of enzyme resulted from the change in the configuration of enzyme by the coordination of metal ions, and not from the catalytic action of metal ions enhanced by the coordination of enzyme. This was supported by the fact that the catalysis of compounds containing amino groups, active sites of enzyme, remarkably depended on the stereo-configuration. In the enzyme-model system, Mn^{2+} was generally preferable to Cu^{2+} and Ni^{2+}. The catalytic actions of Cu^{2+} and Ni^{2+} were lowered by the complex formation with the active sites. This may solve the question why, in enzymatic reactions, Mn^{2+} having small complex-forming ability is more selective and effective than Cu^{2+} and Ni^{2+} with large complex-forming abilities.

It is well known that metal ions paly an important part in enzymatic reactions, and interesting reports have been published by many authors.[1] Though the role of metal ions is very complicated, it must be noted that a metal ion is specific for the activation of an enzyme, and this specificity should offer a key to the question on the role of metal ion in an enzymatic reaction.

From the concept that the interaction between metal ions and the residual groups of an enzyme is an important factor for enzyme activity, Steinberger and Westheimer[2] have investigated the effect of various coordinating ligands upon copper ion catalysis in the decarboxylation of dimethyloxaloacetic acid, and stated that negative ions, such as citrate and acetate, diminished the catalytic activity of cupric ion, while complexing agents, which did not destroy the charge of the copper ion, did not destroy its catalytic ability. Rund and Plane[3] reported that catalytic activities of manganous and nickel ions for the decaboxylation of dimethyloxaloacetic acid were enhanced in the presence of *o*-phenanthroline, and the enhancement rate was completely comparable to those in the presence of the enzyme.

The present authors also found that α,α'-dipyridyl increased the catalytic activities of divalent cations, such as manganous, cobaltous, nickel and zinc ions, for the decarboxylation of oxaloacetic acid, but both of α,α'-dipyridyl and *o*-phenanthroline selectively destroyed the catalytic ability of cupric ion. Cupric ion catalysis was enhanced only with histidine and its derivatives. The specific enhancement of catalytic activities of metal ions in the presence of such ligands was discussed from a view point of the stereo-configuration of metal complexes and the back donation of the $d\pi$(metal ion)–$p\pi$-(ligand) bonding. The effect of these ligands on the metal ions catalysis appears different from that in the metal-enzyme system, and therefore it seemed unreasonable that the metal-α,α'-dipyridyl or *o*-phenanthroline system was an enzyme-like model.

Many of the works on the role of metal ion in the enzymatic decarboxylation have been carried out mainly from a view-point of catalytic abilities of metal ions, but little attention has been paid

to the activation of the enzyme with metal ions. In this paper, a brief discussion on the role of metal ions in the enzymatic reaction was also made from the results obtained in various metal-ligand systems and in some amino compound systems, and an idea that metal ions acted as an enzyme activator, was proposed.

Experimental

Material. A reagent grade oxaloacetic acid was obtained from the Tokyo Kasei Co., Ltd. The aqueous solution was freshly prepared before use. Solutions of metal ions were made up by dissolving the reagent grade chloride salts and the concentrations were gravimetrically determined. Reagent grade coordinating agents were used without further purification, but ethylenediamine, diethylenetriamine and triethylenetetramine were purified by distillation. Buffer solutions were prepared from sodium hydroxide solution and acetic acid or monochloroacetic acid.

Experimental Procedure. The rate of decarboxylation of oxaloacetic acid was determined by measuring the pressure of carbon dioxide gas evolved in Walburg flasks. A freshly prepared solution of oxaloacetic acid was introduced into the main room of a reaction vessel and a solution of a catalyst was put into the sub-chamber of the vessel. All test solutions contained 4×10^{-3}M oxaloacetic acid, 2×10^{-4}M cupric ion or 4×10^{-4}M other divalent metal ions, and 4×10^{-2}M acetic acid or monochloroacetic acid (buffer), in the final concentration. The vessel was immersed in a water bath held at 30.00 ± 0.01°C, and after about five minutes, the catalyst was transferred to the main room and then the solution was stirred. Pressure readings were made at regular intervals. Since decarboxylation reactions follow first order kinetics with respect to the concentration of oxaloacetic acid, the data were treated in the usual manner to determine the observed first-order rate constants.

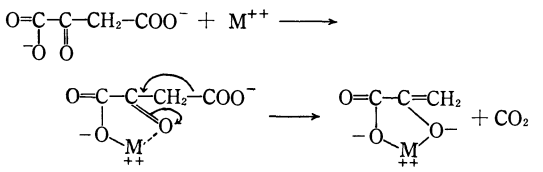
loacetic acid depends largely upon the pH value. This dependency can be caused by the fact that the rate depends on the concentration of oxaloacetic acid anions.[2] The first order rate constants of metal-ion-catalyzed decarboxylation of oxaloacetic acid also depend on pH (Fig. 2). Catalysis with manganous, cobaltous, nickel and zinc ions give maximum near pH 5.00 and that cupric ion, at pH 4.00. The decrease in the catalytic activity above the optimum pH may be due to the formation of metal hydroxide, besides decrease in hydrogen ion concentration. Because copper hydroxide is more stable than the other metal hydroxides, the decrease of the catalysis begins in a lower pH region. The catalytic activities of these metal ions are related to the electronegativities of the metal or the stabilities of the metal-oxaloacetic acid chelates.[4] The order at pH 4.00 is $Mn \ll Co < Ni < Cu > Zn$.

Effect of ligands. The effect of various coordinating agents on the nickel and cupric ion catalysis in decarboxylation of oxaloacetic acid was studied at pH 5.00, and the results are summarized in Table 1. The catalytic activities of nickel and cupric ions are somewhat reduced glycine, cystein and acetylacetone, and strongly hindered with ethylenediamine (en), diethylenetriamine (dien), triethylenetetramine (trien) and cyanide. The phenomena can be explained by the fact that the latter chelates are more stable than the former. Steinberger and Westheimer[2] have reported that the ligands, which do not destroy the charge on the cupric ion, do not destory the catalytic activity. However, in the present experiment, even neutral ligands, such as en, dien, trien and imidazole, destroy the catalytic activities of metal ions. The decrease in the catalytic activities may result from the fact that the electronegativities of metal ions are decreased by the coordination of complexing agents, and the stability of the metal-substrate compounds is lowered with competition with the complexing agents.

Specific Enhancement of Metal Ions with α,α'-Dipyridyl and *o*-Phenanthroline. In contrast to the above complexing agents, there are special cases where the catalytic activities of metal ions are enhanced by the coordination of ligands. Rund and Plane[3] showed that *o*-phenanthroline enhanced the catalytic activities of manganous, nickel and zinc ions. We also found that α,α'-dipyridyl enhanced the catalysis with divalent ions, but both the complexing agents selectively destroyed the cupric ion catalysis. As seen in Table 2, the catalytic activities of the metal ions, except cupric ion, are enhanced in the presence of two moles or less of these agents per mole of the metal ion, and the enhancement is also related to the electronegativity of the metal ion: The order is $Mn < Co < Ni > Zn$. But the addition of three moles of *o*-phenanthroline decreases the activities of cobaltous, nickel and zinc ions, and the addition of three moles of α,α'-dipyridyl decreases the activities of cobaltous and nickel ions. The decrease may be caused by the fact that all the coordination sites of the metal ions are occupied with the ligands to form the 1 : 3 chelates. In the case of manganous ion with *o*-phenanthroline and α,α'-dipyridyl, and zinc ion with α,α'-dipyridyl, where the decrease in the activity is not observed, the 1 : 3 chelates are not formed even in the presence of three moles of the agents, because of the low stability of the chelates. Generally, the catalysis of metal chelate compounds is stereo-specific, and the characteristics of the atomic orbital (symmetry, orientation, *etc.*) of the metal ions controls the coordination with substrate. Activation of metal ions with α,α'-dipyridyl and *o*-phenanthroline may be due to the specific configuration of the metal chelates

4) J. F. Speck, *J. Biol. Chem.*, **178**, 315 (1949).

and to the increasing electronegativities of the metal ion coordinated with the ligands. From the fact that the catalysis of metal ions is enhanced even in the 1 : 2 chelates, the metal ions must be six-coordinate and octahedral, in order to bind to a substrate which acts as a bidentate ligand, as follows:[2]



Complex (I) Complex (II)

The selective loss of the activity of cupric ion by the chelation can be subsequently explained by the square-planer configuration (dsp^2) of copper complexes.

As described above, the substrate (oxaloacetic acid) more easily combines to metal ion of octahedral configuration, when the metal ion is coordinated with α,α'-dipyridyl or *o*-phenanthroline molecules. However, basides these ligands, many other complexing agents form the octahedral chelate compounds. The specific enhancement with α,α'-dipyridyl and *o*-phenanthroline must, therefore, result from the change in the electronegativities of metal ions, in addition to the stereo-configuration effect. The electronegativities of metal ions coordinated with these ligands are probably increased by the back donation from an occupied $d\pi$ orbital of the metals to an empty $p\pi$ orbital of nitrogen atoms of the ligands. The increasing electronegativity promotes the decomposition of complex (I) to complex (II), as well as the formation of complex (I), in the mechanism described above, and thus enhances the decarboxylation rate. In copper complexes, the effect of the back donation is overcome by the stereo-configuration effect.

Specific Enhancement of Catalytic Activity of Cupric Ion with Histidine and Its Derivatives. The catalytic activity of cupric ion is selectively enhanced with histidine (hid), histidine methyl ester (ϕ-me) and histamine (him), while the activities of manganous and zinc ions are not affected, and the activities of cobaltous and nickel ions are decreased by them. As shown in Table 3, the increasing order of cupric ion catalysis is as follows: ϕ-me $>$ hid $>$ him $>$ *N*-ace-ϕ $\simeq$ H_2O $\simeq$ Bu-NH_2 $\geq$ imid $\geq$ DBA $\gg$ gly-ϕ, where *N*-ace-ϕ is *N*-acetylhistidine; Bu-NH_2: butylamine; imd: imidazole; DBA: diamino-butyric acid; and gly-ϕ: glycylhistidine. Histidine is less effective than histidine methyl ester. This may be attributed to the coordination of carboxyl group of the former. The presence of two moles of histidine or histidine methyl ester per mole of copper ion becomes less effective, but this tendency is not observed even in the presence of three moles of histamine. This indicates that histamine complex is less stable, and explains the fact that histamine is less effective than histidine and histidine methyl ester. Diaminobutyric acid, in which imidazol ring of histidine is replaced by amino group, and *N*-acetylhistidine, in which amino group of histidine is blocked, does not influence the activity. The activity is enhanced neither with imidazole nor normal amine. The results indicate that the catalytic activity of cupric ion is enhanced with ligands containing imidazole ring and amino group, but not with ligands containing only imidazole or only amino group. The fact suggests that the stereo-configuration of copper chelate compound is important for the enhancement of the catalysis. It may be considered that the configuration distorted by the Jahn-Taller effect is favorable to be coordinated with substrate. Imidazole ring is indispensable also to the back donation from a $d\pi$ orbital of copper ion to a $p\pi$ orbital of imidazole nitrogen.

Table 3. Enhancement of catalytic activity of copper ion with ligand

Moles of ligand (per mole of metal)	k min^{-1} $\times 10^2$	k_0 min^{-1} $\times 10^2$ (no ligand)	Relative rate
1 hid-me	10.7	5.78	1.85
2 hid-me	8.44	5.78	1.46
1 hid	9.77	5.78	1.69
2 hid	7.69	5.78	1.33
3 hid	7.05	5.78	1.22
1 him	6.13	5.78	1.06
2 him	6.65	5.78	1.15
3 him	6.65	5.78	1.15
1 *N*-acet-hid	5.66	5.78	0.98
2 *N*-acet-hid	5.54	5.78	0.96
2 Bu-NH_2	5.66	5.78	0.98
2 imid	5.32	5.78	0.92
1 DBA	5.43	5.78	0.94
1 gly-hid	3.12	5.78	0.54

pH: 5.00; oxaloacetic acid: 4×10^{-3}M; Cu: 2×10^{-4}M; hid-me: histidine methyl ester; hid: histidine; him: histamine; *N*-acetyl-hid: *N*-acetyl-histidine; Bu-NH_2: butylamine; imid: imidazol; DBA: diaminobutyric acid; gly-hid: glycyl-histidine.

In contrast to the case of α,α'-dipyridyl and *o*-phenanthroline chelate compounds, the catalytic activities of cobaltous and nickel histidine chelate compounds are lower than those of the metal aquo-ions. The reason for this is not yet evident, but it probably results from the difference in the configuration and/or from the weak back donation in the latter chelate compounds.

Consideration on the Role of Metal Ions as Enzyme Activator. It is interesting to reveal the role of metal ions in the enzyme-catalyzed decarboxylation of oxaloacetic acid. Speck[4] has reported

that enzyme of the decarboxylation of oxaloacetic acid required metal ions to have full activity, and in most cases, manganous ion was more effective, while cupric and nickel ions were less effective. The order was Mn>Co>Ni>Cu<Zn. Rund and Plane[3] have described that manganous ion catalysis was enhanced sixteen times or more by the coordination with *o*-phenanthroline, but nickel ion catalysis showed only two-told increase, and they concluded that this activation behavior was almost the same as in the metal-enzyme systems.

In this research, however, the enhancement of manganous ion catalysis is the smallest among metal ions studied in either case of α,α'-dipyridyl or of *o*-phenanthroline (*cf.* Table 2), and the situation is not the same as in the enzyme system. The difference between Rund and Plane's result and the present result might be due to experimental conditions, especially to the metal ion concentration and accordingly, the ligand concentration. They carried out their experiments with 5.78×10^{-2}M manganous ion and with 8.5×10^{-5} or 2.64×10^{-3}M nickel ion, but we kept the metal ion concentration constant, 4×10^{-4}M, because α,α'-dipyridyl and *o*-phenanthroline acted as catalyst, when the concentration exceeded 10^{-3}M. Rund and Plane did not consider the catalysis of the ligands and so they might have overestimated the enhancement of manganous ion catalysis.

As described above, the enhancement of metal-ligand systems and metal-enzyme systems appears different, that is, manganous ion is not as effective in the former system, but very available in the latter. This may lead to the idea that in enzyme system, metal ions are enzyme activator rather than catalyst and may change the configuration of enzyme protein favorable to interact with substrate.

In order to examine whether enzyme activity is correlated with the configuration or not, the catalysis of some compounds containing amino groups considered to be an active site of enzyme,[5] was studied. Table 4 shows the first-order rate constant of decarboxylation reaction in the absence of any metal ions. As seen in the table, the catalysis is not always positively related with the number of amino groups, but the catalytic activity of diamino compounds remarkably depends upon the apparent distance between two amino groups. Ethylenediamine is most active; urea, in which two amino radicals combine the same carbon atom, and trimethylenediamine and pentamethylenediamine, in which three or five carbon atoms keep away two amino radicals, are less effective. This strongly suggests that catalytic activity is very sensitive to the setero-configuration of enzyme, or to the configuration of active sites.

TABLE 4. CATALYTIC ACTIVITY OF THE COMPOUND CONTAINING AMINE GROUPS

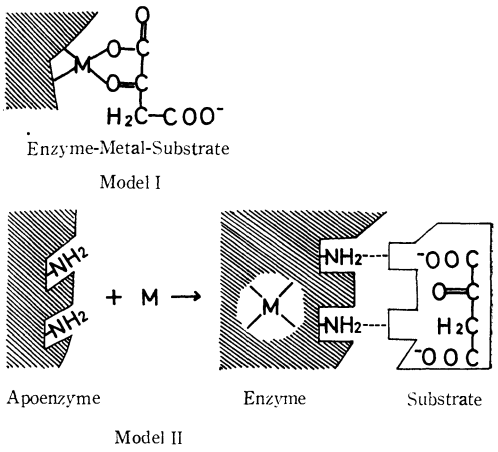

Fig. 3. Models for the activation of an enzyme with a metal ion.

From the above results, it seems reasonable to assume that enzyme activation results from the change in the configuration of enzyme caused by the coordination of metal ions (model II in Fig.3), but not from the increase in the metal ion catalysis caused by the coordination of enzyme (model I in Fig. 3). It is not true that electronegativity of manganous ion increases much in the presence of enzyme and becomes greater than that of nickel or cupric ions.

Although model II is no more than imagination at the present time, it is expected to elucidate the role of metal ions in enzymatic reaction.

Mechanism of Isotopic Exchange of Trisacetylacetonatoaluminum with Acetylacetone-^{14}C in Organic Solvents

Kazuo SAITO and Kazuyo MASUDA

Chemistry Department, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received July 19, 1969)

The kinetic study concerning isotopic exchange of acetylacetone (acacH) and trisacetylacetonatoaluminum [Al(acac)$_3$] (*Bull. Chem. Soc. Jap.*, **41**, 384 (1968)) has been extended to solutions in various organic solvents. Similar catalytic actions of water and acid were observed, and the concentration of acacH did not affect the rate, so that the kinetic formula is expressed by

$$R = [\text{complex}](k_1+k_2[H_2O]+k_1'[\text{acid}]+k_2'[\text{acid}][H_2O])$$

The rate constants and activation parameters are listed in Table 1. The k_1 values are zero in non-polar solvents such as toluene and xylenes, whereas the k_2 values are greater in these solvents than in polar solvents such as tetrahydrofuran and ethylacetate. The activation enthalpy is practically constant in these solvents, regardless of the participation of catalysts. The third and the fourth term seem to represent acid-catalysed reaction paths involving different proton carriers. The whole result appears to support our previous tentative conclusions that the exchange proceeds *via* an intermediate in which one of the acetylacetonate ligands is present as unidentate, and that the ease with which the free end recombines with the aluminum ion is responsible in determining the reaction rates.

In a previous paper we reported the isotopic exchange kinetics of trisacetylacetonatoaluminum [Al(acac)$_3$] and acetylacetone-^{14}C in tetrahydrofuran and postulated a plausible mechanism.[1] One of the three acetylacetonate ligands seemed to be present as unidentate with considerably long life time, and break of the remaining bond appeared to be the rate determining step. The catalytic effect of water and some acids was understood to retard the recombination of free end of the unidentate ligand by occupying the vacant coordination site of aluminum ion and the free end of unidentate acetylacetonate, respectively.

We have extended the study in other organic solvents, ethylacetate, toluene, *o*-, *m*- and *p*-xylene, in order to make clear the exchange mechanism. The exchange rate has been measured in solutions containing varying amounts of the complex, free acetylacetone (acacH), water and acids at various temperatures, and the rate formulae, rate constants and activation parameters have been discussed.

Experimental

Materials. Acetylacetone-^{14}C and trisacetylacetonatoaluminum were synthesized by the same method described previously.[1] The specific activity of the acacH was *ca.* 0.02 mCi per mg, and it contained water of the order of 10^{-1}M.

Extra pure grade ethylacetate was shaken with an aqueous solution of sodium hydrogen sulfite, water, aqueous solution of sodium carbonate and a saturated calcium chloride solution, dried with calcium chloride, distilled, further dried with phosphorus pentoxide and distilled. Toluene and xylenes were shaken with concentrated sulfuric acid, water, sodium hydroxide solution and water, dried with calcium chloride, refluxed with sodium and distilled.

m-Toluic acid and phenol were sublimed at 5 mmHg. Reagents for the scintillation counting, anisole, *p*-terphenyl and *p*-di-(5-phenyl-2-oxazolyl)-benzene (POPOP) were purified as mentioned previously.

Experimental Procedure. The method is essentially the same as that used previously.[1] Trisacetylacetonatoaluminum was precipitated crystalline within 6 hr by pouring an aliquot of the reaction mixture (*e. g.* 1 m*l*) into chilled petroleum ether (−20°C, 20 m*l*). The exchange reaction stopped instantaneously and no zero time exchange was observed.

Since the solvents and the free ligand acacH contained a significant amount of water, the water content of the reaction mixtures was determined by Karl-Fischer titration in a mixture of pyridine and ethyleneglycol (5+1). Little change in water content was observed within a given kinetic run. Five or six aliquots were withdrawn during one kinetic run, and altogether about two hundred kinetic runs were carried out.

The absorption spectra of the reaction mixtures were identical with the sum of those of [Al(acac)$_3$] and acacH in all the solvents, and no reaction other than isotopic exchange took place, regardless of the presence of water and the acids.

Measurements. Coincidence liquid scintillation counting was employed.[1] The counting rate at the

1) K. Saito and K. Masuda, This Bulletin, **41**, 384 (1968).

end of the exchange reaction (infinite time) was calculated from that of acacH-^{14}C and the used amounts of [Al(acac)$_3$] and acacH. The absorption spectra in the visible and ultraviolet region were measured with a Hitachi EPU-2A spectrometer.

Results

The experimental results were treated with McKay's formula

$$R = -2.3\frac{3ab}{3a+b}\cdot\frac{\log(1-F)}{t}, \qquad (1)$$

where a and b denote the concentrations of the complex with three exchangable ligands and that of the free ligand, respectively. F is the fraction of reaction and t the lapse of time in minutes. Good linear relationship was observed between $\log(1-F)$ and t in each run, and between R and a in all the solvents used. (diagram similar to Fig. 1 of Ref. 1). Hence the rate is expressed by $R=k_0a$.

Figure 1 shows the relationship between k_0 and the concentration of water in ethylacetate solutions at various temperatures. Figure 2 gives similar relationships in toluene at various temperatures, and Fig. 3 those in *o*-, *m*- and *p*-xylene at 25°C. The full and the open circles in Fig. 2 denote k_0 values obtained in the presence of different amounts of free ligand. Since acacH-^{14}C contained a small amount of water, change in b brought about the change in water concentration, and the influence of b was not examined individually. However, the fact that the full and the open circles are on the same line at a given temperature clearly indicates that k_0 is independent of b. The straight lines are expressed by

$$k_0 = k_1 + k_2[H_2O]. \qquad (2)$$

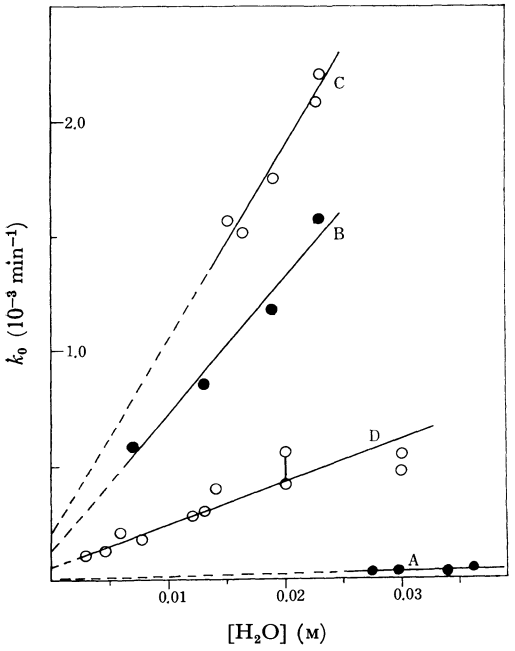

Fig. 1. Relationship between k_0 and the concentration of water in ethylacetate.
A (0°C), B (30°C), C (35°C) in ethylacetate; D (25°C) in tetrahydrofuran. (b=0.070M)

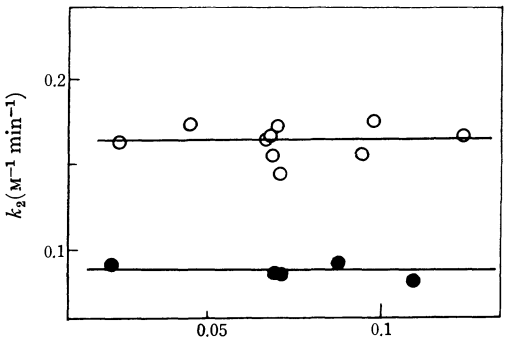

Fig. 4. Influence of the concentration of acetylacetone on the k_2 values.
○ 25°C in toluene, ● 35°C in ethylacetate

The slope and the intercept of Figs. 1, 2 and 3 correspond to k_2 and k_1, respectively, under the given conditions. The lines in Figs. 2 and 3 pass the zero point, to indicate that k_1 is almost zero in toluene and xylenes. No difference in rate constant was observed in the three isomers of xylene.

Figure 4 shows the influence of b upon k_2 in ethylacetate and in toluene. It further demostrates that k_2 is independent of b.

The exchange reaction is catalysed by acids. When m-toluic acid and phenol were used, the relationship between k_0 and acid concentration was similar to that in Fig. 3 of Ref. 1 in less than 0.021M acid in the solvents. Hence the catalytic effect increases linearly with the increase in acid concentration. Figure 5 shows the influence of water concentration upon the exchange rate in the presence of a given amount of m-toluic acid at various temperatures in ethylacetate and at 25°C in toluene.

Similar diagrams were obtained by use of phenol in place of m-toluic acid in ethylacetate. It appears as if the acid catalysis operates in two ways with and without the aid of water. The overall relationship is thus expressed by

$$k_0 = k_1 + k_2[H_2O] + k_1'[\text{acid}] + k_2'[\text{acid}][H_2O]. \quad (3)$$

The intercept and the slope of lines in Fig. 5 correspond to k_1' and k_2' of Eq. (3), respectively at a given temperature. The third and the last term of Eq. (3) express the acid catalysis operating with and without the aid of water, respectively.

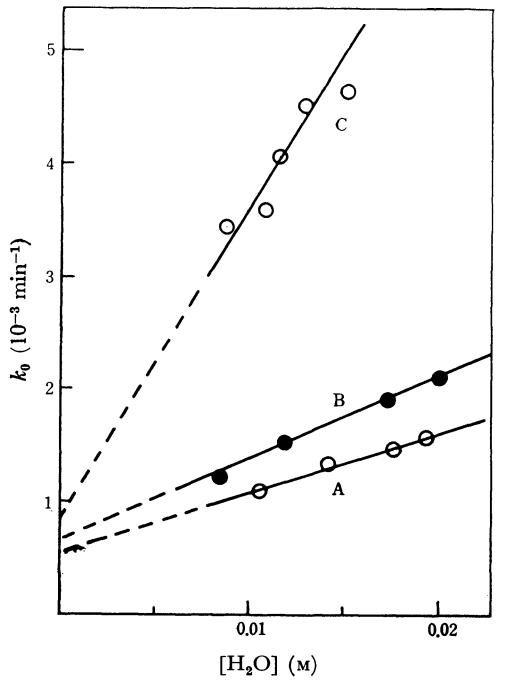

Fig. 5. Influence of the concentration of water upon the k_0 values in the presence of a given amount of m-toluic acid.

(b=0.070M, [m-toluic acid])=0.090M)

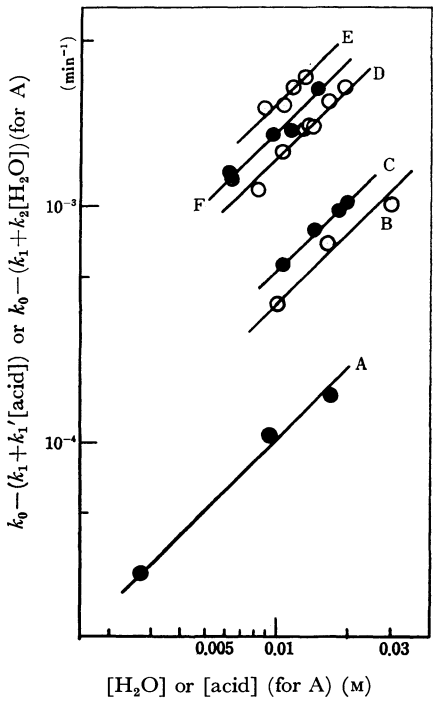

Fig. 6. Logarithmic plots indicating the influence of water in the presence of a given amount of m-toluic acid, and that of m-toluic acid in the presence of a given amount of water.
A: 25°C in tetrahydrofuran, [H$_2$O], 0.027M, [acid] varying;
B: 25°C in tetrahydrofuran, [H$_2$O] varying, [acid], 0.015M;
C: 25°C in ethylacetate, [H$_2$O] varying, [acid], 0.009M;
D: 25°C in toluene, [H$_2$O] vaying, [acid] none;
E: 25°C in toluene, [H$_2$O] varying, [acid], 0.004M;
F: 25°C in o-xylene, [H$_2$O] varying, [acid] none.

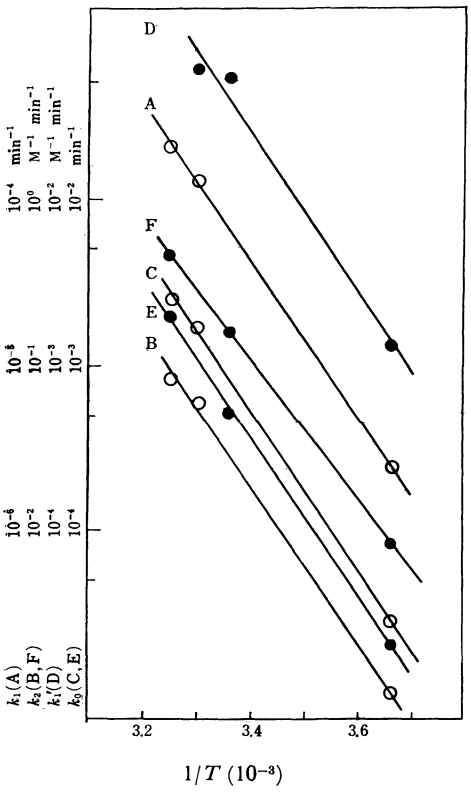

Fig. 7. Arrhenius plots of the rate constants of Eq. (3) in various solvents.
A: k_1 in ethylacetate; B: k_2 in ethylacetate;
C: k_0 in ethylacetate ([H_2O]=0.027M, [acid] none);
D: k_1' in ethylacetate;
E: k_0 in tetrahydrofuran ([H_2O]=0.027M, see the text);
F: k_2 in toluene.

Figure 6 is the log-log plots indicating the influence of water in the presence of a given amount of acid, and that of *m*-toluic acid in the presence of a given amount of water. The k_1 and the k_2 values were obtained in the absence of acid, and the k_1' values from the intercept of Fig. 5. These diagrams with a slope 45° demonstrate that Eq. (3) is quite appropriate in the present systems.

Figure 7 gives the Arrhenius plots of k_1, k_2, k_1' and k_0 in the solvents. The k_1 and k_1' values were obtained by extrapolation on Fig. 1 and Fig. 5, respectively, and their accuracy cannot be high enough. However, it is noteworthy that the values in tetrahydrofuran and ethylacetate are practically the same and that in toluene does not differ much. In tetrahydrofuran the Arrhenius activation energies were not obtained individually for k_1 and k_2. The E_a values were, however, obtained in the presence of varying amounts of water, and they were all found to be equal to 22 kcal per mole. Hence it is clear that both k_1 and k_2 have the same E_a values.

Table 1 summarizes the kinetic constants obtained in various solvents, together with the dielectric constants and dipole moments and the activation parameters in the solvents. The values for the acid-catalyzed paths do not seem very accurate, because they were obtained on the basis of extrapolated values and their approximate values are given in the footnote.

Discussion

Dissociation Mechanism. Since the exchange rate is independent of the concentration of acetylacetone, regardless of the presence of catalyst such as water and acid, the reaction must proceed through

Table 1. Rate constants and activation parameters at 25°C

Fig. 8. Plausible reaction mechanism.
(acac$^-$) denotes unidentate acetylacetonato ligand.

the dissociation mechanism, in which the break of metal-ligand bond is responsible for determining the rate. Whenever a bidentate chelate ligand undergoes isotopic exchange, two reaction mechanisms can be considered: (i) The break of one of the metal-ligand bonds is the rate-determining step, and the remaining bond breaks rapidly. The catalytic effect is understood by considering that water molecule or acid proton approaches the coordinated oxygen atom to assist the bond rupture. (ii) The ligand can be present as unidentate with considerably long life time, and break of the remaining bond is the rate-determining step. Catalytic actions can be interpreted by assuming that water molecule and the acid proton occupy the vacant coordination site of aluminum ion and the negatively charged free end of unidentate ligand, respectively, and retard recombination of the free end.

From the experimental results, we tend to conclude that mechanism (ii) is more plausible (Fig. 8). The activation enthalpies in tetrahydrofuran and ethylacetate are the same, regardless of the presence of catalysts, and that in toluene does not differ much. If (i) were operating, the ease of break of one of the metal-ligand bonds would be affected by the catalysts, and the $\Delta H^{\neq}$ values for k_1, k_2, *etc.* should have different values. Whenever (ii) operates, on the other hand, the rate constants are dependent on the ease with which the free end of unidentate ligand recombines with the metal ion. The transition state would involve elongation of the remaining bond of unidentate ligand, and be affected little by the protonation at the free end of the same ligand or by the occupation of coordination site on the aluminum ion by water molecule.

The k_1 Path. The fact that k_1 value is zero in toluene and xylenes, whereas it is greater in tetrahydrofuran and ethylacetate, seems to be related to the dipole moment and the dielectric constant of the solvents. We believe that activation entropy is responsible for such a difference. Polar solvents can occupy the free end of unidentate ligand or the vacant coordination site of metal ions to retard the recombination and leave more chance for the remaining bond to be broken.

Comparison of activation enthalpy, however, could also account for the difference. Since the present metal-ligand bond is regarded rather ionic, coordination of polar solvent molecule on the vacant coordination site would decrease the effective charge of the aluminum ion to make the remaining metal-ligand bond weaker, and to decrease the $\Delta H^{\neq}$ value. Such an interpretation is alternatively expressed as the small dielectric constants of the aromatic hydrocarbons being unfavorable for the break of aluminum-oxygen bond. These two contributions cannot be distinguished, unfortunately, because the k_1 value is zero.

The k_2 Path. The greater k_2 values in aromatic hydrocarbons than in polar solvents might be correlated with the ease with which water molecules coordinate the vacant site of the metal ion. The affinity between water and solvent molecules would be greater in tetrahydrofuran and ethylacetate than in toluene and xylenes.

In the latters, water molecules would have more chance to be present near the complex molecules and to creep in the coordination site whenever one of the aluminum-oxygen bond is broken, so that the recombination of unidentate ligand is retarded to a greater extent. Further, in these solvents, the coordination of water molecules to the vacant coordination site would decrease the effective charge of the cation and make the ionic metal-ligand bond weaker. Thus the activation enthalpy for the k_2 path could become smaller than that for the k_1 path, although the actual value for the latter cannot be known.

In polar solvents, on the other hand, the k_2 term is regarded to represent a reaction path in which water molecule occupies the vacant coordination site in place of the solvent molecule. Hence the difference in the rate constants k_1 and k_2 would not be so remarkable as in the non-polar solvents.

Acid Catalysis. The acid catalyzed reaction path operates in two ways. The k_1' path represents a reaction mechanism in which the acid acts as a

proton source without cooperation with water, whereas the k_2' path that operating with the aid of water. So far as the role of acid is to provide protons to the free end of unidentate ligand, the difference between the two paths consists in the kind of proton carrier. Hydroxonium ions must be the carrier for the k_2' path, while the acid molecule itself or the solvent molecule would be the proton carrier in the k_1' path.

As seen in Table 1, acid catalysis is more marked in toluene than in ethylacetate or tetrahydrofuran. Since protons have less affinity with the solvent molecule in toluene than in the polar solvents, acid molecules themselves would be the more plausible proton carrier in the former solvent. They would have greater possibility to be present near the complex molecule, to be ready to transfer protons to the free end of unidentate ligand, and retard the recombination to a greater extent. It would be also possible that the acid anion occupies the vacant coordination site as water molecule does in the k_2 path, whenever proton transfer takes place. Such a cooperative effect cannot be expected when the solvent molecule carries proton in the polar solvents. A similar trend is observed with the k_2' values. When hydroxonium ions carry protons, proton transfer to the free end of unidentate ligand can be accompanied by the addition of water molecule to the vacant coordination site of aluminum ion, and a cooperative effect is expected with a greater probability in toluene than in the polar solvents. The relative figure of the k_1' and the k_2' values would be related to the competition between water and the acid anion or the solvent molecule as proton carrier. Such a competition would be ruled by various factors including acid strength in the non-aqueous media and also affinity of water with the solvent molecule.

Importance of the Unidentate Complex as Intermediate. Aluminum complexes are generally regarded as substitution labile,[2] except for a few cases.[1,3] Rapid establishment of ligand interchange equilibria and racemization was demonstrated by Fortman and Sievers on the basis of p.m.r. coalescence measurement with acetylacetonato, hexafluoroacetylacetonato and hexamethylacetylacetonato complexes of aluminum.[4] They postulated several possible intramolecular reaction mechanisms, but gave no conclusion as to which of them is most plausible. We have pointed out the importance of an intermediate state involving a unidentate ligand, but our result is not enough for choosing the most appropriate one. We are essentially dealing with slow reactions, and our "rapid reaction" could be slower than their reaction by several orders. Whenever the free end of unidentate ligand recombines with the aluminum ion without undergoing isotopic exchange reaction, the life time of intermediate must be long enough to allow some kinds of steric change which can bring about the inversion of individual tris complex molecules.

Although our experiment cannot provide useful information concerning the "twist mechanism," it clearly rules out any kind of intermolecular mechanism and seems to establish the importance of unidentate intermediate in considering the reaction mechanism of ligand substitution in chelate compounds.

We wish to express sincere thanks to Nishina Memorial Foundation for grant-in-aid. We are also indebted to Mr. Hiroaki Kido for useful discussion, and to Miss Mizue Tachikawa for help in experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 125—129 (1970)

Studies on Dithiocarbamates. XII. Kinetic Studies on the Hydrolysis of Mesoionic 4,5-Diphenyl-1,3,4-thiadiazole

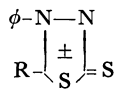
P. B. TALUKDAR, S. BANERJEE and A. CHAKRABORTY

Research and Development Division, East India Pharmaceutical Works, Calcutta-61, India

(Received March 28, 1969)

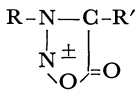
Kinetic studies of the compound given in the title were conducted in aqueous alcohols over a wide range of pH. The observed rate constants are dependent on the hydroxide-ion concentration as well as polarity of the medium. Hydrolytic decomposition is characterised by a small magnitude of entropy (ΔS^*) and negative salt-effect. Mechanism consistent with these facts has been suggested.

We had been interested for some time in the physicochemical properties of heterocyclic systems containing –NCS fragment as an essential part of their structure.[1-4] In continuation of this work, we recently reported[5] the synthesis and spectral characteristics of a series of mesoionic 1,3,4-thiadiazoles (I). This provided us with an opportunity to examine the hydrolytic behaviour of a typical compound (II) as a representative member of the series.



I

II, R=ϕ



III

Quite apart from their structural peculiarities,[6,7] mesoionic compounds (I and III) were also reported to have interesting pharmacological properties.[6,7] Consequently, fairly extensive kinetic[8-10] data are now available on more readily accessible sydnone derivatives (III), which show sensitivity to both acid and alkali. Comparative data on mesoionic thiadiazoles (I) are highly desirable as it is anticipated that any intrinsic difference in properties between these two systems is bound to have profound reflection on the observed data. With this objective in view, our studies are mainly concerned with effects of pH, temperature, solvent composition and ionic strength on the rate constants. These results, in conjunction with the isolation of a derivative of the product of hydrolysis in alkaline condition provide sufficient evidence on the probable course of degradation of II under alkaline condition.

Experimental

Materials. Mesoionic 4,5-diphenyl-1,3,4-thiadiazole (II) has been previously described.[5,7] AR-grade solvents were fractionated over metallic sodium and mid-fractions were stored in amber-coloured bottles

prior to their uses, and calibrated by checking their specific-gravities against literature values. Conductivity water was prepared in an all-glass apparatus from distilled water over potassium permanganate.

Acetate buffers were used for studies under acidic conditions, but phosphate and borate buffers were used under alkaline conditions; ionic strength (μ) was maintained at around 0.1 with requisite amount of KCl and the pH values were checked in a standard Cambridge pH-meter. The pH values recorded in Table 1 refer to those observed under the actual experimental condition (after 24 hr) after mixing the required amount of solvents and stock buffers. Higher ionic strength was achieved through addition of extra amount of KCl to the required quantity of buffer.

Spectrophotometric measurements were carried out with a Hilger UVISPEK spectrophotometer in 1 cm cells.

Kinetic Measurements. Initial experiments have shown that the characteristic long wavelength band[5,7] of the mesoionic thiadiazole appears at 382—383 mμ under the projected experimental condition, and the band position remains practically unchanged with change in pH; hence all kinetic runs were followed by measuring the loss of intensity of this band at 382 mμ.

A fairly concentrated solution of the substrate was first prepared in an appropriate solvent so that the observed optical density is around unity. After the thermal equilibration of the stock solutions, aliquots were mixed and the fall in intensity was followed until at least 80% of the substrate reacted. Other details were the same as before.[2,4]

Constancy of the thermostatic bath was within ± 0.2°C and the accuracy of the data was better than 3% by agreement between duplicate experiments.

Product Study. 200 mg of the compound was first dissolved by warming in about 30 m*l* of ethanol; it was cooled to 25°C and diluted with an equal volume of water. To the yellow solution, aqueous NaOH (10%) was added dropwise with stirring at 25°C maintaining the pH at 9—10. When there was no more fading away of colour (about 30 min), pH was adjusted at 5—6 with drops of acetic acid and gently warmed on a steam bath for about 5 min. A solution of *p*-nitrobenzaldehyde (120 mg) in minimum quantity of alcohol was added with swirling to the above solution and the mixture was heated on a steam bath for another 10 min. On cooling down to room temperature, a yellow precipitate was obtained; this was collected, washed with a few drops of ethanol.

Two crystallisations from ethanol yielded 85 mg (50%) of pale yellow needles, mp 149.5—150°C, with immediate solidification and remelts at 169—170°C; λ_{max}^{EtOH} 226 mμ (ε, 18750) and 325 mμ (ε, 20060). IR (Nujol): 1660 (–CO, amide) and 1640 (–C=N) cm^{-1}. Found: N, 12.28%. Calcd for $C_{20}H_{15}N_3O_3$: C, 12.17%.

Identity of the product was established by comparison with an authentic sample of *p*-nitrobenzylidene derivative (IX) of *N*-benzoyl-*N*-phenylhydrazine synthesized by the following method:

A solution of phenylhydrazone of *p*-nitrobenzaldehyde (200 mg; mp 159—160°C) in 30 m*l* of dry benzene was refluxed with equimolar amounts of benzoyl chloride and pyridine for 10 hr. After working up in the usual way, the residue was crystallised from ethanol to give pale yellow needles, mp 169—170°C, with similar characteristics and identical absorption bands as the above compound.

Results and Discussion

Effects of pH and Temperature. The apparent first order rate-constants at various pH in 50% aqueous ethanol are shown in Table 1. Data clearly show appreciable acceleration of rate with rise in pH so much so that it is extremely difficult to measure the rate at a higher pH (>10.5). On the other hand, the reaction is extremely sluggish between pH 7—8 and there was practically no change in optical density in acidic buffers (4.90 and 3.65) over a week.

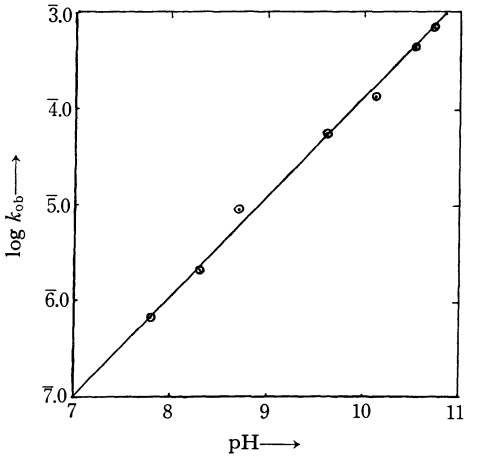

Fig. 1. pH-rate profile in 50% aqueous ethanol at 25°C and μ=0.05.

The observed behaviour of II in the acidic region is quite a surprise when one recalls the facile degradation of sydnones under a similar condition to yield the appropriate hydrazines.[10,11] However, the significance of the data becomes readily comprehensible from the pH-rate profile (Fig. 1) where the slope is almost equal to unity suggesting specific hydroxide-ion catalysed reaction at the rate-limiting step. Presumably, the reaction is first-order with respect to hydroxide ion concentration. Similar specific hydroxide-ion catalysed hydrolysis has been observed with some sydnone derivatives.[9]

That the observed reaction is also first-order with respect to the substrate is shown not only by the excellent first-order plots (log o.d. *vs.* time), but also by the constancy of half-lives ($t_{1/2}$=24—25 min) at five different initial concentrations (0.8 to 2.0×10^{-3}M) of the substrate in 50% ethanol at 25°C for pH=10.5 and μ=0.05. Evidently, the overall reaction is a clean second-order one. Hence, the rate law for the observed reaction is

11) R. A. Eade and J. C. Earl, *J. Chem. Soc.*, **1946**, 591.

$$-\frac{dA}{dt} = k[A][OH]^-$$

$$= k_{ob}[A], \text{ for a given pH.}$$

Thus $k_{ob}=k[OH]^-$, hence the bimolecular rate-constants for the hydroxide-ion catalysed reaction could be obtained from k_{ob}; these are shown in Table 1 and are reasonably constant under identical conditions (No. 1—7).

Table 2. Temperature dependency of rate constants in 50% aqueous ethanol at pH=10.50 and μ=0.05

Temp. °C	10^4 k_{ob} in sec^{-1}	Kinetic parameters
15	1.379	E_A=20.19 kcal/mol
20	2.239	ΔH^*=19.60 kcal/mol
25	4.606	ΔG^*=22.02 kcal/mol (at 25°)
30	7.932	ΔS^*=−8.13 e.u.

Data on the temperature dependency of rate-constants are shown in Table 2. The derived activation parameters are quite comparable to those reported[9] for the base-catalysed decomposition of sydnones and to other bimolecular reactions. Although the absolute value of ΔS^* could not be emphasized, the small negative value is highly significant. It is now recognised that, for a unimolecular reaction, the magnitude of ΔS^* is usually very small and tends to be zero.[12] Interpretation of such data is extremely difficult,[13] but in the given instance it undoubtedly reflects the small difference between the reactant and the transition-state with respect to their imposed constraints. The situation could be resolved by assuming the formation of an initial transition complex through the rate-determining attack of the hydroxide ion followed by smooth and rapid rearrangement to another intermediate prior to its decomposition.

The Effect of Variation in Solvent Composition. The influence of the variation in solvent composition on the rate-constant is also included in Table 1. Although the same quantity of buffer was used in each case, and the ionic strength was maintained at the same level, the observed pH of the medium, as anticipated, shows considerable variation with change in the nature of the co-solvent. The impact of solvent composition on the rate-constants is, therefore, apparently submerged in the apparent first-order rate-constants due to inherent difference in pH of the medium. Assuming that there is no significant difference in the ionisation of water for the solvents under consideration, the calculated second-order rate-constants clearly demonstrate the expected order of solvent effect where the rate-constants increase with increasing polarity of the medium. This apparently indicates ionic character of the transition state. But no attempt is made here to correlate the rate-constants with any known[14] parameter of the solvent, because microscopic polarity in the cybotactic[15] region of the reacting species is extremely difficult to be adequately expressed by known parameters of the solvent.

Parker[16] has already discussed the mode of solvation in a protic solvent where hydrogen-bonding is considered to play a vital role. It has already been observed by us[5] that λ_{max} of the thiadiazole (II) is quite sensitive to the protic character of the solvent. In the given instance, then, it might be true that the increased population of a specific dipolar form[6,7] of II (which is stabilised through hydrogen-bonding) makes an effective contribution in increasing the rate in a more polar solvent. At the same time, solvation to the transition-state, which is largely anionic in character, appears to be favoured in more polar medium suggesting appreciable charge dispersion[17] at the transition state. This ought to be viewed against the small magnitude of ΔS^* as noted earlier. Although no attempt has been made to find out the changes in ΔS^* by changing the solvent composition, it is probably the difference in the solvation of the reactant[18] rather than the transition-state that appears to be important here; however, possibility of the changes in ΔH^* can not be altogether discarded and the origin of the solvation effect is still a matter of debate.[19]

From all accounts, it appears reasonable to exclude water as a direct participant and its role is essentially associated with solvation phenomenon. Thus, kinetic data in solvents of similar composition (50% aqueous methanol, ethanol and 2-propanol, Table 1) tend to confirm this, but comparatively higher rate in 50% methanol may be due to some other specific interactions. Alternatively, hydroxide-

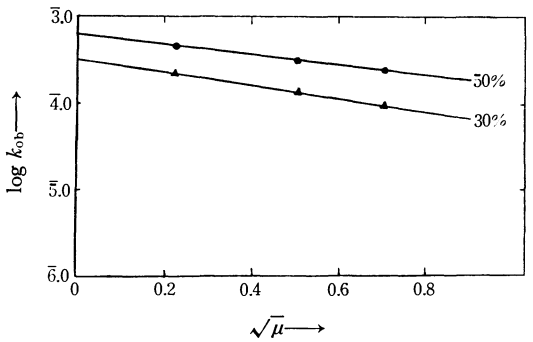

Fig. 2. Effect of electrolyte on the rate.

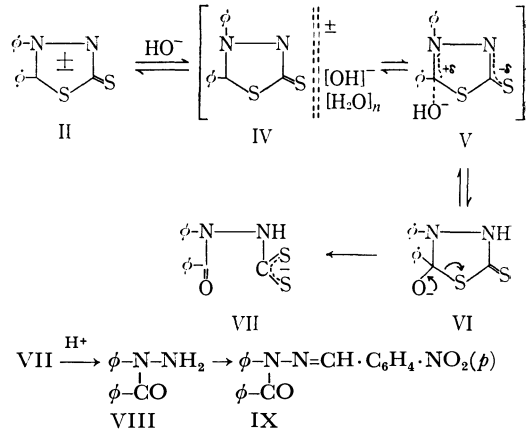
ion is known to be a structure-maker[20] and with a suitable orientation may lower the activation energy in the formation of the tetrahedral intermediate (see below).

Salt-effect on the Rate Constants. Data for the effect of the ionic strength (μ) in the reaction medium are presented in Table 1 for three different alcohol-water compositions. In all cases rate retardation is observed for increased values of μ. Qualitatively, this is consistent with the salt-effect upon ion-molecule reaction;[21] for example, fairly large electrolyte effect is observed for the attack of hydroxide-ion on *p*-nitrodiphenylphosphate in water.[22] Actually, the plots of log k_{ob} against $\sqrt{\mu}$ is linear (Fig. 2), the lower the proportion of alcohol, the larger the slope (−0.6 and −0.75 at 50% and 30% ethanol respectively). Again, from the plot of the slope against % water, the intercept yields a value almost equal to unity. Thus the predicted salt-effect in absence of alcohol (*i. e.*, in 100% water) has got the value as required by limiting Deybe-Hückel equation for reaction between two oppositely charged species, each carrying a unit charge.

However, our results could not be directly compared with those reported[9] for sydnones where the effect of electrolyte on the acid-catalysed reaction was examined. But it is still more difficult to account for such salt-effects as pointed out recently by Bunton and Robinson.[29] According to them it is highly unlikely that ion-pairing is important in aqueous alcohol. Further, possibility of changing the lyate ion from OH^- to more nucleophilic alkoxide-ion[23] with increase in alcohol content could not be a significant factor under the experimental set up. It has also been suggested[20] that for anion-molecule reaction in polar hydroxylic solvent, the transition state is stabilised relative to the nucleophilic anion by cations of low charge density (*e. g.* K^+) and this is apparently consistent with our observation.

Alternatively, the negative salt-effect may be attributed to preferential solvation of K^+ and Cl^- by water so that less water is available as solvating species.[24] The magnitude of salt-effect should, in that case, be more pronounced in a less polar medium; but this is contrary to our experience. Consequently, the observed electrolyte effect could be reasonably attributed to its interaction at the transition-state.

Product Isolation and Mechanism of Degradation. Any mechanistic interpretation on the alkaline decomposition of II must, therefore, satisfy the following facts: (1) first-order dependence on hydroxide-ion concentration, (2) rate increases with increased polarity of the medium, (3) small magnitude of ΔS^*, and (4) the negative salt-effect. In accordance with these facts the following scheme is suggested:



The most difficult step in the proposed scheme is to locate the site of the attack of hydroxide-ion. The same difficulty was encountered in explaining the base-catalysed decomposition of sydnones and consequently, two alternative mechanisms, involving positions 2 and 5 were proposed.[8,25] It is difficult to comprehend a situation where the attack of hydroxide-ion occurs on the carbon atom bearing the exocyclic sulphur atom with a large formal negative charge. In this respect we are in agreement with the views of Garrett[8] on sydnone derivatives.

What is intended here is to show that the solvated thiadiazole (II) becomes highly polarised by the approach of the hydrated hydroxide-ion so as to form a complex (IV) in a rate determining step.

25) E. B. Roche and L. B. Kier, *Tetrahedron*, **24**, 1672 (1968).

This rapidly rearranges, possibly involving OH^- transfer through water clusters,[26] to give the tetrahedral intermediate (VI). The intermediate, in turn, collapses in a fast step to yield the dithiocarbazinate (VII) under the alkaline condition. In support of the main sequence of the reaction, we have already isolated *N*-benzoyl-*N*-phenylhydrazine (VIII) as *p*-nitrobenzylidene derivative (IX) in fair yield. Isolation of the same compound in a poorer yield has been recently claimed[27] but no data were provided. We plan to continue our studies in order to resolve the details of the proposed mechanism.

We thank Mr. P. Bagchi, Research Director, for his keen interest and Dr. S. K. Das Gupta for IR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 129—134 (1970)

Mass Spectra of Diaryl Disulfides, Diaryl Thiolsulfinates and Diaryl Thiolsulfonates

Seizi KOZUKA, Hideo TAKAHASHI and Shigeru OAE

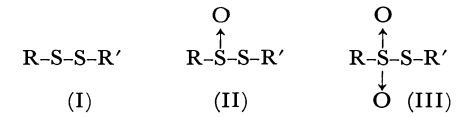
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received April 30, 1969)

The mass spectra of diaryl disulfides, diaryl thiolsulfinates and diaryl thiolsulfonates have been studied by analyzing metastable peaks and mass numbers. The main fragmentation observed for the disulfides was the cleavage of the S–S bond while the fragmentation of thiolsulfinates was similar to that of disulfides after elimination of oxygen. In the case of thiosulfonates, however, no such deoxygenation was observed, formation of sulfonium ion and one oxygen migration from the sulfone sulfur to the thiol sulfur were observed. Formation of thiabenzonium ion was observed in the mass spectra of sulfinates and sulfonates.

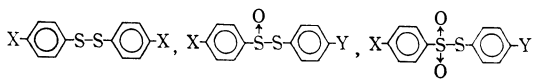
The mass spectra of organic sulfur compounds have been investigated considerably in recent years, and those of alkyl and diaryl sulfides,[1-4] sulfoxides[2,5,6] and sulfones[5-7] have been well understood.

However, the mass spectra of the aromatic compounds containing S–S bond, *i.e.*, disulfides (I), thiolsulfinates (II), and thiolsulfonates (III) have received rather scant attention except for diphenyl disulfide.[4]



(R, R′=aryl)

This paper describes a detailed study on the electron impact fragmentation of these three types of sulfur compounds where R and R′ are aryl groups. The following compounds were subjected to mass spectrometric analysis.



Ia X=H, b X=CH_3, c X=Cl, d X=OCH_3, e X=NO_2

IIa X=H, Y=H, b X=H, Y=CH_3, c X=CH_3, Y=CH_3, d X=H, Y=OCH_3

IIIa X=H, Y=H, b X=CH_3, Y=CH_3, c X=H, Y=NO_2, d X=H, Y=Cl

Results and Discussion

Diaryl Disulfides. Of first group of compounds (Ia—Ie), the mass spectrum of only the unsubstituted compound (Ia)[4] has been reported. The substituent effect on the fragmentation has not been investigated. The main spectra of these compounds are summarized in Table 1.

TABLE 1. RELATIVE ABUNDANCE OF MAJOR PEAKS AND METASTABLE PEAKS OF DIARYL DISULFIDES

Compd. / Ion	Relative Abundance Ia	Ib	Ic	Id	Ie
M	86	75.8	42	38.6	100

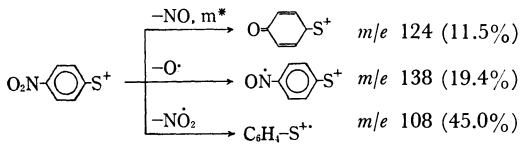
Metastable peak					
M→M-(SH)	present	present	—	—	—
M→M-(S_2)	present	present	—	—	present

A few characteristic features of these spectra may be summarized as follows.

1) All the compounds give prominent parent peaks.

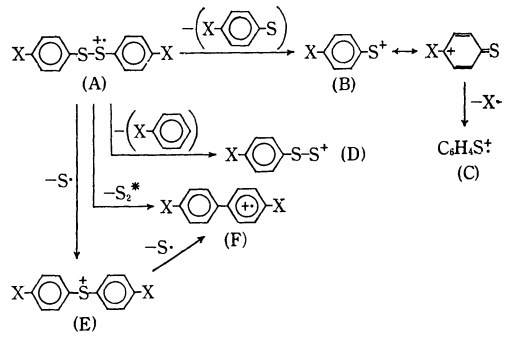
2) The largest peaks for the compounds are fragment peaks formed by cleavage of the S–S bond except in the case of the nitro compound. The anomaly of the nitro compound may be due to the facile decomposition of the ion formed by cleavage of the S–S bond. In this case, three distinctive peaks observed (*i.e.*, *m/e*, 138, 124 and 108) suggest the succeeding decomposition of the daughter ions.



Scheme 1

3) Elimination of S or S_2 from the parent ions was observed, although the process was minor.

4) The relatively high intensity of the fragment having mass number 108 is to be noted. This ion is probably formed by the subsequent cleavage of the X–C bond of the X-C$_6$H$_4$-S$^+$ ion. The intensities of these ions are apparently affected by the substituent X and decrease in the order $-NO_2 > -Cl > -CH_3 > -OCH_3$. This order is consistent with the relative stability of the precursor ions. These observations suggest the fragmentation scheme of of these diaryl disulfides as shown below:

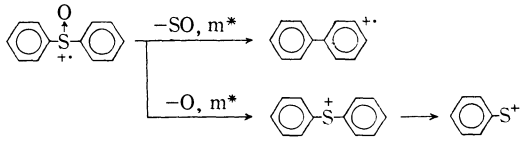


Scheme 2

The main fragmentation process for these compounds is (A)→(B)→(C) and a small portion of the parent ion undergoes decomposition through other pathways.

Ion (F) may be formed either by the direct desulfurization of the parent ion or through ion (E). The direct process is confirmed by the aid of the metastable peak. However, the pathway giving (F) from (E) is also not unreasonable in view of the similar fragmentation of diarylsulfides.[6]

Diaryl Thiol Sulfinates. The mass spectra of diaryl sulfides were investigated by Natalis *et al.*[1,4,5] and the main fragment peaks reported corresponded to those of the diaryl cation and the sulfenium ion formed by the loss of one aryl group. On the other hand, diaryl sulfoxides are known to give the following fragmentation.



These results suggest that the oxidation of sulfur atom of diaryl sulfides does not give rise to any distinctive difference in mass spectra of these compounds. Thus, it is interesting to compare the mass spectra of diaryl thiolsulfinates with those of the corresponding disulfides.

The main spectra of the sulfinates are summarized in Table 2.

As was expected, all the sulfinates give no parent peak or a very small one and the spectra are similar to those of disulfides, hence the general fragmentation patterns for these compounds are initial elimination of oxygen followed by cleavage of the S–S bond or the elimination of sulfur, similar to the fragmentation of the disulfides.

A question arises as to whether the spectra were simply from the sulfinates, since the thiolsulfinates are known to undergo thermal disproportionation to

Table 2. Relative abundane of major peaks and metastable peaks of diaryl thiolsulfinates

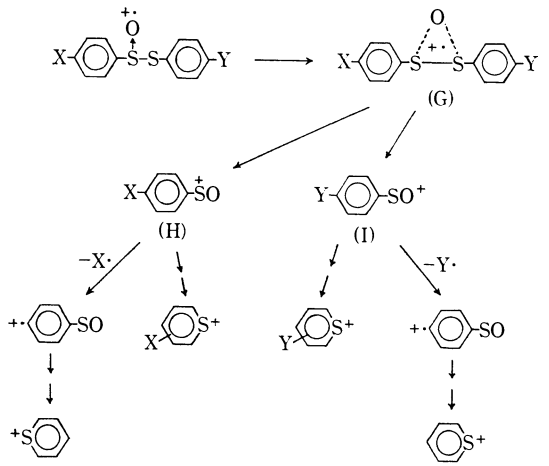
give the corresponding thiolsulfonates and disulfides.[8]

In the present study, only small peaks corresponding to thiolsulfonates were observed.

The peaks are, however, too small to be expected from disproportionation and moreover the whole pattern of the spectra is quite different from the combined spectra of the equimolar mixture of the thiolsulfonate and the corresponding disulfide. Therefore it should be assumed that the spectra show just the fragmentation of thiolsulfinates.



Scheme 3

In addition to these processes, a fragmentation giving thiabenzonium ion was observed as in the case of diaryl sulfoxides,[6] shown in Scheme 3.

The path giving the thiabenzonium ion from diphenylsulfoxide was confirmed by the presence of the metastable peak and the component of the ion was also determined by means of high resolution mass spectrometry.[6] On the other hand, the ion of the mass number 97 in this work seems to be formed in a somewhat different way since these peaks appear at the same mass number even in methyl-substituted compounds, although there were also small peaks corresponding to the substituted thiabenzonium ion. Thus the process giving the thiabenzonium ion must include the elimination process of the substituent and hence is considered as a rearrangement ion.

Comparing these spectra with those of diaryl sulfoxides, a minor but noticeable difference is observed in deoxygenation. Although similar deoxygenation is observable in the case of diaryl sulfoxides the parent peaks are always observed quite clearly, unlike the case of the thiolsulfinates which undergo deoxygenation almost exclusively. The

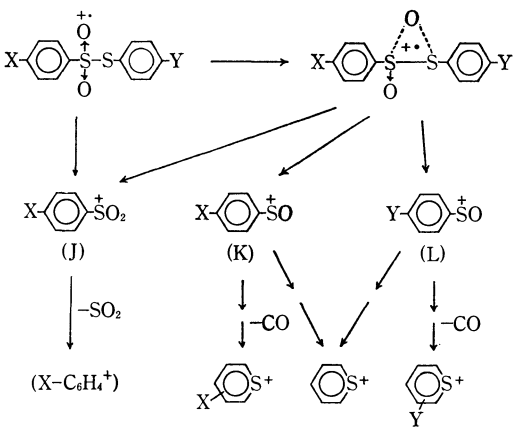

Scheme 4

observation that thiolsulfinates undergo more facile deoxygenation than the sulfoxides seems to conflict with the strength of the S–O bonds of these compounds obtained from IR spectra.[9] The facile deoxygenation in diaryl thiolsulfinates, however, may be rationalized in terms of resonance stabilization of the daughter ions. Namely, although the S–O bond of thiolsulfinate is stronger than that of sulfoxide, the deoxygenation of the former gives disulfide ions which is undoubtedly much more stable than sulfide ions formed by the deoxygenation of sulfoxides. The initial ionization to introduce a positive charge on the oxygen atom of the S–O bond would be easier with thiolsulfinate than with sulfoxide since the positive charge on the sulfur atom can be delocalized to a greater extent more with the former than the latter. This resonance stabilization perhaps outweighs the small difference in the bond strength resulting in the more facile deoxygenation with thiolsulfinate than sulfoxide.

Diaryl Thiolsulfonates. Mass spectrometric analyses were also carried out with the sulfur compounds containing one more oxygen atom around the S–S bond *i. e.*, diaryl thiolsulfonates. The common spectral features of these compounds are summarized in Table 3. As the mass spectra of these thiolsulfonates give the matastable peaks corresponding to the path from the parent ions to the fragments (J), (K) and (L), an intermediate with three-membered ring containing oxygen may be postulated. The main fragmentation scheme for these sulfonates can be depicted as shown in Scheme 4. This includes the cleavage of the S–S bond before or after the migration of one oxygen atom from the sulfone sulfur to the thiol sulfur.

The oxygen migration at the two sulfur atoms appears to be an important process in the fragmentation of diaryl thiolsulfonates. This oxygen migration is also observed in the mass spectra of diaryl thiolsulfinates but minor since the initial elimination of the oxygen is the major process in the fragmentation of thiolsulfinates. On the other hand, the elimination of oxygen atom from the sulfonate linkage is not observed. This difference between the sulfonates and the sulfinates is in good accordance with the difference in the bond strength of the S–O bonds.[9] Similar observations have also been made for the mass spectra of diphenyl sulfoxide in which deoxygenation was found to be minor but no such process was found in that of diphenyl sulfone.[6]

Formation of the thiabenzonium ion is also found in these cases. It is suggested that the formation of the thiabenzonium ion is a common phenomenon with sulfur compounds having an S–O bond adjacent to phenyl group.

The common pattern of the cleavage for these sulfur compounds *i. e.*, disulfides, thiolsulfinates and thiolsulfonates is the cleavage of the S–S bond. Cleavage involving one oxygen migration is also a common process for the sulfinates and the sulfonates.

Experimental

The spectra were recorded with a Hitachi RMU-6E single focus mass spectrometer using 80 eV at the emission

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 135—138 (1970)

Syntheses of Benzo[e]-1,3,4-triazepine Derivatives from 2-Aminobenzophenones[1)]

Takumi ISHIWAKA, Mitsuru SANO, Kakuzo ISAGAWA and Yasaburo FUSHIZAKI

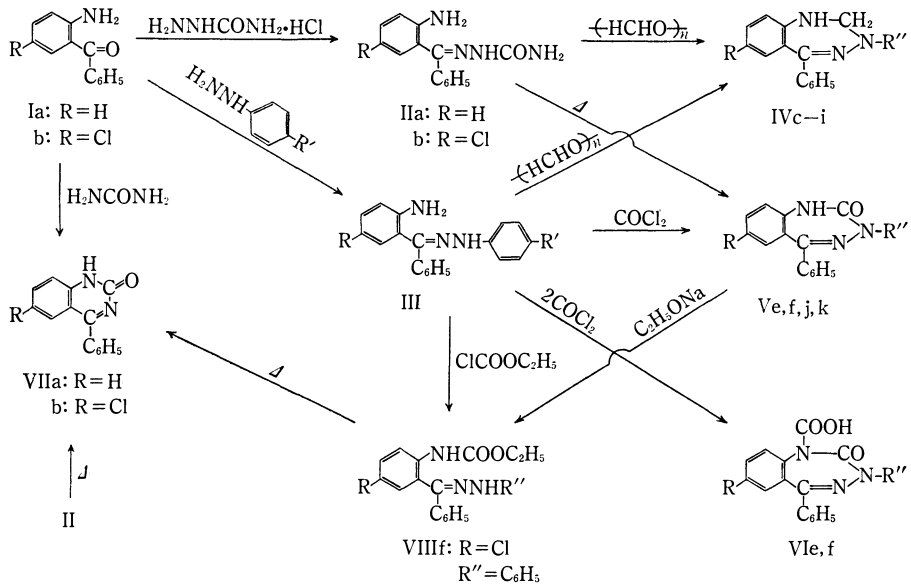
Department of Applied Chemistry, Faculty of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Received May 15, 1969)

2-Aminobenzophenone semicarbazones (II) or 2-aminobenzophenone phenylhydrazones (III) were cyclized to 3,7-disubstituted 5-phenyl-2,3-dihydro-1*H*-benzo[*e*]-1,3,4-triazepines (IV) by treating them with paraformaldehyde. On the other hand, 3,7-disubstituted 2-oxo-5-phenyl-2,3-dihydro-1*H*-benzo[*e*]-1,3,4-triazepines (V) were prepared by the fusion of II at 190—195°C or by the treatment of III with phosgene. In the latter reactions, 1-carboxy derivatives (VI) of V were obtained by using two equimolar amounts of phosgene. Vf was treated with sodium ethoxide to give a ring-cleavage product, 5-chloro-2-ethoxycarbonylaminobenzophenone phenylhydrazone (VIIIf), which was then fused to afford 6-chloro-1,2-dihydro-2-oxo-4-phenylquinazoline (VIIb).

Although some 7-substituted 2-oxo-5-phenyl-2,3-dihydro-1*H*-benzo[*e*]-1,3,4-triazepines have been prepared by Sulkowski and Childress[2,3)] in recent years, the syntheses of 3,7-disubstituted benzo[*e*]-1,3,4-triazepines and 2-oxo-benzo[*e*]-1,3,4-triazepines have never been reported. Now, this paper will report the syntheses of several new benzo[*e*]-1,3,4-triazepines and 2-oxo-benzo[*e*]-1,3,4-triazepines from 2-aminobenzophenones (I), and will describe their properties.

Compounds Ia and Ib[4,5)] were treated in the customary way with semicarbazide hydrochloride



c-k: R and R'' are shown in Table 1

or phenylhydrazines to give semicarbazones (IIa and IIb) or phenylhydrazones (III). 3,7-Disubstituted 5-phenyl-2,3-dihydro-1*H*-benzo[*e*]-1,3,4-triazepines and 3,7-disubstituted 2-oxo-5-phenyl-2,3-dihydro-1*H*-benzo[*e*]-1,3,4-triazepines were prepared according to the methods outlined below (Scheme 1).

The first method employed was the condensation of II or III with paraformaldehyde in refluxing xylene. The compounds IV shown in Table 1 were obtained by this method.

The second method was the intramolecular condensation. IIa and IIb gave 2-oxo-benzo[*e*]-1,3,4-triazepines (Vj and Vk respectively) on fusion at 190—195°C. The fusion of IIa and IIb at 230—240°C, however, did not give the 2-oxo-benzo[*e*]-1,3,4-triazepines, but instead produced the corresponding 1,2-dihydro-2-oxo-4-phenylquinazolines (VIIa) and (VIIb), which were identified by their preparation from Ia or Ib and urea.[6]

The third convenient approach was the treatment of III (R=R′=H, or R=Cl, R′=H) with phosgene according to the method of Sulkowski.[2] In this reaction, it was found that a small amount of 1-carboxy-3,5-diphenyl-2-oxo-2,3-dihydro-1*H*-benzo[*e*]-1,3,4-triazepine (VIe) along with a desired 2-oxo-benzo[*e*]-1,3,4-triazepine Ve, and the 1-carboxy-7-chloro derivative (VIf), along with Vf, were formed. By using two equimolar amounts of phosgene, the yields of VIe and VIf were increased to 16% and 30% respectively.

Several new compounds prepared in the course of this work, are summarized in Table 1.

Vf brought about a ring-cleavage reaction in the presence of sodium ethoxide to afford 5-chloro-2-ethoxycarbonylaminobenzophenone phen-

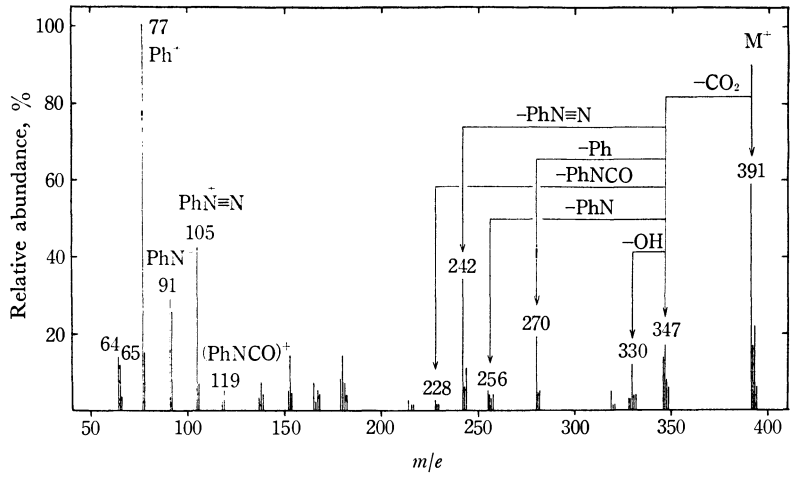

Fig. 1. Mass spectrum of VIf.

ylhydrazone (VIIIf), which was also prepared by the reaction of III (R=Cl, R'=H) with ethyl chlorocarbonate. VIIIf was heated at 170—175°C to give VIIb.

The UV, IR, and NMR data for the 2-oxo-benzo[e]-1,3,4-triazepine derivatives are shown in Table 2. By comparing the UV spectra of Ve and Vf with those of VIe and VIf, it is found that the absorption bands of VIe and VIf are situated in a region of wavelength longer than those of the corresponding Ve and Vf. The IR spectra (chloroform) of VIe and VIf showed the bands at 1785 cm^{-1} and 1650 cm^{-1} due to two carbonyl groups; the lower-frequency band can be assigned to the carbonyl group of lactam. The facts that the lactam C=O groups of both VIe and VIf appear at a lower frequency than those of Ve and Vf (KBr disk), and that the carboxylic C=O groups of VIe and VIf exist in a region of higher frequency,*1 suggest the presence of strong intramolecular hydrogen bonds in VIe and VIf. The mass spectrum of VIf is shown in Fig. 1, where the molecular ion peak is observed at *m/e* 391 (relative isotope ratio, 35.7%) and where the fragment at *m/e* 347 (relative isotop ratio, 33.7%), which corresponds to 7-chloro-2-oxo-benzo[e]-1,3,4-triazepine Vf or 7-chloro-3,5-diphenyl-2-hydroxy-benzo[e]-1,3,4-triazepine, is formed by the loss of CO_2 from the molecular ion. Furthermore, the relative abundance of the molecular ion peak is quite strong, so the molecular ion is probably more stable.

*1 Mori and his co-workers[7] discussed the intramolecular hydrogen bonds of α-hydroxy carboxylic and *o*-hydroxy benzoic acids by measuring their infrared carbonyl stretching absorption spectra. They reported that *trans*-carbonyl C=O groups of salicylic and mandelic acids could be expected at 1750 cm^{-1} and 1785 cm^{-1} respectively.

7) N. Mori, Y. Asano, T. Irie and Y. Tsuzuki, This Bulletin, **42**, 482 (1969).

Experimental

All the melting points are uncorrected. The infrared spectra were recorded with a Hitachi EPI-S2 infrared spectrophotometer. The ultraviolet spectra were obtained using a Hitachi EPS-2U recording spectrophotometer. The NMR spectra were determined on a Hitachi R-20 spectrometer, while the mass spectrum was determined with a Hitachi Model RMU-6D spectrometer.

General Method for the Preparation of Benzo-[e]-1,3,4-triazepines (IV). *i*) A solution of equimolar amounts of II and paraformaldehyde (5 mmol each) in 50 m*l* of dry xylene was refluxed for 6 hr. The reaction mixture was concentrated *in vacuo*. The residual oil was taken up in 50 m*l* of ether, the insoluble material was removed by filtration, the filtrate was evaporated to dryness *in vacuo*, and the residue was purified by recrystallization.

3-Carbamoyl-5-phenyl-2,3-dihydro-1H-benzo[e]-1,3,4-triazepine (IVc). Pale yellow needles. UV λ_{max}^{EtOH} mμ ($\varepsilon\times10^{-4}$): 229 (3.24), 299(0.88); IR(KBr): 3490, 3350, 1705 cm^{-1}.

3-Carbamoyl-7-chloro-5-phenyl-2,3-dihydro-1H-benzo[e]-1,3,4-triazepine (IVd). Pale yellow needles. UV λ_{max}^{EtOH} mμ ($\varepsilon\times10^{-4}$): 235 (2.89), 292(1.06); IR(KBr): 3430, 3280, 1695 cm^{-1}.

ii) A solution of equimolar amounts of III and paraformaldehyde (5 mmol each) in 50 m*l* of dry xylene was refluxed for 6 hr. After the solvent had then been removed, the residue was dissolved in benzene and chromatographed on silica gel with the same solvent. The first eluate (about 70 m*l*) was concentrated *in vacuo*, the residual oil was solidified by adding *n*-hexane, and the resulting crystals were purified by recrystallization.

3,5-Diphenyl-2,3-dihydro-1H-benzo[e]-1,3,4-triazepine (IVe). Yellow needles. UV λ_{max}^{EtOH} mμ ($\varepsilon\times10^{-4}$): 230(3.41), 331(1.05); IR(KBr): 3430 cm^{-1}: NMR ($CDCl_3$): δ 6.62—7.60 (m, 14H, aromatic protons), δ 5.14(s, 1H, NH), δ 4.97 ppm(s, 2H, CH_2).

7-Chloro-3,5-diphenyl-2,3-dihydro-1H-benzo[e]-1,3,4-triazepine (IVf). Yellow prisms. UV λ_{max}^{EtOH} mμ ($\varepsilon\times10^{-4}$): 233(2.95), 256^{s}(2.34), 333(0.95); IR(KBr): 3410, 1600

cm^{-1}; NMR($CDCl_3$): δ 6.70—7.69(m, 13H, aromatic protons), δ 5.05(b, 1H, NH), δ 4.92 ppm (s, 2H, CH_2).

7-Chloro-5-phenyl-3-(4-tolyl)-2,3-dihydro-1H-benzo[e]-1,3,4-triazepine (IVg). Yellow needles. UV λ_{max}^{EtOH} mμ ($\varepsilon\times10^{-4}$): 234(2.54), 255^{s}(2.21), 338(0.77); IR(KBr): 3400, 1610 cm^{-1}; NMR($CDCl_3$): δ 6.68—7.72(m, 12H, aromatic protons), δ 4.95(b, 1H, NH), δ 4.92(s, 2H, CH_2), δ 2.31 ppm (s, 3H, CH_3).

7-Chloro-3-(4-chlorophenyl)-5-phenyl-2,3-dihydro-1H-benzo-[e]-1,3,4-triazepine (IVh). Yellow needles. UV λ_{max}^{EtOH} mμ ($\varepsilon\times10^{-4}$): 232(2.06), 265(1.77), 335(0.69); IR (KBr): 3400, 1590 cm^{-1}; NMR ($CDCl_3$): δ 6.70—7.76 (m, 12H, aromatic protons), δ 5.03(b, 1H, NH), δ 4.87 ppm (s, 2H, CH_2).

7-Chloro-3-(4-ethoxycarbonylphenyl)-5-phenyl-2,3-dihydro-1H-benzo[e]-1,3,4-triazepine (IVi). Yellow needles. UV λ_{max}^{EtOH} mμ ($\varepsilon\times10^{-4}$): 236.5(1.72), 269(1.01), 336.5(1.21); IR(KBr): 3390, 1690, 1610 cm^{-1}; NMR($CDCl_3$): δ 6.72—8.12(m, 12H, aromatic protons), δ 5.13(b, 1H, NH), δ 4.99(s, 2H, CH_2), δ 4.35(q, 2H, CH_2), δ 1.38 ppm (t, 3H, CH_3).

3,5-Diphenyl-2-oxo-2,3-dihydro-1*H*-benzo[*e*]-1,3,4-triazepine (Ve). To a solution of 1.44 g (5 mmol) of III (R=R'=H) and 2 m*l* of triethylamine in 20 m*l* of benzene, a solution of 20 m*l* of benzene containing 0.50 g of phosgene (5 mmol) was stirred in, drop by drop, at 5—10°C. After having been stirred at room temperature for 2 hr, the reaction mixture was poured into water to remove the triethylamine hydrochloride. The crude product was collected by filtration; subsequent recrystallization from acetone afforded 0.20 g of Ve as yellow prisms.

A small amount of the 1-carboxy derivative (VIe) was obtained from the benzene solution by the same manner as was used in the preparation of VIe (described below).

7-Chloro-3,5-diphenyl-2-oxo-2,3-dihydro-1*H*-benzo[*e*]-1,3,4-triazepine (Vf). This compound was prepared by the same procedure as has been described for the preparation of Ve. 1.61 g (5 mmol) of III (R=Cl, R'=H) and 0.50 g of phosgene gave 0.69 g of Vf as yellow needles.

2-Oxo-5-phenyl-2,3-dihydro-1*H*-benzo[*e*]-1,3,4-triazepine (Vj). IIa (1.27 g, 5 mmol) was heated to 190—195°C for 1 hr. After cooling to room temperature, the resulting dark solid was shaken with 50 m*l* of ethanol, the insoluble material was removed, and the filtrate was taken to dryness *in vacuo*. The residue was washed with 30 m*l* of methylene chloride and recrystallized from ethanol to afford 0.24 g of Vj as pale yellow needles.

7-Chloro-2-oxo-5-phenyl-2,3-dihydro-1*H*-benzo-[*e*]-1,3,4-triazepine (Vk). IIb (1.44 g, 5 mmol) was worked up according to the procedure described for the preparation of Vj. Recrystallization from ethanol afforded 0.34 g of Vk as yellow needles.

1-Carboxy-3,5-diphenyl-2-oxo-2,3-dihydro-1*H*-benzo[*e*]-1,3,4-triazepine (VIe). To a solution of 1.44 g (5 mmol) of III (R=R'=H) in 12 m*l* of benzene containing 2 m*l* of triethylamine, 1.00 g (10 mmol) of phosgene in 20 m*l* of benzene was stirred in, drop by drop, at 5—10°C, and then the resulting solution was stirred at room temperature for an additional 2 hr. After the reaction mixture had then been washed with water and dried over anhydrous magnesium sulfate, the benzene was removed and the residue was recrystallized from a mixture of ethanol and benzene to afford 0.28 g of VIe as yellow needles.

1-Carboxy-7-chloro-2-oxo-5-phenyl-2,3-dihydro-1*H*-benzo[*e*]-1,3,4-triazepine (VIf). This compound was prepared by the same procedure as has been described for the preparation of VIe. 1.61 g (5 mmol) of III (R=Cl, R'=H) and 1.00 g (10 mmol) of phosgene gave 0.59 g of VIf as yellow needles.

1,2-Dihydro-2-oxo-4-phenylquinazoline (VIIa). IIa (0.76 g, 3 mmol) was fused at 230—240°C for 3 hr. After cooling to room temperature, the resulting solid was shaken with 50 m*l* of warm ethanol, the insoluble part was removed by filtration, and the yellow solid obtained by the evaporation of the solvent from the filtrate was recrystallized from a mixture of ethyl acetate and ethanol to afford 0.37 g of VIIa as pale yellow prisms; mp 243—245°C; yield 55%.

Found: C, 75.48; H, 4.67; N, 12.83%.

The product was identified by means of mixed-melting-point measurements and by a comparison of its UV and IR spectra with those of the sample obtained from the reaction of Ia with urea.[6]

6-Chloro-1,2-dihydro-2-oxo-4-phenylquinazoline (VIIb). 3-mmol portions of IIb and VIIIf were fused at 230—240°C and 170—175°C respectively. The resulting solid was worked up as has been described above for VIIa and recrystallized from a mixture of ethyl acetate and ethanol to afford VIIb as colorless needles; mp 256—258°C; yields, 0.28 g (36%) and 0.24 g (31%) respectively.

These products were identified by means of mixed-melting-point measurements and by a comparison of their UV and IR spectra with those of the sample obtained from the reaction of Ib with urea.

5-Chloro-2-ethoxycarbonylaminobenzophenone Phenylhydrazone (VIIIf). *i) From Vf.* Into a solution of 0.70 g (2 mmol) of Vf in 150 m*l* of ethanol, a solution of 10 m*l* of ethanol containing 50 mg (22 mmol) of sodium metal was added. After the solution had then been refluxed for 6 hr, the solvent was removed; the residual oil was solidified by adding a small amount of ethanol. The crude crystals were recrystallized from ethanol to afford 0.49 g (62%) of VIIIf as pale yellow needles; mp 174—175°C. UV λ_{max}^{EtOH} mμ ($\varepsilon\times10^{-4}$): 238(2.10), 300(0.87); IR(KBr): 3300, 3410, 1735, 1600 cm^{-1}; NMR ($CDCl_3$): δ 6.69—8.53(m, 13H, aromatic protons), δ 11.62(s, 1H, NH), δ 4.28(q, 2H, CH_2), δ 1.45 ppm(t, 3H, CH_3).

Found: C, 67.08; H, 5.13; N, 10.58%. Calcd for $C_{22}H_{20}N_3O_2Cl$: C, 67.09; H, 5.12; N, 10.67%.

ii) From III (R=Cl, R'=H). Into a solution of 1.61 g (5 mmol) of III (R=Cl, R'=H) in 30 m*l* of dry benzene containing 1 m*l* of triethylamine, a solution of 0.54 g (5 mmol) of ethyl chlorocarbonate in 20 m*l* of dry benzene was stirred in, drop by drop, at room temperature over a 30-min period. After the solution had been refluxed for 6 hr and cooled at room temperature, a benzene-insoluble solid was removed by filtration. The brownish-yellow oil which was obtained by the evaporation of the solvent from the filtrate was solidified by adding a small amount of ethanol. The crude crystals were recrystallized from ethanol to afford 1.16 g (59%) of VIIIf as pale yellow needles; mp 170—172°C.

The product was identified by means of mixed-melting-point measurements and by a comparison of its IR and NMR spectra with those of the above sample.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 139—142 (1970)

Studies on the Baudisch Reaction. II. The Copper(II)-Hydroxylamine Complex[1)]

Iwao TANIMOTO

Faculty of Home Economics, Kyoto Women's University, Higashiyama-ku, Kyoto

(Received May 16, 1969)

Kinetic investigation of the Baudisch reaction indicates that the reaction follows first-order kinetics, and the isokinetic temperature lies at −11°C. Both kinetic studies and product studies require the formation of a phenol-copper-hydroxylamine-hydrogen peroxide complex during the course of the reaction. It was found that the yield of *o*-nitrosophenol which is the main product of the Baudisch reaction is counterbalanced by that of catechol according to the pH of the reaction system. Maximum yield of *o*-nitrosophenol is attained in the lower pH region (pH=2.5—3.5). Catechol which is the main product in the higher pH region (pH>4) seems to be produced through the same complex.

Several tentative mechanisms on the Baudisch reaction—the conversion of aromatic hydrocarbons or phenols to *o*-nitrosophenol by hydrogen peroxide, hydroxylamine hydrochloride, and copper(II) ion—were submitted by several investigators,[2-4)] but they could hardly explain our findings.[1,5)] We pointed out that the marked steric effect of a methyl group occupying a position meta to the phenolic hydroxy group and the exclusive production of the ortho isomer might be the reflection of the formation of a bulky copper complex as an intermediate. In this paper, it is shown that this consideration has been further confirmed by spectroscopic and kinetic studies.

Results and Discussion

Copper(II)-Hydroxylamine Hydrochloride Complex in the Reaction Medium. In order to investigate the nature of the complex which might be produced during the course of the reaction, several experiments were undertaken. In methanol, the mixture of anhydrous copper(II) salt and hydroxylamine hydrochloride showed a characteristic absorption spectrum. The absorption maxima were at 230 and 273 mμ (Fig. 1).

A study by the molar ratio method showed that

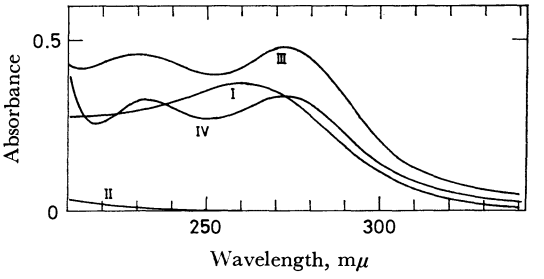

Fig. 1. Absorption spectrum of a copper-hydroxylamine hydrochloride complex in methanolic medium: I, $CuSO_4$ anhyd. (2×10^{-3}M); II, $NH_2OH\cdot HCl$ (4×10^{-3}M); III, $CuSO_4$-$NH_2OH\cdot HCl$ (1 : 2); IV, $Cu(OH)_2$-$NH_2OH\cdot HCl$ (1 : 2).

hydroxylamine hydrochloride combined with copper(II) ion in the mole ratio of 2 : 1 to form a complex species.[6)] Since a mixture of this methanolic complex solution and phenol solely produced *o*-nitrosophenol when it was treated with hydrogen peroxide, the species observed by spectroscopy seems to be a precursor of the actual complex which is produced during the course of the Baudisch reaction. The copper(II)-hydroxylamine hydrochloride complex could also be detected in aqueous medium by spectroscopy.

Kinetic Studies. Kinetic measurements for the formation of *o*-nitrosophenols from phenols were

1) Part I: K. Maruyama, I. Tanimoto and R. Gotō, *J. Org. Chem.*, **32**, 2516 (1967).

2) a) O. Baudisch, *Naturwissenschaften*, **27**, 768 (1939). b) O. Baudisch and S. H. Smith, *ibid.*, **27**, 769 (1939). c) O. Baudisch, *J. Amer. Chem. Soc.*, **63**, 622 (1941).

3) G. Cronheim, *J. Org. Chem.*, **12**, 1 (1947).

5) K. Maruyama, I. Tanimoto and R. Goto, *Tetrahedron Lett.*, **1966**, 5889.

6) A copper(II)-hydroxylamine complex $CuSO_4$-$2NH_2OH$ reported by M. Adams and E. Overman (*J. Amer. Chem. Soc.*, **31**, 637 (1909)) is insoluble in methanol and different from the complex described here. However, the insoluble complex also reacted with phenol and hydrogen peroxide in the acidic medium to give *o*-nitrosophenol. It seems likely that the active complex involved in the Baudisch reaction is a protonated species.

TABLE 1. KINETIC DATA FOR THE BAUDISCH REACTION[a)]

a) All reactions were conducted under nitrogen atmosphere. Phenol (1×10^{-2} mol), copper (II) nitrate (1×10^{-2} mol) and hydroxylamine hydro chloride (2×10^{-2} mol) were stirred in 198 m*l* of a Walpole buffer (pH 2.50) after the addition of a hydrogen peroxide solution (30%) (2 m*l*). The temperature was controlled within ±0.1°C.
b) The entropy of activation was calculated at 10.0°C.
c) The reaction was conducted at 0.4°C.
d) The reaction was conducted at 10.3°C.

carried out. Phenol, *o*-, *m*- and *p*-cresols, *o*-, *m*- and *p*-chlorophenols, 2,5- and 3,5-xylenols were studied. The concentration of phenol at any time was assumed to be given by the difference between its initial concentration and the concentration of the product. The experimental kinetic plots gave first-order kinetics in the phenols in spite of the fact that other reactants, *i. e.* copper(II) salt, hydroxylamine hydrochloride and hydrogen peroxide, were not contained in a very large excess over the phenols in the reaction system; a logarithmic plot of the data gave a straight line from 15 min to 90 min after the reaction started. Therefore, the following reaction steps are compatible with the kinetics if we assume that steps 1 and 2 proceed fast enough to produce complex I and the conversion of complex I in step 3 is a slow rate-determining

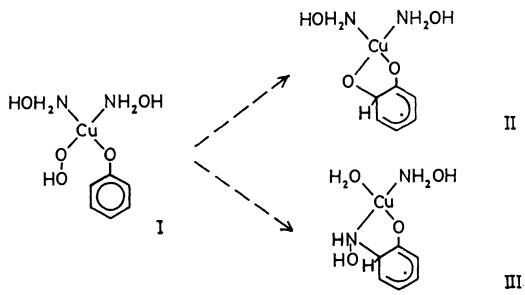
$$Cu^{2+} + \text{Phenol} \xrightarrow{\text{fast}} \text{Cu-Phenolate} \quad (1)$$

$$\text{Cu-Phenolate} + x\text{NH}_2\text{OH} + \text{H}_2\text{O}_2 \xrightarrow{\text{fast}} \text{Complex I} \quad (2)$$

$$\text{Complex I} \xrightarrow{\text{solw}} \cdots \longrightarrow o\text{-Nitrosophenol} \quad (3)$$

step, because in such a case the limiting factor in determining the concentration of complex I is the amount of phenol. At present, the details of the reaction steps from complex I to *o*-nitrosophenol are not known, but the thermodynamic quantities for the reactions seem to give an important clue to this point.

In Table 1, first-order rate constants have been tabulated together with the thermodynamic quantities of the reactions. The negative values of $\Delta S^{\neq}$ for all of the reactions studied suggest that the reactions require a highly ordered arrangement of atoms in the transition state. In fact, the large negative value of $\Delta S^{\neq}$ for the reaction of phenol may be explained if one assumes the ring-closure process to form cyclic complex II or III from a



copper-hydroxylamine-phenolate complex I. The reaction pathway from complex I to complex II or III is not known as yet, but radical nature of attack may be assumed[7)] in spite of the fact that the activation energies suggest somewhat electrophilic attack on the aromatic ring (see Table 1). However, as can be seen from Table 1, the reactions are predominantly controlled by entropy

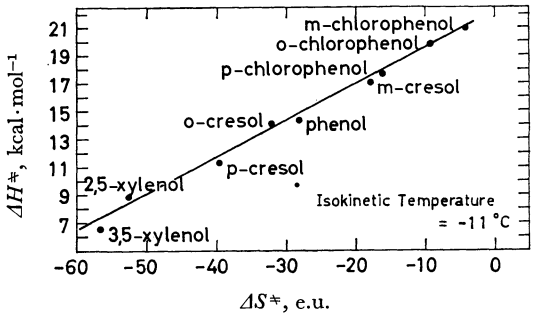


Fig.2. Isokinetic plot for the Baudisch reaction of phenols in aqueous medium. The enthalpy of activation was calculated from energy of activation by subtracting 0.6 kcal·mol^{-1}.

7) J. K. Kochi, *J. Amer. Chem. Soc.*, **84**, 774 (1962); *ibid.*, **85**, 1958 (1963).

factor, *viz.*, the reaction of highest energy of activation has the highest rate of reaction. A plot between enthalpy of activation and entropy of activation is sufficiently linear (Fig. 2). The existence of the linear relationship indicates a constant mechanism for the related series of reactions. The isokinetic temperature calculated by the method of least squares was -11°C. Thus, near room temperature, the Baudisch reaction is conducted in the region in which the entropy of activation is a commanding factor.

The Catechol Production. From preliminary experiments, it was found that the yield of *o*-nitrosophenol is seriously affected by pH values of the system. Therefore, the identification of other reaction products was attempted and the effect of pH on the yield of the products was investigated. In 1955, Brackman and Havinga investigated the oxidation of phenol under conditions identical with the Baudisch conditions, but they failed to find *o*-nitrosophenol and catechol.[8] However, even in the Baudisch system, phenol was converted predominantly to catechol in the pH region higher than 4.0 (Fig. 3). On the other hand, neither catechol nor hydroquinone were found under the optimum conditions for *o*-nitrosophenol formation (pH=2.5—3.5). Catechol and hydroquinone were found in the molar ratio of 1.8 at pH 5.5 where no *o*-nitrosophenol was produced. The absence of resorcinol in the reaction products was confirmed by thin layer chromatography. Since the selective formation of ortho isomer is not generally observed when a free hydroxy radical is responsible for the hydroxylation of phenol,[9,10] the predominant formation of catechol under the Baudisch conditions will be due to a copper(II)-hydroxylamine-hydrogen peroxide-phenol complex I. Furthermore, yield of catechol much higher than that formed by the reaction of phenol with simple copper(II) ion and hydrogen peroxide was observed under the Baudisch conditions (Fig. 3). This fact indicates that the production of catechol from phenol was much promoted by the formation of complex I.

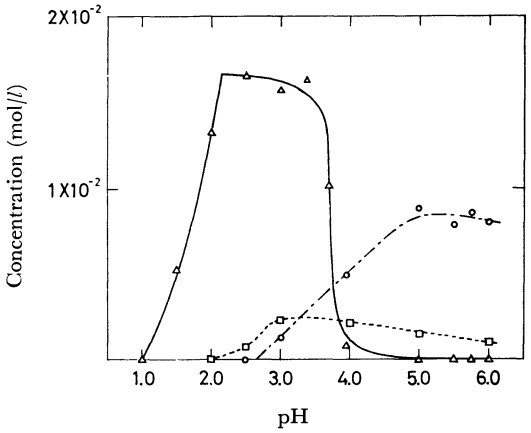

Fig. 3. pH dependence of the formation of *o*-nitrosophenol and catechol from phenol: (—△—) *o*-nitrosophenol; (---○---) catechol, under the Baudisch conditions; (—□—) catechol, by copper(II) nitrate and hydrogen peroxide. All of the reactions were conducted at 30°C for 30 min under a nitrogen atmosphere. The maximum concentration of catechol produced the Baudisch reaction may be comparable with that of *o*-nitrosophenol, because our estimation of catechol may be slightly low owing to the limited extraction of catechol.

At pH 5.5, coppper(II) nitrate was reduced to a brownish white precipitate in the aqueous mixture of phenol and hydroxylamine hydrochloride and had no ability to achieve *o*-nitrosation. However, the mixture retained the ability for catechol production. Even if the pH of the mixture was brought again to pH 2.5, the ability to achieve *o*-nitrosation was not restored. The results indicate that a reduced form of the copper complex has no ability to achieve *o*-nitrosation of phenol, but is responsible for *o*-hydroxylation.

It seems most likely that the complex which is responsible for the formation of catechol is essentially the same as that responsible for the formation of *o*-nitrosophenol. However, in the higher pH region, the copper in the complex is reduced and catalyzes *o*-hydroxylation only. In the lower pH region, the reducing power of hydroxylamine is probably suppressed by the protonation and copper(II)—indispensable for the *o*-nitrosation of phenol—is retained in the reaction system.

Experimental

Materials. *m*- and *p*-Cresols were purified according to the method of Brückner,[11] the boiling point of *m*-cresol was 202°C (lit, 202.2°C) and that of *p*-cresol was 201°C (lit, 202.5°C). *m*- and *p*-Chlorophenols were purified *via* their benzoates, as in the case of phenol.[12] The benzoate of *m*-chlorophenol (mp 69—70.5°C, lit, 71°C) and the benzoate of *p*-chlorophenol (mp 85—86°C, lit, 87—88°C) were hydrolyzed to the phenols, and the phenols were used after distillation. Copper(II) hydroxide was prepared according to literature.[13] Reagent grade 30% hydrogen peroxide solution was obtained from Mitsubishi Chemical Co. and iodometric titration showed that the concentration was 10.2 M. Other

reagents were reagent grade and, if necessary, were used after further purification. Silica gel G (Merck, according to Stahl) was used as an absorbent in thin layer chromatography.

Spectrophotometry. The ultraviolet spectrum of copper(II) sulfate solution (2×10^{-3}M) or hydroxylamine hydrochloride solution (4×10^{-3}M) was determined using 1 mm quartz cell with a recording spectrophotometer.

To prepare stock copper(II)-hydroxylamine hydrochloride complex solution, anhydrous copper(II) sulfate (0.160 g, 1×10^{-3} mol) or copper(II) hydroxide (0.0976 g, 1×10^{-3} mol) was dissolved in a small amount of concentrated methanolic solution containing 0.138 g (2×10^{-3} mol) of hydroxylamine hydrochloride and the resulting mixture was diluted to 10 m*l* with methanol. After the stock solution was diluted 50-fold determination of its ultraviolet spectrum was carried out.

Determination of *o*-Nitrosophenol. General procedures for the Baudisch reaction and the determination of *o*-nitrosophenol produced were described previously.[1]

Kinetic Studies. The general procedure for the Baudisch reaction described previously[1] was used under conditions controlled by a Walpole buffer (pH 2.5). Determination of *o*-nitrosophenols was carried out at intervals of 20 min.

Determination of Catechol. Copper(II) nitrate trihydrate (1.208 g, 5×10^{-3} mol) and phenol (0.471 g, 5×10^{-3} mol) were dissolved in 100 m*l* of a suitable Walpole buffer or an acetic acid-sodium acetate buffer. After the mixture was stirred with 1 m*l* of 30% hydrogen peroxide solution for 30 min at 30°C under nitrogen atmosphere, 20 m*l* of the reaction mixture was pipetted out and acidified with 2 m*l* of concentrated hydrochloric acid. The acidified solution was extracted with 20 m*l* of ether and the twice each with 5 m*l* of the same solvent. After being washed with water, all of the extract was extracted with 10 m*l* of aqueous 5% sodium hydroxide and then with 5 m*l* of the solution. The aqueous extracts were brought together and acidified with 1N hydrochloric acid and diluted to 100 m*l*. Catechol was determined spectroscopically according to the method of Willard and Wooten.[14] In the reactions under the conditions of the Baudisch reaction, hydroxylamine hydrochloride (0.695 g, 1×10^{-2} mol) was added to the above reaction mixture just before the addition of hydrogen peroxide.

Ratio of Catechol to Hydroquinone. The ethereal extract (50 m*l*) from 50 m*l* of the reaction mixture was evaporated to about 10 m*l* and submitted to thin layer chromatography. The unidimensional ascending technique was employed in a benzene-methyl ethyl ketone-2% aqueous formic acid (90 : 10 : 10) system. When the solvent front was allowed to ascend about 15 cm, the plate was dried and run in the same solvent again. After the plate was dried, Folin-Ciocalteu reagent[15] was sprayed on it and the blue spots due to catechol and hydroquinone were scraped separately into small beakers. To each of the beakers 2.5% potassium dihydrogen phosphate solution (2 m*l*) was added[9] and then 1 m*l* of Folin-Ciocalteu reagent. The dark green solution was filtered using sintered glassfilters and each of the filtrates, together with washings, was diluted to 10 m*l* with water. The intensity was then measured at 520 mμ after the sample solution was kept at 35°C for 30 min.

The work was supported in part by a Research Grant from Kyoto Women's University. The author wishes to express his gratitude to Professor Kazuhiro Maruyama, Kyoto University, for his stimulating suggestions and discussions. Studies on Interactions of Isocyanides with Transition Metal Complexes. IV.*1 Dicarbonyl(isocyanide)-π-cyclopentadienylacylmolybdenum*2

Yasuhiro YAMAMOTO and Hiroshi YAMAZAKI

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received May 23, 1969)

Isocyanides were treated with π-$C_5H_5Mo(CO)_3R$ (R=CH_3, CH_2Ph) in benzene at room temperature to give π-$C_5H_5Mo(CO)_2$(isocyanide)COR (A), which exist as a *trans*-isomer in the solid state and as a mixture of *trans*- and *cis*-isomers in solutions, based on the NMR spectra. The structures of the compounds (A) are discussed on the basis of the spectroscopic studies. Studies on *trans* to *cis* isomerization were also carried out kinetically.

In the previous paper, we have reported that isocyanides insert into the alkylnickel sigma bonds of triphenylphosphine-π-cyclopentadienylalkylnickel to give π-cyclopentadienyl(isocyanide) alkylalkyliminomethylnickel.[1] In the course of our studies on this series,[2,3] we obtained dicarbonyl(isocyanide)-π-cyclopentadienylacylmolybdenum as a mixture of *cis*- and *trans*- isomers in solutions by the reactions of isocyanides with tricarbonyl-π-cyclopentadienylalkylmolybdenum.

Reactions of tricarbonyl-π-cyclopentadienylalkylmolybdenum with phosphorus ligands have been studied under a variety of conditions to give dicarbonyl(phosphorus ligand)-π-cyclopentadienylacylmolybdenum.[4,5] These monosubstituted compounds, π-$C_5H_5Mo(CO)_2(PR_3)COR$, can be expected to exist as *cis*- and *trans*- isomers. However, the structures of the resultant complexes have consisted solely of the *trans*-isomer, and existence of a *cis*-isomer has not been known as yet.

We wish to report the isomerism between *cis*- and *trans*-dicarbonyl (isocyanide)-π-cyclopentadienylacylmolybdenum, and their temperature- and time-dependent phenomena.

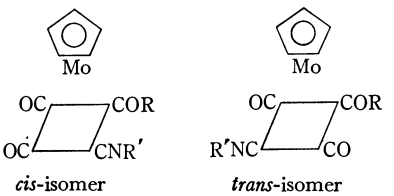
Results and Discussion

Preparation and Identification of π-$C_5H_5Mo(CO)_2(CNR')COR$. Treatment of *t*-butyl isocyanide with tricarbonyl-π-cyclopentadienylmethylmolybdenum, π-$C_5H_5Mo(CO)_3CH_3$, in benzene at room temperature gave yellow crystals **1**, which were soluble in most organic solvents and stable to air in the solid state. Compound **1** was formulated as π-$C_5H_5Mo(CO)_3(CNC(CH_3)_3)CH_3$, based on the elementary analysis. The structure was characterized by spectroscopic study and chemical reaction. The infrared spectrum showed four bands at 2140, 1962, 1880 and 1615 cm^{-1}; the first band was attributable to a terminal isocyanide group, the last band to a ketonic carbonyl group and the other two bands to the terminal carbonyl groups. The reaction of *t*-butyl isocyanide with π-$C_5H_5Mo(CO)_2(PPh_3)COCH_3$ also gave compound **1**. It was concluded from the results that compound **1** was π-$C_5H_5Mo(CO)_2(CNC(CH_3)_3)COCH_3$. The NMR spectrum showed two signals for each of cyclopentadienyl, isocyanide and acyl protons, suggesting the existence of two isomers, *cis*- and *trans*-isomers, which were depicted as follows.

The reaction with 2,6-dimethylphenyl isocyanide gave a similar complex, π-$C_5H_5Mo(CO)_2(C_9H_9N)COCH_3$ **2**. π-$C_5H_5Mo(CO)_3CH_2Ph$ was allowed to react with *t*-butyl isocyanide to give π-$C_5H_5Mo(CO)_2(CNC(CH_3)_3)COCH_2Ph$ **3** which were shown to exist as a mixture of *cis*- and *trans*-isomers in solutions by NMR spectrum. The complexes prepared here are summarized in Tables 1 and 2.

It should be noted that the benzylic methylene



cis-isomer *trans*-isomer

protons of the isomer (a) in C_6D_6, as shown in Fig. 1, consist of two relatively sharp resonances of equal intensity separated by 4.2 cps, suggesting the magnetic nonequivalence of methylene protons of the isomer (a).

The origin of the magnetic nonequivalence has been the subject of several investigations.[6,7] Two reasons may be generally considered for the origin of magnetic nonequivalence of the methylene protons: (1) the restricted rotation of the methylene and (2) the existence of an asymmetric moiety adjacent to the methylene. In both cases, the protons of a methylene group display AB-type nuclear magnetic resonance spectra.[6]

Thus, if the phenylacetyl group is in *cis* position to a *t*-butyl isocyanide ligand in the complex **3**, the *cis*-isomer will be more sterically inhibited than the *trans*-isomer. Furthermore, there is no plane of symmetry in the *cis*-isomer.

It is reasonable to conclude that the isomer (a) is assigned to a *cis*-isomer and the isomer (b) to a *trans*-isomer.

The only two central peaks of the AB quartet were

−10	77	23	68	32

observed in the NMR spectrum of the benzyl protons of the *cis*-isomer, because of large $J_{AB}/\delta_B-\delta_A$ value and also of low concentration of the *cis*-isomer. In this assignment the cyclopentadienyl proton resonance of a *cis*-isomer exists in the lower field than that of a *trans*-isomer.

In an attempt to examine the structures of the complexes **1**, **2**, and **3** in the solid state, the crystalline samples of the complexes are dissolved in deuteriochloroform at −50°C and NMR spectra were recorded at this temperature. Only the *trans*-isomer was present in the solutions. When the solutions were allowed to reach room temperature, the growth of the cyclopentadienyl resonance due to the *cis*-isomer could be observed. It seems reasonable to assume that in the crystalline state these complexes exist only as the *trans*-isomer.

Trans-structures of the complexes **1**, **2**, and **3** in the solid state were also supported by infrared spectra. It is known that stereochemistry of the monosubstituted compounds π-$C_5H_5Mo(CO)_2LX$ (L=phosphorus ligands, X=alkyl, acyl, halogen) is assigned from the optical densities, D_a and D_s, of the asymmetric and symmetric CO stretching vibrations.[8,9] The application of this rule to the complexes **1**, **2**, and **3** suggests that they are *trans*-forms.

Temperature- and Time-dependent Phenomena in the Isomerism of Dicarbonyl(isocyanide)-π-cyclopentadienylacylmolybdenum. The compounds **1**, **2**, and **3** were found to exist as the *trans*-isomer in the solid state, and as a mixture of *cis*- and *trans*-isomers in solutions. The final equilibrium position scarcely depends on solvents, and the equiliblium mixtures of *cis*- and *trans*-π-$C_5H_5Mo(CO)_2(CNR')COR$ in a variety of solvents contained *ca.* 65% of the *trans*-isomer, as shown in Table 3.

The temperature-dependence of equilibrium positions was also observed. Thus, the concentration of the *trans*-isomer increased with lowering temperature, as shown in Table 4.

The *trans* to *cis* isomerization was briefly studied kinetically and found to proceed at a conveniently measurable rate of −3—−10°C in $CDCl_3$, although it was impossible to measure the isomerization rate at room temperature.

Kinetic study showed that the reactions were first-order in the *trans*-isomer, because there was a very small change in the rate constant accompanying an almost fivefold change in concentration, as shown in Table 5. Added *t*-butyl isocyanide did not depress the rate, and this may suggest that isomerization was not responsible for the dissociative mechanism, such as had been observed in the *cis* to *trans* isomerization of $Mn(CO)_3(P(OPh)_3)_2Br$.[10] Detailed kinetic studies will be reported later.

TABLE 5. RATES OF ISOMERIZATION OF *trans* TO *cis*-π-$C_5H_5Mo(CO)_2(CNC(CH_3)_3)COR$ IN $CDCl_3$

R	°C	mol/ml(10^4)	$k(10^3)$
CH_2Ph	−3	1.67	37.7
CH_2Ph	−10	1.70	15.0
CH_3	−3	1.97	40.6
CH_3	−3	9.30	39.8
CH_3	−10	1.49	16.9
CH_3	−10	7.47	16.7

Origin of Magnetic Nonequivalence of Methylene Protons in π-$C_5H_5Mo(CO)_2(CNC(CH_3)_3)COCH_2Ph$. In an attempt to resolve whether the restricted rotation or the existence of a molecular asymmetric center is responsible for the magnetic nonequivalence of the methylene protons in the *cis*-isomer, studies on the temperature dependence of complex **3** were carried out in various solvents.

At 23°C the *cis*-isomer has a relatively broad peak at 6.09τ in the proton NMR spectrum in CS_2, which is attributable to the methylene protons. On lowering of temperature this became a little broad band and was split into doublet at −9°C. When the solution was chilled to −50°C, the absorption

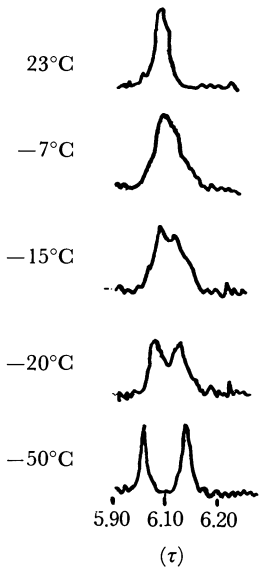

Fig. 2. Temperature dependence of the methylene protons of *cis*-π-$C_5H_5Mo(CO)_2(CNC(CH_3)_3)COCH_2Ph$ in CS_2.

at 6.09τ was split into two relatively sharp signals at 6.06 and 6.14τ, in an approximate relative intensity 1:1, as shown in Fig. 2.

The average position of two new peaks at −50°C is found quite near the original peak at 23°C.

In the proton NMR spectrum in C_6D_6, the methylene proton resonance of the *cis*-isomer at room temperature appeared as two peaks at 5.70 and 5.62τ. They became relatively broad with rise of temperature, and at 65°C the spectrum consisted of one single broad peak, as shown in Fig. 3. An attempt to measure the spectra at higher temperatures was unsuccessful, because of decomposition

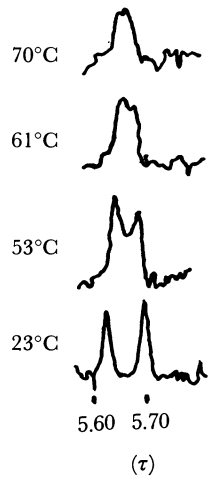

Fig. 3. Temperature dependence of the methylene protons of *cis*-π-$C_5H_5Mo(CO)_2(CNC(CH_3)_3)COCH_2Ph$ in C_6D_6.

of complex **3**. Accordingly, we could not observe a sharp singlet resonance which might be derived from rapid rotation of the phenyl acetyl group.

Although we cannot rule out response for the magnetic nonequivalence arising from the existence of the asymmetric center, it seems more reasonable to assume that the steric inhibition of free rotation of the phenyl acetyl group causes the methylene group to be magnetically nonequivalent.

Decarbonylation of π-$C_5H_5Mo(CO)_2(CNC(CH_3)_3)COCH_2Ph$ (3). Decarbonylation of complex **3** was briefly studied. With ultraviolet irradiation in benzene, evolution of carbon monoxide occurred to give complex **4**, π-$C_5H_5Mo(CO)_2(CNC(CH_3)_3)CH_2Ph$ characterized by the absence of an acyl carbonyl band from the infrared spectrum. Contrary to expectation, there was no evidence for the existence of the isomers. Thus, the NMR spectrum in CS_2 showed four signals at 8.51 (singlet, 9H, $(CH_3)_3C$) 7.16 (singlet, 2H, CH_2), 4.91 (singlet, 5H, C_5H_5) and 3.00τ (singlet, 5H, C_6H_5).

In an attempt to confirm the structure of complex **4**, the NMR spectrum in lower temperatures was studied.

The spectrum at −60°C gave rise to only a minor change as compared to the room-temperature spectrum. Difference in each chemical shift was observed.

If complex **4** is a *cis*-isomer, the benzylic methylene protons are expected to be magnetically nonequivalent as has been observed in complex **3**. No line splitting suggests that **4** is a *trans*-isomer. The relative intensities of the terminal carbonyl bands in the infrared spectrum also suggests *trans*-forms for **4**.

In the decarbonylation mechanism of acylmanganese carbonyl derivatives, it is known that the acyl CO becomes coordinated and a coordinated CO is eliminated.[11] If decarbonylation reaction of π-$C_5H_5Mo(CO)_2(CNC(CH_3)_3)COCH_2Ph$ proceeds through a similar mechanism, decarbonylation from the *cis*-isomer will preferentially proceed. However, there is no evidence that the *cis*-isomer is the first decarbonylation product, and since it is not isomerized subsequently to the *trans*-isomer, its mechanism remains undecided at present.

Experimental

Reactions were carried out under a nitrogen atmosphere. All melting points are uncorrected. The infrared spectra were obtained by a Perkin-Elmer 521 spectrometer. The NMR spectra were recorded by a Varian Model A-60 instrument, using tetramethylsilane as an internal standard.

Materials. Various isocyanides[12] and tricarbonyl-

11) For example: R. J. Mawby, F. Basolo and R. G. Pearson, *J. Amer. Chem. Soc.*, **86**, 5043 (1964).

12) I. Ugi and R. Meyer, *Chem. Ber.*, **93**, 239 (1960).

π-cyclopentadienylalkylmolybdenum[13] were prepared according to the procedures in literatures.

Reaction of Tricarbonyl-π-cyclopentadienylbenzylmolybdenum with *t*-Butyl Isocyanide. *t*-Butyl isocyanide (0.26 g) in benzene (5 m*l*) was added dropwise to a stirred solution of tricarbonyl-π-cyclopentadienylbenzylmolybdenum (1.0 g) in benzene (15 m*l*). After 9 hr at room temperature, the reaction mixture was evaporated to about 5 m*l* under reduced pressure and chromatographed on alumina, benzene being used as eluant. The orange yellow fraction was collected, and the solvent was evaporated almost to dryness. Recrystallization from THF-*n*-hexane gave π-$C_5H_5Mo(CO)_2$-$(CNC(CH_3)_3)COCH_2Ph$ (0.69 g, 57.5%).

The reactions of tricarbonyl-π-cyclopentadienylalkylmolybdenum with isocyanides were also carried out by the same procedures described above to give the corresponding dicarbonyl-π-cyclopentadienyl(isocyanide)acylmolybdenum.

Reaction of Dicarbonyl-π-cyclopentadienyl(triphenylphosphine)acetylmolybdenum with *t*-Butyl Isocyanide. *t*-Butyl isocyanide (0.3 g) in benzene (5 m*l*) was added dropwise to a solution of π-C_5H_5Mo-$(CO)_2(PPh_3)COCH_3$ (0.52 g) in benzene (15 m*l*). After 9 hr, the reaction mixture was evaporated to about 5 m*l* under reduced pressure and chromatographed on alumina, benzene being used as eluant. The yellow fraction was collected and solvent was evaporated almost to dryness. Recrystallization from benzene - *n*-hexane gave π-$C_5H_5Mo(CO)_2(CNC(CH_3)_3)COCH_3$ (0.16 g 48%).

Decarbonylation of π-$C_5H_5Mo(CO)_2(CNC(CH_3)_3)$-$COCH_2Ph$(3). Compound **1**(1.6 g) in THF (25 m*l*) was irradiated with ultraviolet light at room temperature. After 30 hr, the reaction mixture was evaporated to about 10 m*l* under reduced pressure and chromatographed on alumina, using benzene as eluant. Evaporation of the yellow fraction and recrystallization of the residue from *n*-hexane - benzene gave π-$C_5H_5Mo(CO)_2$-$(CNC(CH_3)_3)CH_2Ph$ (0.43 g, 25%, mp 68—72°C). Found: C, 58.46; H, 5.56; N, 3.85%. Calcd for $C_{19}H_{21}NO_2Mo$: C, 58.32; H, 5.54; N, 3.58%.

Determination of Rates of Isomerization. *trans* to *cis* isomerization was determined by following the appearance of cyclopentadienyl protons resonance of the *cis*-isomer. For rate studies of the isomerization of *trans*-π-$C_5H_5Mo(CO)_2$(isocyanide)COR, the solid complex was dissolved in $CDCl_3$ at −50°C and its rate of isomerization was followed in the desired temperature. Approximately 2 min was allowed for the system to attain the measured temperature. Typical changes in spectra with time are shown in Fig. 4. The spectrum at $t=0$ min is that of *trans*-π-$C_5H_5Mo(CO)_2$(isocyanide)-COR, and at $t=\infty$ that of the equilibrium position. First-order rate constants were obtained from the slope of plots of $\ln(A-A_\infty)$ *vs.* t, time, where A is a magnitude of the *trans*-complex at time t. A_∞ is *trans*-content in the equilibrium position.

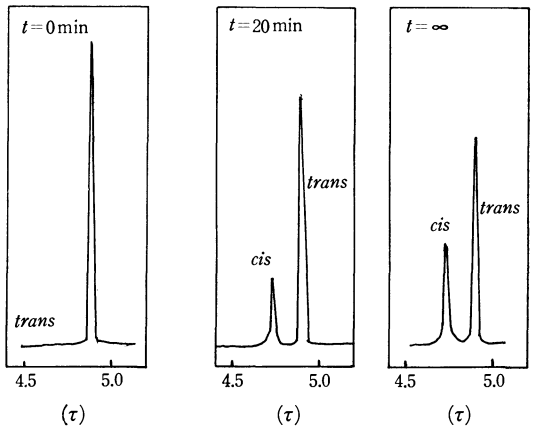

Fig. 4. NMR spectra during the isomerization of *trans*-π-$C_5H_5Mo(CO)_2(CNC(CH_3)_3)COCH_2Ph$ in $CDCl_3$ at −10°C.

Anionic Copolymerization of Butadiene and 1,1-Diphenylethylene

Heimei Yuki and Yoshio Okamoto

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received June 6, 1969)

The anionic copolymerization of butadiene (M_1) and 1,1-diphenylethylene was investigated in tetrahydrofuran (THF) and benzene, using *n*-butyllithium (*n*-BuLi), Na-naphthalene, and Na- and K-dispersions as initiators. An alternating copolymer was formed in THF, where the reaction proceeded without termination and chain-transfer reactions. The monomer reactivity ratios, r_1, were 0.13 (Li^+), 0.09 (Na^+), and 0.09 (K^+) in THF at 0°C. The r_1 values in benzene at 40°C were 54 (Li^+), 0.71 (Na^+), and 0.10 (K^+). The order of rate constants in THF was $k_{12}>k_{11}>k_{21}$; the last of these was $0.27 M^{-1} sec^{-1}$, with *n*-BuLi at 0°C.

In a preceeding paper,[1] the anionic copolymerization of isoprene (M_1) and 1,1-diphenylethylene (M_2) was reported. In the present work, the anionic copolymerization of butadiene (M_1) and 1,1-diphenylethylene (M_2) was investigated. The results obtained were similar to those of the copolymerization reported in the preceeding paper.

Experimental

Materials. Butadiene (Phillips, polymerization grade) which had been dried over Molecular Sieves was mixed with solvent-free *n*-BuLi just before use; it was then redistilled into a glass ampoule *in vacuo*.

The methods of preparing and purifying the other materials, such as 1,1-diphenylethylene, THF, benzene, and *n*-BuLi, were described in the preceeding paper.[1] The Na- and K-dispersions were prepared in *n*-heptane.

Polymerization. The purified butadiene was first transferred into a known amount of a solvent on a vacuum line, and then the mixture kept under a vacuum was weighed to determine the amount of the monomer transferred. All the mixture was then distilled under a high vacuum into a large amount of the solvent. The solution thus obtained was transferred to glass ampoules with a hypodermic syringe under dry argon. To the ampoules, 1,1-diphenylethylene and initiator were added with syringes. After a given reaction period, the polymerization was terminated by adding a small portion of methanol. The polymer was precipitated in methanol and then filtrated, dried, and weighed. The mother liquor of the polymer precipitation was evaporated at a reduced pressure; the unchanged 1,1-diphenylethylene was thus recovered as a residue. The refractive index and the infrared spectrum of the residue were very similar to those of 1,1-diphenylethylene, indicating that the residue contained a small amount of a compound of a low molecular weight, a compound which was formed by a side reaction.

Electronic Spectrum. The electronic spectrum was taken with a Hitachi 124 Spectrophotometer.

NMR Spectrum. The spectrum of the polymer was measured on a JNM-4H-100 Spectrometer at 100 MHz in a carbon tetrachloride solution at 60°C, using tetramethylsilane as the internal standard.

Molecular Weight. The molecular weight of the polymer was measured in benzene at 37°C with a Mechrolab Vapor Pressure Osmometer, Model 301A.

Viscosity. The solution viscosity of the polymer was taken in toluene at 30.0°C, the concentration of the polymer being 0.5 g/dl.

Results

The rate of the copolymerization of butadiene (M_1) and 1,1-diphenylethylene (M_2) was investigated in THF at 0°C with *n*-BuLi. Figure 1 shows the results. The reaction was completed in 60 min, by which time almost all the butadiene had been consumed. The yield for the alternating copolymerization, which forms a copolymer, $-(M_1M_2)_n-$, is also shown in Fig. 1. This yield reached nearly 100%, indicating that an alternating copolymer was formed.[1] A linear relationship was obtained between the polymer yield (curve B in Fig. 1) and the molecular weight of the polymer, as is shown in Fig. 2. The molecular weight measured nearly agreed with the one calculated for the living polymer system, which proceeds alternatingly. There was also a good linearity between log yield and $\log[\eta]$. The relationship between the average molecular weight and intrinsic viscosity was $[\eta]=4.0\times10^{-4}M^{0.60}$ (in toluene at 30°C).

The copolymerizations in THF and in benzene were carried out by using *n*-BuLi, Na-naphthalene, Na- and K-dispersions. All of the copolymers were powders with a softening point of *ca.* 130°C, except for the viscous copolymer obtained in benzene by *n*-BuLi. The copolymer composition, $[m_1]/[m_2]$, was calculated from the polymer yield, as the butadiene was completely incorporated into the copolymer. Some of the results are shown in Table 1. The composition was checked by

elementary analysis and NMR spectroscopy. The results are listed in Table 2. The data supported the composition shown in Table 1. The monomer reactivity ratio, r_1, was calculated by means of the integrated Mayo-Lewis copolymer composition equation.[2] The r_1 values are shown in Tables 3 and 4. In THF at 0°C, the values were almost constant, regardless of the initiators used. Although it has been shown that $NaB(Ph)_4$ depresses the dissociation of an ion to free ions,[3] the r_1 value was not affected by the presence of $NaB(Ph)_4$ in the copolymerization initiated by Na-naphthalene in THF. In benzene at 40°C, however, the values were 54, 0.71, and 0.10 with *n*-BuLi, Na-, and K-dispersions respectively. The copolymerization carried out in benzene without an initiator gave

no polymer, even after 187 hr at 40°C (Table 3). With Li^+ as a counter ion, the r_1 value was strongly influenced by the solvent; with Na^+ and K^+, less influence of the solvent was observed (Table 4).

The microstructures of butadiene in the homopolymer and in the alternating copolymer were investigated by NMR spectroscopy. Figure 3 shows the spectrum of the alternating copolymer obtained with *n*-BuLi in THF. The polybutadiene obtained by *n*-BuLi in THF had 82% 1,2- and 18% 1,4-structures, while the alternating copolymer had 30% 1,2- and 70% 1,4-structures.

The copolymerization in THF at 0°C was followed spectrophotometrically. As soon as *n*-BuLi was added to a monomer solution at $[M_1]_0/[M_2]_0=0.53$, an absorption maximum due to a diphenylethylene anion appeared at 496 mμ. Its optical density had been almost constant for 5 hr,

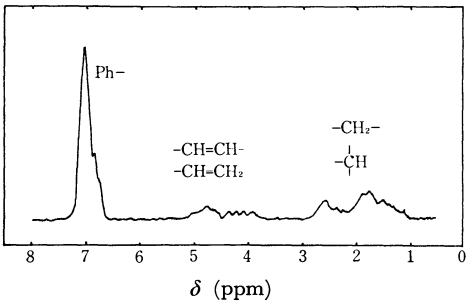

Fig. 3. NMR spectrum of the alternating copolymer of butadiene and 1,1-diphenylethylene. (in CCl_4 at 60°C)

in which time the polymerization had been completed. The molar extinction coefficient was 1.7×10^4; this agrees the value found in the copolymerization of isoprene and 1,1-diphenylethylene.[1)] These results suggest that almost all of the living ends in the system were 1,1-diphenylethylene anions.

Discussion

The results of the copolymerization investigated in this work were very similar to those found in the copolymerization of isoprene and 1,1-diphenylethylene.[1)] Both the copolymerizations in THF proceeded in living systems to give alternating copolymers, and all the r_1 values determined under the same reaction conditions were very similar. The rate of the consumption of butadiene was first-order with respect to its own concentration, as is shown in Fig. 4; this figure was obtained by analyzing the results in Fig. 1. This means that the reverse reaction between the 1,1-diphenylethylene anion and butadiene can be disregarded.[1)]

$$\sim\sim M_2^- + M_1 \underset{k_{-21}}{\overset{k_{21}}{\rightleftarrows}} \sim\sim M_1^-$$

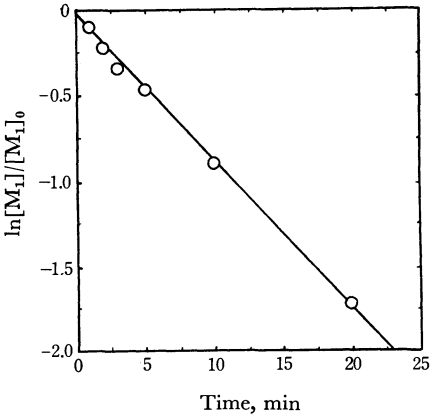

Fig. 4. Anionic copolymerization of butadiene (M_1) and 1,1-diphenylethylene (M_2)—First order plot. Reaction conditions are shown in Fig. 1.

From Fig. 4, we can get $k_{21}=0.27\text{M}^{-1}\text{ sec}^{-1}$. Various rate constants determined in the copolymerizations in THF employing methyl derivatives of butadiene as a component are collected in Table 5. The reactivities (k_{21}) of the dienes decreased with an increase in the methyl group. The retarding effect of the group, however, was different for two living ends, the styryl anion and the diphenylethylene anion, indicating that the steric effect also affects the reactivities of the dienes. As to the reactivity of the anion (k_{12}), the isoprenyl anion should be more reactive as a result of the electron-donating effect of the methyl group. However, the butadienyl anion was more reactive to 1,1-diphenylethylene than the isoprenyl anion. This must also be caused by the steric factor. Similar results were reported in the addition reactions of styrene to styryl and α-methylstyryl anions, in which the styryl anion was more reactive.[9]

Table 5. Rate constant in THF

b) Li, 0°C, this work and Ref. 1.
c) Li, 22°C, Ref. 4.
d) Na, 25°C, Ref. 6.
e) This was obtained from r_1 in Table 6 and k_{11}.

The monomer reactivity ratios, r_1, obtained in the copolymerizations of 1,1-diphenylethylene (M_2) and conjugated dienes (M_1) by means of *n*-BuLi are summarized in Table 6. In THF, 1,1-diphenylethylene is more reactive to the M_1 anion than the corresponding M_1 monomer. In benzene, however, isoprene and butadiene are more reactive than 1,1-diphenylethylene. The effects of the solvent and initiator in Tables 4 and 6 suggest that the r_1 value may increase with a decrease in the polarity of the carbon-metal bond.

a) at 0°C b) at 40°C c) at 22°C

The microstructures of butadiene, isoprene, and 2,3-dimethylbutadiene in the homopolymers and in the alternating copolymers with 1,1-diphenylethylene are summarized in Table 7; all of the polymers were formed in THF by means of *n*-BuLi. The 1,4-structure was greater in the alternating copolymer than in the homopolymers, and the order of the content of the 1,4-structure was 2,3-dimethylbutadiene>isoprene>butadiene. In the alternating copolymer of 2,3-dimethylbutadiene and 1,1-diphenylethylene, no 1,2-structure was present because of its big steric hindrance. However, in the case of the butadiene-diphenylethylene alternating copolymer, the 1,2-structure existed because of its lower steric hindrance. These results suggest that the microstructure of the dienes in the alternating copolymer is controlled strongly by the steric effect. In orther words, the effect must affect the rate constant, k_{12}, as has been described above.

Studies of Phenylxanthyl and Its Analogues by Electron Spin Resonance

Kazuhiro MARUYAMA, Masaharu YOSHIDA and Katsuya MURAKAMI

Department of Chemistry, Faculty of Science, Kyoto University, Yochida, Sakyo-ku, Kyoto

(Received June 7, 1969)

Phenylxanthyl, phenylthioxanthyl, phenylselenoxanthyl, 9-phenylfluorenyl, dioxadehydrocoranthryl, and their derivatives were studied by the electron spin resonance (ESR) technique, and the odd-electron distribution in the radicals was examined. From the results, the angle between the plane of the phenyl group and the plane of the rest of the molecule was estimated at about 63°. Since these radicals are in equilibria with their dimers, heat of reaction in the system was also determined on two of them. Some discussion of the correlation between the heat of reaction and the molecular shape was undertaken.

The distribution of the odd-electron in a molecule can be determined directly by the ESR technique. In this study, phenylxanthyl and its analogues, I—XI, were examined by this method. Since, in their structural features, these radicals have a form in which two or three phenyl groups of triphenylmethyl are bridged, the investigation of these radicals is interesting, especially in the correlation between the structure and the odd-electron distribution.

Results and Discussion

All the radicals examined here were produced in a vacuum-sealed sample tube by treating the corresponding chlorides dissolved in a suitable solvent with amalgamated silver. The ESR measurements were made at room temperature in solutions, using THF as the solvent except in the cases of compounds IX and X. Since these compounds are scarcely dissociated to the radical form at room temperature, their ESR measurements were conducted at an elevated temperature (80°C) using xylene as the solvent.

The proton hyperfine coupling constants obtained by the analyses of the ESR spectra are tabulated in Table 1. The coupling constant due to the proton was assigned tentatively by comparison with the spectra obtained from the measurements of non-substituted phenylxanthyl and the substituted phenylxanthyl derivatives, with reference to the results of the HMO calculations. Finally, such assignments were substantiated by comparison with the ESR spectrum of d_5-phenylxanthyl. Since phenylthio- and phenylseleno-xanthyl have shown spectra quite similar to that of phenylxanthyl, as can be seen in Fig. 1, the assignments of the corresponding protons to the respective coupling constants were straightforward. As to the other compounds (IX, X, and XI), the analyses of the spectra

and the assignments of the proton coupling constants were made quite analogously. The coupling constants obtained from the analyses of the spectra were reconfirmed by simulation with a computer.

It is interesting to compare the proton hyperfine coupling constants of these phenylxanthyl derivatives with that of triphenylmethyl, in which there is no bridge connecting the two phenyl groups. The proton hyperfine coupling constants of triphenylmethyl have been measured by several investigators. The values of the coupling constants for the respective protons reported by Ayscough and his co-workers[1] are $a_{\mathrm{H_{ortho}}}$: 2.55 gauss, $a_{\mathrm{H_{para}}}$: 2.78 gauss and $a_{\mathrm{H_{meta}}}$: 1.11 gauss. Although the value of the coupling constant can be slightly affected by the species of solvent used, those of the phenyl protons of phenylxanthyl as well as of the thio- or seleno-derivatives are outstandingly reduced compared with those of the corresponding protons of triphenylmethyl. This indicates the smaller delocalization of the odd-electron on the phenyl group. This may be due to the $C_{1'}$–C_9 bond twist of phenylxanthyl and its analogues. In view of the molecular model, the $C_{1'}$–C_9 bond of phenylxanthyl can be said to be forced to twist strongly because of the repulsion which might operate among C_1–H, C_8–H, $C_{2'}$–H, and $C_{6'}$–H. The results of HMO calculations performed under the consideration of the $C_{1'}$–C_9 bond twist are

** Angle of deviation from the co-planar position.
*** c_1, c_3, c_9 and $c_{4'}$ are coefficients of the corresponding atomic orbitals in a molecular orbital where odd electron is found.

shown in Table 2.

The variation in the value of $(c_{4'}/c_1)^2$ with the value of the twisted angle is figured in Fig. 2, where $(c_1)^2$ and $(c_{4'})^2$ represent the odd-electron density on the respective carbon atoms (C_1 and $C_{4'}$).

By a comparison of the ratio of the coupling constants ($a_{H4'}/a_{H_1}$) experimentally obtained with the value in Fig. 2, the angle of twist of the $C_{1'}$–C_9 bond can be estimated to be about 63° for phenylxanthyl. Therefore, it may be assumed that there is a comparable order of $C_{1'}$–C_9 bond twist for thio- or selenoxanthyl derivatives, too. Such a situation is partly reflected in the equilibrium between a radical and the dimer. The relative stability of phenylxanthyl and of 9-phenylfluorenyl in comparison with that of the dimers was determined by the ESR technique (see Fig. 3). The values obtained are tabulated in Table 3, along with those of other compounds.

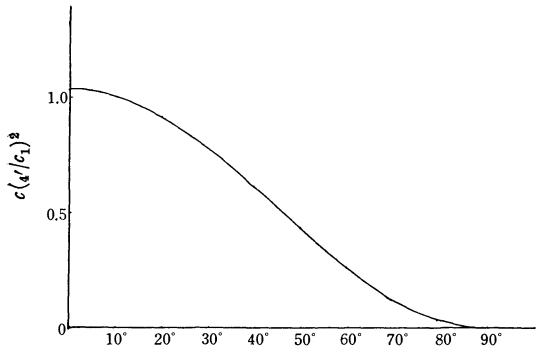

Fig. 2. Relation between $(c_4'/c_1)^2$ and angle of deviation from the co-planar position.

Since the degree of dissociation of a dimer to the radical is determined simply by the relative stability between the dimer and the resulting radical, the degree of dissociation must be controlled by two main factors. One is the stabilization of the radical due to the delocalization of the odd-electron, while the other is the steric repulsion around the bond-forming center (the central carbon atom) to

dimerize. The former causes the potential energy of radical to be lower, while the latter causes that of its dimer to be higher. The latter is the predominant factor in the dissociation of hexaphenylethane derivatives to triphenylmethyls.[2] Therefore, the lower heat of reaction in the system

2) W. Theilacker, H. Schultz, U. Baumgarte, H.-G. Prossler, W. Rohde, F. Thater and H. Uffmann, *Angew. Chem.*, **69**, 322 (1957).

of the equilibrium between phenylxanthyl and its dimer compared with that in the cases of triphenylmethyl and 9-phenylfluorenyl can be reasonably concluded to be the result of the larger steric repulsion around the central carbon atom due to the phenyl group being situated nearly perpendicular to the rest of the molecule. The larger value of the coupling constants (1.95 gauss) due to 2′,4′,6′-protons of 9-phenylfluorenyl compared with the value of the coupling constants (0.55 gauss) of the 2′,4′,6′-protons of phenylxanthyl may be considered to be a direct reflection of the more favorable situation for the co-planarity of phenyl and fluorenyl groups in IX because of the less repulsive force between C_1–H, C_8–H, $C_{2'}$–H, and $C_{6'}$–H. Moreover, it is consistent with the higher heat of reaction in the system. The larger coupling constant (2.97 gauss) of the 3,7,11-protons of dioxadehydrocoranthryl (XI), in which three phenyl groups are forced to be co-planar, supports the above discussion.

Experimental

Materials. All the free radicals examined were made *in situ* by shaking their chlorides with amalgamated silver in a vacuum cell, and the ESR spectra were immediately observed. The chlorides were prepared from the corresponding alcohols by treatment with gaseous hydrogen chloride in ether. The method of synthesizing chlorides and their physical constants are shown in Table 4.

The ESR spectra were measured by means of a 3BX-type spectrometer manufactured by the Japan Electron Optics Lab.

Determination of the Heat of Reaction. A known amount of chloride was dissolved into a known amount of tetrahydrofuran in a cell suitable for ESR measurements, and then it was evacuated and treated with amalgamated silver which had previously been prepared in the cell. The signal intensity was measured at various temperatures according to the usual way (magnetic field modulation: 5 gauss). The $\ln S$(S: signal intensity) *vs.* $1/T$ plot gave directly the heat of reaction in the system of equilibrium. A DPPH solution dissolved in THF of a known concentration was used as the standard solution.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 156—162 (1970)

Tri(hetero)substituted Carbonium Ions. I. Neighboring-Group Participation of the *N,N*-Dimethyldithiocarbamate Function Involving the Intermediacy of 2-Dimethylamino-1,3-dithiolanylium Ion*1

Takeshi NAKAI, Yoshio UENO and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 10, 1969)

The equimolar reaction of 1,2-dichloroethane with sodium *N,N*-dimethyldithiocarbamate was studied in various solvents. As major products, ethylene bis(*N,N*-dimethyldithiocarbamate) and 2-dimethylamino-1,3-dithiolanylium salt (the perchlorate or the tetraphenylborate) were obtained in yields, largely varying with the solvent used. On the basis of the solvent effect on the product ratio, and kinetic experiments it has been verified that neighboring-group participation of the *N,N*-dimethyldithiocarbamate function would be involved through the intermediacy of the isolated anchimeric carbonium ion, and that such participation is more predominant in nonpolar aprotic solvents such as dioxane and tetrahydrofuran. The mechanism of the reaction between 2-dimethylamino-1,3-dithiolanylium ion and the dithiocarbamate anion was established.

In previous papers[1-4] we reported that polymers containing the dithiocarbamate function ($-SCSNR_2$) are effective as a photosensitive resin. They were conveniently prepared by polymer reactions since no monomer with the function was readily available. We undertook to prepare *S*-vinyl *N,N*-dialkyldithiocarbamate by dehydrochlorination of *β*-chloroethyl dithiocarbamate. However, *β*-chloroethyl dithiocarbamate could not be isolated from the equimolar reaction of 1,2-dichloroethane with *N,N*-dialkyldithiocarbamate anion, but some unexpected observations described below were made. It was found that the vacuum pyrolysis of ethylene bis(*N,N*-dialkyldithiocarbamates) afforded *S*-vinyl *N,N*-dialkyldithiocarbamates in good yields, and their radical polymerizabilities were compared with those of the oxygen analogs.[5]

The observations obtained in the equimolar reaction between 1,2-dichloroethane (I) and sodium *N,N*-dimethyldithiocarbamate hydrate (II) are as follows: (i) the expected monosubstituted product, *β*-chloroethyl *N,N*-dimethyldithiocarbamate (III) could not be obtained at all; (ii) as major products, the disubstituted ethylene bis(*N,N*-dimethyldithiocarbamate) (IV) and 2-dimethylamino-1,3-dithiolanylium ion*2 (V) (as the perchlorate) were isolated in yields varying with the solvent. The results led us to study the mechanism of this equimolar reaction.

In the present paper we describe neighboring-group participation of the *N,N*-disubstituted dithiocarbamate function involving the intermediacy of the isolatable anchimeric cation*3 (V) in the reaction of 1,2-dichloroethane with the dithiocarbamate anion, mainly on the basis of the solvent effect on the product ratio and kinetic experiments.

Results and Discussion

The Solvent Effect on the Product Ratio. The equimolar reactions of 1,2-dichloroethane (I) with sodium *N,N*-dimethyldithiocarbamate (II) were undertaken at 60°C for 6 hr in various solvents. The dithiocarbamate anion completely disappeared during reaction under this condition. Ethylene bis(*N,N*-dimethyldithiocarbamate) (IV) and 2-

*2 Carbonium ion is more precisely expressed as 2-dimethylamino-1,3-dithiolan-2-ylium ion. In our papers "1,3-dithiolanylium ion" means "1,3-dithiolan-2-ylium ion."

*3 The term "anchimeric cation" refers to cyclic carbonium ion formed *via* intramolecular S_N reaction involving a neighboring group, such as V and VII.

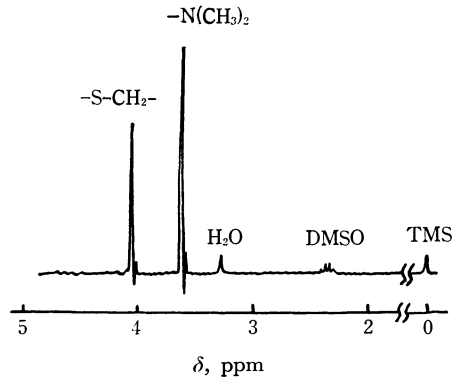

Fig. 1. The NMR spectrum of 2-dimethylamino-1,3-dithiolanylium perchlorate (Vb) in DMSO-d_6.

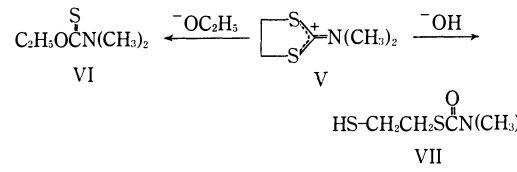
dimethylamino-1,3-dithiolanylium salt (V) were obtained as major products. Ethylene bis(dithiocarbamate) was identified by comparisons of both spectral data with that of authentic sample and the mixed mp determination.

The dithiolanylium salt (V) was isolated as perchlorate by treatment of an aqueous layer of the reaction mixture with sodium perchlorate. The structure of the perchlorate Vb was confirmed by elemental analysis and an independent preparation according to the reported method.[6] The NMR spectrum (Fig. 1) of the perchlorate was superimposable, exhibiting two singlet signals at δ 4.08 ($-CH_2-S-$) and 3.62 ppm (CH_3-N). Dithiolanylium ion was also isolated as the tetraphenylborate (Vc) in higher yields than the perchlorate Vb, but not quantitatively because Vc dissolved in water. The formation of dithiolanylium ion can be explained by the intramolecular nucleophilic substitution (S_Ni) reaction of β-chloroethyl dithiocarabamate (III) formed.

The reaction of I with II in ethanol afforded ethyl thioncarbamate (VI) and β-mercaptoethyl thiolcarbamate (VII) as well as major products described above. The thioncarbamate (VI) was identified by comparison of physical properties and spectral data of the authentic sample. The thiolcarbamate (VII) exhibits a strong absorption band at 1650 cm^{-1} due to $\nu_{C=O}$ for $-S-CO-N<$ and was treated with lead acetate to give a precipitate of the lead mercaptide. The formation of VI was not observed with reactions in other solvents than ethanol. Separate experiments suggested that these by-products were formed through ethanolysis and hydrolysis of 2-dimethylamino-1,3-dithiolanylium ion (V), respectively.[7]



The product compositions for the equimolar reactions in various solvents are given in Table 1. The results indicate that the product ratio is largely dependent on the nature of the solvent. From the effect on the product ratio, solvents may be classified into three groups; dipolar protic (EtOH, EGOH), dipolar aprotic (DMF, DMSO, CH_3CN) and nonpolar aprotic (dioxane, THF). The yield of IV increases in the order: nonpolar>dipolar aprotic>dipolar protic. It may be noted that, especially in dioxane and THF, the disubstituted product (IV) was more favorably formed under the equimolar condition. The fact cannot be

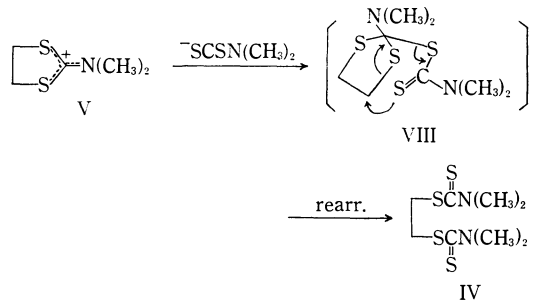
explained by two successive simple S_N2 reactions, I→III→IV, but suggests that the dithiocarbamate function in III somewhat participates in the second substitution process, III→IV.

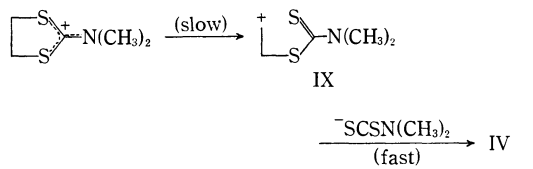
The Reaction of the Dithiolanylium Ion (V) with the Dithiocarbamate Anion (II). Winstein and co-workers have reported that the acetolysis of *trans*-2-acetoxycyclohexyl brosylate was about 630 times faster than that of the *cis*-isomer. This was interpreted by anchimeric assistance of the neighboring acetoxy group through the presumed acetoxonium ion.[8] Later the cation was isolated as the tetrafluoroborate *via* another route.[9] The dithiolanylium ion (V) isolated in the present work corresponds to the anchimeric acetoxonium ion. Thus, the reaction of the dithiolanylium perchlorate (Vb) with the dithiocarbamate anion was carried out first.

The perchlorate Vb was allowed to react with the dithiocarbamate salt (II) at 50°C in DMF to result in the quantitative formation of ethylene bis(dithiocarbamate) (IV). Possible mechanism for the formation of IV may be considered as follows:

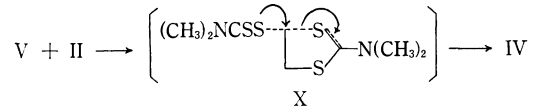
Mechanism A



Mechanism B

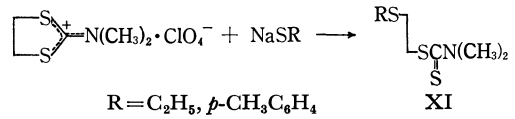


Mechanism C



Mechanism A involves initial addition of the anion at the position of lowest electron density, *i. e.*, the centered carbon (sp^2) atom of V to afford the adduct VIII followed by rearrangement to the product IV. Mechanism B consists of initial conversion of the stabilized carbonium ion V into the unstable ion IX which rapidly reacts with the anion to give IV (S_N1 type), while mechanism C involves attack of the anion at the neutral carbon (sp^3) atom of the position 4 in V through the transition state X (S_N2 type).

Firstly mechanism A can be eliminated by our observation that the perchlorate Vc also reacts with mercaptides incapable of rearrangement to result in the formation of β-mercaptoethyl dithiocarbamates (XI).



R=C_2H_5, *p*-$CH_3C_6H_4$ XI

Kinetic experiments indicate that the reaction of Vc with II fits in a second-order rate equation with respect to both reactants. The fact excludes mechanism B which should fit in a first-order rate equation. In conclusion, the dithiocarbamate anion attacks the C-4 atom to give IV through a concerted S_N2 type mechanism (mechanism C). The Arrehnius plots for the reaction in DMF is shown in Fig. 2. Activation parameters, $\Delta H^{\neq}$ and $\Delta S^{\neq}$, were 23.0 kcal/mol and +3.7 *e.u.*, respectively.

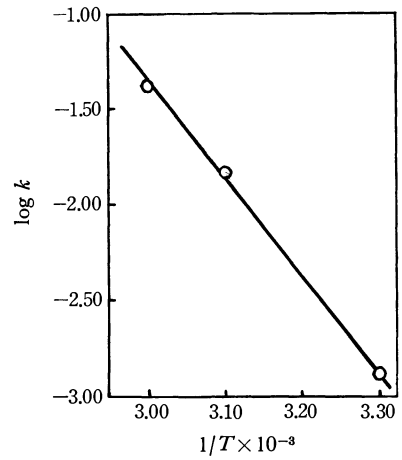


Fig. 2. The Arrehnius plot for the reaction of Vb with II in DMF.

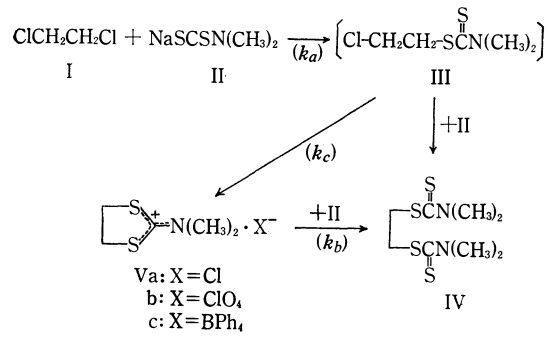
Reaction Scheme. From results obtained, the formation of IV can be interpreted by the following scheme involving the intermediacy of the isolated anchimeric cation V.

Dichloride I reacts with II initially to give the monosubstituted III followed by rapid cyclization to the stable carbonium ion V. The carbonium ion further reacts with II to afford the disubstituted product (IV). The alternative formation of IV arising from the direct reaction of III with II not

8) For example, a) S. Winstein and R. E. Buckles, *J. Amer. Chem. Soc.*, **64**, 2780 (1942); b) S. Winstein, E. Grunwald and R. E. Buckles, *ibid.*, **70**, 816 (1948); c) S. Winstein, E. Grunwald and L. L. Ingraham, *ibid.*, **70**, 821 (1948).

9) C. B. Anderson, E. C. Friedrich and S. Winstein, *Tetrahedron Lett.*, **1963**, 2037.



via Va might be neglected since the cyclization was rapid ($k_c \gg k_a$). In short, steps kinetically determining the product ratio are the process I→III (k_a) and Va→VI (k_b). It is expected that the rate of each product-determining process will be differently affected by the nature of the solvent used, and that the solvent effects on each process will be reflected in the product ratio.

The Neighboring-group Participation of the Dithiocarbamate Function. The rates (k_a) of the reaction I→III were obtained from those of reactions of *n*-butyl chloride with the dithiocarbamate ion. The rates (k_b) of the reaction Va (unisolatable)→IV were obtained from those for the reaction Vb→IV. The reactions were followed by determining the amount of the unreacted dithiocarbamate anion after given intervals. Kinetic experiments were carried out at 60°C in ethanol, DMF and dioxane, which represent dipolar protic dipolar aprotic and nonpolar aprotic solvent, respectively.

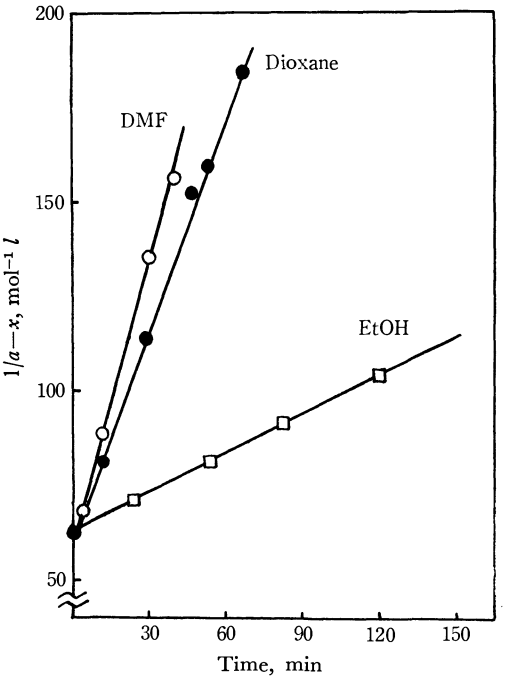

Fig. 4. The second-order rate plots for the reactions of Vb with sodium *N,N*-dimethyldithiocarbamate.
The initial concn.=0.0162 mol/*l*

Second-order rate plots for the equimolar reactions with II of *n*-butyl chloride and 2-dimethylamino-1,3-dithiolanylium perchlorate (Vb) in various solvents are shown in Figs. 3 and 4, respectively. Rate constants obtained for both reactions are summarized in Table 2.

Table 2. Rate constants for equimolar reaction with II of *n*-butyl chloride (k_a') and the perchlorate Vb (k_b') (60°C)

Solvent (Dielectric constant)	$10^3 k_a'$ (l mol^{-1}sec^{-1})	$10^3 k_b'$ (l mol^{-1}sec^{-1})	k_b'/k_a'	Product ratio* IV/V
EtOH (24.3)	0.4	7.34	18.4	0.092
DMF (36.7)	70.8	40.9	0.58	0.30
Dioxane (2.2)	0.3	34.0	113	1.32

* A more accurate product ratio for the equimolar reaction of I with II could be calculated from IV%/(100-IV%) in Table 1 as it is difficult to isolate Va quantitatively.

In conclusion, the rate of the first process (k'_a) was in the order: dioxane≈EtOH≪DMF, while that of the second (k'_b) was in the order: EtOH≪ dioxane<DMF. It is interesting to note that k'_a for DMF is very large, and that k'_b/k'_a for dioxane is significantly large, compared with those for EtOH and DMF. The unusual rate enhancement in DMF for the reaction of *n*-butyl chloride with II can be attributed to two major factors;

(i) the enhanced nucleophilicity of the dithiocarbamate anion with DMF, which is in agreement with many other observations for the S_N reactions in dipolar aprotic media[10] and (ii) the enhanced electrophilicity of the alkyl chloride due to the complex formation between the alkyl chloride and DMF molecules.[11] The rate enhancement in dioxane for the reaction of carbonium ion V with the anion can be explained by the consideration that the rate of the reaction between a cation and an anion increases with the decrease of the ionization power of the solvent since activation in such reaction requires partial neutralization of charge.[12]

Most important is the fact that in dioxane the second displacement reaction V→IV is about one hundred times faster than the first I→III, which might account for the more favorable formation of the disubstituted product (IV) in the equimolar reaction of I with II. This also led to the conclusion that participation of the neighboring dithiocarbamate function in III may be involved in the second substitution process III→IV, together with the solvent effect on the product ratio described above. In other words, dichloride I reacts with anion II to form the monosubstituted intermediate (III), which further reacts with II more readily to result in the favorable formation of the disubstituted product (IV) through the intermediacy of the isolated anchimeric cation V.

Neighboring-group participation*4 ($k'_b/k'_a>1$) was also observed in the reaction in ethanol, but less predominant than in dioxane. In DMF, the participation was not kinetically observed ($k'_b/k'_a<1$). Consequently IV may be also formed from the direct reaction of III with II not *via* V.

From the results, the relationship between rate data for each product-determining steps and the product ratio is summarized with respect to the nature of the solvent in Table 3.

Table 3. Rate data and the product ratio

Solvent	Rate of the process			Product ratio
	I→III		V→IV	IV/V
Dipolar protic	slow	<	slow	small
Dipolar aprotic	fast	>	fast	medium
Nonpolar aprotic	slow	≪	fast	large

In dipolar protic and aprotic solvents, rate difference between two kinetically product-determing steps was not so large. In nonpolar aprotic solvents, the rate difference is significantly large and consequently neighboring-group participation of the dithiocarbamate function is more predominant. This is reflected in the favorable formation of the disubstituted product (IV) in the equimolar reaction of I with II.

Such participation of the dithiocarbamate function can account for the observation that, in equimolar reactions of α,ω-dichloroalkanes with the dithiocarbamate anion (II) in ethanol, the yield of the corresponding alkylene bis(dithiocarbamate) increases in the order: 1,4-dichlorobutane>1, 3-dichloropropane>1, 2-dichloroethane, indicating that such participation increases in the same order.[13] This fact also suggests that the rate of reaction of the corresponding anchimeric carbonium ion with II increases in the same order, which has been verified.[14] Furthermore, kinetical evidence that neighboring-group participation of this function is involved in the polymer reaction of poly(vinyl chloride) with sodium *N,N*-diethyldithiocarbamate in DMF and THF has been obtained.[15]

Experimental*5

Equimolar Reactions of 1,2-Dichloroethane (I) with Sodium *N,N*-Dimethyldithiocarbamate (II) in Various Solvents. Into a solution of I (19.8 g, 0.20 mol) in 80 m*l* of the solvent was added a solution of sodium *N,N*-dimethyldithiocarbamate hydrate (II)*6

*4 Neighboring-group participation in the present work might be considered to be essentially the same as the "anchimeric assistance" proposed by Winstein[8] for solvolytic (S_N1) reactions. The phenomenon in which the cyclic compound is formed by participation of the neighboring group is called "anchimerism,"[13] and was used in a preliminary communication of this work.*1 However, this term is not appropriate for our present observation since it does not mean rate enhancement by a neighboring group.

*5 All melting and boiling points were uncorrected. Infrared and ultraviolet spectra were recorded on Hitachi infrared EPI-S2 and recording EPS-2 spectrophotometers, respectively. The NMR spectrum was obtained with a Varian Associates Model A-60 spectrometer in a dimethylsulfoxide-d_6 solution using tetramethylsilane as an internal standard.

*6 The dithiocarbamate salt contains two molecules of the coordinated water: T. Nakai and M. Okawara, This Bulletin, **41**, 707 (1968).

(36.0 g, 0.20 mol) in 120 ml of the solvent. The reaction mixture was stirred at 60°C for 6 hr in nitrogen atmosphere. Sodium chloride formed was filtered off and the filtrate was concentrated in reduced pressure. The mixture was poured into 300 ml of cold water to give a white precipitate, ethylene bis(*N,N*-dimethyldithiocarbamate) (IV), which was filtered, dried *in vacuo* and weighed; mp 187—189°C (lit,[16] 189°C); IR (KBr): $\nu_{C=N(thiourelde)}$[17] 1495 cm^{-1}; UV: λ_{max}^{EtOH} 250, 277 mμ.

A portion of the filtrate was treated with an excess of an aqueous solution of nickel chloride to produce no precipitate of the nickel salt, indicating that the dithiocarbamate anion completely disappeared during reaction. The filtrate was extracted with ether. A given volume of the aqueous layer was treated with an excess of an aqueous solution of sodium perchlorate to give a white precipitate, 2-dimethylamino-1,3-dithiolanylium perchlorate (Vb), which was then filtered, dried *in vacuo* and weighed; mp 179—181°C (recrystalized from acetone); UV: $\lambda_{max}^{H_2O}$ 249 mμ (ε=13000). The NMR spectrum shows two singlet signals at δ 4.08(2H) and 3.62 ppm (3H) (Fig. 1).

Found: C, 24.48; H, 4.18; N, 5.58%. Calcd for $C_5H_{10}ClNO_4S_2$: C, 24.24; H, 4.08; N, 5.66%.

A given volume of the aqueous layer was treated with an excess of an aqueous solution of sodium tetraphenylborate to afford a white precipitate, the dithiolanylium tetraphenylborate (Vc), which was filtered, dried *in vacuo* and then weighed; mp 134—136°C (recrystallized from acetonitrile).

Found: C, 74.81; H, 6.50; N, 3.22%. Calcd for $C_{29}H_{40}BNS_2$: C, 74.51; H, 6.47; N, 3.00%.

Authentic 2-dimethylamino-1,3-dithiolanylium salts were prepared by treating β-hydroxyethyl *N,N*-dimethyldithiocarbamate with *p*-toluenesulfonyl chloride in DMF[6] followed by sodium perchlorate or sodium tetraphenylborate.

The ethereal layer was dried over anhydrous sodium sulfate and the solvent was removed *in vacuo* to give a small amount of yellow oily residue. The infrared spectrum (liq. film) showed a strong absorption band at 1650 cm^{-1} due to -S-CO-N<. In the case of the reaction in ethanol, the oily residue was distilled in the reduced pressure to give ethyl *N,N*-dimethylthioncarbamate (VI) and β-mercaptoethyl *N,N*-dimethylthiolcarbamate (VII) in 5.5% and 3.9% yield, respectively. Physical properties of product VI are as follows: bp 81—82°C/10 mmHg (lit,[18] 82.6°C/10 mmHg); $n_D^{25°C}$ 1.5082 (lit,[19] $n_D^{20°C}$ 1.5075); UV: λ_{max}^{EtOH} 250.5, 285 mμ (lit,[20] 250.5, 285 mμ). Thioncarbamate (VI) was transformed with ethyl bromide into thiolcarbamate,[21] which was identified by means of spectral and physical data with the authentic compound. The physical data for thiolcarbamate (VII) are as follows: bp 112—117°C/4 mmHg; $n_D^{25°C}$ 1.5840; IR (neat): 1650, 1495 cm^{-1} (-S-CO-N<). The product was treated with a mercuric chloride solution to give a precipitate of the mercury mercaptide: mp 122—128°C; IR (KBr): $\nu_{C=O}$ 1635 cm^{-1}, and was oxidized to disulfide: mp 83—84°C (recrystallized from cyclohexane); IR (KBr): $\nu_{C=O}$ 1640 cm^{-1}.

Found: N, 8.10%. Calcd for $C_{10}H_{20}N_2O_4S_4$: N, 8.54%.

Product compositions obtained from the equimolar reactions in various solvents are shown in Table 1.

Reaction of 2-Dimethylamino-1,3-dithiolanylium Perchlorate (Vb) with Sodium *N,N*-Dimethyldithiocarbamate (II). A mixture of 2.5 g (0.01 mol) of perchlorate and 2.0 g (0.01 mol) of sodium salt in 20 ml of DMF was stirred at 60°C for 4 hr. The mixture was poured into a large amount of cold water to produce 2.6 g (98%) of a white precipitate: mp 187—189°C (recrystallized from DMF). The precipitate showed no depression upon a mixed mp determination with the authentic ethylene bis(*N,N*-dimethyldithiocarbamate) (IV), and its infrared spectrum was in complete agreement with that of the authentic sample.

Kinetic Runs. The rates of both reactions of *n*-butyl chloride and 2-dimethylamino-1,3-dithiolanylium perchlorate (Vb) with sodium *N,N*-dimethyldithiocarbamate were followed by measuring quantities of the unreacted dithiocarbamate anion after given intervals. The dithiocarbamate anion was gravimetrically determined from the quantity of the nickel chelate precipitated by treating an aqueous layer of the sample with an excess of an aqueous solution of nickel chloride. An exampe of the calibration curve is shown in Fig. 5. All reactions were carried out at 60°C under equimolar conditions.

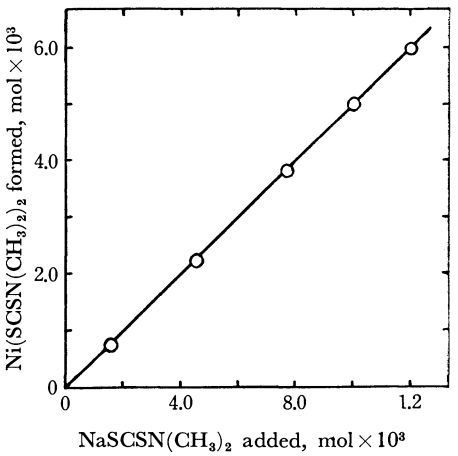

Fig. 5. The calibration curve for the determination of the dithiocarbamate anion.

Initial concentrations for reactions of *n*-butyl chloride and the dithiolanylium perchlorate were 0.050 and 0.016 mol/*l*, respectively.

n-Butyl chloride (0.5785 g) was dissolved in a solution of 1.1650 g of sodium *N,N*-dimethyldithiocarbamate in 125 m*l* of the solvent placed in a constant-temperature bath at 60±0.2°C. At various intervals a 25.0-m*l* aliquot of the yellow solution was removed and poured into cold water (*ca.* 50 m*l*). The sample solution was immediately extracted with ether, then the aqueous solution was treated with an excess of an aqueous solution of nickel chloride giving green precipitates of nickel chelate. The nickel chelate was collected in a glass filter which had been weighed. The glass filter was dried *in vacuo*. An example of results is given in Table 4. All plots of $1/a-x$ against time showed straight lines (Fig. 3).

2-Dimethylamino-1,3-dithiolanylium perchlorate (Vb) (1.000 g) was dissolved in a solution of 0.725 g of sodium *N,N*-dimethyldithiocarbamate in 150 m*l* of the solvent. At various intervals a 50.0-m*l* aliquot was removed and poured into cold water (*ca.* 100 m*l*) giving white precipitates of ethylene bis(*N,N*-dimethyldithiocarbamate) (IV). The precipitates were filtered off and the aqueous layer was treated with an excess of an aqueous solution of nickel chloride giving green precipitates of the nickel chelate. The quantity of the nickel chelate was measured as in the case of the reaction of *n*-butyl chloride with II. An example of results is shown in Table 5. All plots of $1/a-x$ against time showed straight lines (Fig. 4).

2-Substituted Imino-1,3-dithiolanes. Their Thermal Ring-isomerizations and Reactions with Epoxides*1

Yoshio UENO, Takeshi NAKAI and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 10, 1969)

Thermal ring-isomerization and reactions with epoxides of 2-substituted imino-1,3-dithiolanes (I) were studied. The methylimino (Ia) and ethylimino derivatives (Ib) were found to be ring-isomerized to the corresponding 3-alkyl-1,3-thiazolidine-2-thione (V) at about 200°C, while the phenylimino compound (Ic) was not isomerized even under more drastic conditions. The influence of various additives including Lewis acids was also examined. In contrast to the oxygen analog of I, these imino compounds were not polymerized with Lewis acids, and catalysis of any additives on isomerization was not observed. The possibility that I thermally dissociated into methyl isothiocyanate and ethylene sulfide followed by their recombination to V would be excluded by the observation that the reaction of alkyl isothiocyanate with ethylene sulfide at 150°C afforded I in good yield. Reactions of I with epoxides were carried out regarding the isomerization mechanism. All these imino compounds reacted with epoxides to give the 2-oxazolidone derivatives (III) in good yield. Mechanisms of the ring-isomerization and formation of III have been suggested, and the difference in reactivity between I and its oxygen analog has been discussed.

In a previous paper[1] we reported that 1,2-dichloroethane reacted with sodium *N,N*-dialkyldithiocarbamate to result in the formation of 2-dialkylamino-1,3-dithiolanylium ions involving participation of the dithiocarbamate function as an internal nucleophile. In a similar way, 2-alkylimino-1,3-dithiolanes were obained by the reaction of 1,2-dichloroethane with sodium *N*-monoalkyldithiocarbamate in the presence of base. We were prompted to investigate the reactivities of 2-substituted imino-1,3-dithiolanes (I) in view of the following. (1) On the addition of acid catalysts (A) such as Lewis acids, the imino compounds are expected to form complex II, the structure of which resembles that of dithiolanylium ion III. The type of carbonium ions have been demonstrated to be the interesting reactive species.[2]

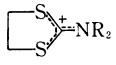
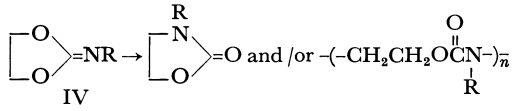
II



III

(2) Ring-isomerization[3] and ring-opening polymerization[4] of the oxygen analogs of I, *i. e.*, 2-substituted imino-1,3-dioxolanes (IV), have been reported. However, no information has been available on the imino-dithiolanes. Burkhardt has suggested that 2-benzoylimino-1,3-dithiolane considerably resists ring-isomerization as compared with oxygen analog.[5]



IV

In the present work we studied the possibility of ring-isomerization or ring-opening polymerization of imino-dithiolanes (I) and their reactions with epoxides.

Results

Preparation of Imino-dithiolanes (I). 2-Methylimino- (Ia) and 2-ethylimino-1,3-dithiolane (Ib) were obtained in yields of 67 and 26%, respectively, by the reaction of 1,2-dichloroethane with the corresponding sodium *N*-alkyldithiocarbamate at 60°C in the presence of potassium carbonate. 2-Phenylimino-1,3-dithiolane (Ic) was obtained in 73% yield by the reaction of 2-dimethylamino-1,3-dithiolanylium perchlorate with aniline.[2]

The infrared spectra of these imino compounds showed a strong absorption band around 1600 cm^{-1} due to the C=N group (Fig. 1). The NMR spectrum of Ia displayed a three-proton signlet at δ3.10 (*N*-methyl) and a four-proton multiplet in the region of 3.20—3.70 ppm (ring-methylene). (Fig. 2a). It is of interest that the ring-methylene protons of Ic appeared at 3.32 ppm as a singlet form.

Thermal Ring-isomerization. Ring-isomerization of these imino-dithiolanes was undertaken by heating in a sealed tube in the presence or absence of an additives listed in Table 1. Among additives employed, $AlCl_3$, BF_3OEt_2, H_3PO_4 and $FeCl_3$ have been reported to be effective as catalysts for the ring-isomerization or the ring-opening polymerization of the oxygen-analogs IV.[3,4] It was found that Ia was ring-isomerized above 200°C into 3-methyl-1,3-thiazolidine-2-thione (Va) in 48% yield in the absence of an additive. The results are summarized in Table 1. Results indicate that any additives used neither increase the yield of Va nor lower the isomerization temperature. Ring-opening polymerization was not observed. These observations are in direct contrast to those of oxygen analogs IV. The infrared spectrum of the isomerized product Va showed no absorption band at 1600 cm^{-1} and a new band at 1500 cm^{-1} due to the –S–CS–N< structure (Fig. 1). The NMR spectrum of Va confirmed the structure (Fig. 2b).

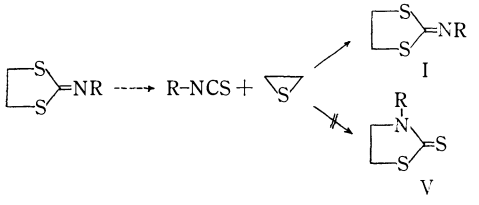
The phenylimino derivative (Ic), however, did not ring-isomerize and only the starting material was recovered almost quantitatively after heating at 200 or 250°C.

Reactions of Isothiocyanates with Ethylene Sulfide. Isolation of a small amount of methyl isothiocyanate during the distillation of Ia suggests that Ia may thermally dissociate into the isothiocyanante and ethylene sulfide. In order to examine the possibility that V might be formed through recombination of these dissociated fragments, the reaction of isothiocyanate with ethylene sulfide were carried out in the presence of triethylamine at 120—140°C in a sealed tube. Methyl isothiocyanate reacted with ethylene sulfide to give Ia (not Va) in 40% yield. When the reaction temperature was raised to 200—220°C, Va was formed probably *via* the ring-isomerization of Ia formed. Similarly phenyl isothiocyanate afforded Ic in 83% yield.



These observations indicate that the isomerized product V is not formed directly from the isothiocyanate and ethylene sulfide.

This fact is in agreement with the observation that isocyanate reacts with epoxides to give 2-imino-1,3-dioxolanes (IV), in some instances followed by the subsequent ring-isomerization to the 2-oxazolidones.[6]

Reactions of the Imino-dithiolanes with Epoxides. Recently Russian chemists have reported that the 2-phenylimino-1,3-dithiolane (Ic) reacted with epoxides at 80—90°C to afford the 2-oxazolidone derivatives (VI),[7] the details of which have not been accessible. The fact that the phenylimino derivative, which did not ring-isomerize, reacted with epoxides under the mild condition leads us to a further study on the reaction of other imino-dithiolanes with epoxides.

2-Methylimino-1,3-dithiolane (Ia) reacted with propylene oxide and epichlorohydrin at 90°C in the presence of triethylamine to produce 5-methyl- (VIa) and 5-chloromethyl-2-oxazolidone (VIb), respectively, in yields of 64% and 67%. The structure of product VI was determined by elemental analysis and spectral data (IR and NMR). The infrared spectra of VIa and VIb showed the characteristic band of the oxazolidone-carbonyl group at

1700 cm^{-1}. The NMR spectrum of VIa completely supports the oxazolidone structure (Fig. 3). The possibility of structure VII could be eliminated based upon the results of systematic NMR studies of oxazolidone derivatives.[8]

Discussion

On the Mechanism of Ring-isomerization. Experimental results described above of the ring-isomerization of the imino-dithiolanes (I) are summarized as follows, comparing them with oxygen analogs IV;

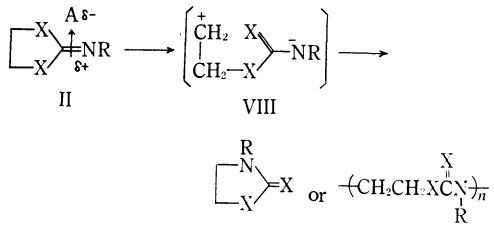
(1) 2-Alkylimino-1,3-dithiolanes were ring-isomerized to the thiazolidine-2-thione (V) under a severer condition than that for the oxygen analogs.

(2) Both the phenylimino- and the benzoylimino-dithiolane failed to be ring-isomerized, whereas their oxygen analogs with the same substituents isomerized more readily at lower temperatures.

(3) Acid additives were ineffective or they resulted in lower yields of the isomerized products. This is significantly different from the case of the oxygen analogs.

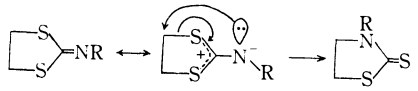
(4) In all cases, polymeric materials were not obtained with any Lewis acids. This fact is in direct contrast with that of the oxygen analogs.

These fact substantially exclude the following mechanism involving carbonium ion VIII which has been accepted for both the ring-isomerization[3] and the ring-opening polymerization[4] of the oxygen analogs.



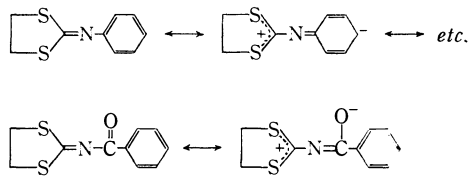
II VIII

Thus we propose another possible mechanism for the ring-isomerization concerned, which involves concerted attack of the nonbonded electron pair of the nitrogen atom on the carbon atom of the ring-methylene through the S_N-2-like transition state.

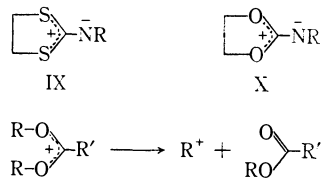


I I′ V

Structure I′ is more favorable than that of the ordinary imino compounds since the positive charge is more stabilized by the electron-donating character of the sulfur atoms. This fact is in agreement with the observation that 2-dialkylamino-1,3-dithiolanylium ions are considerably stable.[2] Although this unimolecular mechanism is sterically unfavorable and has not been completely established, this may explain the four experimental results described above. The electron density on the nitrogen atom is lowered either by the complex formation between the acidic additive and the imino compound (see (3)) or by electron delocalization to the other part of the molecule for 2-phenylimino-1,3-dithiolane (Ic) and the benzoylimino derivative shown below (see (2)).

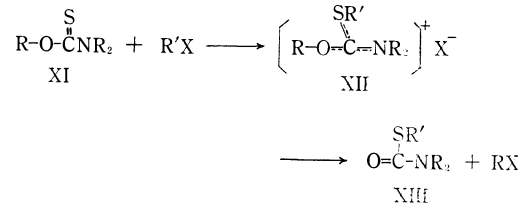


In conclusion, the difference in mechanism for ring-isomerization between the imino-dithiolanes and the imino-dioxolanes might be ascribed to the difference in stability between carbonium-ion like species IX and X. It has been accepted that the carbon-oxygen bonds in dialkoxycarbonium ions cleave more readily into the alkyl cation and the ester than the carbon-sulfur bonds in dialkoxythiocarbonium ions.[9]



IX X

This fact may be supported by the observation that the thioncarbamate XI reacts readily with alkyl halides to form triheterosubstituted carbonium ion XII followed by exclusive transformation into thiolcarbamate XIII.[9]



XI XII XIII

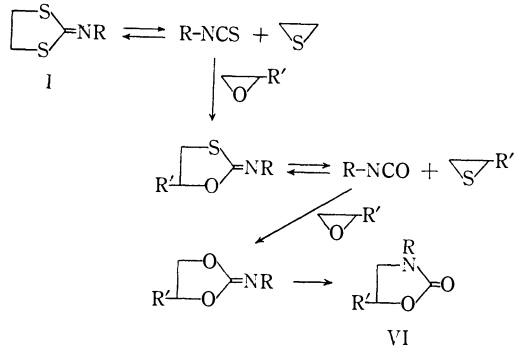
On the Mechanism for the Formation of 2-Oxazolidone Derivatives from Imino-dithiolanes and Epoxides. There are two possible mechanisms for the formation of the 2-oxazolidone

8) J. E. Herweh, T. A. Fogjia and D. Swern, *J. Org. Chem.*, **33**, 4029 (1968).

9) A. F. Schoberl and A. Waguer, "Houben-Wyle: Methoden der Organishen Chemie," Vol IX, George Thieme Verlag, Stuttgart (1955), p. 837.

derivative in the reaction of imino-dithiolane with epoxide.

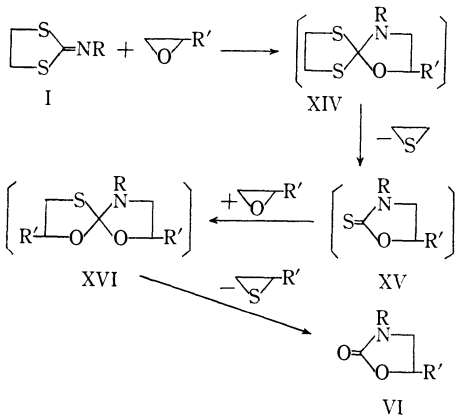
Firstly scheme A involves initial thermal dissociation of I into isothiocyanate and episulfide followed by a known subsequent reaction of isothiocyanate with epoxide giving 2-imino-oxothiolane. The imino-oxothiolane formed dissociates into isocyanate and episulfide followed by the reaction of isocyanate with epoxide to afford 2-imino-dioxolane, which, in turn, ring-isomerizes leading to the formation of VI.



Scheme A

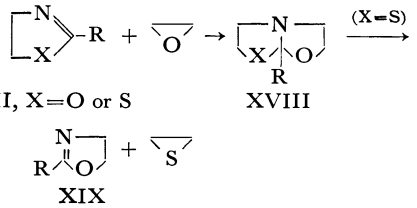
However, it is doubtful whether the dissociation of imino-dithiolane occurs at low temperatures such as 90°C. The fact that the formation of thioureas was not observed on treatment of Ia in the presence of excess aniline at 150°C, considerably reduces the possibility of occurrence.

The other mechanism, Scheme B, involves initial cycloaddition of epoxide to imino compound (I) followed by elimination of episulfide from the resulting spirocyclic compound (XIV), and then by further cycloaddition of epoxide to the thiocarbonyl group in oxazolidine-2-thione (XV) formed to yield another spirocyclic compound XVI. This, in turn, eliminates episulfide leading to the formation of VI.

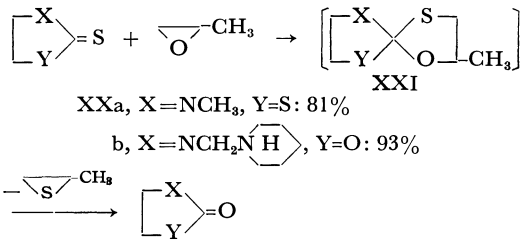


Scheme B

In support of the processes, I to XIV and XIV to XV, the following examples have been reported by Feinauer;[10] thia(or oxa)zolines (XVII) reacts with epoxide to yield the bicyclic compound XVIII *via* cycloaddition of epoxide to the *endo* C=N group, and in the case of X=S, loss of episulfide is followed leading to the formation of 2-oxazoline (XIX).



Little information on the reaction of the thiocarbonyl group with epoxides has been available in literature. In order to demonstrate the process XV→XVI→VI, we carried out the reaction of various thiocarbonyl compounds including oxazolidine-2-thione (XV) with epoxides. It was found that the thiocarbonyl group was readily converted to the corresponding carbonyl group in good yields presumably *via* spirocyclic adduct XXI as shown below. A detailed report on this type of reaction will be presented in a subsequent paper.[11]



We assume that the mechanism given in Scheme B is considered more likely for the reaction of imino-dithiolanes with epoxides.

Experimental

General. All melting and boiling points are uncorrected. The IR spectra were recorded with a Hitachi EPI-S2 spectrometer. The NMR spectra were determined with a Japan Electron Optics C-100 spectrometer. Chemical shifts are reported in parts per million (ppm) from tetramethylsilane as an internal standard.

Materials. Sodium *N*-monoalkyldithiocarbamates were prepared by the reaction of the aqueous solution of alkylamine with carbon disulfide in the presence of sodium hydroxide. 2-Dimethylamino-1,3-dithiolanylium perchlorate was obtained by a method reported.[1] Methyl isothiocyanate and ethylene sulfide were prepared by standard methods. Other reagents and solvents were commercial products and used after purification by standard methods.

2-Methylimino-1,3-dithiolane (Ia). To a suspension

10) R. Feinauer, *Angew. Chem. Int. Ed. Engl.*, **5**, 894 (1964).

11) Y. Ueno, T. Nakai and M. Okawara, This Bulletin, **43**, 168 (1970).

of sodium methyldithiocarbamate (25.8 g, 0.20 mol) in absolute ethanol (200 ml), 1,2-dichloroethane (50 g, 0.50 mol) was added, and the mixture was then heated at 60°C for 1 hr. After cooling, a suspension of anhydrous potassium carbonate (27.6 g, 0.20 mol) in absolute ethanol (50 ml) was added, the reaction mixture was stirred at 60°C for further 4.5 hr, and the mixture was cooled followed by extraction with ether. The ethereal solution was dried over anhydrous sodium sulfate and the solvent was removed in reduced pressure. The residue was distilled giving a yellowish liquid (9.2 g, 35%); bp 79—81°C/0.45 mmHg; n_D (22°C) 1.6032. The IR and NMR spectra of Ia are given in Figs. 1 and 2a, respectively.

Found: C, 36.06; H, 5.30; N, 10.51%. Calcd for $C_4H_7NS_2$: C, 35.64; H, 5.39; N, 10.23%.

A higher boiling-point distillate obtained as a by-product was separated into 3-methylthiazolidine-2-thione (Va) and ethylene trithiocarbonate on column chromatography of active alumina.

The methylimino compound was also prepared by another method starting from methylamine and carbon disulfide. To a solution of carbon disulfide in ethanol, aq. methylamine solution was added drop by drop with vigorous stirring and cooling in an ice bath, where the temperature was kept below 30°C. The resulting clear orange-colored solution was added to 1,2-dichloroethane, and the mixture was stirred at 60°C for 1 hr. The yellowish solution was treated with concd. hydrochloric acid and the organic impurities were extracted with ether. An aqueous solution of potassium carbonate was added to neutralize the aqueous layer, and extracted with ether. The ethereal solution was dried over anhydrous sodium sulfate and the solvent evaporated. Work-up gave the imino compound (Ia) in 67% yield.

2-Ethylimino-1,3-dithiolane (Ib) was prepared in 26% yield as in the case of Ia; bp 85—87°C/0.30 mmHg; n_D (27°C) 1.5839; IR (neat): 1595 cm^{-1} (C=N).

Found: C, 40.19; H, 6.09; N, 9.34%. Calcd for $C_5H_9NS_2$: C, 40.81; H, 6.17; N, 9.52%.

2-Phenylimino-1,3-dithiolane (Ic) was prepared by the reaction of 2-dimethylamino-1,3-dithiolanylium perchlorate with aniline in 73% yield according to the procedure reported;[2] mp 47—48°C (lit,[2] 47—48°C); IR (KBr disk): 1570 cm^{-1} (C=N); NMR (CCl_4): δ 3.32 (s, CH_2S), 6.55—7.10 ppm (m, aromatic protons).

Ring-isomerization of Imino-dithiolane (I). Many attempts to isomerize Ia were made under various conditions as shown in Table 1. In the presence of aluminum chloride, imino-dithiolane Ia (1.3 g, 0.01 mol) and a small amount (*ca.* 0.1 g) of aluminum chloride were sealed in a tube. The tube was heated at 200°C for 3 hr in an oil-bath. After cooling, the tube was carefully opened and the reaction mixture was extracted several times with ether. The ethereal solution was evaporated *in vacuo*. Recrystallization of the residue from ether yielded 0.61 g (47%) of 3-methylthiazolidine-2-thione (Va); mp 68—69°C (lit,[12] 68—69°C); UV: λ_{max} (H_2O) 265 mμ (lit,[13] 265 mμ). The IR and NMR spectra of Va are given in Figs. 1 and 2b, respectively.

Found: C, 36.06; H, 5.30; N, 10.51%. Calcd for $C_4H_7NS_2$: C, 36.15; H, 5.31; N, 10.65%.

As in the case of Ia imino compound Ib was isomerized to 3-ethylthiazolidine-2-thione (Vb) in 67% yield in the absence of any additive; bp 155—157°C/2.5 mmHg; n_D (22°C) 1.625.

Found: C, 40.84; H, 6.34%. Calcd for $C_5H_9NS_2$: C, 40.81; H, 6.17%.

Ring-isomerization of Ic failed both under same conditions and at higher temperature (250°C), and only the starting material (Ic) was recovered.

Reactions of Isothiocyanates with Ethylene Sulfide. Methyl isothiocyanate (4.0 g, 0.055 mol), ethylene sulfide (3.0 g, 0.030 mol), and triethylamine (3.0 g, 0.03 mol) were heated in a sealed tube at 120—140°C for 3 hr. After cooling the tube was carefully opened. Distillation of the resulting mixture in the reduced pressure gave 2.7 g (41%) of 2-methylimino 1,3-dithiolane (Ia). The IR spectrum, the boiling point and the refractive index of this distillate were identical with those of the authentic sample.

In a similar fashion the reaction of phenyl isothiocyanate with ethylene sulfide gave 2-phenylimino-1,3-dithiolane (Ic) in 83% yield.

Reaction of Imino-dithiolane Ia with Epoxides. Imino-dithiolane Ia (2.0 g, 0.015 mol), propylene oxide (2.0 g, 0.034 mol) and triethylamine (0.1 g) were sealed in a tube. The tube was heated at 140—150°C for 7 hr in an oil-bath. After cooling the tube was carefully opened. Distillation of the reaction mixture gave 3,5-dimethyl-2-oxazolidone (VIa) in 64% yield: bp 90—95°C/1 mmHg (lit,[14] 92°C/1.5 mmHg); IR (neat): 1700 cm^{-1} (C=O).

The reaction of Ia with epichlorohydrin was carried out at 90°C for 27 hr as in the case of propylene oxide, to give 3-methyl-5-chloromethyl-2-oxazolidone (VIb) in 67% yield; bp 94—96°C/0.3 mmHg; IR (neat): 1700 cm^{-1} (C=O).

Found: N, 9.36%. Calcd for $C_5H_8ClNO_2$: N, 9.14%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 168—172 (1970)

Reactions of Various Thione-compounds with Epoxides. A New Method for the Transformation of the C=S Bond into the C=O*1

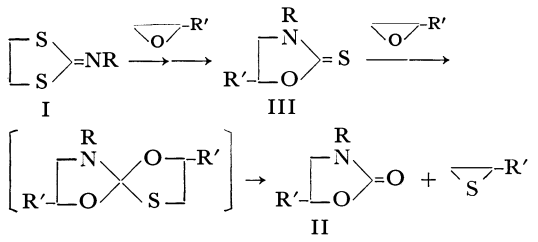
Yoshio UENO, Takeshi NAKAI and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

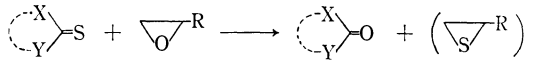
(Received June 10, 1969)

The reactions of propylene oxide (PO) with various thione-compounds containing two α-hetero atoms including dithiocarbamates, thioncarbamates, trithiocarbonates and thioureas, and their cyclic analogs were studied in the presence of triethylamine or boron trifluoride etherate as a catalyst. It was found that most of these thione-compounds reacted with PO at 170—180°C to afford the corresponding one-compounds in good yields. This type of reaction may provide a new method for the transformation of the C=S bonds in thione-compounds into the C=O bonds. Boron trifluoride etherate appeared to be more effective than triethylamine as the catalyst. The mechanism which involves initial cycloaddition of PO to the C=S bond followed by elimination of propylene sulfide was proposed for the transformation. The reactivities of these thione-compounds were significantly affected by whether they are cyclic or open-chain and by the nature of the α-hetero atoms: the cyclic thione-compounds were more reactive then the open-chain analogs except for a pair of thioureas and the enhancement by the α-hetero atoms was in the order: N,O≈N,N>N,S>S,S. Both observations may be interpreted in terms of basicity of the thione-compounds. These results also support the proposed mechanism for the formation of 2-oxazolidones from 2-substituted imino-1,3-dithiolanes with epoxides in our preceding paper.

In the preceding paper[1] we have reported that 2-substituted imino-1,3-dithiolane (I) reacted with epoxides giving the oxazolidone derivatives (II). The mechanism for the formation of II has been assumed to involve the cycloaddition of epoxide to the C=S bond of the intermediate 1,3-oxazolidine-2-thione (III) followed by elimination of episulfide, as illustrated below.



The transformation, however, of the thione-compound into the one-compound with epoxide is not found in literature. The purpose of the present study is to ascertain the proposed mechanism for the formation of II and to extend this type of reaction to a method for the transformation of the C=S bonds in various thione-compounds into the C=O bonds. Thus, the reactions of a variety of thione-compounds including the oxazolidine-2-thione (III) with epoxides were studied. This paper describes a new method for the transformation of the C=S bond in the thione-compound into the C=O bond and clarifies the scope and limitation of this method.



Results

We investigated open-chain and cyclic thione-compounds containing two α-hetero atoms including *S*-methyl *N*,*N*-dimethyldithiocarbamate (IV) and a cyclic analog, *N*-methyl-1,3-thiazolidine-2-thione (V) [X, Y = N and S], *O*-methyl *N*,*N*-dimethylthioncarbamate (VI) and a cyclic analog, *N*-piperidinomethyl-1,3-oxazolidine-2-thione (VII) [X, Y=N and O], dimethyl trithiocarbonate (VIII) and a cyclic analog, 1,3-dithiolane-2-thione (IX) [X, Y=S], and tetramethylthiourea (X) and a cyclic analog, *N*,*N'*-dimethyl-1,3-imidazolidine-2-thione (XI) [X, Y=N].

Oxazolidine-2-thione (VII) was prepared in 88% yield by the reaction of oxazolidine-2-thione with formaldehyde and piperidine. Other thione-compounds were either commerically-available materials or prepared by previously-reported methods.

The reaction of the thione-compound with propylene oxide (PO) was carried out in the presence of

*1 Presented at the 22nd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1969.

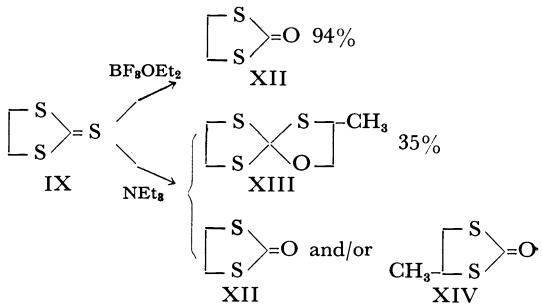
 (XI)	−2.4	A		60[h,i]	1680

a) The reaction temperature: 170—180°C; time: 6.5 hr.
b) The acidities of the conjugate acids of the thione-compounds reported by M. J. Janssen (see Ref. 4).
c) A=NEt_3; B=BF_3OEt_2.
d) The present work (see Experimental section).
e) The starting material was recovered in 92% and 64% yield for VI and VIII, respectively.
f) The reaction conditions; 130—140°C, 5 hr; based on the picrate.
g) The distillate was contaminated with a small amount of triethylamine and unidentified one-compouunds were also obtained (see the text).
h) The reaction conditions: 150°C, 6.5 hr.
i) The starting material was also recovered in 28% yield.

a small amount of triethylamine or boron trifluoride etherate at 170—180°C in a sealed tube. Products obtained were identified by elemental analyses, spectrometric methods (IR and NMR) and comparison of their physical properties with those of the authentic samples. Results obtained are summarized in Table 1.

In the case of 1,3-dithiolane-2-thione (IX) a great difference in product between BF_3OEt_2 and NEt_3 was observed; the reaction in the presence of BF_3-OEt_2 gave the expected product, 1,3-dithiolane-2-one (XII) in 94% yield, whereas the reaction in the presence of NEt_3 afforded a spirocyclic compound XIII as a major product along with one-



compounds XII and/or XIV.

The spirocyclic compound was identified by

(A) H_2C–S, S–CH_2(B); H_2C–S, O–C–CH_3(D); H(C)

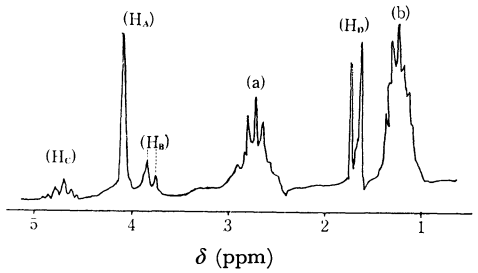


Fig. 1. The NMR spectrum of the spirocyclic compound XIII (CCl_4).
The signals (a) and (b) are due to the protons of the contaminating triethylamine (see the text).

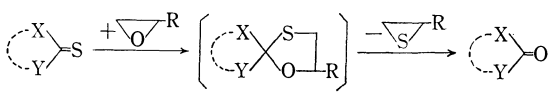
NMR spectrum (Fig. 1) which shows a singlet at δ 4.01 ppm (4H, –S–C$\underline{H}_2$–C$\underline{H}_2$–S–), two doublets at 1.67 (3H, –CH–C$\underline{H}_3$) and 3.75 ppm (2H, –C$\underline{H}_2$–CH–), a multiplet centered at 4.55 ppm (1H, –CH_2–C$\underline{H}$–) and other signals assigned to the protons of the contaminated triethylamine at 1.3 (–CH_2–C$\underline{H}_3$) and 2.8 ppm (–C$\underline{H}_2$–CH_3) (the ratio of 3 : 2). The contamination of triethylamine was also observed in the elemental analysis (Found: N, 0.89%). The spirocyclic compound (XIII) is not very stable. After standing at room temperature for three weeks redistillation of XIII gave one-compounds.

In all cases the episulfide eliminated was detected in the distillation trap tube.

Discussion

Examination of structures of products reveals that the thione-compound is converted into the corresponding one-compound. The fact that the oxazolidine-2-thione (VII) can be easily transformed into the 2-oxazolidone supports a possibility of the proposed mecahnism for the formation of the oxazolidone (II) from the reaction of 2-substituted imino-1,3-dithiolane (I) with epoxides.[1] The results suggest that this type of reaction provides a new method for the transformation of the C=S bonds in thione-compounds into the C=O bonds.

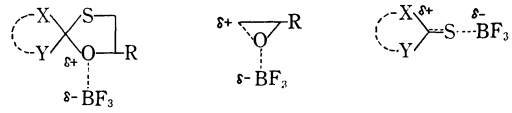
Isolation of the spirocyclic intermediate in the case of IX suggests the cycloaddition-elimination mechanism for the transformation, as illustrated below.



XV

Information on the elimination of episulfide from sulfur containing five-membered heterocycles is available.[2]

Catalytic Effect. As shown in the cases of IV and IX, boron trifluoride etherate appears to be more effective than triethylamine as a catalyst. It should be noted that in the case of IX the one-compound was obtained in the presence of BF_3OEt_2 whereas the spirocyclic intermediate was isolated in the presence of NEt_3. The results may be explained by the fact that BF_3OEt_2 enhances the elimination of episulfide from the oxothiolane (XV) by interaction with the hetero atoms in the ring (XVI) as well as the cycloaddition by interaction with both substrates (XVII and XVIII) while NEt_3 would activate only substrates but not the intermediate.



XVI XVII XVIII

Structural Effects on Reactivities. Examination of yields of products (Table 1), which might be regarded as an approximate measure of the reactivity, indicates that the reactivities of the thione-compounds studied might be significantly affected by whether these compounds are cyclic or open-chain and by the nature of the α-hetero atoms (X and Y); the cyclic thione-compounds are more reactive than the open-chain analogs except for a pair of thioureas and the enhancement by the α-hetero atoms is in the order: N,O≈N,N>N,S>S,S.

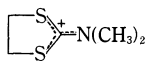
It should be noted that the yield of the one-compound appears to be parallel with the basicity (pK_a) of the thione-compound for both an open-chain and cyclic series (Table 1); the correlation was nearly linear. The fact may account for the two structural effects on the reactivities of the thione-compounds described above. The basicity of the thiocarbonyl group would be more enhanced both by the replacement of the α-hetero group (X and Y) with the stronger electron-donating group and the ring-structure. This would be due to the greater delocalization of the positive charge in structure XIX by the greater supply of electron from the α-hetero atoms.

XIX

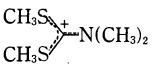
The fact that the positive charge is more delocalized by ring-closing is in line with our observation

2) R. Feinauer, *Angew. Chem. Int. Ed. Engl*, **5**, 894 (1966).

that 2-dimethylamino-1,3-dithiolanylium ion (XX) is more stabilized than an open-chain analog XXI. This might be explained by the more developed 1,3-overlap in the ring system based upon spectral and kinetical observations.[3]



XX



XXI

In comparison with other thione-compounds, it is remarkable that cyclic thiourea XI has lower basicity and less reactivity than the open-chain X. These observations might be explained by steric hindrance to the protonation at the thione-sulfur atom by the N-methyl group arising from the severely restricted rotation around the (S=) C–N bond.[4] Accordingly this effect appears to be very operative in lowering the reactivity of XI toward epoxide.

The results suggest the limitation that only thione-compounds of which pK_a is at least over -5.0 may be transformed into the corresponding one-compounds with epoxides.

Experimental

Melting and boiling points are uncorrected. Infrared and ultraviolet spectra were recorded with Hitachi EPI-S2 and recording EPS-2 spectrometers, respectively. NMR spectra were obtained with a Japan Electron Optics C-100 spectrometer. Chemical shifts are reported in part per million (ppm) from tetramethylsilane as an internal standard.*2

Materials. Propylene oxide (PO) was dried over calcium hydride and then distilled: bp 35°C. Triethylamine was dried over calcium hydride and then distilled: bp 88—89°C. Commercial boron trifluoride etherate was used without purification.

Thione-compounds. The following thione-compounds were either commercially available materials or prepared. *S*-Methyl *N,N*-dimethyldithiocarbamate (IV), mp 46—47°C; dimethyl trithiocarbonate (VIII), bp 85—88°C/5 mmHg; 1,3-dithiolane-2-thione (IX), mp 35—36°C; tetramethylthiourea (X), mp 77—78°C; *N,N'*-dimethyl-1,3-thiazolidine-2-thione (XI), mp 110—112°C.

N-Methylthiazolidine-2-thione(V) was obtained by the thermal ring-isomerization of 2-methylimino-1,3-dithiolane[1]: mp 68—69°C. *O*-Methyl *N,N*-dimethylthioncarbamate (VI) was prepared by the reaction of 2-dimethylamino-1,3-dithiolanylium perchlorate (XX) with sodium methoxide[5]: bp 81—82°C/10 mmHg.

N-Piperidinomethyl-oxazolidine-2-thione (VII) was prepared as follows. Into a stirred solution of 4.4 g (0.05 mol) of oxazolidine-2-thione in 20 m*l* of ethanol was added 7.5 m*l* of 30% formalin. 5 m*l* of piperidine was added drop by drop to the mixture below 10°C. The mixture was stirred at room temperature for 30 min, then at 40—60°C for an additional 30 min. The mixture was cooled in an ice box giving 8.2 g (88%) of precipitates of VII: mp 58—59°C (ethanol).

Found: C, 53.98; H, 8.06; N, 13.99%. Calcd for $C_9H_{16}N_2OS$: C, 53.55; H, 8.07; N, 13.71%.

A General Method for the Reactions of Thione-compounds with Propylene Oxide. The thione-compound (*ca.* 5 g), a slight molar excess of propylene oxide and a small amount of the catalyst were sealed in a hard-glass tube, and heated at 170—180°C for 6.5 hr. After cooling and carefully opening the tube the volatile materials were removed *in vacuo*. Distillation in the reduced pressure or recrystallization from an appropriate solvent of the residue gave the corresponding one-compound.

Reactions of 1,3-Dithiolane-2-thione (IX) with PO. *Triethylamine Catalyst.* 1,3-Dithiolane-2-thione (5.4 g) and PO (3.5 g, 0.05 mol) was heated at 170—180°C for 6.5 hr in the presence of triethylamine (1 m*l*). Distillation of the residue gave two distillates; bp 90—110°C/7 mmHg and bp 132—138°C/4 mmHg (2.7 g). The former showed a carbonyl band at 1650 cm^{-1}, however the latter did not show any absorption bands in the carbonyl region. The latter was a reddish liquid with an unpleasant odor, and was distilled after standing for three weeks giving a small amount of a low-boiling distillate spectrometrically identical with the former. The NMR spectrum (Fig. 1) of the latter confirms the structure and indicates that the distillate was contaminated with triethylamine used as a catalyst.

Found: S, 50.59; N, 0.86%. Calcd for $C_6H_{10}OS$: S, 49.44; N, 0%.

Boron Trifluoride Etherate Catalyst. In the presence of a few drops of BF_3OEt_2 the reaction was carried out under the same conditions. Distillation of the residue gave one distillate of 1,3-dithiolane-2-one (XII) in 94% yield: bp 82—90°C/0.23 mmHg. The distillate was solidified by standing at room temperature: mp 31—32°C (lit,[6] 31°C). The IR spectrum of the product was identical with that of the authentic sample.

Identifications of Products. Products obtained are summarized in Table 1 along with yields and infrared carbonyl bands. Products were identified by elemental analyses, the spectrophotometric methods and comparison of their physical properties with those of the authentic samples as follows.

S-Methyl N,N-dimethylthiolcarbamate: bp 87—89°C/30 mmHg; n_D 1.4938 (21°C) (lit,[7] bp 115—116°C/89 mmHg; n_D 1.4932 (30°C)). This compound was identical with the authentic sample prepared by the reaction of *O*-methyl *N,N*-dimethylthioncarbamate with methyl iodide[8] or by the hydrolysis of bis(methylthio)-dimethylaminocarbonium perchlorate (XXI).[9]

N-Methylthiazolidine-2-one. Bp 85—87°C/0.3 mmHg

pK_a Measurement. The value of pK_a of the thione-compound was obtained by the method by Janssen.[4] The molar extinction coefficients (ε) in the UV spectra of *N*-methyl-thiazolidine-2-thione (V) were measured in 98% and 15% sulfuric acid and water. The value of pK_a was calculated from the equation

$$pK_a = H_0 + \log [(\varepsilon_M - \varepsilon_B)/(\varepsilon_{BH} - \varepsilon_M)],$$

where H_0 denotes Hammett's acidity function($H_0 = -0.66$ for 15% sulfuric acid[13]) and ε_B, ε_M and ε_{BH} represent the molar extinction coefficients in water, and 15% and 98% sulfuric acid, respectively. The experimental data for V are shown in Table 2.

Table 2. Measurement of pK_a of V

Wavelength mμ	ε_B	ε_M	ε_{BH}	pK_a

Effects of Alkyl Halides on the γ-Ray Induced Polymerization of Ethylene in Liquid Carbon Dioxide

Miyuki HAGIWARA, Hidemasa OKAMOTO and Tsutomu KAGIYA

Japan Atomic Energy Research Institute, Takasaki Radiation Chemistry Research Establishment, Takasaki, Gumma

(Received June 13, 1969)

The ^{60}Co γ-ray induced polymerization of ethylene in a liquid carbon dioxide solvent was carried out under a pressure of 400 kg/cm^2 at 30°C in the presence of such alkyl halides as CH_2Cl_2, $CHCl_3$, CCl_4, C_2H_5Cl, C_2H_5Br, C_2H_5I, $C_2H_4Cl_2$, $C_2H_2Cl_4$, C_2Cl_6, C_2F_6, C_2F_5Cl, $C_2F_4Cl_2$, $C_2H_3Cl_3$, and $C_2F_2Cl_4$, and their effects on the polymerization rate and the molecular weight of the polymer formed were investigated. Both the rate and the molecular weight were increased by adding $C_2F_4Cl_2$, C_2F_5Cl, and C_2F_6. A study of the radiolysis of these three fluorocarbons by mass spectrometric analysis showed that bond scissions of these substances took place mainly at the C–C bond. When other halogen compounds besides the three fluorocarbons were added to the reaction mixture, the rate and the molecular weight were decreased and C–X (X: halogen) bond scission was predominant in those substances. On the basis of these results, the role of the additives in the polymerization was discussed in relation to their radiolysis reactions.

In previous papers,[1-3] liquid carbon dioxide was found to be a useful solvent for the γ-ray induced polymerization of ethylene. It was shown from a kinetic study of the polymerization that the rate of initiation increased with an increase in the concentration of the carbon dioxide solvent. The role of the solvent in the initiation has been ascribed to the fact that the absorption step of radiation energy depends on the electron density of the reaction mixture. Further, the radiolysis products of the solvent were found to have some effects on the termination reaction of the polymerization.

3) M. Hagiwara, H. Mitsui, S. Machi and T. Kagiya, *ibid., Part A-1*, **6**, 721 (1968).

In consideration to their high electron density and high chemical reactivity, alkyl halides are expected to have various radiation-induced effects on the polymerization. In this paper, the effects of various alkyl halides on the polymerization of ethylene in liquid carbon dioxide will be investigated, and the role of the additives will be discussed in relation to their radiolysis reactions.

Experimental

The reaction vessel was a stainless-steel autoclave with a capacity of 100 m*l*. The ethylene used was 99.9% pure (free of CO and H_2S) and contained less than 5 ppm of O_2. The carbon dioxide was 99.99% pure; its major impurities were H_2O (37 ppm), CH_4 (20 ppm), and O_2 (2 ppm). The alkyl halides were all reagent-grade and were refined in a usual way. Both liquid carbon dioxide and alkyl halide were first charged into the vessel (liquid CO_2, 20 g; alkyl halide, 5 g). Ethylene was then fed in to about 400 kg/cm² at 30°C. The density of the reaction system could thus be kept almost constant in all experiments. The reaction temperature was controlled within ±0.5°C by using an automatic controller during the course of the reaction. The irradiation of ^{60}Co γ-rays was carried out for 3 hr at a dose rate of 2.5×10^4 rad/hr. The amount of polymer formed was determined by direct weighing. The number-average molecular weight of the polymer thus formed was obtained from the intrinsic viscosity measurements using Tung's formula.[4] Infrared absorption spectra were recorded for film samples in the range of 4000—400 cm^{-1}. Mass spectra for several kinds of alkyl halides were taken on a Hitachi mass spectrometer, Model RMU-6, under a pressure of 10^{-3} mmHg.

Results and Discussion

Polymerization in the Presence of Various Alkyl Halides. The polymer yield and the number-average molecular weight of the polymer formed in the presence of various alkyl halides are summarized in Table 1. The number of moles of the polymer chain, defind as the ratio of the polymer yield to the molecular weight, $M_p/\bar{M}_n$, is also listed in the last column of the table. The polymer yield and the polymer's molecular weight were found to decrease in many cases when alkyl halides were added to the reaction mixture. However, when some fluorocarbons, such as C_2F_6, C_2F_5Cl and CF_2ClCF_2Cl, were added, both the rate and the molecular weight increased. In the series of polymerizations in the presence of C_2H_5Cl, C_2H_5Br, or C_2H_5I, ethyl chloride or bromide gave about the same yields and molecular weights, though they were much lower than those without additives. On the other hand, ethyl iodide gave an extremely low yield. Polychlorinated hydrocarbons, such as CH_2Cl_2, $CHCl_3$, CCl_4, CH_2ClCH_2Cl, $CHCl_2$-$CHCl_2$, and C_2Cl_6, did not show any change in the yield. On the other hand, the molecular weight decreased markedly with an increase in the number of chlorine atoms in the molecule of the additives. This relation between the molecular weight and the number of chlorine atoms was also observed with the use of fluorocarbons.

Table 1. Effects of alkyl halides on polymer yield, molecular weight and number of moles of polymer chain

Alkyl halide	Polymer yiled M_p, g	Molecular weight $\bar{M}_n\times10^{-4}$	Number of moles of polymer chain $N_p\times10^4$ mol/*l*
——	0.816	13.9	0.59

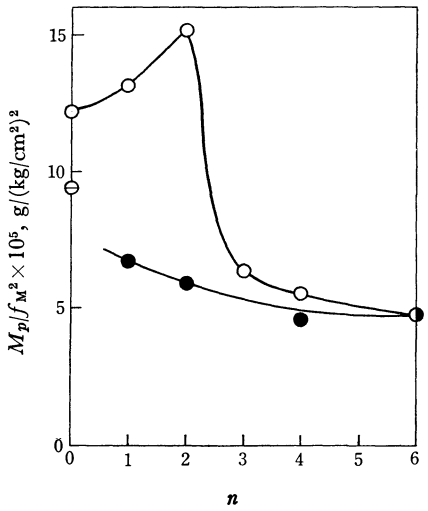

Fig. 2. The amount of polymer formed *vs.* the number of chlorine substitution of halogenated ethane derivatives: (⊖) free; (●) $C_2H_{6-n}Cl_n$; (○) $C_2F_{6-n}Cl_n$. Reaction pressure, 400 kg/cm²; temperature, 30°C; dose rate, 2.5×10^4 rad/hr; time, 3 hr; carbon dioxide, 20 g; halogenated ethane derivative, 5 g.

as is given in Fig. 1. In the case of $CFCl_2CFCl_2$, both C–Cl stretching bands (603, 633, 658 cm^{-1}) and C–F stretching bands (1000, 1156, 1190 cm^{-1}) were observed. The role of the additives and their radiolysis products in the polymerization and the step of their introduction into the polymer chain will be discussed below.

Polymerization in the Presence of Halogenated Ethane Derivatives. Using the results listed in Table 1, the polymer yields are plotted in Fig. 2 against the number of the chlorine substitution for two series of halogenated ethane derivatives, *i.e.*, $C_2H_{6-n}Cl_n$ and $C_2F_{6-n}Cl_n$, where n stands for the number of the chlorine substitution.

The fugacity of ethylene of the reaction system is inevitably changed depending on the nature of the additives. Several authors have previously reported that the polymerization rate and the polymer molecular weight are proportional to the square of ethylene fugacity.[2] Hence, the polymer yields in Fig. 2 are divided by the square of ethylene fugacity to normalize them to a unit of fugacity.

It can be seen that the yield under a unit of fugacity is much smaller in the presence of chlorinated hydrocarbons than that of the blank experiment without additives, and that it decreases gradually with the increase in the number of the chlorine substitution. On the other hand, in the case of fluorcarbons, it increases with the number of the chlorine substitution and passes through a maximum at $n=2$; thereafter it decreases with an increase in the number of the substitution. Thus, CF_2ClCF_2Cl gives a maximum yield which is about 1.5 times as large as that of the blank experiment. However, in the cases of $CF_2ClCFCl_2$ and $CFCl_2CFCl_2$ the yield becomes almost the same as that of the corresponding chlorinated hydrocarbons.

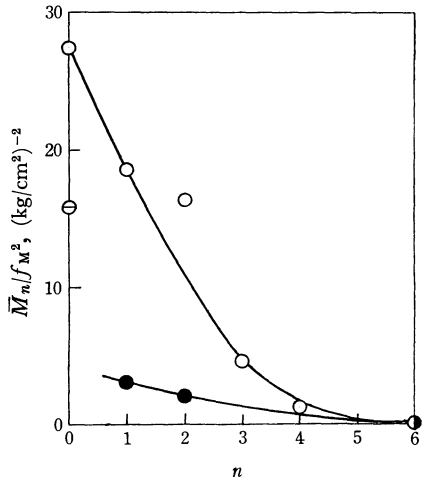

Fig. 3. Molecular weight *vs.* the number of chlorine substitution of halogenated ethane derivatives. Reaction conditions and notes are the same as Fig. 2.

Figure 3 shows the relation between the molecular weight of the polymer (normalized to a unit of ethylene fugacity) and the number of the chlorine substitution. In the series of chlorinated ethanes, the molecular weight under a unit of fugacity is markedly reduced by additives and decreases with the number of the chlorine. The decrease in the molecular weight with the chlorine content is also observed in the case of fluorocarbons. However, in the latter case, the molecular weight is larger than that in the case of no additives in the lower region of the chlorine substitution (less than $n=2$).

Futher, in Fig. 4, the number of moles of the

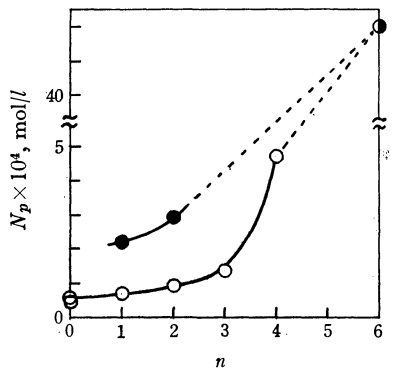

Fig. 4. Number of polymer chains *vs.* the number of chlorine substitution of halogenated ethane derivatives.
Reaction conditions and notes are the same as Fig. 2.

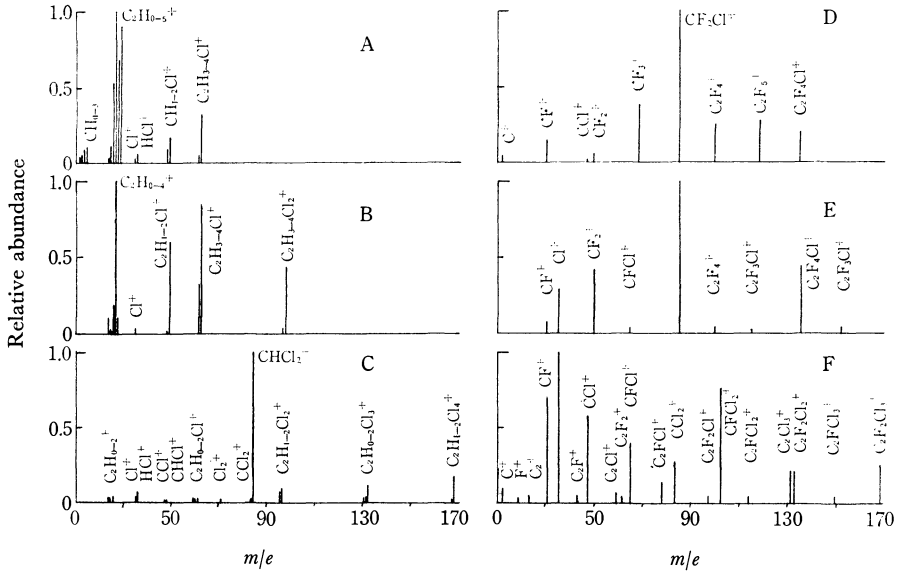

Fig. 5. Mass spectra of halogenated ethane derivatives: (A) C_2H_5Cl; (B) CH_2ClCH_2Cl; (2) $CHCl_2CHCl_2$; (D) C_2F_5Cl; (E) CF_2ClCF_2Cl; (F) $CFCl_2CFCl_2$.

polymer chain is also plotted against the number of chlorine substitution. The number of the polymer chain is shown to increase with the chlorine substitution in both hydro- and fluorocarbons.

From the results presented above, the increase in the polymer yield in the order of $C_2F_6 < C_2F_5Cl < CF_2ClCF_2Cl$, which is reported in Fig. 2, may be ascribed to the increase in the rate of initiation. The promoting effects of these fluorocarbons on the propagation reaction should also be considered in terms of the following results, obtained in the presence of C_2F_6. Thus, as is shown in Figs. 2 and 3, both the yield and the molecular weight increase upon the addition of C_2F_6. On the other hand, the number of the polymer chain is shown in Fig. 4 to be almost the same as that of the blank experiment. In contrast to the cases of C_2F_6, C_2F_5Cl, and CF_2ClCF_2Cl, the yield and the molecular weight are depressed by the addition of other fluorocarbons, such as $CF_2ClCFCl_2$ and $CFCl_2CFCl_2$, and all the chlorinated hydrocarbons employed. This means that these additives contribute mainly to promoting the termination reaction. Further, the decrease in the moleculr weight and the increase in the number of the polymer chain with the chlorine substitution suggest that the chlorine atom in these compounds plays an important role in the chain-transfer reaction.

Thus, from the point of view of their characteristic roles, the halogenated ethanes may be classified into two different groups. One group, such as C_2F_6, C_2F_5Cl, and CF_2ClCF_2Cl, promotes the polymerization, while the other group, such as $CF_2ClCFCl_2$, $CFCl_2CFCl_2$, C_2H_5Cl, CH_2ClCH_2Cl, $CHCl_2CHCl_2$ and C_2Cl_6, retards it.

Free Radicals from the Radiolysis of the Additives and Their Role in the Polymerization. In Fig. 5, the relative abundance of the ions detected by the mass spectrometer is plotted against the *m/e* for several halogenated ethane derivatives. The large relative abundance of the $C_2H_{0-5}^+$ ions in C_2H_5Cl and that of the $C_2H_{0-4}^+$, and $C_2H_{3-4}^+$ ions in CH_2ClCH_2Cl indicates that the bond cleavage by radiation occurs mainly at C–Cl and C–H in these compounds. On the other hand, C_2F_5Cl and CF_2ClCF_2Cl are shown to cleave mainly at the C–C bond, since CF_2Cl^+ and CF_3^+ in C_2F_5Cl, and CF_2Cl^+ in CF_2ClCF_2Cl, are observed to be predominant in their spectra. Moreover, the figure shows that the cleavage in highly-chlorinated ethane derivatives occurs at the C–C and C–Cl bonds about equally.

These mass spectrometric data suggest that such radicals as $CF_3\cdot$ and $CF_2Cl\cdot$ are mainly produced by the C–C bond dissociations of C_2F_5Cl and CF_2ClCF_2Cl, which promote the polymerization. Further, several kinds of hydrocarbon radicals, chlorine atoms, and highly-chlorinated radicals, such as $CHCl_2\cdot$ and $CFCl_2\cdot$, are produced by the use of C_2H_5Cl, CH_2ClCH_2Cl, $CHCl_2CHCl_2$, and $CFCl_2CFCl_2$, which retard the polymerization.

From this information on the effect of halogenated compounds on the polymerization and on the structure of their radiolysis products, it might be said that CF_3 or CF_2Cl radicals act as initiators of the polymerization. However, hydrocarbon radicals, chlorine atoms, or highly-chlorinated radicals act mostly in the termination rather than in the initiation reaction of the polymerization.

In view of the fact that the rate of cross combina-

tion is faster than that of the combination of the radical with the same structure, a cross termination reaction between the growing chain radical and the radical generated from the added halogen compounds is considered to be important. The relative fraction of the cross termination can be expressed in terms of the rate constants, $k_{AR}/(k_{AA}k_{RR})^{0.5}$, for the following reactions:

$$A\cdot + A\cdot \rightarrow A_2 \qquad k_{AA} \qquad (1)$$
$$R\cdot + R\cdot \rightarrow R_2 \qquad k_{RR} \qquad (2)$$
$$A\cdot + R\cdot \rightarrow AR \qquad k_{AR} \qquad (3)$$

where A· represents a halogen-containing radical, and R·, a growing radical.

Many data have recently been accumulated on the cross combination reactions of low-molecular-weight alkyl radicals with or without halogen atoms.[5-9] The values of $k_{AR}/(k_{AA}k_{RR})^{0.5}$ for $R=CH_3$ and C_2H_5 do not differ from each other; both lie between 1.5—2.6. Hence, the difference in the effects of the additives on the ethylene polymerization may be ascribed to the difference in the reactivities of the radicals formed by the radiolysis to the ethylene monomer rather than that to the growing radicals.

The relative reactivity of CF_3, CH_3, and CCl_3 radicals to the ethylene monomer can be evaluated in terms of their activation energies, E_a, in the following addition reactions:

$$CF_3\cdot + CH_2{=}CH_2 \rightarrow CF_3{-}CH_2CH_2\cdot \qquad E_{aCF_3} \qquad (4)$$
$$CH_3\cdot + CH_2{=}CH_2 \rightarrow CH_3{-}CH_2CH_2\cdot \qquad E_{aCH_3} \qquad (5)$$
$$CCl_3\cdot + CH_2{=}CH_2 \rightarrow CCl_3{-}CH_2CH_2\cdot \qquad E_{aCCl_3} \qquad (6)$$

Recently, a two-constant approximate formula (7) was proposed for the evaluation of the activation energy of the radical substitution reaction in the gaseous phase:[10]

$$E_a = D_i - \alpha D_f(1+\beta D_i) \qquad (7)$$

In this formula, D_i is the dissociation energy of the initial system, and D_f, that in the final system, while α and β are constants. In estimating the activation energies of the above addition reactions, (4), (5), and (6), D_i corresponds to D_π, the π-dissociation energy of ethylene. Hence,

$$E_a = D_\pi - \gamma D_f \qquad (8)$$

where γ is equal to $\alpha(1+\beta D_\pi)$. Since the D_π is constant in the reactions (4), (5), and (6), Eq. (8) shows that the activation energy depends solely upon the dissociation energy of the bond formed in the final system, D_f, and that it decreases with an increase in D_f. The C–C bond dissociation energies for CF_3–CH_3 and CH_3–CH_3 are 90[11]—117[12] and 83[13] kcal respectively, while that for CCl_3–CH_3 is estimated by thermodynamic calculation to be 77.7 kcal.[14,15] Since the order of the C–C bond dissociation energies for CF_3–CH_2CH_2·, CH_3–CH_2CH_2·, and CCl_3–HC_2CH_2· is the same as that for the corresponding compounds, such as CF_3–CH_3, CH_3–CH_3, and CCl_3–CH_3, the order of the activation energies of the reactions (4), (5), and (6) may be considered to be: $E_{aCF_3} < E_{aCH_3} < E_{aCCl_3}$.

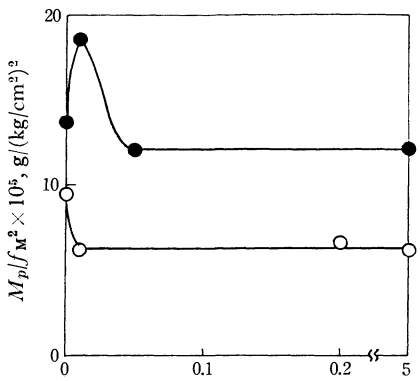

Fig. 6. The amount of polymer formed *vs.* the amount of C_2Cl_6 added. Reaction pressure, 400 kg/cm²; temperature, 30°C; dose rate, 2.5×10^4 rad/hr; time, 3 hr; carbon dioxide, 20 g; C_2F_6, 5 g; C_2F_4, (○) free, (●) 1 mol% to C_2H_4.

Figure 6 shows the results of the polymerization carried out in the presence of the mixture of C_2Cl_6 and C_2F_6. In the polymerization in the C_2F_6 solvent, the polymer yield under a unit of ethylene fugacity is markedly depressed by the addition of a very small amount of C_2Cl_6. Moreover, when a small amount of C_2F_4 (1 mol% to C_2H_4) was added to the mixed solvent of C_2Cl_6 and C_2F_6, the yield increases in the low-concentration range of C_2Cl_6, but declines to a constant value as the amount of C_2Cl_6 increases. The decrease in the yield, however, is shown to become less pronounced than in the case without C_2F_4. These facts suggest that the chlorine-

containing radicals produced by the radiolysis of C_2Cl_6, which will act as a terminating agent of the growing radicals, are effectively scavenged by C_2F_4, and that they are changed into highly-fluorinated radicals which contribute mainly to the initiation reaction. The decrease in the polymer yield at high concentrations of C_2Cl_6 may be ascribed to the reaction between the growing radicals and the radicals from C_2Cl_6, which are not scavenged by C_2F_4.

Amino Acids and Peptides. I. Syntheses of *p*-Methoxybenzyl *p*-Nitrophenyl Carbonate, *p*-Methoxybenzyl Carbazate, and *p*-Methoxybenzyloxycarbonyl Amino Acids[1] with *p*-Methoxybenzyl Chloroformate

Shōsuke Sōfuku, Mitsuo Mizumura and Akira Hagitani

Department of Chemistry, Faculty of Science, Rikkyo (St. Paul's) University, Toshima-ku, Tokyo

(Received June 16, 1969)

A new method for the syntheses of *p*-methoxybenzyl *p*-nitrophenyl carbonate, *p*-methoxybenzyl carbazate, and *p*-methoxybenzyloxycarbonyl amino acids has been devised. These compounds were obtained in satisfactory yield from sodium *p*-nitrophenolate, 85% hydrazine hydrate, and several amino acids with *p*-methoxybenzyl chloroformate prepared from anisyl alcohol and phosgene in the presence of dimethylaniline in dry ether at −5—−10°C. This direct *p*-methoxybenzyloxycarbonylation of amino acid with the chloroformate is more convenient than the usual Weygand method.

The *p*-methoxybenzyloxycarbonyl [Z(OMe)][2] group has been widely used as a blocking substituent of the amino moiety of amino acids in peptide synthesis.[3,4] This group allows an easier removal by trifluoroacetic acid than the parent group (carbobenzoxy)[5] without the methoxy substituent. *p*-Methoxybenzyloxycarbonyl amino acids[6] were obtained for the first time by the reaction of isocyanocarboxylic acid esters with anisyl alcohol and subsequent hydrolysis. Later Weygand and Hunger[7] prepared these compounds in a synthesis analogous to that of the *t*-butyloxycarbonyl amino acids.[8] The Z(OMe) group was introduced with the use of *p*-methoxybenzyl *p*-nitrophenyl carbonate (II) or *p*-methoxybenzyloxycarbonyl azide prepared by the reaction of *p*-methoxybenzyl carbazate (III) with nitrous acid. Their method has been used in many cases, but the synthesis of II and III involves many steps, and the yields are not so high.

Recently, Schnabel *et al.*[9,10] reported the syntheses of *p*-methoxybenzyloxycarbonyl amino acids with *p*-methoxybenzyl fluoroformate. Jones and Young[11,12] described a method for synthesizing *p*-methoxybenzyl-1-piperidyl carbonate by the use of *p*-methoxybenzyl chloroformate (I). In this method I was prepared from anisyl alcohol and phosgene in dry ether at 20°C, and was coupled with 1-hydroxypiperidine in dry ether at 0°C. For the preparation of *p*-methoxybenzyloxycarbonyl

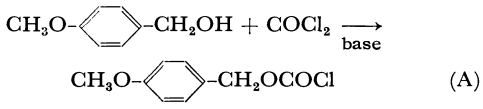
amino acid, *p*-methoxybenzyl-1-piperidyl carbonate and amino acid ester hydrochloride were stirred with sodium acetate in dioxane at 20°C for 24 hr. After the publication of our short communication[1] Honda *et al.*[13] reported a convenient method of synthesis of *p*-methoxybenzyloxycarbonyl amino acids and *p*-methoxybenzyl carbazate with the use of *p*-methoxybenzyl chloroformate.

In the present investigation, I could be prepared readily from anisyl alcohol (1 eq.) and phosgene (3 eq.) in the presence of dimethylaniline (1 eq.) in dry ether at below 0°C. This reagent was very useful for the preparation of *p*-methoxybenzyl *p*-nitrophenyl carbonate (II)[14] and *p*-methoxybenzyl carbazate (III).[15]

p-Methoxybenzyloxycarbonyl amino acids could be prepared directly from a number of amino acids and I under the conditions of the Schotten-Baumann reaction without any accompanying racemization.

Results and Discussion

Reagent I was prepared by the following reaction:



(I) (A)

Though reaction (A) could take place without a base, its addition was better for the removal of hydrogen chloride from the reaction solution. Because of the instability of I, the amount of phosgene required and the effectiveness of the base used for the preparation of I were examined by comparing the yields of II in combination with the reactions (A) and (B). Among the hydrochlorides of the bases, the one of dimethylaniline was most easily filtered off.

Addition of three equivalents of phosgene to anisyl alcohol in the presence of one equivalent of dimethylaniline gave the best yield of product II, as shown in Table 1.

After the completion of reaction (A), it was necessary to remove the salt completely by filtration and excess phosgene by evaporation under a reduced pressure at below 0°C. I was immediately dissolved in a suitable solvent, and used for succeeding reactions. The temperature of the reaction mixture was maintained as low as possible to prevent the degradation of I. For the preparation of II, sodium

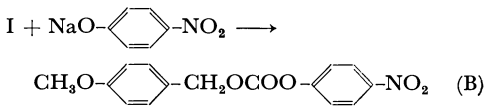
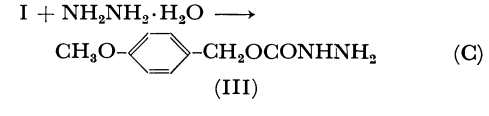
p-nitrophenolate dried by azeotropic dehydration with xylene was used.



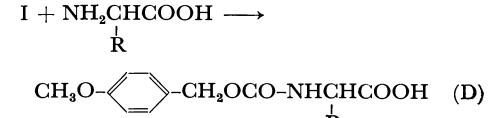
(II) (B)

In the preparation of III, it was not necessary to use anhydrous hydrazine. It could be obtained with 85% hydrazine hydrate[16] in a satisfactory yield.



(III) (C)

Preparation of *p*-methoxybenzyloxycarbonyl amino acids was carried out with two equivalents of I and four equivalents of sodium hydroxide for an amino acid in a mixture of water and tetrahydrofuran (5 : 1).



(D)

In the case of L-serine, carbobenzoxylation of the amino group has been devised,[17] and one equivalent of I was added. The crude product contained only a small amount of *N,O*-di-Z(OMe)-L-serine, which was detected by thin layer chromatography (solvent; chloroform : methanol : acetic acid=95 : 5 : 3)[18];

Table 2. Results of the preparation of *p*-methoxybenzyloxycarbonyl amino acids

Compound	Yield %	Mp °C	$[\alpha]_D$	Solvent (c 2.0)	Temp. °C
Z(OMe)-glycine	80.0	95—98			
		95—98*3			
Z(OMe)-L-alanine	65.4	78—81	−11.5	acetic acid	22
		74—75*1	−11.9*1		
Z(OMe)-L-aspartic acid	40.9	125—127.5	+10.3	acetic acid	18
		122.5—124*1	+ 7.1*1		
Z(OMe)-L-glutamic acid	46.1	109—112	− 5.6	acetic acid	22
		109—111*1	− 7.44*1		
Z(OMe)-L-serine	53.3	94—96.5	+ 6.5	acetic acid	20
		97—98*1	+ 7.1*1		
		92—94*2	+ 5.8*2		
Z(OMe)-L-valine DCHA	79.2	162—165	+ 3.3	methanol	20
		162—166*4	+ 2.8*4		
Z(OMe)-L-leucine DCHA	88.7	159—162	− 6.0	methanol	21
		162*1	− 6.67*1		
Z(OMe)-L-phenylalanine DCHA	75.1	159—162	+22.7	methanol	21
		157—159*1	+22.6*1		
Z(OMe)-L-proline DCHA	82.6	145—147	−23.1	methanol	20
		147.5—149*1	−25.1*1		
Z(OMe)-L-methionine DCHA	87.9	150—153	+ 6.0	methanol	21
		152—153*1	+ 3.35*1		
α-*N*-Z(OMe)-δ-*N*-Z-L-ornithine DCHA	33.4	133—135	+ 6.3	methanol	19
		121—122*5	− 4.0*5		

Values, *1 from Ref. 7, *2 from Ref. 10; [α] value at 578 mμ, *3 from Ref. 11, *4 from Ref. 12 and *5 from Ref. 22.
DCHA: dicyclohexylammonium salt, Z(OMe): *p*-methoxybenzyloxycarbonyl, Z: benzyloxycarbonyl.
All melting points are uncorrected.

N-Z(OMe)-L-serine was purified by recrystallization. As shown in Table 2, some products were obtained as the salts of dicyclohexylamine.[19] The *p*-methoxybenzyloxycarbonyl amino acids were recrystallized from ethyl acetate - petroleum ether, and the dicyclohexylammonium salts from ethanol - petroleum ether.

Each derivative gave one spot in thin layer chromatography[18] and was examined by infrared spectrum for –O–CO–N group.[20,21]

Experimental[23]

***p*-Methoxybenzyl Chloroformate (I).** Phosgene (21 m*l*, 0.3 mol) was measured into a glass trap which had been cooled in a dry ice-acetone jar, and poured into a 500-m*l* two-necked conical flask containing 100 m*l* of dry ether, and cooled in an ice-salt bath. A solution of 12.4 m*l* of anisyl alcohol (0.1 mol) in 100 m*l* of dry ether was added in portions to the above solution over a period of 10 min. Then a solution of 12.7 m*l* of dimethylaniline (0.1 mol) in 100 m*l* of dry ether was added dropwise over a period of 1 hr, and the mixture was stirred for 2 hr at −5——10°C. After filtration of the dimethylaniline hydrochloride formed in the reaction, the filtrate was evaporated under reduced pressure at below 0°C. Twice more 100 m*l* of dry ether was added to the oily residue and evaporation was repeated to remove excess phosgene completely. The residue was immediately dissolved in a suitable solvent and the solution was used for the following reactions.

***p*-Methoxybenzyl *p*-Nitrophenyl Carbonate (II).** To a solution of 0.1 mol of I in 300 m*l* of dry xylene, 17.7 g of powdered dry sodium *p*-nitrophenolate (0.11 mol) was added in portions over a period of 10 min with vigorous stirring at 0——5°C. After 3 hr at this temperature, it was stirred overnight at room temperature and for 1 hr at 30°C. Excess sodium *p*-nitrophenolate and sodium chloride were filtered off, and the filtrate was washed successively with 0.5N hydrochloric acid, N sodium carbonate, and water, and then dried over anhydrous sodium sulfate. The filtered solution was evaporated *in vacuo*. Recrystallization of the residue from ethanol gave the pure product. Yield, 20.0 g (66.0%); mp, 104.5—105.5°C (lit,[7] 96—97°C). IR spectrum (KBr): 1760 cm^{-1}.

23) The infrared spectra were recorded on a Shimadzu Model IR 27-B Spectrophotometer.

Found: C, 59.52; H, 4.43; N, 4.73%. Calcd for $C_{15}H_{13}NO_6$: C, 59.41; H, 4.32; N, 4.62%.

p-Methoxybenzyl Carbazate (III). A solution of 0.1 mol of I in 100 m*l* of dry ether was added in portions over a period of 10 min to a mixture of 29.4 g of 85% hydrazine hydrate (0.5 mol) and 50 m*l* of ether with vigorous stirring at −30—−60°C. A white precipitate was immediately formed. After 30 min, 300 m*l* of water was added and the mixture was filtered. The precipitate was thoroughly washed with water. The amount of this precipitate was two-thirds of the total product, and the other one-third was isolated from the ether layer. The combined product was recrystallized from ethyl acetate-petroelum ether. Yield, 15.0 g (76.5%); mp, 74—75°C (lit,[7] 71—74°C). IR spectrum (KBr): 1690, 3330 cm^{-1}.

Found: C, 55.36; H, 6.31; N, 14.32%. Calcd for $C_9H_{12}N_2O_3$: C, 55.09; H, 6.16; N, 14.28%.

p-Methoxybenzyloxycarbonylglycine. A solution of 0.1 mol of I in 70 m*l* of tetrahydrofuran was added in portions over a period 10 min to a solution of 3.75 g of glycine (0.05 mol) in 200 m*l* of N sodium hydroxide containing 40 m*l* of tetrahydrofuran with vigorous stirring at 0—5°C. After 2 hr under these conditions, the reaction mixture was washed with 100 m*l* of ether, and acidified with 21 g of citric acid (0.1 mol) at 0—5°C, and the product was extracted with 500 m*l* of ethyl acetate. The organic layer was washed with water, dried over anhydrous sodium sulfate, and concentrated *in vacuo*. The resulting residue was crystallized from ethyl acetate and petroleum ether as fine crystalline plates; yield, 9.57 g. IR spectrum (KBr): 1695 cm^{-1}.

Found: C, 55.14; H, 5.52; N, 6.00%. Calcd for $C_{11}H_{13}NO_5$: C, 55.24; H, 5.48; N, 5.86%.

p-Methoxybenzyloxycarbonyl-L-alanine. By the same method as for Z(OMe)-glycine, 8.32 g of rod crystals of pure product was obtained from 4.45 g of L-alanine (0.05 mol) and 0.1 mol of I. IR spectrum (KBr): 1690 cm^{-1}.

Found: C, 56.94; H, 5.83; N, 5.70%. Calcd for $C_{21}H_{15}NO_5$: C, 56.90; H, 5.98; N, 5.54%.

p-Methoxybenzyloxycarbonyl-L-aspartic Acid. To a solution of 6.65 g of L-aspartic acid (0.05 mol) in 1.5N sodium hydroxide (200 m*l*) containing tetrahydrofuran (40 m*l*), 0.1 mol of I in tetrahydrofuran (70 m*l*) was added in portions over a period of 10 min at 0—5°C. The mixture was stirred for 2 hr at this temperature, then washed with ether (100 m*l*), and acidified with 35 g of citric acid; the product was extracted with ethyl acetate (500 m*l*). The organic layer was washed with water and dried over anhydrous sodium sulfate. The solution was concentrated under reduced pressure, and recrystallization of the residue from ethyl acetate-petroleum ether gave a pure granular product. Yield, 6.07 g. IR spectrum (KBr): 1710 cm^{-1}.

Found: C, 52.54; H, 5.25; N, 4.84%. Calcd for $C_{13}H_{15}NO_7$: C, 52.34; H, 5.41; N, 4.70%.

p-Methoxybenzyloxycarbonyl-L-glutamic Acid. By the same method as for Z(OMe)-L-aspartic acid, the crude product was obtained from 7.36 g of L-glutamic acid (0.05 mol) and 0.1 mol of I, and crystallized as pure granules (7.20 g) from ethyl acetate and petroleum ether. IR spectrum (KBr): 1710 cm^{-1}.

Found: C, 53.76; H, 5.22; N, 4.58%. Calcd for $C_{14}H_{17}NO_7$: C, 54.00; H, 5.50; N, 4.50%.

p-Methoxybenzyloxycarbonyl-L-serine (A). To a solution of 10.5 g of L-serine (0.1 mol) in a mixture of N sodium hydroxide (200 m*l*) and 40 m*l* of tetrahydrofuran, a solution of 0.1 mol of I in 70 m*l* of tetrahydrofuran was added in portions over a period of 10 min with vigorous stirring at 0—5°C. The reaction mixture was stirred at this temperature for 2 hr, and then washed with 100 m*l* of ether, and acidified with 21 g of citric acid at 0—5°C. An oily product was extracted with ethyl acetate. The solution was washed with water, dried over anhydrous sodium sulfate, and then concentrated under reduced pressure to dryness.

Reacrystallization of the residue from ethyl acetate and petroleum ether gave 12.8 g of the crude product (mp 87—96°C). This was again crystallized from the same solvents and 7.84 g of the pure product A was obtained. Concentration and cooling of the mother liquor gave 3.8 g of the mixture of A and *O,N*-di-Z(OMe)-L-serine (B). After recrysatllization was repeated twice from ethanol, 1.07 g of B was obtained. From the mother liquor 1.16 g of A was recovered.

Compound A, total yield, 9.0 g. IR spectrum (KBr): 1685 cm^{-1}. TLC (Wakogel B-O): R_f,[18] 0.2.

Found: C, 53.74; H, 5.70; N, 5.18%. Calcd for $C_{12}H_{15}NO_6$: C, 53.53; H, 5.62; N, 5.21%.

Compound B, mp 115—116.5°C (dec). $[\alpha]_D^{17}$ +16.67 (*c* 3, acetic acid). IR spectrum (KBr): 1765, 1650 cm^{-1}. TLC (Wakogel B-O): R_f,[18] 0.6.

Found: C, 58.28; H, 5.41; N, 3.29%. Calcd for $C_{21}H_{23}NO_9$: C, 58.19; H, 5.35; N, 3.23%.

p-Methoxybenzyloxycarbonyl-L-valine Dicyclohexylammonium Salt. Z(OMe)-L-valine was prepared by the same procedure as was used for the Z(OMe)-glycine, *viz.*, an oily residue was obtained from 5.85 g of L-valine (0.05 mol) and 0.1 mol of I. This residue was dissolved in 100 m*l* of ether, and 9.96 m*l* of dicyclohexylamine (0.05 mol) was added at 0—5°C. The white precipitate was filtered and washed with ether. Pure needle crystals were obtained by recrystallization from ethanol and petroleum ether; yield, 9.15 g. IR spectrum (KBr): 1710, 1630 cm^{-1}.

Found: C, 67.26; H, 9.23; N, 6.32%. Calcd for $C_{26}H_{42}N_2O_5$: C, 67.50; H, 9.15: N, 6.05%.

p-Methoxybenzyloxycarbonyl-L-leucine Dicyclohexylammonium Salt. This was synthesized by the same method as was used for the Z(OMe)-L-valine from 6.55 g of L-leucine. Pure dicyclohexylamine salt (21.15 g) was obtained as needle crystals after recrystallization from ethanol and petroleum ether. IR spectrum (KBr): 1710, 1630 cm^{-1}.

Found: C, 68.04; H, 9.07; N, 6.01%. Calcd for $C_{27}H_{44}N_2O_5$: C, 68.03; H, 9.31; N, 5.88%.

p-Methoxybenzyloxycarbonyl-L-phenylalanine Dicyclohexylammonium Salt. This was prepared from 8.25 g of L-phenylalanine by the same method as mentioned above. Pure white needle crystals (19.18 g) were obtained after recrystallization from ethanol and petroleum ether. IR spectrum (KBr): 1700, 1635 cm^{-1}.

Found: C, 70.76; H, 8.35; N, 5.83%. Calcd for $C_{30}H_{42}N_2O_5$: C, 70.55; H, 8.29; N, 5.49%.

p-Methoxybenzyloxycarbonyl-L-proline Dicyclohexylammonium Salt. From 5.75 g of L-proline (0.05 mol), this salt was prepared by the same method as described for Z(OMe)-L-valine dicyclohexylammonium salt. Recrystallization from ethanol and petroleum ether gave 19.02 g of pure minute crystalline plates.

IR spectrum (KBr): 1700, 1635 cm^{-1}.

Found: C, 68.02; H, 8.90; N, 6.20%. Calcd for $C_{26}H_{40}N_2O_5$: C, 67.79; H, 8.76; N, 6.08%.

***p*-Methoxybenzyloxycarbonyl-L-methionine Dicyclohexylammonium Salt.** This *p*-methoxybenzyloxycarbonyl amino acid was prepared from 7.46 g of L-methionine (0.05 mol) and 0.1 mol of I by a procedure similar to the synthesis of L-valine derivative. Its dicyclohexylamine salt was obtained as a white precipitate. Recrystallization of the salt from ethanol and petroleum ether gave pure needle crystals; yield, 21.76 g. IR spectrum (KBr): 1705, 1635 cm^{-1}.

Found: C, 63.14; H, 8.86; N, 5.76%. Calcd for $C_{26}H_{12}N_2O_5S$: C, 63.12; H, 8.56; N, 5.66%.

***α*-*N*-*p*-Methoxybenzyloxycarbonyl-*δ*-*N*-benzyloxycarbonyl-L-ornithine Dicyclohexylammonium Salt.** α-*N*-*p*-Methoxybenzyloxycarbonyl-*δ*-*N*-benzyloxycarbonyl-L-ornithine, an oily compound, was prepared from 13.3 g of *δ*-*N*-benzyloxycarbonyl-L-ornithine[24] (0.05 mol) by the same procedure as for Z(OMe)-glycine.

It was dissolved in ether (100 m*l*), and 9.96 m*l* of dicyclohexylamine (0.05 mol) was added at 0—5°C. The white precipitate formed was filtered and washed with ether (14.34 g, mp 129—135°C). This was recrystallized from ethanol and petroleum ether. Yield, 10.2 g of pure product. IR spectrum (KBr): 1695, 1630 cm^{-1}.

Found: C, 66.91; H, 7.91; N, 6.94%. Calcd for $C_{34}H_{49}N_3O_7$: C, 66.75; H, 8.07; N, 6.87%.

The authors wish to express their thanks to the staff of the Research Laboratory of the Chugai Pharmaceutical Co., Ltd., for their elemental analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 181—187 (1970)

Study on the Binding Nature of Acridine Orange to DNA by Means of Flow Dichroism

Hiroko TAKESADA (née YAMAGAMI), Etsuko SAITO (née MORIGUCHI), Hitoshi FUJITA, Kenshi SUZUKI and Akiyoshi WADA*1

Chemistry Division, National Institute of Radiological Sciences, Chiba

(Received June 19, 1969)

The binding nature of acridine orange to DNA was studied by means of equilibrium dialysis and flow dichroism with spectrophotometric analysis. The adsorption isotherm of the acridine orange-DNA system was obtained by means of equilibrium dialysis. From the experiment, the binding constant (K) and the fractional amount of the binding site to the total number of nucleotides (f) were estimated for native- and heat-denatured DNA. Under a shear gradient, the acridine orange-DNA complex showed a negative dichroism in visible region as well as in the ultraviolet region. This implies that acridine orange is oriented on DNA rather perpendicularly to its main axis, like base pairs. The magnitude of the dichroism of the complex at 500 mμ, near the visible absorption peak of acridine orange, was larger than each value of the complex and that of the DNA itself (260 mμ). The transition moment corresponding to the absorption at 500 mμ may be oriented in a more orderly manner and/or more nearly perpendicularly to the main axis of DNA than that corresponding to 260 mμ.

It was found that acridine orange (AO) acted as a sensitizer in the photodynamic inactivation of transforming DNA extracted from *Diplococcus pneumoniae* and that the inactivation was mediated by the dye bound to the DNA.[1] The damage to DNA accompanying the inactivation must resulted from an energy migration system involving the bound dye. In order to clarify the mechanism of the photodynamic action of DNA at a molecular level, physico-chemical studies of the binding of the dye to DNA are required.

The primary interest should be in the binding amount of the dye and the mode of binding. The nature of the acridine dye-DNA complex has been

*1 Visiting Researcher from Department of Physics, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo.

1) H. Fujita, H. Yamagami, E. Moriguchi, K. Suzuki and A. Wada, presented at the 17th Annual Meeting of The Chemical Society of Japan, 1964.

reported on by many investigators.[2-8] Lerman[5] proposed an intercalation model; *i.e.*, acridine is inserted into the space between adjacent base pairs of DNA. He also[6] measured the polarized fluorescence and the dichroism of a flowing quinacrine-DNA solution and emphasized the former, which was considered to be strong evidence for his model. This model is supported by some other evidences also, *i.e.*, the reactivities of an acridine and amino groups of bases,[7] the mass per unit length,[9] the sensitized fluorescence,[10] the delayed fluorescence,[11] and the autoradiography.[12] The differential flow dichroism is one of the most sensitive techniques for demonstrating the arrangement of dye on DNA as well as the base-arrangement in a DNA molecule.[13] Nagata *et al.*[14] studied the interaction of polynuclear aromatic hydrocarbons, 4-nitroquinoline 1-oxides, and various dyes with DNA by applying the flow dichroism method developed by Wada and Kozawa.[15] In the present study, we measured the differential flow dichroism of the AO-DNA complex with the absorption spectra in order to obtain basic data for the interpretation of the photodynamic action. In addition to this, the binding constant and the fractional amount of the binding site to the total number of nucleotides were determined from the results of quantitative equilibrium dialysis.

Experimental

DNA. Pneumococcal DNA (R/Sm) was used throughout the present work in relation to the study of bacterial transformation. It was prepared by Marmur's method.[16] Bacteriophage T_2-DNA extracted by the method of Mandel and Hershey[17] was also used in the flow dichroism measurements. Denatured DNA was prepared by heating native DNA in a boiling-water bath for 15 min and by then rapidly chilling it in ice water.[18] Partially-denatured DNA was made by placing a solution of native DNA in a 0.001M phosphate buffer containing 0.0001M EDTA and 0.0025M NaCl (pH 7.0) at temperatures near but below the 'melting' temperature, *i. e.*, 62.5 and 64°C, for 15 min, followed by rapid chilling. The concentration of the DNA was determined from its optical density ($\varepsilon_{258}=6600$).

Dye. AO (Tokyo Chemical Industry) was purified in the following way.[19] It was dissolved in a mixture of water and ethanol (1 : 1), and 0.1N NaOH was added to precipitate it in the form of a free base. The dried precipitate was recrystallized twice from a mixture of water and ethanol (1 : 9). Finally the crystal was dried in a vacuum over P_2O_5. The purified AO base was identified by its melting point. A stock solution was prepared by dissolving a purified AO-base in water and by then neutralizing it with HCl.

Buffer Solution. The buffer solutions used were 0.15M NaCl+0.015M sodium citrate (pH 7.3) and a 0.001M phosphate buffer containing 0.0001M EDTA and 0.0025M NaCl (pH 7.0). The former, called the standard saline-citrate solution (abbreviated as SSC), was used in the study of equilibrium dialysis. The latter, with a low ionic strength, was used in the measurements of the flow dichroism in order to minimize the amount of unbound dye.

AO-DNA Complex. The mixture of AO and DNA was shaken vigorously in a test tube with a stopper and then stored in the dark for several hours to allow it to attain equilibrium. The composition of the mixture or the complex was expressed as the molar ratio of the nucleotide to the added dye, P/D, or of the nucleotide to the bound dye, P/D_b.

Absorption Spectrum. Measurements of the absorption spectra in the visible- and ultraviolet regions were made at room temperature by a Cary-14 spectrophotometer or by a Shimadzu spectrophotometer (Model QR-50). Silica cuvettes with a 1-cm light path were used. For diluted solutions, cuvettes with a 5-cm light path were used, while for concentrated ones a 0.8-cm silica spacer was used to make the light path 0.2 cm.

Equilibrium Dialysis. A Visking cellophane tube (23 A, 20/32) was used. The cellophane tube was washed with distilled water and conditioned by being immersed in SSC for more than 12 hr before use. Dialysis was performed with Erlenmeyer flasks in the dark. The cellophane bag containing 4 m*l* of the DNA solution was immersed in 20 m*l* of a dye solution. Equilibrium was attained after 16 to 20 hr of mechanical shaking at 30°C in a water bath. The measurements of the optical density of the inner- and outer solutions were made at room temperature. The adsorption of the dye to the cellophane membrane was estimated to be 15 to 20% of the total amount of dye, but it was presumed

that such adsorption did not affect the equilibrium between the inner- and outer solutions.

Flow Dichroism. The details of the theory and the apparatus for the measurement of the flow dichroism were reported by Wada and Kozawa.[15]

(a) Apparatus. Measurements were made by a Shimadzu spectrophotometer equipped with an attachment. A transparent rotating cell of fused silica and a polarizer of calcite are included in this attachment. The gap between the outer- and the inner coaxial cylinders is 0.5 mm; therefore, the light-path length is 1.0 mm. The rotation speed of the inner cylinder was measured by a tachometer. The direction of the electric vector of the plane-polarized light chosen was either perpendicular or parallel to the flow axis.

(b) Measurements. The reduced flow dichroism is defined as:

$$\Delta\varepsilon/\varepsilon = \frac{\varepsilon_{//}-\varepsilon_{\perp}}{\varepsilon} = \frac{(-\log I_{//}/I_{\perp})-(-\log I_{//0}/I_{\perp 0})}{(-\log I/I_0)} \times A$$

where $I_{\perp 0}$ and $I_{//0}$ are the intensities of incident polarized lights with the electric vector perpendicular to and parallel to the flow axis respectively, where $I_{\perp}$ and $I_{//}$ are the intensities of transmitted polarized lights with the electric vector perpendicular to and parallel to the flow axis respectively, and where A is a factor depending on the concentration of the solution and on the light path of the cell.

In the present study two sorts of measurements were made: (1) measurements of $\Delta\varepsilon/\varepsilon$ over a range of wavelengths (λ) at a constant velocity gradient (3090 sec^{-1}), and (2) measurements of $\Delta\varepsilon/\varepsilon$ at 260 and 500 mμ at various velocity gradients (G). The extent of the flow dichroism is a measure of the orientation both of a macromolecule itself to the flow axis and of the chromophore in the macromolecule to the molecular axis. The reduced flow dichroism at a perfect orientation, $B(\alpha)$, was estimated from the following relation:

$$\Delta\varepsilon/\varepsilon = A(G/\Theta)\cdot B(\alpha)$$

supposing that DNA is a rigid ellipsoid of evolution.[13] In this equation, G is the velocity gradient, Θ is the rotary diffusion constant, and α is the angle between the long axis of the macromolecule and the plane of the chromophore. Theoretically, $-B(\alpha)$ takes a value from -3.0 to 1.5, with α from 0 to 90 degrees.[15]

Experimental Results

Absorption Spectra. Figures 1 (A) and (B) show two series of absorption spectra; they were obtained by adding native and denatured DNA solutions respectively of various concentrations to an AO solution of a given concentration (0.9×10^{-5}M). It can be seen in Fig. 1(A) that the absorption maximum shifts from 492 to 500 mμ and that the molar extinction coefficient at the wavelength corresponding to the maximum absorption increases with an increase in the concentration of native DNA. In this series, an isosbestic point is observed at 490 mμ. The quantitative estimation of the bound dye in the equilibrium dialysis was made at this wavelength. At low P/D ratios, the shoulder at about 470 mμ is remarkably higher for denatured DNA (Fig. 1 (B)) than for the native DNA. It is gradually lowered, however, with an increase in the P/D ratio, finally attaining the same level as that for native DNA. In the case of denatured DNA, it appears that an isosbestic point is present at 485 mμ, but, contrary to the case for native DNA, the absorption curve of free AO does

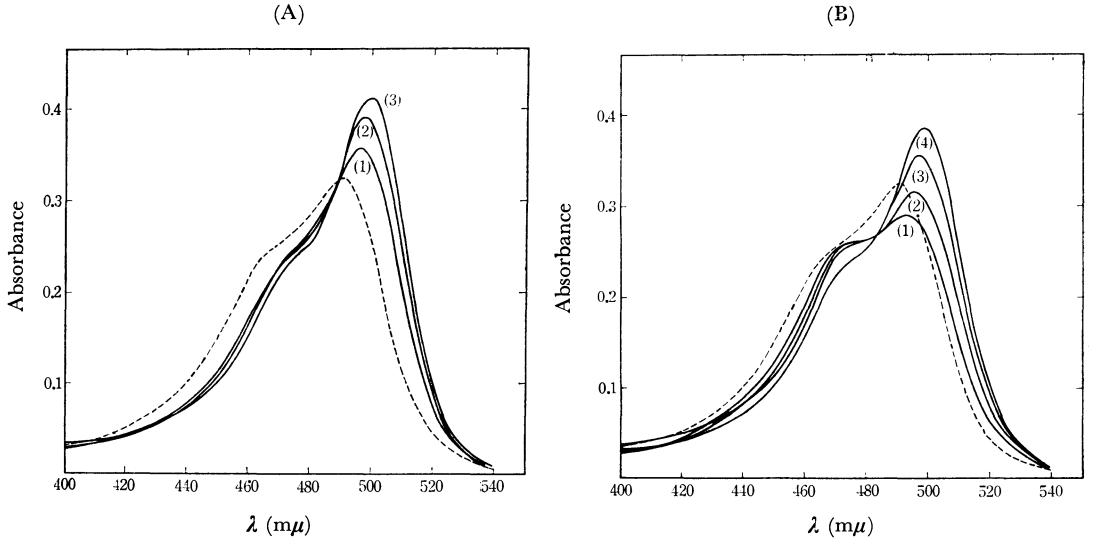

Fig. 1. The change of the absorption spectrum of AO solution by the addition of DNA (*Diplococcus pneumoniae*). The concentration of AO in SSC was 0.9×10^{-5}M. (A) Native DNA: ------, without DNA. ——, (1), (2) and (3) are the spectra in which P/D ratios are 10, 20 and 50, respectively. (B) Denatured DNA: ------, without DNA. ——, (1), (2), (3) and (4) are the spectra in which P/D ratios are 5, 10, 20 and 50, respectively.

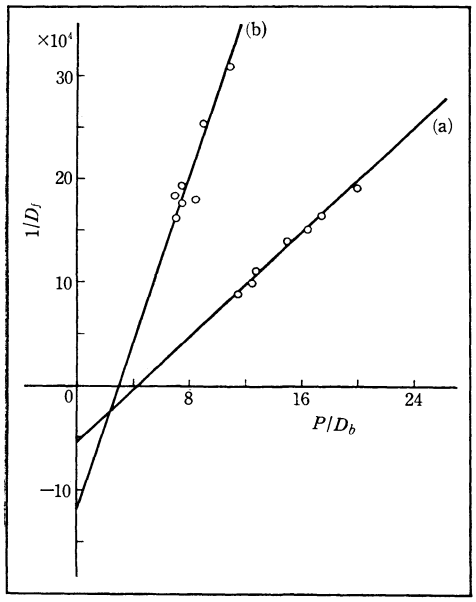

Fig. 2. Adsorption isotherm of AO to DNA in SSC at 30°C. The concentration of DNA (*D. pneumoniae*) was 20 μg/ml or 40 μg/ml (6 or 9×10^{-5}M$_p$).
(a) native DNA; (b) denatured DNA

not pass over this point, as can be seen in Fig. 1 (B). However, since it was shown by equilibrium dialysis that more than 80% of the dye cations were bound to the DNA even at ratios as low as 5, for convenience the extinction coefficient at 485 mμ was used to determine the amount of bound dye.

Equilibrium Dialysis. The adsorption isotherm was obtained in the following way. The binding constant (K) of one AO cation to a site on DNA was assumed not to be variable even if neighboring sites had been occupied by other AO cations. Then, if the fraction (f) to the total amount of nucleotides (P) in DNA is involved in forming a complex with AO, K must be given by $K=D_b/(Pf-D_b)\cdot(D_f)$. In this equation, D_f and D_b are the amounts of the unbound free dye and of the bound dye respectively. They were calculated from the optical density of the outer solution and from the difference in the optical densities of the inner- and outer solutions. P was obtained from the optical density at 258 mμ of the DNA solution. If $1/D_f$ is plotted against P/D_b, the intercept on the ordinate must give K, and that on the abscissa, $1/f$ (see Fig. 2). The values obtained at 30°C are, for the native DNA, $K=5.5\times10^4$ l/mol and $1/f=4.3$, and for the denatured DNA, $K=1.2\times10^5$ l/mol and $1/f=3.0$. Both K and f were larger for denatured DNA than for native DNA. Since the molar concentration of DNA was taken to be sufficiently lower than that of the buffer itself, the difference in the concentration of electrolytes between the inner- and outer solutions was considered to be negligible.

Flow Dichroism of the Complex. The AO-DNA complex showed a negative flow dichroism

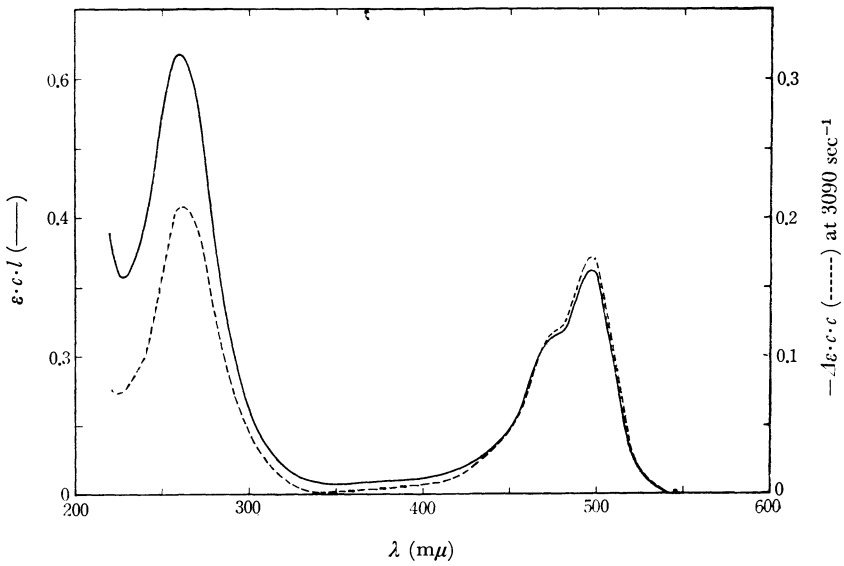

Fig. 3. Absorption spectrum (——) and differential flow dichroic spectrum (------)of AO-DNAcomplex. The concentrations of DNA and AO were 1.5×10^{-3}M$_p$ and 1.87×10^{-4}M, respectively. DNA and AO were dissolved in 0.001M phosphate buffer containing 0.0001M EDTA and 0.0025M NaCl (pH 7.0). Under this condition, more than 99.6% of AO cations are bound to DNA and the ratio of nucleotide to bound dye (P/D_b) is about 8.

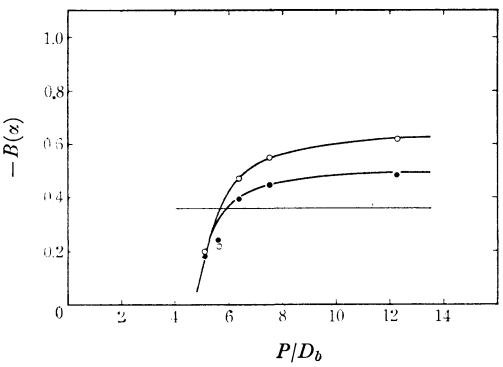

Fig. 4. The differential flow dichroism at varying P/D_b ratios of the complex of AO and native DNA. The concentration of DNA was 4.0×10^{-4} to 1.58×10^{-3}M$_p$ in 0.001M phosphate buffer containing EDTA and NaCl (see the legend of Fig. 3). The complex was prepared through the equilibrium dialysis at 30°C. —○—, complex at 500 mμ; —●—, complex at 260 mμ; ———, DNA (4.9×10^{-4}M$_p$) at 260 mμ.

in the visible region as well as in the ultraviolet region. Figure 3 shows the results of the differential flow dichroism of the complex at a P/D_b ratio of 8 over a range of wavelengths at a constant velocity gradient (3090 sec^{-1}). The dichroism of the complex measured with varying P/D_b ratios at 260 mμ and 500 mμ is shown in Fig. 4. The value of $-B(\alpha)$ of pneumococcal DNA at 260 mμ was 0.36. This is smaller than that of the complex at 260 or 500 mμ above a P/D_b of 6. At a P/D_b of 12, the value at 500 mμ of the complex was 1.7 times that of the DNA at 260 mμ. The lower values of $-B(\alpha)$ in the region of P/D_b below 6 may be due to the formation of intermolecular aggregates of the complex. Contrary to the case of pneumococcal DNA, the value of $-B(\alpha)$ at 260 mμ of the bacteriophage T_2 DNA-AO complex was nearly equal to the value at 500 mμ and also to the value of DNA itself (Preliminary experiment).

The value of $-B(\alpha)$ for DNA is very sensitive to its molecular conformation. For example, the value was diminished by partial denaturation depending on the temperature at which the DNA had been treated. The preparations of partially denatured DNA with different values of $-B(\alpha)$ at 260 mμ were equilibrated with AO at 20°C by dialysis and the flow dichroism of the complexes was measured. As is shown in Table 1, the values of the complexes at 260 mμ were decreased by elevating the treated temperature, as were those of the DNA. The value at 500 mμ of the complex, the DNA of which had been treated at 62.5°C, was larger than that of the corresponding DNA; the same tendency was seen in the complex with the native DNA.

Table 1. The effect of partial denaturation of DNA on the values of $-B(\alpha)$ of DNA (*D. pneumoniae*) and its complex with AO*

	Complex with AO		DNA
	at 500 mμ	at 260 mμ	at 260 mμ
Native DNA	0.66	0.46	0.41
Heated at 62.5°C	0.46	0.27	0.24
Heated at 64.0°C	0.15	0.15	0.15

* The concentration of DNA is 1.18×10^{-3}M$_p$. P/D_b=10.5 to 13.1
The buffer solution is the same as described in the legend of Fig. 3.

Discussion

For the analysis of the equilibrium dialysis and the flow dichroism, the amount of dye bound to DNA should be determined as accurately as possible. However, the concentration of the dye can not be simply determined from the optical density, since the observed spectrum of AO in the presence of DNA is composed of the spectra corresponding to the free monomer, the bound monomer, the free aggregate and the bound aggregate of the dye; that is, it changes depending on the P/D ratio. When various amounts of native- or denatured DNA were added to the AO solution, a series of spectra were obtained. The clear isosbestic point was observed for the native DNA-AO system. For the denatured system, the real isosbestic point was not observed, but the absorption curves passed over one point in the P/D-ratio range from 5 to 50. The extinction coefficients at these wavelengths were used for the calculation of the concentration of AO.

As may be seen in Fig. 1, the absorption spectra of the AO-denatured DNA mixture are very similar to that of the AO-native DNA mixture in the region of high P/D ratios, but it is rather different at low ratios. It is likely that, in a mixture with an extremely high P/D ratio, the dye cations bound to DNA must keep a large distance between them and so there should be very little dye-dye interaction. Therefore, the conformational change of DNA does not produce any spectral modification at such high P/D ratios. On the contray, an interaction between bound dye cations can be expected at low P/D ratios. Actually, this sort of interaction appears to occur more strongly on the denatured DNA-AO complex, since the shoulder band at about 470 mμ in the absorption spectrum is higher for the denatured DNA than for the native DNA, when the spectra for these complexes are measured at the same P/D ratio.

From the f value obtained by the adsorption isotherm, it appears that AO cations can bind to native DNA up to the ratio of 1 to 4.3 nucleotides at most. On the other hand, the ratio was 1 to 3 in the case of denatured DNA. The binding constant, K, for the denatured DNA was about twice as large

as that for the native DNA. Thus it was concluded that a large amount of AO can bind to the denatured DNA than to the native DNA. This suggests that the bases may provide further binding sites since they must come to be exposed to an outer medium by the denaturation, or that the denaturation facilitates, in some way, the adsorption of dye-aggregates to DNA, while the total number of binding sites does not increase.

The f value for the native DNA is in agreement with the saturation value of the "strong binding" obtained for the proflavine-herring sperm DNA system at an ionic strength of 0.1 at 20°C by Peacocke and Skerret.[20] Chambron *et al.*[21] investigated the thermodynamics of the interaction of proflavine and calf thymus DNA. They obtained values of $\log K=5.30$ ($K=2.0\times10^5$) and $1/f=6.1$ at 35°C, and values of $\log K=5.50$ ($K=3.2\times10^5$) and $1/f=4.4$ at 20°C, for the complex with the native DNA at an ionic strength of 0.1. The K values for their system are 4 to 5 times as large as that for the present system, while the f values for their system seem to be a little smaller than that of the present system. This discrepancy may be due to the differences in the experimental conditions and in the methods of estimating the values. They introduced the interaction energy between two bound dye-cations into their calculation, whereas we neglected it.

The principle of the ultraviolet flow dichroism of DNA must also be applicable to AO cations firmly bound to DNA. Since the oscillator dipoles of the π–π^* transition of bases and dye are known to be in the plane of these aromatic molecules, the magnitude of $-B(\alpha)$ gives an index of the orientation of the bases or dye to the long axis of the DNA molecule. The experimental results on the AO-DNA complex may be summarized as follows: (1) The AO-DNA complex gave a negative flow dichroism in the visible as well as in the ultraviolet region.

(2) The complex of pneumococcal DNA and AO gave a larger $-B(\alpha)$ value at 500 mμ than at 260 mμ, while both values are over that of DNA itself.

(3) A reduced dichroism, $(\Delta\varepsilon/\varepsilon)$, was almost constant throughout any visible region at the velocity gradient of 3090 sec^{-1}.

The theoretical value of $-B(\alpha)$ is 1.5 at 90 degrees of α,[15] but the observed values are much smaller. This may be attributed to the coexistence of random coiling parts in the DNA and small fragments, which were made during the extraction process, and/or of a folding structure of DNA like a hairpin with residual proteins.

The dichroism at 500 mμ of the complex must be due to the AO cations bound to DNA, since it was not observed in the absence of DNA. The (1) evidence suggests that the plane of the bound AO is nearly parallel to the plane of the bases in DNA. If AO cations are inserted into the spaces between base pairs parallel to them, the dichroism shown by bound dye could not be over the value for the DNA. However, the experimental result presented in (2) is not consistent with this view. According to the viscosity measurements,[5] DNA becomes longer and straighter by the binding of acridine dyes in solution. Considering that a longer molecule can be oriented more easily and gives a higher value of $-B(\alpha)$,[13] the present result that the $-B(\alpha)$ at 260 mμ of the complex is larger than that of DNA itself is reasonable. One model to explain the $-B(\alpha)_{500\,m\mu} > -B(\alpha)_{260\,m\mu}$ relation in the complex is that AO cations bind selectively to ordered parts rather than to disordered parts of DNA. However, this model is inconsistent with the results of equilibrium dialysis. Another model is as follows: On some loose structure of DNA, the transition moment corresponding to the absorption at 500 mμ may be oriented in a more orderly manner and/or nearly perpendicularly to the main axis of the DNA compared with that corresponding to 260 mμ. If the transition moments of 500 and 260 mμ were in the directions parallel to the long and short axes of AO respectively, the transition moment along the long axis could be oriented more in parallel to the plane of bases, but the other moment would be slightly declined. Actually, in the case of bacteriophage T_2-DNA which is believed to be more intact and to have better chain regularity,[13] the $-B(\alpha)$ at 500 mμ of the complex was nearly equal to the values at 260 mμ of the complex and of the DNA itself.

It can be seen in Fig. 3 that the dichroic spectrum is almost identical with the absorption spectrum. The shoulder band at about 470 mμ is also observed in the dichroic spectrum, and $\Delta\varepsilon/\varepsilon$ is almost constant over the range of wavelengths in the visible region. If the shoulder band in an absorption spectrum is attributed to dye-aggregates, the shoulder in a dichroism at the same wavelength might be also due to the dye-aggregates. However, it would be impossible to insert the dye-aggregates, even if they are dimers, into the spaces between base pairs in the sense of the intercalation model. Thus, the observed shoulder at about 470 mμ in the dichroic spectrum at the P/D_b ratio of 8 may be attributed to the characteristic of the AO monomer, as has been suggested by Zanker.[22]

As has been mentioned earlier, the intercalation model is supported by several pieces of evidence.

20) A. R. Peacocke and J. N. H. Skerrett, *Trans. Faraday Soc.*, **52**, 261 (1956).

22) V. Zanker, *Z. Physik. Chem.*, **199**, 225 (1952).

On the other hand, Peacocke *et al.*[23,24] proposed a modified intercalation model based on their spectrophotometric analysis. In this model, when acridine cations are bound by the "process 1" (defined by them), the acridine lies between successive nucleotide bases on the same polynucleotide chain, in a plane approximately parallel to the base planes, in which the cationic-ring nitrogen is as close as possible to a phosphate group of DNA and in which the edges of the acridine rings (positions 1—4 or 6—9) partially overlap the base ring(s) of DNA. The present dichroic measurements show that the plane of the acridine dye is oriented parallel to that of the bases rather than perpendicular. However, by this method we can not distinguish between the intercalation model and the modified one. Although the nature of binding site is still obscure, it is very likely that phosphate groups and the spaces between adjacent base pairs of DNA act as sites of binding with acridine dye.

Study on Oxazolopyrimidines. I. Synthesis and Spectroscopic Properties of 7-Aminooxazolo[5,4-*d*]pyrimidines

Yozo Ohtsuka

Sagami Chemical Research Center, Ohnuma, Sagamihara

(Received June 19, 1969)

Several 2- and 5-substituted oxazolo[5,4-*d*]pyrimidines have been prepared from 5-amino-4-cyanooxazole derivatives *via* *N*-ethoxymethylene intermediates in order to compare them with purine derivatives. Spectroscopic data and some chemical properties of these compounds were examined. A convenient method for the preparation of a starting material was described.

Oxazolo[5,4-*d*]pyrimidines, whose chemical structure is similar to that of natural purines, are of interest as antimetabolites.[1] These compounds may also serve as models for 9-substituted purine skeletons and as synthetic intermediates for several biologically important materials. Although several of them have been prepared mainly from pyrimidine derivatives,[1,2] relatively little attention has been paid to oxazolopyrimidines, because probably none of these compounds has been found in natural products or their biological activities are indistinct. The object of the present study is twofold: one is to compare the physico-chemical data of oxazolopyrimidine and purine derivatives and the other is to find new reactions from these compounds to purine derivatives.

7-Aminooxazolo[5,4-*d*]pyrimidine may be considered the 9-0-analog of adenine. In this paper, the synthesis and spectroscopic properties of a number of 7-aminooxazolo[5,4-*d*]pyrimidine derivatives are described.

Results and Discussion

5-Amino-4-cyanooxazoles (I). Several 2-substituted 5-amino-4-cyanooxazoles were prepared by the known method.[3] For the 2-unsubstituted derivative (Ia), new and convenient method of preparation were found. One of them, the reduction of phenylazomalononitrile by zinc and formic acid afforded the compound (Ia) with a fairly good yield.

The resulting formamidomalononitrile seems to cyclize readily to the oxazole compound under acidic conditions. Hence, the product obtained by the reduction of isonitrosomalononitrile under a similar condition was also confirmed to be compound (Ia). No detectable difference was observed by the addition of acid anhydride in the system. Under the latter condition, the formation of acylaminomalononitrile has been cited in a patent.[4]

The chemical property of compound (Ia) was examined briefly. An attempt to obtain the *N*-acetyl derivative was unsuccessful. On being warmed with alkali, it decomposed to water soluble fragments. With acid it was hydrolyzed to formamidocyanoacetamide, and with hydrogen peroxide

7-Aminooxazolo[5,4-d]pyrimidine Derivatives (IIIa—i). Direct condensation of 5-amino-4-cyanooxazole (Ia) with formamidine to yield 7-aminooxazolopyrimidine (IIIa) has been reported to give a low yield.[3] However, it was found that the yield and the method of purification were improved by the application of Taylor's method of

N-Ethoxymethylene intermediates (II) (Tables 1 and 2) react readily with aqueous ammonia to 7-aminooxazolopyrimidines (Table 3).

Spectroscopic Properties of 7-Aminooxazolopyrimidines. *a) NMRS pectra.* The spectra for 7-aminooxazolopyrimidines in DMSO-d_6 solution, together with the assignments, are presented in Table 4. The chemical structures of these compounds are well supported by the spectra. The chemical shift of the C–H proton on the pyrimidine ring, δ_{H-5} (corresponding to the H-2 for purines), approaches the value for 9-substituted purines, such as adenosine and inosine,[6] as expected from the chemical structure. It seems to indicate the total aromatic system of the molecules in which the effect of 5-substitution on δ_{H-2} is nearly equal to that of 2-substitution on δ_{H-5}. Such a correlation of the chemical shifts with reactivity parameter of the substituents has been established in purine derivatives.[7] On the other hand, the 2-substituents have a greater influence on the chemical shifts of the N–H proton at 7-position than the 5-substituents. Geometrical proximity of the former substituent may be responsible for it.

b) IR Spectra. Existence of 7-NH_2 group in those molecules are expressed in the spectra in 3000 cm^{-1} region and near 1670 cm^{-1}. The latter band seems to correspond to that of adenine at 1672 cm^{-1}.[8] The bands attributed to the NH_2 group are removed by deuteration. The broad band in the 2900—2400 cm^{-1} region in the spectra of purine derivatives[8] disappears in the spectra of oxazolopyrimidines. This is in accordance with the previous assignment that the band is aroused from the interaction between the imidazole proton and the external group, $-NH_2$ or $-OH$, of purine bases. The bands in 1620—1500 cm^{-1} region are common to pyrimidine derivatives.[9] The band near 1050 cm^{-1} is attributed to the C–O–C deformation vibration of oxazole ring, but it is not characteristic enough for analysis.

c) UV Spectra. The total absorption curve of IIIa is similar to those of adenine, 9-methyladenine and related compounds.[10,11] As shown in Table 4, the oxazolopyrimidines have two absorption bands between 200 and 260 mμ region which are presumably due to π–π^* transitions. The band at around 250 mμ corresponds to the 260 mμ band of adenine which has been correlated with the $A_{1g}\rightarrow B_{2u}$ transition of benzene.[12] Such a blue shift of the band in going from adenine to oxazolopyrimidines can be seen in a comparison of analogous pairs; benzoxazole[13] and benzimidazole,[12] $\Delta\lambda=4$ mμ, and hypoxanthine (pH$<$9) and adenine, $\Delta\lambda=11$ mμ.[10]

This may be explained by the difference in the conjugation of the heteroatoms with the aromatic systems. The spectra did not change substantially in the aqueous solution in the pH-range of 4—9.

d) Mass Spectra. The characteristic peaks of some oxazolopyrimidines are shown in Table 5. These data indicate the principal fragmentation process of 7-aminooxazolopyrimidine ring system. The most intense peak of the compounds is that of the molecular ion. The primary fragments occur

at M−27, due to loss of HCN, and in the case of 5-methyl derivatives at M−41, due to loss of CH_3CN. This fact and subsequent fragmentation show that the initial expulsion of HCN fragment originated uniquely from C-5–N-4. This process is followed by the expulsion of CO fragment which is observed in the spectra of all the compounds in the table as the peak at M′−28 (M′=M−28 or M−41). The CO fragment must have originated from C-3a–O-3. The third process produces the peak *m/e* 55 due to the expulsion of HCN, or in the case of 2-methyl derivatives, the expulsion of CH_3CN. It is inferred to involve N-1–C-2. It is very probable that the ND_2 compound (IIIa′) produces the DCN fragment which suggests the amino group participation in the process. Another minor process of the step is the expulsion of NH(ND) instead of HCN(DCN).

The characteristic fragmentation pattern of purine bases has shown the succesive expulsion of three molecules of HCN.[14] The fragments do not originate exclusively from the same site of the molecules (in the case of adenine or hypoxanthine),[15] while the ring expulsion of thiazolo[5,4-*d*]pyrimidine has been reported to occur from the fixed site of the molecule.[16] The result of oxazolopyrimidine is parallel to that of thiazolopyrimidine. In both cases, the primary process is the pyrimidine ring rupture and subsequent process is determined by the nature of five-membered rings.[17]

From these spectroscopic properties, the following conclusion can be drawn. The molecule of 7-aminooxazolopyrimidines constitutes a totally aromatic system and some of their properties are similar to those of 9-substituted adenines. However, the nature of the individual ring seems to be kept to some extent. This is caused probably by the decreased contribution of the lone-pair electron of heteroatom with the conjugated system.

Experimental

Synthesis of 5-Amino-4-cyanooxazole (Ia). *Method A.* A mixture of 45 g of zinc powder and 300 m*l* of 99% formic acid was warmed to 40°C under nitrogen with gentle stirring. To the suspension, 30 g of pulverized phenylazomalononitrile[18] was added portionwise until the reaction became self-sustaining, at which point the bath was removed to maintain the temperature at 40—50°C. After the addition, the reaction mixture was stirred for 30 min. The solid was filtered off and washed thoroughly with formic acid. The combined solution of the washings and filtrate was concentrated to nearly dryness under reduced pressure keeping the bath temperature below 40°C. Adding about 50 m*l* of water to the residue, evaporation was repeated. The final residue was allowed to stand overnight in a refrigerator. Resulting crystals were washed with a small quantity of water and taken up in 100 m*l* of water in which the residual acid was neutralized with ammonia. Recrystallization from water gave the product, 9.0 g (47%). This product was confirmed to be identical with the authentic 5-amino-4-cyanooxazole[3] from the mixed melting point determination, IR and NMR spectra.

About 3 g of colorless crystals were also obtained from the mother liquid of the recrystallization. This compound, mp 157—158°C, was identified as formamidocyanoacetamide, from its IR spectra (C≡N; 2160 cm^{-1}, amide; 1710 and 1670 cm^{-1}) and from the fact that the prolonged heating of the material in formic acid afforded formamidomalonodiamide.[19]

Method B. Analogous reduction was conducted using the ether solution of isonitrosomalononitrile[20] instead of phenylazomalononitrile. The product was identical with that produced by method A, but the yield was considerably lower. No difference was observed by the reduction in the presence of acetic anhydride.

Reaction of 5-Amino-4-cyanooxazole (Ia). Alkaline oxidation by hydrogen peroxide and acid hydrolysis of Ia were examined.

a) To an ice-cooled mixture of 1.0 g of Ia and 0.56 g of KOH in 20 m*l* of ethanol, 20 ml of hydrogen peroxide (30%) was added with stirring. After 1 hr, colorless crystals were obtained (0.6 g), which were identified as formamidocyanoacetamide (see method A). After standing for 2 days at room temperature, the precipitate was filtered off (0.4 g). Its analysis and IR spectra agreed with those of oxamide.

b) A solution of 1.0 g of Ia in 30 m*l* of formic acid (85%) was heated under reflux for 2 hr. After cooling, the solution was evaporated, and the residue was recrystallized from a small quantity of water. This product was confirmed to be formamidocyanoacetamide.

Preparation of *N*-Ethoxymethylene Intermediates. Compound I (5 g), 30 m*l* of acetic anhydride and 30 m*l* of orthoesters (including tetraethyl orthocarbonate) were heated under reflux for 7 hr. After concentrating the reaction mixture, the residue was distilled under reduced pressure. Yields and analytical data are summarized in Table 1 and structures confirmed from spectroscopic data are shown in Table 2.

Preparation of 7-Aminooxazolo[5,4-d]pyrimidines. *N*-Ethoxymethylene intermediates and a little excess of 14% ammonia water were stirred at room temperature for 30 min. Oxazolopyrimidines were separated as colorless crystals. Yields and analytical data are listed in Table 3.

Determination of Physical Properties. Melting points were measured on a hot-stage apparatus and were not corrected. The IR, Mass, NMR and UV spectra were determined with a Perkin-Elmer 337, Hitachi RMU-6E, Varian HA-100 and Carry-14 spectrometer respectively. Conditions of these measurements are cited in each table.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 192—195 (1970)

Cyanoethylation of Copper, Nickel, and Palladium Glycinates*1

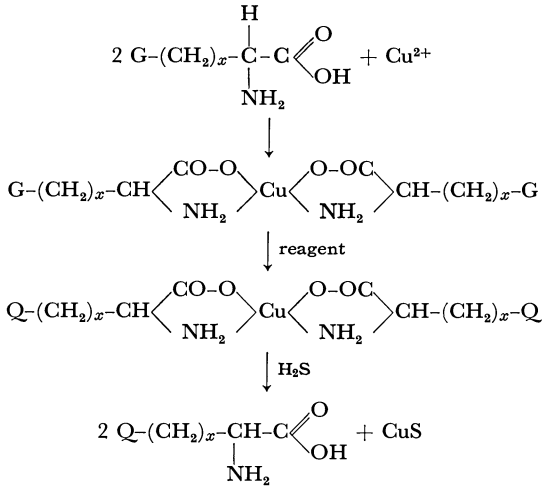
Toshiyuki SHONO, Yuko YAMASHOJI and Koichiro SHINRA

Department of Chemical Technology, Faculty of Engineering, Osaka University, Yamada-kami, Suita

(Received June 20, 1969)

The present authors attempted the cyanoethylation of the methylene group in glycine by means of the reaction between acrylonitrile and copper, nickel, and palladium glycinates. The cyanoethylation of *N*-salicylideneglycinato-aquo copper (II) was also carried out. Four kinds of cyanoethylated complexes were obtained by changing the reaction conditions in the case of copper glycinate. In general, acrylonitrile reacted only with the hydrogen atoms of the amino group. In the case of *N*-salicylidene-glycinato-aquo copper (II), which has no hydrogen atom on the nitrogen atom, however, two methylene hydrogens were cyanoethylated with acrylonitrile.

Masking by coordination has been found to be useful in many of the synthetic reactions of α-amino acid molecules.[1] The general procedure involves coordination with a copper(II) ion to tie up the carboxyl and the α-amino group, leaving the other functional groups free to react with a reagent.



In 1956, Akabori and his co-workers synthesized threonine from copper(II) glycinate and acetaldehyde.[2] In doing so they utilized ligand polarization in addition to masking by coordination. The methylene group in copper glycinate may be more active than in free glycine, and the amino group in the copper chelates may be protected from side reactions by the coordination effect.

Recently Harada and Oh-hashi[3] have synthesized various β-hydroxy-α-amino acids using *N*-salicylideneglycinato-aquo copper(II), while Nakahara *et al.*[4] has prepared several amino acids by the reaction of this complex with various halides. In 1950, Mckinney *et al.*[5] reported the treatment of an aqueous solution of alkali metal salts of glycine with acrylonitrile. This reaction, however, have only a mono-*N*-cyanoethyl compound. In view of the masking effect and ligand polarization mentioned above, the present authors attempted the cyanoethylation of the methylene group in glycine by reactions between acrylonitrile and copper, nickel, and palladium glycinates. For the same reason, the cyanoethylation of *N*-salicylidene-glycinato-aquo copper(II) was carried out.

Experimental

The Cyanoethylation of Copper(II) Glycinate. Copper(II) glycinate was prepared according to the method described by Akabori *et al.*[2] 0.02M of copper glycinate was dissolved in 200 m*l* of aqueous pyridine composed of 150 m*l* of water and 50 m*l* of pyridine. Into this solution, acrylonitrile was stirred drop by drop. After refluxing the mixture, the dark-blue solution was evaporated to precipitate a blue complex, which was then recrystallized from water. Four kinds of cyanoethylated complexes were obtained by changing the reaction conditions, as Tables 1 and 2 show.

Regeneration of the Ligand. The cyanoethylated complex was dissolved in hot water and neutralized with hydrochloric acid. Hydrogen sulfide gas was bubbled through the solution until the blue color had disappeared, and then the precipitated cupric sulfide

Table 1. The cyanoethylation of copper(II) glycinate

Code	Reaction conditions: Temp. (°C)	Time (hr)	Mole ratio (glycinate/AN)	Appearance of compound	Yield (%)	Infrared absorption max. of ν C≡N(cm⁻¹)
1	80	4	1/2	Blue-violet needles	50	2250
2	110	4	1/2	Dark blue needles	50	(disappeared)
3	80	4	1/20	Blue plates	60	2245 and 2265
4	80 110	4 4	1/20	Light blue needles	40	2250

was filtered. The solution was neutralized with aqueous sodium carbonate and evaporated to dryness. The white residue obtained was recrystallized from water.

The Cyanoethylation of Palladium Glycinate. Palladium glycinate was prepared according to the method described by Pinkard *et al.*[6]

0.02M of palladium glycinate was dissolved in 80 m*l* of aqueous pyridine composed of 40 m*l* of pyridine and 40 m*l* of water. To this solution, 0.08M acrylonitrile was added, drop by drop. Then the temperature was gradually raised and the reaction was continued for 4—5 hr at the boiling point. After an insoluble matter had been filtered out, the solution was evaporated to obtain a brownish porous material (yield 40%). The product was recrystallized from water.

The infrared spectrum of this complex is shown in Fig. 1, where it is compared with palladium(II) *N*-cyanoethylglycinate. The infrared spectrum of palladium(II) *N*-cyanoethylglycinate shows one NH stretching band at 3230 cm^{-1}, while this complex has no absorption band in this region.

The results of the elementary analysis of the complex (tetracyanoethylglycinate) were as follows:

Found: C, 39.75; H, 4.47; N, 17.66%. Calcd for $C_{16}H_{20}N_6O_4Pd\cdot H_2O$: C, 39.75; H, 4.55; N, 17.36%.

The NMR spectra of this complex were compared with *N*-cyanoethylglycine (CH_2 at τ=7.70 in DMSO-d_6) and palladium(II) *N*-cyanoethylglycinate (CH_2 at τ=6.67 in DMSO-d_6). The signal centered at τ=6.40 in DMSO-d_6 was considered to be due to the methylene group of the glycine part.

The Cyanoethylation of Nickel Glycinate. Nickel glycinate was prepared according to the method described by Sen *et al.*[7]

The cyanoethylation was carried out under the same conditions as was the cyanoethylation of palladium glycinate. As this complex could not be recrystallized, it was repeatedly reprecipitated from an ethanol-water system to produce a light blue powder in an 80% yield. The infrared spectrum agreed with that of the authentic nickel *N*-cyanoethylglycinate prepared from cyanoethylglycine and basic nickel carbonate.

The Cyanoethylation of *N*-Salicylideneglycinato-aquo Copper(II): [SAGCu(II)H_2O]. SAGCu(II)H_2O was prepared by the method of Nakahara.[8] 0.02M of SAGCu(II)H_2O was dissolved in 50 m*l* of hot pyridine. Into this solution, 0.04M of acrylonitrile was stirred, drop by drop. The temperature was gradually raised to the boiling point of the solvent, after which the reaction was continued for 3—4 hr. After the reaction had been completed, the solution was evaporated to precipitate a dark green complex; this complex was then recrystallized from water to obtain deep green needles in a yield of 35%. The cyanoethylated complex of the *N*-salicylideneglycinato copper(II) coordinated with pyridine was dark brown, while the hydrate was dark green. Slow recrystallization from water yielded deep green needles forming a hexa-hydrate complex. This hexa-hydrated complex lost water to the mono-hydrated complex when dried under reduced pressure

Table 2. The elementary analyses of copper(II) cyanoethyl glycinates

Code	Proposed structures	Elementary analyses
1		Calcd for $C_{10}H_{14}N_4O_4Cu.H_2O$: C, 35.77; H, 4.80; N, 16.69; Cu, 18.92%. Found: C, 35.93; H, 4.83; N, 16.98; Cu, 19.13%.
2		Calcd for $C_5H_{10}N_2O_3$:* C, 41.10; H, 6.85; N, 19.18%. Found: C, 40.99; H, 6.97; N, 19.65%.

------ Palladium(II) tetracyanoethylglycinate

at 80—90°C for 5 hr.

The elementary analysis of the mono-hydrate form gave the following results:

Found: C, 49.38; H, 4.20; N, 11.44; Cu, 17.32%. Calcd for $C_{15}H_{15}N_3O_4Cu$: C, 49.38; H, 4.14; N, 11.52; Cu, 17.42%.

The Synthesis of *N*-Cyanoethylglycine. *N*-Cyanoethylglycine was prepared according to the method of Mckinney *et al.*[5]

Copper *N*-Cyanoethylglycinate. *N*-Cyanoethylglycine was dissolved in hot water, and then basic copper carbonate was added to precipitate *N*-cyanoethylglycine copper. The product was recrystallized from water to produce blue violet needles.

Palladium *N*-Cyanoethylglycinate. *N*-Cyanoethylglycine was dissolved in water, and then $K_2(PdCl_4)$ was added. After standing for 24 hr, the solution was neutralized with aqueous sodium hydroxide. The separated yellow solid was recrystallized from water to produce yellow needles.

Nickel *N*-Cyanoethylglycinate. The basic nickel carbonate was added in small portions to a hot aqueous solution of *N*-cyanoethylglycine to produce nickel *N*-cyanoethylglycinate. As the complex could not be recrystallized, purification was carried out by repeated reprecipitation from an ethanol-water system until a light blue, deliquescent powder was obtained.

Results and Discussion

The infrared spectrum (Fig. 2) of the (code 1) complex is in good agreement with the spectrum of the copper *N*-cyanoethylglycinate.

In the (code 2) complex the cyano group is hydrolyzed to the acid amide form (NH stretching at 3400 cm^{-1}, NH_2 deformation at 1620 cm^{-1}). The

------ Copper(II) tetracyanoethylglycinate (code 3)

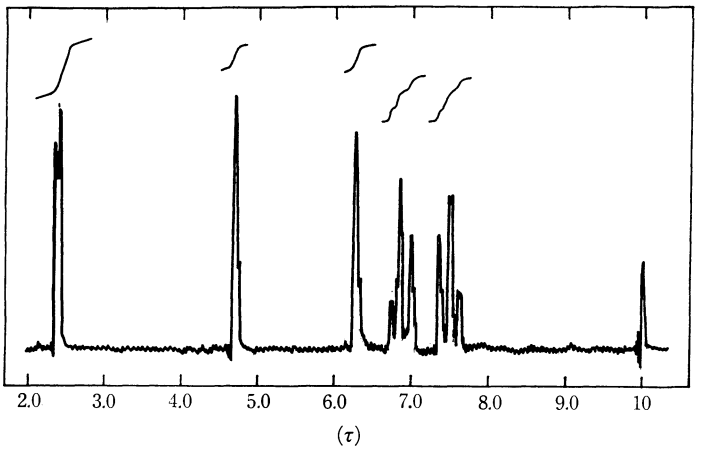

Fig. 3. The NMR spectrum of *N,N*-bis(cyanoethyl)glycine *p*-bromophenacyl ester (60 Mc, in $CDCl_3$)

appearance of two absorption bands due to CN stretching vibrations near 2250 cm^{-1} and the disappearance of the NH stretching vibration at 3200 cm^{-1} of the complex (code 3) suggest that two cyanoethyl groups were introduced to the amino nitrogen atom. From the results of the elementary analysis, the complex may be considered to be hydrate. As it was difficult to purify the complex, the copper was precipitated as copper sulfide and the organic ligand was isolated as the *p*-bromophenacyl derivative (light yellow needles, mp 63°C). The NMR spectrum of the *p*-bromophenacyl ester (see Fig. 3), obtained using chloroform-d as the solvent, that the acid part of the ester is *N,N*-bis(cyanoethyl)-glycine (CN stretching at 2250 cm^{-1}, CO stretching at 1733 and 1697 cm^{-1}).

The (code 4) complex was obtained by raising the reaction temperature to 110°C. On the basis of a comparison of the infrared spectra, it may be supposed that one of the cyanoethyl groups introduced at first was hydrolyzed to the amide group (one CN streching band and a new NH stretching band appeared).

As the SAGCu(II)·H_2O had no active hydrogen atom on the nitrogen atom, the two active hydrogen atoms of the glycine methylene group were cyanoethylated with acrylonitrile.

In the case of copper, palladium, and nickel glycinate, the amino group was supposed to be protected by coordination and cyanoethylation should have occurred at the methylene group of the glycine part. However, acrylonitrile reacted with the hydrogen atoms of the amino group. From the copper glycinate, a tetracyanoethyl complex was obtained by the additonal cyanoethylation of the dicyanoethylated compound, but no higher cyanoethylation occurred. The results for the nickel glycinate were the same as for the cyanoethylation of glycine itself, metal complexing had no effect.

In comparison to nickel glycinate, the palladium glycinate was easily cyanoethylated to the tetracyanoethyl compound. In this case, the cyanoethyl group was stable and was not hydrolyzed by alkali. As we would expect two cyanoethyl groups to be replaced on the free glycine, the reaction was repeatedly attempted by changing the amount of alkali and acrylonitrile. However, only the mono-*N*-cyanoethyl compound was obtained.

It is of interest that though only one of the amino hydrogens in free glycine was cyanoethylated in alkali, the two hydrogen atoms were replaced when coordinating with a transition metal ion (Cu^{2+}, Pd^{2+}, but not Ni^{2+}).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 196—200 (1970)

Synthesis of Corticotropin Peptides. IX. Synthesis of [1-Glycine]-ACTH(1—18)-Octadecapeptide Amide

Hideo Otsuka, Masaru Shin, Yasuhiko Kinomura and Ken Inouye

Biochemistry Division, Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received June 20, 1969)

The synthesis is decribed of an octadecapeptide, glycyl-tyrosyl-seryl-methionyl-glutamyl-histidyl-phenyl-alanyl-arginyl-tryptophyl-glycyl-lysyl-prolyl-valyl-glycyl-lysyl-lysyl-arginyl-arginine amide, corresponding to the first eighteen amino acid residues of corticotropin except for the amino end which has been replaced by a glycine for the serine in the native hormone. The protected end product was obtained by two different coupling procedures, the active ester and the catalyzed carbodiimide, from the amino-terminal decapeptide and the octapeptide of carboxyl end. The over-all yields of the peptide, for the final coupling, deblocking and purification steps, in the active ester and the carbodiimide procedures were approximately forty and thirty per cent, respectively. The synthetic octadecapeptide amide has been shown to possess a high adrenal corticotropic activity, which is comparable to that of the corresponding l-serine octadecapeptide amide, and a lipolytic activity which is significantly lower than that of the l-serine analog.

In a previous communication we reported the synthesis of a corticotropin peptide, ACTH(1—18)-amide (I), which was shown to possess a high steroidogenic potency.[1] In 1963 Lebovitz and Engel reported that the amino-terminal serine of porcine corticotropin could be converted into a glycine without loss of corticotropic activity.[2] This implies that the hydroxymethyl group of amino-terminal serine is not essential for the activity in case of the native hormone. In connection with this finding, the synthesis of a peptide, corresponding to the first eighteen amino acid residues of adrenocorticotropin (ACTH) except for the amino end which was substituted by a glycine for the serine in the parent peptide I, was undertaken as an attempt to prepare analogs of corticotropin peptides. Here will be described the synthesis of the octadecapeptide amide, glycyl-tyrosyl-seryl-methionyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycyl-lysyl-prolyl-valyl-glycyl-lysyl-lysyl-arginyl-arginine amide (II), which may be designated as [Gly[1]]-ACTH(1—18)-NH_2 for abbreviation.[3]

In the final reaction leading to the protected end product, the fragment corresponding to the first ten amino acid residues was coupled with the one corresponding to the rest of the molecule by two different procedures, the *N*-hydroxysuccinimide-catalyzed carbodiimide method[4] and the active ester method.[5] The syntheses of both fragments as intermediates have been already reported.[6]

A protected decapeptide Boc-Gly-Tyr-Ser-Met-Glu(OBu^t)-His-Phe-Arg-Trp-Gly-OH (III)[6a] and a partially protected octapeptide H-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-Lys(Boc)-Arg-Arg-NH_2 (IV),[6b] which had been converted into the hydrochloride, were coupled with *N*,*N*′-dicyclohexylcarbodiimide (DCC) in the presence of *N*-hydroxysuccinimide as a catalyst to lead to the formation of a protected octadecapeptide Boc-Gly-Tyr-Ser-Met-Glu(OBu^t)-His-Phe-Arg-Trp-Gly-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-Lys(Boc)-Arg-Arg-NH_2 (V). The crude product was submitted for purification to chromatography on a column of carboxymethyl cellulose (CMC) in the 50% *t*-butanol - 2M ammonium acetate (pH 5.70) system (Fig. 1). The purified V was obtained in a yield of 50% and was found to be homogeneous in thin-layer chromatography. The protecting groups of V were then removed by treatment with 90% trifluoroacetic acid to liberate the octadecapeptide II. The crude product was, after having been converted into the acetate by treatment with an anion-exchange resin (acetate form), purified on

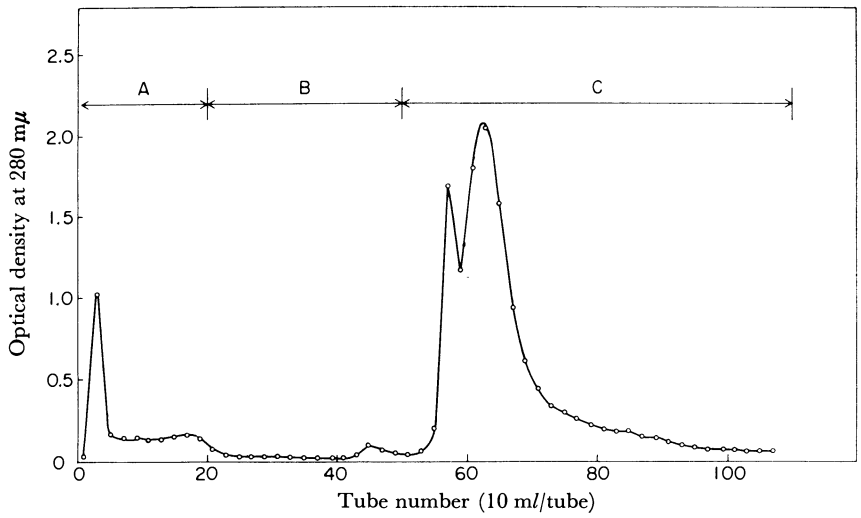

Fig. 1. Chromatography of protected octadecapeptide amide (V) on a carboxymethyl cellulose column. Material: crude product, 0.139 g. Column: carboxymethyl cellulose (Serva, 0.44 meq/g), 1.6×9 cm. Solvent: A, 50% *t*-butanol; B, 50% *t*-butanol - 2M ammonium acetate, pH 5.70 (99 : 1, 150 m*l*) through a mixing chamber containing 50% *t*-butanol (150 m*l*); C, 50% *t*-butanol - 2M ammonium acetate, pH 5.70 (98: 2, 300 m*l*) through a mixing chamber containing 50% *t*-butanol - 2M ammonium acetate, pH 5.70 (99 : 1, 300 m*l*).

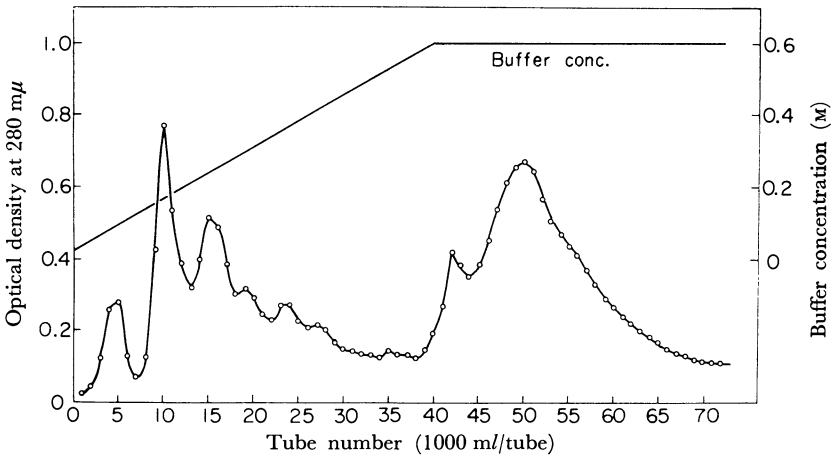

Fig. 2. Chromatography of octadecapeptide amide (II) on a carboxymethyl cellulose column.[7] Material: product obtained from crude protected octadecapeptide amide (V, 11.8 g). Column: carboxymethyl cellulose (Brown, 0.78 meq/g), 6.9×78 cm. Solvent: ammonium acetate buffer (pH 6.5).

a CMC column in the ammonium acetate buffers with successive concentration and pH gradients. The purified material was recovered from the main peak in a yield of 59%.

In an alternative procedure to obtain peptide II, decapeptide III was first esterified with *N*-hydroxysuccinimide by the DCC method[5] and the resulting active ester isolated was coupled with the acetate of octapeptide IV in the presence of triethylamine. The product was, without further purification, treated with 90% trifluoroacetic acid to remove the protecting groups. The crude octadecapeptide trifluoroacetate was converted by treatment with Amberlite IRA-400 (acetate form) into the acetate,

7) The data were taken from part of an experiment performed by Dr. Ikuo Kikkawa and staff of this Laboratory under the supervision of one of us (H.O.). We thank Dr. Kikkawa for permission to include this synthesis in the present communication.

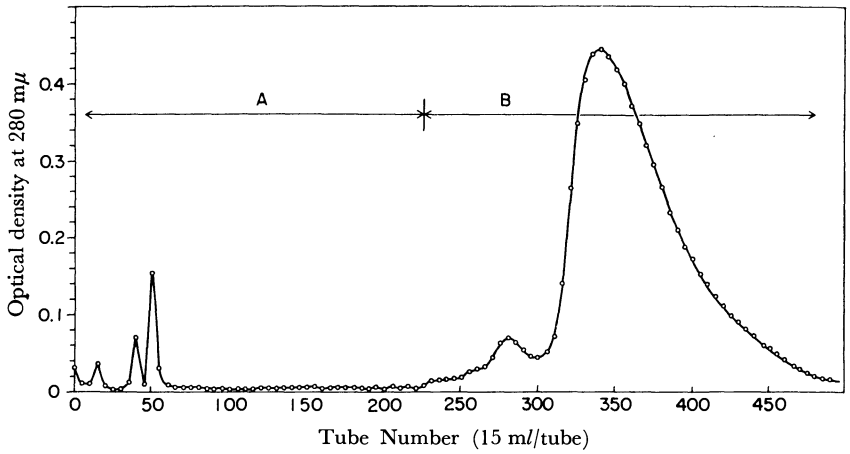

Fig. 3. Rechromatography of octadecapeptide amide (II) on a carboxymethyl cellulose column.[7] Material: partially purified II, 0.300 g. Column: carboxymethyl cellolose (Brown, 0.78 meq/g), 3.8×28 cm. Solvent: A, ammonium acetate (pH 6.5) with a linear concentration gradient of 0.025—0.6M, 3300 ml; B, 0.6M ammonium acetate (pH 6.8).

which was, after having been incubated with mercaptoethanol, submitted to chromatography on a CMC column using the ammonium acetate buffer (pH6.5) with a linear concentration gradient (Fig. 2). The octadecapeptide II was thus obtained in an over-all yield of 50% for the final coupling step. Further purification was carried out on a CMC column in the same manner as above in a recovery of 80% (Fig. 3).

In both cases peptide II obtained was found to be homogeneous to ninhydrin, Pauly, Ehrlich, Sakaguchi and methionine (PtI_6'') reagents in paper chromatography. Quantitative amino acid analysis[8] showed that an acid hydrolysate of the product contained the individual amino acids in the ratios expected by theory with the exception of tryptophan. The tryptophan-tyrosine ratio was determined spectrophotometrically to be unity.[9]

The biological properties of the octadecapeptide II are compared in Table 1 with those of the parent peptide I;[10] the latter has been reported.[1] The lipolytic activity of the Gly^1-analog (II) was found to be significantly lower than that of the Ser^1-peptide (I) and is on the same order of magnitude as that of a native corticotropin when assayed in the rat.[13] The adrenal stimulating activity of peptide II was assayed by three different procedures for the comparison with peptide I. A slightly higher activity was obtained with peptide II as compared with peptide I, when assayed by both *in vivo*[11] and *in vitro*[12] steroidogenesis procedures, whereas peptide II was found to be slightly less active than peptide I when assayed by the adrenal ascorbic acid depletion method. The synthesis of ACTH(1—23)-NH_2

and the corresponding Gly[1]-analog was recently reported by Geiger *et al.*[14] They gave the latter a little higher value of activity as compared with that of the former, using the adrenal ascorbic acid depletion method.

Experimental

Glycyl-tyrosyl-seryl-methionyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycyl-lysyl-prolyl-valyl-glycyl-lysyl-lysyl-arginyl-arginine Amide (II). *a) By the N-Hydroxysuccinimide-catalyzed Carbodiimide Method.* The partially protected octapeptide, H-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-Lys (Boc)-Arg-Arg-$NH_2 \cdot 3CH_3COOH$,[6b] (IV, 0.074 g, 0.05 mmol) was dissolved in 3 m*l* of ice-cold 0.05N hydrochloric acid and the solution was immediately lyophilyzed to give the corresponding trihydrochloride. The protected decapeptide, Boc-Gly-Tyr-Ser-Met-Glu (OBu^t)-His-Phe-Arg-Trp-Gly-OH,[6a] (III, 0.080 g, 0.055 mmol) was dissolved in 1.5 m*l* of dimethylformamide together with the octapeptide hydrochloride obtained above, and to this solution were added *N*-hydroxysuccinimide (0.013 g, 0.11 mmol) and *N,N'*-dicyclohexylcarbodiimide (DCC, 0.014 g, 0.07 mmol) at 0°C. The reaction mixture was stirred at 0°C for one hour and at room temperature for 48 hr. *N,N'*-Dicyclohexylurea (DCU) which formed was filterred off and the filtrate was introduced into ice-cold ethyl acetate (100 m*l*). The precipitates which separated were filtered off, washed with cold ethyl acetate, and dried over phosphorus pentoxide *in vacuo* to afford 0.139 g of the crude product. This crude material (0.139 g) was dissolved in 5 m*l* of 50% *t*-butanol and to this was added Amberlite CG-4B (acetate form, 1.1 cc), and the mixture was shaken for 30 min. After removal of the resin, M mercaptoethanol (0.5 m*l*) was added to the filtrate. The mixture was, after having been incubated at 37°C overnight, subjected to chromatography on a column (1.6×9 cm) of carboxymethyl cellulose (Serva, 0.44 meq/g), using successively the following solvent systems: 50% *t*-butanol (200 m*l*); the one with a linear gradient obtained from 50% *t*-butanol (150 m*l*) and 50% *t*-butanol-2M ammonium acetate, pH 5.70 (99 : 1, 150 m*l*); the one with a linear gradient obtained from 50% *t*-butanol-2M ammonium acetate, pH 5.70 (99 : 1, 300 m*l*) and 50% *t*-butanol-2M ammonium acetate, pH 5.70 (98 : 2, 300 m*l*). The results of chromatography are shown in Fig. 1. Fractions corresponding to the main peak (tubes 55—70) were pooled and the bulk of the solvent was removed *in vacuo*. The residue was lyophilized to give the protected octadecapeptide (V); yield 0.105 g (50% on the weight basis). The material was found to be unreactive to ninhydrin and it behaved as a single component to Pauly and Sakaguchi reagents in thin-layer chromatography (Silica gel G, *n*-butanol-acetic acid-water=4 : 1 : 2 by volume as solvent).

To remove the protecting groups the purified peptide V (0.140 g) was treated with 90% trifluoroacetic acid (2 m*l*) at room temperature for 60 min. After the solvent had been removed *in vacuo* over potassium hydroxide pellets, the residue was dissolved in water, (5 m*l*). The aqueous solution was shaken with Amberlite CG-4B (acetate form, 2.5 cc) for one hour, and then the resin was removed by filtration. To the filtrate M mercaptoethanol (1 m*l*) was added and the mixture was, after having been kept at 37°C overnight, subjected to chromatography on a column (1.6×11 cm) of carboxymethyl cellulose (Serva, 0.44 meq/g), using successively the following ammonium acetate buffers: the one with a linear gradient obtained from 0.075M, pH 5.80 (400 m*l*) and 0.25M, pH 7.00 (400 m*l*); the one with a linear gradient obtained from 0.25M, pH 7.00 (450 m*l*) and 0.40M, pH 8.60 (450 m*l*); 0.40M, pH 8.60 (450 m*l*). Fractions (10 m*l*/tube) corresponding to the main peak (tubes 70—120) were combined and the bulk of the solvent was removed *in vacuo*. The residue was lyophilized repeatedly to constant weight and dried over phosphorus pentoxide *in vacuo* at 60°C to give the pure octadecapeptide (II); yield 0.070 g (59% for the deblocking step, as determined spectrophotometrically),[15] homogeneous (R_f=0.09) to ninhydrin, Pauly, Ehrlich, Sakaguchi and methionine (PtI_6'') reagents in paper chromatography (*n*-butanol-acetic acid-water=4 : 1 : 2 by volume as solvent). $[\alpha]_D^{23.5}$ −51.4±1.9° (*c* 0.472, 0.1N acetic acid). $\lambda_{max}^{0.1N\ NaOH}$=281 mμ (ε 6750), 288 mμ (ε 6490). Amino acid ratios in acid hydrolysate:[8] Ser 0.93, Glu 0.96, Pro 0.98, Gly 3.25, Val 1.00, Met 1.00, Tyr 1.05, Phe 1.00, Lys 3.23, His 1.07, NH_3 1.39, Arg 2.95, Trp 0.46 (decomposed partially with acid). The Trp/Tyr ratio in intact II was determined spectrophotometrically to be 0.91 : 1.[9]

b) By the Active Ester Method.[7] To a solution of Boc-Gly-Tyr-Ser-Met-Glu(OBu^t)-His-Phe-Arg-Trp-Gly-OH[6a] (III, 8.04 g, 5.2 mmol) in 240 m*l* of dimethylformamide were successively added N hydrochloric acid (5.2 m*l*), *N*-hydroxysuccinimide (2.4 g, 20.8 mmol) and DCC (4.3 g, 20.8 mmol) at an ice-salt bath temperature. The mixture was stirred at 4°C for 20 hr. Additional quantities of the succinimide (2.4 g) and DCC (4.3 g) were added and the stirring was continued for 5 hr. After removal of DCU by filtration the filtrate was introduced into 2000 m*l* of ethyl acetate-ether (1 : 1 by volume). The resulting precipitates were filtered off, washed with ethyl acetate-ether and dried *in vacuo* to yield the protected decapeptide active ester hydrochloride; 9.38 g.

H-Lys(Boc)-Pro-Val-Gly-Lys(Boc)-Lys(Boc)-Arg-Arg-$NH_2 \cdot 3CH_3COOH$[6b] (IV, 4.73 g, 3.1 mmol) and triethylamine (4.8 m*l*) were dissolved in dimethylformamide (150 m*l*) and to this solution was added the decapeptide active ester obtained above (9.38 g) at 0°C. The mixture was stirred at 4°C for 4 days, and was then poured into ice-cold ethyl acetate to separate the crude protected octadecapeptide (V), which was filtered off, washed with cold ethyl acetate and dried *in vacuo*; yield 13.11 g.

To this crude product (11.8 g) was added 90% trifluoroacetic acid (120 m*l*) and the mixture was stirred at 0°C for 15 min and at room temperature for 75 min. After the solvent had been removed *in vacuo*, the residue was dried over potassium hydroxide pellets *in vacuo* and was then dissolved in water (*ca.* 50 m*l*). The solution was applied to a column (4.4×30 cm) of Amberlite IRA-400 (acetate form) and the column was washed with water. The effluents were combined and concentrated

14) R. Geiger, K. Sturm, G. Vogel and W. Siedel, *Z. Naturforsch.*, **19b**, 858 (1964).

15) The over-all yield of peptide, calculated on the basis of the amine component used for the final coupling step, is therefore 29.5%.

in vacuo to about 400 m*l*, and to this was added 25 m*l* of M mercaptoethanol. The mixture was, after incubation at 37°C overnight, submitted to a column (6.9×78 cm) of carboxymethyl cellulose (Brown, 0.78 meq/g). The column was eluted with an ammonium acetate buffer (pH 6.5) having a linear concentration gradient of 0.025—0.6M to collect 40 *l* of fractions and then with 0.6M ammonium acetate buffer (pH 6.5) until the desired peptide totally emerged (Fig. 2). Fractions corresponding to the main peak (tubes 44—72) were combined and the bulk of the solvent was removed *in vacuo*. Repeated lyophilization of the residue gave the octadecapeptide (II) as fluffy powder. The material was dried over phosphorus pentoxide at 55°C *in vacuo* to yield 3.17 g (50.2% on the basis of the amine component used for the coupling step, as determined spectrophotometrically); homogeneous to ninhydrin, Pauly and Sakaguchi reagents in paper chromatography (*n*-butanol-acetic acid-pyridine-water=30 : 6 : 20 : 24 by volume (BAPW) as solvent). $[\alpha]_D^{28}$ $-53.6\pm1.9°$ (*c* 0.494, 0.1N acetic acid). Amino acid ratios in acid hydrolysate:[8] Ser 0.96, Glu 0.98, Pro 1.04, Gly 3.00, Val 0.99, Met 0.99, Tyr 0.99, Phe 1.02, Lys 3.00, His 0.99, Arg 3.06.

A 0.3 g-portion of the peptide obtained above was submitted, for further purification, to a column (3.8× 28 cm) of carboxymethyl cellulose (Brown, 0.78 meq/g), using the ammonium acetate buffer (pH 6.5) with a linear concentration gradient of 0.025—0.6M (3300 m*l*) followed by 0.6M ammonium acetate (pH 6.8). The results of this rechromatography are shown in Fig. 3. Fractions corresponding to the main peak (tubes 310—480) were pooled, concentrated and lyophilyzed to obtain the pure peptide II; 0.24 g, $[\alpha]_D^{23}$ $-55.3\pm1.9°$ (*c* 0.510, 0.1N acetic acid). Homogeneous to ninhydrin, Pauly, Ehrlich, Sakaguchi and methionine (PtI_6'') reagents in paper chromatography (BAPW) and in paper electrophoresis (600 V/36 cm, in 2N acetic acid). Amino acid ratios in acid hydrolysate:[8] Ser 0.94, Glu 1.01, Pro 0.99, Gly 3.00, Val 1.00, Met 0.98, Tyr 0.98, Phe 0.97, Lys 2.90, His 0.97, Arg 2.97.

Grateful acknowledgement is made to Mr. Kunio Watanabe and Miss Motoko Nakazawa for able technical assistance, to Dr. Mitsuo Ebata and staff for amino acid analysis, and to Dr. Kaoru Kuriyama and staff for optical rotation measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 200—207 (1970)

Base-catalyzed 1–3 Prototropic Isomerization of Cycloheptatrienes[1]

Kazuko TAKAHASHI, Hiroshi YAMAMOTO[2] and Tetsuo NOZOE[3]

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received June 20, 1969)

The base-catalyzed proton migration (from the 7- to 2-position) and proton exchange (at the 7-position) of cycloheptatrienes carrying an electron-withdrawing group were studied in a medium of aqueous sodium hydroxide or alcoholic potassium hydroxide. The order of the effect of the various substituents upon the relative rates is approximately: $CN > CONH_2 > COO^-$, Ph. The base-catalyzed prototropic isomerization proceeds through: i) the abstraction of a proton of the 7-position by the base, ii) the migration of the resulting carbanion to the allylic position (the rate-determining step), and iii) the recovery of a proton from the solvent. The kinetic study of the isomerization of 7-carboxycycloheptatriene (Ia) discloses the rate of the isomerization (k[the cycloheptatriene][base]) and the parameters ($E_a = 22.6$ kcal/mol, $\Delta H^{\neq} = 22.0$ kcal/mol, $\Delta S^{\neq} = -15.4$ e.u. at 60°). The structure of the cycloheptatrienyl anions formed as intermediates is discussed.

With reference to the migration of the double bonds in cycloheptatrienes, ter Borg *et al.*[4] first described the thermal 1–5 hydrogen shift mechanism, and Chapman, Borden and other groups[5] have recently reported the photochemical 1–7 hydrogen shift shown in Schemes 1 and 2. We have also

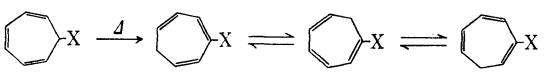
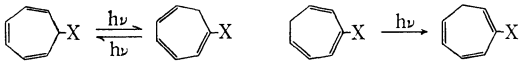


Scheme 1. 1-5 H Shift



Scheme 2. 1-7 H Shift

previously recognized the same mode of the thermal isomerization reaction on various cycloheptatrienes.[6] Now, however, we have found a new type of isomerization catalyzed by the base; this isomerization will be explained herein.

The proton migration in a basic medium was first observed by Buchner and his coworkers,[7] when 7-ethoxycarbonylcycloheptatriene was converted to 2-carboxycycloheptatriene (IIIa) on being refluxed with 10% alcoholic potassium hydroxide, although they did not mention the reaction mechanism. We ourselves have examined the behavior of carboxy-,[8] cyano-, carbamoil-, and phenyl-cycloheptatriene in basic media with the view of clarifying the mechanism of the base-catalyzed isomerization.

Upon heating the 7-substituted cycloheptatrienes mentioned above, the 3-, 1- and 2-substituted isomers were successively formed according to the 1–5 hydrogen shift mechanism; the chemical shifts and the couping constants of the hydrogen atom at the 7-position [H(7)] of each substance, shown in Table 1, were used for purposes of identification throughout the present work. As will be shown below, kinetic study proved that the base-catalyzed isomerization of cycloheptatrienes in dilute alkali generally took place much faster than the thermal 1–5 hydrogen shift.

The complete disappearance of the triplet signal at τ 7.52 due to H(7) in the NMR spectrum of 7-carboxycycloheptatriene (Ia), when the mixture was set aside in 2N sodium deuteroxide for 41 hr at room temperature indicated the proton exchange at the 7-position, while no deuterium exchange was observed when Ia was kept in a neutral medium

such as deuterium oxide-dioxane (1 : 1) for 73 hr at the same temperature. The 7-*d*-7-carboxycycloheptatriene (IIa) thus formed was shown, on the evidence of the NMR (*i. e.* alterations of the signals due to H(7), (1), and (6)], to be isomerized to 7-*d*-2-carboxycycloheptatriene (IV) when warmed at 90°C for 10 hr in the same solvent (2N NaOD). The treatment of Ia with 2.5N sodium hydroxide at 110°C for 4 hr caused an isomerization affording 2-carboxycycloheptatriene (IIIa) in an 80% yield. The rate of the isomerization reaction of Ia to IIIa appears, from the results shown in Table 2, to depend upon the concentration of the base used (this was confirmed by the kinetic study; see below). The secondary isomerization (*i. e.*, IIIa to the other isomers, Va and VIa) was found to be considerably slower than the first-step isomerization under the same conditions, for the compound IIIa or Va remained almost unchanged when kept in 2N sodium hydroxide, even at a higher temperature such as 130°C. An enhancement of the rate of the secondary and subsequent-step isomerization of the carboxycycloheptatriene was, however, observed in a stronger base, as is shown in Tables 3 and 4; the data suggested that IIIa was successively converted to Va and the 1-substituted isomer (VIa). This was confirmed by examining the ratio of the products when IIIa or Va was treated with a concentrated base; these results are shown in Tables 5 and 6. Accordingly, the base-catalyzed proton transfer in the cycloheptatriene was considered to proceed by the step-by-step mechanism illustrated by Scheme 3; the last three compounds (IIIa, Va, and VIa) are at equilibrium.

The effect of the substituents upon the relative rate of the isomerization was studied using other cycloheptatriene derivatives. The enhanced rates of the proton exhange and the isomerization resulted, to a great extent, in a cyano group. Upon the treatment of 7-cyanocycloheptatriene (Ib) with 4% sodium methoxide (in deuterium oxide) for 12 hr at room temperature, the proton exhange at the 7-position similarly took place to afford the deuterated compound (IIb) [no deuterium exchange occurred in deuterium oxide-dioxane (1 : 1)]. The 7-cyano compound (Ib) was readily converted to the 2-substituted isomer (IIIb) with 0.5% alcoholic potassium hydroxide (53% after three days at room temperature) or with 1.3% aqueous potassium hydroxide (80% after 2 hr at 45°C with stirring). Among the above reaction mixtures, a trace of 3-cyanocycloheptatriene (Vb), the secondary isomerization product, was detected (NMR). The rate of the initial isomerization was, however, much faster than those of the secondary or the subsequent isomerization, as was observed in the carboxycycloheptatriene system. It was found in the case of cyanocycloheptatriene that the hydrolysis of the cyano group took precedence over the secondary or tertiary isomerization in 2N aqueous sodium hydroxide; thus, the procedure is applicable to the preparation of IIIa and Va from the corresponding cyanocycloheptatrienes (see the Experimental section).

7-Carbamoilycycloheptatriene (Ic), when kept in 2.5N sodium hydroxide at 75°C for 10 min, gave a mixture consisting of the recovered Ic, the isomer (IIIc), Ia, and IIIa in a ratio of 13 : 14 : 68 : 5 (from NMR). Because Ia was confirmed not to isomerize to IIIa under the above conditions (*i. e.*, IIIa was derived from IIIc), the above ratio of the products suggested that the hydrolysis of the carbamoil group of Ic took place approximately 3.5 times faster than the isomerization of Ic to IIIc.[9]

Table 7. The action of 10% alc. KOH on Id at 84°C

Reaction time (hr)	Yield (%)			
	Id	IIId	Vc	VIb
0.7	40	33	11	11
1.5	16	50	17	16
4		59	21	20

Among the isomerized products of 7-phenylcycloheptatriene[10] (Id), as is shown in Table 7, a small amount of the secondary and the tertiary isomers, Vc and VIb, was present, besides the main product, IIId, on treatment even with a dilute base. The conjugative effect of the aryl group could make the subsequent isomerization easier. The effect of the various substituents upon the relative rates of the isomerization was thus considered to be, by comparison with the semi-quantitative results mentioned above: $CN > CONH_2 > COO^-$, Ph (the rates of the last two appeared to be very similar).

Cycloheptatriene itself, when treated with a mixture of 10N sodium deuteroxide and dioxane (1 : 1) at 90°C for 8 hr, remained completely unchanged. Nor was any deuterium exchange (nor isomerization) observed when 7-methoxycycloheptatriene was refluxed with 9% alcoholic potassium hydroxide for 4 hr. These results showed that a hydrogen atom of a cycloheptatriene should be replaced by an electron-withdrawing group as a requirement for the base-catalyzed proton exchange followed by the isomerization; the isomerization and the exchange rates are in proportion to the acidity of the hydrogen atom of the 7-position of cycloheptatriene.

To clarify the reaction mechanism, a kinetic study of the isomerization of 7-carboxycycloheptatriene (Ia) in a base was carried out. The disappear-

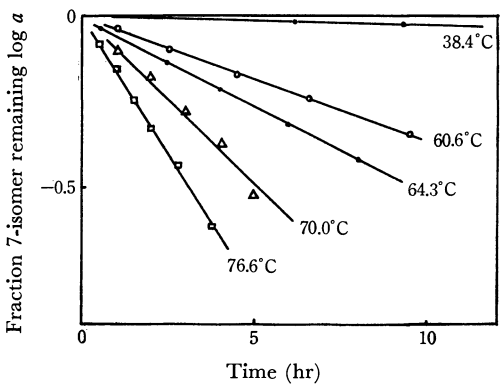

Fig. 1. Plots of the logarithm of the fraction of 7-isomer present *vs.* time at several temperatures.

9) Alkaline hydrolysis of Ic has been reported to afford IIIa but not Ia (Ref. 8a). Present experiment showed that the reaction would competitively undergo through: Ic→Ia→IIIa and Ic→IIIc→IIIa. Successful preparation of Ia from Ic was carried out by treatment with acid (see Experimental part).

10) T. Nozoe, T. Mukai, T. Tezuka and K. Osaka, *Nippon Kagaku Zasshi*, **84**, 662 (1963). They reported that 7-phenylcycloheptatriene (Id), when refluxed with 10% ethanolic sodium hydroxide for 15 hr, gave an isomer which showed a triplet signal (τ 7.76, J=7.0 Hz) due to a methylene group of a phenylcycloheptatriene.

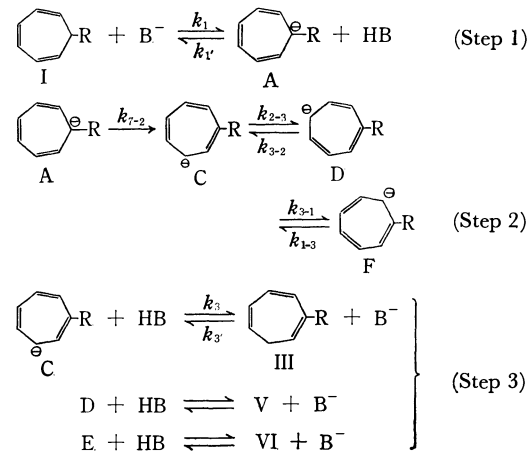
a) The transition state parameters are reported at 60°C.

ance of Ia in 0.996N sodium hydroxide, measured spectrophotometrically, exhibited good first-order kinetics over the temperature range of 38—77°C (see Fig. 1); the observed rate constants, k', are shown in Table 8. The variation in the rates as a function of the concentration of the base was also studied at 76.0±0.1°C, the results being shown in Table 9. Assuming the observed first-order rate constants, k'', to be k[NaOH]^n, the slope of the straight line (Fig. 2), obtained by plotting log k'' against log [NaOH], indicated that n equals 1.0; thus, the rate of the isomerization may be expressed in terms of the following equation:

$$v = k\,[\text{the cycloheptatriene}]\,[\text{base}]$$

The rate constants, k, for the isomerization at the various temperatures in the unit concentration of sodium hydroxide were calculated to be as is shown in Table 8. A plot of the k values against $1/T$ was found to be linear (*cf.* Fig. 3), giving values for the transition-state quantities, $\Delta F^{\ddagger}$, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$ (from Eyring formulation). The results of these calculations are summarized in Table 10.

It can be postulated from the foregoing results that the base-catalyzed isomerization of cycloheptatrienes involved the carbanion formation (Step 1), the migration of the carbanion charge to the allylic position (Step 2), and finally the reformation of the isomerized cycloheptatriene by picking up a proton from the solvent (Step 3), as is illustrated by Scheme



Scheme 4

4. According to the reaction pathways shown here, the rates of the formation of three substances, A, C, and III, can be expressed as follows:

$$\frac{d[A]}{dt} = k_1[I][B^-] - k_1'[A][HB] - k_{7-2}[A] \quad (1)$$

$$\frac{d[C]}{dt} = k_{7-2}[A] + k_{3-2}[D] - k_{2-3}[C] - k_3[C][HB] \quad (2)$$

$$\frac{d[III]}{dt} = k_3[C][HB] - k_{3'}[III][B^-] \quad (3)$$

where k_1, k_1', k_{7-2}, k_{2-3}, k_3, and k_3' are the rate constants of the reactions (Scheme 4); where [I], [A], [C], [D], and [III] are the concentrations (mol/l) of the corresponding substances in Scheme 4 and where B^- and HB are, respectively, the anion of the base and the protonated anion (the solvent).

Although complete deuterium exchange was observed at the 7-position of Ia when it was dissolved in 2N sodium deuteroxide at room temperature, the heating of the solution at a higher temperature was required to cause the isomerization to give IV (as a single product; see above), indicating that Step 2 was the rate-determining process in the isomerization of IIa to IV (*i. e.*, k_1, k_1', $k_3 \gg k_{7-2} \gg k_3'$, k_{2-3}). Upon the treatment of IIIa with 4N sodium deuteroxide at 100°C for 7 hr, the intensities of the methylene signal (τ 7.65) decreased to 0.75 H and the signals due to H(1) (τ 3.42, t) and H(6) (τ 4.64, dt) broadened in the NMR spectrum of the product, showing the formation of a mixture of IV and 7,7-d_2-2-carboxycycloheptatriene. This demonstrated that the proton exchange (with the solvent) at the 7-position preceded the isomerization reaction not only in 7-substituted cycloheptatrienes, but also in the 2-isomers (probably in the other isomers also), although the rates of both the exchange and the isomerization of the latter compounds were considerably slower than those of the former. Besides, the results in Table 5 and 6, as explained above, show that the compounds IIIa, Va and VIa were at equilibrium in stronger bases. Thus, the following relationship can be establisehd: k_3, $k_3' \gg k_{2-3}$, k_{3-2}, k_{3-1}, k_{1-3}.

Consequently, Eqs. (1)—(3) may be simplified as follows:

$$\frac{d[A]}{dt} = k_1[I][B^-] - k_1'[A][HB] \quad (1')$$

$$\frac{d[C]}{dt} = k_{7-2}[A] - k_3[C][HB] \quad (2')$$

$$\frac{d[III]}{dt} = k_3[C][HB] \quad (3')$$

The formation of the intermediates, A and C, in dilute aqueous sodium hydroxide is considered to be a steady-state reaction; thus, $d[A]/dt \simeq O$, and $d[C]/dt \simeq O$. Therefore,

$$\frac{d[III]}{dt} = k_{7-2}[A] = k_{7-2}\frac{k_1[I][B^-]}{k_1'[HB]} = k[I][B^-]$$

where $k = k_1 \cdot k_{7-2}/k_1'[HB] = \text{const.}$

This equation, which is in agreement with our expermental results presented above, would seem to verify the assumption of the three-step isomerization mechanism shown in Scheme 4.

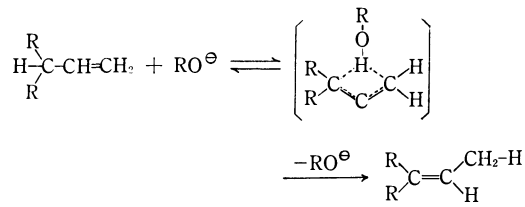
Similarly, when V is formed from III, the rate of the isomerization may be calculated as follows:

$$\frac{d[V]}{dt} = k'[III][B^-]$$

where; $k' = k_{3'} \cdot k_{2-3}/k_3[HB]$

Although k' is probably much smaller than the k shown above, the higher concentration of the base would facilitate the secondary isomerization reaction. This is also in accordance with our experimental results, which show that Va was formed from IIIa only in strong alkali (see above). The equilibrium relationship among the compounds III, V, and VI could be explained similarly. The determination of the equilibrium constants of each reaction in Scheme 4 would be of interest in connection with the relationship to the pk_a values of H(7) of the compounds I, III, V, and VI.

Concerning the base-catalyzed allylic proton transfer, intramolecularity has been observed in various organic solvents and bases, as is explained in Scheme 5, where the isotopic exchange is much slower than the isomerization.[11] Scheme 5



Scheme 5

In our system, however, the rate of proton exchange was much faster than that of the isomerization (*i.e.*, $k_1, k_1' \gg k_{7-2}; k_3, k_3' \gg k_{2-3}$), and no clear evidence of intramolecularity was detected.

The rate-determining step of the isomerization (Step 2 in Scheme 4) involves p-π bond rehybrization to form an allylic carbanion, the structure of which will now be discussed. According to the

F G

molecular orbital theory, a cycloheptatrienyl anion which possesses eight electrons should exist as a triplet diradical in the ground state. The heptaphenylcycloheptatrienyl anion[12] has been reported to be a singlet because of the distortion by the phenyl groups. Dauben,[13] Doering,[14] and their co-workers have reported that they detected the D_{7h} symmetrical (coplanar) cycloheptatrienyl anion by the deuterium exhcange, which occurred randomly on each carbon atom of the seven-membered ring. Under our circumstances, the migration of the anionic charge took place only to the allyclic position (*cf.* Scheme 4); this suggests that the rehybrization is limited within the three carbon atoms concerned, eliminating the possibility of a coplanar cycloheptatrienyl anion (F) as the structure of the intermediate anion. Thus, such a three-carbon coplanar anionic structure as is shown in the formula G seems most probable.

Experimental

The NMR measurements were made at 25°C with a 60 Mc/sec Varian A-60 spectrometer.

7-Carboxycycloheptatriene (Ia). A mixture of 4.35 g of Ic (see below) and 110 m*l* of 2N sulfuric acid was heated at 120°C (bath) for 1 hr. The cooled mixture was brought to pH2 with 6N sodium hydroxide at 0°C, and then extracted with ethyl acetate. The dried extract (over $MgSO_4$) was evaporated and the residue was distilled, giving 3.65 g of Ia as a pale yellow oil, bp 98—100°C/2.5 mmHg λ_{max}^{MeOH} mμ (log ε): 260 (3.52). ν_{max}^{neat} 3300—3020 mbr, 3026 m, 2910 m, 2700 w, 2600 w, 1710 s, 1600 m, 1417 m, 1392 w, 1300 m, 1220 m, 1202 m, 998 w, 930 w, 743 m and 705 s cm^{-1}.

7-Cyanocycloheptatriene (Ib). Although Doering and Knox[15] prepared Ib from tropylium bromide and potassium cyanide in a 87% yield, a slightly modified procedure was used. A mixture of 31.4 g of 7-ethoxycycloheptatriene[6a] and 120 m*l* of 2N hydrochloric acid was stirred at 0°C for 30 min, and then 26.0 g (1.7 equiv.) of potassium cyanide dissolved in 100 m*l* of cold water were slowly stirred in at 0°C (1 hr). After stirring for further 2 hr at room temperature, the mixture was extracted with ether; the dried extract (over $MgSO_4$) was freed from the solvent and distilled, giving 24.7 g of Ib as a colorless oil (92% yield) bp 105°C/27 mmHg. λ_{max}^{MeOH} mμ (log ε): 259(3.70). ν_{max}^{neat} 3030 m, 2220 m, 1684 w, 1592 w, 1429 w, 1381 m, 1269 w, 1193 w, 1104 w, 1010 m, 975 w, 943 w, 802 w, 791 w, 745 s, 702 s and 685 s cm^{-1}.

(Found: C, 81.30; H, 6.08; N, 11.95%).

7-Carbamoilcycloheptatriene (Ic). The procedure followed that of Doering and Knox,[15] and Ic was obtained from Ib as colorless needles in a 47% yield (from ether), mp 140°C (lit,[7b,8a] 141°C). However, benzamide was also present (14%) as a by-product. ν_{max}^{KBr} 3390 s, 3205 s, 3012 m, 1661 s, 1639 sh, 1605 sh, 1429 s, 1387 m, 1269 m, 1209 w, 1140 w, 979 w, 735 s and 698 s cm^{-1}.

The Action of the Base on Ic. A mixture of 100 mg of Ic and 1.2 m*l* of 2.5N sodium hydroxide was heated while being stirred at 70°C for 10 min. The cooled mixture was extracted with ethyl acetate; the organic layer was then washed with 0.5N sodium hydroxide, dried over $MgSO_4$, and evaporated to give 23 mg of colorless needles, which were found (from NMR) to be a mixture of Ic and IIIc (1 : 1.1). The above aqueous layer, combined with the washing, was brought to pH 2 with cold 2N sulfuric acid and extracted with ethyl acetate. The dried extract (over $MgSO_4$) was evaporated to give 61 mg of a yellow oil consisting of Ia and IIIa (15 : 1, from NMR).

7-*d*-7-Carboxycycloheptatriene (IIa). A solution of 136 mg of Ia dissolved in 1 m*l* of 2N sodium deuteroxide was set aside at room temperature for 41 hr and then stirred into 1.4 m*l* of cold 2N sulfuric acid at 0°C. The contents were, after having been stirred for 5 min, extracted with ethyl acetate; the dried extract was then evaporated *in vacuo*, giving 120 mg (88%) of IIa as a yellow oil (on the evidence of NMR).

7-*d*-7-Cyanocycloheptatriene (IIb). To a solution of 40 mg of sodium methoxide dissolved in 1.0 g of deuterium oxide, 50 mg of Ib were added. After having been set aside for 12 hr at room temperature with occasional shaking, the mixture was poured into 3 m*l* of cold 1N sulfuric acid and extracted with benzene. The evaporation of the extract *in vacuo* give 38 mg of IIb as a yellow oil (from NMR).

2-Carboxycycloheptatriene (IIIa). *a)* A mixture of 3.0 g of IIIb (see below) and 24 m*l* of 2.5N sodium hydroxide was refluxed for 3 hr with stirring. A small amount of a black tar formed was removed by decantation from the cooled mixture, which was then taken to pH2 with 6N sulfuric acid at 0°C and extracted with ether. The organic layer was extracted with cold 2N sodium hydroxide. After the acidification (pH 2) of the alkaline solution, the contents were extracted with ethyl acetate. The dried extract (over $MgSO_4$) was evaporated *in vacuo* and distilled at 103°C/3 mmHg, giving 1.27 g (43%) of IIIa as colorless needles. Sublimation at 80°C(bath)/0.1 mmHg gave the pure material, mp 71—72°C (lit[7c,8b] 71.5°C). λ_{max}^{MeOH} mμ (log ε): 261(3.31). ν_{max}^{KBr} 3200—3100 mbr, 3012 m, 2976 sh, 2874 m, 2841 sh, 2653 m, 2545 m, 1692 sh, 1675 s, 1603 m, 1456 w, 1416 m, 1377 w, 1333 m, 1312 s, 1295 s, 1214 w, 1098 w, 925 w, 906 w, 882 w, 804 w, 760 m and 717 s cm^{-1}.

b) A mixture of 1.42 g of Ic and 8 m*l* of 2.5N sodium hydroxide was kept at 120°C (bath) for 1.5 hr, it was brought, after cooling, to pH 2 with cold 6N sulfuric acid, and then extracted with ether. The extract was twice shaken with cold 2N sodium hydroxide. The combined aqueous layer was taken to pH 2 with cold

15) W. von E. Doering and L. H. Knox, *ibid.*, **79**, 352 (1957).

6N sulfuric acid and extracted with ethyl acetate. The evaporation of the organic layer *in vacuo* left a brown viscous tar which recrystallized from water, giving 0.68 g, (48%) of IIIa (from IR), mp 69—70°C.

c) A solution of 100 mg of Ia in 1 m*l* of 2.5N sodium hydroxide was heated at 120°C (bath); the cooled mixture was acidified (pH 2) with 2N sulfuric acid. The precipitate was filtered off and recrystallized from water, giving 80 mg of IIIa (from IR) as colorless plates mp 71—72°C.

2-Cyanocycloheptatriene (IIIb). The material Ib (1.00 g) in 50 m*l* of 0.5% alc. potassium hydroxide was set aside at room temperature for 3 days. After the addition of 100 m*l* of water, the mixture was extracted with ether. The dried extract (over $MgSO_4$) was evaporated at 20°C under reduced pressure and distilled, giving 0.53 g of IIIb as a colorless oil bp 105—108°C/23 mmHg. The NMR data are shown in Table 1.

7-*d*-2-Carboxycycloheptatriene (IV). *a)* A solution of 136 mg of Ia in 1 m*l* of 2N sodium deuteroxide was gently refluxed for 2 hr and then, after cooling, brought to pH 2 with cold 2N sulfuric acid. The precipitate was collected and sublimed at 80°C/0.1 mmHg, giving 90 mg of colorless plates, mp 48—50°C, which were shown to be IV (from NMR; *cf.* Table 1). ν_{max}^{KBr} 3200—3100 mbr, 3003 m, 2950 sh, 2841 m, 2646 m, 2525 m, 1686 sh, 1672 s, 1597 m, 1447 m, 1412 s, 1374 s, 1332 s, 1305 sh, 1292 s, 1209 w, 920 m, 904 w, 894 w, 880 w, 801 w, 758 m and 715 s cm^{-1}.

b) A mixture of 109 mg of IIIa and 1 m*l* of 4N sodium deuteroxide was heated at 100°C(bath) for 7 hr and then treated much as above, giving 97 mg of pale yellow plates, mp 51—55°C. The product was found to be a mixture of IV and 7,7-d_2-2-carboxycycloheptatriene on the evidence of the NMR spectrum (see the main text).

3-Carboxycycloheptatriene (Va). A mixture of 10.0 g of Vb (see below) and 80 m*l* of 2.5N sodium hydroxide was stirred at 20°C for 5 hr, then at 90°C(bath) for 1 hr, and finally at 130°C(bath) for 2 hr. The cooled mixture was brought to pH 2 the careful addition of 2N sulfuric acid and extracted with ethyl acetate. The dried extract (over $MgSO_4$) was freed from the solvent and distilled, giving 7.47 g of colorless needles (70% yield), bp 106—107°C/0.2 mmHg, which sublimed at 80°C(bath)/0.1 mmHg and afforded Va as colorless needles, mp 56—57°C (lit,[7c,8b] 59.5°C). λ_{max}^{MeOH} mμ (log ε): 279(3.79). ν_{max}^{KBr} 3200—3100 mbr, 3030 m, 2967 m, 2865 m, 2825 m, 2660 m, 2545 m, 1675 s, 1610 m, 1536 m, 1435 s, 1408 w, 1395 w, 1340 m, 1294 s, 1236 w, 1200 w, 1190 sh, 1100 w, 968 w, 951 sh, 939 w, 800 w, 770 w and 740 s cm^{-1}.

3-Cyanocycloheptatriene (Vb). The compound Ib (146 g) was heated at 155°C(bath) for 2 hr under a nitrogen atmosphere (1 atm) in a flask stopped with a nitrogen balloon. (This method is frequently used because of convenience and safety in large-scale experiments on thermal isomerization). The distillation of the product gave 130 g of a pale yellow liquid (94%) bp 53°C/0.4 mmHg. This consisted of Vb (more than 90%) and 1-cyanocycloheptatriene (less than 10%), togethe with a trace of the unreacted Ib. (The percentage was derived from the NMR integration.)

Thermal Isomerization of Carboxycycloheptatrienes. When 110 mg of Ia was heated in a sealed tube at 150°C for 3 hr, the NMR spectrum showed the presence of Ia and Va in the ratio of 1 : 1, plus a trace of VIa. The compound IIIa gave a mixture of IIIa and VIa (4 : 1) when heated at 150°C for 5 hr. Similarly, Va afforded a mixture of Va and VIa (*ca.* 1 : 3) when heated at 180°C for 4 hr.

Reaction Rate Measurements. *a) The Base-catalyzed Isomerization of Ia to IIIa in 0.996N Sodium Hydroxide.* An aqueous solution of Ia (*ca.* 1×10^{-2} mol/*l*) in 0.996N sodium hydroxide was prepared. About 1.2 m*l* of the solution in a sealed tube was kept in the vapour of carbon tetrachloride (76.6±0.1°C), methanol (64.3±0.05°C), chloroform (60.6±0.1°C), and dichloromethane (38.4±0.2°C), and in an oil bath equipped with a thermostat (70±1°C). The tubes were taken out at regular intervals, and 1 m*l* of the solution was added to 10 m*l* of a mixture of 1.5N hydrochloric acid and methanol (1 : 9 v/v.). Then 1 m*l* of the dilute solution was added to 10 m*l* of methanol. The reference solution was prepared in a similar manner. The fraction of the 7-substituted cycloheptatriene remaining was calculated from:

$$a = \frac{E_\infty - E}{E_\infty - E_0}$$

where E_0, E_∞, and E are the extinctions of Ia, IIIa and the reaction mixture respectively, at 230 mμ (measured with Hitachi recording spectrophotometer, Model EPS-3). The rate constant, k', was determined from a plot of log a *vs.* the time (Fig. 1).

b) The Base-catalyzed Isomerization of Ia to IIIa in Various Strengths of the Basicity at 76.1±0.1°C. A solution (2×10^{-3} mol/*l*) of Ia in a given concentration of sodium hydroxide was heated in a sealed tube at 76.1±0.1°C (in a carbon tetrachloride vapour bath). Measurements were carried out much as in the foregoing experiment except that 1 m*l* of the reactant was diluted with 9 m*l* of methanol and 1 m*l* with hydrochloric acid strong enough to make the mixture slightly acidic (pH 2). The results are shown in Table 9.

c) Thermal Isomerization of Ia to Va. A solution of 5.839 mg of Ia dissolved in 50 m*l* of isooctane was prepared. About 1.1 m*l* of the solution sealed in a tube were heated at 99.9±0.1°C (water vapor bath). The tube was taken out at regular intervals, 1 m*l* of the solution was diluted with 10 m*l* of isooctane, and the extinction was measured at 280 mμ. The rate constant ($k=1.5\times10^{-6}$ sec^{-1}), calculated much as above, was sought in order to compare it with that of the base-catalyzed isomerization of Ia in 1N sodium hydroxide at the same temperature, the latter being obtainable from Fig. 3 ($k=8.53\times10^{-4}$ *l*/mol·sec). The base-catalyzed isomerization was, therefore, found to be 5—6×10^2 times the thermal reaction under the above conditions. This tendency could generally be the case for the isomerization of cycloheptatrienes with electron-withdrawing substituents. Accordingly, it was concluded that the thermal 1—5 hydrogen shift did not interfere with the measurement of the reaction rate of the base-catalyzed isomerization.

We wish to express our gratitude to the Sankyo Co. for its donation of a research fund which covered a part of the expenses for this work.

The Copolymerization of Alkylene Glycol Nitrate Acrylates and Methacrylates

Masafumi MORIYA and Tadataka YAMASHITA

Department of Applied Chemistry, Faculty of Engineering, Toyo University, Kawagoe-shi, Saitama

(Received June 23, 1969)

The copolymerization of alkylene glycol nitrate acrylates (ANA) and methacrylates (ANMA) [M_2] with styrene [M_1] has been carried out at 60°C. The alkylene glycol mononitrates used were ethylene, propylene, and butylene glycol mononitrates, abbreviated as EGN, PGN, and BGN respectively. For their acrylates and methacrylates, the following abridged notations are used: ENA and ENMA, PNA and PNMA, and BNA and BNMA respectively. The monomer reactivity ratios, r_1 and r_2, and the Alfrey-Price Q_2 and e_2 values for ANA and ANMA were evaluated as follows: $r_1=0.48$, $r_2=0.08$, $Q_2=0.49$, and $e_2=1.00$ for ENA; $r_1=0.41$, $r_2=0.20$, $Q_2=0.69$, and $e_2=0.78$ for BNA; $r_1=0.35$, $r_2=0.49$, $Q_2=0.99$, and $e_2=0.53$ for ENMA; $r_1=0.36$, $r_2=0.50$, $Q_2=0.98$, and $e_2=0.51$ for PNMA and $r_1=0.37$, $r_2=0.40$, $Q_2=0.90$, and $e_2=0.58$ for BNMA. The polar and steric effects of the ester side chain containing the nitrate group were discussed. ANA was copolymerized with some other divinyl monomers, and the resulting crosslinked copolymer were subjected to the swelling test.

In a previous paper,[1] the preparation and the radical polymerization of alkylene glycol nitrate acrylates (ANA) and methacrylates (ANMA) have been reported, and the activation energy of the overall polymerization of each monomers has been evaluated. However, no articles on the copolymerization of ANA and ANMA with other reactive monomers have been known to us. This paper will be concerned with the copolymerization of ANA and ANMA with styrene and some other divinyl monomers.

Experimental

Materials. ANA and ANMA were prepared by the same method as has been described in the previous paper[1] and were redistilled before use. The physical constants of the monomers are shown in Table 1.

The alkylene glycol mononitrates used are ethylene, propylene, and butylene glycol mononitrates, abbreviated as EGN, PGN, and BGN respectively. For their acrylates and methacrylates, the following abridged notations are used: ENA and ENMA, PNA and PNMA, and BNA and BNMA respectively. PGN and BGN are mixtures of primary and secondary alcohols. Since the isomer ratio of PGN was determined as 4 (primary) : 1 (secondary) by Pujo and Boileau,[2] that of BGN may reasonably be assumed to be nearly 4 : 1, also. The styrene used as a reference in the copolymerization was purified by the usual method and was redistilled before use. 2-Methyl-2-nitro-1,3-propylene diacrylate was prepared according to the method recently reported by Strumza and Altschular.[3] Triethylene glycol dimethacrylate was prepared according to the literature.[4]

TABLE 1. PHYSICAL CONSTANTS OF MONOMERS

Monomer	Bp (°C/mmHg)	n_D^{20}	d_4^{20}
ENA	74—76/4	1.4490	1.252
PNA	81—82/4.5	1.4420	—
BNA	72—75/2.5	1.4440	1.152
ENMA	70—72/2	1.4495	1.203
PNMA	72—74/3	1.4443	1.150
BNMA	76—78/3	1.4458	1.126

Diallyl phthalate and diallyl maleate of the G.R. grade were used after purification by the usual method. 2,2′-Azobisisobutyronitrile (AIBN) of the G.R. grade was used after two recrystallizations from ethanol. Benzoyl peroxide (BPO) of the G.R. grade was used after two reprecipitations from chloroform-methanol. The acetone, methanol, and other solvents used were purified by the usual technique.

Copolymerization Procedure. The copolymerization of ANA and ANMA with styrene was carried out in a sealed glass tube in the presence of 6.1×10^{-3} mol/l of AIBN at 60°C. The resulting copolymers were precipitated by adding a large amount of methanol and were then reprecipitated from acetone-methanol. Most runs were stopped before the copolymerization proceeded to 5% conversion. The composition of the copolymers was determined by nitrogen analysis. The

4) A. Ya. Drinberg, *Zh. Prinkl. Khim.*, **27**, 613 (1954).

monomer reactivity ratios, r_1 and r_2, were calculated by the method of Fineman and Ross.[5]

Copolymerization of ANA with Divinyl Monomers. The copolymerization of ANA with divinyl monomers (0.5—10.0 wt% on ANA) was conducted using 0.5 wt% BPO (on total monomers) in a sealed glass tube at 65°C for 40 hr. The equilibrium of the swelling was measured with disks of the resulting copolymers, 10 mm in diameter and 1 mm thick, placed in acetone at 20°C for 48 hr. The swelling ratio at equilibrium, Q_m, is given as follows:

$$Q_m = [W/0.7995 + W_0(1/\rho + 1/0.7995)]/(W_0/\rho)$$

where ρ is the density of the polymer, W_0 the weight of the polymer, W the weight of the copolymer after swelling, and 0.7995, the density of acetone at 20°C.

Results and Discussion

Copolymerization of ANA and ANMA with Styrene. The resulting copolymers were fluffy white masses. The decomposition temperature of the copolymers was determined to be 205—210°C by differential thermal analysis.

The results of the copolymerization of ANA and ANMA with styrene are summarized in Table 2. As the figures in Table 2 indicate, the rate of copolymerization increases with the concentration of ANA and ANMA in the monomer mixture.

The monomer reactivity ratios, r_1 and r_2, and the Alfrey-Price Q_2 and e_2 values of ANA and ANMA, together with the known values for unsubstituted alkyl acrylates and methacrylates, are shown in Table 3. The monomer-copolymer composition curves for ANA and ANMA, based on the data in Table 2, are shown in Figs. 1 and 2 respectively. From the figures (r_1r_2) in Table 3 and the curves in Figs. 1 and 2, it can be seen that the copolymers

of ANA show a greater alternating tendency than a those of ANMA.

From Table 3, it may be seen that the relative reactivities, $1/r_1$, of ANA and ANMA to the attack of the polystyryl radical are larger than those of unsubstituted alkyl acrylates and methacrylates. Otsu *et al.*[8,9] have recently reported that the relative reactivities of alkyl acrylates and methacrylates to a polystyryl radical are correlated only with the polar substituent constant, σ^*, of the alkyl group in acrylates and methacrylates, and not with their steric substituent constant, E_s, in Taft's equation. The larger relative reactivities of ANA and ANMA in our experiments may also be ascribed to a strong polar effect of the alkyl group containing the nitrate group.

Taking it into consideration that the Q_2 and e_2 values for alkyl acrylates and methacrylates increase as a function of the electron-attracting nature of alkyl substituents,[8,9] the fact that these values for ANA and ANMA are larger than those of unsubstituted alkyl acrylates and methacrylates is readily explicable because of the strong electron-attracting nature of the nitrate group (see Table 4).

higher wave number as the electron-attracting character of alkyl substituents increases.

As compared with both ANA and ANMA, the $1/r_1$ and Q_2 values of ANA are smaller than those of ANMA, while the e_2 values of ANA are larger. This feature can presumably be attributed to the effect of the hyperconjugation and to the electron-releasing nature caused by the presence of the α-methyl group in ANMA.

Thus, the $1/r_1$, Q_2, and e_2 values of ANA and ANMA are larger than those of unsubstituted alkyl acrylates and methacrylates because of the polar effect of the alkyl group containing the nitrate group.

Copolymerization of ANA with Divinyl Monomers. The homopolymers of ANA reported in the previous paper are too soft and tacky to be utilized as elastomers in solid rocket propellants.[1] According to Matsuda *et al.*,[10] useful elastomers with good toughness properties have been produced by the copolymerization of nitrobutyl acrylate (nitro-BA) with some polyglycol dimethacrylates. Therefore, crosslinked polymers obtained by copolymerization with a small amount of divinyl monomers have been studied in this paper. The divinyl monomers used were diallyl phthalate (DAP), diallyl maleate (DAM), triethylene glycol dimethacrylate (TEDM), and 2-methyl-2-nitro-1,3-propylene diacrylate (MNPDA). The molecular weights of chains between crosslinking along main chains, M_c, were evaluated by the same calculation method as was used by Tanaka *et al.*[11] for the copolymers of nitro-BA with some divinyl monomers.

The relationship between the M_c value of the copolymers and the content of divinyl monomers in the monomer mixtures is plotted in Fig. 3, in which also some date for nitro-BA copolymers are given for the sake of comparison. It is found that the M_c value decreases with an increase in the content of crosslinking agents in the monomer mixtures. The M_c values of copolymers of BNA with TEDM are in the same order as those of the corresponding copolymers of nitro-BA. It may be noted that the copolymerization behavior of BNA with TEDM is similar to that of nitro-BA with TEDM.

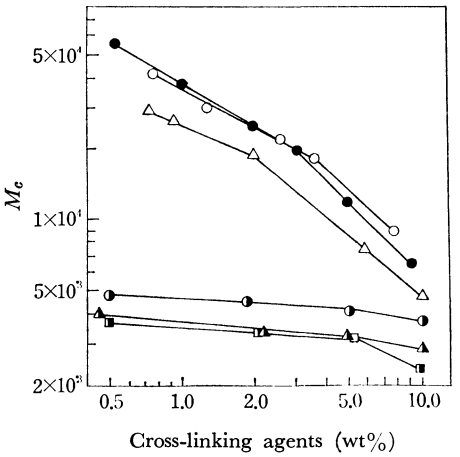

Fig. 3. Plot of M_c *vs.* divinyl monomer content
●: nitro-BA-TEDM, ○: BNA-TEDM,
△: BNA-MNPDA, ◑: BNA-DAP,
◭: BNA-DAM, ◨: ENA-DAM, ●: from Ref. 11

Generally speaking, the M_c values are highest for TEDM copolymers, medium for MNPDA copolymers, and lowest for diallyl ester copolymers. As Tanaka *et al.*[11] have reported, with regard to nitro-BA copolymers, that the tensile strength and the hardness of the copolymers increase and the elongation values decrease with an increase in the crosslinking densities, the elongation values of the copolymers of BNA with diallyl esters appear to decrease with an increase in the crosslinking densities.

Oxidative Coupling Reaction of Phenols with Dichromate

Hiroo TANAKA, Isao SAKATA and Ryoichi SENJU

Faculty of Agriculture, Kyushu University, Hakozaki, Fukuoka

(Received June 23, 1969)

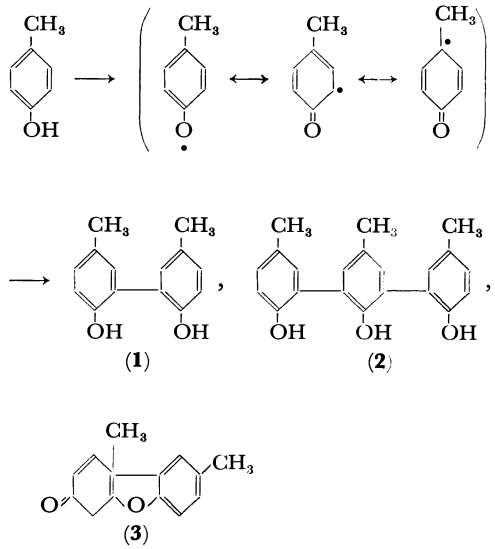
On treatment in an aqueous solution with dichromate, *p*-cresol and creosol readily undergo nuclear oxidative coupling. The yields of dimeric and trimeric cresols and of dimeric ketone are of the same order as the yields of the previously-recorded preparations by one-electron-transfer oxidants. When manganese sulfate is added, these yields are tripled. The probable mechanism of the coupling reaction of phenols with dichromate is discussed.

During the course of an investigation of the mechanism for the gelling reaction of lignin with dichromate,[1,2] it became desirable to examine the coupling reaction of phenols with dichromate.

It has been well known that phenols react with one-electron-transfer oxidants, *e.g.*, persulfate, alkaline ferricyanide or Fenton's reagent, to produce phenoxy-radicals, which then give dimeric or trimeric products by coupling reaction.[3] This oxidation mechanism has been confirmed by the identification of the oxidation products, by the detection of an intermediate phenoxy radical by the ESR technique, and so on. However, the great majority of works on the oxidation of phenols with dichromate have dealt with the preparation of quinone[4]; the only example concerning coupling products was recorded in the case of highly alkylated phenols in 50% acetic acid and 20% sulfuric acid at 50—55°C.[5] Accordingly, it has not yet been established whether the oxidative coupling readily occurs by means of the reaction between phenols and dichromate in an aqueous solution. The present investigation was, therefore, undertaken in order to clarify this problem. In addition, the catalytic effect of the manganese ion upon this reaction will be discussed.

Results and Discussion

The oxidation of phenols by one-electron-transfer oxidants has been reported by a number of workers. In all cases, the initial step has been described as the removal of hydrogen from the phenols by a radical or multivalent metal ion; the further coupling reaction of the resulting aryloxy-radical has also been discussed. For example, the coupling reaction scheme for *p*-cresol is as follows:



In the present experiments, on treatment with the aqueous dichromate, *p*-cresol gave a crystalline fraction (15%) consisting of *ortho*-linked dimeric (**1**) and trimeric (**2**) cresols and the dimeric ketone (**3**) (Table 1); on the other hand, creosol furnished only *ortho*-linked dimeric creosol (7—9%) as a crystalline product (Table 2). Homocatechol, meanwhile, yielded only resinous products. When manganese sulfate was added as a catalyst, the yields of crystalline products from *p*-cresol or creosol were tripled. The total yields of the oxidation products from *p*-cresol were 1.5 times as much as the best yields among the previously-recorded

preparations;[6-13] in other words, half of the starting material was recovered as crystalline oligomers (Table 3).

When larger quantities of dichromate were employed in the oxidation of creosol, greater quantities of the dimer were obtained. In considering the reaction mechanism described below, this result seems to be due to the fact that comparatively more hexavalent chromium exists than tetra- and pentavalent species. An analysis of the residual resinous products showed that demethylation and further oxygenation occurred.

On the dichromate oxidation of homocatechol, unlike the cases of *p*-cresol and creosol, a major part of the precipitate (60%) was an ether-insoluble fraction; this was an alcohol-soluble complicated resin possibly oxygenated. Also precipitates were traces of unidentified polyphenols and carboxylic acid, detected by the paper chromatography of the ether-soluble fraction. It may be thought that the crystalline oligomer is not obtained, for the resulting products are further oxidized, too.

As is shown in Fig. 1, the velocity of the oxidation reaction increases in the following order: homocatechol>creosol>*p*-cresol. This order is proportional to the electron density of the phenolic hydroxyl group. It seems probable that the initial step in these reactions is an abstraction of one electron. Furthermore, it was detected that the addition of

the manganese ion is independent of the velocity change.

The catalytic effect of the manganese ion in chromium oxidation is of peculiar interest. This effect has been described in the case of alcohols,[14] but not in that of phenols. It is known that divalent manganese (Mn^{2+}) is oxidized to trivalent species (Mn^{3+}) with tetra- and pentavalent chromiums, but not with hexavalent species.[15] It is also known that trivalent manganese reacts with phenols to produce a phenoxy radical, which in turn affords a high yield of oxidative coupling products.[16] As Tables 1 and 2 show the yields of the coupling products of phenols with dichromate about triple when a large amount of the manganese ion is added.

From these facts, when the manganese ion is not present, it may be thought that one mole of chromic acid (CrO_4^{2-}) acts as one equivalent to produce the phenoxy radical; that is, only hexavalent chromium may be effective in producing the phenoxy radical, as is shown in Eq. (1), while the tetra- and pentavalent species may be ineffective. On the other hand, in the case of the presence of a large amount of the manganese ion, one mole of chromic acid has the ability of three equivalents because the trivalent manganese ion, which is produced by the reaction between the divalent manganese ion and penta- or tetravalent chromium, may also be effective in producing the phenoxy radical, as is shown in Eqs. (3) and (4). In conclusion, the mechanism for the coupling reaction of phenols with dichromate in the presence of manganese sulfate may be proposed to be as follows:

$$PhOH + Cr(VI) \longrightarrow PhO\cdot + Cr(V) \quad (1)$$

$$PhOH \text{ or } PhO\cdot + Cr(V) \text{ or } Cr(IV) \longrightarrow \text{Complicated products} \quad (2)$$

$$Mn^{2+} + Cr(V) \text{ or } Cr(IV) \longrightarrow Mn^{3+} + Cr(IV) \text{ or } Cr(III) \quad (3)$$

$$PhOH + Mn^{3+} \longrightarrow PhO\cdot + Mn^{2+} \quad (4)$$

$$PhO\cdot + PhO\cdot \longrightarrow Dimer \longrightarrow Trimer \quad (5)$$

In the absence of manganese sulfate, the reaction mechanism may be expressed by Eqs. (1), (2) and (5).

Experimental

Materials and Procedure. The phenols employed in this study were *p*-cresol, creosol, and homocatechol. The phenols and other reagents were of an analytical reagent grade. The oxidation reactions of the phenols with dichromate were carried out in an aqueous solution containing 1.2% acetic acid under gentle stirring, at a constant temperature, and in air. The consumption of dichromate was measured by the iodometry method.

In these oxidations, turbidity appeared within a few minutes after mixing; the product was eventually isolated quantitatively as a precipitate from a brown solution. In order to remove a small amount of inorganic substances, the product was treated with ether. The ether-soluble product was then separated, by 2N sodium hydroxide, into a neutral fraction and an alkali-soluble polyphenol fraction. The oxidation products were identified by a comparison of their melting points and of the results of elemental analyses of them and their derivatives with those of authentic samples. The melting points were measured with Yanagimoto's micromelting-point apparatus, while the elemental analyses were performed in the Analytical Center of Kyushu University.

Oxidation of *p*-Cresol. *(a) Products of Non-catalyzed Oxidation.* An aqueous solution (1 *l*) containing *p*-cresol (10.8 g, 0.1 mol), potassium dichromate (15 g, 0.05 mol), and acetic acid (12 g, 0.2 mol) was allowed to stand for 92 hr at 25°C. The dry weight of the precipitate was 6.3 g (66% of the weight of the oxidation products), of which the ether-insoluble and alcohol-soluble portion; an amorphous brown powder, composed 1.8 g (19%). The ether-soluble fraction gave a pale yellow, crystalline, neutral material (1.9 g, 20%) and a brown, resinous, alkali-soluble polycresol (2.5 g, 26%). The ether extraction of the aqueous filtrate from the oxidation products yielded a trace of an oily material and unchanged *p*-cresol (1.2 g, 13%).

After crystallization from methanol, the neutral fraction yielded Pummerer's ketone as colorless leaflets (1.1 g, 12%); mp 123.5°C (lit,[6-12] mp 122—128°C) (Found: C, 77.90; H, 6.57%). The alkali-soluble polycresols were distilled *in vacuo* to yield two resinous fractions, (A) (bp 150—190°C/1 mmHg; 0.4 g, 4%) and

(B) (bp 210—260°C/1 mmHg; 0.5 g, 5%). The fraction (A) was crystallized from benzene to give 2,2′-dihydroxy-5,5′-dimethyldiphenyl (0.2 g, 2%) as colorless prisms; mp 154—155°C (lit,[6] 153—154°C) (Found: C, 78.03; H, 6.47%). This was characterized as the diacetate; mp 87.5°C (lit,[6] 87—88°C) (Found: C, 72.37; H, 6.14%). When the (A) fraction was treated with bromine (2 molar equiv. per mol) in glacial acetic acid, 3,3′-dibromo-2,2′-dihydroxy-5,5′-dimethyldiphenyl was obtained as colorless prisms, mp 141—142°C (lit,[6] 141—142°C) after recrystallization from aqueous ethanol.

The fraction (B), crystallized from benzene, gave colorless 2,2′,2″-trihydroxy-5,5′,5″-trimethyl-*m*-terphenyl (0.1 g, 1%); mp 196.5—197°C (lit,[6] 194—197°C) (Found: C, 78.62; H, 6.16%). When the fraction (B) was treated at room temperature with bromine (2 molar equiv. per mol) in glacial acetic acid, 3,3′-dibromo-2,2′,2″-trihydroxy-5,5′,5″-trimethyl-*m*-terphenyl was obtained; mp 286—288°C (lit,[6] 284—286°C) (Found: C, 52.76; H, 3.95%).

(b) Oxidation Products Catalyzed with Manganese Ion. A mixture like that in (*a*) was stirred for 92 hr at 25°C with manganese sulfate (0.053 or 0.53 mol respectively). Fractionation and the identification of the oxidation products were performed as above. The results are summarized in Table 1.

Oxidation of Creosol. *(a) Products of Non-catalyzed Oxidation.* The following is a typical preparation carried out on a 0.036 molar scale at 25°C. An aqueous solution (1 *l*) containing creosol (5.0 g, 0.036 mol; insoluble above this value), potassium dichromate (3.6 g, 0.012 mol), and glacial acetic acid (12 g, 0.2 mol) was allowed to stand for 20 hr. The dry weight of the precipitate was 2.84 g (57%), of which the ether-insoluble, amorphous brown powder was 0.74 g (15%). The ether-soluble products were distilled *in vacuo* to yield a resinous material; bp 180—260°C/0.7 mmHg (1.1 g, 22%). This fraction was crystallized from benzene to give 2,2′-dihydroxy-3,3′-dimethoxy-5,5′-dimethyldiphenyl (0.36 g, 7.2%) as colorless needles; mp 130.5—131°C (lit,[17] 130°C) (Found: C, 70.65; H, 6.62%). The diacetate, after recrystallization from alcohol, had a mp of 163°C (lit,[17] 162—163°C) (Found: C, 67.18; H, 6.21%). The oily material other than the above crystalline material had a methoxyl content of 19.9%. The ether-insoluble fraction (soluble in alcohol) did not melt below 300°C, and its methoxyl content was 15.8%, which was less than that of the starting material (22.6%). (Found, after correction for inorganic materials: C, 63.35; H, 5.55%. Calcd for creosol; $C_8H_{10}O_2$: C, 69.54; H, 7.29%). When the proportion of dichromate was higher than in the above experiment, the yield of dimer increased from 7.2% to 9.0% (Table 2).

(b) Oxidation Products Catalyzed with Manganese Ion. A mixture like that in (*a*) was stirred for 20 hr at 25°C with manganese sulfate (0.53 mol). The fractionation and identification of oxidation products were performed by the same method as above. The results are summarized in Table 2.

Oxidation of Homocatechol. An aqueous solution (1 *l*) containing homocatechol (4.5 g, 0.036 mol), potassium dichromate (3.6 g, 0.012 mol), and glacial acetic acid (12 g, 0.2 mol) underwent rapid oxidation at 25°C. A rapid darkening and deposit of particles of a brown, amorphous solid occurred. However, the mixture was left for 5 hr. The crude product (2.7 g, 60% of the weight of homocatechol) yielded a large amount of an ether-insoluble fraction as a brown powder which was thought to be polyphenol. The ether-insoluble fraction, subjected to paper chromatography, appeared to consist of alkali-soluble polyphenols and a small amount of carboxylic acid.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 215—219 (1970)

Cationic Arylation. I. Phenylation of Substituted Benzenes with Benzenediazonium Tetrafluoroborate in Homogeneous Solution

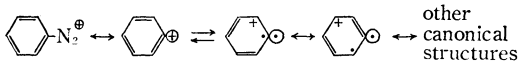
Michio KOBAYASHI, Hiroshi MINATO, Eiichi YAMADA and Nobumasa KOBORI

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo

(Received June 27, 1969)

Substituted benzenes were phenylated with benzenediazonium tetrafluoroborate in homogeneous solutions with DMSO or acetonitrile. The distribution of substituted biphenyls and the partial rate factors indicated that this phenylation was an electrophilic substitution, but the selectivity was much smaller than those of nitration or sulfonylation. Experiments with chlorobenzene-4*d*, anisole-4*d* and chlorobenzene-d_5 showed that both the orientation and partial rate factors did not change with deuterated compounds. Therefore, it was established that the rate-determining step was the addition of phenyl cation to an aromatic nucleus, and not the abstraction of proton from the phenylated intermediate.

Abramovitch and Saha[1] studied the arylation of aromatic compounds with benzenediazonium tetrafluoroborate, and on the basis of the isomer ratios and the apparent total rate ratios they suggested that the phenyl cation initially formed isomerized to a diradical cation.



[I] [IIa] [IIb]

However, the reaction was carried out in heterogeneous media and there was no kinetic control in the reaction conditions. An investigation of this reaction in homogeneous media seemed desirable.

Recently Abramovitch and Gadallah[2] reported the results of the phenylation in mixtures of substituted benzenes and acetonitrile or sulpholan. This prompted us to report on our findings in the phenylation in homogeneous solutions consisting of aromatic solvents and dimethyl sulfoxide (DMSO) or acetonitrile. On the basis of the partial rate factors of substituted benzenes and substituted deuterated benzenes in homogeneous solution the mechanism of the phenylation with benzenediazonium tetrafluoroborate will be discussed.

Experimental

Materials. Dimethyl sulfoxide and acetonitrile were purified according to the methods described in a previous paper.[3] Benzene, toluene, ethylbenzene and chrolobenzene were washed with concentrated sulfuric acid and water successively, dried over calcium chloride, and distilled. Boiling points were 80°C, 110°C, 135.7°C and 131°C, respectively. Anisole was washed with an aqueous sodium hydroxide solution and water, dried over calcium chloride, and distilled; bp 153°C. Methyl benzoate was prepared from benzoic acids and methanol, washed with water, dried over magnesium sulfate, and then fractionally distilled; bp 110°C/50 mmHg. Nitrobenzene was washed repeatedly with a potassium dichromate solution, dried over calcium chloride, and distilled; bp 95.5°C/18 mmHg.

Benzenediazonium tetrafluoroborate was prepared according to the method decribed previously.[3]

Isomeric methylbiphenyls, ethylbiphenyls, methoxybiphenyls, chlorobiphenyls, methoxycarbonylbiphenyls and nitrobiphenyls were prepared as the reference compounds by the methods described in literature.[4] They were purified by elution chromatography, distillation or recrystallization, and their melting points and boiling points agreed with the values in literature. Dibenzyl and β-methoxynaphthalene were purified by recrystallization.

Anisole-4*d* was prepared by the hydrolysis of *p*-methoxyphenylmagnesium bromide in D_2O (isotopic purity, 99.75%, supplied by E. Merck AG, Darmstadt); bp 58°C/15 mmHg. Its isotopic purity was determined to be 92% by mass spectrometry using Hitachi RMU-6B. Chlorobenzene-4d was prepared by the same method from *p*-bromochlorobenzene; bp 131°C. Its isotopic purity was found to be 90%.

Chlorobenzene-d_5 of CIBA Limited was used without further purification. Guaranteed isotopic purity was 99.6%.

Decomposition of Benzenediazonium Tetrafluoroborate. In 20.0 g of dimethyl sulfoxide (DMSO) or acetonitrile 2.0 g of benzenediazonium tetrafluoroborate was dissolved, and the solution was diluted with substituted benzenes (the molar ratio of substituted benzene *versus* the diazonium salts was 50). The homogeneous solution was placed in a bath at 40±0.1°C, and the decomposition was followed by measuring the rate of evolution of nitrogen. After the evolution of nitrogen ceased, the reaction mixture was washed with water to remove the polar solvent, washed with a 5% sodium hydroxide solution to remove acidic products, washed with water, dried over magnesium sulfate, and then the amounts of substituted biphenyl isomers were determined by a Hitachi Gas Chromatograph K-53.

Since the presence of a large quantity of substituted benzenes made the gas chromatographic determination of substituted biphenyls unreliable because of tailing, the determination was carried out after about 80% of substituted benzenes had been evaporated. Chlorobenzene was chosen as the standard for competitive experiments since non-substituted biphenyl easily sublimes. The biphenyl isomers were identified by comparison of their retention times with those of authentic samples, and their amounts were determined by use of calibration curves. Columns used were packed with Apiezon L (10%) on Chromosorb W, and their lengths varied from 1 m to 6 m depending on the ease of separation of isomers.

Results and Discussion

Decomposition of benzenediazonium tetrafluoroborate in homogeneous mixtures of substituted

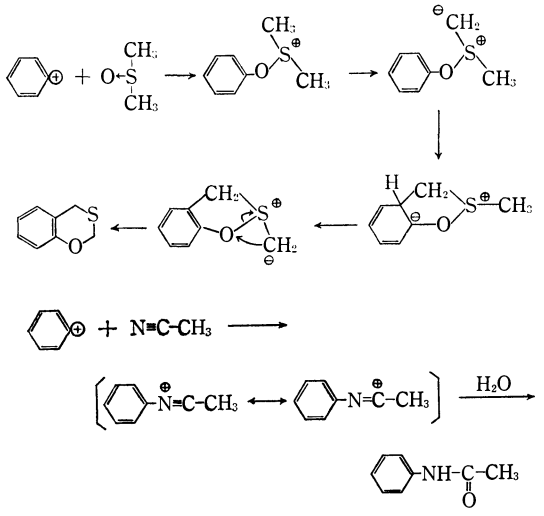
2) R. A. Abramovitch and F. F. Gadallah, *J. Chem. Soc., B*, **1968**, 497.

3) R. Adams, "Organic Reactions," Vol. II, John Wiley and Sons, Inc., London (1957); P. E. Fanta, *Chem. Rev.*, **64**, 613 (1964); M. Kobayashi, E. Yamada, M. Matsui and N. Kobori, *Organic Preparations and Procedures*, in press.

benzenes-DMSO and substituted benzenes-acetonitrile was of first order, and the rate constants are shown in Table 1. The average value of first-order rate constants in DMSO-C_6H_5X was 3.84×10^{-4} (sec^{-1}) and that in CH_3CN-C_6H_5X was 3.27×10^{-4} (sec^{-1}), which were approximately the same as those in pure DMSO and in pure acetonitrile. This shows that benzenediazonium tetrafluoroborate decomposes in these solvent systems to produce phenyl cation and nitrogen gas under the same mechanism.

As products other than substituted biphenyls, 1,3-benzoxathiane (about 8 mol%) was obtained from the reactions in DMSO-C_6H_5X, and acetanilide (about 50 mol%) was obtained from the reactions in CH_3CN-C_6H_5X. Products of dimerization or disproportionation were not found. Apparently the electron-rich oxygen atom of DMSO and nitrogen atom of acetonitrile compete with the aromatic nucleus in reaction with the electrophilic phenyl cation as follows.



Because of these reactions, yields of biphenyls are not so high; 7% in $PhNO_2$-DMSO, 12.4% in PhCl-DMSO, and 20.8% in PhOMe-DMSO.

Orientation for phenylation with benzenediazonium tetrafluoroborate in PhX-DMSO and in PhX-CH_3CN is summarized in Table 2. Benzenes substituted with methoxy, methyl, ethyl and chloro groups are *o,p*-directors, and benzenes substituted with methoxycarbonyl and nitro groups are *m*-directors. This indicates that the reactions are of electrophilic nature. Except for nitrobenzene, more *ortho* and *para* isomers were produced in CH_3CN-PhX than in DMSO-PhX, and especially the amounts of *ortho* isomers were greater. These results are in contrast with the findings that greater amounts of *ortho* isomers were produced in DMSO-PhX than in CH_3CN-PhX by free radical phenylation with phenylazotriphenylmethane.[4]

Table 3 shows the partial rate factors calculated on the assumption that the step of σ-complex formation is rate-determining. Differences between the values in DMSO-PhX and those in CH_3CN-PhX may be ascribed to the difference in the solvation of the transition states and aryl cations. Variations in the partial rate factors in Table 3 are consistent with the electrophilic nature of the reactions except that the selectivity is very small

4) M. Kobayashi, H. Minato, N. Watanabe and N. Kobori, This Bulletin, **43**, 258 (1970).

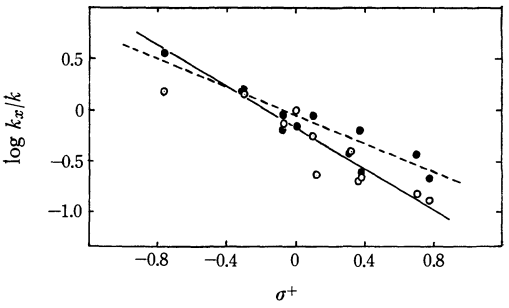

Fig. 1. The Hammett plots for the phenylation of PhX with PhN_2BF_4.
—○—: in CH_3CN, $\rho=-0.82$, $r=0.91$
---●---: in DMSO, $\rho=-0.74$, $r=0.93$

compared with that in nitration[5] or sulfonylation[6] of aromatic compounds. However, the selectivity or the partial rate factors for phenylation with phenyl cation are quite different from those of phenylation with phenyl radical.

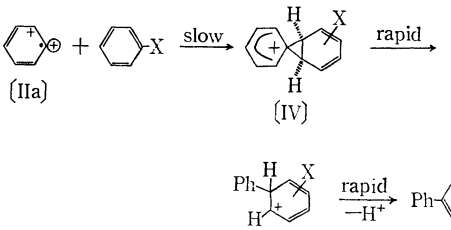
log k_m/k or log k_p/k is better correlated with σ^+ of Brown-Okamoto than σ values Hammett, as shown in Fig. 1. However, the correlation is not so good, and the correlation coefficient is 0.93 in DMSO-PhX and 0.91 in CH_3CN-PhX. The reaction constant, ρ, is small compared with that in ordinary ionic reactions (−0.74 in DMSO-PhX and −0.82 in CH_3CN-PhX), but the fact that it is negative indicates that these reactions are electrophilic and are different from phenylation with phenyl radical.[7,8] Various features of phenylation with phenyl cation are best explained on the assumption that the phenyl cation initially formed isomerizes to a diradical cation [II] with concerted uncoupling of a pair of π-electrons, one of which falls into the vacant sp^2 σ-orbital.[1,9]

Under an oxygen atmosphere yields of phenylation with phenyl radical greatly decrease, whereas those with phenyl cation do not change, as shown by the data with chlorobenzene in Tables 2 and 3. This finding is not inconsistent with the biradical nature of phenyl cation, since the non-reactivity is ascribable to the repulsion between the strongly electrophilic oxygen and the strongly electrophilic phenyl cation.

Abramovitch and Gadallah[2] did not attempt to correlate the partial rate factors with σ^+ or σ. If their values are plotted *versus* σ^+, ρ is −0.66 at 65°C with the correlation coefficient of 0.96. This ρ value is consistent with the value reported in this paper if the difference in the temperatures is taken into consideration.

The correlation in the Hammett plots of our data as well as the data of Abramovitch and Gadallah[2] is much worse than that of ordinary ionic reactions. In an attempt to explain the apparent slight deactivation of the *meta*-position in toluene towards phenylation in CH_3CN-PhMe at 65°C ($k_m/k=0.85$), Abramovitch and Gadallah[2] suggested that the rate-determining step in these reactions was not the formation of σ-complex [III] *via* Scheme 1, but the addition of IIa to a benzene double bond to form the various possible spirocyclopropane phenonium ions [IV], followed by ring-opening to give the three substituted σ-complexes in a product-, but not rate-, determining step.

Scheme 1



Scheme 2

Our data show considerable deactivation of the *meta* position in toluene ($k_m/k=0.60$ in DMSO-PhMe) and in ethylbenzene ($k_m/k=0.74$ in CH_3CN-PhEt and 0.87 in DMSO-PhEt), and these values are in line with their suggestion.

In an attempt to elucidate the mechanism of this phenylation further, isotope effects were examined by use of anisole-4*d*, chlorobenzene-4*d* and chlorobenzene-d_5. The results are shown in Table 4. When anisole-4*d* or chlorobenzene-4*d* was phenylated with benzenediazonium tetrafluoroborate in a mixture with DMSO, the distributions of isomeric biphenyls were approximately the same as those with anisole or chlorobenzene. When

7) G. H. Williams, "Homolytic Aromatic Substitution," Pergamon Press, London (1960).
8) R. Ito, T. Migita, N. Morikawa and O. Simamura, *Tetrahedron*, **21**, 955 (1965).
9) R. W. Taft, *J. Amer. Chem. Soc.*, **83**, 3350 (1961).

a mixture of chlorobenzene-d_5 and benzene was phenylated and the partial rate factors were calculated, the values of k_H/k_D for *ortho*, *meta* and *para* were approximately 1 within experimental error of gas chromatography. These findings show that in phenylation with phenyl cation there is no isotope effect as in the cases of nitration and free radical arylation[10] of aromatic compounds.

So far there is no conclusive evidence which enables us to choose Scheme 1 or Scheme 2 as the mechanism of the phenylation with phenyl cation. However, it has been established that the rate-determining step is the addition of the phenyl cation to an aromatic nucleus, and not the abstraction of proton from the phenylated intermediate.

Cationic Arylation. II. Phenylation of Substituted Benzenes with Phenylazo-*p*-tolylsulfone in Acidic Solutions

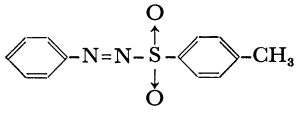
Michio KOBAYASHI, Hiroshi MINATO and Nobumasa KOBORI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo

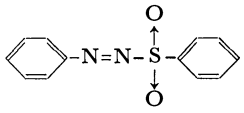
(Received June 27, 1969)

The acid-catalyzed decomposition of phenylazo-*p*-tolylsulfone was studied in PhX, PhX-CH_3CN and PhX-DMSO (X=OCH_3, C_2H_5, CH_3, Cl, CO_2CH_3, NO_2). The decomposition was of first order but was faster with greater concentration of trifluoroacetic acid. The orientation and the partial rate factors for the phenylation of substituted benzenes were quite different from those for the radical phenylation but quite similar to those for the phenylation with phenyl cation generated from $PhN_2^+BF_4^-$. Experiments with deuterated compounds indicated that the abstraction of proton from the phenylated complex was not rate-determining. A mechanism involving phenyl cation was proposed for the acid-catalyzed decomposition of azosulfone.

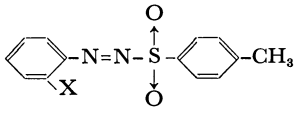
Phenylazo-*p*-tolylsulfone [I] is produced when an aqueous benzenediazonium chloride solution is mixed with an aqueous sodium *p*-toluenesulfinate solution. It is not an ionic compound, and is soluble in organic solvents and insoluble in water. When heated in a solution, it decomposes with evolution of nitrogen.



[I]



[II]



[III] X=Cl, Br

Overberger and Rosenthal[1] studied the kinetics of the decomposition of phenylazophenylsulfone [II] in neutral solutions, and found that its spontaneous decomposition was a free radical decomposition. Bunnett and Happer[2] investigated the decomposition of *o*-halophenylazophenylsulfone [III] in the presence of sodium methoxide, and found that in very dilute sodium methoxide solution the decomposition was homolytic, whereas in concentrated sodium methoxide solution the decomposition proceeded *via* *o*-halophenyl anion as the intermediate.

It seemed of great interest to investigate the decomposition of azosulfones in acidic solutions. The decomposition of phenylazo-*p*-tolylsulfone [I] in the presence of trifluoroacetic acid in substituted benzenes has been investigated, and the results are described in this paper.

Experimental

Materials. Dimethyl sulfoxide, acetonitrile and substituted benzenes were purified according to the methods described in a previous paper.[3]

1) C. G. Overberger and A. J. Rosenthal, *J. Amer. Chem. Soc.*, **82**, 108, 117 (1960).

2) J. F. Bunnett and D. A. R. Happer, *J. Org. Chem.*, **32**, 2701 (1967).

3) M. Kobayashi, H. Minato, E. Yamada and N. Kobori, This Bulletin, **43**, 215 (1970).

Sodium *p*-toluenesulfinate was prepared by the reduction of *p*-toluenesulfonyl chloride with zinc.[4]

Phenylazo-*p*-tolylsulfone was prepared by mixing an aqueous benzenediazonium chloride solution with an aqueous sodium *p*-toluenesulfinate solution at 5°C,[5] and was recrystallized from methanol. Mp 91—92°C.

Kinetic Measurements. To a solution consisting of 2.6 g (0.01 mol) of phenylazo-*p*-tolylsulfone and 39 g (0.5 mol) of benzene, some trifluoroacetic acid was added, and the solution was placed in a constant temperature bath. The rate of nitrogen evolution was measured by a gas burette.

Analyses of Phenylation Products. Phenylazo-*p*-tolylsulfone (2.6 g) was dissolved in a substituted benzene, and trifluoroacetic acid was added; the mixture consisted of 50 mol of a substituted benzene and 5.89 mol of trifluoroacetic acid per mole of phenylazo-*p*-tolylsulfone. The mixture was decomposed in a constant temperature bath at 40.0±0.1°C. In order to examine the effect of polar solvents, 20 g of dimethyl sulfoxide or acetonitrile was added to the above mixture, and these mixtures containing polar solvents were decomposed in a similar manner.

After the decomposition was over, the reaction mixture was washed successively with water, a 5% sodium hydroxide solution and water, and was then dried over anhydrous magnesium sulfate.

The amounts of substituted biphenyls produced were determined by a Hitachi Gas Chromatograph K-53 on a column packed with 10% Apiezon L on Chromosorb W, on the basis of the comparison with authentic samples.

Results and Discussion

Figure 1 shows that the rate of decomposition of phenylazo-*p*-tolylsulfone is of first order. However, the rate is dependent on the amount of trifluoroacetic acid added. Table 1 lists the first order rate constants in benzene at various temperatures in the presence of 5.89 mol or 2.95 mol of trifluoroacetic acid per mole of the azosulfone. These values are much greater than the rate constant obtained by Overberger and Rosenthal[1] for the homolytic decomposition of phenylazophenylsulfone in benzene with calcium oxide suspended ($k_1=2.2\times10^{-5}$ sec^{-1} at 70°C). This great difference cannot be ascribed to the effect of *p*-methyl substituent in phenylazo-*p*-tolylsulfone. These findings suggest that the mechanism of the decomposition in acidic solutions is different from that in neutral solutions.

Figure 2 is the Arrhenius plots of the rate constants shown in Table 1, and the values of the activation energies and the activation entropies were calculated from Fig. 2. These activation parameters fit surprisingly well the isokinetic relationship established for the decomposition of benzenediazonium tetrafluoroborate in various aprotic polar solvents,[6] as shown in Fig. 3. On the basis of these

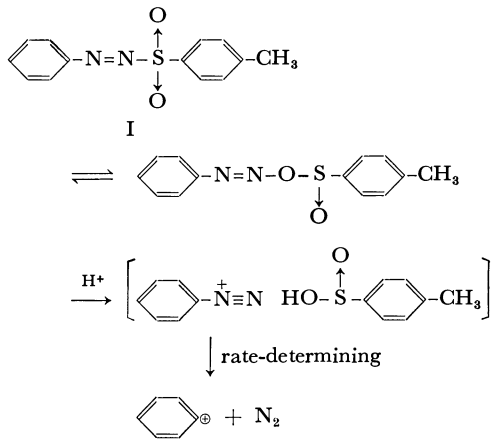
findings, the following mechanism is proposed, in which the generation of phenyl cation from benzenediazonium ion is the rate-determining step.

When trifluoroacetic acid was added to a benzene solution of the azosulfone, a new absorption corresponding to Ar–N$^+$≡N was observed at 2280 cm^{-1}, which gradually disappeared with evolution of nitrogen. This finding is consistent with the above mechanism.

Tables 2 and 3 show the orientation and the partial rate factors for the phenylation of substituted benzenes with the azosulfone in the presence of trifluoroacetic acid. *p*-Toluenesulfinic acid was not



isolated, but *p*-toluenesulfonic acid and phenyl *p*-toluenesulfonate were found. *p*-Toluenesulfonic acid is ascribable to the disproportionation of *p*-toluenesulfinic acid, which Kice and his co-workers reported.[7] Products other than the phenylation products will be discussed in a forthcoming paper. When acetonitrile or DMSO was present, acetanilide or 1,3-benzoxathian was formed, as reported in a previous paper.[3]

When the substituent was $-CO_2Me$ or $-NO_2$, in a substituted benzene alone or in a mixture of a substituted benzene and acetonitrile *meta* derivatives predominate and the partial rate factors were much smaller than unity, whereas in a mixture of a substituted benzene and DMSO *o,p*-derivatives predominate. This abnormality in DMSO-PhX can be ascribed to the ocurrence of both the homolytic and heterolytic decomposition of the azosulfone in this medium, since less protons are available for protonation of the azosulfone owing to the protona-

tion of DMSO. Decompositions in a substituted benzene alone or in CH_3CN-PhX will be discussed further in detail.

The orientation and the partial rate factors in PhX or in CH_3CN-PhX are quite different from those for the radical phenylation of substituted benzenes[8] and quite similar to those for phenylation with phenyl cation generated from benzenediazonium tetrafluoroborate.[3,9] The partial rate factors for *meta* and *para* positions in Table 3 are better correlated with σ values of Brown-Okamoto rather than those of Hammett. However, as Fig. 4 shows,

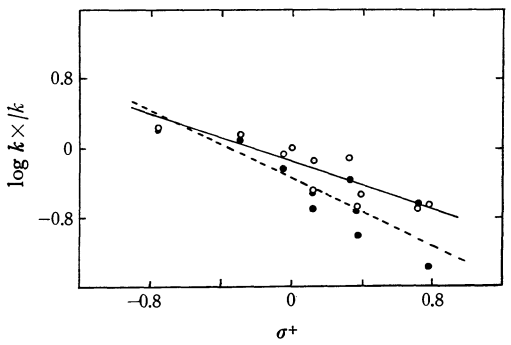

Fig. 4. The Hammett plots for the phenylation with p-TsN_2Ph in acidic solutions at 40°C.
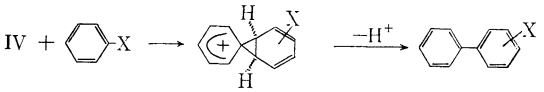
—○—: PhX-CH_3CN, $\rho=-0.69$
—●—: PhX only, $\rho=-1.0$

the correlation coefficient is rather small, and the reaction constant ρ is very small compared with the ρ values of common electrophilic reactions (in PhX, $\rho=-1.0$, $r=0.84$; in CH_3CN-PhX, $\rho=-0.69$, $r=0.87$). These findings indicate that phenyl cation is highly reactive and unselective, and they are consistent with the suggestions made by Abramovitch and Gadallah[9] and by us,[3] which describe phenyl cation as a diradical cation produced by the transfer of one π-electron to the vacant sp^2 orbital.

IV IVa IVb

However, at present there is no further evidence available which can determine whether the phenylation proceeds *via* an ordinary σ-complex shown in Scheme 1 or it proceeds *via* a spiro cation shown in Scheme 2.

Scheme 1



Scheme 2

In order to determine whether or not the abstraction of proton from the complex is the rate-determining step, some experiments were performed with deuterated compounds, and the results are shown

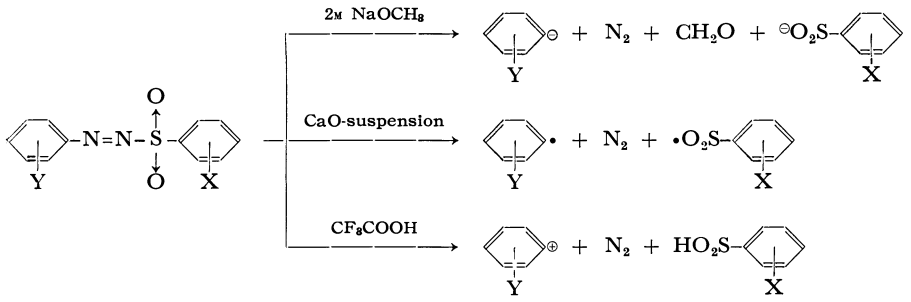
in Table 4. No significant difference in the orientation was found between chlorobenzene-4d and chlorobenzene or between anisole-4d and anisole. The partial rate factors for the phenylation of pentadeuteriochlorobenzene were calculated from a competitive reaction with benzene. The values of k_H/k_D are somewhat smaller than unity, but when experimental errors are taken into consideration, these values are regarded as indicating that there is no isotope effect in phenylation with azosulfone. Therefore, the rate of formation of the complex either in Scheme 1 or Scheme 2 must be much (slower) than the rate of the abstraction of proton from the complex. In the case of spontaneous decomposition of benzenediazonium tetrafluoroborate, the proton-abstracting species is probably DMSO or acetonitrile, whereas in the acid-catalyzed decomposition of the azosulfone the proton abstracting species is probably trifluoroacetate ion. The results of our investigations with benzenediazonium tetrafluoroborate[3] and with phenylazo-*p*-tolylsulfone indicate that regardless of the proton-abstracting species, the abstraction of a proton from the complex must occur very rapidly.

The results of this investigation together with those of Overberger and Rosenthal[1] and those of Bunnet and Happer[2] have established the very interesting features of the decomposition of arylazoarylsulfone, which are summarized as follows. It is of interest to compare the decomposition of the azosulfone with the decomposition of benzenediazonium salts, which yields phenyl radical in an alkaline medium and phenyl cation in an acidic medium.



BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 223—225 (1970)

Cationic Arylation. III. Comparison of Phenylation of Naphthalene with Phenyl Cation and Phenyl Radical

Nobumasa KOBORI, Michio KOBAYASHI and Hiroshi MINATO

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo

(Received June 27, 1969)

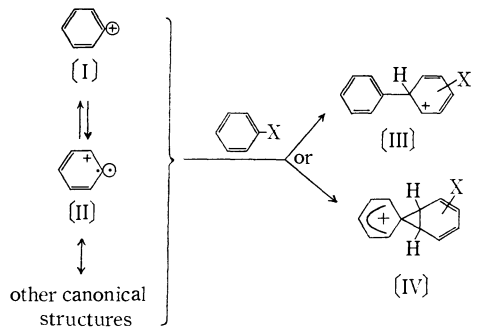
Naphthalene was phenylated with phenyl cation (from PhN_2BF_4) or phenyl radical (from $PhN_2BF_4+NaNO_2$) in dimethyl sulfoxide. Partial rate factors for phenyl radical were somewhat larger than those reported with the phenyl radical generated from *N*-nitrosoacetanilide. Partial rate factors for phenylation with phenyl cation were smaller than those for free radical phenylation and those for common electrophilic substitution reactions. These small partial rate factors for phenyl cation were not compatible with the reaction scheme involving an ordinary σ-complex, and a mechanism involving a spiro cation appeared to be plausible.

In previous papers,[1,2] we reported that phenyl cation was formed from benzenediazonium tetrafluoroborate or phenylazo-*p*-tolylsulfone. The orientation and the partial rate factors for this phenylation appeared to support the hypothesis that the phenyl cation [I] initially formed isomerized to a diradical cation [II] with concerted uncoupling of a pair of π-electrons. However, the mechanism

1) M. Kobayashi, H. Minato, E. Yamada and N. Kobori, This Bulletin, **43**, 215 (1970).

2) M. Kobayashi, H. Minato and N. Kobori, *ibid.*, **43**, 219 (1970).

of the substitution was not completely clear, especially as to whether or not a spiro cation [IV] was the intermediate.



In order to clarify the nature of the phenyl cation and the mechanism of the phenylation, the electrophilic substitution with phenyl cation has been investigated with naphthalene as the substrate, and the results are described in this paper.

Since the isomerization of phenyl cation to a diradical has been postulated, it is of great interest to compare phenylation by phenyl cation with that by phenyl radical. Therefore, the phenylation of naphthalene by the phenyl radical produced from benzenediazonium tetrafluoroborate and sodium nitrate[3] has been investigated, and the results will be compared with those obtained with phenyl cation.

Experimental

Materials. Preparation of benzenediazonium tetrafluoroborate and purification of dimethyl sulfoxide (DMSO) and anisole were previously reported.[1] Naphthalene, extra pure grade of Kanto Chemicals, was used without further purification. α-Phenylnaphthalene, bp 167°C/8 mmHg (lit,[4] 180°C/10 mmHg) and β-phenylnaphthalene, mp 102°C (lit,[4] 103—104°C) were prepared according to the methods described in literature.[4]

Phenylation of Naphthalene with Benzenediazonium Tetrafluoroborate in DMSO. In 20 g of DMSO 2.0 g of benzenediazonium tetrafluoroborate was dissolved and the solution was added to an anisole-naphthalene mixture (the molar ratio of aromatic compounds *versus* the diazonium salts was 50). The homogeneous solution obtained was decomposed in a bath at 40±0.1°C. After the evolution of nitrogen gas ceased, ether was added to the reaction mixture. This mixture was washed with water to remove DMSO, with a 5% sodium hydroxide solution to remove acidic products and then with water. After it was dried over magnesium sulfate, ether, anisole and naphthalene in this mixture were removed in a vacuum. After about 70% of anisole and naphthalene was removed, the residual oil containing arylated products was analyzed by a Hitachi Gas Chromatograph K-53.

Phenylation of Naphthalene with Benzenediazonium Tetrafluoroborate and Sodium Nitrite in DMSO. Anisole (37.056 g, 0.3427 mol), naphthalene (9.748 g, 0.0761 mol) and sodium nitrite (1.736 g, 0.0253 mol) were dissolved in 100 g of DMSO, and this homogeneous solution was stirred vigorously with a mechanical stirrer. Under a nitrogen atmosphere, a solution of 1.467 g of benzenediazonium tetrafluoroborate in 10 g of DMSO was added dropwise into the above solution. Nitrogen gas was evolved immediately and the reaction was complete as soon as the diazonium salt solution was added. The reaction mixture was treated in a manner similar to that described above for the case in the absence of sodium nitrite.

Quantitative Analyses. Methoxybiphenyl isomers and phenylnaphthalene isomers were identified by comparison of their retention times with those of authentic samples, and their amounts were determined by use of calibration curves on a 2 m column packed with Apiezon L (10%) on Chromosorb W at 200°C with a gas-flow of 30 ml/min.

Results and Discussion

Anisole, instead of benzene, was used for competitive phenylation, since non-substituted biphenyls is lost by sublimation during the concentration of the reaction mixture prior to gas-chromatographic analyses. The attack of both phenyl cation and phenyl radical on the aromatic hydrocarbons

resulted in the formation of methoxybiphenyl isomers and phenylnaphthalene isomers, but the compositions of these phenylated products were quite different from each other.

As products other than methoxybiphenyls and phenylnaphthalenes, 1,3-benzoxathian was obtained from the decomposition of benzenediazonium tetrafluoroborate in the absence of sodium nitrite, but not in the presence of sodium nitrite.

The orientation and partial rate factors for phenylation with phenyl cation and with phenyl radical are compared with other related data in Table 1. The orientation and the partial rate factors for phenylation with phenyl cation change to some extent with the molar ratio of naphthalene *versus* anisole.

The partial rate factors for phenylation with the phenyl radical generated from benzenediazonium tetrafluoroborate and sodium nitrite are a little larger than those obtained by Davies, Hey and Williams with the phenyl radical generated from *N*-nitrosoacetanilide as shown in Table 1. It is not easy to determine what is responsible for this difference in the partial rate factors. One could ascribe it to the effect of the polar solvent (DMSO) present in our medium, or to the difference in the hydrogen-abstracting species. However, we recently found that the partial rate factors for the phenylation with the phenyl free radical generated from phenylazotriphenylmethane were not influenced to any appreciable extent by the presence of the polar solvent DMSO.[5] Therefore, it does not seem to be possible to attribute this difference to the effect of solvents.

As for the hydrogen abstracting species, both NO_2 and PhN=NO· are conceivable as the hydrogen-abstracting species in a reaction mixture of benzenediazonium tetrafluoroborate and sodium nitrite as shown in Schemes 1 and 2.

$$PhN_2BF_4 + NaNO_2 \longrightarrow PhN{=}N{-}O{-}NO + NaBF_4$$

Scheme 1

$$PhN{=}N{-}O{-}NO \longrightarrow Ph\cdot + N_2 + NO_2$$

Scheme 2

$$2\,PhN{=}N{-}O{-}NO \longrightarrow PhN{=}N{-}O{-}N{=}N{-}Ph + N_2O_3$$

$$PhN{=}N{-}O{-}N{=}N{-}Ph \longrightarrow Ph\cdot + N_2 + PhN{=}N{-}O\cdot$$

In order to clarify the difference in the partial rate factors due to the origin of the phenyl radicals, the hydrogen-abstracting species in the mixture of benzenediazonium tetrafluoroborate and sodium nitrite must be identified. Such an investigation is being carried out.

As shown in Table 1, the partial rate factors for phenylation with phenyl cation are much smaller than those for nitration, bromination and deuteration, which are typical electrophilic substitution reactions. These data appear to support the hypothesis that the phenyl cation is not an ordinary cation [I] but a diradical cation [II]. If the phenyl cation is an electrophilic radical possessing the properties of both a cation and a radical, it is expected that the values of the partial rate factors for the phenylation with the phenyl cation come between those with electrophilic reagents and those with phenyl radical. However, on the contrary to such expectation, the partial rate factors with phenyl cation were smaller than both of these. A mechanism with which one could explain these findings is the following one, involving the spiro cations [V] and [VI] as the intermediates.

Reaction of Salicylamine with α-Dicarbonyl Compounds. II. Formation of 2,2′-Bibenz-1,3-oxazines

Hajime KANATOMI and Ichiro MURASE

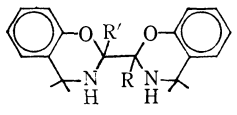
College of General Education, Kyushu University, Fukuoka

(Received June 27, 1969)

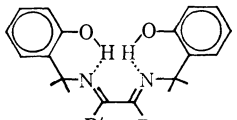
The compounds of a new type, 2,2′-bibenz-1,3-oxazine and its derivatives have been synthesized by the reactions of salicylamines with glyoxal or α-diketones in methanol at a temperature lower than 20°C. The oxazine structures were confirmed by infrared spectroscopy in solid state and by NMR spectroscopy in CCl_4, $CDCl_3$ and chlorobenzene. An oxazine-Schiff base equilibrium was observed in pyridine and in hot chlorobenzene by NMR spectra. It was found that hydrolytic decomposition of 2,2′-dimethyl-2,2′-bibenzoxazine leads to the formation of salicylidenesalicylamine through transamination. The mechanisms were investigated spectrophotometrically.

It has been reported in a previous paper[1] that the reaction of *o*-hydroxybenzylamine (salicylamine) with α-diketones, α-ketoaldehydes, and with α-keto acid ester in hot methanol gave rise to the formation of salicylidenesalicylamine in all cases. It was further found that the reactions proceeded with transamination followed by *trans*-Schiffization between salicylamine and the dicarbonyl compounds, where the former was converted into salicylaldehyde through corresponding Schiff base of the latter, and the Schiff bases were subjected to an exchange reaction at the amine moiety with unreacted salicylamine to yield salicylidenesalicylamine.

Since the initial subject of our investigation had been to obtain condensation products of salicylamine with α-dicarbonyl compounds, for which a bibenzoxazine A or a Schiff base B structure was proposed, the reactions were further examined under different conditions.



A



B

The possibility of forming A or B type compound is suggested from the fact that primary γ-amino alcohols condense with aldehydes or ketones to yield either oxazines or open-chain Schiff base or a tautomeric mixture of them.[2] In our previous experiments, it was found that the reactions did not terminate at the first condensation stage owing to the subsequent reactions. Therefore, it was considered that the reactions at a low temperature might be favorable for the prevent ion of subsequent reactions. Thus, two moles of salicylamine were allowed to react with α-dicarbonyl compounds at a temperature lower than 20°C in methanol, and the condensation products were obtained as expected in fairly good yields. The compounds isolated in this way are listed in Table 1.

McDonagh and Smith[3] have extensively studied a ring-chain tautomerism between oxazines and Schiff bases by means of infrared and NMR spectroscopy for the condensation products of salicylamine with aromatic or aliphatic aldehydes and ketones, and concluded that the products from aliphatic aldehydes and ketones were oxazines in the solid state exhibiting NH absorptions in infrared spectra, and even in solution they existed exclusively as oxazines, because the NMR peaks of the ring methylene protons appeared around at 6.0 τ as an AB pattern with a coupling constant of 17 Hz, and those of imino protons appeared around at 7 τ as weak several peaks.

In the present case, infrared and NMR spectroscopy were also employed for the structure determination.

The infrared spectrum of III in solid state (KBr disk) is shown as an example in Fig. 1. In the high frequency region, there is a sharp absorption at 3340 cm^{-1} and this could be due to an OH or NH group. From the shape of the band it is more

likely due to NH, hydrogen bonded in the crystals. In the double bond region, one can find no absorptions around 1620—1650 cm^{-1} which are in general due to a C=N group of a Schiff base.

From these evidences, the oxazine structure A could be assigned to this compound. Other compounds showed infrared absorption patterns similar to III, exhibiting sharp NH absorptions and no C=N absorptions. The NH frequency of each compound is listed in Table 2 together with analytical data.

It is therefore concluded from the infrared diagnosis that the condensation products of salicylamine with α-dicarbonyl compounds have the bibenzoxazine structure of the type A in solid state.

The NMR spectra of III in various solvents are

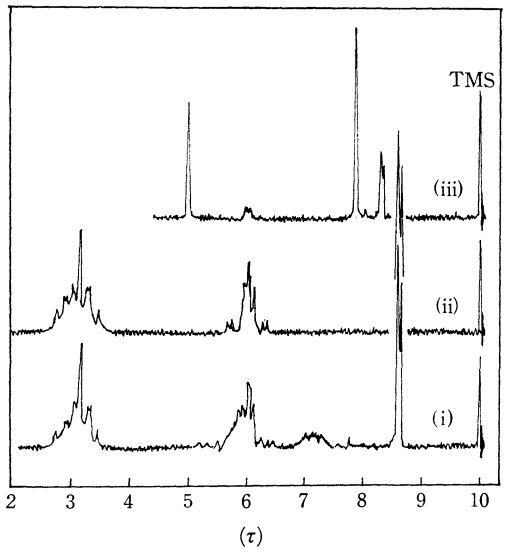

Fig. 2. NMR spectra of III, in CCl_4 (i), in CCl_4+ D_2O (ii), in pyridine (iii).

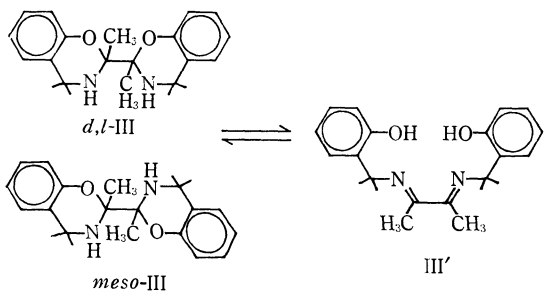
shown in Fig. 2. In CCl_4, a broad signal centred at 7.2 τ and several complex peaks around 6 τ might be due to the imino and the methylene protons of the oxazine rings corresponding to A structure. On deuteration, the coupling of the methylene protons with the imino protons was excluded and the methylene proton resonance appeared as seven peaks as seen in Fig. 2, (ii).

Assuming that III is a mixture of stereo-isomers of bibenzoxazine for which a *d,l-* and a *meso*-configuration is possible, the NMR spectra will exhibit two kinds of patterns corresponding to each isomer, since the magnetic environment of protons especially in the oxazine rings will be different from each other and this will cause a different chemical shift. It is likely that the seven peaks are an overlapping of the two kinds of AB patterns corresponding to the methylene protons of each isomer. The coupling constants are both 17 Hz and the calculated chemical shifts are 5.97 τ, 6.18 τ and 5.80 τ, 6.04 τ respectively. The spliting of the methyl proton resonance at 8.50 τ and 8.45 τ might also be due to the configurational difference of *d,l-* and the *meso*-isomer.



In pyridine, two singlet peaks appeared at 7.75 τ and at 5.02 τ in addition to the bibenzoxazine proton signals as seen in Fig. 2, (iii). These new peaks suggest the formation of another species in the solution. The isomeric Schiff base (III′) is proposed, in which the methyl and the methylene proton peaks appear in a field lower than that of oxazine, because these protons are less shielded. The higher one (7.75 τ) can therefore be assigned to the methyl and the lower one (5.02 τ) to the methylene protons of the Schiff base (III′). Thus, it is seen that the compound exists as an equilibrium mixture of the oxazine (III) and the Schiff base (III′) in pyridine, and the ratio calculated from the intensities of each methyl proton peak will be about 1 : 4.

In chlorobenzene, III exists as a mixture of two isomeric bibenzoxazines at 40°C as seen in Fig. 3, (ii). At 120°C, an equilibrium of oxazine-Schiff

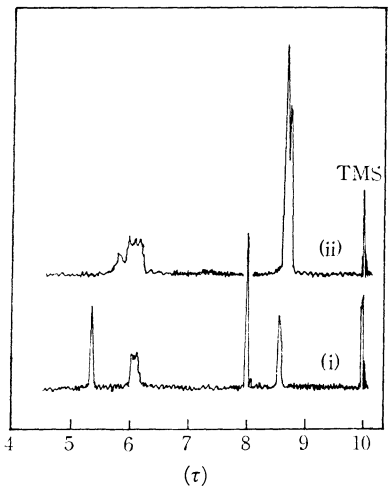


Fig. 3. NMR spectra of III in chlorobenzene, at 120°C (i), at 40°C (ii).

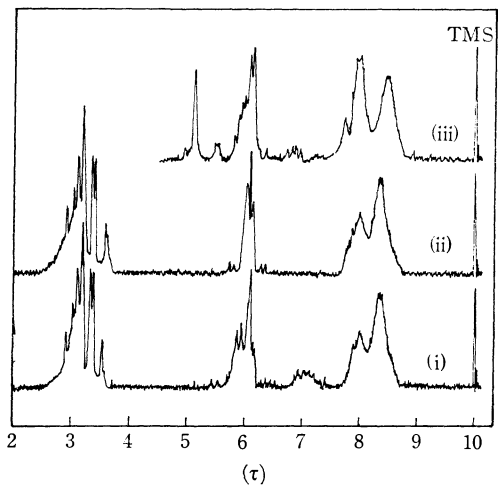

Fig. 4. NMR spectra of IV, in CCl_4 (i), in CCl_4+ D_2O (ii), in pyridine (iii).

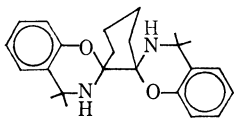
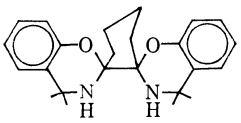
base was observed (i). Proton signals of oxazine rings decreased in intensity and new singlet peaks appeared at 8.05 τ and at 5.30 τ which due to the methyl and the methylene protons of the isomeric Schiff base, respectively. On cooling, these peaks disappeared and the spectrum gave rise to the original pattern. It is interesting to note that an oxazine-Schiff base equilibrium exists even in such a solvent less polar than pyridine.

For compound IV, the oxazine structure in CCl_4 was confirmed. In Fig. 4, (i), several peaks around 8 τ and weak multiplet centred at 7.2 τ are due to the eight protons of the cyclohexane ring and the imino protons respectively. The resonance of the ring methylene protons appeared on deuteration as partially overlapped two AB quartets centred at 6.11 τ and 6.05 τ with coupling constants of both 17 Hz. Each corresponds to those of the *d,l*- and the *meso*-isomer, and the calculated chemical shifts are 6.01 τ, 6.21 τ and 5.95 τ, 6.15 τ, respectively.



d,l-IV



meso-IV

In pyridine, a new singlet appeared at 5.07 τ in addition to similar peaks to those observed in CCl_4. This peak can be assigned to the methylene protons of the isomeric Schiff base for the same reason as the case of III and an equilibrium between the oxazine is evidenced in the solution. The ratio of the oxazine-Schiff base is approximately 2 : 1 from the intensities of the corresponding methylene peaks. In chlorobenzene, similar oxazine-Schiff base equilibrium was observed at elevated temperature (120°C), exhibiting a new singlet peak at 5.53 τ which is due to the methylene protons of the Schiff base.

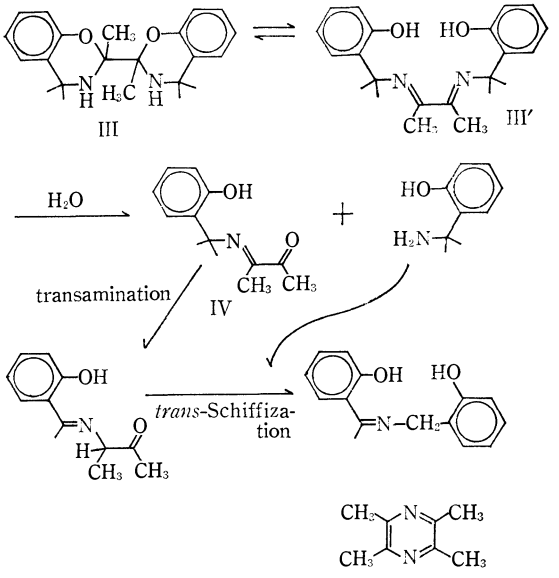
For compound I, well defined NMR spectra in various solvents could not be observed because of low solubility and of instability in solutions. The integrated spectrum in $CDCl_3$, however, shows an AB like pattern centred at 5.86 τ with a coupling constant of about 17 Hz corresponding to four protons of the methylene groups of the oxazine rings. The methine protons attached to the asymmetric carbon atoms are observed as two peaks at 4.91 τ and 4.97 τ. This suggests that I is also a mixture of the *d,l*- and *meso*-2,2′-bibenzoxazine for the same reason as given above.

Although the NMR spectrum was not measured for other compounds listed in Table 1, the oxazine structure can be confirmed by the similarity of their ultraviolet absorption spectra to those investigated above.

Higher homologues of α-diketone such as acetylpropionyl, dipropionyl, and acetylisobutylyl have beeen examined with salicylamine in the same manner as described above. However, the reactions failed to yield the corresponding oxazines, and salicylidenesalicylamine was obtained. It is clear that the transamination took place predominantly even at low temperatures in these cases. 5-Chlorosalicylamine did not react with α-diketones other than 1,2-cyclohexanedione. However, 5-*t*-butylderivative reacted with diacetyl and 1,2-cyclohexanedione to afford the corresponding oxazines. Slightly high acidity of the phenol group or low basicity of the amino group by chloro-substitution may reduce the reactivity. It is seen from these experiments that the formation of bibenzoxazines is limited when salicylamines having appropriate basicities react with α-dicarbonyl compounds which exhibit no steric hindrance.

Although bibenzoxazines have been isolated in well defined crystals, they are never stable in hot solutions, therefore, recrystallization seriously reduced the yield. In the case of III, salicylidenesalicylamine and tetramethylpyrazine were isolated from the 95% methanol solution on prolonged heating. It was found also that such decomposition scarcely occurred in absolute methanol with recovery of III. Assuming the presence of the oxazine-Schiff base equilibrium in methanol as well as in pyridine, the decomposition mechanism is given as shown in Scheme I, where the Schiff base (III′) is subjected to hydrolysis to give the ketimine (IV) and salicylamine. The ketimine (IV) undergoes transamination, and then *trans*-Schiffization between the salicylamine and affords salicylidenesalicylamine. The reaction mechanisms of the latter half have already been discussed.[1)]

A problem which arises from the above evidence



Scheme I

is that the formation of salicylidenesalicylamine may always proceed through the oxazine formation even at elevated temperatures. To elucidate this, the rate of formation of salicylidenesalicylamine from III was measured spectrophotometrically and compared with that from the mixture of salicylamine and diacetyl. For this purpose, the increasing rate of absorbance at 400 mμ was measured, since only salicylidenesalicylamine among the reactants and the products has strong absorption in this region as seen in Fig. 5 and the absorbance is proportional to the concentration of this compound.

In Fig. 6, it is seen that the rate of formation of salicylidenesalicylamine from III in 95% methanol is greater than that in absolute methanol. This clearly indicates that hydrolysis takes part in the reaction as proposed in Scheme I. Further, the rate of formation from the mixture of salicylamine and diacetyl is much greater at the initial period of the reaction than that of hydrolytic decomposition of III. It is therefore obvious that the reaction of salicylamine and diacetyl to form salicylidenesalicylamine at elevated temperature (over 20°C) does not proceed through the initial formation of bibenzoxazine (III), but the Schiff base (III′) is the first product which undergoes further reactions. It should be noted that the formation of bibenzoxazines will take another route and it is only possible in cold.

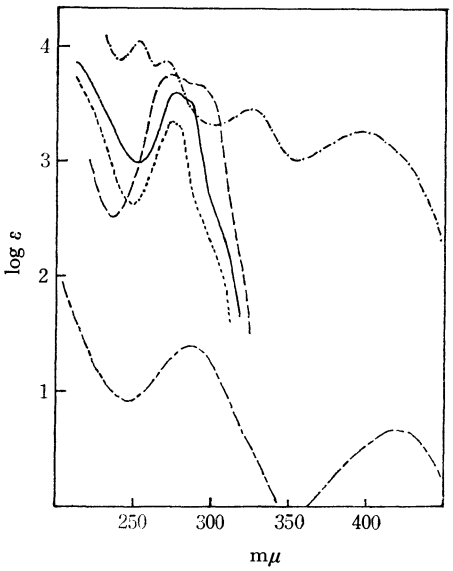


Fig. 5. Absorption spectra in methanol, III (——); salicylamine (------); diacetyl (-----); salicylidenesalicylamine (·—·—·); tetramethylprazine (-----).

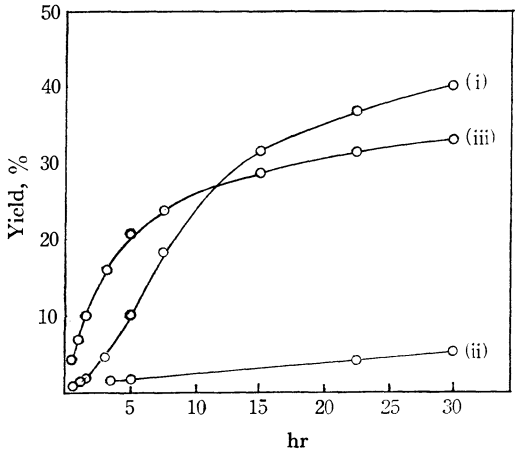

Fig. 6. Rate of formation of salicylidenesalicylamine (25°), (i) from III in methanol (*ca.* 95%), (ii) from III in absolute methanol, (iii) from salicylamine (2 mol)+diacetyl (1 mol) in absolute methanol.

Experimental

Salicylamine. Concerning the preparation of this compound, reduction of salicylaldoxime with sodium amalgam,[4] with aluminum amalgam[5] or catalytic reduction of salicylaldazine with Pd-$BaSO_4$ as a catalyst[6] have been reported. It was found, however, that catalytic reduction of salicylaldoxime by Pd-charcoal in acidic solution best proceeds conveniently in higher yield.

To a solution of salicylaldoxime (40 g) in 650 m*l* of methanol, 5% Pd-charcoal (5 g) and 36 m*l* of concentrated hydrochloric acid were added, and the hydrogenation was carried out at room temperature under atmospheric pressure with vigorous stirring. Exothermic hydrogen uptake ceased after four hours. The catalyst was filtered and the filtrate was evaporated under reduced pressure and the residue was dissolved in 250 m*l* of water. The pH of the solution was brought to 7 by the addition of concentrated ammonia and the undissolved precipitates (2—3 g) were filtered. The filtrate was made alkaline by further addition of ammonia and the resulting colorless crystals were filtered and washed with water. The crude salicylamine was dried over calcium chloride in a vacuum and recrystallized from CCl_4. Yield, 27 g (75%), mp 126°C.

General Procedure for the Preparation of 2,2′-Bibenz-1,3-oxazines. To a suspension of freshly purified salicylamine or its derivative (1 mol) in methanol was added a slight excess of calculated amount (0.5 mol) of α-diketone or aqueous 40% glyoxal, and the mixture was stirred for thirty minutes at a temperature below 20°C. Salicylamine was once dissolved into solution and colorless crystals then gradually separated out. After stirring for additional thrity minutes, the crystals were filtered and washed with cold methanol. Purification of each oxazine except I was carried out by recrystallization from the solvent listed in Table 1. In the case of the acetyl, the reaction was carried out in ice-cold methanol to avoid otherwise inevitable transamintion. The yield of each oxazine is described in Table 1.

Decomposition of 2,2′-Dimethyl-2,2′-bibenzoxazine (III): Formation of Salicylidenesalicylamine. A solution of III (0.9 g, 0.003 mol) in 30 m*l* of 95% methanol was gently refluxed in a nitrogen stream for four hours. The solution turned yellow and it was concentrated to about 5 m*l* under vacuum and kept in a refrigerator overnight. The resulting yellow crystals were filtered and recrystallized from methanol. A pure sample of salicylidenesalicylamine, mp 183—184°C was obtained in 50% yield.

The filtrate from which salicylidenesalicylamine was separated was evaporated to dryness in a vacuum and the residue was colloected. It was sublimed at 80°C in a vacuum (30 mmHg) and colorless crystals, mp 85°C were obtained. The compound was identified as tetramethylpyrazine by infrared spectra and by mixed melting point determination.

The authors express their sincere thanks to Professor Yo Ueda of Faculty of Pharmaceutical Science and Professor Taku Matsuo of Faculty of Engineering of Kyushu University for their kind help in taking NMR spectra and for their valuable discussions. This work was partly supported by a grant from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 231—234 (1970)

Preparation of 1,4-Cycloalkanediones by Hypoiodite Oxidation of Cycloalkanols

Takasi Mori, Kiyohide Matsui and Hitosi Nozaki

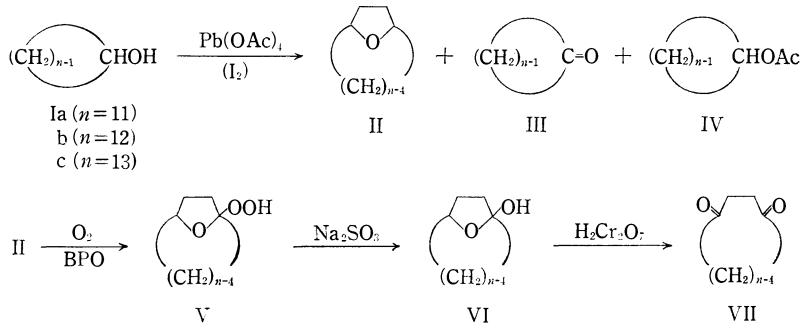
Department of Industrial Chemistry, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received June 27, 1969)

Lead tetraacetate oxidation of 11, 12 and 13-membered cycloalkanols gives improved yields of 2,5-polymethylenetetrahydrofurans II in the presence of iodine. Oxidative cleavage of II furnishes 1,4-cycloalkanediones VII.

Synthesis of [8](2,5)heterocyclophanes recently recorded involves the Paal-Knorr reaction of 1,4-cyclododecanedione (VIIb).[1] A new route has been found for an effective method of preparing homologous 1,4-diketones.*1 This consists of oxidative ring closure of cycloalkanols I to 2,5-polymethylenetetrahydrofurans II and oxidative ring reopening of II into diketones VII.

While this work was in progress, Mihailovic *et al.*[6] reported lead tetraacetate oxidation of 6, 7, 8, 10, 12 and 16-membered cycloalkanols, which yielded cycloalkanones III and cycloalkyl acetates IV as main products. Bicyclic ethers of unknown structures were obtained in the oxidation of large ring alcohols. Tetrahydrofurans II are obtained in improved yields by the synergism of iodine (hypoiodite oxidation[7]). In the absence of iodine the main products were III and IV as recorded by



*1 Simple 1,4-cycloalkanediones hitherto recorded are 6,[2] 7,[3] 8,[4] and 12[5]-membered ones.

a) The yields were determined from peak areas of GLC. In all experiments unidentified products were detected to the amount of 1—5% of all volatile products.
b) TLC of IIb showed one main and two minor spots.
c) A trace of cycloalkene was detected.
d) C_6H_{12} refers to cyclohexane.
e) TLC of IIa and IIc showed single spot.
f) 2,6-Hexamethylenetetrahydropyran was formed in an 11% yield.

Mihailovic.[6] The results are summarized in Table 1.

The yields were determined by gas liquid chromatography (GLC) and separation was effected by column chromatography. The best yields of II were obtained by hypoiodite oxidation conducted in cyclohexane at reflux temperature with lead tetraacetate and iodine in a mole ratio of 1 (alcohol) : 2.0 : 0.7. Although some workers successfully performed hypoiodite oxidation in benzene solution,[8] the present substrates failed to afford satisfactory results in benzene solvent. On careful thin layer chromatographic (TLC) analyses, ethers IIa and IIc showed single spot but IIb three spots as indicated. Following oxidative ring opening established them to be *cis* and/or *trans* tetrahydrofurans (mainly in the case of IIb). Each component was not characterized. The by-products III and IV were identified by comparison with authentic samples. Oxidation of Ia gave low yields of IIa, the byproduct being probably tetrahydropyran derivative (see experimental) formed in an 11% yield.

The effect of iodine is thus characterized by the increase of II at the expense of III and IV. This can be explained by assuming fast decomposition of the intermediate, $>CHOPb(OAc)_3$,[9] otherwise leading to III or IV, and/or by the consumption of lead tetraacetate through reaction with iodine.[10]

The cleavage of ether bond of II was attempted in several ways. Bromine in acetate-buffer, a reagent for oxidative cleavage of ethers recently reported,[11] did not react possibly due to the sparing solubility of II. *p*-Toluenesulfonyl acetate[12] or boron trifluoride in acetic anhydride[13] failed to give satisfactory results due to the formation of olefinic products. Hydroiodic acid afforded the desired 1,4-diiodocyclododecane, but transformation into 1,4-diketone proceeded sluggishly and the formation of olefinic products was again observed.

Finally the cleavage was carried out with success by means of autoxidation. The resulting hydroperoxides V were reduced to hemiketals VI. Chromic acid oxidation of VI afforded 1,4-diketones VII in 45—51% overall yields based on II. Among the 1,4-diketones, the 12-membered VIIb was identified by comparison with authentic sample.[5] The structures of other diketones were ascertained by elemental analyses, IR spectra and most convincingly by NMR spectra. The NMR spectra of VII showed a singlet (4H) at δ 2.62—2.65 (two methylenes between two carbonyl groups) and a diffused triplet (4H) at δ 2.35—2.40 (other α-methylenes).

The hypoiodite oxidation was applied to VIII in order to prepare a 1,4-diketone having one carbonyl group in side chain. The main product was, however, cycloundecyl acetate arising from so called "β-fragmentation,"[14] and tetrahydrafuran

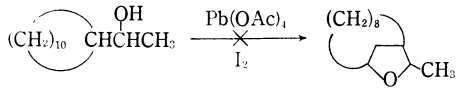
IX was not obtained.



VIII IX

Experimental

All temperatures are uncorrected. NMR spectra were obtained on a JEOL C-60-H spectrometer in CCl_4 solutions with tetramethylsilane as an internal reference. Chemical shifts are given in ppm from this reference with the multiplicity of signals indicated in an abbreviated form. Mass spectra (MS) were measured on a Hitachi RMU 6C spectrometer at electrode voltage 70 eV. GLC was performed on HVSG or SE 30 on Chromosorb W with hydrogen as a carrier gas. TLC was conducted on Silica-gel G with *n*-hexane or benzene as a developing solvent.

Lead Tetraacetate Oxidation of Cycloalkanols (Ia—c). A mixture of $Pb(OAc)_4$ (6.2 g, 14 mmol), $CaCO_3$ (1.6 g, 16 mmol) and anhydrous benzene (40 m*l*) was heated at reflux for 15 min with stirring under nitrogen atmosphere. After cooling, cycloalkanol (I) (12 mmol) was added to the mixture and the whole was heated at reflux for 20 hr with vigorous stirring. The reaction mixture was cooled and inorganic substances were separated by filtration and washed with benzene. The filtrate and washings were combined, washed with aqueous KI, aqueous $Na_2S_2O_3$ and then with water, dried (Na_2SO_4) and concentrated *in vacuo*. The residual oil was subjected to TLC and GLC analyses. Products III and IV were identified by comparison of their R_f values and retention times with those of authentic samples. The yields were determined from peak areas of GLC as summarized in Table 1. Isolation of bicyclic ethers II was difficult due to their low yields and was performed in the hypoiodite oxidation experiments.

Hypoiodite Oxidation of Cycloalkanols (Ia—c). A mixture of $Pb(OAc)_4$ (26.6 g, 60 mmol), $CaCO_3$ (9.0 g, 90 mmol) and cyclohexane (450 m*l*) was heated at reflux for 15 min with stirring under nitrogen atmosphere, cooled and added with cycloalkanol (I) (30 mmol) and I_2 (5.3 g, 21 mmol). Heating and stirring were continued for 2 hr. After cooling, the inorganic substances were filtered and washed with cyclohexane. The combined cyclohexane solution was washed with aqueous $Na_2S_2O_3$ and then with water, dried (Na_2SO_4), and concentrated *in vacuo*. The residual oil was subjected to TLC and GLC, and the yields were calculated from peak areas of GLC (see Table 1). Oxidation of Ia gave a mixture of bicyclic ethers, whose separation was effected by column chromatography on alumina with *n*-hexane as an eluant. Work up of less adsorbed fractions afforded 12-oxabicyclo[7.2.1]dodecane (IIa), which formed a colorless oil, bp 93—96°C/4 mmHg. IR (cm^{-1}, neat): 1090, 1042 (C–O–C). NMR (δ): 4.25—3.80 (m, 2H), 2.20—1.15 (m, 18H). Found: C, 78.7; H, 11.9%. Calcd for $C_{11}H_{20}O$: C, 78.5; H, 12.0%. MS: parent peak at *m/e* 168.

Work up of more adsorbed fractions afforded a colorless oil, bp 93—95°C/3 mmHg. IR (cm^{-1}, neat): 1100, 1048 (C–O–C). NMR (δ): 3.98—3.50 (m,2H), 2.33—0.75 (m, 18H). Found: C, 78.7; H, 11.9%. Calcd for $C_{11}H_{20}O$: C, 78.5; H, 12.0%. MS: parent peak at *m/e* 168. Oxidative cleavage of this bicyclic ether conducted similarly as mentioned below for the preparation of 1,4-diketones from II gave an oily diketone, bp 100—105°C/2 mmHg. IR (cm^{-1}, neat): 1705 (C=O). NMR (δ); 2.70—2.00 (m, 8H), 2.00—0.90 (m, 10H). Found: C, 72.3; H, 9.9%. Calcd for $C_{11}H_{18}O_2$: C, 72.5; H, 10.0%. These data indicate that this ether is not epoxide, oxetane or tetrahydrofuran. The most likely structure should be a tetrahydropyran or 12-oxabicyclo[6.3.1]dodecane. Further information was not obtained due to lack of material.

Oxidation of Ib and work up gave IIb as a colorless oil, bp 97—100°C/3 mmHg. IR (cm^{-1}, neat): 1091, 1055 (C–O–C). NMR (δ): 4.20—3.70 (m, 2H), 2.10—0.75 (m, 20H). Found: C, 79.6; H, 12.2%. Calcd for $C_{12}H_{22}O$: C, 79.1; H, 12.2%. MS: parent peak at *m/e* 182.

Oxidation of Ic and work up gave IIc as a colorless oil, bp 110—114°C/5 mmHg. IR (cm^{-1}, neat): 1085, 1060 (C–O–C). NMR (δ): 4.00—3.50 (m, 2H), 2.05—0.85 (m, 22H). Found: C, 79.7; H, 12.5%. Calcd for $C_{13}H_{24}O$: C, 79.5; H, 12.3%. MS: parent peak at *m/e* 196.

Oxidative Cleavage of Bicyclic Ethers (IIa—c). Oxygen was bubbled at a rate of *ca.* 10 m*l*/min for 20 hr into a mixture of II (8.8 mmol) and benzoyl peroxide (20 mg) heated at 85—90°C. The resulting highly viscous oil was taken up in ether (100 m*l*), washed with aqueous Na_2SO_3 and then with water, and concentrated into about 20 m*l*. This ethereal solution was added with a mixture of $Na_2Cr_2O_7 \cdot 2H_2O$ (2.0 g, 6.7 mmol), concd. H_2SO_4 (2.5 m*l*) and water (10 m*l*), and the whole was stirred for 15 hr at room temperature. The ethereal layer was washed with aqueous $NaHCO_3$ and then with water, dried (Na_2SO_4) and concentrated *in vacuo*. Purification of the residual oil by silica-gel column chromatography with benzene as an eluant afforded the desired diketone VII as a colorless solid or oil.

Oxidation of IIa gave 1,4-cycloundecanedione (VIIa) as a colorless solid, mp 64—65°C (from *n*-hexane), in a 45% yield. IR (cm^{-1}, Nujol): 1703 (C=O). NMR (δ): 2.63 (s, 4H), 2.35 (diffused t, 4H), 1.90—1.05 (m, 10H). Found: C, 72.4; H, 10.0%. Calcd for $C_{11}H_{18}O_2$: C, 72.5; H, 10.0%.

Oxidation of IIb gave 1,4-cyclododecanedione (VIIb) as a colorless solid, mp and mixed mp 78—79°C (from petroleum ether), in a 49% yield. IR spectrum was superimposable with that of authentic specimen.[5] NMR (δ): 2.65 (s, 4H), 2.38 (diffused t, 4H), 1.85—0.95 (m, 12H).

Oxidation of IIc gave 1,4-cyclotridecanedione (VIIc) as a colorless oil, bp 110—113°C/2 mmHg, in a 51% yield. IR (cm^{-1}, neat): 1705 (C=O). NMR (δ): 2.26 (s, 4H), 2.40 (diffused t, 4H), 1.85—0.95 (m, 14H). Found: C, 74.4; H, 10.6%. Calcd for $C_{13}H_{22}O_2$: C, 74.2; H, 10.5%.

Cycloundecylmethylcarbinol (VIII). This alcohol was prepared from cycloundecanecarboxylic acid[15] through MeLi treatment[16] and $LiAlH_4$ reduction in a

66% yield. The product formed an oil, bp 132—133°C/7 mmHg. IR (cm^{-1}, neat): 3370 (OH), 1370 (CH_3). NMR (δ): 3.70—3.27 (m, 1H), 2.37 (broad s, 1H), 1.80—1.20 (m, 21H), 1.09 (d, 3H). Found: C, 78.5; H, 13.5%. Calcd for $C_{13}H_{26}O$: C, 78.7; H, 13.2%.

Hypoiodite Oxidation of VIII. Oxidation was performed in a similar way as mentioned above and the resulting mixture was subjected to TLC and GLC analyses. The main product was cycloundecyl acetate (IVa) isolated in a 29% yield, which was identified by comparison with authentic sample. A trace of unidentified product was detected. No evidence was obtained in support of formation of tetrahydrofuran IX.

The authors are grateful to Professor K. Sisido for his generous help and to Mr. H. Takaya, Nagoya University, for measurement of mass spectra.

Aromatic Sulfonylation. I. Kinetics and Kinetic Isotope Effects in the Sulfonylation*1

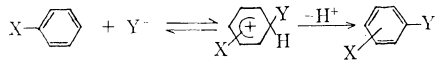
Michio KOBAYASHI, Hiroshi MINATO and Yoshio KOHARA

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo

(Received July 3, 1969)

p-Toluenesulfonylation of toluene, chlorobenzene and bromobenzene in the presence of aluminum chloride was investigated in methylene chloride at 0—20°C. The rate was equal to k_3[TsCl][$AlCl_3$][ArH]. Kinetic hydrogen isotope effects were found for *p*-deuteriotoluene (k_H/k_D= 2.8) and *p*-deuteriochlorobenzene (k_H/k_D=1.98). Infrared studies indicated that not a sulfonyl cation but TsCl-$AlCl_3$ complex was present in the medium. Substitution took place exclusively at *para* positions for halobenzenes, but 13.4% *ortho* and 86.6% *para* isomers were obtained for toluene. Partial rate factors for *para* positions were 52.5($PhCH_3$), 0.224(PhCl) and 0.164(PhBr). A plausible reaction mechanism was proposed, in which the abstraction of proton from the σ-complex was rate-determining.

It is generally understood that electrophilic substitution on an aromatic nucleus involves two steps, *i. e.* formation of a σ-complex and abstraction of proton from the complex.



Kinetic isotope effect has been observed in a few reactions,[1] and for sulfonation the values of k_H/k_D=1.4—2.1[2,3] and 1.14—1.34[4] have been reported. Jensen and Brown[5] and Cerfontain[4] studied sulfonylation, which also involves the attack of a positively charged sulfur on an aromatic nucleus. Both groups found no primary isotope effect, and concluded that removal of proton from the intermediate was not the rate-determining step. Jensen and Brown made a through kinetic study of Friedel-Crafts sulfonylation of aromatics with aluminum chloride by using nitrobenzene or benzenesulfonyl chloride as solvent, and estimated that either sulfonyl cation $ArSO_2^+$ or ion-pair $ArSO_2^+AlCl_4^-$ was the species attacking aromatics.[6-8] However, their results are rather complicated, and both the reaction order and the mechanism vary with the solvent and the aromatics.

In order to clarify the mechanism of sulfonylation, kinetics and isotope effect of the sulfonylation with

p-toluenesulfonyl chloride and aluminum chloride have been investigated. Methylene chloride has been used as the solvent. Though it is a solvent of smaller polarity, it dissolves the TsCl-$AlCl_3$ complex well,[9] and thus it enables us to study the sulfonylation in a homogeneous medium under mild conditions. The results of this investigation will be described in this paper.

Experimental

Materials. *p*-Toluenesulfonyl chloride was recrystallized twice from *n*-hexane; mp 69°C. Toluene and chlorobenzene were shaken with concentrated sulfuric acid, dried over calcium chloride and then distilled. Bromobenzene was dried over calcium chloride and then distilled. Methylene chloride was dried over calcium chloride and over phosphorus pentoxide, and then distilled. Anhydrous aluminum chloride of first grade was used without further purification.

p-Deuteriochlorobenzene was prepared by hydrolysis of *p*-chlorophenylmagnesium bromide in heavy water (Merck, 99.75%); $n_D^{26.4}$ 1.5201; isotopic purity, 89.7 atom %D (by mass spectrometry). *p*-Deuteriotoluene was prepared by hydrolysis of *p*-tolylmagnesium bromide in heavy water (Asahi Chemicals, 99.80%); bp 110°C; isotopic purity, 80.2 atom %D (by mass spectrometry).

Kinetic Measurements. *p*-Toluenesulfonyl chloride and excess aluminum chloride were stirred in 50 m*l* of methylene chloride for 30 min at room temperature. Excess aluminum chloride undissolved was removed by filtration from the solution of TsCl-$AlCl_3$ complex, which was diluted with methylene chloride to 100 m*l*. This solution and 100 m*l* of a methylene chloride solution of an aromatic compound were placed separately in a constant temperature bath, and the reaction was started by mixing these two solutions after 30 min. For less reactive halobenzenes, 10 m*l* each of the mixed solution was sealed in an ampoule, and then these ampoules were placed in a bath. The time of mixing was regarded as the beginning of the reaction. Samples were taken out after suitable intervals, and the complex was decomposed by dilute hydrochloric acid. The methylene chloride solution was dried over magnesium sulfate, and the amount of aryl *p*-tolyl sulfone produced was determined by means of the absorption at 1320 cm^{-1} (ditolyl sulfone) or at 1325 cm^{-1} (halophenyl tolyl sulfone) by a Hitachi infrared spectrophotometer EPI-G_2. The initial concentration of aluminum chloride was determined gravimetrically by treating a portion of the solution with dilute hydrochloric acid, precipitating aluminum hydroxide with ammonia and then converting into aluminum oxide in a platinum crucible.

Sulfonylation of Toluene. The absence of 860 cm^{-1} band showed the absence of *p*-tolyl *m*-tolyl sulfone in the products. The sulfone mixture was found to contain 13.4% *p*-tolyl *o*-tolyl sulfone and 86.6% di-*p*-tolyl sulfone by gas-chromatographic analysis on a 2 m column packed with Chromosorb-SE30 at 230°C (retention time: *p*-tolyl *o*-tolyl sulfone, 19.9 min, *p*-tolyl *m*-tolyl sulfone, 23.5 min, di-*p*-tolyl sulfone, 24.5 min).

** Ref. 10.

Sulfonylation of Halobenzenes. Recrystallization of the product of tosylation of chlorobenzene yielded *p*-tolyl *p*-chlorophenyl sulfone (mp 121°C) and a mother liquor, which was found by elution chromatography to be almost completely *p*-tolyl *p*-chlorophenyl sulfone. Thus it was shown that more than 98% of *p*-toluenesulfonyl chloride reacted at *p*-position of chlorobenzene. Similarly it was found that tosylation of bromobenzene took place almost exclusively at *p*-position.

The reactions were of third order, and the third order rate constants calculated were nearly constant till about 50% reaction as illustrated by typical runs in Tables 2 and 3.

Results and Discussion

Results of kinctic studies of tosylation are summarized in Table 4. Rate constants are larger for the runs with lower concentrations of a substituted benzene. This can be ascribed to the solvent effect due to the decrease of the less polar substance in the medium. Therefore, the activation parameters were obtained on the basis of the runs with similar compositions.

In Fig. 1 values of activation enthalpy were plotted *versus* values of activation entropy, and it was shown that an isokinetic relationship holds with

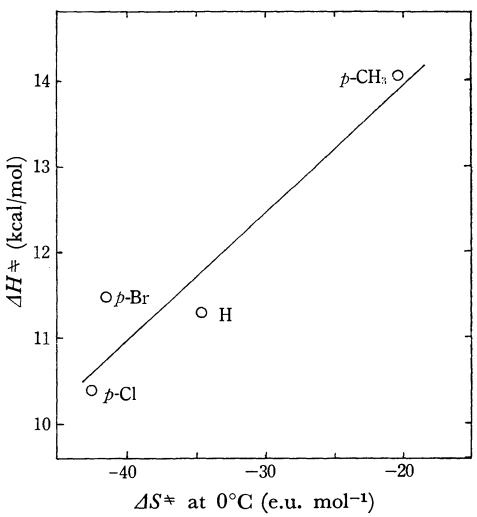

Fig. 1. Isokinetic relationship for the sulfonylation (β=152°K).

r=0.95. The isokinetic temperature, β, was 152°K.

The partial rate factors of *para* positions at 7.0°C were calculated. They were 52.5 for *p*-CH_3, 0.224 for *p*-Cl and 0.164 for *p*-Br. Figure 2 shows

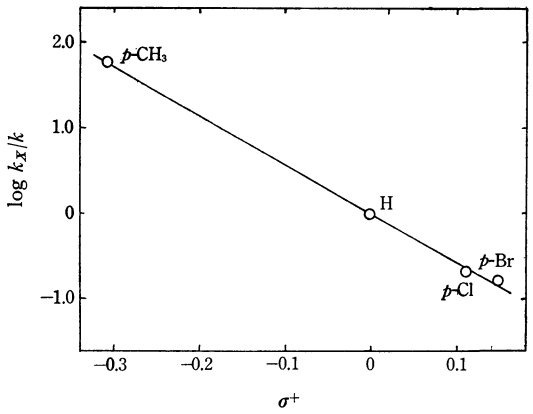

Fig. 2. Hammett plots for the sulfonylation at 7.0°C ($\rho=-5.6$).

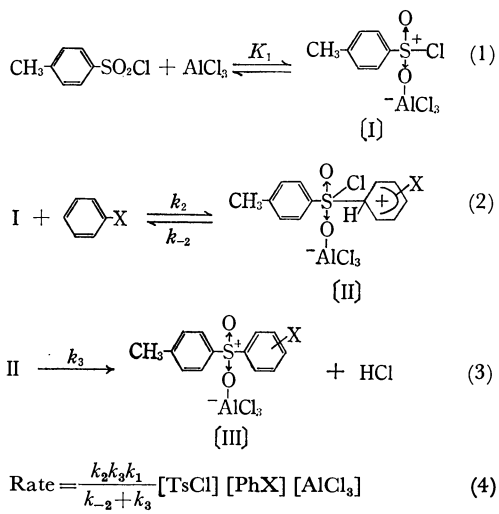
that a good linear relationship holds between these values and σ^+ ($\rho=-5.6$).

Since the rate was proportional to the concentration of each of TsCl, $AlCl_3$ and PhX, the following mechainsm appeared plausible.



$$\text{Rate}=\frac{k_2k_3k_1}{k_{-2}+k_3}[\text{TsCl}]\,[\text{PhX}]\,[\text{AlCl}_3] \qquad (4)$$

Since the reaction was of third order, either step (2) or step (3) is the rate-determining step. In order to clarify the step which controls the rate, kinetic experiments were carried out with deuterated compounds. For *p*-deuteriotoluene $k_3=4.4\times10^{-4}$ $M^{-2}\cdot sec^{-1}$ at 5.0°C and $k_H/k_D=2.8$. For *p*-deuteriochlorobenzene $k_3=8.58\times10^{-6}M^{-2}\cdot sec^{-1}$ at 20.0°C and $k_H/k_D=1.98\pm0.3$. The values previously given were $k_H/k_D=2.0$ for hexadeuteriobenzene and $k_H/k_D=1.77\pm0.2$ for *p*-deuteriobromobenzene.[10] These data clearly confirmed that the hydrogen-abstraction step was the rate-determining step.

This conclusion is in contrast with the finding of Jensen and Brown that in benzenesulfonyl chloride as the solvent there was no kinetic isotope effect.[5] Bosscher and Cerfontain reported a very small isotope effect ($k_H/k_D=1.1$) for the sulfonylation occurring as a side reaction in the sulfonation of benzene with sulfur trioxide in trichlorofluoromethane at −35°C.[4d]

The formation of $TsCl\cdot AlCl_3$ complex and $Ts\cdot Ar\cdot AlCl_3$ complex was checked by means of infrared spctroscopy. The absorptions of asymmetric and symmetric stretching vibrations of the SO_2 group of *p*-toluenesulfonyl chloride in methylene chloride were observed at 1375 and 1175 cm^{-1}, whereas they appeared at 1365 and 1175 cm^{-1} when aluminum chloride was present in the medium. The absorptions due to the SO_2 group in *p*-tolyl *p*-chlorophenyl sulfone in methylene chloride were observed at 1325 and 1160 cm^{-1}, whereas these absorptions shifted to 1305 and 1105 cm^{-1} when aluminum chloride was added to the medium. Lindner and Weber reported that *p*-dimethylaminobenzenesulfonyl chloride absorbed at 1367 and 1160 cm^{-1} and its sulfonyl cation absorbed at 1418 and 1195 cm^{-1}. These facts indicate that not a sulfonyl cation but complexes such as shown in structure I and II are present in the reaction medium and the sulfone produced is also present as the complex III.

Since the rate of sulfonylation of toluene was greater faster than those of halobenzenes, it was expected that the rate of sulfonylation of anisole would be much greater. However, it was found that the rate was extremely solw with anisole. When a methylene chloride solution of anisole, aluminum chloride and *p*-toluenesulfonyl chloride was viewed in infrared, no shift in the sulfonyl absorption was observed, indicating the absence of $TsCl\text{-}AlCl_3$ complex. Formation of $PhOCH_3\text{-}AlCl_3$ complex was suspected, and a solution of anisole and aluminum chloride was compared with a solution of anisole alone by infrared, ultraviolet and nuclear magnetic resonance spectroscopy. The results are shown in Table 5. These spectroscopic observations are consistent with the formation of $PhOCH_3\text{-}AlCl_3$ complex. Apparently the following equilibrium exists, and the $PhOCH_3\text{-}AlCl_3$ complex predominates.

$$TsCl + PhOCH_3\text{-}AlCl_3 \rightleftharpoons PhOCH_3 + TsCl\text{-}AlCl_3$$

* Rate-determining step proposed were underlined.

The findings of this investigation must be compared with those of the thorough study made by Jensen and Brown. They found that in nitrobenzene the rate was equal to k_2[$PhSO_2Cl$][$AlCl_3$] for reactive aromatics whereas the rate was equal to k_3[ArH][$PhSO_2Cl$][$AlCl_3$] for less reactive aromatics. The following reaction sequence was proposed, in which step (6) is rate-determining for more reactive aromatics and step (7) is rate-determining for less reactive aromatics.[6]

$$PhSO_2Cl + PhNO_2 \cdot AlCl_3 \rightleftharpoons PhSO_2Cl \cdot AlCl_3 + PhNO_2 \quad (5)$$

$$PhSO_2Cl \cdot AlCl_3 \rightleftharpoons PhSO_2^+AlCl_4^- \quad (6)$$

$$ArH + PhSO_2^+AlCl_4^- \longrightarrow ArSO_2Ph \cdot AlCl_3 + HCl \quad (7)$$

Jensen and Brown reported that in benzenesulfonyl chloride the rate was equal to k_2[$PhSO_2Cl \cdot AlCl_3$]-[$PhCH_3$] with toluene and the attacking species was $ArSO_2^+AlCl_4^-$, whereas with chlorobenzene the rate was equal to $k_{3/2}$[$PhSO_2Cl \cdot AlCl_3$]$^{1/2}$[PhCl] and the attacking species was $ArSO_2^+$ cation.[7]

$$PhSO_2^+AlCl_4^- \rightleftharpoons PhSO_2^+ + AlCl_4^- \quad (8)$$

The findings of Jensen and Brown are compared with the findings of this investigtaion in Table 6.

A comparison of the orientation and the partial rate factors in Table 6 indicates that both intra- and intermolecular selectivity are greater with TsCl-$AlCl_3$-ArH-CH_2Cl_2 than with $PhSO_2Cl$-$AlCl_3$-ArH. The ρ value in CH_2Cl_2 was -5.6, whereas the ρ value calculated from the data in $PhSO_2Cl$ was -4.8. It is reasonable that in solvents of greater polarity such as nitrobenzene (dielectric constant, 34.092 at 25°C) and benzenesulfonyl chloride the reaction intermediates formed are ion pair $ArSO_2^+$ $AlCl_4^-$ or free cation, which are more reactive and less selective than complex II formed in

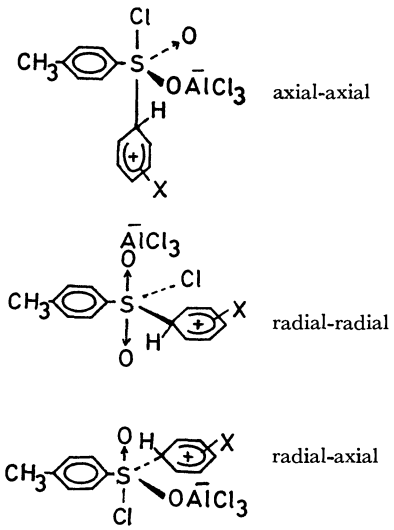

Fig. 4. Transition state of the sulfonylation.

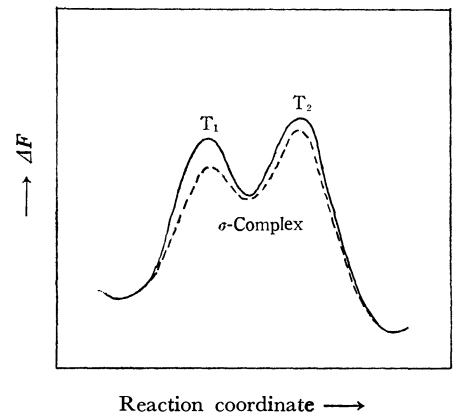

Fig. 3. Energy profile for the sulfonylation.
——: halobenzene ------: toluene

methylene chloride (dielectric constants, 9.08 at 20°C).

The isotope effect found for toluene was greater than that for benzene, chlorobenzene or bromobenzene. This finding may be explained by the energy profile shown in Fig. 3.

It is plausible that the presence of electron-releasing methyl group lowers the transition state T_1 considerably but affects the transition state T_2 very little. If so, k_{-2} as well as k_2 will be greater and k_{-2}/k_3 will be greater with toluene than with halobenzenes, and consequently the isotope effect with toluene is expected to be greater than that with halobenzenes.

It should be pointed out that three different structures are possible for the transition state from complex I to complex II, as shown in Fig. 4. However, at present it is not possible to determine which structure is more advantageous for the addition-elimination reaction discussed here.

On the basis of the reaction rate, reaction orders, activation parameters, orientations, partial rate factors, Hammett's plot, spectroscopic observations and kinetic hydrogen isotope effects, it was concluded that the reaction sequence (1), (2) and (3) best represent the reactions taking place in mixtures of *p*-toluenesulfonyl chloride, aluminum chloride and aromatic compounds in methylene chloride.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 239—245 (1970)

Association of a Reduced Riboflavin Derivative with Purines, Pyrimidines and Nicotinamide

Byung Sul Yu and Yoshimasa Kyogoku

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received July 7, 1969)

Hydrogen bonding of a reduced riboflavin derivative in chloroform has been studied by infrared spectra measurements. The self-association of the reduced form of riboflavin tetraacetate is much stronger than that of the oxidized form. The reduced form can also form hydrogen bonded complexes with some aminopurines, aminopyrimidines, aminopyridines and nicotinamide derivatives. In the bonding with aminopyridines the contribution of a proton transfer must be predominant. At partial reduction states the formation of radicals, semiquinone forms, was detected with the aid of the electron spin resonance. The concentration of free radicals, however, is about 1 per cent of dissolved riboflavin tetraacetate. The infrared spectra at various stage of reduction can be interpreted by the sum of the two individual spectra of the fully reduced and oxidized forms.

In previous papers selective formation of hydrogen bonding between the oxidized forms of riboflavin derivatives and adenine compounds has been reported.[1-3] The association of oxidized riboflavin is thought to be relevant to the intra- and intermolecular interaction of flavin adenine dinucleotide[4-10] and to have an important role in keeping the structure of FAD.[10] The isoalloxazine ring of riboflavin takes hydrogenated and dehydrogenated forms and hence it can be an electron carrier in a respiratory chain. The present work will show the effect of hydrogenation on the association of a riboflavin derivative with other compounds such as purines, pyrimidines and nicotinamide. The results might help to interpret the nature of previously reported complexes like FMN-$FMNH_2$ and NAD^+-$FMNH_2$.[11-15],*1

Experimental

Materials. Riboflavin-2′,3′,4′,5′-tetraacetate and 3-*N*-methylriboflavin-2′,3′,4′,5′-tetraacetate were prepared by the method described previously.[2] 9-Ethyl adenine, 1-cyclohexyluracil, 2′3′-benzylidine-5′-tritylguanosine, 2′,3′-benzylidine-5′-tritylcytidine and 4-aminopyrimidine were purchased from Cyclo Chemical Co., Los Angeles. The other chemicals were obtained from Tokyo Kasei Co. Some of them were used after recrystallization from proper solvents and the others were used without further purification. Chloroform and chloroform-d (Showa Denko Co., Kawasaki) were employed as solvents for the infrared measurements. Chloroform was dried with phosphorous pentoxide and purified by distillation. Chloroform-d was dried by passing through an alumina gel column.

The chloroform solutions of reduced riboflavin derivatives were prepared by shaking the solutions of the oxidized forms with an aqueous solution saturated with hydrosulfite. The solutions were then dried with calcium chloride. Completion of reduction was checked by visible-ultraviolet spectra, disappearance of absorptions at 450 and 350 mμ and appearance of a strong band at 300 mμ. Partial oxidation of the reduced form was done by bubbling oxygen gas in the solution of the reduced form or by mixing it with the solution of the oxidized form. Reduced *N*-methylnicotinamide was prepared from *N*-methylnicotinamide chloride by the method of Rafter and Colowick.[16] Hydrogenation at the 4-C position was confirmed by NMR measurement.

Procedures. Infrared spectra were measured with a Perkin-Elmer 621 spectrophotometer for chloroform solutions in fused quartz cells ranging from 1 to 25 mm in thickness. The spectra in the region 1800—1500 cm^{-1} were obtained by the use of potassium bromide cells with variable thickness. To avoid oxidation by atmospheric oxygen the solutions of the reduced samples were prepared in a dry box filled with nitrogen gas.

Electron spin resonance spectra were taken with a JEOL P-10 spectrometer. The concentration of free radicals was determined by comparison of the integrated area of signals with that of a standard solution of diphenyl picryl hydrazyl (Nakarai Chemical Co., Kyoto). Standard 0.01M solution was made up in chloroform. The visible-ultraviolet spectra were recorded with a Hitachi 124 spectrophotometer.

Determination of Association Constants. The self-association constant of RH was calculated from concentration dependence of a monomer band based on the theory described previously.[17] Eight spectra were recorded at different concentrations between 10^{-2} and 10^{-4}M.

Association constants between A and B can be estimated from the optical density change of the association or nonbonded band of A plotted against the mole ratio of mixing. The tangent lines (Fig. 4) show the optical density change which would occur when all of A bond to B. From the location of the cross point of the two lines, the numbers of moles, m and n, in the following equilibrium can be determined.

$$mA + nB \rightleftarrows A_mB_n$$

The association constant K in the equilibrium may be written as

$$K = \frac{C_{AB}}{C_A{}^m C_B{}^n} \tag{1}$$

where C_A, C_B and C_{AB} are the concentrations of monomer A, monomer B and the complex respectively. The length of L from the cross point to the base line is proportional to C_{0A}, the initial concentration of A, and the height l of the observed curve is proportional to mC_{AB}, the concentration of A which is used for the complex formation. Thus the following relations hold

$$\frac{C_{0A}}{L} = \frac{C_A}{L-l} = \frac{mC_{AB}}{l} \tag{2}$$

Similar relations are written for the component B

$$\frac{C_{0B}}{L} = \frac{C_B}{L-l} = \frac{nC_{AB}}{l} \tag{3}$$

The initial concentration C_{0A} and C_{0B} are related to the total concentration C_0 as follows.

$$C_{0A} = \frac{m}{m+n}C_0, \quad C_{0B} = \frac{n}{m+n}C_0 \tag{4}$$

From the relations (1), (2), (3) and (4) it follows that

$$K = \frac{(m+n)^{m+n-1}\dfrac{l}{L}}{m^m n^n \left(1-\dfrac{l}{L}\right)^{m+n} C_0{}^{m+n-1}} \tag{5}$$

The association constants determined by the above method are only reliable within the order of magnitude.

Results and Discussion

Self - association of Reduced Riboflavin Tetraacetate. *Fully Reduced Form.* The infrared spectra of RH and MeRH are given in Fig. 1. The spectrum of fully reduced RH shows very broad strong bands in the 3 μ region contradicting with the sharp N_3–H stretching band of the oxidized form R. MeRH whose oxidized form does not show any absorption in the 3 μ region also gives a broad band around 3400 cm^{-1}. These evidences indicate that the broad bands come from the hydrogenated NH groups at the N_1 and N_5 positions of the reduced isoalloxazine ring. The carbonyl

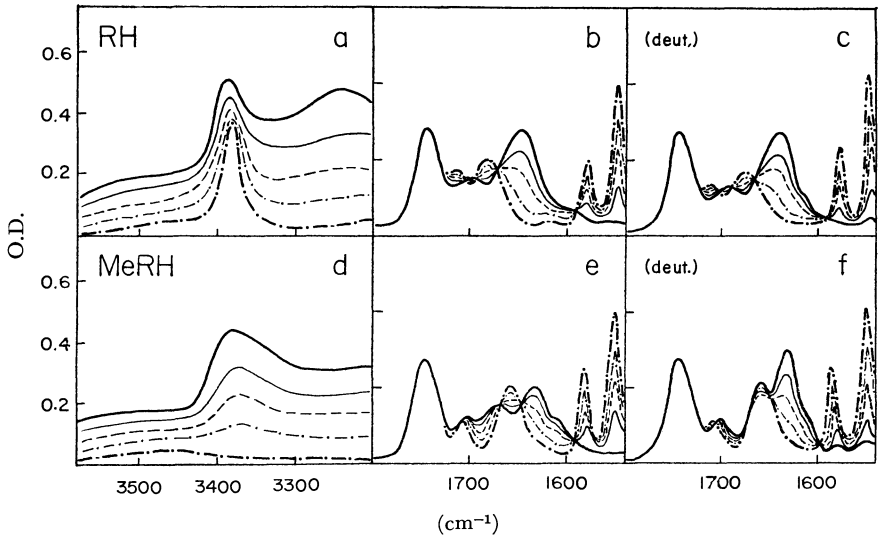

Fig. 1. Infrared spectra of the chloroform solutions of riboflavin tetraacetate (a, b, c) and *N*-methylriboflavin tetraacetate (d, e, f) in the reduced and oxidized forms. The concentration of the solution is 4×10^{-3}M, and the path length is 5 mm for the 3500—3200 cm^{-1} region and 0.5 mm for the 1800—1500 cm^{-1} region. Bold solid line, fully reduced state; bold broken line, fully oxidized state; other three fine lines, partially reduced and oxidized states.

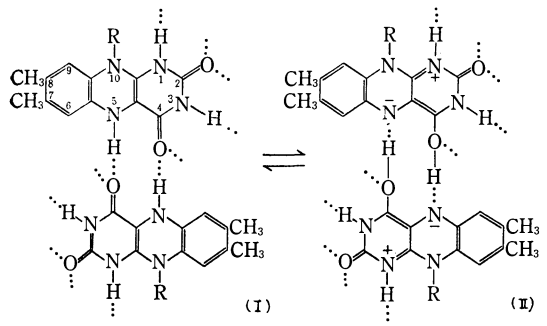
stretching bands at 1715 and 1685 cm^{-1} of R move to lower frequency and the ring stretching bands at 1585 and 1550 cm^{-1} disappear by hydrogenation. The spectral feature of the 6 μ region shows a remarkable change in the conjugated system of the isoalloxazine ring.

The broad strong bands in the 3 μ and 6 μ regions indicate the strong self-association of RH. The fully reduced isoalloxazine ring has three NH and two carbonyl groups and thus four sites can be used for cyclic hydrogen bonds with another RH molecule. Therefore the self-association constant must be at least four times, *i. e.* about $600M^{-1}$, as big as that of R which has two sites for the cyclic dimer formation. From the concentration dependence of the 3400 cm^{-1} band of RH the self-association constant was roughly estimated to be $10^3-10^4M^{-1}$. The ability of the formation of hydrogen bonds of the N_1H and N_5H sites are much stronger than that of the N_3H group. This is understandable because the p*K* values of the N_1 and N_5 protons are around 6.5 whereas that of N_3 is 10.[8] The reduced form is a weak acid. The lower frequency shift of the carbonyl stretching band shows the increase of single bond nature in the associated reduced form. The contribution of the proton transfer form (II) may not be so small.



Partially Reduced State. From the potentiometric, spectral and magnetic resonance observations several investigators concluded that riboflavin is reduced and oxidized in two one electron steps and pass through a semiquinoid state.[12,13,18,19] The infrared spectra of RH and MeRH at successive oxidation states from full reduction to full oxidation are given in Fig. 1. The strong NH band of RH gradually decreases in intensity as the per cent of oxidation is increased. Gradual shifts and intensity changes of absorption bands are also observed in the 1800—1500 cm^{-1} region and isosbestic points are seen at 1670 and 1590 cm^{-1}. It is clear from the results that the infrared spectra at intermediate oxidation are explained by the sum of the spectra of two states, fully oxidized and reduced states, and any new band due to transient intermediate could not be observed. In the visible-near infrared spectrum of the FMN-$FMNH_2$ mixture in aqueous solution two bands were reported in addition to the bands due to FMN and $FMNH_2$, one with

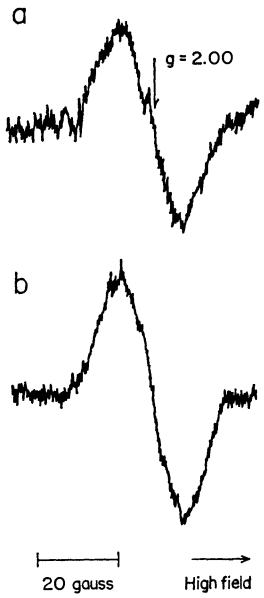

Fig. 2. Electron spin resonance spectra at 50% reduction of 1×10^{-2}M riboflavin tetraacetate in chloroform (a), plus 1×10^{-2}M 9-ethyladenine (b). The spectra were taken at the same instrument setting. Field modulation, 100 kc.

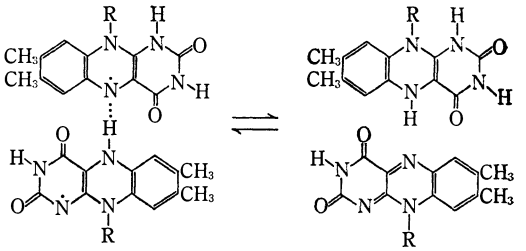
a maximum absorption near 570 mμ and another with a peak at 900 mμ.[12,13] The 570 mμ band was thought to be due to semiquinone, since it increases in intensity to a maximum at about half oxidation together with the increase of the signal intensity of ESR. The 900 mμ band was assigned to the dimer of semiquinone[12] or to the charge transfer complex of FMN-$FMNH_2$.[13] In the present investigation, however, no absorption could be seen in the wavelength region longer than 500 mμ even for the 0.01M solution of RH at 50% oxidation in 1 cm cell. The visible-near infrared spectra of the partially oxidized state did not show the presence of a intermediate species.

ESR was measured for the 0.01M solution of R at 50% reduction and a signal was observed (Fig. 2). From a comparison of the integrated area of the signal with that of DPPH, the concentration of free radicals was calculated to be 1×10^{-4}M, 1% of dissolved R. The signal amplitude did not change one hour after the preparation of the solution. Oxidation of RH by molecular oxygen or by mixing it with R produces radicals, semi-



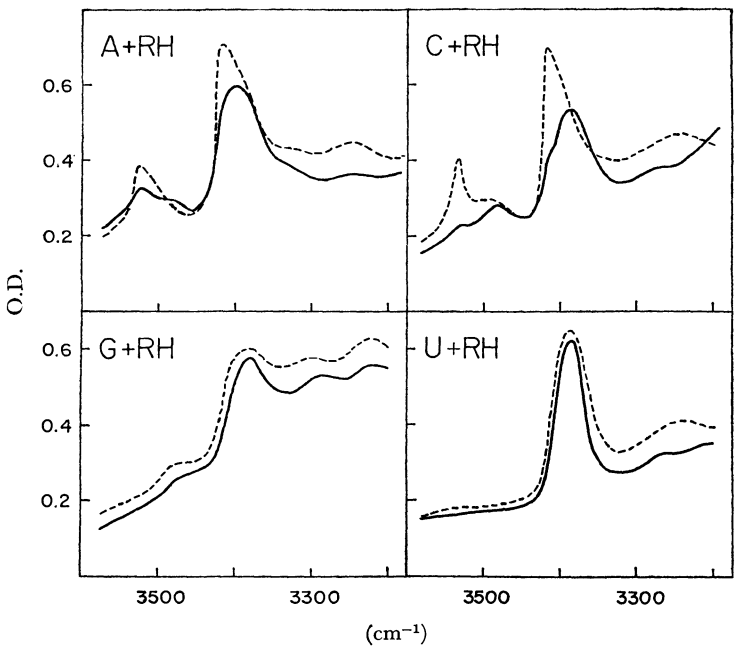


Fig. 3. Infrared spectra of the equimolar mixture solution of reduced riboflavin tetraacetate and one of the A, U, G and C compounds in chloroform. The total concentration is 8×10^{-3}M and the path length is 5 mm. Solid line, observed spectrum; dotted line, calculated sum of the individual spectrum of components.

quinone, which interact to give the fully reduced and oxidized forms as shown above.

Association with Purines, Pyrimidines and Other Related Compounds. *Interaction with 9-Ethyladenine.* Riboflavin tetraacetate formed a hydrogen bonded complex with adenine more strongly than with themselves.[1,2] The infrared spectra of the 1 : 1 mixture of RH and A also show us strong binding of A with RH (Fig. 3). The symmetric and antisymmetric stretching bands of the non-bonded amino group at 3415 and 3525 cm^{-1} become weaker than the calculated sum of the individual spectrum which would be realized if there is no interaction between them. An association band is visible at 3470 cm^{-1}, which is due to the stretching vibration of the partially bonded amino group. The intensity of the non-bonded and association bands changes as a function of the mole ratio of mixing. They reach a maximum or a minimum in the 1 (RH) : 3 (A) region (Fig. 4). RH and A form a complex which consists of three A and one RH molecules in average. The ratio is not unreasonable because RH has four sites to which A can bond with cyclic hydrogen bonds. By an application of the procedure described in the preceding section the association constant of the complex formation was estimated to be 10^7 $(l/mol)^3$ with an assumption $m=1$ and $n=3$.

The intensity of absorption bands also changes as a function of the extent of reduction. The broad band of RH gradually decreases in intensity and the band due to the free N_3H group of R at 3380 cm^{-1} becomes sharp as the extent of oxidation increases (Fig. 5). However, the intensity change of the bands of A at 3415 and 3525 cm^{-1} are not parallel with that of the N_3H group of R. This might be explained by the fact that a RH molecule can bond with three A molecules. Contribution of the intermediate state to the RH-A binding does not seem to be important, since an additional band due to the semiquinone-A complex could not be observed. In fact the concentration of radicals was determined by ESR measurement to be 1 per cent of the dissolved RH at 50% reduction and is not affected by the presence of A.

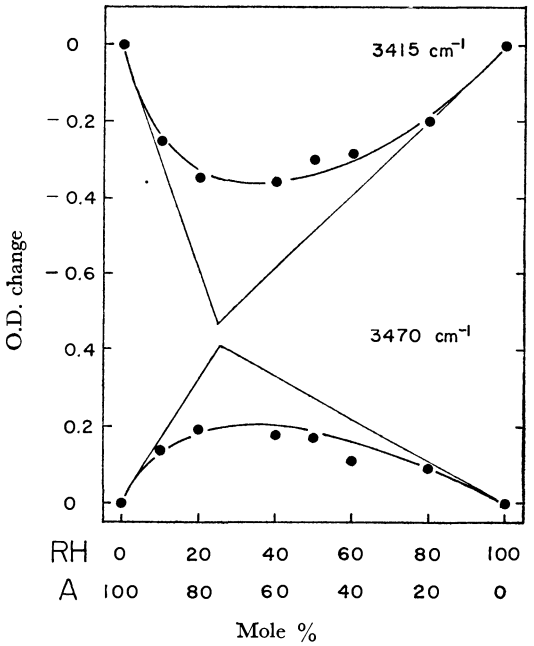

Fig. 4. Change in the optical density of the association band at 3470 cm^{-1} and the non-bonded band at 3415 cm^{-1} as a function of the mole ratio of fully reduced riboflavin tetraacetate and ethyladenine. The optical density of the pure solution is adjusted to zero.

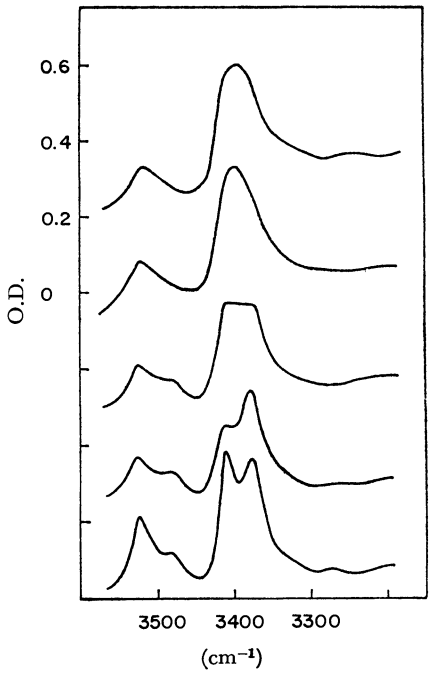

Fig. 5. Infrared spectra of the equimolar mixture solutions of riboflavin tetraacetate and ethyladenine at successive reduction states. Bottom spectrum, fully oxidized state; top spectrum, fully reduced state. The total concentration is 8×10^{-3}M and the path length is 5 mm.

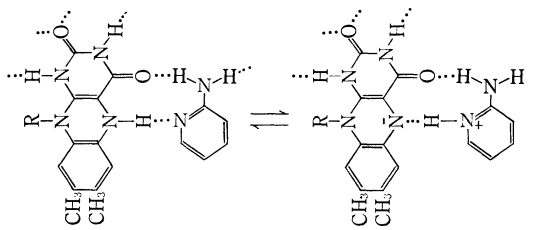
Interaction with Other Compounds. Riboflavin tetraacetate selectively bonded to A and did not interact with other nucleic acid purine and pyrimidine derivatives.[1,2] Whether such specificity still holds for the association of RH was examined. The infrared spectra of the mixtures with G and U show almost the same spectra as the calculated sum of each individual (Fig. 3). A remarkable change, however, is observed in the spectrum of the mixture with C. The symmetric and antisymmetric stretching bands of the free amino group of C at 3415 and 3525 cm^{-1} almost disappear on the addition of RH. The selective binding found

for the oxidized form cannot be observed in the association of the reduced form. To find necessary conditions for the association with RH, several compounds listed in Table 1 were examined for their ability of binding with RH. Association constants were roughly estimated by the variation method described previously. A two + sign in the table shows that the compound interacts with RH as strongly as with A at an association constant in the order of 10^7 (l/mol).[3] A three + sign means stronger complex formation with a constant bigger than 10^8. Weaker bonding than that of A is shown by a one + sign. For all of the associations m and n were assumed 1 and 3 respectively.

From the table it can be concluded that both the amino group and the nitrogen atom in the heterocyclic ring are necessary but are not enough for the association. Acidity or basicisity of the donor and acceptor sites of proton may be associated with the interaction. The pK_a of 4-aminopyrimidine is 5.71, whereas that of 2-aminopyrimidine is 3.54.[20] The latter must be harder to be protonated than the former. This accounts for the fact that 2-aminopyrimidine does not associate with RH. 2-Amino-, 3-amino-, 4-aminopyridines have the pK_a's of 6.86, 5.98 and 9.14 respectively.[20] On the other hand the protons at the N_1 and N_5 positions of RH dissociate around 6.5.[21] RH is a weak acid. Therefore the contribution of proton transfer is expected in the bonding between RH and 2- or 4-aminopyridine. In fact the ring stretching mode at 1600 cm^{-1} of deuterated 2-aminopyridine completely disappears on the addition of RH. A remarkable change in the ring of 2-aminopyridine was shown. On the other hand the ring stretching band of deuterated A at 1610 cm^{-1} still remains in the mixture solution with RH (Fig. 6). In the association of A with RH the ring system is not so affected by hydrogen bonding to the ring nitrogen atoms.



Association with Nicotinamide. As shown in Table 1 and Fig. 7 nicotinamide strongly interacts with RH. The symmetric and antisymmetric stretching bands of the amino group of NA at

Table 1. Association of reduced riboflavin tetraacetate with several compounds

G	—	Pyridine	—
C	++	Nicotinamide	+
U	—	Isonicotinamide	+
2-Aminopyridine	+++	1-Methyl-4-hydronicotinamide	+
3-Aminopyridine	+	Benzamide	—
4-Aminopyridine	++	*o*-Hydroxybenzamide	—
2-Aminopyrimidine	—	1-Phenylurea	—
4-Aminopyrimidine	+	Urethane	—

The + signs denote the strength of interaction of RH with association constants bigger than 10^8 (l/mol)^3 (+++), around 10^7 (++) and smaller than 10^7 (+).

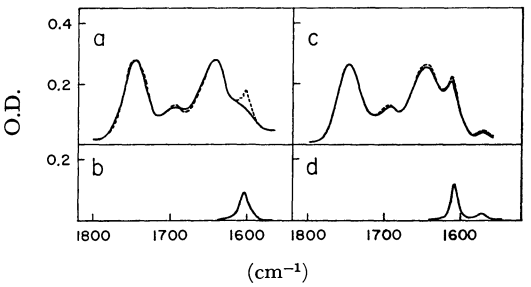

Fig. 6. Infrared spectra of the equimolar mixture solutions of RH and 2-aminopyridine (a), 2-aminopyridine (b), the equimolar mixture of RH and ethyladenine (c) and ethyladenine (d). The compounds are deuterated. The total concentration is 8×10^{-3}M and the path length is 0.5 mm.

3525 and 3410 cm^{-1} decrease in intensity. Although the amino group of NA is used for the association with RH, the scheme shown in the case of the RH-aminopyridine complex is not applicable. The ring nitrogen atom of aminopyridine is the acceptor site of proton in the RH-aminopyridine complex. Reduced *N*-methylnicotinamide whose nitrogen atom is blocked with a methyl group is expected not to interact with RH. However it shows an interaction with RH. Moreover the nitrogen atom of a nicotinic acid derivative is a weaker base than that of pyridine by 1—2 pK units (*ca.* pK_a 2—3).[22] The spectrum of NA in the 1800—1500 cm^{-1} region shows the carbonyl stretching band at 1680 cm^{-1}, which becomes strong and shifts to lower frequency when RH is added to the solution (Fig. 7). It is clear that a hydrogen bond is formed at the carbonyl group of an amide and the following structure can be proposed for the association.

20) A. Albert, R. Goldacre and J. Phillips, *J. Chem. Soc.*, **1948**, 2240.

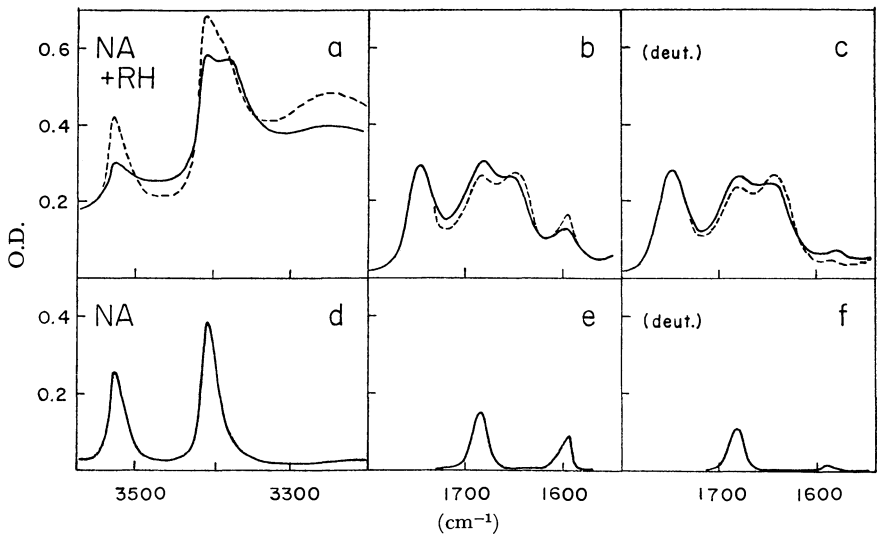

Fig. 7. Infrared spectra of nicotinamide (d, e, f) and the equimolar mixture solutions with reduced riboflavin tetraacetate (a,b,c). Solid line, observed spectra; dotted line, calculated sum of the individual spectrum. The concentration of each solute is 4×10^{-3}M and the path length is 5 mm for the 3500—3200 cm^{-1} region and 0.5 mm for the 1800—1550 cm^{-1} region.

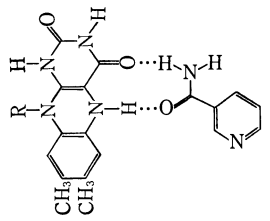

The amide group is almost planar, and there is resonance between the nitrogen and the carbonyl group which may be represented as $N-C=O \rightleftharpoons N^{+}=C-O^{-}$. In fact, infrared studies of nicotinamide-metal ion complexes suggest strongly that the oxygen atom in amides acts as a donor toward electron acceptors.[23,24] The pyridine ring increases the electron density at the oxygen atom of the amide group by inductive and resonance effects. Therefore the acceptor strength for proton at the oxygen atom of NA is expected to be greater than those of urea derivatives. This might be the reason why NA derivatives interact with RH and aliphatic urea derivatives do not.

Nicotinamide adenine dinucleotide in the oxidized form is thought to form a charge transfer complex with $FMNH_2$.[11,14] The visible spectrum of the mixture showed a broad band at 700 mμ which has been thought to be a charge transfer band. An additional absorption at 520 mμ of the mixture of $FMNH_2$ - *N*-methylnicotinamide iodide is also thought to be due to a charge transfer complex.[14] Any absorption, however, could not be detected in the longer wavelength region than 500 mμ in the chloroform system. It is doubtful whether the association found in the present experiment corresponds to the charge transfer complex of NAD^{+}-$FMNH_2$ or not.

Any interaction could not be detected between reduced *N*-methylnicotinamide and R. Radda and Calvin have also failed to observe the association between NADH and FMN which might occur under the catalysis of enzyme.[25] Although RH was found to be able to form strong hydrogen bonds with several compounds, the association of RH is probably of no physiological importance.

The authors wish to express their sincere thanks to Dr. M. Sedaka for the measurement of ESR spectra. Thanks are also due to Professor M. Tsuboi for his encouragement and advice. This work was partly supported by a grant from the U. S. Public Health Service GM10024-05.

(Received July 18, 1969)

9-(3′-Amino-3′-*C*-carboxy-3′-deoxy-β-D-ribofuranosyl)adenine (I) and 9-(3′-amino-3′-*C*-carboxy-3′-deoxy-β-D-ribopyranosyl)adenine (II) have been synthesized. They are the first examples of nucleoside-derivatives which have an α-amino acid structure in their furanose or pyranose ring. A masked derivative (VII) of α-D-*erythro*-pentofuranos-3-ulose was converted into a hydantoin derivative (IX), which was acetolyzed and then treated with dry hydrogen chloride to give an acylglycosyl chloride (XI). Condensation of this derivative with chloromercuri-6-benzamidopurine followed by hydrolysis afforded I. Treatment of the hydantoin derivative (IX) with methanolic hydrogen chloride followed by hydrolysis gave methyl 3-amino-3-*C*-carboxy-3-deoxy-α-D-ribopyranoside (XVII), which has been found to be identical with one of the isomers of methyl 3-amino-3-*C*-carboxy-3-deoxy-α-D-pentopyranoside previously reported. The 1-*O*-acetyl-3-*N*-benzoyl-2,4-di-*O*-benzoyl derivative of ethyl ester of this acid (XVII) was fused with 6-benzamidopurine in the presence of *p*-toluenesulfonic acid and followed by hydrolysis to afford II. Structural proofs for the new nucleoside-derivatives were obtained from their ultraviolet, infrared and nuclear magnetic resonance spectra.

In a previous paper[1] we described the synthesis of a new kind of monosaccharide-derivatives which have an α-amino acid structure in a pyranose. Synthesis of nucleoside-related compounds[2] is in progress in this laboratoy. Interest in nucleoside chemistry has led us to synthesize new derivatives of nucleosides which have an α-amino acid structure in their carbohydrate moiety. Puromycin (III), an antibiotic purine derivative, exhibits carcinostatic and trypanocidal activities. As a biologically active moiety of puromycin, 9-(3′-amino-3′-deoxy-β-D-ribofuranosyl)-6-dimethylaminopurine (IV) was demonstrated by Baker *et al.*[3] 3′-Amino-3′-deoxyadenosine[4] (V) was also found to be about twenty times as active as IV against the transplanted mammary adenocarcinoma of a C_3H mouse. Fukatsu and Umezawa[2] synthesized an adenosine nucleoside of 3-amino-3-deoxy-D-glucose and found it to have a weak anti-HeLa cell activity. As a result, we became interested in the synthesis of aminonucleoside-derivatives which have an α-amino acid structure in the ribofuranose or ribopyranose moiety. The present paper will present the synthesis of adenine nucleosides (I and II) of 3-amino-3-*C*-carboxy-3-deoxy-D-ribofuranose and of its pyranose-form.

The course of synthesis is summarized in Scheme 1.

Synthesis of 9-(3′-Amino-3′-*C*-carboxy-3′-deoxy-β-D-ribofuranosyl)adenine (I). The starting material, 5-*O*-benzoyl-1,2-*O*-isopropylidene-α-D-*erythro*-pentos-3-ulose (VII) was prepared from 5-*O*-benzoyl-1,2-*O*-isopropylidene-α-D-xylofuranose[5] (VI) by oxidation with Pfitzner-Moffatt reagent[6] in a good yield.

According to the Bucherer hydantoin synthesis, as reported by Hoyer,[7] VII was allowed to react with a mixture of potassium cyanide and ammonium carbonate under carbon dioxide atmosphere in an autoclave to afford 5-*O*-benzoyl-3-deoxy-1,2-*O*-isopropylidene-3-*C*-(spiro-5′-hydantoin)-α-D-pentofuranose (IX) as a major product, accompanied by the formation of 5-*O*-benzoyl-1,2-*O*-isopropylidene-

α-D-*erythro*-pent-3-ulose imine (VIII). It is noteworthy that imine (VIII) was obtained as the main product by the usual Bucherer hydantoin synthesis which was carried out under atmospheric pressure without using carbon dioxide.

Hydrolysis of IX with barium hydroxide gave 3-amino-3-*C*-carboxy-3-deoxy-1,2-*O*-isopropylidene-α-D-ribofuranose (XIV), which, on *N*-acetylation with acetic anhydride in methanol, afforded a γ-lactone (XV) showing an infrared absorption band at 1780 cm^{-1}. This lactone-formation indicates that XIV has a structure of 3-*C*-carboxy derivative of 3-amino-3-deoxy-D-ribose and XV is 3-acetamido-3-*C*-carboxy-3-deoxy-1,2-*O*-isopropylidene-α-D-ribofuranose-γ-lactone.

Acetolysis of the hydantoin derivative (IX) with a mixture of acetic anhydride and acetic acid in the presence of concentrated sulfuric acid gave a glassy product of 1,2-di-*O*-acetyl-5-*O*-benzoyl-3-deoxy-3-*C*-(spiro-5′-hydantoin)-D-pentofuranose (X). Its NMR spectrum showed it to be predominantly α-anomer. The pure α-anomer was obtained by crystallization in hot acetone-diisopropyl ether. Assignment of the α-configuration to the product was based on the coupling constant ($J_{1,2}$=4.1 Hz) shown in its NMR spectrum.

Treatment of X with hydrogen chloride in ether gave a syrupy product of 2-*O*-acetyl-5-*O*-benzoyl-1-chloro-1,3-dideoxy-3-*C*-(spiro-5′-hydantoin)-D-pentofuranose (XI). The coupling constant ($J_{1,2}$=4.2 Hz) observed in the NMR spectrum of XI showed that the glycosyl chloride was again α-anomer.

Reaction of the glycosyl chloride (XI) with chloromercuri-6-benzamidopurine produced a masked nucleoside, *i.e.* 9-[2′-*O*-acetyl-5′-*O*-benzoyl-3′-deoxy-3′-*C*-(spiro-5′-hydantoin)-β-D-pentofuranosyl]-6-benzamidopurine (XII). Hydrolysis of XII with 1.5 mol of methanolic barium hydroxide at room temperature gave the deacylated hydantoin-nucleoside, 9-[3′-deoxy-3′-*C*-(spiro-5′-hydantoin)-β-D-pentofuranosyl]adenine (XIII). Further treatment of XIII with excess amount of methanolic barium hydroxide under reflux afforded the desired nucleoside, 9-(3′-amino-3′-*C*-carboxy-3′-deoxy-β-D-ribofuranosyl)adenine (I).

The structures of I and XIII were indicated by their elemental analyses, negative rotations and ultraviolet spectra which showed the characteristic maximum of 9-substituted adenine at 259 mμ. The β-configuration of the products could be interpreted adequately in terms of Tipson's "*trans* rule"[8] as extended by Baker and his co-workers.[9]

The resonance for the anomeric proton of XIII at τ 4.00 appears as a doublet with a coupling constant ($J_{1',2'}$=7.3 Hz) unusually larger than a value of ≦2 Hz[10] which is expected for a β(*trans*) anomeric configuration. However, a similar observation was recently made with 3′-*C*-methyladenosine ($J_{1',2'}$=8.2 Hz) and adenosine ($J_{1',2'}$=6.0 Hz), and discussed by Nutt *et al.*[11] It may be attributed to the deformation of the furanose ring from its usual conformation by the increase in bulky group eclipsing interaction in the nucleosides.

Synthesis of 9-(3′-Amino-3′-*C*-carboxy-3′-deoxy-β-D-ribopyranosyl)adenine (II). In a previous paper,[1] the synthesis of four diastereomers of methyl (−)-3-amino-3-deoxy-3-*C*-ethoxycarbonyl-pentopyranoside from methyl β-D-xylopyranoside has been reported. An isomer (XVIII), which showed the largest R_f-value among the four isomers on thin-layer chromatography (TLC), was hydrolyzed to afford methyl (−)-3-amino-3-*C*-carboxy-3-deoxypentopyranoside, and its partial structure was deduced from NMR spectroscopy and chemical results.

Hydantoin derivative (IX) was treated with methanolic hydrogen chloride to give methyl 3-deoxy-3-*C*-(spiro-5′-hydantoin)-β-D-pentopyranoside (XVI). The coupling constant ($J_{1,2}$=8.5 Hz) in its NMR spectrum indicated that it is a β-anomer. Hydrolysis of XVI with barium hydroxide gave methyl 3-amino-3-*C*-carboxy-3-deoxy-β-D-riboside (XVII). It has been found that this riboside was identical with the methyl (−)-3-amino-3-*C*-carboxy-3-deoxypentopyranoside, their infrared spectra, optical rotations and R_f-values on paper chromatography being identical and mixed melting point showing no depression. Consequently, the structure of isomer (XVIII) was established as methyl 3-amino-3-deoxy-3-*C*-ethoxycarbonyl-β-D-ribopyranoside.

Benzoylation of XVIII yielded methyl 3-benzamido-2,4-di-*O*-benzoyl-3-deoxy-3-*C*-ethoxycarbonyl-β-D-ribopyranoside (XIX), which, on acetolysis, gave the desired product, 1-*O*-acetyl-3-benzamido-2,4-di-*O*-benzoyl-3-deoxy-3-*C*-ethoxycarbonyl-β-D-ribopyranose (XX). Since, in the NMR spectra of XIX and XX, the small coupling constants of $J_{1,2}$=1.6—2.0 Hz and $J_{4,5a}$=1.6—2.0 Hz and a long range coupling constants of $J_{2,4}$=1.2—1.5 Hz were observed, both XIX and XX seem to exist in a 1C conformation.

Attempts to convert XX into an acylglycosyl halide with hydrogen chloride in ether and with hydrogen bromide in acetic acid were unsuccessful. However, when the condensation reaction of XX and benzamidopurine was carried out by the fusion

procedure as reported by Sato *et al.*,[12] using *p*-toluenesulfonic acid as a catalyst, and subjecting the product to chromatography on silica gel, 9-(3′-benzamido-2′,4′-di-*O*-benzoyl-3′-deoxy-3′-*C*-ethoxycarbonyl-β-D-ribopyranosyl)-6-benzamidopurine (XXI) was obtained in a 16.6% yield.

The structure of XXI was indicated by elemental analysis, ultraviolet spectrum, negative rotation and the coupling constant ($J_{1',2'}$=9.0 Hz) in NMR spectrum. The coupling constant ($J_{4',5'}$=9.0 Hz) and the absence of a long range coupling between H-2 and H-4 protons showed that XXI may exist in a Cl conformation. The conversion of conformation between XIX (or XX) and XXI may be due to the change of bulkiness of the aglycones.

Hydrolysis of XXI with barium hydroxide in aqueous methanol followed by purification through an ion-exchange column gave a crystalline nucleoside, 9-(3′-amino-3′-*C*-carboxy-3′-deoxy-β-D-ribopyranosyl)adenine (II) in a 32.7% yield.

Experimental

Thin layer chromatography (TLC) was conducted by the use of silica gel (Daiichi Pure Chemicals Co., Inc.). The prepared plates were activated at 110°C. The spray reagents used were 10% sulfuric acid and 0.5% pyridine solution of ninhydrin. NMR spectra were taken with a Varian A-60D spectrometer at the frequency of 60 MHz in deuteriochloroform and deuteriodimethyl sulfoxide (DMSO-d_6) with tetramethylsilane as an internal standard. Melting point determinations for the samples showing higher melting points than 200°C were carried out on a micro hot stage. Unless noted otherwise, all concentrations were carried out in a rotary evaporator at reduced pressure under 40°C.

5-*O*-Benzoyl-1,2-*O*-isopropylidene-α-D-*erythro*-pentos-3-ulose (VII). To a solution of 5-*O*-benzoyl-1,2-*O*-isopropylidene-α-D-xylofuranose (VI)[5] (10.5 g, 0.0357 mol) in dimethyl sulfoxide (10.5 m*l*) and dry benzene (100 m*l*) containing pyridine (1 m*l*) and trifluoroacetic acid (0.5 m*l*), dicyclohexylcarbodiimide (10.5 g, 0.0509 mol) was added under cooling, and the solution was stirred for 18 hr at room temperature. Ether (100 m*l*) was then added and insoluble matter was filtered off. The organic layer was washed with water (20 m*l*×5) and dried over sodium sulfate. Removal of the solvent yielded a brown syrup containing crystals of dicyclohexylurea. Crystallization from boiling ether afforded a crystalline 5-*O*-benzoyl-1,2-*O*-isopropylidene-α-D-*erythro*-pentos-3-ulose (VII); yield 6.44 g (61.8%), mp 96—97°C, $[\alpha]_D^{23}$ +135° (*c* 3.2, chloroform) [lit,[11] mp 98—99°C, $[\alpha]_D$ +136° (*c* 1, chloroform)].

5-*O*-Benzoyl-1,2-*O*-isopropylidene-α-D-*erythro*-pentos-3-ulose Imine (VIII). A solution of potassium cyanide (100 mg) and ammonium carbonate (350 mg) in water (1 m*l*) was added to a solution of VII (200 mg) in ethanol (1 m*l*) and the mixture was stirred at 50°C for one hour. Evaporation of ethanol from the reaction mixture afforded VIII as needles; yield 120 mg (60.3%). An analytical sample was obtained by recrystallization from diisopropyl ether; mp 162°C, $[\alpha]_D^{20}$ +36° (*c* 0.8, ethanol), ν_{max}^{Nujol} 3400, 1735, 1697 (C=N) cm^{-1}; τ^{CDCl_3} 4.03 (d, C-1H, $J_{1,2}$=3.4 Hz), 8.43, 8.65 [s,s, >$C(CH_3)_2$].

Found: C, 61.54; H, 5.67; N, 5.18%. Calcd for $C_{15}H_{17}NO_5$: C, 61.85; H, 5.88; N, 4.81%.

5-*O*-Benzoyl-3-deoxy-1,2-*O*-isopropylidene-3-*C*-(spiro-5′-hydantoin)-α-D-pentofuranose (IX). A suspension of VII (5.00 g), potassium cyanide (4.45 g) and ammonium carbonate (8.25 g) in methanol (40 m*l*) was stirred under an initial carbon dioxide pressure of 50 kg/cm^2 for 5 hr at room temperature and for additional 5 hr at 55—60°C in an autoclave. The content was evaporated to remove methanol and water (30 m*l*) was added to the residue. The mixture was acidified (pH 1—2) with 3N hydrochloric acid (24 m*l*) and extracted with four 40-m*l* portions of ethyl acetate. Evaporation of the ethyl acetate layer afforded a yellow syrup (5.77 g). TLC (diisopropyl ether) of the syrup showed a main spot (R_f 0.22). Chromatography on silica gel (80 g) in diisopropyl ether-butanone (10 : 1) gave fractions containing a total yield of 2.41 g of crude IX; R_f 0.22. Recrystallization from hot ethyl acetate (15 m*l*) plus diisopropyl ether (15 m*l*) gave the pure hydantoin derivative IX (1.64 g) melting at 195—196°C. From the mother liquor a second crop (0.39 g) melting at 194—195°C was obtained: total yield 32.7%, $[\alpha]_D^{20}$ +34° (*c* 1.02, ethanol), ν_{max}^{KBr} 3345, 3275, 1787, 1739, and 1695 cm^{-1}: τ^{CDCl_3} 0.91 [s, N(3)-H], 3.57 [s, N(1)-H], 3.96 (d, C-1H, $J_{1,2}$=3.7 Hz), 8.44, and 8.64 [s,s >$C(CH_3)_2$].

Found: C, 56.07; H, 5.38; N, 7.47%. Calcd for $C_{17}H_{18}N_2O_7$: C, 56.35; H, 5.01; N, 7.73%.

12) T. Sato, T. Shimadachi and Y. Ishido, *Nippon Kagaku Zasshi*, **81**, 1440 (1960).

Other fractions of R_f 0.49 were collected and evaporated. The residue was crystallized from diisopropyl ether to afford imine (VIII); yield 1.02 g (13.4%), mp 162°C.

3-Acetamido-3-*C*-carboxy-3-deoxy-1,2-*O*-isopropylidene-α-D-ribofuranose-γ-lactone (XV). A mixture of the hydantoin derivative (IX) (362 mg), barium hydroxide octahydrate (3.15 g) and water (24 ml) was stirred at 125°C for 12 hr. The reaction mixture was heated with ammonium carbonate (1.92 g) for 10 min at 110°C and followed by additional heating for 20 min with 1.23 g of ammonium carbonate. The resulting mixture was filtered to remove barium carbonate and the filtrate was washed with ether. The aqueous layer was evaporated to afford a colorless powder of crude 3-amino-3-*C*-carboxy-3-deoxy-1,2-*O*-isopropylidene-α-D-ribofuranose (XIV). A suspension of the crude XIV (430 mg) in methanol (5 ml) was treated with acetic anhydride (1 ml) for 3 hr at room temperature, after which the reaction mixture was evaporated. The residue was purified through a silica gel (10 g) column. Elution with ethyl acetate-benzene (1 : 1) afforded compound XV as prisms; yield 126 mg (50%). Recrystallization from acetone-diisopropyl ether; mp 147—148°C, $[\alpha]_D^{12.5}$ −59° (*c* 1.09, ethanol), ν_{max}^{KBr} 3265, 1780 (γ-lactone), 1657 and 1530 cm^{-1}; τ^{CDCl_3} 3.38 [s, N(1)–H], 4.00 (d, C–1H, $J_{1,2}$=4.0 Hz), 7.96 (s, CO–CH_3), 8.43 and 8.59 [s,s, >$CH(CH_3)_2$].

Found: C, 51.50; H, 5.79; N, 5.38%. Calcd for $C_{11}H_{15}NO_6$: C, 51.36; H, 5.88; N, 5.45%.

1,2-Di-*O*-acetyl-5-*O*-benzoyl-3-deoxy-3-*C*-(spiro-5′-hydantoin)-D-pentofuranose (X). To an ice-cooled solution of the hydantoin derivative (IX) (1.0 g) in acetic acid (7.5 ml) and acetic anhydride (7.5 ml) was added concentrated sulfuric acid (0.8 ml) dropwise and the solution was kept at room temperature for 22 hr. The reaction mixture was shaken with a mixture of 7% aqueous sodium acetate solution (40 ml), ice (10 g) and chloroform (20 ml) in a separating funnel. The aqueous layer was further extracted with three 10-ml portions of chloroform. The combined chloroform layers were dried over sodium sulfate and evaporated to give crude X (1.04 g, 92.7%) as a glassy solid, whose TLC (diisopropyl ether-butanone 3 : 1) showed a single spot having R_f-value of 0.43. A sample (490 mg) of the crude X was crystallized from hot diisopropyl ether-acetone to afford α-anomer of X (101 mg) as needles; mp 137—139°C; $[\alpha]_D^{20}$ +20° (*c* 0.88, ethanol); ν_{max}^{KBr} 3220, 1786, and 1725 cm^{-1}; τ^{CDCl_3} 3.39 (d, C–1H, $J_{1,2}$=4.1 Hz), 3.86 [s, N(1)–H], 4.71 (d, C-2H), 7.83 and 7.89 (s,s, $OCOCH_3$).

Found: C, 53.35; H, 4.63; N, 6.79%. Calcd for $C_{18}H_{18}N_2O_9$: C, 53.20; H, 4.47; N, 6.89%.

The NMR spectrum of the crude X showed that X existed mainly as an α-anomer.

2-*O*-Acetyl-5-*O*-benzoyl-1-chloro-1,3-dideoxy-3-*C*-(spiro-5′-hydantoin)-D-pentofuranose (XI). A mixture of X (500 mg), dry ether (19 ml) and acetyl chloride (0.3 ml) was saturated with dry hydrogen chloride under ice-salt cooling and allowed to stand for 38 hr in a refrigerator. The reaction mixture was evaporated at 30°C and the residual syrup was then dissolved in a small amount of absolute ether and again evaporated. This procedure was repeated three times to afford a syrup which was shown to consist of XI (R_f 0.40) by TLC using diisopropyl ether-butanone (3 : 1). The NMR signals for XI were observed at τ^{CDCl_3} 1.40 [s, N(3)–H], 3.39 (d, C–1H, $J_{1,2}$=4.2 Hz), 3.60 [s, N(1)–H], 4.72 (d, C–2H), and 7.84 (s, $OCOCH_3$).

6-Benzamido-9-[2′-*O*-acetyl-5′-*O*-benzoyl-3′-deoxy-3′-*C*-(spiro-5′-hydantoin)-β-D-pentofuranosyl]adenine (XII). A solution of XI (from 955 mg of X) in dry acetonitrile (35 ml) was stirred with chloromercuri-6-benzamidopurine (1.12 g) at 100—105°C for 2.5 hr. The reaction mixture was filtered while hot and insoluble matter was washed with acetonitrile (3×7 ml). The filtrate and washings were evaporated and the residue was chromatographed on silica gel (25 g). Elution with ethyl acetate-isopropyl alcohol (20 : 1) afforded the condensation product XII as a colorless powder, yield 442 mg (28.6%); $[\alpha]_D^{12.5}$ −32° (*c* 0.9, ethanol); λ_{max}^{MeOH} 230 and 280 mμ; ν_{max}^{KBr} 3280, and 1727 cm^{-1}.

9-[3′-Deoxy-3′-*C*-(spiro-5′-hydantoin)-β-D-pentofuranosyl]-adenine (XIII). To a solution of XII (2.22 g) in methanol (20 ml) was added 0.22N aqueous barium hydroxide solution (52 ml) and the solution was stirred for 24 hr at room temperature. Carbon dioxide gas was passed through the reaction mixture. The precipitate was filtered off and the filtrate evaporated. The residual colorless powder (2.16 g) was crystallized from water to yield crude XIII as pale-brown crytals; yield 472 mg (37%). A sample (300 mg) of the product was dissolved in hot water (10 ml). After removal of a small amount of insoluble matter by filtration, the filtrate was purified through an Amberlite IR-45 (OH^- type) column (1×18 cm). The fractions having an absorption peak at 260 mμ of UV-light were collected and concentrated. The resulting product (145 mg) was recrystallized from hot water to afford an analytical sample of XIII as colorless fine needles; mp 315—320°C (colored at 295°C), $[\alpha]_D^{25}$ −36° (*c* 0.77, dimethyl sufoxide), ν_{max}^{KBr} 1770, and 1725 cm^{-1}, $\lambda_{max}^{H_2O}$ 258.5 mμ (ε 20700), $\lambda_{max}^{0.1N\ HCl}$ 257 mμ (ε 20700) and $\lambda_{max}^{0.1N\ NaOH}$ 259.5 mμ (ε 19900); τ^{DMSO} 4.00 (d, C–1′H, $J_{1',2'}$=7.3 Hz), and 5.07 (d, C–2′H).

Found: C, 42.88; H, 4.54; N, 28.98%. Calcd for $C_{12}H_{13}N_7O_5$; C, 42.98; H, 3.91; N, 29.25%.

9-(3′-Amino-3′-*C*-carboxy-3′-deoxy-β-D-ribofuranosyl)-adenine (I). A mixture of XII (442 mg), methanol (5 ml), barium hydroxide octahydrate (1.24 g) and water (20 ml) was refluxed under stirring for 6.5 hr, after which ammonium carbonate (2.3 g) was added in portions and the mixture was heated for 30 min at 120°C. Barium carbonate was removed by filtration and washed with hot water. The filtrate and washings were collected and evaporated. The residual powder was purified through an Amberlite CG-50 column (pyridine type 1.2×20 cm) using buffer solutions, acetic acid-pyridine-water (2 : 3 : 1000 and 1 : 5 : 500). Fractions containing the product were pooled and concentrated. The residue (55 mg) was recrystallized from water to give an analytically pure sample of IV; mp 202—205°C (decomp.), $[\alpha]_D^{12.5}$ −30° (*c* 0.4, water), ν_{max}^{KBr} 3400, 3140, 1642, and 1600 cm^{-1}, $\lambda_{max}^{H_2O}$ 259 mμ (ε 14900), $\lambda_{max}^{0.1N\ HCl}$ 257 mμ (ε 14800), $\lambda_{max}^{0.1N\ NaOH}$ 260 mμ (ε 15600).

Found:[13] C, 42.71; H, 4.65; N, 27.34%. Calcd for $C_{11}H_{14}N_6O_5$: C, 42.58; H, 4.55; N, 27.09%.

Methyl 3-Deoxy-3-*C*-(spiro-5′-hydantoin)-β-D-pen-

13) The sample was dried over phosphorus pentoxide at 150°C/3 mmHg.

topyranoside (XVI). A suspension of the hydantoin derivative (IX) (640 mg) in 1N methanolic hydrogen chloride (25 ml) was refluxed for 35 hr, after which the reaction mixture was neutralized with basic lead carbonate and filtered. The filtrate was evaporated and the residue (510 mg) was recrystallized from methanol-ethyl acetate to afford XVI as colorless fine crystals; yield 130 mg(31%). An analytically pure sample was obtained by recrystallization from the same solvent as mentioned above; mp 288°C (decomp.), $[\alpha]_D^{12.5}$ −34° (*c* 2.48, water), ν_{max}^{KBr} 1755 (sh.), 1730, and 1717 cm^{-1}, τ^{D_2O} 5.56 (d, C-1H or C-2H, $J_{1,2}$=8.5 Hz), 6.29 (d, C-1H or C-2H) and 6.41 (s, OCH_3).

Found: C, 41.43; H, 5.28; N, 12.08%. Calcd for $C_8H_{12}N_2O_6$: C, 41.38; H, 5.21; N, 12.07%.

Methyl 3-Amino-3-*C*-carboxy-3-deoxy-β-D-ribopyranoside (XVII). A mixture of XVI (130 mg), barium hydroxide octahydrate (707 mg) and water (5 ml) was heated at 65—70°C for 20 hr, after which carbon dioxide gas was passed through the resulting mixture. The precipitate was removed by filtration and the filtrate evaporated. The residue (125 mg) was recrystallized from aqueous acetone to yield XVII as needles; yield 34 mg (29.4%), mp 250°C (decomp.), $[\alpha]_D^{15}$ −43° (*c* 1.0, water), R_f 0.13 (paper chromatography with *n*-butanol-acetic acid-water 4 : 1 : 1).

Methyl 3-Amino-3-deoxy-3-*C*-ethoxycarbonyl-β-D-ribopyranoside (XVIII). As reported in a previous paper,[1] periodate oxidation of methyl β-D-xylopyranoside followed by cyclization with ethyl nitroacetate and successive hydrogenation afforded a diastereomeric mixture of methyl (−)-3-amino-3-deoxy-3-*C*-ethoxycarbonylpentopyranoside, from which, an isomer (XVIII) of a R_f-value 0.73 on TLC could be obtained by column chromatography using ethyl acetate-ethanol (6 : 1). The amino acid which was obtained from XVIII by hydrolysis could also be described. Its partial structure could be described but a definite assignment of the configuration of the amino and carboxyl groups at C-3 could not be made. This amino acid[14] was now found to be identical with the above-mentioned amino acid XVII obtained from XVI by comparison of their melting points, infrared spectra and optical rotations.

Methyl 3-Benzamido-2,4-di-*O*-benzoyl-3-deoxy-3-ethoxycarbonyl-β-D-ribopyranoside (XIX). To a solution of XVIII (3.45 g) in dry pyridine (94 ml) was added benzoyl chloride (8.7 ml) under ice-cooling and kept for 18 hr at room temperature. The reaction mixture was poured into ice-water and extracted with four 50-ml portions of chloroform. The organic layer was washed with saturated aqueous potassium hydrogen sulfate and potassium hydrogencarbonate and evaporated to give a brown syrup. Purification through a silica gel column (200 g, 3.8×40 cm), eluting with *n*-hexane-butanone (5 : 1, 4 : 1 and 3 : 1) gave XIX (3.76 g, 46.4%) as a yellow syrup, which was crystallized by treatment with diisopropyl ether. Recrystallization from diisopropyl ether afforded an analytical sample; mp 135—136°C, $[\alpha]_D^{21}$ −64.3° (*c* 1.32, chloroform), ν_{max}^{KBr} 3415, 1745, 1724, 1673 cm^{-1}; τ^{CDCl_3} 2.98 (s, N-H), 3.72 (m, C-4H), 4.40 (d,d, C-2H, $J_{1,2}$=1.6 Hz, $J_{2,4}$= 1.5 Hz), 5.00 (d, C-1H), 5.39 (d,d, C-5H, $J_{4,5}$=2.0 Hz, $J_{5a,5e}$=12.9 Hz), 5.61 (q, ester CH_2, J=7.3 Hz), 5.90 (d,d, C-5H, $J_{4,5}$=1.7 Hz), 6.56 (s, OCH_3) and 8.66 (t, ester CH_3).

Found: C, 66.06; H, 5.37; N, 2.80%. Calcd for $C_{30}H_{29}NO_9$: C, 65.80; H, 5.39; N, 2.56%.

1-*O*-Acetyl-3-benzamido-2,4-di-*O*-benzoyl-3-deoxy-3-*C*-ethoxycarbonyl-β-D-ribopyranose (XX). A mixture of XIX (500 mg), acetic acid (11 ml), acetic anhydride (11 ml) and concentrated sulfuric acid (0.7 ml) was stirred until the solid was dissolved completely. After standing for 2 days at room temperature, the resulting solution was treated with sodium acetate (3 g) under stirring for 30 min and evaporated. To the residue was added water (15 ml) and ether (15 ml) and the mixture was shaken. The separated ether-layer was washed with a 10% sodium hydrogencarbonate solution, dried over sodium sulfate and evaporated. The residual yellow syrup (585 mg), which was a mixture of two products of R_f-value 0.62 and 0.29 on TLC (*n*-hexane-butanone 3 : 1), was chromatographed on silica gel (20 g). Elution with the same solvent system gave two kinds of pale-yellow syrups; A 168 mg (R_f (0.62) and B 261 mg (R_f 0.29). Treatment of B with diisopropyl ether afforded XX as colorless needles; yield 186 mg (35.4%), mp 155—157°C, $[\alpha]_D^{21}$ −59° (*c* 1.16, chloroform), τ^{CDCl_3} 2.96 (s, N-H), 3.63 (d, C-1H, $J_{1,2}$=2.0 Hz), 3.72 (m, C-4H), 4.38 (d,d, C-2H, $J_{2,4}$=1.2 Hz), 5.25 (d,d, C-5H, $J_{4,5}$=2.0 Hz, $J_{5a,5e}$= 13.1 Hz), 5.60 (q, ester CH_2, J=7.3 Hz), 5.81 (d,d, C-5H, $J_{4,5}$= 1.6 Hz), 7.85 (s, $COCH_3$) and 8.61 (t, ester CH_3).

Found: C, 65.12; H, 5.42; N, 2.62%. Calcd for $C_{31}H_{29}NO_{10}$: C, 64.69; H, 5.08; N, 2.43%.

An additional amount of XX (73 mg) was obtained from the syrup A by treatment with acetic anhydride, acetic acid and sulfuric acid as described above; total yield 49.2%.

6-Benzamido-9-(3′-benzamido-2′,4′-di-*O*-benzoyl-3′-deoxy-3′-*C*-ethoxycarbonyl-β-D-ribopyranosyl)-purine (XXI). A mixture of XX (362 mg) and 6-benzamidopurine (181 mg) was heated to cause it to melt in an oil bath (*ca.* 155°C). *p*-Toluenesulfonic acid (15 mg) was added to the melt and the mixture was heated for 30 min under reduced pressure (5 mmHg). After cooling, the solid mass was pulverized and extracted with ethanol. Evaporation of ethanol gave a glassy product (483 mg), which was then purified through a silica gel column (15 g, 1.2×29.5 cm) with chloroform-ethyl acetate mixtures (10 : 1, 8 : 1 and 3 : 1) to afford XXI as a colorless powder; yield 79 mg (16.6%). Since the product contained a small amount of insoluble matter in ethanol, the product was again treated with ethanol, filtered and the filtrate was concentrated to afford an analytically pure sample; mp 145—148°C, $[\alpha]_D^{8}$ −103°(*c* 0.46, ethanol), λ_{max}^{MeOH} 279 mμ (ε 20700), 230 mμ (ε 41300), τ^{CDCl_3} 2.86 (d, C-1′H or C-2′H, $J_{1',2'}$=9.1 Hz), 3.38 (d, C-1′H or C-2′H), 3.81 (d,d, C-4′H, $J_{4',5'_e}$=6.0 Hz, $J_{4',5'_a}$=9.0 Hz), 5.62 (q, ester CH_2, J=7.2 Hz), and 8.70 (t, ester CH_3).

Found: C, 64.55; H, 4.87; N, 10.38%. Calcd for $C_{41}H_{34}N_6O_9 \cdot C_2H_5OH$: C, 64.57; H, 4.91; N, 10.51%.

9-(3′-Amino-3′-*C*-carboxy-3′-deoxy-β-D-ribopyranosyl)adenine (II). To a solution of XXI (400 mg) in methanol (2.5 ml) was added 0.36N barium hydroxide solution (8.2 ml) and the mixture was kept for 2 days at 37°C. After evaporation of methanol, the residue was diluted with water and carbon dioxide gas was

14) Compound VIA-1 in Table 2 in the previous paper (Ref. 1).

passed through the solution for 30 min. Barium carbonnate was filtered off and the filtrate was washed with four 10-m*l* portions of ether. The aqueous layer was evaporated to afford a colorless powder (558 mg), which was purified through an Amberlite CG-50 pyridine type column (1×15 cm) by using buffer solutions, pyridine-acetic acid-water (1.5 : 1.0 : 1000 and 10 : 2.0 : 1000). Fractions containing the nucleoside was concentrated and the residue (249 mg) was recrystallized from water to yield colorless prisms of II (53 mg, 32.7%); mp 247°C (decomp.). $[\alpha]_D^{18}$ −20° (*c* 0.22, 0.1N HCl), $\lambda_{max}^{H_2O}$ 260 mμ (ε 15700), $\lambda_{max}^{0.1N\ HCl}$ 257 mμ (ε 14400) and $\lambda_{max}^{0.1N\ NaOH}$ 261 mμ (ε 13400).

Found:[13] C, 42.21; H, 4.75; N, 26.74%. Calcd for $C_{11}H_{14}N_6O_5$: C, 42.58; H, 4.55; N, 27.09%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 252—257 (1970)

Studies of the Thiocarbonyl Compounds. I. Syntheses and Thermal Rearrangement of *O,S*-Diaryl Dithiocarbonates*1

Yoshiaki ARAKI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received July 22, 1969)

Various *O,S*-diaryl dithiocarbonates with the general formula of *p*-X-C_6H_4-S-C(=S)-O-C_6H_4-Y-*p* (I) were prepared. When these substances were kept at an elevated temperature, they rearranged smoothly to *S,S*-diaryl dithiocarbonates of this general formula: *p*-X-C_6H_4-S-C(=O)-S-C_6H_4-Y-*p* (II). Kinetic studies showed that the rearrangement followed fairly good first-order kinetics. The rate constants in diphenyl ether at 200°C increased in the order: $Y=OCH_3<CH_3<H<Cl<COCH_3<CN<NO_2$. The entropies of activation were negative, and no crossover products were obtained. A four-membered cyclic structure can be suggested as the transition state for this rearrangement.

It is well known that the reaction mechanism of the formation of olefins by the pyrolysis of xanthate esters which have a β-hydrogen atom in the alcohol moiety, commonly called the Chugaev reaction, is an intramolecular *cis* elimination through a cyclic transition state.[1] On the other hand, xanthate esters which have no β-hydrogen atom, such as methyl benzyl xanthate, rearrange on pyrolysis to give dithiolcarbonates.[2] However, it has been thought that this reaction is unusual, and no mechanistic work has yet been made. It seemed that it would be interesting to investigate whether *O,S*-diaryl dithiocarbonates (I) also rearrange to *S,S*-diaryl dithiocarbonates (II) at elevated temperatures.

$$\underset{\text{(I)}}{\text{Ar-S-C(=S)-O-Ar'}} \xrightarrow{\Delta} \underset{\text{(II)}}{\text{Ar-S-C(=O)-S-Ar'}}$$

The present author synthesized twelve compounds I (I-1—I-12), all of them were new compounds except the diphenyl ester (I-3);[3] he also studied the kinetics of their thermal rearrangements in order to establish the reaction mechanism.

Results and Discussion

Syntheses of *O,S*-Diaryl Dithiocarbonates (I). The compounds I were synthesized by the

Method A: $\text{Ar-S-C(=S)-Cl} + \text{KO-Ar'} \longrightarrow \text{I} + \text{KCl}$

Method B: $\text{Ar-S-C(=S)-Cl} + \text{HO-Ar'} + \text{pyridine} \longrightarrow \text{I} + \text{pyridine}\cdot\text{HCl}$

Method C: $\frac{1}{2}(\text{Ar-S})_2\text{Pb} + \text{Cl-C(=S)-O-Ar'} \longrightarrow \text{I} + \frac{1}{2}\text{PbCl}_2$

c) Ref. 3c and Ref. 3d; mp 51°C. d) Recrystallized from acetone-ethanol.

reaction of a substituted phenol with an aryl chlorodithioformate (Methods A and B). In order to establish the structure of the compounds I, another method (Method C) was also used; in this aryl chlorothionoformates were treated with lead thiophenolates, giving the compounds I. By these three methods, the various compounds I were obtained in good yields. The data are shown in Table 1.

Thermal Rearrangement. In order to examine the possibility of the thermal rearrangement, the compounds I were kept at 200°C without any solvent under a nitrogen atmosphere; the reaction mixture was then analyzed by thin-layer chromatography on silica gel. It was found that the compounds I were gradually converted to other compounds. The elemental analysis showed that the composition of the products was identical with that of original compounds I. The infrared spectra of the products showed peaks at *ca.* 1720 cm^{-1} ($\nu_{C=O}$). These data suggest that the products are *S,S*-diaryl dithiocarbonates (II).

Identification of the Thermal Rearrangement Products. In order to identify the thermal rearrangement products, the compounds II were synthesized by Methods D and E. The results are shown in Table 2. The compounds which

Method D: $\mathrm{Ar\text{-}S\text{-}\overset{\overset{O}{\|}}{C}\text{-}Cl} + \frac{1}{2}\mathrm{Pb(S\text{-}Ar')_2} \longrightarrow$ II $+ \frac{1}{2}\mathrm{PbCl_2}$

Method E: $\mathrm{Ar\text{-}S\text{-}\overset{\overset{O}{\|}}{C}\text{-}Cl} + \mathrm{HS\text{-}Ar'} +$ $\longrightarrow$ II + $\cdot$HCl

were produced by heating the compounds I at 200°C were identified with the compounds II by mixed-melting-point tests and by a comparison of the IR spectra.

Kinetics of the Rearrangement. In order to clarify the influence of the substituents upon the rearrangement rates, the kinetics of the rearrangement were investigated in a diphenyl ether solution. The rates were followed by the ampoule technique and were determined by measuring the amounts of the remaining reactants, I, and of the products, II, by UV spectrophotometry. It was found that the rearrangement followed fairly good first-order kinetics. A typical run is shown in Table 3 and Fig. 1. The first-order rate constants

I-7	—	34.7	−5.3

the energies and entropies of activation were calculated for some of the compounds I. The values are given in Table 6.

In Table 4 it can be observed that electron-withdrawing substituents attached to the migrating group accelerate the rearrangement. The logarithms of the rate constants in Table 4 were plotted against Hammett's σ values (Fig. 2). By means of the method of least-squares, the best straight line was obtained ($\rho=1.87$).

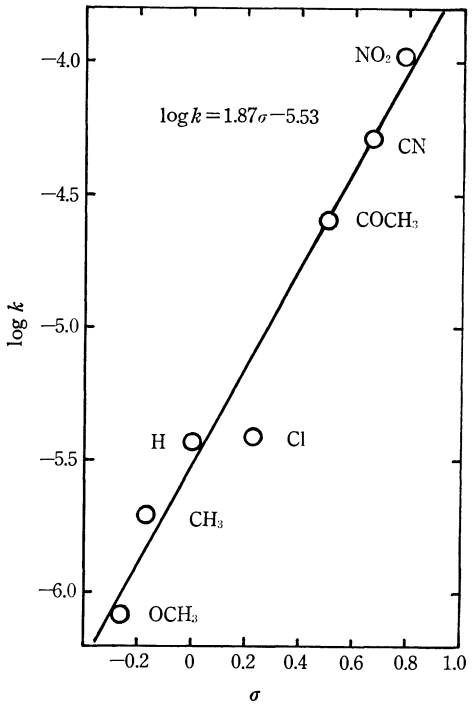

Fig. 2. Hammett plot for rate of rearrangement of  at 200.5±0.1°C.

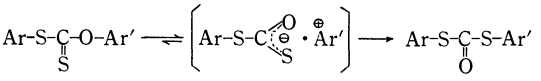
On the other hand, the data in Table 5 show that electron-donating substituents attached to the phenylthio moiety accelerate the reaction. Figure 3 shows a Hammett plot of log k in Table 5 against the σ values ($\rho=-0.41$).

In order to establish the mechanism of the rearrangement of the compounds I, it was necessary to determine whether the mechanism of the rearrangement is intermolecular or intramolecular. A crossover reaction was performed with two compounds of I. That is, an equimolar mixture of I-3 and I-12*[2] was heated without any solvent at 230°C under a nitrogen atmosphere. If the rearrangement is intermolecular, such crossover products as II-4 and/or II-7 should be detected in the crossover reaction mixture in addition to II-3 and II-10. In order to confirm this, the crossover reaction mixture obtained was analyzed by thin-layer chromatography on silica gel. The chromatograms of that reaction mixture, however, showed no detectable amounts of II-4 and/or II-7. This finding suggests that the rearrangement is intramolecular.

Furthermore, if the rearrangement proceeds through an intimate ion-pair,[6] such as in Scheme 1, the order of the rate constants should be the inverse of the experimental results shown in Table 4, because the stability of the aryl cation, which contributes to the reaction rate, should decrease in



Scheme 1

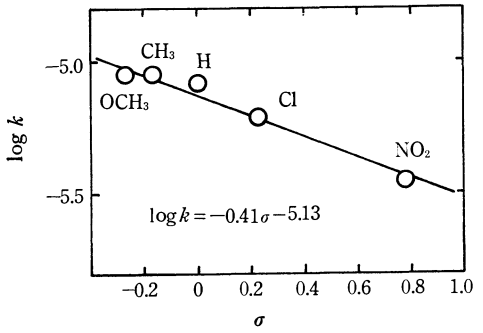


Fig. 3. Hammett plot for rate of rearrangement of  at 170.0±0.1°C.

*[2] I-3 and I-12 were chosen because of their similar rate constants (rate constant of I-12 is 3.39×10^{-5} sec^{-1} at 230.0°C).

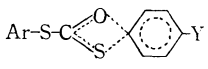
the order: $Y=OCH_3>CH_3>H>Cl>COCH_3>CN>NO_2$.

When these results are taken into consideration, it seems reasonable to conclude that the rearrangement of the compounds I take place through an intramolecular four-membered cyclic transition state, as in Scheme 2:



Scheme 2

Moreover, since the formation of the four-membered cyclic transition state requires a restriction of the rotation, the entropy should decrease in going from the reactants to the transition state. In fact, as is shown in Table 6, the entropies of activation are negative. These data are in agreement with this conclusion. Furthermore, the entropies of activation obtained for the rearrangements of arylimino ethers,[7] diaryl thionocarbonates,[8] and aryl *N,N*-dialkylthionocarbamates,[8e,9] all of which are regarded as having four-membered cyclic transition states, are in the same range as these data. This fact also supports this conclusion.

Consequently, a four-membered cyclic structure (Scheme 2) formed by a nucleophilic attack of the thiocarbonyl sulfur atom on the migrating aromatic ring can be considered to be the transition state in the rearrangement of the compounds I.

This conclusion is also supported by the kinetic data. That is, the positive slope of the straight line in Fig. 2 shows that this rearrangement is a nucleophilic reaction. The increased reactivity in Table 4 can be explained as follows: Since electron-withdrawing substituents decrease the electron density on the reaction center, these substituents facilitate a nucleophilic attack of the thiocarbonyl sulfur atom. On the other hand, electron-donating groups attached to the phenylthio moiety make the electrons on the thiocarbonyl sulfur atom more available for a nucleophilic attack, so these groups accelerate the rearrangement (Table 5).

Investigations of similar rearrangement reactions involving cyclic transition states are now in progress. These results will be reported elsewhere later.

Experimental*3

Materials. The aryl chlorodithioformates were synthesized by the reaction of a corresponding thiophenol, thiophosgene, and sodium hydroxide according to a known method:[3d] *p*-methoxyphenyl-, orange red oil, bp 126—129°C/0.95 mmHg; *p*-methylphenyl-, orange red oil, bp 112—113°C/0.8 mmHg (lit,[10] bp 102—104°C/1.0 mmHg); phenyl-, orange red oil, bp 143—144°C/22 mmHg (lit,[3d] bp 135°C/15 mmHg); *p*-chlorophenyl-, orange red oil, bp 102—103°C/0.8 mmHg; *p*-nitrophenyl-, orange crystals, bp 144—145°C/0.8 mmHg, mp 45.0—46.0°C.

The aryl chlorothionoformates were also prepared by a known method:[3c] phenyl-, colorless oil, bp 74.0°C/5 mmHg (lit,[3c] bp 91°C/10 mmHg); *p*-nitrophenyl-, colorless plates (from *n*-hexane), mp 59.0—60.0°C (lit,[11] mp 59.0—60.0°C).

The aryl chlorothiolformates were prepared as follows: To a solution of 1 mol of phosgene and 1 mol of thiophenol in 600 m*l* of dry toluene, 1 mol of dry pyridine was added gradually under vigorous agitation. The temperature was kept at 20—30°C during the reaction period of 2 hr. Then, the reaction mixture was filtered and the solvent was removed under reduced pressure.*4 The residue was fractionated, and the product was obtained in a high yield: phenyl-, colorless oil, bp 110°C/21 mmHg (lit,[3d] bp 104°C/13 mmHg, bp 150°C/22 mmHg, bp 225—227°C/724 mmHg); *p*-nitrophenyl-, colorless needles (from *n*-hexane), mp 60.0—62.0°C.

***O,S*-Diaryl Dithiocarbonates (I).** The compounds I were prepared by three methods, A, B, and C. Method A was used most often. The results are listed in Table 1.

Method A. Example 1. *O*-(*p*-Nitrophenyl) *S*-(*p*-Methylphenyl) Dithiocarbonate (I-9). To a suspension of 3.54 g (0.02 mol) of potassium *p*-nitrophenolate in 25 m*l* of dry acetone at 0°C in an ice-water bath, there was added, all at once, 3.93 g (0.02 mol) of *p*-methylphenyl chlorodithioformate in 20 m*l* of dry acetone. The resulting mixture was then stirred for 1 hr, with the temperature kept at 5—10°C. Then the cooling bath was removed, and the reaction mixture was stirred for 2 hr at room temperature and poured into *ca.* 500 m*l* of cold water. In this way 5.85 g (96%) of pale yellow crystals with mp 97—99°C was obtained. Recrystallization from ethanol gave 4.40 g (72%) of pale yellow prisms with mp 103.0—103.5°C.

Example 2. *O,S*-Diphenyl Dithiocarbonate (I-3). To 50 m*l* of cooled absolute ethanol, there was added, in small portions, 3.9 g (0.1 mol) of potassium. After hydrogen evolution had ceased, 9.4 g (0.1 mol) of phenol was added. The resulting solution was then added gradually with continuous stirring to a cooled solution of 18.9 g (0.1 mol) of phenyl chlorodithioformate in 50 m*l* of absolute ethanol in an ice-water bath, with the temperature kept at 5—10°C. After the addition had been completed, stirring was continued an additional hour at a temperature below 10°C. The reaction mixture

*3 All boiling and melting points are uncorrected.

*4 At this step, *p*-nitrophenyl chlorothiolformate was solidified.

was then poured into *ca.* 1000 m*l* of cold water; orange crystals with mp 39.0—40.5°C were thus afforded quantitatively. Recrystallization from ethanol gave 17.7 g (72%) of pale yellow plates with mp 42.5—43.0°C.

In this method, when phenyl chlorodithioformate was added to a solution of potassium phenolate in ethanol, diphenyl trithiocarbonate and diphenyl thionocarbonate were obtained, but the compound I-3 was not obtained.

Method B. This method worked well with phenols bearing electron-withdrawing substituents.

Example. *O,S*-Bis(*p*-nitrophenyl) Dithiocarbonate (I-11). To a cooled solution of 1.39 g (0.01 mol) of *p*-nitrophenol and 2.34 g (0.01 mol) of *p*-nitrophenyl chlorodithioformate dissolved in 20 m*l* of dry acetone in an ice-water bath, there was added, all at once, 0.79 g (0.01 mol) of dry pyridine with vigorous agitation. The cooling bath was then removed, and stirring was continued for two more hours at room temperature. The reaction mixture was poured into *ca.* 500 m*l* of cold water; 3.20 g (95%) of orange crystals with mp 160—164°C were thus obtained. Recrystallization from acetone-ethanol gave 2.12 g (63%) of orange prisms with mp 170.0—171.0°C.

Method C. Example. *O,S*-Diphenyl Dithiocarbonate (I-3). A mixture of 7.8 g (0.045 mol) of phenyl chlorothionoformate and 9.7 g (0.023 mol) of lead thiophenolate in 80 m*l* of dry benzene was heated under reflux for 6 hr. After cooling to room temperature, the reaction mixture was filtered and the solvent was removed under reduced pressure to give pale yellow crystals. Recrystallization from ethanol gave pale yellow plates with mp 42.5—43.0°C.

The synthesis of the compound I-11 by this method was attempted. As a result, it was found that, besides I-11, bis(*p*-nitrophenyl) trithiocarbonate and bis(*p*-nitrophenyl) thionocarbonate were formed in large quantities.

***S,S*-Diaryl Dithiocarbonates (II).** The compounds II were prepared by two methods, D and E. Method E was used most often because of its convenience. The data are shown in Table 2.

Method D. Example. *S,S*-Diphenyl Dithiocarbonate (II-3). A mixture of 0.86 g (0.005 mol) of phenyl chlorothiolformate and 1.1 g (0.0026 mol) of lead thiophenolate in 10 m*l* of dry benzene was heated under reflux for 24 hr. After it had then been cooled to room temperature, a white solid was removed by filtration; the filtrate was concentrated to dryness to yield 1.12 g (91%) of white crystals with mp 38—40°C. Recrystallization from ethanol gave white prisms with mp 41.5—42.0°C.

Method E. Example. *S,S*-Bis(*p*-nitrophenyl) Dithiocarbonate (II-11). Into a cooled solution of 1.55 g (0.01 mol) of *p*-nitrothiophenol and 2.18 g (0.01 mol) of *p*-nitrophenyl chlorothiolformate dissolved in 20 m*l* of dry acetone in an ice-water bath, there was added, all at once, 0.79 g (0.01 mol) of dry pyridine with vigorous agitation. The cooling bath was then removed and stirring was continued for two more hours. The reaction mixture was poured into *ca.* 500 m*l* of cold water; 3.36 g (100%) of yellow crystals with mp 188—189°C was thus obtained. Recrystallization from benzene gave pale yellow needles with mp 191.5—192.5°C.

Thermal Rearrangement of I. The rearrangement of I was carried out at 200°C in a test tube without any solvent. That is, *ca.* 500 mg of I was placed in a test tube and heated to 200.5±0.1°C in a constant-temperature bath under a slow stream of nitrogen. On thin-layer chromatography on silica gel, it was shown that the compound I gradually underwent a change to another compound. When the compound I had changed completely, the reaction mixture was chromatographed on a silica gel column using a solvent mixture of benzene and *n*-hexane in order to isolate the product. After the solvent had been removed under reduced pressure, the product was recrystallized and identified by means of its IR spectrum and by a determination of melting-point and of a mixed-melting-point with an authentic sample.

Crossover Reaction. An equimolar mixture of I-3 and I-12 was heated in a test tube without any solvent at 230°C for 1 hr under a slow stream of nitrogen. The resulting mixture was then analyzed by thin-layer chromatography on silica gel with a solvent mixture of benzene-*n*-hexane (1 : 1). The chromatograms showed that II-3 and II-10 were produced. However, neither II-4 nor II-7 was detected.

Kinetic Measurements. The rates were followed by the ampoule technique. That is, approximately 30 mg of I was dissolved in diphenyl ether giving a final volume of 5 m*l*. This corresponds to about a 0.02M solution. About 1 m*l* of this solution was then transferred to each of four ampoules. These ampoules were flushed with nitrogen, sealed, and then immersed in a constant-temperature bath controlled to ±0.1°C. Ampoules were taken out from the bath at appropriate intervals and cooled immediately by immersion in cold water. From each run thus obtained, I and II were separated by thin-layer chromatography on silica gel with a solvent mixture of benzene and *n*-hexane and extracted with chloroform. The absorbance at the wavelength of the maximum absorption (Tables 1 and 2) was measured*5 for the compounds thus isolated in order to determine the relative amounts of I and II. In all cases, a plot of the logarithm of C_t/C_0 against the time in sec, where C_t and C_0 are the concentrations of I at time t and time 0 respectively, gave a straight line, indicating the reaction to be of first-order (Fig. 1). The results of a typical kinetic run are illustrated in Table 3. From these data, the rate constants were calculated (Tables 4, 5, and 6).

The author wishes to express his thanks to Professor Aritsune Kaji for his helpful discussions and encouragement throughout the course of this work. He also wishes to thank Dr. Jun-ichi Hayami for his continuing interest and helpful advice.

*5 A Hitachi Perkin-Elmer 139 UV-VIS spectrophotometer was used for the ultraviolet spectrophotometric measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 258—259 (1970)

Phenylation with Phenyl Radical Generated from Phenylazotriphenylmethane

Michio KOBAYASHI, Hiroshi MINATO, Nobuko WATANABE and Nobumasa KOBORI

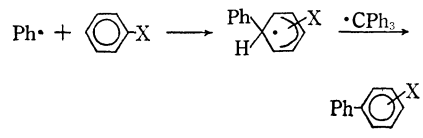
Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

(Received July 25, 1969)

Phenylazotriphenylmethane was decomposed in substituted benzenes, and orientations and partial rate factors for phenylation were determined.

Phenylazotriphenylmethane (PAT) decomposes on heating with evolution of nitrogen to yield phenyl radical and triphenylmethyl radical.[1] Though many investigations have been performed on the reactions of phenyl radicals produced from PAT,[2] no systematic ones on the orientations and the partial rate factors for phenylation by means of PAT have been reported except for a few reports involving limited numbers of substrates.[3] It has long been known that substituted biphenyls are produced when phenyl radical is generated in substituted benzenes,[4] but the details of the mechanism of this homolytic substitution have not been completely clarified yet. Although the absence of kinetic hydrogen isotope effect has been reported for phenylation with *N*-nitrosoacetanilide in contrast with the phenylation by benzoyl peroxide, it has recently been found that kinetic hydrogen isotope effect is observable in the phenylation with phenyl radical produced from benzenediazonium tetrafluoroborate-sodium nitrite, and the importance of the role of a hydrogen abstractor has been pointed out.[5] In view of these findings, it seemed highly desirable to carry out a systematic investigation on phenylation with PAT and to determine whether or not orientations and partial rate factors are different from those of other phenyl radical sources due to the difference in hydrogen abstractors. Such investigation has been performed, and the results will be described in this paper.

$$Ph\text{-}N{=}N\text{-}CPh_3 \rightarrow Ph\cdot + N_2 + \cdot CPh_3$$



Experimental

Benzene and substituted benzenes were purified by the methods described in a previous paper.[6] Ethylbenzene was purified by distillation, bp 131—134°C. The purity of all the aromatic solvents were checked by a Hitachi Gas Chromatograph K53.

Phenylazotriphenylmethane was prepared by the bromine-water oxidation of phenylhydrazotriphenylmethane,[7] which was synthesized from the reaction between phenylhydrazine and triphenylmethyl chloride[8] in ether. Crude PAT was recrystallized from benzene-ethanol, mp 111—112°C (decomp.).

Authentic samples of substituted biphenyls were prepared by the methods described previously.[6]

Results and Discussion

Phenylazotriphenylmethane (PAT) was dissolved in a large excess of a substituted benzene ($PhNO_2$, PhCN, PhCl, PhEt and PhOMe), and the PAT solution was allowed to decompose at 60°C under nitrogen atmosphere. Evolution of nitrogen was almost quantitative and followed a first-order rate equation. The rate constants were about 4.2×10^{-4} sec at 60°C.

Formation of triphenylmethane was almost quantitative, and the total yields of substituted biphenyl isomers were about 50%. The amounts of substituted biphenyl isomers were determined by a Hitachi Gas Chromatograph K53 by use of calibration curves. The orientations and the partial rate factors for phenylation of substituted benzenes by PAT are summarized in Table 1. The partial

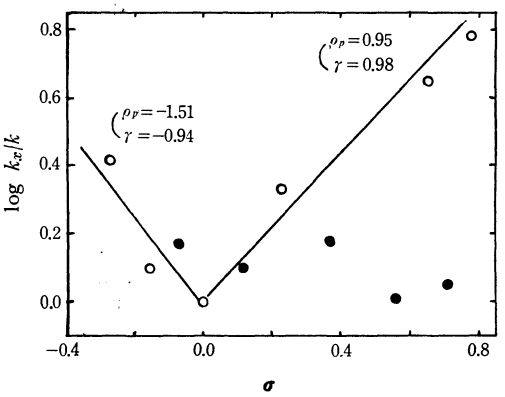

Fig. 1. Hammett plots for phenylation.
—●—: log k_m/k —○—: log k_p/k

rate factors were determined by means of competitive phenylation in a mixture of a substituted benzene and benzene or chlorobenzene as the standard according to the following equation.

$$Ph\cdot + PhH \xrightarrow{k_H} PhPh$$

$$Ph\cdot + PhX \xrightarrow{k_x} Ph\text{-}C_6H_4\text{-}X$$

$$\frac{1}{k_x}\cdot\frac{[PhC_6H_4X]}{[PhX]_0} = \frac{1}{k_H}\cdot\frac{[PhPh]}{[PhH]_0}$$

where $k_H = 6k$

$k_x = 2k_o + 2k_m + k_p$

$[PhX]_0$ and $[PhH]_0$ are the initial concentrations of the aromatic solvents.

When the partial rate factors of meta or para positions were plotted *versus* Hammett's σ values, two straight lines of V-shape were obtained as shown in Fig. 1. The ρ value was −1.51 (correlation coefficient, $\gamma=0.94$) for *p*-substituents of negative σ values and 0.95 ($\gamma=0.98$) for *p*-substituents of positive σ values. Similar V-shape lines were obtained when the partial rate factors of para positions for phenylations with benzoyl peroxide (80°C)[9] or *N*-nitrosoacetanilide (20°C)[10] were plotted *versus* σ values. The ρ_p values obtained for *p*-substituents of negative and positive σ values were −1.42 and 1.14 for benzoyl peroxide at 80°C and −0.39 and 1.27 for *N*-nitrosoacetanilide at 20°C, respectively. The ρ values for PAT and benzoyl peroxide are in fairly good agreement, but the ρ values for *N*-nitrosoacetanilide are quite different from those for PAT and benzoyl peroxide especially with respect to the electron-releasing *p*-substituents. Such difference in the ρ values is probably not ascribable to the difference in temperature. The difference in hydrogen abstractors, the difference in solvents and some other factors are probably responsible for such difference in the partial rate factors. This interesting problem has been currently investigated in our laboratories.

Alkylation of Sodium Dithionite*1

Kuniko Matsuo, Michio Kobayashi and Hiroshi Minato

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo

(Received July 29, 1969)

Reaction between sodium dithionite and triethyloxonium fluoborate under nitrogen yielded an unstable oil capable of absorbing oxygen. When it was washed and distilled under reduced pressure, ethyl ethanesulfinate was obtained. The reaction between sodium dithionite and alkyl iodides in water or in DMSO yielded dialkyl sulfone. The reaction between sodium ethanesulfinate and triethyloxonium fluoborate in dichloromethane yielded an oily mixture which was 89% ethyl ethanesulfinate and 11% diethyl sulfone. The reaction of alkyl iodides with an excess of sodium dithionite yielded, besides a sulfone, sodium alkanesulfonate, not sodium alkanesulfinate. Mechanisms of these reactions were discussed.

Sodium dithionite (sodium hydrosulfite) is a powerful reducing agent, and its aqueous solution reduces oxygen efficiently at room temperature. Though it is a readily available compound, its ester has not been reported in literature. Since dithionite anion is an ambident anion like sulfinate anion, alkylation of sodium dithionite may result in the formation of both *S*-alkylated and *O*-alkylated products. Therefore, alkylation of sodium dithionite has been investigated by use of several alkylating agents in various solvents, and results will be described in this paper.

Experimental

Reaction between Sodium Dithionite and Triethyloxonium Fluoborate. Nitrogen was bubbled through 40 m*l* of dichloromethane, and then 2.204 g (0.0127 mol) of anhydrous sodium dithionite was suspended in the dichloromethane. Under nitrogen atmosphere 4.784 g (0.0252 mol) of triethyloxonium fluoborate was added to the suspension, and the mixture was stirred for 4.5 hr at room temperature. Inorganic salts were filtered, and the filtrate was washed with 100 m*l* of water and dried over anhydrous magnesium sulfate. Dichloromethane was removed by distillation, and ethyl ethanesulfinate was obtained by distillation of the residue at 66°C/30 mmHg. The yield was 0.284 g (0.18 mol per mol $Na_2S_2O_4$ initially present and 0.42 mol per mol $Na_2S_2O_4$ consumed; see below). It was identified by comparison of its infrared and nuclear magnetic resonance spectra with those of the authentic sample.

As a separate experiment a similar mixture of sodium dithionite and triethyloxonium fluoborate was stirred under the same conditions for 4.5 hr, and the inorganic residue was analyzed for sodium dithionite. It was found that 56% of sodium dithionite remained unreacted.

Reaction between Sodium Dithionite and Methyl Iodide. In 25 m*l* of deaerated water 5.046 g (0.0284 mol) of sodium dithionite and 12 g of methyl iodide (0.080 mol) were dissolved, and the mixture was stirred and refluxed (40—50°C) for 105 min under nitrogen atmosphere. The organic components were extracted with dichloromethane, and the dichloromethane solution was dried over magnesium sulfate. Evaporation of the solvent yielded crystals of dimethyl sulfone; 0.24 g (9%), mp 105.5—106.0°C.

Reaction between Sodium Ethanesulfinate and Triethyloxonium Fluoborate. Pure sodium ethanesulfinate was prepared by alkaline hydrolysis of ethyl ethanesulfinate, which was synthesized from ethanesulfinyl chloride and ethanol.[1] It was dried in vacuum at 120°C.

To 3.130 g (0.0270 mol) of dried sodium ethanesulfinate, 30 m*l* of a dichloromethane solution containing 5.48 g (0.0290 mol) of triethyloxonium fluoborate was added, and the mixture was stirred for 5 hr at room temperature. Inorganic solids were filtered, and the filtrate was washed with water and then dried over magnesium sulfate. Evaporation of dichloromethane yielded an oil which was identified by its infrared spectrum to be a mixture of ethyl ethanesulfinate and diethyl sulfone. The yield was 2.35 g (0.70 mol per mol of sodium ethanesulfinate). The amounts of the two components were determined by use of the absorption at 890 cm^{-1} for the ester (ε=222) and the absorption at 1320 cm^{-1} for the sulfone (ε=748). The molar ratio of the ester and the sulfone was found to be 88.7 : 11.3.

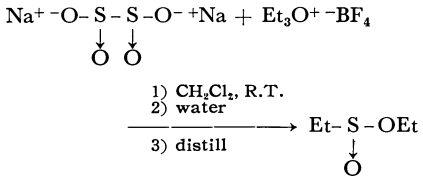
Results and Discussion

When sodium dithionite and triethyloxonium fluoborate were stirred in dichloromethane at room temperature for 4.5 hr and then the solvent was removed, an oily residue was obtained, which was capable of absorbing oxygen. Attempts to crystallize the residue failed, and distillation under reduced

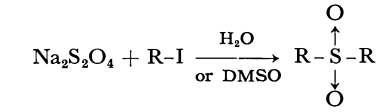
*1 Part XVIII of Organic Sulfur Compounds.

1) E. J. Corey and T. Durst, *J. Amer. Chem. Soc.*, **90**, 5550 (1968); I. B. Douglass, *J. Org. Chem.*, **30**, 634 (1965).

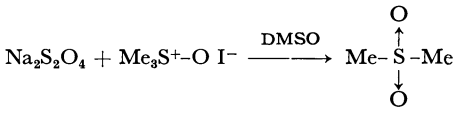
pressure did not yield identifiable products. However, when the oil was washed with water and then distilled under reduced pressure, ethyl ethanesulfinate was obtained in 42% yield (on the basis of the sodium dithionite consumed). Thus, this reaction is regarded as a one-step synthesis of ethyl ethanesulfinate.



When methyl iodide was refluxed with sodium dithionite in water or in 20% methanol-water or in dimethyl sulfoxide, dimethyl sulfone was the only product. From ethyl iodide diethyl sulfone was obtained under similar conditions. When trimethylsulfoxonium iodide was stirred with sodium dithionite in dimethyl sulfoxide at 60°C, dimethyl sulfone was obtained.



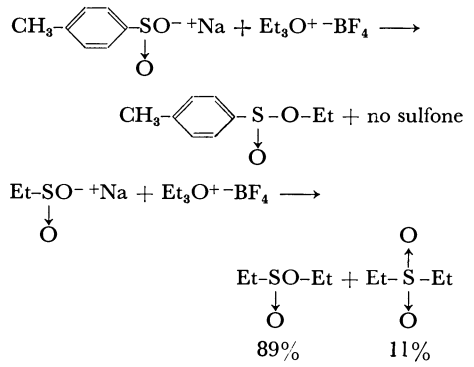
(R = Me or Et)



The findings that a powerful alkylating agent ($Et_3O^+-BF_4$) can attack oxygen atoms while weaker alkylating agents (RI, $Me_3S^+O\ I^-$) can react only with sulfur atoms are in line with the results obtained for alkylation of sodium *p*-toluenesulfinate.[2]

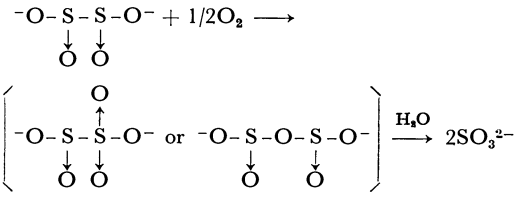
It should be mentioned that anhydrous sodium dithionite is extraordinarily insoluble in organic solvents. It is insoluble not only in non-polar organic solvents but also in such polar solvents as acetonitrile, dimethyl sulfoxide, *N,N*-dimethylformamide, hexamethylphosphoramide, nitromethane, acetone and alcohols.

It was previously reported that *O*-alkylation takes place exclusively when sodium *p*-toluenesulfinate was treated with triethyloxonium fluoborate in dichloromethane.[3] However, there have been no reports describing a similar reaction with sodium alkanesulfinate. When sodium ethanesulfinate was stirred with triethyloxonium fluoborate in dichloromethane for 5 hr and then the solvent was evaporated, the residual oil was found to be composed of 89% ethyl ethanesulfinate and 11% diethyl sulfone. This difference in the reactivities of arenesulfinate



anion and alkanesulfinate anion may be ascribable to the delocalization of the lone pair on sulfur due to the resonance involving benzene ring in the case of arenesulfinate anion and to the lack of such delocalization in the case of alkanesulfinate anion.

No quantitative determinations have been reported as to the absorption of oxygen by a sodium dithionite solution. When sodium dithionite was dissolved in deaerated water and then a measured amount of oxygen was introduced, it was found that half a mole of oxygen was absorbed per mole of sodium dithionite. The reaction is probably expressed as follows.



When sodium dithionite and triethyloxonium fluoborate were stirred in dichloromethane and then the solvent was evaporated, the oily residue obtained was capable of absorbing oxygen. It is possible that this mixture contained diethyl dithionite, though attempts for its characterization did not succeed.

As for the mechanism of the reaction between sodium dithionite and triethyloxonium fluoborate, various routes are possible such 1) *O*-alkylation twice, 2) *O*-alkylation followed by *S*-alkylation, 3) the reverse of 2), 4) *S*-alkylation twice, *etc.* Since no sulfone was found as a product and diethyl sulfone was a product from the reaction between the triethyloxonium salt and ethanesulfinate anion, the mechanisms involving ethanesulfinate anion as a chief intermediate can be excluded. Since no α-disulfone was found and the hydrolysis of an α-disulfone yields ethanesulfinate anion,[4] the possibility 4) can be excluded. Possibilities 2) and 3) would yield ethyl ethoxysulfinyl sulfone, which does not appear to be capable of absorbing oxygen,

2) J. S. Meek and J. S. Fowler, *J. Org. Chem.*, **33**, 3422 (1968).

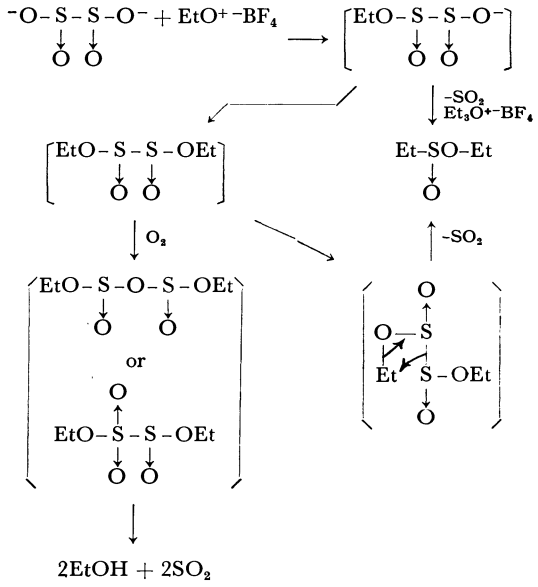
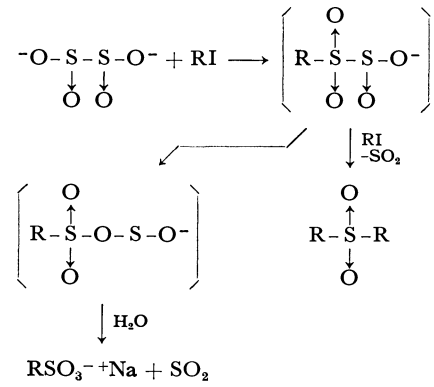
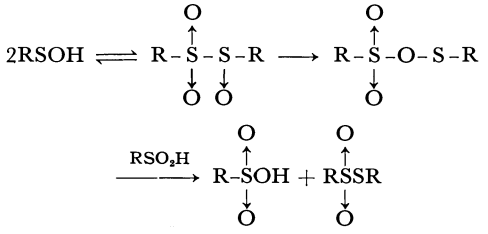
nor to yield ethyl ethanesulfinate upon further reaction. On the basis of various findings and considerations, the following mechanism appears to be most plausible.



The reaction between sodium dithionite and alkyl iodides probably involves alkanesulfonylsulfinate anion as an intermediate. In order to check whether or not an alkanesulfinate anion is formed as an intermediate, 5 mol of sodium dithionite were treated with a mole of ethyl iodide in water under nitrogen. Evaporation of water and extraction with ethanol yielded sodium ethanesulfonate, and no soidum ethanesulfinate. In several experiments with sodium dithionite and alkyl iodides, yields of sulfones were always low and usually less than 9%. The formation of sodium alkanesulfonate and the low yields of sulfones may be explained by the following scheme.



The intermediate alkanesulfonylsulfinate resembles alkyl alkanesulfinyl sulfone studied by Kice and his co-workers, who established that a sulfinylsulfone homolytically decomposes and the combination of the radicals formed yields sulfonyl sulfenyl anhydride.[5]



Grateful acknowledgement is made to the donors of the Petroleum Research Fund, administered by the American Chemical Society, for support of this research.

Ultrasonic Study of Molecular Compounds of Oxalic Acid with Urea, Thio-urea and Allyl-thiourea

Sheo PRAKASH, Om PRAKASH and C. V. CHATURVEDI

Chemical Laboratories, University of Allahabad, Allahabad-2, India

(Received March 13, 1969)

Urea is known to form an inclusion compound with a few dicarboxylic acids, such as oxalic acid. The work has been extended to ascertain the formation of such compounds with thiourea and allyl thiourea by measuring the ultrasound velocity in the aqueous medium and the present note deals with such study.

A suitable optical glass-cell[1] was designed for keeping the solution and with the help of the filter, the light of wavelength 3656.71 Å from a mercury vapour lamp was allowed to fall at right angles to the path of ultrasound waves. As shown by Debye and Sears[2] ultrasound waves traversing a liquid set up a periodical inhomogeneity which acts as an optical grating. The diffraction pattern was photographed on orthochromatic AGFA plates and the distance between fringes was measured by a comparator.

The source of ultrasonic power was a generator having a gold plated circular quartz crystal 1″ in diameter as transducer. The 0.1M solution of oxalic acid, urea, thiourea and allyl thiourea were prepared in double distilled water. All reagents were A. R. grade. Mixtures of various composition were prepared by adding to fixed volume of oxalic acid, different volumes of urea, thiourea and allyl thiourea solution and then the total volume was raised to 50 m*l*. In each case photographs for the diffraction pattern of the solutions were taken at 25° ± 0.1°C. The density of each mixture was measured just after the velocity measurement with the help of density bottle. Adiabatic compressibility of each mixture was calculated using the equation $\beta=1/V^2\rho$ where V is the ultrasonic velocity and ρ the density of the solution. Compressibility lowering values of mixtures were obtained by subtracting the compressibility of mixtures from the compressibility of water which is 44.04 $cm^2/dyne \times 10^{12}$. The probable errors involved in the measurement of the ultrasonic velocity and compressibility are 0.15 and 0.4 per cent respectively.

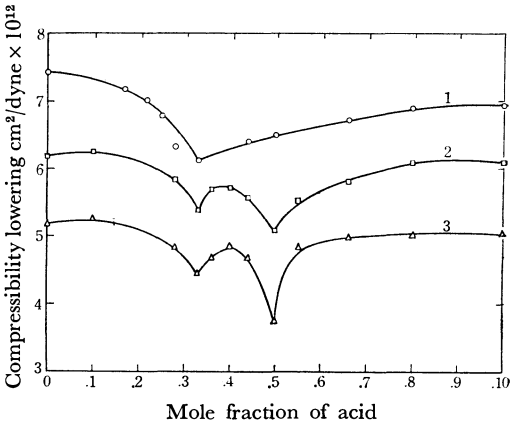

Fig. 1. Variation of compressibility lowering with composition at fixed temperature mixtures are equi-molar (0.1M).
1. Urea+Oxalic acid, 2. Allyl thiourea+Oxalic acid 3. Thio-urea+Oxalic acid

From the figure, it is observed that in each case the sound velocity and compressibility lowering decreases at first with increase in mole fraction of oxalic acid, it passes through a minimum and then increases. In case of urea a break is obtained at 1-oxalic acid - 2- urea composition in conformity with the result of Radell and Brodman,[3] while in the other two there are two breaks, one corresponding to 1 : 1 and the other to 1 : 2. The minima in the curves indicate the stoichiometry in which the reactant interact and thus they exhibit the composition of the compounds formed.

Study of Raman Spectra of Complex Halide Anions of Mercury(II) in Solution

J. R. SARAF, R. C. AGGARWAL and J. PRASAD

Lucknow University, Lucknow, India

(Received April 2, 1969)

From a study of Raman spectra, Delwaulle[1-3] obtained evidence for the existence of mixed halide complex anions $[HgI_nCl_{4-n}]^{2-}$ and $[HgI_nBr_{4-n}]^{2-}$, but she failed to get definite evidence for the corresponding complex anions containing bromide and chloride. Woodward and co-workers[4] confirmed the formation of complex anions $[HgI_nBr_{4-n}]^{2-}$. Aggarwal[5] estalbished the existence of the complex anion $[HgCl_2Br_2]^{2-}$ from physico-chemical studies of the system $HgCl_2$-KBr-H_2O.

The aim of the present work is to investigate the formation of mixed halide (Cl^- and Br^-) complex anions of mercury(II) with the help of Raman spectra.

TABLE 1. $[HgCl_2:KCl=1:2]$-KBr-H_2O SYSTEM

Solution No.	Relative concentration			$\Delta\nu$ cm^{-1}	Intensity (visual)
	$[Hg^{II}]$	$[Cl^-]$	$[Br^-]$		
1	1	4	0	270	s
2	¼	4	0	272	s
3	¼	3⅞	⅛	270	s

11	¼	1¼	2¾	183	s
12	¼	1	3	182	s
13	1	0	4	170	s

The solutions corresponding to Table 1 were prepared by dissolving different amounts of KBr in solutions containing $HgCl_2$ and KCl always in the molar ratio $\geqslant 0.5$. The Hg^{II}/(Halide) ratio was kept constant at 1/16 in all the solutions except solution Nos. 1 and 15. This ratio was selected to enable us to observe the changes in the Raman shifts due to successive replacement of Cl^- by Br^- from the complex $[HgCl_4]^{2-}$ on the progressive addition of KBr.

From the table it is seen that with a gradual increase in the ratio Br^-/Cl^-, hereinafter to be represented by x, the shift due to $[HgCl_4]^{2-}$ ($x=0$), is lowered in value. These results may be explained by assuming that Br^- ions take part in the formation of mixed halide species and thus the shift in the position of maximum intensity to a lower value is, presumably, due to the successive replacement of chloride ions by bromide ions.

The solutions corresponding to Table 2 were prepared by dissolving varying quantities of KBr

in solutions containing $HgCl_2$ and KCL always in 1 : 1 molar ratio. In a solution No. 1, with $x=0$, two lines are observed corresponding to $[HgCl_3]^-$ and $HgCl_2$ in agreement with the observations of earlier workers.[6] The intensity of these lines decreases with increasing value of x (soln. 1 to 4). With further increase in the value of x, Raman shifts are obtained at lower $\Delta\nu$ values which are more or less similar to those observed in the solutions of Table 1 containing Hg^{2+}, Br^- and Cl^- ions. The similarity of the Raman shifts observed in solutions of Tables 1 and 2 suggests the formation of similar mixed halide anions in the two different series of solutions.

A comparison of the results of Tables 1 and 2 further shows that the position of maximum intensity falls to a minimum value of 183 cm^{-1} in Table 1 as against 175 cm^{-1} in Table 2. This suggests that the Cl^- ions are more labile in the complex anion $[HgCl_3]^-$ as compared to $[HgCl_4]^{2-}$. The greater lability of $[HgCl_3]^-$ enables the formation of mixed halide complexes of Hg^{II} in which the number of the Br^- ions appears to be greater than those formed from $[HgCl_4]^{2-}$.

Another series of solutions was prepared by dissolving varying amounts of KCl in solutions containing $HgBr_2$ and KBr always in 1 : 1 molar ratio. When $x=0$ a line 183 cm^{-1} corresponding to the complex anion[7] $[HgBr_3]^-$ is obtained. With the addition of Cl^- ions this line shifts gradually to a minimum value 175 cm^{-1} when $x=1/7$. Since the bromo complexes of Hg^{2+} are more stable than the corresponding chloro complexes, the replacement of Br^- ions by Cl^- ions is not favoured and hence the observed shifts to lower $\Delta\nu$ side produced on addition of Cl^- ions to $[HgBr_3]^-$ ions can only be due to formation of a four-coordinated complex of Hg^{2+} *viz.* $[HgBr_3Cl]^{2-}$.

The fourth series of solutions was prepared by dissolving $HgCl_2$ and KBr in different molar proportions *viz.* 1 : 2, 1 : 3, 1 : 4 and 1 : 6. In 1 : 2 solution two strong lines at $\Delta\nu$ 191 and 270 cm^{-1} are observed. The shifts at 270 may be attributed to the anion $[HgCl_4]^{2-}$ while the other at 191 cm^{-1} is, in all probability, due to the mixed halide complex anion formed in solutions.

It is interesting to note that in all the series of solutions except that in Table 1 the minimum shift is almost the same indicating the existence of similar species in these solutions at some state.

Our observations compare favourably with those made by Delwaulle and Woodward from a study of mixed halide complex anions of mercury(II). We find that the shifts, in each series, lie between the $\Delta\nu$ values of $[HgCl_4]^{2-}$ and $[HgBr_4]^{2-}$ suggesting the formation of mixed halide complex anions as shown below:

	$[HgCl_4]^{2-}$	increasing Br^-/Cl^-	$[HgBr_4]^{2-}$
$\Delta\nu$ (cm^{-1})	270	255 ⟶ 176	170

With the increasing Br^-/Cl^- ratio anions likely to be formed are $[HgCl_4]^{2-}$, $[HgCl_3Br]^{2-}$, $[HgCl_2Br_2]^{2-}$, $[HgClBr_3]^{2-}$ and $[HgBr_4]^{2-}$— the shifts decreasing in the order given. Broadness of the lines in many cases suggests the simultaneous existence of more than one complex anion in solution. The position of maximum intensity corresponds to the species present in relatively greater concentration.

The authors wish to express their grateful thanks to Dr. B. G. Gokhale, Professor and Head of the Physics Department, Lucknow University for providing all possible facilities and for his keen interest in the progress of the work.

Action of Pyridine upon Organotin Compounds of the R_2SnO–SnR'_2X_2 Mixed Type

Taichi HARADA*1

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received April 7, 1969)

In a previous paper, the author[1] reported various new organotin complexes of the mixed type R_2SnO–SnR'_2X_2. The position of halogens have not been determined and the problem whether these complexes are monomeric or polymeric in the solid state remains to be solved. The present investigation was performed in order to obtain further information regarding the chemical structure.

Experimental

$(Me_2SnO)_2$–$SnMe_2Cl_2$, by adding pyridine in water, gave Me_2SnO and pyridine hydrochloride. The same products were obtained from Me_2SnO–$SnMe_2Cl_2$ in aqueous and alcoholic solutions. Et_2SnO–$SnMe_2Cl_2$ gave a mixture of Et_2SnO, Me_2SnO and pyridine hydrochloride.

However, Me_2SnO–$SnMe_2Cl_2$,[3] Et_2SnO–$SnMe_2Cl_2$[1] and n-Bu_2SnO–$SnMe_2Cl_2$,[1] in benzene or petroleum ether, gave the pyridine complex. This compound was identical with Me_2SnCl_2–$2NC_5H_5$ obtained from Me_2SnCl_2 and pyridine in benzene, which was confirmed by comparison of both infrared spectra shown in Fig. 1 and the melting point (163°C).[4,5,6b] Et_2SnO–$SnEt_2Cl_2$ reacted with pyridine giving mainly Et_2SnCl_2–$2NC_5H_5$ (1.0 g of the sample gave 0.55 g of crystals, mp 135°C), which was identical with that obtained from Et_2SnCl_2 and two moles of pyridine. This was confirmed by infrared spectrum shown in Fig. 2 and the melting point (135°C).[5] In the case of n-Bu_2SnO–Sn n-Pr_2Cl_2, n-Pr_2SnCl_2–$2NC_5H_5$ (mp 114°C)[5] was obtained, on the contrary $H(Et_2SnO)_3OH$–$SnEt_2Cl_2$ was not reacted with pyridine.

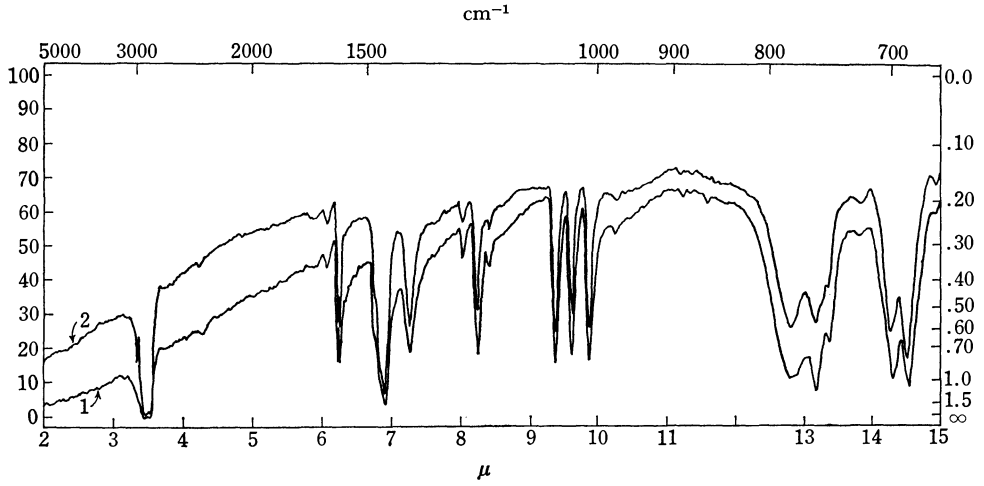

Fig. 1. Infrared spectra of Me_2SnCl_2–$2NC_5H_5$.
1. Obtained from Me_2SnCl_2 and pyridine
2. Obtained from Et_2SnO–$SnMe_2Cl_2$ and pyridine

4. Obtained from Et_2SnO–$SnEt_2Cl_2$ and pyridine

Results and Discussion

From the results it is concluded that the complex $R'_2SnX_2 \cdot 2NC_5H_5$ is formed according to the following reaction.

$$R_2SnO \cdot SnR'_2X_2 + 2NC_5H_5 = R'_2SnX_2 \cdot 2NC_5H_5 + R_2SnO.$$

This reaction is very important for the investigation of the positions of halogens. The erroneous structure for Et_2SnO–$SnEt_2Cl_2$ in question is a linear structure, $ClEt_2Sn$–O–$SnEt_2Cl$, proposed by Pfeiffer and Brach,[6a] or a dimeric form, proposed by Brown, Okawara and Rochow,[3] and by Okawara and Wada.[7] The former structure should take up two moles of pyridine to form $ClEt_2Sn\cdots O\cdots SnEt_2Cl$, or should not take up any
$\quad\quad\quad

Thus the question has not been settled only by means of molecular weight determination. If the formation of the compounds $R_2SnO\text{-}SnR'_2X_2$[1,13] and $R_2SnO\text{-}SnR_2X_2$ is considered as a result of the pyridine complex formation, the structure of the compound in question should take $Et_2SnO\cdot SnEt_2X_2$ linking (or less probably its polymer), rather than $XEt_2Sn\text{-}O\text{-}SnEt_2X$ (or its polymer). On the other hand, the compound $R°(R_2SnO)_3\text{-}OR°\text{-}SnR'_2X_2$ ($R°$ = alkyl of solvent alcohol or H of water)[1] takes the form $R°OR_2Sn\text{-}O\langle{}^{SnR_2}_{SnR'_2X_2}\rangle O\text{-}SnR_2OR°$ at first, and then gradually turns to a stable form $R°OR_2Sn-O\langle{}^{SnR_2X}_{SnR_2'X}\rangle O-SnR_2OR°$ by the migration of one of the halogens, since this type compound does not yield the pyridine complex but indicates free OH stretching band[14] in the case ($R°=H$).

The author wishes to thank Dr. Yonezo Morino, Emeritus Professor, the University of Tokyo, for his interest and encouragement throughout this work. Thanks are also due to members of the Second organic chemistry laboratory, the Institute of Physical and Chemical Research, for the measurements of infrared spectra.

An Electron Spin Resonance Study of the Anion Radicals of 2,1,3-Benzoselenadiazole and Related Compounds

Mamoru KAMIYA and Yukio AKAHORI

Shizuoka College of Pharmacy, Oshika, Shizuoka

(Received April 10, 1969)

In the course of several recent ESR studies[1,2] of the aromatic anion radicals containing selenadiazole- or thiadiazole-ring little has been established about the effects of the preparation conditions on the spin distribution or about the electronic situation of the selenium atom. In the present work the titled anion radicals have been prepared first by metal reductions in several solvents at low temperatures. The solvent effect on the nitrogen hyperfine splitting constants is discussed in terms of a meso-ionic structure associated with the present compounds. Also, a few remarks are given about the possibilities of *p*- and *d*-orbital models for the selenium atom using information about the experimental hydrogen hyperfine splitting constants.

Experimental

The ESR measurements were done with a JES-3BS-X-type spectrometer with 100 kc/sec field modulation at −60—+20°C. The line separations were checked by referring to the spectra of an aqueous solution of peroxylamine disulfonate. The *g*-values were determined with a sample marker of Mn^{2+} in MgO. The anion radicals were prepared by a standard technique of metal reduction. Solvents used (THF, DME, DMF, THP, and Me-THP) were all obtained from the Merck Co. and were carefully dried by the usual methods. The 2,1,3-benzothiadiazole[3] and -benzoselenadiazole[4] were synthesized by reactions of *o*-phenylenediamine with thionyl chloride and selenium dioxide respectively. The 2-methyl-2,1,3-benzotriazole was obtained by the reaction of benzotriazole with diazomethane.[5] The compounds were purified by repeated sublimations under a high vacuum.

Results and Discussion

The instabilities of the former two anion radicals are predicted by the active metalation reactions as has been reported previously.[6] In fact, the hyperfine spectra of benzothiadiazole and benzoselenadiazole anion radicals could be observed only below a temperature of −40°C; at room temperature the sample solutions allowed to come in contact with a metal mirror readily yielded intensely-coloured solutions (purple in the former

and yellow in the latter) which showed rather asymmetric singlets with $g=2.004_0$—2.004_5 and $\Delta Hmsl=15$—20 gauss. This suggests the existence of more than one radical species although the existence of only one mono-negative radical species has been suggested from a study of the absorption spectrum of the metal-reduced benzoselenadiazole solution in THF.[7] 2,1,3-Benzoxadiazole produced no ESR signals in metal reduction; it simply showed a colour-change to dark green.

Some of the spectra are illustrated in Fig. 1, while the hyperfine splitting constants determined from the spectra are summarized in Table 1. The results indicate the noticiable facts that, as for benzothiadiazole and benzoselenadiazole, a decrease in a^N and a concurrent increase in the sum of a^H take place in the sequence of; DMF$<$THF$\approx$DMF$<$THP$\approx$Me-THP, although both a^N and a^H are not much affected by the cation species and no metal splittings are detected in any case.

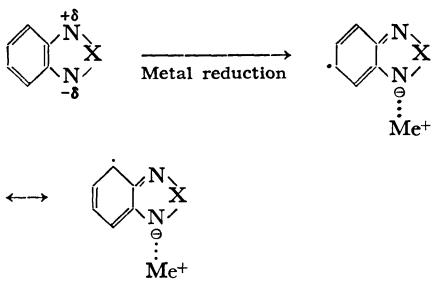
	HMO	ρ	0.029	0.281	0.073	0.068	0.063
	McLachlan	ρ	0.030	0.325	0.054	0.055	0.051

Accordingly, it may be assumed that there exists a specific solvent effect giving rise to a decrease in the nitrogen spin density followed by an increase in the nitrogen electronegativity. A probable explanation of the current effect is that, because of the meso-ionic structure associated with these compounds, the above tendency is more promoted in a solvent with less ability at solvating cations according to the resonance structures of the anion radicals which enable a selective electrostatic interaction between the nitrogen and the metal cation as shown below.



The effects of temperatures on the hyperfine splitting constants appeared to be somewhat complex as a result of the variations in the line-width.

Meanwhile, we found that the spectrum of the benzoselenadiazole anion radical has a pattern very similar to that of 2-methyl-2,1,3-benzotriazole, as is illustrated in Fig. 1 (b) and (c). This indicates that the replacement of the selenium atom with the *N*-methyl group has little effect on the spin distribution. Hückel- and McLachlan-calculations of spin densities based upon a *p*-orbital model for the selenium atom yielded the values of $h^{\cdot\cdot}_{Se}=1.0$—1.1 and $k_{SeN}=0.2$—0.3 as the optimum parameters for reproducing an equal spin density of the four ring carbons. It should be noted here that these parameters do not reflect the solvent effect on the nitrogen hyperfine splitting constant since the equality of the four a^H values holds in various solvents. (In the McLachlan calculation the λ-value involved in a corrected Coulomb integral, $\alpha_r(\alpha_r=\alpha^\circ_r+2\lambda\rho^\circ_r\beta)$, was taken to be 1.2, while $h^{\cdot}_N$ and k_{CN} were fixed as the well-accepted values of $h^{\cdot}_N=0.5$ and $k_{CN}=1.0$.) The spin- and electron-densities calculated with the optimum parameters are given in Table 2.

By comparing the current results with those for benzothiadiazole,[2] we can conclude that the conjugation of the nitrogen atom with an adjacent carbon atom is greater in benzoselenadiazole; this conclusion indicates that, as has previously been mentioned, if a major contribution to the hybrid

structure contains a meso-ionic form with oppositely-charged nitrogens, this form should be more associated with benzoselenadiazole because the exchange of the nitrogen charges is essentially intermediated by the C–C conjugated bonds between the two nitrogens. This assumption is in harmony with the observed reactivities in mono-nitrogen quarternisation[9] (benzoselenadiazole>benzothiadiazole), which can be activated by the presence of negatively-charged nitrogen.

A *d*-orbital model accepted for the sulfur atom[2] was also tested; the optimum parameters were found to be $h_{Se}=0.1-02.$, $k_{NSe}=0.05-0.07$, and $k_{SeSe}'=1.0$. However, this model seems to be unreasonable, as has been indicated in dibenzoselenophene,[10] in part at least because of a too small k_{NSe} value as compared with k_{NS} (=0.8) in benzothiadiazole.[2]

Coordination Chemistry of Lanthanide Elements. I. Complexes of Trivalent Lanthanide Halides with Trimorpholino Phosphine Oxide

J. T. DONOGHUE and E. FERNANDEZ[1)]

Department of Chemistry, University of Arkansas, Fayetteville, Arkansas, U. S. A.

(Received May 10, 1969)

In previous papers we have reported on complexes of lanthanides[2,3)] and transition metals[4)] with phosphoryl donors. The ligand hexamethyl phosphoramide $O=P[N(CH_3)_2]_3$ has been found to form two series of lanthanide complexes: $LnCl_3 \cdot 3HMPA$ and $Ln(ClO_4)_3 \cdot 6HMPA$ in which the coordination number was found to be six. This coordination number, although not unique for lanthanides, is sufficiently unusual to be of interest. For hexamethyl phosphoramide complexes, it was concluded that the steric requirements of the amide molecule were of prime importance in directing the coordination number of six for the lanthanides. The steric requirements of the amide are such as to obscure the natural tendency for coordination number to decrease from left to right in the lanthanide series. In this paper we report complexes of lanthanide halides with trimorpholino phosphine oxide.

Experimental

Preparation of Compounds. 0.001 mol of anhydrous lanthanide halide was dissolved in 25 m*l* of hot absolute alcohol. A solution of 0.003 mol of trimorpholino phosphine oxide in 25 m*l* of hot absolute ethanol was prepared. These solutions were mixed together and allowed to stir until cool. All reactions were carried out in a nitrogen atmosphere. After cooling, 75 m*l* of absolute ether were added to the solutions to complete precipitation. The solids were filtered under nitrogen and washed five times with 10 m*l* portions of cold, absolute ether. The dried solids were stored *in vacuo* over H_2SO_4. Analytical data for the ligand and its complexes are reported in Table 1.

Conductivity Measurements. Conductivities of nitromethane solutions of the complexes were obtained using an Industrial Instruments Inc. conductivity bridge which had been previously calibrated with 0.01N KCl solution. The results are summarized in Table 1.

Spectral Measurements. Infrared spectra for the free ligand and its complexes were obtained using a Perkin-Elmer 337 spectrophotometer. The results for the phosphoryl stretching frequency $\nu_{P=O}$ of trimorpholino phosphine oxide and its complexes are reported in Table 1.

Reagents. Trimorpholino phosphine oxide was obtained from Aldrich Chemical Co. and was used without further purification. Analytical data are given in Table 1.

Lanthanide halides were obtained from American Potash and Chemical Corporation and were 99.9+% pure and were used without further purification.

All other chemicals used in this study were reagent grade.

Results. Analytical, conductivity, and infrared spectral data are summarized in Table 1.

Discussion

All of the complexes studied were found to be quite hygroscopic and it was necessary to perform most operations with the exclusion of air. No attempts were made to record melting points for these complexes. The colors of the complexes were found to be essentially the same as those of the anhydrous chlorides.

The analytical data (Table 1) suggest that the complexes may be formulated as $LnCl_3 \cdot 3L$ (L=trimorpholino phosphine oxide, O=P- $[N\langle^{CH_2CH_2}_{CH_2CH_2}\rangle O]_3$). No tendency to reduction of coordination number in progressing across the lanthanide series with decreasing crystal radius of the lanthanide ions was exhibited.

Infrared spectra of mulls of the ligand and its complexes were obtained and interpreted in terms of the location of the phosphoryl stretching frequency, $\nu_{P=O}$, of the ligand. The phosphoryl frequency (Table 1) was found to decrease on coordination in every case. Reductions are on the order of 15—20 cm^{-1}. This is taken as evidence that the site of coordination in the ligand is at the phosphoryl oxygen of the ligand. These shifts, though not as large as those noted for transition metal complexes,[4] are in the same direction as those noted for transition metal complexes.

Conductivities of the complexes in nitromethane solutions suggest that the species are non-electrolytes in nitromethane and accordingly must contain coordinated halide ion. The species may be thus formulated as $[LnCl_3L_3]$ species.

The data presented may be collectively interpreted to infer that in these lanthanide complexes of trimorpholino phosphine oxide, the coordination number of the lanthanides is six for all cases studied. This is in agreement with results obtained when the ligand is hexamethyl phosphoramide[2,3] or diphenyl sulfoxide.[5]

The most common coordination numbers exhibited by lanthanides in complexes containing monodentate ligands are eight and seven.[6-8] With hexamethyl phosphoramide as ligand, in the

complexes $LnCl_3 \cdot 3HMPA$ and $Ln(ClO_4)_3 \cdot 6HMPA$, it was possible to interpret the failure of the lanthanides to achieve apparent maximum coordination numbers higher than six, as due to the steric requirements of the ligand itself.[2,3] However, for trimorpholino phosphine oxide the situation may involve other factors. In complexes of triphenylphosphine oxide, whose steric requirements are similar to those of trimorpholino phosphine oxide, coordination numbers higher than six have been found in derivatives of the type $LnX_3 \cdot xL$. It might be expected that trimorpholino phosphine oxide would exhibit similar behavior, but it does not. Clearly some factor other than ligand steric requirement is involved in determination of coordination number in lanthanide complexes of trimorpholino phosphine oxide.

The Preparation of Niobium Stannide by the Iodide Process

Takeshi KAWAI and Shiro IWATA

Research Reactor Institute, Kyoto University, Kumatori-cho, Sennan-gun, Osaka

(Received May 31, 1969)

Nb_3Sn has been prepared by various methods[1,2] because of its good characteristics as a superconductor. This paper will describe the applicability of the iodide process, one of the chemical transport reactions, to the preparation of Nb_3Sn.

Experimental

A Sintered Source Material. About 10 g of a blend of a stoichiometric mixture of Nb and Sn powder*1 was divided into 10 parts; pellets (6 mmϕ × 8 mm) were then made under a pressure of 3×10^3 kg/cm^2. These pellets were sintered at 1000°C for 10 hr in a flow of Ar gas at a flow rate of 2 *l*/min.

The Iodide Process. To carry out the closed-tube transport experiment, fused silica tube (0.8 cm in int. diam., 0.015 cm in wall thickness, and 20 cm in length) containing the source material and a known amount of the transport agent, iodine,*2 was sealed off after evacuating and out-gassing treatment.

This reaction tube was placed in a horizontal tube furnace, which was so designed that the reaction region (5 cm) of this closed system could be uniformly heated at 900°C, and the deposition region (5 cm), at 1000°C. The transport region (10 cm) between the reaction and deposition regions had a linear temperature gradient.

We obtained a thin layer of Nb_3Sn deposited on the silica tube wall at a rate of 0.3 mg/hr.

The chemical compositions of the Nb_3Sn was determined by X-ray fluorescence spectrometric and chemical analytic methods.[1] In the chemical method, the niobium was determined as niobium pentoxide, Nb_2O_5; after volatilizing the tin as its bromide, the tin was determined iodometrically. In the X-ray spectrometric method, a ratio method was employed in which the net intensities of the X-ray spectral lines of niobium and tin were measured and their ratio calculated. The purity of Nb_3Sn was 70.0±0.2 wt% Nb, 29.6±0.3 wt% Sn (Calcd, Nb, 70.13 wt% Sn, 29.87 wt%).

The X-ray powder diffraction pattern yielded a lattice constant of 5.3 Å for vapor-deposited niobium stannide with a β-tungsten structure.

Results and Discussion

(1) Effects of the Stoichiometry of the Sintered Source Material. The weight ratio of Nb to Sn in the source materials influences the stoichiometry of the deposits. The composition of deposits as a function of the weight ratio of Nb to Sn in the materials is shown in Fig. 1. As a general tendency, the ratio of Nb to Sn in deposits increases with an increase in this ratio in the materials.

These results may be attributed to the fact that the free-energy changes of Nb and Sn iodides are different; also, Nb and Sn show different reactivities for I_2 molecules because of their differences in intermolecular forces between the gaseous iodine molecules and each atom of the material.*3

The dispersion of data results from the following

1) R. S. Holmes, *RCA Rev.*, **25** (1964).

2) T. L. Chu and J. R. Gavaler, *J. Electrochem. Soc.*, **113**, 1289 (1966). Von H. J. Bode, R. G. Maier and G. Wilhelm, *Z. Naturforsch.*, **19a**, 804 (1964).

*1 Nb and Sn powder were obtained from Mitsuwa Pure Chemicals, Ltd., and Wako Pure Chemicals, Ltd., respectively, and their purity were 99.5% as given by producer.

*2 The iodine was vacuum distilled from the capsule into the reaction tube.

*3 T. Kawai (to be published).

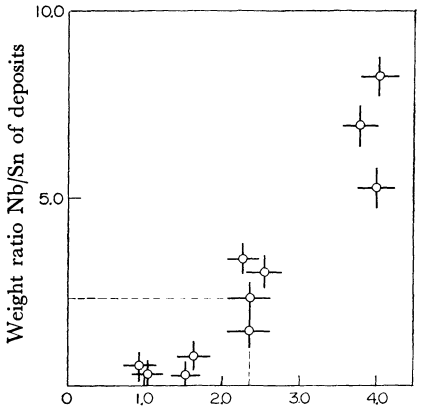

Fig. 1. Effects of the stoichiometry of the sintered source material.

reasons: 1) a small amount of Sn on the surface of these pellets evaporated for sintering because of its volatility, and 2) the mixture was not blended uniformly.

This problem should be resolved by pulverizing these sintered pellets again and using this powder as a source material. However, it is evident that, to obtain a stoichiometric Nb_3Sn, it is necessary to maintain a Nb/Sn ratio of approximately 2.4 in the source materials.

(2) Effects of the Initial Amount of a Transport Agent.[3] The dependence of the transport rate upon the initial amount of the agent, I_2, is depicted in Fig. 2.

In the small-amount range of I_2, the transport rate is approximately proportional to the square root of the concentration.*3 In this range, it may be supposed that the heterogeneous chemical reaction in the reaction region is the rate-determining step.

Above 1.5×10^{-5} mol/cm^3, the transport rate is very litttle dependent on the amount of I_2, because the diffusion rate of gaseous iodides determines the total kinetic rate of the iodide process. We are, therefore, able to obtain the glossy Nb_3Sn deposited on a silica tube wall in this range.

Above 5×10^{-5} mol/cm^3, the natural convection of gaseous iodides may be attributed to the transport rate, and the quantity deposited increases rapidly, but the deposit is a powder and does not have uniform properties.

(3) Other Important Problems. When we apply the iodide process or, in general, the chemical transport reaction to the deposition of the Nb_3Sn film on various substrates, there are other important problems besides the two effects pointed out previously.

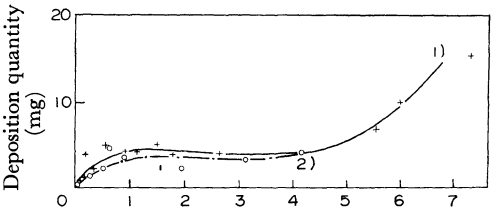

Fig. 2. Effects of the initial amount of a transport agent.

	the temp. of the react. region. °K	the temp. of the deposit. region. °K	a transport length. cm
1) (+)	1173	1273	10
2) (○)	1173	1223	7

The preparing conditions of the pellets.

	pressure kg/cm^2	sintering times hr	sintering temp. °C
1)	$1-3\times10^3$	9—10	1000
2)	3×10^3	10	1000

We must understand how to choose the temperature in the reaction and in the deposition region. In this experiment, we have fixed the temperatures of the reaction and the deposition region at 900 and 1000°C respectively, basing these values on the thermodynamic analysis of Zr and V iodides and on the results of the spoon-gauge experiment.*4

If we had the thermodynamic data of Nb iodides, we could solve the above problems, but these data have not yet been obtained.

In an attempt to solve these problems, we should have further information in addition to the thermodynamic data of Nb iodides, that is, information 1) the chemical form of iodides which contribute to the transport of Nb_3Sn; 2) the heterogeneous reaction rate between gaseous iodines and Nb-Sn surface atoms, and 3) the thermal decomposition rate of gaseous iodides or the deposition rate of Nb_3Sn from the vapor phase.

As to the first point, we have done investigations with the spoon-gauge and the DTA instrument.*5 From this information and from the data of the NbI_5-Nb phase diagram reported by Seabaugh and Corbett,[4] it follows that NbI_3 and NbI_4 contribute more to the transport than does Nb_3I_8. For Sn, it can be deduced from the thermodynamic analysis that SnI_2 is more favorable than SnI_4.

3) T. Hashino and T. Kawai, *Trans. Faraday Soc.*, **63**, 3088 (1967).

*4 T. Kawai and S. Iwata (to be published). The spoon-gauge has been made by Nishiyama Seisakusho Ltd, Osaka, and has the sensitivity of 0.1 mmHg as a result of the improvement of a spoon-form.

*5 A length of 3 cm fused-silica tube containing samples was sealed off and used as a DTA sample container. T. Kawai and S. Iwata (to be published).

4) P. W. Seabaugh and J. D. Corbett, *Inorg. Chem.*, **4**, 176 (1965).

As for the second and third points, we are going to investigate them experimentally and theoretically.

The authors wish to express their deep gratitude to Mr. Hiroo Katsuya, Sumitomo Denko Co., Kumatori-cho, Sennan-gun, Osaka, for his preparation of the sintered pellets, and to Mr. Mitsuru Tsuyama, Shimadzu Seisakusho Ltd., Kyoto, for his measurement of the DTA data.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 275—276 (1970)

Reactions of Nitrogen Oxides with Isocyanide

Takeo SAEGUSA, Shiro KOBAYASHI and Yoshihiko ITO

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received June 6, 1969)

Various types of oxidizing agents, such as metal oxides,[1] ozone,[2] peracid,[3] *etc.*, are known for the oxidation of isocyanide to isocyanate. We wish to report the reduction of nitrogen oxide and dinitrogen oxide with isocyanide. Nitrogen oxides are reduced to elementary nitrogen and the isocyanide is oxidized to isocyanate.

Nitrogen oxide is reduced more readily than dinitrogen oxide. The results are shown in Table 1 (Exp. No. 1—4). The main gaseous product was nitrogen, whose amount roughly satisfies the stoichiometric relation:

$$RNC + NO \longrightarrow RNCO + \tfrac{1}{2} N_2$$

Small amounts of dinitrogen oxide (yield = about 10%; based upon nitrogen oxide) and carbon dioxide (less than a few percent) were formed as by-products. The production of carbon dioxide may be attributed to the hydrolysis of the product isocyanate with water which is present as impurity. The amine from the isocyanate hydrolysis may have been converted into the corresponding urea by the second molecule of isocyanate. In fact, a small amount of urea was isolated from the reaction mixture.

The nitrogen oxide-isocyanide reaction proceeded even at atmospheric pressure. Nitrogen oxide gas was passed at rate of 1.5 *l*/hr through a mixture of 50 mmol of cyclohexyl isocyanide and 10 m*l* of toluene (solvent) at 95°C for 10 hr. Cyclohexyl isocyanate was produced in 56% yield.

Dinitrogen oxide also oxidized isocyanide into isocyanate. Only 22% of cyclohexyl isocyanide was converted into isocyanate even after the reaction at 120—130°C for 16 hr (Exp. No. 5).

$$RNC + N_2O \rightarrow RNCO + N_2$$

From the reaction conditions and the conversion rate, we see that the oxidizing reactivity of dinitrogen oxide is much lower than that of nitrogen oxide. This finding does not support a mechanism of

Table 1. Reaction of nitrogen oxides with isocyanide

stepwise reduction of nitrogen oxide to nitrogen through the intermediate stage of dinitrogen oxide.

It is interesting to compare the reaction of phosphite with nitrogen oxide with that of isocyanide. It has been reported that nitrogen oxide reacts with triethyl phosphite to produce triethyl phosphate and dinitrogen oxide in liquid phase at room temperature, and that dinitrogen oxide has no tendency to oxidize triethyl phosphite under the same reaction conditions.[4]

$$(EtO)_3P + 2NO \rightarrow (EtO)_3PO + N_2O$$

However, we found that dinitrogen oxide also has the capacity of oxidizing triethyl phosphite to triethyl phosphate at higher temperatures and pressures. Thus, triethyl phosphate was obtained in more than 80% yield by the triethyl phosphite-dinitrogen oxide reaction under the same reaction conditions as described in the cyclohexyl isocyanide-dinitrogen oxide reaction.

$$(EtO)_3P + N_2O \rightarrow (EtO)_3PO + N_2$$

Experimental

General Procedure. A mixture of isocyanide and solvent was placed in a 50 m*l* stainless-steel pressure tube, to which nitrogen oxide (or dinitrogen oxide) was compressed to 20 kg/cm^2 at room temperature. The pressure tube was closed and the content was heated without shaking or stirring. After the reaction, the gases were trapped and analyzed by glpc with a column of silica gel (column temp. -78°C for nitrogen and nitrogen oxide and 40°C for dinitrogen oxide and carbon dioxide). Isocyanide and isocyanate were analyzed also by glpc with columns of silicone DC 550 and PEG 6000.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 276—277 (1970)

Reaction between Anilines and Excess of Methyl Vinyl Ketone*1

Atsushi KAWASAKI and Yoshiro OGATA

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received June 13, 1969)

Substituted anilines add to methyl vinyl ketone forming 4-anilino-2-butanone derivatives,[1-3] *i. e.*, 1 : 1 adducts. Since the adducts are secondary amines, their addition to methyl vinyl ketone is also expected. Many reports are concerned with 4-anilino-2-butanone,[1-3] but there has been no report on the formation of *N,N*-bis(3-oxobutyl)-anilines. The authors found that excess of methyl vinyl ketone can give *N,N*-bis(3-oxobutyl)anilines in a phosphate buffer of dioxane.

$$ArNH_2 + CH_2{=}CHCOCH_3 \rightarrow ArNHCH_2CH_2COCH_3$$

$$ArNHCH_2CH_2COCH_3 + CH_2{=}CHCOCH_3 \rightarrow ArN(CH_2CH_2COCH_3)_2$$

Mono- and dibasic phosphate ions were found to be effective catalysts for the addition of aniline to methyl vinyl ketone to form 4-anilino-2-butanone.[1] This reaction was effectively carried out in 0.025M phosphate buffer of dioxane-water (50 : 50 or 60 : 40 in volume%). Formation of 1 : 2 adducts requires an excess (more than 2 mol equiv.) of methyl vinyl ketone and a longer reaction time because of the lower reactivity of the sterically hindered secondary amines.

The structure of the products was determined by elemental analysis, IR and NMR spectra as shown in Tables 1 and 2.

The melting points of these compounds are higher than those of 1 : 1 adducts, and the NH absorption bands are absent. Both aniline derivatives having an electron-withdrawing and an electron-releasing substituent afford 1 : 2 adducts. The yields of 1 : 2 adducts lower than those of the corresponding 1 : 1 adducts may be explained by the contamination of 1 : 1 adducts having a lower nucleophilicity than that of parent anilines. The contaminating 1 : 1 adducts are removed completely by recrystallization from petroleum ether (*p*-methyl and unsubstituted derivatives) or chloroform (*p*-nitro derivative). NMR spectra were assigned as shown in Table 2. It is interesting to note that *p*-substituents affect the chemical shifts

of the acetyl (a) or methylene (b,c) protons which are remote from them.

The reaction path may involve the phosphate ion-catalyzed addition of the resulting 4-anilino-2-butanone to methyl vinyl ketone as in the addition of aniline to methyl vinyl ketone.[1)]

Experimental

IR and NMR spectra were determined by a Perkin-Elmer grating IR spectrophotometer Model 337 and a Varian HA-100 apparatus, respectively.

Materials. Methyl vinyl ketone and substituted anilines were purified as reported previously.[1)]

***N,N*-Bis(3-oxobutyl)-*p*-toluidine.** *p*-Toluidine (1.07 g, 0.01 mol) and methyl vinyl ketone (1.68 g, 0.024 mol) were dissolved in a mixture of 8 m*l* of dioxane and 8 m*l* of 0.025M phosphate buffer. The solution was kept standing at room temperature with occasional stirring for 15 hr. After addition of a saturated sodium chloride solution (10 m*l*), the reaction mixture was extracted twice with ether (each 10 m*l*). The ethereal extract was washed with water, dried with anhydrous sodium sulfate, and the solvent was removed *in vacuo*. The residue (1.75 g) was recrystallized from petroleum ether, giving 0.94 g (38%) of colorless crystals of *N,N*-bis(3-oxobutyl)-*p*-toluidine, mp 61—62°C. The residue contains 4-(*p*-toluidino)-2-butanone.

Other products were obtained by a similar procedure.

The authors wish to thank Toray Co. for the measurement of NMR spectra, members of Professor Sasaki's laboratory for the elemental analysis and Mr. T. Nakamura for his assistance.

On the Nature of the First Ionization Potential of Tropolone

Pill-Soon SONG and Michael A. LATINO

Department of Chemistry, Texas Technological University, Lubbock, Texas 79409, U. S. A.

(Received June 6, 1969)

Information concerning ionization potentials of molecules provides an important clue to their electronic states. An interesting question as to the nature of the first ionization potential of tropolone is whether the first ionization potential represents energy to remove an electron from the non-bonding orbital on oxygen or from a π-molecular orbital. Higasi *et al.* measured the first ionization potentials of tropolone and related molecules.[1] They measured the ionization potential (vertical) of tropolone mass spectrometrically using two different methods of evaluation; namely, 9.86 eV by the critical slope method and 9.83 eV by the linear extrapolation method. The ionization has been interpreted to originate from the nonbonding electron orbital on the carbonyl oxygen. Higasi *et al.* concluded that the higher ionization potential of tropolone than tropone is then, due to the intramolecular hydrogen bonding in the former. On the other hand, the lower ionization potential (9.43 eV) of 2-amino tropone than tropolone is interpreted as being due to weaker hydrogen bonding. However, they have not ruled out a possibility of the π-electron ionization potential being the lowest. This Note is concerned with that last point.

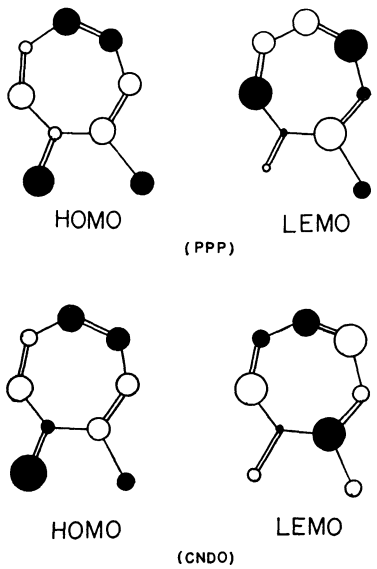

Fig. 1. Wavefunctions of the highest occupied (HOMO) and lowest empty (LEMO) molecular orbitals of tropolone calculated by the PPP and CNDO methods. The dark and open circles represent plus and minus signs, respectively, and the radius indicates an approximate magnitude of the LCAO coefficients.

The symmetry of the highest occupied (HOMO) and lowest empty (LEMO) MOs is of interest to characterize excitation and ionization processes in the molecule. Figure 1 shows HOMO and LEMO obtained from PPP SCF MO[2,3] and CNDO/2 SCF MO[4] computations.[2-4] It turns out that both HOMO and LEMO are of π-orbital origin. The HOMOs from PPP and CNDO appear to be in close agreement. Our calculations using both methods, therefore, suggest that the lowest ionization potential is due to the ionization of π-electron. If we apply Koopmans' theorem, we obtain the first ionization potentials of 8.75 eV (π, PPP) and 9.93 eV (π, CNDO) for tropolone. Furthermore, the molecular orbital of non-bonding character (63% of the MO is made up of the carbonyl oxygen nonbonding orbitals) is predicted to have an energy significantly lower (by 2.4 eV) than the HOMO shown in Fig. 1. This would qualitatively mean that the second ionization potential may be of the nonbonding origin. Numerical agreement between the CNDO-calculated and experimental ionization potentials of tropolone may be fortuitous since Koopmans' theorem ionization potentials are frequently higher than observed values. Furthermore, CNDO tends to yield poor eigenvalues.[5] Nevertheless, relative ordering of the π- and σ-HOMOs with an energy gap of 2.4 eV appears to be sufficiently large to warrant further experimental investigations of ionization potentials of tropolone and substituted tropolone series. It has been observed that CNDO correclty predicted the first ionization potential of pyridine being of σ-type, although the same method failed to predict the

observed ordering of the two types of ionization potentials for pyrazine in which the energy difference is rather small.[5] In the present case, the energy spacing of 2.4 eV is sufficiently large.

In connection with our prediction discussed above, it is useful to describe ionization potentials of related molecules. Tropilidene(cycloheptatriene) has an ionization potential of 8.55 eV.[6] Obviously, the ionization potential here is π-type. It is therefore an interesting question whether the carbonyl group in tropone lowers the π-HOMO energy of the seven-membered ring system sufficiently to place it below the nonbonding level. The interpretation given by Higasi *et al.*[1] implies such a situation. The ionization potential of 2-amino tropone is lower than that of tropone and tropolone.[1] Higasi *et al.* interpret this trend to be due to weaker intramolecular hydrogen bonding in 2-amino tropone than in tropolone. However, since substituent effects on ionization potential of non-bonding electron are relatively small,[7] there exists a possibility that the lowering of the ionization potential of tropone by 2-amino substitution reflects the π-electron ionization process. Further experimental and theoretical investigations are certainly warranted to establish the nature of the ionization process in tropolone series.

Dipole Moment of the Triethylamine-Iodine Complex

Akinobu FUNATSU*1 and Koichi TOYODA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto

(Received June 23, 1969)

One of the present authors[1] has recently reported that his experimental measurements of the dipole moment of the triethylamine-iodine (Et_3N-I_2) complex have confirmed the value previously reported by Tsubomura and Nagakura[2] in a dioxane solution. The very large value, 12D, for the experimental dipole moment of this complex in a dioxane solution, combined with the ultraviolet spectra, suggests very strongly that the predominant species in this solution is an ion pair such as triethylamine hydroiodide ($Et_3N \cdot HI$). Kobinata and Nagakura[3] measured the dipole moment of the $EtNH_2$-I_2 and Et_2NH-I_2 complexes and obtained the following results: 6.2—6.5 and 6.2D in benzene, and 7.0D for the Et_2NH-I_2 complex in dioxane. We believe these experimental results support the foregoing suggestion. Subsequently, Boule[4] has been able to measure the dipole moment of this complex in *n*-heptane and has found a much lower value, 5.5—5.7D. We have reinvestigated the dipole moment of the Et_3N-I_2 complex in cyclohexane and in benzene, whose importance as a typical example is so great that extra efforts to obtain accurate data are justified.

Experimental

The Et_3N and cyclohexane were purified by the procedure given by Nagakura and Gouterman.[5] They were stored under an N_2 atmosphere in a desicator before use. The iodine was resublimed and stored in a dark bottle until use. The benzene for "Chromatographic Purposes" was used after having been dried over sodium and distilled under a N_2 atmosphere. The dielectric constants of the solutions were measured with a home-

made resonance-method apparatus which used the electric circuit reported by Nakagawa.[6] A dielectric-constant-measurement cell with cylindrical platinum electrodes was used. The densities of the solutions were measured by the use of a pycnometer[7] for volatile liquids. The temperature was kept constant within 25.00 ± 0.05°C during the series of measurements. The dipole moment of nitrobenzene obtained by means of this apparatus was 4.12D in a benzene solution at 25°C. In each series of measurements, benzene or cyclohexane solutions containing a fixed concentration of Et_3N and various concentrations of iodine were used. The latter concentrations ranged from 0 to 3×10^{-3} mol/*l* in benzene solutions and from 0 to 7.2×10^{-4} mol/*l* in cyclohexane solutions; they never exceeded a 15th of that of amine in the solution. The dipole moments of the complex increased with an increase in the amine concentration in a mixed solvent containing benzene or cyclohexane and an amine. The dipole moments of the complexes were obtained by the use of the Kobinata-Nagakura method[3] modified by the ordinary Halverstadt-Kumler method.[8] Nagakura[9] noticed that a white precipitate appears at sufficiently high concentrations when there is a large excess of amine. These white crystals have been identified as $Et_3N\cdot HI$ by means of a comparison between the infrared spectrum of the white crystals and that of a synthetic salt.

Results and Discussion

We found that the present complex is unstable in a benzene solution as well as in a dioxane solution. As is shown in Fig. 1, the dielectric

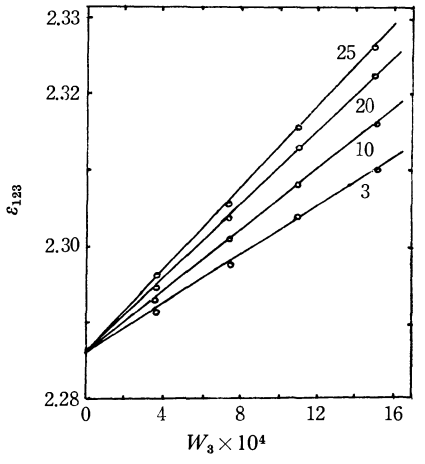

Fig. 1. The relation between the dielectric constant of the solutions (ε_{123}) and the weight fraction of complexes (W_3) in benzene. The Arabic numerals in the figure show the times passed in minutes starting from mixing the solutions.

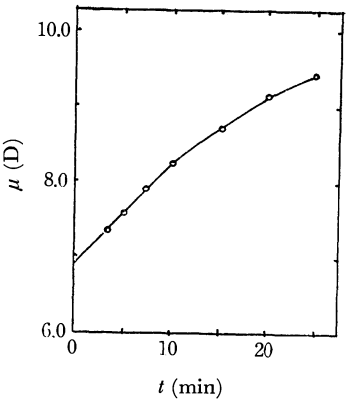

Fig. 2. The relation between the dipole moment (μ) and the time (t) in benzene.

constants of the benzene solutions increase with the time minutes after the two solutions are mixed. Furthermore, each time, the relationship between the weight fractions of the complex and the dielectric constants or the densities of the solutions is linear. These linearities seem to show that, under the present experimental conditions, the dipole-dipole interaction between the complexes or ions is negligibly small. The dipole moments of the complex were calculated from the slopes of these straight lines on each run by the use of only the first term of the Kobinata-Nagakura equation,[3] for the residual terms were negligibly small compared with the first term. Figure 2 shows the relation between the time and the dipole moments of the present complex obtained in this way. In a benzene solution, the values of the dipole moment of the complex obtained by extrapolating the results to zero time are 6.55, 6.85, and 6.94D. We were not able to find that the dielectric constants and the densities of the solutions change with the time in cyclohexane within 30 min

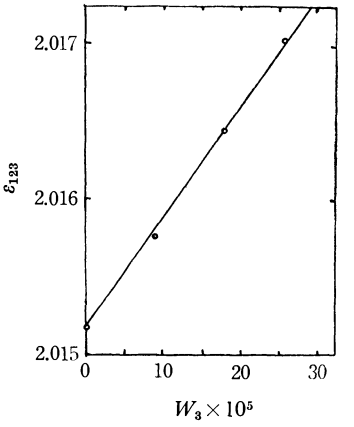

Fig. 3. The relation between ε_{123} and W_3 in cyclohexane. This straight line is able to express $\varepsilon_{123}=2.01516+7.467W_3$.

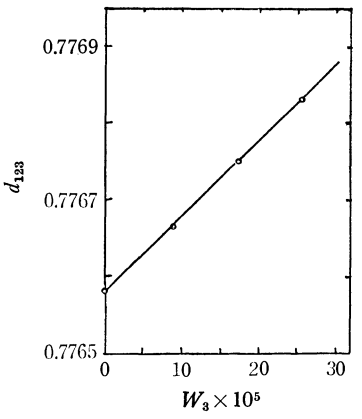

Fig. 4. The relation between the density of the solutions (d_{123}) and the weight fraction of the complexes (W_3) in cyclohexane. This straight line is able to express

$$d_{123}=0.77658+1.020W_3.$$

after the two solutions were mixed. In cyclohexane solutions, the relations between the observed dielectric constants or the densities of the solutions and the weight fraction of the complexes for a series of measurements within 30 min after the mixing of the two solutions are shown in Figs. 3 and 4. The experimental values of the dipole moment of the complex thus obtained in a cyclohexane solution are 5.23, 5.60, and 5.65D. These values are in good agreement with the Boule values.[4]

From the dipole moment thus obtained, the contribution of the dative structure in the present complex can be estimated at 30%, assuming that it takes a geometrical configuration of the trimethylamine-iodine complex[10] and that the negative charge in the dative structure is on the center of the iodine molecule.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 281—282 (1970)

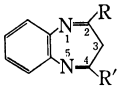
Oxidation of 2,4-Diphenyl-1,5-benzodiazepine with Peracetic Acid

Masakatsu MATSUMOTO, Akira IIO and Teijiro YONEZAWA

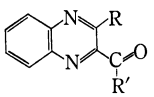
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received June 27, 1969)

It has been reported that two 1,5-benzodiazepines, (I-a: R,R′=CH_3) and (I-b: R=CH_3, R′=Ph), undergo oxidative ring-contraction with peracetic acid or monopersulfuric acid.[1] In a recent publication,[2] we have also reported the photooxidation of the dimethyl- (I-a) and the diphenylbenzodiazepine (I-c: R,R′=Ph) in benzene; the diphenylbenzodiazepine (I-c) is oxidized photochemically at the 3-CH_2 group, as in the oxidation of the benzodiazepines (I-a) and (I-b). In the present paper, we will report the oxidation of the diphenylbenzodiazepine (I-c) with peracetic acid.

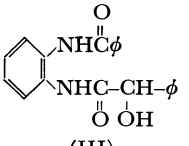


(I)



(II)

When the diphenylbenzodiazepine (I-c) was oxidized with peracetic acid, the corresponding ring-contraction product, 2-benzoyl-3-phenylquinoxaline (II-c), was not obtained; rather, Compound A, mp 154—156°C, was obtained as the main product, together with 2-phenylbenziminazole (IV), *N*-benzoyl-*o*-nitroaniline (V), and *N*,*N*′-dibenzoyl-*o*-phenylenediamine (VI). The NMR spectrum of Compound A in hexadeuteriodimethylsulfoxide showed two doublets (at τ=4.92(J=4.0 Hz, 1H) and τ=3.35 (J=4.0 Hz, 1H)), three multiplets (centered at τ=2.75 (5H), τ=2.40 (5H), and τ=2.15 (4H)), and two singlets (at τ=0.35 (1H) and τ=−0.10 (1H)). The doublet at τ=3.35 and the two singlets disappeared upon the addition of of D_2O. The infrared spectrum appeared in KBr $\nu_{C=O}$ at 1645 cm^{-1} and in ν_{N-H} and ν_{O-H} at 3370 −3220 cm^{-1}. The mass spectrum showed a parent peak at *m/e* 346. On the basis of these results, Compound A was identified as an amine (III).



(III)

From the facts that, in the oxidation with peracetic acid, the diphenylbenzodiazepine (I-c) gave

1) J. A. Barltrop, C. G. Richards, D. M. Russell and G. Ryback, *J. Chem. Soc.*, **1959**, 1132.

2) T. Yonezawa, M. Matsumoto and H. Kato, This Bulletin, **41**, 2543 (1968).

the amide (III), while the dimethyl- (I-a) and the methylphenylbenzodiazepine (I-b) gave acetylquinoxalines (II: R′=CH_3, a: R=CH_3, b: R=Ph), it is thought that, in the mechanism of the oxidative ring-contraction shown by Barltrop *et al.*,[1] there may be a subsequent, reversible reaction between the intermediates an alcohol (VII) and a quinoxaline (VIII), which plays important roles.*1

In the case of the diphenylbenzodiazepine (I-c), the alcohol (VII) formed at first might undergo ring-contraction to form the quinoxaline (VIII), which they might suffer further oxidation to give the amide (III), while in the case of the dimethyl- (I-a) and the methylphenylbenzodiazepine (I-b), the alcohol (VII) might form a 3,6-diaza-4,5-benzotropone (IX) by succesive oxidation and the 6-oxo intermediate (IX) is thought to be rearranged.

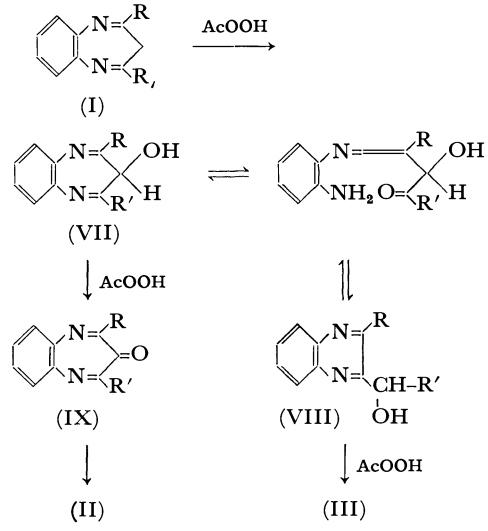
Experimental

2,4-Diphenyl-1,5-benzodiazepine (I-c). This was prepared by the condensation of dibenzoylmethane with *o*-phenylenediamine catalysed by *p*-toluenesulfonic acid in xylene;[1] colourless needles, mp 140.0°C, crystallized from methanol.

Oxidation of I-c with Peracetic Acid. A mixture of the diazepine (I-c) (0.5 g) and hydrogen peroxide (0.90 m*l* of a 30% aqueous solution) in 30% aqueous acetic acid (30 m*l*) with a slight amount of H_2SO_4 was set aside for two days. As the reaction proceeded, the violet reaction mixture turned dark brown. The reaction mixture was basified and filtered, and then the solid part was crystallized from hot water, giving pale brown crystals melting at 154—156°C, which were identified at the amide (III) described previously, in a yield of 44%.

Found: C, 72.91; H, 5.21; N, 8.20%. Calcd for $C_{21}H_{18}O_3N_2$: C, 72.82; H, 5.24; N, 8.09%.

The filtrate was extracted with methylene chloride, the extracts were condensed, and the residue was chromatographed in methylene chloride on silica gel. Then *N*-benzoyl-*o*-nitroaniline (V) mp 92°C from aqueous methanol, 2-phenylbenziminazole (IV) mp 313°C from methanol, and *N*,*N*′-dibenzoyl-*o*-phenylenediamine (VI) mp 324°C from ethanol*2 were obtained successively in yields of 8, 9, and 3% respectively. The three products, IV, V, and VI, were identified by comparing the IR spectra with those of authentic materials.



*1 As the intermediates VII and VIII, some other forms can be considered.

*2 Many articles have given 300—303°C as the mp of compound VI.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 282—284 (1970)

The Oxidation State of ^{126}I Arising from the (n,2n) Reaction in Inorganic Iodine Compounds

Nobufusa SAITO and Fumitoshi AMBE

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received June 27, 1969)

A comparison of the chemical effects of the (n,γ) and (n,2n) reactions has been thought to present a basis for deciding whether or not the final state of recoil atoms is dependent on the initial recoil energy, since the (n,2n) reactions are estimated to impart a far larger recoil energy to the atoms than the (n,γ) reactions induced by thermal neutrons. In an earlier paper, we reported that ^{78}Br arising from the (n,2n) reaction gave nearly the same retention as ^{80m}Br from the (n,γ) reaction in $NaBrO_3$.[1,2] However, almost concurrently, Aten and his co-

2) F. Ambe, H. Sano and N. Saito, *Radiochim. Acta*, **9**, 116 (1968).

workers reported that ^{126}I arising from the (n,2n) reaction showed a considerably lower retention than ^{128}I from the (n,γ) reaction in KIO_3.[3] Recently, Dupetit and Aten have reported similar experiments on $CsIO_3$[4] and $CsIO_4$.[5] The present work was undertaken in order to see if this difference found between the behavior of ^{126}I and ^{128}I is a general phenomenon in inorganic iodine compounds of different types.

KIO_3, $KH(IO_3)_2$, I_2O_5, and $NaIO_4$ were irradiated with fast neutrons obtained from the 66 cm cyclotron of this Institute, and the distribution of the ^{126}I produced by the $^{127}I(n,2n)^{126}I$ reaction among various oxidation states was determined. The results were compared with data found in literature on the ^{128}I from the $^{127}I(n,\gamma)^{128}I$ reaction.

Experimental

The samples were commercially-available reagents of a high purity. They were irradiated for 3 hr with fast neutrons obtained by bombarding a metallic lithium target with 3.5 MeV deuterons accelerated in the cyclotron. The temperature of the samples during the neutron irradiation was slightly higher than room temperature. The neutron flux was 10^6—10^7 neutrons/cm^2·sec. The irradiated samples were subjected to the following chemical separation procedure within a few hours after neutron irradiation. The irradiated KIO_3 and $NaIO_4$ were dissolved in water, while the $KH(IO_3)_2$ and I_2O_5 were dissolved in aqueous solutions containing a large excess of KOH. The alkaline solutions were then carefully neutralized with dilute nitric acid. ^{126}I atoms in different oxidation states were separated by the following chemical procedures after an appropriate amount of a carrier (I^-, IO_3^- or IO_4^-) had been added: (1) Iodine atoms in the lower oxidation states (I^-, I_2 and IO^-) were precipitated as AgI. (2) Iodine atoms in the lower oxidation states were separated by exchange extraction with I_2 dissolved in CCl_4. (3) IO_3^- ions were precipitated as $Ba(IO_3)_2 \cdot H_2O$. (4) IO_3^- and IO_4^- ions were separated from iodine atoms in the lower oxidation states by an anion-exchange procedure.[6] (5) IO_4^- ions were precipitated as KIO_4. The radioactivity of ^{126}I was measured by means of a NaI scintillation counter after the short-lived nuclides had decayed. The data were reproducible with allowable deviations, and the results obtained by the different procedures were in good agreement.

Results

The results obtained are shown in Table 1. Storage for several hours at room temperature was found to cause no detectable change in the chemical distribution of ^{126}I in the irradiated materials. In I(V) compounds a slight increase in the parent form was observed after storage exceeding 24 hr at room temperature. In Table 2 the data on the (n,γ) reaction reported by previous workers are summarized. A comparison of Tables 1 and 2 indicates that for both I(V) and I(VII) compounds the distribution of radioactive recoil iodine atoms is considerably different for the (n,γ) and (n,2n) reactions. It may thus be concluded that, for all the I(V) compounds studied, the retention of ^{126}I is lower than that of ^{128}I; this conclusion is in accordance with the previous report on KIO_3 and $CsIO_3$.[3,4] Since we found no significant difference between the behavior of the recoil bromine arising from the $^{79}Br(n,\gamma)^{80m}Br$ and $^{79}Br(n,2n)^{78}Br$ reactions in $NaBrO_3$,[1,2] it is unlikely that the difference observed in the iodine compounds stems from the difference in recoil energy accompanying each nuclear reaction. We also reported previously that the ^{80m}Br and ^{82}Br arising from the (n,γ) reactions showed slightly different retention values in various bromates, and interpreted the difference as resulting from the highly-converted isomeric transition of ^{82m}Br to ^{82}Br after the (n,γ) reaction.[7,8]

Table 1. Oxidation state of ^{126}I arising from the (n,2n) reaction (the present work)

Compound	I^-+I_2 (%)	IO_3^- (%)	IO_4^- (%)
KIO_3	44±1	56±1	<1
$KH(IO_3)_2$	60±1	40±1	<1
I_2O_5	44±1	56±1	<1
KIO_4	4±1	94±2	2±1

Table 2. Oxidation state of ^{128}I arising from the (n,γ) reaction (a summary of data of previous workers)

Compound	I^-+I_2 (%)	IO_3^- (%)	IO_4^- (%)	Reference
KIO_3	33	67	0	a)
$KH(IO_3)_2$	47	53	0	a)
I_2O_5	31	69	0	b)

8) N. Saito, F. Ambe and H. Sano, *Radiochim. Acta*, **7**, 131 (1967).

Thus, it may be possible that the difference observed in the retention of ^{126}I and ^{128}I is also a result of an internal conversion process of the excited ^{126}I or ^{128}I.

We are grateful to Mr. A. Shimamura for his technical assistance in the neutron irradiations.

Recoil Reactions of Fluorine-18 in Hexa- and Pentammine Cobalt(III) Salts

Nobufusa SAITO, Fumitoshi AMBE, Shizuko AMBE and Akira SHIMAMURA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received June 27, 1969)

Several investigations have been reported on the recoil reactions of chlorine,[1] and bromine[2-7] in cobalt complex salts. However, no report has been made on the recoil reactions of fluorine in similar compounds. In this note we wish to report on the chemical fate of the ^{18}F recoil atoms produced by three types of nuclear reactions in hexa- and pentamminecobalt(III) salts.

The samples were prepared by traditional methods and identified by means of absorption spectra of the aqueous solutions in visible region. Analytical results of the cobalt, nitrogen, and fluorine content were satisfactory for the present purpose.

The $^{19}F(n,2n)^{18}F$ Reaction. Recoil reactions of ^{18}F following the $^{19}F(n,2n)^{18}F$ reaction were studied in $[Co(NH_3)_6]F_3$ and $[Co(NH_3)_5F](NO_3)_2 \cdot H_2O$. The samples were irradiated with fast neutrons at an ambient temperature for 1—3 hr. The fast neutrons were obtained by bombarding a metallic lithium target with 3.5 MeV deuterons accelerated in the 66 cm cyclotron of this Institute. The neutron flux was 10^6—10^7 neutrons/cm^2·sec.

The irradiated sample was dissolved in a slightly alkaline solution containing the carriers. The solution was shaken with a 1% oxine-chloroform solution in order to eliminate 2.5 hr ^{56}Mn produced by the (n,α) reaction from ^{59}Co. The aqueous phase was washed with chloroform and passed through a column of a cation-exchange resin, Diaion SK#1 in the sodium form. The resin was then washed with a sufficient amount of water which had been made slightly alkaline with ammonia. ^{18}F atoms in the form of fluoride ions passed through the column, while those in the ligand of cobalt complex cations were adsorbed on the resin. A tracer experiment confirmed that there occurred no appreciable isotope exchange reaction of fluorine atoms between fluoride and $[Co(NH_3)_5F]^{2+}$ ions during the course of separation procedure.

The annihilation γ-rays of the positron emitted by the 111 min ^{18}F were measured by means of a single-channel γ-ray spectrometer equipped with a NaI scintillation detector.

The ligand yield (the fraction of the recoil atoms found as the ligands of the complex ions[2]) was $5.3 \pm 0.1\%$ for $[Co(NH_3)_6]F_3$ and $17.8 \pm 0.3\%$ for $[Co(NH_3)_5F](NO_3)_2 \cdot H_2O$.

The $^{17}O(d,n)^{18}F$ Reaction. $[Co(NH_3)_6](NO_3)_3$ and $[Co(NH_3)_5F](NO_3)_2 \cdot H_2O$ were bombarded with 3 MeV deuterons for 5 min. The beam current was 0.05—0.5 A/cm^2. Although the target assembly was cooled with water, the temperature of the samples during bombardment might have been higher than room temperature. The samples were considerably decomposed by the heat and by the radiation (about 10^9 rad) to which the samples were exposed during irradiation. The chemical distribution of the ^{18}F produced by the $^{17}O(d,n)^{18}F$ reaction was determined by a procedure similar to that employed in the case of the (n,2n) reaction. As was expected from the inconstancy of the conditions of irradiation, the reproducibility of the results was low. The ligand yield was 2—7% for $[Co(NH_3)_6](NO_3)_3$ and 5—17% for $[Co(HN_3)_5F](NO_3)_2 \cdot H_2O$.

The $^{16}O(t,n)^{18}F$ Reaction. $[Co(HN_3)_6](NO_3)_3$ or $[Co(NH_3)_5F](NO_3)_2 \cdot H_2O$ was mixed with lithium carbonate in the gram-formula weight ratio of 1 to 2. The mixture was irradiated with

neutrons for 5 min at the temperature of dry ice in the rotary specimen rack of the TRIGA Mark II reactor of Rikkyo University. The neutron flux was about 5×10^{11} neutrons/cm^2·se. The ligand yields of ^{18}F produced by the ^{16}O(t,n)^{18}F reaction (which was induced by the tritons from the ^{6}Li(n,α)T reaction) were determined to be $5\pm1\%$ for $[Co(NH_3)_6](NO_3)_3$ and $4\pm1\%$ for $[Co(NH_3)_5F](NO_3)_2\cdot H_2O$.

From the observations described above, it can be concluded that some of the ^{18}F atoms, produced by the (n,2n), (d,n), and (t,n) reactions, form ^{18}F-labeled cobalt complex ions as has been reported for radioactive chlorine and bromine atoms following various nuclear reactions in similar compounds.[1-7]

Decomposition of Benzenediazonium Tetrafluoroborate in Aprotic Polar Solvents

Kazuhiro ISHIDA, Nobumasa KOBORI, Michio KOBAYASHI and Hiroshi MINATO

Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

(Received June 27, 1969)

The decomposition of aryldiazonium tetrafluoroborate has been investigated in dimethyl sulfoxide, acetonitrile, nitromethane, dimethylformamide and acetone.

Experimental

Materials. Dimethyl sulfoxide was dried with calcium hydride and distilled at 86°C/25 mmHg. Acetonitrile was refluxed with phosphorus pentoxide, and then distilled at 81°C. Nitromethane was dried with calcium chloride and then distilled at 101°C. Dimethylformamide was distilled at 153°C. Acetone was treated according to the method of Hudson and Wardill,[1] and distilled at 56.5°C. Benzenediazonium tetrafluoroborate was prepared by the addition of an aqueous hydrogen tetrafluoroborate solution to a benzenediazonium chloride solution obtained from the aniline purified by distillation at 109°C/30 mmHg. The crystals were filtered, washed successively with cold water, ethanol and ether, and then they were dried *in vacuo*.

Kinetic Measurements. The diazonium salt was decomposed in a water bath, the temperature of which was regulated within ±0.1°C. The rate of decomposition was followed by measuring the evolution of nitrogen gas by use of a gas burette.

Results and Discussion

The decomposition of benzenediazonium tetrafluoroborate in these solvents were of first order. The first-order rate constants in these five solvents are shown in Table 1. Figure 1 shows the plots of $\log k$ *versus* $1/T$, and the activation parameters obtained from Fig. 1 are shown in Table 2. Figure 2 shows that the values of activation energies and activation entropies fit an isokinetic relationship very well. The activation entropy was small in a solvent with a small activation energy, and *vice versa*. The isokinetic temperature was 311°K.

It was found that the decomposition of benzenediazonium tetrafluoroborate in DMSO yielded

7.8% of 1,3-benzoxathian, 25.0% of phenol and 32.5% of *o*-hydroxybenzyl methyl sulfide. The results of both kinetic studies and product studies are best explained by the monomolecular decomposition of the diazonium ion to phenyl cation and nitrogen.

Thus, the decomposition in these aprotic polar solvents is in quite a contrast with the decomposition in methanol[2] or in pyridine,[3] in which the decomposition was homolytic and phenyl radical was the intermediate. Methanol and pyridine are rather strong nucleophiles, and attack the diazonium cation to yield a diazoether or a triazene, which undergoes homolyses. The nucleophilicity of the solvents used in this investigation was not strong enough to cause the combination with the diazonium ion. However, the polarity of these solvents is apparently large enough to assist the formation of phenyl cation stabilized by solvation.

It was found that the rate of decomposition of benzenediazonium tetrafluoroborate in an aqueous DMSO solution was approximately the same as that in pure DMSO. This indicates that the mechanism of decomposition in an aprotic polar solvent is similar to the mechanism reported for decomposition in water.[4a,4b]

Addition Compounds of Boron Nitride with Alkali Metals and Their Catalytic Activity

Chie MUGIYA, Noriko OHIGASHI, Yoshihiro MORI and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received July 11, 1969)

Boron nitride consists of parallel-layer planes, in each of which boron and nitrogen atoms occupy alternate sites on regular hexagonal lattice. Therefore, the structure of boron nitride (BN) bears a relation to graphite; the distance between the planes (3.30 Å) is almost the same as in graphite (3.345 Å), and their interatomic distances in the hexagonal plane are close, 1.45 Å (for boron nitride) and 1.42 Å (for graphite). However, because of the greater electronegativity of nitrogen as compared with that of boron, there is an uneven distribution of the electrons, giving a partly ionic character to the lattice. The nuclear magnetic resonance study of the bonding has led to the conclusion that boron nitride has a 45% double-bond resonating configuration.[1]

It is well known that graphite reacts with striking readiness with the molten alkali metals, potassium, rubidium and cesium, or their vapours, to form alkali metal-graphite lamellar compounds.

Recently, a strong chemisorption was found on these lamellar compounds of graphite by the methods of hydrogen-deuterium exchange reaction and ortho-parahydrogen conversion.[2]

The similarity of the structures of graphite and boron nitride led Croft and Rudorff to attempt the preparation of boron nitride intercalation compounds.[3,4] However, because of the difficulty of preparing and identifying them, there remains some ambiguity.

In this paper, we will discuss the preparation of boron nitride alkali metal compounds and their catalytic activity.

Experimental Procedures

Boron nitride, a white powder provided by Borax Consolidated, Ltd., and the Showa Denko Co., was used to prepare its alkali metal complexes.

Among the alkali metals, commercial-grade sodium and potassium metals were employed, while the rubidium and cesium were obtained by the reduction of their chlorides by calcium metal. The purified alkali metal was admitted into a vacuum reaction vessel, in which a degassed boron nitride powder was kept, by distillation. By further heating at 200°C for two or three days in an electric furnace, the reaction between alkali metal and boron nitride was completed. The Cs-BN complex was deep blue.

The principle of the kinetic studies of parahydrogen-orthohydrogen conversion and of hydrogen-deuterium equilibration over these complexes has already been reported.[2] These studies were carried out at room temperature and at 77°K in a constant-volume reaction system which was protected from grease and other condensable gases by traps cooled in liquid nitrogen.

For electrical conductivity measurements, a small piece of boron nitride (3.7 mm in diameter, 1.5 mm thick) was fused at around 3000°C in an arc-imaging furnace to make a fused specimen. The thin aluminum films evaporated onto both sides of the fused specimen were used as electrodes.

Results and Discussion

Boron nitride is a typical electric insulator, its observed electrical conductivity at 15°C and apparent activation energy being 10^{-17}—10^{-22} Ω^{-1} cm^{-1} and $\sim$1 eV respectively. The ionization potential, estimated from its photoemission in a vacuum ultra-violet region, was about 5.6 eV.*1 The details of the experimental procedure have already been reported.[6]

No catalytic activity was found on the powder specimen of boron nitride at all. However, the complexes between BN and alkali metals revealed a marked catalytic activity for such reactions as para-orthohydrogen conversion and hydrogen-deuterium equilibration. Table 1 summarizes their kinetic data. It can be seen form Table 1 that

		77	non-detectable
	$pH_2\rightleftharpoons oH_2$	295	4.2×10^{-2}
		77	1.4×10^{-3}

* $k=\frac{2.303}{t}\log\left(\frac{C_0-C_e}{C_t-C_0}\right)$; where C_0, C_e and C_t are concentrations of para-H_2 at the initial point, in equilibrium at the given temperature, and after t min, respectively. For D_2, the similar calculation is applied.

the rate constants have about the same magnitude for both the reactions at room temperature, and that only para-$H_2\rightleftharpoons$ortho-H_2 conversion can be catalyzed at 77°K, implying that at higher temperatures the reactions occur by the chemical mechanism, and at lower temperatures, by the physical one.

We have already reported that graphite makes lamellar complexes with alkali metals, which are very active in the above catalytic reactions.[2] Though a quantitative comparison of catalytic activity can not be made between BN- and graphite-alkali metals complexes since the surface area has not yet been measured, it seems that boron nitride complexes have an activity comparable with graphite.

What is the cause of this activity over the BN-complexes? The promotion may take place by means of an electron transfer from the alkali metal to a partner molecule: ($nM^+\cdot BN^{n-}$). The excess charge on the B–N hexagonal skeleton may give a predominant mechanism of catalytic activity. However, we could not find any detectable change in the crystal structure of boron nitride upon the addition of alkali metals.

A more detailed and systematic study will be required to establish the structures of these complexes and the nature of the catalytic active sites.

The Preparation of Some Trialkylstannylferrocenes*1

Toshihiro Dodo,*2 Hideo Suzuki and Toshio Takiguchi

Department of Synthetic Chemistry, Kiryu College of Technology, Gunma University, Tenjin-cho, Kiryu

(Received July 17, 1969)

During the last decade, several papers dealing with triorganosilyl-,[1-5] triorganogermyl-[6] and diorganophosphyl[7]-substituted ferrocenes have appeared. However, there has been an entire absence of descriptions of the triorganostannyl-substituted ferrocenes. The present authors wish to report herewith on the preparation of a series of mono- and 1,1′-bis(trialkylstannyl)substituted ferrocenes, as shown in Table 1, by the reaction of lithioferrocenes with the corresponding trialkyltin chlorides. The NMR and IR data of the products well characterized their chemical structure; they are given in Table 2.

Experimental

Trialkylstannylferrocenes. The lithiation of ferrocenes was performed by the use of *n*-butyllithium

according to a method previously reported;[1] the metalation was confirmed in advance of the reaction with trialkyltinchloride by carbonation to give the mixed mono- and dicarboxyferrocenes. As an example, the preparation of the triethylstannylferrocenes will be described.

Triethylstanylferrocenes. A 20.0 g (0.11 mol) sample of ferrocene in 300 m*l* of anhydrous tetrahydrofuran was lithiated by the use of 300 m*l* of a 0.41 molar solution of *n*-butyllithium in anhydrous ether. A solution of triethyltin chloride (132.7 g 0.6 mol) in 180 m*l* of ether was added to the above orange-

yellow lithiated ferrocene suspension over a period of 4 hr at below −60°C. After the addition, the mixture was stirred at −30°C for 15 hr, and then at room temperature for a further 30 hr, during which period the colored precipitate seemed to be dissolved to give a dark red solution. The whole mixture was then concentrated on a steam bath to about 500 m*l*, and the concentrate was repeatedly washed with water to neutrality and dried over calcium chloride. The complete removal of unreacted ferrocene was effected by repeated freezing out in a dry ice-acetone mixture followed by sublimation at 3 mmHg. The remaining liquid was fractionated through a packed column to give triethylstannylferrocene (4.7 g 10.7%) and 1,1′-bis-(triethylstannyl)-ferrocene (12.5 g, 19.4%), both being high-boiling mobile liquids with a distinct brown color.

Procedures analogous to those used for the triethyl-derivatives gave the tributyl- and tripropyl-derivatives, as is shown in Table 1.

The authors' thanks are due to Dr. H. Watanabe for his kind discussion on the various phases of this work and to the Hitachi Chem. Ind. Co. for the supply of dicyclopentadiene used herein.

SHORT COMMUNICATIONS

Oxidation of Propylene Adsorbed on Oxide Catalysts

Yutaka KUBOKAWA, Takehiko ONO, Takeshi TOMINO and Norio YANO

Department of Applied Chemistry, University of Osaka Prefecture, Sakai, Osaka

(Received October 15, 1969)

Although the oxidation of olefins on oxide catalysts has been investigated by many workers, the nature of the adsorption complex during the oxidation reaction still remains to be unclarified.[1] In the present work, the interaction of oxygen with propylene adsorbed on various oxides was investigated. On the catalyst[2] which had already adsorbed propylene it was found that the amount of oxygen adsorbed increased markedly compared to that on the cleaned catalyst. In the case of Co_3O_4, the increase in the amount of oxygen adsorbed was proportional to the amount of propylene previously adsorbed as seen in Fig. 1. On ZnO the amount of oxygen adsorbed on propylene-covered surface was very small at 0°C. After the measurement at 0°C the temperature of the catalyst was raised in oxygen. It was found that an appreciable adsorption of oxygen occurred above 80°C. The amount of oxygen adsorbed at 80°C after contact for 3 hr was also proportional to the amount of propylene adsorbed.

After the oxygen adsorption experiment, the oxygen remaining in the gas phase was removed by Töpler pump and desorption experiments were carried out. It was found that the desorbtion of oxygen as well as of propylene decreased markedly compared to the desorption in the case where only oxygen or propylene had been adsorbed. This suggests that enhancement of the oxygen adsorption results from the interaction of oxygen with propylene adsorbed with the formation of an adsorption complex.

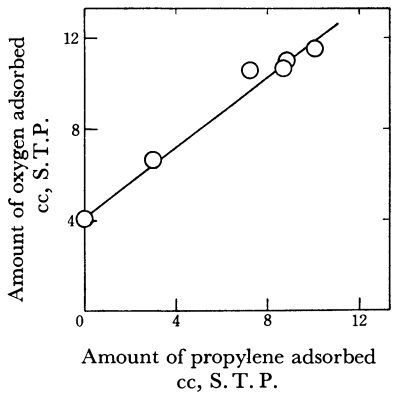

Fig. 1. Enhancement of oxygen adsorption on Co_3O_4 (8.55 g; 100 m²).

After formation of the propylene-oxygen complex, the temperature of the catalyst was raised in steps in oxygen. It was found that the complex was oxidized to carbon dioxide and water. The result obtained with ZnO is shown in Fig. 2. It is seen that the amount of oxygen reacted at each stage passes through two maxima, one corresponding to the uptake at 80°C with the formation of complex, and the other corresponding to the reaction at 350°C with the formation of carbon dioxide. This suggests that the oxidation of propylene adsorbed on ZnO proceeds in the two consecutive steps, *i.e.*, the complex formation with a low activation energy, and the oxidation of the complex to carbon dioxide and water with a high activation energy. It was found that such a two step mechanism could be applied in the catalytic oxidation of propylene on oxides as well as the oxidation of propylene adsorbed. Details will be published in a forthcoming paper.

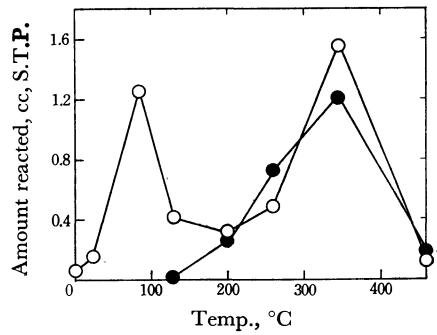

Fig. 2. Interaction of oxygen with propylene adsorbed on ZnO (5 g; 15.3 m²), —○—, O_2 reacted; —●—, CO_2 formed.

2) Prior to the experiment the catalyst was evacuated at 450°C. The time of evacuation was 24 hr on Co_3O_4 and 10 hr on ZnO.

The Structure of an Antibiotic, B-58941

Takashi SUZUKI

Research and Development Division, Takeda Chemical Ind., Ltd., Higashiyodogawa-ku, Osaka

(Received October 7, 1969)

Streptomyces fradiae var. acinicolor B-58941 produced a basic macrolide[1] (I), $C_{37}H_{59}O_{12}N$, *m/e* 709 (M^+), mp 229°C, $[\alpha]_D^{22}$ −88.4° (*c* 1, $CHCl_3$), UV: 240 mμ (log ε: 4.21), IR: 2705, 1738, 1730, 1715, 1682, 1615 cm^{-1}, NMR*[1]: 9.71 (1H, COH), 6.54 (1H, d, 16Hz), 6.34 (1H, d, 16Hz), 2.52 (6H, $-NMe_2$), 1.40 (3H, –C–Me), 1.3—1.0 (15H, 5 *s*-Me), 0.87 (3H, t), similar to acumycin[2] and cirramycin B.[3]

I gave the diacetate (II), $C_{41}H_{63}O_{14}N$, mp 121°C, which lacked a free OH, and a monothiosemicarbazone which showed a new signal at 7.52 ppm (1H, t, $-N{=}CH{-}CH_2-$) in its NMR spectrum.

The mild hydrolysis of I afforded a neutral sugar (III), $C_6H_{10}O_3$, *m/e* 130 (M^+), UV: 280 mμ (log ε: 1.27), IR: 3420, 1720 cm^{-1}, NMR: 5.7—5.0 (1H, O–CH), 4.6—3.8 (1H, Me–CH), 2.3—1.8 (4H), 1.5—1.1 (3H, *s*-Me), positive to Fehling's reagent and iodoform reaction, and a basic substance (IV, B-58941-B), $C_{31}H_{51}O_{10}N$, mp 123°C, UV: 240 mμ (log ε: 4.11), IR: 2725, 1740—1710, 1687, 1620 cm^{-1}, which appeared to be very similar to cirramycin A_1 (CMA_1) in its physicochemical and biochemical properties. The periodate oxidation of III yielded one mole each of acetaldehyde and succinaldehydic acid. III was concluded to be 2,3,6-trideoxyhexopyranos-4-ulose.

From the hydrolysate of IV mycaminose[5] (V), $C_8H_{17}O_4N$, was obtained. The catalytic reduction of I gave a tetrahydro product which lacked an absorption maximum at 240 mμ and showed the presence of a new signal due to *s*-Me and the loss of the *t*-Me. The treatment of IV with KI-AcOH afforded a compound, UV: 281 mμ (log ε: 4.09), which showed a new signal at 1.78 ppm (3H, (s), C=C–Me).

The structure of CMA_1 has been proposed by Kawaguchi *et al.*,[4] but the position of the attachment of the macrolactone moiety ot V has not been established. The author has undertaken NMR spin-decoupling studies of II. As Fig. 1 shows, all the protons in II were unambiguously assigned, and the structure of IV was shown to be in good agreement with that of CMA_1. The signal due to H_3, which was coupled to H_2 and H_4, showed a downfield shift upon acetylation, whereas the signal due to H_5 (doublet-like) did not shift. This certainly establishes that the anomeric hydroxyl of V is combined with the C_5–OH of II. Since the anomeric H'_1 is coupled to H'_2, which shifts downfield upon acetylation, III should be bonding at the C'_4–OH of V. In conclusion, the structure I may be proposed for B-58941.

Hydroxylation of Toluene and Xylenes with *t*-Butyl Hydroperoxide-Aluminum Chloride

Shizunobu HASHIMOTO and Wataro KOIKE

Department of Applied Chemistry, Doshisha University, Karasuma-imadegawa, Kamikyo-ku, Kyoto

(Received July 18, 1969)

Although extensive studies of the oxidation reactions of various organic compounds with hydroperoxides have been carried out, the oxidation of an unactivated aromatic nucleus by hydroperoxides has been neglected. Hamilton *et al.*[1] have, however, reported on the hydroxylation of aromatic compounds by hydrogen peroxide in the presence of ferric ion and catecol. They showed that the use of alkyl hydroperoxides, such as ethyl and *t*-butyl hydroperoxides, instead of hydrogen peroxide was ineffective in the hydroxylation in the catalytic system. We wish to report here our preliminary results of a synthetically-useful method for introducing a hydroxy group directly into the aromatic nucleus of simple methylbenzenes, using *t*-butyl hydroperoxide in the presence of aluminum chloride.

In a typical experiment, a solution of 0.05 mol of the peroxide in 30 m*l* of toluene was added to a stirred mixture of 0.1 mol of aluminum chloride and 90 m*l* of toluene at −20°C over a half hour period. After having been stirred for an aditional 2 hr at this temperature, the reaction mixture was poured into ice cold hydrochloric acid. After the usual working-up, cresols (*o*- : *m*- : *p*-=56 : 8 : 36) were obtained in a 76 mol% yield, accompanied by *t*-butyltoluenes (*m*- : *p*-=65 : 35) in a 78 mol% yield.

An electrophilic mechanism for this hydroxylation is predicted by the cresol-isomer distribution and by the necessity that aluminum chloride be present.[2] The rates of this hydroxylation of methylbenzenes relative to benzene obtained by the competitive method[3] were *m*-xylene : *p*-xylene : *o*-xylene : toluene : benzene=136.6 : 63.5 : 62.1 : 13.8 : 1.0. The relative rates in our system with methylbenzenes were somewhat higher than those from electrophilic oxygenation with diiospropyl peroxydicarbonate - aluminum chloride[4] ($K_{toluene}/K_{benzene}$ =9.6), and with di-*t*-butyl peroxide-aluminum chloride[5] ($K_{toluene}/K_{benzene}$=10.4). Our results suggest, therefore, that the oxidizing agent is an electrophile which exhibits a high substrate selectivity.

Information was obtained concerning the nature of the oxidizing species by carrying out the reaction of *n*-butyl hydroperoxide with toluene in the presence of aluminum chloride at −20°C for 2 hr. In this case, the oxygenation products were obtained not as phenolic metarials but as alkyl aryl ethers, namely, *n*-butyl tolyl ethers (10 mol%). This indicates that the oxidizing agent is not the hydroxy group but the alkoxy group.

On the basis of the experimental findings, the following electrophilic substitution process may be proposed for the title reaction, where the *t*-butyl oxonium ion (I) is the oxidizing agent. Since *t*-butyl hydroperoxide is prone to dissociate essentially in the form of $t\text{-BuOO}^{\delta-}\text{–H}^{\delta+}$, alumium chloride may initially co-ordinate with the peroxide at the oxygen ($\delta-$) to cause the heterolytic fission of the O–O bond. I attacks the aromatic substrate to form, presumably, a *t*-butyl aryl ether (II). The free phenol should arise from the subsequent dealkylation of II under the present reaction conditions,[6] followed by treatment with hydrochloric acid:

$$t\text{-BuOOH} + AlCl_3 \longrightarrow \underset{(I)}{t\text{-BuO}^+} + [AlCl_3(OH)]^-$$

$$I + ArH \longrightarrow \underset{(II)}{ArOBu\text{-}t} + H^+$$

$$II + ArH + AlCl_3 \longrightarrow ArOAlCl_2 + ArBu\text{-}t + HCl$$

$$ArOAlCl_2 \xrightarrow[H^+]{H_2O} ArOH + HOAlCl_2$$

1) G. A. Hamilton, J. W. Hanifin, Jr., and J. P. Friedman, *J. Amer. Chem. Soc.*, **88**, 5269 (1966).

2) The yield of phenols was dependent on the ratio of aluminum chloride to peroxide, at least a 2 : 1 molar ratio being required for good results.

3) a) The relative rates were determined by gas-liquid chromatography. b) The relative rates of xylene *vs.* toluene were *m*-xylene : *p*-xylene : *o*-xylene=9.9 : 4.6 : 4.5.

4) P. Kovacic and S. T. Morneweck, *J. Amer. Chem. Soc.*, **87**, 1566(1965).

5) S. Hashimoto, W. Koike and T. Murachi, *Kogyo Kagaku Zasshi*, **72**, 2015 (1969).

6) *t*-Butyl phenyl ether underwent rapid decomposition in toluene at −20°C in the presence of aluminum chloride. The essentially quantitative dealkylation yielded phenol and *t*-butyltoluenes. However, *n*-butyl phenyl ether did not decompose under the condition.

Dose-rate Dependency of the Radiation-induced Polymerization of Ethylene in an Aqueous Solution of *tert*-Butyl Alcohol

Shiro SENRUI, Hirondo KURIHARA and Masaaki TAKEHISA

Takasaki Radiation Chemistry Research Establishment, Japan Atomic Energy Research Institute, Takasaki, Gumma

(Received October 20, 1969)

Recently, Suganuma *et al.*[1,2] have reported the kinetics of the radiation-induced polymerization of ethylene in the presence of *t*-butyl alcohol. Judging from the dose-rate dependency of STY (polymerization rate, mole ethylene/*l*/hr), they concluded that the monomolecular termination process played an important role.

We wish to report an attempt to elucidate the effect of the dose rate on the polymerization of ethylene in the presence of *t*-butyl alcohol and water.

The rate of the polymerization of ethylene was determined by measuring the yield in a 100-cc (internal volume) autoclave in which the pressure was held constant at 400 kg/cm^2 during the polymerization. The differential STY increased with an increase in time at an initial stage of the polymerization, while in the succeeding stage it became constant and was independent of the time. In this region, the reaction seems to be stationary on the concentration of active species. As is shown in Fig. 1, the differential STY in the latter stage was proportional to the square root of the dose rate. This suggests that the active species are mutually terminated.

As has been described above, the bi-molecular termination is assumed for this polymerization. The correlation between the active species concentration, [R·], and the reaction time, t, is given as:

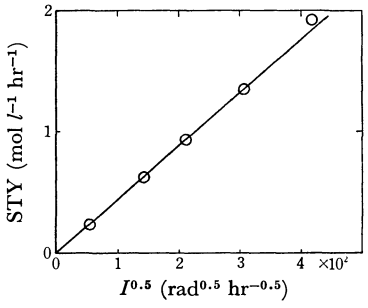

Fig. 1. Dose rate dependency of differential STY in the stationary state.

$$[\mathrm{R}\cdot] = \frac{\sqrt{K_i I}\{\exp(2\sqrt{K_i I k_t}t)-1\}}{\sqrt{k_t}\{\exp(2\sqrt{K_i I k_t}t)+1\}} \quad (1)$$

From the long-chain approximation, the overall polymerization rate, R, is given as:

$$R = R_p = K_p[\mathrm{R}\cdot] \quad (2)$$

By introducing Eq. (1) into Eq. (2) and integrating it, the polymer yield, M_p, is given as:

$$M_p = \frac{K_p}{k_t}[\ln\{1+\exp(2\sqrt{K_i I k_t}t)\}-\ln 2-\sqrt{K_i I k_t}t] \quad (3)$$

This equation indicates that the differential STY in the latter stage is proportional to the square root of the dose rate, as is shown in Fig. 1. The relationship between M_p and 2 $(K_i I k_t)^{0.5}t$ should be shown as a normalized curve, regardless of the dose rate and the reaction time.

If it is assumed that M_p is proportional to I^α, the dose-rate exponent, α, can be calculated by the use of Eq. (3). As is shown in Fig. 2, α varies with the dose rate and with the reaction time in the range from 0.5 to 1.0. This shows that the type of termination reaction can not be decided simply from the value of α, for this relation is calculated by assuming bi-molecular termination.

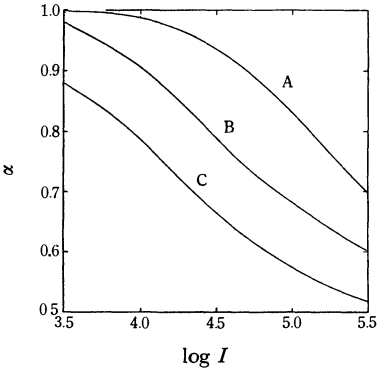

Fig. 2. Dose rate dependency of α.
A: 0.5 hr B: 1.0 hr C: 2.0 hr

The dose-rate exponent, α, shown in Fig. 2, is in good agreement with the experimental results. This fact can not be explained by the monomolecular termination mechanism alone, indicating that the bi-molecular termination process plays an important role.

Precise investigations of reaction mechanism are now under way and will be reported elsewhere.

The Asymmetrically-selective Oxidation Reaction of 3,4-Dihydroxyphenylalanine Catalyzed by the Poly-L-lysine-copper(II) Complex

Masahiro HATANO, Tsunenori NOZAWA and Michio YONEYAMA

The Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received November 8, 1969)

Many polymer-metal complexes[1,2] have been found to exhibit high catalytic efficiencies in comparison with the low molecular analogs. However, no polymer-metal complex showing an asymmetrically selective catalysis has been reported. In this communication we wish to report that the oxidation reaction of 3,4-dihydroxyphenylalanine (DOPA) can be catalyzed by the poly-L-lysine-copper(II) complex (PLL-Cu(II)) with an appreciable asymmetric selectivity. This is the first example of a synthetic polymer-metal complex used to catalyze a reaction with an asymmetric selectivity. Most of the experimental details have been reported elsewhere.[1] At several temperatures from 25 to 10°C, the circular dichroism of the catalyst and the rate of the oxidation reaction were measured. These kinetic and circular dichroism results are collected in Table 1, which indicates that the initial oxidation rate of D-DOPA (V_D) is greater than that of L-DOPA (V_L) and that the ratio of the rate of D-DOPA to that of L-DOPA (V_D/V_L) increases with a decrease in the reaction temperature measured, reaching 1.5 at 10°C. These observations seem to be of great interest by analogy with the catalytic behavior of enzymes. It has been reported that the asymmetric induction in the oxidation reaction may be attributed to the selective formation of the substrate-catalyst complex.[1] It is evident from Table 1 that, at a constant T_{Cu}/T_N*1 (0.13), the asymmetric selectivity ratio in the reaction increased with an increase in the α-helix content in the catalyst. However, when the T_{Cu}/T_N was varied, the selectivity did not increase with the α-helix content. That is, the catalyst prepared at $T_{Cu}/T_N=0.05$ exhibited almost no selectivity, though it had a much higher α-helix content than the catalyst prepared at $T_{Cu}/T_N=0.13$. These results mean that the α-helix structure in the catalyst may be necessary, but may not be sufficient to show an appreciable selectivity. The chief difference, other than the α-helix content, between the catalyst prepared at $T_{Cu}/T_N=0.05$ and that prepared at $T_{Cu}/T_N=0.13$ may be the distances between the cupric complex units along the polymer chain,*2 because the asymmetric structure in a cupric complex unit did not differ very much, judging from the fact that the molar ellipticity in the wave length of 240—650 mμ changed little with the variation in the T_{Cu}/T_N ratio.[1] Therefore, the selectivity in the catalysis can not be correlated with the separated cupric complex unit only, but two or more cupric complex units may act cooperatively in the selective catalysis. Consequently, it seems that the results can be explained by the assumption that the helix structure in the catalyst serves to hold the two or more cupric complex units in a special steric configuration, thus forming a site which can bind D-DOPA selectively.

TABLE 1. OXIDATION RATE OF DOPA CATALYZED BY PLL-Cu(II)[a]

T_{Cu}/T_N	Temp. (°C)	V_D	V_L	V_D/V_L	α-Helix content (%)

*1 T_{Cu} and T_N represent the total analytical concentration of the cupric ion and that of lysine residue of PLL in the solution, respectively.

*2 From the results of various experiments, it may be considered that a cupric complex unit is made of a cupric ion coordinated by four amino nitrogens in a plane and one peptide nitrogen at the apical position and that PLL-Cu(II), as a whole, takes a certain helical structure in all T_{Cu}/T_N of 0.05—0.15. These results will be reported elsewhere.

On the Photochemical Decomposition of Bismercuracycloalkanes

Tsutomu SAKAKIBARA, Shigeatsu KURATA and Yoshinobu ODAIRA

Department of Chemical Technology, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka,

(Received October 9, 1969)

In previous papers,[1,2] new information on the photochemical reactions of inorgano- and organomercury compounds has been given. In this communication, an abnormal behavior of alkyl radical in the photolysis of bismercuracycloalkanes will be described.

In a typical experiment, 1.0 g of 1,6-bismercuracyclodecane (I) (n=4) was irradiated in 230 m*l* of benzene for 29 hr at room temperature in carbon dioxide atmosphere with a 120 W low pressure mercury lamp. 83 m*l* of gaseous products was evolved and its glc analysis showed the presence of n-butane (42.0%), butene-1 (42.0%), cyclobutane (5.4%) and lower hydrocarbons (10.5%), which consisted of methane (5.5%), ethane and ethylene (4.2%), and propane and propylene (0.8%). Neither n-octane nor cyclooctane was detected. The results of photolysis of I (n=4) in various solvents are shown in Table 1.

The formation of n-butane, butenes and cyclobutane obviously shows the photochemically homolytic fission of C–Hg bond of I (n=4). Though the formation of cyclobutane seems to take place directly through subsequent C–Hg bond fission of a radical II formed by the photolysis of I (n=4), an alternative path through the intramolecular metathesis of II cannot be eliminated.[3]

It is of interest that the yield of n-butane was almost independent of the hydrogen-donating ability of the solvent (Table 1). Even in the systems without suitable hydrogen-donating agents such as tetrachloroethylene or the solid phase, the formation of n-butane was notable. It is noteworthy that the formation of lower hydrocarbons, such as methane, ethane or ethylene, was significant in all cases. Similar results were found in the photochemical reaction of 1,7-bismercuracyclododecane (I) (n=5) in benzene, *viz.*, in addition to pentenes and cyclopentane, the products contained a considerable amount of n-pentane and lower hydrocarbons.

In order to clarify the results, detection of the radical species formed during the photochemical reaction of I (n=5) was made by ESR studies. Though no diradical intermediate could be detected, a spectrum assinged to a cyclic alkyl radical I-a or I-b was obtained. Characteristics of the hyperfine structure of this radical were as follows; g-factor (2.0022), hyperfine coupling constant (in Gauss) ($A^{H}_{\alpha}=A^{H}_{\beta 1}=22.5$, $A^{H}_{\beta 2}=2A^{H}_{\beta 1}$).[4]

From the ESR result, it may be concluded that the radical I-a or I-b, generated from I (n=5) through the hydrogen-abstraction by other radicals such as II (n=5), must lead to the formation of lower hydrocarbons *via* further decomposition of C–Hg bonds.

A mechanism involving an inter- or intramolecular hydrogen-abstraction by the photochemically formed radical intermediate II should be given for the photochemical decomposition of I.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 297—300 (1970)

Kinetic Studies of the Pulse Radiolysis of *trans*-Stilbene in Several Solvents*[1]

Hisashi UEDA*[2]

The Department of Chemistry, The Ohio State University, Columbus, Ohio 43210, U. S. A.

(Received June, 10, 1969)

The kinetics of the transient species of *trans*-stilbene in several solvents were studied using single pulsed electron beam (0.5 μsec × 300 mA) and the spectroscopic method. The species existing immediately (0—20 μsec) after a pulse is found to disappear according to a sum of two first-order decay-rate equations. The temperature dependence of the formation and decay of this species shows that there are two different *trans*-stilbene cations, R_s and R_f, which have almost identical absorption spectra but different formation and decay rates. The rate constants for R_s were not affected by the temperature, however, those for R_f were strongly affected. R_f is not found in the solution of *trans*-stilbene in 1,2-dichloroethane if a small amount of CCl_4 is added. Some effects of the dielectric constant were observed on the decay-rate constant of R_f. From these facts, it can be concluded that R_f is formed by an ordinary transfer of a hole from the solvent cation to the solute molecule. As R_s seems to be formed by a mechanism other than that of R_f, a possible scheme for it has been discussed.

The decay kinetics of the ionic species in solution have already been studied by the electrochemical method.[1,2] It was found that the solvation or the dielectric properties of the solvent greatly affect the decay kinetics of the ions. In the present work, therefore, the effect of the dielectric constant on the decay kinetics of the ionic transient species formed by ionizing radiation was investigated.

The kinetic data for the formation and the decay of the cation of *trans*-stilbene in alkyl-halides have already been included in a previous paper, together with the spectroscopic data.[3] The kinetic analyses in the previous paper, however, were carried out only for the time period of 0—9 μsec after a pulse; this method has, the present author believes, led to the right conclusion. Nevertheless, it is expected that some more information can be obtained by including the variation of the optical densities due to the ions still left 10—20 μsec after a pulse. Therefore, some further analyses of the rate curves are another purpose of the present study.

Experimental

The experimental procedures are the same as those reported in the previous paper.[3] The acetonitrile (AN) was purified by passing it through a vacuum-dried layer (30 cm) of alumina in a vacuum and by successive distillations in a vacuum. The solvents used were AN, carbon tetrachloride (possessing the two extreme values of dielectric constants, 35.99 and 2.25, at 25°C), *n*-butylchloride (BuCl), 1,1-dichloroethane (11DCE), 1,2-dichloroethane (12DCE), 1,1,2-trichloroethane (TCE), 1,1,2,2-tetrachloroethane (TECE), and 2-methyl tetrahydrofuran (MTHF) whose dielectric constants are between those two extremes.

Results

Figure 1 shows that the attempts to analyse the kinetic data with second-order rate curves were unsuccessful. For this reason, analyses with first-order rate curves were attempted; however, here the results were not successful, either. However, Fig. 2 shows that the decay rate of the transient species of *trans*-stilbene in AN consists of two processes with two different first-order rate constants, k_s and k_f, where the suffix f signifies that the rate is faster than that with s at 25°C. It will be seen that the decay curve, C, of the total light absorption can be interpreted as the sum of the two rate curves, S and F, the faster and the slower decays at 25°C. The rate curves obtained with 11DCE, CCl_4 MTHF, and all the other solvents have exactly the same shape, each consisting of two first-order rate curves, S and F. The kinetic constants for the S and F curves obtained with various solvents are listed in Table 1. In Fig. 3, the values of A_f and A_s (the relative values of the initial amount of the

transient species decaying with k_f and k_s) expressed in the scale of optical density are plotted against the temperature. The solvent used for this experiment was 11DCE because that substance has the lowest

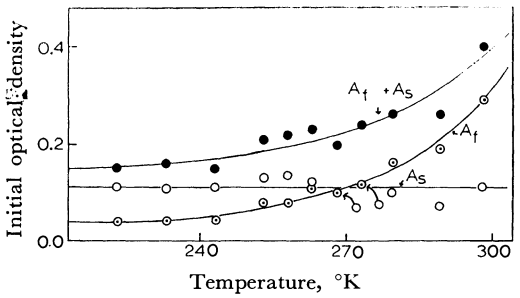

Fig. 3. The temperature dependence of the initial optical density, at 490 mμ, of the solution of *trans*-stilbene in 11DCE at the concentration of 1.40×10^{-2} mol/*l*. Explanations of A_f and A_s are in text.

melting point (−98°C) among the solvents used. It was found that A_s is constant in the temperature region studied and that it is 0.11. It was also found that k_s is constant in the same temperature region and is 3.70×10^4 sec^{-1}. In Table 1, the A_f, A_s, k_f, and k_s values are shown for various solvents and mixed solvents of BuCl and 11DCE. In Table 2 the effects of the solute concentration on the k_f, A_f, and A_s values are shown.

Discussion

A second-order rate has been observed for a recombination process of free radicals; for this reason, a second-order rate has been expected for the decay of ions in a solution. In the present study, however, second-order rates can not be used for the analyses of the results. All are precisely interpreted by the sums of first-order rate equations. Similar types of decay rates have also been observed for the decay of trapped electrons in rigid glass matrices.[4] In these cases, however, the analyses of the rate curves were qualitative and the components were selected rather arbitrarily. Recent work[5,6] has indicated (I) that the ratio of the two (though in some papers three components have been postulated[4]) components is affected by the temperautre, the wavelength of the bleaching light, *etc.*, and (II) that the addition of a scavenger affects only the component with the slower decay rate.

In the present case, the consideration of a pseudo-first-order reaction might be necessary. In Table 2, the values of k_f slightly depends on that of A_f, but the values of the k_f/A_f ratio is not constant. The value of k_s does not depend on that of A_s and can ont be interpreted by a pseudo-first-order reaction. Another possibility is that the cation disintegrates spontaneously: $(RH^+) \rightarrow R\cdot + H^+$. This, however, would leave a free radical R· which should have some light absorption in the near UV region. No such formation has been found in the solutions studied. Therefore, some other type of charge neutralization with a first-order rate must be considered.

b) mol/*l*.

In the previous paper it was established that the cation of *trans*-stilbene is formed in the solvents typically represented by 11DCE. Also, an anion can be assigned to the spectrum from a solution in MTHF.[3,7] In CCl_4 the spectrum[3] is almost completely different from that of the cation reported to be formed in polycrystalline CCl_4 by Shida and Hamill.[7] This fact might lead to the conclusion that the transient species formed in CCl_4 in the liquid phase is not an ionic species. However, the addition of a small amount of NH_3 destroyed the optical density due to the transient species observed in CCl_4 almost completely.[3] This indicates that the transient species observed in CCl_4 is also of cationic origin. In AN it is uncertain if the existing species is either one of the ions or both. The shape of the decay curve obtained with AN, shown in Figs. 1 and 2, is identical with those in the other solvents used in this study. Therefore, it is highly probable that the transient species observed have ionic natures in all the cases studied.

In Table 1, it will be seen that the number of C-Cl bonds in a unit volume of the solvent determines A_f. If CCl_4 or C_2Cl_6 exists in the solution, A_f decreases or disappears. The addition of a small amount of CCl_4 or C_2Cl_6 may result in a small decrease in the overall dielectric constant of the solution. The real effect of these compounds, however, will not be through the dielectric constant, but by a means similar to the one by which CCl_3CH_3 and CCl_3CHCl_2, when used as solvents, did not give the solute cations.[3] The absorption spectra of the transient species obtained by CCl_4 are entirely different from those obtained by other solvents, *e.g.*, 12DCE; therefore, the extinction constant at 380 mμ may be considerably larger than that of the pure stilbene cation, at 490 mμ. This would make it possible to interpret the large A_f and A_f/A_s values for CCl_4.

The k_f values for BuCl, 11DCE, and TECE decrease in that order. As the dielectric constant is also expected to increase in that order, it seems that the larger the dielectric constant of the solvent, the smaller the k_f. Such a tendency has also been found for the mixtures of BuCl and 11DCE.

Let the species with the k_f rate constant be named R_f, and that with k_s, R_s. The facts that the temperature strongly affects the formation of R_f, and that the decay rate of R_f, *i.e.*, k_f, is affected by the dielectric constant of the solvent, lead to the conclusion that the normal charge-transfer mechanism from the solvent cation to the solute molecule yields R_f. The effect of CCl_4, which acts as if it were a scavenger to the solute cation, R_f, in 12DCE can also be well explained by this mechanism. The charge transfer between 12DCE is intercepted by one of the added CCl_4 molecules during the

7) T. Shida and W. H. Hamill, *J. Chem. Phys.*, **44**, 2375 (1966).

charge transportation to a solute molecule; then, some chemical reaction at this CCl_4 molecule is started. At any rate, CCl_4^+, if once formed in the liquid phase, should not be good for the production of the solute cation.

It is hard to say if A_s is affected by the dielectric constant of the solvent, as is shown in Table 1. The difference between R_s and R_f is that A_s is little affected by either the temperature or the added CCl_4. The A_s value for MTHF, in which the *trans*-stilbene anion has been obtained, is also similar to those obtained by several of the alkyl halides used.

The k_s values, it seems, do not depend on the dielectric constant of the solvent. The large value for acetonitrile is puzzling, but it is possible to say that the large dielectric constant of acetonitrile does not contribute to the stability of the R_s.

As the R_s is not affected by the temperature or the added CCl_4, the formation of R_s should be different from that of R_f. As the absorption spectra for R_f and R_s are identical,[3] they must be identical species with different routes of formation and decay.

The main purpose of this work, to establish the effect of the dielectric constant of the solvent on the formation and decay kinetics of the solute ions, has not been achieved conclusively, on the other hand, our knowledge of the values of the dielectric constants of the solvent compounds used in this study, especially those values under the influence of a strong electrostatic field, is very little. If these values were known exactly, the present data could perhaps be interpreted in a different way.

The formation and the decay of the solute cation include many steps such as: (A) the excitation of the solvent molecule to form S*′; (B) the partial stabilization of S*′ to form S*; (C) excitation transportation to a solute molecule; (D) excitation transfer to the solute molecule to form R*′ (E) the partial stabilization of R*′ to form R*; (F) the transportation of the excitation or the counterexcitation, and (G) recombination. Here "excitation" is taken in a wide sense and can include both ionization and simple excitation. The rate-determining steps for the formation and the decay processes will be only a few of them. Therefore, a direct determination of the entire process based on the observed reaction rate, which is determined by the rate-determining steps only, will be imperfect. The decay process of the solute cation includes at least the (E), (F), and (G) steps. Even when only the rate-determining step is temperature-independent and proceeds by a first-order rate, while the remaining two steps are not temperature-independent and do not so proceed, the overall result to be observed can be temperature-independent and can proceed with a first-order rate. On the other hand if any one of these steps is destroyed by the scavenger like CCl_4, all the steps seem to be destroyed by the scavenger. For these reasons, it would not be safe to say that the temperature independent kinetic data-obtained for R_s allow us to exclude the possibility of any thermal movements of charged species leading to the formation and decay of R_s.

However, the formation of R_s should be somehow different form that of R_f. As it has been concluded that R_f is formed by a normal charge transfer from a solvent cation to the solute molecule, some other mechanism should be found for R_s. A tentative scheme for R_s may be the following excitation transfer leading to an ion-pair formation:

$$\text{Solvent}_a \rightsquigarrow \text{Solvent}_a^*$$

$$\text{Solvent}_a^* + \text{Solvent}_b \rightarrow \text{Solvent}_a + \text{Solvent}_b^*$$

$$\text{Solvent}_p^* + \textit{trans}\text{-stilbene} \rightarrow \text{Solvent}_p^- + R_s^{(+)}$$

$$R_s^{(+)} + \text{Solvent}_p^- \rightarrow \textit{trans}\text{-stilbene} + \text{Solvent}_p,$$

where the asterisk signifies a non-ionic excited state. The suffix letters are for the identification of each solvent molecule. The plus sign in the parentheses indicates that this R_s species has a net positive charge. As no charge transfer is involved in these schemes, a temperature-independent rate can be expected. Since no transportation of a positive or a negative charge is involved in the decay process of the solute cation, it can proceed with a first-order rate.

The determination of the *G*-value for the formation of the cation of *trans*-stilbene has not been attempted in this work. The determination of the *G*-value is essentially the determination of the extinction constant of the light abosrption by the cation of *trnas*-stilbene. This naturally includes the preparation of a solution of the cation of *trans*-stilbene with a known concentration, and such a preparation can not be done easily. For this reason, the *G*-value determination was reserved for future experiments.

The author wishes to thank Mr. Jerome Brandon for his cooperation in the experiments involved in this study.

Studies on Nylon Monolayers. I. Pressure-Area Curves for Nylon Monolayers on Water

Toshiko SEIMIYA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received April 21, 1969)

The conditions under which nylon monolayer spread on water exhibits a reproducible and well-defined *F-A* curve favorable for detailed investigation of the surface chemical properties of nylon were studied. For this purpose monolayers of Nylons 6 and 8 were spread from such solvents as methyl alcohol, methyl alcohol saturated with calcium chloride, aqueous solution of 90% formic acid and the mixture of phenol and benzene in 1 : 3 volume ratio. The effects of the nature of these solvents, the volume of spreading solution, surface aging and substrate pH on the properties of spread film were studied. It was found that the monolayers can be classified into two different types of film, A and B, according to the behavior of *F-A* curve against compression. The type A film appeared usually at the first compression of the spread film. *F-A* curve of A film varied according to the nature of the spreading solvent and the film was unstable. It readily underwent change to type B by being allowed to stand after the film was compressed to a certain extent, by increasing the volume of the spreading solution or merely by compressing film A to a sufficiently high surface pressure. *F-A* curve of type B film obtained was almost independent of the nature of the spreading solvent and repetition of compression and expansion of the film.

The surface pressure-area curve (*F-A* curve) of nylon monolayer on distilled water has been studied by many investigators[1-6] since the study by Crisp.[7] Recently studies on monolayers of nylon homologues having from three to twelve CH_2 groups in a monomer chain have been reported.[8] However, in most of these studies, various spreading solvents were used without confirming the reproducibility of *F-A* curves of the monolayers, *viz.*, most of the *F-A* curves were obtained only by a single compression of the film. Thus, it is very difficult to draw any conclusion as to whether or not the *F-A* curves are reversible, film substance changes its state, loss of the film substance occurs, and aging or hysteresis appears upon compression and expansion of the film. It is rather unexpected that such fundamental studies have not yet been well established although these troublesome phenomena frequently occur upon careful observation. Accordingly, the present author felt it necessary to examine first of all a well defined condition under which reproducible measurements of nylon monolayer are possible.

The present study deals with the effect of the nature of the spreading solvent, amount of spreading solution, aging and substrate pH upon the nature of monolayers of Nylons 6 and 8.

Experimental

Materials. The samples used in the present study were Nylon 6 of Toyo Rayon Co. and Nylon 8 of Nippon Rayon Co. For the purification,[8] the flakes of Nylon 6 were dissolved in the aqueous solution of formic acid and those of Nylon 8 in methyl alcohol, and both samples were precipitated by adding water to these solutions. The precipitates were extracted with ethyl ether for about 20 hr, using Soxhlet apparatus and the extract was evaporated to dryness *in vacuo*. The spreading solvents used were methyl alcohol saturated with calcium chloride (CM), methyl alcohol (MA), aqueous solution of 90% formic acid (FA) and the mixture of phenol and benzene in volume ratio of 1 : 3 (BP). Surface active contaminants were removed from the solvent by ordinary methods to the extent that the solvents, when spread on water, evaporated and compressed, showed the surface pressure being less than 0.1 dyn/cm which was the sensitivity of the surface balance. The concentration of nylon in the solutions was 0.3 mg/m*l*. Water was obtained by refluxing first an aqueous solution of acidic, then alkaline potassium permanganate, followed by repeated distillations. The substrate solution used was distilled water or dilute hydrochloric acid.

Methods. The surface pressure was measured by Wilhelmy type surface balance of ± 0.1 dyn/cm accuracy. The trough and barrier made of polymethyl methacrylate were crylate a coated with purified paraffin. The size of the trough was $200 \times 60 \times 10$ mm. The hanging-plate

was made from microscope cover glass of 11.0×7.5×0.13 mm in size. The spreading solution of nylon was slowly applied by a micro-syringe onto the surface. Unless otherwise stated, an aliquot of 15 μl of sample solution was spread on water surface of 120 cm^2 in area, and the compression of the film was started 20 min after the spreading. This was found sufficient for the film to attain a steady state. This film was compressed at the rate of 8 mm/min by a mortor driven barrier. The rate is conventionally chosen but is the one usually adopted in such measurements.[5] The trough was enclosed in a glass cabinet and the evaporation of water from and the dissolution of carbon dioxide into the substrate water were avoided by passing a current of humid nitrogen free from carbon dioxide slowly and continuously. The measurements were carried out in an air thermostat held at 25±0.5°C.

Results and Discussion

The Effect of the Nature of Spreading Solvent. The *F-A* curves for Nylons 6 and 8 monolayers spread from CM, MA, FA and BP are shown in Figs. 1a, 1b, 2a, 2b and 2c. The first compression curves of *F-A* are denoted by A. After the first compression to a sufficiently high surface pressure, the films were expanded to the initial area, and the second compression was started after allowing them to stand for about an hour. The *F-A* curves thus obtained are denoted by B.

In some cases expansion and compression were repeated but the results gave the same *F-A* curve as that of B. It was shown that two types of film A and B are obtained in all cases, namely the film appearing at the first compression and the film at the second and further compressions. The film of the type A obtained by the first compression varies in the shape of *F-A* curve according to the nature of the spreading solvent, while the type B film is more condensed and the differences in *F-A* curve due to the nature of solvent and the repetition of the compression are far smaller than the type A film. From these facts together with the fact that the *F-A* curve of the type B film is fairly reproducible, the present author considers it best to measure the B film for the study of nylon monolayer under a well defined condition. Independence of type B film of the rate of compression is likely to hold since the shape of *F-A* curve of this film is independent of the effective rate of compression (the rate referred to the fractional area) which actually changes when an apparent rate is held constant at 8 mm/min. Type B film is also independent of the aging as mentioned later. The present study has been made also under such conditions.

In this connection, it is noted that most studies on nylon monolayers reported up to the present were made for the film corresponding to that of type A of our experiments, and discussion based upon such measurements inevitably becomes ambiguous and unreliable. For the film of the type B, we further examined the loss, if any, of the film substance due to its dissolution into the substrate. For this purpose, the spreading solution was applied with and without the aid of a specially prepared glass applicator having a small hollow at its top as shown in Fig. 3. The applicator was immersed

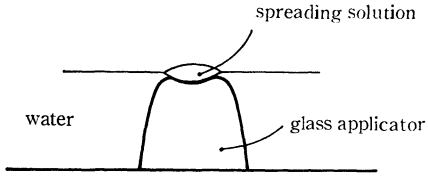

Fig. 3. Schematic representation of glass applicator.

just beneath the water surface and the spreading solution was slowly applied at the top of the applicator. Hardly any difference was observed between the *F-A* curves of monolayers spread with and without the aid of the applicator for both Nylons 6 and 8 dissolved in BP, CM, and MA except for the monolayer of Nylon 8 spread from FA, where the monolayers spread without using the applicator exhibit lower *F-A* curves both for A and B films as shown in Fig. 4. The difference in the case of FA solvent may be due to its insufficient nature as a spreading solvent. As shown in Table 1, it is evident that FA is larger in density and surface

Table 1. Physical properties of solvent

Solvent	Density (d_4^{20})	Surface tension (γ^{20})
FA	1.220	37.6 dyn/cm
MA	0.7915	22.6
CM	0.9264	22.9
BP	0.9766	30.4

tension than other solvents. These differences in properties suggest the less spreadability and the larger tendency to draw the solute into the substrate solution in the case of FA. Thus, the use of FA without the applicator is not favorable for spreading Nylon 8, while the coincidence as a whole of *F-A* curves of B type for the other different solvents may be taken as an indication of the film free from the loss of the substance during spreading. As to the film dissolution into the substrate solution during or after spreading the film, we further note that *F-A* curve of film B is reproducible under repeated compressions during which the possibility of the rapid reversible dissolution and redeposition of the film substance were confirmed not to occur except for the case in Fig. 4. This rapid dissolution and redeposition, if they happen, might produce pressure increase on the clean side of the water surface of Langmuir trough, but they could not be detected actually even after a long aging of the film under a high surface pressure. These facts lead to the conclusion that the dissolution of nylon into the subsolution is considered negligible for the monolayers except for the Nylon 8 monolayer spread from FA without using the applicator. The glass applicator was herefore used hereafter only in the case of FA as a spreading solvent.

Aging of Film before Compression. The effect of aging of the spread film on the *F-A* curve was measured for both Nylons 6 and 8 monolayers. After the monolayer was spread from the solution it was left to stand for from 20 min to 20 hr before

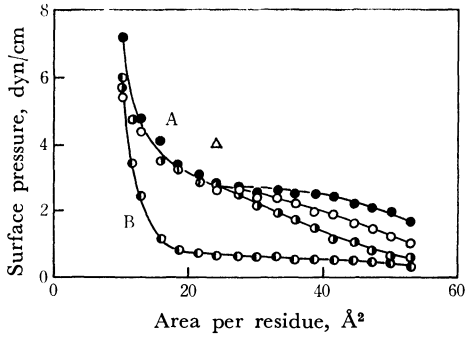

Fig. 5. Nylon 6 dissolved in BP on distilled water.
●: First compression after 20 min aging (film A)
○: First compression after 3½ hr aging (film A)
◑: First compression after 18 hr aging (film A)
◐: Second compression of above three films (film B)
△: Surface pressure under a rapid compression

the compression was started. There was no appreciable difference in the *F-A* curves for the films spread from CM and MA, but the *F-A* curve for Nylon 6 spread from BP (Fig. 5) which was more expanded than the one spread from CM showed a tendency of aging. In Fig. 5 pressure decreased during a prolonged aging of about 18 hr and the *F-A* curve of type A gradually shifted towards type B. When the original film of type A was compressed 20 min after spreading up to the molecular area of about 24 Å²/residue, at relatively high speed (about 10 times the ordinary rate, 8 mm/min) the surface pressure increased to the point indicated by the open triangle in Fig. 5 which is higher than the corresponding point on curve A obtained under the ordinary rate of compression (solid circle). Thus type A film of Nylon 6 spread from BP apparently exhibited a more expanded behavior than that from the other solvent when it was compressed immediately after the spreading. However this state seemed unstable and the film showed a tendency to condense even when it was left to stand at a lower surface pressure without compression. The plateau region described in an other report[5] was also observed in *F-A* curve for Nylon 6 (Fig. 1b) obtained by compressing the film 20 min after the spreading. This may be explained as a result of mutually opposite actions of pressure increase by compression and decrease by the above mentioned tendency of film condensation presumably becoming distinct at higher pressure.

Effect of the Volume of Spreading Solution. In order to examine the effects of the volume of spreading solution and the initial amount of film substance on the surface pressure, *F-A* curve of Nylon 6 film spread from 15 μl (standard volume)

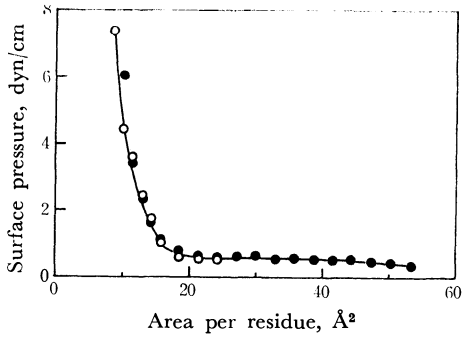

Fig. 6. *F-A* curves of Nylon 6 monolayer spread from BP on distilled water.
●: 15 μl spreading solution; second compression
○: 30 μl spreading solution; first compression

and 30 μl of the BP solutions on the aqueous surface of the same area (120 cm²) were compared (Fig. 6). When the film was spread from twice the standard volume of spreading solution, the *F-A* curve of type B appeared at the first compression and no change occured on further repetition of expansion and compression as shown by open circles in Fig. 6. This is markedly different from the FA curve for the film spread from 15 μl solution shown in Fig. 1b and also in Fig. 6.

The Nylon 8 monolayers which were spread from 5, 10, 15 and 20 μl of MA solutions showed, under repeated compresion, transition in type of *F-A* curves from A to B for all films except for the one spread from 5 μl solution which showed only one type of film A. The last case is expected to occur since the extent of compression of the film as expressed in area per residue is apparently insufficient to change A film to B.

As can be seen in Fig. 2a, film B is condensed to about one half of film A. Therefore, it may be presumed that a reaction like condensation of nylon monomer residues has occurred in this case in the monolayer of type B as a whole. This is probably due to the tendency of film contraction particularly increasing at high compression of film A. Types of the film, spread and compressed under varying amounts of spreading solution are shown in Table 2.

TABLE 2. THE TYPE OF FILM UNDER VARIOUS CONDITIONS

Spreading solution	Spreading volume	First compression	Further compression
Nylon 6 in BP	15 μl	A	B
	30	B	B
Nylon 8 in MA	5	A	A
	10	A	B
	15	A	B
	20	A	B

Concentration of spreading solution, 0.3 mg/ml
Initial spreading area, 120 cm²

A general tendency can be seen that the type A film appears at first compression and type B film at second and further compressions. Type A film obtained by spreading monolayer of Nylon 6 from BP solution is unstable and shows a tendency to undergo transition into type B by merely being kept at the initial spreading state of fairly large area, or by immediate compression of the film after being spread from twice the standard volume of the solution of the specified concentration. In the case of Nylon 8 film spread from MA, it is observed that the surface pressure of the type A film drops rapidly and the type B film finally appears when it is compressed and kept at certain small area. These fats also indicate the importance of the ratio, R, of the amount of film substance to the initial area of spreading for the study of nylon monolayer. It is likely that the appearance of the type A film only, A and B films, and B film only is dependent respectively on the value R being below, within, and beyond a certain range proper to the substance.

Effect of Substrate pH. The effect of acid in the substrate water on nylon film has mostly been studied with sulfuric acid having concentration greater than 1 N, where the *F-A* curve is more expanded than that on distilled water.[1,3,7,8] However, useful information can also be obtained from measurements of the film on acid substrate of concentration below 0.1 N, since nylon exhibits an amphoteric nature in this region.[9] Measurements were made for the *F-A* curve of the nylon monolayer on hydrochloric acid of concentration ranging from zero to 0.1 N. Measurement of the type A film on the acid substrate gave the result that both the *F-A* curves of Nylon 6 monolayer spread from CM solution and Nylon 8 monolayer from FA solution showed the film of more expanded type on acid than on distilled water (Figs. 1a and 2b) while Nylon 8 film from MA solution gave a curve almost independent of pH ranging from 2.0 to neutral (Fig. 2a). The film was more expanded than for the former two films, but contrary to the former films the area decreased below pH 1.1 (Figs. 1a and 2a).

It is known that the nylon molecules are usually in the extended state in acid solution where the molecules bear positive charges due to the addition of H^+ ion to the amide group.[8] A similar state of affairs may prevail in the case of monolayers shown in Figs. 1a and 2b, but this effect cannot explain the condensation of monolayer of Nylon 8 at pH 1.1 shown in Fig. 2a. The type B film of Nylon 8 obtained from MA also gave films independent of pH. Thus we have found fairly stable nylon monolayers of type B and in some cases type A which are obtained by spreading MA solution of Nylon 8 on acid and neutral water substrate.

In conclusion it should be emphasized that for the study of the monolayer of nylon on water, it is important to establish the conditions of monolayer preparation and of *F-A* curve measurement. Thus, it is necessary to specify clearly the nature of solvent, the concentration and the amount of spreading solution, pH of the substrate, the method of application of the spreading solution, the manners of compression and expansion of the monolayer with regard to the reproducibility of *F-A* curves and the aging of the monolayer. A check of the preservation of the substance in the monolayer during the spreading and compression is also important, although it is not carried out because of the difficulty of practice.

The author wishes to express her thanks to Professor T. Sasaki of Tokyo Metropolitan University for his guidance throughout this experiment. The author also thanks Assistant Professor M. Muramatsu for his advice. The cost of this research was defrayed from the Scientific Research Grant of the Ministry of Education.

Studies of Nylon Monolayers. II. Compression Characteristics of the Nylon 8 Monolayer on Water

Toshiko SEIMIYA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received June 20, 1969)

It was reported in the preceding paper that two types of film, A and B, can be distinguished in *F-A* curves for monolyers of Nylons 6 and 8 on the basis of the difference in behavior in relation to compression and expansion. In the present experiment, the compression and expansion were repeated for the monolayers of Nylon 8 spread from methyl alcohol in order to study the *F-A* characteristics of these films in detail. It was found that, during the process of first compression, the pressure drops rapidly and the transition of film A to film B occurs beyond a certain degree of compression of the monolayer. The transition was interpreted as the condensation of the monomer residue of the nylon molecule. The equations of the state for the expanded film were found to apply better than Singer's equation for both types of film, A and B. Further, the effect of the concentrated sulfuric acid solution (3 and 6 N) as a substrate on the *F-A* curve was examined. There were little difference in the behavior of the monolayers on 3 N sulfuric acid irrespective of the spreading solvent used, but the difference was marked on dilute hydrochloric acid.

In the preceding paper,[1] two types of film, A and B, were distinguished in *F-A* curves for the monolayers of Nylons 6 and 8 on the basis of the difference in behavior of the film in relation to compression and expansion.

In the present paper we will study these films in detail. Nylon 8 spread from methyl alcohol (MA) was used for the study of the *F-A* curve, because MA gives the most stable film on a neutral substrate, thus facilitating the measurement. Singer's approximate formula for polymer film and the equation of expanded film were applied to these data, and their applicability was checked. The effect of the concentrated sulfuric acid solution as a substrate on the *F-A* curve of Nylon 8 was also studied.

Experimental

The sample of Nylon 8 used was purified by dissolving it in MA and then by precipitating on addition of water. The precipitates were treated with ethyl ether in order to remove any impurities and were then dried *in vacuo*. MA was used mainly as a spreading solvent, but in some special cases formic acid (FA) and benzene-phenol mixture (BP) were also used. The concentration of nylon in the spreading solution was 0.3 mg/m*l*. The distilled water was prepared by refluxing an aqueous solution of acidic potassium permanganate and by distilling it three times, first with the addition of excess alkali. Aqueous solutions of 3 and 6 N sulfuric acid were used as substrates. The surface pressure was measured by a Wilhelmy balance using a glass hanging-plate. Special care was taken to withdraw the sufficiently-dipped plate just prior to the measurement in order to keep the receding angle at zero. The surface pressure-area curves (*F-A* curves) were plotted under various experimental conditions, as has been described in the preceding paper.[1]

Results and Discussion

Repetition of Compression and Expansion. A typical *F-A* curve for Nylon 8 is shown in Fig. 1. In this figure, the monolayer spread from the MA solution on the aqueous surface of a large area at pH 6 was first compressed, then expanded, and finally again compressed. The compression of the film was started from the point 0 to the point 1, as is shown in Fig. 1; then, after 15 min's rest at the point

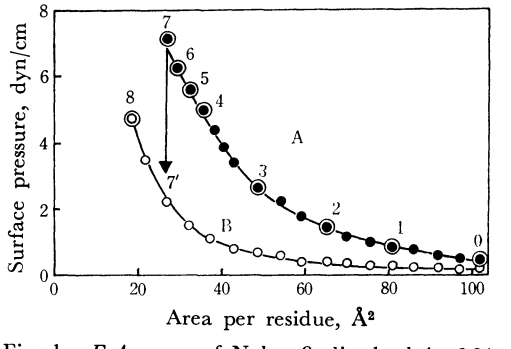

Fig. 1. *F-A* curve of Nylon 8 dissolved in MA on distilled water.
●: Film A
○: Film B

1 and the confirmation of no change in the surface pressure, the film was expanded again to the point 0 and finally compressed further to the point 2. Thus, the compression and expansion to the point 0 were repeated till the point 7 was reached along the curve A. An abrupt and irreversible change occurred at the point 7 where the surface pressure fell to the point 7′ simply on standing, as is indicated in Fig. 1. Such a change occurred rather suddenly and rapidly when the surface film was compressed to a 24—27 Å²/residue. Further compression proceeded along the curve B and the point 8 was reached. The full curve of the film B was realized when the film A, after the compression to the point 7, was expanded to the initial area of the 0 point and the second series of compression was started. The point 8 was again reached at the end of such compression. A further series of expansions and compressions of the film resulted in the same curve B.

The above behavior has been proved to occur for the monolayer spread from the solution which had been aged for from 0 to 50 days after preparation. It has been reported that the surface pressure depression occurs when the spreading solution is kept for a long time after preparation; this has been ascribed to the hydrolysis of nylon by sulfuric acid in the spreading solvent.[2] However, no such effect was found in the present experiment.

In order to examine the dissolution of nylon film into the substrate water, we have made two experiments. In the first experiment, each solvent, MA and FA, was dropped on the monolayer surface at the points of compression of 2, 3, 7′, and 8, but no change could be observed in the surface pressure after the dissolution of these solvents. In the second experiment, the surface pressure of the clean side of the substrate surface coexisting with the monolayer on the opposite side was measured. It was found that the pressure remained zero for about 1 to 2 hr after the spreading of the monolayer, even under a high compression of the film at the point 7′. These two facts, together with the reproducibility of the *F-A* curve mentioned above, confirm that the film substance is not lost from the monolayer either by a drag of the solvent as it spreads and dissolves in water or by a direct dissolution from the monolayer after it has been spread on the water.

Equation of State. First, an approximate form of Singer's equation[3] for the monolayers of polymers:

$$FA = kT(1+A_0/A)/x \qquad (1)$$

was tested for its applicability. Here, A_0 denotes the co-area of a residue in a molecule, and x, the degree of polymerization. The plot of FA against $1/A$ is shown in Fig. 2. As is shown in this figure, a linear relation is obtained for the film B; this

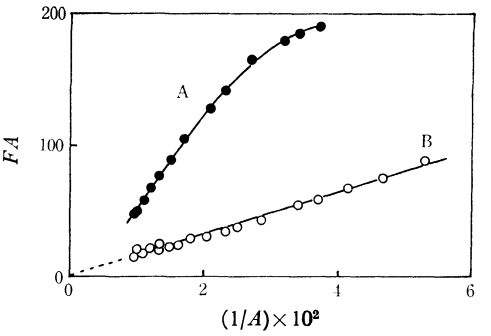

Fig. 2. Examination of Singer's approximate equation.
●: Film A
○: Film B

suggests a fairly good applicability of the above equation, but for the film A the plots largely deviates from linearity. Next, the applicability of the equation of the state for an expanded film:[4]

$$(F-F_0)(A-A_0) = kT \qquad (2)$$

was examined. Here, F_0 denotes a constant, independent of F and A. By means of a trial-and-error method, values of F_0 and A_0 were found which gave the best linearity when $F-F_0$ was plotted against $1/(A-A_0)$. As is shown in Fig. 3, the plots

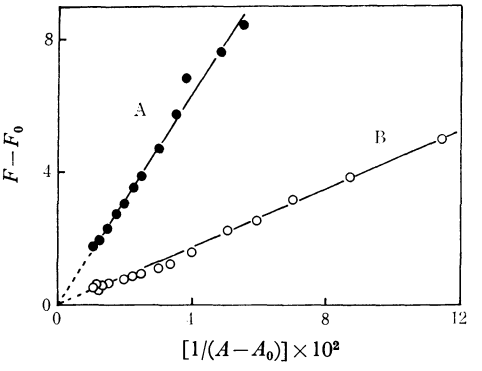

Fig. 3. Examination of equation of state for expanded film.
●: Film A
○: Film B

are on straight lines passing through the point of origin both for the A and B films. Here, $F_0=-1.35$ (dyn/cm), and $A_0=9$ (Å²/residue) for the film A, and $F_0=-0.35$, and $A_0=10$ for the film B. The values of $F_0=-1.30$, and $A_0=10$ can also be used to show a good linear plot for the film A. Thus, it is evidnet that, as a whole, Eq. (2) expresses the behavior of both the A and B films better than Eq. (1). Further, the constant of the right-hand side of Eq. (2) was calculated from the inclination of the two straight lines, A and B, in Fig. 3. The values

2) H. Hotta, This Bulletin, **27**, 80 (1954).
3) S. J. Singer, *J. Chem. Phys.*, **16**, 872 (1948).
4) I. Langmuir, *ibid.*, **1**, 756 (1933).

are about 1/3 kT and 1/10 kT for the A and B films respectively, instead of the kT shown in Eq. (2). This indicates that the equation:

$$(F-F_0)(A-A_0) = ikT$$

is applicable for both films, with $i=1/3$ for the film A and $i=1/10$ for the film B. Thus, two equations:

$$(F-F_0)(3A-3A_0) = kT$$

and $$(F-F_0')(10A-10A_0) = kT$$

are obtained for the A and B films. This means that the actual co-areas of the nylon residue are about three times and ten times as large as the co-area of the apparent residue. Thus, the groups of residues of these sizes seem to behave as a kinetic unit in the films A and B, and the condensation of the film may be understood as the formation of such clusters of residues in a polymer molecule.

Behavior of Nylon Monolayers on the Concentrated Acid Substrate. In the previous work,[1] the effect of acid on the nylon monolayer was studied by measuring the *F-A* curve on a dilute acid solution (concentration below 1/10 N), but in the present experiment concentrated sulfuric acid which is commonly used for studies of the nylon monolayer, was used as the substrate solution.[5-8] The *F-A* curve obtained for the monolayers on 3 and 6 N sulfuric acid solution are shown in Fig. 4. For the substrate of the 3 N sulfuric acid solution, the film A shows nearly the same *F-A* curve as on distilled water, but it tends to flatten when the compression proceeds beyond the area of about 35 Å²/residue. The film B exhibits the same curve as that of the monolayer spread on distilled water and no flattening is observed. When the 6 N sulfuric acid solution is used as the substrate, the expansion of the film is more marked than that of the film on distilled water for both the films A and B, as is shown in Fig. 4. As has been described before,[1] the film of Nylon 8 gives type-A curves of varying degrees of condensation on the dilute acid substrate; however, it expands again when the substrate becomes strongly acidic. These expansions of film on a strong acid substrate can be explained in terms of interaction between the monolayer and the hydrogen ion, interaction which results in repulsion among the molecules in the charged monolayer. As has been mentioned above, the *F-A* curve obtained on the strong acid substrate shows a tendency to flatten in the high-pressure region. However, it is not proper to explain this as a property of the equilibrium state, as is generally done:[2,5-9] it is better explained as a non-equilibrium state of the transition of the film from A to B, as has been noted.

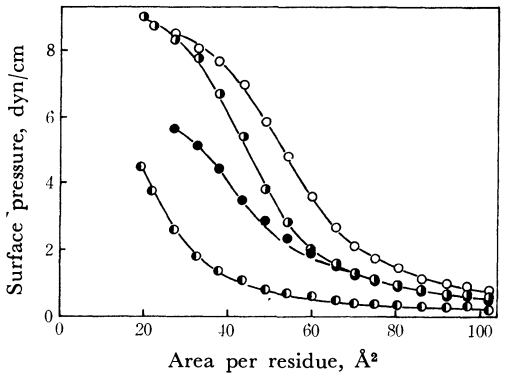

Fig. 4. *F-A* curves of Nylon 8 monolayer spread from MA on sulfuric acid.
●: 3 N, film A ○: 6 N, film A
◐: 3 N, film B ◑: 6 N, film B

In the preceding paper,[1] it has been reported that the *F-A* curves on distilled water differ according to the solvents used, as is shown in Fig. 5. However, for the films spread on the 3 N sulfuric

acid substrate, only a little difference could be noted for the films spread from MA, FA, and BP solvents, as Figs. 4 and 6 show. The *F-A* curves of the nylon monolayer on an acid substrate of the 3 N sulfuric acid solution are often reported to show a tendency to expand more than that on the substrate of a neutral pH because of the absorption of the hydrogen ion.[5-8] However, for Nylon 8 no such phenomena are found, at least not for the solvents of MA and BP.

Studies of the Nylon Monolayer. III. The Interaction between the Nylon Monolayer and Acid Dye

Toshiko SEIMIYA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received July 15, 1969)

The interaction of the monolayers of the Nylons 6 and 8 with the acid dye Orange II was studied by measuring the surface pressure of the nylon monolayers with and without Orange II in the substrate water. No change in the surface tension with the time was observed for the aqueous solution of Orange II in the concentration and pH ranges studied. The interaction between the nylon monolayers (film B) and Orange II was examined by observing the change in the *F-A* curve of the nylon monolayer due to the addition of Orange II to the substrate and the spreading of the solution. The presence of dye in a spreading solution has little effect, while the pH's of the both the spreading solution and the substrate exhibit a marked effect on *F-A* curves. The observed interaction is compared with the behavior of practical dyeing in bulk of the solution.

The interaction between monolayer and dye has been studied by several investigators[1-5] as a simple model of actual dyeing phenomena. It is evident that pressure-area (*F-A*) measurement does not offer reliable information about the interaction between dye and monolayer unless the measurement is conducted for a monolayer of exactly-defined conditions, conditions which produce a sufficiently reproducible *F-A* curve characteristic of the monolayer. The published reports are not satisfactory[6,7] from this point of view. In our previous paper,[8] the conditions of the formation of a reproducible monolayer characteristic of the Nylons 6 and 8 were reported. The present paper will describe our study of the interaction between the monolayers of the Nylons 6 and 8 prepared under such conditions and Orange II, which is commonly used for dyeing nylon.

Experimental

Materials. For the preparation of Orange II, 3.5 g of sulfanilic acid were reacted with 1.2 m*l* of hydrochloric acid and 1.4 g of sodium nitrate. The diazo compound thus obtained was slowly added to a dilute aqueous sodium hydroxide solution containing 3 g of *β*-naphthol. After coupling had been completed, the product was precipitated by adding 8 g of sodium chloride to the solution. The Orange II thus obtained was purified by repeated recrystallization from ethyl alcohol, followed by a Soxhlet extraction with ethyl ether to remove the residual impurities. The product was finally dried *in vacuo*. The Nylons 6 and 8 were purified by dissolving them in an aqueous solution of formic acid and in one of methyl alcohol respectively, and by then precipitating them by adding water to these solutions. The precipitates were extracted with ethyl ether and dried *in vacuo*.

Water was obtained by refluxing an aqueous solution of acidic potassium permanganate and by subsequent distilling, first with the addition of excess alkali, and then without the addition.

Methods. The surface tension and surface pressure were measured by means of a Wilhelmy torsion balance. The pH of the substrate water for the nylon monolayer was controlled with hydrochloric acid to about unity (called acid) or without any special control (pH≃6; called "neutral"). The change in the pH between before and after the *F-A* measurements was less than 0.1. The spreading solution was prepared by dissolving the Nylon 6 in methyl alcohol saturated with calcium chloride (CM), and the Nylon 8 in methyl alcohol (MA) or an aqueous solution of formic acid (FA). The concentrations of the spreading solutions were 0.3 mg/m*l*. The details of the experimental procedures were the same as those presented in a former report.[8]

Results and Discussion

Surface Tension of an Aqueous Orange II Solution. It has been reported that the surface tension of an aqueous Orange II solution gradually decreases with the time as a result of the adsorption of Orange II at the air-water interface.[6] It is of interest whether or not the Orange II is really surface-active and how long it takes the surface tension of its aqueous solution to attain its equilibrium. For this purpose, we measured the change in the surface tension of an aqueous Orange II solution with the change in the concentration with the time. No change with the time was observed for any concentration or pH of the solutions studied. The surface tension *vs.* the concentration of the aqueous Orange II solution is shown in Fig. 1. It is confirmed that the surface tension of water is not affected by the addition of Orange II up to a concentration of 1×10^{-3} mol/*l*, while beyond that point it gradually decreases. The adsorption of Orange II is, therefore, considered to be zero for solutions with concentrations of less than 1×10^{-3} mol/*l*. Figure 2 shows the pH dependence of the surface tension of an aqueous solution of 2.57×10^{-4} mol/*l* Orange II. A considerable decrease in the surface tension can be seen in the strongly acid region. It may be noted in this connection that an appreciable decrease in surface tension extending over a period of 20 hr has been reported for an aqueous Orange II solution.[6] In the present experiment, however, the change in the surface tension with time was not observed during a period of 180 min for the ranges of the concentration of

Orange II and the pH of the substrate studied. Here, it may be suggested that the trace of an impurity present in distilled water sharply influences the results obtained.

***F-A* Curves of Nylons 6 and 8 on an Aqueous Orange II Solution.** The *F-A* curves for the Nylon 6 spread from CM on 5.73×10^{-4} mol/*l* Orange II solutions of pH 6.4 and 1.6 are shown in Fig. 3. Here, and in all of the following experiments, the surface pressure is expressed as the difference between the surface tension of water or an aqueous Orange II solution with and without a monolayer. The *F-A* curves measured on an aqueous Orange II solution for both neutral and acid substrates show those of a more expanded type than the blank *F-A* curve on the substrate containing no dye. This behavior is in good agreement with results reported in the literature.[6]

The *F-A* curves of the Nylon 8 spread from neutral MA on both neutral and acid substrates containing Orange II are shown in Fig. 4. Here, the two types of monolayers, A (expanded type) and B

(condensed type), were distinguished, as is shown in Fig. 5, by the gradual change in surface pressure beyond a certain compression, much as in former reports.[8,9] This decrease in the surface pressure of the nylon monolayer spread on the Orange II substrate appearing at a high compression is opposite to what has been previously reported.[6] The monolayers of both A and B film on the acid substrate undergo expansion as a result of the presence of Orange II; the expansion is especially remarkable for the film B (Fig. 4b). In the case of the neutral substrate, the A film rather condenses on the Orange II substrate, while the B film is not affected by the presence of the dye (Fig. 4a). The surface pressure was further measured for the nylon monolayer prepared by adding Orange II to both the substrate and the spreading solution. The *F-A* curves obtained are shown in Fig. 6 for a neutral spreading solution and in Fig. 7 for an acidic one.

same substrate (Figs. 9a and 9b).

The results mentioned above are summarized in Table 1. In this table we can see differences in the behavior of monolayers, particularly the interactions between the dye and the Nylon 8 in the states of monolayers spread under different conditions. Several remarks can be made:

(1) The A-type film spread on the substrate without Orange II is sensitive to the pH, while the B-type film is not (Nos. 2 and 4).

(2) The difference is hardly observable between the *F-A* curves of monolayers spread from the solutions containing and not containing the dye, if the rest of the conditions are the same (Nos. 1 and 5, 3 and 6, 7 and 10).

(3) The change in pH markedly influences the *F-A* curves. The surface pressure of B-type films compared at a high compression of $A=20$ Å^2/residue showed the largest film pressure for the neutral spreading solution on the acid substrate (Nos. 3 and 6), but in other cases the film pressure was fairly low (Nos. 1, 2, 4, 5, 7, 8, and 9). If the interaction between dye and nylon is expressed as an increase at a certain pressure of the area of the nylon monolayer due to the introduction of a dye in the substrate water, the B-type film spread from a neutral solvent on an acid substrate containing dye shows the largest interaction in the case of MA (Nos. 3 and 6). However, under the same conditions the interaction is rather ambiguous for the A-type film (Nos. 3 and 6). This is because of the unstable nature of the A film, as has been stated in the former report. Thus, because of its reproducible nature, the B film proved to be useful for the study of interactions of this kind.

(4) However, when FA was used as a spreading solvent, the interaction between dye and nylon has been confirmed for the monolayer spread from an acidic solution on an acidic substrate, judging from the expansion of the monolayer (Nos. 10 and 12).

(5) As will be shown in a later section, the Nylon 8 becomes insoluble in MA when treated with hydrochloric acid, but the solubility in FA is not affected by such treatment. These facts are considered to be closely related to the reactivity of the dye with the nylon spread from FA even under acidic conditions. While the H^+ ion in the substrate helps the expansion of the Nylon 8 and dyeing with Orange II, the above effect of the H^+ ion on the solubility of nylon in a spreading solvent proved to play an important role. Thus, the results of the present study confirm the view that, for the monolayer dyeing, the state of the monolayer and the dye should be taken into account; the overall conditions for optimum deying correspond to the systems Nos. 3 and 6 for MA, and Nos. 10 and 12 for FA.

(6) It should be noted that, as has been mentioned above, the interaction between monolayer and dye inferred in the present paper is marked in the smaller-area region (Nos. 3 and 6). However, a reverse case of monolayer interactions has also been reported, a case in which the increase in surface area is marked at a smaller surface pressure and vanishes at a larger surface pressure of the monolayer.[10] Such a difference in behavior might be closely related to the nature of the interaction in the monolayer, the interaction presumably being stronger in the present experiment, where it appears at a high compression.

(7) In the case of bulk dyeing, that is, the usual dyeing of nylon fibers in a dyeing solution, the spreadability of molecules has no significance, and the diffusion of dye into the nylon fiber is the rate-determining step for dyeing, so a relatively long time (more than a day) is required for dyeing. On the other hand, in the case of monolayer dyeing the process of dyeing is sensitive to the spreading conditions, but the rate itself is very fast. Thus, the monolayer dyeing can offer some useful knowledge for the study of the mechanism of dyeing, apart from the rate problem.

(8) As has already been stated, we made an experiment in which the spreading solution contained both Orange II and the Nylon 8, but the results were not appreciably different from the monolayer spread from the solvent containing the Nylon 8 alone, as may be seen by comparing, for instance, Experiments Nos. 1 and 5, 3 and 6, or 10 and 12.

Further Experiments Concerning the Interaction between the Nylon and Dye in the Bulk of the Solution. *(1) Bulk Dyeing.* The amount of Orange II taken up in the dyeing process was measured by colorimetry for 100 mg of the Nylon 8 in a 2.61×10^{-4} mol/*l* solution of Orange II. The amounts of equilibrium dyeing measured after about 24 hr were 3.28×10^{-5} mol/g Nylon 8 for the neutral solution, and 4.70×10^{-4} mol/g for the acid solution of pH unity. The amount of the end amino group of the Nylon 8, as determined by potentiometric titration,[11] was 3.50×10^{-5} equivalent/g nylon; this value was in agreement with the amount of Orange II dyed from the neutral solution, while the amount dyed from the acid solution was far more than the amount expected from the amino content. This is essentially in agreement with the general trend of the dyeing mechanism of nylons with acid dyes.[12]

(2) Paper Chromatography. A drop of aqueous Orange II was placed as a spot on filter paper (Toyo Roshi, No. 50) previously soaked with a 1% nylon-methanol solution. After the paper had been dried, the spot was eluted with water of 6 and 1 pHs. The distance of the spot eluted was then

Table 2. Movement of Orange II on filter paper

pH of eluent	Treatment of filter paper	Movement of dye spot
6	Treated with nylon	4.65cm
	Untreated	4.65
1	Treated with nylon	0.75
	Untreated	1.75

compared with that obtained for untreated filter paper. The results are shown in Table 2. With an eluent of pH 6 no difference was found in the distance travelled by the spot on the filter papers treated and not treated with a nylon solution. However with an eluent of pH 1, the distance travelled on the treated paper was less than half the length travelled on the untreated filter paper; this may be interpreted as an indication of a distinct interaction at pH 1.

(3) Solubility. The solubilities of the dyed Nylon 8 in MA and FA were also measured: they are qualitatively listed in Table 3. As can be seen in this table, the insoluble nature of the Nylon 8 in MA is not due to dyeing, but is caused merely by the treatment with hydrochloric acid. MA does not dissolve the treated Nylon 8, even at an elevated temperature, while FA is a good solvent for the Nylon 8 at room temperature under any conditions. Such a difference in solubility probably influences the spreadability of the nylon monolayer when these solvents are used, and this in turn probably influences the processes of monolayer dyeing, as has been mentioned already.

Stochastic Model for Chemical Relaxation

Kenji ISHIDA

Department of Applied Chemistry, Ibaraki University, Hitachi

(Received June 25, 1969)

The stochastic formulation of chemical rate equations requires that the process of chemical relaxation should be accompanied with the fluctuation of chemical composition. It is shown that the factor Γ, which Eigen and de Maeyer introduced in the thermodynamic analyses of chemical relaxations, may be interpreted as the fluctuation of chemical composition.

For chemical phenomena, in general, the concept of fluctuation is almost out of question. According to the stochastic theory of chemical kinetics,[1] the fluctuation of chemical composition in an ordinary reaction system is negligibly small compared with the mean value derived from the deterministic theory.[2] There is, however, a chemical phenomenon for which the fluctuation of chemical composition may become an important factor to the description of chemical rate process. It is chemical relaxation. The chemical relaxation we treat in this paper is the process of equilibriation to a constant stationary state after a stepwise perturbation due to the change of a state variable (*e.g.*, temperature jump). If such a chemical relaxation is stochastically treated the fluctuation of chemical composition is explicitly included in the integrated relaxation equation through the relation to equilibrium constant. It is of significance that the stochastic theory of chemical kinetics makes it possible to relate the fluctuation of chemical composition to equilibrium constant.

One-step Reaction

As an introduction to the stochastic model for

1) For an extensive review of this work, see D. A McQuarrie, "Stochastic Approach to Chemical Kinetics," Methuen, London (1967).

2) It has been recently discussed by Oppenheim *et al.* that the stochastic formulation must be reduced to the deterministic formulation in the thermodynamic limit: $N\to\infty$, $V\to\infty$, N/V is constant, where N is the total number of molecules in the system with volume V (I. Oppenheim, K. E. Shuler and G. H. Weiss, *J. Chem. Phys.*, **50**, 460 (1969)).

chemical relaxation, we consider the case of one-step reaction A⇌B taking place in a closed system.

Let $P_{n_A,n_B}(t)$ be the probability that the number of A and B molecules found in the reacting system at time t are n_A and n_B, respectively. According to the stochastic theory of chemical kinetics, then, it follows that the probability distribution $P_{n_A^{(0)},n_B^{(0)}}(0)$ for the system in the initial chemical equilibrium is given by

$$P_{n_A^{(0)},n_B^{(0)}}(0) = \frac{N!}{n_A^{(0)}!\,n_B^{(0)}!}\left(\frac{k_{-1}^{(0)}}{k_1^{(0)}+k_{-1}^{(0)}}\right)^{n_A^{(0)}} \times\left(\frac{k_1^{(0)}}{k_1^{(0)}+k_{-1}^{(0)}}\right)^{n_B^{(0)}} \quad (1)$$

where $N=n_A^{(0)}+n_B^{(0)}$ is the total number of molecules in the system and $k_1^{(0)}$ and $k_{-1}^{(0)}$ denote the transition probabilities per one molecule and per unit time for the reactions A→B and B→A, respectively.[3] If the system governed by the equilibrium probability distribution (1) is disturbed by changing one of the external state variables, which define the thermodynamic equilibrium for the system, it approaches its new stable equilibrium in the manner described by the equation

$$\begin{aligned} dP_{n_A,n_B}(t)/dt = {} & k_1(n_A+1)P_{n_A+1,n_B-1}(t) \\ & -(k_1 n_A + k_{-1}n_B)P_{n_A,n_B}(t) \\ & +k_{-1}(n_B+1)P_{n_A-1,n_B+1}(t) \\ & (0 \leqq n_A, n_B \leqq N) \end{aligned} \quad (2)$$

on the basis of the idea that chemical reaction is Markov process homogeneous in time. In this equation, k_1 and k_{-1} are the transition probabilities in the relaxing system and $P_{N+1,-1}(t)=P_{-1,N+1}(t)=0$ is assumed. Solving Eq. (2) under the initial condition (1), we obtain the binomial distribution

$$P_{n_A,n_B}(t) = \frac{N!}{n_A!\,n_B!}\{p_A(t)\}^{n_A}\{p_B(t)\}^{n_B} \quad (3)$$

where

$$p_A(t) = \frac{k_{-1}}{k_1+k_{-1}} + \frac{\dfrac{k_{-1}^{(0)}}{k_1^{(0)}+k_{-1}^{(0)}}k_1 - \dfrac{k_1^{(0)}}{k_1^{(0)}+k_{-1}^{(0)}}k_{-1}}{k_1+k_{-1}}\,e^{-(k_1+k_{-1})t}$$

and

$$p_B(t) = 1 - p_A(t)$$

Equation (3) represents the probability distribution in the course of the relaxation process under consideration. The expected value of the number of A molecules, $\langle n_A\rangle$, is given by $\langle n_A\rangle = Np_A(t)$. Since the expected value $\langle n_A^{(0)}\rangle$ in the initial equilibrium state is $\langle n_A^{(0)}\rangle = Np_A(0) = Nk_{-1}^{(0)}/(k_1^{(0)}+k_{-1}^{(0)})$, the change of the number of A molecules due to the perturbation, $\Delta\langle n_A\rangle = \langle n_A^{(0)}\rangle - \langle n_A\rangle$, can be written as

$$\Delta\langle n_A\rangle = N\left(\frac{k_{-1}^{(0)}}{k_1^{(0)}+k_{-1}^{(0)}} - \frac{k_{-1}}{k_1+k_{-1}}\right)(1-e^{-(k_1+k_{-1})t}) \quad (4)$$

or

$$\Delta\langle n_A\rangle = N\left(\frac{1}{K_1^{(0)}+1} - \frac{1}{K_1+1}\right)(1-e^{-t/\tau_1}) \quad (5)$$

where we have introduced the equilibrium constant $K_1^{(0)}=k_1^{(0)}/k_{-1}^{(0)}$ and $K_1=k_1/k_{-1}$ and the relaxation time $\tau_1=(k_1+k_{-1})^{-1}$.

When the change δZ of an external state variable Z is applied to the system in the initial chemical equilibrium, the equilibrium constant for the relaxing system can be expressed by

$$K_1 = K_1^{(0)}\{1 + (\partial \ln K_1/\partial Z)_0 \delta Z\} \quad (6)$$

where the subscript 0 denotes the initial state. Substituting Eq. (6) into Eq. (5), we obtain

$$\Delta\langle n_A\rangle = N\frac{K_1^{(0)}}{(K_1^{(0)}+1)^2}\left(\frac{\partial \ln K_1}{\partial Z}\right)_0 \delta Z(1-e^{-t/\tau_1}) \quad (7)$$

The initial probability distribution (1), however, has the variance

$$\begin{aligned} \sigma^2(0) &= \langle (n_A^{(0)} - \langle n_A^{(0)}\rangle)^2\rangle \\ &= Nk_1^{(0)}k_{-1}^{(0)}/(k_1^{(0)}+k_{-1}^{(0)})^2 \end{aligned} \quad (8)$$

We now give an elementary discussion of this equation. The factor $k_1^{(0)}/(k_1^{(0)}+k_{-1}^{(0)})$ represents the transition probability per one molecule and per unit time for A→B under the condition that either forward or reverse reaction occurs and similarly the factor $k_{-1}^{(0)}/(k_1^{(0)}+k_{-1}^{(0)})$ the conditional transition probability for B→A. Since, however, the forward and reverse reactions in the reacting system in chemical equilibrium are considered to occur almost

---

3) If Eq. (2) for the reacting system before perturbation is solved with the initial condition $P_{N,0}(0)=1$, Eq. (1) is obtained as the equilibrium probability distribution which is independent of the initial condition.

This probability distribution can be also derived by the statistical-mechanical procedure as follows. In the ideal gas phase reaction, the equilibrium probability distribution for each component is given by the Poisson distribution

$$p(n_\gamma^{(0)}) = e^{-\lambda_\gamma(p.f.)_\gamma}\{\lambda_\gamma(p.f.)_\gamma\}^{n_\gamma^{(0)}}/n_\gamma^{(0)}! \quad (\gamma = A, B)$$

where λ_γ is the absolute activity of γ-component and $(p.f.)_\gamma$ the partition function. However, as the convolution of Poisson distributions is also the Poisson distribution, the probability distribution for the total number of molecules, $n_A^{(0)}+n_B^{(0)}=N$, is

$$p(N) = e^{-\{\lambda_A(p.f.)_A+\lambda_B(p.f.)_B\}} \times\{\lambda_A(p.f.)_A+\lambda_B(p.f.)_B\}^N/N!$$

It follows that the conditional probability distribution for an arbitrarily fixed N, $p(n_A^{(0)}, n_B^{(0)}\,|\,N)$, is given by the binomial distribution,

$$\begin{aligned} p(n_A^{(0)}, n_B^{(0)}|N) &= p(n_A^{(0)})p(n_B^{(0)})/p(N) \\ &= \frac{N!}{n_A^{(0)}!\,n_B^{(0)}!}\left\{\frac{(p.f.)_A}{(p.f.)_A+(p.f.)_B}\right\}^{n_A^{(0)}} \times \left\{\frac{(p.f.)_B}{(p.f.)_A+(p.f.)_B}\right\}^{n_B^{(0)}} \end{aligned}$$

where the thermodynamic condition of chemical equilibrium, $\lambda_A=\lambda_B$, is used. This is equivalent to Eq. (1) because of $(p.f.)_B/(p.f.)_A=\langle n_B^{(0)}\rangle/\langle n_A^{(0)}\rangle=k_1^{(0)}/k_{-1}^{(0)}=K_1^{(0)}$.

simultaneously with various reaction probabilities, the chemical compositions must be more or less fluctuating about the expected values. The fluctuation $\sigma^2(0)$ may therefore be regarded as the expected value of such an event. We then have in place of Eq. (8)

$$\sigma^2(0) = NK_1^{(0)}/(K_1^{(0)} + 1)^2 \tag{9}$$

which tells us the relation of fluctuation to equilibrium constant. On applying Eq. (9) to Eq. (7), we find that

$$\Delta\langle n_A\rangle = \sigma^2(0)\left(\frac{\partial \ln K_1}{\partial Z}\right)_0 \delta Z(1 - e^{-t/\tau_1}) \tag{10}$$

To the same approximation, this can be also written as

$$\Delta\langle n_A\rangle = \sigma^2(\infty)\left(\frac{\partial \ln K_1}{\partial Z}\right)_0 \delta Z(1-e^{-t/\tau_1}) \tag{11}$$

because the relation between $\sigma^2(0)$ and the fluctuation $\sigma^2(\infty)$ in the new chemical equilibrium is given by

$$\begin{aligned}\sigma^2(\infty) &= NK_1/(K_1 + 1)^2 \\ &\simeq \sigma^2(0)\left\{1 - \frac{K_1^{(0)} - 1}{K_1^{(0)} + 1}\left(\frac{\partial \ln K_1}{\partial Z}\right)_0 \delta Z\right\}\end{aligned} \tag{12}$$

where Eqs. (6) and (9) have been used and $|(K_1^{(0)}-1)/(K_1^{(0)}+1)|<1$ holds for all possible values of $K_1^{(0)}$.

It is instructive to compare such a stochastic analysis with the theory of Eigen and de Maeyer. We transform the fluctuation $\sigma^2(\infty)$ as follows:

$$\begin{aligned}\sigma^2(\infty) &= Np_A(\infty)\{1 - p_A(\infty)\} \\ &= \langle n_A\rangle_\infty\langle n_B\rangle_\infty/N \\ &= (1/\langle n_A\rangle_\infty + 1/\langle n_B\rangle_\infty)^{-1}\end{aligned} \tag{13}$$

where $\langle n_A\rangle_\infty = Np_A(\infty)$ and $\langle n_B\rangle_\infty = Np_B(\infty)$ are the mean numbers of A and B molecules in the new chemical equilibrium, respectively. The last expression of Eq. (12) is in form in agreement with the factor Γ that Eigen and de Maeyer have introduced through the thermodynamic considerations of chemical relaxations.[4]

According to the stochastic nonequilibrium thermodynamics of chemical reactions,[5] the fluctuation $\sigma^2(\infty)$ can be closely correlated to the chemical affinity A by

$$\sigma^2(\infty) = \left\{-\frac{1}{\boldsymbol{k}T}\left(\frac{\partial A}{\partial \xi}\right)_\infty\right\}^{-1} \tag{14}$$

where $\boldsymbol{k}$ is Boltzmann's constant, T the temperature of the relaxing system in chemical equilibrium and ξ the degree of advancement. Since the chemical affinity is expressed in the form

$$A = \boldsymbol{k}T\{\ln(\langle n_A\rangle/\langle n_A\rangle_\infty) - \ln(\langle n_B\rangle/\langle n_B\rangle_\infty)\}$$

it can be easily shown that Eq. (14) is equivalent to Eq. (13). From the stochastic point of view, therefore, the factor Γ of Eigen and de Maeyer is to be interpreted as the fluctuation of chemical composition.

To test this theory for other chemical relaxations, we take a second-order reaction $A+B\rightleftarrows C$ as an example. The stochastic process for this reaction is described by

$$\begin{aligned}dP_{n_C}(t)/dt = {} & k_2\{n_A^{(0)} - (n_C - 1 - n_C^{(0)})\} \\ & \times \{n_B^{(0)} - (n_C - 1 - n_C^{(0)})\}P_{n_C-1}(t) \\ & -[k_2\{n_A^{(0)} - (n_C - n_C^{(0)})\} \\ & \times \{n_B^{(0)} - (n_C - n_C^{(0)})\} + k_{-2}n_C]P_{n_C}(t) \\ & +k_{-2}(n_C + 1)P_{n_C+1}(t)\end{aligned} \tag{15}$$

where $P_{n_C}(t)$ denotes the probability that the number of molecules of chemical species C existing in the relaxing system at time t is n_C, $n_A^{(0)}$, $n_B^{(0)}$ ($\geq n_A^{(0)}$) and $n_C^{(0)}$ are the numbers of A, B and C molecules in the initial chemical equilibrium and k_2 and k_{-2} the transition probabilities per molecule and per unit time for the forward and reverse reactions, respectively. Since the difference between $\sigma^2(0)$ and $\sigma^2(\infty)$ is not so large, as is clear from Eq. (12), it has been assumed that the numbers of A, B and C molecules in the initial chemical equilibrium are given by $n_A^{(0)}$, $n_B^{(0)}$ are $n_C^{(0)}$ in the probabilistic mean of $P_{n_A^{(0)},\, n_B^{(0)},\, n_C^{(0)}}(0)=1$. If the inequality $n_C - n_C^{(0)} \ll n_A^{(0)}, n_B^{(0)}$, which corresponds to the linear approximation in the usual analysis of chemical relaxation, holds during the relaxation process, Eq. (15) is reduced to

$$\begin{aligned}dP_{n_C}(t)/dt = {} & k_2\{(n_A^{(0)}n_B^{(0)} + n_B^{(0)}n_C^{(0)} + n_C^{(0)}n_A^{(0)}) \\ & -(n_A^{(0)} + n_B^{(0)})(n_C - 1)\}P_{n_C-1}(t) \\ & -[k_2\{(n_A^{(0)}n_B^{(0)} + n_B^{(0)}n_C^{(0)} + n_C^{(0)}n_A^{(0)}) \\ & -(n_A^{(0)} + n_B^{(0)})n_C\} + k_{-2}n_C]P_{n_C}(t) \\ & +k_{-2}(n_C + 1)P_{n_C+1}(t)\end{aligned} \tag{15'}$$

Solving this differential-difference equation by the use of the generating function of $P_{n_C}(t)$,

$$G(\theta, t) = \sum_{n_C=0}^{\infty} \theta^{n_C}P_{n_C}(t), \qquad |\theta| \leqq 1$$

we obtain, as the solution subject to the initial condition

4) M. Eigen and L. de Maeyer, "Technique of Organic Chemistry," 2nd Ed., Vol. VIII, part 2, ed. by S. L. Fries, E. S. Lewis and A. Weissberger, Interscience Publishers, Inc., New York, N. Y. (1963), p. 934. In deriving the thermodynamic relation of the change of concentration to that of equilibrium constant, they have defined the factor $\Gamma_m = 1/(\sum_i \nu_i^2/\bar{m}_i)$, where ν_i is the stoichiometric coefficient and $\bar{m}_i$ the molality in chemical equilibrium state. The index of Γ, however, changes with the kind of concentration variable. Whatever concentration variables may be used, the factor Γ is correlated to the fluctuation of chemical composition. For example, the factor Γ for the chemical relaxation of $A\rightleftarrows B$ has been given by $\Gamma_\alpha = 1/(1/\bar{\alpha}+1/(1-\bar{\alpha})) = \bar{\alpha}(1-\bar{\alpha}) = K_0/(1+K_0)^2$, where $\bar{\alpha}$ is the mole fraction of chemical species A and $K_0=(1-\bar{\alpha})/\bar{\alpha}$ the equilibrium constant. The factor Γ_α is consistent with $\sigma^2(\infty)/N = p_A(\infty)\{1-p_A(\infty)\}$, if it is assumed that $p_A(\infty)=\bar{\alpha}$.

5) K. Ishida, *J. Phys. Chem.*, **70**, 3806 (1966); **72**, 92 (1968).

$$P_{n_C^{(0)}}(0) = 1,\ i.e.,\ G(\theta, 0) = \theta^{n_C^{(0)}},$$

$$G(\theta, t) = \{k_2(n_A^{(0)} + n_B^{(0)}) + k_{-2}\}^{-\frac{n_A^{(0)} n_B^{(0)}}{n_A^{(0)} + n_B^{(0)}} - n_C^{(0)}} \times \{k_{-2} + k_2(n_A^{(0)} + n_B^{(0)})e^{-t/\tau_2} + k_2(n_A^{(0)} + n_B^{(0)})(1 - e^{-t/\tau_2})\theta\}^{\frac{n_A^{(0)} n_B^{(0)}}{n_A^{(0)} + n_B^{(0)}}} \times \{k_{-2}(1 - e^{-t/\tau_2}) + [k_2(n_A^{(0)} + n_B^{(0)}) + k_{-2}e^{-t/\tau_2}]\theta\}^{n_C^{(0)}} \quad (16)$$

where $\tau_2 = \{k_2(n_A^{(0)} + n_B^{(0)}) + k_{-2}\}^{-1}$ is the relaxation time. Since, then, the mean number of C molecules, $\langle n_C \rangle$, is given by $\theta \partial G/\partial\theta \,|_{\theta=1} = \langle n_C \rangle$, we have as the deviation from the initial value, $\Delta\langle n_C \rangle = \langle n_C \rangle - n_C^{(0)}$,

$$\Delta\langle n_C \rangle = \frac{k_2 n_A^{(0)} n_B^{(0)} - k_{-2} n_C^{(0)}}{k_2(n_A^{(0)} + n_B^{(0)}) + k_{-2}}(1 - e^{-t/\tau_2}) \quad (17)$$

By the procedure given in Appendix I, we can transform Eq. (17) into the equation involving the fluctuation of chemical species C

$$\Delta\langle n_C \rangle = \sigma_C^2(\infty)\left(\frac{\partial \ln K_2}{\partial Z}\right)_0 \delta Z(1 - e^{-t/\tau_2}) \quad (18)$$

which is of the same form as Eq. (11). In Eq. (18), $K_2 = k_2/k_{-2}$ is the equilibrium constant and the fluctuation for chemical species C is given by

$$\sigma_C^2(\infty) = \frac{(n_A^{(0)} n_B^{(0)} + n_B^{(0)} n_C^{(0)} + n_C^{(0)} n_A^{(0)})K_2}{\{1 - (n_A^{(0)} + n_B^{(0)})K_2\}^2} \quad (19)$$

which has been calculated by the formula

$$\sigma_C^2(t) = (\theta^2 \partial^2 G/\partial\theta^2 + \theta \partial G/\partial\theta)|_{\theta=1} - (\theta \partial G/\partial\theta\,|_{\theta=1})^2$$

When, however, it is taken into consideration that the approximation $\langle n_C \rangle^2_\infty - n_C^{(0)2} \ll n_A^{(0)} n_B^{(0)} + n_B^{(0)} n_C^{(0)} + n_C^{(0)} n_A^{(0)}$ holds for the chemical relaxation we are concerned with, Eq. (19) can be transformed into the form of the factor Γ of Eigen - de Maeyer,

$$\sigma_C^2(\infty) = (1/\langle n_A \rangle_\infty + 1/\langle n_B \rangle_\infty + 1/\langle n_C \rangle_\infty)^{-1} \quad (20)$$

where $\langle n_A \rangle_\infty = n_A^{(0)} - (\langle n_C \rangle_\infty - n_C^{(0)})$ and $\langle n_B \rangle_\infty = n_B^{(0)} - (\langle n_C \rangle_\infty - n_C^{(0)})$. We thus see from Eqs. (11) and (18) that the stochastic theory of chemical relaxation may make it possible to evaluate the fluctuation of chemical composition.

Two-step Reaction

Up to the present, we have stochastically discussed only the chemical relaxations of one-step reactions, but we must also investigate along the same line as in the preceding section how the fluctuation of chemical composition appears in the chemical relaxation of multiple-step reaction. For instance, we can take up a two-step reaction $A \rightleftarrows B \rightleftarrows C$. For practical purposes, however, we are interested in the reaction such as $A + B \rightleftarrows C \rightleftarrows D$.

It is necessary to write down the equation describing the stochastic process for the chemical relaxation of this reaction. Let us denote by $n_A^{(0)}$, $n_B^{(0)}$, $n_C^{(0)}$ and $n_D^{(0)}$ the numbers of A, B, C and D molecules present in the initial equilibrium system, respectively. If the changes of the numbers of A (and B), C and D molecules from the equilibrium values due to the change of an external state variable Z are chosen as the random variables, which assume the realized values x, y and z at time t, the joint probability distribution $P_{x,y,z}(t)$ satisfies the linear equation similar to Eq. (15′)

$$\begin{aligned} dP_{x,y,z}(t)/dt = {} & \kappa_1\{n_A^{(0)} n_B^{(0)} + (n_A^{(0)} + n_B^{(0)})(x+1)\}P_{x+1,y-1,z}(t) \\ & + \kappa_{-1}(n_C^{(0)} + y + 1)P_{x-1,y+1,z}(t) \\ & - \{\kappa_1(n_A^{(0)} n_B^{(0)} + (n_A^{(0)} + n_B^{(0)})x) \\ & + (\kappa_{-1} + \kappa_2)(n_C^{(0)} + y) + \kappa_{-2}(n_D^{(0)} + z)\}P_{x,y,z}(t) \\ & + \kappa_2(n_C^{(0)} + y + 1)P_{x,y+1,z-1}(t) \\ & + \kappa_{-2}(n_D^{(0)} + z + 1)P_{x,y-1,z+1}(t) \end{aligned} \quad (21)$$

where κ_1 and κ_{-1} are the transition probabilities for the forward and reverse reactions of $A + B \rightleftarrows C$ and similarly κ_2 and κ_{-2} the transition probabilities for $C \rightleftarrows D$. Defining the generating function $P_{x,y,z}(t)$ by

$$G(\theta_1, \theta_2, \theta_3; t) = \sum_{x,y,z=0}^{\infty} \theta_1^x \theta_2^y \theta_3^z P_{x,y,z}(t)$$

we obtain, from Eq. (21),

$$\begin{aligned} \frac{\partial G}{\partial t} = {} & -\kappa_1(n_A^{(0)} + n_B^{(0)})(\theta_1 - \theta_2)\frac{\partial G}{\partial \theta_1} \\ & + \{\kappa_{-1}\theta_1 - (\kappa_{-1} + \kappa_2)\theta_2 + \kappa_2\theta_3\} \\ & \times \frac{\partial G}{\partial \theta_2} + \kappa_{-2}(\theta_2 - \theta_3)\frac{\partial G}{\partial \theta_3} \\ & - \{\kappa_1 n_A^{(0)} n_B^{(0)}(1 - \theta_2/\theta_1) + \kappa_{-1} n_C^{(0)}(1 - \theta_1/\theta_2) \\ & + \kappa_2 n_C^{(0)}(1 - \theta_3/\theta_2) + \kappa_{-2} n_D^{(0)}(1 - \theta_2/\theta_3)\}G \end{aligned}$$

This partial differential equation is to be solved with the initial condition $G(\theta_1, \theta_2, \theta_3; 0) = 1$, which means that $P_{0,0,0}(0) = 1$. The solution can be written in the form

$$\begin{aligned} G(\theta_1, \theta_2, \theta_3; t) = {} & \theta_1^{-\frac{n_A^{(0)} n_B^{(0)}}{n_A^{(0)} + n_B^{(0)}}} \theta_2^{-n_C^{(0)}} \theta_3^{-n_D^{(0)}} \\ & \times \left\{\sum_{i=1}^{3} p_i(t)\theta_i\right\}^{\frac{n_A^{(0)} n_B^{(0)}}{n_A^{(0)} + n_B^{(0)}}} \left\{\sum_{i=1}^{3} q_i(t)\theta_i\right\}^{n_C^{(0)}} \\ & \times \left\{\sum_{i=1}^{3} r_i(t)\theta_i\right\}^{n_D^{(0)}} \end{aligned} \quad (22)$$

where $p_i(t)$, $q_i(t)$ and $r_i(t)$ will be given in Appendix II.

For the sake of simplicity, we restrict ourselves to investigate how the change of the number of D molecules in the relaxing system can be related to the fluctuation. From Eq. (22), we obtain as the expected value

$$\langle z \rangle = \frac{n_A^{(0)} n_B^{(0)}}{n_A^{(0)} + n_B^{(0)}} p_3(t) + n_C^{(0)} q_3(t) + n_D^{(0)}\{r_3(t) - 1\} \quad (23)$$

where we have used $(\theta_3 \partial G/\partial\theta_3)\,|_{\theta_1=\theta_2=\theta_3=1} = \langle z \rangle$. If the equilibriation in the first stage is much faster than in the second, it follows that $\kappa_1(n_A^{(0)} + n_B^{(0)})$ and

κ_{-1} are sufficiently large compared with κ_2 and κ_{-2}. We then have the inequality $\alpha \gg \beta$ and the approximations

$$\alpha = \kappa_1(n_A^{(0)} + n_B^{(0)}) + \kappa_{-1}$$

and

$$\beta = \frac{\kappa_1(n_A^{(0)} + n_B^{(0)}))\kappa_2}{\kappa_1(n_A^{(0)} + n_B^{(0)}) + \kappa_{-1}} + \kappa_{-2}$$

In such a case, Eq. (23) may be written as

$$\langle z\rangle = \left\{\frac{n_A^{(0)}n_B^{(0)}}{n_A^{(0)}+n_B^{(0)}} + n_C^{(0)} - n_D^{(0)}\frac{\kappa_{-2}\alpha}{\kappa_1(n_A^{(0)} + n_B^{(0)})\kappa_2}\right\} \times \frac{\kappa_1(n_A^{(0)} + n_B^{(0)})\kappa_2}{\alpha\beta}(1 - e^{-t/\tau_2}) \quad (24)$$

where $\tau_2=\beta^{-1}$ denotes the relaxation time. If, however, we introduce the equilibrium constants $\kappa_1/\kappa_{-1}=K_1$, $\kappa_2/\kappa_{-2}=K_2$, $n_C^{(0)}/n_A^{(0)}n_B^{(0)}=K_1^{(0)}$ and $n_D^{(0)}/n_C^{(0)}=K_2^{(0)}$, we obtain, by the same procedure as in the transformation from Eq. (17) to Eq. (18)

$$\langle z\rangle = \sigma_D^2(\infty)\left\{1 + \frac{n_A^{(0)}n_B^{(0)}}{n_A^{(0)}n_B^{(0)} + n_B^{(0)}n_C^{(0)} + n_C^{(0)}n_A^{(0)}} \times \frac{(\partial \ln K_1/\partial Z)_0}{(\partial \ln K_2/\partial Z)_0}\right\}(\partial \ln K_2/\partial Z)_0\delta Z(1 - e^{-t/\tau_2}) \quad (25)$$

where the fluctuation $\sigma_D^2(\infty)$ for chemical species D in the new chemical equilibrium state is given by

$$\sigma_D^2(\infty) = \left\{\frac{n_A^{(0)}n_B^{(0)}}{n_A^{(0)}+n_B^{(0)}} + n_C^{(0)} + n_D^{(0)}\right\} \times \frac{\kappa_1(n_A^{(0)} + n_B^{(0)})\kappa_2}{\alpha\beta}\left\{1 - \frac{\kappa_1(n_A^{(0)} + n_B^{(0)})\kappa_2}{\alpha\beta}\right\}$$

Since the first stage of the reaction is considered to be in stationary state, it may be expected that

$$|(\partial \ln K_1/\partial Z)_0/(\partial \ln K_2/\partial Z)_0| = |n_D^{(0)}/(n_C^{(0)} + n_D^{(0)})|$$

It is then concluded that Eq. (25) is reduced to

$$\langle z\rangle = \sigma_D^2(\infty)(\partial \ln K_2/\partial Z)_0\delta Z(1 - e^{-t/\tau_2}) \quad (26)$$

which is of the same form as Eqs. (11) and (18).

We can in general say that chemical relaxation should be accompanied with the fluctuation of chemical composition.

Appendix I

The first member on the right-hand side of Eq. (17) can be written in the form

$$\frac{k_2n_A^{(0)}n_B^{(0)} - k_{-2}n_C^{(0)}}{k_2(n_A^{(0)} + n_B^{(0)}) + k_{-2}} = \sigma_C^2(\infty)(K_2 - K_2^{(0)}) \times \frac{n_A^{(0)}n_B^{(0)}\{(n_A^{(0)} + n_B^{(0)})K_2 + 1\}}{(n_A^{(0)}n_B^{(0)} + n_B^{(0)}n_C^{(0)} + n_C^{(0)}n_A^{(0)})K_2} \quad (A.1)$$

where the fluctuation (19) and the equilibrium constants $n_C^{(0)}/n_A^{(0)}n_B^{(0)}=K_1^{(0)}$ and $k_2/k_{-2}=K_2$ have been used. If we apply $K_2=K_2^{(0)}\{1+(\partial \ln K_2/\partial Z)_0\delta Z\}$ to Eq. (A.1), we have, by neglecting the terms of higher order than the first of δZ,

$$\frac{k_2n_A^{(0)}n_B^{(0)} - k_{-2}n_C^{(0)}}{k_2(n_A^{(0)} + n_B^{(0)}) + k_{-2}} = \sigma_C^2(\infty)\left(\frac{\partial \ln K_2}{\partial Z}\right)_0\delta Z \times \left\{1 - \frac{n_A^{(0)}n_B^{(0)}}{n_A^{(0)}n_B^{(0)} + n_B^{(0)}n_C^{(0)} + n_C^{(0)}n_A^{(0)}}\left(\frac{\partial \ln K_2}{\partial Z}\right)_0\delta Z\right\} \simeq \sigma_C^2(\infty)\left(\frac{\partial \ln K_2}{\partial Z}\right)_0\delta Z \quad (A.2)$$

since it is necessary that $1 \gg |(\partial \ln K_2/\partial Z)_0\delta Z| > 0$ for the linearization such as Eq. (15′).[6] We thus obtain Eq. (18) from Eq. (17).

Appendix II

In Eq. (22), $p_i(t)$, $q_i(t)$ and $r_i(t)$ $(i=1, 2, 3)$ have the following expressions:

$$p_1(t) = \frac{\kappa_{-1}\kappa_{-2}}{\alpha\beta} - \frac{\kappa_1(n_A^{(0)} + n_B^{(0)})(\kappa_2 + \kappa_{-2}-\alpha)}{\alpha(\alpha-\beta)}e^{-\alpha t} + \frac{\kappa_1(n_A^{(0)} + n_B^{(0)})(\kappa_2 + \kappa_{-2}-\beta)}{\beta(\alpha-\beta)}e^{-\beta t}$$

$$p_2(t) = \frac{\kappa_1(n_A^{(0)} + n_B^{(0)})\kappa_{-2}}{\alpha\beta} + \frac{\kappa_1(n_A^{(0)} + n_B^{(0)})(\kappa_{-2}-\alpha)}{\alpha(\alpha-\beta)}e^{-\alpha t} - \frac{\kappa_1(n_A^{(0)} + n_B^{(0)})(\kappa_{-2}-\beta)}{\beta(\alpha-\beta)}e^{-\beta t}$$

$$p_3(t) = \frac{\kappa_1(n_A^{(0)} + n_B^{(0)})\kappa_2}{\alpha\beta} + \frac{\kappa_1(n_A^{(0)} + n_B^{(0)})\kappa_2}{\alpha(\alpha-\beta)}e^{-\alpha t} - \frac{\kappa_1(n_A^{(0)} + n_B^{(0)})\kappa_2}{\beta(\alpha-\beta)}e^{-\beta t}$$

$$q_1(t) = \frac{\kappa_{-1}\kappa_{-2}}{\alpha\beta} + \frac{\kappa_{-1}(\kappa_{-2} - \alpha)}{\alpha(\alpha - \beta)}e^{-\alpha t} - \frac{\kappa_{-1}(\kappa_{-2} - \beta)}{\beta(\alpha - \beta)}e^{-\beta t}$$

$$q_2(t) = \frac{k_1(n_A^{(0)} + n_B^{(0)})\kappa_{-2}}{\alpha\beta} - \frac{\kappa_1(n_A^{(0)} + n_B^{(0)})\kappa_2 + \kappa_{-1}\kappa_{-2} - (\kappa_{-1} + \kappa_2)\alpha}{\alpha(\alpha - \beta)}e^{-\alpha t} + \frac{\kappa_1(n_A^{(0)} + n_B^{(0)})\kappa_2 + \kappa_{-1}\kappa_{-2} - (\kappa_{-1} + \kappa_2)\beta}{\beta(\alpha - \beta)}e^{-\beta t}$$

$$q_3(t) = \frac{\kappa_1(n_A^{(0)} + n_B^{(0)})\kappa_2}{\alpha\beta} + \frac{\kappa_2(\kappa_1(n_A^{(0)} + n_B^{(0)}) - \alpha)}{\alpha(\alpha - \beta)}e^{-\alpha t} - \frac{\kappa_2(\kappa_1(n_A^{(0)} + n_B^{(0)}) - \beta)}{\beta(\alpha-\beta)}e^{-\beta t}$$

and

$$r_1(t) = \frac{\kappa_{-1}\kappa_{-2}}{\alpha\beta} + \frac{\kappa_{-1}\kappa_{-2}}{\alpha(\alpha-\beta)}e^{-\alpha t} - \frac{\kappa_{-1}\kappa_{-2}}{\beta(\alpha-\beta)}e^{-\beta t}$$

$$r_2(t) = \frac{\kappa_1(n_A^{(0)} + n_B^{(0)})\kappa_{-2}}{\alpha\beta} + \frac{\kappa_{-2}(\kappa_1(n_A^{(0)} + n_B^{(0)})-\alpha)}{\alpha(\alpha - \beta)}e^{-\alpha t} - \frac{\kappa_{-2}(\kappa_1(n_A^{(0)} + n_B^{(0)}) - \beta)}{\beta(\alpha - \beta)}e^{-\beta t}$$

$$r_3(t) = \frac{\kappa_1(n_A^{(0)} + n_B^{(0)})\kappa_2}{\alpha\beta} + \frac{\kappa_{-2}(\kappa_2 + \kappa_{-2} - \beta)}{\alpha(\alpha - \beta)}e^{-\alpha t} - \frac{\kappa_{-2}(\kappa_2 + \kappa_{-2} - \alpha)}{\beta(\alpha - \beta)}e^{-\beta t}$$

where α and β $(\alpha>\beta>0)$ are the roots of the equation

$$\eta^2 - \{\kappa_1(n_A^{(0)} + n_B^{(0)}) + \kappa_{-1} + \kappa_2 + \kappa_{-2}\}\eta + \kappa_1(n_A^{(0)} + n_B^{(0)})(\kappa_2 + \kappa_{-2}) + \kappa_{-1}\kappa_{-2} = 0$$

and $\sum_{i=1}^{3} p_i(t) = \sum_{i=1}^{3} q_i(t) = \sum_{i=1}^{3} r_i(t) = 1$ and $p_i(\infty)=q_i(\infty)=r_i(\infty)$ are satisfied.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 319—325 (1970)

The Paramagnetic Species Formed on the Surfaces of Various Oxides by Naphthalene Derivatives

Hisashi UEDA

Government Chemical Industrial Research Institute, Tokyo, Meguro-ku, Tokyo

(Received July 1, 1969)

The ESR intensities from the paramagnetic species formed by mixing a naphthalene derivative with an oxide powder were studied after the mixture had been heated at various temperatures. The measurements were made at 20°C. As additives 1-nitronaphthalene, 1-naphthol, 1,4-naphthoquinone, naphthalic acid, 1-naphthylamine, 1-nitroso-2-naphthol, naphthalene, triphenylene, and anthracene were used. As oxides, alumina, Al_2O_3-MoO_3, silicagel, TiO_2, MgO, MoO_3, CuO, and $ZnCrO_4$ were used. The ESR intensities obtained by the first six oxides depended only on the ionization potential of the additives, while those obtained by CuO and $ZnCrO_4$ did not. The ESR intensities obtained when 1-naphthol was mixed with alumina samples with various surface areas were exactly proportional to the surface areas of the alumina specimens used. It was concluded that, in the first six oxides, the additives are chemisorbed by the oxides at the active-oxygen anion sites on the surface. The introduction of either NH_3 or N_2O onto the adsorbed species formed on Al_2O_3-MoO_3 particles decreased (in the case of NH_3) or increased (in the case of N_2O) the ESR intensities. From these facts, it is concluded that a cationic complex, (naphthalene derivative$^+$-O^{2-}), is formed on the surface of these six oxides. In the case of CuO, the presence of (Cu^+-naphthylamine$^+$) is concluded.

The effects of various additives on the ESR intensities of zinc oxide were previously studied by the present author;[1] it was found that the surface ionization of the aromatic additive on the particle of zinc oxide, $Ar+ZnO \rightarrow Ar^+ + (ZnO)^-$, is in an equilibrium with the transfer of the hole from Ar^+ to Zni (interstitial zinc atom), $Ar^+ + Zni \rightarrow Ar + Zni^+$. Though the surface ionization of the aromatic compound on silica-alumina has long been established using perylene, diphenylethylene, and diphenylamine as additives,[2,3] the detailed mechanism has not yet been made clear. In some recent studies, the formation of a negative ion is claimed for the system consisting of an oxide and nitrobenzene.[4-6] Therefore, some criterion is strongly desired with which it is possible to predict the type of paramagnetic species to be formed on the surface from an additive compound with a particular type of molecular structure or functional group. Hoping to obtain a generalized solution for this problem, we have tested systems consisting of various oxides and naphthalene derivatives with various substituted functional groups together with anthracene and triphenylene, which it is also possible to consider as naphthalene derivatives. Naphthalene derivatives have been selected because (1) their ionization potentials are lower than those of the benzene derivatives with the same functional groups; (2) the desired substituted compounds are easier to acquire than those of anthracene or other, larger condensed-ring compounds, and (3) the ionization energies may be calculated as a problem of the variation in h and k by a proper molecular orbital theory.

Experimental

The additive compounds were used after recrystallization. Benzene, the solvent for the additive solution (0.2 mmol of a solute in 2.0 m*l* of the solvent), was used after having been shaken with concentrated sulfuric acid and by subsequent distillations. Special reagent-grade oxides, shown in Table 3, were used without further purification. The additive solution (2.0 m*l*) was poured on the oxide (1.0 g) and the solvent was evaporated in air. After the evaporation of the benzene, the mixture was placed in an ESR sample tube and was then evacuated to at least 10^{-2} mmHg (or to the vapor pressure of the additive). The sample thus prepared was examined first at room temperature. After the measurement, the tube was placed in a copper block with a hole to fit the diameter and the length of the sample tube, heated to 50°C for three minutes, and then cooled to 20°C. Then the measurement was made. Identical operations were repeated at different heating

temperatures, 100, 150, 200, and 250°C. The ESR intensity measurements were made using the same microwave power and at the same crystal current. Carbon powder ground with alumina and sealed in a vacuum was used as the intensity standard by measuring it between each ten measurements of the additive-oxide samples.

Results

In Table 1 the relative values of the ESR intensities obtained from Al_2O_3-MoO_3 (10%) containing various additives, after the sample had been heated at 250°C, x_1, x_2, x_3, u_1, u_2, and u_3, are shown. In the table, x denotes the intensity of the line with $g=2.004\pm0.001$ and with δH_{msl} smaller than 10 gauss, and u denotes the intensity of the line with $g=1.9328$. Both x and u are relative values, and so they are shown on different scales. The suffix 1 denotes the value for the sample in vacuum, 2 that for the sample in N_2O (350 mmHg), and 3 that for sample in NH_3 (300 mmHg). In Fig. 1, the x_1 values of Table 1 and the corresponding values for different oxides, *i.e.*, Al_2O_3, MoO_3, MgO, TiO_2 and silicagel, are plotted against the light absorption wave number in kilo Kaiser of the additve. The wave number value used here is equal to $10^7/\lambda_{max}$, where λ_{max} denotes the maximum peak wavelength in mμ of the absorption peaks observed below 500 mμ.*1 Figure 2 shows the spin concentration obtained by γ-alumina with 1-naphthol at room temperature *versus* the surface area of the alumina sample, which was measured by the helium-nitrogen BET method. The results show that unpaired electrons are formed on the surface and that the concentration is 3.3×10^{11} spins/cm^2, which may be compared with the value reported by Rooney and Pink, 2×10^{11} spins/cm^2 for perylene-silica-alumina. Table 2 shows the line-width at the maximum slope of the singlet ESR absorption, with $g=$

*1 Some of the additives absorb in the near IR region; this phenomenon must be due to a different type of transition and so was ignored.

2.004 ± 0.001, for the species formed by various additives. It can be seen that both the δH_{msl} and g values depend upon the additives. In Table 3 the same quantities as in Table 2 are shown for various oxides mixed with 1-nitroso-2-naphthol as the additive. The results show that the oxides also slightly affect the spectroscopic constants. In the case of perylene-silica-alumina, the hyperfine splitting was partly resolved in the spectrum. In the present study only 1-nitroso-2-naphthol gave a

hyperfine structure in the spectrum (three lines), but this structure disappeared when the specimen was heated at higher temperatures. Figure 3 shows the same quantities as those in Fig. 1 except for CuO (filled circles) and $ZnCrO_4$ (white circles). In this figure, the ESR intensities are stronger only for the additives which have either –OH or a $-NH_2$ group, or which are Lewis bases. Figure 4 shows the dependence of the relative ESR intensities for the sample consisting of CuO and 1-naphthylamine on the temperature of the heat treatment at 100, 150 and 200°C. The vertical amplitude of the spectrum at 200°C is six times as strong as that at 100 or 150°C. In Fig. 5 the temperature dependence of the relative (all on the same scale) ESR intensities for alumina and Al_2O_3-MoO_3, with 1-naphthol as the additive and with or without N_2O or NH_3 are shown. It can be seen that when both N_2O and Mo^{6+} exist on the surface they give the same type of activity to the surface of alumina, while NH_3 gives the opposite activity.

Discussion

The determination of the sign of the electric charge on an organic ionic species is often difficult[7,8] if the available information is limited to the spectroscopic data. Such difficulty increases if the spectroscopic measurement is made for a solid sample. In the case of zinc oxide[1] the presence of the electron donor, Zni, which gave the line with $g=1.96$ and which could easily be identified, has already been established. By using this fact, the sign of the aromatic ionic species on zinc oxice was determined. In some studies, the criterion that the electronegativity of the functional group attached to the aromatic ring determines the sign of the ionic species to be formed by that compound, has been used. However, it seems that this criterion is not as good as the one stating that the type of environment, in which the ionization occurs, determines the sign of the ionic species. This latter criterion can be written, alternatively, as stating that the atmosphere, the solvent, the matrix or the nature of the surface where the ionization occurs determines the type of the ionic species to be formed, rather than the intrinsic nature of the additive or the solute. Generally speaking, an aromatic compound with a low ionization potential, typically represented by perylene, also has a large electron affinity. In other words, it is equally easy to form an anion and a cation. The results obtained by radiation chemical studies of rigid glass solid solutions of aromatic compounds in solvents of various chemical structures have indicated that the matrix determines the sign of the electric charge of the ionic species to be formed.[9] In the present work, the additives with lower ionization potentials gave stronger ESR intensities, as is shownin Fig. 1. It cannot directly be concluded, for the foregoing reason, that cations were giving the ESR signals. However, the facts in Fig. 1 at least indicate that ionic species are formed.

Recently many studies have been made of ionic intermediates in radiation chemistry. Probably the most reliable method for the discrimination of ions in condensed phases has been the addition of N_2O or NH_3 to observe its effects on the formation of ionic intermediates. If an aromatic hydrocarbon is dissolved in an aliphatic ether and if this solution is irradiated, the electron primarily formed by ionizing radiation is captured by the solute molecule to form its negative ion. This formation of the negative ion can be effectively prevented by adding a small amount of N_2O to the solution, since N_2O scavenges the electron primarily formed.[10] If N_2O is added to a system in which a cation is to be formed, it increases the amount of the cation.[8] On the other hand, if NH_3 is added, it scavenges the positively-charged molecular species.[8] The results in Table 1 show that, for all the additives studied, the ESR intensities are partly cancelled by NH_3 and increased by N_2O. It seems that Table 1 provides enough evidence to establish the formation of a cation or a cation-like species in these systems. The results in Fig. 2 show that the phenomenon is a surface process.

In the case of the silica-alumina-perylene system, a carefully-created anaerobic environment was needed for the formation of the cation. This also indicates that the ionization is a surface process. The ESR data in Tables 2 and 3 show that the molecular orbital for the unpaired electron is made by an admixture of the wave functions of both the oxide and the additive orbitals. In other words, the unpaired spin is both on the oxide and the additive sides. Therefore, the additive is adsorbed by the oxide particles by chemisorption. The fact that the positive ions of the oxides shown in Fig. 1 (for example, the Mg^{2+} of MgO) do not affect the spectrum indicates that the chemisorption takes place at the O^{2-} site of the surface by an overlapping of its $2p$ orbital and the π-orbital of the aromatic additive molecule. If the cation of the oxide, *e.g.*, Mg^{2+}, accepts the electron directly from the additive molecule, what determines the ESR intensity will be both the electron affinity of the cation of the oxide and the ionization potential of the additive molecule. The results in Fig. 1 indicate that only the ionization potential of the additive determines the ESR intensity. The difference in the total intensities of the

10) G. Scholes and M. Simic, *Nature*, **202**, 895 (1964); S. Sato, T. Terao, M. Kono and S. Shida, This Bulletin, **40**, 1818 (1967).

ESR signal for different oxides indicates that the ionization which follows the chemisorption takes place on those O^{2-} ions which are in or which occupy certain active sites on the surface, probably somehow extruding above the surface. This assumed O^{2-} is written as O^{*2-} in this paper. Therefore, the nature of the surface-active sites at which the chemisorption occurs may be concluded to be quite similar for all the oxides shown in Fig. 1, while their relative concentrations are different for different oxides.

In the case of CuO and $ZnCrO_4$, the ESR intensities are strong only for the additives which have either $-NH_2$ or -OH groups. This is probably due to the fact that, in these oxides, the bond between the metal cation and oxygen is weak; as a result, there are few active O^{*2-} ions on the surface because the O^{*2-} ions can escape from the surface more easily than O^{2-} ions. Incidentally, it is assumed that a chemical bond is formed between the lone pair of the $-NH_2$ or -OH group and the metal cation of the oxide, *e.g.*, Cu^{2+}. A good piece of evidence to support this speculation is the spectrum shown in Fig. 4. At room tmeperature (CuO-1-naphthylamine) gives a broad ESR spectrum with $g=2.050$. When the sample is subjected to heat treatment at 100°C, a hyperfine splitting consisting of seven lines with an approximate intensity ratio of 1 : 2 : 2 : 2 : 2 : 2 : 1 appears, with its absorption center at $g=2.050$. If the splitting factor due to the amino-nitrogen is twice as large as that of amino hydrogen, these seven lines can most reasonably be interpreted by $a_H=14.6$ gauss and $a_N=29.2$ gauss. The large *s*-character or isotropy of this unpaired spin shows that one of the sigma lone-pair electrons is donated to the 3*d* orbital of Cu^{2+}. Between 100°C and 150°C, naphthylamine approaches Cu^{2+}; directing its $-NH_2$ group toward the Cu^{2+} ion. The (Cu^{2+}-naphthylamine) weak complex thus formed becomes a more strongly-combined charge-transfer complex (Cu^{+}-naphthylamine^{+}) at 200°C, giving rise to the strong ESR absorption at $g=2.004$; this indicates that the unpaired electron is mostly on the (naphthylamine^{+}) side.

In the past literature, the formation of the positively-charged species has been handled as a hole transfer from an active site or acid center to the adsorbed (it is not certain if a chemisorption or a van der Waals adsorption has been assumed) aromatic molecule. This theory does not, however, work well when the following two facts are to be interpreted. Firstly, if there are such holes (naturally having unpaired electrons), they and their counterparts (electrons or anions) should be observed even when no additives are added, provided that the electrons are not in the conduction band. Secondly, by such a mechanism the increment in the signal intensity in the presence of N_2O cannot be interpreted. If the active site consists of a proton, the counter anion should be O^{2-} or OH^{-}. For such systems, the effect of N_2O on the ESR intensity cannot be expected. The fact that the quenching of the ESR intensity by NH_3 is not done thoroughly also indicates that such a hole transfer is not true. If the active site consists of a proton, it should be very effectively scavenged by NH_3. These facts suggest that the formation of the positively-charged species is governed by several equilibrium reactions among O^{*2-}, trapped electrons (T^{-}), the aromatic additive (Ar), N_2O, and NH_3 (if these are added).

The existence of some electron traps can be concluded from Fig. 5. In the naphthol-alumina sample, the ESR intensity begins to decrease if the temperature of the heat treatment is above 100°C. This is not due to the thermal decomposition of the positively-charged species, for in the naphthol-Al_2O_3-MoO_3 system no such decrease in intensity is found as far as to a heat treatment temperature of 250°C. In the latter sample, a signal due to Mo^{5+} ($g=1.9328$) appears together with the line $g=2.004$. By these facts, the decrease in the ESR intensity in alumina is concluded to be caused by a recombination of the trapped electron and the cation complex formed. If Mo^{6+} is present, the electron is also trapped by Mo^{6+} to form Mo^{5+}; therefore, the recombination between the trapped electron and the cation complex, though it is probably still taking place, is far slower than that in the alumina-naphthol sample.

The following equilibrium equations describe the surface reactions leading to the cation complex:

$$ArO^{*2-} \rightleftarrows Ar^{+}O^{*2-} + e^{-};\ K_i \qquad (1)$$

$$e^{-} + T \rightleftarrows T^{-};\ K_t \qquad (2)$$

$$T^{-} + Ar^{+}O^{*2-} \rightleftarrows T + ArO^{*2-};\ K_r \qquad (3)$$

Ar denotes an additive, T denotes an electron trap such as Mo^{6+} and T^{-} denotes the trapped state, *e.g.*, Mo^{5+}. Only two of (1), (2) and (3) are independent; therefore, (1′) and (3′) are used for the analysis of the data. In (1′) and (3′), x denotes $[Ar^{+}O^{*2-}]$, u denotes $[T^{-}]$, and t denotes [T].

$$[ArO^{*2-}]\cdot K_i = x\cdot[e^{-}] \qquad (1')$$

$$u\cdot x\cdot K_r = t\cdot[ArO^{*2-}] \qquad (3')$$

As the total concentration of the positively-charged species is equal to that of the negatively-charged species (the suffixes used are those in Table 1):

$$x_1 = u_1 + [e^{-}] \qquad (4)$$

From (1′), (3′) and (4), we obtain:

$$x_1^2 = [ArO^{*2-}]\cdot K_i + t_1\cdot[ArO^{*2-}]/K_r$$

is derived. As K_r is large, and as $t_1/K_r\cdot K_t$ can be neglected,

$$x_1 = \sqrt{[ArO^{*2-}]\cdot K_i}$$

$$t_1 = u_1\cdot x_1\cdot K_r/[ArO^{*2-}]$$

are obtained. If N_2O is added to this system,

$$N_2O + T^{-} \rightleftarrows N_2O^{-} + T;\ K_s \qquad (5)$$

is expected in addition to (1), (2) and (3).*2 Then,

$$u_2 \cdot [N_2O] \cdot K_s = t_2 \cdot [N_2O^-]$$

is derived. In this case, (4) should be altered:

$$x_2 = u_2 + [e^-] + [N_2O^-] \quad (6)$$

Together with (1') and (3'), and neglecting $t/K_r \cdot K_i$, (6) gives:

$$x_2 = \sqrt{[ArO^{*2-}] \cdot (K_i + [N_2O] \cdot K_s/K_r)}$$

Therefore,

$$(x_2/x_1)^2 - 1 = [N_2O] \cdot K_s/K_i \cdot K_r \equiv Y_{21}$$

$$1/Y_{21} \cdot x_1^2 = K_r/[N_2O] \cdot [ArO^{*2-}] \cdot K_s$$

are obtained. As $[ArO^{*2-}] \cdot [N_2O]$ will be equal for all the additives used, the value on the left side gives the relative value of K_r. t_2 is shown in the same way as t_1:

$$t_2 = u_2 \cdot x_2 \cdot K_r/[ArO^{*2-}]$$

If NH_3 is added,

$$Ar^+O^{*2-} + NH_3 \rightleftarrows ArO^{*2-} + NH_3^+ \; ; \; K_c$$

$$x_3 \cdot [NH_3] \cdot K_c = [ArO^{*2-}] \cdot [NH_3] \quad (7)$$

take place instead of (3). The equation corresponding to (4) or (6) is:

$$x_3 + [NH_3^+] = u + [e^-] \quad (8)$$

From (7), (8), (1'), and (3'), and neglecting $t/K_r \cdot K_i$,

$$x_3^2 = [ArO^{*2-}] \cdot K_i/(1 + [NH_3] \cdot K_c/[ArO^{*2-}])$$

$$(x_1/x_3)^2 - 1 = [NH_3] \cdot K_c/[ArO^{*2-}] \equiv Y_{13}$$

are obtained. Since $K_c/[ArO^{*2-}]$ should be equal for all the additives, Y_{13} gives the relative value of K_c. The relative values of $[ArO^{*2-}] \cdot K_i$, t_2, $K_r/[ArO^{*2-}] \cdot [N_2O] \cdot K_s$, and $[NH_3] \cdot K_c/[ArO^{*2-}]$ are shown in Table 4.

It is well-known that the $-NO_2$ group in an aromatic nitro compound deaccelerates a nucleophillic substitution reaction, while an amino group on an aromatic amine accelerates it. These facts show that these groups greatly change the electron densities on some particular carbon atoms of the aromatic ring. The drawing of a direct analogy between such facts and the criterion for the determination of the sign of the electric charge in an ionic species on the oxide surface seems to be wrong for the following reasons. It is not the free cation, Ar^+, but the chemisorbed species, Ar^+O^{*2-}, that is formed by the charge transfer from Ar to T. The cation complex, Ar^+O^{*2-}, can also be written as $(ArO^*)^-$, which it is possible to describe as an anion. This view may also be related to the fact that a strictly anaerobic condition was needed for the observation of the "perylene cation" on silica-alumina. The rate constants of O_2 and N_2O when reacting with a hydrated electron are comparable and are very large. Therefore, O_2 has a strong ability to destroy an anion, but not a cation. On the other hand, the cation of perylene has been observed in a mixture of O_2 and anhydrous HF.[11] Therefore, the "perylene cation" previously reported might not have been the free cation. Perylene$^+O^{*2-}$ or $(perylene\text{-}O^*)^-$ might be a more proper form to describe the paramagnetic species observed. Therefore, to use the electron density distribution function of "Ar" and not that of "ArO^{*2-}" to predict the formation of either a cation or an anion on an oxide surface is not right.

As is shown in Table 4, the activities of Mo^{6+}, *i.e.*, t_2, are not the same for different additives, though its chemical concentrations are all the same.

TABLE 4. RELATIVE VALUES OF SURFACE REACTION CONSTANTS FOR Al_2O_3-MoO_3

Additive	For ArO^{*2-}		For Ar^+O^{*2-}	
	$[ArO^{*2-}] \cdot K_i$	t_2	$\frac{K_r}{[ArO^{\circ 2-}] \cdot [N_2O] \cdot K_s}$	$\frac{[NH_3] \cdot K_c}{[ArO^{*2-}]}$
1-Naphthol	3.02×10^{3}	1.23×10^{-3}	2.89×10^{-5}	2.4×10
1,4-Naphthoquinone	1.54×10^{2}	8.40×10^{-3}	1.73×10^{-4}	3.2×10^{-1}
1-Nitroso-2-naphthol	1.05×10	5.25×10^{-3}	1.85×10^{-3}	1.4×10^{-2}
1-Nitronaphthalene*	1.00	1.00	1.00	1.00
Anthracene	1.35×10^{-2}	1.39×10^{2}	3.16	1.00
1-Naphthylamine	8.35×10^{-4}	4.50×10^{-2}	1.46×10^{-3}	7.9×10^{-2}
Triphenylene	3.80×10^{-5}	4.61	6.95×10^{2}	$\simeq0$
1,8-Naphthalenedicarboxylic acid	3.52×10^{-5}		7.39×10^{2}	$\simeq0$
Naphthalene	2.10×10^{-5}	8.44	7.50×10^{3}	$\simeq0$

* The values for this compound are put to be the standard values.

*2 It may be more proper to use the chemical equations, $N_2O+e^- \rightleftarrows N_2+O^-$, and so on, instead of (5). Though the negative-charge transfer to N_2O itself has been established, the behavior and fate of N_2O on the solid surfaces investigated in this study have not yet been made clear. Therefore, further discussion or theoretical treatment, beyond (5), of the fate of N_2O after scavenging an electron or an anion has been omitted in the present report.

11) W. Ij. Aalbersberg, G. J. Hoijtink, E. L. Mackor and W. P. Weijland, *J. Chem. Soc.*, **1959**, 3049.

This is partly due to the fact that the system studied is not a homogeneous solution; therefore, the equilibria in (2), (3) and (5) are more involved than those to be found with a homogeneous system like an equeous solution of Mo^{6+}. From (5) and (3),

$$N_2O + ArO^{*2-} \rightleftarrows Ar^+O^{*2-} + N_2O^-;\ K_s/K_r$$

is derived. In this reaction, Mo^{6+}-Mo^{5+} functions as a catalyst. The different activities of Mo^{6+} for different kinds of Ar mean that the catalytic activities of Mo^{6+}-Mo^{5+} are different for different kinds of Ar. This is due to the heterogeneous nature of the system.

In my previous paper,[1] no rule was found for the relation between the physical properties of the additives and the ESR intensities obtained by use of them. This is partly due to the fact that the compounds used in the previous paper consisted of rather varied types of substances. Such complexity has been avoided in the present work by using naphthalene derivatives.

The measurement of the active sites in a catalyst by means of the "additive-ESR-method" cannot be done so simply as has been thought possible. The selection of a proper additive with known equilibrium constants, a proper temperature, and a proper atmosphere to "develop" the paramagnetic species seems to be important.

The author wishes to thank Dr. N. Todo and Mrs. M. Yamadaya of his Institute for their helpful suggestions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 325—330 (1970)

Radiative Lifetime Measuements of Some Excited States of N_2^+ and CH

Tsuguo SAWADA and Hitoshi KAMADA

Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received July 2, 1969)

Time-sampling technique has been applied to radiative lifetime measurements. The time resolution of the apparatus was about 10 nsec. The excited molecules were produced by electron bombardment of N_2 and CH_4. The measured lifetimes of $N_2^+(B^2\sum_u^+)$, $CH(A^2\Delta)$ and $CH(B^2\sum^-)$ are $(6.5\pm0.5)\times10^{-8}$ sec, $(4.3\pm0.2)\times10^{-7}$ sec and $(7.6\pm0.4)\times10^{-7}$ sec, respectively. Band oscillator strengths have been computed on the assumption that the electronic transition moment is constant in the range in which the transition takes place.

For the study of unstable chemical species such as ions and free radicals, the knowledge of radiative lifetime is indispensable. As a matter of principle transition probabilities and oscillater strengths can be determined by measuring absorption coefficients. Some investigations[1,2] on OH and CN molecules along this line have been reported. However, there are difficulties in the determination of absorption coefficients of unstable chemical species. Experimental data on the measurements of the concentration of the molecules excited to upper states are not always available.

On the other hand, it is possible to calculate reliable transition probabilities and oscillator strengths from the measurements of the radiative lifetime. The lifetime measurements for a number of well known molecule transitions have recently been reported. The following two methods have been reported on the measurements of the lifetime.

(a) Direct measurement of decay time[3,4]
(b) Phase shift method[5,6]

The radiative lifetimes fall in the range 10^{-9} to 10^{-6} sec for allowed transitions. In (a), the lifetime is obtained from the decay time of the emitted light. Thus a good time resolution is required in the apparatus.

In this paper, the results of the lifetime measurements of $N_2^+(B^2\sum_u^+)$, $CH(A^2\Delta)$ and $CH(B^2\sum^-)$ by means of the time sampling method are reported. These excited molecules are produced by pulsed beam electron impact below 300 eV.

Absorption oscillator strengths of the $N_2^+(B^2\sum_u^+ X^2\sum_g^+)$, the $CH(A^2\Delta-X^2\Pi)$ and the CH $(B^2\sum^- -X^2\Pi)$ are calculated on the assumption that the

electronic transition moment is constant in the range in which the transition takes place.

Theory

The radiative lifetime $\tau_{v'}$ of the upper vibrational level in an electronic transition can be expressed by summing over fine structures due to rotational and electron spin

$$1/\tau_{v'} = A_{v'} = \sum_{v''} A_{v'v''} \quad (1)$$

where $A_{v'v''}$ is the Einstein coefficient. The oscillator strength $f_{v'v''}$ is defined as

$$f_{v'v''} = 1.51 \cdot (G'/G'') \cdot A_{v'v''} \cdot \lambda^2_{v'v''} \quad (2)$$

where λ is the wavelength in cm, $A_{v'v''}$ in sec^{-1} and G'/G'' is equal to the ratio of the upper to lower electronic statistical weights as defined by Mulliken.[7]

The band intensity is related to the Franck-Condon factor $q_{v'v''}$[8] as

$$I_{v'v''} = K \cdot N_{v'} \cdot \lambda^{-4}{}_{v'v''} \cdot R_e^2 \cdot q_{v'v''} \quad (3)$$

where K is a constant, $N_{v'}$ is the population of the upper vibrational level v'. R_e is an electronic transition moment. On the assumption that R_e is not a slowly varying function of the internuclear distance but a constant for all v'-v'' transitions in a given band system, the ratio $A_{v'v''}/A_{v'}$ is expressed as

$$A_{v'v''}/A_{v'} = q_{v'v''} \cdot \lambda^{-3}{}_{v'v''} / \sum_{v''} q_{v'v''} \cdot \lambda^{-3}{}_{v'v''} \quad (4)$$

$A_{v'v''}$ can be expressed by the product of $A_{v'}$ and the Franck-Condon factor to a good approximation.

$$A_{v'v''} = A_{v'} \cdot q_{v'v''} \quad (5)$$

In order to calculate the oscillator strengths for individual bands, the theoretical computations of the Franck-Condon factors must be available.

Experimental

An electron gun was used for the formation and excitation of unstable molecules from sample gases. Figure 1 shows a schematic diagram of the electron gun. The emitter is an indirectly-heated oxide-coated cathode which emits at a temperature below 1000°K. However, it can be poisoned easily by organic or other vapors with loss of emission and discoloration. The electron energy can be varied from 30 to 300 eV, and a current about 3 mA can be produced. The first grid is a control grid which is biased by a potential of −50 V.

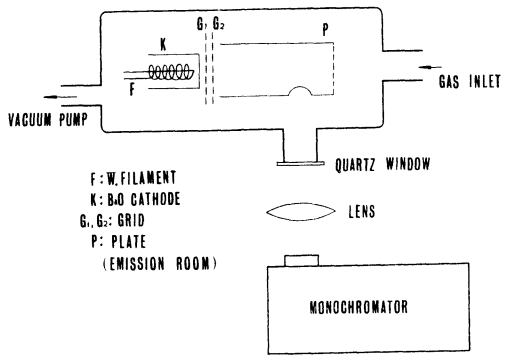

Fig. 1. Schematic diagram of the electron gun.

The pulse applied to the control grid is 50 V in amplitude and is controllable in duration up to 1.0 μsec. The rise and fall time of this pulse is 4.0×10^{-9} sec (4 nsec) and 6.0×10^{-9} sec (6 nsec), respectively. The excitation room is a cylindrical plate, 8 mm in diameter and 20 mm in length. The emitted light can be taken out from the hole, 6 mm in diameter, as shown in Fig. 1. The emitted light is made monochromatic with a small Nippon-Jarrel Ash grating monochromator.

A good time resolution is required for the measurements of lifetimes. In order to measure periodic faint

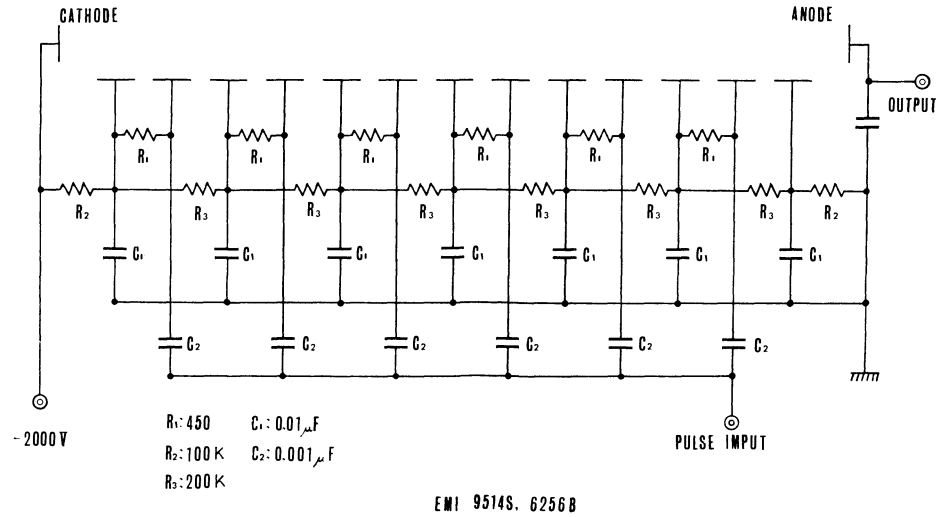

Fig. 3. Circuit of the pulsed photomultiplier.

light intensity, the photomultiplier sampling technique[9] can be utilized. Thus, the pulsed photomultiplier samples the output of periodically emitted light, and this sampling pulse is phased slowly by means of the variable delay circuit. The emitted light is then recorded as a function of time on a X-Y recorder. The advantage of this method is that the output current inside the phototube can be combined to the high-input impedance vacuum-tube voltmeter to detect very faint light. This sampling technique is applicable to time-resolved spectroscopy at a fixed phase of a periodic light. The block diagram of the apparatus is shown in Fig. 2. The master generator produces two equal pluses at a repetition rate variable from 1 to 10 k Hz. One pulse is fed to the Control grid of the electron gun after a fixed delay circuit, and the other initiates the sampling pulse. Th delay time of this pulse increases slowly and continuously by a motor-driven 50 kΩ variable resistance. The variable delay network consists of a phantastron circuit and a cathode follower. The delay time can be moved to 10 μsec in six steps. The pulse applied to photomultiplier is 100 V in amplitude. The 3C-2V coaxial cable is used as a pulse-forming network, and its length determines the pulse duration. The minimum pulse duration obtained is about 20 nsec. The sampled phototube signal is integrated with a simple RC network by which the time constant of the recording system is determined. The output of the voltmeter is recorded on the X-Y recorder, and the delay time is scanned at a rate determined by the speed of the motor and the grear ratio.

Figure 3 indicates a schematic diagram of the pulsed photomultiplier circuit. The method which has been most widely used is that in which the high voltage pulse is applied directly to the cathode and the dynodes.[9] However, it is difficult technically to produce an extremely stabilized high-voltage pulse, which is needed to reduce fluctuations of the phototube gain. The dynodecontrolled technique is therefore used in the present measurements.[10] The gating pulse is applied to the alternate dynodes throught the load resistance, the potentials of which are the same as those of the adjacent dynodes during the closed-gate period. EMI 9514S and 6256B as the head-on type photomultiplier and in some cases 931A and 1P21 as the side-window type are used for detection of light.

Since the actual gated period is equal to the sampling pulse duration minus the transit time of the electron in the photomultiplier, the time resolution is ultimately determined by the transit time spread.[11] In the dynode-controlled technique, the background current during the closed gate period must also be controlled to a lower value in order to obtain better time resolution.

Results and Discussion

Lifetime Measurements. a) *He Lines.* Measurements of the radiative lifetime of three excited states are summarized in Table 1. Our data agree well with those of other investigators within the range of experimental errors. Measurements were made at an electron energy of 80 eV.

Table 1. Lifetimes of He terms[a]

a) Unit: 10^{-8} sec
b) This value was measured at a gas pressure of 11 μ.

9) C. F. Hendee and W. B. Brown, *Philips. Tech. Rev.*, **19**, 50 (1958).

10) H. M. Crosswhite, D. W. Steinhaus and G. H. Dieke, *J. Opt. Soc. Amer.*, **41**, 299 (1951).

11) S. Minami and K. Nishikawa, *Applied Opts.*, **5**, 173 (1968).

Variations of the lifetime with the gas pressure were examined. However, except for that of 3^1P level no significant dependence was recognized within the range of the gas pressure from 1.0 μ to 10 μ. It is well known that the 3^1P-2^1S transition is affected by the trapping of resonance radiation because of 3^1P level corresponding to the upper level of the 537A resonance line.[12] Our data for the 3^1P level

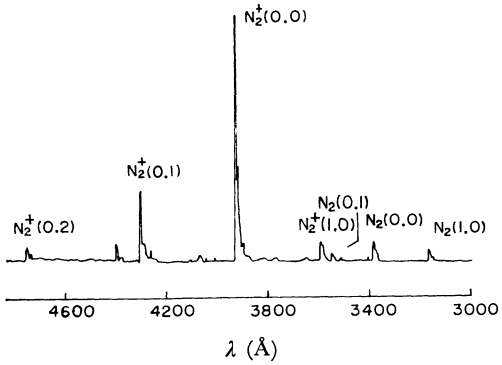

Fig. 4. Emission spectrum obtained from nitrogen (gas pressure 5 μ) excited by 120 eV electrons.

shown in Table 1 were obtained at a gas pressure of 11 μ. Because of the decrease of the trapped resonance radiation, the lifetime measured at a lower pressure can be considered to be a measure of the resolving time of the apparatus. The minimum resolving time obtained was about 10 nsec.

b) $B^2\Sigma_u^+$ *State of* N_2^+. Figure 4 shows the emission spectrum obtained from the bombardment of N_2 gas at an electron beam of 120 eV. The measurement was made at a pressure of 5 μ. The spectrum consists of the $B^2\Sigma_u^+$-$X^2\Sigma_g^+$ system of N_2^+ and the $C^3\Pi_u$-$B^3\Pi_g$ system of N_2. The result agrees well with those of other measurements.[3,5] The radiative lifetime was measured by use of 0.5 m grating monochromator (about 15Å bandwidth) in order to separate various emission bands. The dependence of the lifetime for the (0,0) band of N_2^+ upon the electron energy is shown in Fig. 5. The apparent lifetime increases slowly up to an electron energy of 100 eV, and remains constant beyond it. A similar tendency has been reported by Bennet and Dalby,[3] who assumed that this was due to a mixing of other bands, since they used interference filters of about 100Å bandwidth instead of a monochromator. The fact that our experiments with a monochromator showed a similar tendency indicates that their interpretation is not correct. This cannot be ascribed to the cascade population of the $N_2^+(B^2\Sigma_u^+)$, because no higher electronic states are known from which the transitions to this level are allowed. It is highly desirable to investigate the lifetime down to the excitation threshold.[13] However, the measurements near the threshold were unreliable because of the low signal level compared with the noise level. The value obtained above 100 eV was taken as the lifetime of the N_2^+ $(B^2\Sigma_u^+)$. A lifetime

$$(6.5\pm0.5)\times10^{-8}\ \text{sec}$$

was obtained. The variation of the lifetime with gas pressure was not recognized within the range of our experiments from 1 μ to 5 μ. It can be considered that neither the collision quenching effect nor the trapped resonance radiation has significant influence on the lifetime in the range of the gas pressure below 5 μ.[4] The decay curve

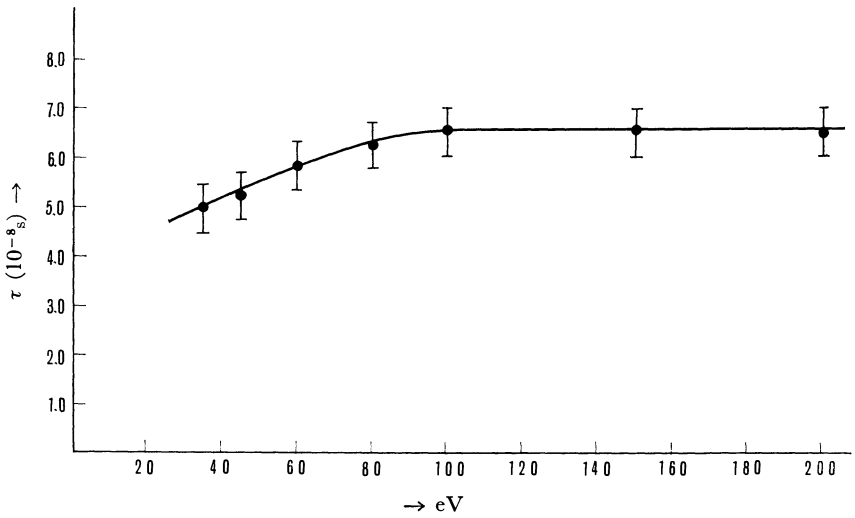

Fig. 5. The dependancy of the lifetime of the $N_2^+(B^2\Sigma_u^+)$ level upon electron energy.

13) R. E. Fox, *J. Chem. Phys.*, **35**, 1379 (1961).

was plotted as a function of time on semilogarith mic graph paper to determine the mean lifetimes. The observed decay was closely exponential.

c) $A^2\Delta$ and $B^2\sum^-$ States of CH. Figure 6 shows the spectrum obtained when CH_4 was bombarded with 100 eV electrons. The spectrum was taken with a small grating monochromator (15 Å bandwidth). The emission bands of the CH($A^2\Delta$-$X^2\Pi$) and the CH($B^2\sum^-$-$X^2\Pi$) are observed together with several atomic lines such as H_β, H_γ and H_δ. There are some other emission bands which seem to be those of CO^+. The formation of CO^+ is perhaps due to the reactons between the excited carbons and the oxide coated cathode. Similar

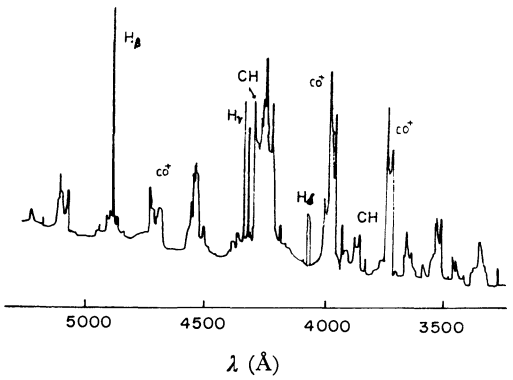

Fig. 6. Spectrum observed when methane (gas pressure of 5 μ) was bombarded with 100 eV electrons. The monochromator (15 Å bandwidth) was used.

results were also obtained from the bombardment of C_2H_4 and C_2H_6. The strong band observed at 4300 Å is the (0,0) band of the ($A^2\Delta$-$X^2\Pi$) system of CH. The (0,0) band of the ($B^2\sum^-$-$X^2\Pi$) system of CH is observed near 3900 Å though its intensity is small.[14,15] The radiative lifetimes were measured by use of a small monochromator in order to separate interfering bands. The dependence of the apparent lifetime of the CH($A^2\Delta$) state upon the electron energy is shown in Fig. 7. The lifetime is almost constant within the range of the electron energy from 40 eV to 150 eV. Below 40 eV, the emitted light intensity decreases so markedly that no accurate measurements can be done. The lifetime of the CH($A^2\Delta$) state was independent of the pressure in the range from 1 μ to 10 μ. Similar results have been reported.[16,17] It seems that both the collision quenching and the trapped resonance radiation do not occur. The duration of the pulsed electron beam was 1.0 μsec. The sampling pulse width was varied up to 0.3 μsec, but the change of lifetime was negligible. We conclude the lifetime for the CH($A^2\Delta$) level as

$$(4.3\pm0.2)\times10^{-7}\,\text{sec}$$

This value is a little lower than those of Bennet and Dalby,[16] and Fink and Welge.[17] Bennet and Dalby used interference filters with the 100 Å bandwidth for the lifetime measurements. Fink and Welge measured τ using the phase shift method with the 20 Å bandwidth monochromator. The bandwidth in our experiment was the same as that of Fink and Welge. The lifetime for the CH($B^2\sum^-$) level

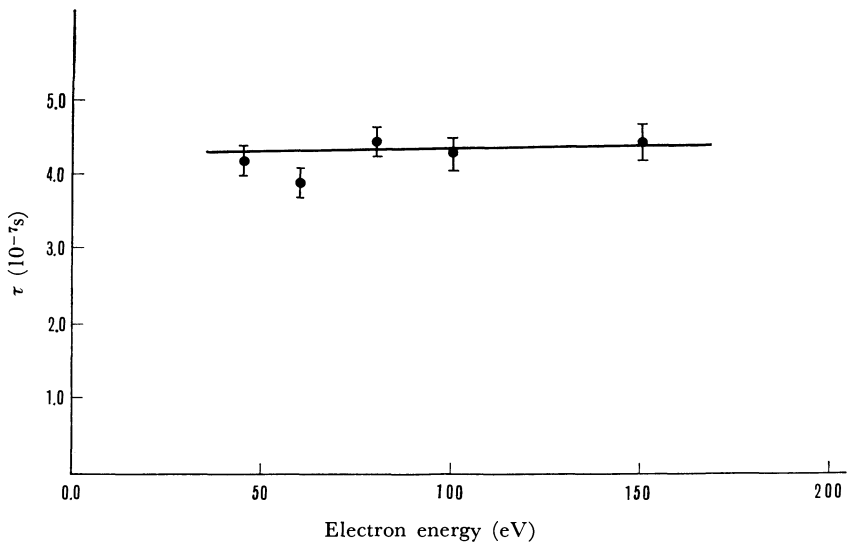

Fig. 7. The dependancy of the lifetime of the CH($A^2\Delta$) level upon electron energy.

17) E. H. Fink and K. H. Welge, *ibid.*, **46**, 4315 (1967).

at an electron energy of 100 eV was

$$(7.6\pm0.4)\times10^{-7}\ \text{sec}$$

No variation of lifetime with the gas pressure was observed within the range from 5 μ to 10 μ. Precise investigations below 100 eV could not be done for the CH($B^2\sum^-$) state because the intensity of the emitted light was too small.

It should be examined whether cascading effects from higher electronic states occur. However, higher electronic states allowed to combine with $A^2\Delta$ and $B^2\sum^-$ are not yet known. Therefore, it may be assumed that the possibility of cascading effects is ruled out.

Oscillator Strength. Oscillator strengths $f_{v'v''}$ for individual bands can be calculated from Eq. (2), using the lifetimes of the upper level v'. It is necessary to know the theoretical calculations of the Frannck-Condon factors $q_{v'v''}$. Nicholls[18] has computed them numerically for the various band systems of N_2 and N_2^+. The oscillator strengths for the (0,0) band of the ($B^2\sum_u^+$–$X^2\sum_g^+$) of N_2^+ is evaluated using q_{00} value of Nicholls to be

$$f_{00}=(2.3\pm0.2)\times10^{-2},$$

where the wavelength used is 3914 A. G'/G'' is equal to unity. This value agrees very well with the results of Jeunehomme, $(2.47\pm0.18)\times10^{-2}$. Similar calculations were made for the (0.0) bands of CH($A^2\Delta$–$X^2\Pi$) and CH($B^2\sum^-$–$X^2\Pi$) respectively. Recently, Huo[19] has computed the Franck-Condon factor q_{00} for the ($A^2\Delta$–$X^2\Pi$) transition of CH. By use of Huo's value ($q_{00}=0.9905$), for the (0,0) band of CH($A^2\Delta$–$X^2\Pi$),

$$f_{00}=(6.5\pm0.3)\times10^{-3}$$

was obtained. The wavelength used is 4313 Å. For the CH($B^2\sum^-$—$X^2\Pi$),

$$f_{00}/q_{00}=(1.5\pm0.1)\times10^{-3}$$

was obtained. No theoretical calculation of the Franck-Condon factor for the above electronic transition has been reported. Hence, f_{00}/q_{00} was calculated insted of f_{00}. The wavelength used is 3880 Å. The results of this work are summarized in Table 2.

TABLE 2.

Molecule	Transition	Lifetime (10^{-8} sec)	Oscillator strength
N_2^+	$B^2\sum_u^+$–$X^2\sum_g^+$	6.5±0.5	0.023±0.002[a]
CH	$A^2\Delta$–$X^2\Pi$	43±2.0	0.0065±0.0003
CH	$B^2\sum^-$–$X^2\Pi$	76±4.0	0.0015±0.0001[b]

a) The calculated Franck-Condon factor is that of Nicholls.[18]
b) This value is f_{00}/q_{00} instead of f_{00}.

In the calculation of the oscillator strengths, as described previously, we assumed that electronic transition moment is independent of the internuclear separations.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 331—334 (1970)

Radiative Lifetime Measurements of $N_2(C^3\Pi_u)$, $NH(A^3\Pi)$ and $NH(c^1\Pi)$

Tsuguo SAWADA and Hitoshi KAMADA

Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received July 25, 1969)

The radiative lifetimes of $N_2(C^3\Pi_u)$, $NH(A^3\Pi)$, and $NH(c^1\Pi)$ states were measured by the use of the time-sampling technique. The excited molecules were produced by the electron bombardment of N_2 and NH_3 gas. The lifetimes obtained in this experiment for $N_2(C^3\pi\Pi)$, $NH(A^3\Pi)$, and $NH(c^1\Pi)$ were $(4.8\pm0.3)\times10^{-8}$ sec, $(4.1\pm0.2)\times10^{-7}$ sec, and $(4.3\pm0.2)\times10^{-7}$ sec respectively. The oscillator strengths of the respective transitions were also calculated.

Th radiative lifetimes of several unstable chemical species, such as ions or free radicals, have been measured by several investigators.[1-4] Knowledge of lifetimes is very important in the field of astrophysics and spectroscopy. Particularly, oscillator strengths and dipole transition probabilities can be obtained from the lifetimes provided that the theoretical or experimental Franck-Condon factors are known.

We wish to report here on one radiative-lifetime measurements of $N_2(C^3\Pi_u)$, $NH(A^3\Pi)$, and $NH(c^1\Pi)$. These excited molecules are produced by electron impact below 200 eV, and the lifetimes are obtained by determining the fluorescence decay directly. Lifetime measurements of the $N_2(C^3\Pi_u)$ level have been performed previously,[1,2,5,6] but there have been different interpretations of the collision quenching and cascading effect. In this paper, new evidence will be reported. In the case of NH, Bennet and Dalby[7] measured $NH(A^3\Pi)$, and Fink and Welge[2] measured $NH(A^3\Pi)$ and $NH(c^1\Pi)$, using the phase shift method. We studied these lifetimes in more detail and obtained slightly different results.

The approximate absorption oscillator strengths of the $(C^3\Pi_u-B^3\Pi_g)$ system of N_2 and the $(A^3\Pi-X^3\Sigma)$ system and the $(c^1\Pi-a^1\Delta)$ system of NH were calculated on the assumption that the electronic dipole strengths are constant for each v''-progression.

Experimental

The excited molecules are formed by the bombardment of pulsed low-energy electrons (15—200 eV) at a repetition rate of 5 Hz. The emitted light from excited molecules is dispersed with a small Nippon-Jarrel Ash grating monochromator and detected by a photomultiplier. The photomultiplier (EMI 6256S, 9514S) detects light only during the pulsed period. The gate pulse is fed into the alternate dynodes of the photomultiplier through the load resistance. The potentials of the alternate dynodes are the same as those of the adjacent dynodes during the closed-gate period. This pulse is phased slowly by means of a variable-delay network. Then, the emitted light intensity is recorded as a function of the time on a recorder. This method is called the time-sampling technique. The time-resolution used in this experiment was about 10 nsec. The details of the apparatus will be published elsewhere.[8]

Results and Disussion

Lifetime Measurement of $N_2(C^3\Pi_u)$. When N_2 gas at a pressure of 1 μ is bombarded with electrons below 200 eV, the emission of the $(C^3\Pi_u-B^3\Pi_g)$ system of N_2 appears very readily. The peak at 3371 Å is the (0,0) band. The peaks at 3577 Å and 3805 Å are the (0,1) band and the (0,2) band respectively. The radiative lifetime was measured

for the (0,0) band of N_2 by the use of a 0.5 m grating monochromator (about 15 Å bandwidth) in order to separate the other emission bands. τ was measured as a function of the gas pressure in order to investigate the collision quenching effect. This is shown in Fig. 1. No such strong dependence of τ upon the pressure was observed in the region below 5 μ. Fink and Welge[2] reported a slow decrease in τ with a decrease in the gas pressure. This dependence was in the wrong direction to be explained by collision quenching, and so they spoke of the possibility of some chemical reactions. However, Jeunehomme[5] indicated a marked increase in τ at pressures lower than 70 μ. He explained this dependence on the basis of the presence of a recombination process between slow electrons and molecular ions. Our results indicate that both possibilities, that of chemical reactions and that of the presence of a recombination process, can be ruled out at pressures below 5 μ.

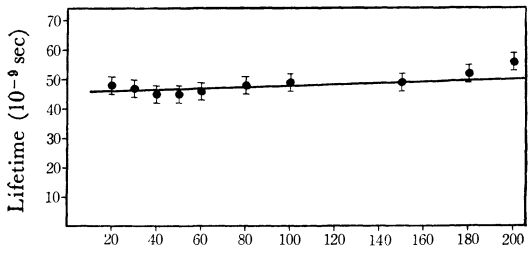

Fig. 2. The dependence of radiative lifetime of $N_2(C^3\Pi_u)$ level upon electron energy.

Figure 2 shows the energy dependence of τ. There appears a slight decrease with a diminishing in the electron energy. This indicates the existence of some cascading states. Similar tendencies have been reported by Bennet and Dalby[1] and by Fink and Welge.[2] However, their results show a more marked decrease in τ than do ours. In order to check the cascading effect in detail, the width of the excitation electron-pulse was varied within a wide range (0.02 μsec—0.3 μsec) at a constant electron energy. If there are some long-lived cascading states, the measured lifetime should be affected by the excitation electron-pulse duration. Thus, if the lifetimes of the initial states in the cascades are different from that of the $N_2(C^3\pi\Pi)$ state, the relative excitation of these states may depend upon the electron pulse duration. The radiative lifetime decreased slightly (17% from 0.02 μsec to 0.3 μsec) when the electron-pulse duration was shortened. These results indicate strongly the presence of some long-lived cascading states. Extrapolating to the excitation threshold and zero pulse duration, we obtained:

$$(4.8\pm0.3)\times10^{-8}\ \text{sec}$$

as the radiative lifetime of the $N_2(C^3\Pi_u)$ level. Our result agrees very well with Jeunehomme's extrapolated value, $(4.9\pm0.5)\times10^{-8}$ sec.

Lifetime Measurement of NH($A^3\Pi$) and NH($c^1\Pi$). When NH_3 is bombarded Eith 100 eV electrons, the ($A^3\Pi$–$X^3\Sigma$)system and the ($c^1\Pi$–$a^1\Delta$) system of NH appear within the wavelength region of 3240—3400 Å. Th emission spectrum is shown in Fig. 3. The peak at 3360 Å is the (0,0) band of the NH($A^3\Pi$–$X^3\Sigma$) system, while the wide-spread emission from 3240 Å to 3400 Å is the (0,0) band of the NH($c^1\Pi$–$a^1\Delta$) system.

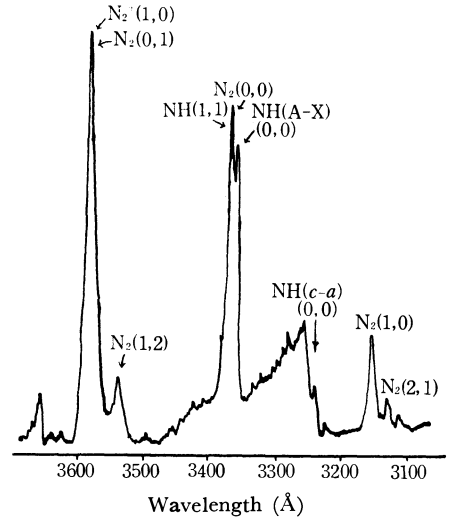

Fig. 3. The emission spectrum obtained when NH_3 gas was bombarded with 100 V electrons at a gas pressure of 0.5 μ.

The apparent lifetime of the NH($A^3\Pi$) level was measured as a function of the electron energy in order to investigate the cascading effect and the trapped resonance radiation. The (0,0) band of the $N_2(C$–$B)$ system appears near the (0,0) band of the NH(A–X) system. Therefore, the grating monochromator (10 Å bandwidth) was used to separate the interfering bands.

The bands at 3370 Å consist of the (1,1) band of the NH(A–X) system and the (0,0) band of the $N_2(C$–$B)$ system, as is shown in Fig. 3. The energy dependence of τ at a constant wavelength of 3365 Å is shown in Fig. 4 (b), and at one of 3358 Å, in Fig. 4 (a). In Fig. 4 (a), the lifetime is constant within the range from 60 V to 200 V, but τ decreases with a diminishing in the electron energy at 3365 Å. This effect can be explained as the mixing effect of the N_2 (0,0) band rather than the cascading from the higher electronic states. The time-resolved spectrum within the wavelength region from 3000 to 3600 Å at a fixed delay-time of 0.1 μsec after the cut-off of the excitation electrons[9] showed that the (0,0) band of the $N_2(C$–$B)$

9) T. Sawada and H. Kamada, unpublished data.

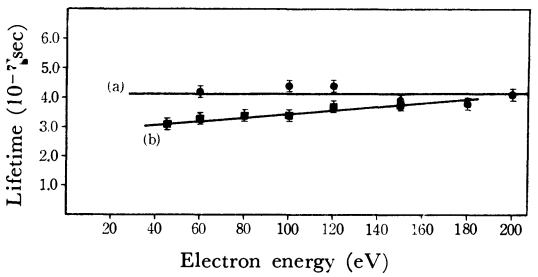

Fig. 4. The dependence of radiative lifetime of $NH(A^3\Pi)$ level upon electron energy.
The fixed wavelength, (a) 3358 Å, (b) 3365 Å

system is superimposed upon the (1,1) band of NH with an intensity of about 55% at an energy of 200 eV. It can be assumed that the effect of the interfering band is considerably eliminated in the lifetime measurement at 3358 Å. No significant pressure-dependence was observed in the range from 1 μ to 5 μ. A lifetime of

$$(4.1\pm0.2)\times10^{-7}\ \text{sec}$$

was obtained. This value agrees within the limits of experimental error with that of Fink and Welge,[2] $(4.6\pm0.8)\times10^{-7}$ sec, measured by the phase shift method. Bennet and Dalby[1] obtained $(4.25\pm0.6)\times10^{-7}$ sec using an interference filter with a 100 Å bandwidth. Figure 5 shows the emission decay of the $NH(A^3\Pi)$ level plotted on the semilogarithmic graph.

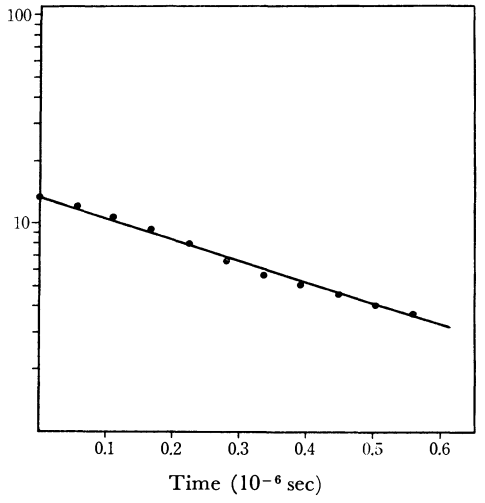

Fig. 5. Semilogarithmic plot of the emission decay associated with the $(A\text{-}X)$ system of NH.

The radiative lifetime of the $NH(c^1\Pi)$ level was measured at a fixed wavelength of 3240 Å. The energy dependence of τ within the range from 45 eV to 150 eV was investigated. However, no significant effect was observed. Consequently, the possibility of the cascading effect from the higher electronic states should be investigated in detail. The $NH(d^1\Sigma)$ level can be allowed to combine with the $NH(c^1\Pi)$ level,[10] but it can be assumed that the cascading from the level is negligibly small. No variation in τ with the gas pressure was observed within the range of our experiment, from 1 μ to 5 μ. A lifetime of

$$(4.3\pm0.2)\times10^{-7}\ \text{sec}$$

was obtained. This value agrees with Fink and Welge's value $(4.3\pm0.4)\times10^{-7}$ sec. The exponential decay of the $NH(c^1\Pi)$ level is plotted in Fig. 6.

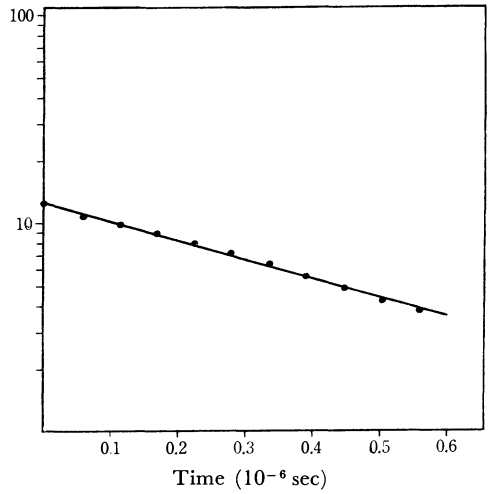

Fig. 6. Semilogarithmic plot of the emission decay associated with the $(c\text{-}a)$ system of NH.

Oscillator Strength. The radiative lifetime, $\tau_{v'}$, of the upper vibrational level in an electronic transition can be expressed by summing over the fine structure due to rotational and electron spin;

$$1/\tau_{v'} = A_{v'} = \sum_{v''} A_{v'v''}$$

where $A_{v'v''}$ is the Einstein coefficient. On the assumption that the mean-square electronic transition moment, $R_e^2(v')$, is constant for all v''-progressions, approximate absorption oscillator strengths can be obtained from this equation:

$$f_{v'v''} = 1.51\cdot(G'/G'')\cdot q_{v'v''}\cdot\lambda^2_{v'v''}/\tau_{v'}$$

where G'/G'' is the ratio of the upper electronic statistical weight to the lower, as defined by Mulliken,[11] where $q_{v'v''}$ is the Franck-Condon factor, and where $\lambda_{v'v''}$ is the wavelength in cm.

In calculating oscillator strengths, it is necessary to use the theoretical calculations of the Franck-Condon factors. The oscillator strengths for the (0,0) band of the $(C^3\Pi_u\text{-}B^3\Pi_g)$ system of N_2 is evaluated by use of the q_{00} value of Nicholls as:

$$f_{00} = (1.6\pm0.1)\times10^{-2}.$$

10) R. W. B. Pearce and A. G. Gaydon, "The Identification of Molecular Spectra," Chapman & Hall Ltd., London (1950).
11) R. S. Mulliken, *J. Chem. Phys.*, **7**, 14 (1939).

The wavelength used here is 3371 Å. G'/G'' is equal to one.

Similar calculations were carried out for the (0,0) band of the NH($A^3\Pi$–$X^3\sum$) and the (0,0) band of the NH($c^1\Pi$–$a^1\Delta$). However, no theoretical calculations of the Franck-Condon factors for the above electronic transitions have been reported. Hence, f_{00}/q_{00} was calculated instead of f_{00}. Thus, for the (0,0) band of NH($A^3\Pi$–$X^3\sum$) we obtained:

$$f_{00}/q_{00} = (8.3\pm0.4) \times 10^{-3}$$

and for the (0,0) band of NH($c^1\Pi$–$a^1\Delta$) we obtained:

$$f_{00}/q_{00} = (3.9\pm0.2)\times10^{-3}$$

where the wavelengths were 3360 Å and 3350 Å. It may be assumed that the Franck-Condon factors for the (0,0) bands of NH(A–X) and NH(c–a) are almost equal to one.

The authors are indebted to Mr. Yasuhisa Saito of the Toshiba Co., Ltd., for his assistance in constructing the electron gun.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 334—339 (1970)

Alternating Copolymerization of β-Cyanoacrolein with α-Methylstyrene

Ichiro TAKEMURA and Hiroshi SUMITOMO

Faculty of Agriculture, Nagoya University, Chikusa-ku, Nagoya

(Received July 4, 1969)

Alternating copolymer was obtained in the system of β-cyanoacrolein (CAL) and α-methylstyrene (α-MeSt). In the presence of air copolymerization proceeds even without any radical initiator at room temperature. In the radical initiated copolymerization of α-MeSt (M_1) and CAL (M_2), the values of monomer reactivity ratios $r_1=0.033$ and $r_2=0$ were obtained. Neither the rate of copolymerization nor viscosity number of the copolymer formed were influenced by the presence of air in the reaction system. The result of copolymerization in the ternary system involving methyl acrylate (MA) could not be entirely explained by the copolymerization equation given by Alfrey and Goldfinger for the three component system. It was found that the composition of the copolymer formed changed with the solvent dilution. Formation of 1 : 1 molecular complex between the monomers was evidenced by the application of the continuous variation method to α-MeSt-CAL system. It was concluded that the molecular complex due to some donor-acceptor type interaction between CAL and α-MeSt plays an important role in the copolymerization.

In the radical copolymerization of β-cyanoacrolein (CAL) with styrene (St), the monomer reactivity ratios were determined and the result was discussed with consideration of penultimate effect.[1] The radical copolymerization of CAL with acrylonitrile was also investigated, compared with that in CAL-St system.[2] It was reported that CAL induced the polymerization of *N*-vinylcarbazole (VCZ) which was cationic polymerization induced by the donor-acceptor type interaction between CAL and VCZ.[3]

The present study is concerned with the alternating copolymerization of CAL with α-methylstyrene (α-MeSt).

Experimental

Materials. CAL was synthesized from β-cyanopropionaldehyde.[1] α-MeSt was washed successively with 5% aqueous solution of sodium thiosulfate, water, an aqueous solution of sodium hydroxide and water, and dried on anhydrous sodium sulfate. Methyl acrylate (MA) was purified by distillation. Benzoylperoxide (Bz_2O_2) was purified by reprecipitation in chloroform (solvent) methanol - (precipitant) system. Dioxane was distilled after refluxing with sodium. Tetrahydrofuran (THF) was also purified in the same way. Benzene was purified in the usual way.

Copolymerization. Copolymerization of CAL with α-MeSt was carried out in dioxane in an evacuated sealed tube at 80°C using Bz_2O_2 as an initiator. Copolymerization in the systems of CAL-MA, α-MeSt-MA and CAL-α-MeSt-MA were also conducted by the same method. The resulting copolymer was precipitated into a large excess of methanol. The copolymer thus isolated was purified by the precipitation from the system of tetrahydrofuran (solvent) - methanol (precipitant).

a) A, air; V, vacuum.
b) THF, $c = 0.2$ g/100 ml, 25°C.
c) M_n(VPO) = 2380.

Determination of Polymer Composition. The compositions of the copolymers obtained in the systems of CAL - α-MeSt and CAL-MA were determined from nitrogen analysis by the Kjeldahl method. Those for α-MeSt - MA and α-MeSt - CAL - MA systems were determined by elemental analysis.

Measurement of Solution Viscosity. Viscosity number, η_{sp}/c, of a copolymer was measured at the concentration of 0.2g/100 ml in THF at 25°C with use of an Ostwald viscometer.

Nuclear Magnetic Resonance Spectrum. Nuclear magnetic resonance (NMR) spectrum was measured in carbon tetrachloride and carbon tetrachloride-methylene chloride mixture at 60°C with a Japan Electron Optics JNM-4H-100 spectrometer.

Continuous Variation Method. Continuous variation method applied to α-MeSt - CAL system was carried out in benzene using a quartz cell with a path length of 1 mm.

Results and Discussion

The results of the preliminary experiment of the copolymerization of CAL with α-MeSt are summarized in Table 1.

Although no homopolymerization of both CAL and α-MeSt takes place under the present conditions, copolymerization between them proceeds at room temperature in the presence of air even without any initiator.

The results of infrared analysis and the contents of α-MeSt in the products suggest the formation of 1 : 1 alternating copolymer of CAL with α-MeSt. The rate of copolymerization and the viscosity number of copolymer obtained are independent of the presence of air in the reaction system. This is curious from the view point of conventional free radical polymerization. In Figs. 1 and 2 are shown the results of copolymerization carried out in dioxane with benzoyl peroxide (Bz_2O_2) as an initiator at 80°C, with varying composition of monomer feed in the system of α-MeSt (M_1) and CAL (M_2).

○, Experimental value; —, Calculated from $r_1=0.033$ and $r_2=0$.

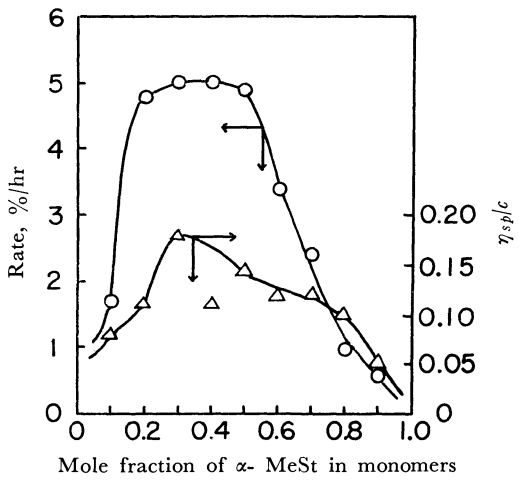

Fig. 2. Influence of monomer composition on the rate of copolymerization and on η_{sp}/c of copolymer in α-MeSt-CAL system.

As shown in Fig. 1, α-MeSt contents of the copolymer are 50 mol% within experimental error throughout the range of the monomer composition. There is a remarkable agreement between the experimental values and the curve calculated from the values of monomer reactivity ratios, $r_1=0.033$ and $r_2=0$. r_1 has a very small value and $r_2=0$, and the product r_1r_2 is nearly equal to zero. This means that both monomers have a very large alternating tendency.

The fact that the viscosity number of the copolymer has a maximum at the mole fraction of α-MeSt of about 0.40 indicates that there may be some interaction between CAL and α-MeSt as shown in Fig. 2. Q and e values obtained for the monomers are given in Table 2.

CAL[b)]	0.53	2.07

a) Ref. 4.
b) Obtained from copolymerization in CAL-St and CAL-AN systems.

Both monomers have large e values of the opposite sign. Thus some donor-acceptor type interaction is expected to take place between the monomers. In Table 3 is given the comparison of the monomer reactivity ratios between the observed values and those calculated from Q and e values.

of P α-MeSt, the phenyl proton signal appears at the value 2.95—3.20, whereas the signal is seen as a singlet at 2.90 in the copolymer. The difference may be explained as follows. In P α-MeSt, the phenyl proton signal shifts to the higher field with splitting due to the shielding effect of the benzene ring in the sequence of α-MeSt unit. However, in the copolymer the shift is attributed to the alternation of CAL and α-MeSt units.

In the IR spectra of acrolein homopolymer and its copolymer with CAL, a weak C=O absorption band appears and there exist strong C–O–C absorption bands due to the substituted tetrahydropyrane ring formed between adjacent pendant aldehyde groups. On the other hand, the spectrum of the copolymer of CAL and α-MeSt indicates that aldehyde group remains free.[5)]

From these facts it seems that some interaction between CAL and α-MeSt plays an important role

in the alternating copolynerization in the system of CAL and α-MeSt. Although coloring was not observed when CAL was mixed with α-MeSt, an absorption maximum by the continuous variation method appeared at the molar ratio of CAL to α-MeSt of around one as shown in Fig. 4. This means that some molecular complex due to a donor-acceptor type interaction between CAL and α-MeSt was formed.

In Table 4 and Fig. 5 are summarized the results of terpolymerization including CAL, α-MeSt and methyl acrylate (MA).

MeSt and CAL. The following monomer reactivity ratios were determined in α-MeSt - MA and MA-CAL systems. The composition curve in these copolymerization systems are shown in Figs. 6 and 7.

MA (M_1) - α-MeSt (M_2), $r_1=0.13$ and $r_2=0.21$;
MA (M_1) - CAL (M_2), $r_1=2.73$ and $r_2=0$.

The Alfrey-Goldfinger's equation[6] was used for the anlaysis of the results in the ternary system. If k_{22} equals zero, since no homopolymerization of CAL occurs, the composition relationship in the ternary system is given as follows.

$$\frac{m_1}{m_2}=\frac{M_1}{M_2}\times\frac{(M_1+M_2/r_{12}+M_3/r_{13})(M_1/r_{31}+M_2/r_{32}+M_3/r_{31}R)}{(M_1+M_3/R)(M_1/r_{31}r_{12}+M_2/r_{32}r_{12}+M_3/r_{13}r_{32})}$$

$$\frac{m_1}{m_3}=\frac{M_1}{M_3}\times\frac{(M_1+M_2/r_{12}+M_3/r_{13})(M_1/r_{31}+M_2/r_{32}+M_3/r_{31}R)}{(M_1/r_{13}+M_2/r_{32}+M_3)(M_1/r_{13}+M_2/r_{12}R+M_3/r_{13}R)}$$

The value of R was determined from Q-e values, but not experimentally. Copolymerization parameters thus obtained are listed in Table 5.

Calculation of R using the results of terpolymerization and the binary copolymerization parameters gives $R\leqq 0$, except for B-6 and B-10. R calculated from the Q-e values is about 112 as shown in Table 5. If $R\cong 0$, it follows that $k_{21}\cong 0$ or $k_{21}\ll k_{23}$. Thus the relation $R=0$ should be discorded because it is inconsistent with the large alternating tendencies of CAL and α-MeSt, the reactivity of each monomer deduced from Q and e values and the existence of a donor-acceptor type interaction between CAL and α-MeSt. With respect to M_1 (mole fraction of

α-MeSt in monomers) above 0.3, we have $R\cong 0$. If M_1 becomes smaller R tends to deviate gradually from zero. Deviation is very remarkable as to T-5 and B-8 where M_1 is very small. This shows that R changes with monomer composition. It is concluded that the equation proposed by Alfrey and Goldfinger can not be applied to the present ternary system.

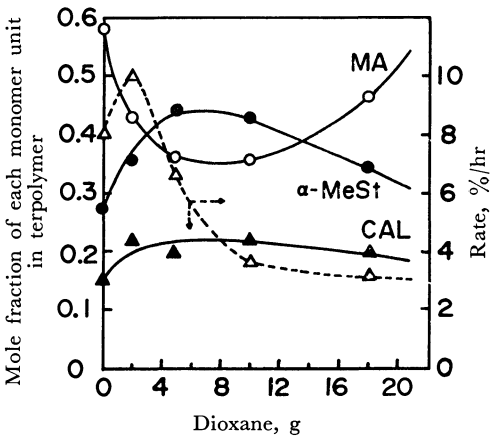

Fig. 8. Effect of solvent dilution on α-MeSt-CAL-MA terpolymerization.
Monomer composition, α-MeSt : CAL : MA = 1.5 : 1.5 : 7
Total amount of monomers, 8.02 g

The effect of solvent dilution on terpolymerization was investigated. The composition of the terpolymer varies with the amount of dioxane added as seen in Fig. 8. It should also be noted that a maximum of the rate appears with the addition of a small amount of the solvent.

This behavior is very different from that of general radical copolymerization, and can not be explained by the Alfrey-Goldfinger equation. Iwatsuki and Yamashita[7)] have discussed similar behaviors found in the systems of chloroethylvinylether-maleic anhydride-acrylonitrile and *p*-dioxene-maleic anhydride-acrylonitrile.

The change in the composition of terpolymer and the rate of copolymerisation seems to be much larger than the estimated values from the simple solvation effect of dioxane. Hence it appears that the interaction between each monomer would change with the addition of solvent and that species with different reactivities are formed in the system. The results show that the interaction between CAL and α- MeSt is very strong even in the terpolymerization. It is concluded that the complex formation between CAL and α-MeSt due to some donor-acceptor type interaction plays a very important role in the copolymerization system of CAL and α-MeSt.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 340—344 (1970)

Mechanism of Hydrogen Formation in the Vapor Phase Radiolysis of Methanol

Tatsuo YAMAMOTO

Tokyo Metropolitan Isotope Research Center, Setagaya-ku, Tokyo

(Received July 19, 1969)

The yields of isotopic hydrogen in the vapor phase radiolysis of deuterated methanol(CH_3OD) were found to be $G(H_2)=6.1$, $G(HD)=5.3$ and $G(D_2)=0.2$. The molecular yields of isotopic hydrogen were also determined by adding propylene as a radical scavenger, $G_M(H_2)=1.5$, $G_M(HD)=0.6$ and $G_M(D_2)\sim 0$. In order to estimate the contribution of ionic species for the formation of hydrogen, the ion-molecule reaction of CH_3OD has also been investigated by using a mass spectrometer of the differential pumping type. The product ions, such as $(CH_3OCH_3CH_3OD)D^+$ or $(CH_3OD)_3D^+$, which were considered to be formed by the higher order ion-molecule reactions were observed. The mechanism of hydrogen formation was discussed on the basis of the ionic, the molecular and the radical mechanisms.

Although extensive studies of the radiolysis of methanol have been carried out in the liquid phase, little attention has been paid to vapor phase radiolysis.[1-4]

Baxendale *et al.*[1] calculated the yields of radiolysis products of CH_3OD from mass spectral data, considering the ion-molecule reactions. In the ion-molecule reactions of CH_3OD^+ and CH_2OD^+ with CH_3OD, they assumed that only H^+ transfer from CH_3OD^+ or CH_2OD^+ occurred to form CH_3ODH^+. However this is not true, because recent studies[5-7] on ion-molecule reactions of CH_3OD indicate that D^+ transfer also occurs from OD as well as H^+ transfer from CH_3 and CH_2.

Prasil[8] also calculated the relative yields of products using the quasi-equilibrium theory in semi-classical approximation, considering direct excitation as well as ionization. However, the molecular yield of hydrogen thus obtained seemed to be larger compared with the experimental values.

In order to obtain information on the vapor phase radiolysis of methanol, the ion-molecule reaction of methanol was also studied by a conventional mass spectrometer.[5] However, it is very doubtful that the mechanism of ion-molecule reactions thus obtained can be applied to the mechanism of vapor phase radiolysis of methanol, since radiolysis is usually made at considerably higher pressure compared with that in the mass spectrometer.

The present investigation has been undertaken in order to elucidate the mechanism of hydrogen formation in the vapor phase radiolysis of CH_3OD.

The following experiments were carried out.

(1) The isotopic composition of hydrogen formed by γ-radiolysis was determined by mass spectrometric analysis, and the molecular yields of isotopic hydrogen were also estimated by adding propylene as a radical scavenger.

(2) The ion-molecule reaction of CH_3OD was studied in the pressure range of $6\times10^{-3}-1\times10^{-1}$ mmHg with a mass spectrometer of the differential pumping type.

Experimental

Materials. Deuterated methanol, CH_3OD, from Showa Denko Co. (99%) was used without further purification. Before irradiation, the sample was thoroughly degassed by the freezethaw method. Propylene and nitrous oxide from Takachiho Chem. Indust. Co. were used after purification by distillation.

Irradiation and Analysis. A glass reaction vessel of about 700 m*l* with a break-seal was used. Before introducing the sample into the reaction vessel, both the sample preparation system and the reaction vessel were flamed out several times in a vacuum. Deuterated methanol vapor of about 60 mmHg was irradiated at room temperature with a ^{60}Co source of 3000 Ci. The molecular yield of hydrogen was determined by

adding a few percent propylene as a hydrogen atom scavenger. Dose rate was determined with nitrous oxide of 200 mmHg on the basis of $G(N_2)=10.0$.[9] Energy absorbed by methanol was calculated from the electron densities. The dose rate was approximately 3.3×10^{18} eV·g^{-1}·hr^{-1} and the total dose was $\sim10^{20}$ eV·g^{-1}.

After irradiation, the amount and composition of products volatile at liquid nitrogen temperature were determined by gas burette and mass spectrometric analysis.

Ion-Molecule Reaction. In order to investigate the ion-molecule reaction in the higher pressure range, a Hitachi mass spectrometer, Model RMU-5, was rearranged and equipped with an ion source of the differential pumping type. The relevant dimensions of the ion soruce are: electron beam hole 0.02 cm; ion exit slit 0.02×0.5 cm^2; repeller electrode-ion exit slit 0.31cm and center of electron beam-ion exit slit 0.25 cm. Electron bombardment was carried out at 70 eV. Pressure of the ionization chamber could not be measured directly, but was estimated from the pressure of the sample reservoir by the conventional method[10] using methane. The revised ion source made it possible to carry out experiment at the pressure of ionization chamber up to about 0.14 mmHg.

Results

Gamma Radiolysis. The G value of each isotopic hydrogen obtained with and without propylene in the system is shown in Table 1. The total yield of isotopic hydrogen G_{total}(hydrogen), is found to be 11.6. This value is somewhat higher than that obtained by Baxendale.[1] In contrast with the results in the liquid phase radiolysis, the yield of H_2 is higher than that of HD. The yield of D_2 is very small as shown in Table 1.

Table 1. Observed yields of isotopic hydrogen

	$G(H_2)$	$G(HD)$	$G(D_2)$	G(Total)
Total yield	6.1	5.3	0.2	11.6
Molecular yield	1.5	0.6	~0	2.1

Addition of propylene as a hydrogen atom scavenger reduces the total hydrogen yield from G_{total}(hydrogen)=11.6 to G_{total}(hydrogen)=2.1, which corresponds to the molecular yield of isotopic hydrogen. The molecular yield of H_2 is about 2.5 times greater than that of HD, and the molecular yield of D_2 is negligibly small.

Ion-Molecule Reaction. In the pressure range of 0.006–0.02 mmHg, the relation between the ionization chamber pressure and the ion current fraction of each ion, $(i_j/\sum i_j)$, where i_j is the ion current for jth ion and $\sum i_j$ the total ion current, is

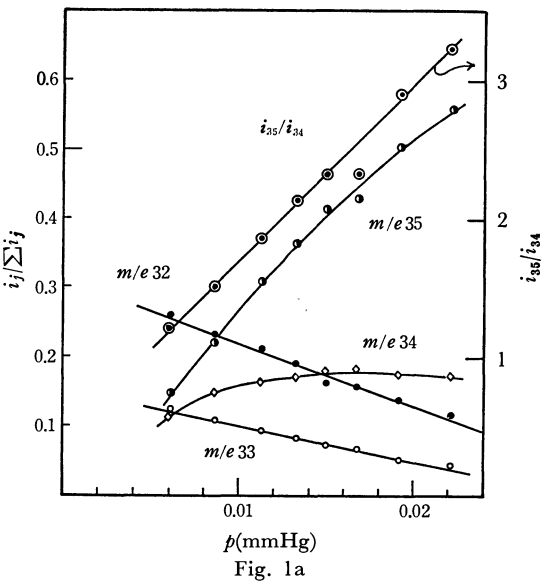

Fig. 1a

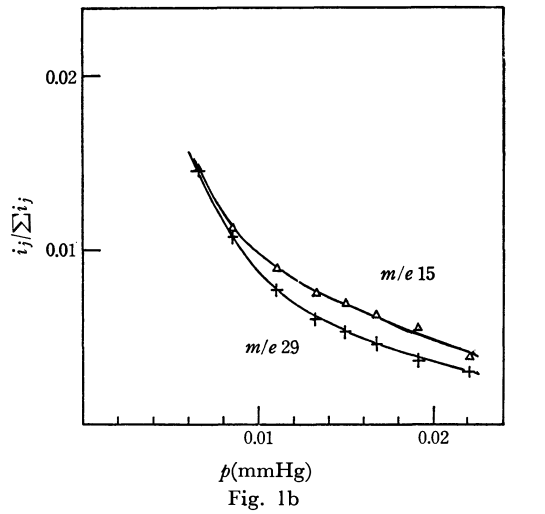

Fig. 1b

Fig. 1a, b. Relation between ionization chamber pressure and $i_j/\sum i_j$ or i_{35}/i_{34}.

shown in Fig. 1. We see that all primary ions decrease as the ionization chamber pressure increases. These primary ions are considered to decrease by either one of the ion-molecule reactions, such as proton or deuteron transfer, hydride ion transfer or charge transfer. On the other hand, as reported by Hyatt *et. al.*[7], $i_{CH_3OD_2^+}/i_{CH_3ODH^+}$ increases with the increase in the ionization chamber pressure. Table 2 shows the results obtained at the higher pressures up to 0.14 mmHg. At 0.14 mmHg, only a trace of CH_2OD^+, which is the most abundant primary ion at low pressure, is observed and the ratio $i_{CH_3OD_2^+}/i_{CH_3ODH^+}$ exceeds 10. We see that the primary ions and the lower order product ions decrease and the higher order product ions increase with the increase in pressure. The results

indicate that the ion-molecule reactions occur successively to form the higher order product ions at a higher pressure. It is also clear that the deuteronated ions formed by the higher order ion-molecule reactions are much greater than the protonated ions. Munson[11] also observed the higher order product ions using CH_3OH and presented the mechanism of their formation.

Discussion

Ionic Mechanism. Primary processes in radiation chemistry are mostly caused by secondary electrons with energies less than 100 eV. A number of discussions for the ionic mechanism of radiolysis have been made on the basis of the results obtained by mass spectrometer at low pressure. As shown in Table 2, the higher order product ions, which do not appear in mass spectrum at low pressure, are observed remarkably at higher pressure, indicating that the contribution of these higher order product ions must be considered in the ionic mechanism of radiolysis. It can be assumed that fragment ions are formed from parent ion by the unimolecular decomposition in a much shorter time than collision time of parent ion with neutral molecule at the pressure employed in radiolysis experiments. Thus the abundance of ions formed primarily by the irradiation of ^{60}Co γ-rays should be the same as that in the usual mass spectrum. Table 3 shows the fragmentation processes and abundance of various ions in the mass spectrum of CH_3OD and the possible types of ion-molecule reactions. According to the types of ion-molecule reactions, these primary ions react with neighboring CH_3OD molecules to form the secondary ions, CH_3ODH^+ and $CH_3OD_2^+$. As the pressure increases, these secondary ions react further with CH_3OD molecules by the reactions such as.

$$CH_3ODH^+ + CH_3OD \rightarrow CH_3OD + CH_3ODH^+ \quad (1a)$$

$$\rightarrow CH_3OH + CH_3OD_2^+ \quad (1b)$$

$$CH_3OD_2^+ + CH_3OD \rightarrow CH_3OD + CH_3OD_2^+ \quad (2)$$

Secondary ion CH_3ODH^+ can transfer either a proton or a deuteron by reaction (1a) or (1b). Secondary ion $CH_3OD_2^+$ will not change its identity by reaction (2) since only a deuteron can be transferred. Therefore, the ratio $i_{CH_3OD_2^+}/i_{CH_3ODH^+}$ increases with the increase in the ionization chamber pressure. The ions, such as $(CH_3OCH_3)D^+$, $(CH_3OD)_2H^+$ and $(CH_3OD)_2D^+$, are formed by the following reactions.

$$CH_3ODH^+ + CH_3OD \rightarrow (CH_3OCH_3)D^+ + HDO \quad (3)$$

$$CH_3OD_2^+ + CH_3OD \rightarrow (CH_3OCH_3)D^+ + D_2O \quad (4)$$

$$CH_3ODH^+ + CH_3OD \rightarrow (CH_3OD)_2H^+ \text{ or } (CH_3ODCH_3OH)D^+ \quad (5)$$

$$CH_3OD_2^+ + CH_3OD \rightarrow (CH_3OD)_2D^+ \quad (6)$$

Table 2. Variation of relative ion current with ionization chamber pressure

m/e	Ion	Relative ion current(%) Pressure (mmHg) 0.07	0.10	0.14
32	CH_2OD^+	4.1	0.7	0.2
34	CH_3ODH^+	9.4	5.5	3.2
35	$CH_3OD_2^+$	65.4	51.9	34.1
48	$(CHOCH_3)D^+$	9.6	11.9	9.7
67	$(CH_3OD)_2H^+$	1.0	1.6	3.3

H: Hydride ion transfer
C: Charge transfer
d: Dissociative charge transfer

11) M. S. B. Munson, *J. Amer. Chem. Soc.*, **87**, 5313 (1965).

From the fact that the higher order product ions, $(CH_3OCH_3CH_3OD)D^+$ and $(CH_3OD)_3D^+$, were also observed, it is reasonable to assume that the primary ions formed in the radiolysis are ultimately converted to deuteronated ions by successive ion-molecule reactions. These product ions recombine with electrons, and dissociate into D atoms, not H atoms, and products.

$$(CH_3OCH_3CH_3OD)D^+ + e \rightarrow D + \text{Products} \quad (7)$$

$$(CH_3OD)_3D^+ + e \rightarrow D + \text{Products} \quad (8)$$

D atom formed by reaction (7) or (8) reacts with CH_3OD and abstracts H atom from the methyl group of CH_3OD to give HD.

$$D + CH_3OD \rightarrow HD + CH_2OD \quad (9)$$

$$D + CH_3OD \rightarrow D_2 + CH_3O \quad (9')$$

The direct formation of molecular hydrogen (D_2) by neutralization reactions and the formation of D_2 by reaction, (9'), if any, are negligibly small, because of the very small observed value of $G(D_2)$. Furthermore it can not be considered that molecular hydrogen HD is formed preferentially by neutralization reactions.

Baxendale and Sedgwick[1] explained that a part of molecular hydrogen is produced from excited methanol molecule which is formed by the neutralization reaction of secondary ion, CH_3ODH^+,with electron. As shown in Table 2, higher order ions are produced by successive ion-molecule reactions. It may be reasonable to consider that hydrogen is not formed molecularly from the excited molecules by the neutralization reactions of these higher order ions with electrons. Therefore, hydrogen formed through ion-molecule reactions followed neutralization is considered to be only HD by the reactions (7), (8) and (9).

As shown in Table 3, the primary ions are also accompanied with atomic or molecular hydrogen.

Table 4. Yield of isotopic hydrogen calculated from data in Table 3

	H_2	HD	D_2
M_i/N	0.67	1.21	0
M_{i-m}/N	0.24_6	0.01_6	0
G_i	2.6	4.7	0
G_{i-m}	1.0	0.1	0

N: number of ion pair produced
M_i: number of isotopic hydrogen produced through the ionization of CH_3OD
M_{i-m}: number of isotopic hydrogen produced molecularly by the fragmentation of CH_3OD^+
G_i: G-value of isotopic hydrogen produced through the ionization of CH_3OD
G_{i-m}: G-value of isotopic hydrogen produced molecularly by the fragmentation of CH_3OD^+
G-values are calculated by the following equation using $W=25.9$ eV.

$$G = \frac{100}{W} \times \frac{M}{N}$$

The yields (M_i/N) of isotopic hydrogen are shown in Table 4, where M_i is the number of molecules produced through ionization of CH_3OD and N is the number of ion pairs induced by irradiation. From these data, the total yield of isotopic hydrogen through ionization is estimated to be $M_i/N(H_2)=0.67$ and $M_i/N(HD)=1.21$. By the saturation current method, Ohma and Sakurai[4] obtained $M/N(H_2)=3.00$ for the ionic yield of hydrogen from CH_3OH, where M is the number of hydrogen molecules produced. Combining $M/N(H_2)=3.00$ with the observed $G_{total}(\text{hydrogen})=11.6$, the energy to produce an ion pair from methanol (W) is calculated to be 25.9 eV. Baxendale and Sedgwick obtained $W=27.7$ eV on the assumption that molecular hydrogen was also produced by the decomposition of excited methanol molecule formed by the neutralization of $CH_3OH_2^+$ with electron. The yield of isotopic hydrogen through ionization, G_i, can then be estimated from the relation, $G_i(\text{hydrogen})=100/W\times[M_i/N(\text{hydrogen})]$, and $G_i(H_2)=2.6$ and $G_i(HD)=4.7$ were obtained.

Molecular Mechanism. The observed molecular yields of hydrogen are $G_M(H_2)=1.5$ and $G_M(HD)=0.6$. On the other hand, as shown in Table 4, molecular yields by the fragmentation of CH_3OD^+ are $G_{i-m}(H_2)=1.0$ and $G_{i-m}(HD)=0.1$.

The fact that the value of W=25.9 eV is more than twice the ionization potential(10.85 eV) suggests that directly excited CH_3OD molecule may well be formed by reaction (10) and that the excited molecule thus formed may give hydrogen by the molecular mechanism, reaction (11).

$$CH_3OD \rightsquigarrow CH_3OD^* \quad (10)$$

$$CH_3OD^* \rightarrow H_2, HD + \text{Formaldehyde} \quad (11)$$

The molecular yields of hydrogen formed by the dissociation of CH_3OD^*, $G_m(H_2)$ and $G_m(HD)$, can be estimated as

$$G_m(H_2) = \underset{1.5}{G_M(H_2)} - \underset{1.0}{G_{i-m}(H_2)} = 0.5$$

$$G_m(HD) = \underset{0.6}{G_M(HD)} - \underset{\mathbf{0.1}}{G_{i-m}(HD)} = 0.5\,.$$

Porter and Noyes[12] investigated the photolysis ($\lambda<200$ mμ) of CD_3OH vapor and obtained 80% HD and 20% H_2 as unscavengeable hydrogen. A similar result was also obtained by Hagege *et al.*[13] ($\lambda=124$ and 185 mμ). If one considers that the excited molecules formed by radiolysis are the same as those formed by photolysis, the ratio of $\Phi(H_2)$ to $\Phi(HD)$ in the photolysis of CD_3OH must correspond to the ratio of $G_m(D_2)$ to $G_m(HD)$ in the radiolysis of CH_3OD. In the present investigation, $G_M(D_2)$ was found to be negligibly small, indicating that $G_m(D_2)$ is also negligible. There-

12) R. P. Porter and W. A. Noyes, Jr., *ibid.*, **81**, 2307 (1959).
13) J. Hagege, S. Leach and C. Vermeil, *J. Chim. Phys.*, **62**, 736 (1965).

fore, it is clear that radiolysis and photolysis are quite different in the mechanism of hydrogen formation.

There is also some possibility that hot hydrogen atom may be a source of unscavengeable hydrogen, but at present no definite information concerning quantitative estimation has been achieved. However, the fact that $G_M(D_2)$ is negligibly small indicates that the contribution of hot hydrogen atom may not be so large.

Radical Mechanism. The observed total hydrogen yield, G_{total}(hydrogen)=11.6, can not be explained only by ionic and molecular mechanisms, because the sum of the yields by the two mechanisms, G(hydrogen)=8.3, is much smaller than the observed value. The difference can only be explained by assuming that hydrogen atoms formed by the dissociation of CH_3OD^* are also the precursors of hydrogen molecules. The calculated yields by the radical mechanism, $G_r(H_2)$ and G_r(HD), are found to be 3.0 and 0.1 which indicates that reaction (11a) is more important than reaction (11b).

$$CH_3OD^* \rightarrow H + CH_2OD \quad (11a)$$

$$CH_3OD^* \rightarrow D + CH_3O \quad (11b)$$

The results obtained by direct photolysis[12,13] and by the mercury-photosensitized decomposition of methanol vapor[14] show that reaction(11b) is more important than reaction(11a). The difference between radiolysis and photolysis can be explained as follows. In the photolysis data, the energy of light applied was lower than the ionization potential of methanol molecule, but enough to excite methanol molecule electronically. The absorption band of methanol vapor is observed in the vacuum ultraviolet region λ_{max} 174 mμ, and attributed to the (n-σ^*) transition which corresponds to the excitation of the non-bonding electron of oxygen atom in methanol.[15] Therefore, the formation of hydrogen atom by the scission of O–H bond in the primary process is explained by the assumption that the excitation of methanol molecule by the absorption of ultraviolet light is limited to the oxygen atom of methanol molecule, and thus causes the scission of O–H bond of methanol molecule. In radiolysis, it is well known that most of the excited molecules are formed by the interaction of electrons. Thus, it is reasonable to consider that the induced excitation energy is not localized but distributed at random among methanol molecule. Therefore, the scission of C–H bond occurs more easily than that of O–H bond, because the bond energy of C–H is lower by about 10 kcal/mol than that of O–H.

TABLE 5. CALCULATED YIELDS OF ISOTOPIC HYDROGEN ON THE BASIS OF IONIC, MOLECULAR AND RADICAL MECHANISMS

	$G(H_2)$	G(HD)	$G(D_2)$
Ionic	2.6	4.7	—
Molecular	0.5	0.5	—
Radical	3.0	0.1	—
Observed	6.1	5.3	0.2

The yields are defined as follows :
Ionic : yields of isotopic hydrogen, formed molecularly as well as radically, through the ionization of CH_3OD
Molecular : yields of isotopic hydrogen formed molecularly by the dissociation of directly excited methanol molecule (CH_3OD^*)
Radical: yields of isotopic hydrogen formed radically by the dissociation of directly excited methanol molecule (CH_3OD^*)

The calculated yields of isotopic hydrogen in each radiolysis mechanism are summarized in Table 5.

The author wishes to thank Dr. Gisuke Meshitsuka and Dr. Yoshiharu Shinozaki for their useful discussions. The author is also indebted to Mr. Yukio Inokoshi for his assistance in the experimental works.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 345—349 (1970)

Electronic States of *p*-Chloranil and Its Anion-Radical as Revealed by Their Infrared Spectra

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo, Hokkaido

(Received July 31, 1969)

The infrared spectra (650—4000 cm^{-1}) of *p*-chloranil and its anion-radical were measured. Appreciable frequency differences between their corresponding bands were noted. The fundamental frequencies were assigned, and the simple UBFF's were determined for both the neutral and anion-radical molecules. Their stretching force constants for the bonds in the conjugated systems are related to the bond orders. The values of the bond orders thus obtained for *p*-chloranil and its anion-radical were in good agreement with those evaluated by the molecular-orbital calculation, except for the C=O bond in the anion-radical. In view of these results, it was concluded that the difference in the infrared spectra between these two molecules was almost entirely attributable to the difference in their electronic structures caused by an odd electron on the *p*-chloranil anion-radical. The bond lengths were also estimated on the basis of the bond orders. It was shown that the application of this method might bring valuable knowledge on the molecular and electronic structures of ion-radicals as well as of neutral molecules in general.

It has been noticed that the infrared spectrum of a neutral molecule is appreciably different from that of its ion-radical molecule.[1-5] Obviously, the difference in spectra may be attributed to the difference in their intramolecular force fields. Up to now, however, there has been no attempt to explain the spectrum difference by the use of normal coordinate analysis.

The present paper will describe the infrared spectra of *p*-chloranil and its anion-radical (*i.e.*, the semiquinone ion). The *p*-chloranil molecule is a well-known electron acceptor, and its anion-radical (see Fig. 1) is quite stable. The purpose of this paper is to make a normal coordinate analysis for these molecules and to discuss their molecular and electronic structures on the basis of their intramolecular force fields. In this respect, it is interesting to investigate the effect of an extra electron upon the *p*-chloranil anion-radical.

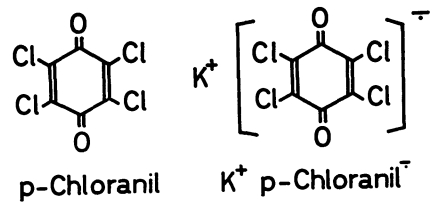

Fig. 1. *p*-Chloranil and its anion-radical salt with potassium cation.

Experimental

Commercially-available *p*-chloranil was purified by recrystallization from benzene and then by sublimation *in vacuo*. Its anion-radical salt with the potassium cation (K^+ *p*-Chloranil$^-$) was synthesized according to the method of Torrey and Hunter.[6] The infrared spectra of these solid compounds were measured as Nujol mulls in the range from 650 to 4000 cm^{-1} using a HITACHI EPI-S2 infrared spectrophotometer. Alternative

——*p*-Chloranil, ----K^+*p*-Chloranil$^-$

Fig. 2. Infrared spectra of *p*-chloranil and K^+ *p*-chloranil$^-$.

measurements in the regions where the absorption due to Nujol appears were made using hexachlorobutadiene mulls. The spectra for these compounds are reproduced in Fig. 2. Since the counter cation of the salt is a simple metal cation, the observed spectrum of the salt in the region from 650 to 4000 cm^{-1} should be solely due to that of the anion-radical itself. The values of the absorption peaks observed for *p*-chloranil and its anion-radical are listed in Table 1.

Normal Coordinate Treatment for In-plane Vibrations

The molecular and crystal structures of *p*-chloranil were determined by Chu, Jeffrey and Sakurai.[7] Since the molecular and crystal structures of K^+ *p*-Chloranil$^-$ have not yet been ascertained, it was assumed that the molecular structure of the anion-radical was almost identical with that of *p*-chloranil. This assumption means that the ***G*** matrix calculated for *p*-chloranil was also used for the anion-radical (see below). Since only the intramolecular vibrations are expected to appear in the region from 650 to 4000 cm^{-1}, the vibrational spectra of the crystalline compounds can be approximately treated under the molecular point group D_{2h}. Generally, the effect of crystal fields on vibrational frequencies is small. Therefore, as the first approximation, its contribution to the spectra of *p*-chloranil and of the anion-radical was ignored in our treatment. Hence, thirty normal modes of vibrations for *p*-chloranil or its anion-radical were reduced to the symmetry species:

$$\Gamma = 6A_g + 5B_{1g} + 5B_{2u} + 5B_{3u} + 1B_{2g} + 3B_{3g} + 2A_u + 3B_{1u}\,, \qquad (1)$$

where the first four are the in-plane vibrations, and the rest, the out-of-plane vibrations.[8] We calculated only the in-plane vibrations, because no out-of-plane vibration is expected to appear in the region now under consideration.

Wilson's ***GF*** matrix method was used in this work. The representation of each type of internal coordinate for in-plane fundamental vibrations is given in Fig. 3. A simple Urey-Bradley force field was employed as the potential function. Therefore, four bond-stretching (K(C=O), K(C=C), K(C-C) and K(C-Cl)), five angle-bending (H(O=C-C), H(C-C-Cl), H(C=C-Cl), H(C-C-C), and H(C=C-C)), and five non-bonded repulsion force constants (F(O=C-C), F(C-C-Cl), F(C=C-Cl), F(C-C-C), and F(C=C-C)) were necessary. At

Table 2. Force constants for *p*-chloranil and its anion-radical (md/Å)

Force constant	*p*-Chloranil	Its anion-radical
K(C=O)	9.7	7.3
K(C=C)	6.6	6.1
K(C–C)	3.0	3.5
K(C–Cl)	2.67	2.67
H(O=C–C)	0.32	
H(C–C–Cl)	0.08	
H(C=C–Cl)	0.08	
H(C–C–C)	0.229	
H(C–C=C)	0.25	
F(O=C–C)	0.80	
F(C–C–Cl)	0.928	
F(C=C–Cl)	0.928	
F(C–C–C)	0.30	
F(C–C=C)	0.37	

$F' = -0.1F$.

this time, it was assumed that the stretching force constants of *p*-chloranil were different from those of the anion-radical, while the other force constants of *p*-chloranil were almost the same as the corresponding ones of the anion-radical. The initial values of the force constants were transferred from the values for benzene and its chloro-derivatives.[9,10] Refinements of the force constants were then carried out by the trial-and-error method*1 making use of the Jacobian matrices. The final sets of force constants thus obtained for these molecules are shown in Table 2. In both of these molecules, the calculated values of the fundamental vibrations (see Table 1) agreed well with the observed values, except for the following two points, which remain to be elucidated:

(1) Two absorption peaks were observed, at 752 and 715 cm^{-1} for the neutral molecule or at 725 and 694 cm^{-1} for the anion-radical, while only one fundamental in-plane vibration was expected to appear around this region.*2 To assign one of them to an out-of-plane vibration is improbable, because such a vibration should appear in the region below 650 cm^{-1}.

(2) The calculated 1288 cm^{-1} band in the anion-radical cannot be assigned to any of the observed bands, presumably because of its weak intensity.

Since a total of 14 force constants were evaluated from an experimental assignment of 6 frequencies, we suspect that these values of the force constants are not the best ones for each of these compounds. However, the stretching force constants are still meaningful, because the observed fundamental frequencies are almost all due to the stretching modes. In the discussion below, we will discuss only the difference in the stretching force constants between *p*-chloranil and its anion-radical.

As is shown in Table 2, appreciable differences in the force constants were found in K(C=C), K(C–C), and K(C=O)—namely, K(C=C) = 6.6 md/Å, K(C–C) = 3.0, and K(C=O) = 9.7 for *p*-chloranil, while K(C=C) = 6.1, K(C–C) = 3.5, and K(C=O) = 7.3 for the anion-radical. From these results, we can see that the stretching force constants for the bonds in the conjugated systems are strongly affected. It is expected that the extra electron on the anion-radical is the essential factor causing the decrease in the values of K(C–C) and K(C–O) and the increase in the value of K(C–C), compared to the values of *p*-chloranil.

Discussion

According to Coulson and Longuet-Higgins,[11] the stretching force constant of a bond (12) in a conjugated system can be expressed by:

$$K(12) = \{(1-p(12))K_s + p(12)K_d\} + \left[\left\{\frac{K_sK_d(s-d)}{K_s(1-p(12))+K_dp(12)}\right\}^2 \frac{\pi(1212)}{2}\right], \quad (2)$$

where K_s and K_d are the force constants associated with pure single and double bonds respectively; where $p(12)$ is the bond order, and $\pi(1212)$, the self-polarizability, of the bond (12), and where s and d are the bond lengths of pure single and double bonds respectively.

Carbon-Carbon Bonds. In a homopolar carbon-carbon bond, the second term, involving the self-polarizability, may be small.[12] In this case, the stretching force constant, $K(12)$, is predominantly determined by the bond order, $p(12)$. The lower part of Fig. 4 shows the empirical relation of $K(12)$ to $p(12)$, in which several standard points indicated by the open circles are connected smoothly. They were determined on the basis of the values of $K(12)$ and $p(12)$ for the carbon-carbon bonds in the ethylene, benzene, and butadiene molecules.[9,13] Little contribution of $\pi(1212)$ to $K(12)$ is best shown

9) Y. Kakiuchi, *Nippon Kagaku Zasshi*, **75**, 143 (1954).
10) J. R. Scherer, *Spectrochim. Acta*, **20**, 345 (1964).
*1 The calculations were carried out on a HITAC 5020E at the Computer Center, The University of Tokyo.
*2 In *p*-bromanil, the corresponding bands were found at 705 and 650 cm^{-1}, and in its anion-radical, at 684 and 618 cm^{-1}. The bands at 752 and 725 cm^{-1} in *p*-chloranil and its anion-radical shifted to 650 and 618 cm^{-1} in *p*-bromanil and its anion-radical respectively, whereas the speculation of a similar shifts is not adequate to the cases of the other bands. For this reason, the bands at 752 and 725 cm^{-1} in *p*-chloranil and its anion-radical were assigned to the fundamental vibrations of the C-Cl stretching mode.

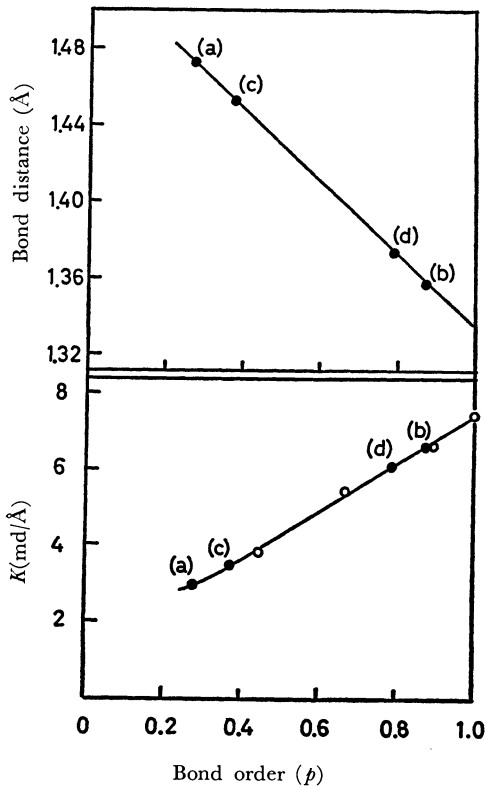

Fig. 4. The lower part illustrates the empirical relation between $K(12)$ and $p(12)$ of a carbon-carbon bond, and the upper part, the relation of $l(12)$ to $p(12)$. (a) and (b) show the values due to C–C and C=C bonds for *p*-chloranil, and (c) and (d), those for its anion-radical, respectively. Open circles indicate the standard points based on the values of $K(12)$ and $p(12)$ in the ethylene, benzene and butadiene molecules.

by the approximate linearity between the $K(12)$ and $p(12)$ values. We cannot adopt the K(C–C) value of ethane as K_s, because the value of K_s should not be that due to the C_{sp^3}–C_{sp^3} bond of ethane, but that due to the C_{sp^2}–C_{sp^2} bond, with $p(12)=0$.

TABLE 3. THE VALUES OF THE BOND ORDERS OF p(C–C), p(C=C) AND p(C=O) FOR *p*-CHLORANIL AND ITS ANION-RADICAL

Bond	*p*-Chloranil		*p*-Chloranil⁻	
	IR[a]	MO[b]	IR[a]	MO[b]
C–C	0.27	0.20	0.37	0.32
C=C	0.87	0.96	0.79	0.83
C=O	0.82	0.91	0.40	0.79

a) The values obtained from the stretch force constants.
b) The values calculated from the molecular orbitals.

By the use of this empirical formula, we can evaluate the bond orders of the C=C and C–C bonds for *p*-chloranil and its anion-radical. From the values of K(C=C) and K(C–C) in their infrared spectra, the p(C=C) and p(C–C) values for these molecules were estimated to be as shown in Table 3. It seems that the extra electron on the anion-radical leads to a decrease in p(C=C) of 0.08 and to an increase in p(C–C) of 0.10, compared to the values of the neutral *p*-chloranil. In order to confirm this result, we further calculated the p(C=C) and p(C–C) values of these molecules by the use of their molecular orbitals. For simplicity, the SCF molecular orbitals of *p*-benzoquinone were used,[14] because the electronic state of the π-conjugated system in *p*-chloranil can be regarded as very similar to that in *p*-benzoquinone. We also assumed that the extra electron enters into the lowest-vacant orbital of *p*-benzoquinone. This orbital has the irreducible representation of the symmetry, b_{3g}, where the coefficients of the O_7, C_1, C_2, and C_3 atomic orbitals were assumed to be represented by -0.3564, $+0.3315$, $+0.3627$, and -0.3627 respectively.[14] With these assumptions, we calculated the values of p(C=C) and p(C–C) for these molecules from their molecular orbitals, as is shown in Table 3. This calculation suggests that the extra electron causes a decrease in p(C=C) of 0.13 and an increase in p(C–C) of 0.12, compared to the values of *p*-chloranil. These results are in good agreement with those evaluated from the infrared spectra.

There is a well-known relation between the bond order and the bond length, l, of a carbon-carbon bond.[12] This was illustrated in the upper part of Fig. 4. In this relation, p(C=C) and p(C–C) derived from the infrared spectra give l(C=C) and l(C–C) respectively. These values of l(C=C) and l(C–C) for *p*-chloranil and its anion-radical are collected in Table 4. The estimated l(C=C) and l(C–C) values of *p*-chloranil are in good agreement with the results of the X-ray study.[7] Table 4 shows that the unpaired electron on the anion-radical may cause an increase of 0.01 Å in l(C=C) and a decrease of 0.02 Å in l(C–C), compared to the values of *p*-chloranil. However, no observation of the molecular structure of the anion-radical has yet been made.

Carbon-Oxygen Bond. If we take $K_s=5.0$ md/Å and $K_d=10.7$ for C=O bond, values proposed by Bratoz and Besnainou,[14] and neglect the contribution of the self-polarizability to the stretching force constant, those force constants for *p*-chloranil and its anion-radical give the values of p(C=O) as 0.82 and 0.40 respectively. These values should be compared with those of 0.91 and 0.79 respectively calculated from their molecular orbitals. In *p*-chloranil, the agreement is rather satisfactory.

14) S. Bratoz and M. S. Besnainou, *J. Chem. Phys.*, **34**, 1142 (1961).

Table 4. The values of the bond lengths of l(C=C) and l(C-C) for *p*-chloranil and its anion-radical
(in unit of Å)

Bond	*p*-Chloranil		*p*-Chloranil$^-$	
	IR[a]	Obsd[b]	IR[a]	Obsd[c]
C-C	1.47	1.477	1.45	(1.44)
C=C	1.36	1.342	1.37	(1.38)

a) The values estimated from the bond orders, which were derived from the stretching force constants in the infrared spectra.
b) The observed values by the X-ray study; see Ref. 7.
c) The values estimated in the *p*-benzoquinone anion-radical from its molecular orbitals; see O. Kikuchi and K. Someno, This Bulletin, **40**, 2972 (1967).

Although there is a definite trend towards less bond order, no quantitative agreement is obtained for the anion-radical. One reason for this might be the neglect of the self-polarizability.

As for the relation between the force constant and the bond length of a C=O bond, Badger proposed the following equation:[15]

$$K(\mathrm{C{=}O}) = 1.86/\{l(\mathrm{C{=}O}) - 0.68\}^3, \qquad (3)$$

where K and l are in md/Å and Å units respectively. For *p*-chloranil and its anion-radical, the values of l(C=O) derived from their force constants by Eq. (3) were 1.26 Å and 1.31 Å respectively. The former value is rather larger than the observed value of 1.195 Å.[7] Although the agreement is not satisfactory, we may expect than the C=O bond length of the anion-radical is longer than that of *p*-chloranil by 0.05 Å; however, no experimental result is available at present.

15) R. M. Badger, *J. Chem. Phys.*, **3**, 710 (1935); see also J. A. Ladd, W. J. Orville-Thomas and B. C. Cox, *Spectrochim. Acta*, **20**, 1771 (1964).

Concluding Remarks. The present investigation clearly shows that the predominant factor in the frequency differences between *p*-chloranil and its anion-radical is the difference in their electronic structures. Nevertheless, we noticed some disagreements between the C=O bond orders obtained from their infrared spectra and those obtained from their molecular orbitals. We consider that these disagreements may be caused by the frequency shifts due to the crystal-field effect as well as by the neglect of the self-polarizability. The crystal-field effect may be more important for the ion-radical salts than for neutral molecular crystals.

Rigorously speaking, the $\boldsymbol{G}$ matrix for the anion-radical is not identical with that for *p*-chloranil, since the bond lengths of the anion-radical estimated from the bond orders were found to be slightly different from those of *p*-chloranil. The difference in their $\boldsymbol{G}$ matrices may make some contribution to the frequency difference. However, this contribution is negligibly small for the bands due to the stretching modes.

The set of force constants presented in Table 2 cannot be regarded as a unique solution. In this sense, it is important to note the couplings between the stretching force constants and the other force constants. However, our primary interest exists in studying the difference in the force constants between *p*-chloranil and its anion-radical. We consider that the set of force constants presented here is reliable enough for this purpose.

In conclusion, the application of the infrared spectra of a neutral molecule and its ion-radical can bring about valuable knowledge as to their molecular and electronic structures, such as bond lengths and bond orders. It is interesting to see that their frequency differences give some information concerning the nature of the half-filled orbital in the ion-radical molecular orbitals.

The author would like to express his appreciation to Professor Yoshio Matsunaga and Dr. Takao Iijima for their kind advice regarding this work.

Electrochemical Properties of α-Ferric Oxide in Sulfuric Acid Solutions

Hiroshi YONEYAMA and Hideo TAMURA

Department of Chemical Technology, Faculty of Engineering, Osaka University, Suita, Osaka

(Received August 4, 1969)

I-V curves of the α-Fe_2O_3 electrode containing different amounts of Ti were obtained potentiostatically in H_2SO_4 solutions. The anodic current, indicating the dissolution reaction, was almost constant and was not affected by the a_{H^+} of the electrolyte in the potential range 0.4—1.0V *vs.* SCE, but it was dependent on the conductivity of the electrode. It was suggested that the dissolution reaction of this electrode is governed by the electron-transfer mechanism, much as is that of the heavily-doped N-type Ge. The flat-band potential of the α-Fe_2O_3 electrode was estimated on the basis of the capacity measurement. This potential changed with the a_{H^+} of the electrolyte.

The mechanism of electric conduction in 3*d* transition metal oxides[1] deviating a little from stoichiometry have been considered to be different from that in the usual semiconductors, such as Ge and ZnO. In a previous paper[2] we studied redox reactions on lithiated NiO showing P-type conduction and made it clear that the electrical property of the electrode determined the electro chemical reactions on it. A study of the electrochemical reactions of N-type 3*d* transition metal oxide is a useful course of study in elucidating the effect of the electrical property of the electrode on the reactions. α-Fe_2O_3 containing Ti is a typical N-type semiconductor among 3*d* transition metal oxides.[3,4] Therefore, we planned to study the electrochemical properties of α-Fe_2O_3 as a step in the study of the reactions on this electrode. In this paper the polarization behavior and the differential capacity of this electrode will be discussed.

Experimental

Electrode. High-purity Fe power (99.99% up) was dissolved in hot H_2SO_4 solution, and then the hot solution was filtered. $FeSO_4$ was precipitated from the filtrate on cooling it. The precipitate was washed by decantation, filtrated, and washed with deionized water and then with CH_3OH. After having been dried, the $FeSO_4$ was decomposed to Fe_2O_3 in the air at 450°C. The Fe_2O_3 prepared in this way was mixed with 0.2—1.0 atom % Ti in the form of high purity TiO_2 (99.9% up) and ground in an agate mortar. The mixture was pressed into a tablet at 2.25 t/cm² (15 mm dia and 3—4 mm thick). This tablet was fired in the air for 4.5 hr at 1200°C and for 5 hr at 1300°C. The tablets shrank to a diameter of about 10 mm during sinterring, though they still had an apparent porosity of about 20%. Platinum contacts on the end faces of the tablet were made by firing platinum powder pasted on them at 1250°C as a contact material for soldering a lead wire. As the electrical lead was needed for mechanical strength, the vapor-deposition technique was not adopted for making the contact on α-Fe_2O_3. The conduction type of the sample was checked by thermo-electromotive force measurements and was found to be of the N-type, as had already been reported by Morin[3] and by Verway and his co-workers.[4] This sample was fabricated into a electrode in the same way as was used in the study of the lithiated NiO electrode,[5] after the apparent resistivity of the sample had been estimated by the voltage-drop method. Silver and indium were also used to make the electrical contact to α-Fe_2O_3. Ag contact was made by firing Ag powder pasted on an end face of the tablet of α-Fe_2O_3 at 900°C. Indium contact was made by soldering the indium, though the soldering was often unsuccessful. In the case of indium contact, the contact area was restricted to a part of an end face of the tablet of α-Fe_2O_3, since impregnation of a benzene solution of polystyrene was necessary after mounting a specimen in glass tube. The sample used in this study had the Ti content and contact material shown in Table 1. The electrode area was estimated by the method described previously.[5] In this estimation the ac resistance measured in 2 N H_2SO_4 was chosen as the resistance of the electrode. After all the measurements described below, the α-Fe_2O_3 specimen was taken out of the glass tube and its surface was erased with emery paper. The specific resistivity of the α-Fe_2O_3 used in this study was then estimated by the four-probe method.[6] This value is shown in Fig. 1 as a function of the Ti content.

Cell Equipment. The cell equipment has been described previously.[2] The counter electrode was a platinized platinum net (2×4 cm). The test electrode was conditioned by pre-electrolysis in 0.1 N H_2SO_4 at 1.2V and 0.2V *vs.* SCE each 20—30 min.

Electrolyte. 0.1, 0.2, 0.5, and 1.0 N H_2SO_4 were

Results and Discussion

When the electrode was polarized potentiostatically, the current flow was suppressed in the 0.4—1.0 V potential region. Typical I-V curves are shown in Fig. 3. The current attained a stationary value within 5 min—2 hr[8] after the potential setting. I-V curves was usually obtained with a potential raising, but if it was done with a potential lowering from 1.5 V the steady-state current was somewhat smaller. The I-V curves can be separated into three regions, as is indicated in Fig. 3. In the

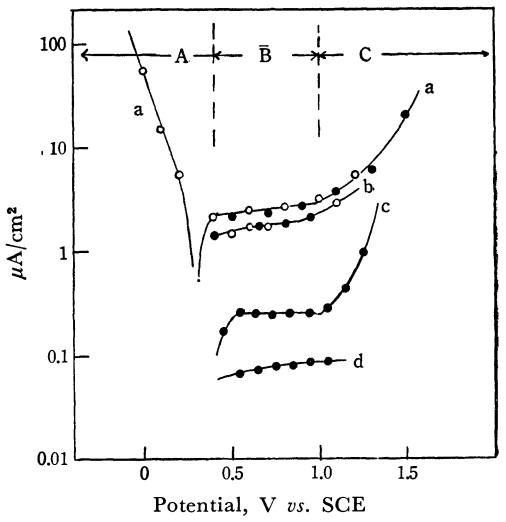

Fig. 3. I—V curves of α-Fe_2O_3 in H_2SO_4 solutions. Electrode had the following Ti content. (atom%). a; 1.0, b; 0.6, c; 0.4, and d; 0.2 electrolyte: —○— 1 N —●— 0.1 N

region A, the I-V curve refers to the hydrogen evolution reaction or the reduction reaction of the electrode, while oxygen evolution possibly occurs in the region C. In the region B the current was not affected by the stirring of the electrolyte or by the concentration of sulfuric acid, as Fig. 3 shows. According to the potential-pH diagram,[9] Fe_2O_3 is not stable in the region B. In order to clarify the nature of the current in the region B, the quantity of Fe dissolved into the electrolyte was determined by colorimetric method after the electrode C had been polarized potentiostatically at 0.9 V for a known period and then compared with the quantity of electricity passed through during the polarization. As a result, 16 μA·H produced 32.5 μg Fe; *i.e.*, one faraday amounts to 54.5 g Fe. From this result, the current in the region B can be said to refer to the anodic dissolution reaction of the electrode.

When a N-type semiconductor comes in contact with a metal having a large work function, a potential barrier is formed on the contact face depending on the difference between their work functions, and then a space-charge layer is created in the interface. As platinum has a large work function, 5.10 eV,[10] a potential barrier should have been formed on the interface between Pt and α-Fe_2O_3. Such a potential barrier occasionally controls the current flow. However, the Pt-α-Fe_2O_3 contact did not control the electrochemical reactions even if the potential barrier existed at the contact face, for generally a current flow is hindered cathodically by this barrier

7) S. Toshima and I. Uchida, *Denki Kagaku*, **34**, 624 (1966).

8) Nearly 2 hr was required at 0.5 V with the potential raising measurement.

if the electrochemical reactions are controlled by this barrier, but a distinct current appeared in the region A. Moreover, a distinct cathodic current showing the reduction of Fe^{3+} was observed in the potential comparable to the region B.[11] The suppression of the anodic current flow in the region B does not, therefore, stem from Pt-α-Fe_2O_3 contact.

In the anodic dissolution reaction of the common semiconductors, a saturation current is usually observed in N-type semiconductors.[12-14] The holes are connected with this current flow. As a hole probably exists in α-Fe_2O_3,[15] hole-connected mechanism cannot be simply denied. In order to clarify this point, an I-V curve was obtained in the electrolyte containing Ce^{4+}. If hole is connected with the anodic dissolution reaction, the current should increase in the electrolyte containing Ce^{4+} compared with the case when only H_2SO_4 is present because the holes injected from the reduction of Ce^{4+} would participate in the dissolution reaction.[16] Of cource, this method may not be complete for determining the kind of charge carrier involved in the reaction, since some particular effects, such as the Hall effect and carrier injection, which can be observed in common semiconductors have not been observed in 3*d* transition metal oxides.[1] The I-V curves obtained in each electrolyte are shown in Fig. 4. The current decreased slightly in the electrolyte containing Ce^{4+}. The mechanism of hole transfer is, therefore, doubtful. In addition, Fig. 1 shows that the current in the region B was the larger for the electrode with a smaller resistivity.

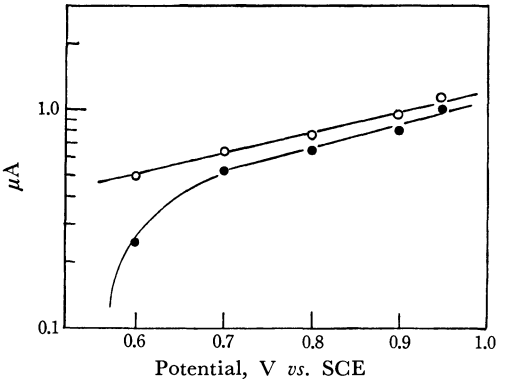

Fig. 4. I—V curves of α-Fe_2O_3 in the electrolyte of —○— 1 N H_2SO_4 and —●— 0.01 M Ce^{4+}/1 N H_2SO_4. Measurement was carried out with potential decreasing direction at the B electrode.

If it is assumed that the resistivity of α-Fe_2O_3 is almost completely determined by the electron density and its mobility,[15] these results lead to the conclusion that the electron in the electrode is connected with the current in the region B. The situation in which the dissolution reaction of the α-Fe_2O_3 electrode proceeds by means of electron transfer is similar to the one observed in the dissolution reaction of heavily-doped N-type Ge.[17] The nearly constant current observed in the region B conceivably appears as a result of the formation of a potential barrier in the electrode surface region or as a result of so-called "passivation" which occurs at the iron electrode in the potential comparable to the region B.[18] The former mechanism is obeyed in the following hypothesis. The energy band of α-Fe_2O_3 will be bent upwards at the electrode in the potential comparable to the region B, since the flat-band potential of α-Fe_2O_3 is quite low as will be presented below. If the electron in the intermediate of the dissolution reaction must jump over this energy barrier in order to flow into the electrode during the process of the dissolution reaction, the current flow would naturally be hindered by this barrier,

though its intermediate and its energy state are not clear at present. The finding that the activation energy of the reaction indicated by the current in the region B, 4.8 kcal/mol, was almost equal to that of the electrical transference of α-Fe_2O_3 estimated from the Pt-α-Fe_2O_3-Pt system, 5.0 kcal/mol, may support this mechanism.

The capacitance *C*-electrode potential *V* curves of the B electrode are shown in Fig. 6. *C* monotonously decreases with an increase in the electrode

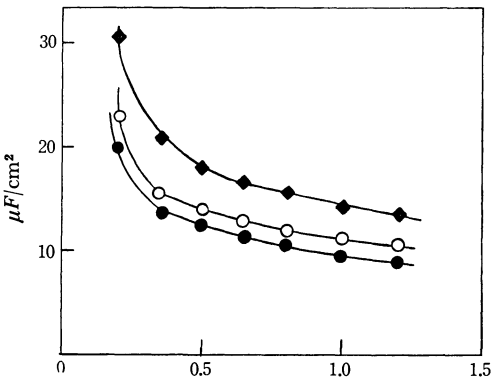

Fig. 6. Differential capacity of α-Fe_2O_3 containing Ti (1.0 atom%) in 0.1 N H_2SO_4. Contact material; Pt —◆— 2.5 kc —○— 5 kc —●— 10 kc

potential. The *C*-*V* curves of the A, C and D electrodes are similar to that of the B. *C* was of an order of 10 μf/cm², as Fig. 6 shows. This is comparable to the double-layer capacity, as has often been pointed out,[19,20] and the measured *C* value normally refers to the space charge in the semiconductor surface region. Similarly, capacitance may be fixed in the passivation film when the passivated film exists on the electrode.[21] Therefore, if it is assumed that the measured *C* value refers to the space-charge capacity induced in the electrode surface, an abnormally large value of *C* may indicate that the estimation of the surface area was incorrect. Unfortunately, the correct estimation of the true surface area of the electrode of a sintered body is very difficult, especially on the oxide electrode. If the measured *C* value can be ascribed to the space-charge capacity in the electrode surface, then the flat-band potential can be estimated from the Mott-Schottky relation.[19-21] The discrepancies in the *C* values measured at various frequencies shown in

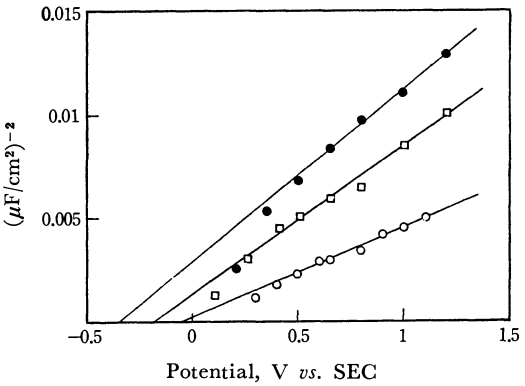

Fig. 7. Mott-Schottky plot for αFe_2O_3 electrode having platinum contact under exhaustion condition. electrode B —●— 0.1 N H_2SO_4 —□— 0.5 N H_2SO_4 —○— 1 N H_2SO_4

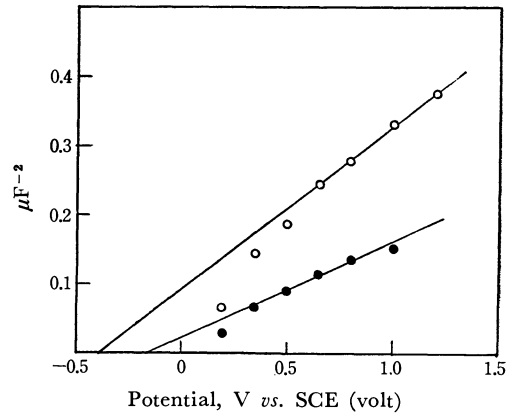

Fig. 8. Mott-Schottoky plot for αFe_2O_3 electrode having indium contact under exhaustion condition. —○— 0.1 N H_2SO_4 —●— 1 N H_2SO_4.

Fig. 6 are due to the Faradic process or to the slow surface state on the electrode surface.[22] As the measured *C* values are more confused by these effects the lower the frequencies adopted, $1/C^2$-*V* curves were obtained on the basis of the *C* value at 10 kc; they are shown in Figs. 7 and 8 for the A and B electrodes respectively. The finding that the $1/C^2$-*V* curves show a linear relation above 0.5 V indicates that the space-charge layer was fixed in the electrode surface region above 0.5 V, since the *C* connected with the space-charge layer on the interface between α-Fe_2O_3 and the contact metal would be diminished with an increase in the electrode potential even if it did exist. The coincidence of the flat-band potential of the A electrode with that of the B indicates that a energy barrier on the interface between the contact metal and α-Fe_2O_3 did not have any serious effect on the *C*-*V* curves, for the energy-barrier height which may be formed on

the interface between Pt and α-Fe_2O_3 will be different from the one on the contact face between In and α-Fe_2O_3. Pt has a larger work function, 5.10 eV,[10] than In because In makes an ohmic contact with ZnO, which has the lower work function of 4.3 eV.[23]

The estimated flat-band potentials in the electrolytes having different activities a_{H^+} of the proton are collected in Table 1. After the acid concentration of the electrolyte had been analytically determined and the liquid junction potential between the electrolyte and saturated KCl solution had been corrected according to Henderson's equation, the average values of the flat-band potential shown in Table 1 were plotted against a_{H^+}. They are presented in Fig. 9. The dependence of the flat-band potential on a_{H^+} may be attributed to the specific adsorption of the proton on the surface of the electrode, as has been observed at the lithiated NiO electrode.[20] The flat-band potential, E, of the α-Fe_2O_3 electrode in the acid electrolyte was changed with a_{H^+} according to the following experimental equation estimated by the least-squares methode,

$$E(\text{NHE}) = 0.45 + 0.35 \log a_{H^+}$$

The authors wish to thank Shinnichi Hamamatsu for preparing the electrode.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 355—358 (1970)

Charge-Transfer Interaction and Chemical Reaction. II. Interaction of s-Triaminobenzene with Several Electron Acceptors

Tsuguo YAMAOKA*1 and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received August 5, 1969)

The charge-transfer interaction was studied for systems including s-triaminobenzene as electron donor. The formation of 1 : 1 stable outer (π,π) complexes at room temperature was observed for the systems including s-trinitrobenzene, trininitrotoluene and tetracyanobenzene as electron acceptors. From the analysis of the observed absorption intensities and peak positions of charge-transfer bands, the equilibrium constants of these complexes were determined and the ionization potential of s-triaminobenzene was estimated to be 7.3—7.4 eV. Chloranil was found to form a stable outer (π,π) complex with s-triaminobenzene only at low temperature, and to be led to a substitution reaction by raising the temperature. The spectrum of the reaction intermediate, the inner (σ) complex of s-triaminobenzene with chloranil, was observed at ~500 mμ. A tentative reaction mechanism was proposed.

Aromatic amines are known to act as electron donors and to form charge-transfer (abbreviated hereafter to CT) complexes with a number of electron acceptors.[1,2] Several workers have reported that some aromatic amines are led to chemical reactions with strong electron acceptors through CT complexes.[3-5] In the preceding paper[6] we gave electronic absorption spectra for solutions containing aniline and chloranil in the mixed solvent of ether-isopropyl alcohol (3 : 1) at various temperatures ranging from 36°K to room temperature. We found that these two molecules form a stable outer (π,π) complex at low temperatures below 200°K but with raising temperature they react with each other yielding 2,5-dichloro-3,6-dianilino-*p*-benzoquinone.

s-Triaminobenzene (abbreviated hereafter to TAB) is known to exhibit a characteristic feature in the fact that protonation occurs more easily on the ring carbon atom than on the nitrogen atom at room temperature and the triaminobenzenium ion is formed.[7] In this connection, we undertook to make a further study on the electron-donating property of TAB, paying special attention to the relation between the CT interaction and chemical reaction. Trinitrotoluene (TNT), s-trinitrobenzene (TNB), tetracyanobenzene (TCNB) and chloranil were used as electron acceptors.

Experimental

Materials. TAB was synthesized and purified by the method described previously.[7] Aniline and dimethylaniline were distilled under reduced pressure just before use. *p*-Phenylenediamine was purified by repeated recrystallizations from ethyl ether.

TNT and TNB were recrystallized twice from ethanol and thereafter once from ethyl ether. Chloranil was recrystallized three times from acetone. TCNB[8] was purified by recrystallization from ethanol: mp 258°C in a sealed tube in agreement with the value in literature.[9]

Chloroform was purified by distillation after washing with water. Methylene chloride was dried over calcium chloride and distilled. Ethyl ether was treated with sodium metal and distilled.

Measurements. Electronic absorption spectra were measured with a Cary recording spectrophotometer Model 14M. The spectra at low temperatures were measured by immersing cells in a quartz Dewar vessel containing liquid nitrogen or dry ice-acetone as a refrigerant. Infrared spectra were measured with a Hitachi EPI 2 spectrophotometer, Nujol mulls being used.

Results and Discussion

Outer (π,π) Complex Formation of TAB with TNT, TNB and TCNB. We measured absorption spectra for various solutions containing TAB as an electron donor and TNT, TNB and TCNB as electron acceptors. Chloroform, ethyl ether and methylene chloride were used as solvents. The results show that TAB interacts with electron acceptors such as TNT, TNB and TCNB to give new absorption bands due to neither electron donor nor acceptor in near ultraviolet and visible regions. Some of the observed bands are shown in Fig. 1. The maximum appears at 440 mμ (in chloroform) and 460 mμ (in ethyl ether) for the TAB-TNT complex; at 460 mμ (in chloroform) and 493 mμ (in ethyl ether) for the TAB-TNB complex; at 420 mμ and 530 mμ for the TAB-TCNB complex in methylene chloride. The peak positions (in eV) of the bands are plotted against those of the CT bands for the hexamethylbenzene (abbreviated hereafter to HMB) complexes with the corresponding acceptors.[2,10] The result given in Fig. 2 shows that the points lie on a straight line. This supports the view that the new bands are interpreted as the CT absorption.

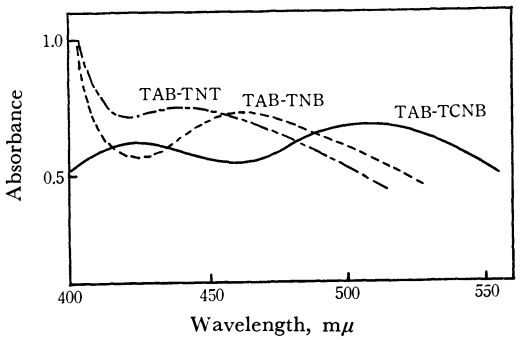

Fig. 1. Spectra of the TAB complexes with TCNB (——) in methylene chloride, and with TNB (- - -) and TNT (— - —) in chloroform.

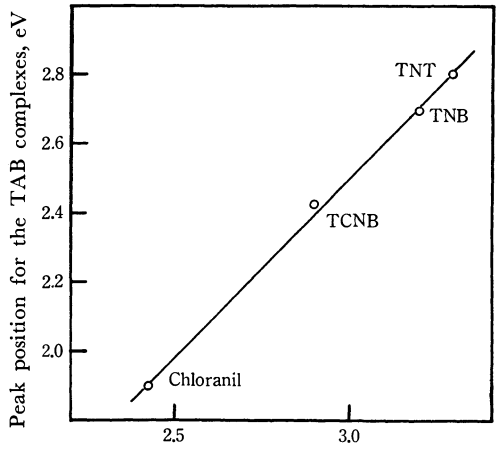

Fig. 2. Plots of the peak positions (in eV) of the new bands observed for the TAB complexes with several electron acceptors in ethyl ether against those of the CT bands for the HMB complexes with corresponding electron acceptors in cyclohexane.

Figure 3 shows that plots of the CT band positions observed for the TNT or TNB complexes with aniline, TAB, dimethylaniline and *p*-phenylenediamine in chloroform against the ionization potentials of the donors except for TAB.[11] From this figure, the electron donating ability of TAB is found to be stronger than that of aniline and weaker than that of dimethylaniline, and its ionization potential can be estimated to be 7.3—7.4 eV.

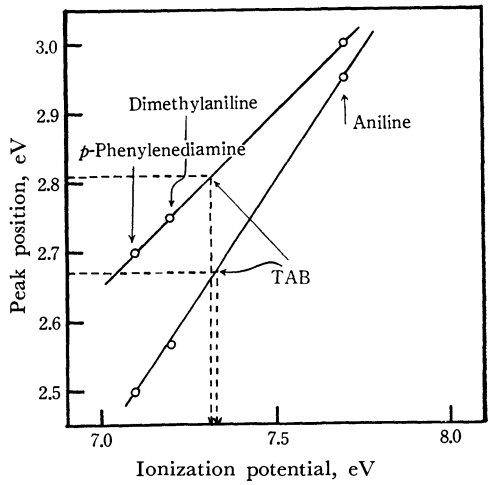

Fig. 3. Plots of the peak positions (in eV) of the CT bands observed for the TNT and TNB complexes against the ionization potentials of aromatic amines as electron donors.

Benesi-Hildebrand plots[12] were carried out for the system containing TAB-TNT and TAB-TNB in chloroform, the well-known straight-line relationship being obtained.[13] This means that 1 : 1 complexes are formed for these systems. The equilibrium constants (K) and the molar extinction coefficients at 25°C were obtained. The results are summarized in Table 1.

13) The concentrations of electron donor C_D and acceptor C_A used for the Benesi-Hildebrand plots are as follows: For TAB-TNT complex, $C_D=2.96\times10^{-3}$ mol/*l*, $C_A=4.04\times10^{-2}$, 2.45×10^{-2}, 1.70×10^{-2} and 1.15×10^{-2} mol/*l*; for TAB-TNB complex, $C_D=2.81\times10^{-4}$ mol/*l*, $C_A=5.56\times10^{-2}$, 2.50×10^{-2}, 1.61×10^{-2} and 1.21×10^{-2} mol/*l*.

Table 1. Equilibrium constant (K) and molar extinction coefficients of CT bands for the TAB-TNT and TAB-TNB system

Complex	K(mol^{-1} l)	ε_{max}
TAB-TNT	15	500
TAB-TNB	20	600

According to Fig. 1, the two CT bands are clearly observed at 420 and 503 mμ for the TCNB-TAB complex in methylene chloride. The frequency difference $\Delta\nu$ between the two peaks is 3920 cm^{-1}. Iwata *et al.*[2] first found that the CT complexes of TCNB with some electron donors show the two CT bands with $\Delta\nu$ values of 5400—6700 cm^{-1}, and these values correspond to the theoretically evaluated energy difference between the two lowest vacant orbitals of TCNB. This means that the two closely located vacant orbitals of the acceptor play an important role in the appearance of the two CT bands for the TCNB complexes. The energy difference (3920 cm^{-1}) is considerably smaller for the TAB-TCNB complex than for the other TCNB complexes. This seems to be related with the fact that the TCNB complex with mesitylene which has the same symmetry as TAB shows a smaller $\Delta\nu$ value than the TCNB complexes with benzene, toluene, durene and hexamethylbenzene.

Outer or Inner Complex Formation and the Reaction of TAB with Chloranil. As mentioned above, TAB forms the stable 1 : 1 outer (π,π) complexes with TNT, TNB and TCNB at room temperature. However, when it interacts with chloranil, the situation seems to be more complex. A blue color formation was observed when TAB was mixed with chloranil in mixed solvent of ether-isopropyl alcohol (3 : 1) at the liquid nitrogen temperature.[14] The color of the solution rapidly turned red immediately after the rigid solution was melted with raising temperature and finally became yellow. However, when the solvent is ethyl ether, the blue color is considerably stable below dry ice-acetone temperature.

The absorption spectra of the TAB-chloranil complex under various conditions are shown in Fig. 4. Curve 1 measured at the liquid nitrogen temperature shows the absorption peak at 660 mμ. This band may be regarded as a CT band. This is supported by the fact that the transition energy of this absorption band fits well into the straight line representing the relation between the CT transition energies of the TAB and hexamethylbenzene complexes with the respective electron acceptors, as is shown in Fig. 2. The blue color of the solution became weaker with rising temperature and this

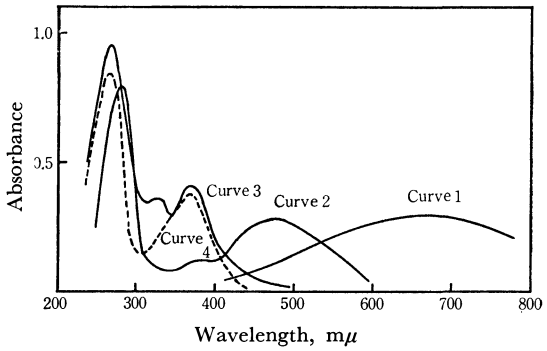

Fig. 4. Time dependence of the spectra for the solution containing 10^{-3} mol/l chloranil and a large excess amount of TAB in 1 : 3 mixed solvent of isopropyl alcohol and ethyl ether. Curve 1, the outer (π, π) complex; curve 2, the inner (σ) complex; curve 3, the adduct of the both components; curve 4, the spectrum of the ring protonated TAB.

color change was found to be reversible for the temperature change near −170°C.

As mentioned above, the blue solution containing TAB and chloranil in mixed solvent of ether-isopropyl alcohol turns red in the intermediate state and finally yellow with increasing temperature. The spectral change is shown in Fig. 4. By raising the temperature, curve 1 due to the outer (π,π) complex changes into curve 2 with the absorption peaks at 500 and 370 mμ, and finally we can obtain curve 3, the absorption spectrum of the product which shows the peaks at 220, 272, 320 and 370 mμ.

It is worth noting that curve 2 of Fig. 4 is similar to the absorption spectra observed[15] with the chloranil-methylamine and chloranil-methoxide ion systems which produce the inner complex shown in Figs. 5(a) and 5(b). A similar spectrum was also observed when *N*,*N*-dimethyl-*m*-phenylenediamine, *m*-phenylenediamine or *m*-aminophenol is mixed with chloranil in the etheral solution. We conclude that the spectrum originates from the inner complex[16] shown in Fig. 5(c). This structure was also supported by the molecular orbital calculation.[17]

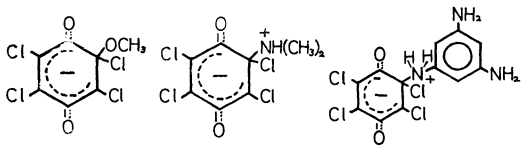
Let us consider the absorption spectrum given by curve 3 in Fig. 4. The spectrum, except for the

14) Actual mixing was carried out by iterating a process of adding only a small amount of the donor solution of room temperature to a large amount of the acceptor solution at liquid nitrogen temperature.

15) The chloranil-methylamine (in ether and water mixed solvent) and chloranil-methoxide ion (in methanol) systems show the absorption peak at 505 and 475 mμ, respectively. Although these peak wavelengths are somewhat dependent upon the solvent, they, particularly the latter correspond to the 475 mμ peak of curve 2.

16) Any attempt to isolate the inner complex was unsuccessful, because it easily decomposes on filteration from solutions and on vaporization of solvents.

17) T. Nogami, K. Yoshihara, T. Yamaoka and S. Nagakura, to be published.



(a) (b) (c)

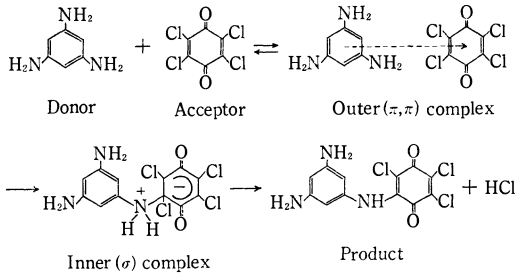
Fig. 5. Structures of intermediate σ complexes.

peak at 320 mμ, agrees well with that of 1,3,5-triaminobenzenium ion.[7,18] The existence of this ion in the system was also demonstrated by the fact that the infrared spectrum measured for the precipitate (in Nujol mulls) produced in the presence of an excess amount of TAB is the same as that of the triaminobenzenium ion.[7]

The peak at 320 mμ seems to be due to another product. This view is supported by the fact that the relative intensity of the 320 mμ band to the bands changes with the conditions.[19] A fairly pure product with the band at 320 mμ is obtained as a precipitate[20] when an excess amount of chloranil is mixed with TAB in acetone. By an analogy with the products of similar reactions of chloranil with aromatic or aliphatic amines,[6,21,22] the precipitate is expected to be 2,5,6-trichloro-3-triaminobenzo-*p*-benzoquinone or/and 2,5-dichloro-3,6-bis(triaminobenzo)*p*-benzoquinone. Elementary analysis shows that the main part of the precipitate in the presence of an excess amount of chloranil is the former.

Found: C, 41.73; H, 4.13; N, 12.9; Cl, 27.37%. Calcd for the former ($C_{12}H_8N_3Cl_3O_2$): C, 43.24; H, 2.40; N, 12.64; Cl, 31.98%. The discrepancy of elementary analysis from the calculated is due to the difficulty in the separation of the triaminobenzenium ion from the precipitate[23] and also to its hygroscopic property. The elementary analysis data can be expalined by taking account of the mixing of small amounts of the triaminobenzenium ion and water. At least it may be concluded that the main product is not 2,5-dichloro-3,6-bis (triaminobenzo)*p*-benzoquinone. The NMR spectrum measured for the deuterated DMSO solution of the precipitate is consistent with the above-mentioned structure of the main product.[24]

From the above-mentioned results on the structures of the reaction intermediates and products, a possible mechanism of the reaction is proposed as follows:



Hydrogen chloride produced in the above reaction attacks TAB to yield the triaminobenzenium ion.[7] For this reason we can observe its absorption spectrum for reaction products.

Increasing the concentration of TAB in solution, we can expect to produce 2,5-dichloro-3,6-bis-(triaminobenzo)*p*-benzoquinone together with 2,5,6-trichloro-3-triaminobenzo-*p*-benzoquinone and the triaminobenzenium ion. Actually, elementary analysis of the product shows that the mixture of the above compounds is precipitated. A similar tendency was also observed by Kumanotani *et al.*[21] for the toluquinone-*n*-butylamine system.

The above-mentioned mechanism with the outer (π,π) and inner (σ) complexes as intermediates was demonstrated to be correct by analyzing the results of the temperature dependence of the decay curve of the inner (σ) complex.[17] The details of this analysis together with a kinetic study on the other systems will be published.

The authors wish to express their gratitude to Professor Takahiro Tsunoda, the University of Chiba, for his continuous encouragement throughout the course of this research. They are also greatly indebted to Dr. Keitaro Yoshihara and Mr. Takashi Nogami for their helpful discussion.

19) For example, the 320 mμ band becomes relatively stronger for the product obtained from the dilute solution containing a great excess amount of chloranil.

20) The precipitate exhibits no infrared band due to the 1,3,5-triaminobenzenium ion. However, it is shown to include a small amount of the ion from visible and ultraviolet absorption measurement.

22) D. Buckley, H. B. Henbest and P. Slade, *J. Chem. Soc.*, **1957**, 4891.

23) We tried to separate each product by chromatography and other methods, but we were not successful mainly because of the very small solubility of the precipitate.

24) The NMR spectrum of the precipitate in deuterated DMSO solution shows three peaks at τ=6.40, 4.30 and 2.80 which are assigned to the proton signals of NH_2, ring and NH from their τ values and intensities. For the purpose of comparison, the NMR spectra of triaminobenzene and diphenylamine were also measured with the results: τ=7.20 (NH_2 proton), 4.60 (ring proton) for triaminobenzene; τ=1.89 (NH proton) for diphenylamine.

Steric Structure of L-Proline Oligopeptides. IV. Proton Magnetic Resonance Studies of L-Proline Oligopeptides*[1]

Hirofumi OKABAYASHI*[2] and Toshizo ISEMURA

Division of Physical Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received August 16, 1969)

The NMR spectra of *t*-amyloxycarbonyl-L-proline oligopeptides were measured and compared with those of two poly-L-prolines, I and II. The α-CH resonance peaks of the oligopeptides were observed at sheilding values of 5.2 and 5.4 ppm, values which were in accord with those of the α-CH resonance peaks of the poly-L-prolines I and II, respectively. The behavior of the α-CH peaks was related to the conformation of the L-proline oligopeptides. Moreover, the contribution of the two terminal L-proline residues to the α-CH resonance peaks was discussed.

In our preceding papers,[1,2] we have made configurational studies of L-proline oligopeptides by such methods as infrared absorption spectra, far-ultraviolet absorption spectra, optical rotatory dispersion, and circular dichroic spectra. The results have led to the conclusions presented below.

In *t*-amyloxycarbonyl-L-proline oligopeptides, the helical structures of the poly-L-proline II-type begin to appear at the tetramer, and the molecules of the pentamer, hexamer, and octamer have a helical structure similar to that of the poly-L-proline II.

The structures of the poly-L-prolines I and II have already been established by the X-ray diffraction method.[3,4] The I form has a right-handed helical structure with a residue translation of 1.85 A, in which the peptide bonds are in the *cis* configuration, while the formII is left-handed with a residue translation of 3.12 A and with the peptide bonds *trans*.

In this work, high-resolution proton magnetic resonance spectroscopy was used for the study of the steric structure of *t*-amyloxycarbonyl-L-proline oligopeptides; the configuration of the peptide groups of the oligomers will be discussed by comparing the NMR spectra of these oligomers with those of the poly-L-prolines I and II. Especially, the differences between the configurations of the two terminal L-prolyl residues and those of the other L-prolyl residues will be described.

Sakai, Okabayashi and Isemura[5-7] have already observed a marked difference in the magnetic shielding values of the α-CH peaks of the poly-L-prolines I and II.

Experimental

The L-proline oligopeptides used in the present investigation were as follows: *t*-amyloxycarbonyl-L-proline (monomer), *t*-amyloxycarbonyl-L-prolylproline (dimer), *t*-amyloxycarbonyl-L-prolylprolylproline (trimer), *t*-amyloxycarbonyl-L-prolylprolylprolylproline (tetramer), *t*-amyloxycarbonyl-L-prolylprolylprolylprolylproline (pentamer), *t*-amyloxycarbonyl-L-prolylprolylprolylprolylprolylproline (hexamer), and *t*-amyloxycarbonyl-L-prolylprolylprolylprolylprolylprolylprolylproline (octamer).

These oligopeptides were synthesized by Dr. S. Sakakibara (Peptide Center, Institute For Protein Research, Osaka University, Osaka) and one of the present authors (H. Okabayashi).

The poly-L-proline I was synthesized by the polymerization of L-proline-*N*-carboxyanhydride in acetonitrile. The molecular weight was *ca.* 6000. The poly-L-proline II was prepared by transforming the poly-L-proline I into the form II in an acetic acid solution.

The deuterochloroform (isotopic purity: 99%), tetradeuteroacetic acid (isotopic purity: 99%), tetradeuteromethanol (isotopic purity: 99%), and tetramethylsilane used for spectroscopy were manufactured

by E. Merck Aktiengesellschaft, Darmstedt, Germany. These solvents were used without further purification. Tetramethylsilane (TMS) was used as an internal reference for all the resonance peaks. All the proton magnetic resonance spectra were obtained on a Japan Electron Optics Laboratory (Jeolco) model JNM-4H-100 NMR spectrometer at a frequency of 100 MHz. The spectra of L-proline oligomers at a temperature of 26 ± 2°C were accumulated thirty-two times, using a spectrum accumulator (Jeolco model JPA).

Results and Discussion

According to the NMR studies which have been made by Sakai, Okabayashi, and Isemura,[5-7] the magnetic shielding value of the α-CH peak of the poly-L-proline I was different from that of the form II. The α-CH peaks of the form I appeared at the shielding value of 5.5_{ppm} in a mixed solvent (deuterochloroform : tetradeuteroacetic acid = 8 : 1), and that of the poly-L-proline II, at 5.2 ppm in tetradeuteroacetic acid.

This difference might be due to the different configurations of the peptide groups of the two poly-L-prolines.

Figure 1 show the NMR spectra of the pyrrolidine rings of *t*-amyloxycarbonyl-L-proline and of poly-L-prolines in CD_3COOD. The peak assignments are also included in Fig. 1. The NMR spectrum of the poly-L-proline I in tetradeuteroacetic acid was obtained by measuring it rapidly, as soon as the sample had been completely dissolved. In tetradueteroacetic acid the α-CH peak of the poly-L-proline I has a shielding value of 5.4_{ppm}, and that of *t*-amyloxycarbonyl-L-proline, one of 5.7_{ppm}.

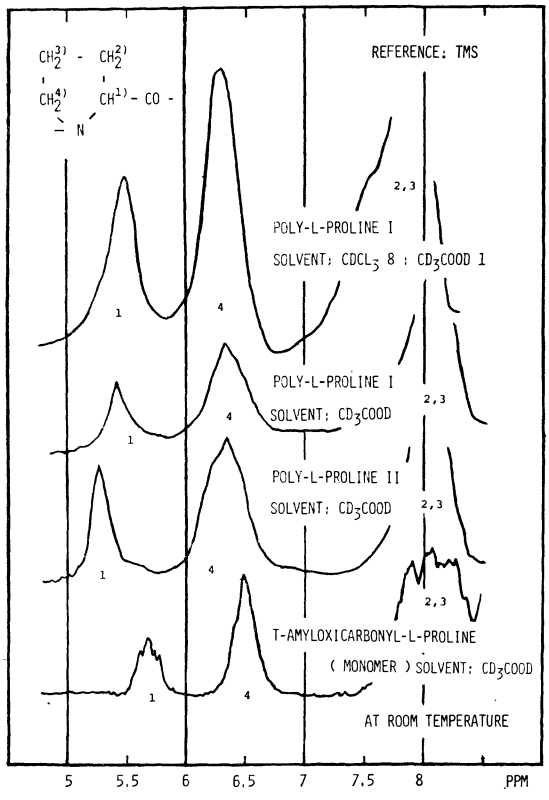

Fig. 1. NMR spectra of *t*-amyloxycarbonyl-L-proline, poly-L-prolines I and II at 26°C.

Figure 2 gives the NMR spectra of *t*-amyloxycarbonyl-L-proline oligopeptides in comparison with those of the poly-L-prolines I and II. The spectra of the oligomers were accumulated thirty-two times by means of the spectrum accumulator.

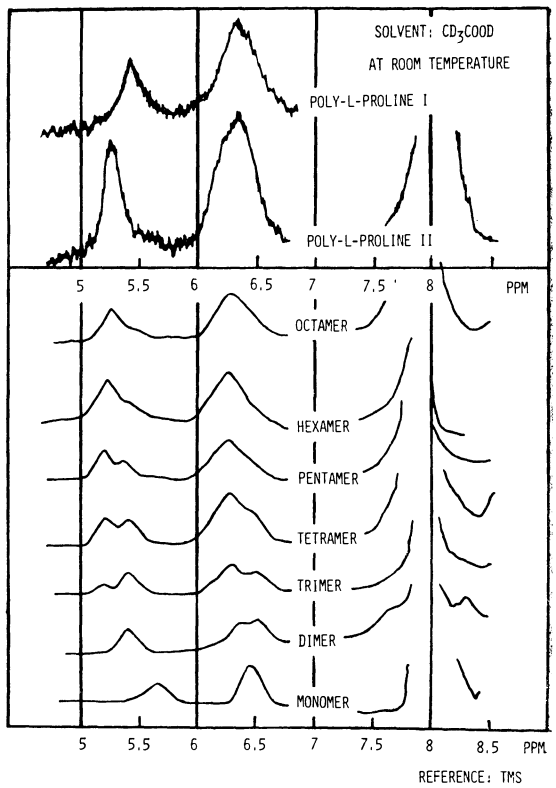

Fig. 2. NMR spectra of *t*-amyloxycarbonyl-L-proline oligopeptides, poly-L-prolines I and II at 26°C.

In the NMR spectra of the dimer, the resonance peak of 5.4_{ppm} is assigned to the two α-CH protons of the dimer. Since the shielding value of the α-CH resonance peak of the dimer is in agreement with that of the poly-L-proline I, it seems that the coincidence suggests the configuration of the dimer. However, it does not always follow that the α-CH resonance peak of the dimer corresponds to the *cis* configuration of the peptide groups of the poly-L-proline I. For the two L-proline residues of the dimer can be regarded as the terminal residues. It is unreasonable to identify the two terminal residues of the dimer with the two residues of the poly-L-proline I. Although there is a probability that the dimer has the *cis* configuration of the peptide group,

TABLE 1. THE RATIOS OF THE AREAS OF THE α-CH PEAKS AT 5.2_{ppm} TO THOSE OF THE OTHER α-CH PEAKS AT 5.4_{ppm}

Oligomers	Trimer	Tetramer	Pentamer	Hexamer	Octamer
Experimental values* (B/A)	2.01 ± 0.03	1.08 ± 0.02	0.66 ± 0.02	0.51 ± 0.02	0.35 ± 0.01
Theoretical values (B/A)	2	1	$2/3\fallingdotseq0.67$	0.5	$1/3\fallingdotseq0.33$

A = Area of the peak at 5.2_{ppm}. B = Area of the peak at 5.4_{ppm}.
* These experimental values were calculated from the NMR spectra of L-proline oligopeptides accumulated for thirty-two times by spectrum accumulator.

the NMR measurement at 100 MHz does not a resolution sufficient to make clear the configuration of the dimer. The NMR spectra at 220 MHz will give the configuration of the two L-proline residues of the dimer.

In the NMR spectra of the trimer, tetramer, pentamer, hexamer, and octamer, two α-CH peaks were observed. The magnetic shielding values of the two peaks in the five oligomers are 5.2 and 5.4_{ppm}. The resonance position of the α-CH peak at 5.2_{ppm} is the same as the α-CH resonance spectrum of the II poly-L-proline gives. Furthermore, as L-prolyl residues increase, the α-CH resonance peak of 5.2_{ppm} increases in intensity, whereas that of 5.4_{ppm} decreases in intensity, as can be well seen in Fig. 2. The behavior of the α-CH resonance peak of 5.2_{ppm} indicates that the peptide groups of the oligomers assume a *trans* configuration with an increase in the chain length.

The fact that the oligopeptides larger than the tetramer assume the conformation of the poly-L-proline II (peptide bonds: *trans*) was established by various methods, as has already been mentioned. Nevertheless, the peak attributable to the conformation of the poly-L-proline I (peptide bonds: *cis*) appears fairly clearly in the NMR spectra of the oligopeptide. If we assume that the α-CH peaks of terminal residues appear around the same position as that for the *cis* configuration, the α-CH peaks of terminal residues may be expected to decrease very regularly with the function of the length of the peptide chain. This inference was clearly suggested by the experimental findings.

In order to discuss the effect of the terminations, it is convenient to assume that, in the α-CH resonance peaks of L-proline oligopeptides, all the α-CH peaks at the magnetic shielding value of 5.4_{ppm} in tetradeuteroacetic acid are to be attributed to the α-CH protons of the two terminal L-proline residues. As has already been mentioned, one of the α-CH peaks at 5.2_{ppm} may be ascribed to the trans configuration of the peptide bonds in the oligopeptides. On the basis of the above assumptions, the ratios of the intensities of the two terminal α-resonance peaks to those of the other α-CH peaks can easily be calculated.

The experimental values of the ratios are obtained from the ratios of the areas of the α-CH resonance peaks at 5.2_{ppm} to those of the other α-CH peaks at 5.4_{ppm}. These experimental ratios are summarized in Table 1, along with the theoretical values.

The experimental values are compared with the theoretical values in Table 1. The agreement of the experimental values with the theoretical values is satisfactory. These facts show that the previous inference is plausible. That is, it may be concluded that the *L*-proline residues placed between the two terminal residues have a poly-L-proline II-like configuration.

In the NMR spectra of the oligopeptides, the change in the δ-CH_2 resonance peaks should be noteworthy. These δ-CH_2 resonance peaks might be related to the conformation of the oligomers. However, it is difficult to obtain information about the configuration of these oligopeptides from the δ-CH_2 resonance peak.

Further information about the effect of the terminal residues on the α-CH resonance peaks and the δ-CH_2 resonance peaks of L-proline oligopeptides can be obtained from the NMR spectra of L-proline oligopeptides, including the deuterized L-prolines.

The authors are grateful to Mr. O. Masuda for recording the NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 362—367 (1970)

Crystal and Molecular Structure of Di-μ-chloro-bis(π-1-ethoxycarbonyl-2-hydroxyallyl)dipalladium(II)

Kunio ODA, Noritake YASUOKA, Tatzuo UEKI,*1 Nobutami KASAI*2 and Masao KAKUDO

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received August 25, 1969)

The crystal and molecular structures of di-μ-chloro-bis-(π-1-ethoxycarbonyl-2-hydroxyallyl)-dipalladium, $(C_6H_9O_3PdCl)_2$ have been determined from the three-dimensional data. The crystals are triclinic; space group $P\bar{1}$; with one dimeric molecule per unit-cell; $a=4.80$, $b=10.31$, $c=10.64$ Å, $\alpha=117.4$, $\beta=102.3$, and $\gamma=84.1°$. The final discrepancy index is 14.0% for 1208 reflections. The two palladium atoms are joined by two chlorine bridges to form a square planar arrangement. The molecule possesses a center of symmetry which coincides with a crystallographic center of symmetry in the crystal; the overall coordination scheme of the palladium atom is similar to that established for the π-allyl palladium chloride dimer. The dihedral angle between the plane of four atoms [Pd, Pd', Cl, and Cl'] and the π-allyl plane is 108. There are intermolecular hydrogen-bonds between the enolic hydroxyl group of one molecule and the carbonyl-group of the other molecule related by the center of symmetry.

A number of π-allylic complexes have been synthesized from palladium(II) chloride and various mono-olefins or conjugated di-olefins.[1] However, few complexes have been synthesized from unsaturated ketones and esters.

The ethanolysis of diketene is accelerated by the addition of sodium tetrachloropalladate(II).[2] The yellow crystals separated at the end of this reaction were identified as di-μ-chloro-bis-(π-1-ethoxycarbonyl-2-hydroxyallyl)dipalladium(II) on the basis of the analytical data, the molecular weight, and the infrared spectrum. The same complex was also prepared directly by the reaction of palladium(II) chloride with ethyl acetoacetate in water.

The IR data reveal that, instead of the usual chelate structure, the complex may have a π-allylic linkage. The stretching absorption bands of O–H and C=O groups are both shifted to lower frequency, indicating the existence of intra- or intermolecular hydrogen-bonding.

Proton magnetic resonance spectra are frequently utilized as one of the most powerful tools in the structural study of π-allylic metal complexes. Unfortunately, however, no suitable inert solvents are available for the present complex. Thus, the three-dimensional X-ray analysis of this complex was carried out in order to determine the exact structure; a preliminary report has already been reported.[3]

Experimental

Di-μ-chloro-bis-(π-1-ethoxycarbonyl-2-hydroxyallyl)-dipalladium, $(C_6H_9O_3PdCl)_2$, was recrystallized as yellow needles in a dark place from a benzene solution. The complex is easily decomposed by the irradiation of the benzene solution by visible light.

By the use of Cu$K\alpha$ radiation, the unit-cell dimensions were determined from (*hk*0), (*h*0*l*), and (0*kl*) Weissenberg photographs, on which the powder patterns of tungsten ($a=3.16535$ Å) were superposed for the calibration. In the least-squares refinement of the cell dimensions, 26 high angle reflections were used.

$$a = 4.80\pm0.01\text{ Å}, \quad \alpha = 117.4\pm0.2°,$$
$$b = 10.31\pm0.06\text{ Å}, \quad \beta = 102.3\pm0.1°,$$
$$c = 10.64\pm0.06\text{ Å}, \quad \gamma = 84.1\pm0.3°.$$

The volume of the unit cell, U, is 457 Å^3; $D_m=1.96$ (by flotation in an aqueous solution of $ZnBr_2$); with $Z=1$ (as a dimeric molecule $(C_6H_9O_3PdCl)_2$; $M=542.0$) $D_c=1.97$ g·cm^{-3}. There was no symmetry in the X-ray photographs except that imposed by the Friedel condition, and the space group is either $P1$ or $P\bar{1}$.

Nickel-filtered Cu$K\alpha$ radiation was used to collect equi-inclination Weissenberg data for the layers from

$(0kl)$ through $(3kl)$ and from $(hk0)$ through $(hk4)$ by the multiple-film technique. In all, 1323 independent reflections were obtained, but the refinement was carried out by using 1208 reflections with 2θ less than 120°. The relative intensities were estimated visually, and then corrected for Lorentz and polarization factors. As the dimensions of the crystal used in the experiment were about $0.05\times0.08\times0.10$ mm, the absorption correction was ignored ($\mu=98$ cm^{-1}).

Determination and Refinement of the Structure

In the three-dimensionsl Patterson function, the vectors of Pd-Pd′, Pd-Cl, and Pd-Cl′ lie on the same plane, and a centro-symmetrical arrangement of two palladium and two chlorine atoms was easily derived. Therefore, the space group was assumed to be $P\bar{1}$, the structure has been determined satisfactorily in this space group. The other non-hydrogen atoms were found on the three-dimensional electron density map based on the positions of the palladium and chlorine atoms. The positional and isotropic thermal parameters were then refined by a block-diagonal least-squares procedure. After four cycles, the residual, R, was reduced to 0.167 for 1068 non-zero reflections. The isotropic thermal parameters for palladium and chlorine atoms were then expressed in their anisotropic form, using the expression:

$$T = \exp\{-(\beta_{11}h^2 + \beta_{22}k^2 + \beta_{33}l^2 + \beta_{12}hk + \beta_{23}kl + \beta_{13}hl)\},$$

and the least-squares refinement was continued. After a further five cycles of refinement, R was 0.140 ($R=0.170$ for all reflections). At this stage, the refinement was assumed to be finished, since the maximum shift of coordinates was less than 1% of the estimated standard deviation. Hydrogen atoms could not be located on the three-dimensional difference-synthesis, and their contributions to the calculated structure factors have not been estimated.

Throughout the refinement, the neutral atomic scattering factors were taken from those given by Hanson *et al.*[4] The Patterson function was calculated on a NEAC-2200 computer of this university, with the program written by one of the present authors (N.Y.). The least-squares refinement and other calculations were carried out on a HITAC-5020E computer at the University of Tokyo, with programs written by Dr. Tamaichi Ashida.

The final atomic positional parameters, along

with their estimated standard deviations, are given in Table 1, while the thermal parameters are shown in Table 2. The observed and calculated structure factors are given in Table 3.

Results and Discussion

A plan of the molecule is shown in Fig. 1. The bond distances and angles, along with their estimated standard deviations are listed in Table 4. Figure 2 shows the molecule viewed parallel to the plane containing the chlorine bridge along the Cl-Cl′ line. The refinement is not enough to make a detailed discussion of the bond distances and angles, which may be due to a strong thermal vibration or disorder in the ligand group. Nevertheless, some conclusions can be drawn.

The most important conclusion drawn from the present structure determination is that the π-allyl coordination of the ethyl acetoacetate group to the palladium atom is established for this complex. The coordination configuration resembles those found in the dimeric π-allylpalladium chloride.[5]

Four heavier atoms, palladium and chlorine and their centrosymmetric equivalents, lie on the same plane. This plane of the four atoms fits the equation:

$$-0.765X + 0.595Y + 0.247Z = 0\,.$$

where the orthogonal axes, X, Y, and Z, refer to the triclinic axes by the following transformation:

$$X = ax\cdot\sin\gamma + cz(\cos\beta - \cos\alpha\cdot\cos\gamma)/\sin\gamma$$

$$Y = by + ax\cdot\cos\gamma + cz\cdot\cos\alpha$$

$$Z = cz\{(1 - \cos^2\alpha - \cos^2\beta - \cos^2\gamma + 2\cos\alpha\cdot\cos\beta\cdot\cos\gamma)/\sin^2\gamma\}^{1/2}\,.$$

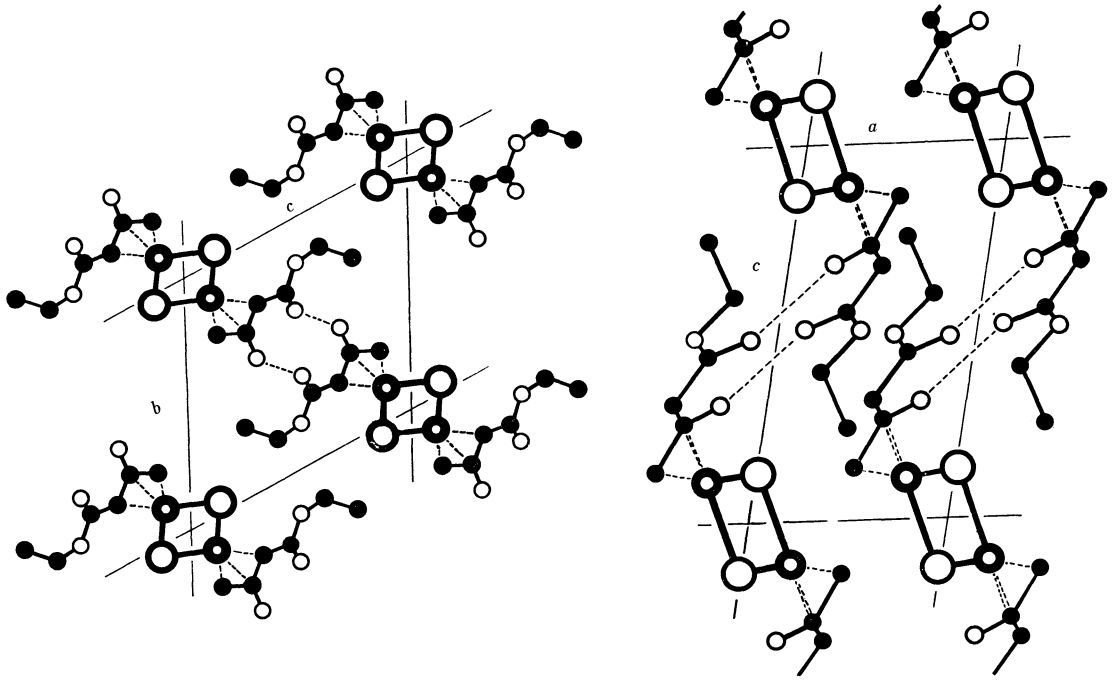

Fig. 3(a) Fig. 3(b)

Fig. 3. Crystal structure.
(a) Projected down along the *a* axis, and (b) Projected down along the *b* axis.

The π-allyl fragment, which must be planar, makes an angle of 108° with this plane of four atoms (Fig. 2) and an angle of 106° with the plane containing the palladium and two carbon atoms, C(1) and C(3). These two values are very similar to those found in other allyl complexes.[6-8] The two carbon atoms of the π-allyl fragment, C(1) and C(3) are 0.13 and 0.10 Å respectively below the plane of the four atoms, while the C(2) atom is 0.72 Å above the plane.

The distance of Pd-Pd′ is 3.418±0.006 Å, which with the values which have previously appeared in the literature;[5,6] this Pd-Pd distance indicates that there is no metal-metal interaction. The average palladium-chlorine distance of 2.41±0.01 Å is identical, within the range of experimental error, with that in dimeric π-allylpalladium chloride, 2.413±0.002 Å.[5] The angle of Cl-Pd-Cl′ is 89.4±0.4°, which is very close to the expected square planar value of 90°. The three palladium-carbon distances are also equal, with a mean of 2.12±0.05 Å, which corresponds to that of 2.117±0.008 Å found in dimeric π-allylpalladium chloride.[5] Recently, it was pointed out that the bonding of the metal to the allyl group is not always symmetrical.[6] A typical example of the symmetrical bonding is π-allylpalladium chloride, while a representative unsymemtrical one is triphenylphosphine-2-methylallylpalladium chloride.[9] In the present complex, however, the symmetrical bonding is again observed.

The C(4) atom bonded to C(3) is 0.32 Å out of the plane of the π-allyl fragment, bent towards the palladium, as can be seen in Fig. 2. The hydroxyl group, a part of the ligand which is attached to the central carbon atom of the π-allyl fragment, does not lie on the π-allyl plane; O(1) is 0.13 Å out of the plane, bent towards the palladium. This value is smaller than that in the triphenylphosphine-2-methylallylpalladium chloride[9] and other π-allylpalladium complexes.[6,7] The shift from the plane may result from the interaction of hydrogen bonds discussed below and from the σ-π electron mixing in the ligand with the metal atom in a way which has been discussed for metal-cyclic ligand bonds by Kettle.[10]

The crystal structure is shown in Fig. 3. The intermolecular atomic contacts less than 4.5 Å were calculated for this complex. None of them, however, is short enough to suggest any significant deviations from normal van der Waals interactions except for the hydrogen bonds.

The hydrogen bonding, between the enolic hydroxyl group of one molecule and the carbonyl group of the other molecules related by the center of symmetry, forms endless sheets of molecules extended along the *c* axis. This hydrogen bond distance is 2.81±0.04 Å.

The authors wish to express their deep thanks to Professor Shinichi Kawaguchi and his co-workers of the Osaka City Univesity for their kindness in supplying crystals and in engaging in helpful discussions. The authors are also indebted to Dr. Tamaichi Ashida for his computer programs.

Microwave Spectrum of Ethylene Episulfone

Yuji NAKANO, Shuji SAITO and Yonezo MORINO

Sagami Chemical Research Center, Sagamihara-shi, Kanagawa

(Received August 29, 1969)

Microwave spectra of normal, ^{13}C-, and ^{34}S-isotopic species of ethylene episulfone have been investigated. Analysis of the spectra shows that the molecule has the C_{2v} symmetry. The structural parameters obtained from the spectral data for the normal and ^{13}C-ethylene episulfone are: $r(C\text{–}C)=1.590\pm0.011$ Å, $r(C\text{–}S)=1.731\pm0.006$ Å, $r(S\text{–}O)=1.439\pm0.006$ Å, $\angle CSC=54°40'\pm15'$, and $\angle OSO=121°26'\pm30'$, on the assumption that the C–H distances and the $\angle HCH$ and $\angle H_2CC$ angles are the same as those of ethylene sulfide. Stark-effect measurements have yielded a value of 4.41 ± 0.05 D for the dipole moment along the *a* axis. The structure obtained has been compared with those of other related molecules.

Molecules containing the sulfur atom have recently acquired great importance in the field of organic chemistry because they exhibit specific behavior in their chemical reactions. One of the best ways to understand the characteristics of the sulfur-containing compounds is to consider them from the point of view of the molecular structure.

Fundamental molecules which contain sulfur atoms in various oxidation states have been studied by microwave spectroscopy. The r_s structure of dimethyl sulfide was determined by Pierce and Hayashi[1] and by Dreizler and Rudolph,[2] while that of dimethyl sulfoxide was determined by Feder *et al.*[3] As for the structure of three-membered ring compounds, Cunningham *et al.*[4] obtained the r_0 structure of ethylene episulfide, and Saito,[5] that of ethylene episulfoxide. Alkyl sulfones have not been subjected to study by microwave spectroscopy, though there have been a number of investigations by means of X-ray crystallography.[6–8] Desiderato and Sass reported an unusually long distance (1.60 Å) for the ring carbon-carbon bond and a rather short distance (1.73 Å) for the carbon-sulfur bond for *cis*-2-butene episulfone.[8] They pointed out that the anomalies could be explained by a model in which the charge and/or bonds were highly delocalized. Pochan *et al.*[9] determined the three-membered ring stucture of cyclopropanone by microwave spectroscopy; their finding was somewhat similar to that of *cis*-2-butene episulfone in the point of the long carbon-carbon bond.

We have studied the microwave spectrum of ethylene episulfone with the aim of determining its molecular structure accurately. The results obtained settle the controversy regarding the carbon-carbon bonds of episulfone compounds in a convincing way, and, when combined with earlier microwave spectroscopic studies of the simplest and fundamental sulfides and sulfoxides, they provide further insight into the properties of alkyl sulfone compounds.

Experimental

The spectra were observed with a conventional 110 kHz square- or sinusoidal wave Stark modulated spectrometer. Frequencies were reproducible to ±0.1 MHz or better. The sample of ethylene episulfone used in this study was prepared by passing the sulfur dioxide gas through an ether solution of diazomethane cooled at about $-20°C$ according to the method of Hesse and Majmudar[10] and then stored at $-10°C$. Measurements were made at room temperature at a pressure of about 0.01 mmHg. The intensity of the lines decreased slowly in a few hours because of the decomposition or adsorption of the sample in the absorption cell. For the measurement of the ^{13}C-isotopic species, the sample was allowed to flow through the cell in order to maintain the signal-to-noise ratio as high as possible.

by using an oscilloscope. All the *a*-type *R*-branch transitions of $J=2\leftarrow1$ and $3\leftarrow2$ were assigned by means of their well-resolved Stark patterns. Several *Q*-branch transitions were measured by means of a recorder. It was found that the intensities of the transitions depended upon the parity of the limiting prolate quantum number, K_{-1}; the ratios of the intensities of the transitions with even values of K_{-1} to those of the transitions with odd values were about ten to six. This fact suggests that the ethylene episulfone molecule has a C_2 symmetry along the *a* axis, and that there are two sets of two hydrogen atoms interchangeable by rotation about the C_2 axis.[11] Hence, it can be concluded that ethylene episulfone has the C_{2v} molecular symmetry, as shown in Fig. 1. The frequencies of the observed transitions are given in Table 1. The *R*-branch transitions of the ^{34}S-isotopic species in natural abundance were easily identified by means of their Stark effects and by their locations relative to the lines of the normal species. Since the ^{13}C-isotopic species has two equivalent carbon positions, the spectral lines will exhibit half the intensity of the lines for the ^{34}S-isotopic species. It was, however, difficult to assign the transitions of the ^{13}C-isotopic species in natural abundance, because their S/N ratios were about 20 and they were apt to be masked or disturbed by other strong lines. Since the vapor pressure of ethylene episulfone is low below 0°C, it was impossible to increase the intensity of the ground-state lines by cooling the absorption cell. Among the nine *R*-branch transitions of $J=1\leftarrow0$, $2\leftarrow1$, and $3\leftarrow2$, only five transitions were observed and assigned. The observed transitions for ^{13}C- and ^{34}S-isotopic species are listed in Table 2.

B. Rotational Constants. The rotational constants of the normal species were determined in the rigid-rotor approximation by using the frequency of the $1_{01}\leftarrow0_{00}$ transition and the values of $(A-C)/2$ and κ obtained from $(A-C)/2$ *versus* κ plots of the *Q*-branch transitions. The results thus obtained are shown in Table 3. The rotational constants for the ^{13}C- and ^{34}S-isotopic species were calculated from three low-J transitions; they are also listed in Table 3. Large errors associated with the A rotational constants for the ^{13}C- and ^{34}S-isotopic species arose from the lack of observed

Q-branch lines. Using the rotational constants shown in Table 3, the transition frequencies were calculated; the differences between the calculated and the observed frequencies are given in Tables 1 and 2. The discrepancies seem to be primarily due to the neglect of the centrifugal distortion effects.

C. Dipole Moment. The Stark-effect coefficients were measured for the $M=0$, $1_{01}\leftarrow 0_{00}$ transition and for the $M=0$ and 1 components of the $2_{02}\leftarrow 1_{01}$ transition. The effective electrode spacing was determined from the measurements of the Stark effect of the $1\leftarrow 0$ transition of OCS, using its dipole moment of 0.71521 D obtained by Muenter.[12] The observed values of the Stark coefficients are shown in Table 4. The dipole moment was determined to be 4.41 ± 0.05 D along the a axis.

a) Values in MHz·(V/cm)$^{-2}$.

D. Molecular Structure. As has been described above, the microwave data are strongly indicative of the C_{2v} symmetry for ethylene episulfone; hence, the structural calculations have been carried out on this basis. Since no studies have been made of the deuterated species of ethylene episulfone, scarcely no structural information about the methylene groups was obtained from the moments of inertia for the normal, ^{13}C-, and ^{34}S-isotopic species. We assume that the structural parameters related to the methylene groups are the same as those of ethylene sulfide, that is, r(C–H) = 1.078Å, ∠HCH = 116°0′, and ∠H_2CC = 151°43′,[4] as were assumed for ethylene episulfoxide.[5] Moreover, the moments of inertia for the ^{34}S-isotopic species cannot be used to obtain the molecular structure, for the sulfur atom is located only 0.24 Å from the center of gravity. Four structural parameters between heavy atoms, the S–O and C–S distances and the ∠OSO and ∠CSC angles, were calculated from the moments of inertia for the normal and ^{13}C-isotopic species. First, we used all the moments of inertia simultaneously, but this led to an unreasonable structure, because the I_a and I_c of the normal species and the corresponding moments of inertia for the ^{13}C-species had an almost parallel dependence on the structural parameters to be determined. Therefore, the structure of ethylene episulfone was determined from three moments of inertia for the normal species and the I_b of the ^{13}C-species. The results are given in Table 5. The errors quoted were estimated from the uncertainties of the rotational constants.

Discussion

Two distinct features of the structure of ethylene episulfone are the long C–C bond and the rather short C–S bond. Though the C–C and C–S bond distances obtained above deviate from the corresponding normal single-bond distances by amounts considerably larger than the estimated errors, it is valuable to consider the accuracies of the structure determined in this study. Besides the errors associated with the uncertainties of the rotational constants, there are uncertainties which originate in the assumption made with regard to the methylene groups. It might be expected that the C–H bond distances of ethylene episulfone are different from those of episulfides and episulfoxides, for α hydrogen atoms are highly activated by the introduction of a sulfone group.[13] To estimate the uncertainties due to the unestablished C–H bond distances, a trial calculation was done on an assumption that the C–H distances are longer by 0.01 Å than the value cited in Table 5. The calculated results show that the changes of the distances are −0.002 Å for the C–C bond and +0.001 Å for the C–S bonds; both values are within the estimated uncertainties listed in Table 5. Thus, an unusually long C–C bond and short C–S bonds have been established for ethylene episulfone in spite of the tentatively-assumed C–H distances.

TABLE 5. r_0 STRUCTURE OF ETHYLENE EPISULFONE

r(S–O)	1.439±0.006 Å
r(C–S)	1.731±0.006 Å
r(C–C)[a]	1.590±0.011 Å
∠OSO	121°26′±30′
∠CSC	54°40′±15′
Assumed parameters	
r(C–H)	1.078 Å
∠CHC	116° 0′
∠H_2CC	151°43′

a) C–C distance is not independent of the other parameters listed above.

In order to make the remarkable properties of ethylene episulfone clear, it would be helpful to compare the C–C and C–S bond distances and the ∠CSC and ∠OSO bond angles of related compounds. Table 6 indicates that the three-membered-ring structure of ethylene episulfone is very similar to that of *cis*-2-butene episulfone, although the structure of the former was determined by gas-phase microwave spectroscopy, and that of the

latter, by X-ray crystallography.[8] The C–S bond distances of dimethyl sulfide[1] and dimethyl sulfoxide[3] are nearly equal, and those of ethylene episulfide[4] and ethylene sulfoxide[5] are also almost identical. The C–S distance is 0.02 Å longer for alkyl episulfone than for dialkyl sulfone. This difference may be attributable to the ring strain. In accord with the fact that the C–S distance of dimethyl sulfone is shorter than those of dimethyl sulfide and dimethyl sulfoxide, the C–S distance of ethylene episulfone is also shorter than those of ethylene episulfide and ethylene episulfoxide. The decrease is, however, remarkable for the latter; it amounts to 0.09 Å, and, in fact, the C–S distance is almost equal to that of thiophene.[14] Thus, it can be concluded that the C–S bond of ethylene episulfone has a considerable double-bond character.

Contrary to the well-known fact that the C–C bonds of usual three-membered-ring compounds, such as ethylene oxide,[4] ethylene episulfide,[4] ethylene episulfoxide,[5] ethylenimine,[15] and phosphirane,[16] are shorter than the normal C–C single bond, the C–C bond of ethylene episulfone is longer than the normal C–C single bond by the unusually long distance of 0.05 Å. The C–C distance obtained by the present study seems to be the longest among those of the three-membered-ring molecules studied so far by microwave spectroscopy or by other spectroscopic methods. According to the recent study of cyclopropanone by Pochan *et al.*, the length of the C–C bond perpendicular to the CO bond is unusually long (1.575 Å), while that of the C–C bond adjacent to the CO bond is considerably short (1.475 Å).[9] They stated that the 1.575 Å C–C bond was the longest, but in actuality the C–C bond in ethylene episulfone is longer by 0.015 Å.

It is most likely that the unusually long C–C bond distance is strongly correlated with the short C–S bond distance; for instance, the migration of electrons from the C–C bond to the C–S bonds would bring about the increase in the double-bond nature of the latter and the loosening of the former bond. At any rate, the above findings will be interesting in connection with the molecular orbital calculations and will be important and suggestive for the consideration of the reaction mechanisms involving these molecules. Furthermore, the similarity between the structures of ethylene episulfone and cyclopropanone gives interesting support to the similarities between the chemistry of carbonyl and sulfone compounds.

The structures of the SO_2 group of ethylene episulfone, dimethyl sulfone, and *cis*-2-butene episulfone are approximately the same as that of sulfur dioxide.[17] It must be added that the observed value of the dipole moment of ethylene episulfone is close to the sum of the bond moment of the C–S bond for ethylene sulfide[4] and that of the S–O bond for ethylene episulfoxide.[5]

Frequency Distribution, Specific Heat, and Young's Moduli of Orthorhombic Polyethylene with Skeletal Approximation

Teizo KITAGAWA and Tatsuo MIYAZAWA

Institute for Protein Research, Osaka University Joan-cho, Kita-ku, Osaka

(Received September 2, 1969)

In preliminary studies on the frequency distribution, specific heat and Young's moduli of the orthorhombic polyethylene crystal, methylene groups were treated as single dynamic units. Inter-methylene force constants were estimated from the intermolecular potential function of methane and from deBoer's potential function. Dynamical matrices of acoustic vibrations were constructed. A practical method was worked out for deriving the frequency distribution of acoustic vibrations from the volume enclosed in constant-frequency surfaces in a three-dimensional phase-difference space. With reference to specific heat in the lowest temperature region, inter-methylene force constants were adjusted. An efficient method was used for calculating the frequency distribution of crystal vibrations of chain-polymers. The frequency distribution of orthorhombic polyethylene crystal and specific heats in low temperature region were calculated in agreement with experimental results. A simple approximate method was used for treating Young's moduli of orthorhombic chain-polymer crystals. Applicability of the skeletal approximation is discussed.

Experimental specific heat[1-4] of polyethylene with various degree of crystallinity was extrapolated to 100% crystallinity and specific heat of the crystalline region and amorphous region was obtained by Wunderlich.[5] Stockmeyer and Hecht[6] treated the lattice dynamics of a model crystal with anisotropic force field in a tetragonal lattice. Tarasov[7] treated a chain-polymer crystal model as elastic rods with weak inter-rod interactions. These over-simplified models might be useful in studying temperature dependence of specific heat. However, these models are not applicable for analysing spectroscopic data including infrared and Raman frequencies.

For polymer-chain crystals, the specific heat of the crystalline region is proportional to the third power of absolute temperature in the lowest temperature region, but is nearly proportional to temperature at intermediate temperatures below 70°K. Thus, experimental specific heat may be reproduced[5] by adjusting characteristic frequencies (ν_{D3} and ν_{D1}) of a combination of the three-dimensional and one-dimensional Debye models. However, if the frequency distribution of the combined Debye models is quite different from the actual distribution, the physical meaning of characteristic frequencies (especially ν_{D1}) is not clear.

Specific heat of crystalline material is due to the frequency distribution of crystal vibrations which depend upon the force field. The intramolecular force field of polyethylene[8] and hydrocarbon molecules[9-11] were studied and a general theory of polymer-chain vibrations was derived.[12-14] However, for the purpose of studying frequency distribution, specific heat or neutron-scattering cross sections theoretically, normal vibrations of acoustic branches and optical branches of the three-dimensional crystal need be treated.

A general method of group-theoretical analysis of crystal vibrations was reported previously[15] for orthorhombic crystals. Furthermore, general matrix methods were derived for studying molecular crystals and chain-polymer crystals and for

approximately calculating the frequency distribution of low frequency lattice vibrations. In the present study, a practical method of calculating frequency distributions of chain-polymer crystals was developed and frequency distribution, specific heat and Young's moduli of polyethylene crystal were treated. Methylene groups were approximately regarded as single dynamic units since internal vibrations of methylene groups lie above 700 cm^{-1} and thus contribute little to specific heat below 150°K. The present study has been reported in a short communication.[16]

Force Field of Polyethylene Crystal

Crystal Structure. The X-ray diffraction of the orthorhombic polyethylene crystal (P_{nam}) was analysed by Bunn.[17] Two molecular chains pass through a unit cell along the c axis and there are four methylene groups per unit cell. Lattice constants at room temperature are $a_0=7.40$, $b_0=4.93$ and $c_0=2.54$ Å, with the bond length of 1.53 Å (C–C) and the bond angle of 112°(C–C–C). The setting angle of the main-chain plane (angle α in Fig. 1) is 48.7°.

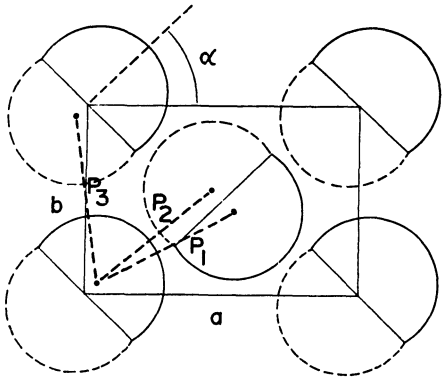

Fig. 1. Interchain potential of polyethylene crystal (skeletal approximation).

Intrachain Force Field. For normal vibration treatment, the force field of the polyethylene crystal was expressed as the sum of the intrachain terms and interchain terms.

$$V(\text{crystal}) = V(\text{intrachain}) + V(\text{interchain}) \quad (1)$$

The intrachain force field used was the Urey-Bradley force field,[9]

$$V(\text{intrachain}) = \frac{1}{2}\sum[K_r(\Delta r)^2 + K_\phi(\Delta\phi)^2 + K_q(\Delta q)^2 + K_t(\Delta t)^2] \quad (2)$$

where K_r, K_ϕ, K_q and K_t are force constants associated with the bond-stretching (Δr), angle-bending ($\Delta\phi$), repulsion (Δq) and internal-rotation coordinates (Δt). The values of intrachain force constants were adjusted (Table 1) so as to reproduce the frequency-dispersion curves of the isolated polyethylene chain.[8] The number of each type of terms per unit cell is listed in Table 1.

Table 1. Force constants and equilibrium distances

	N	d(Å)	Force constant
K_r	4	1.53	4.0 md/Å

K_ϕ	4		0.59 md·Å

N; number of potential terms per unit cell.

Interchain Force Field. There are three types of close contacts (p_1, p_2 and p_3 in Fig. 1) between methylene groups of neighboring chains. Accordingly, the interchain force field was expressed as

$$V(\text{interchain}) = \frac{1}{2}\sum[P_1(\Delta p_1)^2 + P_2(\Delta p_2)^2 + P_3(\Delta p_3)^2] \quad (3)$$

where P_1, P_2, and P_3 are the force constants associated with the intermethylene stretching coordinates Δp_1, Δp_2 and Δp_3. These force constants were adjusted with reference to the experimental specific heat[18] at temperatures below 10°K where P_1 and P_2 were taken equal (intermethylene distances are nearly equal).

Acoustic Branches and Specific Heat

Normal Vibration Treatments. For an orthorhombic crystal, normal modes are specified with phase-difference vector $\boldsymbol{\delta}(\delta_a,\delta_b,\delta_c)$, whose components are phase differences of atomic displacements between adjacent unit cells along the a, b, and c axes. A group-theoretical method for constructing symmetry coordinates of orthorhombic crystals was described previously.[15]

For orthorhombic polyethylene, there are four methylene groups per unit cell. If methylene groups are treated as single dynamic units, there are twelve vibrational modes for any given phase-difference vector. Twelve Cartesian symmetry coordinates were described.[15] In the present study, dynamical matrices were diagonalized with a NEAC 2201 electronic computer.

16) T. Miyazawa and T. Kitagawa, *J. Polym. Sci., Part B*, **2**, 395 (1964).
17) C. W. Bunn, *Trans. Faraday Soc.*, **35**, 482 (1939).
18) W. Reese and J. E. Tucker, *J. Chem. Phys.*, **43**, 105 (1965).

Acoustic Branches. Specific heat of a crystal in the lowest temperature region is due to acoustic vibrations of lowest frequencies. Since the frequency distribution of these acoustic vibrations is proportional to the second power of frequency, the specific heat is proportional to the third power of absolute temperature. For a chain-polymer crystal, the coefficient may be derived as a function of interchain force constants.

For an orthorhombic crystal, three acoustic vibrations are reduced, in the limit of $\boldsymbol{\delta}\to 0$, to translations (B_{1u}, B_{2u}, B_{3u}) along the a, b, and c axes. Actually, however, three frequencies are degenerate and accordingly the eigenvector matrix ($\boldsymbol{L}_S$) of the dynamical matrix ($\boldsymbol{D}_S$) is not uniquely determined. The eigenvector matrix $\boldsymbol{L}_S(0)$ may be obtained approximately after diagonalization of $\boldsymbol{L}_S(\boldsymbol{\delta}_0)$ for a very small $\boldsymbol{\delta}_0$.

The eigenvector matrix $\boldsymbol{L}_S(0)$ may be used in deriving the dynamical matrix $\boldsymbol{H}(\boldsymbol{\delta})$ of acoustic vibrations. Thus, elements of the dynamical matrix $\boldsymbol{D}_S(\boldsymbol{\delta})$ [12×12] are expanded up to second power of δ_a, δ_b and δ_c and subsequently are subjected to the orthogonal transformation with $\boldsymbol{L}_S(0)$. In the transformed matrix, cross terms for overall-rotational modes (about the chain axis) and translatory acoustic modes are proportional to the first power of δ_a, δ_b and δ_c. Thus, the second-order perturbation treatment is applied for obtaining the dynamical matrix $\boldsymbol{H}(\boldsymbol{\delta})$ of translatory acoustic modes along the a, b and c axes, respectively,

$$\left.\begin{aligned} H_{11} &= A_1\delta_a^2 + B_1\delta_b^2 + C_1\delta_c^2 \\ H_{22} &= A_2\delta_a^2 + B_2\delta_b^2 + C_2\delta_c^2 \\ H_{33} &= A_3\delta_a^2 + B_3\delta_b^2 + C_3\delta_c^2 \\ H_{23} &= D_1\delta_b\delta_c \\ H_{13} &= D_2\delta_a\delta_c \\ H_{12} &= D_3\delta_a\delta_b \end{aligned}\right\} \quad (4)$$

For the orthorhombic crystal of polyethylene, the coefficients A, B, C and D were obtained as functions of interchain force constants (Table 2). The diagonal element H_{33} is associated with the translatory mode along the c axis and accordingly is independent of P_1 since the contact line (p_1) is perpendicular to the axis. Also, the translatory mode along the c axis involves intrachain distortions and accordingly C_3 is a sum of interchain terms (P_2 and P_3), and a constant intrachain term of 0.0620. It may be mentioned also that C_1, C_2 and C_3 are independent of P_1 because the contact p_1 is between adjacent chains in the ab plane (perpendicular to the c axis). Similarly, A_1, A_2 and A_3 are independent of P_3 because the contact p_3 is between adjacent chains along the b axis (perpendicular the to a axis).

TABLE 2. THE COEFFICIENTS (A, B, C AND D) OF DYNAMICAL MATRIX ELEMENTS FOR ACOUSTIC MODES

H_{11}	A_1	$= 0.0143P_1 + 0.0201P_2$
	B_1	$= 0.0143P_1 + 0.0201P_2 + 0.0110P_3$

H_{22}	A_2	$= 0.0035P_1 + 0.0124P_2$
	B_2	$= 0.0035P_1 + 0.0124P_2 + 0.0646P_3$
	C_2	$= 0.0124P_2 + 0.0161P_3$
H_{33}	A_3	$= 0.0033P_2$
	B_3	$= 0.0033P_2 + 0.0056P_3$
	C_3	$= 0.0033P_2 + 0.0014P_3 + 0.0620$
H_{23}	D_1	$= 0.0127P_2 + 0.0191P_3$
H_{13}	D_2	$= 0.0162P_2$
H_{12}	D_3	$= 0.0142P_1 + 0.0315P_2$

Constant-frequency Surfaces. Frequencies [$\nu_i(\boldsymbol{\delta})$] of three acoustic vibrations may be obtained from eigenvalues [$\lambda_i(\boldsymbol{\delta})$] of a dynamical matrix $\boldsymbol{D}(\boldsymbol{\delta})$,

$$\lambda_i(\boldsymbol{\delta}) = [2\pi c\nu_i(\boldsymbol{\delta})]^2 \quad (5)$$

If off-diagonal terms are negligible as compared with diagonal terms, then eigenvalues (λ_i) approximate to diagonal elements (H_{ii}) and constant-frequency surfaces of acoustic vibrations are ellipsoids in the phase-difference space. The sum of volumes enclosed in three constant-frequency surfaces is given as

$$v(\nu) = (4\pi/3)\times 8\pi^3c^3\nu^3\sum_{i=1}^{3}(A_iB_iC_i)^{-1/2} \quad (6)$$

Actually, however, off-diagonal elements of dynamical matrices are not negligible as compared with diagonal elements, and accordingly diagonalization of dynamical matrices is required. In practical treatments, it may be recalled that all elements of dynamical matrices Eq. (4) are given as quadratic forms of components (δ_a, δ_b, δ_c) of phase-difference vector ($\boldsymbol{\delta}$). Accordingly with the use of spherical polar coordinates[19] in $\boldsymbol{\delta}$ space, phase-differences are now written as

$$\left.\begin{aligned} \delta_a &= |\boldsymbol{\delta}|\cdot\sin\theta\cos\phi \\ \delta_b &= |\boldsymbol{\delta}|\cdot\sin\theta\sin\phi \\ \delta_c &= |\boldsymbol{\delta}|\cdot\cos\theta \end{aligned}\right\} \quad (7)$$

where $|\boldsymbol{\delta}|$ is the length of a phase-difference vector $\boldsymbol{\delta}$. Substituting Eq. (7) into Eq. (4), it may be seen that frequencies (ν_i) of acoustic vibrations are proportional to $|\boldsymbol{\delta}|$ and ratios

$$\rho_i(\theta,\ \phi) = |\boldsymbol{\delta}|/\nu_i(\boldsymbol{\delta}) \quad (8)$$

depend upon the angles θ and ϕ in $\boldsymbol{\delta}$ space. Accordingly, dynamical matrices are now expressed as $\boldsymbol{H}(|\boldsymbol{\delta}|, \theta, \phi)$ and are diagonalized for a given $|\boldsymbol{\delta}|$ but for many samples of θ and ϕ. Then for the ith acoustic branch, the constant-frequency (ν) surfaces may be obtained by numerical calculation of ratios $\rho_i(\theta,\phi)$ as functions of θ and ϕ. The volume enclosed in a constant-frequency (ν) surface of the ith branch is given as

$$v_i(\nu) = (8\nu^3/3)\int_0^{\pi/2}\int_0^{\pi/2}[\rho_i(\theta,\ \phi)]^3\sin\theta\,d\theta\,d\phi \quad (9)$$

19) W. V. Houston, *Rev. Mod. Phys.*, **20**, 161 (1948).

since, for orthorhombic crystals, the irreducible zone of the $\boldsymbol{\delta}$ space is one-eighth of the first Brillouin zone.[15] In practical calculation, numerical integration is carried out with divisions of $\Delta\theta=\pi/90$ and $\Delta\phi=\pi/36$ (confirmed to be sufficiently fine). The sum of volumes enclosed in constant-frequency surfaces of three acoustic vibrations is given as

$$v(\nu) = (8\nu^3/3)\sum_{i=1}^{3}\sum_{\phi}\sum_{\theta}[\rho_i(\theta,\ \phi)]^3 \sin\theta\cdot\Delta\theta\Delta\phi \qquad (10)$$

$$\theta = \pi/180,\ 3\pi/180,\cdots,\ 89\pi/180$$

$$\phi = \pi/72,\ 3\pi/72,\cdots,\ 35\pi/72$$

Frequency Distribution. Under the cyclic boundary condition, allowed phase-difference vectors are distributed uniformly in the first Brillouin zone. Accordingly the number (per unit cell) of acoustic vibrations lying below a given frequency (ν) is given as $v(\nu)/8\pi^3$ since the total volume of the first Brillouin zone is $8\pi^3$. For an orthorhombic crystal containing n equivalent groups (or molecules), the normalized fraction of the number of acoustic vibrations lying between ν and $\nu+d\nu$ is given as $g(\nu)d\nu$, where $g(\nu)$ is obtained by differentiation.

$$g(\nu) = d[v(\nu)/8\pi^3 n]/d\nu = \gamma\nu^2 \qquad (11)$$

$$\gamma = \{\sum_{i=1}^{3}\sum_{\phi}\sum_{\theta}[\rho_i(\theta,\ \phi)]^3 \sin\theta\}\times(\Delta\theta\Delta\phi/n\pi^3) \qquad (12)$$

For the orthorhombic crystal of polyethylene, the number of methylene groups per unit cell is $n=4$.

Specific Heat. The specific heat of a crystal is given as the sum of terms due to crystal vibrations,

$$C_v/R = \sum_{\nu} G(\nu)u^2\exp(-u)[1-\exp(-u)]^{-2} \qquad (13)$$

$$u = hc\nu/kT \qquad (14)$$

where $G(\nu)$ is the normalized distribution (histogram at ν) of vibrational frequencies. In the lowest temperature region, the specific heat is primarily due to the frequency distribution of acoustic vibrations [Eq. (11)]. Accordingly, $G(\nu)$ in Eq. (13) is replaced with $g(\nu)d\nu$ and the integration is carried out yielding

$$C_v/R = \gamma(k/hc)^3T^3\int_0^{\infty} u^4\exp(-u)[1-\exp(-u)]^{-2}du$$

$$= 25.98\,\gamma\,(k/hc)^3T^3 \qquad (15)$$

The value of C_v/RT^3 is therefore proportional to γ which depends upon interchain force constants.

For orthorhombic polyethylene, inter-methylene force constants may be estimated from the intermolecular potential function of methane or from deBoer's potential function (to be discussed later). If estimated values of three constants (P_1, P_2 and P_3) are adjusted under fixed relative ratios, the value of γ is nearly proportional to $P^{-3/2}$. For polyethylene, the value of $10^5C_v/RT^3$ is experimentally obtained as 1.9 (by Isaacs[3]) or as 1.68 (by Tucker and Reese[18]). In the present study, intermethylene force constants were adjusted to $P_1=P_2=0.025$ and $P_3=0.003$ md/Å so that $10^5C_v/RT^3$ is calculated as 1.86.

Frequency Distribution and Specific Heat

Factor-group Modes. For the orthorhombic crystal of polyethylene, there are five lattice modes with $\boldsymbol{\delta}=0$ (factor-group modes, Fig. 2). The B_{2u}, B_{1u} and A_u modes are antiparallel translatory modes along a, b and c axes and A_g and B_{3g} are rotatory modes around the chain axis.[20] These frequencies were calculated as 153, 104 and 47 cm^{-1} and 97 and 100 cm^{-1} with the intermethylene force constants (Table 1).

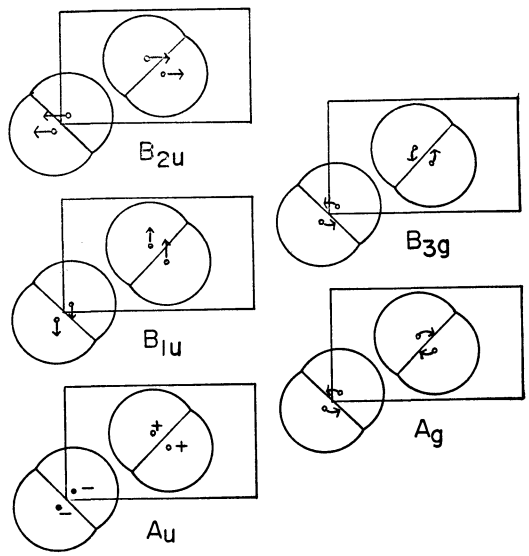

Fig. 2. Lattice vibrations ($\boldsymbol{\delta}=0$) of orthorhombic polyethylene.

Dispersion Curves. For any given phase-difference vector $\boldsymbol{\delta}$, there are eight vibrations of polyethylene below 700 cm^{-1}. Frequencies of these vibrations vary with $\boldsymbol{\delta}$. As an example, the dispersion curves are shown in Fig. 3 for $\boldsymbol{\delta}=(0,0,0)\rightarrow(0,0,\pi)$. It may be noted that, as $\boldsymbol{\delta}\rightarrow 0$, five optical branches become the factor-group modes (Fig. 2) and three acoustic branches are reduced to overall translations along the a, b and c axes. Symmetry assignments (Δ_1—Δ_4) of dispersion curves were made by a group-theoretical treatment.[15] Dispersion curves of the same symmetry species do not intersect one another.

Sampling of Phase-difference Vectors. The frequency distribution of a crystal may be calculated after normal-coordinate treatments of crystal vibrations with all possible phase-difference vectors. Under the cyclic boundary condition, phase-difference components along the a, b or c axis are

20) S. Krimm, C. Y. Liang and G. B. B. M. Sutherland, *J. Chem. Phys.*, **25**, 549 (1956).

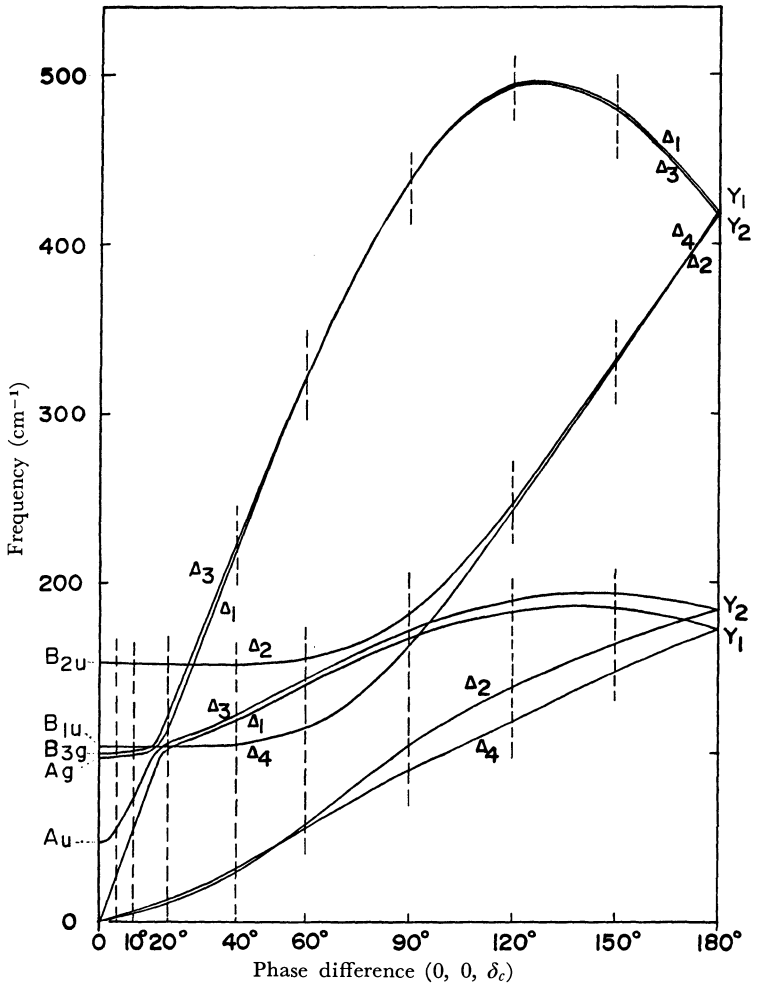

Fig. 3. Dispersion curves [$\boldsymbol{\delta}=(0, 0, 0)\rightarrow(0, 0, \pi)$] of vibrational frequencies of orthorhombic polyethylene (skeletal approximation).

uniformly distributed in the region $-\pi<\delta\leqq\pi$. For an orthorhombic crystal, however, the irreducible volume in $\boldsymbol{\delta}$ space is one eighth ($0\leq\delta\leq\pi$) of the first Brillouin zone.[15]

Vibrational frequencies of chain-polymer crystals change little with δ_a or δ_b, because the interchain force field is much weaker than the intrachain force field. On the other hand, vibrational frequencies change sensitively with δ_c and accordingly it is advisable to take many more values of δ_c than of δ_a or δ_b.

In the present study on polyethylene, the phase-differences of δ_a or δ_b were given nine values (10, 30, 50, ..., 150, and 170°) at an interval of 20°. On the other hand, the phase-difference of δ_c were given 540 values (1/6, 3/6, 5/6, 7/6,..., 1077/6, and 1079°/6 at an interval of 1°/3, yielding a total of 43,740 δ vecotrs in the irreducible volume. However, computation of vibrational frequencies for these many δ vectors is not practical and accordingly it was desirable to use an interpolation method. Thus, for every set of δ_a and δ_b, dynamical matrices were diagonalized to yield vibrational frequencies only for each of ten values of δ_c (0, 5, 10, 20, 40, 60, 90, 120, 150, and 180°). These δ_c values were selected nonuniformly so as to reproduce low-frequencies satisfactorily for small δ_c values (Fig. 3).

Interpolation. For frequency-interpolation, a cubic equation was constructed as

$$\nu(\delta_c) = \mathrm{d}_0 + \mathrm{d}_1\delta_c + \mathrm{d}_2\delta_c^2 + \mathrm{d}_3\delta_c^3 \qquad (16)$$

which satisfies frequencies (ν_1, ν_2, ν_3, and ν_4) for successively selected values of $\delta_c=\delta_1$, δ_2, δ_3 and δ_4. Equation (12) may be used for $\delta_2<\delta_c<\delta_3$ and is applicable to δ_c values of 5—150°. However, the equation for $\delta_1=90°$, $\delta_2=120°$, $\delta_3=150°$ and $\delta_4=180°$ was also used for δ_c values of 150—180°. In practical computation, Eq. (16) was rewritten as

$$\nu(\delta_c) = (\nu_1\ \nu_2\ \nu_3\ \nu_4)\cdot\boldsymbol{w}_\delta \qquad (17)$$

$$\boldsymbol{w}_\delta = \begin{bmatrix} 1 & 1 & 1 & 1 \\ \delta_1 & \delta_2 & \delta_3 & \delta_4 \\ \delta_1^2 & \delta_2^2 & \delta_3^2 & \delta_4^2 \\ \delta_1^3 & \delta_2^3 & \delta_3^3 & \delta_4^3 \end{bmatrix}^{-1} \begin{bmatrix} 1 \\ \delta_c \\ \delta_c^2 \\ \delta_c^3 \end{bmatrix} \tag{18}$$

and the $\boldsymbol{w}_\delta$ vector was used commonly for any set of δ_a and δ_b. For the δ_c values of 0—5°, a quartic equation was constructed as

$$\nu(\delta_c) = d_0' + d_2'\delta_c^2 + d_4'\delta_c^4 \tag{19}$$

which satisfies frequencies for $\delta_c = 0$, 5 and 10°. Vibrational frequencies thus calculated with the interpolation method were confirmed to agree, better than ± 0.7 cm^{-1}, with those calculated with diagonalization of dynamical matrices. Thus, the computation time consumed in frequency calculations for 43740 $\boldsymbol{\delta}$ vectors was drastically reduced.

Frequency Distribution. The frequencies of a total of 349920 vibrations of orthorhombic polyethylene were collected. The frequency distribution was constructed with the frequency interval of 1 cm^{-1} and was then normalized to the vibrational degree of freedom of a methylene group below 700 cm^{-1},

$$\sum_\nu G(\nu) = 2 \tag{20}$$

The frequency distribution histogram of polyethylene crystal (skeletal approximation) is shown in Fig. 4 with a frequency interval of 5 cm^{-1}. Two peaks appear at about 500 and 200 cm^{-1}, as expected previously from dispersion curves of an isolated chain of polyethylene.[8] Existence of these peaks was confirmed by scattering experiments of thermal neutron from crystalline polyethylene.[21,22]

Specific Heat. The normalized frequency distribution $G(\nu)$ [Eq.(20)] was substituted into

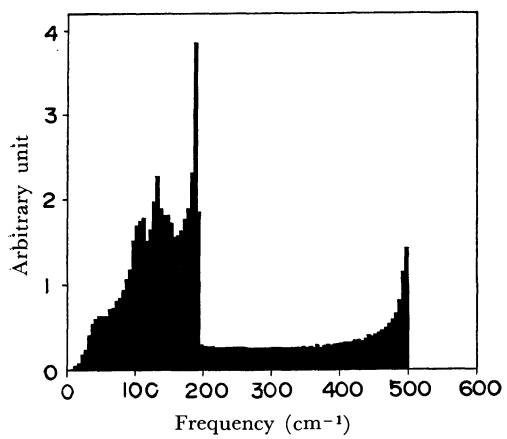

Fig. 4. The frequency distribution histogram of orthorhombic polyethylene crystal (skeletal approximation).

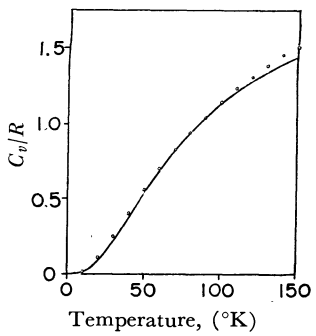

Fig. 5. Specific heat (C_v/R) of orthorhombic polyethylene crystal; open circles: experimental,[5] solid line: calculated with the skeletal approximation.

Eq. (13) and the specific heat at constant volume was obtained as shown in Fig. 5. At temperatures above ~15°K, calculated values of C_v/R gradually deviate from the T^3 law and then become nearly proportional to T, in good agreement with experimental values.[5] The specific heat (C_v/R) due to internal modes of methylene groups was estimated as small as 0.002 at 100°K and as 0.038 at 150°K.

Young's Moduli

Chain-polymer Crystal. For chain-polymer crystals, Young's modulus along the chain direction (c axis) depends primarily upon the intrachain force field whereas Young's moduli along the a or b axes depend primarily upon the interchain force field. Comparison of the calculated and experimental values of Young's moduli (a or b axes) serves as a check on calculated force constants of the interchain force field.

Intrachain forces of chain-polymer crystals are much stronger than interchain forces. Accordingly, in treating Young's moduli along the a or b axes, intrachain displacements (Δc) may well be neglected. Under homogeneous deformation, the potential energy of orthorhombic chain-polymer crystals may be written with two external-deformation coordinates (Δa and Δb) and an internal-deformation coordinate ($\Delta\alpha$) [Fig. 1],

$$V = \frac{1}{2}\tilde{\boldsymbol{\beta}}\boldsymbol{C}\boldsymbol{\beta} \tag{21}$$

$$\tilde{\boldsymbol{\beta}} = (\Delta a\ \Delta b\ \Delta\alpha) \tag{22}$$

where $\boldsymbol{C}$ is the elastic stiffness constant matrix. Then, in equilibrium, the tension (f_a) along the a axis is balanced with $-\partial V/\partial \Delta a$ and the tension (f_b) along the b axis is balanced with $-\partial V/\partial \Delta b$, but the internal tension (f_α) is always equal to zero so that $\partial V/\partial \Delta\alpha = 0$. Under homogeneous deformation, therefore,

$$\boldsymbol{\beta} = \begin{bmatrix} S_{11} & S_{12} & S_{13} \\ S_{21} & S_{22} & S_{23} \\ S_{31} & S_{32} & S_{33} \end{bmatrix} \begin{bmatrix} f_a \\ f_b \\ 0 \end{bmatrix} \tag{23}$$

21) H. R. Danner, G. J. Safford, H. Boutin and M. Berger, *J. Chem. Phys.*, **40**, 1417 (1964).
22) W. R. Myers, J. L. Donovan and J. S. King, *ibid.*, **42**, 4299 (1965).

where $\boldsymbol{S}(=\boldsymbol{C}^{-1})$ is the elastic compliance matrix. From Eq. (23) Young's moduli along the a and b axes are derived as

$$\left.\begin{aligned} E_a &= a_0/b_0c_0S_{11} \\ E_b &= b_0/a_0c_0S_{22} \end{aligned}\right\} \quad (23)$$

Relative ratio of external and internal deformations $[(\Delta a/a_0) : (\Delta b/b_0) : \Delta\alpha]$ is equal to $[(S_{11}/a_0) : (S_{21}/b_0) : S_{31}]$ under the tension of f_a, but is equal to $[(S_{12}/a_0) : (S_{22}/b_0) : S_{32}]$ under the tension f_b.

Polyethylene. Young's moduli (in unit of 10^{11} dyne/cm^2) of orthorhombic polyethylene crystal were calculated as $E_a=0.9$ and $E_b=0.3$, from the interchain force constants at lowest temperatures. In comparison, experimental values[23] at room temperature are $E_a=0.4$ and $E_b=0.3$.

Discussions

Intermethylene Force Constants. Effective force constants of $CH_2\cdots CH_2$ contacts (p) are useful for studying crystal vibrations and solid state properties of hydrocarbon polymers. Intermethylene force constants may be transferred from the second derivative (kcal/Å^2) of intermolecular potential (V) of methane,[24]

$$d^2V/dp^2 = 2.008\times 10^9/p^{14} - 1.630\times 10^5/p^8 \quad (25)$$

Thus for intermethylene contacts of $p_1=4.12$, $p_2=4.18$ and $p_3=4.51$ Å, intermethylene force constants at room temperature were calculated as $P_1=0.018$, $P_2=0.015$ and $P_3=0.002$ md/Å, respectively. If these intermethylene constants at room temperature are used, the specific heats at temperatures below 10°K are calculated slightly larger than the experimental data, indicating that intermethylene constants at <10°K should be larger than those at room temperature. In fact, at lower temperatures, intermethylene contacts become shorter and intermethylene force constants are expected to become larger than those at room temperature.

In treating elastic constants of polyethylene crystal, interchain force constants were derived by Odajima and Maeda[25] from deBoer's repulsive potential function[26] for H$\cdots$H contacts (x). Force constants (in unit of md/Å) are given as

$$d^2V/dx^2 = 150\cdot\exp(-3.53x) \quad (26)$$

In the present study, Eq.(26) was transferred to the case of intermethylene force constants. Actual intermethylene contacts (p) were converted to corresponding H$\cdots$H contacts (x),

$$x = (r_H/r_{CH_2})p \quad (27)$$

where r_H and r_{CH_2}, are van der Waals' radii[27] of hydrogen (1.2Å) and methylene group (2.0Å). Thus, from intermethylene contacts, force constants of orthorhombic polyethylene crystal were estimated as $P_1=0.024$, $P_2=0.022$, and $P_3=0.003$ md/Å. With reference to experimental specific heats at temperatures below 10°K, these values of force constants were only slightly adjusted to yield the final set of force constants as listed in Table 1. Equations (26) and (27) were also used for estimating effective interchain force constants of orthorhombic polyoxymethylene crystal.[28]

Constant-frequency Surfaces. In the dynamical matrices of acoustic vibrations of polyethylene crystal, off-diagonal elements may not be neglected as compared with diagonal elements. Accordingly, constant-frequency surfaces of polyethylene are much distorted from ellipsoidal surfaces. However, if off-diagonal elements are neglected, constant-frequency surfaces become ellipsoidal, and the specific heat ($10^5C_v/RT^3$) in the lowest temperature region is calculated as 1.02, that is much smaller than the theoretically correct value of 1.86. Accordingly, off-diagonal elements of dynamical matrices can not be neglected, and the volume enclosed in constant-frequency surfaces need be numerically integrated with Eqs. (7)—(10).

Frequency Distribution. The prominent peaks of the frequency distribution (Fig. 4) at 500 and 200 cm^{-1} correspond to the maximum frequencies of the dispersion curves of the C–C–C bending branches and C–C internal-rotation branches around δ_c values of 120—150° (Fig. 3). In the region 450—200 cm^{-1}, four dispersion curves of the C–C–C bending branches are almost straight and depend little upon δ_a or δ_b. Accordingly, the frequency distribution is nearly constant in the region 450—200 cm^{-1}, as expected similarly for Debye's one-dimensional elastic continuum.[29]

In the frequency distribution of polyethylene (Fig. 4), there is a peak at the high-frequency cut-off of 500 cm^{-1} but, with Tarasov's model, no peak is expected to appear at the one-dimensional characteristic frequency (ν_{D1}). With the three-dimensional Debye model, a peak is expected to appear at the cut-off frequency (ν_{D3}) below which the frequency distribution is proportional to ν^2. In the frequency distribution of polyethylene (Fig. 4), a ν_{D3} peak can not be identified uniquely among several peaks due to low-frequency optical modes. The characteristic frequencies were adjusted[5] to $\nu_{D1}=375$ cm^{-1} and $\nu_{D3}=85$ cm^{-1} so as to reproduce experimental specific heat. However, these can not be identified uniquely in the frequency

distribution of polyethylene (Fig. 4).

Skeletal Approximation. In the normal vibration treatment of orthorhombic polyethylene crystal by Tasumi and Shimanouchi,[30] hydrogen atoms as well as carbon atoms were treated as single dynamic units and the factor group frequencies were calculated as 134(A_g), 109(B_{3g}), 99(B_{2u}), 71(B_{1u}), and 55 cm^{-1}(A_u). It may be remarked that the requencies of the rotatory modes (A_g and B_{3g}) are higher than the frequencies of the translatory modes (B_{2u} and B_{1u}). In the present study, the lattice dynamics of polyethylene was studied where methylene groups were treated as single dynamic units at sites of carbon atoms. With this skeletal approximation, the frequencies of the rotatory modes are lower than the frequencies of the translatory modes.

30) M. Tasumi and T. Shimanouchi, *J. Chem. Phys.*, **43**, 1245 (1965).

In the rotatory modes of polyethylene chain about the axis, displacements of carbon atoms are much smaller than those of hydrogen atoms. Accordingly, changes in intermethylene contacts are much smaller than in inter-hydrogen contacts. Therefore, the rotatory frequencies calculated with the skeletal approximation are lower than those calculated by Tasumi.[30]

On the other hand, in the translatory modes of polyethylene chain, displacements of carbon atoms are equal to displacements of hydrogen atoms. Accordingly, changes in intermethylene contacts do not differ much from changes in inter-hydrogen contacts and the skeletal approximation is fairly applicable. In fact, intermethylene force constants estimated from deBoer's potential function were only slightly adjusted so as to reproduce experimental specific heat in the lowest temperature region.

Nuclear Magnetic Resonance in Paramagnetic Solution. Proton Magnetic Resonance Studies of Some Substituted Aniline Derivatives in the Presence of Paramagnetic Ni(II) and Co(II) Acetylacetonates

Teijiro YONEZAWA, Isao MORISHIMA, Yoshinori AKANA and Kazuhiko FUKUTA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received September 9, 1969)

To study the geometrical and electronic structures of molecules, the paramagnetic shifts of substituted aniline proton resonances due to complexing with nickel or cobalt acetylacetonates, $M(AA)_2$ (M=Ni or Co), were observed. The NMR spectra of solutions containing an excess of aniline derivatives and $M(AA)_2$ show contact (for $Ni(AA)_2$) and pseudocontact (for $Co(AA)_2$) shift ratios for various ligand protons. The contact shift ratios for N–H and $N–CH_3$ protons reveal that the NH_2 or NHR group of aniline derivatives is not coplanar with the aromatic ring for the coordinated molecules. This was confirmed by pseudo-contact shift studies.

Recently we have been interested in the NMR spectra of solutions containing ligand molecules and the paramagnetic metal chelate.[1] The paramagnetic ("contact") shifts and the dipolar ("pseudo-contact") shifts have been pointed out as being useful in the elucidation of the structure of the complex, the nature of metal-ligand bonding, and the mechanism of the odd-electron distribution.[1] From a simple observation of the relative contact shift of different protons in a ligand molecule with the oriented nitrogen lone pairs available for bonding with the metal, the electron-spin distribution occurring through the σ or π bond framework of a ligand molecule is made clear.[1d]

In the present work the paramagnetic contact and pseudocontact shifts of substituted aniline proton resonances due to complexing with nickel or cobalt acetylacetonate, $M(AA)_2$, were studied.

Previously Kluiber and Horrocks reported similar observations and discussed spin delocalization through a π-orbital in relation to a metal-ligand interaction.[2] In the present investigation, we have studied the configuration of such metal complexes from different points of view. We have indicated

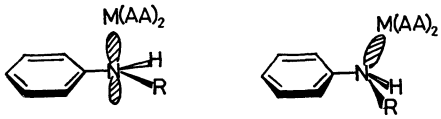
that the amino group coordinated to metal acetylacetonate is non-planar and has the hybridized nitrogen lone-pair orbital available for bonding with the metal.

Aniline may be considered to be a molecule of the general type of NH_2X, in which X is an unsaturated system which may act as an electron reservoir. A recent microwave study[3] has shown that the amino-nitrogen atoms in these types of molecules (aniline; X=C_6H_5; formamide, X=CHO; cyanamide, X=CN; nitramide, X=NO_2) retain, to a greater or lesser extent, pyramidal configurations.

In the present investigation we have examined the orientation of nitrogen lone-pair electrons of aniline by a study of the paramagnetic proton shifts. For this study we have selected a series of substituted aniline derivatives (1—11) and examined the structures of complexes to determine whether they take a planar (I) or a non-planar structure (II).

Planar Non-Planar



(I) (II)

N-Phenyl aziridine (11) was used as the molecule with a typical non-planar structure (II) at the nitrogen atom.

11. 
The NMR spectra of solutions containing an excess of aniline derivatives and $M(AA)_2$ (M=Ni or Co) provide isotropic contact and pseudocontact shifts.[1b,c] The contact shift reflects the mode of the odd-electron distribution in which σ and/or π orbital are concerned, while the pseudocontact shift depends on the geometric structure of the complexed molecules.

It has been well established that induced paramagnetic shifts of protons of ligand complexed with $Ni(AA)_2$ come predominantly from isotropic contact interaction, while the corresponding shift for $Co(AA)_2$-complex system involves the shift due to both contact and pseudocontact interactions.[1] The contact interaction shift is described by Eq. (1):

$$\left(\frac{\Delta\nu}{\nu}\right)_i = \left(\frac{\Delta H}{H}\right)_i = -A_i \frac{\gamma_e}{\gamma_H} \frac{g\beta S(S+1)}{3kT} \qquad (1)$$

where A_i is the isotropic hyperfine contact interaction constant for the ith proton and where the other symbols have their usual meaning.[1] A_i is a measure of the amount of unpaired spin density at the ith proton. The other isotropic mechanism, the pseudocontact interaction (spin dipole-dipole interaction), may be important if there is an anisotropy in the g-tensor of the paramagnetic complex. The shift due to this cause is described by Eq. (2) for axially-symmetric molecules:[1]

$$\left(\frac{\Delta\nu}{\nu}\right)_i = \left(\frac{\Delta H}{H}\right)_i = -\frac{\beta^2 S(s+1)}{27kT}(g_{//} + 2g_\perp) \times (g_{//} - g_\perp)\frac{3\cos^2\theta_i - 1}{r_i} \qquad (2)$$

Here, θ_i is the angle between the ligand-field axis of the complex and the radius vector, r_i, from the metal atom to the ith proton, and $g_{//}$ and $g_\perp$ are g-factors parallel and perpendicular to the ligand-field axis respectively. In the present study, the metal-nitrogen bond serves to define the ligand-field axis.

For mono-N-substituted anilines, the relative contact shift of N–H and N–methyl protons was found to be nearly the same at that for alkyl amines. This is an evidence of a pyramidal structure of the amino-nitrogen atom of aniline derivatives. The preference for non-planar configuration of complexed anilines was further confirmed by pseudocontact-shift studies. The location of metal coordinated at the nitrogen atom was determined from the pseudocontact shift for the $Co(AA)_2$ system.

Experimental

All the chemicals except for the No. 11 compound were obtained from a standard commercial source (Tokyo Kasei Co.). The *N*-phenylaziridine was given kindly by Mr. Kondo of our department. Commercially-available $Ni(AA)_2$ and $Co(AA)_2$ were dried *in vacuo* over 24 hr at 55°C.

The proton spectra were obtained at 60 MHz for $CDCl_3$ solutions containing various amounts of ligand and $Ni(AA)_2$ or $Co(AA)_2$. A typical spectrum is shown in Fig. 1 from $CDCl_3$ solutions of $Ni(AA)_2$ and $Co(AA)_2$ containing excess *N*-methyl-*m*-methyl aniline. The paramagnetic shifts of benzene-ring and N-CH_3 protons were observed at 0.8 M ligand and 0.3 M $Ni(AA)_2$ (0.1 M $Ni(AA)_2$ for N-H protons) concentrations in deuterochloroform at room temperature, using tetramethylsilane as the internal standard.

Results and Discussion

The proton-resonance positions in a paramagnetic solution were shifted from a diamagnetic position to a higher or lower field by an amount proportional to the concentration of $Ni(AA)_2$ or $Co(AA)_2$. The large isotropic resonance shifts allow us to observe proton spin-spin splitting in the simplest, first-order spectra of aniline derivatives in the presence of $Co(AA)_2$ (see Fig. 1-c).

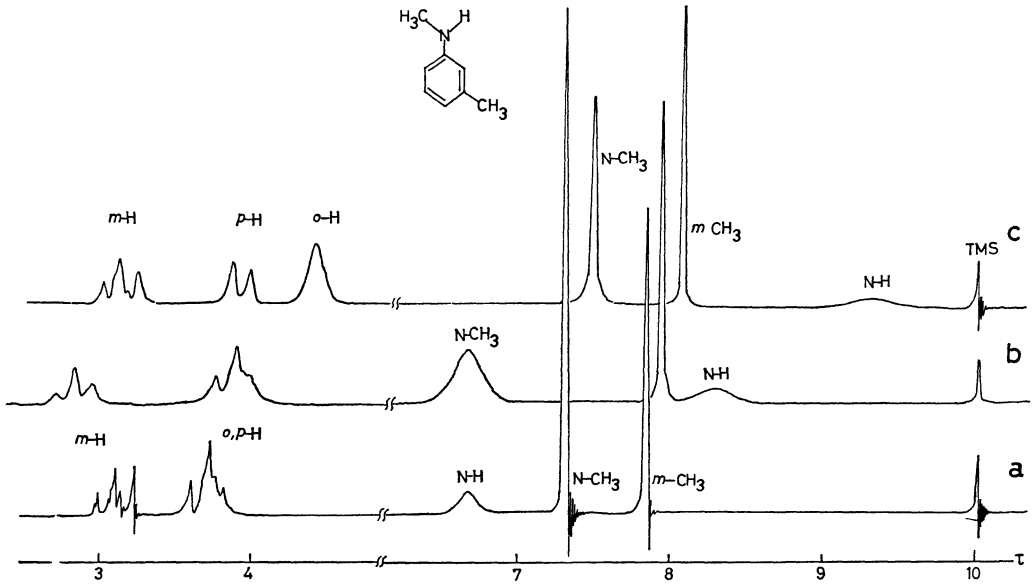

Fig. 1. Proton spectrum of *N*-methyl-*m*-methyl aniline alone and in the presence of $Ni(AA)_2$ or $Co(AA)_2$ in $CDCl_3$ solution.

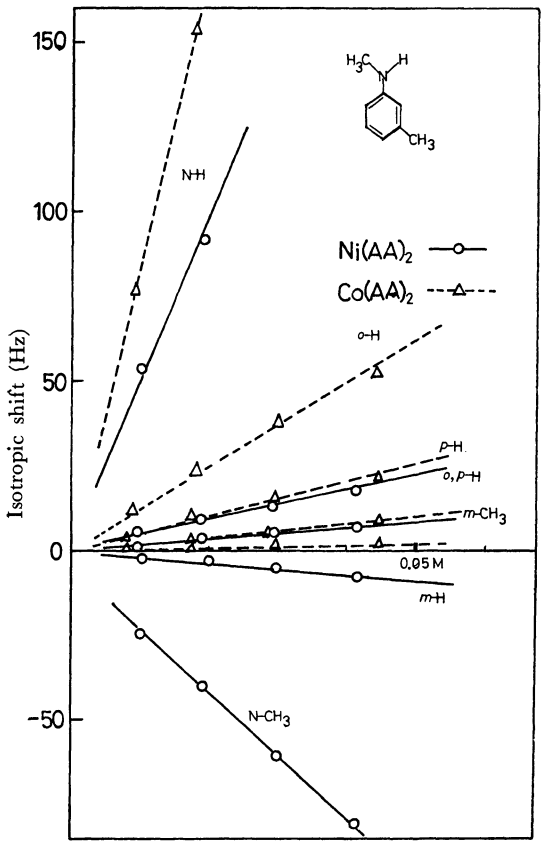

Fig. 2. Plots of the isotropic paramagnetic shifts *vs.* concentration of $Ni(AA)_2$ or $Co(AA)_2$ in $CDCl_3$ solution.

The observed coupling constants of *ortho-meta* and *meta-para* couplings for aniline are 7.5 Hz and 7.1 Hz respectively, for example. The observed isotropic shifts for ring and *N*-substituent protons are plotted against the amount of added $M(AA)_2$. A representative linear plot is given for *N*-methyl-*m*-methylaniline in Fig. 2. The concentration employed here ranges from 0 to 0.82 mol/*l* for ligand molecules and from 0 to 0.05 mol/*l* for $M(AA)_2$. The relative paramagnetic shifts for each proton are equal to the relative values of the slope of the linear plots for each proton. These values are given in Tables 1 and 2, taking the shift of the *ortho* proton in each molecule as 10.00. A positive or negative sign stands for an upfield or a downfield paramagnetic shift respectively. The N-H proton signal became broad and shifted strongly upfield for both nickel and cobalt systems. Phenyl-ring protons exhibit alternating upfield and downfield shifts with no attenuation, characteristic of π-orbital spin delocalization.[1c] The similar magnitudes but opposite signs for the contact shifts of a methyl group and a phenyl proton of the same position in aniline derivatives are also characteristic of the π-delocalization predicted by the theory of McConnell.[4] For the $Co(AA)_2$ system the corresponding proton resonance shifts are all upfield except for that of the *para*-methyl group. Unequal for *ortho* and *para* ring protons were observed, unlike as in the $Ni(AA)_2$ system. For both systems, mono- and di-*N*-alkyl anilines coordinate much less effectively

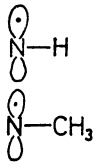
with $M(AA)_2$ presumably because of steric effects, but the observed isotropic shift ratios for ring protons are almost the same as those observed for non-*N*-substituted anilines.

The N–H and N-CH_3 or N-CH_2 proton resonances exhibit different magnitudes and opposite signs for contact shifts in the $Ni(AA)_2$ system. If the amino group in the coordinated *N*-alkyl anilines takes a coplanar configuration, similar magnitudes but opposite signs for contact shifts of N–H and N-CH_3 or N-CH_2 proton resonances should be observed, as predicted by the theory of McConnell.[4]

A metal-nitrogen bond of the planar configuration would involve a pure *p* atomic orbital on the nitrogen which is orthogonal to the σ-plane and would give rise to similar magnitudes but opposite signs for the contact shifts of N–H and N-CH_3 protons. However, the relatively small value of the observed contact shift for N-CH_3 protons compared with that for N–H rules out this expectation and suggests a non-planar configuration of the amino group for coordinated aniline derivatives.

Now let us enter upon a further quantitative discussion of this problem. The relative value of hyperfine coupling constants for N–H and N-CH_3 protons in which an electron spin is localized on the *p* atomic orbital of the nitrogen is given by McConnell's relation:[4]



$$a_H = Q\rho_N$$

$$\frac{a_{CH_3}}{a_H} = \frac{Q_{CH_3}}{Q_H} \simeq 1.2$$

The value of a_{CH_3}/a_H can be obtained from the ESR studies.[5] The relative contact shifts for these protons become equal to this value. Table 3 gives the relative contact shifts for *N*-methyl- and *N*-ethylanilines, together with that for benzyl aniline reported by Fitzgerald and Drago.[6] The values are all very small compared with those predicted by McConnell's relation, but they are very close to the value for benzylamine with a non-planar configuration. The rapid attenuation of contact shifts for the N-CH_3 or N-CH_2 group appears to be due to spin delocalization through the σ system.[7,8] The above results and considerations strongly suggest a pyramidal configuration of the nitrogen atom.

Table 3. The ratio of contact shifts for NH and NCH_3 or NCH_2 protons

Ligand	$\Delta\nu_{NCH_3}/\Delta\nu_{NH}$
	−0.35
	−0.14
	−0.33[a]

a) Taken from Ref. 6.

It should be noted that the value of $\Delta\nu_{CH_2}/\Delta\nu_{NH}$ is much smaller for *N*-ethylaniline than for the *N*-methyl derivative. This singularity is not due to the decrease in electron transfer by hyperconjugation in going from CH_3 to CH_2 groups, but to the more pyramidal nature of the configuration of

the *N*-ethyl group, in which the electron spin on the nitrogen atom transfers to the CH_2 proton through a σ delocalization mechanism with a rapid attenuation.

The lone-pair electrons on a nitrogen atom belong to the hybrid (sp^3) orbital, which can overlap with the π atomic orbitals of the phenyl ring; *i.e.*, the lone-pair AO need σ bonding with the metal is conjugated with other π-orbitals of the ligand. Therefore, the spin which is delocalized onto the ligand through the metal-ligand bond may be distributed in the ligand in a typical π-orbital pattern. The delocalized π-orbital occupied by an odd electron can involve either the highest occupied π-orbital (lone-pair orbital) or the lowest-vacant orbital of the ligand. These can be distinguished by comparing the observed contact shifts with the spin densities calculated by a molecular orbital method.

Table 4 shows that a relation can be observed between the experimental data and the spin-density distribution calculated for the highest occupied MO of the ligand. This means that the lowest vacant orbital which is antisymmetric to the molecular axis does not interact with the AO of the metal. The spin correlation is not explicitly included in the standard MO calculations, but small positive spin densities might become negative if spin correlation is introduced. The simplest method of estimating the effects of spin correlation is that of McLachlan,[9] in which the α and β spins are allowed to occupy separate Hückel-type orbitals. The results of this calculation are also shown in Table 4.

Negative spin densities can be predicted at the *meta* position on the basis of the experimental results. A comparison of the experimental relative contact shifts with the theoretical relative spin densities shoes a fairly good agreement. The calculated values for *meta* position are generally somewhat lower than the observed values, particularly for *p*-methyl aniline. However, the correspondence between the spin-density distribution in coordinated *p*-methylaniline and that in the radical anion of its related compound, *N*,*N*-dimethyl-*p*-toluidine (Table 6), is fairly good. A comparison of the spin density distribution in coordinated molecules and in the corresponding radical anions leads to some other interesting conclusions (Table 6). For radicals, the spin density on a *para*-carbon atom is larger than that on a *ortho*-carbon atom. This is also true for the benzyl radical with an isoelectronic structure of coordinated aniline and its radical anion. This trend can be reproduced by a molecular orbital calculation (Table 4). Extended Hückel calculations including non-bonded interaction for planar and non-planar structures of aniline yield unequal spin densities on *ortho* and *para* protons (Table 5). However, the contact shifts for *ortho* and *para* protons are equal; this appears to be characteristic of the paramagnetic metal complex of aniline derivatives. An increase in the positive spin density (downfield contact shifts) on the *ortho* proton may result from additional spin delocalization through direct overlap between the metal *d* orbital and the proton 1*s* orbital in question.

Spin delocalization to the methyl or methylene

group adjacent to sp^2-hybridized carbons containing an unpaired electron has been explained by hyperconjugation. A different value of Q should be found for each alkyl group. The Q value for the directly-bonded proton, Q_{CH}, is normally -22.5 G, while that for methyl group ranges from 29 G to 27 G.[10] We evaluated Q_{CH_3} or Q_{CH_2} values for alkyl groups attached to the phenyl ring, using the relation:

$$Q_{CH_3} = Q_{CH}\frac{a_{CH_3}}{a_H} = Q_{CH}\frac{\Delta\nu_{CH_3}}{\Delta\nu_{CH}}$$

where $\Delta\nu_{CH_3}$ and $\Delta\nu_{CH}$ are proton contact shifts for each position (*ortho*, *metha*, and *para*). This relation holds as long as the spin densities on the carbon atoms to which methyl or the proton is attached are equal. This is approximately verified by the MO calculations (Table 4). The Q values thus obtained are listed in Table 7. They decrease in the order: *m*-$>$*o*-methyl$>$*o*-methylene protons. This trend probably reflects an interaction between the coordinated metal and the corresponding methyl or methylene group. This interaction is minimized for the *p*-substituted group, in which the substituent is located far from the metal. The Q_{CH_3} value for aminotroponiminate, in which such an interaction does not operate, shows a normal value of 27.0 G.[10] The Q_{CH_2} value is slightly smaller than the Q_{CH_3} value. This finding is considered to be due to the hindrance of electron transfer through hyperconjugation resulting from the steric interaction between the methyl or ethyl group and coordinated $M(AA)_2$.

corresponding $Ni(AA)_2$ data, is due to the pseudo-contact effect, as has been well established for pyridine-type bases complexed with $Co(AA)_2$.[1b]

Here we separate the contact and pseudo-contact shifts in $Co(AA)_2$ systems following the method of Horrocks.[1c] The procedure is as follows. The basic assumption is that the spin density will distribute itself in a manner which is independent of the metal to which it is coordinated; that is, that the ratios of the spin densities at the various carbon atoms (*ortho*, *meta*, *para*) will be the same for the Co(II) and Ni(II) systems, and hence the ratios of the isotropic shifts due to the contact interaction will be the same in these two cases. The pseudo-contact shifts are related to each other by the ratio of calculated geometric factors:

$$\frac{3\cos^2\theta_i - 1}{r_i^3} : \frac{3\cos^2\theta_j - 1}{r_j^3}$$

The bond lengths and bond angles used in estimating the geometric factors listed in Table 8 are given in Table 9. The geometric factor is sensitive to the location of the metal with respect to the amino group, that is, to the metal-nitrogen bond length and to the M–N–C angle. Three angles (90°, 109°, and 129°) and several M–N distances for each angle were adopted. The best geometry was obtained when the agreement of the ratios of the corrected cobalt contact shifts and the observed nickel shifts was obtained. The observed $Co(AA)_2$ isotropic shifts, the necessary pseudo-contact shift correction, and the actual contact shifts for the cobalt complexes of some aniline derivatives are given for three typical geometries of the complex in Table 8. A sizable upfield pseudo-contact shift is evident for the substituted aniline complex of $Co(AA)_2$, implying that $g_{//} < g_{\perp}$. The agreement

TABLE 9. STRUCTURAL PARAMETERS USED IN CALCULATING GEOMETRIC FACTORS AND MOLECULAR ORBITALS

Bond	Distance (Å)	Angle
N-C	1.37	*N*-phenylaziridine
N-CH_3	1.48	C-C	1.40	
C-H (sp^2)	1.08	
C-CH_3	1.49	
C-H (sp^2)	1.09	
N-CH_2	1.49	
CH_3-CH_2	1.48	$\theta_1=\theta_2=\theta_3=120°$

is satisfactory for the non-planar structure with the M–N–C angle of 120° and the M–N distance of 2.2Å. For the planar structure (I), agreement is obtained only when the M–N distance has the unreasonably large value of 4.3Å. The same situation was found to be true for other aniline derivatives. In these circumstances, the planar structure is ruled out.

To further substantiate the structure of the complexed molecule, we examined *N*-phenylaziridine, for which the M–N–C angle is nearly fixed at 120° because of the hybrid orbital of nitrogen lone pairs. Satisfactory agreement is obtained for the configuration of the M–N–C angle of 120° and the M–N distance of 2.0 Å. The 2.0 Å distance appears to be acceptable for the metal-nitrogen coordination complex.

Thus, studies of contact and pseudo-contact shifts demonstrate conclusively that the geometry surrounding the nitrogen atom of the substituted aniline-$M(AA)_2$ coordination complexes (M=Ni or Co) is pyramidal and that the metal-ligand interaction is essentially σ. In aniline, the nitrogen lone pair is available for σ-bonding with the metal and can overlap with the π atomic orbital of the phenyl ring.

Let us now briefly discuss the non-planarity of the free aniline molecule. It seems premature to draw any firm conclusion about the non-planar structure of free aniline derivatives on the basis of the present study. There have been theoretical and experimental investigations of this problem.[11] From the electronic spectra and theoretical calculations, the configuration of aniline has not yet been established. However, molecular-polarizability (Kerr constant)[12] and microwave studies[3] have provided evidence for a pyramidal structure of the nitrogen atom in aniline. As to the *N*-substituted aniline, the ultraviolet spectra indicate that the $N(CH_3)_2$ group in dimethylaniline is bent out of the ring plane.[12] The angle between the ring-to-N bond and the NH_2 plane is found to be about 45°. This angle would be 54°44′ if the orbitals surrounding the nitrogen atom were oriented tetrahedrally.[11] The angle of nearly 60° found for the aniline-$M(AA)_2$ complex in the present study appears to be slightly larger than that for free aniline. This is probably the result of deformation due to metal-ligand complex formation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 388—393 (1970)

The Polarographic Behavior of Several α-Keto Acids in Buffered Solutions Containing *o*-Phenylenediamine, and Its Analytical Application

Tamotsu WASA, Morihiko ORITA, Shingo YOSHIDA and Sôichirô MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai,

(Received May 20, 1969)

Such α-keto acids as glyoxylic (I), pyruvic (II), α-ketobutyric (III), mesoxalic (IV), oxalacetic (V), and α-ketoglutaric acid (VI) condense with *o*-phenylenediamine (OPD) to form two kinds of products, depending on the pH values of the reaction mixtures. The condensation product formed at pH values lower than 4 gives a well-defined reduction wave ($E_{1/2}$ *vs.* SCE at pH 2.0: −0.490 V for I, −0.587 V for II, −0.592 V for III, −0.181 V for IV, −0.590 V for V, and −0.576 V for VI) at a potential more positive than that of free α-keto acid, while the other product, formed at pH values between 4 and 8, gives an oxidation wave ($E_{1/2}$: −0.1 — −0.2 V *vs.* SCE for all α-keto acids at pH 6.0). From the present polarographic investigations, it was deduced that the condensation product giving the reduction wave is probably 2-hydroxyquinoxaline derivatives and that the product giving the oxidation wave is benzimidazoline derivatives. A linear relation was obtained between the wave height for the reduction of the condensation product and the concentration ($(0.5—20)\times 10^{-4}$ M) for each α-keto acid under appropriate conditions. The reduction wave of the condensation product was used for the determination of II in a commercial product containing II as an impurity.

Since the first work by Shikata and Shoji[1] (1928) on the reduction wave of α-keto acids at a dropping mercury electrode, systematic studies of the polarographic behavior of pyruvic acid and related compounds in buffered solutions have been made by several authors;[2-6] this reduction wave has also been used for the determination of α-keto acids in biological materials.[7] However, the reduction wave is partially reaction-controlled in nature, especially for glyoxylic acid and mesoxialic acid; the limiting current varies intricately with the temperature and with the pH value of the electrolytic solution. For analytical use of this reduction wave, therefore, the experimental conditions must be strictly controlled.

On the other hand, the methods of the chromatographic separation[8,9] and the fluorometric determination[10] of α-keto acids utilizing the 2-hydroxyquinoxalines (HQ)[11] which are formed by the condensation of α-keto acids with *o*-phenylenediamine (OPD) have been developed. The polarographic behavior of several HQ derivatives and a method for the determination of α-keto acids after the paper-chromatographic separation of their HQ's were also reported by Brockelt and Pohloudek-Fabini.[12]

The present authors have previously reported on the polarographic behavior of various carbonyl compounds in buffered solutions containing an excess of OPD, and on the application of the polarograms of the condensation products to the determination of each carbonyl compounds.[13-18]

The present paper will describe the polarographic behavior of several α-keto acids, *i.e.* glyoxylic acid (I), pyruvic acid (II), α-ketobutyric aicd (III),

mesoxalic acid (IV), oxalacetic acid (V), and α-ketoglutaric acid (VI), in various buffered solutions containing an excess of OPD, and on a method for determining such α-keto acids by using the polarograms of the condensation products.

Experimental

Materials and Reagents. The α-keto acids used were commercial products and were used without further purification: I, sodium glyoxylate monohydrate; IV, calcium mesoxalate trihydrate (Tokyo Kasei Kogyo Co.); II, sodium pyruvate (E. Merck AG.); III, α-ketobutyric acid; VI, α-ketoglutaric acid (Wako Pure Chem. Ind.), and V, cis-oxalacetic acid (Sigma Chem. Co.). The stock solutions (about 10^{-2} M) of α-keto acids, except for IV, were prepared by dissolving the chemicals in redistilled water; IV was dissolved in dilute hydrochloric acid. The HQ derivative corresponding to each of α-keto acids was prepared according to the method of Morrison[19] by condensing α-keto acid with OPD in dilute acetic acid. The HQ derivative of V was not obtained because of the β-decarboxylation[9] which is catalyzed by OPD, and the product obtained was found to be 2-hydroxy-3-methylquinoxaline by thin-layer chromatography. The stock solutions (about 10^{-2} M) of HQ's were prepared by dissolving the products in 50% ethanol or 50% ethanol containing an equimolar amount of sodium hydroxide. OPD was a product for chromatography from E. Merck AG.; the stock solution of about 0.1 M was prepared fresh daily by dissolving OPD in redistilled water or 0.5 N hydrochloric acid. As the buffer solution, the Britton-Robinson buffer (BR) was mainly employed. In the experiments for HQ's without OPD, 0.001% Triton X-100 was used as the maximum suppressor, but in the presence of an excess of OPD in the electrolytic solution no suppressor was added, since the condensation products showed no maximum. All the other chemicals were the same as those in previous works.[14-18]

Apparatus and Procedures. The apparatus and the experimental procedures for the polarographic investigations were almost the same as those reported in previous papers.[14-18] The characteristics of the capillary used were $m=1.96$ mg/sec and $t=3.97$ sec/drop in a buffer solution when the height of the mercury reservoir was 69 cm at 0 V *vs.* SCE. The accuracy of the temperature control was ±0.1°C. The final pH value of the polarographic solution was measured with a glass electrode pH-meter. The pK values of the authentic HQ derivatives were evaluated from the pH-titration curves for 10^{-2} M HQ's containing 50% ethanol and 1 M potassium chloride. The pH-titration was carried out coulometrically at a constant current of about 10 to 20 mA in a titration cell equipped with a platinum cathode, a silver anode, and a glass indicator electrode.[20]

The cyclic voltammetric experiments were carried out using a multipupose instrument employing solid-state operational amplifier circuitry and with a three-electrode configuration, similar to that reported by Goolsby and Sawyer.[21]

Results and Discussion

When α-keto acid was treated with OPD in buffered solutions of various pH values by the procedure described above, all the α-keto acids examined show a well-defined reduction wave at a potential more positive than that of the original acids at pH values below 4 (Fig. 1a), while there was a well-defined oxidation wave in the pH range between 4 and 8 (Fig. 1c). The relation between

21) A. D. Goolsby and D. T. Sawyer, *Anal. Chem.*, **39**, 411 (1967).

the heights of the waves and the pH values of reaction media are presented in Fig. 2. The ill-defined reduction wave obtained at pH values above 7 (Fig. 2, dashed line) seems to be due to the reduction of the α-keto acid which had not reacted, because the half-wave potentials are in rough accord with those for free acids. Consequently, it is evident that two kinds of the products were produced by the condensation reactions of α-keto acid with OPD, depending on the pH values of the reaction mixtures.

Reduction Wave of the Condensation Product. Figure 2 shows that the reduction wave rapidly increases in height with a decrease in pH in the range below 4. The effect of the concentration of hydrochloric acid on the condensation reaction of α-keto acid with OPD was examined in the range from 0.05 to 2 N; the results obtained are shown in Fig. 3. The wave height, which is equivalent to the amount of the condensation product, had its maximum value in the range of 0.1 to 1 N hydrochloric acid. The same effect was also observed with sulfuric acid instead of hydrochloric acid.

α-Ketoglutaric acid: 5×10^{-4} M; OPD: ○—8×10^{-2}, ●—4×10^{-2}, ◑—2×10^{-2}, and ◒—8×10^{-3} M

Figure 4 shows the relation between the wave height of the condensation products and the time elapsed after the addition of VI to the electrolytic solutions containing OPD in various concentrations in 0.25 N hydrochloric acid. With the increase in the concentration of OPD, the growing velocity of the reduction wave increased. A similar effect was also observed for all the other α-keto acids; the time required to reach the maximum value of the limiting current was 20—60 min with the concentrations of OPD higher than 2×10^{-2} M. Moreover, the saturation wave height obtained for each α-keto acid was found apparently to correspond to that of the authentic HQ of the same concentration.

The pH dependence of the wave heights of the condensation products, which were prepared by condensing α-keto acids with OPD in 0.25 N hydrochloric acid and by then neutralizing them with 1 N sodium hydroxide, is given in Fig. 5. The same pH-dependence was obtained for all the α-keto acids other than IV ; the limiting current remains almost constant at pH values lower than 9, while with an increase in pH above 9 a new second reduction wave (curve b), whose half-wave potential of about 100 mV more negative than that of the first wave (curve a), grows at the expense of the latter, which disappears at a pH value of about 11. For the condensation product of IV, a more complicated behavior was observed, as may be seen in Fig. 5 (dashed line): the reduction wave split into two waves at a pH value of about 2.

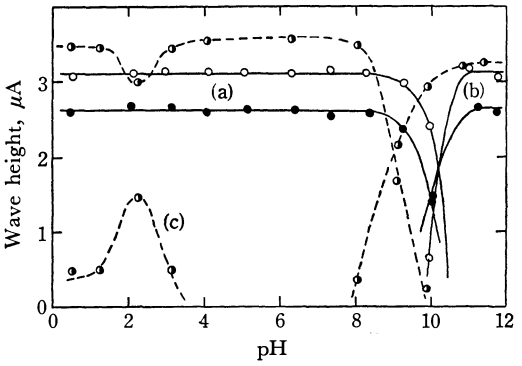

Fig. 5. pH-Dependence of the reduction waves of the condensation products (about 5×10^{-4} M) at 25°C.
—●— I, —○— II (III, V, and VI), --◑-- IV; (a)—1st wave, (b) and (c)—2nd wave

The half-wave potentials of the condensation products are listed in Table 1 as a function of the pH value, together with the pK value. The condensation products for each α-keto acid prepared in acidic media of pH lower than 4 were identical in polarographic behavior with the corresponding authentic HQ's obtained by Morrison's method;[19]

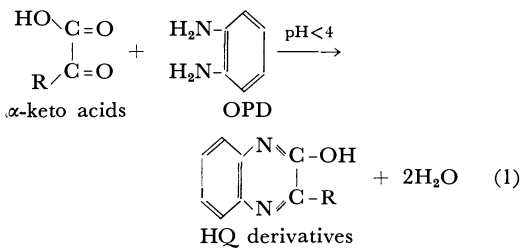
the present results are also in accordance with the observation by Brockelt and Pohloudek-Fabini,[12] when the pH values of their electrolytic solutions are corrected, taking into account the alcohol error caused by the 50% ethanol addition. As has been reported by Hinsberg,[11] the reaction may be written as:



The limiting current for each condensation product at pH values lower than 9 or higher than 11 was the diffusion-controlled current, since the wave height varied in proportion to the square root of the height of the mercury reservoir. By comparing the wave height for the HQ derivatives with that for dimethylquinoxaline[15] at the same concentration, a two-electron reduction was deduced for the reduction wave of HQ.

A cyclic voltammogram of 2-hydroxy-3-methylquinoxaline with a hanging mercury drop electrode is given in Fig. 6 (a); it is typical of the cyclic voltammetric behavior exhibited by the HQ derivatives examined: the electron-transfer step exhibits no reversal peak upon scan reversal about 160 mV past the cathodic peak. Though this result seemingly suggests that the electron transfer is irreversible, a small a. c. peak was observed at the potential crresponding to the d. c. wave for each HQ derivative over all the pH range studied (pH 0—12), the peak height being about one-tenth of that for dimethylquinoxaline at the same concentration. From both of these results, the electrode reaction of HQ derivtives, though a more complete explanation of the mechanism must await further investigation, may be deduced to be a reversible two-electron transfer, followed by a fast chemical reaction.[22]

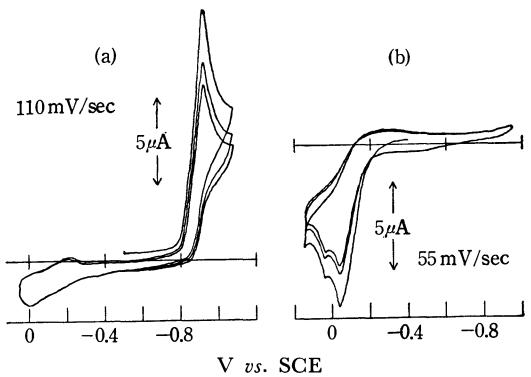


Fig. 6. Cyclic voltammograms of the condensation products of II with OPD at 25°C.
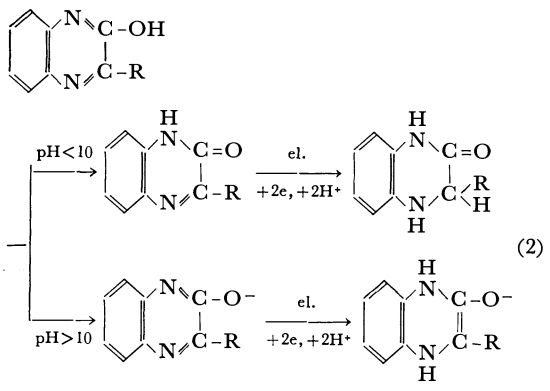
a) cathodic peak of 2-hydroxy-3-methylquinoxaline (5×10^{-4} M) in BR buffer (pH 6.0)
b) anodic peak of II (5×10^{-4} M) in BR buffer (pH 6.0) containing 2×10^{-2} M OPD; condensation: 30 min

22) Joe L. Sadler and Allen J. Bard, *J. Amer. Chem. Soc.*, **90**, 1979 (1968).

From the facts that the pH values, at which the height of the first wave is equal to that of the second wave, were found to be near the pK values (Table 1) for the hydroxyl group of each HQ and that HQ derivatives were proved by the spectrophotometric study[23] to be present in the aqueous solution largely as the amide form, it may be concluded that the first and the second reduction wave of HQ are due to the reduction of the undissociated tautomeric amide form and the dissociated enol form respectively. The electrode reaction may be written as:



(2)

Oxidation Wave of the Condensation Products. The pH-dependence of the oxidation waves of the condensation products of α-keto acids with OPD (shown in Fig. 2 and Table 1) was, in general, very similar to that observed for monoaldehydes:[16,17,24] the wave heights, which are equivalent to the amount of the condensation product, attain their maximum value in the pH range between 6 and 7.5, and then decrease beyond this pH region. Figure 7 shows the change in the anodic limiting current in buffered solutions (pH: 7.17, 6.10, and 5.30) containing II and OPD with the time elapsed after the addition of OPD. At pH values higher than 6 the condensation reaction was slow (curve b). On the other hand, at pH values lower than 6 the condensation product was unstable (curve c), though the condensation reaction itself was very rapid. At a pH value of about 6 the reaction of every α-keto acid with OPD attained its equilibrium state within 20—60 min after the addition of OPD and the condensation products were comparatively stable (curve a). The oxidation wave was also diffusion-controlled.

A representative cyclic voltammogram of the condensation product is shown in Fig. 6 (b): the electron-transfer step exhibits no cathodic peak upon scan reversal. Moreover, from the facts that no a. c. polarogram was observed with the condensation product and that no reduction wave was obtained with the oxidation product prepared by aeration through the solution containing the condensation product, the electrode reaction may be considered to be irreversible.

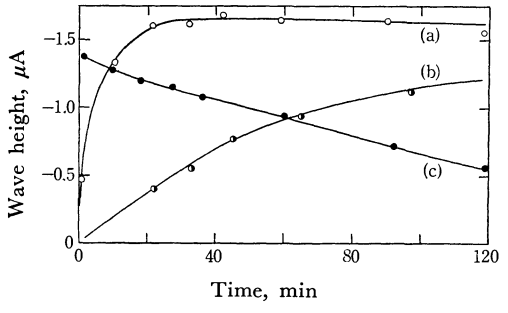


Fig. 7. Change of the oxidation wave for 5×10^{-4} M ,II with time in BR buffer containing 4×10^{-2} M OPD at 25°C.
a) pH 6.10, b) pH 7.17, and c) pH 5.30

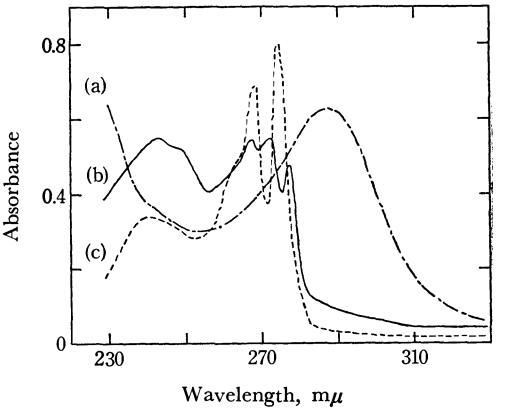

Fig. 8. UV-absorption spectra of the oxidation products corresponding to I (b), II (c), and IV (a) in BR buffer (pH 6.0).
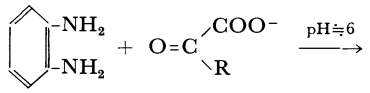
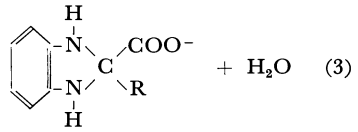
α-Keto acid: 2×10^{-3} M; OPD: about 1×10^{-4} M
Spectrum was recorded for the condensation product after complete oxidation with air.

Figure 8 shows the UV-absorption spectra of the air-oxidation products. The absorption curves obtained for II, III, V, and VI were similar to each other, but they were entirely different from that for IV. The curves for I, II, and III were also identical with those of benzimidazole and the oxidation products from the condensation product of OPD with acetaldehyde and with propionaldehyde respectively. From the results described above, it may be concluded that the condensation products exhibiting oxidation waves are benzimidazolines and that their electro-oxidation products are benzimidazole derivatives, as has previously been reported for aldehydes[16,17] and ketones.[25] Their reactions may be expressed as follows:

23) G. W. H. Cheeseman, *J. Chem. Soc.*, **1958**, 108.
24) M. Fedoroňko, J. Königstein and M. Bullová, *Chem. Zvesti*, **22**, 25 (1968).
25) R. C. Elderfield and J. R. McCarthy, *J. Amer. Chem. Soc.*, **73**, 975 (1951).

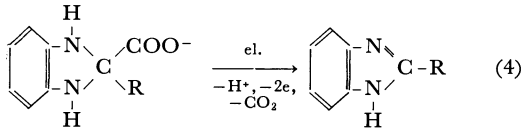


OPD α-keto acids



(3)

benzimidazolines



(4)

Analytical Application. From the results described above, the following conditions are recommended for the determintion of α-keto acids by using the reduction wave of the condensation products with OPD: 0.1—1 N for the concentration of hydrochloric acid, (2—4) × 10^{-2} M for the concentration of OPD, 25°C for the temperature, and 20—60 min for the condensation time. To avoid the precipitation of the condensation products, it is desirable to add ethanol (about 10% in volume) to the reaction mixture. Under these conditions, a linear relationship was obtained between the concentration of each α-keto acid in the range of (0.5—20) × 10^{-4} M and the wave height of the corresponding condensation product, as may be seen in Fig. 9.

Alcohols, carbohydrates, monocarbonyl compounds such as aliphatic aldehydes and ketones, and all carboxylic acids except α-keto acids did not interfere with the determination of α-keto acid. Since the condensation products of glyoxals[14,15] behave in a way similar to that of α-keto acids at the dropping mercury electrode, the presence of any glyoxal may interfere with the determination of α-keto acids.

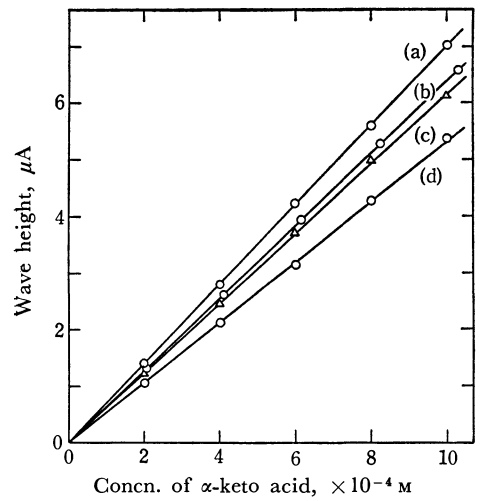


Fig. 9. Relationships between the wave heights (cathodic) of the condensation products and the concentrations of α-keto acids in 0.25 N HCl at 25°C. OPD: 5 × 10^{-2} M; condensation: 30 min a)—IV, b)—II (III and VI), c)—V, and d)—I

As an application, the determination of II in commercial products containing II as an impurity was carried out by means of the standard addition method; some of the analytical results obtained are presented in Table 2, together with those obtained by the direct polarographic method.[7] When no interfering substance is present in the sample, the results obtained by the two methods are in good agreement with each other. Even in the case of the sample containing a substance interfering with the direct polarographic method, the present polarographic OPD method is valid because the half-wave potentials of the condensation products shift to more positive potentials than that of free α-keto acid.

Table 2. The results of the determination of II in commercial products

OPD: 5 × 10^{-2} M, 0.5 N HCl, 25°C, 60 min

Sample	Pyruvic acid content, %	
	Polaro. OPD method	Direct polaro.*
Lactic acid (95%)	0.0112	0.0113
Lactic acid (75%)	0.0084	0.0105
Acidophilus milk (liquid)	0.0119	0.0153
Acidophilus milk (powder)	0.0064	0.504

* According to the procedure of Ref. 7, p. 269.

With regard to the oxidation wave, a linear relationship was also observed between the concentration of each α-keto acid and the wave height under strictly controlled conditions. However, the wave height changes with the concentration of OPD since the equilibrium constant for the condensation reaction seems to be relatively small, much like that for monoaldehydes,[16,17] and it decreases with time since the condensation product is easily oxidizable with the dissolving oxygen. For analytical purposes, therefore, the concentration of OPD in the reaction mixture should be kept in a large excess and should be kept constant, and the dissolving oxygen should be removed by a stream of nitrogen immediately after the preparation of the electrolytic solution.

The authors wish to express their thanks to Dr. Masanosuke Takagi for his helpful discussions and suggestions during this work and to Mr. Iwao Abe for his assistance in the experimental work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 394—397 (1970)

Isotope Effect of Molten Thallous Nitrate in Countercurrent Electromigration

Isao OKADA and Nobufusa SAITO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received July 8, 1969)

The isotope effect of the thallous ion in the countercurrent electromigration of molten thallous nitrate has been measured at 219°C. The relative internal mobility difference between $^{203}Tl^+$ and $^{205}Tl^+$, $\Delta V/V_{Tl}$, has been determined to be 0.00035 ± 0.00002. The mass effect $\mu_{Tl}=(\Delta V/V_{Tl})/(\Delta M/M_{Tl})$, has been calculated to be -0.035 ± 0.002, and this value has been compared with those of alkali nitrates previously determined.

Several studies have been made of the mass effects*1 of internal mobilities[1] in countercurrent electromigration with a variety of molten alkali nitrates.[2-7] However, no data on the mass effects have been published for other molten nitrates. This report will be concerned with the mass effect of the internal mobilities of thallous nitrate in a molten state.

Experimental

The experiments were performed in the cell shown in Fig. 1. A mixture of desiccated lithium and potassium nitrates was poured into a quartz beaker and melted by electric heating. On the other hand, a separation tube made of Vycor glass was packed with quartz powder (100—150 mesh size) and placed into a vessel containing molten thallous nitrate. After the molten nitrate had been soaked up to the upper end of the diaphragm of quartz powder in the separation tube, it was transferred into the quartz beaker. Then electromigration was immediately started. A platinum wire and an aluminum tube were used as the anode and the cathode of the electromigration respectively. The temperature of the separation tube was kept at 219 ± 3°C,*2 and a mixture of nitrogen dioxide and oxygen was introduced into the cathode compartment at a constant rate throughout the electromigration. When the electromigration had terminated, the separation tube was taken out from the quartz beaker. After cooling, the surface of the tube was thoroughly cleaned, and the tube was cut into several fractions. The salt in each fraction was leached out with water. In order to determine the thallium content of each fraction, aliquots of the fractions were poured on a column of an anion exchange resin, Dowex-1 (100—200 mesh), of the OH-form. The thallium ion was eluted with distilled water. The thallium in the the effluent was then determined by means of Andrew's titration.

Sodium iodide was added to another aliquot of each fraction. After the resulting precipitate of TlI had been filtered, the potassium in the filtrate was determined gravimetrically as potassium tetraphenylborate. The lithium content of each fraction was determined by spectrophotometry.

The isotopic ratio of thallium in each fraction was measured with an Atlas CH-4 mass spectrometer equipped with a double-filament ion source for surface ionization. The ionizing and vaporizing filaments were made of rhenium ribbons. The distance between these filaments was about 2 mm. Background and memory effects were eliminated by boiling the ionization box in distilled water for 20 min and by then heating *in vacuo* both ionizing and vaporizing filaments at about 2500°C with a current of 5A for 30 min. The sample (about 10 μg as thallium) was painted on the vaporizing filament in the form of thallous nitrate. After the ionization box had been placed in the ion-source compartment of the mass spectrometer, the ionizing filament was slowly heated electrically up to about 1200°C. The ion current of thallium was found to be stable after about 30—50 min. The ion current of ^{205}Tl was controlled to about 3×10^{-12} A at the collector by adjusting the temperature of the ionizing filament.

*1 Mass effect, μ, is defined as the ratio of relative mobility difference, $\Delta V/V$, to relative mass difference, $\Delta M/M$, of two isotopes. It is expressed as $\mu=(\Delta V/V)/(\Delta M/M)$.

*2 The thermogravimetric analysis of thallous nitrate has indicated that no thermal decomposition of the nitrate takes place below 300°C with a heating rate of 2°C/min.

Results and Discussion

Four runs of electromigration were carried out. The results of these experiments are summarized in Table 1. For one of these experiments, the detailed experimental conditions and the results obtained are given in Table 2.

For the calculation of the relative internal mobility difference of isotopic ions of thallium, $^{203}Tl^+$ and $^{205}Tl^+$, a formula presented by Klemm[8] can be reformed as follows:

$$\varepsilon = (V_{203}-V_{205})/V_{Tl}$$
$$= (\boldsymbol{F}/Q)\{(x_0+1)/x_0\}\sum_i (x_i-x_0)N_i/(x_i+1) \quad (1)$$

where V_{203}, V_{205}, and V_{Tl} are the internal mobilities of $^{203}Tl^+$, $^{205}Tl^+$, and the thallous ion; where x_i and x_0 are the isotopic ratios of ^{205}Tl to ^{203}Tl in the ith fraction of thallium salt in the separation tube after and before electromigration respectively; where N_i is the equivalent quantity of the thallous ion in the ith fraction; where Q is the transported charge, and where $\boldsymbol{F}$ is the Faraday constant.

The mean square error of the relative internal mobility difference, σ_ε^2, is expressed as:

$$\sigma_\varepsilon^2 = (\partial\varepsilon/\partial x_0)^2\sigma_{x_0}^2 + \sum_i (\partial\varepsilon/\partial x_i)^2\sigma_{x_i}^2 + \sum_i (\partial\varepsilon/\partial N_i)^2\sigma_{N_i}^2$$
$$= (\boldsymbol{F}/Qx_0)^2\sum_i [\{x_i+x_0^2)N_i/(x_i+1)^2\}(\sigma_{x_0}^2/x_0^2)$$
$$+ (x_0+1)^4N_i^2\sigma_{x_i}^2/(x_i+1)^4$$
$$+ (x_0+1)^2(x_i-x_0)^2\sigma_{N_i}^2/(x_i+1)^2] \quad (2)$$

where σ_{x_i} and σ_{x_0} are the standard deviation of the isotopic ratio in the ith fraction of the thallium in the separation tube after and before electromigration respectively, and where σ_{N_i} is the mean deviation of the equivalent quantity of thallous ion in the ith fraction. The values of ε are calculated by Eq. (1) only for the fractions in which ^{205}Tl is enriched. If Eq. (1) is applied to the region of the separation tube where the contents of lithium and potassium nitrates are negligibly small as compared with thallium, the calculated value of ε can be regarded as that of pure thallous nitrate.

The isotopic ratio before electromigration: 2.381±0.006

The calculations based on the results of Experiments Nos. 1, 2, 3, and 4 have shown that the mean values of the relative internal mobility difference between ^{203}Tl and ^{205}Tl and of the internal mass effect,[1] μ_{Tl}, for thallous nitrate are 0.00035± 0.00002 and −0.035±0.002 respectively.

In order to compare the mass effect of thallous nitrate with those of the alkali nitrates so far measured, the mass effects of these cations are plotted as a function of the cationic radius[9] in Fig. 2. Figure 2 clearly demonstrates that, the larger the cationic radius, the lower the internal mass effect of molten nitrates.

It is of interest that the linear relationship between the cationic radius and the internal mass effect which is observed for alkali nitrates also holds for thallous nitrate.

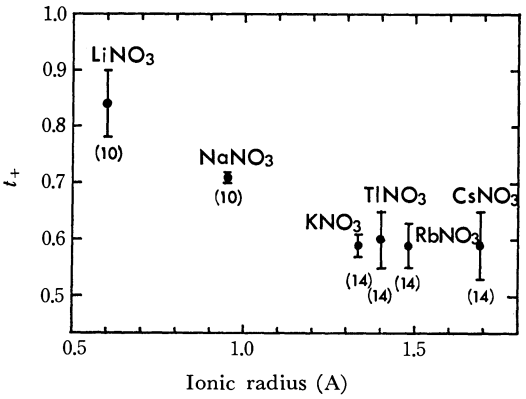

Fig. 3. Relationship between the cationic radius and the transport number of cation in the molten nitrates.
Figures in parentheses stand for the reference number.

9) L. Pauling, "The Nature of the Chemical Bond," 3rd Ed., Cornell Univ. Press, New York (1960) p. 516.

It has been suggested by Duke and Owens[10] that the transport number of cations in pure molten nitrates can be expressed as $t_+=r_-/(r_++r_-)$, where r_+ and $r_-(=2.19$ A,[11] 2.3 A[12]) are the ionic radius of the cation and nitrate ions respectively. Therefore, the transport number of the cation for nitrates is nearly a linear function of the cationic radius, as is shown in Fig. 3: $t_+=1-r_+/(r_++r_-)\fallingdotseq 1-kr_+$ $(r_+\ll r_-)$, where k is a constant.

It can be expected that, as the transport number of the cation increases, the value of the internal mass effect will also increase.[13] In fact, this trend has been observed in these nitrate systems.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 397—400 (1970)

Chromium(III) Complexes with Iminodiacetic Acid or *l*-Aspartic Acid*[1]

Hisayuki MIZUOCHI,*[2] Shuichi SHIRAKATA, Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received July 29, 1969)

The formation constants of chromium(III) complexes with iminodiacetic acid (IDA) and *l*-aspartic acid (Asp) as the terdentate ligands were determined by the pH method in the ionic strength, $\mu=0.1$ and at 25°C: their values were $\log k_1=10.9$ and $\log k_2=10.5$ for IDA and $\log k_1=10.1$ and $\log k_2=9.5$ for Asp, respectively. That the overall formation constants of chromium-(III)-IDA complexes obtained were slightly larger than those of the corresponding -Asp complexes was explained by the stronger chelate effect in the former complexes than in the latter ones. The solid chromium(III) complexes with IDA and Asp were also prepared. Based on chemical analyses and the conductivity measurement or the behavior toward the ion exchangers, the chemical formulas of these complexes are possibly $K[Cr(ida)_2]\cdot 3H_2O$ and $K[Cr(OH)_2asp]$ respectively. X-Ray powder diffraction patterns indicated that the former crystalline complex has tetragonal unit lattice, the axial parameter being $a=14.57$ and $c=12.38$ Å, whereas the latter is amorphous solid.

The formation constants of chromium(III) complexes with glycine and α-alanine as the natural amino acids,[1] anthranilic acid, picolinic acid and 8-hydroxyquinoline,[2] behaving as the (N,O)-type, bidentate ligands, have already been determined. In the series of studies on the formation constants of chromium(III) complexes, the iminodiacetic acid (abbreviated as IDA) and *l*-aspartic acid (abbreviated as Asp) were selected as the (N,O,O)-type, terdentate chelate ligands. We intend first to determine the formation constants of chromium-(III) complexes with IDA and Asp in order to compare their stability with that of glycine and to discuss the difference between them.

A series of the systematic syntheses of the chromium(III) complexes containing diamines and dicarboxylic acids as mixed ligands has been investigated.[3] The complexes with nitrilotriacetic acid and its homologues as the artificial amino acids which can behave as quadridentate ligands were synthesized, and their coordinating structures have been discussed.[4] However, no details of the comparative syntheses of chromium(III) complexes with the amino acids which can behave as the terdentate chelate ligands are known. The second purpose of this study is to prepare chromium(III) complexes with IDA and Asp in the solid phase.

Experimental

Materials. The stock solution of hexaaquochromium(III) perchlorate for the measurement of the formation constants was prepared as described in a previous paper.[1] IDA as a chelating agent used was of highest commercial grade supplied by Dojin Institute of Pharmaceutical Chemistry, and Asp was of special grade by Wako Pure Chemical Industries, Ltd.

Formation Constant Measurements. The formation constants of chromium(III)-IDA and -Asp complexes were determined by the pH method as described.[1] The pH value was measured with a Toa Denpa pH meter, model HM-8. The pH value decreased very slowly as the complex formation proceeds in the mixed solution of hexaaquochromium(III) perchlorate and IDA or Asp, owing to the inertness of chromium(III) complexes. When the decrease of the pH values ceased and the value remained constant for one or one-and-half months, the equilibrium of the complex formation reaction was presumed to be attained. It was also checked by the invariance of the optical density of the reaction solution. In order to see whether some effects upon the pH value due to the unexpected circumstances appear or not, the pH of the solution of the respective chelating agent alone, in the absence of hexaaquochromium(III) perchlorate, was occasionally measured as a blank test for the measurement of the formation constant. It was confirmed that the values remained unchanged during the desired period. Thus, after the pH value of the solution in question became constant, the formation constants were calculated.

Preparation of Complexes. In order to prepare solid chromium(III) complexes with IDA, an aqueous solution of chromium(III) nitrate was mixed with that of IDA in the mole ratio 1 : 3, and then was allowed to boil for a few minutes. After potassium hydroxide was added to the solution to keep the pH value at 3.5—4, it was concentrated to some extent and then ethanol was poured into it. After the solution had been stood for a while, fairly large, red crystals were deposited. If the solution was kept in an ice-box, scale-like, red crystals were produced. Results of chemical and thermal analyses of the crystalline chromium(III)-IDA complex obtained above were as follows: Found: Cr, 12.82; K, 9.73; C, 23.56; N, 6.51; H, 3.75; H_2O, 12.42%. Calcd for $K[Cr(ida)_2]\cdot 3H_2O$: Cr, 12.77; K, 9.60; C, 23.59; N, 6.88; H, 3.93; H_2O, 13.27%.

The content of crystalline water was evaluated from the result of the thermogravimetric analysis by a thermobalance.

Synthesis of crystalline chromium(III) complex with *l*-aspartic acid corresponding to that with IDA which has the composition of 1 : 2 mole ratio was unsuccessful. However, another type of complex was prepared at higher pH. About five grams of *l*-aspartic acid in 500 m*l* of water was warmed on the water bath. After it was dissolved, 5 g of chromium(III) nitrate trihydrate was added and the solution was heated for ten minutes. When 20 g of potassium carbonate were gradually added into the solution with stirring, it turned from reddish-violet to bluish-green. As soon as a scale-like film was formed on the surface of the solution, it was filtered while hot. The yield was very poor, 20 mg at most. The result of analysis was as follows: Found: Cr, 20.56; K, 14.22; C, 21.69; H, 2.13%. Calcd for $K[Cr(OH)_2asp]$: Cr, 20.30; K, 15.26; C, 20.09; H, 2.11%.

Other Measurements. Measurements of the conductivity in an aqueous solution, thermogravimetric analysis and X-ray diffraction in the solid state were carried out with a Yokogawa Universal Bridge, BV-Z-13A, a Shimadzu TM-1A type Thermobalance and a Rigaku-Denki Geiger-flex X-ray Analyzer, respectively.

Results and Discusson

Continuous Variation Method. Prior to determination of the formation constants of the complexes, the continuous variation method was applied to the system of the hexaaquochromium(III) perchlorate and IDA or *l*-aspartic acid. The results obtained by this method at pH 2, and 3—4 are shown in Fig. 1 for IDA complex and in Fig. 2 for *l*-aspartic acid complex, where the increase of the optical density due to the complex formation was plotted against the mole ratio of the ligand to the sum of metal ion and ligand. The optical density of the solution for Cr(III)-IDA system was measured at both the first and second absorption maxima of $[Cr(ida)_2]^-$, 522 mμ and 389 mμ which were reported by Yamasaki and Ito.[5] Those for Cr(III)-Asp system was measured also at the same wavelength since the corresponding absorption maxima of $[Cr(asp)_2]^-$ are close to those of the former complex.

Since the maxima in the curves shown in Fig. 1 are all found to appear in the mole ratio of metal ion

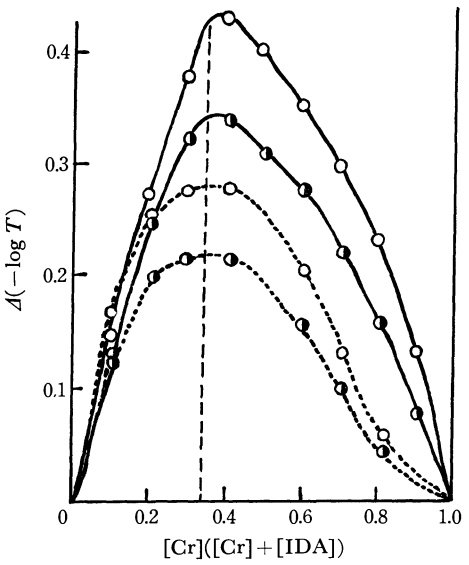

Fig. 1. Continuous variation method for Cr(III)-IDA system.
Full curve: at pH 3—4, Broken curve: at pH 2
○ 522 mμ, ◑ 389 mμ

5) K. Yamasaki and S. Ito, *Proc. Japan Acad.*, **42**, 1077 (1966).

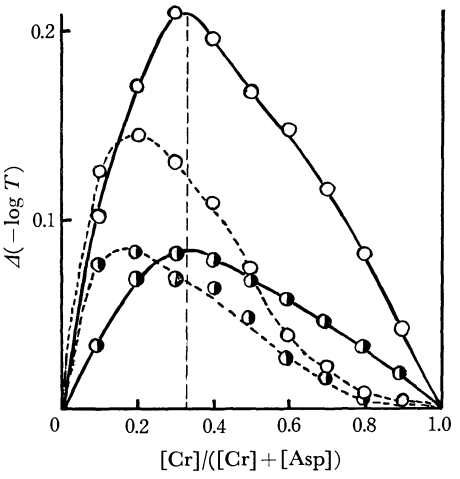

Fig. 2. Continuous variation method for Cr(III)-Asp system.
Full curve: at pH 3—4, Broken curve: at pH 2
○ 522 mμ, ◑ 389 mμ

versus ligand, 1 : 2, the composition of the predominant complex species formed in the solution at pH 2—4 may be $[Cr(ida)_2]^-$. On the other hand, in the case of *l*-aspartic acid complexes as shown in Fig. 2, the maxima in the curves at pH 2 appear in the mole ratio 1 : 3, whereas those at pH 3—4, in the ratio 1 : 2. Hence, the predominant complex species formed may have a composition $[Cr(Hasp)_3]$ at pH 2, and a composition $[Cr(asp)_2]^-$ at pH 3—4.

Conductivity and Behavior toward Ion Exchanger. The results of the molar conductivity of the complex, $K[Cr(ida)_2]\cdot 3H_2O$, in the aqueous solution obtained were 95, 102, 108, 108 and 117 at concentrations of 1/100, 1/250, 1/500, 1/1000 and 1/2000 M, respectively. The complex anion was found to be adsorbed by the anion exchanger, Dowex × 1. It seems that the complex is 1 : 1 valency-type salt and, therefore, the anion is 1 : 2 type complex.

In the solution containing hexaaquochromium(III) perchlorate and *l*-aspartic acid more than three times of chromium(III) salt at pH 2, the complex was found to pass through both cation and anion exchangers, Dowex × 1-Na-form and Dowex-× 50-Cl-form, without being adsorbed, but at pH 4, it was adsorbed only by anion exchanger. Therefore, it is presumed that the anionic complex is 1 : 2 type as given by $[Cr(ida)_2]^-$.

Formation Constants. IDA and Asp seem to dissociate in the following manner in an aqueous solution:

$$^+H_2N\text{-}\langle^{COO^-}_{COOH} \overset{pK_1}{\rightleftharpoons} {}^+H_2N\text{-}\langle^{COO^-}_{COO^-} \overset{pK_2}{\rightleftharpoons} HN\text{-}\langle^{COO^-}_{COO^-}$$

where all the formulas are expressed only by the functional amino and carboxylate groups without describing the detailed skeleton in each molecule, and K_1 and K_2 are the first and second acid dissociation constants, respectively. In order to determine these values, the aqueous solution of these amino acids in the absence of chromium(III) salt was titrated with the standard solution of sodium hydroxide in the ionic strength $\mu=0.1$ and 25°C. In terms of titration these constants were evaluated by[6]

$$K_1 = [H^+](aC_A + [H^+])/\{C_A - (aC_A + [H^+])\}$$

in the lower pH range, and by

$$K_2 = [H^+]\{(a-1)C_A - [H^+]\}/[C_A - \{(a-1)C_A - [OH^-]\}]$$

in the higher pH range, where C_A is the total concentration of amino acid, a, the numbers of moles of base added per mole of amino acid present, $[H^+]$ and $[OH^-]$, the concentrations of hydrogen and hydroxide ions respectively. The values for IDA obtained are $pK_1=2.59$ and $pK_2=9.23$. As those for Asp, $pK_1=3.70$ and $pK_2=9.62$ were used from a reference.[7]

The concentrations of the amino acids non-coordinated to either metal or hydrogen ion, $[A^{2-}]$, and the average number of the ligand coordinated to one mole of metal ion, n were calculated by[6]

$$[A^{2-}] = \{(2-a)C_A - [H^+] + [OH^-]\}/\{2[H^+]^2/K_1K_2 + [H^+]/K_2\}$$

$$\bar{n} = \{C_A - [H^+]/K_1K_2 + [H^+]/K_2 + 1)[A^{2-}]\}/C_M$$

where C_M is the total concentration of metal.

The formation curves, $\bar{n}$ *vs.* $p[A^{2-}]$, are shown in Fig. 3. By applying the successive approximation method to the values of the stepwise formation constants of chromium(III) complexes with the amino acids found in Fig. 3, the correct values were obtained and are summarized in Table 1 together with those of chromium(III) complexes with glycine.[1]

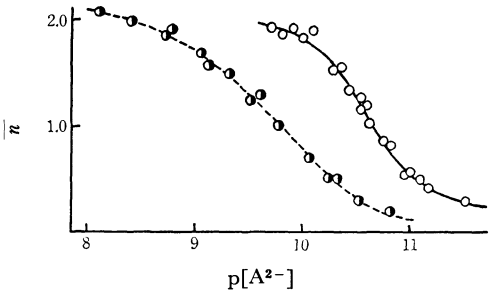

Fig. 3. Formation curve, $\bar{n}$ *vs.* $p[A^{2-}]$ for Cr(III)-IDA (—○—) and Cr(III)-Asp (--◑--) complexes.

Table 1. Formation constants of chromium(III) complexes with amino acids (μ=0.1, 25°C)

	$\log k_1$	$\log k_2$	$\log k_3$	$\log \beta$*
Cr(III)-IDA	10.9	10.5	—	21.4
Cr(III)-Asp	10.1	9.5	—	19.6
Cr(III)-Gly	8.62	7.65	5	21.3

* β: overall formation constant

As shown in this table, the formation constants of chromium(III) complexes with IDA are slightly larger than those of the corresponding Asp complexes. This fact can be explained by the difference in the coordinating structures, *viz.*, IDA is a terdentate ligand in the complex, forming two five-membered chelate rings with chromium, where Asp seems to form one five-membered and one six-membered chelate rings as terdentate ligand in the complex.

The overall formation constants of Cr-IDA and Cr-Gly (glycine abbreviated as Gly) complexes are apparently equal to each other. This might be explained as follows.

One IDA complex anion, $[Cr(ida)_2]^-$, contains two IDA molecules coordinating totally with two nitrogen and four oxygen atoms, whereas one glycine complex molecule, $[Cr(gly)_3]$ (gly is the abbreviated form of glycinate anion), contains three glycinate anions coordinating entirely with three nitrogen and three oxygen atoms. If the bond energy of nitrogen with chromium is assumed to be larger than that of oxygen atom, the above glycine complex should be more stable than the IDA complex, so far as the coordinating atoms are concerned.

On the contrary, two molecules of IDA anions form four chelate rings in the $[Cr(ida)_2]^-$ complex, but three glycinate anions form three chelate rings in the $[Cr(gly)_3]$ complex, though their chelate rings formed are all five-membered. A large number of chelate rings in IDA complex than in Gly complex will cause larger entropy change in the former complex formation.

Therefore, the result that the overall formation constants of IDA and Gly complexes are comparable with each other can be explained by the fact that the larger chelate effect in IDA complex is balanced by the stronger bonding force in the latter complex formation.

X-Ray Powder Diffraction Analysis. The results of X-ray powder diffraction analysis for the solid IDA complex, $K[Cr(ida)_2]\cdot 3H_2O$, are listed in Table 2, which shows that it is hexagonal with a tetramolecular unit having the axial parameters $a=14.57$ Å and $c=12.38$ Å.

The solid Asp complex, $K[Cr(OH)_2asp]$ was found to be amorphous by X-ray diffraction. When the complex stored over sulfuric acid in a desiccator was exposed to moist air, it gradually began to jump in the same fashion as chromium(III) phthalato[8] and maleato[9] complexes, which was attributed to the absorption of water vapor. The maximum amount of water vapor absorbed by the above chromium(III) aspartato complex was 13.00% for the dried sample. From this value, the solid complex formed by the absorption of water was presumed to have the formula $K[Cr(OH)_2asp]\cdot 2H_2O$, in which the calculated value of the amount of water absorbed is 13.67%.

Separation Factors for Several Lanthanon Pairs Obtained at 60°C in the Ion-Exchange System Involving EDTA

Zenzi HAGIWARA and Masaru NOGUCHI*1

Faculty of Engineering, Tohoku University, Aramaki, Sendai

(Received July 29, 1969)

With a view to the accurate determination of the separation factors of adjacent rare-earth pairs between the aqueous and resin phases, measurements have been carried out at 60°C in the exchange system involving EDTA and Dowex 50W, X-8, 50—100 mesh. Under the same experimental conditions as were used for the isolation of the rare earths by ion exchange, the separation factors at 60°C were found to be 3.43 for Nd-Sm, 1.37 for Eu-Gd, 1.84 for Tb-Y, 1.54 for Y-Dy, 2.83 for Tb-Dy, 1.84 for Dy-Ho, and 2.02 for the Ho-Er and Er-Tm pairs. Further, the observed values were discussed from the viewpoints of both thermodynamics and the real elution of the rare earths by an ion-exchange column.

The isolation of individual rare-earth elements has been intensively performed by the cation-exchange method,[1,2] employing either ethylenediamine-*N*,*N*,*N*′,*N*′-tetraacetic acid (EDTA, H_4Y) or *N*′-(2-hydroxyethyl)ethylenediamine-*N*,*N*,*N*′-triacetic acid(HEDTA) as the eluant. In this case, elutions[3,4] at high temperatures brought about a preferable result for the separation of some lanthanon mixtures as compared to those at lower temperatures. Generally, an increase in the elution temperature gives a larger separation factor (α) and a smaller H.E.T.P. (height equivalent to a theoretical plate)[5-7] due to particle or film diffusion. These two terms are related to the evaluation of column efficiency in the ion-exchange process. The present authors, however, found experimentally that, in the separation of the rare-earth mixture, an increase in the temperature is not always effective for the improvement of α-value for special rare-earth pairs in the presence of a chelating agent. Therefore, a basic study of the temperature dependence of the separation factor is important. In order to make a theoretical treatment of the elution system involving rare earths and EDTA species at a high temperature, it is necessary to get precise information on the separation factors of two adjacent rare earths obtained at the same teaperature as the elution.

Previously, the present authors reported on the separation factors[8] for such adjacent rare-earth pairs as Sm–Nd, Eu–Gd, Tb–Y, Y–Ho, and Er–Tm in the presence of EDTA at 30°C; considerable differences were observed between the calculated values and those determined by experiment. The present study was undertaken in order to find more reliable separation factors for some lanthanon pairs at 60°C, (such factors are necessary for the analysis of a real elution system at the same temperature) and to compare them with the values calculated from the thermodynamic data. Further, with the aid of the experimental results obtained by the ion-exchange elution of the rare earths at 60°C, we determined whether or not the observed α-values at 60°C are correct.

Experimental

Materials Used. The rare earths were supplied in the form of oxides, such as Nd_2O_3, Sm_2O_3, Eu_2O_3, Gd_2O_3, Tb_4O_7, Y_2O_3, Dy_2O_3, Ho_2O_3, Er_2O_3, and Tm_2O_3, by the Shinetsu Chemical Industry Corp.; they all had high purities, greater than 99.99%. Each oxide was dissolved with a slight excess of hydrochloric acid under heating, and the rare-earth ions were adsorbed on a resin of the hydrogen form to prepare the rare-earth form. The other chemicals used were of an analytical grade; a Dowex 50W, X-8, 50—100 mesh was employed as the cation exchanger.

Experimental Procedures. Using the column method, various rare-earth forms of resins containing small amounts of hydrogen and ammonium were prepared. These preparations[8] have previously been described. Thus, the description of the methods is omitted

here. Throughout the experiments, Dowex 50W, X-8, 50—100 mesh was used. The following resins and solutions were prepared for the experiments:

Composition for the Rare-earth Forms of Resins (equivalent fraction).

Sm-resin: $\overline{Sm}=0.8472$; $\overline{NH_4}=0.0547$; $\overline{H}=0.0981$.
Gd-resin: $\overline{Gd}=0.8784$; $\overline{NH_4}=0.0559$; $\overline{H}=0.0657$.
Y - resin: $\overline{Y}=0.9213$; $\overline{NH_4}=0.0312$; $\overline{H}=0.0475$.
Dy-resin: $\overline{Dy}=0.8778$; $\overline{NH_4}=0.0412$; $\overline{H}=0.0809$.
Ho-resin: $\overline{Ho}=0.8665$; $\overline{NH_4}=0.0343$; $\overline{H}=0.0991$.
Er-resin: $\overline{Er}=0.8924$; $\overline{NH_4}=0.0243$; $\overline{H}=0.0833$.
Tm-resin: $\overline{Tm}=0.9096$; $\overline{NH_4}=0.0121$; $\overline{H}=0.0782$.

Composition of the Rare-earth Solutions(mol/l)

Nd-soln.: $Y_f=0.00250$; $Nd_T=0.01374$; $NH_{4T}=0.00997$; pH=2.59.
Eu-soln.: $Y_f=0.00193$; $Eu_T=0.01461$; $NH_{4T}=0.00745$; pH=2.41.
Tb-soln.: $Y_f=0.00169$; $Tb_T=0.01440$; $NH_{4T}=0.00650$; pH=2.21.
Y-soln.: $Y_f=0.00023$; $Y_T=0.01331$; $NH_{4T}=0.00473$; pH=2.19.
Dy-soln.: $Y_f=0.00143$; $Dy_T=0.01487$; $NH_{4T}=0.00575$; pH=2.05.
Ho-soln.: $Y_f=0.00130$; $Ho_T;=0.01449$; $NH_{4T}=0.00503$; pH=2.13.
Er-soln.: $Y_f=0.00082$; $Er_T=0.01488$; $NH_{4T}=0.00353$; pH=2.00.

The barred quantities refer to the composition of the indicated species in the resin, and the subscript quantities, to the concentrations of the indicated species in the aqueous phase. Further, the symbol Y_f represents the excess of anionic species of EDTA present in the uncombined form with the rare earth. Therefore, the total concentration of EDTA is equal to the sum of Ln_T and Y_f, disregarding the presence of Ln^{3+} in the prepared rare-earth solutions. The resin and aqueous phases are expressed in the equivalent fraction and in moles per liter respectively.

Equilibrium Experiment. After mixing a definite amount of the prepared rare-earth resin containing small amounts of hydrogen and ammonium with a proper volume of the rare-earth solution, the resulting mixture was shaken for 96 hr in a constant-temperature bath kept at 60°C. After equilibration, the resin was separated from the aqueous phase, and the rare earths in both phases were determined in order to find the separation factor. The analytical procedures have been described in detail in the foregoing paper.[8]

Resutls and Discussion

The equilibrium compositions of the adjacent rare-earth pairs are listed in Table 1, in which the mole fraction is used as the concentration unit for the two phases. The observed α-values are also given in the same table; they are found from the relation:

$$\alpha_{Ln_2}^{Ln_1}=\left(\frac{m_{\overline{Ln_1}}}{m_{\overline{Ln_2}}}\right)\left(\frac{m_{Ln_2}}{m_{Ln_1}}\right) \quad (1)$$

where $m_{\overline{Ln_1}}+m_{\overline{Ln_2}}=1$ (resin phase) and $m_{Ln_1}+m_{Ln_2}=1$ (aqueous phase). The Ln_1 and Ln_2 symbols represent adjacent rare-earth elements, and m, the mole fraction. The barred quantities refer to the resin phase, and the unbarred, to the aqueous phase. The average values of the separation factors obtained at 60°C are tabulated in Table 2, in which the α-values calculated from the

calorimetric data[9] of the formation of the Ln-EDTA chelates and from the ratio of the stability constants[10-11] are also given. The α-values at 30°C are given as well in order to compare the values at different temperatures.

The α-values in the second column in Table 2 were calculated using Eq. (4), which will be given below. The following relationships held, employ-

9) J. L. Mackey, J. E. Powell and F. H. Spedding, *J. Amer. Chem. Soc.*, **84**, 2047 (1962).
10) G. Schwarzenbach, R. Gut and G. Anderegg, *Helv. Chim. Acta*, **37**, 937 (1954).
11) E. J. Wheelwright, F. H. Spedding and G. Schwarzenbach, *J. Amer. Chem. Soc.*, **75**, 4196 (1953).

ing the thermodynamic quantities ($\Delta H°$, $\Delta S°$, and $\Delta F°$):

$$\Delta F^{\circ}_{Ln_1} = -\boldsymbol{R}T \ln K_{Ln_1Y} = \Delta H^{\circ}_{Ln_1} - T\Delta S^{\circ}_{Ln_1} \quad (2)$$

$$\Delta F^{\circ}_{Ln_2} = -\boldsymbol{R}T \ln K_{Ln_2Y} = \Delta H^{\circ}_{Ln_2} - T\Delta S^{\circ}_{Ln_2} \quad (3)$$

The combination of the above equations leads to the following form:

$$\log \alpha^{Ln_1}_{Ln_2} = \log \frac{K_{Ln_2Y}}{K_{Ln_1Y}} = -\frac{(\Delta H^{\circ}_{Ln_2} - \Delta H^{\circ}_{Ln_1}) - T(\Delta S^{\circ}_{Ln_2} - \Delta S^{\circ}_{Ln_1})}{2.303\,\boldsymbol{R}T} \quad (4)$$

The α-values in the fourth column in Table 2 were calculated by means of the following relation[8]:

$$\alpha^{Ln_1}_{Ln_2} = \frac{K_{Ln_2Y}}{K_{Ln_1Y}} \quad (5)$$

As is shown in Table 2, the separation factors for the Nd-Pm and Pm-Sm pairs were calculated using a value of K_{PmY} found by interpolation of the data obtained by Mackey *et al.*[9] (Fig. 1).

In the present study, the temperature dependence of the separation factor is almost identical between the observed and calculated values except for the α-value for the Nd-Sm pair; the experimental results show that the effect of the temperature on α seems to be very small for such rare-earth pairs as Tb-Dy, Dy-Ho, Ho-Er, and Er-Tm. The α-values for the Dy-Ho, Ho-Er, and Er-Tm pairs obtained at 333°K are in good agreement with the calculated values obtained by introducing the thermodynamic data[9] into Eq.(4). On the other hand, the Er-Tm separation factor obtained at temperatures of 298 and 333°K by the use of Eq. (5) seems to be too high. A value of 2.83 for the Tb-Dy separation factor is indirectly found from the experimental data of 1.84 for α^{Tb}_{Y} and 1.54 for α^{Y}_{Dy}; this is consistent with the calculated value of 2.87 at 333°K.

The α^{Y}_{Dy} found at 303°K is too low compared to the value of 2.59 at 298°K obtained by using Eq. (4); the former is rather close to the value obtained from the ratio of the two stability constants of the Ln-EDTA chelates. Further, the observed Tb-Y separation factors at both temperatures show fairly large discrepancies from the calculated values.

As a result of the analysis of the elution behavior of the rare-earth mixture containing Tb, Y, and Dy, the value of α^{Tb}_{Y} and α^{Y}_{Dy} obtained in this study may be concluded to be reasonable. In the temperature range from 25 to 60°C, the elution sequence of these elements with a solution of 0.015 M EDTA buffered with NH_4OH (pH=8.5) is: Dy→Y→Tb. In the elution of a mixture involving Dy, Y, and Tb through a copper-retaining bed with the aid of 0.015 M EDTA (pH=8.5), the rare-earth band arrived at a steady-state condition after travelling for a proper distance on the column. In such a state, the Tb-Y cut at the tail of the adsorption band is obviously sharper than the Dy-Y cut at the front. In other words, the inherent overlap region with Tb and Y is actually less than that with Dy and Y, as is to be expected from a comparison of the H.E.T.P./log α term. This fact supports the observed α-values for these pairs.

Using 0.015 M EDTA (pH=8.5) as the eluant, the following two elution experiments were carried out at 60°C with a flow rate of 10 ml/min (I.D. 22 mm-column). In one of the experiments, the rare-earth-sorption band with an equimolar mixture of Tb and Y (bed dimensions: 2.2×35 cm) was eluted down the retaining bed with Dowex 50 W, X-8, 50—100 mesh (2.2×90 cm). In the other run, the rare-earth band with an equimolar mixture of Dy and Y (bed dimensions: 2.2×70 cm) was eluted down the retaining bed (2.2×180 cm). In both runs, the length of the retaining bed is enough for the steady state to be attained during elution. The rare-earth eluates issuing from the column were analyzed to observe the change in the composition of the overlap region of the rare-earth band.

After a steady state had been established throughout the elution system by the displacement of the rare-earth band, the overlapping area with the two rare-earth components was fixed to a definite composition gradient; the shape of the boundary is independent of further elution distance. In this case, the following relationship[12] finally holds, if the ion exchange is regarded a countercurrent extraction: $\log R_n/R = n \log \alpha = (\log \alpha/\text{H.E.T.P.})L$, where L is the distance between the two points on the resin; n, the number of theoretical plates, and α and R, the separation factor for the adjacent rare earths and their molar ratio respectively. Thus, the plateheight value can be found from the above relationship. Under the previously-described conditions, the H.E.T.P.-values are found to be 1.2 cm for the elution of the Tb-Y mixture and 2.0 cm for the elution of the Dy-Y mixture.

The length of the overlap region with 99.9% pure adjacent Ln_1 and Ln_2 products can be calculated from this relation:

$$L = \frac{6(\text{H.E.T.P.})}{\log \alpha} \quad (6)$$

where the value of 6 as $\log R_n/R$ is found for the above conditions. Therefore, if any pure product is desired, it is necessary for the length of a sorption band of the rare earth in the column to exceed L. Taking H.E.T.P.=1.2 cm and $\alpha^{Tb}_{Y}=1.84$ at 60°C for the Tb-Y pair, L is equal to 27 cm, while a value of 28 cm was experimentally obtained. A good agreement is seen between them. In the case of the Dy-Y pair, taking H.E.T.P.=2.0 cm

12) J. E. Powell and H. R. Burrholder, *J. Chromatogr.*, **29**, 210 (1967).

and $\alpha_Y^{Dy}=1.54$ at 60°C, L is equal to 64 cm; this is near the observed value of 65 cm. In both calculations, the α-value was assumed to be constant throughout the whole mixed zone with rare earths.

One of the present authors deduced the following relationship[4] for film-diffusion control in ion exchange:

$$Z(X_{Ln_2}) = H_f\left\{-\frac{\alpha}{\alpha-1}\ln X_{Ln_2} + \frac{1}{\alpha-1}\ln(1-X_{Ln_2}) - 1\right\} \quad (7)$$

where $Z(X_{Ln_2})$ is the distance of the plane with the concentration of X_{Ln_2} from the gravity center of the rare-earth boundary involving Ln_1 and Ln_2, where α is the separation factor, and where H_f is the plate-height value due to film diffusion. The X_{Ln_2} symbol is expressed in the concentration unit of the equivalent fraction of the Ln_2 species, while both Z and H_f are expressed in centimeters. As Z is a function of X_{Ln_2}, the length of the rare-earth band required to get 99.9% pure products in a steady state can be calculated. The substitution of $\alpha_Y^{Tb}=1.84$ into Eq. (7) gives:

$$Z(X_{Tb}) = H_f\{-5.04\log X_{Tb} + 2.74\log(1-X_{Tb}) - 1\} \quad (8)$$

Therefore, we obtain:

$$Z_1(X_{Tb}) = -9.22\,H_f \text{ at } X_{Tb}=0.999$$

$$Z_2(X_{Tb}) = 14.12\,H_f \text{ at } X_{Tb}=0.001$$

Thus, the length of the overlap region necessary for obtaining 99.9% Tb and Y products can be found by adding the absolute values of Z_1 and Z_2 at $H_f=1.2$ cm:*2

$$L = |Z_1| + |Z_2| = 28 \text{ cm}$$

In the elution of the Y-Dy pair, when $\alpha_{Dy}^{Y}=1.54$ and $H_f=2.0$*2 are introduced into Eq. (7), the length of the band required to get 99.9% Y and Dy products is found to be 65 cm; this value is in excellent agreement with the value obtained in the elution experiments at a steady state. Therefore, it can be concluded that the α-values obtained for the Y-Dy and Tb-Y pairs in the exchange system with EDTA are satisfactory.

On the other hand, an increase in the temperature effects an increase in the Eu-Gd separation factor, as may be seen in Table 2. The α-value at 60°C was 1.37 in the presence of EDTA; this was lower than the value calculated from Eq. (4), while a vlue of 1.5 was obtained for the pair at 92°C by another study.[12] Considering the variation in α with the temperature, the observed value of 1.37 seems to be reasonable.

*2 The H_f-values were found graphically by a curve-fitting method described in a previous paper.[4]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 406—408 (1970)

Cobalt(III) Complexes with Schiff Bases Obtained from Salicylaldehyde Derivatives and Alkanol Amines*[1]

Shoichiro YAMADA,* Yoshio KUGE** and Kuniko YAMANOUCHI*

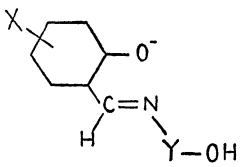
* *Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka*

** *Public Health Institute, Morimachi, Higashi-ku, Osaka*

(Received July 31, 1969)

Cobalt(III) complexes with Schiff bases (X-SAL.Y-OH) obtained from salicylaldehyde derivatives and alkanol amines ($H_2N.Y$-OH) were synthesized as crystals. Two types of diamagnetic cobalt(III) complexes were obtained, one being green (type A) and the other red (type B). In the complexes of type A with the general formula [Co(H-SAL.R)$_3$], where R=$CH_2CH_2CH_2OH$ and $CH_2CH_2CH_2OCH_3$, the ligands are considered to function as bidentate ligands, the terminal hydroxyl or methoxy groups not being bound with the cobalt(III) ion. In the complexes of type B with the general formula Co(X-SAL.Y-OH)(X-SAL.Y-O), where X=H and 3-CH_3O, and Y=CH_2CH_2, $CH_2CH(CH_3)$ and $C(CH_3)_2CH_2$, the ligands function as terdentate ligands.

In previous papers[1-3] we reported nickel(II) and copper(II) complexes with Schiff bases obtained from salicylaldehyde derivatives and alkanol amines (formula I), and disclosed that the behaviour of the alcoholic hydroxyl group varies depending



Formula I

upon the kind of the central metal ions on the one hand and upon the nature of the ligands on the other. In this connection, it seems worthwhile to examine the corresponding complexes with other metal ions and to compare the results with the previous ones. The present paper deals with cobalt(III) complexes with the ligands denoted by formula I.

Experimental

Materials. The cobalt(III) complexes, which are shown in Table 1, were prepared according to the following three methods, (1) from cobalt(II) acetate, (2) from bis(salicylaldehydato)- or bis(substituted salicylaldehydato)-cobalt(II) and an alkanol amine, and (3) from cobalt(II) acetate and a Schiff base. These methods are similar to those previously described.[4,5] In methods (1) and (3), sodium carbonate or sodium ethanolate was added to the reaction mixture. Purification was carried out by recrystallizing the crude products from suitable organic solvents like methanol, ethanol or chloroform.

The complexes of the [Co(H-SAL.R)$_3$] type (type A), obtained as dark-green crystals, are insoluble in water but soluble in methanol, ethanol, chloroform, benzene and pyridine.

The complexes of the Co(X-SAL.Y-OH)(X-SAL.-Y-O) type (type B), obtained as red or brownish red crystals, are insoluble in water, slightly soluble in chloroform and benzene, and souble in methanol and ethanol. The solubility in any of these solvents is not high enough to allow any determination of the molecular weights of these complexes.

Analytical data of these complexes are shown in Table 1.

Measurements. Electronic absorption spectra were determined with a Shimadzu MPS-50L spectrophotometer and a Shimadzu QR-50 spectrophotometer. Infrared spectra were determined with a Hitachi-EPI-2 IR-spectrophotometer.

The diamagnetism of the complexes was detected by the Gouy method.

Results and Discussion

Two types of complexes were obtained with the ligands of formula I, one being green (type A) and the other red (type B). Since both these complexes

* With two water molecules of crystallization
** With three water molecules of crystallization
*** With one water molecule of crystallization

are diamagnetic, they are concluded to be cobalt(III) complexes of a low-spin type. It is well known that cobalt(III) (d^6) complexes of a low-spin type usually have an octahedral configuration.

The electronic spectra of these complexes are shown in Fig. 1. The spectra of the complexes of type A are very similar to those of Co(H-SAL.-alkyl)$_3$.[4,6,7] The close similarity in the spectra indicates that these green complexes (type A) may take a configuration similar to that of the Co(H-SAL.-alkyl)$_3$ type, namely a *mer*-configuration.[8]

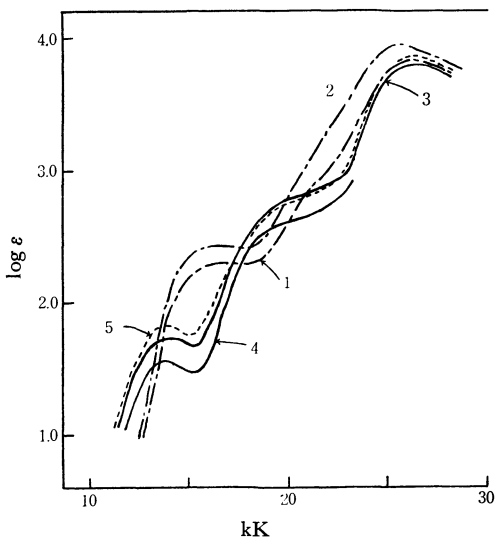

Fig. 1. Electronic absorption spectra of Co(H-SAL.R)$_3$ (type A) and Co(H-SAL.Y-O) (H-SAL.Y-OH) (type B): 1, R=$CH_2CH_2CH_2OH$ (type A), in ethanol; 2, R=*n*-C_3H_7 (type A), in ethanol; 3, Y=$C(CH_3)_2CH_2$ (type B), in methanol; 4, Y=$C(CH_3)_2CH_2$ (type B), in the solid state (by reflectance); 5, Y=$CH_2CH(CH_3)$ (type B), in chloroform.

Their spectra in pyridine are nearly the same as those in non-donor solvents, showing that the configuration of the complexes in non-donor solvents is retained, when dissolved in pyridine. It is thus found that the ligands H-SAL.R function as bidentate ligands in the complexes of type A, the terminal hydroxyl and the methoxy group not being bound with cobalt(III) ion. Inspection of the steric condition shows that the hydroxyl group at the γ-position may not be as favorable as that at the β-position, as in the complexes of the B-type, for coordination with the central metal ion.[1,4,5] It is known that the coordinating ability of the methoxy group is much lower than that of the hydroxyl group.

The red cobalt(III) complexes of type B may be formulated as Co(X-SAL.Y-O)(X-SAL.Y-OH), where Y denotes CH_2CH_2, $CH_2CH(CH_3)$ and $C(CH_3)_2CH_2$ for X=H and 3-CH_3O. The presence of the ligand X-SAL.Y-OH in these complexes is supported by infrared spectra, which have absorption peaks at about 3000 to 3500 cm^{-1} due to the hydroxyl group.*2 The electronic absorption spectra of all the complexes of type B in solution or in the solid state (Fig. 1) are similar to each other, showing that these cobalt(III) complexes have a similar configuration, and that the configuration in the solid state is retained in solution. It should be noted that the main features of these spectra, with absorption maxima at about 14 kK (log ε 1.5—2.0), about 20 kK (log ε 2.5—3.0) and about 26.5 kK (log ε 3.7—4.0), are remarkably similar to those of bis[2-(salicylideneamino)alkanoato]cobaltate(III) complexes, which show absorption maxima at 15.0 kK (log ε 1.95), 19.8 kK (log ε 2.75) and 26.5 kK (log ε 3.7)[9]. It seems, therefore, very likely that the red complexes of type B have a configuration similar to that of the bis[2-(salicylideneamino)alkanoato]-complexes, which were

concluded previously to be uninuclear, octahedral cobalt(III) complexes.[9] Thus, in the complexes of type B, the ligands are found to act as terdentate ligands.

For coordination compounds of type $M(ABC)_2$, many isomers are possible, where the notation ABC denotes a terdentate ligand bearing three different ligating atoms. It is to be noted that the *d-d* band maxima at the lowest frequencies of the complexes of type B lie at remarkably low frequencies (about 14.0 kK), as compared with those of the complexes of the $[Co(X\text{-}SAL.alkyl)_3]$ type (about 16.1 kK). It is expected that the complexes of the *trans*-$[Co(N)_2(O)_4]$ type may show remarkable splitting of the *d-d* band, and the splitted component might appear in the region of considerably low frequencies. The arrangement of the ligand atoms shown in Fig. 2(a) or (b) is highly probable for the structure of the complexes of type B, since such a configuration would yield a *d-d* band maximum at the lowest frequency. However, it is not possible at the present stage to draw a definite conclusion about the precise configuration. Another possibility like a binuclear configuration might not be completely excluded. The low solubility of the complexes of type B did not allow any determination of molecular weight.

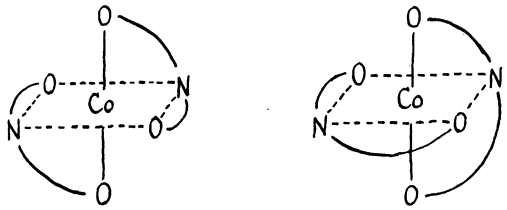

Fig. 2. Proposed configurations for Co(X-SAL.-Y-O)(X-SAL.Y-OH).

It has thus been revealed that all the cobalt(III) complexes obtained are octahedral, six-coordinated. This result, which is different from that for the corresponding nickel(II) and copper(II) complexes,[1,2] is in agreement with the general tendency of cobalt(III) to form much more stable, octahedral complexes as compared with nickel(II) or copper(II).

Financial support of this work by the Ministry of Education is gratefully acknowledged.

*2 It is probable that the hydroxyl group forms a hydrogen bond with an oxygen atom of the neighbouring ligand. More detailed study was not carried out.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 409—414 (1970)

Metal(II) Complexes of Ethylenediaminemonoacetic Acid (EDMA). Polarographic Studies of Cadmium(II) and Lead(II)-EDMA Complexes

Yuki FUJII, Teiko UEDA and Mutsuo KODAMA

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received August 2, 1969)

In the present paper, the d.c. polarographic behavior of cadmium(II) and lead(II) ions in ethylenediaminemonoacetate (EDMA) solutions was studied systematically. Since these metal(II) ions in an EDMA solution behave reversibly in a polarographic electrolysis, the compositions and the stability constants of cadmium(II)- and lead(II)-EDMA complexes could be estimated successfully from the shift of the half-wave potential of these metal(II) ions due to the complex formation with EDMA. The cadmium(II) ion was found to form complexes of 1-to-1 and 1-to-2 compositions with EDMA, and the electrode reaction mechanism was established to be:

$$CdX^+ + 2e^- + nH^+ + Hg = Cd(Hg) + H_nX^{n-1}$$
$$\uparrow\downarrow$$
$$CdX_2$$

The successive formation constants of cadmium(II)-EDMA complexes, $(K_1)_{CdX}$ and $(K_2)_{CdX}$, were determined to be 3.01×10^8 and 5.65×10^4 respectively. On the other hand, the lead(II) ion forms only one complex with 1-to-1 composition. In the presence of the chloride ion, the lead(II) ion was found to form a mixed ligand complex involving the chloride ion as well as a normal complex, PbX^+, and the electrode reaction could be formulated as:

$$PbX^+ + 2e^- + nH^+ + Hg = Pb(Hg) + H_nX^{n-1}$$
$$\uparrow\downarrow$$
$$PbXCl^0$$

The equilibrium constants, $(K_1)_{PbX}(=[PbX^+]/([Pb^{2+}]\cdot[[X^-]))$ and $K^{Cl}_{PbX}(=[PbXCl^0]/([PbX^+]\cdot[Cl^-]))$, were determined to be 1.69×10^8 and 1.01×10 respectively. The effect of the zinc(II) ion on the half-wave potential of the cadmium(II) ion in an EDMA solution was also studied. From the positive shift of the half-wave potential due to the presence of the zinc(II) ion, the formation constant of the zinc(II)-EDMA complex with a 1-to-1 composition was estimated to be 1.58×10^8.

Polarographic studies have been made extensively by numerous investigators on the metal complexes of aminopolycarboxylic acids.[1-4] Generally, it has been accepted that cadmium(II) and lead(II) complexes of aminopolycarboxylic acids which have acetic acid groups behave irreversibly in a polarographic electrolysis.[1-3,5] In a previous paper,[6] we ourselves reported that although ethylenediaminetetrapropionic acid (EDTP) has four carboxylate groups and two amino groups, the cadmium(II) ion forms complexes of 1-to-1 and 1-to-2 compositions with EDTP and undergoes a reversible two-electron reduction at the dropping mercury electrode. The formation of the cadmium(II)-EDTP complex with a 1-to-2 composition may indicate that only one propionate group and two amino groups of EDTP anion act as the electron-donating groups in the complex formation reaction with the cadmium(II) ion. Whether or not the reversible nature of the cadmium(II)-EDTP complex can be related to its characteristic structure seems to be very interesting. Therefore, to get much fuller and more accurate information about the above subject, we tried to study the polarographic behavior of the cadmium(II) ion in an ethylenediaminemonoacetic acid (EDMA) which has only one acetate group and compared it with that in the EDTP solution. This attempt was also important in establishing a precise description of the properties of EDMA as a ligand. In this paper, we studied thoroughly the d.c. polarographic

behavior of cadmium(II) and lead(II) ions in the EDMA and determined the solution equilibria between EDMA and these ions. The effect of the zinc(II) ion on the polarographic behavior of the cadmium(II) ion in the EDMA solution was also investigated.

Experimental

Reagents. All the chemicals were of an analytical reagent grade and were used without further purification. The standard solution of cadmium(II) perchlorate was prepared by dissolving pure metallic cadmium in perchloric acid (1+2). Its concentration was determined by EDTA titration, using Eriochrom Black T as the indicator.[7] The methods of the preparation and standardization of the zinc(II) perchlorate solution have been given previously.[8] The standard solution of lead(II) nitrate was prepared by dissolving a known amount of lead nitrate in redistilled water. The preparation and purification of EDMA dihydrochloride were also described in a previous paper.[9]

Apparatus and Experimental Procedures. All the apparatus (polarographs and a glass electrode pH meter) and the experimental procedures employed have been described previously.[4] The rate of the flow of mercury, m, and the drop time, t_d, of the dropping mercury electrode used in the present study were 0.839 mg/sec and 3.92 sec respectively at a mercury height of 60 cm in an air-free 0.10 M acetate buffer solution (μ=0.20) of pH 4.80 at 0.0 V *vs.* SCE.

Results and Discussion

D. C. Polarographic Behavior of the Cadmium(II) Ion in an Ethylenediaminomonoacetate Solution. The polarographic behavior of the cadmium(II) ion in an EDMA solution with an ionic strength of 0.20 was studied in the pH range from 6.00 to 7.00. In this study, no buffer reagent was used, because the sample solutions always contained a large excess of uncomplexed EDMA and had enough buffer capacity to maintain the pH value of the solution constant. Under the above pH conditions, the cadmium(II) ion in the EDMA solution invariably gave a single well-difined polarographic wave (Fig. 1). Although the results are not given here, its wave height was exactly proportional to the square-root of the effective mercury pressure on the dropping mercury electrode and to the bulk concentration of the cadmium(II) ion. The log-plot analysis of the polarogram gave linear relations with reciprocal slopes falling into the range from 33 to 37 mV. The results will not be shown here. From the above experimental facts, it can be concluded that the

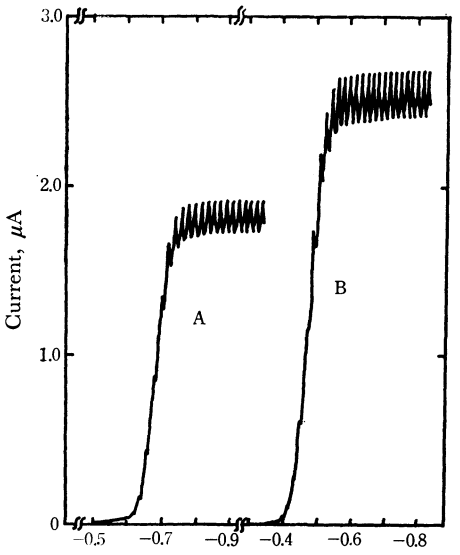

Fig. 1. D.C. polarograms of cadmium(II) and lead(II) ions in the EDMA solution.
A: Concentration of cadmium(II) ion=0.371 mM
Concentration of uncomplexed EDMA=20.0 mM
Concentration of chloride ion=40.0 mM
25°C, μ=0.20, pH=6.95
B: Concentration of lead(II) ion=0.50 mM
Concentration of uncomplexed EDMA =15.0 mM
Concentration of chloride ion=60.0 mM
25°C, μ=0.20, pH=6.45

cadmium(II) ion in the EDMA solution undergoes a two-electron reversible reduction at the mercury electrode. Therefore, the solution equilibria between the cadmium(II) ion and EDMA could be determined successfully by the conventional polarographic method employed previously.[6,10-12] As was mentioned in a previous paper,[4] an EDMA anion X^- can be effected to act as a tridentate ligand. Hence, the cadmium(II) ion will also form complexes with 1-to-1 and 1-to-2 compositions, CdX^+ and CdX_2^0. If both 1-to-1 and 1-to-2 complexes are formed, the electrode reaction of the cadmium(II) ion in the EDMA solution at the DME can be assumed to be:

$$\begin{array}{l} CdX^+ + 2e^- + nH^+ + Hg = Cd(Hg) + H_nX^{n-1} \\ \quad\Updownarrow \\ CdX_2^0 \end{array} \qquad (1)$$

where H_nX^{n-1} indicates protonated EDMA species.

Consequently, as was discussed in connection with the d.c. polarography of the copper(II) ion in an EDMA solution,[4] the shift of the half-wave potential of the cadmium(II) ion due to the complex formation with EDMA can be derived thermodynamically as:

$$\Delta E_{1/2} = (E_{1/2})_{Cd^{2+}} - (E_{1/2})_{CdX} = 0.0296\left[\log\left(\frac{(K_1)_{CdX}}{(\alpha_H)_X}\cdot[X]_f + \frac{(K_1)_{CdX}(K_2)_{CdX}}{(\alpha_H)_X^2}\right)\cdot[X]_f^2 + \log\frac{k_{CdX}}{k_{Cd^{2+}}}\right] \quad (2)$$

where $(E_{1/2})_{CdX}$, $(E_{1/2})_{Cd^{2+}}$, $k_{Cd^{2+}}$, k_{CdX} and $(\alpha_H)_X$ have their usual meanings.[13] $[X]_f$ and (K_i) in Eq. (2) denote the concentration of uncomplexed EDMA and the successive formation constants of cadmium(II)-EDMA complexes.

Equation (2) clearly indicates that when solution's pH is kept constant, the plot of antilog $(\Delta E_{1/2}/0.0296+\log(k_{Cd^{2+}}/k_{CdX}))/[X]_f$ against $[X]_f$ will give a linear relation the slope and the intercept of which will correspond to $(K_1)_{CdX}(K_2)_{CdX}/(\alpha_H)_X^2$ and $(K_1)_{CdX}/(\alpha_H)_X$ respectively. This relation was examined experimentally at pH 6.95. A typical linear relation is shown in Fig. 2. From the intercept and the slope of the linear relation in Fig. 2, the $(K_1)_{CdX}$ and $(K_2)_{CdX}$ values were estimated to be 3.01×10^8 and 5.65×10^4 respectively. The formation of a mixed ligand complex involving the chloride ion could be ruled out, because when the other experimental conditions were kept constant, the half-wave potential was independent of the chloride-ion concentration. If the above conclusion is correct, the dependence of the half-wave potential on the solution pH can be estimated exactly with the aid of Eq. (2) and using the $(K_1)_{CdX}$ and $(K_2)_{CdX}$ values determined. The pH dependence of the half-wave potential was calculated and compared with that observed experimentally (Table 1). The agreement of the caluculated values with those determined experimentally can be regarded as satisfactory. This agreement clearly gives strong support to the electrode reaction mechanism proposed by the present authors.

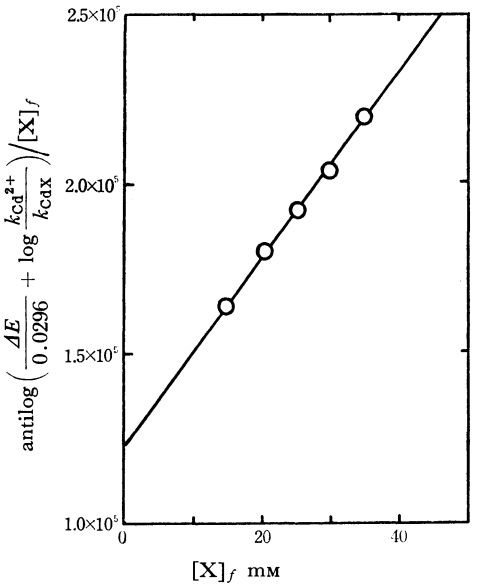

Fig. 2. Determination of successive formation constants of cadium(II)-EDMA complexes. Concentration of cadmium(II) ion=0.371 mM 25°C, μ=0.20, pH=6.95

Table 1. The effect of pH on the half-wave potential

μ=0.20, 25°C
Concentration of cadmium(II) ion=0.371 mM
Concentration of uncomplexed EDMA=20.0 mM

pH	Half-wave potential V *vs.* SCE	$\Delta E_{1/2}$, mV Obsd	$\Delta E_{1/2}$, mV Calcd
6.00	-0.603_0	0	0
6.41	-0.626_5	$23._5$	21.8
6.94	-0.665_0	$62._0$	56.0

The effect of the zinc(II) ion on the half-wave potential of the cadmium(II) ion in the EDMA solution was also studied. The cadmium(II) ion in the EDMA solution containing the zinc(II) ion was also found to behave reversibly in a polarographic sense. The log-plot examination at pH's lower than 7.5 gave linear relations with reciprocal solpes falling in the rang from 30 to 33 mV. The results are not shown here. When the total concentration of the zinc(II) ion added, $[Zn(II)]_t$, is larger than that of EDMA, $[X]_t$, and when all the EDMA species in the solution exist in the form of ZnX^+, the concentration of the uncomplexed cadmium(II) ion can be given by:

$$[Cd^{2+}] = \frac{[Cd(II)]_t}{1+\frac{(K_1)_{CdX}}{(K_1)_{ZnX}}\frac{[ZnX^+]}{[Zn^{2+}]}} \quad (3)$$

where $[Cd(II)]_t$ is the total concentration of the cadmium(II) ion and where $(K_1)_{ZnX}$ is the formation constant of ZnX^+. Therefore, the half-wave potential of the cadmium(II) ion in the solution containing an excess of the zinc(II) ion over EDMA can be expressed as:

$$E_{1/2} = E_{Cd^0} + 0.0296\left[\log\frac{k_{Cd(Hg)}}{k_{Cd^{2+}}} + \log\left(1+\frac{(K_1)_{CdX}}{(K_1)_{ZnX}}\frac{[X]_t}{[Zn(II)]_t-[X]_t}\right) - \log f_{Cd^{2+}}\right] \quad (4)$$

The symbols used in Eq. (4) have their usual meanings.[6] Hence, the difference in the half-wave potential between the cadmium(II) aquo

complex and the cadmium(II) ion in the solution containing EDMA and the zinc(II) ion can be given approximately by:

$$\Delta E_{1/2} = 0.0296\left[\log\left(1+\frac{(K_1)_{CdX}}{(K_1)_{ZnX}}\frac{[X]_t}{[Zn(II)]_t-[X]_t}\right)\right] \quad (5)$$

This relation clearly indicates that the plot of anti log ($\Delta E_{1/2}$/0.0296) *vs.* $[X]_t/([Zn(II)]_t-[X]_t)$ should give the linear relation with an intercept of unity. This relation was examined experimentally on the solution of pH 6.00. A linear relation could be obtained between the antilog ($\Delta E_{1/2}$/0.0296) and $[X]_t/([Zn(II)]-[X]_t)$. A typical linear relation is shown in Fig. 3. This fact clearly indicates that, in the presence of an excess amount of the zinc(II) ion, the EDMA species exists exclusively in the form of ZnX^+. From the slope of the above linear relation, $(K_1)_{ZnX}$ was estimated to be 1.58×10^8. This value seems reasonable, for the stability constants of zinc(II) complexes of polyamines and aminopolycarboxylic acids have been reported to be nearly identical with those of corresponding cadmium(II) complexes.[13]

D. C. Polarographic Behavior of the Lead(II) Ion in an EDMA Solution. The d.c. polarographic behavior of the lead(II) ion in an EDMA solution was also studied in the pH range from 6.50 to 8.50. The lead(II) ions in the EDMA solution also gave a well-defined single wave (Fig. 1), the height of which was exactly proportional to the square-root of the effective pressure on the DME and to the bulk lead(II) ion concentration. Under the present experimental conditions, the log-plot examination invariably gave linear relations with reciprocal slopes falling into the range from 30 to 33 mV. Therefore, the lead(II) ions in the EDMA solution can also be concluded to undergo a two-electron reversible reduction. The lead(II) ion has been reported to form only the complex of a 1-to-1 composition with nitrilotriacetic acid (NTA).[13] This fact clearly indicates that the coordination number of the lead(II) ion is four under the usual experimental conditions. For this reason, in the presence of the chloride ion, the lead(II) ion can be expected to form a normal complex with a 1-to-1 composition, PbX^+, and a mixed ligand complex involving the chloride ion, $PbXCl^0$, with EDMA. If the lead(II) ion in the EDMA solution containing the chloride ion form a mixed ligand complex as well as a normal complex, the electrode reaction of the lead(II) ion at the mercury electrode can be assumed to be:

$$\begin{array}{l} PbX^+ + 2e^- + nH^+ + Hg = Pb(Hg) + H_nX^{n-1} \quad (6) \\ \quad\Updownarrow \\ PbXCl^0 \end{array}$$

Consequently, the shift of the half-wave potential of the lead(II) ion due to the complex formation with EDMA can be given by:

$$\Delta E_{1/2} = 0.0296\left[\log\frac{(K_1)_{PdX}}{(\alpha_H)_X}(1+K^{Cl}_{PbX}[Cl^-]) + \log[X]_f + \log\frac{k_{PbX}}{k_{Pb^{2+}}}\right] \quad (7)$$

where $k_{Pb^{2+}}$ and k_{PbX} are the diffusion current constants of the lead(II)-aquo and -EDMA complexes respectively, and where $(K_1)_{PbX}$ and K^{Cl}_{PbX} are defined thusly: $(K_1)_{PbX}=[PbX^+]/[Pb^{2+}]\cdot[X^-]$ and $K^{Cl}_{PbX}=[PbXCl^0]/[PbX^+]\cdot[Cl^-]$.

Equation (7) clearly indicates that, if the mixed ligand complex, $PbXCl^0$, is also formed, the plot of the anitilog($\Delta E_{1/2}$/0.0296+log $k_{Pb^{2+}}/k_{PbX}$−log $[X]_f$) against the concentration of the uncomplexed chloride ion, $[Cl^-]$, should give a linear relation when the other experimental conditions are kept constant. This relation was examined experimentally on the solution of pH 6.45. A linear relation was found between the antilog[$\Delta E_{1/2}$/0.0296+log $k_{Pb^{2+}}/k_{PbX}$−log$[X]_f$] and $[Cl^-]$ (Fig. 4). From the slope and the intercept of the above linear relation, the K^{Cl}_{PbX} and $(K_1)_{PbX}$ values were estimated to be 1.08×10 and 1.69×10^8 respectively.

Equation (7) also shows that when the other experimental conditions are kept constant, the following relation should hold between the shift of the half-wave potential and log $(\alpha_H)_X$:

$$\frac{\Delta E_{1/2}}{\Delta\log(\alpha_H)_X} = 29.6\text{ mV} \quad (8)$$

This relation was also examined experimentally. The results are given in Table 2. The shift of the half-wave potential calculated with the aid of Eq. (8) agreed well with that observed. Using the

Concentration of lead(II) ion=0.50 mM
25°C, μ=0.20, pH=6.45

K^{Cl}_{PbX} value determined, the effect of the concentration of the uncomplexed EDMA on the half-wave potential of the lead(II) ion was also studied. Equation (7) shows that when the solution pH is kept constant, the plot of $\Delta E_{1/2}-0.0296$ log $(1+K^{Cl}_{PbX}\times[Cl^-])$ against log $[X]_f$ should give a linear relation. This was also examined satisfactorily. The results obtained are shown in Fig. 5. From the above results and discussion, it can safely be concluded that, under the present experimental conditions, the lead(II) ion forms PbX^+ and $PbXCl^0$ and the electrode reaction mechanism of the lead(II) ion in an EDMA solution can be given by Eq. (6).

As has been stated above, both cadmium(II) complexes of EDTP and EDMA undergo a reversible two-electron reduction at the dropping mercury electrode. The former complex may contain two six-membered rings involving a metal-oxygen bond, while the latter may contain two five-membered rings involving a metal-oxygen bond. Therefore, the reversible behavior of the cadmium(II)-EDTP complex can hardly be ascribed to the structure of EDTP, in which all acetate groups of ethylenediaminetetraacetate are replaced by propionate groups to give terminal rings of six rather than five members. It should also be mentioned here that cadmium(II)-aminopolycarboxylate complexes which have larger stability constants behave irreversibly, whereas those which have smaller stability constants behave reversibly. Generally, the larger stability constant is considered to correspond to the greater affinity of the ligand for the metal ion. The greater affinity for the metal ion will, then, produce the more pronounced change in the electronic structure of the metal ion. On the basis of the above discussion, the cadmium(II) ion in the EDTP and EDMA complexes may be said to have an electronic structure not significantly different from that of the cadmium(II) aquo complex, which undergoes a typical reversible reduction. This may also account for the reversible behavior of the cadmium(II)-EDTP and -EDMA complexes.

Since the cadmium(II) ion can form complexes

of a 1-to-2 composition with EDTP and EDMA, in both cadmium(II) complexes two ligands are considered to be attached to each cadmium(II) ion with four nitrogens and two oxygens. Considering the well-known fact that the cadmium(II)-amine complex behaves reversibly in a polarographic electrolysis,[14] this may mean that the nature and the number of donor atoms also play an important role in the determination of the polarographic behavior of cadmium(II)-aminopolycarboxylate complexes. In order to describe the precise relation between the polarographic behavior of the cadmium(II)-aminopolycarboxylate complex and its structure, however, further systematic investigations should be conducted.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 414—418 (1970)

Preparation of Chromium(III) and Cobalt(III) Complexes with *l*-Leucine-*N*,*N*-diacetic Acid*[1]

Akira UEHARA, Eishin KYUNO and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received August 7, 1969)

l-Leucine-*N*,*N*-diacetic acid (abbreviated as LDA) and the complexes thereof were prepared as follows: $K[Cr(OH)(lda)(H_2O)]\cdot 3H_2O$ (violet) (I), $[Cr(lda)(H_2O)_2]$ (bluish violet) (II), $[Cr(lda)(H_2O)_2]\cdot 2H_2O$ (grayish violet) (III), $(enH_2)_{1/2}[Cr(OH)(lda)(H_2O)_2]$ (green) (IV), $[Cr(lda)(o\text{-phen})]\cdot 2H_2O$ (brownish orange) (V), $K[Cr(lda)(acac)]\cdot H_2O$ (blackish violet) (VI) and $K[Co(OH)(lda)(H_2O)]\cdot H_2O$ (bluish violet) (VII), where lda, en, *o*-phen and acac are the abbreviations of *l*-leucine-*N*,*N*-diacetate ion, ethylenediamine, *o*-phenanthroline and acetylacetonate ion, respectively. Except for Complex IV, LDA behaves as a quadridentate ligand. In Complex IV, it acts as a terdentate one. It was found from electronic absorption spectra that in Complex I, LDA behaves as a quadridentate in a solid state and as a terdentate ligand in an aqueous solution, whereas in cobalt(III) complex VII corresponding to I, LDA behaves as a quadridentate. Stepwise liberation of the coordinated water molecules in Complexes II and III could be detected by means of Derivatograph. Complex VII showed "Dehydration-Dimerization Reaction" upon being heated.

Preparation and properties of chromium(III) complexes with ammoniatriacetic acid (ATA) or with its derivatives have been reported.[1-5] Although these agents have a maximum of four coordinating sites, the coordinating behaviors somewhat differ from each other due to the slight differences in their structures and chemical properties. As an example, the ligands which can form three five-membered chelate rings such as ATA or AIPDA act not only as a quadridentate of $N\text{–}O_3$ type but also as a terdentate ligand of O_3 type.[1,4] ATA, APDA and AEDA can also behave as a terdentate ligand of $N\text{–}O_2$ type.[1,3,5] In spite of the analogous structure of APDA and AEDA, the latter behaves with difficulty as a quadridentate due to the weaker coordinating ability of oxygen atom in the sulfonic than that in carboxylic group.

In a series of studies on chromium(III) and cobalt(III) complexes with ATA and its derivatives, the preparation of *l*-leucine-*N*,*N*-diacetic acid and the complexes thereof were undertaken in order to investigate how LDA behaves toward the two metals.

For the sake of convenience, the rational formula of LDA is given in Table 1 with respect to ATA as the mother chelating agent and the other related agents.[1,3,5]

Experimental

Preparation of *l*-Leucine-*N*,*N*-diacetic Acid, $C_{10}H_{17}O_6N$. Thirteen grams of *l*-leucine was dissolved in 50 m*l* of water containing 6 g of sodium hydroxide

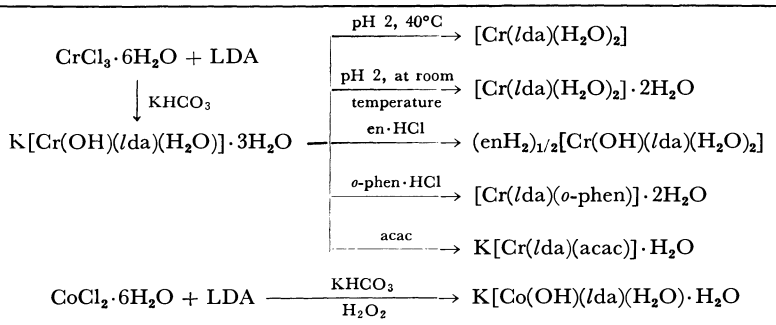
Table 2. Preparative scheme for Cr-, Co-LDA complexes



(A). 70 m*l* of water containing 19 g of monochloroacetic acid was gradually neutralized with 17 g of sodium hydrogen carbonate (B). B had to be added gradually to A since rapid addition produces deposit of *l*-leucine. The mixture was heated on a water bath, 30 m*l* of water containing 12 g of KOH being added. Heating was continued for about 1 hr till the condensation reaction was completed. After the solution was cooled, concentrated hydrochloric acid was added little by little to the solution with scrubbing of the wall of the reaction vessel with a glass rod, when white powdered crystals were deposited. Recrystallization was achieved by dissolving the crude products in sodium hydrogen carbonate solution and by adjusting the pH of the solution to 3. Yield about 8 g.

Found: N, 5.66; 48.49; H, 6.86%. Calcd for $C_{10}H_{17}O_6N$: N, 5.63; C, 48.57; H, 6.92%.

Preparation of Complexes. Preparation of the complexes is schematically shown in Table 2.

Potasium Hydroxo-*l*-leucine-*N*,*N*-diacetatoaquochromate(III) Trihydrate, K[Cr(OH)(*l*da)(H_2O)]·$3H_2O$ (I). Twenty five grams of chromium chloride hexahydrate and 24 g of LDA were added to about 300 m*l* of water. The mixture was heated on a water bath until LDA was completely dissolved. To the resulting violet solution, about 10 g of potassium hydrogen carbonate were added, when vigorous bubbling took place. Heating of the solution was continued until the bubbles subsided. When the solution was concentrated, a tar-like residue was deposited out. The supernatant layer was discarded by decantation. The residue was dissolved in about 300 m*l* of water. The pH of the violet solution was then adjusted to 6—7 by adding an appropriate amount of potassium hydrogen carbonate. The resulting solution was concentrated to about 200 m*l* and was stood in a refrigerator. Violet crystals were obtained. Recrystallization was carried out from water. Yield about 5 g. The crystals were used as material to prepare the following complexes, II to VI.

Found: N, 3.31; C, 28.31; 5.43%. Calcd for K[Cr(OH)(*l*da)(H_2O)]·$3H_2O$: N, 3.47; C, 28.58; H, 4.84%.

The use of ammonium carbonate, instead of potassium hydrogen carbonate as described above, produced the corresponding ammonium salt which is also violet.

Found: N, 7.28; C, 31.18; H, 6.48%. Calcd for NH_4[Cr(OH)(*l*da)(H_2O)]·$2H_2O$: N, 7.25; C, 30.90; H, 6.51%.

***l*-Leucine-*N*,*N*-diacetatodiaquochromium(III), [Cr(*l*da)(H_2O)$_2$] (II).** Five grams of Complex I was dissolved in 200 m*l* of hot water and then a few drops of hydrochloric acid were added. As the solution was gradually concentrated at about 40°C, violet crystals were depo-sited out. The crude crystals were recrystallized from a concentrated hot aqueous solution. Yield about 1.5 g.

Found: N, 4.22; C, 36.18; H, 5.43%. Calcd for [Cr(*l*da)(H_2O)$_2$]: N, 4.51; C, 35.56; H, 5.42%.

***l*-Leucine-*N*,*N*-diacetatodiaquochromium(III) Dihydrate, [Cr(*l*da)(H_2O)$_2$]·$2H_2O$ (III).** Preparation was carried out in a manner similar to that used for II, except that the solution was stood at room temperature instead of 40°C. The crystals have a grayish violet

color. Recrystallization was achieved from water. Yield about 2 g.

Found: N, 3.81; C, 32.62; H, 5.38%. Calcd for $[Cr(l\text{da})(H_2O)_2]\cdot 2H_2O$: N, 3.88; V, 32.54; H, 5.19%.

Ethylenediamine Hydroxo-*l*-leucine-*N*,*N*-diacetatodiaquochromate(III) $(enH_2)_{1/2}[Cr(OH)(l\text{da})(H_2O)_2]$ (IV). Five grams of Complex I was dissolved in 200 m*l* of water and then 4 g of ethylenediamine hydrochloride was added. Gradual concentration on a water bath gave a deposit of green crystals. Another crop of crystals were obtained from the resulting cool solution. Recrystallization was carried out from water. Yield about 2 g.

Found: N, 7.37; C, 34.79; H, 6.12%. Calcd for $(enH_2)_{1/2}[Cr(OH)(l\text{da})(H_2O)_2]$: N, 7.22; C, 35.03; H, 5.93%.

***l*-Leucine-*N*,*N*-diacetato-*o*-phenanthrolinechromium(III) Dihydrate, $[Cr(l\text{da})(o\text{-phen})]\cdot 2H_2O$ (V).** Two grams of *o*-phenanthroline was added to 200 m*l* of water containing 5 g of Complex I. After the pH of the solution was adjusted to 4—5, it was heated on a water bath. Heating was continued until brown crystals began to deposit. Although the crystals are slightly soluble in water, recrystallization can be made from hot water. Yield about 3 g.

Found: N, 8.21; C, 51.59; H, 5.08%. Calcd for $[Cr(l\text{da})(o\text{-phen})].2H_2O$: N, 8.43; C, 51.91; H, 4.72%.

Potassium *l*-Leucine-*N*,*N*-diacetatoacetylacetonatochromate(III) Monohydrate, $K[Cr(l\text{da})(\text{acac})]\cdot H_2O$ (VI). Two-hundred milliliters of aqueous solution containing 5 g of Complex I and 1.5 g of acetylacetone was heated on a water bath and then was concentrated to about 50 m*l*. The solution being stood in a refrigerator for a few days, blackish violet crystals were obtained. The crude products were recrystallized from a water-alcohol mixture (1 : 4). Yield about 2 g.

Found: N, 3.09; C, 39.75; H, 5.29%. Calcd for $K[Cr(l\text{da})(\text{acac})].H_2O$: N, 3.03; C, 39.20; 5.19%.

Potassium Hydroxo-*l*-leucine-*N*,*N*-diacetatoaquocobaltate(III) Monohydrate, $K[Co(OH)(l\text{da})(H_2O)]\cdot H_2O$ (VII). One-hundred grams of LDA was added to 300 m*l* of water containing 100 g of cobalt(II) chloride hexahydrate and then the mixture was heated on a water bath. About 50 g of potassium hydrogen carbonate was gradually added. After the pH of the solution was adjusted to 6—7, about 10 m*l* of 28% hydrogen peroxide solution was dropped into the solution in order to oxidize the cobalt(II) ion. Bluish violet crystals were obtained from the solution stood at room temperature. Recrystallization was achieved from water. Yield about 20 g.

Found: N, 3.54; C, 30.41; H, 4.82%. Calcd for $K[Co(OH)(l\text{da})(H_2O)]\cdot H_2O$: N, 3.72; 30.78; H, 4.71%.

Apparatus. Molecular rotatory power was measured with Model MP-IT Polarimeter supplied by Applied Electric Lab., Ltd. The other apparatus used in this paper were the same as described previously.[1-5]

Results and Discussion

IR Spectra. The infrared absorption spectra were measured in their nujol mull state in order to ascertain whether or not the carboxylic group was coordinated. Table 3 shows their IR data. Assignments by Busch and Bailar[6] were also applied in this paper. The bands observed at 1738 and 1580 cm^{-1} in LDA itself were assigned to free carboxylic acid and carboxylate ion, respectively. Only one band was observed in all the complexes in the range ($\sim$1650 cm^{-1}) where the presence of the coordinated carboxylate groups can be detected.

Molar Conductivities. Molar conductivities were measured in an aqueous solution at 25°C for examination of the type of electrolytes for the complexes. The results are given in Table 4, together with their magnetic moments evaluated from magnetic susceptibilities measured at 20—23°C. Numerical data of conductivities for Complexes I, IV, VI and VII are within 110 to 160 mho cm^{-1}, indicating that these complexes are the 1 : 1 type electrolytes. The value for IV (157 mho cm^{-1}) is somewhat larger than that expected. This seems to be due to the partial dissociation of the hydrogen ion from enH_2^{2+}. Small conductivities for II, III and V suggest that they are non-electrolyte complex species.

Magnetic Moments. The effective magnetic moments of these complexes were evaluated from the magnetic susceptibilities measured by the Gouy method. The results are shown in Table 4. The magnetic moments for I to VI are in region of 3.75—

VI	54.45	(1.98)	78.13	(2.28)
VII	53.10	(2.28)	75.38	(2.32)

The spectra for Complex I in an aqueous solution and in a solid state are shown in Fig. 1 together with those for the corresponding ATA complex in a solution. The spectra for Complex I and the corresponding ATA complex both in solution are quite similar, whereas the spectrum for Complex I in a solid state is considerably different from the former two. The facts suggest that, like the ATA complex, LDA actsas a quadridentate (N_1–O_3 type) in a solid state but as a terdentate (O_3 type) in an aqueous solution.

Figure 2 shows the spectra in an aqueous solution for Complexes II, III and [Cr(ata)$(H_2O)_2$] in which ATA acts as a quadridentate ligand. Close resemblance between these spectra suggests that the structures of these complex species are analogous with each other and LDA behaves as a quadridentate.

Figure 3 shows the spectra in solution and solid state for Complex IV and those for the corresponding ATA complex in solution in which ATA behaves as a terdentate ligand (O_3 type). Similarity among these spectra suggests that the structures of Complex IV are identical in solid state and solution, and that LDA behaves toward metal as a terdentate

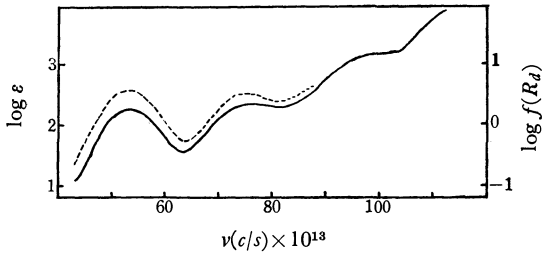

Fig. 4. Electonic spectra for the solution (——) and the solid (·····) of Complex VII.

(O_3 type) as in the case of the ATA complex.

The spectra for Complex VII in a solid state and in an aqueous solution are shown in Fig. 4. We see that both spectra resemble each other, showing the same structures. This is different from Complex I. This might be mainly due to the ease of aquation in the latter complex, *viz.*, the chromium(III) complex may more easily undergo an aquation than the corresponding cobalt(III) complex.

Thermal Decomposition Processes in Complexes II, III and VII. Thermal decomposition of the complexes was measured with a Derivatograph[7,8] in a constant nitrogen stream with heating rate 1°C/min. Five-hundred milligrams of the samples was used in each experiment. The derivatograms for Complexes II, III and VII are given in Fig. 5.

Complex III, first, lost two moles of crystalline water at 100°C and liberated stepwise two moles of coordinated water at 190 to 230°C in the second step.

For Complex II having no crystalline water, a similar liberation of two moles of coordinated water could be detected at 190—235°C as in the second step of III.

Complex VII lost one mole of crystalline water at 100°C and the weight loss, corresponding to one mole of water, was detected at 190—200°C.

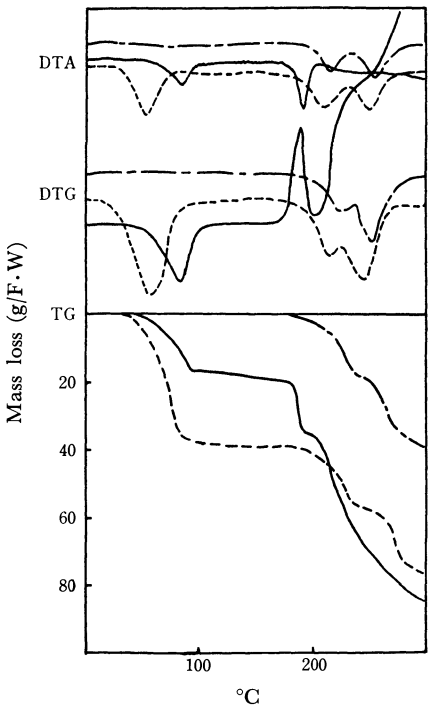

Fig. 5. Derivatograms for Complexes II (—·—), III (- - -) and VII (——).

It is of interest that an exothermic peak appears on DTA curve in the corresponding temperature range. At this step the color of the sample turned from bluish violet to reddish violet. From the results, the dimerization reaction seems to proceed at this step, resulting in the formation of the diol complex as shown by

$$2K[Co(OH)(l\text{da})(H_2O)] \xrightarrow[-2H_2O]{\text{at } 190—200°C} K_2[Co(l\text{da})\langle{}^{H}_{O}\rangle_{O}^{H}(l\text{da})Co].$$

A more detailed discussion and the kinetics for this reaction will be published elsewhere with illustrative examples.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 419—423 (1970)

Kinetics of Multidentate Ligand Substitution Reactions. VIII. Substitution Reactions of Diethylenetriaminepentaacetic Acid with Nickel(II) Iminodiacetate and Aspartate Chelates and of Cyclohexane-1,2-diamine-*N*,*N*,*N*′,*N*′-tetraacetic Acid with the Nickel(II) Aspartate Chelate

Mutsuo KODAMA and Teiko UEDA

Department of Chemistry, Ibaraki University, Mito

(Received August 21, 1969)

The substitution reactions of diethylenetriaminepentaacetic acid (DTPA) with nickel(II) chelates of iminodiacetic acid (IDA) and aspartic acid (Asp) and of cyclohexane-1,2-diamine-*N*,*N*,*N*′*N*′-tetraacetic acid (CyDTA) with the nickel(II) chelate of aspartic acid were studied by employing the polarographic method. All the reactions studied were found to proceed through the following two simultaneous reaction paths:

$$\text{i)}\quad \begin{array}{l} NiX^0 + Z^{m-} \rightleftharpoons NiZ^{2-m} + X^{2-} \\ \quad\uparrow\downarrow \text{rapid} \\ NiX_2^{2-} \end{array}$$

$$\text{ii)}\quad \begin{array}{l} NiX^0 + HZ^{1-m} \rightleftharpoons NiZ^{2-m} + HX^- \\ \quad\uparrow\downarrow \text{rapid} \\ NiX_2^{2-} \end{array}$$

where NiX^0 and NiX_2^{2-} denote nickel(II)-IDA or Asp chelates of 1-to-1 and 1-to-2 compositions respectively, and where Z^{m-} indicates a completely-deprotonated DTPA or CyDTA anion. From a comparison of the rate constants of substitution reactions involving the nickel(II)-aspartate chelate with the corresponding rate constants of substitution reactions involving the nickel(II)-iminodiacetate chelate, the six-membered ring of the nickel(II)-aspartate chelate, as compared with its five-membered ring, was concluded to be more labile in the substitution reaction.

In our laboratory, a series of substitution reactions involving nickel(II)- and cobalt(II)-aminopolycarboxylate chelates have been studied kinetically.[1-4] In the substitution reaction involving Eriochrom Black T (BT), from a comparison of the rate constants the reaction intermediate was found to have the structure in which the leaving aminopolycarboxylate anion forms a five-membered ring with the metal ion through one nitrogen group and one oxygen group (Glycinate mechanism).[2]

Diethylenetriaminepentaacetic acid (DTPA) and cyclohexane-2,2′-diamine-*N*,*N*,*N*′,*N*′-tetraacetic acid (CyDTA) were found to displace aspartate and iminodiacetate anions from their nickel(II) chelates at measureable rates. Although both aspartic acid (Asp) and iminodiacetic acid (IDA) have one nitrogen group and two carboxylate groups, the former can form chelates which have one five-membered ring and one six-membered ring with metal ions, while the latter forms chelates which have two five-membered rings. Therefore, by comparing the rate constants for the substitution reactions of the nickel(II)-aspartate chelate with those of the nickel(II)-iminodiacetate chelate, one can determine which of the above two nickel(II) chelates is substitution-inert. In this connection, it would be worthwhile to conduct a kinetic study of the substitution reactions of nickel(II)-aspartate and iminodiacetate chelates with DTPA and CyDTA. This investigation will also provide further important information about the nature of the reaction intermediate in the substitution reaction involving the metal-aminopolycarboxylate chelate. In this paper, the kinetics of the substitution reactions of DTPA with nickel(II)-Asp and IDA chelates and of CyDTA with the nickel(II)-Asp chelate were investigated systematically.

Experimental

Reagents. The preparation of the standard nickel(II) nitrate solution was described in a previous paper.[4] The methods of purifying CyDTA and DTPA and preparing their standard solutions have also been given previously.[3] L-Aspartic acid and iminodiacetic acid were recrystallized from their aqueous solutions. The standard solutions were prepared by dissolving known amounts of recrystallized Asp and IDA in redistilled water. All the other chemicals used were of an analytical-reagent grade and were used without further purification.

Apparatus and Experimental Procedures. All the d.c. polarograms and current-time curves were recorded automatically by employing a Yanagimoto pen-recording polarograph PA-102 or a Hitachi recorder QPD-54. The dropping mercury electrode (DME) used in this study was also described previously.[5] All the experimental procedures were the same as these employed previously.[4] All the current-time curves were measured in the pH range from 9.00 to 10.50 in solutions with an ionic strength of 0.20 and containing a large excess of complexed and un-complexed Asp or IDA over DTPA or CyDTA. Therefore, all the substitution reactions could be treated as pseudo first-order reactions. In this study, no buffer reagent was used because all the sample solutions contained un-complexed aspartic acid or iminodiacetic acid, which has enough of a buffer capacity to maintain the solution pH constant over the entire pH range covered.

Results and Discussion

As was found in the substitution reaction of the nickel(II)-NTA chelate with DTPA,[4] in all the substitution reactions studied the plot of $\log(i_0/i_t)$ against time, t, give linear relations which pass through the point of origin, provided that all the other experimental conditions are kept constant (Fig. 1). Here, i_0 and i_t mean the wave-heights of DTPA or CyDTA at time $t=0$ or t respectively.[4] When the other experimental conditions were kept constant, the slope of the above linear relation was not influenced by the addition of a nickel(II)-DTPA or -CyDTA chelate, and it was independent of the initial concentration of DTPA or CyDTA. However, it was exactly proportional to the concentration of the nickel(II)-Asp or -IDA chelate with a 1-to-1 composition, $[NiX]_t/(1+K_2[X]_f/(\alpha_H)_X)$. Here, $[NiX]_t$, $[X]_f$, and $(\alpha_H)_X$ mean the total concentration of the nickel(II)-Asp or -IDA chelate, the concentration of uncomplexed Asp or IDA, and the (α_H) value of Asp or IDA respectively. K_2 is the second successive formation constant of the nickel(II)-Asp or -IDA chelate. Typical results are shown in Tables 1, 2, and 3. As is illustrated in Figs. 2 and 3, the product of the log-plot slope and $2.303\cdot(\alpha_H)_Z\cdot(1+K_2[X]_f/(\alpha_H)_X)/[NiX]_t$ was a linear function of the hydrogen ion concentration,

and the log-plot slope is given by:

$$\text{log-plot slope} = (k_i + k_{ii}[H^+]) \times \frac{[NiX]_t}{2.303\cdot(\alpha_H)_Z\cdot\left(1+\dfrac{K_2\cdot[X]_f}{(\alpha_H)_X}\right)} \quad (1)$$

where $1+K_2\cdot[X]_f/(\alpha_H)_X$ is practically identical with $K_2\cdot[X]_f/(\alpha_H)_X$ under the present experimental conditions. Therefore, all the substitution reactions studied can be concluded to proceed through the following two simultaneous reaction pathways and, therefore, k_i and k_{ii} in Eq. (1) can be equated with k_1^+ and k_2^+/k_d respectively (here, k_d denotes the k_4 of CyDTA or k_5 of DTPA):

i) $NiX^0 + Z^{m-} \overset{k_1^+}{\rightleftarrows} NiZ^{2-m} + X^{2-}$
$\uparrow\downarrow$ rapid
NiX_2^{2-}

ii) $NiX^0 + HZ^{1-m} \overset{k_2^+}{\rightleftarrows} Ni^{2-m} + HX^-$
$\uparrow\downarrow$ rapid
NiX_2^{2-}

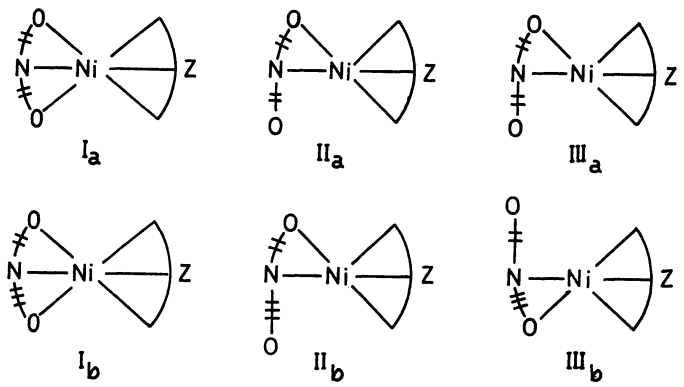

Fig. 4. Reaction intermediates.

substitution reaction of the nickel(II)-Asp chelate with DTPA proceeded too rapidly for us to determine the rate accurately at room temperature, the current-time curves were measured at 1.0°C. The rate constants for the substitution reaction of the nickel(II)-IDA chelate with DTPA determined at 1.0°C are also listed in Table 4.

As is shown in Table 4, the k_2^+ values of the nickel(II)-Asp chelate systems are about seven times as large as those of the nickel(II)-IDA chelate systems. Since the k_1^+ values could be determined less accurately, only the k_2^+ values were used for the comparison of the rate constants. From the above results and discussion, it might be expected that the substitution reaction involving the nickel(II)-Asp chelate proceeds through a mixed ligand reaction intermediate (activated complex) similar to that in the substitution reaction of the nickel(II)-IDA chelate. As was discussed previously,[2] we can estimate the structure of the reaction intermediate by comparing the rate constant calculated on the basis of the proposed reaction intermediate and the observed rate constant. If the Ni(II)-DTPA or -CyDTA segments in the reaction intermediates of both substitution reactions have the same structure, and if the Ni(II)-Asp and Ni(II)-IDA segments in the reaction intermediate have the I_a and I_b structures respectively, the k_2^+ value for the reaction of the nickel(II)-Asp chelate must be equal to that for the reaction of the nickel(II)-IDA chelate, because the rates of dissociation of aspartate and iminodiacetate anions from the reaction intermediate are considered to be identical. If both aspartate and IDA anions in the reaction intermediate form only one five-membered ring with a nickel(II) ion (II_a and II_b), the k_2^+ value for the substitution reaction of the nickel(II)-Asp chelate must be about six times as large as that for the reaction of the nickel(II)-IDA chelate, because the stability constant ratio corrected for the statistical factor between nickel(II)-IDA and -Asp chelates of a 1-to-1 composition[7] is estimated to be 6.0. On the other hand, if the Ni(II)-Asp segment in the reaction intermediate has the six-membered ring and the Ni(II)-IDA segment, a five-membered ring (III_a and III_b), the k_2^+ value for the reaction of the nickel(II)-IDA chelate should be three times as large as that for the reaction of the nickel(II)-Asp chelate. Here, nickel(II) chelates of α-aninate and β-alaninate were used as models. For the reaction intermediates where nickel(II)-IDA and -Asp segment include only one nitrogen bond, the k_2^+ value for the reaction of nickel(II)-Asp must be twelve times as large as that for the reaction of the nickel(II)-IDA chelate.

As is shown in Table 4, the k_2^+ values for the substitution reactions of the nickel(II)-Asp chelate with both DTPA and CyDTA are almost seven times as large as those for the reactions of the nickel(II)-IDA chelate. This fact clearly indicates that all the present substitution reactions also proceed through the glycinate reaction intermediate (II_a and II_b), as in the case of the substitution reaction of BT.[2] With metal ions, the aspartate anion can form the chelate with five- and six-membered rings. Therefore, the finding that the reaction of the nickel(II)-Asp chelate proceeds through the reaction intermediate II_b clearly shows that the five-membered ring, as compared with the six-membered ring, is more inert in the substitution reaction.

The present authors wish to thank the Ministry of Education for its financial support.

Stereochemistry of Trimethylenediaminetetraacetatocobaltate(III)*[1]

Hiroshi OGINO, Masatake TAKAHASHI and Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University Katahira-cho, Sendai

(Received September 5, 1969)

Conformation of trimethylenediaminetetraacetatocobaltate(III) (Cotrdta$^-$) was inferred from the measurement of proton nuclear magnetic resonance spectra. It was found that K[Cotrdta]·$2H_2O$ crystals are mixtures consisting of equimolar amounts of the crystals of K[$(+)_{546}$-Cotrdta]·$2H_2O$ and those of K[$(-)_{546}$Cotrdta]·$2H_2O$; that is, so-called "spontaneous resolution" was found. The absolute configuration of optically active Cotrdta$^-$ was determined by the measurements of optical rotatory dispersion (ORD) and circular dichroism (CD) curves and by the reaction with ethylenediamine to form tris(ethylenediamine)cobalt(III) cation.

The cobalt(III) complexes with ethylenediaminetetraacetate(edta), propylenediaminetetraacetate (pdta) and *trans*-1,2-cyclohexanediaminetetraacetate(cydta) have been extensively investigated. In these complexes, the chelate rings around the central cobalt(III) ions are all five-membered.

Recently, the syntheses of cobalt(III)[1] and chromium(III)[2] complexes with trimethylenediaminetetraacetate(trdta)*[2] have been reported, and it was verified that a quadrivalent trdta anion in each metal complex is hexadentate.[1,2] In trdta complex, a six-membered chelate ring involving two nitrogen atoms is formed, in contrast with complexes with edta, pdta and cydta.

As trdta complex occupies an important position in a series of complexes of edta and its homologues, the stereochemical investigations on Cotrdta$^-$ are dealt with in this paper.*[3]

Experimental

H_4 trdta*[4] and K[Cotrdta]·$2H_2O$ were prepared in the same way as has been reported.[1]

H[Cotrdta]·$3H_2O$. K[Cotrdta]·$2H_2O$ (4.4 g) dissolved in 20 m*l* of water was passed through Dowex 50 W X-8 cation exchange resins in hydrogen form. The equivolume of ethanol was then added to the solution. After the solution had been cooled to 0°C, the reddish violet crystals separated were collected and washed with ethanol and ether. The compound was recrystallized from water by the addition of ethanol.

Ag[Cotrdta]·H_2O. To a solution of 2 g of silver nitrate dissolved in 50 m*l* of water was added 1 g of sodium hydroxide dissolved in 50 m*l* of water. Silver oxide thus obtained was washed several times by decantation. After the total volume of the solution was adjusted to be 50 m*l* with water, 4.5 g of H[Cotrdta]·$3H_2O$ was added to the solution. The solution was stirred at 60°C for 20 min and filtered. To the filtrate, 200 m*l* of ethanol was added. The compound deposited was collected and washed with ethanol and ether and then air-dried. The crystals were recrystallized from water by the addition of ethanol.

Ba[Cotrdta]$_2$·$8H_2O$. To 4.2 g of H[Cotrdta]·$3H_2O$ dissolved in 40 m*l* of water 1.6 g of barium hydroxide was added. The solution was stirred at 65°C for 20 min and filtered. To the filtrate was added 40 m*l* of ethanol. The compound deposited was washed and recrystallized in the same way as Ag[Cotrdta]·H_2O.

Resolution of Cotrdta$^-$. The resolution of Cotrdta$^-$ was carried out by a similar method to that for Copdta$^-$ and Cocydta$^-$.[4,5]

[*d*-Co$(NO_2)_2$en$_2$][$(-)_{546}$Cotrdta]·$3H_2O$.*[5] Resolving agent, *cis*-[*d*-Co$(NO_2)_2$en$_2$]Br (en denotes ethylenediamine) was prepared according to the direction by Dwyer and Garvan.[6] *cis*-[*d*-Co$(NO_2)_2$en$_2$]Br (21.1 g)

was suspended in 800 m*l* of water at 60°C. To this suspension, 29.2 g of Ag[Cotrdta]·H_2O dissolved in 200 m*l* of water at 60°C was added and shaken vigorously for 10 min.*6 After filtration of silver bromide, the filtrate was evaporated to 100 m*l* under reduced pressure at a temperature 55°C. The solution was cooled to 0°C, and the brown diastereoisomer [*d*-$Co(NO_2)_2en_2$][(−)$_{546}$Cotrdta]·$3H_2O$ deposited was collected, which was recrystallized from water by the addition of ethanol, washed with ethanol and ether, and then air-dried. An aqueous solution of the diastereoisomer gave $[\alpha]_{546}=-850\pm30°$. The rotation did not change after recrystallization. The filtrate was reserved for the preparation of [*l*-$Co(NO_2)_2en_2$][(+)$_{546}$Cotrdta]·$3H_2O$.

K[(−)$_{546}$Cotrdta]·2H_2O. Fifteen grams of [*d*-$Co(NO_2)_2en_2$][(−)$_{546}$Cotrdta]·$3H_2O$, 15 g of potassium iodide and 40 m*l* of water were ground up in a mortar for 5 min and cooled to 0°C for 1 hr. After removal of the [*d*-$Co(NO_2)_2en_2$]I precipitated, equivolume of ethanol was added to the solution. K[(−)$_{546}$Cotrdta]·$2H_2O$ thus obtained was washed with ethanol and ether, and then air-dried. A solution of K[(−)$_{546}$Cotrdta]·$2H_2O$ gave $[\alpha]_{546}=-1560\pm60°$, and the rotation did not change after recrystallization.

[l-$Co(NO_2)_2en_2$][(+)$_{546}$Cotrdta]·3H_2O. To the filtrate reserved in the resolution of [*d*-$Co(NO_2)_2en_2$][(−)$_{546}$Cotrdta]·$3H_2O$ mentioned above, 20 g of barium iodide was added and shaken vigorously. After the solution had been cooled to 0°C, [*d*-$Co(NO_2)_2en_2$]I precipitated was removed by filtration. Equivolme of ethanol was added to the solution. The solution was cooled to 0°C and allowed crystallization of Ba[Cotrdta]$_2$·$8H_2O$. The compound collected was recrystallized from water by the addition of ethanol.

Three grams of Ba[Cotrdta]$_2$·$8H_2O$ was dissolved in 20 m*l* of water at 60°C. *cis*-[*l*-$Co(NO_2)_2en_2$]Br (2.1g) and 0.94 g of silver sulfate were mixed in 80 m*l* of water at 60°C and the solution was added to the solution of Ba[Cotrdta]$_2$·$8H_2O$. The solution thus obtained was shaken vigorously for 10 min. The silver bromide and bariumsulfate precipitated were removed. Subsequent procedures were the same as those for preparation of [*d*-$Co(NO_2)_2en_2$][(−)$_{546}$Cotrdta]·$3H_2O$. The diastereoisomer [*l*-$Co(NO_2)_2en_2$][(+)$_{546}$Cotrdta]·$3H_2O$ gave $[\alpha]_{546}=870\pm30°$.

K[(+)$_{546}$Cotrdta]·2H_2O. This compound was prepared from [*l*-$Co(NO_2)_2en_2$][(+)$_{546}$Cotrdta]·$3H_2O$ by the same procedure as that for the preparation of K[(−)$_{546}$Cotrdta]·$2H_2O$. The solution of K[(+)$_{546}$Cotrdta]·$2H_2O$ gave $[\alpha]_{546}=1600\pm60°$.

The elementary analyses of the compounds prepared in this work are given in Table 1.

Apparatus The proton nuclear magnetic resonance spectra were recorded with a Varian A-60 NMR spectrometer. Sodium trimethylsilylpropanesulfonate (DSS) was used as internal standard.

Polarimetric measurements at sodium D line were done by a JASCO model DIP-SL automatic polarimeter. ORD and CD curves were recorded with a JASCO model ORD/CD-5 polarimeter.

Goniometric measurements of crystals were carried out by a STOE microscope two-circle-polarizing optical goniometer.

Results and Discussion

Conformation of Cotrdta$^-$. From the measurement of the infrared spectra of K[Cotrdta]·$2H_2O$, it has been reported that a quadrivalent trdta anion in this complex is hexadentate.[1)]

NMR spectrum of Cotrdta$^-$ in deuterium oxide is shown in Fig. 1. From the intensities and the chemical shifts of signals, signals centered at 2.8 ppm can be assigned to the protons attached to the carbon atoms of trimethylenediamine ring, and eight peaks ranged at 3.3 to 4.3 ppm can be assigned to be acetate protons. The latter eight

*6 Resolution of Cotrdta$^-$ can be done by using Ba[Cotrdta]$_2$·$8H_2O$. The procedure is the same as that given in the preparation of [*l*-$Co(NO_2)_2en_2$]-[(+)$_{546}$Cotrdta]·$3H_2O$.

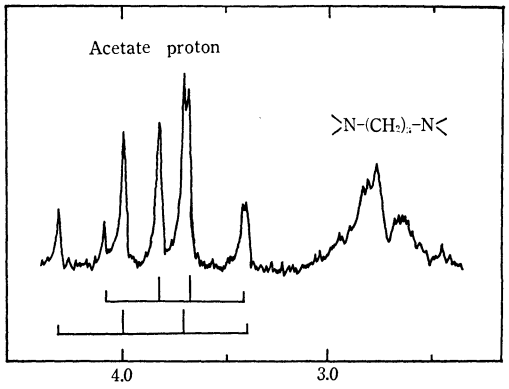

Fig. 1. NMR spectrum of K[Cotrdta]·$2H_2O$ in deuterium oxide.

peaks are attributed to two overlapping AB splitting patterns similar to the eight signals of acetate protons of Coedta$^-$.[7-10] Several parameters of NMR spectra of Cotrdta$^-$ are compared with those of Coedta$^-$ in Table 2.

It is shown in Table 2 that signals of protons attached to the carbon atoms of trimethylenediamine ring are in higher field than those of ethylenediamine ring. This is due to the increasing shielding effect from the applied magnetic field with the increase of methylene group.

The two AB splitting patterns of acetate protons in Cotrdta$^-$ can be attributed to the presence of two acetate rings in N–Co–N plane (in-plane acetates) and of two acetate rings out of N–Co–N plane (out-of-plane acetates), respectively. AB patterns centered at 3.735 ppm were assigned to in-plane acetate and those centered at 3.855 ppm were assigned to out-of-plane acetates, with reference to the data of Coedta$^-$[9,10] and the kinetic study of deuteration reaction of Cotrdta$^-$.*7

The presence of two kinds of AB protons in Cotrdta$^-$ complex means that the magnetic environments of two nitrogen atoms in this complex are equivalent. Unless these magnetic environments are equivalent, it is expected that Cotrdta$^-$ gives four different AB splitting patterns of acetate protons. As an example, it was reported that Copdta$^-$ gives four different AB splitting patterns of acetate protons.[8] In this case, the magnetic environments of two nitrogen atoms are not equivalent by the presence of a methyl group on N–C–C–N chelate ring.

The results of NMR spectra rule out the possibility of the following boat forms as the conformation of trimethylenediamine ring in Cotrdta$^-$:

In the form (A), the magnetic environments of two nitrogen atoms are apparently non-equivalent. In the form (B), as the protons attached to the central carbon atom of trimethylenediamine approach closely one of out-of-plane acetate rings, the equivalence of two nitrogen atoms does not hold. Furthermore, molecular models show that these forms are strained considerably.

It was revealed that the trimethylenediamine chelate ring in tris(trimethylenediamine)cobalt(III) cation is of a chair form.[11] It was, however, found that such a molecular model of Cotrdta$^-$ in which trimethylenediamine chelate ring is of a chair form and trdta anion in the complex is hexadentate could not be constructed.

Figure 2 shows the most probable conformation which explains the experimental results mentioned above, in which cobalt(III) ion, two nitrogen atoms and one central carbon atom of trimethylenediamine (C_6 in Fig. 2) lie in the same plane,

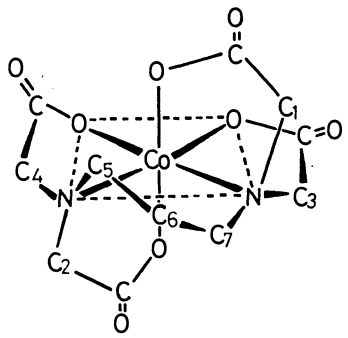

Fig. 2. The most probable conformation of Cotrdta$^-$.
(There is a two-fold axis through Co and C_6.)

and carbon C_5 is above and carbon C_7 below this plane. In this conformation, there is a two-fold axis through a cobalt(III) ion and central carbon atom of trimethylenediamine, C_6. Accordingly, the magnetic environments of two nitrogen atoms in this complex are equivalent. A survey with the use of a molecular model suggested that the in-plane acetate rings in this complex are more strained than the out-of-plane acetate rings.

Spontaneous Resolution of K[Cotrdta]·2-H_2O. When hot solutions saturated with K[Cotrdta]·$2H_2O$ were cooled slowly, fairly large crystals appeared.*8 It was found that each crystal deposited is classified to either forms as shown in Fig. 3. The largest crystal obtained up to date is 1 cm along b axis as shown in Fig. 3. Thus, one can distinguish visually the form to which the crystal deposited belongs. Crystal form A in Fig. 3 is the mirror image of form B. It was found that crystals belonging to A form give *levo* rotation at both 546 mμ and sodium D line and crystals belonging to B form give *dextro* rotation at the same wavelengths. In order to know the accurate value of rotation, single crystals deposited from the solution of racemic K[Cotrdta]·$2H_2O$ were dissolved into 5 m*l* water and the optical rotation of the solutions were measured at sodium D line in 1 cm cell. Fig. 4 shows the results thus obtained. The ordinate in Fig. 4 denotes the value of observed rotation in degree and the abscissa the concentration of K[Cotrdta]·$2H_2O$. The value of rotation of K[$(+)_D$Cotrdta]·$2H_2O$ resolved by using[*l*-$Co(NO_2)_2en_2]^+$ is also plotted in Fig. 4. The plots of crystals belonging to form A lie on a single straight line. The plots of crystals belonging to form B and K[$(+)_D$Cotrdta]·$2H_2O$ resolved with [*l*-$Co(NO_2)_2en_2]^+$ also lie on a straight line. These two straight lines are mirror images of each other within experimental error. This means that each single crystal must contain either *d*- or *l*-isomers. This is a new example of so-called "spontaneous resolution."

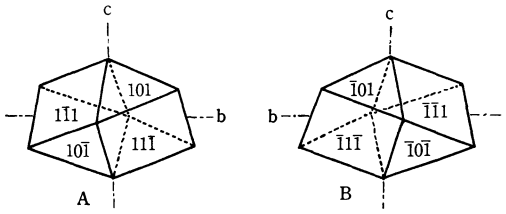

Fig. 3. Two crystal forms of K[Cotrdta]·$2H_2O$.

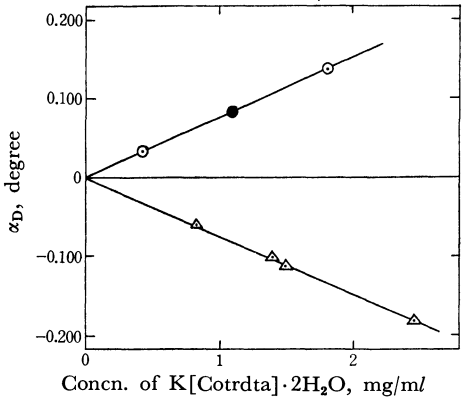

Fig. 4. The relation between optical rotation at sodium D line and the concentration of K[Cotrdta]·$2H_2O$. △ denotes single crystals belonging to form A in Fig. 3 and ○, single crystal belonging to form B in Fig. 3. ● denotes K[$(+)_D$Cotrdta]·$2H_2O$ resolved with [*l*-$Co(NO_2)_2en_2]^+$. Each single crystal is dissolved into 5 m*l* of water.

ρ represents the polar distance and φ, the azimuth of each crystal face.

It was found that crystals shown in Fig. 3 belong to orthorhombic system. The axial ratios are $a : b : c = 0.5534 : 1 : 0.6858$.

Crystal has a cleavage parallel to (010). Accord-

*8 The solubilities of K[Cotrdta]·$2H_2O$ at 10, 15, 20, 25 and 30°C were 18.1, 22.9, 27.3, 31.8 and 37.4 g/100 m*l*, respectively.

Table 4. The reactions of $(+)_{546}$Coedta$^-$ and $(+)_{546}$Cotrdta$^-$ with 50% aqueous ethylenediamine

Reaction	$(+)_D$Co(en)$_3^{3+}$ resulted, %	$(-)_D$Co(en)$_3^{3+}$ resulted, %	Ref.
$(+)_{546}$Cotrdta$^-$ +50% aq. en → Co(en)$_3^{3+}$ + trdta^{4-}	56	44	This work
$(+)_{546}$Coedta$^-$ +50% aq. en → Co(en)$_3^{3+}$ + edta^{4-}	56.6	43.4	14

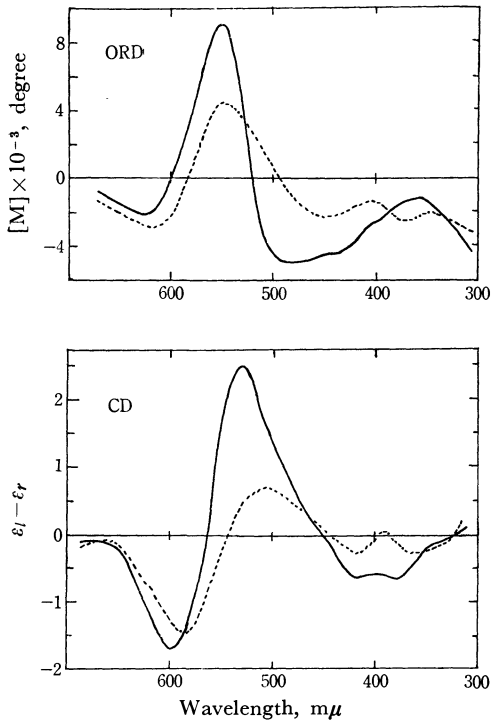

Fig. 5. The ORD and CD curves of $[(+)_{546}$-Cotrdta$]^-$ (——) and $[(+)_{546}$Coedta$]^-$ (----).

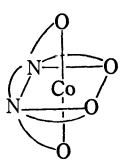
ing to this, some modifications of the crystal form shown in Fig. 3 were sometimes found in the crystals of K[Cotrdta]·2H$_2$O.

Absolute Configuration of Optically Active Cotrdta$^-$ Ion. In Fig. 5, the ORD and CD spectra of $[(+)_{546}$ Cotrdta$]^-$ are compared with those of $[(+)_{546}$ Coedta$]^-$. The absolute configuration of $[(+)_{546}$ Coedta$]^-$ has been determined as follows:[12]



The shape and positions of ORD and CD spectra of $[(+)_{546}$ Cotrdta$]^-$ are quite similar to those of $[(+)_{546}$Coedta$]^-$. Therefore, it can be concluded that the absolute configuration of $[(+)_{546}$ Cotrdta$]^-$ is the same as that of $[(+)_{546}$ Coedta$]^-$. This agrees with the result reported by Van Saun and Douglas.[3]

Busch *et al.*[12-14] reported that [Coedta]$^-$ reacts with ethylenediamine (en) to form tris(ethylenediamine)cobalt(III) cation (Co(en)$_3^{3+}$) with partial retention of optical activity. Weakleim and Hoard[15] reported that in-plane acetate rings in Coedta$^-$ are more strained than out-of-plane acetate rings. From this fact, Busch *et al.* clarified the mechanim of the reaction between Coedta$^-$ and ethylenediamine, in which the first group to be displaced in replacing EDTA by ethylenediamine should be one of the in-plane acetate groups.

In this study the reaction between Cotrdta$^-$ and ethylenediamine was investigated and it was found that Cotrdta$^-$ reacts with ethylenediamine to form Co(en)$_3^{3+}$ similar to Coedta$^-$ system. Table 4 shows a comparison of the reactions of Coedta$^-$[14] and Cotrdta$^-$ with ethylenediamine. The degree of retention of optical activity in reaction between $(+)_{546}$Cotrdta$^-$ and ethylenediamine is essentially the same as that in the reaction between $(+)_{546}$-Coedta$^-$ and ethylenediamine. The results shown in Table 4 support the conclusion that absolute configuration of $(+)_{546}$Cotrdta$^-$ is the same as that of $(+)_{546}$Coedta$^-$ and that the in-plane acetate rings in Cotrdta$^-$ are more strained than the out-of-plane acetate rings.

The authors wish to thank Professors K. Omori and K. Saito, Faculty of Science, and Professor T. Isobe, Research Institute for Chemistry of Non-aqueous Solutions, Tohoku University, for their help and advice in connection with the goniometric and the ORD, CD spectrometric measurements.

BULLETIN OF THE CHEMICAL SOCEITY OF JAPAN VOL. 43 429—438 (1970)

The Mechanism of Photochromism, Thermochromism and Piezochromism of Dimers of Triarylimidazolyl

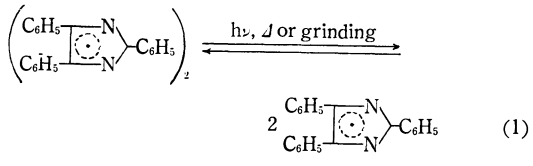
Koko MAEDA and Taro HAYASHI*1

Department of Chemistry, Faculty of Science, Ochanomizu University, Bunkyo-ku, Tokyo

(Received October 29, 1968)

A stable free radical, 2,4,5-triphenylimidazolyl, which was produced by oxidation of 2,4,5-triphenylimidazole, dimerizes to yield two dimers, a photochromic dimer and a piezochromic dimer. The photochromic dimer shows thermochromism and photochromism at temperatures between −196°C and about 200°C both in solution and in solid state. The piezochromic dimer shows piezochromism in solid state and thermochromism both in solution and in solid state. Spectroscopic and kinetic studies showed that photochromism, thermochromism and piezochromism are caused by radical dissociation of the dimers of triphenylimidazolyl on irradiation, heating and grinding. Dimers of substituted triphenylimidazolyl also showed these phenomena which are due to the same mechanism as that of the dimers of triphenylimidazolyl.

In the study of the mechanism of chemiluminescence of 2,4,5-triphenylimidazole (lophine)[1] we obtained new compounds by oxidation of lophine.[2] One compound exhibited photochromism[2] and thermochromism both in solution and in solid state[3,4] with irradiation and change of temperature. The other isomeric compound which is convertible to the former by recrystallization exhibited piezochromism[5] on grinding at room temperature, showing a reddish-purple color reversibly. By spectroscopic and kinetic studies it was shown that the photochromic compound is a dimer of triphenylimidazolyl, and the photochromism, thermochromism and piezochromism of the two compounds are due to reversible dissociation of the dimers into triphenylmidazolyl radical which is shown by the following reversible reaction.



(1)

White and Sonnenberg[6] reported that the photochromic and piezochromic compounds are isomeric dimers which are different in the positions of combination of the 2,4,5-triphenylimidazolyl radical and are in equilibrium with the radical in solution.

We found that[7] besides photochromism at room temperature, showing a reddish-purple color, the photochromic dimer showed photochromism at low temperatures between about −150°C and −196°C, showing a violet color.

In the present paper, the mechanisms of photochromism, thermochromism and piezochromism of the dimers of triarylimidazolyl are reported. The photochromism at low temperatures was reported previously.[8]

Experimental

Materials. The Piezochromic Dimer of Triphenylimidazolyl.[2] To a solution of lophine (1 g) in 2 N ethanolic potassium hydroxide (100 ml) about 500 ml of 2% aqueous solution of potassium ferricyanide was gradually added for 1.5 hr with stirring by a stream of oxygen at 10°C. A reddish-purple color first appeared and then an almost colorless precipitate was formed gradually. The precipitate filtered was washed with water repeatedly and then dried *in vacuo*; 1 g of the piezochromic dimer (piezo-dimer) was obtained; almost colorless fine powder, mp 191—192°C.

Found: C, 84.73; H, 5.28; N, 9.19%. Calcd for $C_{42}H_{30}N_4$ (dimer of triphenylimidazolyl): C, 85.40;

*2 Determined in a dim light by the cryoscopic method in solutions prepared in the dark.

H, 5.12; N, 9.48%.

Piezo-dimer is soluble in benzene, toluene and other aromatic hydrocarbons, carbon tetrachloride, chloroform, acetone, ethyl acetate and pyridine and slightly soluble in methanol, ethanol, ether and *n*-hexane.

As another method to prepare the piezo-dimer, 200 m*l* of 5% aqueous solution of sodium hydroxide containing 20 g of bromine was added to a solution of lophine (1 g) in 2 N ethanolic solution of potassium hydroxide (100 m*l*) with stirring by a stream of oxygen at 10°C during 1.5 hr. A reddish-purple color first appeared and then an almost colorless precipitate was formed gradually. The precipitate filtered was washed with water repeatedly and dried *in vacuo*; 1 g of piezo-dimer was obtained.

The Photochromic Dimer of Triphenylimidazolyl.[2] By slow recrystallization of piezo-dimer from benzene at 5°C in the dark light yellow crystals of the photochromic dimer (photo-dimer) were obtained.

Found: C, 85.20; H, 5.50; N, 9.41%. Calcd for $C_{42}H_{30}N_4$: C, 85.40; H, 5.12: N, 9.48%.

Photo-dimer is soluble in benzene, acetone, ethyl acetate, pyridine, chloroform and carbon tetrachloride and slightly soluble in ether and *n*-hexane, mp 199—201°C.

Photo-dimer was also prepared by oxidation of lophine according to the method of Khun and Kainer[9] who obtained tetraphenylpyrryl radical by oxidation of tetraphenylpyrrole with lead dioxide. When lophine (0.3 g) was heated in benzene (100 m*l*) with lead dioxide (10 g) for 2 hr at 80°C with stirring by a stream of nitrogen, a reddish-purple solution was obtained. After the solution was cooled to room temperature, lead dioxide was filtered. The reddish-purple filtrate was concentrated under nitrogen atmosphere at room temperature in the dark under reduced pressure. By standing the concentrated solution for 1 day in the dark, a small amount of photo-dimer was obtained.

The Dimers of Substituted Triphenylimidazolyl. Piezo-dimers of substituted triphenylimidazolyl, shown in Table 1, were prepared from the corresponding imidazoles by oxidation with potassium ferricyanide in ethanolic potassium hydroxide. Photo-dimer of these triarylimidazolyls were obtained by recrystallization of the corresponding piezo-dimers.

Spectroscopic Measurements. Measurements of the absorption spectra and kinetic studies were carried out with a Hitachi recording spectrophotometer, EPS 2 type. Temperatures between room temperature and 60°C were controlled within ± 0.5°C by circulating hot water from a thermostat to the cell room of the spectrophotometer. Deaerated solutions were used in all spectroscopic measurements.

Electron Spin Resonance Absorption. Kinetic measurements by the ESR method were carried out by the Japan Electron Optics Laboratory JES 3B type ESR spectrometer (100 kc modulation) with deaerated solutions. Spin concentrations of piezochromic systems were measured by a Japan Electron Optics Laboratory JES P-10 type ESR spectrometer (100 kc modulation) which has a JES 1D-2 type integrator. The hyperfine structure of the ESR spectrum was measured by a Hitachi ESR spectrometer.

Irradiation. Sunlight or the 365 mμ light of a high pressure mercury lamp filtered through a Toshiba glass filter UV-D1B, was used.

Results and Discussion

Formation of Piezo-dimers and Photo-dimers. Lophine which showed an absorption maximum at 303 mμ in ethanol showed a red shift

toward 326 mμ in 2N ethanolic potassium hydroxide, whereas *N*-methyl- and *N*-ethyl-lophine phenylimidazole anion in alkaline solution. When lophine was oxidized in a mixture of ethanolic potassium hydroxide and benzene with an aqueous solution of potassium ferricyanide, a reddish-purple substance was produced and transfered to a benzene layer which separated out from an aqueous layer when an excess of the potassium ferricyanide solution was added. The reddish-purple benzene solution showed absorption maxima at 347 and 554 mμ and an ESR signal (*g* 2.003), attributable to the triphenylimidazolyl radical. These facts show that on oxidation of lophine piezo-dimer was produced from triphenylimidazole anion through the triphenylimidazolyl radical.

Because oxidation of monophenylimidazoles did not give the corresponding radicals and diphenylimidazoles gave corresponding radicals only in a small amount, substitution of three phenyl groups in the imidazole ring seems to be favorable for formation of the radicals and their dimers.

Photochromism in Solutions. Light yellow solutions of photo-dimer in various organic solvents quickly turned reddish-purple on irradiation at room temperature and the color gradually reverted to the original color on standing in the dark at room temperature. The change in intensity of photochromic color with time of irradiation, shown in Fig. 1, was measured by the change in absorbance at absorption maximum (347 mμ in benzene, 346 mμ in *n*-hexane). The maximum absorbance at the photo-stationary state depended on the intensity of the irradiation light, concentration of solution, solvent and temperature. The rate of fading in the dark was not accelerated by irradiation with visible light.

Photo-dimer gradually lost photochromic activity in solutions with prolonged irradiation. Duration time of photochromic activity varied with the solvent and also with coexistence of oxygen. For example, in a deaerated benzene solution the duration time was one year or longer, whereas in ethanol and toluene it was very short even in a deaerated solution. The loss of activity is due to hydrogen abstraction from the solvent by triphenylimidazolyl radical which reverts to lophine or oxidation with dissolved oxygen.

A light yellow solution of photo-dimer in *n*-hexane which was prepared in a darkened room at room temperature showed an absorption maximum at 270 mμ (ε 1.6×10^4) which obeyed Beer's law. The reddish-purple solution obtained with

Table 2. Photochromic changes of the color and the absorption maximum of photo-dimer in ethanol

Dimer	Before irradiation		After irradiation	
photo-dimer	light yellow	(270 mμ)	reddish-purple	(270, 348, 554 mμ)
photo-dimer -CH_3	light yellow	(280 mμ)	bluish-violet	(280, 365, 583 mμ)
photo-dimer -Cl	almost colorless	(274 mμ)	violet	(274, 368, 585 mμ)
photo-dimer -2-Cl	almost colorless	(268 mμ)	violet	(268, 366, 575 mμ)*

* Measured in benzene as the solubility of photo-dimer-2 Cl in ethanol is too low for measurement of the absorption spectrum of the colored form.

irradiation showed new absorption maxima at 346 and 548 mμ with decrease of absorbance at 270 mμ. When the reddish-purple solution was kept in the dark at room temperature, the absorbances of the new bands gradually decreased with recovering of the absorbance at 270 mμ. A similar photochromic variation was also observed in other solvents, for example in benzene, as shown in Fig. 2. Photo-dimers -CH_3, -Cl and -2-Cl also exhibited similar photochromism. The photochromic changes in color and absorption maxima are shown in Table 2.

The absorbances at 347 and 554 mμ of the reddish-purple benzene solution of photo-dimer at different concentrations (7×10^{-6}—5×10^{-5} mol/l) were measured immediately after irradiation. The results are shown in Fig. 3. As can be seen the

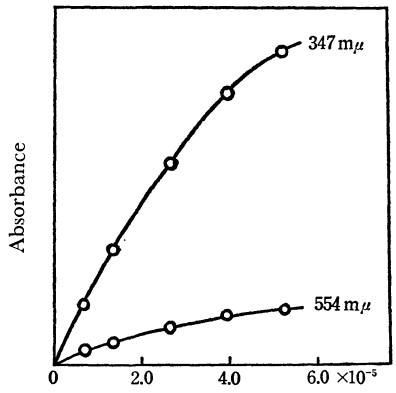

Fig. 3. Variation of the absorbance of the absorption maximum in a photochromic colored benzene solution of photo-dimer, measured immediately after irradiation.
Irradiation: 365 mμ light for 2 min. Temp.: 10.0°C.

absorbances of the photochromic absorption maxima did not obey Beer's law as the absorbances of absorption maxima at 347 and 554 mμ due to thermochromism of photo-dimer were negligibly small under the present conditions.

Photo-dimer and photo-dimers -CH_3, -Cl and -2-Cl also exhibited a similar photochromism in plastics, such as polystyrene and butyral resin.

A light yellow benzene solution of photo-dimer (1.48×10^{-4} mol/l) which was prepared in the dark gave no ESR in the dark at room temperature, whereas the reddish-purple benzene solution produced by irradiation at room temperature showed ESR with g 2.003 (a single peak singal with a line width about 9 gauss). On standing the colored solution in the dark at room temperature, the signal intensity of ESR gradually decreased. The decrease corresponded to the decrease of the absorbance in the visible region. The photochromic colored benzene solutions of photo-dimers -CH_3, -Cl and -2-Cl also showed ESR absorption.

A highly resolved hyperfine structure of an ESR spectrum shown in Fig. 4 was observed in benzene.[10]

Radical formation in the photochromic system was also confirmed by the following chemical evidence. When a light yellow solution of photo-dimer in carbon tetrachloride was brought into contact with oxygen under irradiation with sunlight at room temperature, a reddish-purple color produced on irradiation slowly faded with gradual absorption of oxygen. After about 20 hr the solution turned yellow. A brownish-yellow crystalline residue was obtained by evaporation of the solvent under reduced pressure. It was probably peroxide, because it melted with evolution of gas and liberated iodine from potassium iodide in an acetic acid solution. When nitrogen monoxide was passed into a reddish-purple solution of photo-dimer in oxygen-free benzene under irradiation at room temperature, the solution gradually turned light yellow and almost colorless crystals separated. As the crystals gave a positive Leibermann's test and decomposed at about 105°C with evolution of gas, the colorless crystals are likely to be an addition product of nitrogen monoxide with the radical. When an ethanolic solution of photo-dimer (0.12 g/300 ml) was irradiated for about 5 days with sunlight at room temperature, a reddish-purple color first appeared and then gradually faded. From the solution, lophine (0.11 g) and acetaldehyde which was identified as a dimedone derivative (0.057 g) were obtained. Acetaldehyde seems to arise from ethanol by reaction with the radical under irradiation. When an ethanolic solution of hydroquinone was added to the reddish-purple benzene solution of photo-dimer under irradiation, the color turned almost colorless and lophine was isolated from the solution.

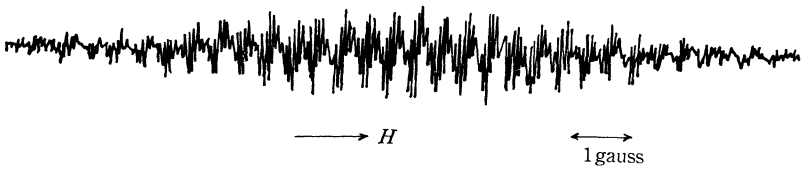

Fig. 4. The ESR spectrum of a photochromic colored benzene solution of photo-dimer.

10) The measurement was carried out by Dr. Koichi Ito of Osaka University.

By using the reaction with hydroquinone the degree of photo-dissociation of photo-dimer in reaction (1) was estimated in benzene at the photostationary state. To a reddish-purple benzene solution (4.7×10^{-5} mol/l, 10 ml) obtained by irradiation with the 365 mμ light for 3 min at room temperature, an ethanolic solution of hydroquinone (9.1×10^{-5} mol/l), was added under a stream of nitrogen. From the volume of hydroquinone solution added to extinguish the color, the degree of the photo-dissociation was estimated to be 0.15 by the following equation.

$$\underset{\text{hydroquinone}}{C_6H_4(OH)_2} + \underset{\text{triphenylimidazolyl radical}}{2C_{21}H_{15}N_2} \longrightarrow$$

$$\underset{\text{benzoquinone}}{C_6H_4O_2} + \underset{\text{lophine}}{2C_{21}H_{16}N_2}$$

The degree of photo-dissociation of photo-dimer was also estimated from molecular weight determination. The molecular weight of photo-dimer determined in a benzene solution under a dim light by the cryoscopic method (0.1127 g in 20.13 g of benzene) was 600 which corresponds to the molecular weight 590 of the dimer $C_{42}H_{30}N_4$, whereas the apparent molecular weight measured immediately after irradiation for 5 min with sunlight at 6°C was 500 (freezing point depression $\Delta t=0.057$°C). From the apparent molecular weight, the degree of photo-dissociation in benzene was estimated to be 0.18. The measurements of the weights of photo-dimers -CH_3, -Cl and -2-Cl in benzene before and after irradiation also showed decrease of the molecular weight on irradiation.

Kinetic Study of Photochromism in Solutions with ESR.[11] In order to confirm the mechanism of photochromism of photo-dimers represented by the reversible reaction (1), the rates of decrease of the radical concentration in the photochromic systems were measured by ESR. The rate of decrease of the radical concentration caused by recombination of the radical to the dimer was expected to obey the second order rate law.

The single peak signal shown by a reddish-purple benzene solution of photo-dimer (1.48×10^{-4} mol/l) gradually decreased with time in the dark. The rate of decrease of the relative signal intensity was successively measured by the height of a signal, h (cm), according to the following procedure. When the recording of the first signal was completed, the sweeping direction of the magnetic field was reversed and the second signal was recorded immediately. Similar procedures were repeated about 20 times for about 15 min at 23.0°C. Since the line width of the signals was 9.3 gauss during the measurement, the height h is assumed to be proportional to the radical concentration. The height h was used in place of the concentration of the radical in the reaction rate expression for the recombination of the radical. The differences between the reciprocals of h at time t and h_0 at $t=0$, $(1/h-1/h_0)$, were plotted against time t. The plots gave a straight line, as shown by (1) in Fig. 5, showing that the rate of decrease of ESR signal intensity obeyed the second order rate law, expressed by $1/h-1/h_0=k't$.[12]

Temp.: 23.0°C. Irradiation: 365 mμ light for 3 min.

A similar result was obtained for photo-dimer -CH_3 as shown by the straight line (2) in Fig. 5.

Kinetic Study of Photochromism in Solutions by the Spectroscopic Method.[3] The radical mechanism shown by the reversible reaction (1) is also supported by spectroscopic measurements. The degree of photo-dissociation α of photo-dimer at a photo-stationary state in benzene ($c=3.38\times10^{-5}$ mol/l) at 15.0°C was estimated to be about 0.30 from the change of absorbance at 280 mμ (ε 2.6×10^4) measured before and after irradiation for 3 min (thickness of the solution layer; 1 cm). The degree of photo-dissociation of photo-dimers in the photo-stationary state, shown in Table 3, was estimated in a similar way.

From the absorbances at 347 and 554 mμ and the degree of photo-dissociation α of photo-

Irradiation: 365 mμ light for 3 min.

was obtained. Absorbance at the absorption maximum, A_λ, is the sum of the absorbance A_p due to photochromism and A_t due to thermochromism. A_p was obtained by subtraction of A_t measured before irradiation from A_λ. The concentration of triarylimidazolyl radicals, C_r, at time t were calculated from the relation, $A_p=\varepsilon C_r l$. The values of $(1/C_r-1/C_{r_0})$ increased linearly with time, as shown in Fig. 6 (photo-dimer) and 7 (photo-dimer-CH_3).

Rate constants, activation energies and pre-exponential factors of the Arrhenius equation for the recombination reaction of the triarylimidazolyl radicals in the photochromic systems of photo-dimers are shown in Table 5.

Photochromism of Photo-dimer in Solid State.[4] On irradiation of light yellow fine crystals of photo-dimer at room temperature the color of the crystals turned light reddish-purple. The color hardly faded in the dark at room temperature, whereas the rate of reversion to the original color was accelerated by heating above 40°C. The color rapidly disappeared when the colored solid was subjected to contact the vapor of organic solvents, such as ether, acetone or benzene, at room temperature. This indicates that photo-dimer exhibits photochromism also in solid state. The light reddish-purple crystals also exhibited a strong ESR signal of a single peak (g 2.003) at 20°C at which the signal intensity hardly decreased in the dark. On standing in the dark at 45°C the signal intensity gradually decreased with fading of the photochromic color. The absorption spectrum of the photochromic colored crystals was measured in solid state by both the opal-glass

* Measured by the opal-glass transmission method.

transmission method and the potassium bromide disk method which gave the same spectrum. The spectrum showed an absorption maximum at 563 mμ as shown in Fig. 8. Although the maximum shifted 9 mμ to wavelengths longer than 554 mμ in the benzene solution, a reddish-purple solution obtained by dissolution of the reddish-purple crystals in benzene in a dim light showed a maximum at 554 mμ immediately after dissolution. These findings indicate that the photochromic color appeared in a solid state is also attributed to triphenylimidazolyl radical produced by dissociation of photo-dimer with irradiation.

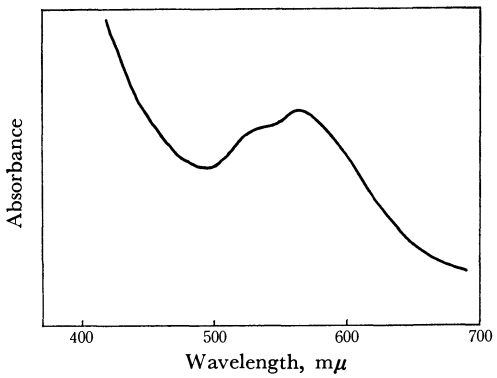

Fig. 8. Absorption spectrum of the photochromic colored solid of photo-dimer, measured by the opal-glass transmission method.

The decay rate of the ESR intensity of the photochromic colored crystals was measured in solid state at 46.0°C and 63.0°C. Differing from the rate in a benzene solution, the decay rate of the signal intensity did not obey the second order rate law.

Photo-dimers -CH_3, -Cl and -2-Cl also exhibited photochromism in solid state. Photochromic changes of the color and absorption maxima measured in solid state by the opal-glass transmission method are shown in Table 6. Benzene solutions prepared by dissolving the photochromic colored crystals in a dim light showed the same absorption maxima as those in the photochromic benzene solutions.

Thermochromism of Photo-dimer in Solutions. When a light yellow benzene solution of photo-dimer was heated in a dim light, a light reddish-purple color and an ESR signal were observed at 40°C and were enhanced with the rise of temperature. On cooling in the dark, the color reverted to the original color with diminution of ESR signal intensity. The fact shows that photo-dimer exhibits thermochromism in solutions above room temperature. Photo-dimer-CH_3, -Cl and -2-Cl also showed thermochromism in solutions. The color and absorption maxima due to thermochromism are the same as those thermochromism of photo-dimers in solutions is

also the same as that of photochromism.

The equilibrium constanst for the thermal dissociation of photo-dimer in benzene were estimated at different temperatures from the variation of the absorbance at 554 mμ with the concentration of the dimer. The measurement was carried out at high concentrations, such as 10^{-3}—10^{-2} mol/l, because coloration due to thermochromism is relatively weak, and at such concentrations the absorption band of λ_{max} 347 mμ overlapped with the tail of the band of the dimer (λ_{max} 273 mμ) but the absorption band of λ_{max} 554 mμ which has a relatively small molar absorptivity did not. The equilibrium constants K shown in Table 7 were calculated by the relation $K=2A^2/\varepsilon(2C\varepsilon-A)$, where ε is the molar absorptivity of λ_{max} at 554 mμ of the radical.

TABLE 7. EQUILIBRIUM CONSTANT OF PHOTO-DIMER OF THE THERMOCHROMIC SYSTEM IN BENZENE

mean $K\times10^7$	1.2	1.9	4.9

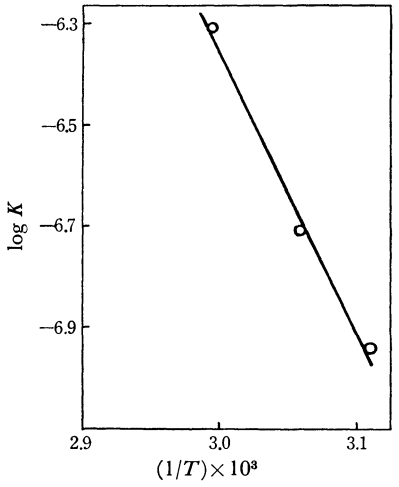

Fig. 9. Plot of logarithm of the equilibrium constant for the thermal dissociation of photo-dimer in benzene against reciprocal of absolute temperature.

From the slope of the straight line shown in Fig. 9, ΔH for the dissociation of photo-dimer in benzene was estimated approximately to be 26 kcal/mol.

Thermochromism of Photo-dimer in Solid State.[4] When light yellow fine crystals of photo-dimer were heated in a dim light, a light reddish-purple color appeared at about 170°C and a deep reddish-purple melt was obtained on melting. On cooling the colored crystals from about 180°C, the light reddish-purple color rapidly reverted to the original light yellow color. A light reddish-purple solution prepared by dissolving a small amount of the reddish-purple crystals in benzene in a dim light showed a weak absorption maximum 554 mμ of triphenylimidazolyl radical immediately after dissolution. When the crystals of photo-dimer which show no ESR signal at room temperature were heated in the dark, a weak signal of a single peak (g 2.003) began to appear at about 50°C and was enhanced with rise of temperature as shown in Fig. 10. On cooling the reddish-purple crystals from about 170°C to room temperature, the signal intensity rapidly decreased to vanish at room temperature.

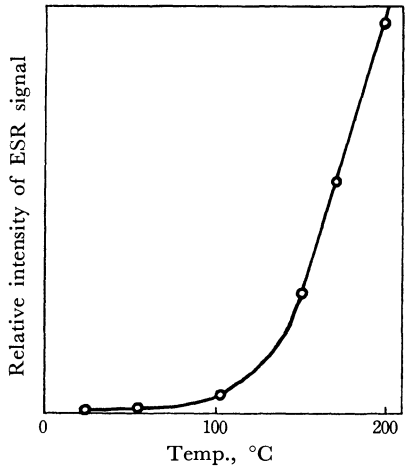

Fig. 10. Variation of the signal intensity of ESR due to thermochromism of photo-dimer in solid state.

This indicates that the mechanism of thermochromism of photo-dimer in solid state is also the same as that of photochromism and thermochromism in solutions. Photo-dimers -CH_3, -Cl and -2-Cl also showed thermochromism in solid state.

Thermochromism of Piezo-dimer in Solid State. When the solid of piezo-dimer was heated, the color turned light reddish-purple at about 180°C. The color rapidly faded on cooling. A deep reddish-purple melt was obtained on melting. When the solid of piezo-dimer which shows a weak ESR signal at room temperature was heated, the signal intensity increased with the rise of temperature. This fact shows that piezo-dimer exhibits thermochromism in solid state above about 180°C. The weak ESR signal observed at room temperature is due to a small amount of triphenylimidazolyl radical produced by the oxidation of lophine and remained without dimerization.

Table 8. Piezochromic change in color and absorption maximum

Dimer	Color		λ_{max} (mμ) after grinding
	before grinding	after grinding	
piezo-dimer	almost colorless	reddish-purple	563
piezo-dimer-CH_3	light violet	greenish-blue	589
piezo-dimer-Cl	light violet	dark blue	591
piezo-dimer-2-Cl	almost colorless	light violet	580

Piezochromism of Piezo-dimer.[5] The solid of piezo-dimer turned deep reddish-purple by grinding in a mortar or pressing at a pressure of about 10—50 kg/cm^2 at room temperature. The colored solid reverted very slowly to the original almost colorless solid on standing for several days in the dark at room temperature. The rate of fading of the color was accelerated by heating to 50°C. These facts show that piezo-dimer exhibits piezochromism. When the solid was ground at 80°C, it showed a reddish-purple color during grinding, but when grinding was stopped, the color quickly disappeared. When the piezochromic colored solid was subjected to contact the vapor of organic solvents, such as ether, ethanol, acetone or benzene at room temperature, the reddish-purple color rapidly disappeared. Since the rate of fading of the piezochromic color at room temperature was very slow and the temperature at which the thermochromic color was first observed was 180°C in solid state, piezochromism is not due to a rise of temperature which may occur by grinding or pressing.

A very intense ESR signal ($g=2.003$) appearing by grinding piezo-dimer decreased very slowly at room temperature, but rapidly at a higher temperature such as 50°C.

The absorption spectrum of the piezochromic colored solid was measured by both the opal-galss transmission method and the potassium bromide disk method which gave a similar spectrum to that of the photochromic colored solid of photo-dimer shown in Fig. 8. The absorption maximum at 563 mμ agreed with that of the photochromic colored solid which showed a red shift of about 9 mμ, as compared with the absorption maximum in the photochromic colored benzene solution.

Piezo-dimers -CH_3, -Cl and -2-Cl also exhibited piezochromism. The changes in color and absorption maxima due to piezochromism are shown in Table 8. These results indicate that the mechanism of piezochromism is due to dissociation of the bond between the imidazolyl radicals into the triarylimidazolyl radicals caused by mechanical work.

The spin concentration of piezo-dimer after grinding for 5 min in an agate mortar was measured with ESR. The spin concentration and the degree of piezochromic dissociation are shown in Table 9. The spin concentration increased with the time of grinding.

Table 9. Spin concentration and degree of piezochromic dissociation of piezo-dimer

Piezo-dimer	Spin concentration (spin/g) (degree of piezochromic dissociation)*1	
	before grinding	after grinding*2
Sample 1	7.2×10^{16} (3.6×10^{-3}%)	3.3×10^{19} (1.6%)

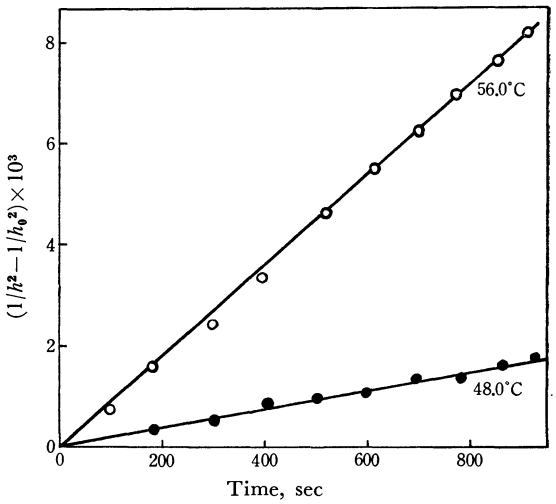

Fig. 11. Plot of $(1/h^2-1/h_0^2)$ against time t in the fading process of piezochromism of piezo-dimer.
h: height of a signal at time t
h_0: height of a signal at time $t=0$

The decay rates of the signal intensity of ESR due to piezochromism of piezo-dimer were measured at 48.0 and 56.0°C. The decrease of the relative signal intensity, h, with time virtually obeyed the relation $1/h^2-1/h_0^2=k't$, as shown in Fig. 11. As the line widths of the signals were almost constant during the measurement, h could be assumed to be approximately proportional to the concentration

of triphenylimidazolyl radical. Differing from the case of photochromism in benzene, the result seems to show that the rate of recombination of the radical in the fading process of piezochromism obeys the third order rate law.

Also in the case of piezo-dimer-CH_3, the decay rates of the signal intensity due to piezochromism, measured at 52.0, 58.0 and 65.0°C were found to obey the third order rate law.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 438—442 (1970)

Reaction of Alkylidenephosphoranes with Nitrosyl Chloride and Decomposition of α-Hydroxyiminophosphonium Chlorides Formed

Chikahiko EGUCHI, Kin-ya AKIBA and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received April 10, 1969)

The reaction of stable alkylidenephosphoranes with nitrosyl chloride in THF gave α-substituted α-hydroxyiminomethyltriphenylphosphonium chloride (A) in high yields. In the case of active alkylidenephosphoranes, "transylidation" took place simultaneously and a mixture of A and α-substituted methyltriphenylphosphonium chloride was obtained along with corresponding amounts of nitrile and triphenylphosphine oxide. By thermal decomposition, all α-hydroxyiminomethyltriphenylphosphonium chlorides (A) afforded nitriles and triphenylphosphine oxide.

Recently we have reported that the reaction of alkylidenephosphoranes with nitric oxide afforded nitriles, aldehydes and phosphine oxide.[1] In connection with this reaction, we attempted the reaction of alkylidenephosphoranes with nitrosyl chloride.[2]

Zbiral and Fenz reported formation of nitriles from acylmethyltriphenylphosphonium salts with ethyl nitrite,[3] but they could not obtain any intermediate.

Trippett, Walker and Hoffmann reported formation of α-substituted α-hydroxyiminomethyltriphenylphosphonium bromides by the reaction of α-bromonitroalkanes ($RCHBrNO_2$) with triphenylphosphine and also formation of nitriles by decomposition of the bromides with alkali.[4] They could isolate the bromides only when the substituents (R) were methyl and ethyl.

We wish to report here formation of α-substituted α-hydroxyiminomethyltriphenylphosphonium chlorides (A) as intermediates and their decomposition to nitriles.

Results and Discussion

When stable α-substituted methylenetriphenylphosphoranes ($Ph_3P{=}CHR$; I: R=COPh and II: R=CO_2Me) were allowed to react with nitrosyl chloride in tetrahydrofuran (THF) solution, α-substituted α-hydroxyiminomethyltriphenylphosphonium chlorides (A-I and A-II) were produced as precipitates in good yields according to reaction (3) (see Table 1).

From the filtrate, benzoyl cyanide and triphenylphosphine oxide were isolated in the case of I, and in the case of II, methyl cyanoformate was determined by g.l.c. In both cases, no α-acylmethyltriphenylphosphonium chlorides (B) were detected in spite of careful examination. This fact suggests that reaction (4) does not take place in these cases.

When α-hydroxyimino-α-benzoylmethyltriphenylphosphonium chloride (A-I) was refluxed in chloroform, benzoyl cyanide (86—98%) and triphenylphosphine oxide (82—93%) were obtained. The

same products were also obtained in 73% yield by the decomposition of A-I in molten state.

However, in a similar decomposition of α-hydroxyimino-α-methoxycarbonylmethyltriphenylphosphonium chloride (A-II), complicated results

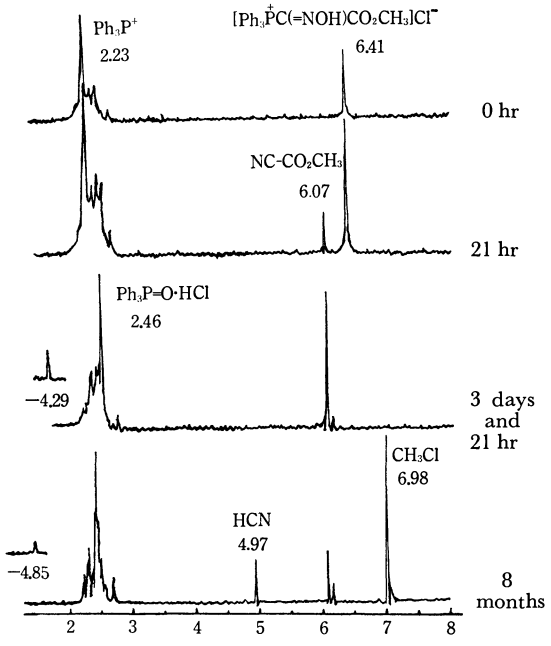

Fig. 1. Decomposition of $[Ph_3\overset{+}{P}C(=NOH)CO_2CH_3]Cl^-$ in $CDCl_3$ at room temperature.

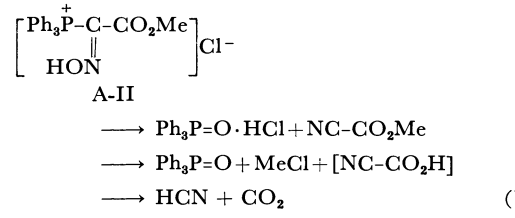
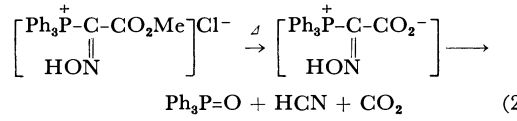
were obtained. When chloroform solution of A-II was allowed to stand at room temperature for 4 days, only methyl cyanoformate and hydrochloride of triphenylphosphine oxide were formed quantitatively (Fig. 1). These yields were determined by NMR (Fig. 1) and also by g.l.c. The signals in Fig. 1 were assigned in comparison with those of authentic samples. On further standing, it was found from Fig. 1 that methyl cyanoformate decomposed into methyl chloride, hydrogen cyanide and carbon dioxide. To realise this fact, stability of methyl cyanoformate was checked under several conditions by NMR.

In chloroform solution, methyl cyanoformate was stable in the presence of triphenylphosphine oxide at room temperature for 4 days but slowly trimerized (in 40% yield after one year) in the presence of hydrogen chloride without decomposition. But when the solution was heated at 40°C for 20 hr in the presence of both triphenylphosphine oxide and hydrogen chloride, the ester was decomposed into methyl chloride, hydrogen cyanide and carbon dioxide. The last result is explicable by reaction (1).



This decomposition of the ester is analogous to the fission of alkyl groups of esters and ethers by triphenylphosphine hydrobromide.[5]

The thermal decomposition of A-II in molten state gave a small amount (9%) of methyl cyanoformate and large amounts of methyl chloride, hydrogen cyanide and carbon dioxide. In this case, a direct decomposition as shown in reaction (2) cannot be ruled out.[6]



When active α-substituted methylenetriphenylphosphoranes (III: R=Ph and IV: R=*n*-Pr) were allowed to react with nitrosyl chloride in THF, a mixture of α-substituted α-hydroxyiminomethyltriphenylphosphonium chloride (A) and α-substituted methyltriphenylphosphonium chloride (B) precipitated immediately, and the resulting nitrile (RCN-1 in Table 2) and triphenylphosphine oxide were determined from the filtrate. Formation of

* Yields are based on the initial phosphonium bromide.

these products are ascribable to reaction (4), and this is supported by the fact that B and RCN-1 were obtained in about equal amount.

In order to decompose A in the precipitates (A+B), the precipitates were refluxed in THF or in chloroform. From the filtrate, nitrile (RCN-2 in Table 2) was determined by g.l.c. and B was obtained by usual work up. Unfortunately, isolation of A-III and A-IV from the precipitates was not successful, but their existence is shown by the formation of RCN-2.

These results can be explained by the following scheme.

$$Ph_3P{=}CHR + NOCl \longrightarrow \left[\begin{array}{c} Ph_3\overset{+}{P}\text{-}CHR \\ | \\ O{=}N \end{array}\right]Cl^-$$

I: R=COPh
II: R=CO_2Me
III: R=Ph

$$\left[\begin{array}{c} Ph_3\overset{+}{P}\text{-}C\text{-}R \\ \| \\ HON \end{array}\right]Cl^- + Ph_3P{=}CHR$$

A

$$\longrightarrow [Ph_3\overset{+}{P}\text{-}CH_2R]Cl^- + RCN + Ph_3P{=}O \quad (4)$$

B

$$\left[\begin{array}{c} Ph_3\overset{+}{P}\text{-}C\text{-}R \\ \| \\ HON \end{array}\right]Cl^- \xrightarrow{\Delta} Ph_3P{=}O + RCN + HCl \quad (5)$$

A

In the cases of stable alkylidenephosphoranes (I and II), reaction (4) was not observed because of their low basicities.[7] On the other hand, in the cases of active alkylidenephosphoranes (III and IV), reaction (4) seems to compete with reaction (3), and a mixture of A and B was obtained as precipitates. The ratio of A-III to B-III was 17 : 23 and that of A-IV to B-IV was 15 : 32, assuming that the amount of RCN-2 correspond to the amount of A.

Although this method is not generally adequate for the synthesis of usual nitriles, it would be useful for preparation of special types of nitriles, because *p*-toluenesulfonyl cyanide[8] was prepared only by this method.

$$RSO_2\text{-}CH{=}PPh_3 + NOCl \xrightarrow{\text{pyridine}} RSO_2\text{-}CN + Ph_3P{=}O$$

Experimental

Materials. Phosphonium salts were prepared from organic halides and triphenylphosphine: phenacyltriphenylphosphonium bromide,[9a,b] mp 268.5—271.0°C; methoxycarbonylmethyltriphenylphosphonium chloride, mp 151—152°C; benzyltriphenylphosphonium bromide,[10] mp 269.0—271.0°C; benzyltriphenylphosphonium chloride,[11] mp 299.5—301.2°C; *n*-butyltriphenylphosphonium bromide,[11,12] mp 232—233°C; and *n*-butyltriphenylphosphonium chloride, mp 217—218.5°C.

Benzoylmethylenetriphenylphosphorane,[9a] mp 180.0—180.5°C, and methoxycarbonylmethylenetriphenylphosphorane,[13] mp 168.0—168.5°C, were prepared by the method described in literature.

Benzylidene- and *n*-butylidenetriphenylphosphoranes were prepared from the corresponding phosphonium bromides and sodium amide prepared *in situ* in liquid ammonia.[14] Evaporation of ammonia, extraction with anhydrous THF and filtration afforded the salt-free solution of the phosphoranes.

Nitrosyl chloride was prepared by Coleman's method[15] and distilled three times before use.

Methyl cyanoformate as an authentic sample was prepared by dehydration of methyl oxamate with phosphorus pentoxide,[16] bp 99—100°C.

Synthesis of α-Benzoyl- and α-Methoxycarbonyl-α-hydroxyiminomethyltriphenylphosphonium Chlorides. A typical procedure is described below.

a) α-Hydroxyimino-α-benzoylmethyltriphenylphosphonium Chloride (A-I). A solution of 3.40 g (0.052 mol) of nitrosyl chloride in 170 m*l* of anhydrous THF was added dropwise to a solution of 19.0 g (0.050 mol) of benzoylmethylenetriphenylphosphorane in 400 m*l* of anhydrous THF over 50 min at −30—−20°C with stirring. As soon as the solution of nitrosyl chloride was added, white precipitates appeared and the solution showed a light blue color, which disappeared after addition of about half the nitrosyl chloride solution. After the addition, the mixture was stirred for additional 15 min at room temperature. The white precipitates (A-I) were filtered, and washed with anhydrous THF and acetone. Yield 16 g (0.036 mol, 72%), dec. point 134—135°C. IR (in C_4Cl_6): 2500 (ν_{OH}) (shifted to 2600 cm^{-1} in chloroform), 1645 (ν_{CO}), 1275, and 1050 cm^{-1}. $\lambda_{max}^{CHCl_3}$: 266 ($\varepsilon=1.49\times10^4$), 271 ($1.53\times10^4$), and 277.5 mμ ($1.34\times10^4$).

Found: C, 69.94; H, 4.62; N, 3.04%. Calcd for $C_{26}H_{21}NO_2PCl$: C, 70.04; H, 4.75; N, 3.14%.

After removal of THF from the filtrate, the residue was extracted with petroleum ether (bp 40—60°C), and the extract was distilled under reduced pressure to yield 1.25g (0.0095 mol, 18%) of benzoyl cyanide, bp 77—78°C/10 mmHg, mp 31.0—32.1°C, IR (Nujol): 2240 (ν_{CN}) and 1680 cm^{-1} (ν_{CO}).

Insoluble part in petroleum ether was washed three times with ether to afford 2.2g (0.0079 mol, 16%) of triphenylphosphine oxide, mp 153.5—155°C.

b) α-Hydroxyimino-α-methoxycarbonylmethyltriphenylphosphonium Chloride (A-II). This salt was prepared by addition of a solution of 4.00g (0.061 mol) of nitrosyl chloride in 200 m*l* of anhydrous THF to a solution of 20.0g (0.060 mol) of methoxycarbonylmethylenetriphenylphosphorane in 350 m*l* of anhydrous THF at −50 — −40°C. Appearance of the reaction was similar to that of a), except that the color of the solution changed to cherry pink. Yield 19.0g (0.0476 mol, 80%), dec. point 128—129°C. IR (in C_4Cl_6): 2220 (ν_{OH}) (shifted to 2540 cm^{-1} in chloroform), 1730 (ν_{CO}), 1275, and 1070 cm^{-1}. $\lambda_{max}^{CHCl_3}$: 262.5 (shoulder), 270 ($\varepsilon=6.45\times10^3$), and 277.5 mμ ($4.69\times10^3$).

Found: C, 62.97; H, 4.78; N, 3.40%. Calcd for $C_{21}H_{19}NO_3PCl$: C, 63.09; H, 4.79; N, 3.50%.

The filtrate was analyzed by g.l.c. (diisodecyl phthalate, 78°C; dibenzyl ether, 74°C), and found to contain 0.986g (0.0116 mol, 19%) of methyl cyanoformate and a trace of carbon dioxide. Attempt to isolate methyl cyanoformate by distillation was unsuccessful, but 2.24g (0.00805 mol, 13%) of triphenylphosphine oxide was obtained from the residue.

Decomposition of α-Benzoyl- and α-Methoxycarbonyl-α-hydroxyiminomethyltriphenylphosphonium Chlorides (A-I and A-II). *a) For A-I.* 1) In boiling chloroform. A solution of 4.0g (0.09 mol) of A-I in 200 m*l* of chloroform was refluxed for 22 hr. After generation of hydrogen chloride ceased and the chloroform was removed, the residue was treated by the procedure described in "synthesis of A-I" to afford 1.15g (0.0088 mol, 98%) of benzoyl cyanide and 2.2g (0.00785 mol, 87%) of triphenylphosphine oxide.

2) In molten state. Heating of 2.2g (0.0049 mol) of A-I at 140°C (bath temperature) for 45 min gave 0.468 g (0.0036 mol, 73%) of benzoyl cyanide and 0.985 g (0.00353 mol, 72%) of triphenylphosphine oxide.

b) For A-II. 1) In molten state. In an oil bath, 3.16g (0.0079 mol) of A-II was gradually heated and then at 200°C (bath temperature) for further 3 hr under dry nitrogen stream. The liquid collected with a dry ice-ethanol trap was analyzed by g.l.c. and found to contain methyl cyanoformate (9%), methyl chloride and hydrogen cyanide. The residue in the reaction flask was recrystallized from ethyl acetate-petroleum ether to yield 1.8g (0.0065 mol, 82%) of triphenylphosphine oxide.

2) A solution of A-II (*ca.* 2%) was allowed to stand at room temperature for 4 days and the resulting methyl cyanoformate was determined simultaneously both by NMR (91%) and by g.l.c. (95%).

A solution of 1.09g (0.00274 mol) of A-II in 65 m*l* of chloroform was refluxed for 25 hr. The formation of methyl cyanoformate (15%), methyl chloride, and hydrogen cyanide was observed by g.l.c.

Reaction of Benzylidenetriphenylphosphorane with Nitrosyl Chloride. To a solution of 3.30g (0.0505 mol) of nitrosyl chloride in 250 m*l* of anhydrous ether was added dropwise a solution of salt-free benzylidenetriphenylphosphorane (0.050 mol) in 150 m*l* of anhydrous THF under nitrogen at −40 — −30°C with stirring. After the addition, the reaction mixture was stirred for a further 10 min at room temperature. White precipitates (C) thus formed were filtered, washed with anhydrous THF and anhydrous ether, and dried over phosphorus pentoxide *in vacuo*. Yield 12.1g. The filtrate was analyzed by g.l.c. (Apiezon grease M, 197°C) to contain 1.85g (0.018 mol, 36%) of benzonitrile, the isolation of which was unsuccessful. The residue was recrystallized from ether to yield 3.9g (0.014 mol, 29%) of triphenylphosphine oxide.

A suspension of C (3.5g) in 50 m*l* of anhydrous THF was refluxed for 35 hr and 0.269g (0.0026 mol) of benzonitrile was determined by g.l.c. The precipitates insoluble in anhydrous THF were recrystallized twice from chloroform-ethyl acetate to yield 1.7g (0.0048 mol) of benzyltriphenylphosphonium chloride, mp 295.5—297.0°C. A mixed mp with authentic benzyltriphenylphosphonium chloride (mp 299.5—301.2°C) was 299.0 301.0°C and that with benzyltriphenylphosphonium bromide (mp 269.0—271.0°C) was 277.5—281.0°C. From this result, the precipitates C were found to consist of α-hydroxyiminobenzyltriphenylphosphonium chloride (A-III) and benzyltriphenylphosphonium chloride (B-III). The yields were 18 and 30% on the basis of the initial benzyltriphenylphosphonium bromide, respectively.

Reaction of *n*-Butylidenetriphenylphosphorane with Nitrosyl Chloride. The procedure and the reaction scale were the same as those of benzylidenetriphenylphosphorane. The white precipitates (D) thus obtained were very hygroscopic. Yield 10.9g. The filtrate was analyzed by g.l.c. (Polyethylene glycol, 120°C), and found to contain 1.32g (0.019 mol, 38%) of *n*-butyronitrile, the isolation of which was unsuccessful. Chromatography of the residue of distillation on silica gel with benzene gave 3.82g (0.0137 mol, 27%) of tri-

16) A. Weddige, *J. Prakt. Chem.*, **10**, 197 (1874).

phenylphosphine oxide.

A solution of D (2.3g) in 79 m*l* of chloroform was refluxed for 20 hr and the reaction mixture was analyzed by g.l.c., and found to contain 0.109g (0.0016 mol) of *n*-butyronitrile. From the solution chloroform was removed, and the residue was recrystallized three times from chloroform - ethyl acetate to afford 1.20g (0.0034 mol) of *n*-butyltriphenylphosphonium chloride, mp 218.0—219.0°C (Found: Cl, 9.85%). A mixed mp with authentic sample (mp 217.0—218.5°C) was 217.5—218.5°C and that with *n*-butyltriphenylphosphonium bromide (mp 232.0—233.0°C) was 222.5—224.5°C.

From this result, the precipitates (D) were found to consist of α-hydroxyimino-*n*-butyltriphenylphosphonium chloride (A-IV) and *n*-butyltriphenylphosphonium chloride (B-IV). The yields were 15 and 32% on the basis of the initial *n*-butyltriphenylphosphonium bromide, respectively.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 442—446 (1970)

The Stereochemistry of Hydrogenation and Hydrogenolysis. XI.[1] The Stereochemistry of the Reduction of 3-Methyl-4-chromanone*[1]

Kaoru HANAYA

Department of Chemistry, Faculty of Science, Yamagata University, Koshirakawa-cho, Yamagata

(Received April 14, 1969)

3-Methyl-4-chromanone (VIII) was reduced with a metal hydride complex, by the Meerwein-Ponndorf method and by catalytic hydrogenation. When VIII was reduced with a metal hydride complex and the Meerwein-Ponndorf method, *trans*-3-methyl-4-chromanol (IX) was produced as the main product. In the catalytic hydrogenation, VIII gave a *cis*-3-methyl-4-chromanol (X) as the main product over Raney nickel, but over the palladium catalyst the *trnas* isomer was larger than the *cis* isomer. These results indicate that, on Meerwein-Ponndorf and metal hydride reductions, the more stable product was formed as the main product; in the catalytic hydrogenation over the Raney nickel catalyst, VIII seems to be adsorbed mainly on the opposite side of the methyl group of the C-3 position and is hydrogenated to give the *cis* isomer, whereas, over the palladium catalyst, hydrogenation seems to proceed under the effect of "product development control over the catalyst" and the *trans* isomer is produced in a high yield.

In the previous papers of this series, the reductions of 2-phenyl-1-tetralone(I),[2] 2-acetoxy-1-tetralone (II),[3] and 2-methyl-1-tetralone(III)[4] were reported. In the catalytic hydrogenation over the Raney nickel, I and II gave *cis*-2-phenyl-1-tetralol (IV) and *cis*-2-acetoxy-1-tetralol(V) respectively in high yields, whereas III gave a mixture of about equivalent quantities of *cis*-2-methyl-1-tetralol(VI) and *trans*-2-methyl-1-tetralol(VII), but over a palladium catalyst VII was formed in a larger amount than VI, along with hydrocarbons resulting from hydrogenolysis. From these results, it is considered that, on the catalytic hydrogenation, the phenyl or acetoxyl group works as a catalyst hindrance to the adsorption of I or II on a catalyst, while the methyl group does not act as so much a hindrance to the adsorption of III. However, the different behaviour observed in the catalytic hydrogenation of III over Raney nickel and palladium catalysts has not yet been discussed. In the metal hydride reduction of I, II, and III, I and II afforded *cis* isomers as the main products, whereas III gave the *trans* isomer in a larger amount than the *cis* isomer. On the Meerwein-Ponndorf reduction of I and III, if acetone was removed, the *cis* isomer was produced mainly, whereas the *trans* isomer was produced mainly when the reaction mixture was refluxed without removing the acetone. From these results, it can be considered that, in the reduction with metal hydride complex, the phenyl or acetoxyl group sterically hinders the carbonyl carbon atom of I or II from the attack of the hydride ion, but the methyl group of III does not exert any such steric hindrance. On the Meerwein-Ponndorf reduction, if acetone is removed, the reaction may proceed under the effect of steric hindrance. On the other hand, if the reaction mixture is refluxed without removing the acetone, the more stable product is formed as the main product.

In order to obtain further information on the stereochemistry of the reduction of cyclic ketones

1) Part X: K. Hanaya, *Nippon Kagaku Zasshi*, **90**, 314 (1969).

*1 Presented at the 21st Annual Meeting of the Chemical Society of Japan, Osaka, April, 1968.

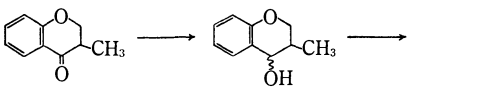
and on the different behavior of these ketones in catalytic hydrogenation over nickel and palladium catalysts, the reduction of 3-methyl-4-chromanone (VIII) was investigated.

Results and Discussion

The reduction of 3-methyl-4-chromanone (VIII) was carried out by the catalytic, metal hydride complex, and Meerwein-Ponndorf methods. The results of these reductions are shown in Table 1.

The configurations of the product alcohols (IX and X) have been established by the synthesis of *trans*-3-methyl-4-chromanol (X) *via* the hydroboration[5] of 3-methyl-3-chromene (XI), which had itself

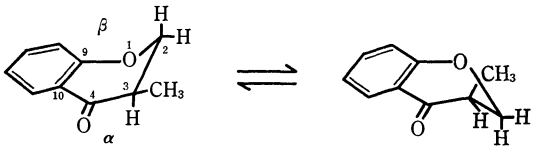


(VIII) (XI) (X)

been prepared by the dehydration of 3-methyl-4-chromanol with *p*-toluenesulfonic acid in benzene, and by the examination of the NMR spectra of IX, X, and their acetates. In the NMR spectra of IX, X, and their acetates, the values of the 3,4-coupling constant ($J_{3,4}$=4.8Hz) of X and its acetate are larger than those ($J_{3,4}$=3.4Hz) of IX and its acetate. In view of the Karplus relationship,[6] these results indicate that, in X and its acetate, the methyl group is *trans* to the hydroxyl or acetoxyl group, while in IX and its acetate it is *cis*.

From the experimental results shown above, the stereochemistry of the reduction of VIII can be considered to be as follows.

VIII is considered to have the conformations shown in Fig. 1, which are similar to those of γ-chromanone proposed by Philbin and Wheeler.[7]



(A) (B)

Fig. 1. Conformations of VIII.*2

The conformation of the methyl group in the 3-position of VIII may be assumed to be quasi-equatorial, as usual. Therefore, the preferable conformation of VIII will be the A-form of Fig. 1.

The reduction of VIII with the metal hydride complex gave the *trans* isomer as the main product. On the Meerwein-Ponndorf reduction VIII, if the acetone was removed, the *cis* isomer was produced mainly, whereas if the reaction mixture was

7) E. M. Philbin and T. S. Wheeler, *Proc. Chem. Soc.*, **1958**, 167.

*2 Philbin and Wheeler have been proposed that five atoms in the heterocyclic, O_1, C_3, C_4, C_9, and C_{10}, are coplanar. However, the present author has considered that C_2, C_3, and the 4-keto group are not coplanar with the adjacent benzene nucleus.[8] A study of the conformations of γ-chromanone derivatives is now in progress.

8) K. Hanaya and K. Furuse, *Nippon Kagaku Zasshi*, **89**, 1002 (1968); K. Hanaya, *ibid.*, **90**, 314 (1969).

refluxed without removing the acetone, the *trans* isomer was produced mainly. These results parallel the findings on III. On reduction with the metal hydride complex, the steric structure near the carbonyl group influences the stereochemical course of the reaction, rather than the whole steric structure of the molecule. When a hydride ion attacks the carbonyl carbon atom, the methyl group of the 3-position of VIII does not seem to exert any steric hindrance; this reaction proceeds under the effect of "product development control." On the Meerwein-Ponndorf reduction of VIII, a consideration of its reaction mechanism[9] suggests that the reaction will proceed under the effect of steric hindrance if the acetone is removed. On the other hand, if the reaction mixture is refluxed without removing the acetone, the reaction mixture will easily reach an equilibrium in which the *trans* isomer predominates.

In the case of the catalytic hydrogenation over the Raney nickel catalyst, VIII afforded the *cis* isomer as the main product, while over the palladium catalyst, VIII gave the *trans* isomer as the main product. In the catalytic hydrogenation of VIII over the palladium-charcoal-B, the *trans* isomer was obtained preferably, even at the initial stage of hydrogenation (Expts. 7, 8, and 9). Therefore, it is considered that the predominant formation of the *trans* isomer was not due to the isomerization of the *cis* isomer.

Generally, the course of the hydrogenation of ketones can be represented as involving three steps, as is shown in Fig. 2: Step 1, the formation of a first adsorbed intermediate; Step 2, the formation of a half-hydrogenated intermediate, and Step 3, the formation and desorption of the product.

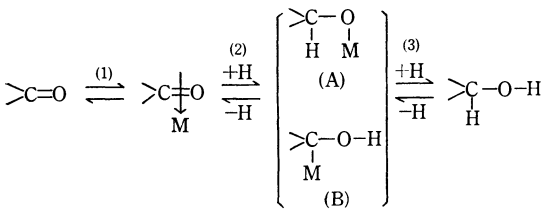

Fig. 2

When the molecule of VIII shown as in Fig. 1-A adsorbs over a catalyst, the adsorption seems to be hindered more at the β-face of the molecule than at the α-face. It is considered that the predominant production of the *cis* isomer in the Raney nickel catalyst hydrogenation of VIII is caused by this catalyst hindrance. The nickel catalyst is considered to have a larger affinity for the oxygen atom than the palladium catalyst.[10] Therefore, on the catalytic hydrogenation of VIII over the Raney nickel catalyst the molecule does not desorb easily, but it will be hydrogenated rapidly when the carbonyl group is strongly adsorbed. That is, on the Raney nickel catalyst, the stereochemistry of hydrogenation may be controlled mainly by the first adsorption step of the molecule and, therefore, by the steric interaction between the molecule and the catalyst surface. On the other hand, since the palladium catalyst does not have a strong affinity for the oxygen atom, the products are not determined by the step of adsorption of the molecule, but, rather, by the step of the transfer of hydrogen from the catalyst surface to the molecule. That is, in the catalytic hydrogenation of VIII over the palladium catalyst, a large contribution of the second or third process will give a stable isomer predominantly. There are two possible states, (A) and (B), to be considered for the half-hydrogenated state, as is shown in Fig. 2. Bent and Keevil[11] reported that the free energy of the addition of sodium to a carbonyl group is at least 5 kcal more negative in the case of the oxygen atom. This fact indicates that sodium is much more firmly attached to oxygen than to carbon. In view of this fact, the oxygen-metal bond may be formed more easily than the carbon-metal bond, and the hydrogenation of ketones may proceed mainly *via* the (A)-type half-hydrogenated state. Besides, in the case of the hydrogenation of VIII, the (B)-type may be expected to be less stable than the (A)-type because of a more severe nonbonded interaction between the quasi-equatorial carbon-metal bond and the hydrogen atom at the peri-position than between the quasi-equatorial oxygen-metal bond and the hydrogen atom in the peri-position. The palladium-catalyzed hydrogenation of VIII will proceed *via* the half-hydrogenated state, as is shown in Fig. 3, and will give the *trans* isomer predominantly.

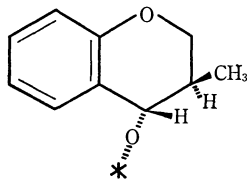

Fig. 3

On the basis of the previous works and the present work, the catalytic hydrogenation of 1-tetralone and 4-chromanone derivatives having the substituent at the α-position of carbonyl group may be summarized as follows. When the substituent is sterically bulky, as in the case of the phenyl or

acetoxyl group, the molecule is hydrogenated in the adsorbed state on the catalyst surface at the opposite side to the substituent, not dependent on the sort of catalyst. On the other hand, when the substituent is relatively small, as in the case of the methyl group, the catalyst hindrance has the largest influence with nickel catalyst, while the hydrogenation over the palladium catalyst is not influenced by the catalyst hindrance, but will give thermodynamically more stable products predominantly because of the large influence of the reaction process of the transfer of hydrogen from the catalyst surface to the molecule.

Experimental

3-Methyl-4-chromanone (VIII). VIII was prepared by the catalytic hydrogenation of 3-methyl-4-chromone[12] over Raney nickel in ethanol. Bp 125—128°C/11 mmHg; The oxime, mp 154—156°C(lit,[13] mp 156°C). IR(liquid film): 1680(C=O) cm^{-1}. NMR(CCl_4): 1.15 (3H, doublet, J=6.9 Hz, CH_3), 2.75 (1H, multiplet, methine at the 3-position), 4.2(2H, multiplet, methylene at the 2-position), and 7.25 ppm(4H, multiplet, benzene-ring protons).

The Catalytic Hydrogenation of VIII. Two hundredths of a mole of VIII, 40 m*l* of ethanol or 10 m*l* of acetic acid, and the catalyst (0.5 g of Raney nickel, 0.2 g of 5% Pd-C-B, 0.1 g 5% Pd-C-A, 0.2 g of 5% Pd-$CaCO_3$ or 0.2 g of 5% Pd-$BaSO_4$) were shaken under hydrogen at an ordinary temperature and pressure. After the theoretical amount of hydrogen had been absorbed, the catalyst was filtered off and the ethanol or acetic acid was distilled off. The products were analyzed by gas chromatography.

Reduction of VIII with $NaBH_4$. A solution of VIII(5.0 g) in ethanol (100 m*l*) was added over a 30-min period to a well-stirred mixture of sodium borohydride (2.4 g) in ethanol (100 m*l*) at 0°C. After the mixture had then been allowed to stand for 24 hr at room temperature, water (50 m*l*) was added and the ethanol was removed under reduced pressure. The residue was acidified with dilute hydrocholric acid, the solution was extracted with ether, and the ether solution was washed with a sodium bicarbonate solution and then with water, and dried over anhydrous sodium sulfate. After the evaporation of the ether, the residue were analyzed by gas chromatography. The oily residue was dissolved in hot ligroin and then cooled in an ice bath. *trans*-Rich crystals of 3-methyl-4-chromanol were thus obtained. The recrystallization of them from ligroin gave the pure *trans*-chromanol (X) (mp 97—98.5°C) (1.5 g). NMR ($CDCl_3$): 0.97(3H, doublet, J=6.9 Hz, CH_3), 2.01(1H, multiplet, methine at the 3-position), 2.17(1H, singlet, OH), 4.0(2H, multiplet, methylene at the 2-position), 4.3(1H, doublet, J=4.8 Hz, methine at the 4-position), and 7.0 ppm(4H, multiplet, benzene-ring protons).

Found: C, 73.44; H, 7.46%. Calcd for $C_{10}H_{12}O_2$: C, 73.14; H, 7.37%.

12) A. Schonberg and A. Sina, *J. Chem. Soc.*, **1950**, 3344.

13) J. Colonge and A. Guyot, *Bull. Soc. Chim. Fr.*, **1958**, 325.

Reduction of VIII with $LiAlH_4$. To a well-stirred suspension of lithium aluminum hydride (0.3 g) in dry ether (50 m*l*), VIII (0.8 g) dissolved in dry ether (50 m*l*) was added over a 30-min period at 0°C; the mixture was then stirred at room temperature for 12 hr. Water (10 m*l*) and 20% sulfuric acid (5 m*l*) were then added, and the ether layer was separated. The aqueous solution was extracted with ether, and the combined ether extracts were washed with a sodium bicarbonate solution and then with water and dried over anhydrous sodium sulfate, and the ether was removed. The products were analyzed by gas chromatography.

Meerwein-Ponndorf Reduction of VIII. *Method A (The acetone was removed).* The ketone (0.02 mol) was mixed with an aluminum isopropoxide solution (prepared from 2.24 g of aluminum and 80 m*l* of dry isopropyl alcohol) and isopropyl alcohol (20 m*l*), and was then distilled slowly until acetone was no longer detectable in the distillate. The isopropyl alcohol was then removed by vacuum distillation, the residue mixed with water, and diluted hydrochloric acid was added until all the precipitated solid had dissolved. The solution was extracted with ether, and the extract was washed with a 5% sodium carbonate solution and with water, and dried over anhydrous sodium sulfate. After the evaporation of the ether, the residue was analyzed by gas chromatography. The residue oil was then distilled under reduced pressure to give 2.0g of *cis*-chromanol (IX) (bp 140—142°C/12 mmHg). The identity of IX was ascertained by a study of its IR spectrum, by gas chromatography, and by a study of its NMR spectrum. NMR ($CDCl_3$): 1.05(3H, doublet, J=6.9 Hz, CH_3), 2.0(1H, singlet, OH), *ca.* 2.2(1H, multiplet, methine at the 3-position), 4.05(2H, multiplet, methylene at the 2-position), 4.53(1H, doublet, J=3.4 Hz, methine at the 4-position), and 7.0 ppm(4H, multiplet, benzene-ring protons).

Method B (The acetone was not removed but refluxed). A solution of VIII (0.01 mol) and an aluminum isopropoxide solution (prepared from 1.12 g of aluminum and 40 m*l* of dry isopropyl alcohol) and isopropyl alcohol (10 m*l*) were refluxed for 4 hr. The reaction products were then treated as above. The residue was analyzed by gas chromatography.

3-Methyl-3-chromene (XI). 3-Methyl-4-chromanol (2.0 g) was heated with 0.2 g of *p*-toluenesulfonic acid in 200 m*l* of benzene for 10 hr. The water was successively removed by azeotropic distillation; the benzene layer was washed with a sodium bicarbonate solution and water, and the benzene was distilled off under reduced pressure. 1.5 g of XI was thus obtained. This compound was checked by a study of its IR spectrum and by gas chromatography.

The Hydroboration of XI. To a solution of 0.4g of sodium borohydride in 10 m*l* of diglyme containing 1g of XI, there was added 0.85 m*l* of boron trifluoride etherate under cooling with ice. The mixture was stirred for 3 hr at room temperature before the excess hydride was decomposed with water. The organoborane was oxidized at room temperature by the addition of 5 m*l* of a 3N solution of sodium hydroxide, followed by the drop-by-drop addition of 6 m*l* of 30% hydrogen peroxide. The reaction mixture was then extracted with ether, and the extract was washed five times with equal volumes of a saturated salt solution in order to remove the diglyme. The extract was then dried over

anhydrous sodium sulfate, and the solvent was removed. The residue was recrystallized from ligroin to give *trans*-chromanol (X) (mp 97—98°C) (0.8g).

3-Methylchroman (XII). The mixture of 2g of VIII, 0.2g of the 5% Pd-C-A catalyst, and 50 m*l* of ethanol was shaken under hydrogen at an ordinary temperature and pressure. After 2 mol of the hydrogen had been absorbed, the catalyst was filtered off and the residue were distilled under reduced pressure to give 1.2g of XII (bp 94.5—96°C/9 mmHg). This compound was checked by a study of its IR spectrum, by gas chromatography, and by a study of its NMR spectrum. NMR(CCl_4): 1.03 (3H, doublet, J=6.9 Hz, CH_3), 1.9—2.9 (3H, multiplet, methine at the 3-position and methylene at the 4-position), 3.8(2H, multiplet, methylene at the 2-position) and 6.9 ppm (4H, multiplet, benzene-ring protons).

***cis*-3-Methyl-4-acetoxychroman (XIII) and *trans*-3-Methyl-4-acetoxychroman (XIV).** XIII and XIV were prepared by the acetylation of IX and X by means of the acetic anhydride-pyridine method at room temperature overnight. These products were checked by a study of their IR spectra, by gas chromatography, and by a study of their NMR spectra. IR (liquid film): XIII, 1725, 1225 (-O-CO-CH_3) cm^{-1}; XIV, 1735, 1230(-O-CO-CH_3) cm^{-1}. NMR($CDCl_3$): XIII, 0.98(3H, doublet, J=6.9 Hz, CH_3), 2.08(3H, singlet, -O-CO-CH_3), *ca.* 2.4(1H, multiplet, methine at the 3-position), 4.0(2H, multiplet, methylene at the 2-position), 5.98(1H, doublet, J=3.4 Hz, methine at the 4-position), and 7.1(4H, multiplet, benzene-ring protons); XIV, 1.0(3H, doublet, J=6.9 Hz, CH_3), 2.08(3H, singlet, -O-CO-CH_3), *ca.* 2.3(1H, multiplet, methine at the 3-position), 4.14(2H, multiplet, methylene at the 2-position), 5.65(1H, doublet, J=4.8 Hz, methine at the 4-position), and 7.05(4H, multiplet, benzene-ring protons).

Instrumentation. The gas chromatographic analysis of the reduction products were carried out with a Hitachi Model K-53 apparatus, fitted with a 45-m Golay column coated with PEG 4000 and equipped with a flame-ionization detector. The nitrogen carrier-gas inlet pressure was 1.5 kg/cm^2, and the column temperature was 180°C. The NMR spectra were measured on a Hitachi H-60 high-resolution nuclear spectrometer. The sample was dissolved in $CDCl_3$ or CCl_4, containing TMS as the internal reference. The IR spectra were measured with a Hitachi EPI-S infrared spectrometer.

The author wishes to express his deep gratitude to Professor Sekio Mitsui of Tohoku University and to Professor Akira Kasahara of Yamagata University for their kind guidance and encouragement throughout this study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 446—447 (1970)

Study of the Sapogenins from *Albizzia lebbek* Benth. Seeds

I. P. VARSHNEY and Geeta BADHWAR

Department of Chemistry, G. S. Technological Institute, Indore-3, India

(Received March 25, 1969)

The seeds of *Albizzia lebbek* Benth. from Madhya Pradesh have been found to contain a mixture of saponins which on hydrolysis gives echinocystic acid (I), oleanolic acid (II) as major sapogenins and an unidentified sapogenin (not albigenin) in traces. The albigenic acid (III) earlier reported to be present has been shown to be an alcoholic hydrochloric acid isomerisation product of echinocystic acid.

The seeds and pods of *Albizzia lebbek* Benth. have been found to be a rich source for saponin and sapogenin contents.[1,2] Varshney *et al.*[1,2] have isolated a saponin mixture from the seeds collected from Utter Pradesh (U. P.), which on hydrolysis with 10% sulphuric acid yields three sapogenins, echinocystic acid (I), oleanolic acid (II) and a third sapogenin in trace (in the proportion 75: 20: trace).

Later Barua and Raman[3] studied the whole beans of *Albizzia lebbek* Benth. (containing pods and seeds), collected from Bengal, and reported that the hydrolysis of the crude saponin with hydrochloric acid in ethanol yields four sapogenins, echinocystic acid (I), oleanolic acid (II), albigenic acid (III) and albigenin (IV). It may be noted that the two extra sapogenins (albigenin and albigenic acid) reported by these authors[3] may be either present in pods or in the seeds from Bengal and absent in the seeds from U. P. studied by Varshney *et al.*,[1,2] or may be the artifact of alcoholic hydrochloric acid hydrolysis. To clarify this, the present work has been undertaken.

II R'=H; R''=COOH; Δ^{12-13}
III R'=OH; R''=COOH; Δ^{13-18}
IV R'=O; R''=H; Δ^{13-18}

Finely powdered *Albizzia lebbek* Benth. seeds collected from Madhya Pradesh (M. P.) were defatted with petroleum ether and exhausted with ethanol. The ethanolic extract on concentration and subsequent treatment in the usual manner gave a saponin which was purified by dissolving in a small quantity of methanol, and by adding to large amounts of ether/acetone a number of times. This caused precipitation of the saponin as a light brown coloured powder satisfying all the tests for saponins.

Half of the saponin was hydrolyzed with 10% sulphuric acid by heating on a boiling water bath for one hour and then refluxing for another hour (*cf.* Varshney *et al.*[1,2]), and the remainder of the saponin with ethanolic hydrochloric acid (using the same procedure as that of Barua and Raman[3]). The sapogenins obtained by sulphuric acid hydrolysis on thin layer chromatography showed three spots, two present in major quantity and the third one in trace only, *viz.* echinocystic acid (I), oleanolic acid (II) and an unidentified one, as earlier reported by Varshney *et al.*[1,2] The sapogenins obtained by ethanolic hydrochloric acid hydrolysis showed the presence of four prominent spots, corresponding to echinocystic acid (I), oleanolic acid (II), albigenic acid (III), and the fourth may be identical with albigenin (IV), confirmed by alongside chromatography (TLC) with authentic samples. This conclusively showed that albigenic acid (III) and most possibly albigenin (VI) are artifacts formed by the ethanolic hydrochloric acid hydrolysis of the saponin as they are not obtained in the sulphuric acid hydrolysis product of the same saponin. During alcoholic hydrochloric acid hydrolysis the migration of the double bond takes place from 12—13 position to 13—18 position yielding albigenic acid (III) from echninocystic acid (I) (I → III). This type of migration is not rare and was earlier reported by Spring *et al.*[4] All the four sapogenins were separated by repeated column chromatography on silica gel and identified by melting points, (mp obtained (I) 306—308°C (II) 305—306°C, (III) 280—281°C and (IV) 224—226°C; lit. echinocystic acid, 305—312°C, oleanolic acid, 310°C, albigenic acid, 280—281°C and albigenin, 226—228°C).

The possibility of the shifting of the double bond in the case of albigenic acid (III) was ruled out by Barua and Raman[3] by heating echinocystic acid (I) with ethanolic hydrochloric acid. It might be possible that such migration might not have taken place in their case due to some reason such as the variation in the conditions and concentration *etc.* as the experimental details of such experiment are not given.[3] In our repeated attempts, when free echinocystic acid (I) was heated with ethanolic hydrochloric acid (20%) it always yielded a number of products (3 new products and one starting material *i.e.* echinocystic acid) as shown by the thin layer chromatography. Starting with TLC pure echinocystic acid, the major product corresponded with albigenic acid (III) on thin layer chromatography. Therefore albigenic acid (III) is nothing but an alcoholic hydrochloric acid isomerisation product of echinocystic acid (I) and is not present in *Albizzia lebbek* plant, seeds or pods either as free genin or as saponin.

The albigenin (IV) is present in very small quantities in ethanolic hydrochloric acid hydrolysis product only, and this can also be a product of alcoholic hydrochloric acid isomerisation and probably some type of oxidation is taking place in the hydrolysis process itself, which might be giving rise to 16-keto acid by the partial oxidation of the echinocystic acid giving rise to a β-ketonic acid which decarboxylates in the hydrolysis process and the migration of the double bond taking place simaltaneously yielding albigenin (IV). It might also be possible that the third sapogenin (unidentified) present in trace in sulphuric acid hydrolysis product might be isomerising with ethanolic hydrochloric acid hydrolysis process yielding albigenin (IV). Therefore the aqueous sulphuric acid is a better hydrolyzing agent for saponins than alcoholic hydrochloric acid as the latter brings about isomerisation as reported in this paper and by Spring *et al.*[4] and some times corresponding ester is also formed.[5,6]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 448—452 (1970)

Studies of Hydrogenolysis. LVII.[1] Catalytic Hydrogenation of Benzalacetophenone Oxide

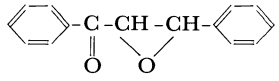
Akiko SOHMA*[1] and Sekio MITSUI

Department of Applied Science, Faculty of Engineering, Tohoku University, Aoba, Sendai

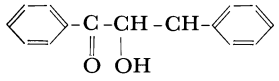
(Received April 5, 1969)

The effects of catalysts and an additive, sodium hydroxide, on the catalytic hydrogenation of benzalacetophenone oxide (I) have been studied for the purpose of elucidating the selectivity of the catalysts on the hydrogenation. The catalytic hydrogenation over palladium or Raney nickel led to the formation of the hydroxyketones as the primary products resulting from the hydrogenolysis of the epoxide ring. 1,3-Diphenylpropane-1,2-diol (III) was obtained by the catalytic hydrogenation over palladium, while 1,3-diphenylpropane-1,3-diol (VI) and III were yielded over Raney nickel. Under the basic conditions III was predominantly produced even over Raney nickel. Over platinum oxide, 2,3-epoxy-1,3-diphenylpropan-1-ol (VIII) was the primary product of the hydrogenation of the carbonyl group of I. In the hydrogenolysis of VIII, 1,2-diol (III) was produced regardless of the species of the catalysts.

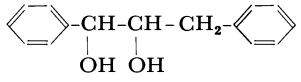
It has been shown by Herz[2] that the catalytic hydrogenation of benzalacetophenone oxide (I) gave two diphenylpropanediols, which he considered to be the diastereoisomeric α-glycols, and that the mode of hydrogenation followed I—II—III, regardless of the species of the catalysts and solvents.



(I)



(II)



(III)

On the other hand, Mitsui and his co-workers[3] reported that both α-glycol and β-glycol were obtained from the cleavage of the carbon-oxygen bond of the epoxide ring at different positions; α-glycol was obtained from the hydrogenation over palladium-charcoal, and β-glycol, from that over Raney nickel.

In order to study the selectivity of the catalysts and the effect of the additive, sodium hydroxide, on the catalytic hydrogenation of epoxyketones, benzalacetophenone oxide was hydrogenated over Raney nickel, palladium charcoal-B[4] or platinum oxide respectively in ethanol at room temperature and at atmospheric pressure. In addition to these catalytic hydrogenations, metal hydride reduction has also been carried out.

Results and Discussion

A quantitative analysis of the reduction products by gas chromatography was performed as their diastates. A qualitative analysis of the primary reduction product was carried out by means of thin-layer chromatography.

In accordance with the previous report,[3] the catalytic hydrogenation of I over palladium charcoal yielded 2-hydroxy-1,3-diphenylpropan-1-one (II) with the consumption of one mole of hydrogen, and 1,3-diphenylpropane-1,2-diol (III) (65% of *erythro*-III, 25% of *threo*-III), and other substances with the consumption of two moles of hydrogen. Diastereoisomers, *erythro*-, and *threo*-III have been prepared and characterized by Bonner and Raunio.[5] The catalytic hydrogenation of I over palladium charcoal-B to which sodium hydroxide had been added gave 1-hydroxy-1,3-diphenylpropan-2-one (IV) preferentially. The rate of the hydrogenation became slower after the consumption of one mole of hydrogen.

The Raney nickel-catalyzed hydrogenation of I

*1 Present address; Department of Chemistry, University of Hirosaki, Bunkyo-cho, Hirosaki, Aomori.

1) Part LVI; Y. Sugi and S. Mitsui, for publication.

2) W. Herz, *J. Amer. Chem. Soc.*, **74**, 2928 (1952).

3) S. Mitsui, Y. Senda, T. Shimodaira and H. Ichikawa, This Bulletin, **38**, 1898 (1965).

4) Method B: E. C. Horning, "Organic Synthesis," Coll. Vol. III, p. 686, (1955). This was named by Mitsui and Saito as the catalyst containing trace base: S. Mitsui and H. Saito, *Nippon Kagaku Zasshi*, **82**, 890 (1961).

5) W. A. Bonner and E. K. Raunio, *J. Org. Chem.*, **31**, 291 (1966).

yielded 3-hydroxy-1,3-diphenylpropan-1-one (V) and 2-hydroxy-1,3-diphenylpropan-1-one (II) as the initial products; almost equal amounts of 1,3-diphenylpropane-1,3-diol (VI) and 1,3-diphenylpropane-1,2-diols (III) were produced on further hydrogenation. In this case, a considerable amount of the deoxygenation product of the epoxide was obtained.

Semi-hydrogenation over Raney nickel to which sodium hydroxide had been added resulted in the formation of α-hydroxyketones (mainly II), while exhaustive hydrogenation led to α-glycol (80% of *erythro*-III, 10% of *threo*-III) and other substances. The fact that only a small amount of 1,3-diphenylpropan-1-ol (VII) was formed seems to indicate that the sodium hydroxide in the reaction mixture may resist the elimination of the oxygen atom of the epoxide.[6]

Though the hydrogenation over palladium or Raney nickel led to the formation of the hydroxyketones as a result of the cleavage of the epoxide ring, over platinum oxide epoxy alcohol VIII was the primary product resulting from the hydrogenation of the carbonyl group[7] of I. Other primary products formed over platinum oxide were α-hydroxyketone II and β-hydroxyketone V. The exhaustive hydrogenation yielded α-glycol III (rich in *erythro*-III) from VIII and β-glycol VI from V. The deoxygenation product, VII, was obtained over platinum oxide as well as over Raney nickel. On the other hand, hydrogenation over platinum oxide to which sodium hydroxide had been added resulted in the formation of epoxy alcohol VIII as the primary product; then α-glycol III, which was rich in the erythro isomer, was obtained, by adding hydrogen continuously.

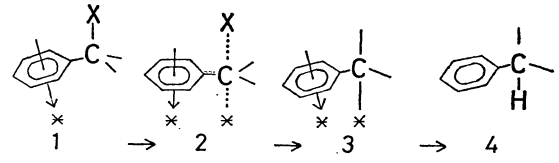
The lithium aluminum hydride reduction of benzalacetophenone oxide (I) yielded 77% of 1,2-diols III, 18% of 1,3-diols VI, and a small amount of another product. The metal hydride which was active toward the reduction of carbonyl compounds and epoxide gave epoxy alcohol VIII, α-hydroxyketone II, and β-hydroxyketone VI as the primary products in the course of the reduction. Since sodium borohydride is inactive toward the reduction of the epoxide, epoxy alcohol VIII was the only reduction product. The further hydrogenation of the product, VIII, over palladium charcoal-B yielded 54% of *erythro*-III and 46% of *threo*-III.

From these results, it is obvious that the mode of the hydrogenation of benzalacetophenone oxide is greatly affected by the species of catalysts and the additives (Chart I). Mitsui and Imaizumi have reported that the hydrogenolysis of optically-active α-methyl or α-ethylstyrene oxide gives optically-active products with the retention of the configuration over Raney nickel and with the inversion of the configuration over Raney nickel in the presence of sodium hydroxide, potassium bromide, or cesium chloride as well as over palladium or platinum oxide.[8] Similar trends have been observed in the hydrogenolysis of *trans*-dimethylstilbene oxide.[9]

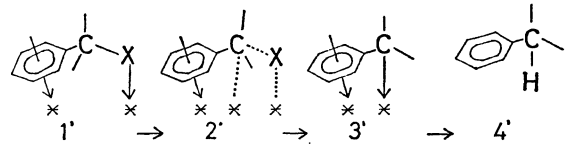
It is considered that, on the hydrogenolysis over Raney nickel, hydrogen may attack the carbon atom from the same direction as the oxygen atom of epoxide. Consequently, the reaction proceeds with the retention of the configuration. On the other hand, over Raney nickel with a small amount of alkali as well as over palladium or platinum, the hydrogen may attack from behind the carbon-oxygen bond and the reaction proceeds with the inversion of the configuration.

It is known that the catalytic hydrogenolysis of benzylic substituents is relatively easy. The high reactivity of the benzylic substituents on the catalytic hydrogenolysis may be attributed to the ease of formation of the π-benzyl intermediate. This reaction includes the adsorption of the substrate on the catalyst (1 or 1′), the cleavage of the C–X bond (2 or 2′), the formation of the π-benzyl intermediate (3 or 3′), the hydrogenolysis of the π-benzyl intermediate, and the desorption of the product from the catalyst (4 or 4′). The reaction path (A or B) determines the stereospecificity of the product; the hydrogenolysis proceeds with the retention of the configuration in Path B, whereas the configuration is inverted in Path A.[10]

Path A



Path B



Taking account of the stereochemical results obtained in the catalytic hydrogenolysis of benzylic-

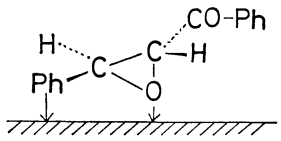

Fig. 3

type compounds, the epoxide ring may be hydrogenolyzed with the inversion of the configuration over a palladium catalyst in such a way as in Fig. 1, in which the cleavage of the benzylic C–O bond occurs selectively. On Raney nickel hydrogenolysis, the rupture of the benzylic C–O bond may occur as is shown in Fig. 2. Moreover, since Raney nickel has a strong affinity for the oxygen atom, the adsorption state shown in Fig. 3 is also plausible. In this case, the hydrogenolysis of the epoxide ring occurs at homobenzylic C–O bond because of its strain, affording β-hydroxyketone V. The addition of an alkaline substance to the Raney nickel catalyst decreases the rate of the reaction of the species, whose epoxide oxygen is adsorbed on the catalyst surface.[8] Consequently, the reaction preferably proceeds taking the adsorption state, as is shown in Fig. 1. Regardless of the species of the catalysts, the cleavage of the oxirane ring of VIII proceeds to give α-glycols selectively, in contrast to the case of the hydrogenolysis of α-ketoepoxide I.

In the case of platinum oxide to which sodium hydroxide had been added, *erythro*-III was favorably obtained from the epoxy alcohol VIII which was produced as a semihydrogenation product; however, reduction with sodium borohydride gave almost equal amounts of *erythro*-VIII and *threo*-VIII.

The catalytic hydrogenation of α-hydroxyketone II lead to the formation of *erythro*-glycol III. This process may be well specurated on the basis of Bonner and Raunio.[5]

The formation of 1-hydroxy-1,3-diphenylpropan-2-one suggests that I was isomerized to phenylbenzylglyoxal (XI) prior to reduction. This isomerization occurred in the presence of palladium charcoal, sodium hydroxide, and hydrogen, while it did not occur if any one of these three components was lacking.

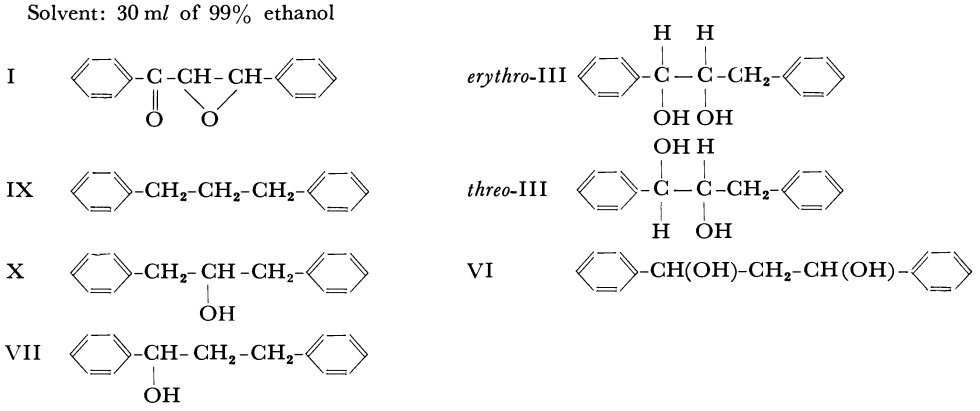
Solvent: 30 m*l* of 99% ethanol



ethanol were stirred with hydrogen at room temperature and at atmospheric pressure. The determination of the initial products in the course of the hydrogenation was done by thin-layer chromatography (T.L.C. on silica gel, chloroform 99 : methanol 1). After the hydrogen uptake had ceased with the absorption of two moles of hydrogen, the catalyst was filtered and ethanol was distilled off. The residue was acetylated with acetic anhydride in pyridine at room temperature. After having been kept standing for 12 hr, the reaction mixture was treated as usual. The products were dissolved in benzene and analyzed by V.P.C. The experimental data are summarized in Table 1.

Benzalacetophenone Oxide (I). I was prepared by the method of Weitz and Scheffer[11] by the epoxidation of benzalacetophenone; mp 90°C; 73% yield.

***threo*-1,3-Diphenylpropane-1,2-diol (*threo*-III).** *threo*-III was prepared by the method of Bonner and Raunio[5] by the *cis* hydroxylation of *trans*-1,3-diphenyl propene;[12] mp 62°C.

***erythro*-1,3-Diphenylpropane-1,2-diol (*erythro*-III).** *erythro*-III was prepared by the catalytic hydrogenation of benzalacetophenone oxide (1) over palladium charcoal-B at an ordinary temperature and at atmospheric pressure. After the hydrogen uptake had ceased with the absorption of two moles of hydrogen, the residue was fractionally recrystallized from the benzene-ligroin mixture to give pure *erythro*-III; mp 82°C; 62% yield.

2-Hydroxy-1,3-diphenylpropan-1-one (II).[13] II was prepared by the catalytic hydrogenation of benzalacetophenone oxide over palladium charcoal-B with the absorption of one mole of hydrogen; mp 66°C (recrystallized from the benzene-ligroin mixture); 50% yield.

1-Hydroxy-1,3-diphenylpropan-2-one (IV).[14] IV was prepared by the catalytic hydrogenation of benzalacetophenone oxide over palladium charcoal-B containing a small amount of sodium hydroxide, with the absorption of one mole of hydrogen; mp 114°C (recrystallized from the benzene ligroin mixture); 70% yield.

1,3-Diphenylpropan-1-ol (VII). VII was prepared by the catalytic hydrogenation of benzalacetophenone over palladium charcoal-B; bp 146—147°C/0.9 mmHg; 90% yield.

2,3-Epoxy-1,3-diphenylpropan-1-ol (VIII). VIII was prepared by reduction with sodium borohydride in methanol at room temperature. The reaction mixture was treated by the usual method. The product was recrystallized from a petroleum ether-benzene mixture. The epoxy alcohol VIII, whose melting point was 65°C, proved to be a mixture of 70% of the *erythro* and 10% of *threo*-isomer. The yield was 30%.

1,3-Diphenylpropan-2-ol (X). X was prepared by the catalytic hydrogenation of 1,3-diphenylpropane-1,2-diol over palladium charcoal-B containing one drop of concentrated hydrochloric acid at an ordinary temperature and at atmospheric pressure.

1,3-Diphenylpropane (IX). IX was prepared by the catalytic hydrogenation of 1,3-diphenylpropene.[12]

Reactions of Thioamides with Haloacids*1

Ahmedhusen SHAIKH, Akiko CHINONE and Masaki OHTA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

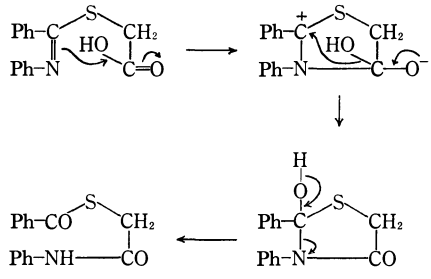
(Received May 8, 1969)

The reactions of *S*-carboxymethylisothioamide RC(=NR')SCHRCOOH with acetic anhydride proceeded through various courses depending on the reaction conditions and the structure of thioamides. When *S*-carboxymethylisothiobenzanilide (IIa) was treated with a mixture of acetic anhydride and triethylamine in the cold, an intermediate (A), presumably 2-hydroxy-2,3-diphenylthiazolidin-4-one (V), was isolated which was readily converted to benzoylthioacetanilide (IIIa). Attempts to convert A or IIIa to a mesoionic compound failed. Under the same reaction conditions as for IIa, *S*-carboxymethylisothiobenz-*p*-chloroanilide (IIb) afforded benz-*p*-chloroanilide, while corresponding *p*-anisidide (IIc) gave only tarry product. Attempts to obtain a mesoionic product from pyrrolidine-2-thione or thiocaprolactam and bromoacetic acid were unsuccessful. However, condensation of pyrrolidine-2-thione with α-chlorophenylacetic acid followed by treatment with a mixture of acetic anhydride and triethylamine gave eight-membered rearranged product (XII).

In previous papers,[1,2] we showed that the reaction of thiobenzanilide (Ia) with bromoacetic acid afforded three different products depending on the kinds of condensing agents and the reaction conditions. On refluxing a benzene solution of Ia and bromoacetic acid, benzoylthioglycolic acid anilide (IIIa) was obtained. It was proposed that the reaction proceeded *via* the pseudobase (V). Condensation of Ia with bromoacetic acid in the presence of triethylamine afforded *S*-carboxymethylisothiobenzanilide (IIa) which gave 5-acetyl-2,3-diphenyl-4-thiazone (IVb) by treatment with acetic anhydride, whereas treatment of Ia with a mixture of acetic anhydride and triethylamine gave 2,3-diphenyl-4-thiazone (IVa).

We found that when IIa was treated with a cold mixture of acetic anhydride and triethylamine, a new intermediate (A) of mp 143°C was obtained. When A was treated with ethanol, benzene or chloroform, benzoylthioglycolic acid anilide (IIIa) was obtained. Attempts to convert A or IIIa to IVa by treating with a mixture of acetic anhydride and triethylamine were unsuccessful. Elementary analysis indicated the composition of A to be $C_{15}H_{13}NO_2S$. Two structures having this composition may be taken into consideration, *viz.*, 2-hydroxy-2,3-diphenylthiazolidin-4-one (V) and 4-oxo-2,3-diphenylthiazolinium hydroxide (VI). Although we were unable to determine the structure of A unequivocally by IR or NMR spectra, pseudobase structure V seems to be more preferable to VI.

The mechanism of the formation of IVa from IIa by the action of acetic anhydride in the presence or absence of triethylamine was discussed in a previous paper.[2] The process was assumed to be similar to that proposed for the formation of sydnone from *N*-nitroso-*N*-phenylglycine, in which mixed acid anhydride is formed as an intermediate. From the present observation, it is clear that IVa is not derived from IIIa or A by internal dehydration. For the mechanism of the formation of IIIa, a probable scheme is shown below, which is quite similar to that proposed for the reaction of imidoyl chloride and glycolic acid.[3]



When *S*-carboxymethylisothiobenz-*p*-chloroanilide (IIb) was treated with a mixture of acetic anhydride and triethylamine in the cold, benz-*p*-chloroanilide was obtained instead of the rearranged product. When *S*-carboxymethylisothiobenz-*p*-anisidide (IIc) was treated with acetic anhydride in the presence or absence of triethylamine, only tarry matter was obtained.

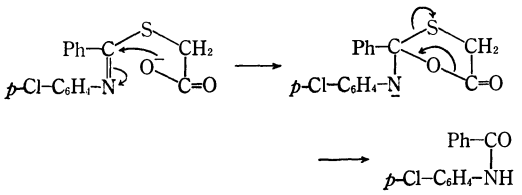
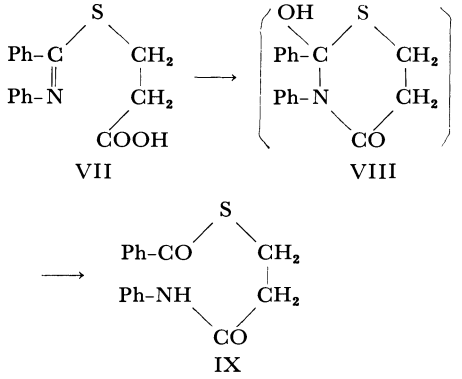
The mechanism for the formation of benz-*p*-chloroanilide may be explained by assuming that the electron attractive chlorine atom would lower the nucleophilicity of nitrogen atom and enhance the electrophilicity of carbon atom of >C=N- grouping. The latter effect would favor the attack of anion in preference to the attack of nitrogen on carbonyl carbon atom and the cleavage of C–S bond may ensue.



An unexpected result obtained in the case of thiobenz-*p*-anisidide, where the *p*-methoxy group would favor the formation of mesoionic compound by enhancing the nucleophilicity of nitrogen, may be ascribed to the instability of the mesoionic compound which would decompose if formed.

Our findings on the rearrangement of *S*-carboxymethylisothioamide prompted us to extend the reaction to the analogous *S*-(*β*-carboxyethyl)isothiobenzanilide (VII) obtained by condensing thiobenzanilide with *β*-bromopropionic acid in the presence of triethylamine. When VII was treated with a mixture of acetic anhydride and triethylamine in the cold, the intermediate analogous to A was not isolated and by working up the reaction mixture, *β*-benzoylthiopropionanilide (IX) was obtained. In this case, the rearrangement proceeds probably *via* the pseudobase (VIII).

Anticipating some information on the effect of substituents upon the reaction courses and the possibility of preparing 4-thiazone having an aliphatic substituent at 2 or 3 position, reaction of several other *N*-substituted thioamides with bromoacetic acid were attempted. Thioacetanilide (Id), when reacted with bromoacetic acid in the presence of



VII VIII IX

triethylamine in benzene at room temperature, gave an oily intermediate (IId). Treatment of this intermediate with a mixture of acetic anhydride and triethylamine gave a rearranged product, acetylthioacetanilide (IIIb). Attempts to obtain mesoionic compound by cyclizing IId with a mixture of acetic anhydride and boron trifluoride or acetic anhydride and triethylamine were unsuccessful.

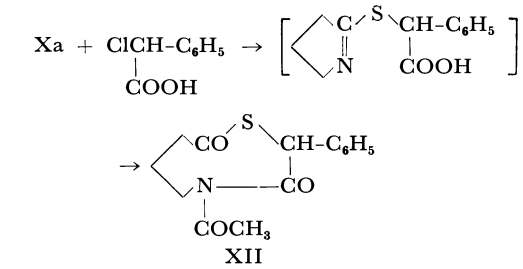
Reaction of pyrrolidine-2-thione (Xa) or thiocaprolactam (Xb) with bromoacetic acid in the presence or absence of triethylamine were also carried out and the intermediate (XIa and XIb or their hydrobromides) were obtained, which could not be cyclized to the mesoionic compounds either amine or with DCC in nitromethane.

The reaction of Xa with *α*-chlorophenylacetic acid in the presence of triethylamine, followed by treatment with a mixture of acetic anhydride and triethylamine, gave the acetylated rearranged product (XII) instead of the mesoionic compound. In a similar reaction, however, Xb did not react

with α-chlorophenylacetic acid to give the rearranged product or the mesoionic compound and tarry substance was obtained.



XII

Experimental

Intermediate (A). A solution of 5.0 g of thiobenzanilide, 3.3 g of bromoacetic acid and 5.0 g of triethylamine in 25 m*l* of benzene was heated for 1 hr at 50°C. Triethylamine hydrobromide was filtered off and washed with benzene. The combined filtrates were concentrated in a vacuum to obtain reddish viscous oil, which was dissolved in a cold mixture of 7.5 m*l* of acetic anhydride and 7.5 m*l* of triethylamine. Within a few minutes, crystals separated out. After 10 min the crystals were collected by filtration, washed well with a mixture of petroleum ether and diethyl ether (5 : 1) and dried quickly to give 4 g of pale yellow crystals, mp 143°C.

Found: C, 66.16; H, 5.01; N, 5.44%. Calcd for $C_{15}H_{13}NO_2S$: C, 66.42; H, 4.79; N, 5.16%.

β-Benzoylthiopropionanilide (IX). A solution of 2.1 g of thiobenzanilide, 1.5 g of β-bromopropionic acid and 1.4 g of triethylamine in benzene (25 m*l*) was refluxed for 2 hr. After cooling, triethylamine hydrobromide was filtered off, washed with benzene, and the combined filtrate was concentrated in a vacuum to give reddish viscous oil, which was dissolved in a cold mixture of 3 m*l* of acetic anhydride and 3 m*l* of triethylamine. A small amount of triethylamine hydrobromide separated was filtered off and the filtrate was concentrated in a vacuum to remove acetic anhydride. The resulting reddish oil was allowed to stand for one week over sodium hydroxide in a desiccator. To a partly crystallized mass, a mixture of carbon tetrachloride and petroleum ether (1 : 1) was added, and the crystals were collected and recrystallized from chloroform solution by adding petroleum ether to give colorless crystals, mp 140—141°C. The yield was 1.15 g.

Found: C, 67.53; H, 5.27; N, 5.01%. Calcd for $C_{16}H_{15}NO_2S$: C, 67.36; H, 5.26; N, 4.91%. IR(KBr): 3290 and 1640 cm^{-1} (–CONH–)

Reaction of Thiobenz-*p*-chloroanilide with Bromoacetic Acid. A solution of 3.6 g of thiobenz-*p*-chloroanilide, 2.1 g of bromoacetic acid and 3.0 g of triethylamine in 25 m*l* of benzene was heated at 50°C for 3 hr. The precipitated triethylamine hydrobromide was filtered off and the solvent was removed by evaporation in a vacuum. This left a viscous oil, which was dissolved in 6 m*l* of acetic anhydride and left standing overnight. Acetic anhydride was removed by vacuum distillation. To the residual crystalline mass ether was added and the crystals were collected by filtration and washed with ether to obtain 0.9 g of *p*-chlorobenzanilide identified by its mp (195°C) and by comparison of IR spectrum with that of an authentic sample.

A similar experiment was carried out using a mixture of 5 m*l* of acetic anhydride and 5 m*l* of triethylamine instead of acetic anhydride. Only a minute amount of *p*-chlorobenzanilide was obtained as an identifiable product.

Acetylthioacetanilide (IIIb). To a solution of 3.0 g of Id and 2.8 g of bromoacetic acid in 40 m*l* of benzene, 4.0 g of triethylamine was added and stirred for 3 hr at room temperature. The precipitates were filtered off and the filtrate was concentrated in a vacuum to give reddish oil, which was dissolved in a mixture of 5 m*l* of acetic anhydride and 5 m*l* of triethylamine and left standing overnight. The reaction mixture was then poured into ice water and after several hours the brownish semi solid mass was recrystallized from water to give 1.6 g of colorless needles of mp 94—96°C.

Found: C, 57.70; H, 5.56; N, 7.03%. Calcd for $C_{10}H_{11}NO_2S$: C, 57.41; H, 5.30; N, 6.70%.

IR: 3230, 3185, 3060, 1705, 1650, 1690 cm^{-1}.

2-Carboxymethylthio-1-pyrroline Hydrobromide (XIa-HBr). A solution of 2.5 g of Xa and 3.5 g of bromoacetic acid in 30 m*l* of benzene was heated on a water bath for 1 hr. After cooling the solution, the precipitates were collected and recrystallized from acetonitrile to give 5.8 g of colorless crystals of the hydrobromide of XIa; mp 126—128°C.

Found: C, 30.23; H, 4.26; N, 5.82%. Calcd for $C_6H_{10}NO_2SBr$: C, 30.01; H, 4.16; N, 5.83%. IR: 3450, 3200, 1730, 1605 cm^{-1}.

7-Carboxymethylthio-3, 4, 5, 6-tetrahydro-2*H*-azepine Hydrobromide (XIb-HBr). A solution of 1.2 g of thiocaprolactam and 1.4 g of bromoacetic acid in 30 m*l* of benzene was refluxed for 1 hr and after cooling, the precipitates were collected and recrystallized from acetonitrile to give 2.3 g of colorless crystals of the hydrobromide of XIb; mp 124—125°C.

Found: C, 35.91; H, 5.19; N, 5.47%. Calcd for $C_8H_{14}NO_2SBr$: C, 35.82; H, 5.22; N, 5.22%. IR: 3350, 2940, 1720, 1600 cm^{-1}.

***N*-Acetyl-2-phenyl-hexahydro-1,4-thiazocine-3,8-dione (XII).** A solution of 1.0 g of Xa, 1.7 g of α-chlorophenylacetic acid and 3 m*l* of triethylamine in 30 m*l* of benzene was heated on a water bath for 1 hr. The precipitates were filtered off and the filtrate was concentrated to give brownish oil, to which 5 m*l* of acetic anhydride and 5 m*l* of triethylamine were added and allowed to stand overnight. The precipitates were collected and recrystallized from ethanol to give 1.1 g of colorless crystals; mp 133—134°C.

Found: C, 60.54; H, 5.31; N, 5.04%. Calcd for $C_{14}H_{15}NO_3S$: C, 60.64; H, 5.45; N, 5.05%. IR: 2950, 1765, 1666, 1655 cm^{-1}.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 456—461 (1970)

Studies of Phosphorylation. IV. The Phosphorylation of Nucleosides with Phosphorus Trihalide.[1]

Masaharu YOSHIKAWA, Mitsuru SAKURABA and Koji KUSASHIO

Central Research Laboratories, Ajinomoto Co., Inc., Kawasaki

(Received May 8, 1969)

The treatment of a 2′,3′-*O*-isopropylidene nucleoside with phosphorus trichloride in the presence of trimethyl phosphate and subsequent hydrolysis gave a nucleoside 5′-phosphite in an excellent yield. Triaryl phosphates, trialkylphosphine oxides, and trialkyl phosphites were also found to be potential accelerators of the reaction. Their effects were comparable to that of trimethyl phosphate. The similar treatment of a 5′-*O*-acetyl nucleoside gave mixed nucleoside 2′- and 3′-phosphites in an approximate mole ratio of 4 : 6. The reaction intermediate, nucleoside phosphorodichloridite, was subjected to partial hydrolysis, giving the corresponding monochloridite. The product was readily oxidized to give the 5′-nucleotide. Chlorine was generally suitable as an oxidizing agent, but iodine gave better results for guanosine derivatives than did chlorine or bromine. The treatment of an unprotected nucleoside with phosphorus oxychloride in a trialkyl phosphate, prior to the reaction with phosphorus trichloride, could be used for the synthesis of a nucleoside 2′(or 3′),5′-diphosphate in a good yield.

Two methods have been reported for the preparation of nucleoside 5′-phosphates from 2,′3′-*O*-substituted nucleosides *via* the corresponding 5′-phosphites: phosphorylation with *O*-benzylphosphorous *O*,*O*-diphenylphosphoric anhydride, followed by oxidation with *N*-chlorosuccinimide,[2] and condensation with phosphorous acid by di-*p*-tolylcarbodiimide or dicyclohexylcarbodiimide, followed by oxidation with potassium permanganate.[3,4] The latter method has also been used in the preparation of nucleoside 2′(or 3′)-phosphites and- phosphates from the corresponding 5′-*O*-substituted nucleosides.

Holý *et al.* have reported that the treatment of adenosine with triethyl phosphite in dimethylformamide containing hydrochloric acid, followed by alkaline hydrolysis, gives a mixture of adenosine 2′- and 3′-phosphites in a 60% yield. A similar reaction, but carried out with triphenyl phosphite in place of triethyl phosphite, yielded a mixture of 2′(or 3′)-phosphite and 2′(or 3′),5′-diphosphite.[5]

The phosphorylation of a 5′-*O*-substituted nucleoside to give the corresponding 2′(or 3′)-phosphate has been carried out successfully by the condensation of the nucleoside with 2-cyanoethyl phosphate by dicyclohexylcarbodiimide,[6] but when dibenzyl phosphorochloridate was used, the reaction was not achieved because of the inertness of the chloridate to the secondary hydroxyl groups of nucleoside sugar.[7] The present authors attempted to prepare guanosine 2′(or 3′)-phosphate from 5′-*O*-acetylguanosine and pyrophosphoryl tetrachloride in triethyl phosphate, but the yield was 50% at best. A better method, using P^1,P^1-diphenyl P^2-morpholinopyrophosphorochloridate, has been described by Ikehara and Tazawa.[8]

Recently, Honjo *et al.*[9] have reported that the reaction of 2′,3′-*O*-isopropylideneinosine with phosphorus trichloride in acetone (or methyl ethyl ketone) in an open vessel and subsequent hydrolysis gave inosine 5′-phosphate as the major product, although similar treatment in a closed vessel gave mainly inosine 5′-phosphite. The route *via* nucleoside phosphorodichloridite was considered to be a more plausible mechanism than the phosphorylation with phosphorus oxychloride formed by the air oxidation of phosphorus trichloride.

Secondary alkyl phosphorodichloridites have been prepared by the treatment of secondary alcohols

with phosphorus trichloride under mild warming conditions.[10] This method, however, could not be directly adapted to the synthesis of nucleotides because of the highly heat-sensitive nature of nucleoside phosphorodichloridites in an acidic condition.

We have attempted to find some potentially active promotors for the reaction of a nucleoside with phosphorus trichloride at a low temperature. The method involving the reaction of 2′,3′-*O*-isopropylidene and 5′-*O*-acetyl nucleosides with a phosphorus trihalide in the presence of an appropriate organo-phosphorus compound gave nucleoside 5′- and 2′(or 3′)-phosphites respectively. The oxidation of a nucleoside phosphorochloridite with a halogen offered a convenient method for the synthesis of a nucleoside 5′- or 2′(or 3′)-phosphate. The reaction of phosphorus trichloride with a nucleoside 5′-phosphorodichloridate proceeded readily. The subsequent hydrolysis of the product after oxidation gave a nucleoside 2′(or 3′),5′-diphosphate in a good yield. This paper will deal with the synthesis of the nucleoside phosphite and phosphate using phosphorus trihalide.

Results and Discussion

Phosphorylation of 2′,3′-*O*-Isopropylidene Nucleoside. Trialkyl phosphate has shown an excellent effect in the phosphorylation of a wide field of nucleosides with phosphorus oxychloride, as has been reported in a preceding paper.[1] The addition of a trialkyl phosphate to the reaction mixture of 2′,3′-*O*-isopropylideneinosine with phosphorus trichloride caused an even more remarkable promotion and resulted in a high yield of inosine 5′-phosphite after hydrolysis, in contrast with the low yield (14%) in the reaction with phosphorus trichloride alone, as is shown in Table 1. The effect was greater with a lower alkyl phosphate. The addition of a triaryl phosphate, such as triphenyl or diphenyl tolyl phosphate, in place of a trialkyl phosphate was also useful in promoting the reaction.

An increase in the amount of a trialkyl phosphate resulted in an acceleration of the reaction. Hence, the reaction must be discontinued quickly because of the rapid decomposition of the produced 5′-phosphorodichloridite. On the phosphorylation of 2′,3′-*O*-isopropylideneinosine with two mole-equivalents of phosphorus trichloride in trimethyl phosphate, only a quarter of an hour at 0°C was enough to give inosine 5′-phosphite in a 93% yield after hydrolysis; if the reaction period was prolonged, the yield was about 60%.

The oxidation of a nucleoside phosphite was carried out successfully by a halogen and yielded a nucleoside 5′-phosphate in a good yield. After the phosphorylation mixture had been poured into ether, the 2′,3′-*O*-isopropylideneinosine 5′-phosphorodichloridite (II) thus precipitated was centrifuged and dissolved again in fresh trimethyl phosphate.

The direct treatment of the solution with chlorine resulted in a serious decomposition of the nucleoside

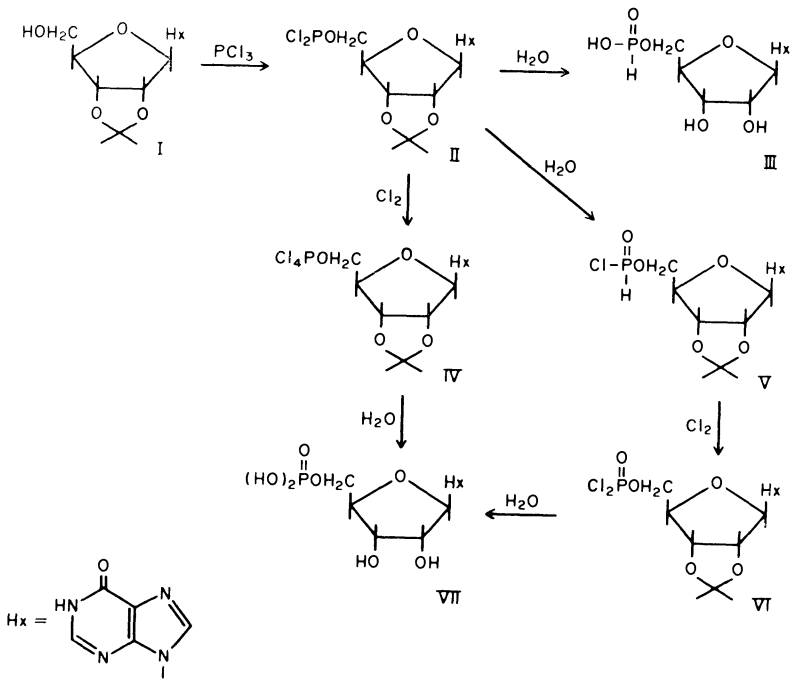
* 5 mmol of 2′,3′-*O*-isopropylidene nucleoside was treated at 0°C.

** The results of phosphorylation with phosphorus tribromide comparable to phosphorus trichloride are shown in parentheses.

10) G. M. Kosolapoff, "Organo-phosphorus Compounds," John Wiley & Sons, New York (1950), p. 180.



because of the probable instability of the tetrachlorophosphorane (IV) produced during the reaction. However, inosine 5′-phosphate (VII) was obtained in a 73% over-all yield from the starting nucleoside (I) by the careful partial hydrolysis of the phosphorodichloridite (II) by adding about an equimolar amount of water per mole of the intermediate II and by the subsequent oxidation of V with chlorine. Other halogens, such as bromine and iodine, could also be used for oxidation in the same way, but a number of usual oxidizing agents could not be used for this purpose.*1

The use of phosphorus tribromide in place of phosphorus trichloride resulted in a lower yield of a nucleoside 5′-phosphite. Especially, the treatment of 2′,3′-*O*-isopropylideneinosine with phosphorus tribromide alone gave only a trace of inosine 5′-phosphite.

The addition of a trialkylphosphine oxide or trialkyl phosphite to this reaction gave good results in spite of the ineffectiveness of both on phosphorylation with phosphorus oxychloride. However, the latter's effectiveness as an additive decreased sharply according to the increase in the carbon numbers of the alkyl group.

This method is generally applicable to the synthesis of other 5′-nucleotides; the results are shown, along with the results of the investigation of 2′,3′-*O*-isopropylideneinosine, in Table 1.

Phosphorylation of 5′-*O*-Acetyl Nucleoside. The reaction of 5′-*O*-acetyladenosine with a large excess of phosphorus trichloride did not give adenosine 2′(or 3′)-phosphite. The addition of a small amount of triethyl phosphate to the reaction mixture also resulted in only a small percentage of the phosphorylation product, unlike the case of a 2′,3′-*O*-isopropylidene nucleoside. However, adenosine 2′(or 3′)-phosphite was produced in a quantitative yield by the treatment of 5′-*O*-acetyladenosine with two mole-equivalents of phosphorus trichloride in triethyl phosphate and by subsequent hydrolysis. The phosphorylation was completed after a longer period than that needed for 2′,3′-*O*-isopropylideneadenosine. The mole ratio of the adenosine 2′- and 3′-phosphites was 36 : 64, which was very close to the result reported by Holý.[5] Since other 5′-*O*-acetyl ribonucleosides also produced mixtures of the corresponding 2′- and 3′-phosphites in similar mole ratios, as is shown in Table 2, it was clear that the 2′-hydroxyl group was less reactive than the 3′-hydroxyl group.

An oxidation giving a mixture of adenosine 2′- and 3′-phosphates in a 84% yield was carried out by a similar technique to that used for inosine 5′-phosphate. In the course of an investigation of the oxidation of a nucleoside 2′(or 3′)-phosphorodichloridite, it was found that the ease of oxidation depended upon the kind of halogen used and was generally in the order: chlorine > bromine > iodine. However, the oxidation of guanosine 2′(or 3′)-phosphorodichloridite with chlorine gave only a trace of the corresponding phosphate because of the destruction of the heterocyclic nucleus, which was detected by the loss of the ultraviolet absorption. In this case, the highest yield was

*1 The investigation of the oxidation was carried out with the cooperation of Mr. Takashi Yamashita.

* 0.04 mol of nucleoside was treated successively at 0°C by 0.08 mol of phosphorus oxychloride, 0.08 mol of phosphorus trihalide for 1 hr, 0.48 mol of water and 0.12 mol of halogen for 2 hr in 100 m*l* of trimethyl phosphate.

** This represents the time of the first phosphorylation with phosphorus oxychloride.

achieved by less reactive iodine.

Synthesis of Nucleoside 2'(or 3'),5'-diphosphate. It is known that the 2'- and 3'-hydroxyl groups were inactive compared with the 5'-hydroxyl group. On the other hand, a nucleoside 2'(or 3')-phosphorodichloridite in a reaction mixture was relatively stable even over a prolonged reaction time, despite the sharp decomposition of the 5'-phosphorodichloridite. Thus, the differences in reaction rate between sugar 2'(or 3')- and 5'-hydroxyl groups, and in stability between the corresponding phosphorodichloridites, interfered with the extension of this procedure to the synthesis of a nucleoside 2'(or 3'),5'-diphosphate directly from an unprotected nucleoside.

A combination of phosphorus oxychloride and phosphorus trichloride was utilized for the synthesis. An attempt at the phosphorylation of an unprotected nucleoside in one step with a mixed solution of the combining phosphorylating agents in a trialkyl phosphate resulted in failure. This is considered to be due to the markedly rapid reaction of the unprotected nucleoside with phosphorus trichloride in comparison with that with phosphoryl chloride and to the different properties, described above. However, the treatment of an unprotected nucleoside with phosphorus trichloride, after phosphorylation with phosphorus oxychloride sufficient to give a nucleoside 5'-phosphorodichloridate, and subsequent oxidation gave an excellent yield of the corresponding diphosphate. All of these procedures were carried out in one solution without the isolation of the intermediate.

Experimental

Detection and Analysis of Nucleotides. Paper chromatographies were developed by the ascending technique on Toyo Roshi No. 51 paper with Solvent 1: *n*-propyl alcohol - concentrated ammonium hydroxide - water (20 : 20 : 3), and Solvent 2: isopropyl alcohol - saturated ammonium sulfate - water (2 : 79 : 19). The nucleotides were detected by ultraviolet light and by spraying on a Hanes-Isherwood reagent, as has previously been descrived.[11] The yields were estimated by means of the ultraviolet absorption intensities of the solutions eluted from the spots with 0.1 N hydrochloric acid.

Nucleoside 2'(or 3')-phosphites, 2'(or 3')-phosphates, and 2'(or 3'),5'-diphosphates were chromatographed on thin layers of MN-Cellulose powder 300 (0.25 mm

11) M. Yoshikawa and T. Kato, This Bulletin, **40**, 2849 (1967).

thick) (Macherey, Nagel & Co., Germany) on a glass plate (20×20 cm) using the ascending technique with Solvent 3: isopropyl alcohol - saturated ammonium sulfate - 0.5 M sodium acetate (2 : 79 : 19). For nucleoside diphosphates, the faster-running compounds were assumed to be 2′,5′-diphosphates, judging from the behavior of inosine 2′,5′-diphosphate.

The R_f values are summarized in Table 4.

TABLE 4. R_f VALUES OF NUCLEOTIDES

Phosphorylation of 2′,3′-*O*-Isopropylideneinosine with Phosphorus Trichloride (as a Typical Example). To a cold mixture of phosphorus trichloride (8.7 m*l*, 100 mmol) and trimethyl phosphate (1.17 m*l*, 10 mmol), 1.54 g (5 mmol) of 2′,3′-*O*-isopropylideneinosine were added; the mixture was stirred for 1 hr at 0°C and then poured into 50 m*l* of ether. The precipitate was separated by a centrifuge and dissolved in about 30 m*l* of ice water, and the aqueous solution was hydrolyzed at 70°C after being adjusted to pH 1.5 with 6 N sodium hydroxide. Paper chromatography showed the presence of inosine 5′-phosphite in a 90% yield, as is shown in No. 3 of Table 1.

The effects of the other additives used in the same manner instead of trimethyl phosphate are summarized in Table 1, along with those of some other 2′,3′-*O*-isopropylidene nucleosides.

The solution was neutralized, absorbed on a Dowex 1×8 ($HCOO^-$) (50—100 mesh) column, and eluted with 0.02 N formic acid. The fraction of inosine 5′-phosphite was neutralized with 6 N ammonium hydroxide and concentrated to about 20 m*l*. Ammonium inosine 5′-phosphite (1.23 g) was separated by the addition of 60 m*l* of ethyl alcohol and purified by reprecipitation from the aqueous solution with ethyl alcohol.

Found: C, 32.96; H, 5.00; N, 19.09; P, 8.77%. Calcd for $C_{10}H_{16}O_7N_5P \cdot H_2O$: C, 32.70; H, 4.94; N, 19.08; P, 8.43%.

The product was converted into inosine 5′-phosphate in a 39% yield by permanganate oxidation according to the method described by Schofield and Todd.[3]

Synthesis of Inosine 5′-Phosphate. To a solution of 0.87 m*l* (10 mmol) of phosphorus trichloride in 11.7 m*l* (100 mmol) of trimethyl phosphate, 1.55 g (5 mmol) of 2′,3′-*O*-isopropylideneinosine were added on cooling; the mixture was then stirred at 0°C for 15 min. The reaction mixture was poured into about 100 m*l* of ether. The precipitate was separated by a centrifuge and dissolved in 10 m*l* of trimethyl phosphate. The solution was partially hydrolyzed with 0.09 m*l* (5 mmol) of water on cooling, and then 1.68 *l* (7.5 mmol) of chlorine was introduced into the sealed vessel of the solution. After having been vigorously stirred for 45 min at 0°C, the solution was treated with 100 m*l* of ether and the precipitate was hydrolyzed at pH 1.5 in a manner similar to that described above. Inosine 5′-phosphate was obtained in an over-all yield of 73%, as estimated by paper chromatographical analysis.

Phosphorylation of 5′-*O*-Acetyladenosine with Phosphorus Trichloride (as a Typical Example). To a solution of phosphorus trichloride (1.3 m*l*, 15 mmol), in 20 m*l* (125 mmol) of triethyl phosphate, 1.55 g (5 mmol) of 5′-*O*-acetyladenosine were added, and the mixture was stirred at 0°C for 1 hr. After the treatment of the reaction mixture with ether, the precipitate was dissolved in concentrated ammonium hydroxide and the solution was allowed to stand overnight at room temperature. This solution was found by chromatographical analysis to contain adenosine 2′- and 3′-phosphites in the mole ratio of 36 : 64 and in a total yield of 94%.

The results of the phosphorylation of several 5′-*O*-acetyl nucleosides with phosphorus trihalide are summarized in Table 2.

The alkaline solution was concentrated to about 10 m*l* and then adjusted to pH 1 with concentrated hydrochloric acid. After the acidic solution had been kept overnight in a refrigerator, the precipitate was filtered and dried. The mixture of adenosine 2′- and 3′-phosphites (1.14 g) thus obtained was reprecipitated from diluted alkali - hydrochloric acid.

Found: C, 35.58; H, 4.33; N, 21.21; P, 9.41%. Calcd for $C_{10}H_{14}O_6N_5P$: C, 36.26; H, 4.26; N, 21.15; P, 9.35%.

Synthesis of Adenosine 2′- and 3′-Phosphates. After working up in the same way with the method described in the previous experiment, the solution of the phosphorylated mixture was hydrolyzed carefully with 0.8 m*l* (45 mmol) of water: 0.5 *l* (22.5 mmol) of chlorine gas was then gradually passed through the solution at 0°C with stirring. After stirring had been continued for 3 hr, the reaction mixture was poured into a cold diluted ammonium hydroxide; analysis by paper chromatography showed adenosine monophosphate to be produced in an over-all yield of 84%. The solution was then concentrated to about 10 m*l* under reduced pressure, acidified to pH 1 with concentrated hydrochloric acid, and kept in a refrigerator. A white powder of adenosine monophosphate (1.08 g) was obtained by filtration; it was identical in paper-chromatographical

behavior in solvents 1 and 2 with authentic adensosine 3′-phosphate. However, on thin-layer chromatography in Solvent 3, it was recognized to be a mixture of adenosine 2′- and 3′-phosphates in a mole ratio of 50 : 50.

Found: C, 33.83; H, 4.22; N, 20.00; P, 8.57%. Calcd for $C_{10}H_{14}O_7N_5P \cdot \frac{1}{2}H_2O$: C, 33.72; H, 4.42; N, 19.66; P, 8.48%.

Synthesis of the Disodium Salt of Guanosine 2′- and 3′-Phosphates. 5′-*O*-Acetylguanosine (1.63 g, 5 mmol) was phosphorylated much as has been described above, hydrolyzed partially, and oxidized for 9 hr at 5—10°C by 5.7 g (22.5 mmol) of iodine in place of chlorine gas. The resulting solution was poured into 100 m*l* of ether, and then the precipitate was dissolved in diluted ammonium hydroxide after centrifuging. Paper chromatography showed the presence of guanosine monophosphate in an 85% yield. The alkaline solution was then evaporated under reduced pressure, and the aqueous solution of the residue was adsorbed on a Dowex 1×2 (Cl^-) (100—200 mesh) column. The column was washed with water and eluted with 0.1 M sodium chloride in 0.003 N hydrochloric acid. The eluate was concentrated and adsorbed again on active carbon. The active carbon was washed with water and eluted with 0.5 N ammonium hydroxide. To the eluate, 6 N sodium hydroxide was added in small portions, with care taken to maintain the pH under 9 until no more ammonia was eliminated by concentration. The solution was then concentrated to about 10 m*l*, and 30 m*l* of ethyl alcohol was gradually added to it. The mixture of the disodium salt of guanosine 2′- and 3′-phosphates (1.19 g) thus obtained was recrystallized from water - ethyl alcohol and identified in a manner similar to that used for adenosine 2′- and 3′-phosphates.

Found: C, 28.74; H, 3.24; N, 16.55; P, 7.34%. Calcd for $C_{10}H_{12}O_8N_5PNa_2 \cdot H_2O$: C, 28.26; H, 3.32; N, 16.47; P, 7.28%.

Synthesis of the Dibarium Salt of Inosine 2′,5′- and 3′,5′-diphosphates (as a Typical Example). After the treatment of inosine (10.7 g, 0.04 mol) with phosphorus oxychloride (7.4 m*l*, 0.08 mol) in 10 m*l* of trimethyl phosphate for 4 hr at 0°C, phosphorus trichloride (7.0 m*l*, 0.08 mol) was added to the solution and the mixture was stirred for 1 hr. Water (8.6 m*l*, 0.48 mol) was then carefully added to the solution, and chlorine gas (2.7 *l*, 0.12 mol) was passed through with stirring. After 2 hr of oxidation at 0°C, the reaction mixture was poured into about 1 *l* of ether; the precipitate was hydrolyzed with 0.5 *l* of ice water and neutralized with 6 N sodium hydroxide. Paper chromatography revealed the presence of inosine diphosphates in a 78% yield.

In a similar manner, nucleoside diphosphates are obtained in high yields. The results are summarized in Table 3. The neutralized solution was passed through a column of a Dowex 1×2 (Cl^-) (50—100 mesh). The column was washed with water and eluted with 0.015 M sodium chloride in 0.003 N hydrochloric acid, and subsequently with 0.2 M sodium chloride in 0.003 N hydrochloric acid. The latter eluate was neutralized with 6 N sodium hydroxide, concentrated to about 100 m*l* under reduced pressure, and filtered to remove the sodium chloride. A saturated solution of 22 g of barium acetate was then added to the filtrate, and the precipitate was collected and dried. The mixture of dibarium inosine 2′,5′- and 3′,5′-diphosphates (15.4 g) thus obtained was dissolved again in 6 N hydrochloric acid, filtered, neutralized with 6 N sodium hydroxide, and reprecipitated by adding a barium acetate solution.

Found: C, 15.87; H, 2.24; N, 7.01; P, 8.24%. Calcd for $C_{10}H_{10}O_{11}N_4P_2Ba_2 \cdot 3H_2O$: C, 15.95; H, 2.14; N, 7.44; P, 8.23%.

Thin-layer chromatography showed the presence of two components with R_f values of 0.81 and 0.76 (mole ratio, 48 : 52). The faster-running component was identical with the inosine 2′,5′-diphosphate which was separated on the column chromatography of a Dowex 1×2 (Cl^-) according to the method reported by Mitsugi *et al.*[12] The slower-moving component was similarly identified as inosine 3′,5′-diphosphate.

The authors are indebted to Dr. Tetsuya Kato for his continuing guidance.

Hammett Correlation in Mass Spectra. Substituent Effects for the Migratory Aptitude of the Aryl Group in the Unimolecular Ion Decomposition of Diaryl Sulfones

Toshikazu NAGAI, Tetsuo MAENO and Niichiro TOKURA

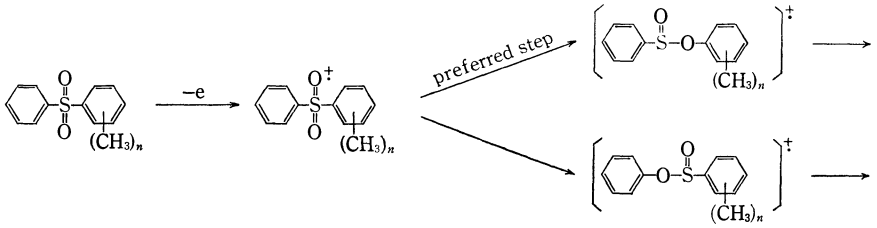
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received June 16, 1969)

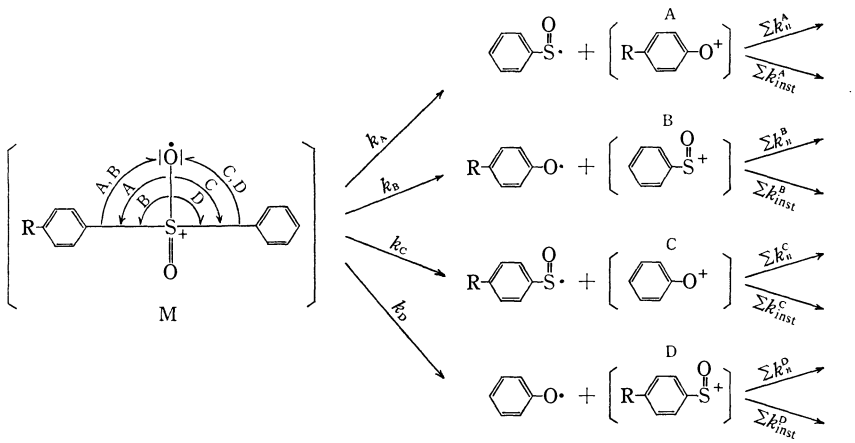
The migratory aptitude of the aryl group in the unimolecular ion decomposition reaction of *p*-substituted diaryl sulfones has been examined. Both electron-donating and -withdrawing substituents showed to be capable of increasing the migratory aptitude. On the other hand, a kinetic treatment allowed a satisfactory Hammett correlation ($\rho=0.3$) on the total abundances of the fragment ions. The energy of the cleaved bond and the production stability were shown to be important factors in the effect of the substituent on the ion decomposition.

In the mass spectra of methyl-substituted diaryl sulfones, the aryl S→O migration has been observed by Meyerson and his co-workers.[1] They have demonstrated that the migratory aptitude apparently increases with an increase in the substitution of the phenyl group by the electron-donating methyl group, and suggested that the electron deficiency is largely localized in a non-bonding oxygen orbital and that, hence, an aryl group better able to function as an electron donor should preferentially migrate (Scheme 1).

In order to obtain further information about substituent effects in the migratory aptitude on diaryl sulfones, we have now dealt with a variety of the *p*-substituted compounds, applying a kinetic method. The results we obtained on the driving



Scheme 1



Scheme 2

1) S. Meyerson, H. Drews and E. K. Fields, *Anal. Chem.*, **36**, 1294 (1964).

force of the aryl migration were somewhat different from those obtained by Meyerson and his coworkers.

Results and Discussion

By increasing the electron energy, a variety of fragment ions were formed, along with the A, B, C, and D ions (Scheme 2), as is shown in Fig. 1a. Thus, the voltage of the ionizing electrons used was chosen to be 20 eV in order to keep the products from further decomposition (Fig. 1b).

The ratios of the fragment ions (C+D) due to the migration of the unsubstituted aryl group to those (A+B) of the *p*-substituted aryl group were examined; they are shown in Table 1.

These ratios indicate, interestingly, that both electron-donating and -attracting substituents are capable of increasing their migratory aptitude, indicating a further factor in the migratory aptitude in addition to that proposed by Meyerson *et al.*,[1] that an aryl group better able to function as an electron donor should preferentially migrate.

Thus, we carried out a kinetic study in order to examine the relative rate of bond cleavage. The method by Bursey and McLafferty.[2-4] was modified which was applicable to substituted benzophenone systems involving no phenyl migration.

The concentratioons of ions (A, B, C, and D) in the source of the mass spectrometer were assumed to be dependent on their rates of formation and depletion (whether by further decomposition, $\sum k_n^{A-D}$ or by instrumental removals, $\sum_{inst}^{A-D}$,) according to Scheme 2; the rate of the appearance of A+B+C+D in the source is shown as Eq. 1:

$$\frac{d\{[A]+[B]+[C]+[D]\}}{dt} = (k_A + k_B + k_C + k_D)[M] - \{(\sum k_n^A + \sum k_{inst}^A)[A] + (\sum k_n^B + \sum k_{inst}^B)[B] + (\sum k_n^C + \sum k_{inst}^C)[C] + (\sum k_n^D + \sum k_{inst}^D)[D]\} \quad (1)$$

By the steady-state approximation, Eq. (2) is obtained:

$$(\sum k_n^A + \sum k_{inst}^A)[A] + (\sum k_n^B + \sum k_{inst}^B)[B] + (\sum k_n^C + \sum k_{inst}^C)[C] + (\sum k_n^D + \sum k_{inst}^D)[D] = (k_A + k_B + k_C + k_D)[M] \quad (2)$$

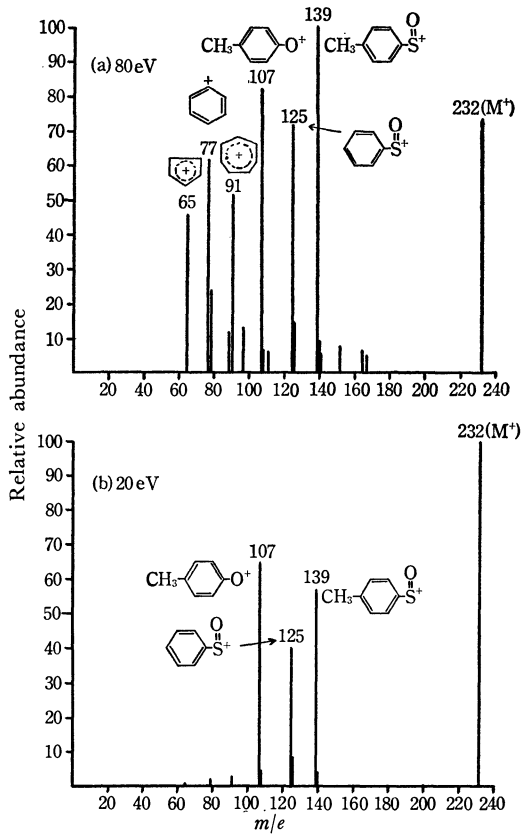


Fig. 1. Relative abundance of the fragment ions of *p*-methyldiphenyl sulfone recorded at 80 eV (a) and 20 eV (b). The peaks below *m/e* 65 are omitted here.

In the present case, if the voltage of the ionizing electrons is so low (20 eV) that no further decomposition products of the A, B, C, and D ions appear in the mass spectrum, then $\sum_n^{A-D}$ vanishes and Eq. (2) is reduced to Eq. (3), since the instrumental parameters do not vary greatly from compound to compound; *i.e.*, $\sum k_{inst}^A = \sum k_{inst}^B = \sum k_{inst}^C = \sum k_{inst}^D \equiv \sum k_{inst}$.

$$\frac{[A]+[B]+[C]+[D]}{[M]} = \frac{k_A + k_B + k_C + k_D}{\sum k_{inst}} \quad (3)$$

Z/Z_0 values defined as in Eq. (4) are given in Table 2, where the suffix zero refers to an unsubstituted compound:

Table 1. The relative abundances of the fragment ions formed by aryl migration

TABLE 2. RELATIVE INTENSITIES OF THE FRAGMENT IONS IN THE MASS SPECTRA OF *p*-SUBSTITUTED DIPHENYL SULFONE RECORDED AT 20 eV

R	$\frac{[A]}{[M]}$	$\frac{[B]}{[M]}$	$\frac{[C]}{[M]}$	$\frac{[D]}{[M]}$	Z	$\log\frac{Z}{Z_0}$
NH_2	0.700	0.028	0	0.096	0.824	−0.477
OCH_3	1.075	0.021	0	0.285	1.381	−0.253
CH_3	0.660	0.409	0	0.570	1.639	−0.178
H	0	1.235	0	1.235	2.470	0
Cl	0	2.190	0	0.695	2.885	0.068
COOH	0	2.420	0	1.292	3.712	0.177
CN	0	2.068	0.291	0.485	2.844	0.061
NO_2	0	1.655	0.974	0.658	3.287	0.124

$$\frac{Z}{Z_0} \equiv \frac{[A]+[B]+[C]+[D]/[M]}{[A_0]+[B_0]+[C_0]+[D_0]/[M_0]} = \frac{k_A+k_B+k_C+k_D}{k_A^0+k_B^0+k_C^0+k_D^0} \equiv \frac{k}{k^0} \quad (4)$$

The correlation of these data with the Hammett σ^+ constants[5] indicates a small positive ρ value (+0.37), as is shown in Fig. 2.

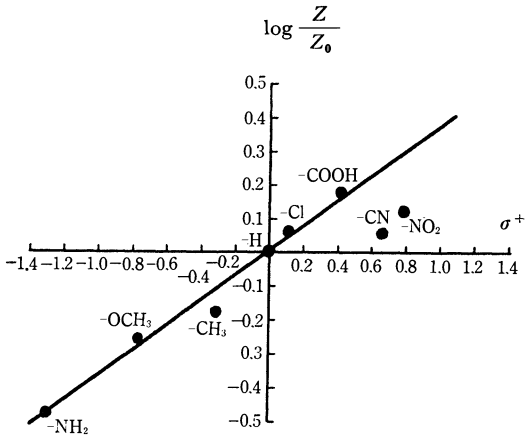

Fig. 2. Relative intensities of the total fragment ions in the mass spectra of *p*-substituted diphenyl sulfones recorded at 20 eV (derived from Eq. (3)) *vs.* σ^+ values.

For this reaction, σ values were less appropriate, indicating the presence of a full positive charge on the substituted molecular ion. Although the total abundances of fragment ions allowed a satisfactory Hammett correlation to be obtained, the effect of a substituent on the abundance of the individual fragment ions was not satisfactorily correlated by the Hammett equation.

In addition to the above-mentioned Z/Z_0 values, we found that Y/Y_0 values as defined in Eq. (5)

$$\frac{Y}{Y_0} \equiv \frac{\ln(1+Z)}{\ln(1+Z_0)} = \frac{k_A+k_B+k_C+k_D}{k_A^0+k_B^0+k_C^0+k_D^0} \equiv \frac{k}{k^0} \quad (5)$$

were applicable to the Hammett correlation, since

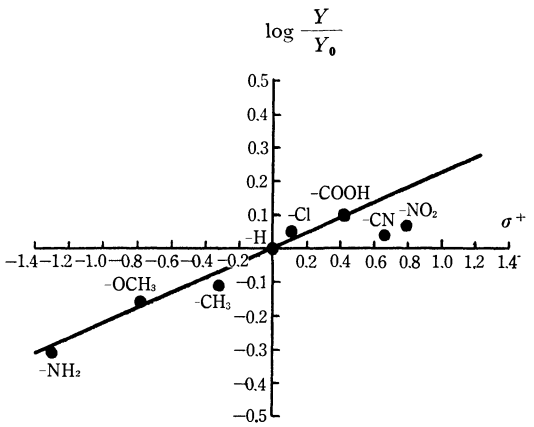

Fig. 3. Relative intensities of the total fragment ions in the mass spectra of *p*-substituted diphenyl sulfones recorded at 20 eV (derived from Eq. (6)) *vs.* σ^+ values.

the proposed values resulted in nearly the same Hammett correlation as in the case of the Z/Z_0 values, as may be seen in Fig. 3.

The coincidence of the two values can be explained by the following considerations.

Applying the general solution of the rate equation of two successive first-order reactions[6] to the present unimolecular competitive reaction shown by Scheme 2 under conditions of negligible $\sum k_n^{A-D}$ rates, Eq. (6) can be obtained by using the equation of $[M]_0 = [M] + \sum_{N=A}^{D}[N]$, where $[M]_0$ is the concentration of [M] at $t=0$:

$$\sum_{N=A}^{D}[N] = \frac{\sum_{N=A}^{D} k_N}{\sum k_{inst} - \sum_{N=A}^{D} k_N}\left([M] + \sum_{N=A}^{D}[N]\right)e^{-\sum_{N=A}^{D} k_N t} - \frac{\sum_{N=A}^{D} k_N}{\sum k_{inst} - \sum_{N=A}^{D} k_N}\left([M] + \sum_{N=A}^{D}[N]\right)e^{-\sum k_{inst} t} \quad (6)$$

5) H. C. Brown and Y. Okamoto, *J. Amer. Chem. Soc.* **80**, 4979 (1958).

6) A. Frost and R. G. Pearson "Kinetics and Mechanism," 2nd Ed., John Wiley & Sons, New York (1961), p. 166.

Assuming $\sum k_{inst} \gg \sum_{N=A}^{D} k_N$, there results:

$$\frac{\sum_{N=A}^{D}[N]}{[M]} = \frac{\sum_{N=A}^{D} k_N([M] + \sum_{N=A}^{D}[N])}{\sum k_{inst}[M]} e^{-\sum_{N=A}^{D} k_N t} \quad (7)$$

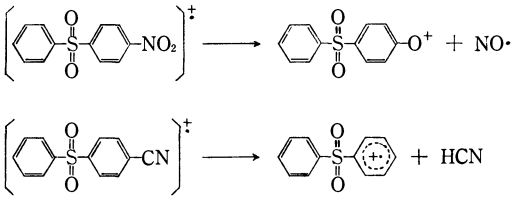
$$\ln \frac{[M] + \sum_{N=A}^{D}[N]}{[M]} = \sum_{N=A}^{D} k_N t - \ln \frac{\sum_{N=A}^{D} k_N}{\sum k_{inst}} + \ln \frac{\sum_{N=A}^{D}[N]}{[M]} \quad (8)$$

Equation (9) will be obtained if Eq. (3) is substituted for Eq. (8):

$$\ln \frac{[M] + \sum_{N=A}^{D}[N]}{[M]} = \sum_{N=A}^{D} k_N t \quad (9)$$

This situation yields Eq. (5).

As for the greater deviation from the Hammett correlation in the cases of nitro- and cyano-substituents, as Figs. 2 and 3 show, there is a very large destabilization factor of the substituents, since a large abundance of an ion, M^+–NO or M^+–HCN, was formed.



Now, we can explain the findings on the migratory aptitude shown in Table 1.

The ionization potential of sulfur is much lower than that of oxygen, and the ionization of ArSO is much easier than that of ArO; hence, ArO^+ is more sensitive to the substituent effect than $ArSO^+$, as may be seen in Table 2. Namely, the electron-donating group stabilizes ArO^+ more (preferential formation of A) than $ArSO^+$.

Thus, the increase in the migratory aptitude by the electron-donating group is attributable to the product-ion stability, though the over-all rate of bond cleavage is rather slow in the case of the electron-donating substituents, as the Hammett correlation indicates.

On the other hand, it is evident that the electron-withdrawing substituents cause a more rapid cleavage of the bond. In this case, the substituted phenyl carbon-sulfur bond will undergo a readier cleavage than the unsubstituted phenyl carbon-sulfur bond because of the effect of the substituent on the energy of the cleaved bond, for electron-withdrawing substituents destabilize the positive charge.

This may be the reason why the migratory aptitude increases with the substitution of the phenyl ring even by the electron-attracting group, because the effect of the energy of the cleaved bond overcomes the effect of the product-ion stability.

These two effects, the product-ion stability and the energy of cleaved bond, should make an important contribution to the driving force in the ion-decomposition reaction.

Experimental

The compounds used in this study were synthesized by the methods in the literature: diphenyl sulfone,[7] mp 128°C; *p*-aminodiphenyl sulfone,[8] mp 176°C; *p*-methoxydiphenyl sulfone,[9] mp 89—90.5°C; *p*-methyldiphenyl sulfone,[10] mp 124.5°C; *p*-chlorodiphenyl sulfone,[11] mp 91°C; *p*-cyanodiphenyl sulfone,[12] mp 117—118°C; *p*-nitrodiphenyl sulfone,[13] mp 140—141°C, and *p*-phenylsulfonylbenzoic acid,[14] mp 267—268°C. They contained no impurities detectable by mass spectrometry.

The spectra were recorded on a Hitachi RMU-6E single-focusing instrument with both inlet and source temperatures of 250°C.

Alkoxysilanes. IV. Preparation of Alkoxysiloxy Derivatives of Titanium

Yoshimoto ABE and Ichiro KIJIMA

Department of Industrial Chemistry, Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received July 7, 1969)

Alkoxysiloxy derivatives of titanium and polymeric substances with Ti-O-Si bonds were prepared. The reaction of titanium tetra-isopropoxide or bis(acetylacetonato)di-isopropoxytitanium with tri-*t*-butoxysilanol led to the formation of the derivatives of $[(Bu^tO)_3SiO]_nTi(OPr^i)_{4-n}$ ($n=2$ and 3) and those of $[(Bu^tO)_3SiO]_2Ti(AcAc)_2$ respectively. In both of these series, the absorption peak of the Ti-O-Si bond in the IR spectrum shifted toward a lower wave number from the compounds of $n=2$ to those of $n=3$. The reaction of titanium tetra-isopropoxide with di-*t*-butoxysilanediol, as expected, gave a polymeric substance. In the reaction with bis(tri-*t*-butoxysiloxy)-silanediol, however, an unexpected cyclic compound consisting of the Ti-O-Si bond was obtained; its presence was confirmed by a study of the IR and NMR spectra, by elemental analysis, and by molecular-weight determination. In order to obtain a linear polymer, the reaction of the titanium acetylacetonato chelate with the silanediols was carried out to give a reddish-brown, highly viscous liquid or solid. These polymeric substances were soluble in common organic solvents and have an appreciable hydrolytic stability, but only a moderate thermal stability.

In order to obtain thermally-stable polymers, the syntheses of alkylsiloxy derivatives of metals containing the M–O–Si heterosiloxane bond have been studied. However, no alkoxysiloxy derivatives of metals have been investigated. We have already reported on the preparation of alkoxysiloxy derivatives of antimony[1] during the course of an investigation of a series of alkoxysiloxy derivatives of metals. In the present work, the authors have tried to prepare alkoxysiloxy derivatives of titanium.

Alkoxysiloxy derivatives of titanium were afforded by the following reactions:

$$M(OPr^i)_4 + nROH \rightarrow (RO)_nM(OPr^i)_{4-n} + nPr^iOH \quad (I)$$

$$(AcAc)_2M(OPr^i)_2 + 2ROH \rightarrow (AcAc)_2M(OR)_2 + 2Pr^iOH \quad (II)$$

$$M(OPr^i)_4 + (RO)_2Si(OH)_2 \rightarrow \text{polymer} + \text{cyclic compound} \quad (III)$$

$$(AcAc)_2M(OPr^i)_2 + (RO)_2Si(OH)_2 \rightarrow \text{polymer} \quad (IV)$$

where M=Ti, R=$(Bu^tO)_3Si$, and $n=2$ and 3.

In reaction (I), the products of $n=2$ and 3 were obtained, but it was difficult to obtain tetrakis (tri-*t*-butoxysiloxy)titanium ($n=4$) even by the reaction of tris(tri-*t*-butoxysiloxy)isopropoxytitanium with tri-*t*-butoxysilanol in a sealed tube. Molecular-weight determinations showed that these compounds were monomeric.

Breed and Haggerty[2] reported that the reaction of bis(acetylacetonato)di-isopropoxytitanium with triphenylsilanol did not yield the corresponding derivative, but, rather, the disproportionation product, tetrakis(triphenylsiloxy)titanium. In this work we found that the alkoxy groups in the acetylacetonato chelate were easily displaced to form bis (tri-*t*-butoxysiloxy) bis(acetylacetonato)titanium in a good yield (80%) according to reaction (II). The products from reactions (I) and (II) are soluble in all common organic solvents except alcohol, and the acetylacetonato chelate is more stable to hydrolysis than the others. These products were also confirmed, by a study of their IR and NMR spectra, to have the structures shown in Table 1. It has previously been established that the absorption peak due to the titanosiloxane bond Ti–O–Si is in the region from 910 to 930 cm^{-1}.[3] The alkoxysiloxy derivatives of titanium also showed their peaks in the same region. When the absorption in the compound of $n=2$ was compared with that of $n=3$, it was found to shift to a lower wave number by 15 cm^{-1} from the former to the latter. In the NMR spectra of $n=2$, the signal of methyl protons due to isopropyl groups appears as a doublet at 8.82 τ, whereas in $n=3$ it shifts to an appreciably

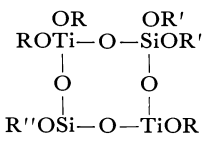
The figures in the parentheses indicate the shoulder.

lower field (8.78 τ, singlet). These facts seem to result from the large difference in proton number between the methyl protons (81H) of the tri-*t*-butoxysiloxy group and those (6H) of the isopropyl group and from the low wave number-shift in the IR spectra of the Ti–O–Si bond. On the other hand, the peak of the tri-*t*-butoxysiloxy derivative of the titanium acetylacetonate chelate due to the Ti–O–Si bond is at a wave number lower by 30 cm^{-1} than that of $n=2$. The NMR spectra of this compound show signals at 5.82 (–CH=) and 9.36, 9.45 τ (shoulder), probably due to the *t*-butyl and methyl groups in the acetylacetonato group. Usually, the tri-*t*-butoxysiloxy group exhibits a signal in the vicinity of 8.70 τ, and the enol type of acetylacetone, at 8.03 and 4.50 τ. Therefore, the high field-shift of the derivative may be attributed to the coordination of acetylacetone to the titanium atom.

Since, in reactions (I) and (II), the exchange reaction between titanium tetraalkoxides and tri-*t*-butoxysilanol had been carried out easily, it was expected that polymers with the Ti–O–Si bond in the molecular main chain might be obtained by reactions (III) and (IV). In the case of R=*t*-Bu, reaction (III) gave only polymeric substances of a pale yellow solid very soluble in organic solvents (it decomposed at about 200°C), although the structure was not confirmed. In the case of R=$(Bu^tO)_3Si$, however, a crystalline substance with a sharp melting point (decomposition) was produced by recrystallization from benzene. The results of the elemental analysis, the molecular-weight determination, and a study of the NMR (Fig. 1) and IR spectra revealed that the structure of the product consisted of an eight-membered ring containing Ti–O–Si bonds, as is shown below:



where R=*i*-Pr and R′=$(Bu^tO)_3Si$

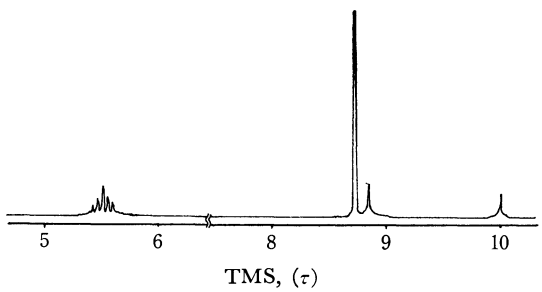


Fig. 1. NMR spectra of cyclic titanosiloxane.

The fact that the reaction of titanium tetraalkoxide with the similar, bifunctional silanediol gave rise to the formation of a polymeric product in one case or a cyclic tetramer in another is thought to be attributed to the difference in the steric hindrance between substituents in the silanediols. Reaction (IV) gave dark reddish, resinous products. These products were treated with active charcoal and activated alumina to give transparent, reddish-orange products which were highly soluble in common organic solvents, able to form a fiber, and resistant to hydrolysis. The results of the elemental analysis were in accordance with the calculated value for a linear structure,  . The molecular-weight determination of the polymeric substances by the vapor-pressure method indicated that the degree of polymerization of the polymer containing the tri-*t*-butoxysiloxy group (about 2) was lower than that with the *t*-butoxy group (27—28). This is probably due to the larger steric effect of the side chain in the former.

As Fig. 2 shows, the decomposition of the polymers takes place at 150 to 200°C and a remarkable weight loss (about 60%) is observed from 200 to 300°C. As compared with the polyalkoxysiloxanes[4]

4) Y. Abe and I. Kijima, This Bulletin, **42**, 1118 (1969).

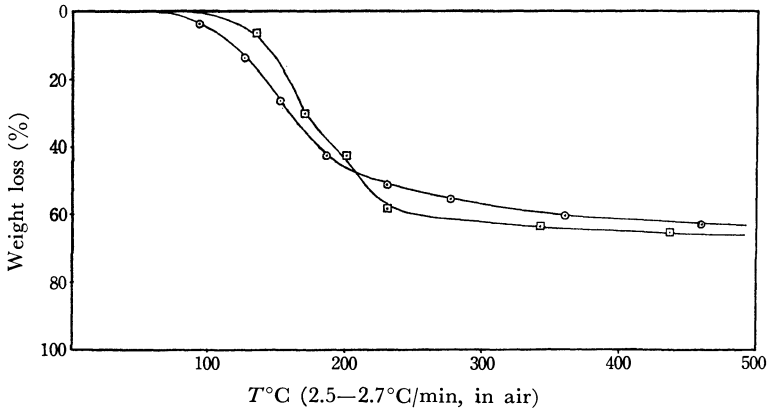

Fig. 2. TGA curve of polybis(acetylacetonato)titanosiloxane.
⊙; $[-Ti(AcAc)_2-O-Si(OBu^t)_2-O-]_n$, ⊡; $[-Ti(AcAc)_2-O-Si[OSi(OBu^t)_3]_2-O-]_n$

and polyalkoxysilanes[5] already reported on, the low thermal stability of the polymers may be attributed to the difference in electronegativity between the heteroatom and silicon in the heterosiloxane bond.

Experimental

All the experiments were carried out under a dry atmosphere or nitrogen purge. The melting points and boiling points were uncorrected.

Materials. Commercially-available titanium tetra-isopropoxide was redistilled before use.[6] The bis(acetylacetonato)di-isopropoxytitanium was obtained by the method described in the literature.[7] The tri-*t*-butoxysilanol and bis(tri-*t*-butoxysiloxy)silanediol were prepared by the method already described.[4] Although di-*t*-butoxysilanediol was obtained by Miner and Bryan,[8] in this work it was prepared by the hydrolysis of di-*t*-butoxydichlorosilane in the presence of aniline: to a solution of 5.0 g (0.281 mol) of water, 26.1 g (0.281 mol) of aniline, and 150 m*l* of ether made homogeneous by adding 50 m*l* of acetone, 34.5 g (0.140 mol) of the dichlorosilane, dissolved in 100 m*l* of dry ether, were stirred in, drop by drop, at from −5 to −10°C. After a 30-min refluxing the aniline hydrochloride was filtered out, and solvent was removed *in vacuo*. The residual white solid was dissolved by adding light petroleum ether. After the precipitate had been removed, the filtrate gave 20.1 g (69%) of needle crystals; mp 101—102°C. Found: C, 47.03; H, 9.79; Si, 13.18%. Calcd for $C_8H_{20}O_4Si$: C, 46.13; H 9.61; Si, 13.46%.

Tris(tri - *t* - butoxysiloxy) - isopropoxytitanium. To a solution of 8.3 g (0.0292 mol) of titanium tetra-*i*-propoxide in 70 m*l* of benzene, 23.1 g (0.0876 mol) of tri-*t*-butoxysilanol were added. The mixture was refluxed for 1 hr, and then the solvent was removed, along with the alcohol formed. On evaporating to dryness *in vacuo*, the residue was recrystallized from *n*-hexane to give 13.4 g (63%) of crystalline plates, mp 157—160°C. Attempts to distil at 250 to 300°C *in vacuo* (1 mmHg) failed because of its decomposition. Found: C, 52.82; H, 10.30; Si, 9.38; Ti, 5.34%. mol wt, 896.

Bis(tri-*t*-butoxysiloxy)di-isopropoxytitanium. A mixture of 29.0 g (0.102 mol) of tri-*t*-butoxysilanol and 100m*l* of benzene was refluxed for 1.5 hr. After the solvent had been removed, along with the alcohol formed, the residue was fractionally distilled to give 41.0 g (60%) of a transparent liquid; bp 161—162°C/1 mmHg, n_D^{20} 1.4304. Found: C, 50.59; H, 10.61; Si, 8.11; Ti, 6.23%; mol wt, 780. Calcd for $C_{30}H_{68}O_{10}Si_2Ti$: C, 51.99; H, 9.88; Si, 8.11; Ti, 6.91%; mol wt, 697.

Bis(tri - *t* - butoxysiloxy)bis(acetylacetonato)titanium. A mixture of 4.7 g (0.0129 mol) of bis(acetylacetonato)di-isopropoxytitanium, 6.8 g (0.0258 mol) of tri-*t*-butoxysilanol, and 60 m*l* of benzene was refluxed for 1 hr. After the subsequent removal of the solvent, the residue was distilled to give 7.7 g (77.5%) of a dark brown liquid, bp 187—188°C/1 mmHg, which solidified at room temperature as soon as distilled; mp 96—98°C. Found: C, 52.41; H, 9.16; Si, 7.39; Ti, 6.12%. Calcd for $C_{34}H_{69}O_{12}Si_2Ti$: C, 52.71; H, 9.07; Si, 7.27; Ti, 6.20%.

Reaction of Titanium Tetra-isopropoxide with Bis(tri-*t*-butoxysiloxy)silanediol. A solution of 4.7 g (0.015 mol) of titanium tetra-isopropoxide and 9.1 g (0.015 mol) of the silanediol in 50 m*l* of benzene was refluxed for 2 hr. The removal of the solvent and subsequent evacuation yielded a white solid (12.7 g), which was recrystallized from benzene to give 5.0 g (44%) of crystalline plates, mp 177—179°C (decomposed). Found: C, 47.67; H, 8.90; Si, 11.22; Ti, 6.65%, mol wt, 1810. Calcd for $C_{60}H_{136}O_{24}Si_6Ti_2$: C, 47.80; H, 9.08; Si, 11.18; Ti, 6.37%; mol wt, 1504.

Preparation of Polybis(acetylacetonato)titanosiloxanes from the Reaction of Bis(acetylacetonato)di-isopropoxytitanium with Silanediols. *From Bis(tri-t-butoxysiloxy)silanediol.* A mixture of 6.3 g (0.0173 mol) of the acetylacetonato chelate, 10.2 g (0.0173 mol) of the diol, and 40 m*l* of toluene was refluxed for 1 hr. After the solvent had been removed, the residue was heated at 110—120°C for 3 hr and then at 150—

5) Presented at the 21st Annual Meeting of the Chemical Society of Japan, Osaka, April, 1968.

6) The authors wish to thank the Matsumoto Pharmaceutical Co. for the supply of titanium tetraalkoxides.

7) A. Yamamoto and S. Kambara, *J. Amer. Chem. Soc.*, **79**, 4344 (1957).

8) C. S. Miner and L. A. Bryan, *Ind. Eng. Chem.*, **39**, 1368 (1947).

160°C for 2 hr more to give 15.7 g of a dark reddish, resinous solid, fusing point, 37—50°C, which was soluble in benzene, *n*-hexane, ether, acetone, and methanol. Attempts to purify this substance by fractional precipitation failed. Therefore, the raw product was subjected to analysis.

Found: C, 47.90; H, 8.81; Si, 9.22; Ti, 10.12%; mol wt, $832 \times n$.

On the other hand, the residue left after the removal of the solvent was heated at 100—120°C under reduced pressure (2—3 mmHg) to give a transparent, highly viscous resinous material. Although the fusing points were raised by heating at elevated temperatures, a remakable discoloration was apt to occur.

From Di-t-butoxysilanediol. After 1 hr's refluxing of a solution of the acetylacetone chelate (7.3 g, 0.0201 mol), the silanediol (4.2 g, 0.0201 mol), and 50 m*l* of toluene, the solvent was removed and the solution heated gave a highly viscous, reddish resinous matter (8.7 g). Due to the difficulty of purification mentioned above, the analytical data were obtained from the crude product.

Found: C, 46.38; H. 7.12; Si, 6.55%; mol wt, 12400. Calcd for $(C_{18}H_{32}O_8SiTi)_n$: C, 47.79; H, 7.13; Si, 6.21%; mol wt, $452 \times n$.

Analysis. The silicon was determined by a method similar to that described by Bradley.[9] The titanium was determined to be titanium dioxide after weighed sample had been decomposed by an aqueous alcohol solution containing ammonia.

We should like to thank Professor Yojiro Tsuzuki for his valuable advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 469—472 (1970)

Anionic Telomerizations of Styrene with Some Aromatic Amines[1)]

Teruzo ASAHARA, Manabu SENŌ and Sadayoshi TANAKA

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received July 8, 1969)

The anionic telomerizations of styrene with some aromatic amines catalyzed by sodium metal were investigated. *o*-Toluidine, *m*-toluidine, *p*-toluidine, 2,4-xylidine, 2,5-xylidine and 3,4-xylidine were used as the aromatic amines. Each amine reacted with styrene to give an addition product, which was identified as *N*-substituted 2-phenylethylamine. Though both α-hydrogen atoms on α-carbon atoms and hydrogen atoms attached to nitrogen atoms of the aromatic amines are weakly acidic, only the latter hydrogen atoms were detached by alkali species under the present experimental conditions. The formations of the products were discussed from the standpoint of anionic telomerization.

In previous papers, the base-catalyzed reactions of styrene with butylamines[2)] and the telomerizations of this monomer with secondary aliphatic amines[1)] were reported. Wegler and Pieper[3)] investigated the reactions of styrene with various amines in the presence of alkali metal and found that aniline combined with styrene into *N*-phenyl-2-phenylethylamine. Pines and Wunderlich[4)] reported that toluene and ethylbenzene react with styrene in the presence of sodium metal to form monoadducts, 1,3-diphenylpropane and 1,3-diphenylbutane, and diadducts, 1,3,5-triphenylpentane and 1,3,5-triphenylhexane, respectively. Therefore, it is interesting to study which type of compound is produced when aromatic compounds containing both α-hydrogens on α-carbons and an amino group neighboring an aromatic nuclei react with styrene in the presence of alkali matel.

In this paper the reactions of toluidines and xylidines with styrene and the structures of the products will be reported on. The reaction scheme will also be discussed.

Results and Discussion

Reactions of Styrene with Aromatic Amines. *o*-Toluidine, *m*-toluidine, *p*-toluidine, 2,4-xylidine, 2,5-xylidine, and 3,4-xylidine reacted with styrene in the presence of sodium metal to produce *N*-substituted 2-phenylethylamine **1**. The compounds

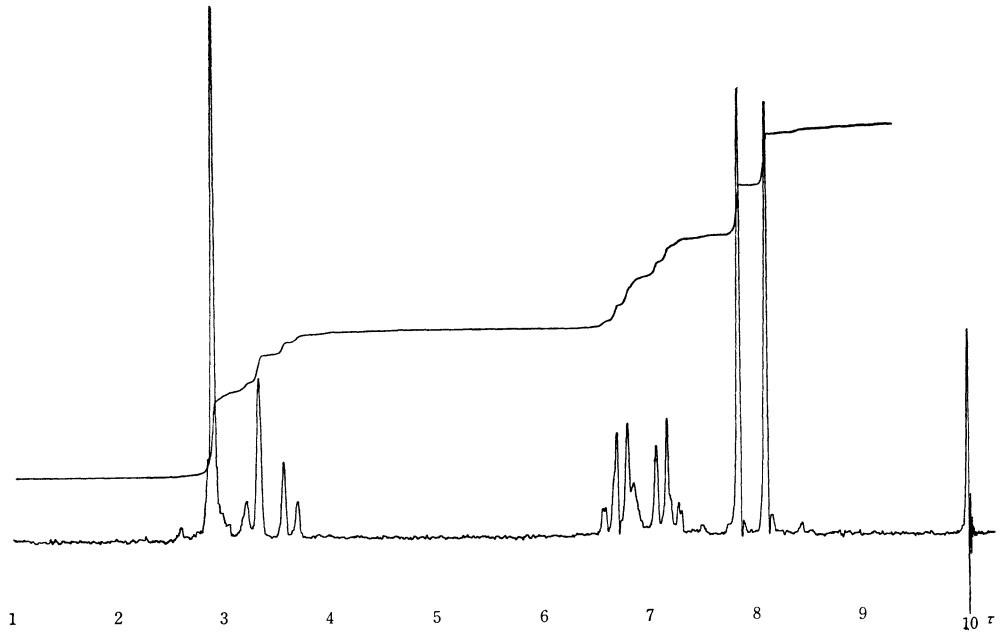
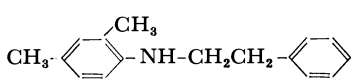
a) The molar ratio of styrene to amine was 2 : 1. 0.7 g of sodium was used in each reaction.
b) Boiling points were uncorrected.
c) Yields were calculated on the basis of amine added.



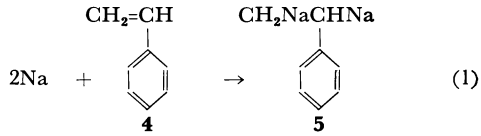


(**1d**)

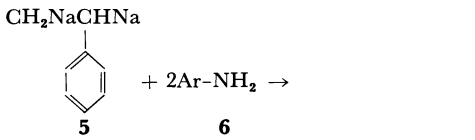
Fig. 1. The proton NMR spectrum of product **1d**.

gens attached to α-carbon atoms and those connected to the nitrogen of toluidines are weakly acidic. The proton NMR spectrum of each product showed a methyl singlet near 8τ; this is consistent with structure **1**. The reaction products derived from xylidines were analysed in the same way and were identified as **1**. Each product has still six methyl hydrogens and a hydrogen belonging to the –NH– group, whose signal (near 6.8τ) disappeared in the presence of heavy water. The proton NMR spectrum of **1d** is shown in Fig. 1 as an example.

Reaction Scheme. In the first step, sodium metal may add to styrene **4** to give an organometallic compound **5**, which then transmetalates with an aromatic amine.

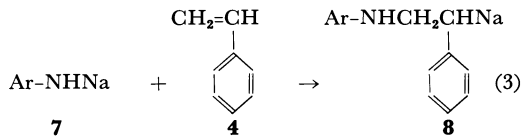


(1)

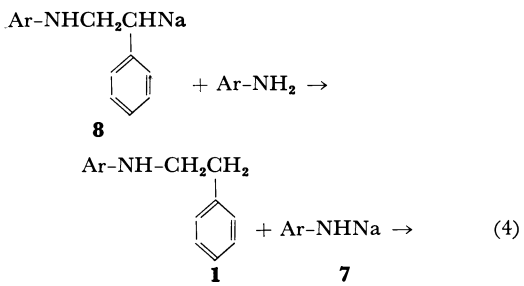


(2)

Compound **7** combines with styrene to produce an organosodium salt **8**, and **8** reacts with the amine **6**. Thus, the product **1** is obtained.

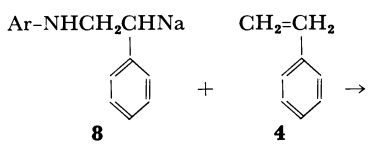


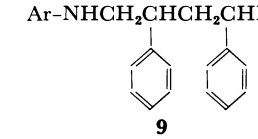
(3)



(4)

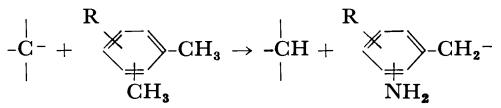
The organosodium compound **8** may react with styrene, and styrene may compete with the amine **6** for the sodium salt **8**, but the rate of reaction (5) is far slower than that of reaction (4) in the present experiment.



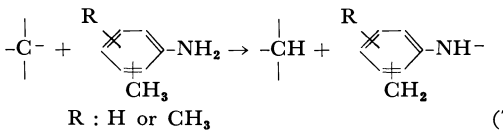


(5)

Carbanions such as **5** and **8** react more readily with hydrogen atoms attached to the nitrogen than with those of the methyl group in the following reactions:



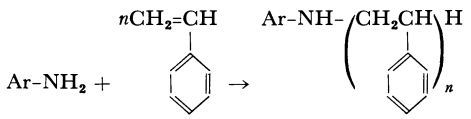
(6)



R : H or CH_3 (7)

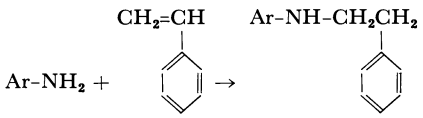
Following the concept of proton-donors and proton-acceptors, carbanions are bases and hydrogen compounds are acids, and the acid strength of the methyl hydrogens is weaker than that of the hydrogens of amino group. Therefore, reaction (7) exceeds reaction (6) in the reaction rate, and not compound **2** but compound **1** is obtained.

If an aromatic amine and styrene act as a telogen and a taxogen, respectively, the following equation of the telomerization reaction may be presented:



(8)

On combining Eqs. (3) and (4), we obtain Eq. (9):



(9)

Thus, reaction (9) may be regarded as a special case among anionic telomerization reactions (8). In other words, when a chain-transfer reaction is much faster than a propagation reaction, anionic telomerization reaction of the type (9) are realized. An organosodium compound, Ar–NNa–CH_2CH_2– , which is a weaker base than Ar–NHNa, may be too stable for another telomerization reaction (10) to take place.

Experimental

Physical Data. The molecular-weight determination by vapor-pressure osmometry was carried out in benzene at 37°C on a Hewlett Packard Model 302 vapor-pressure osmometer. The proton NMR spectra were recorded on a Hitachi Model R-20A spectrophotometer, using tetramethylsilane as the internal standard in carbon tetrachloride. For mass spectral analysis, a Hitachi RMU-6D mass spectrometer was employed, with the electron beam energy at 80 eV.

Material. The styrene was dried over anhydrous magnesium sulfate and was distilled under reduced pressure. All the aromatic amines except 3,4-xylidine were dried over sodium hydroxide and were distilled *in vacuo*. The 3,4-xylidine was recrystallized from ligroin.

***N*-(2,4-dimethylphenyl)-2-phenylethylamine (1d).** To 37.0 g of 2,4-xylidine and 0.7 g of finely-sliced sodium metal which had been heated to 150±1°C, 62.5 g of styrene was added, drop by drop, over a 0.8-hr; the reaction was then continued for a further 3.2 hr. After 55 m*l* of water and 50 m*l* of benzene had been added to the reaction mixture, the solution was neutralized with hydrochloric acid and washed with water, and the organic layer was separated, dried, and distilled *in vacuo* to give 45.4 g (67.1%) of the product, **1d**, at 160—162°C/2 mmHg. Some parts of the styrene and amines added were recovered unreacted by the distillation, and the residues were very small in quantity.

The other products were synthesized by similar procedures. Table 2 summarizes the results on the characterization of the compounds.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 43 473—480 (1970)

Anomalous Products Obtained by Nitration of Pentamethylbenzene, Pentaethylbenzene, and Some Mixed Penta-alkylbenzenes[1)]

Hitomi SUZUKI and Kiyomi NAKAMURA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received July 9, 1969)

Pentamethylbenzene has been nitrated with fuming nitric acid to give mainly a mixture of nitropentamethylbenzene and 2,3,4,5-tetramethylbenzyl nitrate. Other isomeric nitrates were not formed in any significant amount. 6-Nitro-2,3,4,5-tetramethylbenzyl nitrate, 2,3,4,5-tetramethylbenzyl alcohol, 2,3,4,5-tetramethylbenzaldehyde, 2,2′,3,3′,4,4′,5,5′,6-nonamethyldiphenylmethane, and 2,2′,3,3′,4,4′,5,5′-octamethyl-6-nitroxymethyldiphenylmethane were the minor products. Pentaethylbenzene gave a mixture of nitropentaethylbenzene and α-methyl-2,3,4,5-tetraethylbenzyl nitrate along with some products of oxidation. Preferential side-chain attack occurred at the primary alkyl group *ortho* to the unsubstituted ring position. Thus, 1-methyl-2,3,4,5-tetraethylbenzene was found to give benzyl nitrate and α-methylbenzyl nitrate nearly in equal amounts, while 3-methyl-1,2,4,5-tetraethylbenzene was found to give them in an approximate ratio of 1 : 3. 1,3,4-Trimethyl-2,5-diisopropylbenzene underwent extensive nitrodealkylation, and 3,4-dimethyl-2,5-diisopropylbenzyl nitrate was the only side-chain substituted product identified.

Electrophilic substitution of polysubstituted aromatic systems often gives unusual results which have deviated considerably from the established pathways for lightly substituted compounds. One of such examples is the nitration of penta-alkylbenzenes, where the action of the nitrating agent usually results in the replacement of one of the alkyl groups to form dinitrotetra-alkylbenzenes. Nitration of pentamethylbenzene to dinitroprehnitene was first observed by Gottschalk,[2)] who suggested that hydrocarbon underwent disproportionation to prehnitene and hexamethylbenzene under the influence of acid, and that dinitroprehnitene was formed by nitration of prehnitene. Pentaethylbenzene was also found to behave similarly towards the nitrating agent, giving 3,6-dinitro-1,2,4,5-tetraethylbenzene.[3)] Reinvestigation of the reaction, however, revealed that the products were not so simple as had been described in literature.[4,5)] The present paper deals with anomalous products from nitration of pentamethylbenzene, pentaethylbenzene, and some related mixed penta-alkylbenzenes.

Results and Discussion

When pentamethylbenzene was nitrated at −5—0°C with an excess of fuming nitric acid in chloroform or methylene chloride, the product was a light brown oily solid, the major component of which was readily identified as a benzyl nitrate from very strong infrared bands at 1271 and 1624 cm^{-1} ($-ONO_2$), and a prominent PMR peak at 4.63 τ (CH_2). Weak carbonyl and hydroxylic absorptions were also observed. Careful chromatographic treatment of the crude product on alumina gave unchanged hydrocarbon, polymethyldiphenylmethanes (XV and XXI), nitropentamethylbenzene, and tetramethylbenzyl nitrates from the light petroleum eluates; 6-nitro-2,3,4,5-tetramethylbenzyl nitrate (XII) and 2,3,4,5-tetramethylbenzaldehyde (XIII) from the benzene eluates; and a substantial amount of 2,3,4,5-tetramethylbenzyl alcohol (XI) from the ether eluates. Undoubtedly the alcohol was derived from the benzyl nitrate through the hydrolysis during the elution. Thus, the original mixture was composed mainly of 2,3,4,5-tetramethylbenzyl nitrate (III), the identity of which was further confirmed by comparison with the authentic specimen, prepared from prehnitene (I) through chloromethylation and subsequent treatment of the chloride (II) with silver nitrate in acetonitrile (Fig. 1). Other isomeric tetramethylbenzyl nitrates were also formed, but only in slight amount (less than 5%) as compared to the 2,3,4,5-tetramethylbenzyl isomer. Analysis of these minor products were carried out by gas-liquid chromatography and PMR spectroscopy. Since benzyl nitrates were not thermally so stable, gas-chromatographic analysis was carried out after their conversion into acetates. 2,3,4,6-Tetramethylbenzyl nitrate (IV) greatly exceeded 2,3,5,6-tetramethylbenzyl nitrate (V) in amount.

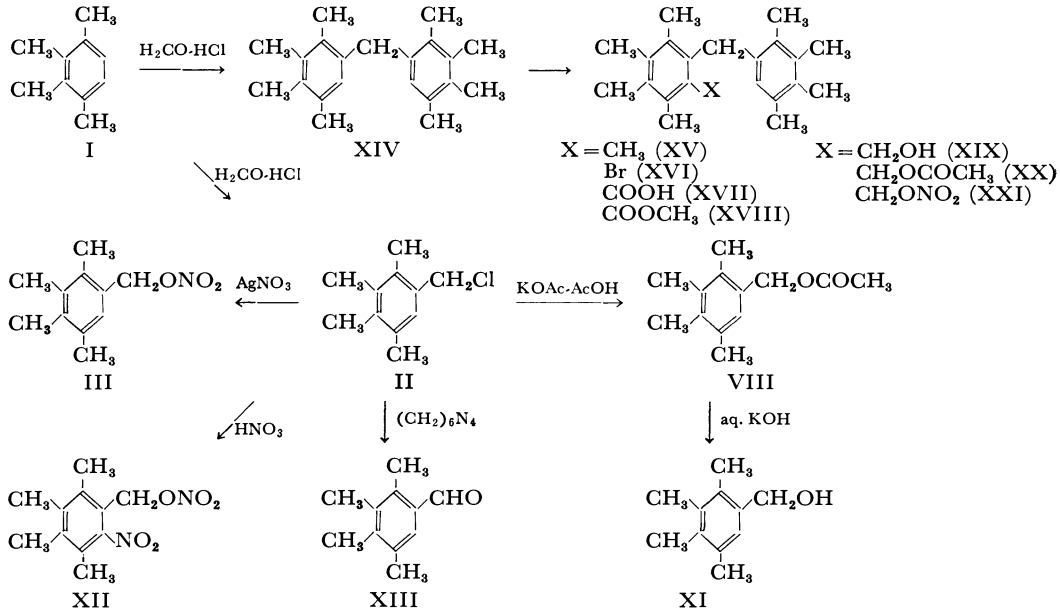

Fig. 1

PMR spectra of the light petroleum eluates showed a pair of weak, ill-resolved peaks of relative areas 1 to 2, at 3.87 and 6.05 τ. As is apparent from the structural correlations,[6] this spectral pattern strongly suggests the presence of polyalkyldiphenylmethanes. Of these the minor component was concentrated in the earlier eluates and readily identified as 2,2′,3,3′,4,4′,5,5′,6-nonamethyldiphenylmethane (XV) by spectral comparison with an authentic specimen. Another diphenylmethane with an extra peak at 4.41 τ could be isolated from a mixture of benzyl nitrates through their conversion into acetates, followed by chromatography on alumina. The later eluates gave a small amount of fine prisms, mp 170—172°C, which had the formula $C_{24}H_{32}O_2$ and showed a sharp infrared peak at 1733 cm^{-1}; PMR peaks at 8.18, 7.71—7.94, 6.09, 5.05, and 4.05 τ with relative areas 3 : 24 : 2 : 2 : 1. The peak at 8.18 τ is due to the acetoxy group, and the peaks at 7.71—7.94 τ due to eight methyl groups of two phenyl groups. The peaks at 5.05 and 6.09 τ arise from the methylene group. The remaining peak at 4.05 τ corresponds to an aromatic proton, the appearance of which at high field indicates its presence *ortho* to the methylene bridge.[6] The above spectral data agree with the structure 2,2′,3,3′,4,4′,5,5′-octamethyl-6-acetoxydiphenylmethane (XX), and therefore the original diphenylmethane is formulated as 2,2′,3,3′,4,4′,5,5′-octamethyl-6-nitroxymethyldiphenylmethane (XXI). These diphenylmethanes were probably derived from the self-condensation of III, or from the condensation of III with pentamethylbenzene. XV may also be derived from XXI through the hydride ion abstraction, as has been demonstrated by the easy conversion of pentamethylbenzyl compounds into hexamethylbenzene.[7] In fact, 2,3,4,5-tetramethylbenzyl chloride (II) heated with trifluoroacetic acid was found to give some XV besides other products.

2,3,4,5-Tetramethylbenzaldehyde (XIII) probably arose from the acid-[8] or base-catalysed[9] conversion of nitrate into aldehyde, and was isolated as a semicarbazone. The semicarbazone showed double melting which may be characteristic for the ones derived from tetramethylbenzaldehydes.[10] In contrast to nitration by mixed acid, the use of fuming nitric acid yielded dinitroprehnitene only in a small amount.

Pentaethylbenzene could be nitrated by fuming nitric acid to give a pale yellow syrup, the main component of which was again a benzyl nitrate since the product showed strong infrared bands at 1275 and 1627 cm^{-1} ($-ONO_2$) and PMR peaks at 8.26 (CH_3, d) and 2.83 τ (CH, q). Absorption due to carbonyl and hydroxylic groups was weak. Repeated chromatography of the crude product on alumina, however, gave 2,3,4,5-tetraethylstyrene (XXVII) accompanied by some unchanged hydrocarbon and nitropentaethylbenzene from the light petroleum eluates; an orange-yellow syrup with a strong carbonyl absorption from the benzene

** Numerals in parentheses refer to the number of methyl groups.

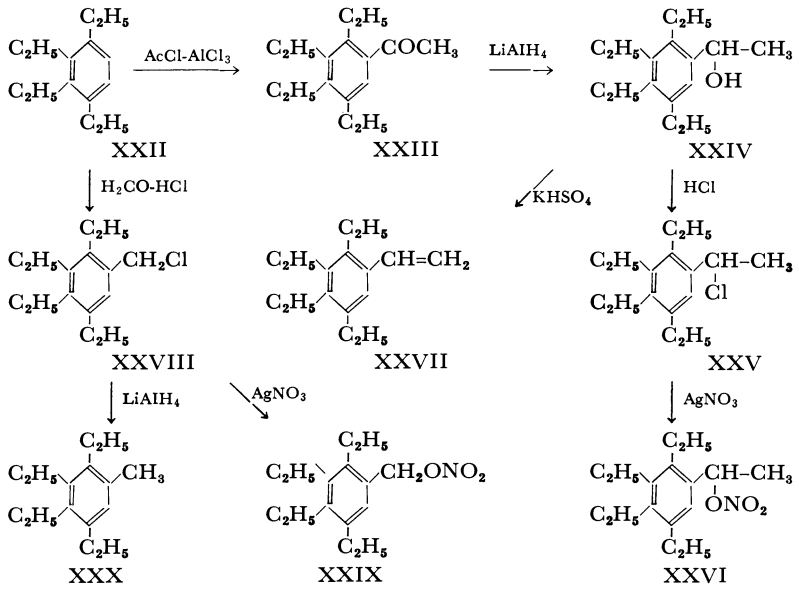

Fig. 2

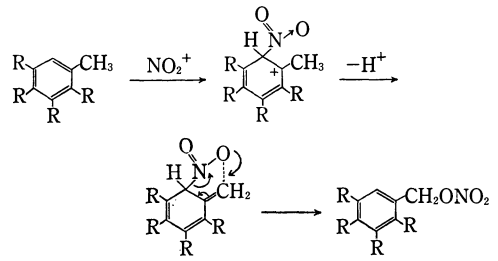
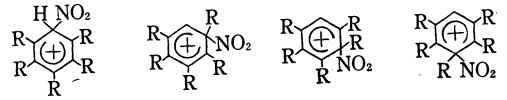
eluates; and finally a considerable amount of α-methyl-2,3,4,5-tetraethylbenzyl alcohol (XXIV) from the ether eluates. Therefore, the original nitrate was formulated as α-methyl-2,3,4,5-tetraethylbenzyl nitrate (XXVI) which underwent either hydrolysis to alcohol, or β-hydrogen elimination to the unsaturated hydrocarbon during chromatographic treatment. The structure proof of these products was made by a series of syntheses starting from 1,2,3,4-tetraethylbenzene (Fig. 2). The conversion of the α-methylbenzyl chloride (XXV) into the nitrate (XXVI) by treatment with silver nitrate in acetonitrile was not as simple as expected, and gave a mixture of several substances, although nitrate was still the main product.

With pentamethylbenzene and pentaethylbenzene, attack by nitric acid on the side-chain was almost limited to the alkyl groups adjacent to the unsubstituted position. The nuclear-to-lateral migration of the nitro group has been proposed

for such side-chain nitrooxylation of penta-alkylbenzenes.[11]



The preferred formation of the 2,3,4,5-tetra-alkylbenzyl nitrate over the 2,3,4,6-tetra-alkyl- and 2,3,5,6-tetra-alkyl isomers may be explained by the greater contribution of the intermediate benzenonium ions XXXV and XXXVII than XXXVI and XXXVIII, and the easier proton removal from the least hindered alkyl groups adjacent to the free ring position.



XXXV XXXVI XXXVII XXXVIII

High selectivity in the side-chain substitution is probably concerned with the slow step of the proton transfer from the alkyl groups of the benzenonium intermediate. Kreienbuhl and Zollinger reported that pentamethylbenzene rapidly formed an adduct with nitronium tetrafluoroborate, but showed lower reactivity towards nitration than benzene.[12] Koptyug, Krysin, and Gorfinkel also showed the nitration of 2,3,4,5,6-pentamethyldiphenyl to occur at the unsubstituted ring.[13] These results indicate that the decomposition of benzenonium ion into any side-chain products is a slower step than the nuclear hydrogen replacement, and that both processes can only compete more effectively in such a crowded system as penta-alkylbenzene.

The importance of the steric role in determining the orientation of the side-chain substitution may be understood from the nitration of some mixed penta-alkylbenzenes. The synthesis of these hydrocarbons was carried out by the routes illustrated in Figs. 2 and 3. The PMR spectra of the nitration product from 1-methyl-2,3,4,5-tetraethylbenzene (XXX) showed a methylene singlet at 4.57 τ ($-CH_2ONO_2$) and a methine quartet at 3.79 τ ($-CH(ONO_2)CH_3$), the ratio of signal intensities being 1.8 : 1, while the product from

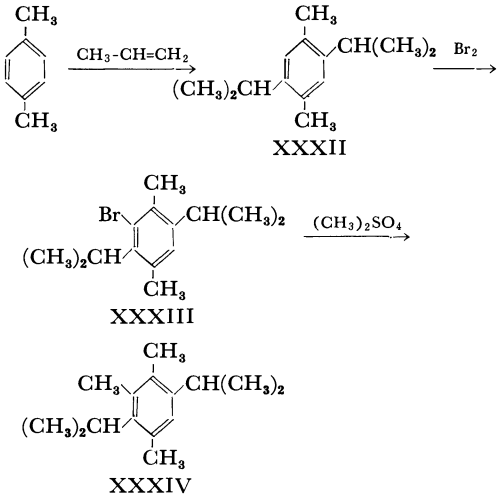


Fig. 3

3-methyl-1,2,4,5-tetraethylbenzene (XXXI) showed these signals at 4.43 and 3.78 τ with relative areas of 1 : 1.9, indicating the preferred proton release from the least hindered side-chain. Appearance of the methine signals nearly at the same position as that (3.82 τ) of XXVI indicates the attack by nitric acid on the ethyl group adjacent to the unoccupied ring position. Otherwise, the signal will appear at lower field owing to the van der Waals interactions between the $-CH(ONO_2)CH_3$ group and the two ortho alkyl groups.[14] A large downfield shift of the ring proton signal relative to the parent hydrocarbons is also consistent with the presence of $-CH(ONO_2)CH_3$ group in its vicinity. In XXX the methyl group is somewhat more reactive than the ethyl group, but the order is reversed in XXXI.

Overcrowding in pentaethylbenzene is readily understood from the marked difference in the ability of hexamethylbenzene and hexaethylbenzene to form complexes with Lewis acids.[15] Thus, the increased attack on the 3-alkyl group of XXXI as compared to XXX may be explained in terms of the increasing contribution of ion XXXVII due to the more favorable steric requirements in XXXI with respect to XXX for the access of the nitronium ion to the 2-position (Fig. 4). Attachment of the nitronium ion at the 2-position of XXXI is also facillitated not only by the favorable orientation of alkyl groups to stabilize ion XXXVII, but also by the relief of the steric strain arising from the vicinal disposition of five alkyl groups.

XXX XXXI

Fig. 4

The side-chain nitrooxylation seems to be limited to the methyl and ethyl groups; the isopropyl group remains unchanged or is replaced by a nitro group during the reaction. 2,5-Diisopropyl-1,3,4-trimethylbenzene underwent extensive nitrodealkylation, and the alumina chromatography of the product gave mainly a mixture of nitro compounds. 3,4-Dimethyl-2,5-diisopropylbenzyl alcohol was obtained from the ether eluates as the sole side-chain substituted product identified. The methyl signal due to $-C(ONO_2)(CH_3)_2$ is expected to appear at about 8.0—8.2 τ, between the two clusters of aliphatic and aromatic methyl peaks. Since the PMR spectrum of the reaction product showed only weak absorption in this region, we may conclude that side-chain substitution has not occurred to any significant extent in the isopropyl group. Because of the enhanced stability of the cation, as well as the decreased ease of hyperconjugative proton release from the isopropyl group, nitrodealkylation in this system comes to compete well with the side-chain substitution.

Experimental

Infrared spectra were determined in Nujol on a DS-402G spectrophotometer and only prominent peaks are recorded; PMR spectra were obtained in deuteriochloroform with a Varian A-60A spectrometer against internal tetramethylsilane.

Pentamethylbenzene (mp 50—52°C),[16] pentaethylbenzene (bp 155—156°C/24 mmHg),[17] 1,2,3,4-tetraethylbenzene (bp 134—136°C/23 mmHg),[18] and 1,2,4,5-tetraethylbenzene (bp 129—132°C/23 mmHg)[19] were prepared as described in literature.

2,3,4,5-Tetramethylbenzyl Nitrate (III). A warm solution of silver nitrate (10.2 g) in acetonitrile (30 m*l*) was added all at once to a magnetically stirred solution of 2,3,4,5-tetramethylbenzyl chloride (9.2 g)[20] in acetonitrile (20 m*l*). The mixture was stirred for several hours, and the silver chloride was filtered. After removal of the solvent in a vacuum, the residue was crystallized from light petroleum to yield 9.2 g (88%), mp 45—46°C. IR: 712, 751, 760, 811, 858, 882, 888, 962, 1269 ($-ONO_2$), 1289, 1620, and 1635 cm^{-1} ($-ONO_2$).

Found: C, 63.1; H, 7.4; N, 6.7%. Calcd for $C_{11}H_{15}NO_3$: C, 63.1; H, 7.2; N. 6.7%.

2,3,4,6-Tetramethylbenzyl Nitrate (IV, mp 42—44°C) and **2,3,5,6-Tetramethylbenzyl Nitrate** (V, mp 115—116°C) were prepared in a similar way from 2,3,4,6-tetramethylbenzyl chloride (VI)[21] and 2,3,5,6-tetramethylbenzyl chloride (VII)[22], respectively. The former was less stable than the other two isomers, and underwent slow decomposition on storage under diffused light.

IV: IR; 715, 755, 823, 860, 904, 1115, 1134, 1270 ($-ONO_2$), and 1631 cm^{-1} ($-ONO_2$). Found: C, 63.4; H, 7.3%. Calcd for $C_{11}H_{15}NO_3$: C, 63.1; H, H, 7.2%.

V: IR; 710, 759, 874, 895, 964, 1017, 1273 ($-ONO_2$), 1299, and 1614 cm^{-1} ($-ONO_2$). Found: C, 62.9; H, 7.2%. Calcd for $C_{11}H_{15}NO_3$: C, 62.9; H, 7.2%.

2,3,4,5-Tetramethylbenzyl Acetate (VIII). A mixture of II (3 g), sodium acetate (4.4 g), and acetic acid (7.5 g) was heated under gentle reflux for 6—7 hr. The reaction mixture was diluted with water, extracted with ether, washed with dilute sodium bicarbonate, and dried ($MgSO_4$). The ether was evaporated and the residue was crystallized from light petroleum to give colorless plates, mp 46—48°C. IR; 872, 920, 961, 1026, 1241 ($-O-COCH_3$), and 1732 cm^{-1} ($-COCH_3$).

Found: C, 75.8; H, 9.0%. Calcd for $C_{13}H_{18}O_2$: C, 75.7; H, 8.8%.

The above procedure applied to VI and VII gave **2,3,4,6-tetramethylbenzyl acetate (IX**, bp 166—167°C/22 mmHg) and **2,3,5,6-tetramethylbenzyl acetate (X**, mp 92—93°C), respectively.

IX: IR; 864, 955, 1021, 1233 ($-O-COCH_3$), and 1739 cm^{-1} ($-COCH_3$). Found: C, 75.8; H, 9.2%. Calcd for $C_{13}H_{18}O_2$: C, 75.7; H, 8.8%.

X: IR; 876, 927, 956, 1019, 1077, 1234 ($-O-COCH_3$), and 1733 cm^{-1} ($-COCH_3$). Found: C, 75.4; H, 8.9%. Calcd for $C_{13}H_{18}O_2$: C, 75.7; H, 8.8%.

2,3,4,5-Tetramethylbenzyl Alcohol (XI). The acetate was dissolved in ethanol and hydrolysed with aqueous potassium hydroxide under gentle reflux. The mixture, when poured into water, gave alcohol, which was crystallised from ethanol to give colorless needles, mp 81—82°C. IR; 995, 1025, 1076, 3256, and 3338 cm^{-1}; PMR, 7.88 (CH_3, m), 7.6 (-OH, variable), 5.65 (CH_2), and 3.19 τ (ArH).

Found: C, 79.8; H, 9.9%. Calcd for $C_{11}H_{16}O$: C, 80.4; H, 9.8%.

6-Nitro-2,3,4,5-tetramethylbenzyl Nitrate (XII). A solution of II (3.7 g) in chloroform (10 m*l*) was carefully nitrated at 0—2°C with fuming nitric acid (d= 1.50, 6.5 g). Quenching with water and removal of the solvent gave a syrupy product, which gave nitrate from ethanol as pale yellow leaflets, mp 100—101°C. Yield was poor. IR; 708, 759, 844, 877, 975, 1277 ($-ONO_2$), 1535 ($-NO_2$), and 1636 cm^{-1} ($-ONO_2$); PMR, 7.83 (CH_3), 7.71 (2 CH_3), 7.66 (CH_3), and 4.64 τ (CH_2).

Found: C, 52.0; H, 5.8; N, 10.9%. Calcd for $C_{11}H_{14}N_2O_5$: C, 52.0; H, 5.6; N, 11.0%.

2,3,4,5-Tetramethylbenzaldehyde (XIII). To a mixture of II (15 g) and ethanol (65 ml) was added with shaking hexamine (12 g) and water (15 ml). The mixture became pale yellow, and the chloride disappeared. After being stood overnight, an additional 50 ml of water was added, and the mixture was heated under reflux for 3 hr, poured into water, and the oily product was extracted with ether. Removal of the solvent, followed by distillation under reduced pressure gave aldehyde boiling at 159—160°C/23 mmHg, which soon solidified to crystalline mass, mp 39—43°C. IR; 755, 792, 836, 887, 1004, 1082, 1208, 1276, 1563, 1596, and 1692 cm^{-1}; PMR, 7.78 (2 CH_3), 7.67 (CH_3), 7.52 (CH_3), and 2.76 τ (ArH).

Found: C, 81.0; H, 9.1%. Calcd for $C_{11}H_{14}O$: C, 81.5; H, 8.6%.

The semicarbazone crystallized from ethanol as white needles. It melted at 209—210°C to a liquid which quickly solidified and remelted at 235—242°C with decomposition. Similar phenomena were reported for semicarbazones from 2,3,4,6-tetramethyl- and 2,3,5,6-tetramethylbenzaldehydes.[10]

Found: C, 65.5; H, 7.9%. Calcd for $C_{12}H_{17}N_3O$: C, 65.7; H, 7.8%.

6-Bromo-2,2',3,3',4,4',5,5'-octamethyldiphenylmethane (XVI). A solution of bromine (13 g) in chloroform (30 ml) was added dropwise to the stirred mixture of 2,2',3,3',4,4',5,5'-octamethyldiphenylmethane (XIV, 21 g)[23] and chloroform (100 ml) using a small amount of iodine as catalyst. Bromination proceeded to completion within a short time. The organic layer was washed with dilute sodium bicarbonate and dried ($CaCl_2$). The solvent was evaporated off to leave white crystals (27.2 g), mp 179—182°C. Chromatography on alumina using ligroin as eluant could raise the mp up to 187—189°C, but some dibromide could not be throughly removed from XVI because of the slight difference in solubility in ordinary solvents.

Found: C, 68.8; H, 7.4%. Calcd for $C_{21}H_{27}Br$: C, 70.2; H, 7.5%.

2,2',3,3',4,4',5,5'-Octamethyldiphenylmethane-6-carboxylic Acid (XVII). The Grignard reagent was prepared from a mixture of XVI (17 g), magnesium turnings (2.7 g), and dry tetrahydrofuran (150 ml) by the dropwise addition of ethyl bromide (10.9 g) over a period of 2 hr. The mixture was heated at 50—55°C for 3 hr, and then poured onto crushed dry ice. Dilute hydrochloric acid was added to dissolve the magnesium salt, and the tetrahydrofuran was evaporated off. The precipitated solid was dissolved in dilute sodium hydroxide and after filtration over Norit was reprecipitated with hydrochloric acid. Recrystallization from ethanol gave prisms (12 g, 78%), mp 231—232°C. IR, 880, 937, 1045, 1089, 1192, 1216, 1281, 1305, 1696 (-CO), and 3430 cm^{-1} (-OH); PMR, 8.02 (2 CH_3), 7.98 (CH_3), 7.93 (3 CH_3), 7.83 (3 CH_3) 7.75 (CH_3), 6.25 (CH_2), and 4.04 τ (ArH).

Found: C, 81.7; H, 8.9%. Calcd for $C_{22}H_{28}O_2$: C, 81.4; H, 8.9%.

Treatment of the acid XVII with ethereal solution of diazomethane gave **2,2',3,3',4,4'5,5'-octamethyl-6-carbomethoxydiphenylmethane (XVIII)**, mp 165—166°C.

Found: C, 81.9; H, 9.0%. Calcd for $C_{23}H_{30}O_2$: C, 81.7; H, 8.9%.

2,2',3,3',4,4',5,5'-Octamethyl-6-hydroxymethyldiphenylmethane (XIX). The direct reduction of the carboxylic acid XVII with lithium aluminum hydride could not be accomplished. Methyl ester XVIII dissolved in dry tetrahydrofuran was reduced with lithium aluminum hydride to give alcohol XIX, which was crystallized from ligroin and melted at 195—196°C. IR, 724, 841, 869, 985, 1032, 1068, and 3300 cm^{-1}; PMR, 7.92 (2 CH_3), 7.86 (CH_3), 7.73 (3 CH_3), 7.66 (2 CH_3), 6.08 (CH_2), 5.58 (CH_2O), and 3.99 τ (ArH).

Found: C, 85.0; H, 9.9%. Calcd for $C_{23}H_{30}O$: C, 85.1; H, 9.7%.

Alcohol XIX was readily acetylated to yield **2,2',3,3',4,4',5,5'-octamethyl-6-acetoxymethyldiphenylmethane (XX)**, mp 175—176°C.

Found: C, 81.7; H, 9.1%. Calcd for $C_{24}H_{32}O_2$: C, 81.8, H, 9.1%.

2,3,4,5-Tetraethylacetophenone (XXIII). To the preformed aluminum chloride (18 g)-acetyl chloride (12 g) complex[24] in carbon tetrachloride (50 ml), a solution of 1,2,3,4-tetraethylbenzene (XXII, 25 g) in the same solvent (50 ml) was added at 0—10°C over a period of 1 hr and the reddish brown mixture was stirred for 4—5 hr, then poured into dilute hydrochloric acid. The organic layer was washed with dilute sodium carbonate followed by water, and dried ($CaCl_2$). The solvent was removed and the residue was distilled to give the ketone (21 g, 68%) as nearly colorless liquid, bp 177—178°C/37 mmHg. IR, 864, 881, 957, 1057, 1160, 1229, 1273, 1352, 1375, 1447, 1548, 1590, and 1684 cm^{-1}; PMR, 8.7—9.0 (4 CH_3, m), 7.55 (-$COCH_3$), 7.0—7.7 (4 CH_3, m), and 2.84 τ (ArH).

Prolonged treatment of the ketone with a sodium acetate-buffered solution of semicarbazide hydrochloride in aqueous methanol separated 2,3,4,5-tetraethylacetophenone semicarbazone as white needles, mp 177—181°C.

Found: C, 70.7; H, 9.7; N, 14.5%. Calcd for $C_{17}H_{27}N_3O$: C, 70.6; H, 9.4; N, 14.5%.

***α*-Methyl-2,3,4,5-tetraethylbenzyl Alcohol (XXIV).** To a suspension of lithium aluminum hydride (2.8 g) in dry ether (100 ml) was added, dropwise and with stirring, XXIII (17 g) in dry ether (80 ml). Following the completion, the mixture was refluxed for 3 hr, and then stood overnight. An excess of the reducing agent was decomposed with ethyl acetate, and dilute sulfuric acid was cautiously added with stirring to the externally cooled solution. The organic layer was separated, washed with dilute sodium carbonate followed by water, and dried ($MgSO_4$). Ether was evaporated and the residue was distilled to yield alcohol XXIV as colorless syrup (12 g, 70%), bp 182—184°C/25 mmHg, which slowly solidified to crystalline mass, mp 43—53°C (lit,[25] 51—52.5°C). IR, 863, 898, 930, 1003, 1057, 1074, 1122, 1270, and 3220—3280 cm^{-1}; PMR, 8.7—9.0 (5 CH_3, m), 7.2—7.6 (4 CH_2, m), 7.0 (OH, s, variable), 4.99 (CH, q), and 2.89 τ (ArH).

Found: C, 82.3; H, 11.4%. Calcd for $C_{16}H_{26}O$: C, 82.0; H, 11.2%.

To a vigorously stirred solution of alcohol in methylene chloride, hydrogen chloride was passed. The reaction mixture was washed with aqueous sodium bicarbonate, dried ($MgSO_4$), and the solvent was removed *in vacuo* to give **α-methyl-2,3,4,5-tetraethylbenzyl chloride (XXV)** as colorless syrup, which on an attempt to distill in a vacuum resulted in decomposition to nondistillable polymeric substances. IR, 885, 981, 1023, 1955, 1075, 1194, 1216, 1265, 1377, and 1450 cm^{-1}; PMR, 8.6—9.0 (4 CH_3, m), 8.19 (CH_3, d, J=6.4 Hz), 7.2—7.7 (4 CH_2, m), 4.18 (CH, q, J=6.4 Hz), and 2.83 τ (ArH).

Chloride XXV in acetonitrile was treated with silver nitrate and a little calcium carbonate. The solution was filtered off from the silver salt, and the solvent was removed under reduced pressure to give a pale yellow syrup, which was identified as impure **α-methyl-2,3,4,5-tetraethylbenzyl nitrate (XXVI)** by infrared and PMR spectroscopy. Nitrate underwent decomposition on heating. IR, 869, 894, 1057, 1279 (-ONO_2), 1378, 1451, and 1635 cm^{-1} (-ONO_2); PMR, 8.6—9.0 (4 CH_3, m), 8.28 (CH_3, d, J=7 Hz), 7.2—7.6 (4 CH_2, m), 3.82 (CH, q, J=7 Hz), and 2.79 τ (ArH).

2,3,4,5-Tetraethylstyrene (XXVII). A mixture of XXIV (12 g), potassium hydrogen sulfate (0.5 g), and *t*-butylcatechol (0.5 g) was slowly distilled under reduced pressure and the fraction boiling at 99—110°C/3 mmHg was collected.[26] The oil was chromatographed on alumina using light petroleum as eluant. Redistillation of the eluate gave pure XXVII as a colorless oil, bp 103—104°C/3 mmHg. Yield, 2.0 g (18%). IR, 888 (isolated ArH), 9.05, 989, and 1624 cm^{-1} (-$CH{=}CH_2$); PMR, 8.7—9.0 (4 CH_3, m), 7.2—7.6 (4 CH_2,m), 4.82, 4.48 and 2.97 (-$CH{=}CH_2$; J_{trans}=17.8 Hz, J_{cis}= 11.0 Hz, J_{gem}=1.8 Hz), and 2.87 τ (ArH).

Found: C, 89.0; H, 11.2%. Calcd for $C_{16}H_{22}$: C, 88.8; H, 11.2%.

2,3,4,5-Tetraethylbenzyl Chloride (XXVIII). A mixture of XXII (17 g), 37%-formalin (30 g), and concentrated hydrochloric acid (300 m*l*) was stirred at 70—80°C, while a stream of hydrogen chloride was introduced with intermittent check of the organic part by gas chromatogaphy. Upon cooling, the chloride precipitated from the reaction mixture as white plates, which were removed, washed, and recrystallized from light petroleum to yield white prisms (14 g, 65%), mp 51—52°C. IR, 713, 887, 1161, 1251, and 1273 cm^{-1}; PMR, 8.6—9.0 (4 CH_3, m), 7.0—7.5 (4 CH_2, m), 4.95 (CH_2), and 3.05 (ArH).

Found: C, 75.6; H, 9.7%. Calcd for $C_{15}H_{23}Cl$: C, 75.4; H, 9.7%.

Treatment of chloride XXVIII with silver nitrate gave **2,3,4,5-tetraethylbenzyl nitrate (XXIX)** as colorless syrup. IR, 756, 855, 916, 938, 963, 1058, 1273 (-ONO_2), and 1635 cm^{-1} (-ONO_2); PMR, 8.7—9.0 (4 CH_3, m), 7.1—7.6 (4 CH_3, m), 4.12 (CH_2), and 3.01 τ (ArH).

Found: C, 67.9; H, 9.0%. Calcd for $C_{15}H_{23}NO_3$: C, 67.9; H, 8.7%.

Lithium aluminum hydride reduction of XXVIII in tetrahydrofuran gave **1-methyl-2,3,4,5-tetraethylbenzene (XXX)**, bp 145—146°C/21 mmHg. PMR; 8.7—9.0 (4 CH_3, m), 7.76 (CH_3, s), 7.2—7.7 (4 CH_2, m), and 3.29 τ (ArH).

Found: C, 88.1; H, 12.1%. Calcd for $C_{15}H_{24}$: C, 88.2; H, 11.8%.

3-Methyl-1,2,4,5-tetraethylbenzene (XXXI) was similarly prepared from 1,2,4,5-tetraethylbenzene, and boiled at 153—155°C/28 mmHg. PMR, 8.7—9.0 (4 CH_3, m), 7.77 (CH_3, s), 7.2—7.6 (CH_2, m), and 3.26 τ (ArH).

3-Bromo - 2, 5 - dimethyl-1, 4-diisopropylbenzene (XXXIII). A solution of 1,4-dimethyl-2,5-diisopropylbenzene (XXXII, 47.5 g)[27] in carbon tetrachloride (150 m*l*) was treated in presence of iodine catalyst with bromine (40 g) in carbon tetrachloride (40 m*l*). The reaction mixture was poured into water, the carbon tetrachloride layer was removed and washed with dilute sodium bisulfite followed by water. After drying ($CaCl_2$), the solvent was removed and the residue was distilled under vacuum to give XXXIII (31 g, 46%), bp 130—131°C/4 mmHg, which soon solidified to prisms, 36—38°C. PMR, 8.89 (2 CH_3, d, J=6.5 Hz) 8.74, (2 CH_3, d, J=6.6 Hz), 7.77 (2 CH_3), 7.07 (CH, sep J=, 6.5 Hz), and 3.60 τ (ArH).

Found: C, 62.7; H, 8.0%. Calcd for $C_{14}H_{21}Br$: C, 62.5; H, 7.9%.

1,3,4-Trimethyl-2,5-diisopropylbenzene (XXXIV). The Grignard reagent was prepared from a mixture of XXXIII (29 g), magnesium turnings (3.3 g), and dry tetrahydrofuran (80 m*l*) using ethyl bromide as the auxiliary halide. The reagent was then treated with vigorous stirring and efficient cooling with a solution of dimethyl sulfate (30 g) in tetrahydrofuran (25 m*l*), and stood overnight. The mixture was poured into dilute hydrochloric acid, and the organic layer was washed, the solvent was removed, and the residue was refluxed with ethanolic sodium ethoxide for 1 hr. Dilution with water, followed by the ordinary working-up yielded hydrocarbon (9.4 g, 42%), bp 127—129°C/11—12 mmHg. PMR, 8.91 (2 CH_3, d, J=8.2 Hz), 8.78 (2 CH_3, d, J=8.3 Hz), 8.01 (CH_3), 7.92 (CH_3), 7.86 (CH_3), 6.6—7.3 (CH, m), and 3.72 τ (ArH).

Found: C, 88.4; H, 12.0%. Calcd for $C_{15}H_{24}$: C, 88.1; H, 11.8%.

Nitration of Pentamethylbenzene. A solution of pentamethylbenzene (14.8 g) in chloroform (50 m*l*) was vigorously stirred and fuming nitric acid (d=1.50, 31.5 g) was added during a period of over 30 min. The mixture was poured into water, and the organic layer was washed with dilute sodium bicarbonate and water. Removal of the solvent in a vacuum gave a partly crystalline, syrupy substance (19.3 g), which showed strong infrared absorption at 1271 (-ONO_2), 1370 (-NO_2), 1460, 1525 (-NO_2), and 1624 cm^{-1} (-ONO_2); PMR peaks at 7.7—7.9, 6.05, 4.63, 4.67, 4.4—4.5, 3.87, 3.26, 3.22, 3.06, an 2.93 τ, indicating the presence of a considerable amount of benzyl nitrates. Weak absorption due to carbonyl and hydroxylic groups was also observed. Thin-layer chromatography of the syrup showed practically no formation of dinitroprehnitene. Chromatography on alumina using light petroleum as eluant gave unchanged pentamethylbenzene (0.8 g), and nitropentamethylbenzene (6.0 g). The latter was obtained as nearly colorless needles from ethanol, mp 158—159°C, and had strong infrared ab-

26) M. S. Newman, J. R. LeBlanc, H. A. Karnes and G. Axerad, *J. Amer. Chem. Soc.*, **86**, 868 (1964).

27) E. C. Kooyman and A. Strang, *Rec. Trav. Chim. Pays-Bas*, **72**, 329 (1953).

sorption at 840 and 1525 cm^{-1} ($-NO_2$); PMR peaks at 7.79 and 7.89 τ. Use of a short alumina column gave tetramethylbenzyl nitrates from light petroleum fractions, but the separation was unsatisfactory. Diphenylmethanes appeared over a wide range of the eluates; XV was concentrated in the early eluates, and XXI came out with tetramethylbenzyl nitrates or nitropentamethylbenzene. A light brown syrupy substance (*ca.* 1 g) from the benzene eluates showed a strong carbonyl absorption and gave a semicarbazone, mp 209—210°C and 235—242°C, which was identified as 2,3,4,5-tetramethylbenzaldehyde semicarbazone by comparison with the authentic specimen. The presence of 6-nitro-2,3,4,5-tetramethylbenzyl nitrate was also confirmed by spectroscopy and thin-layer chromatography. Further elution with ethanol or ether yielded a soft crystalline mass, trituration of which with a little light petroleum gave white needles (*ca.* 7 g, mp 72—78°C) identified as 2,3,4,5-tetramethylbenzyl alcohol.

Nitration of Pentaethylbenzene. A solution of pentaethylbenzene (22 g) in chloroform (50 m*l*) was vigorously stirred and fuming nitric acid (d=1.50, 31.5 g) was introduced at −5—0°C over a period of 30 min. A similar working-up as above gave a light brown, syrupy substance (26 g), which showed prominent infrared peaks at 864, 896, 1059, 1280 ($-ONO_2$), 1381 ($-NO_2$), 1454, 1465, 1526 ($-NO_2$), and 1635 cm^{-1} ($-ONO_2$); PMR peaks at 8.6—9.0 (CH_3, m), 8.26 (CH_3, d, J=7 Hz), 7.2—7.6 (CH_2, m), 3.82 (CH, q, J=7 Hz), 2.35 and 2.64 τ (ArH). Thin-layer chromatography of the syrup showed two main spots, neither of which corresponded to 5,6-dinitro-1,2,3,4-tetraethylbenzene or 3,6-dinitro-1,2,4,5-tetraethylbenzene. The syrup could be separated by repeated chromatography on alumina into several substances; 2,3,4,5-tetraethylstyrene as colorless thick oil (*ca.* 7 g), readily identified by its characteristic twelve peaks due to the vinyl group and confirmed by comparison with the authentic specimen; nitropentaethylbenzene as pale yellow crystals (3.8 g, mp 86—90°C), which showed strong infrared bands at 786, 1059, and 1525 cm^{-1} ($-NO_2$); PMR peaks at 8.95—8.71 (5 CH_3, m) and 7.1—7.7 τ (5 CH_2, m). Found: C, 73.0; H, 9.8; N, 5.6%. Calcd for $C_{16}H_{25}NO_2$: C, 73.0; H, 9.5; N, 5.3%. The minor fractions from the benzene eluates showed strong carbonyl absorptions, but they were not further investigated. A syrup (9.6 g) from the ether eluates gave on cooling a white crystalline mass (5.9 g, mp 43—62°C), which was spectroscopically identical with the authentic α-methyl-2,3,4,5-tetraethylbenzyl alcohol. The original nitrate was undoubtedly converted by repeated chromatography into unsaturated hydrocarbon and alcohol.
